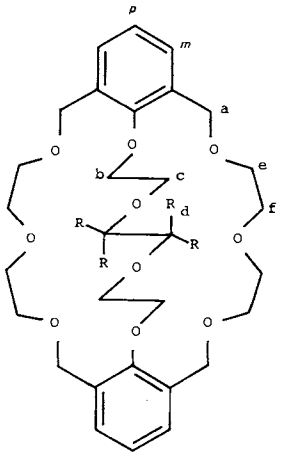
ond sphere coordination with $[Pt(NH_3)_4]^{2\oplus}$, mainly on account of the hydrogen bonding of its ammine ligands to the carbonyl oxygen atoms of the two pairs of amide linkages that characterize the entrance to the receptor cavity of each molecule.[1] Since we suspect that these interactions, rather than any structural property of the dication, prevent its total encapsulation, we decided to investigate adduct formation of $[Pt(NH_3)_4]^{2\oplus}$, both with **1** and with its pinacol analogue **2**.[1-3]



1, R = H
2, R = Me

The X-ray crystal structure[4] of $[Pt(NH_3)_4 \cdot \mathbf{1}][PF_6]_2$[5] (Fig. 1) reveals the presence of two crystallographically independent 1:1 adducts. The gross conformations of both receptor molecules are very similar[6] to that observed[2] in the 1:1 adduct of **1** and $[Rh(cod)(NH_3)_2]^{\oplus}$ (cod = 1,5-cyclooctadiene), there being an approximate C_2 symmetry axis passing through the middle of the C-C bond of the central polyether chain, the Pt atom, and bisecting two pairs of Pt-NH_3 bonds. In contrast to the encapsulation of $[Pt(NH_3)_4]^{2\oplus}$ by two macropolycyclic crown ether bisamide receptor molecules, here the dication is nearly totally enveloped in both instances by a single receptor molecule **1**. It is notable that, in the absence of a bulky organic ligand such as is present[6] in $[Rh(cod)(NH_3)_2]^{\oplus}$, $[Pt(NH_3)_4]^{2\oplus}$ inserts itself (Fig. 1) still further into the receptor cavity. As a consequence, all four ammine ligands are involved in hydrogen bonding interactions with all three polyether chains participating. All ten oxygen atoms of **1** lie within 3.3 Å of a nitrogen atom of the tetraammine. Another key

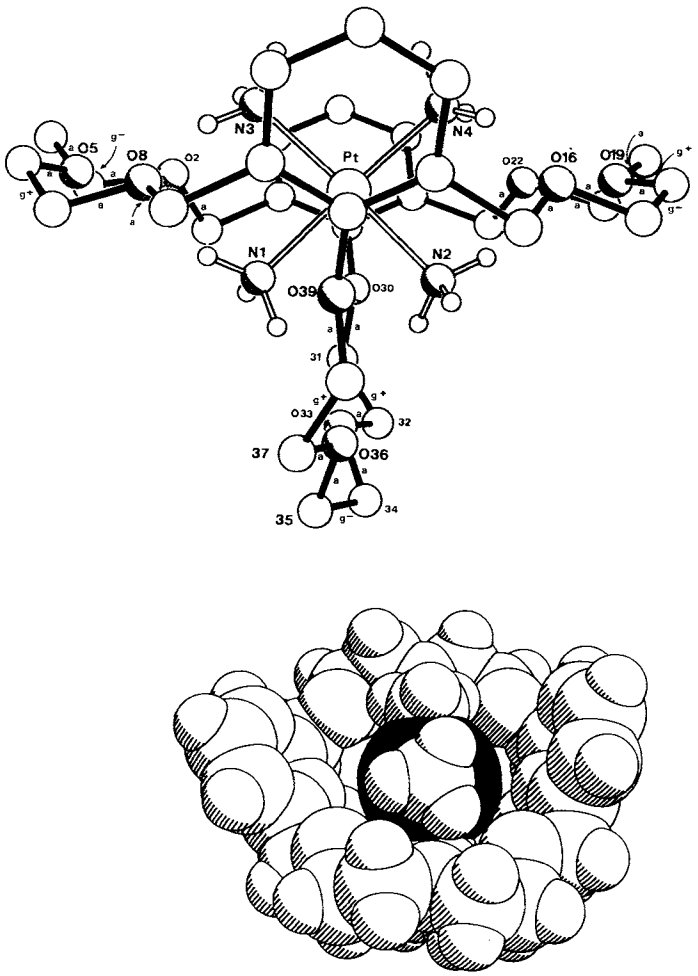


Fig. 1. Top: Structure of one of the $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$ dications in the crystal. Distances for N1 to O8, O30, O33, O36, and O39: 3.22, 3.25, 3.15, 3.21, and 3.07 Å, respectively. Those for N2 to O16, O19, O30, and O33: 3.27, 3.30, 3.03, and 3.18 Å, respectively. Those for N3 to O2, O5, and O8: 3.13, 3.08, and 3.13 Å, respectively. Those for N4 to O16, O19, and O22: 3.12, 3.04, and 3.27 Å, respectively. Atoms N1 and N2 are displaced 1.62 and 1.63 Å respectively, and atoms N3 and N4 both 1.18 Å on opposite sides of the mean plane described by the six peripheral oxygen atoms. Cleft angle between the mean planes of the aromatic rings is 62°. The conformations of the three polyether chains are indicated in terms of their *gauche* (*g*) or *anti* (*a*) geometries. — Bottom: Space-filling representation of the second $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$ dication in the crystal looking into the receptor cavity. The Pt atom is blackened.

feature of this structure is the involvement of the middle two oxygen atoms (O33 and O36) of the central polyether chain in hydrogen bonding interactions to N1 and N2.

Table 1 records ^{1}H-NMR spectroscopic data which sug-

Table 1. ^{1}H-NMR chemical shift data [δ values ($\Delta\delta$ values) in CD_3COCD_3] [a].

	m	*p*	a_A	a_B	b	c	d(H)	d(Me)
1	7.25	6.96		4.53[b]	4.09	3.91	3.76	—
$[Pt(NH_3)_4 \cdot \mathbf{1}][PF_6]_2$	7.48	7.22		ca. 4.6 [c]	4.27	4.04	3.95	—
	(+0.23)	(+0.26)			(+0.18)	(+0.13)	(+0.19)	
2	7.25	6.95	4.79	4.26	3.99	3.99	—	1.31
$[Pt(NH_3)_4 \cdot \mathbf{2}][PF_6]_2$	7.46	7.19	4.91	4.33	4.22	4.01	—	1.39
	(+0.21)	(+0.24)	(+0.12)	(+0.07)	(+0.23)	(+0.02)		(+0.08)

[a] The spectra were recorded at ambient temperature on a Bruker AM250 spectrometer using the signal of CD_2HCOCD_2H in the CD_3COCD_3 as reference. The $\Delta\delta$ values in brackets indicate the shifts with respect to the appropriate receptors **1** and **2**. [b] The rate constant ($k_c = 322\ s^{-1}$) at the coalescence temperature ($T_c = -52$°C) of this AB system ($\Delta\nu_{AB} = 42.5$ Hz, $J_{AB} = 10.4$ Hz) corresponds to a $\Delta G_c^{\ddagger}$ value of 10.3 kcal mol^{-1} for the conformational inversion [2] of the free receptor **1**. [c] In the presence of 1 equivalent of $[Pt(NH_3)_4][PF_6]_2$, the coalescence temperature ($T_c = +18$°C) of the AB system ($\Delta\nu_{AB} = 136$ Hz, $J_{AB} = 10$ Hz) is considerably higher for a very similar rate constant ($k_c = 307\ s^{-1}$), reflecting a substantial increase in $\Delta G_c^{\ddagger}$ to 13.7 kcal mol^{-1}. This observation provides further evidence for the existence of the $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$ dication in CD_3COCD_3 solution.

gest that the gross structural features of $[Pt(NH_3)_4 \cdot \mathbf{1}][PF_6]_2$ are retained in [D$_6$]acetone solution. Significant downfield shifts are observed for the methylene protons in the polyether chains as well as for the aromatic protons. Further evidence for 1 : 1 adduct formation was obtained in the ^{1}H-NMR spectrum, recorded at $-80\,^\circ$C, of a [D$_6$]acetone solution of **1** and $[Pt(NH_3)_4][PF_6]_2$ in a 2 : 1 molar ratio. Multiplets for the aromatic protons centered at $\delta = 7.50$, 7.25, and 7.00 with relative intensities of 2, 3, and 1, respectively, indicate the presence of equal amounts of the 1 : 1 adduct and the free receptor **1** undergoing equilibration on the ^{1}H-NMR time scale (cf. Table 1).

Although the ^{1}H-NMR spectrum of $[Pt(NH_3)_4 \cdot (\mathbf{2})_2][PF_6]_2$ run at $-80\,^\circ$C also shows that a 1 : 1 adduct exists in equilibrium with **2** in [D$_6$]acetone solution, the X-ray structure analysis[4] (Fig. 2, top) of the crystalline adduct of **2** and $[Pt(NH_3)_4][PF_6]_2$ reveals a 2 : 1 stoichiometry in the crystal. The dication is engulfed by the two symmetry-related molecules of **2** (Fig. 2, bottom). There are no fewer

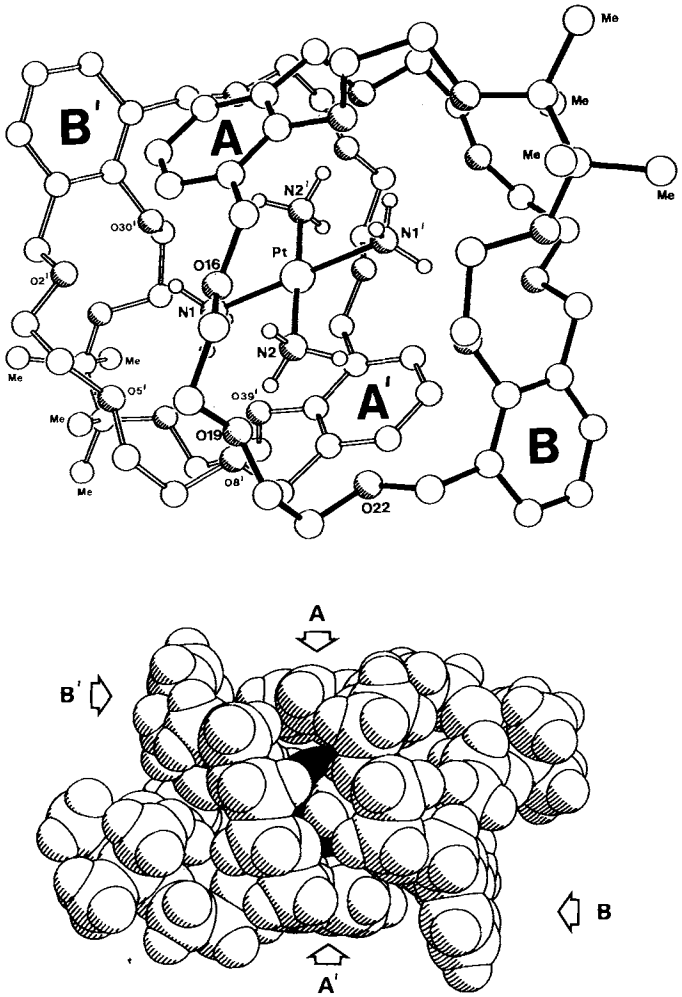

Fig. 2. Top: Skeletal illustration of the $[Pt(NH_3)_4 \cdot (\mathbf{2})_2]^{2\oplus}$ dication in the crystal. One receptor molecule is shown with open bonds. Distances for N1 to O2′, O5′, O8′, O30′, and O39′: 3.21, 3.00, 3.21, 3.25, and 3.26 Å, respectively. Those for N2 to O8′, O16, O19, and O22: 3.00, 3.06, 3.05, and 3.26 Å, respectively. Equivalent distances exist for the symmetry related N1′ and N2′. Cleft angle between the mean planes of the aromatic rings **A** and **B** is 102°. Angle between the mean planes of ring **A** and PtN1N1′N2N2′ is 8° and the Pt atom lies 3.53 Å from the **A** ring plane. The dihedral angle between the mean planes of the aromatic rings **A** and **B**′ is 78° and the distance between their centroids is 4.92 Å. The centroid-centroid vector is inclined 10° to the normal to ring **B**′.—Bottom: Space-filling representation of the 2 : 1 adduct with the Pt atom blackened.

than 18 contacts of < 3.30 Å between the four ammine ligands and ether oxygen atoms in the two receptors. In addition to these cohesive noncovalent binding forces, there are pronounced attractive edge-to-face electrostatic interactions between the aromatic rings **A** and **B**′, and **A**′ and **B** (Fig. 2, top). This T-shaped geometry is characteristic of that associated with the global potential energy minimum for two interacting aromatic rings.[7–9] In turn the $[Pt(NH_3)_4]^{2\oplus}$ dication is sandwiched between aromatic rings **A** and **A**′ in a mutually near parallel arrangement with interplanar separations of ca. 3.5 Å.

Comparison of Figures 3 and 1 (top) demonstrates the principal differences in the conformations of the polyether chains in the $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$ and $[Pt(NH_3)_4 \cdot (\mathbf{2})_2]^{2\oplus}$ dica-

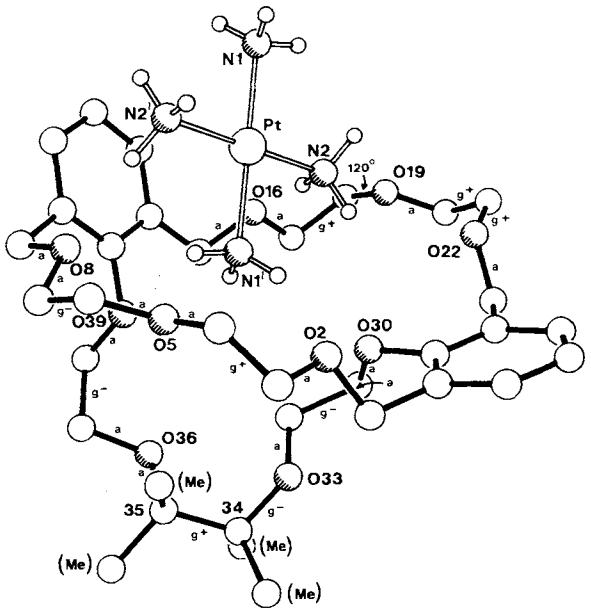

Fig. 3. Perspective view of a portion of the 2 : 1 adduct $[Pt(NH_3)_4 \cdot (\mathbf{2})_2]^{2\oplus}$: a polyether receptor has been removed from the structure shown in Figure 2 (top). The conformations of the three polyether chains are indicated in terms of their *gauche* (*g*) or *anti* (*a*) geometries.

tions. The major desymmetrizations take place in the C20 to O22 and C31 to O33 regions of **2**. This results in an opening of the receptor cleft and a filling-in by the methylene group at C32 of the bottom of the cavity.[10] Clearly, the nature of the second sphere coordination of transition metal complexes can change between solution and solid states.

[3] We chose to examine the macrobicyclic polyethers **1** and **2** as potential second sphere ligands for $[Pt(NH_3)_4]^{2\oplus}$ because they provide examples of conformationally-mobile and conformationally-constrained receptors, respectively; see also ref. [2].

[4] Crystal data for $[Pt(NH_3)_4 \cdot \mathbf{1}][PF_6]_2 \cdot 0.25\,EtOH$: triclinic, $a = 10.401(4)$, $b = 21.552(7)$, $c = 22.165(7)$ Å, $\alpha = 75.00(3)$, $\beta = 79.94(3)$, $\gamma = 76.35(3)^\circ$, $V = 4629$ Å^3, space group $P\bar{1}$, $Z = 4$ (2 independent complexes), $\rho_{calc} = 1.62$ g cm^{-3}, $\mu = 73$ cm^{-1}, 7790 independent observed reflections [$|F_o| \geq 3\sigma(|F_o|)$, $\theta \leq 50^\circ$], $R = 0.064$, $R_w = 0.069$.—Crystal data for $[Pt(NH_3)_4 \cdot (\mathbf{2})_2][PF_6]_2$: monoclinic, $a = 10.825(3)$, $b = 16.318(8)$, $c = 23.744(9)$ Å, $\beta = 101.58(3)^\circ$, $V = 4109$ Å^3, space group $P2_1/c$, $Z = 2$

(the adduct possesses a center of symmetry) $\rho_{calc} = 1.45$ g cm^{-3}, $\mu = 41$ cm^{-1}, 3620 independent observed reflections [$|F_o| \geq 3\sigma(|F_o|)$, $\theta \leq 50°$], $R = 0.031$, $R_w = 0.032$. All hydrogen atoms were obtained from a ΔF map and these groups refined as rigid bodies. The $PF_6^{\ominus}$ ions in $[Pt(NH_3)_4 \cdot (\mathbf{2})_2][PF_6]_2$ are disordered and were refined as two distinct orientations of occupancies 0.65 and 0.35. Data were measured on a Nicolet R3m diffractometer using the ω-scan routine with graphite monochromated $Cu_{K\alpha}$ radiation. In both cases, the structures were solved by the heavy atom method and empirical absorption corrections were applied. Both structures were refined anisotropically. Further details of the crystal structure investigation can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[5] *Experimental:* $[Pt(NH_3)_4 \cdot \mathbf{1}][PF_6]_2$: A solution of **1** (7.3 mg, 0.013 mmol) and $[Pt(NH_3)_4][PF_6]_2$ (7.2 mg, 0.013 mmol) in Me_2CO/EtOH (1 ml) was filtered and Et_2O was layered on top until a faint permanent precipitate was observed. After 24 h, colorless crystals, suitable for X-ray investigation, were obtained of the 1 : 1 adduct [6.1 mg, 42%, m.p. 238–242 °C with decomposition, *m/z* (positive-ion FABMS), 970 for $[M - PF_6^{\ominus}]^{\oplus}$.— $[Pt(NH_3)_4 \cdot (\mathbf{2})_2][PF_6]_2$: A solution of **2** (6.2 mg, 0.01 mmol) and $[Pt(NH_3)_4][PF_6]_2$ (5.6 mg, 0.01 mmol) in CH_2Cl_2/Me_2CO (1 ml) was filtered and Et_2O was layered on top until a faint permanent precipitate was observed. After 24 h, colorless crystals, suitable for X-ray investigation, were obtained of the 2 : 1 adduct [m.p. 238–242 °C with decomposition].

[6] In both independent complexes, the polyether components of the macrorings display the *a ag*$^-$ *a ag*$^+$ *a a* conformation from C1 to C9 and from C15 to C23 observed [2] in $[Rh(cod)(NH_3)_2 \cdot \mathbf{1}]^{\oplus}$. The only major differences in the receptor conformations of the two independent complexes are in the torsional geometries of the central polyether chains from C32 to O39. In $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$, there is an *ag*$^+$*a aga*$^-$*a ag*$^+$*a* conformation from O30 to O39 whereas the analogous polyether chain in $[Rh(cod)(NH_3)_2 \cdot \mathbf{1}]^{\oplus}$ reads *ag*$^-$*a ag*$^+$*a ag*$^-$*a*.

[7] R. O. Gould, A. M. Gray, P. Taylor, M. D. Walkinshaw, *J. Am. Chem. Soc. 107* (1985) 5921.

[8] S. K. Burley, G. A. Petsko, *Science 229* (1985) 23; *J. Am. Chem. Soc. 108* (1986) 7995.

[9] A. M. Z. Slawin, N. Spencer, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1987*, in press.

[10] Recalling the fact that 2,2,3,3,11,11,12,12-octamethyl-1,4,7,10,13,16-hexaoxacyclooctadecane adopts an all-*gauche* conformation when it forms a 1 : 2 adduct with 2 equivalents of BH_3NH_3 (D. R. Alston, J. F. Stoddart, J. B. Wolstenholme, B. L. Allwood, D. J. Williams, *Tetrahedron 41* (1985) 2923), there is no apparent reason why the central polyether chain in the $[Pt(NH_3)_4 \cdot (\mathbf{2})_2]^{2\oplus}$ dication (Fig. 3) should exist in a different conformation from that observed (Fig. 1) for the $[Pt(NH_3)_4 \cdot \mathbf{1}]^{2\oplus}$ dication. Interestingly, in CD_3COCD_3 solution at low temperatures ($T_c = -70$ °C), the singlet observed in the ^{1}H-NMR spectrum for the methyl protons in $[Pt(NH_3)_4 \cdot \mathbf{2}][PF_6]_2$ separates ($\Delta\nu = 30$ Hz) into two equal intensity signals. The rate constant of 67 s^{-1} calculated at the coalescence temperature (T_c) corresponds to a $\Delta G_c^{\neq}$ value of 10.0 kcal mol^{-1}. We have ascribed this temperature-dependent behavior tentatively to hindered rotation about the C34–C35 bond of the pinacol unit in an otherwise conformationally-symmetrical polyether chain.

Crystal Structure of the η^1-Allyl-Grignard Compound Bis(allylmagnesium chloride-TMEDA)**

By *Michael Marsch, Klaus Harms, Werner Massa,* and *Gernot Boche**

Although allyl-transition-metal complexes[1] and, more recently, also allyllithium compounds[2–4] have been studied in the solid state, the determination of the crystal structure of an allyl-Grignard compound has thus far not been reported. Herein we report on the crystal structure of bis(allylmagnesium chloride-TMEDA) **1** (TMEDA = tetramethylethylenediamine).

[*] Prof. Dr. G. Boche, M. Marsch, Dr. K. Harms,
Priv.-Doz. Dr. W. Massa

Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (SFB 260).

The allylmagnesium chloride-TMEDA complex formed on treatment of allylmagnesium chloride in tetrahydrofuran (THF) with TMEDA crystallizes as the dimer **1**.[5,6] The two allylmagnesium chloride-TMEDA units are coupled via a Mg–Cl–Mg–Cl four-membered ring in which the Mg–Cl and Mg–Cl′ distances are markedly different (240.0(1) pm and 269.4(1) pm, respectively).

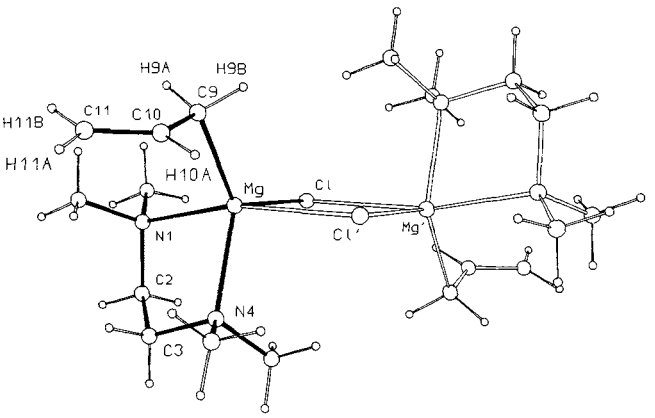

Fig. 1. Crystal structure of **1**. The atoms are represented by spheres with arbitrary radii. Selected bond lengths [pm] and angles [°]: Mg-Cl 240.0(1), Mg-Cl′ 269.4(1), C9-Mg 217.9(3), C10-Mg 300.5(3), Mg-N1 228.5(2), Mg-N4 221.1(2), C9-C10 144.2(4), C10-C11 133.5(4); Mg-C9-C10 110.5(2), C9-C10-C11 130.2(3), H9A-C9-H9B 109(2), H11A-C11-H11B 119(2), C9-C10-H10A 114(1), C11-C10-H10A 115.5(1.5), C10-C11-H11A 123.6(1.6), C10-C11-H11B 117.3(1.6), Cl-Mg-Cl′ 84.69(3), Mg-Cl-Mg′ 95.32(3), Cl-Mg-C9 125.29(7), N1-Mg-C9 99.26(8), N1-Mg-N4 80.28(7), Cl-Mg-N4 107.18(6), Cl′-Mg-N4 87.84(5); torsion angle [°]: C11-C10-C9-Mg −109.2(3), C11-C10-C9-H9A 14(1), C11-C10-C9-H9B 138(1).

The characteristic feature of **1** is the η^1-allyl-magnesium bond. The C9–Mg distance is 217.9(3) pm and thus lies in the range of C–Mg distances in alkyl-Grignard compounds.[7] There should be no bonding between C10 and Mg (300.5(3) pm). From the size of the C10-C9-Mg angle (110.5(2)°) and of the torsional angle C11-C10-C9-Mg (−109.2(3)°) it follows that the Mg atom juts out significantly from the allyl-CCC moiety. As a consequence H9A and H9B are twisted "inwards".

In contrast to the Grignard compound **1**, in many allyl-transition-metal complexes,[1] and in (1,3-diphenylallyllithium-diethyl ether)$_n$ **2**,[3] one finds η^3-structures; allyllithium-pentamethyldiethylenetriamine **3** contains at least a markedly unsymmetric η^3-(if not an η^2-)allyl-lithium bond.[4] Comensurate with the η^1-structure of **1** the C-C distances in the allyl moiety are different: C10-C11 133.5(4) pm and C9-C10 144.2(4) pm. The C9-C10-C11 angle is noticeably widened (130.2(3)°) and reaches almost the size of the CCC angles in the allyllithium compounds **2** (131(1)°)[3] and **3** (131.5(3)°).[4] The bond angles at C9 correspond to tetrahedral geometry and those at C11 to trigonal geometry (see caption to Fig. 1). The hydrogen atoms H10A, H11A, and H11B lie in the C9-C10-C11 plane.

An η^1-structure in allyl-Grignard compounds in *solution* had been concluded earlier by *Roberts* et al. from their classical NMR investigations.[8] The proof for such a structure was furnished by *Schlosser* and *Stähle* by means of the isotope-perturbation method.[10] *Benn* and *Rufińska* et al. confirmed the η^1-structure with ^{25}Mg-NMR data[11] and

$^1J(^{13}C,^{13}C)$ coupling constants.[11h] Ab initio calculations on ("*gaseous*") allylmagnesium hydride also favor an η^1-structure.[12] Marked deviations from the solid-state structure of **1** are found in the C9-C10 bond length, which is 149.9 instead of 144.2(4) pm, and in the location of the Mg atom, which according to the calculations assumes a position representing "a compromise between a "classical" geometry and a bridged structure."[12]

Summary: The structure of **1** in the solid state should serve as a good model for the structure of allyl-Grignard compounds in solution and as a criterion for further calculations.

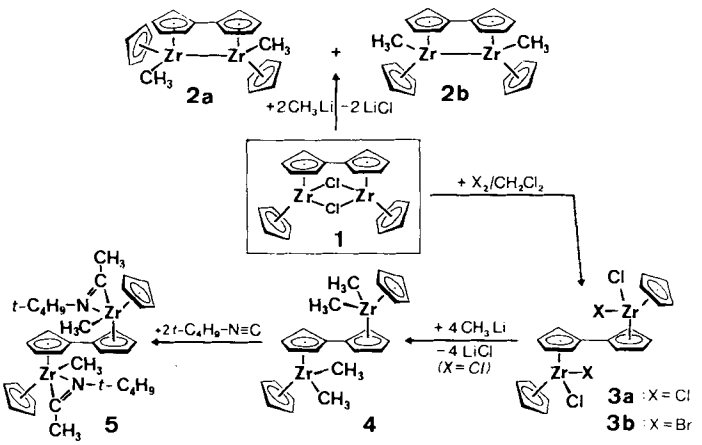
Dinuclear Fulvalene Complexes of Tri- and Tetravalent Zirconium**

By *Wolfgang A. Herrmann,* Tomás Cuenca, Babil Menjón*, and *Eberhardt Herdtweck*

The high reactivity of organozirconium(III) compounds, which also includes extreme sensitivity to air, has hitherto precluded a systematic development of this class of compounds comparable to that of organotitanium(III) compounds, whose chemistry is very well documented.[1,2] In view of the importance of low-valent organozirconium species in catalytic processes[1,3] we have directed our attention to the synthesis of polynuclear systems of this type exploiting the fulvalene bracketing effect and have recently reported on the zirconium(III) derivative **1**, a complex which is readily accessible by reductive CC-coupling of zirconocene dichloride with sodium.[4] We have now also succeeded in carrying out the directed methylation and oxidation of this derivative, thus opening up the possibility of further functionalization.



Reaction of 2.1 molar equivalents of methyllithium with **1** in the complete absence of air, moisture and light leads to formation of the chlorine-free methylation product **2**, a red solid, in 65% yield; NMR spectroscopic data (^1H, ^{13}C) show that **2** is formed as a *cis/trans*-mixture **2a** + **2b**.[5]

2 is one of the few unequivocally characterized alkyl compounds of *tri*valent zirconium;[1,2] it can be stored without decomposition for prolonged periods of time only in the absence of light and oxygen at temperatures below −20°C. The directed solid-state thermolysis of pure **2** (200°C/15 min/vacuum) yields chiefly methane as gaseous cleavage product (94%) together with small amounts of ethane, propane, propene and *cis*-2-butene. This finding can be explained in terms of initial formation of an unstable $ZrCH_2Zr$ species, which continuously decomposes like other μ-methylene complexes.[6]

Moreover, owing to its ready oxidizability, **1** can for example be converted in good yields (80–90%) into the CC-

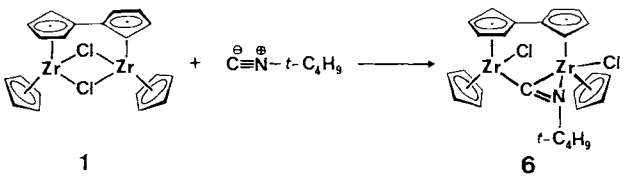
coupled greenish-yellow zirconocene dihalide complexes **3a** and **3b**. Even upon further reaction of **3** the fulvalene bracket between the two zirconium atoms remains intact. Thus, exhaustive methylation with methyllithium or methylmagnesium bromide in the molar ratio 1:4.2 leads to the tetramethyl derivative **4**,[7] a crystalline, yellow substance, whose methyl groups are capable of undergoing CC-coupling: treatment of **4** with **2** molar equivalents of isocyanide (e.g. *tert*-butyl isocyanide) at room temperature leads, via insertion of the NC function into Zr–CH_3 bonds, to smooth formation of the yellow azazirconiacyclopropene complex ("iminoacyl" complex) **5**; the η^2-fixation of the NC ligand is confirmed by the IR and ^{13}C-NMR spectra ($\tilde{\nu}$(CN) = 1637 cm^{-1}; δ(CN) = 234 ppm [C_6D_6]).[8,9]



1 **6**

Both chloro-bridges in the extremely reactive zirconium(III) complex **1** are opened upon reaction with isocyanide; with *tert*-butyl isocyanide, the derivative **6** is formed.[10]

The optimal orientation for the $\eta^1:\eta^2$-bridge coordination of the NC ligand is achieved by a twisting of the two zirconocene moieties through 22.6° about the C11–C21 bond joining them (Figure 1). The isocyanide ligand is puckered [$\sphericalangle$(C-N-C1) = 130.5(1)°], while the sequence of atoms Zr1-C-N, on the other hand, is almost linear

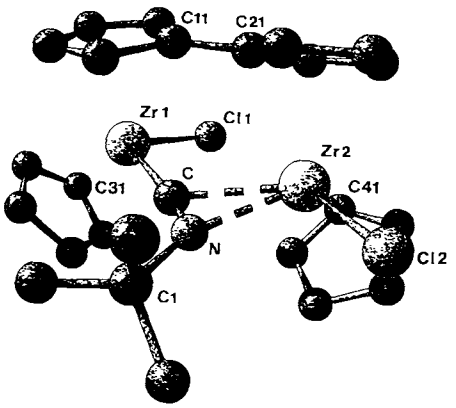


Fig. 1. Crystal structure of the fulvalene-bridged isocyanide complex **6** (SCHAKAL-representation, without hydrogen atoms). Selected bond lengths [pm] and angles [°]: Zr1-C 218.0(2), C-N 124.9(2), N-C1 151.7(2), Zr2-C 236.5(1), Zr2-N 221.2(1), Zr1-Cl1 250.5(1), Zr2-Cl2 258.3(1), C11-C21 140.9(2), Zr1-C11...15 250.0 (mean value), Zr1-C31...35 250.8 (mean value), Zr2-C21...25 254.8 (mean value), Zr2-C41...45 251.6 (mean value); Zr1-C-N 168.0(1), C-N-C1 130.5(1), Zr1-C-Zr2 122.1(1), Zr2-N-C1 148.2(1), C-N-Zr2 81.0(1).

[168.0(1)°].[11] As expected, the Zr1–C bond, with a length of 218.0(2) pm, is considerably shorter than a Zr–methyl bond (230–236 pm[1]), and the NC bond (124.9(2) pm) is somewhat shorter than a normal N=C bond.[1] The atoms Zr1, Zr2, Cl1, C, N, and C1 lie almost in a plane. The two zirconium atoms are so far apart (398 pm) that a bonding interaction between them can be disregarded. The electronic differences caused by the side-on complexation of the isocyanide ligand allows for the bonds from Zr-2 being longer than the corresponding bonds from Zr1. Diazoalkanes yield complexes structurally analogous to **6** (*N,N*-coordination).[12]

It is thus demonstrated that zirconium(III) complexes of the fulvalene series are functionalizable with retention of the oxidation state as well as with oxidation of the metal center, and no degradation or bond formation reactions to give mono- or oligomeric species are likely to occur because of the stable fulvalene bracket.

Experimental

2a/2b: A solution of **1** (1.02 g, 2 mmol) in toluene was treated at −78 °C with a 1.6 M solution of methyllithium in hexane (2.6 mL, 4.2 mmol) and the stirred mixture heated within ca. 2 h to −20 °C. The resulting reddish-brown solution was filtered off from insoluble material at −78 °C and evaporated to dryness under vacuum. **2a/2b** was washed with cold *n*-hexane and diethyl ether and dried under vacuum. Yield: 620 mg (65%).

3a/3b: A solution of **1** [4a] (5.11 g, 10 mmol) in toluene was treated with a stoichiometric amount of Cl_2 or Br_2, respectively, dissolved in CH_2Cl_2. The oxidation product **3a** or **3b**, respectively, immediately precipitated as a yellow solid. After 2 h, the product was evaporated down in a vacuum and the residue washed with tetrahydrofuran, *n*-hexane, and acetone. Yield: 5.30 g (90%) of **3a** or 5.40 g (80%) of **3b**, respectively.

4: A suspension of **3a** (582 mg, 1 mmol) in toluene (20 mL) was treated at −78 °C with a 1.6 M solution of CH_3Li in hexane (2.6 mL, 4.2 mmol). After warming to room temperature the yellow solution was separated from the sediment on dry celite, evaporated to dryness, and the resulting residue washed with diethyl ether and *n*-hexane; yellow crystals from toluene/hexane; yield 461 mg (92%).

5: A solution of **4** (501 mg, 1 mmol) in toluene was treated at room temperature with *t*-C_4H_9NC (0.25 mL, 2.2 mmol). After 15 h the mixture was filtered and the filtrate evaporated to dryness. Recrystallization of the residue from toluene/*n*-hexane furnished yellow crystals of **5**; yield 400 mg (60%).

6: A solution of **1** (500 mg, 0.98 mmol) in toluene (70 mL) was treated at room temperature with *t*-C_4H_9NC (110 µL, 0.98 mmol); the dark-violet solution immediately turned red. After filtration the solution was evaporated to dryness and the residue washed with *n*-hexane and diethyl ether. Yield: 490 mg (85%); m.p. 216 °C (decomp.).

Precipitates with β-Pleated Sheet Structure by Mixing Aqueous Solutions of Helical Poly(D-lysine) and Poly(L-lysine)**

By *Jürgen-Hinrich Fuhrhop,* Matthias Krull,* and *Georg Büldt*

Alkaline solutions of poly(D-lysine) ($c=3\times10^{-2}$ monomol/L, pH = 11; mean chain length n = 373, Sigma) and poly(L-lysine) ($c=3\times10^{-2}$ monomol/L, pH = 11; n = 430, Sigma) are stable and remain clear for weeks on storage under nitrogen at room temperature. The solution of poly(L-lysine) contains *P*- or right-handed helices, which are characterized by their molar ellipticities $[\theta]_\lambda$ per amino acid residue in CD spectra.[1,2] The $[\theta]$-values immediately after preparation of the solution and those after a week differ only slightly: $[\theta]_{219}=-31000$ and -27000, resp.; $[\theta]_{206}=-30000$ and -28000, resp.; $[\theta]_{189}=74000$ and 70000 grad cm^2/dmol, resp. The same holds for the *M*-helix of poly(D-lysine): $[\theta]_{219}=31000$ and 34000, resp.; $[\theta]_{206}=31000$ and 33000, resp.; $[\theta]_{189}=-73000$ and -71000 grad cm^2/d mol, resp. In D_2O, both solutions also show IR bands at 1636 cm^{-1}, which are typical for α-helices.[3]

When equal volumes of the clear solutions are mixed, a colorless precipitate is formed within a few minutes. The racemic mixture precipitates almost quantitatively, the association constant K is greater than 9×10^8 monomol lysine/L. To our knowledge, a similar phenomenon has previously only been observed in the case of the methyl esters of the *M*- and *P*-helical polyglutamates in organic solvents.[4] We explain the precipitation of the racemate in terms of an irreversible union of the disordered terminals of the *P*- and *M*-helices (= α-structures) and accompanying formation of insoluble pleated structures (= β-structures). The β-structures then grow at the cost of the α-structures. An intermediary coiling of the whole polypeptide does not occur.

We propose an antiparallel pleated sheet as the most likely structure for the racemic aggregate, i.e. a structure corresponding to the "polar pleated sheet" described by *Pauling* and *Corey*.[5] The impairment of aggregation, by the side chains, would in this case be minimal, so that pleating and curling of the individual sheets to fibers[6] should be less pronounced. The lengths of the hydrogen bonds linking the skeletal framework are also minimal in this structure (Fig. 1). The steric hindrance in the racemic β-structure is less than in the pure enantiomer.

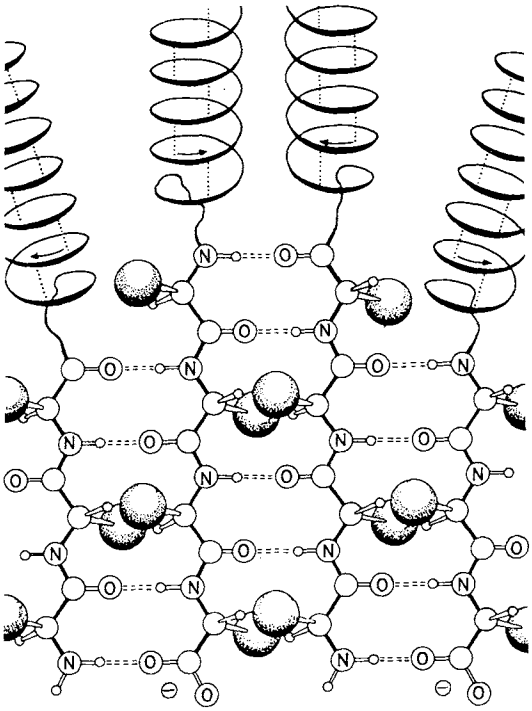

Fig. 1. Model for the aggregation of right-handed (*P*-) helices of poly(L-lysine) and left-handed (*M*-)helices of poly(D-lysine) and for the formation of a racemic pleated structure. The large spheres symbolize the $NH_2-(CH_2)_4$-residue.

The assumption of a β-structure for the racemic precipitate is based on the following: 1) The visual and electron microscopic images of the precipitate point to a pleated structure (Fig. 2a). 2) The X-ray reflections of the precipitate are consistent with a pleated structure, but not with helices.[7,8] X-ray powder photographs of the precipitate (Fig. 2b) show rings at 0.46 (chain interval), 0.74, and 1.46 nm (pleat interval),[7,8] whereas the characteristic reflections at 0.54 and 0.15 nm for a helix are missing. The rings between 2.0 and 4.9 nm point to superstructures, which are also visible in electron micrographs (Fig. 2a). 3) The strong amide-I band at $\tilde{\nu}=1688$ cm^{-1} in the IR spectrum is typical for pleated structures.[3] 4) The marked increase in the fluorescence of the pigment 6-(toluidino)-2-

naphthalenesulfonic acid suggests an insertion of the pigment into the hydrophobic region of the micellular pleated structure during the precipitation.[9] No films could be prepared from the solutions of the pure enantiomers which would give well-defined electron microscopic images.[10]

The spontaneous structural transformation upon mixing the enantiomeric helices is a further example for the chiral bilayer effect postulated by us[11] for aggregates with a hydrophobic bilayer. This effect is the reason for the helical fibers of chiral amphiphiles aggregating and precipitating only slowly and the racemic hydrophobic bilayers rapidly forming insoluble crystal platelets on union of the two enantiomeric helices. The effect has been demonstrated previously with helical aggregates of chiral fatty acids in organogels[12] and with *N*-alkylgluconamides in aqueous gels.[11] Its validity demonstrated here also for polymers may be regarded as an indication of the relevance of the effect for biological organisates in which polymer fibers play a dominating role (e.g. collagen in muscles).[13] In these cases it can be predicted that racemic crystals precipitate on addition of the enantiomeric polymer-fiber. If the hydrophobic effect dominates in the stabilization of the chiral fiber,[11] pleated structures should form in the racemate. In the case of chiral fibers in non-aqueous media[4] or membranes, dipole interactions should dominate and the helices should remain intact during the precipitation.[12] In both cases the chirality of the fibers appears to be a necessary prerequisite for the longevity of metastable organisates.

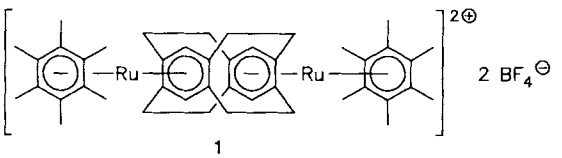
Electron Delocalization in Diruthenium Complexes of Polycyclic Arenes**

By *Klaus-Dieter Plitzko* and *V. Boekelheide**

Related to the discovery of the Creutz-Taube ion,[1] a tremendous amount of work has been done with respect to both experimental examples[2] and the theory[3] of intramolecular one-electron-transfer in mixed-valence ions. Much less is known about intramolecular multi-electron-transfers. Only recently, we reported on **1**, the first example of a discrete mixed-valence molecular ion (class II), showing a



1

net, two-electron transfer.[4] Almost simultaneously, the first, quantitative, theoretical analysis of an intramolecular two-electron transfer, using the vibronic coupling model (PKS), has appeared.[5] As an outgrowth of our studies on diruthenium complexes of [2$_n$]cyclophanes, we have been interested in various types of hydrocarbon ligands. Prior work by *Hendrickson* et al.[6] indicated that diiron complexes of polycyclic arenes show mixed-valence properties involving one-electron transfer. It was important, therefore, to study some examples of diruthenium complexes of polycyclic arenes in order to compare their properties, as mixed-valence ions involving net two-electron transfers, with those of **1**.

We now report on the preparation and properties of the bis(η^6-hexamethylbenzene)diruthenium complexes of phenanthrene, **3**, and 9,10-dihydrophenanthrene, **6**. The cation of **3** is a typical class II, mixed-valence ion, quite similar to the cation of **1**, but having a much larger thermal energy barrier for electron transfer. Quite surprisingly,

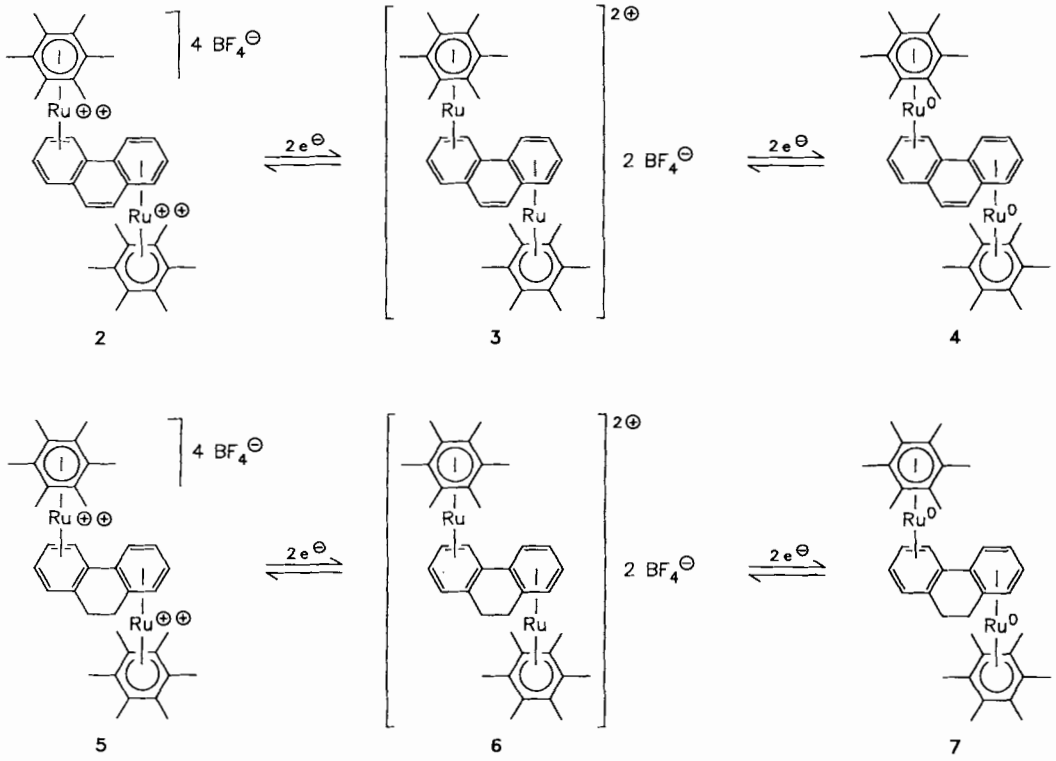
though, **6** shows electron delocalization throughout the temperature range experimentally accessible. At present it is not certain whether **6** is an average-valence ion with complete electron delocalization, or whether it is a class II ion with a very low thermal energy barrier to electron transfer. In either case, the cation of **6** is a highly unusual ion involving the lower oxidation states of ruthenium.

son of the ^{1}H-NMR spectrum of **3** with the ^{1}H-NMR spectra of the model compounds, (η^6-hexamethylbenzene)(η^6-phenanthrene)ruthenium(II) and (η^6-hexamethylbenzene)(η^4-phenanthrene)ruthenium(0), clearly shows that the two different ruthenium environments present in **3** correspond to a Ru^{II} site and a Ru^0 site.[7] This is further supported by a comparison of the corresponding ^{13}C-



The preparation of the complexes **2** and **5** proceeded readily in high yield by the reaction of phenanthrene and 9,10-dihydrophenanthrene, respectively, with the solvate of (η^6-hexamethylbenzene)ruthenium(II) bis(tetrafluoroborate) following the usual procedure,[4] but using propylene carbonate as solvent.[7] Cyclic voltammetry and coulometry measurements of **2** showed two, reversible, two-electron reduction waves corresponding to the formation of **3** and **4**; $E^{I}_{1/2}$ (vs. SCE) $= -0.185 \pm 0.005$ V and $E^{II}_{1/2} = -0.677 \pm 0.005$ V. From the difference (492 mV) between the two redox potentials, the comproportionation constant (K_c) for the equilibrium, $\mathbf{2} + \mathbf{4} \rightleftharpoons 2\,\mathbf{3}$, is calculated to be 4.4×10^{16}. Similarly, cyclic voltammetry and coulometry measurements of **5** showed two, reversible two-electron reduction waves corresponding to the formation of **6** and **7**; $E^{I}_{1/2}$ (vs. SCE) $= -0.195 \pm 0.005$ V and $E^{II}_{1/2} = -1.77 \pm 0.010$ V. The difference in redox potentials in the case of the 9,10-dihydrophenanthrene derivatives is 982 mV, indicating the comproportionation constant (K_c) for the equilibrium, $\mathbf{5} + \mathbf{7} \rightleftharpoons 2\,\mathbf{6}$, to be 1.6×10^{33} and suggesting a strong electron delocalization for **6**. Separate chemical reductions of **2** and **5**, respectively, using bis(hexamethylbenzene)ruthenium(0) as a reducing agent,[4] made possible the isolation of both **3** and **6** as dark red crystals in quantity and in high yield.[7]

From the ^{1}H-NMR spectra of **3** and **6**, given in Table 1, it is apparent that **3** has two different sets of aromatic protons and two different types of methyl protons. Compari-

Table 1. ^{1}H-NMR data for **3** and **6**. hmb = hexamethylbenzene.

