Unsaturated Molecules Containing Main Group Metals

By Michael Veith*

Molecules in which there are neighboring electrophilic and nucleophilic centers are unusually reactive. Oligomerization can be prevented only by bulky groups attached to the main group metal atom that would act as electron pair acceptor, or to the basic non-metal atom. The basic and the acid centers behave as a single unit in chemical reactions; the system is similar to a "double bond" whose π-electron density is largely concentrated at one atom. The unsaturated nature of these molecules can be seen in (for example) their addition reactions with hydrogen compounds of non-metals, or in reactions that are distantly related to cycloadditions at homopolar double bonds. The selection of suitable reaction partners leads to polycyclic, cage-like molecules containing metal atoms. If these atoms possess lone pairs (as is usual in the lower oxidation states of the third and fourth main groups), these can be utilized to form bonds to further (Lewis acid) metal centers. In some cases large assemblies can be built up from polycyclic systems in this way; a characteristic of these assemblies is a one-dimensional array of metal atoms. Commonly occurring structural features of the polycyclic species are tetrahedra, trigonal bipyramids and cubes.

1. Introduction

Two properties of metallic elements are particularly conspicuous on their incorporation into molecules: their low electronegativity (compared with the ligands) and their marked tendency to maximize their coordination number. The resulting electrophilicity at the metal atom causes nucleophiles to attack this part of the molecule preferentially and the first reaction step is thus coordination. Such an intermolecular reaction can lead to a stable compound that is generally described as a Lewis acid/Lewis base complex.[1]

Here we wish to consider only those Lewis acids in which one or more non-metal atoms bearing lone pairs are bound to the electrophilic main group metal. Such compounds thus formally contain neighboring Lewis acid and Lewis base centers, which can lead to intra- or intermolecular interactions. The compounds are generally unstable with respect to oligomerization because of the marked heteropolar contribution to the metal/non-metal bond. An expansion of the coordination at the metal atom results, which can be interpreted as filling an electron vacancy.[1] Although this model may seem very primitive and superficial (it is concerned largely with "counting electrons") it should nevertheless be noted that parallels between the oligomerization of such special Lewis acid/Lewis base systems and of element-element double bonds do exist. This can be illustrated by a comparison of the reactivity of the aluminum compound **1** with that of the isosteric or (in the broader sense) isoelectronic molecules **2**, **3** and **4** (Scheme 1).

A common property of compounds **1**–**4** is that they oligomerize or polymerize under suitable (generally different)

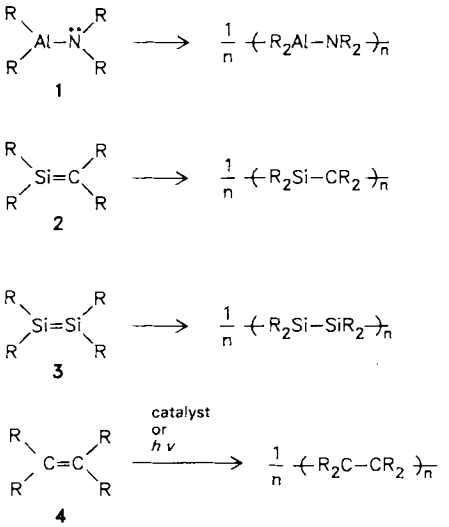
conditions. Compound **1** reacts instantaneously to form four- or six-membered rings (depending on the substituent R) that do not decompose to the monomers even at high temperatures.[2,3] Compound **2** is also converted spontaneously into the corresponding oligomer; it can be obtained as a monomer only by the use of sterically demanding substituents R (kinetic stabilization).[4-6] Compound **3** possesses a completely non-polar double bond (in contrast to **1** and **2**), but here again the monomer is only stable when such kinetic effects are exploited.[7] Monomers of **2** and **3** are obtained as extremely short-lived intermediates when suitable precursors are photolyzed or thermolyzed; they can be chemically identified by trapping reactions.[8,9] The ethene derivatives **4**, on the other hand, are kinetically especially stable with respect to their oligomers and polymers and can only be converted into these photochemically or catalytically.[10,11]



R = organic or inorganic substituent

Scheme 1.

It is apparent from this comparison of the compounds **1**–**4** that the tendency to oligomerize is correlated with the polarity of the relevant bond and that heavy elements (because of their reluctance to form π-bonds[12]) amplify this effect. Compounds such as **1**, which contain a Lewis acid and a Lewis base, can be classified on the basis of a simple model as "unsaturated" and represent, at least formally, a limiting case of the double bond. Irrespective of the contributions of the individual mesomeric forms **5a** and **5b**, this can be represented as follows for a main group metal M and a non-metal X:

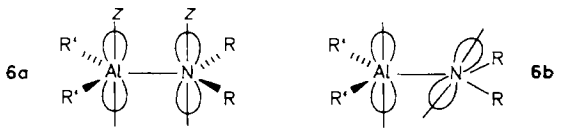
In this review we have not considered it important to present evidence for the existence of one or the other mesomeric form (there are incidentally other possible formulations, e.g. as an ion pair); we prefer to show how this model can be exploited synthetically. The reactivity of the compounds is best represented, not by treating M and X in **5** separately as acid and base but by considering the cooperation of both centers—*similarly* to the behavior of double bonds. We concern ourselves with compounds of type **5** that either exist as monomers under normal conditions or can be assumed as intermediates. After considering the general principles we present examples that are mostly drawn from our own work.

2. The Synthesis of Metallacycles with Lewis Acid and Lewis Base Centers

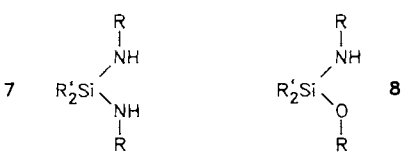
2.1. The Choice of Ligand at the Metal Atom

As already explained, compounds that, like **1**, contain a Lewis acid and a Lewis base center are unstable with respect to oligomerization. Apart from the use of sterically demanding groups (to reduce the tendency to intermolecular reactions), one further important point should be considered; this will be discussed with respect to **1** as an example. An intramolecular stabilization of the aluminum atom (by a contribution from limiting structure **5b**) is only possible if the occupied orbital on the N atom possesses the same symmetry as the acceptor orbital (p_z on the Al atom); this would require an sp^2 hybridization of the nitrogen. An additional requirement, however, is that both p orbitals are parallel (**6a**). It can be shown, for an open chain system with free rotation about the bond joining the Lewis acid to the Lewis base, that both conditions presented here (steric requirements, electronic effects) tend to compete with, rather than reinforce, each other.

In tris(bis(trimethylsilyl)amino)aluminum (R = $SiMe_3$, R′ = $N(SiMe_3)_2$ in **6**), which indeed contains three-coordinate aluminum,[13,14] the R_2N-moiety is however rotated by 50° from the $(R')_2Al$ moiety (as depicted in **6b**). Because of this large dihedral angle between the p_z orbitals, there can only be a weak donor-acceptor interaction between the two atoms.



If the aluminum and nitrogen atoms are incorporated in a small ring system, however, such a rotation is no longer possible. This consideration prompted us to incorporate electrophilic metal atoms in ligand systems derived from the donor-substituted silanes **7**[15] and **8**,[16] which should lead to high stabilization. Starting from **7** and **8**, we can in



principle construct compounds containing any metallic element (see formulas **9**–**15**; the Roman subscripts refer to the main group number. For examples see also Table 1). All the molecules **9**–**15** share the common feature that the

metal atom (Lewis acid) formally possesses six outer electrons and is adjacent to two non-metal atoms with "non-bonding" electron pairs.

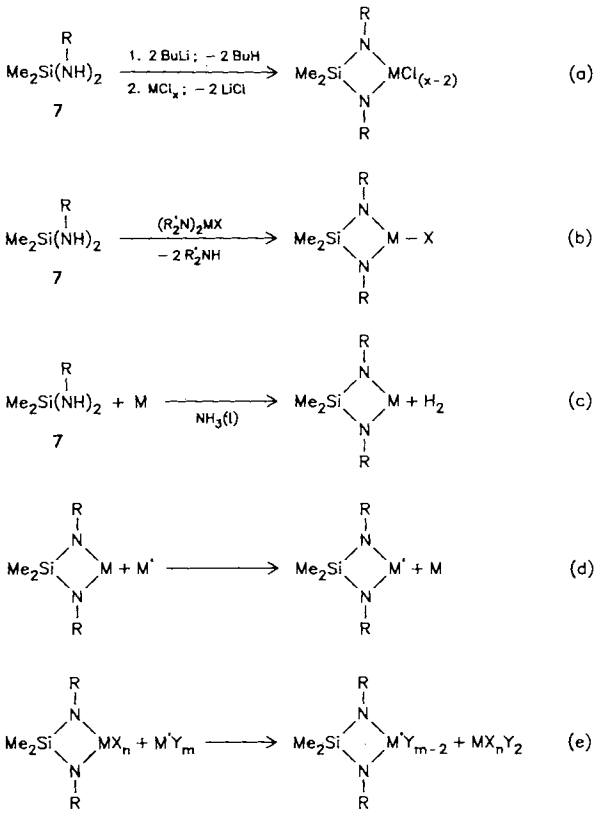
The ring structure and the stabilizing effect of silicon on the sp^2 hybridization at the nitrogen or oxygen atom should ensure the coplanarity of the generally trigonal planar ligand spheres at the metal and the non-metal atom (assuming monomeric structures). The metal atoms can display either their maximum oxidation state or an oxidation state two units lower (**13**, **14**); they may be present as metal cations (**15**). Any organic group R may be chosen, but the principle of "kinetic stabilization" should be borne in mind; *tert*-butyl groups have proved especially useful. The completion of the outer electron complement and the coordinative saturation of the metal atom in **9** and **10** are achieved by bonds from donor molecules.

2.2. Synthesis of the Metallacycles

The metallacycles **9**–**15** can be synthesized by a variety of methods,[18] some of which are presented as examples in Eqs. (a)–(f). Corresponding syntheses can be carried out with compound **8**. The most important and generally applicable syntheses are (a), which proceeds with "salt formation", and the redox or metal exchange reactions (d) and (e), respectively. The amine transfer reaction (b), the direct hydrogen–metal exchange (c) and the thermolysis (f) are of more specialized interest.[19,24] We have so far succeeded in preparing the compounds listed in Table 1. Attempts to prepare a compound corresponding to formula **11** led (for magnesium) only to $[Me_2Si(NtBu)(OtBu)]_2Mg$.[22]

3. Properties and Structures of the Metallacycles 9–15

Mass spectrometry in the gas phase, molecular weight determinations in solution and X-ray structure analyses in the solid state all show that the compounds **9**–**15** are



(a) (b) (c) (d) (e) (f)

Table 2. Structures of some metal-containing cyclic molecules in different states of matter. E.N. = electronegativity.

Compound	M	E.N. [25] of the metal atom	Degree of association: Gas phase	Benzene soln.	Crystal

14c	Pb^{II}	1.87	monomeric	monomeric	—

either monomeric or dimeric; none of them forms a "coordination polymer". Table 2 shows that physical conditions (e.g. the state of matter) and the electronegativity of the metal atom both have a direct influence on the tendency to dimerize; as expected, the tendency to coordinative saturation at the metal is greater for more electropositive metals and for more closely neighboring molecules. The indium derivative **12c**, for example, is monomeric in the gas phase but dimeric in benzene solution and in the solid state. Interesting results have been obtained for the tin derivative **14b**; crystallization from hexane yields a monoclinic modification in which monomers and dimers are both present in the lattice,[26] but crystallization from molten material gives a second, triclinic, modification that only contains dimers.[27]

All the compounds that contain lower valent metals and are monomeric are also colored; the heavier the metal atom, the further the light absorption is shifted to the red (**14a** is yellow, **14b** red, **14c** dark red). Dimerization is accompanied by a marked change in color; molten **14b** (containing only monomers) is red, the monoclinic modification (1:1 monomer:dimer) orange, the triclinic modification (only dimers) pale yellow.[27] The differing coordination numbers at the metal are obviously reflected in the color of the compounds, as is also the case for tin(II) amides.[28] The cations containing elements of the fifth main group (**15a–d**), like the corresponding isoelectronic compounds **14**, are also colored.[24]

Figures 1–3 show the results of X-ray structure analyses of the compounds **14b** and **15c** (as examples of monomeric units) and of **12c** and **9a** (as examples of different types of dimers). In **14b** and **15c** the four-membered ring is almost planar and the N-atoms trigonal planar coordinated. As discussed in Section 2, this causes the empty p orbitals on the metal atoms[30] and the filled p orbitals on the nitrogen atoms to be parallel. A resonance formula corresponding to **5b** is possible from strictly geometric considerations but does not appear to lead to a noticeable shortening of the M–X bond. The molecule $Sn[N(SiMe_3)_2]_2$ is, like **14b**, monomeric in the gas phase; electron diffraction studies show that the Si_2N planes are not coplanar with, but are instead orthogonal to, the SnN_2 plane; however, the Sn–N bond length is identical to that in **14b**.[31]

The dimeric **12c** (Fig. 2) can be considered as a cycloadduct of two monomeric units. The dimer of **14b**[27] and the magnesium compound **10a**[20] display a similar structural type. Common to all three molecules is a polycyclic structural element consisting of three edge-bridged perpendicular four-membered rings ("step structure"). The electron transfer from the λ^4-N atom to the In atom is reflected in the drastically lengthened bonds to this atom, compared with the λ^3-N atom.[29] As in [2+2]-cycloaddition reactions of ethene derivatives,[32] the bond lengths in the addition product are all increased with respect to those in the starting materials. The structural data for **10a**, **12c** and **14b** can be transcribed as the chemical formulas **16a–c** (R = *t*Bu; M = Mg, In, Sn; X = THF, Me or lone pair).

There is however a danger of reading too much into the formulas **16a–c** as regards the real electronic states; the formal charges in **16a** might be taken to indicate a high electron density at the metal atom, which would be incon-

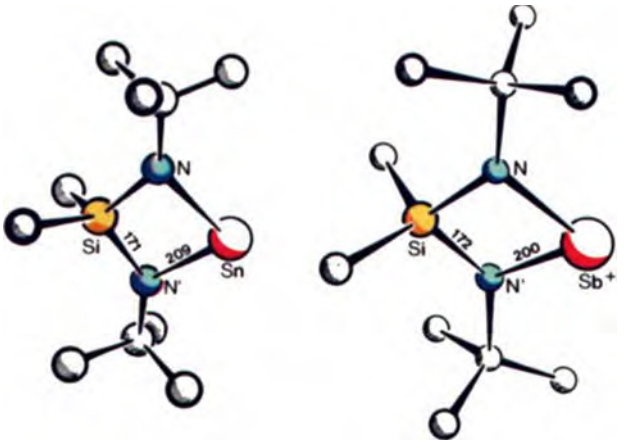

Fig. 1. Molecular structures of **14b** [27] (left) and **15c** (without counterion) [28] (right). Here and in the following figures, the metal atoms (acceptors) are colored red or orange, the donor atoms blue or green; C-bonded H-atoms omitted (distances in pm).

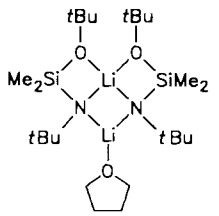
16d

sistent with the electronegativities of the elements M and N.[25] The donor-acceptor bond shown by an arrow in **16b** should differ appreciably in length from the N–M single bond; this is indeed the case for dimeric **14b**,[27] but not for dimeric **12c**.[29] Finally, there are formulations such as **16c** with ionic charges, which are structurally difficult to distinguish from **16a**. Although the formulas **16a–c** are fairly readily comprehensible for the molecules discussed here, more complicated systems are more difficult to formulate in a similar manner and are thus more liable to misinterpretation. To avoid this problem, it is often more sensible to dispense with the formulas with formal charges and arrows, as in **16d**; each line represents an electron pair, irrespective of the nature of the bond (2-center 2-electron or donor-acceptor). The reader will be able to interpret the particular bonding implied by, for instance, the four-coordinate nitrogen atom.

In contrast to the compounds **10a**, **12c** and **14b** (dimer), in which all metal atoms are coordinatively saturated (which usually implies a noble gas configuration), dimeric **9a** (Fig. 3) contains two lithium atoms, only one of which is four-coordinate; the other is bonded to two nitrogen atoms and the oxygen of a donor tetrahydrofuran molecule, resulting in the unusual coordination number three.[33] The point symmetry of **9a** is close to C_2 symmetry, the twofold axis passing through both lithium atoms and the donor oxygen. This oxygen displays trigonal planar coordination, and is thus, like the λ^3-lithium atom, sp^2 hybridized. It can be shown that the dihedral angle between the p orbitals of both atoms (ca. 45° in **9a**) results from steric effects that make a parallel arrangement impossible. It is not clear why the structure of the lithium derivative **9a**[19] is so different from that of the isoelectronic magnesium derivative **10a**; **9a** does not react with excess tetrahydrofuran. As for **16**, different representations of the formula are possible; we prefer **17**, corresponding to **16d** (cf. lithium compounds in Ref. [34]). The structural type **9a**



17 [= (9a)$_2$]

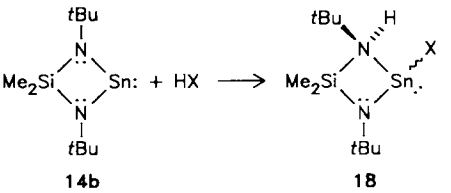
(Fig. 3) is preserved in exchange reactions of the donor THF (as shown by X-ray structure determinations of **9b** and **9c**); this feature is however restricted to lithium compounds.[19]

4. Reactions of Monomeric Metallacycles

The concept advanced in Sections 1 and 2, of regarding the Lewis acid/Lewis base systems defined at the outset as limiting cases of molecules with a π double bond, can be tested by methods other than structural analysis. Unsaturated molecules are expected, in particular, to undergo addition reactions. We shall here analyze selected reactions of the monomeric metallacycles to see if this expectation is borne out in practice. We restrict ourselves to the addition of hydrogen compounds of non-metals and their derivatives to the molecules **14** and to reactions that may by extended analogy be regarded as cycloadditions (for further examples see, e.g., Refs. [35, 36]).

4.1. Addition of Hydrogen Compounds of Non-Metals to 14

The tin(II) compound **14b** (monomeric in solution) reacts with hydrogen compounds H–X (X = halogen, C_5H_5) according to the general equation (g).[37,38] The germanium compound **14a** also reacts in this way.[39] The ad-



(g)

14b 18

18a–d: X = C_5H_5, Cl, Br, I

dition products **18a–d** can be isolated and characterized; Figure 4 shows the result of an X-ray structure determination of **18b**.[38] As expected, the λ^4-N–Sn bond is appreciably longer than λ^3-N–Sn ($\Delta = 40$ pm). The *cis* position of the hydrogen and chlorine atoms (with respect to the ring plane) is caused by steric effects. Molecules of the type **18**

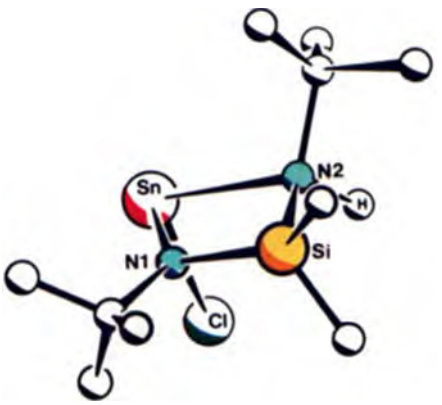


Fig. 4. Molecular structure of **18b** [37].

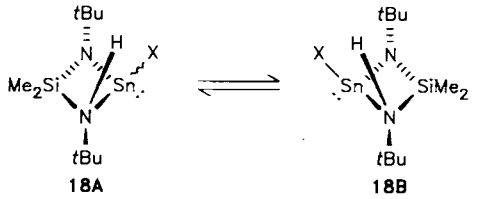
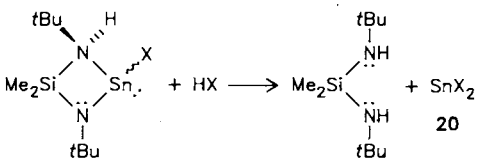
are conformationally unstable in solution (as shown by temperature-dependent NMR studies); equation (h) shows the equilibrium involved[37–39] (only two of the four possible isomers are represented (cf. Ref. [37])). **18A** and **18B** are mirror images; each contains two chiral centers (λ^4-N and Sn). The formal replacement of the SnX group in **18** by ElX_2 (El = Al, Ga, In, Tl; X = Me or halogen) leads to compounds that are similar to **18** in many respects, especially with regard to temperature-dependent "ligand redistribution" within the molecule.[21,29]



18A **18B** (h)

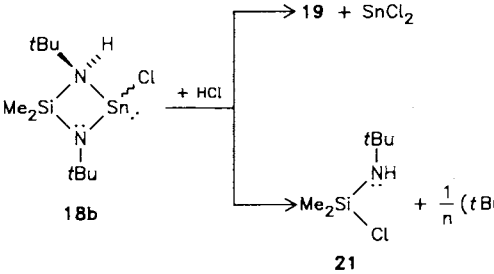
Apart from the explicitly mentioned hydrogen compounds in Eq. (g), alcohols, thiols and secondary amines can also react in a similar manner with **14b**; the difference is that the intermediate **18** cannot be isolated. The reaction continues by further addition of HX and breaking of both Sn–N bonds, leading to the bis(amino)silane **19** and derivatives **20** of divalent tin [Eq. (i)].[37–39] Dihalides of tin are



18 **19** **20** (i)

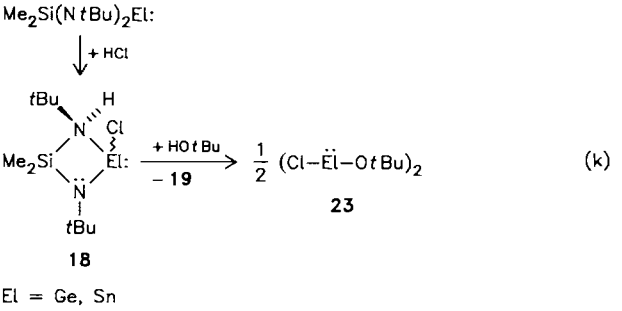
20a–d: X = C_5H_5, NMe_2, O*t*Bu, S*t*Bu

also obtained when compounds **18** are allowed to react with a further mole equivalent of hydrogen halide, but interesting side reactions also take place [Eq. (j)] for compound **18b**.[37] The ratio of products $SnCl_2$ and **22** can be influenced by temperature and concentration.



18b **21** **22** (j)

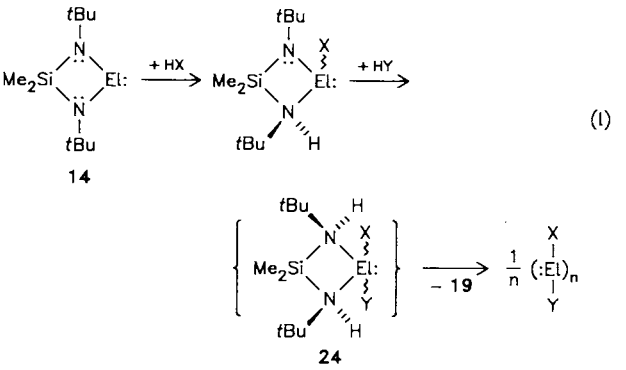
Whereas alternative methods of preparing **20a–d**[40] are available, the addition reaction (g) is particularly suitable for preparing asymmetrically substituted germanium(II) or tin(II) compounds[41] such as **23** [Eq. (k)], which are otherwise obtainable only with difficulty or not at all.[39] The cyclic species **14a**, **b** function in Eq. (k) in two separate reaction steps as formally unsaturated systems; the Lewis acid/base adduct **24** is obviously unstable [Eq. (l)]. The



18 **23** (k)

El = Ge, Sn

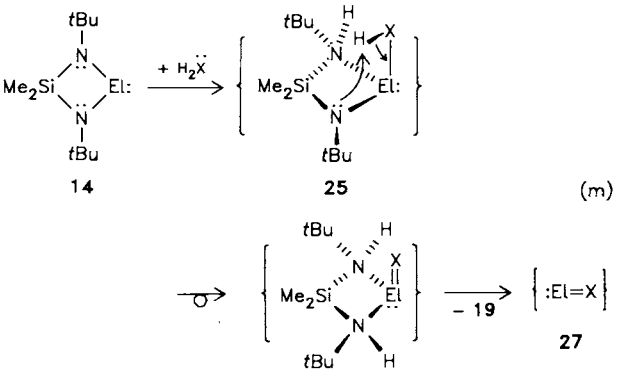
bis(amino)silane **19** is, for a coordinating molecule, extremely bulky (because of the *tert*-butyl groups on the nitrogen atoms) and thus dissociates readily from the metal



14 **24** (l)

atom. A detailed consideration of the reaction sequence (l) raises the question whether two hydrogen atoms can be simultaneously transferred to **14**, rather than in two separate steps. Such a reaction could be expected with hydrogen compounds that contain two element–hydrogen bonds, such as primary amines or water. Since the basic group X is only available for reaction once (in contrast to the successive reactions (l)), double bonds should be formed in the product after addition of the hydrogen, as shown in Eq. (m). The intermediates **25** and **26** are hypothetical and serve only to demonstrate the analogy to reaction (l).

The experimental test of this idea indeed shows that the reaction of compound **14** with primary amines (and in principle also with water) leads, apart from to the quantitatively generated bis(amino)silane **19**, to a compound whose empirical composition corresponds to formula **27**[23a,42] or that contains **27** as a constituent of a larger molecule.[43] The product should however not be repre-



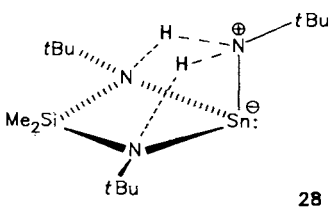
14 **25** **26** **27** (m)

X = NR, O

sented as a monomer containing a double bond, but rather as a tetramer. Figure 5 shows the molecular structure of $(SnNtBu)_4$, which contains a central Sn_4N_4 cube.[44] All the "bond lines" between tin and nitrogen atoms can be interpreted as σ bonds. A more detailed discussion of this and related bonding systems is presented in Section 4.2.

Fig. 5. Molecular structure of $(SnNtBu)_4$ [44].

Equation (m) could be formally classified as a simple substitution reaction, where the element El in **14** is replaced by two hydrogen atoms. A thorough analysis of the reaction of *tert*-butylamine with the bis(amino)stannylene **14b** shows that the first step should be formulated as an addition reaction.[45] The unstable intermediate **28** was successfully characterized by a low temperature X-ray structure determination. The nitrogen of the *tert*-butylamine in **28** interacts not only with the tin atom, but also via hydrogen bonds with the nitrogen atoms of the diazasilastannetane ring. The N_2Sn group of **14b** thus functions as a "trihapto" ligand with respect to the NH_2 group of the primary amine; this is an attractive confirmation of the concept that both Lewis bases and the Lewis acid act together as one unit. In this connection the *formal* similarity between the N_2Sn system and an allyl anion should be noted,[46] since both are equipped with 4π electrons distributed (localized or delocalized) over three atoms.



28

A similar formal analogy seems to exist between the formation of isocyanides (isonitriles)[46] and the formation of tetrameric iminogermylenes, -stannylenes and -plumbylenes[42] [Eq. (n)]. However, whereas the reaction of the heavy carbene analogues takes place by an addition mechanism, the reaction of carbenes with primary amines has as its first step the insertion of $:CX_2$ into the N–H bond; a base-induced elimination of HX follows.[47] The special stability of the "inert electron pair" of the heavy main group element is obviously an important factor in determining the differing reactivities of $:EIX_2$ and $:CX_2$.[48a]

$$:CX_2 + R{-}NH_2 \xrightarrow{OH^{\ominus}} 2\,HX + :\overset{\ominus}{C}{\equiv}\overset{\oplus}{N}{-}R$$
$$:EIX_2 + R{-}NH_2 \longrightarrow 2\,HX + \tfrac{1}{4}(:EIN{-}R)_4 \qquad (n)$$

El = Ge, Sn, Pb; X = basic substituent

Methylene phosphoranes are, in the broader sense, isoelectronic with primary amines (cf. formulas **29**, **30**) (for the similar relationship between phosphorus ylides and silylamines see Ref. [48b]). It is therefore not surpris-

$H_2\overset{\ominus}{C}{-}P^{\oplus}R_3$ **29** $\qquad$ $H_2\ddot{N}{-}CR_3$ **30**

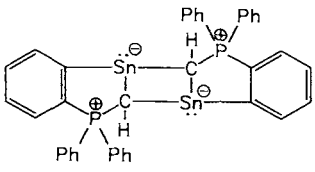
ing that methylene phosphoranes also react with the stannylene **14b**, the addition and subsequent thermolysis leading to the bis(amino)silane **19** and the product **31** [Eq. (o)].[49] Compound **31** can be isolated in the form of

$$Me_2Si(N\,tBu)_2Sn \xrightarrow[2)\ \Delta T]{1)\ +\ H_2CPR_3} \mathbf{19} + \frac{1}{n}\,[SnCPR_3]_n \qquad (o)$$

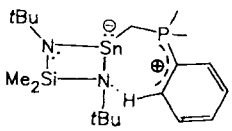
14b $\qquad$ **31**

red crystals for R = Ph. The X-ray structure analysis shows that **31** does not contain a central tin-carbon cube (analogous to the iminostannylenes) but instead is a polycyclic compound (**32**).

Clearly a phenyl ligand is involved in the reaction of **14b** with the phosphorane. The reactive intermediate can be isolated and structurally characterized (as in the reaction of **14b** with *tert*-butylamine). It is an addition product that contains a tin–carbon bond and a $N\cdots H{-}C$ bridge[49] (**33**). The carbanion, stabilized at the *o*-carbon of the phenyl ring, can then displace the λ^4-N atom at tin; this explains the formation of the five-membered ring in **32** (for the experimental verification and the further reaction steps cf. Ref. [49]).



32



33

4.2. Reactions between Unsaturated Element–Metal Compounds

Ethene and acetylene and their derivatives are generally stable with respect to oligomerization to cyclobutanes, tetrahedranes or cubanes; this stability is primarily kinetic[50] (see e.g. tetra-*tert*-butyltetrahedrane[51]). As mentioned in the introduction, molecules with a polar "double bond"

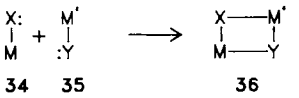
(e.g. **1** and **2**) are appreciably more reactive and therefore easily convertible into oligomers; this property can be utilized to prepare cyclic and polycyclic molecules containing metal atoms. The use of sterically demanding ligands (either on the metal or the non-metal atom) largely avoids the formation of polymers.

The polycyclic compounds described below arise from multiple acid-base reactions of unsaturated starting materials containing metal atoms. In some cases the starting materials are only obtainable as intermediates because of their high reactivity; the comments on the mechanisms involved should therefore be interpreted with caution. With this reservation we present a simple model with which the formation of the compounds can be formally described:

1) The starting materials always come together in such a manner that the nucleophilic and electrophilic centers are adjacent; in other words, the arrangement of atoms in the polycyclic products is such as to neutralize the polarity of the starting materials.

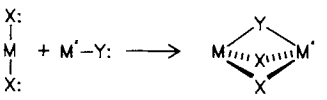
2) The metal atoms tend, by increasing their coordination number, to acquire an electron configuration corresponding (at least) to the next noble gas. They can act as multiple acceptors to several donors.

In our classification of these reactions, we consider the number of atoms involved; this is a loose analogy to cycloaddition reactions of unsaturated hydrocarbons.[32b] As an example, see Eq. (p); this can be described as a [2+2]-cycloaddition involving the interaction of a Lewis acid/base pair **34** with a second pair **35**. An important differ-



34 **35** **36** (p)

ence from the hydrocarbon reactions is that the size of the new ring is not necessarily given by the number of interacting centers in the reaction; for instance, the three centers of **37** react with the two centers of **35** to give not a simple ring system but the polycyclic compound **38**. The reason for this is the multiple acceptor nature of the metal atom M′ in **35** towards the two bases X of **37**.

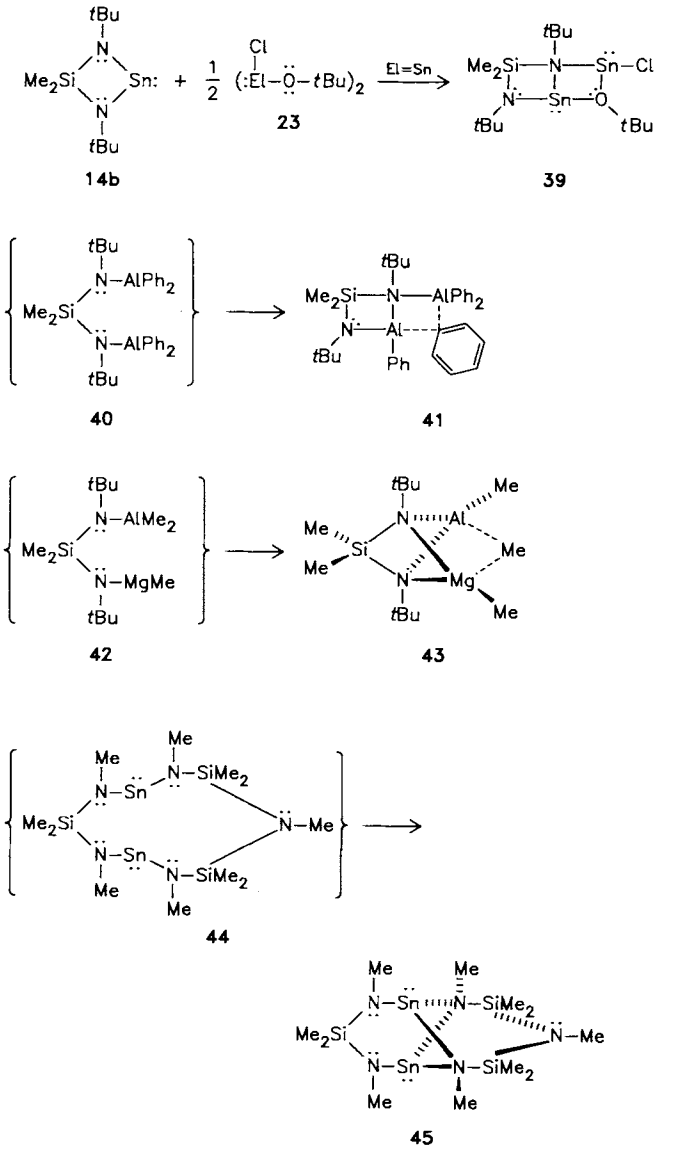


37 **35** **38**

4.2.1. [2+2]-Additions

As already mentioned, the dimers described in Section 3 can be considered to arise from [2+2]-additions of the monomeric Lewis acid/base systems. Further examples of this reaction type are given in Scheme 2.

The reaction of the bis(amino)stannylene **14b** with the asymmetrically substituted tin(II) compound **23** proceeds by dissociation of dimeric **23** and addition of the resulting monomer to one of the tin–nitrogen bonds of **14b**, leading to **39**, which has been characterized by X-ray structure determination.[39] For steric reasons the molecule **40**, which is equipped with two acid and two basic centers, cannot

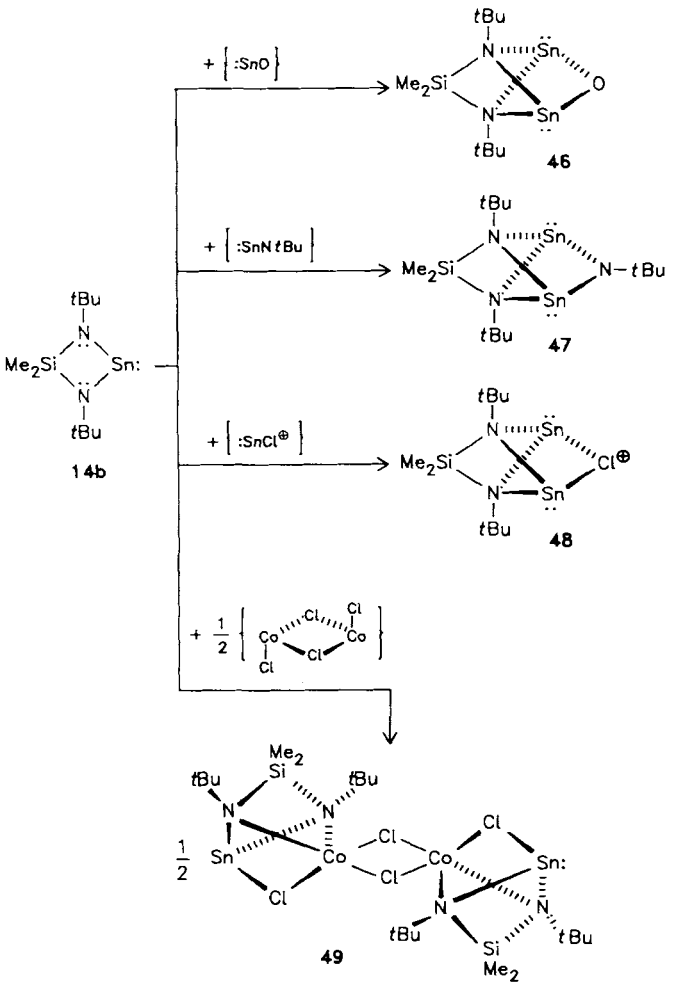


Scheme 2.

"react" intramolecularly to give a tricyclic product in which both nitrogen atoms function as bases. In **41** a three-center, two-electron bond, in which the carbon atom of a phenyl group and two aluminum atoms take part, serves to complete the coordination of the metal atoms.[29] The tricyclic product just mentioned *is* obtained, however, if an atomic arrangement as in **42** is provided. A three-center two-electron bond must also be assumed in **43** to complete the coordination at magnesium.[52] Another intramolecular double addition enables the tricyclic **45** to be "constructed" from **44**.[53]

4.2.2. [3+2]-Additions

The ability of the SnN_2 group in **14b** to coordinate through all three centers, rather than just two, has been discussed in Section 4.1. This property is particularly marked when **14b** comes into contact with extremely reactive molecules containing metal atoms with unusually low coordination number (Scheme 3).

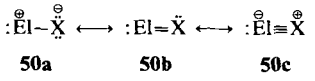


Scheme 3.

The reaction product in each case is a hexatomic system of three rings containing as a structural element a distorted tetrahedron, two opposite edges of which are bridged by one atom each (Fig. 6). The products **46**–**49** all contain the starting molecule **14b**; it coordinates via both nitrogen atoms to the metal atom (Sn or Co) and its tin atom functions as acceptor. The recently discovered molecule **49** shows that transition metals can also function as acceptors.[55] SnO and SnN–*t*Bu are probably generated as reactive intermediates in the hydrolysis[43] or *tert*-butylaminolysis[42] of **14b**, respectively, and are then trapped by excess **14b** to give **46** and **47**. The latter decomposes irreversibly at 210 °C by a first-order reaction to give **14b** and $(SnNtBu)_4$[4a]—evidence for the existence of an SnN–*t*Bu intermediate. The polycyclic compound **48** is formed, together with the anion $SnCl_3^{\ominus}$, in the reaction of **14b** with two mol equivalents of tin(II) chloride.[56]

Fig. 6. Structure of **46** as a structural unit in the compounds $Me_2Si(NtBu)_2Sn_2O \cdot SnCl_2$ [43] and $[Me_2Si(NtBu)_2Sn_2O]_2 \cdot Me_2Si(NtBu)_2Sn(O)_2Sn(NtBu)_2SiMe_2$ [45].

The intermediates SnO and SnN–*t*Bu can be regarded as heavy homologues of carbon monoxide or *tert*-butyl isocyanide respectively[36] (see Ref. [57] concerning the existence of Ph–NSi). However, whereas the limiting structures **50b** and **50c**, involving multiple bonds, are clearly

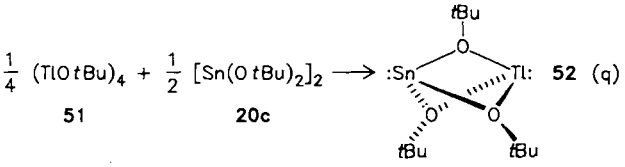


50a **50b** **50c**

El = C, Si, Ge, Sn, Pb; X = O, N*t*Bu

dominant for carbon, the structure **50a**, which involves a single bond, is probably more important for the heavier homologues.[36] The differing bonding schemes are reflected in the properties of the compounds. Carbon monoxide and organic isocyanides are monomeric; the corresponding compounds of the higher homologues, where existent, are tetrameric (see next Section). In the compounds **46**–**48**, several such tin species form part of the respective molecules.

The isoelectronic substitution of the low-valent main group element and of the nitrogen in ElN–R leads formally to alkoxides of univalent elements of the third main group, which have been known for a long time.[58] These alkoxides should correspond electronically to the iminocarbene analogues (see e.g. formula **50a**). As expected, thallium(I) *tert*-butoxide reacts smoothly with tin(II) *tert*-butoxide in a [3+2]-addition [Eq. (q)].[59] The distorted trigonal bipyramidal structure of the SnO_3Tl framework of **52** is easily recognized in Figure 7.



51 **20c** **52** (q)

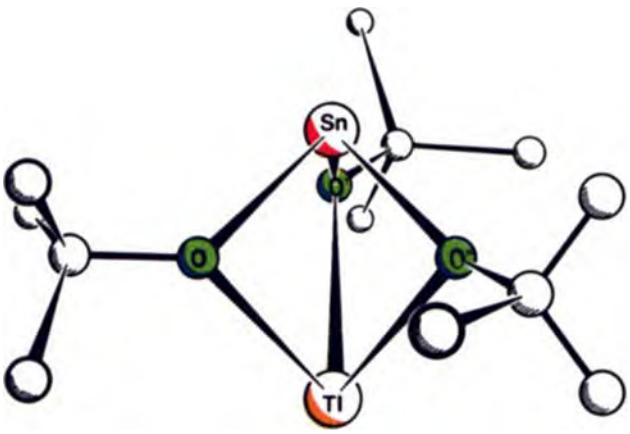


Fig. 7. Molecular structure of **52** [59].

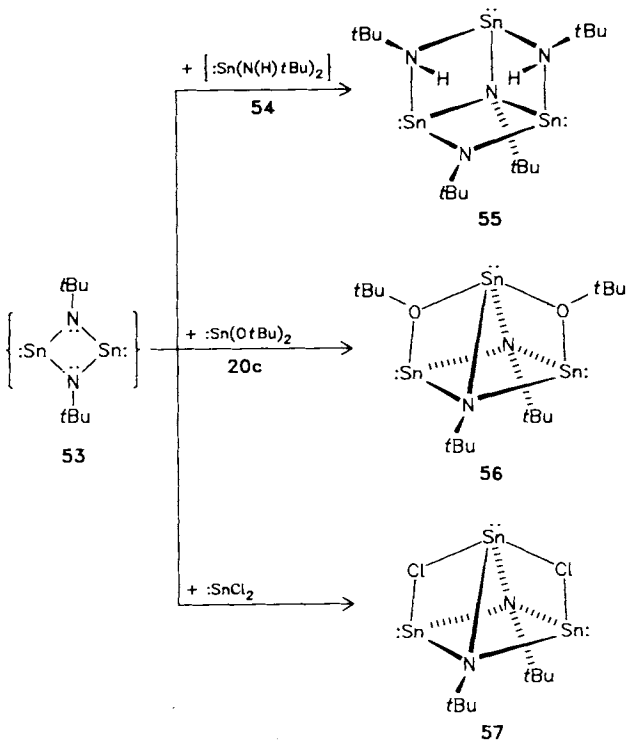
4.2.3. [3+3]- and [3+4]-Additions

Trifunctional systems containing one acid and two base functions react with the same compounds, but in a manner depending on the strength of the base. Whereas **14b**, for example, reacts with one equivalent of SnN-*t*Bu to give stable polycyclic **47**, **20c** reacts with two equivalents of SnN-*t*Bu. From these two equivalents one can construct the four-membered ring **53**, which formally displays two acid and two basic functions and is isoelectronic with a cyclobutadiene. As can be seen from Scheme 4, this ring can be trapped by reactions with various trifunctional molecules. The reaction of **53** with the equally unstable **54** is a [3+3]-addition resulting in a seco-norcubane skeleton **55**;[42a,60] all four centers of **53**, however, react with the three centers of **20c**, and this causes one of the tin atoms of the product **56** to be four-coordinate.[61] The structural difference between **56** (with a central seven-atom framework consisting of two bipyramids with a common face) and **55** may be attributed to the three-coordinate oxygen and four-coordinate nitrogen respectively. The preparation of **57** also depends on a [4+3]-addition.[36,56] An X-ray structure



Scheme 4.

analysis has shown that the molecular units **57** link to form a polymer; one of the chlorine atoms acts as a bridge to two adjacent λ^3-tin atoms, itself acquiring square planar coordination (Fig. 8).

4.2.4. [2+2+2+2]- or [4+4]-Additions

There are a large number of molecules with the cubane structure whose formation can in general be attributed

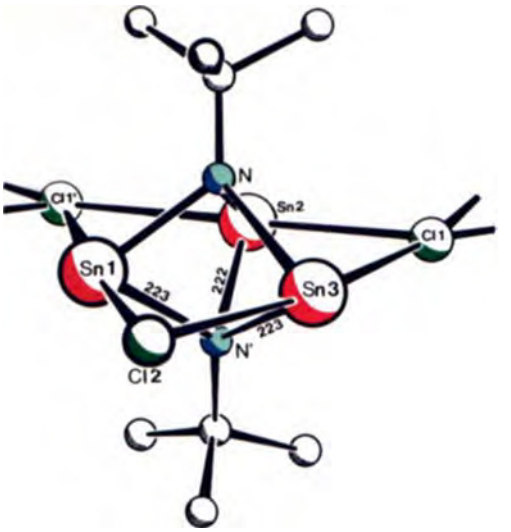


Fig. 8. Section of the crystal structure of **57** [36, 57]. The local symmetry of the $Sn_3(NtBu)_2Cl_3$ unit is close to D_{3h}.

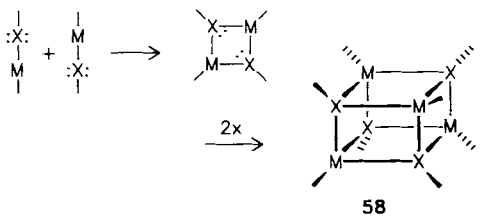
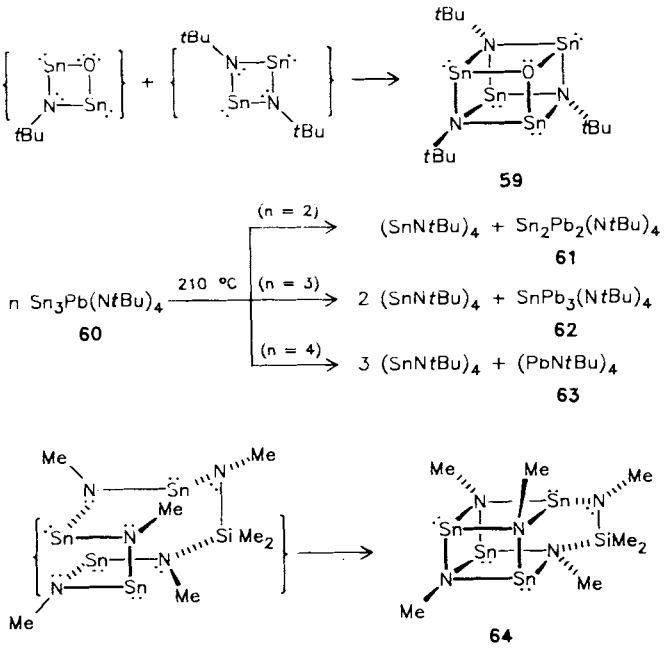
to the reaction of doubly unsaturated acid-base systems. Examples are organoberyllium alkoxides $(RBeOR')_4$,[62] iminoalanes $(RAlNR)_4$,[63] and thallium(I) alkoxides $(TlOR)_4$,[58] to name only three typical representatives. Retrosynthetic considerations lead to the assumption that monomeric units first come together in pairs to form four-membered rings, pairs of which then mutually complete their coordination spheres by forming a cubane system **58** [Eq. (r)].



(r)

With light elements and less bulky substituents, higher oligomers than tetramers can be formed,[64] whereas with heavy elements (in particular low-valent metals with an "inert" s-electron pair) the preferred use of pure p orbitals leads exclusively to cubane-type arrangements.[35b,36] The formation of tetrameric iminogermylenes (e.g. $(GeN\text{-}tBu)_4$[23a,65]), iminostannylenes $(SnNR)_4$ (R = isopropyl, 1,1-dimethylhydrazyl,[42b] *tert*-butyl,[42a,44] benzyl[44]) and iminoplumbylenes (e.g. $(PbNtBu)_4$[23a]) can be described in an analogous manner (cf. also Fig. 5).

Apart from these "homogeneous" oligomers of doubly unsaturated acid-base systems, there are also a series of compounds that are formed from non-identical starting materials (e.g. by "scrambling" reactions) or that formally arise from an intramolecular [4+4]-cycloaddition (e.g. to give **64**). Some of these compounds are presented in Scheme 5; for the exact preparative details the reader should consult the original references (**59**,[44,66,67] **60**–**63**,[23a] **64**[53]). Figure 9 shows the structure of the molecule **64**, which is analogous to basketane.[68]



Scheme 5.

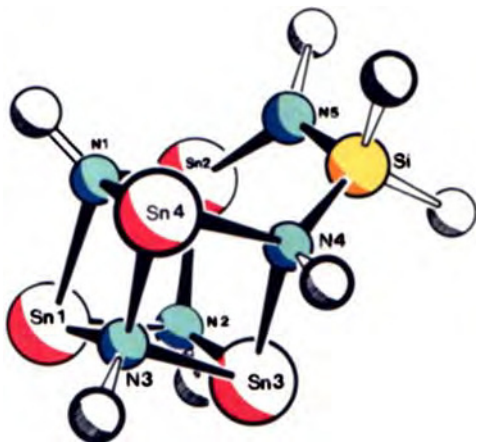


Fig. 9. Molecular structure of **64** [53].

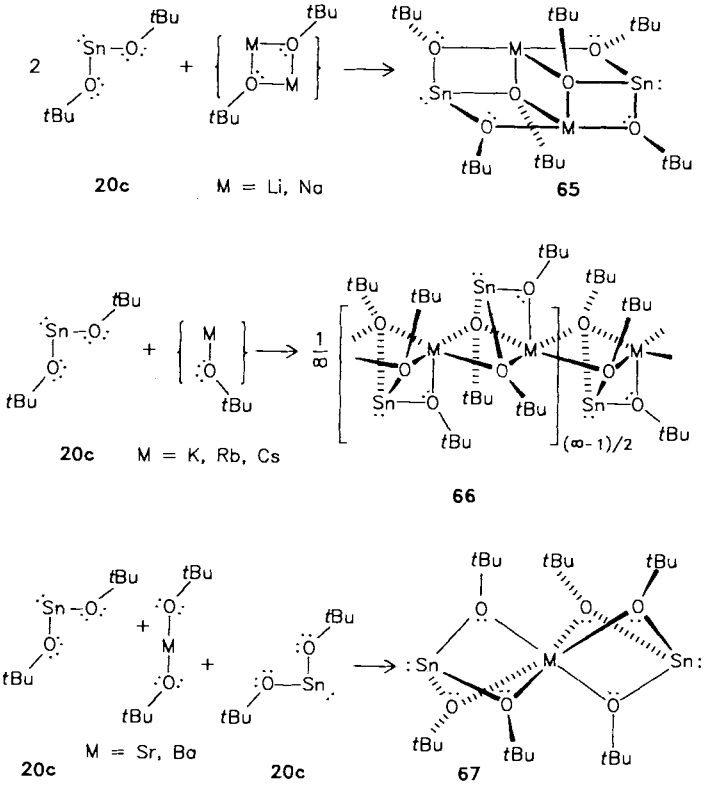
4.2.5. Additions Involving Several Acid and Base Centers

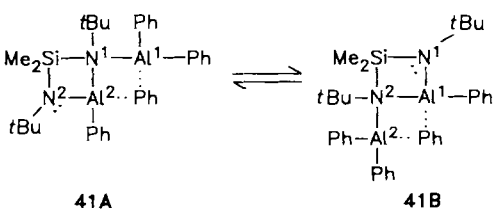
Metal alkoxides of the first and second main groups form oligomeric, in some cases molecular, compounds in which the metal atoms tend to compensate for their lack of electrons by acquiring as many oxygen donors as possible;[69,70] they should therefore be ideal starting materials for addition reactions with trifunctional acid-base systems. This is indeed confirmed in the reactions of metal *tert*-butoxides with tin di-*tert*-butoxide (Scheme 6). An X-ray structure determination shows that the metal atoms Li and Na in molecule **65**[71] are four-coordinate, the tin atoms three-coordinate and the oxygen atoms three- or four-coordinate. The polycyclic unit $Sn_2O_6M_2$ is composed of two seco-norcubane-analogous subunits that share a common face. The reaction of **20c** with the alkoxides of the heavy alkali metals leads to polymeric arrangements of trigonal bipyramidal cages $Sn(OtBu)_3M$ (**66**), in which the alkali metal atom is coordinated by five oxygens and forms the link between the cages (cf., on the other hand, **52**).[71] The larger radius (and possibly the accessibility of d orbitals) is associated with a larger coordination number for K, Rb and Cs. The alkoxides of the alkaline earth elements strontium and barium react with the tin alkoxide **20c** to form the molecules **67**, which contain six-coordinate alkaline earths (the reaction corresponds to a [3+3+3]-addition; $Mg(OtBu)_2$ and $Ca(OtBu)_2$ do not react).[72]



Scheme 6.

5. Properties of Metallapolycycles

The polycyclic species described in Section 4 are thermally more stable when the point symmetry of the central framework is high and the distribution of the peripheral ligands is isotropic. Whereas $(SnNtBu)_4$, for example, can be heated to above 250°C without decomposing, **47** decomposes within a few hours at 210°C to **14b** and $(SnNtBu)_4$.[42a] Molecules that possess, in addition to the donor and acceptor functions that are bound to each other, further coordinatively unsaturated bases (e.g. the three-coordinate nitrogen atoms in **39**, **41**, **55** and **64**) can display intramolecular valency fluctuation; this is shown here for molecule **41**. The temperature-dependent ^{1}H-NMR spectrum shows that there is an equilibrium between **41A** and **41B** [Eq. (s)]. The fluctuation within compound **41** is



(s)

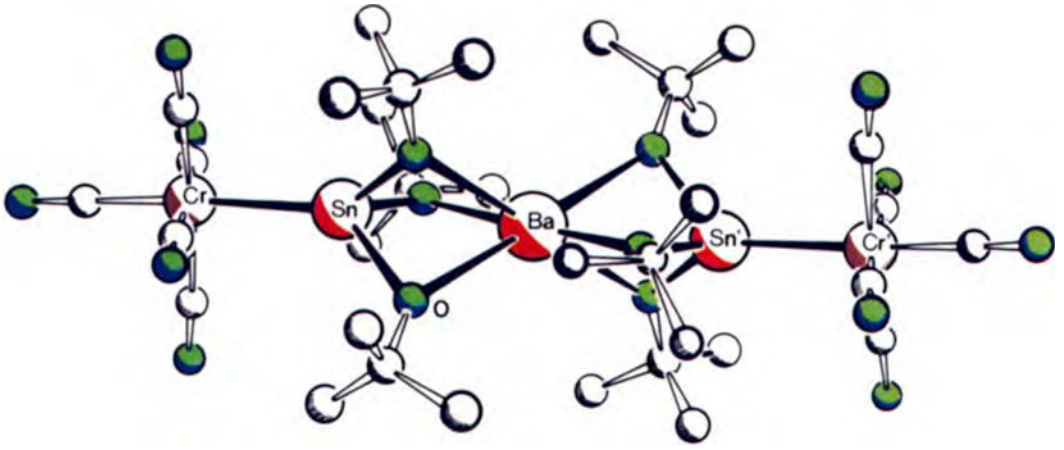


Fig. 10. Molecular structure of **70** [78].

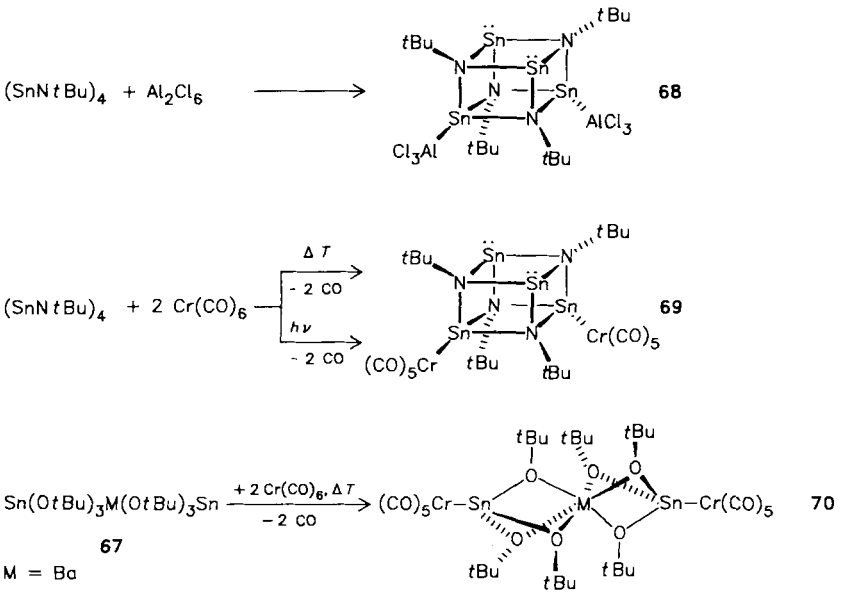
caused by the competition between the donors N2 and N1 for a coordination site at a further aluminum atom (for a more detailed discussion see Ref. [29]). Similar competition leads to intramolecular dynamic exchange of formal donors in molecules **39**,[39] **55**,[60] and **64**.[53]

Our description of the compounds presented in Section 4 as polycyclic molecules is a necessary consequence of the model we use to interpret their formation. If, on the other hand, the accumulation of metal atoms in these compounds is accentuated, then an alternative bonding model arises in which the metal cluster[73] of the central framework is described, the non-metal ligands serving only to neutralize its charge. There is however neither structural nor spectroscopic evidence[44] to give this model particular support.

Polycyclic compounds that contain low-valent metal atoms with lone pairs should be able to utilize these to act as electron donors. Since the heavy metals can additionally function as electron acceptors, it is conceivable that, under special conditions, the molecules may aggregate to form "coordination polymers" with metal-metal interactions. We have only found one compound in which different tin atoms act as acceptors and donors (in the crystal). The crystal structure of $(SnNNMe_2)_4$[42b] involves an undulating ribbon of approximately equidistant tin atoms—irrespective of whether the contacts are intra- or intermolecular. The compound is a red solid (in contrast to the colorless iminostannylenes that only involve van der Waals contacts between molecules); it decomposes above 50°C to β-tin, nitrogen, methane, ethane and dimethylamine.

Compounds **68**, **69** and **70**, synthesized as shown in Scheme 7, confirm that the low-valent metal atoms can react as bases with strong Lewis acids such as $AlCl_3$ or with transition metal fragments (the intermolecular interactions in $(SnNNMe_2)_4$ have been discussed in terms of other models too[42b]). Compound **68** is the first chemically and structurally characterized example of an adduct of a tin(II) compound and a main group Lewis acid; the synthesis is strikingly simple considering that the compound contains a new type of metal-metal bond. The tin-chromium bond in **69**, however, is already familiar from other examples.[75,76] In both **68** and **69**[77] it is only possible to add two metal fragments to the tetrameric iminostannylene. We have not succeeded in synthesizing a molecule



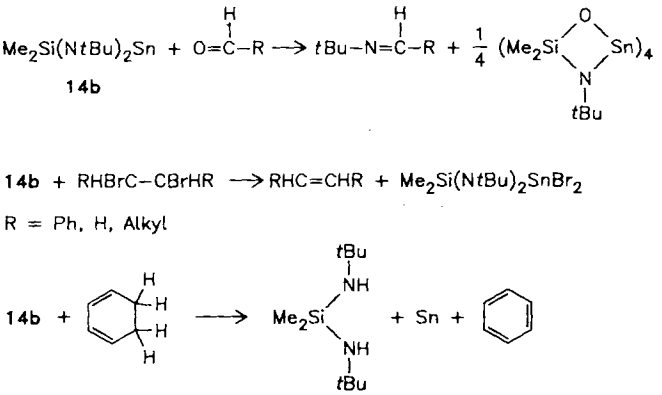
Scheme 7.

in which all four tin atoms are bound to metal fragments, either by using drastic conditions or by substituting $Mo(CO)_6$ or $W(CO)_6$ for $Cr(CO)_6$.[77]

The reaction that leads to the polycyclic compound **70** (Fig. 10) seems particularly promising as a pointer to future research. The addition of two metal fragments to **67** converts the linear arrangement of three metal atoms to a chain consisting of five metal atoms.[78] Preliminary studies suggest that this principle can be arbitrarily extended.

6. Concluding Remarks

The technical interest in main group metals is mainly concerned with the elements themselves or with metal ions in solution or in the solid state. Except for organometallics[79] and other specialized compounds such as alkoxides[69] and metal amides,[18,69] molecular compounds of these elements play only a modest role. The cyclic and polycyclic metal compounds described in this review are noteworthy because they allow the transfer of the metal atoms to nonpolar solvents and thus satisfy one condition necessary for homogeneous reactions with other species. The synthetic potential of these compounds is illustrated in Scheme 8 by some reactions of **14b** with organic molecules; the low oxidation state of the metal atom permits both addition and redox reactions (for further redox reactions see Ref. [80]).



Scheme 8.

Aliphatic or aromatic aldehydes are converted into *tert*-butylimines;[81] the initial step in this quantitative reaction is the [2+2]-addition of the polar C-O bond to one of the ring tin-nitrogen bonds of **14b**.[81] The tin atom acts as a halogen acceptor (and is thus oxidized) in the conversion of bromoalkanes to ethenes.[82] The possibility of using **14b** as an oxidizing agent has been realized only in the conversion of hexadiene to benzene.[37a]

I am grateful to my co-workers for their valuable contributions to the work described here (see References). Financial assistance was generously given, at various times, by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the State of Lower Saxony, and by Hoechst AG.

Totally Synthetic Routes to the Higher Monosaccharides

New Synthetic Methods (63)

By Samuel J. Danishefsky and Michael P. DeNinno

The evolution of a strategy to synthesize the title compounds is described. Three principal developments allowed realization of this goal: (1) the attainment of high margins of diastereofacial selectivity and regioselectivity in the construction of pyranoid systems via the Lewis acid-catalyzed cyclocondensation reaction of activated dienes and aldehydes; (2) the exploitation of stereoselective reactions for functionalization of the pyranoid matrix; and (3) the discovery of stereoselective reactions for extending the chiral biases of pyranoid systems to newly emerging stereogenic centers on side chains. The coordination of these components in the synthesis of target systems of high biological interest is described.

1. Introduction

The vast majority of monosaccharides of biological interest have continuous networks of five (pentoses) or six (hexoses) carbon atoms.[1,2] Among the most widely known monomeric sugars are the pentoses, ribose and arabinose, and the hexoses, glucose, mannose, and galactose. While such monosaccharides are found in free form, they are more widely encountered as integral units of biooligomers and biopolymers. Thus, phosphodiester bonds at the 3- and 5-positions of ribose provide the connectivity for ribonucleotides in RNA. L-Arabinose is found in conjugated form in various glycoproteins. Homopolymers of simple hexoses (e.g., cellulose, glycogen, and starch) provide invaluable support material and energy storage depots. In addition, simple hexoses are often covalently linked to other natural products as glycoconjugates (e.g., macrolide antibiotics and glycolipids).

The existence of a few naturally occurring C_7 monosaccharides has been known for some time.[3] In the past thirty years, however, a group of natural products of broadly varied biological function has been shown to contain monosaccharide arrangements containing eight to eleven consecutive carbon atoms. We refer to such compounds as "complex" monosaccharides or as "higher" monosaccharides. Ordinarily, the compounds are not present in free form, but exist as substructural units in glycoconjugates or as the sugar unit in novel nucleosides.[4] Often the compounds in which these higher monosaccharides are found have valuable biological properties. A partial listing of these systems is given in Figure 2.

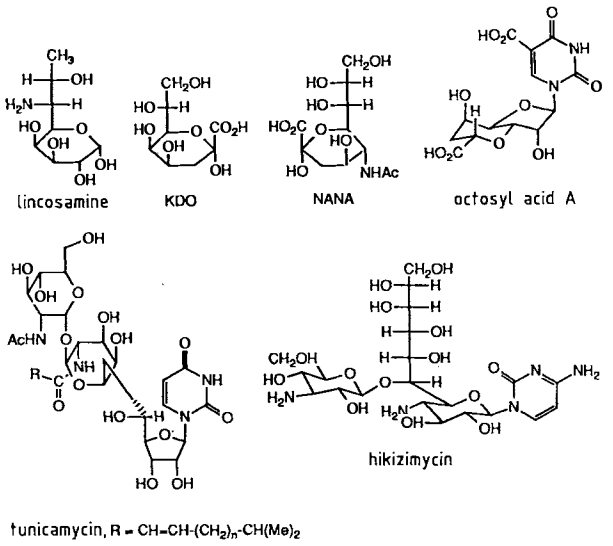

Fig. 2. Examples of higher (complex) monosaccharides. KDO = 3-deoxy-D-*manno*-2-octulosonic acid; NANA = N-acetylneuraminic acid.

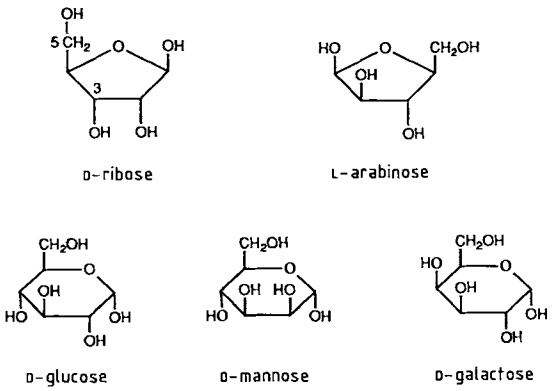

Fig. 1. Frequently occurring pentoses and hexoses.

Lincosamine, an amine octose (cf. Fig. 16), is a component of the commercially important antibiotic lincomycin.[5] Another octose, KDO (cf. Fig. 17),[6] is an important connecting link in the membrane structures of Gram-negative bacteria. The octosyl acids (cf. Fig. 11) are unusual eight-carbon bicyclic sugars which are *N*-glycosidically linked to novel pyrimidine bases.[7] Certain octosyl acids are powerful phosphodiesterase inhibitors,[8] presumably because of their rough structural similarity to cyclic AMP.

Various neuraminic acids[9,10] are encountered as sialic acid residues in glycoconjugates: *N*-acetylneuraminic acid (NANA) is a prime example (cf. Fig. 18). The extent of "sialidation" of oligosaccharides and glycoproteins has vast consequences ranging from influence on the viscosities of various biological fluids to the governance of immunogenic responses.

A C_{11} complex monosaccharide substructure is found in the antihelminthic nucleoside hikizimycin.[11] The mechanism of action of hikizimycin is not presently known. By contrast, a great deal of study and progress has been realized in understanding the mode of action of the bacterially derived tunicamycins (cf. Fig. 12).[12, 13] These compounds have become valuable resources for studying the fine details of the bioprocessing of complex polysaccharides. The tunicamycins apparently function by inhibiting the enzyme UDP-galactose transferase.

Another unusual type of complex monosaccharide is one where there is a carbon glycosidic bond connecting a simple hexose or pentose system with an aromatic framework. Intriguing examples of such linkages are found in the vineomycins[14] and in the papulacandins (Fig. 3).[15] Antitumor activity has been ascribed to both systems.

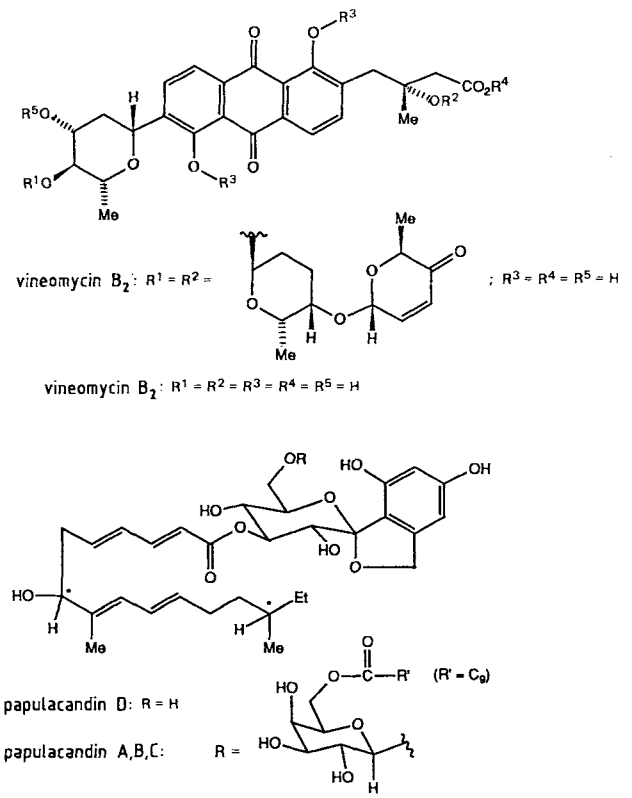

Fig. 3. Monosaccharides with aromatic groups.

As part of a broader effort to identify new reactions and new strategies that might be of utility in organic synthesis, we undertook an exploration into the possibilities for the total synthesis of target systems of the types described above. Our hope was that some new chemistry could be learned as we struggled with these formidable synthetic problems.

2. An Early Discovery

In formulating a program designed to achieve totally synthetic routes to these natural products, we were guided by several considerations. From a biological standpoint, total synthesis appeared to provide possibilities for the assessment of the consequences of structural modification on activity. In many instances, de novo synthesis rather than "retro-fitting" of the natural product offered the most attractive possibility for achieving subtle changes in stereochemistry.

Of course, the motivation from the standpoint of pure chemistry was the challenge of generating such highly oxygenated structures in the laboratory and in coping with the stereochemical subtleties posed by these targets. Serious chemical issues would inevitably be confronted in addressing such challenges. It seemed not unlikely that a successful solution to these problems could have broader implications for synthesis.

The development of a new synthetic reaction type encouraged our entry into this field. In the classical Diels–Alder reaction, the dienophilic framework is comprised of two carbon centers connected by either a double or a triple bond. In connection with the classical "all carbon" Diels–Alder reaction, we had developed access to a new class of highly activated and highly functionalized siloxydienes.[16] These systems, of which compound **1** is prototypical, emerged as very valuable reagents. They are readily prepared from the corresponding α,β-unsaturated ketones. The electron-donating effects of the 1- and 3-oxygen functions are synergistic, thus serving to endow such dienes with a high degree of reactivity and apparently total regiospecificity vis à vis electron-withdrawing dienophiles. Moreover, the functionality endowed by such dienes to their corresponding cycloadducts can be very nicely exploited in the synthesis of polyfunctional target systems. Several total syntheses of biologically active natural products were achieved in our laboratory via recourse to the activated diene concept in the all-carbon Diels–Alder reaction.[16] Happily, the broad potential of the method has not escaped the attentions of many other laboratories in the pursuit of worthy target systems.[17]

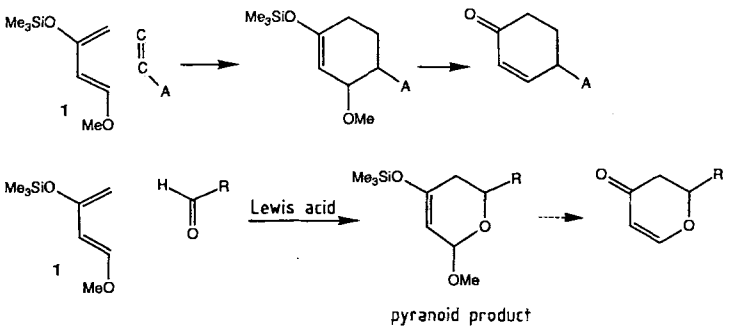

Fig. 4. Above: All-carbon Diels–Alder reaction with siloxydienes; A = activating group (CO, C≡N, NO_2). Below: Lewis acid–catalyzed ring formation of dienes with aldehydes. The overall reaction giving the dihydropyranone is formally a cyclocondensation.

In connection with a fully synthetic route to saccharides, including the higher carbon sugars of the type shown in Figure 2, it was of great interest to investigate the possibility that oxygenated dienes would furnish cycloaddition

products with carbonyl groups, particularly those contained in aldehydes.[18,19] Initial results indicated that such reactions could not be readily effected by strictly thermal means.

However, *James Kerwin*, then a graduate student in our laboratory, found that under the influence of Lewis acids, cyclocondensation of diene **1** with aldehydes can be realized.[20] Other research in our laboratory indicated that, under appropriate catalysis, a remarkably broad range of siloxydienes will react with virtually any aldehyde.[21,22] We had thus developed a concise synthetic entry to pyranoid systems which might serve as intermediates in the synthesis of the pyranose segment of sugars, including complex monosaccharides. Moreover, by exploiting well-known principles and mechanisms of carbohydrate chemistry, the pyranose systems could be converted into furanoses.

3. Stereoselective Routes to Functionalized Pyrans

With a sound route to the basic carbohydrate matrix available, reliable methods were developed to elaborate the interior structure and to incorporate the oxidation and stereochemical patterns found in the monosaccharides of interest. The availability of diverse options proved to be most helpful in being able to approach virtually every member of the series. It was possible to use very heavily oxygenated dienes (e.g., compound **2**), thus producing in the cyclocondensation product the functionality necessary to obtain galactosyl types of sugars.[21] Alternatively, methodology was developed to introduce the oxygen function subsequent to cyclocondensation by oxidation with manganese(III) acetate.[23] In this way, glucose-like stereochemistry is generated at C-4.

Another important reaction was the reduction of the keto group at C-3. When carried out with the reagent system sodium borohydride–Ce(III) chloride (Luche reagent), equatorial alcohols are obtained.[24] Thus, very rapid and highly stereoselective routes to the "glucal" and "galactal" families were available (Fig. 5).

The CC double bond of the galactal and glucal precursors can be functionalized either equatorially or axially at C-2 with high stereoselectivity. Thus, the reaction of *meta*-chloroperbenzoic acid (MCPBA) on the free alcohol (OH unprotected) in the glucal-type system leads to incorporation of a β-hydroxyl group at C-2 (i.e., mannose-like configuration). However, if the hydroxyl group at C-3 is first blocked, MCPBA introduces an α-hydroxyl group (such as is encountered in glucose) at this center. The same stereochemical flexibility is available in the galactal series, thus providing fully synthetic access to either galactose or talose stereochemistry (Fig. 6).

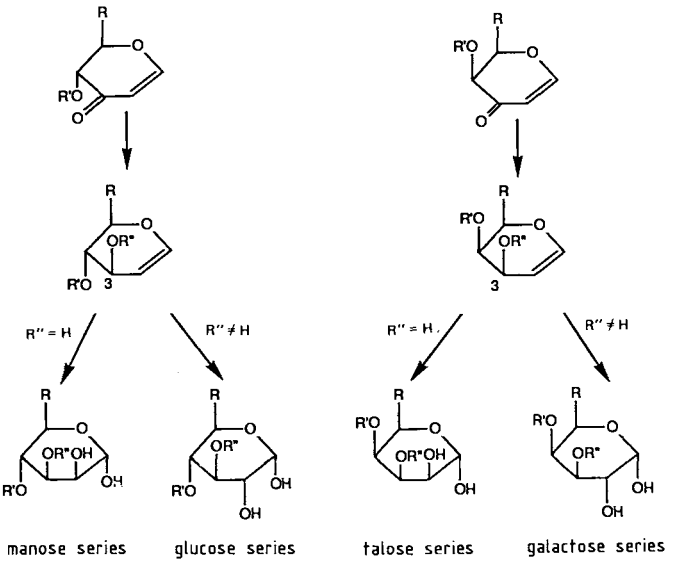

Fig. 6. Totally synthetic approach to some hexoses (for the initial steps, see Fig. 5).

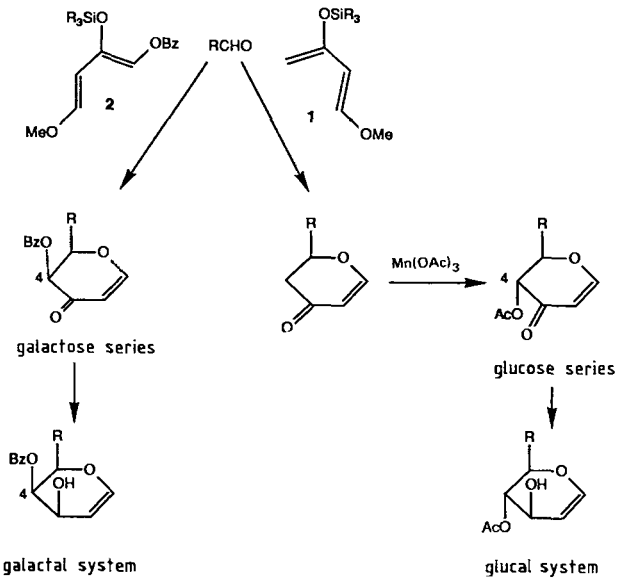

Fig. 5. Syntheses of the galactal and glucal systems. Bz = benzoyl.

As a result of these and other reactions, we had reached the stage where the pyranose (as well as the furanose) rings of the simple sugars could be synthesized in virtually any stereochemical pattern. It also proved possible to delete oxygen atoms and to replace certain oxygen-based centers with nitrogen-based functions. This methodology was used in the synthesis of several novel C_6 monosaccharides such as daunosamine and fucose.[21] Daunosamine is the sugar component of the antitumor agents daunorubicin and adriamycin.[25]

Two applications of the synthesis of aromatic *C*-glycosides are seen in the synthetic routes to the papulacandins[26] (Fig. 7) and the vineomycins[27] (Fig. 8). In the case of the papulacandins, the cyclocondensation of diene **1** with aldehyde **3** generated dihydropyranone **4**. A vinyl group was then introduced by conjugate addition. Product **5** was eventually converted into **6**, setting the stage for an oxidative spiroketalization leading to aglycone **7**.

The route to vineomycin B_2 aglycone passed through ketoaldehyde **8**. Cycloaddition with diene **9** was specific at the aldehyde group. The silyl enol ether functionality of the intermediate cycloadduct **10** was then exploited in a

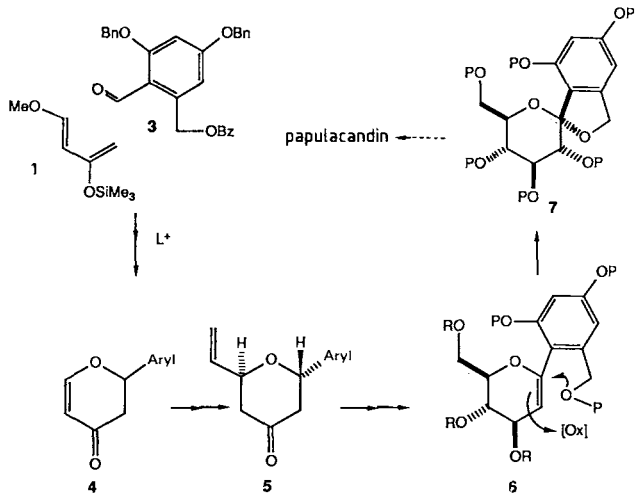

Fig. 7. Syntheses of papulacandins (cf. Fig. 3). Bn = benzyl, P = protecting group, L^+ = Lewis acid ($Yb(fod)_3$).

achieve control over the relationship of the newly emerging stereogenic centers with those present in the original ring. It was through the development of a "menu" of stereoselective reactions to accomplish these chirality extensions that the goal of total synthesis of the complex monosaccharides was furthered.

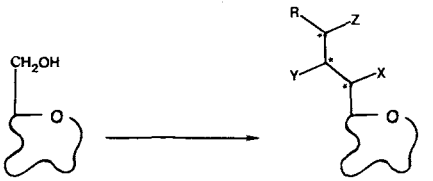

Fig. 9. Generation of chiral centers on the side chain.

One particularly attractive approach focused on a reiterative sequence (Fig. 10). Cyclocondensation of aldehyde

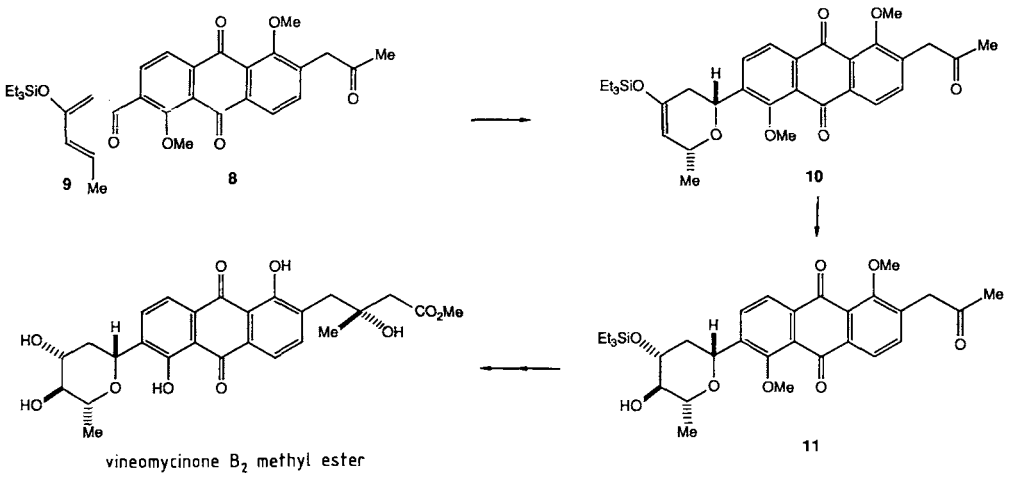

Fig. 8. Synthesis of the aglycone of vineomycin B_2 as its methyl ester (cf. Fig. 3).

hydroboration reaction. *Thus, in two steps (cycloaddition and hydroboration) the entire stereochemistry of the aryl C-glycoside was established (see compound 11).*

4. Chirality Extensions and Reiterative Cyclocondensation

At this juncture, we had reached the stage of a general synthesis of pyranosides, including those linked to an aromatic residue. We could install in the ring virtually any pattern of oxygenation and stereochemistry of interest. However, to make more progress, it would be necessary to move outward from the relatively safe matrix of the pyranoid ring to its less charted side-chain periphery. The challenge lay in developing "lines of communication" between the dissymmetric ring systems and the stereogenic centers that would have to be elaborated on the side chain. This prognosis is set forth in Figure 9, wherein the goal is that of installation of stereogenic centers on a side chain of a pyran ring. Needless to say, it would be necessary to

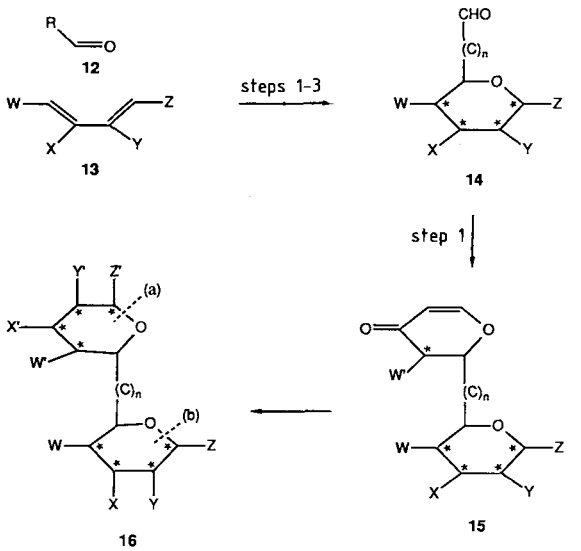

Fig. 10. Iterative cyclocondensation. 1. Cyclocondensation; 2. generation of stereochemistry; 3. formation of an aldehyde group on the side chain.

12 with diene **13** under Lewis acid catalysis would establish the pyranoid matrix. This stage would be followed by the sorts of stereochemical adjustments discussed above. The third stage of the plan called for the unveiling of a new aldehyde on the side chain (see compound **14**). There would then follow another cyclocondensation reaction to give compound **15**. Further adjustments of functionality and stereochemistry would generate a bis-pyranoid system, **16**. In principle, cleavage of either the "a" or "b" bond, or neighboring bonds thereof, might be part of the scheme.

For this program to be attractive, a high degree of diastereofacial selectivity would have to be realized. *The dissymmetric array present in the aldehyde must guide the sense of the subsequent cyclocondensation reaction* (see step **14** → **15**).

This reiterative cyclocondensation strategy was applied to the total syntheses of octosyl acid A,[28] peracetyltunicaminyluracil,[29] and peracetyl-β-methylhikosamide.[30] We first describe the synthesis of octosyl acid A (Fig. 11). The "ribose aldehyde" **18** is itself available by total synthesis[29] via benzoyloxydihydropyranone **17**,[31] which in turn is prepared by cyclocondensation of diene **2** with formaldehyde. For practical purposes, however, we prepared **18** from D-ribose. Cyclocondensation of aldehyde **18** with the parent diene **1** under various forms of Lewis acid catalysis afforded, with very high stereoselectivity, the bis-saccharide **19**.[32] Thus, the ribose ring had induced the sense of chirality at C-1 in the newly fashioned pyranone. The stereogenic center at C-3′ was formed through simple Luche reduction (see compound **20**). At this stage the derived pyranoid ring was cleaved, exposing the octose **21**. After suitable functional group adjustments, the mesyl-substituted cyclic stannane **22** was generated. Fortunately, the otherwise difficult ring closure of the 3-hydroxyl group of the ribose with the C-7 center of the side chain proved to be possible via the tin derivative.[28]

The same dihydropyranone **19** was employed in a total synthesis of peracetyltunicaminyluracil[29] (Fig. 12). In this case, a different pathway was employed. The dihydropyranone ring was cleaved by ozonolysis (bond "a") and subsequent treatment with alkaline hydrogen peroxide (bond "b"). The resultant β-hydroxyacid **23** was converted into the protected aldehyde **24**. Under the influence of the novel binary catalyst system, boron trifluoride etherate-

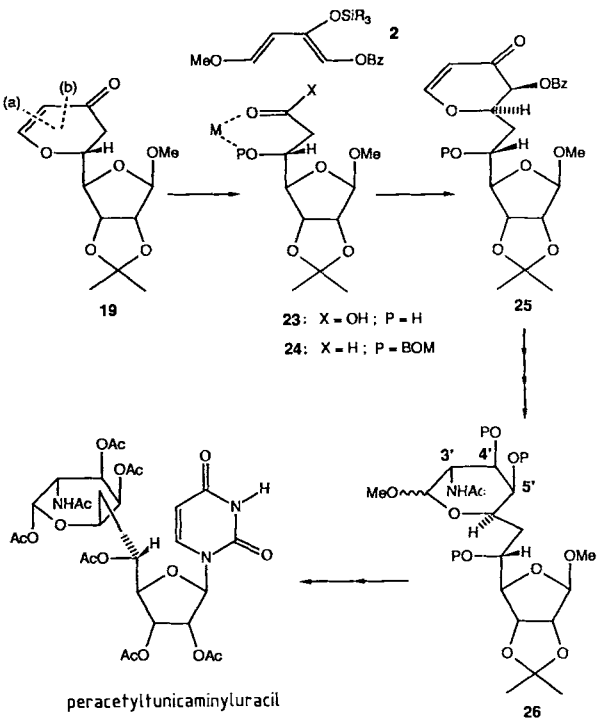

Fig. 12. Synthesis of peracetyltunicaminyluracil. BOM = benzyloxymethyl, M = metal.

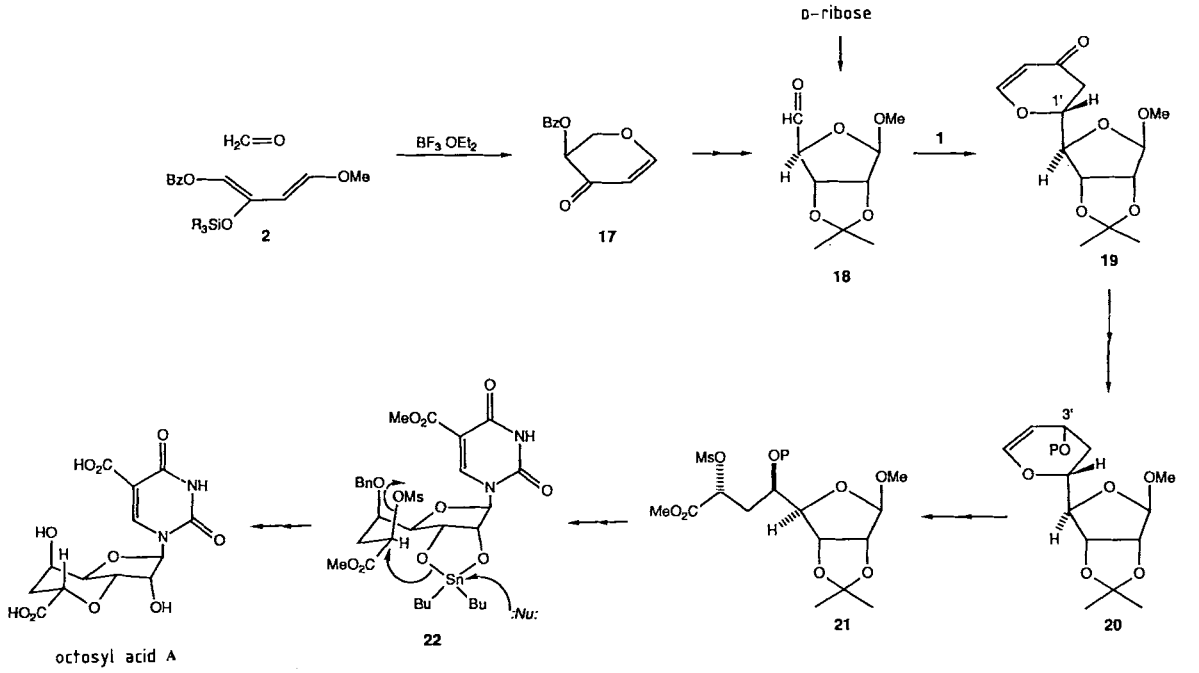

Fig. 11. Synthesis of octosyl acid. Ms = methanesulfonyl.

Ce(III) acetate, the cyclocondensation of aldehyde **24** with diene **2** was highly stereoselective. The sense of the reaction can be rationalized by postulating the chelated conformer of **24** shown in Figure 12. Attack of the diene **2** occurs from the less hindered face. The newly fashioned dihydropyranone ring of **25** was advantageously employed for incorporation of the required functionality and stereochemistry at C-3′ and C-4′ (see compound **26**). Installation of the uracil function in the ribose ring proved to be the most difficult phase of the effort, but eventually was accomplished.[29]

A striking application of this strategy was achieved in the total synthesis of peracetyl-β-methylhikosamide, **36** (see Fig. 13). Cyclocondensation of furfural with diene **2** was followed by highly stereoselective ring functionalization reactions, leading to compound **28**. The furan ring was degraded to eventually produce aldehyde **29**. This same aldehyde, in optically active form, is much more readily obtained from D-galactose.

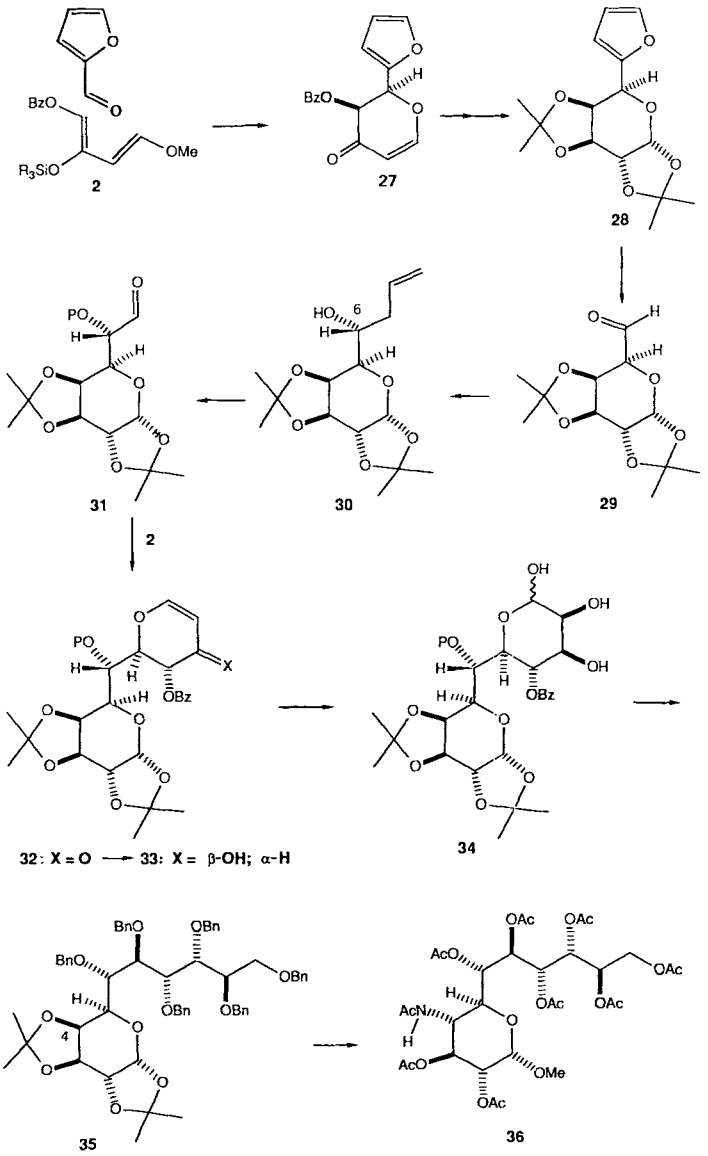

Fig. 13. Synthesis of peracetyl-β-methylhikosamide **36**. P = benzyl.

In the next step, the configuration of C-6 was properly adjusted, taking advantage of a very stereoselective addition of allyltrimethylsilane to the aldehyde function under the influence of boron trifluoride etherate (cf. Fig. 14). The homoallylic alcohol functionality of compound **30** was converted into the α-benzyloxyaldehyde system **31**. Cyclocondensation of this aldehyde with diene **2** via magnesium bromide catalysis under apparent chelation control afforded the *trans*-disubstituted dihydropyranone **32**. Reduction of this compound with $NaBH_4$–$CeCl_3$ led to the glucal-like system **33**. Because of the influence of the free 3-hydroxyl group, epoxidation occurs via *syn* attack on the double bond leading to the D-*manno* configuration in the newly fashioned pyranose system (see compound **34**). Reductive cleavage of the hemiacetal linkage, followed by protection gave the hexabenzyl system **35** with *the proper configuration at nine contiguous oxygenated carbon atoms.* By suitable manipulations, the axial 4-hydroxyl group was selectively exposed. Inversion of the derived mesylate with sodium azide set the stage for completion of the synthesis of system **36**.

It is appropriate to point out that in both the tunicaminyluracil and hikosamine syntheses we were exploring new notions concerning the transmission of stereochemical information. In these syntheses all stereochemical relationships were achieved by inductions, which were accomplished without recourse to artificial auxiliaries. There is also no recourse to coupling of components with prearranged chirality. All stereochemistry flows from the mechanistic character of the carbon–carbon bond forming and oxidation-reduction reactions (see Section 5).

We have also explored another type of chirality extension reaction involving nucleophilic addition of allyltrimethylsilane to several dialdoses under the influence of various Lewis acids. Some remarkable discoveries were registered[33] (Fig. 14). First, this Sakurai[34] reaction is highly stereoselective. Thus, with the ribose aldehyde **18**, either the (5*R*) epimer **37a** or the (5*S*) epimer **37b** can be ob-

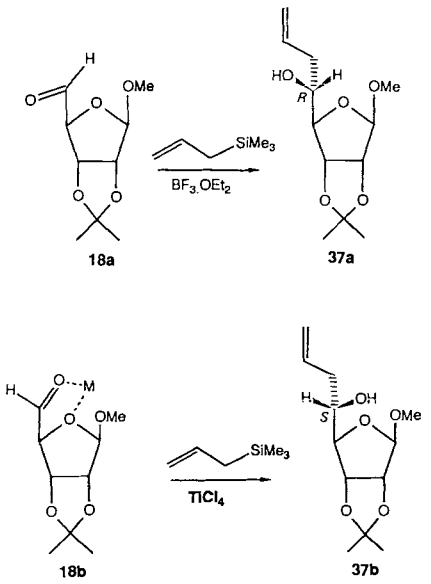

Fig. 14. Influence of the catalyst on the configuration at C-5 of compound **37**.

tained with high stereoselectivity (> 10 : 1) through the simple expedient of changing the Lewis acid catalyst from boron trifluoride etherate to titanium tetrachloride. Product **37a** corresponds to that expected from attack in the Cram-Felkin[35a,b] sense, while **37b** would be the one produced by attack of the allyl group from the less hindered face of the *syn*-conformer **18b**. That titanium tetrachloride should favor the reactive *syn*-conformer **18b** seems reasonably ascribable to chelation. Similar selectivities have been observed with the galactose aldehyde (see **29**→**30**). It should be noted that the product **37a** has the configuration at C-5 that is appropriate for reaching intermediate **23** used in the tunicaminyluracil synthesis. This conversion has in fact been accomplished.[36]

5. Applications to Lincosamine, KDO, and NANA

We turned next to the total syntheses of lincosamine,[37] KDO,[38] and NANA[39] (see Fig. 2) from non-carbohydrate sources. Our strategy at the outset was to concern ourselves with issues of functionality and relative stereochemistry. These matters have now been solved in the context of our syntheses of the racemates. It is not difficult to imagine how the chemistry described below can be applied to the preparation of the required enantiomers by starting with naturally derived, optically pure starting materials.

In the first stage of these syntheses (Fig. 15), suitable aldehydes were combined with appropriate dienes to afford dihydropyranones which were already well advanced toward the target systems. The pyranoids were subsequently

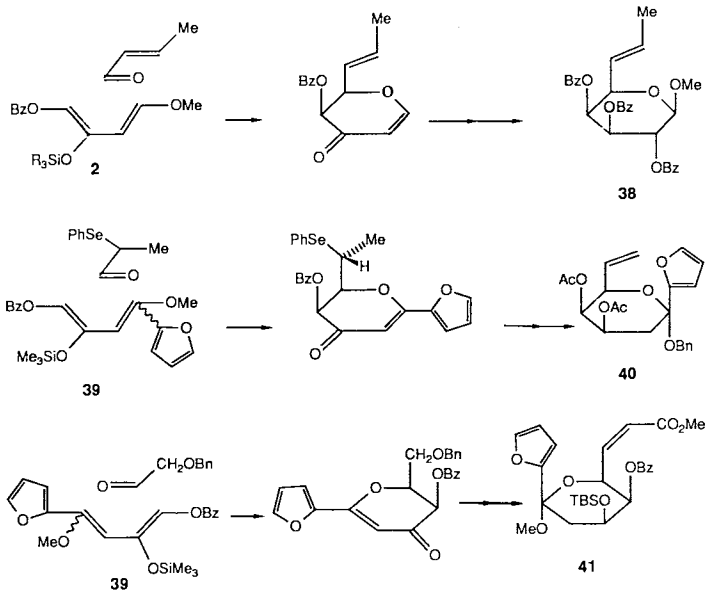

Fig. 15. Synthesis of the enepyranosides **38**, **40**, and **41**. TBS = *tert*-butyldimethylsilyl.

functionalized using stereoselective reactions of the type previously discussed, thereby affording the enepyranosides **38**, **40**, and **41**. We now addressed the question of stereoselectivity in the attack of various electrophiles on these enepyranosides.

Fortunately, in each case we were able to find highly stereoselective reactions of these olefinic linkages with electrophiles. These findings are part of a broader investigation of this type of stereochemical question.[40] Pending accumulation of a more comprehensive collection of data and a satisfactory correlative theory, extrapolations beyond the cases shown here are not without risk.

Two highly stereospecific reactions were observed upon treatment of enepyranoside **38** with osmium tetroxide and with aqueous *N*-bromosuccinimide (Fig. 16). The former

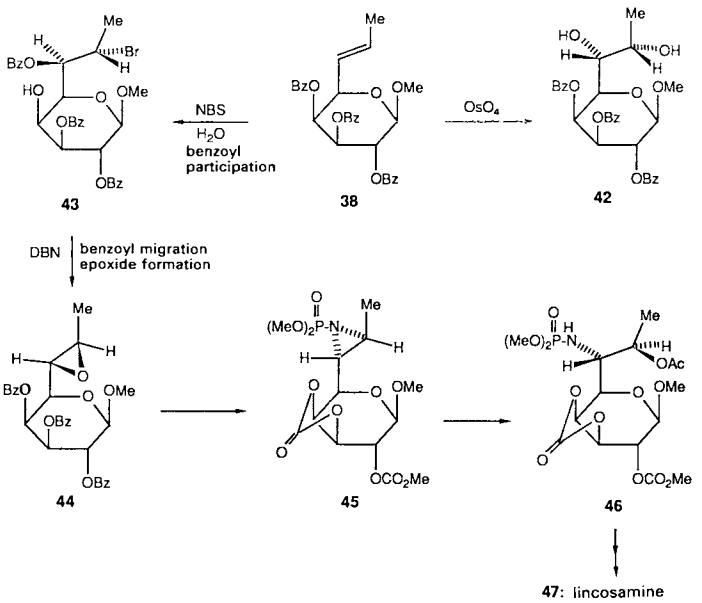

Fig. 16. Synthesis of lincosamine **47** (see Fig. 2 for formula). NBS = *N*-bromosuccinimide; DBN = diazabicyclononane.

reaction gave quite cleanly compound **42**. The latter reaction, proceeding in the same stereochemical sense, afforded the rearranged hydroxybenzoate **43**. Conversion of diol **42** into the lincosamine series proved to be unattainable. However, success was achieved via compound **43**, which reacts with diazabicyclononane to afford, by another rearrangement, the epoxide **44**. The latter was converted into the phosphoaziridine **45** by a lengthy but logical series of transformations. Solvolytic inversion of **45** at C-7 afforded **46** and, eventually, fully synthetic access to α-methyllincosamide.[37]

We turn now to the synthesis of KDO (Fig. 17). Hydroxylation of the vinylpyranoside **40** with osmium tetroxide afforded, in a highly stereoselective reaction, the diol **48** with the side-chain stereochemistry corresponding to

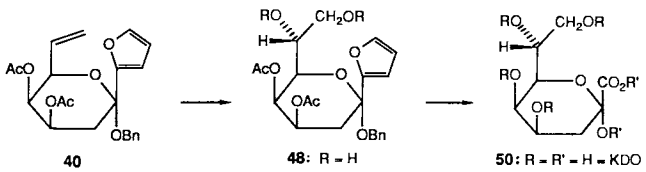

Fig. 17. Synthesis of *rac*-3-deoxy-*manno*-2-octulosonic acid (KDO) **50**.

KDO. The furan surrogate had served us well. It had conferred high reactivity to diene **39** in the cyclocondensation reaction, facilitated construction of the benzylketosidic linkage en route to compound **40**, and withstood a variety of transformations which might have been problematic with a carboxyl (or alkoxycarbonyl) group at C-1.

In the terminal phase of the KDO synthesis, compound **49**, readily derived from diol **48**, underwent oxidation and deacetylation through the action of ruthenium dioxide and sodium metaperiodate. Racemic KDO, **50**, was thereby obtained.[38]

To reach NANA (Fig. 18), the sense of the hydroxylation reaction required was opposite to that observed in the case of pyranosides **38** and **40**. The α,β-unsaturated ester **41** was employed for two reasons. It was conjectured that the steric consequence of the (*Z*) configuration and the electronic effect of sharply attenuating the nucleophilicity of the alkene would converge to change the diastereofacial sense of attack of the osmium tetroxide. Fortunately, this turned out to be the case, in that a virtually stereospecific reaction took place, affording diol **51**. Shortly thereafter, through a sequence that included reduction of the ester group at C-9 and oxidation of the furyl group, compound **52** became available to us.

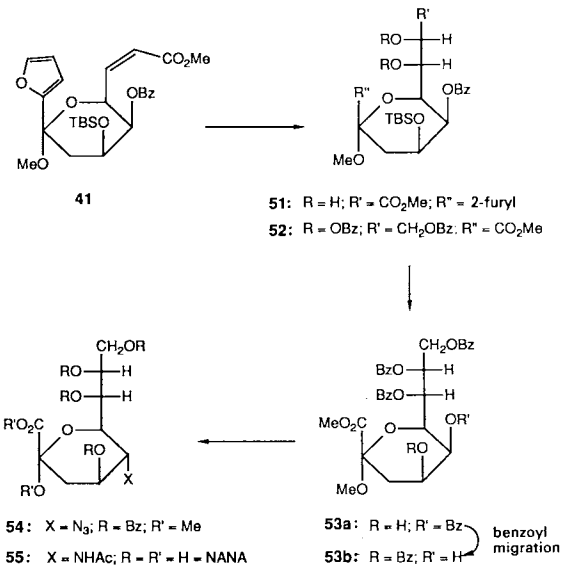

Fig. 18. Synthesis of *rac-N*-acetylneuraminic acid (NANA) **55**.

It was not purely by chance that we now found ourselves with a *tert*-butyldimethylsilyl-protected oxygen at C-4 (equatorial) and a benzoyloxy group at C-5 (axial). *Cleavage of the silyl function from C-4 set into motion the expected migration of the benzoyl group from the C-5 oxygen to the C-4 oxygen, thus specifically liberating the axial 5-OH group.* After suitable activation (by mesylation) and displacement (by azidolysis) the equatorial azide **54** was in hand. Shortly thereafter, fully synthetic NANA **55** took up its place of honor in our collection of fully synthetic complex monosaccharides.

6. Outlook

As indicated above, our involvement with the higher carbon monosaccharides was spurred by the challenges associated with synthesizing such compounds and by the opportunities that they presented to develop new chemistry. Of course, many of the syntheses leave unexplored significant issues of process improvement. Moreover, in some instances we have left unaddressed the matter of synthesizing the biologically active enantiomer rather than the racemate. We do not view this as posing a particularly difficult problem. There are available for this purpose many enantiomerically pure aldehydes of relevance. Since a great deal has been learned about the facial selectivity of the cyclocondensation reaction, some excellent prospects can be pursued for communicating the dissymmetry of the chirons to the emerging saccharide.

The really serious challenge that engages our attentions involves building upon the chemistry learned in this program to produce new compounds of value. It is likely that this goal would be served by inserting the complex monosaccharides into oligosaccharide settings similar to those in which they are housed in nature. Particularly fascinating possibilities in this regard present themselves in the KDO and NANA areas. Our further research in the carbohydrate domain will attempt to deal with this type of problem and opportunity.

Support for this program was provided by various grants from the U. S. Public Health Service and from the Merck Foundation. A special sense of gratitude and indebtedness is extended to the creative and resourceful colleagues in our laboratory at Yale. Some worked out the chemistry of the cyclocondensation reactions. Others worked on particular total syntheses. Their names are individually identified in the various publications cited above. It is to their vision and meticulous experimentation that we dedicate this article.

Stereoselective Aldol Reactions with α-Unsubstituted Chiral Enolates

New Synthetic Methods (64)

By Manfred Braun*

Dedicated to Professor George Büchi on the occasion of his 65th birthday

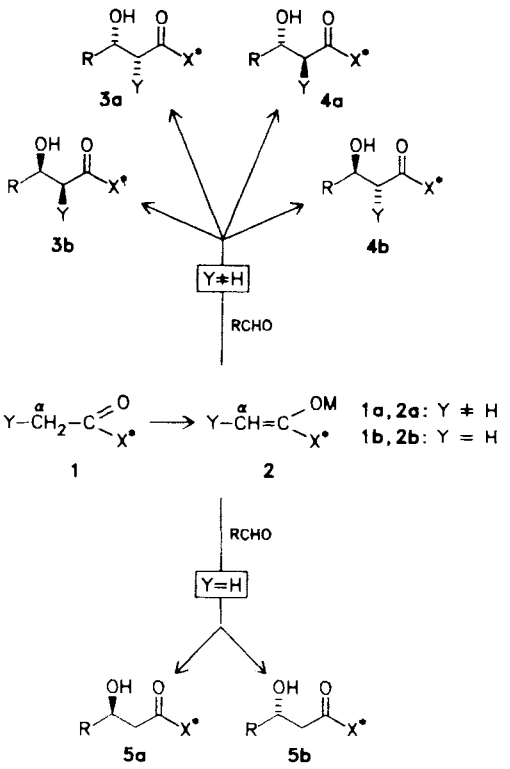
The aldol reaction is among the most important methods of forming carbon-carbon bonds. The addition of an enolate to an aldehyde leads to the formation of at least one chiral center. In the case of α-substituted enolates it has to a large extent been possible to control the product stereochemistry, while the aldol reaction of α-unsubstituted chiral enolates was for many years a "problem child" for synthetic chemists because of its insufficient stereoselectivity. Progress in this area has only been made in the last few years using either new chiral auxiliaries or alternatives to the aldol reaction.

1. Introduction

The aldol reaction, the classical method for the construction of carbon chains with oxygen functionality in 1,3-positions,[1] has undergone a remarkable renaissance in the last twenty years. The impulse for this development was given by the increasingly ambitious synthetic goals which were provided in particular by the macrolide and polyether antibiotics with their many functional groups. New and particularly *stereoselective* variants of the aldol reaction have proved to provide the key to success.[2]

On the assumption that a carbonyl compound **1a** with a substituent Y in the α-position functions solely as the C–H acid component (forming the enolate **2a**), and that an aldehyde RCHO functions only as the carbonyl-active component,[3] the four stereoisomeric adducts **3a**, **b** and **4a**, **b** can be formed. Using suitable metals M and optimized reaction conditions, the preparation of either the *syn*- or *anti*-diastereomers[4] **3** or **4** is possible. In addition, the use of chiral auxiliaries X* permits further differentiation between **3a** and **3b** or **4a** and **4b**, so that each of the products **3a**, **3b**, **4a** and **4b** can be obtained as an almost pure enantiomer.[2,5]

When instead of the reagents **2a** the α-unsubstituted enolates **2b** (which can be obtained by deprotonation of acetyl derivatives **1b**) are used, the situation is apparently simplified in that now only one new chiral center is formed, so that the problem of *syn-anti* isomerism ("simple diastereoselection"[2c]) is no longer present. However, the transition from the α-substituted enolate **2a** to the unsubstituted chiral reagent **2b** is unexpectedly accompanied by the almost total loss of the ability of the latter to discriminate between the two enantiotopic sides of an aldehyde ("enantiofacial differentiation"[6]), so that the specific preparation of one of the diastereomers **5a** and **5b** is not possible. While for example the boron enolate **6a** reacts with isobutyraldehyde to give almost solely the product **7**, the amount of the other three isomers being in total less than one percent, the addition of the α-unsubstituted enolate



6b, using the same metal and the same chiral auxiliary, to the same aldehyde gives a 52:48 mixture of the hydroxyketones **8** and **9**.[7,8] Similar observations have been made with chiral ketone and amide enolates[9–13] and with deprotonated dihydrooxazoles[14] and hydrazones.[15]

The key role played by the α-substituent in enantiofacial differentiation is not easily understood. In the case of the kinetically controlled aldol reaction of the boron enolates **6a** and **6b**, an interpretation has been provided by *Evans* et al.[2d,e] It is based on the Zimmerman-Traxler model[16] of a six-membered transition state with a chair conformation, the aldehyde substituent R occupying an equatorial position. It appears plausible that the approach of the aldehyde to the enolate takes place from that side which faces away from the isopropyl residue of the oxazolidone, so that of the four diastereomeric transition states **10**–**13**

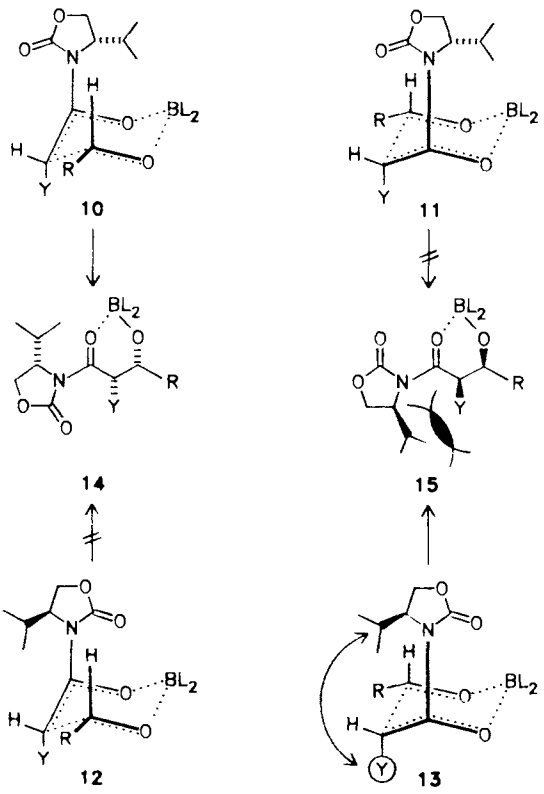
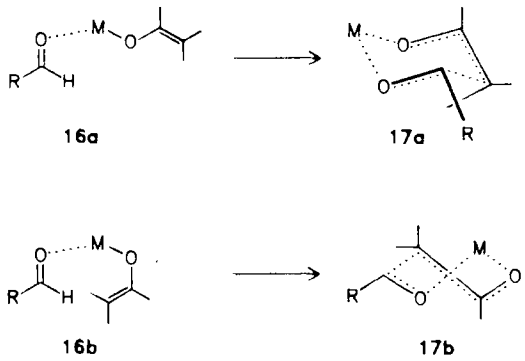
only the two (**10** and **13**) with the isopropyl group in "*exo*" position must be taken into consideration. Stereoselectivity is only observed when one of them is clearly favored. In the case of the propionic enolate **6a** this seems to



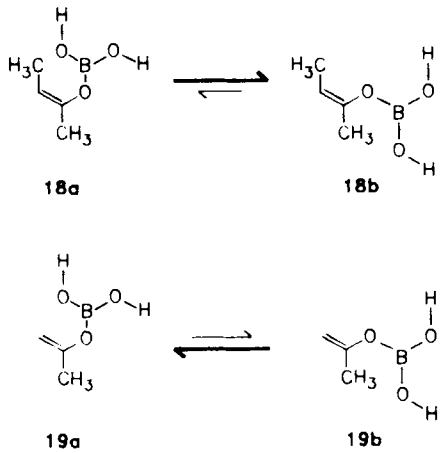
L = *n*-C_4H_9; **a**: Y = CH_3; **b**: Y = H

be the case: the mutual repulsion of the isopropyl group and the substituent Y must be responsible for the fact that the transition state **10a** is favored, so that the borinate **14a** is formed. In contrast, starting from the unsubstituted enolate **6b** no appreciable steric hindrance is present in the chair form **13b**, so that neither of the transition states **10b** and **13b** is particularly favored; thus the chelates **14b** and **15b** are formed in almost equal amounts.

Another explanation for the non-existent enantiofacial selectivity of α-unsubstituted chiral carbonyl compounds, which can also be extended to include ketone and ester enolates, takes into account that boat- or twist-shaped transition states can successfully compete with the chair model.[2c,e] *Hoffmann*, *Cremer* et al. have recently pointed out that a twist boat **17b** can easily be formed from the U-configuration of the enolate **16b**, while the intermediate with the zigzag conformation **16a** is the suitable precursor for the chair-type transition state **17a**.[17]

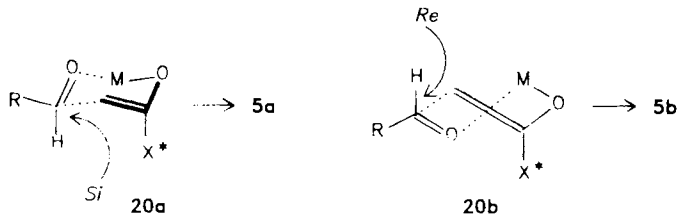


STO-3G calculations for the boron enolates **18** and **19** show that for the (*Z*)-enolate of butanone the W-form **18b** is clearly more stable (by 3–5 kcal/mol) than the U-conformation **18a**. In the case of the acetone derivative **19** the α-substituent is not present, and as a result the corresponding arrangement **19b** is no longer favored, but is in fact somewhat less stable (by 1–2 kcal/mol) than the U-conformer **19a**.[17,18]



Thus it is conceivable that in aldol additions of α-unsubstituted enolates both the chair and the twist transition states are involved, as they have almost the same activation

energy. When, as indicated in formulas **20a** and **20b**, the enantiotopic faces of an aldehyde are in each case attacked preferably, product mixtures result in which the diastereomers **5a** and **5b** are formed in almost equal proportions.

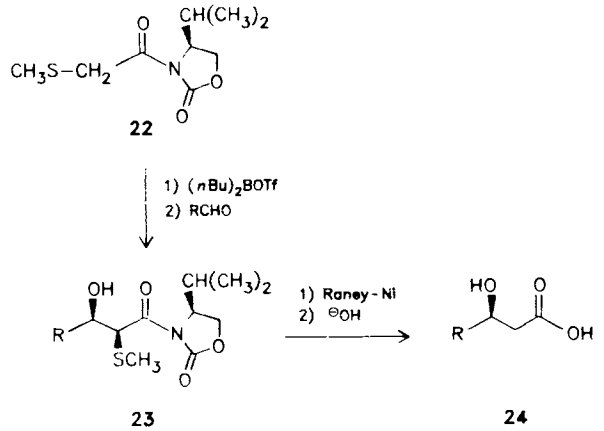


Further investigations on the structure and reactivity of these metal enolates are however necessary in order to support such interpretations of the non-existent stereodifferentiation. Here we shall discuss the progress which has recently been made in the directed *synthesis* of enantiomerically pure β-hydroxycarbonyl compounds of the type **21** and *ent*-**21** using new modifications of the aldol reaction.[19]

2. The Addition of Chiral Metal Enolates to Aldehydes and Unsymmetrical Ketones

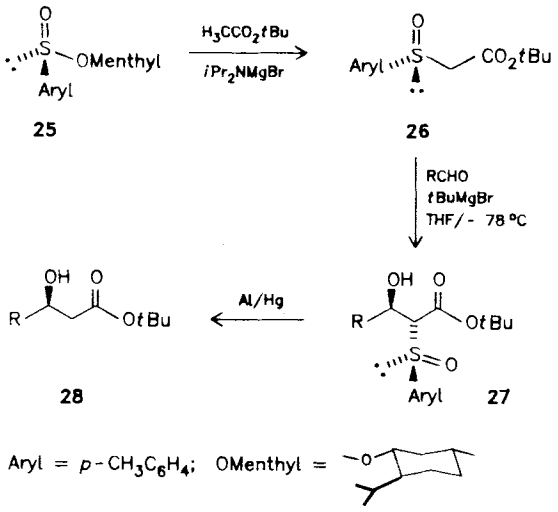
2.1. Reversible Introduction of an α-Substituent

The incorporation of an α-substituent which serves to guarantee good stereoselectivity and which can be removed after carrying out the aldol addition is an obvious solution. Thus when the derivative **22** of (methylthio)acetic acid is converted into its boron enolate and allowed to react with aldehydes, the main products are the *syn*-diastereomers **23** (in analogy to the corresponding reaction of the propionic reagent **6a**). Desulfurization using Raney nickel, followed by saponification, gives β-hydroxycarboxylic acids **24** with an optical purity of 85-99%; the chemical yields are reported to be good.[7]



R = $(CH_3)_2CH$, n-C_3H_7, CH_3, C_6H_5; Tf = CF_3SO_2

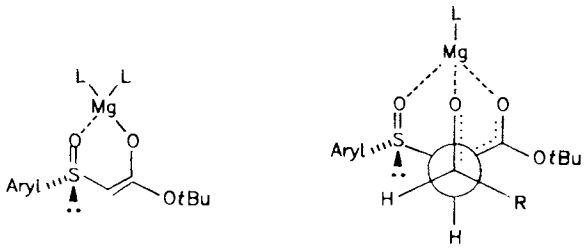
Furthermore, an α-substituent can also serve as a carrier of the chiral information. Thus *Solladié* and *Mioskowski* observed several years ago[20] that the α-sulfinic ester **26** adds (after deprotonation by a Grignard reagent) diastereoselectively to aldehydes. Reductive removal of the sulfinyl function from the crude products gives the β-hydroxyesters **28** in chemical yields of 50-85% (enantiomeric excess as shown).[21-23]



Aryl = p-$CH_3C_6H_4$; OMenthyl =

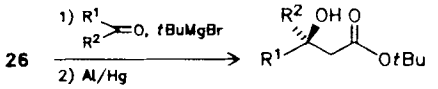
R = C_6H_5, 91% *ee*; R = n-C_7H_{15}, 86% *ee*; R = n-C_8H_{17}, 87% *ee*; R = n-$C_{11}H_{23}$, 80% *ee*; R = nPr–C≡C, 80% *ee*; R = nBu–C≡C, 84% *ee*; R = C_6H_5–C≡C, >90% *ee*. THF = tetrahydrofuran

The favored formation of the excess diastereomer **27** is explained by the transition state model **30**, in which the magnesium atom is chelated by the enolate, sulfoxide and carbonyl oxygens. It appears plausible that the approach of the aldehyde to the enolate **29**[24] occurs from the side of the non-bonding electron pair of the sulfur atom (opposite to the aryl residue) and that the group R of the aldehyde occupies a position *anti* to the sulfinyl substituent.[21]



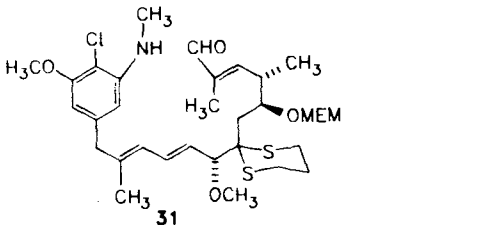
Aryl = p-$CH_3C_6H_4$; L = Ligand

The ester **26** can also be added to unsymmetrical ketones, whereby the degree of stereoselectivity varies greatly from substrate to substrate.[22,23]

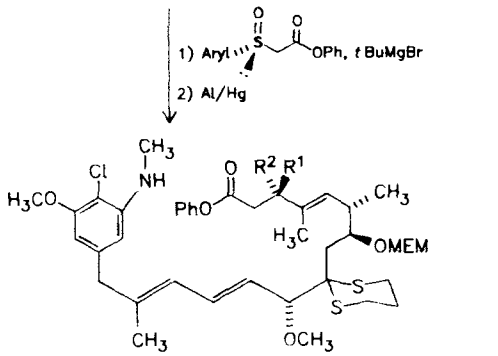


R^1 = C_6H_5, R^2 = CH_3, 68% *ee*; R^1 = CF_3, R^2 = C_6H_5, 20% *ee*; R^1 = *cyclo*-C_6H_{11}, R^2 (in this case and in the following compounds) = CH_3, 95% *ee*; R^1 = $CO_2C_2H_5$, 8% *ee*; R^2 = CH_2CH_2OAc, 40% *ee*; R^1 = nPr–C≡C, 48% *ee*; R^1 = n-C_5H_{11}–C≡C, 36%

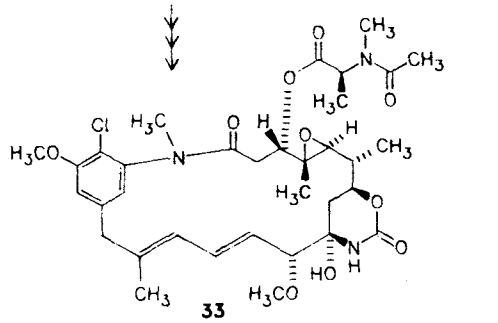
This method has also been used successfully in a total synthesis of maytansin **33**:[25] when the carbon chain of the aldehyde **31** is lengthened by introducing an acetate residue, a 92:8 mixture of the diastereomers **32a** and **32b** is obtained. The main product **32a** can then be converted in several steps into the macrocycle **33**.



31



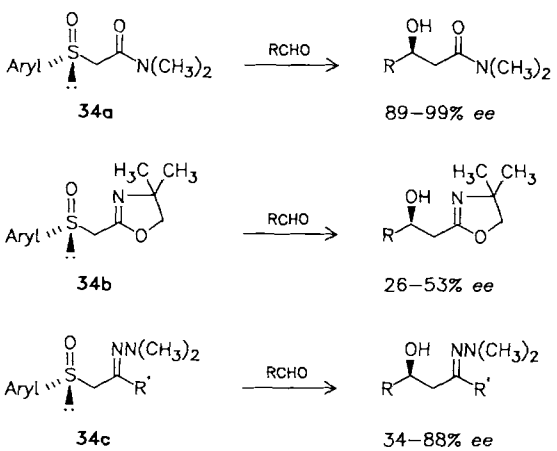
32a: R^1 = H, R^2 = OH; **32b**: R^1 = OH, R^2 = H



33

Aryl = *p*-$CH_3C_6H_4$
MEM = $CH_2O(CH_2)_2OCH_3$

The stereoselectivity of the Solladié-Mioskowski reagent **26**, which can be prepared from the enantiomerically pure menthyl sulfinate **25**, is impressive. This method has, however, the disadvantage that the chirality of the auxiliary reagent is destroyed subsequent to carbon–carbon bond formation. Utilizing the same concept, sulfinyl-substituted acetamides **34a**,[26] dihydrooxazoles **34b**[27] and hydrazones **34c**[28] can be converted with varying degrees of stereoselectivity into the corresponding β-hydroxycarbonyl compounds.



34a 89–99% *ee*

34b 26–53% *ee*

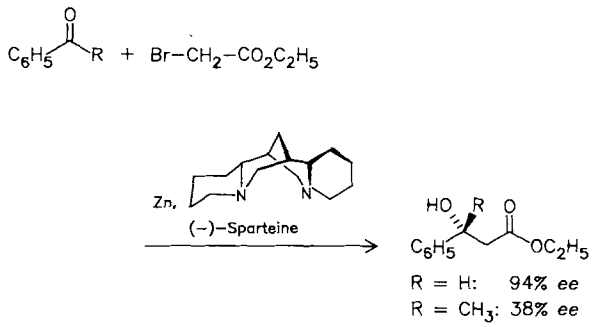
34c 34–88% *ee*

Two additional reaction steps, those involving introduction and removal of the α-substituent, are the price paid for the often remarkable chemical and in particular optical yields which can be attained using this method.

2.2. Enolates without an α-Substituent

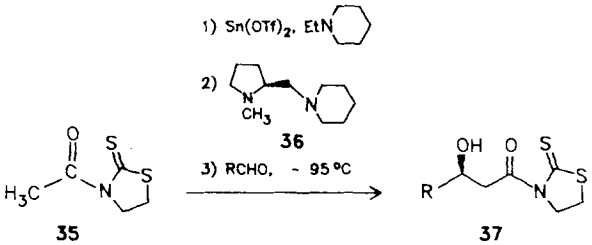
2.2.1. Chiral Complexing Agents

Chiral auxiliaries which are not covalently bonded are often used in asymmetric syntheses, since they can normally be readily separated from the product.[29] Thus *Guetté* et al. studied the Reformatsky reaction in the presence of the bidentate ligand (−)-sparteine.[30] Depending on the type of carbonyl-active component used, large variations in the enantioselectivity are observed, as shown by the examples cited (benzaldehyde and acetophenone); a further disadvantage is that the chemical yields are low (21 and 16% respectively).



R = H: 94% *ee*
R = CH_3: 38% *ee*

The proline derivative **36** appears to be superior to the alkaloid sparteine: when the tin enolate of the *N*-acetylthiazolidine thione **35** is added to aldehydes in the presence of the diamine **36**, the products **37** can be obtained with enantiomeric excesses between 65 and over 90%. Their hydrolysis to β-hydroxycarboxylic acids **24** in corresponding optical purity is possible.[31] Similarly, thioesters of acetic acid can (also via tin enolates) be added enantioselectively to aldehydes (58–80% *ee*).[32]

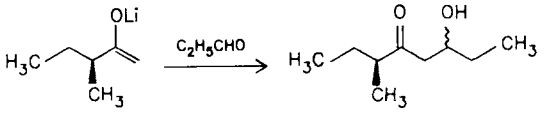


R = C_6H_5, 65% *ee*; R = $(CH_3)_2CH$, >90% *ee*; R = $C_6H_5CH_2CH_2$, >90% *ee*; R = C_2H_5, 90% *ee*; R = *cyclo*-C_6H_{11}, 88% *ee*; R = *n*-C_6H_{11}, 90% *ee*

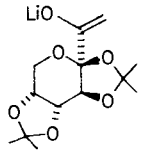
In contrast to some of the methods presented in Section 2.2.2, the use of chiral complexing agents gives *enantiomerically pure* end products only in exceptional cases (e.g. after enrichment via crystallization[33]).

2.2.2. *Covalently Bonded Chiral Auxiliaries*

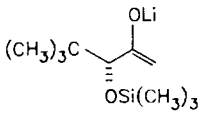
In a fundamental investigation on the addition of the chiral lithium enolate **38** to propanal, *Seebach* et al. observed only poor diastereoselectivity (57 : 43).[34] The reagents **39** and **40** show absolutely no enantiofacial differentiation with respect to aldehydes.[10,11]



38

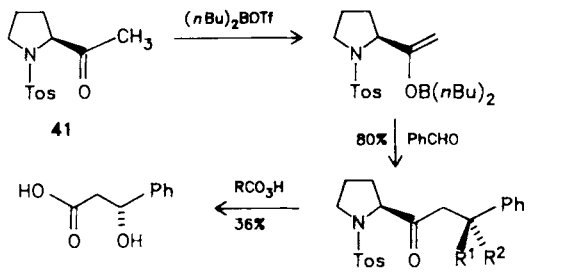


39



40

Reaction of the proline derivative **41** with benzaldehyde, on the other hand, yields the adducts **42a** and **42b** in the ratio of 83 : 17. However, this is also an "immolative" method, since the removal of the heterocycle by Baeyer-Villiger oxidation causes the chirality of the auxiliary reagent to be "sacrificed".[9]



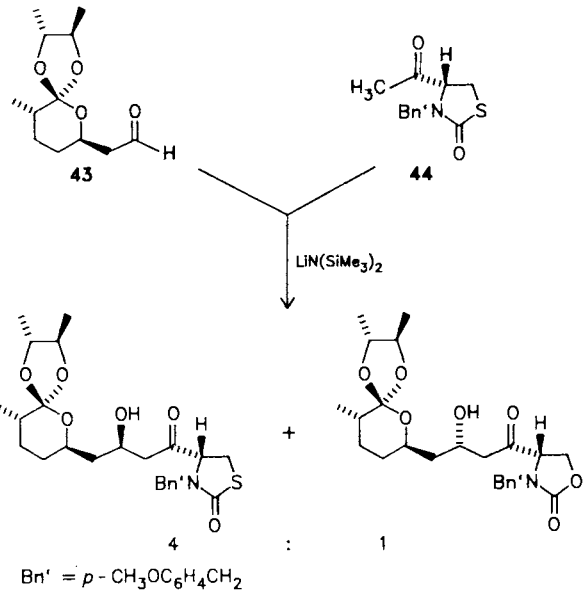
41

42a: R^1 = H, R^2 = OH
42b: R^1 = OH, R^2 = H

Comparable stereoselectivity is also obtained in the aldol reaction between the two enantiomerically pure partners **43** and **44**. Here, however, the chiral auxiliary of the methyl ketone **44** is incorporated into the target molecule (+)-latrunculin B.[35]

Even using "RAMP"- and "SAMP"-hydrazones, reagents which have proved themselves in the stereoselective α-alkylation of carbonyl compounds, the β-hydroxyketones **45** can be obtained only with enantiomeric excesses between 31 and 62%. The total chemical yields lie between 51 and 82%.[15]

An increase in selectivity is however observed using the enamide (azaenolate) **47**, an intermediate which is formed in the deprotonation of the oxazolidine **46** ($R^1 = CH_3$).[36]

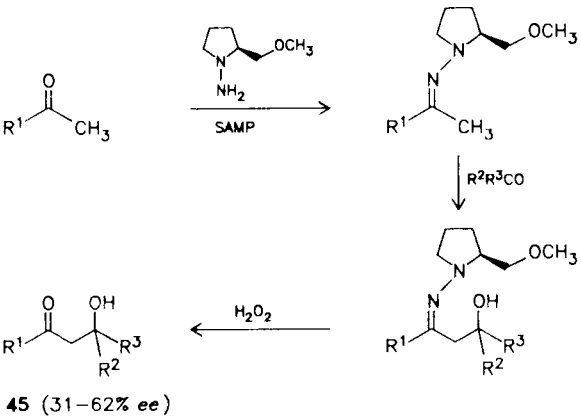


43 **44**

4 : 1

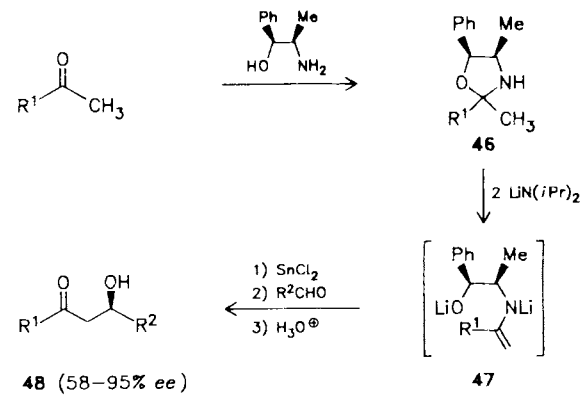
Bn' = *p*-$CH_3OC_6H_4CH_2$

The optical purity of the ketones **48** obtained (in ca. 60% chemical yield) after transmetalation, aldehyde addition and removal of the auxiliary reagent norephedrine is 58–86%. If acetophenone or *tert*-butyl methyl ketone is used instead of acetone, values of 70 to 95% *ee* are obtained.



45 (31–62% *ee*)

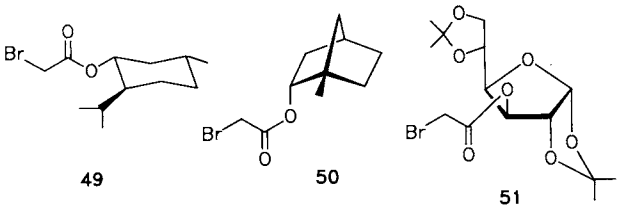
Many attempts have been made to prepare non-racemic β-hydroxycarboxylic acids **24** by the addition of chiral derivatives of acetic acid to aldehydes or unsymmetrical ketones.[37] Sufficient stereoselectivity, combined with acceptable chemical yields, were however obtained neither



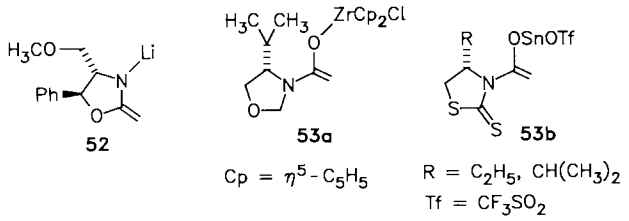
46

47

48 (58–95% *ee*)



49 50 51



52 53a 53b

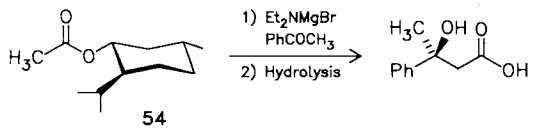
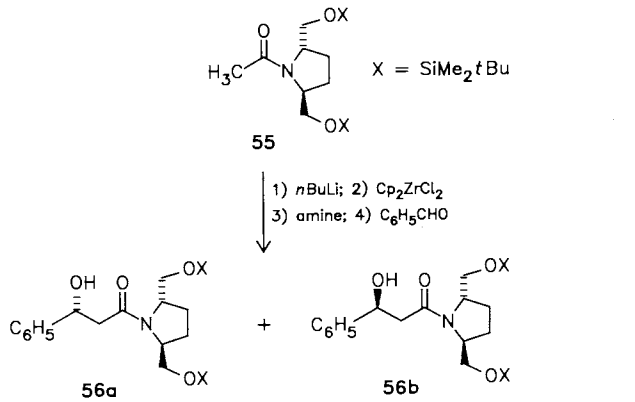
from the Reformatsky reaction of esters of bromoacetic acid **49**–**51**[38] (in part in the presence of chiral amines[39]) nor using the lithiated oxazolidine **52**[14] or the amide enolate **53a**.[12] The tin derivative **53b**, structurally related to the latter, however reacts with α,β-unsaturated aldehydes to give products with diastereomer ratios of ca. 95 : 5.[40]

A report by *Mitsui* et al.[41a] of an unusually high stereoselectivity (93% *ee*) in the addition of menthyl acetate **54** to acetophenone was later corrected by the Solladié group:[41b] the real *ee* value is 58% for acetophenone and propiophenone, the chemical yields being ca. 50%. The latter fall in the reactions of **54** with methyl cyclohexyl ketone and with benzaldehyde to 30 and 6% respectively, although the optical purities are 66 and 82%.[42]



54

The use of the acetamide **55**, which has been added (after conversion to the zirconium enolate) to benzaldehyde in the presence of various amines, also does not permit the simultaneous achievement of sufficient stereoselectivity and good chemical yields of the product **56a**/**56b**.[13]

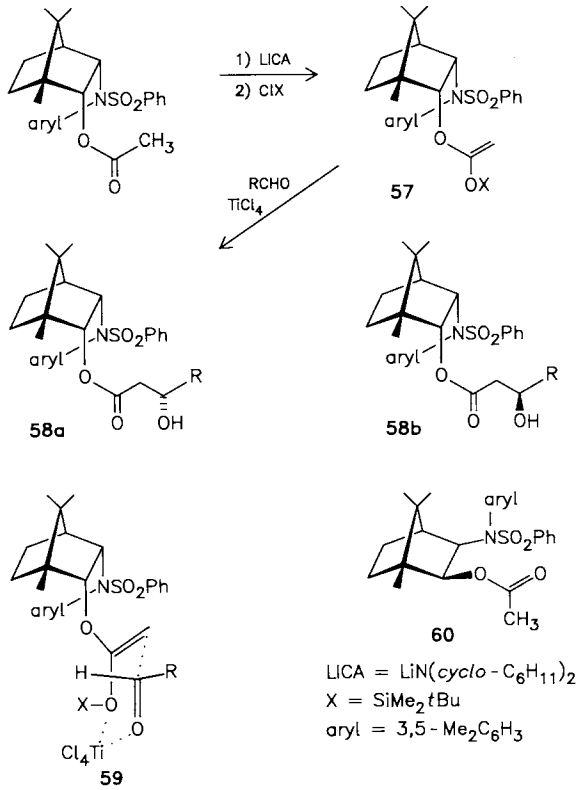


55

56a + 56b

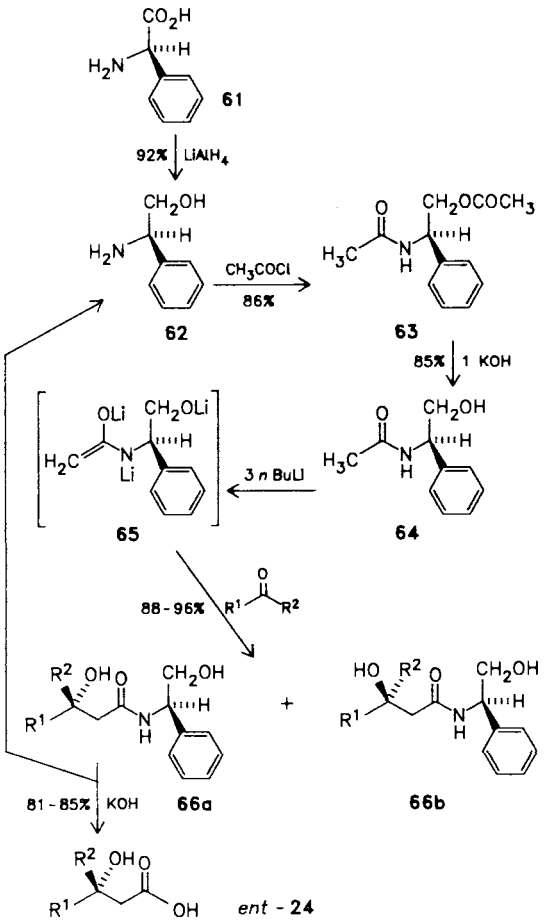
Amine	56a : 56b	Yield [%]
$[(CH_3)_2CH]_2NH$	3.7 : 1	97
$(C_2H_5)_2NH$	5.3 : 1	62
n-$C_4H_9NH_2$	8.5 : 1	20

A considerable improvement was made by *Helmchen* et al. with the $TiCl_4$-catalyzed addition of the ketene acetal **57** to aldehydes, whereby diastereomer ratios **58a** : **58b** of better than 93 : 7 can be obtained.[43] The preferred attack of the reagent **57** at the *Re*-side of the aldehyde is in agreement with the model **59**. The excess diastereomers **58a** can be obtained in a pure state by recrystallization; hydrolysis leads to β-hydroxycarboxylic acids *ent*-**24**. Enantiomeric end products **24** can similarly be formed from the ester **60**.



57 58a 58b 59 60

With the motivation that chiral α-unsubstituted enolates **2b** should be available in simple ways starting from enantiomerically pure auxiliary reagents which in turn should be as cheap as possible, we recently studied the reaction of (*R*)-*N*-acetyl-α-phenylglycinol **64** (see Scheme 1).[44,45] With *n*-butyllithium the triple deprotonation to the enolate **65** is possible; this adds to aldehydes or to acetophenone, forming the isomers **66a**/**66b**. The diastereomer ratios are given in Scheme 1. Alkaline hydrolysis of the adducts **66a**/**66b** leads to the corresponding carboxylic acids *ent*-**24**. The preparation of the chiral amide **64** is carried out as follows: (−)-phenylglycine **61** is first reduced by lithium aluminum hydride to the aminoalcohol **62**, which is *N*- and *O*-acylated by acetyl chloride to give **63**. Heating with one equivalent of potassium hydroxide in aqueous methanol leads to selective hydrolysis[46] of the ester **63**, yielding the amide **64**. Phenylglycinol **62** is liberated during the hydrolysis of the adducts **66a**/**66b** and can be reused. The product mixtures **66a**/**66b** afford after only a single recrystallization the pure excess diastereomers **66a** in yields between 25 and 43% (with respect to the amide **64**); hydrolysis of these gives enantiomerically pure β-hydroxycarbox-



Scheme 1. Addition of (*R*)-**64** to achiral aldehydes and to acetophenone. Examples:

R^1	R^2	**66a** : **66b**	**66a** + **66b** [%]
C_6H_5	H	80 : 20	96
$(CH_3)_3C$	H	83 : 17	95
$(CH_3)_2CH$	H	78 : 22	93

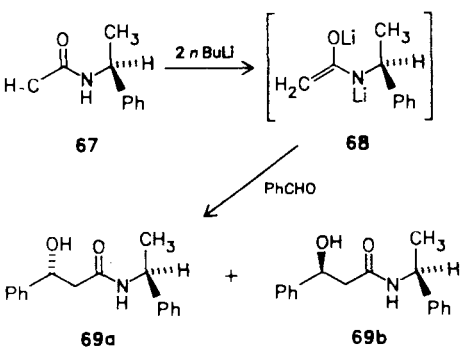
C_6H_5	CH_3	82 : 18	88

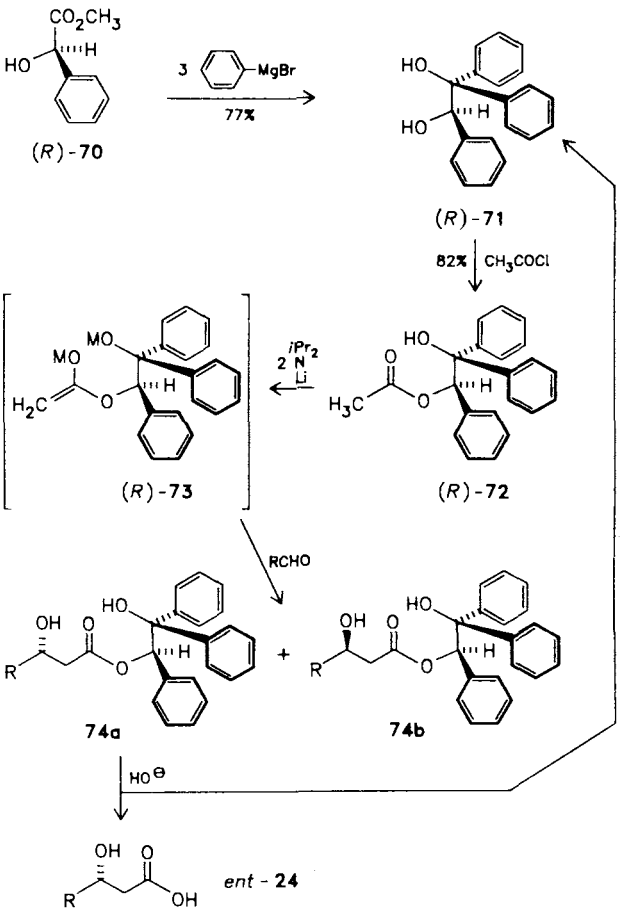
ylic acids *ent*-**24**. Both (*R*)- and (*S*)-phenylglycine are commercially available.

The hydroxymethylene group of the *N*-acetylphenylglycinol **64** shows itself not only to be useful in the amide hydrolysis, but (in the form of the deprotonated alkoxide in **65**) it also has a positive influence on the stereoselectivity of the addition: the lithium enolate **68** of the *N*-acetyl-α-phenylethylamine **67** reacts with benzaldehyde to give



the diastereomers **69a**/**69b** only in the ratio 60 : 40. In addition, alkaline hydrolysis of the adduct does not occur.[47]

With the goal of improving the diastereoselectivity, we then studied the aldol reaction of (*R*)- and (*S*)-2-acetoxy-1,2,2-triphenylethyl acetate **72** (cf. Scheme 2).[48] In the light of our experience with the phenylglycine derivative **75**, we expected that the hydroxyl group (deprotonated to the alkoxide) in the ester **72** would also have a positive influence on the enantiofacial differentiation with respect to aldehydes. When a suspension of the acetic acid derivative **72** is treated in THF with two equivalents of lithium diisopropylamide, a clear solution of the enolate **73** (M = Li) is formed; this, after transmetalation with magnesium bromide or iodide, is reacted with aldehydes at −120 to −135 °C using the cosolvents dimethyl ether or isopentane. The diastereomers **74a**, **b** are formed in the proportions shown in Scheme 2. Mild alkaline hydrolysis leads to β-hydroxycarboxylic acids *ent*-**24** in corresponding optical purity. The chemical yields of the products **24** lie between 76 and 85% overall (2 steps). The chiral reagent **72** can readily be prepared from methyl mandelate **70**: this is first converted by phenylmagnesium bromide into the

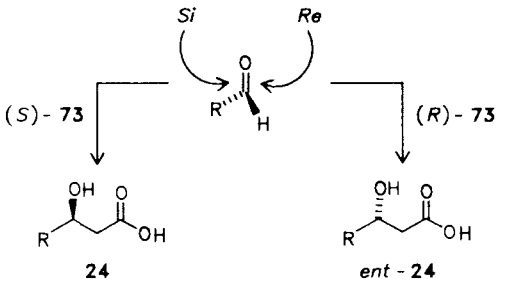


Scheme 2. Addition of (*R*)-**72** to achiral aldehydes. Examples:

R	**74a** : **74b**
C_6H_5	50 : 1
$(CH_3)_2CH$	25 : 1
n-C_3H_7	11 : 1

diol **71**,[49,50] which can then be converted into the ester **72** by acetyl chloride in the presence of pyridine (selective esterification of the secondary hydroxyl group). Both enantiomers of the reagent **72** are easily available, since both (*R*)- and (*S*)-mandelic acid are inexpensive commercial products. In this method the chiral auxiliary is also recovered from hydrolysis of the adducts **74a**, **b** in an unracemized state as the diol **71**.

In all cases which we have so far studied, the (*R*)-configurated reagent **73** attacks the aldehyde from the *Re*-side, the (*S*)-enolate correspondingly from the *Si*-side.[51]

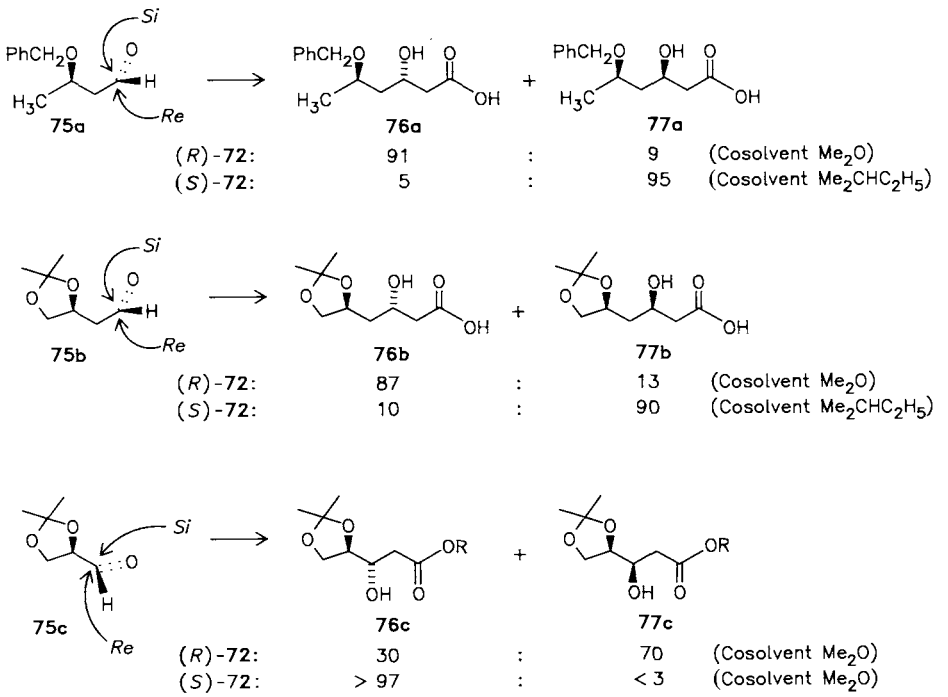


If however homochiral aldehydes **75** (see Scheme 3) are allowed to react with both enantiomers of an enolate **2b**, it must be expected that the diastereofacial selectivities of aldehyde and enolate will work together in one of the combinations ("matched pair"), but be opposed in the other ("mismatched pair").[2f] Thus, after hydrolysis, differing product ratios **76** : **77** will be observed in the two cases: the matched pair gives a larger, the unmatched pair a smaller diastereomer excess.

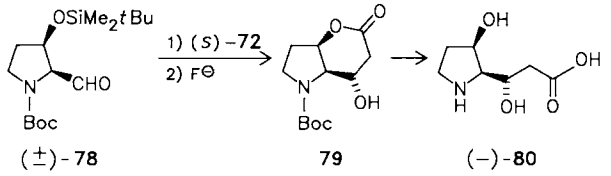
One possibility of controlled and predictable synthesis of both the *anti* and the *syn* isomers **76** or **77** occurs when the reagent selectivity of the enolates (*R*)- or (*S*)-**73** dominates, so that it is able to overcompensate the diastereofacial ("inherent") selectivity of the aldehydes **75**. It can be seen from Scheme 3 that the selective synthesis of *anti* or *syn*-configured carboxylic acids is actually possible in the cases **76a/77a** and **76b/77b**.[52,53] As in the case of the achiral aldehydes, the deprotonated ester (*R*)-**72** here also attacks (independent of the chirality of the substrates **75a** and **75b**) mainly from the *Re*-side (→**76a**, **b**), while the (*S*)-reagent **72** attacks preferably from the *Si*-side (→**77a**, **b**) with comparable stereoselectivity. The diastereofacial selectivity of the aldehydes **75a**, **b** towards lithium and magnesium enolates of *achiral* acetates is low, so that *anti*- and *syn*-products **76a**, **b** or **77a**, **b** are formed in approximately equal amounts.[53,54] In the $TiCl_4$-catalyzed addition of silyl enol ethers and in reactions with several organometallic reagents (particularly those containing boron and titanium) the stereochemistry can be controlled by the chirality of the substrate in the sense of "chelate control".[55] A recent review article contains a detailed treatment of this concept for stereoselective synthesis.[56]

In contrast to β-alkoxy-substituted aldehydes such as **75a** and **75b**, the isopropylidene glycerinaldehyde **75c** also exhibits a clear inherent selectivity towards organolithium compounds.[57] Thus the diastereomers **76c/77c** (R = CH_3) are formed from the lithium enolate of methyl acetate in the ratio of 85 : 15.[58] An increase in the *anti*-selectivity can be attained using the (*S*)-reagent **72**, which here also attacks preferably from the *Si*-side. The *lk*-topicity does in fact also dominate in the addition of the (*R*)-ester **72**, but in this mismatched pair the preference for the *syn* isomer **77c** is only low.[53]

Joullie et al.[59] recently reacted (*S*)-**72** with the (racemic) aldehyde **78**; after removal of the minor diastereomer, they obtained (−)-detoxinine **80** via the lactone **79**.

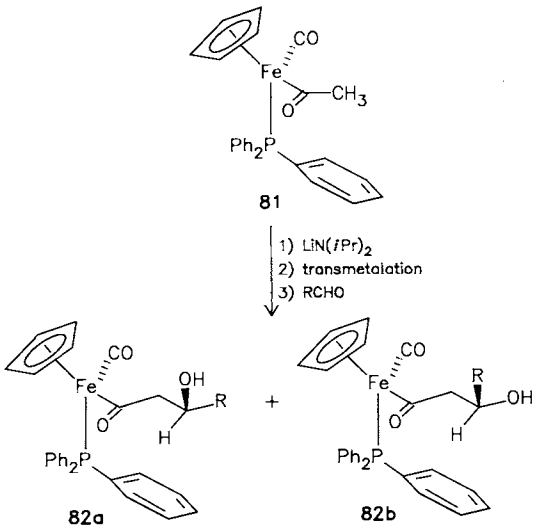


Scheme 3. Reaction of (*R*)- and (*S*)-**72** with chiral aldehydes **75** in tetrahydrofuran.



2.2.3. *Metal Atoms as Chiral Centers*

The creative idea of using a transition metal as a chiral auxiliary was realized almost simultaneously by the groups of *Liebeskind*[60] and *Davies*.[61] The acetyliron complex **81** adds (after deprotonation and transmetalation) to aldehydes at $-100\,^{\circ}C$ with a very high diastereoselectivity to give the products **82a/82b**. Removal of the iron complex gives the corresponding β-hydroxycarboxylic acids **24**. Enantiomerically pure starting material is however not very readily available, since it must be prepared by resolution of a racemate.[62] Thus until now all aldol reactions have also been carried out using the racemic acetyl derivative **81**. The *lk*-configuration of the excess diastereomer **82a** ($R=C_2H_5$) was demonstrated by an X-ray structure analysis.[63]



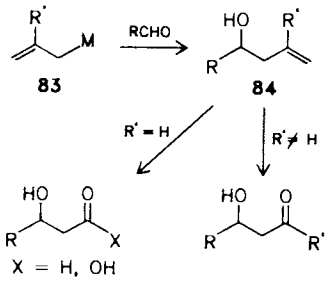
R	Transmetalation with	82a : 82b	Ref.
Ph	iBu_2AlCl	3.7 : 1	[60]
Ph	Et_2AlCl	20 : 1	[61]
Ph	$SnCl_2$	1 : 12	[60]
*i*Pr	iBu_2AlCl	8.2 : 1	[60]
*i*Pr	Et_2AlCl	> 100 : 1	[61]
Et	iBu_2AlCl	5.2 : 1	[60]
Et	Et_2AlCl	> 100 : 1	[61]
*t*Bu	Et_2AlCl	> 100 : 1	[61]

The inadequate enantiofacial selectivity of α-unsubstituted enolates **2b** towards aldehydes has thus very recently been improved with the help of new chiral reagents. For a longer time prior to this, attempts had been made to bypass the problematic aldol reaction in such cases and to seek a route to enantiomerically pure β-hydroxycarbonyl compounds such as **21** or **24** using alternative methods. The following section contains a short account of such attempts.

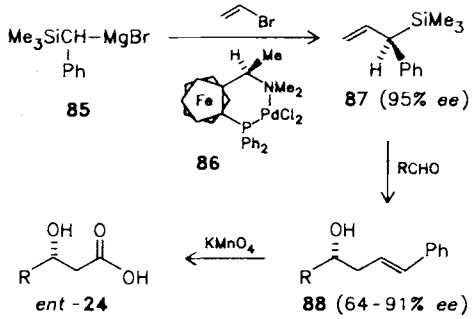
3. Alternatives to the Aldol Reaction

3.1. Allylmetal Reagents as Masked Enolates

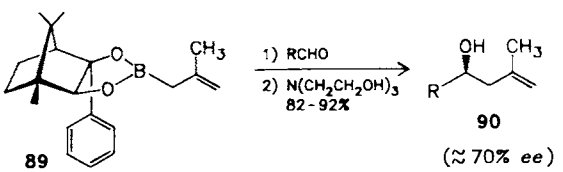
Since carbon–carbon double bonds can generally be readily cleaved to give ketones, aldehydes or carboxylic acids, a homoallyl alcohol **84** can serve as precursor for a β-hydroxycarbonyl compound; thus an organometallic reagent **83** with a σ-bonded allyl residue can be regarded as a masked enolate.[64]



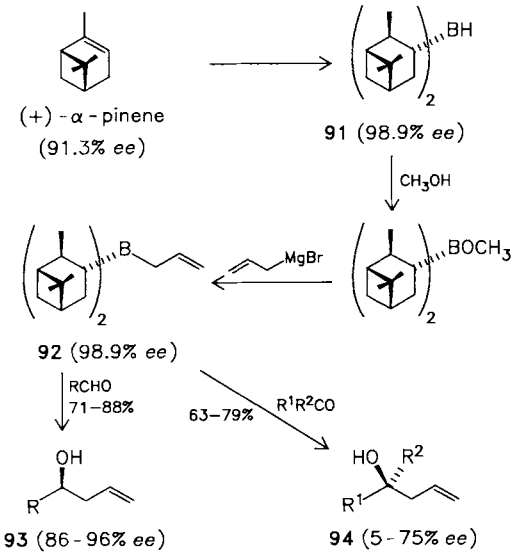
The silane **87** can be added enantioselectively to aldehydes in the presence of $TiCl_4$; the alcohols **88** thus obtained can be cleaved to β-hydroxycarboxylic acids *ent*-**24** without any decrease in optical purity.[65] The allylsilane **87** is formed in 95% enantiomeric excess by coupling the Grignard reagent **85** with vinyl bromide in the presence of the chiral catalyst **86**.[66]



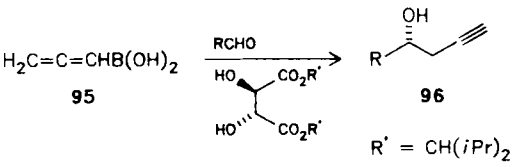
Chiral allylboron reagents have been used (particularly in the groups of *Hoffmann*,[67] *Midland*,[68] and *Brown*[69]) as substitutes for enolates:[70] thus, the boronic ester **89** obtained from (+)-camphor adds to aldehydes and gives (after cleavage of the borate intermediate with nitrilotriethanol) the alcohols **90** in ca. 70% enantiomeric excess.[67]



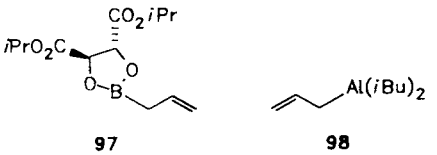
An increase in the selectivity can be obtained with the help of the allylborane **92**, which can be obtained in almost 99% optical purity from α-pinene. Apparently the hydroboration of α-pinene affords predominantly that diastereomer of diisopinocamphenylborane which contains the same enantiomers of α-pinene. Thus, the borane **91** is obtained as a crystalline product with a higher enantiomeric excess than that of the starting terpene.[71] It is thus possible to start from commercial (+)- or (−)-α-pinene of about 91% optical purity. After introduction of the allyl substituent, the addition of the borane **92** to aldehydes and to unsymmetrical ketones gives the alcohols **93** or **94** with in some cases excellent enantioselectivity.[69]



Esterification of the propadienylboronic acid **95** with tartaric acid derivatives also yields an effective transmitter of chirality: the homopropargyl alcohols **96** are obtained in 92–99% *ee*; the chemical yields are between 78 and 90%.[72] Since carbon-carbon triple bonds can be transformed into carbonyl compounds using known methodology,[73] this method can also be considered to be equivalent to the aldol reaction.



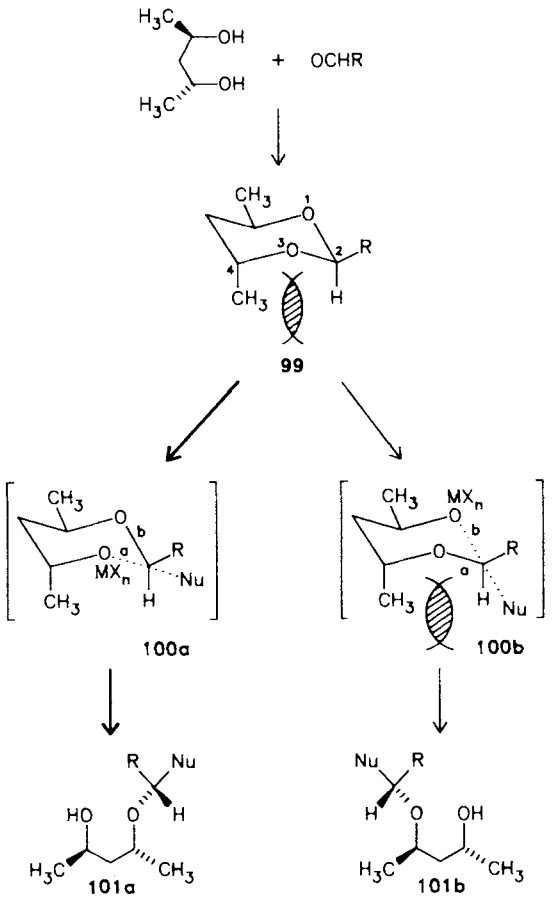
Addition reactions of the analogous allylboronic esters **97** to aldehydes have recently been described (79–87% *ee*).[74]



As a last example, the transfer of the allyl residue from the organoaluminum compound **98** to aldehydes occurs in an enantioselective manner (53–84% *ee*) when the chiral complexing agent **36** is added.[75]

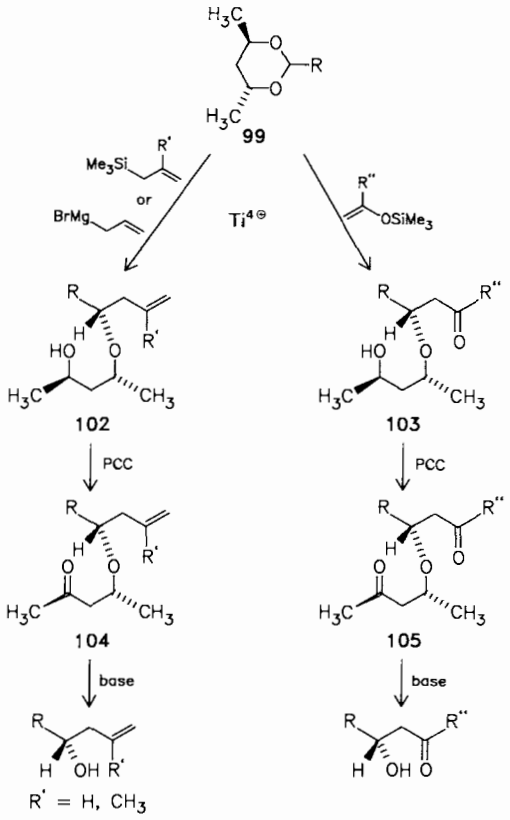
3.2. The Use of Chiral Acetals and Lactones

A further concept which by-passes the aldol reaction of α-unsubstituted enolates **2b** is the following: the aldehyde itself is converted temporarily into the chiral partner and then allowed to react (as diastereoselectively as possible) with an achiral enol ether or enolate equivalent (see Section 3.1).[76] *Johnson* et al.[77] chose the 1,3-dioxanes **99**, which can readily be obtained by acetalization using enantiomerically pure 2,5-pentanediol, as chiral aldehyde derivatives. The ring opening reaction with a nucleophile, catalyzed by Lewis acids MX_n, should occur in an S_N2 manner and will then lead (depending whether the bond a or b is broken) to the diastereomer **101a** or **101b**. The hindrance to the axial substituents in 2- and 4-position ($CH_3 \leftrightarrow H$) which is present in the ground state is reduced when the bond a is broken. Since this is not the case when the bond b is lengthened, the transition state **100a** should be favored over **100b**.

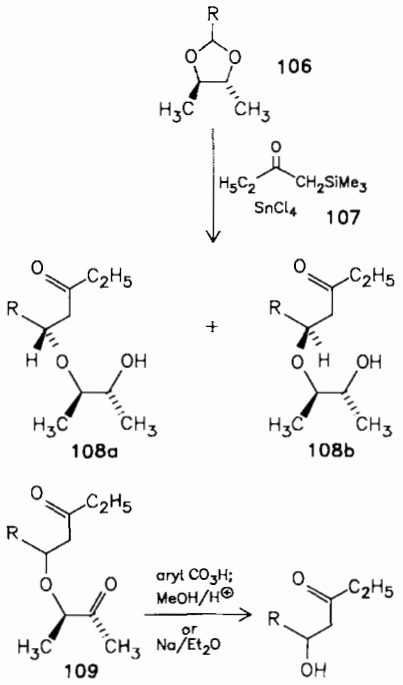


It is indeed the case that when allylsilanes,[78] allylmagnesium bromide[79] or silyl enol ethers[80] are added to dioxanes **99** the products **102** and **103** are formed in excess, with an average diastereoselectivity of 95 : 5. The removal of the chiral auxiliary is carried out by oxidation with pyridinium chlorochromate to the ketones **104** and **105**, from

which in turn homoallyl alcohols or β-hydroxyketones are liberated by base-catalyzed β-elimination of methyl 1-propenyl ketone ("retro-Michael addition").

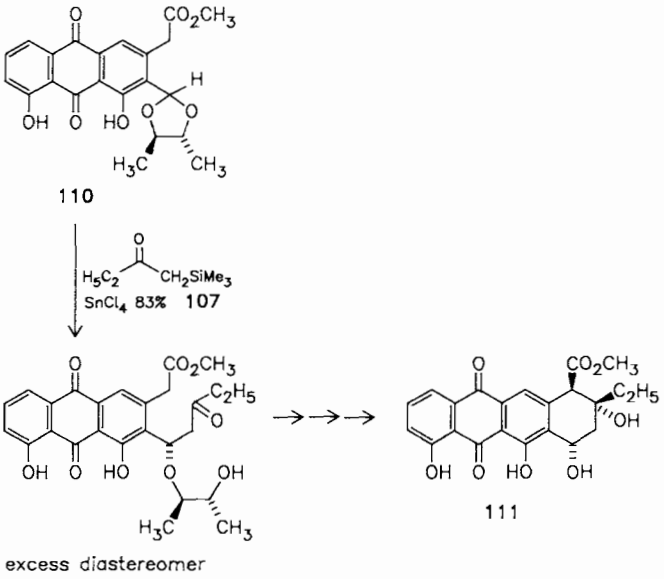


A similar diastereoselective ring opening of the chiral dioxolanes **106** occurs with the α-silyl ketone **107**: the adducts **108a/108b** are formed in a ratio of up to 16:1. In this case the chiral auxiliary is removed by oxidation to the diketone **109** followed by a Baeyer-Villiger rearrangement

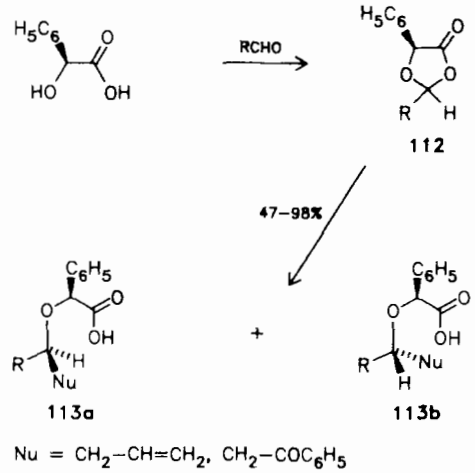


and transesterification with methanol.[81] Reductive cleavage of the α-alkoxyketones of type **109** is also possible.[82]

With the help of this method *Kishi* et al.[81] were able to synthesize aclavinone **111** starting from the acetal **110**; a diastereoselectivity of 10:1 is attained in the key step.

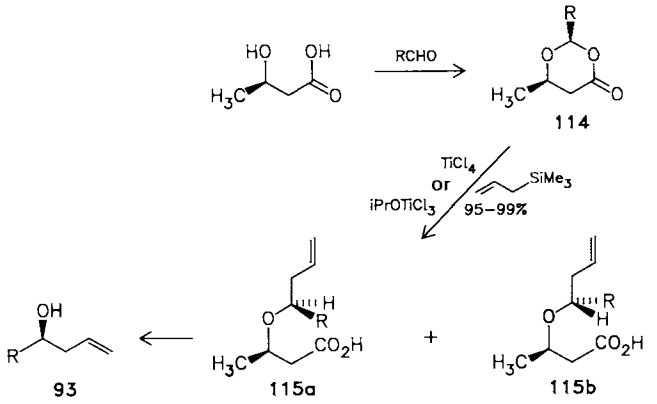


In the nucleophilic opening of the lactones **112** and **114**, the carboxylate functions as the leaving group rather than the alkoxide; this is to be expected on the basis of the acidities of the corresponding conjugate acids. Thus, when the dioxolanones **112** are reacted with allyltrimethylsilane or with silyl enol ethers in the presence of BF_3-etherate or $SnCl_4$ the carboxylic acids **113a/113b** are formed, the diastereomers **113a** being in excess (ratio 63:37 to 93:7).[83] The heterocycles **112** obtained from the condensation of aldehydes with mandelic acid are mainly *cis*-configurated.[84] In this case the cleavage of the chiral reagent occurs by means of oxidative decarboxylation using lead tetraacetate.



The reaction of aldehydes with 3-hydroxybutyric acid, which is readily available in both enantiomeric forms (see

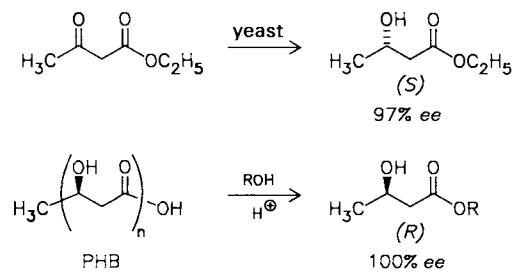
Section 3.3), gives mainly the *cis*-dioxanones **114**, which can usually be obtained in a pure state by recrystallization. As shown by *Seebach* et al.,[76,85] these heterocycles also react diastereoselectively with allylsilanes; the ratios of the products **115a** and **115b** are ca. 97:3. Treatment with lithium diisopropylamide liberates the homoallyl alcohols **93**.



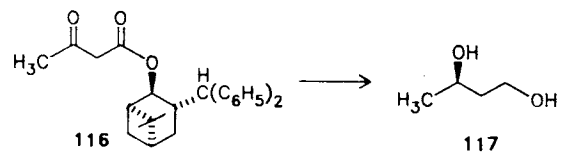
The common feature of all these methods for nucleophilic substitution at acetals is that the chirality of the auxiliary reagent is eventually destroyed.

3.3. Further Methods for the Preparation of Enantiomerically Pure β-Hydroxycarboxylic Acids

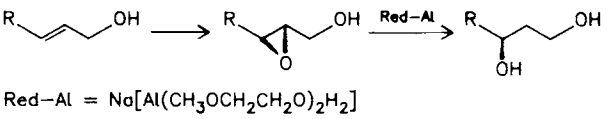
Enantioselective reduction permits the conversion of the often readily available β-ketocarboxylic acids or their esters into the corresponding alcohols. Besides the use of chirally modified hydride transfer reagents,[86] microbial methods are continually becoming more popular.[87] An example of the latter is the reduction of ethyl acetoacetate to (*S*)-3-hydroxybutyric acid ethyl ester in the presence of bakers' yeast.[88] The (*R*)-enantiomer can easily be obtained by depolymerization of the commercially available polyhydroxybutyric acid ("PHB").[89]



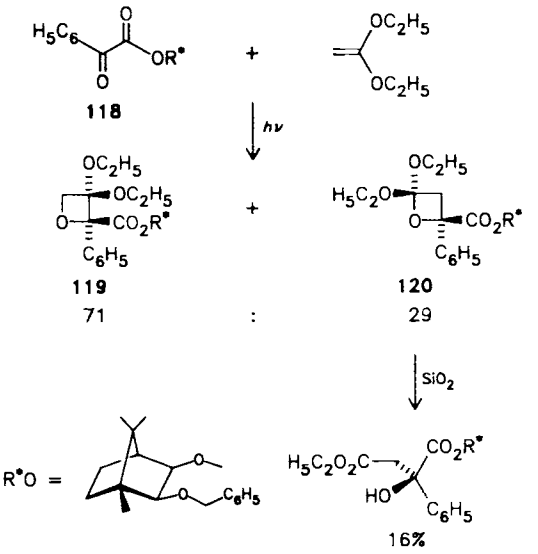
The diastereoselective reduction of the β-ketoester **116** gives (after reductive cleavage of the chiral auxiliary) the (*R*)-diol **117** with a maximum of 43% *ee*.[90]



In the approach used by *Masamune*,[2f] 1,3-diols with a high degree of optical purity are obtained by stereoselective epoxidation of allyl alcohols using the Katsuki-Sharpless reagent,[91] followed by regioselective opening of the oxirane ring.



A review of the use of the Paterno-Büchi reaction as an alternative to the aldol reaction has appeared recently.[92] Thus, while the reaction of 1,1-diethoxyethylene with the chiral phenylglyoxylic ester **118** gives mainly the unwanted regioisomer **119**, the oxetane **120** is formed in an almost diastereomerically pure state and can undergo ring opening to give the hydroxy ester.[93]



4. Future Prospects

Today various reliable methods are available which make possible a stereoselective addition of chiral α-unsubstituted enolates **2b** to aldehydes. Several alternatives to the aldol reaction also provide effective routes to almost enantiomerically pure β-hydroxycarbonyl compounds **21** or **24**. The future is likely to bring further developments and applications in this area, one which had for an astonishingly long time resisted the attempts of synthetic chemists.

Note added in proof (November 21, 1986): Reetz et al. have succeeded in carrying out the enantioselective addition of ketene acetals to aldehydes with a chiral Lewis acid.[94] A further acetic ester derived from camphor has found application in aldol reactions after conversion into the corresponding silylketene acetal.[95] Finally, *Seebach* et al. have recently described a new route to almost enantiomerically-pure β-hydroxycarboxylic acids with "self-reproduction of the stereogenic center."[96]

I thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Karl Winnacker and Konrad Adenauer Fundations for their support of our work.

We are also grateful to BASF AG and Hoechst AG for generous gifts of (R)- and (S)-mandelic acid. The results from our own group which are presented here were obtained by my co-workers Dr. Ralf Devant and Dipl.-Chem. Ulrike Mahler, to whom my sincere thanks are due.

[4] S. Masamune, S. A. Ali, D. L. Snitman, D. S. Garvey, *Angew. Chem. 92* (1980) 573; *Angew. Chem. Int. Ed. Engl. 19* (1980) 557; the *syn-anti* nomenclature suggested therein appears to be increasingly accepted by other authors, see, e.g., Refs. [2d, 17, 56]. - In addition this review uses the *lk*(like)-*ul*(unlike)-nomenclature for the description of the topicity of the approach of reagent and substrate: D. Seebach, V. Prelog, *Angew. Chem. 94* (1982) 696; *Angew. Chem. Int. Ed. Engl. 21* (1982) 654.

[5] High *anti*-selectivity is in general more difficult to achieve than *syn*-selectivity (compare Ref. [2]). For more recent approaches to the solution of this problem see: A. I. Meyers, Y. Yamamoto, *Tetrahedron 40* (1984) 2309; C. Palazzi, L. Colombo, C. Gennari, *Tetrahedron Lett. 27* (1986) 1735 and Ref. [43].

[6] Having regard to the diastereomeric transition states which are involved in these reactions, several authors use the term "diastereofacial selectivity" (cf. [2c]).

[7] D. A. Evans, J. Bartroli, T. L. Shih, *J. Am. Chem. Soc. 103* (1981) 2127.

[8] An increase in the selectivity can however also be attained using other counterions. Thus the addition of the lithium enolate **6b** (Li instead of $B(n\mathrm{Bu})_2$) to benzaldehyde yields the diastereomers **8/9** in the ratio of 87:13, while this ratio can be reversed to 25:75 when $Ti(O\mathrm{i}Pr)_3Cl$ is used (R = Ph): M. Nerz-Stormes, E. R. Thornton, *Tetrahedron Lett. 27* (1986) 897.

Laser Chemistry—What is Its Current Status?

By Karl Kleinermanns and Jürgen Wolfrum*

In recent years, various methods have been developed to observe and to influence the course of chemical reactions using laser radiation. By selectively increasing the translational, rotational, and vibrational energies and by controlling the relative orientation of the reaction partners with tunable infrared and UV lasers, direct insight can be gained into the molecular course of the breaking and re-forming of chemical bonds. Examples for the application of lasers include the synthesis of monomers such as vinyl chloride and polymers such as polyethylene, the synthesis of biologically active substances such as vitamin D_3, the separation of isotopes, the removal of impurities, the production of catalysts, glasses, and ceramics, and the deposition and ablation of material on surfaces. Finally, several applications of lasers in medicine are discussed.

1. Introduction

Irradiation with light can strongly affect the course of chemical reactions. The best known example is photosynthesis in plants. In addition, electromagnetic radiation is the most important aid in determining the structure, properties, and chemical behavior of molecules. In spite of great successes, spectroscopy with conventional light sources has not been able to answer many interesting questions. Only the practical realization of the principle of stimulated emission (first formulated by *Einstein*[1]), in the microwave region in 1955[2] and in the visible spectral region in 1960,[3] led to a decisive advance. As in many other areas of science and technology, the laser has also created numerous new possibilities for chemistry.[4] Particularly the introduction of tunable laser light sources, such as the dye laser,[5] and the development of linear and nonlinear optical techniques, such as laser-induced fluorescence (LIF), resonant multiphoton ionization (REMPI), coherent anti-Stokes Raman scattering (CARS), laser Raman spectroscopy on surfaces (SERS), photoacoustic spectroscopy (PAS), laser magnetic resonance spectroscopy (LMR), and Doppler-free absorption spectroscopy, allow virtually every spectroscopic state of an atom or molecule to be observed with high resolution, from the far infrared with wavelengths of several millimeters to the vacuum ultraviolet with wavelengths in the nanometer range.[6] The higher sensitivity allows observation of single atoms in ultramicroanalysis. Further, laser spectroscopy allows nonintrusive observation of rapidly changing chemical processes, such as combustion with high temporal, spectral, and spatial resolution.[7]

The high power of laser light sources within a narrow spectral region allows specific degrees of freedom of molecules to be excited in order to initiate or to influence reactions and to investigate the reaction products state-selectively. In this way, the relative velocity of reaction partners can be adjusted very precisely over a wide region, molecules allowed to rotate faster or slower, and bonds in a molecule stretched to various degrees; with polarized laser light, the mutual orientation of chemical species during the course of a reaction can be specified. Moreover, short-lived "transition states" of chemical reactions can be observed. In the first part of this article, the selective excitation and observation of chemical transformations with the aid of laser radiation is exemplified by reactions in the gas phase.

The progress achieved in laboratory investigations in controlling the course of reactions by excitation with laser light suggests that the newly developed methods could also be used for the production of new products or the improvement of syntheses. However, it was found that, for large-scale reactions performed in chemical reactors, the energy exchange between molecules and the deactivation of excited molecules take place very quickly and that "memory" effects with respect to the initially prepared state only rarely influence the reaction. In spite of these limitations, a number of interesting laser-induced chemical processes have been described in recent years. In the second part of this article, selected examples of the application of high-power lasers for initiating chemical transformations are presented.

2. Influence of the Specific Excitation of Molecular Degrees of Freedom on the Course of Chemical Reactions

The dependence of the rate of chemical reactions on the energy supplied is daily laboratory experience for the chemist. Often, the energy of the reaction partners can be represented by a temperature and the dependence of the reaction rate on temperature by a simple Arrhenius equation. The Arrhenius parameters obtained in this way do not, however, provide any information on the contribution of specific degrees of freedom of the reaction partners to overcoming the energy barrier of the reaction. In the following examples, reactions in the gas phase are used to show how information on the molecular course of reaction can be obtained in experiments with lasers.

2.1. Translational Excitation

Chemical reactions of fast ("hot") atoms from nuclear recoil and photolysis processes have long been investigated by analysis of their stable end products.[8] On bombarding ^{6}Li with neutrons, for example, tritium (^{3}H) atoms with a recoil energy of 2.7 MeV are formed. Collisions then retard these fast ^{3}H atoms to the "chemical" energy range around 20 eV to give a broad, continuous distribution of velocities. Thus the reaction energy cannot be controlled directly. Narrow-bandwidth laser light of high intensity and short pulse length (10^{-8} s), on the other hand, allows high concentrations of atoms with defined velocities to be produced by photodissociation (Fig. 1).

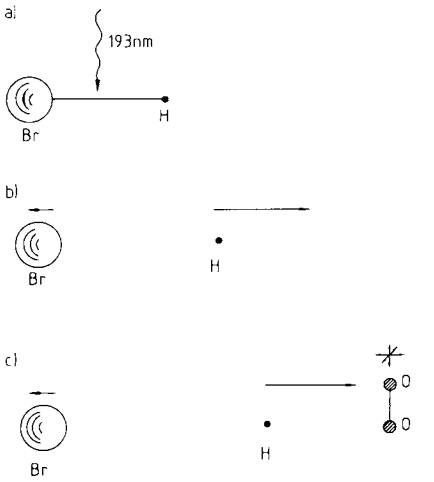

Fig. 1. Production of fast hydrogen atoms by photolysis with short-wavelength laser radiation. a) The ArF excimer laser photolyzes a suitable hydrogen-atom precursor such as HBr. b) The photolysis energy $h\nu$ is considerably greater than the dissociation energy of HBr and is more than 98% converted into the translational energy of the hydrogen atom, because the heavy bromine atom is more or less stationary compared with the light hydrogen atom. The hydrogen atom then passes with a velocity of 23 km s^{-1} through the reactor until it collides with an oxygen molecule. The average velocity of the oxygen molecule at room temperature is more than two orders of magnitude smaller than that of the hydrogen atom, so that, to a good approximation, the velocity of H relative to O_2 is the same as the velocity of the hydrogen atom. In this way, a collision energy of 251 kJ mol^{-1} is obtained. By changing the photolysis wavelength and the hydrogen-atom precursor, the velocity of the hydrogen atom can be set over a wide range and collision energies from 80 kJ mol^{-1} to over 400 kJ mol^{-1} can be attained.

As an example, the reaction (a) of translationally excited hydrogen atoms H^T with oxygen is examined. This endothermic reaction leads to the formation of two reactive radicals and is the most important chain-branching step in numerous oxidation and combustion processes.[9, 14]

$$H^T(^2S) + O_2(^3\Sigma_g^-) \longrightarrow OH(^2\pi, v, J, f) + O(^3P) \qquad (a)$$

$\Delta H_0 = 69.9$ kJ/mol

v = vibrational quantum number,
J = rotational quantum number,
f = fine structure quantum number

One experimental setup that can be used to investigate reaction (a) and other reactions of fast atoms with molecules is shown in Figure 2. It consists of a flow system

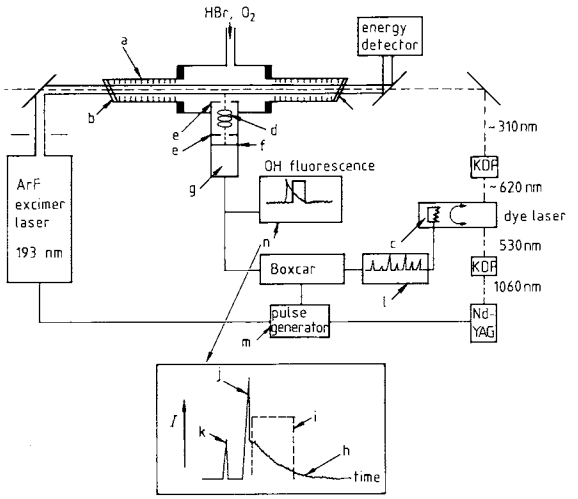

Fig. 2. Setup for state-specific and time-resolved investigation of reactions of fast atoms with molecules. The photolysis pulse of the ArF excimer laser (193 nm, 200-mJ pulse energy, 15-ns pulse length) and the analysis pulse of the Nd-YAG laser-pumped dye laser pass through the flow reactor coaxially. The reactor is equipped with collimators (a) in the side-arms, which partially remove the laser light scattered at the quartz windows (b). The analysis laser (0.2-cm^{-1} spectral band width, 12-ns pulse length and 0.1-1-mJ pulse energy) employs the laser dye Rhodamine 640. After frequency doubling (potassium diphosphate crystal), the OH radicals can be excited between 306 and 311 nm (tuning by a "grating" (c)). If the wavelength of the analysis laser is changed, the OH radicals absorb and fluoresce at different excitation wavelengths with varying strength, depending on how favorably the corresponding vibrational-rotational fine-structure state is populated by reaction (a). The fluorescence intensity is detected by a photon detector (g) after passing a lens system (d), collimators (e), and a filter (f). This intensity is a measure of the probability with which a particular OH state is excited by the chemical reaction. The signal current (h) released by the fluorescence at the photomultiplier is summed over many laser pulses using a "boxcar" system in an adjustable time region ("box") (i) beyond the interferring stray light (j, k) and then plotted against the analysis laser wavelength on a recorder (l). The analysis time is varied by starting the two lasers with two trigger pulses, time-delayed with respect to each other. Typical analysis times are 40-100 ns at a partial pressure of 5 mbar HBr and 50 mbar O_2. Owing to the short analysis times and the low concentrations of species, one avoids secondary reactions and deactivation of the fast hydrogen atoms and the excited OH radicals by collisions.

combined with a photolysis laser for producing hot hydrogen atoms and a frequency-doubled dye laser for state-specific, time-resolved detection of the OH radical by means of laser-induced fluorescence (LIF). The measurements show that the OH radicals formed in reaction (a) are rotationally very highly excited[10] (Fig. 3).

In order to compare the experimental rotational distribution with a calculated rotational distribution, the motion of the three atoms over a quantum-mechanically (ab initio) calculated H-O_2 potential hypersurface[11] is followed by stepwise integration of the classical equations of motion for various initial conditions (relative velocities, orientation of the collision partners, rotational and vibrational states of O_2).[12] The greater part of the relative translational energy of the reactants is converted into rotational energy of the product OH, in qualitative agreement with experimental results. However, careful quantitative comparison still shows distinct discrepancies (Fig. 3). For a collision energy of 251 kJ/mol (ca. 60 kcal/mol), the theoretical cross section, i.e., the reaction probability integrated over the collision parameters and other initial conditions, is a factor of 3 smaller than the experimental value. This discrepancy is particularly disturbing because the absolute

rate constant of reaction (a) at high temperatures, a sensitive parameter, for example in the mathematical modeling of combustion processes,[9] needs to be known exactly. The larger cross section found experimentally has been confirmed by more recent measurements[13] of the thermal rate constants $k_1(T)$ at higher temperatures (1500–2500 K); thus, the values calculated using the quantum-mechanical potential hypersurface are much too low.

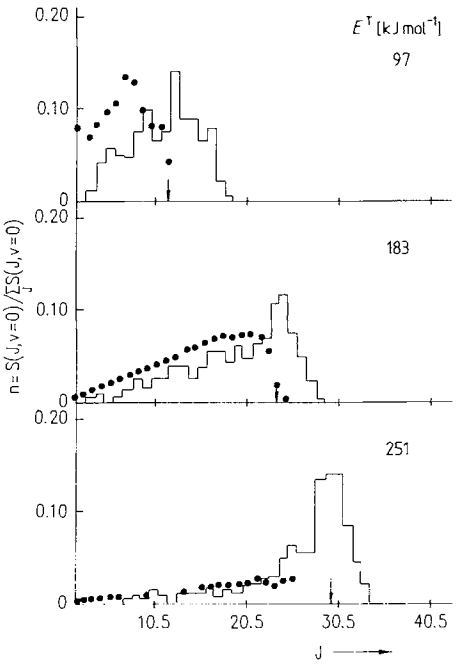

Fig. 3. Rotational excitation of OH (v=0) produced by reaction (a). The points show the experimental, the curve (histogram) the calculated distribution at collision energies of 97, 183, and 251 kJ mol^{-1}. At very high excitation (J > 23.5), OH (v=0) predissociates from the $^2\Sigma$ state and no longer fluoresces. The arrows show the maximum rotational excitation obtainable for complete conversion of the reaction energy into rotational energy. The collision energies E^T given here have an uncertainty of ± 10%.

The fine structure distribution also provides interesting information on reaction dynamics. For instance, the OH λ-doublet excitation shows that the π^+ components are favored.[10,15] As explained in Figure 4, this means that, at high collision energies, the H^T–O_2 reaction proceeds mainly on the initial plane. By using polarized photolysis and analysis laser light, the flight direction of the photolytically produced hydrogen atoms can be specified and the orientation of the OH product radicals relative to the flight direction of the hydrogen atoms measured. Strong polarization effects were found experimentally[16]—the OH angular momentum vector, J_{OH}, lies perpendicular to the velocity vector of the hydrogen atoms, v_H (Fig. 5).

2.2. Rotational Excitation

Because rotational states are energetically very close together and can be rapidly deactivated, the influence of reactant rotation on the course of reactions is investigated using an arrangement with crossed molecular beams to avoid interfering collision processes. Infrared transitions of an HCl or HF molecular laser are used for selective excitation of rotational states in HCl and HF molecules. Typ-

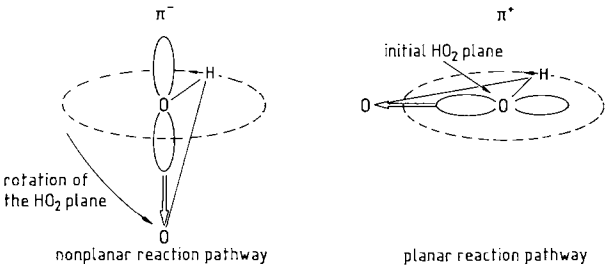

Fig. 4. The physical difference between the two λ-doublet components π^+ and π^- arises from interaction of the electronic spin-orbit momentum with the rotation of the molecule. For fast rotation of the OH radical, the unpaired electron in the p orbital on oxygen is no longer able to follow the movement of the atomic nuclei. If the p orbital lies in the OH rotational plane, the electron distribution on the oxygen atom changes, becoming increasingly spherical. In contrast, for a π^- configuration, the oxygen atom moves in the nodal plane of the p orbital and thus continues to "see" a dumbbell-shaped electron environment, even for fast rotation. This leads to a splitting of the energies of the π^+ and π^- configurations, which increases with increasing rotational energy. Experimentally, at 183 kJ mol^{-1} collision energy, three OH radicals were found in the π^+ state for each OH radical in the π^- state [15]. This shows that the unpaired electron formed after bond cleavage of O_2 stays in an orbital in the rotational plane of the OH radical. During the reaction, most of the HO_2 complexes do not rotate out of the initial plane, because of the short reaction time at high collision energies.

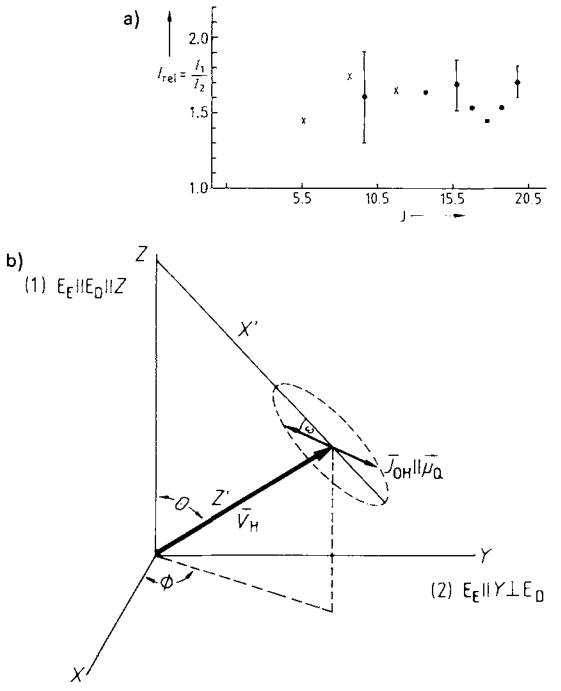

Fig. 5. a) Experimental polarization effects at 251-kJ mol^{-1} collision energy. J is the rotational quantum number; the ordinate is the polarization ratio, I_{rel}, the ratio of the fluorescence signal intensity for polarization of the photolysis laser E_D parallel to the analysis laser E_E and perpendicular to it. The electric vectors of the laser radiation at 193 (×) and 307 nm (•) are rotated independently. b) The laser beams lie parallel to the laboratory X axis, the detector parallel to the Y axis. The molecular coordinates are X′ and Z′; $\vec{v}_H$ is the velocity vector of the hydrogen atoms, and J_{OH} the angular momentum vector in the molecular coordinate system. On excitation of a Q transition (ΔJ = 0) of the OH radical, fluorescence intensities and polarization ratio can be calculated from the projection of the Q transition moments μ_Q ($\| J_{OH}$ for high rotational states) on the laboratory axis [16]. For the orientation $J_{OH} \perp v_H$, the calculation is in agreement with the experimental polarization ratio of 1.60.

ical results are shown in Figure 6. Initially, a decrease in the reaction probability with increasing degree of rotational excitation is observed. A possible explanation is that a particular orientation of the reaction partners, e.g., colinear, often gives the reaction path of lowest energy. With increasing rotation of the molecule, however, the potential forces are less and less able to orient the reaction partners satisfactorily with respect to one another and the reacting atom is increasingly "protected" from the reaction partner. If the rotational excitation is further increased, the steric hindrance plays a lesser role as a result of the rapidly increasing total energy, i.e., the "cone of acceptance" rapidly expands. In addition, because of the higher total energy, more states become accessible on the product side, which leads to a further increase in the reaction probability.

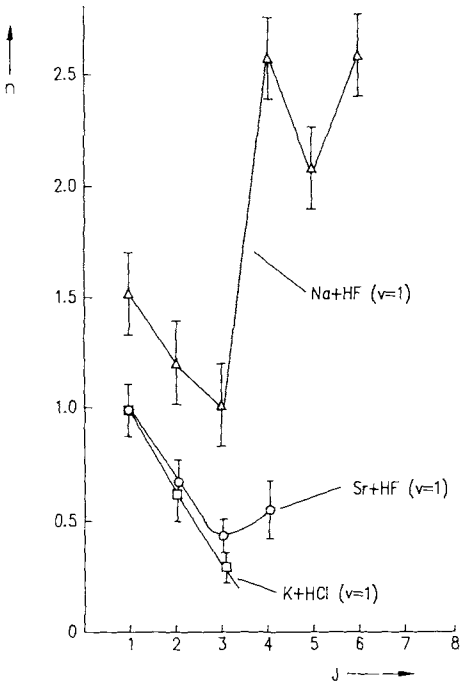

Fig. 6. Investigation of the dependence of the reaction cross section on rotational excitation in the following reactions: K + HCl (v = 1, J) ⟶ KCl + H, Sr + HF (v = 1, J) ⟶ SrF + H, and Na + HF (v = 1, J) ⟶ NaF + H. n = relative reaction cross section; J = rotational quantum number.

If a long-lived intermediate complex is formed during the reaction, the additional rotational energy is distributed statistically over the various degrees of freedom of the product; i.e., "memory" of the energy form of the original excitation is largely lost. Thus, in the reaction

$$Ca(^1S) + HF(X\,^1\Sigma^+_g, v = 1, J = 0\text{-}7) \longrightarrow CaF(X\,^2\Pi, v', J') + H(^2S)$$

X = electronic ground state

Zare et al.[18] observed statistical vibrational excitation of CaF following selective rotational-vibrational excitation of HF.

With the laser-induced fluorescence technique described in Section 2.1, the rotational states of the products could be investigated for a large number of reactions. For instance, the reactions of $O(^3P)$ atoms with saturated and unsaturated hydrocarbons, amines, and aldehydes lead to OH product radicals with low rotational excitation, which can be attributed to the weak rotary torque involved in the almost colinear, direct abstraction of the hydrogen atom.[19] In contrast, the rotational excitation of OH produced by reaction of excited oxygen atoms $O(^1D)$ with H_2 and HCl is extremely high. With saturated hydrocarbons, one observes overlapping of two distributions. This can be traced to a direct, colinear abstraction path (low rotational excitation) and a parallel reaction path with insertion of $O(^1D)$ into the C–H bond (high rotational excitation via decay of a highly excited "alcohol").[20]

2.3. Vibrational Excitation

A connection between chemical reactivity and the efficiency of the vibrational energy exchange between molecules was first postulated by *Franck* and *Eucken* more than 50 years ago.[21] However, systematic investigations in this area only became possible through the development of powerful and tunable infrared lasers.[22,23] The reaction of hydrogen molecules with hydrogen atoms or their isotopes, as the simplest example of a bimolecular reaction of neutral species, is particularly suitable for a theoretical investigation of the influence of selective vibrational excitation of reacting species (see energy diagram, Fig. 7). The energy required for vibrational excitation of the hydrogen molecule considerably exceeds the Arrhenius activation energy (E_a), the threshold energy (E_0), and the height of the energy barrier (E_c) of the reaction in the vibrational ground state.

E_c was first calculated quantum mechanically by *London*[24] more than half a century ago. The value he obtained is not very different from the results of modern ab initio calculations.[25] This good agreement disappears, however, when a more exact calculation is performed according to *London*'s valence bond method.[26] The classical methods for the study of reaction kinetics are difficult to apply to this reaction, because known concentrations of vibrationally excited hydrogen molecules have to be produced and detected. Only the application of CARS spectroscopy has allowed direct, quantitative detection of hydrogen molecules in selected vibrational and rotational states. It was shown that when the H_2 molecule is excited to the first vibrational state, only about a third of the vibrational energy is used to overcome the energy barrier E_c.[27] Thus, the reaction of vibrationally excited hydrogen molecules still shows an energy barrier, whose height can be predicted both from classical and from quantum-mechanical calculations of the course of reaction on the ab initio potential hypersurface, in good agreement with the experiments.[28] More recent measurements of the absolute value of the rate constant by CARS spectroscopy[29] agree well with the results of quasi-classical trajectory calculations.[30] This is also the case for the results of experiments with translationally excited hydrogen atoms.[31]

The results obtained from study of the hydrogen exchange reaction on the efficiency of a selective vibrational excitation cannot be simply transferred to similar reac-

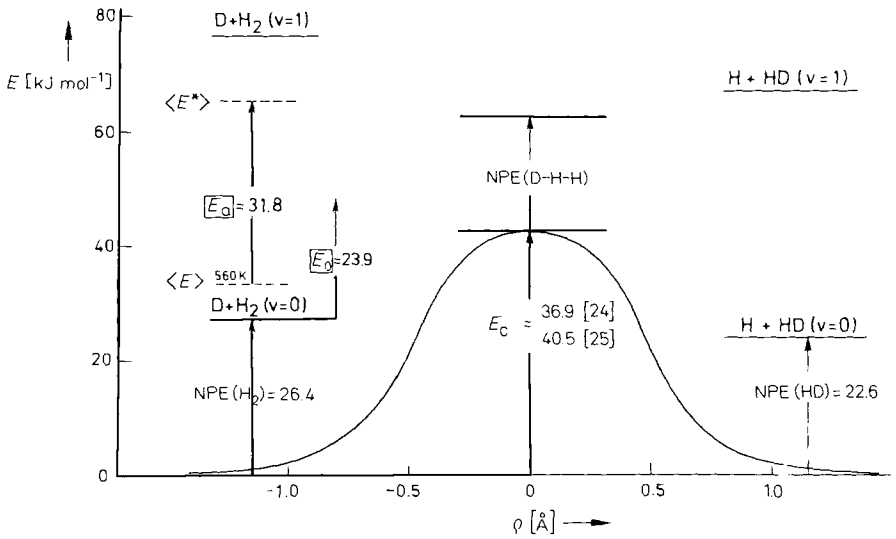

Fig. 7. Characteristic energy requirements of the hydrogen exchange reaction. E_a is the Arrhenius activation energy, E_0 the minimum collision energy that leads to reaction (threshold energy), and E_c the height of the potential energy barrier of the reaction in the vibrational ground state. $\langle E \rangle$ is the average thermal energy of all binary collisions per unit time and $\langle E^* \rangle$ the average kinetic energy of all collisions per unit time that lead to reaction. NPE is the zero point energy of vibration, ρ the reaction coordinate.

tions. Thus, investigations of the also thermoneutral reaction

$$^{37}Cl + H^{35}Cl\,(v=1) \longrightarrow H^{37}Cl\,(v=1,0) + {}^{35}Cl$$

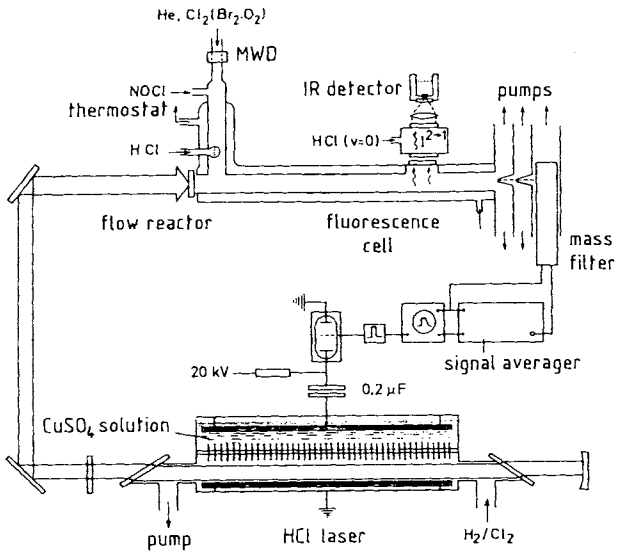

Fig. 8. Experimental setup for the investigation of reactions of vibrationally excited hydrogen halide molecules with the aid of time-resolved molecular-beam mass spectrometry. A discharge flow reactor is coupled through a molecular beam sampling system directly to the ion source of a quadrupole mass spectrometer. The HCl molecules are vibrationally excited isotope selectively by the infrared radiation of an HCl laser. The degree of the vibrational excitation is determined from the intensity of the infrared emission. A filter cell with cold HCl absorbs the infrared radiation of the transition HCl (v = 1) → HCl (v = 0) resonantly and transmits the wavelengths of the transition HCl (v = 2) → HCl (v = 1). From the ratio of the infrared intensity with and without the HCl cell, the degree of excitation of the HCl molecules can be determined directly. Chlorine, bromine, or oxygen atoms, which are produced by dissociation in a microwave discharge (MWD), react in the flow system with the vibrationally excited HCl molecules. The reaction products are detected mass spectrometrically.

demonstrate very effective use of the vibrational energy for overcoming the energy barrier.[32] The experimental setup for investigation of the reaction is shown schematically in Figure 8. The experimental rate constants of the reaction in the states HCl (v = 0) and HCl (v = 1) are given in Figure 9. The high efficiency with which the vibrational energy is used to overcome the energy barrier causes the chemical reaction, with increasing temperature, to proceed preferentially via the excited vibrational states. Thus, the temperature dependence of the reaction deviates significantly from that predicted by an Arrhenius equation. The dynamics of the reaction have been simulated by classical, semiclassical, and quantum-mechanical calculations.[33] Particularly

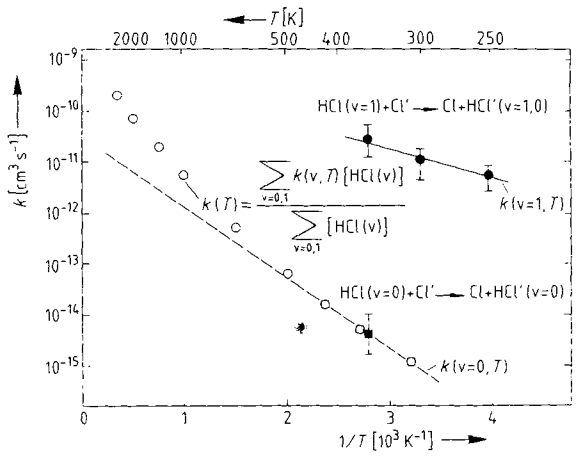

Fig. 9. Contributions of the vibrational ground state (v = 0) and the first excited state of HCl (v = 1) to the rate constant of the reaction Cl + HCl(v) → Cl + HCl(v'). The strong rise in reaction rate after vibrational excitation has the effect that, at higher temperatures ($T > 500$ K), marked deviations from the Arrhenius line are observed. Measured rate constants: □, ■ for HCl (v = 0), ● for HCl (v = 1); ○, calculated rate constants from the contributions of HCl (v = 0) and HCl (v = 1).

in very strongly endothermic reactions can vibrational excitation be used effectively for increasing the rate of reaction. Thus, in the reaction[34]

$$Br + HCl(v) \longrightarrow HBr(v=0) + Cl$$

an increase in the reaction rate constant by more than ten orders of magnitude can be obtained by vibrationally exciting the HCl molecule from $v=0$ to $v=2$. This dramatic increase in the rate constant can be used to separate chlorine isotopes (Fig. 10). ^{35}Cl atoms from HCl can be transformed in this way into $Br^{35}Cl$, which because of its different chemical and physical properties can be readily separated from the reaction mixture.

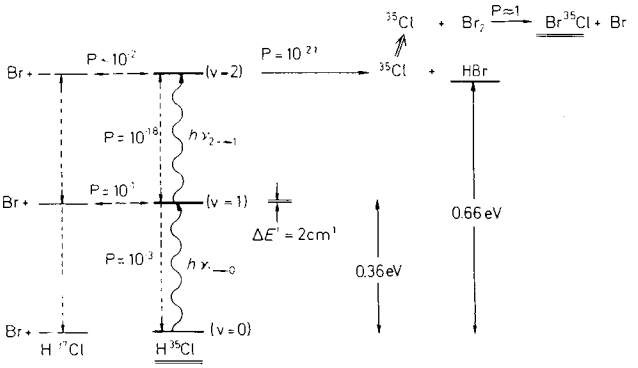

Fig. 10. Energy diagram for the reaction of Br atoms with isotope-selectively excited HCl molecules. P gives the probability for the transfer of vibrational energy between laser-excited $H^{35}Cl$ and $H^{37}Cl$ and for the course of a reaction in the various collision processes, respectively. The Br atoms react preferentially with $H^{35}Cl$ ($v=2$). The resulting ^{35}Cl atoms further react with molecular bromine to give easily separated $Br^{35}Cl$. $\Delta E'$ is the energy difference between $H^{35}Cl$ ($v=1$) and $H^{37}Cl$ ($v=1$).

Investigations of the reactions of polyatomic molecules in specifically excited vibrational states are much more difficult to perform. One main problem is the decoupling of the vibrational energy-transfer processes from the processes leading to reaction. Interesting model molecules are substituted methanes.[35] For example, Figure 11 shows the energy flow in CH_3F after excitation of the CF stretching vibration ν_3 with a CO_2 laser. By almost resonant vibrational energy transfer, subsequent collisions rapidly populate higher states ($2\nu_3$, $3\nu_3$) of this stretching vibration, resulting in a "metastable," mode-selective excitation of the CF stretching vibration. Through local Coriolis resonance between the third overtone of ν_3 and the CH stretching vibration ν_4, part of the energy can be channeled into this CH stretching vibration. Simultaneously, depending on pressure, CH bending vibrations (ν_6, ν_2, ν_5) are excited by collisions with further molecules, the excitation energy being provided by the thermal energy of the surrounding gas. In the subsequent resonant vibrational energy transfer, higher states of these vibrations can be populated, from which the CH stretching vibration ν_1 is reached by Fermi resonance. Examples of reactions of vibrationally excited polyatomic molecules are the reaction of laser-excited ozone molecules with nitric oxide[23,36] and that of fluorine with unsaturated hydrocarbons in a low-temperature matrix.[37]

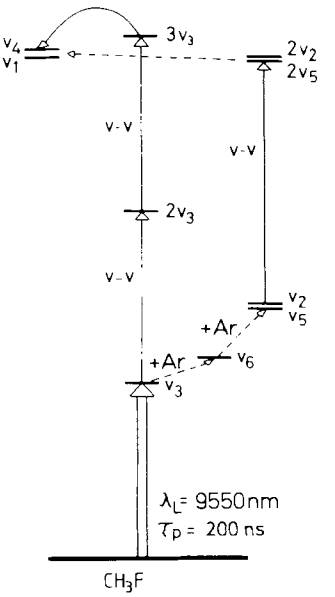

Fig. 11. Paths for the collision-induced intramolecular vibrational energy transfer in CH_3F. Laser radiation with wavelength λ_L and pulse length τ_p.

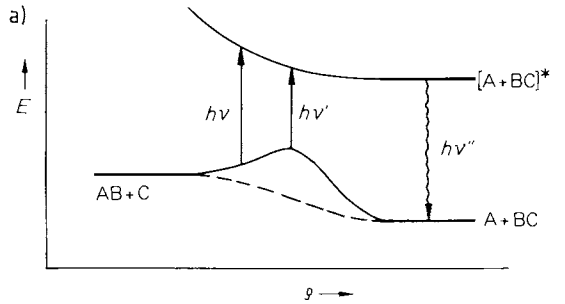
2.4. Electronic Excitation

In the following, no attempt is made to give a detailed overview of the reaction behavior of electronically excited atoms and molecules. Rather, using selected examples, it is shown how reactants can be selectively oriented with respect to one another, regions of "transition states" probed, and reaction rate constants for high excitation far above the reaction threshold investigated using electronic excitation with laser light.

At some stage in the course of a chemical reaction, new bonds are formed and old bonds broken, so that neither "reactants" nor "products" are in effect present. The direct investigation of such "transition states" has long been the chemist's dream. Figure 12a shows that a range of such transition states can be excited with laser light having a wavelength that is nonresonant with the reactant or product states. Among the reactions investigated[38] was that of $K(4s^2S)$ atoms with NaCl using excitation with laser light in a crossed molecular beam experiment (Fig. 12b).[39] As the reaction partners approach, the states of the species mutually "perturb" each other and their energy changes. When the wavelength of the laser light is finally resonant with the $Na^*(3p^2P)$-KCl state, excitation to this state occurs and light emission at $\lambda = 589$ nm ($Na^*(3p^2P) \rightarrow Na(3s^2S)$ transition, sodium D-line) is observed, as shown in Figure 13 as a function of excitation wavelength. Emission at 589 nm occurs even on excitation with longer-wavelength light. The missing energy comes from the exothermicity of the reaction and thermal energy of the reactants. By improving the signal-to-noise ratio of the measurements, it should be possible to recognize structures in the spectrum and identify areas of longer residence time of the complex on the ground-state hypersurface from the intensity maxima.



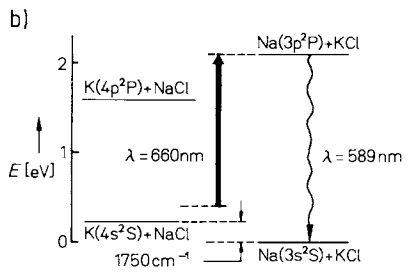


Fig. 12. a) "Transition state" spectroscopy of an exothermic reaction. The emitted frequency ν'' is higher than the radiated frequencies ν or ν'. The missing energy comes from the heat of reaction and the thermal energy of the reactants. b) Energy level diagram of the K-NaCl reaction. 1750 cm^{-1} corresponds to the heat of reaction.

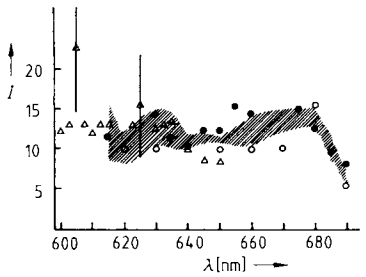

Fig. 13. Luminescence signal from the reaction K $(4s^2S)$ + NaCl → $Na^*(3p^2P)$ + KCl, occurring in crossed molecular beams, as a function of the excitation wavelength. Only when all three beams are present *simultaneously* (K, NaCl, and laser beam) is intense luminescence at 589 nm observed. The dotted area in the diagram gives the average of two or more measurements. The differently marked data points refer to measurements on different days.

In addition to emission from laser-excited "transition states," emission from *chemically* excited intermediate complexes also has been observed. As Figure 14 shows, *Polanyi* and co-workers[40] were still able to detect fluorescence from the reaction

$$F + Na_2 \longrightarrow FNaNa^{+*} \longrightarrow NaF + Na^*(3p^2P)$$

far from the sodium D-line. This "wing" fluorescence originates from Na* near NaF (and hence also from $FNaNa^{+*}$). The higher intensity of the long-wavelength "wing" is due to the fact that the upper and lower potential surfaces tend to lie closer together at intermediate configurations (cf. Fig. 12a).

Following excitation into "repulsive states," structured emission spectra were observed, even though a rapid dissociation follows the excitation.[41,42] These fluorescence

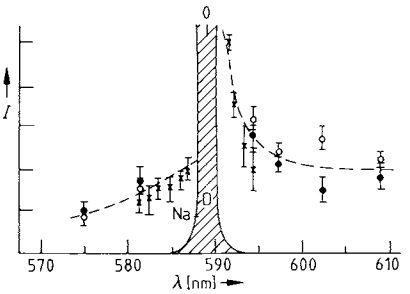

Fig. 14. Emission of the "intermediate complex" $FNaNa^{+*}$ formed in the reaction F + Na_2 → NaF + Na*.

spectra provide information on the previously inaccessible temporal course of a bond rupture. From the frequency shift of the emission lines relative to the excitation wavelength, the vibrational frequency in the electronic ground state is obtained up to the vicinity of the dissociation limit (Fig. 15). Fluorescence occurs when the continuum wave function of the upper (repulsive) potential surface overlaps favorably with vibrational wave functions of the lower (bonding) electronic ground state. In a direct dissociation, later times in the course of photodissociation correspond to more elongated bonds and hence emission to higher vibrational states of the electronic ground state (cf. Fig. 15, vertical optical transition). For example, following excitation at $\lambda = 266$ nm, CH_3I dissociates within femtoseconds to CH_3 and I. Although the dissociation is about six orders of magnitude faster than the spontaneous emission, fluorescence is still observed. Optical transitions to highly excited states of the CH_3 "umbrella vibration" of CH_3I are only observed in combination with excited C-I stretching vibrations.[42] This behavior can be attributed to the fact that the C-I bond has to be elongated considerably before the methyl group opens from the tetrahedral geometry in CH_3I to the planar form in the CH_3 product radical.

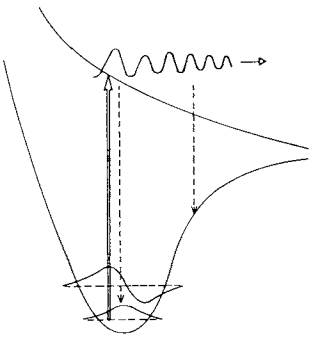

Fig. 15. Scheme for laser-induced fluorescence spectroscopy on repulsive surfaces. A molecule is excited by a UV laser into a dissociative state. In spite of rapid decay, fluorescence (dotted line) occurs when continuum wave functions and vibrational wave functions favorably overlap.

The influence of the orientation of the reaction partners with respect to one another, observed indirectly in experiments involving rotational excitation of the reactants, can also be observed directly using laser techniques. With polarized laser light, molecules having a particular orientation can be selectively excited, since the probability for ab-

sorption of light is at a maximum when the transition dipole moment is parallel to the electric field vector. With this method, *Zare* and co-workers[17b,43] were able to show that the reaction of polarized, excited iodine molecules with indium atoms occurs faster in "head-on" collisions than in a "side-on" attack (Fig. 16).

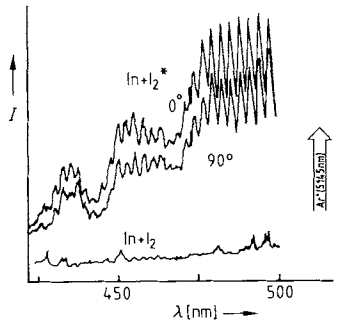

Fig. 16. LIF spectrum of InI from the reaction $In + I_2^* \rightarrow InI + I$. Iodine was excited into the $B(^3\Pi)$ state with a linearly polarized $Ar^{\oplus}$ ion laser at 514.5 nm. The transition moment here lies parallel to the iodine molecular axis. On orienting the electrical vector parallel to the In beam (0°), the reaction proceeds more rapidly ("head-on" collisions) than for perpendicular orientation (90°). The lowest curve gives the fluorescence measured upon switching off the laser.

Different wavelengths of light can be employed to selectively excite molecules having different orientations. Thus, SrF from the reaction of strontium atoms with vibrationally excited HF (excitation to v = 1, J = 1 by a polarized HF infrared laser) is more highly vibrationally excited after a side-on than after a head-on collision. Calculations show[44] that when the reaction occurs at the energetically more favorably angled alkali-metal–HF orientation, energy is preferentially transferred to the internal degrees of freedom of the product molecule.

Polarized laser light can also be used to influence the orientation of the electron orbitals in atoms. The excitation of $Ca(^1S_0)$ to $Ca(^1P_1)$ results in transfer of charge from a spherical s orbital to a dumbbell-shaped p orbital. The transition moment lies in the direction of the Ca p orbital, so that this orbital is aligned with the electrical vector of the laser light. In the reaction of $Ca(^1P_1)$ with HCl, the CaCl $A(^2\Pi)$ state is formed preferentially when the calcium p orbital is aligned perpendicular to the calcium beam. In contrast, the CaCl $B(^2\Sigma^+)$ state is excited preferentially when the Ca p orbital lies parallel to the calcium beam (formation of a σ_p orbital in CaCl).[45] "Memory effects" on the initial state have also been observed in the reaction of $O(^3P)$ atoms with saturated hydrocarbons. *Luntz* and *Andresen*[19a] showed that $O(^3P_2)$ atoms give rise preferably to the $^2\Pi_{3/2}$ spin-orbit states of the OH radical for symmetry reasons.

By electronic excitation of molecules with lasers, specific rate constants, $k(E)$, for unimolecular reactions can be measured directly. *Troe* and co-workers have investigated the isomerization of various cycloheptatrienes in their electronic ground states by means of thermal isomerization[46] as well as stationary[47] and direct, time-resolved[48] photoisomerization. On excitation of cycloheptatriene molecules in the ultraviolet spectral region, light absorption ($S_0 + h\nu \rightarrow S_1$) is followed by rapid internal conversion to vibrationally highly excited levels of the electronic ground state (S_0^*, Fig. 17). The hot cycloheptatriene molecules isomerize faster with decreasing wavelength. From the increase in the absorption signal with time, the specific rate constants could be determined directly. Figure 18 shows that a statistical model of $k(E)$ is in good agreement with the experimental results.

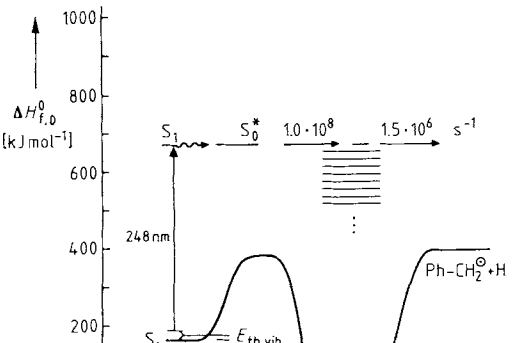

Fig. 17. Potential energy scheme for the photoisomerization of cycloheptatrienes. Electronic excitation into the S_1 state is followed by rapid internal conversion to vibrationally excited CHT in the electronic ground state (S_0), which with rising excitation energy isomerizes increasingly faster to toluene.