3: ^{1}H-NMR (CD_2Cl_2, 360 MHz): $\delta = 7.63$–7.61 (m, 2H, 7,8-H), 7.43–7.39 (m, 1H, 6-H), 7.15–7.12 (m, 1H, 5-H), 6.36 (tt, $J_1 = 5.76$, $J_2 = 1.08$ Hz, 1H, 2-H), 6.29 (dd, $J_1 = 5.76$, $J_2 = 1.08$ Hz, 1H, 9-H), 5.98 (tt, $J_1 = 5.76$, $J_2 = 1.08$ Hz, 1H, 3-H), 4.15 (dd, $J_1 = 5.76$, $J_2 = 1.08$ Hz, 1H, 10-H), 3.68–3.66 (m, 1H, 1-H), 3.22 (dd, $J_1 = 5.76$, $J_2 = 1.08$ Hz, 1H, 4-H), 2.04 (s, 18H, hmb-CH_3-Ru^{II}), 1.90 (s, 18H, hmb-CH_3-Ru^0)

6: ^{1}H-NMR (CD_2Cl_2, 360 MHz): $\delta = 5.84$ (tt, $J_1 = 5.04$, $J_2 = 1.08$ Hz, 2H, 2,7-H), 4.85 (tt, $J_1 = 6.84$, $J_2 = 1.08$ Hz, 2H, 3,6-H), 4.71 (dd, $J_1 = 5.04$, $J_2 = 1.08$ Hz, 2H, 1,8-H), 4.12 (dd, $J_1 = 6.84$, $J_2 = 1.08$ Hz, 2H, 4,5-H), 2.13 (s, 36H, hmb-CH_3), 2.03 (d, $J = 9.6$ Hz, 2H, 9,10-H), 1.52 (d, $J = 9.6$ Hz, 2H, 9,10-H)

NMR spectra.[7] Thus, on the NMR time scale at room temperature the mixed-valence ion **3** has a frozen conformation corresponding to **3a** or **3b** as shown below. The thermal energy barrier for this postulated equilibrium must

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0707-0701 $ 02.50/0

be quite large, though, since the ^{1}H-NMR spectrum of **3** in [D$_6$]ethylene glycol is unchanged over the temperature range of 25 to 170°C.

In sharp contrast to the data for **3**, the ^{1}H-NMR spectrum of **6** is completely symmetrical, showing a singlet for the methyl protons, two doublets for the bridging methylene protons, and signals for four aromatic protons. The ^{13}C-NMR spectrum of **6** is likewise completely symmetrical.[7] Furthermore, a solution of **6** in $CD_2Cl_2/CHClF_2$ showed no NMR-spectroscopic change over the temperature range of 25 to −135°C. Thus, **6** must be a delocalized average-valence ion or, if class II, the thermal energy barrier for intervalence electron transfer must be very low. A decision between these two possibilities is not easily made and will require further study.[8] The sharp contrast in the properties of **3** and **6** illustrates the remarkable difference a double bond can make. Also, fast electron transfer in diruthenium complexes of polycyclic arenes can apparently rival, or exceed, that present in diruthenium complexes of [2$_n$]cyclophanes.

Macrocyclic Dienes by Metathetic Dimerization of Cycloheptene and Cyclooctene on Re_2O_7/Al_2O_3**

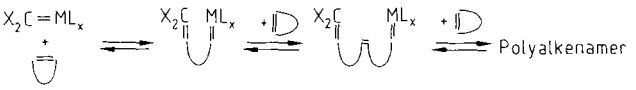
By *Siegfried Warwel,* Hans Kätker,* and *Claudia Rauenbusch*

Dedicated to Professor Friedrich Asinger on the occasion of his 80th birthday

The present syntheses of cyclic hydrocarbons are limited at the C_{12}-ring; 1,5,9-cyclododecatriene is also prepared on an industrial scale by butadiene-cyclotrimerization.[1] We report here on a simple one-step synthesis of the C_{14}-ring and of the C_{16}-ring starting from technically accessible cycloheptene and cyclooctene, respectively, using olefin metathesis[2] as reaction principle.

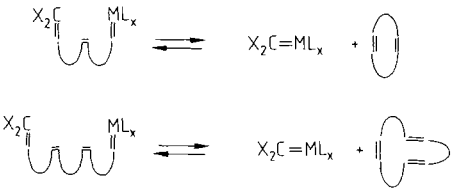
The metathesis of cycloolefins normally leads to unsaturated, mainly linear polymers, the "polyalkenamers", as major products and to cyclooligomers as byproducts. This bimodal product composition can be explained in terms of the carbene mechanism, the generally accepted mechanism for olefin metathesis:[3]

- linear polymers are formed via metallacyclobutanes as central intermediates by intermolecular reactions of the cycloolefins with the carbenemetal complexes (active catalytic species) formed from homogeneous or heterogeneous metathesis catalysts (Scheme 1).



Scheme 1.

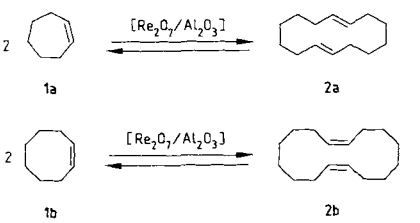
- cyclic oligomers are formed by intramolecular reactions of the carbenemetal center of a growing polymer chain with C=C double bonds of the same molecule; Scheme 2 shows possible reaction routes for dimer and trimer formation.



Scheme 2.

The amount of oligomers can of course be increased significantly by using the Ziegler-Ruggli dilution principle in the case of cyclooctene,[4] but the preparative exploitation of the reaction, e.g. for the synthesis of macrocyclic dienes, has so far never been resorted to because of the low yields.[5]

With Re_2O_7/Al_2O_3 as catalyst and by carrying out the reaction in a Soxhlet-like cycling apparatus, in which only small amounts of cycloolefin are continuously fed through the catalyst as fix bed by a low-boiling solvent (pentane, hexane), we have now been able to smoothly convert cycloheptene **1a** into 1,8-cyclotetradecadiene **2a** and cyclooctene **1b** into 1,9-cyclohexadecadiene **2b** and larger macrocycles. The activity of the catalyst could be increased even further by addition of $Sn(CH_3)_4$ to Re_2O_7/Al_2O_3 (see also ref. [6]).



A characteristic feature of our method, besides the low reactant concentration on the catalyst, is a short contact residence time and thus the rapid removal of the metathesis product, whereby secondary reactions to higher oligomers and polymers are impaired. Surprisingly, **1a** and **1b** behave quite differently in the metathesis reaction (Table 1). The reaction of cyclooctene **1b** leads to an homologous series of cyclic oligomers, including the desired 1,9-cyclohexadecadiene **2b**, but also containing the higher polyenes in larger concentrations. In contrast the reaction of cyclo-

[**] Olefin Metathesis, Part 14. This work was supported by the Fonds der Chemischen Industrie.—Part 13: S. Warwel, W. Winkelmüller, *J. Mol. Catal. 28* (1985) 247.

heptene **1a** leads preferentially to 1,8-cyclotetradecadiene **2a** with a selectivity of 80%.

Table 1. Metathetic dimerization of cycloheptene **1a** and cyclooctene **1b** on Re_2O_7/Al_2O_3 activated by $Sn(CH_3)_4$.

	Cycloheptene **1a**	Cyclooctene **1b**
Conversion [%]	85	90
Selectivity to **2** [%]	80	34
Yield of **2** [%] [a]	68 (**2a**)	30 (**2b**)
Product composition [wt.-%] [b]		
Dimer	80 (**2a**)	34 (**2b**)
Trimer	8	26
Tetramer	1	12
Pentamer	trace	7
Higher oligomers and polymers	11	21

[a] Isolated diene, yield referred to **1**. Yields in the absence of $Sn(CH_3)_4$: for **2a** 60%, for **2b** 25%. [b] Determined by GC: 50 m × 0.25 mm ID, fused silica, OV1. Temperature program: 50–280 °C, 5 min isotherm, 8 °C/min (1.0 bar N_2) and gel permeation chromatography (GPC): polystyrene-gel cross-linked with 2% divinylbenzene, tetrahydrofuran (THF) as eluent [11].

With both cyclic dienes the thermodynamic equilibrium mixture of the configurational isomers is formed (Table 2). In the case of **2a** this consists of 90% of the *trans,trans*-isomer, whereas in the case of **2b** an almost statistical mixture of the three possible stereoisomers is formed.

Table 2. Proportion of configurational isomers of **2a** and **2b** [%] [a]; equilibrium values according to [7] in brackets.

Isomer	**2a**	**2b**
trans-trans	87.8 (90.2)	16.2 (17.7)
cis-trans	8.7 (7.5)	57.5 (59.2)
cis-cis	3.5 (2.3)	26.3 (23.1)

[a] Determined by GC, cf. Table 1.

We attribute the preferred formation of the C_{14} ring in the metathesis of cycloheptene to the exceptional conformational stability of *trans,trans*-1,8-cyclotetradecadiene.[8]

Experimental[10]

2a: A mixture of **1a** (11.6 g, 0.12 mol) and *n*-pentane (45 mL) was heated to boiling in a 250 mL three-necked flask. The vapor phase was fed through a heated tube and condensed in a high-efficiency condenser. The condensate was then passed through a heated spiral cooler, where it was brought to 35 °C and transferred dropwise onto a fixed bed of 6.7 g Re_2O_7/Al_2O_3 (3.5 wt.-% Re_2O_7 on γ-Al_2O_3, Akzo CK 300 Al_2O_3; for preparation of catalyst: cf. ref. [9]), previously saturated with 5.8 mL of a 0.25 M solution of $Sn(CH_3)$ in *n*-hexane. After passage through the catalyst the reaction mixture was fed back into the flask, where the products of metathesis were enriched, while unchanged **1a** was again fed to the catalyst by the low-boiling solvent. After 24 h the solvent and unchanged **1a** were distilled off. Sublimation of the residue at 60 °C/10^{-3} torr afforded 7.9 g (68%) of **2a**. M.p. 64 °C, correct elemental analysis. MS (70 eV): *m/z* 192 ($M^{\oplus}$, 12%), IR (KBr): 3045 (=C–H); 2975, 2940, 2875 (ν-CH_2–); 1650 (C=C); 1475, 1445 (δ-CH_2–); 980 (γ=C–H); 722 (γ=C–H) cm^{-1}. ^{1}H-NMR (90 MHz, TMS): δ = 1.33 (s, 12H); 2.02 (s, 8H); 5.20 (m, 4H).—As expected, the metathesis of **2a** with ethene in an autoclave (50 bar, 90 °C), using the same catalyst, afforded exclusively 1,8-nonadiene. Hydrogenation of **2a** on Pd/C led quantitatively to cyclotetradecane.

2b: Catalyst and reactants: 11.2 g of Re_2O_7/Al_2O_3 saturated with 9.7 mL of a 0.25 M solution of $Sn(CH_3)_4$ in *n*-hexane; 22.7 g (0.21 mol) of cyclooctene, 140 mL of *n*-hexane. Procedure as above, but catalyst temperature 50 °C, reaction time 72 h, and isolation of **2b** by rectification. Yield of **2b**: 6.3 g (30%). B.p. 115 °C/10^{-3} torr. Correct elemental analysis. MS (70 eV): *m/z* 220 ($M^{\oplus}$, 21%). IR (KBr): 3005 (=C–H); 2980, 2920, 2850 (ν–CH_2–); 1650 (C=C); 1460, 1440 (δ–CH_2–); 970 (γ=C–H); 725 (γ=CH) cm^{-1}. ^{1}H-NMR (90 MHz, TMS): δ = 1.31 (s, 16H); 2.03 (s, 8H); 5.40 (m, 4H).—As expected the metathesis of **2b** with ethene in an autoclave (50 bar, 90 °C) using the same catalyst afforded exclusively 1,9-decadiene. Hydrogenation of **2b** on Pd/C led quantitatively to cyclohexadecane.

Questions of Assignment

In a communication[1] published at the end of 1986 in *Angewandte Chemie*, *Adam* et al. included the following statement in footnote[1] regarding our article[2] on cycloadditions to homodienes: "... the assignment of the ^{1}H-NMR spectrum of their product **3** formed from TCNE and **1** is questionable." The assignments of the *endo* and *exo* cyclopropyl protons of compound **3** are in fact reversed. This is one of the rare cases where the signal of the *exo* proton appears at lower field than that of the *endo* proton. Evidence for the correct assignment is provided by the larger coupling constants for the coupling between the *exo* proton and the *cis* proton of the three-membered ring.

An Introduction to Organometallic Chemistry

Despite the strong tradition of organometallic chemistry that exists in the German-speaking world, there has for several decades been a lack of secondary literature in that language which combines the qualities of competent expertise, balanced content, a modern style, and convenient presentation. *Christoph Elschenbroich* and *Albrecht Salzer* are therefore to be applauded on having now written a textbook based on their obviously excellent course of lectures on the subject, namely:

Organometallchemie. By *Ch. Elschenbroich* and *A. Salzer*. Teubner, Stuttgart 1986. 472 pp., paperback, DM 42.00.—ISBN 3-510-03501-4.

The response of this reviewer to the authors' commendably self-critical reflections in their preface is that no-one else has ever achieved so much as they have done here! Furthermore, I predict that this will be a unanimous verdict on the book.

The authors, in a very clever and instructive presentation based on examples, have managed to extract, from the cornucopia of organometallic reactions, compound classes and structures, all the important concepts which have become firmly established in this interdisciplinary and complex branch of modern chemistry. The contents are arranged in a conventional way according to groups of elements ("Main-group organometallics, pp. 23–196), types of ligands ("Transition metal complexes", pp. 218–384), extent of aggregation ("Metal-metal compounds and transition metal atom cluster compounds", pp. 385–410), and applications ("Organometallic homogeneous catalysts", pp. 412–441). Nevertheless, the danger of merely producing a list of compounds and reactions has been recognized and avoided, and the contents of the chapters are well balanced one with another. The authors' boldness in simplifying the subject matter works to the reader's advantage by stimulating him to reflect further on principles of reactivity and structure, and helps him to recognize the broad features which are common to the organic chemistry of main-group and sub-group elements. Thus, from the unavoidably large mass of chemical data, there emerges again and again the underlying plan of this student text, which is based on showing the resemblances and differences in behaviour between the elements. At points where a deeper understanding of relationships of a more far-reaching and general nature becomes necessary, the authors include "digressions" into fundamental aspects of spectroscopy and bonding theory. This type of presentation will be much appreciated, especially by advanced chemistry students such as graduates working for higher degrees. However, these are by no means the only groups of readers who will find the book useful. An industrial chemist too could save himself much time by reading up on modern catalytic processes in *Elschenbroich* and *Salzer*; he would, moreover, obtain an economically priced source of instruction in this subject, and a review of new developments which are at present mainly of academic interest, such as multiple bonds between atoms of silicon or transition metals, or methods for synthesizing cluster compounds. At the price of DM 42 this 470-page book is within everyone's means. University and technical institute lecturers too will not only thumb twice through this book, once from front to back, then in reverse, and not just for mere curiosity—and will then reward the authors with gratitude and admiration. We will all learn from the book, will discard our old lectures and insert new material, will refer back to other monographs cited therein—in short, we will work from this book!

Compared with other books in the field of organometallic and organo-heteroelement chemistry, including those in English, "Elschenbroich and Salzer" is a unique achievement, which one hopes will have a stimulating effect on future standards in the secondary chemical literature. In view of this high recommendation, it would seem churlish to search for printing errors in this first edition.

Syntheses of Fluoroorganic Compounds. By *I. L. Knunyants* and *G. G. Yakobson*. Springer, Berlin 1985. vii, 299 pp., bound, DM 218.00.—ISBN 3-540-15077-3

Despite having been shortened to one volume, this English language version of the two-volume Russian work with the same title still contains more than 300 synthetic methods for organofluorine compounds. Apart from a few descriptions of preparative methods for intermediates, the methods nearly all originate from the relevant laboratories of the Soviet Academy of Sciences. They have previously been published in Russian language scientific journals, but English translations exist in only a few cases. This book therefore provides specialist readers with details, not readily accessible elsewhere, of experimental work in Russian centers of research in organofluorine chemistry. It is probably the first such publication on this specialist topic in the English-speaking world.

Some of the method of presentation in this book is undoubtedly borrowed from the well-known "Organic Syntheses" series. A single self-contained chapter is devoted to each compound, the same formal sequence of presentation being maintained for each substance. After the chemical name, the structural and molecular formulae, molecular weight, and physical data (so far as these are known), a list of the most important published methods of preparation is given, followed by the experimental details of the method itself. In some cases the chapter concludes with a list of other compounds having similar structures which can be prepared by the same method. Evidence of revision of the previous edition is seen in the inclusion of comments on critical features of the preparative method described.

The book is divided into three sections, each having a systematic structure. Each section begins with methods for preparing fluorinated hydrocarbons, then deals with derivatives containing other halogens as substituents, and then, so to speak following the conventional structure of an organic chemistry textbook, treats compounds which contain the various functional groups. Each section concludes with a list of the numerous literature references cited in the text. Subject and formula indexes at the end of the book facilitate searching for particular compounds.

The first section deals with "Fluoroaliphatic Compounds", and has been compiled by a team of authors at the Moscow laboratory of the Soviet Academy of Sciences. The main emphasis is on the chemistry of fluoro-olefins

and their derivatives, in particular the highly toxic compound octafluoro-isobutene ($LC_{50}=0.5$ ppm!).

The main subject of the second section, entitled "Fluoroaromatic Compounds", are the perfluoro-arenes, on the basis of which the Novosibirsk research group led by *G. G. Yakobson* has developed an extensive area of chemistry, here described in a very expert fashion.

L. M. Yagupolski et al., of the Kiev laboratory of the Soviet Academy of Sciences, have produced the third section on "Aromatic Compounds with Fluorinated Side Chains". The main type of fluorinated side chain dealt with is the trifluoromethyl group. As one would expect, the conversion of carboxyl groups into CF_3 substituents using SF_4 assumes an important role here, whereas only a few examples of fluorine-chlorine exchange in the corresponding chlorinated starting materials using SbF_3 are given, and that using hydrogen fluoride is not mentioned at all.

This compilation of synthetic methods for organofluorine compounds is not only of interest to organofluorine chemists in academic or industrial laboratories. It is also of value to the preparative organic chemist, as the methods have generally been chosen such that no special equipment is needed to put them into practice; information is also given in an introductory chapter concerning the toxicities of the most important fluorinating agents and reactive fluorine-containing products, together with advice on handling them.

The positive impression gained from the book as a whole is somewhat diminished by an abnormally large number of printing errors in the text and structural formulae, leaving the user with a feeling that, for whatever reason, careful correction of the proofs has been omitted.

High-Performance Liquid Chromatography in Biochemistry. Edited by *A. Henschen, K.-P. Hupe, F. Lottspeich,* and *W. Voelter.* VCH Verlagsgesellschaft, Weinheim 1985. xiii, 638 pp., bound, DM 198.00.—ISBN 3-527-26057-9

Practice of High-Performance Liquid Chromatography. Edited by *H. Engelhardt.* Springer, Berlin 1986. xii, 461 pp., bound, DM 198.00.—ISBN 3-540-12589-2

Biochemical research is scarcely imaginable without the use of chromatographic methods for analytical and preparative work, and the latest high performance versions have vastly improved the precision and speed of separations and the accuracy of quantitative analysis. The first of these two books, which includes contributions from authors in the German-speaking world, is of great interest to all who work in this field, since, following the appearance of a number of symposium volumes and one less successful attempt at the topic (Hancock and Sparrows: HPLC Analysis of Biological Compounds), we now have for the first time a complete summary of the basic principles and scope of applications to all the relevant classes of substances.

The book has as its introduction three chapters which deal with the fundamentals of chromatography, the column as the heart of the chromatographic set-up, and the remaining experimental requirements for analytical and preparative work. The presentation of this material is relatively condensed, but is essentially adequate as a basis for beginners. However, the instrumentation section really does no more than list components, without discussing the advantages and disadvantages of different arrangements.

A further group of articles deals with individual classes of substances: amino acids, peptides and proteins, peptide hormones, biogenic amines, lipids, carbohydrates, nucleic bases, nucleosides and nucleotides, porphyrins, steroidal hormones, vitamins, organic acids, and substances present in plant tissues. These articles contain many illustrations and typical examples of separations, and details of columns and mobile phases that can be used, usually summarized in the form of tables with a more detailed discussion in the text. Information is also given on detection problems and the optimized pre-treatment of the sample, which in biological materials often includes an extraction step. Unfortunately the details of the methods are not always collected together in a form which stands out clearly from the text, in the way that they are set out in the example given for the section on porphyrins.

The subject index and bibliography are very comprehensive, though the literature cited extends only up to 1981 in some cases, and in no case later than 1982. Thus, as often occurs in books of this kind, topicality has been sacrificed in favor of keeping to a pristine appearance of the text, a policy which one must sometimes feel to be a disadvantage in such a fast changing field. This can be seen in the case of proteins, where it has not been possible to take account of the very extensive knowledge gained recently on retention mechanisms for biological macromolecules and on the mechanisms and kinetics of denaturation in contact with the carrier. The latter point is, in fact, of considerable importance, since it has now led to a shift of emphasis away from reversed phases towards biocompatible systems (ion exchange chromatography, hydrophobicity chromatography, and affinity chromatography).

However, despite the above shortcoming this is a book which will deservedly become a standard work on the subject, and its purchase can be well recommended, even for inclusion in one's personal collection. Against the general tendency to deal with ever narrower specialized topics, this book brings together theoretical fundamentals and practical applications in a form which is suitable even for newcomers, and at the same time affords a look out beyond one's own "backyard fence".

The title of the second book could easily lead to misunderstanding. This work, written through the collaboration of an international team of authors, is definitely not intended as a general source of advice on HPLC laboratory practice; instead it deals with a few selected aspects, mainly of a practical nature, burdened with only a little theory. Separation mechanisms are discussed in detail only in two of the chapters, on liquid-liquid chromatography and on ion pair liquid chromatography. Other sections which treat questions of general importance are those on quantitative analysis, special requirements for high resolution preparative work, and sample preparation together with methods for automating it. The chapter on column switching techniques also includes discussions on pre-concentration from complex mixtures, and on the removal of interfering substances before analysis. This group of topics is introduced by a descriptive list of the various components available for HPLC systems, which is impressive in its wide scope and completeness, including even automatic control equipment and data recording (although columns are not included!). The various ideas are not simply listed, but are discussed.

The second half of the book is devoted to applications, which include a wide variety of fields such as forensic chemistry, the separation of lipids, analysis of natural and synthetic drugs, analysis of psychotropic substances in body fluids, HPLC of amino acids and proteins, the separation of nucleic acid metabolites present in physiological

fluids, and lastly the chromatography of coal and oil products. Careful editorial attention is apparent in this part of the book too; for example, one feature deserving special praise is that important steps in sample preparation and preliminary separation into different types of substances are always clearly emphasized, rather than being buried in the rest of the text.

All the chapters are quite well balanced with regard to length, although it is true that this can sometimes give grounds for criticism. Thus, for example, three pages on "HPLC of proteins" simply does not do justice to the wide range of applications that exists in this field of work. It would have been more sensible here to limit the length of the chapter by confining the discussion to amino acids.

Because of the rather arbitrary collection of topics which it brings together, it is difficult to recommend this very well produced book to a specific group of readers. Many will at first be interested only in individual chapters, and beginners in the field will regret the absence of chromatographic fundamentals. Consequently few readers will consider it for their own bookshelves, but it certainly ought not to be omitted from any library.

Science of Ceramic Chemical Processing. Edited by *L. L. Hench* and *D. R. Ulrich*. John Wiley, New York 1986. 594 pp., bound, $ 90.30.—ISBN 0-471-82645-6

With the growing interest during recent years in new materials, especially in advanced ceramics, and the high expectations that are associated with them, their chemistry has attracted an increasing amount of attention. This trend is catered for by a series of international symposia entitled "Ultrastructure Processing of Ceramics, Glasses and Composites", held at two-yearly intervals since 1983. The papers of the second of these meetings (1985) are published in this book, edited by *Hench* and *Ulrich*.

The title "Science of Ceramic Chemical Processing" could easily mislead German-speaking readers, as the term "ceramics" is used here in its broader sense to include also glasses, a usage which differs from that of the German "Keramik". In fact fewer than half of the sixty papers are concerned with technical ceramics in the narrower sense. The majority deals instead with glasses, general colloid chemistry, and organic polymers, some of those in the last category having only a tenuous connection with ceramics.

It would be best to regard the papers presented here as having the common theme of "Ultrastructure (chemical) processing". Ultrastructures, also referred to by some authors as "nanostructures", can be taken to mean ordering phenomena in solids with a scale of distances intermediate between the Angström dimensions of molecular structures and the micron dimensions typical for particulate structures. Essentially three main routes for the production of such materials are discussed, namely the sol-gel technique, the processing of colloidal particles with a well-defined size distribution, and the conversion of covalent polymers, e.g. polysilanes, polycarbosilanes and polysilazanes. The sol-gel technique received especially detailed coverage at this meeting; the 35 papers on this topic dealt with both the scientific basis of the technique and with its applications, but nevertheless one got the impression that the high hopes that are held for this process have not yet been realized in practice. On p. 121 *J. D. Mackenzie* quite rightly says that "The science of sol-gel processing is still in its infancy at present". The same is also true of the two other routes mentioned above.

With regard to the book as a whole, the comments that generally apply to books of conference proceedings are, of course, also true here. The quality of the papers, and the amount of care put into writing them, varies greatly from author to author. A number of the articles have already been published elsewhere, and there are many instances of overlapping and repetition. Articles on highly specialized topics are sometimes grouped together in an unrelated fashion. The editors have succeeded in imposing a certain amount of structure by dividing the book into six chapters: Sol-gel science, Applications of sol-gel processing, Materials from organometallic precursors, Ultrastructure in macromolecular materials, Micromorphology science, and Quantum chemistry. The presentation, the printing and the quality of the illustrations are all good. The detailed subject index provided at the end of the book is also a welcome feature.

Despite the limitations mentioned, this book, in common with the preceding symposium volume (published in 1984), can be recommended to all those readers seeking a review of the latest developments in this topical interdisciplinary field between chemistry, chemical engineering and materials science.

The Nerve Growth Factor: 35 Years Later (Nobel Lecture)**

By Rita Levi-Montalcini*

1. Neurogenesis and Its Early Experimental Approach

"Embryogenesis is in some way a model system. It has always been distinguished by the exactitude even punctilio, of its anatomical descriptions. An experiment by one of the great masters of embryology could be made the text of a discourse on scientific method. But something is wrong, or has been wrong. There is no *theory* of development in the sense in which Mendelism is a theory that accounts for the results of breeding experiments. There has therefore been little sense of progression or timeliness about embryological research. Of many papers delivered at embryological meetings, however good they may be in themselves ... one too often feels that they might have been delivered five years beforehand without making anyone much the wiser, or deferred for five years without making anyone conscious of a great loss".[1]

This feeling of frustration so incisively conveyed by these considerations by *Peter Medawar*, pervaded, in the forties, the field of experimental embryology, which had been enthusiastically acclaimed in the mid-thirties, when the upper lip of the amphibian blastopore brought this area of research to the forefront of the biological stage. The side branch of experimental neuroembryology, which had stemmed out from the common tree and was entirely devoted to the study of the trophic interrelations between neuronal cell populations and between these and the innervated organs and tissues was then in its initial vigorous growth phase. It in turn suffered from a sharp decrease in the enthusiasm that had inflamed the pioneers in this field ever since *R. G. Harrison* delivered his celebrated lecture on this topic at the Royal Society in London in 1935.[2] Although alternate 'wax and wane' cycles are the rule rather than the exception in all fields of human endeavor, in the biological sciences the 'wane' is all too often indicative of a justified loss of faith in the rational and methodical approach that had at first raised so much hope.

A brief account of the state-of-the-art of experimental neuroembryology in the forties, when interest in this approach to the study of the developing nervous system was waning, is a prerequisite for understanding the sudden unforeseeable turn of events which resulted in the discovery of the Nerve Growth Factor (NGF).

2. Experimental Neuroembryology in the Early Forties

The replacement, in 1934 by *Viktor Hamburger*, of the chick embryo with that of the amphibian larva as object of choice for the analysis of the effects of limb bud extirpation on spinal motor neurons and sensory nerve cells innervating the limbs,[3] signed the beginning of a long series of investigations centered on the analysis of this and related experimental systems in avian embryos. Here I shall

only list the major advantages offered by the chick embryo over amphibian larvae as object of neurological investigations.

The avian nervous system is built according to a more elaborate design than that of amphibians, and it lends itself to a more rigorous analysis of its nerve centers than that of lower vertebrates. Extensive fundamental studies on the nervous system of the chick embryo, with use of the invaluable silver specific techniques by *Ramon y Cajal* and co-workers, extended recently by myself and other investigators,[4, 5] provided a very accurate blueprint of most nerve centers and their developmental history during neurogenesis. This allowed the detection of even small infractions to normal developmental rules in experimentally manipulated embryos. At variance with ontogenetic processes in amphibians, in chick embryos the same processes unfold according to a rigidly scheduled time sequence which never departs from the anticipated. It is therefore possible to compare the central and peripheral nerve centers of experimental and control specimens in embryos incubated under the same temperature and other environmental conditions. The analysis in amphibian larvae was extended to the brain, spinal cord, and peripheral nervous system and various experimental situations. In the chick embryo it was mainly confined to the study of the effects called forth by extirpation of limb primordia or implantation of additional wing or leg buds on their innervating motor and sensory nerve centers. In 1934, *Viktor Hamburger* published an article[3] on the effects of wing bud extirpation on the development of the brachial spinal motor segment and sensory dorsal root ganglia innervating the wing. He came to the conclusion that the hypoplasia of motor nerve cells of the ventral horn, and of other nerve cells of the same hemisection of the spinal cord, resulted from lack of stimuli centripetally transmitted by nerve fibers of the first differentiated neurons. These normally exert a regulatory effect on proliferation and differentiation of neighboring nerve cells. A reinvestigation of the effects produced by limb bud extirpation, prospected a different control mechanism of the developing nerve centers by peripheral tissues. Through serial studies of silver stained embryos, the conclusion was reached that the severe hypoplasia of nerve centers deprived of their fields of innervation, resulted from death of differentiated neurons and not from failure of recruitment of neurons from a pool of still uncommitted nerve cell precursors.[6, 7] In 1947, *Hamburger* invited me to join him for the purpose of reinvestigating together this problem. This invitation marked the beginning of a thirty year period that I spent at Washington University, and of my life-long friendship with *Viktor*. Our 1949 article[7] confirmed the hypothesis previously submitted by *G. Levi* and myself. The satisfaction of this confirmation of an important theoretical issue, and the successful analysis of other neuroembryological problems[8, 9] was, however, perturbed by the realization of the low resolution power of the techniques in our possession for in-depth exploration of the tremendously complex neurogenetic processes. The temptation to abandon the experimental analysis of the developing nervous system and move into the phage field, in full blossom in the nineteen-forties, did, however, not take hold thanks to unpredictable and most fortunate events which occurred at the same time and opened a new era in developmental neurobiology.

3. The Unexpected Break: A Gift from Malignant Tissues

In a 1948 article, a former student of *Viktor Hamburger*, *Elmer Bueker*, reported the results of a bold and imaginative experiment consisting in the graft of fragments of mouse sarcoma 180 into the body wall of three-day chick embryos. The histological study of the embryos fixed 3–5 days later, showed that sensory nerve fibers emerging from adjacent dorsal root ganglia had gained access into the neoplastic tissue while no motor nerve fibers entered into the tumor.[10] The author concluded that histochemical properties of the fast growing mouse sarcoma offered a favorable field for growth of sensory fibers. This condition, in turn, resulted in a slight but consistent volume increase of these ganglia as compared to that of homologous ganglia innervating the wing of the contralateral side. *Viktor* and I reinvestigated this remarkable phenomenon adopting the method I had developed during my first neuroembryological studies, i.e., that of a daily inspection of control and experimental embryos serially sectioned and impregnated with a specific silver technique. Our results confirmed those reported by *Bueker*, but at the same time uncovered other effects elicited by grafts of the mouse tumor which hardly fit in with the hypothesis that they were in the same range and of the same nature as those called forth by transplants of normal embryonic tissues. They differed from the latter in the following, most significant, respects: sympathetic and not only sensory fibers gained access into the neoplastic tissues, where they built a network of extraordinarily high density; nerve fibers branched at random between tumoral cells without, however, establishing synaptic connections with them; sensory and sympathetic ganglia innervating the tumor underwent a progressive increase in volume, attaining, in the case of sympathetic ganglia, a size about six times larger than that of the corresponding control ganglia.[11]

Subsequent experiments uncovered another astonishing deviation from the norm in embryos bearing transplants of mouse sarcoma 180 or of another tumor of identical origin, known as sarcoma 37. It was found that embryonic viscera which in normal specimens are devoid of innervation, such as the mesonephroi, or which become scarcely innervated only in late developmental stages, such as the sex glands, the thyroid, the parathyroid, and the spleen, were loaded with sympathetic nerve fibers at early embryonic stages.[12] A patent infraction of all developmental rules came to light with the finding of thick sympathetic fiber bundles inside the veins of the host, where they protruded in the form of large neuromas obstructing blood circulation (Fig. 1). All sympathetic chain ganglia, and not only ganglia adjacent to or in direct connection with neoplastic tissues, were enormously enlarged. The hypothesis that these anomalous effects could result from the release by neoplastic cells of a soluble, diffusible agent which altered the differentiative and growth properties of its target cells, received full confirmation from experiments transplanting one or

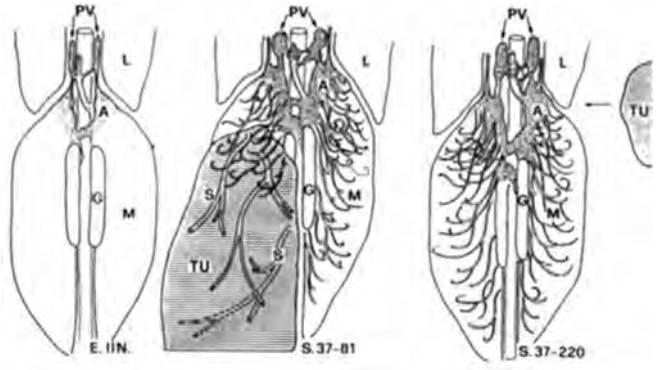

Fig. 1. Semi-diagrammatic reconstruction of a normal 11-day chick embryo (E. 11N), of an 11-day embryo carrying an intra-embryonic transplant of mouse sarcoma (S. 37-81), and of an 11-day embryo with transplant of sarcoma 37 on the chorio-allantoic membrane (S. 37-220). Note the hyperplastic growth of the prevertebral chain ganglia in embryos carrying tumor transplants. Visceral nerve fibers from these ganglia invade the nearby mesonephroi. A, adrenal; G, gonad; L, lung; M, mesonephros; PV, prevertebral ganglia; S, sensory nerves; TU, tumor (from Ref. [12]).

the other mouse sarcoma onto the chorio-allantoic membrane of 4-6 day chick embryos in such a position as to prevent a direct contact between embryonic and neoplastic tissues (Fig. 2). Embryonic and tumoral tissues were, however, in reciprocal connection through the circulatory system. The finding that these extra-embryonic transplants elicited the same effects as intraembryonic grafts gave definite evidence for the diffusible nature of the tumoral nerve growth promoting factor.[12, 13]

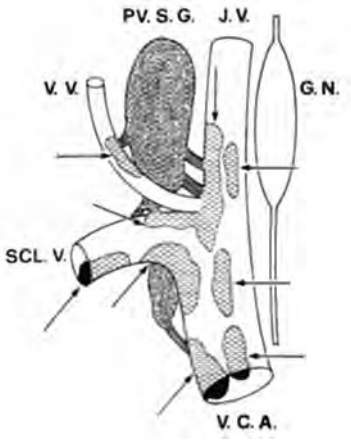

Fig. 2. Sixteen-day chick embryo with intra-embryonic tumor (sarcoma 180). Ingrowth of sympathetic nerve fibers into the Jugular, Vertebral, Subclavian, Anterior Caval Veins. G.N., Ganglium Nodosum; J.V., Jugular Vein; PV. S.G. Paravertebral Sympathetic Ganglion; SCL.V., Subclavian Vein; V.C.A., Anterior Caval Vein; V.V., Vertebral Vein. Arrows point to nerve agglomerations (from Ref. [12]).

Attempts to replicate these effects by implanting dried tumor pellets or by injecting extract of either sarcoma were unsuccessful. I then thought of resorting to the tissue culture technique, which I had practiced with *G. Levi* at the University of Turin. Lack of facilities in this field in the Department of Zoology at Washington University, prompted me to ask Professor *Carlos Chagas*, Director of the Biophysics Institute of the University of Brazil in Rio de Janeiro, whether he would approve of me joining him as a scientific guest at his institute. There, a friend of mine, *Hertha Meyer*, had built and was director of a most efficient tissue culture unit. Upon approval and invitation by Professor *Chagas*, I boarded a plane for Rio de Janeiro, carrying in my handbag two mice bearing transplants of mouse sarcomas 180 and 37.

4. The Nerve Growth Factor at Its Early in-vitro and in-vivo Debut

"The tumor had given a first hint of its existence in St. Louis but it was in Rio de Janeiro that it revealed itself, and it did so in a theatrical and grand way, as if spurred by the bright atmosphere of that explosive and exhuberant manifestation of life that is the Carnival in Rio".[14]

The discovery of the growth response elicited by a soluble tumoral agent revealed the receptivity of developing nerve cells to hitherto unknown humoral factors, and in this way opened a new area of investigation. The in-vitro bioassay also offered a practical and invaluable tool for uncovering the identity card of this factor and paving the way for the study of its mechanism of action. Ink drawings which I enclosed in several letters mailed from Rio to *Viktor*, give an eloquent account of the spectacular way in which this still unknown agent revealed itself. Sensory and sympathetic ganglia explanted from 8-day chick embryos in a semi-solid medium in proximity to but not in contact with fragments of mouse sarcoma 180 or 37, produced, in a 24 hour period, a halo of nerve fibers of maximal density on the side facing the tumor[15] (Fig. 3). The euphoric state

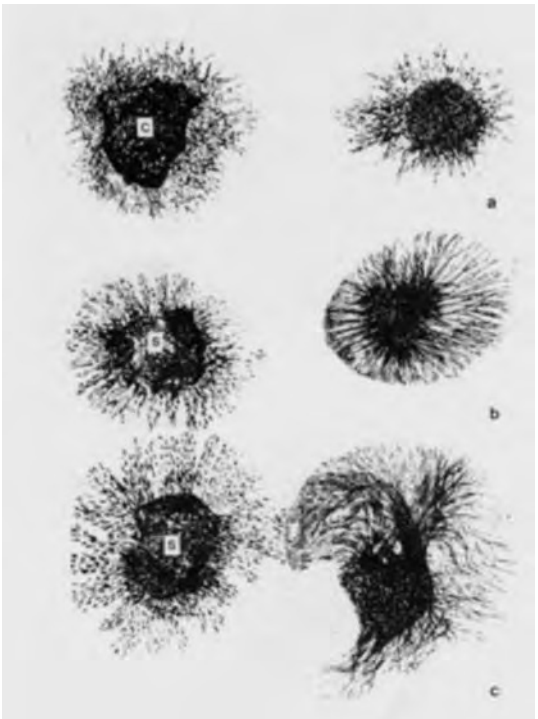

Fig. 3. Drawings illustrating the in-vitro "halo" effect on 8-day chick embryo sensory ganglia cultured in the presence of fragments of mouse sarcoma 180 for 24 hours (b) or 48 hours (c). In (a), the ganglion, which faces a fragment of chick embryonic tissue, shows fibroblasts but few nerve fibers. In (b) and (c), the ganglia, facing fragments of sarcoma 180, show the typical "halo" effect elicited by the growth factor released from the sarcoma. Note in (c) the first evidence of a neurotropic effect of the growth factor.

elicited by this discovery was, however, dampened shortly after by the discovery that normal mouse tissues, at variance with those of chick embryos, induce a milder (Figs. 3a), but not substantially different effect from that of mouse sarcomas. In retrospect, this should have alerted us to a novel and even more significative aspect of these in-vitro experiments; namely, the widespread presence of the factor endowed with nerve growth promoting activity in normal and neoplastic tissues. The failure to realize the significance of this 'mouse effect' was beneficial rather than detrimental, since for the next two years our attention was entirely focussed on the study of the chemical nature of the factor released by the two mouse sarcomas, in much larger quantities than from normal mouse tissues.

A young biochemist, *Stanley Cohen*, who joined our Group shortly before my return from Rio, isolated from the two tumors a nucleoprotein fraction endowed with the in-vitro nerve growth promoting activity.[16] Chance, rather than calculated search, signed a new, most fortunate turn of events. In order to degrade the nucleic acids present in this active fraction, *Stan* made use of snake venom which contains, among other enzymes, also the nucleic acid degrading enzyme, phosphodiesterase. Its addition in minute amounts to the nucleoprotein tumor fraction was expected to suppress the formation of the fibrillar halo if nucleic acids rather than the protein were responsible for the nerve growth promoting effect elicited by this fraction. The startling result was a marked increase in the density of the fibrillar halo around the ganglia incubated in the presence of the tumoral fraction treated with snake venom. Since a dense fibrillar halo was produced also around ganglia cultured in the presence of minute amounts of snake venom alone, it became apparent that the venom itself was a most potent source of nerve growth promoting activity. On the basis of biochemical studies, *Cohen* was in fact able to show that equivalent growth stimulation effects were obtained by 15000 μg of a sarcoma 180 homogenate and 6 μg of the moccasin snake venom. From the latter, after several purification steps, he isolated a non-dialyzable, heat-labile particle endowed with nerve growth promoting activity, identified in a protein molecule of molecular weight of the order of 20000.[17, 18] Microgram quantities of the purified snake venom fraction endowed with nerve growth promoting property, when injected daily into the yolk of 6–8 day chick embryos for a 3–5 day period, resulted in the overgrowth of sensory and sympathetic ganglia and excessive production of their fibers. Sympathetic nerve bundles branched profusely into the viscera and protruded into the cavity of the veins, mimicking in all details the effects elicited by grafts of mouse sarcomas.[19]

If chance brought to our attention the unforeseeable presence of two nerve growth promoting sources in mouse sarcomas and in snake venom, the subsequent finding that mouse submandibular salivary gland extract added in a minute quantity to the culture medium elicits an even denser and more compact fibrillar halo, was the result of a calculated search. These glands, as the homologues of the snake venom glands, were chosen by *Stanley Cohen*[20] as more likely than other organs screened with the in-vitro bioassay, to store the nerve growth factor (NGF). These results were soon followed by purification and identification by *Cohen* of the salivary factor in a protein molecule of evaluated molecular weight of 44000.[20] Its availability in larger quantities than the venom NGF, and its moderate toxicity when injected in a highly purified form, made possible the exploration of its biological activity in neonatal, young, and adult mammals.[21] The results of these investigations signaled the beginning of an ever more extensive and systematic in-vivo and in-vitro analysis of the salivary NGF, of its chemical structure, mechanism, and spectrum of action. Only the most significant findings reported from several laboratories in original and review articles will be considered in the following pages.

5. The Vital Role of NGF in the Life of Its Target Cells

In spite of, or perhaps because of its most unusual and almost extravagant deeds in living organisms and in-vitro systems, NGF did not at first find enthusiastic reception by the scientific community, as also indicated by the reluctance of other investigators to engage in this line of research. The finding that a protein molecule from such diverse and unrelated sources as mouse sarcomas, snake venom, and mouse salivary glands, elicited such a potent and disrupting action on normal neurogenetic processes, did not fit into any conceptual pre-existing schemes, nor seem to bear any relationship to normal control mechanisms at work during ontogenesis. It was in this skeptical atmosphere that NGF asserted, in a most forceful way, its vital role in the life of its target cells. Previous in-vitro experiments had shown that incubation of snake venom with its antiserum inhibited the fiber outgrowth induced by the venom NGF. A specific antiserum to salivary NGF likewise abolished the formation of the in-vitro fibrillar halo. These results suggested testing the effect of daily injections of small amounts of this antiserum (AS-NGF) in neonatal rodents. Inspection of treated mice under stereo and optical microscopes at the end of the first month revealed the near total disappearance of sympathetic para- and prevertebral chain ganglia.[22–24] This dramatic effect, which deprives newborn rodents and other neonatal mammals injected with antiserum to salivary NGF of the sympathetic system, without interfering with their normal development and vitality, became known as immunosympathectomy.[25, 26] The same treatment produces much less damaging effects in young and adult animals.