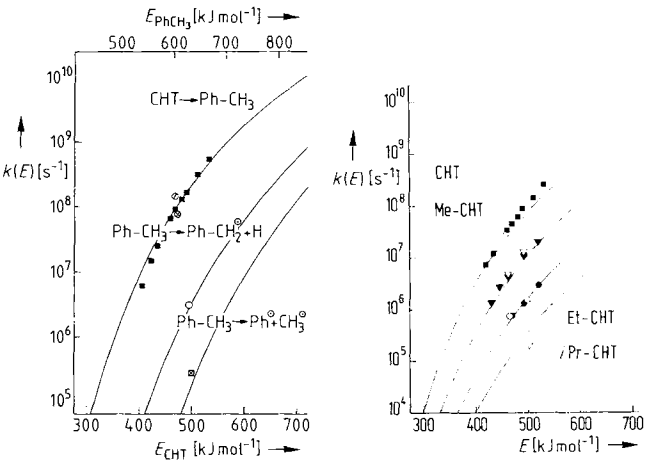

Fig. 18. Specific rate constants, $k(E)$, for the unimolecular isomerization of cycloheptatriene. ○, ∅, ⊗, ▽, ⊠, direct, time-resolved measurements by excitation with laser light; ●, ▼, ■, stationary photoisomerization experiments (Stern-Volmer extrapolation); solid line, statistical calculation according to RRKM theory.

3. Lasers in Synthesis

It would seem obvious to use the methods described for the selective control of chemical reactions for making new products or improving synthetic procedures. Under the typical conditions of industrial chemical processes (high pressures, reactions in the liquid phase, large molecules), however, a selected molecular state cannot, in most cases,

be held stable until the actual reaction stage. The exchange of energy between the degrees of freedom within a molecule and between various molecules usually occurs on a time scale of 10^{-13} to 10^{-10} s, whereas the reaction times themselves are considerably longer. On the other hand, nonthermal isomer and isotope distributions as well as nonthermal radical concentrations from laser-induced dissociation and isomerization processes can readily be maintained under industrial chemical conditions and used for producing new or appreciably purer products or for producing products with lower energy consumption. Here, the use of the laser offers a number of advantages over conventional light sources: (1) extension of the available range of wavelengths; (2) the selective excitation of just one kind of molecule (e.g., for isotope separation or ultrapurification), because of the narrow spectral bandwidth of the laser light; (3) spatially and temporally controllable, homogeneous excitation of the reaction volume, because of the possibilities of pulsed operation and strong collimation; (4) the possibility of multiphoton excitation, because of the high power density.

As shown in Figure 19, Hg or Xe lamps are preferable as light sources for industrial photochemistry both in terms of investment and operational cost as well as in terms of maintenance expenditure, long-term power, and lifetime. For economic application of lasers in this area, the effective cost of the photons must lie considerably below that of the desired product (Fig. 20). One should remember that, generally, the product price is determined only to a small extent by the photochemical step involved in the production process and that techniques employing lasers have to compete not only with conventional photochemical processes, but also with other routes of synthesis. Optimally, the use of lasers should result in several improvements simultaneously, such as cheaper starting materials, fewer or more valuable side products, and fewer or cheaper process steps. In particular, the production of cheap mass-produced chemicals by the use of lasers is only worthwhile if very high quantum yields (number of product molecules produced per photon generated) can be achieved in radical chain reactions.

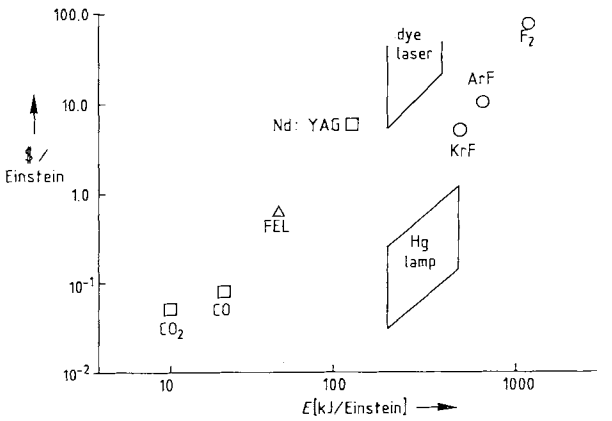

Fig. 19. Photon costs for laser light as a function of photon energy. 1 Einstein is 1 mole of light quanta. FEL = free electron laser. Conventional lamps are at present considerably more inexpensive as light sources than lasers.

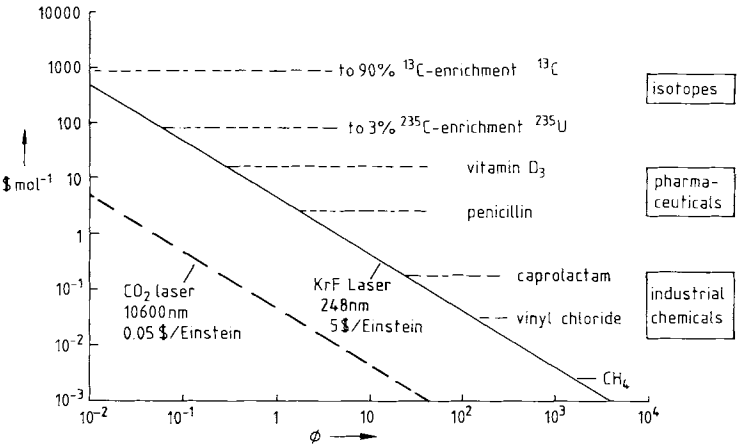

Fig. 20. Influence of quantum yield on product cost. The ordinate gives the cost in dollars per mole of product for conventional chemical syntheses. The application of lasers for production of cheap mass-produced chemicals is only economical at very high quantum yields, Φ.

3.1. Laser-Induced Radical Chain Reactions

Vinyl chloride (VC), the monomer of PVC, is produced industrially mainly by thermal cleavage of HCl from 1,2-dichloroethane (DCE) in a chain reaction. With a worldwide production of over 25×10^6 metric tons per year, VC is one of the leading products of chemical industry in terms of quantity. The advantage of photolytic over thermal initiation of the chain reaction is that the unimolecular process

$$C_2H_3Cl_2 \xrightarrow{+\text{inert gas}} C_2H_3Cl^{\circ} + Cl^{\circ}$$

is rate-determining with a low energy barrier. This leads to a low activation energy for the overall reaction and hence to lower reactor temperatures, higher conversions, and fewer side products. The use of laser radiation to initiate the chain reaction also permits detailed investigations of the reaction kinetics. Radicals may thereby be produced in

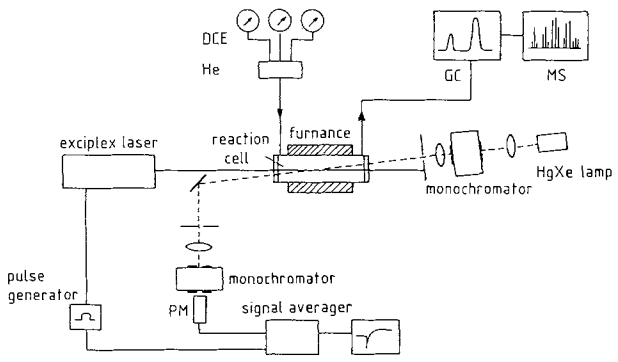

Fig. 21. Experimental setup for the investigation of laser-induced radical chain reactions for the synthesis of VC. The products are detected by time-resolved UV spectroscopy, gas chromatography (GC), and mass spectrometry (MS). PM = photomultiplier.

a wide concentration range and the reactions followed as a function of time. Figure 21 shows the experimental setup required. The formation of vinyl chloride can be followed

directly by time-resolved UV spectroscopy. The entire spectrum of products is recorded with the aid of a GC-MS system. The experimental data can be compared with those obtained from a kinetic model, which for a given temperature and pressure, simulates the whole course of the reaction (Fig. 22) by using a system of coupled differential equations for the elementary chemical steps. From a comparison of the experimental data with the predictions of

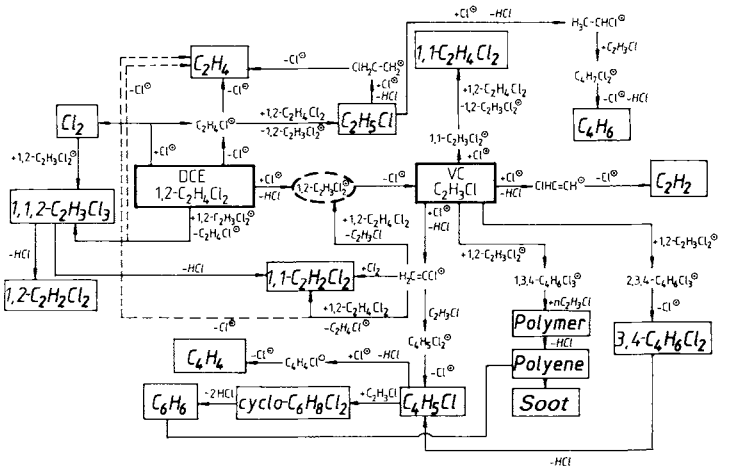

Fig. 22. Reaction paths for the cleavage of hydrogen chloride from dichloroethane, $1,2\text{-}C_2H_4Cl_2$, in a laser-induced chain reaction.

the model, missing rate constants of selected elementary steps can be determined. The pressure and temperature dependence of the laser-induced VC formation can then be used to predict the efficiency of conversion of DCE to VC for industrial conditions. The calculations show that laser photocatalysis results in a clear increase in the efficiency. The addition of chain carriers such as chlorine can increase the quantum yields by over 10^5. A pilot plant for the laser-induced conversion of DCE to VC, which is presently under construction, is shown schematically in Figure 23. DCE is first heated in a tubular reactor. A segment of the reactor is then irradiated with a powerful excimer laser, which is tuned to a wavelength at which the absorption by the medium is as small as possible. Owing to the high parallelism of the laser beam, a steady, small concentration of active chlorine atoms can be generated in a very large volume and hence long chains are produced. At the same time, irradiation of the wall and hence the initiation of heterogeneous processes is to a large extent avoided. With laser radiation, faster conversion at lower temperatures can be achieved compared with other processes. Thus, both higher total conversions and reduced formation of side products are possible simultaneously. Like the thermally initiated process, the laser-induced production of vinyl chloride consumes energy. Therefore, besides the radiation intensity, the rate of heat transport from the walls into the gas is a limiting factor for the shortening of the reaction times. In addition, the interactions between the laser radiation and the reaction medium, which arise from the density and concentration gradients in flow reactors and can lead to undesired beam divergence and focusing,

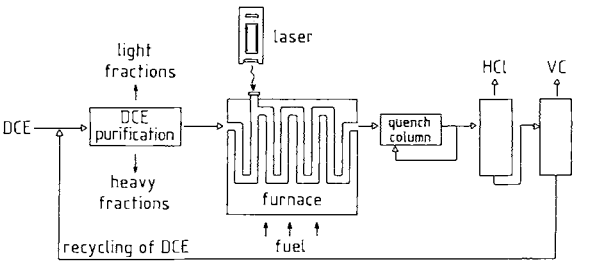

Fig. 23. Pilot plant for the production of vinyl chloride using an excimer laser.

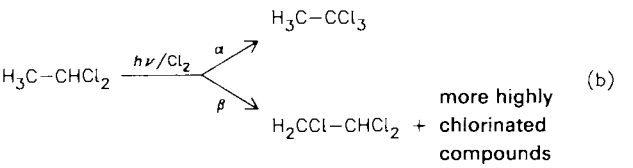
have to be investigated in detail. A further problem in the industrial application of laser photolysis is the contamination of the windows through which the laser beam is admitted to the chemical reactor. One possibility is to flush the window with inert gas or cold DCE, which has a much lower absorption owing to the strong temperature dependence of the UV absorption of DCE. Under certain conditions, the laser itself can "burn" the windows clean by virtue of its high intensity. Compared with conventional photolysis setups, the required transmission surface is considerably smaller here. Overall, the use of high-power UV lasers in synthesis remains to be explored. Compared with the discharge lamps employed to date, the good spatial and spectral collimation of the laser radiation is particularly advantageous. This avoids too high radical concentrations in the vicinity of the light source and allows the required production of reactive radicals under the extreme conditions of pressure and temperature often encountered in large-scale industrial processes.

In the chlorination of 1,1-dichloroethane [Eq. (b)], hydrogen atoms can be replaced at two different positions. The desired α-substitution product, 1,1,1-trichloroethane, is employed as a metal degreaser in place of the more poisonous trichloroethylene. The maximum value of the α:β ratio is 9:1 using lasers compared with 1:1 for the classical thermal method and ca. 4:1 using a Hg lamp. The maximum selectivity is obtained when low-energy chlorine atoms, produced by the photolysis of ICl (from a mixture of iodine and chlorine) at 450 nm, are used as chain carriers.[49]



(b)

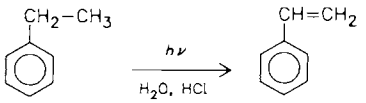
Ethylene can be produced from methane in the presence of chlorine at high pressure and temperatures around 900 °C via a chain reaction [Eq. (c), (d)].[50] Under these

$$CH_4 + Cl_2 \longrightarrow CH_3Cl + HCl \quad (c)$$

$$2\,CH_3Cl \longrightarrow C_2H_4 + 2\,HCl \quad (d)$$

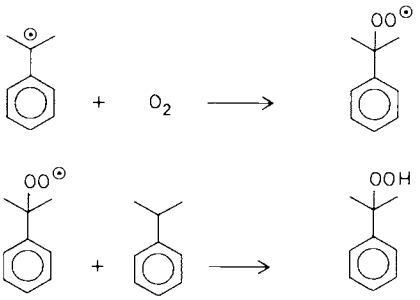
conditions, however, numerous undesired side products are formed. The methyl chloride produced in the first step [Eq. (c)] can alternatively be obtained in high quantum yield (ca. 10^4) at 200°C using a KrF laser (248 nm). The second step [Eq. (d)] can be initiated by an ArF laser (193 nm), although with a quantum yield of only 1.[51]

The dehydration of ethylbenzene to styrene [Eq. (e)] is catalyzed by OH initiator radicals obtained by photolysis (193 nm) of water vapor at 1 atm with an ArF laser; O_2 is added to prevent premature styrene polymerization.[52] Quantum yields of 10^5 at 500°C and 10^3 at 300°C were attained.



(e)

The photooxidation of cumene to cumene hydroperoxide [Eq. (f), (g)], a precursor of methylstyrene, is another example of a laser-induced chain reaction. In the thermal oxidation with air, numerous undesired side products are formed, whose amount can be reduced by lowering the temperature. By using photoinitiation, the reduction in reaction rate that occurs can be compensated for. At 351 nm (XeF laser), a quantum yield of approximately 500 is attained.[53] At shorter wavelengths (249 nm, KrF laser), the yield is reduced owing to photolysis of the product, cumene hydroperoxide.



In the photooxidation of isobutane to *t*-butyl hydroperoxide, irradiation (351 nm) with a XeF laser also leads, on addition of chain carriers (HBr), to higher quantum yields, and higher selectivity is attained compared with thermal reactions.[54]

The ketene produced by rapid pyrolysis of acetone at 700°C can only be obtained in relatively small yields (ca. 20%) because of the rapid thermal decomposition that follows. By starting the chain reaction photochemically using a KrF laser (248 nm), higher conversions can be achieved. As in the production of VC, the quantum yield falls with increasing irradiation intensity.[55]

3.2. Laser-Induced Polymerization

Conventional light sources for photopolymerization in layers for reprographic technology as well as for curing synthetic insulating materials have already been applied in industry. Because only the initiator needs to be excited for photopolymerization, large quantum yields can, in principle, be achieved. As an example, the laser-induced, high-pressure polymerization of ethylene is considered in more detail. Numerous investigations have provided information on chemical and phase equilibria as well as kinetic parameters.[56] Thermally induced radical polymerization of ethylene has a number of disadvantages. Long induction periods result from the need to heat the monomer/initiator mixture. Also, the use of a multicomponent mixture (monomer/initiator/regulator) is usually necessary. Polymerization requires initiation by means of heat transfer, initially from the walls. The polymer coating so formed raises the heat transfer resistance of the reactor walls considerably. In the exothermic polymerization process, however, the removal of heat from the reactor is also an important parameter. Indeed, on exceeding a critical temperature, explosive decomposition of the monomers can occur. In contrast, providing the necessary initiation energy with the aid of laser radiation allows controlled and homogeneous initiation of the polymerization process. Figure 24 shows an experimental setup for investigating the UV laser-induced polymerization of ethylene at pressures up to 3000 bar and temperatures up to 300°C in the fluid phase. By means of quantitative infrared and near-infrared spectroscopy, the quantum yields and time course of the polymerization process as a function of pressure, temperature, and laser intensity can be studied directly over a wide range of conversions. Figure 25 shows the time course of the polymer formation as monitored by measuring the absorption of the second overtone of the C–H stretching vibration following initiation of the polymerization with a KrF laser (248 nm). As with the irradiation of DCE, one can work in a region of low absorption and hence achieve very large penetration depths in the starting material. However, the weak ethylene absorption at 248 nm (absorption cross section $\sigma = 2 \times 10^{-4}$ m^2 mol^{-1} at 100°C) is strongly influenced by impurities such as O_2. The absorption of the reaction product, polyethylene, at these wavelengths can be neglected. In the above experiments, quantum yields of 10^4 could be achieved and rate constants for the propagation and termination reactions of polymeriza-

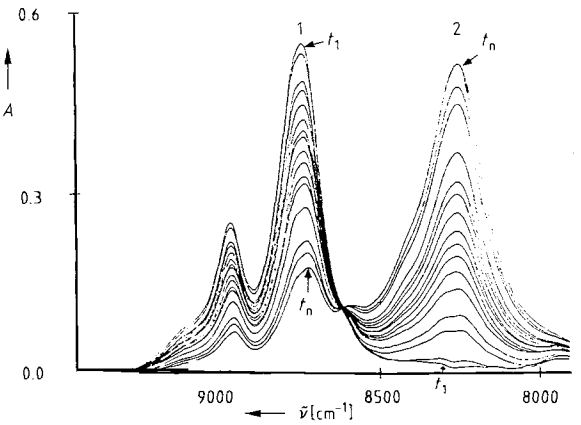

Fig. 25. Observation of polymer formation in C_2H_4 using the overtone spectrum of the CH stretching vibration after irradiation with a KrF laser. 1 = monomer band; 2 = polymer band; A = absorption. t_1 = start, t_n = termination of spectral recording.

tion could be measured directly as a function of pressure and temperature.[56]

Polymerization by photochemical activation has also been achieved with infrared lasers[57] and continuously operating ion lasers; the laser-initiated copolymerization of cyclohexene oxide with maleic anhydride is two orders of magnitude more efficient than is the case for irradiation with conventional UV lamps.[58] On introducing a suitable photoinitiator, very rapid cross-linking in epoxy acrylate layers can be obtained by irradiation with an N_2 laser (337 nm). Up to 450 cross-link points are produced per absorbed photon. About 10^3 double bonds are polymerized for each initiator radical produced.[59] However, polymerization can also be initiated by laser photoionization. Cations can thereby be generated either from suitable, thermally stable salts[60] or by direct photoionization of the monomer via multiphoton processes.[61] The high temporal resolution feasible with laser photolysis also allows detailed investigations of the elementary processes involved in radical polymerization.[62] By introducing photochemically active catalysts, polymerization of acetylene and ethylene can be achieved in 3-μm-thick layers within the irradiation zone of an $Ar^{\oplus}$ ion laser (257.2 nm).[63] Interesting insight into the kinetics of the polymerization process can also be obtained using holographic techniques.[64,65]

The irradiation of varnish coatings with excimer and dye lasers allows, even at very low intensities, very rapid polymerization without the use of solvents or heat. In this way, transparent coatings of 200-μm thickness and pigmented coatings of 20-μm thickness can be produced more than an order of magnitude faster than by the processes used previously.[66]

Laser-induced polymerization allows three-dimensional structures to be produced with high spatial resolution. To this end, two different laser beams are focused simultaneously on a point in a monomer solution, so that polymerization is initiated by two-photon excitation of the monomer or of the cross-linker. By controlling computationally the spatial position of the laser overlap zone of several micrometers diameter, one aims to produce complex, highly precise plastic prototypes and raw forms.[67]

3.3. Organic Photochemistry with Lasers

The photolytic ring opening of 7-dehydrocholesterol (7-DHC) (Fig. 26) to give vitamin D_3, via previtamin D_3 (P_3), has long been employed for the large-scale synthesis of vitamin D_3.[68] The three isomers lumisterol (L_3), tachysterol (T_3), and P_3 can be interconverted by irradiation with UV light, whereby the photostationary composition depends strongly on wavelength. Table 1 and Figure 26 show that the use of two laser wavelengths rather than irradiation with a Hg lamp leads to a considerable improvement in the yield of the desired vitamin D_3 precursor P_3.[69,70] Irradiation with short UV light pulses in the picosecond range decreases the photolysis of P_3 and improves the ratio of P_3 to the undesired T_3 by another factor of 3.[71]

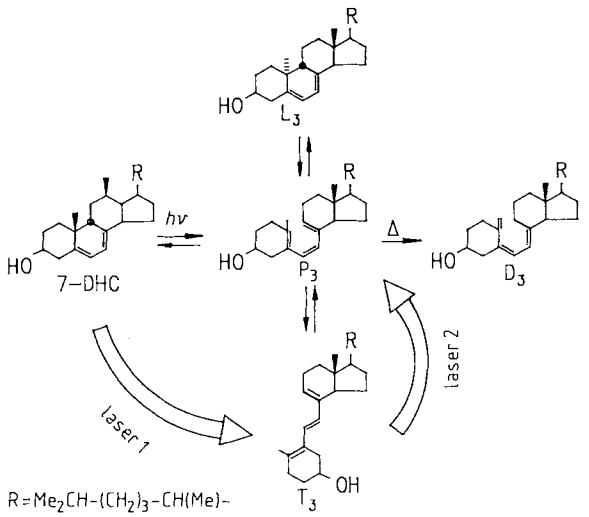

Fig. 26. Synthesis of vitamin D_3.

Table 1. Photostationary composition of the mixture upon irradiation of the vitamin D_3 precursor [69].

Light source	% 7-DHC	% T_3	% L_3	% P_3
Low-pressure Hg lamp	1.5	75.0	2.5	20.0
Medium-pressure Hg lamp	3.4	26.0	17.0	53.0
KrF laser (248 nm)	2.9	71.0	—	26.0
XeCl laser (308 nm)	13.0	3.4	42.0	35.0
KrF + N_2 laser (334 nm)	0.1	11.0	9.0	80.0

The results of the laser experiments allow improvements in the conventional photochemical process: namely, the KrF laser (248 nm) and the N_2 laser are replaced by a low-pressure Hg lamp (254 nm) and a medium-pressure Hg lamp equipped with a suitable filter, respectively. In the production of special vitamin D_3 metabolites for medical diagnostics, an increase in yield by a factor 5 is achieved by the use of lasers.[72]

Peroxides, which are produced from azoalkanes, are important intermediates in the synthesis of the beetle attractant pheromone frontalin.[73] Alone in North America, the beetles *Dendroctonus brevicomis* and *D. frontalis* cause more than a billion dollars worth of damage to wood annually. Frontalin (Fig. 27) can be produced from the azoalkane **1** via the endoperoxide **2**. The 364-nm line of the $Ar^{\oplus}$ laser is particularly suitable for this synthesis, since this

wavelength is absorbed sufficiently by the sensitizer benzophenone but not by the azoalkane **1**. In contrast, direct light absorption by the azoalkane results in loss of N_2 and formation of a singlet diradical which undergoes C–C bond closure to give an undesired product.

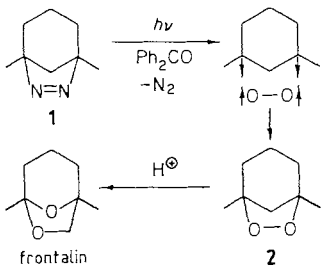

Fig. 27. Synthesis of frontalin. Direct photolysis of **1** results in the formation of a triplet diradical which reacts with O_2.

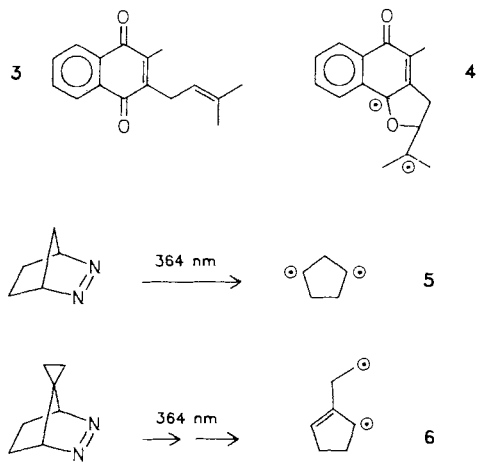
Similarly, certain azoalkanes can be converted into endoperoxides by laser photolysis followed by scavenging of the resulting diradicals with O_2. From those endoperoxides, substances for preventing (prostacyclins) or promoting (thromboxane) blood clotting can also be produced.[73] The photodecomposition of vitamin K, **3**, which leads to termination of respiration in living cells, can be traced back to the reaction of the preoxetane diradicals **4** with O_2.[73] By using high O_2 partial pressures (>10 bar) and photosensitization with benzophenone, the diradicals **5** and **6** can be scavenged in high yields as the corresponding peroxides.[74]



With high-power pulsed lasers, sufficiently high concentrations of radicals can be produced for direct spectrally and temporally resolved detection.[75] Also, higher triplet and singlet states can be reached by successive absorption of laser pulses in the nanosecond and picosecond range (Fig. 28).[76] For a triplet-state lifetime of 10^{-4} to 10^{-7} s, laser intensities of 10^4–10^7 W cm^{-2} are sufficient and are easily attainable using excimer lasers at pulse lengths around 10^{-8} s. In this way, the quantum yield of the photocyclization of carvone **7** to carvone camphor **8** [Eq. (h)] in ethanol can be increased 70-fold compared with the single-

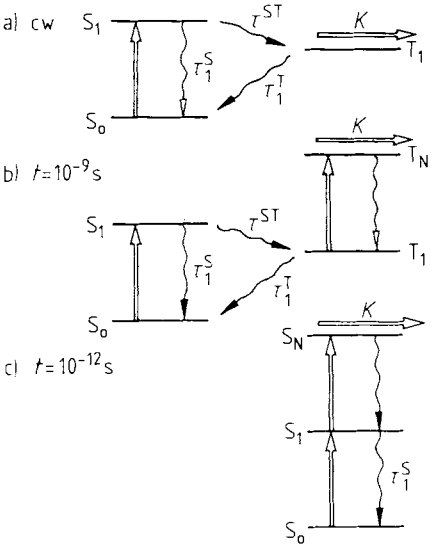


Fig. 28. Reaction possibilities of polyatomic molecules after single-photon and multiphoton excitation by laser pulses of differing duration. a) The relatively small intensity of the continuous (CW) laser leads to excitation only of the S_1 or T_1 state. b) With laser intensities of 10^4–10^7 W cm^{-2} and pulse lengths in the nanosecond range, higher states can also be reached by successive absorption of photons. c) The direct excitation into higher singlet states requires intensities of 10^9–10^{10} W cm^{-2} and pulse lengths of 10^{-12} s. Molecules in higher singlet or triplet states can undergo new reactions (K). τ_1^S, τ_1^T, and τ^{ST} are the characteristic lifetimes of the S_1 state, the T_1 state, and the transition from the S_1 to the T_1 state.

photon excitation.[77] The direct excitation to give higher singlet states requires laser pulses of around 10^{-12} s, since, for the intensities of 10^9–10^{10} W cm^{-2} required for pulses of 10^{-8} s, the damage threshold of the condensed phase is considerably exceeded. Excitation of maleic acid with pi-

Angew. Chem. A 601 Fo. 4 + 5 WERK FACHA A60102

cosecond pulses at 265 nm results not only in photodimerization, but, with increasing intensity, also in addition of water to the double bond.[76] Here, the direct cleavage of water by multiphoton excitation apparently plays an important role.[79] The use of ultrashort light pulses of high intensity could open interesting new approaches to the photochemistry of energy-rich double bonds: for example, in the development of optical switches, the construction of organic molecules for energy and information storage, and the synthesis of active substances. Still little used is the selective production of enantiomers by photolysis with polarized light, already described in the 1930s by *W. Kuhn* et al.[80]

The intensive efforts to apply organic glasses and polymers to optical storage of data[81] have already been reported in detail.[65,82] More recently, both for inorganic[83] and for organic[84] materials, interesting results have been achieved by "multicolor" photoionization (simultaneous irradiation with photons of various wavelengths).

3.4. Separation of Isotopes with Lasers

The high frequency sharpness of the electromagnetic radiation possible with the laser has given new impetus to investigations of the photochemical separation of isotopes, which was first attempted over half a century ago.[85] A specific isotope of an element (either in the elemental state or in a molecule) is excited selectively by narrow-band laser light and converted into an ion, isomer, or dissociation or reaction product that can be more readily separated chemically or physically (Fig. 29). The focus of interest was initially the uranium isotope ^{235}U.[86] The most developed process for this so far, AVLIS (*a*tomic *v*apor *l*aser *i*sotope *s*eparation), employs the selective multiphoton ionization of uranium atoms (Fig. 29a) with dye lasers, pumped by powerful copper vapor lasers with high repetition frequency (10 kHz).[87] Besides uranium and plutonium, numerous other elements can be isotope-selectively enriched by this method.[88]

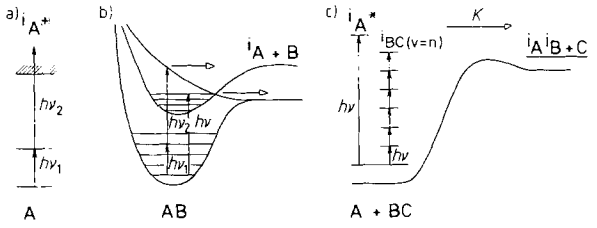

Fig. 29. Possibilities for photochemical separation of isotopes with the laser. ^{i}A represents a particular isotope of the element A. For details, see text.

Following the observation of isotope-selective, infrared multiphoton dissociation of SF_6 with the aid of CO_2 lasers,[22] analogous experiments were performed with UF_6. The radiation required for excitation of the fundamental vibrations of UF_6 at 16 μm can be obtained by rotational Raman scattering of CO_2 laser radiation on para-hydrogen.[89] However, the UF_6 gas beam has to be strongly cooled to obtain the necessary differences in absorption between $^{238}UF_6$ and $^{235}UF_6$. By further selective vibrational excitation of UF_6, clear differences are obtained in the UV absorption spectra[90] of $^{238}UF_6$ and $^{235}UF_6$, which can be used for the isotope-selective dissociation shown in Figure 29b. The laser powers at 308 nm required for industrial application are in the 100-kW range.[91] Besides UF_6, other uranium compounds, such as $UO_2(OCH_3)_6$[92] and uranium complexes[93] were investigated. The technique was also applied successfully for the enrichment of plutonium isotopes by selective excitation of PuF_6.[94] In nuclear power reactors, zirconium is used as a containment material for fuel rods. Isotope separation is of interest since ^{91}Zr has a neutron-capture cross section more than an order of magnitude larger than the other isotopes. Indeed, the selective ionization of ^{91}Zr was reported recently.[95] Because the economic use of nuclear fission is developing more slowly and with more difficulty than was originally assumed, the requirement for additional capacity for isotope separation of uranium is smaller than predicted. This is also true for deuterium,[96] which is required for reactors using natural uranium. Tritium can be enriched (e.g., for experiments in controlled nuclear fusion) by multiphoton excitation of $^3HCCl_3$[97] and $^3HCF_3$[98] with an IR laser.

The isotope-selective dissociation by one-photon excitation (Fig. 29b) can also be achieved by selective excitation of predissociative states, as for isotopes of carbon in formaldehyde.[99] ^{13}C-labeled compounds can be used in medical diagnostics, for example, in metabolic investigations in place of radioactive ^{14}C-labeled compounds, and in NMR tomography. An annual requirement of several hundred kilograms of ^{13}C is to be expected. An industrially relatively well developed process for laser-induced production of carbon isotopes is presented schematically in Figure 30.[100] Laser-induced multiphoton dissociation (Fig. 29c) of Freon 22 (CF_2HCl) results in the formation of C_2F_4, from which ^{13}C-enriched CF_2HCl can be obtained by thermal addition of HCl.[101] The cost of the CO_2-laser photons required for this process can be reduced still further by employing a continuous-discharge CO_2 laser.[102] Enrichment of ^{13}C-isotopes via multiphoton dissociation of CF_3Br[103] is more expensive, because of the considerably higher cost of the starting material. Isotopes can also be enriched by selective excitation of bimolecular exchange[34, 104] or addition reactions.[105]

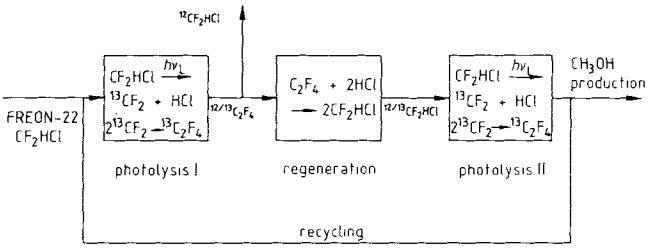

Fig. 30. Production of ^{13}C-enriched compounds by multiphoton dissociation of Freon-22. Photolysis I ($\lambda = 9.5$ μm) leads to a mixture of $^{12/13}C_2F_4$ and $^{12}CF_2HCl$. After separation of $^{12}CF_2HCl$, the remaining $^{12/13}C_2F_4$ is reconverted into $^{12/13}CF_2HCl$ and further enriched with the ^{13}C-isotope by photolysis II ($\lambda = 9.5$ μm).

3.5. Photochemical Purification with Lasers

The selective photochemical removal of impurities with lasers is exemplified by the purification of gaseous SiH_4 (the starting material for the preparation of pure silicon for semiconductor production) from compounds such as AsH_3, PH_3, and B_2H_6, which are difficult to remove chemically. Contamination of such p- and n-charge carriers, even at a ratio of $1:10^9$, can negatively influence the functioning of integrated circuits. Whereas in conventional methods the entire material is subjected to the purification process, the laser acts only on the impurities. Thus, laser irradiation at $\lambda = 193$ nm is absorbed four orders of magnitude more strongly by PH_3 and by AsH_3 and two orders of magnitude more strongly by B_2H_6 than by SiH_4. For an impurity of 1%, more than 99% of the AsH_3 and 40% of the PH_3 and B_2H_6, but only 1% of the SiH_4 is photolyzed.[106] The end products of this photolysis are readily separable solid polymers or gaseous compounds. Laboratory experiments show that the purification process even proceeds ef-

ficiently at atmospheric pressure, so that, for impurities of several ppm, typical absorption cross sections of 10^{-17} cm^2 and reactor lengths of several meters, more than 50% of the laser light is absorbed. Extremely high-purity silane is important for the economic production of electricity from sunlight, since the efficiency of silicon solar cells depends strongly on the impurities present. Further examples of efficient purification of gases are the separation of $COCl_2$ from BCl_3[107] and of CCl_4 from $AsCl_3$[108] and the destruction of dioxin.[109]

Lanthanoids and actinoids can be efficiently separated and purified by exciting the narrow absorption bands of their compounds in the visible and UV.[110] The excitation is still selective even for higher absorber densities in the liquid phase. The new oxidation states formed by the photoredox processes enable the compounds to be readily separated. Figure 31 shows the separation of europium [Eq. (i)] as an example, whereby the hydroxyl radical has to be scavenged, e.g., by isopropanol, to avoid the reverse reaction. The quantum yield for $Eu^{3\oplus}$ photoreduction at

$$Eu^{3\oplus} + H_2O \xrightarrow{193\ nm} Eu^{2\oplus} + H^{\ominus} + OH^{\circ} \quad (i)$$

$$Eu^{2\oplus} + SO_4^{2\ominus} \longrightarrow EuSO_4\downarrow$$

193 nm was given as 5% at 90% conversion, whereby up to a three-hundred-fold enrichment of europium was measured in the precipitate after irradiation of binary europium/lanthanoid mixtures. H_2S in CO/H_2 synthesis gas was photolyzed selectively with an ArF laser and the sulfur released was removed by adsorption on a metal surface.[111] In this way, sulfur impurities could be reduced from 10 ppm to 1 ppm. A spectroscopic selectivity (excitation only of H_2S in the synthesis gas) of 10^7 was measured in the wavelength range 210–220 nm. Quantum yields (H_2S molecules removed per absorbed photon) of 0.4 (1 atm) to 1.0 (10 torr) were achieved. In particular, the use of a laser is interesting for the removal of "fine impurities" (< 1 ppmH_2S), since catalysts based on copper (e.g., those used for production of methanol from synthesis gas) have lifetimes of about one year if the H_2S impurities in the CO/H_2 mixture can be reduced to less than 1 ppm.

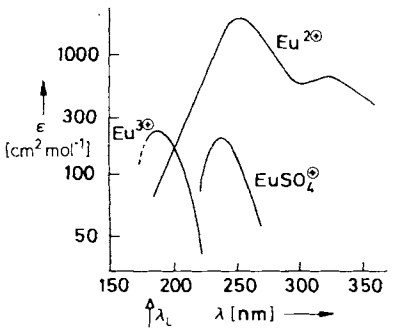

Fig. 31. Laser-induced separation of lanthanoids. The absorption spectra of europium in various oxidation states show that the $Eu^{3\oplus}$ ions can be selectively reduced in the liquid phase with the aid of an ArF excimer laser ($\lambda_L = 193$ nm). The $Eu^{2\oplus}$ ions formed are precipitated as $EuSO_4$ after reaction with sulfate ions.

3.6. Synthesis of Defined Solids and Catalysts with Lasers

Pyrolysis of gas mixtures with laser radiation can be used to produce catalytically active solids of variable composition (Fig. 32). After complete mixing of the gaseous starting materials and their rapid heating in the laser beam,

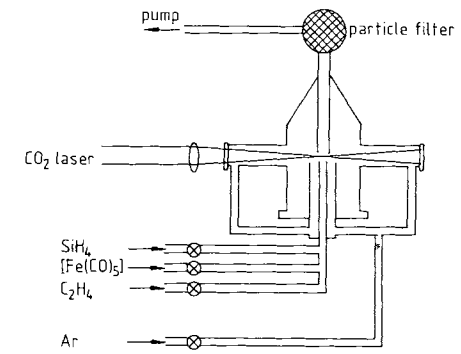

Fig. 32. Synthesis of Fe/Si/C catalysts by CO_2 laser pyrolysis of gaseous starting materials. By varying the partial pressures of the components and the laser intensities, catalysts with varying properties can be produced.

very small solid particles with homogeneous structure and large surface area are obtained. Figure 33 shows the yield of alkanes and alkenes obtained from the Fischer–Tropsch synthesis with laser-synthesized Fe/Si/C catalysts. Whereas with saturated hydrocarbons mainly methane is formed, with olefins considerably longer chains are obtained. By optimizing the composition of the laser-synthesized catalysts, higher selectivity and preferential formation of the valuable light olefins (C_2–C_4) can be achieved.[112] By a similar process to that described in Figure 32, powders of defined composition can be obtained for the production of specialty ceramics.[113] Irradiation of $[Fe(CO)_5/SiH_4$,[114] NH_3/SiH_4,[115] $(Me_3Si)_2NH$,[116] or $SiH_4/NH_3/CH_4$[117] gas mixtures with a CO_2 laser leads to particularly fine, pure, spherical, relatively non-clumping, and almost identically sized Si/Fe, Si_3N_4, and Si/C/N grains for the production of special ceramics.

Metal carbonyl catalysts can be UV-photoactivated instead of thermally activated. Active centers are formed by cleavage of one or more CO ligands, often resulting in ca-

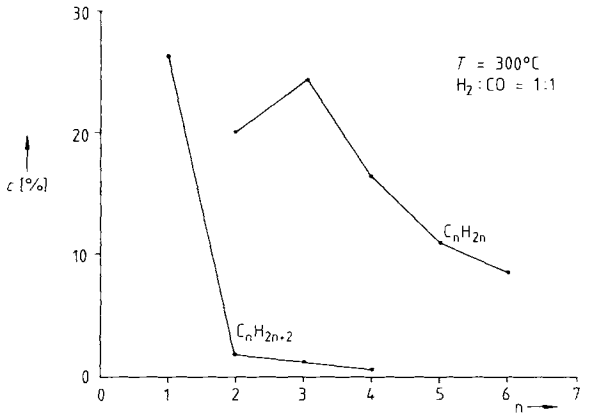

Fig. 33. Fischer–Tropsch synthesis with laser-produced Fe/Si/C catalysts. n = number of C atoms; c = amount of product in %.

talytic activity even at room temperature. Besides polymerization (Section 3.2), the isomerization and hydration of alkenes with $[Fe(CO)_5]$ catalysts[118,119] and the silylation of alkenes and aldehydes[118,130] with $[Co_4(CO)_{12}]$ catalysts upon irradiation with a XeF laser or a frequency-doubled Nd-YAG laser have been investigated. For the isomerization of 1-pentene, quantum yields of 10^3 and "turn-over" rates (quantum yield per average lifetime of the catalyst) of 4×10^3 s^{-1} at 50% conversion of 1-pentene can be achieved. Broad-band light sources such as flash lamps lead more readily to direct photolysis and to undesired side products.

Metallic glasses having unusual compositions and properties and other metastable phases can be produced by irradiation with intense laser pulses. Short laser pulses lead here to extremely rapid heating and melting, followed by very rapid cooling and solidification. Cooling rates of up to 10^{12} K s^{-1} have been obtained for alloy films after heating by means of picosecond laser pulses.[121]

3.7. Laser-Induced Deposition of Materials on Surfaces

In conventional, thermally induced deposition of materials from the gas phase (*c*hemical *v*apor *d*eposition, CVD), relatively high temperatures (600–900 °C) are required. The temperature can be reduced to 350–450 °C by employing electrical discharges in plasma CVD. However, undesired species can be formed in wall reactions and interfere with the process, and radiation damage can be induced in the deposited films; moreover, in order to ensure the stability of the discharge, only a restricted range of pressures is available and the reaction volume can only be controlled to a very limited extent. The LICVD method (*l*aser-*i*nduced *c*hemical *v*apor *d*eposition) for controlled deposition of selected species offers many advantages: control of the irradiation area from μm^2 to cm^2 and of the irradiation time from 10^{-14} s to continuous operation, no wall effects, and independent control of the substrate temperature for production of layers with extremely high purities.

Figure 34 shows schematically three possibilities for the LICVD method.[122] In the pyrolytic process (I), the laser light is generally not absorbed by the reaction gas, but is used instead to produce strong localized heating at the substrate surface. Because of the strong temperature gradient formed, the material is deposited in a narrowly defined region, so that transport from the gas phase can occur from various directions. The pyrolytic method can be applied over a wide range of pressures and allows deposition rates on the order of 1 to 10^2 $\mu m\ s^{-1}$, a factor of 10^2 to 10^4 higher than with a conventional CVD process.[123] In process II, a better directed and more homogeneous beam of the material to be deposited is obtained than in the ion vaporization technique otherwise generally employed.[124] In the photolytic process (III), selective excitation of dissociating states is employed. The products of laser dissociation can either be condensed directly on the surface or allowed to react chemically with other species present in the surface layer. As shown in Figure 35 III, the laser can also be focused directly on the surface and moved over it.

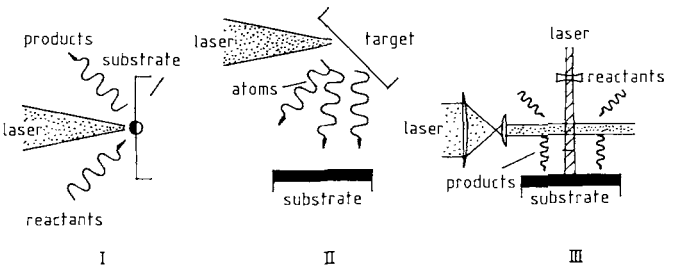

Fig. 34. Possibilities for the photochemical deposition of materials from the gas phase by means of IR or UV lasers. For details, see text.

Frequency-doubled $Ar^{\oplus}$ lasers ($\lambda = 257$ nm) can be used to deposit Cd from $Cd(CH_3)_2$,[125] Zn from $Zn(CH_3)_2$,[126] and Ni from $[Ni(CO)_4]$.[127] Because of the nonlinearity of the grain-formation process, spatial resolution of 0.2 to 0.5 μm is obtained. In conjunction with computer control of the laser beam, it is therefore possible to "draw" complex electronic circuits directly onto a substrate.[128] Besides metallic conducting layers, insulators and semiconductor layers can also be deposited. In addition to continuously operating ion lasers, CO_2 and UV-excimer lasers can be employed, which permit the production of large-surface-area, thin layers, e.g., amorphous Si layers for the production of cheap solar cells.[129] The rate of deposition can be increased considerably by the participation of the photoelectrons produced by the UV excimer laser.[130] Information on the primary processes occurring on applying the radiation of a UV-excimer laser for the deposition of metals from organometallic compounds (MOCVD) can be obtained using multiphoton mass spectrometry with time-of-flight analysis. This technique allows the production of an entire mass spectrum with high sensitivity by using a single laser pulse.[131] The species involved can be identified from both their absorption spectra and their masses. In this way, the formation of tellurium atoms and dimers upon photolysis of $Te_2(CH_3)_2$ at two different laser wavelengths, the energy states of the Te atoms formed, and the energy distribution within the molecular fragments can be determined directly. Use of ultrashort light pulses appreciably facilitates the detection of unstable parent ions.[132] Further, the deposition and dissolution rate of metals at liquid/solid boundaries can be increased considerably ($> 10^3$) by the use of laser radiation. The laser beam is directed onto the cathode in an electrolyte solution and the laser wavelength chosen so that the electrolyte absorbs as little as possible.[133,134] Metal deposition without electric current is also feasible.

4. Ablation and Processing of Materials with Lasers

Two types of material processing with lasers can be distinguished: thermal, nonreactive processing and chemical processing. In thermal processing, the sample is heated locally and brought to melting and evaporation. Welds and cuts can be made on the sample. This method is applied in a modified form to anneal defects on surfaces, to recrystallize, to harden materials, or to alloy locally. In chemical processing, chemical reactions are initiated by the laser radiation.

4.1. Processing of Polymer and Semiconductor Materials

In principle, any laser with sufficient power density is suitable for processing of polymer materials and substrates for microchips. Recently, however, several significant advantages of UV lasers have become apparent,[134] particularly when microscopically fine and precise work with clean edges is required. These types of requirements arise especially in the production of chips of very high information density (microlithography), but also in "microwriting" on polymer materials and in micromanipulation of biological objects. A significant advantage of UV light is that at wavelengths below ca. 350 nm the energy of single photons is sufficient to break chemical bonds. In contrast to IR lasers, whose radiation can penetrate more deeply and excite vibrations in polymer molecules, leading to thermal decay, the use of UV lasers results in cleavage of bonds where the photon density is highest, i.e., on the surface. This leads predominantly to monomer fragments and very clean ablation edges.[135] By laser decomposition of halogen compounds adsorbed on surfaces, fine patterns can be etched in semiconductors, glasses, metals, ceramics, and other materials.[136]

The following processes occur in etching:

Photodissociation	CH_3Br	$\longrightarrow CH_3^{\odot} + Br^{\odot}$	
Chemisorption	n(Br)	$\longrightarrow$ (nBr):(GaAs)	$\Delta H < 0$
Surface erosion	(nBr):(GaAs)	$\longrightarrow GaBr_n + As$	
Evaporation	GaBr (solid)	$\longrightarrow$ gallium bromide (g)	

Free halogen atoms are removed from the gas phase by radical scavengers, so that the etching process occurs only in the direct vicinity of the laser beam. The method is also applicable to liquid/solid boundaries.

5. Application of Lasers in Medicine

Most of the laser applications described below are not yet accepted in routine clinical practice. The application of the laser in surgery offers a number of advantages: stypsis, precise work, reduction in the number of instruments required, contact-free tissue ablation, asepsis, minimal damage to the surrounding tissue.[137] In respiratory tract or gynecological operations, the laser light can be led directly to the site of operation via light guides.

For laser light to interact with tissue, it must first be absorbed. Several simple observations can be made:

1. The interaction with IR radiation is best described in terms of absorption by water. The interaction is predominantly thermal in nature.
2. The absorption properties with respect to visible light are determined by the pigmentation of the tissue in question.
3. The further one goes into the UV, the more important photochemical effects become. At wavelengths below 200 nm, photoablation occurs almost exclusively. Here, the interaction of light with polymers (Section 4.1) can serve as a model.

This overview says nothing about the influence of power density on the interaction of laser light with tissues. Table 2 shows the variety of interactions possible and how they can be applied in medicine. The data in Table 2 are collected mostly from ref. [137, 138]. Table 3 gives an overview of the lasers used in medicine and their applications, which will be illustrated below with no attempt at completeness.

The aim of *angioplasty* with lasers is to open sclerotic blood vessels.[140] The use of lasers operating in the visible or infrared, however, results in carbonized edges and bubblelike lesions in the vessel tissues, which remain after removal of the stenosis.[141] Thrombocytes attach themselves to such edges and are the starting point for a new stenosis. Very recently, it was shown that these problems do not arise when ArF excimer lasers are used.[142] The edges of the recanalized tissue are smooth (Fig. 35).[143]

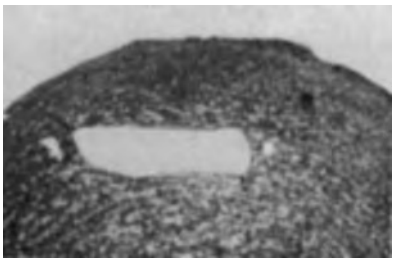

Fig. 35. Histological section through aorta tissue that has been recanalized using an ArF laser. Enlargement ca. 100-fold; laser power ca. 50 J cm^{-2} [143].

Table 2. Medically useful interactions of light and matter.

Power density	Type of interaction	Mechanism	Application
mW/cm^2	Biostimulation [139]	Influencing certain parts of metabolism	Healing of inflammations and wounds
kW/cm^2	Coagulation	Denaturation and resulting clotting of proteins, etc., at local temperatures of 40–80 °C	"Glueing" of tissue parts; clotting of bleeding
MW/cm^2	Evaporation	Water evaporates (partly explosively) from the tissue; breakdown of tissue structure	Cutting of tissues analogous to the surgical knife but contact-free.
GW/cm^2	Photoablation Photodisruption	Individual bonds are broken	Cold evaporation of tissue parts
TW/cm^2	Formation of microplasms	Molecules are ionized so that electron avalanches occur	Destruction of "hard" materials such as gallstones

Table 3. Possibilities for application of material processing in medicine

Laser type	Working wavelength [nm]	Presumed nature of interaction with tissue	Penetration depth into the skin	Main use following interaction [a]						Areas of medical application [b]				
				A	B	C	D	E	U	V	W	X	Y	Z
ArF excimer	193		Surface				×	×	×					
KrF excimer	248		Very small			(×)	×	×	×					
XeCl excimer	308		Small			×	×	×	×					
$Kr^{\oplus}$ ion	407		Deep	×	×	×				×				
$Ar^{\oplus}$ ion	516		Very deep	×	×	×				×	×	×	×

In *tumor therapy with lasers*, two methods are being explored. One attempts to coagulate tumors directly[144] and the other uses the laser for photodynamic therapy (PDT).[145] In PDT, dyes are employed that absorb light of a particular wavelength preferentially and are either incorporated selectively in the tumor tissue or are more slowly degraded by the tumor tissue. An example is provided by the hematoporphyrin derivatives (HpD), which are incorporated selectively by the vessel tissue of tumors. If the tumor is irradiated with a red laser (e.g., He-Ne laser), the HpD-labeled tumor tissue absorbs selectively. HpD is decomposed photolytically, so that oxygen radicals are formed, which as strong cytotoxins interfere with the blood vascular system of the tumor and hence cut off its supply of nutrients. Other dyes, such as phthalocyanines, are incorporated preferentially in the mitochondria of cancer cells and after laser irradiation interfere with the metabolism of these cells.

Numerous tumors can be temporarily degraded by use of PDT. Nevertheless, baring individual exceptions, cancers cannot be cured in this way, since the metastases are not treatable and the effects of PDT on various tumors vary greatly.[146]

PDT is still being investigated to some extent in animal experiments for the treatment of bladder tumors,[147] breast cancer,[148] gynecological tumors,[149] intestinal cancer[150] and lung tumors. The selectivity for certain tumors might be increased by coupling monoclonal antibodies to HpD.[151]

A very attractive application of lasers in *gastroenterology* could be in the destruction of gallstones. In contrast to kidney stones, 90% of which can be destroyed by a lithotripter without an operation, gall stones are insensitive to fluid shock waves. In contrast, laser pulses of high power density destroy gall stones, probably after forming microplasms which break the stones from within. For this type of application, the excimer laser is probably the most suitable.

All *lasers* that are suitable for coagulation of tissue can also be applied to *stop stomach hemorrhages* by thermally clotting the blood. In contrast to drug therapies to stop hemorrhages, one can work very well locally with the laser and thereby avoid irritating the neighboring tissue.

In *neurosurgery*, lasers have long been used to treat tumors in the brain.[152] In particular, the possibility of precise, contact-free operation is made use of since in brain surgery, even more than for other parts of the body, it is important to protect healthy neighboring tissue. Most recently, first results on the application of lasers in microsurgery were reported.[153] Here, the coagulating action of a focused laser was used to reconnect interrupted nerve connections very precisely.

In *dermatology*, hemorrhages that form in the skin by perforation of capillary vessels can be treated by the green light of the $Ar^{\oplus}$ laser[154] and the frequency-doubled Nd-YAG laser. In this way, blood clots are destroyed and simultaneously capillary vessels are closed. Less specific is work with the CO_2 laser, whose thermal effect is used, for example, to remove warts or tatoos.[155]

The development of laser treatment methods in ophthalmology is the most advanced and illustrates clearly how completely different results can be achieved by choosing a suitable laser wavelength. With an Nd-YAG laser, one can reach areas just behind the eye lens on account of the shallow penetration depth of IR light. Membranes can therefore be opened, through which intraocular overpressure

can be released. The green light of the $Ar^{\oplus}$ laser,[156] the frequency-doubled light of the Nd-YAG laser,[157] or the blue light of the $Kr^{\oplus}$ laser can be used to reach the fundus of the eye, the retina, through the transparent eye lens and the transparent vitreous humor, for example to "weld" (coagulate) detached areas of the retina. For corrections of curvature defects of the cornea, on the other hand, wavelengths that are absorbed by the cornea, such as those of excimer laser light, are needed.[158] With the aid of cylindrical lenses, excimer laser pulses are imaged to a streak-formed cross section, which is used to change the radius of curvature in the desired manner.

In treatment of opthalmic disorders, another important advantage of the laser is apparent: often, the laser, which is required for material processing, i.e., operational tasks, can be employed by means of a suitable regulation technique for diagnosis and analysis of the operation results. This not only reduces the number of instruments required for the operation but but also reduces the irritation to which the eye is exposed.[159]

6. Summary and Outlook

Twenty-five years after its discovery, the laser is irreplaceable in many areas of basic chemical research. The use of lasers provides a direct approach to the investigation of the molecular details of chemical reactions. The results can be compared directly with predictions based on quantum-mechanical calculations. The data so obtained on reaction cross sections and rate constants of elementary chemical processes can be used as a basis for detailed mathematical modeling of chemical reactions, which in the future will have the same significance that tables of thermodynamic values have at present. Investigations with lasers will increasingly provide information on numerous kinetic processes in gases, liquids,[160, 161] and solids as well as in biological systems. A significant breakthrough in the investigation of changes in molecular structures in the course of chemical and biological processes is to be expected from the extension of the laser principle to the X-ray region. Although stimulated emission has been observed down to wavelengths of 21 nm, for the region of several nm considerable difficulties still have to be overcome,[6b, 161] because extremely high pumping efficiencies are required owing to the short lifetimes of excited states in the X-ray region.

Although the cost of laser photons is at present markedly above that of photons from conventional light sources, photochemical synthesis with lasers can afford a number of interesting results. In particular, the laser-photochemical production of thin layers of metal, insulators, and semi- and superconductors will acquire increasing technological importance, not only for newer processing techniques for semiconductor components and circuits, but also particularly for the development of integrated sensors for controlling automated finishing processes. The application of lasers for the production of larger quantities of isotopically pure compounds, specific pharmaceuticals, initiation of chain reactions in the production of monomers or the polymerization of coating layers, and the production of powders for ceramics and catalytically active material will depend on how far the costs of laser photons can be further reduced and whether lasers with higher powers and lifetimes become available. For some technical applications, such as laser printers and material processing using CO_2 lasers, these requirements have already been met. For excimer lasers, systems with powers in the kW range will be realized in the near future. It is at present hard to estimate how far new laser principles, such as the free electron laser (FEL), will allow high powers and efficiencies in a wide range of wavelengths from the infrared to the ultraviolet to be attained. So far, FEL systems have only been operated in the infrared and visible spectral regions, whereby extreme demands on the quality of the electron beam are made.

It is assumed that, besides the production of chemical products and the processing of technical materials, high-power lasers will be of particular interest for applications in medicine. A significant advantage of the laser is that one can penetrate inside the body using light guides. However, for this purpose, very high laser powers often have to be transported if specific photochemical effects, and not just thermal effects, are desired in the processing of biological material. Suitable optical materials still need to be developed for this purpose.

We thank numerous colleagues for sending material for the review and Dr. K. O. Greulich (Heidelberg) for compiling the section on the application of lasers in medicine. Financial support for our work was received from the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Bundesministerium für Forschung und Technologie.

$[(\eta^5\text{-}P_5)Fe(\eta^5\text{-}C_5Me_5)]$, a Pentaphosphaferrocene Derivative**

By *Otto J. Scherer** and *Thomas Brück*

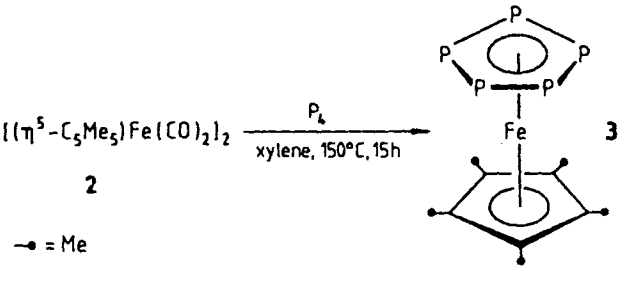
After having demonstrated that *cyclo*-P_5 could be stabilized as bridging ligand in the mixed-valence triple-decker complex **1**,[17] we then attempted to realize the classical

$[(\eta^5\text{-}C_5Me_5)Cr(\mu,\eta^5\text{-}P_5)Cr(\eta^5\text{-}C_5Me_5)]$

1

sandwich coordination of this ligand (cyclo-$P_5^{\ominus}$ as 6π electron donor). Success was achieved upon cothermolysis of **2** with white phosphorus.

Pentamethylpentaphosphaferrocene **3** forms sublimable, green crystals which can be handled in the presence of air and which begin to melt (with partial sublimation and slight decomposition) at 270°C when heated in a sealed tube. **3** is very soluble in dichloromethane, readily soluble in benzene and toluene, and moderately soluble in pentane.



In the ^{1}H-NMR spectrum (200 MHz, 293 K, C_6D_6, TMS int.) of **3** a sharp singlet is observed at $\delta = 1.08$ which is shifted 0.6 ppm upfield compared to that of decamethylferrocene $[(\eta^5\text{-}C_5Me_5)_2Fe]$ **4**.[3] In comparison to the $^{13}C\{^1H\}$-NMR signals of **4**,[2,3] those of **3**[2] are shifted slightly downfield. The $^{31}P\{^1H\}$-NMR signal shows a continuous downfield shift within the series triple-decker **1** ($\delta = -290.5$[1]), monophosphaferrocene $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}PC_4H_4)]$ **5** ($\delta = -67.5$[4]), **3** (81.01 MHz, C_6D_6, 85% H_3PO_4 ext., $\delta = 153.0$ (s)), and $Li(P_5)$ ($\delta = 470$[5]). In the mass spectrum,[2] the most intense peak is the molecular peak of **3**, followed by the peak for $M^{\oplus} - P_2$. So far, all attempts to prepare a single crystal suitable enough for an X-ray structure analysis have failed, both by sublimation as well as recrystallization. *cyclo*-$P_5^{\ominus}$ is probably formed from $P_3^{\ominus}$ and P_2.[6]

Experimental

A mixture of **2** [7] (980 mg, 2.3 mmol) and P_4 (1500 mg, 12.1 mmol) in xylene (80 mL) was stirred under reflux for 15 h and the insoluble material removed by filtration on a D3 frit and extracted three times with 80 mL each of CH_2Cl_2 (393 mg of residue after drying under high vacuum). The solvent was removed from the combined extracts under oil-pump vacuum. After three extractions with 50 mL each of pentane there remained 726 mg of a brown solid whose composition could not be unequivocally established. After removal of the solvent from the green extracts (oil-pump vacuum), the residue remaining behind was sublimed. At 60°C/0.01 torr, excess phosphorus was removed; between 90° and 110°C, green needles sublimed on the wall of the glass vessel. Recrystallization from pentane furnished 175 mg of **3** (yield 11%). Correct elemental analysis.

$(Me_3Si)_2N-P=NSiMe_3$ as Educt for Electron-Rich Phosphorus-Nitrogen Ligands**

By *Otto J. Scherer,** *Karin Göbel*, and *Jürgen Kaub*

Of the tervalent phosphorus double bond systems described so far, the amino(imino)phosphanes in particular display an unusual diversity of coordination properties.[1] We have now found that reaction of $[Fe_3(CO)_{12}]$ **1** with $(Me_3Si)_2N-P=NSiMe_3$ **2** not only leads to formation of the unusual tridentate 6e-donor ligand **B** (stabilized in the cluster **3**) but also gives the phosphanediyl (phosphini-

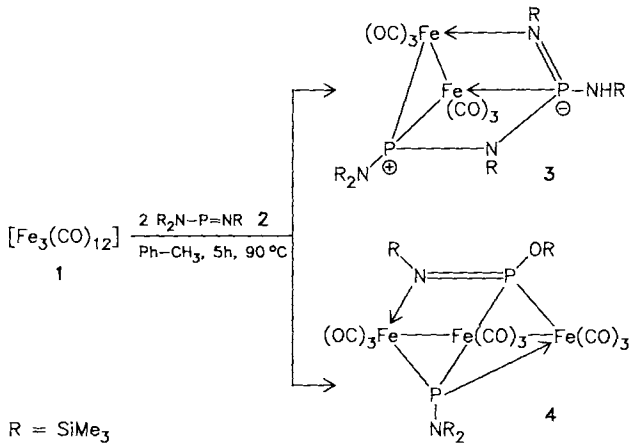
dene) $(Me_3Si)_2NP$ and the first hydroxy(imino)phosphane derivative $Me_3SiO-P=NSiMe_3$ (both stabilized in the cluster **4**). A conceivable route to **B** is the heterolytic opening of the PP bond of **A**, which itself can be formed by [2+1] cycloaddition of **2**.[2a,b] Probably $Me_3SiO-P=NSiMe_3$ is formed from $(Me_3Si)_2N-P=O$ by Me_3Si migration (cf. the conversion of complexed $iPr_2N-P=NtBu$ into complex-stabilized $iPr_2N-P=O$[2c] as well as the reaction of $Ph_3P=NR'$ with $Fe(CO)_5$ and R''NCO, which gives, inter alia, Ph_3PO[3]; Me_3SiNCO could be detected in the solution by IR spectroscopy). Nothing is as yet known about the mechanism of formation of $(Me_3Si)_2NP$.



From the complex reaction mixture ($^{31}P\{^1H\}$-NMR control) obtained on reaction of **1** and **2**, it has so far been possible to isolate, in addition to **3** and **4**, also black **5a** and **5b** as derivatives of the intensively studied phosphanediyl-Fe_3 clusters.[4]

$[Fe_3(CO)_9(\mu\text{-}CO)\{\mu_3\text{-}PNR'(SiMe_3)\}]$ **5a**, R'=H; **5b**, R'=$SiMe_3$

3 and **4** form respectively orange and dark-red crystals which are readily soluble in ether, pentane, benzene, and toluene. The NMR and IR data of **3**–**5** (Table 1) show no unusual features (cf. Refs. [1, 4, 7]). In **3**, (Fig. 1) the tripod-like 6e-donor ligand **B**, attaches to the $Fe_2(CO)_6$ fragment in such a way that a polycycle is formed whose skeletal unit is a strongly distorted trigonal prismatic array with an open edge (N1N3). From the crystal structure analysis[5] it follows that the P1–N1 bond length of 1.605(5) Å is the shortest endocyclic P–N bond of this molecule. In contrast to the trigonal planar coordinated N4 (sum of angles 359.3°), N1 (353.3°) and N3 (346.1°) are slightly pyramidally configurated. The skeletal geometry requires a very short P1···P2 distance of 2.430(3) Å (cf. Ref. [6]).

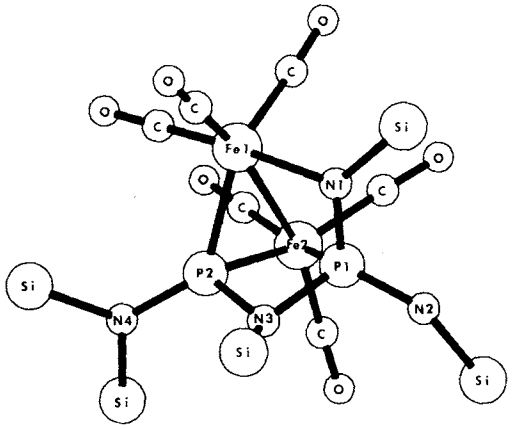

Fig. 1. Crystal structure of **3** (methyl groups omitted for clarity). Selected bond lengths [Å] and angles [°] (see also text): Fe1-Fe2 2.616(1), Fe1-P2 2.250(2), Fe2-P1 2.227(2), Fe2-P2 2.210(2), Fe1-N1 2.123(5), P1-N1 1.605(5), P1-N3 1.742(5), P2-N3 1.730(5), P1-N2 1.659(5), P2-N4 1.692(6); Fe2-Fe1-P2 53.37(5), Fe2-Fe1-N1 80.4(1), Fe1-Fe2-P1 68.78(6), Fe1-Fe2-P2 54.81(6), P1-Fe2-P2 66.41(7), Fe2-P1-N1 106.0(2), Fe2-P1-N3 96.2(2), N1-P1-N3 105.8(3), Fe1-P2-Fe2 71.82(6), Fe1-P2-N3 104.8(2), Fe2-P2-N3 97.1(2), Fe1-N1-P1 94.2(3), P1-N3-P2 88.8(2); N1···N3 2.671(7) Å.

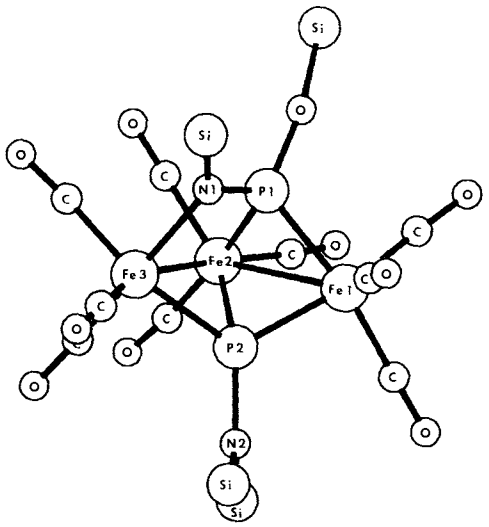

Fig. 2. Crystal structure of **4** (methyl groups omitted for clarity). Selected bond lengths [Å] and angles [°] (see also text): Fe1-Fe2 2.736(2), Fe2-Fe3 2.672(2), Fe1-P2 2.183(3), Fe2-P2 2.278(3), Fe3-P2 2.250(3), Fe1-P1 2.198(3), Fe2-P1 2.233(3), Fe3-N1 2.072(9), P1-N1 1.597(8), P1-O 1.553(7), O-Si 1.684(7), P2-N2 1.710(6); N1-P1-Fe1 117.7(3), N1-Fe3-P2 90.1(2), P1-Fe1-P2 79.3(1), P1-Fe2-P2 76.6(1), Fe1-Fe2-Fe3 88.05(7), Fe1-P2-Fe3 116.0(1), P1-O-Si 157.8(6); P1···P2 2.800(9), Fe1···Fe3 3.775(2) Å. The angles of the Fe_2P triangle and of the Fe_2PN square differ only slightly from those in **3**.

The skeleton of **4** (Fig. 2)[5] can be imagined as being built up of an Fe_3P "butterfly" (angle between the Fe1Fe2P2 and Fe3Fe2P2 planes = 123.9°), bridged by $Me_3SiO-P=NSiMe_3$ in the *cis* form as μ_3-PN ligand (dihedral angle OP1N1Si = 32.1°). Both nitrogen atoms (N1 359.9°, N2 359.8°) are trigonal planar coordinated, and the length of the P1–N1 bond (1.597(8) Å) lies in the expected range (cf. Ref. [1]). The P2–N2 bond length (1.710(6) Å) is comparable with the P–N bond length in the phosphanediyl complex $[\mu\text{-}(Me_3Si)_2NP\{Cr(CO)_5\}_2]$ (1.697(3) Å).[7]

Experimental

3 and **4**: A suspension of **1** (755.5 mg, 1.5 mmol) in toluene (7 mL) was treated with 835.7 mg (3 mmol) of **2** [8]. The mixture was stirred for 5 h at 90°C. After removal of the solvent (oil-pump vacuum), the dark-red, oily residue was taken up in 3 mL of acetonitrile and stored in the refrigerator for 2 d. The precipitate that formed was separated from the mother liquor and then re-cooled (2 d, refrigerator). Altogether three crops of a red precipitate were obtained; these were combined and taken up in 20 mL of pentane. After filtration over filter flocks and evaporation of the filtrate to 1 mL, dark-red **4** crystallized at −30°C as a mixture of diastereomers (I : II ≈ 2 : 1); yield 100 mg (8.2% referred to **1**). Repeated recrystallization from ether at −30°C furnished pure **4** I (X-ray structure analysis). On storing the combined acetonitrile filtrates in a refrigerator for three weeks an orange precipitate separated out, which upon recrystallization from a little pentane at −30°C furnished 5 mg (0.3%) of **3** (exclusively diastereomer I, X-ray structure analysis) as orange crystals.

5: The oily residue obtained after removal of toluene from the reaction solution of **1** and **2** was taken up in ether and cooled to −75°C for ca. 12 h; **5** separated as a black precipitate. This was dissolved in 30 mL of ether. After filtration through filter flocks and evaporation of the filtrate to 3 mL, 193 mg (22%) of **5** crystallized out on cooling to −75°C as a 3 : 1 mixture of **5a** and **5b**. The yield could be increased to 290 mg (33%) by allowing **1** and **2** to react in a molar ratio of 1 : 1 in benzene for 1 h at 75°C.

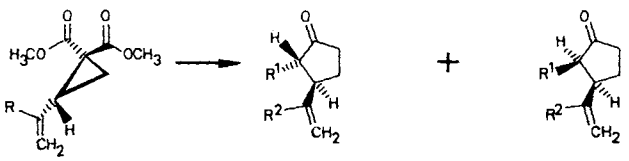
Total Synthesis of the Pseudoguaianolide (+)-Confertin**

By *Gerhard Quinkert,* Hans-Günther Schmalz, Egon-Walzer, Teresa Kowalczyk-Przewloka, Gerd Dürner,* and *Jan W. Bats*

The three-membered ring compounds **1a** (preparation, see ref. [1a]; absolute configuration, see ref. [1b]) or *ent*-**1a** (preparation, see ref. [1b, 2]) serve as enantiomerically pure building blocks in the synthesis of (+)-estrone,[1a] (−)-norgestrel,[3] or (−)-methyl jasmonate.[1b,2] They are accessible by chirality-inducing cyclopropanation and can be transformed by stereospecific ring expansion into the 2-alkyl-3-vinyl-substituted cyclopentanone derivatives **2a/3a**, **2b/3b**, or *ent*-**2c**/*ent*-**3c**[4] (see Scheme 1).



1 **2** **3**

a: R = H
b: R = CH_3

a: $R^1 = CH_3$; $R^2 = H$
b: $R^1 = C_2H_5$; $R^2 = H$
c: $R^1 = CH_2-C\equiv C-C_2H_5$; $R^2 = H$
d: $R^1 = R^2 = CH_3$

Scheme 1. Stereospecific ring expansion of enantiomerically pure three-membered ring building blocks of type **1** (preparation, see ref. [1a, 5]).

We have now employed the enantiomerically pure diastereomers **2d/3d**, prepared from dimethyl (*R*)-2-isopropenylcyclopropane-1,1-dicarboxylate **1b** (preparation and absolute configuration, see ref. [5]), for the synthesis of the sesquiterpene lactone (+)-confertin **14** (see Scheme 2).

In order to construct the hydroazulene system, we utilized an intermolecular Michael addition of the thermodynamically more stable enolate anion of **2d/3d** onto acrylonitrile, which results in exclusive formation of the *trans*-adduct **4**, and a Lewis-acid-catalyzed intramolecular hetero-ene reaction of **7** to give a mixture of isomers **8** and **9**, which were not separated, but rather directly converted via the constitutional isomers **10/11** into **12**.

The ketone **12**, whose structure was established by single-crystal X-ray diffraction analysis,[6] reacts, under conditions of kinetic control, regioselectively at C7 and stereoselectively from the α side with ethyl α-bromoacetate (93%).[7] The resulting alkylation product was transformed via **13** into (+)-confertin **14** in analogy to the synthesis of (±)-confertin *rac*-**14**[8] by *Schlessinger* et al.[9d] and *Heathcock* et al.[9f] This represents the first total synthesis of an enantiomerically pure pseudoguaianolide and makes accessible once again another cyclopentanoid target compound from a chiral cyclopropane derivative. Control of the Molecular Weight of Polyethene in Syntheses with Bis(ylide)nickel Catalysts

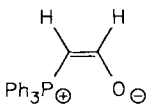
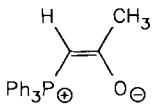
By *K. Alexander Ostoja Starzewski** and *Josef Witte*

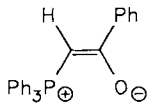
We recently reported on highly active Ni-catalyst systems for ethene polymerization. These were generated from bis(cyclooctadiene)nickel(0), $Ni(cod)_2$, a carbonyl-stabilized and a non-stabilized ylide, $Ph_3PCR^1C(O)R^2$ and $R^3_3PCR^4R^5$, respectively.[1] In the catalytically active, square-planar nickel complex, the non-stabilized ylide is structurally intact C-coordinated, whereas the stabilized ylide is PO-coordinated due to rearrangement. The activity of the catalyst can be optimized by variation of the intact ylide ligand; but modification of the substituent R^2 in the carbonyl-stabilized ylide ligand also increases the catalytic activity in the $Ni(cod)_2/Ph_3PCHC(O)R^2/Me_3PCH_2$ system: On going from the formylmethylene(triphenyl)phosphorane **1a** via the acetyl derivative **1b** to the benzoylmethylene(triphenyl)phosphorane **1c** (R^2 = H, Me, Ph) the turnover number increases to ca. 0.5×10^5 moles ethene per mole of nickel.[1]



1a



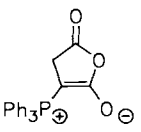
1b



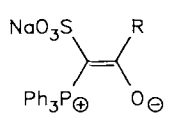
1c

Characterization of the polymers showed that the average chain length of the ethene polymerizates also increases with increasing catalyst activity. The intrinsic viscosities in tetralin at 140 °C do not, however, exceed 0.2 dL/g, which corresponds to molecular weights M of about 5×10^3 g/mole.[2] We have therefore tried to noticeably increase the range of molecular weights accessible with this Ni-catalyst system by further variation of the carbonyl-stabilized ylide ligand.

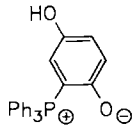
With the three ligands **2a**–**2c**, we have indeed been able to obtain novel, very active bis(ylide)nickel polymerization catalysts, which afford access to polyethene (PE) in practically all molecular weight ranges from PE waxes and hard waxes through high molecular weight high-density polyethene (HDPE) to ultrahigh molecular weight polyethene (UHMW-PE) with $M \geq 10^6$ g/mole (Table 1).



2a



2b



2c

The new catalysts are obtained in situ by stoichiometric reaction of the three components in toluene at 40–60 °C (cf. Ref. [1]). The triphenylphosphane-maleic anhydride adduct **2a**[3] has so far found no use as ligand; the sulfonated benzoylmethylene(triphenyl)phosphorane **2b**, R = C_6H_5, and the triphenylphosphane-benzoquinone adduct **2c**,[3] on the other hand, have already been employed successfully in combination with nickel(0) complexes and triphenylphosphane as catalysts for the synthesis of low-molecular weight PE waxes (α-olefins),[4,5] but nothing was known about the formation of high molecular weight PE in this connection.

The **2a**-catalysts are soluble in non-polar solvents, whereas the **2b**- and **2c**-catalysts are nearly insoluble. The **2b**-catalysts are soluble in dimethylformamide (DMF), and polymerizations can be initiated with DMF/toluene solutions; the resulting polyethene, however, has a relatively low molecular weight (Table 1); the intrinsic viscosities usually lie below 1 dL/g, i.e. the molecular weights are below 5×10^4 g/mole.

Regarding molecular weight control,[6] the **2c**-catalyst system is the most versatile. Depending upon which non-stabilized ylide is used, the intrinsic viscosities of the PE samples in tetralin at 140 °C reach values of up to 10 dL/g and more, from which molecular weights of $\geq 10^6$ g/mole can be calculated. In these catalyst systems, which are free of alkylaluminum compounds,[7] termination and transfer reactions can accordingly be suppressed as a function of the ligand in favor of an uninterrupted growth of the polymer chains. The second ylide ligand[8] and the polarity

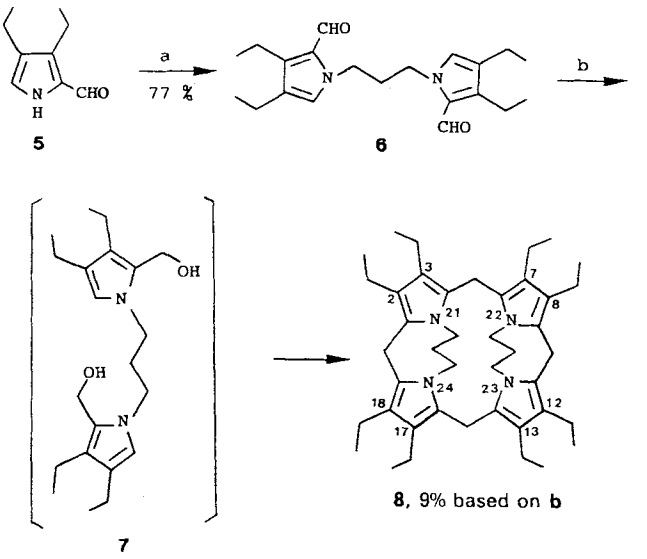
reactive dialcohol **7**, which was allowed to react in situ (see Scheme 1) at −60 °C. Work-up and chromatographic purification furnished the 21,24:22,23-bis-trimethylene-2,3,7,8,12,13,17,18-octaethylporphyrinogen **8** as the tetrahydrate in the form of fine needles that are stable on drying (m.p. 109 °C).[10] According to spectroscopic data, especially MS and ^{1}H-NMR data, **8** is a dimeric condensation product of **7**.

Biomimetic Synthesis of a Twofold *N,N'*-Bridged Porphyrinogen**

By *Ralf Timmermann, Rainer Mattes,* and *Burchard Franck**

Among the reactions of heme biosynthesis,[1,2] the cyclizing condensation of four molecules of the monopyrrole precursor porphobilinogen **1** is of particular significance for the development of biomimetic syntheses. **1** and structurally related pyrrole derivatives undergo highly selective acid-catalyzed condensation to give the porphyrinogens, the cyclic tetrapyrrole precursors of the porphyrins.[3,4] In continuation of our studies on the practicability of this *biomimetic*[5] *cyclotetramerization* we were able to synthesize novel, non-planar and fourfold expanded porphyrinogens **4a**[6] and **4b**[7] by acid-catalyzed condensation of the monopyrroles **2** and **3**, respectively, and to convert them into the corresponding porphyrins. We now report on the use of this biomimetic principle for the synthesis of the twofold *N,N'*-bridged porphyrinogens **8** from the trimethylenedipyrrole **7**, which can be regarded as a simplified *N,N'*-bridged dimer of porphobilinogen **1**.

The readily accessible[8] 3,4-diethyl-2-formylpyrrole **5** was alkylated in the form of its potassium salt with 1,3-dibromopropane to the dialdehyde **6** using a method described by *Burger* and *Dreier*.[9] For activation prior to acid-catalyzed condensation, **6** was reduced to the very



Scheme 1. Synthesis of **8** from **5** [8]. Reaction conditions: a) KOH/dimethyl sulfoxide, 1,3-dibromopropane, room temperature, 14 h; chromatography on silica gel (Merck 0.063–0.2 mm), petroleum ether/ether 4:1. b) $NaBH_4$/MeOH, room temperature, 20 min; *p*-TosOH/AcOH/MeOH, −60 °C; chromatography on Al_2O_3, Activity III (Woelm), petroleum ether/ether 95:5 [10].

An isomeric structure with crossed trimethylene bridges, the 21,23:22,24-bis-trimethylene derivative, could be ruled out on the basis of the MS and ^{1}H-NMR data and by the isolation and structural elucidation of a condensation intermediate. Thus, as expected for **8**, preferred splitting of the molecule into two halves took place in the mass spectrometer; in the case of crossed coupling this would re-

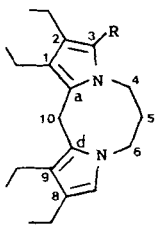
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

quire the very unlikely cleavage of four bonds. A crossed condensation product is also irreconcilable with the ^{1}H-NMR data, because, in contrast to **8**, it would be centrosymmetric and would not exhibit splitting of the methyl and methylene signals of the ethyl side chains into two triplets and quadruplets, respectively. Furthermore, it can be assumed that the acid-catalyzed condensation of **6** first leads intramolecularly to **9b**, from which only **8** can be formed.



9a, R = H

9b, R = CH_2OH

If the condensation is carried out with suppression of the intermolecular reaction (dilution, high temperature, and large amounts of catalyst) a crystalline product is obtained as well-formed needles in 12% yield (m.p. 92°C). From a crystal structure analysis (Fig. 1) it followed that the product was the tetrahydrodipyrrolo-1,5-diazocine **9a**, formed from the initial hydroxymethylene product **9b** by elimination of formaldehyde.

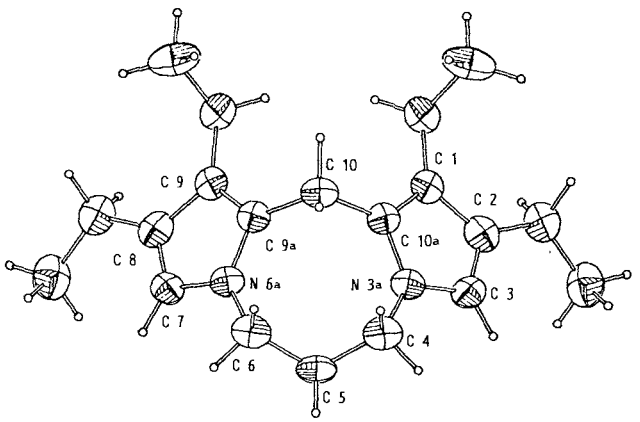


Fig. 1. Crystal structure of **9a**. Selected bond lengths [pm]: C(10a)-N(3a) 137.4(3), N(3a)-C(3) 138.3(3), C(3)-C(2) 135.9(5), C(2)-C(1) 142.4(3), C(1)-C(10a) 138.1(4). Interplanar angle between the pyrrole rings: 111° [10].

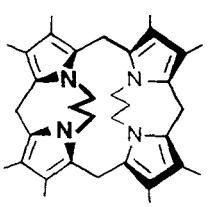
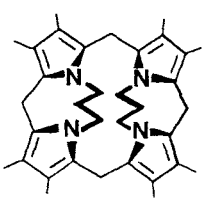
In **9a** the pyrrole rings are tilted at 111° to each other in a roof-like fashion. Assuming that **9a** is a structural element of **8**, only **8a** and **8b** of the four possible configurations of **8** come into question, of which, according to model considerations, the cage-like configuration **8a** is sterically favored.



8a



8b

In contrast to the unbridged *N,N',N'',N'''*-tetramethylporphyrinogen **4a**,[6] in the new porphyrinogens **8a** and **8b** there are strong steric interactions in the center of the molecule, thus rendering a planarization of the molecule difficult. As a consequence, **8** cannot be dehydrogenated like **4a** to the corresponding porphyrin.

Nickel Complexes with a Propellane Structure**

By *Harald Schwager, Carl Krüger, Richard Neidlein,* and *Günther Wilke**

Stable complexes of low-valent transition metals with fluorine-substituted hydrocarbons have been the subject of numerous studies over the past 20 years.[1] Of particular interest is the nature of the bonding in these complexes compared to that in non-fluorinated systems. The observa-

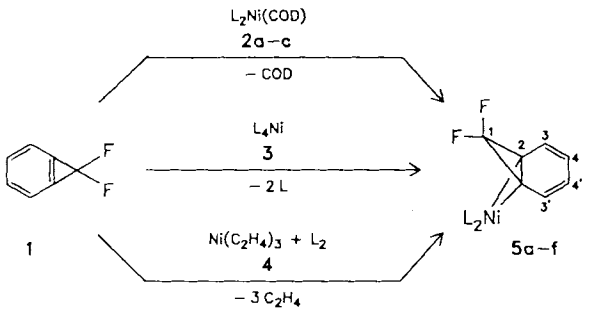
tion that the reactivity of cyclopropabenzene towards nickel(0) depends drastically on the other ligands, as demonstrated for example in the transition from trimethylphosphane to triethylphosphane,[2] directed our interest to the reaction behavior of the difluorocyclopropabenzene **1**[3] toward nickel(0) compounds. We report here a facile entry to the novel class of compounds of the nickelatricyclo-[4.1.1.0^{1,6}]octadienes **5** having a propellane structure.

Reaction of **1** with the nickel(0) complexes **2** or **3**, or with a 1 : 1 mixture of tris(ethene)nickel(0) **4** and a nitrogen chelate ligand leads in high yields to nickel compounds of type **5** (Scheme 1).[4, 5] **5** is the product of removal of the olefin and phosphane ligands and addition of the central three-membered ring double bond of **1** to the nickel atom. The compounds **5**[6] are stable at room temperature, but decompose however on exposure to atmospheric oxygen. In solution, the complexes—with exception of **5c** and **5d**—slowly eliminate **1** at temperatures below −20°C.



Product	Ligand	Educt	Solvent	T [°C]	t [h]	Yield [%]
5a	L = PMe_3	**2a**	pentane	−30	0.1	93
5b	L = PEt_3	**2b**	pentane	−20	3	61
5c	L_2 = dcpe	2c	toluene	+25	20	68
5d	L = PPh_3	3	toluene	+25	6	92
5e	L_2 = TMEDA	**4**	Et_2O	−78 to +25	1	87
5f	L_2 = bpy	**4**	Et_2O	−78 to +25	1	84

Scheme 1. Synthesis of **5a–f** (unsystematically numbered). COD = *cis,cis*-1,5-cyclooctadiene; dcpe = ethylenebis(dicyclohexylphosphane); TMEDA = tetramethylethylenediamine; bpy = 2,2′-bipyridyl.

The nuclear resonance spectra[7] are reconcilable with the given propellane structure. In the ^{31}P-NMR spectra of **5a–d** a double doublet is observed which results from the coupling of the equivalent phosphorus atoms with the two ^{19}F nuclei. Considering only homonuclear couplings in the ^{1}H-NMR spectra of **5**, the non-equivalent protons H-3, H-3′, H-4, and H-4′ show the splitting pattern of an AA′BB′ system (δ_A = 5.6–6.5 and δ_B = 5.3–5.8). The norcaradiene partial structure of the difluorosubstituted ligand follows from the ^{13}C-NMR spectra. The chemical shift of the carbon atom C-2 bonded to the nickel atom (δ = 33–52) (see Table 1) supports the given structure, since a chemical shift of $\delta \approx 100$–120 would be expected for a cycloheptatriene partial structure. The C-2 signal of **5** is shifted more than 80 ppm upfield compared to the corresponding signal of **1**.[8] This upfield shift confirms the loss of aromaticity due to complexation in **1**. As a result of the deshielding effect of the fluorine atoms, the C-1 singlet of **5** is observed at relatively low field.

Table 1. ^{13}C-NMR data of the nickelatricyclooctadiene moiety of **5a–e** (75.5 MHz, [D$_8$]THF, δ referred to TMS, J in Hz) [a]. For numbering see Scheme 1.

	5a	**5b**	**5c**	**5d**	**5e**

δ(C-1)	103.7 s	102.7 s	103.6 s	102.7 s	113.3 s
J(C-1,F)	284.6	285.3	282.5	287.9	285.5
δ(C-2)	49.0 s	48.4 s	51.2 s	52.3 s	33.1 s
J(C-2,F)	56.0	54.9	57.0	52.1	45.5
	7.0	6.6	7.1	7.3	18.7
δ(C-3)	124.1 d	124.2 d	123.4 d	125.4 d	122.1 d
J(C-3,F)	7.3	7.9	8.3	7.1	6.8
	—	—	—	—	1.9
δ(C-4)	123.0 d	123.2 d	125.9 d	122.8 d	120.4 d

[a] Due to the poor solubility of **5f**, a detailed analysis was not possible; the observed signals, however, lie in the expected region.

In the case of **5b**, the structure type derived from NMR spectra was confirmed by an X-ray structure analysis.[9] The carbon atoms bound to the nickel atom have a bond length of 1.514(9) Å, significantly longer than an aromatic CC bond.

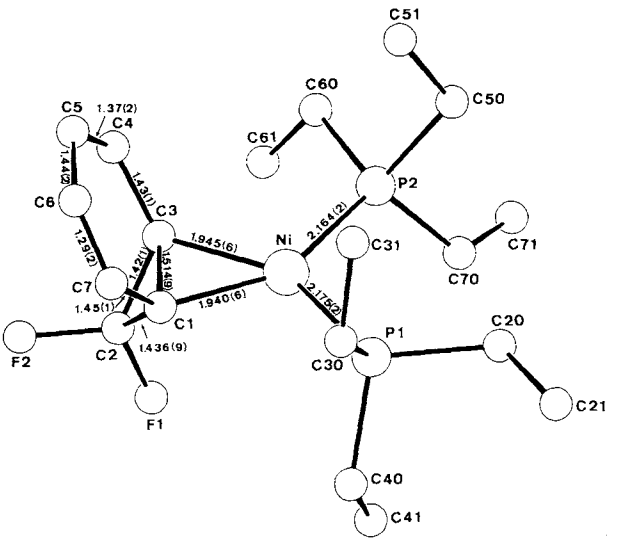

Fig. 1. Crystal structure of 8,8-difluoro-7,7-bis(triethylphosphane)-7-nickelatricyclo[4.1.1.0^{1,6}]octa-2,4-diene **5b**. Important bond lengths in Å.

The X-ray structure analysis of **5b** and the ^{1}H- and ^{13}C-NMR spectra suggest that **1** reacts with nickel(0) complexes by a formal oxidative addition.

Reactions of (η^3-Allyl)(η^5-cyclopentadienyl)palladium with Cyclopropabenzenes

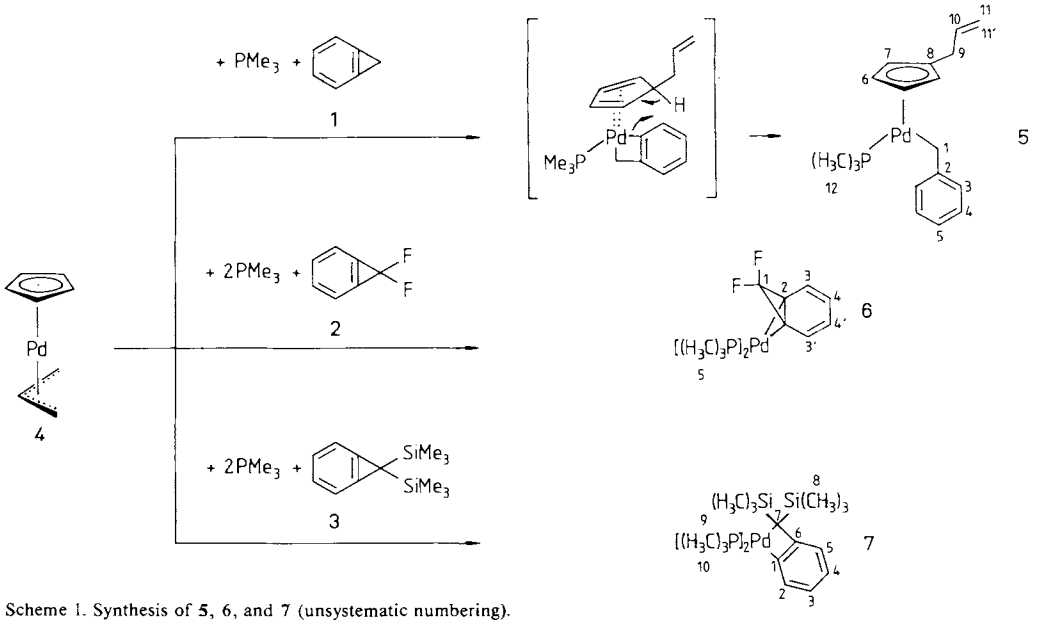
By *Harald Schwager, Reinhard Benn,* and *Günther Wilke**

We have recently described[3–6] the reactions of nickel(0) complexes with cyclopropabenzene **1**,[1] difluorocyclopropabenzene **2**,[2] and bis(trimethylsilyl)cyclopropabenzene **3**.[3] Irrespective of the ligands on the nickel(0) and of the substitution at the methano bridge of the respective cyclopropabenzene, these reactions lead either to a bismethano-bridged nickel[13]annulene,[4] to nickeltricyclooctadienes,[5] or to nickelacyclobutabenzenes.[3,6] The cyclopropabenzenes behave both in a similar manner as well as in a completely different manner towards (η^3-allyl)(η^5-cyclopentadienyl)palladium **4**.[7]

Reaction of cyclopropabenzene **1** with the palladium(II) complex **4** and trimethylphosphane (Scheme 1) affords, in almost 80% yield, the compound **5**, which is a red oil stable at room temperature, and which can be obtained in pure form by crystallization at low temperature. According to an elemental analysis, **5** has the composition $C_{18}H_{25}PdP$, i.e. the allyl- and the cyclopentadienyl-ligand are not removed: this is in contrast to the reaction of **4** with 3,3-dimethylcyclopropene and trimethylphosphane.[8] The NMR data indicate the presence of a σ-bonded benzyl moiety.

The complex **5** stabilized by trimethylphosphane[9] can be formed by alkylation of the cyclopentadienyl moiety by the allyl ligand, addition of a cyclopropabenzene molecule with opening of one of the two CC single bonds of the three-membered ring, and hydrogen migration to the cyclopropabenzene. A metallacycle is presumably involved as an intermediate (Scheme 1).

2 reacts smoothly with **4** in the presence of trimethylphosphane (Scheme 1) with preservation of the three-membered ring and loss of aromaticity to give the palladatricyclooctadiene complex **6** with a propellane structure, i.e. the central three-membered ring double bond of **2** adds to the palladium atom with loss of the allyl and cyclopentadienyl ligands. **6** is sensitive to oxidation and is also thermally labile (for analogous nickel complexes see Ref. [5]). The nuclear magnetic resonance spectra are consistent with the proposed propellane structure.[10] In the ^{31}P-NMR spectrum, a signal with triplet-like splitting of 7.6 Hz is observed at δ = −22.2. The signals of the non-equivalent protons H-3, H-3′, H-4, and H-4′ in the ^{1}H-NMR spectrum show the splitting pattern of an AA′BB′ system (δ_A = 6.42 and δ_B = 5.85); considering only homonuclear couplings.



Scheme 1. Synthesis of **5**, **6**, and **7** (unsystematic numbering).

Reaction of **3** and **4** and trimethylphosphane leads in high yields to the palladacyclobutabenzene **7** (Scheme 1).

Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)
[+] NMR investigations.

7 is also the product of the displacement of the allyl- and cyclopentadienyl-ligands and insertion of the palladium into one of the two CC single bonds of the three-membered ring of **3**. The complex **7** is stable at room temperature, but decomposes on exposure to atmospheric oxygen. The nuclear resonance spectra[10] confirm the proposed structure. The ^{31}P-NMR spectrum is that of an AX spin system ($\delta = -22.0/-29.9$, $J(P,F) = 25.3$ Hz). The different P-C-7 coupling constants (70.7 and 4.6 Hz) rule out a quasi square-planar arrangement at the palladium. Moreover, the NMR data of **7** are consistent with those for the analogous nickel(II) complex.[3, 6]

Thus, with the synthesis of the compounds **5**, **6**, and **7** it has been possible for the first time to obtain well defined products by reaction of palladium complexes with cyclopropabenzenes. In analogy to the reactions with nickel(0) complexes,[3–6] reaction of **2** and **3** with the palladium(II) complex **4** leads to formation of a metallatricyclooctadiene **6** and a metallacyclobutabenzene **7**, respectively. In contrast, the parent compound **1** reacts with **4** to give a benzyl complex **5**. An analogous compound could not be obtained with nickel.

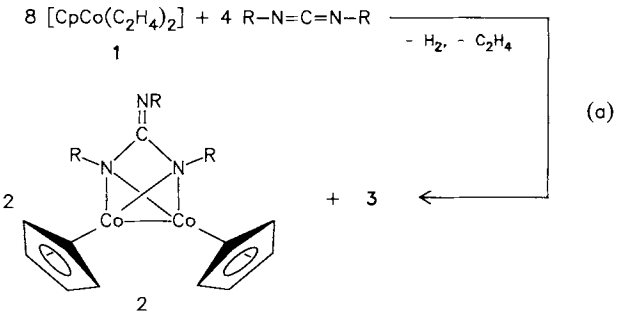
A Triple Decker Sandwich Structure by Reaction of Cyclopentadienylbis(ethylene)cobalt with Carbodiimides: an Unusual Cyclopentadienylcobalt Oligomer**

By *Sergio Stella, Carlo Floriani,* Angiola Chiesi-Villa,* and *Carlo Guastini*

A variety of metal-mediated organic reactions, including insertion, cycloaddition, reductive coupling, C–H bond cleavage, lead to C–C bond formation. These reactions are usually performed by potentially coordinatively unsaturated species, a prototype of which is the [CpCo] (Cp = η^5-C_5H_5) fragment, which forms a variety of $CpCoL_2$ derivatives.[1] Two general aspects of the reactivity of the [CpCo] unit are relevant: the metal can promote reactions between functional groups; moreover it can react with a preformed organometallic species. The latter reaction usually leads to some unpredictable polymetallic structures. We wish to report here the reaction of cyclopentadienylbis(ethylene)cobalt **1**[2] with carbodiimides which emphasizes both the above mentioned aspects of [CpCo] reactivity.

Carbodiimides undergo reductive disproportionation[3] to alkyl isocyanide and the dianion *N,N',N''*-trialkylguanidinediide upon reaction with **1**, which, however, is able to elaborate a quite unusual transformation of the isocyanide fragment.[4]



R = *cyclo*-C_6H_{11}

Two crystalline solids, **2** and **3**, are formed according to reaction (a).[5] The complex **2**[5] is a diamagnetic dinuclear complex, the structure of which has been confirmed by an X-ray analysis. Figure 1 shows the structure of **3**,[6] with selected bond distances and angles. The molecule can be viewed as a triple-decker sandwich in which Co1 and Co3 share a quite unusual organometallic fragment. This consists of two fused five-membered rings, each one containing a cobalt atom. Such a fragment is almost planar, with Co2 and Co4 deviating by only 0.094(1) and 0.329(1) Å, respectively, from the C27, C28, C29, C30, N1, N2 plane. The structural data are consistent with both delocalized (**3A**) as well as with localized double bonding (**3B**).

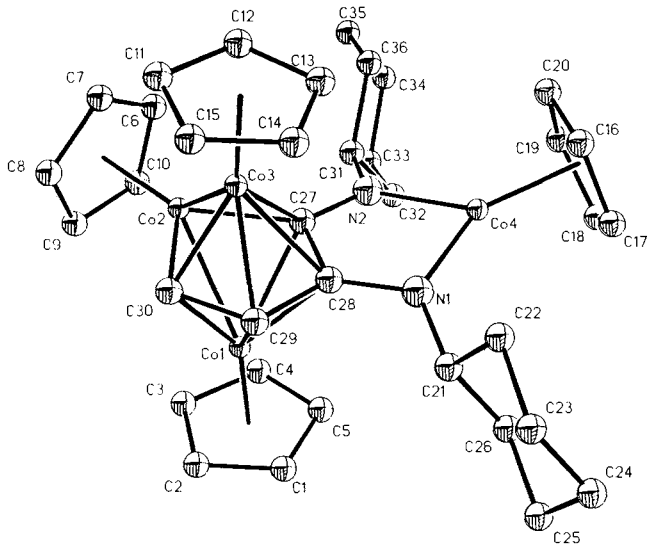

Fig. 1. Crystal structure of the complex **3**. Bond distances [Å]: Co2-C27, 1.963(6); Co2-C30, 1.914(7); C29-C30, 1.457(8); C28-C29, 1.438(9); C27-C28, 1.502(8); C28-N1, 1.358(8); C27-N2, 1.316(9); Co4-N1, 1.913(6); Co4-N2, 1.946(5); Co1-Cp1, 1.704(6); Co2-Cp2, 1.749(6); Co3-Cp3, 1.704(8); Co4-Cp4, 1.736(7); Co1-S, 1.686(2); Co3-S, 1.700(2). Cp1, Cp2, Cp3, Cp4 refer to the centroids of the rings C1···C5; C6···C10; C11···C15; C16···C20, S refers to the centroid of the ring C27, C28, C29, C30, Co2.

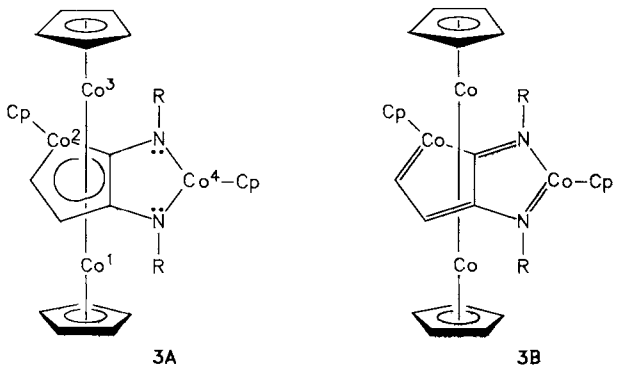
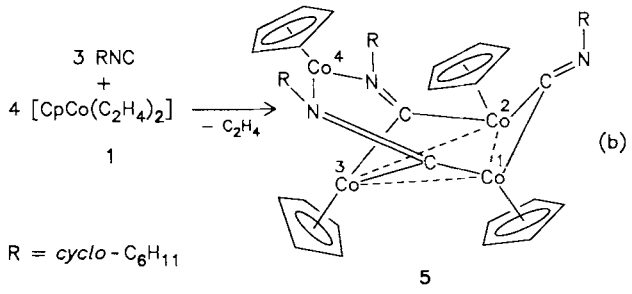


It should be mentioned that there are in each case significant differences between the two Co2–C bonds and the two Co4–N bonds (see Fig. 1). A length of Co–C 1.902(3) was recently reported for the double bond in the carbene complex **4**.[7]

[CpCo=C–N(Me)–CH_2–CH_2–N(Me)(SPh)] **4**

The planarity of the ring system, however, allows for a certain amount of electron delocalization over the two rings. The cyclopentadienyl rings bonded to Co1 and Co3 are almost parallel to the common five-membered ring; the dihedral angles are 4.9(2) and 3.5(2)°, respectively. The distances of Co1 and Co3 from the plane of this ring are very similar to the distances from the Cp rings; in contrast, the Co2-Cp and Co4-Cp distances are significantly longer. The structure **3A** (delocalized) can be described as a triple decker sandwich having 32 valence electrons, while the structure **3B** (localized) requires 33 valence electrons for the triple decker; Co4 has 19 valence electrons. Although the 32e configuration, in which Co4 has 16 valence electrons is more likely, since CpCo and RB are isolobal, the spin distribution in complex **3** must be known before one of the hypotheses can be ruled out. Complex **3** is paramagnetic (two unpaired electrons), as expected for both configurations ($\mu = 2.69$ BM at 292 K).[8]

The diazadimetallapentalene-type fragment is formally formed by co-oligomerization of ethylene with two isocyanide molecules, which are set free during the reductive dimerization of dicyclohexylcarbodiimide in reaction (a). In order to ascertain whether **3** can be formed from cyclohexyl isocyanide and **1**, we carried out reaction (b).[9]



The resulting tetranuclear complex **5** contains only [CpCo] and cyclohexyl isocyanide units, and no ethylene. The structure is shown in Figure 2 with selected bond distances and angles.[10] The $Cp_3Co_3(RNC)_3$ core can be depicted as a six-membered ring with a chair conformation in which two nitrogens bind a fourth [CpCo] unit. The Co···Co distances compare with those commonly found in $[CpCo]_n$ clusters like $Cp_3Co_3(CO)_3$,[11a] $Cp_4Co_4(CO)_2$,[11b] and $[Cp_3Co_3(COTiCp_2)_2]$.[11c] The Co–C bond distances,

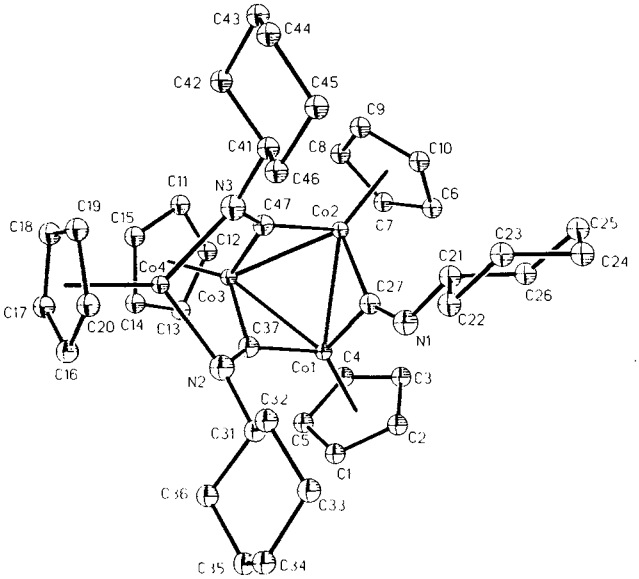


Fig. 2. Crystal structure of the complex **5**. Bond distances [Å]: Co1-C27, 1.91(1); Co1-C37, 1.85(1); Co1-Cp1, 1.77(1); Co2-C27, 1.90(1); Co2-C47, 1.83(1); Co2-Cp2, 1.76(1); Co3-C37, 1.84(1); Co3-C47, 1.87(1); Co3-Cp3, 1.76(1); Co4-N2, 2.038(9); Co4-N3, 2.022(9); Co4-Cp4, 1.91(2); C27-N1, 1.21(1); C37-N2, 1.30(1); C47-N3, 1.32(2); Co1-Co2, 2.513(2); Co1-Co3, 2.457(2); Co2-Co3, 2.483(2).

though significantly different from each other, vary within the range of lengths found for $Co–C_{(\mu\text{-}CO)}$ bonds in the known $[CpCo]_n$ clusters.[11] The C–N bond distances including the distance to Co4 are significantly longer than C27–N1. The proximity of C37 and C47 [2.42(1) Å] would

indicate that the diazadimetallapentalene skeleton can be formed by such a structure. This result, however, seems to rule out the preliminary stage of the reaction between **1** and carbodiimides serving for the generation of isocyanides only. The reaction must be much more complex.

[4] Dicyclohexyl- and di-*p*-tolyl-carbodiimides gave the same results. Details will be given only for reactions with dicyclohexylcarbodiimide.

[5] Procedure for **2**: **1** (1.03 g, 5.7 mmol) was added to a solution of dicyclohexylcarbodiimide (1.45 g, 7.0 mmol) in hexane (50 mL). The dark solution obtained was heated at 50°C for 10 min, then evaporated to 30 mL and allowed to stand for ca. 12 h. A mixture of green, **2**, and red, **3**, crystalline solids was removed by filtration. On storing the mother liquor at room temperature for two days, 0.65 g of complex **2** (41%) separated out. IR (nujol): $\tilde{\nu}$(C=N) = 1638 cm^{-1}. ^{1}H-NMR (300 MHz, C_6D_6): δ = 4.72 (s, 10H); 2.7-1.1 (m, 33H); MS: m/z = 551.—Procedure for **3**: **1** (2.38 g, 13.3 mmol) was added to a solution of dicyclohexylcarbodiimide (2.74 g, 13.3 mmol) in hexane (50 mL). The resulting solution was kept at −20°C for ca. 12 h and then filtered. The filtrate, after standing at room temperature for two days, yielded a mixture of crystalline **1** and **2**, which was removed by filtration. The mother liquor, after standing for ca. 12 h, furnished 0.40 g of **3** as a red crystalline solid (yield 32%). MS: m/z = 740. The results were independent of the Co/carbodiimide molar ratio used. Compounds **2** and **3**, R = *p*-tolyl instead of cyclohexyl, crystallized simultaneously, and could only be separated mechanically under the microscope. The elimination of hydrogen, as required from the stoichiometry, was not proven.

[6] **3** is triclinic, space group $P\bar{1}$, a = 11.118(3), b = 14.696(5), c = 9.804(3) Å; α = 97.78(3), β = 98.93(3), γ = 93.65(2)°; V = 1562.0(8) Å^3, Z = 2; ρ_{calcd} = 1.574 g cm^{-3}; $\lambda(Mo_{K\alpha})$ = 0.7107 Å), $\mu(Mo_{K\alpha})$ = 21.1 cm^{-1}; crystal dimensions 0.32 × 0.48 × 0.66 mm^3. The intensities of 4882 reflections were measured at room temperature (3° < θ < 24°) on a Philips PW 1100 diffractometer using $Mo_{K\alpha}$ radiation. The structure was solved by the heavy-atom method and refined anisotropically (full-matrix least squares). All calculations were carried out using the SHELX-76 program. For 3591 unique observed reflections [$I > 3\sigma(I)$], the final R value was 0.052 [12].

[9] Procedure for **5**: A solution of **1** (1.12 g, 6.25 mmol) in hexane was treated with cyclohexyl isocyanide (1.36 g, 12.5 mmol). The oily product formed showed two CN bands at $\tilde{\nu}$ = 2090 and 1975 cm^{-1} (hexane). On addition of a further amount of **1** (1.00 g, 5.60 mmol) a maroon solution was obtained, which on standing for two days gave crystals of **5** (1.1 g; 60%). IR (nujol): $\tilde{\nu}$(C≡N) = 1765 and 1710 cm^{-1}. ^{1}H-NMR (300 MHz, C_6D_6): δ = 4.84 (s, 20H), 2.1-1.3 (m, 33H); MS: m/z 824.

[10] **5**: monoclinic, space group $P2_1/c$, a = 13.620(3), b = 13.533(3), c = 20.567(6) Å; β = 93.03(3)°; V = 3786(2) Å^3, Z = 4; ρ_{calcd} = 1.445 g cm^{-3}; $\lambda(Mo_{K\alpha})$ = 0.7107 Å, $\mu(Mo_{K\alpha})$ = 17.5 cm^{-1}; crystal dimensions 0.25 × 0.45 × 0.59 mm^3. Data collection and solution of structure as in the case of **3**. 7028 reflections measured at room temperature (6° < 2θ < 47°), 2407 independent reflections with $I > 3\sigma(I)$; R = 0.052 [12].

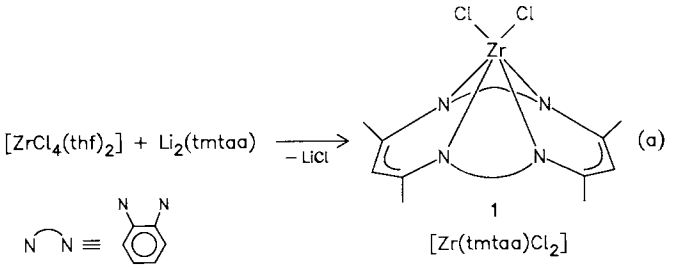
A New Class of Organozirconium(IV) Compounds: Alkyl Derivatives of Tetramethyltetraazadibenzo[14]annulenatozirconium(IV)**

By *Carlo Floriani,* Stefano Ciurli, Angiola Chiesi-Villa, and Carlo Guastini*

Zirconium-carbon functionalities are prototypes for studying fundamental organometal reactions.[1] Such functionalities are stabilized by ancillary ligands, normally by cyclopentadienyl- and substituted cyclopentadienyl-,[1,2] but also by a few alkoxo- and amido-ligands.[3,4] Macrocyclic and polydentate square planar ligands are very well known stabilizers for metal-carbon functionalities in iron and cobalt chemistry.[5] Apart from one exception, nothing has been reported about such a stabilizing effect in the chemistry of the early transition metals.[6] We now report on easily accessible zirconium compounds which can serve for the preparation of electron-rich complexes and organozirconium derivatives. For this purpose we used the ligand tetramethyltetraazadibenzo[14]-annulene, (H_2TMTAA).[7]



The complex **1** was prepared according to reaction (a) in tetrahydrofuran.[8] **1** crystallizes with two molecules of THF. The ligand has the usual saddle-shape conformation with the metal atom located 1.070(2) Å above the N_4 plane and the chlorine atoms arranged *cis* to each other [Cl-Zr-Cl, 85.6(1)°]. A similar structure was reported for the analogous titanium derivative.[9] Complex **1** could be alkylated with Grignard reagents as shown in reactions (b) and (c).[10,11]

The complex **2** obtained according to reaction (b) is stable in the solid state, while in solution it undergoes a rather complex, and not yet clarified, transformation. Such

a transformation may involve some alkyl migration to the ligand, as observed in the synthesis of **3**. Although reaction (c) was carried out at low temperature, the only identified product was **3**,[11] which does not undergo any further transformation even in boiling THF.

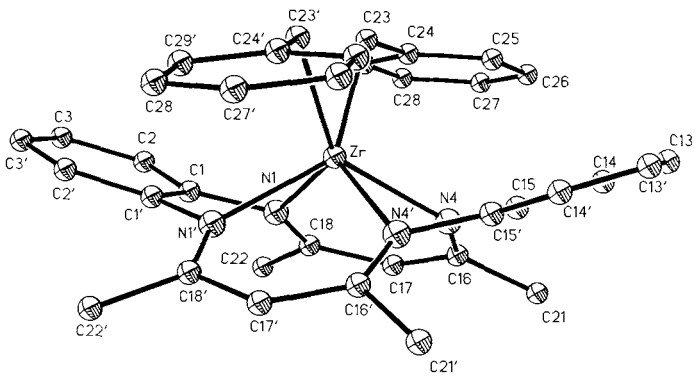

Fig. 1. Crystal structure of the complex **2**. Bond distances [Å]: Zr-N1 2.195(8), Zr-N4 2.184(8), Zr-C23 2.371(12); bond angles [°]: C23-Zr-C23' 80.1(4), N1-Zr-N1' 72.6(3), N1-Zr-N4 82.6(3), N1-Zr-N4' 124.5(3).

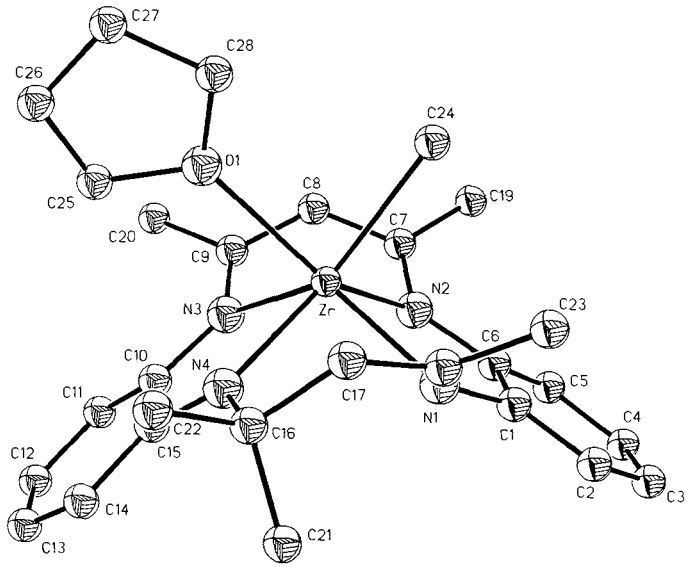

Fig. 2. Crystal structure of the complex **3**. Bond distances [Å]: Zr-N1 2.135(5), Zr-N2 2.188(5), Zr-N3 2.191(4), Zr-N4 2.129(6), Zr-C24 2.418(6), Zr-O1 2.387(5); bond angles [°]: C24-Zr-O1 80.3(2), N1-Zr-N2 70.7(2), N1-Zr-N4 85.2(2), N3-Zr-N4 71.5(2), N2-Zr-N3 77.8(2).

The structures of **2**[12] and **3**[13] are shown in Figures 1 and 2, respectively. Complex **2** has C_m symmetry with the TMTAA ligand in a saddle shape conformation. The zirconium atom lies 1.019(2) Å above the N_4 plane. The Zr-N bond distances are about the same as in complex **1**. The Zr-C bond distance [2.371(12) Å] lies in the upper range of Zr-C bond distances, as is usually found in the case of sterically demanding substituents.[14] The two benzyl groups are arranged *cis* to each other and form an angle of 80.1(4)°, which compares with the mean value for the Cp_2ZrR_2 series.[14] There is nothing unusual in the structural parameters of the TMTAA ligand,[15] excepting the slight modification of bond distances and angles close to the metal because of the large displacement of zirconium from the N_4 plane.

In complex **3** the overall geometry of the ligand is strongly altered by the methylation, while the zirconium atom maintains a comparable coordination geometry; it protrudes from the N_4 plane by 1.049(1) Å and binds THF and the methyl group in a *cis* arrangement [C24-Zr-O1, 80.3(2)°]. The Zr-C distance [2.418(2) Å] is significantly longer than in the corresponding cyclopentadienyl derivatives.[14] TMTAA is transformed into a threefold negatively charged ligand by the methylation at one of the C=N groups. The two Zr bonds to the nitrogens of the more saturated part of the ligand [Zr-N1 and Zr-N2] become significantly shorter than the other two. Alkylation of the ligand diminishes the electron delocalization within the carbon chain linking N1 and N4, and two of the C-N bonds, namely C16-N4 [1.430(1) Å] and to a lesser extent C18-N1 [1.361(8) Å], approach the length of a C-N single bond.

A significant structural difference between **2** and **3** is the orientation of the plane defined by the L_2Zr moiety. In **2**, the C23-Zr-C23' plane is parallel to the N1-N1' and N4-N4' vectors, whereas in **3** the O1-Zr-C24 plane is essentially perpendicular to the N1-N2 and N3-N4 vectors. The structure of **3** poses the question of how the alkylation of the ligand occurs. It could be a case of either a direct alkylation at the imino group or of a methyl migration from the metal to the ligand. The insertion of a C=N group into a M-C bond is known;[16] in the present case, however, the imino carbon atom and metal are too far apart.

The organometallic compounds **2** and **3** should make it possible to establish a chemistry comparable with that of the corresponding cyclopentadienyl derivatives as regards the zirconium-carbon functionalities.

[8] Procedure for **1**: A solution of H_2TMTAA (32.7 g, 95.0 mmol) in THF (300 mL) was treated with a solution of LiMe (190.0 mmol) in ether. After removal of the ether a solution of $ZrCl_4(thf)_2$ (35.8 g, 95.0 mmol) in THF (250 mL) was added. The suspension, which contained a yellow crystalline solid, was refluxed for twelve hours; yield of **1**·2THF 46.6 g (75.0%). ^{1}H-NMR ($CDCl_3$, 300 MHz): δ = 1.78 (m, 8H), 2.44 (s, 12H), 3.68 (m, 8H), 5.59 (s, 2H), 7.45 (m, 4H), 7.56 (m, 4H). The structure of **1** was confirmed by an X-ray analysis.
[9] V. L. Goedken, J. A. Ladd, *J. Chem. Soc. Chem. Commun. 1982*, 142.
[10] Procedure for **2**: A suspension of **1** (2.10 g, 3.24 mmol) in ether (500 mL) was treated at −50°C with 6.53 mmol of $PhCH_2MgCl$. The mixture was stirred for 36 h at −20°C. Dioxane (1.2 mL) was added to the resulting red-orange solution, which was stirred for two hours and then evaporated to dryness. The residue was taken up in toluene (200 mL) at −20°C and the resulting solution filtered and cooled to −50°C. After two days, 0.46 g (23%) of orange-red crystals of **2** separated out. ^{1}H-NMR (C_6D_6, 300 MHz): δ = 1.88 (s, 4H), 1.89 (s, 12H), 4.77 (s, 2H), 6.85 (m, 10H), 7.12 (m, 4H), 7.25 (m, 4H).
[11] Procedure for **3**: The synthesis was carried out as reported for **2**; **3** was obtained (62%) as a red-orange crystalline solid. ^{1}H-NMR (C_6D_6, 300 MHz): δ = −0.39 (s, 3H), 1.53 (s, 3H), 1.93 (s, 3H), 2.02 (s, 3H), 2.13 (s, 3H), 2.16 (s, 3H), 4.58 (s, 1H), 5.10 (s, 1H), 6.68-7.16 (m, 8H), 1.35 (m, 4H), 3.54 (m, 4H).
[12] **2**, space group *Pnma*, a = 16.028(3), b = 20.666(4), c = 9.018(2) Å, V = 2987(1) Å^3, Z = 4, ρ_{calcd} = 1.37 g cm^{-3}; $F(000)$ = 1280, $\lambda(Mo_{K\alpha})$ = 0.71069 Å, $\mu(Mo_{K\alpha})$ = 3.91 cm^{-1}. The structure was solved by the heavy atom method and refined anisotropically for all non-hydrogen atoms. All the hydrogen atoms were located by difference methods and introduced into the final refinement as fixed contributors (U_{iso} = 0.10 Å^2). 1063 unique observed reflections [$I > 3\sigma(I)$] collected at room temperature (6° < 2θ < 45°) were used, R = 0.063. The intensities were corrected for absorption [17].
[13] **3**: space group $P2_1/n$, a = 19.895(5), b = 14.771(5), c = 9.072(4) Å, β = 93.85(3)°, V = 2655(2) Å^3, Z = 4, ρ_{calcd} = 1.34 g cm^{-3}; $F(000)$ = 1120, $\lambda(Mo_{K\alpha})$ = 0.71069 Å, $\mu(Mo_{K\alpha})$ = 4.32 cm^{-1}. Solution of structure as in the case of **2**. 2430 unique observed reflections [$I > 3\sigma(I)$] collected at room temperature (6° < 2θ < 48°) were used, R = 0.044 [17].

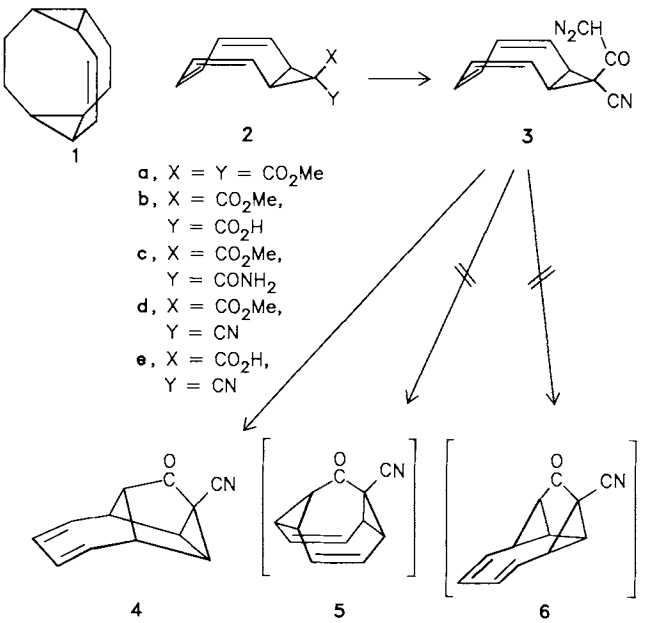
Unusual 1,6-Addition of a Carbenoid**

By *Michael Birkhahn, Eckehard V. Dehmlow,** and *Hartmut Bögge*

Tetracyclo[4.4.2.0^{2,10}.0^{5,7}]dodeca-3,8,11-triene **1** is a highly symmetric but as yet unknown representative of the $(CH)_{12}$ hydrocarbons. A conceivable entry to compounds of this type would be via intramolecular carbenoid addition in a suitably substituted bicyclo[6.1.0]nonatriene. As a model reaction we have investigated the decomposition of the diazoketone **3**.



Reaction of cyclooctatetraene with dimethyl diazomalonate in CCl_4 in the presence of $[Rh_2(OAc)_4]$ affords **2a**, together with small amounts of bis- and tris-adducts. Selective hydrolysis of the *exo* ester group to give **2b** (3 h boiling of **2a** with KOH/MeOH), followed by conversion into the amide **2c**, then into the nitrile **2d**, and finally hydrolysis, affords **2e** (1 h boiling of **2d** with KOH/MeOH) (Table 1). The relative position of the acid group and the nitrile group follows from analogous reactions in the bicyclo[4.1.0]heptane series[1] and from the fact that tetrahydro-

[+] X-ray structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie and by BASF AG (supply of cyclooctatetraene).

2e (prepared from 1,5-cyclooctadiene) forms a bromolactone. The diazoketone **3**, which is readily accessible from **2e**, is undoubtedly present in the given stretched conformation.[2,3] Planarization of the eight-membered ring in the transition state of a carbenoid addition, and probably also intermediary complex formation with the transition metal employed, could facilitate cyclopropanation of the distant double bond (to give **5**) or of a proximal double bond (to give **6**). However, 11-oxotetracyclo[5.4.0.0^{2,9}.0^{8,10}]undeca-3,5-diene-10-carbonitrile **4** was actually formed in the Rh^{II}-catalyzed decomposition of **3** (boiling in CH_2Cl_2 in the presence of $[Rh_2(OAc)_4]$. Whereas the NMR spectra only ruled out **6** and other unsymmetrical products, the X-ray structure analysis (Fig. 1)[4] ruled out **5**, **6**, and other conceivable rearrangement products. Wolff rearrangement of **3** (Ag_2O/CH_3OH) afforded the chain-expanded ester ($R-CO-CHN_2$(**3**)$\rightarrow R-CH_2-CO_2CH_3$) in 34% yield together with 3% of **4**. Vacuum pyrolysis of **3** (350°C/0.3 mbar) without metal compound led predominantly to resinification; **4** was detectable in traces. **4** itself is stable up to 500°C/0.1 mbar.

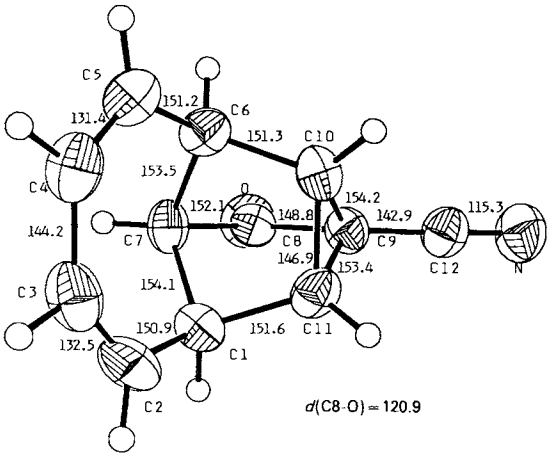

Fig. 1. Crystal structure of **4**. Bond lengths in pm (standard deviations 0.3–0.5 pm).

The basic carbon skeleton of **4** is present in the tetracyclic sesquiterpene longicyclene, whose total synthesis involves a "normal" carbene addition to a double bond.[5] The 1,6-addition to a triene described in this communication is to the best of our knowledge novel. It is apparently enforced by steric compression in the transition states, which would lead to the products "actually expected".

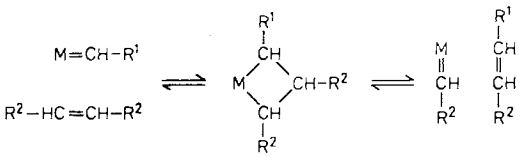
First Four-Membered Metallacycles of Rhenium**

By *Henricus J. R. de Boer, Bartholomeus J. J. van de Heisteeg, Martina Flöel, Wolfgang A. Herrmann,* Otto S. Akkerman,* and *Friedrich Bickelhaupt**

Four-membered metallacycles of rhenium were hitherto unknown. The smallest stable ring system of this metal documented so far is the rhenacyclopentane $[(\eta^5-C_5H_5)(CO)_2Re(CH_2)_3CH_2]$;[1] its lower homologue $[(\eta^5-C_5H_5)(CO)_2Re(CH_2)_2CH_2]$ has been postulated as an unstable intermediate, but has not been unequivocally characterized.[1a] This gap in the large and rapidly growing number of metallacyclobutanes[2,3] is all the more striking as oxidic rhenium compounds belong to the most active catalysts of olefin metathesis besides those of molybdenum and tungsten if the metals are present in higher oxidation states.[4] According to the generally accepted mechanism of this industrially valuable reaction, rhenacyclobutanes must play an important role as intermediates (Scheme 1), particularly if they carry an oxo function at the metal atom. We now wish to report the first stable four-membered ring compounds of rhenium: the rhena(v)cyclobutane **3a** and the rhena(v)cyclobutabenzene **3b**, as derivative of a (previously unknown) rhena(v)cyclobutene.



Scheme 1.

As indicated in Scheme 2, for the synthesis of the rhenacycles **3a** and **3b** we chose the route via 1,3-di-Grignard compounds, which has already proven useful for metallacyclobutanes of the main group and transition metals.[4,5] A simple method has recently been developed for the synthesis of the dichloride **1**, the substance we required as precursor for **3a**, **b**.[6] **3a** is best prepared by reaction of **1** with the 1,3-di-Grignard reagent **2a**[7] in diethyl ether at room temperature. After work-up as usually employed in Grignard chemistry (cf. *Experimental*), a dark-red powder was obtained which dissolved in benzene to give a violet-red solution. On the basis of spectroscopic data[8] the product was characterized as **3a**, which still contained ca. 7% of an impurity.[9] Particularly characteristic is the AX pattern for the diastereotopic geminal methylene protons on α- and γ-C ($\delta(A)=3.42$, $\delta(X)=1.08$; $^2J(AX)=11.2$ Hz). Due

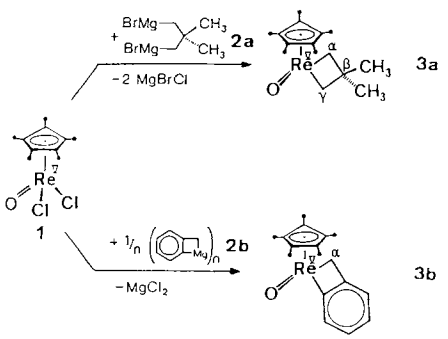
[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 35. This work was supported by the Netherlands Foundation for Chemical Research (SON) (financial support for *H. J. R. de B.*), by the Netherlands Organization for the Advancement of Pure Research (ZWO), by the Deutsche Forschungsgemeinschaft, and by the Bundesministerium für Forschung und Technologie (Bonn).—Part 34: W. A. Herrmann, E. Herdtweck, M. Flöel, U. Küsthardt, J. Kulpe, J. Okuda, *Polyhedron*, in press.

to the two different substituents on the rhenium (C_5Me_5 and O) the two sides of the four-membered ring are not equivalent.



Scheme 2.

Compound **3b** was obtained analogously as a slightly impure brown powder by reaction of **1** with the organomagnesium reagent **2b**[5] in tetrahydrofuran (THF) at −78 °C. Once again, the constitution follows conclusively from the spectroscopic data,[8] especially from the AX pattern for the geminal methylene protons on C_α ($\delta(A)=3.61$, $\delta(X)=1.88$; $^2J(AX)=13.9$ Hz).

The new rhenacycles are thermally stable; in particular, the high stability of **3a** is surprising: no decomposition was observed to take place after 3 h at 80 °C or after 1.5 h at 100 °C. In the mass spectrometer, on the other hand, metathetical degradation of **3a** took place with formation of isobutene. The stability of rhenacycles of type **3** would suggest that such rhenium(v) complexes may be accessible via alternative routes. From the point of view of future catalytic studies, likely alternatives of interest are the metal-centered opening of cyclopropabenzene and its derivatives[10] and the [2+2] addition of olefins to intermediate fragments such as $[(\eta^5\text{-}C_5Me_5)Re(=O)(=CH_2)]$.

Experimental

3a: A solution of **2a** [7] (0.25 mmol) in diethyl ether (35 mL) was added to **1** (101.8 mg, 0.25 mmol) in a closed high-vacuum system at room temperature. The precipitate of magnesium salts was filtered off and the filtrate evaporated to dryness. The resulting dark-red residue was dissolved in C_6D_6; the product yield (determined by quantitative ^{1}H-NMR spectroscopy ($C_6(CH_3)_6$ as internal standard), was 50% [8].

3b: A suspension of **2b** [5] (0.278 mmol) in THF (60 mL) was added to a suspension of **1** (113.1 mg, 0.278 mmol) in THF (50 mL) in a closed high-vacuum system at −78 °C. The mixture was stirred for 1/2 h at −78 °C, 2 h at −20 °C and 1/2 h at room temperature. After subsequent removal of ca. 90 mL of THF by distillation at room temperature, the residue was treated with 20 mL of dioxane. The precipitate of magnesium salts was filtered off and the filtrate evaporated to dryness. The resulting brown residue was dissolved in C_6D_6 and analyzed by quantitative ^{1}H-NMR spectroscopy (see **3a**). Yield of pure **3b**: 60% [8].

$[CH_3C_6H_5BiCl_2][AlCl_4]$ and $[(CH_3)_6C_6BiCl_2][AlCl_4]$—Compounds containing η^6-Arene-Complexed $BiCl_2^{\oplus}$ Units

By *Walter Frank,* Jürgen Weber,* and *Elisabeth Fuchs*

It has been known for more than a century, i.e. since the discovery of the Menshutkin complexes, that element(III) halides of the 5th main group of the periodic system form arene complexes.[1] Results of X-ray structure investigations are available, e.g., for the compounds **1**–**4**.

$C_6H_6(SbCl_3)_2$[2a] **1** $1,3\text{-}(CH_3)_2C_6H_4(SbCl_3)_2$[2b] **2**

$1,3,5\text{-}(CH_3)_3C_6H_3BiCl_3$[3] **3** $(CH_3)_6C_6(BiCl_3)_2$[3] **4**

Many aspects of interest to structural chemists and theoretical chemists should emerge from a comparison of these compounds with arene complexes of cationic species such as $SbCl_2^{\oplus}$ or $BiCl_2^{\oplus}$. Nevertheless, the η^6-arene complexation of such units has so far never been systematically studied. A first attempt in this direction was undertaken by *Amma* et al., who were able to characterize, albeit only incompletely, a compound of the composition $C_6H_6AlBiCl_6$.[4]

In the course of our studies on the ability of aluminum trichloride to abstract chloride ions from bismuth(III) chloride in the presence of toluene or hexamethylbenzene, we isolated the extremely hydrolysis-sensitive title compounds **5** (yellow, "soft" crystals, m.p. 83 °C) and **6** (orange crystals, m.p. 180 °C), respectively.[5] (The compositions (elemental analyses) are given in the reaction equations.)

$$BiCl_3 + \tfrac{1}{2}Al_2Cl_6 \xrightarrow[CH_3C_6H_5]{\Delta} CH_3C_6H_5AlBiCl_6 \quad \mathbf{5}$$

$$BiCl_3 + \tfrac{1}{2}Al_2Cl_6 + (CH_3)_6C_6 \xrightarrow[CH_3C_6H_5]{\Delta} (CH_3)_6C_6AlBiCl_6 \quad \mathbf{6}$$

[*] Dr. W. Frank, J. Weber, E. Fuchs
Anorganische Chemie der Universität
Im Stadtwald, D-6600 Saarbrücken (FRG)

In each case, twinned crystals were obtained; splitting of these, for preparation of samples for a structure analysis, was possible only in the case of the hard compound **6**. According to a crystal structure analysis[6] **6** exists as a centrosymmetric dimer (point symmetry $\bar{1}$ (C_i)) (cf. Fig. 1). Two

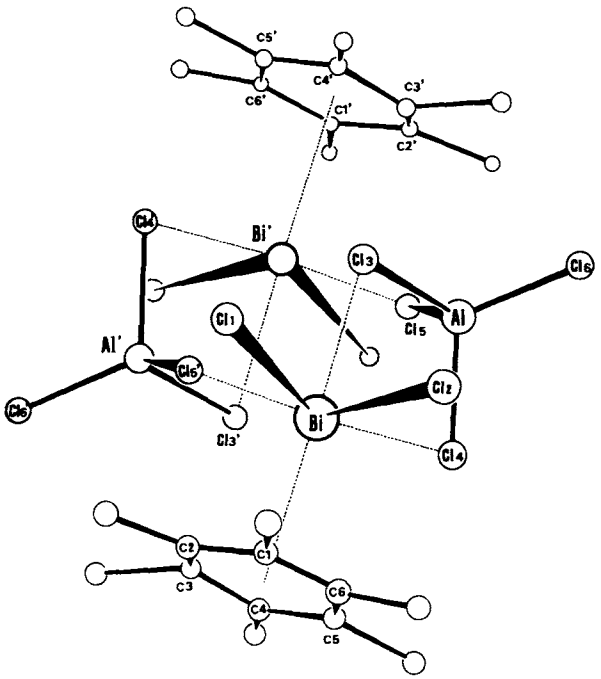

Fig. 1. Crystal structure of the dimeric unit of **6**. The carbon atoms of the methyl groups are not marked, and the hydrogen atoms have been omitted. Selected bond lengths [pm] and angles [°] (for further details see Fig. 2 and caption thereto): Al-Cl3 215.8(4), Al-Cl4 211.9(4), Al-Cl5 210.1(4), Al-Cl6 207.9(4); Cl-Al-Cl 105.2(1)–112.2(2); mean values: C_{arene}-C_{arene} 139(1), C_{arene}-C_{methyl} 152(1), C_{arene}-C_{arene}-C_{arene} 120.6(7).

$AlCl_4$ groups are arranged between two η^6-arene-complexed $BiCl_2$ units. Two Cl atoms are bound to the one Bi atom, and a third Cl atom is bound to the other Bi atom—similarly to the situation in the bis(benzene)gallium(I) tetrachlorogallate(III) dimer.[7] As expected, the $AlCl_4$ "tetrahedra" show a distinct deviation from the $\bar{4}3m$-(T_d) symmetry (cf. caption to Fig. 1), which is found in $Na[AlCl_4]$.[8] The bismuth atom has in addition to two short Cl-contacts, three other Cl-contacts (cf. Fig. 2). As shown by an analysis of the Bi–C distances (caption to Fig. 2) the planar aromatic ring is tilted with respect to the central atom. This is revealed by an observed angle of 10° between the line connecting the bismuth atom and the center of the aromatic ring and the normal to the best C1–C6 plane. As expected, the Bi-$arene_{center}$ distance of 272 pm in **6** is markedly shorter than in **3** (311 pm) or **4** (307 pm).[3] No unusual bonding situation is observed within in the hexamethylbenzene ligand. If the center of the aromatic ring is regarded as a coordination site, a strongly distorted octahedron results as coordination figure for the bismuth atom. In the crystal lattice, only van der Waals forces are effective between the dimers of **6**.

$[\{[(CH_3)_6C_6BiCl_2][AlCl_4]\}_2]$ **6**

Collectively, the structural parameters justify **6** being regarded as arene-stabilized $[\{[BiCl_2][AlCl_4]\}_2]$.

All attempts to synthesize $(CH_3)_6C_6BiCl_3$ led instead to the already well-known compound **4**.[3] In comparison, suitable crystals of $CH_3C_6H_5BiCl_3$[1b] are easily accessible;

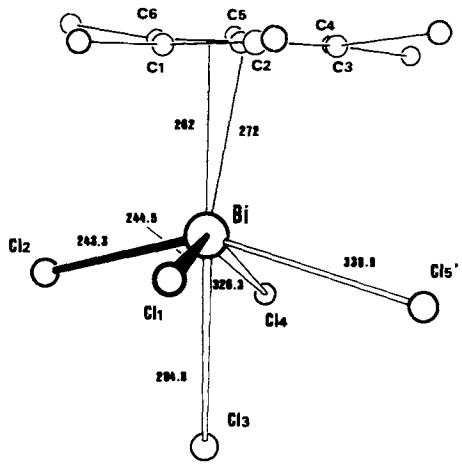

Fig. 2. Coordination figure of the bismuth atom, viewed parallel to the best plane of the six carbon atoms of the aromatic ring. Selected bond lengths [pm] and angles [°]: Bi-C1 275.2(9), Bi-C2 295.2(8), Bi-C3 317.6(9), Bi-C4 321.5(9), Bi-C5 308.0(9), Bi-C6 285.8(8); Cl1-Bi-Cl2 92.8, Cl1-Bi-Cl3 85.3, Cl1-Bi-Cl4 151.4, Cl1-Bi-Cl5′ 86.5, Cl2-Bi-Cl3 84.2, Cl2-Bi-Cl4 83.2, Cl2-Bi-Cl5′ 154.4, Cl3-Bi-Cl4 66.1, Cl3-Bi-Cl5′ 70.2, Cl4-Bi-Cl5′ 85.2. The standard deviations of the Bi-Cl distances and Cl-Bi-Cl angles are 0.3 pm and 0.1°, respectively.

an X-ray study of this compound, as well as further attempts at elucidating the structure of **5**, are presently under way.

High-Pressure LiGe with Layers Containing Two- and Four-Coordinate Germanium Atoms**

By *Jürgen Evers,* Gilbert Oehlinger, Gerhard Sextl,* and *Hans-Otto Becker*

LiGe is unique among the monogermanides of the alkali metals. Whereas the germanium atoms in LiGe form a three-dimensional network at normal pressure (NP),[1] they form discrete tetrahedra in NaGe,[2] KGe,[3] RbGe,[3] and CsGe.[3] More densely packed high-pressure (HP) phases can be prepared for the monogermanides with M = Na–Cs, but these still contain discrete Ge_4 tetrahedra[4,5] and, therefore, like the NP phases, they are Zintl phases (formally M^+Ge^-).[6] We have now found that LiGe can also be transformed into an HP phase in which, surprisingly, layers containing two- and four-coordinate germanium atoms are present.

NP LiGe is obtained by fusion of a stoichiometric mixture of lithium (m3N) and germanium (semiconductor quality) under argon at 650 °C in a molybdenum crucible. In order to prevent evaporation of lithium during the synthesis, the molybdenum crucible was heated in a closed system (iron crucible with conical sealing edges and a copper gasket). A copper trace analysis carried out by atomic absorption spectroscopy on NP LiGe showed that, under the preparation conditions, the copper gasket is sufficiently inert (< 50 ppm Cu). All operations with the open iron crucible were performed under purified argon in a glove box. NP LiGe was transformed in a belt-type apparatus at 4 GPa and 500 °C in 10 min in boron nitride or iron crucibles. By rapid cooling to room temperature and releasing the pressure, the HP phase can be metastably quenched to ambient conditions.

The HP phase is about 7% more densely packed than the NP phase. Heating to approximately 200 °C at normal pressure results in quantitative transformation of the HP phase into the NP phase in an exothermic reaction. Weissenberg and precession photographs of an HP LiGe crystal reveal the Laue symmetry *4/mmm* with systematic extinctions, leading directly to the space group $I4_1/amd$. Patterson and Fourier syntheses give the approximate positional parameters. The quality of the crystal was not sufficiently good for a measurement on a four-circle diffractometer. For this reason, the positional parameters of the HP phase were refined by a profile analysis of the Guinier powder diffractogram (computer-controlled Huber G644, capillary with 0.3-mm ∅, $Cu_{K\alpha 1}$ radiation) according to the Rietveld method. The diffractogram was recorded from 14 to 94° (2θ-range) in steps of 0.02° (4000 data) and corrected for absorption ($\mu \cdot r = 1.78$). The program of *Young*[7,8] with a modified PL factor[9] was used for the profile analysis, taking into account the Guinier geometry. An R value of 4.8% was obtained for 52 reflections using a Lorentz function. The occupation of the Ge and Li sites is ordered and stoichiometric within the limits of error. The observed and calculated diffractograms are shown in Figure 1. (In the measured diffractogram, an additional reflection at $2\theta = 26.38°$ with an intensity of $0.06 \cdot I_{max}$ is obtained, due to another HP phase with approximately 1:1 stoichiometry.) The crystallographic data for the phases NP LiGe[1] and HP LiGe are shown in Table 1.

Table 1. Crystallographic data for NP LiGe [1] and HP LiGe [a].

	Normal-pressure phase [1]	High-pressure phase
Space group	$I4_1/a$	$I4_1/amd$
Lattice parameters [pm]	$a = 975(2)$	$a = 405.29(1)$
	$c = 578(2)$	$c = 2328.2(3)$
Formula unit per unit cell	16	12
Volume of the unit cell [pm^3]	549.5×10^6	382.4×10^6
ρ_{calcd} [g/cm^3]	3.85	4.14
ρ_{exp} [g/cm^3]	3.75	4.1

HP LiGe crystallizes in a new type of structure. The number of neighbors, the distances, and the germanium bond angles for the NP and the HP phase are summarized in Table 2. In both phases, the Ge atoms have eight Li neighbors and vice versa. The eight Li–Ge distances in the HP phase consist of only four different values (from 270 to 288 pm), whereas in the NP phase eight different values are found (from 264 to 324 pm). Therefore, the Li–Ge distances show less variation in the HP phase and, on average, they are shorter than in the NP phase. Furthermore, the Li atoms in the HP phase have one more Li neighbor up to 288 pm than those in the NP phase.

Table 2. Number of neighbors, distances, and germanium angles for NP LiGe [1] and HP LiGe.

Normal pressure phase [1]	High-pressure phase [a]	
Ge neighbors	*Ge_I neighbors*	*Ge_{II} neighbors*
- 8 Li: 264, 266, 272, 281, 299, 317, 322, 324 pm	- 4 Li_I: 287 pm - 4 Li_{II}: 288 pm	- 2 Li_I: 270 pm - 2 Li_{II}: 284 pm - 4 Li_{II}: 288 pm
- 3 Ge: 255 (2×), 260 pm	- 4 Ge_{II}: 270 pm	- 2 Ge_I: 270 pm - 2 Ge_{II}: 304 pm
∢GeGeGe: 105, 109, 118°	∢GeGeGe: 97 (2×), 116° (4×)	∢GeGeGe: 97°
Li neighbors	*Li_I neighbors*	*Li_{II} neighbors*
- 8 Ge: 264, 266, 272, 281, 299, 317, 322, 324 pm	- 4 Ge_{II}: 270 pm - 4 Ge_I: 287 pm	- 2 Ge_{II}: 284 pm - 4 Ge_{II}: 288 pm - 2 Ge_I: 288 pm
- 3 Li: 283, 288 pm (2×)	- 4 Li_{II}: 288 pm	- 2 Li_{II}: 266 pm - 2 Li_I: 288 pm

[a] Maximum error for HP phase: Ge-Ge, Li-Ge, ±1 pm; Li-Li, ±2 pm; ∢GeGeGe, ±0.1°.

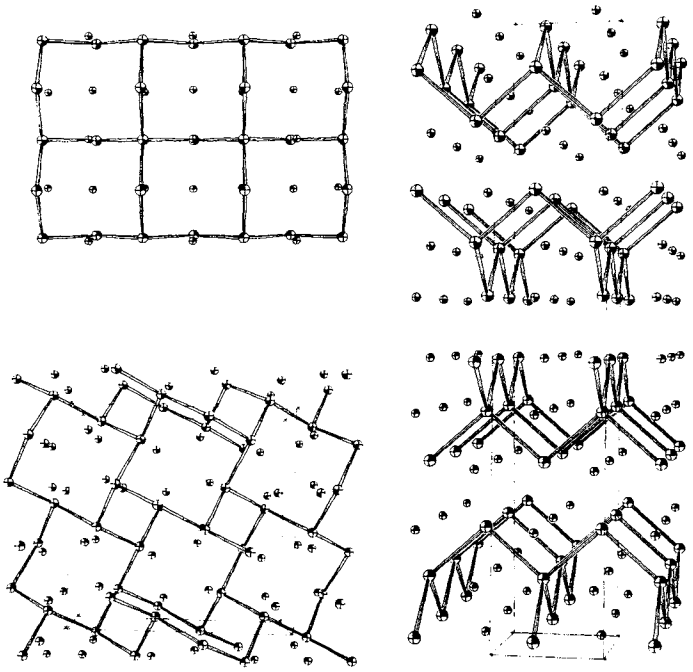

Fig. 2. Left above: View along [001] at a layer of puckered eight-membered rings in HP LiGe. The Li_I atoms lie at the centers of the eight-membered rings, the Li_{II} atoms alternately above and below the two-coordinate bridging atoms. Left below: View along [001] at the network formed by eight-membered rings in NP LiGe. The Li atoms lie, as distorted Li_4 tetrahedra, in the cavities of the eight-membered rings. Right: View along [100] at the layer structure of two-coordinate and four-coordinate germanium in the sequence ABCDA in HP LiGe.

On the other hand, the Ge–Ge distances slightly increase from 257 pm in the NP phase to 270 pm in the HP phase. The germanium bond angles in the HP phase are decreased by approximately 8° in comparison to the NP phase. In HP LiGe, the Ge_I atoms are bonded to four other germaniums, the Ge_{II} atoms to two others. They are present in a 1 : 2 ratio and form puckered eight-membered rings (Fig. 2, left above). The Li_I atoms lie in the centers of the eight-membered rings, the Li_{II} atoms alternately above and below the Ge_{II} atoms. In the NP phase, puckered eight-membered rings are also found, but they are shifted by one edge against each other and form a network of three-coordinate germanium atoms (Fig. 2, left below). Here, the Li atoms are arranged as distorted Li_4 tetrahedra in the cavities of the eight-membered rings. In the HP phase, the eight-membered rings are linked with common edges in layers (Fig. 2, left above), which are stacked in the order ABCDA... (Fig. 2, right). Connection of the two-coordinate Ge_{II} atoms with the two neighboring Ge_{II} atoms in a neighboring layer leads to a planar arrangement. However, the resulting distances of 304 pm (Table 2) are 13% longer than the Ge_I–Ge_{II} bonds (270 pm). Therefore, a network containing only four-coordinate Ge atoms is not formed.

In accordance with the Zintl–Klemm model,[6] four-coordinate Ge atoms have no formal negative charges, three-coordinate have one, and two-coordinate Ge atoms have two negative charges. Therefore, NP LiGe (formally Li^+Ge^-) is a Zintl phase, and HP LiGe (formally $(Li^+)_3Ge^0(Ge^{2-})_2$) is no longer a Zintl phase owing to the lack of charge balance.

It is worthwhile to compare HP LiGe with its analogues formed from heavy elements of group IV of the periodic table. In LiSn,[10] a layer structure composed of four-coordinate Sn atoms with 8 : 8 coordination is formed, which is therefore no longer a Zintl phase. Apparently, the lithium compounds are no longer Zintl phases if, on the one hand, germanium is replaced by the more metallic tin at normal pressure or, on the other hand, germanium becomes more metallic owing to a high-pressure treatment, for example in HP LiGe. The last member of this class of 1 : 1 compounds with 8 : 8 coordination is LiPb. The ideal CsCl-type structure is found in the high-temperature modification ($T > 214$°C); in the low-temperature modification, a slightly distorted rhombohedral structure is found ($\alpha = 89.5$°).[11] The structural units in LiPb are centered cubes, which are uniformly stacked. In LiSn, the cubes are distorted but stacking remains unchanged. Finally, in HP LiGe uniform stacking is also absent: in this case, distorted cubes form blocks which are twisted by 90° against each other.

LiGe is the first compound of a strongly electropositive metal with an electronegative element to the right of the Zintl boundary in which the NP phase still belongs to the Zintl phase but the HP phase no longer. Other promising candidates for such pressure-induced transitions are NaGe, NaSn, and NaPb.

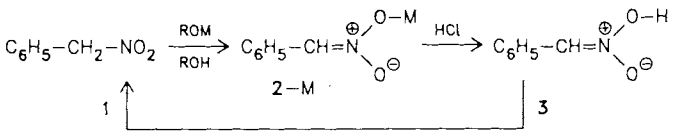
Crystal Structure of [α-Nitrobenzyllithium · Ethanol]$_n$; A Lithium Nitronate-Ethanol Interaction**

By *Gerhard Klebe, Karl Heinz Böhn, Michael Marsch,* and *Gernot Boche**

Ninety-three years ago, *Holleman*[1a] described the conversion of phenylnitromethane **1** into the sodium salt ("nitronate") **2**-Na. Shortly thereafter, *Hantzsch* et al.[1b] found that protonation of **2**-Na leads to an isomer of **1**, the phenylmethanenitronic acid **3**, which is slowly transformed into **1** in solution (see also ref. [1c]).



Numerous applications have been reported for nitronates in synthesis.[2] Nitronates are of particular interest in substitution reactions that proceed through electron transfer.[3] Here we report on the crystal structure of a lithium nitronate, the title compound [**2**-Li · C_2H_5OH]$_n$ (see Fig. 1a).[4]

2-Li, which is prepared from **1** with lithium ethoxide in ethanol,[5] crystallizes with ethanol in a molar ratio of 1 : 1 as a polymeric aggregate. Two **2**-Li · C_2H_5OH species are present in the asymmetric unit of the unit cell. Each lithium atom is bound to three oxygen atoms of three different nitronate ions and to an oxygen atom of an ethanol molecule, resulting in the formation of Li-O-N-O-Li-O six-membered rings. These "annelated" rings are connected through Li and O atoms forming an infinite, ribbonlike structure, which is further stabilized by internal hydrogen bonds. As a part of this framework, three six-membered rings are shown in Figure 1b. The conformation of these rings is close to a boat form. With respect to a "best" plane through the four basal atoms (Li1, N8, O9, O29) of this boat, the planes through the atoms of two neighboring phenyl rings (Fig. 1a) are oriented nearly parallel whereas those through the atoms of the two remaining phenyl rings are arranged nearly perpendicular. In the $C_6H_5CHNO_2$ moiety, the "best" plane through C7, N8, O9, O10 is twisted by 15.2° with respect to a plane through C1 to C6. This twisting and the significant expansion of the bond angles to values larger than 120° indicate a reduction of the van der Waals repulsion between H1 and O10 (distance 236 pm). Related bond angles were found for **2**-Si(*t*-Bu)Me_2.[6] The C7-N8 bond (129 pm) is significantly shorter and the N8-O9 and N8-O10 bonds (133 and 130 pm, respectively) are significantly longer compared with similar bonds in uncharged nitro compounds.[7]

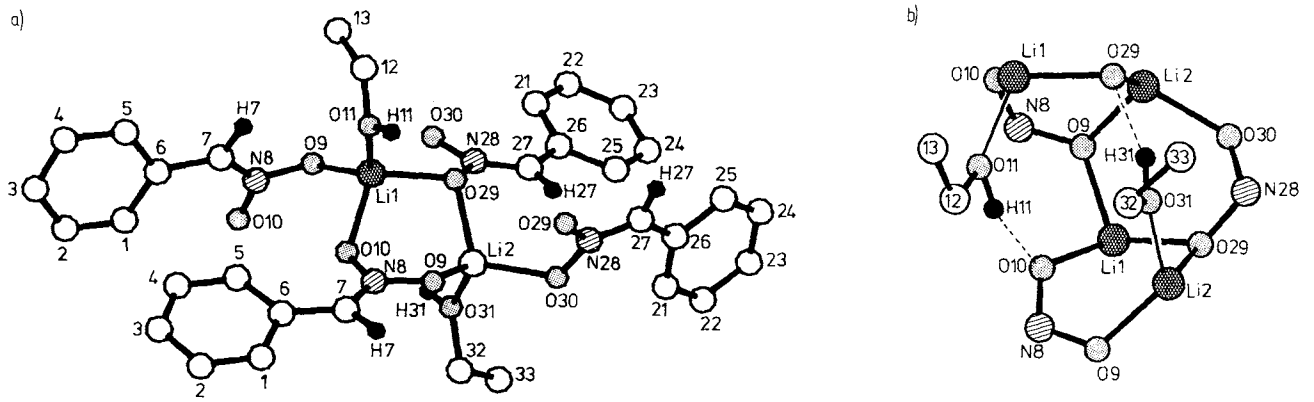


Fig. 1. a) Crystal structure of [**2**-Li · C_2H_5OH]$_n$. The H atoms on the phenyl ring and the ethyl moiety have been omitted; the C atoms are only labeled by numbers. A Li-O-N-O-Li-O six-membered ring is shown which has been extracted from the infinite, ribbonlike framework of "annelated" six-membered rings. The additional rings are connected through the oxygen atoms of the NO_2 groups (cf. Fig. 1b). As indicated by the numbering scheme, the part shown in Fig. 1a is built up from two Li atoms, two ethanol molecules, and four $C_6H_5CHNO_2$ moieties, of which two are related by a symmetry operation.—Space group $Pna2_1$, selected by means of intensity statistics; $a = 732.4(1)$, $b = 1703.6(3)$, $c = 1640.8(4)$ pm, $Z = 8$ (2 formula units per asymmetric unit). Data collection at ca. 230 K with monochromated $Cu_{K\alpha}$ radiation, profile analysis, structure solution by direct methods; refinement with 1351 reflections with $F > 4\sigma(F)$ leads to $R = 0.054$, SHELXTL program [12]. The alkyl moiety of one of the ethanol molecules is disordered over two positions (C32, C32', C33, C33'); only one arrangement is shown in the figure. The positions of the H atoms on the anions and the ordered atoms of ethanol were determined by difference Fourier synthesis. Important distances [pm] and angles [°] (average values or ranges): Li-O 191.9(10)-197.9(10); C-C(phenyl) 136.3(9)-141.5(8); C7-N8 129.3(7); N8-O9 133.2(6); N8-O10 130.1(5); O-Li-O 99.7(4)-122.3(4); C1-C6-C7 126.8(5); C6-C7-N8 126.5(5); C7-N8-O10 124.7(5).—b) Three "annelated" Li-O-N-O-Li-O six-membered rings of the infinite structure of [**2**-Li · C_2H_5OH]$_n$. For clarity, except for the C atoms of ethanol, all atoms that are not directly involved in the ring structure have been omitted: OH···O hydrogen bonds of ethanol to the nitro group: O11···O10 272.6(10) pm; O31···O29 281.6(10) pm; O-H···O (averaged) 158°.—Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52057, the names of the authors, and the journal citation.

Ethanol, which is used as solvent and which is formed as reaction product from lithium ethoxide, is incorporated into the crystal.[8] In spite of the fact that for one of the

ethanol molecules a disordered arrangement of the carbon atoms on two positions is found, the difference Fourier synthesis reveals two peaks in the neighborhood of O11 and O31 which can be assigned to two protons on the ethanolic oxygens. Furthermore, these maxima are suitably oriented for a hydrogen-bond formation to the oxygen atoms of the vicinal nitro groups. The geometry of these hydrogen bonds matches that normally found for such bonds (Fig. 1b).[9]

The presence of an OH···O hydrogen bond in the crystal structure of $[\mathbf{2}\text{-Li}\cdot C_2H_5OH]_n$ is in agreement with the findings for nitronates taken from acidity measurements on nitro compounds in protic solvents.[10] For example, in alcohol or water nitromethane is appreciably more acidic ($pK_a(H_2O) = 10.21$)[11] than in aprotic dimethyl sulfoxide ($pK_a = 17.2$).[10] In the protic solvent the nitronate form is stabilized by the formation of OH···O hydrogen bonds.

As mentioned earlier, the nitronate **2**-Na is protonated to form the nitronic acid **3** and not the nitro compound **1**. Accordingly, it might be tempting to use the structure correlation principle to assign the geometry of the fragment formed by the phenylmethylnitronate and the ethanol to an incipient step of such a protonation reaction. However, it has to be kept in mind, that any conclusion taken from structure correlations gain their significance and reliability from the statistical evaluation of a large data set containing the fragment under consideration embedded in various environments. Thus, to support the outlined assumption, the results for $[\mathbf{2}\text{-Li}\cdot C_2H_5OH]_n$ have to be completed by further examples.

Synthesis of Nitriles via the Ylide Anion of Sodium Cyanotriphenylphosphoranylidenemethanide

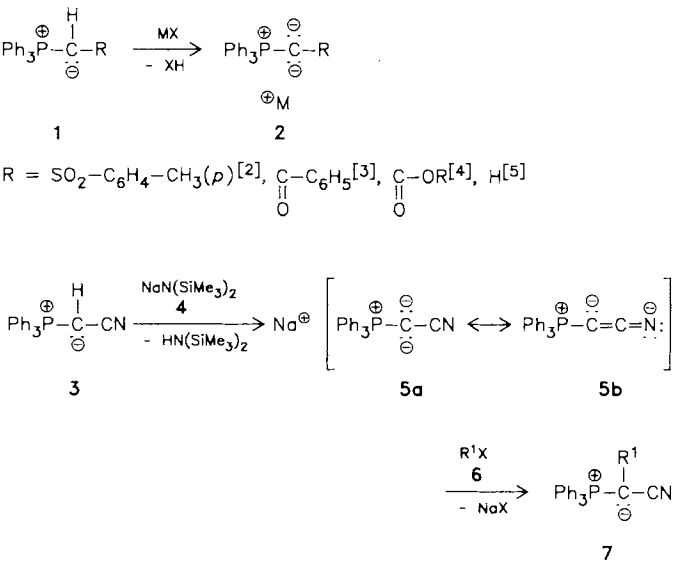
By *Hans Jürgen Bestmann** and *Martin Schmidt*

In phosphonium ylides, the phosphorus atom is capable of stabilizing quasi two negative charges.[1] For this reason, anionic compounds of type **2** may be generated from ylides **1** that have an H atom in the α position to phosphorus.[2–5]

We have now been able to deprotonate cyanomethylenetriphenylphosphorane **3** with a benzene solution of sodium bis(trimethylsilyl)amide **4** to give the salt **5** having an ylide anion.

Compound **5** is isolated, upon evaporation of the solvent, as a yellow, air- and moisture-sensitive powder, thus allowing the first spectroscopic investigation of such a species. In the IR spectrum of **5**, the nitrile band appears at $\tilde{\nu} = 2000\ cm^{-1}$; in comparison, $\tilde{\nu} = 2130\ cm^{-1}$ in the case of **3**.[6] Whereas the ^{31}P-NMR signal of **3** appears at $\delta = 23.2$ (H_3PO_4 as external standard), that of **5** occurs at $\delta = 2.5$, a value that is similar to that found for the *N*-substituted triphenylphosphoranylidene ketenimines ($\delta = 2.3$–5.0).[7] We conclude from this that the resonance structure **5b** strongly contributes to the electron distribution in **5**. The ^{13}C-NMR signal of the ylidic C atom appears at $\delta = 6.60$; $J_{PC} = 94.6$ Hz. The coupling constant shows that the anion **5** has a smaller $P\text{-}C_\alpha\text{-}C_\beta$ angle than open-chain phosphacumulene ylides.[7,8]

Compound **5** reacts with halogen compounds **6** to give the cyanomethylenetriphenylphosphoranes **7**, which are thereby accessible more readily in greater variety than previously. Examples are listed in Table 1.[9]



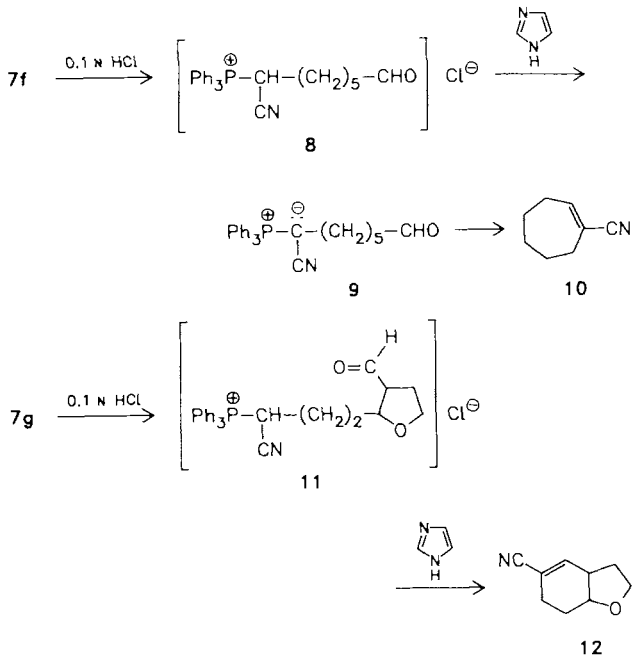
[*] Prof. Dr. H. J. Bestmann, Dipl.-Chem. M. Schmidt
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (FRG)

Table 1. Cyano ylides **7** prepared from **5** and the halogen compounds **6**.

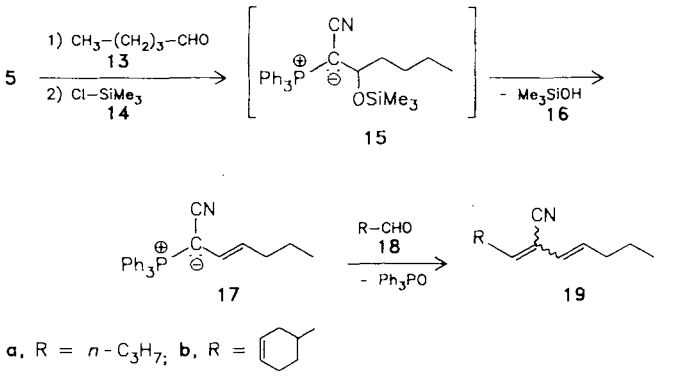
	X	R^1	**7** Yield [%]	M.p. [°C]
a	Cl	$CH_2-C_6H_5$	74	124
b	Br	$CH_2-CH=CH_2$	72	101-102
c	I	CH_3	93	171-172 [a]
d	I	$n-C_4H_9$	78	71-72
e	Cl	$CH_2-Si(CH_3)_3$	73	125-127
f	Br		88 (crude)	oil
g	Cl		51	103-105
h	Cl	$Si(CH_3)_3$	86	142-144
i	Br	Br	85	164 [b]

[a] M.p. = 172-173 °C [6]. [b] M.p. = 162.5-164.5 °C [10].

The cyano ylides **7** react in the usual way with aldehydes to give α,β-unsaturated nitriles.[6] Of particular preparative interest appears to us to be the following possibility for the construction of cyclic compounds of this kind. Treatment of **7f** with 0.1 N HCl results in cleavage of the acetal groups to give the phosphonium chloride **8**. When a solution of **8** in dichloromethane is added to a solution of imidazole in the same solvent at reflux temperature, the ylide **9** is formed as the primary product. Intramolecular Wittig reaction results in conversion of **9** into the cycloheptenecarbonitrile **10** (yield 52%, b.p. = 95 °C/15 torr). The synthetic potential of this reaction sequence is demonstrated by the analogous transformation of **7g**[11] via **11** into the bicyclic nitrile **12** (yield 71%, b.p. = 58-59 °C/0.01 torr).



The reaction of **5** with aliphatic aldehydes and subsequently with trimethylchlorosilane **14** opens up a flexible approach to 2-cyano-1,3-dienes such as **19**, which are of interest for syntheses involving dienes with inverse electron demand.



a, R = $n-C_3H_7$; **b**, R =

When **5** is allowed to react first with valeraldehyde **13** and subsequently with trimethylchlorosilane **14**, not the expected product **15** but rather the α,β-unsaturated cyano ylide **17** (yield 58%, m.p. = 97-99 °C), formed by loss of trimethylsilanol **16**, is isolated. Compound **17** can react with aldehydes **18** to give 2-cyano-1,3-dienes **19** (**19a**, yield 48%, b.p. = 60-64 °C/0.3 torr (kugelrohr distillation); **19b**, yield 72%, b.p. = 94 °C/0.05 torr).

Reaction of **5** with the carboxylic esters **20** in benzene results in formation of the insoluble sodium alkoxides **21**. After removal of the solvent, the acyl cyano ylides **22** are obtained. They can undergo thermolysis to give the alkyne carbonitriles (cyanoacetylenes) **23**.[12] Nonoptimized results are shown in Table 2, in which example **c** shows that chiral carboxylic esters can also be employed.

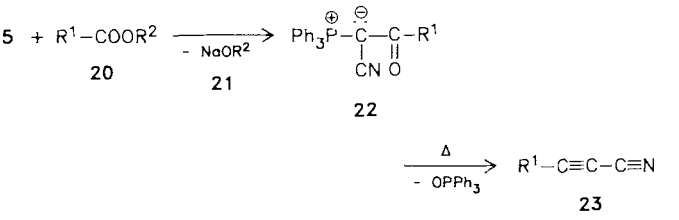


Table 2. Acyl cyano ylides **22** prepared from **5** and the carboxylic esters **20**; alkyne carbonitriles **23** prepared by thermolysis of **22**.

R^1	**22** Yield [%]	M.p. [°C]	**23** Yield [%]	B.p. [°C/torr]
a C_6H_5	78	207 [a]	84 [b]	[b, c]
b $(CH_2)_8-CH=CH_2$	65	95	21	76-77/0.07
c 	72	137-148 [d]	26	42-50/0.05 [e]

[a] M.p. = 208 °C [12]. [b] According to [12]. [c] M.p. = 38-39 °C. [d] Melting range of the mixture of diastereomers. [e] Bath temperature, kugelrohr distillation ($[\alpha]_D^{20} = -3.1°$, $c = 1.4$ ($CDCl_3$)); mixture of diastereomers.

Experimental Procedure

A) Synthesis of **7**: **3** (9.03 g, 30 mmol) and **4** (5.49 g, 30 mmol) were stirred together in 150 mL of dry benzene at room temperature, until a clear, orange-yellow solution of **5** was obtained (ca. 1 h). Compound **6** (30 mmol) was then added to this cooled, stirred solution. After addition, the reaction mixture was allowed to stir for 20 h at room temperature (**7f** and **7g**: 3 d at 40-50 °C), and the inorganic salt was filtered off under suction. Removal of

the solvent gave a usually oily residue, which was dissolved in ca. 50 mL of ethyl acetate. Addition of hexane until the solution became cloudy resulted in the crystallization of the compounds **7** at −20°C (cf. Table 1).

B) Synthesis of **22**: **20** (30 mmol) was added to a solution of **5** (30 mmol) in benzene prepared according to A above, and the reaction mixture was heated at reflux for 2 h. After cooling to room temperature, the reaction mixture was worked up as described under A (cf. Table 2).

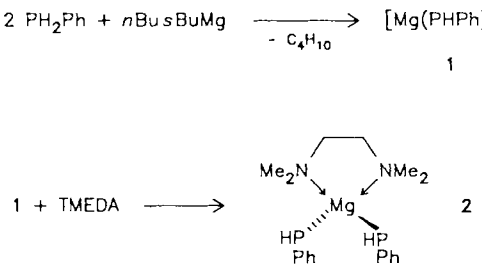
Magnesium Phosphides—Synthesis and Structure of [Mg(PHPh)$_2$(tmeda)]**

By *Evamarie Hey, Lutz M. Engelhardt, Colin L. Raston,** and *Allan H. White*

The synthesis of organomagnesium reagents and their utility in organic and organometallic chemistry is well known.[1] Inorganic magnesium reagents, however, remain largely unexplored. For example, little is known about magnesium phosphides[2,3] and their use as transfer agents of $PR_2^{\ominus}$ has not been investigated. We now report the synthesis and spectroscopic properties of the magnesium phosphides **1**[3,4] and **2**,[5] and the X-ray crystal structure determination of **2**, which to our knowledge represents the first crystallographic study of a magnesium phosphido complex.

The relatively new reagent *n*Bu*s*BuMg, whose potential is slowly being realized,[6] was found to selectively metalate PH_2Ph in heptane under mild conditions. The product, **1**, is assumed to have a polymeric structure containing bridging $PHPh^{\ominus}$ groups which are cleaved by tetramethylethylenediamine (TMEDA) to yield a monomeric hydrocarbon-soluble bis(phosphido) complex, **2**.



Compounds **1** and **2** show characteristic ν(P–H) absorptions at 2280 and 2262/2250 cm^{-1}, respectively. The ^{31}P-NMR spectrum of **2** shows two virtual triplets centered at $\delta = -123.65$ and -123.70 ppm in a ratio of ca. 2:1 ($(^1J + {}^3J)/2 = 198.5$ Hz, both triplets), corresponding presumably to coupling to two protons in each of the *meso* and *rac* diastereoisomers that are possible for two chiral P centers attached to magnesium. No ^{25}Mg–^{31}P coupling was evident and we were unable to obtain a ^{25}Mg-NMR spectrum,[7] probably because of the low site symmetry at the quadrupolar ^{25}Mg nuclei.

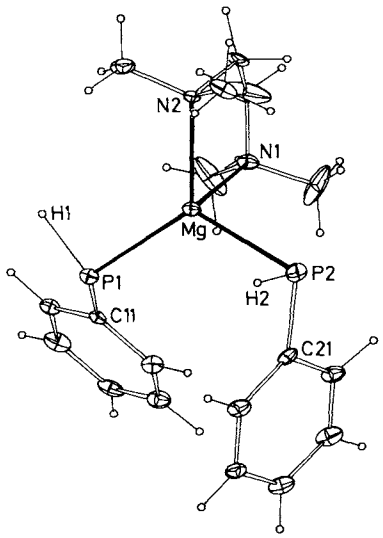


Fig. 1. Crystal structure of **2** showing 20% thermal ellipsoids. Hydrogen atoms have arbitrary radii of 0.1 Å; H1 and H2 were located in a difference map but not refined. Selected bond lengths [Å] and bond angles [°]:Mg-P1, Mg-P2 2.592(5), 2.587(5); Mg-N1, Mg-N2 2.306(8), 2.226(8); P1-C11 1.822(8), P2-C21 1.821(10); P1-Mg-P2 122.5(1), P1-Mg-N1, P1-Mg-N2 100.9(3), 126.0(3), P2-Mg-N1, P2-Mg-N2 100.1(3), 110.1(3), N1-Mg-N2 79.9(3), Mg-P1-C11 122.6(4), Mg-P2-C21 98.4(5).

The X-ray structure of **2** (Fig. 1),[8] obtained from a crystal selected from a bulk sample of inseparable isomers, was of the *rac* isomer. The magnesium centers have a distorted tetrahedral environment with the P1–Mg–P2 angle (122.5(1)°) greater than the N1–Mg–N2 angle (79.9(3)°). The Mg–P distances are virtually equivalent (2.592(5) and 2.587(5) Å) and compare with those in MgP_4 (2.608–2.862 Å);[9] the P–C distances are also equivalent. However, the Mg–P–C angles differ considerably (122.6(4) and 98.4(5)°). The associated hydrogen atom positions, although not satisfactorily resolved beyond difference map artifacts, suggest pyramidal dispositions. Interestingly, the nitrogen centers of monodentate amido ligands bound to magnesium are trigonal.[6]

The only other X-ray structures of phenylphosphido complexes, namely, **3**[10] and **4**,[11] and the results of other investigations[12] show that the properties and reactivity of the $PHPh^{\ominus}$ group are largely dependent on the nature of the metal and coligands.

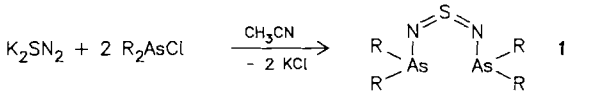
[14] *Experimental procedure* for **6**: **5** (0.23 g, 0.42 mmol) was allowed to react with **1** (0.10 g, 0.41 mmol) in 20 mL of tetrahydrofuran at ca. 20°C. Cooling of the mixture to ca. −30°C afforded green crystals of **6** [13] (0.15 g, 53% yield), which were washed with hexane and dried in vacuo.

$As_4S_5N_{10}$—A Diaminosulfane Derivative with Two Bicyclic Arsino Sulfur Diimides**

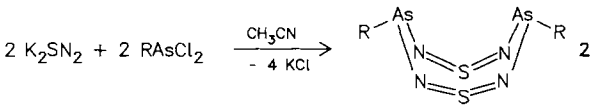
By *Max Herberhold,* Karlheinz Guldner, Alfred Gieren, Catalina Ruiz-Pérez,* and *Thomas Hübner*

The reaction of the salt K_2SN_2 with organoarsenic chlorides has proved useful for the synthesis of the arsenic-substituted sulfur diimides **1** and **2**.[1,2] According to the X-ray structure analysis of **1** (R = Ph), the sulfur diimide skeleton in the bis(diorganoarsino) sulfur diimides **1** has the *Z/Z* configuration;[2] the eight-membered ring in **2** (R = *t*Bu) has the boat form.[2] Compounds of type **1** were first described in 1984;[1] eight-membered ring compounds of type **2** with R = Me,[3] Ph,[4] and Mes[4] had been obtained previously.



$K_2SN_2 + 2\ R_2AsCl \xrightarrow[-\ 2\ KCl]{CH_3CN}$ **1**

R = Me, *t*Bu, *cyclo*-C_6H_{11}, Ph

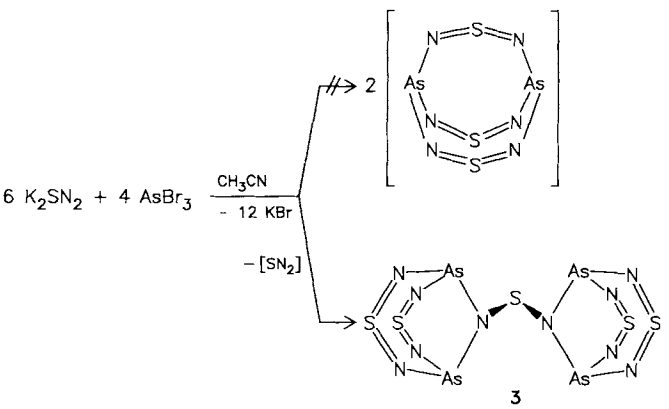


$2\ K_2SN_2 + 2\ RAsCl_2 \xrightarrow[-\ 4\ KCl]{CH_3CN}$ **2**

R = *t*Bu

Surprisingly, the corresponding reaction of K_2SN_2 with arsenic halides AsX_3 (X = Cl, Br, I) does not lead to the expected cage compound $As(NSN)_3As$, even though the analogous silicon compound, $MeSi(NSN)_3SiMe$,[5] is known. Instead, **3** is formed preferentially in the course of a redox reaction.

Starting from $AsBr_3$, compound **3** is obtained in about 40% yield as red, moderately air-stable crystals, which are poorly soluble in hydrocarbons and diethyl ether, moderately soluble in acetonitrile, and very soluble in dichloro-



$6\ K_2SN_2 + 4\ AsBr_3 \xrightarrow[-\ 12\ KBr]{CH_3CN}$ // → 2 [ ] ; $-[SN_2]$ → **3**

methane. In the mass spectrum, the peaks for the molecular ion $As_4S_5N_{10}^{\oplus\oplus}$ (m/z 600) and for $As_2SN_3^{\oplus}$ (m/z 224) are very intense. In the IR spectrum, the two bands at 1143/1119 (vs) can be tentatively assigned to the ν_{as}(NSN) stretching mode, and the bands at 1069/1039 (s) to the ν_s(NSN) stretching mode of the sulfur diimide units in the bicyclic moieties.

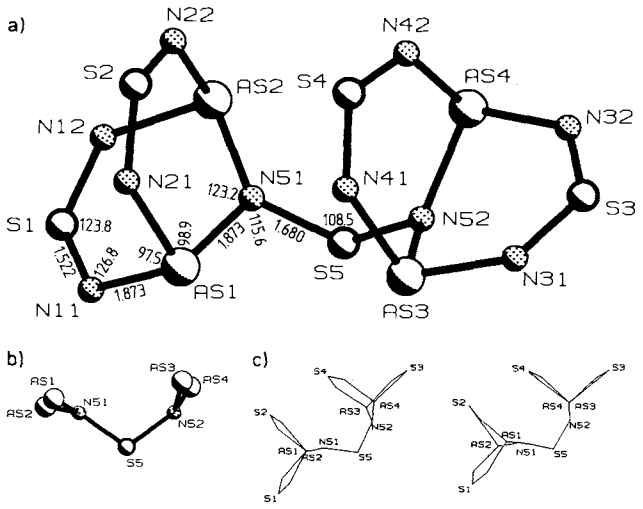

Fig. 1. Crystal structure of **3**. a) Bond lengths [Å] and angles [°] averaged over *mm*2 symmetry. b) Diaminosulfane moiety projected onto N-S-N. c) Projections in the directions As1-As2 and As3-As4.

The structure of **3** (Fig. 1) was determined by X-ray structure analysis of $3 \cdot 0.5CH_2Cl_2$.[7] A diaminosulfane derivative is found in which two bicyclic [$As_2S_2N_5$] units are coupled through a sulfur atom. In both the entire molecule and the two cages, the highest possible symmetry *mm*2 is reduced to 2. However, even this symmetry is not strictly imposed. The structure of the As(NSN)$_2$As eight-membered rings is comparable to that in compounds of the type **2**[2,4] and in $[Os_3(CO)_{10}\{\mu\text{-}(t\text{Bu})As(NSN)_2As(t\text{Bu})\}]$.[8] The N=S=N groups have the geometry characteristic of sulfur diimides[9] (S=N bonds: 1.522 Å) and are nearly coplanar with the directly bonded As atoms. The As···As distance (3.295 Å) in **3** is significantly smaller than that in comparable compounds[2,4,8] and even shorter than that in **1** (R = Ph) (3.379 Å).[2] The shorter As···As distance is accompanied by a reduction of the As-N=S, N-As-N, and N=S=N angles in the eight-membered rings. The diaminosulfane moiety $As_2N-S-NAs_2$ has the geometry[10,11] characteristic of this structural unit with the lone pairs of electrons on the N atoms in the N-S-N plane; the N atoms are situated 0.16(2) Å (N51) and 0.32(3) Å (N52) outside of the plane of their three binding partners ("transoid arrangement of electron pairs"[10]); the S-N bonds (1.680 Å) are somewhat shorter than a S-N single bond.

Experimental Procedure

A suspension of K_2SN_2 (0.58 g, 4.2 mmol) [6] in acetonitrile (100 mL) was allowed to react at −40°C with a solution of $AsBr_3$ (0.88 g, 2.8 mmol) in ether (20 mL). After thawing, the orange-brown mixture was stirred for 2 h, filtered through Na_2SO_4 (anhydrous), concentrated to half of the original volume, and cooled to −30°C. The crude product **3** separated out as an orange-red powder (0.17 g, 40%), which can be recrystallized from CH_2Cl_2 or ether/CH_2Cl_2 (5/1). Red crystals ($3 \cdot 0.5CH_2Cl_2$), dec. above 138°C. IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1143 (vs), 1119 (vs), 1069 (s), 1039 (s), 1027 (vs), 966 (w), 912 (w), 805 (w), 722 (w), 662 (s), 632 (m), 590 (s), 495 (vs), 470 (sh), 457 (s), 410 (s), 391 (w).

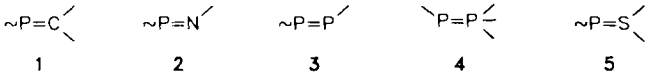
Imino-, Phosphoranylidene-, and Sulfuranylidenephosphanes by 1,3-Silyl Migration**

By *Frank Zurmühlen* and *Manfred Regitz**

Compounds containing λ^3 phosphorus with coordination number 2, such as methylenephosphanes ("phosphaalkenes") **1**,[1,2] iminophosphanes **2**,[3] and phosphanylidenephosphanes ("diphosphenes") **3**,[4] play an important role in current developments in phosphorus chemistry. We describe here the preparation of low-coordinate phosphorus compounds of types **2**, **4**, and **5** from silylated phosphides and acid chlorides, the P/X double bond being introduced by 1,3-silyl migration.[5]



1 **2** **3** **4** **5**

Iminophosphanes **2** are known[3] (albeit without the =NOR structural unit); phosphoranylidenephosphanes **4** are largely uninvestigated;[6] sulfuranylidenephosphanes were up to now completely unknown.

The reaction of nitrosyl chloride **7a** with the lithium phosphide **6a**[7] in pentane at −50°C affords, after distillative workup (200°C, kugelrohr) the thermally extremely stable iminophosphane **9a**; the conceivable dimerization

[a] At 20°C, unless otherwise given. [b] C_6D_6, 85% H_3PO_4 (ext.). [c] $CDCl_3$, TMS (int.). [d] Decomposition. [e] Sequence λ^5,λ^3-phosphorus. [f] See formula.

does not occur for steric reasons. The corresponding reactions of phosphinic chlorides **7b**, **c** with **6b**[8] and of sulfinic chlorides **7d**, **e** with **6b**[8] and **6c**[9] afford the phosphoranylidene and sulfuranylidenephosphanes **9b**, **c** and **9d–g**, respectively.[10] Except for the oil **9d**, all these compounds are crystalline and sensitive to moisture; in addition, **9b**, **c** are thermally labile. The silyl migration **8** → **9** is apparently so fast that **8** cannot be detected by ^{31}P-NMR spectroscopy.

The elemental analyses and the ^{31}P-NMR spectroscopic data support the constitution of the two-coordinate phosphanes and exclude the possibility of isomers of type **8**. Moreover, in no case is the splitting of the silyl methyl signals by the phosphorus, which is expected for **8**, observed.

The strongly low-field shifted ^{31}P-NMR resonance of **9a** (Table 1) is characteristic of iminophosphanes.[11] In the case of **9b**, **c**, the λ^3 phosphorus appears at remarkably high field (Table 1), which points to the ylide character of this compound. The $^{1}J_{P,P}$ coupling constants are 429 and 433 Hz, respectively.[12] For **9d–g**, two phosphorus resonances having different intensities but relatively large chemical shifts were found in each case (Table 1); this can be ascribed to the presence of *E*/*Z* isomers. The same distribution of isomers is also revealed by ^{1}H-NMR spectroscopy (silyl methyl signals).[13] The positions of the ^{31}P-NMR resonances are in good agreement with those of methylenephosphanes having similar patterns of substitution.[1]

Experimental Procedure

9f: A 1.45 M solution of methyllithium in ether (15 mL) was added at 20°C to a solution of the phosphane **6c** (5.8 g, 21.8 mmol) (H instead of Li) [9] in diethyl ether (20 mL) and the reaction solution was evaporated to dryness. The residue was dissolved in pentane (50 mL) and the resulting suspension added to a solution of **7e** (4.4 g, 21.8 mmol) in pentane (50 mL). After 12 h, the lithium chloride was removed by centrifugation, the solution was evaporated, and the residue was distilled at 160–170°C (oven temperature)/10^{-3} torr in a kugelrohr apparatus. Yield 5.8 g (68%) colorless oil, which crystallizes from pentane at −76°C. M.p. = 88°C.

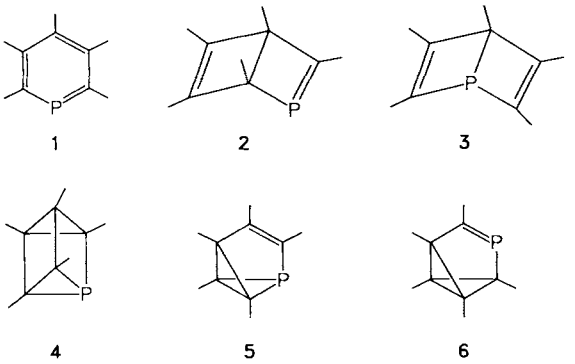
Isomerization Reactions in the System Dewar-Phosphinine/Phosphaprismane/ Phosphabenzvalene/Phosphinine**

By *Karsten Blatter, Wolfgang Rösch, Uwe-Josef Vogelbacher, Jürgen Fink,* and *Manfred Regitz**

Of the classical valence isomers of the phosphinines **1**, only the 2-Dewar-phosphinines **2** have been described to date.[1] Starting from these compounds, we have now synthesized the 1-Dewar-phosphinines **3**, the phosphaprismanes **4**, and the phosphabenzvalenes **5** having a $\lambda^3\sigma^3$ phosphorus. The isomers **6**, with two-coordinate phosphorus, still remain unknown.



Heating of the 2-Dewar-phosphinine **7** for four days in the absence of solvent at 160 °C and subsequent workup of the crude product by kugelrohr distillation (165 °C/10^{-3} torr) followed by chromatography[2] gave the 1-Dewar-phosphinine **9** (m.p. = 39 °C; colorless crystals; yield 44%). The change in the coordination of the phosphorus upon the isomerization **7** → **9** is accompanied by a strong high-field shift of the ^{31}P resonance (Table 1). Furthermore, in contrast to **7**, the bicyclic compound **9** shows four olefinic carbon atoms in the ^{13}C-NMR spectrum (Table 1).

It is logical to postulate the existence of the phosphinine **8** as the intermediate in the Dewar-phosphinine/Dewar-phosphinine rearrangement **7** → **9**.[3] Indeed, the phosphinine **8** (for preparation from **13** and structure, see below) produced photochemically from **9** ($\lambda \geq 280$ nm, $CDCl_3$) can undergo reverse isomerization under authentic, thermal conditions.

Irradiation of the bicyclic compound **7** for 4 h at −40 °C[4] results in relatively fast intramolecular [2 + 2] cycloaddition to form, as the main product, the phosphaprismane **10** (m.p. = 71 °C; colorless crystals; yield 40%); in addition, the phosphinine **8** and the phosphabenzvalene **14** (each 10%) are formed. The NMR data of **10** confirm its tetracyclic structure (Table 1): no signals are found in

Table 1. ^{1}H- [a], ^{13}C- [b], and ^{31}P-NMR data [c] for the phosphinine **8** and for the valence isomers **9**, **10**, **13**, and **14** as well as the derivative **15**.

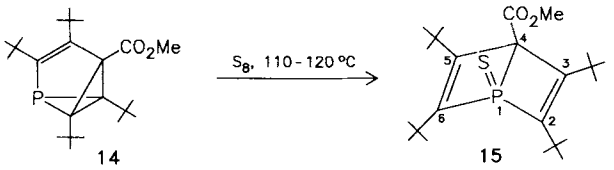
[**] Phosphorus Compounds with Unusual Coordination, Part 16. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. — Part 15: M. Regitz, W. Rösch, T. Allspach, U. Annen, K. Blatter, J. Fink, M. Hermesdorf, H. Heydt, U. Vogelbacher, O. Wagner, *Phosphorus Sulfur*, in press.

the region of olefinic carbon atoms and the phosphorus resonance exhibits the expected diamagnetic shift ($\delta = -130.2$) relative to **7** ($\delta = 314.8$).

The mixture of products formed under the same conditions upon "prolonged" photolysis (13 h)[4] of **7** demonstrates that the two isomers **8** and **14** are the photochemical secondary products of the phosphaprismane **10**, which is the primary product formed upon irradiation of **7**. Chromatographic separation of the products affords only **8** (m.p. = 71 °C; yellow crystals) and **14** (m.p. = 76 °C; colorless crystals; ratio ≈ 1 : 1). Observation of this reaction by ^{31}P-NMR spectroscopy reveals that, in the photolysis solution maintained at −40 °C, only **14** ($\delta = -83.3$) and apparently another phosphabenzvalene **13** ($\delta = -89.8$) are present, but no **8**. Upon workup (20 °C), the isomer **13** is transformed thermally into the phosphinine **8**. A clear picture of the reaction is afforded by irradiation of **8** at −40 °C,[4] which gives only **13** (^{31}P-NMR); upon thawing of the solution, the heteroaromatic compound **8** is formed once again.

The formation of the phosphabenzvalenes **13** and **14** from **10** can be explained as follows: either the C-2/C-3 and the C-4/C-5 bonds (→ **11**) or the C-5/C-6 and C-4/C-3 bonds (→ **12**) are broken and the diradicals thus formed lead to product formation [**11** → **13** (→ **8**) and **12** → **14**].

The constitution of the phosphabenzvalenes is in accord with their NMR spectra (Table 1). An X-ray crystal structure analysis was carried out for the phosphinine **8**; it reveals a twisted boat form, which is due to steric factors; the atoms C-2 and C-5 correspond to the "stern" and the "bow," respectively. The angles formed with the idealized plane of the base are 17.9° (twisting around the P1/C3 axis) and 33.7° (twisting around the C4/C6 axis). To the best of our knowledge, this is the largest deviation of an aromatic or heteroaromatic ring from planarity observed so far.[5]



Finally, heating of the phosphabenzvalene **14** with sulfur in the absence of solvent (12 h, 110–120 °C) results in formation of the 1-Dewar-phosphinine sulfide **15** (m.p. = 107 °C, colorless crystals, yield 65%). The ^{1}H- and ^{13}C-NMR spectra reveal the consequences of the resulting C_s symmetry (Table 1). The chemical shift of the phosphorus ($\delta = 39.3$) corresponds to that found for 1-methyl-1-phosphacyclohexane 1-sulfide ($\delta = 33.9$).[6] Furthermore, a crystal structure analysis of **15** is available.[7]

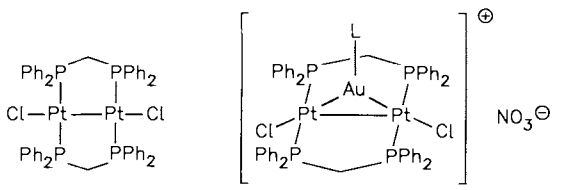
New $AuPt_2$ A-Frame Cluster Complexes**

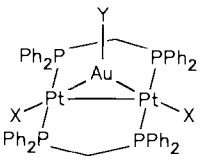
By *Gilles J. Arsenault, Ljubica Manojlović-Muir,* Kenneth W. Muir, Richard J. Puddephatt,** and *Ilse Treurnicht*

The chemistry of the metal-metal bond in diplatinum(I) complexes such as **1** and in analogous gold(II) complexes has been developed rapidly, and many fundamental reaction pathways of binuclear complexes have been found.[1,2] Although many unsaturated and electrophilic reagents add to the metal-metal bond of **1**, no direct additions of electrophilic metal fragments to form cluster complexes have been found.[3] For example, whereas "CH_2," from CH_2N_2, adds to the metal-metal bond of **1**, the isolobal $SnCl_2$ inserts into a Pt-Cl bond instead.[4,5] We report here that electrophilic gold fragments, AuX or $AuPPh_3^{\oplus}$, add to the Pt-Pt bond of **1** whereas similar copper or silver fragments do not.



1

2a, L = PPh_3
2b, L = $Ph_2PCH_2PPh_2AuCl$
2c, L = $Ph_2P(CH_2)_2PPh_2AuCl$



3a, X = Y = Cl
3b, X = Y = C≡C*t*Bu
3c, X = C≡C*t*Bu, Y = Cl
3d, X = C≡C*t*Bu, Y = I

Reaction of **1** with $[Au(NO_3)(PPh_3)]$ or $[AuCl(SMe_2)]$ gave the cationic **2a** or neutral **3a**, respectively, in nearly quantitative yields. They have NMR spectra typical of A-frame complexes.[4,6] The complex **3b**,[6] prepared by reaction of $[Pt_2(\mu\text{-dppm})_3]$[7] (dppm = $Ph_2PCH_2PPh_2$) with

$AuC{\equiv}CtBu$,[8] reacted with CH_2Cl_2 to give **3c**. Complex **3c** reacted with NaI to give **3d**,[6] whose structure was determined crystallographically (Fig. 1).[9]

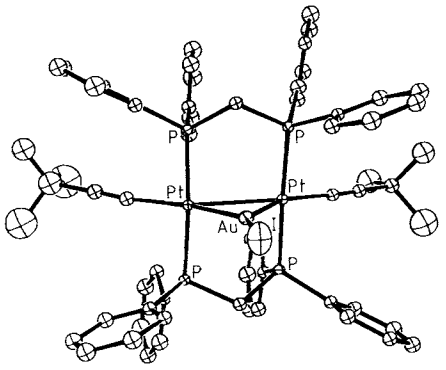

Fig. 1. The molecular structure of **3d**, with carbon atoms not labeled and the atomic thermal ellipsoids displaying 20% probability. Selected bond lengths [Å] and angles [°] are: Au-I 2.580(2), Pt-P 2.274(5)–2.289(6), Pt-C 2.01(3), 2.02(3); Pt-Au-Pt 64.5(1), Au-Pt-C 151.0(7), 151.7(6), Pt-C-C 172(2), 177(2). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (U.K.), upon quoting the names of the authors and the journal citation.

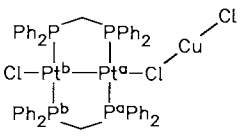
In contrast to the ease of formation of Pt_2Au clusters as described above, it has not yet been possible to prepare derivatives of silver or copper. Thus, reaction of **1** with $[M(NO_3)(PPh_3)]$, M = Cu or Ag, gave **4** and MCl (replacement of $Cl^{\ominus}$ by PPh_3). Similarly, reaction of **1** with one or two equivalents of $[Cu(MeCN)_4]^{\oplus}$ gave **5a** or **5b**, respectively, and CuCl. Reaction of **1** with excess CuCl gave a 1 : 1 adduct; however, it was not an A-frame complex but was tentatively assigned the unusual structure **6**, involving the addition of CuCl to a chloride ligand of **1**. Complex **6** was fluxional in solution, and solutions slowly deposited CuCl. A useful citerion of structure of **6** was the low-tem-

$[Pt_2Cl(PPh_3)(\mu\text{-dppm})_2](NO_3)$ **4**
$[Pt_2Cl(MeCN)(\mu\text{-dppm})_2]^{\oplus}$ **5a**
$[Pt_2(MeCN)_2(\mu\text{-dppm})_2]^{2\oplus}$ **5b**



6

perature ^{195}Pt-NMR spectrum,[6] which gave two signals due to nonequivalent Pt atoms, and the coupling constant ^1J(PtPt) (10334 Hz), which was greater than in the parent **1** (8145 Hz[10]); the A-frame clusters have lower ^1J(PtPt) values: 6980 ± 50 Hz and 6200 ± 100 Hz for complexes **2a** and **3a**, respectively.

Some digold reagents gave behavior of both gold and copper/silver reagents. Thus reaction of **7**, n = 1 or 2, with two equivalents of **1** gave **2b** or **2c** respectively, and $[Pt_2Cl(NO_3)(\mu\text{-dppm})_2]$. The first gold atom adds to the Pt–Pt bond of **1**, while the second gold abstracts chloride from the second molecule of **1**. We believe that steric hindrance prevents the expected formation of bridged bis(A-frame) complexes in these cases.

$[(NO_3)Au(\mu\text{-}Ph_2P(CH_2)_nPPh_2)Au(NO_3)]$ **7**

The structure of **3d** (Fig. 1) shows that the AuI fragment symmetrically bridges the Pt_2 unit to form a triangular Pt_2Au cluster. The PtAu [2.656(2) and 2.661(2) Å] and PtPt [2.837(1) Å] separations are all indicative of bonding interactions. The clusters **2** and **3** are therefore considered to contain a 3-center-2-electron Pt_2Au group, in which the platinum and gold atoms have 16e and 14e configurations, respectively. These complexes are the first examples of 42e Pt_2Au clusters. The only other known trinuclear Pt–Au cluster is the 40e cluster complex **8**.[11]

$[PtCl(PEt_3)_2(AuPPh_3)_2]^{\oplus}$ **8**

Within the coinage metals, it is clear that gold has by far the greatest ability to form heteronuclear PtM (M = Cu, Ag, Au) bonds.

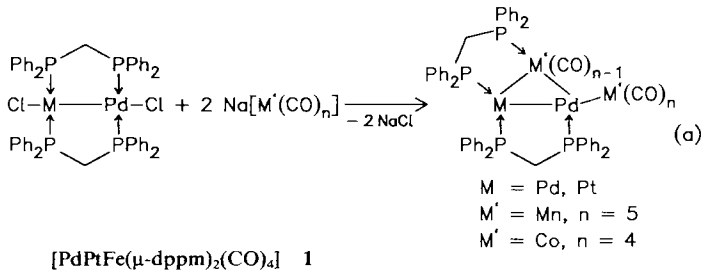
Mixed-Metal Cluster Formation by Carbonylmetalate-Induced Pt–P Bond Cleavage in $[PtCl_2(Ph_2PCH_2PPh_2]$**

By *Pierre Braunstein,* Nicolas Guarino, Claude de Méric de Bellefon,* and *Jean-Luc Richert*

The synthesis and structural characterization of the first mixed-metal clusters containing the $Ph_2PCH_2PPh_2$ (dppm) ligand [Eq. (a)][1] showed that the mobility of this ligand, i.e., the lability of the Pd–P bond, is greater than expected from previous studies carried out on $Pd(\mu\text{-dppm})_2Pd$ systems.[2] In the case of $Pd(\mu\text{-dppm})_2Pt$ systems, we found that regioselective insertion of the metal carbonyl fragment takes place into the Pd–P bond,[3] although evidence for Pt–P lability could also be found in the isomerization of **1**.[4] The $Pd(\mu\text{-dppm})_2Pt$ system is usually rigid,[5] with only few exceptions.[6]



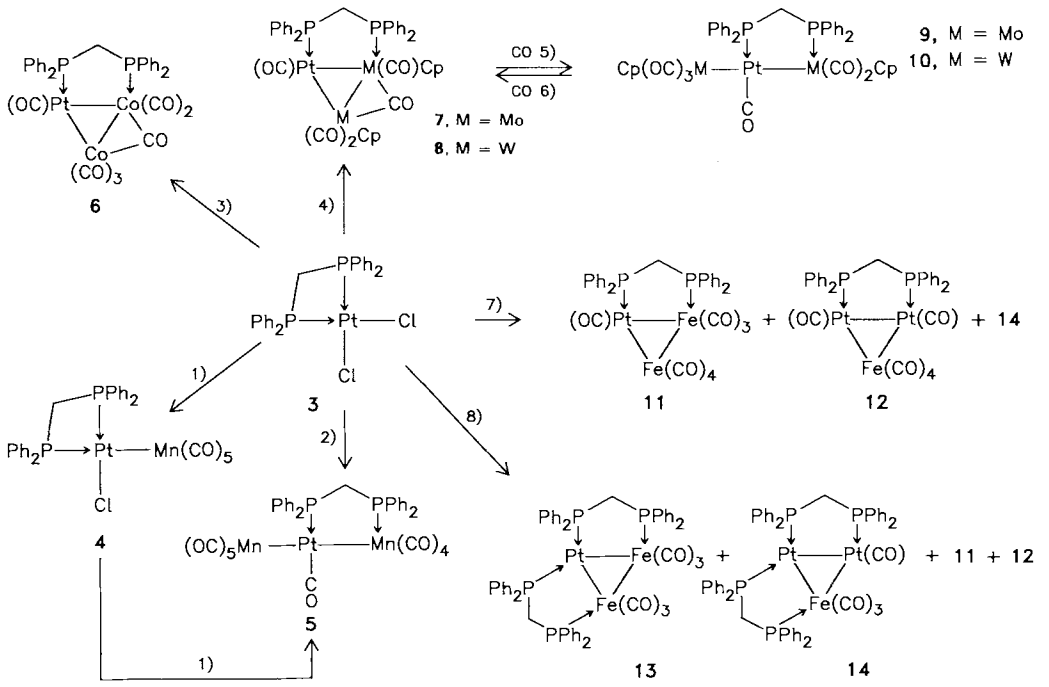
(a)

[PdPtFe(μ-dppm)$_2$(CO)$_4$] **1**
trans-[Pt{Mn(CO)$_5$}$_2$(CO)$_2$] **2**
[PtCl$_2$(Ph$_2$PCH$_2$PPh$_2$)] **3**

We thought that reaction (a) could perhaps be extended to simple mononuclear complexes, such as **3**, containing a chelating dppm whose opening could result in new dppm-bridged mixed-metal clusters (Scheme 1). The features that all reactions of Scheme 1 have in common are the formation of one or more Pt–M bonds and the retention of at least one Pt–P bond. The differences observed in either the nature or the reactivity of the new complexes depend on the nature of the carbonylmetalate anion.

The complex **4** results from the replacement of only one chloride ligand in **3** by $[Mn(CO)_5]^{\ominus}$ (reaction 1) and represents a rare example of a heterobimetallic complex containing a chelating dppm ligand.[7] **4** reacts further with a second equivalent of $[Mn(CO)_5]^{\ominus}$, affording the trinuclear complex **5**. This suggests that **4** could be an intermediate in the direct synthesis of **5** from **3** (reaction 2). The crystal structure of the linear trinuclear complex **2**, which is related to **5**, has been previously determined.[8]

Reaction of **3** with two equivalents of $[Co(CO)_4]^{\ominus}$ (reaction 3) or of $[M(CO)_3Cp]^{\ominus}$ (M = Mo, W; Cp = η^5-C_5H_5) (reaction 4) results in formation of the heterotrinuclear clusters **6** or of **7** (M = Mo) and **8** (M = W), respectively. In these cases, no intermediate species corresponding to **4** could be detected when only one equivalent of these anions was used: the clusters **6**, **7**, and **8** were the only products isolated, along with 50% of the starting material **3**. Clusters **7** and **8** reversibly add CO under ambient conditions with selective opening of the M–M bond, affording **9** and **10**, respectively (reactions 5, 6). The more strongly Mn-bound



Scheme 1. 1) 1 equivalent Na[Mn(CO)$_5$], tetrahydrofuran (THF), 20°C, 3 h. 2) 2 equivalents Na[Mn(CO)$_5$], THF, 20°C, 3 h. 3) 2 equivalents Na[Co(CO)$_4$], THF, in 1 h from 0 to 20°C, then 3 h at 40°C. 4) 2 equivalents Na[M(CO)$_3$Cp]·2DME (dimethoxyethane), THF, 50°C, 4 h. 5) 1 atm CO, THF, 0.1 h. 6) Dry at 20°C in vacuum. 7) 10 equivalents [Fe$_2$(CO)$_9$], THF, 20°C, 12 h. 8) 1 equivalent Na$_2$[Fe$_2$(CO)$_8$], THF, 0–20°C, 5 h.

carbonyls do not allow a reversible CO elimination to occur with **5**. The transoid M–Pt–M arrangement in **5**, **9**, and **10** is suggested by the ^1J(PtP) values (not consistent with a phosphorus *trans* to a M–Pt bond[7d]) and by steric considerations.

The selectivity of formation of the iron–platinum clusters was found to depend on the iron carbonyl reagent.

[**] We thank Atochem for a grant to *J.-L. R.*, the CNRS for financial support (ATP Chimie Fine 4384), and Johnson-Matthey Co. Ltd. for a generous loan of $PtCl_2$.

Thus, with $[Fe_2(CO)_9]$ (reaction 7), a known dehalogenating reagent, the new clusters **11** and **12** and the known **14**[6c] were formed and could be separated by column chromatography. With $Na_2[Fe_2(CO)_8]$ (reaction 8), the new cluster **13** was isolated, together with the clusters **11**, **12**, and **14** (30% yield). The complex redox reactions encountered particularly in the Pt–Fe systems involve ligand migrations that occur under very mild conditions. Thus, CO migration from M to Pt occurs during the synthesis of **5**–**8**, **11**, and **12**, while one of the phosphorus atoms of the chelated dppm becomes attached to M or to a second Pt atom in **5**–**8** and **11**–**14**. In the case of **13**, moreover, complete transfer of a dppm ligand has occurred since this cluster contains two dppm ligands but only one Pt atom.

These types of mixed-metal clusters are of particular interest because of the dppm-assisted metal–metal bond formation and the recent use of the palladium analogue of **14** as a precursor for a heterogeneous carbonylation catalyst which selectively transforms *o*-nitrophenol into benzoxazol-2-one.[4] The reactions reported here involve the opening of a P–M bond of a chelating dppm ligand, which is also observed with other reagents.[6, 7c, 9] The products **5**–**14** contain at least one Pt(μ-dppm)M five-membered ring, which is more stable than the Pt(η^2-dppm) four-membered ring in **3** and **4**. The general applicability of this method, which employs readily available precursors, is being further evaluated.

Experimental Procedure and Spectroscopic Data

All new compounds isolated gave satisfactory elemental analyses. The ^{1}H-, ^{31}P{^{1}H}-, and ^{195}Pt{^{1}H}-NMR spectra were recorded on an FT-Bruker WP 200 SY spectrometer at 200.13, 81.02, and 42.95 MHz, respectively. TMS, 85% H_3PO_4 in H_2O, and 0.3 M $K_2[PtCl_4]$ in D_2O were used as standards.

4: 65% yield after recrystallization from THF/hexane at 20°C.—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 2056 (vs), 1976 (s, br), 1954 (vs, br), 1933 (vs, br).—^{31}P{^{1}H} (THF/C_6D_6): $\delta = -36.2$ (d with Pt satellites, ^2J(PP) = 60, ^1J(PtP) = 2241 Hz, 1 P; P *trans* to Mn), −47.4 (d with Pt satellites, ^2J(PP) = 60, ^1J(PtP) = 3364 Hz, 1 P; P *trans* to Cl).

5 (from reaction 2): 90% yield after recrystallization from THF/hexane at −30°C.—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 2073 (m), 2022 (s), 1996 (m), 1966 (s, br), 1923 (m, br).—^{1}H ($CDCl_3$): $\delta = 4.28$ (t with Pt satellites, ^2J(PH) = 10.3, ^3J(PtH) = 50.8 Hz, 2 H; CH_2).—^{31}P{^{1}H} (THF/C_6D_6): $\delta = 57.5$ quadrupole-broadened signal, not resolved, 1 P; MnP), 19.3 (d with Pt satellites, J(PP) = 79, ^1J(PtP) = 3515 Hz, 1 P; PtP).

6: 81% yield after recrystallization from THF/pentane at −30°C.—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 2052 (vs), 2017 (vs), 1995 (s, br), 1988 (s, br), 1757 (m, br).—^{1}H ($CDCl_3$): $\delta = 4.63$ (t with Pt satellites, J(PH) = 10.7, ^3J(PtH) = 48.0 Hz, 2 H; CH_2).—^{31}P{^{1}H} ($CDCl_3$): $\delta = 22.2$ (quadrupole-broadened signal, not resolved, 1 P; CoP), −1.5 (d with Pt satellites, ^2J(PP) = 26, ^1J(PtP) = 3295 Hz, 1 P; PtP).—^{195}Pt{^{1}H} ($CDCl_3$): $\delta = -2502$ (dd, ^1J(PtP) = 3294, ^2J(PtP) = 47 Hz).

7: 71% yield after recrystallization at −30°C.—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 1921 (s), 1901 (vs), 1849 (s), 1778 (s).—^{1}H ($CDCl_3$): $\delta = 5.32$ (s, 5 H; Cp), 5.24 (s, 5 H; Cp), 4.13 (t with Pt satellites, ^2J(PH) = 9.5, ^3J(PtH) = 55 Hz, 2 H; CH_2).—^{31}P{^{1}H} ($CDCl_3$): $\delta = 46.3$ (d with Pt satellites, J(PP) = 45, ^2J(PtP) = 118 Hz, 1 P; MoP), 27.3 (d with Pt satellites, J(PP) = 45, ^1J(PtP) = 4062 Hz, 1 P; PtP).

8: 47% yield after extraction with CH_2Cl_2/hexane = 1/1 and recrystallization from THF/Et_2O at −30°C.—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 1918 (s), 1895 (vs), 1838 (s), 1776 (s).—^{1}H ($CDCl_3$): $\delta = 5.41$ (s, 5 H; Cp), 5.27 (s, 5 H, Cp).—^{31}P{^{1}H} ($CDCl_3$): $\delta = 15.3$ (d with W and Pt satellites, J(PP) = 53, ^1J(WP) = 327, ^2J(PtP) = 114 Hz, 1 P; WP), 21.6 (d with Pt satellites, J(PP) = 53, ^1J(PtP) = 3936 Hz, 1 P; PtP).

9 and **10**: Characterized in solution only; spectroscopic yield 100%.—**9**: IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 1935 (s), 1899 (vs), 1832 (s).—^{31}P{^{1}H} ($C_6D_5CD_3$): $\delta = 42.8$ (d with Pt satellites, J(PP) = 71, ^2J(PtP) = 213 Hz, 1 P; MoP), 6.6 (d with Pt satellites, J(PP) = 71, ^1J(PtP) = 3445 Hz, 1 P; PtP).—**10**: IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 1932 (s), 1900 (vs), 1822 (s).

11 (from reaction 7): 65% yield after purification by column chromatography (silica gel, CH_2Cl_2/hexane = 35/100 v/v).—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 2054 (s), 2019 (s), 1979 (s, br), 1960 (s, br), 1930 (w, sh), 1908 (w).—^{1}H (C_3D_6O): $\delta = 5.12$ (dd with Pt satellites, $^2J(P_PH) = 12.0$, $^2J(P_{Fe}H) = 10.6$, J(PtH) = 45.1 Hz, 2 H; CH_2).—^{31}P{^{1}H} (THF/C_6D_6): $\delta = 53.9$ (d with Pt satellites, J(PP) = 49, ^2J(PtP) = 12 Hz, 1 P; FeP), 14.7 (d with Pt satellites, J(PP) = 49, ^1J(PtP) = 3151 Hz, 1 P; PtP).—MS (CI): m/z 915 ($M^{\oplus}$), successive loss of eight CO molecules. This cluster was also characterized by X-ray analysis: P. Braunstein et al., unpublished results.

12 (from reaction 8): 19% yield after purification by column chromatography (silica gel, CH_2Cl_2/hexane = 70/100 v/v).—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 2047 (s), 2018 (s), 1994 (s), 1942 (s), 1909 (s).—^{1}H (C_3D_6O): $\delta = 6.14$ (t with Pt satellites, ^2J(PH) = 11.5, ^3J(PtH) = 68.0 Hz, 2 H; CH_2).—^{31}P{^{1}H} (THF/C_6D_6): $\delta = -2.4$ (s with Pt satellites, ^1J(PtP) = 3187, ^2J(PtP) = −74, ^1J(PtPt) = 1373, J(PP) = 30 Hz; the parameters were determined using the spin simulation program PANIC (Bruker).—MS (CI): m/z 998 ($M^{\oplus}$), successive loss of six CO molecules. This cluster was also characterized by X-ray analysis: P. Braunstein et al., unpublished results.

13 (from reaction 8): 1% yield after purification by column chromatography (silica gel, CH_2Cl_2/hexane = 70/100 v/v).—IR (THF): $\tilde{\nu}$(CO) [cm^{-1}] = 1991 (s, br), 1941 (s, br), 1928 (s, br), 1858 (w, br).—^{1}H (C_3D_6O): $\delta = 4.28$ (t with Pt satellites, ^2J(PH) = 9.7, ^3J(PtH) = 37.8 Hz, 2 H; CH_2).—^{31}P{^{1}H} (THF/C_6D_6): $\delta = 56.6$ (m, 2 P; FeP), 21.7 (m with Pt satellites, ^1J(PtP) = 3250 Hz, 2 P; PtP).—MS (FD): m/z 1215 ($M^{\oplus} - CO$), 1075 ($M^{\oplus} - 6CO$).

The Poisonous Cloud, Chemical Warfare in the First World War. By *L. F. Haber*. Clarendon Press, Oxford 1986. xiv, 415 pp., hardcover, £ 35.00.—ISBN 0-19-858142-4

The cloud of poisonous gas that settled over the British and French trenches at Ypres on 23 April 1915 was considered by some people to mark a turning point in the technological conduct of war and by most people as an act of barbarism and a violation of the Hague Convention. *Fritz Haber* (1886–1934), the German chemist and Nobel laureate (for the "synthesis of ammonia from air"), is generally regarded, and probably rightfully so, as the inventor of gas warfare. Since then, an immense amount of writing has been devoted to this topic from a variety of standpoints: neutral and purely technological, nationalistic and glorifying, humanistic and condemnatory, hateful and damning. The most recent work is a monograph by *L. F. Haber*.

Who is *L. F. Haber*? He is the son of *Fritz Haber*, Reader in Economics at the University of Surrey, and a prominent scholar of the history of industrial chemistry. We do not wish to ask why *L. F. Haber* has written this book. Beyond doubt, however, he has presented us with a superb, exceedingly objective work, based in part on new sources of information.

After a personal and historical introduction, the events surrounding the first chlorine gas attack at Ypres are described. In the following chapters, the author shows how reaction and counterreaction led to an escalation of chemical warfare on both sides and how chemical warfare underwent technological development without, however, becoming a decisive factor in the First World War. The threat posed by this new weapon was greatly overestimated by both sides, in part because of the ignorance of the general public and the helplessness of the military in coming to terms with technological and scientific matters. The sources of information are excellently documented. Both the author's personal knowledge of the subject matter and the collaboration of *Fritz Haber*'s English counterpart, the chemist Sir *Harold Hartley*, proved very useful in this respect. The two scientists met in 1921 after *Fritz Haber* had been awarded the Nobel prize and subsequently developed a relationship verging on friendship. With *Hartley*'s support, *Fritz Haber* was offered a laboratory at the Chemical Institute in Cambridge after he was forced to leave Germany in 1933. *L. F. Haber* presumably met *Hartley* through his father.

A few words need to be said about the "prostitution of science" for the purpose of gas warfare. It is nearly impossible for us, in 1987, to morally judge the way researchers thought and acted in 1914. In any case, the prostitution did not involve money. We Germans today, morally drained by the period of National Socialist rule and grown lazy by current prosperity, are hardly capable of imagining what national spirit and patriotism meant at that time. It is even harder for a younger generation in Germany to grasp that Jewish Germans were then involved in military research for their beloved mother country. In this connection, the biography of the mathematician *Richard Courant* (1888–1972), who worked in Göttingen and was also forced to leave Germany in 1933, is of particular interest (Constance Reid: *Richard Courant - Der Mathematiker als Zeitgenosse*, Springer, Heidelberg 1979). During the First World War, *Courant* invented the "ground telegraph," which was clearly a less inhuman discovery, if war inventions can be measured at all in such terms. In *Haber*'s book, we encounter such names as *Herbert B. Baker, J. B. Conant, Karl Duisberg, James Franck, Herbert Freundlich, Fritz Haber, Otto Hahn, Sir Harold Hartley, Walter Nernst*, Sir *William Pope*, and *J. F. Thorpe*, and even the famous correspondence between *Fritz Haber* and *Hermann Staudinger* is mentioned. "Staudinger replied placatingly, and his dignified pacifism contrasts sharply with *Haber*'s intemperate self-justification. The correspondence ended inconclusively but it showed that the Chemical Warfare controversy cut across professional lines." Such personal remarks, however, occur only seldomly in the book. Overall, the book presents an exact technological and historical account of gas warfare in 1914–1918.

Little mention is made of why chemical warfare did not take place during the Second World War. And completely unaddressed is the issue of the nerve gases stored at present in the arsenals of the superpowers, the effect of which would be to kill people like flies are killed with insect spray: shaking, vomiting, foaming at the mouth, while fully conscious—this is the vision of "Chemical Warfare" in the second half of the 20th century. Let us hope that the poisonous cloud remains history.

Frontiers in Bioinorganic Chemistry. By *A. V. Xavier*. VCH Verlagsgesellschaft, Weinheim 1986. xiii, 736 pp., bound, DM 185.00.—ISBN 3-527-26460-4

This book contains the texts of the papers presented by the invited speakers at the 2nd International Conference on Bioinorganic Chemistry, held in Portugal in April 1985. The 69 papers are contained in 12 chapters, with more than 700 pages. Owing to the interdisciplinary nature of bioinorganic chemistry, there is some degree of unavoidable overlapping between the papers, e.g. when iron–sulfur proteins are discussed from the standpoint of the kineticist or that of the spectroscopist.

Iron is the dominant transition metal in the living world, and for that reason it is not surprising that the lion's share of the contributions (more than a third) are concerned either directly or indirectly with that element. In addition to the permanent oxygen carrier hemoglobin (and myoglobin), which has recently been studied with particular regard to electron transfer reactions between the heme group and a redox-active metal (ruthenium, iron or copper) at the protein surface, much attention is also given to progress in understanding the action of hemerythrin, the second most important oxygen carrier after hemoglobin. Other iron-related topics treated here are the transport and storage of iron, and cytochromes.