Two alternative hypotheses were submitted to explain the mechanism underlying the destructive effects of the antiserum: 1) a complement-mediated cytotoxic effect, or 2) the inactivation of NGF or of an NGF-like protein essential for differentiation and survival of sympathetic nerve cells. Although the first hypothesis was favored in early articles, the second progressively gained support and is now generally accepted on the basis of this and an in-vitro experimental approach which provided additional, unequivocal evidence of the essential role NGF plays in the early differentiation stages of its target cells. The in-vitro experiments consisted of the dissociation of sensory and sympathetic nerve cells from ganglia of 8–11 day chick embryos and their incubation in minimum essential media. Nerve

cells failed to survive unless nanogram quantities of NGF were added daily to the culture medium.[27] The in-vitro evidence for the role of NGF in the early phases of development of sensory nerve cells received confirmation from subsequent experiments, which proved that administration of NGF antiserum to rodent fetuses[28,29] and autoimmunization of pregnant rodents against endogenous NGF result in failure of sensory ganglia to undergo normal development.[30]

6. NGF as a Retrograde Trophic Messenger and Tropic Factor

The evidence in favor of the hypothesis that immunosympathectomy results from removal, by AS-NGF,[31] of circulating endogenous NGF, posed the questions of how NGF reached its target cells and what were its sources of production. Subsequent experimental pharmacological and surgical approaches provided satisfactory answers to both questions, and, in view of the interest in these problems, the techniques and main findings will be briefly reported.

Administration to neonatal rodents of drugs such as 6-hydroxydopamine, which destroys adrenergic nerve endings,[32] or of vinblastine, which blocks axonal transport,[33] results in death of the large majority of sympathetic nerve cells in their most active phase of differentiation and growth. The degenerative effects produced by these pharmacological components compare in magnitude to those produced by administration of AS-NGF and result in the destruction of para- and prevertebral sympathetic ganglia through a process which became known as chemical sympathectomy.[32,33] A third experimental manipulation, consisting of the surgical transectomy of postganglionic axons of superior cervical ganglion performed in neonatal rodents, results in the death of about 90% of immature sympathetic cells in this ganglion.[34] The experimental evidence that in all instances nerve cell death is prevented by supply of exogenous NGF,[30,35-37] demonstrates the vital role played by this molecule in the life and differentiation of these cells. The subsequent demonstration that labeled NGF is taken up by nerve endings of sympathetic[38] or sensory fibers[39] and is retrogradely transported to the cell perikarya, lent strong support to the concept of NGF as a trophic messenger, conveyed through nerve fibers from peripheral cells to the innervating neurons. Disconnection of the partners by chemical or surgical axotomy results in the death of differentiating nerve cells deprived of this essential molecule.

At the same time as the vital role of NGF in developing sympathetic and sensory nerve cells was assessed and its retrograde transport from peripheral tissues was well documented, another important property of NGF—its ability to direct growing or regenerating axons of sensory and sympathetic fibers along its concentration gradient (neurotropism)—was definitely established through different in-vivo and in-vitro experimental approaches.[40-45]

The first strong evidence for an NGF neurotropic effect was obtained from experiments of daily micro-injections of NGF into the floor of the fourth ventricle. A 7-day treatment resulted in the penetration of fiber bundles originating from sympathetic ganglia into the neural tube and in their ending at the level of experimentally produced NGF pools[40-41] (Fig. 4). In-vitro experimental approaches gave more rigorous proof that neurites of NGF target cells grow along an NGF concentration gradient and change their route according to the changed position of the NGF releasing pipette.[42] While these studies unequivocally establish the NGF neurotropic effect as independent from its trophic action, they leave unanswered the question of whether this effect is exerted through a local control of growth cone motility,[43] altered adhesion of this locomotor organelle to the substratum,[44-45] or via other mechanism(s).[46-47]

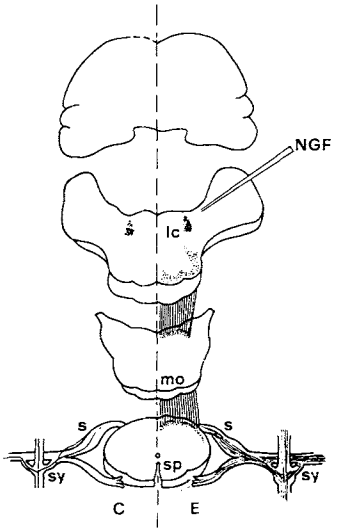

Fig. 4. Diagrammatic representation of sympathetic fiber bundles which enter the spinal cord and medulla oblongata from adjacent sympathetic ganglia in intracerebrally NGF injected neonatal rats. Left half: control (C). Right half: experimental (E) case. NGF, site of injection of NGF into the floor of the fourth ventricle; lc, locus coeruleus; mo, medulla oblongata; sp, spinal cord; s, sensory ganglia; sy, sympathetic ganglia. Sympathetic fibers run across the sensory ganglion and enter into the neural tube with the dorsal roots (from Ref. [40]).

7. Neuronal and Non-Neuronal Target Cells

As indicated in Table 1, targets of NGF action that have been well characterized up to now, can be classified under three main categories: 1) neural-crest derivatives; 2) central nervous system (CNS) neurons; and 3) cells of non-neuronal origin. For a thorough analysis of the many and diversified effects exerted by NGF on each one of these cells, the reader is referred to review articles on this specific matter.[47-52] I wish to make in this context only some general considerations.

A generally valid rule is that all cells are maximally responsive to NGF action during their early differentiation; the response undergoes progressive restriction in the adult, without, however, being totally effaced. Long sympathetic neurons and sensory neurons, with particular reference to those of the dorso-medial quadrant of spinal ganglia in chick embryo,[12] provided a most valuable system for demonstrating the three main activities of NGF, i.e., 1) its

vital trophic role during the early developmental stages, 2) its ability to enhance differentiative processes such as neurite outgrowth, and 3) its ability to guide the growth or regeneration of neurites along its own concentration gradient.[43-44] These same cells offered an in-vivo model system to study the introduction of enzymes involved in neurotransmitter synthesis[53] and were also instrumental in providing the first demonstration of NGF retrograde transport[54] and its role as a trophic messenger.[55] While sensory and sympathetic cells played a key role in revealing these properties of NGF, chromaffin cells and their neoplastic counterpart, the clonal cell line PC12, became the models of choice for studying the capacity of NGF to modulate phenotypic expression and the molecular mechanism subserving this process.[56] The phenotypic shift induced by NGF both in chromaffin[57-58] and PC12 cells,[56,59] resulting in their neuronal differentiation accompanied by a plethora of chemical, ultrastructural, and morphological changes characteristic of the neuronal rather than glandular phenotype, is too well known to warrant a detailed description.[50] These cells, moreover, uncovered the startling capacity of NGF to act as both a mitogenic[60] or antimitotic agent,[56] even within the context of the same clonal cell line PC12 and of a mutated version of it.[61] This, in turn, clearly pointed to the 'versatility' of NGF receptors and of their transduction machinery, whose message is evidently read and interpreted in different ways according to the cell type and previous cell history. The 'priming model' prospected to give a molecular account for the very fast and very slow onset of neurite outgrowth occurring, respectively, in sensory and sympathetic cells[24] on the one hand and PC12 cells on the other,[50] is an excellent example of the contribution of these latter cells to studies on the mode of action of NGF.

Other examples of the wide and at the same time diversified NGF effects are illustrated by other sympathoadrenal derivatives such as paraganglia, small intensely fluorescent cells (SIF), and carotid body cells.[62-64] The capacity of NGF to modulate phenotypic expression is impressively evidenced by the SIF cells, which have been hypothesized as immediate precursors of both sympathetic and chromaffin cells. When these cells are cultured under appropriate conditions, they can be channeled towards the first or the second phenotype in media supplied with NGF or with dexamethasone.[63,64] Such an interplay, even in fully differentiated cells, between NGF and steroid hormones, is also indirectly suggested by in-vivo studies on the short adrenergic neurons which innervate, in both sexes, the genito-urinary systems.[65]

In more recent years, two new populations came to the forefront of studies on NGF target cells: CNS neurons and cells originating from the hematopoietic system.

Small and large neuronal populations located in different brain areas have been shown to exhibit all properties and responses typical of sensory and sympathetic cells, such as: 1) the presence of specific receptors,[66] 2) retrograde transport of NGF,[67] 3) increased neurotransmitter synthesis with special reference to acetylcholine,[68-70] and 4) trophic response manifested as protection by exogenous NGF administration to selective noxious treatments or surgical transections otherwise leading to cell death.[71,72] A role for NGF in the development of as yet unidentified hypothalamic brain centers has been suggested by the finding that injections of affinity purified polyclonal antibodies against NGF in rat fetuses induce a severe postnatal neuroendocrine syndrome.[29] The loop of an unquestionable NGF role in brain is completed by the demonstration that other nerve cells, especially those located in the hippocampus and cortical areas, manufacture large quantities of NGF mRNA and of NGF protein, thus closing the functional link between NGF-producing and NGF-responding cells.[73-75] As indicated in the last section of this article, although the range of NGF action in the CNS is qualitatively comparable to that previously observed in peripheral neurons, the actual extent of the NGF role in brain is far from foreseeable due to the vast repertoire of possible responses from nerve cells in the CNS.

An analogous general consideration holds for the effect exerted by NGF on mast cells and possibly on other cells of the immune system. The increased in-vivo and in-vitro number of mast cells following NGF treatment,[76,77] as well as the effect of this growth factor on histamine release,[78-80] point to an unquestionable role in the physiology of these cells. It is not yet clear, however, whether such an effect is exerted through a generalized action on all mast cell precursors or through a sort of clonal selection mechanism. The more recent report of an NGF effect on other spleen cells such as mononuclear cells[81] and the existence of NGF receptors on thymocytes,[82] clearly suggests that the NGF action extends also to cells belonging to a network of enormous functional significance. The role played by histamine as an immunomodulator and the obvious involvement of spleen cells in the immune response of the organism would indicate new scenarios in which NGF may gain access, not through a back door, but through the main entrance.

Table 1. Targets of NGF action.

Neural crest Derivatives	Sympathoadrenal cells	Long sympathetic neurons
		Short sympathetic neurons
		Cells of paraganglia (carotid & abdominal paraganglia)
		SIF (small intensely fluorescent) cells
		Chromaffine cells: normal, neoplastic (PC12)
	Sensory neurons	
Central nervous system	Cholinergic neurons	Corpus striatum, basal forebrain, septum, nucleus diagonal band of Broca
	Adrenergic, indoleaminergic & peptidergic neurons	Xenopus laevis tadpoles
Non neuronal origin	Mast cells	

8. The I.D. Card of NGF

The sequencing of mouse submandibular gland NGF, achieved in 1971,[83] not only provided invaluable information on its primary structure but was recently instrumental in the preparation of synthetic oligonucleotides which resulted in the identification of NGF cDNA.[84] The cloning, which followed in rapid succession, of mouse,[84] human,[85] bovine[86] and chick[87] genes, demonstrated their high degree of homology. The NGF gene, located in the human species on the proximal short arm of chromosome 1,[88] codes for a large polypeptide of 307 amino acid residues, which, upon cleavage, yields a mature NGF subunit protein with 118 amino acids and, possibly, other peptides of unknown function and with no sequence homology with presently identified proteins.[84] NGF is a dimer made up of two identical subunits held together by non-covalent bonds. The dimer can be isolated as such,[89] or in the form of a complex consisting also of two other proteins, one with an esteropeptidase activity, probably involved in processing an NGF precursor, and the other with an as yet unknown function.[90-92] While it remains to be established whether each NGF subunit is biologically active, it has been demonstrated that a covalently cross-linked form of the dimer maintains full activity.[91,92] Between the two well-identified molecular entities of NGF and of its coding gene, which can be visualized as the summit and the base of an iceberg, there are several other possible intermediate forms of unknown nature and biological properties. Their identification would answer important questions such as: Are other biologically active peptides coded for by the NGF gene? What is the significance of different splicing in different cells of NGF mRNA?[93] Is the processing of pre-pro-NGF identical in all neuronal and non-neuronal cells or, as in other peptides,[94] do alternate processing pathways result in the production of peptides endowed with different biological functions? Since the same peptides may undergo post-transcriptional or post-translational modification, the submerged areas of the NGF iceberg loom very large.

Studies on the immunological and biological relatedness of NGFs purified from different species strongly support the hypothesis that the site(s) of interaction with their receptors has (have) remained structurally more constant than is the case for other epitopes, which are probably free to mutate in view of their less fundamental biological functions.[95]

9. NGF, Growth Factors and Oncogenes

The discovery of NGF and, soon thereafter, of EGF led to the biological identification of an ever-growing list of polypeptide growth factors.[48] In the seventies, another apparently unrelated area of biology came to the forefront of research with the discovery of single gene products (oncogenes) causing transformation. PGF and oncogene research, pursued at first independently from each other, converged when homology between some oncogenes and growth factors or their receptors was shown by sequence analysis. Evidence is steadily increasing that excessive synthesis or an altered version of PGFs or of their receptors may result in transformation of recipient cells.[95-98] More recently, the demonstration that the opposite is also true, namely that certain oncogene products may induce differentiation of recipient cells, called attention to another facet of this intricate interplay between differentiative and transforming processes. Examples are H-*ras* and V-*src*, whose expression into PC12 cells[99,100] results in mitotic arrest and neuronal differentiation comparable to that elicited by NGF; further examples will certainly follow. The obvious conclusion is that a given polypeptide growth factor, or intracellular proteins playing essential roles in the cell cycle or in the differentiation of some cells, may exert markedly different actions in distinct cell types. In the case of NGF, one wonders if and how other actions are elicited by this versatile molecule. For instance, is an altered version of NGF or of its receptors capable of causing transformation of some recipient cells, as has been shown for other PGFs? If this is the case, could NGF in a modified version or its receptors be implicated in neoplasia in the central and peripheral nervous systems?

10. NGF in Exocrine Glands: a Fortuitous Presence or a Biological Function?

The early discovery that mouse submandibular glands synthesize and release into the saliva large quantities of NGF, that the synthesis of this protein molecule is under the control of testosterone and of thyroxine,[101,102] and that the NGF protein content is about tenfold higher in male than in female mice, remained puzzling and unexplained findings for about three decades. The conflicting but altogether negative attempts to reveal the presence of this molecule in the circulating blood,[49,51] and the lack of any adverse effects on sympathetic and sensory cells by removal of these glands, which deprived these rodents of such a large NGF source, militated against the hypothesis that salivary NGF gains access to their target cells. An alternative biological function for salivary NGF was first hypothesized by our group,[103] and recently proved by us[104] and another investigator.[105] We demonstrated that intraspecific fighting, experimentally induced in adult male mice by 6–8 weeks of social isolation, results in massive NGF release into the blood stream, an event prevented by previous sialoadenectomy. Since injections of NGF induce weight and size increase of the adrenal glands[105] and stimulate the synthesis of the catecholamine key enzyme, TH,[106] we suggested that such a massive discharge into the blood circulation of endogenous salivary NGF may be instrumental in defense and/or offense mechanisms of vital significance for male mice that engage in intraspecific fighting among individuals of the same sex. In favor of this hypothesis is a recent report that aggressive behavior results in the release into the blood of another biologically active protein, renin, synthesized in the same tubular portions of these glands.[107] The mechanism triggering this NGF release is not yet understood, nor whether other stations are activated and play a role in this specific stress syndrome.

As for the presence of large NGF sources in snake venom[18] and male genital organs,[108, 109] they may be conceived as instances of bizarre evolutionary gene expression. Alternatively, in these cases NGF may subserve other functions which may somehow be linked with the poisonous action of snake venom, or the reproductive activity of the genital apparatus. In the case of snake venom, one can envisage the possibility that a highly specific neurotropic molecule such as NGF is utilized by reptiles as a carrier of other neurotoxins devoid of specific receptors in the central and peripheral nervous systems. For instance, enzymes such as phospholipases, phosphodiesterases, and proteases of various nature, which by themselves may lack specific recognition sites in target cells, may exploit NGF as a carrier to gain access inside cells wherever there are specific NGF receptors. The widespread distribution of these specific molecules also in several non-neuronal cells could offer some toxins or enzymes a better access to their target organs.

In the reproductive tract, NGF could participate in fertilization mechanisms by cytoskeletal mediated activation of spermatozoa locomotion much in the same way as in neurite outgrowth, or by favoring egg implantation, via inhibition of rejection through the immune system. This latter hypothesis is presently under investigation (*Geraci, Cocchiara,* and *Calissano*) by assessing the effect of NGF on uterine mast cells which, through histamine release, are postulated to prevent the local immune reaction.[110]

11. Foreseeable Approaches and Predictions of the Unpredictable

The most obvious among the foreseeable approaches is the search for other NGF target cells, using the ever more sophisticated in-vivo and in-vitro techniques which became available during the past few decades from the molecular to the supercellular levels. It was this multimodal approach which in recent years led to the discovery of NGF target cells in the CNS of lower and higher vertebrates and in cell lineages playing a role in the immune system. This list is likely to increase, as the search extends to other neuronal and non-neuronal cell populations. Furthermore, one should take into account the fact that some of these populations are receptive to NGF mainly during developmental stages in prenatal life. This was already demonstrated in sensory cells of avian and mammalian species,[49, 51, 52] and in cells lining the third ventricle in amphibian tadpoles[111] and prenatal and neonatal rodents (*Aloe* and *Levi-Montalcini*, unpublished observations). Likewise, the systematic screening of neuroendocrine and hematopoietic cell lines in in-vitro and in-vivo systems may reveal other as yet uncovered roles of this growth factor.

Another foreseeable approach, now in progress in many laboratories, is the search and characterization of NGF-like factors active on other neuronal populations. These factors may be subdivided into two major classes: 1) those coded by the NGF gene itself but processed through alternate post-transcriptional or post-translational pathways leading to PGFs with a somewhat different structure and function; 2) other proteins or peptides having the trophic, chemotactic and/or differentiative activity of NGF, but coded by other genes.

The search and identification of factors belonging to the first group will take advantage of the techniques of molecular biology and immunology. These should provide valuable information on some of the still unexplored, submerged areas of the NGF iceberg, dealing with the processes of the NGF gene transcription or translation. Of particular importance would be the identification of the NGF sequence responsible for its binding to receptors which may presumably trigger a given cellular response.[47] As previously surmised,[95] this portion has possibly been better conserved than other parts of the molecule. Once identified, it will be feasible to introduce, in its synthetic counterpart, amino acid substitutions and/or chemical modifications and explore the biological potency of the newly manufactured peptide. This approach should not only provide invaluable information on the nature and properties of the NGF active center, but, hopefully, will result in the synthesis of peptides endowed with an activity even higher than that of NGF itself, so brilliantly achieved in the field of other biologically active peptides.[112, 113]

Within this category of studies on NGF and its coding gene, one can conceive a strategy aimed at exploiting the property of non-neuronal cells in peripheral tissues and of neurons and satellites in the CNS to manufacture and release NGF by resorting to pharmacological agents that modify NGF gene expression or processing. The well-established finding that NGF synthesis is increased following transection of nerve fibers connecting NGF receptive nerve cells to their targets[114] or via hormonal action,[101, 102] is an additional indication of the remarkable plasticity of the mechanisms controlling NGF gene expression. It is conceivable that this property might be modulated by pharmacological agents acting on the same path as those involved in the regulation of the synthesis and release of NGF.

The search for neurotrophic factors coded by genes other than the NGF gene could take advantage, at least in its main strategy, of the classical approach so successfully applied in the isolation and identification of NGF. Two main causes may explain why extensive work invested in this attempt has not been so successful in providing evidence for the existence of other PGFs activating different neuronal cell lines: 1) the lack of fast and reliable bioassays such as those developed for NGF, and 2) the failure to detect large sources of these factors comparable to those fortuitously discovered in early NGF studies. The realization of rapid, highly reliable bioassays can, however, now be achieved by resorting to the use of most stringent, chemically defined media, permitting survival and differentiation of only given cell types, upon addition to the medium of putative growth factors extracted from different sources and screened with the in-vitro bioassay for their potential specific growth enhancing activity. The problem of finding by sheer chance large sources of NGF-like peptides, such as those which played a key role in the discovery of NGF, can be solved by resorting to techniques of protein chemistry and recombinant DNA technology. Only a few micrograms of purified protein suffice in order to decipher the sequence, prepare the corresponding cDNAs,

identify the gene of the PGF in question, and express it in bacteria, thus replacing a search once guided by unpredictable strikes of luck by a rational and systematic strategy.

Predictions of the unpredictable are encouraged by the same history of NGF which may be defined as a long sequence of unanticipated events, which each time resulted in a new turn in the NGF unchartered route and opened new vistas on an ever-changing panorama. This trend, which became manifest from the very beginning and in fact alerted me to the existence of NGF, is perhaps the most attractive, even though elusive, trait of this thirty-five year long adventure. One can at present only predict where future developments are most likely to occur. The main causes of unpredictability of the findings reside in the intricacy of the new surroundings where NGF is moving—the CNS and the immune system—rather than in NGF itself. The enormous complexity of these two networks, which on the basis of recent findings are closely interrelated and influence each other through bidirectional signals,[115, 116] opens endless possibilities for NGF activation of distinct repertoires of cells belonging to one or the other system. How many indirect effects can be elicited by direct NGF action on cholinergic, adrenergic, and peptidergic neurons interlinked via fiber pathways and humoral channels or through short-distance diffusion? Likewise, how many effects could follow the simple histamine release by NGF-activated mast cells, considering the well-established role of this amine as an immunomodulator or an immunosuppressor? These considerations hold also for the potential utilization of NGF in brain and immunosystem disorders. For instance, whenever cell death or specific neuronal populations may be linked to a decreased local availability of neurotrophic factors, such as NGF, its exogenous supply or stimulation of its endogenous production via pharmacological agents may offer a promising approach to presently incurable diseases.

I shall end this account of the unfolding of the NGF story with a remark made more than a decade ago by *Viktor Hamburger*: "... the fact that this discovery, which grew out of a seemingly peripheral problem (peripheral in every sense of the word), has blazed so many new trails is its greatest contribution to neuroembryology"[117] Studies in this last decade have not only provided new strong evidence of the most important contributions of NGF in the field of neuroembryology, but also have brought to the fore its significance in the more general field of neuroscience and its prospective role in the immune system.

I dedicate this article to Viktor Hamburger, who promoted and took part in this search, and to whom I am forever indebted for invaluable suggestions and generosity. Without him, the Nerve Growth Factor would never have come to our attention. To my dear friends, Pietro Calissano and Luigi Aloe, I wish to express my deepest gratitude for their fundamental contributions. In this thirty-five year long investigation, a large number of colleagues, research associates and graduate students took part in this scientific adventure. I am particularly indebted to and very gratefully acknowledge the most important work performed by two of them: Drs. Piero Angeletti and Vincenzo Bocchini. To Professor Carlos Chagas, for his generous hospitality in the Biophysics Institute of the University of Brazil, and to Dr. Hertha Meyer who helped me in devising the tissue culture bioassay of NGF, my warmest thanks.

Epidermal Growth Factor (Nobel Lecture)**

By Stanley Cohen

1. Introduction

Upon the foundations provided by experimental embryology, endocrinology, cell biology, biochemistry, and molecular biology, the intricacies of the regulatory processes that occur during embryonic development are slowly coming to light. While the importance of "classical" hormones in the control of growth and development has long been recognized, we now know that many more intercellular signals are involved in these highly complex processes. The recent advances in this area have, somewhat unexpectedly, also provided mechanisms that may lead to a more detailed understanding of important biomedical questions, such as the growth behavior of malignant cells.

My own efforts in this area of research over the past thirty years have been directed toward the understanding, on a biochemical level, of two biological observations, both initially made in the Department of Zoology, directed by Dr. *Viktor Hamburger*, at Washington University.

The first observation was that of Dr. *Rita Levi-Montalcini* who noted that certain mouse tumors, when implanted into chick embryos, released a factor that stimulated the growth of specific embryonic neurons. The second biological observation was made during my study of the nerve growth factor detected in male mouse submaxillary glands. It was noted[1] that when crude submaxillary gland preparations were injected into newborn mice, unexpected "side effects" not related to the activities of nerve growth factor, were produced. These effects included precocious eyelid opening (6–7 days, compared with 12–14 days for controls) and precocious tooth eruption (5–6 days, compared with 8–10 days for controls).

After I transferred to the Biochemistry Department at Vanderbilt University in 1959, these "side effects" were to become the focus of my research. From my training in embryology, I felt that any substance that altered the timing of specific developmental processes would be of biological significance. I, of course, did not foresee that the biochemical mechanism by which these extracts induced precocious eyelid opening would be related to those involved in oncogenic transformation by one class of retroviruses. This lecture summarizes briefly some of the thoughts and key experiments that have led to our present understanding of epidermal growth factor (EGF).

2. The First Decade

By employing precocious eyelid opening as an assay, the factor, a small protein, responsible for these effects was isolated from murine submaxillary glands in the early 1960s.[2] Histological examination (see Fig. 1) of control and EGF-treated newborn animals (mouse, rat, rabbit) revealed that the observed precocious eyelid separation was the consequence of a more generalized biological effect, namely, an enhancement of epidermal growth and keratinization.[3] The apparent precocious incisor eruption induced by EGF was, in reality, caused by an enhanced differentiation of the lips of the treated animals.

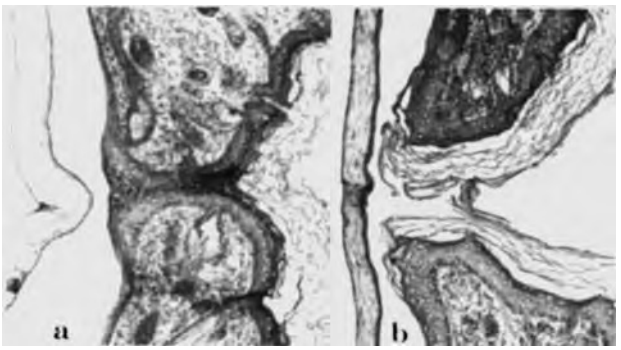

Fig. 1. Cross sections of the eyelid area from control (a) and experimental (b) eight-day-old rats. The experimental animal had received daily injections (1 μg per g body weight) of the active protein. × 100. (Reprinted from *J. Invest. Dermatol. 40* (1963) 1–5.)

Since these were whole animal experiments, we were faced with the problem of whether the factor operated directly on epidermal cells or whether growth was induced indirectly, possibly by the increased production of a more "classical" hormone.

The techniques of tissue and organ culture seemed ideally suited for resolving this problem. A preliminary organ culture study was carried out during a sabbatical at the Instituto Superiore di Sanità in Rome in collaboration with Drs. *Rita Levi-Montalcini* and *Domenica Attardi*, and the study subsequently was continued at Vanderbilt University. The name epidermal growth factor was first used in the initial reports of these studies.[4] The results demonstrated that EGF directly stimulated the proliferation of epidermal cells in organ cultures of chick embryo skin; this mitogenic action of EGF, therefore, did not necessarily depend on other systemic or hormonal influences. During these experiments, the range of responsive animals was widened to include birds as well as mammals, suggesting that knowledge of the evolutionary origins of EGF would contribute to our understanding.

By 1970 we had accumulated a spectrum of information regarding many aspects of the physiology of EGF:

1. We described a series of metabolic alterations (enhancement of polysome formation, induction of ornithine decarboxylase, etc.) that accompany the growth-stimulating effects of EGF on epidermal cells. Many of these

changes are now known to take place in a variety of cells when a growth stimulus is applied.

2. We identified the tubular cells of the submaxillary gland, which in the mouse exhibit sexual dimorphism, as the major site of synthesis of EGF in this species and noted, with the aid of a radioimmunoassay, that the synthesis of EGF, especially in female mice, was markedly enhanced by the administration of testosterone.
3. We demonstrated that, in crude homogenates of the mouse submaxillary gland, EGF existed as a high-molecular-weight noncovalent complex (≈ 75000 Da) consisting of two molecules of EGF and two molecules of an EGF-binding protein that possessed arginyl esterase activity.
4. On a more practical level, we and others found that the topical application of EGF accelerated corneal re-epithelialization in rabbits with wounded corneas.

The reader is referred to a number of early review articles wherein this information is detailed and references are provided.[6,7] By the end of the first decade, I was convinced that EGF plays a normal physiological role in many species, either during embryonic development or in homeostasis; what this role was at the whole animal level and how EGF interacted with cells at the molecular level were problems for the future.

3. The Second Decade

The development of a rapid, essentially two-step procedure for isolation of milligram quantities of EGF from murine submaxillary glands in the early 1970s[7] permitted the purification of sufficient quantities of mouse-derived EGF (mEGF) for a thorough characterization. This single technical advance opened the door to the application of many biochemical methodologies and insights. Amino-acid analysis revealed that mEGF is a 53-residue polypeptide, entirely devoid of alanyl, phenylalanyl, or lysyl residues.[8] The primary sequence of mEGF[9] and the position of the three internal disulfide bonds[10] were determined and are depicted in Figure 2. Though mEGF has yet to be crystallized and subjected to X-ray diffraction analysis, considerable spectroscopic data has been accumulated suggesting that the hormone has little periodic secondary structure; the presence of β-sheet structures has been detected (reviewed in Ref. [11]).

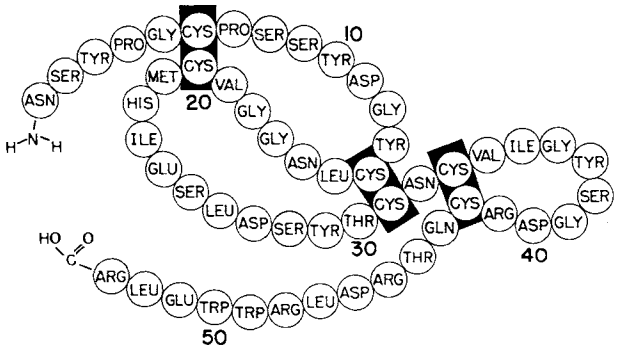

Fig. 2. The amino-acid sequence of EGF with placement of disulfide bonds. (Reprinted from *J. Biol. Chem. 248* (1973) 7669–7672.)

At about this time (1973) a new facet of the biology of EGF was uncovered. *Armelin*[12] and *Hollenberg* and *Cuatrecasas*[13] were the first to report that fibroblasts in culture responded to EGF with enhanced DNA synthesis. These findings were corroborated in our laboratory with human fibroblasts.[14,15]

The finding that mouse-derived EGF was a potent mitogen for human cells indicated that receptors for EGF were present on human cells and, therefore, a polypeptide similar to EGF might be found in human tissue. We took two approaches in an attempt to isolate EGF-like molecules from human urine. First, an immuno-affinity column procedure (using anti-mouse EGF antibodies) was used to partially purify a substance from human urine that was similar to the mouse hormone in its biological activity.[16] In another approach, we developed a sensitive and specific radioreceptor competitive-binding assay for EGF-related polypeptides, using cultured human fibroblasts and ^{125}I-labeled mouse EGF, that permitted the isolation of microgram quantities of pure growth factor from protein concentrates of human urine.[17] The biological effects of the purified human polypeptide were qualitatively identical to those previously described for the mouse growth factor. These included the stimulation of the proliferation in vitro of fibroblasts and corneal epithelial cells, as well as the induction of precocious eyelid opening in the newborn mouse, which still remains the most specific biological assay for EGF. The amino-acid compositions of the human and mouse polypeptides differed, but clear similarities were noted. Both polypeptides apparently competed for the same site on the cell membrane and antibodies to the mouse polypeptide cross-reacted with the human hormone. We concluded that we had isolated the human counterpart of murine EGF.

As is usual in science, an unexpected and completely new aspect of the biology of EGF emerged with the report by *Gregory*[18] that urogastrone, a gastric antisecretory hormone isolated from human urine, appeared to be identical to human EGF and closely related to murine EGF. Human EGF (urogastrone) and murine EGF are now believed to invoke identical response in all target cells. The relationship between human EGF and urogastrone could only have been detected from a structural comparison of these molecules; even today, no rationale is available to connect inhibition of acid secretion and stimulation of cell growth.

Given a cell culture system (human fibroblasts) in which EGF acted as a "growth factor," we were faced in 1975 with a rather formidable task: how does EGF stimulate cell growth? Although neuronal uptake and retrograde transport of nerve growth factor had been demonstrated in 1974,[19] almost all endocrinologists were of the opinion that peptide hormones, after binding to their receptors on the plasma membrane, were released into the extracellular environment.

Our initial experiments[20] utilizing ^{125}I-EGF and human fibroblasts confirmed the presence of plasma membrane receptors for EGF. Two additional and significant observations were made. First, the binding of ^{125}I-EGF to the

cell surface of intact fibroblasts was rapidly followed by proteolytic degradation of the growth factor by a cell-mediated process. Secondly, it was noted that NRK cells lost their ability to bind ^{125}I-EGF following transformation by the Kirsten virus. The former observation directed us to an examination of the possibility that cell-bound EGF was internalized prior to degradation.[21] The latter observation was later generalized to include a variety of cells transformed by retroviruses[22] and eventually led *George Todaro* and others to isolate the EGF-related polypeptide, α-transforming growth factor (α-TGF), and to propose the autocrine hypothesis.[22]

As a step in defining the biochemical events that occur during and subsequent to the interaction of EGF with the cell surface, we examined the metabolic fate of the bound hormone. We came to the conclusion[21] that subsequent to the initial binding of ^{125}I-EGF to specific plasma membrane receptors, the EGF-receptor complex is internalized and the hormone is ultimately degraded in lysosomes. These conclusions, drawn from studies of the interaction of ^{125}I-EGF with human fibroblasts, were based on the following series of observations:

1. Cell-bound ^{125}I-EGF was rapidly degraded to [^{125}I]monoiodotyrosine at 37°. At 0°, however, cell-bound ^{125}I-EGF was not degraded, but slowly dissociated from the cell surface.
2. When the binding of ^{125}I-EGF was first carried out at 37° and the cells then incubated at 0°, almost no release of cell-bound radioactivity was detected.
3. Degradation of ^{125}I-EGF, but not binding, required metabolic energy.
4. The degradation was blocked by drugs that inhibit lysosomal function, such as chloroquine and ammonium chloride.
5. When ^{125}I-EGF was bound to cells at 0°, the hormone was readily accessible to surface-reactive agents, such as trypsin and antibodies to EGF. However, when the hormone was bound to cells at 37° it was much less accessible to either of these reagents.
7. Exposure of fibroblasts to EGF resulted in an apparent loss of plasma membrane receptors for EGF.

Taken together, these observations, which have subsequently been extended by others to a number of polypeptide hormones, provided quantitative biochemical evidence for a complex mechanism through which cells interact with extracellular regulatory signals.

The challenge of direct visualization of the internalization of EGF was approached using three general procedures: the preparation and tracing of fluorescent derivatives of EGF,[23,24] the tracing of ^{125}I-EGF by electron microscopic autoradiography,[25] and the preparation and tracing of EGF-ferritin conjugates by electron microscopy.[26,27]

Although all three morphological approaches confirmed the original biochemical studies with ^{125}I-EGF,[21] the use of the biologically active EGF-ferritin conjugate provided the clearest and most direct picture of the metabolic fate of EGF. At 4° the EGF-ferritin conjugate specifically bound to the plasma membrane of cells and appeared to be randomly distributed on specific receptor sites. When the cells were warmed to 37°, the EGF-ferritin redistributed on the surface of the plasma membrane within one minute to form many small clusters. The clusters of receptor-bound EGF-ferritin molecules were then rapidly internalized into endocytic vesicles. Within 30 min approximately 84% of the ferritin was seen in multivesicular bodies that were considered to be lysosome-related. These data also provided morphological evidence for the hypothesis that "down-regulation" of surface receptors for EGF involves internalization of intact hormone-receptor complexes. A diagram that illustrates our conclusions is presented in Figure 3. It was subsequently demonstrated, by metabolic labeling and immunoprecipitation with anti-receptor antibodies, that EGF-mediated internalization of the EGF-receptor complex is associated not only with the degradation of EGF but also with enhanced degradation of the receptor.[28]

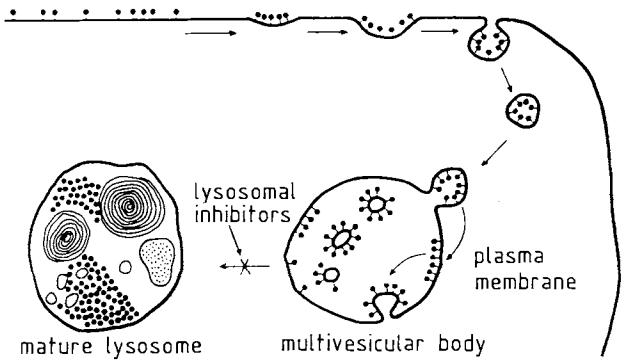

Fig. 3. Diagram of ferritin-EGF (F-EGF) interaction with A-431 cells. F-EGF-receptor complexes, identified by the characteristic spatial relationship of particles and membrane (4- to 6-nm separation), are apparent at initial binding and are preserved through the processes of clustering, pinocytosis, and incorporation into multivesicular bodies. Further incubation at 37°C allows disruption of the F-EGF-receptor complex (attested by pools of free ferritin), a process blocked by the presence of amines. (Reprinted from *Proc. Nat. Acad. Sci. USA 76* (1979) 5689–5693.)

A critical question in this area of hormone research is whether the intracellular processing of hormones and their receptors is related to, or necessary for, the generation of biological responses to the hormone. My opinion is that no clear experimental evidence exists to answer this very important question.

In view of our inability to define the relevance of receptor-mediated internalization to the growth factor's biological activity and our belief that cellular alterations induced by EGF result from the amplification and propagation of a series of "signals" generated during the binding and internalization of the hormone, we sought, in the late 1970s, to obtain a cell-free system that responded in vitro to the addition of EGF. Since the A-431 human epidermoid carcinoma cell line had been shown to have an extraordinarily high concentration of EGF receptors ($2-3 \times 10^6$ receptors/cell),[29,24] we utilized a membrane preparation from these cells to look for an EGF-dependent alteration of membrane structure and/or function. Like the technical turning point that the rapid purification of milligram quantities of EGF provided (see above), the identification of the A-431

cell line as an enriched source of EGF receptors has been instrumental for both biochemical and molecular biological studies of the mechanism of action of EGF.

As expected, membranes from these cells were able to specifically bind relatively large quantities of ^{125}I-EGF. Since phosphorylation and dephosphorylation reactions participate in the control of many metabolic pathways and membranes contain endogenous protein kinases and phosphatases, a study[30] was initiated to assess the possible role of EGF as a modulator of these regulatory processes. Aliquots of the A-431 membrane preparation were examined for their ability to phosphorylate endogenous membrane components and to determine whether the binding of EGF resulted in a perturbation of this biochemical system. The incubation of A-431 membranes at 0° with [γ-^{32}P]ATP in the presence of Mg^{2+} or Mn^{2+}, resulted in the incorporation of radioactivity into trichloroacetic acid-insoluble material. Of key importance was the discovery that the prior addition of EGF to the reaction mixture resulted in a threefold enhancement of the phosphorylation of endogenous membrane-associated proteins (Fig. 4).

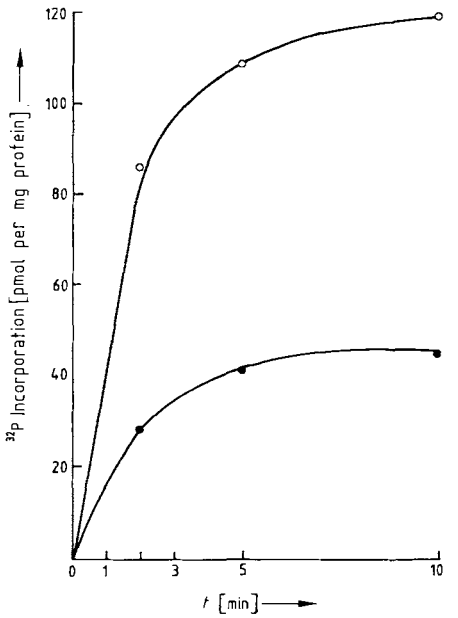

Fig. 4. Stimulation by EGF of the incorporation of ^{32}P-phosphate from [γ-^{32}P]ATP into cell membranes. The reaction mixtures contained A-431 membrane (27 μg protein), HEPES buffer (20 mM, pH 7.4), $MnCl_2$ (1 mM), [γ-^{32}P]ATP (15 μM, 8×10^5 cpm), EGF (40 ng), and bovine serum albumin (7.5 μg) in a final volume of 60 μL. The reaction tubes were placed on ice and preincubated for 10 min in the presence (○) or absence (●) of EGF. The reaction was initiated by the addition of labeled ATP, and incubation at 0°C was continued for the indicated times. The reaction was terminated by pipetting 50-μL aliquots onto squares (4 cm^2) of Whatman 3 MM filter paper and immediately dropping the paper into a beaker of cold 10% trichloroacetic acid (TCA) containing 0.01 M sodium pyrophosphate. The filter papers were washed extensively with pyrophosphate-containing 10% TCA at room temperature, extracted with alcohol and ether, and dried, and the radioactivity was measured in a Nuclear Chicago gas-flow counter. (Reprinted from *Nature 276* (1978) 409-410.)

The enhanced incorporation of ^{32}P into the membrane preparations was specific for EGF; the major phosphorylated membrane components detected were proteins having molecular weights of ≈170000 Da and 150000 Da. The addition of EGF to A-431 membrane preparations stimulated the phosphorylation of not only endogenous membrane proteins, but also a number of exogenously added protein substrates.

It was suggested at that time (1978) that the phosphorylation of membrane or membrane-associated components might be an initial event in the generation of intracellular signals that regulate cell growth. The reader is referred to a review[31] that summarized our knowledge as of 1979.

By the end of this second decade, I was encouraged and excited by the prospect that we had made a significant inroad into the understanding of the mechanism of action of EGF at the cellular and biochemical level.

4. The Third Decade

The detection of a direct effect of EGF on a chemical reaction in a cell-free system led to a more detailed biochemical characterization of the reaction in A-431 membranes and to its extension to membrane preparations from normal human placenta and cultured human fibroblasts.[32-34] The EGF-stimulated kinase activity of A-431 membranes was not removed by extraction of the membranes with a variety of solutions, such as high salt or urea, suggesting that the kinase, receptor, and substrates were integral membrane proteins. We, at this time, were aware of reports from several laboratories[35-37] that the molecular weight of the putative receptor for EGF, as detected by cross-linking with ^{125}I-EGF, was in the range of our major phosphorylated membrane glycoproteins, i.e., 150-170 kDa.

Our studies provided the following data concerning the mechanism by which EGF regulated protein phosphorylation in the cell-free A-431 membrane system:

1. Activation of the membrane-associated kinase activity by EGF was a rapid process, even at 0°.
2. Dephosphorylation reactions in the membrane also occurred with great rapidity, but were not affected by the presence of EGF.
3. EGF does not cause the release from the membrane of either a soluble protein kinase or a modulator of the kinase.
4. The EGF-induced activation of the membrane kinase could be reversed by removal of the hormone from the membrane by anti-EGF IgG, indicating that proteolytic activation was not involved.

We originally assumed, on the basis of data that clearly indicated different heat sensitivities of the receptor and the kinase,[32] that at least two separate entities were involved. However, the possibility that the receptor and the kinase activities were present in the same molecule was raised by two unexpected observations. First, A-431 membranes could be solubilized by detergents with retention of EGF-enhanced phosphorylation activity as well as ^{125}I-EGF binding activity. Second, the EGF-receptor and the EGF-dependent kinase activity, as well as the substrate, were copurified by EGF affinity chromatography as a major 150-kDa protein.

We originally had reported[32] that the EGF-stimulated protein kinase phosphorylated mainly threonine residues, and in this and other regards it resembled the kinase activity of the transforming protein of Rous sarcoma virus (RSV). Soon thereafter, however, it was reported that the RSV-associated protein kinase and other tumor virus-associated protein kinases[38,39] actually phosphorylated tyrosine residues, originally mistakenly identified as threonine due to co-migration of the two phosphorylated amino acids in the electrophoretic system employed. Since we had employed a similar electrophoretic system, we reinvestigated the nature of the EGF-stimulated protein-kinase reaction and discovered that the affinity-purified EGF-activated receptor-kinase also phosphorylated tyrosine residues.[40]

To determine whether the EGF-receptor-associated kinase activity might be due to trace contamination with $pp60^{src}$, we looked for an interaction of the EGF receptor-kinase preparations with $pp60^{src}$ antisera. Although the receptor kinase was able to specifically phosphorylate these anti-src antibodies, the receptor-kinase was not precipitated by such antisera.[41,42] We interpreted these results to mean that while the EGF receptor-kinase might be related to $pp60^{src}$, the two kinases were not identical.

We then attempted to further purify the EGF receptor.[43] When the previous affinity purification procedure[34] was applied to A-431 membrane vesicles in the absence of Ca^{2+}, the receptor-kinase was isolated as a 170-kDa protein. The 150-kDa receptor protein initially observed in preparations from scraped membranes has been shown to be a proteolytic fragment of the 170-kDa native species, produced by the action of a Ca^{2+}-dependent neutral protease.[44,45]

The receptor properties of both the 170-kDa and 150-kDa preparations were demonstrated not only by their capacities to bind ^{125}I-EGF, but also by covalent cross-linking to ^{125}I-EGF. The major functional difference between the 170- and 150-kDa preparations appeared to be the ability of the former to "autophosphorylate" at a rate five to ten times greater than the latter. This observation is now understandable since it is now known that the major autophosphorylated tyrosine residues are located near the carboxy-terminus of the 170-kDa receptor and are not present in the 150-kDa proteolytic fragment.

We addressed the question whether the three domains present in our receptor preparation (binding, kinase, and substrate) reside in one or more than one molecule by applying more stringent purification procedures. The three domains remained associated not only following EGF affinity chromatography but also lentil lectin-Sepharose chromatography, indicating that both the receptor and the kinase are associated with lectin-reactive carbohydrate groups. More importantly, the three detectable domains remain associated following electrophoresis in nondenaturing gels and immunoprecipitation using antisera to the purified receptor. Although these results were not considered definitive, they encouraged speculation that all of the domains were present in the same molecule.