The emphasis on iron in this book does, however, reflect to some extent a difficulty that besets research in bioinorganic chemistry, namely that elements whose electronic, optical, or other properties are favorable for spectroscopic measurements receive more intensive study than those which are more difficult to observe. For example, zinc, which is the second most abundant transition metal in nature, is treated in only one paper.

Topics concerned with the biochemistry of nickel (methanogenic bacteria, toxicity, carcinogenicity) form a sec-

ond major theme. Other contributions are concerned with molybdenum, with trace elements in general, with biominerals, and with environmental aspects (with regard to Ni, Al, As, and Pu). Quite a long chapter is devoted to the use of spectroscopic methods in bioinorganic chemistry.

The chapter entitled "Nucleic Acid-Metal Ion Interactions" contains two excellent contributions on the reactions of metals with nucleosides and nucleotides and on the structure and stability of metal-nucleotide complexes. However, there is also a regrettably much too short "abstract" on the very interesting topic of the role of metals in the replication and transcription of nucleic acids and their translation into proteins, which also contains too few references.

A further chapter is headed "Metals in Medicine". The choice of topics here does not seem entirely a happy one. There are two good contributions on the nature and treatment of metabolic disturbances caused by zinc, and on the use of gold compounds in arthritis therapy, but also one on the development of a pharmaceutical product from the initial idea to its application, which seems out of place, having no obvious connection with bioinorganic chemistry. One looks in vain here for a paper reporting on new developments in the area of platinum cytostatics, which seems a bad omission in view of the current importance of this class of compounds in the treatment of various cancers.

Apart, however, from these few criticisms, "Frontiers in Bioinorganic Chemistry" succeeds well as a presentation of the current situation in this field.

Plasma Polymerization. By *H. Yasuda*. Academic Press, New York 1985. x, 432 pp., bound, $ 62.00.—ISBN 0-12-768760-2

Plasma polymerization means the formation of polymeric substances from organic vapors in low temperature plasmas (i.e. electrical discharges in gases). The polymers are formed at pressures between 10^{-2} and 10 mbar and near-ambient temperatures, usually as thin films on glass, metal or polymer substrates. Although the effect has been known for many years (the earliest paper cited is that by *P. de Wilde*, published in 1874 in Ber. Dtsch. Chem. Ges.), its existence had not been much noticed up to about 1960. Attention was first drawn to this particular type of synthesis and its potential technical importance in a publication by *J. Goodman*. Since 1970 the American Chemical Society has held regular symposia on the topic, so contributing appreciably to the spreading of interest in the technique.

Plasma polymerization is an interdisciplinary topic, which is best approached from the background of thin-film technology in association with high-vacuum preparative techniques. The author begins with some introductory chapters which cover the fundamental basis of plasma polymerization, the kinetic theory of gases and the theory of plasmas, dealing with the ionization of molecules by electron impact, ion-molecule reactions, reactions of excited molecules, and also the effects of the accompanying UV radiation. This is followed by a summary of the kinetics of polymerization, with particular emphasis on polymerization by free radicals, ionic polymerization, and radiation-induced polymerization. While plasma polymerization has little in common with addition polymerization, it is closely related to radiation-induced polymerization; on the other hand, it is a particular type of vacuum polymerization.

It is not until Chapters 6 and 8 that the author comes to the central theme and the main part of the book, namely the reaction kinetics and mechanisms of plasma polymerization. To systematically describe the enormous variety of reactions, which is a consequence of the varied and multifunctional nature of the building blocks and the smallness of many of these, is a daunting task. The products are for the most part highly branched and cross-linked, and often differ from conventional polymers. The methods for analyzing them are also discussed here.

An intermediate chapter deals with the opposite process which accompanies plasma polymerization, whereby material is removed in the plasma (etching process), and with the deposition of material by sputtering which also occurs. This is followed by a detailed chapter on the experimental arrangements used, and the effects of the many experimental variables which critically influence the results obtained.

As a result of their molecular structures the polymers deposited often show unusual properties, which can give them some technological importance. In particular they show extremely strong adhesion to the support, and are highly resistant chemically. These and other characteristics, along with their electrical properties, especially their conductivities and dielectric constants, are the subject of the last two chapters of the book.

Eleven years have passed since the publication of the last monograph dealing with this topic (Hollahan and Bell: *Techniques and Applications of Plasma Chemistry*), and books such as that of *Baddour* and *Timmins*, and that of *McTaggart*, are already as old as 18 years. For this reason alone the publication of the present book is to be welcomed. It contains so many new results, in a concise and readable form, that it must be recommended for reading by specialists in the field. In interpreting experimental results the author has tended to disregard alternative explanations proposed by others; such a bias can be accepted in view of the author's competence.

Metalloproteins. Pt. 1: Metal Proteins with Redox Roles. Pt. 2: Metal Proteins with Non-Redox Roles. Edited by *P. Harrison*. VCH Verlagsgesellschaft, Weinheim 1985. Pt. 1: xi, 256 pp., bound, DM 138.00.—ISBN 3-527-26136-2; Pt. 2: xii, 339 pp., bound, DM 166.00.—ISBN 3-527-26137-0

Volumes 6 and 7 of the series *Topics in Molecular and Structural Biology* deal with the enormous progress that has occurred in inorganic biochemistry (also called bioinorganic chemistry) in the last twenty years. This is quite a demanding task, since the questions surrounding the role of metal ions in living organisms cross the conventional boundaries of research specialisms, and the multidisciplinary nature of the undertaking stretches the holistic point of view to its limits. There are already several series of progress reports in green, orange or blue covers, which for more than ten years have been presenting bioinorganic matters. Is this an opportune time to extend the range of colors? The editor *Pauline Harrison* and the publishers are to be congratulated on the idea of presenting the current

state of knowledge, in the form of twelve articles whose topics have all been treated previously in various monographs, such as that on cytochrome P-450 which was recently reviewed (*Angew. Chem. 98* (1986) 195; *Angew. Chem. Int. Ed. Engl. 25* (1986) 294). It is an advantage for both the already involved and the uncommitted reader to be able to absorb in a condensed form, and in comparatively few pages, twelve topical and representative pieces of work on which current ideas and activity in the bioinorganic field are based. Of course, the authors had to be selective in presenting examples rather than reviews of an encyclopedic nature.

Part 1 deals with proteins in which transition metal atoms are the functional centers. Recent results on blue copper proteins are discussed in the light of known structures *(Elinor T. Adman)*. Under the heading cytochrome C the main topics discussed by *C. Greenwood* are cytochrome C peroxidase, and nitrate reductase with the redox processes on which its action depends. Under iron-sulfur proteins *(A. J. Thomson)*, those treated as examples of this group are the aconitase and nickel-containing hydrogenases, the latter being especially topical as new territory. In the discussion of superoxide dismutases *(A. E. G. Cass)*, the emphasis is on reaction kinetics and mechanism. The camphor-5-exo-hydrolyase derived from *Pseudomonas putida* is discussed in a particularly instructive way in the chapter on the structure and chemistry of cytochrome P-450 *(R. I. Murray, M. T. Fisher, P. G. Debrunner, S. G. Sligar)*. Thanks are due to the well-known Sussex group *(D. J. Lowe, R. N. F. Thorneley, B. E. Smith)* for a short contribution on the virtually never-ending story of nitrogenase.

Part 2 is devoted to fragmentation, regulation, transport and storage phenomena in proteins. In the chapter *Metalloproteinases (T. Hofmann)*, the emphasis is on new structural data for carboxypeptidase A (bovine pancreas) and on microbial thermolysin. The abundance, structure, and function of troponin C and calmodulin are discussed from a comparative point of view *(R. J. A. Grand)*. *M. Forgac* and *G. Chin* give a concise account of the ($Na^{\oplus}$,$K^{\oplus}$)- and ($Ca^{2\oplus}$)-ATP-ases, whose structural geometries have not yet been clarified. In the sections on metallothioneins *(P. E. Hunziger, J. H. R. Kägi)*, transferrins *(J. H. Brook)* and oxygen-carrying proteins *(M. Brunori, M. Coletta, B. Giardina)*, the material has been summarized very successfully from a learning standpoint, as the presentation is easy to read, explicit, and not spoiled by too great an urge to show the authors' detailed knowledge of the literature.

This bold undertaking deserves one's goodwill. It might also effect a "metal catalyzed reaction" in promoting a greater appreciation of the art of good presentation!

Hopping Conduction in Solids. By *H. Böttger* and *V. V. Bryksin*. VCH Verlagsgesellschaft, Weinheim 1985. 398 pp., bound, DM 140.00.—ISBN 3-527-26451-5

The subject matter of the book is undergoing an explosive growth, as is well-documented by some thousand references, of which around 400 are from the period 1983–1985. The authors have succeeded in tracing shortcuts through the sometimes densely proliferating original literature. At times, the presentation attains the clarity of textbooks for well-established fields of research; that is not always the case, but no blame for it may be put on a work which impressively summarizes such a wealth of material.

The first chapter discusses basic elements in the theory of hopping transport. Following a historical survey, the presentation (for which only standard notions of solid state physics are required) highlights the Kubo-formula, the polaron canonical transformation, the Hartree-Fock-decoupling and the generalized master equation. The second chapter is devoted to the small polaron. The extensive third chapter (more than half of the book) deals with hopping conduction in disordered systems, the main subjects being DC- and AC-hopping conductivity, non-ohmic hopping conduction and the Hall-effect. Here the physical principles of the theory of random media are also discussed: Anderson- and Mott-transitions, percolation, fractals, continuous-time random-walks, and effective-medium theories. The following short fourth chapter deals with diffusive atomic (or ionic) motion classically, a topic which might well have been treated at an earlier stage. The fifth and final chapter is the mixing-pot for extensive results of recent developments, and is a rich mine of interesting, in some cases not yet solved, research problems.

Under the cover of a textbook, the work also displays many facets of a review article and can be recommended both to graduate students and to specialists in the field. Reading is rendered easy by adequate author and subject indexes, by very good cross references and by judicious repetitions in the text. Disregarding its price, the book is well-suited as a basis for lectures and seminars.

Difficulties in the Emergence of the Polymer Concept—an Essay**

By Herbert Morawetz*

1. Introduction

The inauguration of the Max-Planck-Institut für Polymerforschung is a milestone in the long and tortuous road over which the study of polymers emerged as a scientific discipline and gained recognition by the scientific establishment.[***] It is hard to believe that *Partington*'s monumental "History of Chemistry"[1] published in 1964 does not refer to "polymers" in the index, refers to *Staudinger* only in connection with his work on diazomethane and ketene, and still refers to polystyrene as "metastyrol." Yet, we should remember that students of polymers are not unique in being victims of such glaring prejudice. In his inaugural address as rector of the University of Bonn, a little over a hundred years ago, *Kekulé*[2] complained that "one-sided representatives of so-called humanistic studies, who also confuse the application of chemistry with its scientific work, tend towards the unjustified view that chemistry ought to be taught at polytechnic schools and not at universities."

2. Three Early Experiments

What should we regard as the earliest significant polymer experiment? I shall suggest three that come to mind. The first could be the demonstration by the blind *John Gough* in 1805[3] that natural rubber heats up when stretched and contracts when a loaded sample is heated. *Gough* interpreted his results in a rather fanciful way. For instance, the contraction of a stressed rubber specimen on heating "is occasioned by the absorption of caloric fluid in the same manner that ropes are obliged to contract by absorption of water." Yet, the phenomena he described were real and it took more than a century to formulate their interpretation. The second choice might be *Faraday*'s analysis of rubber latex in 1826.[4] He showed that the aqueous phase contains protein and he gave a reasonably accurate figure for the elemental composition of the rubber. It is little known that he also recorded in his notebook an experiment in which he heated rubber with sulfur. All he observed was hydrogen sulfide generation and he concluded that heating organic compounds with sulfur might be a novel way to reduce their hydrogen content![5] This may surely be regarded as one of the great missed opportunities in the history of science!

My third choice is the 1839 report by *Simon*, a Berlin pharmacist, who first isolated styrene from a natural resin and noted that styrene distillation left a residue whose amount increased with the time the styrene was stored.[6] He assumed that the product was styrene oxide. A few years later, *Simon*'s experiment was repeated by *Blyth* and *Hofmann*[7] who showed conclusively that no oxidation was involved. To determine the nature of the transformation, they nitrated the styrene and the residue remaining after distillation and characterized them by the N/C ratio. They reported that this ratio changed from 1/8 to 1/7 and concluded that the original substance, C_8H_8, had been transformed into C_7H_7.

3. The Origin of the Term Polymer

The origin of the term "polymer" is rather curious. It was the result of the isolation, by *Faraday*, of butene for which he found a gas density twice as high as that of ethy-

[*] Pof. H. Morawetz
Polytechnic University
333 Jay Street, Brooklyn, NY 11201 (USA)

[**] Lecture presented at the inauguration of the Max-Planck-Institut für Polymerforschung on March 11, 1986, in Mainz.

[***] Note added by the editorial staff: The author of this article has written a history of macromolecular chemistry (H. Morawetz: *Polymers. The Origins and Growth of a Science*, Wiley, New York 1985), which was reviewed in this journal (*Angew. Chem. 98* (1986) 1039).

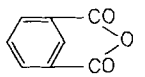
 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0202-0093 $ 02.50/0

lene, although the two substances had the same elemental composition.[8] This puzzled *Faraday*, since he believed that the elemental composition defines a chemical compound. He was clearly unaware of a paper by *Gay-Lussac*,[9] who had pointed out as early as 1814 that "the composition of acetic acid does not differ significantly from that of ligneous matter.[*]... This is a new proof that the atomic arrangement in a compound has great influence on its character."[**] But this paper was also unknown to *Berzelius*, who was astounded by *Faraday*'s finding[10] and suggested that his new gas be referred to as a "polymer" of ethylene. According to *Berzelius*' definition, a polymer had to have the same elemental composition as a reference substance and this criterion was used rigorously a century later by *Staudinger*, who objected, therefore, to the application of this term to the products of polycondensations. *Berzelius*' definition paid no attention to molecular structure, so that all through the nineteenth century we may find statements describing, for example, styrene, C_8H_8, as a polymer of acetylene, C_2H_2, or even lactic acid, $C_3H_6O_3$, as a polymer of formaldehyde, CH_2O. Our current usage of the term was defined by *Carothers*,[11] who called polymers substances whose "structure may be represented by $-R-R-R-$ where "$-R-$" are bivalent radicals which, in general, are not capable of independent existence."

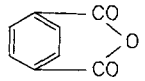
4. The Second Half of the 19th Century—Important Experiments and Misconceptions

In spite of the mistaken characterization of "metastyrol" by *Blyth* and *Hofmann*, this and similar products of transformation were soon considered to be "polymeric." We may well wonder how this concept could have arisen at a time when gas densities were the only reliable measures of molecular size. An increasing molecular weight was then estimated from a rising boiling point or inferred from an increasing density and the softening temperature of solids, which was not differentiated from a melting point. Considering the crudity of such methods, it is remarkable that *Berthelot* arrived at an understanding of the conversion of vinyl compounds into polymeric chain molecules. He reasoned[12] that on addition of an olefin to a chain with a terminal double bond, the unsaturation would be retained, so that there was no reason why very long chains should not be produced, although, as he stressed, the possibility of the formation of such chains did not ensure that they would be produced under some given conditions. *Berthelot* isolated the dimer, trimer, and tetramer of pentene and estimated from their heat of combustion the heat of polymerization. His long lecture on "la polymérie" presented to the Chemical Society of Paris in 1863 may well be regarded as the first intensive treatment of the subject. We should admire his insight and not stress unduly some of his more extravagant theories on the nature of catalysis or his cautious suggestion that the principle of polymerization may perhaps also apply to atoms, so that sulfur might be viewed as the dimer of oxygen and tellurium its tetramer.

A considerable number of vinyl monomers were polymerized before the end of the nineteenth century although the nature of the process was generally not understood. We should not be misled by the expression "hochpolymer" in the German literature of that time, which could refer to association complexes of small molecular species as well as to large molecules. The nature of polycondensation was understood by *Lourenço*,[13] who, between 1859 and 1863, studied the condensation of ethylene glycol and described the products up to the hexamer. He should also be given credit for having understood the concept of copolymerization—something which seemed surprisingly difficult when it was considered again sixty years later. There were, of course, other results which obviously involved polycondensation, but they were misunderstood mainly for two reasons: (1) Nothing was known about the constraints on molecular geometry, so that there was no hesitation in assigning to the products of ester interchange of resorcinol or hydroquinone with diphenyl carbonate[14] the structures **1** and **2**, respectively.



1



2

(2) There was a strong bias toward assigning a unique structure to a reaction product, particularly if it appeared to be crystalline. Thus, the condensation of salicylic acid was represented as leading to a cyclic tetramer[15] and the product of the condensation of succinic acid with ethylene glycol was thought to be the cyclic dimer.[16]

5. The Early 20th Century—New Arguments against the Existence of Polymers

The strong resistance to the concept of long-chain molecules involving only normal chemical bonds had several causes. The major opposition was due to the emergence of the concept of colloids as aggregates of a large number of small molecules. This "colloidal state" was supposed to be responsible for a high solution viscosity, low diffusion rate, gelation, and the failure of substances such as "metastyrol" to crystallize. Most important, it was frequently stated that "colloid solutions" cannot be expected to follow the laws of physical chemistry which were supposed to be restricted to "true solutions." It was also widely believed that solubility decreases necessarily with molecular size, so that the solubility of substances such as "metastyrol" seemed incompatible with a polymeric nature. Later, with the introduction of X-ray crystallography, the small

[*] His analysis was inaccurate. Cellulose was isolated from wood only 25 years later. However, he also pointed out that starch, which could be obtained pure at that time, has the same elemental composition.

[**] "Cette composition de l'acide acétique ne differe pas sensiblement de celle de la matière ligneuse qui ne jouit en aucune manière des propriétés acides. Voilà donc deux corps composés de carbon, d'oxigène et d'hydrogène, en même proportions, dont les propriétés sont eminemment differentes. C'est une nouvelle preuve que l'arrangement de molécules dans un composé a la plus grande influence sur le caractère neutre, acide ou alcalin de ce composé. Le sucre, la gomme et l'amidon conduisent encore a la même conclusion ..."

size of the unit cell of substances such as cellulose and *Hevea* rubber seemed to suggest a small molecular size. It is true that *Polanyi*[17] wrote in 1921 that the unit cell of cellulose allows two alternative interpretations: It could contain either two disaccharide segments of long polysaccharide chains, or two cyclic disaccharides. But he never returned to this argument, which seems to have been generally overlooked at the time. *Polanyi* wrote ruefully forty years later:[18] "Unfortunately I lacked the chemical sense to eliminate the second alternative—I should have been better occupied in establishing definitely the chain structure." We may also refer to some rather quaint arguments against the existence of long-chain molecules: The influential organic chemist *Karrer* ridiculed in 1921[19] the notion that starch could consist "of dozens or hundreds of glucose molecules joined by glucosidic bonds" since "it is improbable that a plant in converting sugar to a reserve substance from which it might soon have to be recovered would perform such complex work." Finally, *Hermann Mark* recalls that at a tempestuous farewell lecture given by *Staudinger* at the ETH in Zürich in 1925, one of the speakers compared *Staudinger*'s championship of long-chain molecules to the report of some traveler in Africa that he had seen a zebra which was 400 meters long. Who could believe such nonsense!

6. *Staudinger*'s Decision to Concentrate on Polymer Studies

Staudinger's conviction that "hochmolekular" compounds consist of covalently bonded long-chain molecules was first expressed in a paper published in Switzerland in 1919[20] and elaborated at some length in Berichte der Deutschen Chemischen Gesellschaft during the following year.[21] *Staudinger* cited three examples, polyoxymethylene (then called paraformaldehyde), "metastyrol," and *Hevea* rubber, for which, as he acknowledged, *Pickles*[22] had previously proposed a linear structure. It is fair to say that at that time *Staudinger*'s view was largely intuitive with little experimental evidence, but he was determined to prove his point and he had the courage to concentrate henceforth on a field which was viewed with undisguised contempt by many of the leading organic chemists of that time. As for this first communication on high-polymeric compounds, four features deserve our attention: It contained a clear description of the concept of polydispersity. It also contained a statement that "it makes no sense to carry out molecular weight determinations on such substances," justified by the observation that ebullioscopic and cryoscopic data would only reflect the presence of low-molecular-weight impurities. It raised the question of the chemical nature of the ends of chains formed by the addition of unsaturated monomers: Here *Staudinger* observed that with sufficiently long chains the concentration of these reactive sites would be reduced to a point where their presence would not be significant. Similar arguments, claiming that reactivities of chemical structures decrease with the length of chains to which they are attached may strike us today as farfetched, but such arguments were commonly accepted for a long time. Finally, *Staudinger* believed that "hundreds of molecules will add to each other until equilibrium, which may depend on temperature, concentration, and solvent, has been attained."

In view of *Staudinger*'s eminent role in establishing the polymer concept, it is of some interest to inquire what may have been the influences which induced him, a man with a solid reputation in classical organic chemistry, to concentrate after 1920 on a field which appeared so unpromising at the time. While the answer is necessarily speculative, there are some pointers worth considering. In his memoir,[23] *Staudinger* writes warmly about the "outstanding personality" of *Carl Engler*, in whose chemical institute at Karlsruhe he spent the five years 1907-1912 as "Extraordinärer Professor." It is, therefore, of some interest that *Engler* wrote as early as 1897,[24] in speculating about the origin of petroleum, that molecules with double bonds may undergo "slow addition to complex structures" and that "one need not assume that only similar molecules assemble." (It may even be significant that *Engler*'s wording "lagern sich zusammen" was adopted by *Staudinger* in his 1920 paper). *Engler* was well ahead of his time in speculating as early as 1904 about the relationship between autoxidation and polymerization,[25] and *Staudinger* became involved for the first time with polymerization when he advised *Engler*'s student *Lautenschläger* on his thesis dealing with "Autoxidation and polymerization of unsaturated hydrocarbons,"[26] *Staudinger* became involved for the first time with polymerization processes.

7. 1920–1940: The Classical Age of Polymer Science

A number of experimental results that were incompatible with the view of the colloid school made surprisingly little impression on the scientific community. *Duclaux* and *Wollman*[27] carried out a fractional precipitation of cellulose nitrate solutions and found that the fractions differed in their solution viscosities. This result would have been clearly incomprehensible if cellulose were an aggregate of small molecular species. In 1925 *Hock*[28] found that when a stretched rubber specimen was frozen in liquid air and shattered, it broke up into fibers—a result which certainly suggested a fibrous structure for the constituent molecules. During the same year *Katz*[29] published his finding that *Hevea* rubber, amorphous in the relaxed state, yields a sharp X-ray diffraction diagram when stretched. In reporting this sensational observation, he wrote that "molecules or parts thereof" are being oriented, but although he was unhappy with the notion that the small unit cell signifies that rubber is composed of small molecules, he did not dare to conclude that it is composed of molecular chains.

In 1926, *Sponsler* and *Dore*[30] published their interpretation of the X-ray diffraction by cellulose. It is important to note that they started with the observation that "a satisfactory formula for cellulose must account for its physical properties." Thus, they were clearly predisposed to reject the notion that cellulose represents an aggregate of small molecules or that "lattice forces are here comparable in their magnitude and nature to the valence forces: The whole crystallite appears as a large molecule."[31] They proposed a chain structure on the basis of rather limited data, but their result had the fateful flaw that it contra-

dicted solid chemical evidence that cellulose is composed of cellobiose residues. This tended to reinforce the skepticism of organic chemists regarding the utility of the crystallographic method.

One of *Staudinger*'s most fruitful ideas was the concept of model chain molecules, analogous to natural macromolecules but offering experimental advantages for their study. He reasoned that since studies of *Hevea* rubber are complicated by the chemical sensitivity due to its unsaturation, polystyrene, an amorphous synthetic polymer, would be a suitable analogue. In the case of cellulose, a highly crystalline material, he proposed to study the polymers of formaldehyde, since here the properties of a continuous series of oligomers could be compared with those of the high polymer. The results of this study showed quite unambiguously that the polymer is built up on the same principle as the oligomers which could be characterized by standard chemical techniques.[32] It contained another most important generalization: The ends of long-chain molecules are randomly distributed in the crystallites, so that X-ray diagrams cannot be used for an estimation of molecular weights.

The paper on formaldehyde polymers by *Staudinger* and his students may be said to have provided for the first time incontrovertible evidence on the chain structure of a high polymer. The crystallographic method was soon to be applied successfully by *Meyer* and *Mark* to cellulose, silk fibroin, chitin, and *Hevea* rubber.[33] In the case of cellulose, a correction of the interpretation by *Sponsler* and *Dore* showed that the X-ray data were fully compatible with the chemical evidence that the chains are composed of repeating cellobiose units. In the case of rubber, the crystal structure was shown to indicate a *cis*-1,4 enchainment of isoprene residues, contrary to the *trans* structure championed by *Staudinger*. It is remarkable that these papers were submitted from an industrial laboratory which was sufficiently farsighted to realize that such structural studies would form the basis for the development of successful artificial fibers.

At about the same time, *Staudinger* proposed a method by which the molecular weight of polymers could be deduced from their solution viscosity.[34] Although his theory assumed a rigid rodlike structure for chain molecules and was incorrect even on this basis, the use of the parameter that became known as the "Staudinger index" provided for the first time a cheap and convenient method for the characterization of the molecular size of polymers. In that way it advanced polymer science even though it led to incorrect values for molecular weights.

However, *Staudinger*'s solution viscosity theory had also an unfortunate side effect in that it contributed to the bad relations between the *Staudinger* school and the polymer chemists emphasizing physico-chemical techniques, particularly *Meyer, Mark,* and *Kuhn*. These men listed incontrovertible arguments for the flexibility of chain molecules, but *Staudinger* and his students chose to disregard them. It is hard for us today to understand that even phenomena such as rubber elasticity, the swelling of cross-linked polymer gels, and the dramatic increase in the viscosity of poly(acrylic acid) solutions when they are neutralized were not considered by *Staudinger* as incompatible with the model of rigid rodlike polymer chain molecules. On the other hand, two of *Staudinger*'s arguments must have seemed convincing:[35] (1) He felt that the easy crystallization of chain molecules could not be understood if randomly coiled chains had to assume extended shapes in the crystal. (2) He believed that the small volume change when crystalline polymers melt implied a packing efficiency in the melt which could not be achieved with randomly coiled chains. My conversations with *Staudinger*'s widow have indicated to me that there was also possibly a deeper psychological cause for these controversies: *Staudinger* seems to have been haunted by the conviction that physical chemists looked down on organic chemistry and that they expected, in particular, physical chemistry to provide all significant progress in the understanding of polymers. Since he believed that the study of macromolecules was opening a vast new area of activity for organic chemistry, he reacted to the perceived slight with passionate emotion.

8. Macromolecular Chemistry and Molecular Biology—Little Interaction despite Common Methods

Finally, I should like to comment briefly on the relation between the development of synthetic macromolecular science and the rise of molecular biology. The idea that very large molecular structures are involved in the life process was expressed already by *Kekulé* in his inaugural address at the University of Bonn, referred to above.[2] He cited *Pflüger* as believing that "these mass molecules ... through constant change of position of polyvalent atoms change the connection between individual molecules so that the whole ... is in a sort of living state." Later, colloid chemists were fascinated by the idea that their field played a central role in explaining the life process. This may be exemplified by *Pauli*[36] writing that "the colloid chemistry of proteins provides an approach to the obscure region which scientists contemplate today only with the silent longing for the promised land—the physical chemistry of living matter." *Staudinger* expressed a similar sentiment when he wrote in his memoir that he had chosen as a young man "to study chemistry in order to enter more readily into the problems of botany" and he concluded his Nobel Prize lecture in 1953 with some speculations concerning macromolecules and life.[23]

Clearly, a number of experimental techniques are equally applicable to the study of synthetic polymers and the investigation of proteins and nucleic acids with which molecular biology is concerned. Let us see then how the developments of the macromolecular concept in these two fields compared with each other.

For a long time, protein chemistry was just as influenced by the skepticism concerning the possible existence of very large covalently bonded molecules as the chemistry of synthetic polymers—particularly since the great *Emil Fischer*[37] had expressed his doubt of the existence of proteins with molecular weights exceeding 4000. It was only when *Svedberg*'s ultracentrifuge study of hemoglobin showed that it consisted of particles with a discrete molecular weight, that he abandoned his preconception that proteins

are aggregates of small molecules with a variable particle size, such as he had observed with inorganic colloidal dispersions.[38] Yet, *Svedberg* told his student, *B. G. Rånby* that he was completely unaware of *Staudinger*'s existence at the time he developed the ultracentrifuge. The study of globular proteins, which have a uniquely defined sequence of a relatively large number of comonomers and a unique conformation in their "native state" and which exhibit denaturation phenomena, raised obviously different problems compared with polystyrene or rubber. Crystallographic data on synthetic polypeptides were useful in confirming the structure of the α-helix[39] as one of the structural elements of proteins, and studies of helix-coil transitions in polypeptide solutions[40] continue to be motivated by the hope that they might lead to a full understanding of the principles governing chain folding in globular proteins. The utility of this approach is yet to be proved.

Nucleic acids were assigned for a long time a tetranucleotide structure.[41] The realization of their high molecular weight was probably delayed owing to difficulties in their isolation, which led to various degrees of degradation. This made *Feulgen*[42] refer in 1935 to the "bad reputation" of DNA. He showed that an enzyme can convert a gelling preparation "a" into a non-gelling product "b." Study of these two materials in the ultracentrifuge led *Schmidt* and *Levene*[43] to conclude that the preparation "a" with a molecular weight of 200000-1000000 was depolymerized by *Feulgen*'s enzyme to the tetranucleotide. But what did they mean by depolymerization? As late as 1938 they referred[44] to the "dissociation of the tetranucleotides of high molecular weight to those of lower molecular weight," suggesting that they viewed the heavy particles as loose aggregates. Only the flow birefringence study of *Signer*, *Caspersson*, and *Hammarsten*,[45] published during the same year, established the rodlike nature of the DNA particle.

We can see from the examples detailed above that the interaction between polymer chemists and the practitioners of molecular biology was minimal. Most of the time they went their separate ways with little awareness of each other.

Sulfur Oxides as Ligands in Coordination Compounds

By Wolfdieter A. Schenk*

Donor molecules undergo dramatic changes in their chemical properties on coordination to a transition-metal atom. Highly reactive species can be trapped and studied as ligands. Conversely, stable compounds can be activated to undergo novel reactions. Sulfur dioxide complexes have generally been studied from a structural viewpoint, their reactivity having been somewhat neglected. The unstable sulfur oxides SO, S_2O, and S_2O_2 are still often regarded as laboratory curiosities. Their successful stabilization in transition-metal complexes has now made them accessible to detailed study, in the course of which many relationships to the chemistry of SO_2 complexes have become apparent.

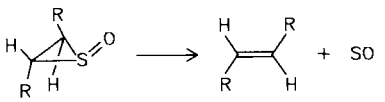
1. Introduction

The first complexes with SO_2 were reported in 1938 by *Gleu* and co-workers.[1,2] However, only when spectroscopic and structural studies revealed the versatility of the SO_2 ligand did the interest in this class of compounds become widespread.[3,4] Investigation of their chemical reactivity was essentially confined to studies of SO_2 dissociation from the complexes and of the "sulfate reaction," i.e., the oxidation with O_2 to give sulfate complexes.[4]

SO is in equilibrium with SO_2 at high temperatures; it is an intermediate in the combustion of compounds containing sulfur.[5] Early reports of the isolation of SO[6] and of the investigation of its properties[7] had to be revised on the basis of mass-spectrometric evidence;[8] SO disproportionates extremely rapidly, mostly according to Equation (1),

$$3\,SO \longrightarrow S_2O + SO_2 \qquad (1)$$

with the dimer S_2O_2 (also highly unstable) as an intermediate.[5,9] Under pressures of a few millibars, the S_2O polymerizes to form polysulfur oxides of variable composition, SO_2 being given off.[5] Many sulfoxides decompose thermally[10-21] or photochemically[22] with elimination of SO, which can be identified spectroscopically[21] or by trapping reactions.[10,12,13,16,18,20] The thermolysis of thiirane 1-oxides, in particular, has proved to be a useful method of generating SO in solution [Eq. (2)].[10,11,16,19]



$$+ \; SO \qquad (2)$$

R = H, Ph

Further possible sources of SO and S_2O are represented by reactions (3) and (4).[23] SO and S_2O have also been postulated as short-lived intermediates in the electrolytic reduction of SO_2[24] and in the $Li/SOCl_2$ battery.[25]

$$RSO_2N{=}S{=}O + Ph_3P \longrightarrow RSO_2N{=}PPh_3 + SO \qquad (3)$$

$$RSO_2N{=}S{=}O + Ph_3PS \longrightarrow RSO_2N{=}PPh_3 + S_2O \qquad (4)$$

Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

The lower sulfur oxides also include the compounds S_nO (n = 6–10) and S_7O_2, which have been obtained by oxidation of the corresponding sulfur homocycles with peracids. Recent reviews of these compounds are available.[26]

2. Complexes with SO_2

2.1. Structure and Bonding

The small molecule SO_2 displays a fascinating variety of bonding modes (Fig. 1), which can be understood in terms

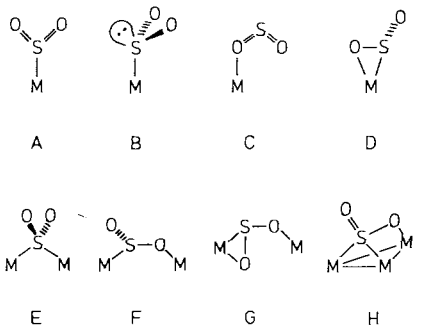

Fig. 1. Types of SO_2 complexes.

of the frontier orbitals shown in Figure 2.[3-5] The HOMO and LUMO are symmetry-equivalent to the frontier orbitals of a carbene, and complexes of type A (Fig. 1) are thus closely related in structure to carbene complexes; repre-

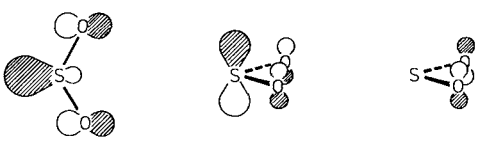

Fig. 2. The frontier orbitals of SO_2 and their energies [eV].

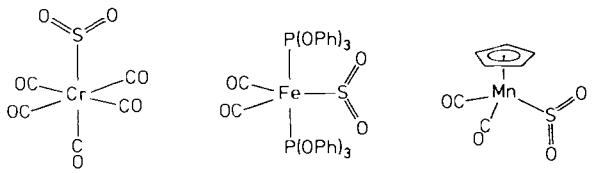
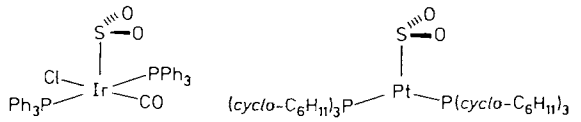
sentative examples are shown in Figure 3. SO_2 coordinates to electron-rich transition-metal fragments to form complexes of type B (Fig. 1). *Vaska*'s SO_2 complex **4**[31,32] and



1a[27] **2**[28,29] **3**[30]

Fig. 3. η^1-SO_2 complexes with planar-coordinated sulfur (type A in Fig. 1).

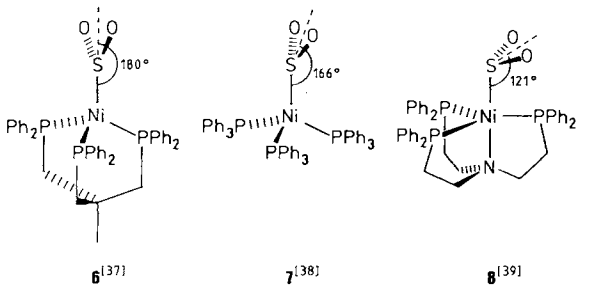
the platinum complex **5**[33] can be cited as examples (Fig. 4). Compounds such as **4** and **5** may be viewed as analogues of the amine adducts of SO_2,[34,35] since the bonding electron pair is formally provided by the transition metal.



4[32] **5**[33]

Fig. 4. η^1-SO_2 complexes with pyramidally coordinated sulfur (type B in Fig. 1).

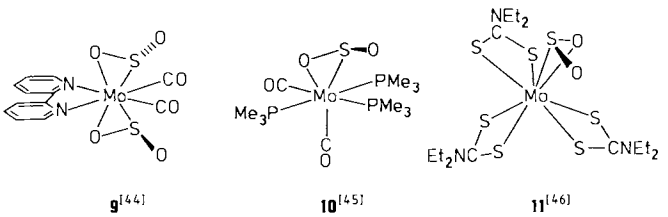
A more detailed analysis shows that, as in nitrosyl complexes, a bent (here pyramidal) geometry (A→B) can be expected when the σ^* orbital, which is antibonding with respect to the M–S bond, and the b_1 orbital of the SO_2 are of similar energy and one of them is occupied.[36] The nickel complexes **6**,[37] **7**,[38] and **8**[39] (Fig. 5) demonstrate especially clearly the transition from planar to pyramidal geometry. Complex **7** is the only known example of an SO_2 complex that is comparable structurally to slightly bent nitrosyl complexes.[40]



6[37] **7**[38] **8**[39]

Fig. 5. Transition from planar-coordinated to pyramidally coordinated sulfur.

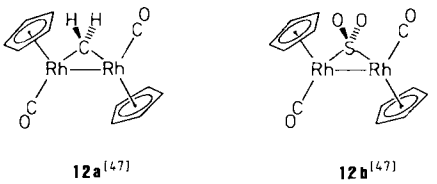
Hard Lewis acids coordinate preferentially to the oxygen (type C in Fig. 1). The adduct $SO_2 \cdot SbF_5$[41] is the prototype of such systems, but several transition-metal complexes of this sort have been recently isolated.[42,43] Since the LUMO of SO_2 has an appreciable coefficient at the oxygen atom, SO_2 can also coordinate side-on to a transition metal (type D in Fig. 1). The energetically unfavorable and poorly polarizable a_2 orbital then serves as the donor orbital. This type of coordination is therefore also limited to electron-rich complexes such as **9**,[44] **10**,[45] and **11**[46] (Fig. 6).



9[44] **10**[45] **11**[46]

Fig. 6. η^2-SO_2 complexes (type D in Fig. 1).

In polynuclear complexes, SO_2 is, almost without exception, a carbene-type 2-electron bridging ligand (type E in Fig. 1); the close analogy between CR_2 and SO_2 is illustrated by the complexes **12a** and **12b**[47] (Fig. 7). In contrast to the corresponding carbonyl complexes, SO_2-bridged complexes are characterized by severely limited or even nonexistent intramolecular CO exchange.[47,48] This is due to the great preference of the "single-faced" π-acceptor SO_2 for the bridging position; indeed, no polynuclear SO_2 complex with terminal SO_2 is known.



12a[47] **12b**[47]

Fig. 7. Analogy between μ-CH_2 and μ-SO_2 complexes.

The structural types F,[49] G,[50] and H[51] (Fig. 1) are each represented by one X-ray crystal structure. They may be considered as products of an electrophilic attack on the oxygen atoms of complexes of types B, D, and E, respectively; the SO_2 in F, G, and H functions as a 4-electron donor.

The structural variety that has been briefly discussed here makes SO_2 complexes an ideal model for studying the relationship between the nature of the transition-metal fragment L_nM, the nature of the ligand coordination, and reactivity.

2.2. Synthesis

2.2.1. Mononuclear Compounds

Because of its ready accessibility and ease of manipulation, almost all syntheses start from free SO_2, which is added to either isolable complexes or to coordinatively unsaturated complex fragments generated in situ. Reactions (5)[31] and (6)[52] are typical examples. Complexes **1a** and **1c** were first observed in solution by *Strohmeier* et al.,[53] but only with the discovery of reaction (6) did the highly substitution-labile pentacarbonyl complexes become accessible. Analogous methods led to the synthesis of a series of phosphane-substituted complexes, *cis*-

$[M(CO)_4(PR_3)(SO_2)]$[52] (M = Cr, Mo, W), and of the cations $[M(CO)_5(SO_2)]^{\oplus}$ (M = Mn, Re),[54] $[CpCr(NO)_2(SO_2)]^{\oplus}$, and $[CpFe(CO)_2(SO_2)]^{\oplus}$[55] (Cp = η^5-C_5H_5). The phosphane-substituted derivatives are markedly more stable than the parent compounds **1a–c**, since the replacement of one CO group by a donor ligand raises the energy of one of the three t_{2g} orbitals of the metal and thus strengthens the back-bonding into the b_1 orbital of the SO_2.

$$[Ir(PPh_3)_2(CO)Cl] \overset{SO_2}{\rightleftharpoons} [Ir(PPh_3)_2(CO)(Cl)(SO_2)] \quad (5)$$

4

$$[M(CO)_5Cl]^{\ominus} \xrightarrow[-NaCl]{NaBPh_4} \{M(CO)_5\} \xrightarrow{SO_2} [M(CO)_5(SO_2)] \quad (6)$$

1a–c

M = Cr (**1a**), Mo (**1b**), W (**1c**)

The chromium triad provides a large number of SO_2 complexes of various substitution types; these have revealed relationships between the arrangement of donor and acceptor ligands and the nature of the SO_2 coordination (η^1 planar or η^2). The complexes were obtained by replacement of labile neutral ligands such as tetrahydrofuran, acetone, or acetonitrile by SO_2.[52,56,57] The oxidative cleavage of M–M bonds with AsF_5 in liquid SO_2 provides another interesting synthetic route.[58]

$$[Ru(NH_3)_4(SO_3H)_2] \xrightarrow{HCl} [Ru(NH_3)_4Cl(SO_2)]^{\oplus} \quad (7)$$

13

$$[Ru(NH_3)_5(SO_3)] \xrightarrow{H^{\oplus}} [Ru(NH_3)_5(SO_2)]^{2\oplus} \quad (8)$$

14

The SO_2 complexes isolated by *Gleu* and co-workers in 1938 also represented the first examples of the generation of SO_2 at a metal complex. The two ruthenium complexes **13** and **14** were formed by acid hydrolysis [Eq. (7)[1] and (8)[2]]. Later, the manganese complex **3**[59] and the square-planar compounds **15a,b** and **16a,b**[60] were also synthesized [Eq. (9) and (10)]. *Kubota* and *Loeffler* reported the thermally induced rearrangement of sulphinato complexes

$$[CpMn(CO)_2\{OS(NEt_2)_2\}] \xrightarrow{H_2O} [CpMn(CO)_2(SO_2)] \quad (9)$$

3

$$[M(PR_3)_2Cl(OSNR')] \xrightarrow{H_2O} \begin{matrix} R_3P & SO_2 \\ & M \\ Cl & PR_3 \end{matrix} \quad (10)$$

M \ R	*i*Pr	*cyclo*-C_6H_{11}
Rh	**15a**	**15b**
Ir	**16a**	**16b**

$$\begin{matrix} L & N_2 \\ & Ir \\ Cl & L \end{matrix} + RSO_2Cl \longrightarrow \begin{matrix} L & SO_2R \\ & Ir \\ Cl & L \end{matrix} Cl \longrightarrow \begin{matrix} L & SO_2 \\ & Ir \\ Cl & L \\ & R \end{matrix} Cl \quad (11)$$

L = PPh_3; R = Me, Et, Pr, Ph, ...

[Eq. (11)].[61] The spectroscopic data, particularly ν(SO), cannot however be reconciled with the formulation of the products as octahedral Ir^{III} complexes. The iron complex **2** is formed in surprisingly good yield according to Equation (12).[29] Complexes **2**, **15a**, and **16a** can also be obtained by oxidation of the corresponding SO complexes (see Section 3.3).

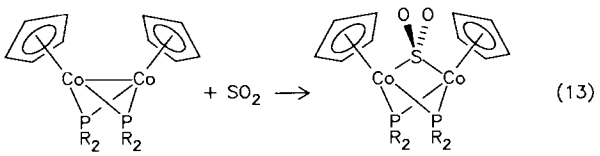
$$[FeH_2(CO)_2\{P(OPh)_3\}_2] + SO_2Cl_2 \xrightarrow[-2\,Et_3N\cdot HCl]{2\,Et_3N} [Fe(CO)_2\{P(OPh)_3\}_2(SO_2)] \quad (12)$$

2

The reactions (7) to (12) are of minor importance as synthetic routes to SO_2 complexes but they demonstrate the diverse reactivity of sulfur–oxygen compounds with respect to transition-metal centers.

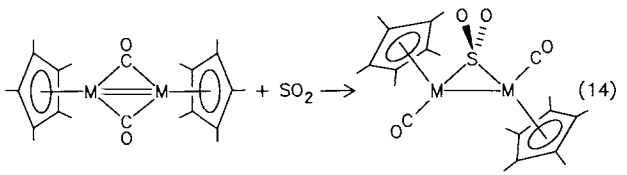
2.2.2. *Polynuclear Compounds*

The isolobal relationship between SO_2 and CR_2 leads one to expect that SO_2 can coordinate to complexes with metal–metal bonds, the process being accompanied by a lowering of the metal–metal bond order. Examples are provided by the reactions (13)[62–64] and (14).[65] The well-known insertion of SO_2 into nonbridged M–M single bonds can also be included here.[66,67] Coordinatively unsa-



(13)

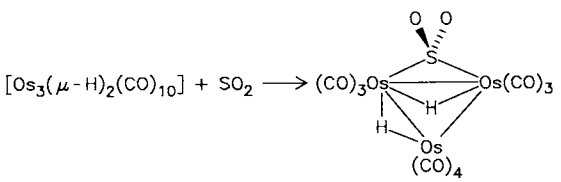
R = Me, Ph



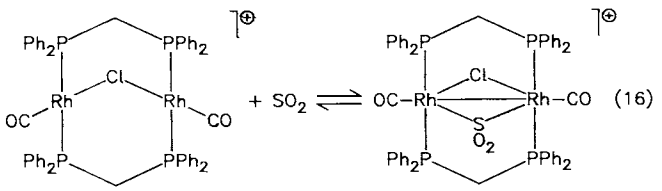
(14)

M = Co, Rh

turated polynuclear complexes add SO_2 readily [Eq. (15)].[68] Equation (16)[74,75] is a typical example of the (often reversible) coordination of SO_2 to an A-frame complex.[69–75] The enormous versatility in the reactivity of



(15)



(16)

polynuclear systems is revealed in numerous further reaction types : ligand substitution at μ-SO_2 complexes,[70,75-77] uptake of SO_2 with bridge cleavage,[78,79] cluster formation from smaller units,[51,80-84] and replacement of labile ligands by SO_2.[48] Even CO can often be easily replaced by SO_2.[47,51,73,76,79,85,86] This method was used to prepare **17**, an SO_2-bridged heterometallic complex [Eq. (17)].[87,154]

$$[MoRhCl(dppm)_2(CO)_4] + SO_2 \longrightarrow \textbf{17} + CO \quad (17)$$

17

$$[Mo_2(\mu\text{-}S)_2(CN)_8]^{6\ominus} \xrightarrow{O_2} \textbf{18} \quad (18)$$

18

Reaction (18) is worthy of mention in connection with the oxidation of sulfur by microorganisms; an SO_2 bridge is formed from a μ-sulfido ligand, but the mechanism is unknown.[88,89] Closely related reactions are the formation of thiosulfito and dithiosulfato complexes by air oxidation [Eq. (19)[90] and (20)[91]].

$$[Co_2(CN)_{10}(\mu\text{-}S_2)]^{6\ominus} \xrightarrow{O_2} [(NC)_5Co\text{-}S\text{-}S(O)_2\text{-}Co(CN)_5]^{6\ominus} \quad (19)$$

$$MoS_4^{2\ominus} \xrightarrow{O_2} \left[\begin{array}{c} S \\ O \\ S \end{array}\!\!>\!Mo\!<\!\begin{array}{c} S \\ O \\ S \end{array}\!\!>\!Mo\!<\!\begin{array}{c} S \\ S \\ O \end{array}\right]^{2\ominus} \quad (20)$$

2.3. Reactivity

2.3.1. Loss or Substitution of SO_2

The SO_2 complexes of type A or D (Fig. 1) that were discovered before 1980 were nearly all stable with respect to loss of SO_2. This led to the assumption that SO_2 ligand lability was diagnostic for type-B coordination.[4,92] The concept of "lability" was interpreted as ready, reversible loss of SO_2 [Eq. (21)][92] or as ready substitution of SO_2 [Eq. (22)].[4] Reaction (21) can obviously be reversible on a preparative scale only when $[ML_n]$ is a stable, isolable compound; the reversibility of SO_2 loss is therefore a consequence of the properties of the $[ML_n]$ moiety and not necessarily of the SO_2 complex itself. It is clear why type-B complexes lose SO_2 readily; the pyramidality results from an antibonding interaction between the a_1 orbital of the SO_2 and an occupied metal orbital of σ symmetry. However, a series of type-A SO_2 complexes have now been prepared that also lose SO_2 readily, even if the process is not macroscopically reversible. These are exemplified by the pentacarbonyls **1a–c**, which decompose in the solid state at 0°C with loss of SO_2 or exchange the coordinated SO_2 within seconds even with weak donor ligands.[52] The SO_2 is probably lost by a dissociative mechanism, the first step of which is represented by Equation (21).

$$[ML_n(SO_2)] \rightleftharpoons [ML_n] + SO_2 \quad (21)$$

$$[ML_n(SO_2)] + L' \longrightarrow [ML_nL'] + SO_2 \quad (22)$$

For SO_2 substitution, however, there are several further possible mechanisms, which make the usefulness of a simple reactivity criterion for the nature of the SO_2 coordination seem questionable. For example, the square-planar d^8-complexes **15a,b** and **16a,b**, which are thermally extremely stable, react smoothly with CO, CO/SO_2 exchange taking place.[60] A detailed examination revealed an associative mechanism; the pentacoordinate intermediates **19a,b** could be spectroscopically identified at low temperature [Eq. (23)].[93] In this case the ease of substitution of the SO_2 is clearly dependent on the nature of the attacking ligand.

$$\textbf{16a, b} + CO \longrightarrow \textbf{19a, b} \rightleftharpoons \textbf{20a, b} + SO_2 \quad (23)$$

a, R = *i*Pr; **b**, R = *cyclo*-C_6H_{11}

SO_2 substitution at electron-deficient complexes could be induced (similarly to CO substitution at metal carbonyls[94]) by nucleophilic attack on the sulfur. Several examples of this reaction type are indeed known (see Section 2.3.4).

2.3.2. Substitution of Other Ligands in the Complex

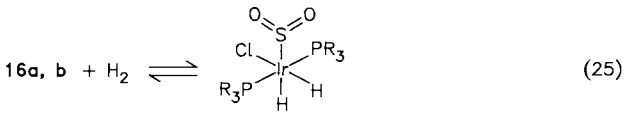
Electron-rich SO_2 complexes whose M–S bond is not labile to substitution may sometimes undergo substitution of other ligands. *Gleu* and co-workers reported the reversible aquation of the complex **13** [Eq. (24)].[1] The cationic rhodium complexes $[RhLL'(SO_2)]^{\oplus}$ (L = PEt_3, PMe_2Ph; L' = bis(3-diphenylphosphinopropyl)phenylphosphane) release the monodentate phosphane ligand reversibly in solution.[95] The substitution of acetonitrile and triphenylphosphane in $[Mo(PPh_3)_2(MeCN)(CO)_2(SO_2)]$ made accessible a series of dicarbonylmolybdenum complexes of types A and D (Fig. 1).[45,96] Such ligand substitutions are also possible at polynuclear complexes; examples have been found for A-frame complexes[70,74,75] and for the trinuclear platinum complexes $[Pt_3L_3(\mu\text{-}SO_2)_3]$.[77]

$$[Ru(NH_3)_4Cl(SO_2)]^{\oplus} + H_2O \longrightarrow \underset{\textbf{13}}{} \quad (24)$$

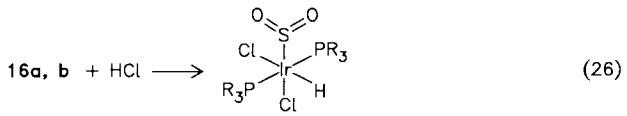
$$\underset{\textbf{21}}{trans\text{-}[Ru(NH_3)_4(H_2O)(SO_2)]^{2\oplus}} + Cl^{\ominus}$$

2.3.3. Coordinative and Oxidative Addition

Coordinatively unsaturated SO_2 complexes (exemplified by the d^8-compounds **15a,b** and **16a,b**) should readily undergo addition reactions. Indeed, **16a,b** react not only with CO (see Section 2.3.1) but also with H_2 and HCl [Eq. (25) and (26)].[93] Reaction (25) is reversible; the dihydridoiridium(III) complexes **22a,b** lose H_2 slowly in solution at room temperature, and **23a,b** eliminate HCl on treatment with base.[93] Complexes **16a,b** are thus surprisingly similar to compounds of the Vaska type. This underlines the close relationship between CO and SO_2 complexes and may serve as a basis for future reactivity studies.



16a, b + H_2 ⇌ **22a, b** (25)



16a, b + HCl ⟶ **23a, b** (26)

a, R = *i*Pr; **b**, R = *cyclo*-C_6H_{11}

2.3.4. Reactions at Coordinated SO_2

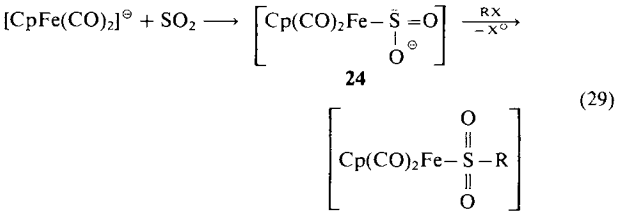
The first example of a nucleophilic attack at the sulfur atom was again presented by *Gleu* et al.[2] The reversible transformation of the SO_2 ligand into an $SO_3H^{\ominus}$ ligand [Eq. (27)] clearly occurs by attack of H_2O or $OH^{\ominus}$, facilitated by the positive charge of the complex. To the best of our knowledge, there is only one further example of attack on sulfur by a base; in this reaction, a μ-SO_2 ligand is converted into a terminal $SO_3R^{\ominus}$ ligand [Eq. (28)].[48]

$$[Ru(NH_3)_5(SO_2)]^{2\oplus} + H_2O \rightleftharpoons [Ru(NH_3)_5(SO_3H)]^{\oplus} + H^{\oplus} \quad (27)$$

14

$$[Ir_4(CO)_9(\mu\text{-}CO)_2(\mu\text{-}SO_2)] + MeO^{\ominus} \longrightarrow [Ir_4(CO)_8(\mu\text{-}CO)_3(SO_2OMe)]^{\ominus} \quad (28)$$

In principle, type-B SO_2 complexes (Fig. 1) should undergo electrophilic attack at sulfur. Reaction of $[Pt(PPh_3)_2(SO_2)]$ with MeI and $MeOSO_2F$ have indeed been mentioned,[3] but no details were given. The anionic complex **24**, obtainable at low temperature according to Equation (29)[67] and isolable as the potassium salt,[97] can be smoothly alkylated at sulfur with a variety of reagents RX.[67,97,98] Sulfinato complexes with unsaturated substituents R ($CH_2CH{=}CMe_2$, $CH_2C{\equiv}CMe$) can thus be obtained that are inaccessible by insertion of SO_2 into the Fe-C bond of the corresponding organoiron complex $[CpFe(CO)_2R]$ because of competing rearrangement reactions.[98] The loss of optical activity on reacting **24** with (*R*)-PhMeCHBr,[99] and also the formation of side products such as $[Cp_2Fe_2(CO)_4]$ and $[CpFe(CO)_2X]$, indicate that radical intermediates play a role in reaction (29).[67]



24

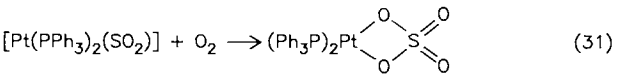
(29)

Examples of electrophilic attack at oxygen are more numerous. The compound $[Ru(CO)_2(PPh_3)_2(\eta^2\text{-}SO_2\cdot SO_2)]$ arises by attack by the Lewis acid SO_2 on the *exo* oxygen of an η^2-SO_2 ligand.[100] The formation of the binuclear complex $[Mo(CO)_2(py)(PPh_3)(\mu\text{-}SO_2)]_2$ (py = pyridine) may also be interpreted as the attack of a coordinatively unsaturated metal fragment on the *exo* oxygen.[50,96] However, attempted addition of BF_3, protonation, or methylation have been unsuccessful.[45,96] The high energy of the Si–O bond has been exploited in many cases for facile electrophilic attack at oxygen [Eq. (30)]. Competition studies indicate that η^2-coordinated SO_2 is much more easily silylated than η^1-coordinated.[57]

$$[\{M\}(SO_2)] + Me_3SiOSO_2CF_3 \longrightarrow [\{M\}(SO_2SiMe_3)]^{\oplus}SO_3CF_3^{\ominus} \quad (30)$$

{M} = metal fragment of the type $M(PR_3)_n(CO)_{5-n}$ with M = Cr, Mo, W; n = 2, 3

Numerous SO_2 complexes of the platinum metals react with molecular oxygen to give sulfato complexes; an example is given in Equation (31).[101] This reaction is considered as diagnostic for η^1-pyramidal coordination of SO_2,[4]



(31)

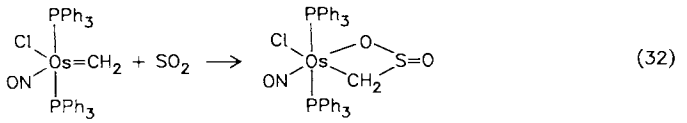
but some exceptions are known.[33,95,102] Recent studies show that the first step is the replacement of complexed SO_2 by O_2,[33] followed by electrophilic attack by the free SO_2 on the coordinated O_2.[103]

2.3.5. Reduction, SO_2 Insertion, and Related Reactions

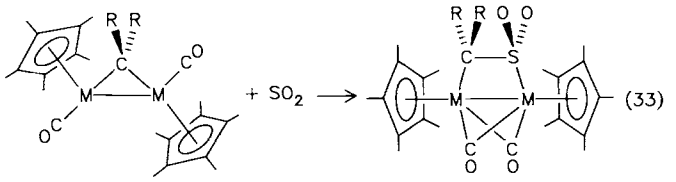
This Section reports some further reactions that are important with respect to transition-metal-mediated transformation of SO_2. The reduction of $[Ru(NH_3)_5(SO_2)]^{2\oplus}$ **14** with zinc amalgam gives $[(NH_3)_5Ru{-}S{-}S{-}Ru(NH_3)_5]^{4\oplus}$.[104] The reduction of $[MoCl(S_2CNEt_2)_3]$ with zinc amalgam in CH_2Cl_2/SO_2 results in the formation not only of the Mo^{III}-complex $[Mo(S_2CNEt_2)_3(SO_2)]$ **11**, but also of the analogous $SOCl_2$ complex $[Mo(S_2CNEt_2)_3(SOCl_2)]$.[46] The reactions of $[Pt(PPh_3)_2(SO_2)]$ with CS_2 and of $[Pt(PPh_3)_2(CS_2)]$ with SO_2, which both lead to the dithiocarbonate complex $[Pt(PPh_3)_2(S_2CO)]$,[105] also proceed by unknown mechanisms. The sterically more protected complex **5** and its analogue with CS_2 instead of SO_2 as ligand undergo only

CS_2/SO_2 exchange. This may indicate that the formation of the dithiocarbonate complex can only occur when CS_2 and SO_2 are simultaneously coordinated to platinum.[33]

Innumerable examples of the insertion of SO_2 into transition-metal-carbon σ bonds are known.[4,5,106] SO_2 can react with terminal or bridged methylene complexes by insertion[65] or [2+2] cycloaddition[107] [Eq. (32) and (33)].



(32)



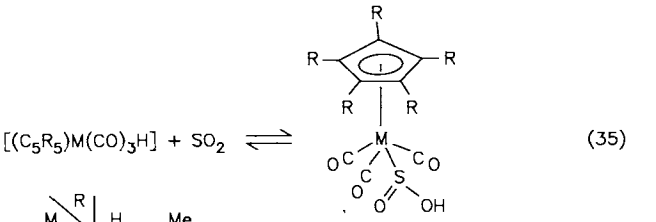
(33)

M = Co, Rh; R = H, Ph

A report of a rapid tautomerism in the hydrido-SO_2 complexes $[MH(CO)(PPh_3)_2(SO_2)]$ (M = Rh, Ir) [Eq. (34)][108] could not be substantiated.[109]

$$[MH(CO)(PPh_3)_2(SO_2)] \rightleftharpoons [M(CO)(PPh_3)_2(SO_2H)] \quad (34)$$

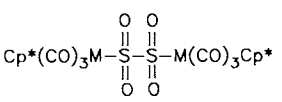
The first authentic example of insertion of SO_2 into a metal-hydrogen bond is shown in Equation (35).[110] The X-ray structure analysis of **25a**, in which all hydrogen



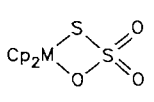
(35)

M \ R	H	Me
Mo	**25a**	**25b**
W	**26a**	**26b**

atoms could be located, unambiguously proves the pyramidal coordination at sulfur; both S-O bonds are distinctly longer (d(S=O) 151.5(6), d(S–OH) 163.7(6) pm) than those in SO_2 complexes. Reaction (35) is reversible, but over longer periods of time reduction products such as **27a** (from **25b**) or **27b** (from **26b**)[110] and μ-sulfido complexes[111] are formed. One μ-sulfido complex, $[Cp_2Mo_2(\mu\text{-}S)_2(\mu\text{-}S_2)]$, is known to catalyze the reduction of SO_2 to sulfur with H_2.[112] An insertion analogous to Equation (35) may be the first step in the formation of the thiosulfato complexes **28a**, **b** from $[Cp_2MH_2]$ and SO_2.[113]



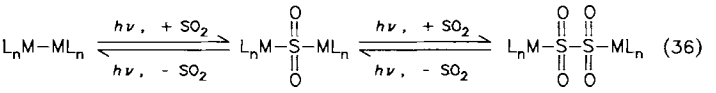
27a, b



28a, b

Cp* = η^5-C_5Me_5; a, M = Mo; b, M = W

Light-induced insertion of SO_2 has been used to obtain μ-dithionite complexes [Eq. (36)].[114] Reaction (36) is reversible; the radicals $[L_nM]^{\ominus}$ and $[L_nMSO_2]^{\ominus}$ are probably intermediates. This type of intermediate is probably responsible also for the formation of **29**, which is obtained along with **24**, on reaction of $[CpFe(CO)_2]^{\ominus}$ with SO_2 (see Section 2.3.4).[67,114]



(36)

29, 30a, b

L_nM = $CpFe(CO)_2$ **(29)**, $Mn(CO)_5$ **(30a)**, $Re(CO)_5$ **(30b)**

The well-known reduction of SO_2 to the radical anion $SO_2^{\odot\ominus}$ can also occur with organometallic compounds. One example is the reaction with dibenzenechromium, in which, as shown by ESR spectroscopy, a radical pair is generated [Eq. (37)].[115] The ensuing disproportionation to the salt $[(C_6H_6)_2Cr]_2(S_4O_{10})$ is not well understood. An X-ray structure analysis shows that the anion is a bis-SO_2 adduct of dithionate.[115]

$$[(C_6H_6)_2Cr] + SO_2 \longrightarrow [(C_6H_6)_2Cr]^{\oplus} + SO_2^{\odot\ominus} \quad (37)$$

The examples presented here demonstrate the versatile reactivity of SO_2 in combination with transition metals. The task of fitting together the isolated reaction patterns so far discovered in order to form a complete picture will have to be left to future studies.

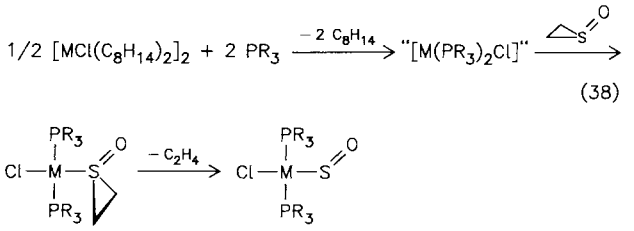
3. Complexes with SO

3.1. Synthesis

Attempts to trap SO with reactive transition-metal complexes cannot be regarded as promising because of its extremely rapid disproportionation [Eq. (1)].[9] *Agarwala* et al. reported that thermolysis of *trans*-2,3-diphenylthiirane 1-oxide in the presence of $[Rh(PPh_3)_3X]$ (X = Cl, Br) afforded products $[Rh(PPh_3)(SO)(\mu\text{-}X)]_2$, but these were identified solely on the basis of IR spectra and PPh_3-induced degradation.[116] The analogous reaction with $[Ir(dppe)_2]^{\oplus}$ (DPPE = 1,2-bis(diphenylphosphino)ethane), however, gave complex **31**. The disproportionation of SO

$[Ir(dppe)_2(S_2O)]^{\oplus}$ **31**

obviously competes successfully with its complexation.[117] This problem can be avoided if reaction (2) is transferred to the coordination sphere of a transition metal. The first unambiguously characterized complexes with terminally bound SO were indeed obtained in this way [Eq. (38)].[118,119] Reaction (38) proceeds smoothly at temperatures below 0°C, whereas free thiirane 1-oxide decomposes to SO and C_2H_4 only above 100°C.[11,12,16,19] The coordination to a transition metal thus lowers the activation energy for ring opening by an appreciable amount. Reaction (38) cannot be automatically extended to other



(38)

M \ R	*i*Pr	*cyclo*-C_6H_{11}
Rh	**32a**	**32b**
Ir	**33a**	**33b**

systems[120] (see Section 4.1); the only comparable reaction is the generation, in moderate yield, of the SO-bridged complexes **34a**, **b**

$[\{(RC_5H_4)Mn(CO)_2\}_2(\mu\text{-SO})]$ **34a**, R = H; **b**, R = Me

by the photochemical reaction between $[(RC_5H_4)Mn(CO)_3]$ and thiirane 1-oxide (R = H,[121] Me[119]) or diphenylthiirene 1-oxide (R = Me[122]).

Polynuclear complexes with bridging SO are readily accessible by the oxidation of sulfido complexes. The known examples of this reaction type are summarized by Equations (39)–(41). The formation of complexes **36b**,**c** is supported only by spectroscopic evidence.

$$[\{(C_5R_5)Mn(CO)_2\}_2(\mu\text{-S})] \xrightarrow{O_2} [\{(C_5R_5)Mn(CO)_2\}_2(\mu\text{-SO})] \quad (39)$$

34a, **c**

a, R = H[123]; **c**, R = Me[124]

$$[\{Fe_3(CO)_9\}(\mu\text{-S})_2] + \text{CPBA} \longrightarrow [\{Fe_3(CO)_9\}(\mu\text{-S})(\mu\text{-SO})] \quad (40)$$

35[117, 125]

CPBA = 3-chloroperbenzoic acid

$$[\{Fe_2Pt(CO)_6(PPh_3)_2\}(\mu\text{-E})_2] + \text{CPBA} \longrightarrow [\{Fe_2Pt(CO)_6(PPh_3)_2\}(\mu\text{-E})(\mu\text{-EO})] \quad (41)$$

36a-c[117]

a, E = S; **b**, E = Se; **c**, E = Te

Three related reactions probably proceed similarly, but are less well understood: the synthesis of **35** from $[Fe(CO)_5]/NaOH/Na_2SO_3/H_2O_2$,[126] of **37** from $[p_3Rh(S_2CO)]^{\oplus}$[127] (P_3 = 1,1,1-tris(diphenylphosphinomethyl)ethane), and of **38** from cobalt sulfide and cyanide by air oxidation.[128] Attempts to prepare the μ-SeO complex analogous to **37** led instead to the μ-Se_2 complex.[129]

$[(p_3Rh)_2(\mu\text{-SO})_2]^{2\oplus}$ **37** $[Co_4(CN)_{12}(\mu\text{-S})_3(\mu\text{-SO})]^{8\ominus}$ **38**

As a preparative method, the oxidation of sulfido ligands has its limits. It proved impossible to oxidize the second chalcogen atom of the cluster **35**;[117, 125] the electron-withdrawing SO group apparently makes further electrophilic attack more difficult. *Balch* et al. have reported that the A-frame complex $[\{Pd_2(dppm)_2Cl_2\}(\mu\text{-S})]$ (DPPM = bis(diphenylphosphino)methane) is oxidized to the μ-SO_2 complex even when only one equivalent of CPBA is used.[130]

In two cases thionyl chloride proved a suitable reagent for the introduction of an SO ligand: namely, the preparation of **35** from $[Fe_3(CO)_9(\mu\text{-S}t\text{Bu})]^{\ominus}$[131] and the synthesis of **39**[29] by a reaction analogous to Equation 12. *Vanderpool* and *Abrahamson* reinvestigated the oxidative addition

$[Fe\{P(OPh)_3\}_2(CO)_2(SO)]$ **39**

of thionyl chloride to the Vaska complex[132, 133] and found that the expected product $[Ir(PPh_3)_2(CO)Cl_2(SOCl)]$ is only formed when $SOCl_2$ is always in excess; otherwise, the SO_2 adduct **4** (Fig. 4) is formed, possibly by a second addition step followed by decomposition of the intermediate μ-SO complex.[134]

3.2. Structure and Bonding

The frontier orbitals of SO are largely similar in energy and size to those of CO (Fig. 8);[119] the two extra valence electrons occupy the antibonding 3π orbital and are responsible for the $^3\Sigma^-$ ground state of SO. On coordination to an $[M(PR_3)_2Cl]$ fragment (M = Rh, Ir), these electrons bring about the bending of the M–S–O unit; spin pairing takes place, resulting in a lone pair localized at the sulfur.[119] The coordination of diatomic molecules in linear, bent, or side-on geometry has been thoroughly analyzed by *Hoffmann*.[135] According to his analysis, the compounds **32a**,**b** and **33a**,**b**, like $[Rh(PiPr_3)_2Cl(O_2)]$,[136] should prefer the η^2 coordination, but the electronic asymmetry of the SO ligand makes the bent η^1 coordination more favorable. Less electron-rich systems would have to be employed to realize linear coordination.[137]

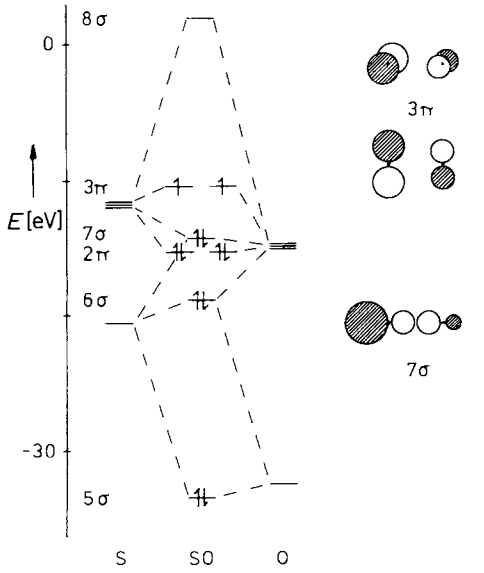


Fig. 8. MO diagram and frontier orbitals of SO [119].

Each known coordination mode of SO has been confirmed by one X-ray structure analysis (Fig. 9). Disorder of Cl and SO in the crystal of **33a** allowed only a rough de-

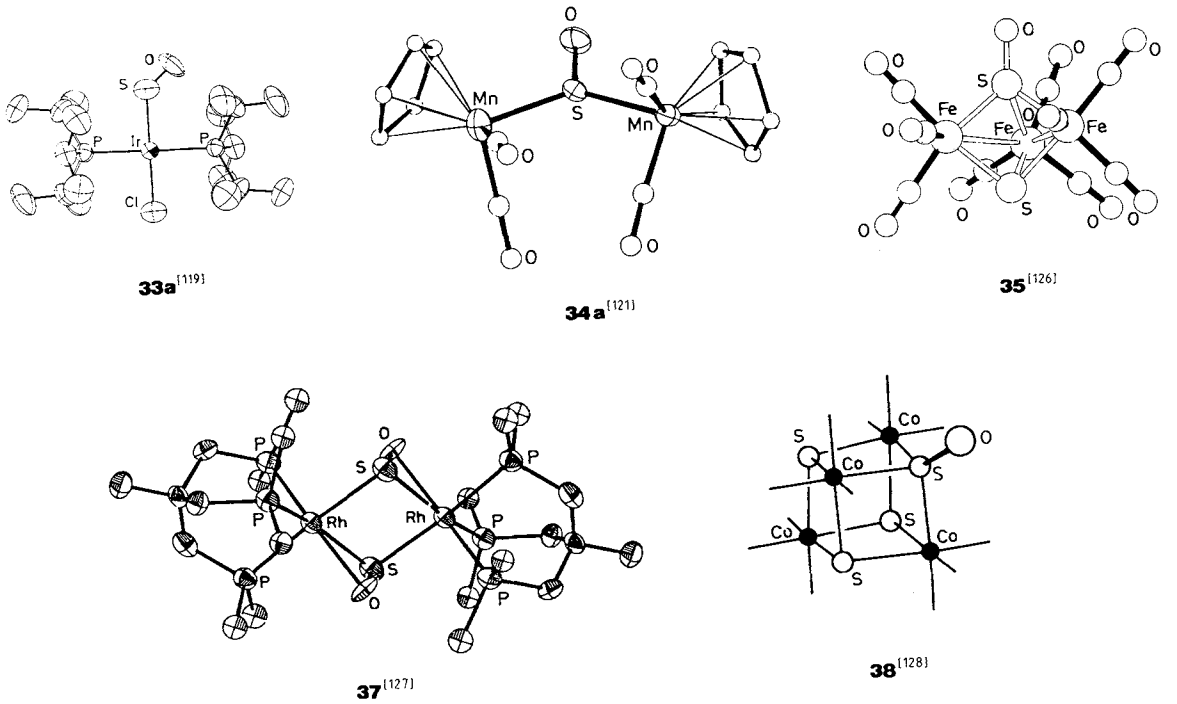

Fig. 9. Structures of the SO complexes **33a**, **34a**, **35**, **37**, and **38** in the crystal. (The unlabeled atoms are carbon atoms.)

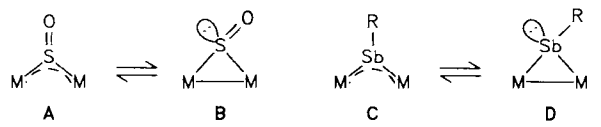
termination of the S–O bond length (139 pm),[119] some 9 pm shorter than in free SO.[5] However, the SO stretching frequency of **32a,b** and **33a,b** (ca. 1070 cm^{-1}) is markedly lower than in free SO (1136.7 cm^{-1}[5]), which unambiguously indicates a weakening of the S–O bond on coordination.

The accommodation of a further metal fragment at the lone pair of a bent M–SO group leads to μ^2-bridged complexes of the type **34**. The long Mn–Mn distance of 386.2(1) pm in **34a** rules out metal–metal bonding,[121] and SO thus functions here as a 4-electron donor (Scheme 1, **A**). A conceivable alternative would be the valence tautomer **B** with Mn–Mn bonding and a bent SO unit as 2-electron donor. The same tautomerism is seen in the isoelectronic stibinidene (stibanediyl) complexes (Scheme 1,

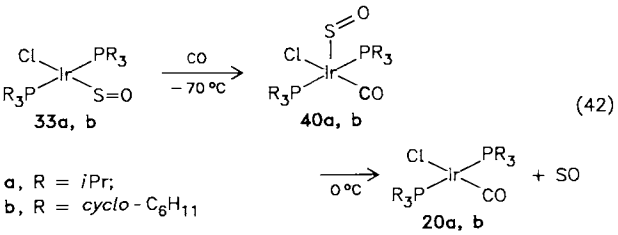


Scheme 1.

C and **D**) and is responsible for the amphoteric behavior toward Lewis acids and bases.[138] The μ-SO complexes **34a–c** should show similar chemical properties. SO also contributes four electrons to the bonding in the *nido*-cluster **35** and in the binuclear complex **37**. Noteworthy in the structure of **35** is the S–S contact of 272 pm, which could indicate a weakly bonding S–S interaction.[126] Complex **37** is the only known example of side-on coordination of SO. The S–O bond is lengthened to 168(1) pm,[127] which is approximately equal to the sum of the single-bond radii of S and O (175 pm). The cobalt cluster **38** can be better described as containing $S^{2\ominus}$ and $SO^{2\ominus}$ (rather than SO) ligands, each acting as a 6-electron donor.[128] The very low S–O stretching frequency (995 cm^{-1}) supports this view.

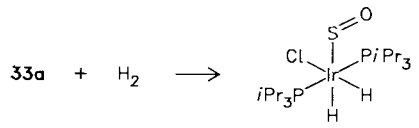
3.3. Reactivity

The most extensively studied compounds are the square-planar d^8-complexes **32a,b** and **33a,b**. Whereas the rhodium complexes **32a,b** react with CO, even at −70 °C, with displacement of the SO ligand, the analogous iridium complexes **33a,b** form the pentacoordinate intermediates **40a,b** [Eq. (42)]. These decompose in solution at 0 °C but in the solid state only at room temperature; the SO given off can be identified by mass spectrometry.[119] Complexes **32a,b** and **33a,b** are thus promising new reagents, from



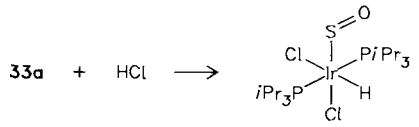
(42)

which SO can be released under much milder conditions than, for example, those of Equation (2). Complex **33a** undergoes oxidative addition with H_2 and HCl [Eq. (43) and (44)].[139] The products, **41** and **42**, respectively, correspond to the $Ir^{[1]}$–SO_2 complexes **22a** and **23a**, respectively. The reactions (42)–(44) thus demonstrate the close analogy between SO and SO_2 complexes.



(43)

41



(44)

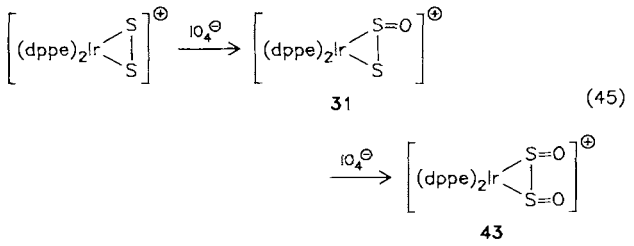
42

Another typical property of η^1-bonded SO is that it is easily oxidized. For example, CPBA converts **32a** and **33a** into the SO_2 complexes **15a** and **16a**, respectively.[119] Oxygen in the air is sufficient to oxidize the iron complex **39** to **2** (Fig. 3).[29] Bridging SO, however, is not easily oxidized, which is consistent with its role as a 4-electron donor.

4. Complexes with S_2O and S_2O_2

4.1. Synthesis

Almost all known syntheses of S_2O and S_2O_2 complexes are based on the oxidation of S_2 units bound to metal centers. *Schmid* et al. succeeded in preparing the first complexes of unstable sulfur oxides in this way [Eq. (45)].[140, 141] CPBA has proved once again to be a useful



(45)

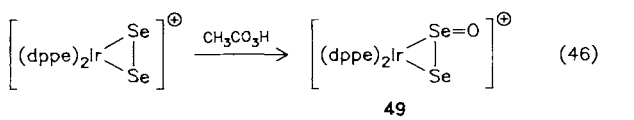
31

43

electrophilic oxygen-transfer reagent; apart from **31** and **43**, the mononuclear compounds **44**–**48** were synthesized.

$[Cp_2NbCl(S_2O)]$ **44**[116] $[Cp^*Mn(CO)_2(S_2O)]$ **45**
$[Cp^*Mn(CO)_2(S_2O_2)]$ **46** $[Cp^*Re(CO)_2(S_2O)]$ **47**
$[Cp^*Re(CO)_2(S_2O_2)]$ **48**[124]

The synthesis of the first Se_2O complex by oxidation with peracetic acid [Eq. (46)][117] is particularly worthy of



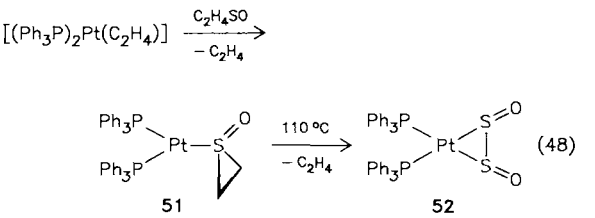
(46)

49

mention. Occasionally the oxidizing power of atmospheric oxygen has proved sufficient; **45**[142] and (in low yield) the S_2O-bridged complex **50** [Eq. (47)][143] were prepared in this way.

(47)

50



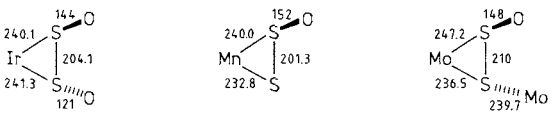
(48)

51 52

Lorenz and *Kull* have recently reported the synthesis of a thiirane 1-oxide complex of platinum, **51**, which is converted into the S_2O_2 complex **52** at 110°C [Eq. (48)].[144] Complex **51** is unusual in several respects (apart from its stability): its phosphorus atoms are nonequivalent in the ^{31}P-NMR spectrum and its SO stretching frequency (953 cm^{-1}) lies well outside the expected range for *S*-coordinated sulfoxides.[145] An η^2-SO coordination has also been considered for **51**, which would however be without precedent.[145] Three-membered rings bearing electronegative substituents usually undergo insertion reactions with Pt^0 complexes, forming platinacyclobutanes,[146] but the authors rule out this possibility for **51**. The SO frequencies given for **52** are also unusual; they lie ca. 200 cm^{-1} lower than for **43**,[117] **46**, and **48**.[124]

4.2. Structures

X-ray structure determinations have been reported for three compounds; relevant details are summarized in Figure 10. On coordination to a $[Cp^*(CO)_2Mn]$ fragment, the S–S bond length, in particular, increases appreciably (free S_2O: *d*(S-S) 188.2 pm, *d*(S-O) 146.4 pm, ∢(SSO) 118.3°[5]).[142] This is attributable to charge transfer from the HOMO of the metal fragment to the π^* orbital of S_2O. The high π-acceptor capability of the S_2O ligand is also reflected in the CO force constant (15.83 N cm^{-1}), which is significantly greater than in the starting material $[Cp^*Mn(CO)_3]$ (15.30 N cm^{-1}).[124] The S–O bond also is weakened on coordination, as can be seen from the increased bond length and the reduced stretching frequency (1156 to 1056 cm^{-1}).[142] In the binuclear complex **50**, the S–S bond is longer than a normal single bond.[143] This presumably corresponds to the first stages of breaking the S–S bond, a process that is complete in the cluster **35** (Fig. 9).



43[140] **45**[142] **50**[143]

Fig. 10. Part of the structure of the S_2O_2 complex **43** and the S_2O complexes **45** and **50** in the crystal. Bond lengths in pm.

The oxidation of $[Ir(dppe)_2(S_2)]^{\oplus}$ to the S_2O_2 complex **43** leaves the geometry of the IrS_2 ring practically unchanged. The S–S bond length, which in free S_2O_2 also corresponds to a single bond (202.5 pm),[5] is only marginally increased. However, the S_2O_2 ligand in **43** displays a torsion angle of 68°,[140] whereas the free molecule is planar. Complexes **46** and **48** are formed as mixtures of two isomers; presuma-

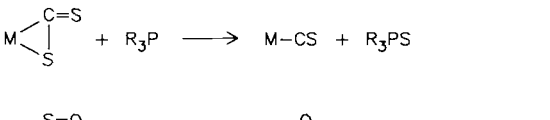
bly one is the *anti* isomer corresponding to **43** and the other is the *syn* isomer.[124]

4.3. Reactivity

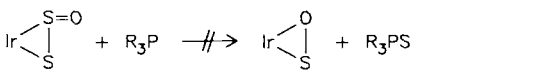
S_2O_2 complexes are characterized by ease of reduction. In solution the complexes **46** and **48** undergo spontaneous conversion to the S_2O complexes **45** and **47**, respectively;[124] **43** can be deoxygenated to **31** with PPh_3.[141] More reactive still is the Se_2O compound **49**, which, for example, oxidizes thiols to disulfides.[117]

With excess PPh_3 the S_2O and S_2O_2 complexes are reduced to various products. Complex **44** gives $[Cp_2Nb(O)Cl]$ and Ph_3PS.[117] Complex **43** is broken down completely to $[Ir(dppe)_2]^{\oplus}$, Ph_3PO and Ph_3PS being formed in a 1 : 1 ratio.[140]

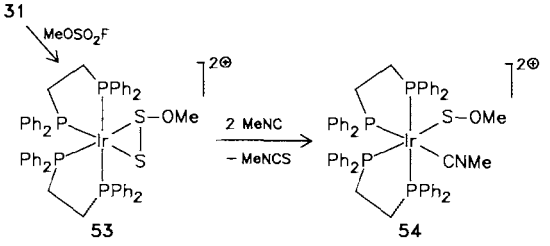
The attempt to convert **31** into an η^2-SO complex, by analogy with the abstraction of sulfur from CS_2 complexes [Eq. (49)],[147] was unsuccessful [Eq. (50)].[117] Nucleophilic attack on the endocyclic sulfur is successful, however, if the oxygen is first methylated [Eq. (51)].[148]



(49)



(50)



(51)

Complex **53** was characterized by X-ray structure determination; a comparison with the S_2O complex **45** shows a conspicuously (10 pm) longer S–O bond. The end product **54** can be considered as an Ir^{III} complex of the *O*-methylsulfenate ligand $MeOS^{\ominus}$.

5. Complexes with SO_3 and with Cyclic Sulfur Oxides

SO_3 is a strong Lewis acid and therefore reacts with a variety of bases to form adducts having tetracoordinated sulfur.[5] (Transition-metal complexes of the form $[L_nM(SO_3)]$ can, consistent with their chemical properties, be regarded as sulfito complexes; i.e., the bonding electron pair is, as usual, considered to originate from the ligand.) A coordination at oxygen is only conceivable with the strongest Lewis acids. Examples are the adducts with $SbCl_3$ and $SbCl_5$,[149] which, however, have also been formulated as chlorosulfates.[150] No structure determinations have been performed.

The compounds **55**[151] and **56**[152] have been unambiguously demonstrated to be *O*-adducts. On coordination, the conformation of the S_8O ring undergoes reversible change, the oxygen changing its position from axial to equatorial. The S–O bond in **55** is longer than that in free S_8O by 7 pm and the neighboring S–S bonds shorter by 9 pm. Similar bond lengths are found in the adduct **56**, in which the $OSbCl_5$ groups, however, are axial. Complex **56** is notable in particular for its formation from S_6O.[152]

$S_8O \cdot SbCl_5$ **55** $S_{12}O_2 \cdot 2SbCl_5$ **56**

Sulfur rings are easily opened and broken down to smaller units by transition-metal complexes; the only example of an intact S_n molecule as a ligand is in the compound $[Ag(S_8)_2]AsF_6$.[153] In view of the lability of cyclic sulfur oxides, it is likely to be difficult to obtain transition-metal complexes containing them as ligands. They may, however, be suitable sources of smaller S_nO units.

6. Summary and Prospects

Many preparative and structural studies have demonstrated the versatility of SO_2 as a ligand. Correlations between structure and reactivity are beginning to be recognized. Future studies will be able to build on these results and to develop the chemistry of coordinated SO_2. The chances of generating otherwise unstable compounds in the protecting environment of a transition metal seem particularly promising.

The unstable lower sulfur oxides SO, S_2O, and S_2O_2 can be stabilized in mono- and polynuclear metal complexes. Preliminary results show that the analogous selenium and tellurium compounds are also accessible, but studies of the reactivity of these compounds are still in their infancy. The experience gained with SO_2 complexes should be transferable to such systems and should thus help to exploit the lower sulfur oxides as synthetic "building blocks."[155]

I should like to thank Prof. Dr. M. Herberhold and Prof. Dr. E. Weiss for making unpublished results available, my co-workers, in particular Dr. Franz-Erich Baumann and Dipl.-Chem. Johanna Leissner, for carrying out much of our own work that has been described here, Dr. Christian Burschka for X-ray structure determinations, and the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG for generous financial assistance.

Nuclear Quadrupole Interaction and Time-Resolved Perturbed γ-γ-Angular Correlation Spectroscopy: Applications in Chemistry, Materials Science, and Biophysical Chemistry

New Analytical Methods (31)

By Anton Lerf* and Tilman Butz

The study of nuclear quadrupole interactions, i.e. of the strength, symmetry, and orientation of the electric field gradient tensor, yields valuable information on charge density distributions on an atomic scale. Apart from the nowadays "conventional" methods of NMR and Mössbauer spectroscopy there is yet another technique: time-resolved perturbed γ-γ-angular correlation spectroscopy. This technique is very well suited for applications in chemistry (e.g. comparative studies of bond conditions of inorganic complexes in the solid and in solution or in the melt), in molecular biology (e.g. intramolecular dynamics in biomolecules), and in materials science (e.g. investigation of catalyst surfaces) because of, inter alia, the extremely small sample requirements and the temperature independence of the sensitivity. The variation of the electric field gradient tensor (strength, symmetry, possibly orientation) is observed as a function of external parameters or, in the case of reactions, as a function of the degree of reaction. The interpretation of results requires the assignment of observed signals to known species or configurations. In this progress report we review modern areas of application of perturbed angular correlation spectroscopy.

1. Introduction

NMR and Mössbauer (ME) spectroscopy are well established techniques that have become indispensable in chemical laboratories. In contrast, a further hyperfine spectroscopic technique, namely perturbed angular correlation (PAC), is practically unknown to chemists. The reasons for this are that the technique requires the use of radioactive material, and that its application was for decades almost exclusively confined to the domains of the nuclear physicist.[1-8] Only since about 1970 has it been applied to any notable extent to problems in solid state physics, chemistry, and biology.

The method relies on the fact that, due to conservation of angular momentum, the direction of emission of a particle in a nuclear decay is strictly correlated with the orientation of the nuclear spin. Since the nuclear spins are normally randomly oriented, "information" on the spatial correlation is lost. If, on the other hand, the nuclei are oriented in an applied external magnetic field at very low temperatures, different count-rates can be measured with detectors positioned at 0° and 90° with respect to the axis of orientation; this difference is called anisotropy. Since orientation of the nuclei[6] usually requires temperatures in the mK range, such a method of measurement is not suitable for chemical applications. There is, however, a further method for the detection of anisotropy: angular correlation (theoretically predicted in 1940,[9] first demonstrated experimentally in 1947[10]). For this, excited nuclei, which decay via a particle cascade (see Fig. 1), are used. With the observation of the first particle, a sub-ensemble of the ensemble of randomly oriented nuclei is selected. By measuring in coincidence, only those second particles which are emitted by this sub-ensemble are detected. This leads, irrespective of the nature of the particles (α,β,γ-particles or CE[*]), to different coincidence count-rates in detectors positioned at 90° and 180°. However, the measurement of α- and β-particles is less suited for applications in chemistry, as these particles are easily absorbed in the reaction vessel. The nuclear orientation can also be achieved by nuclear reactions via particle bombardment in accelerators. If the

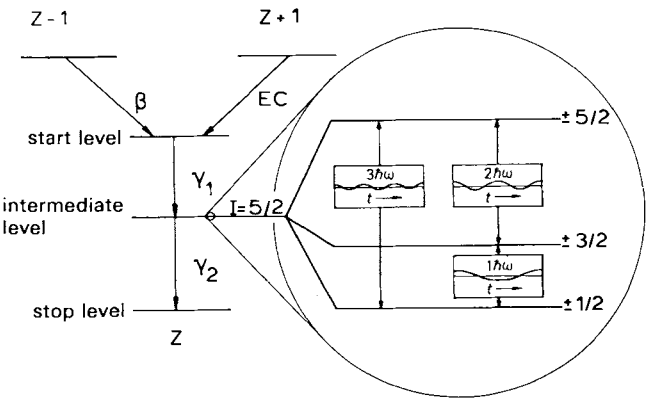

Fig. 1. Left: Schematic description of the decay of an excited nucleus with nuclear charge Z via a γ-γ-cascade. The start level can be populated via β-decay (mother isotope with nuclear charge Z−1) or via an EC-process (EC = electron capture; mother isotope with nuclear charge Z+1). If the start level itself is sufficiently long-lived ($\tau_{1/2} \geq 1$ h), one speaks of an isomeric decay. Right: Magnified presentation of the intermediate I = 5/2 level, split by NQI. If the lifetime τ_N of this state is sufficiently long ($\tau_N = 1$ ns–1 μs) the nuclear spin precession frequencies $n\omega$ (or their superposition) corresponding to the energy differences can be observed (see also Section 2).

angular distribution of the emitted particles is referred to the direction of the beam the "perturbed angular distribution" (PAD)[11] is obtained. A large number of isotopes are available for PAD studies,[11] of which ^{19}F[12] is very promising for applications in chemistry, provided the problems associated with radiation damage in the sample are brought under control. Until now, almost exclusively γ-γ-angular correlation spectroscopy has found applications in chemistry. The angular correlation can be perturbed via the interaction of nuclear moments with extranuclear fields,[13-15] provided the nucleus remains in the intermediate excited state for a sufficiently long time. Perturbations by magnetic interactions, especially by hyperfine fields in magnetically ordered systems, have been studied extensively and are well documented in Tables[16] and review articles by *Rinneberg*[17] and *Forker* and *Vianden*.[18] A second way to perturb the angular correlation is based on the interaction of the nuclear quadrupole moment with electric field gradients (EFG). These result from the charge density distribution, which, in turn, reflects the nature of the chemical bond. The investigation of the nuclear quadrupole interaction (NQI) by PAC was boosted when time integral PAC was superseded by the time differential method (TDPAC spectroscopy).[*] Since the latter technique yields much more detailed information (e.g. it resolves sites differing in charge density distribution in the same material) we restrict ourselves to this method in this article. The application of TDPAC spectroscopy to chemically oriented questions is reviewed in several articles.[17-22] *Vargas*[19] and *Adloff*[20] concentrate on chemistry after nuclear decays ("hot atom chemistry", "after-effects", see also *Thun*[23]).

Here, we report on modern TDPAC spectroscopic investigations which open a wider area of applications in chemistry. A brief introduction to NQI and to the theory of TDPAC spectroscopy is followed by a description of experimental aspects (instrumentation, data treatment, sample preparation). Further, we discuss the advantages and disadvantages of this technique compared to NMR and Mössbauer spectroscopy. In the subsequent overview of areas of application of TDPAC spectroscopy in the border region between chemistry, physics and biology we select examples to show how this technique is capable of yielding new information that cannot be obtained otherwise. Apart from some studies on liquids, the examples from the area of materials science form the largest part of the article (amorphous solids, surfaces, probe-specific interactions on an atomic scale, structural phase transitions, and solid state reactions). Biological applications of TDPAC spectroscopy are discussed only briefly, since they are reviewed extensively in a recent article by *Bauer*.[24]

2. Theory of Nuclear Quadrupole Interactions

A non-spherical nucleus, when subjected to an inhomogeneous electric field, adopts certain orientations with respect to the gradient of this field,[25-27] i.e. it behaves similarly to a magnetic dipole in a magnetic field. The quantum-mechanical description yields for an axially symmetric EFG the energy eigenvalues

$$E_m = e^2 q Q \frac{3m^2 - I(I+1)}{4I(2I-1)} \quad \text{with } m = -I, -I+1, \ldots, I-1, I \qquad (1)$$

Here, eQ denotes the nuclear quadrupole moment, eq the largest component of the EFG tensor ($= V_{zz}$), I the nuclear spin, and m the quantum number which describes the possible orientations. For example a nuclear state with spin $I = 5/2$ splits into 3 substates (cf. Fig. 1), whose energy differences are

$$\Delta E_{m,m'} = E_m - E_{m'} = 3e^2 q Q(m^2 - m'^2)/40, \qquad (2)$$

i.e. $\Delta E_{\pm 3/2, \pm 1/2} = 6e^2 qQ/40 \equiv \hbar\omega_0$,
$\Delta E_{\pm 5/2, \pm 3/2} = 12e^2 qQ/40 \equiv \hbar 2\omega_0$,
$\Delta E_{\pm 5/2, \pm 1/2} = 18e^2 qQ/40 \equiv \hbar 3\omega_0$

In analogy to the Larmor precession one can imagine a nuclear spin precession with frequencies ω_0, $2\omega_0$, and $3\omega_0$. The EFG is defined as a traceless tensor, which in the principal coordinate system can be written as

$$\begin{pmatrix} V_{xx} & 0 & 0 \\ 0 & V_{yy} & 0 \\ 0 & 0 & V_{zz} \end{pmatrix} \quad \text{with} \quad V_{xx} + V_{yy} + V_{zz} = 0 \qquad (3)$$

The components are ordered in such a way that $|V_{zz}| \geq |V_{xx}| \geq |V_{yy}|$, and one defines the asymmetry parameter as follows:

$$\eta = |(V_{xx} - V_{yy})/V_{zz}| \qquad (4)$$

If $V_{xx} = V_{yy}$, then $\eta = 0$ and there is axial symmetry; otherwise one obtains $0 < \eta \leq 1$. A deviation from axial symmetry modifies the splitting of energy levels and, hence, the precession frequencies.

The relation between the charge distribution $\rho(r)$ and the EFG tensor can be written:

$$V_{\kappa\nu}(r) = \int \rho(r') \frac{(3\kappa\nu - \delta_{\kappa\nu} r'^2)}{|r - r'|^5} dx'dy'dz' \qquad (5)$$

$\kappa, \nu = x, y, z$; $\delta_{\kappa\nu}$ = Kronecker symbol (= 1 for $\kappa = \nu$; = 0 otherwise)

If a multipole expansion of the charge distribution is carried out, one notes that only the $l = 2$ multipole components contribute to the EFG. In principle one can deduce the EFG from point charge models or semi-empirical binding models,[24-28] from ab initio calculations of the charge distribution,[29,30] or from experimentally determined charge distributions.[31] Generally, the agreement between experiment and theory is poor. The main problem is the exact description of the quadrupolar core polarization—especially for the heavy elements—which is caused by an external EFG ("Sternheimer-effect"[32]). Despite these problems in the theoretical treatment of the EFG tensor, the experimental determination of its orientation, symmetry and magnitude provides very useful information for the chemist where other techniques fail.

[*] In integral PAC spectroscopy the coincidence count-rate is measured as a function of angle between detector without any time resolution. In contrast, in TDPAC spectroscopy the events are resolved in the time elapsed between the arrival of the first particle in one detector and the arrival of the second particle in the other detector.

3. TDPAC—A Short Introduction

3.1. Theory of TDPAC

The theory of time differential perturbed angular correlation[33, 34] will be outlined here only inasfar as it is relevant to the contents of this article.

The angular correlation can be written

$$W(\theta) = 1 + A_2 P_2(\cos\theta) + \ldots^{[*]} \tag{6}$$

Here, $W(\theta)$ denotes the coincidence count-rate between the two quanta which are detected at an angle θ with respect to each other. P_2 is a Legendre-polynomial. A_2 is the anisotropy of the cascade, which depends exclusively on nuclear properties.

If the nucleus remains for a period of time τ_N in the intermediate state (Fig. 1), the coincidence count-rate for samples without preferred orientation can be written as a function of θ and the time t as follows

$$W(\theta,t) = \exp(-t/\tau_N)(1 + A_2 G_2(t) P_2(\cos\theta) + \cdots) \tag{7}$$

$G_2(t)$ is the so-called perturbation function. In the case of an axially symmetric, static[**] EFG one obtains, e.g., for $I = 5/2$:

$$G_2(t) = \sum_{n=0}^{3} a_n \cos(n\omega_0 t) \tag{8}$$

$a_0 = 0.2;\ a_1 = 0.371;\ a_2 = 0.286;\ a_3 = 0.143$

Here, ω_0 denotes the precession frequency [cf. Eq. (2)]. This perturbation function contains all information on the NQI. The following modifications occur in practice:

(1) The finite solid angle of the detectors reduces the observable anisotropy A_2.

(2) Inequivalent probe sites in the unit cell or inequivalent sites due to the coexistence of several phases in the sample lead to a superposition of perturbation functions, e.g. for a two-phase system

$$G_2(t) = \alpha G_2^{I}(t) + (1-\alpha) G_2^{II}(t) \tag{9}$$

(3) A finite frequency distribution around a mean precession frequency ω_0 due to inhomogeneities yields, e.g., for a Lorentzian frequency distribution with a half width at half maximum δ, damped oscillations or line-broadening of the Fourier-transformed $G_2(t)$:

$$G_2(t) = \sum_{n=0}^{3} a_n \exp(n\delta\omega_0 t)\cos(n\omega_0 t) \tag{10}$$

(4) The finite time resolution of the spectrometer suppresses higher frequencies progressively. A crude approximation of the convolution of $\exp(-t/\tau_N)G_2(t)$ with the time resolution function of the spectrometer, which frequently is assumed to be Gaussian with a width ($\sim$HWHM) τ_{res}, yields

$$G_2(t) = \sum_{n=0}^{3} a_2 \exp\left(-\frac{1}{2}\tau_{res}^2 n^2 \omega_0^2\right)\cos(n\omega_0 t) \tag{11}$$

Note that the finite time resolution does not yield damped oscillations, but rather modified amplitudes of the cosine terms.

(5) The above Equations (6)–(11) have to be modified for samples with texture or oriented crystals. It is still possible, however, to use perturbation functions of the type described in Eq. (8). The intensities of the cosine terms then depend on the crystal orientation.

(6) If the EFG tensor deviates from axial symmetry, then the intensities and precession frequencies are also functions of the asymmetry parameter η.

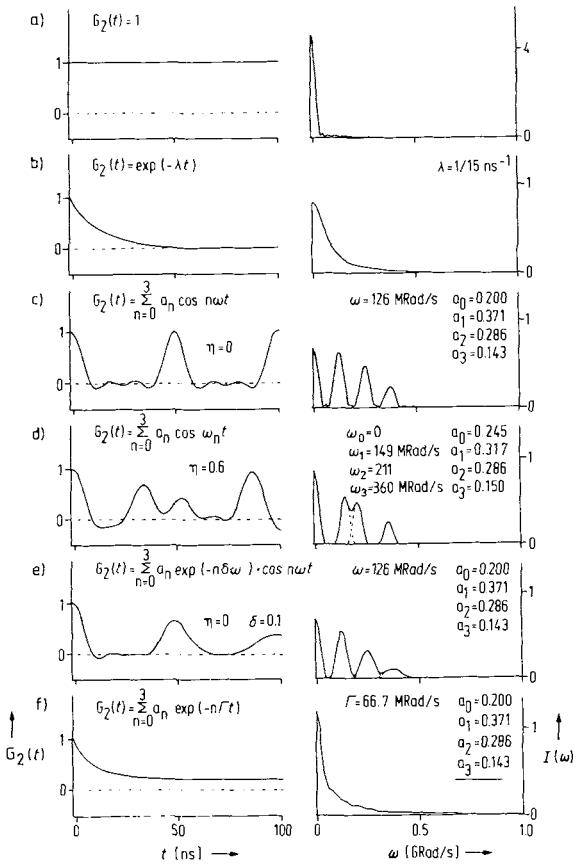

Fig. 2. Various typical perturbation functions $G_2(t)$ (left) and their Fourier-transforms (right, intensity $I(\omega)$ in arbitrary units) for pure NQI ($I = 5/2$, samples without preferred orientation). a) Absence of a perturbation, e.g. $V_{zz} = 0$ or extremely fast relaxation (decoupling of the nuclear spin from the environment). The width of the peak at $\omega = 0$ results from the time interval and the window function used (Kaiser-Bessel, $\beta = 4$). b) Fast relaxation (isotropic rotator) [33, 34]. The decay constant is proportional to the product of the mean square of the precession frequency and the reorientational correlation time. The Fourier transform is a Lorentzian, convoluted with the instrumental resolution function (cf. a). c) Time-independent NQI with axial symmetry ($\eta = 0$). d) Time-independent NQI with axial asymmetry ($\eta = 0.6$). e) As c), but with an additional frequency distribution $\delta = 0.1$ around the mean precession frequency ω. f) Time-independent NQI with a half width $\Gamma = 66.7$ Mrad/s centered around a mean frequency zero. The Fourier transform consists of three Lorentzians and a delta-function, convoluted with the instrumental resolution function (cf. a).

[*] Higher terms of the form $A_4 P_4(\cos\theta)$ are frequently neglected.

[**] Here, "static" means that, on the one hand, the variation of the EFG is very slow compared to the precession period $2\pi/\omega_0$, but, on the other, that the fluctuations (e.g. due to lattice vibrations) are so fast that the nucleus is unable to follow them and "feels" the time average only.

For illustration we show in Figure 2 a few important perturbation functions with their corresponding Fourier transforms.

3.2. Instrumental

Any TDPAC measurement requires the detection of a pair of γ-quanta which are characterized by their energy. Moreover, the time between the emission of the first and the second quantum has to be measured as accurately as possible. Finally, the detection efficiency per detector should be as close as possible to 100%, because the detection probability for a delayed coincidence is the product of two individual probabilities and would otherwise become excessively small.

Our TDPAC spectrometer (Fig. 3) consists of four detectors arranged in one plane. Each detector consists of a scintillation crystal (e.g. NaI(Tl), 1.75″×2″ ∅) with optical coupling to a photomultiplier. The information obtained from the detectors is processed in two different ways and analyzed independently. In the so-called "slow" circuit the signals are analyzed with respect to their γ-energies (proportional to the pulse area) and coincidences of suitable pulses from two detectors are formed (here, time resolution plays no role!). In the so-called "fast" circuit the time difference between two pulses is accurately analyzed, irrespective of the pulse height (energy). For this, the time of arrival in a detector is determined by a "constant-fraction trigger" (CFT) (rise of the pulse) and fed into a time-to-amplitude converter (TAC). The analog output signal of this TAC is stored in a multichannel analyzer (MC) via an analog-to-digital converter (ADC), provided a valid coincidence for one of the possible detector combinations was found in the "slow" circuit. According to the detector combination the corresponding subgroup of the multichannel analyzer is addressed via a "routing" unit. The activity of the sample must be kept sufficiently low (~ 10 μC) as to ensure that no further nuclear decay takes

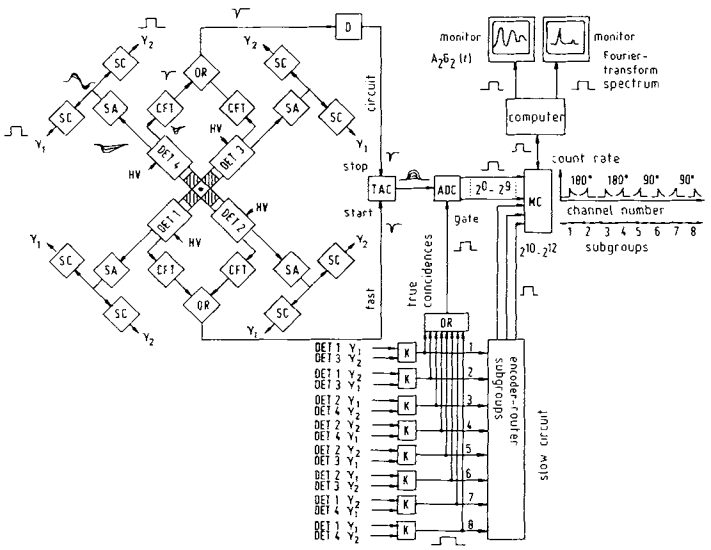

Fig. 3. Block diagram of a four-detector TDPAC spectrometer. DET = detector, HV = high voltage supply, OR = or gate, D = delay, SA = spectroscopy amplifier, SC = single-channel discriminator, K = coincidence, ● = sample. For details see text.

place during the pulsed operation of both circuits and the data storage in the multichannel analyzer (typically 10–20 μs). In this way, eight (out of 12 possible) coincidence spectra are stored simultaneously. Aside from a constant background, which results from chance coincidences (two nuclei decay at approximately the same time and the corresponding γ-quanta hit by chance two detectors and imitate a coincidence), one obtains an exponentially decaying curve of "true" coincidences; the precession signal $A_2G_2(t)$ is superimposed onto this curve (lifetime of the intermediate state!). The exponential curve decays to the right, if the start detector detects γ_1, and to the left if it detects γ_2. The zero time is shifted to the center of a multichannel subgroup by a delay line in the stop line. Further details on the "fast-slow" principle are given in Refs. [17, 35].

3.3. Data Processing

The data reduction starts with the substraction of the chance coincidence background in each subgroup. This background is determined from that part of the spectrum which contains no "true" coincidences, i.e. the range of "negative" time. Then all spectra decaying to the left are inverted, and all eight spectra are shifted to a common zero time t_0. This t_0 of each subgroup is predetermined by measuring prompt coincidences, e.g. using a ^{22}Na source. At the same time, the instrumental time resolution τ_{res} is also determined. We can now write the following ratio

$$R(t) = 2\,\frac{\sqrt[4]{W_{13}W_{31}W_{24}W_{42}} - \sqrt[4]{W_{14}W_{41}W_{23}W_{32}}}{\sqrt[4]{W_{13}W_{31}W_{24}W_{42}} + 2\sqrt[4]{W_{14}W_{41}W_{23}W_{32}}} \qquad (12)$$

where, W_{ij} denotes the "true" coincidence count rate between the detectors i (γ_1) and j (γ_2). The exponential decay factors cancel (exactly for $\tau_{res} = 0$). Moreover, the efficiencies of the detectors also cancel. This ratio is commonly presented as the so-called TDPAC spectrum, and for a powder sample we have $R(t) = A_2G_2(t)$ (A_4G_4-term neglected). Since the number of "true" coincidences decreases with time, the statistical accuracy also decreases with increasing delay time between the emission of γ_1 and γ_2 (error bars increase).

In many cases computer fits of appropriate theoretical functions [e.g. Eq. (10)] are performed. For this, complete analytical expressions for the effect of finite time resolution, as described in Ref. [36], are used. In addition to these fits, Fourier transforms of the reduced data $R(t)$ are very useful. In order to suppress side lobes we use a Kaiser-Bessel weighting function and implement the data set with an appropriate number of zeros to reduce truncation effects and to provide the required 2^N data points for the "fast Fourier transform routines". The calculation of $A_2G_2(t)$ and its corresponding Fourier-transformed spectrum is performed on a desk computer connected directly to the spectrometer, quasi on-line.

3.4. Isotopes and Sample Preparation

The radioactive isotopes are produced either in nuclear reactors (neutron capture), or in accelerators or cyclotrons

Table 1. Isotopes suitable for TDPAC spectroscopy according to [17]: The isotopes marked with an asterisk have been the most frequently used until now; mother isotope with half-life $\tau_{1/2}$; type of decay to the daughter isotope (cf. also Fig. 1); γ energies of the cascade; spin I and half-life $\tau_{1/2}$ of the intermediate state, and the anisotropy A_2 of the cascade.

Mother-isotope	$\tau_{1/2}$	Decay	Daughter-isotope	γ-Energy [keV]	I	$\tau_{1/2}$ [ns]	A_2 [%]

[a] Triple cascade (40 keV unobserved).

(nuclear reactions by particle bombardment). Table 1 gives a list of isotopes which are well suited for TDPAC spectroscopy according to the following criteria: Long lifetime of the mother isotope (or of the isomeric state); large anisotropy of the cascade; not too low γ-energies (absorption!); low degree of conversion of transitions (emission of conversion electrons instead of γ-quanta); suitably long lifetime of the intermediate state; large nuclear quadrupole moments.

The choice of isotope may present problems but should be guided by the following criteria: (1) In the ideal case one of the constituents of the sample under investigation has an isotope with an isomeric decay (no nuclear transmutation), i.e. there are neither problems with the sample preparation nor with "hot atom chemistry" (chemical or electronic after-effects[23,37]). (2) If the mother isotope is a constituent of the sample, there are no preparation difficulties, but one must bear in mind that, since the measurement is carried out on a foreign atom (impurity atom), chemical after-effects, e.g. the breaking of weak bonds,[37] can occur; electronic after-effects can occur if the rearrangement of the electron shell (for EC there is an Auger-cascade!) proceeds too slowly compared to the lifetime of the start level. This problem will not be encountered with metals, but may be with semiconductors and insulators. (3) If the daughter isotope is a constituent of the sample under investigation, there can be impurity-specific problems during sample preparation only. (4) If neither the mother nor the daughter isotope is a constituent of the substance of interest, there can be impurity-specific problems both during preparation and in the measurement.

It is not suggested that all of these problems will always be encountered. However, they should be considered before starting an investigation. After all, for a whole series of interesting applications an impurity probe is an absolute requirement (e.g. for nuclear transmutation doping, and for impurity-defect complexes). Generally, a substutional incorporation of the probe is desirable. This is best achieved when mother/daughter isotopes and the host material under investigation form isomorphous compounds or alloys with complete miscibility. In principle, two sample preparation procedures can be distinguished: (1) The radioactive probe is introduced into the substance under investigation during preparation. (2) The probe is produced in the ready-made sample through a nuclear reaction (irradiation with neutrons or ions), provided only negligible amounts of another radioactive isotope are produced besides the desired isotope. In the second case (but not in the first) one generally has to remove simultaneously produced radiation defects by annealing. In principle, 10^{10}–10^{12} probe atoms suffice, so only very small amounts of substance are required for an investigation. However, the preparation of a sample without an inactive carrier, i.e. without other, non-radioactive isotopes of the same element, is frequently difficult.

3.5. Comparison of Methods

In this section the advantages and disadvantages of TDPAC compared to the other better-known hyperfine spectroscopic techniques NMR/NQR and ME will be discussed. The main disadvantage of TDPAC is that one has to work with radioactive material. However, the activity levels required are very low (10–100 μC). In contrast thereto there are enormous advantages:

(1) The sample quantities can be very small (typically 1...100 mg).
(2) There is essentially no limitation to the choice of reaction vessel material because of the high energies of the γ-rays used (contrary to ME).
(3) The sensitivity is independent of temperature (no Debye-Waller factor as in ME; no Boltzmann factor as in NMR).
(4) Insensitivity to vibrations (contrary to ME): one can use, e.g. a stirred bath.
(5) No magnetic field is required and no radio frequency field (as in NMR).
(6) Small NQI's are more easily resolved then in ME.
(7) Contrary to NMR and ME it is practically impossible, for instrumental reasons, to detect only a part of the entire hyperfine spectrum (velocity range or field variation too small); moreover, the signal (= anisotropy) is a constant, which depends on nuclear properties only. This means that the sum of all observed spectral components of a TDPAC spectrum is constant. Therefore the sum of all inequivalent probe sites must always add up to 100%, even in heterogeneous systems (although problems can arise due to insufficient time resolution).
(8) Other than in the case of ME and NMR, there is practically no way in which the observed linewidth in the Fourier-transformed spectra (damping of the oscillations in the A_2G_2-spectrum) can be influenced by instrumental means; this means that small site inhomogeneities can be detected with high reliability.
(9) Reorientational motions of the EFG can generally be identified unequivocally and are easily distinguished from static inhomogeneous EFG-distributions.

(10) Finally, the isotopes that are suitable for TDPAC spectroscopy complement those amenable for ME and NMR in a useful way.

4. Applications to Solutions and Melts

For solutions and melts one normally obtains TDPAC spectra similar to those in Figure 2b, i.e. an exponential decay of the anisotropy with a decay constant[33,38]

$$\lambda_k = k(k+1)\tfrac{3}{5}\tau_c\langle\omega^2\rangle(4\cdot I(I+1)-k(k+1)-1) \quad k=2,4^{[*]} \qquad (13)$$

where $\langle\omega^2\rangle$ denotes the average squared NQI-frequency and τ_c the reorientational correlation time (tumbling motion). An estimate of $\langle\omega^2\rangle$ can be made by freezing the solution. If the value in the frozen solution agrees with that of the solid starting material which is to be dissolved, we have in both cases the same complex or the same ion complex. (If this is not the case then depolymerization or ligand exchange reactions must have taken place during dissolution.) One then assumes that the species in frozen solution are identical to those in the liquid state. This assumption is most likely justified for shock-freezing. When $\langle\omega^2\rangle$ is known, one can derive from λ_k the correlation time τ_c, which itself depends on the volume V of the tumbling species, on the temperature T, and on the viscosity η[**] of the solution, via the Debye-formula[40]

$$\tau_c = \frac{\eta V}{k_B T} \quad (k_B = \text{Boltzmann's constant}) \qquad (14)$$

Normally, the volume of the dissolved species is derived from the correlation time. By comparing measured values for $\langle\omega^2\rangle$ and τ_c for two different species one can distinguish between ligand exchange and polymerization processes: if the values for τ_c are comparable, but those for $\langle\omega^2\rangle$ differ, both species have a comparable size but differ in coordination or ligation, respectively; if the values for $\langle\omega^2\rangle$ are comparable, but those for τ_c differ, we have the same coordination, but a different degree of polymerization.

Despite the fact that the sensitivity of TDPAC spectroscopy is well demonstrated by a large range of observed decay constants,[41,42] only very few systematic studies have so far been carried out on solutions, the substances to be dissolved, and the frozen solutions. Examples are Hf-complexes[39] and $Cd(CH_3)_2$[22] in non-aqueous solvents. These complexes retain their integrity upon dissolution and, with the exception of Hf(tropolone)$_4$, are unsolvated in dimethylformamide and chloroform, where ligand exchange reactions occur and where associates are formed. With $^{99}Mo(^{99}Tc)$ the molybdate polymerization was studied as a function of pH.[43] Further studies, partly incomplete, have been carried out on In-porphyrins,[44] on aqueous In-solutions over the entire pH range,[45] and on Hf-solutions in HCl (0.01-9 M).[46-48] Further, the kinetics of $OH^{\ominus}/F^{\ominus}$ exchange in aqueous Hf-solutions[49] and of In-binding to AMP, ATP and other biomolecules has been investigated.[50]

Similar studies have been carried out on metal melts[51,52] and chalcogenide melts[*][53] with special emphasis on precursors of compound and associate formation. Such associates (discrete coordination sphere!) occur whenever heteroatomic interactions dominate over homoatomic interactions.

5. Applications in the Border Region of Solid State Chemistry/Physics

5.1. Amorphous Solids

In contrast to diffraction techniques and EXAFS studies, which in amorphous systems yield radical distributions of the nearest neighborhood only,[**] the determination of the NQI (tensor rank 2!) yields information on both the radial *and* angular distribution. From the hyperfine spectra, a V_{zz},η-distribution can be derived which serves to characterize the short range order.[54] The great advantage of TDPAC is that recrystallization processes and molecule and compound formation are observable at an extremely early stage. Here, the NQI parameters are assumed to be known and serve for an identification of intermediates and final products.

Despite the high sensitivity of TDPAC spectroscopy to variations in charge distribution in the near neighborhood of the probe atoms, and despite its virtual independence of long-range order, only a few TDPAC investigations have so far been carried out on amorphous systems. In the case of amorphous Ga[55] and Bi[56] [probe: $^{111}In(^{111}Cd)$], the model of "random dense packing of hard spheres" yields, in the point charge approximation, a V_{zz},η-distribution in good agreement with the observed spectra. In Figure 4 the time spectra and the corresponding Fourier transforms are shown for $^{111}In(^{111}Cd)$ in amorphous $In_{80}Ag_{20}$ and in the fully crystallized final state.[56] In accord with the composition and the In-Ag phase diagram, chiefly In_2Ag is formed, apart from metallic In-segregations. There is no short range order in the amorphous state, which can also be well described in the model of "random dense packing of hard spheres".

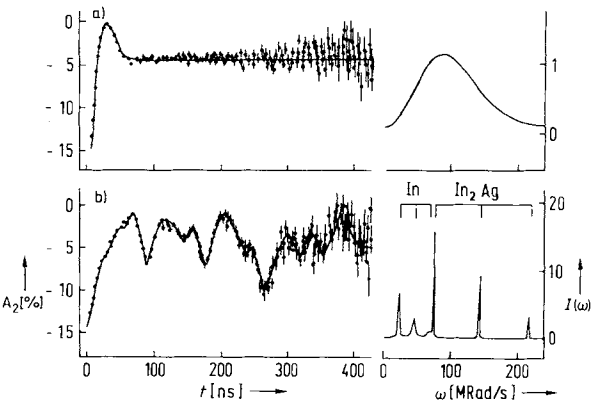

Fig. 4. TDPAC spectra (left) and corresponding Fourier transforms (right) of $^{111}In(^{111}Cd)$ (a) in amorphous $In_{80}Ag_{20}$ and (b) after recrystallization [56].

[*] For the case where $\eta \neq 0$ see Ref. [39].

[**] Not to be confused with the asymmetry parameter η.

[*] Investigated TDPAD-spectroscopically.

[**] Exception: "near edge structure" in EXAFS [57].

In a further investigation with $^{111}In(^{111}Cd)$, simultaneous compound formation (Ni-phosphides) and annealing of defects was observed in nickel amorphized by phosphorus-ion implantation.[58]

It should be emphasized that in the few TDPAC studies that have been carried out on solidified solutions, there is a wide temperature range below the solidification temperature in which molecules exhibit dynamics similar to that observed in the fluid phase ("superviscous state"[59-61]).

5.2. Surfaces

One can distinguish two extreme types of surface: The "perfect" surface (single crystals, ultra-high-vacuum!) and the "technical" surface with fractal dimension[62] (porous materials). For TDPAC spectroscopy, the radioactive probe is applied in atomic form in the first case (due to the small surface area in carrier-free form!), and in molecular form in the second case.

In the case of nearly perfect surfaces the identification of atomic configurations requires NQI parameters (V_{zz}, η, orientation) sufficiently different from each other and from the bulk values. It is also possible to monitor surface reactions identifying product species via the hyperfine parameters of already known species. Such studies are of great interest, especially for technical surfaces, where many of the conventional surface-sensitive techniques can only be used with difficulty, if at all. This is especially true for in situ studies, e.g. in the presence of reactive gases.

Up to now, only one study with $^{111}In(^{111}Cd)$ on an epitaxially grown In(111) surface has been reported in the literature.[63,64] The surface NQI was found to be roughly twice as large as the bulk value. In order to demonstrate that a probe at the surface was observed and not a probe-gas complex, a monolayer of non-radioactive indium was deposited. Then, only the bulk signal was observed, demonstrating the extremely short-range nature of the NQI in this system. Above 150 K, diffusion from the surface into the bulk was observed. Both the EFG orientation as well as the measured asymmetry parameter show that the probe environment is not that of a perfect (111) surface.

TDPAC investigations of reactions on technical surfaces have only been carried out on supported molybdenum catalysts (on Al_2O_3).[65] Figure 5a shows the TDPAC spectrum of $^{99}Mo(^{99}Tc)$ in a 0.24 M ammonium paramolybdate (APM) solution (case of fast relaxation, cf. Fig. 2b). When Al_2O_3 (surface area $\sim 150\ m^2/g$) is impregnated with this solution the tumbling motion of molybdate ions is stopped by adsorption and, hence, a static NQI (cf. Fig. 2c/d) is observed (see Fig. 5b). From a comparison of the V_{zz}- and η-values with those for crystalline APM (Fig. 5c), one can conclude that preferentially heptamers (or higher polymolybdates) are adsorbed. These polymolybdates remain intact after drying and calcination up to approximately 773 K. They can be completely decondensed by post-impregnation with K_2CO_3, which leads to a loss of catalytic activity for hydrodesulfurization.

Treatment of the calcined oxidic precursor with H_2/H_2S does not yield MoS_2, as commonly assumed, because the observed hyperfine interaction is about 30% higher than for crystalline MoS_2.[66] The discrepancy most likely results from hydrogen uptake during reduction/sulfidation, as has been shown by in situ studies on highly disperse "H_xMoS_2".[66] The proton uptake is hardly detectable by EXAFS, since it does not lead to an appreciable change in the Mo-S distance; however, it drastically modifies the charge balance and, hence, the NQI.

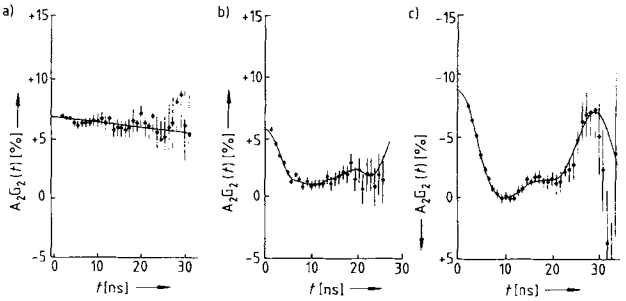

Fig. 5. TDPAC Spectra of $^{99}Mo(^{99}Tc)$ at 300 K. a) $(NH_4)_6[Mo_7O_{24}]$(APM) in aqueous solution; b) Al_2O_3 support impregnated with this solution, moist; c) crystalline APM·$4H_2O$, dissolved after irradiation, precipitated with EtOH. The spectra a) and b) were recorded with the 739 keV–181 keV cascade, the spectrum c) with the 739 keV (40 keV)–141 keV cascade. With $\omega = 230$ Mrad/s for crystalline APM·$4H_2O$ and a reorientational correlation time $\tau_c = 140$ nsec (derived from the spectra of solutions) a volume of 220 ± 50 Å^3 is determined, comparable to that of the $[Mo_7O_{24}]^{6\ominus}$ ion. The spectrum of the impregnated Al_2O_3 consists of a static contribution and a contribution with fast relaxation (the anisotropy does never reach or fall below zero, as in Figs. 2c–e). From this the degree of adsorption can be determined.

5.3. Probe-Atom-Specific Interactions on an Atomic Scale

5.3.1. Probe Atom–Defect Interactions

Usually,metals are irradiated at low temperatures (e.g. 4.2 K) with high energetic particles (photons, electrons, protons, neutrons, ions) in order to create defects (radiation damage). If the host metal has not been previously doped with probe atoms (= impurity atoms), the radiation damage can be at the same time as probe-ion implantation. In addition, vacancies can be frozen out by quenching the melt. Plastic deformation at room temperature, on the contrary, produces mainly extended defects (e.g. dislocations).[*]

The annealing of defects is usually carried out by isochronous tempering: the samples are kept for a fixed time (e.g. 10 min) at consecutively increasing temperatures and then cooled down to one and the same low measuring temperature. The defects—mainly interstitial atoms and vacancies—can be observed by TDPAC spectroscopy because they are in many cases trapped by the probe atoms during annealing and thus form probe atom-defect complexes. Otherwise they would be "invisible" due to their low concentration. Different complexes usually have different values for V_{zz} and η and, above all, differ in their EFG-tensor orientation. By the determination of these quantities—single crystal measurements are required to determine the orientation—the complexes can be charac-

[*] For compounds there are in addition defects due to non-stoichiometry or due to incorporation of components of another valency. The only TDPAC-example up to now for the latter case is the Ca- or Y-substitution in ZrO_2, in which the oxygen diffusion was studied [67].

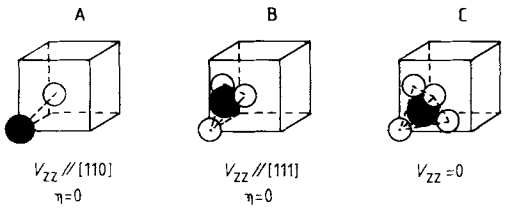

Fig. 6. Three different impurity-vacancy complexes in fcc lattices after [68]; ● = impurity atom, ○ vacant site. The first two complexes **A** and **B** can be distinguished according to the orientation of V_{zz}. The complex **C** (one impurity atom 4 vacant sites) shows no NQI and hence cannot be distinguished from a substitutional impurity without vacancies (these two types of coordination can be distinguished via the magnetic interaction [69]).

terized on an atomic scale. Figure 6 shows a selection of simple impurity-vacancy complexes. Defect production by various particle beams (and various particle energies!) and quench experiments are helpful for complex identification. The potential of PAC is recognized in the case of two or more coexisting complexes; the variation of the individual fractions with temperature yields information on the formation and dissociation enthalpies of the coexisting complexes and on their sequence during annealing. Usually, the *quantitative* interpretation of the individual fractions, including the "nearly unperturbed" fraction, and of the V_{zz} and η values still presents some problems. For the latter, however, there are now theoretical approaches.[70]

Since there are several review articles on the investigation of radiation damage in cubic (bcc, fcc) metals[71–76] we shall quote but a single example here. Gold, an fcc metal, was doped with ^{111}In(^{111}Cd), irradiated with 3 MeV electrons at 4.2 K, and isochronously annealed.[74,77,78] Figure 7 shows that at an annealing temperature $T_A = 77$ K there are

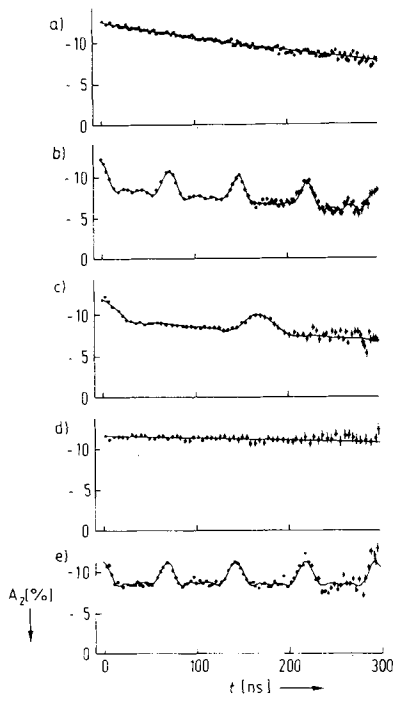

Fig. 7. TDPAC spectra of ^{111}In(^{111}Cd) in gold, irradiated with e^- at 4.2 K, and measured at 4.2 K after isochronous annealing at T_A = a) 77, b) 257, c) 320, d) 873 K. e) Spectrum of melt-quenched gold (T_A = 257 K) a) no impurity-defect complexes. b)+c) At first a discrete high-frequency component is observed (rapid sequence of signal maxima in b), and then a low-frequency component (in c) on top of a slowly decreasing background. d) All probes are in an unperturbed cubic environment.

defects present (slight decrease of the anisotropy with time), but they are not yet "trapped" by probe atoms. At $T_A = 257$ K about 30% of the probe atoms form a complex of type **A**. This is verified by comparison with a melt-quenched sample (cf. Fig. 7e) and above all by the determination of the EFG orientation. At $T_A = 320$ K a probe atom/3-vacancies complex (or a dislocation loop) is formed.

Investigations have likewise been carried out on the hcp-metals Cd[79,80] and Zn[81] and the compounds InSb,[84] InP[84,85] and $CdSiP_2$[86] [probe always ^{111}In(^{111}Cd)],[*] for which, because of the variety of possible defect types (differences in the sub-lattices?!), the interpretation of the TDPAC data becomes progressively more difficult. Interestingly, it is possible to "decorate" probe atom-vacancy clusters with atoms such as He,[87,88] C,[89] and O.[90] This leads to a shift of the NQI to higher V_{zz}-values. Such processes are of technical importance, since they, e.g., contribute to material embrittlement in reactors, above all in fusion reactors.

5.3.2. *Probe Atom–Impurity Atom Interactions*

Metal–Metal Interactions: In all the TDPAC studies thus far undertaken, noble metals were used as the reaction media for studying attractive interactions between probe atoms and impurity atoms, which are frequently also added in a high dilution.[91–93] The methodology is as described in Section 5.3.1 with the exception that, instead of defects, impurity atoms are introduced.

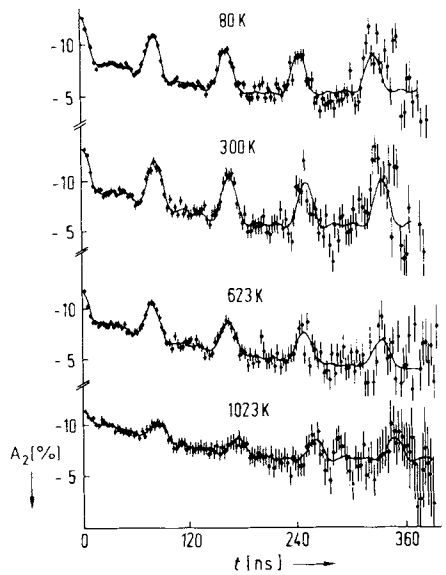

Fig. 8. TDPAC spectra of ^{111}In(^{111}Cd) in $Rh_{0.005}Cu_{0.995}$ at various temperatures, after [91].

Figure 8 shows an example for an attractive interaction between ^{111}In(^{111}Cd) and Rh in a copper matrix. The discrete frequency component, which is due to In–Rh pairs, progressively vanishes with increasing temperature as a result of pair dissociation.[**]

[*] Investigations of defects in semiconductors like Si [82] and Ge [83] and in insulators, respectively, are still at an exploratory stage [71, 72].

[**] For higher impurity concentrations higher aggregates of the type $In-Rh_n$ ($n > 1$) are formed [91].

From the temperature dependence of this discrete component one can derive the formation enthalpy. For the probe atom-impurity atom complexes in various metallic matrices thus far investigated, this enthalpy frequently agrees with the heat of formation calculated according to *Miedema*[94] for an intermetallic phase of the corresponding combination of elements and corrected for the coordination number.[95] If there is a pronounced tendency for the probe atom and impurity atom to form intermetallic phases, one should not overlook the possibility of molecule formation, even at very low concentrations. If these molecules are insoluble in the host matrix, aggregation and segregation occurs, in analogy to binary systems.[*] This, of course, poses the question of how many formula units of this aggregate are necessary in order to identify it as a "segregation" in the host matrix. It is suggested that one can speak of compound formation whenever all the NQI parameters (V_{zz}; η) of this probe atom-impurity atom complex are essentially identical to those of the pure intermetallic phase, even in the extreme case of a complex consisting of atoms of a single formula unit only.[**]

Metal-nonmetal interactions: An interesting example of the formation of a A_2B_3-type compound is the oxidation of In in a silver matrix.[101-104] Already at an In-concentration of 0.25 atom-%, two In-sites are observed with an ^{111}In(^{111}Cd) probe with V_{zz}- and η-values characteristic of In_2O_3, provided the oxidation temperature and the oxygen supply are sufficiently high. Parameters of the reaction kinetics can be derived from the "In_2O_3" fractions as a function of reaction time.[101, 103] Another example is the trapping of hydrogen at impurity atoms in metals.[105]

A remarkable special case is the conversion of a probe atom into a host atom by nuclear transmutation. Here, the probe atom-impurity atom interaction is so to speak "switched off" and the subsequent temporal evolution of the system is observed. However, a sufficiently long-lived start level of the γ-γ cascade (see Fig. 1) is required in order to allow sufficient time for the impurity atom to diffuse away. The only examples for this so far are the systems ^{181}Hf(^{181}Ta) in a Ta-matrix with oxygen,[106] hydrogen,[107] and oxygen and hydrogen simultaneously bound to it.[108]

5.4. Structural Phase Transitions

At structural phase transitions not only the lattice positions of the constituents change, but also, of course, the electron density distributions. This is usually easily detected via a variation of the NQI parameters. Despite the superiority of diffraction techniques to hyperfine techniques for the investigation of structural phase transitions, there are, nevertheless, cases where the structural changes are minute, despite large variations of the electron density distribution. Then, in contrast to diffraction techniques, there is no problem in determining the number and population of inequivalent sites by hyperfine spectroscopy. Furthermore, information on dynamic processes in the time window of hyperfine spectroscopy can be gained, e.g. fluctuations, and rotation and diffusion processes, which can be inferred only indirectly from diffraction data.[*]

Since the measurements are usually carried out with impurity probes, it is necessary to consider carefully for each system to what extent the dynamic processes are impurity-atom-specific.

5.4.1. *Displacive Phase Transformations*

Antiferroelectric Phase Transitions: Yeshurun et al.[108] have investigated the NQI at ^{181}Hf(^{181}Ta) probes in antiferroelectric $PbHfO_3$ and observed a critical behavior in the immediate vicinity of both phase transitions: on the one hand, the EFG diverges in a dispersion-like manner and additional high frequency spectral components show up, while on the other, one observes temperature-dependent linewidths. All observed effects are correlated with the sublattice polarization and the sublattice susceptibility, respectively. Apparently there are fluctuations in the vicinity of the phase transition, which slow down sufficiently to become noticeable in the NQI parameters.

"Charge-Density-Wave" Systems:[**] Among the "charge-density-wave" (CDW) systems the transition metal dichalcogenide 2H-$TaSe_2$ has been the most extensively studied.[110] This is built up from hexagonal layers with the sequence Se-Ta-Se Se-Ta-Se ... (in the 2H-modification the Ta has a trigonal prismatic coordination and the repetition length comprises two Se-Ta-Se sandwiches). The symmetry breaking at the onset of the CDW manifests itself in a redistribution of electron density, which is revealed in a dramatic way by the deviation of the EFG tensor from axial symmetry. In fact, this effect is much more pronounced than the changes in the electronic transport properties or in the associated lattice distortions. It is known from electron diffraction experiments that the commensurate superstructure is formed by three identical wave vectors, 120° apart from each other. Thus the two-dimensional unit cell with the dimensions $3a \times 3a$ (a = lattice constant in the hexagonal plane) comprises nine Ta-atoms. The phase between the charge density maximum/minimum and the Ta-lattice is virtually indeterminable from these measurements. From TDPAC measurements with ^{181}Hf(^{181}Ta) probes in this material (as for 2H-TaS_2; see Fig. 9) the number and population of inequivalent Ta-sites can be measured immediately.[112] One finds three sites with equal populations (A, B, C), one of which exhibits an extremely large asymmetry parameter ($\eta_A = 0.64$ for 2H-$TaSe_2$ and

[*] An example for this is the segregation of In dissolved in Al [96].

[**] The question of compound formation also arises in several very dilute binary systems, provided the probe and matrix exhibit a pronounced tendency towards compound formation. Whether this actually happens, or whether the impurity atoms are indeed highly diluted and on substitutional sites, could easily be decided by comparing NQI data of the dilute system with those of the relevant intermetallic phases for the corresponding element combination. With the exception of a few studies [97, 98], no attention has been paid to this problem in discussing the huge amount of data for EFG values in metals [99, 100].

[*] Dynamic processes in the GHz to THz-range can be investigated by inelastic diffraction methods.

[**] In CDW systems we have a static modulation of the conduction-electron density. With such, *Wilson* et al. [109] explained the formation of superstructures in some transition-metal chalcogenides with layer structures. Meanwhile CDW phenomena have been observed in several quasi one- and two-dimensional, metallic conducting compounds [111].

$\eta_A = 0.35$ for 2H-TaS_2, both at 10 K). At this lattice site $|V_{zz}|$ decreases compared to the unperturbed system above the CDW onset temperature; at the other two sites $|V_{zz}|$ slightly increases. Together with the orientation of the EFG-tensor determined on single crystals, it follows that the electron density maximum is centered *between* three Ta atoms and that the electron density must be fairly concentrated because of the relatively small perturbation of the peripheral Ta atoms (B, C) (formation of "Ta_3-clusters").

5.4.2. *Polymorphic Phase Transitions*

Besides the 2H-modifications of TaS_2 and $TaSe_2$, which are stable at room temperature, there is a high-temperature modification for both compounds with octahedrally coordinated Ta and a repetition length 1 (1T-TaX_2: CdI_2 structure type), which can be retained as a metastable phase by quenching rapidly to room temperature. Furthermore, there are modifications with alternating layers of both coordinations ($4H_b$, 6R). In Figure 10 the observed precession frequencies with $^{181}Hf(^{181}Ta)$ probes in TaS_2[113] and $TaSe_2$ during heating and cooling cycles are shown. In both systems, below 600 K and 500 K respectively, irreversible transitions from the 1T- to the 2H-structure take place, which are "smeared" over a broad temperature range and proceed via shear-transformations.[114] In this range, broad frequency distributions are observed rather than a superposition of 1T- and 2H-modifications.

For $TaSe_2$, the frequency jumps in the high-temperature range are exactly at those temperatures where structural transformations from the 2H to the mixed coordination phase and ultimately to 1T and back to 2H (with a large hysteresis) were observed according to X-ray data;[114] for TaS_2 there are no X-ray data available. In the mixed coordination phase, upon heating there is a *unique* well-defined precession frequency despite the simultaneous occurrence

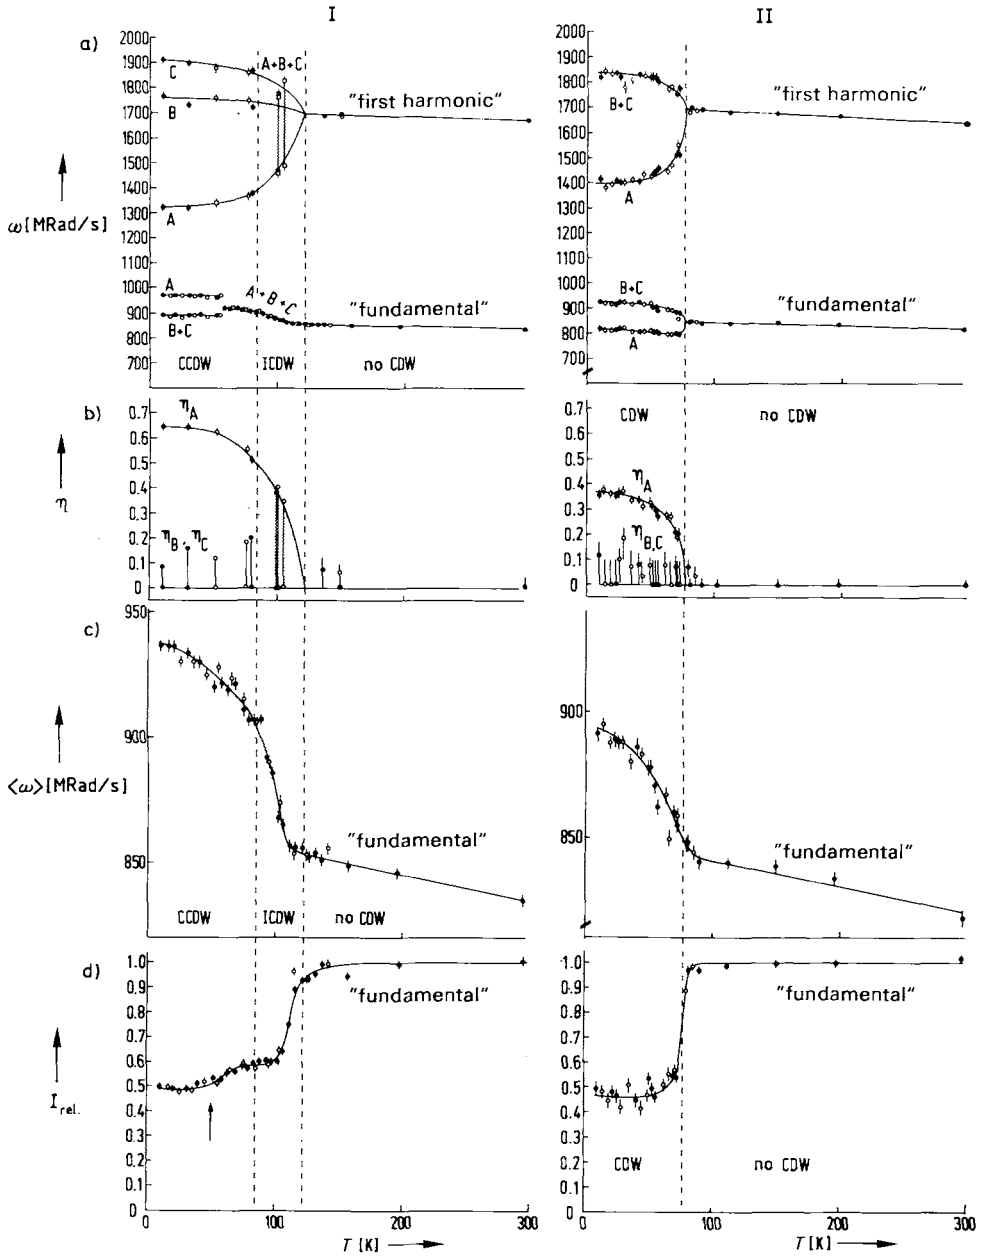

Fig. 9. NQI parameters versus temperature for the CDW phase of 2H-$TaSe_2$ (I) and 2H-TaS_2 (II) from TDPAC measurements with $^{181}Hf(^{181}Ta)$ probes (CCDW: commensurate CDW; ICDW: incommensurate CDW). a) Precession frequencies ω for fundamental (observable when the crystal is oriented with V_{zz} perpendicular to the detector plane) and first harmonic (observable when V_{zz} is in the detector plane midway between two detectors); the latter is resolved for 2H-$TaSe_2$ into three inequivalent Ta-sites (A, B, C) with equal population. Note, that in both cases V_{zz} at the A-site decreases at the CDW onset due to the development of η_A, despite an increase of ω_A (fundamental) in the case of 2H-$TaSe_2$. b) Asymmetry parameter: η_A increases at the CDW onset as for a second order phase transition; η_B and η_C are both small and can not be separated. c) Average precession frequency (fundamental): for 2H-$TaSe_2$ a small change in slope is observed when passing from the ICDW to the CCDW. ● = Measurement point on cooling, ○ = measurement point on heating. d) Relative peak-height (fundamental): for 2H-$TaSe_2$ the peak-height drops slowly at the CDW onset, but rapidly for 2H-TaS_2. This points to the absence of an ICDW in 2H-TaS_2. In addition, there is for 2H-$TaSe_2$ in the CCDW region a further small step (arrow), which is related to a change in the CDW stacking perpendicular to the layers.

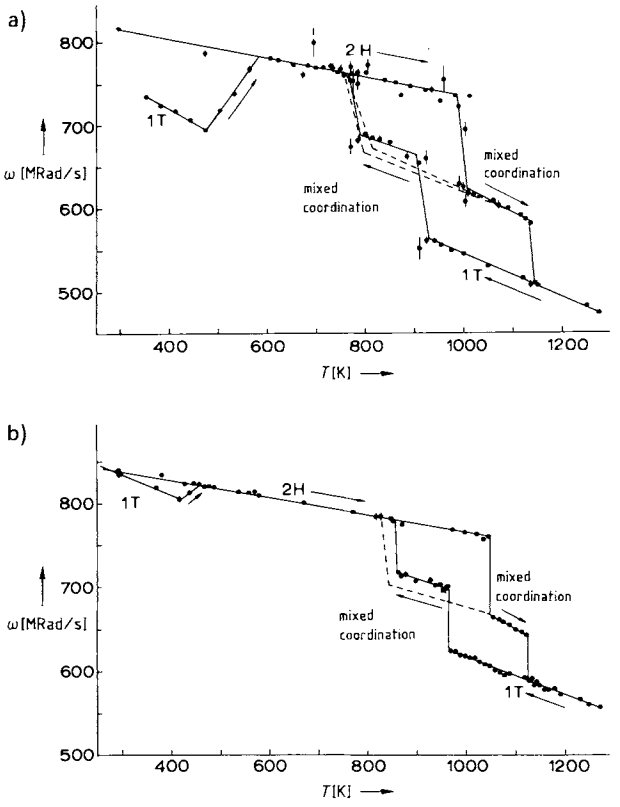

Fig. 10. Precession frequencies ω (fundamental) for $^{181}Hf(^{181}Ta)$ probes a) in TaS_2, b) in $TaSe_2$ versus temperature. The heating and cooling cycles are indicated by arrows. One clearly observes the polymorphic phase transitions with the sequence: 1T→2H – mixed coordination → 1T → mixed coordination → 2H with an extremely large hysteresis. The dashed lines represent measurements (no data points are shown for the sake of clarity), where the sample was cooled starting from the mixed coordination phase. It is clear that the two mixed coordination phases are not identical. In contrast to the low-temperature form, in the high-temperature form a unique sharp frequency is observed, despite the coexistence of Ta-atoms with trigonal-prismatic and octahedral coordination. The linear temperature dependence of the EFG over a wide temperature range is remarkably identical for 2H-TaS_2 and 2H-$TaSe_2$.

of two different metal coordinations, whose frequencies are markedly different in the pure modifications. A possible explanation would be a rapid coordination fluctuation at the Ta, as one would expect for Ta diffusion (within and perpendicular to the layers). The mixed coordination phase achievable upon cooling differs from that obtained upon heating mainly by the occurrence of substantial line-broadening, which could be a consequence of incomplete averaging by diffusion. This "diffusion picture" is further substantiated by the fact that in the case of TaS_2 the static TDPAC signal already begins to disappear several 100 K below the transition from the 2H- to the mixed coordination phase.[113] This is only possible if motional processes occur, e.g. the melting of the Ta sublattice or, at least, a "bound diffusion" of Ta without macroscopic transport.

5.4.3. Order-Disorder Transitions

So far only two types of such transitions have been investigated: the reorientational motion in ion-complexes and the sublattice melting in ion conductors. In the TDPAC spectra of many salts of $HfF_6^{2\ominus}$ and $HfF_7^{3\ominus}$, [probe: $^{181}Hf(^{181}Ta)$] one mostly observes a sharp transition from a static to a dynamic behavior (cf. Fig. 2c and b).[115–123] The analysis of the relaxation spectra yields the reorientational correlation time. In the case of the hexafluorides the $TaF_6^{\ominus}$ (nuclear transition!) complex rotates, whereas, in the case of the heptafluorides it is not clear what sort of a coordination $TaF_7^{2\ominus}$ has,[124] nor whether the observed dynamics results from coordination fluctuations[124] or from $TaF_7^{2\ominus}$ rotations.

Sublattice melting has been observed, e.g., in Ag_2S and Ag_2Se with a $^{111}In(^{111}Cd)$ probe.[125] At high temperatures the static interaction disappears, thus indicating that the $In^{3\oplus}$ ions become highly mobile. The activation energy for the motion of the $In^{3\oplus}$ ions was derived from the temperature dependence of the correlation times and this compares well with the activation energies for $Ag^{\oplus}$ ions. The diffusion constants for $Cd^{2\ominus}$ and $In^{3\oplus}$ in Ag_2S, determined with radioactive tracers, are only about a factor of 3 smaller than that for the $Ag^{\oplus}$ ion. Both facts suggest that the rapidly diffusing Ag ions, being present in excess, carry the $In^{3\oplus}$ ions along with them.[*]

Phase transitions in metal-hydrogen systems as well as hydrogen diffusion processes have been investigated in the metals Pd, Hf, Ta and Nb [probes: $^{99}Rh(^{99}Ru)$, $^{100}Pd(^{100}Rh)$, $^{181}Hf(^{181}Ta)$] and are described in a review article by *Weidinger*.[128]

5.4.4. Other Lattice Instabilities

In the following we briefly present a few systems which exhibit lattice instabilities, although at present there is no reliable evidence for the presence of a structural phase transition. In $HfTe_5$, a compound consisting of $HfTe_3$ chains, in which the Hf is surrounded trigonal-prismatically by Te atoms, and which are interconnected via Te chains, one observes [$^{181}Hf(^{181}Ta)$ probes] with decreasing temperature (starting from 300 K) an increase in η from 0.25 to 1, a characteristic V_{zz}-η distribution, and, below about 80 K, a complete collapse of the static TDPAC spectrum (see Fig. 11).[129]

This anomaly is very likely related to the anomaly observed in electronic transport properties at 75 K. Interestingly, this "collapse" of the spectrum is essentially suppressed by very small concentrations of radiation defects (displacements) produced by neutron activation.[129, 130]

Finally, we refer to materials with electric switching properties: $^{111}In(^{111}Cd)$ in InSe[131] and $^{181}Hf(^{181}Ta)$ in HfS_2.[130, 132] In both cases one observes the occurrence of an additional NQI frequency, which is exactly twice the normal component. In the case of InSe it was shown that this additional component could be switched on and off. At present, it is unclear whether this is structure related or of dynamic origin.

[*] The investigation of diffusion mechanisms is more interesting than the determination of the diffusion constant by TDPAC. So far only investigations using $^{111}In(^{111}Cd)$ in Ag and Zn have been carried out[126, 127].

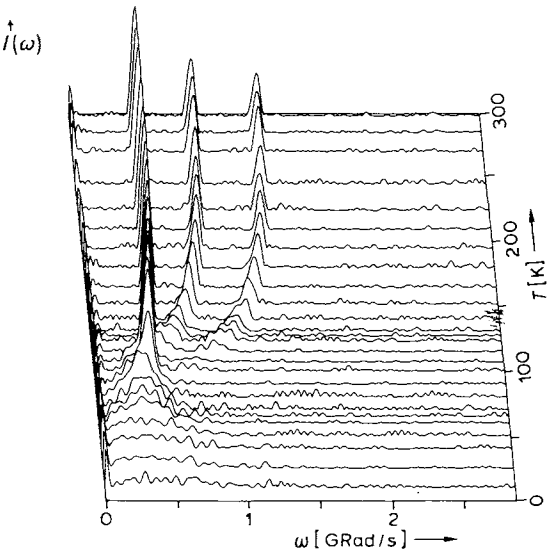

Fig. 11. Fourier-transformed TDPAC spectra of ^{181}Hf(^{181}Ta) probes in a $HfTe_5$ single crystal versus temperature. Upon cooling, the first harmonic shifts towards the fundamental (i.e. the asymmetry parameter becomes $\eta = 1$); simultaneously, the harmonics broaden considerably without a significant broadening of the fundamental. Starting at 90 K the fundamental also "melts away". This scenario is characteristic for critical fluctuations in the vicinity of an incompletely developed phase transition which "freeze out" on the hyperfine time scale.

5.5. Solid State Reactions

The application of TDPAC to the investigation of solid state reactions is based on the possibility of determining individual constituents of phase mixtures *quantitatively* with the help of known hyperfine parameters of the individual phases. The separation of various species is the more successful the more different the associated NQI parameters (V_{zz}, η, orientation). Substances, which do not lead to a NQI of the probe due to symmetry, are absolutely indistinguishable. Generally speaking, the identification of the initial and final products presents no problems, especially if phases with high quality are prepared efficiently (adequate preparation and reaction performance). The identification of intermediate products becomes problematic whenever they cannot be produced separately and as single phases, or when they are, e.g., highly disordered or non-stiochiometric despite an adequate reaction performance. An essential advantage of TDPAC over many other spectroscopic techniques is that the sensitivity of detection is largely sample-independent, i.e. the relative fractions of the observed spectral components are identical with the mole fractions of the individual phases. The efficacy of TDPAC fully emerges only in in-situ applications. Thus, it is possible to monitor the temporal evolution of the different mole fractions non-destructively under practically all reaction conditions, provided the reaction can be slowed down sufficiently or—better—provided the data collection times can be drastically shortened by multi-detector systems with high efficiency.

In the field of solid state reactions there have been isolated studies of the dehydration/rehydration reaction of $HfF_4 \cdot 3H_2O$,[133] the thermal decomposition of $(NH_4)_2ZrF_6$,[134] the formation of $CuIn_2$ at interfaces,[135] the oxidation of Hf metal,[113] internal oxidation processes in silver alloys[101-104] (cf. Section 5.3.2), and of gas-phase transport reactions in-situ.[113, 136]

Systematic investigations of solid state reactions have thus far only been made on intercalation reactions in the layered compound 2H-TaS_2, and these will now be discussed in more detail.

Metal ions and molecular ions can be intercalated both chemically and electrochemically between neighboring sulfur layers.[137, 138] The radioactive probe ^{181}Hf(^{181}Ta) resides on Ta-sites. During the intercalation the NQI is modified by a charge transfer from the intercalate to the host in the immediate vicinity of the intercalate and registered by the probes in the metal plane.[139][*]

In Figure 12 the Fourier-transformed TDPAC-spectra during the electrochemical intercalation of $Li^{\oplus}$ ions close to equilibrium, i.e. at very low surface current densities, are shown.[139, 140] It can be clearly seen, that the signal of the empty host material decreases with increasing Li uptake, while a new component shows up on the low-frequency side. Beyond an uptake of $Li/TaS_2 \approx 1/3$ a single-phase region is observed. The average precession frequency $\langle\omega\rangle$ depends approximately linearly on the charge transfer.[139] The variation of the linewidth in the single-phase range shows that the mobility of the Li ion is not sufficient to average out site inequivalences completely. One should not conclude from the two-phase region at the beginning of the reaction that a miscibility gap in the Li/TaS_2 phase diagram actually exists. Rather, this apparent miscibility gap is related topologically to the lattice expansion due to the intercalation and the associated coherent intercalation front and disappears after homogenization at high temperatures.[140]

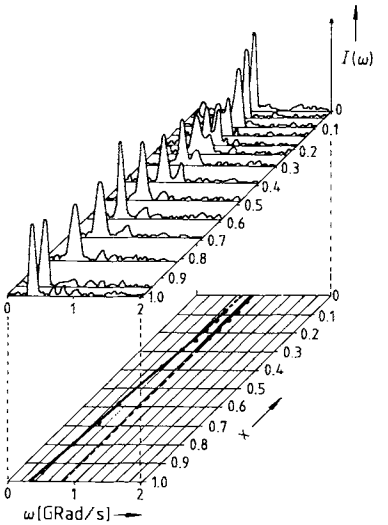

Fig. 12. Fourier-transformed TDPAC spectra (top) of ^{181}Hf(^{181}Ta) probes in 2H-TaS_2 as a function of the electrochemical lithium intercalation for near-equilibrium conditions and the projection of the peak positions (bottom) connected by solid lines (dashed lines: extrapolation) after [139]. At the beginning one observes a lithium-deficient phase apart from the unreacted 2H-TaS_2; above a lithium content of $x \approx 0.3$ there is a single phase with continuously increasing lithium content (continuously decreasing precession frequency). The variation of the linewidth is attributed to ordering phenomena at $x \approx 2/3$ and, by definition, at $x = 1$).

[*] If the intercalate diffuses rapidly enough the probes register a unique, time-averaged charge transfer (proportional to the intercalate packing density). Otherwise there are, for intercalate/Ta ratios < 1, inequivalent Ta-sites, depending on the intercalate arrangement, which, however, are very similar due to the large Ta-intercalate distance.

The creation of non-equilibrium structures, i.e. of coexisting phases with different Li content, at high prism surface current densities and the subsequent monitoring of their equilibration is shown in Figure 13.[140] It is possible to assign phases with a well-defined Li content to the different spectral components in the TDPAC spectra. Studies of this kind can only be performed in situ. Here, metastable non-equilibrium structures in an electrode material were successfully revealed for the first time. These can be detected only in an integrated way in macroscopic parameters such as, e.g., the electrochemical potential.

The electrochemical intercalation of hydrated metal ions such as, e.g., $K^{\oplus}_{aq}$ proceeds similarly to that of unsolvated $Li^{\oplus}$, with the following exceptions (Fig. 14):[139] (a) due to the high intercalate mobility the reaction proceeds always close to equilibrium; (b) at the beginning of the reaction one observes an additional intermediate phase (two successive two-phase regions); (c) the single-phase range terminates already at $x \approx 0.42$ due to the onset of water decomposition.

In contrast to Li_xTaS_2, where all interlayer gaps are uniformly filled (such compounds are called first stage), we have here the possibility of filling only every second interlayer gap at the beginning of the reaction (2nd stage),[*] and the formation of a coherent intercalation front is avoided. The intermediate phase described above is identified as a second stage with the same intercalate packing density (per intercalated layer!) as in the subsequent first stage at the onset of the single phase region.[*] As soon as the formation of the first stage sets in ($x \approx 0.13$), small temporary shifts of the characteristic precession frequencies are observed. In the case of the more strongly hydrated $Gd^{3\oplus}$ ions these effects are more pronounced.[142] The intercalate packing density enhancements which are correlated with these peak migrations are related to stacking faults due to the uncorrelated nucleation.[141] Apparently, it is energetically favorable to tolerate packing density pile-ups temporarily at the formation of the first stage. Such details of the intercalation process are difficult to observe or to interpret with macroscopic techniques.

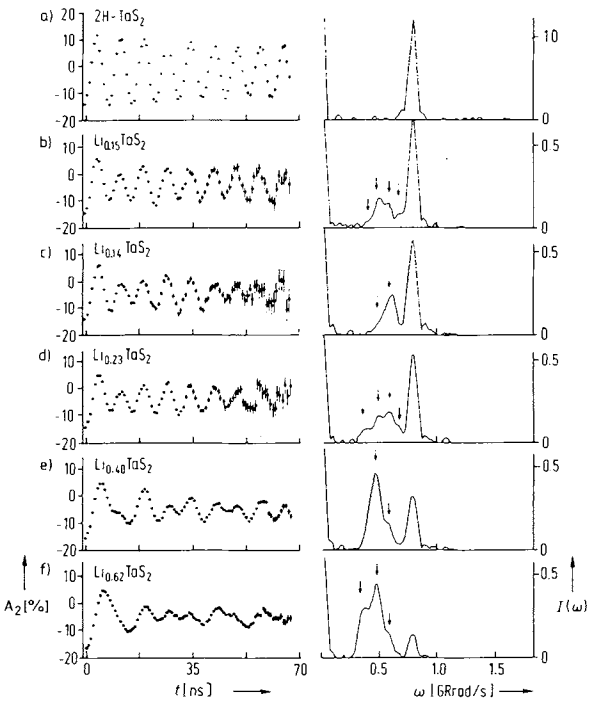

Fig. 13. TDPAC spectra (left) and corresponding Fourier transforms (right) of $^{181}Hf(^{181}Ta)$ probes in a 2H-TaS_2 crystal during electrochemical lithiation under extreme non-equilibrium conditions [140]. a) Empty host material. b) Reduction at 200 μA (prism surface current density ca. 5000 μA/cm²) until a lithium uptake of $\langle x \rangle \approx 0.15$; one observes four different phases (arrows) which differ in the lithium concentration. c) Subsequent oxidation at 100 μA until $\langle x \rangle \approx 0.14$; the most lithium-rich phase (lowest frequency) disappears and the inner-crystalline equilibration superimposes the deintercalation, as shown by the decrease in the peak of the empty host material. d) Subsequent reduction at 100 μA; again, four different phases are produced. e) When the current is reduced to 20 μA, the most lithium-rich phase disappears. f) At an uptake of $\langle x \rangle \approx 0.62$, a large fraction of the phase with maximum lithium content is already formed; here, the intercalation slows down very much, i.e. even at 25 μA there is essentially lithium metal deposition.

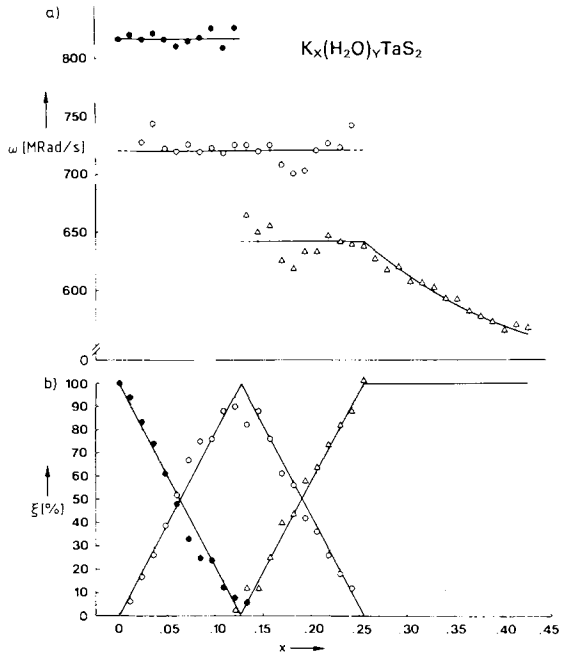

Fig. 14. a) Precession frequencies ω of $^{181}Hf(^{181}Ta)$ probes in 2H-TaS_2 during electrochemical intercalation of hydrated $K^{\oplus}$ ions; b) corresponding mole fractions (ξ) versus charge transfer [139]. There are two consecutive two-phase regions, and then starting from $x = 0.26$ there is a single-phase range. ● = TaS_2, ○ = second stage, △ = first stage.

Further studies deal with the chemical intercalation of Li (via *n*-butyllithium),[139, 143] In, Ga, Sn, Cd (all thermally),[144] GaIn-eutectic (room temperature),[144] and the electrochemical intercalation of unsolvated Ag[113] and hydrated $Fe^{2\oplus}$.[145] In the latter case the oxidation of $Fe^{2\oplus}$ to $Fe^{3\oplus}$ enables the formation of new and interesting compounds.

6. Applications in the Border Region between Physics and Biology

Since there are extremely few isotopes of elements suitable for TDPAC spectroscopy which have a physiological function in biomolecules, it is understandable that this spectroscopic technique has hitherto played only a very

[*] Instead of the formation of higher stages [138] the fully uncorrelated intercalation with near neighbor layer exclusion is discussed as well [141].

[*] Based on TDPAC spectra alone the intermediate phase could also be a first stage with half the intercalate packing density.

minor role in biology. There are two ways of labeling the probes: (1) The unspecific labeling of the biomolecule. Here, the dissolved probe is added to the biomolecule in solution and the binding can be recorded quantitatively by comparing spectra of the dissolved probe (cf. Fig. 2b) with that of the bound probe (cf. Fig. 2c-f); (2) the specific labeling of the biomolecule and the metal substitution in metalloenzymes. The "label" can be offered as free ions or "packed", as, e.g., in EDTA or serum albumin.

For the TDPAC measurements the labeled biomolecules can be present in solution, immobilized in highly viscous solutions, as polycrystals (precipitates, lyophilized) or as single crystals. The last case often presents difficulties due to prolonged crystallization times, especially when using isomeric isotopes, which generally have lifetimes of one hour or less. Provided the radioactive isotope can be separated from the inactive carrier there are no problems with regard to sample quantities.

One can roughly distinguish two areas of applications of TDPAC spectroscopy in biology: (1) Coordination studies. Here, nonequivalent sites are identified and characterized according to their different NQI parameters (V_{zz}, η). (2) Molecular dynamics. Here, on the one hand, the tumbling motion of the biomolecule in solution is studied, on the other, one can investigate the intramolecular dynamics provided the molecules are immobilized.

6.1. Coordination Studies

The only systematic investigations have been carried out by *Bauer* et al.[24] on Zn-containing enzymes in highly viscous solutions, in which Zn was substituted by ^{111m}Cd ($\tau_{1/2}=48$ min). *Bauer* et al.[146] demonstrated that although the isotope ^{111}In(^{111}Cd) would appear much more suitable for the spectroscopic examination due to its longer lifetime ($\tau_{1/2}=2.8$ d) it was, in fact, not practical for this purpose, the reasons being that In-chemistry is radically different from that of Zn-chemistry, that aqueous In-solutions tend to precipitate as hydroxides at physiological pH values,[147] and that after-effects due to nuclear transmutation can be problematic. The loss of enzymatic activity due to the Zn/Cd-exchange can be recovered partly or fully by adjusting the pH.[148] An impressive example of how sensitively different Cd-ligations in various enzymes are reflected in different NQI parameters is illustrated in Figure 15. *Bauer* tried to correlate absolute values of V_{zz} and η with different coordinations and different ligands.[24] In this way changes in the coordination at substrate or inhibitor binding were investigated in various systems as a function of pH. Of particular interest is the study of carboxypeptidase,[24] which shows that there are different conformations in the crystalline state and the highly viscous solution. In the case of carboanhydrase one observes a significant "site heterogeneity" despite the immobilization, which possibly is caused by ligand exchange not yet fully stopped, or by slow internal molecular dynamics which is still occurring.

Relatively new are the first investigations of the Cd-binding in metallothioneines[149] which play an essential role in heavy metal detoxification of organisms.

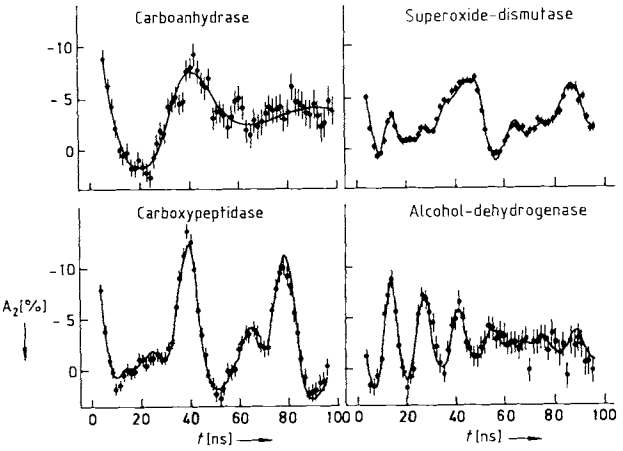

Fig. 15. TDPAC spectra of specifically bound ^{111m}Cd probes in four different metalloenzymes (Cd/Zn substitution) in highly viscous solutions [24].

6.2. Molecular Dynamics

For the investigation of the tumbling motion of biomolecules in solution,[150-152] almost without exception ^{111}In(^{111}Cd) was bound unspecifically to the biomolecule. The determination of the reorientational correlation time from the spectra is problematic, since the few available spectra of immobilized molecules are very featureless and indicate an extreme site heterogeneity.

This could be a consequence of the unspecific binding of the "labels". However, investigations of specifically bound ^{111}In(^{111}Cd) in serum albumin[152] and in porphyrins[44] in the immobilized state also showed very featureless spectra, thus suggesting more fundamental problems, e.g. chemical after-effects. Finally, the investigation of the macromolecular dynamics with "packed labels" such as ^{111}In(^{111}Cd) in serum albumin is problematical, because a molecular "label" can exhibit its own dynamics. Apart from very indirect hints towards *intramolecular* dynamics in hemoglobin compared to myoglobin,[153] there is only one direct indication of intramolecular reorientational motion,[154] in the system trypsinogen/trypsinogen-pancreatic trypsin inhibitor (PTI). Here, the disulfide bridge between cysteine 191 and cysteine 220 in the so-called activation domain of trypsinogen, which can be selectively reduced, was labeled with ^{199m}Hg ($\tau_{1/2}=43$ min) and the NQI was studied as a function of temperature between 195 K and 319 K (see Fig. 16). At 195 K one observes several discrete Hg-sites which can be assigned to different conformations of the active center. The flexibility of the activation domain of trypsinogen, which is considered to cause the blocking of the enzymatic activity, is clearly revealed in a temperature-dependent reorientational correlation time. In this way an activation enthalpy of 8 kcal/mol and a correlation time of about 10 ns at room temperature were determined. The use of an atomic label, which is extremely small compared to the total mass of the activation domain and therefore does not influence the flexibility of the activation domain, promises to yield system-specific results rather than results that reflect the local dynamics of the label. A control experiment with the trypsinogen-PTI complex at 300 K and 320 K did not reveal any intramolecular

reorientational motion within the easily accessible time range from about 1 ns to 200 ns. This is consistent with the fact that this complex has a rigid activation domain[155].

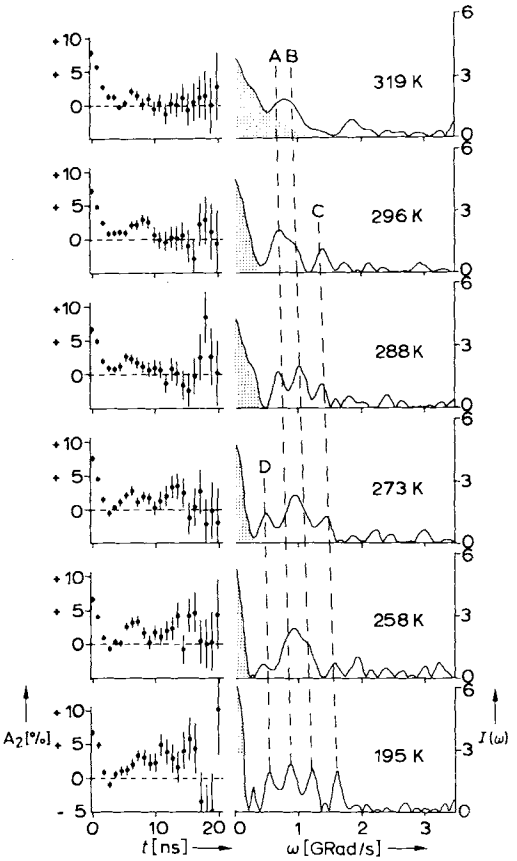

Fig. 16. TDPAC spectra (left) and corresponding Fourier transforms (right) of ^{199m}Hg labels specifically bound between cysteine-191 and cysteine-220 in precipitated trypsinogen versus temperature [154]. The dashed lines represent various Hg-conformations (A-D) of the active center of trypsinogen. The width of the dotted area at $\omega = 0$ is a measure of the intramolecular reorientational motion in the activation domain of trypsinogen.

7. Outlook

Since TDPAC spectroscopy always requires radioactive samples, this technique presumably will never become as widespread as NMR/NQR or ME. However, a great deal would be gained if the existing facilities of TDPAC spectroscopy, which are excellent in Germany, were jointly used and further developed by chemists, physicists and biologists to a much larger extent. Prerequisite for this are the willingness to cooperate, the encouragement of such a cooperation by moral and financial support, the readiness to learn the "language" of the respective partner (whether a colleague from a different faculty or an expert from a related discipline), and, most important, the intensified development of existing spectrometers, all of which must be regarded as inefficient. For example, only 1% of all γ-γ-coincidences is actually recorded, and on-line data analysis is seldom possible. Here, multi-detector systems (e.g. 6 instead of the usual 4 detectors) with high acceptance and optimized scintillator geometry (e.g. conical), an improved time resolution at unchanged high detection efficiency (e.g. BaF_2 crystals instead of NaI(Tl) or plastic scintillators), and a massive computer support can help a great deal (such a spectrometer is presently under construction in the physics department at the Technische Universität, München). The data collection time per spectrum can easily be reduced to one hour or a few minutes compared to the currently typical times of the order of one day. "Armed" in such a way, the new applications listed in Table 2 ("authors desire") seem to be within reach. One should not, of course, restrict oneself to the description of the stationary state, but rather study the processes in situ.

Table 2. Future areas of application of TDPAC spectroscopy in the border region of physics/chemistry/biology.

Field of Research	Examples
Liquids/ Solutions	Polymetalate chemistry (e.g. of Zr, Mo, Hf, Ta, Pb), Lewis Acid-Base reactions (charge redistribution), crystallization in metal melts
Cryochemistry	Matrix isolation, "low temperature chemical vapor deposition"
Glasses/ Amorphous systems	hydrogels, oxide gels (kinetics of recrystallization, structure); halogenide glasses (kinetics of recrystallization, structure, hydrolysis); metallic glasses (kinetics of recrystallization, oxidation)
Surfaces	Ideal: growth processes, reactions; fractal: reactions, catalysis
Electrochemistry	Electrochromic displays, battery electrodes, Ionic conductors (also based on polymers); electrocrystallization (non-equilibrium processes during dendritic crystal growth)
Phase transitions	Incommensurate structures, lattice instabilities ("turbulent crystal", chaos), switching behavior (optic, electronic), "memory-effects"
Solid state reactions/ Metallurgy	In situ studies of solid state reactions [corrosion (oxidation, sulfidation), sintering, reactions in crystals of organometallic complexes] and preparation methods [ion implantation (also "ion-mixing"), laser treatment (metastable phases, "non-equilibrium solidification")], first steps of compound formation on an atomic level, segregation (also spinodal decompositon), annealing of defects in compounds, defect aggregation in non-stoichiometric phases
Polymers	Metal polymers, polymer dynamics, switching behavior
Biochemistry/ Biophysics	Intramolecular dynamics, membrane dynamics, toxicology of heavy metals

We are greatly indebted to Prof. Dr. K. Andres and Prof. Dr. G. M. Kalvius for the excellent research facilities they put at our disposal in their institutes, and gratefully acknowledge the enthusiastic cooperation of the following diplomands, Ph.D-students and guests: Dr. H. Ernst, Dr. W. Biberacher, R. Mühlberger, A. Hübler, H. Gierisch, C. Vogdt, S. Saibene, U. Klapp, Dr. A. Vasquez, Dr. H. Saitovitch. We are also indebted to Prof. Dr. J. O. Besenhard, Prof. Dr. R. Huber, and Prof. Dr. H. Knözinger for their kind cooperation in solving the mainly interdisciplinary problems. Our work was generously supported through funds for material and personnel by the Bundesministerium für Forschung und Technologie and the Deutsche Forschungsgemeinschaft.

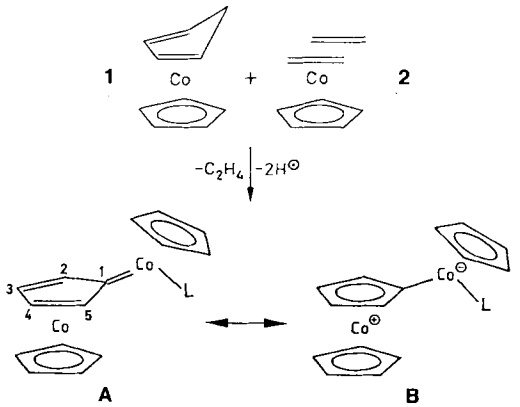
Conversion of η^4-Bound Cyclopentadiene into the Complexed Carbene Cyclopentadienylidene

By *Hubert Wadepohl** and *Hans Pritzkow*

The activated *exo* CH bond of η^5-cyclopentadienyl-η^4-cyclopentadienecobalt **1** readily undergoes reactions such as hydride abstraction[1] or addition to activated alkynes.[2] We now report a reaction in which *both* CH bonds of the methylene group are cleaved and a novel, binuclear carbene complex of cyclopentadienylidene is formed.

Complex **1** reacts at 50°C with the Jonas reagent $[CpCo(C_2H_4)_2]$ **2** (Cp = cyclopentadienyl)[3] to form the turquoise, very air-sensitive binuclear complex **3a**, which is poorly soluble in nonpolar solvents. The ethylene ligand in **3a** readily undergoes substitution by CO and PMe_3 to give **3b** and the extremely air-sensitive **3c**, respectively.



3a, L = C_2H_4; **3b**, L = CO; **3c**, L = PMe_3

According to MO calculations, free cyclopentadien-1-ylidene is expected to be bent (18°) and to exhibit alternation of the CC bond lengths (C2(4)–C3(5) short, C1–C2(5) medium, C3–C4 long).[4] Complex **3** can be represented formally by the resonance structures **A** and **B**. Examples of μ-η^4,η^1 coordination of cyclopentadienylidene (**A**) were previously unknown. In this case, we expect to find a geometry of the bridging ligand characteristic of η^4-cyclodiene complexes: CC bond alternation (C3–C4 short, C2(4)–C3(5) medium, C1–C2(5) long) and puckering around C2···C5 away from the metal atom. In an η^5,η^1 bridge (**B**), the bonds are expected to be nearly equal in length and only minor deviations from planarity (for steric reasons) are expected to be observed. In the binuclear complexes with η^5,η^1-C_5H_4 bridges[5] that have been studied by X-ray diffraction, the picture is complicated by the presence of a metal–metal bond. In those cases, the ligand is bent toward the π-bonded metal atom; C3–C4 is shorter than the other bonds in the ring.[5]

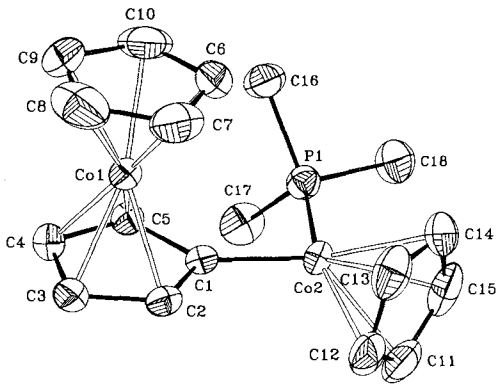


Fig. 1. Structure of **3c** in the crystal. Important bond lengths [Å] and angles [°] (standard deviation 0.004–0.006 Å, 0.3°): Co1–(C2···C5) 2.029···2.056, Co1–(C6···C10) 2.039···2.097, Co2–P1 2.150, Co2–C1 1.881, Co2–(C11···C15) 2.073···2.119, C1–C2(5) 1.447 (1.441), C2(5)–C3(4) 1.411 (1.418), C3–C4 1.406; Co2–C1–C2 125.2, Co2–C1–C5 133.9, P1–Co2–C1 97.0.

According to X-ray structure analysis,[6] **3c** adopts the μ-(η^4-diolefin, η^1-carbene) structure **A** (Fig. 1). The bridging ligand is coordinated through its diene moiety to a CpCo group. The CC bond lengths in the planar diene moiety (C2···C5, plane E1) are equal, and the bonds to the carbene carbon atom C1 are somewhat longer. C1 is bonded to the $CpCo(PMe_3)$ fragment by a very short bond (1.881(4) Å),[7] and is located 0.12 Å off E1 on the side opposite to Co1. The corresponding bond in the μ-(η^5,η^1-cyclopentadienylidene) complexes is surprisingly long; its length corresponds to that of metal–alkyl bonds.[5] The dihedral angle E1/E2 (E2: C2,C1,C5) is 7.7° in **3c**. In the crystal, the plane passing through Co2, P1 and the center of the Cp ring C11 to C15 is perpendicular to E1. However, the conformation is more symmetric on the NMR time scale in solution (only two ^{13}C-NMR signals for C2–C5). Considering the isolobal relationship[8] $CH_2 \leftrightarrow CoCp(L)$ [ML_4, Co^I, d^8], complex **3** is analogous to mononuclear complexes with pentafulvene as ligand. Typical diene systems are present in the η^4-pentafulvene complexes of type **4** with dihedral angles E1/E2 of 22.3° for **4a** and 8.0° and 10.4° for **4b** (cod = 1,5-cyclooctadiene).[9] No bond exists between the ring carbon atom C1 and the metal atom in **4**.[10] On the other hand, the Co1–C1 distance in **3c** (2.240 Å) still indicates the existence of a bonding interaction. In summary, the structural findings for **3c** indicate a small contribution of the dipolar "ylide" resonance structure **B** to the actual structure. The situation is similar in the cationic fulvene complexes **4c** (angle E1/E2 4.4°) and **4d** (angle E1/E2 8.8°).[11]

d, R = Ph, ML_n = $Rh\{P(OPh)_3\}_2^{\oplus}$

4

The solution chemistry of cyclopentadienylidene reveals it to be an electrophilic singlet carbene.[12] This behavior is due to the interaction of the carbene orbitals with the antiaromatic 4π-electron ring system.[4, 13] The very low frequency of the carbonyl band[14] of **3b** ($\tilde{\nu}$(CO) = 1903 cm^{-1} (THF)), on the other hand, indicates that the carbene ligand is an extremely good σ-donor. The resulting high electron density at Co2 exerts a destabilizing effect on the Co–P bond in **3c**, which reacts smoothly with CO to give **3b**. Complex **3** is an example of the reversal of the Lewis acid–base properties of a carbene upon complexation. This may be ascribed to the fact that the diene π^* orbital involved in the bond to Co1 is no longer available for an interaction with the electron pair of the carbene carbon atom.

Experimental Procedure

3a: **2** (1.60 g, 8.88 mmol) in 50 mL of petroleum ether (PE) was added to **1** (1.57 g, 8.26 mmol) in 50 mL of PE at 50°C. The dark solution was then concentrated under vacuum to ca. 70 mL. After standing at room temperature for 24 h, the solution was decanted from the precipitated crystals, which were washed with PE and recrystallized from toluene. Green platelets (700 mg **3a**, 2.06 mmol, 25% yield). M.p. = 146°C (dec.).—^{1}H-NMR (300 MHz, C_6D_6): δ = 4.75 (s, 5H; Cp), 4.44 (m, 2H; 2 × CH), 4.2 (m, 7H; Cp + 2 × CH), 3.63 (*m*; 2H of C_2H_4), 2.10 (m; 2H of C_2H_4).—^{13}C-NMR (75.5 MHz, C_6D_6): δ = 85.0 (d), 81.6 (d), 81.0 (d), 78.7 (d), 35.0 (t); the signal for C1 could not be observed for any of the compounds **3**.

3b, **3c**: **3a** was allowed to react with 1 bar CO (−60°C to room temperature) or with excess PMe_3 (room temperature), respectively, in toluene. After removal of the solvent from the filtered, deep green solution, analytically pure **3b** (L = CO, 97%) was obtained; **3c** (L = PMe_3) was recrystallized from toluene (68%). **3b**: green needles (dec. above 200°C). Correct C,H analyses.—^{1}H-NMR (90 MHz, C_6D_6): δ = 4.85 ("s," 7H; Cp + 2 × CH), 4.5 (m, 2H; 2 × CH), 4.23 (s, 5H; Cp).—^{13}C{^{1}H}-NMR (75.5 MHz, C_6D_6): δ = 87.3, 83.7, 82.2, 79.9. **3c**: green platelets (dec. above 170°C).—^{1}H-NMR (90 MHz, C_6D_6): δ = 5.0 (m, 2H; 2 × CH), 4.54 (s, 5H; Cp), 4.32 (s, 5H; Cp), 3.87 (m, 2H; 2 × CH), 1.40 ("s," 9H; PMe_3).—^{13}C{^{1}H}-NMR (75.5 MHz, C_6D_6): δ = 92 (br), 80.1, 78.6, 75.9, 21 (br).

A Biocatalyst for the Preparation of (*R*)- and (*S*)-2-Hydroxycarboxylic Acids**

By *Haike Skopan, Helmut Günther,* and *Helmut Simon**

We have reported several times on the use of *Proteus vulgaris* in the presence of a catalytic amount of methyl- or benzylviologen to reduce structurally diverse 2-oxomono- and 2-oxodicarboxylates to (*R*)-2-hydroxycarboxylates, such as (*R*)-**1** (R = alkyl, arylalkyl, etc.) of very high enantiomeric purity [reaction (a)]. Possible electron donors include hydrogen, formate, and the cathode of an electrochemical cell (for electron flow and conditions, see ref. [1]). Productivity numbers are thereby attained that are approximately one to three orders of magnitude larger than those obtained in, for example, the reduction of carbonyl groups with yeast.[1–3] The reductase catalyzing these reactions does not employ NADH or NADPH;[3] its natural electron donor is still unknown. We have not been able to effect reversal of reaction (a) using methyl- ($MV^{2\oplus}$) or benzylviologen, even when we employed, for example, hexacyano-

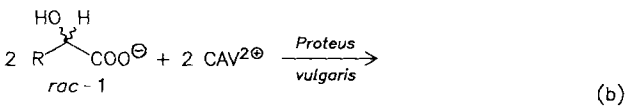
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 145) and the Fonds der Chemischen Industrie. We thank *C. Frank* and *L. Riesinger* for dedicated and skilled work. We thank Dr. *P. Rauschenbach* and *F. Wendling* for working out the conditions of the HPLC analyses.

ferrate(III) or other electron acceptors with a relatively positive redox potential, which should remove every trace of reduced viologen and thereby make the overall reaction exergonic.

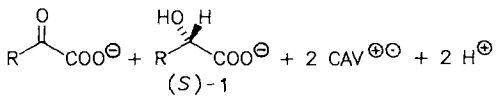
However, the dehydrogenation of (*R*)-2-hydroxycarboxylates, (*R*)-**1**, with carbamoylmethylviologen [$CAV^{2\oplus}$ = 1,1'-bis(carbamoylmethyl)-4,4'-bipyridinium dication] is possible. This viologen, which may be prepared by reaction of 4,4'-bipyridine with chloroacetamide,[2] exhibits a redox potential E_0' of -295 mV, which is thus 145 and 70 mV less negative than those of methyl and benzylviologen, respectively.

The kinetic parameters are of considerable importance for the preparative application of enzymes. The K_M values for the dehydrogenation reaction [cf. reaction (b)], carried out with crude extracts of *Proteus vulgaris* are 0.05 for $CAV^{2\oplus}$, 0.76 for (*R*)-lactate, 0.15 for (*R*)-3-phenyllactate, and 0.58 mM for (*R*)-2-hydroxy-4-methylpentanoate. These values are rather favorable for attaining complete conversions.

The dehydrogenation of (*R*)-2-hydroxycarboxylates, (*R*)-**1**, is also possible in the presence of (*S*)-2-hydroxycarboxylates, (*S*)-**1**. The K_i values, also determined with crude extracts, are 33, 77, and 100 mM for the (*S*) enantiomers of lactate, 3-phenyllactate, and 2-hydroxy-4-methylpentanoate, respectively. Thus, in the case of racemic mixtures of 2-hydroxycarboxylates, *rac*-**1**, the (*R*) enantiomer is selectively converted into the 2-oxocarboxylate, the (*S*) enantiomer remaining unchanged. To date, we have found no 2-oxomono- or 2-oxodicarboxylate that cannot be reduced with *Proteus vulgaris*. Since reaction (a) can now be carried out in reverse [reaction (b)], it is possible to obtain (*S*)-2-hydroxycarboxylates, (*S*)-**1**, starting from *rac*-**1**. The pH optimum of reaction (b) is in the range of 8.5 to 9.0.



(b)



(c)

For preparative purposes, the $CAV^{\oplus\odot}$ produced in reaction (b) must be converted back into $CAV^{2\oplus}$. $CAV^{\oplus\odot}$ undergoes ready oxidation in an electrochemical cell at a carbon electrode (glassy carbon or carbon felt) at about -400 mV (versus a standard calomel electrode). Since the rate of reaction is proportional to the amount of current, this method has the advantage that the conversion is given by the product of current × time.

Surprisingly, regeneration of $CAV^{2\oplus}$ is also possible by shaking with air, without fast loss of enzyme activity [reaction (c)]. As a reductase, the enzyme is very sensitive toward oxygen; as a dehydrogenase, it is not. With *Proteus vulgaris* cells it is possible to carry out reactions (b) and (c) for 10–20 hours. During the regeneration of $CAV^{2\oplus}$ with O_2, we have not observed even traces of H_2O_2.[4]

Examples for the preparation of (*S*)-2-hydroxycarboxylates from racemic mixtures are given in Table 1. Analysis of the products is carried out enzymatically with (*R*)- and (*S*)-lactate dehydrogenase and NAD or by HPLC on RP-18 phases or on Chiral-I columns.[5]

Since carboxyl groups can be transformed in a variety of ways, it is possible to prepare numerous chiral compounds starting from the two enantiomers of 2-hydroxycarboxylic acids and 2-hydroxydicarboxylic acids. Although there have been recent reports of the use of pyridine-nucleotide-dependent 2-oxoacid reductases for the preparation of (*R*)- and (*S*)-2-hydroxycarboxylic acids,[6,7] their scope of application is narrower than that for the oxidoreductase from *Proteus vulgaris*. For example, no 2-oxodicarboxylates are accepted as substrates, and the specific activity in the crude extract of the organism is at least one order of magnitude smaller. There has been no report so far whether these pyridine-nucleotide-dependent reductases can be used in the form of whole cells.

Table 1. Preparation of (*S*)-2-hydroxycarboxylates, (*S*)-**1**, from racemic mixtures of 2-hydroxycarboxylates, R–CHOH–$COO^{\ominus}$, *rac*-**1**, by dehydrogenation of the (*R*)-2-hydroxycarboxylates, (*R*)-**1**.

R in *rac*-**1**	Mixture employed		Procedure	Result
CH_3	lactate	300 μmol	In 30 mL of 0.1 M phosphate buffer (pH 8.5) with 2 mM $CAV^{2\oplus}$ and 10 mg of *P. vulgaris*. In electrochemical cells (graphite electrode at -440 mV versus standard calomel electrode), 47% of the lactate had been dehydrogenated by the time the current had fallen to zero. After thermal deactivation of the microorganism, the product pyruvate was reduced to (*S*)-lactate in the same cell in the presence of (*S*)-lactate dehydrogenase and with regeneration of NADH [8].	252 μmol of (*S*)-lactate [a]. No (*R*)-lactate detected enzymatically.
$(CH_3)_2CHCH_2$	2-hydroxy-4-methylpentanoate	3.3 mmol	As above in 55 mL of anolyte with 1.5 mM $CAV^{2\oplus}$ and 32 mg of *P. vulgaris*. No current after 5 h.	After HPLC, 1.62 mmol of oxocarboxylate and 1.57 mmol of hydroxycarboxylate. According to analysis on a Chiral-I column, the (*S*) enantiomer had >95% *ee*.
CH_3	lactate	100 μmol	Each racemate was dissolved in 3.0 mL of Tris-HCl (pH 8.5) containing 2 mM $CAV^{2\oplus}$ and 20 mg of *P. vulgaris* and the mixture was shaken under air for 4 h at 35°C.	No (*R*) compound detected enzymatically. Pyruvate and 2-oxoglutarate were metabolized. In the other cases, 50–51 μmol of 2-oxocarboxylate and the same amount of (*S*)-hydroxycarboxylate were present.
$PhCH_2$	3-phenyllactate	100 μmol		
C_2H_5	2-hydroxybutyrate	100 μmol		
$(CH_3)_2CH$	2-hydroxy-3-methylbutyrate	100 μmol		
$^{\ominus}OOC-(CH_2)_2$	2-hydroxyglutarate	100 μmol		

[a] The pyruvate formed as an intermediate is partly degraded by the cells.

The findings presented here also demonstrate that, by using viologen-dependent enzymes and by selecting viologens having different redox potentials, it is possible to shift at will the equilibrium position of a reaction. An example is the equilibrium constant for reaction (a): $K = 2.8 \times 10^{10}$ for methylviologen ($E_0' = -440$ mV) at pH 6.0; $K = 3.5$ for $CAV^{\oplus\oplus}$ ($E_0' = -295$ mV) at pH 8.5. Of these ten orders of magnitude, five are due to the difference in pH (the hydrogen ion concentration is squared in the expression for the mass action law) and five are due to the difference in redox potential of methyl- and carbamoylmethylviologen.

This is not possible for pyridine-nucleotide-dependent oxidoreductases, because the enzymatically active pyridine nucleotide analogues so far known differ only slightly in their redox potentials.

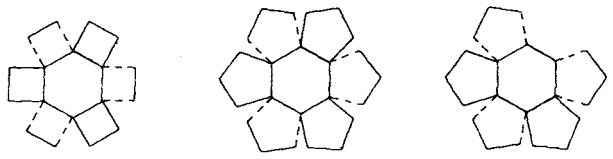
Heptacyclo[19.3.0.0^{1,5}.0^{5,9}.0^{9,13}.0^{13,17}.0^{17,21}]-tetracosane([6.5]coronane)**

By *Detlef Wehle* and *Lutz Fitjer**

Polycyclic hydrocarbons in which a central m-membered ring ($m = 4, 6, 8 \ldots$) is coupled to m peripheral n-membered rings ($n = 3, 4, 5 \ldots$) such that each edge of the central ring is simultaneously an edge of a peripheral ring ([m.n]coronanes[1]) were previously unknown. They have an unusual topology and should exhibit interesting chemical and physicochemical properties. Examples are the [6.4]coronane **1** and the [6.5]coronane **2**, whose synthesis should be possible via cascade rearrangements of pentaspiranes.[2,3] We report here on the use of such a cascade for the synthesis of the coronane **2** and of its incomplete analogue **3**.

We explored two possibilities for the synthesis of **2**: first, addition of allylmagnesium bromide to **4**,[3] rearrangement of the expected homoallyl alcohol **5a** (OH_{axial}) to **6**, and cyclization with diisobutylaluminum hydride (DIBAH)[4] to give **2** and/or **7** (see Scheme 1); second, hydrozirconization[5] followed by bromination[5] of **6** to give **10** and cyclization with tri-*n*-butyltin hydride[6] to give **2** (see Scheme 2). These approaches led not only to the synthesis of **2** and **3** but also to several surprising results.



1 **2** **3**

Thus the addition of allylmagnesium bromide to **4**[3] afforded not only the homoallyl alcohol **5a** (m.p. = 145 °C) but also its conformational isomer **5b** (m.p. = 154–156 °C) with an equatorial OH group. Both alcohols have such high barriers to inversion [$\Delta G^{\ddagger}_{413} = 134.9$ kJ/mol (**5a**) and 136.9 kJ/mol (**5b**)][7] that they can be studied separately. In order to induce the rearrangement, we took advantage of the antiperiplanar arrangement of the hydroxyl group and the axial bonds of the neighboring cyclobutane rings in **5a**, which favors the 1,2-shifts. Reaction with thionyl chloride in pyridine afforded the expected[3] hexacyclic diene **6** (m.p. = 189–196 °C),[8a] whose cyclization with DIBAH was then studied. Only at 160 °C and upon addition of six molar equivalents of DIBAH did the reaction proceed beyond simple addition of the hydride to the vinyl group and hence formation of **8** (glassy solid),[8] which had already been observed at 80 °C. However, GC/MS analyses provided no evidence for a cyclization with formation of **2** and/or **7**. Instead, after 72 h at 160 °C, the reaction mixture consisted of 49% **8** and 26% **9** (m.p. = 24–27 °C),[8a]

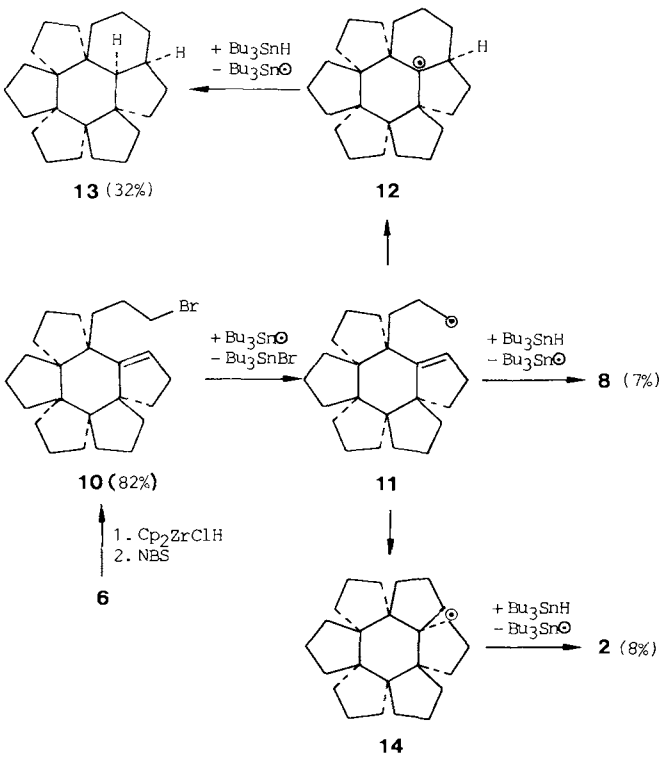
and after 11 d at 160°C, 13% **8** and 49% **9** were present. The mechanism of the fragmentation remains to be explored.

Compound **9** was separated by gas chromatography and hydrogenated over platinum dioxide in glacial acetic acid to give **3** (glassy solid).[8a] We have studied this incomplete [6.5]coronane in order to gain insight into the properties expected for **2**. Its ^{13}C-NMR spectrum (50.3 MHz, $CHFCl_2$[9]) exhibits only eleven signals at −78°C [δ = 21.50, 21.81, 23.21, 30.23, 37.14, 38.29, 39.55, 45.42 ($C_{sec.}$), 48.57 ($C_{tert.}$), 53.27, 55.98 ($C_{quart.}$)], which are only in accord with a rapidly inverting species in the all-*cis* configuration (effective symmetry: C_s). At −130°C, 21 signals are observed [δ = 20.35, 20.84, 21.81, 22.20, 25.52, 28.94, 31.60, 35.46, 36.60, 37.37, 37.63, 39.26, 40.49, 45.45, 45.82, 47.58, 50.49, 52.21, 53.26, 55.51, 55.83] which must be ascribed to a fixed conformation having C_1 symmetry. Which of the five conceivable conformations (one chair, two twist-boat, and two boat conformations) is involved must remain an open question, although force field calculations[10] support a flattened chair conformation ($\Sigma|\omega|_{central\ ring} = 245°$). In order to estimate the barrier to inversion, we followed the coalescence of the resonance lines of the quaternary carbon atoms at δ = 52.21 and 53.26. From the frequency difference ($\Delta\nu$ = 52.7 Hz) and the coalescence temperature (−115 ± 5°C) and using the Gutowsky-Holm relation and the Eyring equation, an extremely low value of $\Delta G^{\neq}_{153} = 31.3 \pm 1.1$ kJ/mol for the free energy of activation resulted. It thus appeared certain that the [6.5]coronane **2** would be characterized by a similar low barrier to inversion.

We then investigated the synthesis of **2** via the second approach outlined above (Scheme 2). For this purpose the diene **6** was first hydrozirconized with zirconocene chloride hydride[5] and then brominated with *N*-bromosuccinimide (NBS).[5] Chromatography on silica gel with hexane afforded pure **10** (m.p. = 35–37°C).[8a] In order to carry out the cyclization, a solution of **10** in benzene was heated with 2.0 equivalents of tri-*n*-butyltin hydride and 0.2 equivalents of azobisisobutyronitrile for 38 h at 80°C. Complete consumption of **10** led to the formation of at least eight products, including, as main product, the heptacyclic **13** (m.p. = 164°C)[8a] and, as side products, the already known **8** and the sought [6.5]coronane **2** (m.p. = 222–224°C).[8a] Separation was achieved by a combination of column and gas chromatography.[8b]



Scheme 2.

The structural assignment of **13** is based on the available spectroscopic data,[8a] especially on the number, position, and multiplicity of the signals in the ^{13}C-NMR spectrum. The configuration results from the fact that the radical **11** can only attack the double bond from the side shown and the resulting **12** should be configuratively stable. It is not surprising that **13** is preferentially formed although it is the product of an unfavorable *endo-trig* ring closure according to *Baldwin*'s rules.[11, 12]

The structure and configuration of the title compound **2** could be assigned unequivocally. The ^{13}C-NMR spectrum (50.3 MHz, CD_2Cl_2) shows only three signals at 20°C at δ = 21.24, 40.07 ($C_{sec.}$), and 56.80 ($C_{quart.}$), which are only in accord with a rapidly inverting species in the all-*cis* configuration (effective symmetry: D_{3d}). On account of the extremely low solubility of **2**,[13] we had to always use [D_2]dichloromethane for the low-temperature ^{13}C-NMR investigations. At −80°C, the signal at δ = 40.07 clearly began to broaden, until, at −94°C, the lowest temperature attainable in [D_2]dichloromethane, it exhibited a halfwidth (12 Hz) five times that of the still sharp signals at δ = 21.24 and 56.80. We are therefore certain that this signal will be split at lower temperature into two resonances, as expected for a fixed chair conformation. Even the most careful estimate of the coalescence temperature (−100°C) and the frequency difference (20 Hz) gives the expected low value, $\Delta G^{\neq}_{173} = 36$ kJ/mol, for the corresponding barrier to inversion.

Most interesting is the finding that the barriers to inversion of **5a** and **5b** are extremely high, whereas those of **2** and **3** are extremely low. This clearly indicates that on going from spiroannelation, as in **5a,b**, to edge-annelation, as in **2** and **3**, the central ring is flattened in the ground state[14] and the 1,2-interactions are reduced in the transition state. Both effects should be even more pronounced in the [6.4]coronane **1**.[14] Therefore, we expect the barrier to inversion for **1** to be even smaller than that for **2**.

Oxidative Addition of Hydrogen Telluride to Organometallic Fragments**

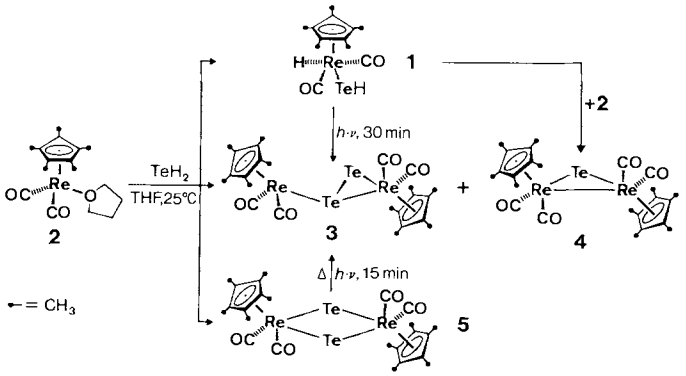
By *Wolfgang A. Herrmann,* Christian Hecht, Eberhardt Herdtweck,* and *Heinz-Josef Kneuper*

A large number of reports have appeared recently concerning the advantages of using simple binary hydrides, such as GeH_4, SnH_4, AsH_3, and TeH_2, to incorporate unsubstituted main-group elements into organometallic complexes.[1] Examples of compounds thus formed under mild conditions and usually in good yields, are the tin and tellurium compounds $L_XM{=}Sn{=}ML_X$ (linear) and $L_XM{=}Te{=}ML_X$ (bent), respectively ($L_XM = (\eta^5\text{-}C_5R_5)Mn(CO)_2$; R = H, CH_3).[2,3a] The star-shaped complex $[(\mu_3\text{-Te})\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_3]$ was also obtained in this way.[3b] The working hypothesis that is used to explain the formation of these unusual complexes involves an initial oxidative addition of the element hydride to the reactive complex fragment L_XM according to Equation (a), followed by coupling with elimination of H_2.[1,4j] This suggestion, which so far has remained more or less speculative, is now supported by the first successful oxidative addition of hydrogen telluride to a transition metal.

$$L_XM + EH_a \longrightarrow L_XM\begin{matrix}\diagup EH_{a-1}\\ \diagdown H\end{matrix} \quad \cdots\cdots \text{(a)}$$

A

Treatment of the substitution-labile solvent complex **2**, generated by photolysis, with externally generated, acid-free hydrogen telluride in tetrahydrofuran at room temperature in the dark (!) affords, after column-chromatographic workup of the crude product at low temperature, the four new organorhenium complexes **1** and **3**–**5** (Scheme 1). The components of the hydride TeH_2 are completely maintained only in the mononuclear complex **1**. According to ^{1}H- and ^{125}Te-NMR spectroscopy and an X-ray diffraction study, **1** is a TeH/H complex of type **A** with nearly square-pyramidal coordination around the transition-metal atom and a *trans* arrangement of the ligands TeH and H (Fig. 1a, Table 1).



Scheme 1.

Isolated **1**, a dark red-brown solid, is thermally stable under inert atmosphere but remarkably photolabile. Irradiation with UV light, filtered through Duran glass, results in the nearly quantitative transformation of **1** to **3** with elimination of H_2; **3** is the most stable of the four complexes. This complex contains an unsymmetrical Te_2 bridge (Fig. 1b, Table 1), which until now had only been observed in organometallic compounds containing sulfur or selenium.[6,7] The bond lengths in the Re_2Te_2 skeleton are in accord with the number of electrons in this fragment. Thus, the Re2-Te2/1 distances [279.3(<1)/280.6(<1) pm] are consistent with a π-type side-on complexation of a Te_2 fragment,[8] and the Re1–Te1 distance [263.2(<1) pm] is not inconsistent with the postulated ReTe double bond. By way of contrast, ReTe single bonds are estimated to have lengths of ca. 285 pm.[9]

Complex **3** can also be obtained from the isomeric complex **5** either photochemically (irradiation with UV light in THF) or thermally (refluxing THF). This unusual isomerization reaction is restricted to the constitution of the Re_2Te_2 skeleton.

The red-brown complex **4**, which contains a Re_2Te three-membered ring and is formed in only small amounts,

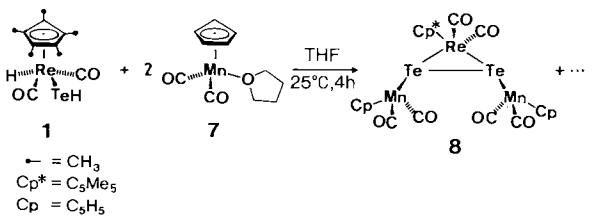
has C_2 symmetry in the solid (Fig. 1c, Table 1). Whereas the analogous manganese compound $[(\mu\text{-Te})\{(\eta^5\text{-}C_5Me_5)Mn(CO)_2\}_2]$ exhibits no bonding interactions between the manganese atoms on account of the MnTe double bond, with the MnTeMn angle being expanded to 124° [d(Mn···Mn) = 421 pm], the ReTeRe angle in **4** is only 72° and the (bonding) ReRe distance (314 pm) is comparable to that of $[Re_2(CO)_8(\mu\text{-}C_4H_6)]$ (311.4 pm).[10]

Even though the ReTe bonds (267.9(< 1) pm) may have some double bond contributions, the electron density at the tellurium bridge is still sufficient to make this atom nucleophilic. Thus, **4** can be protonated or methylated at −78°C with HBF_4 or $CF_3SO_2OCH_3$, respectively. The product of protonation is not only thermally labile, but can also be readily deprotonated reversibly, even with weak bases. The methylation product **6** is isolable in pure form.

$[(\mu\text{-}TeCH_3)\{(\eta^5\text{-}C_5Me_5)Re(CO)_2\}_2]^{\oplus}PF_6^{\ominus}$ **6**

According to the results presented here, it would appear that the hydridotellurium complex **1** should play a key role in the construction of multinuclear organometallic complexes containing "naked" tellurium. Complex **1** reacts with excess solvent complex **2** with elimination of H_2 to give the Re_2Te compound **4** in good yield (70% based on **1**) (Scheme 1). Complex **1** also readily loses hydrogen in the presence of other organometallic complexes and is therefore suitable for the construction of heteronuclear tellurium complexes. For example, **1** reacts at room temperature in the dark with the solvent complex **7**, which is known to be substitutionally labile, to give, in a straightforward reaction, the novel Mn_2Te_2Re complex **8**, which, according to a single-crystal X-ray structure analysis, may be regarded as an organometallic isolobal analogue of *cis*-1,2-dimethylcyclopropane (Scheme 2, Fig. 1d, Table 1).



Scheme 2.

^{125}Te-NMR spectroscopy, which has hardly been used so far, proved to be a quick and highly sensitive method for determining the constitution of the new complexes (shift range ca. 1800 ppm; Table 2), especially for locating the hydrogen atoms, which are difficult to find by X-ray diffraction analysis. The key compound **1** furnishes an excellent example for the use of this method (Fig. 2).

Experimental Procedure

A solution of $[(\eta^5\text{-}C_5Me_5)Re(CO)_3]$ (1.00 g, 2.47 mmol) in 250 mL of THF was irradiated at 15°C in a quartz-glass immersion-lamp apparatus. The irradiation was carried out for approximately 90 min, during which time the liberated CO was repeatedly pumped out of the apparatus. The brownish yellow solution of **2** was transferred to a Schlenk tube fitted with a glass inlet, and excess TeH_2 (generated externally from Al_2Te_3/4 N HCl) was then admitted. The reaction mixture was allowed to stir for 4 h in the dark and then evaporated; the residue was chromatographed on a Florisil (100-200 mesh) column at −20°C. *n*-Hexane, colorless $[(\eta^5\text{-}C_5Me_5)Re(CO)_3]$; *n*-hexane/toluene (5/1), **1** as an extended yellow band; *n*-hexane/toluene (3/1), **4** as a

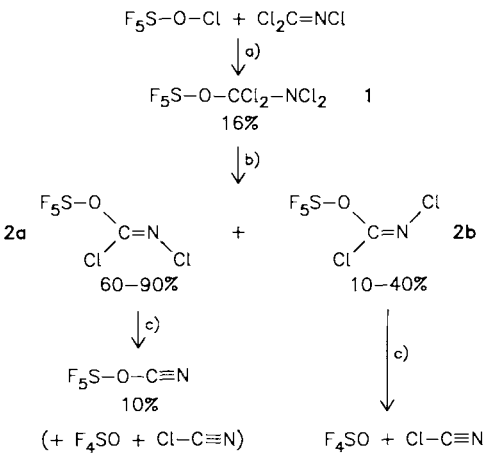
Sulfur Pentafluoride Cyanate, $F_5S-O-C\equiv N$**

By *Arno Schmuck* and *Konrad Seppelt**

Sulfur pentafluoride isocyanate, $F_5S-N=C=O$, is a long-known, chemically and structurally investigated compound.[1–3] The analogous tellurium compound, $F_5Te-N=C=O$, has been synthesized by three routes: in two of these, the cyanate formed as an intermediate undergoes immediate rearrangement to the isocyanate.[4,5] However, one of these reactions, when applied to selenium, afforded the cyanate, $F_5Se-O-C\equiv N$, which could only be identified as such after laborious physical investigation.[5,6]

We have now succeeded in augmenting the series of known isomers, $F_5S-N=C=O$, $F_5Se-O-C\equiv N$, and $F_5Te-N=C=O$, by synthesis of $F_5S-O-C\equiv N$ (Scheme 1). $F_5S-O-Cl$[7] reacts with $Cl_2C=NCl$[8] ("cyano trichloride") to give **1**. Compound **1** eliminates chlorine spontaneously in the presence of mercury to give the isomers **2a** and **2b**, which can be separated by gas chromatography on Chromosorb on a 2-m halocarbon column. The structural assignment of the two isomers can be made on the basis of the nuclear magnetic resonance data in analogy to the isomers of $F_5S-O-CF=NCl$.



Scheme 1. a) Reaction in $C_2F_4Cl_2$ (Freon 114) at −120 to −70 °C; b) Hg, −20 °C, 4 h stirring; c) Hg, 25 °C, ultrasound.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *F. Seel* (Saarbrücken/Munich) for the loan of his Cady codistillation apparatus.

Only the (*Z*) isomer **2a** undergoes further elimination of chlorine in the presence of mercury at room temperature to afford the desired $F_5S-O-C\equiv N$ as a colorless liquid (b.p. = 5 °C) in 10% yield. The product always contains $Cl-C\equiv N$ as a contaminant, which can only be removed with difficulty by codistillation.

The differentiation between the cyanate $F_5S-O-C\equiv N$ and the isocyanate $F_5S-N=C=O$ is based on two observations: (1) Like $F_5Se-O-C\equiv N$ (1104 cm^{-1}), $F_5S-O-C\equiv N$ exhibits a strong IR absorption at $\tilde{\nu}=1111$ cm^{-1}, which is assigned to ν(CO) and is characteristic of cyanates.[9] (2) With respect to chemical shift and line halfwidth, the ^{14}N-NMR spectra of $F_5S-O-C\equiv N$ and $F_5Se-O-C\equiv N$ are in close agreement ($\delta=-194$ and -189.2; $\nu_{1/2}=57$ and 60 Hz) and differ strongly from those of $F_5S-N=C=O$[6] and $F_5Te-N=C=O$[6] ($\delta=-271.8$ and -303.9; $\nu_{1/2}=120$ and 160 Hz). Physical data for **1**, **2a**, **2b**, and $F_5S-O-C\equiv N$ are summarized in Table 1.

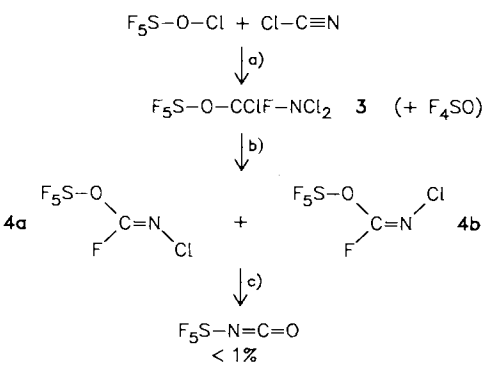
MS (80 eV), base peak (m/z)	239 M^+-Cl_2	239 M^+		150 M^+-F

The complicated method of preparation cannot be simplified. $F_5S-O-Cl$ reacts with $Cl-C\equiv N$ to give **3**,[10] which reacts with zinc to give **4a** and **4b**[11] (ca. 1.3 : 1). Apart from traces of $F_5S-N=C=O$, **4a**, and **4b**, they afford only decomposition products upon reaction with zinc at 250 °C (Scheme 2).



Scheme 2. a) −196 to +25 °C; b) Zn, 50 °C; c) Zn, 250 °C.

From these results, we conclude that at high temperatures $F_5S-O-C\equiv N$ undergoes rearrangement to give $F_5S-N=C=O$, accompanied by decomposition products. Of the six possible chalcogen pentafluoride cyanates and isocyanates, four are now known. It should be possible to synthesize $F_5Se-N=C=O$ as well; the synthesis of $F_5Te-O-C\equiv N$, on the other hand, will be difficult.

Heterometallic Polyhydride Raft Formation: A Comparison of Syntheses using Alkoxides of Copper and Gold**

By *Bruce R. Sutherland, Douglas M. Ho, John C. Huffman,* and *Kenneth G. Caulton**

There has been much recent interest in the formation of mixed transition-metal/coinage-metal complexes, particularly those containing hydride ligands.[1,2] The usual strategy for the formation of such compounds involves the reaction of reagents such as $ML_x^{\ominus}$ (M = Cu, Ag, Au; L = PPh_3, CH_3CN) with previously formed metal hydrides.[3–5] Recently, we reported an alternative method involving the reaction of $[CuO\mathit{t}Bu]_4$ with $[OsH_4(PMe_2Ph)_3]$ to give the Cu_3Os_3 cluster $[CuOsH_3(PMe_2Ph)_3]_3$ with elimina-

tion of *t*BuOH.[6] We report here a comparative study of the reaction of the dinuclear polyhydride complex $[Re_2H_8(PMe_2Ph)_4]$ **2** with either $[Ph_3PCuO\mathit{t}Bu]_2$ **1** or its gold analogue $[Ph_3PAuO\mathit{t}Bu]$ **6**.[7]

$$1/2[Ph_3PCuO\mathit{t}Bu]_2 + [Re_2H_8(PMe_2Ph)_4] \xrightarrow{C_6H_6} 1/2[Re_2CuH_7(PMe_2Ph)_4]_2 + \mathit{t}BuOH + PPh_3 \quad (a)$$

1 **2** **3**

The reaction of $[Ph_3PCuO\mathit{t}Bu]_2$ **1**[8] with the rhenium complex **2** is complete within the time of mixing [Eq. (a)].[9] The dark brown product can be isolated in essentially quantitative yield by removing the solvent and volatile by-products. Neither evolution of H_2 nor deposition of elemental copper is observed. These results, the ^{1}H-NMR spectrum, and an X-ray diffraction study[11] of crystals of **3** grown from toluene/hexane confirm the structure. The tetradecahydrido complex **3** is the most hydride-rich neutral cluster yet reported. The six metal atoms are arranged in a centrosymmetric, nearly planar parallelogram (Fig. 1) reminiscent of the structures found for clusters **4** and **5**.

$[Re_4Cu_2H_{16}(PMe_2Ph)_8]^{2\oplus}$ **4**[12]

$[Mn_4Cu_2H_6(CO)_{12}\{(EtO)_2POP(OEt)_2\}_2]$ **5**[13]

The 14 hydride ligands adopt four different modes of bonding in **3**: six hydrides bound to only Re (two terminal, four Re-Re bridging) and eight hydrides bound to Re and Cu (six Re-Cu bridging, 2 Re_2Cu bridging). Solution molecular-weight measurements indicate that this aggregate is maintained in solution.[14] The ^{1}H-NMR spectrum of **3**[15] shows a quintet for the hydride resonances (i.e., coupling to four P spins), indicating that although significant scrambling is occurring, the hydrides never move past the copper to the other Re_2P_4 unit in this rapid migration. At -80°C, the hydride resonance resolved into two broad peaks with an intensity ratio of 3:4, indicating that the ligation to copper has significantly hindered hydride mobility compared with that in $[Re_2H_8(PMe_2Ph)_4]$ **2**, which is still fluxional at -80°C. At -80°C, the ^{31}P{^{1}H}-NMR spectrum of **3** shows two signals, corresponding to the inequivalence of Re1 and Re2.

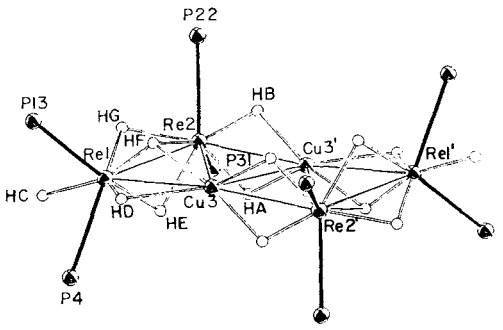

Fig. 1. ORTEP drawing of the crystal structure of **3**, omitting the methyl and phenyl groups. Primed metals and all unlabeled atoms are related to those labeled by a center of symmetry. Selected structural parameters: Re1-Re2 2.5683(7), Re1-Cu3 2.6258(10), Re2-Cu3, 2.6517(10), Cu3-Cu3' 2.5267(14) Å, Re-H distances range from 1.31(8) to 1.81(8) Å, Cu-H distances from 1.93(8) to 2.00(7) Å. Re2-Re1-Cu3 65.05(3), Re1-Re2-Cu3' 113.26(3), Re1-Cu3-Re2' 173.15(3), Re1-Cu3-Cu3' 115.57(4), Re2-Cu3'-Cu3 65.23(3)°.

The close stoichiometric and structural similarity of **3** and $[Re_4Cu_2H_{16}(PMe_2Ph)_8]^{2\oplus}$ (synthesized by very different procedures[3]) raises the question of their interconvertibility [Eq. (b)]. Indeed, the two compounds have been shown to be related by a Brønsted acid/base equilibrium, an interesting contrast to the H_2 elimination which follows protonation of early-transition-metal or main-group-metal hydrides.

$$[Re_4Cu_2H_{14}(PMe_2Ph)_8] \underset{KH}{\overset{2H^\oplus}{\rightleftharpoons}} [Re_4Cu_2H_{16}(PMe_2Ph)_8]^{2\oplus} \quad (b)$$

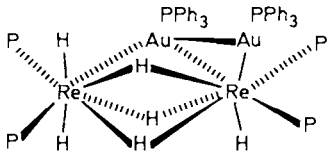
3

In order to determine the influence of the coinage metal on this cluster condensation synthesis, the reaction of **2** with $[Ph_3PAuO\mathit{t}Bu]$ **6** was also examined. The Re_2 complex **2** reacts rapidly (< 1 min) at room temperature with two equivalents of $[Ph_3PAuO\mathit{t}Bu]$ **6**[16] to give a mixture of two black isomers, which, on the basis of spectroscopy, can be formulated as **7** [Eq. (c)].

$$2[Ph_3PAuO\mathit{t}Bu] + [Re_2H_8(PMe_2Ph)_4] \xrightarrow{C_6H_6} [Re_2H_6(AuPPh_3)_2(PMe_2Ph)_4] + 2\mathit{t}BuOH \quad (c)$$

6 **2** **7**

The two isomers can be readily separated based on their differing solubilities in benzene.[17] For the major isomer, **7a**, ^{31}P{^{1}H}-NMR[18a] indicates that the two $AuPPh_3$ units are inequivalent at room temperature as are the two rhenium centers of the dimer (two PMe_2Ph phosphorus resonances are observed). This, coupled with the observation of three distinct hydride resonances in the ^{1}H-NMR, suggests a configuration as shown in Scheme 1, where $AuPPh_3$ replaces one terminal and one bridging hydride in the $Re_2H_8P_4$ structure. An Au-Au bond is suggested in **7a** based on comparison with analogous complexes.[1,2]



7a

Scheme 1. Proposed structure of **7a**. P = PMe_2Ph.

Spectroscopic data[18b] on the minor isomer, **7b**, suggests a symmetric configuration (i.e., the two $AuPPh_3$ units are equivalent). This was confirmed by an X-ray diffraction study[19] on a crystal grown from tetrahydrofuran (THF)/ether. The structure of **7b** consists of a centrosymmetric (planar rhomboidal) arrangement of four metal atoms with the Au atoms symmetrically bridging the two Re atoms (Fig. 2). Surprisingly, this isomer does *not* have proximate gold centers. The overall geometry of **7b** bears a strong resemblance to the structure of the parent compound $[Re_2H_8(PMe_2Ph)_4]$ **2**,[20] except that a *trans* pair of bridging hydrides have been replaced by $AuPPh_3$ units. The remaining six hydrides are bound only to Re and show no interaction with the Au atoms in contrast to the case with Cu (compound **3**).

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0202-0136 $ 02.50/0

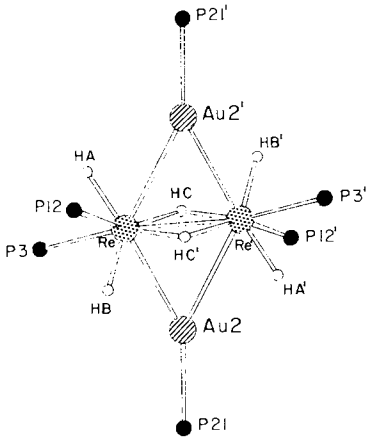


Fig. 2. ORTEP drawing of the crystal structure of **7b**, omitting methyl and phenyl groups for clarity. Primed and unprimed atoms are related by a crystallographic center of symmetry. Selected structural parameters: Au-Re 2.7625(9), Au-Re' 2.7725(10), Re-Re' 2.5644(10), Au-P 2.270(2), Re-P3 2.343(2), Re-P12 2.334(2), Re-HA 1.52(6), Re-HB 1.51(7), Re-HC 1.56(8), Re'-HC 1.90(8) Å; P3-Re-P12 99.40(7), Re-Au-Re' 55.20(2), Au-Re-Au' 124.80(2)°.

Both **7a** and **7b** are remarkable in that—in contrast to **2** and **3**—neither shows any evidence for fluxional behavior of hydride at 25°C. It is likely that the H/AuPPh$_3$ exchange impedes the interchange of hydrides from one end of the dimer to the other. The static character of the gold centers can be confirmed since the two isomers **7a** and **7b** do not interconvert in solution, even upon extended heating (90°C, 24 h). Compound **7a** is the first example of a gold/transition-metal complex that contains stereochemically rigid AuPPh$_3$ groups at 25°.

In addition to demonstrating the versatility of alcohol elimination as a rational route to mixed-metal clusters, the present work reveals that gold tenaciously retains phosphane ligands and thus phosphane-gold fragments serve as capping groups in cluster growth reactions. Copper, on the other hand, exhibits a tendency to be a linking group, thus promoting cluster growth to higher aggregates. This also explains the surprisingly different stoichiometries of the reactions of [Ph$_3$PCuO*t*Bu]$_2$ **1** and [Ph$_3$PAuO*t*Bu] **6** with [Re$_2$H$_8$(PMe$_2$Ph)$_4$] **2**. At the heart of these differences is the apparently greater affinity of copper for Cu–H and perhaps even Cu–Cu interactions; note that in [Re$_4$Cu$_2$H$_{14}$(PMe$_2$Ph)$_8$] **3**, copper is surrounded by four hydride ligands.

[9] The liberated PPh$_3$ slowly reacts with **2** to give [Re$_2$H$_6$(PMe$_2$Ph)$_4$(PPh$_3$)] + H$_2$ [10]. Consequently, isolation of product **3** is easier from the reaction of **2** + 1/4[CuO*t*Bu]$_4$ in benzene; this latter reaction is an order of magnitude slower than the reaction in Equation (a). Thus, reaction of **2** with [CuO*t*Bu]$_4$ (Re : Cu = 2 : 1) in a minimum amount of benzene on a 20-mmol scale is complete (^{1}H-NMR) after 48 h to give **3** in 90% isolated yield after removal of the solvent.

The Copolymer of 2,6-Pyridinedimethanethiol and 1,4-Benzenedimethanethiol**

By *Giovanni Modica, Silvia Maffi, Enzo Montoneri,* Luigi Giuffré,* and *Antonio Grassi*

Aromatic polymers containing sulfur in the backbone chain (e.g., polyarylene sulfides, $+C_6H_2X_2S+_n$, X = H or Me) are commercially available[1] as non-cross-linked, melting, and highly stable materials which are insoluble at room or medium temperature. Such polymers with pyridine rings in the chain are not known. Yet polypyridinediyl sulfides would be desirable alternatives to cross-linked, insoluble, nonmelting polyvinylpyridines,[2] which cannot be processed to obtain technologically useful products (e.g., membrane sheets or films). The thermal stability and an-

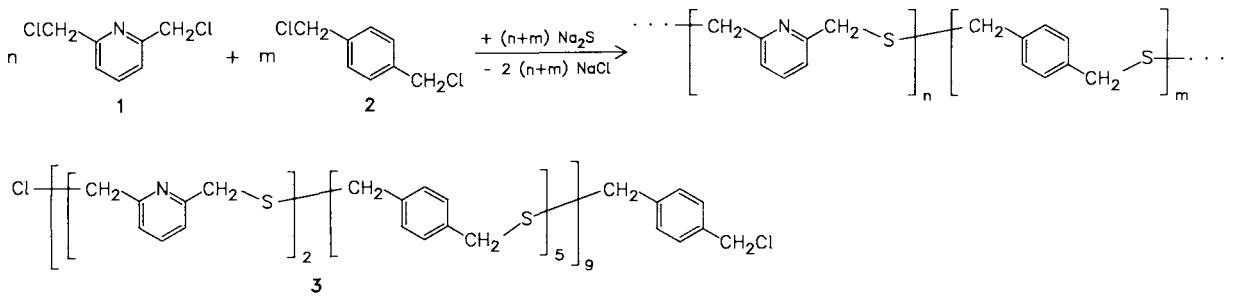
[**] This work was supported by the Ministero della Pubblica Istruzione (art. 65, DPR 382/80 (40%), 1983).



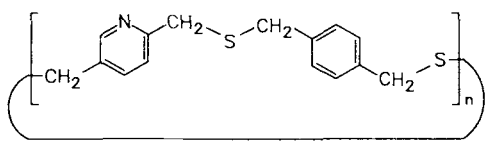
ion-exchange potential of polyvinylpyridines are exploited by manufacturing composite structures.[3]

With the aim of obtaining polymers that contain nucleophilic pyridine rings and are at the same time insoluble, melting, and processable (e.g., in the form of free-standing films), we have carried out the reaction between bis(chloromethyl) aromatic derivatives and sodium sulfide.[4] The reaction occurs readily at moderate temperature (78 °C) and with high conversion ($\geq 89\%$ (mol/mol)). The selectivity and the product molecular weight, however, vary significantly depending on the reacting monomers.

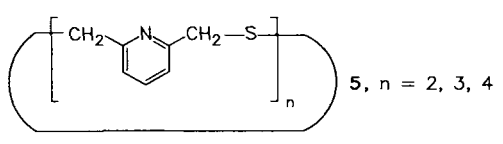
2,6-Bis(chloromethyl)pyridine **1**[5] and 1,4-bis(chloromethyl)benzene **2** reacted with sodium sulfide to give the copolymer **3** in high yields (100 **1***/**1** = 88.8 and 100 **2***/**2** = 99.8, **1** and **2** are the initial molar amounts of the monomers, **1*** and **2*** are the moles of monomers found as repeating units in the copolymer **3**). The copolymer **3** is insoluble in all common solvents, does not undergo significant weight loss up to 200 °C, melts at 177 °C, and yields a free-standing film upon melt pressing.

The IR spectrum (KBr pellet or neat) did not change after heating the product: its most intense bands are at 1580, 1540, and 1455 cm^{-1} (stretching vibrations of the 2,6-disubstituted pyridine ring) and at 1510 and 1420 cm^{-1} (stretching vibrations of the 1,4-disubstituted benzene ring). The X-ray diffraction powder pattern exhibits six very broad, poorly resolved bands in the 2θ range from 16 to 30 (centered at 20.87, 17.79, 23.29, 16.58, 27, and 19 in order of decreasing intensity).

The formation of the copolymer **3** is surprising since an analogous elimination reaction between the sodium salt of 1,4-benzenedimethanethiol and 2,5-bis(bromomethyl)pyridine in ethanol[6] has been reported to yield **4**, which is soluble in chloroform.



4, n = 1, 2



5, n = 2, 3, 4

Contrary to the synthesis of **3** but similarly to that of **4**, the reaction of **1** with Na_2S in the absence of **2** failed to yield a polymer. The sharp peaks in the X-ray diffraction pattern of the reaction product (Fig. 1) reveal a high degree of crystallinity such as found in low-molecular-weight compounds.[7] The elemental analysis corresponds to the

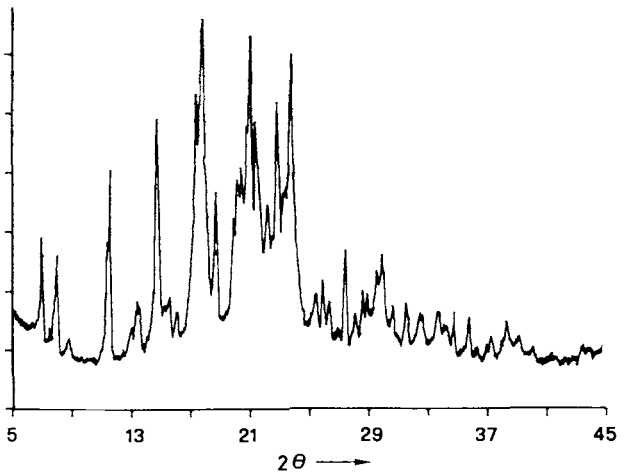


Fig. 1. X-ray powder diffraction pattern of poly(2,6-pyridinediylmethylene-thiomethylene) **5**.

formula CH_2-pyridinediyl-CH_2-S after allowing for 2% water content (confirmed by thermogravimetric analysis up to 120 °C); the absence of chlorine (unlike the case of the copolymer **3**) can only be interpreted on the basis of the cyclic structure **5**. The highest mass spectrum peak at *m/z* 548 indicates n = 4; no chlorine mass peaks were observed. However, peaks at 411 and 274 either could be interpreted as fragments of the tetramer **5** or, more in line with the NMR data, indicate the presence of other oligomers (the trimer and dimer) in the product. Indeed, the product was found to melt over a wide temperature range (128–180 °C) and differential scanning calorimetry showed a series of endothermic, broad, and poorly resolved bands with maxima at 124.5, 157 and 173 °C, and no weight loss.[8] Contrary to the copolymer **3**, the low-molecular-weight product **5** is soluble in chloroform. Its NMR spectrum ($CDCl_3$, int. TMS) shows a complex aromatic multiplet pattern at $\delta = 6.96$–7.56 (3 H) and three main singlets at $\delta = 3.97$, 3.79, and 3.74 (1.76, 1.56, and 0.68 H). The same resonances were reported for the protons of the *ortho* methylene group in the CH_2-pyridinediyl-CH_2-S unit in **4**:[6] 3.70 for **4**, n = 1, and 3.94 for **4**, n = 2.[9]

The results show that the possibility of obtaining high-molecular-weight polymers from bis(chloromethyl) aromatic derivatives and sodium sulfide strongly depends on the starting monomers. It appears that oligomerization of disubstituted pyridines can be inhibited and the formation of high-molecular-weight polymers containing pyridine rings in the backbone chain can be accomplished by reacting the pyridine reagent with an excess of the *p*-disubstituted benzene.

[7] The presence of small amounts of low-molecular-weight compounds in the product **3** was excluded on the basis of the absence of their characteristic X-ray pattern, particularly in the low-angle portion ($7 \leq 2\theta \leq 15$), which (for **3**) was totally free of bands.
[8] Weight loss (34%) occurred between 210 and 350 °C.
[9] By analogy, the three CH_2 proton resonances are tentatively assigned to the di-, tri-, and tetramers **5**, n = 2, 3, and 4, respectively. The proton shielding with increasing ring size could be reasonably accounted for by a corresponding decrease of steric hindrance, which makes likely intramolecular shielding of the CH_2 fragment: these groups, as shown by inspection of molecular models, can fall within the shielding cones of the pyridine rings, owing to increased conformational flexibility.

The Crystal Structure of Mn_2O_7

By *Arndt Simon,* Richard Dronskowski, Bernt Krebs,** and *Bernhard Hettich*

Dedicated to Professor Oskar Glemser on the occasion of his 75th birthday

Mn_2O_7 was first studied by *Aschoff*[1] in 1860. Important insights into the synthesis and properties of the compound were provided by the work of *Glemser* and *Schröder*[2] (cf. also ref. [3]). At room temperature, Mn_2O_7 is a volatile, dark red oil, which solidifies at 5.9 °C to give red crystals with green reflectance. The compound detonates when it is warmed to above 55 °C, when it is struck, or when it comes into contact with organic compounds.

The properties of Mn_2O_7 support a molecular structure for the solid state consisting of corner-sharing pairs of MnO_4 tetrahedra.[4] The initially suggested average distance $d(Mn-O) = 165$ pm[4] has been replaced by the newer values $d(Mn=O) = 158$ pm and $d(Mn-O) = 176$ pm for terminal and bridging O atoms, respectively, which were predicted by *Trömel*[5] on the basis of bond length-bond strength considerations. The IR spectra of Mn_2O_7, condensed from the gas phase at 12 K, indicate an Mn-O-Mn angle of 150 to 160°.[6]

Single crystals of Mn_2O_7 for X-ray diffraction analysis could be grown on a diffractometer, using a *Bridgman* technique,[7] by immediately cooling the X-ray capillary after filling it with liquid Mn_2O_7. The results of the X-ray crystal structure analysis are shown in Figures 1 and 2.

Mn_2O_7 forms monoclinic crystals in the space group $P2_1/c$ with eight formula units per unit cell.[8] The density calculated from the X-ray data at -30 °C, $\rho_{-30} = 2.79$ g cm^{-3}, is considerably larger than the measured density of the liquid, $\rho_{+20} = 2.396$ g cm^{-3}.[2]

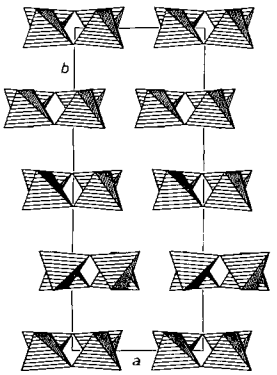

Fig. 1. Projection of the crystal structure of Mn_2O_7 along [001] with representation of the molecules as polyhedra [12].

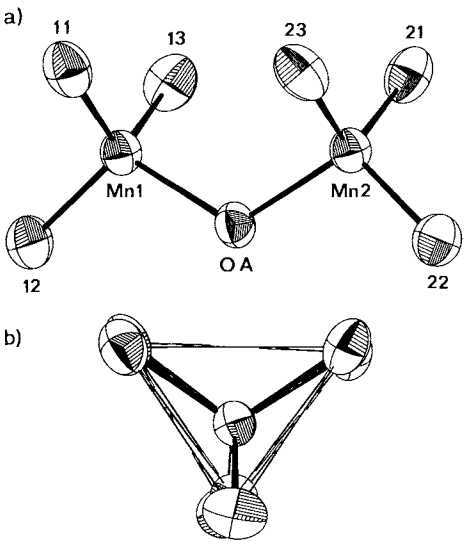

Fig. 2. Molecular structure of Mn_2O_7 (ORTEP II, ellipsoids with 50% probability). a) Viewed as in Fig. 1. b) Newman projection along the Mn1-Mn2 axis. The Mn-O bond lengths [pm] (standard deviation 0.3 pm), corrected for libration of the MnO_4 tetrahedra, for the Mn1/Mn2- and Mn3/Mn4-containing, symmetry dependent molecules are: Mn1-OA 177.0, Mn1-O11/13 160.5, Mn1-O12 158.9, Mn2-OA 177.0, Mn2-O21/23 159.6, Mn2-O22 158.4, Mn3-OB 177.3, Mn3-O31/33 160.0, Mn3-O32 158.4, Mn4-OB 176.6, Mn4-O41/43 159.9, Mn4-O42 158.2. The Mn-O-Mn angles at OA and OB are 120.7(2)°. Those angles that involve bridging atoms lie between 107.8 and 108.4°, the remaining between 110.3 and 111.3 °C.

The distances between the Mn atoms and the bridging O atoms are 177.0(3) pm, in excellent agreement with the previously estimated bond lengths.[5] The average value of the distance between the Mn and the terminal O atoms (159.5(8) pm), is also in agreement with predictions. More careful examination reveals that the bonds between the Mn atoms and the terminal O atoms, which lie in the Mn1-OA-Mn2 plane, are slightly shorter (158.5(3) pm) than those between the Mn atoms and the remaining terminal O atoms (160.0(4) pm). This difference in lengths can be easily explained in terms of the electrostatic repulsion between the Mn atoms.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0202-0139 $ 02.50/0

The Mn-O-Mn bond angle (120.7°) is considerably smaller than that measured for (amorphous?) Mn_2O_7 films.[6] However, it is possible that the two findings are not in contradiction. In the crystal, the small angle leads to the intramolecular formation of a nido-octahedral arrangement for the bridging and the four terminal O atoms (cf. Fig. 2b), which is augmented to form an octahedron by a further O atom from an adjacent molecule.

This indicates that the Mn_2O_7 molecules are packed in a way to yield a close-packed arrangement of all O atoms. Indeed, the Mn_2O_7 structure can be described in terms of an fcc lattice of the O atoms; the actual positions of the O atoms deviate, on the average, by 24 ± 5 pm (contraction of the neighboring tetrahedral voids occupied by Mn) from the ideal lattice positions. The formation of a close-packed structure explains the unusual increase in the density of Mn_2O_7 upon crystallization.

Comparison of the crystal structures of Mn_2O_7, Tc_2O_7, and Re_2O_7 reveals interesting similarities and differences: In Tc_2O_7,[10] discrete M_2O_7 molecules with tetrahedrally surrounded M atoms also occur, but the M-O-M angle is 180°. The molar volume of Tc_2O_7 (86.5 $cm^3\ mol^{-1}$) is considerably larger than that of Mn_2O_7 (79 $cm^3\ mol^{-1}$). In contrast, for the three-dimensional network of Re_2O_7,[11] with tetrahedrally and octahedrally surrounded Re atoms, a molar volume of 78 $cm^3\ mol^{-1}$ is found, which is close to that of Mn_2O_7. This comparison shows that Tc_2O_7 occupies a special position in the series of compounds, indicating, for example, that transformations under pressure might take place.

Experimental Procedure

$KMnO_4$ (ca. 50 mg) was treated with H_2SO_4 (+20% SO_3). After a short period of time, Mn_2O_7 separated out as a dark, oily ring around the reaction mixture and was sucked into a carefully cleaned capillary (0.2-mm Ø, 20-mm continuous column of liquid). The (open) capillary was cooled immediately with liquid N_2 in order to prevent interruptions of the column of material by the formation of O_2 bubbles, and it was then mounted at −10°C on a four-circle diffractometer. Suitable crystals, which were nearly aligned along [001] in the direction of the axis of the tube, were obtained in a temperature gradient of $-10/+20$°C [7] and improved by variation of the temperature between ca. 0 and 5°C, continuously monitoring via X-ray diffraction.

CO_2 Elimination from Vinylene Carbonate Radical Anions and Charge Reversal in $C_2H_2O^{\odot\ominus}$: Reactions Involving the Radical Anion and Cation of Oxirene?**

By *Ben L. M. van Baar, Nikolaus Heinrich, Wolfram Koch, Ron Postma, Johan K. Terlouw,* and *Helmut Schwarz**

Vinylene carbonate **1** reacts with low-energy electrons in the gas phase to give, via elimination of CO_2, a metastable radical anion $C_2H_2O^{\odot\ominus}$, which loses an electron to form C_2H_2O.[1] It has not been possible so far to elucidate the structures of the intermediate radical anions or of the neutral molecules of empirical formula C_2H_2O (**2a**–**5a** and **2b**–**5b**, respectively). This is not surprising in view of the confusing chemistry of this small species.[2, 3]

We report here on gas-phase experiments, supplemented by extensive ab initio MO calculations, that show that

elimination of CO_2 from $\mathbf{1}^{\odot\ominus}$ results in the formation of **3a**, the radical anion of the ketocarbene **3b**. Spontaneous loss of an electron from the metastable **3a** affords the ketene **5b**. Charge reversal[4] via collision-induced 2-electron loss from **3a** results mainly in formation of the ketocarbene radical cation **3c**. Depending on its internal energy, it undergoes decomposition or isomerization to the long-sought and theoretically predicted[5] oxirene radical cation **2c**.

Electron attachment to **1** in a ZAB-2F mass spectrometer results in loss of CO_2 and formation of $C_2H_2O^{\odot\ominus}$ ions, which were mass-selected by employing tandem mass spectrometry (MSMS).[6] The collisional activation (CA)[7] spectra were then recorded. The CA spectrum of $C_2H_2O^{\odot\oplus}$ formed by spontaneous loss of an electron from $C_2H_2O^{\odot\ominus}$, followed by collisional reionization mass spectrometry,[8] is identical in all respects with the CA spectrum of **5c** produced from **5b**.[9] This indicates that spontaneous electron loss from $C_2H_2O^{\odot\ominus}$ leads to **5b**. However, the following experiment and ab initio results (described below) strongly suggest that $C_2H_2O^{\odot\ominus}$ is not present as **5a** but rather as **3a**. If charge reversal is allowed to take place in a collision experiment of the $C_2H_2O^{\odot\ominus}$ ions (vertical removal of two electrons), the CA spectrum shown in Figure 1 is obtained. This spectrum cannot be simulated by a linear combination of the CA spectra of **5c** and **4c**. In contrast, more detailed comparison with the CA spectra of these ions[9] indicates that only a few percent of **4c** and **5c** are formed upon generation of "reactive" $C_2H_2O^{\odot\oplus}$ ions from $C_2H_2O^{\odot\ominus}$. On the basis of the spectrum, therefore, the intermediacy of at least one, previously unknown, $C_2H_2O^{\odot\oplus}$ species is suggested. We propose formation of **3c**, the radical cation of ketocarbene **3b**, the most important ionic fragmentation products of which are the ion at *m/z* 29 ($HCO^{\oplus}$), produced by loss of CH, and that at *m/z* 26 ($C_2H_2^{\odot\oplus}$), produced by deoxygenation. *m/z* 41 corresponds presumably to the ion $H-\overset{\oplus}{C}=C=O$, which can also arise directly from **3c**.

According to ab initio calculations,[5] **3c** is not stable. The radical cation undergoes decomposition (see preceding paragraph) or isomerizes to **2c** (via ring closure) and **4c** or **5c** (via H migration). The reaction **3c**→**4c** is unlikely for energetic reasons.[5] The spontaneous process **3c**→**5c** should, on account of the large enthalpy of formation of **3c**,[5] yield highly excited **5c**, which, in turn, should decompose spontaneously into CO and $CH_2^{\odot\oplus}$. Indeed, we believe that the signal at *m/z* 14 (Fig. 1) may originate from the reaction **3c**→**5c**→$CH_2^{\odot\oplus}$ + CO. However, what is the explanation for the observation that the vertical removal of two electrons from **3a** does not only lead to fragments but also to a *stable* ion at *m/z* 42 ($C_2H_2O^{\odot\oplus}$), which has a lifetime $t > 10^{-5}$ s? The only possible explanation is that the radical cation **3c**, generated with only a small amount of excess energy, undergoes isomerization to **2c**, the radical cation of oxirene **2b**. **2c** is theoretically predicted[5] to reside in a sufficiently deep potential well so that fragmentation processes are not favored.

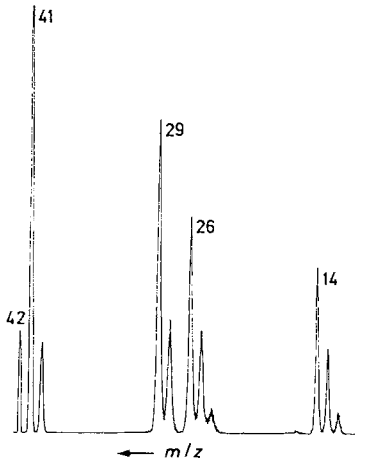

Fig. 1. CA spectrum of $C_2H_2O^{\odot\oplus}$ ions generated by charge reversal from $C_2H_2O^{\odot\ominus}$.

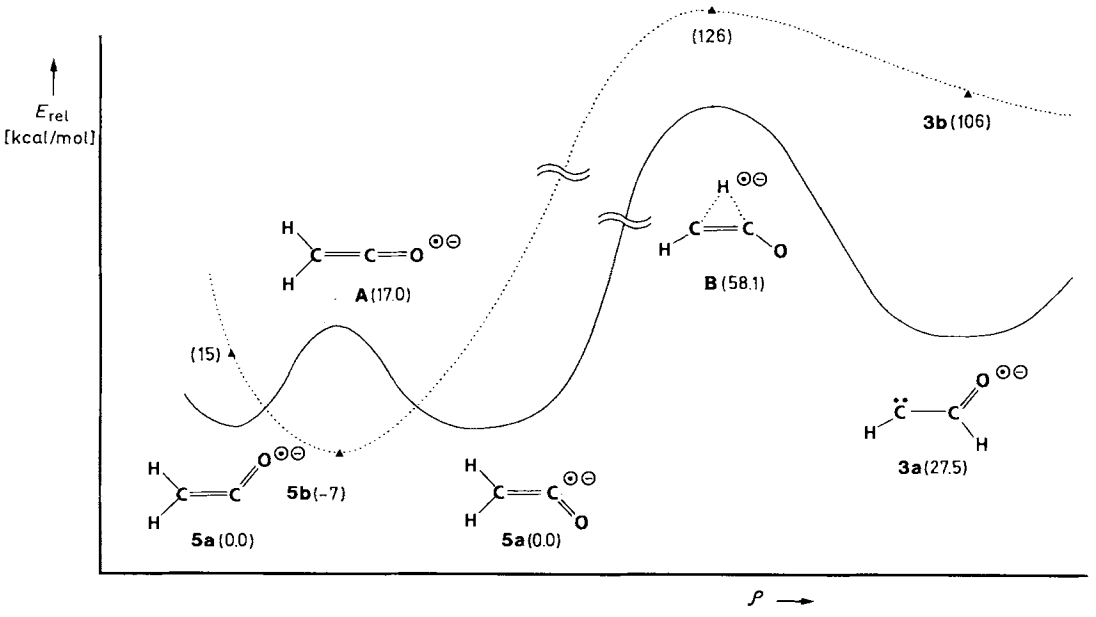

Fig. 2. Schematic potential hypersurface for species of empirical formula $C_2H_2O^{\odot\ominus}$ (——) and C_2H_2O (-----). The calculations were carried out at the MP3/6-311++G(d,p)//6-31+G(d) level. ρ = reaction coordinate; **A**, **B** = transition states; relative energies in parentheses.

Let us return to the initially posed question as to the structure of the $C_2H_2O^{\oplus\ominus}$ ions. Supplementing and supporting the results of the experiments, ab initio calculations (performed at the MP3/6-311++G(d,p)//6-31+G(d) level) yielded the following results:[10] **3a** (and several of its conformers), like the bent form of **5a**,[12] exist in potential minima (Fig. 2). **3a** is about 27.5 kcal/mol less stable than **5a**; the barrier for the isomerization **3a** → **5a** is 30.6 kcal/mol. Positive electron affinities are predicted for both species. The experimental observation that electron loss nonetheless occurs from **3a** must be due to the fact that **3a** is generated with excess energy upon electron attachment to vinylene carbonate **1**. If this amount of energy is large enough to overcome a barrier of about 30 kcal/mol (or less, if tunnel effects play a role), then the reaction **3a** → **B** → **5a** ⇄ **A** results necessarily in electron loss to form ketene **5b**; the latter is identified in the experiment. The radical anion of oxirene, **2a**, plays no role in the chemistry of the $C_2H_2O^{\oplus\ominus}$ species. **2a**, which is about 100 kcal/mol less stable than **3a**, corresponds, moreover, to a saddle point of second order (two imaginary frequencies).

[10] The notation MP3/6-311++G(d,p)//6-31+G(d) means that the calculation of individual points for the geometries optimized at a 6-31+G(d) level [11a] was carried out with the 6-311++G(d,p) basis set [11c], which is more than sufficient for anions. The effects of electron correlation were taken into consideration by perturbation calculations (according to Møller-Plesset [11d,e]) up to third order (MP3). The extended (+) basis sets are described in [11f]. Minima and maxima were unequivocally located by an analysis of the force-constant matrix. Complete data for geometries and energies of the structures reported here (and their conformers) are available on request.

[12] The fact that ketene has a negative electron affinity [Prof. E. Illenberger (Berlin), Prof. N. M. M. Nibbering (Amsterdam), private communication] does not contradict the ab initio results. Vertical electron attachment to **5b** yields the transition state **A**, corresponding to the topomerization of **5a**. In the process **A** → **5a** crossing with the hypersurface of the neutral C_2H_2O molecule (broken line in Fig. 2) occurs; this results in spontaneous electron loss with re-formation of **5b**.

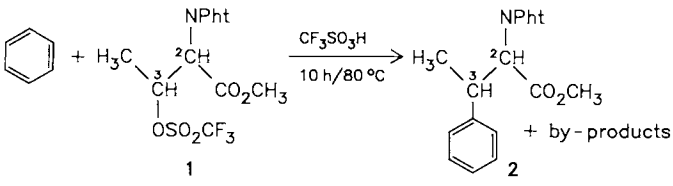
Stereoselective Alkylation of Aromatic Compounds with Threonine Trifluoromethanesulfonates**

By *Franz Effenberger** and *Thomas Weber*

Dedicated to Professor Rudolf Gompper on the occasion of his 60th birthday

Alkyl trifluoromethanesulfonates (alkyl triflates) have only been used in special cases for the alkylation of aromatic compounds.[1] We have now succeeded in synthesizing the *N*-protected triflates of (*S*)- and (*R*)-serine methyl ester as well as the *N*-protected triflates **1** of all diastereomeric threonine methyl esters in very good yields and with complete retention of configuration. This was accomplished by treating the *N*-phthaloyl-protected amino acid esters with trifluoromethanesulfonic anhydride in the presence of pyridine. With the triflates of the serine and threonine esters, it was possible to alkylate benzene and benzene derivatives to obtain phenylalanine and β-methylphenylalanine esters **2**, respectively.

These reactions proceed with retention of configuration at C-2 of the amino acid ester under all conditions employed. Of particular interest but difficult to predict was the stereochemistry at C-3 of the β-methylphenylalanine esters **2**. The Friedel-Crafts alkylation of aromatic compounds with optically active alkylating agents usually proceeds with extensive racemization.[2] However, *Suga* et al., in particular, have shown that alkylation with optically active compounds can also be carried out without significant racemization if special structural properties are fulfilled.[3] In general, these alkylations occur with inversion of confi-



1 **2**

[**] Electrophilic Aromatic Substitution, Part 32. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *T. W.* thanks the Fonds der Chemischen Industrie for a doctoral fellowship.—Part 31: F. Effenberger, F. Reisinger, K. H. Schönwälder, P. Bäuerle, J. J. Stezowski, K. H. Jogun, K. Schöllkopf, W. D. Stohrer, *J. Am. Chem. Soc.*, in press.

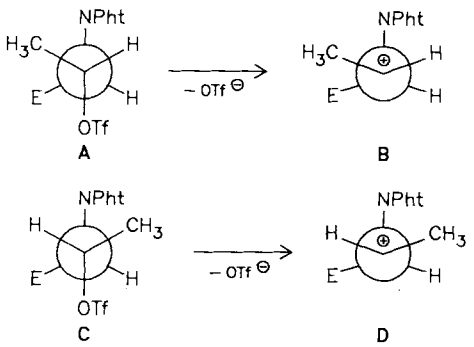
guration of the attacking C atom of the alkylating agent. Retention was observed for alkylation with β-phenylalkyl halides: in the first step, intramolecular alkylation with inversion results in the formation of a cyclohexadienylium intermediate, which, in the second step, again with inversion, reacts with the aromatic compound.[4]

In the alkylation of benzene with the triflates of the *N*-phthaloylthreonines **1a,b** and the *N*-phthaloylallothreonine methyl esters **1c,d**, we obtained in every case the β-methyl-*N*-phthaloyl phenylalanine methyl esters **2**. The overall yields of **2** are between 20 and 40%, because, in addition to the substitution of **1** to give **2**, substantial elimination occurs to give α,β- (25–30%) and β,γ-dehydroamino acid esters (35–40%).

Whereas the configuration at C-2—as previously mentioned—is maintained upon the reactions of **1a–d** to give **2**, the threonine (**1a,b**) and allothreonine (**1c,d**) derivatives show diverse behavior upon alkylation with respect to the stereochemistry at C-3.

The threonine derivatives **1a,b** react largely with retention at C-3, whereas the allothreonine derivatives **1c,d** afford diastereomeric mixtures in the ratio of 2:3. The characterization and structural assignments of the four diastereomers **2a–d** were determined by comparison of their optical rotations and ^{1}H-NMR data with literature values.[5] For **2a**, we confirmed the configuration by carrying out an X-ray structure analysis.[6] Furthermore, we were able to show that the product obtained by acid hydrolysis of **2a**, removal of the phthaloyl protecting group, and acetylation is identical with the reported (2*S*,3*S*)-*N*-acetyl-β-methylphenylalanine.[7]

The high stereoselectivity observed in the alkylation of benzene with **1a, b** and the different behavior of **1c, d** can be explained in terms of the different conformations of the carbenium ions **B** and **D**, which are formed as intermediates in the alkylation.



E = CO_2CH_3; Tf = SO_2CF_3

Alkylation of benzene with (*S*)- and (*R*)-1-methyl-2-phthaloylaminomethyl triflate **3** results in partial retention, whereas with methyl (*S*)-3-trifluoromethanesulfonyloxybutyrate, (*S*)-**4**, complete racemization is observed. We conclude from this that, in the dissociation step, the threonine derivatives **1a,b** prefer conformation **A**, whereas the allothreonine derivatives **1c,d** prefer conformation **C**. In the carbenium ion **B** formed from **A**, rotation is rendered difficult by the two large neighboring substituents (CH_3, CO_2CH_3); moreover, the aromatic compound can react only from the bottom side with **B**, because the cationic center is blocked from above by the *N*-phthaloyl group. This explains the retention observed in the reactions of **1a,b**. For the cationic intermediate **D**, on the other hand, no or at most only a small hindrance to rotation is expected, which is confirmed by the results of the reactions of **1c,d**.

In analogy to the reactions of benzene, alkyl- and alkoxybenzenes can also undergo reaction with the triflates **1** of the threonine ester. In a one-pot procedure, it is also possible to synthesize phenylalanines and β-methylphenylalanines such as **2** from the corresponding aromatic compounds, the *N*-protected esters of serine and threonine, and trifluoromethanesulfonic anhydride (without isolation of the triflates of type **1**). Trifluoromethanesulfonic acid can be precipitated as its barium salt and thus recovered.

Experimental Procedure

2a: *N*-phthaloyl-*O*-(trifluoromethanesulfonyl)-(2*S*,3*R*)-threonine methyl ester **1a** (1.58 g, 4 mmol) and trifluoromethanesulfonic acid (0.61 g, 4 mmol) were stirred in 8 mL of benzene for 10 h at 80°C under dry atmosphere. The excess benzene was then removed in vacuo. After addition of water to the residue, the mixture was extracted with chloroform. The combined organic phases were dried over $MgSO_4$ and evaporated; the residue was chromatographed on silica gel with petroleum ether/ethyl acetate (9:1). Yield 300 mg (24%) **2a**, m.p. = 107°C (petroleum ether), $[\alpha]_D^{20}$ = −139.1° (*c* = 1, $CHCl_3$) and 10 mg (0.77%) **2c**, oil, $[\alpha]_D^{20}$ = −120.5° (*c* = 0.6, $CHCl_3$).

One-pot procedure: *N*-phthaloyl-(2*S*,3*R*)-threonine methyl ester (0.53 g, 2 mmol) and trifluoromethanesulfonic anhydride (0.56 g, 2 mmol) were allowed to react as described above. Yield 0.15 g (23%) **2a**, $[\alpha]_D^{20}$ = −138.3° (*c* = 1, $CHCl_3$).

Asymmetric Synthesis of Cyclic α-Amino Acids by the Bislactim Ether Method**

By *Ulrich Schöllkopf,** *Rolf Hinrichs*, and *Ralph Lonsky*

Dedicated to Professor G. Quinkert on the occasion of his 60th birthday

Optically active α-methylproline **10a** and its analogues **10b** and **11** are of interest because of their potential biological activity as competitive enzyme inhibitors.[2] (*S*)-α-Methylproline (*ent*-**10a**) was prepared by *Seebach* et al.[3] from naturally occurring L-proline in an asymmetric synthesis. This synthesis, although elegant, has the disadvantage that it cannot be applied to ring homologues without modification, because homologues of proline do not exist in the "chiral pool" of nature. We report here a very flexible asymmetric synthesis of 2-methyl-1-azacycloalkane-2-

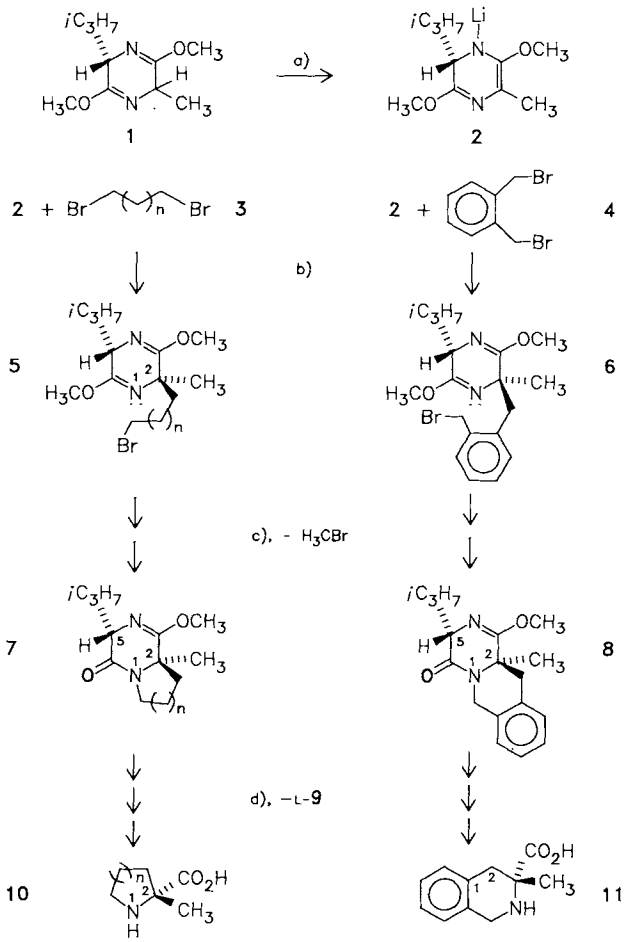
[**] Asymmetric Syntheses via Heterocyclic Intermediates. Part 32.—Part 31: [1].

carboxylic acids of the types **10** and **11** according to the bislactim ether method.[4] The cyclic amino acid is constructed during the synthesis by diastereoselective alkylation (**2** + **3/4** → **5/6**).



3, 5, 7, 10: a, n = 1: b, n = 2

	7a	7b	8
Yield [%]	81[a]	76[b]	75[a]
(2*R*,5*S*) : (2*S*,5*S*)[8]	97:3	97.5:2.5	98.5:1.5

[a] Based on **1**. [b] Based on **5b**.

Scheme 1. Synthesis of cyclic amino acids. a) BuLi, tetrahydrofuran (THF), −78°C, 2 equivalents *N,N'*-dimethyl-2-imidazolidinone (*N,N'*-dimethylethyleneurea, DMEU). b) 3.0 equivalents **3** or **4**, 12 h at −78°C, then warming to room temperature [7]. c) **7a**: distillation of **5a**; **7b** and **8**: dimethylformamide (DMF), 1 equivalent NaI, reflux 2 h or 1 h, respectively [9]. d) 20 mL conc. HBr (2.0 mmol), reflux 18 h for **7a**, **b**, 40 h for **8**, concentration in vacuo, heating with propene oxide in ethanol [10]. The (nonsystematic) numbering is given for configurational assignment and assignment of the NMR signals.

The synthesis starts from **1**, the commercially available bislactim ether of *cyclo*-(L-Val-Ala) [or *cyclo*-(D-Val-Ala)].[5,6] Compound **1** was lithiated to give **2**, which was allowed to react with the dihalide **3** or **4** to give the intermediates **5** or **6**, respectively, which, in turn, gave **7** or **8** in a thermal reaction. Compounds **5** and **6** are formed with high asymmetric induction.[8] In the case of **5b** and **6**, the cyclizations **5** → **7** and **6** → **8** require heating in DMF in the presence of sodium iodide.[9] Compound **5a**, on the other hand, cyclizes already upon distillation. When the compounds **7** and **8** are heated with hydrobromic acid, they undergo hydrolysis to valine **9** and to the (*R*)-2-methyl-1-azacycloalkane-2-carboxylic acids **10** and **11**, respectively. From the mixture of the amino acid hydrobromides remaining after removal of the excess hydrobromic acid, the amino acids may be isolated by short heating (15 min) in ethanol with propene oxide. Compound **9** may easily be separated from the target molecules **10** and **11**, either by chromatography or by crystallization.[10,12] The ^{1}H-NMR data for compounds **5**, **7**, **8**, **10**, and **11** are collected in Table 1.

Table 1. δ(^{1}H) values of **5**, **7**, **8**, **10**, and **11** from 200 MHz spectra.

$[Ag_4(SCH_2C_6H_4CH_2S)_3]^{2-}$, a Novel Polynuclear Silver Thiolate with Trigonal-Planar Coordination of All Silver Atoms and a Central $[Ag_4S_6]$-Cage**

By *Gerald Henkel,* Peter Betz,* and *Bernt Krebs*

Parallel with the increasing interest being shown in transition metal-sulfur chemistry, numerous complexes with thiolate ligands have been synthesized in the past few years. These include, inter alia, the anions **1**–**4**,[1–4] which, because of similar coordinative properties, are formed both by monovalent copper (M = Cu) as well as by monovalent silver (M = Ag).

$[M_5(S\,t\mathrm{Bu})_6]^-$ **1**

$[M_5(SPh)_7]^{2-}$ **2**

$[M\{SC_6H(CH_3)_4\}_2]^-$ **3**

$[AgM_8(SCH_2CH_2S)_6]^{3-}$ **4**

Surprisingly, however, all attempts to isolate a silver thiolate complex containing the $[M_4S_6]$ center that is quite common in copper thiolate chemistry and has been found for example in the compounds **5**–**8**[5–8] have so far been unsuccessful, even though the existence of $[Ag_4(SPh)_6]^{2-}$ has already been speculated upon in the literature.[9]

$[Cu_4(SCH_3)_6]^{2-}$ **5**

$[Cu_4(SPh)_6]^{2-}$ **6**

$[Cu_4(SCH_2CH_2S)_3]^{2-}$ **7**

$[Cu_4(SCH_2C_6H_4CH_2S)_3]^{2-}$ **8**

We now report on the synthesis and structure of the anion **9**, the first compound with a tetrahedro-Ag_4-octahedro-$(\mu\text{-}S)_6$ cage; with tetraphenylphosphonium bromide in methanolic solution, **9** forms pale yellow prisms of the salt **10**.

$[Ag_4(SCH_2C_6H_4CH_2S)_3]^{2-}$ **9**

$[Ph_4P]_2[Ag_4(SCH_2C_6H_4CH_2S)_3]\cdot 6\,MeOH$ **10**

[**] This work was supported by the Bundesminister für Forschung und Technologie, by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, and by the Fonds der Chemischen Industrie.

The tetranuclear cluster **9** is, moreover, the only silver thiolate complex known so far in which all silver atoms are surrounded by a trigonal planar array of sulfur atoms. It is formed upon reaction of 10 mmol of $AgNO_3$ with 10 mmol of $Na_2(SCH_2C_6H_4CH_2S)$ in 100 mL of methanol. According to the results of an X-ray structure analysis (Fig. 1),[10] crystals of **10** contain, besides Ph_4P^+ ions and discrete cluster anions **9**, also ordered and disordered methanol molecules in the ratio 2:1, which are not bound to metal atoms and presumably contribute to the stability of the crystal lattice.

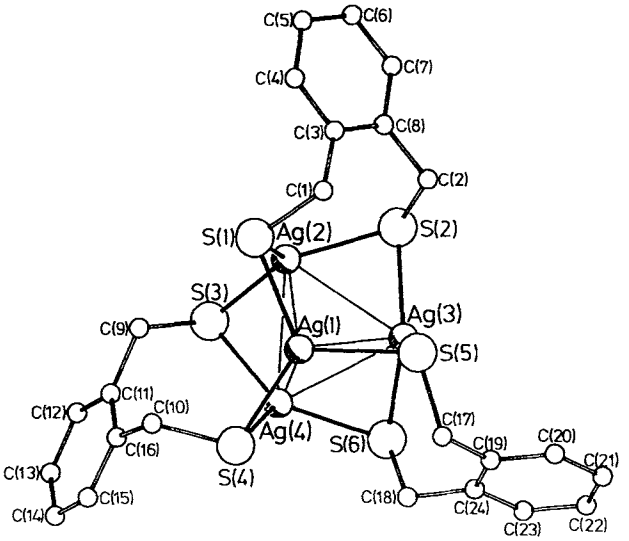

Fig. 1. Structure of the dianion **9** in crystals of **10** (without hydrogen atoms). Bond length ranges [Å]: Ag···Ag 2.998(1) to 3.085(1) (mean value 3.044), Ag-S 2.449(1) to 2.588(1) (mean value 2.505), S-C 1.835(5) to 1.844(5) (mean value 1.840). Angle ranges [°]: Ag-S-Ag 73.56(3) to 76.45(4) (mean value 74.82), S-Ag-S 112.26(4) to 132.88(4) (mean value 119.84), Ag-S-C 100.1(2) to 109.4(2) (mean value 104.8).

All six sulfur atoms of the *o*-xylene-α,α′-dithiolate ligands bridge two silver atoms each with Ag-S-Ag bridge angles in the range of 73.56(3) to 76.45(4)° (example: S(1) bridges Ag(1) and Ag(2)); the silver has a distorted trigonal-planar sulfur coordination. Ag(2), Ag(3), and Ag(4) are each chelated by one ligand (example: Ag(2) is chelated by S(1) and S(2)), while Ag(1) is surrounded by three sulfur atoms of three ligands.

The central $[Ag_4S_6]$ unit of **9** is in its idealized form an octahedron whose vertices are formed by sulfur atoms; half of its faces are occupied by silver atoms, constructed as shown schematically in Figure 2.

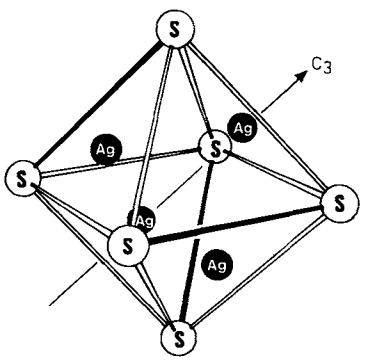

Fig. 2. The $[Ag_4S_6]$ cage as idealized center of **9** with edges of the octahedron (without silver-sulfur bonds). Sulfur atoms that belong to the same ligand are those connected by bold-face edges.

Thereby, the resulting silver tetrahedron and the sulfur octahedron have a common centroid. Although the anion **9** is chiral because the six sulfur atoms are functional groups of bidentate ligands, both enantiomers occur with equal abundance in the centrosymmetric crystals of **10** (cf. Ref. [10]). In Figure 2 the sulfur atoms which belong to the same ligands are connected by filled edges of the octahedron.

In its idealized form **9** has C_3 symmetry, whereby the threefold axis passes through Ag(1) and the center of the Ag(2)-Ag(3)-Ag(4) triangle. The mean S-Ag-S valence angle is 119.84° and thus indicates that the AgS_3-coordination centers are not completely planar. The S-Ag-S chelate angles, with an average value of 112.62°, are very small. Compared to the corresponding copper compound,[8] the larger metal-sulfur bond lengths lead to a diminution of the angle in the chelate ring of about 5°. In addition to the small angle in the chelate ring, the atoms Ag(2), Ag(3), and Ag(4) are each characterized by a somewhat larger (example: S(1)-Ag(2)-S(3); mean value 115.20°) and a very much wider valence angle (example: S(2)-Ag(2)-S(3); mean value 131.58°). Moreover, there are two shorter (mean value 2.468 Å) and one somewhat longer Ag-S bond (mean value 2.572 Å) around each of the atoms Ag(2), Ag(3), and Ag(4). Interestingly, there are differences in the bond lengths within the S-Ag-S chelate fragments, the longer bonds being formed to the sulfur atoms that are also bound to Ag(1) (example: Ag(2)-S(1)). Compared to this, valence angles of 113.30(4), 122.77(4), and 123.78(4)° and Ag-S bond lengths of 2.475(1), 2.521(1), and 2.532(1) Å are observed at Ag(1). Thus, the distortion of the real molecule is clearly documented, since C_3 symmetry requires equal valence angles and equal bond lengths.

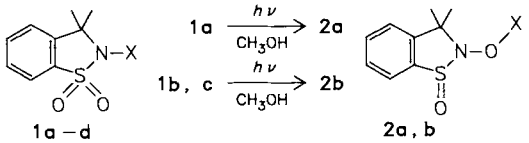
Unusual Photoisomerization of a Cyclic Sulfonamide**

By *Dietrich Döpp,* Carl Krüger,* Peter Lauterfeld,* and *Eleonore Raabe**

Dedicated to Professor Howard E. Zimmerman on the occasion of his 60th birthday

The light-induced cleavage of the R-S, S-N, and N-R′ bonds in open-chain sulfonamides $R-SO_2-NH-R'$ has already been well documented and it has been demonstrated that the resulting fragments undergo radical-type reactions.[1] We have now found that 3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1,1-dioxide **1a** (readily accessible in two steps from saccharin[2]) is rapidly and completely converted into its isomer 2-hydroxy-3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1-oxide **2a** upon irradiation in methanol with the quartz-glass filtered light of a low-pressure mercury vapor lamp ($\lambda = 254$ nm).[3] Crystalline **2a** can be stored for long periods; in solution, however, it notably isomerizes back to **1a** (especially under influence of acid).



a, X = H; **b**, X = CH_2OCH_3
c, X = $CH_2OCH(CH_3)_2$; **d**, X = CH_3

The crystal structure analysis[4] of **2a** (Fig. 1) clearly shows the distorted and folded five-membered ring with trigonal-pyramidal N and S atoms. The hydroxyl H atom (H2) is bound by an almost linear intermolecular hydrogen bridge to the sulfoxide O atom (O1′) of a neighboring molecule (Fig. 2).

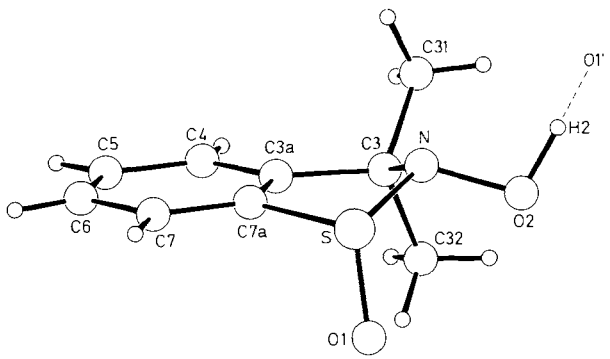


Fig. 1. Crystal structure of **2a**. Important bond lengths [Å] and angles [°]: S-N 1.695(1), N-C3 1.499(2), C3-C3a 1.504(2), C3a-C7a 1.386(2), C7a-S 1.786(2), S-O1 1.492(1), N-O2 1.418(2), O2-H2 1.03(3), H2···O1′ 1.68(3); C7a-S-N 86.9(1), S-N-C3 115.5(1), N-C3-C3a 100.7(1), C3-C3a-C7a 114.4(1), C3a-C7a-S 112.3(1), C7a-S-O1 106.7(1), O1-S-N 113.5(1), S-N-O2 109.0(1), O2-N-C3 113.4(1), C31-C3-C32 111.4(2).

2a is to our knowledge the first example of a sulfinohydroxamic acid.[5] A color formation with iron(III) ions, as found in the case of the hydroxamic acids, is not observed. Reduction of **2a** with potassium iodide solution 0.2 N in hydrochloric acid afforded about equal amounts of the expected 3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1-oxide and **1a**.[3] Upon gas-phase pyrolysis (600 °C, 10^{-3} torr) **2a** is rearranged into **1a**, which is stable at this temperature.[3]

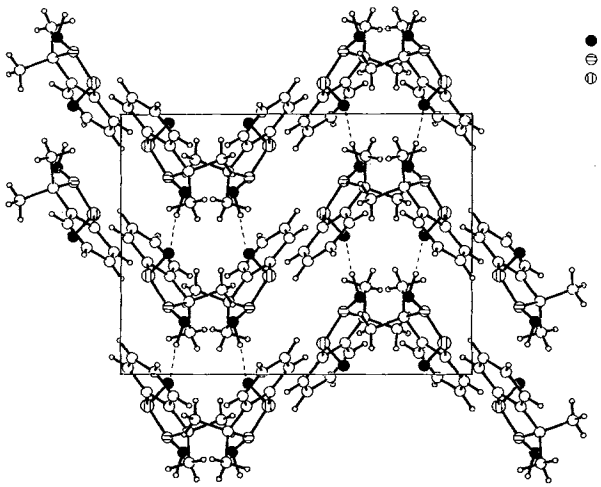

Fig. 2. Packing of racemic **2a** in the crystal.

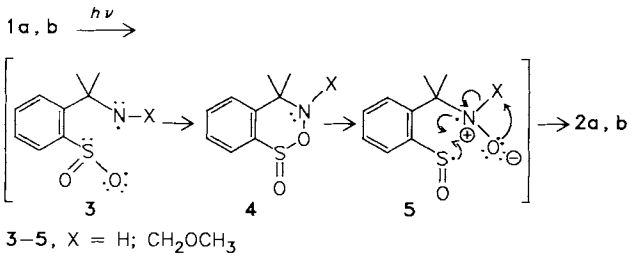
Under the same conditions, the dihydrobenzothiazoles **1b**, **c** are converted into **2b**; in the case of **1c** this additionally implies replacement of the isopropoxy group by a methoxy group. Thus, in the course of the isomerization, not only an H atom but also a group with a sufficiently electrophilic C atom can be transferred from the N atom to the O2 atom. 2,3,3-Trimethyl-2,3-dihydro-1,2-benzothiazole 1,1-dioxide **1d**, on the other hand, is photolyzed only slowly and gives a complex product mixture.

We are at present directing our efforts towards clarification of the course of both the photochemical forward (**1** → **2**) and the thermal or acid-catalyzed reverse reaction (**2** → **1**). It is highly unlikely that either of the reactions does not involve intermediates. Our working hypothesis is that the photoisomerization of **1a**, **b** is initiated by a cleavage of the S-N bond, and that **3** is then transformed via the conceivable intermediates **4** and **5** into **2a**, **b**.



Experimental

2a: A solution of **1a** (1.00 g, 5.08 mmol) in anhydrous methanol (140 mL) was irradiated with a Hanau-TNN-15 lamp (15 W) through a water-cooled immersion well for 2.5 h with N_2-purging. The oily residue obtained upon concentration immediately crystallized and, after washing with acetone furnished 710 mg (71%) of colorless crystals, m.p. 112 °C.

Metzger in *Houben-Weyl-Müller: Methoden der Organischen Chemie, Band X/4*, Thieme, Stuttgart 1968, especially p. 217 and references cited therein. Even a computer-controlled substructure search in the CA Registry File gave no positive result.

Azulene as Unusual η^6-Ligand and as η^6:η^4-Bridge in Mo-Complexes**

By *Susanne Töfke* and *Ulrich Behrens**

Investigations of the structure of transition metal-azulene complexes show a preferred coordination of the metal atom to the five-membered ring with formation of a π-cyclopentadienyl system. In addition, there is a tendency for dinuclear complexes to be formed.[1, 2]

We have now found a novel type of η^6-coordination of azulene, namely in the mononuclear complex $[(C_{10}H_8)(C_6H_6)Mo]$ **1** (Fig. 1).[3]

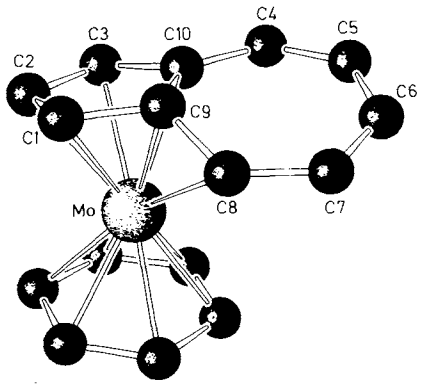

Fig. 1. Crystal structure of **1** [3]. Selected bond lengths [Å]: Mo-center of five-membered ring 1.898(1), Mo-center of benzene ring 1.758(1), Mo-C1 2.231(6), Mo-C2 2.342(6), Mo-C3 2.346(5), Mo-C9 2.125(5), Mo-C10 2.257(5), Mo-C8 2.447(6), C1-C2 1.380(9), C2-C3 1.405(8), C3-C10 1.416(7), C10-C4 1.442(7), C4-C5 1.349(8), C5-C6 1.410(9), C6-C7 1.342(9), C7-C8 1.457(10), C8-C9 1.422(8), C9-C10 1.454(7), C1-C9 1.443(8).

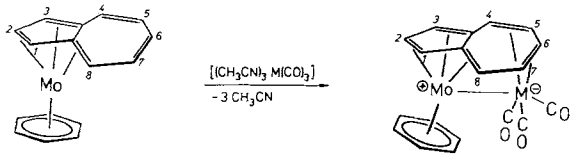
[**] Transition Metal-Fulvene Complexes, Part 30. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 29: F. Edelmann, O. Koch, U. Behrens, *J. Organomet. Chem. 311* (1986) 111.

The azulene molecule is coordinated via the fulvene system formally contained in it to the [(benzene)Mo] fragment. Similarly as in η^6-coordinated mononuclear fulvene complexes,[4] the "exocyclic" double bond is markedly bent (33°) with respect to the five-membered ring. The bonds in the azulene ligand have very different lengths; they approximate to a system of alternating double and single bonds. In non-coordinated azulene[5] and in the η^5-bonded mononuclear [(azulene)$Cr(CO)_3$] complexes,[2] on the other hand, no bond length alternance occurs. Other than in the case of **1**, the azulene ligand is planar in such complexes.

Metal-ligand fragments of the type $M(CO)_3$ (M = Cr, Mo, W) can add to **1** with formation of dinuclear complexes **2**. Surprisingly, the azulene in them is $\eta^6:\eta^4$ coordinated – a hitherto unknown form of coordination for azulene.[6] In contrast, in the case of the dinuclear complexes of the type [(μ-azulene)$M_2(CO)_6$] (M = Cr, Mo), which are isoelectronic with **2**, the metal atoms are $\eta^5:\eta^5$-coordinated.[7]



1 **2**

a, M = Cr; **b**, M = Mo; **c**, M = W

All azulene complexes have fluxional behavior in solution: The coordination of the C-atoms 4 and 8 interchanges rapidly. As a consequence, only five signals are observed for the eight azulene protons in the ^{1}H-NMR spectra.[8] The same holds true for the ^{13}C-NMR spectra.[8] In all complexes the region of slow exchange is not reached on cooling to 193 K.

Experimental

All operations were carried out under N_2.

1: A suspension of dibenzenemolybdenum (1.64 g, 6.5 mmol) and azulene (0.92 g, 7.2 mmol) in toluene (60 mL) was stirred for 5 d at 95°C. The blue solution slowly turned reddish violet. The solution was filtered off and evaporated to dryness. Excess azulene was removed by washing with 10 mL of cold pentane and the residue was recrystallized from toluene/hexane. On cooling to −78°C reddish-violet crystals were formed. Yield 1.22 g (62%); m.p. 250°C (dec.); correct elemental analysis.

2: A solution of **1** (310 mg, 1.0 mmol) and [$(CH_3CN)_3M(CO)_3$] (M = Cr, Mo, W) in THF (30 mL) was boiled under reflux for 5 h. The mixture was then filtered and the filtrate evaporated to dryness. The red residue was dissolved in CH_2Cl_2, covered with the same volume of hexane, and stored at −30°C. After a few days the complexes **2** crystallized out. Yields, m.p. (dec.). $\tilde{\nu}$(CO) in CH_2Cl_2: **2a**: 220 mg (50%) of dark red needles; 210°C; 1921, 1853, 1820 cm^{-1}.—**2b**: 410 mg (85%) of dark brown crystals; 185°C; 1935, 1859, 1824 cm^{-1}.—**2c**: 100 mg (18%) of a red crystalline powder: 175°C; 1931, 1853, 1815 cm^{-1}.

Novel Ni-Clusters with Se and PR_3 (R = Ph, Et) as Ligands**

By *Dieter Fenske** and *Johannes Ohmer*

Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

Reaction of [$MCl_2(PPh_3)_2$] (M = Co, Ni) with $E(SiMe_3)_2$ (E = S, Se) in tetrahydrofuran (THF) or toluene leads to the formation of metal-rich clusters.[1] So far we have been able to characterize the following compounds:[2]

$[Co_4E_4(PPh_3)_4]$ $[Co_6E_8(PPh_3)_6]$ $[Co_7S_6(PPh_3)_5Cl_2]$ $[Co_9Se_{11}(PPh_3)_6]$

$[Ni_8S_6Cl_2(PPh_3)_6]$ $[Ni_8S_5(PPh_3)_7]$ $[Ni_{34}Se_{22}(PPh_3)_{10}]$

The structures of the complexes are apparently dependent upon the ratio $MCl_2:PPh_3:E(SiMe_3)_2$ and on the solvent used. For this reason we have now examined the reaction of $Se(SiMe_3)_2$ with [$NiCl_2(PR_3)_2$] (R = Ph, Et) and $(NBu_4)[NiCl_3(PPh_3)]$ in MeCN or toluene. Within a few minutes a crystalline, black precipitate is formed which consists of Ph_3PSe and several cluster compounds. In the case of the complexes with PPh_3 ligands, only a small fraction of the residue can be dissolved upon extraction with solvents such as THF, toluene, $C_2H_4Cl_2$ and CH_2Cl_2. If these solutions are covered with a layer of hexane, **1**–**3** are obtained in crystalline form. The yields are small (10–20%). From the elemental analyses of the insoluble residues it

$[Ni_6Se_5(PPh_3)_6]$ **1** $[Ni_{12}Se_{11}(PPh_3)_8Cl][NiCl_3(PPh_3)]_2$ **2**

$[Ni_{15}Se_{15}(PPh_3)_6]$ **3** $[Ni_{12}Se_{12}(PEt_3)_6]$ **4**

[*] Prof. Dr. D. Fenske, Dipl.-Chem. J. Ohmer
Institut für Anorganische Chemie der Universität

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank the Institut für Kristallographie der Universität Karlsruhe for help with the measurements of the crystal structure data.

follows that they also consist of metal-rich clusters; their structures, however, are as yet unknown.

In contrast only a small amount of insoluble residue is obtained upon reaction of $[NiCl_2(PEt_3)_2]$ with $Se(SiMe_3)_2$ in toluene. When the filtrate is covered with a layer of hexane, black **4** crystallizes. **1**, **3**, and **4** are diamagnetic, whereas **2** is paramagnetic. All four complexes are practically insoluble in organic solvents; consequently, a characterization of the complexes by means of NMR spectroscopy is very difficult. The IR spectra of **1**–**4** are very similar, they differ only below $\tilde{\nu}=750\ cm^{-1}$.

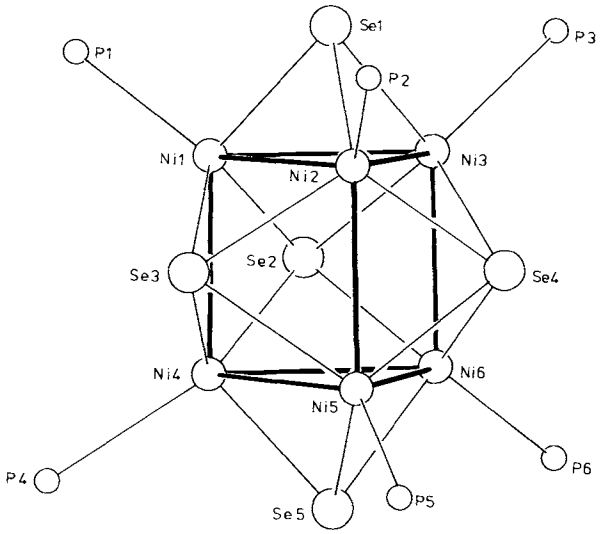

Fig. 1. Crystal structure of **1** (without phenyl groups) [3]. Important bond lengths [pm] (±0.3 pm) and angles [°] (±0.1°). Ni1-Ni3 273.0, Ni1-Ni2 277.4, Ni2-Ni3 276.8, Ni4-Ni5 273.0, Ni5-Ni6 275.2, Ni4-Ni6 279.8, Ni1-Ni4 260.6, Ni2-Ni5 263.3, Ni3-Ni6 266.3, Ni-P 217.9-219.4, (μ_3-Se)-Ni 226.4-227.2, (μ_4-Se)-Ni 237.2-241.9; Ni-Ni-Ni 59.0-61.4 (in the Ni_3-faces), 89.2-91.9 (in the Ni_4-faces), Ni-(μ_3-Se)-Ni 74.0-76.2, Ni-(μ_4-Se)-Ni 66-71.6 and 104.7-106.3.

Crystal structure analyses of **1**–**4**[3] revealed the following: **1** (Fig. 1) contains a trigonal-prismatic Ni_6 cluster in which each Ni atom is coordinated in a distorted tetrahedral fashion to three Se atoms and to the P atom of a PPh_3 ligand. The lengths of the (μ_3-Se)-Ni and (μ_4-Se)-Ni bonds are different. In the Ni_6 cluster the Ni-Ni bonds within the triangular faces (Ni1-Ni3 and Ni4-Ni6) are significantly longer than the distances between these faces. A cluster of similar structure is present in the $[Pt_3(CO)_3(\mu_2\text{-}CO)_3]_2^{2\ominus}$ ion.[4] However, in this instance the bonds in the Pt_3 faces (266 pm) are shorter than the distances between these faces (304 pm). The 92e-cluster **1** contains two electrons more than one would expect according to the 18-electron rule and the topological electron counting rules.[5]

Although octahedral Ni_6 clusters, e.g. $[Ni_3(CO)_3(\mu_2\text{-}CO)_3]_2^{2\ominus}$, are well known,[6] we have so far been unable to isolate any compounds of this structure type. The structures of **2**–**5**, however, show that the synthesis of face-to-face linked Ni_6 octahedra is possible. Figure 2 shows the structure of the $[Ni_{12}Se_{11}(PPh_3)_8Cl]^{2\oplus}$ ion (cation of **2**) which formally consists of bound Ni_9Se_9- (Ni1-Ni9,Se1-Se9) and Ni_3Se_2-clusters (Ni10-Ni12, Se10, Se11). These fragments have already been found in $[Ni_9S_9(PEt_3)_6]^{2\oplus}$ **5**, $[Ni_3Se_2(PEt_3)_6]^{2\oplus}$ **6**, and $[Ni_3S_2Cp_3]$ ($Cp=\eta^5\text{-}C_5H_5$).[7] In the dioctahedron of **2** there are three planes (●, ◍, ◎), each of which is formed from three Ni(Δ) atoms and three Se atoms. Within these layers the Ni-Ni bonds are longer than the corresponding distances between the layers.

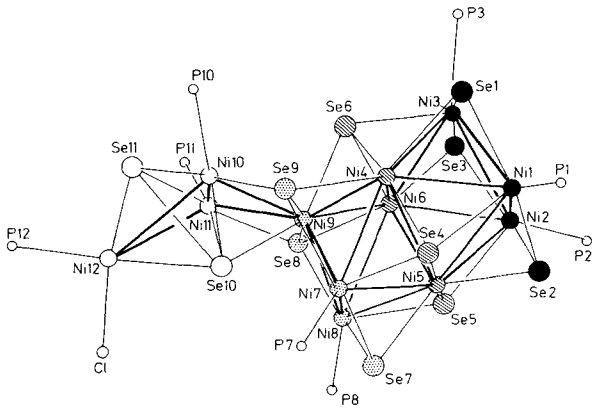

Fig. 2. Structure of the cation **2** in the crystal (without phenyl groups) [3]. Important bond lengths [pm] (±0.4 pm) within the polyhedral faces of 3 Ni atoms (Δ): Δ[Ni1-Ni2-Ni3] 296–299, Δ[Ni4-Ni5-Ni6] 289-308, Δ[Ni7-Ni8-Ni9] 268-313, Δ[Ni5-Ni7-Ni8] 273-313, Δ[Ni4-Ni6-Ni9] 253-308, Δ[Ni3-Ni4-Ni6] 279-308, Δ[Ni1-Ni2-Ni5] 276-296, Δ[Ni9-Ni10-Ni11] 261-283, Δ[Ni10-Ni11-Ni12] 283-311, and between the Ni_3 planes: Ni1-Ni4 266, Ni2-Ni6 277, Ni4-Ni7 289, Ni6-Ni8 289; (μ_3-Se)-Ni 225-232, (μ_4-Se)-Ni 229-246, Ni-P 217-220, Ni12-Cl 220; and bond angles [°] (±0.2°): Ni-(μ_3-Se)-Ni 71-82, Ni-(μ_4-Se)-Ni 66-72 and 120-135.

The polyhedral surfaces of the dioctahedron in **2**, like those in **5**, are capped by μ_3-Se- (Se1-Se3, Se7) and μ_4-Se-ligands (Se4-Se6). Se8 and Se9 are bound to three Ni atoms of the dioctahedron (Ni-Se: 233-245 pm) and at the same time act as bridges to Ni10 and Ni11, respectively (Ni-Se: 230-233 pm). The Ni-Ni bonds from Ni9 are relatively short, while those within the Ni10-Ni12 cluster are rather long (283-311 pm). This points to weak interactions between the atoms Ni10-Ni12, which are bound to a μ_3-Se- (Se11) and a μ_4-Se-ligand (Se10, Ni-Se: 229-232 pm). The distance between Se10 and Se11 is very short (311 pm) and thus compares with the corresponding distance in **6**. With exception of Ni4-Ni6 and Ni9 all the Ni atoms are bound to the P atom of a PPh_3 ligand. Ni12 is additionally coordinated to a $Cl^{\ominus}$ ligand. This Ni-Cl bond is the reactive site of the molecule, at which the clusters can grow by reaction with $Se(SiMe_3)_2$ and $NiCl_2$. On the basis of the topology of the Ni and Se atoms, **2** could be regarded as an intermediate en route to higher condensed clusters with *trans*-face-coupled octahedra.

Comparable structures occur in molybdenum-rich chalcogenides. Here, compounds could be isolated which are formed by "condensation" of M_6E_8 units (E = S, Se)[8] and, e.g., contain $[Mo_{12}Se_{14}]^{2\ominus}$, $[Mo_{18}Se_{20}]^{4\ominus}$, $[Mo_{24}Se_{26}]^{6\ominus}$, and $[Mo_{30}Se_{32}]^{8\ominus}$ clusters.[9] The molecular structures of **3** (Fig. 3) and **4** (Fig. 4) clearly indicate that such cluster structures can also be formed in the case of nickel. **3** and **4** respectively consist of four and five coupled, slightly distorted Ni_6 octahedra.

In contrast to the Chevrel phases and to $[(Co_9Se_{11}(PPh_3)_6]$ the basal faces (**3**: Ni1-Ni3, Ni13-Ni15; **4**: Ni1-Ni3) are not occupied by Se ligands. All other polyhedral faces are capped by μ_3-Se- (**3**: Se1-Se3, Se13-Se15, Ni-Se: 226-231; **4**: Se1-Se3, Ni-Se 227-234 pm) or μ_4-Se-ligands (**3**: Se4-Se12, Ni-Se: 231-249, **4**: Se4-Se6, Ni-Se: 232-244 pm). Most remarkable in **4** is that the distance of the μ_4-Se-ligands to N1, Ni2, Ni3, with a value of 244-246 pm, is ca. 12 pm greater than that to the other Ni atoms. A similar behavior is also found in **3** with the Se-ligands Se4-Se6 and Se10-Se12. In contrast, the (μ_4-Se)-

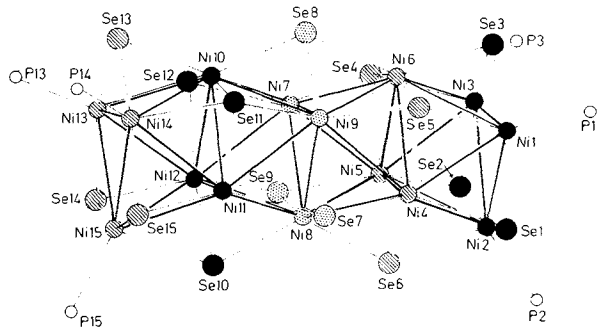

Fig. 3. Crystal structure of **3** (without phenyl groups) [3]. Important bond lengths [pm] (±0.6 pm) within the polyhedral faces of 3 Ni atoms: Δ[Ni1-Ni3] 296–301, Δ[Ni4-Ni6] 288–291, Δ[Ni7-Ni9] 282–291, Δ[Ni10-Ni12] 288–290, Δ[Ni13-Ni15] 295–302, and between the Ni_3 faces: Δ[Ni1-Ni3]-Δ[Ni4-Ni6] 275–288, Δ[Ni4-Ni6]-Δ[Ni7-Ni9] 270–275, Δ[Ni7-Ni9]-Δ[Ni10-Ni12] 271–277, Δ[Ni10-Ni12]-Δ[Ni13-Ni15] 270–278; (μ_3-Se)-Ni 226–231, (μ_4-Se)-Ni 231–249, Ni-P 218–221; and bond angles [°] (±0.2°): Ni-(μ_3-Se)-Ni 70.6–83.3, Ni-(μ_4-Se)-Ni 66.8–78.0 and 130.5–133.5.

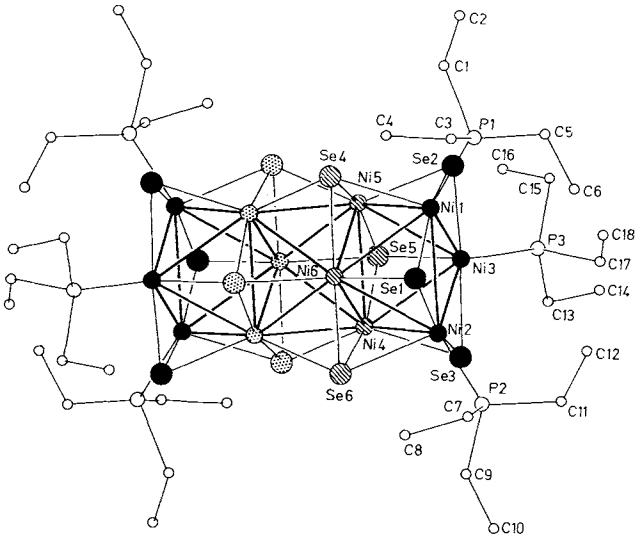

Fig. 4. Crystal structure of **4** (without H atoms) [3]. Important bond lengths [pm] (±0.6 pm): Δ[Ni1-Ni3] 295–297, Δ[Ni4-Ni6] 288–293, Ni1-Ni6 276, Ni1-Ni5 278, Ni2-Ni4 277, Ni2-Ni6 278, Ni3-Ni4 272, Ni3-Ni5 275, (μ_3-Se)-Ni 227–234, (μ_4-Se)-Ni 232–246, P-C 180–184, C-C 151–154, Ni-P 216–217. The bond angles of the cluster are of the same order of magnitude as those for **3**.

Ni bonds from Se7–Se9 can be divided into two short (231–233 pm) and two long bonds (238–240 pm). Both **3** and **4** contain Ni atoms in different bond situations:

1) Ni atoms of the basal faces are each bound to two μ_3-Se-, one μ_4-Se- and one PR_3-ligand as well as to four Ni atoms.
2) Ni atoms inside the octahedra chain are either coordinated to one μ_3-Se- and three μ_4-Se-ligands (**3**: Ni4–Ni6, Ni10–Ni12; **4**: Ni4–Ni6) or to four μ_4-Se-ligands (**3**: Ni7–Ni9). These metal atoms are each bound to six further Ni atoms.

3 and **4** contain parallel layers (distance 216(3) pm, deviation from the plane ±10 pm), each of which is formed from three Ni atoms and three Se atoms. Within these layers, the Ni–Ni bonds have different lengths. The longest are found in the external Ni_3 faces (**3**: Δ[Ni1-Ni3], Δ[Ni13-Ni15], **4**: Δ[Ni1-Ni3], i.e. between the atoms which are bound to PR_3.

Markedly shorter are the Ni–Ni bonds in the inner layers (**3**: Δ[Ni4-Ni6], Δ[Ni7-Ni9], Δ[Ni10-Ni12]; **4**: Δ[Ni4-Ni6]). As in the case of **5**, the shortest Ni–Ni distances are observed between the layers (**3**: 270–288; **4**: 272–278 pm). These values are relatively large compared to those found in other complexes with Ni_3 faces.[10]

The 222e- and 180e-clusters **3** and **4** contain respectively 30 and 24 electrons more than would be expected according to the 18-electron rule. Apparently, increasingly more antibonding states are occupied in **3** and **4**. This is also evident from the fact that **3** and **4** have eight valence electrons per Ni atom, whereas the Chevrel phases contain 3.33–4.33 valence electrons per metal atom.[11] We can conclude therefore that even still larger clusters are formed in the reactions described here. Their characterization however is problematic owing to decreasing solubility. The composition of these compounds should correspond to the formula $[Ni_{3n+3}Se_{3n+3}(PR_3)_6]$ (n = number of coupled octahedra).

Experimental

1: A solution of $(NBu_4)[NiCl_3(PPh_3)]$ (10.03 g, 0.015 mmol) in toluene (100 mL) was treated with 3.2 mL (0.015 mol) of $Se(SiMe_3)_2$. The solution immediately turned black. After 5 days reaction time the fine crystalline precipitate was filtered off. On treatment with THF, 4 g of precipitate dissolved. After covering the solution with a layer of heptane, dark brown crystals of **1** were isolated. Yield 20%.

2: A suspension of $[NiCl_2(PPh_3)_2]$ (15.03 g, 0.023 mol) in MeCN (150 mL) was treated with 10.0 mL (0.047 mol) of $Se(SiMe_3)_2$. After 5 days reaction time the precipitate was filtered off (6 g). This was first treated with 100 mL of toluene and then recrystallized from 100 mL of THF. Upon covering the THF solution with a layer of hexane, **2** separated out at the interface. Yield 10%.

3: A solution of $(NBu_4)[NiCl_3(PPh_3)]$ (8.08 g, 0.012 mol) in MeCN (100 mL) was treated with 5.4 mL (0.025 mol) of $Se(SiMe_3)_2$. After 5 days reaction time about 6 g of a fine crystalline precipitate separated out. For removal of the Ph_3PSe the precipitate was treated with 50 mL of toluene. After addition of 100 mL of CH_2Cl_2 (to the insoluble residue) 1.2 g of **3** dissolved. Upon covering the solution with a layer of hexane, black crystals of **3** separated out at the interface. Yield 10%.

4: A solution of $[NiCl_2(PEt_3)_2]$ (5.6 g, 0.023 mol) in toluene was treated with 5.0 mL (0.023 mol) of $Se(SiMe_3)_2$. After 4 days reaction time ca. 100 mg of a fine crystalline precipitate separated out. This was filtered off and the filtrate was covered with a layer of heptane. Black crystals of **4** could be isolated. Yield 20%.

Chromatographic Separation of Higher Polythionates $S_nO_6^{2\ominus}$ (n = 3...22) and Their Detection in Cultures of *Thiobacillus ferrooxidans*; Molecular Composition of Bacterial Sulfur Secretions**

By *Ralf Steudel,** *Gabriele Holdt, Thomas Göbel,* and *Willem Hazeu*

The exact analytical characterization of polythionates[1] is difficult,[2] since such compounds readily decompose and interconvert, especially in solution; they are therefore also formed along with each other in many reactions, and, moreover, form a long homologous series $S_nO_6^{2\ominus}$, where, according to *Weitz* et al.,[3] n can assume values of up to ca. 40. Hydrophilic sulfur sols after *Oden*,[4] are said to contain even polythionic acids with up to 140 S atoms;[5] such acids are then water-insoluble and form fine globules. *Weiss* and *Göbl*[6] recently reported on the ion-pair chromatography of sulfur-oxygen anions ($S_2O_4^{2\ominus}$, $S_2O_3^{2\ominus}$, $S_2O_6^{2\ominus}$, $S_4O_6^{2\ominus}$), which we have been able to extend to polythionate ions containing up to 13 S atoms.[7] The anions are separated on an organic stationary phase with aqueous acetonitrile containing some sodium carbonate and tetra-*n*-butylammonium hydroxide or dihydrogenphosphate. Since the retention times of the $S_nO_6^{2\ominus}$ ions increase with the square of n,[7] we have now used a concentration gradient for the two ionic components of the eluent, whereby all members up to $S_{22}O_6^{2\ominus}$ are separated and individually detected in the UV detector (215 nm). Figure 1 shows the chromatogram of an $S_nO_6^{2\ominus}$ solution (n = 4...18) that was prepared from S_7Cl_2 and $Na_2S_2O_3$ according to Equation (a),[7] and which, because of the other chlorosulfanes contained in the S_7Cl_2[8] and because of concomitant disproportionation reactions, also contained numerous polythionates other than $S_{11}O_6^{2\ominus}$.

$$2\,Na_2S_2O_3 + S_7Cl_2 \longrightarrow Na_2S_{11}O_6 + 2\,NaCl \qquad (a)$$

During the elution with an acetonitrile-water mixture (30/70 v/v) the concentrations of $(NBu_4)H_2PO_4$ and Na_2CO_3 in the mixture were lowered linearly within 10 min from 2 and 1 mmol/L, respectively, to zero. Under these conditions (flow rate 1 mL/min), $S_{11}O_6^{2\ominus}$ appeared in the detector after 12.3 min, and $S_{18}O_6^{2\ominus}$ after 28.4 min.[9]

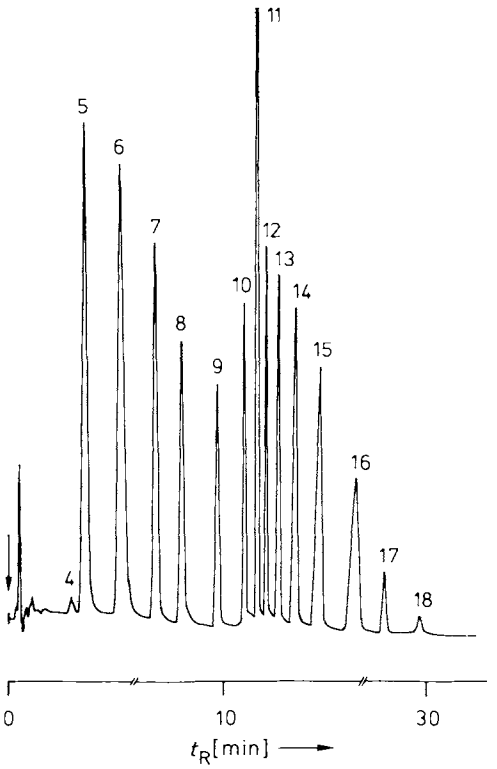

Fig. 1. Chromatogram of a polythionate mixture on octadecylsilane (C18) with a linear concentration gradient for the counterion ($NBu_4^{\oplus}$) and the inorganic "modifier" (Na_2CO_3). The scale for the retention time t_R is not linear; ordinate: UV detector signal. The arrow marks the injection point. The numbers relate to the number of sulfur atoms in the molecule.

In order to separate still higher polythionates, the concentration of the organic "modifier" acetonitrile was increased from 30 to 40% and the linear concentration gradient of the two salts shortened to 5 min (2→0 mmol/L). Under these conditions, however, the lower polythionates were no longer separated. In the chromatogram of a mixture of $Na_2S_nO_6$, which was prepared according to *Weitz* et al.[3c] by reaction of $K_2S_2O_3$ with S_2Cl_2 in concentrated hydrochloric acid and subsequent ion exchange with NaCl, and which, according to a sulfur analysis, contained anions with up to 40 S atoms,[3c] the members up to $S_{22}O_6^{2\ominus}$ were recognizable; by further modification of the chro-

[**] Sulfur Compounds, Part 106. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 105: R. Steudel, D. Jensen, B. Plinke, *Z. Naturforsch. B 42* (1987), in press.

matographic conditions probably even higher anions could have been separated. The concept of a very long homologous series of the polythionic acids is therefore justified.

Thiobacillus ferrooxidans (*T.f.*) is a chemolithotrophic bacterium which participates in the sulfur cycle in nature and plays an important role in the bacterial leaching of mineral ores. *T. f.* thrives at low pH value and draws energy from the oxidation of $Fe^{2\oplus}$ ions or from sulfur in lower oxidation states (sulfide, elemental sulfur, thiosulfate, polythionates).[10] These compounds are oxidized, in part, via unknown intermediates to sulfate;[11, 12] with an oversupply of substrate, *T. f.* oxidizes a part of the educt to elemental sulfur (S^0), which is deposited extracellularly as minute globules and is degraded again as required;[11, 12] with other thiobacilli, even polythionates up to $S_8O_6^{2\ominus}$ have been detected in the culture medium.[11] The molecular nature of the S^0, which is present in liquid form, is still unclear.

We have treated suspensions of *T. f.*[13] (150 mL with ca. 200 mg of dry mass per liter) at 30°C with a tetrathionate solution (100 mL; 5–10 mmol/L) under vigorous passage of air and taken samples after definite time intervals; these samples were cooled rapidly to 0°C, centrifuged, and the aqueous phase tested for polythionates (1). The centrifugate (cells and S^0) was extracted with various solvents and the extracts were examined by reversed phase HPLC[14] on elemental sulfur (2). During the oxidation the increasing turbidity due to S^0 formation was also measured by the absorbance at 430 nm.

1. In the aqueous phases (pH ca. 3) all polythionates up to $S_{13}O_6^{2\ominus}$ were detected; on using pentathionate as substrate and previously deep-frozen cells, even all anions up to $S_{17}O_6^{2\ominus}$ were detectable (Fig. 2). The concentrations of the individual polythionates passed through a maximum during the oxidation, while the turbidity continually increased.
2. Extraction of the cells (containing S^0) with CS_2 furnished solutions, which besides containing S_8 (ca. 98%) also contained small amounts of S_6, S_7, S_9, and S_{12} (Fig. 3); extraction with a methanol-water mixture (95/5 v/v) yielded solutions of $S_nO_6^{2\ominus}$ and sulfur, which consisted of 96–98% of S_8 and 2–4% of S_7 and S_6. Repeated extraction continually afforded further S_n solutions independent of the solvent used; this indicates that S^0 is either also deposited intracellularly and then only slowly extracted, or that the hydrophilic surface of the S^0 globules (vide infra) hinders the extraction of S_n. The S_8 concentration increased with increasing turbidity.

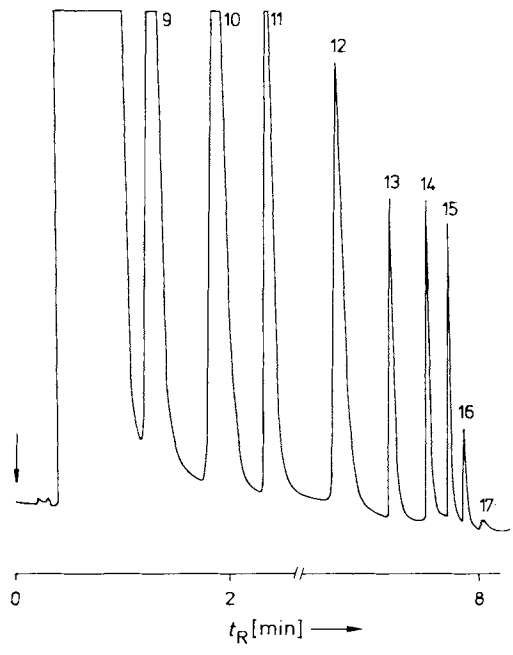

Fig. 2. Chromatogram of the polythionates which were formed in a culture of *Thiobacillus ferrooxidans* after incubation with $K_2S_5O_6$.

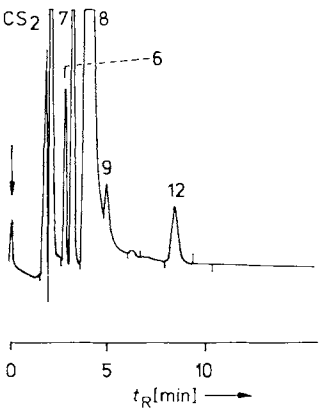

Fig. 3. Chromatogram of the CS_2 extract of *Thiobacillus ferrooxidans* after incubation with tetrathionate (column: Radial-Pak 10C18 (Waters), eluent: methanol; cf. Ref. [14]).

When the cells were extracted before addition of tetrathionate, neither polythionates nor sulfur rings were detectable. Our results can be explained in terms of the following (and analogous) reactions:

$$S_4O_6^{2\ominus} + H_2O \longrightarrow HS_2SO_3^{\ominus} + HSO_4^{\ominus} \quad (b)$$

$$2\,HS_2SO_3^{\ominus} \rightleftharpoons HS_4SO_3^{\ominus} + HSO_3^{\ominus} \quad (c)$$

$$2\,HS_4SO_3^{\ominus} \rightleftharpoons HS_8SO_3^{\ominus} + HSO_3^{\ominus} \quad (d)$$

$$HS_8SO_3^{\ominus} \rightleftharpoons S_8 + HSO_3^{\ominus} \quad (e)$$

$$HSO_3^{\ominus} + 1/2\,O_2 \longrightarrow HSO_4^{\ominus} \quad (f)$$

$$2\,HS_2SO_3^{\ominus} + 1/2\,O_2 \longrightarrow S_6O_6^{2\ominus} + H_2O \quad (g)$$

$$2\,HS_2SO_3^{\ominus} \rightleftharpoons S_5O_6^{2\ominus} + H_2S \quad (h)$$

The availability of enzymes for the catalysis of reactions such as (b), (f), and (g) in thiobacilli is well known;[11, 12] the other reactions are known from laboratory experiments.[15] The irreversible oxidation of sulfite to sulfate as in Eq. (f) drives the equilibrium reactions (c)–(e) to the right. Instead of the hydrolysis (b), a reduction of tetrathionate to thiosulfate followed by a disproportionation of the thiosulfate analogously to (c), is also conceivable as primary step.[16]

The first detection of polythionates containing more than 10 sulfur atoms and unstable sulfur rings S_n ($n \neq 8$) in a biological system demonstrates the importance of the sulfanemonosulfonic acids HS_nSO_3H[17] as intermediates, since polysulfur compounds can be rapidly and reversibly synthesized and degraded and transported only via these highly reactive and readily soluble substances in a strongly acidic, aqueous medium. The hydrophilic S^0 globules most likely consist of a hydrophobic nucleus of mainly S_8 (with traces of other S_n-rings, which hinder crystallization) on whose surface long-chain polythionate ions[18] are deposited by hydrophobic interaction with the aqueous medium such that the droplet as a whole becomes hydrophilic (Fig.

4); the approximate "formula" for S^0 is therefore: $x S_8 \cdot y H_2S_nO_6 \cdot z H_2O$.—$S_8$, which is very sparingly soluble in water (solubility of α-S_8 at 25 °C: 5 μg/kg[19]), can, e.g., be rapidly reactivated[20] via reactions such as (e) and, in this way, can even be transported through membranes.

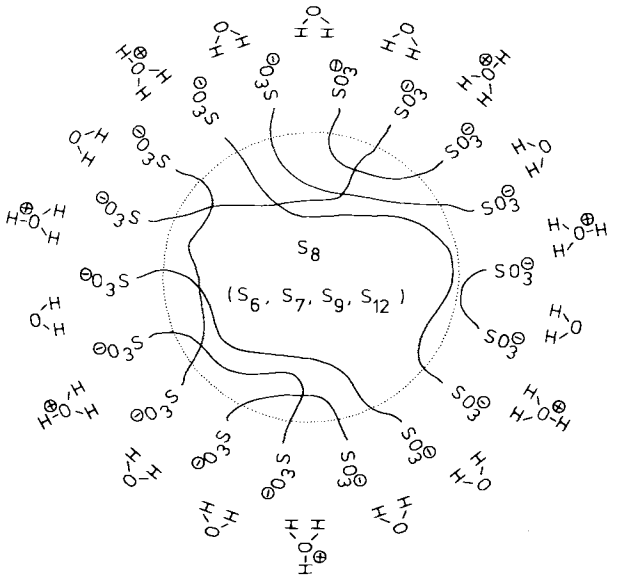

Fig. 4. Simplified model of a sulfur globule as is formed extracellularly by *Thiobacillus ferrooxidans*. It consists mainly of S_8 and small amounts of other compounds (S_6, S_7, S_9, and S_{12}) which impede crystallization, as in globules of supercooled liquid sulfur. Long-chain polythionate ions are deposited on the surface and make the globule hydrophilic. Hence it is surrounded by a hydrate-sheath in which cations are possibly also present. The average density of such a micelle must be significantly smaller than that of liquid sulfur (1.85 g/cm³).

The chromatographic detection of polythionates as described here, which, e.g., requires a concentration of only 5 μg/mL in the case of the tetrathionate, should now be extended to a systematic search for these compounds in the culture media of other sulfur bacteria.

CC-Linkages of Ethene with CO_2 on an Iron(0) Complex—Synthesis and Crystal Structure Analysis of $[(PEt_3)_2Fe(C_2H_4)_2]$

By *Heinz Hoberg,* Klaus Jenni, Klaus Angermund,* and *Carl Krüger*

We recently reported the 1/1 CC-linkage of CO_2 with 1,3-butadiene on an iron(0) system.[1] We have now extended our investigations to reactions of ethene on iron(0) complexes. CC-linkages between ethene and CO_2 can be controlled on nickel(0) in such a way that, depending on the ligand, either propionic acids[2] or *n*-pentenoic acids[3] are formed in the course of acid hydrolysis. On molybdenum(0) or tungsten(0) complexes acrylic acid is formed.[4]

We have now found that the iron(0) system induces further unexpected CC-coupling steps between CO_2 and ethene. The π-bonded ethene in the well already known 18e-complex ethenebis[*P,P'*-ethylenebis(diphenylphosphane)]-iron(0)[5] does not react with CO_2 (5 bar, 80 °C) to give the carboxylate. However, we have been able to prepare a novel ligand-Fe^0-C_2H_4 complex on which the desired CC couplings are possible for the first time.

In the reduction of $FeCl_2$ with Mg*[6] in tetrahydrofuran (THF) in the presence of ethene and PEt_3 the 16e-complex bis(ethene)bis(triethylphosphane)iron(0) **1** is formed in 72% yield [m.p. 16 °C (dec.), paramagnetic, black crystals].[7]

$$FeCl_2 + Mg^* + 2\,C_2H_4 + 2\,PEt_3 \xrightarrow[-30\,^\circ C]{THF} (PEt_3)_2Fe(C_2H_4)_2 + MgCl_2$$

1

The structure of **1** (Fig. 1) was determined by a crystal structure analysis. In the crystalline state the complex has C_2 symmetry, with the symmetry axis passing through the Fe atom and bisecting the P1-Fe-P1* angle. The metal atom is surrounded pseudotetrahedrally by two ethene molecules and two triethylphosphane molecules (angle between the plane through the atoms Fe, P1 and P1* and the plane through the iron atom and the midpoints of the C1-C2 and C1*-C2* bonds: 89.9°); the ethene ligands, however, form an angle of 35.8° with respect to each other (torsion angle C1-C2-C1*-C2*).

[+] Crystal structure analysis.

For investigating the behavior of **1** towards CO_2 the complex was first dissolved in THF at $-78\,^{\circ}C$ and treated with a stream of CO_2 (1 bar). This, however, merely resulted in "reductive disproportionation" to iron carbonate and carbon monoxide,[10] and not in the desired formation of carboxylate. Apparently, the molar ratio PEt_3/Fe of 2:1 asserted for **1** is too small for this.

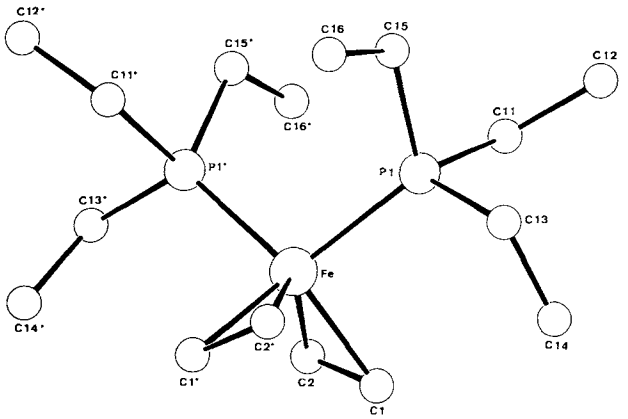

Fig. 1. Crystal structure of **1** [8], $a=14.572(6)$ Å, $b=7.314(3)$ Å, $c=18.487(8)$ Å, $\beta=98.13(3)^{\circ}$, $V=1950.6$ Å^3, $T=100$ K, $\lambda=0.71069$ Å, $C2/c$, $Z=4$, $\rho_{calc}=1.19$ g cm^{-3}, $\mu_{(Mo)}=9.23$ cm^{-1}, empirical absorption correction (0.911 min., 1.135 max.), 2658 reflections measured ($\pm h \pm k + l$), 1347 independent reflections, 1271 observed reflections ($I \geq 2\sigma(I)$), H-atom positions found but not refined, 87 refined parameters, $R=0.028$, $R_w=0.036$ ($w=1/\sigma^2(F_0)$), maximum residual electron density 0.27 e/Å^3). Selected bond lengths [Å] and angles [°]: Fe-P1 2.267(1), Fe-C1 2.083(2), Fe-C2 2.105(3), P1-C11 1.854(2), P1-C13 1.855(3), P1-C15 1.850(2), C1-C2 1.382(4); P1-Fe-P1* 106.2(1), P1-Fe-C1 98.0(1), P1-Fe-C2 120.0(1), C1-Fe-C2 38.5(1), C1-Fe-C1* 100.4(1), C1-Fe-C2* 103.3(1), C2-Fe-C2* 128.9(1) [9].

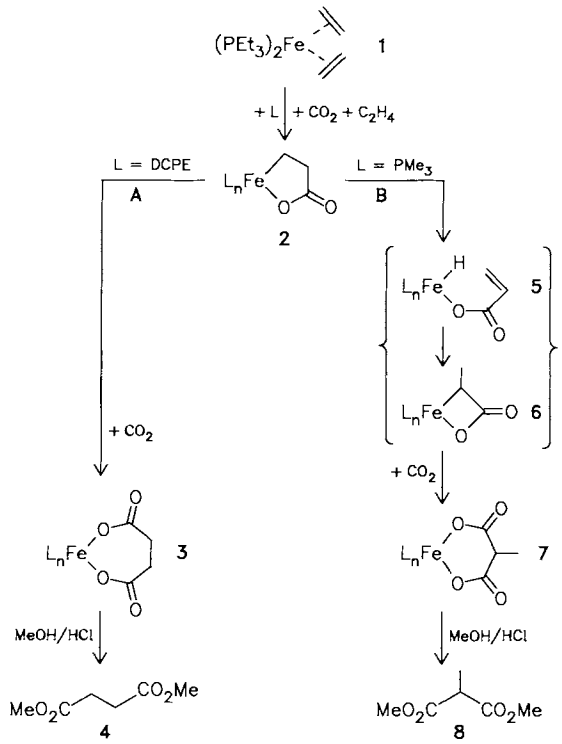

Table 1. Influence of ligands on the yield and molar ratio of the dicarboxylic acids **4** and **8** in the reactions of **1** with CO_2.

L	Molar ratio L/**1**	Yield [%]	Molar ratio **4/8**
PMe_3	3/1	60	1/400
$[Me_2P-CH_2-]_2$ (DMPE)	1/1	57	1/7
$[(c\text{-}C_6H_{11})_2P-CH_2-]_2$ (DCPE)	2/1	49	10/1

A CC-linkage between ethene and CO_2 is achieved on iron(0) when the reaction is carried out after addition of further ligands such as, e.g., PMe_3, *P,P'*-ethylenebis(dicyclohexylphosphane) (DCPE), or *P,P'*-ethylenebis(dimethylphosphane) (DMPE).[11] The iron carboxylates formed thereby could be recognized by the C=O stretching vibration bands at 1580 cm^{-1} in the IR spectrum. The type of carboxylate formation that had taken place was determined by acid-hydrolysis of the complex mixture in methanol on the basis of the methyl ester that was formed (Table 1). Surprisingly, no monocarboxylic acids but exclusively dicarboxylic acids, namely succinic acid **4** and the isomeric methylmalonic acid **8**, are formed.

As can be seen from Table 1 the ligands have a significant influence on the course of the CC coupling reaction. Whether this is of a steric or electronic nature or due alone to the chelate-effect of the bidentate phosphanes cannot be inferred from the present observations. Apparently the iron carboxylates **3** and **7** derive from a common unstable intermediate, the oxaferracyclopentanone **2**.

Whereas the formation of **4** (insertion of CO_2 into the Fe-C σ-bond of **2** to give **3**, Route **A**) is comparable with the corresponding reaction sequences in the reaction of 1,3-butadiene on nickel(0)[12] and iron(0) systems,[1] the reaction course **B** is postulated for the unexpected formation of **8**: β-H elimination leads to **5**; renewed hydrometalation affords the methyloxyferracyclobutanone **6**,[13] from which **7** is formed by CO_2 insertion. Finally, the diester **8** is liberated from **7** by methanolic HCl.

[11] *Typical procedures* for **4** and **8**: 1.48 g (4.25 mmol) of **1** and 0.97 g (1.29 mL, 12.76 mmol) of PMe_3 were dissolved in 70 mL of THF (−78 °C); the solution was then treated, via a buret, first with 286 mL (12.76 mmol) of ethene, and then with 286 mL (12.76 mmol) of CO_2. With careful equalization of built-up pressure, the solution was slowly warmed (6 h) to room temperature, whereupon a dark brown precipitate separated out. This was filtered off and dried. Yield: 1.12 g; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1580 (C=O). The dried solid was treated at −30 °C with 4 mL of 6 N methanolic HCl. After 24 hours' stirring the solution was neutralized with $NaHCO_3$. The volatile components were distilled off under vacuum (2×10^{-4} bar). According to a GC analysis the distillate contained 0.93 mg (6.36×10^{-3} mmol, 0.15%) of **4** and 370.84 mg (2.54 mmol, 59.76%) of **8**. The products were identified by comparison of the MS spectra obtained after combined GC-MS with literature data and quantitatively determined by calculation from the GC curves taking into consideration the response factors referred to isopentyl acetate as internal standard. The reactions of **1** in the presence of the ligands DMPE and DCPE in the molecular ratios given in Table 1 were carried out analogously.

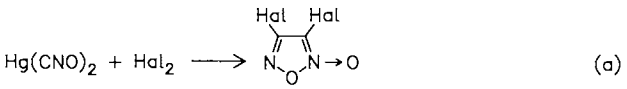
[13] Ring contractions have also been observed on platinacyclopentane complexes (cf. G. B. Young, G. M. Whitesides, *J. Am. Chem. Soc. 100* (1978) 5808), tantalacyclopentane complexes (cf. S. L. McLain, J. Sancho, R. R. Schrock, *ibid. 101* (1979) 5451), and oxanickelacyclohexanone complexes (cf. K. Sano, T. Yamamoto, A. Yamamoto, *Chem. Lett. 1982*, 695).

Isolation and Photoisomerization of Simply Substituted Nitrile Oxides**

By *Günther Maier** and *Joaquim Henrique Teles*

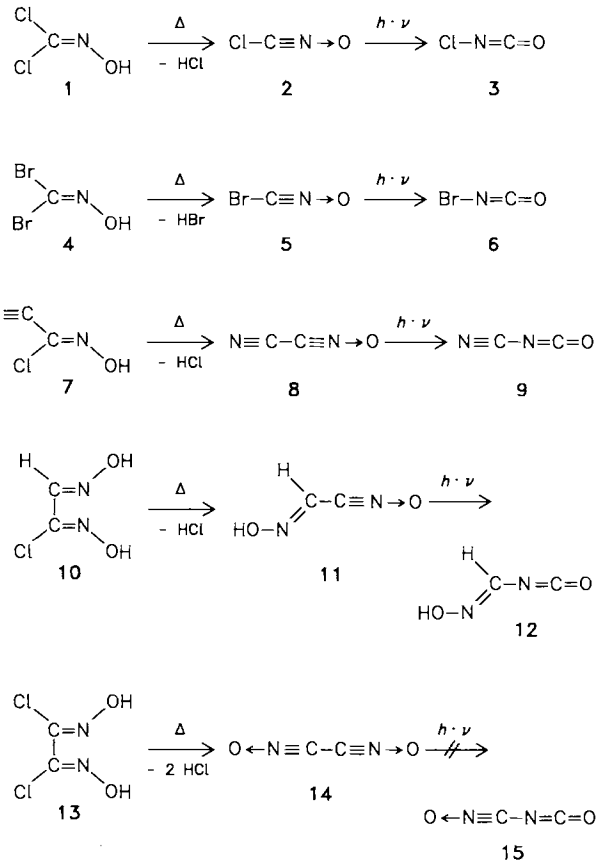
The haloformonitrile oxides **2** and **5** should, according to *Wieland*,[1] be formed as intermediates upon reaction of the mercury salt of fulminic acid (formonitrile oxide) with chlorine and bromine to give the respective dihalofuroxanes [Eq. (a)]. The in situ generation of **2** and **5** from the



(a)

corresponding hydroximic acid halides by HHal-elimination with bases[3] has attracted renewed interest in connection with the synthesis of the antitumor reagent acivicin.[2] Furthermore, molecules such as **2**, **5**, **8**, and in particular their photoisomers, could perhaps occur in interstellar space.[4] Both aspects have prompted us to attempt the direct detection of such species.

When the fragments formed in the gas-phase pyrolysis (600 °C, 10^{-5} torr) of the dihaloformoximes **1** and **4** are condensed with argon on a cold window ($T = 10$ K) the halonitrile oxides of interest, namely **2** and **5**, can be detected as main products on the basis of their typical IR bands[5] (Table 1). Of the five fundamental vibrations to be expected for a linear atomic arrangement[6] only two are intense enough for observation.[7] Besides these, the IR absorptions of the respective hydrogen halides and, to a lesser extent, those of the corresponding haloisocyanates **3** and **6**, respectively, are also observed.



The structures of **2** and **5** follow also from the fact that these compounds are smoothly converted into the haloisocyanates upon irradiation in the matrix ($\lambda = 254$ nm, 10 min),[8] as shown by a comparison with the spectra of authentic samples[9] of **3** and **6**. Vacuum pyrolysis of chlorocyanoformoxime **7** at 400 °C leads to formation of cyanogen mono-*N*-oxide **8**, which can be isolated as the only product besides HCl in the argon matrix.[10] In the case of a linear structure, seven bands should occur in the IR; five were observed (Table 1). Irradiation in the matrix ($\lambda = 254$ nm, $t = 20$ min) affords cyanogen isocyanate **9**[11] and C_2O.[12] Gas-phase pyrolysis of chloroglyoxime **10** analogously afforded the nitrile oxide **11**. Its constitution follows, once again, from the IR spectrum (Table 1); irradiation of **11** in the matrix at 10 K affords the isocyanate **12** (IR bands at 3638, 2276, 1646, and 976 cm^{-1}) within 2 min.

Table 1. IR spectra [Ar matrices, 10 K, $\tilde{\nu}$ [cm^{-1}] (relative intensity)] of the nitrile oxides **2**, **5**, **8**, and **11**.

Assignment	**2**	**5**	**8** [b]	**11** [c]
ν_s(CNO)	1326.3 (100)	1305.6 (100)	1445 (25)	1453 (34)

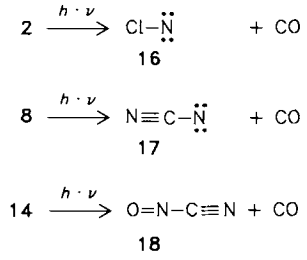
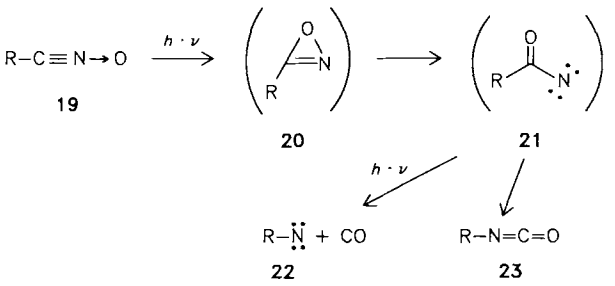
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

As expected, flash vacuum pyrolysis of dichloroglyoxime **13** leads to smooth formation of the well-known cyanogen di-*N*-oxide **14**, which is stable up to $-45\,^{\circ}C$.[13] A special feature of this series is that photoexcitation of **14** ($\lambda = 254$ nm) does not lead to the isocyanate **15**, but to nitrosyl cyanide **18**.[14] This photoreaction is to be seen in



context with the observation that the bands of chloronitrene **16**[15] also appear in the IR spectrum after prolonged irradiation of the nitrile oxide **2** in argon at 10 K and that not only the photostable isocyanate **9** but also C_2O is obtained upon photochemical excitation of **8**. This reaction is probably best explained in terms of the formation of cyanonitrene **17** (detectable on using light of wavelength 229 nm), from which nitrogen is split off. The atomic carbon formed thereby is finally trapped by the carbon monoxide that is still present in the argon cage (the intensity of the CO band decreases upon prolonged irradiation).

The "breakaways" in the photochemically-induced nitrile oxide-isocyanate rearrangement can be accounted for in terms of a theoretically justifiable mechanism[6, 16] if one assumes that the nitrile oxides **19** are converted via the oxazirenes **20** into the acylnitrenes **21**. The latter can subsequently rearrange to the isocyanates **23** or be cleaved in a second photo-step to give nitrene **22** and carbon monoxide. Since it has been confirmed experimentally, at least in the case of R = CN, that the carbon monoxide does not originate from the isocyanate, a process **23** → **22** is also not very likely in the case of other residues R.



Summary: Simple nitrile oxides are readily accessible by gas-phase pyrolysis of the corresponding hydroximic acid halides. We are confident that this method will prove advantageous in the preparative use of simply substituted nitrile oxides.

$^2H,^2H$-COSY and $^2H,^2H,^{13}C$-RELAY NMR Experiments for the Analysis of Deuteriated Compounds**

By *Detlef Moskau* and *Harald Günther**

The homonuclear shift correlation technique (COSY[1c]) introduced by *Jeener*[1a] and *Ernst* et al.[1b] is one of the most important 2D-NMR spectroscopic methods. The cross peaks occurring between anisochronous nuclei are due to scalar spin-spin coupling, which generally leads to characteristic line splittings in a one-dimensional spectrum. COSY-NMR spectra therefore afford immediate structural information and are indispensable, in particular, for the detection of connectivities in complicated NMR spectra.

An attractive aspect of the COSY-NMR experiment is that cross peaks can even be obtained when the coupling between two nuclei is not resolved in a one-dimensional spectrum because of line broadening.[2] Such situations are encountered with quadrupolar nuclei whose lines are usually strongly broadened by fast relaxation, so that line splittings due to homonuclear spin-spin couplings are not observed.[3] Consequently, line assignments in the 1D-NMR spectrum are rendered difficult or impossible. Although even the COSY-NMR experiment is not unproblematical for such nuclei because of the dependence of the cross-peak intensities on the magnitude of the scalar coupling and the relaxation time T_2[4], successful $^{11}B,^{11}B$-,[5] $^{51}V,^{51}V$-,[6] and $^6Li,^6Li$-correlation experiments[7] show that COSY-NMR spectroscopy is possible with quadrupolar nuclei and is most useful for the elucidation of structures.

We now report on the COSY- and RELAY-NMR spec-

troscopy of the quadrupolar nucleus deuterium. Figure 1 shows the homonuclear two-dimensional $^2H,^2H$-shift cor-

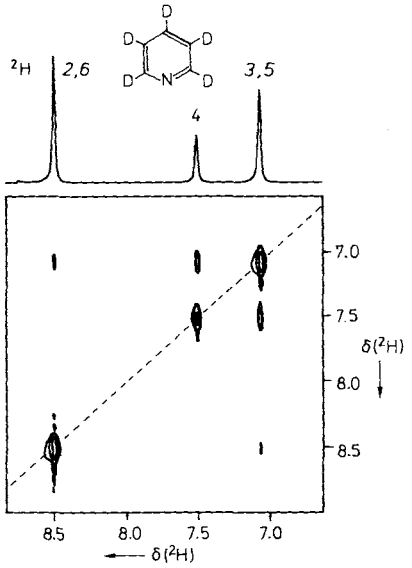

Fig. 1. $^2H,^2H$-COSY-NMR spectrum of [D_5]pyridine (in C_6F_6 3 : 1) with pulse sequence (a); cross peaks for vicinal deuterons. Spectral window 300 Hz, 64 t_1 increments of 3.3 ms, relaxation interval 5 s, $\Delta = 0.4$ s, $t_2 = 1.71$ s, 32 accumulations, phase cycle of the Bruker standard software, data processing with sine functions, measurement time 4.3 h. From the width of the signals in the 1D spectrum one gets $T_2^*(^2H) = 0.3$ s; the cross signal intensities are respectively 3 and 25% of the diagonal signal intensity.

relation for [D_5]pyridine. As can be calculated from the vicinal $^1H,^1H$-coupling constants of pyridine ($J(2,3) = 4.88$, $J(3,4) = 7.67$ Hz[8]) and the ratio $\gamma(^1H)/\gamma(^2H) = 6.51$,[9] the corresponding $^2H,^2H$-couplings are only 0.1 and 0.2 Hz, respectively. Since they are not resolved in the 1D-NMR spectrum the recommended modification of the Jeener pulse sequence with a constant interval Δ before and after the mixing pulse was used for accentuating smaller couplings. Furthermore, the COSY-45 variant[4] for the reduction of diagonal signal intensities also proved useful:

$$^2H:\ 90°/\text{---}t_1\text{---}/\text{-}\Delta\text{-}/45°/\text{-}\Delta\text{-}/\mathrm{FID}(t_2) \qquad (a)$$

For perdeuteriated compounds of unknown constitution, this assignment method is the method of choice, since geminal and vicinal interactions are detected.

A homonuclear polarization transfer is also a component of the RELAY method,[10] which enables a correlation of neighboring ^{13}C nuclei via vicinal protons. The pulse sequence for the analogous $^2H,^2H,^{13}C$-RELAY-NMR experiment, in which smaller couplings are likewise preferably detected by a suitable choice of the intervals $t_1(0)$ and Δ_1, and the $^2H,^2H,^{13}C$-RELAY-NMR spectrum of [D_5]pyridine are shown in Figure 2. The assignment of the ^{13}C-signals is documented by the corresponding cross peaks. The experiment extends the earlier described $^2H,^{13}C$-shift correlation,[11] but, since it necessitates long measuring times, it is only of interest when $^2H,^{13}C$ correlation experiments and $^2H,^2H$-COSY-NMR spectroscopy fail because of signal overlap.

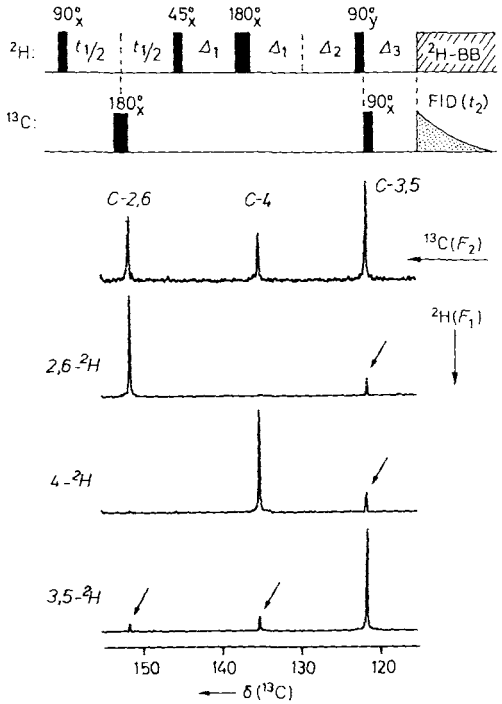

Fig. 2. Pulse sequence for the $^2H,^2H,^{13}C$-RELAY-NMR experiment and the result obtained for [D_5]pyridine. The traces of the two-dimensional data matrix parallel to the ^{13}C-shift axis (F_2) are shown. Besides the RELAY signals (arrows) there also appear the intense signals of the $^2H,^{13}C$-shift correlation over the direct $^1J(^{13}C,^2H)$ coupling. Spectral window 300 (F_1) and 3500 Hz (F_2), 64 t_1 increments of 3.3 ms with $t_1(0) = 0.4$ s, relaxation interval 4 s, $\Delta_1 = 0.2$ s, polarization transfer interval $\Delta_2 = 1/2J(^{13}C,^2H) = 20$ ms, refocusing interval $\Delta_3 = 5$ ms, $t_2 = 0.14$ s, 160 accumulations, phase cycle of the Bruker standard software, data processing with sine function in F_1 and exponential multiplication in F_2, measuring time 14.1 h.

Has Quantum Chemistry Grown Up?

This question is prompted by the appearance of the following two new books:

A Handbook of Computational Chemistry. By *T. Clark*. Wiley, Chichester 1985. 332 pp., bound, £ 35,80.—ISBN 0-471-88211-9.

Semi-empirical Methods of Quantum Chemistry. By *J. Sadlej*. Ellis Horwood, Chichester 1985. 386 pp., bound, £ 42.50.—ISBN 0-85312-167-2

Instead of giving a conventional review of these books, I shall try here to examine the development of quantum chemistry since its emergence, and to consider its present state and its continually changing relationship to "established" chemistry.

Quantum chemistry is the application of quantum mechanics to chemistry, even though the activities in which quantum chemists are engaged can vary quite widely. Does a theoretical statement become a useful contribution to our knowledge only when it is expressed as a mathematical formula, or do numbers that are arrived at by less explicit methods, and yet are real in terms of our observations, also have a knowledge value? This question can be put more succinctly as follows: do we want quantum chemistry to provide generalized statements, or are its most useful results those that are more specific to particular substances? At present quantum chemistry is well on the way to adopting a more sceptical attitude towards broad generalizations. Thus, for example, benzene now seems to be the only molecule which is truly aromatic, although some definitions of aromaticity are quite unrelated to material properties, but are of a topological nature, and are therefore shown to be inadequate. Again, the *Hückel* $4n+2$ and $4n$ rules now show more exceptions than regular cases, and elements which are said to be homologous are often radically different. Quantum chemistry today ought not to impose limitations on the scope of its applications, e.g. by avoiding the study of compounds not yet prepared synthetically, but instead should test familiar general statements more widely and, where necessary, re-express them in a more restricted form. Theory is thus approaching closer to chemical reality, as it concerns itself more with statements related to particular substances, and rejects over-generalized statements when required. These observations allow us to formulate an up-to-date definition of applied quantum chemistry as the application of computational methods, with the help of a computer, to give data on structures and energies.

We can now see that the question posed in the title can hardly be answered by a simple yes or no. What criteria can be used to judge the development progress of this scientific discipline?

● In the preface to *Clark*'s book *Paul von Ragué Schleyer* writes: "The chemist now has incredibly powerful mathematical tools at his disposal. These tools are simple to use. ... The future directions of chemical research are already programmed!" The physicist *Dirac* was moved to express a rather similar hymn of praise in 1929 when he first encountered the Schrödinger Equation. Predictions of this sort were also made during the sixties, when quantum chemistry had passed through its critical first phase of development and become established as a chemical discipline. The essential difference now, though, is that the statements come from chemists, showing that one of the aims of quantum chemistry, namely to become accepted as an integral part of chemistry, has been achieved.

● The first book published on quantum chemistry—and in fact the expression itself—came in 1937 from *Hans Hellmann* (H. Hellmann: *Einführung in die Quantenchemie*, Deuticke, Vienna 1937). If one could ask the author for his view of quantum chemistry today, one might expect a reply something like the following: quantum chemistry is now in its adolescence—much grown in size, enormously powerful, but intellectually immature. Thus, for example, a chemist using a computer program for configurational interaction (CI) calculations, which relies on Brillouin's theorem, does not need to have this theorem in mind each time he does so, nor even ever to know that he is using the theorem. In its application quantum chemistry today is for that very reason a matter of volition rather than of knowledge and ability. Is this a situation that is appropriate to the academic ideal?

● This criticism of the process of growing up can, however, be seen in a different way. In the book by *Clark* an attempt is made for the first time to separate science from technology. From being originally the preserve of a few physicists with a mathematical background, the application of quantum chemistry now no longer calls for an expensive mathematical training, and it is therefore accessible to the whole of the chemical community. This situation reminds one of *Coulson*, who several decades ago was bold enough to venture into chemistry, and successfully replaced the mathematical formalism of quantum mechanics by "primitive patterns of understanding" (C. A. Coulson: *Valence*, Clarendon Press, Oxford 1952).

Clark mainly sticks to his stated intention of not writing a book for theoreticians, which is fortunate, since those brief attempts at theoretical explanations that have been inserted into the text have a confusing effect. Not much can be made of statements like "the Walsh orbitals in cyclopropane are responsible for much of the unusual chemistry of three-membered ring systems", "the Born-Oppenheimer approximation is a very good one, except in the case of extremely flat potential surfaces", or "in the CI treatment there is mixing of electronic states". The section on electron correlation, though, is unforgivable, where it is stated, and illustrated by a diagram, that in the CI treatment the wave function of a singly excited singlet state is mixed with that of the SCF ground-state! What has become of Brillouin's theorem in this case? Inevitably at this point one has misgivings that the knowledge of technology alone might open the way to its misuse.

How do the facilities available for applying quantum chemistry now look? Essentially three programs are described, for which the manner of feeding in the input and the interpretation of the output are described with numerous examples, namely:

1) classical force field calculations (molecular mechanics);

2) semi-empirical MO procedures (MINDO and MNDO);
3) ab initio procedures (GAUSSIAN 82).

The fact that such a wide range of possibilities exists may be taken as an indication of the increasing maturity of quantum chemistry, for only a few years ago it would not have been possible to bring together in a single book computational procedures based on such differing philosophies. The book will be of interest to all chemists who are interested in molecular structure and energetics.

Semi-empirical methods of calculation have made a contribution to the development of quantum chemistry whose importance can scarcely be overestimated. The great heyday of semi-empirical methods occurred in the sixties, and therefore it is hardly to be noticed that the second of the books under review, by *Joanna Sadlej*, should describe the state of the topic in 1978. It has apparently taken seven years for the book to be translated from Polish into English. During that time the following developments have occurred:

1) the CNDO method, and the procedures derived from it, apart from MNDO, have practically disappeared from the journals;
2) studies of molecular structures and energies of reactions have become much more common than the 40 pages here would suggest;
3) semi-empirical calculations of spectroscopic quantities have declined to such an extent that the 95 pages occupied in the book now seem far too many;
4) CNDO calculations on hydrogen bonding are now recognized to be basically incorrect, so that the chapter of 38 pages is now superfluous;
5) the size of compounds for which semi-empirical calculations are indispensable is now considerably larger.

Unhappily the one method which might have been kept unaltered from 1952, and still retains its standing today, namely the extended Hückel theory (EHT), is given only one page in the appendix.

Despite these deficiencies, however, *Joanna Sadlej* shows in her book in a very impressive way the importance of semi-empirical methods in the development of quantum chemistry, particularly through the many examples and their associated literature references. Whereas many of the early books on semi-empirical methods reflect mainly the personal views of their authors, *Sadlej* has tried—successfully for the most part—to remain objective, so as to produce as complete a work as can be achieved by a single author. It is unfortunate that this care is to some extent wasted, since all that this book contains; and a great deal more besides, is contained in volumes 7 and 8, both edited by *G. A. Segal*, in the series *Modern Theoretical Chemistry* (*Semiempirical Methods of Electronic Structure Calculations*, Plenum Press, New York 1977).

The relationship of quantum chemistry to physics and chemistry, and that between the alternative approaches of ab initio and semi-empirical methods, can best be discussed by considering Table 1, which lists the annual totals of papers on quantum chemistry in several journals; the figures in parentheses give the number of papers on ab initio methods included in the total.

Table 1.

Year	*J. Chem. Phys.*	*J. Am. Chem. Soc.*	*Angew. Chem.*
1960	88	1	0
1961	136	0	1
1962	217	1	0
1963	244	14	1
1964	292	7	2
1965	288	19 (1)	3
1966	209	23	2
1967	252	18 (4)	2
⋮	⋮	⋮	⋮
1985	60	145 (121)	6

In the years after 1960 the numbers of quantum chemistry papers in physics journals increased sharply as a result of computer developments. They reached a maximum in the middle of the sixties, and at the same time papers on these topics began to appear in chemical journals, even in those published in countries where a strong traditionalism in chemistry is said to exist. This breakthrough was mainly due to the work of *Dewar* and *Hoffmann*. Quantum chemistry was at that time divided into two camps, the physical (ab initio methods) and the chemically oriented (semi-empirical methods). Papers giving results obtained by ab initio methods were accepted only hesitantly in the chemical literature from the mid-sixties. Now, twenty years later, quantum chemistry work is carried out to a considerably greater extent in chemical than in physical research groups, and semi-empirical methods play only a secondary role, the only appreciable contributions in 1985 for the three journals of Table 1 being 17 on MNDO and 7 on EHT methods. Two of the arguments put forward in the past for using semi-empirical methods, now becoming less valid, are that "qualitative results are often sufficient", and that "calculations on large molecules call for drastic approximations". Meanwhile ab initio calculations have been successfully applied to the spherical C_{60} molecule and to a DNA fragment with three stacked base pairs. The trend in quantum chemistry is plainly towards obtaining numerically reliable results from ab initio calculations.

The development of quantum chemistry is undoubtedly closely linked to that of computers. However, to avoid the possibility of any misunderstanding with regard to quantum chemistry reaching its maturity, this attempt at a study of its historical development will conclude with a quotation from *Coulson:* "Our understanding ... must be in terms of simple physical models which can readily be visualized, and not in terms of numbers gushing from a computer. If our concepts and patterns of understanding are sound they will be supported by rigorous calculation; if not they must be rejected."

Medicinal Chemistry Research in India. By *H. Singh, A. S. Chawla,* and *V. K. Kapoor.* National Information Centre for Drugs and Pharmaceuticals, Lucknow (India) 1985. 184 pp., bound, Rs. 150.00/$ 35.00.—ISBN 81-85042-00-4

Medicinal chemistry is a line of research which has been pursued more intensively in India since independence. This book gives a survey of Indian research in this field, in twenty concise chapters which cover published work up to 1985.

An introductory chapter describes the achievements of Indian pharmaceutical research, six of its drugs having come on to the market. The following sixteen chapters are

devoted to the treatment of specific conditions. The lengths of the various chapters show which are the main areas of emphasis in the research. It will come as no surprise to discover that these areas are the control of fertility, the central nervous system, and the cardiovascular system. On the other hand, the search for an antimalarial drug, which would certainly be of importance to India, appears to receive less attention. Also one looks in vain for papers on antibiotics of the β-lactam type. In contrast to this, there is considerable emphasis on the isolation and structure determination of natural products.

Five chapters deal with chemotherapeutic compounds: anthelmintics, antiprotozoics, fungicides and antibacterial substances, and antiviral and cytostatic agents. Pharmacologically active substances are divided into psychotropic and other drugs which affect the central nervous system, anti-inflammatory agents, local anesthetics, neuromuscular and ganglionic blocking agents, antihistaminics, cardiovascular drugs, diuretics, and agents affecting hyperglycaemia or fertility. Information is given on the effectiveness, state of development, and origin of each pharmacological substance. Descriptions of syntheses and detailed pharmacological information are not included. Regrettably too, structural formulas have often been omitted in favor of systematic chemical names, so as to save space, and the readability of the text has consequently suffered in places.

There is a further chapter dealing with structure-activity relationships and drug design. The references given are mainly to studies which aim to establish quantitative structure-activity relationships (QSAR). The book concludes with two brief chapters describing research on prostaglandins and peptides.

The authors have evidently been concerned to make this as complete a survey as possible, and to include references to all the relevant papers. Accordingly the bibliography, containing more than 1100 references and occupying two-fifths of the text, is very comprehensive. The book is rounded off by a subject and an author index.

Geschichte der Elektrochemie. By *L. Dunsch.* VEB Deutscher Verlag für Grundstoffindustrie, Leipzig 1985. 145 pp., paperback, DM 14.00.—Order no. 5478814

As one scans through the latest issues of scientific journals on display in the library, wondering how valuable this host of publications really is, it is occasionally quite useful to take a look back at the history of one's own particular field. For electrochemists I can recommend for that purpose this little book by *L. Dunsch,* which presents a brief history of the subject. It starts with the mysterious monocell of the Parthians, and continues up to the beginnings of electrode kinetics in the 1940's.

The accounts of the earliest attempts to understand electrical phenomena, of "animal electricity", and of the "glass" and "amber" types of electricity, make enjoyable reading. But while one may smile at some of the misconceptions, or nod one's approval for a brilliant idea, suddenly one asks oneself: why in fact did the frog's leg muscles twitch in the experiments of *Galvani*?—what actually happens at a molecular level within the nerves? To some extent one is annoyed that one still does not know the precise answer, but is comforted on the other hand, by knowing that *Galvani*'s contemporaries would not even have understood the question.

It is exciting to see how concepts have gradually emerged; how, for example, the earliest electrochemical series were established, or when the idea of an ion first appeared. On many of the topics, especially on the great disputes that have occurred, one would like a more detailed account. On what grounds did the respective adversaries base their views? What experimental evidence did they rest on? When was the controversy finally settled, and why? Answers to these questions would of course have expanded the text beyond the bounds of this little volume, but one would nevertheless like to see a fuller account published, perhaps from this same author!

Towards the end of the book we arrive at those questions and techniques which are familiar to us now. We learn something about the beginnings of kinetic studies and pulse techniques, but these developments are not followed up further. It is understandable that the author has refrained from writing the history of an area of research which is still incomplete, but I wish that he had been bold enough to bring us closer to the present situation in electrochemistry.

However, this is on the whole a very successful book. It is nicely illustrated with pictures of apparatus and scientists, and is rounded off by a table of dates, some well chosen literature references, and a list of relevant people with biographical notes which is quite detailed for such a small book.

Electrodes for Potential Measurements in Aqueous Systems at High Temperatures and Pressures

By Leonard W. Niedrach*

The measurement of pH, redox potentials, and corrosion potentials at high temperatures and pressures is often desirable for the control and monitoring of industrial processes; e.g., for controlling water chemistry in conventional and nuclear power generators, for process control in the chemical industry, and for monitoring performance in petroleum extraction and refining. Such measurements are also needed for research on the thermodynamics of high-temperature aqueous solutions including those associated with geothermal and hydrothermal reactions. Zirconia electrodes for these purposes are described, and their application is illustrated with examples. While not yet routinely available on a commercial basis, useful versions can be readily fabricated in the laboratory. Some of the pitfalls encountered in making such measurements at elevated temperatures are also discussed because great care is often required to assure that valid and useful data are being obtained.

1. Introduction

Of considerable concern in the operation of high-temperature aqueous systems is the control of pH and the redox potential because of their importance as process variables in such areas as paper manufacturing, catalysis, polymerization, and petroleum refining. While in some cases adequate information can be obtained from measurements on cooled side streams, it is often more useful to perform the measurements at the process temperature. Under such conditions less time lag is involved, and, more important, unpredicted shifts in equilibria are avoided. The importance of making measurements under process conditions is particularly evident in the case of corrosion potentials. In the nuclear industry, for example, it has been demonstrated that maintaining the corrosion potential of stainless steel below a critical value can be effective in mitigating stress corrosion cracking. For adequate control such measurements must be made under the process conditions.

In recent years much work has been published aimed at the development of suitable electrodes for such measurements. As might be expected, much of the impetus has come from the nuclear industry through a widespread interest in mitigating corrosion problems through an understanding of the theoretical principles and thermodynamic parameters involved. This article reviews some of these developments and describes some of the more useful electrodes. Their applications are illustrated with examples.

2. Description of Electrodes

2.1. Conventional Reference Electrodes

In thinking of a reference electrode one normally focuses on a type that is essentially insensitive to the environment being monitored. Such electrodes are generally fabricated with a highly reversible couple such as the mercury/mercury(I) chloride (calomel) couple or the silver/silver chloride couple in contact with a stable, aqueous po-

tassium chloride solution, and they are capable of establishing a liquid junction with the environment being monitored with only a minor offset or liquid-junction potential at the interface. For applications at ambient temperature the saturated or 3 M calomel and silver/silver chloride electrodes are classical examples. Such high concentrations of KCl cannot be employed at high temperatures, however, because of the strong complexing action on mercury(I) and silver chlorides and the ensuing changes in chloride activity. It has been found, however, that lower concentrations of KCl do function satisfactorily at elevated temperatures, and considerable effort has been devoted to the development of practical reference electrodes based upon the silver/silver chloride couple.

Two variants of the silver/silver chloride electrode have proven most popular for high-temperature applications. One, the *isothermal type*, operates entirely at the temperature and pressure of the environment being monitored. The other, the *thermal junction type*, operates with a thermal junction across the electrolyte bridge, and the reference couple itself is held at ambient temperature. Both have proven quite satisfactory in practice.

Numerous investigators have described a variety of versions of the isothermal-type electrode.[1-4] That of *Indig* et al.[3] will serve as an example for more detailed discussion. As shown in Figure 1, a silver wire coated with silver chloride is contained within a Teflon housing adapted to a Conax pressure fitting. The filling solution of 0.01 M KCl communicates with the external environment through a porous plug. Related structures employing only water as the internal filling solution have been found to perform satisfactorily for measurements in the high-purity water employed in nuclear reactors.[4,5] In this case an excess of silver chloride is added to the Teflon housing and its dissolution in the water within the housing establishes a steady reference potential.

The thermal-gradient-type electrode has also been investigated by a number of workers.[6-8] An example, as described by *Danielson*,[6] is shown in Figure 2. It is assembled within a Teflon tube, which also serves as the electrolyte bridge to the point of interest within the environment being monitored. To permit operation in pressurized systems, the Teflon bridge is retained within metal tubing. The potential offset resulting from the temperature gradient is a function of the temperature difference between the solution and the reference couple as well as the concentration of the salt in the bridge. These effects have been studied by *Macdonald* et al.,[7] who have tabulated relevant offset data.

In our experience, both types of reference electrode function quite satisfactorily. It must be emphasized, how-

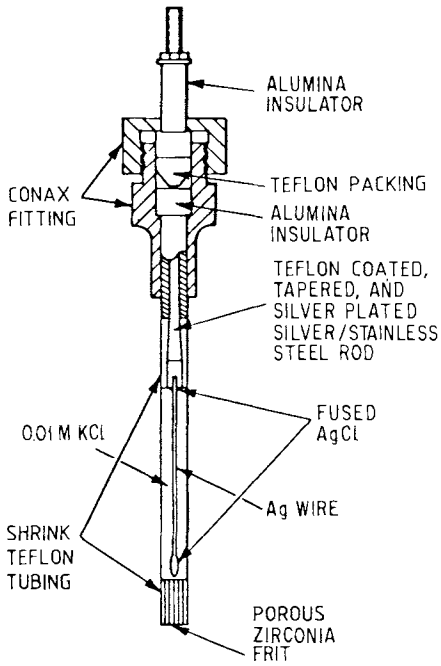

Fig. 1. Isothermal-type reference electrode after *Indig* et al. [3]. Standard Conax fittings establish the pressure boundary. Care must be exercised that the porous zirconia frit forms the only junction with the environment being monitored.

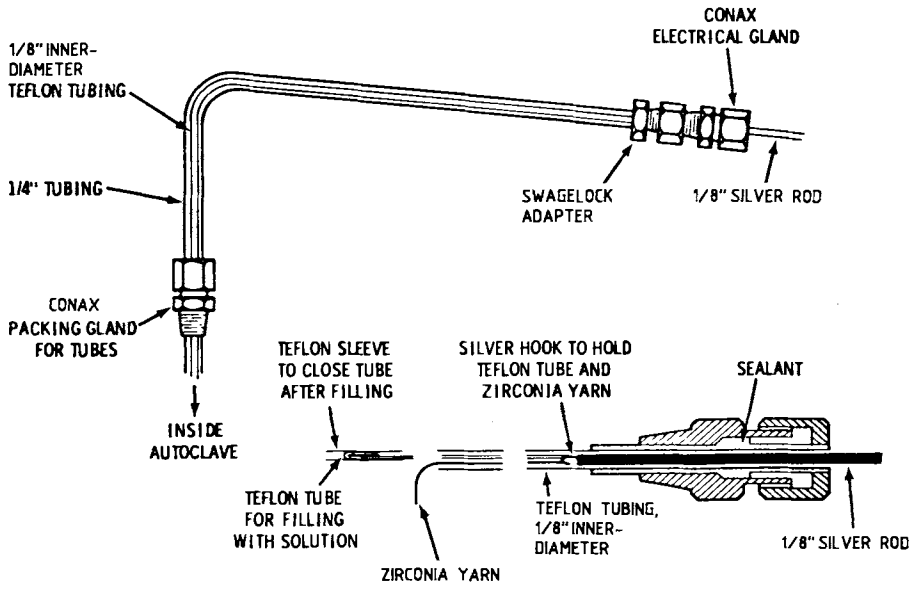

Fig. 2. Thermal-gradient-type reference electrode after *Danielson* [6]. A porous zirconia plug (not shown) forms the junction with the environment being monitored. The zirconia yarn serves to bridge any gaps in the electrolyte that may form during operation without an overpressure.

ever, that both do involve porous junctions between the reference couple and the environment being monitored. In principle, then, exchange of solutes can occur between the two and this can result in drift in the reference potential as chloride is lost or gained by the filling solution. The rate of such drift is dependent upon the magnitude of the concentration gradients and the porosity of the junction.[5] It is also important to consider the expansion of water upon heating to higher temperatures. Thus, upon cooling after use at a high temperature, water will be drawn in from the external environment to further change the chloride concentration within the electrode chamber. This effect is smaller with a thermal-gradient electrode than with an isothermal electrode because less of the filling solution goes through the temperature cycle in the former case.

Another possible source of drift is associated with perfusion of dissolved hydrogen or oxygen into the reference chamber from the environment. Hydrogen can reduce silver chloride to release hydrochloric acid into the solution, thereby contributing to drift by increasing the chloride ion concentration. Conversely, oxygen can oxidize silver in the presence of chloride to form silver chloride and thereby cause drift in the opposite direction. Perfusion is markedly limited by the outer steel tubing employed with the Danielson electrode. A variant of the Indig electrode, in which the Teflon housing is replaced with a zirconia tube, reduces perfusion with that type of electrode.[9]

2.2. Indicator Electrodes

For the monitoring of the redox potential of an environment, a platinum electrode can be used in conjunction with an appropriate reference electrode. Design can vary significantly, the major concern being a reliable seal against the pressure and adequate insulation of the support so that the working area is reasonably well defined. An example is shown Figure 3. A Conax compression seal with a Teflon insert is used to penetrate the pressure barrier and Teflon is used to insulate all but the area designed to contact the environment. Alternatively, a flag-type electrode supported by a Teflon-insulated wire passing through the compression seal may be used.

2.3. pH Electrodes

A wide variety of electrodes have been investigated in order to measure pH at elevated temperatures. They include the classical hydrogen electrode,[10, 11] the palladium hydride electrode,[12, 13] the glass electrode, and metal–metal oxide couples.[14] For general application, the first suffers from a need to know the concentration of dissolved hydrogen in the environment being monitored and from interference from other redox-active species. Metal oxide and palladium hydride electrodes also suffer from interference from other redox-active species. Up to temperatures of about 150 °C the glass electrode can be employed, but at higher temperatures it is severely attacked even by high-purity water. This electrode, however, responds through changes in a membrane potential rather that through the response of electron-transfer couples and is therefore independent of redox-active species in the solution.

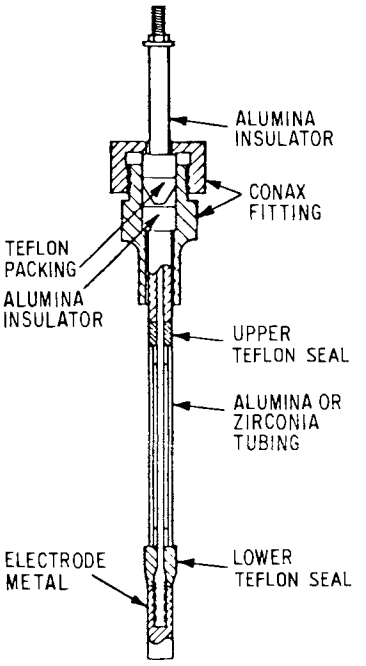

Fig. 3. Metal electrode after *Indig* et al. [3]. The stainless steel support rod is threaded on the lower end to accept the metal electrode. Care must be exercised to assure a tight seal of the metal electrode against the Teflon.

It was more recently found that stabilized zirconia can serve as a membrane-type electrode, much like the glass electrode,[15, 16] but without the major disadvantage of the latter (excessive solubility at high temperatures). This has proven to be the most satisfactory type of pH sensor available for high-temperature studies. Representative designs are shown in Figure 4. In early work sensors were fabricated in a fashion somewhat akin to that of the conventional glass electrode in that a buffered saline solution in contact with a silver wire coated with silver chloride served as the internal element within the membrane sheath[15, 16] (cf. Fig. 4a). Although this type of internal element has been used by others,[17] it has been observed that a dry mix of a metal and its oxide—or two oxides of the same metal in different valence states—is preferable.[18] Such a design, in which the copper–copper(I) oxide couple serves as the internal element, is shown in Figure 4b. Mercury/mercury(II) oxide has also served satisfactorily[16, 19] and the use of silver/silver oxide has also been reported.[19] In another satisfactory approach the internal element has been prepared with platinum left exposed to air.[20]

In the design shown in Figure 4b, a 1/4-in.-outer-diameter tube[*] consisting of zirconia stabilized with yttria (8 wt-%) is retained in a Conax type EG-125 fitting with a seal consisting of Teflon, Vespel, silver, and alumina elements as shown. The dry mix of copper and copper(I) oxide powders (1 : 1 by weight) is packed around a copper wire in a one to two inch long section near the closed end of the zirconia tube. This defines the active region of the

[*] Obtainable from Corning Glass Works/Zircoa, Solon, OH (USA).

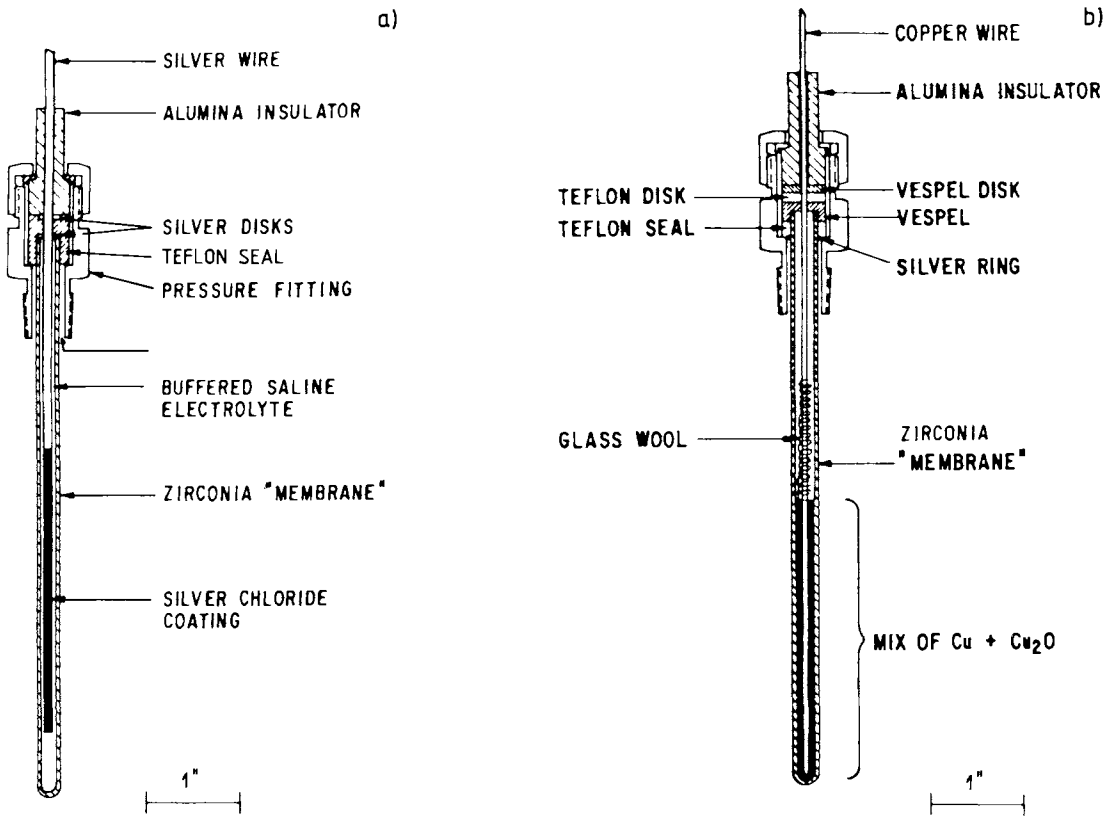

Fig. 4. Schematic diagrams of pH sensors with zirconia "membranes." The diagrams are essentially to scale and none of the dimensions are critical. Clearance between the zirconia tube and the lower portion of the Conax fitting must be provided, if necessary, by enlarging the bore of the fitting. The Teflon and Vespel contacting the zirconia must be machined to fit the outside diameters of the individual tubes, which show considerable variation. For a) and b), see text.

sensor. A backing of glass wool is then added to help confine the powder. Finally, the seal is assembled and tightened with a torque of about 5.7 Nm. This design offers several advantages over the earlier aqueous system: (1) it can be readily prepared by simple mixing of the powders and packing into the tube; (2) it is extremely stable and reproducible; (3) it permits ready designation of the active region of the sensor because the wall is not wetted with a conducting film; and (4) seal fabrication is simplified because of the absence of an internal aqueous phase.

This arrangement has proven highly satisfactory for laboratory work, but because of the thermal properties of the polymeric elements and their tendencies to flow and/or relax, care must be taken to keep them thoroughly confined. For this reason a modification with a brazed metal-to-ceramic seal has been devised.[21]

Because it is relatively new, a brief discussion of the operation of the zirconia pH sensor is perhaps in order. For the sensor shown in Figure 4b, several interphase potentials are involved in series between the external terminal (copper wire) and the solution being monitored. These and the thermodynamic balances involved in the potential-determining reactions at the various interfaces are summarized in Figure 5 according to the approach of *Vetter*.[22] The balances are derived from the fact that at equilibrium the algebraic sum of the electrochemical potentials (${}_i\eta_s$) of the reacting species is zero:

$$\Sigma\ {}_i\nu_s \cdot {}_i\eta_s = 0 \tag{1}$$

where

$${}_i\eta_s = {}_i\mu_s + {}_iz_s \cdot F \cdot {}_i\phi \tag{2}$$

and where ${}_i\mu_s$ is the chemical potential of reacting species s in phase i, ${}_iz_s$ is the charge on the species, ${}_i\phi$ is the Galvani (inner) potential in phase i, ${}_i\nu_s$ is the stoichiometric factor of the species involved in the potential-determining reaction, and F is Faraday's constant.

In summing the interphase potentials between phases 1 and 4, the net change is equivalent to that for the simple copper/copper(I) oxide couple (see Fig. 5):

$$2Cu + H_2O \longrightarrow Cu_2O + 2H^+ + 2e^- \tag{3}$$

The thermodynamics of this reaction is well established.

The membrane may therefore be looked upon as a protective sheath that prevents the metal and its oxide from interacting directly with the solution or redox-active species in the solution. Whereas a copper/copper(I) oxide mix could be exposed to water and dilute acids and bases without significant attack, such would not be the case with strongly acidic or basic solutions. Under any conditions, use of the unsheathed metal/metal oxide mix would necessitate alternative protection from direct interaction with hydrogen or oxygen.

Phases	Thermodynamic balances	Interface potentials
1-2	${}_1\mu_{Cu^0} - ({}_1\mu_{e^-} - F_1\phi) - ({}_2\mu_{Cu^+} + F_2\phi) = 0$	$\Delta\phi_{1-2} = 1/F({}_2\mu_{Cu^+} + {}_1\mu_{e^-} - {}_1\mu_{Cu^0})$
2-3	$({}_2\mu_{O^{2-}} - 2F_2\phi) - ({}_3\mu_{O^{2-}} - 2F_3\phi) = 0$	$\Delta\phi_{2-3} = 1/F(\frac{1}{2}{}_2\mu_{O^{2-}} - \frac{1}{2}{}_3\mu_{O^{2-}})$
1-3		$\Delta\phi_{1-3} = 1/F({}_2\mu_{Cu^+} + \frac{1}{2}{}_2\mu_{O^{2-}} + {}_1\mu_{e^-} - \frac{1}{2}{}_2\mu_{O^{2-}} - {}_1\mu_{Cu^0}) = 1/F(\frac{1}{2}{}_2\mu_{Cu_2O} + {}_1\mu_{e^-} - \frac{1}{2}{}_3\mu_{O^{2-}} - {}_1\mu_{Cu^0})$
3-4	${}_4\mu_{H_2O} - ({}_3\mu_{O^{2-}} - 2F_3\phi) - 2({}_4\mu_{H^+} + F_4\phi) = 0$	$\Delta\phi_{3-4} = 1/F(-\frac{1}{2}{}_4\mu_{H_2O} + \frac{1}{2}{}_3\mu_{O^{2-}} + {}_4\mu_{H^+})$
1-4		$\Delta\phi_{1-4} = 1/F(\frac{1}{2}{}_2\mu_{Cu_2O} + {}_4\mu_{H^+} - {}_1\mu_{Cu^0} - \frac{1}{2}{}_4\mu_{H_2O} + {}_1\mu_{e^-})$

This is thus equivalent to the potential of the following half couple: $Cu^0 + \frac{1}{2}H_2O = \frac{1}{2}Cu_2O + H^+ + e^-$

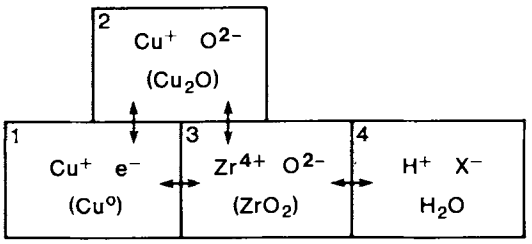

Fig. 5. Interphase potentials and related thermodynamic data for the zirconia pH sensor.

3. Applications

3.1. Measurement of pH

Zirconia sensors are particularly of interest for the measurement of pH at relatively high temperatures and pressures; e.g., 285 °C at 83 bar. When used under these conditions with an appropriate silver/silver chloride reference electrode, they have invariably performed well in both pure water and simulated brines for as long as 40 days. Such performance has been thoroughly documented elsewhere,[18,23] and representative response data obtained in conjunction with a reference electrode of the isothermal type are shown in Figure 6.

Also shown in Figure 6 are the pH responses of a hydrogen electrode and an oxygen electrode under the same conditions. In the latter two cases the same platinized platinum flag was used; however, the redox status of the solutions was changed by equilibrating with either a hydrogen–nitrogen or oxygen–nitrogen mixture. With the hydrogen electrode the response paralleled that of the zirconia electrode since both electrodes are nearly reversible. The response of the oxygen electrode deviates from the theoretically predicted values because of its poorer kinetic behavior.

The data in Figure 7 further emphasize that the zirconia electrode, like the glass electrode, does *not* respond to changes in the redox potential of the environment. These data were obtained while 0.0005 M sulfuric acid, initially aerated, was being fed to the stainless steel autoclave.[16] On switching to a nitrogen purge of the feed stream, the potentials of the autoclave and the platinum flag (oxygen electrode) immediately started to fall while that of the zirconia pH sensor remained constant. After several hours a more rapid drop occurred in the potentials of the autoclave and the platinum electrode. This is attributed to a change in the passivation reaction for the stainless steel autoclave. Instead of the passive film being maintained by the reduction of oxygen to water, water is reduced to liberate hydrogen. The platinum flag then clearly showed its sensitivity to this change in the redox environment. The oxygen-ion-conducting ZrO_2 membrane, however, retained an essentially constant potential. The small, transient increase in potential is believed to have been a response to a real transient in pH associated with the change in the passivation reaction on the stainless steel.

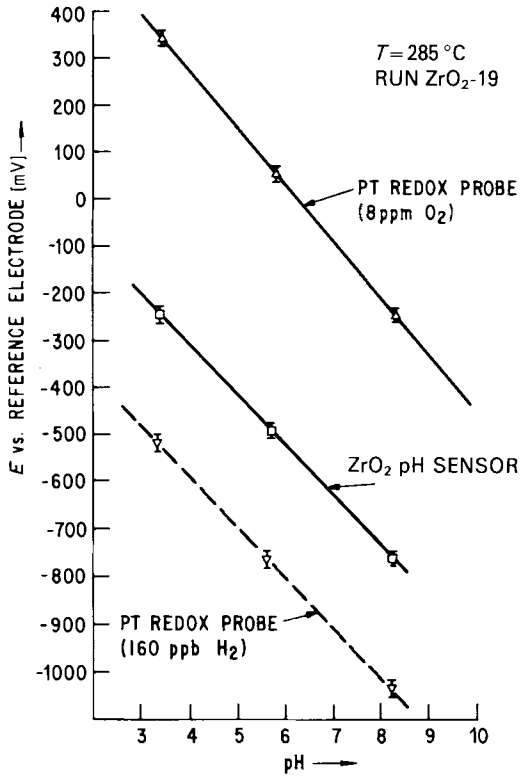

Fig. 6. Variations in the potentials of several electrodes with pH. Reference electrode: silver/silver chloride.

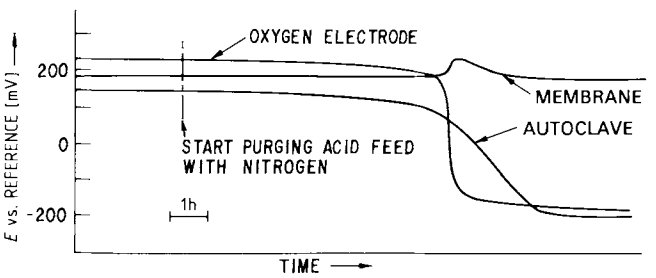

Fig. 7. Behavior of a ZrO_2 pH sensor, the oxygen electrode, and the stainless steel autoclave as the redox potential of the environment is changed at 285 °C. The transient perturbation of the membrane potential at the ZrO_2 pH sensor is believed to reflect a real pH transient associated with a change in the corrosion film on the steel autoclave as the corrosion potential changes. Reference electrode: silver/silver chloride.

An additional example demonstrating the versatility of the zirconia pH sensor is the collection of data in Figure 8 obtained by monitoring pH changes in simulated geothermal brines upon changing the carbon dioxide content and upon introducing hydrochloric acid or base into the solution. The upper portion of the figure shows the changes observed in the solution at 25 °C as measured with a commercial glass electrode (Ingold) while the lower portion shows the measurements at 285 °C. For the latter, two reference electrodes, 13RR and 14RR, of the thermal-gradient type were employed. As much as 100 ppm of sulfide ion (as sodium sulfide) was also introduced into the solution at various times. This had no effect on the instrumentation or the electrodes apart from that caused by the pH changes.

Further examples of the performance of this combination of zirconia pH electrode with a thermal-gradient-type reference electrode are shown in Figure 9 where measured pH values are compared with calculated values for 0.2- and 20-percent brine solutions. In both cases the agreement is excellent.

As noted above, in experiments of this type there is always some chance for bias to creep into the measurements through offsets in either the sensing or reference electrode. It is therefore desirable to calibrate the combination of sensor electrode and reference electrode with known standards. In the brine work, for example, slow drift in the calibration always occurred. Upward displacement of the calibration curve occurred with a 20-percent brine and

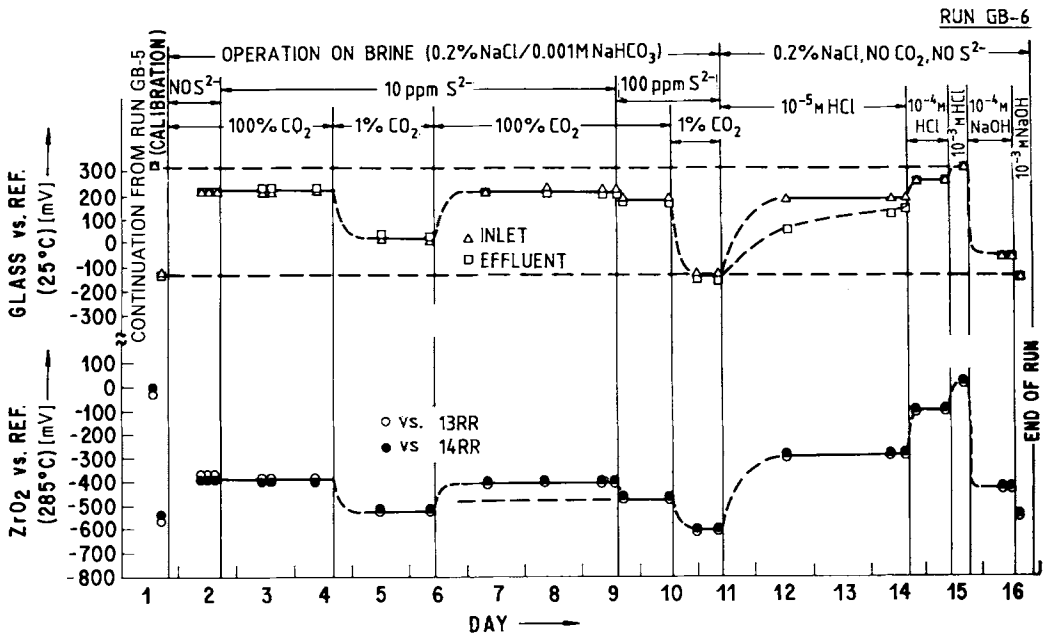

Fig. 8. Potentials of the zirconia pH sensor at 285 °C and glass electrodes at 25 °C versus silver/silver chloride as reference electrode during run GB-6. Two high-temperature reference electrodes, 13RR and 14RR, were used.

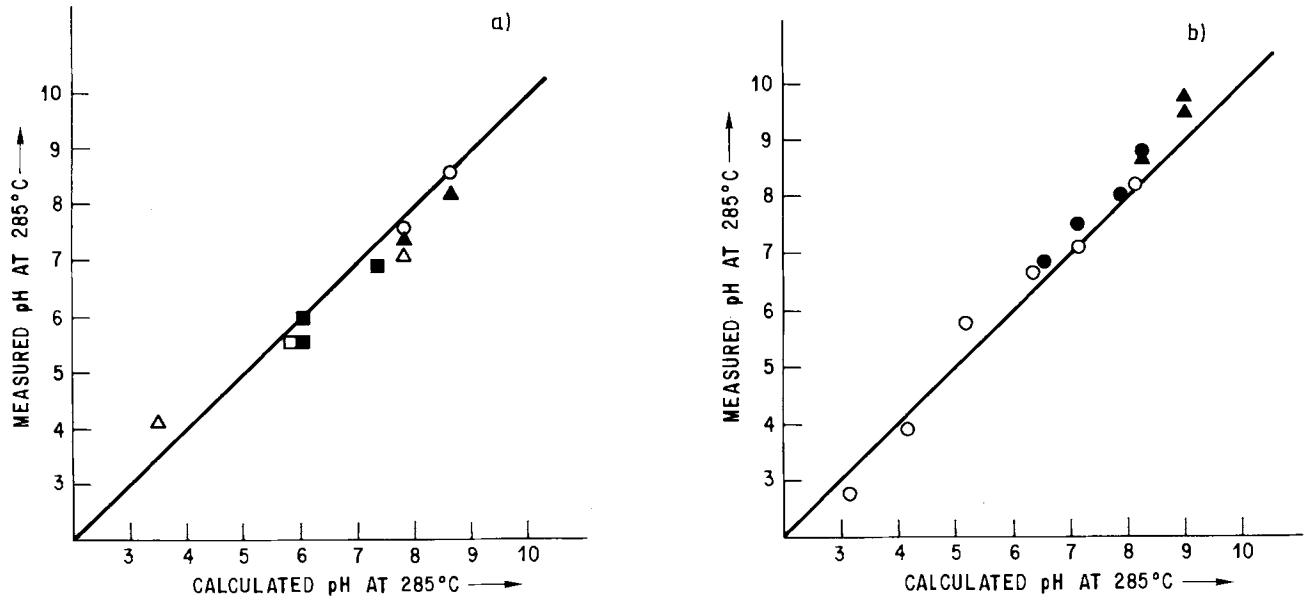

Fig. 9. Correlation between measured and calculated pH at 285 °C for brines. White symbols, no sulfide; black symbols, 10 or 100 ppm sulfide. a) 20% NaCl/0.001 or 0.1 M $NaHCO_3$; circles, triangles, and squares represent runs GB1, GB3, and GB4, respectively. b) 0.2% NaCl/0, 0.001, or 0.1 M $NaHCO_3$; triangles and circles represent runs GB5 and GB6, respectively (cf. Fig. 8).

downward displacements with a 0.2-percent brine. Since the original filling solution in the reference electrode was 0.1 M KCl in all cases, the displacements reflected diffusion of chloride into or out of the reference electrode as a result of the concentration gradients between the internal filling solution and the environment being monitored. This suggests that selection of a filling solution having a chloride concentration close to that of the brine should minimize drift of this type.

3.2. Measurement of Corrosion and Redox Potentials

Corrosion or redox potentials are often measured in order to maintain their values within some favored range. Often these limits are specified in terms of potentials relative to that of the standard hydrogen electrode (SHE). Such values can be derived from measurements against any of the above electrodes, which may serve as reference electrodes when sufficient ancillary information is available. For the conventional type of reference electrode, such as the silver/silver chloride electrode, only the chloride ion content within the electrode chamber must be known. With a knowledge of the pH of the environment, a pH electrode may also serve as a reference electrode. If, in addition, the hydrogen or oxygen activity of the environment is known, the Pt/H_2 (or Pt/O_2) electrode may also serve.

In principle the problem of measuring corrosion or redox potentials should equate with that of measuring the pH. In each case one is interested in the potential between a sensing electrode and a reference electrode. A fundamental difficulty arises, however, in that a convenient, definitive means of calibrating the measurement is available only when measuring pH. In that case a conventional scale has been adopted and convenient standard buffers are available for frequent calibrations to assure the accuracy of the potential measurement even though the reference and/or the sensing electrodes may have suffered drift.

Such standards are not available for corrosion and redox potential measurements. In particular, corrosion potentials are expected to vary considerably with the experimental conditions, the age of the corrosion film, the composition of the metal, etc. For this reason the most stable reference electrode available should be employed for such measurements. If one wishes to be more conservative, at least one additional reference electrode *of another type* should be employed as a check. To underscore this point further, two reference electrodes of the same type cannot be considered as reliable checks upon one another; both could respond to the environment in identical, erroneous ways, or exhibit essentially identical drifts with time.

In connection with the stability of reference electrodes, we have made a number of intercomparisons of the relative stabilities of silver/silver chloride electrodes, zirconia pH sensors, and Pt/H_2 and Pt/O_2 electrodes.[18] As noted in Section 2.1, silver/silver chloride electrodes must be expected to show some drift with time because of their diffusion junctions, especially if temperature cycling of the solution occurs. Such drift has clearly been demonstrated with fillings of 0.01 and 0.1 M KCl.[5] In agreement with *Leibovitz* et al.,[4] we have found that elimination of the KCl and resorting to only the dissolution of an excess of silver chloride gave a more stable potential.[5,24]

Even under these conditions the zirconia pH sensor and the Pt/O_2 electrode[8] have been shown to provide the most stable potential. Figures 10 and 11 show that the most stable correlations are obtained for the potential of the oxygen electrode vs. the ZrO_2 pH sensor. The stability of the Pt/H_2 electrode also falls into this category and in addition is more reliable in establishing a predictable potential.[25] Several types of reference electrode are thus available that can be used as cross-checks on one another if sufficient environmental information is available (namely, the pH and the concentration of dissolved hydrogen or oxygen).

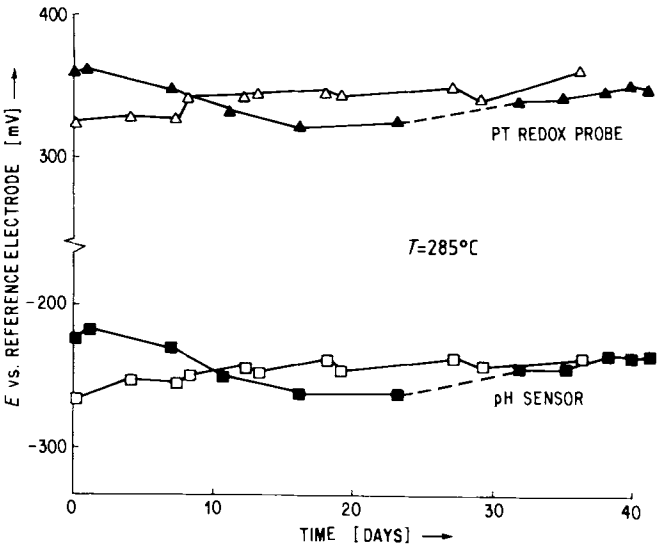

Fig. 10. Potentials of the platinum electrode and the zirconia pH sensor (reference electrode: silver/silver chloride). The solution was aerated so that the platinum was functioning as an oxygen electrode. The silver chloride electrode contained no KCl. The similar temporal changes shown by the platinum and zirconia electrodes suggest that the major cause of the variations lies with the silver/silver chloride electrode. White symbols: Run ZrO_2-19; black symbols: Run ZrO_2-20.

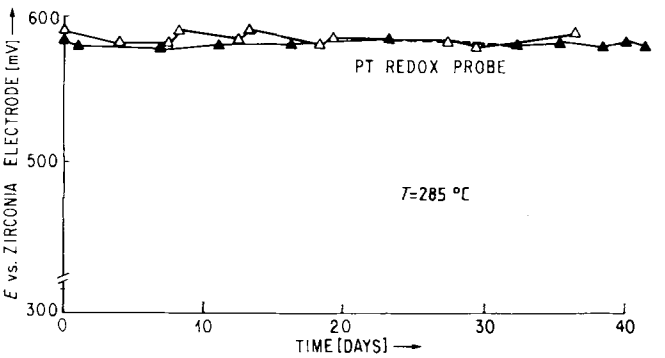

Fig. 11. Potential of the platinum electrode in the aerated solution (reference electrode: zirconia pH sensor). The excellent stability implies that both electrodes are very stable. White triangles: Run ZrO_2-19; black triangles: Run ZrO_2-20.

The focus of interest to date has been in measuring corrosion potentials of stainless steel and other structural materials in the high-purity cooling water of boiling-water

reactors at about 285 °C. Routine measurements of conductivity and pH at ambient temperature assure that the water is indeed pure and therefore has a pH value close to the theoretical neutral point of 5.65 at 285 °C. Routine monitoring of hydrogen and oxygen concentrations—which are the redox-potential-determining species in this case—then permit the calculation of the potential of the hydrogen or oxygen electrode.

The potentials of the various electrodes under consideration vs. the SHE potential at 285 °C have been calculated. With freshly prepared reference electrodes, satisfactory agreement can be obtained with measurements between various pairs of reference electrodes, generally to within ±20–30 mV. With the passage of time, however, drift will sometimes be encountered, especially in measurements involving the silver/silver chloride electrode with the KCl filling.

Based upon our experience, the zirconia pH electrode is preferred for measurements with such relatively pure water systems as the cooling water of boiling-water reactors. This has indeed been our choice for studies of corrosion potentials of stainless steel under so-called normal and hydrogen water conditions. Under normal water conditions, oxygen tends to be somewhat in stoichiometric excess of hydrogen and the platinum electrode behaves much as an oxygen electrode. Under hydrogen water conditions, hydrogen is in excess and the platinum electrode behaves as a hydrogen electrode. The behavior of stainless steel is more complicated.[25] These conditions are of practical interest because the more reducing conditions result in suppression of stress corrosion cracking[26] and much present work is aimed at establishing the value of a critical potential as well as electrochemical means for monitoring the reactor piping.

The data in Figure 12, obtained during studies of crack growth rates of 304 stainless steel under hydrogen water conditions,[24] illustrate the way the corrosion potential responds to changes in the water chemistry. The data were obtained using a zirconia pH electrode, with a copper/copper(I) oxide internal element[24] as the reference electrode. The water chemistry was also followed continuously by analyses of pH, hydrogen and oxygen concentration, and conductivity of the effluent from the autoclave at ambient temperature. Because of the reversibility of the Pt/H_2 electrode, its behavior under changing conditions provided a check on the zirconia electrode during operation under hydrogen water conditions. A silver/silver chloride reference electrode was not used in the work.

In this case the potential measurement was employed as a routine process-control monitor. Shown in Figure 12 are corrosion potentials measured at 285 °C for water nominally containing 160 ppb dissolved hydrogen and no oxygen. At one point, immediately following replacement of a tank of forming gas (nominally 10 percent H_2 in N_2) used to maintain the hydrogen level in the feed stream, the corrosion potential began to rise significantly. Subsequent analysis indicated that the drift had resulted from oxygen contamination in the forming gas to a sufficient extent to introduce 50 ppb into the feedwater. Since the observed effect possibly reflected an influence of the hydrogen–oxygen recombination reaction on the mixed potential of the corroding specimen, additional studies were undertaken.

These examples, drawn from the area of nuclear reactor technology, are perhaps representative of somewhat ideal conditions for such measurements coupled with relatively straightforward means for checking on the validity of the measurements. In situations where complex solutions at high ionic strength are involved, the required additional information concerning pH and redox activity may be too difficult to obtain and correlate to permit valid intercomparisons of the various potential measurements. Under such circumstances extreme caution is required in the interpretation of measured values.

4. Summary and Outlook

Electrodes have been described for the measurement of pH and of redox and corrosion potentials at elevated temperatures. While not yet routinely available on a commercial basis, useful versions can be readily fabricated in the laboratory. In making such measurements at elevated temperatures many pitfalls can be encountered, and great care is required to assure that valid and useful data are being obtained. When possible, direct calibrations to check performance, such as the measurement of pH, should be

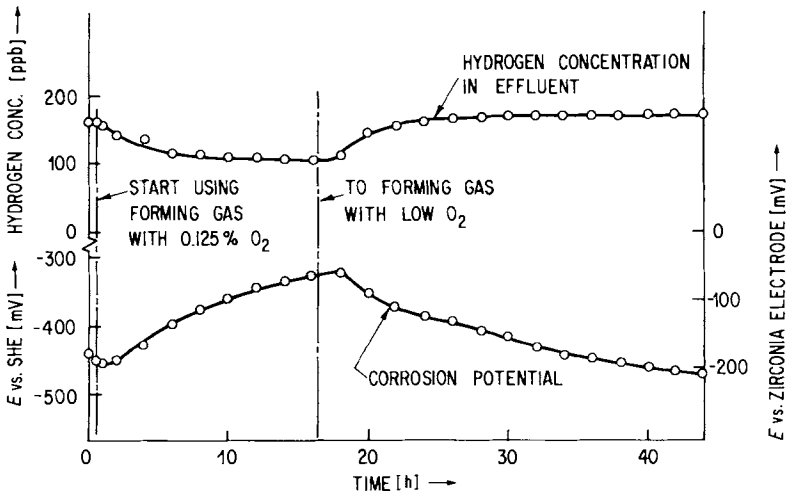

Fig. 12. Transients in the corrosion potential of stainless steel caused by forming gas (N_2 containing 10% H_2) contaminated with 0.125% oxygen. The oxygen content of the gas would introduce 50 ppb O_2 into the water. This amount is stoichiometrically equivalent to only 4 ppb H_2 and would not be expected a priori to have such pronounced effects on the corrosion potential of steel.

made. When such calibration is not possible, it is desirable to employ at least two reference electrodes of different types as a means of protection against undetected, insidious drift of a single reference electrode.

The customized electrodes of today are providing a basis for establishing instrumentation and procedures for their more routine application in the future. As their usefulness becomes more established, commercial versions should become more readily available, and general application should expand.

Neutral and Charged Biradicals, Zwitterions, Funnels in S_1, and Proton Translocation: Their Role in Photochemistry, Photophysics, and Vision

By Vlasta Bonačić-Koutecký,* Jaroslav Koutecký,* and Josef Michl*

A knowledge of the geometries at which excited molecules return to the electronic ground state (S_0) is essential for the understanding of the structures of photoproducts. Particularly good candidates are geometries corresponding to local minima on the S_1 (lowest excited singlet) and T_1 (lowest triplet) surfaces, as well as S_0–S_1 conical intersections (funnels). Given sufficient effort, such geometries can nowadays be found numerically for small enough molecules. Still, it is interesting to ask whether more approximate, but also more general, statements can be made concerning the geometries at which the S_0 and S_1 surfaces closely approach each other. Since many of these are biradicaloid geometries, it is logical to examine the properties of biradicals and related species at some length. After reviewing the two-electron two-orbital model for molecules at biradicaloid geometries, we formulate the conditions under which the S_0 and S_1 surfaces touch. The results obtained for the simple model are supported by ab initio large-scale configuration interaction (CI) calculations for the twisting of ethylene in the polarizing field of a positive charge and for the twisting of charged double bonds and π-donor-to-π-acceptor single bonds, and by similar calculations for "push-pull" perturbed cyclobutadienes, some of which are predicted to have nearly degenerate S_0, S_1, and T_1 states. The likely consequences of these results for the detailed description of the mechanisms of *cis–trans* isomerization, the formation of *t*wisted *i*nternal *c*harge-*t*ransfer (TICT) states, proton translocation, and possibly of the initial step in vision, as well as for the understanding of the regiospecificity of singlet photocycloaddition, are summarized.

1. Introduction: S_0–S_1 Surface Touching

The 3 × 3 CI description of the two-electron two-orbital model for biradicals has been in common use in organic chemistry for over a decade.[1–4] We shall use it to identify the conditions under which the S_0 and S_1 surfaces of a biradical-like species touch or nearly touch. The corresponding regions in the nuclear configuration space have long been recognized[5–13] as important in determining the geometry a molecule will have as it returns to the electronic ground state after the initial excitation in a photochemical event. Although the simple Hückel description leads one to expect an S_0–S_1 "touching" whenever orbital degeneracy in a biradical-like species occurs (e.g., in orthogonally twisted ethylene or in square cyclobutadiene), this is quite unrealistic, and most such touchings are strongly avoided in better approximations. A better tool than inspection of orbital crossings is therefore needed to answer the question, what structural and geometric features are required for the S_0 and S_1 surfaces of a biradical-like species to touch or nearly touch?

In this article, we first review the 3 × 3 CI model for a perfect (homosymmetric[1]) biradical for the reader unfamiliar with prior literature[1–4] on the subject and provide further details that do not seem to have appeared in print before.

After this introduction, we address the case of a perturbed biradical in terms of wave functions based on the most localized pair of orbitals. The two orbitals are allowed to differ in energy (heterosymmetric biradicaloid, a concept that is similar to but not identical with the heterosymmetric diradical category as defined in ref. [1]), to interact (homosymmetric biradicaloid), or to do both (nonsymmetric biradicaloid). We find that the S_0–S_1 touching or near touching occurs when the electronegativity difference of the two localized orbitals just balances the effects of electronic repulsion which tend to keep the S_0 and S_1 surfaces apart.

Although the 3 × 3 CI model serves as a useful initial description of the electronic structure of molecules at biradicaloid geometries, it is far from exact. In particular, the energetic order of closely spaced states obtained from the model can be incorrect. Examples are the change in the order of the S_0 and T_1 states due to dynamic spin polarization[3,14] in twisted double bonds[15] and in disjoint alternant biradicals[16,17] and the reversal of the character of the S_1 and S_2 states in twisted ethylene[18] and along pericyclic reaction paths in systems such as H_2+H_2.[19] Still, those aspects of the results of the 3 × 3 CI model that do not depend on small energy differences are generally correct.

Subsequently, we consider the likely effects of improvements in the theoretical description and find that the con-

clusions concerning S_0–S_1 touching obtained from the 3×3 CI model should remain qualitatively correct. These conclusions are tested by ab initio large-scale CI calculations for two series of examples: polar twisted double bonds and push-pull perturbed cyclobutadienes. As expected from the simple model, in both instances a suitable degree of polarity results in S_0–S_1 touching or near touching (and in S_0–T_1 crossing).

Finally, we discuss briefly the implications of the resulting improvements in the understanding of S_0–S_1 surface touching in the areas of organic and bioorganic photochemistry.

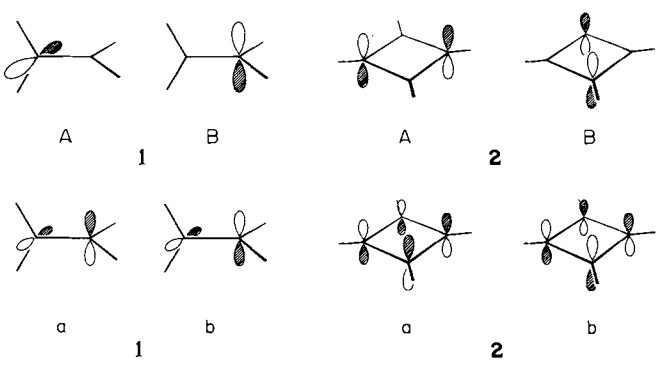
2. The Two-Electron Two-Orbital Model

2.1. General

When two localized orbitals A and B interact weakly or not at all, the single-configuration description of the resulting two-electron states becomes inadequate. This happens in some molecules at all geometries (e.g., O_2, CH_2) and in all molecules at biradicaloid geometries, such as those in which a σ bond has been stretched or a π bond twisted. In this case, since the two electrons do not contribute much, if at all, to covalent bonding in any of the electronic states of the system, all three possible singlet configurations need to be considered on equal footing, hence the term 3×3 configuration interaction. Since there is only one triplet configuration within this model, no configuration interaction is needed for the triplet state.

Biradicals of real interest typically contain many more than two electrons, and these have many more than two orbitals available to them. Nonetheless, it is often possible to describe them more or less successfully by concentrating on only two electrons in two approximately nonbonding orbitals ("active space") and representing the others by a fixed core. This model is adopted throughout Section 2. Illustration is provided by ethylene twisted by 90°, **1**, in which the two localized orbitals A and B are the nonbonding 2p orbitals on the two carbon atoms, and square cyclobutadiene **2**, in which they are the two nonbonding orbitals shown (Scheme 1).

The quantities that characterize the interactions involved when two electrons are contained in two general orbitals $\mathscr{A}$ and $\mathscr{B}$ are collected in Table 1. $\mathscr{A}$ and $\mathscr{B}$ are chosen



Scheme 1. Localized (A, B) and delocalized (a, b) orbitals in twisted ethylene **1** and cyclobutadiene **2**.

Table 1. The quantities characterizing the interactions involved in the 3×3 CI model description of two electrons contained in two orthogonal orbitals $\mathscr{A}$ and $\mathscr{B}$.

Hamiltonian matrix

$$\begin{array}{l} {}^1|\mathscr{A}^2-\mathscr{B}^2\rangle \\ {}^1|\mathscr{A}^2+\mathscr{B}^2\rangle \\ {}^1|\mathscr{A}\mathscr{B}\rangle \\ {}^3|\mathscr{A}\mathscr{B}\rangle \end{array} \begin{pmatrix} E(\mathrm{T})+2K'_{\mathscr{A}\mathscr{B}} & \delta_{\mathscr{A}\mathscr{B}} & \gamma_{\mathscr{A}\bar{\mathscr{B}}} & 0 \\ \delta_{\mathscr{A}\mathscr{B}} & E(\mathrm{T})+2(K'_{\mathscr{A}\mathscr{B}}+K_{\mathscr{A}\mathscr{B}}) & \gamma_{\mathscr{A}\mathscr{B}} & 0 \\ \gamma_{\mathscr{A}\bar{\mathscr{B}}} & \gamma_{\mathscr{A}\mathscr{B}} & E(\mathrm{T})+2K_{\mathscr{A}\mathscr{B}} & 0 \\ 0 & 0 & 0 & E(\mathrm{T}) \end{pmatrix}$$

One-electron integrals

$$S_{\mathscr{A}\mathscr{B}} = \int \mathscr{A}^*(1)\mathscr{B}(1)\,d\tau = 0 \quad \text{(overlap)}$$
$$h_{\mathscr{A}\mathscr{B}} = \int \mathscr{A}^*(1)\mathrm{H}(1)\mathscr{B}(1)\,d\tau \quad \text{[a]}$$

Two-electron integrals

$$J_{\mathscr{A}\mathscr{B}} = \iint \mathscr{A}^*(1)\mathscr{B}^*(2)\frac{e^2}{r_{12}}\mathscr{A}(1)\mathscr{B}(2)\,d\tau_1 d\tau_2 \quad \text{(Coulomb)}$$
$$K_{\mathscr{A}\mathscr{B}} = \iint \mathscr{A}^*(1)\mathscr{A}^*(2)\frac{e^2}{r_{12}}\mathscr{B}(1)\mathscr{B}(2)\,d\tau_1 d\tau_2 \quad \text{(exchange)}$$
$$(\mathscr{A}\mathscr{A}|\mathscr{A}\mathscr{B}) = \iint \mathscr{A}^*(1)\mathscr{A}^*(2)\frac{e^2}{r_{12}}\mathscr{A}(1)\mathscr{B}(2)\,d\tau_1 d\tau_2 \quad \text{(hybrid)}$$

Secondary quantities

$$\gamma_{\mathscr{A}\mathscr{B}} = 2h_{\mathscr{A}\mathscr{B}} + (\mathscr{A}\mathscr{A}|\mathscr{A}\mathscr{B})^* + (\mathscr{B}\mathscr{B}|\mathscr{B}\mathscr{A})$$
$$\gamma_{\mathscr{A}\bar{\mathscr{B}}} = (\mathscr{A}\mathscr{A}|\mathscr{A}\mathscr{B})^* - (\mathscr{B}\mathscr{B}|\mathscr{B}\mathscr{A})$$
$$\delta_{\mathscr{A}\mathscr{B}} = h_{\mathscr{A}\mathscr{A}} - h_{\mathscr{B}\mathscr{B}} + (J_{\mathscr{A}\mathscr{A}} - J_{\mathscr{B}\mathscr{B}})/2$$
$$K'_{\mathscr{A}\mathscr{B}} = [(J_{\mathscr{A}\mathscr{A}} + J_{\mathscr{B}\mathscr{B}})/2 - J_{\mathscr{A}\mathscr{B}}]/2$$
$$E_0 = h_{\mathscr{A}\mathscr{A}} + h_{\mathscr{B}\mathscr{B}} + (J_{\mathscr{A}\mathscr{A}} + J_{\mathscr{B}\mathscr{B}})/4 + J_{\mathscr{A}\mathscr{B}}/2$$
$$E(\mathrm{T}) = E_0 - K'_{\mathscr{A}\mathscr{B}} - K_{\mathscr{A}\mathscr{B}}$$

[a] H(1) is the one-electron part of the Hamiltonian.

to be orthogonal ($S_{\mathscr{A}\mathscr{B}} = 0$). The physical significance of $J_{\mathscr{A}\mathscr{B}}$ is the repulsion between the charge density due to an electron in orbital $\mathscr{A}$ and that due to one in orbital $\mathscr{B}$. The physical significance of $K_{\mathscr{A}\mathscr{B}}$ is the repulsion between the overlap charge density due to the first electron, $e\mathscr{A}^*(1)\mathscr{B}(1)$, and an identical charge density due to the second electron, $e\mathscr{A}^*(2)\mathscr{B}(2)$. The overlap density is large only in those parts of space in which $\mathscr{A}$ and $\mathscr{B}$ both have a large amplitude simultaneously. Thus, $K_{\mathscr{A}\mathscr{B}}$ is a measure of the degree to which the two electrons get in each other's way. For real orbitals $\mathscr{A}$ and $\mathscr{B}$, $J_{\mathscr{A}\mathscr{B}}$ and $K_{\mathscr{A}\mathscr{B}}$ cannot be negative.

The secondary quantities listed in Table 1, $\gamma_{\mathscr{A}\mathscr{B}}$, $\gamma_{\mathscr{A}\bar{\mathscr{B}}}$, and $\delta_{\mathscr{A}\mathscr{B}}$, contain information on the degree to which a two-electron two-orbital system deviates from an "ideal" biradical: $\gamma_{\mathscr{A}\mathscr{B}}$ provides a measure of the interaction between $\mathscr{A}$ and $\mathscr{B}$ and corresponds roughly to twice the resonance integral of semiempirical theories, $\gamma_{\mathscr{A}\bar{\mathscr{B}}}$ is related to the degree of localization of orbitals $\mathscr{A}$ and $\mathscr{B}$, and $\delta_{\mathscr{A}\mathscr{B}}$ provides a measure of the electronegativity difference between $\mathscr{A}$ and $\mathscr{B}$. Specifically, $\delta_{\mathscr{A}\mathscr{B}}$ is equal to the energy difference between the two-electron configuration $\mathscr{A}^2$, in which both electrons reside in $\mathscr{A}$, and the configuration $\mathscr{B}^2$, in which both reside in $\mathscr{B}$. We shall always choose the higher energy orbital as $\mathscr{A}$, so that $\delta_{\mathscr{A}\mathscr{B}} \geq 0$.

The choice of orbitals $\mathscr{A}$ and $\mathscr{B}$ (see Appendix 1). Since we work with the full CI solution within the function space defined by the model, the results must be independent of

any transformation of the orbital basis set. The condition $\gamma_{\mathscr{A}\bar{\mathscr{B}}}=0$ is satisfied by two pairs of real orbitals $\mathscr{A}$ and $\mathscr{B}$: the most localized possible set A, B and the most delocalized possible set a, b. These are related by (1).

$$\begin{aligned} a&=(A-B)/\sqrt{2}\\ b&=(A+B)/\sqrt{2}\end{aligned} \tag{1}$$

The exchange and Coulomb integrals, $K_{\mathscr{A}\mathscr{B}}$ and $J_{\mathscr{A}\mathscr{B}}$, between the two orbitals acquire their minimum values, K_{AB} and J_{AB}, for the most localized choice and their maximum values, K_{ab} and J_{ab}, for the most delocalized choice. This makes physical sense, since the localized orbitals A and B avoid each other in space to the maximum degree possible, while the opposite is true for a and b (Scheme 1). Both integrals, $K_{\mathscr{A}\mathscr{B}}$ and $J_{\mathscr{A}\mathscr{B}}$ are maximized or minimized simultaneously, since their difference is invariant with respect to orbital transformations.

The Appendix also describes an algorithm for finding the most localized and the most delocalized orbital sets starting with an arbitrary real orthogonal set $\mathscr{A}$, $\mathscr{B}$. The values of E_0, $(K'_{\mathscr{A}\mathscr{B}}+K_{\mathscr{A}\mathscr{B}})$, $[(K'_{\mathscr{A}\mathscr{B}}-K_{\mathscr{A}\mathscr{B}})^2+(\gamma_{\mathscr{A}\bar{\mathscr{B}}})^2]$, and $(\delta^2_{\mathscr{A}\mathscr{B}}+\gamma^2_{\mathscr{A}\mathscr{B}})$ are invariant with respect to orthogonal orbital transformations.

2.2. Perfect Biradicals

A perfect (homosymmetric[11]) biradical is one in which the real and orthogonal ($S_{\mathscr{A}\mathscr{B}}=0$) orbitals $\mathscr{A}$ and $\mathscr{B}$ can be chosen in such a way that $h_{\mathscr{A}\mathscr{A}}=h_{\mathscr{B}\mathscr{B}}$, $J_{\mathscr{A}\mathscr{A}}=J_{\mathscr{B}\mathscr{B}}$, and $\gamma_{\mathscr{A}\bar{\mathscr{B}}}=\delta_{\mathscr{A}\mathscr{B}}=\gamma_{\mathscr{A}\mathscr{B}}=0$. Such orbitals have equal energies and do not interact. As shown in the Appendix, the condition $\gamma_{\mathscr{A}\bar{\mathscr{B}}}=0$ implies that the orbitals chosen in this way are either fully localized ($\mathscr{A}=A$, $\mathscr{B}=B$) or fully delocalized ($\mathscr{A}=a$, $\mathscr{B}=b$).

The states and their energies (see Fig. 1). If spin is ignored for the moment, two electrons can be accommodated in two orbitals $\mathscr{A}$ and $\mathscr{B}$ in four ways to produce four configurations: $\mathscr{A}^2=\mathscr{A}(1)\mathscr{A}(2)$, $\mathscr{B}^2=\mathscr{B}(1)\mathscr{B}(2)$, $\mathscr{A}\mathscr{B}=\mathscr{A}(1)\mathscr{B}(2)$, and $\mathscr{B}\mathscr{A}=\mathscr{B}(1)\mathscr{A}(2)$. In the absence of electron repulsion (Hückel approximation), all four wave functions would have the energy $2h_{\mathscr{A}\mathscr{A}}=2h_{\mathscr{B}\mathscr{B}}$. If electron repulsion is taken into consideration, the energy expressions become more complicated. For the choices $\mathscr{A},\mathscr{B}=A,B$ or a, b, we obtain a symmetric split by $\pm K'_{\mathscr{A}\mathscr{B}}$ [Eq. (2)] with respect to E_0 [Eq. (3)].

$$2K'_{\mathscr{A}\mathscr{B}}=(J_{\mathscr{A}\mathscr{A}}+J_{\mathscr{B}\mathscr{B}})/2-J_{\mathscr{A}\mathscr{B}} \tag{2}$$

$$E_0=h_{\mathscr{A}\mathscr{A}}+h_{\mathscr{B}\mathscr{B}}+(J_{\mathscr{A}\mathscr{A}}+J_{\mathscr{B}\mathscr{B}})/4+J_{\mathscr{A}\mathscr{B}}/2 \tag{3}$$

The equivalence of $\mathscr{A}$ and $\mathscr{B}$ demands the use of the combinations $\mathscr{A}^2\pm\mathscr{B}^2$ and $\mathscr{A}\mathscr{B}\pm\mathscr{B}\mathscr{A}$. The in-phase combinations are destabilized and the out-of-phase ones stabilized by $K_{\mathscr{A}\mathscr{B}}$, resulting in four levels at $E_0\pm K'_{\mathscr{A}\mathscr{B}}\pm K_{\mathscr{A}\mathscr{B}}$. The three symmetric spatial wave functions need to be multiplied by the singlet spin wave function, Σ, and the antisymmetric one by one of the three triplet wave functions Θ_i ($i=-1,0,1$), to produce a total of six wave functions that satisfy the Pauli principle and represent a complete basis in a two-electron space. The normalized wave functions S_0, S_1, S_2, and T are the energy eigenstates of a perfect biradical (cf. the Hamiltonian matrix in Table 1). The wave functions and their energies are listed in (4); the expressions for the energies of S_0 and S_1 apply only if the orbitals $\mathscr{A},\mathscr{B}$ are chosen to be equal either to A, B or to a, b. For a general choice, they are $E_0\pm[(K'_{\mathscr{A}\mathscr{B}}-K_{\mathscr{A}\mathscr{B}})^2+(\gamma_{\mathscr{A}\bar{\mathscr{B}}})^2]^{1/2}$.

$$\begin{array}{lll}
S_2 & {}^1|\mathscr{A}^2+\mathscr{B}^2\rangle=(1/\sqrt{2})[\mathscr{A}(1)\mathscr{A}(2)+\mathscr{B}(1)\mathscr{B}(2)]|\Sigma\rangle & E_0+K'_{\mathscr{A}\mathscr{B}}+K_{\mathscr{A}\mathscr{B}}\\
S_0,S_1 & \left\{\begin{array}{l}{}^1|\mathscr{A}\mathscr{B}\rangle=(1/\sqrt{2})[\mathscr{A}(1)\mathscr{B}(2)+\mathscr{B}(1)\mathscr{A}(2)]|\Sigma\rangle\\ {}^1|\mathscr{A}^2-\mathscr{B}^2\rangle=(1/\sqrt{2})[\mathscr{A}(1)\mathscr{A}(2)-\mathscr{B}(1)\mathscr{B}(2)]|\Sigma\rangle\end{array}\right. & \begin{array}{l}E_0-K'_{\mathscr{A}\mathscr{B}}+K_{\mathscr{A}\mathscr{B}}\\ E_0+K'_{\mathscr{A}\mathscr{B}}-K_{\mathscr{A}\mathscr{B}}\end{array}\\
T & {}^3|\mathscr{A}\mathscr{B}\rangle_i=(1/\sqrt{2})[\mathscr{A}(1)\mathscr{B}(2)-\mathscr{B}(1)\mathscr{A}(2)]|\Theta_i\rangle,\ i=-1,0,1 & E_0-K'_{\mathscr{A}\mathscr{B}}-K_{\mathscr{A}\mathscr{B}}
\end{array} \tag{4}$$

Since both $K_{\mathscr{A}\mathscr{B}}$ and $K'_{\mathscr{A}\mathscr{B}}$ are nonnegative, T is the most stable of all four states. The wave function ${}^1|\mathscr{A}^2+\mathscr{B}^2\rangle$ represents S_2, the least stable of the four states. The order of the two singlet states that are represented by the wave functions ${}^1|\mathscr{A}\mathscr{B}\rangle$ and ${}^1|\mathscr{A}^2-\mathscr{B}^2\rangle$, and thus their assignment as S_0 and S_1, depends on the relative magnitudes of $K'_{\mathscr{A}\mathscr{B}}$ and $K_{\mathscr{A}\mathscr{B}}$, which, in turn, are determined by the choice of $\mathscr{A}$, $\mathscr{B}$ as either A, B or a, b.

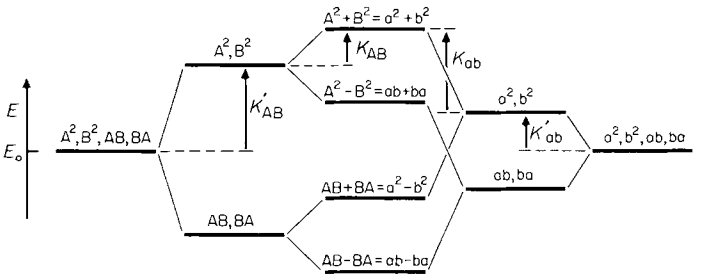


Fig. 1. 3×3 CI model: construction of the energies and wavefunctions of a perfect biradical (center), starting with localized (left) or delocalized (right) orbitals. See also text.

The three simple choices of the orbitals $\mathscr{A}$, $\mathscr{B}$. In Figure 1, the form of the wave functions and the energies associated with them are shown once for the pair A, B and once for the pair a, b. For the localized orbitals A and B, $K'_{AB}\geq K_{AB}$, for the delocalized orbitals a and b, $K'_{ab}\leq K_{ab}$, and the two sets are related by Equation (5).

$$K'_{AB}=K_{ab},\quad K'_{ab}=K_{AB} \tag{5}$$

The different ways in which the same final state wave functions can be expressed in terms of orbital pairs A, B and a, b are shown in Table 2. In terms of A and B, S_0 is given by ${}^1|AB\rangle$ and S_1 by ${}^1|A^2-B^2\rangle$, while in terms of a and b, S_0 is given by ${}^1|a^2-b^2\rangle$ and S_1 by ${}^1|ab\rangle$. It is important to note that for a general choice of the real orbitals $\mathscr{A}$ and $\mathscr{B}$, the wave functions S_0 and S_1 are given by mixtures of contributions from ${}^1|\mathscr{A}\mathscr{B}\rangle$ and ${}^1|\mathscr{A}^2-\mathscr{B}^2\rangle$. However, for

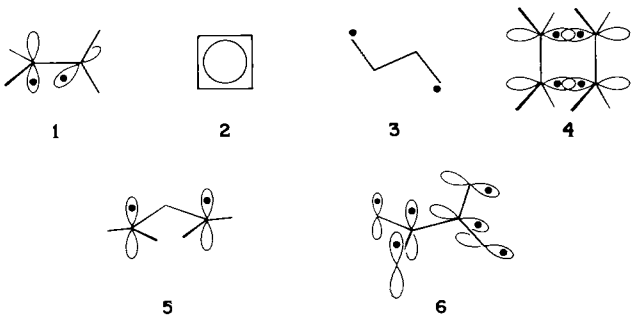
Table 2. State wave functions and energies of a perfect biradical [a].

State	Wave functions: Localized orbitals [b]	Delocalized real orbitals	Delocalized complex conjugate orbitals	Energies
S_2	$(1/\sqrt{2})[A^2+B^2]\|\Sigma\rangle$	$=(1/\sqrt{2})[a^2+b^2]\|\Sigma\rangle$	$=(1/\sqrt{2})[cc^*+c^*c]\|\Sigma\rangle$	$K'_{AB}+K_{AB}=\ K_{ab}+K'_{ab}=\ K_{AB}+K_{ab}$
S_1	$(1/\sqrt{2})[A^2-B^2]\|\Sigma\rangle$	$=(1/\sqrt{2})[ab+ba]\|\Sigma\rangle$	$=(1/\sqrt{2})[c^{*2}+c^2]\|\Sigma\rangle$	$K'_{AB}-K_{AB}=-K'_{ab}+K_{ab}=-K_{AB}+K_{ab}$
S_0	$(1/\sqrt{2})[AB+BA]\|\Sigma\rangle$	$=(-1/\sqrt{2})[a^2-b^2]\|\Sigma\rangle$	$=(i/\sqrt{2})[c^{*2}-c^2]\|\Sigma\rangle$	$-K'_{AB}+K_{AB}=-K_{ab}+K'_{ab}=\ K_{AB}-K_{ab}$
T_i	$(1/\sqrt{2})[AB-BA]\|\Theta_i\rangle$	$=(1/\sqrt{2})[ab-ba]\|\Theta_i\rangle$	$=(i/\sqrt{2})[cc^*-c^*c]\|\Theta_i\rangle$	$-K'_{AB}-K_{AB}=-K_{ab}-K'_{ab}=-K_{AB}-K_{ab}$

[a] Energies are relative to E_0 given by Equation (3). The localized and the delocalized orbitals are related by Equations (1) and (6). For the triplet wave functions, $i=-1, 0, 1$. [b] The four wave functions based on the localized orbitals are used as the basis set in Section 2.3.

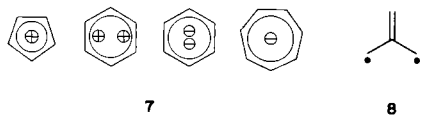
any choice of real orbitals $\mathscr{A}$ and $\mathscr{B}$, the forms of $S_2(^1|\mathscr{A}^2+\mathscr{B}^2|)$ and of $T(^3|\mathscr{A}\mathscr{B}|)$ remain the same.

Biradicals with $K_{AB}=0$, and therefore $K'_{ab}=0$, will be referred to as *pair biradicals* since the condition can be strictly satisfied only if the separation between the orbitals A and B is infinite so that the biradical consists of a pair of distant radical centers. In practice, this condition is nearly satisfied already in biradicals **1** and **2**, and very well satisfied in **3** (Scheme 2). We shall refer to systems such as these as pair biradicals as well. In pair biradicals, S_0 and T as well as S_1 and S_2 are pairwise degenerate.



Scheme 2. Pair biradicals.

Biradicals for which $K'_{\mathscr{A}\mathscr{B}}=K_{\mathscr{A}\mathscr{B}}$ will be referred to as *axial biradicals*.[20] This condition is normally enforced by symmetry (Scheme 3). In axial biradicals, S_0 and S_1 are degenerate.



Scheme 3. Axial biradicals.

Since the S_0 and S_1 wave functions can equally well be written in a form that contains two singly occupied orbitals ("open-shell"), it is natural to ask whether S_2 should not be an equally open-shell state. In fact, S_2 can also be written in the open-shell form if the condition that $\mathscr{A}$ and $\mathscr{B}$ be real is relaxed. In terms of the pair of delocalized, orthogonal, complex conjugate orbitals c and c* given by (6), the wave function for S_2 is $^1|cc^*\rangle$, and $\gamma_{cc^*}=0$.

$$\begin{aligned} c &= (A+iB)/\sqrt{2} \\ c^* &= (A-iB)/\sqrt{2} \end{aligned} \qquad (6)$$

The full set of relations between the three different forms in which the wave functions can be written under the condition $\gamma_{\mathscr{A}\mathscr{B}}=0$ is summarized in Table 2.[20] The threefold symmetry in the stepwise derivation of state energy splittings and wave functions starting with the three sets of orbitals is displayed in Figure 2. It is obvious from the form of the wave functions that all three singlet states can be labeled *open-shell* with equal justification. This becomes particularly clear in the language of natural orbitals.

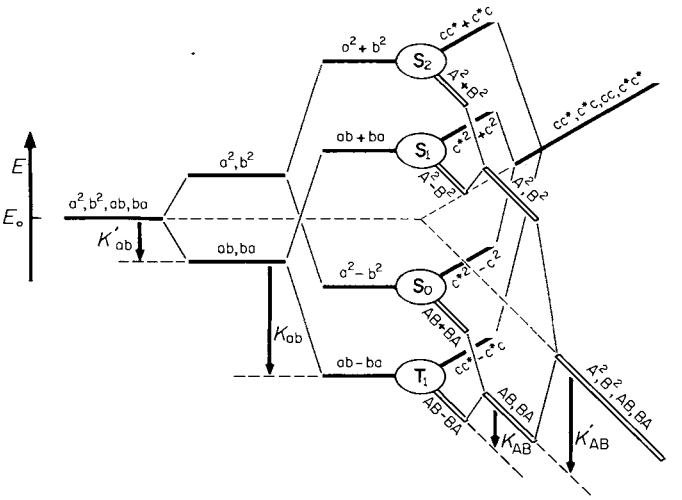


Fig. 2. 3×3 CI model: construction of the energies and wavefunctions of a perfect biradical (center), starting with localized (front right) delocalized (left), or complex (back right) orbitals. See also Figure 1 and text.

Natural orbital occupancies—a measure of biradicaloid character. Natural orbitals (NOs) of an electronic system are defined as those orbitals that diagonalize its exact first-order density matrix (the bond-order and charge-density matrix). These orbitals thus have fractional occupancies n_i (orbital "charge densities") and vanishing interactions ("bond orders" between orbitals). The NOs of a state are uniquely defined once its exact wave function is known. All one-electron properties of a system are additive when expressed in terms of the NOs, $|i\rangle$ [Eq. (7)].

$$\langle\psi|\hat{A}|\psi\rangle = \sum_i n_i\langle i|\hat{A}|i\rangle \qquad (7)$$

In the ground states of ordinary "closed-shell" molecules, all NO occupancies are either close to two, describing a nearly perfectly coupled electron pair, or close to zero. In biradicals and biradicaloids, this is true for all

but two of the NOs, whose occupancies are close to one, describing a nearly perfectly uncoupled electron pair (open shell). This feature has been proposed as a measure of biradicaloid character.[17,22]

Any pair of orthogonal real orbitals $\mathscr{A}$ and $\mathscr{B}$ represents the NOs of the S_0, S_1, S_2, and T states of a perfect biradical in the 3×3 CI model (see Appendix). The density matrices are given by Equation (8).

$$\rho(S_0)=\rho(S_1)=\rho(S_2)=\rho(T)=\begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix} \tag{8}$$

The occupation number of unity for both NOs displays nicely the open-shell, or "perfectly biradical," nature of all four states. The exact equality of the occupation numbers of the two NOs is responsible for the total freedom of choice of the NOs $\mathscr{A}$ and $\mathscr{B}$.

S_0–S_1 surface touching in perfect biradicals. The condition for degeneracy of the S_0 and S_1 states in perfect biradicals is $K'_{\mathscr{AB}}=K_{\mathscr{AB}}$; i.e., S_0 and S_1 touch only in axial biradicals. Examples are atoms such as O and S, linear molecules such as O_2, NH, or B_2H_2, cyclic molecules with $4N$ π electrons in a charged perimeter shaped as a regular polygon, **7**,[21] and other highly symmetric biradicals such as trimethylenemethane **8** (Scheme 3).

In nonlinear molecules, Jahn–Teller distortion will prevent the equilibrium geometry in the S_0 state from coinciding exactly with the high-symmetry geometry considered here. However, we are primarily interested in the S_1 surface, for which just this geometry will be very favorable.

In most perfect biradicals the equality $K'_{\mathscr{AB}}=K_{\mathscr{AB}}$ is not enforced by symmetry so that S_0 and S_1 are split by $2(K'_{AB}-K_{AB})$, typically several dozen kcal/mol. Examples are **1**–**3** and the "antiaromatic" biradicaloid geometries, such as **4**, occurring along ground-state forbidden pericyclic reaction paths (see Scheme 2). Although the S_1 surface still lies relatively low in energy at these geometries, it does not even come close to touching the S_0 surface.[6–13,19,23] The largest S_0–S_1 energy gap is found for pair biradicals formed by stretching a single bond to infinity (e.g., H + H). This gap is equal to J_{AA}, typically hundreds of kcal/mol. On the other hand, K_{AB} vanishes and S_0 is then degenerate with T. A comparison of such "loose" geometries, in which A and B are far separated, with their "tight" counterparts, in which they are close, is of importance in photochemistry as well (e.g., the pair **3** and **4**).[2,10,24] At a loose geometry, E_0 is more negative and J_{AB} is smaller, so that K'_{AB} is larger. If nothing else changes, S_0 and T of a perfect biradical are favored at loose geometries, while the S_1 and S_2 states are not. In the latter states, cyclic conjugation then often favors a tight geometry.

As we shall see in the following, degeneracy of the S_0 and S_1 states is usually far more readily reached or at least approached in biradicaloids than in perfect biradicals.

2.3. Biradicaloids

2.3.1. General

We use the noun "biradicaloid" for all imperfect biradicals;[25] i.e., those in which the real orthogonal orbitals $\mathscr{A}$ and $\mathscr{B}$ either interact ($\gamma_{\mathscr{AB}}\neq0$) or have different energies ($\delta_{\mathscr{AB}}\neq0$) or both, no matter how they are chosen. In the complete basis set of wave functions that has already been used for the perfect biradical (Table 2) the singlet part of the Hamiltonian matrix (Table 1) is given by (9), where $E(T)$, the energy of the triplet state, stands for $E(T)=E_0-K'_{\mathscr{AB}}-K_{\mathscr{AB}}$. Its value may change as various perturbations are introduced, but this is immaterial for the consideration of energy differences.

$$\begin{matrix}{}^1|\mathscr{A}^2-\mathscr{B}^2\rangle\\ {}^1|\mathscr{A}^2+\mathscr{B}^2\rangle\\ {}^1|\mathscr{AB}\rangle\end{matrix}\begin{pmatrix}E(T)+2K'_{\mathscr{AB}} & \delta_{\mathscr{AB}} & \gamma_{\bar{\mathscr{A}}\mathscr{B}}\\ \delta_{\mathscr{AB}} & E(T)+2(K'_{\mathscr{AB}}+K_{\mathscr{AB}}) & \gamma_{\mathscr{A}\bar{\mathscr{B}}}\\ \gamma_{\bar{\mathscr{A}}\mathscr{B}} & \gamma_{\mathscr{A}\bar{\mathscr{B}}} & E(T)+2K_{\mathscr{AB}}\end{pmatrix} \tag{9}$$

The wave functions $|S_0\rangle$, $|S_1\rangle$, and $|S_2\rangle$ obtained by diagonalization have the form shown in Equation (10), and the density matrices are given by Equation (11). For their derivation, see Appendix 2; Appendix 3 shows how the state energies can be found graphically.

$$|S_i\rangle=C_{i,-}\,{}^1|\mathscr{A}^2-\mathscr{B}^2\rangle+C_{i,+}\,{}^1|\mathscr{A}^2+\mathscr{B}^2\rangle+C_{i,0}\,{}^1|\mathscr{AB}\rangle \qquad i=0,\,1,\,2 \tag{10}$$

$$\rho(S_i)=\begin{pmatrix}1+2C_{i,+}C_{i,-} & 2C_{i,0}C_{i,+}\\ 2C_{i,0}C_{i,+} & 1-2C_{i,+}C_{i,-}\end{pmatrix} \tag{11}$$

Diagonalization of $\rho(S_i)$ yields the occupation numbers n_I and n_{II} for the two natural orbitals [Eq. (12)].

$$n_{I,II}=1\pm2C_{i,+}\sqrt{1-C_{i,+}^2} \tag{12}$$

As we have seen already, in a perfect biradical ($\delta_{\mathscr{AB}}=\gamma_{\mathscr{AB}}=0$), $n_I=n_{II}=1$ holds for any choice of orbital basis (for any value of $\gamma_{\bar{\mathscr{A}}\mathscr{B}}$). With increasing perturbation $\delta^2_{\mathscr{AB}}+\gamma^2_{\mathscr{AB}}$, one can approach the limiting case of a closed shell, for which $n_I=2$, $n_{II}=0$.[26] The gradual change from the perfect biradical situation to the ordinary closed-shell situation illustrates very nicely the continuous nature of the conversion of a biradical into a biradicaloid and eventually into an ordinary molecule by the introduction of a suitable perturbation. The physical significance of the parameters $\delta_{\mathscr{AB}}$ and $\gamma_{\mathscr{AB}}$, which describe the perturbation, needs to be discussed next.

According to the definitions given in Table 1, $\delta_{\mathscr{AB}}$ is a measure of the energy difference of orbitals $\mathscr{A}$ and $\mathscr{B}$ while $\gamma_{\mathscr{AB}}$ is a measure of the degree to which they interact. The significance of these quantities depends on the choice of the orbital pair $\mathscr{A},\mathscr{B}$. We have already noted that $\delta^2_{\mathscr{AB}}+\gamma^2_{\mathscr{AB}}$ is invariant to this choice. For any perturbation there is a choice that makes $\delta_{\mathscr{AB}}$ vanish and another choice that makes $\gamma_{\mathscr{AB}}$ vanish, but, in general, these choices correspond neither to the localized orbitals A, B nor to the delocalized orbitals a, b.

Since we wish to work with either the A, B or the a, b orbital set, we must accept the existence of two independent perturbation parameters, δ and γ, but matters simplify in that $\gamma_{AB}=\gamma_{ab}=0$ holds. As shown in the Appendix, the parameters in the two orbital bases are related by (13).

$$\delta_{AB}=\gamma_{ab},\quad \gamma_{AB}=\delta_{ab} \tag{13}$$

To illustrate the physical significance of these quantities, we select orthogonally twisted ethylene as an example of a perfect biradical and consider two types of perturbation: return to planarity and pyramidalization on one of the carbon atoms.

The orbital sets A, B and a, b are shown in **1** (Scheme 1) for the geometry of a perfect biradical. The energies of the two localized orbitals are equal ($\delta_{AB}=0$) and the orbitals cannot interact ($\gamma_{AB}=0$). The same is true of the delocalized orbitals ($\delta_{ab}=\gamma_{ab}=0$). When **1** is distorted toward planarity, the energies of the localized orbitals A and B remain equal ($\delta_{AB}=0$), but the orbitals begin to interact ($\gamma_{AB}\neq 0$). The energies of the delocalized orbitals a and b are no longer equal ($\delta_{ab}\neq 0$)—one orbital eventually becoming the HOMO and the other the LUMO of planar ethylene—but the orbitals do not interact ($\gamma_{ab}=0$).

In contrast, when one of the carbons in **1** is pyramidalized, the energies of the localized orbitals begin to differ ($\delta_{AB}\neq 0$), but symmetry still prevents them from interacting ($\gamma_{AB}=0$). The energies of the delocalized orbitals remain the same, $\delta_{ab}=0$ (since the orbitals are equally distributed over both carbon atoms). However, now we have $\gamma_{ab}\neq 0$, since a and b are not the usual canonical orbitals for **1** pyramidalized on one carbon, which have unequal coefficients on the two carbon atoms. Upon simultaneous planarization and pyramidalization, δ_{AB}, γ_{AB}, δ_{ab}, and γ_{ab} all become nonzero.

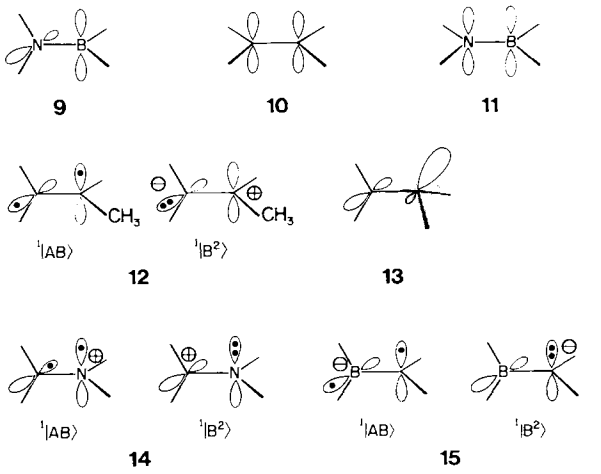
In the perfect biradical **1**, and in its partly planarized form, the delocalized orbitals a, b are identical with the usual canonical MOs. At singly pyramidalized geometries, however, the canonical MOs correspond to the localized orbitals A, B if the geometry is still orthogonal and to neither a, b nor A, B if it is not. Since computer programs normally produce canonical MOs, the algorithm described in Appendix 1 is then needed to convert them into the set A, B or a, b.

It is useful to distinguish three types of biradicaloids:

1. *Homosymmetric biradicaloids*, for which $\gamma_{AB}=\delta_{ab}\neq 0$ and $\delta_{AB}=\gamma_{ab}=0$; i.e., the localized orbitals have equal energies but interact. An example is ethylene at a twist angle other than 90°.
2. *Heterosymmetric biradicaloids*, for which $\delta_{AB}=\gamma_{ab}\neq 0$ and $\gamma_{AB}=\delta_{ab}=0$; i.e., the localized orbitals have different energies but do not interact. Examples are orthogonally twisted, singly pyramidalized ethylene and orthogonally twisted propene.
3. *Nonsymmetric biradicaloids*, for which both $\delta_{AB}=\gamma_{ab}\neq 0$ and $\gamma_{AB}=\delta_{ab}\neq 0$; i.e., the localized orbitals have different energies and interact as well. An example is propene at a double-bond twist angle other than 90°.

These definitions are compatible with the more usual definition of biradicaloids as biradical-like species in which the canonical nonbonding MOs have different energies. It is important to recall that the use of the terms homosymmetric and heterosymmetric proposed in ref. [1] is similar to ours but not identical.

It is obvious that for large enough perturbations the two-electron two-orbital system in question may deviate so much from a perfect biradical that its ground-state NO occupation numbers are close to $n_I=2$, $n_{II}=0$, so that ordinarily it would no longer be considered a biradicaloid. Examples are twisted aminoborane **9**, in which δ_{AB} is large, planar ethylene **10**, in which γ_{AB} is large, and planar aminoborane **11**, in which both δ_{AB} and γ_{AB} are large (Scheme 4). Sometimes species such as these are viewed as biradicals when they are in their S_1 or T_1 electronic states, for which $n_I\approx n_{II}\approx 1$.



Scheme 4. Biradicaloids.

In the following, we shall use exclusively the basis of localized orbitals A, B, but the subscripts A, B will no longer be explicitly indicated. The wave functions $^1|A^2\rangle$ and $^1|B^2\rangle$ will be referred to as "hole-pair" configurations and $^1|AB\rangle$ and $^3|AB\rangle$ as "dot-dot" configurations (Scheme 4). When A, B are each localized on a single center, as in **1**, these wave functions actually correspond very closely to valence-bond (VB) structures and would traditionally be referred to as "structures" rather than "configurations." Since we include cases in which A, B are delocalized over several centers, as in **2**, we use the term "configurations."

All results can be transformed to the delocalized basis a, b, which is more convenient in the case of homosymmetric biradicaloids, by making the substitutions $^1|A^2-B^2\rangle\rightarrow{}^1|ab\rangle$, $^1|AB\rangle\rightarrow K\,{}^1|a^2-b^2\rangle$, $K_{AB}\rightarrow K'_{ab}$, $K'_{AB}\rightarrow K_{ab}$, $\delta_{AB}\rightarrow\gamma_{ab}$, and $\gamma_{AB}\rightarrow\delta_{ab}$ (compare matrices (14) and (19)).

2.3.2. Homosymmetric Biradicaloids

When two interacting orbitals ($\gamma\neq 0$) are orthogonal, they generally cannot be perfectly localized. Typically, they correspond to Löwdin-orthogonalized orbitals, each of which is localized mostly on one, but also partly on the other partner atom or atoms.