The question was resolved by a series of experiments designed to identify the EGF-stimulated kinase by affinity labeling.[46,47] When A-431 membrane vesicles were treated with 5′-(*p*-fluorosulfonylbenzyl)adenosine (5′-*p*-FSO_2BzAdo), a reagent previously shown to affinity label ATP or ADP binding sites in a variety of enzymes, the EGF-stimulated kinase was irreversibly inhibited. When A-431 membrane vesicles were labeled with 5′-*p*-FSO_2Bz[^{14}C]Ado and then subjected to sodium dodecylsulfate (SDS)-polyacrylamide gel electrophoresis and autoradiography, most of the covalently attached affinity label migrated with the 170-kDa receptor and its 150-kDa proteolytic fragment. The labeling observed was at an ATP binding site, since it was inhibited by adenosine 5′-iminodiphosphate (AMP-PNP), a hydrolysis-resistant ATP analogue, but not by adenosine, AMP, ADP, GTP, or NAD. Furthermore, after labeling A-431 vesicles or scraped membranes with 5′-*p*-FSO_2Bz[^{14}C]Ado, the receptor was affinity-purified under conditions previously shown to copurify the receptor and the kinase. The receptor was the only component of the purified preparation that contained detectable affinity label. Thus, we concluded that the receptor and the kinase are two domains of the same polypeptide. Lastly, if the EGF-sensitive kinase activity was inactivated, by mild heating or exposure to *N*-ethylmaleimide, the 150-kDa and 170-kDa receptor species could not be labeled with the ATP affinity reagent. The mechanism by which binding of EGF to the external domain of the receptor activates the cytoplasmic catalytic domain is not yet known.[11,48]

That the EGF receptor is a glycoprotein was first suggested by observations that a variety of lectins inhibit the binding of ^{125}I-EGF to cultured human fibroblasts[49] or to human placental membranes[50] and that the receptor may be purified by lectin chromatography.[51] The biosynthesis and glycosylation of the receptor in A-431 cells have recently been addressed in several studies in which cells have been metabolically labeled and the receptor species identified by immunoprecipitation.[48,52]

It is not possible to consider here the thousands of reports regarding EGF and its receptor in biology and medicine. The reader is referred to several recent reviews that summarize various aspects of this ever-burgeoning area.[11,48,53,54]

I now, very briefly, indicate some of the major advances made in other laboratories throughout the world that I believe will lead to a more complete understanding of the role of EGF and its receptor-kinase in growth regulation.

1. The elucidation of the amino-acid sequence of the EGF receptor, deduced from the nucleotide sequence of cDNA clones, and the discovery that the *erb*-B transforming gene of avian erythroblastosis virus probably is derived from the avian EGF receptor.[55]
2. The elucidation of the nucleotide sequence of the cDNA for prepro-EGF, which predicts a protein precursor with a molecular weight of 128000 Da.[56,57] The EGF precursor may be a membrane-spanning protein, conceivably a receptor for an as yet unknown ligand. Of great interest in this regard has been the detection of prepro-EGF in the kidney,[58] the detection of two EGF-related loci (in *Drosophila* and in *Caenorhabditis*) that regulate development,[59,60] and the detection of an EGF-related sequence in the genome of the vaccinia vi-

rus.[61] These findings suggest that EGF is of ancient origin and may have been used for a variety of functional roles.

3. The discovery that both fetal and malignant cells produce an EGF-related protein (α-TGF) that appears to interact with the EGF receptor and mimics the biological activity of EGF.[62]
4. The discovery that the receptors for insulin as well as a number of other growth factors are ligand-activated tyrosine kinases.[48,54]

Although our current working hypothesis is that the initial functional signal transmitted by EGF is related to the tyrosine kinase activity of its receptor, the exact pathway of growth activation, especially between the receptor and cell nucleus, remains elusive. This is true not only for EGF, but also for the other growth factors whose receptors are tyrosine kinases as well as those oncogenes whose products are tyrosine kinases.

5. Where Do We Go from Here?

Do we look for specific cellular proteins whose functions are altered by tyrosine phosphorylation? Is the intracellular translocation of tyrosine kinases of physiological significance? Is it possible that autophosphorylated receptors or related oncogene proteins serve some still unidentified regulatory role? What are the mechanisms for sending stimulatory or inhibitory signals to the nucleus? What is the normal physiological role of EGF during development and homeostasis? The answers to these and a host of other questions must be found before we can fully comprehend this important regulatory system.

To the many colleagues, students, and technical assistants who have contributed to these investigations, I am most grateful. I also wish to acknowledge, with gratitude, the support of the National Institutes of Health and the American Cancer Society.

Diene, Alkyne, Alkene, and Alkyl Complexes of Early Transition Metals: Structures and Synthetic Applications in Organic and Polymer Chemistry

By Hajime Yasuda* and Akira Nakamura*

An unprecedented series of highly reactive alkene- and diene-complexes of the early transition metals (Groups 3A–5A of the periodic system) have been isolated recently. Diene complexes of this sort (M = Ti, Zr, Hf, Nb, Ta) prefer, besides the (η^4-s-*cis*-diene)metal structure, either a novel bent η^4-metallacyclo-3-pentene structure or the unique (η^4-s-*trans*-diene)metal structure. In bis(diene)metal complexes of Nb and Ta the η^4-s-*cis*-dienes assume an unusual *exo-endo* (*supine-prone*) geometry. The M–C bonds in these diene-metal complexes generally exhibit highly polarized σ-bonding along with π-bonding character. The complexes therefore undergo a variety of regio- and stereoselective carbometalations with substrates containing C–C, C–O, or C–N multiple bonds. Examples of the products that can be obtained include ketones, vinyl ketones, unsaturated primary, secondary, and tertiary alcohols, as well as diols and unsaturated acids. Mechanistic studies on the stoichiometric and catalytic conversions of unsaturated hydrocarbons provides, inter alia, some insights into the course of polymerization reactions.

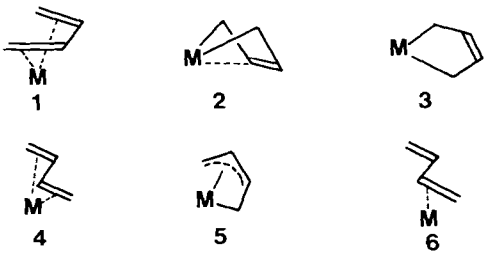
1. Introduction

Organic compounds of the early transition metals (groups 3A–5A of the periodic system) are currently attracting considerable attention because of their fascinating structural features, their mode of M–C bonding, and their unusually high selectivity in carbometalations; all these features distinguish them from the conventional middle and late transition metal complexes. The recent accelerated development of alkene–metal chemistry in this area is largely a consequence of the successful isolation of highly reactive novel species with suitable auxiliary ligands, especially cyclopentadienyl (Cp) and pentamethylcyclopentadienyl (Cp*) ligands. The first part of this article is concerned with new aspects of the structural chemistry of diene-, alkene-, and alkyne- as well as allyl- and pentadienyl-metal complexes of the early transition metals, while the second part deals with the unusual C–C coupling reactions that have been accomplished with these complexes. For an overview of the organometallic chemistry of the early transition metals in its entirety, the reader should consult some of the excellent monographs[1] and reviews on alkylmetal compounds,[2] carbene-complexes,[3] and metallacycles[4] that are available.

2. Remarkable Structural Features of Diene, Alkene, and Alkyne Complexes of the Early Transition Metals

2.1. Structures of η^4-Metallacyclo-3-pentene- and η^4-s-*trans*-Diene-Metal Complexes

Conjugated dienes, typified by 1,3-butadiene, may coordinate to a metal in several ways. The relative contribution of each of the limiting structures **1**–**6** would appear to depend upon the ligands of the metal and the substituents of the diene. The vast majority of middle and late transition metal-diene complexes assume the conventional (η^4-s-*cis*-1,3-diene) structure **1** or the ($1,2$-η^2-s-*trans*-1,3-diene) structure **6**, where the diene interacts with Fe, Ru, Rh, Mo, Mn etc. via alkene π-orbitals.[5] It is now apparent from



X-ray and NMR data that the diene complexes of early transition metals of groups 4A (Ti,[6] Zr,[7–9] Hf[10]) and 5A (Nb,[11] Ta[12]), like those of group 3A (U,[13] Th[13,14]), prefer the bent (σ^2,π-bonded)η^4-metallacyclo-3-pentene structure **2**, the planar (σ^2-bonded)η^2-metallacyclo-3-pentene structure **3** or the novel (η^4-s-*trans*-diene)metal structure **4**. Unequivocal evidence for the structure of type **5** is still lacking. Differentiation of the η^2-structure **6** from its σ-bonded counterpart (2-vinylmetallacyclopropane) seems improbable on the basis of the prediction made by *Dewar* et al.,[15] although the latter geometry is well known in 2-vinylphosphiranes.[16] Typical synthetic routes to these diene complexes involve the use of dienemagnesium reagents[7] or of pentadienyl anions,[17] the chemical or photochemical reduction of the corresponding precursor complex in the presence of the diene,[8,9] metal atom vapor techniques,[18] rearrangements of transitory divinyl complexes,[19] or β-hydride elimination from allylmetal compounds or metallacycles.[20] As typical example of such a

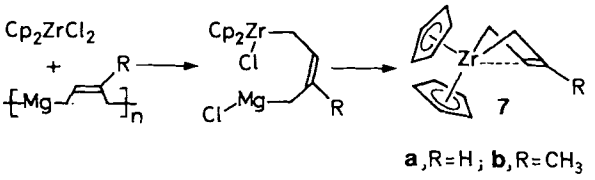
synthesis, a route leading to the isoprenezirconium complex **7b** in high yields from dienemagnesium adducts[21] is outlined. This type of reaction finds universal application in preparative chemistry.



a, R=H; **b**, R=CH$_3$

The complexes **7** kinetically favor the η^4-s-*trans*-coordination **4** but thermodynamically they favor the s-*cis* metallacyclic structure **2**. Thus, the η^4-s-*trans*-butadiene complex of zirconocene can be converted by heating in solution, into the s-*cis*-complex, which, in turn, can be converted by irradiation with UV light into the η^4-s-*trans*-isomer.[9b] Alkyl or aryl substitution of the butadiene ligand in position 2 or positions 2 and 3 always leads to zirconacyclo-3-pentene complexes such as **7**. The strong steric repulsion between the C_5H_5 ligands (Cp) and the substituents (see, e.g., R) should be the crucial factor forcing this type of coordination instead of the η^4-s-*trans*-coordination. Substitution at C-1 or C-1 and C-4, on the other hand, induces preferential formation of the η^4-s-*trans*-diene complexes by conjugation or hyperconjugation.[22]

This situation changes drastically upon replacing Zr by Ti, Ta or Nb. The relative ratios of the s-*cis* and s-*trans* isomers of the complexes are listed in Table 1. Typical examples for the molecular structures of the s-*cis* (type **2**) and s-*trans*-diene complexes (type **4**) are shown in Figures 1[6a] and 2,[7d] respectively.

Table 1. Proportion of s-*cis*-isomers of type **2** in

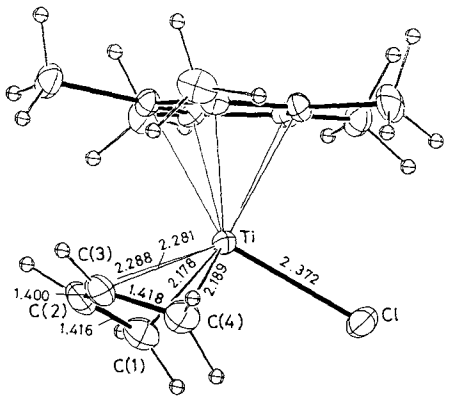

Fig. 1. Molecular structure of a typical s-*cis*-diene complex of type **2**, [$TiCp^*Cl$(butadiene)] (cf. **11b**).

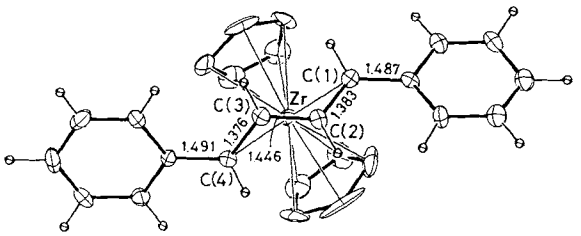

Fig. 2. Molecular structure of a typical s-*trans*-diene complex of type **4**, [$ZrCp_2$(1,4-diphenylbutadiene)].

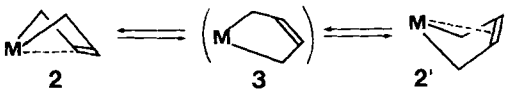
The η^4-metallacyclo-3-pentene complexes **2** of elements of groups 3A–5A generally exhibit fluxional behavior, which may be attributed, on the basis of variable temperature ^{1}H-NMR studies, to rapid ring inversion (flipping) via a transitory planar metallacyclopentene species **3**. From



the shape of the signal pattern, a simple rotational mechanism can be ruled out. More exact direct evidence for ring inversion has recently been provided by a sterochemical labeling experiment with a [CoCp(1,3-diene)] complex whose 1,3-diene ligand was deuteriated in positions 1 and 4.[23] The typical free energy of activation, ΔG^+ (at the coalescence temperature), for the ring inversion in zirconacyclo-3-pentenes such as **7** varies in the range 6.5–17 kcal/mol.[9]

Very unusual is the large value (>25 kcal/mol) for [MCl_2Cp^*(s-*cis*-butadiene)], M = Ta, Nb; Cp* = C_5Me_5.[24] Such a fluxional behavior could arise from the strong σ-bonding character of the M–C bonds at the diene termini. The ^{13}C-^{1}H coupling constant clearly confirms the enhanced sp^3 character of C-1 and C-4.[25] The value of n for sp^n hybridization of the carbon is in the range 2.0–2.2 in the case of conventional diene complexes of the late transition metals (Fe, Rh, etc.), but it reaches 2.7–3.0 in the case of [MCp_2(2,3-dimethylbutadiene)], M = Zr, Hf, and [$ZrCp_2^*$(isoprene)], which remain fluxional even at −90 °C.

The fluxional structure is also apparent in crystallographic data and it is reflected in the dihedral angle (θ) subtended by the C1–M–C4 and C1–C2–C3–C4 planes and the difference in the M–C bond distances (Δd), defined by

$$\Delta d = [d(\text{M–C1}) + d(\text{M–C4})]/2 - [d(\text{M–C2}) + d(\text{M–C3})]/2$$

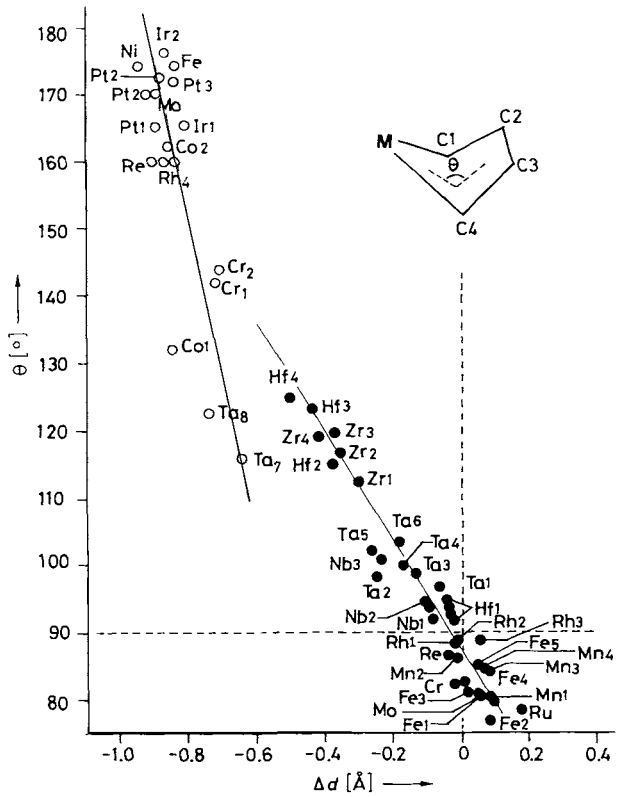


Fig. 3. Correlation plots between dihedral angle (θ) and difference in metal-carbon distances (Δd) in dienemetal complexes of type **1** or **2** (●) and metallacyclopentanes of type **8** (○). Data are selected from Cambridge Crystallographic Database (see ref. [26] for the structural details). The numbers next to the element symbols identify the complexes used.

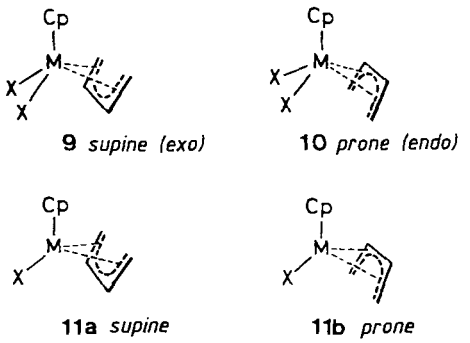
As shown in the correlation plots (Fig. 3), the dihedral angles for s-*cis*-diene complexes (type **1**) of the late transition metals fall in the narrow range of 75–90°, and Δd lies between −0.1 and 0.1 Å, i.e. the M–C1 and M–C4 bonds are nearly equal or slightly longer than the M–C2 or M–C3 bond.[12,26] On the other hand, the corresponding dihedral angles for the complexes of the early transition metals always exceed 90°, with a corresponding change in Δd of −0.4 to 0 Å. Thus, the dihedral angles increase with decreasing Δd. The dihedral angle of the metallacyclopentanes (type **8**), where no interaction takes place between the metal and the inner carbon atoms, is in the range 140–175° for late transition metals, since the four carbon atoms are not coplanar, as in **8b** (the angle given refers to "best planes").[26] In the case of tantala- or cobaltacyclopentanes

8a **8b**

(type **8a**), θ lies in the range 115–130°; this is nearly the same range as for [MCp_2(s-*cis*-butadiene)], M = Zr, Hf. We can conclude, therefore, that the diene complexes of metals of group 4A exhibit rather weak interaction between the metal atom and the inner carbon atoms, consistent with their high fluxional properties, whereas the diene complexes of metals of group 5A exhibit a rigid structure because of the strong π-interaction between the inner carbon atoms and the metal atom. There is also an approximate linear correlation between the dihedral angle (θ) and the difference in the C–C bond lengths (Δl), defined by

$$\Delta l = [l(\text{C1–C2}) + l(\text{C3–C4})]/2 - l(\text{C2–C3})$$

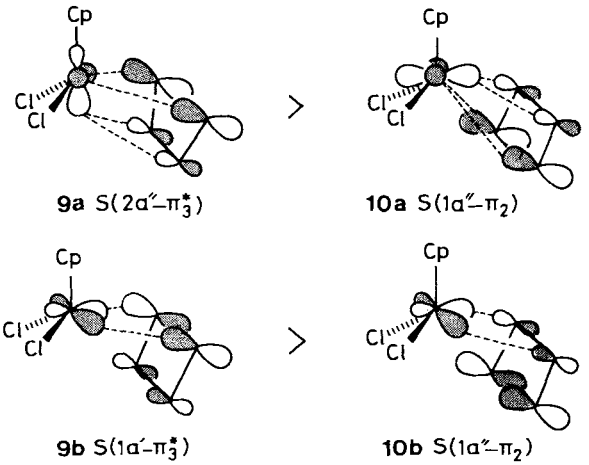
In the case of diene complexes of the late transition metals, Δl lies between −0.1 and 0.0 Å, while in those of the early transition metals it falls in the range 0.0–0.2 Å. Thus, the dihedral angle increases with increasing Δl.[12,26] A fairly good linear correlation is also observed between the values of n for sp^n hybridization of the diene terminal carbons and Δd and Δl.



9 *supine (exo)* **10** *prone (endo)*

11a *supine* **11b** *prone*

The diene complexes of metals of group 5A always have the metallacyclo-3-pentene structure **2**. Two orientations are possible for [MCl_2Cp(diene)], M = Ta, Nb: *supine* and *prone* (we propose this nomenclature because the classical *exo* and *endo* nomenclature does not adequately characterize this type of conformation). A comparison of the total energy of [$TaCl_2$Cp(butadiene)] for the *supine* (*exo*)-type **9** and *prone* (*endo*)-type **10** on the basis of an EHMO calculation revealed that the former is more stable than the latter by 15.7 kcal/mol due to the large overlap integrals S(2a″-π_3^*) of **9a** and S(1a′-π_3^*) of **9b** respectively.[12]

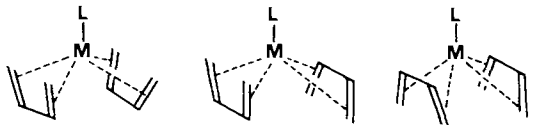


9a S(2a″–π_3^*) **10a** S(1a″–π_2)

9b S(1a′–π_3^*) **10b** S(1a″–π_2)

The dimeric niobium complex $[NbClCp^*(butadiene)]_2$,[11] $[TiClCp^*(diene)]$, diene = isoprene, 2,3-dimethylbutadiene,[6a] as well as $[HfClCp^*(2,3\text{-dimethylbutadiene})]$,[6b] and the molybdenum complex $[MoCp(CO)_2(butadiene, 1,4\text{-diphenylbutadiene})$ exhibit a unique *prone* to $[TaCl_2Cp(C_4H_6)]$[12] as a result of steric repulsion between Cp* or Cp and the methyl groups of the diene ligands, while $[TiClCp^*(diene)]$ complexes (diene = butadiene, 1,4-diphenylbutadiene) exhibit a unique *prone* (*endo*) orientation **11b** (cf Fig. 4).

When a metal complex contains more than one diene, there are many possibilities for its coordination geometry. Thus, the complexes $[LM(diene)_2]$ may assume square-pyramidal or trigonal-bipyramidal structures if the diene ligand is assumed to occupy two coordination sites via its terminal carbon atoms. The bis(diene)metal complexes reported so far all prefer the square-pyramidal structure: the two diene ligands orient themselves in a parallel *supine-supine*(or *exo-exo*) fashion (**12**) with nearly C_{2v} symmetry, while L occupies the apical position. The novel *supine-prone* (*exo-endo*) orientation (**13**), observed for the first time in $[Ta(C_5R_5)(diene)_2]$ (R = H, Me; diene = butadiene, isoprene, 2,3-dimethylbutadiene),[12] has recently also been found in the analogous niobium complexes.[11] A similar *supine-prone* orientation is also found in the mixed-ligand zirconiumcomplex$[ZrCp^*(\eta^4\text{-butadiene})(\eta^3\text{-allyl})]$.[9f]



$[Hf(diene)_2(dmpe)]$, an unusual complex with the formula $[L_2M(diene)_2]$, prefers octahedral geometry[8] (dmpe = 1,2-bis(dimethylphosphino)ethane is a bidentate ligand). Bis(diene)metal complexes with a *prone-prone* (*endo-endo*) orientation (**14**) or a trigonal-bipyramidal conformation are still unknown. The relative stabilities of the conformations estimated from EHMO calculations for $[TaCp(butadiene)_2]$ indicate that the *supine-prone* conformation is more stable than the *prone-prone* or *supine-supine* conformation by 23.3 and 28.2 kcal/mol, respectively, whereas for $[RhCl(butadiene)_2]$, the *supine-supine* conformation is more stable than the *prone-prone* or *prone-supine* conformation by 25.8 and 27.2 kcal/mol, respectively.[7c] The calculated overlap population indicates that $[TaCp(butadiene)_2]$ favors the bent η^4-metallacyclo-3-pentene structure of type **2**, while $[RhCl(butadiene)_2]$ prefers the conventional η^4-s-*cis*-diene coordination of type **1**, in agreement with the crystallographic data. An unusual mixed diene complex, $[TaCp^*(butadiene)(2,3\text{-dimethylbutadiene})]$, also assumes the *prone-supine* structure, as shown in Figure 4.[28]

The s-*trans*-diene coordination to mononuclear species (type **4**), first found in complexes of the early transition metals in the case of $[ZrCp_2(1,4\text{-diphenyl-1,3-butadiene})]$[7d] and $[ZrCp_2(butadiene)]$,[9b] has recently also been found in $[HfCp_2(butadiene)]$[29] and $[MoCp(NO)(2,4\text{-dimethyl-2,4-hexadiene})]$;[30] a bridging s-*trans*-diene coordination, on the other hand, had already been reported for several binuclear and trinuclear metal complexes. $[Mn_2Cp_2(CO)_4(butadiene)]$[31] and $[(Pt_2Cl_6)_2(butadiene)]^{2\ominus}$[32] are typical examples for complexes of type **15**, while $[Mn_2(CO)_8(butadiene)]$[33] and $[Os_3(CO)_{10}(butadiene)]$[34] represent complexes of the type **16**. (The third Os atom does not participate in the coordination.) The s-*trans*-diene molecule coordinated to $ZrCp_2$ or MoCp(NO) has a non-

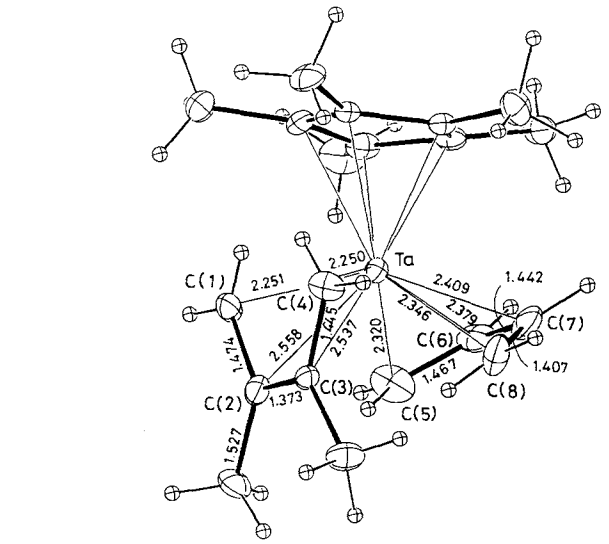


Fig. 4. Molecular Structure of a bis(diene) complex of type **13**, [TaCp*(butadiene)(2,3-dimethylbutadiene)].

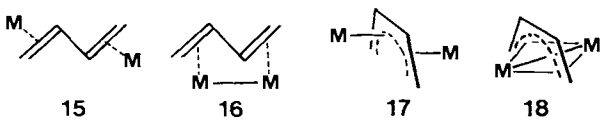

planar arrangement with torsional angles of ca. 124–126° (cf. Fig. 2). As a consequence, the bond lengths of M–C1 and M–C4 are very similar to those of M–C2 and M–C3. In sharp contrast to the behavior of the $[ZrCp_2(diene)]$ complexes, [MoCp(NO)(diene)] thermodynamically favors the s-*trans* coordination rather than s-*cis* coordination (in agreement with Fenske-Hall MO calculations).[30a] The HOMO energy of the former is ca. 0.9 eV lower than that of the latter. The asymmetry of the *trans*-diene ligand enables stabilization of the high-lying occupied orbitals of the MoCp(NO) fragment. The discovery of s-*trans*-diene coordination to mononuclear complexes of the early transition metals is of special importance, since it provides a new aspect of the reaction mechanism of the titanium- or zirconium-assisted oligomerization and polymerization of dienes (see Sections 5.3 and 6.1).

A novel type of binuclear metal complex containing a *cis*-coordinated diene (**17**), $[Rh_2(i\text{Pr}_2\text{PCH}_2\text{CH}_2\text{CH}_2\text{P}i\text{Pr}_2)_2(butadiene)]$, has appeared recently.[35] The butadiene unit is sandwiched between the two rhodium centers; the metal atoms interact with the twisted s-*cis*-butadiene (torsion angle of 45.0°) in an η^3-fashion. Coordination of a bridging s-*cis*-diene to M–M bonded binuclear complexes (**18**), e.g. $[Co_2Cp_2(CO)(butadiene)]$,[36] has also been reported.

The collection of structural details on s-*cis*- and s-*trans*-diene complexes and mononuclear and dinuclear metal species has thus only recently been completed. This information is indispensable for gaining an insight into the reaction mechanism of the oligomerization, polymerization and carbometalation of dienes by early transition metals.

2.2. Characteristic Properties of the M–C Bonding of Alkenemetal- and Alkynemetal-Complexes, and Related Complexes

Several reactive alkene complexes of the early transition metals (M = Ti,[37,38] Ta,[39] Nb[40,41]) have become available in recent years, while a number of alkene complexes of the late transition metals, represented by Zeise's salt, are already well documented. Table 2 lists the structural data for selected ethylene complexes together with the values for the chemical shift in the ^{1}H-NMR spectrum; α is the angle between the normals of the H–C–H planes shown in **19**. It is clear from the data in Table 2 that electron-rich

[a] dmpe = 1,3-bis(dimethylphosphino)propane.

ethylenemetal complexes exhibit relatively large α values and significant lengthening of the ethylene C–C bond; this confirms the enhanced sp^3 character of the carbon atoms. In general, the α value increases with increasing C–C bond length. The δ values—apart from in the case of the Ti complex **43**—are also consistent with the structural data. (In **43** the downfield shift could be explained in terms of the deshielding effect of the Cp* ring.) The enhanced carbon sp^3 hybridization must arise from substantial electron back-donation from the metal.

Alkynemetal complexes show a similar trend with respect to the metal–carbon bonding. In the case of the electron-rich metal complexes there is usually a considerable lengthening of the acetylenic C–C bonds; however, the bite angle β (angle between the two C–C bonds in **20**) is hardly influenced by the metal and ligands.[26,42]

Let us now turn to the allylmetal complexes! For allylmetal complexes, primarily two limiting structures, **21** and **22**, are possible (see also Ref. [43a] for classification of the

21

22

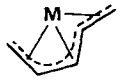
allylmetal complexes). The mode of M–C bonding varies depending upon the valence state of the metal and the hapticity of the ligand. Formally, the Zr^{IV} complexes $[ZrCp_2(CH_2CH{=}CHCH_3)_2]$ and $[ZrCp_2Cl(CH_2CH{=}CHCH_3)]$ exist in a σ-2-butenylmetal form (**21**) at low temperatures.[43b,c] However, low valent allylmetal species, for example $[TiCp_2\{CH_2C(CH_3){=}CHCH_3\}]$, exist in a η^3-*syn* form (**22**).[44] In general, in the compounds of the early transition metals and some nickel compounds,[45] the bond distances between metal and η^3-allyl terminal carbons are nearly equal to or a little shorter than that between the metal and the central carbon atom, while this trend is reversed in the compounds of the electrophilic late transition metals.[26]

When the conjugation is extended further to pentadienyl systems, the ligand should be capable of binding to a metal in σ-, η^3-, and η^5 modes. The structural preference depends on the valence state of the metal and the π-acceptor properties of the ligands. Thus, the ligand in $[ZrCp_2(2,4\text{-pentadienyl})_2]$ and its alkyl-substituted derivatives always prefer the terminally σ-bonded zigzag-like (*E*)-geometry (**23**),[17] while $[M(2,4\text{-dimethylpentadienyl})_2]$, M = V, Cr, Fe, Ti, and $[M(PR_3)(2,4\text{-dimethylpentadienyl})]$, M = Zr, Nb, prefer the U-shaped (**25**) or S-shaped (**26**) η^5-bonded structure, because this type of coordination is effective in stabilizing

23

24

25



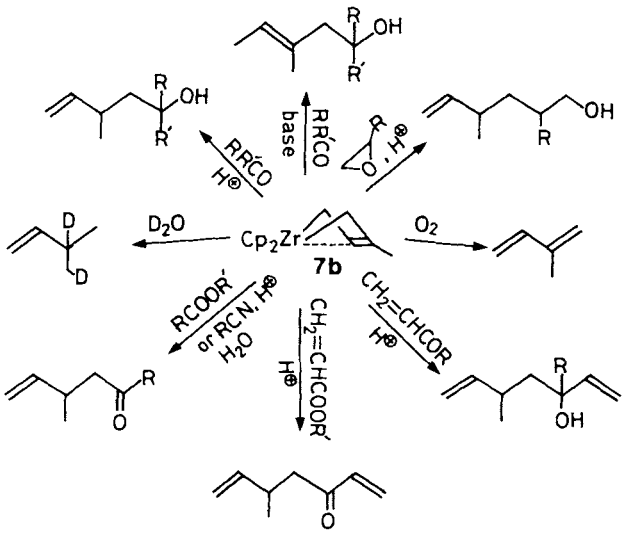
26

the naked or highly coordinatively unsaturated metal species.[46] Note that $[Ti(\eta^5\text{-pentadienyl})_2]$ derivatives are isolable, while $[Ti(\eta^5\text{-cyclopentadienyl})_2]$ is thermally unstable. Transition metal complexes of type **24**, which contain *syn*- or *anti*-η^3-pentadienyl ligands, include $[Fe(PMe_3)_2(C_5H_7)_2]$,[47] $[Co(PMe_3)_3(C_7H_{11})]$,[48] $[Co(CO)_2(PPh_3)(C_5H_7)]$,[49] and $[Mn(CO)_3(PMe_3)(C_5H_7)]$.[50] The manganese complex is converted into the η^5-coordinated isomer upon heating in solution, while the thermodynamic stability is reversed in the case of the cobalt complex. The corresponding change in hapticity for Cp ligands has not yet been well established, except for $[(\eta^3\text{-Cp})(\eta^5\text{-Cp})W(CO)_2]$,[51a] $[MCp_4]$, M = Ti, Zr, Hf,[51b] and some indenyl complexes.[51c-d]

3. Selective Carbometalation of Organic Substrates Containing C–O and C–N Multiple Bonds with Organic Compounds of the Early Transition Metals

3.1. Regio- and Stereoselective Addition of Diene Complexes to Carbonyl Compounds, Nitriles, and Oxiranes

Carbometalation with organic compounds of metals of groups 3A–5A is one of the more important strategies in modern organic synthesis. The metal–carbon bond in these compounds is generally polarized as $M^{\oplus}$–$C^{\ominus}$ and hence renders the carbon site susceptible to electrophilic attack. Dienezirconium complexes, especially those with an unsymmetrical diene, e.g. isoprene, may serve as models for demonstrating the unique chemical behavior of complexes of the early transition metals, for they can readily rearrange into various geometrical isomers (see **1**–**6**) depending on the reaction conditions, and can afford a variety of products upon reaction with numerous unsaturated organic and inorganic molecules. As typical examples of such reactions, the carbometalation of oxygen-containing compounds with [$ZrCp_2$(isoprene)] **7b** and related reactions are illustrated in Scheme 1.[7a] The most striking feature is the exceptionally high regioselectivity (>95%) in the reactions with saturated and unsaturated aldehydes, ketones, and nitriles. The yields exceed 90% in all reactions. The reaction proceeds irreversibly at the sterically more congested 1-position of the isoprene rather than at the sterically favorable 4-position. Subsequent acid cleavage of the product of aldehyde or ketone insertion furnishes 3-methyl-4-penten-1-ol derivatives selectively (>90%), while base-catalyzed cleavage with secondary amines (e.g. pyrrolidine, piperidine) leads to 3-methyl-3-penten-1-ol derivatives.[52a] Esters and nitriles also react at C-1 of the isoprene and afford acylated compounds upon hydrolysis of the adduct.[52b] The mode of this reaction markedly differs from that of the well documented Grignard reaction or the reaction of [$ZrCp_2$(2-butenyl)$_2$] with



Scheme 1. Nucleophilic addition of [$ZrCp_2$(isoprene)] **7b** to oxygenated or nitrogenated unsaturated compounds.

esters, which leads to tertiary alcohols by double allylation. Some of the alkyllanthanoids react analogously with esters, with monoalkylation to give products which can be hydrolyzed to acylates.[53] Especially noteworthy is the highly selective 1,2-addition (>95%) observed in the reaction of dienezirconium complexes with α,β-unsaturated ketones and esters. The regiochemical selectivity may be ascribed to the high ionicity of the Zr–C bond and the high oxophilicity of the zirconium metal together with the rigid tetrahedral geometry of the complexes, since simple [$RTiCl_3$][54] and alkyllanthanoids[55] are also able to promote the selective 1,2-addition to enones. The carbometalation of oxiranes (R = aryl or vinyl) with the isoprenezirconium complex **7b** leads, with 99% regioselectivity, to C–C bond formation between C-1 of the isoprene and C-2 of the oxirane.[56] Thus, the subtle electronic and steric difference existing between C-1 and C-4 of isoprene could be clearly enhanced by complexation to zirconium. Analogous diene complexes, for example [TiCp*Cl(diene)], [$HfCp_2$(diene)], [$TaCl_2Cp$(diene)], [TaCp(diene)$_2$], and [$NbCp$(diene)$_2$], also promote the selective carbometalation, although diene complexes of metals of group 5A generally show relatively low reactivity toward these electrophiles.[57] The selective carbometalation with [$M(OR)_2$(diene)], M = Ti, Zr, generated in situ from $M(OR)_4$ or $M(OR)_2Cl_2$ and dienemagnesium, could be useful for large-scale organic syntheses.

Two reaction pathways seem conceivable: insertion into the *cis*-dienemetal species (Type **2**), and insertion into the s-*trans*-isomer (type **4**). In order to obtain information on the reaction pathways, the reactions of the analogues of **7**, [$ZrCp^*_2$(isoprene)] (100% *cis*) and [$ZrCp^*_2$(butadiene)] (100% s-*trans*), with 2,4-dimethyl-3-pentanone were examined.[25] Both diene complexes are thermally stable even at 90 °C but readily react with the ketone at 30 °C. If the reactions proceed straightforwardly with retention of configuration, each of the stereoisomers might give rise to (*Z*)- and (*E*)-oxazirconacycloheptenes, **27** and **28** respectively. The X-ray analyses of the above two insertion products clearly confirm that both compounds have essentially the same configuration at the double bond, namely a (*Z*)-configuration as in **27** (Fig. 5). Hence, the s-*trans*-diene complex undergoes reaction with change of configuration, while the *cis* isomer retains its geometry. A similar (*Z*)-oxazirconacycloheptene structure is also found in a diphenyl ketone adduct of [$ZrCp_2$(butadiene)] **7a**.[58] However, we cannot immediately conclude that the (*Z*)-form of the isoprene adduct is a direct consequence of the *cis*-structure of the precursor, since an isomerization via **27b** is probable (*vide infra*).

In sharp contrast to the thermally induced reactions, a photoinduced reaction occurs preferentially (78%) at the sterically less crowded 4-position at −70 °C. At this temperature the thermal reaction is completely suppressed.[59] The s-*trans* isomer of the isoprene complex (generated photochemically) also furnishes predominantly the same regioisomer **32b**, even in the absence of light. Thus, the geometry of the coordinated dienes is the crucial factor in determining the regiochemistry. A [2+2]-type oxidative coupling process has been proposed for both the photochemically- and the thermally-induced addition of the s-

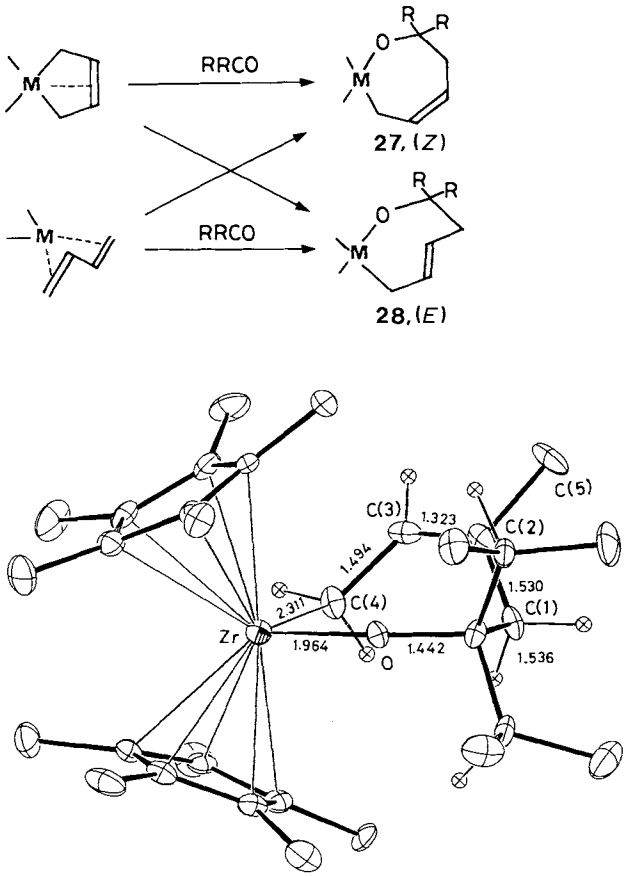


Fig. 5. Molecular structure of a (*Z*)-configurated complex of type **27**, $[Cp_2^*ZrOC(iPr)_2CH_2C(CH_3)=CHCH_2]$. The complex is formed by ketone insertion.

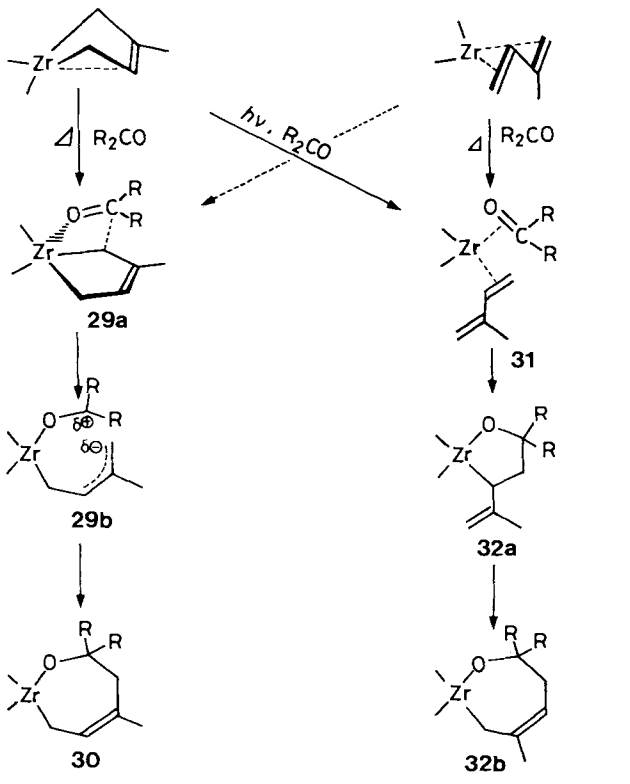
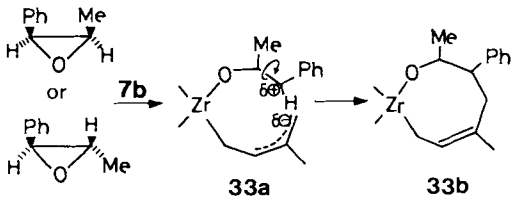
trans-diene complexes, since the regiochemistry is consistent with that found in the addition of the diene complex to unsaturated hydrocarbons (see Section 4). The insertion should proceed via **31**. A competition experiment with a mixture of s-*trans*- and *cis*-butadiene complexes confirmed the higher reactivity of the s-*trans* isomer.[58] On the basis of these findings, a four-centered insertion mechanism or a dipolar mechanism has been proposed for the thermally induced addition reaction of the *cis*-diene complexes. The coupling of a planar zirconacyclo-3-pentene species of type **3** with a carbonyl group via the four-centered transition state **29a** and further reaction via **29b** seems most likely. The C–C bond formation occurs at C-1 with cyclization to give **30**, since substantial negative charge accumulates on the C-1 atom rather than the C-4 atom by the inductive effect of the methyl group. Since the LUMO of [Cp_2Zr(s-*cis*-butadiene)] **7a** has a similar shape as $1a_1$ of the "Cp_2Zr" fragment,[60] the carbonyl group can approach the metal only in the C1–Zr–C4 plane, as shown in **29a**. Actually, such a planar arrangement of the three M–X bonds is commonly seen in pentacoordinated zirconocene derivatives.[61] The attack of allylic carbon atoms (C-2 or C-3) via the usual nonplanar six-membered transition state is forbidden because of this orbital symmetry requirement.

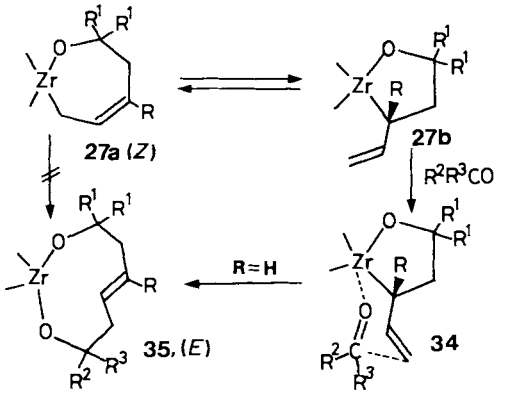


The result of the carbometalation of *cis*- and *trans*-2-methyl-3-phenyloxirane with the isoprene complex **7b** may support the above dipolar insertion mechanism.[56h] The insertion to give **33b** occurs with excellent regioselectivity (100%), but the configuration at C-2 and C-3 of the oxirane is destroyed during the reaction. To explain the free rotation around the oxirane C–C bond prior to the coupling, which leads to a mixture of the diastereoisomers (1 : 2 ratio), a transition state **33a** has been proposed.