The Hamiltonian matrix for the singlet states of a homosymmetric biradicaloid has the block-diagonal form (14).

$$\begin{array}{l} {}^1|A^2-B^2\rangle \\ {}^1|A^2+B^2\rangle \\ {}^1|AB\rangle \end{array}\begin{pmatrix} E(T)+2K' & 0 & 0 \\ 0 & E(T)+2(K'+K) & \gamma \\ 0 & \gamma & E(T)+2K \end{pmatrix} \qquad (14)$$

The antisymmetric wave function $^1|A^2-B^2\rangle$ remains as an eigenstate. It corresponds to $^1|ab\rangle$ and therefore to a

"singly excited" S_1 state. The symmetric functions $^1|AB\rangle$ and $^1|A^2+B^2\rangle$ mix to produce the ground state S_0 and the "doubly excited" state S_2. If the phases of the orbitals are so chosen that $\gamma<0$, S_0 is represented by the in-phase combination of the functions and S_2 by their out-of-phase combination. The energies of the singlet states are given by (15) and an example of their dependence on γ is shown in Figure 3a. The resulting wave functions are listed in (16), where the parameter α, given by Equation (17), describes the mixing of $^1|AB\rangle$ and $^1|A^2+B^2\rangle$ as a result of the perturbation by γ (note that the strength of the perturbation is given by the ratio $|\gamma/K'|$). For $\gamma=0$, the states $|S_0\rangle=(^1|AB\rangle$ and $|S_2\rangle=^1|A^2+B^2\rangle$ are those of a perfect biradical. In the limit of very large negative γ, we have $\alpha=-\pi/4$, and the wavefunction of the S_0 state goes to $(^1|AB\rangle+{}^1|A^2+B^2\rangle)/\sqrt{2}$. This can be rewritten in terms of delocalized orbitals as $|S_0\rangle=^1|b^2\rangle$; i.e., in this limit the simple MO description of the ground state of an ordinary molecule is correct, both electrons occupying the bonding MO.

$$\begin{aligned} E(S_2) &= E(T)+K'+2K+\sqrt{K'^2+\gamma^2} \\ E(S_1) &= E(T)+2K' \\ E(S_0) &= E(T)+K'+2K-\sqrt{K'^2+\gamma^2} \end{aligned} \tag{15}$$

$$\begin{aligned} |S_2\rangle &= \cos\alpha\ {}^1|A^2+B^2\rangle+\sin\alpha\ {}^1|AB\rangle \\ |S_1\rangle &= {}^1|A^2-B^2\rangle \\ |S_0\rangle &= -\sin\alpha\ {}^1|A^2+B^2\rangle+\cos\alpha\ {}^1|AB\rangle \end{aligned} \tag{16}$$

$$\alpha=\frac{1}{2}\tan^{-1}\frac{\gamma}{K'} \tag{17}$$

In all four states of the homosymmetric biradicaloid, the natural orbitals coincide with the delocalized orbitals a and b. Their occupation numbers are obtained from Equation (12). Assuming $\gamma<0$, they are given by (18), which clearly shows the gradual transition from a perfect biradical ($n_a=n_b=1$) to an ordinary molecule ($n_b\approx 2$, $n_a\approx 0$) with increasing perturbation $|\gamma/K'|$ as well as the open-shell nature of the singly excited S_1 state. Clearly, the perturbation γ can only increase the S_0–S_1 gap relative to that for a perfect biradical. Indeed, the gap increases rapidly upon motion away from a 90° twist in **1** or from a square toward a rectangular geometry in **2** and upon decrease of the separation between the radical centers in a radical pair.

$$\left.\begin{aligned} n_a(S_0)=n_b(S_2)= \\ n_b(S_0)=n_a(S_2)= \end{aligned}\right\} = 1\pm\sin 2\alpha = 1\pm[1+(K'/\gamma)^2]^{-1/2} \tag{18}$$
$$n_a(S_1)=n_b(S_1)=n_a(T)=n_b(T)=1$$

As $|\gamma|$ increases, S_0 is stabilized relative to T. When $|\gamma|=2\sqrt{K(K+K')}$ is attained, the two states become degenerate. For even larger values of $|\gamma|$, S_0 lies below T. Instructive examples of the effect of the variation of γ on the S_0–T gap are the π,π 1,3-biradicals **5** (Scheme 2). In these species, γ contains two opposed contributions that nearly cancel and whose relative weight depends critically on the CCC valence angle.[27] Once S_0 drops significantly below T_1, a species is created which most chemists would no longer call a biradicaloid, at least not in its ground state.

2.3.3. *Heterosymmetric Biradicaloids*

The Hamiltonian matrix for singlets has the block-diagonal form (19). $^1|AB\rangle$ remains as an eigenstate and corresponds to the dot-dot configuration with one electron in each of the two localized orbitals. The hole-pair functions $^1|A^2-B^2\rangle$ and $^1|A^2+B^2\rangle$ mix out-of-phase to produce a lower-energy state $|1\rangle$ and in-phase to produce an oppositely polarized higher-energy state $|2\rangle$ (20). Here, β given by Equation (21), is a parameter describing the mixing of $^1|A^2-B^2\rangle$ and $^1|A^2+B^2\rangle$ as a result of the perturbation δ/K (recall that δ is always nonnegative). The singlet state energies are given by (22) and an example of their dependence on the perturbation parameter δ is shown in Figure 3b.

$$\begin{array}{c} \\ {}^1|A^2-B^2\rangle \\ {}^1|A^2+B^2\rangle \\ {}^1|AB\rangle \end{array} \begin{array}{c} \begin{array}{ccc} {}^1|A^2-B^2\rangle & {}^1|A^2+B^2\rangle & {}^1|AB\rangle \end{array} \\ \begin{pmatrix} E(T)+2K' & \delta & 0 \\ \delta & E(T)+2(K'+K) & 0 \\ 0 & 0 & E(T)+2K \end{pmatrix} \end{array} \tag{19}$$

$$\begin{aligned} |2\rangle &= \cos\beta\ {}^1|A^2+B^2\rangle+\sin\beta\ {}^1|A^2-B^2\rangle \\ |1\rangle &= -\sin\beta\ {}^1|A^2+B^2\rangle+\cos\beta\ {}^1|A^2-B^2\rangle \end{aligned} \tag{20}$$

$$\beta=\frac{1}{2}\tan^{-1}\frac{\delta}{K} \tag{21}$$

$$\begin{aligned} E(S_2) &= E(T)+2K'+K+\sqrt{K^2+\delta^2}=E(|2\rangle) \\ E(S_0),E(S_1) &= \begin{cases} E(T)+2K'+K-\sqrt{K^2+\delta^2}=E(|1\rangle) \\ E(T)+2K \end{cases} \end{aligned} \tag{22}$$

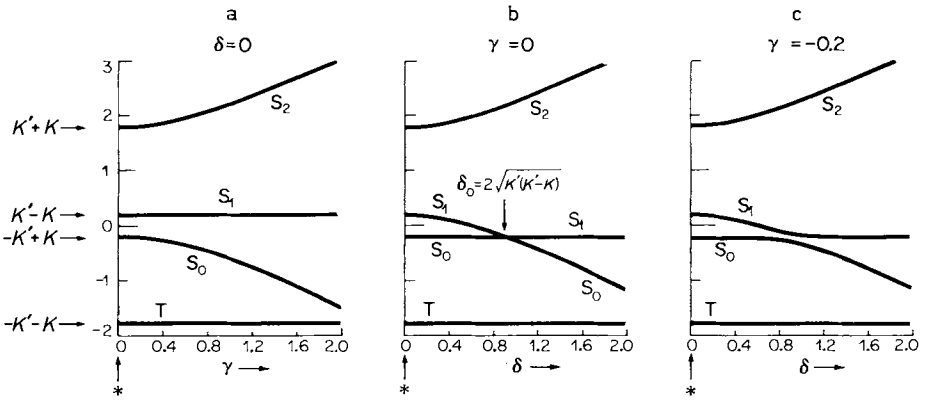


Fig. 3. 3 × 3 CI model: Energies of the singlet and triplet states of a biradicaloid as a function of δ and γ. In the arbitrary energy units chosen, $K=0.8$ and $K'=1.0$. The asterisks indicate the perfect biradical limit ($\delta=\gamma=0$). a) Homosymmetric, b) heterosymmetric, c) nonsymmetric biradicaloid.

In addition to the wave function $^1|AB\rangle$, which represents S_0 or S_1, we thus have the two functions $|2\rangle$ and $|1\rangle$, the latter of which represents either S_1 or S_0. For $\delta=0$, we have $\beta=0$; i.e., the functions $^1|A^2-B^2\rangle$ and $^1|A^2+B^2\rangle$ are not mixed, and the state wave functions remain those of a perfect biradical. As δ grows very large, one obtains $\beta=\pi/4$; the wave function $|1\rangle$ goes from $^1|A^2-B^2\rangle$ to $(^1|A^2-B^2\rangle-{}^1|A^2+B^2\rangle)/\sqrt{2}$, i.e., $^1|B^2\rangle$ and the wave function $|2\rangle$ goes from $^1|A^2+B^2\rangle$ to $^1|A^2\rangle$. This process can be described as a polarization of the hole-pair wave functions $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ into the individual hole-pair configurations $^1|A^2\rangle$ and $^1|B^2\rangle$. In this limit, the simple MO description of the ground state of an ordinary molecule is correct, both electrons occupying the lower-energy orbital B; the simple MO and VB descriptions are identical. Note that only the ratio δ/K counts; i.e., the magnitude of δ required for a given degree of polarization increases as K increases.

In all four electronic states of the heterosymmetric biradicaloid, the natural orbitals coincide with the localized orbitals A and B. Their occupation numbers are obtained from Equation (12). The results are given in (23), are analogous to (18), and show clearly the gradual transition from a perfect biradical ($n_B=n_A=1$) to an ordinary molecule ($n_B\approx 2$, $n_A\approx 0$) with increasing perturbation (δ/K), as well as the open-shell nature of the state described by $^1|AB\rangle$, even in strongly perturbed systems (cf. "charge-transfer" biradicals and "TICT" states, Section 4.3).

$$\left.\begin{aligned} n_B(|1\rangle)=n_A(|2\rangle)=\\ n_A(|1\rangle)=n_B(|2\rangle)=\end{aligned}\right\}=1\pm\sin 2\beta=1\pm[1+(K/\delta)^2]^{-1/2}$$
$$n_A(^1|AB\rangle)=n_B(^1|AB\rangle)=n_A(T)=n_B(T)=1 \qquad (23)$$

In biradicals with small K, and therefore nearly degenerate S_1 and S_2 states according to (4), such as **1** twisted by 90°, even a weak polarizing perturbation δ, such as pyramidalization on one center or the presence of a nearby charge, causes an essentially complete polarization of $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ toward $^1|A^2\rangle$ and $^1|B^2\rangle$. The very high polarizability of twisted ethylene in its S_1 state has been recognized for a long time.[28] In a biradical with a large K, a much larger orbital energy difference between A and B will have to be introduced in order to produce a similar degree of polarization. In an axial biradical with $K=K'$, and therefore degenerate S_0 and S_1 states according to (4), the polarization of $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ toward $^1|A^2\rangle$ and $^1|B^2\rangle$ tends to be incomplete even when the energies of A and B are quite different. Thus, the bending of linear carbene leaves the p orbital A intact but strongly stabilizes B by giving it s character; yet, it is known[29] that $|A^2\rangle$ and $|B^2\rangle$ are still fairly extensively mixed in the description of the S_0 state of even strongly bent CH_2.

Several isolated instances of S_0–S_1 surface touching in biradicaloids at geometries of relatively low symmetry, resulting from a suitable choice of perturbation δ/K in the present terminology, have already been described.[17a,30] The realization that, starting with any general perfect biradical with $K'>K$, a suitable choice of δ will force S_0–S_1 degeneracy opens the way for the rational design of a large number of systems in which the S_0 and S_1 surfaces touch or nearly touch. The significance of this fact in photochemistry has only been recognized relatively recently.[31]

$$\delta_0=2\sqrt{K'(K'-K)} \qquad (24)$$

The point at which the S_0–S_1 degeneracy occurs is given by Equation (24), which clearly displays the limiting cases of a perturbed axial biradical ($K=K'$, $\delta_0=0$) and of a perturbed pair biradical ($K=0$, $\delta_0=2K'=J_{AA}$). Accordingly, it is useful to distinguish three classes of heterosymmetric biradicaloids: (1) weakly heterosymmetric, in which $\delta<\delta_0$, (2) strongly heterosymmetric, in which $\delta>\delta_0$, and (3) critically heterosymmetric, in which $\delta=\delta_0$. We shall now consider the three cases individually (Fig. 3b).

(1) *Weakly heterosymmetric biradicaloids.* For $\delta<\delta_0$, the lowest singlet S_0 is represented by $^1|AB\rangle$, similarly as in a perfect biradical, and S_1 by a mixture of the "hole-pair" configurations $^1|A^2\rangle$ and $^1|B^2\rangle$, with $^1|B^2\rangle$ dominating. This situation is usually encountered in uncharged biradicaloids, where the "dot-dot" configuration $^1|AB\rangle$ involves no formal separation of charges (and is often called covalent), while the hole-pair configurations $^1|A^2\rangle$ and $^1|B^2\rangle$ do (and are often called "zwitterionic"). Examples are 90°-twisted unsymmetric double bonds, such as twisted propene **12** or twisted ethylene pyramidalized at one carbon atom, **13** (Scheme 4).

(2) *Strongly heterosymmetric biradicaloids.* For $\delta>\delta_0$, $^1|AB\rangle$ describes S_1 and the lowest singlet S_0 is represented by a mixture of the hole-pair configurations $^1|A^2\rangle$ and $^1|B^2\rangle$, with $^1|B^2\rangle$ now much more stable than $^1|A^2\rangle$ and usually strongly dominating. If the heterosymmetry is very pronounced (δ large), both electrons are thus kept virtually exclusively in orbital B in S_0, often as a "lone pair." Once δ has exceeded the value $2\sqrt{K'(K'+K)}$, S_0 lies below T, often far below it. For both reasons, strongly heterosymmetric biradicaloids are normally considered not to be biradicaloids at all, at least not in their ground state. If the hole-pair configuration $^1|B^2\rangle$ involves formal separation of charge, such species are usually referred to as zwitterions or ion pairs, with a positive charge on A and a negative charge on B. However, really large δ values are normally reached in systems in which it is the dot-dot configuration $^1|AB\rangle$ that is zwitterionic in that it carries separated formal charges, negative on A and positive on B, while the hole-pair configuration $^1|B^2\rangle$ does not. It is then the excited state S_1 that has both the charge separation and the spatially separated odd electrons and is sometimes referred to as a charge-transfer biradicaloid. Examples of strongly heterosymmetric biradicaloids are molecules containing a noninteracting donor-acceptor pair, such as the 90°-twisted aminoborane **9** and the TICT states of compounds such as *p-N,N*-dimethylaminobenzonitrile, discussed in Section 4.3.

(3) *Critically heterosymmetric biradicaloids.* The case $\delta=\delta_0$, for which we expect S_0–S_1 degeneracy from the simple model, is by far the most interesting for the photochemistry and photophysics of such systems. At this value of δ, the dot-dot configuration $^1|AB\rangle$ has the same energy as the out-of-phase combination of the hole-pair wave functions $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$, which can usually already be quite well approximated by $^1|B^2\rangle$ alone. This situ-

ation is most readily obtained if neither $^1|AB\rangle$ nor $^1|B^2\rangle$ involves formal charge separation. Then, these structures need to differ in translocation of a formal charge, either positive as in **14** or negative as in **15**. Charged biradicaloids thus have a particularly good chance of exhibiting S_0–S_1 degeneracies.

The prescription for causing the S_0–S_1 gap in a perfect biradical to vanish, exactly or nearly, is therefore simple: destabilize the orbital A or stabilize the orbital B to such a degree as to make the energies of the configurations $^1|AB\rangle$ and $^1|B^2\rangle$ approximately equal.

2.3.4. *Nonsymmetric Biradicaloids*

The Hamiltonian matrix for the singlet states is given by (25). Although the expressions for state energies can be written explicitly, they are not instructive. It is preferable to find the solutions for E graphically by use of Equation (26) (see Appendix 3). It then becomes clear by inspection that S_0 and S_1 can only be degenerate when γ vanishes and that the general shape of the $E(S_i)-E(T)$ surfaces is as shown in Figure 4 for one particular choice of constant values for K' and K.

$$\begin{array}{c} \\ ^1|A^2-B^2\rangle \\ ^1|A^2+B^2\rangle \\ ^1|AB\rangle \end{array} \begin{pmatrix} E(T)+2K' & \delta & 0 \\ \delta & E(T)+2(K'+K) & \gamma \\ 0 & \gamma & E(T)+2K \end{pmatrix} \qquad (25)$$

$$[E-E(T)-2K'-K]^2-\delta^2-K^2=2(K-K')\gamma^2/[E-E(T)-2K]+\gamma^2 \qquad (26)$$

The one case of a nonsymmetric biradicaloid in which a solution can be written simply is a perturbed axial biradical ($K=K'$). In this limit, the state energies are given by (27), from which it is seen that the perturbation lifts the degeneracy of S_0 and S_1. The wave functions are given by (28) where α and β are defined by (29).

$$\begin{aligned} E(S_2) &= E(T)+3K+\sqrt{K^2+\delta^2+\gamma^2} \\ E(S_1) &= E(T)+2K \\ E(S_0) &= E(T)+3K-\sqrt{K^2+\delta^2+\gamma^2} \end{aligned} \qquad (27)$$

$$\begin{pmatrix} |S_2\rangle \\ |S_1\rangle \\ |S_0\rangle \end{pmatrix} = \begin{pmatrix} \cos\alpha\sin\beta & \cos\beta & \sin\alpha\sin\beta \\ -\sin\alpha & 0 & \cos\alpha \\ \cos\alpha\cos\beta & -\sin\beta & \sin\alpha\cos\beta \end{pmatrix} \begin{pmatrix} ^1|A^2-B^2\rangle \\ ^1|A^2+B^2\rangle \\ ^1|AB\rangle \end{pmatrix} \qquad (28)$$

$$\begin{aligned} \alpha &= \tan^{-1}\frac{\gamma}{\delta} \\ \beta &= \frac{1}{2}\tan^{-1}\frac{\sqrt{\delta^2+\gamma^2}}{K} \end{aligned} \qquad (29)$$

In the limit $\delta=0$ (homosymmetric biradicaloid), the S_1 and S_2 states remain perfectly balanced with respect to charge when γ is changed from large negative to large positive values (say, by twisting ethylene from the *cis* to the *trans* configuration). As soon as $\delta\neq 0$ (nonsymmetric biradicaloid), this balance is lost since $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ mix. If δ is comparable to the S_1–S_2 separation at the point $\gamma=0$ (i.e., to $2K$ in the present model) or smaller, a large charge imbalance appears only for very small values of γ.

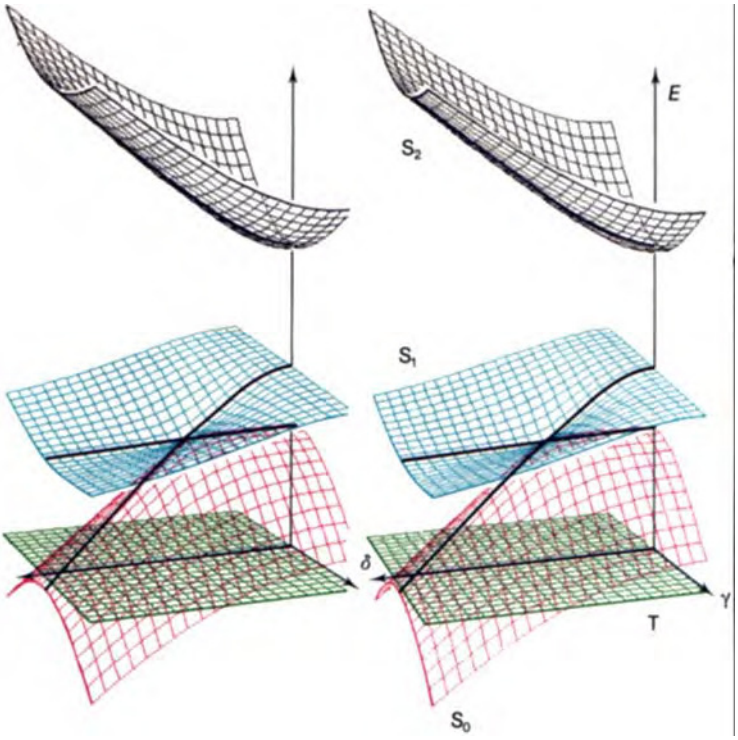

Fig. 4. Excitation energies from the T state (green) to the S_0 (red), S_1 (blue), and S_2 (black) states of a biradicaloid as a function of δ and γ, based on the 3×3 CI model. The origin of the coordinate system corresponds to the perfect biradical limit. In the energy units chosen, $K=1.0$ and $K'=1.5$.

In ethylene, the S_1–S_2 energy gap is very small at orthogonal twist ($K\approx 0$). Therefore, as long as δ is small, this polarization of the S_1 and S_2 states appears and disappears quite suddenly as γ sweeps through zero (sudden polarization[28]). For larger values of δ in pair biradicals and for all values of δ in biradicals with large K values, this polarization develops and disappears much more gradually as the value of γ is changed.

The conclusion to be drawn from Figure 4 is that the choice $\delta\rightarrow\delta_0$ and $\gamma\rightarrow 0$ is optimal when biradicaloids with a small S_0–S_1 energy gap are sought.

2.4. Potential Energy Surfaces

While inspection of the energy differences $E(S_i)-E(T)$ displayed in Figure 4 is useful for classification and comparison of various types of biradicals for any particular choice of K' and K, it does not in itself provide a useful guide for the shape of the potential energy surfaces of a biradicaloid as a function of its geometry and environment, which is of prime interest for a photochemist. In order to obtain such guidance it is necessary to express the reference energy, $E(T)$, as a function of molecular geometry and environmental effects. This will be illustrated for a twisted double bond, starting from nonorthogonal atomic orbitals A, B. Within the two-electron two-orbital model, one obtains Equation (30) for $E(T)$, where E_T^0, given by Equation (31), is the triplet energy at the orthogonal reference geometry ($\gamma=0$) and K'^0_{AB}, K^0_{AB} are also evaluated at this geometry (see Appendix 3).

$$E(\mathrm{T}) = \frac{1}{1-S_{AB}^2}(h_{AA}+h_{BB}+\frac{J_{AA}+J_{BB}}{2}-2K'_{AB}-K_{AB}-2h_{AB}S_{AB})$$

$$= E_{\mathrm{T}}^0 + \frac{1}{1-S_{AB}^2}[(h_{AA}-h_{AA}^0)+(h_{BB}-h_{BB}^0)+(J_{AB}-J_{AB}^0) \quad (30)$$

$$-(K_{AB}-K_{AB}^0)+S_{AB}^2E_{\mathrm{T}}^0-2h_{AB}S_{AB}]$$

$$E_{\mathrm{T}}^0 = h_{AA}^0+h_{BB}^0+J_{AB}^0-K_{AB}^0 \quad (31)$$

For the purposes of qualitative discussion, the difference terms in parentheses can be neglected. Since h_{AB} is approximately proportional to S_{AB}, it is reasonable to approximate $E(\mathrm{T})$ by Equation (32), where c is a constant which reflects the average electronegativity of orbitals A and B. Its value must be positive if a deviation from the perfect biradical geometry produces bonding between orbitals A and B in the ground state, as would ordinarily be the case (e.g., in **1**).

$$E(\mathrm{T}) = E_{\mathrm{T}}^0 + cS_{AB}^2/(1-S_{AB}^2) \quad (32)$$

Since the resonance integral between Löwdin-orthogonalized, localized orbitals A, B is approximately proportional to the overlap between the atomic orbitals A, B, Equation (32) can be transformed into Equation (33), where the constants f and g are both positive.

$$E(\mathrm{T}) = E_{\mathrm{T}}^0 + f[\gamma_{\mathrm{AB}}^2/(1-g\gamma_{\mathrm{AB}}^2)] \quad (33)$$

The shape of the T surface obtained from Equation (33) is shown in Figure 5. Thus, $E(\mathrm{T})$ equals E_{T}^0 if γ vanishes and it increases gradually as $|\gamma|$ increases. This result reproduces the well-known general fact that triplet-state energies are particularly low at geometries at which the two singly occupied orbitals do not interact; after all, upon such interaction the antibonding combination is destabilized more than the bonding one is stabilized.

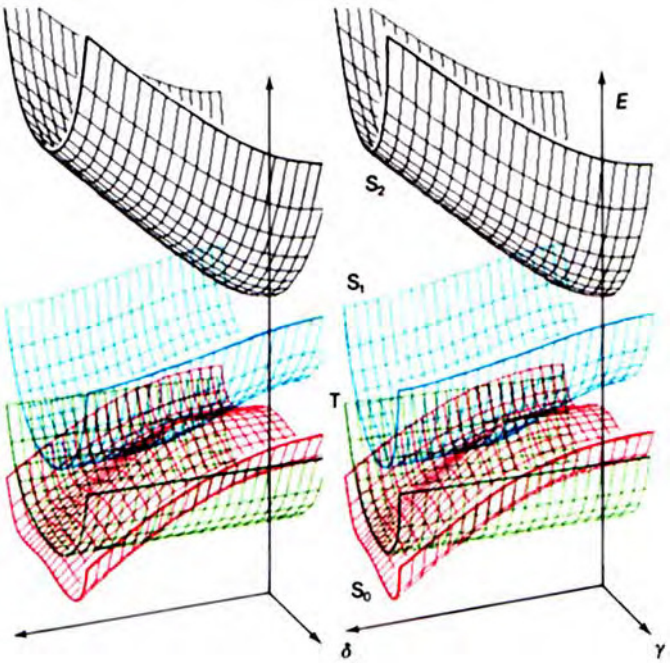

Fig. 5. Energies of the singlet [S_0 (red), S_1 (blue), S_2 (black)] and triplet (green) states of a twisted double bond as a function of δ and γ, based on the 3×3 CI model and Equation (33) for $E(\mathrm{T})$. Core energy, E_{T}^0, K', and K are assumed constant.

The last item to consider is the effect of changes in geometry and solvent environment on δ_{AB} and on E_{T}^0. To a first approximation, the value of δ_{AB} is determined by the value of δ_{AB}, which, in turn, depends primarily on the nature of the atoms on which A and B are located and on the substituents they carry (Table 1). In the following, the appropriate value is labeled δ'. Figure 6 shows the shapes of the singlet potential energy surfaces for a series of such choices of δ. The changes in geometry can be grouped into three categories: (1) those that cause the orbitals A and B to interact (twisting), (2) those that cause changes in δ, and (3) those that change the average electronegativity of the orbitals A and B and thus E_{T}^0. Category (2) includes variations due to the charge-stabilizing or charge-destabilizing effects of the solvent environment. Categories (2) and (3) are normally associated with rehybridization at the centers that carry orbitals A and B. A given geometry change may contribute in more than one category.

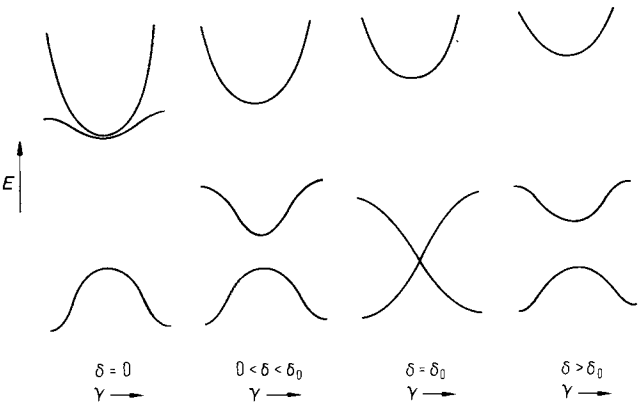

Fig. 6. Schematic representation of the energies of the singlet states of a twisted double bond as a function of γ for four choices of δ.

The effect of the changes of type 1 is already incorporated into Figure 5 in the form of the dependence on γ. The effects of the changes of types 2 and 3 are limited by the steric and other problems that other bonds in the molecule experience upon excessive atom rehybridization or solvent displacement. Their effects on the potential energy surfaces of Figure 5 can then be simulated by adding suitable empirical potentials such as $(\delta-\delta')^4$. This was done in Figure 7, which displays the energies as a function of γ and δ for propene ($\delta' \approx 0$), protonated formaldimine ($\delta' \approx \delta_0$), and aminoborane ($\delta' > \delta_0$). Only in the second case is the S_0–S_1 touching point accessible. The effects of the variations in the average electronegativity could be represented similarly but call for the use of yet another dimension in the graph.

3. Ab Initio Models

3.1. General

Emerging from the netherworld of simple but more or less exactly soluble models to the real world often amounts to a rude awakening. Are actual biradical-like species really described by the simple equations that have been de-

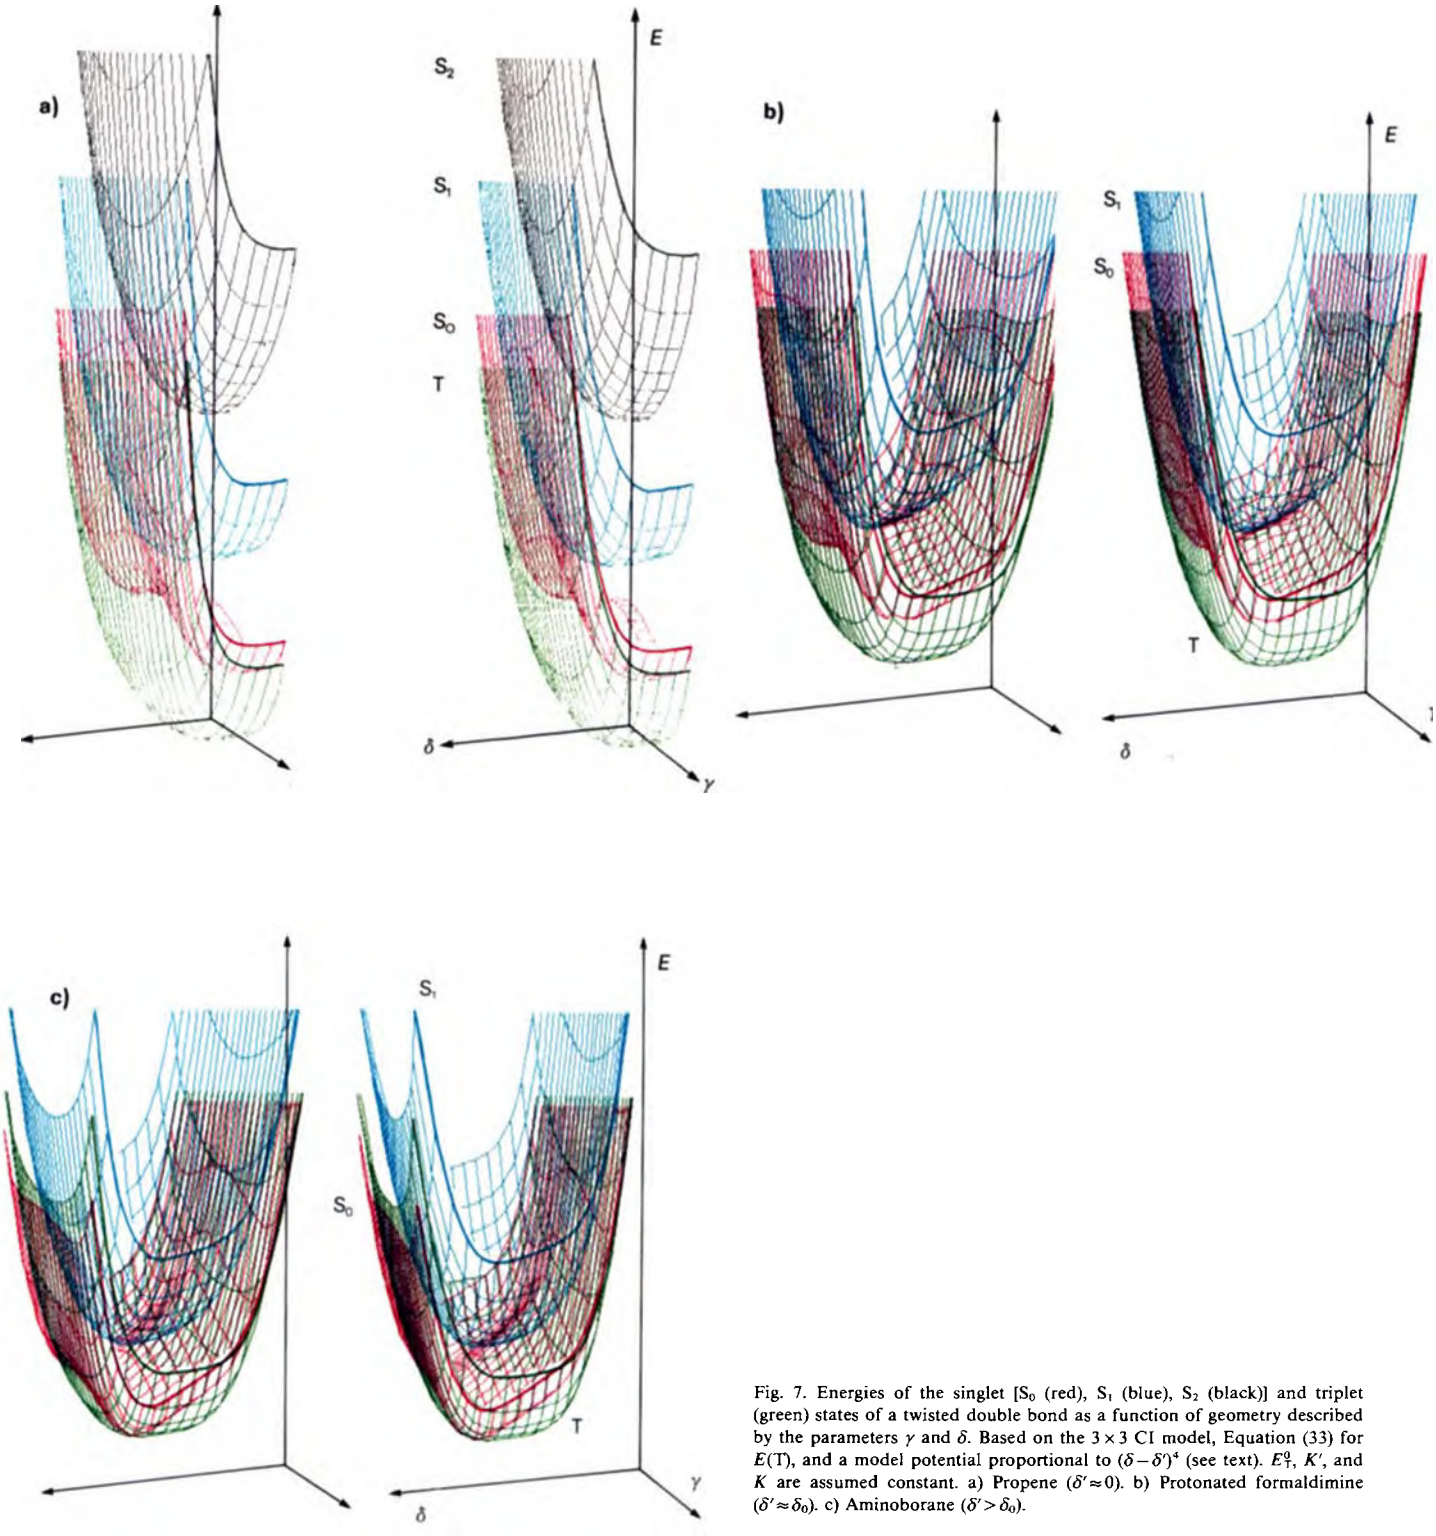

Fig. 7. Energies of the singlet [S_0 (red), S_1 (blue), S_2 (black)] and triplet (green) states of a twisted double bond as a function of geometry described by the parameters γ and δ. Based on the 3×3 CI model, Equation (33) for $E(T)$, and a model potential proportional to $(\delta-\delta')^4$ (see text). E_T^0, K', and K are assumed constant. a) Propene ($\delta'\approx0$). b) Protonated formaldimine ($\delta'\approx\delta_0$). c) Aminoborane ($\delta'>\delta_0$).

rived for the two-electron two-orbital case with a fixed core? Surely they are not, at least not exactly, but perhaps they at least exhibit the predicted behavior qualitatively? Whether an S_0–S_1 degeneracy in a heterosymmetric biradicaloid occurs precisely at $\delta_0=2\sqrt{K'(K'-K)}$ or just close to δ_0 is less important than that it should occur at all as δ is increased from zero.

In order to evaluate the performance of a simple model, one can rely on experiments or on more accurate calculations, i.e., better models. Since we are aware of essentially no experimental information on the main subject of interest here, S_0–S_1 near degeneracies and degeneracies that are not imposed by symmetry (as they are in axial biradicals), we shall take the latter route. We shall select two classes of perfect biradicals, a twisted double bond and square cyclobutadiene, and introduce $\delta\neq0$ either by replacing carbon by heteroatoms or by placing a point charge next to the molecule. Ab initio calculations for these systems at the CI level will then be examined for the expected qualitative effects.

Shortcomings of the simple model. Although ample experimental and theoretical evidence has already estab-

lished that the model is quite adequate in many applications, two well-recognized shortcomings of the model should be mentioned, both having to do with states predicted to be split by $2K$ when K is a small number. These shortcomings are characteristic of the 3×3 CI approximation for singlet states even at the ab initio level.

In perfect biradicals that approach the pair biradical limit of $K=0$, T_1 is expected to lie only a little below S_0 since $2K$ is small. It is now well recognized[3, 14] that, in the presence of additional electrons in the molecule, mechanisms exist for the preferential stabilization of S_0 relative to T_1. These often lead to the reversal of their order. This happens in both examples of interest here, twisted double bonds and square cyclobutadiene. The prediction of an S_0–T_1 crossing, which should occur at $\gamma = 2\sqrt{K(K'+K)}$ in homosymmetric biradicaloids and at $\delta = 2\sqrt{K'(K'+K)}$ in heterosymmetric biradicaloids according to the simple model, is therefore worthless in these cases, although it may still be of some use in biradicals in which K is larger.

While this first shortcoming of the model has no impact on our present interests, the second shortcoming is potentially more serious. When K is small, the S_1–S_2 gap in a perfect biradical is expected to be small, with the $^1|A^2-B^2\rangle$ state below $^1|A^2+B^2\rangle$. Once again, it is now well recognized[18, 19] that other electrons present in real molecules provide mechanisms for a differential stabilization of $^1|A^2+B^2\rangle$ relative to $^1|A^2-B^2\rangle$, so that their order may be reversed. This happens both in twisted double bonds and in square cyclobutadiene. In a sense then, the examples we have selected for testing are such that the simple model is not at its best.

The mechanism provided by the simple model for reaching S_0–S_1 degeneracy in heterosymmetric biradicaloids by polarization of the $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ states toward states described approximately by the $^1|A^2\rangle$ and $^1|B^2\rangle$ configurations and by preferential stabilization of the latter configuration should of course be independent of the initial order of the $^1|A^2+B^2\rangle$ and $^1|A^2-B^2\rangle$ states. For large values of δ, the memory of their initial order at $\delta=0$ will long since have been lost, and δ_0 should be quite large, since K' is large in both reference systems selected for study, as judged by the large S_0–S_1 gap present for $\delta=0$.

3.2. Twisted π Bonds

3.2.1. Ethylene in the Field of a Charge

The simplest test of the proposal that introduction of a sufficient orbital energy difference between A and B will reduce the S_0–S_1 gap and eventually produce an S_0–S_1 touching is offered by a calculation of the electronic states of ethylene in the field of a strong nearby charge. We have performed such calculations using a multireference double (MRD) CI treatment[32, 33] for the simultaneous description of the singlet states of interest.

Figure 8 shows the energies of the two lowest singlet states of orthogonally twisted ethylene in the presence of a positive charge of magnitude q located on the C–C axis at a distance of 1.85 Å from the midpoint of the C–C bond. The large S_0–S_1 gap of 70 kcal/mol present in the absence of the external charge is reduced to zero when the charge is increased, as expected from the simple model considerations (cf. Fig. 3), and the nature of the wave functions changes as predicted. The S_0–S_1 touching occurs when $q = 1.735\,|e|$.

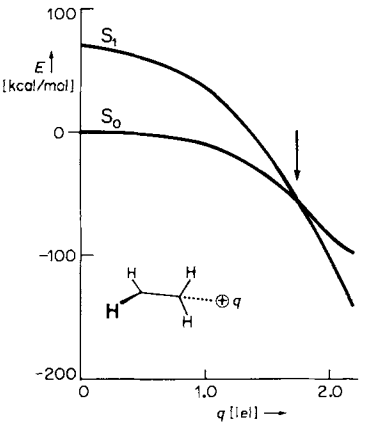

Fig. 8. Ab initio MRD CI calculation of singlet state energies of orthogonally twisted ethylene located next to a positive charge of magnitude q. Bond lengths: C–C 1.416, C–H 1.09 Å; bond angles 120°. The charge lies on the C–C axis 1.85 Å from the midpoint of the bond. Huzinaga double zeta quality basis set, nine reference configurations, except for $q = 1.735\,|e|$ where fourteen were used. (The diagonalized CI spaces contain approximately 5000 configurations. The extrapolated energies toward the full MRD CI space are plotted.)

Figure 9 shows the ethylene S_0, S_1, and S_2 energies as a function of the twist angle for three selected values of the external charge. It displays clearly the gradual transformation of an S_1 minimum into a conical intersection with a vanishing S_0–S_1 gap and then again into an S_1 minimum as the external field effect increases further. The behavior is that expected from the simple model (cf. Fig. 6).

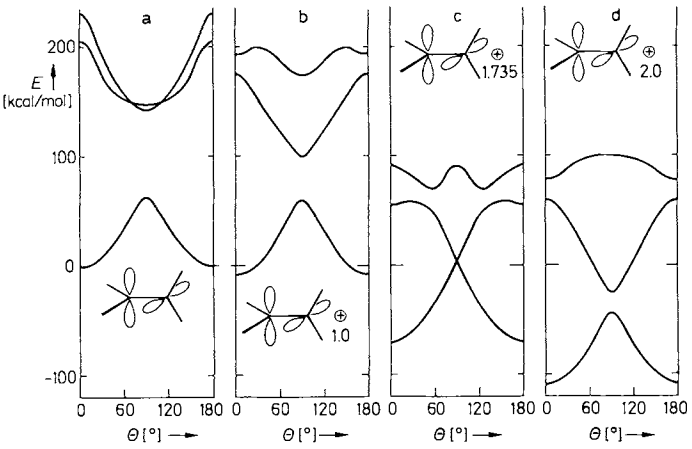

Fig. 9. Ab initio MRD CI calculation of singlet state (S_0, S_1, S_2) energies of ethylene located next to a positive charge $q[|e|]=0$ (a), 1.0 (b), 1.735 (c), and 2.0 (d), as a function of the twist angle (rigid rotation). For details of calculations, see caption to Figure 8.

3.2.2. Polar π Bonds

A more realistic modeling of the effect of increasing electronegativity difference between orbitals A and B on

the S_0–S_1 energy gap is provided by calculations for actual polar molecules. These were performed at a similar level as those described above and have already been published.[31] Figure 10 collects the plots of S_0, S_1, and S_2 energies as a function of the twist angle for ethylene, propene, protonated formaldimine, and aminoborane, providing four examples nicely illustrating the behavior expected from the simple model (Fig. 6): The S_0–S_1 gap is large in the perfect biradical (twisted ethylene), and not much smaller in a weakly heterosymmetric biradicaloid (twisted propene). It is reduced approximately to zero in a critically heterosymmetric biradicaloid (twisted formaldiminium ion) and is again large in a strongly heterosymmetric biradicaloid (twisted aminoborane). With this type of computational example it is difficult to provide a continuous plot such as that of Figure 5; on the other hand, the example illustrates the expected phenomena on real molecular systems.

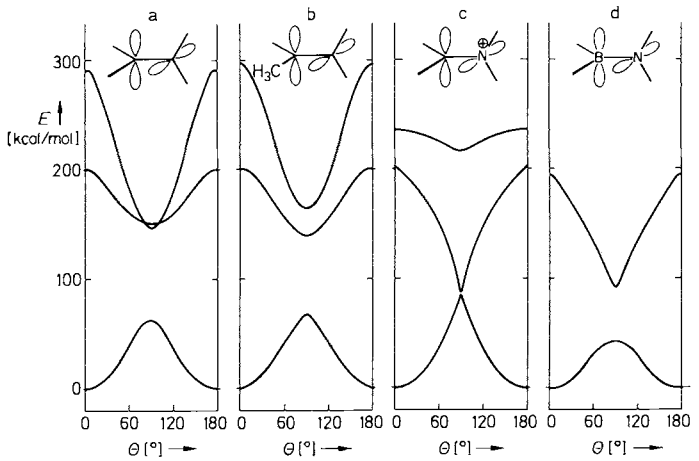

Fig. 10. Ab initio MRD CI calculation of singlet state energies of a) ethylene [31a], b) propene [28e], c) formaldiminium ion [31a], and d) aminoborane [31b] as a function of the twist angle.

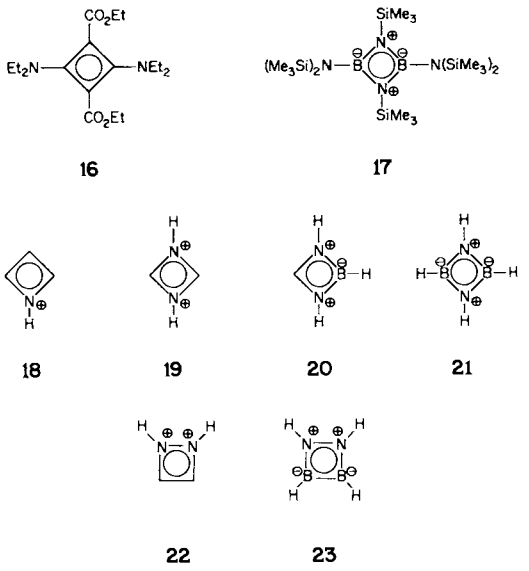
We believe that the ab initio calculations discussed here clearly verify the qualitative concepts derived from the simple model, with respect to both energies and wave functions.

3.3. Push-Pull Perturbed Cyclobutadienes

Cyclobutadienes perturbed by increasing the electronegativity of carbons 1 and 3 and/or decreasing the electronegativity of carbons 2 and 4 provide a second class of examples. This type of substitution pattern is required in order to induce an energy difference between the localized orbitals A and B of **2** (Scheme 1).[34,35a] The relative energy of the hole-pair configurations $^1|A^2\rangle$ and $^1|B^2\rangle$ can be modified either by the introduction of substituents such as CN or $N(CH_3)_2$, or by the replacement of carbon atoms by heteroatoms such as nitrogen or boron. When sufficiently strong, either of these perturbations leads to push-pull stabilized cyclobutadienes, such as **16**[35] and **17**[36] (Scheme 5). Unlike the parent cyclobutadiene and weakly perturbed cyclobutadienes, these molecules are quite stable, with four equal bond lengths in the ring; in their singlet ground state, the configuration $^1|B^2\rangle$ dominates by far.[36,37] While square cyclobutadiene is an archetypical example of a perfect biradical, the known strongly push-pull perturbed cyclobutadienes are so strongly heterosymmetric biradicaloids that one could be reluctant to label them biradicaloids at all.

We are interested in critically heterosymmetric biradicaloids of this type as another illustration of the general principle deduced from the simple model. No such species appear to be known experimentally.



Scheme 5. Perturbed cyclobutadienes.

Figure 11 shows the state energies for a series of perturbed square cyclobutadienes, calculated using the method described in Section 3.2. The geometries have not been optimized but this is not essential to the argument. The energies and wave functions behave just as expected from the simple model. The S_0–S_1 splitting is large in the perfect biradical **2** (ca. 46 kcal/mol); as a result of the gradual stabilization of orbital B relative to A, the splitting vanishes almost completely in the critically heterosymmetric biradicaloids **18** and **19** and is again large in the strongly heterosymmetric biradicaloids **20** (ca. 52 kcal/mol) and particularly **21** (ca. 89 kcal/mol). The triplet lies close to the singlet $^1|AB\rangle$; i.e., close to S_0 in **2** and **18** and close to S_1 in **18**–**21** (the simple model predicts exact singlet–triplet degeneracy in the zero-differential overlap approximation).

The S_1 and T_1 states of the perturbed cyclobutadienes should have minima at square or rhombic geometries, but we expect this to be true of the S_0 state only for sufficiently large values of δ, say in **21** (the work is in progress to verify this computationally). For critically heterosymmetric cyclobutadienes such as **18**, and certainly for weakly heterosymmetric ones, a geometric distortion toward nonzero γ takes place in S_0 (pseudo Jahn–Teller effect, Fig. 7), leading to bond-length alternation.

The results for push-pull perturbed square cyclobutadienes ($\delta_{AB} \neq 0$) can be contrasted with those computed for the opposite substitution pattern ($\delta_{AB} = 0$). In **22** and **23**, the localized orbitals A,B remain degenerate, while the

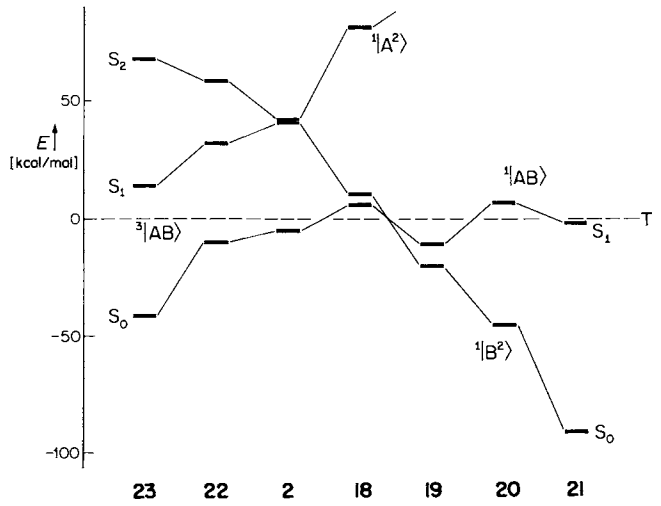


Fig. 11. Ab initio MRD CI calculation of singlet and triplet state energies of square-planar 1,2,3,4-diazadiborete **23**, doubly protonated 1,2-diazete **22**, cyclobutadiene **2**, protonated azete **18**, doubly protonated 1,3-diazete **19**, protonated 1,3,2-diazaborete **20**, and 1,3,2,4-diazadiborete **21**. Bond lengths [Å]: 1.456 Å (all C-C, C-N, and N-B bonds), 1.09 (C-H), 0.985 (N-H), 1.178 (B-H), 4-31G basis. The CI calculation was performed in two steps, using between five and fourteen reference configurations. At first, these were constructed from triplet SCF MOs. For each state, natural orbitals were then computed and used as the basis set for a final MRD CI calculation. (The diagonalized CI spaces contain approximately 10000 configurations. The extrapolated energies toward the full MRD CI space are plotted.)

delocalized orbitals a,b are split ($\gamma_{AB}=\delta_{ab}\neq 0$). The ab initio CI results (Fig. 11, left) show the anticipated behavior: there is no S_0–S_1 crossing, but rather a strong stabilization of S_0 and destabilization of S_2. The decrease in the S_1–T_1 gap is due to the increasing localization of the orbital a (LUMO) on atoms 2 and 3 and of the orbital b (HOMO) on atoms 1 and 4, which gives the $^1|ab\rangle$ configuration considerable charge-transfer character.

4. Conjectures for Photochemical Mechanisms

4.1. General

The general conclusions concerning the conditions for minimal S_0–S_1 gaps and for the location of S_1 minima in biradicaloids that were reached from the simple model and confirmed on a limited number of examples by large-scale CI calculations suggest certain general consequences for singlet photochemical processes. In general, the quantum yield of a particular photoproduct can be viewed as a function of the likelihood that an appropriate funnel leading to S_0 is reached and used and of the likelihood that return to S_0 through that funnel leads to eventual formation of the product. The former is related to the presence and height of the barriers that may separate the funnel geometry from the geometry reached initially after excitation. A complicated series of barriers may have to be overcome and a kinetic description will be correspondingly complex. All else being more or less equal, one might hope that making the funnel deeper will reduce the barriers around it, enhancing the photoprocesses that proceed through it.

In the absence of more detailed information on the shapes of the potential energy surfaces and on the nature of the rate-determining step in reaching the funnel, this statement is no more than a conjecture which will require considerable testing before it can be accepted as valid for any particular class of photochemical reactions. In the following we illustrate the application of the ideas outlined above to a few selected problems in organic photochemistry, without attempting a comprehensive coverage of the literature.

4.2. *cis–trans* Isomerization

There are three ways in which the present results could be pertinent to the mechanism of photochemical *cis–trans* isomerization about double bonds.

1. If twisting about several such bonds is possible in a molecule, according to the above conjecture the twist leading to the deepest funnel should occur preferentially. Other factors such as steric constraints being the same, the simple model suggests that this will be the twist that produces localized orbitals A and B in such a way that the energies of the configurations $^1|AB\rangle$ and $^1|B^2\rangle$ are comparable.

An example is provided by $CH_2{=}CH{-}CH{=}\overset{\oplus}{N}H_2$, which, according to calculations[38] and the above conjecture, should preferentially twist about the C=N and not the C=C bond. The C=N twist is calculated to produce an S_0–S_1 near touching[31,38] since the $CH_2{=}CH{-}\overset{\oplus}{C}H{-}$ + $-\ddot{N}H_2$ and $CH_2{=}CH{-}\overset{\odot}{C}H{-}$ + $-\overset{\odot}{\ddot{N}}H_2^{\oplus}$ structures are of comparable energy (the ionization potential of the allyl radical is 8.13 eV,[39] that of methylamine 9.64 eV[40]). The C=C twist does not produce an S_0–S_1 near touching since $CH_2^{\oplus}-$ + $-CH{=}CH{-}\ddot{N}H_2$ is a much less stable combination than $\overset{\odot}{C}H_2-$ + $-CH{=}CH{-}\overset{\odot}{\ddot{N}}H_2^{\oplus}$.

In the presence of an even larger number of double bonds available for isomerization, the situation becomes more complicated. Also, the relative energies of the various neutral and charged fragment combinations will respond differently to the presence of a polar solvent and to changes in the environment. It is conceivable that a particular combination of molecular structure and organized surrounding is responsible for the specificity of *cis–trans* photoisomerization about only one particular bond in both rhodopsin and bacteriorhodopsin (see Section 4.4).

2. Those twisting motions that lead to a funnel in which the S_0–S_1 gap vanishes may induce an $S_1 \rightarrow S_0$ jump the very first time the funnel region is reached. Dynamical memory ("momentum effect") in the sense that has been discussed in photochemistry repeatedly[9,10,41,42] but, to our knowledge, not actually demonstrated experimentally in a convincing manner, except perhaps in rhodopsin,[43] could then lead to extraordinarily high (or low) quantum yields. In this case, the sum of the quantum yields of processes proceeding through the same funnel could actually exceed unity.

3. As discussed in more detail in Section 4.4, critically heterosymmetric biradicaloids of the protonated Schiff base type could exist in two isomeric ground-state forms, which differ, first, in the location of the positive charge and, second, by an interchange of positions of single and

double bonds. Rotation around formally single bonds is usually easily induced thermally. Thus, *cis-trans* photoisomerization about a formal double bond in one of the forms could proceed by an initial phototransformation into the other form accompanied by a bond shift and subsequent rotation around the now formally single bond in the ground state.

4.3. Twisted Internal Charge-Transfer (TICT) Zwitterionic Excited States

It is of interest to point out the connection between the *cis-trans* isomerization about double bonds and the existence of twisted internal charge-transfer (TICT) zwitterionic excited states[44] in molecules such as **9**, which contain a π-donor moiety (orbital *B*) coupled by a formal single bond to a π-acceptor moiety (orbital *A*). The electronegativities of *A* and *B* differ greatly, and in the S_0 state the wave function is almost exactly of the hole-pair type, $^1|B^2\rangle$. Geometries for which $S_{AB}=\gamma_{AB}=0$ are preferred in the S_1 state (Fig. 7c), which corresponds to the dot-dot configuration $^1|AB\rangle$ and thus is of zwitterionic character, with the donor positively and the acceptor negatively charged. If the donor and the acceptor are connected by a formally single bond, the S_0 state favors a planar geometry (large γ_{AB}). The geometry that is optimal for S_1 can be reached by twisting around this bond to make *A* and *B* orthogonal, hence "twisted internal charge-transfer" ("twisted zwitterion") states.

The spatial separation of *A* and *B* and the large geometry difference between S_0 and S_1 make optical transitions into TICT states from S_0 weak and hard to observe. These states are normally populated by internal conversion from other excited states and observed in emission. The energy of such dipolar states depends sensitively on the polarity of the environment, and they are therefore most readily detected by characteristic solvent shifts of fluorescence.

Although the above description is adequate for a simple donor-acceptor combination such as **9**, in most of the compounds in which TICT emission has been observed the two-electron two-orbital representation of excited states is inadequate in that the donor or the acceptor or both are complicated structures with low-lying locally excited electronic states, such as substituted benzene rings. A typical example is *p-N,N*-dimethylaminobenzonitrile, in which the NMe_2 group acts as the donor and the C_6H_4CN group as the acceptor. These additional locally excited states typically favor planar geometries and thus impose barriers to the twisting motion. Only if the TICT state represents the S_1 surface at least in the vicinity of orthogonal twist does it have a chance to be detected in fluorescence (Fig. 12). Since this highly polar state is preferentially favored by a polar environment, TICT emission is usually though not always observed only in polar solvents.

Also other donor-acceptor systems with zwitterionic excited states can be discussed in terms of the two-electron two-orbital model. Examples are species in which the donor and the acceptor are not attached to each other at all (radical ion pairs) and those in which they are linked by a saturated hydrocarbon chain.[45] Thus, the category of zwitterionic biradicaloid states is more general than the category of TICT states.

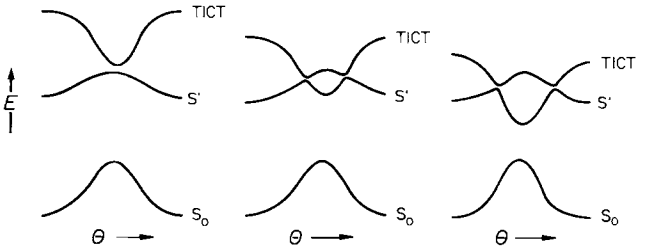

Fig. 12. Schematic representation of three typical cases for the relative energies of a locally excited state (S') and a TICT state as a function of twist angle. From left to right the TICT state is lowered due to variation of donor-acceptor groups and/or polar solvents.

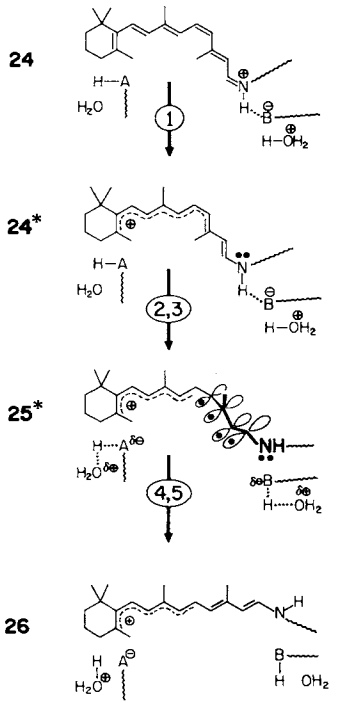
4.4. Proton Translocation and Vision

In charged biradicaloids such as **14** and **15**, the dot-dot $^1|AB\rangle$ and hole-pair $^1|B^2\rangle$ configurations are related by a charge displacement rather than charge separation as was the case in the species discussed in Section 4.3. In order to distinguish between the two cases clearly, such transport of a positive or a negative charge is referred to as charge translocation. In critically heterosymmetric biradicaloids the two configurations are degenerate, and already a relatively small change in the electronegativity difference δ will remove the degeneracy. A small increase in δ, due perhaps to some environmental effect that stabilizes positive charge in the localized orbital A or negative charge in B, will cause the hole-pair configuration $^1|B^2\rangle$ to represent a nondegenerate ground state S_0. A small decrease in δ, such as might be caused by solvent rearrangement that stabilizes positive charge in B or negative charge in A, will cause the dot-dot configuration $^1|AB\rangle$ to represent a nondegenerate ground state S_0. These effects are shown for rhodopsin in Figure 13. Solvated, charged biradicaloids such as these clearly have the potential to be bistable, i.e., to exist in two ground-state isomeric forms that differ by charge translocation and by some perturbation external to the biradicaloid proper. Typically, in the ground state the geometries of these biradicaloids will be distorted so as to make not only δ but also γ different from zero. If this can occur both toward a *cis* and a *trans* geometry in **14** or **15**, up to four separate minima in S_0 may result.

However, if the distortion toward large $|\gamma|$, i.e., toward planarity in **14** or **15**, is excessive, the configurations $^1|AB\rangle$ and $^1|B^2\rangle$ will interact and the charge will become delocalized. In a fluid environment, the system will then most likely end up with a single "*cis*" and a single "*trans*" minimum. As Figure 13 shows, electronic excitation, either $S_0 \rightarrow S_1$ or $S_0 \rightarrow S_1 \rightarrow S_1$, has the potential for isomerizing each form of the solvated biradicaloid into the others via the funnel in S_1 located at the critical value of δ_0 where S_1 and S_0 touch (or nearly touch if γ is small but not zero). The motions required for such isomerization are, first, a geometry change in the biradicaloid that causes γ to vanish, such as a twist of a double bond to orthogonality, and,

second, a change in the rest of the molecule or in the environment that brings δ to the critical value δ_0.

It is interesting to speculate that such bistable charged biradicaloids might be involved in the photobiological mechanism of operation of the visual pigment, rhodopsin. The chromophore is **24**, the protonated Schiff base of 11-*cis*-retinal (Scheme 6), presumably embedded in a relatively rigid environment. The primary event is believed to consist of its excitation to the S_1 state **24***, followed by twisting around the *cis* double bond (and possibly other chain motions, such as those involved in the "hula twist") to produce a charged biradicaloid species and eventually to yield the S_0 state of the *trans* isomer **26**, protonated bathorhodopsin (=prelumirhodopsin), which is 35 kcal/mol higher in energy than rhodopsin.[46] This process occurs on a picosecond time scale; much slower subsequent changes in the ground state modify the conformation of the protein, leading eventually to the production of a nerve impulse.



Scheme 6. Phototransformation of rhodopsin to bathorhodopsin. 1) Vertical excitation. 2) Twist to orthogonality. 3) First half of proton motion. 4) Twist to planarity. 5) Second half of proton motion.

In the initial photoproduct **26**, the nitrogen atom of the Schiff base is still protonated. It has therefore been somewhat of a puzzle that a replacement of exchangeable protons of the protein by deuterium slows down bathorhodopsin formation by a factor of seven; at very low temperatures proton tunneling seems to be involved.[47]

This coupling of the twisting motion with motions of protons in the environment and the large amount of energy stored are naturally accounted for by the reaction scheme proposed in Scheme 6 (Fig. 13), based on the concept of bistability for charged biradicaloids as outlined above. For the purposes of this illustration, we have chosen specific locations for acidic and basic groups in the environment of the chromophore, but other locations and more complicated acidic and basic centers can be envisaged readily. We have chosen a particularly simple chain conformation for bathorhodopsin, but others such as 10-*s-cis* are equally compatible with our proposal.

There is little doubt that a transfer of positive charge from the protonated nitrogen to the polyene chain occurs upon vertical excitation; it has been proposed to be particularly complete in the orthogonally twisted molecule **25***.[48] This translocation of positive charge will change the acid-base properties of protein groups on both ends of the chromophore. A more or less simultaneous protonation of a base near the nitrogen end and deprotonation of an acid near the ionone ring end will change the energy order of the $^1|AB\rangle$ and $^1|B^2\rangle$ configurations, taking the system through the S_0–S_1 touching point at δ_0. As shown in Figure 13, it is then the proton motion coordinate that is responsible for the return to S_0, accounting for the effects of deuteration and the low-temperature tunneling behavior. In this picture, **26** differs from **24** not only in the geometry around the $C_{11}=C_{12}$ double bond and possibly one or more single bonds, but also in the location of charges in the environment; these factors account for the much higher energy content and shifted absorption spectrum of **26**. It is proposed that the new charge positions, along with the presumably poorer mechanical fit of the all-*trans* chromophore into its pocket, then lead to changes in hydrogen bonding and protein conformation.

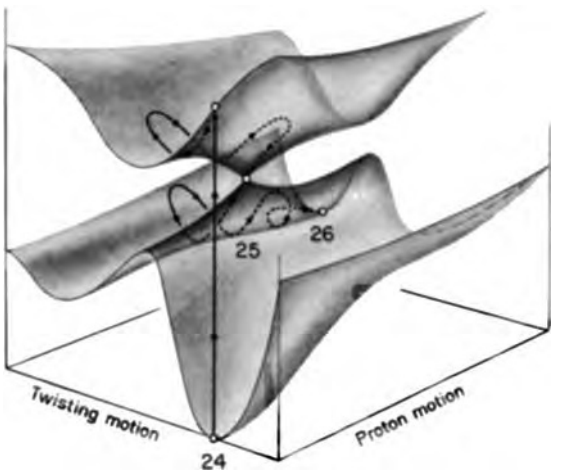


Fig. 13. A schematic representation of the conjectured energies of the S_0 and S_1 states of rhodopsin as a function of twist angle and proton motion in the environment (see also text).

Thermal return from **26** to **24** by deprotonation of the newly formed acid near the nitrogen atom and by reprotonation at the newly formed base near the ionone ring is presumably hindered by the final all-*trans* geometry of the polyene chain, which no longer provides for a close proximity between the nitrogen atom and the newly formed acidic group, so that other processes occur faster.

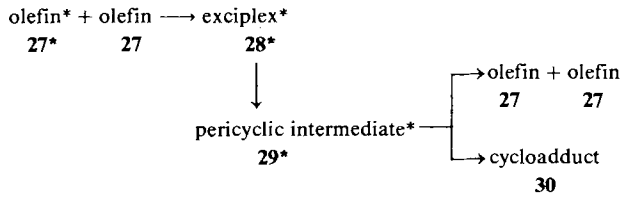
The proposal that some change in protein environment causes an interchange of the nature of the S_0 and S_1 wave functions has been made before;[28c,49] the present formulation is more specific and accounts for the observed effects

of deuteration. It is possible that a similar mechanism with coupled twisting and proton translocation applies in the case of bacteriorhodopsin even though the deuteration effect there is much smaller.[47]

If the present understanding of the basic principles is correct and bistable (or tetrastable) charged critically heterosymmetric biradicaloids can be designed and built into a membrane in proper orientation, it should be possible to construct an artificial charge-pumping photosystem that responds to irradiation at one wavelength by lowering the pH on one side and by increasing it on the other side of the membrane and does the opposite upon irradiation at another wavelength.

4.5. Singlet Photocycloaddition

The following mechanistic scheme has been proposed[19] for singlet photocycloadditions that are ground-state forbidden and excited-state allowed, such as the [2s + 2s] photocycloaddition of two olefins (Fig. 14):



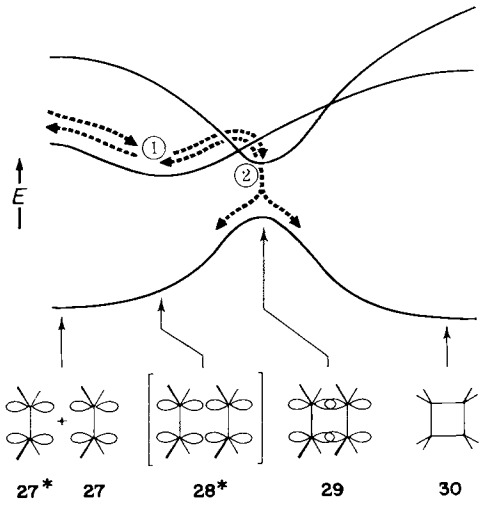


Fig. 14. Schematic representation of the energies of the S_0, S_1, and S_2 states for a concerted cycloaddition of two olefins. ① = excimer or exciplex minimum, ② = pericyclic minimum.

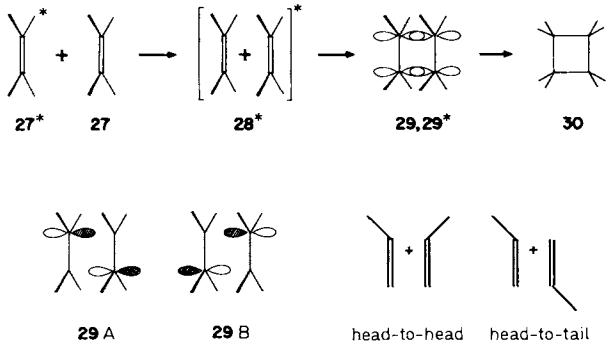
The return from the S_1 to the S_0 state occurs at the geometry of the pericyclic intermediate, which is isoconjugate with an antiaromatic annulene such as square cyclobutadiene and in which there is cyclic bonding between the four centers involved in the photocycloaddition. This preserves stereochemical information, so that the cycloaddition is stereospecific.

This process is of considerable mechanistic and synthetic interest. It is therefore important to develop a predictive capability when more than one regiochemical (head-to-head, head-to-tail) and stereochemical (*exo, endo*) possibility exists for the product structure. Three of the many factors that are likely to affect the outcome are the energies of **28*** and **29*** and the height of the barrier between them.

Simple perturbation theory considerations[50] show that electronic factors always favor the head-to-head regiochemistry and *syn* or *cis* stereochemistry in an excimer. Such considerations, along with an estimate of the energy of the pericyclic intermediate from triplet energies of the two reaction partners, have been used to estimate which cycloadditions will and which ones will not proceed.[51] The *syn* or *cis* adducts are indeed generally formed in the singlet photodimerization of olefins. However, it is known experimentally that some singlet cycloadditions, for instance those of substituted acenaphthylenes and anthracenes, yield head-to-tail products even though no steric or other reasons for this are readily apparent.[52]



Scheme 7. Regiochemistry in [2 + 2] photocycloaddition.

The results described here, in particular the analogy to the isoconjugate perturbed cyclobutadienes, suggest a resolution of the dilemma (Scheme 7): The localized nonbonding orbitals of the pericyclic intermediate, **29** A and **29** B, will have equal energies ($\delta_{AB} = 0$) in head-to-head cyclodimerization but different energies ($\delta_{AB} > 0$) in head-to-tail cyclodimerization. The latter should stabilize the S_1 state of the biradicaloid and produce a deeper pericyclic minimum. If our initial conjecture is correct, this should in turn reduce the barriers around the minimum and thus fa-

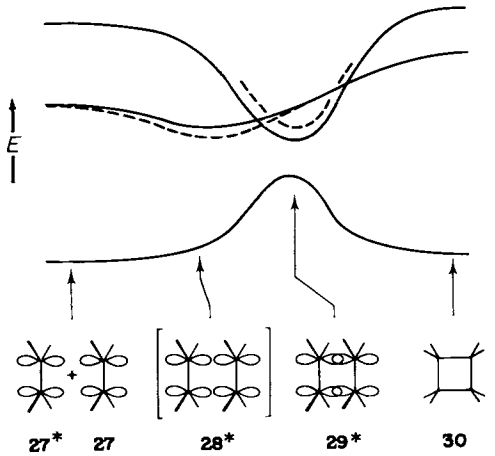


Fig. 15. Regiochemistry in a concerted singlet photocycloaddition. A schematic representation of the singlet energy surfaces S_0, S_1, and S_2 for a head-to-head (---) and head-to-tail coupling (——).

vor the formation of **29*** from the excimer. Thus, the head-to-head geometry is favored by the excimer **28*** and the head-to-tail geometry by the pericyclic intermediate **29*** (Fig. 15); either **28*** or **29*** can dictate which product is formed preferentially.

Similar considerations suggest that excited singlet-state pericyclic reactions hardly ever favor the most symmetrical paths for which most calculations have been done so far (e.g., butadiene $\rightleftarrows$ cyclobutene[7,23]), even though, unlike their triplet counterparts, they develop and preserve cyclic bonding along the reaction path.

5. Summary

We have attempted to formulate a systematic overview of the whole range of biradical-like species, from perfect biradicals to nonpolar, polar, or charged covalent and dative bonds, based on a simple two-electron two-orbital model and on comparison with ab initio calculations for a selected series of examples. Particular attention was paid to identifying the conditions for S_0-S_1 surface touching, which is believed to be of key importance in photochemistry. Several conjectures concerning photophysical and photochemical mechanisms, including that of the primary process in vision, have been formulated.

Appendix

1. Orbital Transformations

A general unitary transformation of the orbitals $\mathscr{A}$ and $\mathscr{B}$ to some new orbital pair $\mathscr{A}_{\omega\phi}$, $\mathscr{B}_{\omega\phi}$ is characterized by a rotation angle ω and complex phase ϕ [Eq. (A1)]. The state wave functions in the new and old orbital bases are related by Equation (A2). For $\mathscr{A}=\mathrm{A}$ and $\mathscr{B}=\mathrm{B}$, special cases of interest are $\phi=0$, $\omega=\pi/4$ ($\mathscr{A}_{\omega\phi}=\mathrm{a}$, $\mathscr{B}_{\omega\phi}=\mathrm{b}$) and $\phi=\pi/2$, $\omega=\pi/4$ ($\mathscr{A}_{\omega\phi}=\mathrm{c}^*$, $\mathscr{B}_{\omega\phi}=i\mathrm{c}$).

$$(\mathscr{A}_{\omega\phi},\mathscr{B}_{\omega\phi})=(\mathscr{A},\mathscr{B})\begin{pmatrix}\cos\omega & -e^{-i\phi}\sin\omega\\ e^{i\phi}\sin\omega & \cos\omega\end{pmatrix}=(\mathscr{A},\mathscr{B})\cup(\omega,\phi) \tag{A1}$$

$$\begin{pmatrix}{}^3|\mathscr{A}_{\omega\phi}\mathscr{B}_{\omega\phi}\rangle\\ {}^1|\mathscr{A}_{\omega\phi}^2+\mathscr{B}_{\omega\phi}^2\rangle\\ {}^1|\mathscr{A}_{\omega\phi}\mathscr{B}_{\omega\phi}\rangle\\ {}^1|\mathscr{A}_{\omega\phi}^2-\mathscr{B}_{\omega\phi}^2\rangle\end{pmatrix}=\begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1-2\sin^2\phi\sin^2\omega & i\sin\phi\sin 2\omega & -i\sin 2\phi\sin^2\omega\\ 0 & i\sin\phi\sin 2\omega & \cos 2\omega & -\cos\phi\sin 2\omega\\ 0 & i\sin 2\phi\sin^2\omega & \cos\phi\sin 2\omega & \cos 2\omega+2\sin^2\phi\sin^2\omega\end{pmatrix}\begin{pmatrix}{}^3|\mathscr{A}\mathscr{B}\rangle\\ {}^1|\mathscr{A}^2+\mathscr{B}^2\rangle\\ {}^1|\mathscr{A}\mathscr{B}\rangle\\ {}^1|\mathscr{A}^2-\mathscr{B}^2\rangle\end{pmatrix} \tag{A2}$$

In the following, we limit our attention to orthogonal transformations of orbitals ($\phi=0$). These have the effect of mixing only ${}^1|\mathscr{A}\mathscr{B}\rangle$ and ${}^1|\mathscr{A}^2-\mathscr{B}^2\rangle$. The transformations given by (A3) then occur.

$$\begin{aligned}&[(K'_\omega-K_\omega),\gamma^-_\omega]=[(K'-K),\gamma^-]\cup(4\omega,0)\\ &(\delta_\omega,\gamma_\omega)=(\delta,\gamma)\cup(2\omega,0)\end{aligned} \tag{A3}$$

Here and in the following, unsubscripted quantities refer to the original orbital choice $\mathscr{A}$, $\mathscr{B}$ ($\omega=0$) and subscripted ones to the rotation angle ω. The repulsion integrals J and J_ω stand for $J_{\mathscr{A}\mathscr{B}}$ and $J_{\mathscr{A}_\omega\mathscr{B}_\omega}$, respectively. E_0, $(K'+K)$, $(J-K)$, $(\gamma^2+\delta^2)$, and $[(K'-K)^2+(\gamma^-)^2]$ are invariant to the rotation. The derivatives with respect to ω are given by (A4). The derivatives $\mathrm{d}K_\omega/\mathrm{d}\omega$ and $\mathrm{d}J_\omega/\mathrm{d}\omega$ vanish when $\gamma^-_\omega=0$, showing that the most localized orbital set A, B (J_ω and K_ω minimized) and the most delocalized one a, b (J_ω and K_ω maximized) fulfill the condition $\gamma^-=0$. Also the set c, c* fulfills it.

$$\begin{aligned}&\frac{\mathrm{d}K'_\omega}{\mathrm{d}\omega}=-\frac{\mathrm{d}K_\omega}{\mathrm{d}\omega}=-\frac{\mathrm{d}J_\omega}{\mathrm{d}\omega}=2\gamma^-_\omega\\ &\frac{\mathrm{d}\gamma^-_\omega}{\mathrm{d}\omega}=4(K_\omega-K'_\omega)\\ &\frac{\mathrm{d}\gamma_\omega}{\mathrm{d}\omega}=-2\delta_\omega\\ &\frac{\mathrm{d}\delta_\omega}{\mathrm{d}\omega}=2\gamma_\omega\end{aligned} \tag{A4}$$

The rotation angle ω needed to produce either A, B or a, b from an arbitrarily chosen initial set $\mathscr{A}$, $\mathscr{B}$ is given by Equation (A5). This equation has a positive root ω_+ and a negative root ω_- in the range of interest, $-\pi/4\le\omega\le\pi/4$. They are related by $\omega_+-\omega_-=\pi/4$. Since Equation (A6) holds, one of the roots transforms $\mathscr{A}$, $\mathscr{B}$ into the localized orbitals A, B ($K'_\omega\ge K_\omega$) and the other into the delocalized orbitals a, b ($K'_\omega\le K_\omega$).

$$\omega=\frac{1}{4}\tan^{-1}\frac{\gamma^-}{K'-K} \tag{A5}$$

$$\frac{\mathrm{d}^2K_\omega}{\mathrm{d}\omega^2}=8(K'_\omega-K_\omega) \tag{A6}$$

Considering the sign of $[\mathrm{d}K_\omega/\mathrm{d}\omega]_{\omega=0}=2\gamma^-$, we see that ω_- yields A, B and ω_+ yields a, b if $\gamma^->0$, and that the opposite holds if $\gamma^-<0$. If $\gamma^-=0$ and $K'>K$, the orbitals $\mathscr{A}$, $\mathscr{B}$ are already equal to the sought orbitals A, B ($\omega=0$). If $\gamma^-=0$ and $K'<K$, $\mathscr{A}$ and $\mathscr{B}$ are equal to a, b and a rotation by $\omega=\pm\pi/4$ is needed to produce A, B. Finally, if $\gamma^-=K'-K=0$, all orbital choices are equally localized or delocalized by our criteria since $[(K'-K)^2+(\gamma^-)^2]$ is an invariant.

2. Density Matrices and Natural Orbitals

In an arbitrary orthonormal basis set $\mathscr{A}$, $\mathscr{B}$, the elements E^Q_P of a one-electron excitation operator E are defined by Equation (A7).[53] Its effect on the wave functions ${}^1|\mathscr{A}^2\pm\mathscr{B}^2\rangle$ and ${}^{1,3}|\mathscr{A}\mathscr{B}\rangle$ is given in Table 3, so that for this singlet basis the diagonal density matrices have the form given in Equation (8) and the transition density matrices are given by Equations (A8) to (A10).

$$E^Q_P=|Q(1)\rangle\langle P(1)|+|Q(2)\rangle\langle P(2)| \quad P,Q=\mathscr{A},\mathscr{B} \tag{A7}$$

$$\langle\mathscr{A}^2+\mathscr{B}^2|E|\mathscr{A}^2-\mathscr{B}^2\rangle=\langle\mathscr{A}^2-\mathscr{B}^2|E|\mathscr{A}^2+\mathscr{B}^2\rangle=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix} \tag{A8}$$

$$\langle \mathscr{A}\mathscr{B}|E|\mathscr{A}^2+\mathscr{B}^2\rangle=\langle \mathscr{A}^2+\mathscr{B}^2|E|\mathscr{A}\mathscr{B}\rangle=\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix} \quad (A9)$$

$$\langle \mathscr{A}\mathscr{B}|E|\mathscr{A}^2-\mathscr{B}^2\rangle=-\langle \mathscr{A}^2-\mathscr{B}^2|E|\mathscr{A}\mathscr{B}\rangle=\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix} \quad (A10)$$

Table 3. The action of the E operator on the four two-electron basis functions of the 3 × 3 CI model.

	$^1\|\mathscr{A}^2+\mathscr{B}^2\rangle$	$^1\|\mathscr{A}^2-\mathscr{B}^2\rangle$	$^1\|\mathscr{A}\mathscr{B}\rangle$	$^3\|\mathscr{A}\mathscr{B}\rangle$
E:	$\sqrt{2}\|\mathscr{A}^2\rangle$	$\sqrt{2}\|\mathscr{A}^2\rangle$	$^1\|\mathscr{A}\mathscr{B}\rangle$	$^3\|\mathscr{A}\mathscr{B}\rangle$
E:	$\sqrt{2}\|\mathscr{B}^2\rangle$	$-\sqrt{2}\|\mathscr{B}^2\rangle$	$^1\|\mathscr{A}\mathscr{B}\rangle$	$^3\|\mathscr{A}\mathscr{B}\rangle$
E:	$^1\|\mathscr{A}\mathscr{B}\rangle$	$^1\|\mathscr{A}\mathscr{B}\rangle$	$\sqrt{2}\|\mathscr{B}^2\rangle$	0
E:	$^1\|\mathscr{A}\mathscr{B}\rangle$	$-^1\|\mathscr{A}\mathscr{B}\rangle$	$\sqrt{2}\|\mathscr{A}^2\rangle$	0

Note that Equation (A10) guarantees that all linear combinations of the configurations $^1|\mathscr{A}\mathscr{B}\rangle$ and $^1|\mathscr{A}^2-\mathscr{B}^2\rangle$ yield the same diagonal density matrix. For any two singlet states $|S_i\rangle$ and $|S_j\rangle$ defined by Equation (10), the transition density matrix is given by Equation (A11). The expressions for one-electron density matrices for perfect biradicals [Equation (8)] and for biradicaloids [Equation (11)] follow.

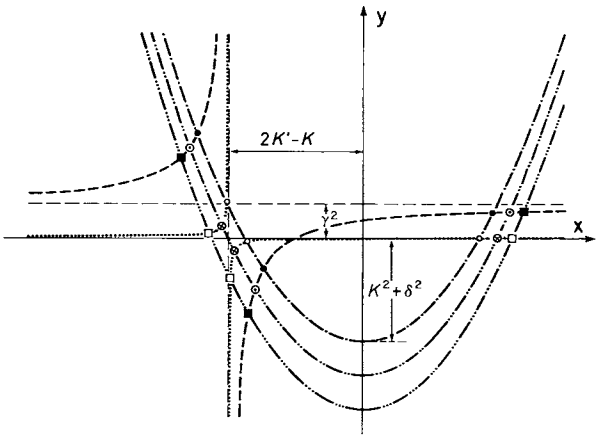

Fig. 16. Graphical solution of Equation (26). Two choices of γ^2 (0 and $\neq 0$; two hyperbolas) and three choices of δ^2+K^2 (three parabolas) are displayed. The three solutions for each of the six cases are obtained as the x coordinates of the points indicated by circles or squares.

$$\langle S_i|E|S_j\rangle=\begin{pmatrix}\langle S_i|S_j\rangle+(C_{i,+}C_{j,-}+C_{i,-}C_{j,+}) & C_{i,+}C_{j,0}+C_{i,0}C_{j,-}+C_{i,0}C_{j,+}-C_{i,-}C_{j,0}\\ C_{j,+}C_{i,0}+C_{j,0}C_{i,+}+C_{j,0}C_{i,+-}-C_{j,-}C_{i,0} & \langle S_i|S_j\rangle-(C_{i,+}C_{j,-}+C_{i,-}C_{j,+})\end{pmatrix} \quad (A11)$$

where $\langle S_i|S_j\rangle=C_{i,+}C_{j,+}+C_{i,-}C_{j,-}+C_{i,0}C_{j,0}$

3. *State Energies of a Nonsymmetric Biradicaloid*

1. *Orthogonal orbitals* $\mathscr{A},\mathscr{B}$. Graphical solutions for E in Equation (26) are found from the x coordinates of the points in which the parabola $y=x^2-(\delta^2+K^2)$ cuts the two branches of the hyperbola $y=2(K-K')\gamma^2/(x-K+2K')+\gamma^2$, where E is given by Equation (A12).

$$E=x+E(T)+2K'+K \quad (A12)$$

As shown in Figure 16, the S_0 root lies below the asymptote $x=K-2K'$ and the S_1 and S_2 roots lie above. The S_0 and S_1 roots approach each other as the product $(K-K')\gamma^2$ goes to zero, provided that the parabola cuts the horizontal line $y=\gamma^2$ near the asymptote. The two roots can coincide only if two conditions are fulfilled simultaneously: (1) the hyperbola degenerates into a pair of lines and (2) the parabola cuts the line $y=\gamma^2$ at $x=K-2K'$. The former condition demands $\gamma=0$ or $K=K'$ or both and the latter condition demands $4K'(K'-K)=\delta^2+\gamma^2$. If $K=K'$, both conditions are satisfied by $\delta=\gamma=0$ (perfect axial biradical). If $K\neq K'$, both conditions are satisfied by $\gamma=0$, $\delta=\delta_0=2\sqrt{K'(K'-K)}$ (critically heterosymmetrical biradicaloid).

2. *Nonorthogonal orbitals* A,B. The expression for the triplet energy E_T^0 is given by Equation (31). The Hamiltonian matrix for the sinjglets is given by (A13) where κ and γ' are given by Equations (A14) and (A15).

$$\begin{matrix}{}^1|A^2-B^2\rangle\\ {}^1|A^2+B^2\rangle\\ {}^1|AB\rangle\end{matrix}\begin{pmatrix}(1-S_{AB}^2)^{-1}E_T^0+2K'_{AB} & (1-S_{AB}^4)^{-1/2}\delta_{AB} & (1-S_{AB}^4)^{-1/2}\gamma_{AB}\\ (1-S_{AB}^4)^{-1/2}\delta_{AB} & (1+S_{AB}^2)^{-1}E_T^0+2(K'_{AB}+\kappa_{AB}) & (1+S_{AB}^2)^{-1}\gamma'_{AB}\\ (1-S_{AB}^4)^{-1/2}\gamma_{AB} & (1+S_{AB}^2)^{-1}\gamma'_{AB} & (1+S_{AB}^2)^{-1}E_T^0+2\kappa_{AB}\end{pmatrix} \quad (A13)$$

$$\kappa_{AB}=K_{AB}+2h_{AB}S_{AB} \quad (A14)$$

$$\gamma'_{AB}=\gamma_{AB}+S_{AB}(h_{AA}+h_{BB})/2 \quad (A15)$$

[20] The use of complex orbitals is advantageous in the case of axial biradicals. These belong to a point symmetry group with a threefold or higher axis of symmetry and their characteristic property is $K'_{AB}=K_{AB}$. If the orbitals A and B are members of a degenerate pair, c and c* will transform according to the representations ε_n and ε_n^*. When $\varepsilon_{2n}\neq\varepsilon_{2n}^*$, it is immediately obvious that the configurations $|c^{*2}\rangle$ and $|c^2\rangle$ cannot interact. Instead, they form two members of a degenerate pair of states, S_0 und S_1 (Table 2). For instance, in molecular oxygen, O_2, $c=\pi_+$, $c^*=\pi_-$, and c^2 and c^{2*} together describe the degenerate state $^1\Delta$. Similarly, in methylnitrene, CH_3-N with $c=2p_+$ and $c^*=2p_-$, c^{*2} and c^2 form the degenerate S_0, S_1 state ^1E. The complex MOs of the π system of regular 4N-electron [n]annulenes of D_{nh} symmetry (7) have served as the starting point for a recently developed classification of the electronic excited states of cyclic π systems derivable from such perimeters [21] (e.g., biphenylene, 9b-azaphenalene, heptalene), similar in spirit to the classical L_b,L_a,B_b,B_a nomenclature for the excited states of aromatic π systems; cf. *Platt's* perimeter model for (4N+2)-electron perimeters: J. R. Platt, *J. Chem. Phys. 17* (1949) 484; W. Moffitt, *ibid. 22* (1954) 320, 1820; E. Heilbronner, J. N. Murrell, *Mol. Phys. 6* (1963) 1; M. Gouterman, *J. Mol. Spectrosc. 6* (1961) 138; J. Michl, *J. Am. Chem. Soc. 100* (1978) 6801, 6812.

[25] The adjective "biradicaloid," as in "a biradicaloid geometry," is used at times, and stands for "of a biradical" or "of a biradicaloid" (as in "a geometry at which the molecule is a biradical or a biradicaloid").
[26] This result is obtained readily from the form which the S_0 wave function takes when $(\delta^2_{\mathscr{A}\mathscr{B}}+\gamma^2_{\mathscr{A}\mathscr{B}})$ grows beyond all bounds. Note that this quantity as well as $C_{0,+}$ are invariant to rotations within the orbital basis set according to Equations (A2) and (A3). Choosing a rotation [Eq. (A1)] by an angle $\omega=(1/2)\tan^{-1}(\gamma_{AB}/\delta_{AB})$ that converts the localized orbital pair A, B into the pair $\mathscr{A}_\omega$, $\mathscr{B}_\omega$ for which $\gamma_{\mathscr{A}_\omega\mathscr{B}_\omega}$ vanishes, and noting that $\gamma_{\mathscr{A}_\omega\mathscr{B}_\omega}$ and $2K_{\mathscr{A}_\omega\mathscr{B}_\omega}$ can be neglected next to $\delta_{\mathscr{A}_\omega\mathscr{B}_\omega}$ in the limit, we see that $C_{0,+}$ approaches $1/\sqrt{2}$, $C_{0,-}$ goes to $-1/\sqrt{2}$, and $C_{0,0}$ goes to zero, so that the S_0 wave function goes to $^1|\mathscr{B}_\omega^2\rangle$. If $\gamma_{AB}=0$, this is $^1|B^2\rangle$, and both electrons are in the more stable localized orbital B. If $\delta_{AB}=0$, this is $^1|b^2\rangle$, and both electrons are in the bonding delocalized orbital b.

Directed Homogeneous Hydrogenation

New Synthetic Methods (65)

By John M. Brown*

Stereochemical control is a major concern in the application of homogeneous catalysis to organic chemistry. In this context, the directed hydrogenation of olefins employing cationic rhodium or iridium catalysts has considerable potential, for very high selectivity can be attained under mild reaction conditions. The only requirement is a polar functional group in proximity to the double-bond which remains bound to the metal during the catalytic cycle and thereby controls the stereochemical course of hydrogen delivery through the constraints of chelation. The substituent is most frequently a hydroxy group OH but can also be an ester, amide or carbamate group; other groups remain to be scrutinized. In cyclic compounds, directed hydrogenation can lead to face-selectivity, and the polar substituent may be in the β-, γ-, or δ-position to the double-bond. Acyclic stereoselection ensues with β- or γ-substituents in appropriate compounds, and the configuration of reduced product is predictable on the basis of simple rules. The application of optically active rhodium complexes leads to useful kinetic resolution procedures.

1. Introduction

The potential of homogeneous hydrogenation for organic synthesis became clear in the 1960's following the demonstration of its feasibility by *Halpern* et al.[1] and the development of effective rhodium and ruthenium catalysts, largely by *Wilkinson*'s group.[2,3] Major advances since then include the development of highly active iridium catalysts[4] and the utilization of cyclopentadienyllanthanoid complexes.[5] Simple olefins can be hydrogenated very readily, and catalyst turnover rates in excess of $1\ s^{-1}$ are attainable.

In modern synthetic chemistry, the need is not so much for high reactivity but rather selectivity in functionally diverse molecules. The simplest manifestation is *site selectivity*, and homogeneous hydrogenation affords a degree of control which is generally unattainable with heterogeneous catalysts. For example, the disubstituted double-bond in carvone is completely hydrogenated in the presence of $[ClRh(PPh_3)_3]$, while the trisubstituted double-bond remains intact.[6] An exceptionally high *enantioselectivity* has been achieved in the catalytic hydrogenation of dehydroamino acids and their esters,[7] but this required the development of optically active chelating bisphosphanes.[8]

When a tertiary center is generated by hydrogenation of an appropriate di- or trisubstituted olefin, two diastereomers may be formed. The potential of homogeneous hydrogenation regarding *diastereoselectivity* had hardly been broached until fairly recently, and earlier efforts tended to concentrate on unsaturated hydrocarbons. When using $[ClRh(PPh_3)_3]$ as catalyst, the extent of stereochemical control is generally small for both *exo*- and *endo*cyclic olefins. In those cases where significant differentiation was observed, the major epimer was formed by approach of hydrogen to the less encumbered face, even when this gave rise to the thermodynamically less favored product.[9]

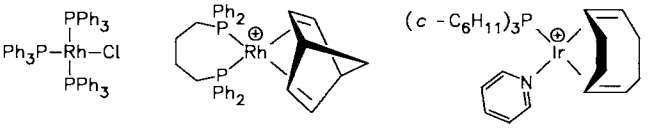

Fig. 1. Structures of the main catalysts used for directed hydrogenation in the homogeneous phase. *Wilkinson*'s catalyst, **A**, is commercially available from a number of sources. The cationic complexes **B** and **C** are readily prepared, and indefinitely stable at room temperature if maintained in an inert atmosphere. Synthesis of **B** (as trifluoromethanesulfonate) according to *Phillip L. Evans* [59]: To a yellow solution of bicyclo[2.2.1]heptadiene-2,4-pentanedionatorhodium (0.093 g, 0.32 mmol) [60] in THF (2 mL) was added trimethylsilyl trifluoromethanesulfonate (67 μL, 0.37 mmol) with stirring. The color changed to orange. Solid *P,P'*-tetramethylenebis(diphenylphosphane) (0.135 g, 0.32 mmol) was then added under Ar with continued stirring. The resulting orange-red suspension was stirred for 1 h and then rapidly transferred to vigorously agitated hexane (50 mL). The product was then filtered and dried in vacuo. Yield 0.224 g (92%) of catalyst **B** as an orange powder, m.p. 211–212°C (dec.), ^{31}P-NMR (CH_2Cl_2): $\delta = 23.6$ ($J_{PRh} = 154$ Hz).—Synthesis of **C** according to *Crabtree* and *Morris* (cf. Ref. [12]): Potassium hexafluorophosphate (0.8 g, 4.3 mmol) and di-μ-chlorodi(1,5-cyclooctadiene)diiridium (1.4 g, 4.2 mmol) were added with stirring to a degassed mixture of pyridine (3 mL), acetone (20 mL), ethanol (10 mL), and H_2O (2 mL). The solvent was removed in vacuo and the resulting yellow solid was washed with degassed H_2O and dried. The 1,5-cyclooctadienebis(pyridine)iridium hexafluorophosphate thus obtained (2.4 g, 96%) was stirred with tricyclohexylphosphane (1.2 g, 4.3 mmol) in dichloromethane for 10 min. The solvent was removed in vacuo and the residue was recrystallized from dichloromethane/ether, filtered, and dried *in vacuo* overnight. Yield of catalyst **C** 3.0 g (92%).

In the ensuing discussion three catalysts will be referred to repeatedly. They are *Wilkinson*'s catalyst, **A**, the cationic rhodium complex **B** derived from *P,P'*-tetramethylenebis(diphenylphosphane), and *Crabtree*'s iridium catalyst **C** (Fig. 1).

Hydrogenations are best carried out using standard inert atmosphere techniques, since the catalyst is sensitive to oxidation once the diolefin ligand has itself been hydrogenated and displaced. If the reaction is slow, traces of metal may be produced, particularly for catalyst **B** in dichloromethane. Addition of one drop of mercury in such cases suppresses any competing heterogeneous hydrogenation.[15] For slow reactions it is better to work at elevated

pressures[17] and small-scale equipment suitable for this purpose is readily available.[61]

An explicit procedure for a rapid hydrogenation requiring only a small quantity of catalyst is given in Table 3.

2. Selectivity in the Hydrogenation of Cyclic Alcohols with Endo- or Exocyclic Double Bond

The key factor in asymmetric hydrogenation of dehydroamino acids is the formation of a chelate rhodium enamide complex in which olefin and amide carbonyl group are bound to the metal.[7] This suggests that any functionality in proximity to the olefin which is capable of binding to rhodium is capable of exerting stereochemical control over the course of hydrogenation. *Facial selectivity*, whereby a polar substituent directs the course of hydrogen addition to a cyclic olefin, illustrates the general principle. If the polar group remains bound to the metal center, then *cis*-delivery of hydrogen is enforced.

Indeed, the potential of directed hydrogenation in this manner was indicated as long ago as 1974 in an experiment by *Thompson* and *McPherson*.[10] The tricyclic unsaturated alcohol **1** was unreactive towards hydrogenation

Table 1. Catalytic hydrogenation of cyclic alcohols with endo- or exocyclic double bonds in dichloromethane (**1** and **11** in benzene). Catalysts **A**, **B**, **C** see Figure 1. Bz = benzoyl.

and catalyst **A** even under forcing conditions. However, up to 20 turnovers can be achieved by first converting the alcohol into the potassium alkoxide; the *cis*-product is then formed exclusively (Table 1). *Thompson* and *McPherson* proposed, very reasonably, that the alkoxide displaces chloride from the coordination sphere and thereby controls the stereochemistry of hydride delivery.

Cationic iridium complexes are catalytically active in non-coordinating solvents but their reactivity is slowly dissipated through the formation of inert dimers. Reduction of 4-terpineol **2c** in dichloromethane occurs slowly (relative to 1-methylcyclohexene) but the catalyst **C** is indefinitely stable and the *trans*-product is formed with 1000:1 selectivity—clear evidence for coordination of the hydroxy group to iridium during the hydrogen-transfer step.[11] Again using catalyst **C** but at rather higher relative concentrations, *Stork* and *Kahne* examined directing effects in the hydrogenation of cyclohexenes such as **1**, **2a–c**, **3a,b**, **4a,b**, **5a,b**, and **6** bearing allylic or homoallylic hydroxyl substitution.[12] In all cases the *trans*-product predominated. Some general trends are apparent from the data which suggest that the order of effectiveness is *tert* > *sec* > *primary* OH; all examples in the first category are stereospecific within experimental error. The high ratio of catalyst to substrate employed in these experiments is probably unnecessary, since rapid hydrogenation was observed for the reactant **3b** employing <2 mol-% of catalyst **B**.[13] The utility of directed hydrogenation as a route to *trans*-hydrindanones was confirmed by *Corey* and *Engler*, with the reaction of **8**.[14]

The reactivity of rhodium complexes in homogeneous hydrogenation diminishes markedly as the degree of substitution on the olefin increases. For this reason directed hydrogenation was examined by employing exocyclic disubstituted olefinic alcohols.[15] 2-Methylenecyclohexanol proved uninteresting, since (unselective) hydrogenation was overridden by isomerization to 2-methylcyclohexanone. For the 3-isomer **9**, catalyst **B** gives exclusively the *trans*-isomer of the hydrogenation product, whilst the bis(triphenylphosphane)-analogue of **B** gave only 91% of the *trans*-isomer. In similar vein a carbocyclic relative of daunosamine was formed with excellent stereoselectivity using catalyst **B**, albeit at 35 mol-%![16] The unreactivity of trisubstituted olefins in Rh-complex-catalyzed hydrogenation can be overcome by working at high pressures, and the stereoselectivity observed is comparable to or better than in iridium-catalyzed reactions at ambient pressure.[17] For catalyst **C**, the stereochemical course of hydrogenation is insensitive to pressure change, even though the catalyst concentration is a significant but undefined variable.[18] There is even one case, the hydrogenation of **8**, where the iridium catalyst fails but the rhodium catalyst **B** succeeds at high pressure. Deuterated *trans*-hydrindanone is readily obtainable from **11** with catalyst **A**.[19]

The parallel development of cationic rhodium and iridium cationic complexes for directed hydrogenation prompted a comparison of their effectiveness using 6-methylenebicyclo[2.2.2]octan-2-ol **12**, where the hydroxy group perturbs an otherwise symmetrical environment.[20] Hydrogenation with catalyst **C** was very rapid, and stereospecific. In contrast, rhodium catalyst **B** effected a much more sluggish reaction in which 1.5% of *cis*-product was formed, and here competitive isomerization to the endocyclic isomer **13** occurred. This trisubstituted olefin was itself reduced rapidly and stereoselectively and accounted for 75% of the total reduction pathway via **12**. This result raises interesting questions about the spatial orientation of the hydroxy group and olefin which are addressed in Section 7.

3. Other Directing Groups for the Hydrogenation of Cyclic Olefins

Acetates of allylic or homoallylic alcohols invariably exhibit poor stereochemical control in hydrogenation.[12] A better result was obtained with the bicyclic ether **14** and the catalyst **B** (Table 2) but substantially lower selectivity was observed, although it proved a more reactive substrate than the parent alcohol. These observations indicate that the nature of the directing group is critical; ethers are inferior to alcohols in their coordinating ability towards iridium(I) ions,[21] and acetates prefer to bind through the more basic carbonyl oxygen, which is not well-disposed for chelate formation in the preferred s-*cis*-conformation.[22]

The OH group has a Brønsted pK_a value of about -2, whilst amides typically have a pK_a of -1 (for *O*-protonation) and esters are in the range of -4 to -7.[23] This encouraged a survey of the directed hydrogenation of the unsaturated esters **15–17**. With rhodium catalyst **B**, reactions were rather sluggish and the iridium catalyst **C** was much more effective. The allylic ester **15** was reduced with essentially complete stereoselectivity.[24] *Schultz* and *McCloskey* have demonstrated that amides are superior to esters in directing power.[25] This result might have been anticipated given the general effectiveness of dehydroamino acids in asymmetric hydrogenation and the mandatory requirement for amide coordination in the catalytic cycle.[26] A series of cyclohexene and cyclohexadienecarboxamides with the amide group attached to a quaternary allyl center were reduced with a selectivity of 100:1 or better using catalyst **C**. All the starting materials **22a,b**, and **23** are readily available by alkylative Birch reduction;[27] in the case of **23**, the *O*-methylprolinamide of *o*-toluic acid, this reaction is enantioselective. Direction by the amide group remains effective as it is attenuated from the double bond whilst the influence of an ester group diminishes (cf. **18**, **20** *versus* **17**, **19**).

These observations have immediate synthetic potential, for an intermediate (**25**) in the total synthesis of pumiliotoxins was exclusively hydrogenated from the amide-bearing face. The unwanted diastereomer predominated in the reduction catalyzed by Pd/C.

4. Selective Hydrogenation of Acyclic Allylic Alcohols

In these face-selective hydrogenations the stereochemical outcome is predictable, since the directing-group must be *cis*-related to the new C–H bonds. The outcome is less certain for acyclic substrates, but it is serendipitous that

many reductions can be carried out with high stereoselectivity.

Kinoshita and co-workers planned an allyl alcohol hydrogenation in a synthetic route to the rifamycin backbone. The first hint of selectivity came when a mixture of the diastereomeric alcohols (23*R*)-**26** and (23*S*)-**26** (Fig. 2) was reduced with hydrogen and a *stoichiometric* quantity of $[ClRh(PPh_3)_3]$ (catalyst **A**). Each component of the mixture gave rise to 95% of a single product.[28] A more clear-cut result was later obtained in the case of the alcohol (21*R*)-**27a** upon employing 24 mol-% of catalyst **A** — almost 100% stereoselectivity. The corresponding TBDMS-ether (21*R*)-**27b** was hydrogenated slowly with 150 mol-% **A** in the same stereochemical sense. The diastereomer (21*S*)-**27a** was reduced without selectivity although its TBDMS-ether (21*S*)-**27b** gave mainly the *syn* product.[29] In a more recent synthesis, compound **28** was hydrogenated in the presence of 25 mol-% **A** to the *anti*-products (selectivity 20 : 1).[30]

Although interesting regarding their stereoselectivity it is not certain whether these hydrogenations arise from coordination of the allylic hydroxy group to rhodium, since its relative configuration with respect to the polyol chain is crucial in determining the stereochemical outcome (cf. the

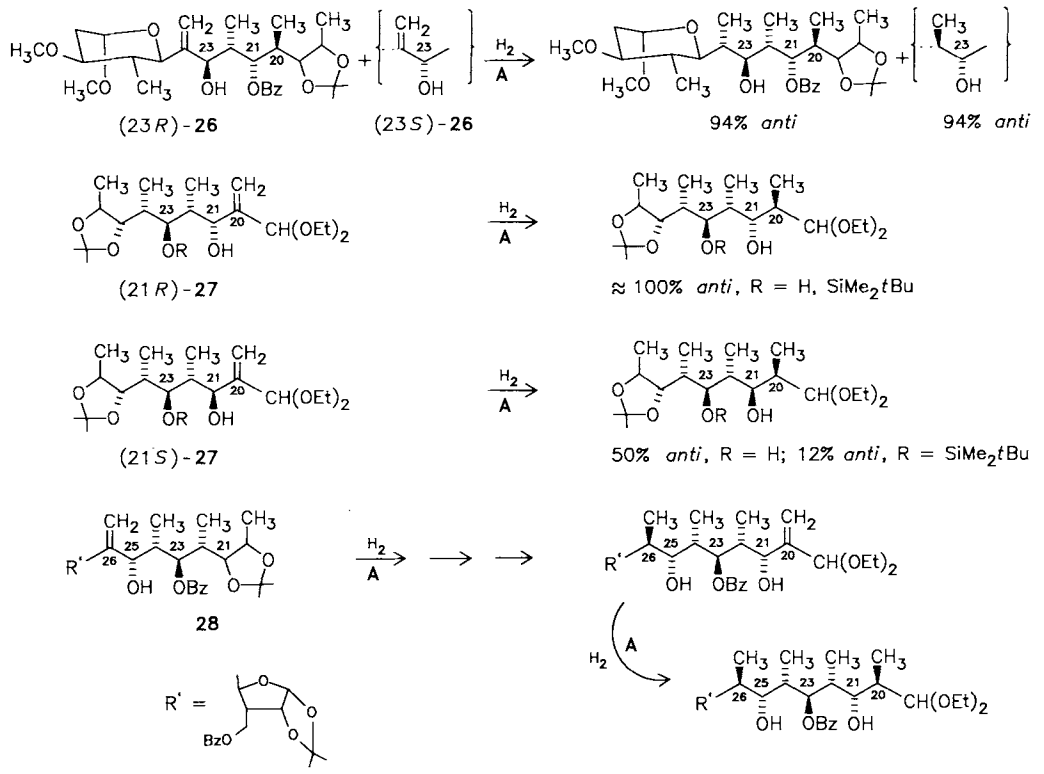

Fig. 2. Reduction steps in *Kinoshita*'s synthesis of the ansa-chain of rifamycin. The numbering scheme is that conventionally applied to rifamycin S. In **27a** R = H, in **27b** R = *tert*-butyldimethylsilyl.

hydrogenation of (21*R*)-**27a** and (21*S*)-**27a**). There is less ambiguity when the *cationic* rhodium complex **B** is employed where there are well-established precedents for hydroxyl-coordination.[21] Under optimum conditions hydrogenation of the disubstituted allylic alcohol **29** proceeds with 97% *anti*-selectivity using 2 mol-% of catalyst **B** (Table 3).[31] The yield is lowered by about 20% because of competing isomerization to the methyl ketone. In the case of the more highly functionalized reactants examined by *Evans* and *Morrissey*, it was found necessary to work at high H_2-pressures and high catalyst loading; but under these conditions isomerization was effectively suppressed.[17] This is probably due to the fact that reduction is first-order in [H_2] but the competing isomerization reaction has a lesser pressure dependence. Note that the disubstituted olefin **30** and its trisubstituted isomer **31** give *syn* and *anti*-isomers of an otherwise identical product.

Electron-withdrawing groups enhance the binding of olefins to rhodium[32] and in consequence of this may also augment their reactivity towards homogeneous hydrogenation.[33] α-(Hydroxyalkyl)acrylates such as **32** are very easily obtained by condensation of aldehydes and acrylates in the presence of tertiary amines:[34] they are hydrogenated rapidly and with extremely high stereoselectivity using catalyst **B**, whereas both catalysts **A** and **C** give slow and ineffective reactions.[35] In the case of compounds **32a–c**, the reaction is even stereoselective in protic solvents such as MeOH which generally override intramolecular hydroxyl-direction. Starting from a given aldehyde, the reaction provides an equivalent to an *anti*-selective aldol-condensation with two straightforward steps. It is both simple and competitive in stereoselectivity to present alternatives (cf. Fig. 3).[36] As shown in Table 3 the α,β-unsaturated γ-hydroxy-ester **33** is again hydrogenated with reasonable selectivity, although its reactivity is much reduced.[37]

In all these examples *anti*-stereoselectivity of the reduction product predominates and it might be thought desirable to provide the equivalent of a *syn*-selective aldol condensation.[36] This objective has been achieved, albeit indirectly. There were a few examples of homogeneous hydrogenation of allenes indicating that the double bond with lesser terminal substitution is reduced regioselectively.[38] It has now been observed that the allenic alcohol **34** is exclusively reduced at the double bond adjacent to the OH-group. Ozonolysis of the product (O_3 then Ph_3P) gave only the *syn*-aldehyde.[39]

5. Kinetic Resolution in Homogeneous Hydrogenation[40]

The best substrates for asymmetric hydrogenation are α,β-unsaturated acids or esters with a chelating group attached to the α-position.[41] This is precisely what the α-(hydroxyalkyl)acrylates **32** have to offer, and what made their reduction with H_2 and asymmetric catalysts of direct interest. The starting material is of course racemic, and in such cases enantioselection leads to kinetic resolution. A general feature of such experiments is that the optical purity of the product diminishes with time, whereas that of the starting material becomes enhanced, particularly so in the latter stages of reaction. In a kinetically well-behaved process, the sharpness of differentiation between the fast and slow reactant enantiomers increases with the relative

[a] Procedure for the hydrogenation of *rac*-**32a**, ethyl instead of methyl ester, to *rac*-ethyl *anti*-3-hydroxy-2-methylbutyrate: To a solution of *rac*-ethyl 3-hydroxy-2-methylenebutyrate (5.00 g, 3.47 mmol) in dichloromethane (40 mL) was added catalyst **B** (0.050 g, 0.2 mol-%, BF_4-salt) under argon, with shaking to complete dissolution. The solution was cooled to −80°, thoroughly degassed by three evacuation/argon atmosphere cycles and then argon replaced by H_2, with the vessel connected to a burette line. The temperature was allowed to rise to ambient (< 20°C, cold water bath) and equilibrated. Stirring was commenced and continued until the theoretical amount of H_2 had been adsorbed (840 mL, ca. 4 h), whereupon gas-chromatographic analysis (180-cm column of Carbowax 20M, 120°C) showed complete reduction. The reaction was then stopped, the catalysts removed by filtration through a short plug of silica gel (Merck 60H), and the solvent removed below 20°C on a rotary evaporator. The residue was distilled in a trap-to-bucket apparatus (40°, 0.1 mm) giving *rac*-**32a** (4.7 g, 93%), 99% isomerically pure by gas-liquid chromatography.—The *anti-syn* ratio increased with decreasing reaction temperature.

reaction rate; Figure 4 shows calculated curves for 5 : 1, 15 : 1 and 35 : 1 ratios.

For the resolution of *ent*-**32b** and **32b** (*R*- and *S*-form, respectively, Fig. 5) the DIPAMP-Rh catalyst is more effective than other asymmetric complexes, a property consistent with the general superiority of such catalysts in the hydrogenation of unsaturated esters.[42] Under optimum conditions, reaction was carried out with 0.5—1 mol-% of catalyst in THF at 0°C to around 70% completion. Starting material and product were then separated by standard chromatographic methods, whereupon the former was obtained with > 90% optical purity.[35] The diastereoselectivity (*anti* : *syn*) observed with the DIPAMP-rhodium catalyst was very high, being 99.6 : 0.4 in a reaction run to 65% completion. The recovered starting material, essentially optically pure (*S*)-enantiomer (**32b**), is hydrogenated much more slowly than the (*R*)-enantiomer *ent*-**32b** and the *anti* : *syn* ratio in the hydrogenation product is 97.4 : 2.6. This means that the sense of enantioselectivity is the same for both *syn* and *anti*-isomer formation (and independent

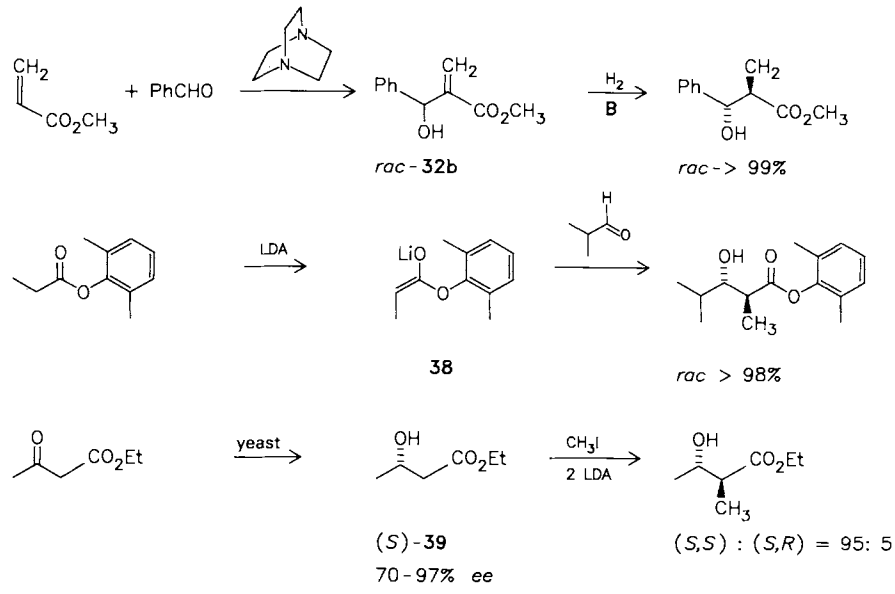

Fig. 3. Comparison between directed hydrogenation (of *rac*-**32b**) of the aldol reaction of the ester **38** lithiated with lithium diisopropylamide (LDA) and the alkylation of the optically active β-hydroxyester (*S*)-**39** generated with yeast enzymes.

of the process leading to *anti*-dominance) with *R*- configuration of the new asymmetric center being preferred.[43]

Double asymmetric induction is evident in the hydrogenation of L- or D-menthyl α-(hydroxyethyl)acrylate.[43,44]

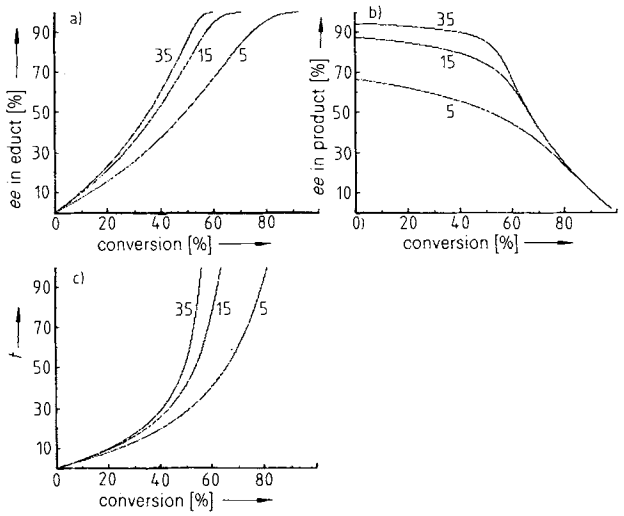

Fig. 4. a), b) Change of enantiomeric purity in a kinetic resolution experiment; c) time conversion diagram; the relative reaction rates of the enantiomers are 5 : 1, 15 : 1 and 35 : 1 (calculated curves). The time in c) is given in arbitrary units.

This leads to greater enantioselectivity (up to 8 : 1) in the reduction of the L-isomer.

These examples extend hydroxyl-directed hydrogenation in a useful way, but what of the effect of other substituents? The *tert*-butoxycarbonyl (Boc) functionality (see **35** in Table 3) is superior to OH in its *anti*-selectivity, and a kinetic resolution of 15 : 1 is observed in the—albeit rather slower—hydrogenation of *rac*-**35** with [(DIPAMP)-Rh]$^{\oplus}$ as catalyst.[45] There are good precedents for anticipating the effectiveness of carbonyl-derived functionalities, as exemplified in Table 2. In an acyclic case, the specifically deuterated dehydrovaline **36** (Table 3) is reduced by HT (H_2 diluted) and catalyst **A** from the direction which indicates participation of the carbonyl group.[46] The 3-substituted dimethyl itaconates **37** could be hydrogenated with high *anti*-selectivity in methanol employing catalyst **B**.[47] When [(DIPAMP-Rh]$^{\oplus}$ was employed as catalyst, kinetic resolution with up to 20 : 1 rate discrimination between enantiomers was obtained, with starting material enriched in the slow-reacting *S* enantiomer remaining. The ready availability of the 3-methoxyitaconate **37d** permitted a test of the relative efficiency of OCH_3 and CO_2CH_3 as directing groups. With catalyst **B**, more than 98% of the (*S,S*)-diastereomer (Table 3) was obtained from the (*S*)-configurated **37d**, indicating that the stereochemical course of reaction is dominated by the CO_2CH_3-group.

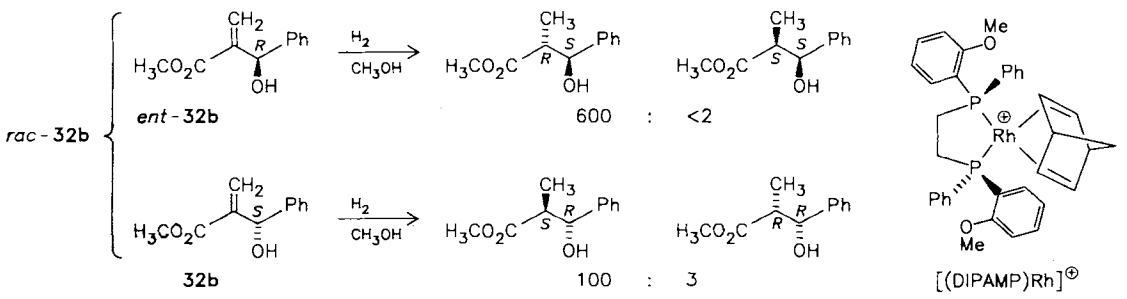

Fig. 5. Estimated initial relative rates of hydrogenation of racemic methyl 2-(α-hydroxybenzyl)acrylate *rac*-**32b** with the (optically active) rhodium complex of (*R,R*)-*P,P'*-ethylenebis[*o*-methoxyphenyl(phenyl)phosphane] (DIPAMP).

The reaction sequence makes a number of unsaturated esters available in good enantiomeric purity (>95% *ee*). The racemate is reduced to the extent of 60–65% with hydrogen in CH_3OH using [(DIPAMP)-Rh]$^{\oplus}$ as catalyst (Fig. 6, step ①). Recovered starting material is then enriched in the (*S*)-enantiomer. Since *anti*-selective hydrogenation is readily achieved, a further reduction employing catalyst **B** (step ②) affords a route to (*S,S*)-2-alkyl 3-methylsuccinates.

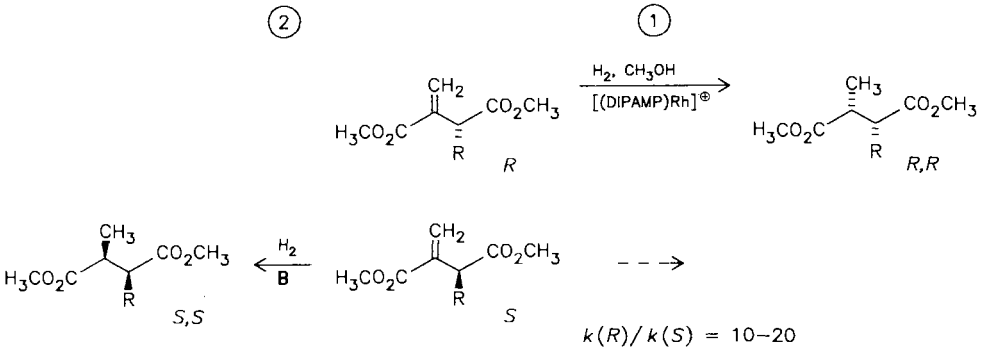

Fig. 6. Step ①: Kinetic resolution in the reduction of 3-alkyl itaconates of type **37** in the presence of (*R,R*)-[(DIPAMP)Rh]$^{\oplus}$ as catalyst. Step ②: Hydrogenation of the enriching enantiometer.

6. Selective Hydrogenation of Acyclic Homoallylic Alcohols

Methods for remote asymmetric induction are far less common than for vicinal asymmetric induction, providing an incentive to discover examples in directed hydrogenation. A simple case for remote induction (hydrogenation of **40** in Table 4) demonstrates the general principle.[31] The diastereoselectivity is only moderate with catalyst **B**, but still rather better than the related case with **41**, where the hydroxyl group has reduced basicity.[48] When a carbonyl group intervenes between the secondary alcohol and disubstituted olefin as in **42**, catalyst **A** gives the most satisfactory result.[49] All these reactions occur in the same stereochemical sense, but in the last one *Evans* et al.[49] suggest that intramolecular H-bonding (CHOH···O=C) is the controlling factor which makes approach to the double bond diastereoselective in the preferred conformation.

Stereospecific hydrogenation of trisubstituted double bonds is an important goal in synthesis, since it provides access to many desirable targets, for example in polyether and macrolide antibiotics. *Evans* et al. have discovered a general method employing directed hydrogenation which has wide applicability.[48] Figure 7 shows a key compound (**50**) for the synthesis of the C1–C10 fragment of ionomycin. The desired stereochemistry at C6 was obtained by directed hydrogenation. This atom is remote from the other chiral centers and hence incorporation by other methods of synthesis would be very difficult. A number of related examples have been described (**43**–**49**) and inspection of the first two of these makes it clear that the allylic alkyl group controls the stereochemical course of the reaction. The same pattern is observed for **45** and **46**, and comparison between **47** and **48** makes it clear that the configuration of the secondary homoallylic alcohol plays only a minor part, overridden by the configuration of the adjacent allylic center (see Section 7). Enantiomerically pure **48** and more particularly **49** illustrate the potential for double asymmetric induction using an optically active catalyst, since the starting materials are homochiral. In both cases the reduction catalyzed by [((+)-BINAP)Rh]$^{\oplus}$[50] was substantially more successful than hydrogenation with catalyst **B** or with [((−)-BINAP)Rh]$^{\oplus}$. The hydroxy ester **49** is an important intermediate in the synthesis of premonensin.[51]

7. Mechanistic Considerations

The wide-ranging applicability of directed hydrogenation suggests that a common principle or set of principles may be involved. A majority of the examples cited are unsaturated alcohols, and in cyclic cases the face-selective hydrogenation observed requires that the hydroxyl group is bound to rhodium or iridium during hydrogenation of the double bond. The only direct evidence for this is in the NMR-characterization of an iridium complex derived from *endo*-bicyclo[2.2.1]hept-5-en-2-ol,[11] although alcohol-bound cationic complexes are known in other cases.[21,52]

For acyclic allylic alcohols, the reaction is invariably *anti*-selective, and this may be rationalized by consideration of non-bonded interactions in the two diastereomeric

chelate complexes of **32a** (Fig. 8). The precursor of the *syn*-product engenders a strongly perturbing 1,2-interaction between the methyl group of the substituent $CH(CH_3)OH$ and the other substituents of the double-bond. This does not arise in the *anti*-precursor, where it is only an hydrogen atom which interacts with the substituents. If correct, this analysis implies that stereoselectivity arises from torsional and non-bonding interactions within the substrate and does not involve the phosphane ligands. The magnitude of discrimination which arises can be quite large since the 300 : 1 diastereoselection observed in α-(hydroxyalkyl)acrylates corresponds to a difference in free energy of 14 kJ mol^{-1} between the transition-states of competing pathways.

In a model for the hydrogenation (Fig. 8, bottom) where the allylic C–H eclipses the neighboring vinyl group (*anti*), the H–C–C=C torsion angle is 180°. This is at variance with models which explain the stereochemical course of hydroboration and other electrophilic additions to double bonds.[53] Here the C–H eclipses C=C (*syn*), so that the torsion angle is 0° (Fig. 8, bottom), in accord with the theoretically derived[54] or spectroscopically observed[55] ground-state conformation of allylic alcohols. This indicates that the geometrical constraints which accompany

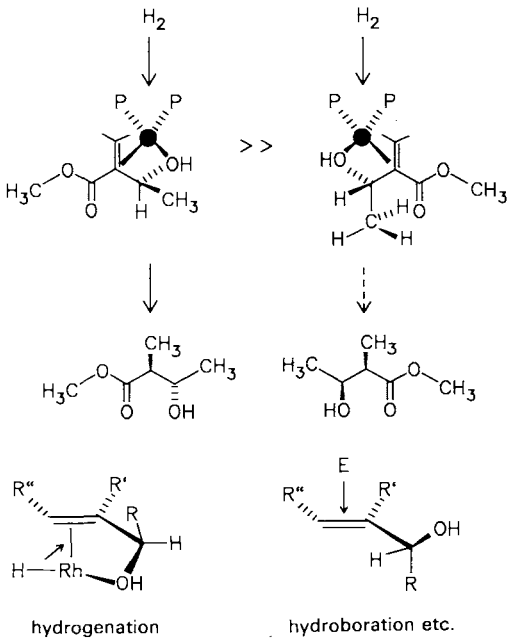

Fig. 8. The origin of *anti*-selectivity in the hydrogenation of allylic alcohols (cf. **32a**)—a comparison between the stereochemical course of hydrogenation and that of other electrophilic additions is also given.

chelate formation are quite stringent and impose a higher energy conformation on the reactant. In the metal-promoted epoxidation of chiral allylic alcohols, the oxygen is coordinated to Mo, V or Ti prior to peroxide delivery from the metal[56] to olefin; in this case, the *syn* isomer is preferred, but of course there is no direct metal-olefin binding.

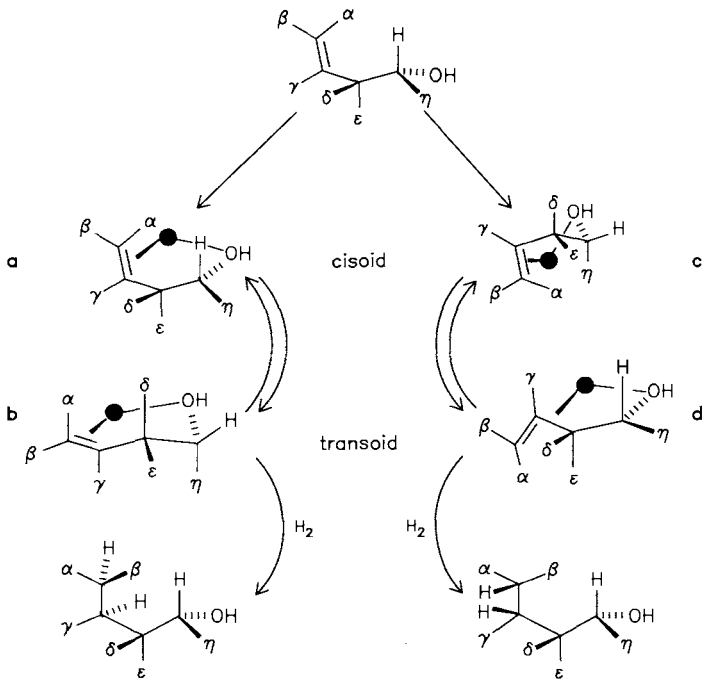

Fig. 9. Pathways for the stereochemical course of directed hydrogenation of homoallylic alcohols. When $\delta = \varepsilon = H$, the preferred intermediates have cisoid structure **a**. When α, $\delta \neq H$, $\varepsilon = H$ the transoid form **d** is preferred, and when α, $\varepsilon \neq H$, $\delta = H$ the transoid form **b** is preferred.

For simple homoallylic alcohols, where a CH_2-group is situated between the double bond and C–O bond, the results are less clear-cut. Additional flexibility in the chelate ring permits two distinct conformers for each configurational isomer. These are designated cisoid (Fig. 9, **a** and **c**) or transoid (Figure 9, *2* and *4*) depending on whether the torsion-angle (HO–C–C–C=) in the chelate ring is around 30° or around 150°. An observed 7:1 preference (as in **40**) corresponds to the major part of reaction proceeding via the cisoid form **a**. (In **40**, γ = phenyl and η = methyl.) In **a**, hydrogen as the smaller substituent in the homoallyl position interacts with the double-bond and particularly with the hydrogen at position α. In the alternative cisoid form **c**, the larger substituent η at the hydroxy-site experiences an unfavorable non-bonded interaction with the hydrogen at position α. There is an interesting corollary in the hydrogenation of exocyclic and endocyclic olefins of the bicyclo[2.2.2]octane series (cf. **12** and **13**). With catalyst **B**, the *di*substituted exocyclic olefin **12** in fixed transoid conformation is hydrogenated more sluggishly and less selectively than the *tri*substituted endocyclic olefin **13** in fixed cisoid conformation.

Nevertheless, *Evans* et al. have demonstrated convincingly that the stereochemical course of hydrogenation can be controlled by allylic substitution at sites δ or ε (Fig. 9). Their examples invariably possess a *Z* alkyl substituent at site α, which will be expected to destabilize the cisoid chelate **a** (and **c**) in favor of the transoid isomers **b** and **d**.[48] Reaction proceeds through the pathway which engenders less allylic 1,3-strain in the coordinated intermediate. If α and δ are alkyl groups and ε is hydrogen, then the chelate **d** is preferred since the interaction between α and ε is less destabilizing than that between α and δ. This correctly predicts the outcome of all their examples (see **43**–**49** in Table 4 and Fig. 7).

For cationic rhodium complex **B**, the catalytic cycle of directed hydrogenation appears straightforward. Although competitive olefin isomerization may occur, all product molecules are dideuterated when reduction is carried out with D_2. Not so for iridium catalyst **C**! Reduction of methyl 3-methyl-2-cyclohexenecarboxylate **15** with D_2 gave a stereoisomerically pure product which, according to the ^1H-, ^2H- and ^{13}C-NMR spectra was evidently a mixture of several isotopomers. Figure 10 shows the ^2H-NMR spectrum of the product, assigned by comparison with cross-sections of the ^{13}C-^1H-NMR shift correlation spectrum.[13] This demonstrates incorporation of deuterium only at C3, and at the C2 and C4 equatorial sites (i.e. exclusively *cis* to the methoxycarbonyl group). This is consistent with isomerization processes which occur during the catalytic cycle of hydrogenation *without* release of the substrate.

In the reduction of *endo*-6-methylenebicyclo[2.2.2]octan-2-ol **12** with D_2 and catalyst **C**, deuterium appears at the methyl group and at the 5-*endo* and 6-position, with all possible D_0–D_3 isotopomers, but dideuteration overall. The ^{13}C-NMR spectrum can be analyzed and computer modelling employed to derive a mechanism which fits the isotopic distribution; it is necessary that each molecule of reactant encounters more than one D_2 as it passes through the catalytic cycle.[56] The pathway delineated in Figure 11 best fits the experimental data. Its novel feature is the ad-

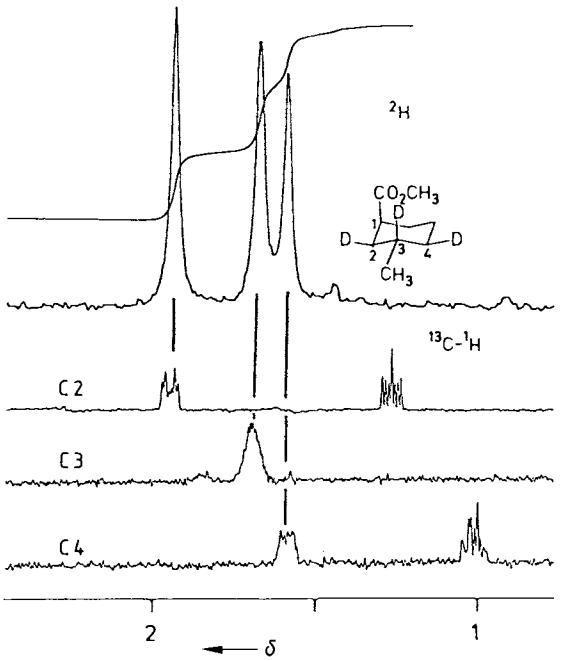

Fig. 10. ^2H-NMR spectrum of the reduction product from methyl 3-methyl-2-cyclohexenecarboxylate **15** and D_2 using catalyst **C**; comparison with the relevant cross-sections of the ^{13}C-^1H-2D-NMR correlation spectrum of the *hydrogenation* product of **15**.

dition of hydrogen to the chelate-stabilized alkyliridium hydride, which can have an appreciable lifetime at room temperature.[57] A number of groups have recently isolated iridium trihydride complexes, the work of *Crabtree* and *Lavin* being particularly pertinent.[58]

These mechanistic subtleties are not perceived without isotopic labeling, but they may help to explain why olefins with varying torsion angles about C=C–C–COH are readily reduced—compare **2a** and **6** (Table 1). Internal isomerization *via* an allyliridium hydride or by Ir-H addition/elimination can provide chelated intermediates of optimum geometry.

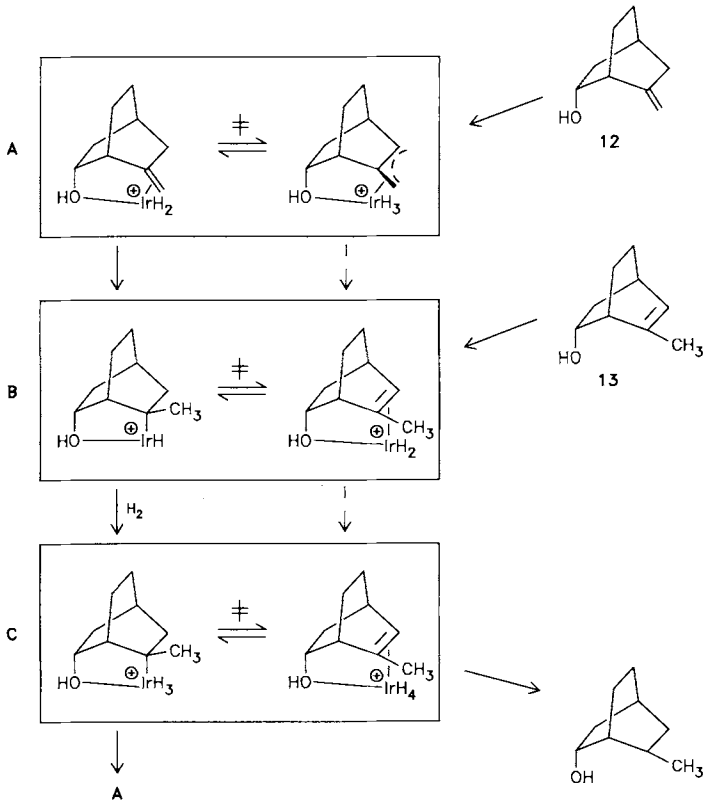

Fig. 11. A pathway for directed hydrogenation of the bicyclo[2.2.2]octanol derivatives **12** and **13** in the presence of the catalyst **C**. This reaction pathway explains the deuterium distribution in the product. (Ligands omitted for clarity.)

8. Comparison of Homogeneous and Heterogeneous Catalysis

An advantage of homogeneous catalysts is, in general, that every batch has identical and predictable reactivity, and poisoning is never a problem.

It has been known for over thirty years that polar groups, particularly the hydroxy group, can influence the stereochemical course of catalytic hydrogenation over metals. Since a book dealing with this topic has recently been published,[62] the discussion that follows will be selective rather than exhaustive.

The choice of metal, support, and solvent are all crucial in heterogeneous hydrogenation, and often all three must be varied before optimum stereocontrol is achieved. Early workers did this in a fairly empirical way. Thus, 2-butylidene-1-cyclopentanol **51a** (Table 5) is reduced most selectively with Raney Ni in ethanol,[63] whilst the corresponding benzylidene derivative **51b** gave little indication of stereochemical control by the hydroxy group because aryl-coordination competed successfully for surface sites.[64] Increasing the ring size diminished stereoselectivity since the relative disposition of hydroxy group and double bond is then less favorable.[65] For the cyclopentylidene analogue **52a**, Raney nickel gave selective hydrogenation but the related tertiary alcohol **52b** added H_2 (in the presence of Pd/C) from the opposite face, reflecting greater steric hindrance to the developing alkyl group along the OH-directed path.[66]

Among cyclohexenol reductions the example **53** is notable, since OH-direction provides the less stable epimer with an axial methyl group.[67] *Kishi* et al. discovered that alumina-supported catalysts were much more responsive to hydroxyl-direction (cf. **54**).[68] With Pd/C the unwanted stereoisomer predominated, whereas Pt on alumina gave 93% of the desired product.

The critical importance of solvent effects was demonstrated during a systematic survey of direction in heterogeneous hydrogenation.[69] In the case of **55a**, the proportion of *syn*-isomer increased from 39% in hexane to 94% in ethanol on using Pd/C; a very similar trend was observed with Pt/C. By comparing substitution effects under standard conditions—see **55a–e** and **56a–d**—an order of haptophilicity towards the catalyst surface was derived with $CH_2NH_2 > CH_2OH \gg CO_2^{\ominus}M^{\oplus} > CO_2H > CO_2Me$.[70] For 2-substituted-7-methylenenorboranes only the CH_2NH_2 group gave any semblance of a directing effect.

Finally, there is an interesting recent example of diastereoselectivity in the hydrogenation of α,β-unsaturated amides in presence of Pd/C using a chiral auxiliary derived from camphor,[71] a system where reduction by H_2 and catalyst **C** gave poor stereochemical control. The success of this hydrogenation of the amides **58** is attributed to coordination of the SO_2-group of the acylsultam to the metal surface, and steric constraints then favor hydrogen delivery to the α-*re*-face of the olefin.

9. Summary

In the context of directed hydrogenation it was stated as recently as 1983 that "only scattered reports have appeared which suggest the possibility of this kind of control in a hydrogenation reaction."[12] Three years later it is fair to say that the method is well-established and affords a particularly simple route to diverse types of structure with

Much of the authors' research presented here was conducted with SERC support, which is gratefully acknowledged. Enthusiastic co-workers have contributed greatly to the development of the project, especially Dr. Ian Cutting, Mr. Phillip L. Evans, Dr. Stephen A. Hall, Dr. Alun P. James, Mr. Peter Maddox and Dr. Ramachandra Naik. Dr. Naik made the early observations on which subsequent work was based.

New Reductive Transformations of Unsaturated Cyclic Hydrocarbons

New Synthetic Methods (66)

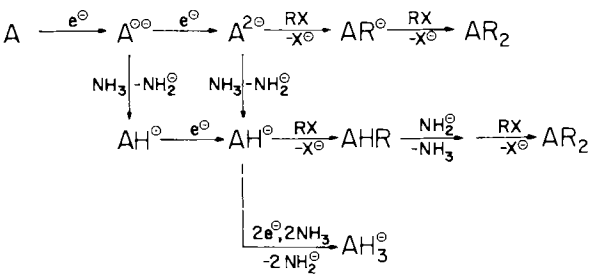
By Klaus Müllen*

The successive reduction of fully conjugated cyclic hydrocarbons leads to singly and multiply charged ions with unusual bonding. The charge distribution in these ions can be determined spectroscopically, and the information so obtained is then used in kinetically-controlled trapping reactions for the regioselective introduction of electrophilic groups. When non-benzenoid substrates are used, syntheses become possible which can either not be carried out or can only be carried out with great difficulty in other ways. Examples of new preparative applications are cycloannelation and bridging reactions as well as polymerization reactions. The ion pair structure of the intermediate and the type of electrophile used are of paramount importance in controlling the mechanism of these reductive transformations.

1. Formation and Reactions of Charged Hydrocarbons

The carbanions arising from electron transfer reactions of fully conjugated cyclic hydrocarbons can readily be trapped by electrophiles. Depending on the type of reagent used, the overall reaction can be a reduction or reductive alkylation,[1,2] but arylation,[3] acylation,[4] silylation[5] or cyanation[6] is also possible.[7] The preparative importance of such reactions lies in the fact that unsaturated hydrocarbons can be modified in a highly selective manner under mild conditions. The selectivity includes not only the position of attack, but also the number of electrophilic reagents which are introduced. There is a large number of experimental possibilities for the reduction of the unsaturated starting material and also for the trapping of the ionic intermediate;[8-14] variation of the method used is well known to change the product spectrum, often radically. However, because factors such as counterion, solvent and temperature have a determining influence on the structure and stability of the ion pairs which are the primary products, it should be useful for the control of the trapping reaction to characterize the labile carbanions in situ using spectroscopic techniques.[15]

It must first be determined which carbanion in the complex overall reaction is actually trapped. Electron transfer can convert the substrate A into a radical anion $A^{\odot\ominus}$ or a dianion $A^{2\ominus}$, and both ions can then react with an electrophile RX (see Scheme 1). However, in liquid ammonia both species can first be protonated by the solvent, so that the types of product and the mechanisms of their formation can vary.[16]



Scheme 1. Mechanisms of the reductive alkylation of a cyclic conjugated hydrocarbon in liquid ammonia.

The second important piece of information is the charge distribution in the π-delocalized carbanions, since the kinetically controlled attack of an electrophile will occur preferentially at the position of highest electron density.[16-18] The synthetic applications of reductions in liquid ammonia have been described in several review articles.[2,9,19-21] The correlation between preparative and mechanistic results which is intended here has three advantages over empirical procedures:

1) Only the knowledge of the π-charge distribution in the ionic intermediate makes it possible to forecast the regioselectivity of the trapping reaction.
2) Such structural information can be taken as a basis for attempts to use new hydrocarbons as substrates for unconventional reductive transformations.
3) When a dianion $A^{2\ominus}$ is dialkylated to AR_2, the intermediate $AR^{\ominus}$ can also be observed spectroscopically. The preparative importance of the separate control of the first and second alkylations will make itself particularly felt when dianions are reacted with bifunctional electrophiles.

The present paper can thus be divided into a section dealing with the structure determination of π-delocalized paramagnetic and diamagnetic carbanions (Section 2) and further sections (Sections 3-6) dealing with preparative applications resulting from the structural information.

2. The Structures of Charged π-Systems

2.1. Highly Charged Ions

The "combined" approach assumes the formation under mild conditions and the detailed spectroscopic characterization of charged hydrocarbons.[22-25] The experimental description of an extended redox sequence is shown in

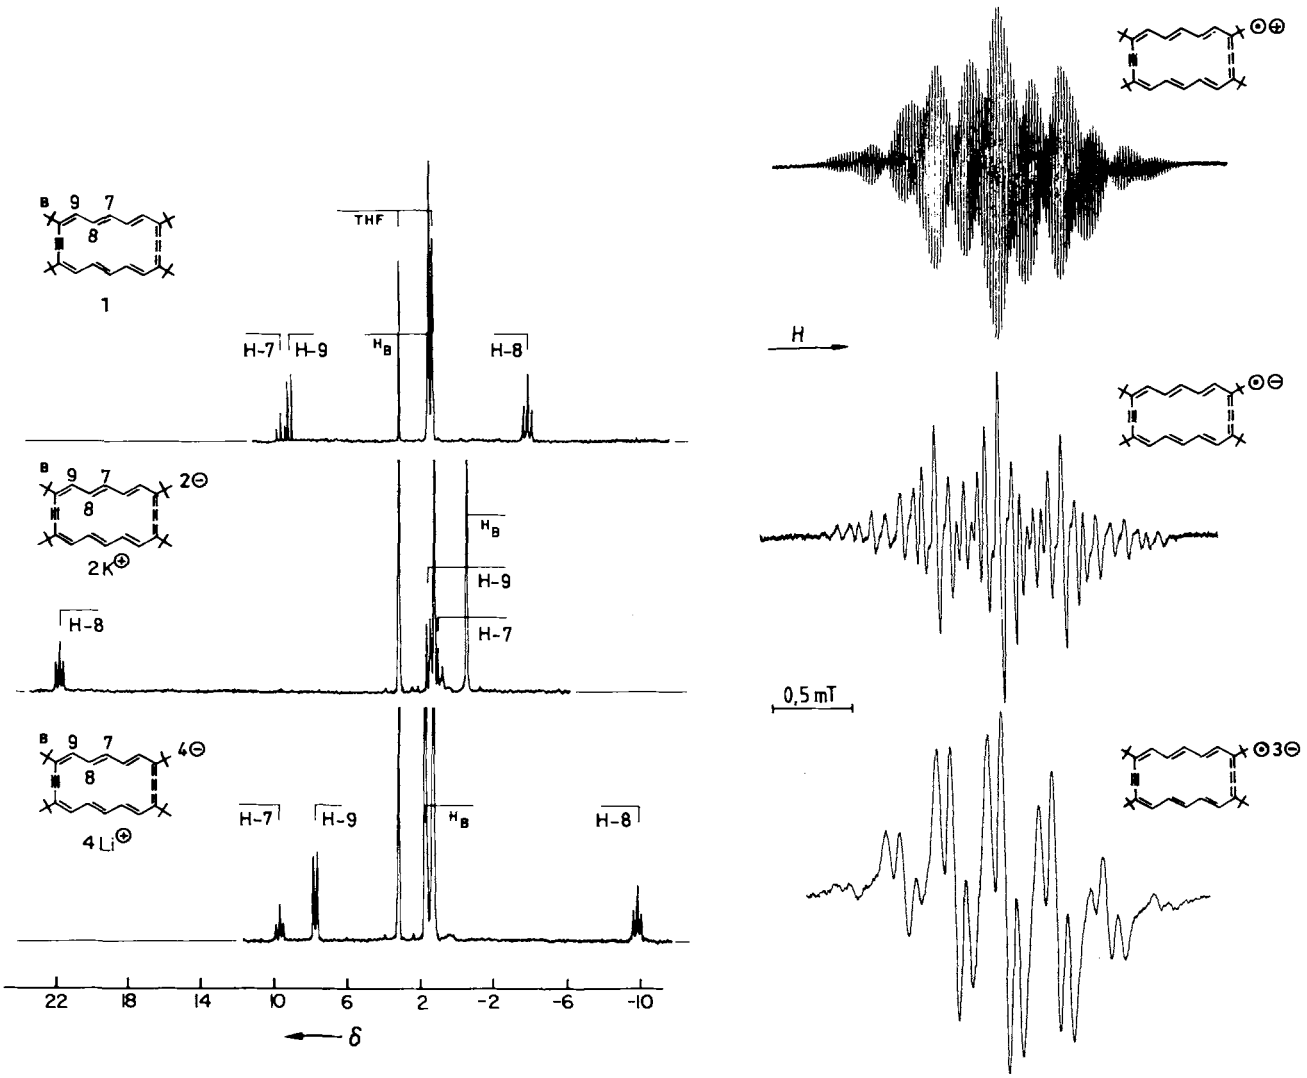

Fig. 1. Ionic species of the [18]annulene derivative **1**. The diamagnetic systems (neutral compound, dianion, tetraanion) are characterized by ^{1}H-NMR spectroscopy (on the left), the paramagnetic systems (radical cation, radical anion, radical trianion) by ESR spectroscopy. The reduction was carried out using lithium or potassium in tetrahydrofuran, the oxidation with aluminum(III) chloride in dichloromethane.

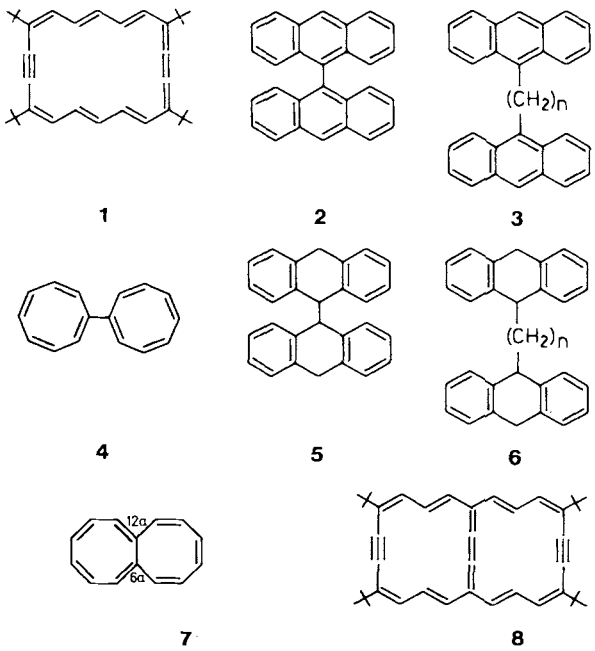
Figure 1 for the example of [18]annulene **1**. Careful control of the redox process makes it possible to characterize the diamagnetic systems (neutral starting material, dianion, tetraanion) as well as the paramagnetic systems (radical cation, radical anion, radical trianion) by means of well-resolved proton NMR or ESR spectra.

The formation of tetraanions from the hydrocarbons **2**,[26] **3**,[27] or **4**[28] appears plausible, since they are built up from separate π-systems and since the monomeric units can form dianions. The selectivity of the protonation of, for example, $2^{4\ominus}$ and $3^{4\ominus}$ to **5** or **6** corresponds to that found for anthracene. In the case of the annulenoannulenes **7**[29] and **8**,[30] which consist of two condensed rings, the formation of stable tetraanions can be explained by the particular redox properties of the sub-rings. In contrast, the formation of a tetraanion from [18]annulene **1**[31,32] can only be explained by assuming that the increase in the electron-electron repulsion is compensated not only by ion-pair effects[32,34] but also by a conjugative stabilization of the π-system.[33,35,36] Cyclovoltammetric studies show that the reduction of the radical anion $1^{\odot\ominus}$ to the di-, tri-



1 2 3 4 5 6 7 8

and tetraanions occurs over a very small total potential range of less than 0.1 V.[31] Electrostatic considerations alone would have led us to expect considerably larger potential differences when the charge is increased; in the case of reduction of benzenoid compounds, the mono- and dianions are indeed separated by about 0.5 V.[24] Thus if during the annulene reduction the ion pair energies do not change drastically, it follows that the increase in the electron-electron repulsion is partially compensated by conjugation.[29,35]

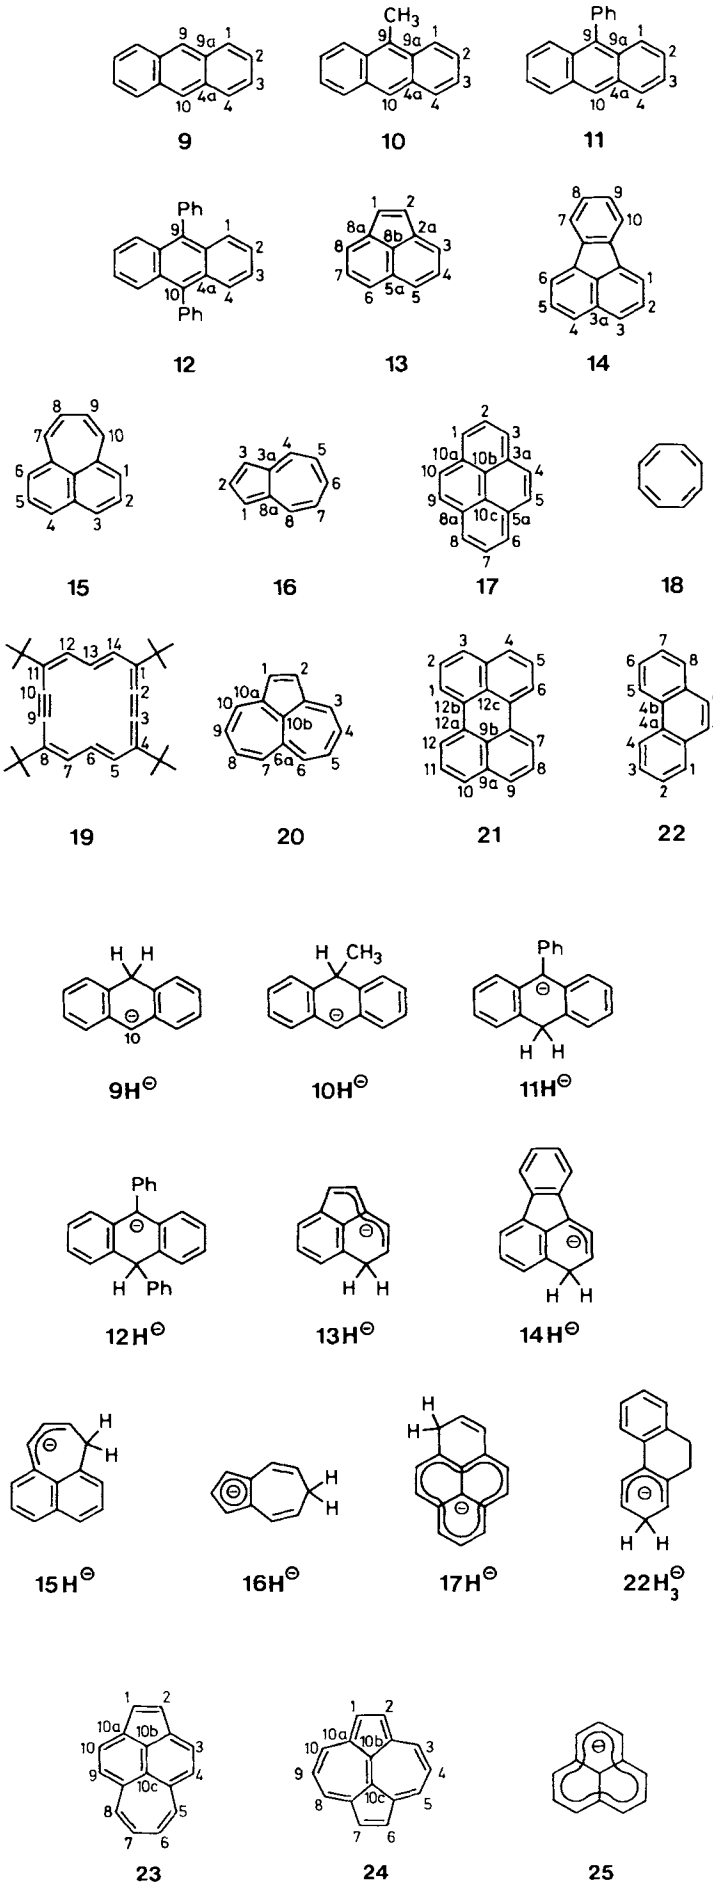
2.2. Charge Distribution and Ion Pair Structure

The ESR spectroscopy of paramagnetic π-systems (e.g. of the mono- and trianions formed in a reduction process) allows us to determine proton hyperfine coupling constants, with the help of which the local spin density at the neighboring π-center can be estimated.[37] Similarly, the NMR treatment of diamagnetic ions often shows a linear correlation between proton or carbon-13 chemical shifts and local π-charge densities.[39,40,44] There is no cogent theoretical justification for this correlation; furthermore, its application requires that other effects such as ring current and ion pair phenomena or the structure dependence of the proportionality constant K_c[45] be taken into account. In spite of this, the NMR-spectroscopic determination of local π-densities (particularly in a series of structurally related systems) can be considered to be a reliable method in the sense of a heuristic principle.

Using a simple MO model, the spin density at the π-center of a paramagnetic π-system is calculated from the square of the AO coefficient in the singly occupied molecular orbital and thus from the π-charge density.[37] The practical result of such a procedure is that the symmetry of the newly occupied frontier orbital in the monoanion can be estimated from spectroscopic parameters, or that vice versa the expected spin or charge density can be estimated from a knowledge of the MO's involved.[38] Making the plausible assumption that the doubly occupied HOMO in $A^{2\ominus}$ is identical to the singly occupied HOMO in $A^{\odot\ominus}$, the spin density distribution in $A^{\odot\ominus}$ can also be used to estimate the expected charge density distribution in $A^{2\ominus}$.[24,41-43]

The total range of the carbon-13 NMR signals of the anthracene dianion $\mathbf{9}^{2\ominus}$[46,47] (lithium salt, tetrahydrofuran [THF]) is much larger than that in the neutral compound, and suggests an inhomogeneous charge distribution in the ionic π-system. The sequence of the charge densities resulting from the relative ^{13}C-NMR chemical shifts q_π(C-9) $> q_\pi$(C-1) $> q_\pi$(C-2) agrees with the sequence of the spin densities for the corresponding radical anion determined by ESR spectroscopy and corresponds to the AO coefficients in the newly-occupied frontier orbital. The existence of a positive partial charge at the quaternary positions in the dianion is indicative of the character of the charge distribution.[48,49]

In the case of benzenoid substrates, it has been predicted from MO models that the excess charge is localized at certain positions; this has been demonstrated by ^{13}C-NMR spectroscopy, since the corresponding signals are shifted to higher field. This is also observed for the non-benzenoid octalene dianion $\mathbf{7}^{2\ominus}$;[29] here the highest local



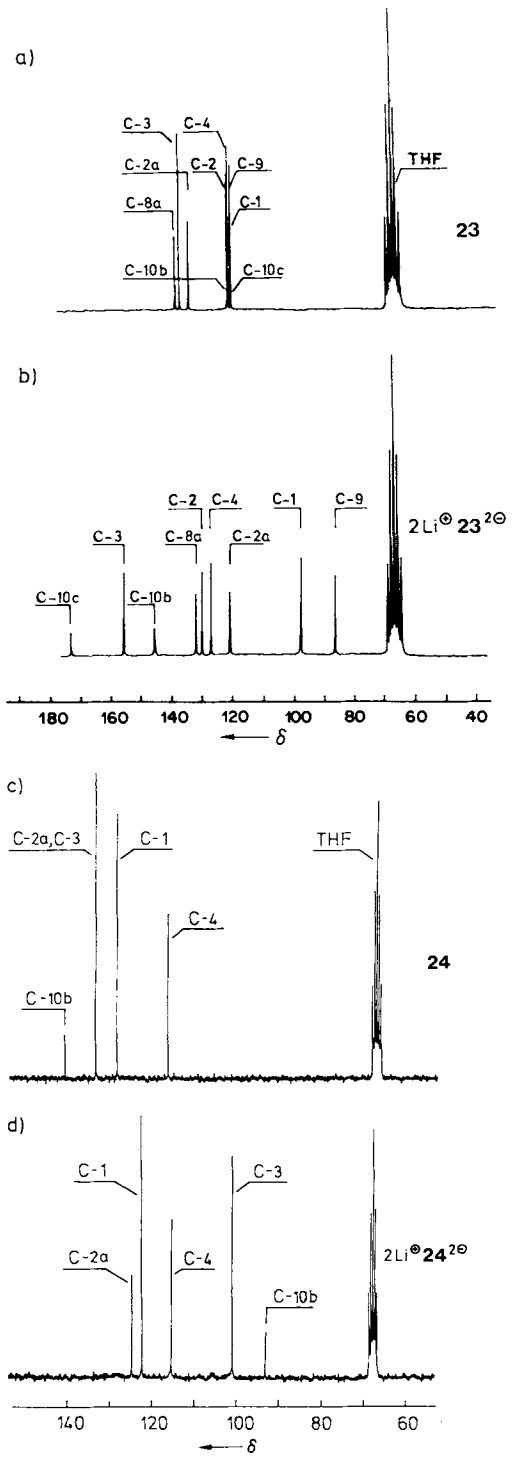


Fig. 2. ^{13}C-NMR spectra of a) cyclohepta[*de*]cyclopenta[*ij*]naphthalene (**23**) and b) its dianion ([D$_8$]THF, lithium salt); c) ^{13}C-NMR spectra of dicyclopenta[*ef*,*kl*]heptalene (**24**) and d) its dianion ([D$_8$]THF, lithium salt).

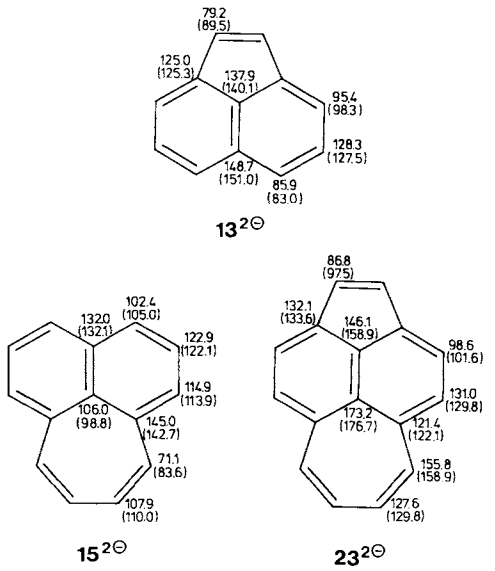
charge density is to be found at the two neighboring quaternary centers C-6a and C-12a.

The radical anions and dianions of pyrene (**17**) and its isomers **23**[50] and **24**[51] differ considerably in the distribution of their spin and charge.[17,52–54] A simple MO model predicts a high charge density at the "inner" ethylene group only for $24^{2\ominus}$, while in $17^{2\ominus}$ and $23^{2\ominus}$ this bridge is not expected to accommodate any excess charge. This difference, which results from the nodal properties of the frontier orbitals, is confirmed by the high-field shift $\Delta\delta_c = -47$ ppm in $24^{2\ominus}$ and the low-field shift $\Delta\delta_c = +50$ ppm in $23^{2\ominus}$ (see Fig. 2) observed on the formation of the dianions.[15,33]

The tricyclic compound aceheptylene (**20**)[55] is structurally related to **24**. From the nature of the LUMO we expect that the reductive formation of a dianion will lead to a pronounced accumulation of charge at the inner angular center. This prediction can be experimentally verified by the drastic high-field shift of the corresponding ^{13}C-NMR signal of more than 60 ppm.[56,57] The charge distribution in $20^{2\ominus}$ is different from that in a related tricyclic compound, the phenalene anion **25**: in **25** there is *no* excess charge at the central position, as can readily be predicted from the nature of the frontier orbital.

The description of π-delocalized anions[59] must also take into account the structure of the ion pair and thus the role played by the counterion and the solvent.[60] Crystal structures of the alkali metal salts show that the counterions are located above or below the systems; in the case of polycyclic substrates they lie preferentially above certain rings.[61–64] A further complication to be considered is that the ion pairs may form aggregates in solution, and that the π-charge distribution predicted by a frontier orbital treatment can be modified by the effects of the counterions. The polarizing effect of the counterions leads to a further increase in the *a priori* high local charge density (see Scheme 2),[15] the influence of the small lithium cation in a contact ion pair being the largest. Even more drastic is the effect of the counterion on going from dilithium to magnesium anthracenediide, as can be shown by ^{13}C-NMR spectroscopy[65]. While $2\,Li^{\oplus}/9^{2\ominus}$ can be described as an ionic system, the corresponding magnesium derivative has a stronger covalent bond between the metal and the centers C-9 and C-10. The result is a considerably smaller excess charge at the terminal benzene rings than in the dilithium salt.



Scheme 2. ^{13}C-NMR chemical shifts (δ_c) of the polycyclic dianions $13^{2\ominus}$, $15^{2\ominus}$, and $23^{2\ominus}$ as lithium and (in brackets) potassium salts ([D$_8$]THF, −30°C).

The structure of the ion pair also influences the reactivity of the substrate, as can readily be shown by the protonation of certain dianionic π-systems occurring in liquid ammonia (see Section 1.3). The acenaphthylene dianion ($\mathbf{13}^{2\ominus}$) is stable in NH_3 as its dipotassium salt.[16] However, the dilithium salt is converted quantitatively into the monoanion $\mathbf{13H}^{\ominus}$, as can be shown spectroscopically. Because of the stronger eigensolvation of $Li^{\oplus}$, the amount of solvent-separated ion pairs increases, and as a result the basicity of the dianion is also increased. The frequently observed temperature dependence of reductive transformations can be interpreted in a similar way as a change in the structure of the ion pair.[66-68] It is generally true that the existence of free ions or of solvent-separated ion pairs is favored at lower temperatures.

2.3. Electron Transfer and Protonation in Liquid Ammonia

The NMR- and ESR-spectroscopic observation of their reduction in liquid ammonia shows[16] that a certain group of unsaturated hydrocarbons, **9**–**17** (group 1), are rapidly protonated subsequent to the electron transfer and thus converted into monoanions; in contrast, the dianions $\mathbf{18}^{2\ominus}$–$\mathbf{21}^{2\ominus}$ of another group, **18**–**21** (group 2) remain unchanged. The following observations should be noted:

1) In each case only one single hydroproduct, $\mathbf{9H}^{\ominus}$–$\mathbf{17H}^{\ominus}$, is formed. The constitution of these anions can be determined from spectroscopic measurements.

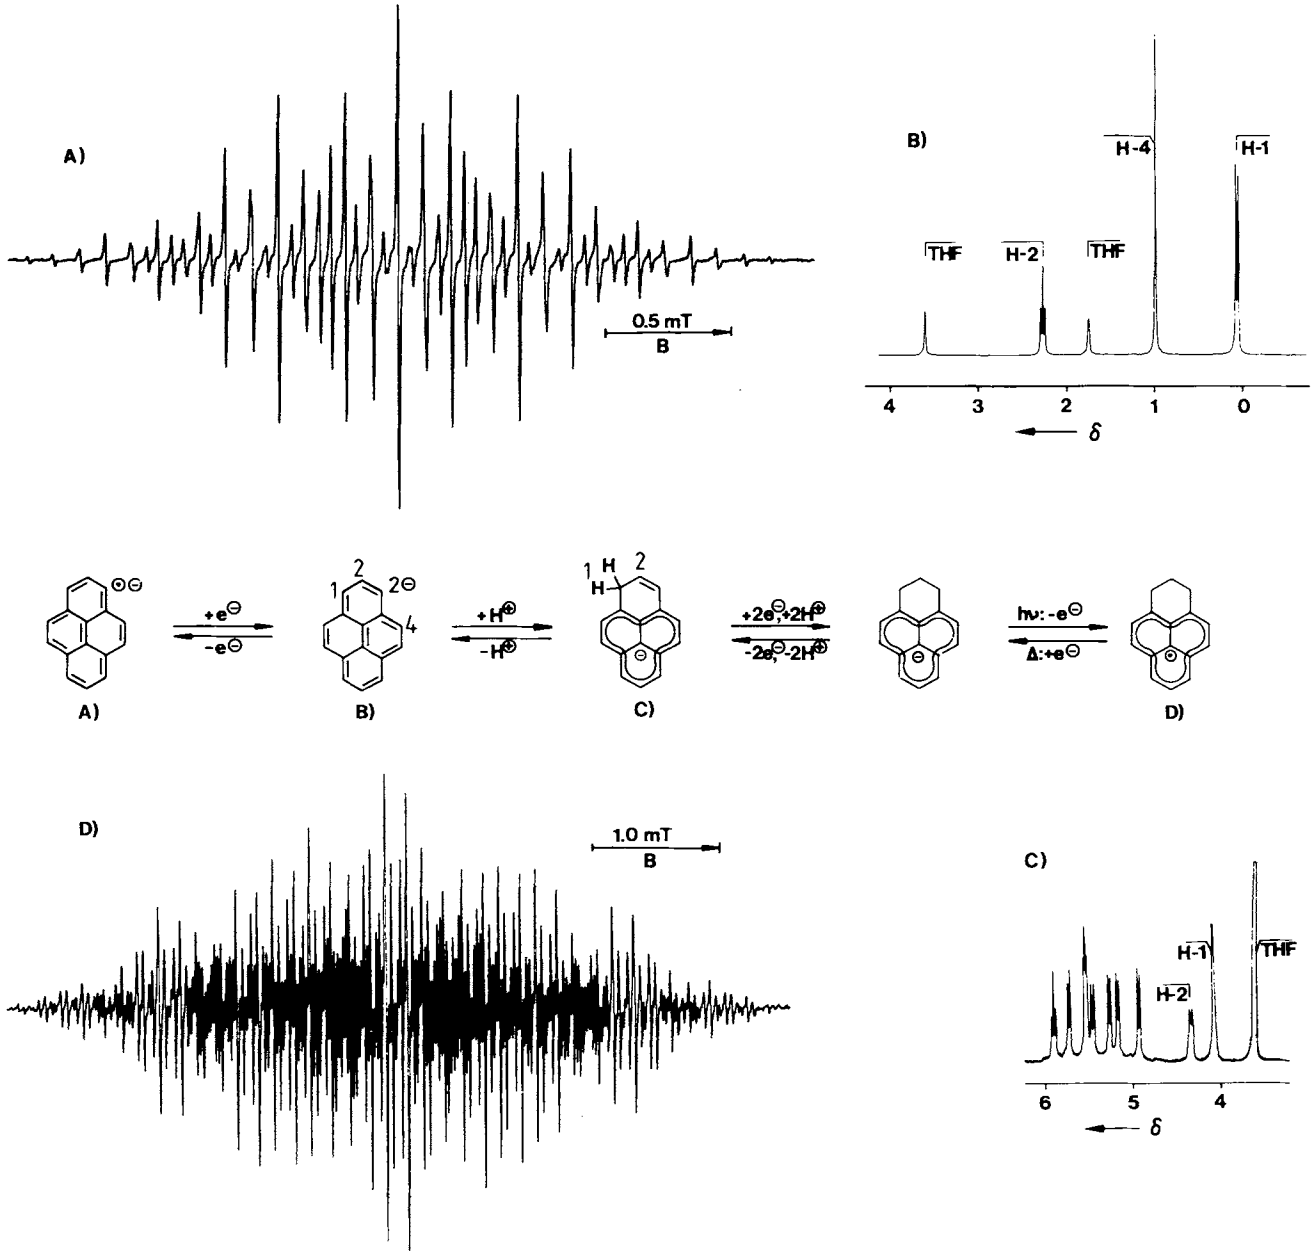


Fig. 3. ESR and ^{1}H-NMR spectroscopic monitoring of the reduction of pyrene (**17**) in liquid ammonia.

2) If there is an equilibrium between monoanion and dianion, the concentration of the latter is too low for it to be detected.
3) The protonation observed is that of the dianion: the corresponding radical anions are stable under the reaction conditions.

Figure 3 demonstrates the spectroscopic observation of the reduction using pyrene (**17**) as an example.

Phenanthrene (**22**) shows a third type of behavior, since in liquid ammonia it forms the trihydro-monoanion $\mathbf{22H_3^{\ominus}}$, even when only two equivalents of alkali metal are used.[18]

The basicity of the dianions can be assessed from the atom localization energies,[69] which result from the difference between the π-energy of the dianion and of the monoanion formed by its protonation. The experimental results can be explained on the basis of the difference between the types **9**-**17** and **18**-**21**; this difference can also be used to predict the behavior of other substrates.

3. Reductive Alkylations using Monofunctional Reagents

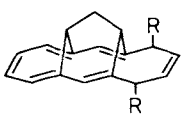
3.1. Benzenoid Hydrocarbons

When hydrocarbons of group 1 (substrates **9**-**17**) are alkylated in liquid ammonia, the protonation (with formation of $\mathbf{9H^{\ominus}}$-$\mathbf{17H^{\ominus}}$) always occurs at the position of highest charge density. In the case of pyrene (**17**) this is position 1. The dianion $\mathbf{17^{2\ominus}}$ is also attacked in this position in non-protic solvents.[16,17,90,91] When **17** is reductively alkylated in NH_3, however, the substrate to be alkylated is no longer $\mathbf{17^{2\ominus}}$ but $\mathbf{17H^{\ominus}}$. As the constitution of the products shows, the electrophile attacks at position 5 in the second ring. Such possibilities of controlling the regioselectivity of the reductive alkylation simply by the choice of solvent also occur in other cases, azulene (**16**) being a typical example.[70-72]

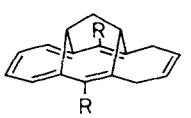
Anthracene (**9**) is a special case: preliminary considerations would indicate that the dianion $\mathbf{9^{2\ominus}}$ and the protonated monoanion $\mathbf{9H^{\ominus}}$ should both be attacked at C-10 of the central benzene ring, so that the choice of solvent will not be relevant to the constitution of the monoalkylhydro derivative produced. In fact, however, only $\mathbf{9H^{\ominus}}$ is attacked at C-10 with high selectivity;[3,23,73-75] the dianion $\mathbf{9^{2\ominus}}$ (THF) is in contrast attacked at C-9(10) as well as at C-1.[76-81]

26

27



28

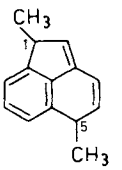


29

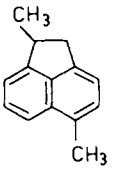
a: R = CH_3 ; **b**: R = $COOCH_3$

ESR[83] and NMR[84,85] spectroscopic results show that the radical ions and dianions of anthracene (**9**) and the bridged [14]annulene **26**[82] have frontier orbitals of the same symmetry type. Reductive alkylation of **26** (NH_3, Li, CH_3Br) gives a 3:1 mixture of the dimethyl adducts **27a** and **28a** in nearly quantitative yield.[84] The positions of attack are as expected, though the regioselectivity of the reaction is apparently less than for anthracene. This can be explained by the fact that $\mathbf{26^{2\ominus}}$, in contrast to $\mathbf{9^{2\ominus}}$, is not protonated by ammonia (see Section 2.3). If a solution of $2\,Li^{\oplus}/\mathbf{26^{2\ominus}}$ in tetrahydrofuran is treated with methyl chloroformate, the products **28b** and **29b** are formed. **29b** is apparently formed from **27b** by a base-induced hydrogen shift. The dihydro derivatives **27**-**29** can be readily dehydrogenated to the corresponding annulenes. This type of reaction is worthy of note, since the direct alkylation and acylation of the annulene is not possible.

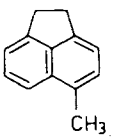
The limits of the use of spectroscopic information are evident from the example of acenaphthylene (**13**). Doubly negatively charged ions $A^{2\ominus}$ react much more rapidly with an electrophile than do singly charged ions such as $AH^{\ominus}$ or $A^{\odot\ominus}$. It is thus in principle possible that $A^{2\ominus}$, although present in a much smaller equilibrium concentration which cannot be detected by spectroscopic means, is the substrate for the primary alkylation step. When **13** is reductively dialkylated in THF, the product formed is as expected **30**, which readily rearomatizes to **31** by means of a proton shift.[86-88] When NH_3 is used as the solvent, the products



30



31



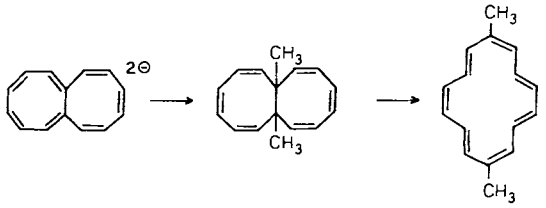
32

obtained are those of a primary alkylation at C-1 as well as at C-5.[89] The formation of **32** observed when methyl iodide is used as the trapping reagent cannot be explained as being due to alkylation of the monoanion $\mathbf{13H^{\ominus}}$ which is the only species observed spectroscopically, but indicates the participation of $\mathbf{13^{2\ominus}}$.[89]

The conclusions from a mechanistic consideration of reductive transformations force a reinterpretation of a number of preparative results.[20,90,91] We shall now proceed to consider new reductive alkylations using *non-benzenoid* starting materials.

3.2. Octalene

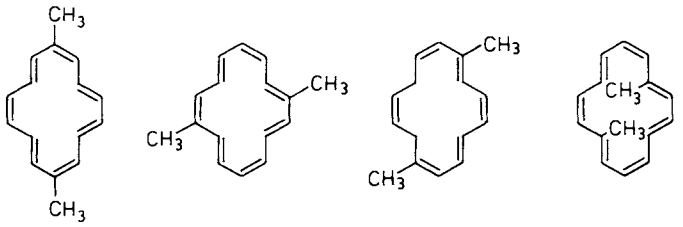
The highest charge density in the octalene dianion ($\mathbf{7^{2\ominus}}$) is at the two bridgeheads.[29] The attack of the electrophile in methylation (dimethyl sulfate, −78°C) also occurs at these positions. However, the primary bicyclic diadduct **33** is not isolated, but instead a [14]annulene, **34**, is obtained; this is formed by an electrocyclic ring-opening (see Scheme 3).[92] In spite of the difficult synthesis of **7**, this route to **34** is useful, even though the yield of the trapping reaction is only 25%. In addition, the formation of the dial-



$7^{2\ominus}$ 33 34a

Scheme 3. The reductive alkylation of octalene 7 via the dianion $7^{2\ominus}$.

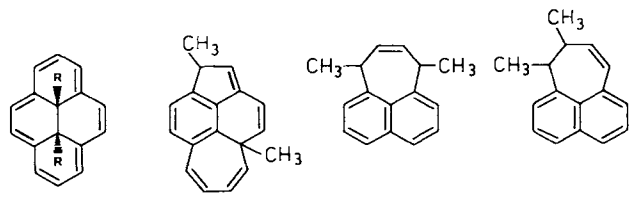
kyl derivative (see isomers **34a–34d**), which is not obtainable by other routes, gives us information on the much-discussed[93,94] conformational transformations in annulenes.[92]



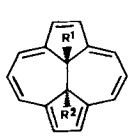
34a 34b 34c 34d

3.3. Pyrene Isomers

Pyrene (**17**) and its isomers **23** and **24** can formally be described as ethylene-bridged 14-center perimeters. The products of the reductive alkylation of pyrene (**17**) mentioned above do not indicate any attack at the inner double bond, a result which is not surprising in view of the charge distribution in $17^{2\ominus}$. The "adduct" **35**[95–97] can only be obtained from a completely different multi-step synthesis. The dimethylation of the isomeric dianion $23^{2\ominus}$ leads to the adduct **36**.[15,33] The kinetically-controlled primary attack occurs at the quaternary position C-4a, the π-conjugation of the naphthalene moiety being destroyed. The reductive formation of **36** corresponds exactly to the conversion of acenaphthylene (**13**) into the diadduct **30**.[86,87] In contrast, the derivative **15**,[15,98] which is structurally related to **23** undergoes alkylation in its seven-membered ring during the reductive transformation, giving products **37** and **38**. These results can readily be explained on the basis of the frontier orbitals involved: the LUMO's of **13** and **23** have the same symmetry, with a nodal plane passing through the central quaternary C-atoms; the LUMO of **15** is different (see Scheme 4).[15,53]



35 36 37 38



39

a: $R^1 = R^2 = CH_3$

b: $R^1 = R^2 = (CH_2)_nX$; n = 2, 3, 8; X = Hal

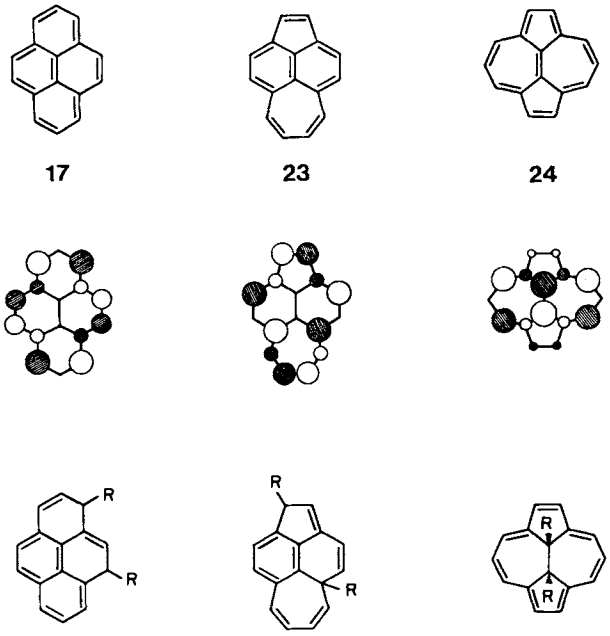
c: $R^1 = CH_3$, $R^2 = H$

d: $R^1 = CH_3$, $R^2 = (CH_2)_3CH_3$

e: $R^1 = CH_3$, $R^2 = (CH_2)_3CH_2Br$

If however the charge distribution in the dianion controls the attack of the electrophiles, then the system $24^{2\ominus}$ (isomeric with $17^{2\ominus}$ and $23^{2\ominus}$) should be suitable for the direct synthesis of a bridged 14π-perimeter, since the highest charge density is localized at C-10b and C-10c. The reaction with alkylating agents gives adducts of type **39** in 60–80% yield.[99–101] This simple annulene synthesis, which starts from a readily prepared material,[51] can be easily modified by varying the electrophile since linear alkyl groups, acyl residues, hydrogen or functionalized alkyl groups can be introduced.[99–101]

In this way it is possible to synthesize substrates which are "tailor-made" for investigating questions on the theory of bonding.[100] From a preparative point of view it is important that the method of reductive alkylation permits an easy manipulation and functionalization of the bridging groups in annulenes, thus paving the way for other synthetic applications (see Sections 5 and 6).

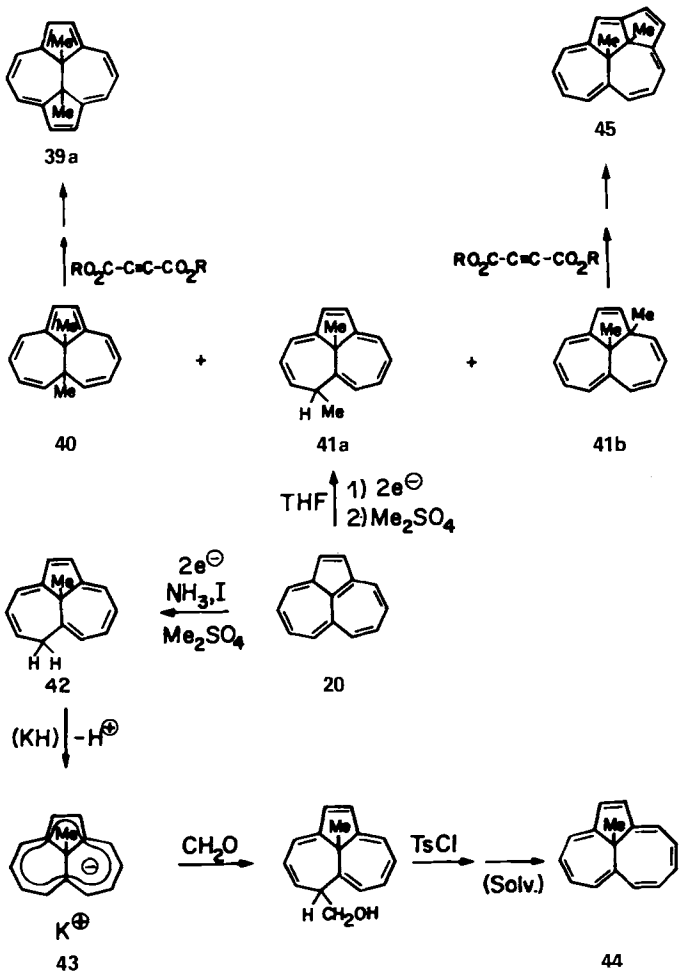


17 23 24

Scheme 4. The reductive alkylation of the pyrene **17** and its isomers **23** and **24**. Top: starting material; center: schematic representation of the LUMO; bottom: products.

3.4. Aceheptylene

The method described above for choosing new substrates for unconventional alkylations leads from the use of a simple MO model via the spectroscopic characterization of the ionic intermediates to preparative applications. This procedure will now be applied to the tricyclic compound aceheptylene (**20**). According to predictions based on spectroscopic measurements $20^{2\ominus}$ should be attacked electrophilically at the central position 10b (in contrast to, say, the phenalene anion **25**[102]). The reaction of $20^{2\ominus}$ with dimethyl sulfate at −20°C in THF does indeed give a



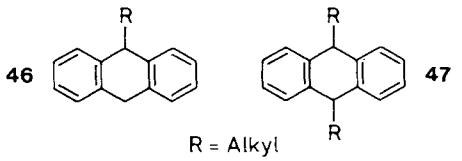
Scheme 5. The reductive alkylation of aceheptylene (**20**) and the further chemical transformations of the trapping products.

mixture of the three dimethyl adducts **40**, **41a**, and **41b** (which can be separated chromatographically); in each case one methyl group has been introduced at the central position (see Scheme 5).[56] If $\mathbf{20}^{2\ominus}$ is trapped with dimethyl sulfate in liquid ammonia instead of in THF, the monomethylation is followed by a rapid protonation, due to the ammonolysis of the dimethyl sulfate occurring in the reaction medium.[103]

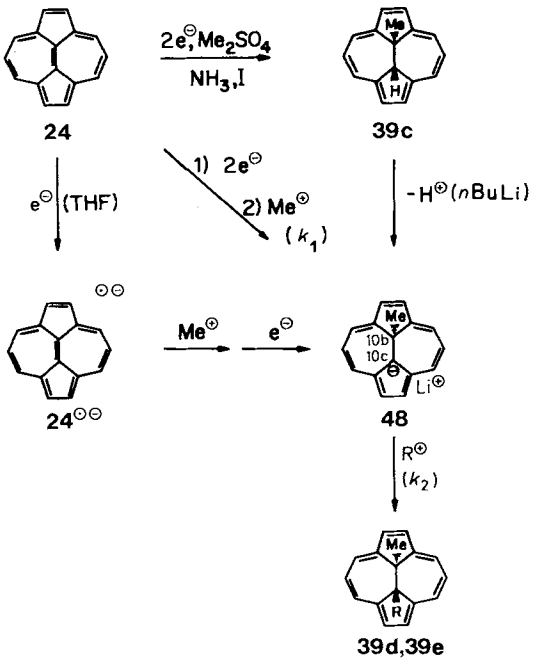
The sole product (89% yield) of this reaction is the derivative **42**, which can now be used for further synthetic transformations. Thus its deprotonation gives the strongly diatropic monoanion **43**, the first 14π-homologue of the cyclopentadienide anion.[104] Hydroxymethylation of **43** with formaldehyde and solvolytic ring-expansion of the corresponding tosylate yield a new methine-bridged [14]annulene **44**,[98,105,106] which is an extension of the series of structurally related 10π-[107] and 12π-systems[108] (though the latter were prepared in completely different ways). Finally, **40** and **41b** react with the diester of acetylenedicarboxylic acid[109] by a [12+2]-cycloaddition process, giving (after decarboxylation) the π-systems **39a** and **45**.[106] Common to these new systems is that they can all be derived from a readily-available trapping product and that, as originally intended, angular positions have been substituted by means of reductive alkylations.[110,111]

4. The Multistep Mechanism of Reductive Alkylations

When a dianion $A^{2\ominus}$ is converted into a diadduct AR_2, only the entry of the first electrophile can be described on the basis of the charge distribution in $A^{2\ominus}$: the second attack is determined by the charge distribution in the intermediate anion $AR^{\ominus}$. It is thus advisable to include the spectroscopic characterization of this species in the study of the two-step mechanism. The anion $AR^{\ominus}$ can be obtained either directly by monoalkylation of $A^{2\ominus}$ or by deprotonation of a monoalkyldihydro derivative AHR. Comparable studies have been carried out for deprotonation and alkylation reactions starting from the dihydroanthracene derivatives **46** and **47** as well as from the analogous phenanthrene systems.[18,22,73,75,112–114]



The formation of **40**, **41a**, and **41b** in the methylation of $\mathbf{20}^{2\ominus}$ demonstrates that the monoanionic intermediate **43**, which can also be obtained by deprotonation of **42**, is no longer attacked regioselectively.[56] However, starting from $\mathbf{24}^{2\ominus}$ we obtain only a single diadduct in good yield, via the lithium salt of the monoanion **48**. The analysis of the ^{13}C-NMR spectra of the monoanions **43** and **48** shows the charge distribution to be such that this apparent discrepancy is explained:[115] in the anion **48**, which is readily prepared by deprotonation of **39c** (see Scheme 6), the excess charge is clearly localized at the central position C-10c, so that the selective conversion into the diadducts **39d** or **39e** is to be expected. Since the dianion $A^{2\ominus}$ reacts



Scheme 6. The two-step mechanism of the reductive alkylation, illustrated for the example of dicyclopenta[*ef*,*kl*]heptalene (**24**).

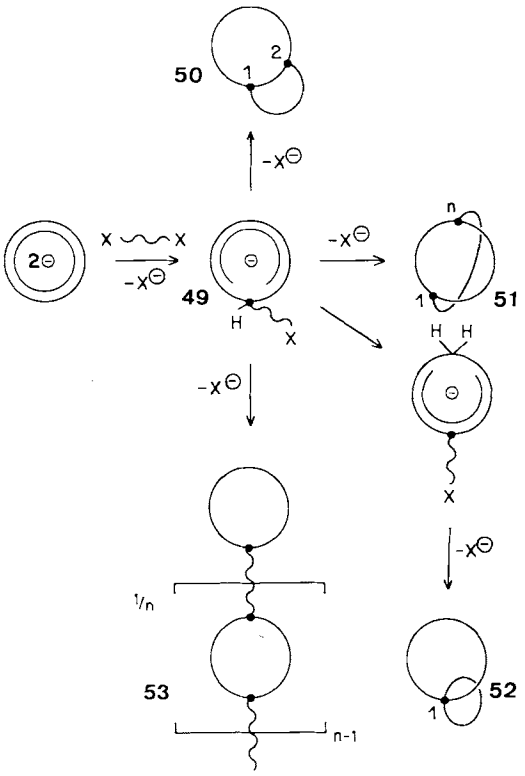
much faster with the electrophile than do either the monoanion $AR^{\ominus}$ or the paramagnetic radical anion $A^{\odot\ominus}$, $AR^{\odot}$ = **48** can be obtained directly from the dianion by using one equivalent of the alkylating agent and then characterized spectroscopically. The consequence for preparative applications (see Section 6) is that diadducts can readily be obtained using two *different* electrophiles.

The in-situ characterization of the monoalkylated ionic species leads to the question of the configuration of the diadduct and thus to the stereochemical course of the second alkylation step. It is known that the reductive alkylation (R = CH_3, C_2H_5) of anthracene gives *cis*-dialkyldihydroanthracenes **47**.[73] However, the diadducts **39**, **40**, and **41b** are *trans*-configurated (the formation of a *cis*-1,2-diadduct is only possible when a bifunctional electrophile is used (see Section 5).[100, 101, 115] The question as to how the course of the trapping reaction is influenced by the structure of the ion pair **48** and by steric hindrance between the electrophile and the alkyl group already present cannot presently be answered decisively.

Any discussion of the two-step mechanism of the reductive alkylation must include the radical anions $A^{\odot\ominus}$ which are formed as intermediates in the production of dianions $A^{2\ominus}$.[8, 80, 117, 118] Reactions of radical anions with electrophiles have in particular been studied in connection with the electrochemical reduction of benzenoid hydrocarbons, whereby the neutral radical $AR^{\odot}$ primarily formed from trapping of $A^{\odot\ominus}$ is at once reduced further at the reduction potential of A to give the anion $AR^{\ominus}$.[8] When the pyrene isomer **24** is reduced electrochemically (acetonitrile, tetra-*n*-butylammonium chloride as supporting electrolyte) in the presence of dimethyl sulfate to the radical anion, the product **39a** (which also results from the alkylation of the dianion in THF) is obtained in 75% yield.[119] One could argue that the generation of a high charge density at the central carbon atoms C-10b/C-10c of the dianion $\mathbf{24}^{2\ominus}$ and at C-10c of the corresponding monoanion **48** is due to the strong polarizing effect of the lithium counterion in a contact ion pair. However, the same regioselectivity is observed when instead of the dianion $\mathbf{24}^{2\ominus}$ the radical anion $\mathbf{24}^{\odot\ominus}$ is used and instead of the small lithium cation the more voluminous, but only weakly polarizing, tetrabutylammonium ion.[119]

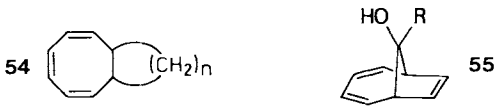
5. Cyclization Reactions using Bifunctional Alkylating Agents

The key ionic intermediate produced in a trapping reaction using *bi*functional alkylating agents can be described by structure **49** (see Scheme 7). The monoanion **49** can undergo a "second alkylation" either at a neighboring position or at a position further removed. In the case of 1,2-attack the result is cycloannelation (product **50**); when the attack is 1,n a bridged product is formed (product **51**).[105] The best-known examples of this type of alkylation come from the chemistry of cyclooctatetraene,[120–122] the dianion $\mathbf{18}^{2\ominus}$ of which gives bicyclo[6.n.0]alkatrienes of the type **54** when allowed to react with 1,n-dihalogenoalkanes.[123–126] 1,4-Attack is not observed, but has been realized for the

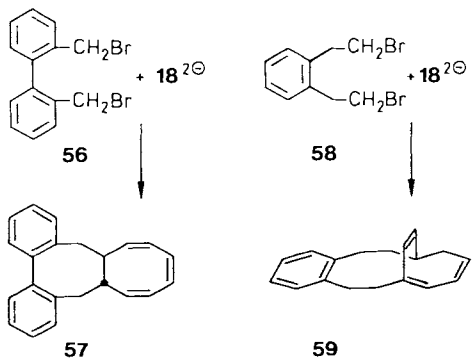


Scheme 7. Reaction between a dianion and a bifunctional electrophile, schematic.

reaction of $\mathbf{18}^{2\ominus}$ with acid chlorides and anhydrides, which give (among other products) bicyclic compounds of the type **55**.[127, 128]

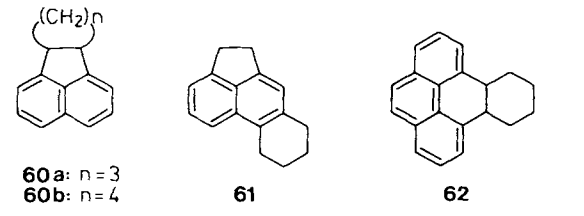


It would be desirable to be able to cyclooctannelate the dianion $\mathbf{18}^{2\ominus}$, giving synthons for new conjugated cyclic π-systems containing a cyclooctatetraene unit. This requires a 1,2-attack by a 1,6-difunctionalized electrophile. The reaction between $\mathbf{18}^{2\ominus}$ and 2,2′-bis(bromomethyl)biphenyl (**56**) does in fact give the desired adduct **57**.[120] While short-chain alkylating agents such as 1,2-dibromoethane give, as expected, only *cis*-configurated products, an X-ray structural analysis of compound **57** shows it to

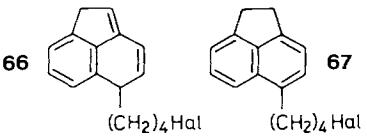


be *trans*. However, when instead of **56** 1,2-bis(2-bromoethyl)benzene (**58**) is used as the alkylating agent, 1,4-attack (followed by a hydrogen shift) occurs, giving **59**.[129]

Reductive alkylations occurring by means of 1,2-attack have also proved themselves useful in the cycloannelation of polycyclic benzenoid compounds: examples are provided by the formation of **60a**, **60b**, and **61** from acenaphthylene[89] and of **62** from pyrene.[90] The syntheses of compounds such as **61** by means of reductive alkylation are clearly superior to other methods for their preparation. Hydrogenated arenes such as **61** and **62** can readily be converted into acephenanthrylene (**63**) or the benzo[*e*]pyrene **64** by dehydrogenation using quinones;[89,90] **63** or **64** are much more readily obtained in this way than for example by means of Friedel-Crafts acylations.

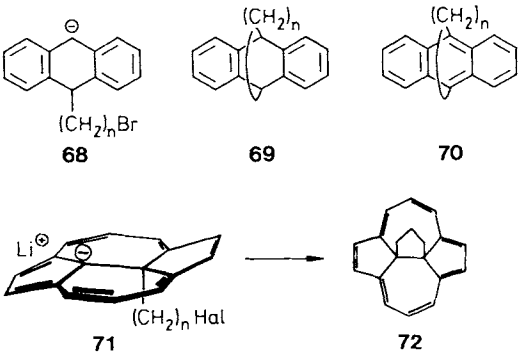


While the adduct **65** is readily cyclized to **62** on the addition of a base, the intermediates produced when the 1-position of acenaphthylene is attacked cannot be detected: only the cyclized products **60a** and **60b** are isolated. In contrast, the primary products **66** and **67** cannot be cyclized, even after addition of base; ring closure can only be carried out starting from **67** by means of a subsequent Friedel-Crafts alkylation.[89]



The monoanion **68** which is formed by the attack of a 1,n-dihalogenoalkane on the dianion of anthracene $\mathbf{9}^{2\ominus}$ is a derivative of the diphenylmethyl anion; as such it has the largest π-charge density at C-10. 1,4-Attack leading to bridged dihydroanthracenes of type **69** is thus favored. In the case of longer-chain bridges (e.g. n = 10), the dihydroanthracenes **69** undergo dehydrogenation to the bridged anthracenes **70**,[130] which are thus readily obtainable via reductive alkylation.

Monofunctional alkylating agents convert the dianion $\mathbf{24}^{2\ominus}$ only into 1,2-adducts with *trans*-geometry. However, when 1,3-dihalogenopropanes are used, the lithium salt of the monoanion **71** (n = 3, Hal = Br) is converted into to the cyclization product **72**.[100] With short-chain alkylating agents ring closure is strongly favored over the formation



of the diadduct **39**; thus the product ratio **72** : **39b** (n = 3, Hal = Cl) is still 2 : 1 even under conditions of inverse addition.[101] Alkylating agents with longer carbon chains (e.g. n = 8) give only the diadduct. If the diadduct is desired as the main product of the reaction with short-chain dihalogenoalkanes (this is important for the formation of functionalized bridging groups), the intermolecular trapping reaction must be drastically accelerated in comparison with the intramolecular process. Thus 3-chloropropyltrifluoromethanesulfonate does indeed give only the diadduct **39b** (n = 3, Hal = Cl).[131]

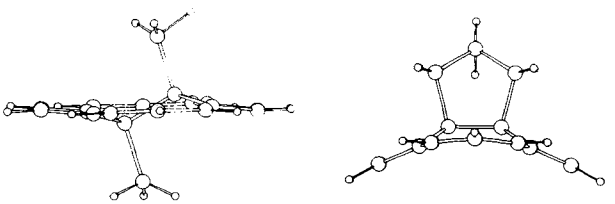


Fig. 4. The crystal structures of the alkylation products **39a** and **72**.

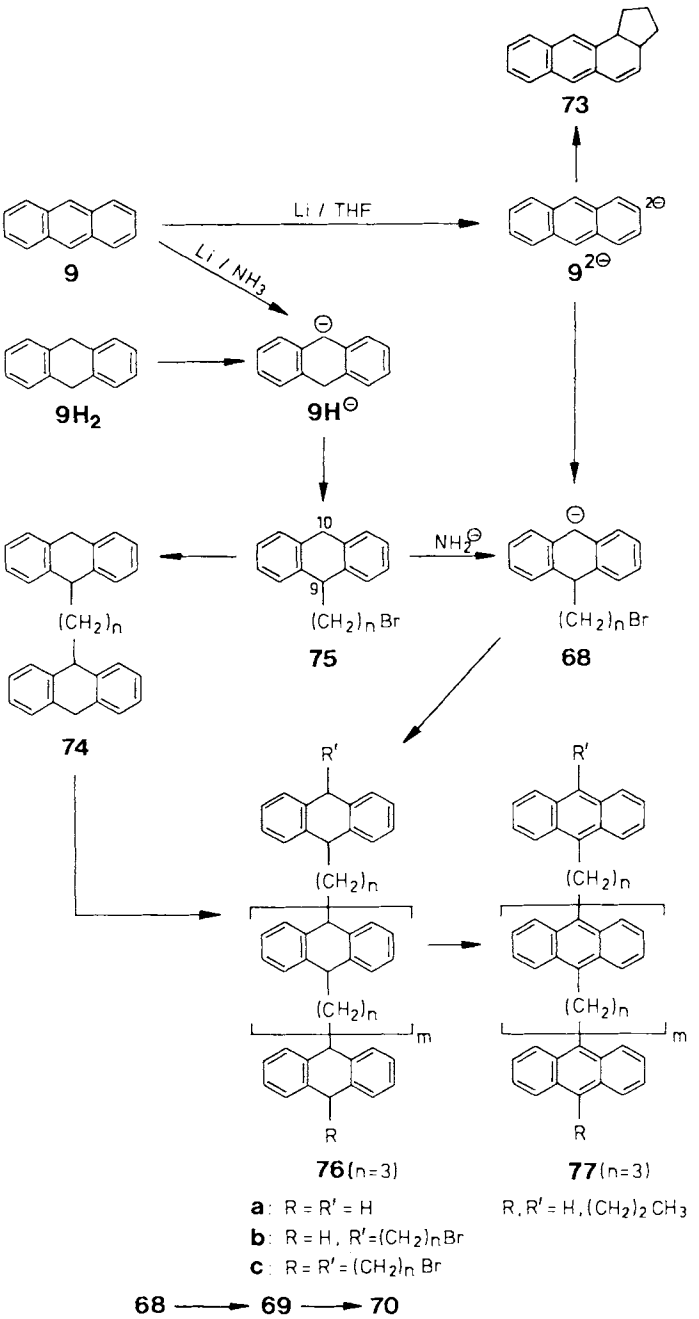
Crystal structures (see Fig. 4) indicate that only the *trans*-bridged annulene **39a** is nearly planar.[100,102] It is thus not surprising that, as shown by NMR, ESR and UV measurements,[100,132,133] compound **72** shows a stronger tendency to double bond fixation. It is important for preparative applications that the preparation of *trans*- and *cis*-bridged perimeters does not require a completely new synthetic approach, but can be made possible by a minor modification of a trapping reaction.

6. Formation of Polymers during Reductive Alkylation

A bifunctional electrophile can attack a dianion in a 1,2- or a 1,n-manner (to give **50** and **51**); apart from spiroannelation (to give **52**) (see Scheme 7),[134,135] the intermediate monoanion **49** has yet another possibility for reaction. If the nucleophilic substitution of the haloalkyl residue by the carbanionic unit occurs intermolecularly rather than intramolecularly, polymers will be formed. In products **53**, dihydro derivatives of the substrate are bridged by polymethylene chains.[79,105,136,137] In the sense of the cycloannelations described previously, this is an unwanted side reac-

tion; however, it can in fact be made useful for preparative purposes. The synthetic possibilities available will be described below taking anthracene (**9**) and dicyclopenta[*ef*,*kl*]heptalene (**24**) as examples.

The complexity of the processes occurring during the reductive alkylation of **9** with bifunctional alkylating agents is shown in Scheme 8. The key intermediates are the 9-(n-bromoalkyl)-9,10-dihydroanthracene **75** and the monoanion **68** formed by its deprotonation. Both species can be produced from anthracene or 9,10-dihydroanthracene in three different ways. When 1,n-dibromoalkane is added to the monoanion $\mathbf{9H}^{\ominus}$, the tetrahydrodianthrylalkanes **74** are formed. As expected, the substituted dihydroanthracenes **75** can be formed by means of inverse addition, i.e. by adding $\mathbf{9H}^{\ominus}$ to a large excess of the alkylating agent.[81] The isolated products **75** can now be converted into the



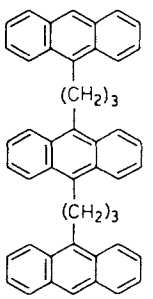
Scheme 8. The reductive transformations of anthracene (**9**).

monoanions **68** by deprotonation. The subsequent reaction of **68** is strongly dependent on the chain length n and the concentration in the reaction medium.[81] As already mentioned, the cyclization products **69**[78,79,81] can readily be obtained under conditions of extreme dilution. The third reaction possibility for **68** and **75** is that of the "polyreaction" to form **76**. Chain formation can be initiated by the linking of two molecules of **68** or by the attack of the nucleophiles $\mathbf{9H}^{\ominus}$ or $\mathbf{9}^{2\ominus}$ on the bromoalkyl residues of **68** or **75**. We have been able to show[81] that **76** is mainly formed via the latter mechanism. A sufficient concentration of the nucleophiles $\mathbf{9H}^{\ominus}$ or $\mathbf{9}^{2\ominus}$ is obtained when **68** or **75** are produced reductively from anthracene.

If the dianion $\mathbf{9}^{2\ominus}$ ($2\,Li^{\oplus}$, THF) is trapped by 1,3-dibromopropane, compounds **9**, **69**, **73** (n = 3) and polymeric material are obtained in yields of 33, 42, 20 and < 5% respectively. Reduction of **9** in NH_3 and alkylation of $\mathbf{9H}^{\ominus}$ give in contrast poly(9,10-dihydroanthrylenetrimethylene) of type **76** in yields up to 90%.[81]

The structures of the polymers of type **76** can be established NMR-spectroscopically. The structural homogeneity of **76** implies that the anthracene systems are linked only at positions 9 and 10. This is due to the extreme selectivity of the reductive alkylation in NH_3 (alkylation of $\mathbf{9H}^{\ominus}$), which is not observed in THF (see above). The fact that the polymer **76** (n = 3) can also be formed by treating the tetrahydrodianthrylpropane **74** (n = 3) with lithium amide and dibromopropane[81] is in agreement with the reaction sequence described here.

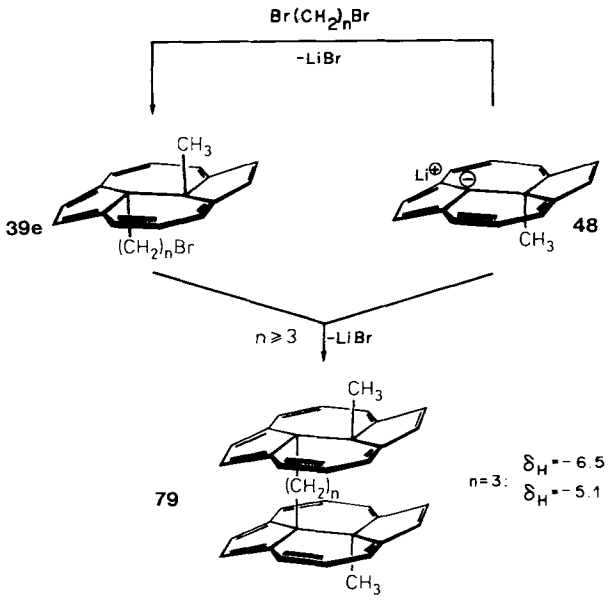
A fascinating aspect of the formation of polymers by means of reductive alkylation (which can also be carried out on a large scale) is provided by the fact that the nature of the unsaturated substrate and of the linking group can be varied, so that polymers of many different types result. The dehydrogenation of **76** gives compounds in which the properties of the original π-system, for example its redox activity, are restored.[81] Spectroscopic and cyclovoltammetric studies show that **77** and lower oligomers such as **78** can serve as "electron stores" and that doping of the hydrocarbons with electrons induces a through-space conjugative interaction between the electroactive units.[138,139]



78

In the case of the pyrene isomer **24**, the bifunctional species which is analogous to the anthracene derivative **68** is the monoanion **71**. If, apart from the intramolecular cyclization described above, **71** were capable of polymer formation as in the anthracene case, a new type of multilayer π-system with variable interlayer distance would be

formed. In contrast to the structure of the phanes, the subunits would here be linked by bridging groups "inside" the π-systems and not by external "clamps". The reaction of **48** and **39e** (analogous to that used for linking $\mathbf{9H}^{\ominus}$ and **68**) to give the double layer **79** occurs almost quantitatively in an inert atmosphere (see Scheme 9).[115] We were also able to prepare "stacked" annulenes with three and more layers.[113] Multilayer hydrocarbons such as **79** have shown themselves to be suitable model compounds for studying successive electron transfer processes, just as is for example **77**:[115,116] with them it is also possible to realize the complete redox sequence from the radical anion to the tetraanion.



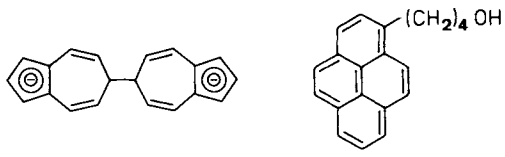
Scheme 9. Construction of double layer annulenes (**79**) from the products of reductive alkylation.

The linking reactions mentioned as examples in this section document the fact that the reductive alkylation of readily available unsaturated derivatives provides a simple method for the synthesis of higher molecular redox-active substances with separate electrophoric groups.[81,136,139]

7. Complications

It is not surprising that reductive conversions of unsaturated hydrocarbons are often accompanied by side reactions.[140,141] A typical example is provided by azulene (**16**), the radical anion of which dimerizes to give **80**. Only the further reduction of **80** causes bond breakage to give the azulene dianion. Depending on the point of the reduction process at which electrophiles are introduced to carry out the trapping reactions, either monomeric or dimeric products are formed.[70,71]

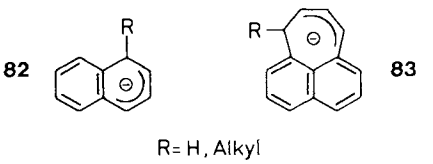
The anions formed in the reductions can attack ethereal solvents such as THF at room temperature in a nucleophilic manner: thus the lithium salt of the pyrene dianion $\mathbf{17}^{2\ominus}$ is converted into an adduct which after dehydrogenation was identified as **81**.[17] The dianions are however not only nucleophiles, but also strong reducing agents, so that electron transfer is able to dominate the planned S_N2-



80 **81**

type alkylation. The following examples of attempted alkylations using 1,2-dibromoethane are typical: the cyclooctatetraenediide $\mathbf{18}^{2\ominus}$ is converted into a bicyclic compound of type **54** (n=2),[124] the dianion $\mathbf{24}^{2\ominus}$ is almost quantitatively reoxidized to the neutral compound, and in the system $Li/NH_3/THF$ anthracene is converted via oxidative coupling of the monoanion $\mathbf{9H}^{\ominus}$ into the tetrahydrodianthryl **5**.[18] It is known that a single electron transfer (SET) can also play a role in the actual S_N-reaction.[142] The rate constants k_{SET} and k_{S_N} for the reaction between π-delocalized carbanions and alkyl halides are known in only a few cases.[143] In addition, it is not clear whether the SET- and S_N-mechanisms really involve two separate processes or only a single process in which the position of the transition state on the reaction coordinate can differ.[143] A final example of side reactions is provided by hydrocarbons such as octalene (**7**)[29] or biphenylene,[111] the reductive conversion of which (just as for example the reaction of the cyclooctatetraenediide $\mathbf{18}^{2\ominus}$ with carbon dioxide[144]) is accompanied by a skeletal rearrangement.[145,146]

The realization of regioselective reductive alkylations finds its limits in cases where several positions in either the dianion $A^{2\ominus}$ or the monoalkylated monoanion $AR^{\ominus}$ have comparable electron densities. Typical examples for the first case are the anthracene dianion $\mathbf{9}^{2\ominus}$ and the acenaphthylene dianion $\mathbf{13}^{2\ominus}$, for the second the monocyclic anions **43**, **82**, and **83**. The latter two species have an allyl



82 **83**

anion structure, further reaction of which can lead to 1,2- and 1,4-diadducts.[147] It is not possible to predict the position of the second alkylation without taking into account additional factors influencing the energy profile of the trapping reaction such as ion pair effects or the soft/hard character[148] of the electrophile and the nucleophile.

8. Summary and Outlook

Reductive transformations of unsaturated hydrocarbons show themselves to be ideal examples for the combined use of preparative, spectroscopic and bond-theoretical methods. Synthetic results can be given a clear mechanistic interpretation, and the spectroscopically established structural information on π-delocalized carbanions can indicate unconventional, simply realizable synthetic routes. A rational selection of starting materials with a suitable topology of the π-system will lead to the synthesis of hydrocar-

bons which are at present unknown but which are ideally suited for reductive transformations.

Finally, it should be emphasized that the mechanistic aspects valid for such reductive transformations are in principle also valid for the attack of nucleophilic reagents on cations produced by oxidation of unsaturated substrates. Preparative applications of this reaction are much more unusual,[42] but are to be recommended in particular for cases in which a regioselectivity different to that observed in reduction is to be expected.

This article is dedicated to my co-workers, since they have made it possible. I thank the Deutsche Forschungsgemeinschaft, the Volkswagenwerk Foundation, and the Fonds der Chemischen Industrie for financial support.

Transcription in Eukaryotes— The Role of Transcription Complexes and Their Components

By Edgar Wingender* and Klaus H. Seifart

The fact that DNA is transcribed into RNA has long been known and has become part of the "central dogma" of molecular genetics. The mechanisms responsible for controlling this process at the individual genes of higher cells (eukaryotes), however, are still not completely understood. RNA polymerases apparently require a number of auxiliary factors (transcription factors) for gene recognition. These factors combine with the enzyme at the gene to form a transcription complex. The structures of these complexes are starting to become clearer; most is known about the control of RNA polymerase III, the enzyme responsible for the synthesis of certain small RNA molecules. The model character of the results obtained with this system is clearly underlined by a series of recent publications. TFIIIA is an especially intensively studied protein, which is a positive regulator for the expression of ribosomal 5S RNA and possesses structural properties that were previously unknown in DNA-binding proteins. It is becoming increasingly evident that the "architecture" of TFIIIA is not an exotic curiosity but probably exemplifies a general structural plan.

1. Introduction

In order to make use of the information set down in the DNA of the chromosomes, the living cell transcribes its genes into RNA (transcription). Regulated gene expression is one of the keys to the differentiation of cells in a multicellular system. The synthesized RNA is then used for its intended purpose: it is incorporated into ribosomes as ribosomal RNA (rRNA) or is translated into proteins on the ribosomes in the form of messenger RNA (mRNA) or is charged with activated amino acids as transfer RNA (tRNA), which plays a key role in protein biosynthesis. There are, in addition, other RNA molecules which have very specialized functions, some of which will be discussed in this article.

Whereas bacterial cells only have one DNA-dependent RNA polymerase, plant and animal cells possess three such enzymes, which are specially adapted for the synthesis of different groups of RNA and have their own transcription systems. RNA polymerase I (or A) transcribes the genes for the large ribosomal RNA molecules (5.8S, 18S, and 28S rRNA), or, more precisely, the gene for their common precursor (45S RNA). RNA polymerase II (or B) synthesizes mRNA. RNA polymerase III (or C) is responsible for the transcription of genes encoding a series of relatively small RNA molecules which consist mainly of tRNA but also include the smallest ribosomal RNA species, 5S rRNA, and certain virus-associated RNAs (e.g., VA_I and VA_{II} RNA of the adenovirus).

None of these polymerases, however, directly recognizes the genes it transcribes; several auxiliary proteins, termed transcription factors (TF), are also required. These factors are divided into initiation, elongation, and termination factors. The initiation factors are of critical importance for the regulation of gene expression and will therefore be the focus of attention in this article. They combine with the enzyme at the gene to form a functional unit—the transcription complex. Electron micrographs of prokaryotic transcription complexes were published a few years ago. Information on the structure and mode of formation of eukaryotic transcription complexes, however, has only been obtained comparatively recently. This progress was made possible by the development of appropriate eukaryotic in vitro systems. Results obtained for polymerase III systems are particularly advanced, because these systems possess certain properties that make them easier to study: (1) in vitro transcription yields a correct product, i.e., initiation and termination both occur; (2) the complexes remain stable for several cycles of transcription, i.e., effective reinitiation takes place and there is a readily measurable accumulation of product; (3) in many cases the product is not subjected to significant post-transcriptional processing; (4) the concentration of transcription factors required is relatively high in comparison with the polymerase II systems. This article will therefore deal mainly with the polymerase III transcription complexes; regulatory elements at the DNA and protein levels will be discussed first before proceeding to consider some functional properties of these complexes. In a short summary, an attempt will finally be made to review present knowledge of polymerase I and II systems in order to describe some general structural properties of eukaryotic gene-regulating proteins that have recently become apparent.

2. Structure of Polymerase III Transcription Complexes

2.1. Promoter Structures

The known genes that are transcribed by RNA polymerase III (pol III genes) share an unusual property: their

[*] Dr. E. Wingender

promoters on the DNA are located not in front of but in the middle of the gene. Detailed studies on genes coding for various tRNA species have yielded a clear picture of the structure and function of their promoters. In these investigations, sections were deleted from the ends of the isolated, cloned genes and replaced by bacterial vector DNA. In addition, particular regions within the gene were replaced by foreign DNA. The transcription capability of these genes was then studied either in vivo by means of microinjection into *Xenopus* oocytes or in vitro by incubating cell extracts in the presence of radioactively labeled nucleoside triphosphates. The newly synthesized and thus radioactively labeled RNA formed in these experiments was subsequently isolated, separated by gel electrophoresis, and visualized with the aid of autoradiography.

These studies showed that, in the case of the gene for initiator methionine tRNA ($tRNA_i^{Met}$), any base may occupy positions 1–7; the same applies to positions from 73 onward and to a region in the middle of the gene (14–50). Changes in bases 8–13 or 51–72, however, led to a considerable reduction or even complete loss of transcription.[1] Similar results were obtained with other tRNA genes.[2,3] It was therefore concluded that tRNA genes have a split promoter whose two parts were then denoted as box (or block) A and box B (Fig. 1). "Consensus sequences" acting as general polymerase III promoters were deduced for both parts of the promoter (Fig. 1) and have since been confirmed by chemical synthesis.[4] Analysis of other genes transcribed by RNA polymerase III have shown that, for instance, the genes for adenovirus VA_I and VA_{II} RNA also have a split promoter structure.[5] The sequences of the two boxes correspond to those of the general scheme (Fig. 1). It was discovered, moreover, that this scheme also applies to genes of the so-called Alu family, which are highly repetitive sequences in the human genome (analogues are found in other species) that can be transcribed to some extent by RNA polymerase III in vitro; their function within the cell, however, is still unknown.[6]

The gene for ribosomal 5S RNA is somewhat different. An internal control region was again identified by deletion experiments performed from both ends of the gene.[7] More recent, detailed investigations, moreover, also indicated the existence of a split promoter.[8,9] However, whereas the first part of the promoter is homologous with box A of the tRNA genes, the second block is not related to box B and has therefore been denoted as box C.

Noteworthy is the distance between the beginning of the gene and box A in the 5S RNA gene, which is much greater than in the other genes—50 base pairs compared with about 10. Experiments in which the combinations of the three different boxes and the distances between them were varied helped to elucidate the function of these promoter elements in the initiation of transcription.[10] Box A is apparently the element from which the transcription machinery determines the starting point for RNA synthesis. Boxes B and C determine whether transcription begins 10 or 50 base pairs, respectively, in front of box A.

It should finally be noted that cases have been reported in which the 5′-flanking sequences of the pol III genes play an essential or modulating role in their transcription. This does not, however, seem to be a general property of these genes.[11]

2.2. Recognition of Genes by Transcription Factors

If purified RNA polymerase III is incubated with DNA in the presence of the four nucleoside triphosphates, a mixture of completely random RNA products is obtained. The polymerase initiates statistically regardless of whether the DNA contains defined genes or not[12] and terminates at one of the following clusters of at least four thymidines.[13] If, on the other hand, purified RNA polymerase is replaced by a suitably prepared cell extract, a defined transcript is produced, which is governed by the correct promoter structures found on the DNA.[12,14] The cell extract evidently contains other transcription factors (TFIII) that are needed for specific gene recognition. They can be separated from one another by fractionation on phosphocellulose and are named according to the order in which they are eluted—TFIIIA, TFIIIB, and TFIIIC.[14] The information so far obtained indicates that factors B and C are required for the transcription of all pol III genes and, in most cases, are sufficient. The additional factor, TFIIIA, is only needed for the synthesis of ribosomal 5S RNA.[8,14]

The function of TFIIIC in tRNA synthesis is analogous to that of TFIIIA in 5S RNA transcription, these factors being the primary proteins responsible for gene recognition and binding. Various methods have been employed to analyze the binding of protein to specific DNA sequences. The "footprinting" experiments are the most important, the principle of which is illustrated in Figure 2. They are usually conducted with endonuclease DNase I, but the methidiumpropyl-EDTA·Fe^{II} complex[15] is being used increasingly as a cleaving agent. An alternative approach is

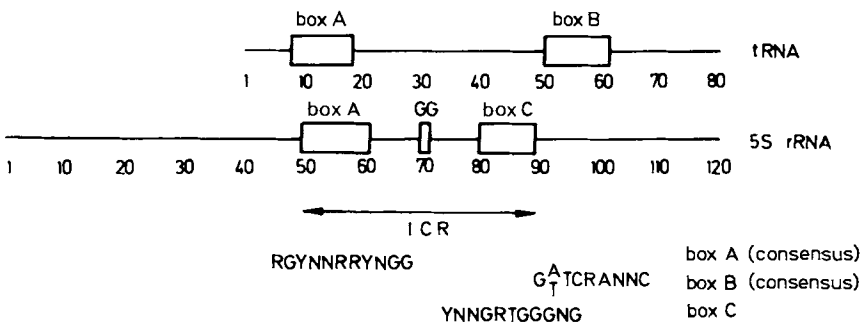

Fig. 1. Promoter structures for RNA polymerase III. tRNA genes, like the majority of other pol III genes, possess a split promotor consisting of two boxes (A and B), which are to a large extent homologous in these genes. The derived consensus sequences are given below. Box A is also found in the internal control region (ICR) of the gene for ribosomal 5S RNA. In addition, this internal control region contains at least two guanine residues (G) and a region referred to as box C. The ribonucleosides are given by the one-letter code described in *Eur. J. Biochem. 15* (1970) 205.