Isoprene-, 2,3-dimethylbutadiene-, and 3-methyl-1,3-pentadienezirconium complexes (with s-*cis* geometry) undergo only the 1 : 1 addition reaction of carbonyl compounds, even when the reaction is carried out at higher temperatures (≈ 100 °C) in the presence of excess carbonyl compound, whereas s-*cis*-butadiene-, pentadiene-, and 2,4-hexadiene-complexes (ca. 1 : 1 mixture of the s-*cis* and s-*trans* isomers) readily add two equivalents of butanal or 3-pentanone in high yields (95%) at lower temperature (30 °C).[17] Especially noteworthy is that the s-*cis*-butadiene complex predominantly forms an (*E*)-dioxazirconacyclo-4-nonene (**35**) as a result of double insertion; upon hydrolysis, **35** selectively affords (*E*)-3-hexene-1,6-diol derivatives. If the second incoming carbonyl compound directly attacks the (*Z*)-oxazirconacycloheptene **27a**, the (*Z*)-analogue of **35** ought to be formed. This controversy can be resolved by assuming an insertion process via a six-membered transition state in a chair form (**34**). The mode of this reaction is, in principle, the same as that postulated for the *threo*-selective incorporation of aldehydes and ketones into zirconium-[43b,62a] or titaniumallyl compounds[62b–c]

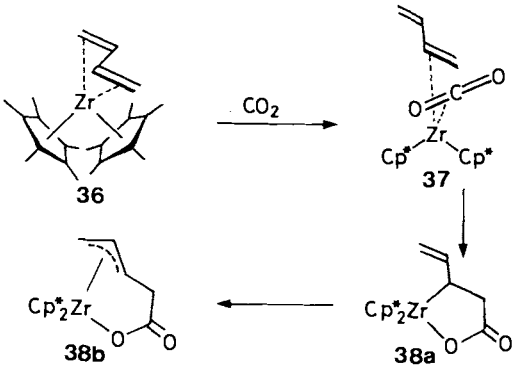
such as $[ZrCp_2(2\text{-butenyl})_2]$, $[ZrCp_2Cl(2\text{-butenyl})]$, and $[TiCp_2(2\text{-butenyl})]$. In the case of ketone or aldehyde adducts of isoprene- and 2,3-dimethylbutadiene-complexes, the equilibrium between **27a** and **27b** may be shifted to the



thermodynamically more favored species **27a**, because the steric repulsion between Cp and tertiary α-carbon interferes with the generation of 3-vinyl-1,2-oxazirconacyclopentanes (**27b**, R = Me). In fact, five- and six-membered 1,2-oxazirconacycloalkenes, $Cp_2\overline{ZrO(CH_2)_n}$ (n = 3, 4, 5) without vinyl component,[63] are completely inert to carbonyl compounds under normal reaction conditions. Despite the presence of a methyl group at C-2, s-*cis*-2-methyl- and s-*cis*-2,4-dimethyl-1,3-pentadienezirconium complexes can promote double insertion, since the carbonyl compound is first attacked predominantly at C-4, affording an intermediate with a conformation similar to **34** (R = H).[64] As an extension of this reaction, the successive insertion of two kinds of electrophiles, e.g., isobutanal/3-pentanone, ethyl acetate/isobutanal, and 3-pentanone/acetonitrile, into both ends of the butadiene molecule to give **35** has been realized by treating $[ZrCp_2$(s-*cis*-butadiene)] with a carbonyl compound at 0°C in hexane and then with the other electrophile in THF at 60°C. However, attempts to carry out addition of the electrophiles in the reverse order, e.g. isobutanal/ethyl acetate or acetonitrile/3-pentanone, met without success.[64]

3.2. Addition of Diene Complexes to CO_2 and Heterocumulenes

Alkenyl- and aryltitanium compounds readily react with CO_2, thus reflecting their high oxophilicity, while alkylzirconium derivatives are not reactive enough for practical purposes.[65] Dienezirconium complexes undergo a variety of reactions, resulting in 1 : 1, 1 : 2 or 2 : 1 addition depending on the bulkiness of the Cp ligand, the geometry of the coordinated diene, and the nature of the alkyl substituents on the diene. $[ZrCp^*_2$(butadiene)] (**36**), containing a bulky pentamethylcyclopentadienyl group together with an s-*trans*-diene ligand, undergoes the 1 : 1 addition reaction, even when excess CO_2 is introduced at elevated temperatures. The reaction should proceed via **37** by oxidative [2 + 2]-coupling or directly with generation of a 3-vinyl-1,2-oxazirconacyclopentan-5-one (**38a**), which immediately



rearranges into the more stable complex **38b**. The C=O group in **38b** is bent away from the metal, as confirmed by the X-ray structure analysis (Fig. 6).[66] A similar metal-

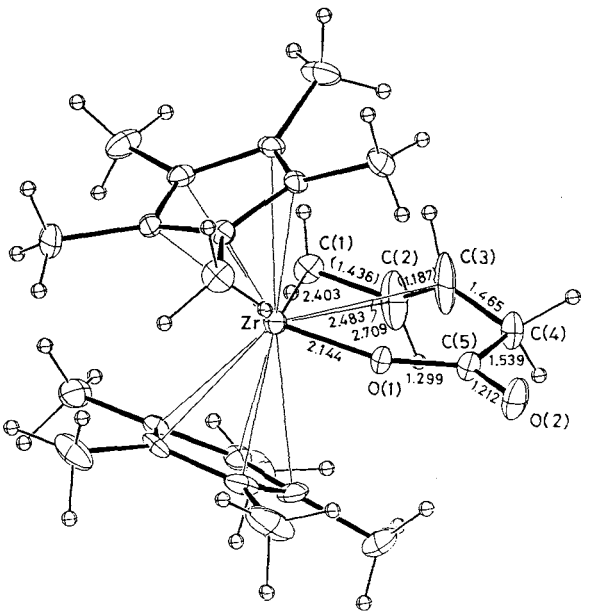


Fig. 6. Molecular structure of the complex $[Cp^*_2\overline{ZrOCOCH_2CH{=}CH{=}CH_2}]$ **38** formed by CO_2 insertion.

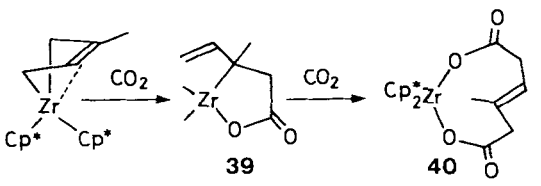
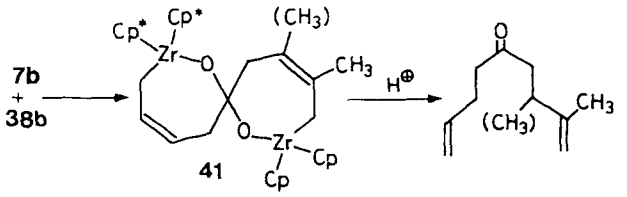
carbon linkage is also found in the product of the stoichiometric reaction between $[MCp_2$(butadiene)], M = Zr,[67] Th,[14] and $[M(CO)_6]$, M = Cr, Mo, W. In sharp contrast to the above reaction, a double insertion of CO_2 yielding **40** occurs at the diene termini when $[ZrCp^*_2$(s-*cis*-isoprene)] or $[ZrCp^*_2$(s-*cis*-2,3-dimethylbutadiene)] is used. This drastic difference may be attributed to the conformational instability of the transient 1 : 1 adduct **39** (i.e. the steric repulsion between the methyl group at the α-carbon atom and the Cp* ligand cannot stabilize the conformation **39** and hence forces a further reaction.[68]

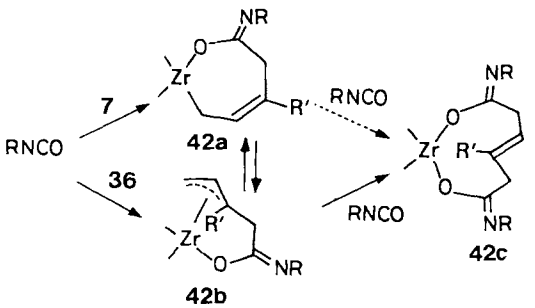
When the Cp* ligand is replaced by a less bulky Cp li-





gand, all the [$ZrCp_2$(s-*cis*-diene)] complexes examined undergo the 2:1 addition reaction leading to dioxadizirconaspiroalkadienes. An example is complex **41**. A reaction pathway for this insertion has been proposed which is based on the stoichiometric reaction between **38b** and **7b**. This sequence affords the expected spiro compound **41**, which yields a mixture of butenyl 2-methylbutenyl ketone and butenyl 3-methylbutenyl ketone in ca. 5:3 ratio on hydrolysis. Thus, a delicate balance of the electronic and steric effects determine the reaction course.

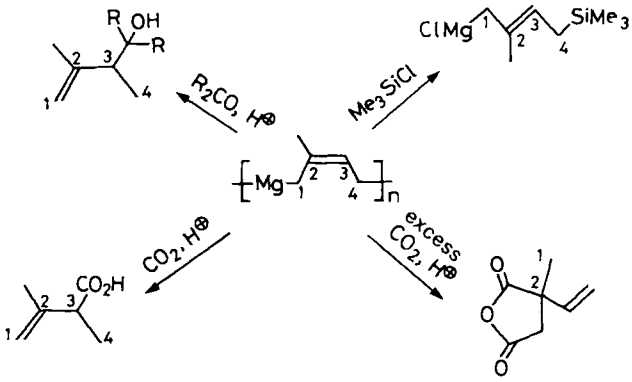
A heterocumulene, RN=C=O (R = Me, *t*Bu, Ph), readily reacts with both [$ZrCp_2$(s-*cis*-butadiene)] **7a** and [$ZrCp^*_2$(s-*trans*-butadiene)] **36** to give *syn*-allyl compounds of type **42b**, while reaction of [ZrL_2(isoprene)], L = Cp, Cp*, with *t*BuNCO gives oxazirconacycles **42a** with (*Z*)-geometry. When **7a**, **7b**, **36**, or **42b** was treated with an excess of reactive PhNCO the 1:2 adduct **42c**, R = Ph, with (*E*)-geometry was obtained in high yield. These results indicate that the conformational stability of the adducts, and not the configuration of the precursor dienemetal complexes, is the crucial factor in determining the geometry [(*E*) or (*Z*)] of the products.[69] The direct transformation of **42a** into **42c** seems very unlikely on steric grounds.



R' = H, Me.

3.3. Regiochemistry of the Reactions of Allylmetal Compounds

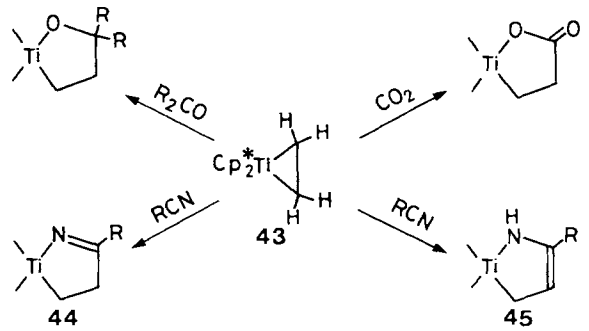
The chemistry of the allylzirconium and -titanium compounds is of fundamental importance for demonstrating the characteristic properties of the complexes of group 4A metals and for unfolding the origin of the fascinating regiochemistry observed in reactions with dienezirconium complexes, since the metal-carbon linkage of metallacyclo-3-pentenes can be regarded as representing a special case of the bis(2-butenyl)metal complexes. [$ZrCp_2CH_3$(3-methyl-2-butenyl)], [$ZrCp_2CH_3$(2-methyl-2-butenyl)], and [$ZrCp_2$(2-butenyl)$_2$], containing σ-bonded allyl groups, react, like the corresponding η^3-2-butenyltitanium(III) compounds, with acetone or ethanal exclusively at C-3 of the 2-butenyl group. High regio- and *threo*-selectivity (85–100%) are observed in reactions with aldehydes.[43b,62] A six-membered chair-like transition state has been proposed for these reactions. The corresponding allylic compounds of main group metals likewise react at C-3, but show almost no *threo*-selectivity.[70] Nine-membered metallacycles, [$ZrCp_2(C_{10}H_{16})$] and [$ZrCp_2(C_8H_{12})$], containing a 4–4 bonded dimeric isoprene or a 1–1 bonded dimeric butadiene unit (see Section 4.2), however, react with isobutanal or 3-pentanone at the 3-position of these ligands, and not at the terminal carbon atoms. Thus, the five-membered ring is crucial for the selective insertion at the terminals of the diene. The 1:1 magnesium–isoprene adduct, (polymeric 2-methyl-2-butenediylmagnesium) exhibits a completely different chemical behavior, as shown in Scheme 2. All of the electrophiles react selectively at C-3 (γ-position), presumably via a conventional six-membered transition state; the transmetalation with trimethylsilyl chloride occurs exclusively at C-4, thus lending support to the reaction pathway leading to **7** (Section 2.1). σ-Pentadienylzirconium compounds of type **23**, higher homologues of allylzirconium compounds, behave similarly, and add aldehydes and ketones selectively at C-3 (γ-position).[17a]



Scheme 2. Mode of reaction between magnesium isoprene (1:1) adduct with electrophiles.

3.4. Nucleophilic Addition of Alkenemetal and Alkynemetal Complexes

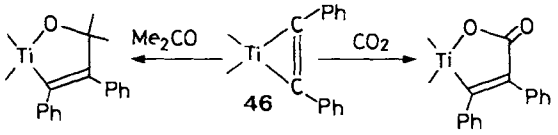
Alkene complexes of group 4A metals readily react with electrophiles in essentially the same manner as described for the diene complexes of these metals, whereas the coordinated olefin in the compounds [MCpH(CH_2=CHR)], M = Ta, Nb, is completely inert. The ethylene complex [$TiCp^*_2(C_2H_4)$] (**43**), undergoes a variety of nucleophilic



Scheme 3. Addition reaction of [$TiCp^*_2(C_2H_4)$] **43** to electrophiles.

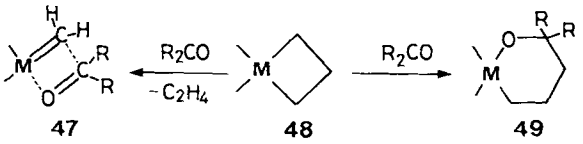
additions, affording oxa- or azametallacycles (Scheme 3).[71] Reactions with ketones and esters are rather complex. *tert*-Butyl and *p*-tolyl cyanide (RCN with bulky R group) undergo direct addition to give **44**, whereas alkyl cyanides with less bulky groups (CH_3, C_2H_5) favor formation of the metallacycloenamine tautomer **45**.

The chemical reactivity of alkyne complexes of Ti and Zr toward electrophiles resembles that of the alkene complexes.[72] The addition of acetone or CO_2 to the 1,2-diphenylacetylene complex **46** led to oxametallacycles. Such a



nucleophilicity has never been demonstrated for the corresponding alkyne complexes of group 5A metals (Ta, Nb) or late transition metals.

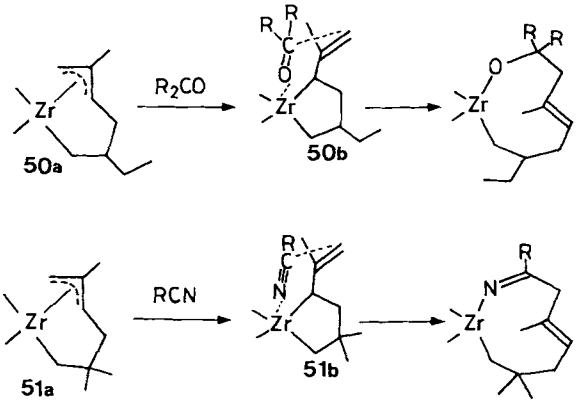
With regard to the alkene complexes, there exist four-membered metallacyclobutanes of type **48** containing W,[73] Ta[74] or Ti[75] which function as alkene-metathesis catalysts or active species for the polymerization or oligomerization of olefins. Stoichiometric reactions of these compounds with electrophiles should provide valuable information about the characteristic properties of their M-C bond, since the complexes are in equilibrium with a methylenemetal-ethylene species. We can observe the enhanced carbene-complex property of **48**, $>M=Cp_2^*Ti$, in the reaction with carbonyl compounds, which is essentially a condensation reaction of the Wittig type (cf. **47**).[75b] Wittig-type reactions are also known for $>M=Cp^*Cl_2Ta$,[74b] 1,3-dititanacyclobutane derivatives[76] and $[Cp_2TiCHR\cdot AlMe_2Cl]$ species.[77] However, such a



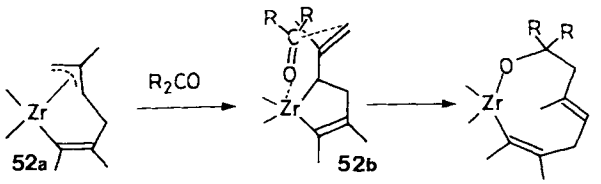
metal-carbene character is virtually lacking in the case of $>M=Cp_2Hf$, i.e., this complex undergoes only normal carbometalation, leading to an oxahafnacyclohexane derivative of type **49**.[78] A related carbenezirconium complex, $[Cp_2Zr=CHCH_2R]$, has recently been isolated by stabilizing it with a trialkylphosphane.[79] Metallacyclopentanes with M = Ti, Zr, Hf (cf. **8**) are less reactive than metallacyclobutanes toward electrophiles and behave similarly to dialkylmetal compounds.

3.5. Metal-Assisted Selective Three-Component Addition

A stepwise three-component addition reaction has been realized by taking advantage of the highly regioselective reaction between dienezirconium complexes and alkenes,



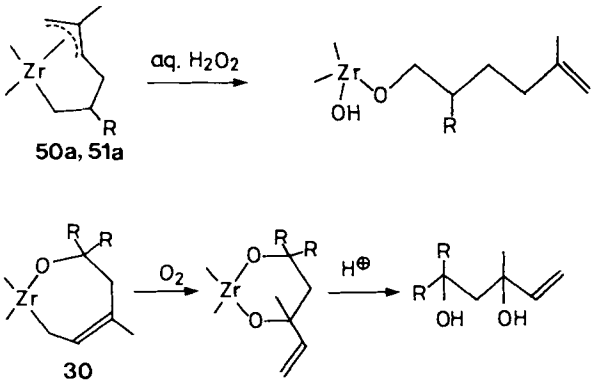
dienes or alkynes (see Sections 4.1 and 4.2). The allylic moiety of the resulting complexes **50a** and **51a** selectively inserts a variety of aldehydes, ketones, esters, and nitriles.[74a] Thus successive diene-alkene-aldehyde, diene-alkene-ketone or diene-alkene-nitrile additions take place in the reaction sphere of $ZrCp_2$ species with excellent regioselectivity (>95%) in ca. 90% yield. Similarly, successive three-component addition of diene-alkyne-aldehyde and diene-alkyne-nitrile has been achieved via the isoprenezirconium complex **52a** with inserted 2-butyne. These processes should have potential utility in organic synthesis, since a variety of combinations can be chosen. It



should be noted that these compounds react in a completely different fashion to the conventional allylzirconium compounds. In **50a**, **51a**, and **52a** the C-C bond formation occurs at the α-position, thus suggesting involvement of the intermediates **50b**, **51b**, and **52b**. In the case of normal allylmetal compounds bond formation takes place at the sterically more crowded γ-position (see, e.g., Scheme 2).

3.6. Oxidation of Complexes of the Early Transition Metals with Hydrogen Peroxide or Air

Generally, oxidation of organozirconium complexes is effected by the addition of aqueous H_2O_2 (30%), *t*BuOOH, *m*-$ClC_6H_4CO_3H$ or even air in some cases. Transformation of an alkylzirconium complex into a zirconium alkoxide, e.g. $[ZrCp_2Me_2]$ into $[ZrCp_2(OMe)_2]$, has already been achieved with these oxidizing agents.[80] However, such protic oxidizing agents are not suitable for the oxidation of allylzirconium, allyltitanium, or dienezirconium complexes, because a protonolysis takes place prior to the oxidation. Therefore, only the alkylmetal part of σ,η³-allyl compounds (**50a**, **51a**) is oxidized with aqueous H_2O_2, whereby monoalcohols are formed in good yield.[81] Oxazirconacycles **30** are however readily oxidized by aqueous

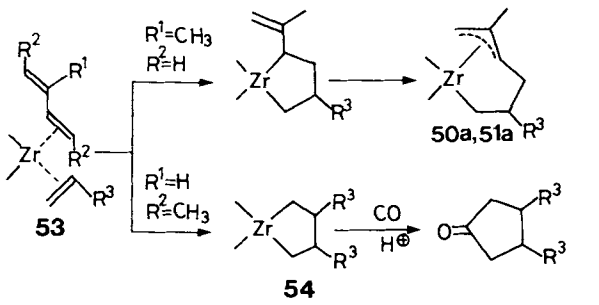


H_2O_2 or by air, whereupon 1,3-diols are formed in high yield (80%) with high selectivity (96%). The diene ligands in $[ZrCp_2(diene)]$, $[TaCl_2Cp(diene)]$, and $[NbCp(diene)_2]$ are readily removed quantitatively in solution by passage of air.

4. Oxidative Coupling of 1,3-Dienes and Alkenes with Unsaturated Hydrocarbons in the "MCp_2" Sphere

4.1. Regioselective Addition of Dienemetal Complexes to Alkenes

Most of the simple alkenes (ethylene, 1-butene, 2-butene, isobutene etc.) rapidly react with both $ZrCp_2$(s-*cis*-diene)] and $[ZrCp_2$(s-*trans*-diene)] complexes (diene = butadiene, isoprene) at ambient temperatures with formation of 1:1 adducts of the type **50a** and **51a**.[82] In the case of the s-*cis*-isoprene complex, the C–C bond formation takes



place quantitatively at the sterically less crowded C-4 atom of the isoprene with >98% regioselectivity. The regiochemistry contrasts sharply with that of the additions to compounds with C–O and C–N multiple bonds. In the case of s-*cis*- and s-*trans*-butadiene complexes the C–C bond formation presumably takes place via the same transition state **53**, $R^1 = R^2 = H$, since the products have the same structure in both cases. Alkenes with internal double bonds (e.g. 2-pentene, 2-hexene) undergo migratory insertion into the isoprene complex **7b** at elevated temperature (>60°C) to give the same compounds as are obtained from alkenes with terminal double bonds (e.g. 1-pentene, 1-hexene). $[Cp_2Zr$(1,4-diphenylbutadiene)], however, is completely inert to these alkenes because of its strong M–C bonding.

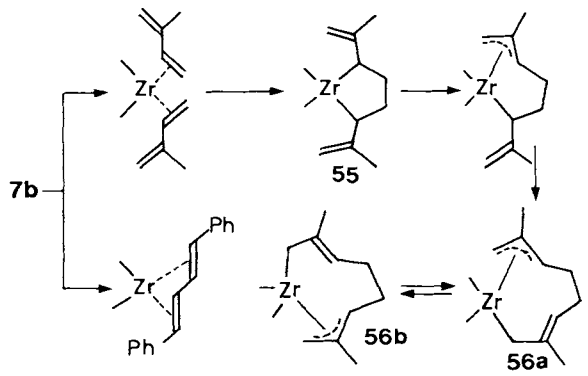
As confirmed by ligand exchange experiments, the relative strength of the diene–zirconium bond is found to decrease in the following order:[83]

1,4-diphenylbutadiene > 2,3-dimethylbutadiene > butadiene > isoprene > 1,3-pentadiene > 1,3-hexadiene > 2,4-hexadiene

The order approximately parallels the π-acidity of the dienes. 2,4-Hexadiene counts among the most weakly bound ligands, so it is very easily displaced by 1-butene or 1-hexene.[17] At the same time, 3,4-dialkylzirconacyclopentanes (**54**) are generated by oxidative coupling between the two 1-alkene molecules in the $ZrCp_2$ sphere. Direct reduction of $[ZrCl_2Cp_2]$ with $NaC_{10}H_8$ or RMgX in the presence of 1-alkenes provides a more convenient route to the compounds **54**.[84] The subsequent carbonylation with CO under atmospheric pressure affords an enolate, which upon hydrolysis furnishes a 3,4-dialkylcyclopentanone in 70–80% yield. The synthesis of cyclopentanones by carbonylation of metallacycles is already well known.[85] The 1,4-diphenylbutadiene and 2,3-dimethylbutadiene ligands are bound to the metal very tightly, and hence they are completely inert toward almost all alkenes. Thus, zirconium complexes of butadiene and isoprene (dienes with a moderate π-acidity) can promote the stoichiometric carbometalation of alkenes.

4.2. Diene–Diene Coupling in the "$ZrCp_2$" Sphere

Conjugated dienes show fairly good reactivity toward $[ZrCp_2$(diene)] complexes. Depending upon the π-acidity of the dienes, either a ligand exchange reaction or a 1:1 coupling reaction takes place.[86] Addition of one equivalent of (*E,E*)-1,4-diphenyl-1,3-butadiene to butadiene-, isoprene-, and hexadienezirconium complexes results in the quantitative displacement of the coordinated dienes, with concomitant formation of $[ZrCp_2$(s-*trans*-1,4-diphenylbutadiene)]. Addition of one equivalent of isoprene to the isoprene complex **7b** at 20°C, on the other hand, promotes 1:1 coupling with formation of the equilibrium mixture **55** ⇌ **56**, (4–4 bonded) together with **75** (3,4-bonded, cf.



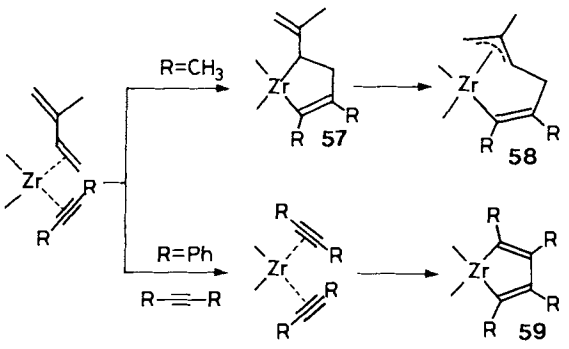
Section 5.3) in a 76:24 ratio. According to the NMR spectrum, the 4–4 bonded compound assumes the thermodynamically more favored structure **56**. The complex **56** could be prepared in a high state of purity by treating $[ZrCl_2Cp_2]$ with a 4–4 bonded isoprene–dimer/Mg adduct,

$[MgC_{10}H_{16}]_n$, at $-20°C$. The corresponding butadiene-dimer complex, $[ZrCp_2(C_8H_{12})]$, is accessible by 1:1 reaction of $[ZrCp_2(butadiene)]$ with butadiene or by reaction of $[ZrCl_2Cp_2]$ with $[MgC_8H_{12}]_n$. The resulting 18e complexes have a fluctional structure: σ-π rearrangement occurs rapidly between **56a** and **56b** even at $-70°C$. The bis(η^3-allyl) structure is favored when these ligands are bound to coordinatively unsaturated species such as Zr(cyclooctatetraene),[87] CpV,[88] etc.

Group 5A metal–diene complexes of the type $[MCl_2(C_5R_5)(diene)]$ and $[M(C_5R_5)(diene)_2]$ (M = Ta, Nb; R = H, Me), are, with exception of $[NbClCp(butadiene)]_2$, generally inert to alkenes and dienes.[89] This is due to the enhanced stabilization of the M–C bonding by strong π-electron donation from internal carbon atoms to vacant metal d-orbitals together with back donation from filled metal orbitals to π* orbitals of the diene C–C bonds. The very strong M–C bonding in these complexes may be the major reason why organic compounds of group 5A metals generally do not catalyze diene oligomerization and polymerization.

4.3. Selective Coupling of Dienes with Alkynes

A series of alkynes readily react with zirconium-diene complexes by way of either a 1:1 addition reaction or a ligand exchange reaction, depending upon the nature of the alkynes.[82,90] Most 1- or 2-alkynes bearing one or more alkyl groups (e.g., 1-butyne, 2-hexyne etc.) react with $[ZrCp_2(s\text{-}cis\text{-isoprene})]$ irreversibly at ambient temperature to give 1:1 addition compounds, where the alkyne binds selectively to the C-4 atom of isoprene. The whole geometry of the resulting σ,η^3-*syn*-allyl compounds **58** (cf. **52a**) is very similar to that of the compounds **50a** and **51a** with inserted alkene. The molecular structure of the complex with inserted 2-butyne is representative of this type of



complexation (Fig. 7). Alkynes with aromatic substituents, however, favor the ligand exchange reaction. A typical example is seen in the stoichiometric reaction between $[ZrCp_2(isoprene)]$ and diphenylacetylene leading to 2,3,4,5-tetraphenylzirconacyclo-2,4-pentadiene (**59**). Analogous zircona- or titanacyclo-2,4-pentadiene derivatives are also accessible by reduction of $[MCl_2Cp_2]$ in the presence of alkynes.[91] Recently, the isolation of alkynezirconium and alkyneytterbium complexes has been reported.

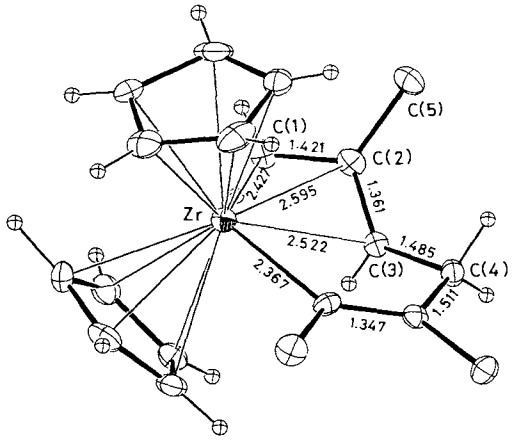


Fig. 7. Molecular structure of a 2-butyne inserted complex of type **58**, $[Cp_2ZrC(CH_3)=C(CH_3)CH_2CH=C(CH_3)=CH_2]$.

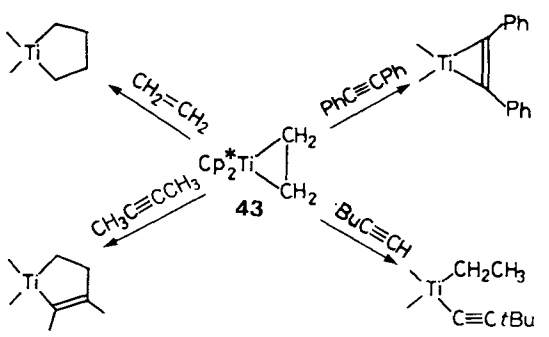
From competition experiments, it can be concluded that the relative reactivity of aliphatic substrates toward $[ZrCp_2(diene)]$ decreases in the following order:

aldehydes > ketones ≈ nitriles ≈ isocyanates > CO_2 > oxiranes ≈ esters ≈ alkynes > dienes > alkenes

4.4. Reactions of Alkenemetal Complexes with Unsaturated Hydrocarbons

$[TiCp^*_2(CH_2=CH_2)]$ (**43**) is a typical alkene complex of an early transition metal which undergoes facile reactions with a variety of unsaturated hydrocarbons.[71] Ethylene reacts reversibly with **43** to yield an equilibrium mixture containing a titanacyclopentane; higher alkenes (propene, butene, etc.), however, are generally inert to **43**, presumably because of the unfavorable steric interaction between the bulky Cp* ligand and the alkyl substituents. Alkynes are more reactive toward **43**; their modes of reaction can be classified into three types (Scheme 4). Alkynes with internal double bonds, whose π-acceptor property is less pronounced, are incorporated into the Ti–C bond to give metallacyclo-2-pentene derivatives, while alkynes which are good π-acceptor ligands exclusively undergo ligand exchange to give, for example, a diphenylacetylene complex, preventing the formation of 2,3-diphenyltitanacyclo-2-pen-



Scheme 4. Coupling reaction between $[TiCp^*_2(C_2H_4)]$ **43** and unsaturated hydrocarbons.

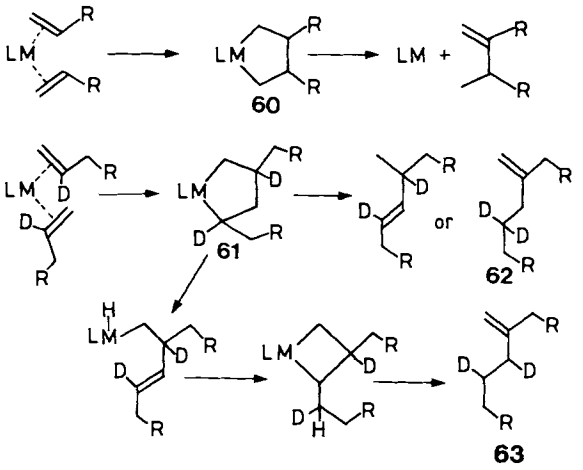
tene. Terminal alkynes, typically *t*BuC≡CH, react with **43** to yield alkynyl(ethyl)titanium compounds. Alkene complexes of Ta and Nb, e.g. $[TaCp_2H(RCH{=}CH_2)]$ and $[NbCp_2H(RCH{=}CH_2)]$, generally do not form metallacycles like the corresponding titanium complexes, but they can undergo ligand exchange reactions with other alkenes and alkynes.[92c]

5. New Aspects of the Catalytic Conversion of Hydrocarbons

5.1. Regioselective Dimerization of 1-Alkenes

The metal-assisted selective linear or cyclic oligomerization of 1-alkenes has recently become a subject of intensive study.[93] Although various homogeneous catalyst systems involving low-valent organonickel[94] and organopalladium species[95] are known to effect the linear dimerization of 1-alkenes, highly regioselective dimerization leading to an isomerically pure head-to-head, head-to-tail or tail-to-tail dimer has been achieved in only a few cases.[96] Recently, selective coupling of propylene has been achieved with $[TaCp^*Cl_2(propylene)]$;[97] the catalytic dimerization leads, with high regioselectivity (95%), to formation of 2,3-dimethyl-1-butene (head-to-head dimer).

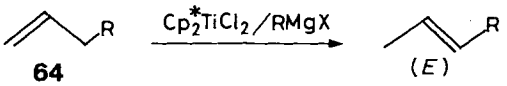
A reaction path via a metallacyclization to give a 3,4-dimethyltantalacyclopentane (**60**) followed by β-hydride elimination has been proposed for the tantalum mediated dimerization.[98] This type of β-elimination has already been confirmed by thermal degradation of titana-[99] and



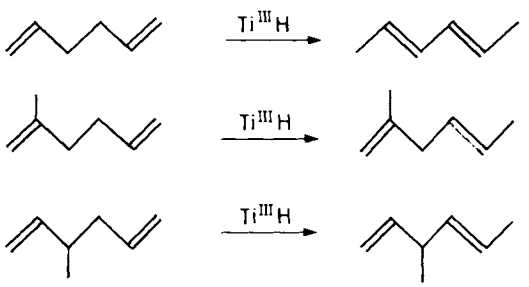
zirconacyclopentanes[100] bearing two Cp ligands. In the case of dimethyl substituted titanacyclopentanes, the formation of 2,4-dimethyltitanacyclopentane is electronically more favorable than that of the 3,4- and 2,5-isomers; according to MO calculations, however, 3,4-dimethyltitanacyclopentane is sterically the more stable.[101] As found in the dimerization of 3,3-dimethyl-1-butene or 1-hexene, when bulky 1-alkenes are employed in the tantalum-mediated dimerization, head-to-tail dimerization predominates over head-to-head dimerization.[98] A novel reaction pathway has been proposed for this reaction based on a labeling experiment using [2-D]-1-hexene. If the head-to-tail dimerization were to arise directly from the β-elimination of the resulting 2,4-dialkylmetallacyclopentane **61**, it should lead to a 4,4-dideuterated 1-alkene derivative (**62**); in practice, however, the two deuterium atoms in **63** are found exclusively at the 3- and 4-positions, thus indicating that the reaction proceeds via a ring closure. A similar ring closure is reported for metallacyclopentanes containing Pt,[102a] Rh,[102b] and Re[102c] atoms. However, an alternative mechanism via an intermolecular ring opening process must be taken into consideration, as has been reported recently for platinacyclopentanes.[102d]

5.2. Selective Migration of the Double Bond of 1-Alkenes

Transition-metal-catalyzed isomerization of 1-alkenes has been extensively studied with soluble metal hydrides[103] or carbonyl metal compounds[104a] and, more frequently, with heterogeneous catalysts.[104b-d] These catalysts generally require a relatively high temperature (>70°C) for initiation of the reaction, and consequently a mixture of isomeric alkenes is formed as a result of the thermodynamic equilibrium. It therefore appears necessary to conduct the catalytic reaction at lower temperatures in order to freeze out the equilibrium. Recently, a catalytic system prepared by reduction of $[TiCl_2Cp_2^*]$ with $NaC_{10}H_8$, *i*PrMgBr, BuLi or $LiAlH_4$ was found to effect a highly stereoselective isomerization of 1-alkenes **64** to (*E*)-2-alkenes



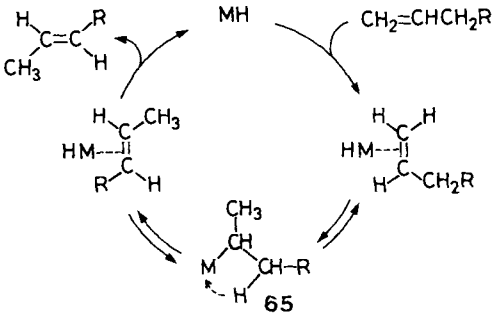
(R=CH_3, C_2H_5, C_6H_5, NEt_2, etc.).[105] The reaction proceeds quantitatively and with extremely high selectivity (>98%) within a few minutes. The maximized turnover is ca. 130 mol/(mol·min) in the case of 1-hexene. 1,5-Hexadiene and 1,7-octadiene are similarly converted into (*E,E*)-2,4-hexadiene and (*E,E*)-2,6-octadiene, respectively, with 99% selectivity. However, this catalyst proved to be inert in attempts to isomerize 2-methyl- and 3-methyl-1-alkenes. Exploiting this property, 2-methyl- and 3-methyl-1,5-hexadiene could be isomerized successfully to pure (*E*)-2- and (*E*)-3-methyl-1,4-hexadiene, respectively, in quantitative



yields. The $[TiCl_2Cp_2]$/*i*PrMgBr and $[TiCl_2Cp_2]/NaC_{10}H_8$ systems containing less bulky auxiliary ligands exhibit similar or higher activity, but the stereoselectivity is much

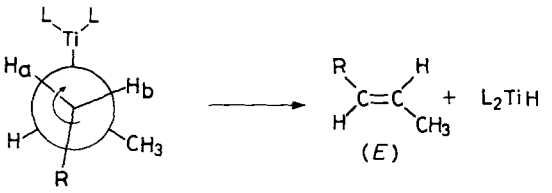
lower (50–75%).[105, 106] The $[ZrCl_2Cp_2]/i$PrMgBr system also promotes selective isomerization (95–99%), but the rate of reaction is less than 1/10 of that observed for the $[TiCl_2Cp^*_2]/i$PrMgBr system.

Two major mechanisms have been proposed for the double bond migration: addition-elimination[103, 107] and 1,3-hydrogen shift.[108a] These two mechanisms are usually differentiated by a deuterium labeling experiment. Since a hydrogen/deuterium scrambling occurs in the closely related reaction between $[TiCp^*_2(CH_2{=}CH_2)]$ (**43**) and a mixture of $CH_3CH{=}CH_2$ and $CD_3CD{=}CD_2$, which presumably proceeds via a hydride species, $[Cp^*(C_5Me_4\text{-}\mu\text{-}CH_2)TiH(CH_2{=}CH_2)]$,[71] the addition-elimination mechanism seems the most likely one for these isomerizations



Scheme 5. Proposed mechanism for the selective isomerization of 1-alkenes to (*E*)-2-alkenes.

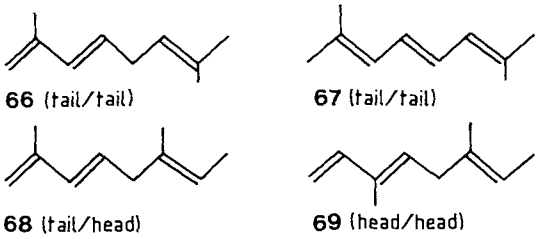
(Scheme 5). A metal hydride reacts reversibly with a 1-alkene to give an alkylmetal derivative (**65**), and then the alkyl group undergoes β-hydride elimination to give either the original 1-alkene or a 2-alkene. The factor which determines the configuration is almost certainly the conformation of the complex **65**, M = Cp^*_2, Ti, with inserted 1-alkene. Informative is the view along the C2–C3 bond. The preferential formation of the (*E*)-isomer will arise from steric re-



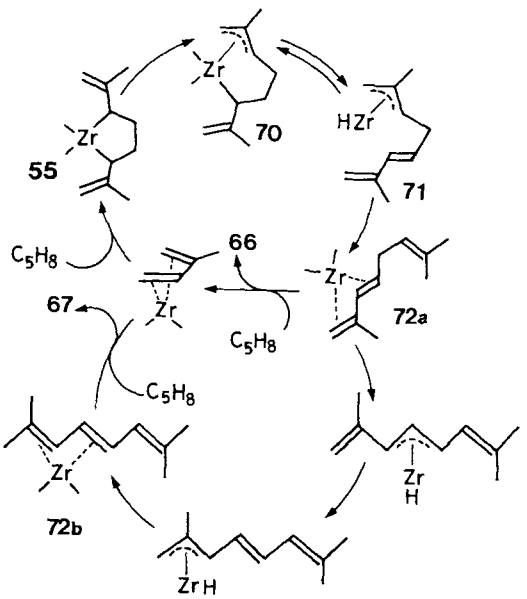
pulsion between R and Cp* or TiCp* as well as between CH_3 and R groups. The RCH_2 group should rotate clockwise for steric reasons to place the Ti and H_a in elipsed position. The subsequent *cis*-elimination yields an (*E*)-2-alkene. For the isomerization of allyl ethers and allylamines, Ir[108b] and Rh[108c] organometallic catalysts were recently found to be more effective than catalysts containing group 3A–5A metals.

5.3. Regioselective Dimerization of Conjugated Dienes

$[ZrCp_2(s\text{-}cis\text{-isoprene})]$ (**7b**) has been found to be a relatively good catalyst for the dimerization of isoprene to 4–4



bonded (*E*)-2,7-dimethyl-1,3,6-octatriene (**66**) at 30 °C and (*E*)-2,7-dimethyl-2,4,6-octatriene (**67**) at 60 °C. An excellent regioselectivity (99%) and ca. 70% conversion was achieved when five equivalents of isoprene were added to the catalyst.[82] A catalytic cycle (Scheme 6) involving a single or double β-elimination sequence has been proposed on the basis of the following findings: 1) The stoichiometric reaction between $[ZrCp_2(s\text{-}cis\text{-isoprene})]$ and isoprene at 10 °C affords **56** (see Section 4.2) or **70** in equilibrium with **56**. 2) The complex **70** is immediately isomerized via **71** to **72a** and **72b** upon warming in benzene to 40 °C without further addition of isoprene. This transformation is confirmed by a chemical trapping experiment with mo-

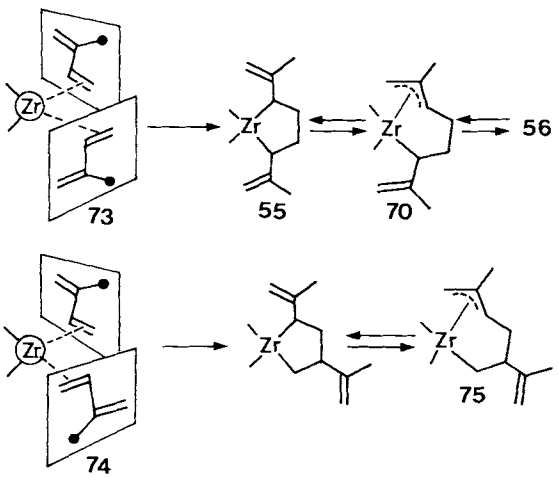


Scheme 6. Proposed mechanism for the selective dimerization of isoprene.

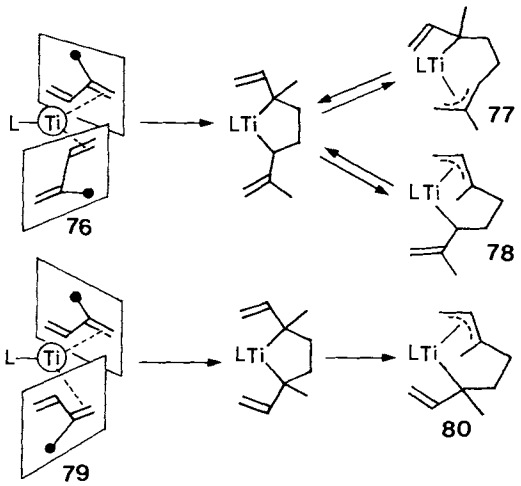
lecular oxygen: a 3 : 2 mixture of **66** and **67** is obtained at the initial stage, but the ratio is reversed (2 : 5) when the solution is kept at 30 °C for prolonged periods of time before treatment with O_2. 3) Addition of 1,4-diphenylbutadiene to **56** leads to a ligand exchange reaction. The 1,4-diphenylbutadiene complex is formed, and **66** and **67** (2 : 5) are liberated. $[HfCp_2(isoprene)]$ also catalyzes the corresponding dimerization at elevated temperatures (80 °C), but the catalytic activity is much lower than that of $[ZrCp_2(isoprene)]$, presumably due to the predominant formation of catalytically inactive metal species of the type **75**.

The mode of reaction changes drastically when diene-titanium complexes are used as catalysts. The complexes are generated in situ by treating [$TiCl_3Cp$], [$TiCl_2Cp$] or [$TiCl_2Cp_2$] with isoprene-Mg adducts or RMgX in the presence of isoprene. These catalysts effect the tail-to-head (**68**) and/or sterically unfavorable head-to-head (**69**) dimerization of isoprene in ca. 3 : 2 ratio, with complete suppression of the tail-to-tail dimerization.[86] The use of bulky auxiliary ligands is highly effective for improving the selectivity. Thus, the sole isomer with tail-to-head bonding was prepared for the first time using [$TiCl_3Cp^*$]/BuMgBr as catalyst. It seems reasonable to postulate that the active species is the isoprene complex of Ti^{III}, not of Ti^{IV}, as can be concluded from the following observations: 1) A Ti^{III} species was detected by EPR spectroscopy. 2) Ti^{IV} compounds are generally easily reduced to Ti^{III} species by treating them with RMgX, Mg etc., while the reduction of Zr^{IV} to Zr^{III} species is quite difficult. 3) The shape and the orientation of the vacant d-orbitals of "$TiCp_2$", as well as the whole geometry, are quite similar to those for "$ZrCp_2$", as predicted from EHMO calculations. This indicates that Ti^{IV} species should, contrary to the observations, produce a tail-to-tail dimer. 4) Isolated [TiClCp*(diene)] complexes of Ti^{IV} (diene = butadiene, isoprene, 2,3-dimethylbutadiene) exhibit very weak or practically no catalytic activity, but the reduction of these complexes with RMgX or Mg leads to excellent catalysis with tail-to-head dimerization.[6]

On the basis of these findings, we can postulate the coordination geometry of the transient bis(diene) complexes. According to molecular models the coordination of two isoprene molecules with geometries **73** and **74** are sterically most favorable for the zirconocene species. The



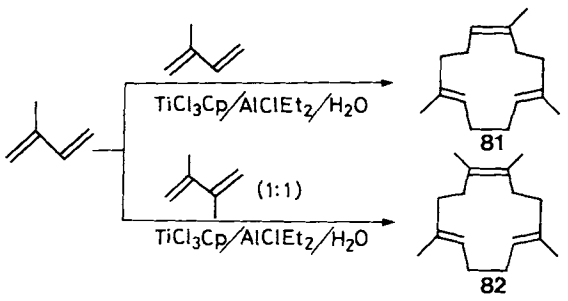
4-4 bonding of isoprene should occur via **73**; subsequent β-elimination from **70** then leads to **72a**. Scheme 6 shows this further reaction to **66** and **67**. If the β-hydrogen elimination proceeds at the metallacycle **55** and the subsequent hydrometalation occurs at the γ-position (referred to **71**), then 1,3,7-octatriene derivatives should be formed instead of the 1,3,6-octatriene derivative **66**. Actually, such a catalytic reaction to produce 1,3,7-octatriene derivatives via an intermediate of type **55** takes place in the Pd-mediated dimerization of 1,3-conjugated dienes.[109a,b] The molecular structure of platinacycles of the type **55** has indeed been confirmed crystallographically.[109c] Unlike **73**, the intermediate **74** will lead to a catalytically inactive complex **75**. The complexes **50a**-**52a**, which are related to **75**, also exhibit no catalytic activity in the dimerization. These results indicate that the methyne group at the β-position is highly resistant to hydrogen elimination. The reaction pathway discussed here is essentially the same as that predicted for the metallacyclization starting from [Cp_2Ti(ethylene)$_2$].[60, 110]



From experimental results, two types of intermediates (**76**, **79**) are conceivable for the titanium-catalyzed dimerization. In the species **76**, two isoprene molecules coordinate in the anti-parallel orientation to avoid the steric repulsion between the two methyl groups. The resulting coordinatively unsaturated 2,5-disubstituted titanacyclopentane should be rapidly transformed into either **77** or **78**. β-Hydrogen elimination from **78** dominates over the elimination from **77**, since the latter has a sterically less favorable conformation. $Zr(OR)_4/AlR_3$ catalysts also promote tail-to-head dimerization.[109d,e] The head-to-head coupling of isoprene most likely proceeds via the intermediate **80**. The coordinatively unsaturated Ti^{III} species has an enhanced σ-acceptor capability and free space around the metal; hence, when the acceptor orbital is suitably positioned, an isoprene molecule can coordinate to a metal at the C1-C2 bond, rather than the C3-C4 bond. This reflects the higher electron density of the Ti^{III} species.