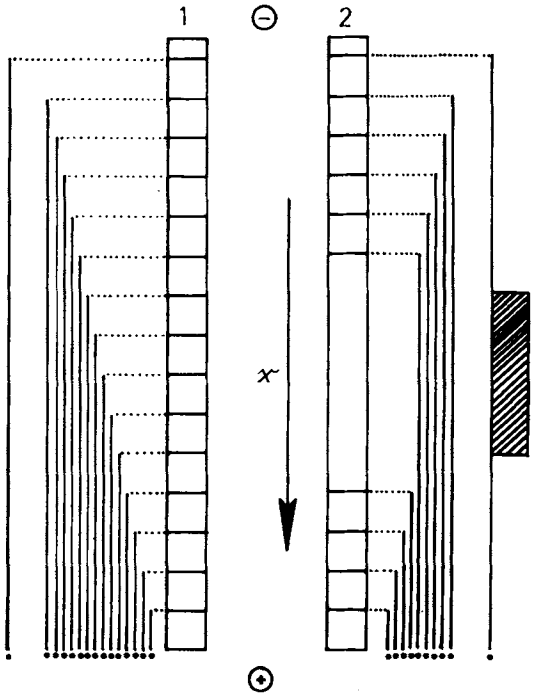

Fig. 2. Footprinting to determine protein binding sites on DNA employs a double-stranded DNA fragment that contains the suspected binding region, the end of one strand being radioactively labeled (—●). Statistical cleavage of a large number of identical fragments yields a mixture of smaller segments of varying lengths. Only those segments that are radioactively labeled (i.e., those derived from one and the same strand) can later be identified; ideally, their lengths will differ by a single nucleotide. The segments can be separated by gel electrophoresis (x = direction of migration) and visualized by autoradiography (1). If the DNA subjected to cleavage is associated with a protein, it will not be fragmented at the protein binding site (▨), the corresponding cleavage products will not be formed, and a "window" then appears in the autoradiogram, which is called the "footprint" (2).

to degrade a DNA-fragment-protein complex from both 3′ ends (with exonuclease III) up to the protected region. The binding position can then be deduced from the size of the remaining fragment. Another method for localizing specific DNA-protein contacts consists in modifying specific bases of the DNA, e.g., in methylating the DNA guanine residues with dimethyl sulfate or ethylating the DNA phosphate residues with *N*-ethyl-*N*-nitrosourea. Investigations are then performed to see how these modifications interfere with the binding of the protein or how binding of the protein protects the DNA against these modifications. Finally, the importance of individual bases in specific protein binding can be established by replacing or deleting the base in question and then carrying out tests of binding or function.

TFIIIA was found to bind specifically to the entire internal control region of the 5S rRNA gene, i.e., to boxes A and C and the region between them;[8] however, protection of the intervening region—apart from two guanine residues—may possibly only be due to steric factors.[14] Contacts in the box C region are particularly strong.[16] The published results are all based on experiments with TFIIIA from the oocytes of *Xenopus laevis*, in which this protein also adopts a storage function for 5S RNA and accounts for 15% of the total cell protein.[17] It still remains to be shown whether these findings are valid for analogous factors in, for example, human cells.

The binding properties of human TFIIIC and a yeast protein that presumably corresponds to TFIIIC to pol III promoters in tRNA and VA RNA genes have been characterized.[18–22] As is the case with the interactions between TFIIIA and the 5S RNA gene described already, the yeast TFIIIC protects the region between the boxes against degradation by DNase I.[21] Some authors have discussed a model which proposes that TFIIIC binds alternately to boxes A and B on passage of the polymerase during transcription.[21] Subsequent binding of other factors or RNA polymerase, however, has not yet been shown to produce any changes (e.g., extension) in the protected DNA regions in any of the cases cited.

2.3. Formation of Transcription Complexes

For a functional transcription complex to be formed at a pol III gene, the gene has to be recognized first. If TFIIIC is allowed to come into contact with the gene for VA RNA, for instance, it binds to the gene promoter so tightly that it is incapable of binding to a subsequently added tRNA gene. In the presence of the other transcription components (TFIIIB, polymerase III, nucleoside triphosphates), only VA RNA is synthesized.[23,24] Evidently, the VA RNA gene forms a stable preinitiation complex with TFIIIC (Fig. 3). Although this factor alone also binds to the tRNA gene it yields a metastable associate from which it can be removed.[23] In this case, TFIIIB is also required in order to produce a complex that is stable against competitive DNA (Fig. 3).

A metastable complex is also formed when TFIIIA binds to the gene for 5S rRNA and becomes stable on association of TFIIIC.[23] TFIIIB combines with this complex in a relatively slow process and is followed by RNA polymerase III (Fig. 3).[26] One of these two last steps is energy-dependent; i.e., it requires ATP. The incorporation of TFIIIB into a stable transcription complex for 5S RNA

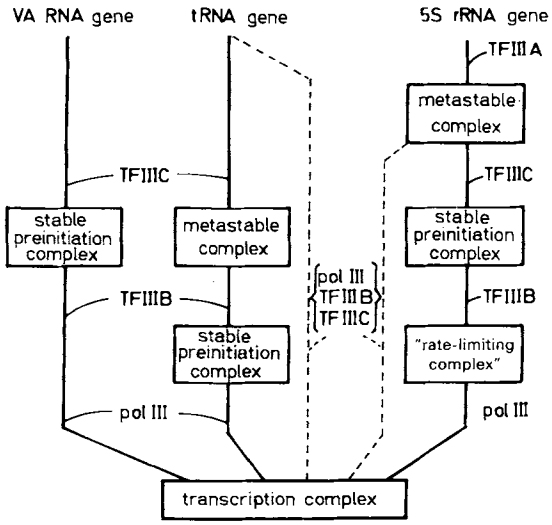

Fig. 3. Formation of transcription complexes at the genes for VA RNA, tRNA, and ribosomal 5S RNA. The steps involved in the successive binding of the individual factors and the alternative, hypothetical pathway in which preformed protein associates are bound (----) are described in the text. TF, transcription factor; pol III, RNA polymerase III.

is time-dependent; transcription begins after a lag phase of approximately 15 minutes.[17] According to recent studies, however, transcription of tRNA and VA RNA with extracts of HeLa cells (a special strain of human cancer cells) starts immediately.[24] This difference may be due to the fact that the factors TFIIIB and TFIIIC needed for tRNA and VA RNA synthesis can exist in association with RNA polymerase III;[26] association of TFIIIA has not yet been detected. These preformed protein–protein associates may possibly initiate and elongate more rapidly, for example, at tRNA genes, than does a mixture of previously separated transcription components (Fig. 3). On the 5S RNA genes, on the other hand, TFIIIA and then a polymerase complex must first assemble, a process that may account for the approximately 15-minute lag phase that is characteristic of 5S RNA.

The functions of the factors that do not initially bind to DNA are still not known. Hitherto, there was no experimental evidence to explain the role that TFIIIC may play in the transcription of 5S RNA genes (e.g., recognition of box A), nor are there any definitive findings relating to the function of TFIIIB. Recent studies, however, strongly suggest that TFIIIC binds to box A of the promoter in 5S RNA genes.[27] Moreover, TFIIIB has recently been purified from yeast and some of its molecular properties have been characterized. It is apparently a protein with a molecular weight of about 60 kDa, but proteins of lower molecular weight are also found in the preparation.[28] Protein kinase activity may be associated with TFIIIB.[28] Our own results indicate that, in any case, TFIIIB may exist as a "polymorphic" protein; the same possibly applies to TFIIIC. The properties of TFIIIA have been studied intensively and will be discussed in Section 5.

3. Properties of Polymerase III Transcription Complexes

3.1. Isolation

Because of the numerous complications encountered in the isolation and characterization of the individual transcription factors in their native forms, it seemed advantageous to develop alternative strategies for studying polymerase III transcription components. Attempts were made to isolate complete, intact transcription complexes as well as to characterize their functions and analyze their composition.

Isolation of functional transcription complexes was achieved by centrifuging complete in vitro transcription systems through glycerol gradients. All the components required for transcription of the genes for 5S rRNA[29] (Fig. 4), tRNA, and VA RNA[25,30] have now been isolated in the form of functional complexes. Kinetic studies on this material revealed that all of the RNA syntheses started without any delay (i.e., 5S RNA transcription no longer displayed a lag phase).[29]

These complexes were isolated not only by centrifugation on glycerol gradients but also by gel electrophoresis.[29] Although the polymerase II complexes isolated by the latter method[31] were inactive, nascent RNA was detected in them in the form of ternary complexes. The isolated polymerase III complexes, in contrast, are active but

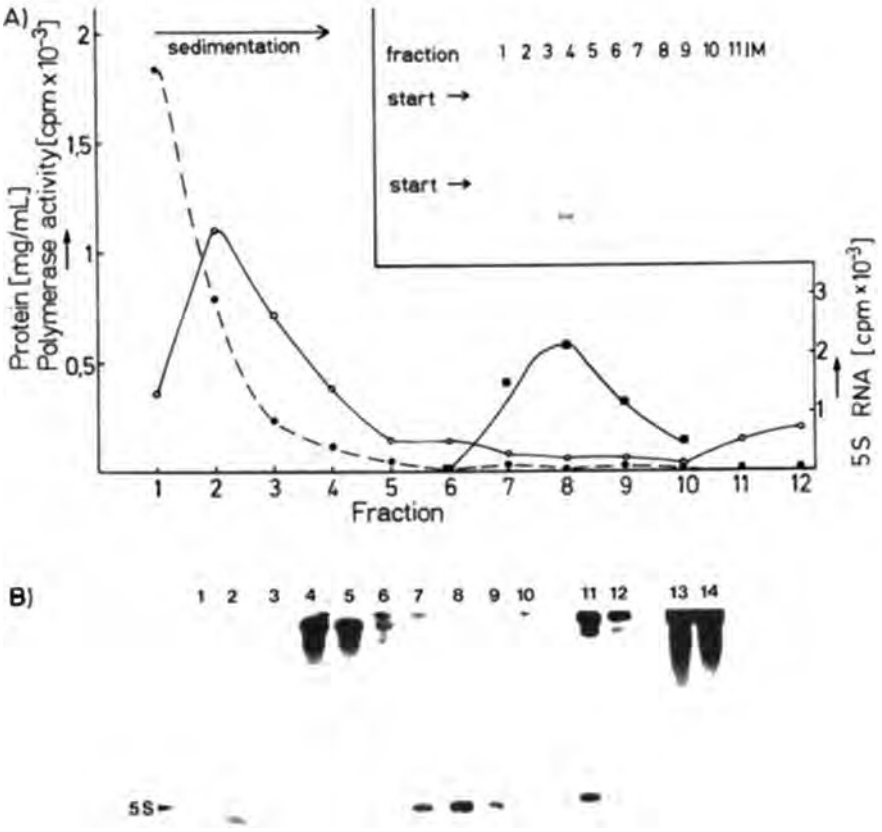

Fig. 4. Isolation of transcription complexes for ribosomal 5S RNA. A) Cytoplasmic extract from human HeLa cells was incubated with plasmid DNA containing the genes for 5S rRNA. The system was then loaded onto a glycerol gradient (20–45%) and centrifuged. After fractionation, the protein profile (---•-), the total polymerase activity (in cpm = counts per minute) (——o——), and the ability to specifically synthesize 5S RNA (——■——, see B) were analyzed. In the insert in the upper right-hand corner, the sedimentation positions of complex-bound (above) and free DNA (below) are shown after electrophoretic analysis on agarose gels; the different mobilities of the free and bound DNA in the gel are clearly visible (M, free DNA on the top gel for comparison). B) The abilities of fractions 1–10 to synthesize 5S RNA on incubation with radioactively labeled nucleoside triphosphates are shown in the correspondingly numbered lanes. The transcripts were separated on polyacrylamide gel and visualized by autoradiography. The position of 5S RNA is given; the bands in fractions 2 and 3 are of nontranscriptive origin. The band in fractions 7–9, however, is due to 5S RNA produced by RNA polymerase III, since it is no longer observed after addition of 200 μg/mL of the mushroom toxin α-amanitin (bands 11 and 12). Lane 13 shows that a specific transcript is not produced if DNA is omitted from the preincubation stage; subsequent addition of DNA does not remedy this (lane 14).

do not contain detectable quantities of the transcript.[29] The transcript appears to be rapidly released in the form of a nucleoprotein particle, as has been demonstrated in the case of 5S RNA.[32]

3.2. Stability of Transcription Complexes

Information about the nature of the interactions responsible for maintaining the structure of a transcription complex can be obtained by studying its stability at high ionic strengths. Comparison with other well-investigated DNA–protein complexes, such as the nucleosomes, can be instructive. These associates are mainly held together by salt bridges between the phosphate groups of the DNA and the basic amino-acid residues of the histones—primarily arginine and lysine side chains. The most stable of these bonds, those between histones H3 and H4 and DNA, are disrupted by salt concentrations slightly higher than 1 M NaCl.[33,34]

We showed that the salt stabilities of 5S RNA and tRNA transcription complexes far surpassed those of the nucleosomes.[24,35] The relevant experiments are presented in Figure 5; transcription components were tested to see whether they could "transfer" from transcription complexes to free, competitive genes or partial complexes. All of the transcription complexes investigated proved to be stable up to at least 1 M KCl, only the polymerase being reversibly released.[24] The complexes for 5S RNA and tRNA can even tolerate KCl concentrations of 2.5 M or more without losing the transcription factors. This property indicates the highly specific nature of the interactions existing in transcription complexes and which must therefore involve other forces besides ionic bonds between basic amino acids and the DNA phosphate backbone.

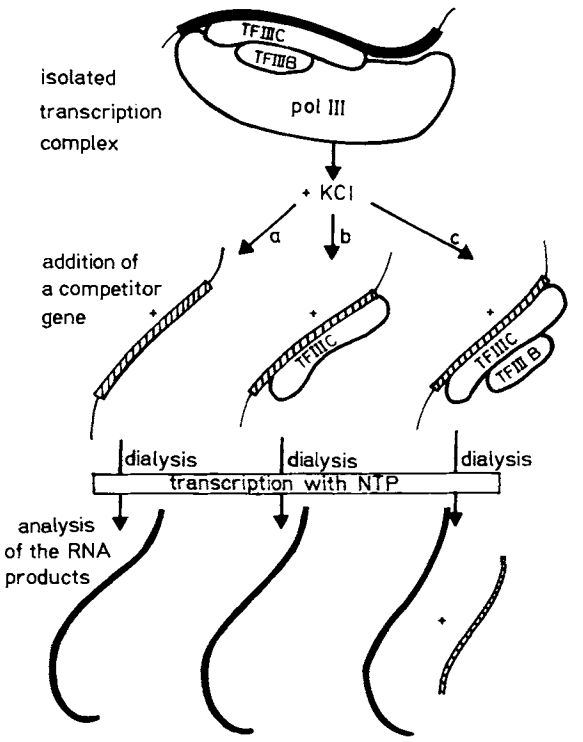

Fig. 5. Stability of transcription complexes at high ionic strengths. Isolated transcription complexes formed, for example, at a VA RNA gene (black) are adjusted to a high salt concentration (e.g., 1 M KCl) and mixed with a functionally equivalent but structurally different gene (e.g., for tRNA, hatched in the diagram) (a), which may also be loaded with TFIIIC (b) or TFIIIC + TFIIIB (c). The preparation is then dialyzed against a solution of low ionic strength, mixed with the four nucleoside triphosphates (NTP), and tested for transcription. RNA is synthesized from the first gene in all cases (black), but the second gene is only recognized if it is loaded with the necessary transcription factors (c): RNA polymerase can "shuttle" from one gene to another at high ionic strengths.

The pronounced stability of the transcription complexes at high ionic strengths encouraged us to attempt their purification by equilibrium centrifugation in cesium sulfate gradients. As expected, the RNA polymerase dissociated from all of the complexes studied but the transcription factors remained partly bound to their respective genes.[24] The resulting purified partial complexes are active on addition of RNA polymerase III; they can be examined by electron microscopy and their composition can be analyzed. Experiments of this kind are currently in progress.

4. Transcription Factors of the Other RNA Polymerases

4.1. RNA Polymerase I

RNA polymerase I transcribes the gene for 45S RNA, the precursor of the larger ribosomal RNA molecules; this precursor is then processed to yield mature 5.8S, 18S, and 28S rRNA. This means that RNA polymerase I is exclusively responsible for the transcription of a single, albeit repeated, transcription unit. Although it only has to recognize one promoter, RNA polymerase I, like all other RNA polymerases, can only do this with the help of transcription factors.

The promoter structures recognized by these factors have been elucidated in a number of organisms by using the methods described in Section 2.1. Unlike the polymerase III promoters, however, the polymerase I promoters vary considerably between different species, the differences reflecting the closeness of the biological relationships between the species in question (for a review see ref. [36]). In simplified terms it can be concluded that the promoter structures for RNA polymerase I lie within the 40 base pairs "upstream" from the rRNA genes and possibly extend to include a few base pairs in the transcribed region. The sequences within these blocks can be further differentiated into those whose deletion reduces transcription efficiency and those that are absolutely essential for transcription.[37] Finally, the thymidine found at position -1 and the guanine at position -16 in front of the gene are highly conserved, suggesting that these bases are of particular importance. Beyond this region there is an "upstream element" from about position -40 to -169 which still requires further investigation and is apparently capable of modulating transcription efficiency.[38]

In accordance with the evolutionary divergence displayed by the promoter structures of the rRNA genes, the transcription factor binding to these genes—the transcription initiation factor (TIF)-IB[39]—also varies between species; it is only exchangeable in comparatively closely re-

lated species, e.g., rat and mouse.[36] This factor, which recognizes the mouse rRNA promoter, has been purified from Ehrlich ascites cells, and digestion with exonuclease III has shown that its binding site is limited to positions -21 to -7.[39] In contrast, the analogous protein from *Acanthamoeba castellanii* protects the region of the homologous rRNA gene from positions -69 to -12 against degradation by DNase I (see Section 2.1 and Fig. 2).[40] It is especially noteworthy that the subsequent binding of RNA polymerase was visualized for the first time in a footprint experiment using this system. The protected region then extends beyond position $+20$; this is not observed with purified polymerase alone.[40]

A second transcription factor is required in addition to TIF-IB for rRNA synthesis, namely, TIF-IA (designated as TFIC by other authors).[41] TIF-IA is closely associated with polymerase I and does not display any DNA-binding properties. Its intracellular concentration varies greatly depending on the physiological state of the cells concerned. Cells in the resting phase do not contain detectable quantities of TIF-IA, and extracts from these cells are accordingly inactive as far as transcription is concerned; they can, however, synthesize rRNA on addition of the isolated factor from exponentially growing cells.[41] Only factor-associated enzyme molecules are probably capable of interacting with TIF-IB and the gene to form a transcription complex. As is the case in the polymerase III system (see Section 2.3), it is evident that protein–protein interactions are of importance for the formation of transcription complexes.

RNA polymerase I transcription complexes have also been detected[42] and isolated[43] by means of ultracentrifugation in a similar fashion to the procedure described in Section 3.1. Their properties (e.g., stability toward competitive genes or at high ionic strengths) are consistent with those of the polymerase III complexes described previously. Study of their composition could reveal, for instance, whether the modulating sequences further "upstream" are still occupied by factors. Glucocorticoid receptors are conceivable in this context because several steroid hormones have been shown to stimulate rRNA synthesis; this effect may possibly be coupled to an increased rate of cell division.[44,45] Furthermore, the region in question has been found to contain sequences that are homologous with the already known receptor binding sites in front of structural genes (cf. Section 4.2).[46]

4.2. RNA Polymerase II

Whereas the polymerase I and III systems and their regulation was relatively easy to elucidate, the RNA polymerase II system is much more complicated. This is easily understood because polymerase II transcribes the large number of protein-coding genes, which are subjected to very subtle regulatory mechanisms, e.g., during cell differentiation. As is to be expected, it appears that there are exceptions to every apparent rule.

The reader is referred to other review articles for a more detailed description of the promotor structures of structural genes.[47,48] In simplified terms, they can be outlined as follows: The "TATA box" ($TATA^{A}_{T}A^{A}_{T}$) is located about 30 base pairs upstream from the starting point of transcription. Many genes possess an additional homologous region further upstream called the "CAAT box" ($GG^{C}_{T}CAATCT$). Additional modulating/activating and regulating sequences may exist even further in front of the transcription start site, some of these being enhancers. The enhancers exert a stimulating effect even if they are positioned downstream from the gene on the DNA or are in the opposite orientation to the gene. According to present knowledge, they are responsible for binding species-, cell- or gene-specific factors. Their effects are counteracted by silencers[49] or dehancers,[50] which will not, however, be discussed in any further detail here. An interesting observation will merely be noted whose significance is still not understood: many of the known enhancers contain sequences that are homologous with the polymerase III promoters (box A and box B) described above.[51]

The subject of polymerase II control is further complicated by the fact that many genes are subjected to hormonal regulation. Special sequences are again involved which will be dealt with in more detail later on in this Section in connection with the hormone receptors that bind to them.

The "mosaic" of polymerase II transcription factors still seems to be rather fragmentary, because it very much depends on the system under investigation. It can therefore only be described with the aid of selected examples. *Roeder*'s group conducted the first systematic studies on polymerase II transcription factors (TFII),[52] the approach used being in principle the same as that described in Section 2.2 for RNA polymerase III and its factors. A transcriptionally active cell extract (from HeLa cells) is fractionated on phosphocellulose and partly on other columns, and the transcription system is then reconstituted by recombination.

These experiments were performed on the major late promoter of adenovirus 2 (AdML). At least three factors were found to be necessary for the transcription of the genes controlled by this promotor: TFIIB, TFIID, and TFIIE.[52] There is also an upstream sequence binding factor (USF) which binds specifically to sequences further upstream and strongly stimulates AdML transcription.[53] No information is so far available as to the functions of TFIIB and TFIIE. It still remains to be established whether they correspond to some of the general transcription factors (e.g., "A factor",[54] "Sp2"[55]) described by other authors. Both factors, but especially TFIIE, can associate with RNA polymerase II.

TFIID appears to be identical with the protein binding to the TATA box.[56,57] Footprint experiments with methidiumpropyl-EDTA·Fe^{II} showed that TFIID bound over a stretch of about 10 base pairs around the TATA box.[53] A protein from *Drosophila* (the "B factor") may be analogous to this factor and prevents DNase I from degrading a 65-base-pair region surrounding the TATA boxes of the histone H3 and H4 genes and the actin 5C gene.[54,58] Interestingly, this TATA-box binding factor is unnecessary in the case of the heat-shock proteins; the A factor and a special heat-shock transcription factor (HSTF) are sufficient for transcription of their genes. The HSTF binds to a region

that is directly upstream from the sequence protected by the TATA binding protein.[58] It thus does not interfere with the binding of the B factor; in fact, simultaneous binding of the two proteins can be demonstrated, but the B factor is apparently without function. HSTF is inactive, however, at the histone genes (for H3 and H4) and the actin 5C gene.[58] Therefore, HSTF is evidently not a general factor but a specific regulator protein with binding affinity for upstream activating sequences.

Sp1 is another protein that binds to a special site; it is a cellular factor that specifically activates several viral promoters; e.g., the early promoters of the SV40 and BK viruses and the promoter of the thymidine kinase gene of the *Herpes simplex* virus (HSV TK).[59] Sp1 has also been shown to bind to cellular promoters. All DNA sequences recognized by this protein contain the common sequence GGGCGG; this base sequence is usually repeated several times in succession but its orientation with respect to the starting point of transcription is not important. It has recently been demonstrated that Sp1 also activates the promoter of the AIDS retrovirus.[60]

The product of the GAL4 gene in yeast *(Saccharomyces cerevisiae)* is a further example of a positive regulatory factor. This protein binds to the upstream activating sequences (UAS) of some galactose-inducible genes via one to four binding sites.[61] Pairs of binding sites display the highest affinities if they are separated by 82–87 base pairs. This form of positive regulation can be counteracted by negative regulation, due to the product of the GAL80 gene. This negative regulation is particularly effective at the dimeric binding sites for the transcription activator.

At this point a proposal concerning the functional mechanism of certain transcription factors will be mentioned. *Di Mauro* et al. showed that even purified RNA polymerase II could recognize a number of yeast promoters, including the regulatory sequences of the GAL1–GAL10 genes or the alcohol dehydrogenase 2 gene (ADH2), when these sequences were made to adopt an optimal topological conformation.[62] These authors recently demonstrated that single-stranded stretches are formed in regulatory regions.[63] One of the functions of transcription factors thus could be to induce a DNA topology that is suitable for transcription.

Finally, hormone-induced gene regulation will be briefly dealt with; this regulation is usually positive as well. In the past few years, particular attention has been paid to the investigation of the mechanism of action of the steroid hormones. These substances bind to "their" receptors in the cytoplasm of the target cell. The resulting hormone–receptor complex then recognizes regulatory sequences in the chromatin, binds to them, and activates the relevant gene. The receptors can thus also be conceived as transcription factors. The binding regions and binding sequences of the glucocorticoid receptors in the 5′-flanking regions of several genes have now been elucidated with the aid of the previously described methods (e.g., deletions, footprint experiments): they are located upstream from certain genes of the MMTV (mouse mammary tumor virus),[64] the uteroglobin gene,[65] the lysozyme gene of the chicken,[66] and the metallothionein genes.[67] Interestingly, the latter genes can bring about induction in another way: their control regions contain metal-responsive elements which increase transcription in response to elevated intracellular concentrations of metal ions. The binding sites are also known for the progesterone receptor in front of the genes for lysozyme[66] and ovalbumin as well as for the estrogen receptor in front of the vitellogenin genes[69] (all in the chicken).

Methods have been developed for the isolation of intact transcription complexes in RNA polymerase II systems. They partly involve electrophoretic procedures or the centrifugation techniques described earlier (see Section 3.1).[43] Purification has not yet reached a stage, however, that allows analysis of the composition of these complexes.

5. Structural Properties of Transcription Factors

5.1. Structure of TFIIIA

TFIIIA requires zinc ions as a cofactor in order to recognize the 5S RNA genes. This was first demonstrated in footprint experiments with *Xenopus* factor A.[70] It was later shown that the human A factor likewise needs zinc in order to function.[34]

The cDNA of TFIIIA was sequenced at about the same time, which meant that its amino-acid sequence was also known.[71] TFIIIA is a basic protein containing 344 amino acids. Computer-aided analysis of its primary sequence showed that, starting at its *N*-terminus, TFIIIA consists of nine repetitions of a specific sequence;[72] the remaining *C*-terminal sequence may be viewed as being composed of three degenerate units of the same structural element.[73] The main feature of this motif is the constant arrangement of a pair of cysteine residues and a pair of histidine residues (Fig. 6), which are assumed to bind a zinc ion by means of tetrahedral coordination. The intervening sequence generally consists of twelve amino acids and is en-

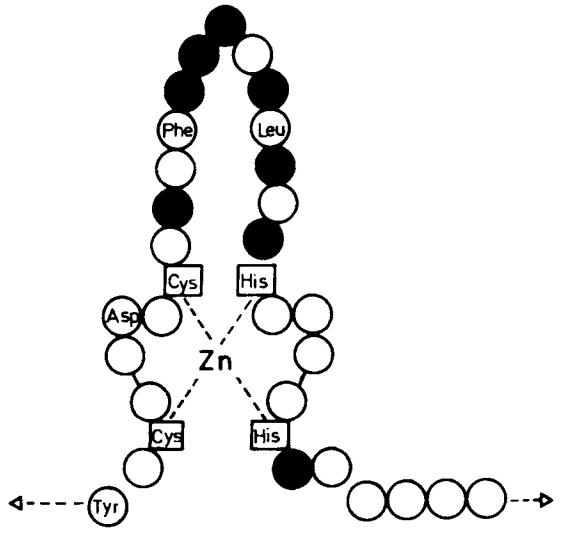

Fig. 6. The finger structure of gene-activating proteins. A metal ion (in TFIIIA, $Zn^{2\oplus}$) is tetrahedrally coordinated by two cysteine thiol groups and two imidazole groups belonging to two histidine residues; in some cases the ion is coordinated by four cysteine SH groups (cf. Table 1, Section 5.2). The intervening and neighboring amino-acid residues are denoted by circles; the names of particularly well conserved amino acids are given and the solid circles represent potential DNA-binding amino-acid residues [72].

visaged as a type of "finger" (Fig. 6) which establishes contact with a specific sequence of DNA bases.[72] Two positions, a phenylalanine and a leucine residue, are highly conserved in this finger.

Since experimental data on the three-dimensional folding of TFIIIA are not yet available, one has to rely on predictions of secondary structure. Predictions have been made by *Brown* et al.[73] and by the present authors using calculations based on the models proposed by *Chou* and *Fasman*[74] and *Robson* et al.[75] These studies indicate that an α-helix consisting of two to three turns is formed in the second half of the finger sequence. This helix includes the amino acids between the conserved phenylalanine and leucine residues but can extend as far as the two histidine residues. The cysteine residues, on the other hand, are located in regions that are less structurally organized or are characterized by a higher β-turn probability, so that they can adopt an arrangement that is suitable for binding zinc.

Helices of similar length, which embed themselves in the major groove of the DNA helix, are also responsible for establishing specific contacts between DNA and bacterial or viral repressors. The "recognition helix" of these proteins also has polar amino acids on the side facing the DNA. The hydrophobic side chains, on the other hand, are found on the other side facing the rest of the protein.[76] Stabilizing contact is thus established with a second α-helix, which is connected to the first by a turn (helix-turn-helix motif).

The TFIIIA structure, in contrast, is stabilized by the presence of a zinc ion; at any rate the structural prediction models do not suggest the existence of other regions with significant α-helix probabilities. The hydrophobicity of the "back," therefore, does not need to be very pronounced and is often restricted to the conserved leucine residue.

5.2. Other "Finger Proteins"

TFIIIA is the first example of a protein that needs metal ions for specific binding to DNA. Discovery of this property raised the question whether TFIIIA is merely an "exotic" protein or whether it conforms to a structural plan that is more generally applicable. A number of protein sequences have since been published that fit in well with the scheme derived from TFIIIA. Their "finger sequences" are compiled in Table 1. The Krüppel (Kr) gene product of *Drosophila* will be dealt with first.[77] This protein is of critical importance for the development and organization of the larval segments; mutations in its gene can produce severe malformations. The gene has been sequenced and four consecutive finger motifs were identified in the subsequently deduced amino-acid sequence—cysteine, histidine, phenylalanine, and leucine residues being located in the expected positions.

Two other *Drosophila* gene products were found to contain mutually homologous regions in which a specific consensus sequence is repeated six or seven times. It was not recognized until later that these sequences were related to the finger motifs of TFIIIA. These proteins are encoded by the serendipity locus (sry) (β- and δ-sry polypeptides);[79] their biological significance is still not clear. However, since their expression is specifically associated with certain stages of development, their functions may be connected with gene regulation.

Finally, a few proteins from yeast cells remain to be mentioned. Two consecutive, partial sequences of ADR1, which activates transcription of the gene for alcohol dehydrogenase 2,[79] fit into the "finger" scheme perfectly. Discrepancies are found, however, in other gene-regulating yeast proteins, namely, GAL4,[80] PPR1,[81] and ARG RII,[82] in which the pair of histidine residues is replaced by a second pair of cysteine residues. Phenylalanine and leucine residues, moreover, are not found in the expected positions, so that the question of homology cannot be answered with certainty.

Nevertheless, the picture of transcription-activating proteins is rounded off by the recently published finding that the finger motif also occurs in the DNA-binding domains of the glucocorticoid and estrogen receptors as well as in the v-erbA gene product. The latter is a virus-encoded protein that is involved in the oncogenic transformation of chicken cells.[83]

5.3. Importance of the Finger Structure

It would certainly be stressing the matter too far to expect all eukaryotic gene activators to contain a finger structure. First of all it must be established whether the proposed model is indeed correct. In addition, it has to be demonstrated whether proteins other than TFIIIA also bind metal ions (presumably zinc) and whether they require them to perform their functions. If this model is assumed to be correct, however, the question is raised as to the specific functions of the finger structure.

The authors of the model suggest that binding of the individual fingers to the DNA is to some extent independent and results in successive, temporary dissociation on passage of RNA polymerase III.[72] These proteins could thus bind to DNA without blocking it, as is the case, for example, with histones. Furthermore, interesting evidence indicating that DNA topology is of importance for transcription relates particularly to TFIIIA.[84,85] By analogy, it could be speculated that the binding of these proteins to RNA will prove to be another of their common features. The binding of TFIIIA to RNA has been intensively investigated; it forms a 7S-RNP particle with 5S rRNA[17] and thus contributes to feedback regulation of the expression of this gene. There is also good reason to believe that the Kr protein binds to its own mRNA or that of another control gene.[77] At any rate it is likely that this extremely interesting class of regulatory proteins will provide further surprising discoveries.

6. Summary and Outlook

The expression of specific genes is controlled by a multitude of components. The promoter structures and regulatory elements of the DNA must be recognized by transcription factors (in the broadest sense of the word). Other factors and RNA polymerase have to be firmly anchored to the gene by means of protein-protein contacts and must

Table 1. Known finger sequences. The amino-acid residues shown in boldface are essential for the finger structure and are thus particularly well conserved; other well-conserved residues are written in italics. In regions containing gaps, the amino-acid residues have been arranged so as to maintain a maximum degree of homology. The individual amino acids are designated according to the one-letter code proposed by *Dayhoff* [86].

then unite to form a functional transcription complex. The necessary components can bind to the DNA successively or in the form of (partly) preformed protein complexes. In any case, the final transcription complex is extremely stable; the stability of its structural core even appears to excel that of the nucleosomes. Further study of the individual components of these complexes will shed considerable light on the mechanisms responsible both for cell differentiation in a given organism and for the regulated interaction between its organs.

Recent preliminary findings concerning the structure of gene-activating transcription factors suggest completely new developments. It seems possible that detailed analysis of the interactions taking place between DNA and proteins containing a "finger motif" may bring us a step forward in deciphering the protein-DNA binding code.

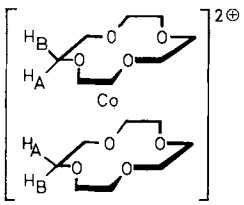
1D and 2D NMR Investigations of the Jump Mechanism of Co^{II} Ions in [12]Crown-4 Stacks**

By *Franz L. Dickert,* Wolfgang Gmeiner, Walter Gumbrecht,* and *Harald Meissner*

Dedicated to Dr. Heinz Kimmel on the occasion of his 60th birthday

The crown ether [12]crown-4 ([12]C4) forms sandwich complexes with divalent metal ions such as Mg^{II}, Co^{II}, Ni^{II}, and Fe^{II},[1,2] which have the composition $[M^{II}([12]C4)_2]^{2\oplus}$. The protons of the CH_2 groups in coordinated [12]C4 are chemically nonequivalent,[2] so that, despite the identical arrangement of the two [12]C4 ligands in complexes such as **1**, two ^{1}H-NMR signals are observed, which, in the case of **1**, have very large chemical shifts on account of the central paramagnetic ion (Fig. 1, signals Ⓐ and Ⓑ). In the ^{13}C-NMR spectrum, on the other hand, only one signal is observed.[2] In order to depict the rapid fluxional processes taking place within the ligands,[2] the chemically equivalent protons in the crown ethers will be symbolized in each case by rings (Fig. 3, rings A and B).



1

Upon addition of free crown ether, [12]C4, to a solution of $[Co^{II}([12]C4)_2][ClO_4]_2$ in deuterated nitromethane, ligand exchange [Eq. (a)] is observed to occur, as revealed by ^{1}H-NMR line broadening (Fig. 1). Coordination of nitromethane is ruled out, because only one ^{1}H-NMR signal is observed for the solvent. As shown by the temperature dependence of the line width of this signal, a more rapid exchange process does not take place.[3] According to conductivity measurements, moreover, no coordination of perchlorate ion occurs.[3]

$$[Co([12]C4)_2]^{2\oplus} + [12]C4^* \rightleftharpoons [Co([12]C4)([12]C4)^*]^{2\oplus} + [12]C4 \quad (a)$$

1 **1'**

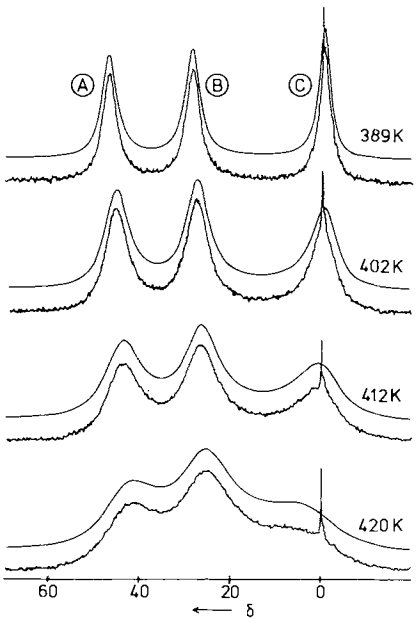


Fig. 1. Experimental and simulated 100-MHz ^{1}H-NMR spectra of 0.4 M $[Co^{II}([12]C4)_2][ClO_4]_2$ and 0.38 M [12]C4 in CD_3NO_2. Ⓐ, Ⓑ, signals of coordinated [12]C4; Ⓒ, signal of free [12]C4.

2D ^{1}H-exchange NMR spectra[4,5] provide information, via cross signals, on the resonance positions undergoing a transfer of magnetization by means of chemical processes (Fig. 2). Such exchange processes are characterized by reciprocal residence times. The "mixing time," the duration

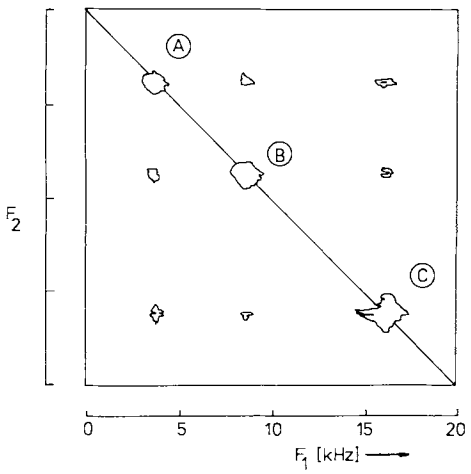

Fig. 2. 2D ^{1}H-exchange NMR spectrum (270 MHz) of 0.4 M $[Co^{II}([12]C4)_2][ClO_4]_2$ and 0.4 M [12]C4 in CD_3NO_2 at 140 °C (pulse sequence, $90°$-t_1-$90°$-t_m-$90°$-t_2; mixing time, $t_m = 1$ ms).

of magnetization transfer in 2D NMR spectroscopy, must be so chosen that its order of magnitude agrees with the chemical residence times. Cross signals observed upon raising the temperature can thus be distinguished from nuclear Overhauser effect (NOE) signals.[4] In addition, NOE plays no role in paramagnetic complexes such as **1**. Although scalar-correlated cross signals can arise, in principle, even in the case of paramagnetic metal complexes,[6] their intensities decrease with increasing line broadening. For this reason, cross signals arising at high temperatures (Fig. 2) may be ascribed to an exchange process.

Surprisingly, the 2D NMR data (Fig. 2), as well as simulation of the 1D NMR spectra[7,8] (Fig. 1), indicate that, in the system **1**/[12]C4, not only an exchange process between free and coordinated crown ether (A↔C and B↔C) but also one between the magnetization A and B (A↔B) is occurring. The mechanism upon which Equation (a) is based is not so simple, therefore, as might have been expected; namely, replacement of the oxygen atoms of a coordinated [12]C4 consecutively by those of the free crown ether.

The experimental results can be best explained by assuming a stacklike aggregation between the complex **1** and free [12]C4 (Fig. 3). This model is also supported by the first-order rate law for the dissociation of the complex in nitromethane,[2] which is surprisingly observed even for relatively small concentrations (0.1 M) of complex and free crown ether. Accordingly, under the conditions of measurement of the ^{1}H-NMR spectra in Figures 1 and 2, a practically quantitative association of complex and free crown ether is presumably occurring. The structure shown in Figure 3 is most likely from a topological viewpoint, since it guarantees an optimal dispersive interaction between the complex and the free ligand.

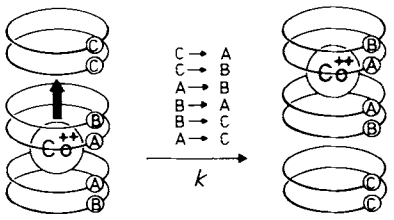

Fig. 3. Stack formation and jump mechanism for the system $[Co^{II}([12]C4)_2]^{2\oplus}$/[12]C4.

The 1D and 2D NMR spectra (Fig. 1 and 2) can be rationalized by assuming that the Co^{II} ion "jumps" through the stack of crown ether rings during the ligand exchange reaction [Eq. (a)]. In this process, the upper, free [12]C4 is bound and the lower, coordinated ligand is released. This also explains the exchange process between the magnetization A and B.

An alternative to this model is the existence of complexes of lower coordination number as intermediates, in which a crown ether is only coordinated through one oxygen atom. It is thereby possible, by flipping the ligand, to achieve likewise an exchange of A and B. A monodentate-bound ligand would undergo ready substitution by free crown ether, however, and magnetization transfer between A and B would no longer occur.

The exact kinetic parameters have been determined by simulation of the spectra (Fig. 1).[7,8] In this way, one obtains rate constants for the jumping of the Co^{II} ions within the [12]C4 stack (110 °C: $k = 105 \pm 10\ s^{-1}$; $\Delta H^{+} = 102 \pm 10$ kJ/mol; $\Delta S^{+} = 57 \pm 20$ J/K mol).

The rate constants or the activation enthalpy of this process provide a very sensitive criterion for the cavity diameter of the macrocycles and the diameter of the ions. A close parallel exists with the pore mechanism[9] in the transfer of ions through biomembranes. In such cases, ions must also pass through channels, e.g., those formed by dimeric gramicidin molecules, the coordinated solvent molecules being removed in the process.

1,1′-Diarsaferrocene**

By *Arthur J. Ashe III,* Samir Mahmoud, Christoph Elschenbroich,* and *Martin Wünsch*

Heterometallocenes of the group 5B elements are of considerable interest for the study of p_π-p_π bonding of main group elements. Although phosphaferrocenes,[1] ring-substituted arsaferrocenes,[2] and stibaferrocenes are known,[3] we wished to obtain the parent 1,1′-diarsaferrocene **1** in order to compare it with bis(arsabenzene)chromium **2**[4] and arsabenzene **3**.[5] Unfortunately, the potential precursor of **1**, 1-phenylarsole **7**, had been available only in low yield through a synthesis involving the explosive 1,4-diiodobutadiyne.[6] We now wish to report on an efficient synthesis of 1-phenylarsole **7** and its conversion to 1,1′-diarsaferrocene **1**.

The readily available mixture of isomeric 1,4-dichloro-1,3-butadienes **6**[7] reacts with dilithiophenylarsane in

ether at 25 °C to afford 1-phenylarsole **7** (25% yield).[8] The reaction is not stereospecific, since either pure (*Z,Z*)- or (*E,Z*)-1,4-dichloro-1,3-butadiene **6** gives 1-phenylarsole **7** in the same yield. Similarly, dilithiophenylphosphane reacts with the mixed 1,4-dichlorobutadienes **6** to give 1-phenylphosphole in 25% yield, a procedure that offers an alternative to available literature preparations of *C*-unsubstituted phospholes.[9] The reaction of 1-phenylarsole **7** with lithium in tetrahydrofuran (THF) followed by treatment with $FeCl_2$ affords 1,1'-diarsaferrocene **1** in 50% yield as deep red, air-stable, monoclinic crystals (m.p. = 195 °C).[8, 10] NMR, UV, and mass spectra are similar to those of 1,1-diphosphaferrocene **4** (for NMR data see Table 1).

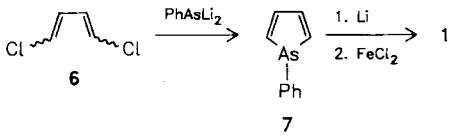

Table 1. ^{1}H- and ^{13}C-NMR chemical shift values (δ values) of **1** and **4** [a].

		1	**4**
^{1}H-NMR	H_α	4.38 [b]	3.79 [c]
	H_β	5.14 [b]	4.88 [c]
^{13}C-NMR	C_α	88.0	79.3 [d]
	C_β	84.0	82.0 [d]

[a] In [D_6]benzene at 300 MHz, δ values relative to TMS. [b] Satisfactory spectral simulation using the Bruker PANIC program is achieved for $J_{2,3}=4.5$ Hz, $J_{2,4}=J_{2,5}=0.9$ Hz, and $J_{3,4}=3.2$ Hz. [c] Satisfactory spectral simulation for $J_{1,2}=37.5$ Hz, $J_{1,3}=5.6$ Hz, $J_{2,3}=4.15$ Hz, $J_{2,4}=J_{2,5}=0.9$ Hz, and $J_{3,4}=2.5$ Hz. [d] See [1a].

Like the parent complex ferrocene **5** and the heteroarene analogue bis(arsabenzene)chromium **2**, **1** may be electrochemically oxidized as well as reduced. Cyclovoltammetry yields the redox potentials $E_{1/2}(\mathbf{1/1}^{\oplus\oplus}) = 0.730 \pm 0.015$ V [−38 °C in 1,2-dimethoxyethane (DME)/tetra-*n*-butylammonium perchlorate (TBAP) versus the saturated calomel electrode (SCE), $v \geq 20$ mV s^{-1}, $I_{pa}/I_{pc} \approx 1.0$] and $E_{1/2}(\mathbf{1/1}^{\ominus\ominus}) = -2.190 \pm 0.01$ V [−40 °C in DME/TBAP vs. SCE, $v \geq 1$ V s^{-1}, $I_{pa}/I_{pc} = 0.98$]. As observed for the couple $[(\eta^6\text{-}C_6H_6)_2Cr]/[\eta^6\text{-}C_5H_5As)_2Cr$ **2**,[4] replacement of two CH units of **5** by two As atoms leads to anodic shifts of the redox potentials (+0.24 V for the oxidation, +0.74 V for the reduction).[11] Obviously, compared with the cyclopentadienyl ring, the arsacyclopentadienyl ring is more effective in withdrawing electron density from the central metal, thereby stabilizing the HOMO of **1**, and in accommodating additional charge into the LUMO. Similar trends are observed in the case of **4**.[12]

Like arsabenzene,[13] 1,1'-diarsaferrocene **1** undergoes rapid acid-catalyzed deuterium exchange. At −20 °C in CF_3CO_2D/CH_2Cl_2, **1** exchanges its four α-protons in 1 min, although heating to 70 °C for 7 h allows only partial exchange at the β-position. In competition experiments, an α-hydrogen undergoes exchange 165 times faster than a hydrogen of ferrocene, while a β-hydrogen exchanges 4 times more slowly than the hydrogen at the 4-position of toluene. Although the scale is only semiquantitative, the relative reactivity of α/β positions must exceed 10^6.[14, 15] Similarly, acetylation with acetyl chloride/$AlCl_3$ in CH_2Cl_2 at 25 °C gives exclusively the α-acetyl derivative of **1**.[16] This large directive effect is much greater than that reported for substituted ferrocenes[17] but is similar to that found for arsabenzene **3**[13] and for metal-complexed heterocycles.[18]

[8] *Experimental procedure*: 7: A solution of **6** (1.58 g, 12.5 mmol) in 50 mL of ether was added dropwise to a solution of dilithiophenylarsane, which had been prepared from 2.0 g (13 mmol) of phenylarsane in 250 mL of ether and 16.3 mL (26 mmol) of 1.6 M *n*-butyllithium in hexane. After 60 min stirring at 25 °C, the solvent was removed and the residue extracted with pentane. Vacuum distillation gave 0.65 g (25%) of 7.—**1**: 7 (0.3 g, 1.27 mmol) and excess lithium wire (0.1 g) in 5 mL of THF were stirred together for 3 h at 25 °C. The deep blue-green solution was decanted into a flask containing 0.06 g (0.45 mmol) of $AlCl_3$ in 30 mL of THF at 0 °C. The solution was then decanted into a flask containing 0.37 g (2.9 mmol) of $FeCl_2$ in 30 mL of THF. After 24 h stirring, the solution was removed and the residue extracted with benzene and purified by chromatography (silica gel, benzene/pentane) to give 200 mg (50%) of red crystals of **1**. [14] At 70 °C in trifluoroacetic acid, pentamethylbenzene undergoes proton isotopic exchange 1.7×10^5 times faster than that measured for the 4-position of toluene [15]. We find that, at −20 °C in mixtures of CH_2Cl_2/CF_3CO_2D, ferrocene **5** undergoes exchange 2.4 times faster than pentamethylbenzene. This allows an approximate comparison between the α and β positions.

Synthesis and Structure of $[(C_5Me_5)_2Mo_2S_4 \cdot SO_3]$: Concerning the Oxidation of Sulfur Ligands in Transition-Metal Complexes

By *Henri Brunner, Ulrich Klement, Joachim Pfauntsch,* and *Joachim Wachter**

The oxidation of coordinated sulfur in transition-metal complexes can result not only in the formation of sulfur

[*] Dr. J. Wachter, Prof. Dr. H. Brunner, Dr. U. Klement, J. Pfauntsch
Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (FRG)

oxides,[1] which would be highly reactive as free species, but also of sulfur-rich anions such as $S_2O_2^{2\ominus}$ and $S_3O_2^{2\ominus}$.[2] Such reactions are of interest as model systems for the microbiological oxidation of $S^{2\ominus}$ and S^0 in nature.[2a] We report here on the unusual oxidation of an $S^{2\ominus}$ ligand to an $S_2O_3^{2\ominus}$ ligand that is coordinated in a novel fashion.

When a dark blue solution of complex **1** is stirred in toluene while being exposed to air (50 °C, 18 h), **2** precipitates in 17% yield as red-violet crystals. Other sulfur-containing complexes, **3**, which can only be separated with difficulty by column chromatography, remain in solution.[3]

Single crystals of **2** suitable for an X-ray structure analysis can be prepared by slow evaporation of a solution of **2** in acetone/CH_2Cl_2 (5:8) exposed to air. The structure of **2** (Fig. 1) is characterized by one each of the following ligands: $S^{2\ominus}$, $S_2^{2\ominus}$, and $S_2O_3^{2\ominus}$, the S atoms of which lie roughly in a plane that is perpendicular to the Mo–Mo axis.[4] The methyl groups of the nearly parallel C_5Me_5 rings are oriented in an eclipsed fashion. This reveals a close structural relationship between **1** and **2**, which is also reflected in their largely similar bonding parameters.[5] A further structural feature, however, is the pseudotetrahedral SO_3 unit fixed at one of the $S^{2\ominus}$ ligands. To the best of our knowledge, thiosulfate ligands bridging two metal centers were previously unknown. Noteworthy, in contrast to the distances in mononuclear, *S*-coordinated thiosulfate complexes, is the very long S4–S5 distance (2.168(2) Å).[6]

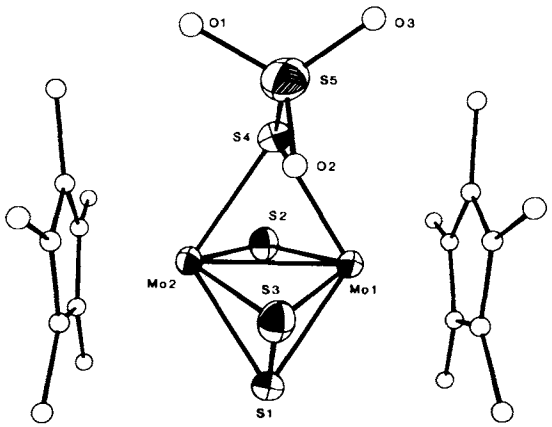

Fig. 1. Structure of **2** in the crystal (ORTEP plot). Selected bond lengths [Å] and angles [°]: Mo1-Mo2 2.628(0), Mo1-S1 2.426(1), Mo1-S2 2.308(1), Mo1-S3 2.432(1), Mo1-S4 2.449(1), S1-S3 2.066(2), S4-S5 2.168(2); Mo1-S1-Mo2 65.50(3), Mo1-S2-Mo2 69.32(3), Mo1-S3-Mo2 65.42(3), Mo1-S4-Mo2 64.91(3), Mo1-S4-S5 113.22(5), Mo2-S4-S5 112.82(5), S4-S5-O 104.4(3) (average).

Significant thermal instability of **2** is indicated by the mass spectra, which only show the molecular ion of **1**, even when the field desorption technique is used. In contrast, the elemental analyses confirm the calculated S/O ratio. The $S_2O_3^{2\ominus}$ ligand is revealed in the IR spectrum (KBr) by the strong $\tilde{\nu}_{SO}$ absorptions at 1246, 1217 (sh), 1207, 1010, and 600 cm^{-1}. A similar pattern is observed for monodentate-bonded sulfate ligands, which is interpreted as being a consequence of local C_{3v} symmetry.[7]

The long S–S distance in the thiosulfate ligand suggests a certain lability of this bond. Indeed, **2** reacts with $[Cr(CO)_5(thf)]$ (CH_2Cl_2/tetrahydrofuran (THF) mixtures, 20 °C) under mild conditions with loss of the SO_3 unit to give the trinuclear cluster **4**,[8] whose structure corresponds to that of the isoelectronic complex **5**[9].

$[(C_5Me_5)_2Mo_2S_4Fe(CO)_2]$ **5**

The formation of **2** may be explained in terms of several steps. Under the reaction conditions, isomerization of **1** to give complexes containing terminal M=S groups[5] precedes the substitution of sulfur by oxygen. The SO_2 thereby formed requires an additional catalytic oxidation, however, by an as yet unidentified complex component. In this way, approximately 37% of the sulfur released from **1** is converted into SO_3, which then adds to **1**.[3] In this connection, it is interesting that the nucleophilic character of the μ-S ligand can already be used to bind SO_2.[10] The simultaneous formation of an SO_2 and an S_2 ligand from an initially sulfur-poor complex by oxidation with air has also been described already.[11] Further experiments are required, however, to elucidate the details of the oxidation mechanism.

[2.2](1,4)Benzo[*g*]chrysenoparacyclophane Dianion: A Novel, Paratropic, Double-Layered Carbanion

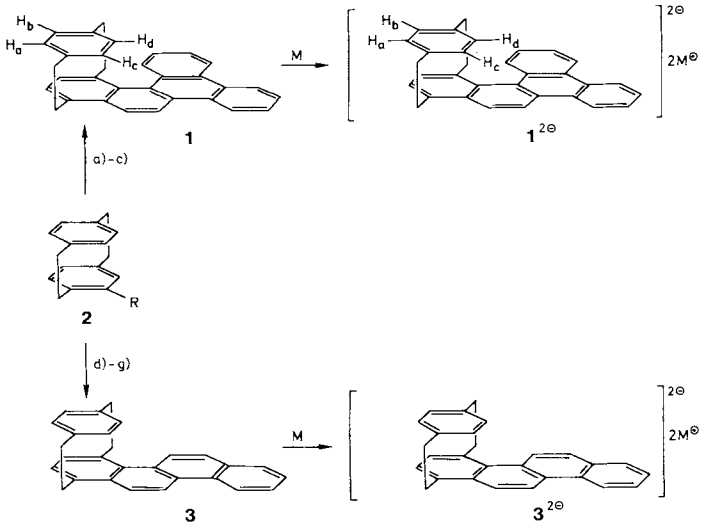
By *Ron Frim, Mordecai Rabinovitz,* Henning Hopf,** and *Joachim Hucker*

Dedicated to Professor Heinz A. Staab on the occasion of his 60th birthday

An outstanding characteristic of the [2_n]paracyclophanes is the through-space interaction of the two fully conjugated π-electron systems of the separate layers. As demonstrated by the electronic properties of these compounds,[1] the two layers afford one overall π-electron system.[2] Very little is known, however, about this interaction in charged paracyclophanes. Diatropic anionic [2.2]paracyclophanes have previously been studied,[3–7] but no paratropic [2.2]paracyclophane systems have been reported.

We wish to report the first [2.2]paracyclophane in which a 4nπ paratropic dianion interacts with a virtually neutral benzene moiety. In this case the benzene ring acts as an "observer," which is located in a well-defined position and can be used to probe the spatial interactions due to both charge and anisotropy effects.

The system of choice is [2.2](1,4)benzo[*g*]chrysenoparacyclophane dianion $\mathbf{1}^{2\ominus}$, obtained by metal reduction of [2.2](1,4)benzo[*g*]chrysenoparacyclophane **1** (Scheme 1). To synthesize this hydrocarbon,[8,9] the phosphonate **2** ($R=CH_2PO(OEt)_2$), prepared from 4-bromomethyl[2.2]paracyclophane **2** ($R=CH_2Br$) by the Arbuzov reaction, was coupled with commercially available 9-formylphenanthrene in a Wittig–Horner reaction. The resulting *trans* olefin,[9] formed in 40% yield, was subsequently photocyclized by irradiation (Hanau TQ 150 lamp) in a toluene solution in the presence of iodine, providing the benzochrysenophane **1**[9] (18%, colorless plates, m.p. = 267–269°, dec.). By an analogous route, the chrysenophane **3**[9] was prepared (34%, colorless needles, m.p. = 149–152°C) with a Wittig reaction between 4-formyl[2.2]paracyclophane **2** (R = CHO) and the ylid prepared from 1-naphthylmethylphosphonium bromide serving as the initial step.



Scheme 1. a) *n*BuLi, THF; b) 9-formylphenanthrene; c) *hν*, I_2, toluene; d) NaH, THF; e) α-naphthyl-CH_2PPh_3Br; f) **2** (R = CHO), THF; g) *hν*, I_2, toluene.

Reaction of **1** with lithium or sodium metal in [D_8]tetrahydrofuran ([D_8]THF) at −78°C afforded deep green solutions, which exhibit well-resolved ^{1}H- and ^{13}C-NMR spectra (Table 1). The ^{1}H-NMR signals appear in the range of $\delta = 10.31$–0.91 for the sodium salt and 9.81–1.14 for the lithium salt. The bridge protons of $\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$ give rise to broad signals at $\delta = 1.14$ (2H), 1.65 (2H), 2.82 (2H), and 3.15 (2H). The dianionic nature of $\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$ and $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$ is deduced from the general similarity of their spectra to those of other dianionic polycycles which were studied previously.[10] Quenching of $\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$ and $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$ with oxygen gave **1** in quantitative yield, proving that no skeletal changes had occurred.

The most revealing part of the spectra of $\mathbf{1}^{2\ominus}$ (both lithium and sodium salts) consists of four doublets (one proton each), which are attributed to the atoms H_a, H_b, H_c,

and H_d of the benzene ring, as deduced from double resonance experiments (Table 1). A conspicuous feature of these spectra is the appearance of extremely low-field bands assigned to H_c and H_d. These signals are registered at $\delta = 10.31$ and 8.68 for $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$, a very low field indeed for a neutral benzene moiety. Similar reduction experiments carried out on **3** resulted in only very broad ^{1}H-NMR signals in the same region as for $\mathbf{1}^{2\ominus}$, and no well-resolved spectrum could be obtained. Quenching of $\mathbf{3}^{2\ominus}$ with O_2 afforded the neutral hydrocarbon **3** in good yield. Prolonged reaction of **1** and **3** with the alkali metals led to cleavage of the cyclophane bridge, as shown by quenching experiments. A similar cleavage was previously observed by *Müllen* et al. in the case of the nonparatropic anthracenophane dianion.[4]

When a double-deck anion such as $\mathbf{1}^{2\ominus}$ is formed, the following spectral phenomena are expected: (a) a high-field shift of the protons of the charged polycyclic moiety due to the negative charge and even more so to the formation of a paratropic 4nπ species;[11,12] (b) a shift of the signals of the neutral benzene ring due to the through-space interaction between the two conjugated layers.

As expected, the protons of the charged polycyclic layer of $\mathbf{1}^{2\ominus}$ show pronounced high-field shifts. The peculiar and unusually pronounced low-field shift of the uncharged benzene ring layer is caused by the through-space interaction between the two π-electron systems and is attributed to the anisotropy of the 4nπ doubly charged polycyclic moiety of $\mathbf{1}^{2\ominus}$. The extremely low-field signals of one proton of the benzene moiety ($\delta = 10.31$ for $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$!) show that this interaction is very significant. In the neutral hydrocarbon **1** the benzene protons H_c and H_d are shifted to higher field (Table 1). H_d is presumably shifted more than H_c,[2a] while H_a and H_b appear in the "normal" aromatic region of the ^{1}H-NMR spectrum. In dianion $\mathbf{1}^{2\ominus}$, owing to its different electronic structure and anisotropy, the same arguments should be reversed. The protons H_c and H_d are more influenced by the paratropicity of the charged 4nπ layer, and the H_d signal is most strongly shifted.

The ^{13}C-NMR spectrum for the aromatic carbons of $\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$ and $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$ are in the range of $\delta = 70$–175 versus a range of $\delta = 120$–140 for **1** (Table 1). The center of gravity of the ^{13}C-NMR spectra of $\mathbf{1}^{2\ominus}/2\,Li^{\oplus}$ and $\mathbf{1}^{2\ominus}/2\,Na^{\oplus}$ did not change significantly. This may arise from the opposing effects of the charge and the anisotropy already mentioned. The failure in observing [2.2](1,4)chrysenoparacyclophane dianion $\mathbf{3}^{2\ominus}$ arises not only from the cleavage of the bridge but also is due to the nature of the dianion.[13] It has been previously demonstrated that the appearance and line shape of polycyclic 4nπ conjugated dianions is a function of several parameters.[12] Similarly, chrysene dianion affords a much less resolved ^{1}H-NMR spectrum than benzo[*g*]chrysene dianion.[10]

From the above it can be concluded that in the first paratropic three-dimensional 4nπ system, $\mathbf{1}^{2\ominus}$, a new aspect of the through-space interaction involves a charged polycyclic layer and a neutral benzene layer, reminiscent of the paracyclophane donor-acceptor systems studied by *Staab* et al.[14]

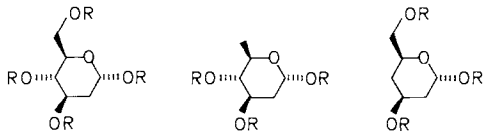
Synthesis of 2-Deoxy Sugars**

By *Bernd Giese,* Kay S. Gröninger, Tom Witzel, Hans-Gert Korth,* and *Reiner Sustmann*

2-Deoxy sugars, particularly the compounds **1**–**3** (R = H, Ac), which are required for the formation of compactin,[1] olivomycin,[2] and milbemycin,[3] are important



1 **2** **3**

targets of natural product synthesis. However, the syntheses of 2-deoxy sugars reported to date have been laborious; they could be prepared, for example, from glycosyl halides by reductive elimination to give the glycals followed by solvomercuration and subsequent demercuration.[4] We have now developed a new method by which glycosyl halides can be converted directly into the 2-deoxy sugars. The procedure is based on the rapid and irreversible migration of the acyloxy group in the β-acyloxyalkyl radical **4** to give the acyloxyalkyl radical **5**.[5]

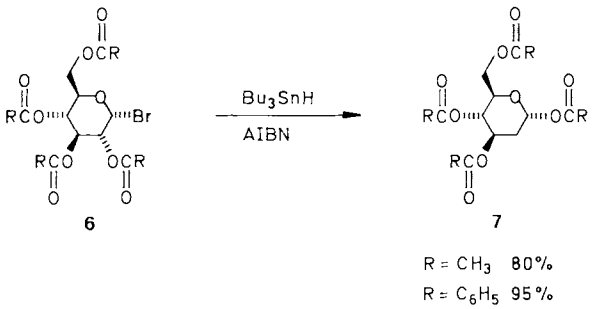
4 5

When glycosyl radicals are generated by halogen abstraction from the corresponding glycosyl halides,[6] it is possible to trap the rearranged radicals by using low concentrations of Bu_3SnH. Thus, addition of a 0.2-molar solution of Bu_3SnH to 0.05-molar solutions of the glucosyl bromides **6** ($R = CH_3$, C_6H_5) in refluxing benzene in the presence of 10 mol-% azobisisobutyronitrile (AIBN) over 12 hours affords the 2-deoxy sugars **7** in 80–95% yields. Analogously, galactosyl, allosyl, and xylosyl bromides afford 70–85% yields of the rearranged reduction products **8**–**10** (Table 1).[7]



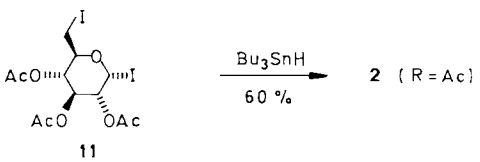
6 7

R = CH_3 80%
R = C_6H_5 95%

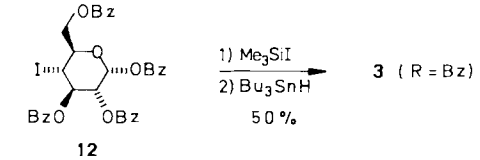
Table 1. Synthesis of 2-deoxy sugars from glycosyl bromides.

Glycosyl bromide	2-Deoxy sugar	Yield [%]
	 **8**	70
	 **9**	70
	 **10**	85

The deoxy sugars **2** and **3** may be prepared from the corresponding dihalides: reduction of the 1,6-diiodide **11**



11



12
Bz = Ph-CO

affords a 60% yield of the deoxy sugar **2** (R = Ac). In order to synthesize **3** (R = Bz), the 4-iodoglucose **12** was subjected to iodination at the anomeric C atom with trimethylsilyl iodide and the product was reduced in situ with Bu_3SnH. Only the acetoxy group on C-2 undergoes migration (to C-1); migration from C-3 to C-4 does not occur.

This new synthetic method opens up a short and general approach to the class of 2-deoxy sugars.

[4] This is also part of an industrial synthesis of compactin which is based on the procedure described in [1] and for which large amounts of Zn and Hg are required.

[5] The migration of acyloxy groups in open-chain radicals has been studied by *Ingold* et al. and by *Beckwith* et al.: L. R. C. Barclay, J. Lusztyk, K. U. Ingold, *J. Am. Chem. Soc. 106* (1984) 1793; S. Saebo, A. L. J. Beckwith, L. Radom, *ibid. 106* (1984) 5119. They obtained rearrangement rates of 10^2 to $10^4\ s^{-1}$ (75 °C). Accordingly, the rearrangement occurs at least two orders of magnitude slower than H transfer from Bu_3SnH to alkyl radicals: C. Chatgilialoglu, K. U. Ingold, J. C. Scaiano, *ibid. 103* (1981) 7739. For the migration of the acyloxy group in glucosyl radicals, see B. Giese, J. Dupuis, K. Gröninger, T. Hasskerl, T. Witzel in H. G. Viehe (Ed.): *Substituent Effects in Radical Chemistry*, Reidel, Dordrecht 1986, p. 283.

Arene Adducts with Weak Interactions: Hexaethylbenzene-bis(tribromoarsane)

By *Hubert Schmidbaur,* Wolfgang Bublak, Brigitte Huber,* and *Gerhard Müller*

The study of arene–metal complexes has expanded in recent years to include the neighboring post-transition metals (Ga, In, Tl;[1] Sn, Pb;[2] Sb;[3] Bi[4]). It appeared that a borderline was reached between Al and Ga, Ge and Sn, and As and Sb, beyond which the interactions between the

[*] Prof. Dr. H. Schmidbaur, Dipl.-Chem. W. Bublak, Dipl.-Chem. B. Huber [+], Dr. G. Müller [+]
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (FRG)

[+] X-ray structure analysis.

components become too weak, and the hapticity is reduced from η^6 to η^3 or η^2. The structures of the Menshutkin complexes of the antimony halides,[5] in particular, show clearly acentric coordination to the arenes,[6] whereas the bismuth halides still prefer hexahapto bonding.[4]

Nonetheless, there is evidence that, at least at low temperatures and for suitably substituted arenes, discrete adducts may even be obtained with *arsenic* halides: for example, *Al. Weiss* et al. used ^{35}Cl-NQR measurements to demonstrate the existence of a phase $C_6H_6 \cdot 2\,AsCl_3$, which is also revealed as a maximum of the liquidus curve (m.p. = −25.5 °C) in the phase diagram.[7] *R. A. Shaw* et al. also showed by means of phase diagrams that hexamethylbenzene forms a 1 : 1 complex with triphenylarsane, which melts as high as 144 °C.[8] The structures of these compounds, however, have remained unknown, and their bonding has been the subject of controversy.[9]

We have now succeeded in synthesizing a complex from hexaethylbenzene and arsenic tribromide and in elucidating its crystal and molecular structure. The adduct is formed from $AsBr_3$ and C_6Et_6 in toluene at room temperature and has a 2 : 1 stoichiometry, in good agreement with the results of *Al. Weiss* et al.[7] The product is easily obtained in the form of large, colorless single crystals, which are only slightly sensitive to air and moisture [Eq. (a)].

$$C_6Et_6 + 2\,AsBr_3 \longrightarrow Br_3As \cdot C_6Et_6 \cdot AsBr_3 \quad \mathbf{1} \qquad \text{(a)}$$

The X-ray structure analysis[10] of the rhombohedral crystals revealed the presence of discrete $Br_3As \cdot C_6Et_6 \cdot AsBr_3$ molecules (Fig. 1) with crystallographic $\bar{3}(S_6)$ symmetry, arranged in strings parallel to the *c* axis. The arsenic atoms are thus strictly η^6-coordinated to the arene. The two independent As–C distances differ by only a negligible amount (Fig. 1). The arsenic atoms are

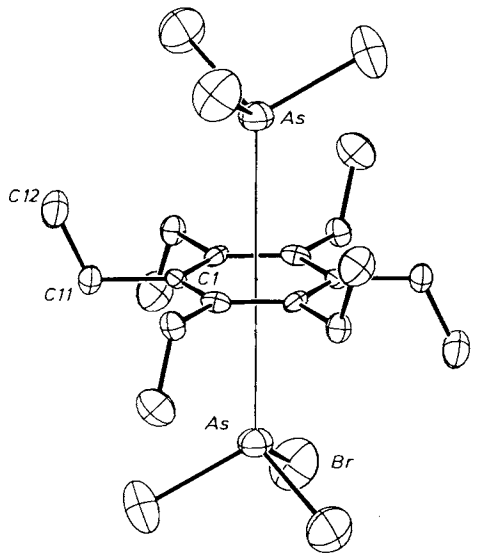

Fig. 1. Crystal structure of **1** (ORTEP plot, thermal ellipsoids at the 50% probability level, without H atoms). Distance [Å] and angles [°]: As-Br 2.322(1), As-C1 3.462(7), 3.456(7), C1-C1 1.412(5), C1-C11 1.521(7), C11-C12 1.509(9); Br-As-Br 98.9(1), C1-C1-C1 120.0(6), C1-C1-C11 120.1(6)/119.9(6), C1-C11-C12 113.3(6).

located at a distance of 3.16 Å from the centers of the aromatic rings. The methyl groups of the ethyl substituents of the arene point alternately up and down and are arranged in a staggered fashion with respect to the bromine atoms of $AsBr_3$. The geometries of the components in **1** differ only slightly from those in free $AsBr_3$[11] and free C_6Et_6.[12] This is also true for the conformation of the ethyl groups. As shown by a space-filling model of the complex (Fig. 2), the η^6-coordination of the $AsBr_3$ unit results in a large number of van der Waals contacts, which probably also contribute appreciably to the stability of **1**, since the arene-arsenic interactions alone—as judged by the distances involved—are quite weak.

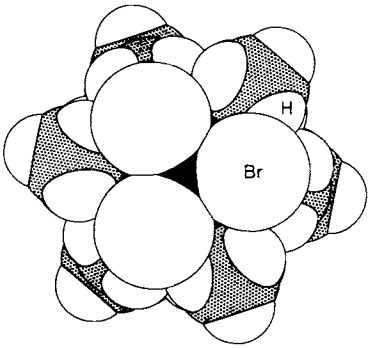

Fig. 2. Space-filling model of **1** as viewed along the $\bar{3}(S_6)$ axis (PLUTO plot), radii [Å]: As 2.0 (black), Br 1.9, C 1.7 (dotted), H 1.2).

The molecules along the string are also related to one another by $\bar{3}(S_6)$ symmetry, i.e., the bromine atoms of neighboring $AsBr_3$ molecules are likewise arranged in a staggered fashion. The intermolecular Br···Br distances (4.373(2) Å) are significantly longer than the typical van der Waals contact of 4.0 Å. Along the *c* axis, the chains are displaced by 1/3 with respect to one another, resulting in an arrangement in which the bromine atoms of one chain and the arene molecules of a neighboring chain lie opposite one another (Fig. 3). Thus, crystalline **1** does not contain the infinite halogen layers that are characteristic of crystalline arsenic trihalides.[11, 13]

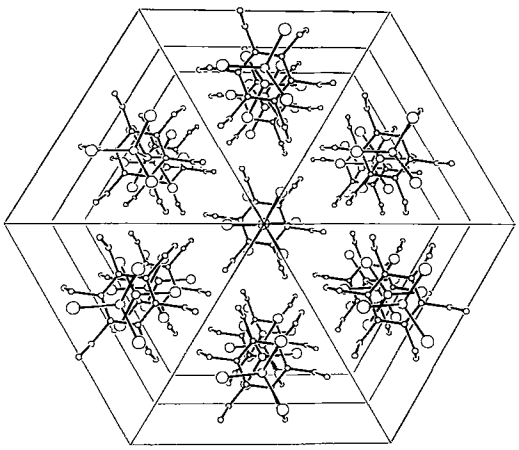

Fig. 3. Perspective view of the crystal structure of **1** along the crystallographic *c* axis (ORTEP plot).

We have been able to show that **1** is only *one* member of a whole series of analogous adducts; their structures, however, need not necessarily be based on the same structural

principle. The NQR data of crystalline $C_6H_6 \cdot 2\,AsCl_3$[7] already reveal that the chlorine atoms exist pairwise at three different sites. Therefore, further details of the structure are necessary before the bonding between the components can be discussed. Only in this way will it be possible to determine whether theoretical concepts based on the structural model derived for one particular species can be extended to other cases. The frequently confirmed observation that the hapticity in the series of As, Sb, and Bi complexes can easily vary between η^6 and smaller η values indicates that the movement of the metal(oid) atoms on the surface of the arenes is characterized by an extremely flat potential energy profile. Accordingly, small perturbations, e.g., steric effects, can have strong effects on the structure.

Experimental Procedure

A solution of C_6Et_6 (0.51 g, 2.07 mmol) in toluene (7 mL) was added to a solution of $AsBr_3$ (1.26 g, 4.00 mmol) in 1.5 mL of toluene at room temperature. The mixture was then cooled to -20°C, which resulted in the formation of large, colorless crystals. The crystals were filtered off, washed with cold toluene (0°C), and dried in vacuo. Yield: 2.34 g (64%); m.p. = 113°C. Correct elemental analyses were obtained. IR (Nujol/CsI): $\tilde{\nu}$ [cm^{-1}] = 1095, 980, 830, 740, 730, 675, 670, 375, 270.

Reaction of Phosphinines with Diazoalkanes: Diphosphachiropteradienes by Intramolecular, Ionic 5s + 5s [6 + 4] Cycloaddition**

By *Gottfried Märkl,* Hans J. Beckh, Klaus K. Mayer, Manfred L. Ziegler,* and *Thomas Zahn*

Compounds containing PC double bonds react with diazoalkanes to give a surprisingly wide spectrum of products, depending on the substituents. Diazomethane and its monosubstituted derivatives react as 1,3 dipoles with acyclic phosphaalkenes, resulting in [3 + 2] cycloaddition[1] to give dihydro-1,2,4-diazaphospholes. Diaryl- and dialkyldiazomethanes react, with elimination of nitrogen, to give phosphiranes.[2] The P=C bond in aza- and diazaphospholes reacts analogously in many cases.[3]

The P=C bond in phosphinines, on the other hand, behaves completely differently. *K. Dimroth* et al.[4] showed that the reaction of 2,4,6-triarylphosphinines with diazoalkanes in the presence of alcohols afforded 1-alkoxy-1-alkyl-λ^5-phosphinines. Analogous behavior was observed by us for the 3,5-diphenylphosphinine **1**, a phosphinine that is unsubstituted in positions 2, 4, and 6 and reacts with all diazoalkanes tested (diazomethane, mono- and disubstituted diazomethanes) in methanol to give the 1-alkyl-1-methoxy-λ^5-phosphinines **2**.[5]

a, R = R' = H; **b**, R = R' = Me; **c**, R = H, R' = Me; **d**, R = H, R' = Et; **e**, R = Me, R' = Ph; **f**, R = R' = Ph; **g**, R = H, R' = CH_2COOMe

In aprotic solvents, on the other hand, **1** exhibits a completely different behavior upon reaction with diazomethane or with mono- and disubstituted diazomethanes. Compound **1** reacts with diazomethane in ether already at 0°C within a few minutes; immediate workup affords **3a**, which is obtained from acetonitrile in 65–70% yield as a colorless, crystalline compound. The X-ray diffraction analysis of **3a** (Fig. 1) revealed a completely unexpected structure,[6] in which two phosphacyclohexene rings are joined through a CH_2 group (between the phosphorus atoms) and three σ bonds to form a system consisting of two five-membered rings and four six-membered rings.

[**] We propose giving the trivial name "chiropterane" to the saturated hydrocarbon, pentacyclo[7.4.0.0^{2,6}.0^{3,11}.0^{5,10}]tridecane corresponding to **6**, because of their batlike structure (bat: Chiroptera). Compounds **3** are accordingly diphosphachiropteradienes.

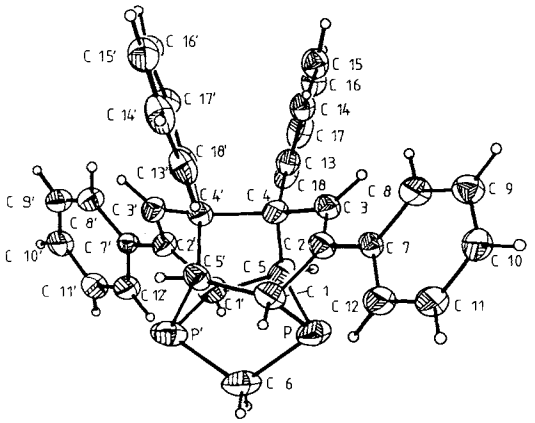

Fig. 1. Crystal structure of **3a**.

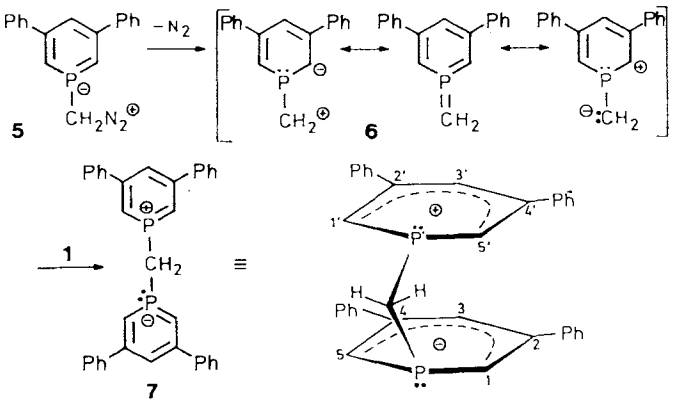
Both the ^{1}H-NMR spectrum and the ^{13}C-NMR spectrum[7] of **3a** are in agreement with this structure (Table 1). The ^{31}P-NMR resonance signal ($\delta = 66.8$) is found at unusually low field for tertiary phosphanes. Similar, extremely low-field shifts were previously observed only for *syn*-7-phosphanorbornenes, *syn*-benzo-7-phosphanorbornenes,[8a] and for tBu$_3$P.[8b] The question whether the low-field shift for **3a** is due to the expansion of the C5–P–C6 angle (97.3°)[6] or to the spatial proximity of the lone pair of electrons to the C2=C3 bond or to the phenyl substituents at C2 remains unanswered. Compound **1** reacts analogously with dimethyldiazomethane, diazoethane, diazopropane, and methylphenyldiazomethane to give the compounds **3b–e** (Table 1). In these cases, too, the ^{31}P-NMR signals for the tertiary phosphanes are found at extremely low field ($\delta = 74$ to 94).

The mass spectra of **3** also exhibit unique features. In the 70-eV spectra, only the molecular ion peak of **1** at m/z 248 is observed and, in some cases (with less intensity), also the radical cation of **6** as the ion fragment [phosphinine-CRR']$^{\oplus\ominus}$, e.g., $[C_{17}H_{13}P{-}CH_2]^{\oplus\ominus}$, m/z 262 for **3a**.[9]

The first step in the formation of **3** (shown for **3a**) is the nucleophilic attack of diazomethane on the $\lambda^3\sigma^2$ phosphorus atom of **1** to give the diazonium salt **5** followed by elimination of N_2 to give the dipolar compound **6** (a cyclic derivative of bis(methylene)phosphoranes, first described by *R. Appel* et al.[10]). The existence of the intermediate **6** is supported by its trapping with alcohols to give the λ^5-phosphinines **2**. Nucleophilic attack of **6** on a second molecule of **1**[11] results initially in formation of the adduct **7**, which consists of two phosphinine molecules **1** and a CH_2 fragment and in which a phosphininyl anion and a phosphininium ion are linked by a CH_2 bridge.



The formation of **7** requires that the diazoalkane employed experience little resonance stabilization, so that the 1,3-dipole **6** is sufficiently nucleophilic to attack a second molecule of **1**. This assumption is supported by the finding that reaction of **1** with diphenyldiazomethane results in formation of the bicyclic phosphirane **9**.[12] In this case, **4**, the intermediate corresponding to **6**, can only undergo stabilization by means of intramolecular ring closure.

Compound **3a** is presumably formed from **7** by ionic, intramolecular [6+4] cycloaddition, resulting in the forma-

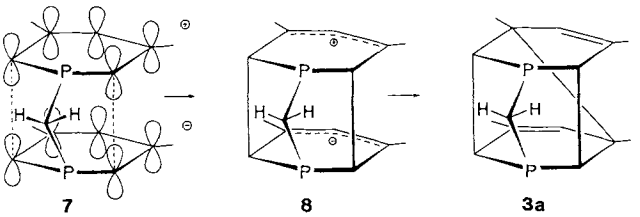
tion of two σ bonds (C1–C5′ and C1′–C5) to give **8**. Intermediate **8**, which consists of an allyl cation moiety and an allyl anion moiety, can undergo stabilization by formation of a (C4–C4′) σ bond to give **3a**.[13]



Whereas especially cationic (3s+4s) and, in special cases, (5s+2s) cycloadditions, as well as anionic (5s+4s) and (3s+2s) cycloadditions, have already been reported,[14] the doubly ionic (5s+5s) reaction postulated here is, to the best of our knowledge, the first of its kind. The assumption of a nucleophilic attack of the diazoalkane on the $\lambda^3\sigma^2$ phosphorus atom as opposed to a 1,3-dipolar cycloaddition on the P=C bond is also supported, for example, by the observation that ethyl diazoacetate no longer undergoes reaction with **1** in aprotic solvents. Thus, the electrophilicity of the phosphinine clearly dominates over its dipolarophilicity.[16]

MNDOC Calculations of the Potential Surfaces for Photochemical α-Cleavage

By *Manfred Reinsch, Udo Höweler,* and *Martin Klessinger**

In contrast to thermal reactions, photochemical reactions have been hardly amenable to semiempirical calculations. There are two reasons for this: the parameters used in semiempirical methods apply only to the ground state, and unacceptably long calculation times are required in order to adequately account for configuration interaction (CI). We show here that it is possible to overcome these difficulties. To accomplish this, the MNDOC method,[1] which is parametrized for explicit calculation of electron correlation and has already been employed for the calculation of excited-state surfaces,[1b] was combined with a CI calculation that was limited by suitable selection criteria, different reference configurations being used for the individual states.[2]

The procedure was applied to formaldehyde, the simplest model compound for studying photochemical α-cleavage. The first three-dimensional potential surfaces of the ground state S_0, the excited (n,π*) states S_a and T_a, and

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. *W. Thiel*, Universität-Gesamthochschule Wuppertal, for a version of the MNDOC program and for valuable discussions and Dr. *J. Downing*, University of Utah (USA), for the DZDO program.

the excited (π,π^*) state T_s of formaldehyde are depicted in Figure 1. The most important parameters used in calculating the potential surfaces, as well as data required for estimating the accuracy of the results, are summarized in Table 1.

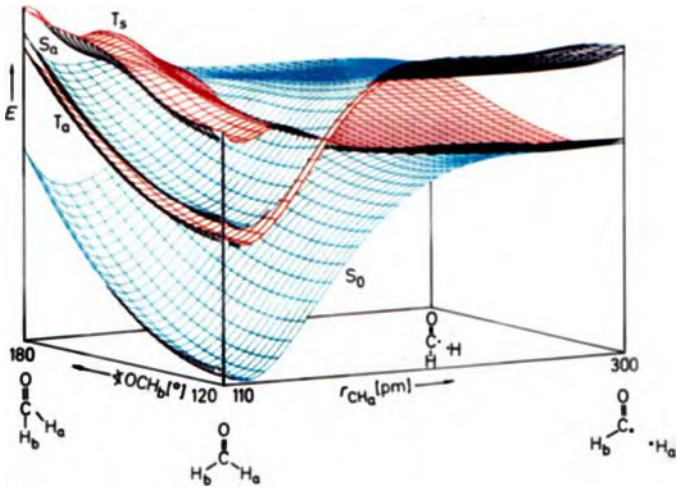

Fig. 1. Potential energy surfaces of the lowest energy singlet and triplet states of formaldehyde as a function of CH_a distance and OCH_b angle. The upper sides of the potential surfaces are blue for singlet states and red for triplet states.

Table 1. MNDOC calculations on formaldehyde (planar conformations). ψ = reference configuration, n_{CI} = number of configurations used in the CI calculation.

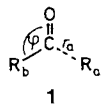
[a] Dissociation energy in the case of S_0, vertical excitation energies in the cases of S_a, T_a, and T_s. [b] Experimental value. [c] Calculated value. [d] Ground state. [e] Calculated at the optimized S_0 geometry.

Plotting of the energies as functions of the distance r_a to the leaving group R_a and the angle φ between the carbonyl group and the substituent R_b in **1** (see Figure 1) clearly reveals which product is produced in which state. This represents a clear advantage over separate correlation of the ditopic reaction to bent and the tritopic reaction to linear primary products, which is usually the case when the α-cleavage is discussed in terms of correlation diagrams.[3]



1

According to Figure 1, the energy of the ground state increases along both coordinates, and the ground state correlates with the diradicaloid $^1D_{\sigma\sigma}$ state. The surfaces of the two (n,π^*) states S_a and T_a stay nearly parallel over the entire region and form, after crossing the (π,π^*) state T_s the $^{1,3}D_{\sigma\pi}$ pair of states. Finally, the (π,π^*) state exhibits a barrier, which is due to an avoided crossing with the highly excited $^3(n,\sigma^*)$ state, and becomes the $^3D_{\sigma\sigma}$ state. All four states are degenerate for an OCH_b angle of 180° and a large CH_a distance.

The reaction coordinates corresponding to the minimum energy path, can be determined for the various states from the contour diagrams in Figure 2. For the reaction in the ground state S_0 and in the (π,π^*) state T_s, the bond angle increases by only a small amount from $\varphi = 125°$ to $\varphi = 130°$; the cross section through the potential surfaces of Figure 1, shown in Figure 3a for $\varphi = 130°$, corresponds

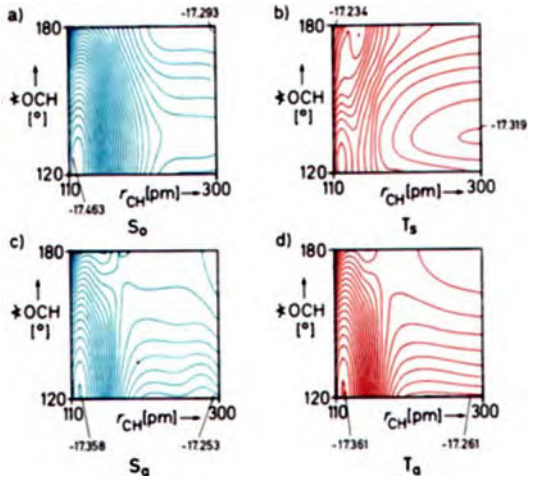


Fig. 2. Contour diagrams of the lowest-energy singlet and triplet states. a) Singlet ground state S_0. b) Symmetric triplet state T_s. c) Antisymmetric singlet state S_a. d) Antisymmetric triplet state T_a. The maximum and the minimum energy value is shown in each diagram. The spacing of the contour lines is 5×10^{-3} a.u.

to the correlation diagram for the ditopic reaction giving the bent acyl radical. On the (n,π*) surface (S_a and T_a), the reaction pathway leads from a point near the ground-state geometry to a linear acyl radical. A cross section through the surfaces of Figure 1 along this pathway is shown in Figure 3b; it corresponds to the correlation diagram for the tritopic reaction giving the linear product. Accordingly, photochemical α-cleavage from the (π,π*) state T_s should lead to bent products and that from the (n,π*) states to linear products. However, it must be noted that the crossing between the triplet states is avoided for a nonplanar conformation. Furthermore, according to Kasha's rule, the reactions arising from the (π,π*) state T_s should have little probability.

In the case of formaldehyde, the barriers in the (n,π*) states are clearly too high for a photochemical reaction,[4] even if the avoided crossing in the case of the nonplanar reaction is taken into consideration. This is in agreement with the experimental results, since in photochemical reactions formaldehyde dissociates mainly into molecular products.[5] Analogous calculations for acetaldehyde and acetone revealed that the general form of the potential surfaces in Figure 1 for α-cleavage is typical, but that the heights of the barriers depend on the molecular structures involved. For instance, the barriers for H cleavage and CH_3 cleavage from the ^{3}(n,π*) state of acetaldehyde are 45 and 80 kJ mol^{-1} greater, respectively, than that for H cleavage from formaldehyde.

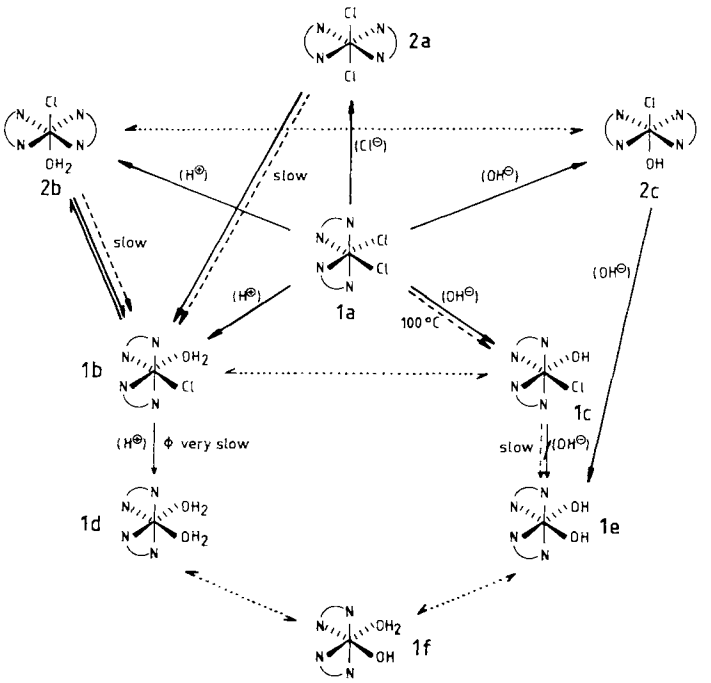
Photoisomerization of Bis(bipyridyl)rhodium(III) Complexes; Synthesis of *trans*-$[Rh(bpy)_2YCl]^{n\oplus}$, Y = Cl, H_2O**

By *Gerd Krüger, Stefan Wieland,* and *Rudi van Eldik**

Investigations of d^6-transition-metal poly(pyridyl) complexes have contributed to the fundamental understanding of inorganic photochemistry.[1] The nature and arrangement of the ligands can crucially influence their photophysical properties and thereby their photochemical behavior. Thus, in addition to the "tuning" of the ligands,[2] their relative position in the complex with respect to an extension of the π system is of great importance.

In octahedral complexes, $[M(bpy)_2XY]^{n\oplus}$, with bidentate-coordinated 1,4-diazabutadienes of the type 2,2′-bipyridyl (bpy), the *trans* arrangement was long thought to be unlikely because of the spatial proximity of the protons (H-6α, H-6β and H6′α′, H-6′β′) of mutually opposing bpy ligands.[3] The bis(bipyridyl) complexes of the d^8 metal ions $Pd^{2\oplus}$ and $Pt^{2\oplus}$, which have mainly a square-planar environment, overcome this steric hindrance by distortion of either the MN_4 portion of the complex or the ligands.[4]

As observed for the very slow thermal exchange reactions, the early photolyses of rhodium(III) complexes, which led to initial excitation of the intraligand states (**1a** with $\lambda_{max} = 311$ nm), the LF states (**1a** with a shoulder at $\lambda = 380$ nm), or eventually the π*(bpy)←d(Rh) CT states, resulted only in photoaquation with retention of the *cis* configuration.[5] However, in a high-pressure kinetic investigation of the reaction mechanism and the quantum yields of the photolysis of **1a**, the first evidence was obtained for a side or subsequent reaction occurring in addition to the photoaquation and having stereochemical consequences similar to those observed in the *cis–trans* isomerization of $[Ru(bpy)_2(H_2O)_2]^{2\oplus}$.[6]



1a: X = Y = Cl
1b: X = Cl, Y = OH_2
1c: X = Cl, Y = OH
1d: X = Y = OH_2
1e: X = Y = OH
1f: X = OH_2, Y = OH

2a: X = Y = Cl
2b: X = Cl, Y = OH_2
2c: X = Cl, Y = OH
2d: X = Y = OH_2

On the basis of UV and ^{1}H-NMR spectroscopic results obtained on photolysis solutions of **1a**–**f**, we now report on the light-induced *cis–trans* isomerization of bis(bipyridyl) complexes and the isolation of the new compounds **2a**Cl and **2b**$(ClO_4)_2$.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Max-Buchner-Forschungsstiftung.

The characterization of the isolated *trans* complex salts is based on the significant redshift of the absorption bands of the d-d transitions compared with those of the *cis* complexes and on comparison of the ^{1}H-NMR spectra of the *cis* and *trans* complexes (as well as on elemental analyses). Whereas the four diastereotopic pyridyl rings of the *cis* complexes with X ≠ Y give, in principle, 16 groups of signals, the pattern of signals for the *trans* complexes is reduced to four groups of signals owing to the higher symmetry, similar to the basic arrangement of free 2,2'-bipyridyl. Rhodium is thus the second transition metal preferring an octahedral environment for which photochemistry opens up a preparative route to the *trans*-poly(bipyridyl) complexes.

The results of irradiation of the pure perchlorates of **1a**, **1b**, and **1d** with light of wavelength 313 nm and at pH values between 2 and 13 are summarized in Figure 1. The thermal exchange reactions at 25°C occur much more slowly than the photochemical exchange reactions. The main products resulting from irradiation of **1a** over the entire pH range are the *cis*-monosubstituted products. Whereas a photostationary equilibrium between **1b** and **2b** is attained in acidic medium, **1c** and **2c** are formed in alkaline medium, the latter of which reacts further to give **1e**. The existence of **2b** or **2c** determines in a characteristic way the UV difference spectrum between irradiated and nonirradiated solutions. Photochemical exchange of the chloride ligand in **1c** could not be observed; in the case of **1b**, it occurs with a small quantum yield ϕ.

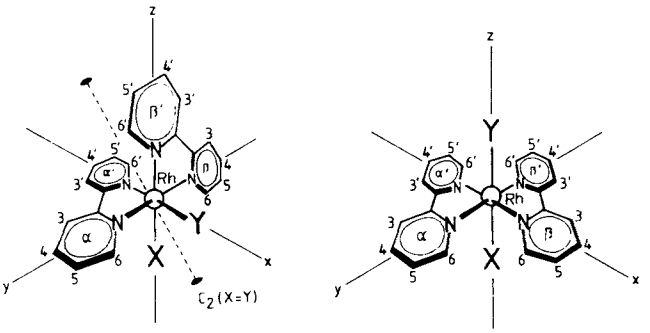

Fig. 1. Reaction scheme for the observed transformations of the rhodium(III) complex ions at 25°C (the charges have been omitted): ——, photochemically at $\lambda = 313$ nm; – – – –, thermally at 25°C unless otherwise noted; · · · · ·, acid-base equilibrium.

The photosubstitution of **2a** to give **1b** and the photoisomerization of **1a** to give **2a** in the presence of an excess of $Cl^{\ominus}$ suggest the existence of a common intermediate, which is formed by light-induced dissociation of a chloride ligand. In accordance with earlier suggestions,[7] this step leads to an equilibrium between two excited square-pyramidal intermediates, which differ in the identity of the ligands in the apical and basal positions. The energetically favored intermediate is that in which the ligands having less σ-donor strength are in the apical position. Since the order of σ-donor strength is $Cl < H_2O < bpy < OH$, this model readily explains the simultaneous formation of **1b** and **2b** and of **1c** and **2c**, respectively, upon photolysis of **1a** in acidic and basic medium. If one assumes that, as in the case of other rhodium complexes, a coordinated water molecule is photolabile, the formation of the photoproduct **2d** only after very long photolysis of **2b** is also understandable.

We thus conclude that inorganic complexes can also be transformed into sterically conjested isomers, which are not available via other routes, by photochemical reactions.

Experimental Procedure

The starting materials afforded correct elemental analyses and appropriate UV and ^{1}H-NMR spectra.

2aCl: **1a**Cl·2 H_2O (1.8 g) was dissolved in 140 mL of 1 M HCl and the resulting, stirred solution was irradiated in a Duran vessel for 110 h with a high-pressure Hg lamp (Hanau TQ 150 Z1) equipped with a filter transparent between 300 and 400 nm. The precipitated, finely divided product was filtered off under suction, recrystallized from 600 mL of 0.01 M HCl, washed with H_2O, EtOH, and Et_2O in that order, and dried in a water-aspirator vacuum over $CaCl_2$. A 36% yield of yellow **2a**Cl was obtained which gave correct C,H,N, and Cl analyses. ^{1}H-NMR (300 MHz, D_2O, standard HDO ($\delta = 4.9$)): $\delta = 9.38$ (d, 4H; H-6), 8.74 (d, 4H, $J(3,4) = 7.5$ Hz; H-3), 8.57 (t, 4H, $J(4,5) = 7.8$ Hz; H-4), 8.10 (t, 4H, $J(5,6) = 5.7$ Hz; H-5); UV/VIS (H_2O): $\lambda_{max} = 250$ (sh) ($\varepsilon = 21200$ M^{-1} cm^{-1}), 307 (sh) (18900), 312.5 (19600), 326 (sh) (8780), 405 (103) nm.

2b $(ClO_4)_2$: As described above, **1b**$(ClO_4)_2 \cdot H_2O$ (1.2 g) was dissolved in 100 mL of H_2O and irradiated for 45 h. The precipitated product was filtered off, recrystallized from 120 mL of 0.01 M $HClO_4$, and washed and dried as described above. A 22% yield of yellow-orange **2b**$(ClO_4)_2$ was obtained, which afforded correct C, H, N, and Cl elemental analyses. ^{1}H-NMR (300 MHz, D_2O, standard HDO ($\delta = 4.9$)): $\delta = 9.43$ (d, 4H; H-6), 8.79 (d, 4H, $J(3,4) = 8.2$ Hz; H-3), 8.64 (t, 4H, $J(4,5) = 7.8$ Hz; H-4), 8.14 (t, 4H, $J(5,6) = 5.5$ Hz; H-5); UV/VIS (0.01 M $HClO_4$): $\lambda_{max} = 248$ (22900), 310 (20000), 323 (sh) (14300), 375 (100) nm.

A New Photosynthesis-like System for the Light-induced Reduction of Water to Molecular Hydrogen**

By *Wolfgang Schuhmann,** *Hans-Peter Josel,* and *Harun Parlar*

The conversion of solar energy into electrical current or storable fuels has been the goal of intensive research for several years. Most interesting is the production of molecular hydrogen as a universally employable, environmentally acceptable fuel having high energy density in terms of weight.[1]

Owing to their similarity to chlorophylls, their photostability, and their photoelectrochemical properties, metal porphyrinates are expected to be good photosensitizers.[2] Adsorption of water-insoluble metal porphyrinate layers onto metal electrodes affords photosensitive semiconductor electrodes, whose photoelectrochemical behavior can be described by the band-bending model.[3] The difference between the Fermi level of the metal electrode and that of the applied dye layer results in an equalization of the

[**] We thank *J. Huber* and *S. Meixner* for their assistance.

chemical potential of the electrons in the contact region and thereby in a bending of the energy bands in the dye layer. The direction and magnitude of this band bending depend only on the relative position of the Fermi levels and largely determine the amount of electron-hole-pair formation and the efficiency of charge separation in the dye layer following excitation with light. In 1978, *Kawai* et al. first described the p-semiconducting behavior of zinc *meso*-tetraphenylporphyrinate adsorbed on platinum electrodes.[4]

We have now investigated the photoelectrochemical behavior of a series of dyes prepared by varying the *meso* phenyl substituents of zinc porphyrinates. These water-insoluble metalloporphyrinates were adsorbed onto platinum electrodes, and their photocurrent properties, i.e., the direction and extent of photoinduced electron-transfer reactions, were examined as a function of the wavelength of the incident light. In contrast to earlier studies,[5] in which exclusively p-type semiconducting behavior was observed with metalloporphyrins adsorbed on aluminum electrodes, the present work shows that several of the metalloporphyrinate layers on platinum electrodes are n-type semiconductors.

The photocurrent spectrum in Figure 1a shows clearly that zinc 5-(4-pyridyl)-10,15,20-tritolylporphyrinate (ZnTTPyP) is n-semiconducting. Excitation with light results in the transfer of an electron from the dye layer to the noble-metal electrode (oxidation of the excited dye molecule). Zinc 5,10,15,20-tetra-(4-pyridyl)porphyrinate (ZnTPyP), on the other hand, is p-semiconducting (Fig. 1b), i.e., the photoexcited electrons are transferred from the dye to acceptors in the surrounding electrolyte.

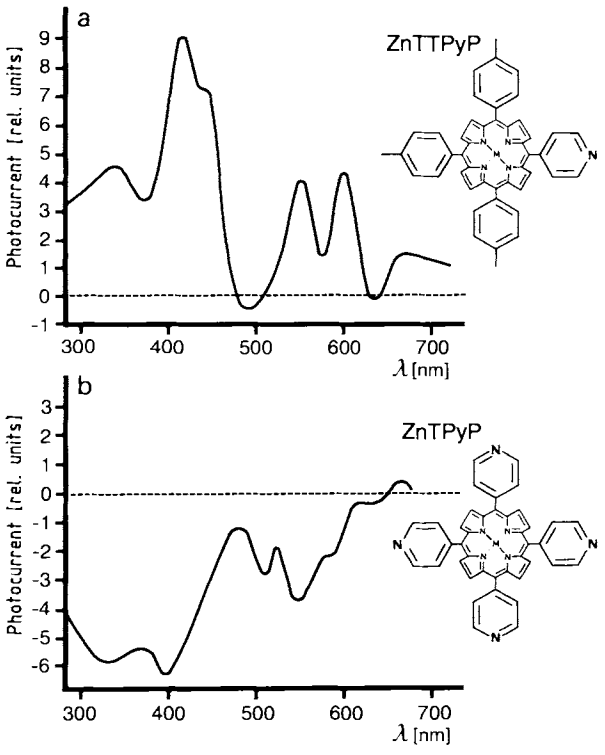

Fig. 1. Photocurrent spectra of a) ZnTTPyP and b) ZnTPyP. Positive values correspond to current flow from the dye layer to the electrode (n-semiconducting, anodic photocurrent); negative values correspond to a current flow from the electrode to the dye (p-semiconducting, cathodic photocurrent). In contrast to the extinction coefficients for the absorption spectrum of metal porphyrinates, the electron transfer appears to occur with greater probability after excitation of the Q band ($\lambda = 500$–600 nm) than after excitation of the Soret band ($\lambda = 425$ nm). The spectra are corrected for the wavelength-dependent intensity of the lamp employed. The experimental setup consists of a xenon lamp, a motor-driven monochromator, and a two-electrode arrangement coupled through a nanoamperemeter. The dye-modified electrode being measured and a platinum counterelectrode are immersed in an aqueous electrolyte containing KCl and the disodium salt of ethylenediaminetetraacetic acid (EDTA). The electrodes are irradiated through a planar polished quartz window.

On the basis of these results, a novel photosynthesis-like system for solar-energy conversion was developed in which the photoinduced reduction of water to molecular hydrogen could be demonstrated upon irradiation with visible light. The potential required for the reduction of water is attained by coupling two a priori independent light-absorption processes at metal porphyrinate-modified platinum electrodes, so that, as in the biological photosynthetic apparatus, two photosystems with different absorption and redox properties work together.

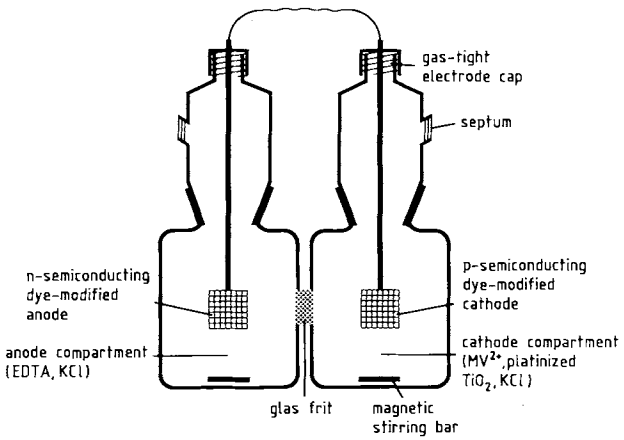

Fig. 2. Photoelectrochemical cell for the reduction of H_2O to H_2.

The results obtained with monochromatic light were verified with polychromatic light that was similar to sunlight by irradiation of dye-modified electrodes in a photoelectrochemical cell with separate anode and cathode compartments (Fig. 2). If a platinum electrode modified with n-semiconducting ZnTTPyP is connected via an external circuit with an electrode modified with p-semiconducting ZnTPyP, polychromatic irradiation of the two electrodes ($\lambda > 455$ nm) results in current flow in the external circuit from the n-semiconducting to the p-semiconducting electrode. The ZnTTPyP anode is immersed in an aqueous electrolyte containing KCl as conducting salt and EDTA as irreversibly oxidizable donor. Dye molecules that undergo oxidation by photoinduced electron transfers are reduced by EDTA and can thus participate again in absorption processes. In the cathode compartment, the ZnTPyP electrode is surrounded by an aqueous electrolyte that contains, in addition to KCl, *N,N*-dimethylbipyridinium dichloride ($MV^{2\oplus}$) as intermediary electron acceptor. Light-induced electron transfer from the irradiated cathode to $MV^{2\oplus}$ is revealed by the formation of the blue radical cation $MV^{\odot\oplus}$. In the presence of a microheterogeneous catalyst—highly disperse, platinized titanium dioxide[6]—$MV^{\odot\oplus}$ is reoxidized to $MV^{2\oplus}$ with simultaneous reduction of water to molecular hydrogen. The formation of hydrogen was monitored quantitatively by subjecting aliquots from the cathode compartment to gas chromatography (Fig. 3).

The electrons that are required in the cathodic dye layer to carry out the reduction are supplied by the photocurrent

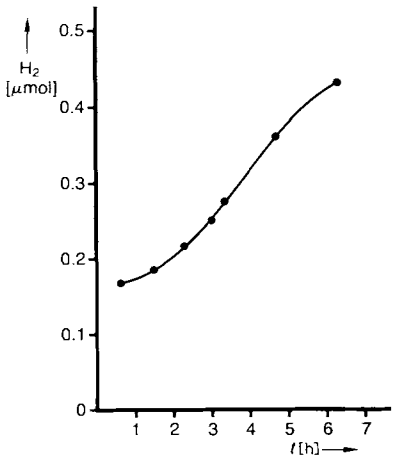

Fig. 3. Time dependence of H_2 formation with the system shown in Figure 2. The system was irradiated with an Osram Ultra-Vitalux lamp (300 W) through a 10-cm water filter and a 455-nm cut-off filter in order to avoid direct band-gap excitation of TiO_2. The quantum yields of H_2 formation were estimated by actinometric experiments with iron oxalate [7]. Taking into consideration the inaccuracy of the quantum current determination for long-wavelength light quanta ($\lambda > 450$ nm), the quantum yield was $< 10^{-3}$.

in the external circuit and are ultimately provided by the irreversible oxidation of the sacrificial electron donor EDTA. This coupling of two a priori independent light-absorption processes is analogous to the light reaction involved in photosynthesis in green plants (Fig. 4). The processes taking place at the anode and cathode compartments are summarized in Scheme 1.

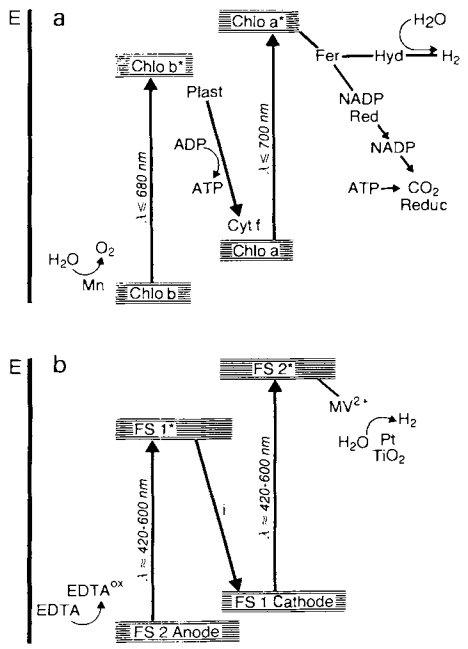

Fig. 4. Schematic comparison of the light reaction involved in the photosynthesis of green plants (a) with the novel photoelectrochemical system (b). The cascadelike sequence of electron-transfer reactions following light excitation of photosystem II in the natural system proceeds from activated chlorophyll to plastoquinone and cytochrome f in analogy to the external circuit of the artificial system. $MV^{2\oplus}$ corresponds to ferrodoxin, and the platinized TiO_2, which serves as reduction catalyst, corresponds to the hydrogenase in photosynthesis. The branch showing CO_2 reduction has no analogy in our artificial solar-energy conversion system.—Mn, manganese complex; Chlo b, chlorophyll b; Chlo a, chlorophyll a; Plast, plastoquinone; Cyt f, cytochrome f; Fer, ferredoxin; Hyd, hydrogenase; NADP Red, NADP reductase; CO_2-Reduct, CO_2 reduction; FS 1, p-semiconducting metal porphyrinate; FS 2, n-semiconducting metal porphyrinate; i, external circuit.

Anode compartment (photosystem II)

$$\text{n-FS} \longrightarrow \text{n-FS}^* \quad \text{(a)}$$

$$\text{n-FS}^* + \text{Pt} \longrightarrow \text{n-FS}^{\oplus} + e^{\ominus}(\text{Pt}) \quad \text{(b)}$$

$$\text{EDTA} + \text{n-FS}^{\oplus} \longrightarrow \text{EDTA}^{ox} + \text{n-FS} \quad \text{(c)}$$

Cathode compartment (photosystem I)

$$\text{p-FS} \longrightarrow \text{p-FS}^* \quad \text{(d)}$$

$$\text{p-FS}^* + MV^{2\oplus} \longrightarrow \text{p-FS}^{\oplus} + MV^{\odot\oplus} \quad \text{(e)}$$

$$2H_2O + 2MV^{\odot\oplus} \xrightarrow{\text{catalyst}} H_2 + 2OH^{\ominus} + 2MV^{2\oplus} \quad \text{(f)}$$

$$\text{p-FS}^{\oplus} + e^{\ominus}(\text{Pt}) \longrightarrow \text{p-FS} \quad \text{(g)}$$

Scheme 1. n-FS = ZnTTPyP; p-FS = ZnTPyP; FS = dye. The reactions described by the equations (a), (b), (d), and (g) take place on the irradiated dye electrodes; reactions (c) and (e) occur in the respective electrode-electrolyte contact regions; and equation (f) represents a reaction in the electrolyte of the cathode compartment. The electron transfer is assumed to take place from the excited triplet states of the porphyrinates. Reductive quenching by EDTA of the dye adsorbed on the anode, with formation of the corresponding dihydroporphyrinate, could be ruled out by observation of the absorption spectrum of dye that was later dissolved from the electrode.

A crucial difference lies in the fact that the efficiency of charge separation following the photosensitization reaction is not determined by a cascade of electron transfer reactions, as in the biological system, but rather by the degree of bending of the energy bands in the dye-noble-metal contact region. This band bending is responsible for the potential gradient that is formed upon irradiation of the electrodes, and thus determines the force applied to the photoexcited electron in the conducting band of the dye semiconductor. This means that the difference between the Fermi levels largely determines the efficiency of charge separation and consequently the efficiency of the conversion of solar energy into chemical energy.

Coupled photosystems such as those described in this communication might be used—after optimization—to convert solar energy into chemically storable energy. This would be an important step toward developing practical solar-energy conversion systems in which hydrogen and oxygen are safely formed from water in separate compartments, all other components of the system being true catalysts.

Synthesis of the Four-Membered Metallacycle $[Cp_2Ti(AsPh)_3]$ via the in situ Reduction of $[Cp_2TiCl_2]$**

By *Paul Mercando, Anthony-Joseph DiMaio*, and *Arnold L. Rheingold**

Bis(cyclopentadienyl)titanium complexes (Cp_2Ti) containing chelating trisulfido,[1a,b] pentasulfido, and pentaselenido ligands ($[Cp_2TiE_5]$, E = S or Se),[1c-f] are well-known and characterized by high reactivity. The isolobal and isoelectronic relationship of a sulfur or selenium atom to a phosphanediyl (phosphinidene) or arsanediyl (arsinidene) fragment prompted us to explore synthetic routes to the analogous $[Cp_2Ti(RE')_n]$ complexes (E' = P or As). *Issleib* et al. prepared $[Cp_2Ti(PPh)_3]$ in moderate yield from $[Na_2(PPh)_4]$ and $[Cp_2TiCl_2]$[1g] and identified the product from its ^{31}P-NMR spectrum, but did not characterize it crystallographically. A related procedure led to the preparation of $[Cp_2Ti(AsEt)_3]$.[1h] The compounds $[Cp_2Ti(PR)_3]$ (R = Ph, Me, Et, and *t*Bu) have been prepared from $[K_2(PR)_n]$ and $[Cp_2TiCl_2]$.[1i] The $(AsPh)_3$ ligand has previously been observed in a late-transition-metal metallacycle, $[(C_5Me_5)Rh(CO)(AsPh)_3]$.[1j]

Following the in situ reduction scheme developed by *Rausch* et al. for the quantitative synthesis of $[Cp_2Ti(PMe_3)_2]$,[2,3] we have obtained good yields of $[Cp_2Ti(AsPh)_3]$ **1** as a moderately air-stable, purple, crystalline product via the reduction of $[Cp_2TiCl_2]$ by magnesium in the presence of *cyclo*-$(AsPh)_6$:

$$[Cp_2TiCl_2] + Mg + 1/2\,cyclo\text{-}(AsPh)_6 \longrightarrow [Cp_2Ti(AsPh)_3] + MgCl_2$$

1

Under the conditions of this reaction, Mg and *cyclo*-$(AsPh)_6$ alone are inert; the apparent ring-opening agent is the reduced Ti species.

Compound **1** has been characterized by ^{1}H-NMR spectroscopy[4] and by an X-ray diffraction study.[5] At room temperature, two singlets for the Cp rings are seen in the ^{1}H-NMR spectrum and no indication of line broadening is seen to 80 °C. In $[Cp_2TiS_5]$, ring conformation flipping produces dynamic effects clearly evident at 80 °C with coalescence occurring at 90 °C.[1c] In $[(Me_5C_5)_2TiS_3]$ only a single methyl peak is seen at room temperature.[1b]

The inequivalence of the Cp rings in **1**, also evident in the solid state, is caused by the arrangement of the phenyl rings (see Fig. 1). Additionally, the bisector of the angle formed by the Ti atom and the centers of the Cp rings is not contained in the As-Ti-As plane. The central $TiAs_3$ rhombus in **1** is essentially flat; the maximum deviation from planarity, which occurs at As2, is 0.018(3) Å. In contrast, the $RhAs_3$ ring in complex **2** is puckered with a dihedral of angle 23.1°.[1i] The TiS_3 ring in $[(Me_5C_5)_2TiS_3]$ is even more puckered, the dihedral angle being 49°.[1a] In **1**, the plane created by the centers of the Cp rings and the Ti atom is perpendicular to the $TiAs_3$ plane (dihedral angle, 89.7(2)°). The angle (133.1(2)°) formed by the Ti atom and the centers of the Cp rings is similar to that found in $[Cp_2Ti(PMe_3)_2]$ (133.2(5) and 134.3(6)° for two independent molecules)[3] and in $[Cp_2TiS_5]$ (average 133.0°).[1d,e] The As1-Ti-As3 angle in **1** (96.8(1)°) is larger than in $[Cp_2Ti(PMe_3)_2]$ (92.9(1)° and 91.5(2)°), but similar to that found in $[Cp_2TiS_5]$ (average 95.0°). The As-Rh-As angle in **2** is considerably more acute (81.41(4)°).[1j]

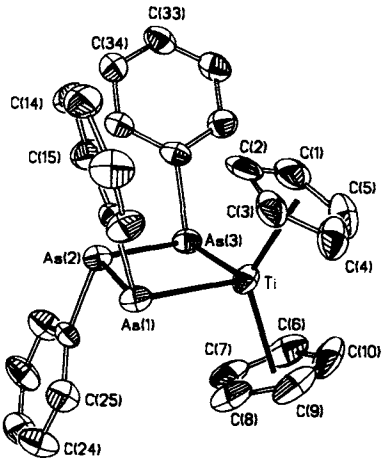

Fig. 1. ORTEP drawing of the crystal structure of **1** (without hydrogen atoms).

$[(C_5Me_5)Rh(CO)(AsPh)_3]$ **2** $[Cp_2Ti{-}CH_2{-}CRR'{-}CH_2]$ **3**

$[\{CpFe(CO)_2\}(AsPh)_2]$ **4**

The Ti-As bond distances (2.668(2) Å to As1 and 2.655(2) Å to As3) appear to be "normal," though little precedent exists: in a bis(dimethylarsino)-*o*-phenylene complex, the average Ti-As bond distance is 2.691 Å;[6] in a 1-diphenylphosphino-2-diphenylarsinoethane complex, it is 2.677(1) Å.[7] The As-As distances (As1-As2 2.431(1) Å and As2-As3 2.442(1) Å) are very similar to a "standard" As-As single bond distance in *cyclo*-$(AsPh)_6$ (average, 2.459 Å).[8] The As1-As2-As3 angle (109.51(6)°) is the largest we have encountered; in *cyclo*-$(AsPh)_6$, the average As-As-As bond angle is 91.1°.[8] The large As-As-As angle is similar to that observed in the isolobal titanacyclobutane complexes **3**: for R = H, R' = Ph, the angle at the central carbon atom is 112.0(3)° and for $R = R' = CH_3$, 110.9(6)°.[9] These complexes also have nearly planar central TiC_3 rhombi. The Ti···As2 distance is correspondingly short (3.173(1) Å), which may signify a weak transannular interaction. In sharp contrast is the As-As-As angle in **2** (82.97(5)°).[1j]

Conventional electron-counting procedures, as applied to **1**, yield a 16-electron Ti environment if the metal is Ti^{IV} and the $(AsPh)_3$ ligand functions as a four-electron donor, or if the metal is Ti^{II} and $(AsPh)_3$ a neutral two-electron donor. The former scheme is preferred if *cyclo*-$(AsPh)_6$ is viewed as an oxidizing agent analogous to *cyclo*-$(S)_8$. The latter becomes credible if **1** is compared to **4**, in which the PhAsAsPh unit functions as a two-electron donor.[10]

If, under similar reaction conditions, *cyclo*-$(AsMe)_5$ replaces *cyclo*-$(AsPh)_6$, the reaction time decreases sharply (1 h vs. 2 d) and the corresponding product, $[Cp_2Ti(AsMe)_3]$, is formed as characterized by ^{1}H-NMR.[11]

Experimental Procedure

To a suspension of pulverized Mg turnings (0.863 g, 35.9 mmol) and *cyclo*-$(AsPh)_6$ (7.321 g, 8.03 mmol) in 50 mL of dry, degassed tetrahydrofuran

[**] This work was supported by the Petroleum Research Fund (administered by the American Chemical Society) and the Center for Catalytic Science and Technology.

(THF) was added [Cp_2TiCl_2] (2.00 g, 8.03 mmol) in 150 mL of THF with stirring. After completion of the addition, the mixture was heated to reflux for 48 h. The reaction mixture slowly turned to a deep blue purple. After cooling and filtering, the solvent was evaporated and the residue dissolved in 400 mL of warm toluene. Following further filtration, the solution was reduced to 200 mL and slowly cooled to −78 °C to provide purple crystals of **1** (60%); m.p. = 212–214 °C (dec.).

Cooperative Effects in the Phase Transformation of Triethylcyclotriboroxane**

By *Roland Boese,* Michael Polk,* and *Dieter Bläser*

In exploratory X-ray structure studies on boron-oxygen and boron-nitrogen compounds we discovered that triethylcyclotriboroxane (**1**)[1] exhibits a reversible first order phase transformation at −82 °C (T_1, heating curves, $\Delta H = 2.88$ kJ/mol) and −89 °C (T_2, cooling curves), respectively.[2] A series of X-ray structure analyses were therefore carried out in the region of the low-temperature (LT) phase[3] and the high-temperature (HT) phase[4] with the aim of clarifying the process of this phase transformation.

Using a computer controlled zone-melting procedure,[5] a cylindrical single crystal of **1** (m.p. −21.5 °C) was grown at −28 °C in a capillary tube mounted on the X-ray diffractometer, viewed with polarized light. The compound **1** crystallizes hexagonally in the space group $P6_3/m$. The single crystal is preserved even on passing through the first order phase transition. On approaching T_2 all reflections hkl with $h-k \neq 3n$ become diffuse and their intensities disappear within a temperature interval of ca. 4 K, i.e. the unit cell reduces to a third of its original volume but still maintaining the space group ($P6_3/m$).

In both phases the molecules of **1** have the same planar conformation with D_{3h} symmetry (Fig. 1a) as well as similar intramolecular bond lengths and angles. In the LT structure the molecules are stacked in columns in such a way that the intermolecular B···O distance is maximally 3.462 Å and 3.410 Å at −90 °C and −160 °C, respectively, when the rings are at their nearest in an eclipsed arrangement. In this arrangement the ethyl groups are equidirectionally oriented (Fig. 1b). In the HT structure there are two different arrangements in the columns: (a) eclipsed stacking with equidirectionally oriented ethyl groups, (b)

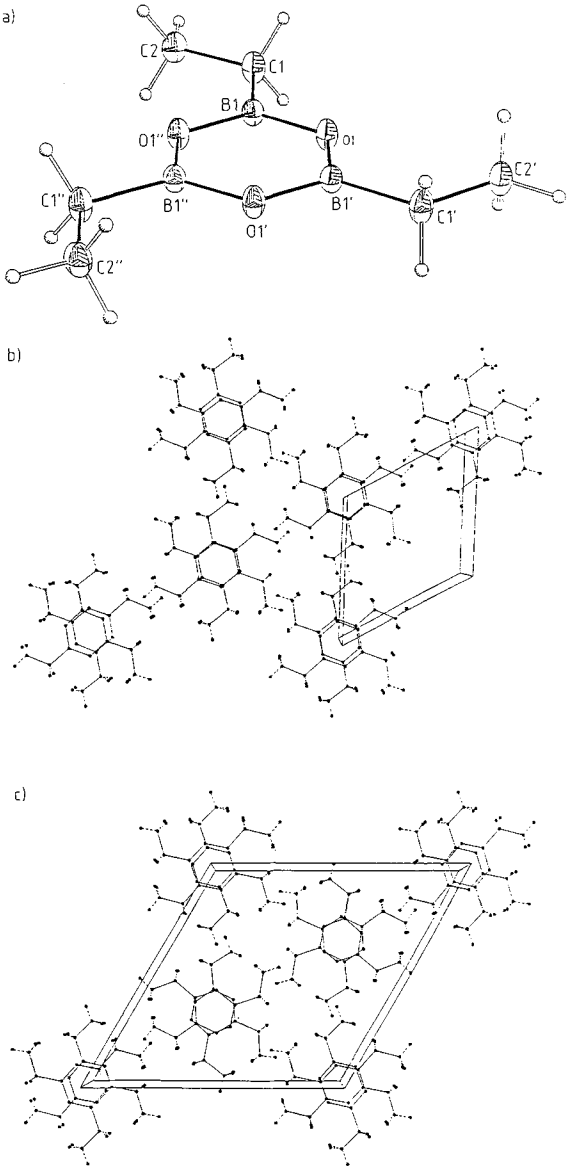

Fig. 1. a) Structure of **1** in the LT phase (−160 °C). Most important bond lengths [Å] and angles [°]: B1-O1 1.380(1), B1-O1'' 1.387(1), B1-C1 1.565(1), C1-C2 1.524(1); B1-O1-B1' 121.6(1), O1-B1-O1'' 118.4(1), O1-B1-C1 121.7(1), O1''-B1-C1 119.7(1), B1-C1-C2 116.8(1). b) Stacking of **1** in the LT phase: view of two layers in the *a*–*b* plane. c) Stacking of **1** in the HT phase: view of two layers in the *a*–*b* plane.

slightly staggered with counterdirectionally oriented ethyl groups. In (b) the rings are rotated by 17.5° with respect to each other. This results in two intermolecular B···O distances, 3.519 Å in (a) and 3.535 Å in (b) ($T=-85$°C) (Fig. 1c).

The transition from the LT phase to the HT phase thus corresponds to a reordering of the packing, during which the ethyl groups and the ring rotate in one third of the molecules. The changeover from equidirectionally oriented ethyl groups to counterdirectionally oriented ethyl groups causes a stretching of the *c* axis. It follows that smaller intermolecular B···O interactions are to be expected for the HT phase than for the LT phase. In contrast, the dimensions of the *a* axis and *b* axis are mainly determined by repulsive intermolecular H···H interactions, as shown in Figure 2. The columns in the HT arrangement can come closer together than in the LT phase. Consequently, the influence of the attractive and the repulsive forces on the alteration of the cell dimensions with temperature is clearly separated because of the unique packing of the molecules in the unit cells.

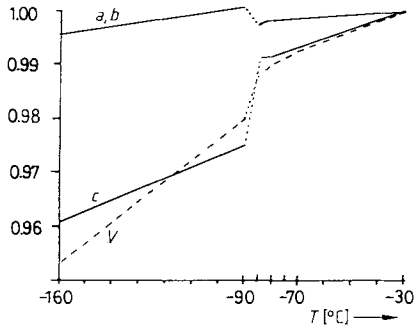

Fig. 2. Change in volume (----) and cell dimensions (——) of **1** with temperature, normalized to the HT phase at −30°C. The volume of the LT phase was multiplied by 3, the *a* and *b* axes were multiplied by $2\cos 30°$.

A comparison with the packing of the molecules of triphenylcyclotriboroxane[6] shows that in this case, intramolecular conjugation (B–C(phenyl)) in the nearly planar system makes an intermolecular B···O interaction unnecessary.[7] No stacking, and, therefore, no corresponding intermolecular interaction of the central benzene ring is even also observed with 1,3,5-trimethylbenzene[8] and 1,3,5-triphenylbenzene.[9] This likewise suggests that the stacking in **1** is effected by the intermolecular B···O interaction.

The course of the phase transformation is best explained using the model in Figure 3 as follows: in the LT phase the heterocycles (ellipses, bodies) are so arranged that the position of the ligands (legs) allow an optimum of B···O interaction (Fig. 3, bottom). Upon heating to above T_1 there is no room in this symmetrical arrangement for thermal motion of the ligands. Therefore, in some molecules at particular points in the crystal (sites of disorder or edges) the ligands start to undergo abrupt changes in their orientation; the heterocycles (bodies) simultaneously rotate somewhat, resulting in less symmetrically oriented ligands. In this way, intermolecular attractive interactions (arms and bodies) are actually reduced, but for the system as a whole this is obviously a more favorable solution than the disruption of the lattice (e.g. melting). The new arrangement (HT structure) finally propagates spontaneously through out the whole crystal (first order transition) and forcibly brings about an increase in volume and, above all, stretching in the direction of the relevant *c* axis which effects the B···O interaction (Fig. 3, top left).

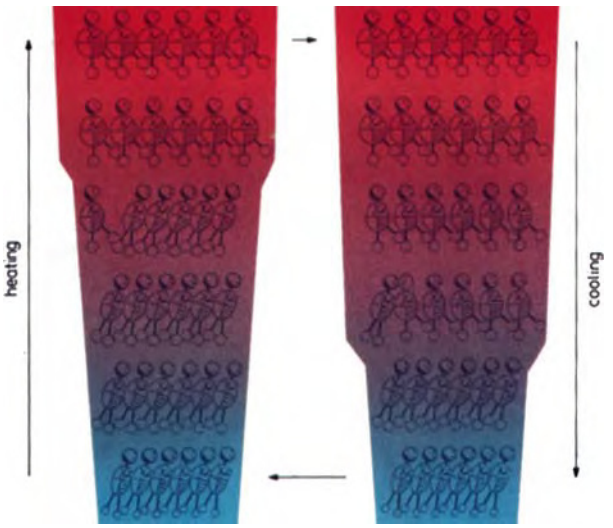

Fig. 3. Models of the phase transition. Left: behavior on heating. Right: behavior on cooling. The volume is represented by the breadth of the rows. The ellipses or bodies represent the heterocycles, the arms correspond to the intermolecular B···O interactions, the legs to the position of the ligands (ethyl groups) and the size of the feet denote their spatial requirement.

On decreasing the temperature to below T_2 (hysteresis) the HT position of the ligands now hinders the thermodynamically more favorable B···O interaction. However there are again molecules at particular points in the crystal whose heterocyclic rings, in order to increase the B···O interaction, overcome the restraints of the wavering ligands and move closer together. This leads to the spontaneous decrease in volume and change to the LT phase.

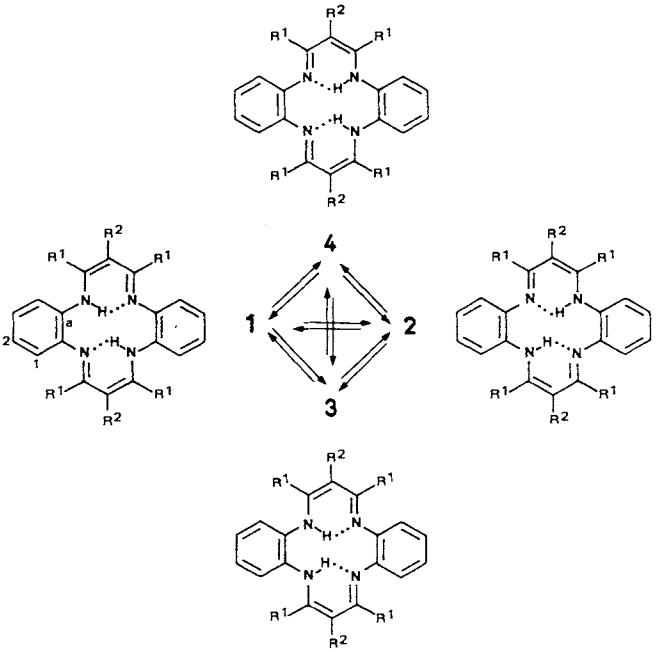
Kinetic ^{15}N-CPMAS-NMR Study of a Double Proton Transfer in a Crystalline Malonaldehyde Diimine Derivative**

By *Hans-Heinrich Limbach,* Bernd Wehrle, Herbert Zimmermann, Ray D. Kendrick,* and *Costantino S. Yannoni**

We report here the rate constants of proton transfer in a strong intramolecularly hydrogen bonded six-membered ring H-chelate of the malonaldehyde type. The data were obtained by dynamic ^{15}N-CPMAS-NMR spectroscopy[1] of crystalline DTAA[2] (Scheme 1). The problem of proton motion in malonaldehyde and its derivatives is a matter of continuing experimental[3-10] and theoretical interest.[11] Evidence for motion along a double minimum potential in these compounds has been obtained using different spectroscopic techniques[3-7] including NMR spectroscopy. Microwave studies[4] indicate a coherent proton tunnel process in gaseous malonaldehyde. So far, these proton transfer processes were found to be so fast that rate constants could not be obtained by NMR or any other method. Using solid state NMR techniques,[12] proton localization was observed for naphthazarine (5,8-dihydroxy-1,4-naphthoquinone)[8,9] and for tropolone[10] at low temperatures, an effect which was, however, caused by intermolecular H-bond formation. This complication does not arise in DTAA. On the other hand, double proton transfers have also been observed in solid porphines.[13,14] However, these compounds are not able to form strong intramolecular H-bonds as do malonaldehyde and its derivatives.

Since solid state proton transfers between nitrogen atoms can be conveniently studied by ^{15}N-CPMAS-NMR spectroscopy of ^{15}N-enriched compounds[13] we have synthesized DTAA-$^{15}N_4$ by slight modifications of the procedures published for the unlabeled compound.[15] The ^{15}N-CPMAS-NMR spectra of DTAA consist of two lines at all temperatures as shown in Figure 1. At low temperature, both the high-field line (which we signify as a), characteristic for an NH environment, and the low-field line (b), characteristic for an sp^2 nitrogen,[16] are sharp. As the temperature is increased, the lines broaden, sharpen again, and move towards each other, but never coalesce. Such line-shape changes are typical for the presence of two un-



Scheme 1. DTAA: $R^1 = H$, $R^2 = CH_3$; TTAA: $R^1 = CH_3$, $R^2 = H$. N 95% for ^{15}N.

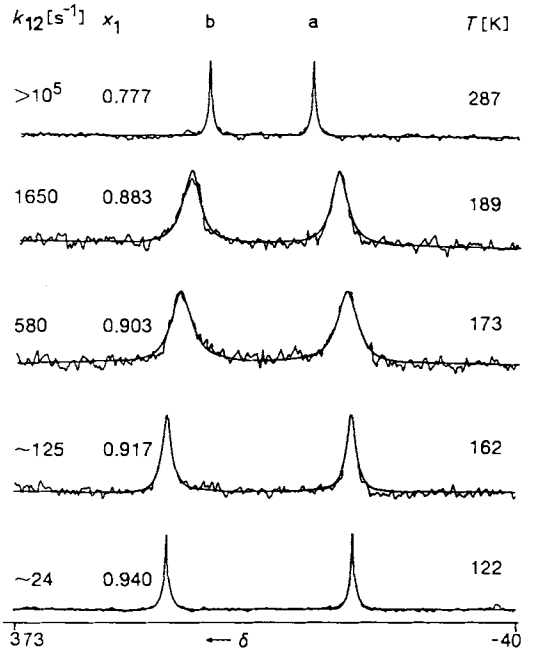


Fig. 1. Superposed experimental and calculated ^{15}N-CPMAS-NMR spectra of enriched DTAA (95% ^{15}N) at 6.082 MHz as a function of temperature. 5 ms cross polarization time, 4 kHz sweep width, 1 s repetition time. Number of scans from 122 to 287 K: 1640, 1770, 6048, 10464, 10464. Reference: external $^{15}NH_4NO_3$. x_1 is the probability of the dominant tautomer **1**, k_{12} the forward rate constant. The linewidth in the absence of exchange was taken from the spectra at 122 and 287 K.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Fonds der Chemischen Industrie.

equally populated interconverting tautomeric states $\mathbf{1} \rightleftharpoons \mathbf{2}$ of the structure $N_aH\cdots N_b \rightleftharpoons N_a\cdots HN_b$.[13, 14] The lineshapes were simulated in terms of two superposed single-spin systems each of which exchanges between the states **1** and **2** shown in Scheme 1. In addition, it was assumed that for the chemical shifts

$$\delta_a(\mathbf{1})=\delta_b(\mathbf{2}) \quad \text{and} \quad \delta_b(\mathbf{1})=\delta_a(\mathbf{2}).$$

In the fast exchange limit, the equilibrium constant K_{12} of the tautomeric process can be calculated according to equation (a), where δ is the line separation at temperature

$$\delta/\Delta = (1-K_{12})/(1+K_{12}), \qquad \text{(a)}$$

T and $\Delta=\delta_a(\mathbf{1})-\delta_b(\mathbf{1})$ is the intrinsic chemical shift difference obtained at low temperatures.[14] The observation of two ^{15}N lines in the fast exchange regime indicates that the degeneracy of the two tautomers **1** and **2** is lifted due to a solid state effect. Approximatively 20% of the minor tautomer **2** is found at room temperature. A reaction enthalpy of $\Delta H_{12}=3.8\pm0.4$ kJ mol^{-1}, a reaction entropy of $\Delta S_{12}=2\pm0.4$ J K^{-1} mol^{-1} and, as rate constant for the forward reaction

$$k_{12}(T)=10^7\exp(-14.7\pm4.2 \text{ kJ mol}^{-1}/RT) \text{ s}^{-1}$$

were found by spectral simulation.

In view of the small temperature range between 160 K and 220 K, over which rate constants could be obtained so far, the temperature dependence of k_{12} given above is tentative and might be subject to a large error. Deuteration of the molecule in the NH sites resulted in dramatic spectral changes. At 210 K, the deuteron transfer is about 10 times slower than the proton transfer. Whereas the entropy difference between the two tautomeric states **1** and **2** found here for crystalline DTAA is negligible, the energy difference is considerable. This inequivalence is absent in solution and arises, therefore, from a solid state effect. Unfortunately, a crystal structure of DTAA, which might suggest the reason for this inequivalence, has not yet been obtained. In accordance with the literature[15, 18, 19] we assign the structures shown in Scheme 1 to the interconverting states **1** and **2**, where a possible van der Waals interaction between the inner protons is minimized. The fact that we find only two ^{15}N lines in the fast exchange regime indicates that the four nitrogen atoms in solid DTAA are pairwise equivalent, i.e. that the two proton transfer units are characterized by the same equilibrium constants (K_{12}) of tautomerism. In other words, both protons jump in concert or one immediately after the other, i.e. the tautomeric states **3** and **4** in Scheme 1 are not significantly populated. This result is in contrast to solid TTAA (Scheme 1), where all four tautomers **1** to **4** were observed.[17] These tautomers interconvert rapidly on the NMR time scale and are characterized by different energies i.e. different temperature dependent populations.

Our working hypothesis as to why the proton transfer in DTAA is much slower than in TTAA is that in TTAA the protons move independently from each other,[17] whereas in DTAA the two proton transfer units are more or less coupled together. Independent support for this idea comes from the observation that tetraaza[14]annulenes such as DTAA are dark red due to an electronic absorption band in the 450-nm region.[19] This band is absent in the yellow TTAA,[18] which correlates with the fact that the four methyl groups of TTAA sterically hinder a coplanar arrangement of the two chelate subunits in the crystal.[20] Thus, the two H-chelate subunits in TTAA are, to a crude approximation, decoupled electronically leading to independent proton motion, in contrast to DTAA. Since malonaldehyde derivatives also show phototautomerism,[21] we would expect a different behavior of DTAA and TTAA when exposed to light.

In summary, we have found evidence not only for a double minimum potential in solid DTAA for the proton motion $\mathbf{1} \rightleftharpoons \mathbf{2}$, but also for a measurable rate process which involves a kinetic isotope effect.

A Novel Route to Azaalkenylidene-Metal Complexes**

By *Helmut Werner,** *Wolfgang Knaup,* and *Michael Dziallas*

In contrast to the well-documented alkenylidenemetal complexes [L_nM=C=CRR'], which have been the subject

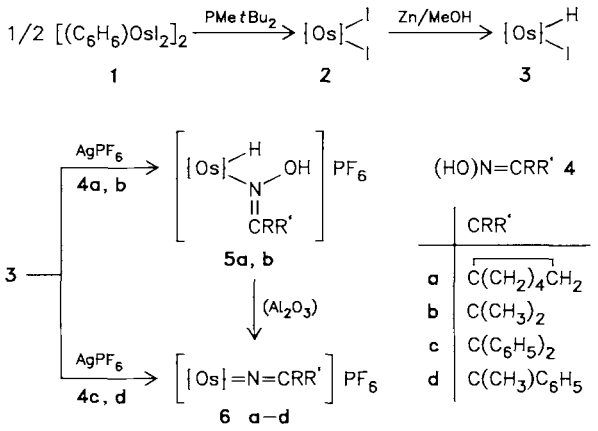
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG. We thank Prof. Dr. *G. Erker* for very valuable discussions.

of intensive studies in recent years,[1] very little is known about the isoelectronic analogues $[L_nM{=}N{=}CRR']^{\oplus}$ with nitrogen instead of carbon in the α-position of the unsaturated ligand. Hitherto, ketimino derivatives such as, e.g., $LiN{=}CRR'$ or $Me_3SiN{=}CRR'$,[2,3] alkylimido complexes $[L_nM{=}NR]$ (R = Me, Et, Pr),[4] 2-substituted azirines,[5] and nitriles[6,7] have been used as building blocks for the M=N=CRR′ unit. *Erker* et al. have recently obtained zirconocene compounds of the type $[(C_5H_5)_2Zr(N{=}CHR)Cl]$ in a very elegant way by hydrozirconation of RCN with $[\{(C_5H_5)_2Zr(H)Cl\}_x]$ and have also characterized the representative with R = Ph by an X-ray structure analysis.[6a]

An attempted direct extension of the *Erker* method to a d-electron-rich transition metal such as osmium met without success. The complex **3**, which can be obtained in very good yields via **2** from the already known complex $[(C_6H_6)OsI_2]_2$ **1** (Scheme 1),[8] reacts with acetonitrile or benzonitrile in the presence of $AgPF_6$ to give the $PF_6^{\ominus}$ salts of the cations $[(C_6H_6)(PMe_tBu_2)OsH(NCR)]^{\oplus}$, R = CH_3, C_6H_5, but these do not rearrange to $[(C_6H_6)(PMe_tBu_2)Os(N{=}CHR)]^{\oplus}$. Far more suitable than nitriles as synthons are the oximes **4**, which on reaction with **3** (and $AgPF_6$) afford the corresponding azaalkenylidene complexes **6** in good yields. In the case of cyclohexanone oxime **4a** and acetone oxime **4b** it was possible by workup at temperatures below −20 °C to isolate the intermediates **5a** and **5b** and to characterize them spectroscopically.[9] Subsequent chromatography on Al_2O_3 led to abstraction of water and formation of **6a** and **6b**, respectively.



Scheme 1. [Os]=$(C_6H_6)(PMe_tBu_2)Os$.

Figure 1 shows the result of the crystal structure analysis of **6c**.[10] The cation contains a trigonal planar coordinated metal atom (with the midpoint of the benzene ring at one edge of the plane) and structurally corresponds to the alkenylidenerhodium complex $[(C_5H_5)(PiPr_3)Rh{=}C{=}CHPh]$.[11] The Os, N, and C7 atoms are almost linear and form a plane with C8 and C14 which is perpendicular (angle 89.9°) to the best plane of P1, Os and the midpoint of the benzene ring. The orthogonality is consistent with the formation of a $d_{\pi}p_{\pi}$ bond between Os and N and concomitantly also explains the short Os-N distance of 188.2(6) pm. A value of 202.4(10) pm is found for an Os-N *single* bond such as in $[Os(NCMe)(PPh_3)_2Br_3]$.[12] The N-C7 distance (127.0(9) pm) is very similar to that in other azaalkenylidene complexes[2b,3,6a] and also agrees with the N-C distances found in 2-azaallenium ions.[13]

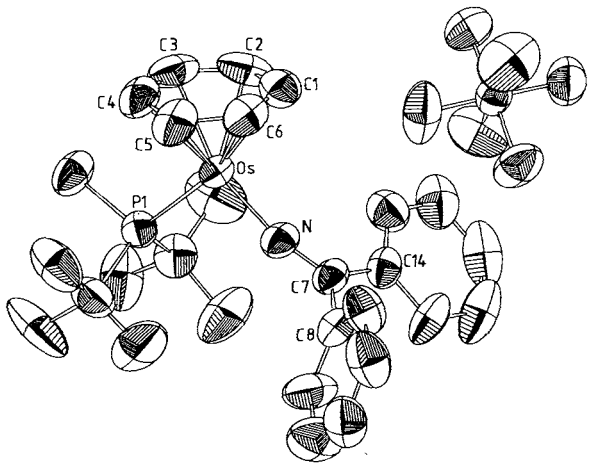


Fig. 1. Structure of **6c** in the crystal. Selected bond distances [pm] and angles [°]: Os-P1 239.2(2), Os-N 188.2(6), Os-C1 222.5(8), Os-C2 215.9(7), Os-C3 221.9(9), Os-C4 223.9(9), Os-C5 219.0(7), Os-C6 222.7(8), N-C7 127.0(9), C7-C8 150(1), C7-C14 147(1); P1-Os-N 92.9(2), Os-N-C7 168.8(5), N-C7-C8 118.5(6), N-C7-C14 121.0(6), C8-C7-C14 120.4(6).

The results of the present study are remarkable in two ways: 1) With the synthesis of **6a–d** it has now been possible for the first time to obtain *azaalkenylidene*metal compounds isoelectronic with a known *alkenylidene*metal complex ($[(C_6H_6)(PiPr_3)Os(C{=}CHPh)]$[14]) with respect to the metallaheteroallene unit M=E=CRR′. 2) The complexes **6a–d** could be prepared very easily by using oximes (HO)N=CRR′ as starting materials, which to our knowledge have so far never been used as building blocks for organometallic complexes.[2b] Since not only numerous oximes but also various halogeno(hydrido)metal compounds $[L_nM(H)X]$ are available, it is conceivable that the method described here opens up a general entry to complexes containing the M=N=CRR′ structural unit.

Experimental

A mixture of **3** (0.085 g, 0.15 mmol) and $AgPF_6$ (0.038 g, 0.15 mmol) was treated with a solution of 0.15 mmol of **4** in 5 mL of CH_2Cl_2 and stirred for a few minutes. After warming to room temperature the mixture was filtered, the filtrate was brought to dryness and the residue chromatographed on Al_2O_3 (Woelm, neutral, activity grade III) with CH_2Cl_2. After removal of the solvent, washing of the residue with pentane, and recrystallization from CH_2Cl_2/pentane, orange-red to red crystals were obtained. Yield 60–70%, correct elemental analyses; equivalent conductivity (in CH_3NO_2): **6a** 69.9, **6b** 69.8, **6c** 73.9, **6d** 71.5 $cm^2\,\Omega^{-1}\,mol^{-1}$. Workup of the reaction mixture obtained from **3**, $AgPF_6$ and **4a** or **4b** below −20 °C afforded, after removal of AgI, yellow solids of the composition **5a** and **5b**, respectively.

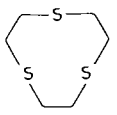
Synthesis and Crystal Structure of the Homoleptic Thioether Ruthenium Complex $[Ru(1,4,7\text{-trithiacyclononane})_2](BPh_4)_2 \cdot 2Me_2SO$**

By *Michael N. Bell, Alexander J. Blake, Martin Schröder,* Heinz-Joseph Küppers,* and *Karl Wieghardt**

Several recent reports have focused on the binding of 1,4,7-trithiacyclononane **1** to transition-metal ions.[1-3] Of particular interest have been the stereochemical and electronic effects of the homoleptic coordination of six sulfur atoms to these metal centers. As a continuation of this work, we have been investigating the coordination and redox chemistry of **1** with the platinum metals and report herein the synthesis, the single-crystal X-ray structure analysis, and the redox properties of the highly stable bis-sandwich ruthenium(II) complex $[Ru(\mathbf{1})_2]^{2\oplus}$.



1

The complex cation $[Ru(\mathbf{1})_2]^{2\oplus}$ could be prepared by reaction of $RuCl_3 \cdot 6H_2O$ with an excess of **1** in Me_2SO at elevated temperatures,[4] or by reaction of $[RuCl_2(C_6H_6)]_2$ with an excess of **1** in methanol at room temperature.[3] Recrystallization of the complex in Me_2SO in the presence of $NaBPh_4$ yielded white crystals of **2**, the X-ray crystal structure of which was undertaken.[5]

$[Ru(\mathbf{1})_2](BPh_4)_2 \cdot 2Me_2SO$ **2**

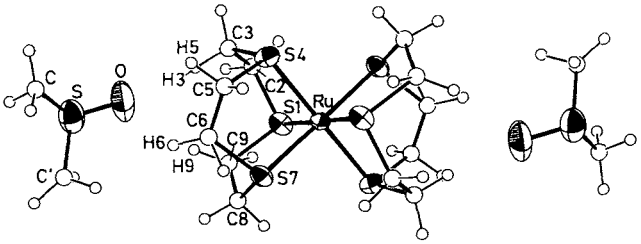


Fig. 1. Crystal structure of the cation and the coordinated Me_2SO molecule in **2**. Bond lengths [Å] and angles [°] around ruthenium: Ru-S1 2.3272(14), Ru-S4 2.3357(14), Ru-S7 2.3331(14); S1-Ru-S4 87.87(5), S1-Ru-S7 88.09(5), S4-Ru-S7 88.26(5). There is no significant interaction between the $BPh_4^{\ominus}$ ions and the cation or the solvent molecules.

The structure analysis (Fig. 1) shows a centrosymmetric cation with the Ru^{II} ion at the inversion center of the molecule; the sulfur macrocycles are each bound to the Ru^{II} center to give an overall octahedral stereochemistry. Only one of the possible conformers is present in the crystal. The two mole equivalents of Me_2SO present in the crystal lattice are well ordered and have full site occupancy. The oxygen atoms of the Me_2SO solvates are slightly closer to S4 than to S1 or S7 and each approaches the outer face of a coordinated sulfur ligand [O···H3 = 2.201(8), O···H6 = 2.419(8), O···H9 = 2.790(8), O···H5 = 3.291(8) Å]. This supplementary interaction is particularly intriguing since it suggests that inclusion of Me_2SO is occurring into the rear cone/cavity formed by **1** on coordination to the metal center (Fig. 2). This is supported by the observation that each Me_2SO molecule can be replaced by a CH_3CN or CH_3NO_2 molecule on recrystallization from these solvents.

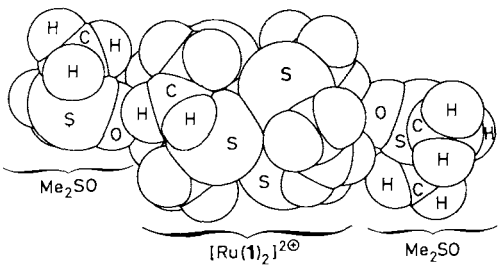

Fig. 2. Space-filling model of $[Ru(\mathbf{1})_2]^{2\oplus}$ showing interactions with two molecules of Me_2SO.

$[Ru(\mathbf{1})_2]^{2\oplus}$ represents the first example of homoleptic thioether coordination to ruthenium and is therefore an important compound with which to probe the electronic properties of thioether ligands in general. $[Ru(\mathbf{1})_2]^{2\oplus}$ is electrochemically inactive between -2.2 and $+1.3$ V vs. $Cp_2Fe/Cp_2Fe^{\oplus}$ ($Cp = \eta^5\text{-}C_5H_5$). Cyclic voltammetry in dried CH_3CN at platinum electrodes shows a quasi-reversible oxidation at $E_{1/2} = +1.41$ V ($\Delta E = 95$ mV, scan

rate = 100 mV s^{-1}), which we tentatively assign to a Ru^{II}/Ru^{III} redox couple, although oxidation of the ligand at these potentials cannot be ruled out. An irreversible reduction is also observed at $E_{pc} = -2.25$ V, leading to the breakdown of the complex, presumably via an unstable Ru^{I} intermediate. The free ligand thereby released can be detected on the return scan as an irreversible oxidation at +0.98 V. The high redox stability of $[Ru(\mathbf{1})_2]^{2\oplus}$ is remarkable and reflects a matching of stereochemical and electronic features of the macrocyclic ligands with those of d^6 Ru^{II} (Table 1).

Table 1. Voltammetric data for the bis-sandwich complexes $[M(\mathbf{L})_2]^{2\oplus/3\oplus}$, M = Fe, Ru.

L	$Fe^{2\oplus}/Fe^{3\oplus}$	$Ru^{2\oplus}/Ru^{3\oplus}$
TACN [a]	+0.13 V [9]	+0.37 V [10]
1 [b]	+0.98 V [2]	+1.41 V

[a] vs. the normal hydrogen electrode in aqueous solution; TACN = 1,4,7-triazacyclononane. [b] vs. $Cp_2Fe/Cp_2Fe^{\oplus}$ in CH_3CN.

We have also prepared the analogous osmium complex $[Os(\mathbf{1})_2]^{2\oplus}$ by reaction of $[OsCl_2(arene)]_2$ with an excess of **1**.[3] The ruthenium complex $[Ru(\mathbf{1})(Me_2SO)_2Cl]^{\oplus}$ can be prepared by reaction of $RuCl_3 \cdot 2H_2O$ with one equivalent of **1** in Me_2SO.[6] We are currently investigating the synthesis of 1:1 platinum-metal complexes of **1** and related tridentate macrocycles and the incorporation of organic and small molecule ligands.

Experimental Procedure

$[Ru(\mathbf{1})_2](ClO_4)_2 \cdot H_2O$: $RuCl_3 \cdot 6H_2O$ (0.1 g, 0.32 mmol) was dissolved in Me_2SO (15 mL) at 200°C. The solution was concentrated to 7 mL and cooled to 20°C, and **1** (0.22 g, 1.2 mmol) was added. The reaction mixture was heated to 140°C for 3 h; on cooling to room temperature a white solid precipitated. This product was dissolved in water and recrystallized by addition of $NaClO_4$ to give $[Ru(\mathbf{1})_2](ClO_4)_2 \cdot H_2O$. Correct elemental analyses (C,H,S).

2: $[RuCl_2(C_6H_6)]_2$ (0.05 g, 0.1 mmol) was treated with **1** (0.08 g, 0.44 mmol) in methanol (15 mL) for 30 min at 20°C. Addition of $NaBPh_4$ afforded a white precipitate, which was recrystallized from Me_2SO to give **2** in 60% yield. Correct elemental analyses (C,H). Recrystallization from CH_3CN or CH_3NO_2 afforded crystals of the corresponding disolvate. Correct elemental analyses (C,H,N). The presence of two equivalents of solvent was confirmed also by ^{1}H-NMR and infrared spectroscopy.

$[Ru(\mathbf{1})(Me_2SO)_2Cl](PF_6)$: $RuCl_3 \cdot 2H_2O$ (0.25 g, 1.01 mmol) was dissolved in Me_2SO (20 mL) and the solution was heated to 160°C for 1.5 h. To the cooled solution was added **1** (0.19 g, 1.05 mmol) and the reaction mixture heated to 60°C for 2 h. To the resulting yellow solution was added $NaPF_6$ and after several days yellow crystals of $[Ru(\mathbf{1})(Me_2SO)_2Cl](PF_6)$ had precipitated. Correct elemental analysis (C,H,S).

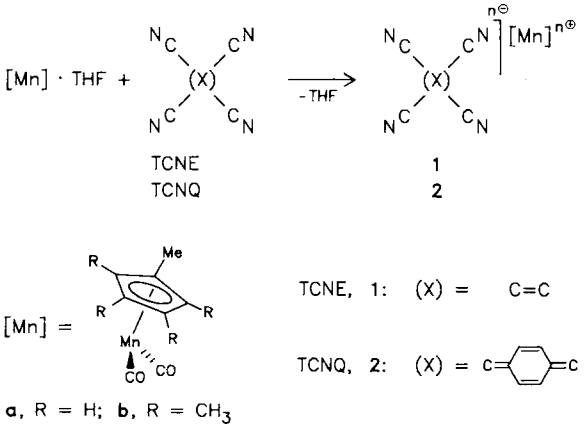
Tetranuclear Mixed-Valence Manganese Complexes with Reduced TCNE or TCNQ as η^4-Bridging Ligands**

By *Renate Gross* and *Wolfgang Kaim**

The concept of single electron transfer (SET) has recently contributed a great deal to an understanding of the reactions of inorganic[1a,b] and organometallic[1c,d] compounds. In most studies reported so far attention has been centered on the mechanistic aspects of known reactions.[1] We now show that application of this concept can also lead to the synthesis of new, unexpected coordination compounds with unusual properties.

When the photolytically generated tetrahydrofuran(THF)-solvate of the organometallic fragment [Mn] (see Scheme 1) is allowed to react with an equimolar amount of tetracyanoethylene (TCNE) or 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ), a spontaneous (!) oxidative addition



Scheme 1. Formation of the TCNE complex **1** and the TCNQ complex **2**; in each case n = 1. For [Mn]·THF, R = H, $E_{ox}^{\ominus} = +0.3$ V [3]; for TCNE and for TCNQ $E_{red} = +0.33$ V vs. SCE.

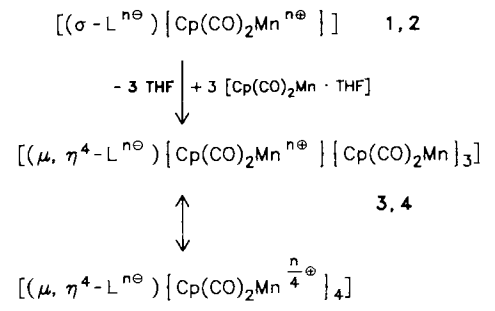
takes place to give isolable 1:1 products **1** and **2**, respectively.[2, 3]

The driving force behind the electron transfer is, in the first instance, the ratio of the redox potentials of the two reactants; there are, however, other arguments for a formulation according to Scheme 1:

- In the complexes **1** and **2** the IR vibration frequencies of the organometal fragments ($\tilde{\nu}_{CO}$) are shifted to higher energies, while those of the coordinated ligands ($\tilde{\nu}_{CN}$ and $\tilde{\nu}_{C\text{-}C}$) are shifted to lower energies[4] (Table 1); the position and intensity of the strong C=C(TCNE)-stretching bands at 1420 cm^{-1}, as also the ^{13}C-NMR data (see *Experimental*), indicate unsymmetric complexes with σ-coordinated organometal fragments[2] and radical anion ligands.[4–7]
- With the electron-rich $C_5(CH_3)_5$-ligands on the metal fragment (**1b**, **2b**), the charge transfer absorption band is shifted to *higher* energies (Table 1); accordingly,[5a] to a first-approximation we have a ligand-to-metal charge transfer (LMCT) transition in which the destabilization of the metal levels primarily affects the target orbital (cf. A) in Scheme 3).
- The reduction potentials of the complexes **1** and **2** are more *negative* than those of the free ligands (Scheme 1, Table 1), reduction potentials of ligands without prior electron transfer generally become more *positive* through coordination.[6]
- The complexes **1** with reduced TCNE are stable and, due to spin–spin coupling (cf. A) in Scheme 3),[7] display narrow NMR signals, whereas the TCNQ complex **2b** dissociates in solvents with higher dielectric constants, for example THF, to give ESR spectroscopically detectable low-spin Mn^{II} species[5b] and free $TCNQ^{\odot\ominus}$.[8]

By far the most impressive consequence of single electron transfer is the increase in the ability to coordinate at the three other σ-coordination centers of the potential μ,η^4-ligands TCNE and TCNQ. As a result of the "cyanophilicity" of the [Mn] fragments[5c] further complexation of **1** and **2** takes place to give the compounds **3** and **4**, respectively, with maximum coordinative saturation (Scheme 2).

The composition of the unexpectedly stable tetranuclear complexes **3** and **4** was confirmed analytically (Table 1);



Scheme 2. Formation of the TCNE complex **3** and the TCNQ complex **4**. L=TCNE or TCNQ; Cp=η^5-$C_5H_4CH_3$ or η^5-$C_5(CH_3)_5$; $Cp(CO)_2Mn$=[Mn].

equivalence of the cyclopentadienyl groups (NMR) and the absence of the C=C stretching band in the IR spectrum indicate inversion symmetry of the tetranuclear complexes. The compounds can therefore be regarded, in the first instance, as mixed valence metal arrangements[5d, 9, 10] with delocalized charge and reduced η^4-bridging ligands, for which the relatively sharp NMR signals indicate considerable spin pairing in the ground state.

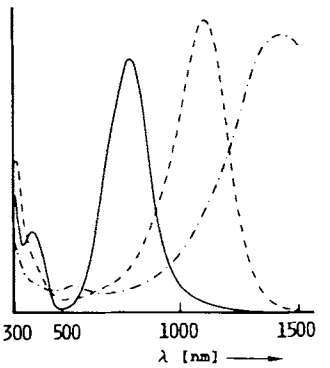


Fig. 1. Absorption spectra of the complexes [(σ-TCNE)|[Mn]|] **1b** (——), [(μ,η⁴-TCNE)|[Mn]|$_4$] **3b** (– – – –), and [(μ,η⁴-TCNQ)|[Mn]|$_4$] **4b** (– · – ·) in toluene (band intensities not to scale, [Mn] = [(η^5-C_5Me_5)$(CO)_2$Mn]). Due to the absorption window in the visible region the tetranuclear complexes have only a slightly green color.

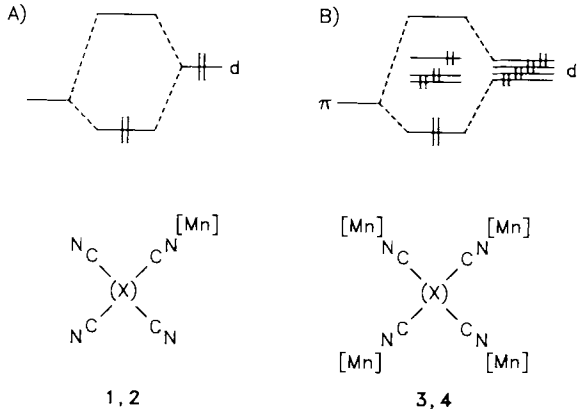
Particularly informative with regard to this unique electronic structure are the electronic spectra (Fig. 1) of the tetranuclear complexes **3** and **4**: aside from the weak LMCT bands, extraordinarily intense ($\varepsilon > 50000\ M^{-1}\ cm^{-1}$) metal-metal charge transfer (MMCT) bands $[Mn^{n\oplus}] \leftarrow [Mn]$[5d] are observed in the IR region; a qualitative orbital level diagram (cf. B) in Scheme 3) allows this to be rationalized in terms of multiple degeneration of the Mn^{I} metal level according to the resonance structure with localized charge (Scheme 2), mixed valence complexes of class III-A[9]).



1, 2 3, 4

Scheme 3. Qualitative orbital level diagrams for the complexes **1**, **2**, and **3**, **4**.

Consistent with the very small transition energies, one observes a striking convergence of the oxidation and reduction potentials (Table 1); all the more surprising is the stability of these compounds, which can *only* be understood considering intramolecular metal-ligand electron transfer with additional contributions from the metal–metal delocalization.[5d]

Experimental

Solutions of photochemically generated [Mn]·THF [11] were treated with the appropriate amount of acceptor ligand, whereupon a momentary (cf. [5a]) color change from red to green or blue occurred. After several hours' stirring the solvent was removed and the residue was subjected to low temperature column chromatography under argon (−20°C; Florisil; eluents: hexane, toluene, ether, THF). The main fractions, after evaporation to dryness, were recrystallized from THF/hexane; some di- and trinuclear complexes were also obtained [12].— **1a**: shiny golden needles (dark green solution), yield 26%, correct C,H,N analysis.— **1b**: shiny golden needles, 58%, correct C,H,N, Mn analysis. ^{1}H-NMR (C_6D_6): $\delta = 1.21$. ^{13}C-NMR (C_6D_6): $\delta = 232.2$ (CO), 117.7, 112.2 (C≡N), 104.6, 104.5 (C=C), 88.7 (CCH_3), 11.1 (CH_3).— **3a**: dark powder, 20% correct C,H,N,Mn analysis. ^{1}H-NMR ([D$_8$]THF): $\delta = 4.70$, 4.51 (CH), 1.83 (CH_3). ^{13}C-NMR (THF): $\delta = 232.2$ (CO), 132.3 (C≡N), 107.6 (C=C), 85.0, 84.0 ($C_5H_4CH_3$), 13.3 (CH_3).— **3b**: dark powder, 24%, correct C,H,N analysis.— **4b**: olive-green platelets, 30%, correct C,H,N analysis. Two Different Intercalate Structures in the Intercalation Compounds of Graphite with Perfluorobutanesulfonic Acid**

By *Bernd Ruisinger* and *Hanns-Peter Boehm**

In graphite intercalation compounds ("graphite salts") with strong acids, e.g. sulfuric acid, layers of anions, e.g. $HSO_4^{\ominus}$, are inserted between the positively charged sheets of the graphite lattice. The interlayer volume not occupied by the anions is filled with acid molecules. A convenient method for the synthesis of graphite salts is by the anodic oxidation of graphite in pure acids.[1,2] Such an electrochemical intercalation leads to formation of stages, in which an intercalated layer is followed by three carbon layers, two carbon layers or one carbon layer (stage 3, stage 2, stage 1). In the course of intercalation of sulfuric acid by galvanostatic oxidation, a small step in the potential curve was observed within the region of the pure stage 2 compound,[2] corresponding to a small current peak in the cyclovoltammetric current/potential curve. At this point the charge of the carbon layers increases without any noticeable change in the interlayer spacing.

We have now found an analogous step (Fig. 1a) in the region of the second stage during the intercalation of perfluorobutanesulfonic acid, $C_4F_9SO_3H$, and a distinct double peak was observed at the corresponding point in the voltammogram (Fig. 1b).

The additional flow of current in the region of the first stage, which corresponds to a step in the potential curve, has never been observed with other acids. X-ray diffraction studies revealed a marked increase in the interlayer spacing after passing through this peak in the voltammogram (see Table 1). The size of the layer separations clearly indicates an intercalation of bilayers, as has also been observed in sheet silicates with intercalated *n*-alkylammonium ions.[3] The increase of ca. 325 pm in each case upon increasing the layer charge within a stage can only be explained in terms of a change in the arrangement of the perfluoroalkyl chains. In the region between the points F and G (Fig. 1) non-integral (001) reflections occur which were

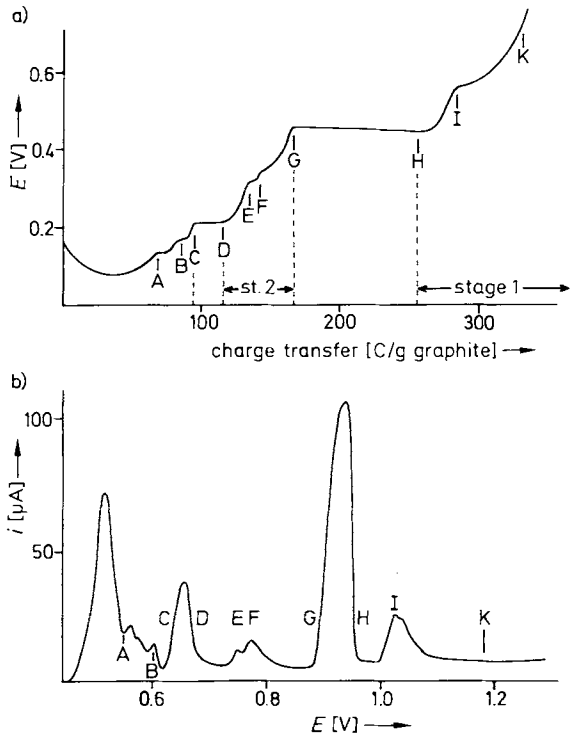

Fig. 1. Electrochemical intercalation of $C_4F_9SO_3H$ in graphite flakes from Madagascar. a) Galvanostatic oxidation: potential E (measured against graphite) as a function of charge transfer in coulomb per gram graphite. In the region of the pure stages the potential increases, in two-phase regions it remains constant. At points B and C stage 3 compounds were observed with similar interlayer spacings; at point A a mixture of stages 4 and 3 was observed. b) Potentiodynamic oxidation: oxidation current i as a function of the potential E (sweep rate 10 μV/s).

shifted in an irregular fashion from the positions for the reflections of the phases with spacings of ≈2100 and ≈2400 pm. This points to structural faults by occasional insertion of thick or thin intercalate layers, respectively.

Table 1. Layer charge and thickness of the layer packets (d_i) in the intercalation compounds of perfluorobutanesulfonic acid in graphite at selected points of the diagram in Figure 1.

Stage	Position in Fig. 1	n in $C_n^{\oplus}$	d_i [pm] [b]
3	C	85	2764 ± 17
2b	E/F [a]	59.5/56	2111 ± 11
2a	G	48	2435 ± 6
1b	I	28	1773 ± 7
1a	K	24	2099 ± 8

[a] A real separation of samples oxidized to points E and F was not possible. [b] The standard deviations are based on an X-ray diffraction diagram with at least ten strictly periodic (00l) reflections. On repeating the intercalation the mean values were within the given standard deviations. Non-integral (00l) reflections appeared in the region between the pure phases. This is not immediately recognized with smaller deviations from the positions of the integral reflections but leads to an increase in the standard deviation.

Such an abrupt change in the structure of the intercalated layers on changing the charge density in the layers of the host lattice has so far never been described in the literature. In contrast, trifluoromethanesulfonic acid behaves like sulfuric acid: It is intercalated in a flat disposition; the interlayer spacing of 804 pm is the same as in graphite hydrogensulfate.[4]

From the results of fluorine determinations, the following formulas can be calculated on the basis of the layer charge:

$C_{28}^{\oplus}(C_4H_9SO_3^{\ominus})\cdot 2.8\,C_4F_9SO_3H$ for phase 1b (1773 pm)

$C_{24}^{\oplus}(C_4F_9SO_3^{\ominus})\cdot 2.5\,C_4F_9SO_3H$ for phase 1a (2099 pm)

The densities of the intercalated layers are calculated to be 1.79 g cm^{-3} and 1.58 g cm^{-3}, respectively. For comparison: the density of the free acid is 1.81 g cm^{-3}. On going from stage 1b to stage 1a very little acid is intercalated, namely 0.1 molecule to one $C_{24}^{\oplus}$ unit.

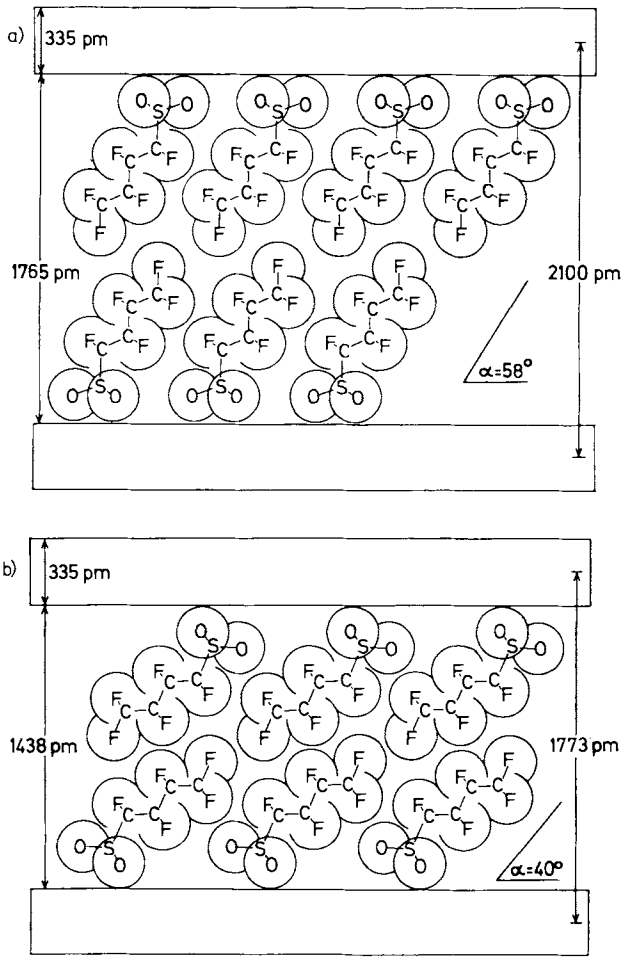

Fig. 2. Model of the phases of the 1st stage of the intercalation compound with $C_4F_9SO_3H$. a) Stage 1a, $d_i = 2100$ pm; b) stage 1b, $d_i = 1773$ pm. The angle α is the angle at which the perfluoroalkyl chains are inclined to the layer planes. The C–C–C bond angle in the chains is 116°. For clarity, the twist of the chains is not taken into consideration.

In the phase with the higher layer charge the carbon layer separation is consistent with the arrangement shown in Figure 2a. The intercalated molecules and ions are oriented with the three oxygen atoms of the sulfonic acid groups on the carbon layers; the C_4F_9 chains are in a slightly distorted *anti* conformation inclined at an angle of 58° to the plane of the layers. In poly(tetrafluoroethylene) the $(CF_2)_n$ chains are twisted into a helix with 15 CF_2 groups in the repeat unit (above 19 °C).[5] Almost the same angle, $\alpha = 56°$, was found in intercalated *n*-alkylammonium ions in layer silicates[3] or metal dichalcogenides, e.g.

TaS_2.[6] Only assumptions can be made about the arrangement of the intercalated molecules in the phases with the smaller interlayer spacing. An undistorted all-*gauche* structure of the C_4F_9 chains is unlikely, because of the size of the fluorine atoms. If, as is assumed, the chains have a twisted *anti* conformation, they must be more strongly tilted at an angle of 40° to the plane of the layers (see Fig. 2b). However, a distorted all-*gauche* conformation or a conformation with *anti* and *gauche* sequences cannot be ruled out. Only one phase was observed for stage 2 as well as stage 1 in the case of the homologous perfluorohexanesulfonic acids. These compounds are not so well ordered; the d_i spacings of ca. 2900 pm and 2620 pm, however, are consistent with the *anti* conformation, analogous to those in Figure 2a.

Experimental

Ca. 4–5 mg of Madagascar graphite (> 99.5% C, flakes of ca. 2 mm diameter) was packed in a platinum gauze pouch and anodically oxidized in perfluorobutanesulfonic acid (liberated from $C_4F_9SO_3K$ [7] with 100% H_2SO_4). Platinum was used as counter electrode; a relatively large piece of graphite foil (Sigraflex) was used as reference electrode. Upon galvanostatic oxidation *well-structured* potential/charge curves were obtained only at a very small current density, e.g. 10 μA with 5 mg of graphite, i.e. less than 500 μA per cm^2 of the prism faces of the graphite flakes. In the potentiodynamic reaction, the current/voltage curves were well-resolved only at a sweep rate below 5–10 μV/s. The use of highly oriented pyrographite (HOPG) gave similar, but not quite so well-structured curves. After a charge transfer corresponding to the selected points of the curves, the oxidation was interrupted and the graphite salt transferred to X-ray capillaries under the acid for taking Debye-Scherrer photographs. For determining the fluorine, the flakes were freed from adhering perfluorobutanesulfonic acid by rinsing with syrupy phosphoric acid and combusted with Na_2O_2/NaOH in a Parr bomb; the fluoride that was formed was determined with an ion-selective electrode by the standard-addition method.

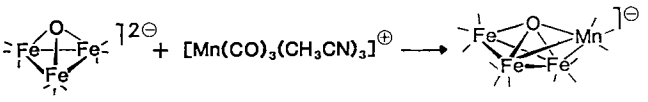
Synthesis and Structure of $[(PPh_3)_2N][Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$: A Butterfly Oxo Cluster**

By *Cynthia K. Schauer* and *Duward F. Shriver**

There has been considerable recent interest in the synthesis of clusters that contain substituent-free main-group elements to provide a conceptual bridge between organometallic chemistry and the areas of inorganic solid-state chemistry and surface chemistry.[1] Among the first-row elements, carbido and nitrido carbonyl clusters are now known which have coordination environments about the main-group atoms ranging from those presumed for surfaces to those observed in solid-state compounds.[2] The synthesis and chemistry of clusters comprised of metal atoms in low oxidation states that contain an oxo ligand is much less well developed. There are only a few examples of clusters containing the μ_3-oxo ligand,[3] a coordination mode common for oxygen atoms bound to surfaces.[4] Additionally, to the best of our knowledge, there are no oxo carbonyl clusters belonging to the interesting class of μ_4-L butterfly clusters, which have been intensely studied recently for L = C and N;[5] nor are there any other higher-nuclearity oxo clusters in which the oxo ligand is bound to more than three metal atoms. We report here on the synthesis and characterization of $PPN[Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$ **2** (PPN = $[(PPh_3)_2N]^{\oplus}$), a mixed-metal cluster which represents the first butterfly oxo compound and is a step toward building higher-nuclearity oxo clusters.



1 **2**

Treatment of the orange-red PPN salt of $[Fe_3(CO)_9(\mu_3\text{-}O)]^{2\ominus}$ **1**[3f] with one equivalent of $[Mn(CO)_3(CH_3CN)_3][PF_6]$[6] in acetone followed by crystallization from Et_2O/pentane gives the dark brown butterfly oxo cluster $PPN[Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$ **2** in 75% yield.[7] The structure of **2** is shown in Figure 1 (see also Table 1).[8] The

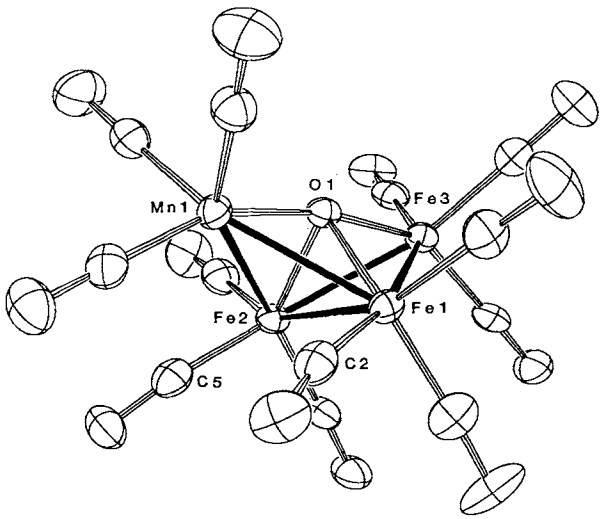


Fig. 1. Crystal structure of **2**. Thermal ellipsoid plot at 40% probability [8].

count of 62 cluster valence electrons, consistent with molecular orbital descriptions of the butterfly carbides,[9] is achieved by counting the oxo ligand as a six electron donor. All oxygen–metal distances are short (average: 1.89(2) Å). The Mn atom occupies a wingtip position in the butterfly arrangement, in contrast to the analogous carbido cluster, $[Fe_3Mn(CO)_{13}(\mu_4\text{-}C)]^{\ominus}$, where the Mn atom occupies a hinge site.[5b] The average Fe–Mn distance (2.61(2) Å) is considerably longer than the average Fe–Fe distance (2.51(1) Å). Two Fe-bound CO ligands form semibridges to the Mn atom (Mn1–C2 = 2.675(5), Mn1–C5 = 2.736(5) Å), consistent with the preference of manganese for a higher coordination number.

$[Fe_4(CO)_{12}(\mu_4\text{-}C)]^{2\ominus}$ **3** $[Fe_4(CO)_{12}(\mu_4\text{-}N)]^{\ominus}$ **4**

[**] This work was supported by the National Science Foundation through the Synthetic Inorganic and Organometallic Program.

In the homometallic carbido and nitrido clusters, **3** and **4**, the bond distance from the heteroatom to the hinge metal (M_h) atoms is considerably longer than the distance from the heteroatom to the wingtip metal (M_w) atoms (Table 1). Such a distinct bonding preference is not observed for **2**. Additionally, the elongation of the M_h–M_w distance relative to the M_h–M_h distance in **3** and **4** is not observed in **2**. The Fe–Fe distances in **2** are nearly unperturbed from those seen in **1** (C_{3v} symmetry).[3f] As a consequence of these unique structural features, the M_w–L–M_w angle in **2** is more acute than in the nitrido and carbido clusters, **3** and **4**, respectively, and the dihedral angle between the two wings of the butterfly in **2** is approximately 10° larger than in **3** and **4**.

Table 1. Structural parameters of μ_4-L butterfly clusters [a].

	2	**3**	**4**
M_h-L [Å]	1.902(4)	1.96(3)	1.900(6)

Ref.	this work	[10]	[11]

[a] M_w, wingtip metal atom; M_h, hinge metal atom. [b] For the first entry, M = Fe; for the second entry, M = Mn.

The oxo clusters **1** and **2** were characterized by ^{17}O-NMR spectroscopy in acetone solution at room temperature on samples enriched with ^{17}O at the oxo ligand. For **1**, the spectrum consists of a resonance for the CO ligands ($\delta = 356$) and one for the μ_3-oxo ligand ($\delta = 107$). For **2**, two distinct resonances are seen for the CO ligands ($\delta = 385$ and 370, intensity ratio 1:3) and the μ_4-oxo ligand resonance is found at $\delta = 93$. The relative positions of the oxo ligand resonances in **1** and **2** is in qualitative agreement with the correlation observed between the oxygen atom coordination number and the ^{17}O chemical shift of the oxygen atom in polyoxometalate systems.[12]

Two resonances for the CO ligands of **2** ($\delta = 214.0$; 225.5; intensity ratio 3:1) were also observed in the ^{13}C-NMR spectrum ($CD_2Cl_2/CHFCl_2$ (1:2), room temperature). These two resonances correspond to the carbonyl ligands bound to the Mn atom and those bound to the Fe atoms. A fluxional process involving equilibration of the hinge and wingtip Fe-bound CO ligands must be occurring at room temperature to account for this pattern. At −50 °C, this equilibration process is not rapid and distinct resonances are seen for the two types of $Fe(CO)_3$ fragments ($Mn(CO)_3$, $\delta = 225.0$; $Fe(CO)_3$, $\delta = 212.1$ and 214.2; intensity ratio 3:3:6).

Unlike the nitrido[5a] and carbido[5b] butterfly clusters and the parent cluster **1**, **2** does not display ready reactivity toward Brønsted acids. Addition of one equivalent of CF_3SO_3H to a CH_2Cl_2 solution of **2** results in only negligible protonation.

The rarity of low-valent oxo clusters seems surprising given the vast chemistry that has been developed for the carbido and nitrido clusters. The apparently facile loss of an oxo ligand as CO_2 in carbonyl-containing complexes may, in part, offer an explanation. For instance, **1** decomposes under CO (1 atm) in acetone over a period of several hours to give CO_2 and lower-nuclearity Fe compounds; such a ready decomposition route is not accessible for nitrido and carbido clusters. If this route for loss of the oxo ligand can be suppressed, higher-nuclearity oxo clusters of low-oxidation-state metals should be accessible utilizing lower-nuclearity oxo clusters as precursors.

The Diradical 2,3,5,6-Tetramethylene-1,4-cyclohexanediyl ("1,2,4,5-Tetramethylenebenzene")**

By *Wolfgang R. Roth,* Reinhard Langer, Martin Bartmann, Birgitt Stevermann, Günther Maier, Hans Peter Reisenauer, Rainer Sustmann,* and *Wolfgang Müller*

The title compound **10**, a disjoint diradical with conjugated non-Kekulé structure, is of topical interest in discussing the limits of the Hunds rule.[1] High-level ab initio SCF-MO-CI calculations lead one to expect a singlet ground state for **10** which lies about 5–7 kcal/mol below the lowest triplet state.[2] We have now checked this prediction experimentally.

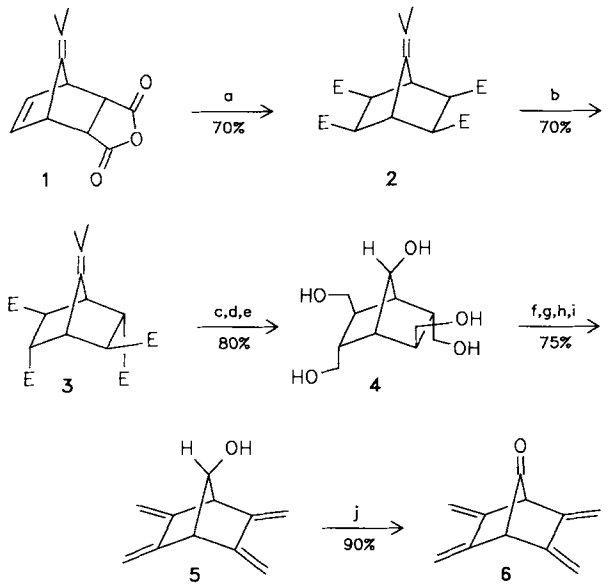
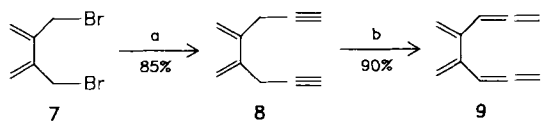
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The synthesis of **10** was accomplished in two ways via the precursors **6** and **9**. Palladium-catalyzed methoxycarbonylation of the Diels-Alder adduct **1** obtained from dimethylfulvene and maleic anhydride afforded the tetracarboxylate **2**, which was found to isomerize under basic conditions to give **3**. Ozonolysis and subsequent reduction furnished the pentaalcohol **4**. Selective substitution of the primary hydroxy groups yielded the tetrahalide, dehydrohalogenation of which afforded access to the tetramethylene compound **5**. Subsequent Swern oxidation led in 25% overall yield to the carbonyl compound **6**[3] (Scheme 1).



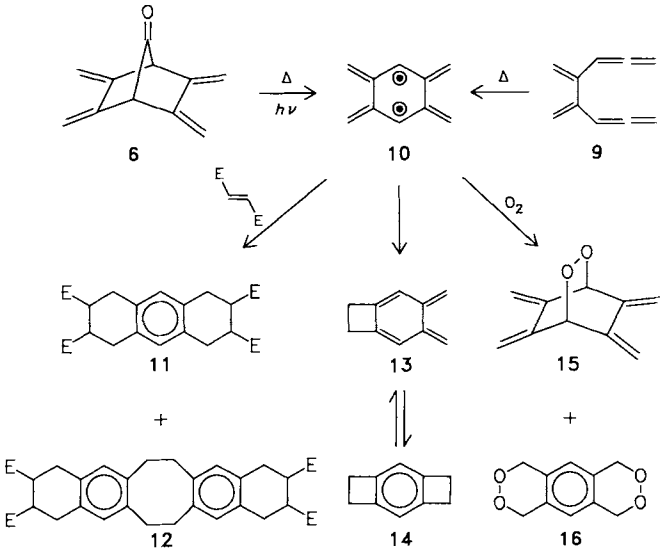
Scheme 1. E=COOMe. a) $CuCl_2$ (anhydrous), Pd/C (10%), CO (5 atm), 60°C, 3 h, MeOH (anhydrous) [4]; b) K_2CO_3, 20°C, MeOH (anhydrous); c) O_3, −78°C, CH_2Cl_2/MeOH (1:1); d) $H_3C-S-CH_3$, −78 to 0°C, CH_2Cl_2/MeOH (1:1); e) $LiAlH_4$, −78 to 60°C, tetrahydrofuran (THF) (anhydrous); f) Ph_3PCl_2/imidazole (1:2), 50°C, 6 h, pyridine/acetonitrile (1:1) [5]; g) ethyl vinyl ether, TsOH, 20°C, 20 min, ether (anhydrous); h) KOH, [18]crown-6, 20°C, 48 h, THF (anhydrous); i) MeOH (anhydrous), TsOH, 20°C, 20 min; j) oxallyl chloride, dimethyl sulfoxide (DMSO), −78°C, CH_2Cl_2 (anhydrous), NEt_3 [6].

A second entry to **10** was possible starting from the dibromide **7**,[7] which can be converted via the diyne **8** into the bisallene **9** (Scheme 2).



Scheme 2. a) CH≡CMgBr, NaI, Cu_2Cl_2, 60°C, 4 h, THF (anhydrous); b) KO*t*Bu/HO*t*Bu/THF (1:30), −60°C, 20 min.

The diradical **10** can be generated from both precursors **6** and **9** thermally, from **6** also photochemically. When working in the gas phase, **6** and **9** quantitatively rearrange to the tetrahydrodicyclobuta[*a*,*d*]benzene **14**; in solution, exclusively polymerization takes place. If **10** is generated in solution in the presence of a fumarate or oxygen, the Diels-Alder adducts **11** and **12**, or the peroxides **15** and **16**, respectively, are formed. These must be trapping products of **10**, since the dihydrocyclobutabenzene derivatives which are derived from **13** are stable under the reaction conditions (80°C).[8]



Irradiation[9] of **6** (313 nm) in an argon matrix leads quantitatively in 45 min to a red substance with characteristic IR bands at 854 and 810 cm^{-1}, which we assign, in analogy to the corresponding bands of the allyl radical,[10] to the out-of-plane CH-vibrations of the diradical **10**. The course of the reaction can be monitored by the disappearance of the carbonyl absorption of **6** at 1795 cm^{-1} and the simultaneous appearance of the carbon monoxide band at 2132 cm^{-1}. **10** is stable towards irradiation with light >300 nm, but not towards short-wavelength rays (254 nm), which cause a rearrangement into **14** via an intermediate **13**.[11] The *o*-quinodimethane structure of **13** is not only suggested by the analogous reaction of the parent compound[8] but also by a comparison of the characteristic IR and UV bands of **13** with those of *o*-quinodimethane.[12]

Informative regarding the multiplicity of the diradical **10** is the ESR spectrum. Irradiation[13] of **6** (310 nm) in an adamantane matrix affords the triplet spectrum shown in Figure 1 ($\Delta m=1$ about 3404 G, $\Delta m=2$ about 1693 G),

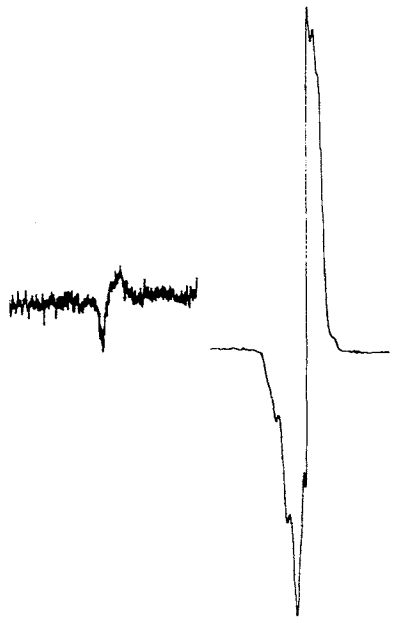


Fig. 1. ESR spectrum of **10** (adamantane matrix, 15 K).
$Hz_1=3351$ G,
$Hx_1=3380$ G,
$Hy_1=3387$ G,
$Hy_2=3419$ G,
$Hx_2=3430$ G,
$Hz_2=3441$ G.

which yields the zero field parameters $|D|/(hc)=0.0042$ and $|E|/(hc)=0.0009$ cm^{-1}. Strict linearity ($r=0.998$) versus $1/T$ was observed for the signal intensity between 15 and 80 K.

Support for this assignment is provided by the UV/VIS spectrum (Fig. 2) with its long-wave bands between 550 and 600 nm ($\lambda_{max}=530$ ($\varepsilon\approx600$), 560 (≈600), 600 (≈400 nm). The position of these bands is in good agreement with the long-wave, forbidden transition at 570 nm calculated for the triplet; these calculations do not lead one to expect any bands for the singlet in this region.[2] Contrary to the theoretical expectations the singlet ground state can accordingly lie 0.02 kcal/mol at most below that of the lowest triplet state, i.e. the states are degenerated, or—what could be more likely—the diradical has a triplet ground state.[14]

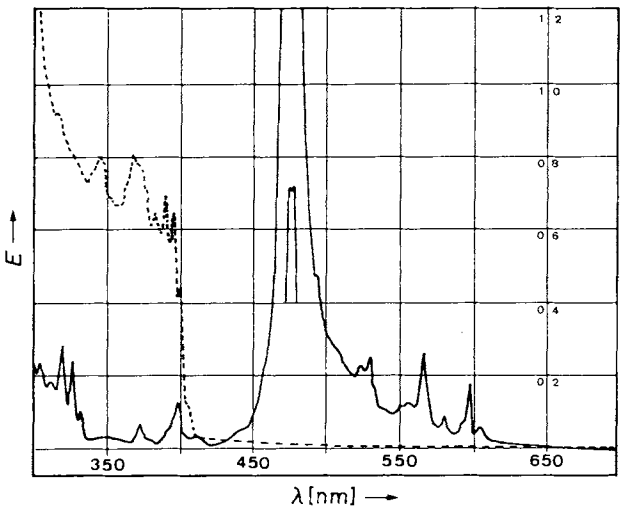

Fig. 2. UV/VIS spectra (argon matrix, 15 K): a) of **10** (——) after 45 min irradiation [9] of **6** at 313 nm; b) of **13** (---) after 15 h irradiation [9] of **10** at 254 nm.

Dinuclear Complexes of Gold(I) Containing Bridging Cyclometalated Arylphosphane or Arylarsane Ligands

By *Martin A. Bennett,* Suresh K. Bhargava, K. David Griffiths, Glen B. Robertson, Wasantha A. Wickramasinghe,* and *Anthony C. Willis*

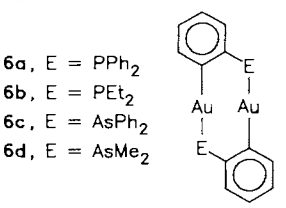
Many complexes have been characterized structurally in which two 1,3-difunctional bidentate ligands hold a pair of gold(I) atoms in a dimeric unit in close contact, the metal-metal distances (2.76–3.02 Å) being close to, or even less, than that in metallic gold (2.88 Å).[1,2] Typical are the di-*n*-propyldithiocarbamate complex **1**, complexes of the methylenebis(diphenylphosphane) series such as **2** and **3**, and phosphorus ylide complexes such as **4** and **5** (Table 1).

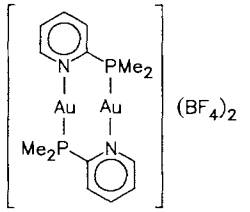
Table 1. Some Au-Au complexes.

	Complex	τ [Au-Au]	Ref.
1	$[Au_2\{\mu\text{-}S_2CN(n\text{Pr})_2\}_2]$	2.76(1)	[3]
2	$[Au_2Cl_2(\mu\text{-}Ph_2PCH_2PPh_2)_2]$	2.962(1)	[4]
3	$[Au_2(\mu\text{-}Ph_2PCHPPh_2)_2]$	2.888(3)	[5]
4	$[Au_2\{(\mu\text{-}CH_2)_2PEt_2\}_2]$	3.023(1)	[6]
5	$[Au_2\{(\mu\text{-}CH_2)_2PPh_2\}_2]$	2.977(1)	[7]

These results suggest that gold(I)-gold(I) dimers of type **6** containing *ortho*-metalated arylphosphanes or arylarsanes should be stable, especially as the isosteric ligand 2-pyridyldimethylphosphane is known to form stable salts of type **7** in which the gold-gold distance is only 2.776(1) Å.[8] A compound related to **6** is the dimer **8**[9] containing *ortho*-metalated benzyldiphenylphosphane,[9] but its structure has not been determined.

Attempts to synthesize **6a** ($E=PPh_2$) by heating $[Au(O_2CMe)(PPh_3)]$ or $[AuMe(PPh_3)]$, with or without added PPh_3, were unsuccessful.[10] However, reaction of $[o\text{-}LiC_6H_4PPh_2]$ with $[AuBr(PEt_3)]$ in ether at -50 °C gives **6a** in good yield as an air-stable, colorless, crystalline solid which is sparingly soluble in organic solvents except CH_2Cl_2 and $CHCl_3$.[11] The complex AuBr($AsPh_3$) can also





7

$[Au_2(o\text{-}C_6H_4CH_2PPh_2)_2]$

8

$[Au(o\text{-}C_6H_4AsPh_2)(PEt_3)]$

[+] X-ray structure analysis

be used as a precursor, but there is considerable competing reduction to metallic gold. Reaction of [*o*-$LiC_6H_4PPh_2$] with AuCl complexes containing more labile ligands such as diethyl sulfide or tetrahydrothiophene does not lead to formation of **6a**.

The mass spectrum (70 eV) of **6a** shows a parent ion, the IR spectrum (KBr disk) contains bands typical of *ortho*-metalation at 1563 (w), 1420 (w), and 723 (m) cm^{-1},[12] and there is a singlet in the $^{31}P\{^1H\}$-NMR spectrum at $\delta = 36.2$ (external standard 85% H_3PO_4) arising from equivalent phosphorus atoms.

Molecules of **6a** have exact inversion symmetry in the solid state[13] and the structure of one such molecule (with H-atoms omitted) is shown in Figure 1.[14] The metallacycle has a twist "recliner" conformation with the carbon atoms displaced by 0.40 and 0.25 Å from the Au_2P_2 plane. The gold and phosphorus atoms are displaced to opposite sides of the phenylene ring planes by 0.60 and 0.10 Å respectively. This twisting deformation is probably a consequence of the steric requirements of the fairly bulky phenyl substituents. The P-Au-C angle is 172.8(1)°. The Au···Au distance (2.8594(3) Å) is typical of gold(I) dimers and suggests a substantial bonding interaction between the metal atoms. The Au-P (2.300(1) Å) and Au-C (2.056(3) Å) distances are unexceptional.

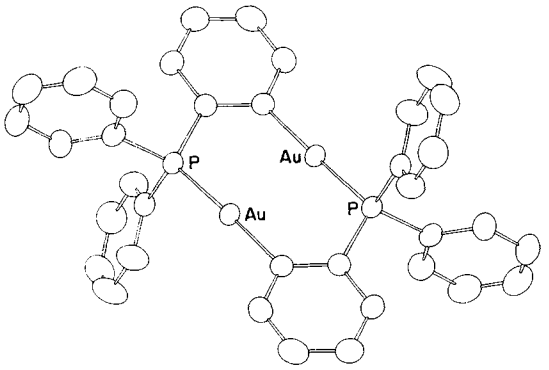

Fig. 1. Crystal structure of **6a** [13, 14].

Other cycloaurated complexes can be made similarly to **6a**, though in generally lower yields; for example **6b** from [AuBr(PEt_3)] and [*o*-$LiC_6H_4PEt_2$] as colorless crystals (ca. 10% yield),[16] **6c** from [AuBr($AsPh_3$)] and [*o*-$LiC_6H_4AsPh_2$] as pale yellow crystals (62% yield), and **6d** from [AuBr(PEt_3)] and [*o*-$LiC_6H_4AsMe_2$], also as pale yellow crystals (18% yield).[17] Treatment of [AuCl(PEt_3)] with [*o*-$LiC_6H_4AsPh_2$] gives the σ-arylgold(I) complex **9** containing an uncoordinated $AsPh_2$ group; the same compound is obtained from **6c** and triethylphosphane. The metallacycle framework in **6b**[18] is very similar to that in **6a**, although it is more nearly planar and the twisting deformation is essentially absent. **6c**[19] is isomorphous with **6a**. Corresponding Au-Au distances are 2.8617(6) and 2.8496(5) Å (**6b**, two independent molecules), and 2.9358(5) Å (**6c**), the longer distance in **6c** reflecting, primarily, the larger covalent radius of arsenic relative to phosphorus.

The new complexes undergo typical oxidative additions with halogens to form dinuclear gold(II) complexes,[20] but an attempt to form a Hg-Au-Au-Hg system by treating **6a** with $HgCl_2$ in THF was unsuccessful. Instead, transmetalation occurred at the σ-aryl group to give the colorless dinuclear complex **10**, which shows a singlet $^{31}P\{^1H\}$-NMR resonance in CD_2Cl_2 at $\delta = 43.2$ with ^{199}Hg satellites ($^3J_{HgP} = 413$ Hz). The Au-Hg distance of 3.112(1) Å in the crystalline mono(tetrahydrofuran) solvate of **10** (Fig. 2)[21] indicates that any metal-metal interaction must be weaker than that in **6a**.

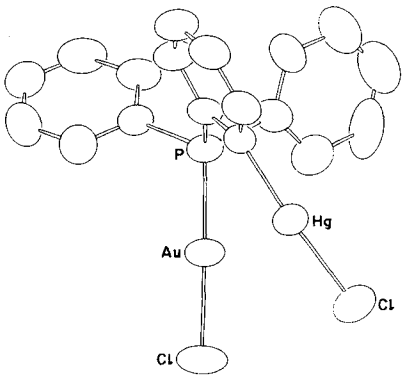

Fig. 2. Crystal structure of **10** [14, 21].

[10] The complex [AuMe(PPh_3)] is known to decompose quantitatively on heating to give ethane, gold, and PPh_3, the process being retarded by added PPh_3: A. Tamaki, J. K. Kochi, *J. Organomet. Chem. 61* (1973) 441.
[11] *Procedure* for **6a**: A solution of *n*-butyllithium in hexane (2.3 ml of a 15% w/w solution) was added to (*o*-bromophenyl)diphenylphosphane (1.16 g, 3.4 mmol) in ether over 0.5 h at room temperature. The resulting precipitate (0.93 g) of (*o*-lithiophenyl)diphenylphosphane containing some ether was washed by decantation with hexane and dissolved in ether (25 mL). This solution was added dropwise to a stirred solution of [AuBr(PEt_3)] (1.1 g, 2.8 mmol) at −70°C. The mixture was stirred for ca. 2 h at −40°C, allowed to come to room temperature, and stirred for a further 1.5 h. The solution was evaporated to dryness in vacuo and the colorless solid residue was washed with ether (3 × 6 mL), methanol (5 × 10 mL), and hexane (3 × 5 mL). It was then extracted with hot dichloromethane (200 mL) to give a purple-tinted solution which was filtered through Celite. Concentration of the colorless filtrate under reduced pressure to ca. 15–20 mL volume gave colorless **6a** (0.8 g, 63%).

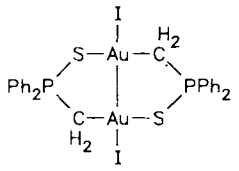
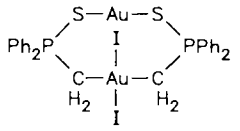
Coupling of Cyclometalated Phenylphosphanes in Dinuclear Gold(II)-Complexes

By *Martin A. Bennett,* Suresh K. Bhargava, K. David Griffiths,* and *Glen B. Robertson*

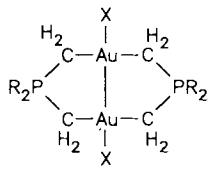
Dinuclear complexes in which two gold(I) ($5d^{10}$) atoms are held in close proximity by a pair of bridging ligands[1,2] undergo oxidative addition with halogens to give two types of product, in both of which the bridging framework is retained. For example, depending on the solvent, addition of iodine to the methylenethiophosphinate-gold(I) dimer $[Au_2\{CH_2P(S)Ph_2\}_2]$ can yield either the isovalent gold(II)-gold(II)(d^9-d^9) complex **1** or the isomeric, heterovalent gold(I)-gold(III)(d^{10}-d^8) complex **2**.[3] Halogens add to the phosphorus ylide complexes $[Au_2\{(CH_2)_2PR_2\}_2]$, R = Me, Et, Ph, to form isovalent gold(II)-gold(II) complexes **3a**[4] and **3b**,[5] but **3c** isomerizes in polar solvents to a heterovalent gold(I)-gold(III) dimer **4**, in which one of the ylide ligands is bound terminally to the gold(III) atom[6] (see Scheme 1).



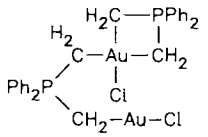
1, r = 2.609(1) Å



2, r = 3.050(3) Å



3a, X = Cl, R = Et
r = 2.597(5) Å
3b, X = I, R = Me
r = 2.660 Å
3c, X = Cl, R = Ph



4, r = 3.184(1) Å

Scheme 1. r = gold-gold distance.

The cyclometalated dimer **5**[7] reacts with bromine or iodine in a 1:1 molar ratio at −78 °C to give orange-red crystalline complexes **6** and **7** in good yield.[8] The fact that both show singlet $^{31}P\{^1H\}$-NMR resonances[9] suggests that the compounds have a symmetrical, isovalent structure and this is confirmed by an X-ray structural analysis of **7**[10] (Fig. 1).[11]

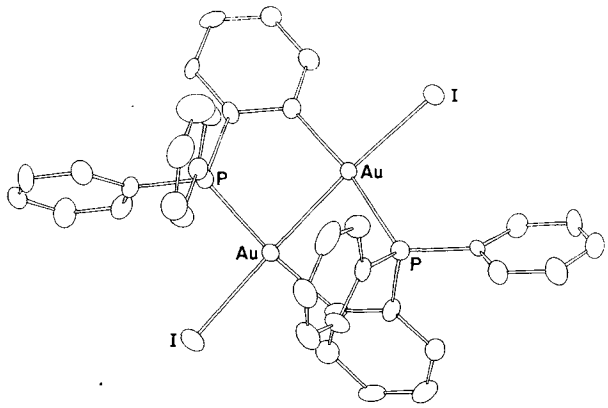


Fig. 1. Crystal structure of **7** [10, 11].

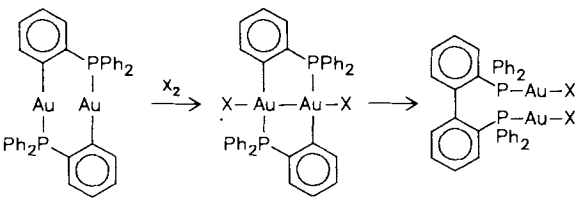
The Au-Au distances in **7** [2.5898(6) Å and 2.5960(7) Å for two independent molecules] are significantly shorter than the corresponding separation in its gold(I)-gold(I) precursor **5** [2.8594(3) Å].[7] Moreover, whereas the metallacycle in **5** has a twist "recliner" conformation, that in **7** adopts a "propeller" conformation in order to reduce nonbonding interactions with the iodine atoms. The basic structure is very similar to that of the cyclometalated platinum(I)-platinum(I) (d^9-d^9) complex **11**[13] in which the axial ligands are phosphanes instead of iodine. The Au-Au distances in **7** are very close to those in the isovalent phosphorus ylide dichloro complex **3a**[4] but are significantly less than those in the diiodo complex **3b**.[5] The Au-I bond lengths in **7** [2.669 Å (av.)] are also significantly shorter than those in **3b** (2.699 Å).[5]

When solutions of **6** and **7** are heated for ca. 12 h in toluene, or are allowed to stand in dichloromethane at room temperature for several days, the color changes from red to pale yellow; the same color change occurs more rap-



5 → (X_2) → **6**, X = Br; **7**, X = I → **8**, X = Br; **9**, X = I

[+] X-ray structure analysis

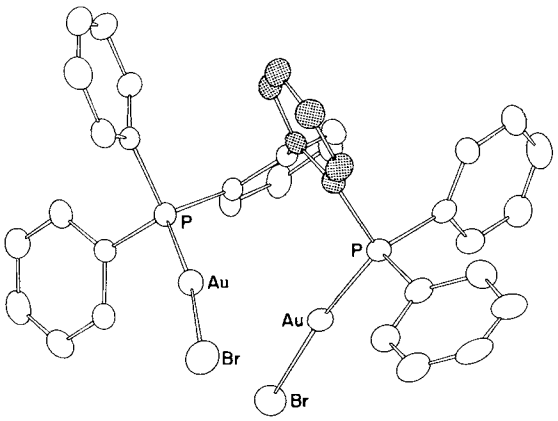

Fig. 2. Crystal structure of **8** [11, 16].

idly on exposure to normal laboratory light. Addition of hexane precipitates colorless, crystalline solids in yields of ca. 70%. The new complexes **8** and **9** are isomeric with their precursors, are dimeric in CH_2Cl_2,[14] and show singlets in their $^{31}P\{^1H\}$-NMR spectra due to equivalent phosphorus atoms.[15] X-ray analysis of the bromo-complex **8**[16] (Fig. 2)[11] shows that it contains a 2,2′-biphenylenebis(diphenylphosphane) ligand.[17] A dihedral angle of 88.6° between the phenyl rings of the biphenyl unit leads to a separation of 3.3013(5) Å between the gold(I) atoms, which are not bound to each other and display their normal linear coordination. The Au–Br and Au–P bond lengths [av. 2.398 and 2.238 Å, respectively] are unexceptional.

Treatment of **9** with aqueous ethanolic NaCN liberates the ligand **10** quantitatively as a white, crystalline solid which melts at 212°C.[18] The value is much higher than the m.p. of 68–70°C reported for a product claimed to be **10** which was isolated in 65% yield from the reaction of Ph_2PCl with 2,2′-dilithiobiphenyl;[19] unfortunately, no spectroscopic data for this compound were reported.

The isomerization of **6** to **8** and of **7** to **9** represents a reductive elimination of two σ-aryl groups at the digold(II) center. The reductive elimination of two σ-alkyl groups at a planar gold(III) center has been studied thoroughly,[20] and the formation of biaryls from aryl-Grignard reagents or aryllithiums in the presence of transition metal halides is well known.[21] The unusual feature in the present case is that the product of reductive elimination is held in the coordination sphere of the metal atoms by the phosphorus donors. This type of behavior has been observed previously only in the case of unsaturated ligands, e.g. in the conversion of the *P,P′*-ethylenebis(dicyclohexylphosphane) tetraphenylnickelacyclopentadiene complex into the corresponding η^4-tetraphenylcyclobutadienenickel compound.[22]

Although the mechanism of the process is as yet unknown, a plausible intermediate in the isomerization could be a heterovalent, salt-like gold(III)–gold(I) species $[\overline{Au^{III}(o\text{-}C_6H_4PPh_2)_2}][Au^IX_2]$, X = Cl, Br. In the cation, the two σ-aryl groups would preferentially occupy *cis* coordination sites,[23] thus favoring reductive elimination and formation of **8** and **9**.

[8] *Procedure* for **7**: A stirred suspension of **5** (300 mg, 0.33 mmol) in toluene (20 mL) contained in a Schlenk flask wrapped in aluminum foil was cooled to −60°C under nitrogen and treated dropwise with a solution of iodine (83 mg, 0.33 mmol) in toluene. The solution was allowed to warm to room temperature and was stirred for a further 1 h. The clear wine-red solution was concentrated in vacuo and hexane (15 mL) was added. On cooling to −10°C, a dark red crystalline solid separated within ca. 12 h. This was filtered in air and washed with hexane (3 × 5 mL) to give **7** (312 mg, ca. 80%), dec. >240°C. Complex **6** was obtained similarly from **5** and bromine. Satisfactory analytical data were obtained for this and other compounds described herein. Both **6** and **7** were found to be dimeric in CH_2Cl_2 by osmometry. **6**: M_r found, 967, calcd., 1076; **7**: found, 1145; calcd., 1170.

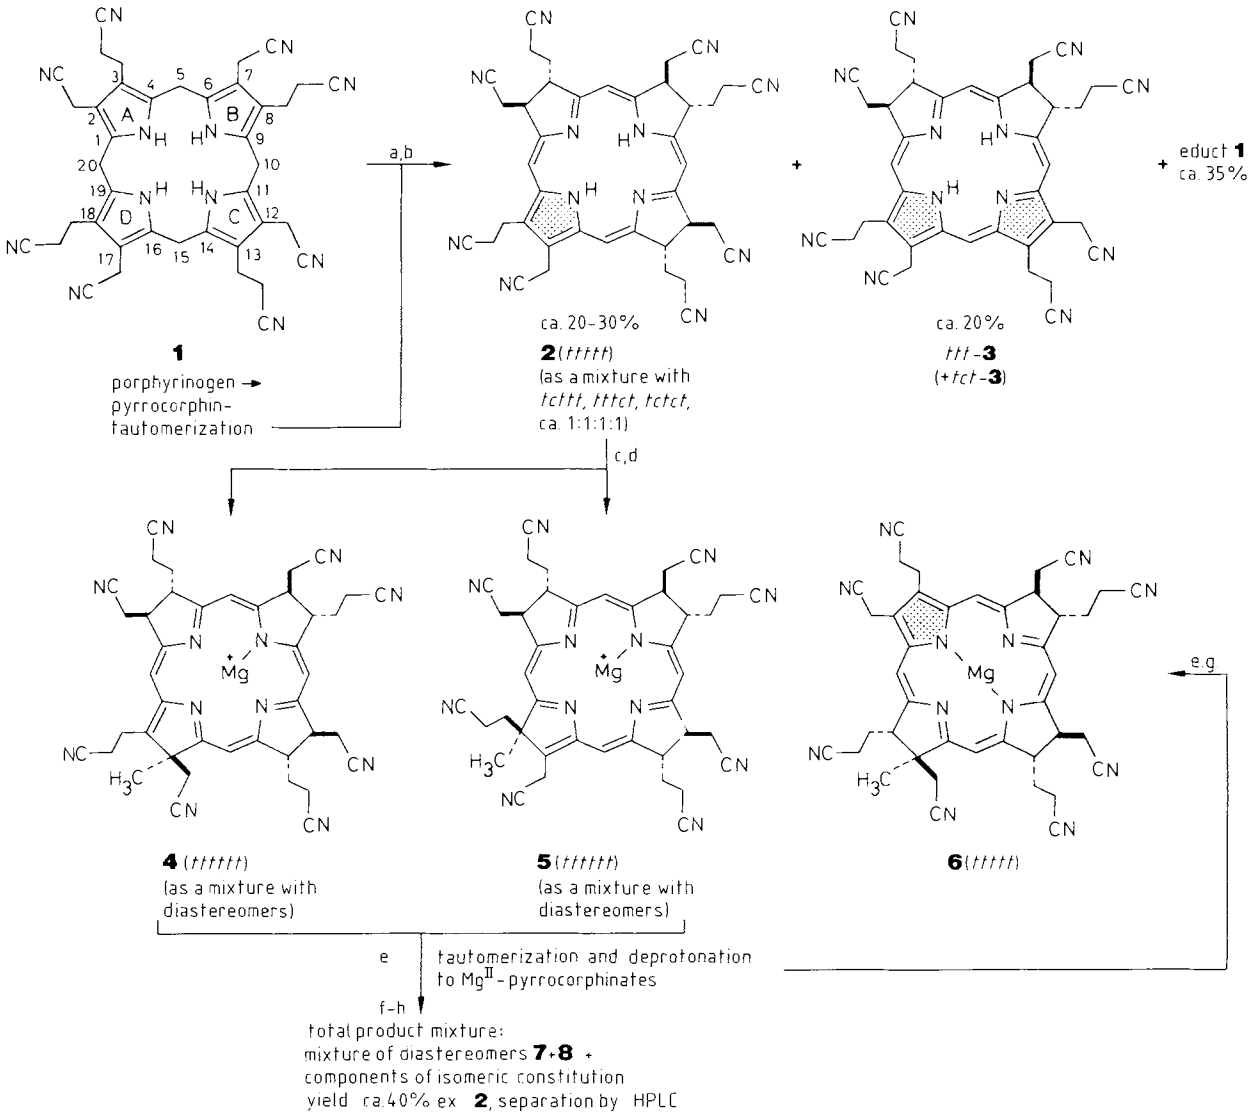
phin tautomerization[1] provides an easy synthetic access to pyrrocorphins (see Scheme 1). This novel type of hydroporphinoid ligand system plays an important role in the biosynthesis of vitamin B_{12};[2] its most notable *chemical* characteristic known so far is the ability of its Mg^{II}-complexes to undergo selective *C*-methylation on the ligand periphery when treated with electrophilic methylating reagents.[3] We now report that the peripheral *C*-methylation of Mg^{II}-uropyrrocorphinate-(type I)-octanitriles shows biomimetic regioselectivity; of the two available reaction sites of the pyrrocorphinic pyrrole ring it is the position bearing an acetonitrile side chain which is preferentially methylated.[4]

The metalating tautomerization of uroporphyrinogen-(type I)-octanitrile **1**[5] with ethylmagnesium bromide and 1,5,7-triazabicyclo[4.4.0]dec-5-ene is experimentally more delicate than that of the octaethylporphyrinogen model. This is due both to the propensity of the nitrile groups to undergo side reactions, and to the higher sensitivity of the tautomerized reaction products to oxidation in basic media.

When **1** was subjected to reaction conditions *a* followed by *b* (Scheme 1), chromatographic separation gave, beside starting material **1** and dehydrogenation products **3**, a fraction containing pyrrocorphins **2**. This fraction was further separated by HPLC into two binary (crystalline) mixtures of diastereomers which were characterized by UV/VIS-, ^{1}H-NMR-spectroscopy and FAB-MS, as well as by analytical HPLC separation of all four diastereomers as their Ni^{II}-complexes.[6]

C-Methylation of the Mg^{II}-complexes of the pyrrocorphin fraction **2**[7] required somewhat more severe conditions than for the octaethyl series,[3a] but nevertheless proceeded cleanly to give the corresponding Mg^{II}-corphin complexes as revealed by UV/VIS spectroscopy (steps *c* and *d*).[7] Direct determination of the constitutional course of the reaction (*C*-methylation to products of type **4** as opposed to **5**) was thwarted by the configurational complexity of the system. This difficulty was overcome by conversion of the entire product mixture into the corresponding mixture of Ni^{II}-isobacteriochlorinates (**7** and **8**); HPLC separation[8] and structural identification (^{1}H-NMR) of the

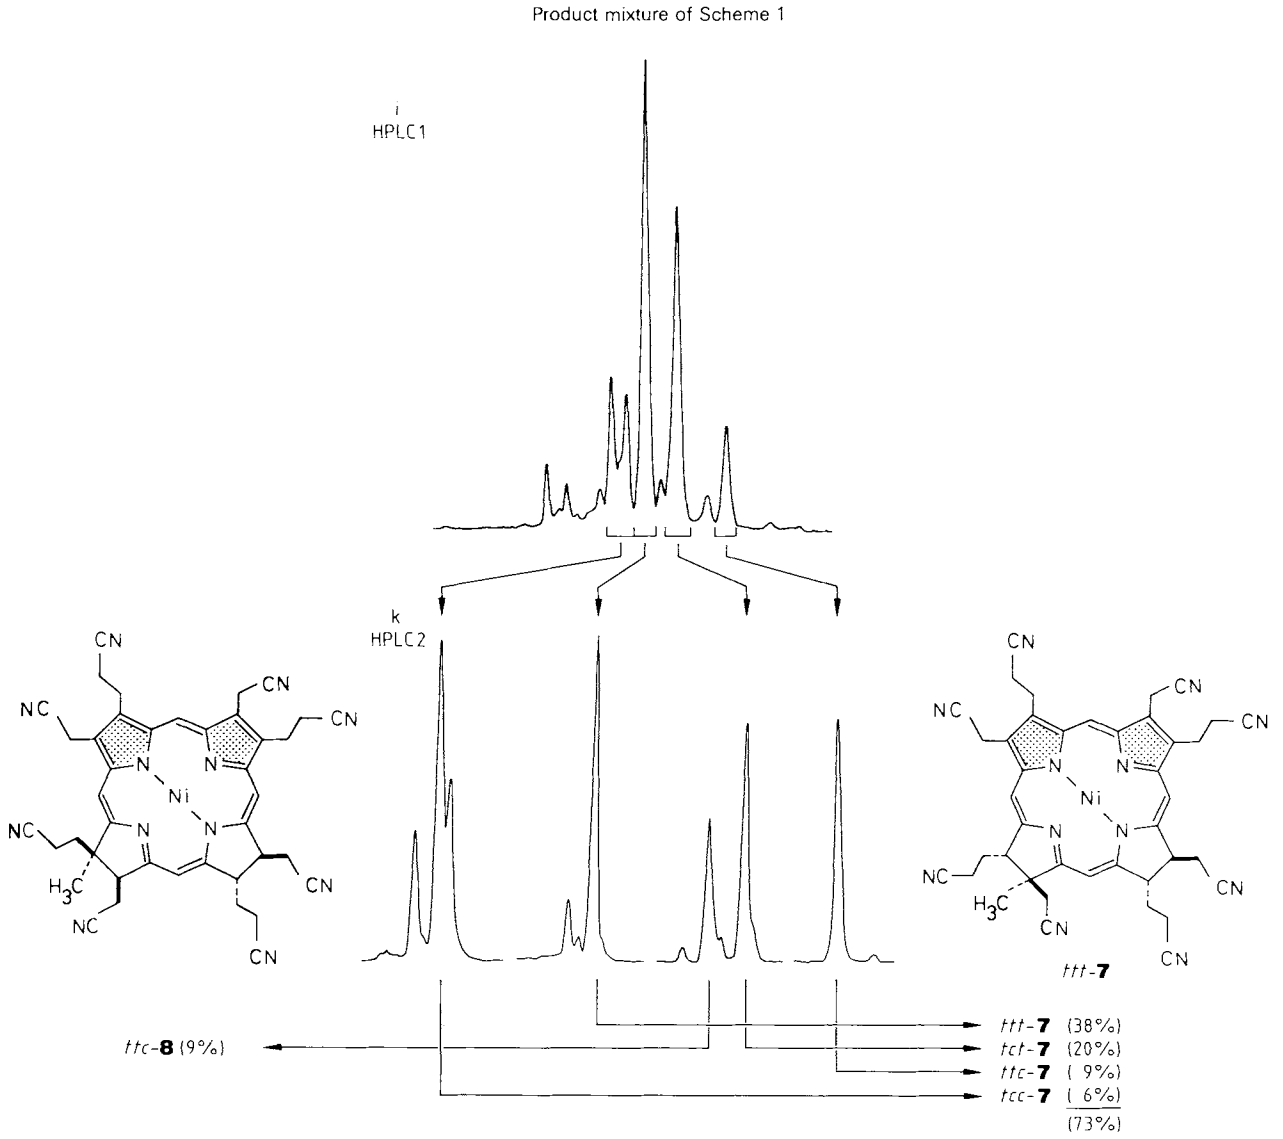


Scheme 1. For the nomenclature of the configuration see ref. [11]; all chiral compounds are racemic. Experimental: a) 9 mol. equiv. 1,5,7-triazabicyclo[4.4.0]dec-5-ene (guanidine base), 5 mol. equiv. For separation see Scheme 2.

main components of this latter mixture was then possible. The key step in the overall transformation (steps *e*–*h*) is the conversion of the primary methylation products (Mg^{II}-corphinates **4** and **5**) into the Mg^{II}-pyrrocorphinates **6** (and pyrrocorphinates of isomeric constitution) involving deprotonation and tautomerization in pyridine; dehydrogenation of these Mg^{II}-pyrrocorphinates proceeded with ease. Conditions and results of the two-step HPLC separation of the mixture of Ni^{II}-isobacteriochlorinates are given in Scheme 2 (*i* and *k*). The five isolated components, identified by ^{1}H-NMR spectra and FAB-MS, made up 82% of the total mixture.[9] Four of them were diastereomers of constitution **7** (73% of the total mixture) and just one (9%) of the identified components had the isomeric constitution **8**. The rest of the reaction mixture (18%) contained at least 10 components which were not identified. The conclusion that product type **7** is unequivocally favored over product type **8** in the *C*-methylation step holds even if all the unidentified components of the mixture were of type **8**.[10]

The structures of the five identified Ni^{II}-isobacteriochlorinates were deduced as illustrated in Scheme 3 (in which the *tct*-**7** isomer is used as an example[7]). The ^{1}H-NMR signal of one of the two CH_2CN groups bound to a nonpyrrolic ring has an AB structure (not ABX), as expected for the presence of a methyl group on a carbon atom bearing a CH_2CN side chain. This carbon must be C-17 in ring D, because the methyl group is correlated by an NOE to the bridge proton which resonates at highest field ($\delta = 6.95$ cf. [1a]). The same proton signal exhibits an NOE with an allylic proton ($\delta = 3.88$), thus indicating that the latter sits on C-13 and lies in a quasi-equatorial position. The bridge-proton signals corresponding to CH-20 and CH-10 show an NOE with the signals of the neighboring allylic protons at C-18 and C-12, but not with those of the methylene groups of the neighboring side chains. This shows that the protons at C-12 and C-18 are quasi-equatorial. The conformation of rings C and D of *tct*-**7** thus assigned (Scheme 3) follows the recently established rules for the conformation of corphinoid Ni^{II}-complexes.[11, 1d]

The common constitution of the main components of mixture **7** indicates that, surprisingly, the transformation **4** → **6** after the regioselective methylation step also pro-



Scheme 2. Experimental: i) HPLC 1: Techsil silica 5 μ/THF-Et_2O 1:2 + 1% H_2O. k) HPLC 2: Techsil silica 5 μ/ethyl acetate-pentane 2:1 + 0.77% H_2O.