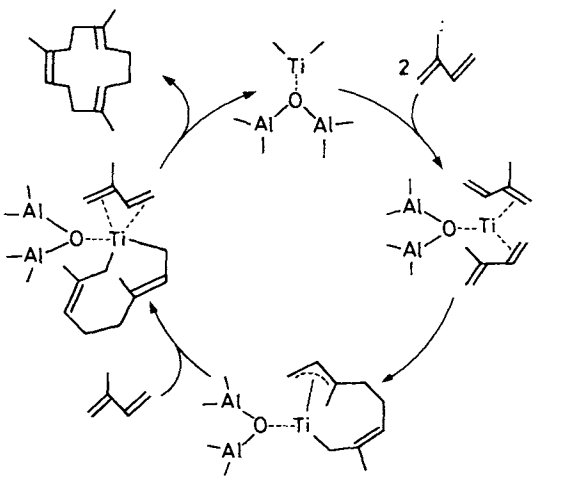
5.4. Highly Selective Cyclotrimerization of Conjugated 1,3-Dienes

Regio- and stereo-controlled catalytic cyclotrimerization of monoalkyl substituted dienes has not yet been accomplished despite concerted efforts by many workers, although several nickel, titanium, and chromium catalyst systems are already known to promote the cyclotrimerization of isoprene and pentadiene, albeit with insufficient regioselectivity.[26, 109f,g] Recently, a novel catalyst system, [$TiCl_3Cp$]/[$AlClEt_2$]/H_2O, was found to be capable of converting isoprene into a single isomer, (*Z*,*E*,*E*)-1,5,10-trimethyl-1,5,9-cyclododecatriene (**81**), with exceptionally high



selectivity (86%).[84] The contaminating product in this system is exclusively 2,4-dimethyl-4-vinylcyclohexene (14%), a compound easily separable by flash distillation. The addition of water is crucial to promote the cyclic trimerization; in the absence of water the reaction furnishes only 2,4-dimethyl-4-vinylcyclohexene in low yield. Both yield and selectivity can be optimized by addition of $[TiCl_3Cp]/[AlClEt_2]/H_2O$ in the ratio 1:3:1. A catalyst prepared by addition of water to a 1:3 mixture of $[TiCl_3Cp]/[AlClEt_2]$ at 20°C exhibits almost the same catalytic activity as that prepared from the product of the reaction of $AlClEt_2$-H_2O (3:1) and $[TiCl_3Cp]$ at 20°C. The addition of products from $AlEt_3$-H_2O and $AliBu_3$-H_2O (3:1) also leads to good catalytic activity but insufficient regioselectivity. Use of alcohols (BuOH etc.) or secondary amines (Bu_2NH etc.) instead of water led to inactivation of the catalysts.

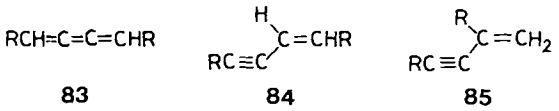
The addition of one to two equivalents of electron donors (NEt_3, pyridine, PBu_3) to the $[TiCl_3Cp]/[AlClEt_2]/H_2O$ system causes a drastic change in the distribution of the products, i.e., a mixture of tail-to-head and head-to-head linear isoprene dimers (cf. **68** and **69**, respectively) was obtained in place of **81**. The association of the EtClAl-O-AlClEt and Ti[11] species is apparently disrupted by the coordination of donor ligands. This behavior would indicate that the diene ligands in the intermediate of the cyclic trimerization have the same coordination geometry as in the intermediate of the linear dimerization. If this assumption is correct, the principle of the catalytic cycle may be represented as in Scheme 7. The present catalytic system is also effective for cyclic homo- and cotrimerization of other dienes. Butadiene is converted with 87% selectivity (90% yield) into (*E,E,E*)-1,5,9-cyclododecatriene, while a 1:1 mixture of isoprene and 2,3-dimethylbutadiene is converted with 85% selectivity into (*E,E,Z*)-1,6,9,10-tetramethyl-1,5,9-cyclododecatriene (**82**) (30% conversion). The polymerization of ethylene and propylene catalyzed by $[MCl_2Cp_2]/AlMe_3/H_2O$ (M = Ti, Zr) is also accelerated by addition of water.[111] These systems, however, require a large excess of $AlMe_3/H_2O$ (1:0.9) component (see Section 6.2).



Scheme 7. Proposed mechanism for the selective cyclotrimerization of isoprene.

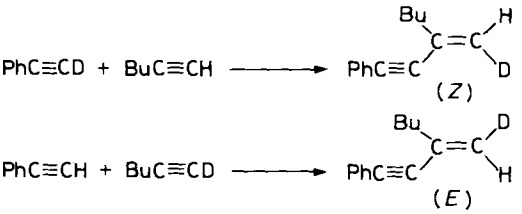
5.5. Regioselective Linear Dimerization of 1-Alkynes

Three different structures are conceivable for the linear dimers of 1-alkynes when steric interference is taken into consideration. A dimer of the type **83** has been prepared in good yield with $[RuH_2(CO)(PPh_3)_3]$[112] and a dimer of the type **84** with $[RhCl(PPh_3)_3]$[113] or $[Cr(OtBu)_4]/ZnEt_2$.[114] The $[TiCl_2Cp^*_2]/[AlEt_2Cl]$ (1:3) system exhibits an excellent catalytic activity and effects the highly regioselective (>99%) dimerization of RC≡CH to 1-buten-3-yne derivatives **85**, R = C_2H_5, C_3H_7, C_6H_{11}, C_6H_5, Me_3Si, Me_3SiCH_2, etc., in quantitative yield.[115] The use of a bulky ligand



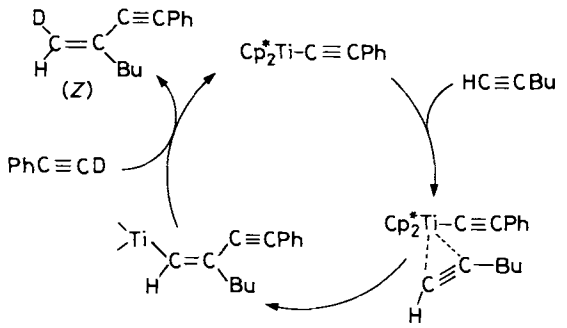
83 **84** **85**

such as Cp* is essential for achieving this type of selective dimerization. When Cp* is replaced by the less bulky Cp ligand only a mixture of cyclic trimers, i.e. 1,3,5- and 1,2,4-trisubstituted benzene is obtained. By exploiting the excellent catalytic activity of $[TiCl_2Cp^*_2]/[AlClEt_2]$, highly selective codimerization of two alkynes has been realized for the first time. A combination of acidic 1-alkynes and less



acidic 1-alkynes provides the best result concerning both selectivity and yield. For example, highly stereo- and regioselective codimerization occurred in quantitative yield when a 1:1 mixture of PhC≡CD (acidic alkyne) and BuC≡CH (less acidic alkyne) or of PhC≡CH and BuC≡CD was used. The (*Z*)- and (*E*)-dimers, respectively, were formed in 98% yield. The reaction completely suppresses the homodimerization of each alkyne. A proposed mechanism for the formation of the (*Z*)-isomer is illus-

trated in Scheme 8. The active species should be the complex [$Cp^*_2TiC{\equiv}CPh$], generated by reaction of [$Cp^*_2Ti^{III}R$] or [$Cp^*Ti^{III}H$] with PhC≡CD, isolation of which is quite difficult.[116] The thermally more stable [$Cp_2M(C{\equiv}CPh)_2$]

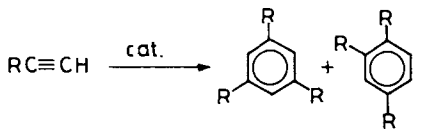


Scheme 8. Proposed mechanism for the selective linear codimerization of 1-alkynes.

species, $M = Ti^{IV}$, Zr^{IV}, are almost catalytically inactive. Insertion of BuC≡CH into the TiC≡CPh bond followed by Ti–C bond cleavage by PhC≡CD leads to regeneration of the [$Cp^*_2TiC{\equiv}CPh$] species.

5.6. Cyclic Trimerization of Alkynes

The selective cyclization of 1-alkynes is of special interest, since the products are of potential commercial utility. Various transition-metal complexes in both high and low oxidation states are known to catalyze the cyclotrimerization of 1-alkynes; however, an efficient regiocontrol has not yet been achieved.[117] $TaCl_5$ and $NbCl_5$ exhibit rela-

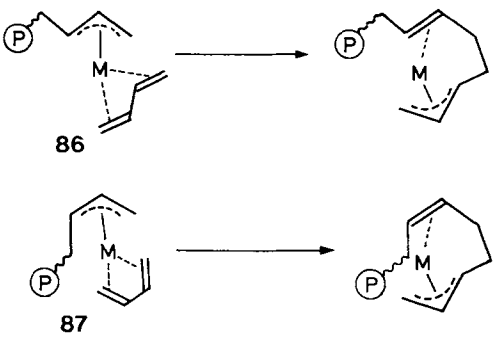


tively high selectivity (ca. 90%) in the conversion of 1-butyne into 1,2,4-triethylbenzene, while the closely related compounds [$TaCl_4Cp$], [$NbCl_4Cp$], [$TiCl_3Cp$], and [$TiCl_4$] are practically inactive. A binuclear low valent niobium complex, [NbClCp(butadiene)]$_2$, and the [$NbCl_4Cp$]/[$AlClEt_2$] system show a similar selectivity in the cyclization of 1-butyne to 1,2,4-triethylbenzene.[117d] Several mechanisms have been proposed for the alkyne cyclization, but the issue is still controversial. The most commonly accepted mechanism involves a metallacyclopentadiene with low valent metal as intermediate which can undergo reductive elimination by the attack of a third alkyne molecule.[118a,b] However, the π-complex multicenter mechanism, in which alkyne molecules are assembled into a ring on one or more metals cannot, as yet, be ruled out.[118c]

6. Stereocontrolled Polymerization of Dienes, Alkenes, and Alkynes

6.1. Stereoselective Polymerization of Conjugated Dienes

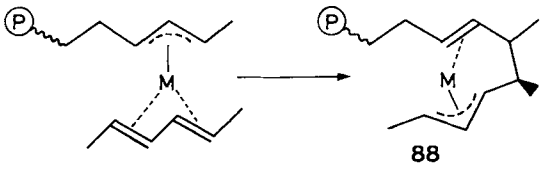
Several mechanisms have been proposed for the stereoselective polymerization of conjugated dienes. The η^4-s-*cis*-coordination (type **1**) of dienes to the metal was postulated to be the determining factor for formation of the *cis*-1,4-polymer[119] and the η^2-s-*trans* coordination (type **6**) for formation of the *trans*-1,4-polymer.[120] In the meantime it has been shown (see Section 2.1) that early transition metals (Zr, Hf, Mo) occasionally prefer the η^4-s-*trans*-(type **4**) rather than the η^2-s-*trans*- (type **6**) or η^4-s-*cis*-butadiene coordination (type **1**). In agreement with this trend, butadiene forms a *trans*-1,4-polymer with $TiCl_4$/$AlEt_3$,[121a] $TiCl_3$/$AlEt_3$,[121b] and VCl_3/$AlEt_3$ catalyst systems.[122] EHMO calculations on the s-*cis*- and s-*trans*-butadiene complexes of $[ZrCl_4]^{n-}$ (n = 0, 1, 2) with C_{2v} symmetry have revealed that the total energy for the s-*trans* complex is similar to or slightly smaller (1.0–2.0 kcal/mol) than that for the s-*cis* complex but significantly smaller than that for the η^2-s-*trans*-butadiene complex [1.8 for Zr^{IV} (n = 0), 9.9 for Zr^{III} (n = 1), and 18.4 kcal/mol for Zr^{II} (n = 2)].[7c] Therefore, the η^4-s-*trans*-diene coordination of type **4**, as in **86**, is regarded as an important factor in the



trans-polymerization of butadiene (Ⓟ signifies polymer). The s-*trans*-diene ligand is smoothly transformed into a *syn*-η^3-allyl complex by insertion into the polymer end. Very high thermal instability and chemical reactivity preclude isolation of the active species. For the *cis*-1,4-polymerization, the reaction pathway via **87** has been proposed. [ZrCp(η^3-butenyl)(s-*cis*-butadiene)], a Zr^{IV} species, has a structure very similar to that of the intermediate **87**,[9f,123] but shows no catalytic activity in the polymerization. A more electron-deficient low-valent allyl(diene)metal species should, on the other hand, be catalytically active.

A terminally disubstituted butadiene, e.g. (*E,E*)-2,4-hexadiene, has been polymerized to a stereoregular polymer with an *erythro-trans*-1,4-diisotactic structure by catalysis with [Ti(acac)$_3$]/[$AlEt_2Cl$] or [Co(acac)$_2$]/[$AlEt_2Cl$].[124] 2,4-Hexadiene, however, favors the s-*trans* coordination to $ZrCp_2$ species.[17] Furthermore, it is reported that the (*E,E*)-isomer of $ZrCp_2$(2,4-hexadiene) is thermally more stable than the (*E,Z*)- or (*Z,Z*)-isomer.[125] The good corre-

lation between the preferred geometry of the complex and the s-*trans* structure of the polymer suggests that the titanium-catalyzed 2,4-hexadiene polymerization may proceed via an intermediate of type **86**. The diene should be coordinated to the metal in an η^4-s-*trans*-(*E*,*E*)-fashion and



88

eventually transformed into the *syn*-allyl species **88** during the insertion into the polymer end. The *trans*-1,4-polymerization of 1,3-pentadiene catalyzed by $VCl_3/AlEt_3$[126] or $[VO(acac)_2]/[AlEt_2Cl]$[127] may be rationalized in essentially the same way as the alternating copolymerization of butadiene and propylene.[128]

6.2. Novel Catalytic Systems for Alkene- and Alkyne-Polymerization

Notable topics in this area involve the discovery of highly reactive systems for homogeneous catalysis (Kaminsky catalysts) having the composition $[MCp_2R_2]/AlMe_3$–H_2O (M = Ti, Zr; R = CH_3, Cl)[111] and a novel reaction mechanism proposed for the polymerization of alkenes[102b, 129a] or alkynes[130] via metallacyclic species. The Kaminsky catalyst is prepared from a large excess of aluminoxane and a metallocene compound (Al : M = 1000 : 1). Its activity in ethylene polymerization is 1000 times higher per Ti atom than that of a typical Ziegler catalyst system, $TiCl_4/AlEt_3$. Isotactic propylene polymerization in homogeneous solution has been realized for the first time with this system, but the exact reaction mechanism still a matter for debate.

In place of the well known Cossee's mechanism, an alternative mechanism via metallacycles has been proposed for the transition-metal-catalyzed alkene polymerization.[131] The reaction pathway via titanacyclobutane species well accounts for the kinetic studies on ring opening polymerization of norbornene and cyclopentene,[129a] but is untenable for the polymerization of linear alkenes.[129b, c] A similar metallacycle-mechanism via tungstenacyclo-1,3-butadiene has also been proposed for the alkyne polymerization with olefin metathesis catalysts.[102b, 130]

7. Conclusion

The chemistry of complexes of the early transition metals is now in a state of rapid development. A variety of highly regio- and stereoselective stoichiometric as well as catalytic reactions has already been realized using specifically designed complexes of the type mentioned in this article. Continued efforts in the preparation and characterization of coordinatively more unsaturated organometallics (e.g., with Ti^{III}, Zr^{III}, Ta^{IV}, Ta^{III}) surely promises further development in this field.

We are indebted to many coworkers whose names are listed in the references. Thanks are also due to Prof. N. Kasai and Prof. Y. Kai of Osaka University for their cooperation in the X-ray diffraction studies and to Prof. P. Legzdins of the University of British Columbia for valuable discussions.

RP-Bridged Metal Carbonyl Clusters: Synthesis, Properties, and Reactions

By Gottfried Huttner* and Konrad Knoll

Dedicated to Professor Larry F. Dahl

Metal carbonyl clusters possess a complicated chemistry that is only beginning to be understood. One of the main current goals in this area is thus an understanding of their reactivity. This article describes the syntheses and reactions of clusters that contain metal carbonyl fragments bridged by a main-group element. But what is the sense of making such clusters still more complicated by the incorporation of main-group elements? The example of μ_3-bridged carbonyl clusters will serve to show that the main-group element plays an important role in the study of reaction paths; it holds the metal carbonyl fragments together even when the bonds between them are broken in the course of a reaction. Trinuclear μ_3-bridged clusters prove to be small enough to allow the analysis of typical cluster reactions (such as the reversible breaking of metal-metal bonds) in terms of single reaction steps. They are also large enough to provide surprises by their multifaceted reactivity. It will be shown that a detailed study of trinuclear RX-bridged metal carbonyl clusters (X = N, P, As, Sb, Bi)—a very small part of carbonyl cluster chemistry—can lead to a better understanding of the general reaction principles involved.

1. Introduction

Low-nuclearity transition-metal carbonyl clusters are regarded[1] as model systems whose study can provide insights into the complicated reaction processes at catalytically active metal surfaces.[2] This fact, together with the hope of employing the clusters themselves in catalytic processes,[3b,4] has led to a considerable research potential in this area. An astonishing variety of cluster frameworks have been synthesized and structurally characterized.[5,6] However, only a few reactions have been analyzed in detail.[7,8] This fact is surprising in view of the large number of known clusters; why is it that we know so much about the structure of clusters and so little about their reactivity? The most important reasons are as follows:

- Large clusters have an aesthetic appeal; the synthesis of even larger and more attractive clusters is so entertaining that researchers easily forget to investigate reactivity.
- Clusters are polyfunctional molecules; all metal-metal and metal-ligand bonds[9] are potential sites of reaction. Selective reactions are unlikely to be achieved without the use of protecting groups.
  Clusters can fragment; metal-metal bonds may break in the course of a reaction at a metal cluster. Therefore, the question often arises whether the reaction has taken place at the cluster itself or at one of its mononuclear fragments.

The goal of understanding the reactions of clusters thus requires that several restrictions be imposed:

- The chemist must abstain from the pleasures of large, attractive clusters and concentrate instead on the satisfaction gained on achieving an insight into their reactivity. Reactions are attractive too!
- The systems to be studied must be restricted to "simple" clusters with the fewest possible reactive sites.
- The variety of potential reactions must be restricted, even for "simple" systems, by the use of suitable protecting groups.

It was with this goal in mind that the reactions of RP-bridged trinuclear clusters, which form the basis of this review, have been studied.

Clusters such as those shown in Figure 1 fulfill the requirement of "simplicity," since their triangles of metal atoms represent the simplest possible case of a metal surface. The μ_3 ligand functions as a "protecting group" that can hold the metal atoms together even when the metal-metal bonds break in the course of a reaction.

1.1. The Scope of this Review[10]

Although the species R-El (El = element of the third to the sixth main group) and also the elements El themselves can in principle function as μ_3-bridging ligands Z in trinuclear clusters, most cluster-specific reactions have been carried out using RP-bridged carbonyl clusters. It is this aspect of cluster chemistry that is reviewed here for the first time. Reactions at clusters with bridging elements of the sixth main group are included here only when they contribute directly to the understanding of the reactivity of the fifth-main-group analogues. Reactions of the well-

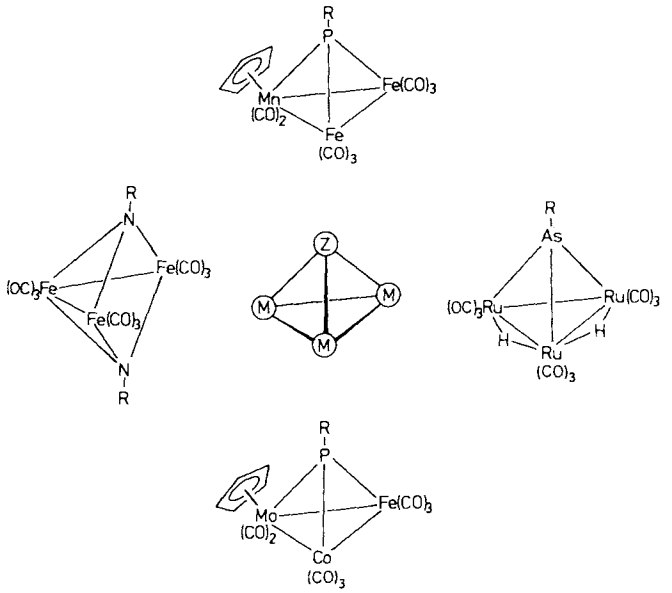

Fig. 1. Examples of μ_3-bridged clusters $[(\mu_3\text{-Z})M_3]$.

studied system $[(\mu_3\text{-RC})Co_3(CO)_9]$ are not discussed, since they have been reviewed already[11] and are generally not cluster-specific insofar as they mostly involve reactions at the organic group R. The μ_2-RX-bridged complexes (X = P, As, Sb, Bi) are not clusters; they are unsaturated systems by virtue of their trigonal-planar coordination at X and their chemistry has also been reviewed.[12, 13]

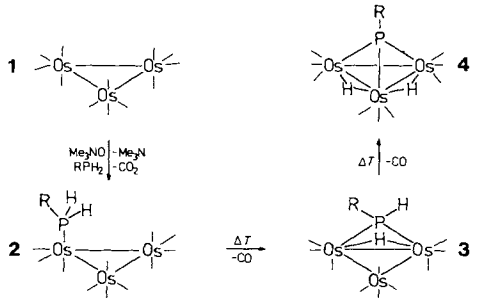
This review concerns itself not only with the reactivity of RX-bridged clusters (X = N, P, As, Sb, Bi; X always stands for an element of the fifth main group), but also with their synthesis, since this subtopic, too, has not yet been reviewed (except for X = N[14]).

2. Synthesis of Clusters with μ_3-RX Bridges

The first compound with a μ_3-RP group, $[(\mu_3\text{-}C_6F_5P)_2Fe_3(CO)_9]$, was synthesized in 1971 by the reaction of the corresponding oligocyclophosphane with iron carbonyls.[15] Although oligocyclophosphanes are established sources of RP fragments,[16] they have not been further used in the synthesis of μ_3-RP-bridged clusters. However, numerous unusual compounds with RX oligomers (X = P, As) as ligands have been prepared.[17] Another preparative method that immediately suggests itself is the reaction of metal carbonyls with RXH_2; this method was also employed very early.[18] Reactions between neutral or anionic metal carbonyls and $RXHal_2$ form another well-documented synthetic approach.[19]

2.1. Syntheses from RXH_2

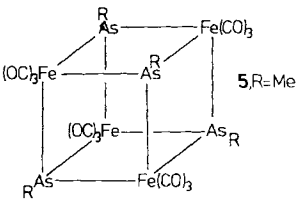
The reaction of $[M_3(CO)_{12}]$ (M = Fe,[20] Ru,[21, 22] Os[22, 23]) with RPH_2 has proved a reliable method of obtaining μ_3-RP-bridged clusters; it leads smoothly and by an easily understood route to the compounds $[(\mu_3\text{-RP})M_3(CO)_9(H)_2]$. Although the reaction with $[Fe_3(CO)_{12}]$ leads, without a detectable intermediate, to good yields of the final product,[20] the reaction steps can be analyzed in detail if the kinetically and thermodynamically more stable $[Os_3(CO)_{12}]$ **1** is used as the carbonyl component (Scheme 1).[22, 23] The



Scheme 1. Stepwise formation of μ_3-RP bridges from RPH_2 [*].

first step is the substitution of an axial carbonyl group by the RPH_2 ligand, which is made possible by oxidation of the carbonyl group to CO_2 by Me_3NO.[24] The intermediate **2** can be thermally decarbonylated; the electron deficit that arises is compensated by the formation of a new Os–P bond and the migration of a hydrogen from phosphorus to a μ_2-bridging position, forming **3**. Intermediate **3** can then undergo thermal decarbonylation, migration of a further hydrogen from phosphorus to a metal–metal edge, and formation of a third Os–P bond to give the final μ_3-RP-bridged cluster **4**.[22, 23]

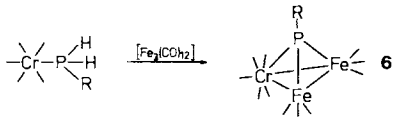
The same reaction pattern has also been demonstrated for the reaction of $[Ru_3(CO)_{12}]$ with RPH_2.[21] The individual steps that have been discussed here in detail are also likely to occur in other reactions where μ_3-RX bridges are formed from polynuclear metal carbonyls and RPH_2[20] or $RAsH_2$,[23] even when the intermediate stages cannot be proved. One such example is the thermolysis of $[(OC)_4Fe(AsMeH_2)]$ to the cubane structure **5**.[25]



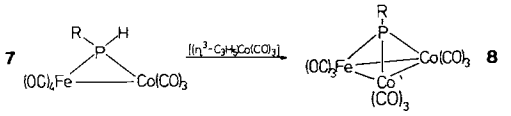
Reactions in which RX groups are formed from RXH_2 precursors can be modified to allow the synthesis of heterometallic RX-bridged clusters: complexed phosphanes or arsanes $[L_nM(RXH_2)]$ react with $[Fe_3(CO)_{12}]$ with the formation of heterometallic μ_3-RX-bridged clusters. In such reactions, the organometallic fragment L_nM is incorporated into the cluster together with the RX group and occupies one position of the triangular base of the μ_3-RX-bridged cluster. An example is the synthesis of **6**.[26] Complexes of primary phosphanes or arsanes react smoothly in this way with $[M_3(CO)_{12}]$ (M = Ru, Os).[26]

Binuclear phosphide complexes (e.g., **7**) with a P–H bond can be used instead of complexes of terminally

[*] Here and elsewhere in the text, a short line extending from a metal atom signifies a CO group.



bonded primary phosphanes; their reactions with reactive metal carbonyls lead to μ_3-RP-bridged clusters such as **8**.[27] Although these reactions often give good yields,

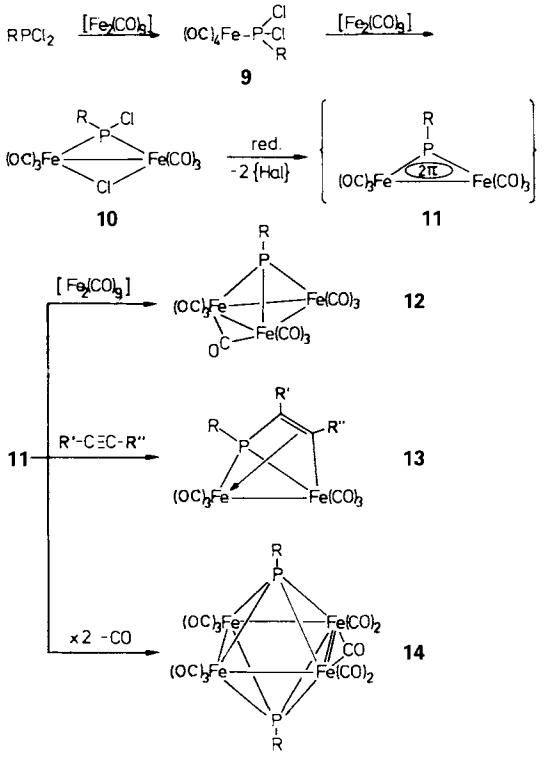


nothing appears to be known about the mechanism. The first step cannot be a simple substitution, because the starting materials $[L_nM(RXH_2)]$ cannot act as donors. The stoichiometry of the reactions show that the bond between M and X is preserved during the reaction. The deciding factor might well be the relative weakness of the P–H or As–H bond, and it seems plausible that radical reactions are involved. Radical insertions into P–H bonds have been thoroughly studied.[28] Furthermore, the radicals $[L_nM(RXH)]^{\odot}$ are expected to be electronically stabilized.[29]

2.2. Syntheses Starting from $RXHal_2$

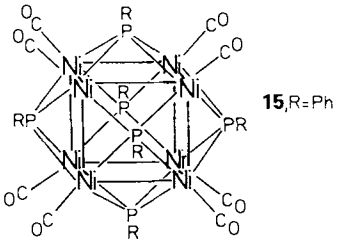
The reactions of metal carbonyls or carbonylmetalates with halides of the heavier main-group elements have been described in the classical studies of *W. Hieber* et al.[30] Early systematic studies of the system $XHal_3/[Co(CO)_4]^{\ominus}$ by *L. Markó* et al.[32,35,36] led to a detailed knowledge of the element-bridged clusters $[(\mu_3\text{-}X)Co_3(CO)_9]$.[31–36] The early structure analyses in this field were almost all performed by *L. F. Dahl* et al.;[34,35] they also recognized the suitability of such reactions for the formation of unusual ligands such as complex-stabilized As_2 in $[Co_2(CO)_6(\mu_2\text{-}\eta^2\text{-}As_2)]$.[35] This synthetic route was not applied to the preparation of μ_3-RX-bridged clusters until fairly recently.[37–39] Scheme 2 shows the detailed course of such reactions for a well-studied example.[40]

Dihalophosphanes react with $[Fe_2(CO)_9]$ to give the $Fe(CO)_4$ derivatives **9**.[40] Further $[Fe_2(CO)_9]$ then reacts to give the binuclear, $(\mu_2\text{-Cl})(\mu_2\text{-RPCl})$-bridged clusters **10**;[40] the first step in their formation can be regarded as the insertion of a carbene-analogous[41] $Fe(CO)_4$ unit into a P–Cl bond. A subsequent decarbonylation, with the formation of a metal–metal bond and the incorporation of a previously terminal chlorine into a bridging position, would then explain the formation of **10**. The reductive dehalogenation of **10** presumably leads to the unsaturated 2π-system **11**, the existence of which is indicated by trapping reactions. Reaction with $[Fe_2(CO)_9]$, which acts as a source of $Fe(CO)_4$, gives the μ_3-RP-bridged cluster **12**.[40] Alkynes stabilize **11** by trapping it as the adduct **13**.[42] In the absence of trapping reagents, **11** undergoes dimerization and decarbonylation to give the doubly μ_4-RP-bridged cluster **14**,[40] which is also accessible by another synthetic route[43] (see Section 9). The products **12**–**14** are all formed in good yields.



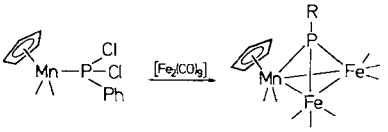
Scheme 2. Stepwise formation of μ_3-RP bridges from $RPCl_2$.

Only in isolated cases can the intermediate stages of the reductive dehalogenation of $RXHal_2$ to μ-RX groups be demonstrated in detail. The reaction of $[Ni_3(CO)_6]_2^{2\ominus}$ with $PhPCl_2$ forms the cluster **15** as the only identifiable product;[44] it consists of a cube of eight Ni(CO) units bridged on all six faces by μ_4-Ph groups.[45]



15, R = Ph

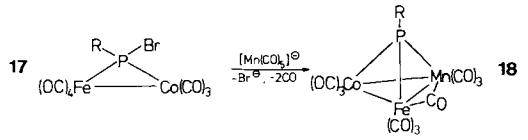
As discussed in Section 2.1 for RXH_2, syntheses based on $RXHal_2$ can also be modified to give heterometallic μ_3-RX-bridged clusters. The first example of such a synthesis is the reaction of $[Cp(OC)_2Mn(PhPCl_2)]$ ($Cp = \eta^5\text{-}C_5H_5$) with $[Fe_2(CO)_9]$ to give **16**.[46] Further applications of this synthetic principle are known.[47–50]



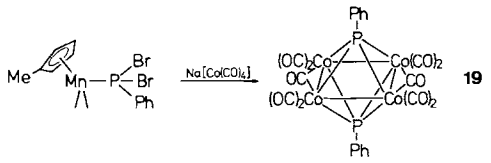
16a, R = Ph

The use of binuclear heterometallic μ_2-phosphido complexes with suitable functional groups on the phosphorus atom provides a simple way of synthesizing μ_3-RP-bridged

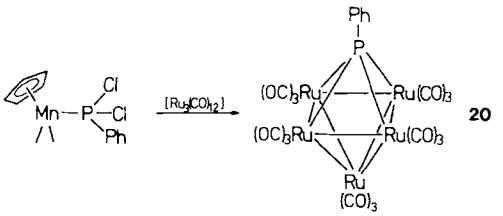
clusters with three different metal atoms; one example is the formation of **18** from **17**.[51] It is not always possible,



however, to introduce RX and L_nM simultaneously into the cluster. The reaction of $[MeC_5H_4)(OC)_2Mn(PPhBr_2)]$ with $Na[Co(CO)_4]$, for example,[52] leads to the well-known cluster **19**, which is more easily prepared by a different

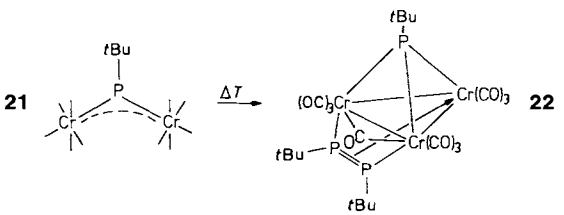


method.[53] The μ_4-RP-bridged cluster **20** arises in a similar manner in the reaction of $[Cp(OC)_2Mn(PhPCl_2)]$ with $[Ru_3(CO)_{12}]$.[54]

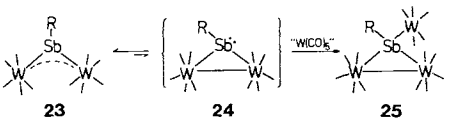


The chemistry of trinuclear μ_3-bridged clusters is connected in several respects with that of binuclear phosphinidene, arsinidene, stibinidene and bismuthinidine complexes $[(L_nM)_2XR]$ (L_nM = 16-electron fragment such as $Cp(OC)_2Mn$, $(OC)_5Cr$):[12, 13]

- The binuclear complexes, in which the main-group element X displays trigonal-planar coordination, are sometimes prepared by similar methods[12, 13] to those used for the μ_3-bridged clusters.
- Trinuclear μ_3-RX-bridged clusters can be regarded as π complexes of such "inidene" complexes[46] (see Section 9).
- Binuclear "inidene" complexes[12, 13, 55] such as **21** can be used to prepare μ_3-RP-bridged clusters (**22**).[56]

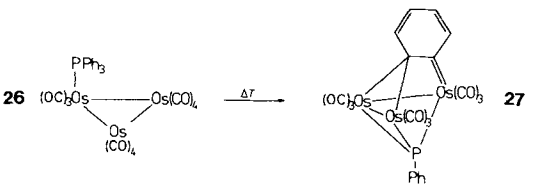


- The stibinidene complexes **23** are in equilibrium (via a valence tautomerism) with metallacyclic stibanes **24**;[12, 13] these can, as Lewis bases, be trapped with 16-electron fragments, forming μ_3-RSb-bridged complexes (**25**).[57]

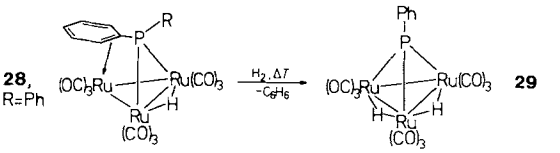


2.3. Synthesis by Cleavage of P–C or P–O Bonds

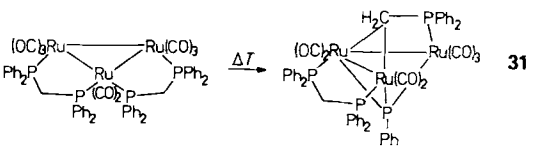
In connection with the use of phosphanes and phosphites as supporting ligands in catalytically active systems,[58] it is interesting to note that R_3P-substituted clusters are converted into μ_3-RP-functionalized complexes on heating.[59] Monodentate phosphanes or phosphites, as well as bidentate phosphane ligands, can fragment to form μ_3-RP groups. For example, the thermolysis of $[Os_3(CO)_{11}(P(OMe)_3)]$ leads to a complex analogous to **20** (POMe instead of PPh, Os instead of Ru).[60] The thermolysis of $[Os_3(CO)_{11}(PPh_3)]$ **26** leads to the cluster **27**, in which the osmium triangle has been opened on one edge and is bridged on one side by a μ_3-PhP group and on the other by an unusually bonded aryne moiety.[61]



The formation of μ_3-RP groups from R_3P ligands clearly takes place in a stepwise manner. The conversion of **28** to **29**[62] shows that R_2P-bridged complexes can play a role here. The phosphido complex **28**, R = Ph, the first example of η^2-coordination of an aryl group bonded to phosphorus (see also Section 8.2), undergoes hydrogenolysis with elimination of benzene to form the μ_3-PhP-bridged complex **29**. (The synthesis of the analogous osmium complex **4** has been described in Section 2.1.).



Bis(phosphino)methane ligands can also fragment in the presence of metal carbonyls to form μ_3-RP groups. The first example of a reaction of this type is the synthesis of **31** from **30**.[63]

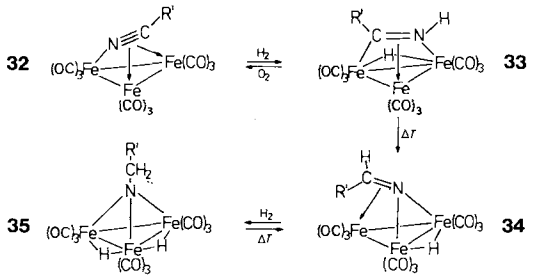


The extension of this principle to the reaction of iron carbonyls with chelating ligands $RHPCH_2PHR$ leads to a wide variety of compounds with μ_3- or μ_4-RP groups; these generally contain further fragments of the ligands, which exhibit widely differing types of coordination.[64]

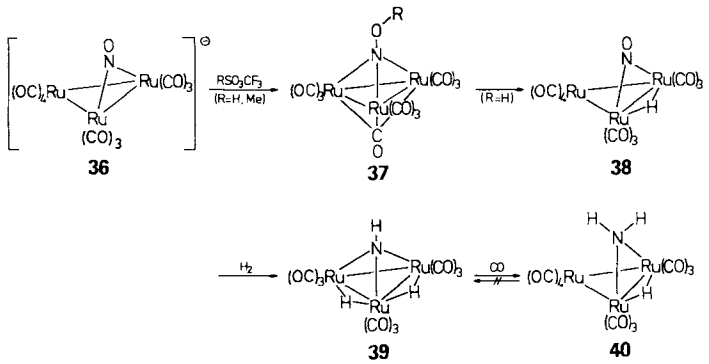
3. Synthesis of Clusters with μ_3-RN Bridges

The synthetic routes to μ_3-RX clusters (X = higher homologues of group five) described in Section 2 are in general not applicable for μ_3-RN-bridged clusters. The energy required to break the stable N–H bonds is usually not compensated by the energy released upon conversion of an amine to a μ_3-bonded nitrene RN. Only for complexes of the heavier transition elements, which tend to form stronger bonds, are such transformations possible. The use of $RNHal_2$ as a starting material (analogously to the method described in Section 2.2) is impossible because of its strongly oxidizing nature. On the other hand, there are many synthetic equivalents for RN (NO,[65,66] RNO_2,[67] RN_3,[68] RCN,[69,70] $(RN)_2S$,[67,71] etc.) that may be used to form μ_3-RN groups and for which there generally are no stable analogues in the chemistry of the heavier homologues. The great variety of synthetic approaches that have been developed along these lines have been reviewed several times,[14] and therefore only selected examples will be presented here.

H. D. Kaesz et al. have carried out an elegant study of the reaction steps involved in the conversion of cluster-bonded nitrile (**32**) to a μ_3-RN ligand (**35**);[69] the most important intermediates are **33** and **34**.[72]



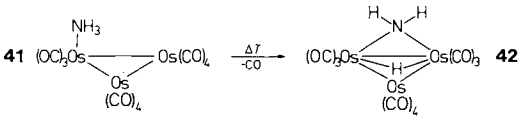
A further well-studied example is the conversion of NO groups to RN moieties.[66] The μ_2-NO group of the anionic complex **36** undergoes electrophilic addition to give the μ_3-RON ligand system of **37**. The μ_3-HON system **37** is



Scheme 3. Stepwise conversion of NO to RN groups.

converted into the tautomeric **38** under base catalysis (e.g., by treatment with $F_3CCOO^{\ominus}$); **38** is apparently more stable thermodynamically than **37** in this case. Cluster **38** reacts with H_2 to give the μ_3-HN-bridged complex **39**. The individual steps of this reaction have not been elucidated, but it is certain that the last step in the formation of the μ_3-NH group does not involve the conversion of μ_2-H_2N to μ_3-HN: Cluster **39** reacts with CO to give the μ_2-H_2N-bridged complex **40**, which, in contrast to its phosphorus analogue **3** (Section 2.1), does not undergo decarbonylation and H migration to form a μ_3-bridged complex (**39**).

Similarly, the thermolysis of **41** ($T = 170$ °C) produces only the μ_2-H_2N-bridged complex **42** (by a single H migration),[74] whereas the μ_2-RHP-bridged complexes analogous to **42** are transformed under relatively mild conditions to the μ_3-RP-bridged complexes (by a further H migration).[22,23] It is however possible for μ_2-RHN groups to



be converted into μ_3-RN groups by thermal activation, as is shown by the decarbonylation of $[(\mu_2\text{-MeHN})(\mu_2\text{-H})Os_3(CO)_{10}]$ to $[\mu_3\text{-MeN})(\mu_2\text{-H})Os_3(CO)_9]$ at $T = 150$ °C.[67] These reactivity differences can be understood in terms of the relative stabilities of the bonds: N–H bonds are more stable than P–H bonds, and M–P bonds (M = Os or Ru) are more stable than M–N bonds.

4. Properties of Trinuclear μ_3-Bridged Carbonyl Complexes

4.1. Bonding

Trinuclear complexes in which metal carbonyl fragments are held together by a μ_3-bridging ligand (as in Fig. 1) are generally diamagnetic and obey the 18-electron rule, which implies a localized bond model. The bridging ligands RX are isolobal analogues of the bridging elements Y (Y = O, S, Se, Te) and formally contribute four electrons to the cluster (see Section 9). Chalcogen bridging elements Y possess a lone pair of electrons which points away from the cluster and can be utilized in the synthesis of larger clusters.[75–77] The μ_3-X ligands (X = N, P, As, Sb) similarly possess a lone pair of electrons with donor properties;[32,52,55,78,79] they contribute three electrons to the cluster. μ_3-RY ligands participate in cluster bonding to the extent of five electrons.

These simple rules for counting electrons are consistent with the assertion that a cluster component containing three valence orbitals and the electrons therein contributes as a unit to cluster bonding.[80] Delocalized bonding models for cage molecules make use of this concept;[80] the counting method employed is therefore adequate for both the 18-electron model and for the newer theories. Both models lead to the same result for the compounds in Fig. 1; for larger clusters (e.g., **14**) the delocalized model is more appropriate (see also Section 9).

Many of the properties of trinuclear μ_3-bridged carbonyl complexes can be derived under the assumption that their HOMO and LUMO are largely metal-centered;[81] the HOMO has M–M-bonding character, the LUMO M–M-antibonding character.[81] Quantum-mechanical calculations support this simple picture.[82,83]

4.2. Analytical Findings

IR spectra: IR spectra in the carbonyl absorption region are very useful for the identification of the compounds discussed here and for following the course of their reactions. As in the case of mononuclear carbonyl complexes, they also provide information about the electron density at the metal atoms, which pass their excess electron density on to the carbonyl groups; the carbonyl absorption frequencies, as expected, become lower with increasing charge density at the metal and higher with increasing positive charge.[84] IR spectra in the longer-wavelength region or Raman spectra, which could provide information about the metal–metal bonding,[85] are unknown for the clusters discussed here.

Electronic spectra: Trinuclear metal carbonyl clusters are colored. The bands in the visible region are associated with electronic transitions between orbitals that are essentially metal-centered. The absorptions are therefore shifted to shorter wavelength as the metal–metal bonding becomes stronger (cf. $[(\mu_3\text{-RP})(\mu_2\text{-H})_2M_3(CO)_9]$: M = Fe, brown; M = Ru, orange; M = Os, pale yellow).

ESR spectra: The absence of a coupling to phosphorus in the ESR signal of the paramagnetic compound $[(\mu_3\text{-RP})Co_3(CO)_9]^{\odot}$,[36] which contains one more electron than expected for a stable compound, led to the conclusion that the singly occupied molecular orbital is exclusively metal-centered.[86] A detailed ESR study of oriented single crystals of $[(\mu_3\text{-S})Co_3(CO)_9]^{\odot}$ came to the same conclusion.[81] The ESR spectrum of the heterometallic cluster anion $[(\mu_3\text{-S})Co_2Fe(CO)_9]^{\odot\ominus}$ indicates a nonuniform distribution of the unpaired electron over the metal atoms.[87,88]

NMR spectra: The ^{31}P-NMR signals of μ_3- or μ_4-RP groups are generally shifted downfield with respect to those of organophosphorus compounds. There is a qualitative correlation between the chemical shift and the color of the compounds; the longer the wavelength of the UV/VIS absorption, the greater is the chemical shift. The ^{31}P-NMR shifts for the series $[(\mu_3\text{-PhP})(\mu_2\text{-H})_2M_3(CO)_9]$ are: M = Os (pale yellow), $\delta = 119$;[23] M = Ru (orange), $\delta = 279$;[26] M = Fe (brown), $\delta = 380$.[20] This observation would imply that the phosphorus chemical shift is determined by the small HOMO–LUMO separation. The extreme chemical shift in binuclear phosphinidene complexes (e.g., $[(\mu_2\text{-}t\text{BuP})(Cr(CO)_5)_2]$, $\delta = 1362$[89]) is rationalized by this model in a straightforward way.

^{13}C-NMR spectra are useful here, as they are generally in metal carbonyl chemistry, for studying CO-scrambling processes.[91]

Mössbauer spectra: Although many μ_3- and μ_4-RP-bridged clusters with iron carbonyl groups are known, Mössbauer spectroscopy has not been used to any significant extent for the analysis of bonding.[92]

Electrochemistry: Since the HOMO in a cluster exhibits metal–metal bonding character and the LUMO metal–metal antibonding character, redox reactions primarily affect the metal–metal bonding system. Metal–metal bonds are relatively weak (at least for 3d metals); therefore, no great expenditure of energy is necessary for one-electron oxidations or reductions. In other words, clusters should be easy to reduce or oxidize electrochemically. The pioneering work of *L. F. Dahl* et al. in this area (on the cluster $[Cp_3Co_3S_2]$) confirms this assertion;[93] it also shows that the total number of electrons in a cluster influences above all the bonding between the metal centers.[94] The μ_3-bridged metal carbonyl clusters do not display such a marked redox activity as the notoriously redox-active sulfur–cubane systems.[95] Single-electron redox processes are found, for example, for $[(\mu_3\text{-RP})Co_3(CO)_9]^{\odot}$[86] and for the corresponding heterometallic clusters in which one or two $Co(CO)_3$ fragments are replaced by other organometallic moieties.[86–88] More often, however, the one-electron reductions of the μ_3-bridged metal carbonyl clusters with noble-gas configurations are irreversible; the occupation of the metal–metal antibonding LUMO weakens the metal–metal bonds and renders the complexes labile to substitution (see Section 4.1). Cyclovoltammograms that appear irreversible in the coordinating solvent CH_3CN are therefore often reversible in the non-coordinating solvent CH_2Cl_2.

The one-electron oxidation of trinuclear metal carbonyl clusters having noble-gas configuration is almost always irreversible; the metal–metal bonds are weakened by removal of an electron from the bonding HOMO and, additionally, the bonding to the carbonyl groups becomes more labile owing to the positive charge. If some of the carbonyl groups are replaced by donor ligands,[96] however, one-electron oxidations can become reversible.[97]

Mass spectra: Most μ_3-bridged trinuclear metal carbonyl clusters give readily interpretable mass spectra, showing the molecular ion and fragments derived from it by successive decarbonylation, even under electron-impact (EI) conditions. A decarbonylation series of doubly positively charged cluster ions is also sometimes observed.

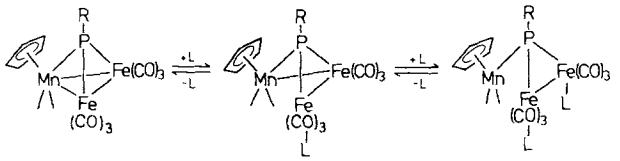
The energetically low-lying LUMO makes the clusters accessible to investigation by negative-ion mass spectrometry;[98] the relative yields of negative ions formed under EI conditions are at least as high as those attained with the standard examples of negative-ion mass spectrometry (e.g., $C_6H_3Cl_2NO_2$[99]). However, whereas these organic compounds almost exclusively give rise to chemically uninformative anion fragments such as $Cl^{\ominus}$ or $NO_2^{\ominus}$,[99] the μ_3-RP-bridged metal carbonyl clusters bear the negative charge themselves.[100] $M^{\odot\ominus}$ is not observed, the strongest signal usually being that of $M^{\odot\ominus} - CO$.[98,100] The lability of the metal–ligand bonds of cluster radical anions[88,101] is thus evident also in the gas phase.

5. Substitution Reactions

5.1. Substitution as an Addition–Elimination Sequence

Substitution reactions at mononuclear carbonyl complexes are usually initiated dissociatively; i.e., the first step is the breaking of an M–CO bond.[102] The activation can be induced thermally, photochemically, by one-electron redox processes, or by other chemical means.[102] For clusters, the same activation processes lead to substitution products. A side reaction, especially for 3d clusters with their weak metal–metal bonding, is the disintegration of

the cluster framework and consequent formation of mononuclear compounds;[103, 104] this can in some cases become the main reaction. Kinetic studies are made more difficult by these side reactions; although the partial fragmentation of the clusters must be seen as a clear indication of the reactivity of metal–metal bonds, the substitution of cluster-bound carbonyl groups is generally considered (by extrapolation from the chemistry of mononuclear complexes) to be based on an M–CO dissociative mechanism.[104] For $[Ir_4(CO)_{12}]$, on the other hand, it had been demonstrated already in an early investigation[105] that such reactions may be initiated associatively. Proof that CO substitution at clusters is mediated by the reactivity of the metal–metal bonds was provided by μ_3-RP-bridged clusters: Heterometallic clusters of the type **16** react with two-electron donors L (L = CO, R_3P, etc.) forming the adducts **43**, in which the ligand L has added to an iron atom with concomitant breaking of a manganese–iron bond.[106] The second manganese–iron bond of **43** reacts similarly, so that the clusters **43** can be converted into the adducts **44** by the action of further L; two metal–metal bonds of **16** are broken in going to **44**. Both reactions are strictly reversible; the stepwise elimination of L from **44** converts it into **43** and then to the closed tetrahedral starting material **16**.[106, 107] This reaction sequence shows for the first time that metal–metal bonds in trinuclear clusters can be opened by the addition of donor ligands and reformed by their elimination.

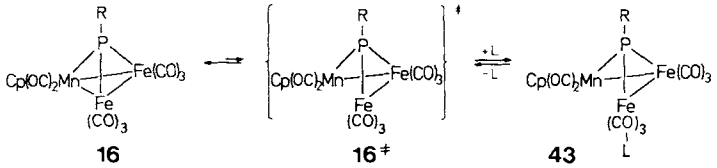


16 **43** **44**

This reactivity pattern was demonstrated some time ago for metal–metal bonds in binuclear complexes[108] and more recently in other trinuclear and in higher-nuclearity clusters;[109] the most striking example is the stepwise "unfolding" of the trigonal bipyramidal cluster $[Os_5(CO)_{16}]$ and its derivatives[110] with the eventual formation of a structure with two vertex-bridging triangles.

5.2. Clusters as Valence-Tautomeric Systems

The mechanism of the reversible opening of a metal–metal bond was investigated by kinetic methods for the system **16/43** in a detailed study.[111] The bond-opening process seems at first sight to follow a second-order rate law (first order in both L and **16**); a large excess of ligand, however, inhibits the reaction, which indicates the existence of a preequilibrium species. The activation parameters for the formation of the species **16**$^+$ involved in this equilibrium (necessarily independent of the nature of L) are $\Delta H^+ = 93$ kJ mol^{-1} and $\Delta S^+ = 34$ J mol^{-1} K^{-1} for **16a**$^+$ (R = Ph). Both values are consistent with the proposed intermediate **16**$^+$ derived from the starting cluster **16** by the breaking of an Fe–Mn bond;[111] the bond enthalpies of 3d metals in clusters are usually ca. 100 kJ mol^{-1},[112] and the activation entropy should be positive



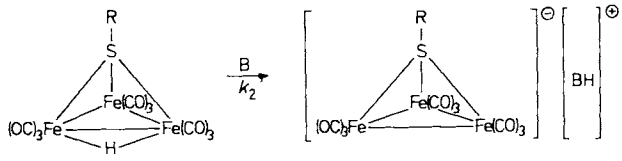
16 **16**‡ **43**

because of the release of strain on forming the edge-opened intermediate. The opening of a metal–metal bond by a two-electron donor L therefore corresponds to the trapping of a bond-opened form that is in valence-tautomeric equilibrium with the closed cluster. The reconversion of **43** to **16** is first order with respect to **43**; the activation parameters for this process suggest that it is initiated by dissociation of L.[111]

The essential result of these studies is that the metal–metal bonds are not broken by the nucleophile L in an S_N2-type reaction, but that an unsaturated form of the cluster with one bond opened (a form in valence-tautomeric equilibrium with the normal cluster) is trapped by the nucleophile.[111]

5.3. Clusters as Sterically Protected Systems

Stereochemical considerations suggest that a direct reaction between a ligand L and a metal–metal bond should barely be possible; metal–metal bonds in saturated carbonyl clusters are so effectively shielded that even a sterically undemanding ligand cannot approach them closely enough to initiate a direct interaction. This is confirmed by kinetic studies of the deprotonation of the cluster **45a** to form **46a** (Table 1).[113]



45 **46**

a, R = *t*Bu

Table 1. Kinetic parameters for the deprotonation of **45a** [a].

Base B	nBuNH$_2$	nBu$_2$NH	nBu$_3$N	[b]
k_2 [L mol^{-1} s^{-1}]	2.8	4.3×10^{-2}	1.5×10^{-3}	6×10^{-4}
k_H/k_D	13	3.6	1.6	1.1

[a] $T = 303$ K; solvent, toluene. [b] 2,2,6,6-tetramethylpiperidine.

The deprotonation in toluene with various amines as the base B is first order both in **45a** and B. The rate constants k_2 decrease with increasing size of B, as do the isotope effects k_H/k_D. The interpretation of these observations is obvious from examination of Figure 2. The space-filling model shows that even as small a base as methylamine can scarcely reach the hydrogen atom that bridges a metal–metal edge. The larger the base, the more activation energy must be expended to deform the cluster sufficiently to allow the base to reach the hydrogen and remove it as a proton. The isotope effects show that the proton transfer step in each case plays a role in determining the reaction rate.

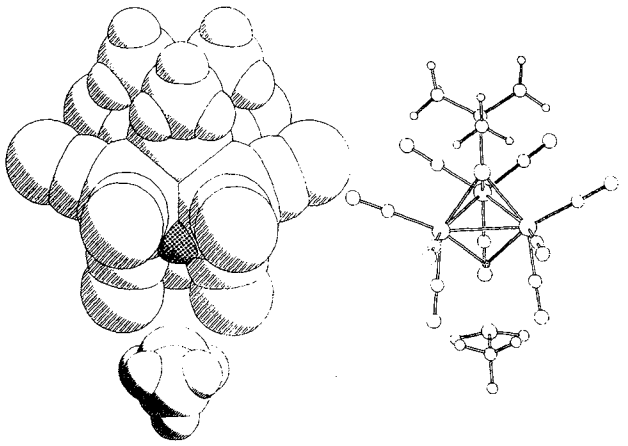


Fig. 2. Steric hindrance in clusters: space-filling model and ball-and-stick model of **45a** and of the base $MeNH_2$. The bridging hydrogen atom is dotted.

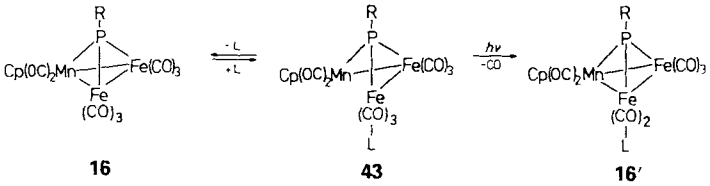
The unusually large isotope effect $k_H/k_D = 13$ observed for the small base nBuNH$_2$ may be ascribed to proton tunneling through a narrow energy barrier.[114]

These studies[113] support the view that a μ_2-H ligand in a tetrahedral carbonyl cluster is very strongly shielded. If a bridging hydrogen above the edge of a metal cluster is so well shielded, the metal-metal bond itself must be even less accessible to direct attack by a nucleophile. Therefore, the metal-metal bonds in carbonyl clusters cannot react directly, but must first be broken.

5.4. Substitution at Saturated Clusters

The photochemical cleavage of metal-metal bonds has been thoroughly investigated.[115, 116] It is therefore not surprising that the formation of the adducts **43** from **16** and L can be markedly accelerated by irradiation;[107] the reactive intermediate is presumably a bond-opened form similar to the species **16**$^+$ invoked for the thermal activation. The selectivity of the reverse thermal reaction **43** → **16** (elimination of L only) is not observed for the photochemical process; CO is eliminated also, leading to the substituted derivatives **16**′.[107] The conversion **16** → **16**′ via the adduct **43** demonstrates one possible mechanism of photochemical substitution at clusters.



16 **43** **16′**

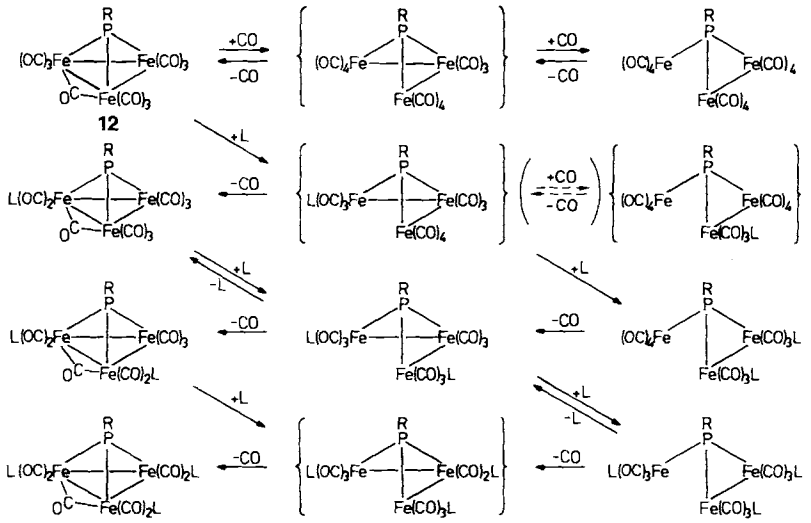
The investigation of the reaction of $[(\mu_3\text{-RP})Fe_3(CO)_{10}]$ **12** with the two-electron ligand $P(OMe)_3$ shows that substitution at clusters can occur by addition-elimination reactions even in the case of thermal activation (Scheme 4).[117] All compounds in Scheme 4 that are not in brackets have been isolated, and all processes indicated by arrows have been studied in detail.[117, 118]

It is probable, from the results discussed here, that substitution reactions of clusters always occur by addition-elimination sequences involving the breaking of metal-metal bonds, as long as the energy required to break a metal-metal bond is no greater than that required to dissociate a peripheral ligand. Such a mechanism is particularly likely for clusters of 3d elements.

For photochemically induced substitutions, the breaking of a metal-metal bond and the associated addition-elimination mechanism is the most probable process irrespective of the relative strengths of the metal-metal and metal-carbonyl bonds (cf. Sections 4.1 and 4.2). Similarly, it can be assumed that the first step of reduction-catalyzed substitution is the breaking of a metal-metal bond (the LUMO is M-M antibonding) (however, see Section 8), and that here, too, addition and elimination are the natural steps of the substitution process.

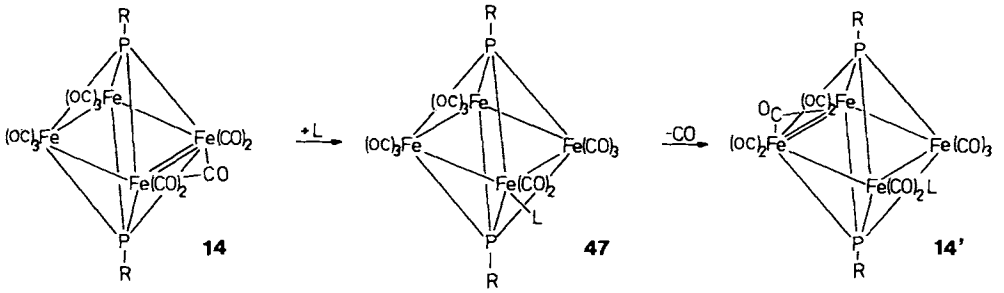
5.5. Addition and Elimination in Unsaturated Clusters

The addition-elimination mechanism is the natural and experimentally well-substantiated route of substitution for unsaturated clusters, i.e., those that possess two electrons



Scheme 4. Addition-elimination sequences for the system **12**/L (L = P(OMe)$_3$).

too few according to the noble-gas rule and thus can accommodate a donor ligand electronically and, usually, also sterically.[119] The cluster geometry is altered comparatively little by the addition of a donor ligand; a formal metal-metal double bond is transformed to a somewhat longer single bond. Unsaturated RP-bridged clusters also display this type of reactivity, as has been shown for the tetranuclear iron compound **14**.[120] The doubly μ_4-RP-bridged **14** is unsaturated according to the noble-gas rule; it possesses two electrons fewer than the rule would predict. Although

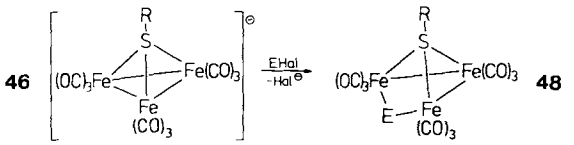


the bond lengths of the cluster do not reveal the localized unsaturation implied by the metal-metal double bond of formula **14**, its ability readily to add two-electron ligands can best be understood in terms of this formula. For L = CO, the reaction sequence **14** ⇄ **47** ⇄ **14** leads, via the adduct **47**, back to the starting complex. If L is a different two-electron ligand, the same reaction sequence corresponds to a substitution reaction that leads to **14'** via an intermediate addition product.[121]

6. Oxidative Addition and Reductive Elimination

6.1. Oxidative Breaking of Metal-Metal Bonds

The formal counterpart of the opening of metal-metal bonds by nucleophiles (see Section 5) is their opening by electrophiles. This reaction type has been observed for μ_3-RP-bridged clusters.[122] However, since the structure of the addition products has not been firmly established,[122] a well-established example from the chemistry of μ_3-RS-bridged clusters will be presented instead. Reaction of the anionic cluster **46** with inorganic electrophiles EHal results in breaking of one iron-iron bond and formation of

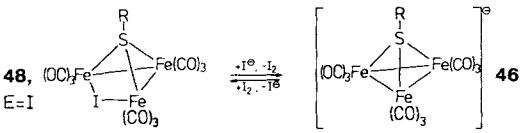


48;[123] the electrophilic groups E are thereby inserted into a metal-metal bond, and the negative charge of the starting cluster **46** is transferred to the halogen. The overall process, as an oxidative addition, corresponds to a standard reaction type observed for mononuclear organometallic compounds,[84] which is also established for some polynuclear compounds.[7]

The cluster **46a** reacts with divalent electrophiles such as $RPCl_2$ or $SOCl_2$ with elimination of *t*BuCl and $Cl^{\ominus}$ to form the doubly μ_3-bridged clusters $[(\mu_3\text{-S})(\mu_3\text{-RP})Fe_3(CO)_9]$ and $[(\mu_3\text{-S})(\mu_3\text{-SO})Fe_3(CO)_9]$, respectively.[124]

6.2. Reductive Elimination

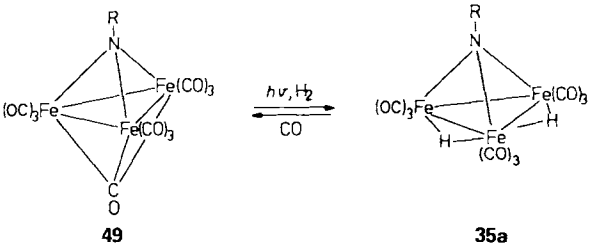
The groups E of the clusters **48** (prepared by oxidative addition) are generally so firmly bound as three-electron bridging ligands that the reverse reaction, the reductive elimination of $E^{\oplus}$, is generally not realizable. The reduction of **48**, E = I, to **46** by reducing agents such as iodide[125] furnishes an exception to this statement and thus shows that such reactions are in principle possible. The re-



ductive elimination and oxidative addition in this system are in equilibrium, so that either **48**, E = I, or **46** may be present in the reaction solution depending on the $I_2/I^{\ominus}$ content.[125, 126]

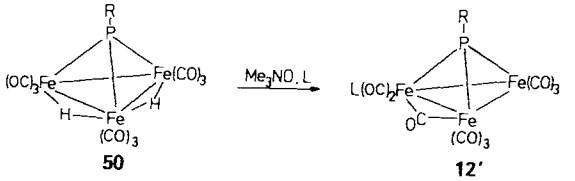
6.3. CO/H_2 Exchange: Hydride Metal Clusters[127]

The bridging carbonyl group in the compounds $[(\mu_3\text{-RX})M_3(CO)_{10}]$ (M = Fe, Ru, Os) can usually be replaced easily by two bridging hydrogen atoms, forming $[(\mu_3\text{-RX})(\mu_2\text{-H})_2M_3(CO)_9]$. The photochemically initiated conversion of **49** to **35a** is an example of such a reaction.[128]



The available evidence would seem to indicate that the photochemical or thermal replacement of CO by H_2 is easier for those clusters $[(\mu_3\text{-RX})(\mu\text{-CO})M_3(CO)_9]$ that contain

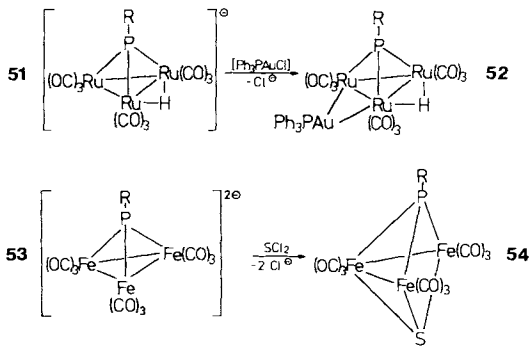
a μ_3-bridging CO. Compounds with a μ_2-CO group, such as $[(\mu_3\text{-RP})(\mu_2\text{-CO})Fe_3(CO)_9]$ **12**, do not give selective reactions with this method.[129] Their conversion to the μ_2-H-bridged clusters **50** must therefore be achieved by indirect routes.[130, 131] The reconversion of the μ_2-H-bridged complexes to the carbonyl-bridged clusters with carbon dioxide is often possible by thermal activation. Chemical methods of activation are also available (e.g., **50** → **12'**).[132]



The mechanism of CO/H_2 exchange (in either direction) is unknown. From Section 5 it seems plausible that the thermally or photochemically induced reactions of $[(\mu_3\text{-RX})M_3(CO)_{10}]$ proceed via breaking of metal–metal bonds. For the symmetrical μ_3-CO-bridged complexes such bond breaking should be homolytic, whereas the results presented in Section 5 suggest that heterolytic bond cleavage should occur for the μ_2-CO-bridged species. The differing reactivities of the two structural variants of $[(\mu_3\text{-RX})M_3(CO)_{10}]$ with respect to CO/H_2 exchange could be explained in this way.

RX-bridged hydride metal clusters such as the ruthenium cluster **29** and the iron cluster **50**, like other clusters with hydride bridges, react with bases, $H^{\oplus}$ being abstracted.[130, 131, 133] The triiron compounds are the strongest acids of the cluster type $[(\mu_3\text{-RP})(\mu_2\text{-H})_2M_3(CO)_9]$.[130, 134] The ruthenium and osmium homologues of **50** are less acidic than **50** itself;[133] this is consistent with the general observation that all metal ligand bonds become stronger when a transition metal in a given complex is replaced by a heavier homologue. Cluster **50** is such a strong acid (for its first dissociation) that it is in equilibrium with its conjugate base even in tetrahydrofuran.[131] The second deprotonation of **50** is, as would be expected, appreciably more difficult, but is possible with strong bases such as $NaNH_2$.[131] The fact that metal cluster hydrides are sterically hindered acids was discussed above (Section 5.3).

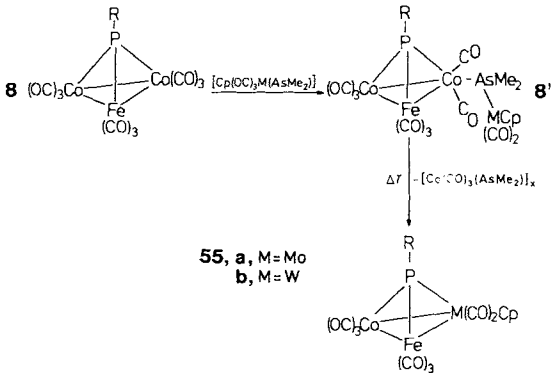
The μ_3-RX-bridged cluster anions undergo a variety of reactions with electrophiles; the synthesis of higher-nuclearity clusters (**51** → **52**)[133] and the introduction of further μ_3-bridging ligands (**53** → **54**)[124] are two examples.



7. Metal-Exchange Reactions

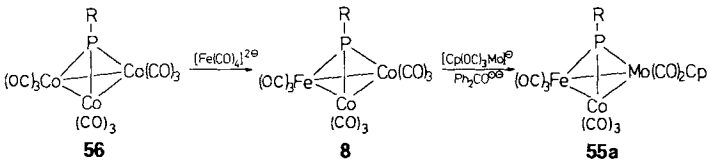
The metal carbonyl fragments $M(CO)_n$ that form part of the base of the clusters $[(\mu_3\text{-Z})(M(CO)_n)_3]$ can be replaced by other organometallic moieties. The cobalt clusters (M = Co) are particularly reactive in this respect; metal exchange occurs for the diamagnetic complexes (Z = RC[136–138]) and for the more labile paramagnetic complexes (Z = RP, S[139]).

The replacement of $Co(CO)_3$ units by the isoelectronic complex fragment $CpM(CO)_2$ (M = Cr, Mo, W) follows a particularly clear course; the metal-substituted arsane $[Cp(OC)_3M(AsMe_2)]$[140] first replaces a carbonyl group at the base of the cluster **8**, forming **8'**. Thermal activation of **8'** leads to the elimination of $[Co(CO)_3(AsMe_2)]_x$, whereby the $Cp(OC)_2M$ group, previously indirectly bound to the cluster, takes the place of the $Co(CO)_3$ unit. This elegant method made possible, for the first time, the synthesis of clusters such as **55**; these are chiral because of the three different metals in the base of the tetrahedron.[141, 142]



Less systematic, but often productive, methods of exchanging metal atoms in the base of a cluster include metathesis with compounds such as $[(CpNiCO)_2]$, $[Co_4(CO)_{12}]$, and $[Fe_2(CO)_9]$.[137, 138, 143–145]

The reaction sequence **56** → **8** → **55a** can be regarded as an example of a redox-catalyzed exchange of metals in the base of a cluster.[139] The replacement of $Co(CO)_3$ by



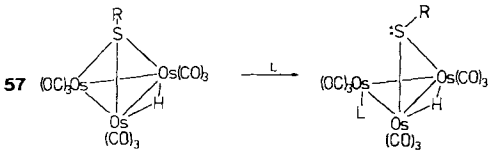
$Fe(CO)_3$ using $[Fe(CO)_4]^{2\ominus}$ necessarily involves intermediate redox stages. The first stage of this reaction could be the breaking of a metal–metal bond and/or carbonyl substitution with $[Fe(CO)_4]^{2\ominus}$ acting as a Lewis base, without any primary electron transfer. The second step, like the conversion of **8** into **55a** mediated by $Ph_2CO^{\odot\ominus}$,[146] is doubtless a redox-catalyzed reaction (cf. Sections 4 and 8.1) in which the bonding in the metal triangle is weakened by the uptake of an electron into the M–M antibonding LUMO.

8. Reactions Involving Participation of the RX Bridge

The examples presented in Sections 5 and 6 have shown that the metal-metal bonds are the reactive sites in μ_3-RX-bridged clusters and that reactions at μ_3-RX-bridged clusters are susceptible to detailed analysis because the metal-X bonds hold the metal carbonyl fragments together. The metal-metal exchange reactions described in Section 7, however, showed that metal-X bonds as well as metal-metal bonds can be broken in the course of a reaction.[147]

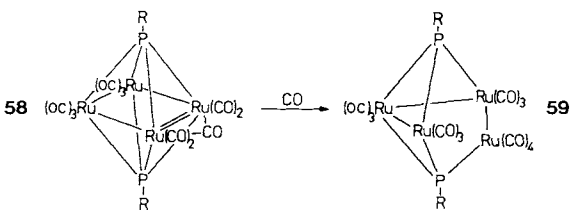
8.1. The Cleavage of M-X Bonds[148]

The bond types involved in a reaction (whether only the metal-metal bonds or, in rarer cases, only the metal-X bonds, or both) clearly depend on the nature of the reagents just as much as they depend on the type of activation or the nature of the cluster. The principles determining the particular mechanism are poorly understood. An important factor determining the reaction path is the relative stability of the metal-metal and metal-X bonds on the one hand and the metal-substrate and X-substrate bonds on the other. The conversion of the μ_3-HN group of **39** to the μ_2-H_2N group of **40** (Scheme 3) is an example of the selective breaking of a metal-X bond by the addition of a two-electron ligand to a μ_3-bridged cluster. The selective opening of the osmium-sulfur bond in **57**[149a] is an even more direct counterpart of the opening of metal-metal bonds by two-electron ligands (Section 5). The osmium-sulfur bond is obviously less stable than the osmium-osmium bond.

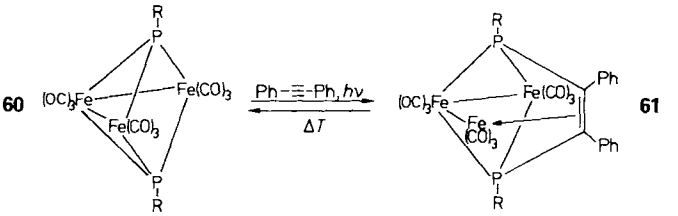


The ability of trinuclear osmium carbonyl compounds to form unsaturated metallacycles (cf. $[Os_3(CO)_{10}(H)_2]$) could also favor the observed reaction path. A similar mechanism has been discussed for the reaction of $[(\mu_3\text{-RP})(\mu_2\text{-H})_2Os_3(CO)_9]$ **4** (which is isoelectronic to **57**) with carbonyl metal fragments.[149b]

An example of the breaking of a metal-phosphorus bond by two-electron ligands is the reaction of the unsaturated ruthenium cluster **58** (homologous with **14**) with CO.[150] Whereas the tetranuclear iron cluster **14** adds CO reversibly to the multiple bond,[120] its ruthenium homologue **58** incorporates two CO groups, one metal-metal and one metal-phosphorus bond being broken.[150] The product **59** can be regarded as a derivative of a complex of

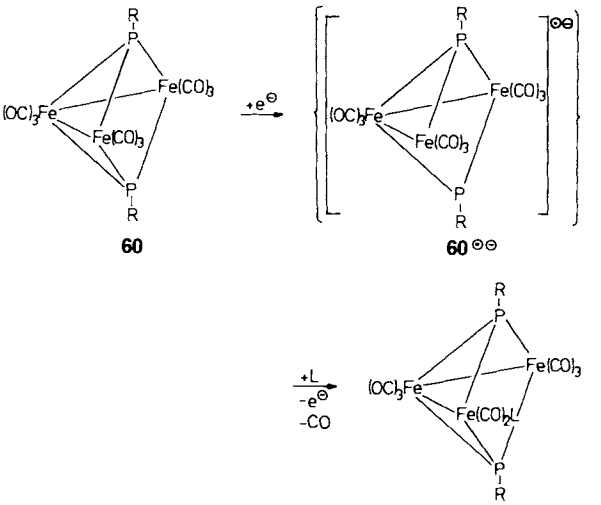


the type $[(\mu_3\text{-RP})_2M_3(CO)_9]$ in which a carbene-analogous $Ru(CO)_4$ group has been inserted into a Ru-P bond. In this case, both metal-metal and metal-phosphorus bonds are involved. An example where only the metal-phosphorus bond is broken is the photochemically initiated addition of diphenylacetylene to **60** to give **61**.[151] Photochemically excited **60** apparently reacts as a diradical with the



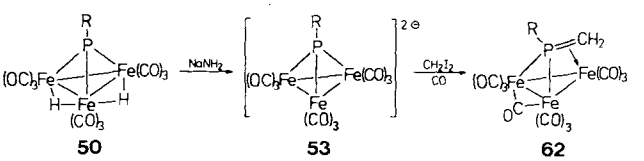
radical centers at phosphorus. Two iron-phosphorus bonds are replaced by two carbon-phosphorus bonds. The reaction is thermally reversible.

Electrocatalytic CO substitution in **60** apparently proceeds similarly.[152] The ESR spectrum of the one-electron reduction product of **60** shows that a species with two different coordinated RP bridges is involved as intermediate. The most probable structure of this intermediate is therefore **60**$^{\odot\ominus}$.[152] Electrochemical activation of μ_4-RP-bridged clusters appears to involve similar steps.[153]

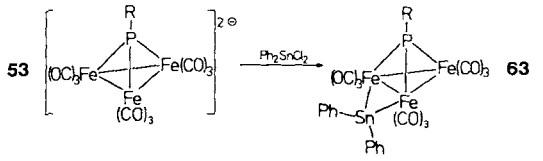


8.2. Addition of Carbenes to μ_3-RP Groups

The pyrophoric dianions **53**[130, 131] react as nucleophiles with CH_2I_2, the CH_2 group adding to a Fe-P bond.[130, 131] The adduct, the complex **62**, can be regarded as a cluster-

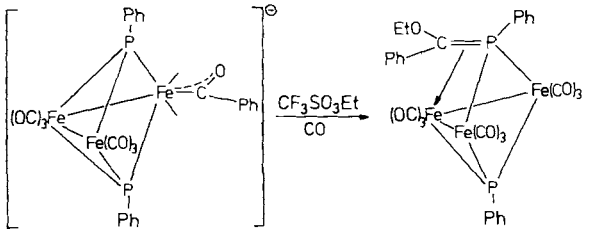


stabilized phosphaalkene.[130, 131, 154, 155] Even if the formation of a phosphaalkene ligand does not necessarily imply the existence of an intermediate with a complex-bound CH_2 group, this still seems probable in view of the fact that **53** reacts with Ph_2SnCl_2 to give **63**, in which the carbene analogue Ph_2Sn bridges one metal edge.[156] The reaction

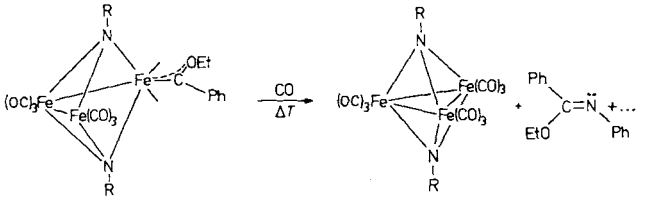


stops at the stage **63** because a further reaction to form a molecule analogous to **62** would involve the formation of an unstable phosphastannaalkene.[157]

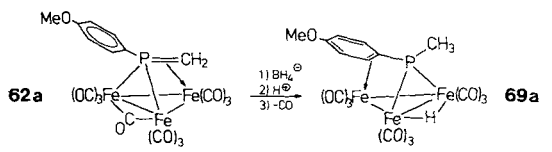
Proof of the migration of a metal-bonded carbene to a μ_3-bridging phosphorus is provided by the conversion of the acylato complex **64** (obtained from $[(\mu_3\text{-PhP})_2Fe_3(CO)_9]$[158]) to the phosphaalkene complex **65** by



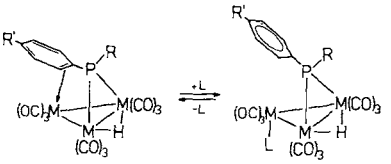
treatment with ethyl trifluorosulfonate.[158] The generation of a Fischer-type carbene complex as intermediate is implied by the isolation of such complexes (**66**) from analogous reactions with $[(\mu_3\text{-PhN})_2Fe_3(CO)_9]$.[158] The carbene complex **66** reacts with CO with the elimination of the corresponding imidoester **68** and the generation of **67**.[158]



Cluster-bound phosphaalkenes can be derived from methylenephosphoranes $R_3P{=}CH_2$ by the formal replacement of two R–P bonds by metal–P bonds. However, whereas methylenephosphoranes are carbon nucleophiles,[160] phosphaalkenes possess an electrophilic center at carbon.[130, 131] Thus **62** reacts with complex hydrides as the nucleophilic reagents at the methylene carbon,[130, 131] its



phosphaalkene group $RPCH_2$ being converted into a μ_2-RPMe phosphido bridge. If R is an aryl group (e.g., *p*-MeO–C_6H_4 in **62a**), the acid workup of the anionic phosphido complexes affords products in which one of the formal double bonds of the aromatic system coordinates to the third (non-phosphido-bridged) metal atom (**69a**, the iron homologue of the ruthenium complex **28**). This coordination mode of an aryl group of a cluster-bound phosphido ligand is also known from other studies[62] (cf. Section 2.3). It is certainly energetically unfavorable from enthalpy considerations alone (the 6π system becomes partially localized); the driving force is entropy, i.e., the chelate effect. Accordingly, the η^2-coordinated aryl group in **28** and **69** is reversibly removed from the coordination sphere by two-electron ligands L, forming **70** and **71**, respectively.[62, 131]

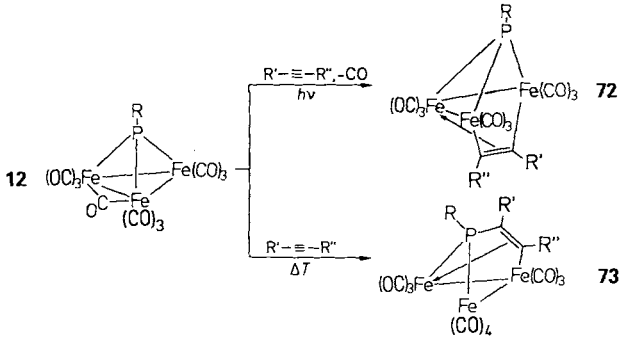


69 M = Fe, R' = OMe **70**
28 M = Ru, R' = H **71**

8.3. Reactions with Alkynes

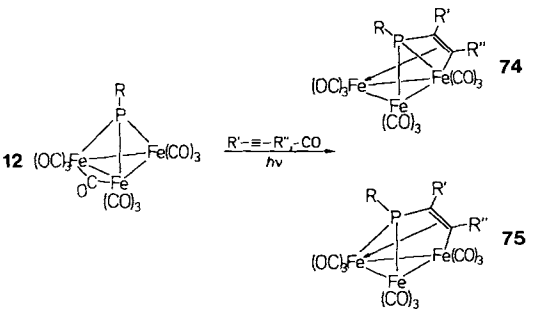
The reactions of polynuclear metal carbonyls are among those cluster reactions that were the subject of early and detailed studies by *W. Reppe*.[161] The basic principles of alkyne bonding in clusters were expounded first by *W. Hübel* and co-workers.[162, 163]

Main-group elements as bridges introduce a new variant into this coordination chemistry; the reactions of **12** with alkynes R'C≡CR'' show that the latter can insert into either Fe–Fe or P–Fe bonds. Depending on the phosphorus substituents R and on the type of activation, compounds **72** are formed by insertion of the alkyne into the Fe–Fe bond and subsequent decarbonylation, and compounds **73** by insertion of the alkyne into the P–Fe

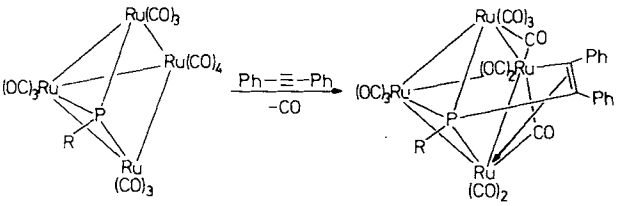


bond.[164] Under suitable conditions, two further isomers of **72**, the compounds **74** and **75**, can be selectively prepared.[165, 166]

Thermal decarbonylation of **76** in the presence of diphenylacetylene leads to the tetranuclear cluster **77**.[167] The C_2 unit links two metal centers that were not directly joined in the starting complex. The reaction is formally similar to the reaction of **60** with diphenylacetylene. How-



ever, the activation steps are different (cf. Section 8.1); the initiating step in the conversion of **76** to **77** could well be the dissociation of CO, which thereby provides a free coordination site. There are too few kinetic analyses available for the individual steps of such reactions to allow an experimentally sound and unified mechanistic model to be postulated. Clusters of type **61** are also formed, for instance, when the tetranuclear clusters **14** are treated with alkynes.[168]



76 **77**

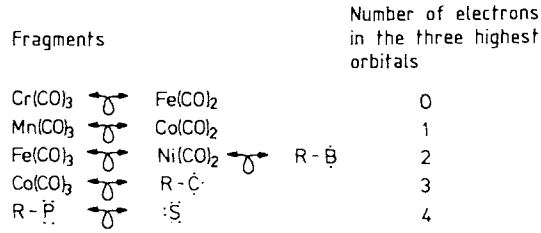
The structures of these alkyne adducts, which appear complicated at first sight, as well as their reactions, can be easily understood using a simple model (see Section 9).

9. Cluster Fragments as π Ligands

According to a concept developed by *K. Wade*,[80] the structure of a cage compound can be derived from the number of electron pairs that are available for bonding in the cluster. The number of electrons that each cluster unit contributes to the total electron balance can be calculated quite simply; each cluster unit is involved in cage bonding via its three highest-lying valence orbitals and the electrons present in them. A main-group element has four (s and p), a transition element nine (s, p, and d) valence orbitals. The number of electrons in the three highest-lying orbitals of a cluster constituent can then be easily counted.

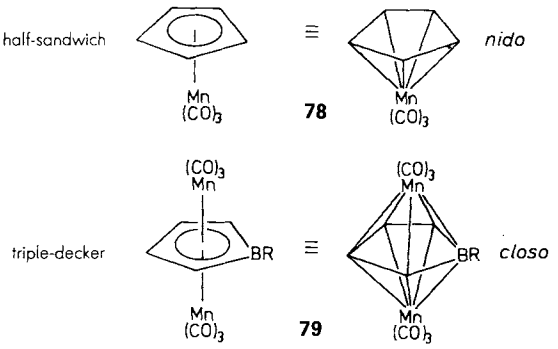
Two examples: (1) The boron in an RB group has an outer shell of four electrons (one from the covalently bound group R and three from itself). It therefore has four electrons fewer than the maximum number it could accommodate (eight electrons in four orbitals) and has just two electrons in its highest three orbitals. (2) An iron atom has eight valence electrons, and the three carbonyl groups in an $Fe(CO)_3$ fragment contribute a further two each; the iron thus acquires a total of 14 valence electrons. Just as for the boron case, the iron has four electrons fewer than the maximum 18 that it could accommodate in nine valence orbitals; i.e., the highest three valence orbitals contain, like the boron of the RB group, a total of two electrons. Groups with equal numbers of electrons in the highest three orbitals can be substituted for each other in a cluster without changing its overall geometry.

The analogy thus demonstrated for RB and $Fe(CO)_3$ was refined by *R. Hoffmann*, who showed that the symmetry properties of the three frontier orbitals of RB and $Fe(CO)_3$ are congruous.[41] This extended isoelectronic relationship (identical symmetry properties of frontier orbitals and identical number of electrons in frontier orbitals) was termed isolobality.[41, 169] Some of the many relationships that can be drawn up in this way are presented in Scheme 5.



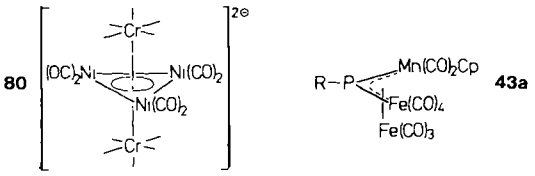
Scheme 5. Isolobal fragments.

Wade's concept states further[80] that if n electron pairs are available for cluster bonding, then the triangular polyhedron with n − 1 vertices will be the stablest form of the cluster. If the number of cluster units is less than n − 1, the cluster geometry can still be described as a polyhedron with n − 1 vertices, only some of which are occupied by cluster constituents. Clusters with all vertices occupied are termed *closo*, those with one missing vertex *nido*, and those with two missing vertices *arachno*. According to this terminology, half-sandwich complexes such as **78** are *nido* type and triple-decker complexes[170, 171] such as **79**[172] are *closo* type.



It is a reversal of this concept that can be developed into an analysis of clusters that is (at least heuristically) useful: Cluster fragments may be regarded as π ligands that—similarly to organic[170] or organoboron[171] π systems—form π complexes or triple-decker compounds.[173] Early examples of such an analysis are the description of the complex **80** as a triple-decker complex of the 2π-electron system $[Ni_3(CO)_6]^{2\ominus}$ by *L. F. Dahl* et al.[174] and the description of a tetrahedral manganese-iron cluster with one bond broken, **43a** (**43**, L = CO), as a π complex of the phosphini-

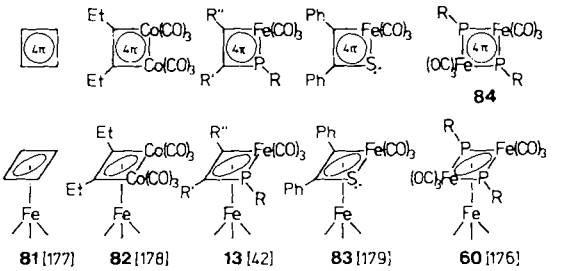
dene complex $[(\mu_2\text{-RP})\{Fe(CO)_4\}\{Mn(CO)_2Cp\}]$ (a homologue of the allyl anion) and $Fe(CO)_3$.[46]



80 **43a**

This model implies a partial localization of the bonds in the cluster; each of the three $Ni(CO)_2$ fragments of **80** possesses two electrons in the highest three valence orbitals, and these are used to form the σ bonds in the Ni_3 triangle. The three remaining valence orbitals of the $Ni(CO)_2$ units, the symmetry of which is suitable for π interactions between them, then acquire two electrons corresponding to the negative charge of the complex.[174] Similar considerations apply to the phosphinidene complex $[(\mu_2\text{-RP})\{Fe(CO)_4\}\{Mn(CO)_2Cp\}]$ as an allylic-anion-analogous 4π system that functions in **43a** as an η^3 ligand.[46]

Any formal dissection of a molecule into units is artificial and can only be justified by the success with which it can be used to classify known facts into a uniform system and with which it can be used to predict previously unforeseen possibilities. Scheme 6 presents a series of complexes (**13**, **60**, and **81**–**83**) that can be regarded as $Fe(CO)_3$ ad-



84

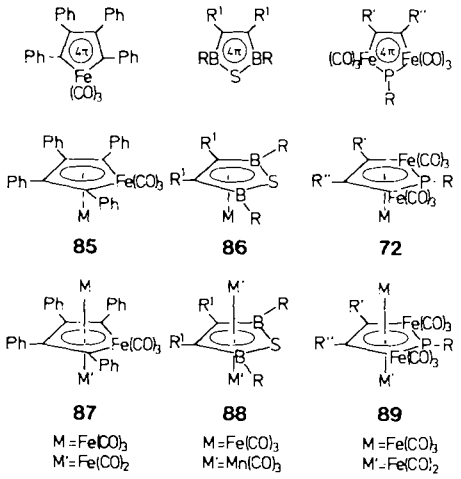
81 [177] **82** [178] **13** [42] **83** [179] **60** [176]

Scheme 6. Cyclobutadiene and analogous four-membered metallacycles as 4π-electron ligands.

ducts of η^4-coordinated cyclic 4π-electron ligands on the basis of the model discussed here.[180] All these 4π-electron ligands are unstable in the free state.[181] Their $Fe(CO)_3$ complexes, however, are stable. The bond lengths in the "π systems," together with the fact that the substituents at carbon and phosphorus lie almost in the ring plane, show that the model used here provides a suitable description of the structural characteristics of the complexes in Scheme 6.