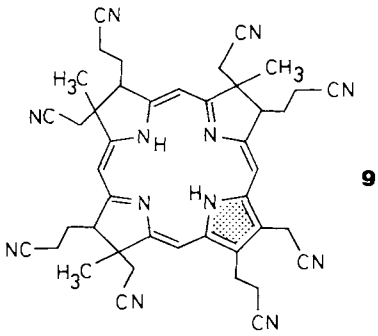
ceeded regioselectively.[12] This implies the possibility that pyrrocorphinates formed in this manner can be further *C*-methylated, and that two repetitions of the methylation-tautomerization procedure should lead to trimethylated pyrrocorphins, among which those of constitution **9** would predominate. Experimentally, trimethylation did indeed prove possible: compound **2** (FAB-MS: $M^+ = 684$), when



9

subjected three consecutive times to the procedures *c*, *d*, *e*, and *f* (Scheme 1), gave first monomethylated (FAB-MS: $M^+ = 698$), then dimethylated ($M^+ = 712$) and finally trimethylated ($M^+ = 726$) pyrrocorphin fractions[13] in spectroscopically determined yields (UV/VIS) of 75, 70, and 45%, respectively. The composition of the product fractions was found to be complex (HPLC). However, we expect this complexity to be mainly configurational and not constitutional. Apparently, what is needed here is diastereoselectivity in addition to the regioselectivity observed in the *C*-methylation steps.

[8] The Ni(II)-complexes of diastereomeric pyrrocorphins and isobacteriochlorins are generally easy to separate by HPLC, in contrast to the metal-free ligands. This difference may be ascribed to the conformational locking of the ligand periphery upon complexation with the nickel ion (see ref. [11]).

[9] Determined by UV/VIS spectroscopy; reference extinction coefficients $\varepsilon_{385} = 52\,700$ and $\varepsilon_{585} = 43\,500$ [6].

[10] We rationalize this regioselectivity by assuming the electron-pair localization energy of the pyrrolic π-system to be lowered at the reacting position through (n→σ*)-conjugation of the lone pair with the C(sp_3)-C(sp)-bond of the (CH_2-CN)-substituent. Steric control can be ruled out (cf. B. Zehnder, *Dissertation*, ETH Zürich No. 7130, 1982).

[12] This becomes comprehensible by supposing that protonation of the position C-20 is a determining step of the tautomerization.

[13] $\lambda_{max}(CH_3CN) \approx 348$ nm (rel. Int. ≡ 1), 356 (0.97), 374 (0.73), 425 (0.10), 460 (0.11), 491 (0.15), 525 (0.13), 566 (0.12) (cf. [1a, 6]).

Structure of Triphenylarsane Diiodide, $[Ph_3As \cdot I_2]$, a Compound Formed in the Thermal Decomposition of $[Mn(OAsPh_3)_3I_2(SO_2)_2]$**

By *Charles A. McAuliffe,* Brian Beagley, George A. Gott, Anthony G. Mackie, Philomena P. MacRory,* and *Robin G. Pritchard*

Our interest in the coordination of small molecules such as sulfur dioxide[1] by $[MnX_2(PR_3)]$ complexes has led us to investigate other manganese(II) systems, and we have recently demonstrated demi-reversible binding of SO_2 in the complex $[Mn(OPPh_3)_4(O_2SI)_2]$ [Eq. (a)].[2]

$$[Mn(OPPh_3)_4(O_2SI)_2] \underset{SO_2}{\overset{129\,^\circ C}{\rightleftharpoons}} [Mn(OPPh_3)_4(O_2SI)I] + SO_2 \qquad (a)$$

[**] This work was supported by the Science and Engineering Research Council (Research Studentship for *GAG*) and the Northern Ireland Department of Education (Research Studentship for *PPM*).

A similar reaction to that used for the preparation of **1** was carried out using MnI_2 and $OAsPh_3$. Addition of sulfur dioxide to a suspension of the $MnI_2/OAsPh_3$ mixture in propyl acetate resulted in a change of color from beige to orange, and the solid that was subsequently isolated was identified as the SO_2-complex **3** (IR data for **3**: $\tilde{\nu}$(O=As), 875 cm^{-1}; $\tilde{\nu}$(SO) 1248, 1080 cm^{-1}). Heating the complex **3** in a rotaflow tube in vacuo at ca. 100°C to test for reversibility of SO_2 binding resulted in the formation of purple-red crystals on the cool parts of the tube. These were shown, by elemental analysis (C,H,I) and an X-ray structure analysis,[3] to be crystals of the I_2-complex [$Ph_3As \cdot I_2$], **4**, the molecular structure of which is shown in Figure 1.

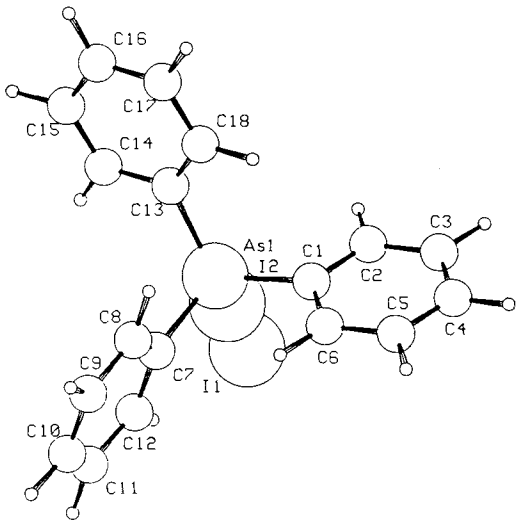

Fig. 1. Molecular structure of [$Ph_3As \cdot I_2$] **4**. Selected bond lengths [Å] and angles [°]: I1-I2 3.005(1), I2-As1 2.64(1); I1-I2-As1 174.8(1), I2-As1-C1-C2 48.5(8), I2-As1-C7-C8 −169.6(7), I2-As1-C13-C14 49.8(9).

Although many other iodine charge transfer complexes are known,[4] [$Ph_3As \cdot I_2$], **4**, is the first compound containing an As-I-I unit that has been crystallographically characterized. The visible spectrum of **4** in toluene solution is typical of other iodine charge transfer complexes, exhibiting absorptions at $\lambda_{max} = 295$ nm ($\varepsilon = 12200$) and 485 nm ($\varepsilon = 850$). Attempts to prepare the complex directly from Ph_3As and I_2 in ethanol, acetone or toluene solutions have been unsuccessful.

The molecule contains a slightly bent As-I-I shaft with three asymmetrically conformed phenyl fins projecting from the arsenic atom (As1-I2-I1) 174.8(1)°). Such a bend is commonly observed in diiodide complexes;[5-9] in this case it is further compounded by an enlarged C13-As1-I2 angle, 119.2(3)°. This is apparently unrelated to intramolecular steric congestion with the shortest non-hydrogen intramolecular contacts involving phenyl rings containing C1 and C7 [I2···C1 3.74(1), I2···C12 3.74(1) Å]. The I-I bond length exceeds that in the uncomplexed I_2 molecule (2.660 Å); this is due to donation of the arsenic's lone pair into the I_2-unit's empty antibonding σ_u orbital and, at 3.005(1) Å, is at the upper limit for uncharged diiodide complexes,[5-9] being surpassed only by some triiodide and pseudotriiodide ions.[10, 11] Some I-I bond lengths are listed in Table 1 for comparison. The weakening of the I-I bond is counterbalanced by an As-I bond which is comparable to those found in other iodoarsane compounds[12-14] with a length, though not the shortest recorded, that is encompassed by the known structures.

Table 1. Comparison of I-I bond lengths in some diiodine compounds.

Compound	I-I [Å]	Ref.
I_2	2.660	
$Ph_3As \cdot I_2$	3.005	
9-cyclohexyladenine $\cdot I_2$	2.764	[5]
1,4-dithiane $\cdot 2I_2$	2.787	[6a]
1,4-diselenane $\cdot 2I_2$	2.870	[6b]
Hexamethylenetetramine $\cdot I_2$	2.830	[7]
Hexamethylenetetramine $\cdot 2I_2$	2.791, 2.771	[7]
N,N'-ethylenethiourea $\cdot 2I_2$	3.147	[8]
$(Dithizone)_2 \cdot 7I_2$	3.215	[8]
$(Ethylenethiourea)_3 \cdot 3I_2$	2.984	[8]
$[Co(C_5H_5N)_4(NCS)_2 \cdot 2I_2]$	2.804	[9]

Several points of interest have emerged from these observations. Firstly, whereas SO_2 will add to $[Mn(OPPh_3)_4I_2]$ to give the bis-adduct $[Mn(OPPh_3)_4(O_2SI)_2]$, **1**, substitution for $OAsPh_3$ occurs in the case of the presumed intermediary $[Mn(OAsPh_3)_4I_2]$ to give "$[Mn(OAsPh_3)_3I_2(SO_2)_2]$", **3**. Of greater importance, however, is the observation that manganese-bound SO_2 appears to be activated and facilely reduces Ph_3AsO to form **4**. Whilst the reduction of organoarsane(v) oxides to organoarsane(III) compounds in strongly acidic media is well known,[15] our present observations suggest that metal-activation of SO_2 greatly assists this process. Further investigations in this connection are currently under way.

Energy Transfer Luminescence of Europium(III) and Terbium(III) Cryptates of Macrobicyclic Polypyridine Ligands**

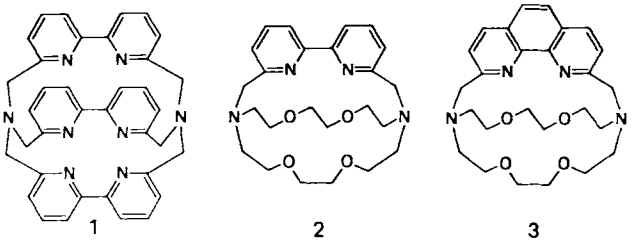
By *Béatrice Alpha, Jean-Marie Lehn,** and *Gérard Mathis*

Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

Cryptate formation by inclusion of a substrate into the intramolecular cavity of a macropolycyclic ligand[1] provides, *inter alia*, an efficient shielding of the bound species from interaction with solvent and other solute molecules. As a consequence the physical and chemical properties of both the included and the external species may be markedly affected.[2] Europium cryptates, e.g., have been found to present a notable emission in aqueous solution at room temperature, whereas simple aqua complexes do not luminesce under the same conditions.[3] This may be attributed to protection of the cryptated europium ions from radiationless deactivation by solvent molecules.[3-6] Similarly, other properties of lanthanoid cryptates, in particular their redox potentials, are also markedly different from those of the aqua complexes.[7,8]

In view of the numerous physical, chemical and biological studies involving luminescent lanthanoid ions, it is of central interest to increase the conversion efficiency of absorbed light into emitted light by making use of energy transfer from excited photosensitive groups of an organic ligand.[9]

We now show that these three features: inclusion, protection, and energy transfer from a ligand group may be combined in a single species: in the photoactive europium and terbium cryptates of macrobicyclic ligands containing α,α′-bipyridine (bpy) and 1,10-phenanthroline (phen) groups as light absorbers (photosensitizers).[10] Cryptates of such ligands with other metal ions are known.[10-12]



1 2 3

The Eu^{III} and Tb^{III} cryptates of ligands **1** and **2** as well as the Eu^{III} cryptate of **3** can be prepared by adding a solution of the corresponding sodium cryptates (as bromides) in a minimum amount of chloroform to a solution containing 1 equiv. of Eu^{III}- or Tb^{III}-salt (nitrate or chloride) in acetonitrile[14] and heating the mixture under reflux for ca. 24 h. After filtration the solution is concentrated under vacuum until it becomes slightly cloudy; it is then left in the cold and the complex crystallizes slowly. The solvent is removed with a pipette and the solid is washed several times with small amounts of CH_2Cl_2/CH_3OH (98/2) and then with ether. The La^{III} complex of **1** has also been prepared. The complexes obtained may be described as the lanthanoid cryptates $[Ln^{3\oplus} \subset L]$ (where $Ln^{3\oplus} = Eu^{3\oplus}$, $Tb^{3\oplus}$ or $La^{3\oplus}$ and L = **1**-**3**) in which the cation is included in the molecular cavity (see Fig. 1), consistent with the crystal structure of related cryptates.[8,11,15] Lanthanoid cryptates are stable complexes and kinetically very inert.[7,16] Introduction of the rigid bpy and phen groups, should render cation exchange particularly difficult and slow.

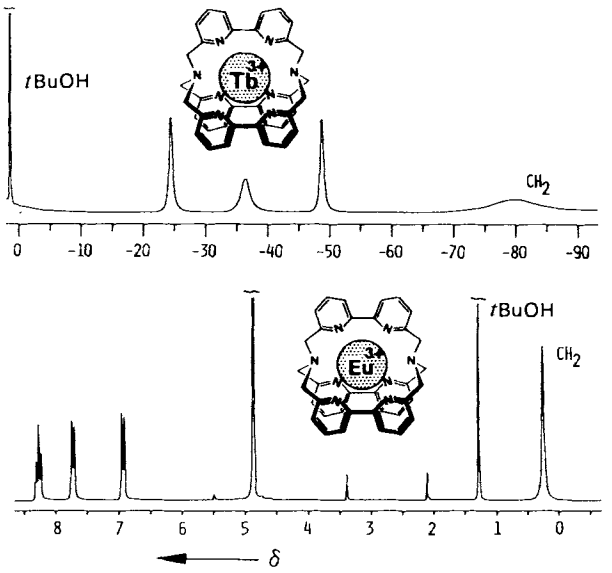


Fig. 1. 200 MHz ^{1}H-NMR spectra of the europium(III) (bottom) and terbium(III) (top) cryptates of the macrobicyclic ligand **1** in D_2O at 20°C; δ values referred to sodium trimethylsilylpropanesulfonate (TMPS); internal reference: *t*BuOH. The peaks between $\delta = 2$-5 in the lower spectrum stem from solvent.

The ^{1}H-NMR spectra of these complexes are highly characteristic, since lanthanoid ions such as $Eu^{3\oplus}$ and $Tb^{3\oplus}$ strongly perturb NMR signals.[17] As illustrated in Figure 1 for ligand **1**, the ^{1}H-NMR spectra of the Eu^{III} and Tb^{III} cryptates of **1**-**3** are very different from those of the corresponding $Na^{\oplus}$ cryptates.[10] For both ions the signals are appreciably shifted; the effect is particularly large for Tb^{III}, which also causes strong line broadening.

Electrochemical studies have shown that the reduction of $[Eu^{3\oplus} \subset \mathbf{1}]$ is reversible (−555 mV, SCE, 0.1 M NMe_4ClO_4); the Eu^{III} state being stabilized with respect to the aqua ion (−625 mV), but much less so than in the case of the Eu^{III} cryptate of the macrobicycle "(2.2.2)".[7]

The photophysical properties of the Eu^{III} and Tb^{III} cryptates of ligands **1**-**3** are of special interest in view of the features discussed above. Some preliminary data are listed in Table 1.[18] Strong red and strong green emissions, respectively, are readily observed for the Eu^{III} and Tb^{III} cryptates of **1**-**3** in aqueous solution at room temperature, whereas the aqua ions do not emit under the same conditions. The excitation spectra are similar to the absorption band of the complexes arising from the ligand groups; the emission spectra are characteristic of Eu^{III} and Tb^{III} luminescence. These data show that in the present cryptates UV light absorbed by the bipy and phen groups is re-emitted as visible light by the complexed lanthanoid ions (see Figure 2 for $[Eu^{3\oplus} \subset \mathbf{1}]$.

These spectral properties may be ascribed to intramolecular energy transfer from the π,π* excited states of the ligand groups to excited levels of the Eu^{III} and Tb^{III} ions,

which then emit from the $^5D_0$ and $^5D_4$ levels respectively. A contribution from charge-transfer absorption[3b] cannot be excluded, although no such band is observed. The efficiency of conversion is high, probably about unity for $[Eu^{3\oplus} \subset \mathbf{1}]$.[18] The light conversion process absorption-energy transfer-emission, **A-ET-E**, performed by these cryptates, is represented in Figure 2.

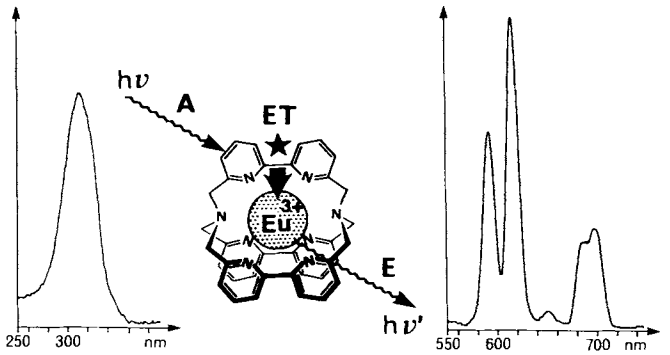

Fig. 2. Illustration of the absorption-energy transfer-emission **A-ET-E** light conversion process performed by the cryptate $[Eu^{3\oplus} \subset \mathbf{1}]$ (center); left: excitation spectrum (emission at 700 nm); right: emission spectrum (excitation at 320 nm); 10^{-6} M aqueous solution of the nitrate at 20°C; uncorrected spectra.

The emission lifetimes of the present europium cryptates (Table 1) are longer than those of the aqua ion (0.11 ms[3b]) and even of the $[Eu^{3\oplus} \subset 2.2.1]$ cryptate (0.215 ms);[3b] this may be due, at least in part, to a better shielding of the included ion by macrobicyclic ligands **1**–**3**. Preliminary measurements gave emission quantum yields above 10^{-2} for the Eu^{III} and Tb^{III} complexes of **1** and **2** (in aqueous solution).[18] This is high for such ions, being in particular at least an order of magnitude higher for $[Eu^{3\oplus} \subset \mathbf{1}]$ than for $[Eu^{3\oplus} \subset 2.2.1]$ (3×10^{-3} in D_2O solution).[3b]

Table 1. Photophysical properties of europium(III) and terbium(III) cryptates of the macrobicyclic ligands **1**–**3** [18] [a].

Cryptate	λ_{exc} [nm]	Lifetime [ms]
$[Eu^{3\oplus} \subset \mathbf{1}]$	300	0.34
$[Eu^{3\oplus} \subset \mathbf{2}]$	310	0.41
$[Eu^{3\oplus} \subset \mathbf{3}]$	280	0.27
$[Tb^{3\oplus} \subset \mathbf{1}]$	302	0.33
$[Tb^{3\oplus} \subset \mathbf{2}]$	310	0.72

[a] All measurements were performed in neutral aqueous solution at 300 K; lifetimes ±20%; the concentrations ranged from 10^{-6} to 10^{-4} M; lifetimes determined at $\lambda_{em} = 619$ nm for Eu^{III} and at $\lambda_{em} = 545.5$ nm for Tb^{III}. Anion: NO_3^-.

The photoactive europium(III) and terbium(III) cryptates described here are efficient luminophores which function as **A-ET-E** light conversion molecular devices, transforming UV light absorbed by ligand groups into visible lanthanoid emission via intramolecular energy transfer. In addition to the interesting photophysical and photochemical features of these and related complexes, a number of potential uses may be envisaged, for instance in the development of luminescent materials and of labels for biological applications[19] such as time-resolved luminescence immunoassays[20] employing monoclonal antibodies.

Diastereoselective Diels–Alder Reaction on Carbohydrate Matrices**

By *Horst Kunz,* Bernd Müller,* and *Dirk Schanzenbach*

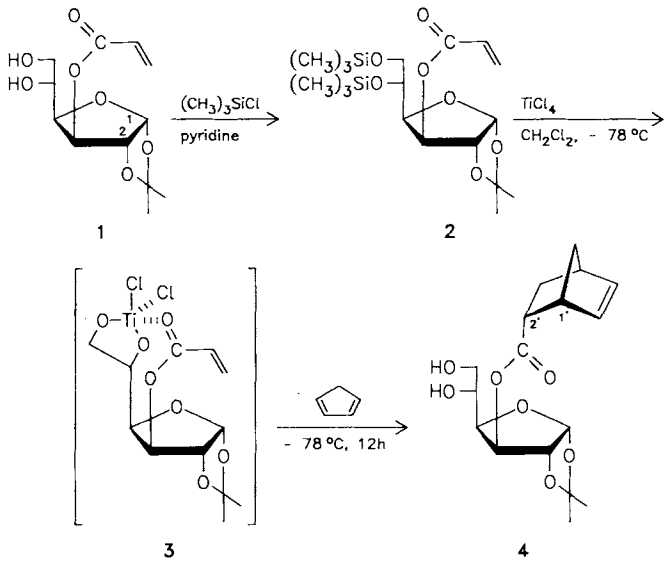
Dedicated to Professor Helmut Hoffmann on the occasion of his 60th birthday

Numerous biochemical, immunological and molecular-biological investigations have shown that carbohydrate determinants play an important role in crucial processes of biological selectivity.[1] If one disregards chiral pool-syntheses, in which the carbohydrate itself is substrate, and some chiral hydride carriers, carbohydrates have been used only in isolated cases for the selective control of chemical processes.[2] Stimulated by our synthesis of glycopeptides as biological recognition structures[3] we have

[*] Prof. Dr. H. Kunz, Dipl.-Chem. B. Müller, D. Schanzenbach
Institut für Organische Chemie der Universität
J.-J.-Becher-Weg 18–20, D-6500 Mainz (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

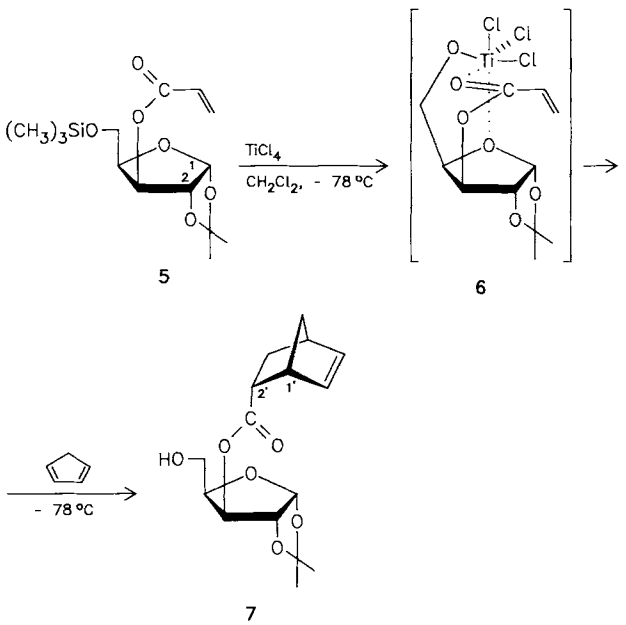
now tried to control diastereoselective reactions using the "chiral information" of the carbohydrates, which may be regarded as stereochemical microchips. We describe here the results of Diels-Alder reactions[4] with acrylates which are esterified with carbohydrate matrices. For diastereoselective Diels-Alder reactions with amide-bound[5] or ester-like bound dienophiles,[6] high inductions have been described. This holds true, in particular, for the titanium tetrachloride-catalyzed reactions of the acrylate of (*R*)-pantolactone.[7] We have now exploited the polyfunctionality and chirality of the carbohydrates in analogous Diels-Alder reactions in order to arrange the dienophile and the Lewis acid catalyst on the carbohydrate matrix such that the attack of the diene and the configuration of the main product can be predicted with high probability. For this purpose the 3-*O*-acryloyl-1,2-*O*-isopropylidene-α-D-glucofuranose **1**, which is readily accessible from 1,2,5,6-di-*O*-isopropylidene-α-D-glucofuranose by esterification with acryloyl chloride/triethylamine and selective cleavage of the 5,6-protecting group with 70% acetic acid, is silylated to give **2** in order that the titanium catalyst can be introduced later. **2** reacts with $TiCl_4$ at −78 °C with a change in



Scheme 1.

color to give **3**; trimethylchlorosilane is formed as a volatile, readily separable by-product. Completion of the exchange can be controlled by thin-layer chromatography. However, because of the instability of the chlorotitanate **3**, its isolation and exact characterization is not possible. The direct reaction of diols such as **1** or their anions with $TiCl_4$, on the other hand, yields HCl- or salt-containing chlorotitanates whose catalytic activity is strongly reduced. In the acrylates **1**–**3**, the α,β-unsaturated carbonyl system is apparently present in the *anti* conformation, since the signals of the vinyl protons appear in the sequence ($\delta_{\beta\text{-}Z} > \delta_{\alpha} > \delta_{\beta\text{-}E}$) characteristic for normal acrylates. This is consistent with the observations made on lactate enoates, in which the Lewis acid catalyst, as here, attacks exclusively at the carbonyl oxygen atom of the enoate.[6] In the reactive complex **3**, the dienophile and the titanium catalyst are so fixed that the *Re* side of the dienophile is shielded, irrespective of which conformation the side chain adopts with respect to the catalyst. The arrangement in which the oxygen atom of the furanose ring can function as sixth ligand for the titanium atom could be especially favorable. Cyclopentadiene can then attack the complex **3** only from the front, and obliquely from above, as shown in Scheme 1. Hence, on preserving the *endo* transition state the (1′*R*,2′*R*)-5′-norbornen-2-ylcarboxylic acid derivative **4** should be formed. The ^{1}H- and ^{13}C-NMR spectroscopic analysis of the adduct, the separation of the diastereomers **4** by flash chromatography,[8] and the reductive cleavage of **4** to give 5-norbornen-2-ylmethanol[9] confirm that the (1′*R*,2′*R*)-diastereomer of the adduct **4** is indeed formed highly selectively (93 : 7). *Exo* configurated isomers could not be detected in the product mixture. The (1′*S*,2′*S*)-diastereomer of **4** formed as by-product presumably arises from the Diels-Alder reaction of the *syn*-rotamer of **3**. The amount of *syn*-rotamer increases with increasing reaction temperature. Reactions of **3** with the less reactive dienes 1,3-cyclohexadiene, 1,3-butadiene and anthracene lead in 12 days at room temperature to formation of the adducts in yields of up to ca. 30%. The diastereoselectivity drops from 82 : 18 (cyclohexadiene) to 78 : 22 to 70 : 30 (anthracene).

We concluded from these findings that the activity of the titanium center should be increased in order to increase the diastereoselectivity. We therefore prepared the 3-*O*-acryloyl-1,2-*O*-isopropylidene-5-*O*-trimethylsilyl-α-D-xylofuranose **5** from 3-*O*-acryloyl-1,2-*O*-isopropylidene-5-*O*-trityl-α-D-xylofuranose by selective acidolytic deblocking in the 5-position and subsequent silylation with trimethylchlorosilane/pyridine. Reaction of **5** with titanium tetrachloride leads to formation of the complex **6** in which the dienophile and the Lewis acid catalyst are arranged similarly as in **3** (Scheme 2). The Lewis acidity in **6**, however, is increased. Cyclopentadiene reacts with **6** to give the adduct **7**, only one diastereomer of which can be detected by chromatography and by 400-MHz ^{1}H- and 100-MHz ^{13}C-NMR spectroscopy.[10] The reduction of **7** to 5-norbornen-2-yl-methanol confirmed that **7** was the expected (1′*R*,2′*R*)-diastereomer.



73%, (*R*) : (*S*) > 98 : 2

Scheme 2.

These results show that the chiral information of carbohydrates can be used for directed stereoselective control by binding reversibly several reaction components in a definite way to the functional groups of the carbohydrate matrix.

BOOK REVIEWS

Chemistry of Hydrocarbon Combustion. By *D. J. Hucknall.* Chapman & Hall, London, New York 1985. viii, 415 pp., bound, £ 39.50.—ISBN 0-412-26110-3

The problems and methods of investigation in the chemistry of hydrocarbon combustion are of an analytical nature. The questions posed are: What types of reactions and intermediates are involved in the combustion? What are the rates of the individual steps in the reaction? How are these steps interconnected with regard to the transfer of matter and energy? The book reviewed here is aimed at obtaining answers to these questions. The treatment of the problem can be divided roughly into three sections:

1. Determining the possible reaction products that can result from oxidation or thermal decomposition under various conditions of combustion (Chapters 1, 2 and part of Chapter 6).
2. A description of the tools used by the combustion chemist, divided into "hardware" (apparatus and investigational techniques), and "software" (information on reaction mechanisms and rate constants).
3. Computer-aided studies which are aimed at simulating and understanding the entire combustion process and the macroscopic observations, starting from reaction mechanisms and kinetic data.

The first group of topics is treated mainly from a historical standpoint. Results obtained for different fuels are followed by a description of theories of hydrocarbon oxidation proposed during the 1920's and 1930's. Similarities of the combustion of various hydrocarbons (induction times, auto-catalytic behavior, negative temperature coefficients, etc.) are outlined, and important stages in the theoretical interpretation (hydroxyl chemistry, branching of reaction chains according to *Semenow*, peroxide theory, etc.) are explained. The development of more sensitive analytical techniques (mass spectrometry, gas chromatography) on the one hand, and the introduction of methods for transient measurements on the other, are reflected in the greater wealth of analytical data and the increasingly detailed reaction mechanisms arising in the 1960's and 1970's (Chapter 2). By this historically oriented treatment, the author puts up with the fact that without a knowledge of the important reaction mechanisms discussed later, the analytical results from early studies and the interpretations based on them appear confusing and lacking an unbroken thread.

Chapters 3 to 5 comprise an excellent review of modern techniques for investigating the basic reactions of combustion processes and measuring their kinetic parameters. This is a critical presentation which also examines theoretical aspects of the interpretation of rate constants and their dependence on temperature and pressure. One chapter is devoted to free radical reactions of the hydrogen-oxygen system and another to those of carbon-containing compounds. It becomes clear how closely related the combustion chemistry of hydrocarbons is to the hydrogen-oxygen system. I enjoyed these chapters the most.

There follows a chapter on the pyrolysis of hydrocarbons, insofar as this is important in relation to combustion reactions, half of this being devoted to soot formation in flames. Here one is a little disappointed at not finding an account of the progress made recently using laser optics methods. Also the fact that soot formation is treated in the chapter on pyrolysis obscures to some extent the important role that oxidation reactions also have in this process.

The book concludes with a briefer survey of methods and progress in modelling complex combustion systems (flames, pyrolyses and oxidations at intermediate temperatures).

Taken as a whole the book mainly has the character of a review. Its strength lies in its concise presentation, limited to the basic essentials, of results from important investigations covering seven decades of combustion research. This is supported by the extremely comprehensive bibliography, containing about 2200 references. Regrettably, though, the author has not quite succeeded in clearly correlating the results of different investigators, nor in reducing complex combustion reactions to their essential features and thereby making them comprehensible to chem-

ists other than combustion specialists. An example is the generalized reaction mechanism for hydrocarbon oxidation on p. 381, which contains reactions such as $R^{\odot} \rightarrow {}^{\odot}R$, and the explanation which follows. Nevertheless, the book is recommended for all combustion chemists, as it will expand their knowledge and thus make their work easier.

Olefin Metathesis and Ring-Opening Polymerization of Cyclo-Olefins. By *V. Dragutan, A. T. Balaban,* and *M. Dimonie.* Wiley, Chichester, and Editura Academiei, Bucharest 1985. 544 pp., bound, £ 34.50.—ISBN 0-471-90267-5

Following the publication in 1985 of the revised second edition, in Rumanian, of the book by *V. Dragutan, A. T. Balaban,* and *M. Dimonie,* an English translation has now appeared, making it accessible to a wider range of readers. It is concerned with the scientific and technological aspects of metathesis reactions of linear and cyclic olefins. Since its discovery by *Banks* and *Bailey* in 1964, catalyzed olefin metathesis has quickly attained considerable importance in organic, macromolecular and organometallic chemistry. The main areas of application emphasized are olefin syntheses (triolefin process, Shell higher olefins process and petrochemicals olefin syntheses), and the synthesis of elastomeric polyalkenes. Consequently, there is a large group of interested readers who will welcome a specialist book on this subject.

Dragutan, Balaban, and *Dimonie* present here, in nine chapters, a broad, application-oriented, survey of metathesis reactions. Chapter 1 contains a short historical overview, and definitions of metathesis reactions such as homometathesis, cometathesis and ethenolysis. In Chapter 2 the common heterogeneous and homogeneous catalysts for metathesis are described as well as reaction variables such as temperature, pressure and solvent. In Chapter 3 the metathesis reactions of linear and cyclic olefins and of alkynes are systematically discussed. Ring-opening metathesis of mono-, bi- and polycyclic olefins is described in detail in Chapter 4. Chapter 5 gives a brief examination of the thermodynamic aspects of the metathesis of olefins and the ring-opening polymerization of cyclic olefins. Chapter 6 deals in detail with reaction kinetics and mechanisms. Each of the intermediate steps in the currently favored carbene mechanism for metathesis reactions of linear and cyclic olefins are examined in detail and the effects of different transition metals, ligands and co-catalysts are discussed. Mechanisms for alkyne polymerization are also dealt with. In Chapter 7 an account is given of the stereochemistry of metathesis reactions, with experimental results and theoretical ideas clearly presented alongside each other. Chapter 8 is devoted to practical applications; this includes discussion both of existing technological processes and of further possible applications to the synthesis of organic compounds. The final chapter contains a comprehensive survey of known metathesis reactions in the form of tables, listed both according to catalysts, and the substrate olefins and alkynes.

The literature cited and discussed covers approximately 2000 publications up to 1982. In view of the wealth of published papers in the area of metathesis in recent years, a further new edition or a supplement will presumably appear before very long.

On the whole, this reference book provides a very comprehensive survey (up to 1982) of the metathesis of linear olefins and the ring-opening polymerization of cyclic olefins. The research findings and the reaction mechanisms are discussed in a lucid manner. The figures and tables are clearly set out and easy to understand. A minor fault is the poor quality printing, especially apparent in some of the figures. The book is primarily suited for chemists working in the metathesis field, whether their objectives are mainly of a chemical (organic, macromolecular or organometallic) or technological nature.

Polymers. The Origins and Growth of a Science. By *H. Morawetz,* Wiley, Chichester 1985. xvi, 306 pp., bound, £ 54.95.—ISBN 0-471-89638-1

Unlike molecular biology or biotechnology, macromolecular chemistry is not a field of technology that attracts the attention of the public at large. Nevertheless, our industrial civilization has become highly dependent upon polymer science, i.e. upon the synthesis and properties of polymers. Polymers in the form of plastics, synthetic fibers, coatings, adhesives, synthetic rubbers and insulating materials make up one of the most important branches of the chemical industry. The standard of living now enjoyed by Western industrial nations would scarcely be conceivable if the materials provided by macromolecular chemistry did not exist.

Herbert Morawetz's book on the origins and growth of polymer science is a 'must' for all those who wish to come to terms with macromolecular chemistry and physics and who are not merely interested in current facts and figures but also want to find out about the internal structure and concepts of this field of science.

In 25 fascinating chapters *Morawetz* describes the intellectual and experimental difficulties that have had to be overcome since the days of *Berzelius* in order to understand the complexity, diversity and dynamics of macromolecular structures and their properties.

Polymer science has profited from the advances made in general chemistry and physics, yet concomitantly it has stimulated these sciences in certain respects. The interest shown by technology and industry in new materials have done their part to accelerate the progress of research. These considerations run through the whole of the book. *Morawetz* deals with already well known examples—the study of the structure and properties of natural and synthetic rubbers, the controversies concerning the structure and properties of cellulose as a basic material in the textile industry, which finally led to the development of synthetic fibers, and the elucidation of the mechanism for the radical polymerization of olefins, which is basic to the organic chemistry of free radicals and has also enabled the synthesis of important plastics.

The achievements of individual research workers can only be appreciated in the light of the knowledge available to them. The ranges and efficiencies of the methods and techniques at their disposal also have to be taken into consideration. *Morawetz* has successfully managed to relate this in an understandable way, he has made a point of substantiating the concepts of each research worker and his scientific competitors by using original quotations. Al-

though some of these have had to be commented in accordance with modern concepts, this has been done carefully and intelligently.

The book is divided into specialized subjects that are arranged in historical order. The achievements of individual scientists are described within the relevant topic, for example biogenic macromolecules, the importance of X-ray structure analysis, the determination of molecular weights, condensation polymerization, rubber elasticity, properties of polymer solutions. The chapters on the origin and growth of molecular biology and its relationship to macromolecular chemistry are also of interest.

The work has been written at a very high scientific level and thus assumes that the reader already possesses a broad knowledge of macromolecular chemistry and the physical chemistry of the condensed state. This accounts for its great appeal to the expert who wants to obtain a complete grasp of the background on which current knowledge is based, especially since most of the themes that are discussed are still of topical interest.

Homogeneous Catalysis with Compounds of Rhodium and Iridium. By *R. S. Dickson*. D. Reidel Publishing Company, Dordrecht 1985. xv, 278 pp., bound, HFl 135.00.—ISBN 90-277-1880-6

In the series *Catalysis by Metal Complexes*, the volume on homogeneous catalysis using compounds of rhodium and iridium has now appeared. This monograph by *Ronald S. Dickson*, containing seven chapters of text, a summary in tabular form of rhodium and iridium catalysts and their applications, as well as nearly 2000 references, gives a detailed survey of the state of research on this topic up to the end of 1982.

After a very brief introduction to catalysis by transition metal compounds in Chapter 1, there follows a chapter on the activation of C–H and C–C bonds (dehydrogenation, H/D isotope exchange, isomerization), then one on C–H bond formation (hydrogenation, hydrosilylation). These are followed by Chapter 4 on carbonylation and hydroformylation reactions, and Chapter 5 on oxidations. Chapter 6 deals with reactions involving functional group removal, and Chapter 7 is devoted to oligomerization, polymerization and cyclization reactions. Within each chapter the reactions discussed are grouped under catalyst types. The appendix contains tables in which the catalyst types dealt with, their applications, and the literature references are collected together.

The author has evidently been concerned to bring order to the flood of detailed information, and has succeeded in providing the reader with a lucid overview of the wealth of studies and results. The summary tables and the literature references (which total 1971) in the appendix make it easier for the reader to get his bearings in this wide ranging field of research, and facilate quick access to the original papers. The alphabetical arrangement of references under first-named authors is especially helpful in that respect. Thus the reader can quickly find information on a particular type of reaction by using the list of contents, on a type of catalyst from the tables in the appendix, or on the work of a particular author from the bibliography. This favorable impression of the book is further reinforced by the inclusion of a carefully compiled subject index.

However, the lucid arrangement of the material is contrasted by a presentation considerably less clear. This is due both to reaction schemes which are not very illustrative, and to the book's catalog-like nature. The readability of the text is also seriously hindered by the monotonous style—for example, almost every section begins with the phrase "... have been used as catalysts for ...". The concern with completeness and clarity has led to a format which does not allow a lively style and terse presentation. Understanding of the reaction schemes, which are thoroughly and critically discussed, is made less easy by unnecessarily adopting a generalized form, and often by a lack of complete stoichiometry, e.g. in Schemes 3.1, 3.3, 3.4, 3.5, and 6.1 the detached ligand (S, CO, or PR_3) is omitted, and in Scheme 2.3 the original complex is ignored.

To summarize, the book is well set out, and the organization of the material is impressive, but it is not easy to read; it will undoubtedly be of considerable value to the specialist, but it will scarcely be attractive for the reader who is looking for an introduction to this field of research.

Organische Chemie. By *S. Hauptmann*. Verlag Harri Deutsch, Frankfurt/M. 1985. 893 pp., bound, DM 48.00.—ISBN 3-87144-902-4

With the appearance in the early sixties of books such as those of *Roberts* and *Caseiro*, *Cram* and *Hammond*, *Morrison* and *Boyd*, and many others, a new sort of textbook was seen to be emerging on to the market. These introductions to organic chemistry were characterized by having their contents arranged according to reaction types (instead of the more traditional arrangement under compound classes), and a thorough discussion of reaction mechanisms, with detailed treatments of, in particular, bonding theory, stereochemistry, and the increasingly important spectroscopic methods. These textbooks were usually also distinguished by their high quality of formula printing, previously unknown in such books, and a clear and concise style. They presented organic chemistry as a well-ordered and systematic branch of science which, even if not fully under our control, is well understood, giving results that generally agree with our predictions. In retrospect it is interesting to note that during those years there were also many other areas of human activity where complicated relationships were accounted for by "theories". Thus, such books were appropriate to the climate of the times, and, first in the USA, then here in Germany, they quickly became the norm. In this country they succeeded to such an extent that textbooks of the more traditional style were no longer used, and furthermore our own authors literally laid down their pens, and soon no competing texts of German language origin were appearing.

Most of us have willingly used and recommended the American textbooks, although really a deficiency ought to have been apparent to us, arising not so much from the books themselves as from their uncritical acceptance into the German educational and training system—more specifically that of the Federal Republic. Textbooks of the sort described above were, and are, written for undergraduates; American students, after taking their bachelor degrees, use textbooks and monographs whose advanced nature is

often evident from their titles. Here, on the other hand, it tends to be assumed that not only undergraduates, but also post-graduate students reading for diplomas and even for doctoral higher degrees can learn about the whole of organic chemistry from books of the former kind. In other words, these books are suited only to a very limited extent for our (present) courses of study; they are too comprehensive for undergraduates, while for post-graduates or for those already in professional jobs they do not go far enough, containing insufficient detailed information for these users.

What, then, are the essential features of an organic chemistry textbook which is better suited to our present time and circumstances? It needs to combine the best characteristics of the two traditions, i.e. it must be up-to-date, lucid, and written from a standpoint of theory and mechanism in the manner of an Anglo-Saxon textbook, while having the encyclopedic and practically-orientated qualities of a traditional German textbook. A hopeless undertaking? Not, it appears, for *Siegfried Hauptman* of the Karl-Marx University, Leipzig, who has attempted singlehandedly to achieve such a synthesis. His "Organic Chemistry" is indeed modern in concept, as is illustrated by the wealth of topics that are treated. These range from the planning of a synthesis to the use of the published chemical literature, from organometallic chemistry to photochemistry and dyestuffs chemistry, from stereochemistry and bonding theory to spectroscopic methods, and many more topics, with nothing of importance omitted. The book is traditional in that it contains a large amount of factual data on substances (melting and boiling points, color, toxicity, etc.), so that one no longer needs to reach for "Karrer" or another classical reference work when these data are needed in a hurry. Many of the old named reactions and historical and biographical details are also referred to. Extensive chapters are given to heterocyclic chemistry, neglected by many other textbooks, and the sections on natural products, with their treatments of the metabolism of carbohydrates, fats and proteins, extend into biochemistry.

Can all this be covered in only 893 pages? It has been helped mainly by the use of a closely spaced text, and by the frequent use of small type and tables. Nevertheless, the question is not so easily dismissed. Covering so many topics incurs risks of a degree of eclecticism, of the bare cataloguing of facts without discussing them, and of underestimating the difficulties faced by the beginner. Thus, for example, the Hückel theory is presented in a way which, though quite correct, is very compressed. I doubt whether the beginner can understand every step of this. In these sections, which come quite early in the book, there is a great risk of encouraging the reader to form habits of blind acceptance and mindless rote learning. Also the pages dealing with the statistical basis of chemistry (Maxwell-Boltzmann statistics, statistical mechanics, etc.) are in my view too much of a good thing—these topics are best left to textbooks on physical chemistry.

The author sometimes falls into the trap of "name-dropping". To mention just two examples, when he mentions spiroconjugation (p. 789) or trimethylsilyl enol ethers in synthesis (p. 551), each in just a single sentence, the reader has encountered a new word but not understood its meaning.

There are remarkably few typographical and factual errors; there is no need to detail them here, as most of them do not confuse the meaning. In future editions no doubt the two pentavalent carbon atoms on p. 501 will disappear. More important, though, is the need to address the book more clearly to an international readership, rather than referring to commercial products only by the names used in the GDR; readers here would prefer to see also names such as nylon, Perlon and aspirin!

On the whole, though, these shortcomings, which are mostly rather better described as aberrations, do not detract significantly from the quality of the book. *Hauptmann* has successfully written a textbook of the eighties which is suited to *our* needs. He is to be congratulated on this achievement, which is in no way diminished by the fact that the book is in many respects similar to the earlier organic chemistry textbook by *Hauptmann, Grafe,* and *Remane,* and owes quite a lot to it. This book, which represents amazingly good value at the price (DM 48.00!) deserves a very wide circulation, amongst students, to learn from it, and amongst lecturers, to teach—and test—from it.

Methods of Enzymatic Analysis. Volume 8. Metabolites 3: Lipids, Amino Acids, and Related Compounds. Edited by *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grassl.* VCH Verlagsgesellschaft Weinheim 1985. xxx, 629 pp., bound, Price per volume when ordering the complete work DM 285.00; single volumes DM 325.00.—ISBN 3-527-26048-X

Volume 8 is the third volume of the third edition to describe methods of analysis for specific metabolites. Its three chapters cover analyses for lipids, amino acids, and amino acid-related compounds, respectively.

The first chapter, which constitutes half of the volume, comprises six sections covering fatty acids and derivatives, phospholipids, apolipoproteins, cholesterol, steroid hormones, and bile acids. Generally, sections divide further into subsections, each of which discusses assay procedures for a single metabolite. Chapter 1 contains much more material than does the corresponding section of the second edition. It reflects the recent development of powerful enzyme immunoassay (EIA) techniques, especially in determinations of apolipoproteins and steroid hormones. Nicotinamide cofactor-linked assays for prostaglandins, 20-ketosteroids, and steroid alcohols are replaced by more specific EIA methods. Other methods that have been updated since the second edition are those for triglycerides, free fatty acids, D-(−)-3-hydroxybutyrate, acetoacetate, phosphatidylcholine, cholesterol, and bile acids. The discussion of cholesterol is expanded and includes methods for the specific determination of high-density lipoprotein and low-density lipoprotein cholesterol in addition to total cholesterol. The section on bile acids is likewise expanded to include methods specific for 3-α-hydroxy or 7-α-hydroxy bile acids as well as methods for total bile acids. The section on 7-α-hydroxy bile acids includes a description of a continuous-flow assay system using immobilized enzymes. Metabolites covered for the first time in the third edition are thromboxane B_2, succinylacetone, sorbic acid, sphingomyelin, glycerophosphorylcholine, phosphatidylcholine, and apo-lipoproteins.

Chapters 2 and 3 discuss methods of analysis for amino acids and amino acid-related compounds, respectively.

The chapters divide into sections, each of which covers procedures for a single compound or a few related compounds. Two-thirds of the assays of the second edition are repeated in Volume 8. The use of isotope dilution in the tRNA loading test for individual L-amino acids is not repeated, however. Assays revised in Volume 8 are those for branched-chain L-amino acids, L-phenylalanine and tyrosine, L-serine, L-lysine, D-amino acids, carbamoyl phosphate, carnitine and acylcarnitines, glutathione, spermine, and spermidine. Compounds addressed for the first time are 2,6-diaminopimelate, citrulline, octopine, arginine and arginine phosphate, histamine, catacholamines, secretonin, polyamines, *meso*-alanopine and D-strombine, and bilirubin. Volume 8 eliminates discussion of some compounds covered in the second edition—γ-aminobutyric acid, 3-hydroxykynurenine, and 3-hydroxyanthanilic acid—and does not include assays for tryptophan, methionine, threonine, cysteine/cystine, histidine, ornithine, or β-alanine.

As in previous volumes of the third edition, each section on a particular metabolite begins with the compound's structure. A general introduction discusses the occurrence, function, anabolism and catabolism of the compound in vivo, methods available for the compound's determination, substance properties relevant to analysis, applications of the analysis, and international reference standards and methods. The review of other methods of analysis provides a useful evaluation of their advantages and disadvantages. An explicit description of the assay procedure follows. This description includes discussion of the assay design, optimized conditions, equipment (both general and specialized), reagents (including preparation, purity required, and stability), preparation and stability of samples, and calculations. Each section concludes with information on the precision, accuracy, sensitivity, limits of detection, sources of error, and specificity of the method plus reference values for the levels of the metabolite in both normal and abnormal tissues and fluids. Appendices to the sections contain special procedures required for the assay, including the preparation of appropriate antibodies for EIA, isolation and immobilization of certain enzymes, preparation of tissues and other physiological samples, and the preparation of special electrodes.

Volume 8 is devoted to material given only 250 pages in the second edition. It contains more background and explanatory text than corresponding sections of the second edition. Each section contains ten to twenty references, including some as recent as 1983 and 1984. Several appendices provide definitions for common symbols, units, and abbreviations and list helpful constants and formulae. The format is quite convenient and amenable to use by workers unfamiliar with enzymatic analyses. The descriptions of procedures are highly detailed, cookbook-style, sometimes even providing sources of particular reagents. As in previous volumes, a drawback is an incomplete index.

This volume is not a comprehensive text, and is not as extensive in the number of assays contained as some of the previous volumes. Still, it contains assays for approximately seventy compounds, many of which are of great biological significance. The chapter on lipids has more than tripled since the second edition. This volume is recommended as a valuable reference work for those doing analyses of biological materials.

Instrumentelle Multielementanalyse. Edited by *B. Sansoni.* VCH Verlagsgesellschaft, Weinheim 1985. xviii, 782 pp., bound, DM 160.00.—ISBN 3-527-26255-3

"The analyst's dream of being able to determine in a single operation all the elements present in a sample appears to be coming close to a reality. Instrumental multi-element analysis allows one to determine up to eighty elements simultaneously." So runs the blurb given for the thick volume named above. The reader can learn to what extent that dream has been realized from this book, excellently produced and edited, which contains the 87 papers presented at a conference on the subject held at the KFA (Nuclear Research Center), Jülich, on April 2–5, 1984. Under the auspices of the eight groups which organized the meeting (A.M.S.El., Arbeitskreis Radioanalytik, AFR, VDEh, DPG Mass Spectrometry Group, GDCh, Deutsche Bunsengesellschaft, and the Geochemical Section of the German Mineralogical Society), the delegates reported on research progress and their experiences with the various multi-element techniques.

Following a detailed and critical introductory survey by the editor (including references to the most important works published up to 1984), the introduction continues with contributions on important trends and on practical problems from the standpoint of academic and industrial scientists. The first four chapters describe determination techniques, other procedures involved in analysis, applications, and comparisons of different techniques.

The following analytical methods are covered: nuclear radiation spectrometry (2 papers), activation analysis (13 papers), mass spectrometry (4 papers), ICP mass spectrometry (1 paper), X-ray fluorescence analysis (6 papers), atomic emission spectrometry (9 papers), forward scattering (2 papers), atomic fluorescence spectrometry (1 paper), atomic absorption spectrometry (1 paper), voltammetry (1 paper), and ion chromatography (1 paper). The chapter on "Other Analytical Procedures" contains excellent critical contributions on pre-concentration, standards, and data processing and evaluation, the latter being considered also from the standpoint of industrial practice. The chapter on "Applications" contains informative contributions from the fields of geoscience (10 papers), environmental studies (4 papers), materials science (1 paper), life sciences and food science (3 papers), radiochemistry and nuclear chemistry (4 papers), archeometry (3 papers), and simultaneous elemental analyses by ICP spectrometry as part of a research center's analytical service (1 paper). The book is rounded off by five papers which compare different techniques, including ICP and DCP atomic emission spectroscopies, AA spectroscopy, XRF spectroscopy, synchrotron radiation XRF, FMS, and neutron activation analysis, by a survey of instruments and manufacturers, and by a comprehensive list of abbreviations commonly used in instrumental analysis, and a good subject index.

The satisfaction of reading this book is increased by the fact that it gives a really up-to-date picture of the current state of elemental trace analysis. The organizers of the conference have succeeded in striking a good balance between the monotechnique specialists, who are usually unduly optimistic about "their" method, and the more pessimistically inclined application strategists. To the optimists the search for improvements in detection capability (often confused with limits of detection) appears to result in steady progress, even though one continues to seek to demonstrate also the accuracy of a particular method by analyzing a small number of selected standard materials. However, results which are entirely valid in the ppm range

are often extrapolated into the ppb region, and no mention is made of matrices to which the method cannot be applied, nor of analyses which have failed. Also it is usually not easy to make comparisons on the basis of purely instrumental detection capabilities obtained with "model analyses", since the time intervals for measuring and integration, the amounts of sample needed, or limitations imposed by varying amounts of interfering elements and/or blanks, are not given. The pessimists, on the other hand, point to the results of ring analytical trials for the ppb region, which continue to be disastrous, even when they come from highly respected laboratories engaged in certifying new standard reference materials. *E. Jackwerth* in his paper expresses this very well as follows: "Each type of sample material behaves differently with regard to trace analysis. It is for this reason that trace analysis procedures can hardly ever be carried over from one material to another without problems arising." This fact is borne out in many more of the contributions; it leads *R. Michel, G. V. Iyengar,* and *R. Zeisler,* in their contribution on multi-element analysis in life sciences, to conclude that much more analytical research remains to be done before reliable data can be produced.

Many of the papers clearly show that, particularly in the region of extremely low trace concentrations, the ability and experience of the analyst are much more crucial than the outlay on equipment. In this respect even an experienced analyst can learn from this book. It can be wholeheartedly recommended for everyone who is concerned with techniques for multi-element analysis.

Carbocation Chemistry. By *P. Vogel.* Elsevier Science Publishers, Amsterdam 1985. xiv, 596 pp., bound, HFl 350.00.—ISBN 0-444-42522-5

"Carbocations can be found everywhere, from interstellar space to your glass of wine", runs the beginning of this journey through chemistry, taking carbocations as its guideline. Seventeen years after the appearance of the first volume of the five-part work "Carbonium Ions" by *Olah* and *Schleyer,* we now have a new comprehensive treatment of the chemistry of carbocations.

The reader is taken straight from the anthocyanins present in red wine to free enthalpy diagrams, and is then given, in about fifty pages, a repetition of some of the fundamentals of physical chemistry. Only on page 61 do we arrive at the main theme, with a discussion on nomenclature and an account of gas-phase studies on carbocations. A systematic treatment of methods for generating carbocations in condensed phases is followed by a chapter on NMR spectroscopic studies in super-acidic solvent systems, with particular attention to the use of isotopic perturbation of degeneracy for distinguishing between situations where there is a single or a double potential minimum. The PMO method is discussed in detail, and used to explain substituent effect in carbocations. Solvent effects on equilibria and rate constants are dealt with, as too are the various mechanistic aspects of solvolysis reactions. In the chapter entitled "Rearrangements", the main topic discussed in detail is the behavior of small alkyl cations (C_3-C_6) in super-acidic media, while the studies using nucleophilic solvents, which are mostly early work, are mentioned only in passing. There is a detailed discussion of transition metal complexes of carbocations, with particular emphasis on the importance of carbocations as a link between organic and organometallic chemistry. The final chapter is devoted to the synthetic aspects of carbocations. In addition to the well-known aromatic electrophilic substitutions, the author discusses reactions with aliphatic compounds, carbocationic cyclization and cycloaddition reactions, and the use of transition metal cations. Thus, apart from polymerizations, all the important aspects of carbocation chemistry are covered.

The book offers a unique survey of the present state of this field of research. With an author index containing nearly 3000 entries, it might be described as the "March" of carbocation chemistry. As the examples chosen are mainly from recent papers, and a detailed subject index is also provided, it affords a convenient means of access to the relevant literature. The book, produced by a photoreproduction technique, is reasonably free from errors, and the structural formulas are clear.

The author has succeeded very well in arranging the material in an orderly fashion for easy assimilation, on the basis of a small number of theoretical principles. This is helped particularly by the many cross-references to analogies in other areas of chemistry. Although I very much like the didactic style of the book, I feel that the author, in trying to write a textbook of physical organic chemistry based on the example of carbocations, has taken things a little too far. Presumably, there will only be relatively few readers who will work through the book from beginning to end, since readers whose aim is to study basic principles will in any case use the conventional textbooks. It can only be hoped that the inexplicably high price will not deter even the libraries from buying it, so that it may be followed in a few years time by an extended second edition.

The Development of a Carbene-like Chemistry with Terminal Phosphinidene Complexes**

By François Mathey

When compared to the chemistry of other well-known electron-deficient species such as carbenes, silylenes, and nitrenes, the chemistry of phosphinidenes RP: is extremely underdeveloped. A critical survey of the literature indicates that this state of affairs probably reflects both an inadequate access to these species and an intrinsic lack of reactivity. Theoretical calculations suggest that it is possible to boost the electrophilicity and to stabilize the singlet state of phosphinidenes by complexation with transition-metal moieties such as $M(CO)_5$ (M = Cr, Mo, W). The corresponding terminal phosphinidene complexes [RP=$M(CO)_5$] show a rich and varied chemistry which often parallels the chemistry of singlet carbenes. Phosphinidene complexes are presently easily accessible through thermal decomposition of 7-phosphanorbornadiene complexes, but their stabilization remains a challenge to be met.

1. Introduction

In parallel with the broad development of the chemistry of carbenes, silylenes, and nitrenes,[1] there have been numerous attempts at developing a useful chemistry of the corresponding 6-electron phosphorus species, the so-called phosphinidenes R–P. The early work has been summarized in two interesting reviews by *Schmidt*[2] and *Regitz* et al.[3] In these early experiments, attempts were made to generate the phosphinidenes either by thermolysis of cyclopolyphosphanes, by reduction of dihalophosphanes, or by cycloreversion of phosphorus heterocycles. Tentative physicochemical proofs of the formation of phosphinidenes were provided only in the first case. Using this approach, *Schmidt* carried out the only systematic study of the chemistry of phosphinidenes so far reported. His most significant results are summarized in Scheme 1. Since then, some new phosphinidene precursors have been proposed,[3] but no significant extension of their chemistry has been unveiled.

In view of the poverty of phosphinidene chemistry, one question immediately arises: what is the reason for the apparent lack of reactivity of these species? The absence of reaction with olefins is especially noteworthy, since carbenes, silylenes, and nitrenes readily react with such compounds to give three-membered rings. A clear demonstration of this lack of reactivity was provided recently by *Diemert* et al.[5] Even when the favorable entropy factors associated with intramolecular reactions are exploited, it has not been possible to condense a phosphinidene with a C=C bond as shown in Equation (1) (THF = tetrahydrofuran). Three explanations for this lack of reactivity are conceivable:

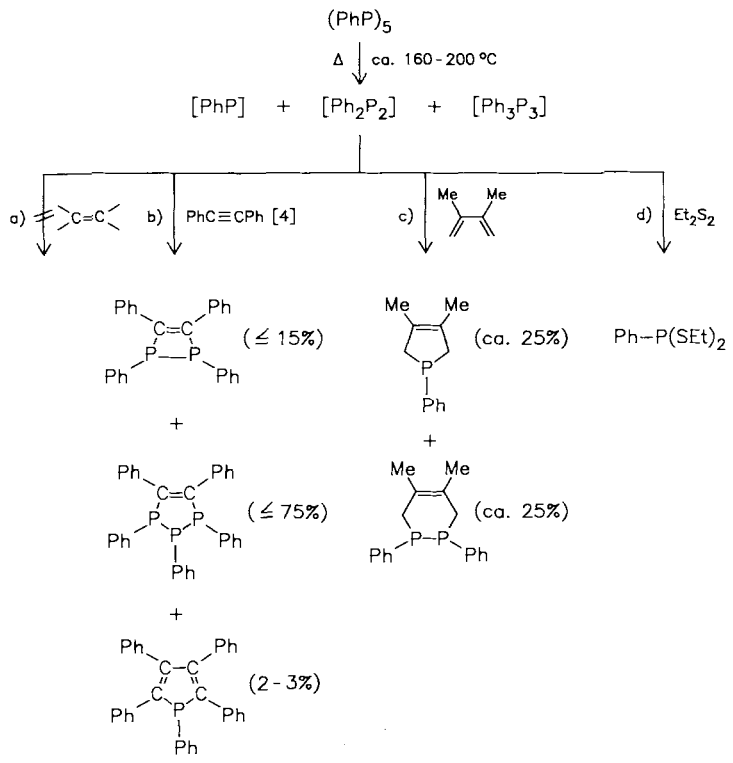
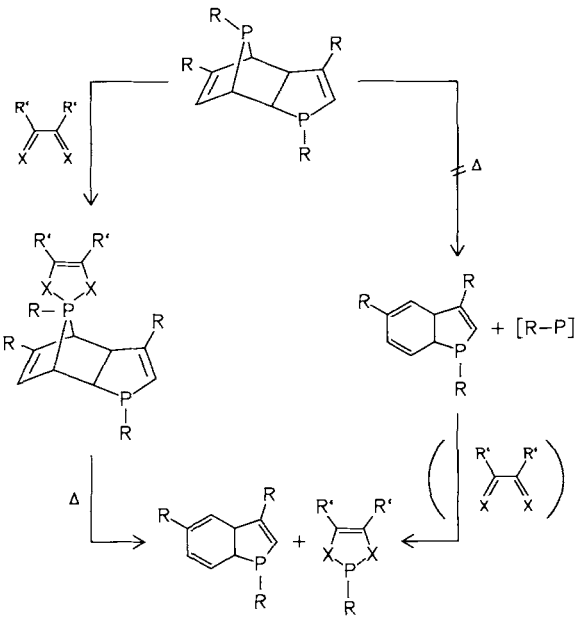
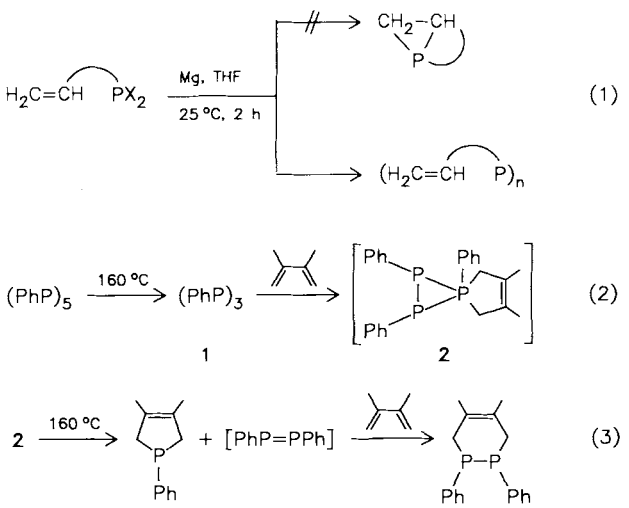


Scheme 1. Reactivity of monomeric and polymeric phosphinidenes.

1. Genuine phosphinidenes have not been generated by the various systems employed so far. For example, although the thermolysis of $(PhP)_5$ at around 400 °C has been demonstrated to produce phenylphosphinidene by mass spectrometric experiments,[2] most of the reactions of pentaphenylcyclopentaphosphane with organic substrates have been carried out at around 160–200 °C, and the products apparently arising from the trapping of phenylphosphinidene might have been formed through different mechanisms. A possible scheme for rationalizing the products obtained from the reaction with conjugated dienes (reaction (c) of Scheme 1) is depicted in Equations (2) and (3). The formation of the phosphorane **2** would be especially favored by the reduction in strain of the three-membered ring of **1** through incorporation into a trigonal-bipyramidal structure.[6] Another example is provided by the thermolysis of 7-phosphanorbornenes containing trivalent phosphorus, an approach initially proposed by *Fluck*[7] and *Quin* et al.[8] The suspected phosphinidene was trapped by conjugated dienes or heterodienes to give dihydrophospholes or dihydroheterophospholes, respectively. Very recently, however, *Quin* et al.[9] demonstrated that this type of reaction does not involve a free phosphinidene (Scheme 2).



Scheme 2. Mechanism of the reaction of 7-phosphanorbornenes with conjugated dienes [9].



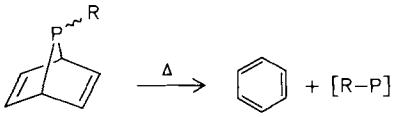
2. The phosphiranes formed according to Equation (1) are expected to exhibit low thermal stability,[10] except when substituted by bulky groups.[11] Thus, any method generating phosphinidenes at high temperatures cannot be used to perform [1+2] cheletropic cycloadditions with C=C bonds.

3. Phosphinidenes themselves might exhibit an intrinsic lack of reactivity. This point will be further discussed below, but the thermodynamic factor can already be stressed. Since P–C bonds are weaker than C–C, Si–C, or N–C bonds,[12] their tendency of formation will be lower. Thus, to say the least, the data concerning the reactivity of phosphinidenes were (and still are today) unsatisfactory and inconclusive. Accordingly, the development of new, reliable ways to generate phosphinidenes remains a logical objective since there is no definitive proof of the effectiveness of the already existing systems. In practice, such a new system must work at a reasonably low temperature (ca. 100 °C). Furthermore, since the ground state of phosphinidenes is a triplet,[13] it would be more interesting (and

hopefully more rewarding!) to generate the phosphinidenes in a singlet excited state in order to achieve higher and cleaner reactivity.

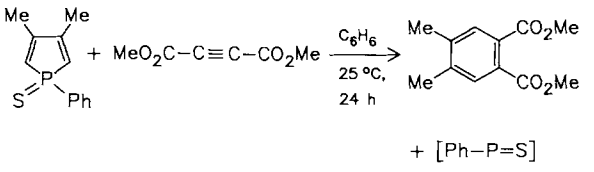
2. Synthesis and Properties of Stable 7-Phosphanorbornadiene Complexes

At the beginning of the 1980s, a quick glance through the literature on phosphinidenes showed that one of the most attractive ways to meet the conditions discussed in Section 1 had not been seriously investigated: namely, the use of 7-phosphanorbornadienes as phosphinidene precursors [Eq. (4)]. This approach offers several potential advantages. The aromaticity of the benzene ring formed could



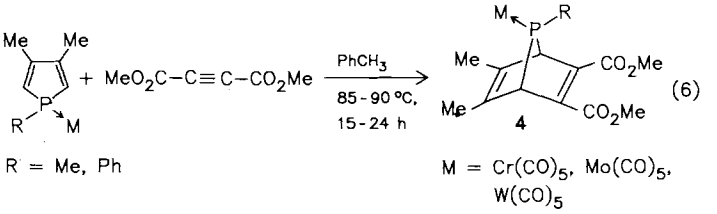
(4)

provide the driving force for a decomposition at low temperatures. Moreover, symmetry reasons suggested that the phosphinidenes thus generated would be singlets if the decomposition followed a concerted mechanism. In fact, similar reasons had previously led to the investigation of 7-silanorbornadienes as precursors of silylenes.[14] However, only two papers[15,17] concerning 7-phosphanorbornadienes are to be found in the early literature. The first report, by *Schmidt* et al.,[15] on the synthesis of a 7-phosphanorbornadiene *P*-oxide was in fact erroneous. Much later, Japanese chemists[16] established that the product of *Schmidt* et al. was a 7-phosphanorbornene and clearly demonstrated that genuine 7-phosphanorbornadiene *P*-oxides had a very low stability; spontaneous decomposition of such a structure was observed at room temperature. The second report, by *Stille* et al.,[17] described the successful synthesis of a benzo-annelated 7-phosphanorbornadiene *P*-oxide by reaction of benzyne with pentaphenylphosphole oxide, but the phosphorus bridge collapsed whenever the reduction of the P=O bond was attempted. A third report, by *Kashman* et al.,[18] again highlighted the low stability of the 7-phosphanorbornadiene structure [Eq. (5)].



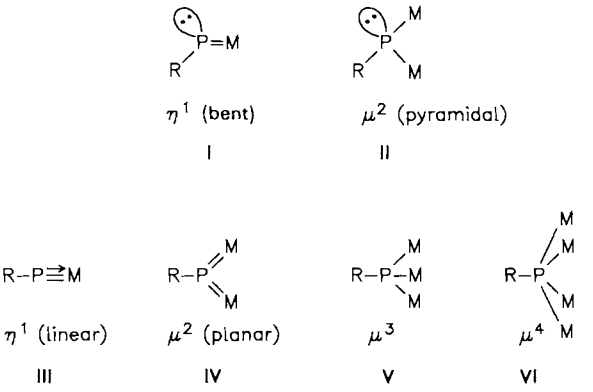
(5)

In spite of these failures, it was quite obvious that the only reasonable way to prepare 7-phosphanorbornadienes remained the [2+4] cycloadditions between electrophilic acetylenic dienophiles and phospholes. The choice of the technique used for masking the phosphorus lone pair, however, remained open. Such a protection is necessary in order to avoid side reactions at phosphorus.[19] Since 7-phosphanorbornadiene *P*-oxides and sulfides appeared unstable, the only practical alternative was to protect phosphorus by complexation. Thus, the reaction of various *P*-coordinated phosphole complexes with dimethyl acetylenedicarboxylate was investigated. It was thereby possible to obtain stable *P*-coordinated 7-phosphanorbornadiene complexes, **4**, with chromium, molybdenum, and tungsten pentacarbonyls as the complexing groups [Eq. (6)].[20]



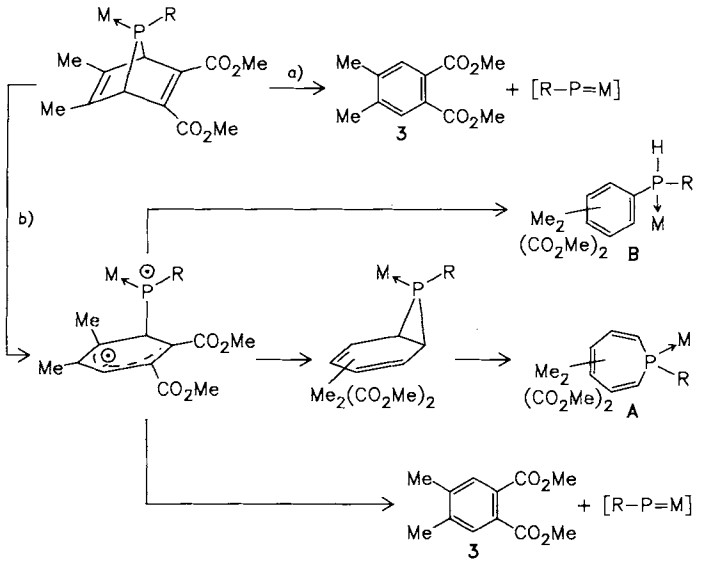
(6)

Other complexing groups such as $Fe(CO)_4$ or CuX are ineffective for the stabilization of the 7-phosphanorbornadiene skeleton. The synthesis of **4** also fails when bulky R groups (e.g., *t*Bu) are used or when the 3,4-dimethyl substitution is not present (fortunately, the corresponding phospholes are especially easy to pepare[21]). The instability of the bicyclic structure is so high that all attempts at decomplexing phosphorus were unsuccessful. Thus, only the chemistry of **4** itself could be studied directly. Mass spectral analysis suggested that **4** might be a convenient precursor of the still unknown terminal phosphinidene complexes [R–P=M] (M = complex fragment).[20] Of the six possible types of phosphinidene complexes (Scheme 3),



Scheme 3. The various types of phosphinidene complexes. **I** and **II**: phosphinidenes as 2-electron donors; **III**–**VI**: phosphinidenes as 4-electron donors.

the terminal complexes **I** were a priori the most interesting ones as far as phosphorus chemistry was concerned, since the lone pair at phosphorus and the low coordination state of phosphorus are favorable features for a high reactivity. Thus, the thermolysis of **4** was carefully investigated. A kinetic study of the decomposition of **4** with R = Ph, $M = W(CO)_5$[22] in the presence of various trapping reagents clearly demonstrated that the reaction is first order in the concentration of **4** and does not depend on either the nature or the concentration of the trapping reagent. The decomposition starts above 100°C and the activation energy of the rate-determining step is 33 ± 1 kcal mol^{-1}. By analogy with the processes occurring during the thermolysis of norbornadienes,[23] the first-order kinetics can be ra-



Scheme 4. Possible pathways for the decomposition of 7-phosphanorbornadiene complexes. The postulated intermediates [R–P=M] react with trapping reagents to give the products.

tionalized by the two decomposition paths outlined in Scheme 4 if it is assumed that steps a and b are rate-determining. However, the formation of the phosphepine complex **A** and the secondary arylphosphane complex **B**, which are the expected side products of path b, was never observed. In all cases, the only isolated by-product was the phthalate **3**. Thus, path a remains as the most likely alternative. Before leaving the subject, it must be noted that it is possible to catalyze the decomposition of 7-phosphanorbornadiene complexes by the use of heavy-metal derivatives such as $Cu^{\oplus}$, $Ag^{\oplus}$, and $Pd^{2\oplus}$ salts.[24] The mechanism of this catalysis is unknown. Photochemical decomposition leads to entirely different products including several new polycyclic structures, which, however, are of no interest as far as phosphinidene chemistry is concerned.[25]

3. Chemistry of Terminal Phosphinidene Complexes

Three theoretical studies of terminal phosphinidene complexes have been reported.[26,27,59] In the first study,[26] $Fe(CO)_3$ was found to be the best possible complexing group for stabilizing phosphinidenes in complexes such as $[RP \rightleftarrows Fe(CO)_3]$.[26] Since the phosphinidene here acts as a 4-electron donor (no lone pair at phosphorus), the chemistry of such complexes (type **III**, Scheme 3) has nothing to do with the chemistry discussed in this article. The second study[27] compared the electronic properties of H–P and [H–P=Cr(CO)$_5$]. The structure of the complex was first optimized using extended Hückel (EH) calculations. This led to a P=Cr bond length of 1.90 Å (vs. 2.3–2.4 Å for the bond in R_3P–Cr(CO)$_5$), which indicates a strong double bond character. The phosphorus atom appeared to be sp^2-hybridized with an H–P–Cr bond angle of 125°. Using this optimized geometry, more precise PS HONDO ab initio calculations then predicted a singlet ground state with a singlet–triplet separation of 12 kcal mol^{-1}, a high localization of both the HOMO and the LUMO at phosphorus, and a net charge of +0.41 e at this atom. Since the ground state of H–P is a triplet with a net charge at phosphorus of −0.05 e, the complexation appeared to stabilize the singlet state and to boost the electrophilicity of the phosphinidene. On the basis of these results, some similarities were expected between terminal phosphinidene complexes and phosphenium ions, $R_2P^{\oplus}$, which also exhibit a high electrophilicity and have singlet ground states.[28] Such similarities have indeed been observed in some cases. The last study[59] compared the electronic properties of [H–P=Cr(CO)$_5$] and [H–P=Ni(CO)$_3$]. As expected, the phosphorus atom appeared to be far less electrophilic in the Ni(CO)$_3$ than in the Cr(CO)$_5$ complex. The results concerning [H–P=Cr(CO)$_5$], however, were different from those of the preceding study.[27] The geometry optimization led to an H–P–Cr bond angle of 110° and to a P–Cr bond length of 2.33 Å which implies a single bond character. The ground state was found to remain a triplet and the LUMO to be very low-lying with a high localization at phosphorus. In view of the discrepancies between these last two studies, there is a clear need for additional theoretical work on terminal phosphinidene complexes. A careful optimization of the geometry seems to be a prerequisite for obtaining reliable results concerning the electronic structure of these species.

Using complexes **4** as precursors, the reactions of terminal phosphinidene complexes with substrates containing O–H and N–H bonds, such as water, ammonia, alcohols, and primary and secondary amines, were first investigated. In all cases, an almost quantitative insertion into the O–H or N–H bonds was observed [Eq. (7)].[29] The huge stabiliz-

$$[R\text{–}P{\equiv}M] + A\text{–}H \xrightarrow[\text{or } 55\,^{\circ}C,\ CuCl]{110\text{–}150\,^{\circ}C} R\text{–}\underset{\displaystyle A}{\overset{\displaystyle H}{\underset{|}{\overset{|}{P}}}}\!\rightarrow M \qquad (7)$$

5

A = OH, NH_2, OR', NHR', NR'_2; M = Cr(CO)$_5$, W(CO)$_5$
R = Me, Ph; R' = Me, Et, Ph

ing effect exerted by the complexing groups upon the RP(H)A ligands is noteworthy. When free, such species are normally unstable except if bulky R or A groups are used.[30] Such a stabilizing effect of the complexation had already been noted by *Huttner* et al. with M = CpMn(CO)$_2$.[31]

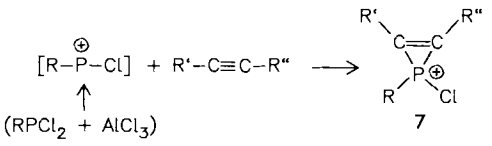
Interesting results were also obtained with alkynes. Terminal phosphinidene complexes readily react with the C≡C bond to give the phosphirene ring of **6** [Eq. (8)].[32,33,43] This reaction allowed the first unambiguous characterization of this heterocycle. A large variety of al-

$$[R\text{–}P{\equiv}M] + R'\text{–}C{\equiv}C\text{–}R'' \longrightarrow \underset{\displaystyle R}{\overset{\displaystyle R'}{\underset{|}{\overset{|}{C}}}}{=}\underset{\displaystyle M}{\overset{\displaystyle R''}{\underset{|}{\overset{|}{C}}}}\!\!-\!P \qquad (8)$$

6

R = Me, Ph; R', R'' = H, Me, Et, Ph, CO_2Et;
M = Cr(CO)$_5$, Mo(CO)$_5$, W(CO)$_5$

kynes have been used including some electron-poor species such as phenylpropiolates. However, probably owing to their high electrophilicity, terminal phosphinidene complexes are unable to react with acetylenedicarboxylates. Subsequent to these initial investigations, *Hogeveen* et al. demonstrated that chlorophosphenium ions are also able to react with alkynes [Eq. (9)],[34] giving the phosphirenium

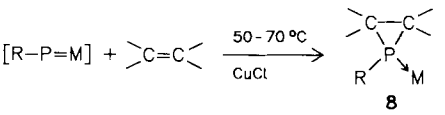


(9)

R = Me, Ph; R', R'' = H, Me

ions **7**. A similar reaction with isolated, stable phosphenium ions was subsequently mentioned by *Cowley* et al.[28] Thus, there is here a clear parallel between the reactivities of terminal phosphinidene complexes and phosphenium ions. However, **7** is only marginally stable at room temperature whereas **6** is almost incredibly stable (when $R = R' = R'' = Ph$ and $M = W(CO)_5$, **6** can be heated at 150°C for 15 h without any noticeable decomposition). This stability is quite striking, because the internal C-P-C bond angle of phosphirenes is around 41–42°, which is by far the lowest value reported for a C-P-C angle in organophosphorus chemistry. The tremendous stabilizing power of $Cr(CO)_5$, $Mo(CO)_5$, and $W(CO)_5$ complexing groups upon tervalent phosphorus derivatives is thus once again highlighted.

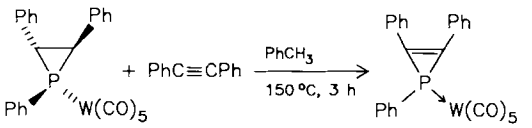
Terminal phosphinidene complexes readily react with olefins to give phosphirane complexes **8** [Eq. (10)].[24]



(10)

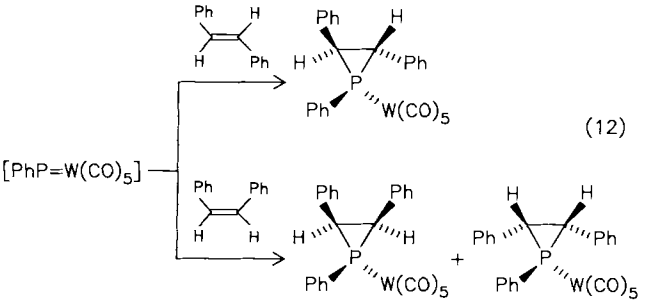
R = Me, Ph; M = $Cr(CO)_5$, $W(CO)_5$

Complexes **8** are somewhat less stable than complexes **6** and their interconversion is possible in some cases [Eq. (11)].



(11)

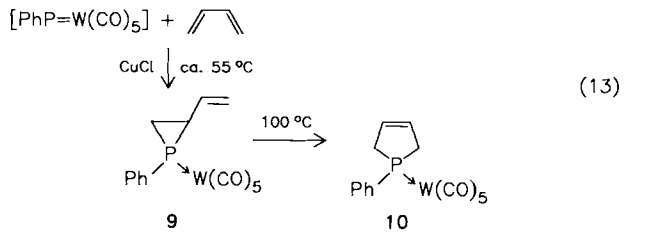
The condensation of terminal phosphinidene complexes onto olefins represents the first successful synthesis of the three-membered phosphirane ring through cycloaddition of a phosphorus unit with an olefin. It parallels the syntheses of cyclopropanes, siliranes, and aziridines from olefins and carbenes, silylenes, and nitrenes, respectively. It is interesting to note here that the condensation of phosphenium ions onto olefins never leads to stable phosphiranium ions. Experiments conducted with *cis*- and *trans*-stilbenes show that the condensation of terminal phosphinidene complexes takes place with retention of the olefin stereochemistry [Eq. (12)]. This suggests that the reaction is a



(12)

genuine concerted cheletropic cycloaddition of a singlet terminal phosphinidene complex with a C=C bond, in exact analogy to the reaction between singlet carbenes and olefins. Moreover, experimental data clearly indicate that terminal phosphinidene complexes react better with electron-rich than with electron-poor olefins. Thus, it seems clear that the cycloaddition P+C=C is inter alia governed by the electrophilicity of phosphorus. This observation in turn suggests that the lack of reactivity of free phosphinidenes toward olefins may partly reflect their lack of electrophilicity.

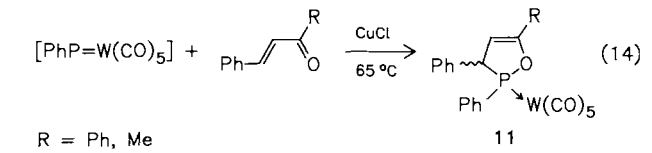
The reaction of terminal phosphinidene complexes with conjugated dienes again underlines their similarity with singlet carbenes. The formation of vinylphosphirane complexes **9**[24] indeed parallels the formation of vinylcyclopropanes from dienes and singlet carbenes. Upon heating, **9** rapidly rearranges to give the corresponding dihydrophosphole complex **10** [Eq. (13)]. *Richter*[35] has observed a



(13)

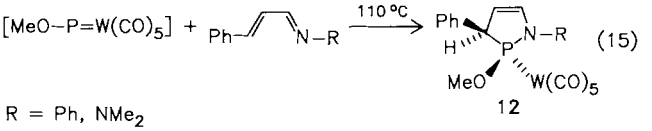
similar rearrangement of free 2-vinylphosphiranes. According to the Woodward–Hoffmann rules, such a formal [1,3] sigmatropic shift is thermally forbidden, and *Richter* has indeed found that it takes place much more readily upon UV irradiation (25°C) than upon heating (150°C). He has rationalized the results of a kinetic study[36] by a radical mechanism involving the homolytic cleavage of the P–C(vinyl) bond of the phosphirane ring. He has also found that the rearrangement of the free phosphiranes is efficiently catalyzed by transition-metal complexes such as $[Ni(cod)_2]$, $[NiCp_2]$, and $[Pd(allyl)_2]$ (cod = 1,5-cyclooctadiene, $Cp = \eta^5$-cyclopentadienyl).[35] This last result is consistent with Equation (13), which indicates that **9** is more prone to undergo such a transformation. Finally, it is interesting to note here that, contrary to terminal phosphinidene complexes, phosphenium ions seem to give directly the 1,4 adducts with conjugated dienes.[28]

The reactions of terminal phosphinidene complexes with some conjugated heterodienes such as α-enones[24]



R = Ph, Me

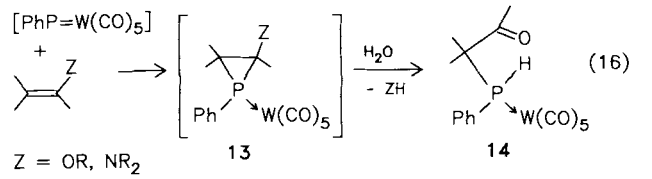
11



R = Ph, NMe_2

12

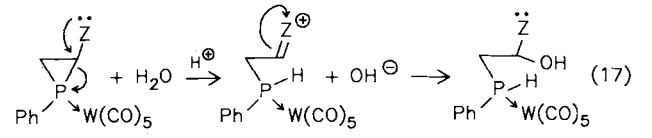
and 1-azadienes[37] were also investigated [Eq. (14) and (15)]. In these cases, the 1,4 adducts **11** and **12** are obtained, but this does not exclude the preliminary formation of the 1,2 adducts with the C=C bonds followed by a rapid [1,2]→[1,4] rearrangement, facilitated by the creation of a strong P-O bond in the case of **11**. In the case of **12**, a good steric control was observed during the cycloaddition, which selectively leads to the less hindered isomer.



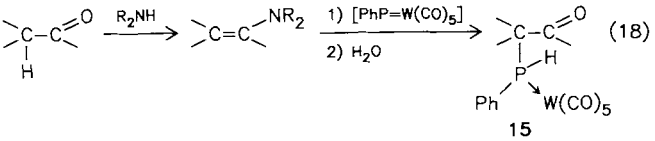
Z = OR, NR_2

13 14

The reaction of terminal phosphinidene complexes with electron-rich olefins such as enol ethers[24] or enamines[38] results in the transient formation of the expected phosphirane complexes **13**, which, however, react very rapidly with water to give functionalized secondary phosphane complexes [Eq. (16)]. The lability of the P-C(Z) bond of **13**

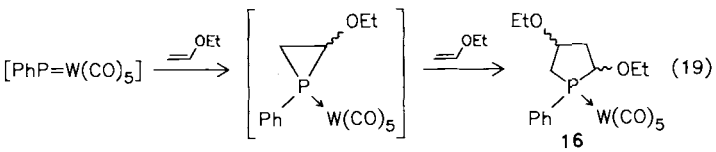


can be related to its polarization. Indeed, theoretical studies have shown that the intracyclic P-C bonds of the phosphirane ring have pronounced π character.[39] As such, they can interact with lone-pair substituents like alkoxy or amino groups in the same way as olefinic π bonds. The normally apolar P-C bonds thus acquire some polarity and become able to react with water [Eq. (17)]. The stability of



15

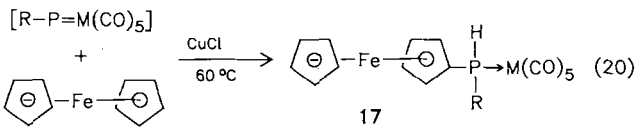
14 once again illustrates the protection provided to the P-H bonds by the $W(CO)_5$ complexing group. Using this kind of chemistry, it becomes possible to selectively insert a phosphinidene unit into a carbonyl-activated C-H bond [formation of **15**, Eq. (18)].[38] Finally, the insertion of an activated olefin into the P-C(Z) bond of an activated phosphirane was also observed in one instance [formation of **16**, Eq. (19)].[24]



16

The net overall result is a formal carbon-carbon coupling between two molecules of enol ether taking place in the "coordination sphere" of phosphorus.

As mentioned earlier, theoretical calculations[27] indicate that terminal phosphinidene complexes are highly electrophilic species. Therefore, electrophilic insertion of the phosphinidene phosphorus into the C-H bonds of some electron-rich aromatic rings appeared to be a possible reaction. Such an insertion was indeed observed in the case of ferrocene [Eq. (20)].[40] Curiously, the reaction does

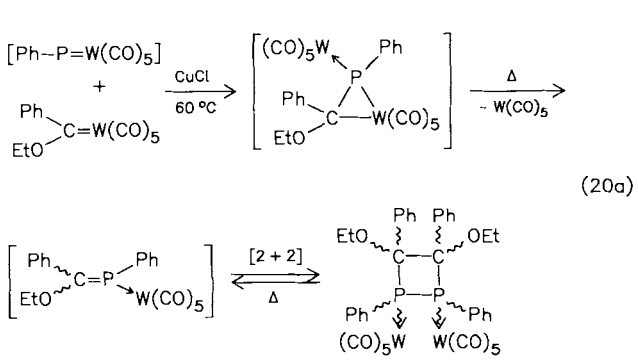


M = Mo, W; R = Me, Ph

17

not work at all in the case of M = Cr, but it is not known at present whether this failure reflects a lack of stability of **17** (M = Cr) or a lack of electrophilicity of the phosphinidene complexes with Cr. Nonetheless, the compounds **17** are particularly interesting since they represent the first known derivatives of this type of secondary phosphane and can serve as a starting material for the synthesis of a wide variety of tertiary ferrocenylphosphanes through metalation of the P-H bond and subsequent reactions.

Rather surprisingly, as shown in Equation (20a), a terminal phosphinidene complex is able to react with an electrophilic Fischer carbene complex to give probably an intermediate σ,π ditungsten complex, which spontaneously loses one metal fragment and then dimerizes to finally yield a single unsymmetrical isomer of a 1,2-diphosphetane. This dimerization is thermally reversible so that it is possible to carry out [4+2] cycloadditions with phosphaalkenes generated only as intermediates. This phosphinidene-carbene coupling offers numerous opportunities for further investigation.



(20a)

It seems appropriate to close this section by some observations concerning the formation of terminal phosphinidene complexes in the absence of trapping reagents. When generated at low temperature, [PhP=W(CO)$_5$] mainly gives the dimer **18** [Eq. (21)].[22]

Complex **18** has also been made by *Huttner* et al.[41] via a different route, which perhaps also involves a transient terminal phosphinidene complex [see Section 6, Eq. (52)]. The formation of **18** means that at least two different decomposition processes of [PhP=W(CO)$_5$] simultaneously take place, the carbene-like dimerization and the cleavage of the P=W bond releasing the third W(CO)$_5$ unit which complexes the P=P bond to give **18**.

4. Synthetic Equivalency of Free Phosphinidenes and Their Terminal Complexes

From the standpoint of the organophosphorus chemist, the usefulness of terminal phosphinidene complexes is limited since all their chemistry takes place in the coordination sphere of a metal. A prerequisite for exploiting the full potential of these species is a mild technique for decomplexation of the phosphinidene ligand. If such a technique is devised, then terminal phosphinidene complexes become the synthetic equivalents of reactive free phosphinidenes with enhanced electrophilicity. Since the best activating group of phosphinidene appears to be pentacarbonyltungsten, the problem was to find a method for converting a phosphane complex, $R_3P\rightarrow W(CO)_5$, into the corresponding free phosphane or phosphane oxide. It is possible to achieve such a decomplexation in two steps [Eq. (22)]. In the first step, the P–W bond is weakened by selective oxidation of tungsten. Then, the phosphorus ligand is displaced from the tungsten(II) complex by a "hard" ligand such as *N*-methylimidazole or 2,2'-bipyridyl. The

$$R_3P\rightarrow W(CO)_5 \xrightarrow[-\,CO]{X_2} R_3P\rightarrow W(CO)_4X_2 \xrightarrow{R'_3N} R_3P \qquad (22)$$

X = Br, I

use of this method is exemplified by the synthesis of the first known tervalent phosphirene, **19**,[42] and by the synthesis of the first known 2-oxo-1,2-dihydrophosphete *P*-oxide, **20**[43] [Eq. (23) and (24)]. Compound **20** probably results from the bromination of the corresponding free phosphane followed by the hydrolysis of the resulting R_3PBr_2 species. The transition metal ends up in the form of insoluble $[(R_3N)_mW(CO)_nX_p]$ complexes, which have not been characterized. Other unpublished experiments conclusively demonstrate that the applicability of this technique is rather wide.

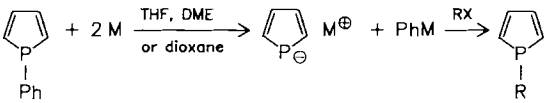
5. Chemistry of Phosphinidene Complexes with Functional Groups

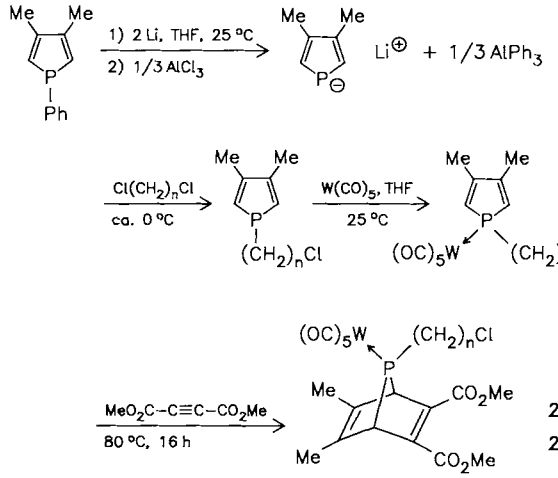
All the chemistry so far described was developed with phenyl- and methylphosphinidene complexes. The extension of these reactions to phosphinidenes bearing functional or heteroatomic groups was necessary in order to expand the synthetic usefulness of terminal phosphinidene complexes in organophosphorus chemistry, to eventually observe novel rearrangements or self-condensations of these new phosphinidenes within the coordination spheres of the complexing metals, and to study the influence of the nature of the substituent on the reactivity of phosphinidenes toward external reagents. For that purpose, the approach via phospholes and 7-phosphanorbornadienes was especially well adapted, since one of the most useful chemical properties of the phosphole ring is the selective cleavage of the external P–C bond of 1-phenylphospholes by alkali metals [Eq. (25), DME = dimethoxyethane].[44]

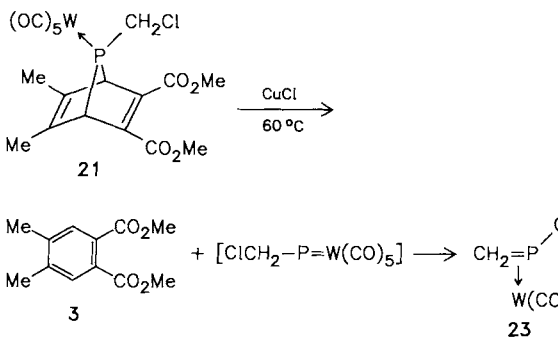


(25)

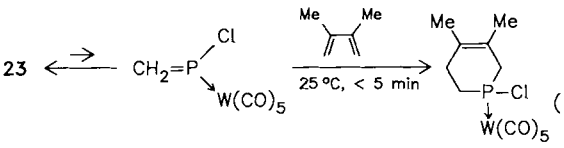
M = Li, Na, K

Using this kind of chemistry, it is possible to replace the phenyl substituent by almost any type of R group. As a first application of this strategy, the chemistry of ω-chloroalkylphosphinidene complexes was investigated. The necessary 7-phosphanorbornadiene complexes were prepared according to Equation (26) in ca. 20% (**21**) and 40% (**22**) overall yield.[45,46] (β-Chloroethylphosphinidene)pentacarbonyltungsten as generated from **22** using the standard conditions has a normal chemistry. On the contrary, when generated in the presence of CuCl, (chloromethylphosphinidene)pentacarbonyltungsten undergoes a very interesting rearrangement to **23** through migration of chlorine from carbon to phosphorus [Eq. (27)].[45] According to preliminary experiments, the presence of CuCl seems to be necessary for the migration of chlorine, but the precise mechanism of this migration remains unknown at the moment. The π-complex **23** is stable up to +65 °C, whereas

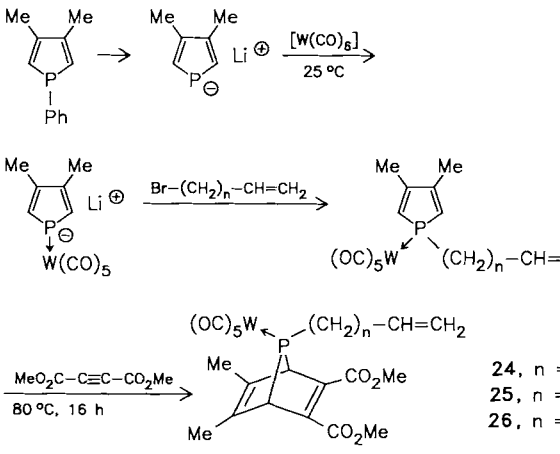




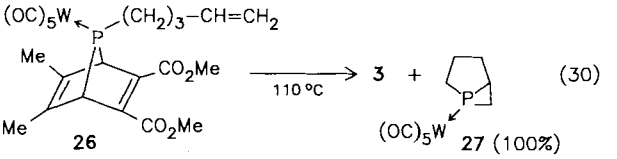
the free phosphane is stable only at low temperatures. The shift of $W(CO)_5$ from phosphorus to the P=C bond is reversible,[47] so that [2+4] cycloadditions with conjugated dienes readily take place [Eq. (28)]. A preliminary study of



terminal phosphinidene complexes incorporating a C=C bond was also performed. The necessary 7-phosphanorbornadiene complexes were prepared according to Equation (29) in ca. 56% (**24**), 53% (**25**), and 47% (**26**) overall

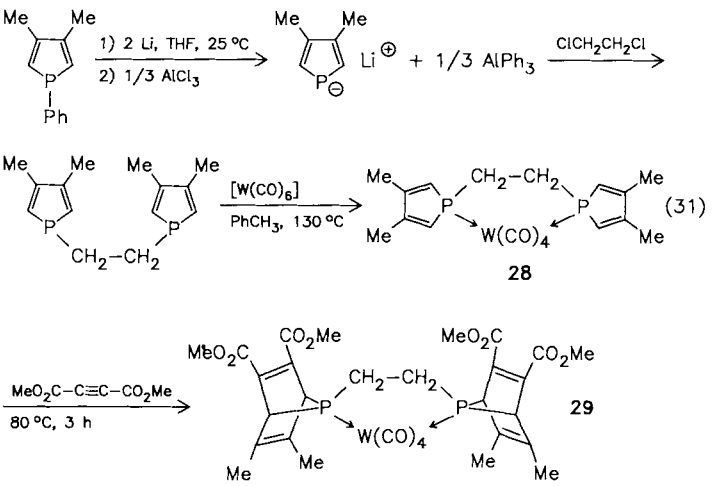


yield.[48] The chemistry of the allyl- and 3-butenylphosphinidene complexes obtained from **24** and **25**, respectively, shows no special features. On the contrary, (4-pentenylphosphinidene)pentacarbonyltungsten undergoes a self-condensation to give **27**; the reaction is so fast that it is practically impossible to trap the phosphinidene with external reagents [Eq. (30)]. The bicyclic structure of **27** is



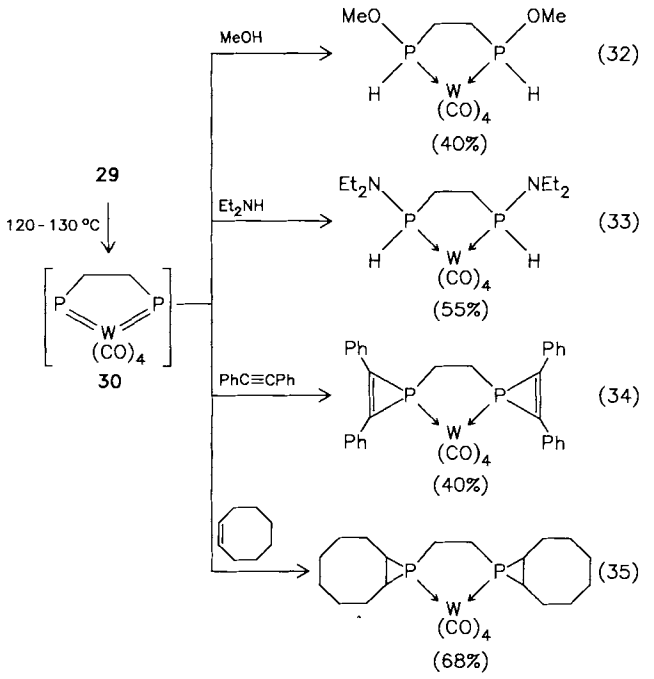
novel. The corresponding free phosphane has recently been obtained by decomplexation of **27** according to Equation (22).[61] This phosphane is especially interesting for the coordination chemist since it has probably the smallest Tolman cone angle so far found.

Finally, a preliminary study of the first chelating bisphosphinidene complex, **30**, was also very recently carried out.[49] The required 7-phosphanorbornadiene complex **29** was prepared as depicted in Equation (31). In **28**, one side

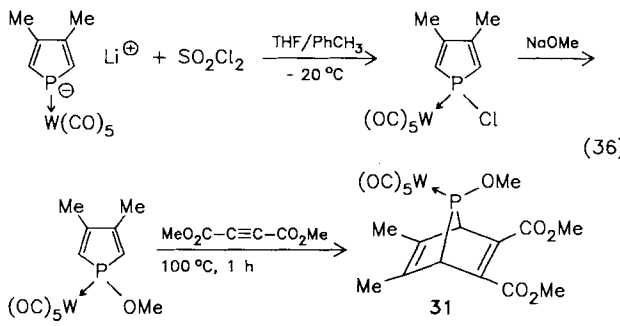


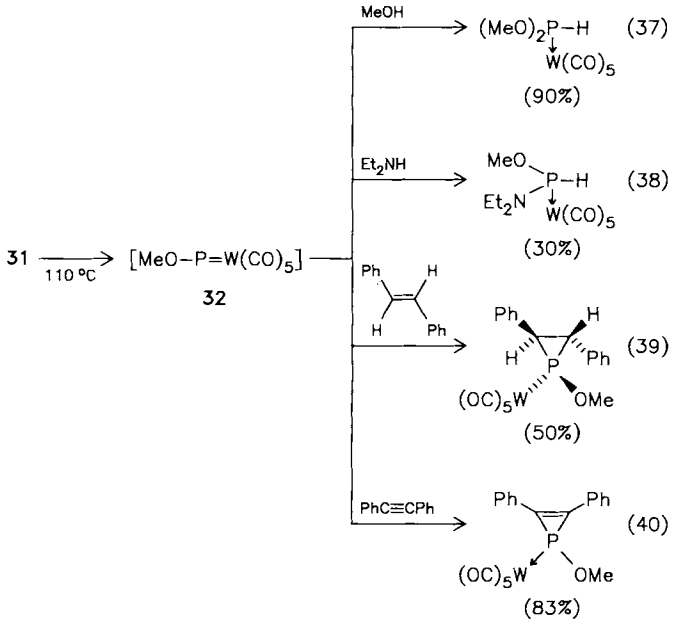
of both dienic systems is well exposed to external attack. Thus, the reaction with acetylenedicarboxylate takes place faster than usual and gives a good yield of **29**. This complex is an efficient generator of **30** as shown in Equations (32)–(35).

All the terminal phosphinidene complexes so far studied incorporate a P–C bond. In the chemistry of carbene complexes, it is well known that alkoxy substituents significantly modify the electrophilicity of the carbenic carbon.[50] For that reason and for expanding once again the applicability of terminal phosphinidene complexes in organophosphorus chemistry, it was interesting to devise an access to alkoxyphosphinidene complexes. The problem was not a trivial one since both 1-halo- and 1-alkoxy-3,4-dimethylphospholes are unknown. The synthesis of the necessary 7-alkoxy-7-phosphanorbornadiene complexes **31** was finally achieved in ca. 25% overall yield via the

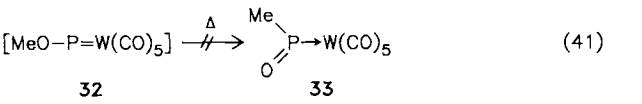


route outlined in Equation (36).[37] Preliminary experiments indicated that the phosphinidene complex **32**, generated from **31**, exhibits completely normal chemical behavior [Eq. (37)-(40)]. In particular, when no trapping reagent is present no rearrangement to give **33** is observed



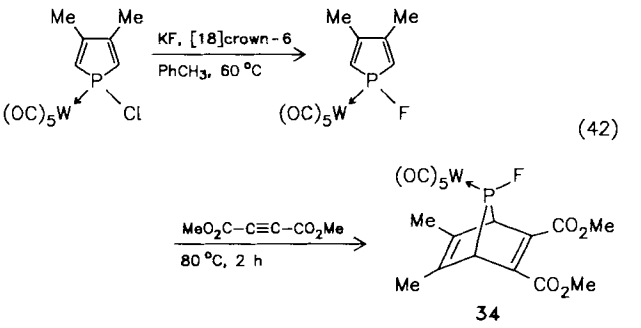


[Eq. (41)], even though similar complexed species are known.[51] In fact, **32** decomposes to give a complicated



mixture of products from which it has been impossible to isolate a dimer similar to **18**. Additional experiments with azadienes [Section 3, Eq. (15)], however, suggested that **32** has a higher electrophilicity and reactivity than its phenyl-substituted analogue.

In the course of the same study,[37] the generation of [F-P=W(CO)$_5$] was attempted, but it appeared that complex **34**, obtained according to Equation (42), is stable up to 160°C.



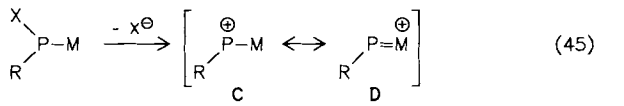
6. Other Routes to Terminal Phosphinidene Complexes and Prospects

As far as organophosphorus chemistry is concerned, the route to terminal phosphinidene complexes via phospholes and 7-phosphanorbornadienes is very satisfactory. The precursor (1-phenyl-3,4-dimethylphosphole) can be made on a large scale[21] (it has been possible to perform its synthesis on a 30-kg scale) and is very easy to handle (low sensitivity to air and low toxicity). Moreover, a large variety of substituents on phosphorus is possible, and the end products can be easily liberated from the corresponding complexes. The most obvious problem that remains to be solved concerns the synthesis of stable terminal phosphinidene complexes. In order to achieve this goal, it is probably necessary to meet two conditions: (1) steric protection of phosphorus by a bulky substituent; (2) the use of a complexing group that imparts less positive charge to phosphorus than either Cr(CO)$_5$, Mo(CO)$_5$, or W(CO)$_5$. Some variations of the complexing group are possible in the phosphole approach. However, the use of bulky substituents at phosphorus is forbidden because such groups block the Diels-Alder cycloaddition which leads to the 7-phosphanorbornadiene skeleton. Thus, it is necessary to devise other routes to terminal phosphinidene complexes. Several such routes have been proposed. The possible intermediacy of a terminal phosphinidene complex was first mentioned by *Huttner* et al.[31] in the chlorination of [CpMn(CO)$_2$(PhPH$_2$)] and [CpMn(CO)$_2$(PhPLi$_2$)] [Eq. (43) and (44)]. However, other mechanisms, which do not imply the intermediacy of [Cp(CO)$_2$Mn=PPh], can explain the

(43)

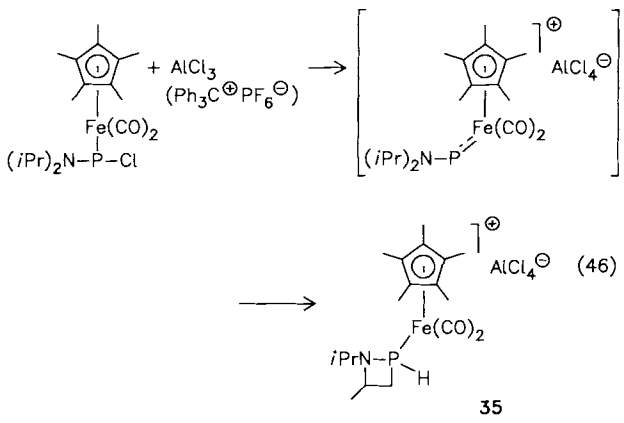
(44)

formation of the observed products. Much more recently, various other approaches have been suggested. One such approach involves the abstraction of a halide ion from a terminal halophosphido complex [Eq. (45)]. The species

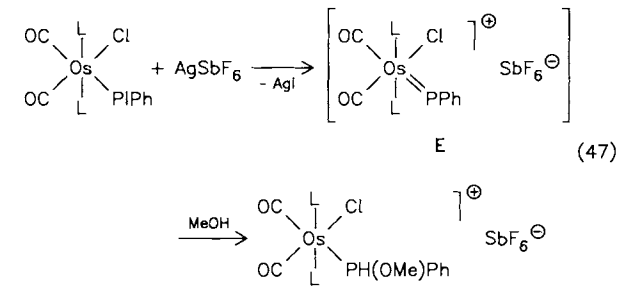


(45)

thus obtained can be viewed either as metallophosphenium cations **C** or as cationic terminal phosphinidene complexes **D**. Their electrophilicity is necessarily very high and it is not surprising to find that this approach has failed to give stable species [Eq. (46)[52] and (47)[53]]. In the



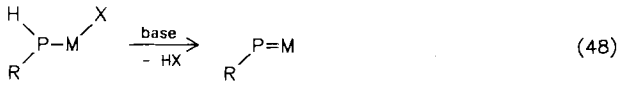
(46)



(47)

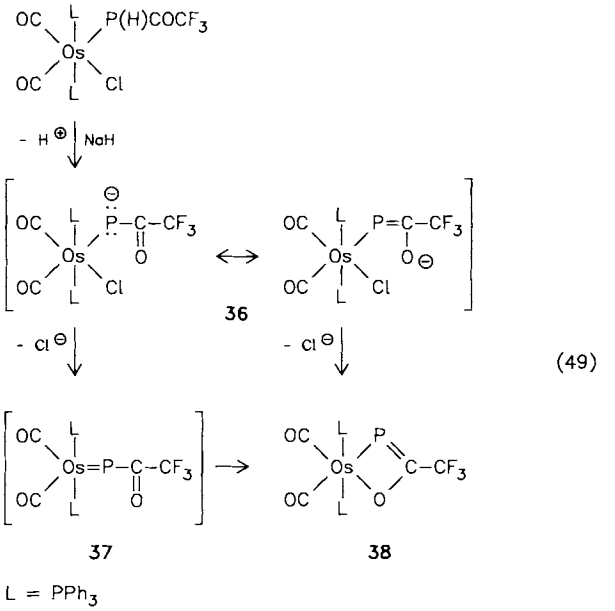
case of **35**, a novel insertion of the phosphinidene phosphorus into one of the C–H bonds of the diisopropylamino group was observed. On the other hand, attempts to trap the osmium-phosphinidene complex **E** [Eq. (47)] with alkynes and olefins failed to give tractable products.[62] Rather than reflecting the large cone angles of the expected phosphirene and phosphirane ligands,[62] this failure might be due to the reduced electrophilicity of the osmium-phosphinidene complex **E** compared with its Cr, Mo, and W analogues.

Another approach, described by *Roper* et al.,[54] relied upon an H–X elimination as shown in Equation (48).



(48)

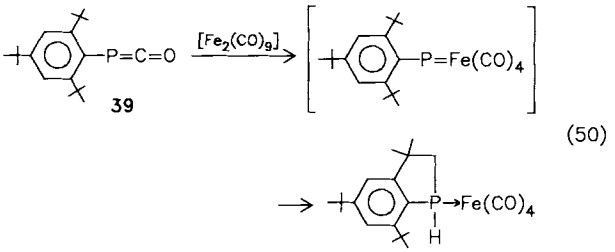
However, this elimination was only carried out in a special case, which does not necessarily involve a transient terminal phosphinidene complex such as **37** [Eq. (49)]. Indeed,



(49)

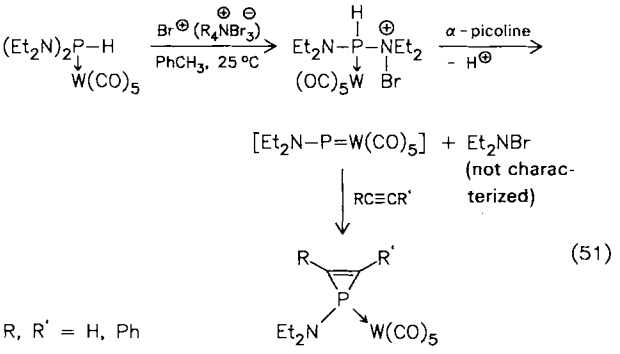
acylphosphido anions similar to **36** are known to have their negative charge partly localized at oxygen.[55] The end-product **38** was fully characterized by X-ray crystal structure analysis.

A terminal phosphinidene complex was also proposed by *Cowley* et al. as an intermediate in the reaction of phosphaketene **39** with $[Fe_2(CO)_9]$ [Eq. (50)].[56] This last result suggests that steric hindrance alone is not sufficient to stabilize terminal phosphinidene complexes.



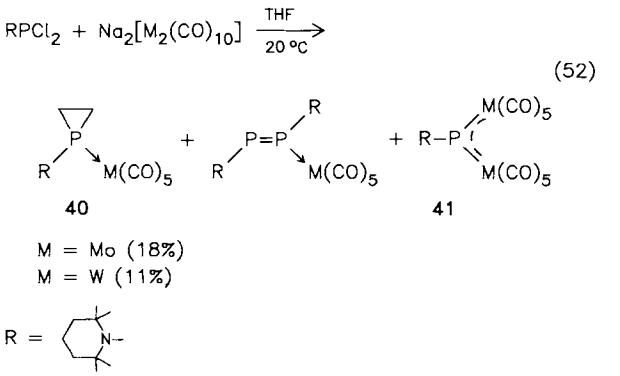
(50)

The search for new syntheses of the phosphirene ring has also led to the discovery of what could be a new route to terminal aminophosphinidene complexes [Eq. (51)].[57] Of course, as in the other examples described here, the intermediacy of the phosphinidene complex is only postulated and not fully proven. Since the attack of bromine can take place either at the P–H bond, at the $W(CO)_5$ complexing group, or at the lone pair on nitrogen, this approach has a limited generality. Replacing one of the dialkylamino



groups by an aryl or alkyl group already suffices to divert the selective attack of bromine at nitrogen. Besides, it seems difficult to generalize this approach to other complexing groups.

Finally, *Huttner* et al.[58] have very recently provided some convincing evidence in favor of the intermediacy of terminal phosphinidene complexes in the reaction of RPX_2 with $Na_2[M_2(CO)_{10}]$ (M = Mo, W). When R = 2,2,6,6-tetramethylpiperidyl, they were able to characterize, among the products of the reaction, the phosphirane complexes **40**, resulting from the trapping of the suspected phosphinidene intermediates by ethylene [Eq. (52)]. Ethylene is thought to be produced by the decomposition of THF after α-metalation. When ethylene is bubbled through the reaction mixture, the formation of **41** (type **IV**, Scheme 3) is suppressed. Complex **40** with M = W was characterized by X-ray crystal structure analysis.



From all the data so far reported, it seems clear that obtaining a stable terminal phosphinidene complex is a difficult task and that success is not granted. However, a lot of useful work remains to be done concerning the chemistry of these species. For example, preliminary experiments indicate that more or less smooth reactions take place with molecules having P-H, P-Cl, and Si-H bonds, as well as with aldehydes, ketones, epoxides, aziridines, trialkylphosphites, etc. Moreover, the use of these complexes as synthetic tools in organophosphorus synthesis looks very promising, especially in the field of potentially biologically active substances containing P-C bonds. Exciting developments are also likely in the field of transition-metal chemistry. It may be possible to use terminal phosphinidene complexes as building blocks for the controlled synthesis of clusters. The reaction of these species with transition-metal multiple bonds also looks promising. Finally, the basic scheme for the activation of a phosphinidene by a transition metal can perhaps be extended to the chemistry of other electron-deficient species such as silylenes, germylenes, and arsinidenes.

The pioneering experiments on terminal phosphinidene complexes were carried out by my co-worker Angela Marinetti. Various aspects of their chemistry have been investigated by my other co-workers J. M. Alcaraz, C. Charrier, B. Deschamps, F. Mercier, N. Maigrot, J. Svara, and N. H. Tran Huy. I owe many thanks to all of them. The help of my colleagues, J. Fischer (X-ray crystal structures, Université Louis Pasteur, Strasbourg), D. Gonbeau, and G. Pfister-Guillouzo (theoretical calculations, Université de Pau et des Pays de l'Adour) is also gratefully acknowledged. Finally, all the work discussed here could not have been carried out without the generous financial support of the Centre National de la Recherche Scientifique and the Société Nationale des Poudres et Explosifs.

Control of the Electronic Structure of Organic Conductors as Exemplified by [NMP][TCNQ] Charge-Transfer Complexes

By Joel S. Miller* and Arthur J. Epstein

Through replacement of cations with neutral molecules of similar shape and polarizability in a highly conducting "metal-like" change-transfer organic conductor, the deliberate control of the electronic structure from a quarter to a half-filled band is possible. This goal has been achieved with the *N*-methylphenazinium (NMP) salt of the tetracyanoquinodimethane (TCNQ) anion by partial replacement of the cation with phenazine. A detailed study of the optical, electrical, and magnetic properties of these conducting molecular solids has lead to the evolution of a broad understanding of the physics of one-dimensional organic conductors and a reinterpretation of the mechanism of electron transport in such solids. Phenomena such as switching from a low coulomb repulsion two-chain conductor to a high coulomb repulsion one-chain conductor as well as soliton-assisted electron transport are observed.

1. Introduction

New quasi one-dimensional (1-D) materials[1] are required to understand the salient features associated with one-dimensionality. To date a variety of 1-D charge-transfer substances exhibiting high conductivity have been studied: organic, e.g., tetrathiafulvalene (TTF) and 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ); inorganic, e.g., $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ (KCP); and covalent polymeric, e.g., poly(thiazyl), $(SN)_x$, and doped polyacetylene, $(CH)_x$.[2-7] However, owing to significant differences in the elemental composition, types of bonding, resultant bandwidths (see Table 1), stoichiometries, and crystal structures, detailed comparisons between and within these classes of materials are difficult to make. Therefore, we approached the situation from a different viewpoint, namely, by studying the physical properties solely as a function of band filling, i.e., Fermi energy.

Table 1. Prototype 1-D conductors.

Class of substance (conducting chain)	Type of bonding (orbitals)	Bandwidth [eV]
Organic (based on TCNQ)	$p_z(b_{2g}\text{-}b_{2g})$	0.2-1.0
Inorganic (based on TCP [a])	$d_{z^2}(a_g\text{-}a_g)$	4
Polymeric [$(SN)_x$] or $(CH)_x$] [b]	covalent bonds $sp^2/p_z/d$	5-10

[a] TCP = tetracyanoplatinate. [b] Intermolecular.

In contrast to "classical" semiconductors, e.g., Si, where doping with electron-deficient (e.g., Ga) or electron-rich (e.g., As) atoms (relative to Si) allows the number of electrons in the conduction band to be varied easily, controlled variation of the band filling of molecular-based materials had not been previously reported.

In this article, we summarize the chemical and physical properties of a series of organic compounds containing separate stacks of cations and anions in the crystal with variable band filling. Extensive study of these unusual systems has advanced our understanding of several central issues, including the role of the coulombic interaction between electrons, the effects of structural disorder, the role of soliton defects for nearly commensurate band fillings, and the mechanism of charge transport.

2. Design of an Organic Conductor with Variably Filled Bands

In order to synthesize an isomorphous series of complexes that differ only in the degree of band filling it is necessary to consider the structural aspects of such a system, for example, the segregated 1-D anion (e.g., TCNQ) and cation chains in Figure 1a. If a delocalized valence electron is removed from an anion (Fig. 1b), less than one valence electron, on the average, is present per anion site. This reduces the coulomb repulsion among the valence

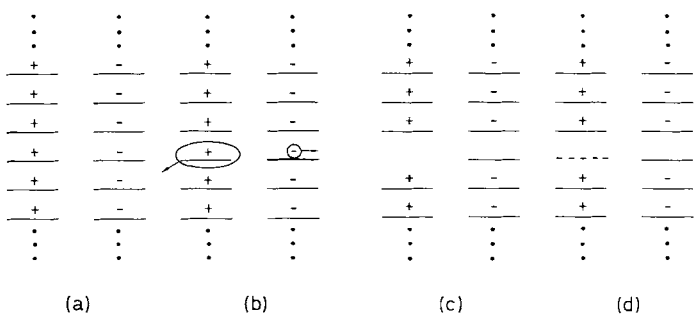

Fig. 1a) Illustration of 1-D charge-transfer salts with segregated cation (e.g., $[NMP]^{\oplus}$) and anion (e.g., $[TCNQ]^{\odot\ominus}$) stacks. b) Removal of an electron from the anion stack and a cation from the cation stack results in less than one valence electron per anion and a void in the cation stack (c). d) Filling the void with a neutral molecule stabilizes the structure.

electrons and thereby stabilizes the system. To conserve charge, however, a counterion must be removed. The cation loss should result in a crystallographic void (Fig. 1c) and lead to collapse of the unit cell. If, however, a neutral molecule of similar size, shape, and polarizability to the deleted cation were able to fill the cation void (dashed line in Fig. 1d), the structure should be stabilized. Through deliberate variation of the number of neutral molecules replacing cations, the number of electrons in the conduction band could be controlled. This would enable modulation of the Fermi energy and concomitant tuning of the physical properties.

3. Synthesis of an Organic Conductor with Variably Filled Bands

With this paradigm in mind, one of the earliest reported TCNQ salts, [NMP][TCNQ] ([NMP]$^{\oplus}$ = *N*-methylphenazinium, **1**)[8] was selected as the model system. The structure of [NMP][TCNQ] (Fig. 2) shows that the methyl groups have two possible orientations; however, local order exists.[9] Replacing the [NMP]$^{\oplus}$ with phenazine (Phen), **2**, complies with the design criteria outlined above, since phenazine has similar size, shape, and polarizability to [NMP]$^{\oplus}$[10] and possesses a rich donor–acceptor chemistry.[11]

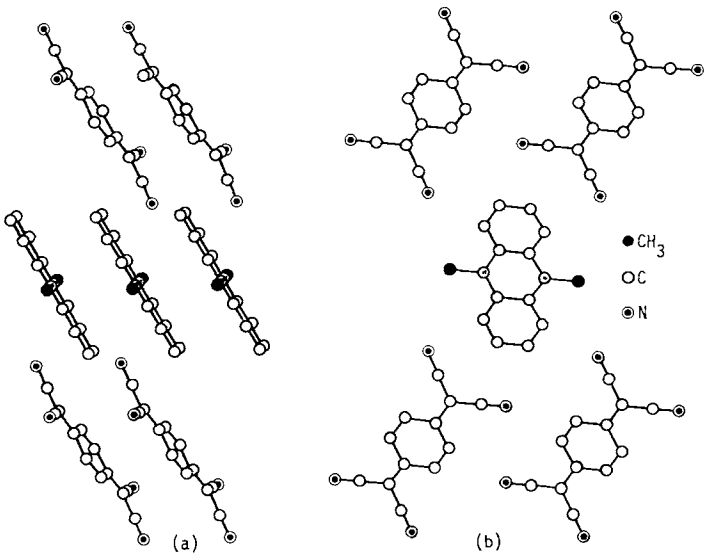

Fig. 2. Crystal structure of [NMP][TCNQ]. a) Side view. b) Top view. Two possible locations for the [NMP]$^{\oplus}$ methyl groups are illustrated by ●.

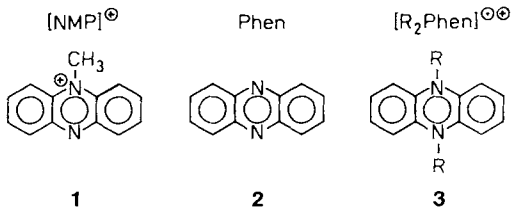
Reaction of Phen, [NMP]$^{\oplus}$, TCNQ, and [TCNQ]$^{\odot\ominus}$ in acetonitrile resulted in the formation of black needlelike crystals of [NMP]$_{1-x}$[Phen]$_x$[TCNQ], which were characterized by solution absorption spectroscopy and X-ray diffraction. Although the crystals are similar in appearance to [NMP][TCNQ], deconvolution of the solution absorption spectra unambiguously verified the presence of phenazine, **2** (λ_{max} = 347.5 nm), as well as *N*-methylphenazinium, **1** (λ_{max} = 259 nm). The degree of [NMP]$^{\oplus}$/Phen replacement,



1 **2** **3**

x, could be determined from the 842-nm absorption of [TCNQ]$^{\odot\ominus}$[10] or from a shift in the a_g vibration at 1420 cm^{-1} for [NMP][TCNQ].[11] The unit cell parameters (Table 2) show that for x = 0.26 and 0.46 the substances are isomorphous to the well-characterized [NMP][TCNQ] (x = 0). Thus, an isomorphous series of 1-D materials, which to a first approximation differ only in the degree of band filling, have been prepared and have enabled the detailed study of the physical properties as a function of Fermi energy.

Table 2. Unit cell parameters for [NMP]$_{1-x}$[Phen]$_x$[TCNQ].

Parameter	x = 0.00	x = 0.26	x = 0.46
a [Å]	3.8682(4)	3.890(8)	3.865(7)
b [Å]	7.7807(8)	7.799(3)	7.611(32)
c [Å]	15.735(2)	15.706(6)	16.329(51)
α [°]	91.67(1)	91.75(6)	93.73(49)
β [°]	92.67(1)	92.96(13)	91.53(31)
γ [°]	95.38(1)	95.45(2)	94.65(20)
V [Å^3]	470.7	473.4	477.4

Up to fifty percent of the [NMP]$^{\oplus}$ in [NMP][TCNQ] can be replaced with phenazine. Thus, the physical properties can be studied continuously from nominally the half-filled band case to the quarter-filled band case.[12] We have recently shown that, in addition to phenazine, 9-methylanthracene, 9,10-dimethylanthracene, 9-methylacridine, etc., can replace [NMP]$^{\oplus}$ in [NMP][TCNQ] and thereby be utilized to modulate the degree of band filling. Replacement of [NMP]$^{\oplus}$ with substituted 5,10-dihydrophenazinium, [R$_2$Phen]$^{\odot\oplus}$ (R = Me, Et), **3**, to form [R$_2$Phen]$_{1-y}$[Phen]$_y$[TCNQ] has been reported; however, y could not be varied (i.e., y = 0.50 and 0.45 for R = Me and Et, respectively).[13] The [R$_2$Phen]$_{1-y}$[Phen]$_y$[TCNQ] complexes crystallize with segregated cation ([R$_2$Phen]$^{\odot\oplus}$/Phen) and anion chains, although [R$_2$Phen]$^{\odot\oplus}$[TCNQ]$^{\odot\ominus}$ (i.e., y = 0) possesses an alternating ···DADA··· structure.[14,15] Since y cannot be varied and only limited physical measurements have been reported, we focus primarily on the [NMP]$_{1-x}$[Phen]$_x$[TCNQ] series of charge-transfer salts in this review.

4. Insight into Physical Processes

The availability of [NMP]$_{1-x}$[Phen]$_x$[TCNQ] ($0.5 > x \geq 0$) has enabled an exhaustive study of the electrical, optical, and magnetic properties of this prototype 1-D conductor. The data has led to a broad understanding of the physics of 1-D conductors and to a reinterpretation of the mechanism of electron transport in these materials. Below we re-

view some of the properties and summarize their significance.

4.1. Variation of Electronic Structure with Conduction Electron Density

Prior to discussing the unusual features of the $[NMP]_{1-x}[Phen]_x[TCNQ]$ system, we review the electronic structure of solids.[3a] In an isolated molecule each orbital, which holds two electrons, has a well-defined energy. When two molecules are brought together close enough for their orbitals to overlap, the energy levels split; adding a third molecule splits the levels into three components. In a solid of perhaps 10^{15} molecules the levels are so numerous and closely spaced that they effectively form a continuous band which can hold 2N electrons for an N-molecule system. If each molecule in the solid has only one electron in the highest occupied orbital, the corresponding band will be only half full.[16]

The degree of band filling determines the electrical properties. Conduction cannot take place in an empty band (because it lacks electrons) or in a full band (because the total population of electrons cannot have any net motion). A metal has a partially filled band, where the electrons can be given a net velocity by shifting some of them to infinitesimally higher energies within the band. An insulator has only filled and empty bands separated by a large energy gap. A semiconductor is like an insulator but has a smaller gap and some mobile charge carriers. The carriers are introduced by impurities, defects, deviations from stoichiometry, or the excitation of electrons from the highest filled (valence) band to the lowest empty (conduction) one.

A metal has a degeneracy of empty and filled levels at its highest occupied energy level, the Fermi energy. For a linear arrangement of molecules (stacks or chains), this degeneracy can be removed by changing the uniform spacing of molecules to periodic spacing, e.g., by dimerization. This so-called Peierls distortion lowers the energy of the filled energy levels and raises the energy of the empty ones.[17]

X-ray diffuse scattering[18] enables the observation of the subtle periodicities in the spacing of molecules along a chain that are a consequence of the Peierls distortion. The length of the repeat unit of the distortion provides a direct measure of the number of electrons in the partly filled energy band (the degree of partial oxidation/reduction). For example, the 1-D character of [TTF][TCNQ] with a degree of charge transfer of 0.59 was determined by observing X-ray diffuse scattering.[18] In some materials, the scattering repeat was observed at one-half the repeat length expected for an ordinary Peierls distortion.[19a] This was postulated to occur when the coulomb repulsion, U, between two electrons on the same unit is much greater than the spread of energy levels, i.e., bandwidth, W.[19] The factors determining the relative magnitude of U and W were poorly understood until insights were made available by our detailed study of $[NMP]_{1-x}[Phen]_x[TCNQ]$.

The study of the temperature-dependent dynamical properties of $[NMP]_{1-x}[Phen]_x[TCNQ]$ revealed unique features of the electronic instabilities of 1-D conductors not previously observed.[20] The diffuse X-ray scattering from the "usual" Peierls periodicity and from the one of half the spacing have often been associated with the independent behavior of the donor and acceptor stacks in two-chain materials, e.g., [TTF][TCNQ], but it is conceivable that both anomalies arise in one stack.[19a] The investigations of $[NMP]_{1-x}[Phen]_x[TCNQ]$ demonstrated the latter case to be true for this system.

X-ray diffuse scattering studies established that for [NMP][TCNQ] ($x=0$) there is partial charge transfer with 2/3 electron per TCNQ and 1/3 electron per NMP molecule.[21,22] As $[NMP]^{\oplus}$ is replaced by phenazine, electrons are depleted from the conduction band; the conduction-electron density is thereby reduced and the diffuse X-ray scattering from the $[NMP]^{\oplus}$/phenazine chain is no longer observed. In contrast, scattering from the TCNQ chain is unaffected except for a shift in the superlattice period due to a reduction in conduction-electron density. This important result demonstrates that disorder within the donor stack has little effect upon the electronic properties of the acceptor stack, in contrast to the earlier analysis of the transport[23] and magnetic[24] data, which indicated that $[NMP]^{\oplus}$ orientational (dipolar) disorder induced localization of the conduction electrons on the parallel TCNQ chains. With increased phenazine substitution for $[NMP]^{\oplus}$ a crossover from a two-chain to an one-chain conducting system is observed (at $x \approx 1/3$). This is coincident with a crossover from the usual distortion period ("$2k_F$" regime) to one of half the repeat distance ("$4k_F$" regime) (Fig. 3).

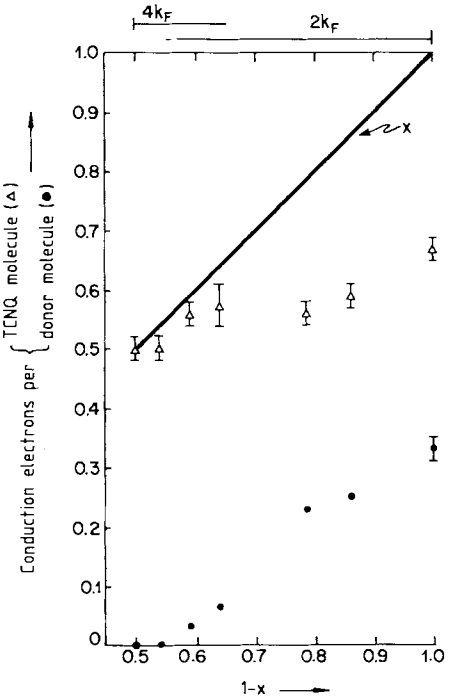


Fig. 3. Number of conduction electrons per TCNQ and per donor molecule vs. NMP concentration, $1-x$, in $[NMP]_{1-x}[Phen]_x[TCNQ]$. The solid line gives the total conduction-electron concentration. The number of conduction electrons per TCNQ is deduced from the periodicity of the Peierls distortion. For $x>0.56$, the additional electrons beyond $x=0.50$ are in soliton states of the TCNQ chain (see text). The concentration ranges where $2k_F$ and/or $4k_F$ are observed are indicated on the top.

There is even a narrow range of electron densities where both types of Peierls distortions are simultaneously observed. There are a comparable number of conduction electrons per TCNQ above and below $x = 1/3$, while the TCNQ bandwidth W remains essentially unchanged. This result confirms the central role of interchain screening in determining the magnitude of U/W.[25] The $4k_F$ anomaly is directly associated with $U/W > 1$; this is revealed by comparing the properties of $[NMP]_{1-x}[Phen]_x[TCNQ]$ samples exhibiting $4k_F$ with those of known large U/W systems and by analysis of other properties of the system, e.g., plasma frequency and magnetic susceptibility.

The crossover from a small to a large U/W regime at $x \approx 1/3$ was predicted from the early spectroscopic studies.[25] The frequency dependence of the polarized reflectivity of $[NMP]_{1-x}[Phen]_x[TCNQ]$ as a function of x (Fig. 4) was the first unequivocal demonstration that the minimum in the reflectivity spectrum (≈ 1 eV), often observed for one-dimensional TCNQ salts, is indeed a collective (plasma) response attributable to the number of charge carriers per unit cell. An anomalous variation in plasma frequency, ω_p, was observed at intermediate n (Fig. 5), which is in remarkable agreement with a change in character of the system from small U/W at high charge density to large U/W at lower charge density.

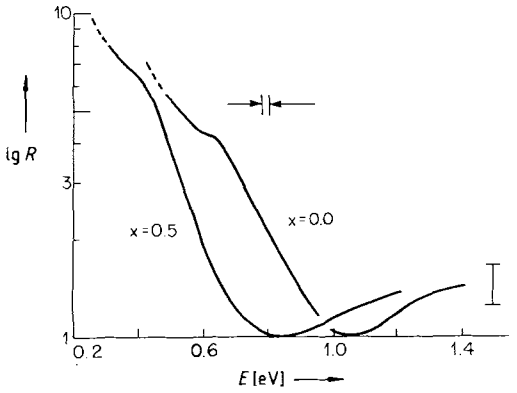

Fig. 4. The logarithm of the reflectivity ($\log R$, arbitrary units) vs. energy of irradiation, E, for $x = 0.0$ and $x = 0.5$; light polarized parallel to the stacking a axis. Note the 0.25-eV redshift on going from $x = 0.0$ to $x = 0.5$. Error bar (right) gives maximum uncertainty; typical spectra were two to three times better. Dashed lines indicate observed rise due (in part) to decrease scattered light (see text).

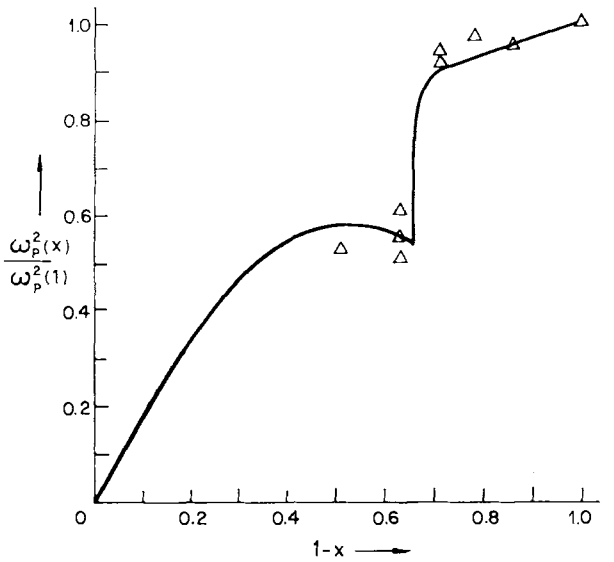

Fig. 5. Normalized plasma frequency as a function of band filling, $1-x$, in $[NMP]_{1-x}[Phen]_x[TCNQ]$. △ : experimental value.

Based on the X-ray diffuse scattering and reflectivity data, a model for the electron energy band structure of $[NMP]_{1-x}[Phen]_x[TCNQ]$ was constructed (Fig. 6). These data indicate that $[NMP]_{1-x}[Phen]_x[TCNQ]$ is a small-bandgap, low-coulomb-repulsion, small-bandwidth semiconductor with conduction bands residing on both donor ($[NMP]^{\oplus}$) and acceptor (TCNQ) stacks (Fig. 6a, $x = 0$). By replacing the $[NMP]^{\oplus}$ with phenazine, conduction electrons are removed from both stacks. Thus, $[NMP]_{0.8}[Phen]_{0.2}[TCNQ]$, like [NMP][TCNQ], is a two-chain conductor. Since conduction electrons reside on both stacks, their coulomb repulsion is reduced and is therefore small relative to the bandwidth (Fig. 6a, $x = 0.2$). Further depletion of conduction electrons leads to an interesting situation at $x \approx 0.33$. For $x < 0.33$, the conduction

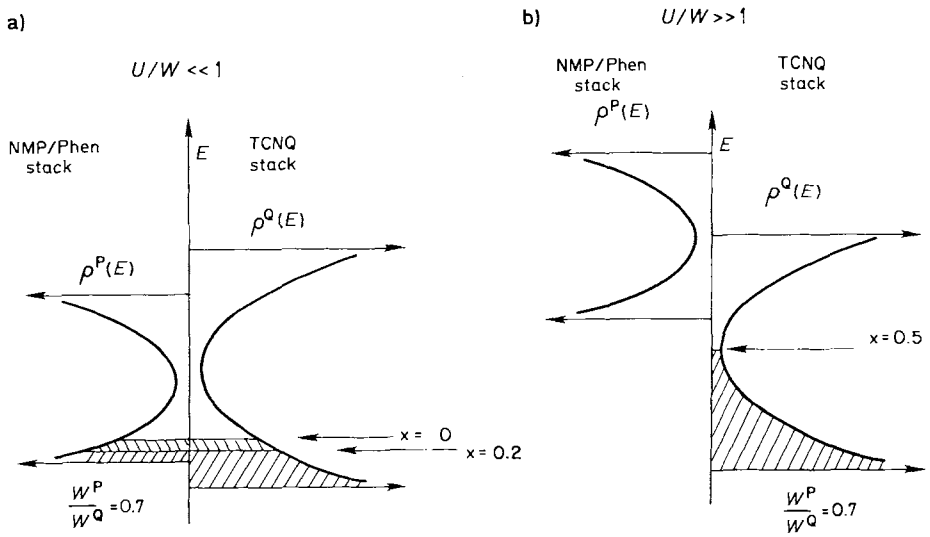

Fig. 6. Electron energy band structure for $[NMP]_{1-x}[Phen]_x[TCNQ]$. a) Small U/W. b) Large U/W. Q = TCNQ; P = NMP/Phen.

electrons are depleted from the donor ([NMP]$^{\oplus}$/Phen) band and the system switches from a two-chain conductor (low coulomb repulsion) to a one-chain conductor (with a relatively high coulomb repulsion relative to W, since all the conduction electrons reside in the TCNQ band); for $x = 0.50$, see Figure 6b. This leads to discontinuities in some of the physical properties (see Fig. 5).

The temperature-dependent magnetic susceptibility, χ,[26] and the results of ESR[27] studies support these conclusions.[26] Below 40 K, $\chi(T) = AT^{-\alpha}$ ($\alpha \approx 0.7$–0.8). This expression is consistent with random exchange among a small number of localized spins.[28] For $x > 1/3$, A decreases owing to the depopulation of the [NMP]$^{\oplus}$/Phen stack such that only unpaired localized spins on the TCNQ chain contribute. For $x < 1/3$, localized spins on both stacks contribute. Above 100 K there are qualitative and quantitative differences in $\chi(T)$ for x greater or less than 1/3. For $x > 1/3$, $\chi(T)$ has a weak maximum near room temperature much like that of [quinolinium][TCNQ]$_2$ with large U/W and an exchange interaction energy of $J \approx 300$ K. For $x < 1/3$, $\chi(T)$ decreases monotonically with increasing temperature. This is consistent with the presence of small U/W on both stacks.

4.2. Solitons in Nearly Commensurate Compositions

The description of the electronic ground state of 1-D conductors with nearly commensurate charge concentration (i.e., number of charges per unit cell being close to a rational fraction) has been a central issue in the field. As noted in Section 4.1, a chain of molecules can undergo a Peierls distortion to lower the system energy leading to a new periodicity of the molecules. For commensurate charge densities, this new periodicity is a small integral number of sites (e.g., for a half-filled band, one electron/site for $U/W \gg 1$; one electron/two sites for $U/W \ll 1$); e.g., for [NMP]$_{0.5}$[Phen]$_{0.5}$[TCNQ], the new periodicity is a dimer (Fig. 7). In Figure 7, the different lengths represent the slightly different molecular shapes that result from the Peierls distortion and the two possible phases of dimerization (shifted by one molecular unit).

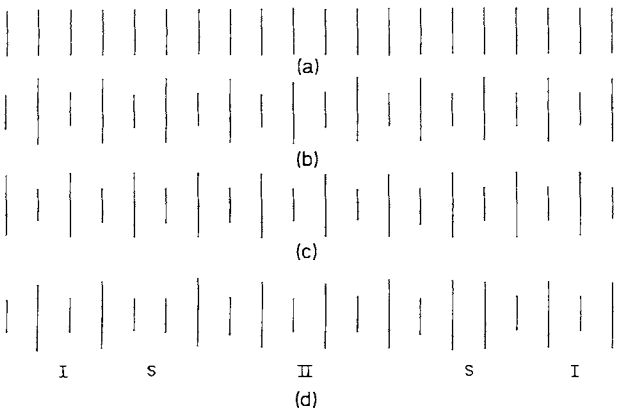

Fig. 7. Schematic illustration of a) uniform chain of molecules, b) dimerized chain of molecules of phase "I," c) dimerized chain of molecules of phase "II,", and d) chain of dimer phase I with segment of dimer phase II within it. The domain walls between phases I and II (and II and I) are the solitons, which can accommodate small numbers of excess charge near the commensurate charge density.

Addition of a few more holes to the TCNQ chain (through Phen replacement of [NMP]$^{\oplus}$) would cause the Peierls distortion to shift to an incommensurate periodicity (nonrational repeat distance). To minimize the reduction in the stabilization energy in going from commensurate to incommensurate structures (for a small charge density range), the system maintains its commensurate structure and accommodates the excess charges in defects (solitons) in the commensurate periodicity (Fig. 7d). The suggestion[29a] that a small excess (or deficiency) of charge relative to the commensurate state is accommodated in polyacetylene, $(CH)_x$, by the formation of spinless solitons of charge $\pm e$ is now well-supported by experimental evidence.[29b] Theoretical studies of highly correlated 1-D charge-transfer salts near the quarter-filled band limit (typified by [NMP]$_{0.5}$[Phen]$_{0.5}$[TCNQ]) have predicted the existence of solitons with quantum observable fractional charges[30] of $\pm e/2$. The results of experimental[31] and theoretical[32] studies of [NMP]$_{1-x}$[Phen]$_x$[TCNQ] ($x \approx 0.5$) as a function of x are a direct demonstration that solitons are experimentally realized in charge-transfer salts. The effects of solitons (and pairs of solitons, or bipolarons) upon the temperature-dependent conductivity,[31,32] $\sigma(T)$, have been observed and can be understood in terms of a model of a decreased gap caused by the presence of the solitons. The concentration regime for soliton formation was identified as $0.50 > x > 0.43$.[31] Additional direct evidence for solitons in the [NMP]$_{1-x}$[Phen]$_x$[TCNQ] system has been obtained by detailed measurements of the optical absorption,[31b,33] thermopower,[31b] X-ray diffuse scattering,[20] and electron spin resonance g value.[27] The role of strong coulomb interactions in stabilizing solitonlike defects in [NMP]$_{1-x}$[Phen]$_x$[TCNQ] has also been suggested.[34]

4.3. A Model for Conductivity

The normalized temperature dependence of the dc conductivity, $\sigma_n(T) \equiv \sigma(T)/\sigma(295\,\mathrm{K})$ (Fig. 8) for [NMP]$_{1-x}$[Phen]$_x$[TCNQ] exhibits several key features: (1) the phenazine-containing samples ($x > 0$) exhibit a similar $\sigma_n(T)$ to [NMP][TCNQ]; (2) the temperature at which the maximum conductivity occurs, T_m, varies with phenazine concentration; and (3) the normalized conductivity, σ_n, varies with phenazine content.

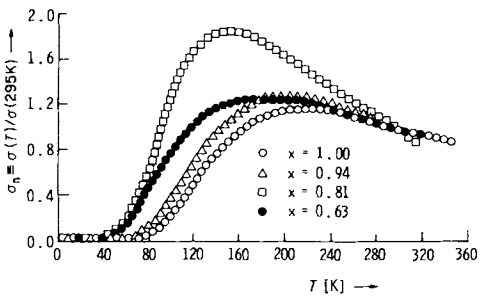

Fig. 8. Temperature dependence of the normalized conductivity for [NMP]$_{1-x}$[Phen]$_x$[TCNQ] (see text).

Conventional wisdom[35] ascribes T_m to a metal–insulator transition temperature such that above T_m metal-like behavior is operative and disorder leading to localization

of conduction electrons and insulating behavior occurs at $T<T_m$.[23] However, the slope ($d\ln\sigma/dT^{-1}$) does not change at T_m, suggesting that one (not two) transport mechanism dominates above 60 K.[36] NMR studies of $[NMP]_{1-x}[Phen]_x[TCNQ]$ confirm that nuclear spin relaxation is not dominated by conduction electrons[37] in contrast to the disorder model prediction.[23b] As confirmed by IR studies,[31b,33] the system is actually a small-bandgap Peierls semiconductor.

To account for the presence of one transport mechanism above 60 K, a new model for the conductivity was developed.[36] For a semiconductor, the conductivity is given by

$$\sigma = ne\mu \qquad (a)$$

where n = number of carriers, e = the fundamental charge of an electron, and μ = mobility. The number of carriers, n, is an exponential function of temperature, T; i.e., $n \propto e^{-E_g/kT}$ (E_g = bandgap), whereas the mobility, μ, is often a power law in temperature, i.e., $T^{-\alpha}$ ($4 \geq \alpha \geq 2$). Thus, Equation (b) is obtained for the conductivity σ (see also Fig. 9).

$$\sigma(\alpha, T) = A\,T^{-\alpha} e^{-E_g/kT} \qquad (b)$$

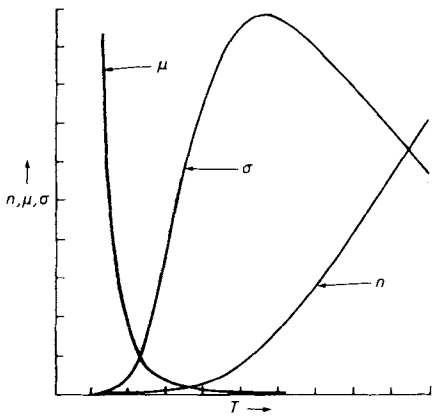

Fig. 9. Schematic temperature dependence of charge-carrier concentration n, the mobility μ, and the conductivity σ.

The conductivity of $[NMP]_{1-x}[Phen]_x[TCNQ]$ ($0.5 < x < 1$; $80\ K < T < 400\ K$) fits Equation (b) very well, although recent IR data indicates that the energy gap is temperature dependent,[31b,33] as expected for a Peierls semiconductor[38] (see below). In general, samples with the same x value may be fit with a relatively unique value of E_g with varying α, reflecting a sample to sample variation in purity (Fig. 10).

Nine of ten a_g TCNQ vibrational modes are found in the absorption spectrum of $[NMP]_{1-x}[Phen]_x[TCNQ]$ ($0.50 \geq x \geq 0.41$).[31] These totally symmetric normally IR-inactive modes become strongly IR active in the presence of oscillations of the phase of the Peierls distortion.[40] Thus, $[NMP]_{1-x}[Phen]_x[TCNQ]$ is a small-bandgap semiconductor at room temperature where it exhibits metal-like conductivity, i.e., $d\sigma/dT < 0$. At low temperatures the optical gaps are in agreement with those calculated in the original semiconductor model.[36]

Direct IR measurements of the bandgap of $[NMP]_{1-x}[Phen]_x[TCNQ]$ are complicated by the polycrystalline nature of the samples necessitated by the small crystal dimensions. Large single crystals of $HNMe_3(I)[TCNQ]$ exhibit a similar $\sigma_n(T)$ dependence near room temperature, enabling verification of these models. The single-crystal reflectivity data for $HNMe_3(I)[TCNQ]$ confirm the presence of a bandgap of 0.16 eV at room temperature where $d\sigma/dT < 0$.[41] Thus, concepts developed during study of $[NMP]_{1-x}[Phen]_x[TCNQ]$ semiconductor systems have been generalized and applied to other 1-D quasi-conductors.

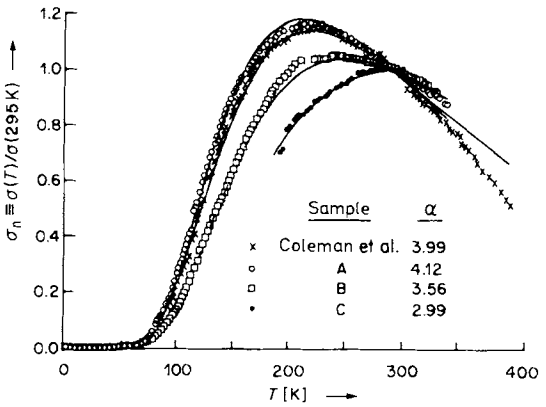

Fig. 10. Normalized four-probe a-axis conductivity versus temperature for representative [NMP][TCNQ] samples. The "Coleman et al." data is from ref. [39]. The solid lines are computer fits to Equation (b) with indicated α.

5. Summary and Outlook

The $[NMP]_{1-x}[Phen]_x[TCNQ]$ "alloy" system has been found to be very rich in physics and chemistry. Through systematic studies several new phenomena have been discovered and new insights into quasi one-dimensional conductors have been obtained:

- The synthesis of an isomorphous series of "metal-like" organic charge-transfer complexes with a variable degree of band filling ("alloying") has been achieved.
- Disorder has been shown to play a secondary role. The electrons are sufficiently delocalized so that the central physics is determined by the Peierls (electron–phonon or Jahn–Teller) interaction and not the disorder.
- The importance of interstack screening in determining the coulomb correlation in 1-D systems has been demonstrated, since we have observed a crossover from small to large U/W regimes with removal of electrons from one of two conducting stacks. Thus, the relative size of U/W is not determined by the charge density of the isolated stacks alone.
- A new model based upon temperature-dependent mobility and carrier concentration for conductivity was developed for $[NMP]_{1-x}[Phen]_x[TCNQ]$. This semiconductor model has been shown to be applicable to a wide range of quasi one-dimensional systems.
- The $[NMP]_{1-x}[Phen]_x[TCNQ]$ system has provided the first direct evidence for solitons in molecular charge-transfer salts. The solitons are predicted to have a fractional charge.

● The presence of a pair of lattice distortions (of $2k_F$ and $4k_F$ periodicities) on the same chain was detected via X-ray diffuse scattering. The coexistence of these two lattice modulations has clarified the understanding of Peierls distortions in two-chain conductors such as [TTF][TCNQ].

The study of $[NMP]_{1-x}[Phen]_x[TCNQ]$ as a function of x has led to the discovery of new phenomena, the development of generalizable physical models, and the better understanding and relative importance of existing concepts. However, with the improved understanding of one-dimensional organic conductors, however, new questions have emerged and are the focus of avid attention in many laboratories throughout the world. The study of variably controlled one-dimensional conductors remains an important aspect of our research. Some of the current topics under investigation include understanding the effects of on-site and near-neighbor coulomb interactions on the simple Peierls and soliton models, together with the related issue of whether the electron-electron or the electron-phonon interaction is the primary driving force for the observed physical properties. Additional effort is still necessary to further quantify the models and concepts presented here and self-consistently fit the myriad data presented. These compounds continue to arouse the curiosity of scientists since they exhibit a wealth of unusual properties of importance to condensed matter physics.

Synthesis of Glycopeptides, Partial Structures of Biological Recognition Components**

New Synthetic Methods (67)

By Horst Kunz*

Dedicated to Professor Leopold Horner on the occasion of his 75th birthday

Glycopeptides are partial structures of the connecting regions of glycoproteins and, like these, always contain glycosidic bonds between the carbohydrate and peptide parts. Glycoproteins are not only widely distributed but are also decisive factors in post-translational biological selectivity, especially in biological recognition. Targeted syntheses of glycopeptides require stereoselective formation of the glycosidic bonds between the carbohydrate and the peptide parts and protective group methods that enable selective deblocking of only one functional group in these polyfunctional molecules. These heavy demands have been met by the well-established use of benzylic protective groups, which can be removed by hydrogenolysis, combined with the use of base-labile 2-phosphonioethoxycarbonyl (Peoc) or 9-fluorenylmethoxycarbonyl (Fmoc) protective groups or of bromoethyl esters, which can be removed under neutral conditions. The acidolysis of *tert*-butyloxycarbonyl (Boc) groups and of *tert*-butyl esters has also been successfully used, although, under acidic conditions, anomerization or rupture of the glycosidic bonds may occur, especially when nucleophiles are present. The stable, two-stage 2-(pyridyl)ethoxycarbonyl (Pyoc) protective groups allow a more reliable synthesis of complex glycopeptides since they can be removed, after modifications, under mild conditions. Particularly suitable for the synthesis of sensitive glycopeptides are the stable allyl protective groups. They can be removed from the complex glycopeptides in a highly selective and effective manner by means of noble-metal catalysts under practically neutral conditions. These methods have been employed to synthesize glycopeptides corresponding to partial structures of interesting glycoproteins. Deprotected glycopeptides representing tumor-associated antigen structures can be coupled to bovine serum albumin, which serves as a biological carrier molecule, without the necessity of using an artificial coupling component (spacer).

1. Glycoproteins as Carriers of Biological Selectivity on Membranes

The complex molecular processes in a biological system can only take place properly when they are selectively controlled. The best known and probably the best investigated of these control processes is the replication and transcription of the genetic code of the deoxyribonucleic acids and the translation of the genetic information in protein biosynthesis.[1] This regulation ensures that the proteins—e.g., decisive biological catalysts (enzymes)—are always dependably produced, so that they can carry out their often highly selective functions in the cell. As a rule, however, a protein performs its function only in specific areas of the cell. Biological selection processes, which occur predominantly on the intracellular and outer-cell membranes, are responsible for guiding a protein that has been newly synthesized on the endoplasmic reticulum to its "work place." This post-translational biological selectivity is clearly based on a receptor-effector interaction in which—at least in eukaryotic cells—the glycoproteins play a decisive role.[2]

That the carbohydrate part of the glycoprotein can play a key role in this process was first shown by *Ashwell* et al.[3] They found that the copper-transport glycoprotein, ceruloplasmin, has a biological half-life of 54 h in rabbit serum. However, after they had removed the terminal *N*-acetylneuraminic acid (sialic acid) residue from the oligosaccharide chain of ceruloplasmin with neuraminidase and thereby uncovered galactose, they found that the resulting asialoceruloplasmin had a half-life of less than 5 min in rabbit serum. They were able to show that this dramatic biological effect is caused by the recognition of the now terminal galactose residue by a specific receptor in the liver cells of the rabbit, a selection mechanism that holds for many analogous glycoproteins and for mammals in general.[3] This galactose-specific receptor in the hepatocyte membrane, which acts like a lectin, is itself a glycoprotein.[4]

The carbohydrate side chain of a glycoprotein also serves as a recognition signal for the directed transport of lysosomal enzymes into the lysosomes of fibroblasts. In this case, terminal mannose-6-phosphate residues are recognized by specific receptors in the membrane which once again are glycoproteins.[5] If the fibroblasts are treated with the antibiotic tunicamycin, which prevents the connection of the carbohydrate side chain to the asparagine amide function during the biosynthesis of the *N*-glycoproteins, then the carbohydrate-free lysosomal enzymes

no longer enter the lysosomes where they carry out their functions.

The importance of glycoproteins in the control of biological processes is clearly demonstrated by the fact that crucial processes, such as cell growth and cell differentiation, are permanently affected when the attachment of carbohydrate side chains to the proteins is blocked.[6] In accord with these results, it has been found that the glycoprotein profiles in the cell membranes of normally growing cells and of tumor cells are very different.[7] The altered glycoprotein structures in the tumor cell membranes appear to be, in part, tumor-associated antigens.[8] The role of the oligosaccharide structures of glycoconjugates as antigen determinants in different blood group systems is well-known.[9] Recent investigations have shown that interactions of the carbohydrate–lectin type are also involved in infection processes. Some bacteria and viruses have surface lectins which bind specifically to carbohydrates on the surface of the host cell and so induce infection.[10]

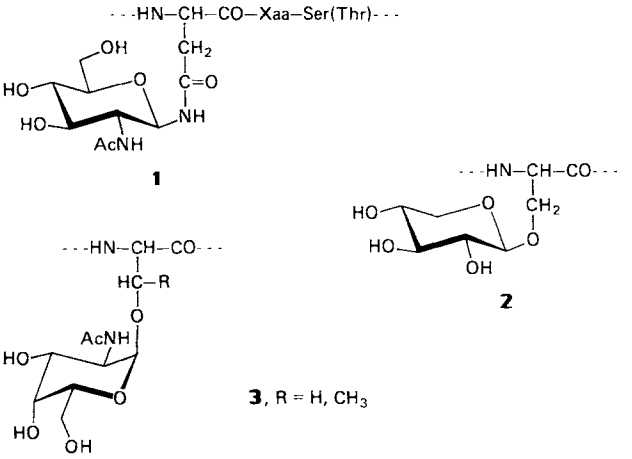
These results of biochemical, molecular biological, and immunological research open up quite new possibilities for the diagnosis and specific treatment of pathogenic processes. For example, the development of selective chemotherapeutic agents, the delivery of active substances to particular tissues by means of selective signal–receptor interactions,[11] and the production of antibodies active against tumor-associated glycoconjugate structures should be realizable.[7,12] In addition, when one considers that the oligosaccharide portion of the glycoproteins often offers protection against the attack of proteolytic enzymes,[13] it should be possible to design orally applicable, active peptides by incorporation of suitable glycoside portions.

Against this background and in light of the highly developed methods of peptide synthesis,[14] interest in glycopeptide synthesis is increasing.

2. The Carbohydrate–Peptide Connecting Region of Glycoproteins

Despite the large number of natural glycoproteins, the types of covalent bonds between the protein and the saccharide part show relatively little variation.[2] Most common are *N*-glycoproteins, **1**, in which the side chain amide function of an asparagine unit is usually joined to an *N*-acetylglucosamine residue through a β-*N*-glycosidic linkage.[15] To this type of structure, whose biosynthesis has been best investigated,[16] belong serum components such as amylases, plasmaproteins (e.g., fibrinogen and transferrin), immunoglobulins, hormones (e.g., chorionic gonadotropin), hormone precursors (e.g., thyroglobulin), and membrane glycoproteins (e.g., glycosyl transferases, band III glycoprotein, rhodopsin, and receptor glycoproteins, including the galactose-specific receptor of the hepatocyte membrane). The *N*-glycoproteins **1** are characterized, furthermore, by a common sequence in the connecting region: the next but one *C*-terminal amino acid following the *N*-glycosylated asparagine is always serine or threonine. The hydroxy group of this unit appears to be involved catalytically in the glycosyl transfer.[17]

Until recently it was assumed that in nature the type-**1** *N*-glycosidic linkage occurred exclusively.[2] More recent investigations, however, have shown that the cell surface glycoproteins of the halobacteria contain *N*-glucosyl-[18] and *N*-galactosaminylasparagine structures.[19] From the glomerular basal membrane of rats a nephritogenic glycopeptide has been isolated in which an α-*N*-glycosidic bond exists between glucose and the peptide part.[20] Glutamine has been suggested as the binding partner.[21]



The second important type of connection between the carbohydrate and peptide portions of glycoproteins is the *O*-glycosidic linkage. The β-glycosidic bond between xylose and serine, **2**, is the characteristic connecting element of the proteoglycans of the extracellular matrix and of connective tissue.[22] The α-*O*-glycosidic linkage between *N*-acetylgalactosamine and serine or threonine, **3**, was first found in the mucous glycoproteins (mucins).[2] It is characteristic of many other serum and membrane glycoproteins, including the blood-group glycoproteins,[23] human glycophorin,[24] epiglycanin[25], and the glycoproteins of the tumor-associated T_N and T antigens.[8]

In collagen and collagen-type macromolecules the β-glycosidic bond between galactose and δ-hydroxylysine occurs almost exclusively.[26] Interestingly, this structural element is also thought to occur in the C1q components of the complement system.[27] For further information about other variants of the glycosidic linkage in *O*-glycoproteins, more comprehensive reviews should be consulted.[2]

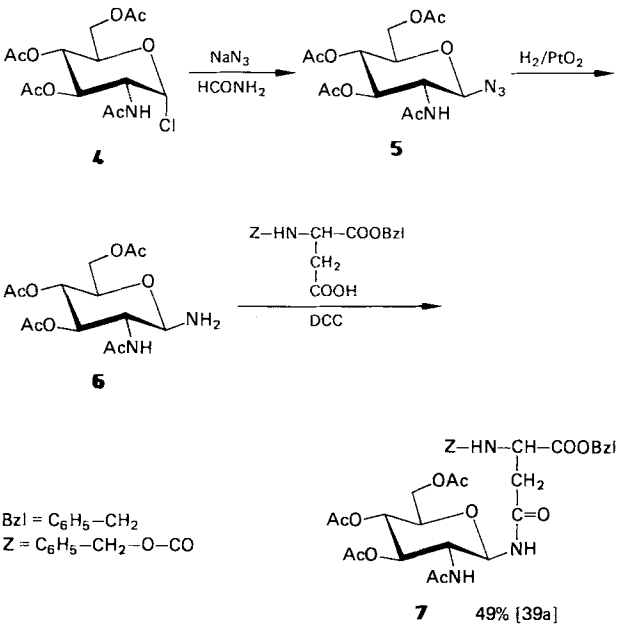
3. Comparison of Glycopeptide and Peptide Synthesis

Even if one looks only at the partial structures of the connecting regions of glycoproteins of types **1**–**3**, it is quite clear that the problems of peptide and carbohydrate chemistry merge in the chemical synthesis of such polyfunctional molecules. Both branches of preparative natural product chemistry were firmly founded by *Emil Fischer*.[28] However, the analytical techniques then available did not allow the great variety and importance of the protein–carbohydrate conjugates to be recognized. Thus, two separate schools of chemistry stemmed from *Emil Fischer*: that of peptide chemistry, with such names as *Max Bergmann*,

Hans Leuchs, and *Emil Abderhalden*, and that of carbohydrate chemistry, with such names as *Otto Warburg*, *Carl Freudenberg*, and *Burkhard Helferich*. For decades thereafter proteins and carbohydrates were largely dealt with separately.[29]

In comparison with peptide synthesis, glycopeptide synthesis requires the protection of many more functional groups, reversibly and with maximum selectivity. Still more important in compounds of types **1**–**3**, however, is the presence of the glycosidic linkage, which must both be formed stereoselectively[30,31] and be retained unchanged during the course of the synthesis.[32]

The oligosaccharides of the glycoproteins constitute a separate field; their structure and biosynthesis have been dealt with in many reviews.[2,6,16,29,33–35] The chemical synthesis of such oligosaccharides has recently been the subject of extended reviews[36,37] and will not be covered further here.



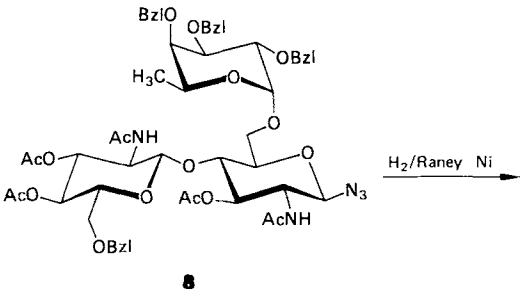
4 **5** **6** **7** 49% [39a]

4. The Formation of Glycosidic Bonds

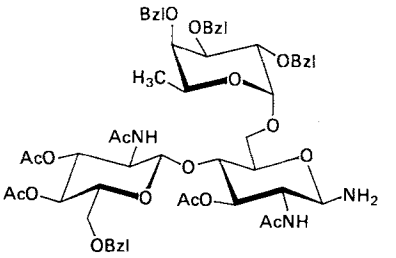
Until the beginning of the 1980s the formation of glycosidic bonds to specific amino acids was the focal point of glycopeptide chemistry. Of special merit is the work of *Jeanloz* and his co-workers,[38] who have focused their attention on the targeted synthesis of glycopeptides in order to obtain standard compounds for use in studying the degradation of glycoproteins. Since the synthesis of *N*- and *O*-glycosyl amino-acid derivatives was reviewed comprehensively in 1985[30] and 1983,[31] only the more important methods and more recent results will be dealt with here.

4.1. The Asparagine–Glucosamine Linkage

The β-*N*-glycosidic linkage between *N*-acetylglucosamine and asparagine, **1**, which is characteristic of the *N*-glycoproteins that are especially important in cell biology, is formed, e.g., in conjugate **7**, by the condensation of *N*-protected aspartic acid α-monoesters with 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosylamine **6** (DCC = *N*,*N*′-dicyclohexylcarbodiimide).[39] Compound **6** is prepared,[30,31] in turn, from the glycosyl chloride **4**[40] via the azide **5**.[41] For the conversion of the chloride **4** into the azide **5**, sodium azide in formamide[42] is more suitable than silver azide, which was formerly used exclusively.[39,41] In the more complex chitobiose series, on the other hand, this method was unsuccessful. The unpleasant silver azide[43] could be replaced, however, by a method involving phase-transfer catalysis with sodium azide in chloroform/water.[44] In contrast to the reduction of other carbohydrate azides, the hydrogenation of glycosyl azides in the *N*-acetylglucosamine series has only been satisfactorily accomplished with platinum catalysts.[30] It is accompanied by the formation of bisglycosylamines as by-products.[45] Our recent investigations, however, show that this hydrogenation also proceeds very well with Raney Ni.[46] This method has the advantage that benzylic protective groups are not attacked. In this way, the selective reduction of the azido function in the complex, fully protected trisaccharide **8** was achieved with the nearly quantitative formation of the amine **9**.[47]



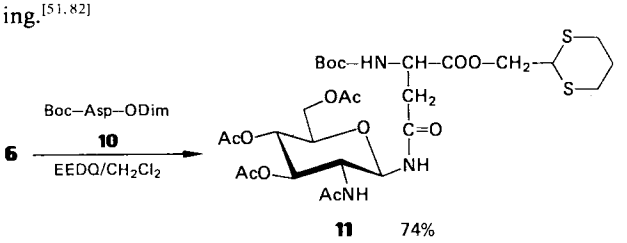
8



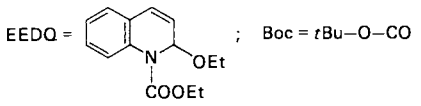
9 92%

For the condensation of glycosylamines of type **6** with *N*-protected aspartic acid α-monoesters to form completely protected *N*-glycosylasparagine derivatives of type **7**, only *N*,*N*′-dicyclohexylcarbodiimide was used at first.[30,31,39] In order to avoid the problem of subsequent selective deblocking, *Garg* and *Jeanloz*[48] studied the reaction of the glucosaminylamine **6**, as well as the corresponding chitobiosylamine, with *N*-benzyloxycarbonyl(Z)aspartic anhydride. However, they always obtained a mixture of the desired *N*-glycosylasparagine derivative and the isomer in which the α-carboxyl group had undergone reaction. Moreover, the method did not afford satisfactory yields of the desired isomer. Of the condensation catalysts employed,[30,31] ethyl 2-ethoxy-1,2-dihydroquinoline-1-car-

boxylate (EEDQ)[49] has proved to be especially effective. For example, the (1,3-dithianyl)methyl (Dim) ester[50] of *tert*-butyloxycarbonylaspartic acid **10** reacts smoothly with **6** in the presence of EEDQ to give the N^4-glucosaminylasparagine ester **11**, which is ready for selective deblocking.[51,82]



11 74%



4.2. The β-Glucosyl-Serine Linkage

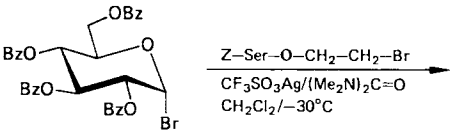
The β-glycosidic linkage to the serine hydroxyl group, in the form of xylose derivatives of type **2**, is especially characteristic of the proteoglycans in the animal kingdom. In the plant kingdom and in fungi, however, other carbohydrates occur as connecting partners; thus, consideration of this type of linkage should not be confined to xylose. This is further justified by the fact that the chemical properties of this bond are not greatly influenced by the type of carbohydrate involved. The first syntheses of glycosylserine compounds of this sort were carried out by means of dihydrooxazole derivatives of glucosamine.[52] Carbohydrate ortho esters react with *N*-protected serine and threonine esters in a similar fashion to give the corresponding glycosides.[53] Xylosylserine conjugates were obtained by *Lindberg* et al. under the conditions of the Koenigs–Knorr reaction.[54,55]

For details of the large number of other β-glycosylserine or -threonine derivatives that have been prepared under Koenigs–Knorr or Helferich conditions, the reader is referred to the comprehensive reviews already published.[30,31] These methods have also been successfully used in the synthesis of galactosyl-δ-hydroxylysine model compounds.[56]

The modern variants of the Koenigs–Knorr reaction are equally well suited to the glycosylation of the serine hydroxyl group. Z-serine-2-bromoethyl ester,[57] for example, reacts with the α-D-glucopyranosyl bromide **12** in the presence of silver trifluoromethanesulfonate/tetramethylurea[58] to form the completely protected glucosylserine derivative **13**.[59] It is interesting that the halogen in the ester protective group is not attacked under these conditions.

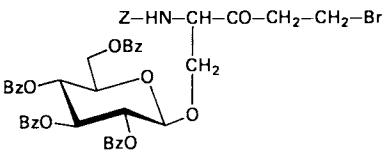
Modern alternatives to the Koenigs–Knorr synthesis[37] have also proved useful in the preparation of *O*-glycosylserine linkages. For example, the xylopyranose **14** was allowed to react with the Z-serine allyl ester **15** by means of the trichloroacetimidate method[37,60] to give, in good yield and with high selectivity, the xylosylserine derivative **16**, in which the hydroxyl groups in the carbohydrate part of the molecule are protected as benzyl ethers.[61]

Compound **16** can also be obtained by reaction of the benzyl-protected xylopyranosyl fluoride **17** with the serine



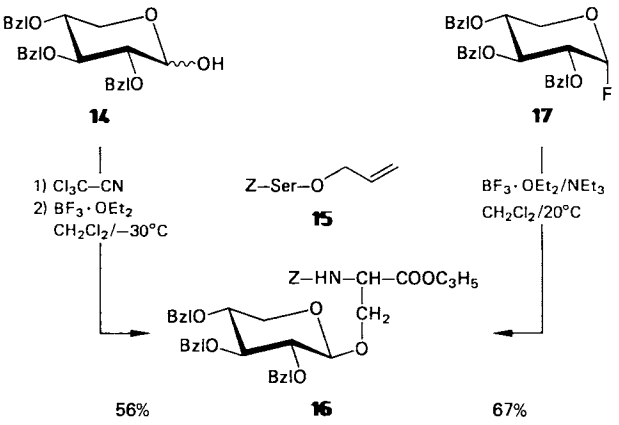
12

Bz = C_6H_5–CO



13 53–81%

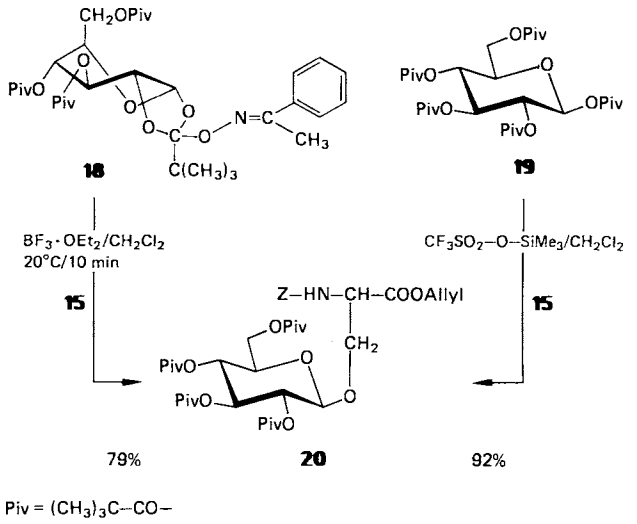
ester **15** in the presence of boron trifluoride etherate and triethylamine.[62] Both reactions have the advantage that they take place rapidly under homogeneous conditions. In both cases, however, the corresponding α isomer is also formed (ca. 1 : 6) and must be removed chromatographically.



The glycosylation with *O*-acyl-protected glycosyl fluorides is highly stereoselective.[62] The products formed in this way, such as **20**, can also be synthesized effectively and under homogeneous conditions when one starts from the novel ortho ester **18** containing an oxime moiety.[63] Finally, the glycosylation of **15** is very smoothly accomplished by allowing the pentapivaloylglucose **19**,[64] as the 1-*O*-acyl sugar, to react with trimethylsilyl trifluoromethanesulfonate.[65] The glycoconjugate **20** is formed stereoselectively and in almost quantitative yield.[66]

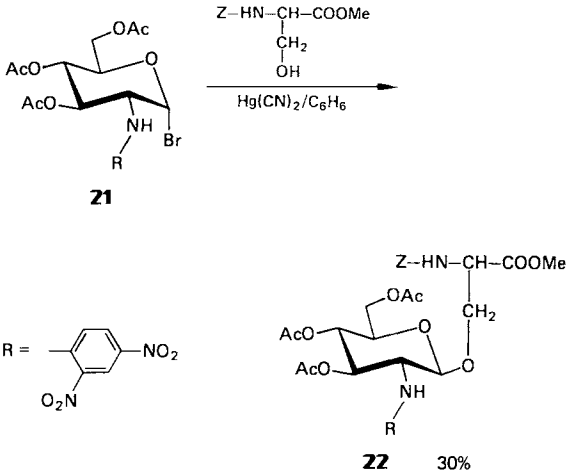
4.3. The α-Glycosidic Serine/Threonine-*N*-Acetylgalactosamine Linkage

The formation of the α-glycosidic linkage between *N*-acetylgalactosamine and serine or threonine (structure type **3**), which is characteristic of many serum and membrane glycoproteins, at first presented great problems. In the corresponding glucose series, substituted glycosyl donors, even with non-neighboring-group-active substituents on C-2, such as the *O*-acetylated 2-deoxy-α-D-glucopyranosyl bromide **21**, reacted with Z-serine methyl ester under Koenigs–Knorr or Helferich conditions to give the β-

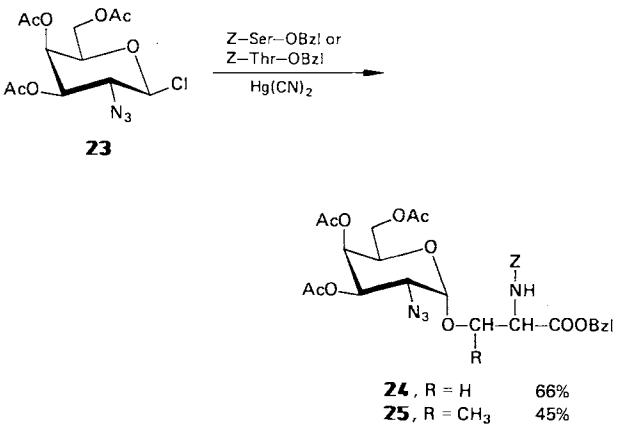


Piv = $(CH_3)_3C$–CO–

glycosyl amino-acid derivative, e.g., **22**,[67] almost exclusively.

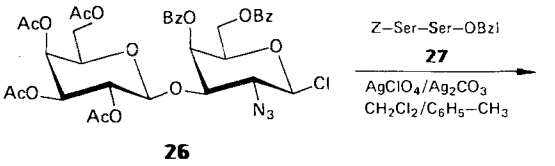


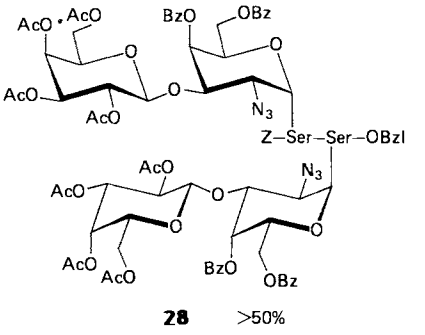
The solution to this problem was found by *Paulsen* et al.[68] Reactive glycosyl chlorides containing the 2-azido function as a non-neighboring-group-active substituent were used as glycosyl donors under the conditions of "in situ anomerization." This method was applied by *Ferrari* and *Pavia*[69] to the glycosylation of serine and threonine. They converted Z-threonine or -serine esters into the desired glycopeptides **24** or **25**, respectively, the precursors



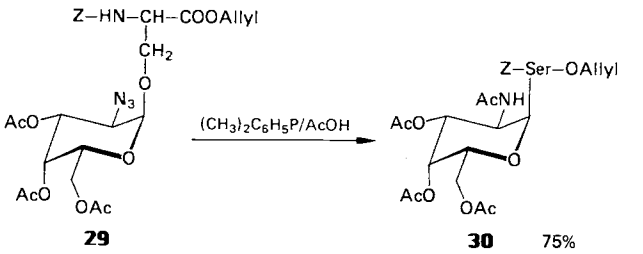
of structures of type **3**, by reaction with the protected 2-azido-β-galactosyl chloride **23**.

The azide method[68] is favored by the fact that 2-azido-glycosyl halides, such as **23**, are readily available by the azidonitration route.[70] In this way, *Paulsen* et al. have worked out an effective α-glycosylation method using the system silver perchlorate/silver carbonate in dichloromethane/toluene.[71] The simultaneous α-glycosidic linking of two disaccharide units to the serylserine derivative **27** by reaction with the glycosyl halide **26** illustrates the power of this method.[72a,b]





The selective reduction of the azido function in complex glycopeptides, such as **28**, is accomplished with nickel tetrahydroborate.[72] After acetylation of the amino group thus formed, structures of type **3** are obtained which embody partial structures of glycoproteins of T-antigen type associated with tumors. The azido group in compounds such as **24**, **25**, or **28** can also be reduced with hydrogen sulfide.[73,74] With dimethyl(phenyl)phosphane in glacial acetic acid it is possible to convert the azido group in the base-sensitive glycosylserine and -threonine derivatives, e.g., **29**, directly into the acetamido group (e.g., **30**).[75]



α-Glycosides of 2-azido-2-deoxygalactopyranose with serine derivatives are also available by means of the trichloroacetimidate method.[76] Another α-glycoside synthesis, without mercury or silver reagents, is based on the activation of the free anomeric hydroxyl groups of benzyl-protected carbohydrate building blocks with trifluoromethanesulfonic anhydride.[77] Similarly, by means of the

azido form, the method can be used in the synthesis of the α-galactosaminylserine and -threonine derivatives.[78] In the glycosylation of the threonine derivatives, in particular, significant amounts of the β anomers are formed and must be separated.

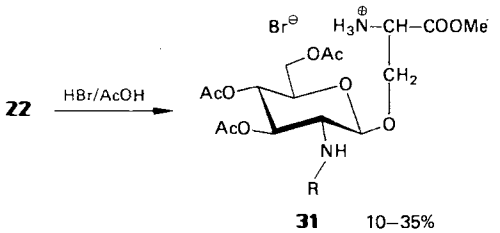
5. Selective Deblocking and Peptide Chain Extension on Glycopeptides

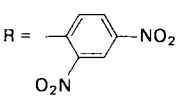
The selective removal of protective groups on glycosyl amino acids and glycopeptides remained an unsolved problem until the end of the last decade.[30,31] Only in particular cases was the selective deblocking of a particular functional group on the polyfunctional glycopeptide achieved and then only with considerable material losses.[67] The origin of these difficulties lies in the presence of glycosidic bonds in these molecules (see Section 3). Since the preparative methods for overcoming this problem were developed only recently and, in contrast to oligosaccharide synthesis[36,37] and to the glycosylation of amino-acid derivatives,[30,31] have not been extensively reviewed and since our research group has been deeply involved in the solution of this problem,[32] this aspect of glycopeptide synthesis will be the main thrust of this review.

5.1. The Lability of Glycosidic Linkages

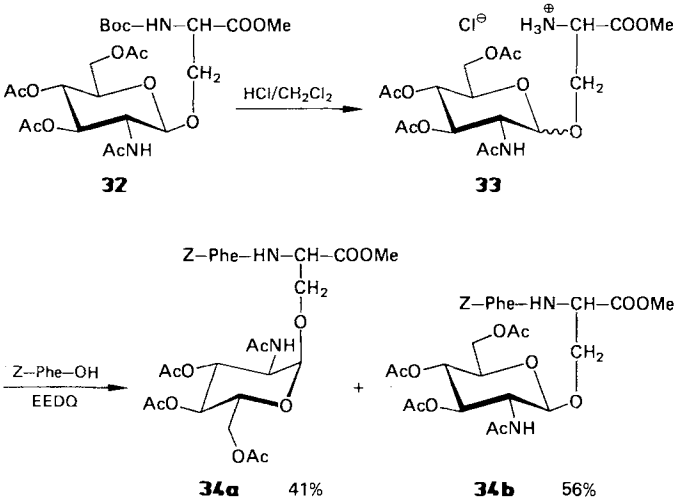
The glycosidic bonds of the glycopeptides, being acetal-like bonds, are always more or less acid-sensitive. The most acid-stable are the *N*-glycosides of type **1** and the glycosyl derivatives of δ-hydroxylysine. Nevertheless, oligosaccharidic glycopeptides contain, besides these relatively stable connecting structures, *O*-glycoside bonds within the oligosaccharide portion, so that the sensitivity toward acids shown in the following examples applies also, in principle, to such glycopeptides.

Attempts to selectively remove the Z group from the glycosylserine derivative **22** by means of hydrobromic acid in glacial acetic acid brought about extensive cleavage of the glycoside bond[67] in addition to formation of the uncharacterized ammonium salt **31**. After *N*-terminal chain extension with Z-amino-acid *p*-nitrophenyl esters, the corresponding glycodipeptides were obtained in 12–34% yield based on **22**.





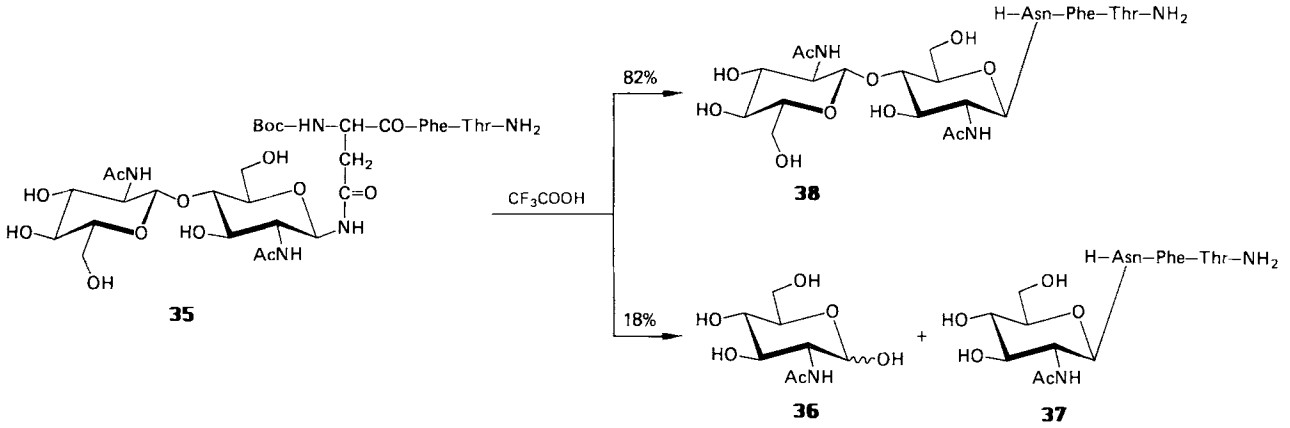
If only weak nucleophiles are present in the solution, the cleavage of the glycoside bond is suppressed; the danger of anomerization, however, is always present. We have observed this in the removal of the Boc group from **32**.[32,79] The *N*-terminal chain extension with Z-phenylalanine revealed that the amino-deblocked intermediate **33** was present as an anomeric mixture. The anomeric glycodipeptides **34a** and **34b**, which exhibit very similar chromatographic behavior, could be separated and their structures



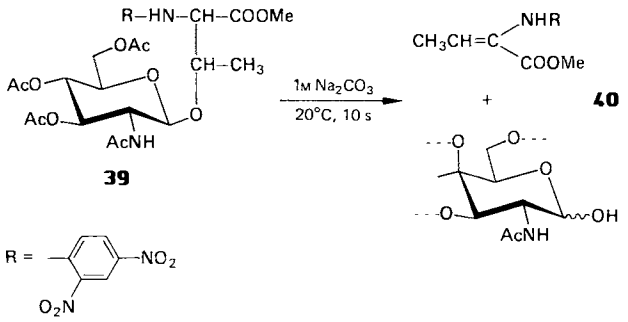
unequivocally characterized.[79] However, the Boc protective group has been used in a solid-phase glycopeptide synthesis in which the removal from the resin was even carried out with hydrofluoric acid in anisole,[80] the glycoside bond remaining intact. This is surprising since hydrofluoric acid normally attacks oligosaccharides and even 1-*O*-acyl monosaccharides very quickly.[62] Nevertheless, more recent work shows that the lability of the *O*-glycosidic bond appears to depend on the structure of the glycopeptide. *Sinaÿ* et al.[81] were able to remove the *tert*-butyl esters of *O*-glycopeptides selectively with trifluoroacetic acid without cleavage of the glycosidic bond. However, weakly nucleophilic trifluoroacetic acid can also cleave glycosidic linkages, e.g., in the chitobiosyl tripeptide **35**. Together with the desired **38**, which represents a partial structure of the human complement factor B, **36** and **37**, the products of cleavage, were obtained in a ratio of 2 : 9.[44,82] Analogues of **35** with acyl-protected carbohydrate portions were not attacked by trifluoroacetic acid at the glycosidic bond.[44] These different results show clearly that the acidolysis of protective groups in glycopeptide synthesis should be checked in each individual case.

The synthesis of glycopeptides of the glycosylserine or -threonine type (**2** or **3**) turns out to be more difficult, because of the characteristic base lability of the *O*-glycosyl-β-hydroxycarboxylic acid derivatives.[83] In fact, this reaction is used analytically to demonstrate the presence of the *O*-glycosylserine or -threonine linkage in glycoproteins.[84] For example, in sodium carbonate solution, the protected glycosylthreonine methyl ester **39** is cleaved quantitatively within seconds, before cleavage of the methyl ester occurs.[85]

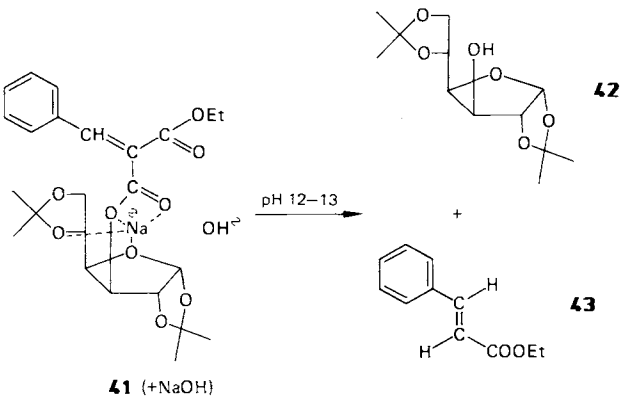
The rate of the β-elimination to α-aminoacrylic acid derivatives, such as **40**, depends on the structure of the glycoconjugate and especially on the substituents on the amino



and carbonyl functions of the amino-acid portion. Esters and amides undergo elimination at room temperature already at pH 9.[85]



Since the benzyl- or *tert*-butyl-ether-protected serine and threonine derivatives commonly used in peptide synthesis are stable, the facile β-elimination of the glycan portion in compounds such as **39** appears, at first sight, to be surprising. It is understandable, however, when one takes into account the complexing ability of carbohydrates with respect to cations and amines. In the saponification of the unsymmetric benzylidenemalonic acid diester **41**, for example, this property explains the removal of only the secondary carbohydrate ester structure.[86]



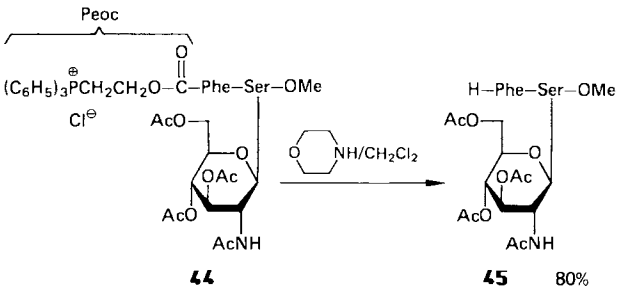
This ability to form complexes is also responsible for the active ester properties of the peptidylcarbohydrate esters that are biologically important in the peptidyl transfer step of protein biosynthesis, i.e., in the transfer of P-site-bound peptidyl-tRNA to the A-site-bound aminoacyl-tRNA.[87]

The base lability and the potential acid lability of the glycopeptides make it necessary, in the synthesis of these compounds, to use protective groups that can be removed under mild and, if possible, neutral conditions. In earlier work only the benzyl and the Z group fulfilled these demands.[30,31] Since they are removed simultaneously upon hydrogenolysis, however, they must be combined with other protective groups for selective deblocking, such as the methyl group, which themselves cannot be removed without destroying the glycoside bond (cf., for example, **39** → **40** and ref. [54, 67]). These problems could only be solved by the introduction of new, more suitable protective groups and the use of other known protective groups in glycopeptide synthesis.

5.2. The Phosphonioethoxycarbonyl (Peoc) Protective Group

Since the 2-triphenylphosphonioethoxycarbonyl (Peoc) protective group[88] can be removed from the amino group even under very mild basic conditions, we used it in our first glycopeptide syntheses.[89] It allowed the targeted synthesis of *N*-glycopeptides when combined with either the *C*-terminal benzyl or the *tert*-butyl group. Owing to the high stability of the Peoc group toward acids, the Peoc-amino acid chlorides,[90] which are stable at room temperature, can be used for chain extension.

The cleavage of the Peoc group with morpholine in dichloromethane is so mild that even the base-labile *O*-glycosylserine linkage remains completely intact, as, for example, in the deblocking of the glycopeptide **44**.[91] The ester groups and the *O*-glycoside bond, which is sensitive to elimination reactions, remain intact so that the peptide



chain can be lengthened specifically at the deprotected amino group in **45**.[*]

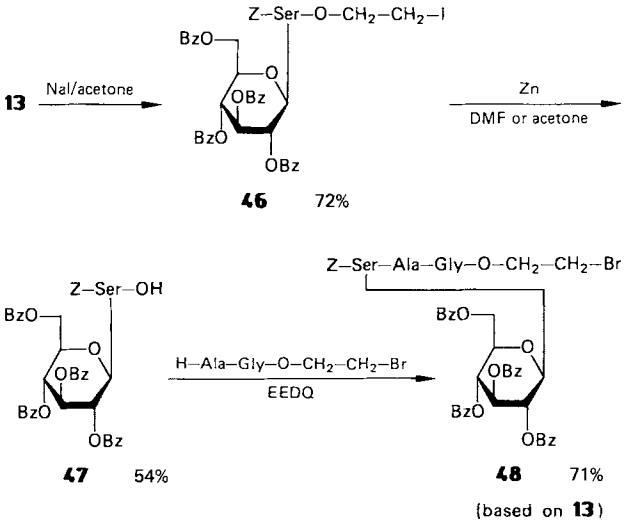
In spite of the advantages of the Peoc group, which, in combination with the easily removable benzyl group, allowed, for the first time, a clean, selective deblocking of a glycopeptide,[89] there are some drawbacks to their general use in glycopeptide synthesis: (1) The Peoc group is a bulky residue which hinders the condensation reaction. (2) The high base-lability of the protective group, which is the basis for its easy removal, demands special care in performing the synthesis. (3) The Peoc protective group is a cationic substituent whose halogen counterion leads to problems in the glycosylation with silver or mercury reagents. Thus, it is necessary to use the Z group in the glycosylation step in the synthesis of the glycopeptide structure **44**.[91] To achieve its selective removal, however, a *C*-terminal methyl ester must be used, whose cleavage can no longer be carried out without breaking the glycoside bond by β-elimination[54,85] (see Section 5.1). From this it is clear that, for targeted glycopeptide synthesis, other alternatives to the benzyl group as a carboxy-protecting group had to be found.

5.3. The 2-Haloethyl Group as a Carboxy-Protecting Group

The use of the 2-bromoethyl group as a reversible carboxy-protecting group for peptide synthesis was first described by *Ugi* et al.,[92] who achieved its cleavage with a supernucleophilic cobalt(I) complex. In our investigations,[57] we had attempted to adopt the bromoethoxycarbonyl (Beoc) group, the precursor of the Peoc group,[93] to protect the carboxy group. We thereby found that the 2-chloro- and 2-bromoethyl esters of amino acids and peptides, after being converted into the iodoethyl ester, could be selectively cleaved with zinc in dimethylformamide (DMF). This neutral deblocking reaction provided the first opportunity to deblock the carboxy function on the base- and acid-labile glycosylserine derivative **13** in the presence of the Z group.[59]

Both the glycosylserine-2-iodoethyl ester **46** and the carboxyl-deblocked product **47** could be isolated and characterized. If the chain extension is performed with crude **46** and **47**, one obtains the glycotripeptide **48** in 71% yield based on **13**.[94] The gentle deblocking of the bromoethyl ester does not destroy either the ester-protecting groups in the carbohydrate part, the *N*-terminal Z protective group, or the *O*-glycoside bond, which easily undergoes elimination reactions.

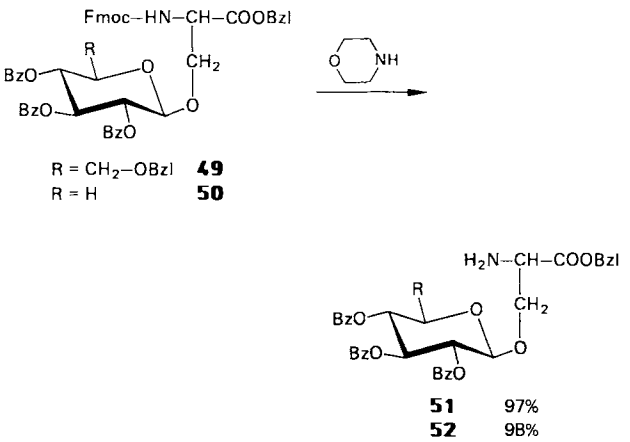
The low yield in the deblocking step can be traced back to the fact that **47** is partly adsorbed on the zinc salts formed and, because of the acid and base lability of the *O*-glycosylserine linkage, cannot be isolated under the workup conditions. These disadvantages can be avoided if the cleavage of the 2-bromoethyl ester is carried out electrochemically.[95,96] The only disadvantage of this method lies in the apparatus required, which is not always readily available.



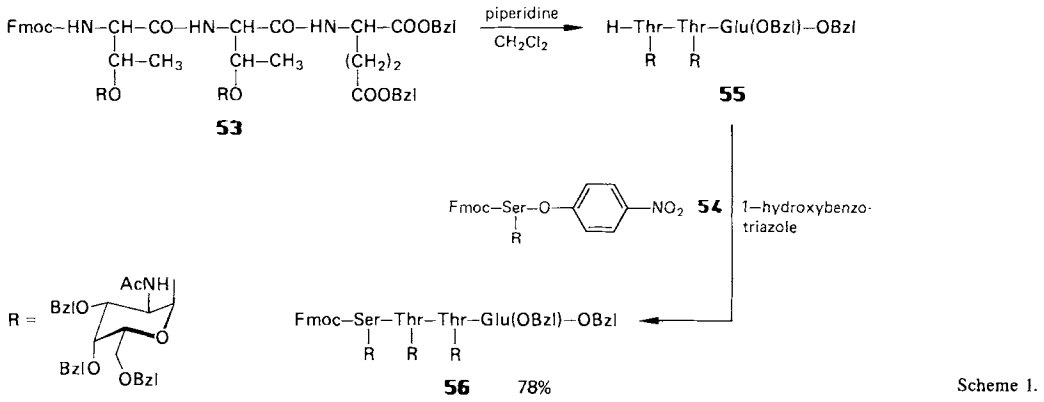
The bromoethyl ester[59,94,96] and the Peoc group,[89,91] together with the reversible protection provided by the Z or benzyl group, allowed, for the first time, effective and selective deblocking and chain extension even on the sensitive *O*-glycosylserine derivatives. The disadvantages mentioned above, however, still make it necessary to seek new methods. It appeared to be especially advantageous to find a protective group for glycopeptide synthesis that, like the Peoc residue, is easy to remove under similarly mild conditions but does not have the inherent disadvantage caused by the cationic structure in the glycosylation reaction. These demands are fulfilled by the (9-fluorenyl)methoxycarbonyl (Fmoc) protective group.[97]

5.4. The (9-Fluorenyl)methoxycarbonyl (Fmoc) Protective Group

The neutral Fmoc protective group[97] is somewhat less base-labile than the Peoc residue. However, we could show that the Fmoc group can be removed selectively, and practically quantitatively, from the protected *O*-glucosyl- and *O*-xylosylserine derivatives, **49** and **50**, respectively, which are sensitive to base-catalyzed β-elimination.[98] In contrast



[*] In some cases, the carbohydrates are given as Haworth formulas, since these, in combination with the shorthand notation for the amino acids, are better suited to represent β-glycosides.



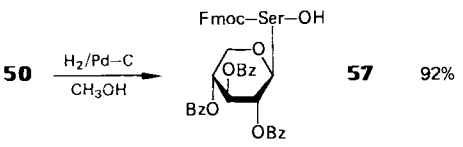
Scheme 1.

to the practice in peptide chemistry, and also to that of *Pavia* et al.,[78,99] who have also described the use of Fmoc, we do not use the relatively strongly basic piperidine ($pK_s \approx 11.1$) but the order of magnitude weaker morpholine ($pK_s \approx 8.3$) to remove the Fmoc group. In this way, we remain below the sensitivity limit above which the glycoside bond would be destroyed.

Once the problem of selective deblocking with retention of the numerous ester structures and the glycoside bond in products such as **51** and **52** has been solved, the subsequent chain extension presents no further problems. Morpholine can be used to remove the Fmoc group selectively and effectively from complex glycopeptides. This emphasizes the general usefulness of this method in the synthesis of glycopeptides.[98]

Ferrari and *Pavia*[100] applied the Fmoc group in combination with active esters, benzyl protective groups being used in the carbohydrate part of the molecule. They thereby synthesized the monosaccharidic T_N-antigen form of the *N*-terminal triglycopentapeptides of human glycophorin with M- and N-blood-group structures.[101] A typical example is presented in Scheme 1.

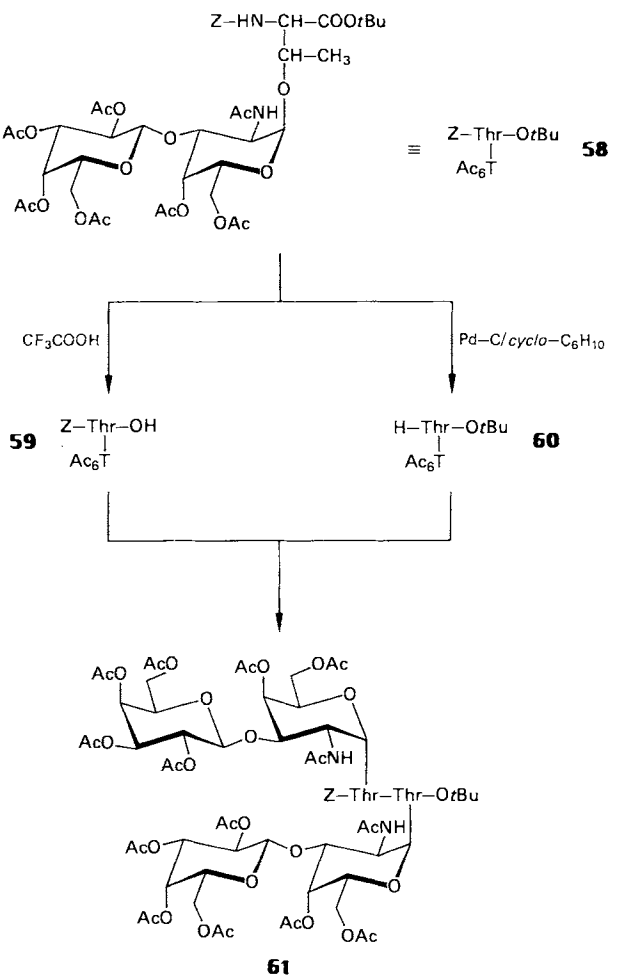
The only drawback to the combined use of Fmoc groups and benzyl esters shown in these examples is the insufficient stability of the Fmoc group during the hydrogenolysis of the benzyl ester.[102] Our own experiments have shown, however, that the Fmoc-*O*-xylosylserine benzyl ester **50** can be selectively cleaved at the *C*-terminus.[103] Thus, in the presence of the Fmoc group, selective *C*-terminal chain extension and the synthesis of larger glycopeptide units, for example, by means of the fragment-condensation technique,[14] is possible.



5.5. The *tert*-Butyl Ester Protective Group in Glycopeptide Synthesis

Despite the risks associated with acid treatment of glycopeptides (see Section 5.1), *Sinaÿ* and *Verez Bencomo*[81] have used the selective cleavage of the *tert*-butyl ester in the presence of the Z group for the construction of *N*-terminal triglycopentapeptides with the disaccharidic T-antigen structure,[104] which is important as a tumor-associated antigen structure.[8] In this way, the completely protected Z-glycosylthreonine *tert*-butyl ester **58** can be deblocked either *C*-terminally to give **59** or *N*-terminally to give **60**.[81]

Upon treatment with EEDQ, the two selectively deblocked compounds give the complex, completely protected, glycodipeptide **61**, which contains the same combination of protective groups as the starting material **58**. By means of this method, *Sinaÿ* and *Verez Bencomo*[104] were able to prepare the *N*-terminal T-antigen triglycopentapep-



tides of glycophorin. The experimental details of this synthesis, however, have not yet been published.[81, 104]

By contrast, *Paulsen* et al.[74] have observed side reactions in the cleavage, with trifluoroacetic acid, of the *tert*-butyl esters of a compound very similar to **58**. They therefore used 98% formic acid for the deblocking. They mention, however, that two rotamers of the Z group are present in the quantitatively obtained product.

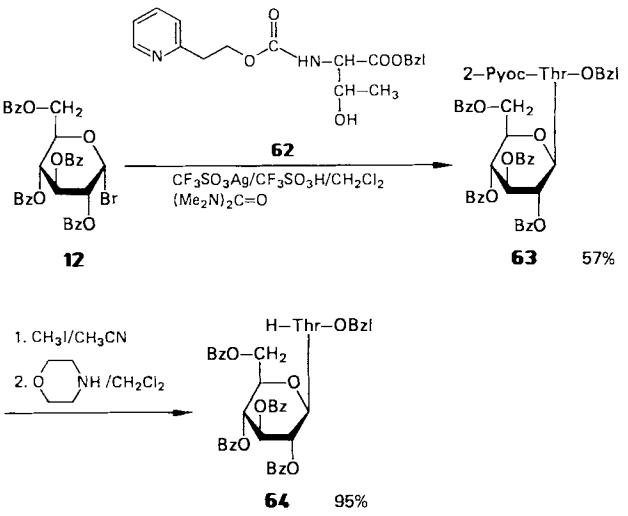
At this point, a brief comment should be made on the structure confirmation of complicated glycopeptides, which is only possible with high-field NMR spectroscopy. The structure confirmations of α-galactosaminylthreonine derivatives, such as **58** and **59**, have proved to be especially difficult since in their ^{13}C-NMR spectra the signals for the α- and β-anomeric carbon atoms are only slightly shifted relative to each other. *Pavia* et al.[77, 78, 100] have found the solution to this problem. They recognized that the ^{13}C-NMR signal for the γ-methyl group of threonine is a very sensitive probe for the anomeric configuration. For the α anomers it appears at $\delta = 18$–20, whereas in the spectra for the β anomers it is shifted about 2 ppm toward higher field.

Finally, a particular problem encountered in the use of *tert*-butyl esters[74, 78, 104] and the Boc group[80] in the syntheses of *O*-glycopeptides should be discussed. For the removal of the *tert*-butyl group, in peptide synthesis, nucleophilic trapping agents, such as 1,2-ethanedithiol,[106] must be added in order to avoid side reactions due to *tert*-butyl cations or *tert*-butyl trifluoroacetate.[107] The presence of these nucleophiles increases the risk of glycoside cleavage during the removal of protective groups under acidic conditions. The effects of powerful protonating agents on the sensitive compounds must be carefully checked in each case. This restriction applies even to the stable *N*-glycosylasparagine (**1**) and *O*-glycosyl-δ-hydroxylysine glycopeptides if oligosaccharide side chains are present. Monosaccharidic glycopeptides of this type have been successfully prepared, however, by means of *tert*-butyl[56] or Boc-protected amino acids, even in a solid-phase synthesis.[108] In the case of the solid-phase-synthesized somatostatin sequence, however, the structure could only be confirmed by mass spectrometry,[108] which usually gives no information about the stereochemistry.

If one wishes to eliminate the uncertainties associated with acid deblocking, one must make use of protective groups, such as Peoc and Fmoc (Sections 5.2–5.4), that are removable under mild conditions. Their disadvantage lies in their permanent sensitivity and, in part, in solubility problems inherent in their use in the synthesis of large glycopeptide units. To overcome these difficulties and to solve the competing requirements for stability of the protecting group during synthesis and lability during deblocking, we have turned our attention to the principle of the two-step protective group.[109]

5.6. The 2-Pyridylethoxycarbonyl (Pyoc) Protective Group

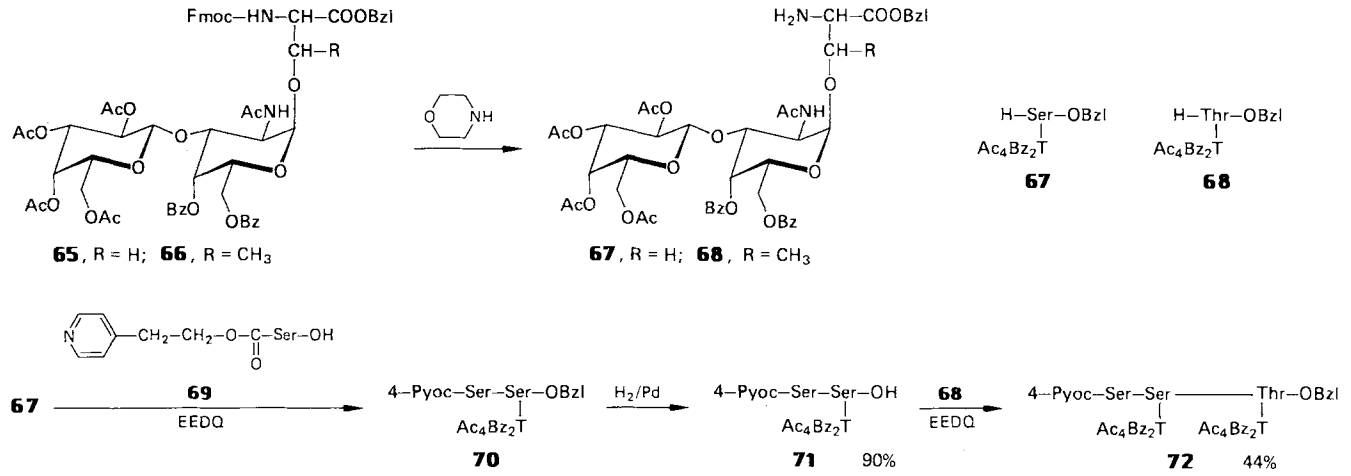
The 2-(2-pyridyl)ethoxycarbonyl (2-Pyoc)[110] and the 2-(4-pyridyl)ethoxycarbonyl (4-Pyoc)[111] protective groups are very stable toward acids and bases but can be removed under very mild conditions, after a simple modification, from the blocked amino function. The glycosylation of the 2-Pyoc-threonine benzyl ester **62** to give **63** with the benzoyl-protected glucopyranosyl bromide **12** by the silver triflate method[58] requires the addition of molar amounts of trifluoromethanesulfonic acid, since, without it, the corresponding ortho ester is formed exclusively.[112] The selective cleavage of the stable Pyoc group from the labile glycosylthreonine derivative **63** is achieved by first methylating the pyridine N atom. The α-methylene group is thereby made so acidic that quantitative cleavage occurs even with morpholine in dichloromethane to form **64**, which can undergo chain extension.[112]



Because of the promotion of ortho ester formation by the Pyoc group, it is advantageous, to employ the Fmoc group in the glycosylation step; the advantages of stability and solubility due to the Pyoc group can then be exploited in the chain extension reactions. This combination method is shown in Scheme 2 for the synthesis of the completely protected, *N*-terminal diglycotripeptide **72** of the glycophorin with M specificity and of the disaccharidic T-antigen structure.[113] The selective removal of the Fmoc group with morpholine[98] also succeeded with the disaccharidic glycosylserine (**65**) and -threonine (**66**) derivatives without destroying the numerous ester groups and the sensitive *O*-glycoside bonds. The free amino compounds **67** and **68** tend to undergo base-catalyzed self-destruction. Therefore, they are immediately condensed with the 4-Pyoc-protected carboxyl components **69** or **71** to give **70** (51% based on **65**) or **72**, respectively. In the cleavage of the benzyl ester **70**, another advantage of the Pyoc group is evident: it is stable toward hydrogenolysis.

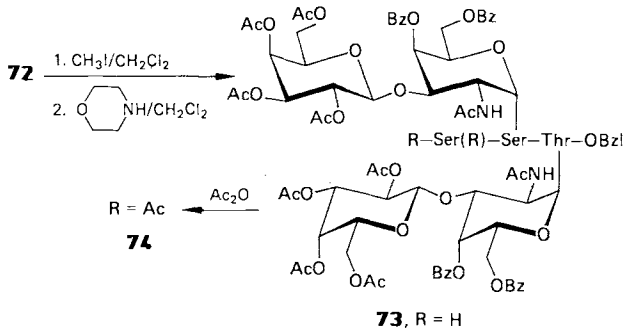
The stable 4-Pyoc group, after conversion to the pyridinium form, can then be removed, completely selectively under mild conditions, from the complex and sensitive glycopeptide **72**. In the base-sensitive product **73**, the free amino group is acetylated to give **74** (76% based on **72**).[113]

These and other glycopeptide syntheses[105, 112, 113] show the efficiency of the Pyoc method. The single restriction is that the alkylation of the stable protective group to give the labile form is not possible in the presence of amino acids that can undergo alkylation, e.g., cysteine.



Scheme 2.

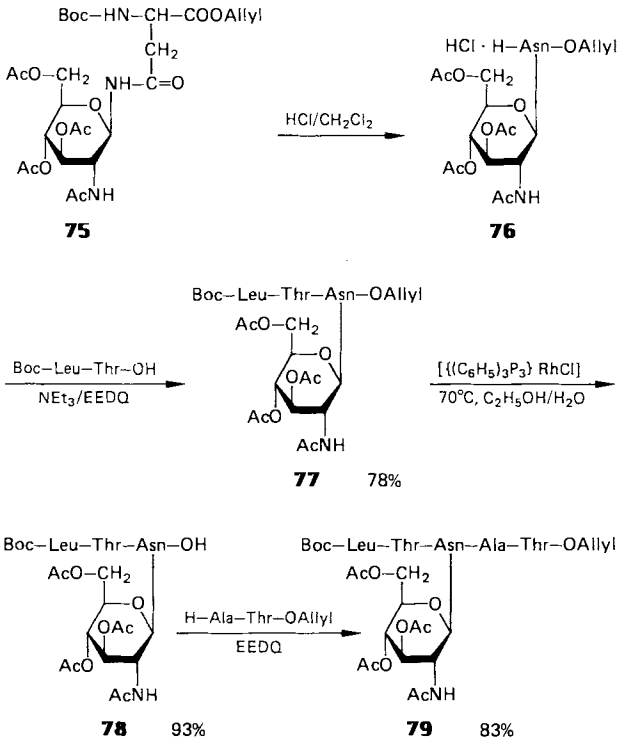
The ideal protective group for glycopeptide synthesis should have a stability similar to that of the Pyoc group but be removable under the mildest conditions, as is the pyridinium form of the Pyoc group, and require no preceding transformations. The allyl protective groups fulfill these requirements.[44,61,114,115]



5.7. Allyl Esters and Allyloxycarbonyl (Aloc) Protective Groups

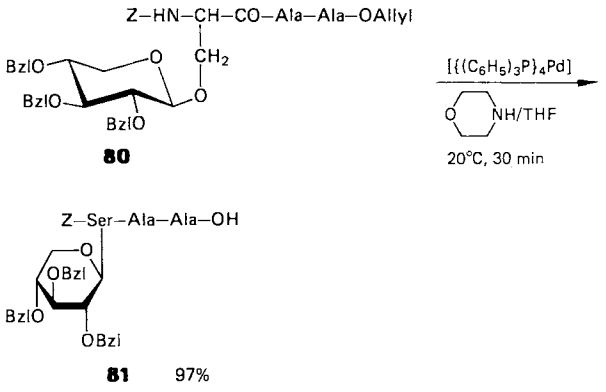
Allyl esters of amino acids are easy to prepare and are stable under a wide variety of glycosylation conditions.[44,61–63,115] In the less sensitive *N*-glycopeptides, such as **75**, the Boc group can be removed selectively in the presence of the allyl ester, either with hydrogen chloride in dichloromethane or with trifluoroacetic acid.[44] The quantitatively formed amino-deblocked product **76** can be *N*-terminally extended, e.g., to glycotripeptide **77**. In order to selectively cleave the allyl group from **77**,[115] the allyl ester is isomerized by means of a rhodium(I) catalyst[116] to a propenyl ester, which, under the reaction conditions, undergoes immediate hydrolysis. Under these neutral conditions, all the other bonds are retained. The practically quantitatively obtained product **78** can then be *C*-terminally extended, e.g., to the glycopentapeptide **79**, a partial structure of human orosomucoid (acidic α_1 glycoprotein).[117] The small allyl group has the advantage that it does not interfere in condensation reactions involving such large molecules, either sterically or by reducing their solubility. The yields are therefore always high.

For the selective allyl ester cleavage in the more sensitive *O*-glycosylserine or -threonine derivatives, which tend to undergo elimination reactions, we have found[61] an

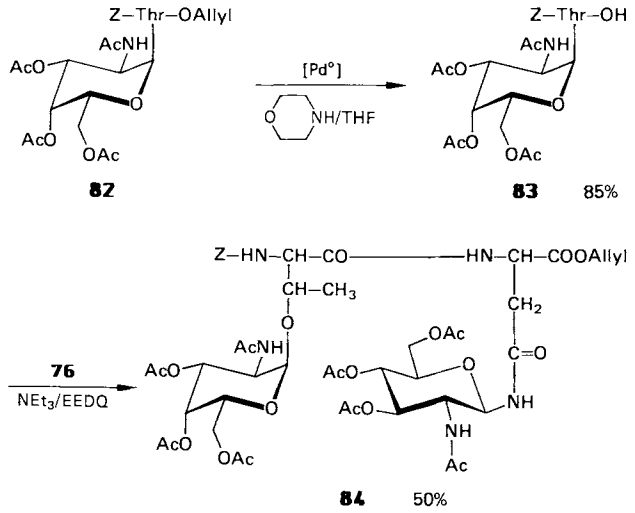


even milder method; namely, the allyl transfer to morpholine[118] as the accepting nucleophile. For example, the xylotripeptide **80** can be deblocked quantitatively and chemospecifically at the carboxy function in 30 min under almost neutral conditions in tetrahydrofuran (THF) to give **81**.[61]

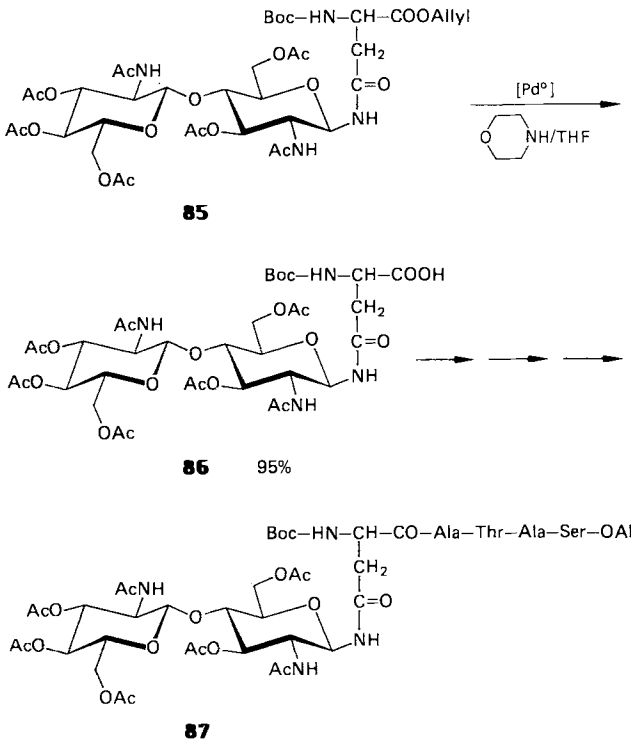
In β-lactam antibiotic synthesis, unknown to us at that time, an allyl ester cleavage in the sense of a palladium(0)-catalyzed transesterification had already been used.[119] Even earlier the cleavage of allyl esters with palladium catalysts and ammonium formate had been described as a variant of hydrogenolysis.[120] However, it requires a tem-



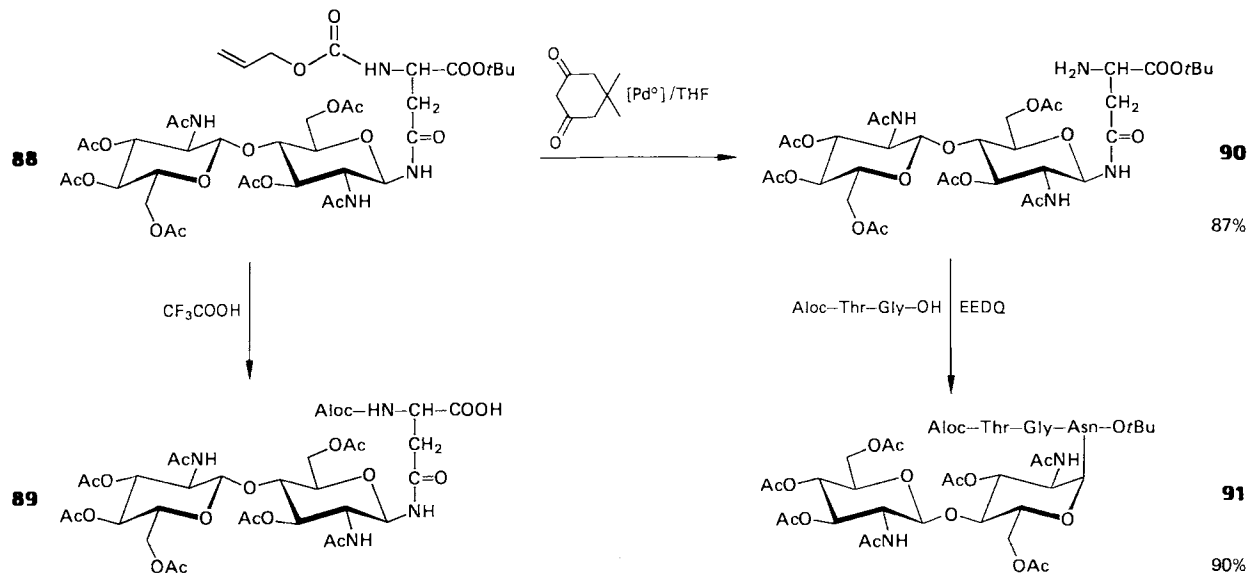
perature of 100 °C and is not usable in glycopeptide synthesis. Morpholine has the advantages that it is easily removed and does not attack the sensitive glycoside bond. The method is also successful with α-galactosaminylthreonine allyl ester **82**. The deblocked product **83** is coupled to the *N*-terminal N^4-glucosaminylasparagine allyl ester **76** to give diglycopeptide **84**, which contains both an α-*O*- and a β-*N*-glycosyl amino acid and embodies a particularly complex partial structure of human glycophorin.[96]



This extremely gentle cleavage of allyl esters under homogeneous conditions works equally well, both selectively and effectively, with the *N*-glycopeptides, such as chitobiosylasparagine **85**. The carboxyl-deblocked product **86**, obtained almost quantitatively, was converted by two chain extensions with dipeptide allyl esters into the chitobiosyl pentapeptide **87**, a partial structure of a transmembrane neuraminidase of an influenza virus.[44]



Palladium(0)-catalyzed allyl transfer to nucleophiles such as morpholine or dimedone (5,5-dimethyl-1,3-cyclohexanedione) can also be used to remove smoothly the allyloxycarbonyl (Aloc) group from peptides and glycopeptides.[114] This protective group, which had already been described,[121] was held to be unuseable, since even under



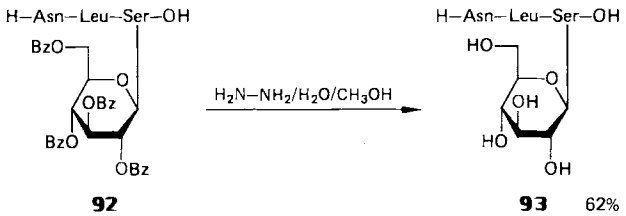
drastic conditions it was only incompletely removed.[122] However, an advantage of the Aloc group is its stability toward trifluoroacetic acid,[114] e.g., in the practically quantitative *tert*-butyl-ester cleavage of the chitobiosylasparagine derivative **88** to **89**.[47] The palladium(0)-catalyzed removal of the Aloc group is not affected by amino acids with nucleophilic groups (e.g., methionine).[114] Since an amino function is thereby deblocked, the CH acid dimedone is better suited than morpholine as the trapping reagent. This method has been employed to obtain compound **90** selectively and practically quantitatively from **88**. Compound **90** can be extended at the *N*-terminus, e.g., to chitobiosyl tripeptide **91**,[47] a partial sequence of the linkage region of a neuraminidase of another influenza virus.[123]

This synthesis is a further example of the use of these methods to construct immunologically interesting glycopeptides. The prerequisite for the immunological investigation of synthetic glycopeptides is, however, that they can be freed of the protective groups on the carbohydrate portion and that they can be bound to suitable carrier molecules.

6. The Removal of Protective Groups in the Carbohydrate Portion and the Attachment of Synthetic Glycopeptides to Proteins

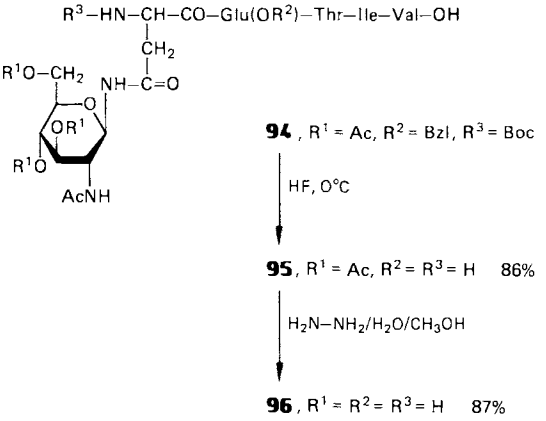
The removal of the protective groups from the carbohydrate part of the molecule is problematic for two reasons: (1) There is the danger of β-elimination from glycosylserine and -threonine derivatives of type **2** and **3**. (2) The amino-acid residues can undergo racemization. Both processes occur under basic conditions when, for example, the ester protective group is cleaved with ammonia or triethylamine in methanol.[54,81] Such side reactions, especially racemization, were recently observed by *Paulsen* et al.[74] during the deblocking of a glycopeptide of the T-antigen type with various bases, e.g., amines. They described the removal of acyl protective groups in the saccharide part, without side reactions, by application of potassium cyanide in methanol/ethanol. With potassium cyanide in methanol, however, 20% racemization occurred in the threonine residue.

With base-sensitive glycosylserine derivatives, such as **92**, we were able to show that acetyl and benzoyl protective groups can be removed very safely and with no racemization by the use of hydrazine in methanol.[98] Excess hydrazine is removed by reaction with acetone.

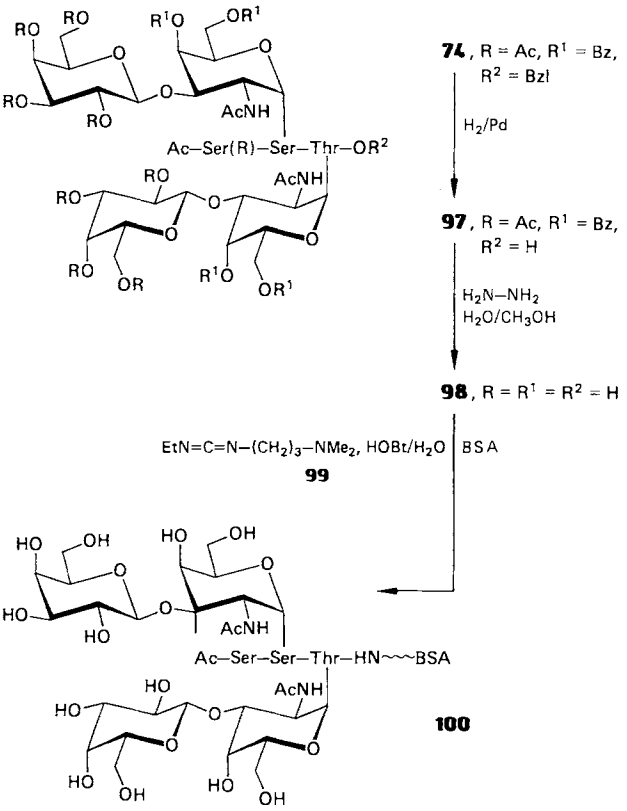


92 **93** 62%

Even *N*-glycopeptides, e.g., **95**, a partial sequence of fibroblast interferon, can be efficiently deblocked by use of the method.[124] In contrast, the hydrogenolytic cleavage of the γ-benzyl-ester group of glutamic acid in **94** did not work, so that the ester had to be removed simultaneously with the Boc group by means of hydrofluoric acid.[124] This demonstrates the limits of heterogeneous hydrogenation of the benzylic protective groups in complex molecules. On small units, the method is particularly suited for glycopeptide synthesis, because it proceeds under neutral conditions. The hydrogenation of benzyl ethers in the carbohydrate part of the glycopeptide was successfully used for deblocking by *Pavia* et al.[78,100]



The cleavage of the numerous ester groups in the complex diglycopeptide **74** was achieved, after hydrogenolysis of the *C*-terminal benzyl ester to **97**, gently and smoothly with hydrazine in methanol.[113] The reaction yields the diglycotripeptide **98**, which, according to *Springer* et al.,[8] embodies the tumor-associated T-antigen structure in a pure state according to the high-field ^{13}C-NMR spectrum. With these selective techniques of synthesis as a starting point, we have been able to attach immunologically rele-



vant and clearly defined glycopeptides, such as **98**, to bovine serum albumin (BSA).[113] The free carboxy group of the synthetic glycopeptide **98** was bound, in water in the presence of 1-hydroxybenzotriazole (HOBt)[125] and with the aid of the water-soluble carbodiimide **99**,[126] to the carrier protein without the use of an artificial spacer, that is to say, in a more or less natural manner. The bonding sites in conjugate **100** are probably largely the ε-amino groups of the lysine residues. According to photometric carbohydrate analysis, 38 of the 60 free amino functions of the protein were connected with the synthetic glycopeptide antigen structure.[113]

7. Outlook

Advances in the methods of preparative chemistry in the last decade have made possible the synthesis of complex, structurally clearly defined glycopeptides corresponding to typical segments of glycoproteins, which themselves, in turn, are the defining factors in biological recognition and selectivity. These new possibilities have emerged, on the one hand, through recent developments in the field of oligosaccharide synthesis[36,37] and, on the other, by means of the solutions presented in this review to the problems that are raised by the targeted synthesis of peptides containing sensitive glycoconjugate structures. The synthetic glycopeptides do not have the disadvantage of microheterogeneity which is characteristic of the natural glycoconjugates. They are obtainable in preparative quantities and can be linked to complex biological carrier molecules. In this form they can be used in interdisciplinary research and applications; for example, for the induction of antibodies, for the simulation of recognition phenomena, and for the determination of the structures of sensitive glycoproteins. In addition, they open up perspectives in the development of tissue-specific drugs and proteolysis-stable peptide factors.

In view of the many side-chain functions on peptides, the further development of glycopeptide syntheses will clearly require additional new methods which extend the protective group techniques presented here for these sensitive molecules.

I would like to give my heartfelt thanks to my co-workers, who have pushed the development of glycopeptide synthesis ahead with commitment, courage, and a treasury of ideas. They are: Regina Barthels-Herweg, Stefan Birnbach, Michael Buchholz, Siglinde Friedrich-Bochnitschek, Wolfgang Günther, Albrecht Harreus, Hermann Kauth, Uwe Klinkhammer, Michael Kneip, Klaus-Jürgen Pees, Waldemar Pfrengle, Wilfried Sager, Marita Schilling, Petra Schultheiss-Reimann, Carlo Unverzagt, and Herbert Waldmann. I would like to thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support, without which this work would not have been possible.

Emission of Microparticles from Automotive Sources—X-ray Photoelectron Spectroscopy in Environmental Analysis

By R. Schlögl*, G. Indlekofer, and P. Oelhafen

In the last fifteen years the necessity for efficient environmental protection has become generally accepted. However, before practical measures can be taken, a comprehensive assessment of the present environmental situation should be made, taking into consideration the risks involved in as well as the positive effects of any planned environmental changes—whether natural or man made. This clearly calls for close cooperation between the various scientific disciplines. For example, the treatment of exhaust fumes from motor vehicles has been of primary importance in measures taken to restrict the recent damage caused to woodland areas. The introduction of 3-Way-Catalyst technology has been regarded as a viable countermeasure. The following report is intended to describe a method for examining some side effects of catalyst usage. Accordingly, the chemical composition of microparticles emitted from combustion motors through the use of catalysts will be examined and some possible changes in the environment caused by such particles will be briefly considered. As in the area of research into catalysts for industrial synthesis a knowledge of the surface structure of such particles, i.e. the boundary layer between emission product and environment, is necessary in the investigation into their effects. Consequently, a surface sensitive technique from solid state physics, X-ray photoelectron spectroscopy (XPS or ESCA) has found novel use in the area of environmental analysis. In the following report emphasis will be placed on the description of measurement techniques and the interpretation of the results obtained. After a critical consideration of the experimental methods, examples from two different series of measurements on diesel and Otto motors equipped with soot filters or 3-way-catalysts respectively, will be given. Hopefully, this report will also stimulate establishment of the use of EPS in environmental research techniques.

1. Introduction

The catalytic cleaning of exhaust fumes from motors of all types is at present of considerable interest in the context of attempts being made to improve our environment.

The effects of such catalysts on the clearly harmful components of exhaust fumes has been thoroughly examined.[1, 2] The side effects of catalyst usage, such as the emission of metal microparticles—smaller than about 50 nm—and the alterations to emitted organic molecules are, however, less well known. This is due, on the one hand, to the fact that research conducted in this area about ten years ago in the USA concluded that such side effects were insignificant[2] and, on the other, to the fact that research methods have mainly concentrated on the analysis of gaseous emissions, while the investigation of sensitive techniques for the analysis of solid microparticles has been neglected.[3] This report describes the first results obtained in this area by means of the XPS technique—a technique that has long been known in analytical and surface physics,[4] but has, until now, been used only to a limited extent in environmental analysis in the USA.[5] A section outlining the possibilities and limitations of XPS in environmental analysis is followed by a section dealing with the experimental conditions. The experimental results then form the subject of the main section, where an attempt has been made to give a representative selection of available spectral data. This data was collected in investigations on the exhaust gases from a stationary diesel motor fitted with various soot filters and on the emissions from a motor vehicle with a 3-way-catalyst, also examined in a field test. The results are presented together in the order of the elements detected, with the main emphasis on gaining useful qualitative information. On the one hand because the quantification of the results is, in principle, methodologically difficult (this is alluded to in several places in the text) and, on the other because other techniques in surface physics (Auger electron spectroscopy or secondary ion mass spectrometry etc.) essentially afford more readily quantifiable results. Since the classical methods of environmental analysis lay emphasis in any case on the quantitative aspects, a further time-consuming and inaccurate *quantitative* method would seem superfluous. Nevertheless, a judicious combination of quantitative results obtained by conventional methods with the quantitative information about the chemical bonding obtained by XPS would greatly help in characterizing and assessing the effect of solid emissions.

The object of this study then is to illustrate the possibilities and limitations of XPS in environmental research in this context and a possible effect of the release of metal-containing microparticles into the environment will also be briefly discussed.

2. The Method

2.1. The Photoemission Experiment

By photoemission is meant the release of electrons by interaction of photons with atoms. Depending upon the energy, one can distinguish between low energy photoemission from valence states (ultraviolet photoelectron spectroscopy, UPS, typical photon energy 10–50 eV) and from energetically low lying core orbitals (X-ray photoelectron spectroscopy, XPS, typical energy values 1200–1500 eV). The kinetic energy of a released electron can be related, to a first approximation, to the corresponding binding energy by setting the sum of kinetic energy and binding energy equal to the (monochromatic) excitation energy. This experimental electron binding energy, which, for core levels differs by about 5% from the quantum mechanically defined dissociation energy, contains information about the nuclear charge of the atom (elemental analysis), while superimposed fine structure yields information concerning the chemical environment of an atom (chemical shift; electron spectroscopy in chemical analysis, ESCA). UPS data can give information concerning the structure of the molecular orbitals or electron bands of a sample.

From a photoelectron spectrum, one can read off the number of electrons (Y-axis) of a particular binding energy (X-axis). The simplified picture of an incoming photon knocking an electron out of an orbital, which then, free of any interactive forces, leaves the atom within 10^{-5} seconds is only a very approximate interpretation of the real process. The spectra can be complicated, due to the many coupling and relaxation interactions involved. This manifests itself in the appearance of characteristic fine structure and in a large linewidth of up to five times the width of the excitation radiation (XPS) of about 1 eV.

The experimental setup is shown schematically in Figure 1. Since electrons have a very small escape depth from any material, experiments must be carried out in ultra-high vacuum. This also avoids any disturbances caused by adsorbed substances. Because of this small escape depth, the information contained in the spectra taken from solid samples refers only to a depth of a few atomic layers.

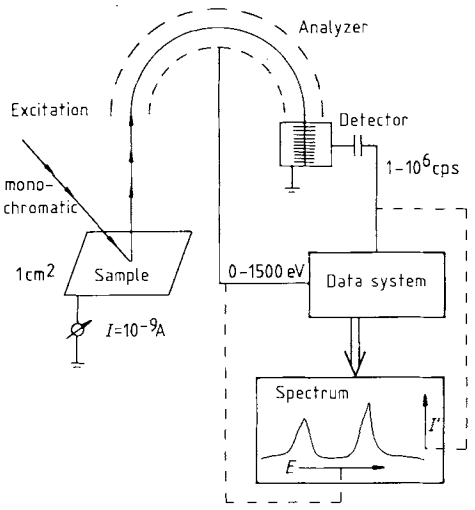

Fig. 1. Schematic representation of the photoemission experiment. For excitation the characteristic X-ray emission of a light element (Mg or Al) is generally used, as also here. In some cases monochromators are used to reduce the natural linewidth of the excitation of ca. 1 eV down to 0.25 eV. Recently, synchrotron radiation has become a valuable light source for photoemission experiments. The dashed lines in the diagram indicate the relations of abscissa and ordinate in the spectrum with the main components of the apparatus. Frequently, the kinetic energy of the electrons is also determined with a cylindrical mirror analyzer. cps = counts per second, I' = intensity.

In an XPS experiment an electrically conducting sample is irradiated with monochromatic X-rays of typically 250 W. The emitted electrons are then collected over a wide angle around the entry column of the normally hemispherical electrostatic analyzer. By application of a continuously changing potential to the hemispherical electrodes of the condensor, which make up the analyzer, only electrons of precisely one particular energy (proportional to the applied potential) will reach the detector. This is often a photomultiplier. Analyzer and detector functions of modern spectrometers are usually controlled by computers. This also enables the spectra to be accumulated, as well as allowing for easy mathematical processing of data by smoothing, background correction, integration, and deconvolution.

2.2. Practical Application

With XPS it is possible to investigate a solid surface for any chemical element, except hydrogen, to a depth of 1–2 nm, both qualitatively and quantitatively. Information concerning the chemical environment of an element (speciation) can also be obtained. Our study was carried out under conditions so chosen that no pretreatment of a sample was necessary. The sample to be investigated was introduced into an ultra-high vacuum chamber; hence, in the room-temperature measurements reported here only the non-volatile components of a surface were detected. The method may therefore be considered as complementary to the conventional methods of gas analysis, in which microparticles tend to disturb the analysis. If it is required that volatile components can be analyzed under these conditions, this may be achieved by cooling the sample to, for example, 78 K.

The detection limit lies between about 0.1% and 1.0% of the surface concentration for the various elements. One necessary condition for the use of this technique is that the sample be conducting; this could, in fact, be achieved with all the samples studied so far.

A particular advantage of XPS is its very high surface sensitivity; this allows for selective investigation of the boundary surface of an emitted particle and its environment and thus makes an estimation of its catalytic potential possible. It is known, for example,[6] that solid particles can play the role of carrier for toxic substances; dangerous substances can, in this manner, be brought into the environment on the surface of a harmless material. Other analytical methods such as the spectroscopic analysis of desorption of such toxic materials or elemental analysis must identify these substances in high dilution in a carrier,[7] while with the method described here, a monolayer coverage of a carrier particle can be easily detected and characterized.

In contrast to the good depth resolution, the lateral resolution on a surface is rather poor. The present measurements are summed over an area of about 5×10 mm^2. This

gives a good statistical analysis over many particles but does not provide any accurate information about the nature of individual particles.

In the case of metals, the XPS analysis of the chemical bonding of an element generally gives very clear-cut information, whereas in the case of organic substances only the type of bonding (e.g. aromatic, aliphatic, heterosubstituted etc.) can be determined. However, since the danger of chemical changes occurring in the sample during analysis is much smaller under XPS conditions than in classical high performance seperation methods[5,7] XPS can also be used to complement these techniques.

The depth of resolution of this technique warrants further mention. The information contained in the spectrum is taken from a depth of about 1–2 nm, i.e. a few atomic monolayers. Hence, the general understanding of the word 'surface' retains its literal meaning: with XPS only the topmost atomic layers are studied, i.e. layers which rarely can be made "visible" by other techniques.

The surface as seen under the microscope constitutes a much thicker layer of the solid; hence differences have often been reported to exist between the visible and the XPS-characterized surfaces. For example, a thin film of aromatic organic material (normally not visible) can, in this way, be seen on the surface of a soot particle. By repeated wearing down of the outer atomic layers, e.g. by bombarding with noble gas ions, the structure and composition of a particle layer can be followed from outside to inside (depth profile).[8]

Quantitative interpretations are rather difficult because of the irregular structure of the particles, but this difficulty may be partially overcome by studying the surface morphology with the electron microscope.[8]

An absolute quantification of the results (e.g. as emission in mg pro km) is, however, difficult. This is more easily achieved with conventional analytical methods;[3] such results can then be better interpreted with the help of bonding and depth distribution data obtained by XPS, and their importance with respect to the environment more easily estimated.[5,8]

Much more accurate are relative quantitative comparisons between different elements contained in the sample or comparisons between element concentrations following various treatments of the same sample (e.g. heating, ion-etching). It was shown that both the covering of the test plates with emitted materials as well as the internal structure of the particle itself are of a heterogeneous nature. It is therefore meaningless to extrapolate data acquired from a depth of a few monolayers to the entire bulk of the emission, as would be required for a quantitative description of the composition of a sample.

With the sampling technique used in the present investigation, only the very small microparticle portion of the emission[3b] was selected. Inspection under the scanning electron microscope revealed that, in general (except in the diesel soot samples), virtually no particles larger than 50 nm were present on the test plates examined. Such small particles are quantitatively characterizable, but only to a limited extent. Since however the emphasis in this study is laid on a qualitative description of the chemical nature of the emission products this was not seen as a serious drawback. It would, of course, be difficult to extrapolate quantitative data from the present measurements for an analysis of the total solid emission. On the other hand, because of the large surface to volume ratio such microparticles are of particular interest with regard to boundary effects such as in heterogeneous catalytic processes. The experiments were carried out as follows: the surface of a clean, conducting substrate (test plate) was exposed to the stream of exhaust gas to be analyzed. Some of the microparticles are deposited on the surface. After exposure for a prescribed length of time the test plate was analyzed in an XPS spectrometer (Leybold-Heraeus LHS 10, Mg excitation 240W). The energy scale was calibrated with the Au $4f_{7/2}$ line at 84.0 eV. In all diagrams the energy scale refers to the binding energy E_b in electron volts (eV). Gold, aluminum, and graphite test plates measuring 9 mm × 13 mm × 0.5 mm proved to be suitable for such experiments. Control experiments ensured that, after appropriate cleaning, only the element and its oxide were detectable. The plates were then exposed at an angle of 45 degrees to the exhaust fumes. In the experiments carried out with diesel motors soot filters and test plates were positioned about 1.5 m and 2.0 m, respectively, behind the exhaust manifold. In the experiments carried out with the automobile the plates were positioned about 10 cm before the end of the exhaust.

The various test plates showed differing capturing abilities for different types of particles: aluminum proved especially suitable for inorganic particles; the variety of inorganic particles adhering to graphite test plates was in contrast much smaller and many elements were found in much smaller concentrations than on aluminum. On the other hand, the spectra of the organic components deposited on graphite were better differentiated and the danger of subsequent reaction with the hot aluminum oxide could be ruled out. A gold test plate, to which the particles under investigation adhere far less easily, was used as a control substrate and was exposed together with an aluminum test plate for recording the platinum spectra, which are strongly affected by the Al-spectra (see Section 4.6).

It was found that there is an optimal exposure time for such experiments which ensures adequate coverage but precludes the deposition of too thick a layer. This avoids both the incidence of insufficient signal intensity and an electrostatic charging of the sample. Thus, for example, it was not possible to analyze a test plate from a longer test run of over 10000 km with an Otto motor.

The recording of the spectra necessitated long measurement times. After reaching ultra-high vacuum (10^{-9} mbar) in the analysis chamber of the spectrometer, 20 hours were needed to record a survey spectrum (all elements, low resolution). The spectra were collected on a data system. By comparison with stored data occasional deteriorations of the samples were recognized and the data therefrom were excluded from analysis. The data system was also used for smoothing and integration and for background subtraction. Since the line shapes of the spectra contained a considerable amount of information, the data was manipulated as little as possible and only raw data used for the final analysis (only a linear background correction was carried out).

For some spectra the satellite excitations from the Mg source were also subtracted from the raw data (Fig. 3, 15–17).

3. Samples

3.1. Diesel Motors with Various Soot Filters

The samples were taken from the exhaust system of a stationary (preignition) diesel motor fitted with a soot filter. The filter consisted of either a simple ceramic base (Al_2O_3–MgO–SiO_2) with activating metal additives or of a noble-metal-impregnated monolith. These filters (Corning) not only retain soot particles but also burn them to CO_2 and H_2O. The necessary activation energy is supplied by catalytic processes such as the dehydrogenation of aliphatic compounds (soot filter as catalyst). Samples of soot precipitate were taken from the walls of the exhaust system both in front of and behind the soot filter. Furthermore, in each case test plates of pure carbon (HOPG graphite) were placed in the exhaust area in front of and behind the filter as well as at the far end of the exhaust system and exposed for typically 16 hours to the exhaust gases.

3.2. Otto Motor with 3-Way-Catalyst

Detailed measurements were carried out on a production automobile equipped with a 3-way-catalyst. The performance of the catalyst was monitored on the basis of the CO emission during an approx. 7000 km test drive. Aluminum and/or graphite test plates were mounted in parallel at the input of the air filtering system and at the end of the exhaust system and examined after deposition of microparticles under various driving conditions (cold starts, city driving, mountain and motorway driving). Temperature measurements taken at intervals at test plates in the exhaust outlet showed values of about 620 °C at the test surfaces. Table 1 gives an overview of the test conditions.

Table 1. Origin of the samples referred to in the text.

Sample	Sampling Point	Testplate material	Motor	Operation
1	Filter support	Indium	Diesel	500 h
2	Before filter 1 [b]	Graphite	Diesel	16 h under load
3	After filter 1 [b]	Graphite	Diesel	16 h under load
4	Before filter 2 [c]	Graphite	Diesel	16 h under load

4. Results

The results obtained for both exhaust cleaning systems will be compared systematically in the order of the elements analyzed. First of all, however, the qualitative survey spectra and the possibility of quantifying the results are discussed. This method of presentation has been chosen so as to correspond with the chronological order in which the results are obtained in the course of an analysis.

4.1. The Survey Spectra

For the qualitative analyses a series of survey spectra were recorded. Figure 2 shows portions of the survey spectra for a test plate positioned behind the impregnated diesel soot filter (sample 5) and for the soot precipitate on the metal lining of the exhaust pipe (sample 1). Table 2 gives a summary of the metals observed. The respective amounts measured are only semiquantitative since an exact calculation would entail physical assumptions about the photoemission which are completely unjustified in such a

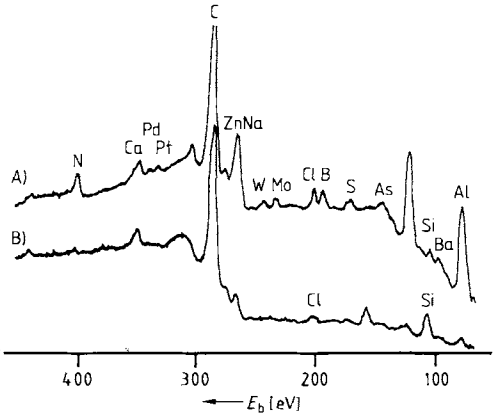

Fig. 2. Survey spectrum of diesel soot. A) Test plate exposed to the exhaust gas (sample 5). B) Sample of the soot deposited in the exhaust pipes (sample 1).

Table 2. Elements of the testplate of sample 6.

Element	Detected core levels [a]	Surface concentration [b]
O	1s	c
C	1s	c
Al	2s, 2p	c
Ca	2s, 2p	b

[a] Where possible, weak Auger lines and overlapping peaks are not taken into consideration. Hence, not all the binding energies that were measured have been listed. [b] The difference to 100% is assigned to aluminium (Al 2p, ca. 74 eV).

complex system (see comments in Table 3). The following points should be noted:

a) Sample 5 contains many elements in a higher surface concentration than the carbon black (Sample 1). This is significant despite the differing layer thicknesses of the two preparations, since the emission intensities of both samples relative to the background intensity were about the same. The peak areas referred to the main carbon peak indicate that the soot is contaminated mainly with calcium silicate. In particular, very few heavy metals are present and the nitrogen content is strikingly low.

b) The main inorganic component detected on the test plates is aluminum in the form of aluminum oxide. In the case of nonmetals the high concentration of N_2 and S that cannot be explained by gaseous components such as SO_2 or NO_x in the samples is surprising, for neither evacuation to 10^{-9} mbar nor subsequent bombardment with $Ar^{\oplus}$ ions led to any change in the respective peaks.

c) Amongst the noble metals, Pd and Pt were observed to be present. The most intense bands of Pt (4f) and Pd (3d) are however obscured by signals from other elements.

d) The presence of the elements Zn, Ce, W, Mo and As was also evident from spectra obtained in regions outside of those shown in Figure 2.

Figure 3 shows a portion of the spectrum of the test plate with sample 6 (Otto motor).

This sample is a typical example of all the samples investigated and will therefore be discussed in detail. The high resolution spectrum indicates the presence of a large number of elements. The majority of these elements appear independently of the presence of an exhaust cleaning system and are also detectable in the emission products of a conventional automobile. This may be seen from the survey spectra of test plates that were installed simultaneously in the input to the air filter and at the exhaust output of an automobile equipped with a catalyst. After satellite subtraction the $Pt\,4f_{7/2}$ line is clearly visible at a binding energy of ca. 70 eV, which is a clear indication of the presence of a 3-way-catalyst. Pt was not observed in any sample taken from the inlet air of the motor. Noticeable in these analyses is the appearance of an intense Pb 4f doublet making up ca. 20% of the total intensity of the spectrum.

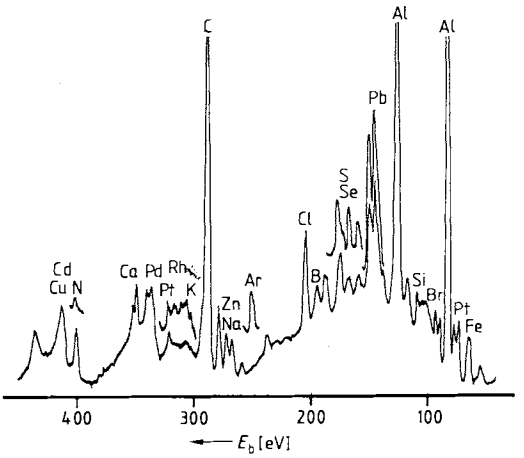

Fig. 3. Survey scans of a test plate from the Otto motor experiments (Sample 6). The complete assignment of the peaks is given in Table 3. The upper trace shows the alteration of the surface after bombardment with $Ar^{\oplus}$ ions.

The data in Table 3 show the quantitative analysis of this spectrum. Since an aluminum test plate was used, the aluminum concentration in these samples cannot be quantitatively determined—qualitative proof of the presence of aluminum was obtained from a simultaneously exposed graphite plate. The concentrations given for the noble metals were obtained from deconvolutions of the multiplets arising from superposition of the noble metal 3d and 4f subspectra with other metal core levels. The error in these estimations must be assumed to be about 25% and originates mainly from the uncertainty in the deconvolution. In order to calculate the concentration of the various elements a universal escape depth must be assumed for all elements. This does not take into account the influence of roughness and unevenness of the sample surface on the observed intensities.

Those regions of the spectrum that have obviously been changed by ion-etching with $Ar^{\oplus}$ ions (5 min, 5 kV, 10 mA, 4 $\mu A/cm^2$) are also shown in Figure 3. Under these conditions, ca. 6 nm would be removed from a smooth and uniform surface. The concentrations of carbon and nitrogen (enriched as organic compounds on the outer surface due to their volatility) are clearly decreased. The prominent Ar 2p peak indicates the presence of a soft, graphitic carbon, into which the Ar is implanted particulary well. Finally, S, Se, Br and Pb are present in an altered chemical state

(chemical shift) and larger quantities after ion-etching. Since the sensitivity of the chemical structure of many of these elements to ion-etching is well known, these alterations will not be discussed any further.

Table 4 shows which elements were detected by us in the above investigations and those which were also looked for with standard techniques under comparable emission conditions in catalyst-treated motor vehicle exhaust fumes.[9] In general, there is good agreement between the two sets of data. However, the core levels of the alkali metals could not be used for a quantitative determination (K and Na were qualitatively detected). The conventional methods, on the other hand, showed no noble metals to be present. We assume that the differing particle sizes in the experiments and the different sensitivities of the methods are responsible. A more accurate quantitative comparison should not be attempted, since the emission sources (US automobiles and European motor cars), the greases and fuels used, and the loading conditions are different.

4.2. The Carbon Spectra

Figure 4 shows the carbon 1s spectra of the test plate with sample 5 and of the soot deposit from behind the noble-metal-impregnated soot filter (sample 1); also shown is the corresponding spectrum of a test plate after exposure behind a non-impregnated diesel soot filter (sample 3). The spectra of samples 3 and 5 do not originate from the graphite test plate, to which the signal at 283.8 eV with ca. 100 times the intensity of the rest of the lines (reference lines in Fig. 4) belongs. When the test plate was examined under the scanning electron microscope the surface was seen to be thickly covered with particles. (Emissions with an average particle size of less than 100 nm from the Otto motor, on the other hand, were only rarely visible on the test plates.)

The spectra in Figure 4 may be interpreted in the following manner: The soot contains a significant proportion of non-graphitic carbon (intensity on the higher binding energy side relative to a graphite reference). If one compares the broad, asymmetric line shapes of the spectra (peak halfwidth 4.2 eV) with those of the spectra of some model aromatic organic compounds (Fig. 5), it follows that at least some aromatic organic components are present on the surface. The complex line shape, which is used as a 'fingerprint' for the class of arenes, is characterized by the high energy-loss feature (shake-up and shake-off) typifying this class of substances.[10] A mixture of such organic compounds yields, by combination of these characteristic structures, the observed wide asymmetric band in which the partial spectrum of the soot-like carbon is hidden (Fig. 4II).

In the analysis of the line shapes, one must also consider carbon-heteroatom structures such as C–N, C–O, C–S, and C–Cl, which, according to partial spectra of the heteroatoms (see Sections 4.3–4.5), are, in fact, present. These

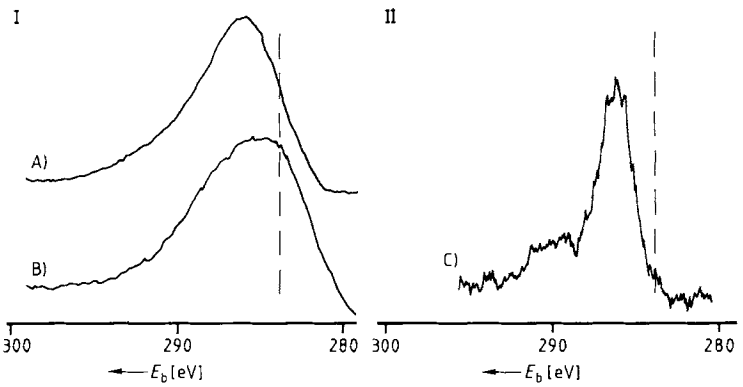

Fig. 4. C1s spectra of test plates exposed to diesel exhaust behind impregnated (I) and non-impregnated (II) soot filters. A) Sample 5; B) sample 1; C) sample 3. Note the influence of noble-metal impregnation (measured with pass energy 100 eV). The dotted line shows the C1s binding energy of graphite.

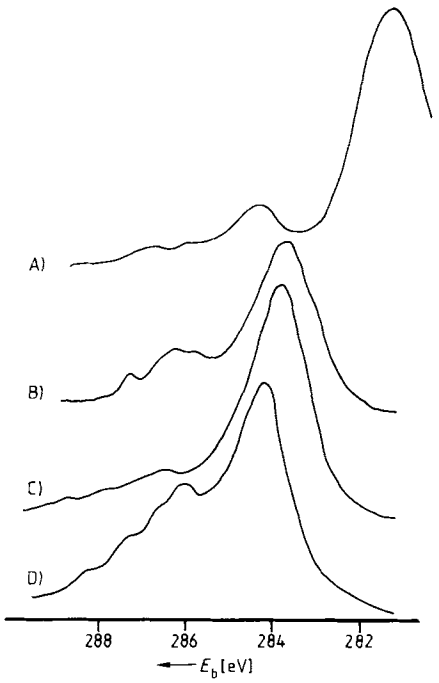

Fig. 5. C1s spectra of some aromatic reference compounds. All samples were measured as thin films sublimed on silver test plates (pass energy 50 eV). A) Coronene. B) Perylene. C) Tetracene. D) Naphthalene.

would not, however, alone explain the observed line shapes, since the chemical shift of the C1s signal in compounds of this nature is smaller than the observed linewidth. Furthermore, the intensities of the lines of the heteroatom partial spectra are so low that only a small portion of the entire C1s spectrum can be attributed to such structures.

Since the carbon on the test plates is not a regularly ordered graphite (also confirmed by X-ray diffraction), a large number of terminal carbon atoms must exist in the form of aromatic hydrocarbons or of their polymerization product—soot. These are normally saturated with either hydrogen or oxygen and thus a significant proportion of the C1s signal intensity at high binding energy may be explained by the presence of hydroxy and carbonyl groups.[11]

From a comparison of Figure 4 with earlier spectra measured by the authors[12] and with the O1s partial spectrum (Section 4.3, Fig. 10) it follows that the soot precipitated on the walls of the exhaust system of the diesel motor contains more aromatic hydrocarbon materials in its outer surface than the surface of the test plate, which exhibits a higher oxygen content and whose C1s binding energy is accordingly shifted to higher values.

Practically no aromatic hydrocarbons are found (narrow signal) on the test plate from behind the non-impregnated soot filter. A shoulder at higher binding energy typical of C-O bonds is clearly recognizable.[12]

The influence of the noble-metal-impregnated soot filter on the composition of the organic emission is shown in Figure 6. The C1s spectra of samples 4 and 5 are also shown. The two test plates were simultaneously exposed to the same exhaust stream at the same temperature. Instrumental broadening of the linewidth (by the analyzer and the doublet of the $Mg_{K\alpha}$ radiation) was corrected by deconvolution with an approximate function. The width at half height of these lines (at 2.2 eV) is still larger than for pure carbon.[12] The marked increase in the amount of arenes and heteroarenes due to the presence of the catalyst may be clearly seen from the additional intensities at high binding energy. It should be noted that the difference in the areas of the two spectra between 286 and 289 eV need not be proportional to the amount of aromatic hydrocarbons present, since according to Figure 5 the intensity measured in this energy range is heavily dependent on the structure of the arene. A comparison of the spectra shows, however, that the nature of the mixture of aromatic hydrocarbons is altered by the presence of a soot filter. This alteration was not detectable when a non-impregnated soot filter was employed. It may be concluded therefore that the dehydrogenating effect of noble-metal additives contributes to an increasing build up of aromatic hydrocarbons and to the incorporation of heteroatoms into the molecular structure.

A high resolution C1s spectrum of the test plate exposed to the exhaust gases of an Otto motor (sample 6) is shown in Figure 7. The line broadening (FWHM: 2.7 eV) due to the presence of arenes and heteroarenes is once again easily recognizable. The line shapes are altered during ion-etching (conditions as for Fig. 3) and the amount of C-O-structures decreases. This is indicative of a purer soot with higher carbon content in the center of the particle.

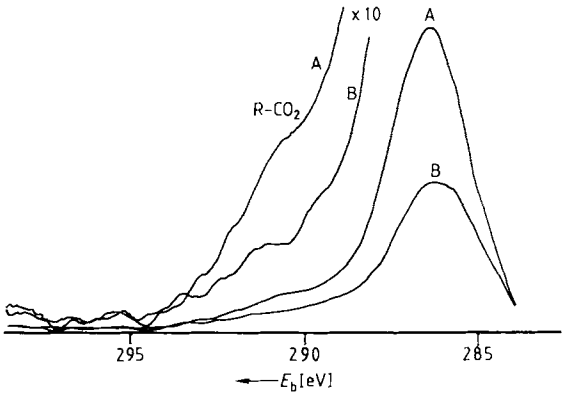

Fig. 7. C1s spectra of sample 6 A) before, B) after ion-etching. In the (normalized) amplified spectra the presence of carbon heteroatom bonds is recognizable. Ion etching removes these structures. These and all the following spectra were measured with an analyzer pass energy of 50 eV.

The heterogeneous composition of the particle from the Otto motor—at least in the cold-start stage—can be seen from the spectra in Figure 8 (sample 7). The outer surface

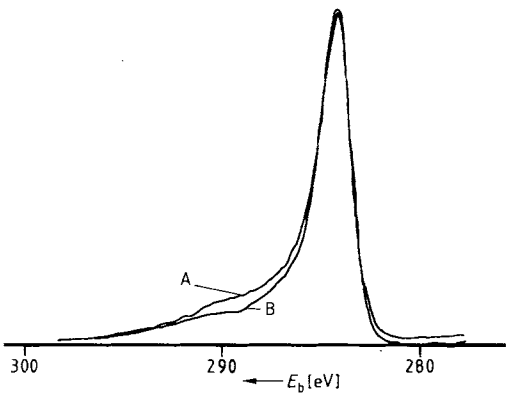

Fig. 6. Influence of noble-metal impregnation of the soot filter on the structure of the emitted carbon compounds. A) Sample 5 (behind the filter). B) Sample 4 (in front of the filter) (pass energy 25 eV).

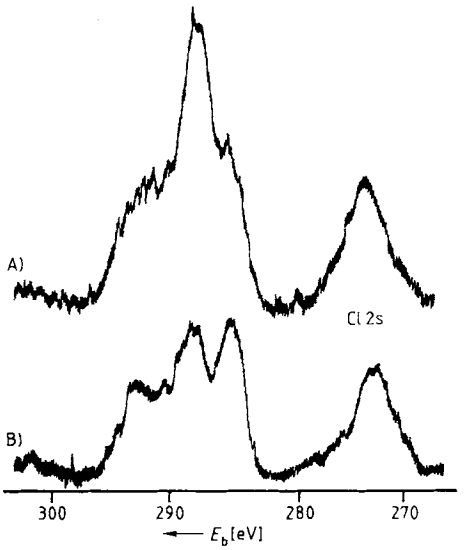

Fig. 8. C1s spectra of sample 7 A) particles emitted in the cold start phase of the Otto motor contained a high proportion of aliphatic compounds. B) These could easily be removed from the particle surface by ion etching.

contains a large proportion of aliphatic hydrocarbons. These can be removed quite easily and almost completely by a brief ion-etching treatment, while the graphitic, aromatic components (to the right of the main line) and the oxo- and chloro-organic compounds abundantly present in this sample (to the left of the main peak and Cl 2s peak) are hardly affected at all.

A quantitative comparison of the carbon emission from the Otto motor under various loading conditions is shown in Figure 9. The intensities of the signals were normalized to the intensity of the Al 2p signal assuming similar coverage. Particularly striking (spectrum B) is the high emission of aromatic hydrocarbons and soot after mixed city and motorway driving. After a drive of similar duration (at a speed of 120 k/h, spectrum A) on a motorway a spectrum of lower intensity signals and a noticeably higher ratio of heteroarenes to aliphatic and aromatic hydrocarbons was recorded. The effect of the higher temperature of the catalyst and test plate under more severe loads is clearly seen from the decrease in the total amount of detectable carbon. It cannot, however, be decided on the basis of these measurements whether the emission has actually been reduced or whether the higher temperature of the test plate has contributed to the loss of carbon (by combustion at the testplate) as a sampling artifact.

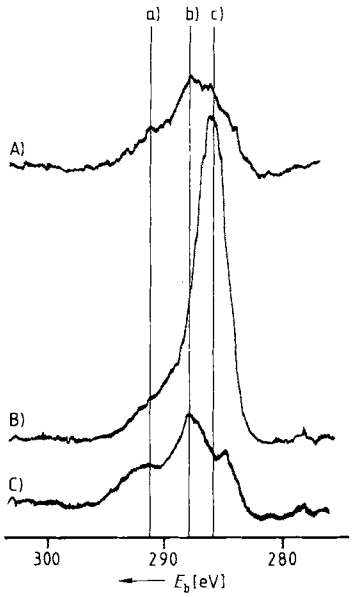

Fig. 9. Comparison of the C1s spectra of the surfaces of soot particles emitted from an Otto motor under various loading conditions. A) Sample 9. B) Sample 11. C) Sample 7 (identical to Fig. 8A). The spectra are normalized to the Al 2p signal intensity. a) Oxo- and halohydrocarbons, b) aliphatic hydrocarbons, and c) soot and graphite.

4.3. The Oxygen Spectra

The O1s spectra obtained in the present study are not very informative,[5,8] since the O1s binding energy for oxide oxygen (O^{2-}) depends relatively little on the chemical environment and the large variety of oxygen compounds in the sample determines the possible shapes of the spectrum. A characteristic spectrum of diesel motor exhaust gases is shown in Figure 10A. Quite a different spectrum (Fig. 10B) was obtained, however, from all diesel soot samples (e.g. sample 1). The lower intensity of the second spectrum is in keeping with the presumed enrichment of aromatic hydrocarbons on these samples (see Section 4.2). The shift of the O1s signal could indicate that acidic hydroxy groups and water dominate on the soots, and basic hydroxy groups and oxides on particles on the test plates.

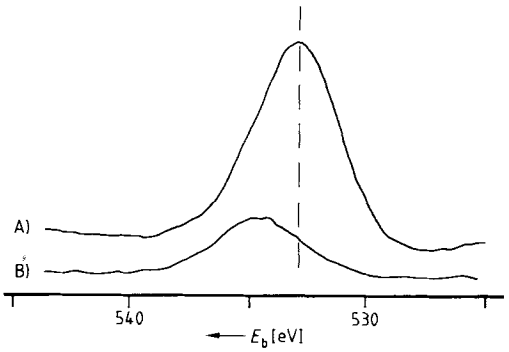

Fig. 10. O1s spectra of soot particles from a diesel motor. A) Sample 3. B) Sample 1 (see Fig. 4B). The reference line indicates an average value for metal oxides.

4.4. The Nitrogen Spectra

The N1s spectra of soot surfaces have already been compared with the cataloged N1s spectra of *N*-heteroarenes.[13] We have now established that in the diesel samples, nitrogen is mainly found on the test plates and rarely on the bulk soot close to the soot filter. A typical spectrum (sample 3) is shown in Figure 11; Figure 12 shows for comparison the N1s spectrum of an activated soot catalyst (Corax 3, not intended for use in motors, treated with HCN gas at 900°C). The binding energies of the nitrogen in the diesel soot and the low energy shoulder in the reference spectrum are typical for heterocyclic nitrogen and for amino groups. Nitro groups (from NO_x) would give rise to a peak at ca. 407.0 eV as in the reference spectrum.[12] Such nitro groups have not been observed in any of the samples from the diesel motor series which attests to the relatively high temperature sensitivity of these functional groups.

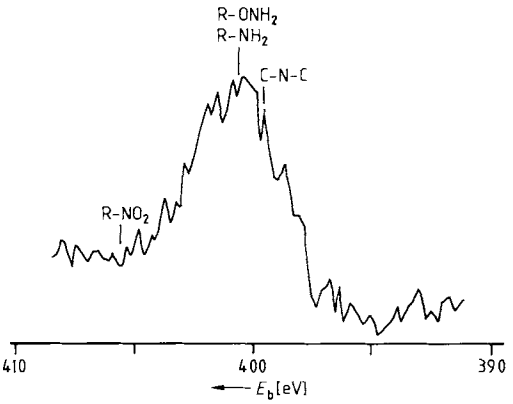

Fig. 11. N1s spectrum of a testplate exposed behind a non-impregnated soot filter (sample 3). The position of the N1s signal is clearly structure-dependent.

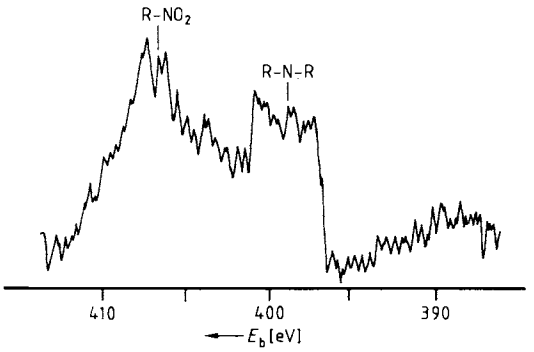

Fig. 12. N1s spectrum of a reference compound. A sample of activated carbon was treated with HCN gas. Note the high sensitivity of the N1s photoemission and the clear separation for various chemical species.

The influence of noble-metal catalysts on the qualitative composition of the types of organic compounds emitted is shown in Figure 13 (sample 5). The N1s binding energy for particles modified by the presence of noble metals is clearly lower than for the particles described in Figure 11. This is indicative of the presence of aromatic amines (signal structure at higher binding energy) and heterocyclics (main components). These types of organic compounds are not emitted in the absence of the catalyst (Fig. 13B).

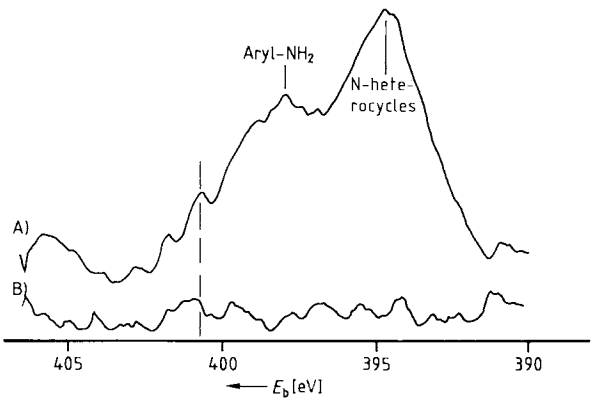

Fig. 13. Influence of a noble-metal impregnated soot filter on the formation of organonitrogen compounds. A) Sample 5. B) Sample 4. The dotted line shows the position of the N1s line of sample 3 (see Fig. 11).

Similar N1s spectra have been observed from emissions from the Otto motor. The spectrum of a test plate used in a test carried out on a motorway is especially interesting (sample 10, Fig. 14); in this sample, cyano compounds analogous to those found with KCN-treated carbon black are also observed as well as amines and nitrogen heteroarenes. Ion-etching experiments show the increased presence of aromatic cyano compounds in the interior of these particles (Fig. 14B); this is also reflected by the similarity to the changes observed in the C1s spectrum.

On one occasion during a test drive in a city center, the presence of chlorinated compounds in the air was established by an intense Cl 2p peak on the test plates taken from the inlet manifold. The presence of nitro groups in the nitrogen spectrum was observed only in this particular case (Fig. 14A). As was shown by repeated ion-etching, the nitro compounds were evenly distributed throughout the sample.

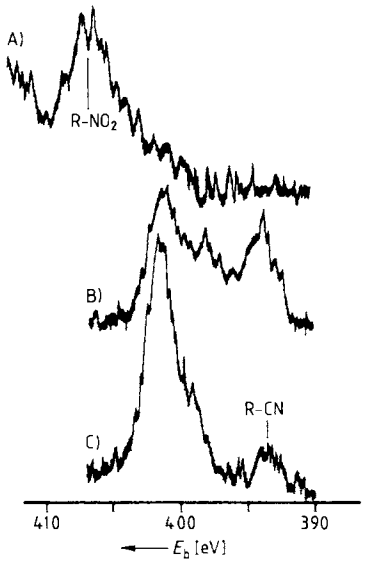

Fig. 14. N1s spectra of the emission products collected during a motorway test of an Otto motor. A) Sample 12. B) Sample 9 after ion etching. C) Sample 9 before ion-etching. Note the presence of cyano compounds in B and C. Only on one occasion (sample 12) were significant amounts of nitro compounds detected (see text).

4.5. The Sulfur Spectra

The sulfur components of emission products from various combustion plants had already been investigated by XP spectroscopy a number of years ago in the USA.[14] Samples taken from diesel motor exhausts contain sulfur with an S2p binding energy of ca. 168.5 eV. From a comparison with values in the literature[15] it may be seen that this value is neither related to sulfate (b.e. ca. 170 eV) nor sulfur, nor even to sulfide (b.e. ca. 160–162 eV). Sulfur in these states is formed in combustion plants.[14] In the present case, however, sulfur is present as part of an organic C–S- or C–O–S-group. These groups seem to be produced under the influence of the catalyst, since in the absence of noble-metal catalyst the exhaust gases contain sulfur only as sulfate or sulfite.

In the spectra obtained from the Otto motor test series under heavy loading conditions (motorway driving and driving in a mountainous terrain) a significant amount of sulfur was observed both in the form of sulfate and of sulfide (see shoulder in the S2p line of Fig. 3).

Since sulfur has a poisoning effect on the catalyst the emission may be seen as a kind of self-cleaning mechanism; the sulfate deposited in small amounts on the surface under normal operating conditions is largely removed at the higher catalyst temperatures caused by heavy loading of the motor.

4.6. The Platinum Spectra

Figure 15 shows the Pt 4f spectrum of a test plate (sample 5) taken from a diesel exhaust. Each of the chemically differently bound platinum atoms show two peaks in this spectrum ($4f_{5/2}$ and $4f_{7/2}$). The reference lines give the positions of some platinum compounds for comparison.[4] The greater amount of the noble metal is obviously present in the formal oxidation state of zero and its chemical envi-

ronment is similar to that of platinum in an industrial synthetic catalyst. (Pt-black is a very finely divided metal of an undefined, non-zero oxidation state and is used as an effective catalyst for hydrogenation in organic chemistry.)

A small portion of the platinum is present in an oxidation state of 4, very probably as the oxide. Its binding energy falls in the valley between the 5/2 and 7/2 components of the main component, giving the impression of a poorly resolved spectrum.

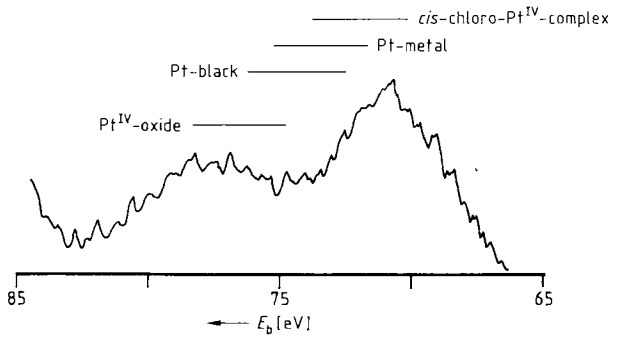

Fig. 15. Pt4f spectra of the emission from a noble-metal-impregnated diesel soot filter (sample 5). The bar lines indicate the positions of the $Pt4f_{7/2}$ peaks of some reference compounds. The length of the lines indicates the error bar mainly given by the uncertainties in the definition of a common energy scale.

Figure 16 shows the Pt4f region of the spectrum of sample 6 (Otto motor exhaust gases) after satellite subtraction and deconvolution. For comparison, the spectrum of a chemically oxidized Pt-foil is also shown (Fig. 13B). One can see how the $Pt4f_{5/2}$ peak is masked by the intense Al2p line and how the detection of Pt compounds in oxidation states of 2 and 4 is thus very difficult in such spectra. A quantitative estimation of the entire amount of Pt in

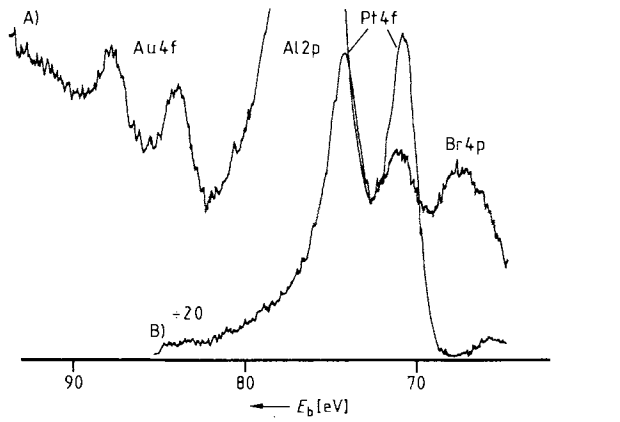

Fig. 16. Comparison of the Pt4f spectra of A) sample 6 and B) an oxidized platinum foil.

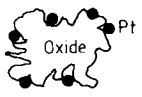
the exhaust samples is therefore not possible. According to these spectra the platinum may exist as a surface oxidized metal particle, which, as in the case of the working catalyst, can be attached to an oxide particle (Scheme 1).



Scheme 1. Schematic representation of the possible deposition of noble-metal particles on larger emitted carrier particles.

The platinum emissions from the 3-way-catalyst under various loading conditions are compared in Figure 17. For this comparison a scaling procedure was used, similar to that described for the comparison of the C1s spectra in Section 4.2. Possible reasons for the shift of the $Pt4f_{7/2}$ lines of automobile emissions with respect to the positions of the lines of a platinum foil are the small particle size[16] and the incorporation of oxygen (without formal oxidation) into the metal lattice.[17] It is obvious that a detailed interpretation of the chemical shifts of such a heterogeneous system is critical, since the definition of a common scale for the binding energies of all microparticles of a macroscopic sample is difficult and since the concept of formal oxidation states for a metal in supported noble metal oxide systems is valid only to a first approximation.

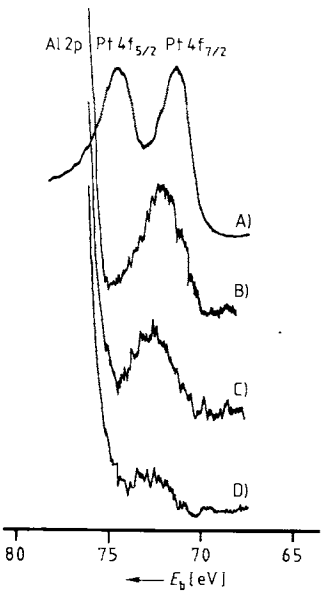


Fig. 17. Comparison of the Pt4f spectra of emissions from an Otto motor under various loading conditions with the spectrum of a platinum foil (A.) Only after subtraction of the intense satellites from the Al2p spectrum are the $Pt4f_{7/2}$ lines visible in full resolution. B) Sample 9. C) Sample 11. D) Sample 7.

5. Concluding Discussion

The first results of the X-ray photoelectron spectroscopic analysis of diesel emissions have shown that a large number of chemical elements, particulary heavy metals, are detectable in the portion of the exhaust emissions that is stable in ultra-high vacuum. On the other hand, the large particles precipitated in the exhaust system of a diesel motor seem to contain very few elements other than iron oxide and carbon particles covered with arenes. Noteworthy is the significant amount of selenium precipitated from the exhaust fumes near the open end of the exhaust system. It can be traced back to sulfur-analogous heterocyclic compounds contained in the diesel oil used.

In both types of motor, the noble metal catalyst seems to aid in the formation of carbon-heteroatom compounds in

the exhaust. From an analysis of the line shapes of the C1s peaks and a comparison with the concentration of the heteroelements it may be seen that the distribution of hydrocarbons on the carbon surface is shifted in favor of aromatic compounds.

The emitted microparticles of soot are composed, for the main part, not of graphite but rather of paracrystalline carbon,[18] which can act as activated carbon; i.e. it may tend not only to attach to a number of various chemical species, e.g. water and hydrophilic compounds (acids), but may also possess a catalytic activity of its own. Nitrogen-containing soot particles are of special importance from the chemical point of view because such systems are efficient catalysts for the oxidation of SO_2 to SO_3.[13]

The platinum emission of the 3-way-catalyst was more difficult to examine since on all test plates the Pt 4f line for higher oxidation states was overlapped by the Al 2p line (the aluminum originating from the catalyst carrier and the generally non-catalyst-specific emission). The observed binding energy of the emitted particles is very similar to that of a pure platinum surface oxidized in a stream of oxygen. As is known from the literature,[16] platinum surfaces and small platinum particles are oxidized by the oxygen present in the air even at room temperature, so that biologically relevant platinum(IV) is formed.[19]

These results at least do not rule out a hitherto only very schematically discussed[20,21] effect of particle emissions on the environment. For a better insight into such effects further studies must be carried out, for example, on the existence of emitted particles on living matter. This has, in fact, been successfully attempted with XPS.[22]

Fine dust particles emitted into the atmosphere can be distributed[23] over the entire environment and can be deposited and accumulated on the surfaces of living matter (e.g. on leaves). In this way a large number of inorganic compounds of catalytic importance are deposited on the surface of plants. Simple contact with polluted air carrying gases such as SO_2 can thus cause a localized build-up of poisons such as sulfuric acid. The inorganic deposits can also aid destructive processes such as halogenation or oxidation of the plant itself. This localized build-up of poisonous substances acts directly on the plants at volume concentrations far in excess of what might be expected from the global analyses of pollutants. Also the serious effects of the enrichment of pollutants in rain water collected by and falling from trees[20] are not difficult to envisage. Only very accurate bulk trace element analysis of plant sections[23] will reveal the extent of contamination of these surfaces. Using the method of surface analysis described here, some exploratory experiments have shown both needle and broad leaf surfaces to be covered with a mixture of inorganic substances. From these considerations we can draw the following important conclusions, which in our opinion, should contribute in no small way to an understanding of the phenomena of environmental pollution: The toxic agents formed by heterogeneous catalytic reactions might not be formed in the atmosphere nor at the site of emission (flue gas plumes, exhausts) but only at the site of action (i.e. site of deposition). Dilution effects would then be largely ineffective. Naturally, such metal oxide particles are conceivably present, not only in emissions from motor vehicles but also in all sources of fine dust particles.

Since the most effective catalysts are the smallest and thus the lightest particles, the statement that the total amount of all particles emitted into the environment has drastically decreased in the last 20 years is only of limited value if one wishes to estimate the influence of the emission of solids on the environment.

In conclusion, it should again be stressed that the analytical method employed here is one which complements conventional methods of gas analysis. It enables an analysis to be carried out on that portion of the emission which is otherwise difficult to examine. Alongside the advantages of high sensitivity for all environmentally relevant elements and the possibility of analysis of the emissions without sample preparations (important for the speciation of elements which are shown to be present in the environment by other methods), the disadvantages such as low selectivity for organic compounds and the rather complicated quantification of the results should also be mentioned.

The authors wish to acknowledge collaboration with the Oekozentrum Langenbruck (Switzerland) from where the samples of the diesel motor test series were obtained. We thank Prof. Dr. H. J. Güntherodt, Dr. K. Noack and Dr. W. Vetter for critical reading of the manuscript. One of us (R. S.) acknowledges financial support from the Swiss National Science Foundation during his stay at Basel University. We thank M. Skottke for the careful typing of the manuscript.

Allylamine Derivatives—a New Class of Active Substances in Antifungal Chemotherapy

By Anton Stütz*

Fungal infections (mycoses) are found throughout the world. Only a few structural classes of compounds currently satisfy the demands of modern chemotherapy in their treatment; hence, the quest for new types of active substances is of major scientific and therapeutic importance. The first representative of a new class of substances—the allylamine derivatives—namely naftifine ((*E*)-*N*-methyl-*N*-(1-naphthylmethyl)-3-phenylallylamine) was discovered by accident and has recently become commercially available as a topical antimycotic. The exploration of structure-activity relationships on the basis of naftifine and new synthetic strategies led to the discovery of the currently most active compound of this type, terbinafine, the first pharmaceutical agent to contain a (*E*)-1,3-enyne structural element. Terbinafine exhibits considerably higher activity than the original "lead" structure naftifine both *in vitro* and *in vivo*; it is also up to one order of magnitude more effective than standard preparations in various chemotherapeutic animal tests after topical or oral administration. According to clinical experience gained so far, terbinafine is well tolerated and shows promising activity against various types of mycoses. Allylamines act as potent, selective inhibitors of fungal squalene epoxidase via a novel mechanism, which, unlike in the case of other inhibitors of steroid biosynthesis, does not depend on cytochrome P450.

1. Introduction

Fungal diseases were until a few decades ago considered to be of minor importance, especially in relation to bacterial infections. This situation has changed. The incidence of observed mycoses has increased significantly in recent years whether this be due to a real increase in the number of infections, to improved methods of diagnosis or to a better awareness of hygiene. Nowadays, mycoses occupy an important position among the infectious diseases.[1-4]

The clinical pictures of mycoses vary widely and depend on the localization of the infection and the state of immunity of the affected individual. *Superficial* mycoses of the skin, mucous membranes, hair and nails may proceed harmlessly but may also involve highly inflammatory processes. They include epidemic diseases such as athlete's foot (Tinea pedis) or nail mycoses (onychomycosis). *Deep* mycoses are often life-threatening systemic infections which, even today, are extremely difficult or impossible to treat.

Human-pathogenic fungi constitute a morphologically and physiologically heterogeneous group of microorganisms. In the more recent literature they are classified into three main groups:

- *Dermatophytes*, pathogens causing dermatophytoses (trichophytosis, microsporosis, epidermophytosis)
- *Budding fungi* (yeasts) and *biphasic fungi*, pathogens causing candidoses, sporotrichosis, and infections that occur outside Europe such as coccidioidomycosis, histoplasmosis, and blastomycosis.
- *Molds* which, for instance, are responsible for aspergillosis and chromomycosis.

[*] Dr. Anton Stütz
SANDOZ Forschungsinstitut
Brunnerstr. 59, A-1235 Wien (Austria)

Fungi, unlike bacteria (prokaryotes), are eukaryotic microorganisms. They are more highly developed living organisms containing a true nucleus, i.e. they possess chromosomes that are enclosed by a nuclear membrane. The basic relationship with highly developed organisms accounts for the fact that it is difficult to treat fungal diseases efficiently and systemically without simultaneously harming the host.

A vast number of substances with antimycotic activity have been reported. Very few, however, satisfy the requirements of modern chemotherapy. Examples of the most important classes of substances are listed in Figure 1:

- Antibiotics
  a) polyenes: e.g. amphotericin B, nystatin
  b) griseofulvin
- Synthetic chemotherapeutic agents
  a) 5-fluorocytosine (flucytosin)
  b) thiocarbamates: e.g. tolnaftate
  c) azoles: e.g. clotrimazole, miconazole, ketoconazole

The latest and at present most intensely studied structural class is that of the azole antimycotics[5] which display a broad spectrum of activities. Azoles are potent inhibitors of ergosterol biosynthesis which is essential for the formation of intact fungal cell membranes. They block an important step in the sequence of reactions leading from lanosterol to ergosterol, namely the oxidative, cytochrome P450-dependent 14α-demethylation (cf. also Fig. 6).[6,7] Initially these compounds were only suitable for topical use but the discovery of ketoconazole a few years ago represented the breakthrough for systemic application.[8] Oral therapy, however, can provoke a number of side-effects[9] (liver toxicity, teratogenicity, interference with steroid hormone metabolism[10,11]) which are at least in part due to marked in-

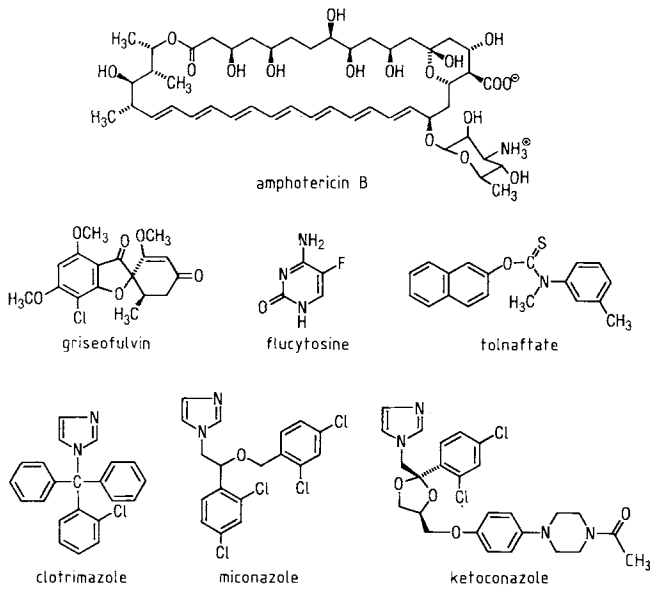

Fig. 1. Structures of representative antimycotics.

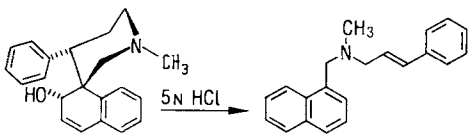
hibition of cytochrome P450-dependent enzyme reactions.[12-14] These effects have recently led to considerable restrictions being imposed on the use of ketoconazole.[15]

Research in the field of antimycotic chemotherapy is now being concentrated throughout the world on the investigation of the azoles and is documented by an exponentially growing flood of publications and patents.[5,16] It remains to be seen whether more effective, more selective and better tolerated compounds of this structural class can be developed.

In view of this restriction of attention to azoles, the search for new structural classes or the chemical investigation of new "leads" presents an alternative which may be of considerable scientific and therapeutic value.

2. Naftifine—an Accidental Discovery

In 1974 *Berney* was working in the Wander Laboratories, Bern (Switzerland), on spironaphthalenones with the aim of finding derivatives that acted on the central nervous system (CNS). After acid hydrolysis of one of these substances, he unexpectedly isolated a compound **1**, whose structure proved to be relatively simple but was previously unknown.[17]



1

1 was subjected to tests in the Sandoz Forschungsinstitut in Wien (Austria) as part of a broadly based routine screening program. *Georgopoulos* et al. were able to show that the compound was highly effective against a number of human-pathogenic fungi. Results initially obtained with fungal cultures *(in vitro)*[18] were also confirmed in experiments on animals *(in vivo)*.[19] Activity was found to be at least as high as that of standard preparations after topical application in the guinea pig-trichophytosis model. Oral activity could only be demonstrated after administering a very high dose that was of no therapeutic relevance.[20]

After extensive investigation of its pharmacological and toxicological properties,[21,22] **1** (generic name: naftifine) was tested intensively for several years in hospitals.[23] Numerous studies have shown that naftifine is a highly effective topical antimycotic. Naftifine was compared with standard topical antimycotics or a placebo in open studies or under double blind conditions on patients with different dermatophytoses and candidoses. Naftifine proved to be equally as effective and in some cases superior to the standards. In many cases clinical symptoms were found to disappear more quickly[24] and an additional antiinflammatory effect was observed.[25]

Naftifine first became commercially available in various countries (the Federal Republic of Germany, Austria, Malaysia, and Singapore) in 1985 under the name Exoderil®.[26]

3. Allylamine Derivatives—a New Class of Antimycotic Agents

During the course of these developments, studies were begun on the mechanism of action[26-28] of naftifine and its chemical investigation to provide the answers to the following questions:

- Can naftifine be assigned to an already known structural class; is it a solitary compound or a representative of a new class of active substances?
- Do definable structure-activity relationships exist and which structural elements are essential for antifungal activity?
- Can this information be used to design new structures with higher activities and/or a broader spectrum of activity?
- Are there any compounds with therapeutically useful oral activities (when naftifine was discovered griseofulvin and 5-fluorocytosine were the only two known antimycotics with oral activity)?

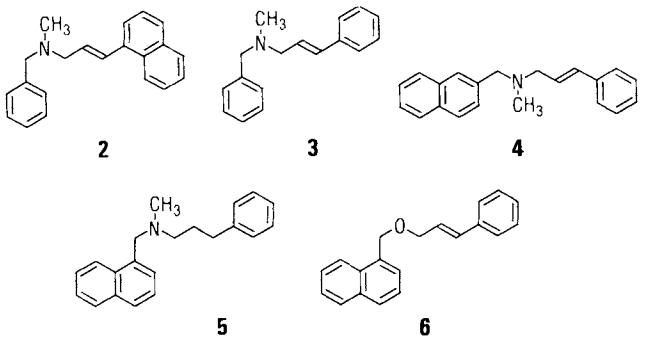
It soon became evident that the antifungal activity of naftifine was specifically associated with defined structural elements which could not be related to any of the known classes of active substances.[29] A great many compounds with similar and, later on, with significantly higher activities were found. As all of the active compounds possessed a tertiary allylamine functionality they were termed the "allylamine derivatives".[30]

A concise and thus somewhat simplified account of the way in which terbinafine, the currently most active compound of this type, was discovered is given in the following section.

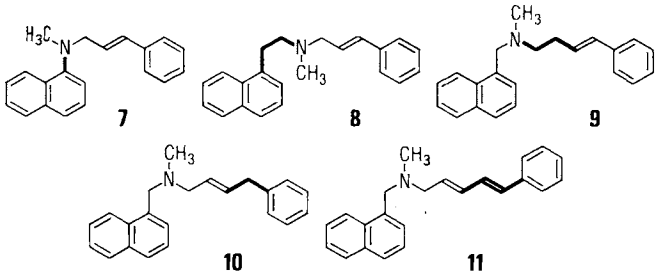
3.1. Basic Structure-Activity Relationships

In order to clarify basic structure-activity relationships the naftifine analogues **2**–**6** were synthesized.[29] They proved to be inactive in antimycotic tests *in vitro*. It was

therefore concluded that the nitrogen atom, the double bond and the 1-substituted naphthalene ring were of importance and also that the aromatic ring systems could not be interchanged.



Compounds **7**–**11** were then studied to see whether the distances between the individual functional groups and between the aromatic systems could be decreased or increased without affecting the activity. These compounds were also either inactive or their activity was several orders of magnitude lower than that of **1**.[29] The altered parts of the molecules are indicated in the formulas by bold print.

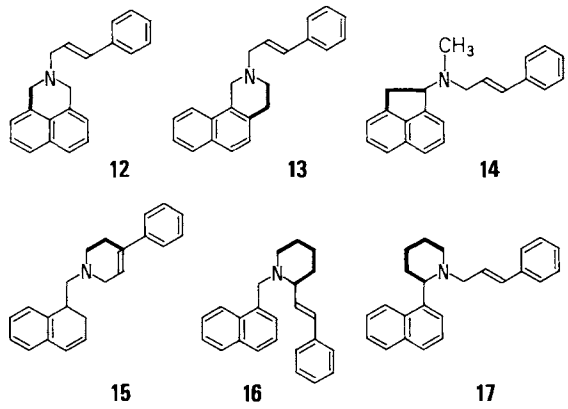


These studies demonstrate that the antifungal properties of **1** do indeed depend on specific structural requirements. Further detailed systematic variation of the individual structural elements confirmed and supplemented these preliminary structure-activity relationships.[29]

3.2. Semirigid Naftifine Analogues

The structure of **1** was subsequently assumed to be essential and its most active conformation was sought. Semirigid analogues were synthesized by incorporating the conformationally flexible structure of **1** in different ring systems; the effects of these changes on biological activity were investigated.[31] In an "all or nothing" effect, four of these compounds (**12**, **13**, **15**, and **16**) proved to be totally inactive while two (**14** and **17**) had activities that were within the same range as that of naftifine **1**.

As the piperidine compound **17** displayed an interesting spectrum of activity and also had a chiral center, it was resolved into its enantiomers. Animal experiments revealed that activity was restricted to the (*R*)-form (shown by X-ray structure analysis[32]). This compound was the first derivative[33,34] to exhibit significantly improved oral activity in the guinea pig-trichophytosis model and proved that the systemic activity of **1** could be increased.



3.3. Systematic Variation of the *N*-Alkenyl Side Chain

In a systematic study the 3-phenylallyl (cinnamyl) group of **1** was replaced by C_{10}-alkyl chains with an increasing number of conjugated double bonds and these compounds (**18**–**22**) were then tested against various human-pathogenic microorganisms (Table 1). Biological activity reaches a clearly defined maximum when there are two conjugated double bonds (**20**). Analogues **21** and **19** with one double

bond more and one double bond less, respectively, are considerably less effective. The derivatives without (**18**) or with four (**22**) conjugated double bonds are virtually inactive.[36]

Variation of the length of the 2,4-alkadienyl side chain has a similar although less pronounced effect, the highest activity being obtained with C_9 to C_{10} (compounds **20**, **25**). The effects of these modifications were also investigated in the guinea pig-trichophytosis model after topical and oral administration (Fig. 2). The activity *in vivo* was found to be even more dependent on the chain length. Topical application of a 2% solution of the derivatives completely cured the animals only in the case of compound **25**; homologue **20** proved to be the most effective compound after oral administration. Changes involving one to three methylene groups produced a decrease or total loss of activity.[36]

These results demonstrate that minor changes in the chemical structure can be critical not only for optimization but also for the possible discovery of a lead substance.

3.4. The (*E*)-1,3-Enyne Group—a New Structural Element in Pharmaceutical Agents

Table 2 reveals that the antifungal activity of compound **25**, which has an (*E,E*)-2,4-alkadienyl side chain (see also Table 1 and Fig. 2), is comparable to that of the lead structure naftifine **1** both *in vitro* and *in vivo*.

Substitution of the double bond between C4 and C5 by a triple bond (compound **27**, see also reduction with diisobutylaluminum hydride in Section 4.1) improves the activities *in vitro* and *in vivo*, especially after oral administration. In the latter case 75 mg/kg of **1** or **25**, for example, is ineffective in the guinea pig-trichophytosis model by mycological criteria, whereas the same dose of the (*E*)-1,3-enyne derivative **27** completely cures the animals. The *trans* configuration is essential for this effect: the corresponding *cis* isomer **30** is less active by several orders of magnitude, as are analogues with an inverted enyne group (**28**) or with two conjugated triple bonds (**29**).[37]

Bearing the results shown in Figure 2 in mind, the alkyl group adjacent to the triple bond in compound **27** was varied (Table 3). Increased branching finally improved the oral efficacy by one order of magnitude in the form of the *tert*-butyl compound **32** (terbinafine)![37,38] The *tert*-butyl

group is, moreover, a prerequisite for activity *in vitro* against *Aspergillus fumigatus* and *Candida albicans*.

Attempts to replace the *tert*-butyl group in (*E*)-2-alken-4-ynylamines by other substituents are summarized in Table 4[39] and include compounds with substantial antifungal activities. The most active compounds in this group *in vivo* are the ether analogue **33** and the derivative **34**, in which the *tert*-butyl group is replaced by a trimethylsilyl residue and which, although its activity is relatively weak *in vitro*, is virtually as effective as terbinafine after oral administration! This is all the more surprising in view of the fact that the ≡C–Si bond is much less stable, both chemically and metabolically, than the corresponding ≡C–C bond.

The conjugated *trans*-enyne group has proved to be an important structural modification for improving the antimycotic activity of allylamines, particularly after oral administration, and as far as we are aware it represents a *novel structural element in pharmaceutical agents*[30,37,40]. Terbinafine (**32**) was shown to be by far the most suitable of this series of enynes for further development. Figure 3 shows a computer simulation of the spatial structure of terbinafine.

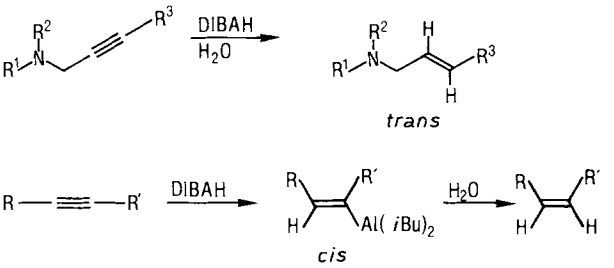
4. Synthetic Aspects

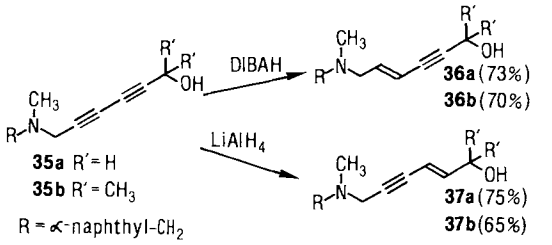
4.1. A New Method of Synthesis for (*E*)-Allylamines

During attempts to develop widely applicable synthetic pathways for allylamine derivatives, a new method was found for the stereoselective *trans* reduction of tertiary

propargylamines with the aid of diisobutylaluminum hydride (DIBAH).[41,42] This reaction occurs under mild conditions (40 °C, toluene, 3 h) and gives high yields. Its trans-stereoselectivity, in contrast to the known *cis*-hydroalumination of disubstituted alkynes,[43,44] is attributable to a neighboring group effect of the α-amine. The reactivity and selectivity clearly differ from those of other reactions

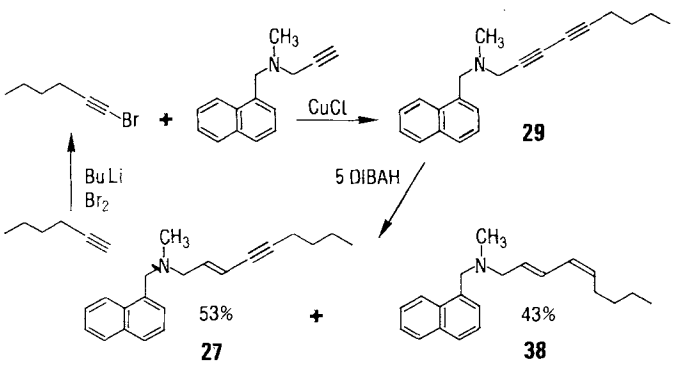


which also involve *trans*-hydroalumination such as the known $LiAlH_4$ reduction of α-hydroxyacetylenes to (*E*)-α-hydroxyalkenes.[45] 1,3-Diynes such as **35**, which contain both a propargylamine and a propargyl alcohol functionality are, for instance converted with DIBAH into **36** and with $LiAlH_4$ at the other triple bond into **37** (Scheme 1).[42]



Scheme 1.

This raises the preparatively and mechanistically interesting question as to whether the reduction of a 2,4-alkadiynylamine with an excess of DIBAH proceeds *trans* at the triple bond between C-2 and C-3 (via a neighboring group effect of the nitrogen) and/or in the "normal" (*cis*) fashion at the other triple bond. Reaction of the diyne **29** (obtained by oxidative coupling) with DIBAH in the molar ratio 1:5 gives an approximately 1:1 mixture of the (*E*)-2-alken-4-ynylamine **27** and the (2*E*,4*Z*)-2,4-alkadienylamine **38** (Scheme 2). The direduction proceeds highly stereoselectively (*EZ*/*EE* = 98/2); this behavior has also been found in other examples.

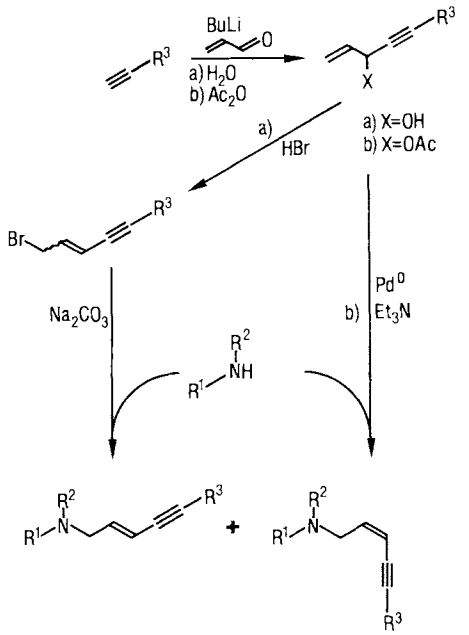


Scheme 2.

The (*E*)-enyne **27**, the product of monoreduction, represented the first breakthrough in efforts to discover highly effective allylamine derivatives with oral activity (see Section 3.4).

4.2. Synthesis of 2-Alken-4-ynylamines

The reaction sequence shown in Scheme 3 has proved to be extremely valuable for synthesizing a large number of differently substituted 2-alken-4-ynylamines: 1-alkynes are lithiated and allowed to react with acrolein in a 1,2-addition. The resulting secondary alcohols are then rearranged with concentrated aqueous HBr [route (a)] to give a stereoisomeric mixture of primary allylic bromides ($E/Z \approx 3:1$).



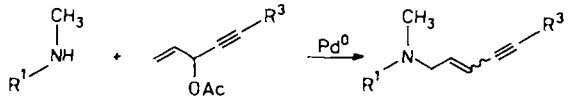
Scheme 3.

After reaction with a secondary amine the stereoisomeric products are separated either chromatographically or in the form of their hydrochlorides by selective crystallization of the *trans* isomers (as in the case of **32**).[37] Alternatively, the allylic rearrangement and *N*-alkylation can also be carried out [route (b)] via π-allylpalladium complexes with the aid of Pd(0) catalysts such as $[(Ph_3P)_4Pd]$ under particularly mild, neutral conditions.[46] Acetylenes with (acid-)sensitive functional groups give satisfactory yields via this route (Table 5). Furthermore, partial selectivity for the (*E*)- or (*Z*)-isomer has been achieved by modifying the experimental conditions or using a polymer-bound Pd catalyst.[47]

5. Mode of Action of Allylamine Derivatives

Accumulation of lipid-like vesicles was observed in electron microscopical studies on fungi treated with naftifine **1**.[48] The assumption that lipid metabolism was in some way affected was confirmed by biochemical investigations and the mode of action of the allylamines was subsequently elucidated.[26-28,49,50]

Table 5. Synthesis of 2-alken-4-ynylamines with the Pd^0-catalyst $[(Ph_3P)_4Pd]$ (5 mol-%) in tetrahydrofuran (15 h); cf. alternative b) in Scheme 3.



R^1	R^3	Yield [%] [a] *E*	*Z*
	$CH_2-S-C_2H_5$	29 (44)	22 (35)
		24 (34)	35 (52)

	$C(CH_3)_3$	47	31

[a] Isolated material; values in parenthesis: yields according to HPLC analysis.

Naftifine, terbinafine and other allylamines interfere in the biosynthesis of ergosterol, an essential sterol in the cell membranes of fungi. They are very efficient inhibitors of squalene epoxidase from *Candida albicans* (terbinafine: $K_i = 3 \times 10^{-8}$ M; Fig. 5) and other fungi and cause intracellular accumulation of squalene (Fig. 4).[30,51,52] Squalene epoxidase is a key enzyme in sterol biosynthesis and is the first enzyme in this reaction pathway that requires molecular oxygen (Fig. 6). *Specific inhibition* of this enzyme was demonstrated *for the first time* with the *allylamines*.[53] At the present time no definite statements can be made about the molecular mechanism occurring at the enzyme.

Squalene epoxidation is an essential step in the biosynthesis not only of ergosterol in fungi but also of cholesterol in mammals. Comparative studies on squalene epoxidase from rat liver and fungi have shown, however, that terbinafine is highly selective for the fungal system. The relevant inhibition constants differ by more than three orders of

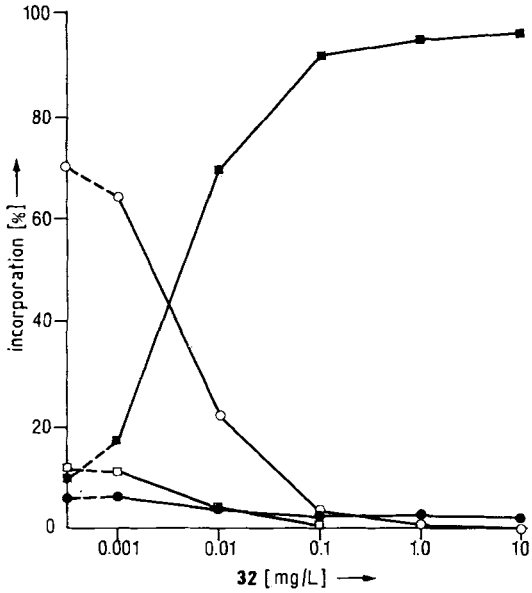

Fig. 4. Effect of terbinafine **32** on sterol biosynthesis in *Candida albicans* cells. Incorporation of ^{14}C-acetate into (○) ergosterol; (●) 4-monomethylsterols; (□) 4,4-dimethylsterols; (■) squalene (after *Ryder* [50]).

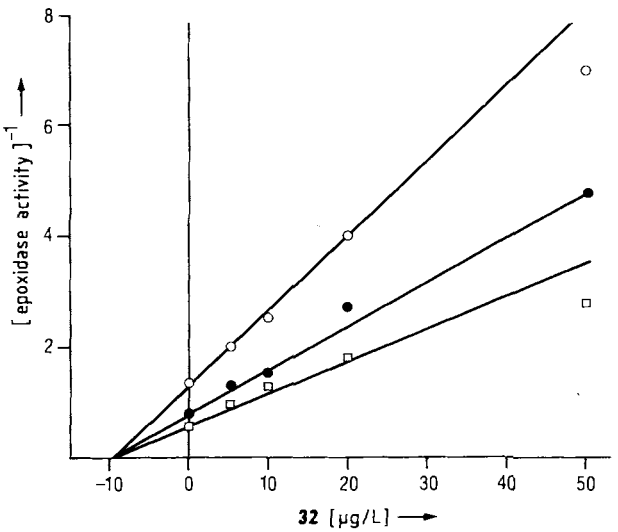

Fig. 5. Inhibition of squalene epoxidase from *Candida albicans* by terbinafine **32**. Dixon plots for three substrate concentrations (after *Ryder* et al. [30]). Substrate (squalene) concentration: ○ 12.8×10^{-6} M; ● 29.9×10^{-6} M; □ 116.2×10^{-6} M. $K_i = 9$ ng/mL (9 μg/L) ~ 3×10^{-8} M.

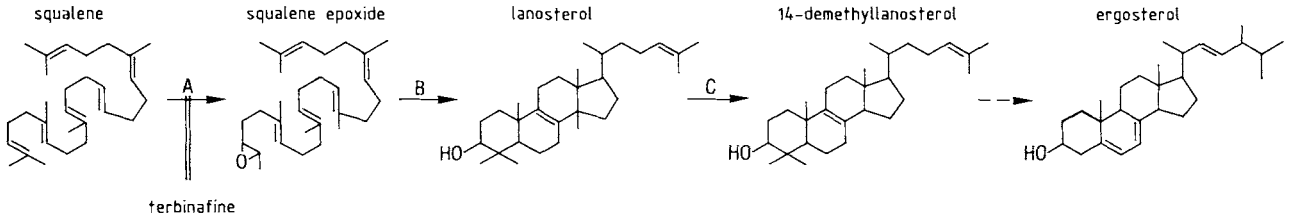

Fig. 6. Steps in the biosynthesis of ergosterol from squalene (after *Ryder* et al. [50]). Enzyme systems: A: squalene epoxidase (squalene monooxygenase, E.C. 1.14.99.7); B: squalene oxidocyclase (lanosterol synthase, E.C. 5.4.99.7); C: lanosterol-14α-demethylase complex, cytochrome P450-dependent; inhibited by azoles.

magnitude.[52] This finding is important as regards the use of terbinafine as a safe, systemically active chemotherapeutic agent without side-effects.

Squalene epoxidation, unlike the 14-α-demethylation of lanosterol, which is the main point of attack of the azole antimycotics, does not depend on cytochrome P 450 enzymes. Furthermore, allylamines do not exhibit an affinity for the cytochrome P 450 systems involved in steroid hormone synthesis in the adrenal glands, the placenta and the testes.[54] This is in agreement with the fact that none of the known side-effects of ketoconazole due to interaction with cytochrome P 450 have been observed in clinical trials carried out with terbinafine.

6. Terbinafine

In vitro terbinafine is effective against a wide range of human-pathogenic fungi (Table 6), but especially against dermatophytes such as *Trichophyton spp.*, *Microsporum canis* and *Epidermophyton flocc.* (MIC 0.0015–0.01 mg/L), *Aspergillus spp.* (MIC 0.02–1.56 mg/L and *Sporothrix schenckii* (MIC 0.1–0.4 mg/L). The sensitivities of yeasts vary more widely, displaying MIC values ranging from 0.1 to >100 mg/L. Terbinafine primarily acts fungicidally against dermatophytes and *Candida parapsilosis* and fungistatically against *Candida albicans*.[30,55–57]

Table 6. Spectrum and minimal inhibitory concentrations (MIC) of terbinafine[30,55] **32**.

Species	Number of strains tested	MIC [mg/L]	
		Range	$\bar{M}$
Trichophyton spp.	64	0.001–0.006	0.004
Epidermophyton flocc.	24	0.001–0.006	0.004
Microsporum canis	24	0.006–0.01	0.007
Aspergillus spp.	7	0.02 –1.56	0.63
Sporothrix schenckii	4	0.1 –0.4	0.2
Candida albicans	78	6.25 –100	29.3
Candida spp.	42	0.1 –>100	33.0

The oral effectiveness of terbinafine **32** is significantly greater than that of naftifine **1**. This was demonstrated by comparing the curative doses (dose at which 100% mycological cure rate is obtained) in the oral guinea pig-trichophytosis model:[35] in the case of naftifine it is 485 mg/kg,[20] and in the case of terbinafine it is 6 mg/kg.[30,58]

In the same model 60 and 80 mg/kg respectively of the clinical standards griseofulvin and ketoconazole were required to achieve a complete cure, these doses are one order of magnitude higher than that of terbinafine.[30,58]

Terbinafine was similarly shown to be more effective than the standards after topical application. Complete mycological cure of guinea pig trichophytosis and microsporosis was observed after treatment with 0.06 and 0.5% solutions of terbinafine respectively for 7 days. Under the same experimental conditions not even 2% solutions of the standards econazole or tolnaftate effected a complete or partial mycological cure. A guinea pig skin infection caused by *Candida albicans* was cured after topical application of a 1% terbinafine solution for 5 days.[30,58]

The pharmacokinetics, biotransformation and tolerance of terbinafine were extensively investigated in laboratory animals and later on in humans.[59–63] The remarkably low toxicity of terbinafine and its lack of teratogenic or embryotoxic effects in animal experiments are especially outstanding features. The plasma concentrations of the parent compound measured in humans and animals after oral administration far exceed its minimum inhibitory concentration despite considerable metabolism. The conditions for clinical application are therefore satisfied both as regards the required concentration of the active substance and drug safety.

Terbinafine is currently being tested world-wide in controlled clinical trials. The results so far obtained from, in some cases, incompleted studies are encouraging. Terbinafine was shown to be at least as effective as griseofulvin in the oral treatment of *Tinea corporis* although the daily terbinafine dose of 250 mg was only half that of the standard griseofulvin dose. In the topical treatment of *Tinea pedis* (athlete's foot) and *Tinea cruris*, terbinafine proved to be significantly more effective than clotrimazole even after only a few days.[64–66] As far as the topical treatment of skin candidiasis was concerned, terbinafine was comparable to clotrimazole.[67] It was also generally well-tolerated after both topical and oral administration.

In view of these studies it can be hoped that terbinafine will prove to be a valuable addition to the arsenal of drugs available for treating mycoses.

7. Conclusion

The allylamines constitute a new class of antifungal compounds with oral and topical activity.[68] This has been documentated not only in the case of naftifine and terbinafine but also with a multitude of derivatives, some of them highly active, which have been described in various patents.[33,69–80] The chemical and biological investigation of these compounds is by no means complete and further work is currently in progress.

The following aspects of these studies could be relevant to the concepts of drug-design and structure-activity relationships: 1) By a combination of systematic structural variation and development of new synthetic methods it was possible to increase the biological activity of a lead compound by several orders of magnitude. 2) In general, the rational approach to antimicrobial chemotherapy attempts to inhibit processes which occur in the pathogen but not in the host. However, as shown in the case of the allylamines, a biosynthetic process common to host and pathogen can be inhibited with a high degree of selectivity towards the microbe.

The work described in this report is the result of several years of intense, interdisciplinary collaboration. I would like to thank all my colleagues whose contributions are cited in the references. I am especially grateful to Dr. G. Petranyi and his co-worker I. Leitner for carrying out the mycological studies and to my own co-workers W. Granitzer, A. Pruckner

and S. Roth for performing the syntheses with skill and dedication. My thanks are also due to Dr. M. Grassberger, Dr. H. Mieth, Dr. N. S. Ryder, Dr. I. Schuster, Dr. P. Stütz and many other colleagues for their many critical discussions and suggestions.

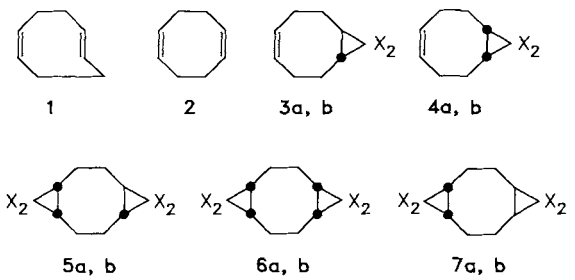
Apparently Nonstereospecific Dihalocarbene Addition—an Explanation**

By *Eckehard V. Dehmlow** and *Thomas Stiehm*

The stereospecific addition of dihalocarbenes to alkenes has been observed in hundreds of cases and, in accordance with the Skell hypothesis, supports the singlet character of these transient species.[1] Only in the case of *trans*-cyclooctene has a nonstereospecific addition of dibromocarbene been observed.[2-4] Isomerization of the starting material occurred concurrently. Dichlorocarbene behaved "normally." We have now investigated the addition of CCl_2 and CBr_2 to the more highly strained *cis,trans*-1,5-cyclooctadiene **1**. In this case, dichlorocarbene also behaves anomalously if it is generated under the conditions of phase-transfer catalysis (PTC).

In agreement with earlier reports,[5] **1** reacted with $:CCl_2$ (generated from ethyl trichloroacetate and sodium methoxide) to give exclusively **3a**, which reacted further to give **5a**. When $:CCl_2$ was generated under PTC conditions, however, a 2:1 mixture of **5a** and **6a** was obtained.



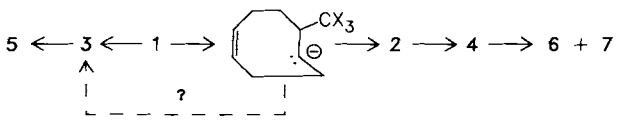
a, X = Cl; b, X = Br

Similar results were obtained for the reaction of **1** with $:CBr_2$. Reaction with potassium *tert*-butoxide/$CHBr_3$ gave only **5b**,[6] whereas with $CHBr_3$/50% aqueous sodium hydroxide/$(PhCH_2)Et_3NCl$ (TEBA) a mixture was once again obtained.[7] It consisted of a 2:1 ratio of **5b** and the *syn/anti* isomers **6b** and **7b**.[8]

The following observations are pertinent to explaining the mechanism of the reaction:

1. When the reaction with $:CCl_2$ was interrupted before completion, the recovered diene consisted of a mixture of **1** and *cis,cis*-1,5-cyclooctadiene **2**, and the monoadduct fraction (10% yield) contained a 2:1 mixture of **3a** and **4a**.[10] The bisadduct fraction (5% yield), on the other hand, consisted of pure **5a**. It is known that the *trans* double bond in **1** is the more reactive one. Apparently, **3a** undergoes further reaction more rapidly than **4a**.
2. Compound **1** did not isomerize to **2** either upon stirring for 24 hours in $CHCl_3$/petroleum ether or upon stirring for 24 hours in CH_2Cl_2/petroleum ether containing 50% aqueous sodium hydroxide and TEBA.
3. Compound **3a** was also stable toward 50% aqueous sodium hydroxide/TEBA.
4. Exposure of the reaction mixture to air did not affect the stereoselectivity. Therefore, radical and triplet-state processes can be excluded.
5. When **1** was allowed to stir for 17 hours in CH_2Cl_2/petroleum ether/50% aqueous sodium hydroxide/TEBA containing a small amount of ethanol (or acetylacetone), however, an 8:1 (or 5:1) mixture of **1** and **2** was isolated.[11] Products of nucleophilic addition to **1** or **2**[12] were not observed.

It is known from competition experiments that $:CCl_2$ generated under PTC conditions is a free singlet carbene.[13] In contrast to other methods of generation, however, this procedure results in a reversible equilibrium between $:CX_2$ and its precursor $CX_3^{\ominus}$.[14] The pK_a values of acetylacetone (9) and ethanol (19) encompass those of $CHBr_3$ (9[15]) and $CHCl_3$ (15[15]). Therefore, instead of the intermediate postulated initially by us, namely, a carbene–alkene complex,[3] it is necessary to assume a reversible nucleophilic addition to **1** accompanied by isomerization to **2**.



Experimental Procedure

1 (1 g, 9.3 mmol) in 40 mL of petroleum ether (30–40°C) and 30 mL of $CHCl_3$ was treated with TEBA (100 mg, 0.44 mmol) or an equivalent amount of Aliquat 336, Bu_4NHSO_4, or Ph_4AsCl. The mixture was then cooled in an ice bath and treated with 1 g of 50% aqueous sodium hydroxide, after which it was allowed to stir for 6 h at room temperature. Yield: 15–24%. M.p. of the preparatively nonseparable mixture of **5a** and **6a** = 115°C. Analysis by HPLC on an RP-18 column with methanol/H_2O = 2/1.

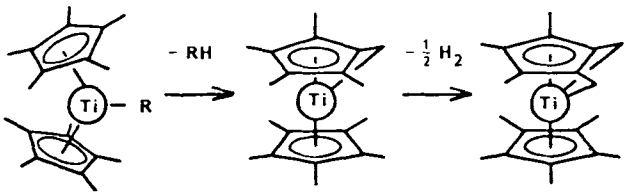
Titanium Hydride Formation through Hydrogen Transfer from 2-Methylpyridine to a Titanium Fulvene Compound; the First Structurally Characterized Terminal Titanium Hydride

By *Johannes W. Pattiasina, Fré van Bolhuis*, and *Jan H. Teuben**

In a study of the thermolysis of compounds of the type $[Cp^*_2TiR]$ ($Cp^* = \eta^5$-C_5Me_5; R = H or alkyl), we observed stepwise hydrogen abstraction from one of the Cp* ligands.[1]



We are currently focusing our attention on the reactivity of these modified Cp* ligands. In **1** the tetramethylfulvene ligand may be coordinated either as a combined cyclopentadienyl-alkyl ligand, the "tucked-in" mode **A**,[2] or as a neutral conjugated triene **B**.[3]

In a series of exploratory studies with a variety of substrates with active protons, e.g., acids and alcohols, **1** reacted as a cyclopentadienyl-alkyl complex with transfer of hydrogen from the substrate to the fulvene ligand, thus restoring the original Cp* ligand.[4]

A completely different and unprecedented reaction took place when **1** was exposed to pyridine derivatives. At −80°C the dark purple **1** reacts quickly with 2-methylpyridine in Et_2O to give a dark green solution, which changes to an intense dark blue on warming to room temperature. Concentration and cooling of the solution to −30°C resulted in the formation of beautiful dark blue crystals of **2**.[5]

$$[Cp^*(C_5Me_4CH_2)Ti] + C_5H_4MeN \xrightarrow{Et_2O}$$

1

$$[Cp^*\{C_5Me_4CH_2(C_5H_3MeN)\}TiH]$$

2

The molecular structure of **2** (Fig. 1)[6] shows that hydrogen transfer from the 6-position of 2-methylpyridine to titanium, concurrent with C–C bond formation between pyridine and the methylene group of the fulvene ligand, has taken place. In this way a Cp* ligand is functionalized with a pyridine ligand to form a chelating ligand.

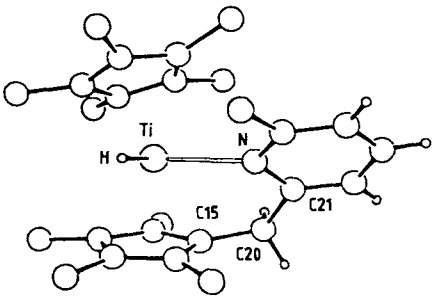

Fig. 1. Molecular crystal structure of $[Cp^*\{C_5Me_4CH_2(C_5H_3MeN)\}TiH]$ **2**.

Compound **2** is the first structurally characterized dicyclopentadienyltitanium hydride with a terminal Ti–H bond. The Ti–H distance (1.70(4) Å) is substantially longer than in other 3d-transition metal terminal hydrides, but comparable with hydrides of the early transition metals of the 4d and 5d series.[7] Until now only structure determinations of titanium hydrides with bridging hydrogen atoms, e.g., complexes containing a Ti–H–Ti, Ti–H–Al, or Ti–H–B structural element, have been published. In these complexes the Ti–H distances vary between 1.69(10) and 1.94(7) Å.[7]

The location of the pyridyl fragment with respect to the Ti atom and especially the Ti–N distance (2.340(3) Å) indicate that we are dealing with a dative Ti–N bond.[8] The angle formed between the Ti atom and the centroids of the substituted cyclopentadienyl rings is 142.7°; the distances between Ti and the centroids (2.086 and 2.064 Å) are close to those found in unsubstituted Cp^*_2Ti derivatives.[9]

The dihedral angle between the plane containing both ring centroids and Ti and the H–Ti–N plane is 91.6°; the H–Ti–N angle is 91(2)°. From this it is clear that **2** has all the characteristics of a regular $Cp^*_2M(L)X$ molecule. The C15–C20 bond deviates slightly from the ring plane (7.4°) toward the metal. The other C(ring)–C(methyl) bonds point away from the metal, thereby producing the normal "dish" shape of the Cp* ligands.[10] The C15–C20–C21 angle (111.5(3)°) shows that C20 is almost perfectly sp^3 hybridized.

The ^{1}H-NMR spectrum of **2**[5] affords assignments of the protons of the cyclopentadienyl ligands. Owing to the paramagnetism of **2**, the signals are broad and shifted strongly. The hydride resonance could not be located, a problem also encountered for the related compound $[Cp^*_2TiH]$.[3] In the IR spectrum, $\tilde{\nu}$(Ti–H) is found at 1475 cm^{-1}, slightly lower than for $[Cp^*_2TiH]$. The assignment was confirmed by the synthesis of the deuteride: $\tilde{\nu}$(Ti–D) was observed at 1065 cm^{-1} ($\tilde{\nu}$(Ti–H)/$\tilde{\nu}$(Ti–D) = 1.38). The ESR spectrum shows a well-resolved doublet, centered at

$g = 1.985$ ($a_H = 11.5$ G), and a clear hyperfine splitting due to interaction with titanium isotopes (^{47}Ti, I = 5/2, ^{49}Ti, I = 7/2, natural abundance 7.28% and 5.51%, respectively, $a_{Ti} = 9.3$ G).

Reaction of **2** with ethylene and DCl also confirmed the presence of a Ti–H functionality.

$$[Ti]H + CH_2{=}CH_2 \longrightarrow [Ti]Et \xrightarrow{D_2} [Ti]D + EtD$$
2 **3** [D]-**2**

$$[Ti]H + DCl \longrightarrow [Ti]Cl + HD$$
2 **4**

$[Ti] = Cp^*\{C_5Me_4CH_2(C_5H_3MeN)\}Ti$

In a Toepler pump controlled experiment, 1 mole of ethylene per mole of Ti was consumed. Compound **3** was isolated as a dark brown, analytically pure crystalline material; it reacts with D_2 to form EtD and [D]-**2** in a 1:1 molar ratio.[11]

The formation of a Ti–H bond through hydrogen transfer from 2-methylpyridine is completely different from what is regularly observed in reactions with compounds of early transition metals of the type $[Cp_2TiR]$[12] or $[Cp^*_2MR]$ (M = Sc,[13] Y,[14] Lu[15]). In the case of a "tucked-in" bonding mode, metalation of the pyridine with hydrogen transfer to the fulvene ligand and formation of $[Cp^*_2Ti(\eta^2\text{-}C_5H_3MeN)]$ is expected.

A further outstanding feature is the conversion of a fulvene ligand into a functionalized pentamethylcyclopentadienyl group. This reaction may be of considerable synthetic importance as an attractive route to bidentate Cp* ligands.

Experimental Procedure

2: **1** (0.574 g, 1.81 mmol) was dissolved in Et_2O (20 mL) and cooled to −196 °C. 2-Methylpyridine (0.168 g, 1.81 mmol) was added and the reaction mixture was warmed to −80 °C. Upon gradually warming the mixture to room temperature, the color of the solution changed from red-purple to dark green and finally dark blue. After stirring for 4 h, the solution was filtered, concentrated to 15 mL, and slowly cooled to −30 °C to give beautiful dark blue crystals. Yield: 0.335 g (0.82 mmol, 45%) of **2**. Correct elemental analysis.

Sequential Configuration Analysis of Peptides**

By *Thomas Bolte, Dahai Yu, Hans-Thomas Stüwe,* and *Wilfried A. König**

Dedicated to Professor Ernst Bayer on the occasion of his 60th birthday

Stereochemical uniformity is an important criterion for the purity of synthetic peptides used as biologically active substances. Although partial racemization can be reliably detected and quantified by capillary gas chromatography on chiral stationary phases such as Chirasil-val®[1] or XE-60-L-valine-(*S*)-α-phenylethylamide,[2] only overall values for the individual amino acids are obtained.

For cases in which the same amino acid occurs repeatedly in the peptide sequence, it would be desirable to determine the degree of racemization as a function of position. Only then is it possible to modify the coupling and/or protecting group strategy in order to suppress racemization.

This problem can be solved by determining the enantiomeric purity of the phenylthiohydantoins (PTH derivatives) obtained by Edman degradation. *Davies* and *Mohammed*[3] used chiral isothiocyanates to show that the cleavage of thiocarbamoyl amino acids and their cyclization to the dihydrothiazolones does not occur without racemization, because an equilibrium is established with a quasi-aromatic, nonchiral tautomeric form. Although the use of chiral isocyanates[4] largely suppressed the racemization, the yields of diastereomeric hydantoins were unsatisfactory and their separation by HPLC incomplete.

Alkylcarbamoyl amino acid esters,[5] on the other hand, are easily separated by gas chromatography. We have used this approach to develop a procedure that allows the amino acids of a linear peptide to be sequentially removed from the *N*-terminus with retention of configuration (Scheme 1). The peptide **1** (0.5–1 mg) is first converted into the *tert*-butylcarbamoyl peptide **2** by reaction with *tert*-butyl isocyanate and pyridine (3:5, 30 °C, 45 min) and then treated with a solution of hydrogen chloride in isopropyl alcohol (1.0 N, 100 °C, 30 min). This results in cleav-

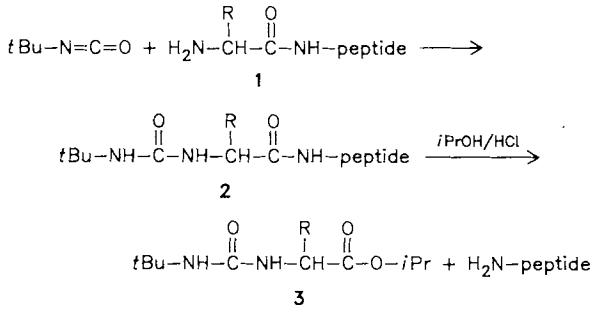
Institut für Organische Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

age of the *N*-terminal amino acid as the *tert*-butylcarbamoyl amino acid isopropyl ester **3**. After extraction of **3** with chloroform, the enantiomer proportions can be determined very exactly by enantioselective gas chromatography (α values 1.07–1.11 on a 25-m glass capillary with XE-60-L-valine-(*S*)-α-phenylethylamide).



Scheme 1. For reaction conditions see text.

Under the given conditions, the use of isopropyl isocyanate and methanolic HCl results in the formation of *N*-isopropylhydantoins in addition to the isopropylcarbamoyl amino acid methyl esters. Although the former can also be separated by gas chromatography, they are not fully configurationally stable. In some cases, it proved to be advantageous to esterify the peptide with HCl/isopropyl alcohol (1.0 N) before the reaction with isocyanate, because the solubility in pyridine and the conversion to the carbamoyl derivative is often considerably improved.

Complete degradation of peptides containing 8–10 amino acids was achieved with 0.5–1 mg of starting material.

The method was used to investigate a synthetic octapeptide having the sequence H-Val-Ala-Leu-Ala-Lys-Lys-Ile-Leu-NH_2, for which gas chromatographic analysis to determine the degree of racemization after hydrolysis gave an unusually high value (8.7% D enantiomer) for Leu. Sequential degradation revealed a perfectly normal value (1.1%) for the D-isomer content of Leu[3] but a totally unexpected value (10.2%) for the D-isomer content of the *C*-terminal Leu. This finding is due to the synthesis of the peptide by the procedure of *Sheppard* et al.[6,7] using a polyacrylamide resin as solid support. In this procedure, the *C*-terminal Leu undergoes esterification with the polymer-bound anchor molecule 4-hydroxymethylbenzoic acid in a 4-dimethylaminopyridine-catalyzed reaction. The long reaction times required for complete esterification may be responsible for the unusually high degree of racemization.

Table 1. Proportion of D enantiomers in the synthetic octapeptide **1**. Gas chromatographic investigation of the *N*-trifluoroacetyl amino acid isopropyl esters after total hydrolysis and the *tert*-butylcarbamoyl amino acid isopropyl esters after sequential degradation.

1 2 3 4 5 6 7 8
H-Val-Ala-Leu-Ala-Lys-Lys-Ile-Leu-NH_2 **1**

Total hydrolysis D enantiomer [%]	Sequential degradation D enantiomer [%]
Σ Ala 3.6	Ala^2 0.8; Ala^4 1.2
Val 1.1	Val <0.3
Σ Leu 8.7	Leu^3 1.1; Leu^8 10.2
Ile 2.2	Ile 2.2
Σ Lys 3.8	[a]

[a] See text.

Comparison of the amounts of racemization after total hydrolysis and after sequential degradation (Table 1) reveals that the hydrolysis of the peptide in 6 N HCl also contributes to the racemization.

A further application of the procedure described here is provided by the investigation of peptide antibiotics, in which D- and L-amino acids are present in various positions.

For some amino acids (Lys, His, Arg, Trp), the carbamoyl derivatives are not sufficiently volatile for gas chromatographic investigation. In these cases, HPLC with chiral supports is a possible alternative. The first positive separation results were obtained with silica gel modified with covalently bound glucose derivatives.[8]

Benzene and Linearly Annelated Arenes as Dienophiles in Diels–Alder Reactions with Inverse Electron Demand

By *Gunther Seitz,* Reinhard Hoferichter,* and *Rolf Mohr*

As prototype aromatic 6π-electron systems, benzene and its simple derivatives show little tendency to react as dienes or dienophiles in [4+2] cycloadditions. Exceptions were observed in the case of extremely reactive dienophiles, such as dehydrobenzene derivatives, hexafluoro-2-butyne, dicyanoacetylene, and allenes, to which benzene adds inter- and intramolecularly as a *diene*.[1,2] Diels–Alder reactions in which benzene or simply substituted benzenes react as *dienophiles* have been rare so far.[3,4]

In bis(trifluoromethyl)tetrazine **1**, an extremely electron-poor diene, the s-*cis* diazabutadiene system exhibits the highest diene reactivity so far observed in Diels–Alder reactions with inverse electron demand.[5] We have now found that **1** can be used especially well to show that benzene and simply substituted benzenes can also exhibit *dienophilic properties*.

Whereas the [4+2] cycloaddition of benzene **2a** to **1** requires 24 h of heating at 140 °C in an autoclave, the donor-substituted benzenes **2b–e** react, in part, under somewhat milder conditions (Table 1).

The Diels–Alder adduct **3a**, which is possibly formed in an equilibrium reaction, cannot be isolated. It undergoes further reaction, in the sense of a [4+2] cycloreversion[6] with elimination of nitrogen, to give **4a** irreversibly. Compound **4a** is sensitive to oxidation and is even oxidized by atmospheric oxygen or excess **1** to give a good yield of the phthalazine **5a**. The constitution of **5a** was confirmed by independent synthesis from **1** and dehydrobenzene **7** (generated from **6**, THF = tetrahydrofuran).[7]

Table 1. Characteristic data for the phthalazine derivatives **5a–e**, **9**, and **11**.

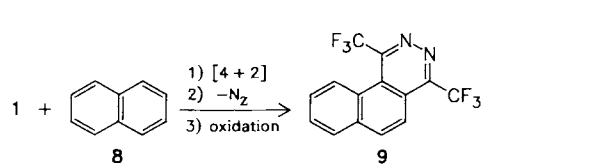
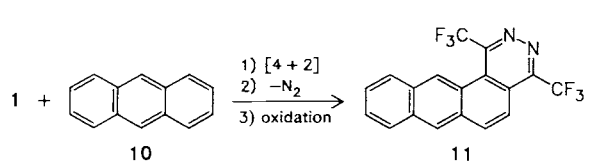
[a] Solvent CH_2Cl_2; only the longest-wavelength maximum is given. [b] Temperature of boiling toluene.

The donor-substituted benzenes **2b–e** react similarly with **1**, resulting in preferential formation[8] of the 6-substituted phthalazines **5b–e** in preparative yields (Table 1).



8 9



10 11

Their constitution can be derived unequivocally from the ^{1}H-NMR spectra (Table 2). The unusual reactivity is in accord with frontier orbital theory[9] and can be predicted on the basis of MNDO calculations.[10]

Linearly annelated arenes such as naphthalene **8** and anthracene **10** also exhibit pronounced dienophilicity, which has hardly been exploited so far in [4+2] cycloadditions.[1,11] Compound **1** reacts with **8** to give the benzophthalazine **9** and with **10** to give the naphthophthalazine **11**. The constitutions of the new compounds **5**, **9**, and **11** are in accord with the analytical and spectroscopic findings (^{1}H-NMR, ^{13}C-NMR, IR, UV, and mass spectra, see also Table 2).

Table 2. ^{1}H- and ^{13}C-NMR data for the phthalazine derivatives **5a–e**; in $CDCl_3$ with a 100-MHz NMR spectrometer if not given otherwise.

5a: ^{1}H-NMR: δ = 8.19 (mc, 2H; aryl H), 8.38 (mc, 2H; aryl H).—^{13}C-NMR: δ = 121.5 (q, $^1J_{CF}$ = 277 Hz; CF_3), 124.0 (m), 124.6 (dq, $^4J_{CF}$ = 3.2 Hz), 134.7 (dd), 150.0 (q, $^2J_{CF}$ = 34 Hz).

5b: ^{1}H-NMR: δ = 2.75 (s, 3H; CH_3), 8.00 (d, 1H, ^3J = 8.7 Hz; aryl H), 8.15 (br s, 1H; aryl H), 8.32 (br d, 1H, ^3J = 8.7 Hz; aryl H).—^{13}C-NMR: δ = 22.7 (q), 121.5 (q, $^1J_{CF}$ = 277 Hz), 122.3 (m), 123.4 (dm, $^4J_{CF}$ = 3 Hz), 124.3 (dm), 124.4 (m), 136.7 (dm), 146.3 (m), 149.5 (q, $^2J_{CF}$ = 34 Hz), 149.7 (q, $^2J_{CF}$ = 34 Hz)

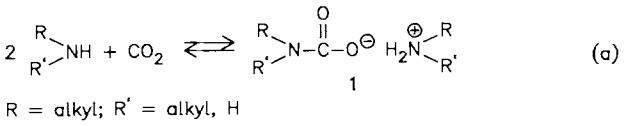
Formation of Oxazolidinones and Oxazinanones by Reaction of Allylamines and of Homoallylamines with Carbon Dioxide and Iodine via Intramolecular Cyclization**

By *Takashi Toda** and *Yoshinori Kitagawa*

Recently, much attention has been focused on the utilization of carbon dioxide in organic synthesis.[1] However, almost all reactions of these types are carried out in the presence of biotin (or its analogues),[2] metal complexes,[3] large amounts of phosphorus compounds,[4] strong bases under high pressure,[5] or combinations of these methods.[6, 7] Furthermore, the reaction conditions are often rather severe.

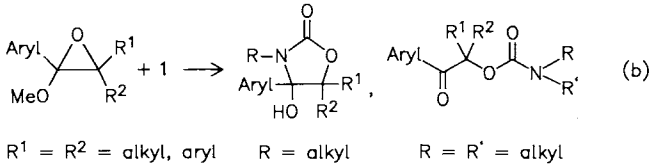
We have been interested in carbon dioxide fixation via ammonium carbamates under mild conditions: without a catalyst, at atmospheric pressure, and, if possible, at ambient temperature. Since several aliphatic amines form stable carbamates **1** [Eq. (a)],[8] these salts were expected to



(a)

R = alkyl; R' = alkyl, H

offer certain advantages in carbon dioxide fixation. We have indeed reported several such reactions.[9] For example, intermolecular reactions between ammonium carbamates and oxiranes (or their synthons) give carbamate derivatives including cyclic carbamates [Eqs. (b)–(d)].



(b)

$R^1 = R^2$ = alkyl, aryl; R^1 = alkyl; R^2 = H — R = alkyl; R' = H — R = R' = alkyl

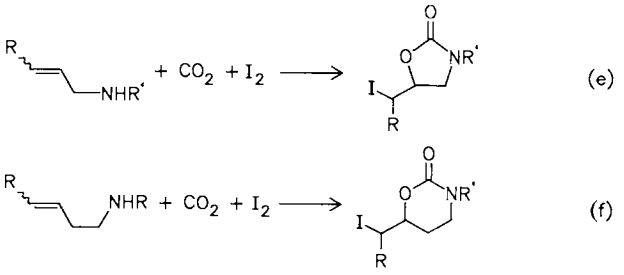
[**] Utilization of Carbon Dioxide in Organic Synthesis via Ammonium Carbamates, Part 8.

Herein we report on the synthesis of oxazolidinone and oxazinanone derivatives by reaction of allylamines and homoallylamines, respectively, with carbon dioxide and iodine via intramolecular cyclization under extremely mild conditions.[10]

Treatment of allyl- or homoallylamines with carbon dioxide in MeOH, followed by treatment with I_2 at ambient temperature for 20 h, gave iodoalkyloxazolidinones [Eq. (e)] or iodoalkyloxazinanones [Eq. (f)], respectively, in



(e)

(f)

Table 1. Yields and some physical properties of the oxazolidinones and oxazinanones. The yields in parentheses are those obtained after prolonged reaction in the presence of Cs_2CO_3 (see text).

Reaction	Amine	Product	Yield [%]	M.p. [°C]	$\tilde{\nu}_{CO}$ (in KBr) [cm^{-1}]
1			61 (70)	117–118.5	1730
2			70 (90)	99–100.5	1735
3			60 (90)	83–84	1730
4			68 (80)	76.5–78	1735
5			52 (80)	134.5–136 [a]	1735
6			41 (60)	142.5–144 [a]	1680
7			54 (70)	150–152 [a]	1690

[a] Decomposition.

fairly good yields (40–70%). The results and some physical properties of the products are summarized in Table 1. Pro-

longed reaction for a week in the presence of Cs_2CO_3 or Na_2CO_3 raised the yields to 70–90%. Since isolation of the intermediate ammonium carbamates is not necessary and the oxazolidinones and oxazinanones are the only isolable products, the reactions constitute one-pot procedures. Moreover, purification of the products is very easy. The structures of the products were deduced from their elemental analyses and from the IR or NMR spectra. As listed in Table 1, all the oxazolidinones exhibit their C=O absorption band near 1730 cm^{-1}, which is in agreement with a five-membered carbamate. The characteristic, strong C=O absorptions for the oxazinanones are observed around 1685 cm^{-1}. The scope and limitations of this reaction are now being studied.

Experimental Procedure

A solution of allylamine (4.0 mmol) in MeOH (4 mL) in an ice-cooled bath was saturated with CO_2. I_2 (2 mmol) was added to the solution, and CO_2 was admitted for an additional 5 min. The reaction mixture was then stirred for 20 h under CO_2 at room temperature. The excess iodine was removed by addition of aqueous $Na_2S_2O_3$, and the MeOH was removed in vacuo at 40°C. Extraction with ethyl acetate, drying over Na_2SO_4, and removal of the solvent gave 5-iodomethyl-2-oxazolidinone, which was purified by recrystallization from ethyl acetate. The reaction of the homoallylamines was carried out similarly. Reaction for one week in the presence of Cs_2CO_3 (2 mmol) raised the yields to the values shown in parentheses in Table 1.

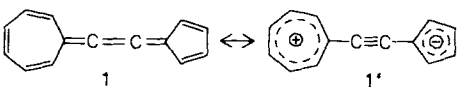
Synthesis and Properties of 1-Cycloheptatrienylidene-2-cyclopentadienylideneethylene Derivatives

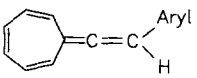
By *Takashi Toda,* Norihiko Shimazaki,* and *Toshio Mukai*

Cycloheptatrienylidenecyclopentadienylideneethylene **1** is a novel system composed of fulvene and heptafulvene units connected by a cumulative double bond. Compound **1** may be considered as a push-pull-type cumulene because of the resonance contribution of the form **1'**. Since cumulenes have been intensively investigated,[1] this system is interesting from the viewpoint of the chemistry of both cumulenes and nonbenzenoid aromatic compounds.



1 **1'**

Only a few examples of this type of compound have been reported in the literature.[2] As part of our investigation of compounds containing both cumulene and cycloheptatrienylidene units, we have already reported on cycloheptatrienylideneethylene derivatives **2**, which dimerized when prepared.[3]

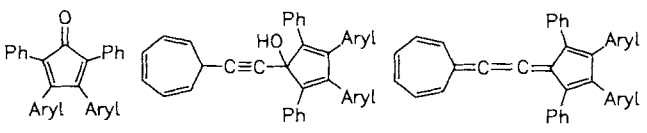


2

Aryl = C_6H_5, p-Br-C_6H_4

We have now synthesized derivatives of **1** (which may be viewed as higher homologues of **2**) and investigated their properties (IR, NMR, and electronic spectra).

Reaction of 2-cycloheptatrienylethynylmagnesium bromide[4] with the tetraarylcyclopentadienones **3a–c**[5] afforded the corresponding cycloheptatrienylcyclopentadienylacetylenes **4a–c** (Table 1). Treatment of these alkynols



3a–c **4a–c** **1a–c**

a, Aryl = C_6H_5; **b**, Aryl = p-Cl-C_6H_4; **c**, Aryl = p-MeO-C_6H_4

with thionyl chloride in the presence of pyridine provided a mixture[6] of the corresponding chlorocyclopentadienyl-

[*] Prof. Dr. T. Toda [+], Dr. N. Shimazaki, Prof. Dr. T. Mukai

Utsunomiya 321 (Japan)

cycloheptatrienylacetylenes and the 1-chloro-1-cycloheptatrienyl-2-cyclopentadienylideneethylenes. Compounds **1a–c** (Table 1) were obtained by treatment of the mixture with excess triethylamine in ether. They are fairly stable in the solid state and give correct $M^{\oplus}$ peaks in their mass spectra. No dimer formation was observed and the compounds gradually decompose in solution.

Table 1. Yields and melting points of the products **1a–c** and **4a–c**.

Compound	Yield [%]	M.p. [°C]
1a	90	183–184 (dec.)
1b	61	198–199 (dec.)
1c	62	147–150 (dec.)
4a	57	182–184
4b	69	198–200
4c	68	121–123

The stretching vibrations due to the cumulene bonds (in KBr; $\tilde{\nu}$ [cm^{-1}] = 2036 m (**1a**), 2040 m (**1b**), 2028 m (**1c**)) resemble those of tri- and tetraarylbutatrienes, whose absorptions were reported[7] at about 2032 cm^{-1}. Compounds **1a–c** exhibit no absorptions in the acetylenic region, however. These values indicate that the small contribution of the resonance structure **1′** is influenced by the substituents on the aryl groups at the 3- and 4-positions of the cyclopentadienylidene ring: the −I effect of Cl in **1b** increases the contribution of the resonance structure corresponding to **1′**; the +M effect of OMe in **1c** decreases it.

The lowest-field ^{13}C-NMR signals of **1a–c** were observed around $\delta = 143$ (in $CDCl_3$). The high-field shift of **1a–c** compared with that of tetraphenylbutatriene ($\delta = 152$)[8] indicates a weak acetylenic character of the central bond of **1a–c**, corresponding to a small contribution of the resonance structure **1′**.

The electronic spectra of **1a–c** showed three different absorption bands: λ_{max} [nm] (ε): **1a**, 280 (27500, sh), 360 (4000, sh), and 538 (13200); **1b**, 287 (29500), 360 (5000), and 547 (37100); **1c**, 280 (25700), 360 (7250), and 545 (19900). The longest-wavelength bands are very broad.[9] An interesting feature of the cumulenes is their emission spectra. When **1a–c** were excited by 360-nm light, emission was observed around 450 nm. Since no emission was observed by excitation of the longest-wavelength absorption band at $\lambda = 530$–560 nm, the fluorescence spectra should be attributed to the emission from the S_2 state.[10]

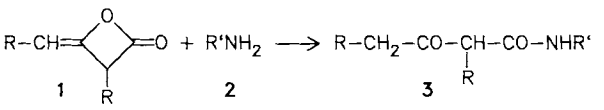
Mycoloylpeptides and Other Lipopeptide Adjuvants from Higher Aldoketene Dimers**

By *Jörg Metzger* and *Günther Jung**

Dedicated to Professor Ernst Bayer on the occasion of his 60th birthday

During the development of carrier/adjuvant systems based on lipopeptides such as tripalmitoyl-*S*-glycerylcysteine,[1] we encountered an interesting side product, which was formed during the acylation of L-cystine bis(*tert*-butyl) ester with palmitoyl chloride (Pam-Cl) and which made the purification of larger batches of the symmetric cystine derivative[1b] more difficult: *N*-palmitoyl(α-palmitoyl)-*N′*-palmitoyl-L-cystine bis(*tert*-butyl) ester. The formation of the α-alkyl-β-ketoacyl moiety Pam(α-Pam) could be explained by the intermediary formation of a 4-alkylidene-3-alkyl-2-oxetanone, **1**, which was experimentally confirmed. Such diketenes, formed from higher fatty acid halides,[2] are known to react with amines **2** to give β-ketoamides **3**[3] (R = long-chain alkyl groups, R′ = alkyl, aryl).



We have optimized this side reaction in order to develop a simple method for the preparation of lipopeptides, particularly mycolic acid derivatives (*N*-(α-alkyl-β-hydroxyacyl) amino-acid derivatives **6**), which are also valuable as adjuvants. Mycolic acids[4a] are found in naturally occurring lipids and, like the muramyldipeptide (MDP), are active components of *Freund's* adjuvant, a mixture of killed tubercle bacteria in paraffin oil that is used for the induction of antibodies.

An example is the toxic trehalose-6,6′-dimycolate ($C_{186}H_{366}O_{17}$, cord factor), isolated from Gram-positive mycobacteria.[4a] *O*-Acylated β-hydroxyacyl moieties are also present in lipid A, the toxic component of the endotoxin[4b] of Gram-negative bacteria. Finally, active analogues of MDP containing mycoloyl moieties are known.[4c] Previous syntheses of mycoloyl amino acids employed mycolic acids isolated from bacteria (semisyntheses).[5]

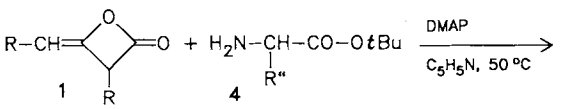
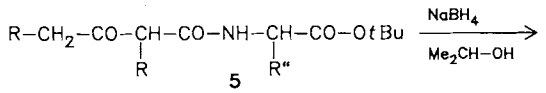
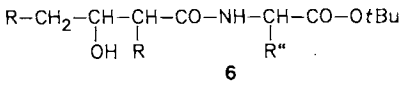
The aldoketene dimers **1** required for our synthesis are readily obtainable from fatty acid halides by reaction with tertiary amines[2] and are stable upon storage. They react with the free amino group of amino acid esters **4** in anhydrous pyridine in the presence of catalytic amounts of 4-dimethylaminopyridine (DMAP) within 2–4 h to give the α-alkyl-β-ketoacyl compounds **5**. In solvents such as dimethylformamide, CH_2Cl_2, or $CHCl_3$ and with bases such as triethylamine or *N*-methylmorpholine, however, mainly the simple acylation product, e.g., the *N*-palmitoyl derivative, is isolated, even when the reaction is carried out for long reaction times and at high temperatures.







The reaction of aldoketene dimers **1** from higher fatty acids with amino acid esters **4** is thus a simple and economical route to novel lipoamino acids. The resulting α-alkyl-β-ketoacyl derivatives **5** (Table 1), after removal of the carboxyl protecting group, are mitogenic compounds (Fig. 1), which, for example, can be covalently linked to the free *N*-terminus of amino-acid or peptide sequences to give lipopeptides that are also biologically active (Fig. 1). Compounds **5** can be quickly reduced to give, in high yield, the mycoloyl compounds **6** (Table 2). For example, the dimeric tetradecylketene **1** (R = *n*-$C_{14}H_{29}$), obtained from Pam-Cl, reacts with alanine *tert*-butyl ester to give a product that can be reduced to a derivative of corynomycolic acid, a C_{32} fatty acid found in the lipids of *Corynebacterium diphtheriae*. The mixture of diastereomers formed in the reduction can, for example in the case of the alanine derivative, be separated on silica gel. However, it is also possible to use the mixture of diastereomers directly as a adjuvant or mitogen in animal experiments. Several of the *two-chain* mycoloyl compounds **6** can be transformed to *three-chain* derivatives by esterification of the OH group. The latter compounds are, in general, stronger mitogens than the non-*O*-acylated compounds **6**. *Four-chain* compounds are accessible via *N*-(α-alkyl-β-hydroxyacyl)-*S*-glycerylcysteine (Fig. 1) or N^{α},N^{ε}-bis[Pam(α-Pam)]lysine. Several of the prepared lipopeptides and amino acids are effective B-cell mitogens.

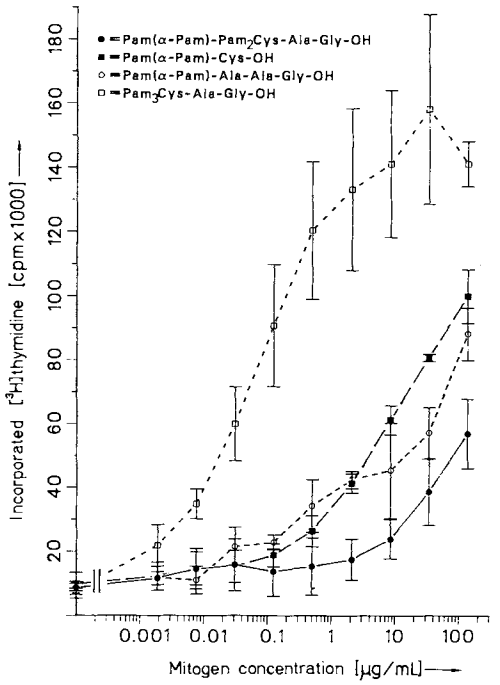

Fig. 1. Mitogenic effect of the two-chain lipids Pam(α-Pam)-L-Cys-OH and Pam(α-Pam)-L-Ala-L-Ala-Gly-OH, prepared from **5**, in comparison to the very potent, three-chain adjuvant *S*-[2,3-bis(palmitoyloxy)-(2*RS*)-propyl]-*N*-palmitoyl-(*R*)-cysteinyl-(*S*)-alanylglycine (Pam_3Cys-Ala-Gly-OH; J.-K. Wiesmüller et al., unpublished results) and the appreciably less active, four-chain derivative *S*-[2,3-bis(palmitoyloxy)-(2*RS*)-propyl]-*N*-palmitoyl(α-palmitoyl)-(*R*)-cysteinyl-(*S*)-alanylglycine (Pam(α-Pam)-Pam_2Cys-Ala-Gly-OH). The dose–response curves were obtained by incorporation of [^{3}H]thymidine in spleen cells of C3H/HeJ mice [6]. The three-chain *O*-acylated lipopeptides prepared from the mycoloyl amino acid esters **6** were also tested in vivo and in vitro [7]. cpm = counts per minute.

For the synthesis of immunogenic peptides and synthetic vaccines, it is important that the α-alkyl-β-ketoacyl moiety, like tripalmitoyl-*S*-glycerylcysteine,[1a] can be introduced at the end of a Merrifield synthesis (Fmoc/*t*Bu strategy). Since the lipid moiety is stable in trifluoroacetic acid, the resulting lipopeptide can be cleaved from the carrier with simultaneous removal of all protecting groups.

Experimental Procedure

N-(α-Alkyl-β-ketoacyl) amino acid *tert*-butyl ester **5**: The fatty acid diketene **1** (1 mmol) was added to a stirred solution of the amino acid ester **4** (1 mmol) in 3 mL of anhydrous pyridine. DMAP (0.1 mmol) was added at 50°C. During the reaction, the color of the solution turned from yellow to a cognaclike color and, after 2–4 h, thin-layer chromatography indicated the consumption of all the diketene. The pyridine was removed in vacuo and the crude product was precipitated from a small amount of chloroform by addition of methanol to the cooled solution. Impurities due to excess diketene could be precipitated from ethyl acetate or diisopropyl ether at 0°C, the usually still yellow or orange product remaining in solution. Final purification of **5** was achieved by flash chromatography on a silica gel column with chloroform.

Mycoloyl amino acid *tert*-butyl ester **6**: The *N*-(α-alkyl-β-ketoacyl) amino acid *tert*-butyl ester **5** (1 mmol) was dissolved in 15 mL of 2-propanol by heating and treated with solid sodium tetrahydridoborate (1 mmol). The reduction product slowly precipitated. After 3 h stirring, the precipitation was driven to completion by neutralization with 0.1 N HCl. The colorless mycoloyl compound **6** was filtered off, washed several times with water, and dried over P_2O_5.

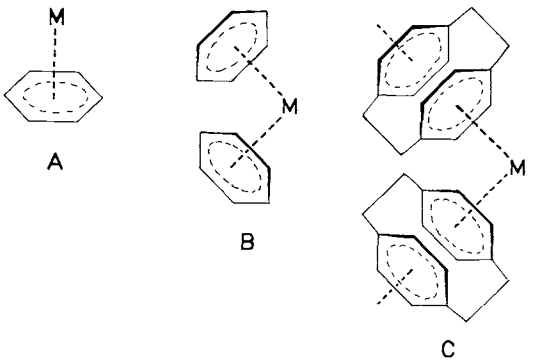
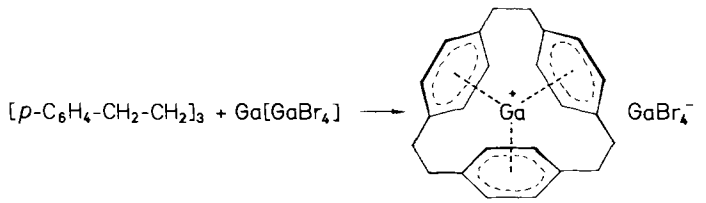
Arene Complexes with Weak Interactions: A Macrocyclic Tris(arene) Complex of Gallium(I) with η^{18} Coordination**

By *Hubert Schmidbaur,* Rudolf Hager, Brigitte Huber,* and *Gerhard Müller*

Main-group metals with an ns^2 configuration form centrically η^6-bonded complexes with aromatic hydrocarbons; however, the long contact distances between the metal and the ring center indicate relatively weak interactions.[1–3] In addition to 1:1 complexes (**A**), 1:2 complexes (**B**), in which the rings are bent toward each other, are known for gallium, indium, and thallium in the oxidation state +1. Owing to the entropy effect, considerable stabilization of this type of bonding is expected (in solution) when the arene ligands are linked.[1] Optimal conditions and thus the greatest tendency of formation and stability should exist, according to this concept, for doubly linked rings, such as those present in cyclophanes. However, all attempts to introduce Ga^+, In^+, or Tl^+ into the cavity between the benzene rings of [2.2]- and [3.3]paracyclophanes,[1,4] as well as between the arene rings of the related naphthalene derivatives,[5] have failed so far. The metal atoms in the resulting adducts are always coordinated to the benzene rings of the cyclophanes from the outside. Nevertheless, the centric η^6 coordination, present in **B**, is still found for the arene ligands, which are bent toward each other (e.g., in **C**).[4]



The knowledge of the preferred contact distances and modes of coordination has now been used by us to achieve centric coordination of the cation Ga^+ in the cavity of [2.2.2]paracyclophane. Indeed, it was surprisingly easy to achieve this novel coordination experimentally. Crystalline $Ga[GaBr_4]$, whose structure was recently elucidated,[6] dissolves in benzene as the dimeric tetraarene complex $[(C_6H_6)_2Ga \cdot GaBr_4]_2$.[7] Upon addition of the cyclophane, such solutions afford crystalline precipitates having the analytical composition of the 1:1 complex **1**.



1

Complex **1** forms colorless, only slightly air-sensitive crystals, which are sparingly soluble in aromatic hydrocarbons and afford solutions exhibiting no electrical conductivity. The latter finding indicates that **1** has pronounced ion-pair character.

The X-ray crystal structure analysis revealed[8] that the metal atom in **1** is indeed located in the interior of the cyclophane macrocycle and is involved in identical centric (η^6) bonding to all three benzene rings (Fig. 1a). The gallium atom is thus equidistant, within narrow limits, from all 18 carbon atoms of the arenes. The distances correspond to values found earlier for similar bonds.[1] Instead of lying completely in the plane defined by the three ring centers (D1, D2, D3), however, the metal lies 0.43 Å above it. Taking into consideration the position of the anion, it becomes immediately clear that this displacement is due to the proximity of a bromine atom (Ga2–Br2 3.388(2) Å),

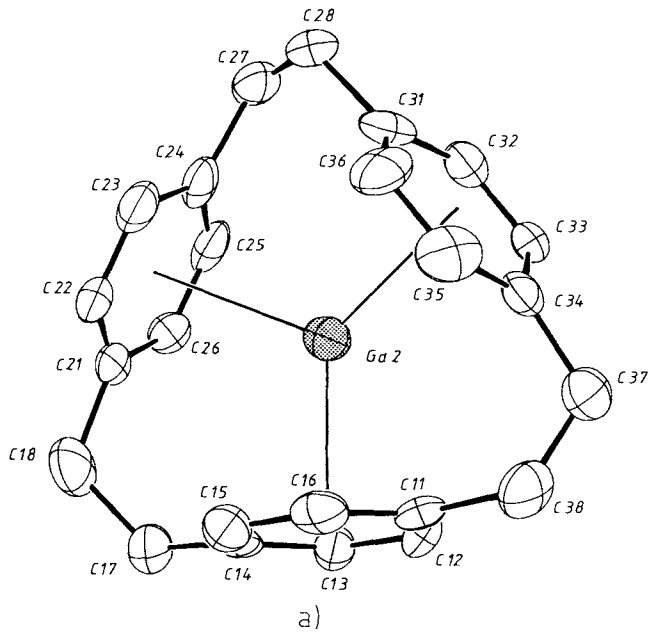

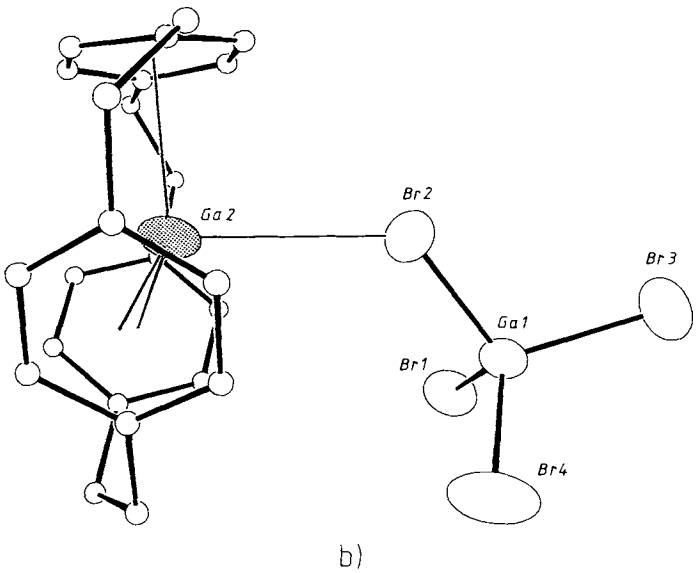

Fig. 1. a) Geometry of the cation of **1** (ORTEP, thermal ellipsoids at the 50% probability level, H atoms omitted). b) Side view of **1**. The Ga^1 atom, Ga2, is clearly displaced from the center of the cyclophane toward the bridging bromine atom, Br2. The three arene rings adjust to this displacement by a slight rotation, whereby, to a good approximation, the η^{18} coordination is retained. Important bond lengths [Å] of **1**: Ga2-C11 2.972(9), Ga2-C12 2.911(8), Ga2-C13 2.925(9), Ga2-C14 2.979(9), Ga2-C15 3.072(9), Ga2-C16 3.053(9), Ga2-C21 3.028(9), Ga2-C22 3.079(9), Ga2-C23 3.048(9), Ga2-C24 2.937(9), Ga2-C25 2.913(9), Ga2-C26 2.949(9), Ga2-C31 2.994(9), Ga2-C32 2.986(9), Ga2-C33 2.953(8), Ga2-C34 2.923(9), Ga2-C35 3.00(1), Ga2-C36 3.02(1), Ga2-D1 2.64, Ga2-D2 2.65, Ga2-D3 2.64, Ga1-Br1 2.333(1), Ga1-Br2 2.319(2), Ga1-Br3 2.313(2), Ga1-Br4 2.305(2), Ga2-Br2 3.388(2).—D1, D2, D3: centers of the three arene rings, C11–C16, C21–C26, and C31–C36.

which induces a distorted coordination geometry approaching that of a tetrahedron (Fig. 1b). Similar ion pairs are presumably present in solution (see above). A space-filling model of the cation clearly shows the perfect spatial fitting of the cyclophane ligand and the metal (Fig. 2).

Complex **1** is the first complex with three centrically coordinated, neutral arene ligands. The central atom contains no less than 19 atoms in its first coordination sphere.

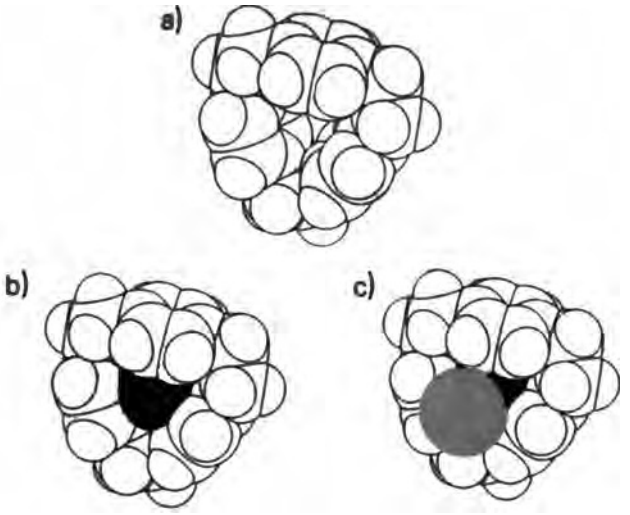

Fig. 2. Space-filling models for understanding the structure of **1**: a) space-filling model of [2.2.2]paracyclophane; b) with Ga^1 (black) in the interior; c) with bridging Br2 atom (grey).—It is readily apparent from a) to c) that the acentric coordination of Ga^1 in the cage is due to the dimensions of the cyclophane interior and the radii of Ga2 and Br2. An additional Br contact from the "backside" of the molecule is made difficult by the resulting reduction in the size of the cyclophane opening.

This high hapticity distinguishes the compound fundamentally from the analogous silver complex, $[C_6H_4CH_2CH_2]_3 \cdot AgClO_4$, in which the metal, instead of completely entering the ligand cavity, remains situated at the edge of the cavity, forming three η^2 bonds to the arene rings.[9] These differences are also found for the [2.2]- and [3.3]paracyclophane complexes of Ga^+, In^+, and Tl^+, on the one hand, and Cu^+ and Ag^+,[4, 10] on the other, as well as for simple arene adducts of these elements.[1, 2, 7] These findings may be regarded as confirmation of the fact that a simple classification of the organometallic compounds described here and in earlier reports cannot be made using simple solvation or van der Waals models, because the marked η^2/η^6 differentiation between d^{10} and $d^{10}s^2$ configurations cannot be explained in this way without additional assumptions. It is especially astounding that the arene coordination in **1** is so efficient that all eight Ga^+ contacts to bromine atoms observed in the crystal of $Ga[GaBr_4]$,[6] with the exception of one, are sacrificed. In all other structurally investigated cases, several anion contacts are retained.[1]

Experimental Procedure

Ga_2Br_4 (140 mg, 0.305 mmol) was dissolved in 10 mL of toluene and then allowed to react with a solution of [2.2.2]paracyclophane (100 mg, 0.323 mmol) [11] in 3 mL of toluene. Complex **1** spontaneously precipitated as a white, finely crystalline solid. Recrystallization from 25 mL of benzene afforded 0.19 g of pure product (81% based on Ga_2Br_4), m.p. = 176 °C. Very careful cooling of benzene solutions from 80 to 20 °C over 100 h afforded single crystals.—IR (Nujol): $\tilde{\nu}$ = 1515, 1435, 812, 802, 584, 465, 275 (νGaBr) cm^{-1}. Complex **1** exhibits no measureable electrical conductivity in benzene or toluene at 23 °C. Correct elemental analyses were obtained. The ^{1}H-NMR spectra show apparently equivalent CH_2 and CH protons for solutions in benzene or toluene, which were very dilute because of the sparing solubility of **1**. Presumably, the environments of the hydrogen atoms are identical on the NMR time scale owing to exchange processes. In polar solvents, desolvation or disproportionation occurs to give metallic gallium and gallium(III).

The Fluorometric Determination of Thymine Glycol as Criterion of the Treatment of Foodstuffs (Biological Material) with Ionizing Radiation

By *Konrad Pfeilsticker** and *Jürgen Lucas*

The treatment of foodstuffs with ionizing radiation[1,2] for the purpose of sterilization and the inhibition of germination or ripening is currently forbidden in the Federal Republic of Germany. Detection of such a treatment is possible with limitations in the case of dried products, especially spices, by chemiluminescence and thermoluminescence.[3] A general method of detection, especially for water-containing biological material has so far been lacking. In the following communication we introduce a new method which, in principle, exploits the sensitivity of DNA to radiation.

In an aqueous DNA solution about 78% of the hydroxyl radicals formed radiolytically from the water react with the bases of DNA. The pyrimidine bases and especially thymine are the most sensitive.[4] A major product formed on radiolysis is 5,6-dihydroxy-5,6-dihydrothymine (thymine glycol),[5] which can now be determined fluorometrically and quantitatively as criterion of irradiation on the basis of the DNA determination method of *Roberts* and *Friedkin*:[6] hydroxyacetone (acetol) is cleaved under alkaline conditions from the radiolytic product thymine glycol bound in the DNA and allowed to react with *o*-aminobenzaldehyde (*o*-ABA) to give the fluorescent 3-hydroxyquinaldine. The oxidation of the thymine with bromine prescribed by *Roberts* and *Friedkin*[6] is hereby replaced by the irradiation.

For precipitation of the nucleic acids and proteins, 5 g of a food sample is dissolved in 25 mL of 6% trichloroacetic acid and the solution homogenized and centrifuged. The precipitate is then subjected to exactly the same homogenization and centrifugation procedure another two times. 10 mL of water is added to the final precipitate and the solution neutralized with 1 M KOH, diluted to 25 g with water, and finally re-homogenized. 400 mg of the homogenate is treated with 35 µL of a solution of 0.1 M ethylenediaminetetraacetic acid (EDTA) in 2.1 M NaOH and incubated for 90 min at 20°C.[7] The sample is then treated with 65 µL of an *o*-ABA solution (prepared according to the method described by *Roberts* and *Friedkin*[6]) and incubated for 20 min at 65°C. The reaction is terminated by addition of 4.5 mL of 0.1 M potassium phosphate buffer (pH 6.9).[6] Before carrying out any measurements the sample must be centrifuged to remove any suspended material. On excitation at $\lambda = 375$ nm the fluorescence at 444 nm is measured. The apparatus is previously calibrated with an aqueous solution of quinine sulfate in 0.1 N H_2SO_4 (0.1 mg/mL) ($IF = 100$) and with distilled water ($IF = 0$) at the same wavelengths (IF = fluorescence intensity).

Some components of the sample interfere and give rise to an increased fluorescence. We have found that this can be largely compensated for, if 400 mg of homogenate treated with 65 mL of an aqueous NH_3-solution (0.08 M) instead of *o*-ABA is used for the blank determination (see Tables 1 and 2, IF(N)). This important finding makes it possible to analyze a sample without recourse to an unirradiated authentic reference sample. The difference between the fluorescence intensities of the sample and the blank corresponds to the thymine glycol present in the sample. The conversion of the relative fluorescence values into absolute values for measuring the thymine glycol content was achieved by means of a calibration curve standardized according to the method described in ref. [6].

Table 1. Fluorescence intensity (IF) and thymine glycol contents in irradiated and unirradiated foodstuffs. TG = thymine glycol; IF(A) = fluorescence intensity with *o*-aminobenzaldehyde; IF(N) = fluorescence intensity with NH_4OH (blank); standard deviation $\sigma = \pm 1.9$ g TG/g sample.

Endenicher Allee 11-13, D-5300 Bonn 1 (FRG)

significant increase in fluorescence intensity could be observed in the irradiated samples, so that the working principle looks very promising. Upon irradiation of the foodstuff samples with 10 kGy, 16–22% of the thymine is converted into thymine glycol (cf. Table 1), if one assumes that the sample material contains 1 g/kg DNA. It follows from Table 1 that it will be possible in this way to derive the applied irradiation dose, besides collecting qualitative information. This also follows from measurements on solutions of pure calf thymus DNA (see Table 2); these measurements also indicate the limits of detection of the method.

Table 2. Fluorescence intensity (*IF*) and thymine glycol content in irradiated and unirradiated calf thymus DNA in aqueous solution (0.5 mg/mL in 0.15 M NaCl). For abbreviations see Table 1.

	Irradiation dose [kGy]			
	0	0.05	5	10
IF(A)	2	3.5	120	143
IF(N)	0.5	0.5	17	27
IF(A) − *IF*(N)	1.5	3.0	103	116
Thymine glycol content [μg TG/mg DNA]	0.35	1.1	32	36
Thymine glycol based on original thymine	0.4%	1.2%	36%	40%

It is interesting in this connection that *Ames*' group[8] determine thymine glycol and thymidine glycol in human and rat urine analytically in order to demonstrate oxidative damage of DNA by mutagens and carcinogens.

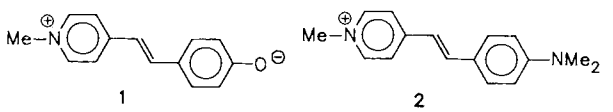
Photoisomerization of Stilbazolium Chromophores with Potential Nonlinear Optical Applications**

By *George L. Gaines, Jr.**

There is currently much interest in the use of organic materials for nonlinear optical applications.[1] The largest values of β, the molecular second-order hyperpolarizability, have been reported for the related stilbazolium chromophores **1** and **2** (and their derivatives with an *n*-alkyl group instead of a methyl group on the pyridinium nitrogen atom).[2-3] Both the nonlinear response and the absorption wavelength (which governs the so-called "transparency-efficiency trade-off") are affected by the nature of the substituents in such chromophores.[4] A number of stilbazolium dyes with other substituents have been prepared, and most of them undergo facile *trans*→*cis* photoisomerization.[5] Protonated **1** (**1H**$^{\oplus}$) is also extensively



1 2

isomerized on irradiation, while **1** appears to be photostable.[6] In neutral solutions, the quantum yield of photoisomerization of **2** is also very low, and the photostationary state has a very small *cis* content.[7] I now report the preparation of some additional substituted methylstilbazolium iodides and observations on their susceptibility to photoisomerization which provide a rationale for the apparent photostability of **1** and **2**.

Table 1. Absorption and emission maxima and photoisomerization of stilbazolium chromophores.

[a] Emission peak wavelength, uncorrected. [b] Decrease in absorbance of long-wavelength band after irradiation to photostationary state. [c] See [12]. [d] See [6].

The *N*-methyl compounds **1**–**6** (Table 1) were prepared by condensing *N*,4-dimethylpyridinium iodide with appropriately substituted benzaldehydes by the method of *Phillips*.[8] Those compounds capable of being protonated (**1**, **2**, and **6**) exhibit pH-dependent absorption spectra (Fig. 1); the pK_a values estimated from the spectra in aqueous buffers are 8.54 (**1H**$^{\oplus}$[6]), 3.53 (**2H**$^{\oplus}$), and 8.15 (**6H**$^{\oplus}$). The stronger the electron-donating ability of the substituent(s), the longer is the wavelength of the longest-wavelength absorption band (Table 1), and also the greater is the solvent sensitivity of this absorption. All of the compounds emit readily detectable fluorescence from solutions in water or ethanol at room temperature (Table 1). As had previously been noted for **1**,[6] protonation of **2** and **6** substantially increases the fluorescence efficiency. Qualitatively, the fluorescence intensities from solutions of **3**–**5**, as well as of

[**] This research was in part stimulated by a subcontract through the University of California, Davis, Department of Electrical and Computer Engineering, from the Air Force Weapons Laboratory, Kirkland AFB, under contract F29601-84-C-0084. I thank Mrs. *P. L. Karas* for technical assistance and one of the referees for helpful comments.

$2H^{\oplus}$ and $6H^{\oplus}$, are comparable to that from solutions of $1H^{\oplus}$, rather than its deprotonated form **1**.

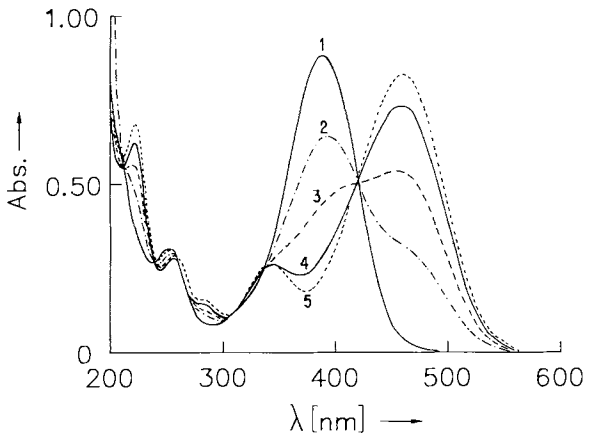

Fig. 1. Absorption spectra of **6** (2.1×10^{-5} M) in aqueous buffer solutions. 1, pH = 6.0; 2, pH = 7.9; 3, pH = 8.4; 4, pH = 9.1; 5, pH = 10.2.

Irradiation of solutions of most stilbazolium dyes in the long-wavelength band leads to isomerization, with a large decrease in the intensity of that band and a concomitant increase in the absorbance of the UV band.[5,6] The spectra of **1** and **2**, however, do not show such changes.[6,7] For example, no detectable spectral change was observed after 12 h of irradiation (in Pyrex, 10 cm from a 100-W medium-pressure Hg lamp) of neutral solutions of **2** in water or ethanol. After irradiation, on the other hand, solutions of $2H^{\oplus}$ exhibit spectroscopic changes exactly analogous to those of $1H^{\oplus}$ (Fig. 2); the photostationary state is attained within less than 15 min under these conditions. Solutions of **3**–**5**, and $6H^{\oplus}$, after irradiation, exhibit spectral changes analogous to solutions of $1H^{\oplus}$. In all cases, these absorption changes are accompanied by substantial decreases in fluorescent emission, as occurs on photoisomerization. Alkaline solutions of **6** are much less photolabile than acidic solutions, but small spectral changes do occur (approximately 4–7% decrease in absorbance at 461 nm after irradiation for 15–75 min.

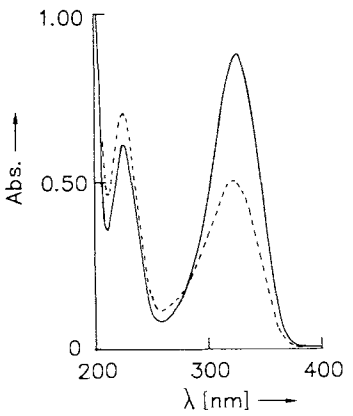

Fig. 2. Spectral change on irradiation of $2H^{\oplus}$ (3.0×10^{-5} M in 0.1 M HCl) to photostationary state (—— before irradiation; ---- after irradiation).

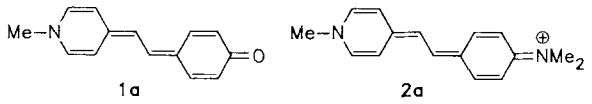
All of the spectral changes observed after irradiation are consistent with *trans*→*cis* photoisomerization. No quantification of the *cis*–*trans* ratio in the photostationary state has been attempted. However, the larger values of ΔA for **3**–**5**, compared with $1H^{\oplus}$, $2H^{\oplus}$, and $6H^{\oplus}$, may be due to excited-state deprotonation in the latter three cases competing with isomerization.[9]

In addition to the benzenoid structure of **1**, a quinonoid resonance structure, **1a**, is also possible; this structure is



1a 2a

stabilized in nonpolar solvents, leading to a further red-shift of the lowest-energy absorption band.[10] Calculations[10b] suggest that the quinonoid form contributes significantly to the first excited state in all solvents; such an interpretation is also consistent with the fact that the dipole moment of the excited state is lower than that of the ground state.[11] In the quinonoid form, the barrier to rotation around the central bond is low, but the cisoid form is thermodynamically unstable by about 11 kcal/mol relative to the transoid form.[10c]

In the case of **2**, a similar resonance structure, **2a**, may be written. Since both **2** and **2a** bear a net charge, solvent polarity effects on the ground state are expected to be less pronounced. This is consistent with the decreased solvatochromism of **2** compared with **1**. Quinonoid resonance structures for **3**–**5** and the protonated compounds $1H^{\oplus}$, $2H^{\oplus}$, and $6H^{\oplus}$ will clearly be less stable than **1a** or **2a**; in the case of **6**, moreover, the *o*-quinone is expected to be of higher energy than the corresponding *p*-quinone. Hence, the accessibility of **1a** and **2a** in the excited state, together with the instability of their cisoid conformers, appear to impart photostability to these particular compounds.

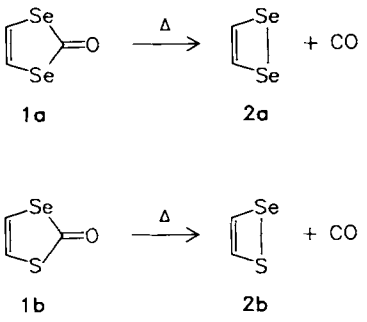
1,2-Diselenete and 1,2-Thiaselenete**

By *Frank Diehl* and *Armin Schweig**

The structure and properties of the valence isomeric 1,2-dithietes and dithiones have been rather satisfactorily documented;[1] in contrast nothing is known about their selenium counterparts, apart from a synthetic route for 3,4-bis(trifluoromethyl)-1,2-diselenete.[2] Mixed sulfur-selenium analogues were hitherto unknown. We report here on the first syntheses of 1,2-diselenete **2a** and 1,2-thiaselenete **2b**. The compounds are formed by gas-phase pyrolysis of 1,3-diselenol-2-one **1a** and 1,3-thiaselenol-2-one **1b**, respectively. The pyrolysis reaction is suitable for the synthesis of other substituted 1,2-diselenetes and 1,2-thiaselenetes too. This provides the first opportunity to systematically investigate the hitherto unknown chemical and physicochemical properties of these systems (e.g. valence isomerism, 6π-aromaticity, photochemistry, and electrical conductivity).



The reactants[3,4] were obtained according to procedures (**1b**) or modified procedures (**1a**) already described in the literature.[5,6] The pyrolyses were carried out in thermal reactors,[7] installed next to the ionization region of a UV-photoelectron spectrometer or as near as possible to the condensation region of a low-temperature cryostat. Optimization of the reactions with respect to the products **2a** and **2b** was achieved on the basis of photoelectron or IR spectra (in argon matrix). If the temperature falls short of the optimum temperature, increasing amounts of the starting materials are observed in the spectra; if however the temperature exceeds the optimum temperature, further reaction of **2a** and **2b** gains significance, as can be readily monitored by the increasing intensity of the acetylene bands in the spectra. At the optimum temperature, ca. 10% of the starting materials still remains in the gas mixtures. In the case of the photoelectron spectra, the product spectra were therefore refined by substraction of the spectra of the reactants (recorded under the same conditions).

The photoelectron spectra thus obtained are shown in Figure 1 together with the known photoelectron spectrum of 1,2-dithiete.[1] It can be seen that the spectra of the two new compounds **2a** and **2b** are very similar to the spectrum of 1,2-dithiete. From previous experience this is essentially true for analogous sulfur and selenium heterocycles[8] (because of the small difference in the electronega-

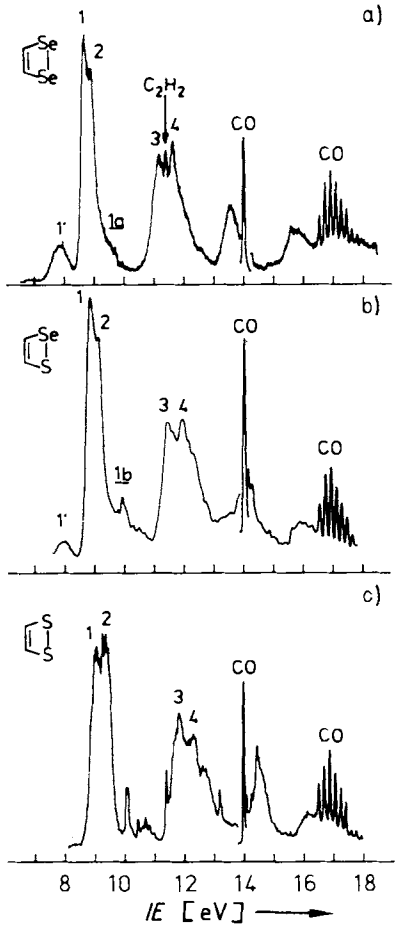


Fig. 1. He(I) photoelectron spectrum (*IE*/eV) of a) 1,2-diselenete **2a**: (1) 8.71, (2) 8.82, (3) 11.18, (4) 11.64, (1') 7.96 (presumably Se_5 [11]); b) 1,2-thiaselenete **2b**: (1) 8.87, (2) 9.13, (3) 11.46, (4) 11.97, (1') 8.04 (presumably Se_5 [11]); c) 1,2-dithiete [1]: (1) 9.05, $^2B_1(\pi)$; (2) 9.36, $^2A_2(\pi)$; (3) 11.83, $^2B_2(\sigma)$; (4) 12.31, $^1A_1(\sigma)$.

tivities of the two elements); thus, the photoelectron spectroscopic findings concomitantly provide unequivocal proof of the structure.

These results are confirmed by low-temperature IR spectra in an argon matrix. **2a** and **2b** show an intense absorption at 734 cm^{-1} (CH-δ_{oop} vibration), i.e. at practically the same wave number, namely 735 cm^{-1}, as 1,2-dithiete.[1] This is consistent with the general rule that the position of the IR absorption bands, in which the heteroatoms do not participate, remain almost unchanged on replacing sulfur by selenium.[9]

The thermal behavior of **1a** and **1b** has parallels in the electron impact-induced fragmentation of the compounds. The main fragmentation products (MS, 70 eV) are: Se_2^+ [*m/z* 160 (90%)], **2a**$^+$ or open form [*m/z* 186 (100%)], and SeS^+ [*m/z* 112 (50%)], **2b**$^+$ or open form [*m/z* 138 (100%)], respectively.[10]

s-Tetrazine as Ligand for Monomeric and Bridged Macrocyclic Metal Complexes**

By *Uwe Keppeler, Sonja Deger, Armin Lange,* and *Michael Hanack**

Dedicated to Professor Ernst Bayer on the occasion of his 60th birthday

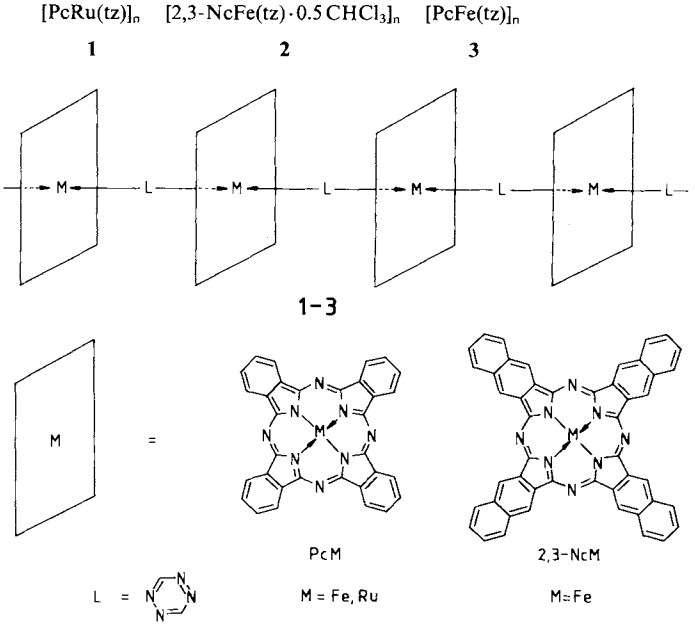
Macrocyclic transition metal compounds can be coupled by bidentate bridge ligands to axially bridged complexes (Scheme 1). In view of their interesting conductivities we have recently prepared and investigated a number of such polymeric complexes.[1]

Phthalocyanine (Pc), tetrabenzoporphyrin and, after development of an improved synthesis, also 2,3-naphthalocyanine (2,3-Nc) have been used as macrocycles, with transition metals such as Fe, Co, Rh and other metals as central metal atom. As coupling bidentate ligands we have not only used neutral ligands such as pyrazine (pyz), diisocyanobenzene and substituted diisocyanobenzenes but also anionic ligands such as cyanide or thiocyanate.[1] It was even possible to prepare a stable coordination compound, $[PcFe(tz)]_n$ **3**, with the unstable species *s*-tetrazine (tz).[2]

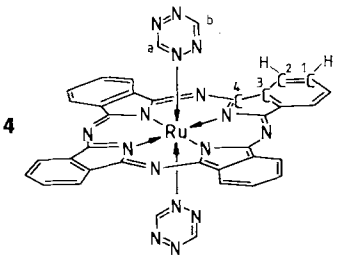
We now report on novel compounds bridged by *s*-tetrazine with phthalocyaninatoruthenium(II) (PcRu) and 2,3-naphthalocyaninatoiron(II) (2,3-NcFe) as metal macrocycles and compare the properties of the compounds **1** and **2** with those of **3** (Scheme 1).

1 and **2** were obtained upon heterogeneous reaction of the metal-macrocycles PcRu and 2,3-NcFe with a small excess of *s*-tetrazine[3] at 70°C and 50°C, respectively, in $CHCl_3$ for one to two days.

2 contained $CHCl_3$ as solvent of crystallization. In the reaction of *s*-tetrazine with PcRu a mixture of the monomer **4** and oligomers, which are soluble in $CHCl_3$, and **1**, which is insoluble in $CHCl_3$, is formed first. **1** was purified by extraction of the soluble fraction with $CHCl_3$. **1** and **2** are, respectively, violet and green, microcrystalline powders which are insoluble in organic solvents (Yield: **1**: 43%; **2**: 70–80%).



Scheme 1. Bridged compounds **1**–**3**.



Only **4** could be obtained in pure form as a monomeric bisaxially coordinated complex; this was achieved by reaction of PcRu with *s*-tetrazine (molecular ratio 1:6) in $CHCl_3$ at 70°C. In order to separate unreacted PcRu, the deep blue solution was filtered off after 1 h and the solvent was removed under vacuum. **4** precipitated as a violet, microcrystalline powder. It still contained varying amounts of uncoordinated *s*-tetrazine, which was removed at 1.5 Pa (yield 40–45%). $[PcFe(tz)_2]$ **5** could not be separated from unreacted PcFe because of its sparing solubility. No monomeric complex was obtained with 2,3-NcFe.

The complexes **1**, **2**, and **4** were characterized by simultaneous TG/DTG/DTA measurements,[4] elemental analyses, and by their IR spectra.

The ^{57}Fe Mössbauer spectra of **2**, **3**, and **5**—with iron as central metal—were used for further characterization. In comparison to the square-planar environment of the iron atoms in PcFe[5] and 2,3-NcFe, a hexacoordinated arrangement of Fe^{II} can be concluded from the values for the isomeric shift δ and the quadrupole splitting ΔE_Q in the case of **2**, **3**, and **5** (Table 1). Pentacoordination can therefore be ruled out in the case of the bridged complexes **2** and **3**. Similar Mössbauer parameters had already been measured in the case of $[PcFe(pyz)_2]$ and $[PcFe(pyz)]_n$.[6] It follows from the ^{57}Fe-Mössbauer spectrum of **5** that unreacted PcFe is still present after the synthesis in ethanol.

X-ray powder diagrams show isomorphism between **3**

and **1**, the reflections in the case of **1** being shifted, as expected, to higher interplanar distances.

The solubility of **4** is satisfactory enough for a characterization by ^{1}H- and ^{13}C-NMR spectroscopy.[7] Noteworthy is the large upfield shift of the two *s*-tetrazine protons, caused by the ring current of PcRu and the unresolved *para* coupling in the free *s*-tetrazine, which is increased to 2.64 Hz by coordination to PcRu. This shows, once more, that phthalocyaninatometal complexes can serve as effective NMR-shift reagents.[8] Thus, both the ^{1}H-NMR as well as the ^{13}C-NMR spectra contribute to a clarification of the type of coordination of the *s*-tetrazine to the metal.[2] The appearance of two signals in each case for the two H and two C atoms of the coordinated *s*-tetrazine rules out an edge-on coordination via two nitrogen atoms.

In solution, complexes **4** tend to form oligomers. These give rise to additional signals (shifted upfield) due to the Pc protons. Such signals have already been observed in the spectra of complexes **4** with diisocyanotetramethylbenzene instead of *s*-tetrazine ($[PcRu(Me_4dib)_2]$).[1e]

The electric dark conductivities of **1**, **2**, **3**, and **4** were measured on pressed disks[9] (Table 2). The bridged compounds **1**, **2**, and **3** exhibit good semiconductor properties without additional doping, which otherwise are only achieved by oxidative doping of the coordination polymers. The conductivity of the monomer **4**, on the other hand, is about a factor of 10^9 lower.

Table 2. Powder conductivity at room temperature (σ_{RT}) and activation energies (E_a) [a] of the compounds **1**–**4**, measured in the dark.

	Compound	σ_{RT} [S/cm]	E_a [eV]
1	$[PcRu(tz)]_n$	0.01 [b]	0.1
2	$[2,3\text{-NcFe(tz)}]_n$	0.3 [b]	0.07
3	$[PcFe(tz)]_n$	0.02 [b]	0.1
4	$[PcRu(tz)_2]$	10^{-11} [c]	—

[a] $\sigma_T = \sigma_0 \cdot \exp\left(-\frac{E_a}{kT}\right)$; temperature range 80–350 K. [b] Four-probe method, 1×10^8 Pa. [c] Two-contact method 1×10^8 Pa.

Various theoretical considerations[10, 11] have indicated that the formation of the chain structure in bridged metal complexes such as **1**, **2**, and **3**, and, dependent thereof, their electrical behavior, is largely determined by the nature of the central metal and of the bridge ligand. The semiconductor behavior of compounds **1**, **2**, and **3** bridged by *s*-tetrazine can be explained in terms of a comparatively low-lying conduction band, whose formation is primarily due to the ligand *s*-tetrazine.

First ENDOR Investigations of Biologically Relevant Organic Radicals in Reversed Micelles**

By *Norbert Bretz, Ingrid Mastalsky, Martin Elsner,* and *Harry Kurreck**

Reversed micelles ("water inside") are attracting increasing attention in biochemical research for several reasons:

a) Since enzymes preferentially function in an aqueous environment their stability toward the denaturing action of hydrophobic solvents can be enhanced by encapsulating them within the water pools of reversed micelles, and their catalytic activity can advantageously be used to enzymatically convert sparingly water-soluble substrates into the desired product in the nonaqueous phase.[1, 2]
b) Modified protein-free cofactors of enzymes, e.g. of flavoproteins, are rarely "good" model compounds since they exhibit undesirable properties that are not met with in intact native enzymes. Embedding of the flavin cofactors in reversed micelles could possibly suppress these properties, aggregate formation by stacking, light sensitivity, and—in the case of the semiquinoid states—radical disproportionation and radical dimerization.
c) For the spectroscopic investigation of free radicals by the magnetic resonance techniques EPR (electron paramagnetic resonance) and ENDOR (electron nuclear double resonance), water is known to be a particularly unsuit-

[**] We thank Dr. *B. Kirste* for helpful discussions and assistance in the simulations of the spectra. *N. B.* thanks Professor Dr. *F. Müller*, University of Wageningen, for a stimulating Fellowship in his laboratory. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

able solvent because of its high microwave dielectric loss. On the other hand, investigations under physiological conditions usually require aqueous buffer solutions. If the paramagnetic species are generated within the water pools of reversed micellar solutions, such systems might enable one to study radicals in water compartments, thereby retaining the nonpolar hydrophobic character of the solution.

In studies on the nature of surfactant-solubilized water pools, interesting results, e.g. about the micellar microviscosities, have been obtained by taking advantage of the sensitivity of EPR measurements of spin probes to their environments[3] (*reporter group technique*[4]). However, evaluation of the important hyperfine data by means of EPR spectroscopy is often hampered by the limited resolution of this technique. In organic radical chemistry ENDOR spectroscopy has found wide application in attempts to overcome this drawback of EPR spectroscopy[5–7], and may therefore offer some prospect of success in the field of reversed micelles, too. The first ENDOR study of an *inorganic* radical ($ON(SO_3K)_2$) was performed in the dodecylammonium propionate (DAP)/toluene and sodium 1,2-bis(2-ethylhexyloxycarbonyl)-1-ethanesulfonate (AOT)/toluene system.[8] It could be shown by monitoring the temperature dependence of the intensity of the high-frequency ^{14}N-ENDOR signal that the micelle water is a more polar and viscous environment for the radical salt than is bulk water. Moreover, the influence of oxygen on the ENDOR response is less pronounced and aggregation of Fremy's salt at higher concentrations is suppressed. (This finding is comparable with the behavior of porphyrins in micelles, i.e., it was found that aggregation of porphyrins is suppressed, too, when they are embedded within micelles.[9, 10])

Here we report on the first successful ENDOR experiments on organic radicals in reversed micelles, with the flavin radical anions, specifically those of lumiflavin, riboflavin, FMN, and FAD as examples. Flavins are known to be ubiquitous redox cofactors in almost all biological redox chains and numerous reviews have been devoted to this field covering the chemical, biochemical and biological aspects of the flavin system (for example, cf. [11, 12]). Despite the fact that stable *aqueous solutions* of flavin radical anions have been obtained—as could be deduced from UV and EPR spectroscopy[13]—for reasons already mentioned it has so far been impossible to obtain ENDOR signals from these samples in fluid aqueous solution. However, radical anions of flavins generated electrochemically in the *nonaqueous solvents* CH_2Cl_2 or hexamethylphosphoric triamide (HMPT) using tetra-*n*-butylammonium tetrafluoroborate as supporting electrolyte could successfully be investigated by ENDOR spectroscopy in liquid solution.[14, 15] Cationic paramagnetic derivatives of flavin model compounds have also been studied by ENDOR spectroscopy in liquid *nonaqueous solvents*, e.g. mixtures of toluene/trifluoroacetic acid.[16] ENDOR investigations of radicals from flavoproteins are restricted to frozen aqueous solutions (for more detailed recent reports, see ref. [7, 16]).

We have been able to prepare remarkably stable solutions of flavin radical anions in hexane/hexanol using cetyltrimethylammonium bromide (CTAB) as surfactant. Figure 1 shows the ^1H- and ^2H-ENDOR spectra[17] of the radical anions of differently deuterated lumiflavins[18] in these reversed micelles (similar ENDOR spectra were obtained for the radical anions of riboflavin, FMN and FAD). The spectra obtained from the micellar solutions generally exhibit a good signal-to-noise ratio and resolution (linewidth ca. 150 kHz). This may be attributed to the fact that exchange processes (chemical and Heisenberg exchange) are essentially suppressed; this is likely under the assumption that each micelle contains, if at all, only *one* radical anion. Effective exchange processes of this kind are known to severely decrease the ENDOR response;[7] it is likely that these effects prevent the detection of ENDOR signals in liquid water.

Whereas the concentrations of *neutral* radicals of the flavins in fluid aqueous solutions are too low to allow ENDOR experiments (for studies of neutral flavin radicals

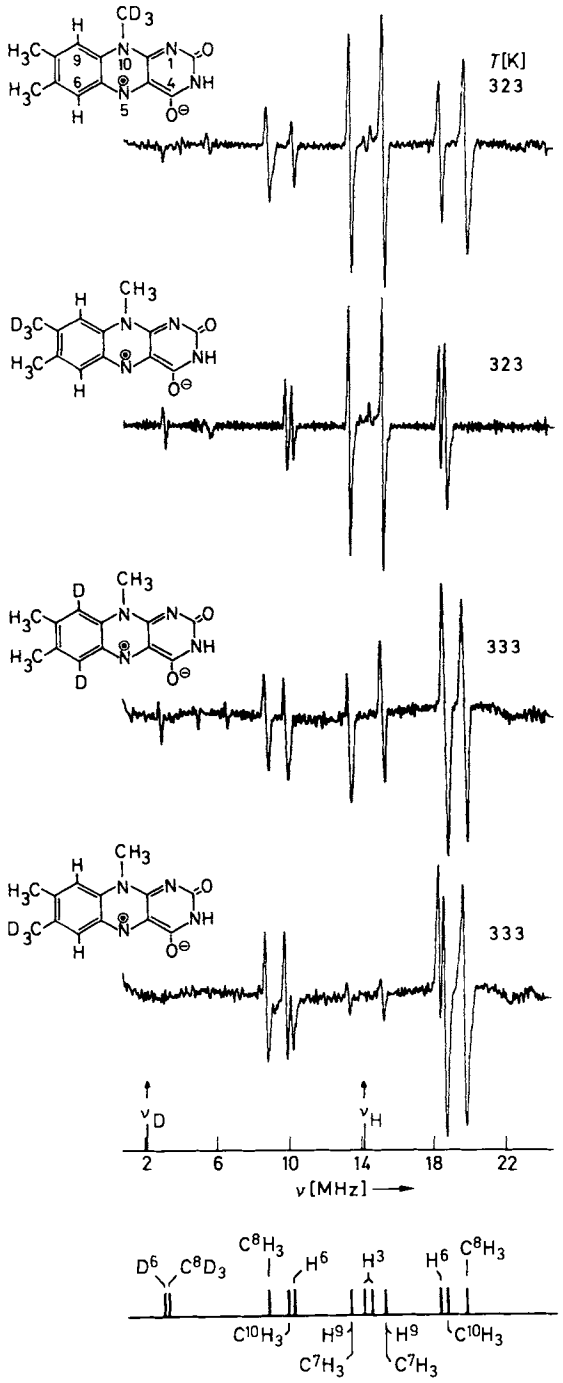

Fig. 1. ^1H- and ^2H-ENDOR spectra of radical anions of differently deuterated lumiflavins in reversed micelles. Assignment of the signals to molecular positions (see bottom) was deduced from the disappearance of ^1H-ENDOR signals on replacement of the respective protons by deuterons.

N5-alkylation is required[19]), higher concentrations of these species can be obtained in reversed micelles since effects such as dimerization and disproportionation are suppressed. Using AOT as surfactant in hexane, the ENDOR spectrum of the neutral radical of lumiflavin-3-acetate was successfully recorded.[20] Moreover, EPR spectra could be obtained from radical states of micellar solutions of flavoproteins, e.g., flavodoxins and glucose oxidase. However, attempts to detect ENDOR signals of these flavoproteins have so far failed. Further work in this interesting area is in progress.

Experimental

A 0.3 M solution of CTAB (recrystallized from ethanol and vacuum dried over silicagel) in hexane/hexanol (6:1) with a w_0-ratio [2d] of 15 ([H_2O]/[CTAB]) was prepared by adding the calculated volume of aqueous buffer solution, typically containing 25 mM of the flavin derivative, 75 mM of EDTA and 50 mM of Tris (pH 10) or pyrophosphate (pH 11) or NaOH (pH 12). The solution was vigorously shaken (1 min) and sonicated (2 × 25 s) to complete homogenization. The phase-stable solution was transferred to the EPR/ENDOR sample tube, degassed and sealed off on a high vacuum line. The radical anions were generated in the EPR cavity by illumination (halogen lamp, 250 W, 15 s intervals, 313 K) until optimum EPR signal intensity was achieved. For performing the ENDOR measurements the sample tube was transferred to an ENDOR cavity. (In situ radical generation was not possible with our ENDOR equipment.)

P_8iPr_4—the First Tricyclo[3.2.1.$0^{2,4}$]octaphosphane**

By *Marianne Baudler,* Bernhard Koll, Christoph Adamek,* and *Rolf Gleiter**

In contrast to cycloalkanes, cyclophosphanes are characterized by their pronounced tendency to form five-membered-ring structural elements.[1] Thus, the $P_8(4)$ unit **1** is an important group of Hittorf's phosphorus[2] and also constitutes the central partial framework of the organophosphanes $P_{10}iPr_4$ **2**[3] and $P_{12}iPr_4$ **3**.[4] Surprisingly, however, only relatively small amounts of the phosphorus hydride P_8H_4 could be identified by mass spectroscopy in the hydrolysis products of calcium phosphide.[5] Attempts to synthesize the corresponding organo derivatives[3,6] likewise showed that the isolated structural unit **1** does not exhibit a pronounced tendency of formation and is only moderately stable with respect to disproportionation reactions. Thus, the most readily accessible derivative, 2,4,6,8-tetraisopropyltricyclo[3.3.0.$0^{3,7}$]octaphosphane with a structure analogous to bisnoradamantane, could only be enriched initially to 15 mol-%,[3] and, more recently, up to 27 mol-%,[6] in a mixture together with other isopropylcyclophosphanes. Owing to the strain in **1**, which is revealed in **3**, for example, by a significant increase in the bond lengths of the two zero bridges,[4] stabilization of **1** is apparently only possible by incorporation into a larger P_n framework. We have now prepared the thermally very stable P_8iPr_4 isomer **4**, which represents a new P_8R_4 structure type having a constitution analogous to homonorbornene.

[**] Contributions to the Chemistry of Phosphorus, Part 176. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 175: M. Baudler, D. Düster, *Z. Naturforsch. B*, in press.

Compound **4** is formed to about 3 mol-% by thermolysis of the product mixture obtained in the reaction of iPrCl$_2$ and PCl$_3$ with magnesium, the main products being P$_7i$Pr$_5$, P$_9i$Pr$_5$, P$_7i$Pr$_3$, and P$_9i$Pr$_3$,[7] as shown by mass spectrometric investigations. In addition, P$_9i$Pr$_3$, P$_7i$Pr$_3$, (PiPr)$_4$, P$_7i$Pr$_5$, P$_6i$Pr$_4$, and small amounts of other isopropylcyclophosphanes are present. Stepwise separation of the thermolyzate (column chromatography, fractional sublimation) afforded **4** as a very pale yellow, oily, oxidation-sensitive liquid of about 95% purity.[8] The composition was established by elemental analysis and the mass spectrum, which revealed a characteristic peak corresponding to the fragment $[M-C_3H_7]^{\oplus}$.

That the framework **1** is not present in **4** is shown by the appearance of ^{31}P-NMR signals in the high-field region typical for phosphorus three-membered ring compounds.[1] The constitution and structure were derived from a complete analysis of the ^{31}P{^{1}H}-NMR spectrum; the order of magnitude and relative signs of the PP coupling constants were determined by "selective population transfer" (SPT) experiments.[9] As shown by the chemical shifts and the $^1J_{PP}$ coupling constants (Table 1), as well as by the splitting

patterns of the individual signal groups, the framework of **4** consists of a norbornane-like P$_7$ group with an annelated three-membered ring. According to the nonequivalence of all the eight P atoms, the substituents on the two-atom bridge are arranged in a *trans* fashion. The *exo* positions of the iPr group on P^7 and the three-membered ring are inferred, on the basis of previous studies,[10] from the relation $\delta(P^6) \gg \delta(P^7)$ and from the large positive $^2J_{P^2P^7}$ coupling. The arrangement of the other substituents is derived from the $^2J_{PP}$ long-range couplings, which exhibit characteristic values depending on the orientation of the lone pairs of electrons relative to each other.[10, 11] Thus, **4** is a 3-*anti*-6-*endo*-7-*exo*-8-*syn*-tetraisopropyl-*exo*-tricyclo[3.2.1.0^{2,4}]octaphosphane (-octaphospha-*exo*-homonorbornene), which, as a result of the asymmetry of the molecule, is present as a pair of enantiomers. According to MNDO calculations[12] for P$_8$Me$_4$, the *exo*-homonorbornene isomer ($\Delta H_f^\circ = -120.1$ kcal/mol) is more stable than the bisnoradamantane isomer ($\Delta H_f^\circ = -115.8$ kcal/mol). The polycycloalkane C$_8$H$_{12}$ corresponding to **4** has already been known for some time.[13]

I II III IV

The P$_8$(4) framework I is derived from the P$_7$(5) and P$_6$(4) frameworks II[14] and III,[15] respectively, by condensation of a one-atom and a two-atom bridge, respectively, and from the P$_9$(3) skeleton IV[7] by removal of a one-atom bridge. These close structural relationships[1, 3] are probably decisive for the thermolytic formation of **4**.

[8] *Experimental procedure:* 51.6 g of a stirred mixture of isopropylphosphanes (obtained by twice reacting iPrPCl$_2$ (123.2 g, 0.85 mol), PCl$_3$ (233.5 g, 1.70 mol), and magnesium (82.6 g, 3.40 mol) in 1200 mL of dry, refluxing tetrahydrofuran for 4 h) was thermolyzed for 7 h at 230°C under inert gas. The white phosphorus formed was condensed from the bright red oil (highly viscous at room temperature) at 10^{-2} torr by means of short-path distillation (bath temperature, 50°C; receiving flask, −196°C). The residue was dissolved in as little n-hexane as possible and chromatographed portionwise three times on Al$_2$O$_3$ with hexane (monitored by ^{31}P-NMR and mass spectroscopy). After combination of the fractions containing the largest amount of **4** and removal of the solvent, the crude product was subjected to high-vacuum fractional sublimation (Hg diffusion pump, cold finger at −196°C); at a bath temperature of 55–60°C and a rate of sublimation of approximately 13 mg/h, 0.22 g of **4** (purity >95% by ^{31}P-NMR) was obtained.

P$_8t$Bu$_6$O$_6$—a Highly Oxidized Cyclophosphane with Intact P Framework**

By *Marianne Baudler** and *Joachim Germeshausen*

Compounds with a framework made up of trivalent P atoms are generally readily oxidizable and therefore frequently undergo spontaneous combustion.[1] In contrast,

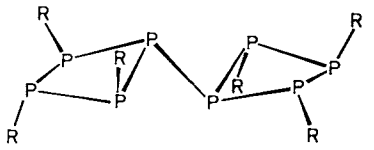
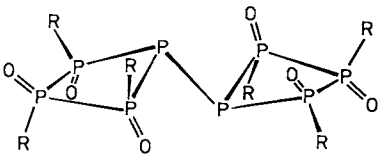
[**] Contributions to the Chemistry of Phosphorus, Part 177. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.—Part 176: M. Baudler, B. Koll, C. Adamek, R. Gleiter, *Angew. Chem. 99* (1987) 371; *Angew. Chem. Int. Ed. Engl. 26* (1987) 347.

hexa-*tert*-butyloctaphosphane **1** is stable for weeks upon exposure to air.[2] We recently synthesized the monooxides P_6tBu_4O and P_7tBu_5O, containing exocyclically bonded oxygen, by oxidation of P_6tBu_4 and P_7tBu_5, respectively, with air.[3] We have now been able to convert **1** into the hexaoxide **2** using other oxidation agents.



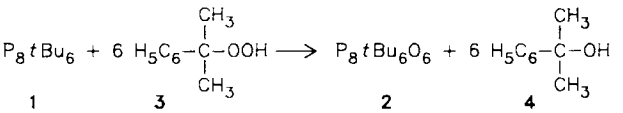
1

R = *t*Bu



2

Compound **1** reacts with pure oxygen in solution only at higher temperatures and then with P–P bond cleavage and formation of mainly 1,2-di-*tert*-butyldiphosphane dioxide as a mixture of the two diastereomers.[4] With hydrogen peroxide, peracetic acid, and cumene hydroperoxide, on the other hand, reaction occurs already at room temperature to form the hexaoxide **2** with retention of the P_8 framework. Above 30°C, however, decomposition to P_2 units also takes place. The oxidation of **1** to **2** with cumene hydroperoxide **3** proceeds especially selectively.



1 **3** **2** **4**

Compound **2** exhibits a pronounced tendency of formation and can be detected in addition to oxygen-poorer oxides by ^{31}P-NMR spectroscopy even at a reactant ratio of 1:1. For reactant ratios of 1:4 up to 1:90, **2** is the main product. By means of high-pressure liquid chromatography (HPLC), the by-product **4** can be separated and **2** can be isolated in analytically pure form.[5] The hexaoxide **2** is a colorless, finely crystalline solid (m.p. = 252–253°C, dec., sealed tube), which is air-stable. It is hardly soluble in organic solvents at room temperature; above about 50°C, it only dissolves with decomposition. In the mass spectrum (15 eV, 150°C), the fragment ion $[M-t\mathrm{Bu}]^{\oplus}$ is observed as the signal group with the highest mass numbers (*m/z* 629, 100%). The IR spectrum shows a band of medium intensity at 1260 cm^{-1} in the region of P=O stretching vibrations.

Proof of the constitution of **2** is provided by the $^{31}P\{^1H\}$-NMR spectrum (121.5 MHz), which, owing to the low solubility of the pure substance, was recorded for the crude product (80 P-% **2**, dissolved in toluene). It shows three multiplets of an $AA'B_2B_2'CC'$ spin system at $\delta = +117$, $+82$, and -57 (intensity ratio 1:2:1). The ^{1}H-coupled spectrum clearly reveals that the two low-field groups correspond to the six *tert*-butyl-substituted P atoms. The splitting patterns of the multiplets are an indication that oxygen is exclusively exocyclically bonded to **1**. Which of the P atoms are present as λ^5 phosphorus follows from the different low-field shifts of the signals of the individual P nuclei compared with the corresponding resonance positions in the starting compound ($\Delta\delta(P_A) = 155$; $\Delta\delta(P_B) = 129$; $\Delta\delta(P_C) = 45$ ppm). Only the organo-substituted P atoms show the strong deshielding expected for an oxidized phosphorus four-membered ring.[3] Accordingly, the product **2** is a 2,2',3,3',4,4'-hexa-*tert*-butyl-1,1'-bicyclotetraphosphane 2,2',3,3',4,4'-hexaoxide. The configuration and conformation should be analogous to those in **1** because of the method of formation.

The fact that **1** cannot be converted into the octaoxide, even with a large excess of **3**, is presumably a result of the relatively small bond angles at the exocyclic bridge (φ(P–P–P) = 96.6°[2]) and thus of the predominantly s character of the lone electron pairs at the "bridgehead" atoms.

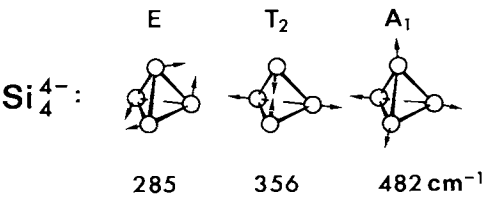
[4] M. Baudler, H. Heumüller, *Z. Naturforsch. B*, in press.
[5] *Experimental Procedure:* 40 mL of a stirred, saturated solution of **1** in toluene (0.4 mmol) was allowed to react at room temperature with 0.52 g of an 80% solution of **3** in cumene (2.7 mmol peroxide, excess), the reaction mixture turning transiently yellow. After concentration of the colorless product solution to 1.6–2.0 mL, **2** was isolated by preparative HPLC (Nucleosil-5 C18 column, methanol, receiving flask at −78°C, rapid evaporation of the solvent at 0°C). The residue was washed three times with 2 mL of pentane, affording 28 mg of pure **2** (10% based on **1**).

Raman Spectrum of the Tetrasilatetrahedrane Anion Si_4^{4-}**

By *Gerhard Kliche, Martin Schwarz,* and *Hans-Georg von Schnering**

We recently reported the synthesis of the red, transparent metal silicides K_3LiSi_4 and $K_7Li(Si_4)_2$.[1] We have now also been able to prepare the long known silicide CsSi[2] as a pure compound in the form of red, transparent crystals,[3] thus making the first measurement of Raman spectra of the alkali-metal silicides possible. This is of special interest because of the tetrahedral structure of the Si_4^{4-} ions.



Si_4^{4-} is isostructural and isoelectronic with the P_4 molecule. Hence, with the symmetry $\bar{4}3m$-T_d one can expect to observe the three vibrations of the species A_1(R), E(R), and T_2(R,IR). However, one has to reckon with band splittings, which, on the one hand, can arise from the site symmetry, which generally deviates from the molecular symmetry, and, on the other, from the space groups and unit cells decisive for the mutual arrangement of the Si_4^{4-} anions. Finally, the anions Si_4^{4-} can only be regarded as iso-

lated units to a limited extent: a) the cations M, as μ_3-ligands, extend the tetrahedrane structures to M_4Si_4 cubane structures (even if with weaker interactions); b) oligomers or polymers are formed via the M-ligands. CsSi crystallizes cubic ($P\bar{4}3n$) with eight isolated Si_4 (or Cs_4Si_4) in the unit cell. Of these, two Si_4 (Cs_4Si_4) possess tetrahedral symmetry $\bar{4}3m$-T_d, although the site symmetry in the space group is only 23-T.[4] The other six Si_4 (Cs_4Si_4) occupy sites of $\bar{4}$-S_4 symmetry. K_3LiSi_4 crystallizes orthorhombically (*Pnma*) with four Si_4 having m-C_s symmetry; these are coupled via two Li atoms to give a one-dimensional infinite chain $^1_\infty[Li_{2/2}Si_4]$. The structure of K_7LiSi_8 (cubic, $Pa\bar{3}$) contains four dimeric Si_4–Li–Si_4 dumbbells with $\bar{3}$-S_6 symmetry, whereby each Si_4 unit (or the pertinent cubane $[K_3LiSi_4]$) belongs to the symmetry $3m$-C_{3v}.

Figure 1 shows the Raman spectra of the three compounds. Almost independently of the completely different crystal structures, three intense bands with only small individual shifts and splittings are observed at about 290, 355, and 480 cm^{-1}. Numerous other bands lie separately therefrom at lower wave numbers. These should contain, besides external lattice vibrations, the librations of the Si_4^{4-} tetrahedra, whereas the three high-frequency bands can be unequivocally assigned to the internal vibrations of species E, T_2 and A_1 of the Si_4^{4-} ions. This convincingly justifies the treatment of the Si_4^{4-} ions as quasi-isolated units. *Bürger* and *Eujen*[5] had already observed two bands at 358 and 334 cm^{-1} in the IR spectrum of (black) CsSi and had assigned them to the T_2 vibration, split by site symmetry effects. Our IR spectra (cf. Fig. 2[6]) of the red, transparent samples of the compounds investigated show 2–3 modes in a region separated from the lattice vibrations (298 K: CsSi: 332, 352, 357 cm^{-1}; K_3LiSi_4: 340, 357 cm^{-1}; K_7LiSi_8: 339, 356 cm^{-1}; 10 K: CsSi: 335, 356, 362 cm^{-1}; K_3LiSi_4: 339, 345, 362 cm^{-1}; K_7LiSi_8: 344, 356, 362 cm^{-1}); the maxima of the higher wavenumbered modes are in good agreement with the maxima of the Raman bands. There are many factors which would suggest that the splitting observed in the IR spectra does not only arise from the different site symmetries of the Si_4^{4-} anions, but is also associated with a coupling of the μ_3 ligands (cations M). A quantitative interpretation however, will only be possible after detailed lattice dynamical calculations. In these calculations, the mode splittings found in the spectra of crystalline white phosphorus (α-P_4, β-P_4) can then also be taken into consideration.[6]

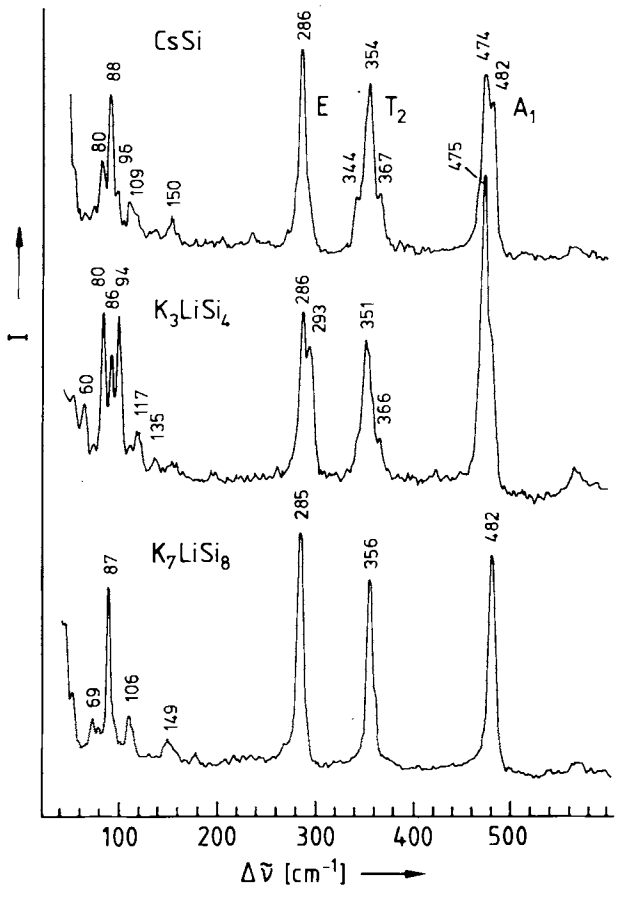

Fig. 1. Raman spectra of the silicides CsSi, K_3LiSi_4, K_7LiSi_8 (room temperature, krypton-ion laser, 676 nm (150 mW), resolution >4 cm^{-1}, back-scattering technique).

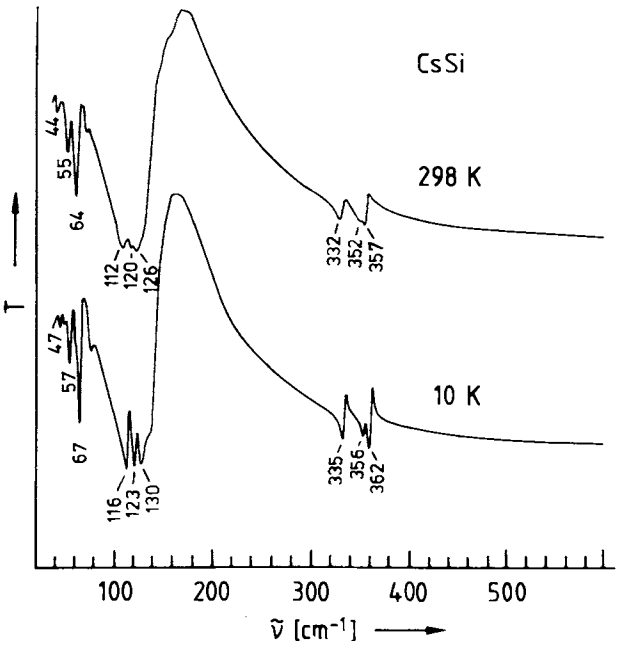

Fig. 2. IR spectra of CsSi at 298 and 10 K (PE pellet, Bruker IFS 113 v). Intense bands <200 cm^{-1}: lattice vibrations.

[a] Data for K_7LiSi_8. [b] Gas-phase, calculation of force constants without anharmonicity correction. [c] Argon matrix. [d] Calculation using $\bar{r}_{xx} = r_{cov.}$ [e] Neon matrix.

In Table 1 the Raman spectrum of the anion Si_4^{4-} in K_7LiSi_8 (minimum mode splittings) is compared with the Raman spectra of P_4, As_4, Sb_4, and Bi_4. The force constants f_d, f'_{dd}, and f_{dd} of a general valence force field were calculated according to the method of *Pistorius*,[7] the bond order N according to the method of *Siebert*,[8] and the mean amplitude of vibration according to the method of *Cyvin*.[9] The analogy of the tetrahedral groups is immediately recognizable. Particularly striking is the large reduction of the vibrational frequencies of Si_4^{4-} compared to those of the (somewhat heavier) P_4 molecule. The force constant f_d(Si–Si) = 1.13 mdyn·Å^{-1} corresponds to the value derived from the IR spectrum (1.05 ± 0.1 mdyn·Å^{-1} [5]); the corresponding value for P_4 is 2.07 mdyn·Å^{-1}. The Si–Si bond in Si_4^{4-} is thus considerably weaker than both the P–P bond in P_4 as well as other Si–Si bonds;[5] this weakening is certainly associated with the negative partial charges of the Si atoms. This is also manifested in the bond order N = 0.60, calculated according to *Siebert*,[8] even if this value is not in very good agreement with the Pauling bond order,[10] PBO = 0.76, obtained alone from the distances d_1(Si–Si) = 235 pm and $\bar{d}_n$(Si–Si) = 242 pm. In any case, the additional ionic interactions with the cations will contribute decisively to the stability of the anions Si_4^{4-}.

Experimental

CsSi, K_3LiSi_4 and K_7LiSi_8 were prepared as described in ref. [1]. The Raman spectra were recorded on polycrystalline fragments of the silicides using a back-scattering technique at room temperature (krypton ion laser, 647 and 676 nm (150 mW); Jarrell-Ash double monochromator, RCA photomultiplier, resolution > 4 cm^{-1}). The IR spectra were recorded on PE pellets with an IFS 113v FT-IR spectrometer (Bruker), resolution 1 cm^{-1}.

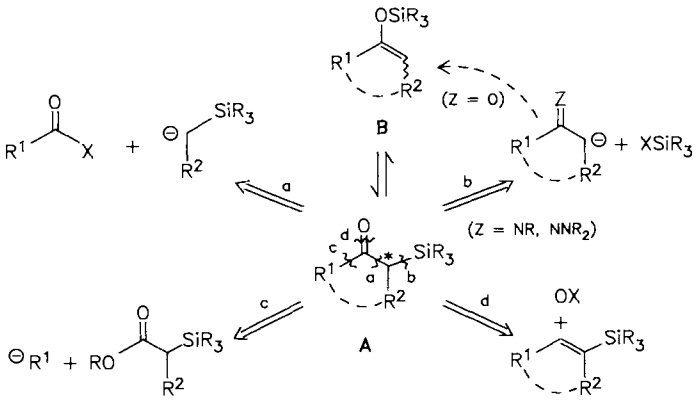
Enantioselective Synthesis of α-Trialkylsilyl Ketones and Aldehydes**

By *Dieter Enders** and *Braj Bhushan Lohray*

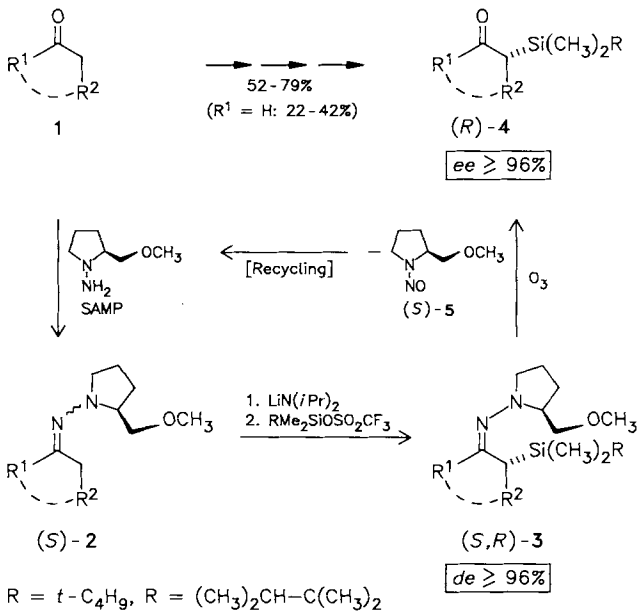
Dedicated to Professor Gerhard Quinkert on the occasion of his 60th birthday

Silylenol ethers **B**[1] and their isomeric α-silyl ketones (β-ketosilanes) **A**[2] are interconvertable.[3] They belong to the synthetically most useful class of compounds in modern carbonyl chemistry. The *O*-silylated compounds **B** are readily accessible by silylation of the ketones (Z = O), whereas the synthesis of the *C*-silylated isomers **A** necessitates recourse to the corresponding azaenolates (Z = NR, NNR_2)[4a–d] or other coupling patterns (see retrosynthesis—Scheme 1).[4e–i]



Scheme 1.

In continuation of our studies on metalated SAMP-/RAMP-hydrazones[5] we have now found that chiral α-silyl ketones and α-silylaldehydes **A** are accessible for the first time enantioselectively and highly enantiomerically pure via route b (Scheme 1). The ketones and aldehydes **1**, after conversion into the SAMP-hydrazones (*S*)-**2**, are metalated with lithium diisopropylamide and *C*-silylated with trialkylsilyl trifluoromethanesulfonates (triflates).[6] The silylhydrazones (*SR*)-**3** (*de* ≧ 96%) thus obtained are cleaved oxidatively and racemization-free with ozone, and afford, after chromatographic separation of (*S*)-**5** (recycling of the chiral auxiliary), the virtually enantiomerically pure (*ee* ≧ 96%) α-silylketones and α-silylaldehydes (*R*)-**4** in overall yields of 52–79% and 22–42%, respectively (Table 1).



Scheme 2.

Professor-Pirlet-Str. 1, D-5100 Aachen (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, by BASG AG, and by Degussa AG. We thank Dr. *H. Wetter*, Ciba-Geigy, Basel, for a gift of chlorodimethylthexylsilane.

Table 1. α-Silyl ketones and α-silylaldehydes **4** synthesized from aldehydes and ketones **1** by enantioselective silylation via SAMP-hydrazones. If not otherwise stated, R = *tert*-butyl.

4	R^1	R^2	Total yield [%]	$[\alpha]_D^{23}$ (c, C_6H_6) [°]	*ee* [%] [b]
(*R*)-**4a**	C_2H_5	CH_3	77	+188.2 (1.5)	≧96
(*S*)-**4a** [c]	C_2H_5	CH_3	74	−182.6 (1.5)	≧96
(*R*)-**4a** [d]	C_2H_5	CH_3	79	+152.0 (1.4)	≧96
(*R*)-**4b** [e]	$-(CH_2)_4-$		59	−173.7 (2.5)	≧96
(*R*)-**4c**	C_6H_5	CH_3	60	+48.4 (2.9)	≧96
(*R*)-**4c** [d]	C_6H_5	CH_3	68	+65.4 (1.1)	≧96
(*R*)-**4d**	2,4-dimethoxyphenyl	CH_3	78	−7.7 (0.6)	≧96
(*R*)-**4e**	2-naphthyl	CH_3	70	−51.4 (1.0)	≧96
(*R*)-**4f**	C_6H_5	C_6H_5	52	−4.8 (1.1)	≧96
(*R*)-**4g**	H	$C_6H_5CH_2$	42 [f]	+77.3 (1.6) [g]	≧96
(*R*)-**4h**	H	n-C_6H_{13}	22 [f]	+59.7 (1.0)	≧96

[a] Cyclopentanone and dibenzyl ketone could be silylated in 80% and 56% total yield, respectively, but with lower enantioselectivity (66 and 48% *ee*, resp.). [b] Determined ^{1}H-NMR spectroscopically with Eu(hfc)$_3$ by comparison with *rac*-**4a**–**h**; in each case the other enantiomer was not detectable. [c] RAMP was used as chiral auxiliary. [d] R = thexyl (1,1,2-trimethylpropyl). [e] (*S*)-(−)-1-amino-2-(1,1-dimethylmethoxymethyl)pyrrolidine was used as chiral auxiliary [7]. [f] The lower overall yields in the case of the aldehydes results from a partial *N*-silylation of (*S*)-**2** [8] or from a partial oxidation of (*S*,*R*)-**3** during the ozonolysis. [g] In diethyl ether.

The optical antipodes (*S*)-**4** can be obtained in the same way by simply replacing SAMP by the enantiomeric RAMP. The ^{13}C-NMR spectroscopically determined diastereomeric excesses of the product hydrazones **3** are in good agreement, within the limits of detection, with the enantiomeric excesses of the products **4** determined by ^{1}H-NMR shift experiments. In all cases, the racemic compounds *rac*-**4** were prepared via the dimethylhydrazones for comparison.[4b,c]

The (not yet confirmed) assignment of the absolute configurations is based on earlier investigations of the electrophilic substitutions via metalated SAMP-/RAMP-hydrazones. Preliminary studies involving the use of the α-silyl ketones **4** in asymmetric synthesis are very promising;[9,10] they are relatively insensitive to racemization.

Experimental

A solution of (*S*)-**2** (10 mmol) in ether (30 mL) was added dropwise to a stirred solution of lithium diisopropylamide (10.5 mmol) (prepared from 6.5 mL of 1.6 N *n*-butyllithium solution and 1.5 mL of diisopropylamine in 30 mL of ether at 0 °C). After 4 h the mixture was cooled to −78 °C and treated at once with 2.3 mL (10 mmol) of *tert*-butyldimethylsilyl triflate[6a] or 2.5 mL (10 mmol) of dimethylthexylsilyl triflate[6b]. After a further two hours' stirring the mixture was allowed to warm up to room temperature within ca. 10 h and was then worked up with ether. The extract was dried over magnesium sulfate and the solvent removed by evaporation. The crude product, (*SR*)-**3**, which was purified by flash-chromatography (silica gel, ether/*n*-pentane 1:4, R_f = 0.4) if necessary, was taken up in 50 mL of *n*-pentane and the solution cooled to −78 °C. Ozone was then passed through the solution until complete oxidative cleavage of the hydrazone (TLC monitoring). After removal of excess ozone by passage of argon, heating, and evaporation to dryness, (*R*)-**4** was separated from the nitrosamine (*S*)-**5** by flash chromatography (silica gel, ether/*n*-pentane 1:4, **5**: R_f = 0.3, **4**: R_f = 0.8).—For recycling of SAMP, (*S*)-**5** was reduced with $LiAlH_4$ in tetrahydrofuran.

"Two-Electron Reduction" of Phosphane-substituted Tricobalt Clusters—Evidence for a 17-Electron Intermediate in the Dissociative ETC Ligand Substitution**

By *Klaus Hinkelmann, Falko Mahlendorf, Jürgen Heinze,* Hans-Thomas Schacht, John S. Field,* and *Heinrich Vahrenkamp**

The reduction behavior of μ_3-alkylidyne tricobalt clusters has been the subject of several investigations.[1] In particular, their ability to engage in efficient ETC processes (ETC = *e*lectron-*t*ransfer *c*hain catalyzed) and thereby to exhibit catalytic activity has recently stimulated new investigations.[2] However, it has so far remained unclear whether these clusters, like other metal clusters,[3] can undergo reversible reduction in multistep redox processes. Although the radical anions of the clusters $[(\mu_3\text{-RC})Co_3(CO)_9]$ are known to exhibit prolonged stability, the dianions undergo irreversible decomposition with destruction of the metal framework.[1] In a new electrochemical investigation of phosphane-substituted derivatives of **1**, we have now observed, surprisingly, that these compounds can be reduced, in part, to give stable dianions via a formally two-electron process. A detailed analysis of the overall redox reaction revealed an unusual mechanism which has not been observed for clusters so far.

$[(\mu_3\text{-MeC})Co_3(CO)_9]$ **1**

$[(\mu_3\text{-MeC})Co_3(CO)_6(PR_2Ph)_3]$ **2a,b**

$[(\mu_3\text{-MeC})Co_3(CO)_8(PR_2Ph)]$ **3a,b**

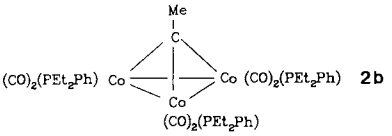
$[(\mu_3\text{-MeC})Co_3(CO)_6(PR_2Ph)_2]$ **4a,b**

a, R = Me; **b**, R = Et

Typical examples are the compounds **2a** and **2b**. Their striking voltammograms (e.g., of **2b**, Fig. 1a) reveal, in addition to an unusually high cathodic wave, the seldomly observed crossing effect as well as two distinct anodic



2b

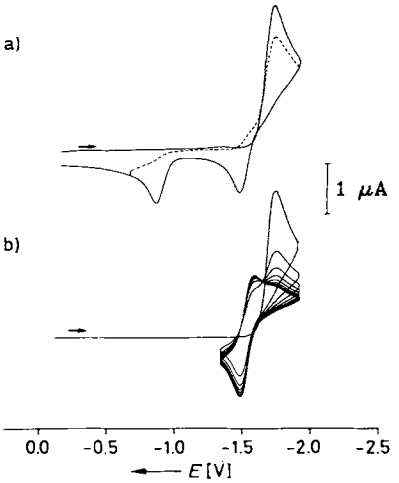


Fig. 1. a) Experimental cyclovoltammogram for the reduction of **2b** ($c = 8 \times 10^{-4}$ M), broken line = second cathodic scan, in CH_3CN/0.1 M Bu_4NPF_6, $T = 24$ °C, $v = 0.4$ V/s, Pt electrode, Ag/AgCl as reference electrode. b) Multisweep cyclovoltammogram (8 sweeps) for **2b**, recorded between −1.3 and −1.9 V; same conditions as in a).

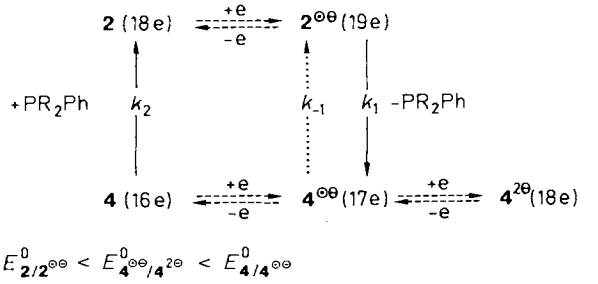
waves in the reverse scan. Only two examples of this type of voltammogram have been reported so far: the 5,6-dihydrobenzo[*c*]quinoline system[4] and the phosphido-bridged rhodium complex $[\{Rh(\mu\text{-}t\text{Bu}_2P)(CO)_2\}_2]$.[5] After the first charge transfer, the former undergoes a conformational flattening, the latter an isomerization from a planar to a tetrahedral structure. Both processes energetically favor the second charge transfer. As a consequence of this, the corresponding voltammograms exhibit a two-electron transfer in the forward scan. In the reverse reaction, such redox systems proceed by two one-electron steps to the neutral state followed by the structural reorganization to the starting compounds. The overall process is thus reversible, but the forward and reverse reactions proceed, in part, via different intermediates.

It would appear reasonable to explain the behavior of **2** by a similar mechanism. The well-known chemical instability of the radical anions of phosphane-substituted tricobalt clusters,[2b] however, suggests another course of reaction (Scheme 1), in which a ligand is eliminated subsequent to formation of the radical anion $\mathbf{2}^{\odot\ominus}$. The resulting species, $\mathbf{4}^{\odot\ominus}$, owing to its higher redox potential, is immediately reduced to the dianion $\mathbf{4}^{2\ominus}$. The reoxidation would then take place in two distinct steps via the monoanion $\mathbf{4}^{\odot\ominus}$ to give the neutral species **4**, to which the stable cleaved ligand (which is still present in the diffusion layer) could be re-added.



$$E^0_{2/2^{\odot\ominus}} < E^0_{4^{\odot\ominus}/4^{2\ominus}} < E^0_{4/4^{\odot\ominus}}$$

Scheme 1. Compound **2** is reduced to $\mathbf{4}^{2\odot}$ by an ECE mechanism; the reoxidation of $\mathbf{4}^{2\ominus}$ to **2** proceeds via an EEC mechanism (E = electrochemical, C = chemical).