Scheme 7 shows a selection of five-membered rings as 4π-electron ligands together with some of their half-sandwich and triple-decker complexes. In the stable $Fe(CO)_3$ complexes **85**, **86**, and **72**, each containing η^5-coordinated π ligands, the bond lengths in the π ligand, together with the fact that the bonds to C, P, and B lie almost in the ring plane, demonstrate once again the usefulness of this model for the interpretation of the structures.

Half-sandwich-type complexes can be "stacked" to form triple-decker complexes. The compounds **87**, first described by *W. Hübel* et al.[182], must be regarded as the first



85 **86** **72**

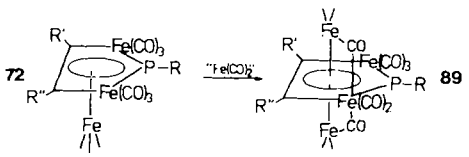
87 **88** **89**

M = $Fe(CO)_3$, M' = $Fe(CO)_2$ | M = $Fe(CO)_3$, M' = $Mn(CO)_3$ | M = $Fe(CO)_3$, M' = $Fe(CO)_2$

Scheme 7. Five-membered metallacycles as 4π-electron ligands.

examples of triple-decker complexes. The compounds **88**[183] and **89**[166] are other variations on this theme; they are consistent with the electron-counting rules for triple-decker complexes, as proposed by *R. Hoffmann* et al.[173] and of course also with *Wade*'s rules. This shows that the partial localization of electrons in fragments that are regarded as π ligands (the model used here) does not lead to inconsistencies; a fully localized description (along the lines of the 18-electron rule) would, in contrast, picture all these triple-decker complexes as unsaturated.[184–186]

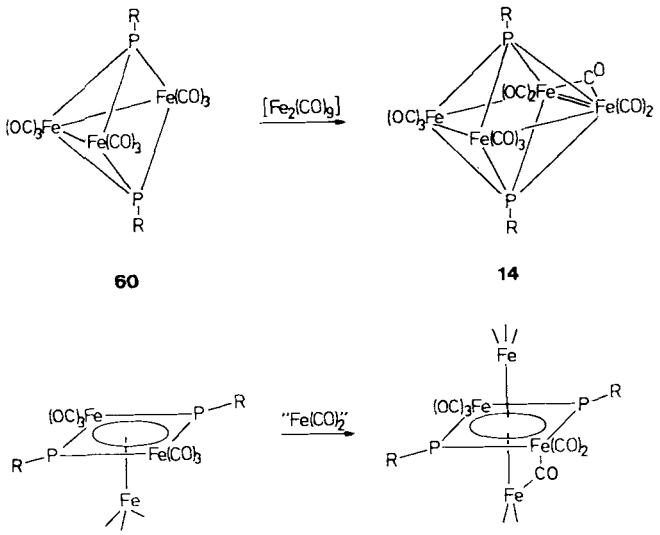
Since **72** had been described as a half-sandwich complex of a metallacyclic π ligand (in the sense of Scheme 7) and its analogy to **86** had been discussed,[164] it seemed worthwhile to test the suitability of **72** for stacking into a triple-decker complex (such as **88**). The reaction of **72** with $[Fe_2(CO)_9]$, as a source of "$Fe(CO)_2$," led, as ex-



72 **89**

pected, to formation of the triple-decker complex **89**.[187] The pronounced stability of the triple-decker structure of **89** is shown, for instance, by the thermal decarbonylation of the compound **77** to a structural homologue of **89**.[167] Sulfur can assume the role of the RP unit in these complexes; this is shown by the formation of an osmium complex structurally homologous to **89** from $[(\mu_3\text{-S})Os_4(CO)_{13}]$ (structurally equivalent to **76**) and alkynes.[188] The formation of an iron-sulfur analogue of **89** from **83** and $[Fe_2(CO)_9]$ is a further example.[189]

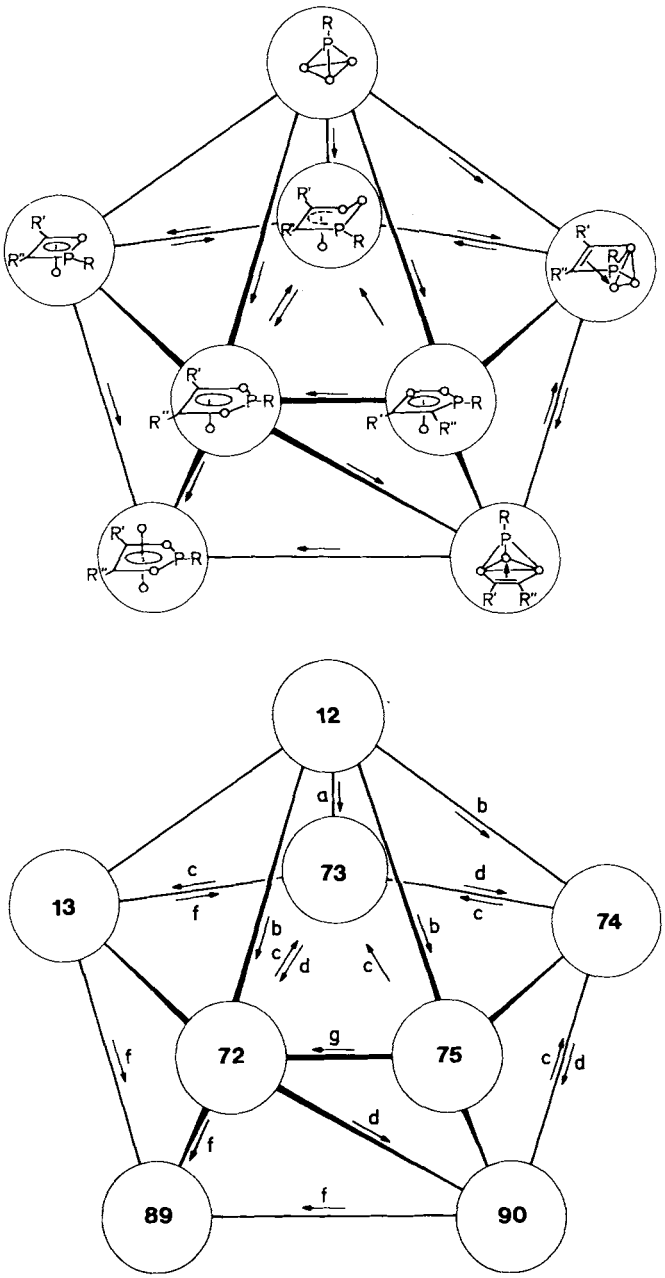
Several cluster-forming processes can be understood using the concept of cluster fragments as π ligands. The reaction of **60** with $[Fe_2(CO)_9]$ leads to the interesting cluster **14**, which is unsaturated according to the noble-gas rule.[43] Cluster **60** may also be regarded, however, as a half-sandwich compound that "stacks" with "$Fe(CO)_2$" to form the triple-decker complex **14**.



The model developed here is useful in that it provides a new and unconventional view of clusters and thus suggests new experiments.

10. Skeletal Rearrangement Processes

Carboranes provide the classic example of skeletal rearrangements of cage compounds.[190] Since *Wade*'s rules regard carboranes and metal clusters as different manifestations of the same bonding concepts,[80] both classes of compounds can be expected to display similar rearrangement processes. The interconversion of different skeletal topologies, however, requires that the bond energies between the units of the cage molecule be similar. The system $[(\mu_3\text{-RP})Fe_3(CO)_{10}]$ **12**/R'C≡CR'' appears to fulfill this requirement for Fe–P, P–C, and Fe–C bonds; all the transformations depicted in Scheme 9 can thus be preparatively realized.[164–166, 187] This scheme, in which the reactions and rearrangements of an organometallic cluster system are presented in the graph of the dodecahedral $B_8H_8^{2\ominus}$ cage,[191] brings together two "different" areas of chemistry in a manner that is more than mere symbolism.



Scheme 9. Skeletal rearrangements in the system **12**/R'C≡CR''. a) R'C≡CR''. b) R'C≡CR'', *hν*. c) CO. d) −CO. e) *hν*, −CO. f) $[Fe_2(CO)_9]$. g) ΔT. **90** = $[(\mu_3\text{-RP})(\mu_3\text{-}\eta^2\text{-R'CCR''})Fe_3(CO)_8]$ [165]. The circles symbolize $Fe(CO)_n$ centers.

11. Summary

Trinuclear, μ_3-RX-bridged metal carbonyl clusters (X = N, P, As, Sb, Bi) represent only a small part of the much wider field of cluster chemistry. Among the many known clusters, they present two advantages; they are "small" (a cluster should contain at least three metal atoms) and they possess a bridging ligand RX that holds the metal atoms together even when metal–metal bonds are broken. This makes possible the kinetic-mechanistic investigation of their reactivity. For such clusters it can be shown that those with weaker metal–metal bonds enter into reactions in a valence-tautomeric form that has one metal–metal bond broken. Substitution of ligands occurs as an addition–elimination sequence with opening and closing of metal–metal bonds. The possibility of analyzing the individual reaction steps depends on the main-group bridging ligand, which is not directly involved in the reaction but instead fulfills the role of a clamp. Under some circumstances, this clamp can be broken, as is shown by the exchange of μ_3-RX-bridged metal carbonyl units by other metal–ligand fragments. Chiral clusters, in which the chirality arises from the framework of the cluster itself, were first made accessible in this way.

The reaction of μ_3-RP-bridged clusters with alkynes shows that both metal–metal and metal–phosphorus bonds can be reactive; the variety of cluster frameworks obtained in such reactions can be described in an integrated manner if fragments of such clusters are regarded as π ligands that can form half-sandwich and/or triple-decker complexes. The diverse rearrangement reactions of the cluster frameworks of the alkyne adducts illuminate perfectly the rela-

tionship with the chemistry of boranes and carboranes and show that the P–C, M–C, and M–P bonds in clusters are very similar in energy to each other.

Our thanks for enthusiastic and stimulating contributions to our own research in this field are due to Dr. B. Sigwarth, Dr. U. Weber, Dr. J. Borm, Dr. L. Zsolnai, Dr. G. Mohr, Dr. J. von Seyerl, Dr. J. Schneider, Dr. B. Pritzlaff, Dr. A. Winter, Dr. O. Scheidsteger, Dr. I. Jibril, Dr. H. Lang, Dipl.-Chem. L.-R. Frank, T. Fässler, and Dipl.-Chem. D. Buchholz. We thank Dr. H. Berke and Dipl.-Chem. K. Evertz for many productive discussions. We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

[9] The word "bond" is used here even when the "observed" bond is not a localized two-center two-electron bond. It indicates more a geometrical relation between two centers; if they are as close as would be predicted from the sum of the covalent radii, they form a "bond"; if the bond is broken, this geometrical condition is no longer fulfilled.

[147] The thermal decomposition of μ_3-RP-bridged clusters breaks both metal–metal and metal–phosphorus bonds. Nearly all clusters of the type $[(\mu_3\text{-RP})Fe_2(CO)_6(ML_n)]$ give the complex $[(\mu_3\text{-RP})_2Fe_3(CO)_9]$ **60** as the end product of thermal decomposition. The thermolysis of $[(\mu_2\text{-}Ph_2P)(\mu_2\text{-H})Ru_3(CO)_9]$ to $[(\mu_3\text{-PhP})Ru_4(CO)_{13}]$ shows that clusters of higher nuclearity can be formed on heating [62].
[148] Reactions in which only the substituents at phosphorus are modified or exchanged (e.g., the conversion of $[(\mu_3\text{-}R_2NP)Fe_3(CO)_{10}]$ to $[\mu_3\text{-}ClP)_2Fe_3(CO)_{10}]$ by HCl [123], are not discussed here, since they do not involve the cluster itself.

[184] The MO analysis of clusters that consist of organometallic fragments and main-group units generally involves the study of interactions between the main-group ligands (e. g., RP [185] or acetylene [186]) and the transition-metal cluster fragment. This method corresponds to the view that "building blocks" with similar orbital energies should be grouped together. The fragment analysis suggested here (which has not yet been substantiated by MO studies) does not follow this method. This can be justified by the view that the interactions between "soft" ligands such as RP, S, or acetylene and transition metals are certainly strongly influenced by overlap, so that the difference in orbital energies between main-group centers and transition-metal centers is no longer so important. We thank Dr. *H. Berke* (Konstanz) for this comment.

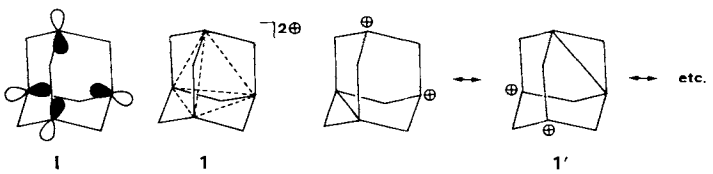
Four-Center Two-Electron Bonding in a Tetrahedral Topology. Experimental Realization of Three-Dimensional Homoaromaticity in the 1,3-Dehydro-5,7-adamantanediyl Dication**

By *Matthias Bremer, Paul von Ragué Schleyer,* Karl Schötz, Michael Kausch,* and *Michael Schindler*

Dedicated to Professor George A. Olah on the occasion of his 60th birthday

Four orbitals placed at the bridgeheads of adamantane extend towards the center of the cage. Of the four possible combinations of phases, only the nondegenerate one, **I**, is



I 1 1′

bonding. The occupation of this molecular orbital by two electrons (Fig. 1)—e.g., as in the dication **1/1′**—should result in considerable stability, provided the overlap is sufficient.

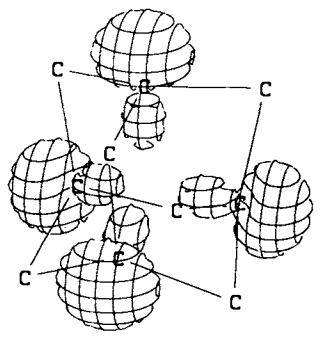


Fig. 1. Jorgensen plot of the highest occupied molecular orbital of **1**. (The STO-3G basis set employed underestimates the overlap of the bridgehead orbitals. The Jorgensen program cannot deal with higher basis sets.)

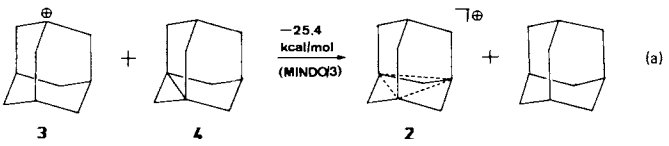
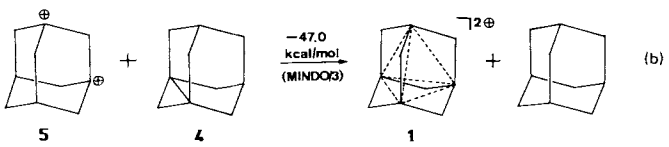
[**] We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, ARDEC, Dover, NJ, and the CONVEX Corporation (the most recent calculations were carried out on a CONVEX C1 computer) for support, Dr. *Alan Reed* (Erlangen) for discussions, and Dr. *W. Bauer* (Erlangen) for the NMR spectra.

Attractive ideas based on *qualitative* molecular orbital considerations often have not survived or have given disappointing results when subjected to experimental test. Homoaromaticity in neutral and carbanionic systems is a case in point.[1] Hence, such ideas are best tested calculationally at an adequate level of quantitative theory before investing the much greater effort needed for an experimental investigation.

When this project was begun a decade ago,[2,3] MINDO/3[4] was employed to evaluate the energies of the isodesmic reactions (a) and (b). The former predicts the



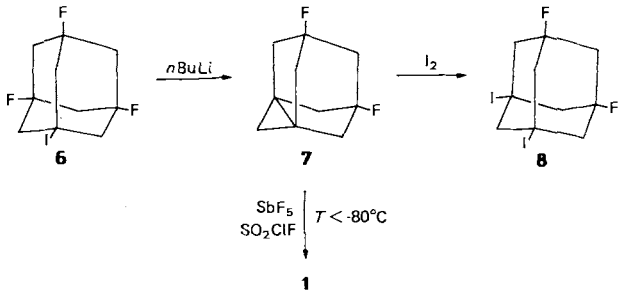
3 4 2



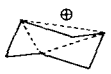
5 4 1

trishomoaromatic 1,3-dehydro-5-adamantyl cation **2**, an intermediate which has been implicated in solvolysis reactions,[5] to be stabilized by about 25 kcal/mol relative to the 1-adamantyl cation **3** and 1,3-dehydroadamantane **4**. Equation (b) indicates that the extension of the two-electron delocalization from three centers (as in **2**) to all four bridgeheads nearly doubles the stabilization. While **1** is tetratrishomoaromatic, this large resonance energy, along with the delocalized electronic structure, qualifies it for the designation "aromatic," as well. While *Olah* et al. have not succeeded in preparing the 1,3-adamantanediyl dication **5**,[6] nor, indeed, any other 1,3-carbodication in solution,[3] the high degree of stabilization indicated for **1** by Equation (b) encouraged us to seek experimental verification.

The problem of obtaining a suitable precursor for dication **1** was complicated by the known instability of 1,3-dehydroadamantane derivatives, e.g., towards reaction with oxygen and polymerization.[5] After a large number of preliminary experiments,[2] a simple route was found. When reacted with mercury(II) fluoride, 1,3,5,7-tetraiodoadamantane[7] gives a trisubstituted product, 1,3,5-trifluoro-7-iodoadamantane **6**, almost exclusively. This obviates the need for tedious chromatographic separations of polyhaloadamantane mixtures. With butyllithium in ether/pentane solution at −80°C, **6** gave (presumably via I–Li exchange and LiF elimination) 1,3-dehydro-5,7-difluoroadamantane **7** directly. As **7** only is stable at room temperature in solution (the solid polymerizes with near explosive exothermicity above 0°C), workup had to be carried out below −30°C. After crystallization from pentane at −70°C, **7** shows ^{13}C- and ^{1}H-NMR spectra typical of dehydroadamantanes.[5,17] Chemical characterization was achieved by reaction of **7** with iodine in hexane; 1,3-difluoro-5,7-diiodoadamantane **8** is formed in over 80% yield.[17]



Kept cold, solid **7** was added to a solution of SbF_5 in SO_2ClF (ca. 5 M) at temperatures below $-80\,^{\circ}C$ in order to prepare the NMR sample. The resulting dication **1** appears to be rather stable in superacid media, as spectra could be taken successfully at temperatures up to $0\,^{\circ}C$. The NMR parameters of **1** are remarkable, and constitute a proof of the nonclassical structure. The ^{13}C-NMR chemical shift of the bridgehead carbons, which share the positive charge at least in a formal sense, comes *upfield* ($\delta = 6.6$ at $-71\,^{\circ}C$, with internal [D_6]acetone/TMS capillary) of the methylene carbon resonances ($\delta = 35.6$), despite the presence of the two positive charges. *Shielded* values are characteristic of hypercoordinate carbocation centers. A good analogy is provided by the trishomocyclopropenyl cation **9**, which exhibits similar NMR parameters: $\delta = 4.9$ (CH) and 17.6 (CH_2).[8]



9

The triplet splitting of the CH_2 group in **1**, $J_{(C,H)} = 165$ Hz, in line with the trend found for adamantane (125 Hz)[9] and the 1-adamantyl cation **3** (148 Hz),[6] confirms not only the formation of dication **1** but also the strong deformation of the C-CH_2-C angles predicted by the calculations. Figure 2 gives the 3-21G ab initio geometry. The $J_{(C,H)}$ value, 168.4 Hz, for **9** is similar.[8] The single, sharp ^1H chemical shift of **1**, $\delta = 3.8$, also is unusual in comparison with $\delta = 4.2$[6] for the α-CH_2 groups of the 1-adamantyl cation, and $\delta = 1.74$[9] for the adamantane methylenes.

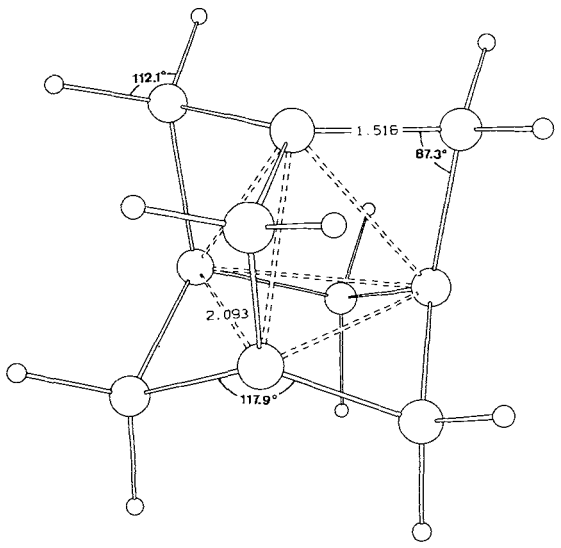


Fig. 2. The 3-21G-optimized structure of the dehydroadamantanediyl dication **1** (distances in Å). The 6-31G*-optimized data are similar: C-C = 1.504, 2.052 Å, C-C-C = 86.0, 118.2°, H-C-H = 114.2°.

These chemical shifts can be analyzed in several ways. If **1** were a classical, rapidly equilibrating dication (an unlikely possibility!), the bridgehead carbon chemical shift should be an average of the values found for the carbocation center in the 1-adamantyl cation **3** ($\delta = 300$)[6] and a cyclopropane bridgehead in 1,3-dehydroadamantane **4** ($\delta = 37.3$).[5] The chemical shift ($\delta = 169$), predicted for the bridgehead carbons by the classical model on this basis, deviates from the experimental value by over 160 ppm! Alternatively, the sums of all the ^{13}C chemical shifts for **1** (240 ppm) and for 1,3-dehydroadamantane **4** (454 ppm) may be used as a classical-nonclassical classification criterion.[10] For typical classical carbodications, the dication-neutral difference is on the order of +800 ppm (i.e., about twice that found on the same basis for monocarbocations). For **1**, the difference is *negative*, −214 ppm! Such negative values (but not as large) are found, e.g., for the related trishomocyclopropenyl cation **9** (−48 ppm),[10] and for the 7-norbornadienyl cation (−96 ppm).[10]

Clearly, the ^{13}C-NMR data for **1** cannot be reconciled with a classical, rapidly equilibrating model. But how well do the experimental shifts compare with those predicted by a nonclassical model? The IGLO (individual gauge for localized molecular orbitals) method has been demonstrated to give good to excellent agreement between calculated and experimental chemical shifts for both classical and nonclassical carbocations.[11] For example, the IGLO (DZ basis set) and experimental (in parentheses) ^{13}C-NMR chemical shifts for the 1-adamantyl cation **3** are: $\delta = 337.7$ (300.0), 57.7 (66.6), 67.8 (87.6), and 37.2 (34.6). When applied to **1** (without prior knowledge of the experimental results), bridgehead ($\delta = 7$) and methylene carbon ($\delta = 33$) chemical shifts were calculated (DZ basis on the 3-21G geometry). The remarkable agreement with the experimental values ($\delta = 6.6$ and 35.6) speaks for itself. The calculated proton chemical shift, $\delta = 3.0$, is lower than experiment ($\delta = 3.8$), but the latter, measured from an internal standard, depends on the magnetic anisotropy of the medium and is somewhat uncertain.

As indicated by population analysis at various theoretical levels (MNDO, MINDO/3, STO-3G, 3-21G), the bonding and charge distribution in **1** are revealing. The positive charge resides not only on the bridgehead carbons but also on the 12 hydrogens; the methylene carbons are neutral or even negatively charged. The overlap among the bridgehead carbons at 3-21G//3-21G (0.38 vs. about 0.7 for a normal C-C single bond),[16] is significant, consistent with the dotted-line representation. Each bridgehead carbon is involved with one electron, and each has a total bond order of 0.5. Charge delocalization in a nearly spherical topology, as well as partial bridging among the bridgehead positions, is responsible for the stability of **1**.

The dehydroadamantanediyl dication **1** now takes its place along with pyramidal cations,[12–14] e.g., those based on $(CH)_5^{\oplus}$ and $(CH)_6^{2\oplus}$, as purely "organic" examples of *three-dimensional aromaticity*[15] which exhibit large resonance energies. *Hückel's* $4n+2$ rule, involving *interstitial* instead of π electrons, can easily be extended to such systems.[15]

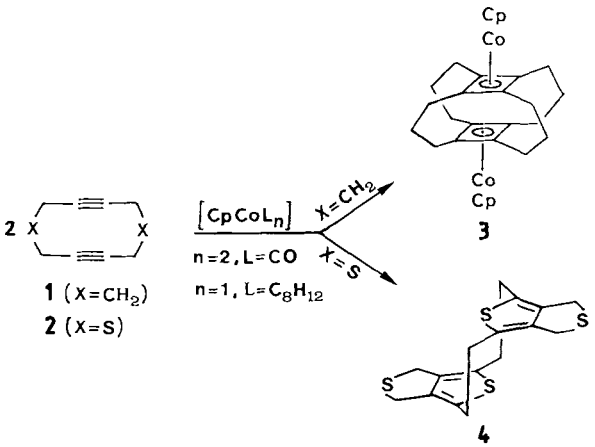
Dimerization of 1,6-Dithiacyclodeca-3,8-diyne in the Presence of Cobalt Complexes. A Simple Synthesis of a [2.2](2,5)Thiophenophane Derivative**

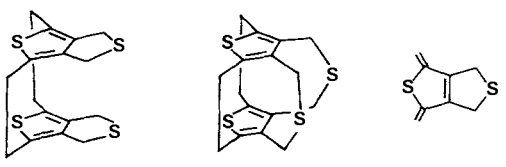
By *Rolf Gleiter,* Michael Karcher, Bernhard Nuber,* and *Manfred L. Ziegler*

Dedicated to Professor Hermann Schildknecht on the occasion of his 65th birthday

Recently, we showed that cyclodeca-1,6-diyne **1** undergoes dimerization in the presence of $[CpCo(CO)_2]$ or $[CpCo(C_8H_{12})]$ ($Cp = \eta^5$-C_5H_5) to give a superphane of cyclobutadiene, **3**, doubly capped by CpCo units.[1]



To test the scope and limitations of this new reaction, we have investigated the reaction of 1,6-dithiacyclodeca-3,8-diyne **2**[2] with $[CpCo(CO)_2]$ and $[CpCo(C_8H_{12})]$. Heating **2** (1.0 g, 5.95 mmol) with $[CpCo(CO)_2]$ (1.07 g, 5.95 mmol) in *n*-octane yielded a colorless product (120 mg) which contained no CpCo unit. The analytical data of the product (see Table 1) showed a molecular weight of 336, and the IR, UV,[3] and NMR data indicated the presence of thiophene units and two nonequivalent CH_2 bridges. When **2** was heated with less than the equimolar amount (10%) of the Co complexes, we obtained the same product. Three structural possibilities, the *anti* and *syn* isomers **4** and **5**, respectively, and the cage compound **6**, are compatible with the spectroscopic data.



From the observation that the most intense peak in the mass spectrum of the product is at *m/z* 168 ($M^{\oplus}$/2), we favored **4** and **5** over **6**.

Table 1. Most relevant physical data of **4**.

IR (KBr): $\tilde{\nu}$ = 2950 (w), 2940 (m), 2920 (m), 2840 (w), 1440 (m), 1430 (m), 1365 (m), 1315 (m), 1170 (m), 1045 (w) cm^{-1}

UV (CH_2Cl_2): λ_{max} (lgε) = 253 (3.91), 288 nm (3.83)

^{1}H-NMR ($CDCl_3$, 300 MHz, TMS): δ = 2.73-2.84, 2.97-3.07 (AA'BB'), 3.94, 3.78 (AB, J_{AB} = 12.8 Hz)

^{13}C-NMR ($CDCl_3$, 75.46 MHz): δ = 146.2 (s), 138.8 (s), 30.3 (t), 27.8 (t)

MS (70 eV): m/z = 336 (2.9%, $M^{\oplus}$), 168 (100%, $M^{\oplus}/2$)

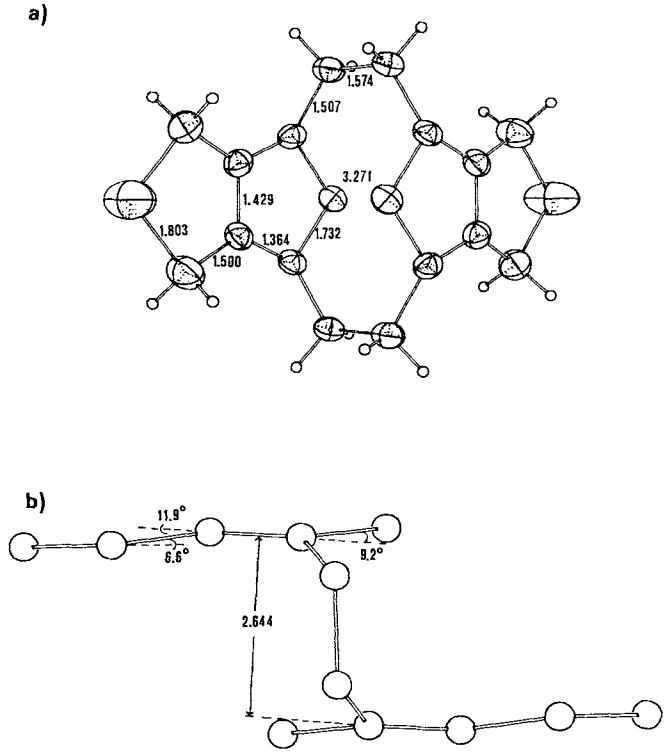

Fig. 1. Crystal structure of **4** with important distances [Å] and angles. a) View from above; b) side-on view.

To solve this structural problem and to obtain further details of the molecular structure, we carried out an X-ray investigation.[4] The results show that **4** is present in the crystal (Fig. 1). The thiophene rings are envelope shaped; the plane C2-S-C5 forms an angle of 9.2° with the plane of the sp^2 carbon atoms. The planes of the latter are separated by 2.644 Å. Similar geometric parameters were found for the parent system [2.2](2,5)thiophenophane.[5]

Concerning the mechanism of the reaction, we assume as intermediate a cobaltacyclopentadiene[6] in which one sulfur center is associated with the metal. Such a complex may yield the exomethylene derivative **7**, which dimerizes to give **4**.

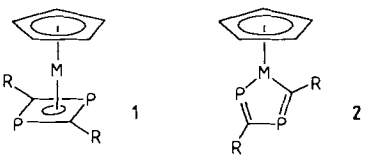
Bis(η^5-cyclopentadienyl)-1,3-diphosphabicyclo[1.1.0]butane-2,4-diylzirconium: A Simple Synthesis of an Unusual Molecule**

By *Paul Binger,* Bruno Biedenbach, Carl Krüger,* and *Manfred Regitz*

Recently, both we[1] and an English group[2] succeeded independently in preparing η^4-1,3-diphosphacyclobutadiene metal complexes **1** (M = Co, Rh; R = *tert*-butyl) starting from λ^3-phosphaalkynes. The 2-metalla-1,4-diphosphacyclopentadienes **2**, which are analogues of the intermediates involved in the numerous reported syntheses of η^4-cyclobutadiene metal complexes,[3] can be postulated as being involved in this cyclodimerization. However,



compounds of the type **2** have never been detected or isolated. We therefore attempted to synthesize analogous compounds of zirconium by reaction of λ^3-phosphaalkynes with [Cp_2Zr] (Cp = η^5-C_5H_5) generated in situ. These coordinatively unsaturated Zr^{II} species react with a variety of alkynes to give zirconacyclopentadiene derivatives.[4-8]

Reaction of [Cp_2ZrCl_2] with magnesium and 2,2-dimethylpropylidynephosphane **3** in the presence of $HgCl_2$[4] afforded orange-red crystals having the stoichiometry [$Cp_2Zr\{P_2C_2(C(CH_3)_3)_2\}$] (53% yield, correct elemental analysis, molecular weight (MS) = 420), to which structure **4** has been assigned. Complex **4** can also be obtained from [Cp_2ZrCl_2], butyllithium, and **3**[7] (yield 26%) or from [Cp_2Zr(butadiene)] and **3**[8] (58%).

[**] This work was supported by the Stiftung Volkswagenwerk.

The ^{31}P-NMR spectrum of **4** (singlet at $\delta = -247$) shows that the new compound cannot be a zirconium complex of the type **1** or **2**. Since the structure of **4** could not be established unequivocally from its ^{1}H- and ^{13}C-NMR spectra,[9] an X-ray crystal structure analysis was performed, the result of which is presented in Figure 1.[10] The X-ray

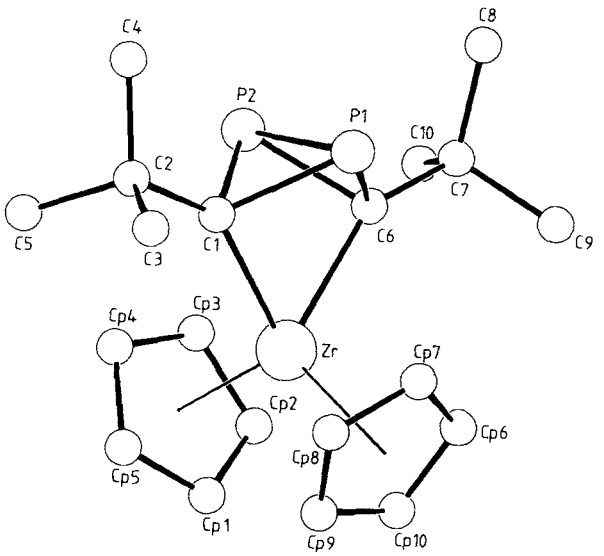

Fig. 1. Crystal structure of **4**. Important bond lengths [Å]: Zr-C1 2.213(3), Zr-C6 2.210(3), C1-P1 1.900(3), C1-P2 1.891(3), C6-P1 1.912(3), C6-P2 1.886(3), P1-P2 2.147(1).

structure reveals that **3** has undergone dimerization to form a folded 1,3-diphosphabicyclo[1.1.0]butane, which is bonded to the metal through two Zr–C σ bonds. These bonds are approximately 0.04 Å shorter than Zr–C_{sp^3} bonds (2.25–2.27 Å).[11] The distance between the bonded phosphorus atoms is only 2.147(1) Å. By contrast, in planar or slightly bent $1\lambda^3,3\lambda^3$-diphosphetanes[12] or $1\lambda^5,3\lambda^5$-diphosphetes,[13] this distance is 2.68–2.75 Å; we measured earlier a P–P distance of 2.73 Å for **1** (M = Co).[1] No bond is evident between Zr and the P1–P2 bridge (Zr-P1, 2.906 Å; Zr-P2, 2.909 Å).

The interplanar angle (123.8°) of the staggered Cp rings bonded to the tetrahedrally coordinated Zr atom is normal for Cp_2Zr systems.[11] The ring puckering characteristic of bicyclobutanes (110–128°)[14] is 100° for **4** (between the planes C1-C6-P1 and C1-C6-P2) and 70° (between the planes P1-P2-C1 and P1-P2-C6). Molecular models[15] reveal that this leads to steric interactions between the Cp rings and the *tert*-butyl groups; for this reason, the *tert*-butyl groups deviate slightly from an eclipsed arrangement along the C1–C6 axis.

Accordingly, complex **4** is derived from a new λ^3-phosphaalkyne dimer. At present, we can only speculate as to how it is formed. Presumably, an initially formed η^4-1,3-diphosphabicyclobutadienezirconium complex **1** (M = ZrCp, R = *tert*-butyl) undergoes transformation to **4**. This suggestion is supported by the observation that the fragments $[CpCoP_2]^{\oplus}$ and $[CpCo(RC{\equiv}CR)]^{\oplus}$ are preferentially formed in the mass spectrum of **1** (M = Co).[1] Furthermore, SCF calculations have shown that diphosphatetrahedrane is significantly more stable than 1,3-diphosphacyclobutadiene.[16]

Experimental Procedure

Compound **3** (2.20 g, 22.0 mmol) [17] was added over 1 h to a suspension of $[Cp_2ZrCl_2]$ (1.67 g, 5.71 mmol), magnesium powder (0.7 g, 28.8 mmol), and $HgCl_2$ (1.55 g, 5.71 mmol) in 40 mL of tetrahydrofuran (THF) at 0°C. The orange-red suspension was then allowed to warm to room temperature, stirred for approximately 15 h, and filtered through Celite, and the THF was removed at approximately 20°C/12 torr. The residue was dissolved in 20 mL of diethyl ether and the resulting solution was filtered once again through Celite and then cooled to −78°C. After approximately 12 h, the orange-red crystals of **4** were filtered off and dried at 10^{-3} torr: 1.27 g (53%), m.p. > 300°C.

The Role of Debye Screening Length in Ordered Arrays of Cylindrical Nickel Dimethylglyoxime Particles**

By *Tsuneo Okubo**

There are many systems of biological interest in which long cylindrical particles of macromolecular dimensions form three-dimensional, hexagonal arrays with an interparticle center-to-center distance that may be several times the diameter of the cylinders.[1,2] *Bernal* and *Fankuchen*[1] carried out detailed X-ray analyses of cylindrical tobacco mosaic virus (length 300 nm, diameter 17 nm) and found

[*] Prof. Dr. T. Okubo
Department of Polymer Chemistry
Kyoto University, Kyoto 606 (Japan)

[**] This work was supported by the Kurata Foundation and the Ministry of Education, Science, and Culture (Japan).

that a distinct ordered phase of the particles formed in solution. The ordering has been clarified experimentally and theoretically and has been ascribed to the interplay between electrostatic interparticle repulsion and attractive van der Waals forces. However, the balancing of these forces in the formation of the ordered hexagonal arrays remains an open question.[3,4] Recently, this author described in detail the lattice structures of heavy spheres (specific gravity 1.05–19.3) in sedimentation equilibrium.[5–7] From these experiments it was concluded that the ordered structure of the spheres is caused by electrostatic intersphere repulsions and elongated Debye screening lengths around the spheres, which are counterbalanced by the force due to the gravitational field.

Monodisperse, cylindrical particles of nickel dimethylglyoxime (length 9.6 μm, diameter 0.12 μm) have now been used to form hexagonal arrays in sedimentation equilibrium. The interparticle distances at different initial concentrations were determined and then used to obtain the Young's modulus of the lattice structures.

The particles were obtained by the reaction of nickel acetate with dimethylglyoxime: 0.5 g of dimethylglyoxime (biacetyldioxime) in 50 mL of ethanol and 0.4 g of nickel acetate in 40 mL of water were added to 200 mL of an aqueous solution (1.75 wt%) of nonionic surfactant OP-30 (polyoxyethylene(30)octylphenyl ether, Nikko Chemicals Co., Tokyo (Japan)). The mixture was stirred and 400 mL of water was added. The scarlet-red sols thus obtained were purified by dialysis against deionized pure water for more than three weeks. The size of the cylindrical (rodlike) particles was determined using an electron microscope. The length and the diameter were 9.6 ± 1.4 μm and 0.12 ± 0.03 μm, respectively. The monodispersity in their sizes was rather high. The zeta potential of the sols was -44.4 ± 1.4 mV in pure water (Lazer Zee meter, model 501, Pen Kem, Inc., Bedford Hills, NY (USA)). The water used for the purification and for solution preparation was deionized by using cation- and anion-exchange resins (Amberlite IR-120B and IRA-400) and further purified by a Milli-Q reagent-grade water system (Millipore Co., Bedford, MA (USA)).

Photographing of the particles of nickel dimethylglyoxime was carried out with a reversed-type metallurgical microscope (Axiomat IAC, Carl-Zeiss, D-7082 Oberkochen (FRG)). The suspension cell was made from a glass tube (height 7 cm, diameter 2 cm), which had an object glass at one end. The ordered structure was observed within several hours after 10 mL of the suspension was introduced into the cell, and reliable data on the interparticle distance could be obtained after 24 h. The height of the sedimentation layer of the cylindrical particles was less than 1 mm in sedimentation equilibrium.

Microscopic observation was made through the object glass at the bottom of the cell. A typical picture is shown in Figure 1. The cylindrical particles are hexagonally arranged in the salt-free suspension. The microscopic observation revealed that the particles behaved like enlarged cylinders according to the Debye screening length (D_1), and the effective sizes of the cylinders including D_1 decreased as the ionic strength of the solvent increased ([NaCl] = 10^{-6}–10^{-3} M). It should be mentioned here that the ordered distribution was observed throughout the whole range of the object glass, although the grain boundaries were often observed. The Debye screening length (D_1) is calculated from Equation (1):

$$D_1 = (4\pi B n)^{-1/2} \quad (1)$$

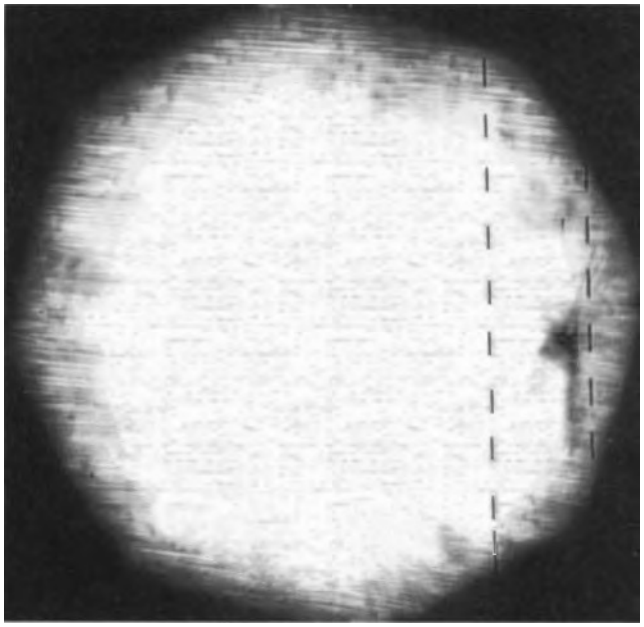

Fig. 1. A typical picture showing the ordered arrays of cylindrical particles of nickel dimethylglyoxime in sedimentation equilibrium. $\phi^* = 0.0816$ vol% in salt-free aqueous suspension. The distance between the dashed parallel lines is 10 μm. The cylindrical particles move around the equilibrium points and are distributed regularly along the object glass.

Here, B is the Bjerrum length given by $e^2/\varepsilon k T$, where e is the electronic charge, ε the dielectric constant of the solvent, and n is the concentration of "free" cations and anions in solution. In the absence of foreign salts, n is the sum of the concentration of diffusible counterions and concentrations of hydrogen and hydroxide ions from the dissociation of water. We have no information on the stoichiometric charge number on the surface of the particle. Furthermore, the fraction of free-state counterions of spherical particles has been reported to be smaller than 0.1.[8,9] In this experiment, the concentration of the free-state counterions could be negligible, or at most does not exceed the concentrations of the hydrogen and hydroxide ions. We estimated the effective ionic concentration of the water used to be ca. 1×10^{-6} M. D_1 was evaluated as 0.43 μm. This calculated value is very close to the experimental value, $D_1 = 0.42$ μm, determined from the extrapolated value of the interparticle distance at the top layer of the sedimentation suspension, $2D_{\mathrm{exp,u}}$ ($= 0.95$ μm). It is clear that the observed value of $2D_{\mathrm{exp,u}}$ is explained satisfactorily by the Debye screening length, although the more reliable repulsive potential of electrical double layers must be taken into account for a quantitative comparison.

It is interesting that the observed interparticle distance at the bottom of the sedimented layer, $2D_{\mathrm{exp}}$, decreased continuously as the initial concentration of the particles increased. This means that the shells of Debye screening length around the cylinders are soft and elastic and can be compressed rather easily by the cylinders of the upper layers owing to the earth's gravity. According to *Crandall* and *Williams*[10] and this author,[5] Young's modulus of the sedimented suspension layer, E, can be estimated from Equation (2):

$$2D_{\mathrm{exp}} = 2D_{\mathrm{exp,u}} - (\rho_{\mathrm{eff}} g l 2 D_{\mathrm{exp,u}} \phi^*)/(100 E) \quad (2)$$

Here, ϕ^* is the initial concentration of nickel dimethylglyoxime sols, g the gravitational constant, ρ_{eff} the effective density, given by the specific gravity of cylinders minus

that of solvent, and l the height of the liquid layer in the observation cell. Figure 2 shows plots of $2D_{exp}$ vs. ϕ^* for the cylindrical particles in the deionized state. The linearity was satisfactory in the region of $\phi^* < 0.05$ vol%, and the values of $2D_{exp,u}$ and E were estimated from the intercept and slope as 0.95 μm and 0.47 Pa, respectively. It is interesting to note that this value of E is similar to those of ordered structures of spherical particles reported hitherto[5-7,9-11] (i.e., between 0.01 to 100 Pa).

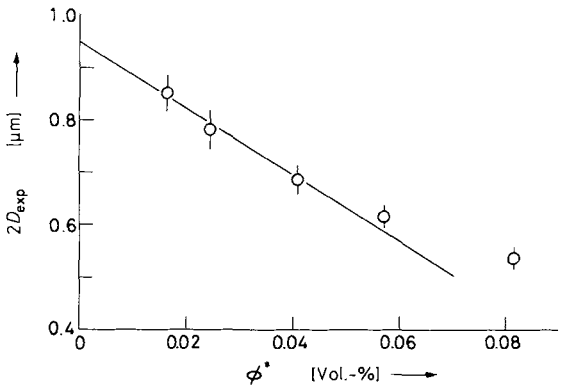

Fig. 2. $2D_{exp}$ vs. ϕ^* plots for cylindrical particles of nickel dimethylglyoxime in salt-free aqueous suspension. $2D_{exp,u} = 0.95$ μm.

These experiments show that the Debye screening length plays an important role in the ordering of the cylinders. Although a quantitative discussion still remains, the ordering of the cylinders can be attributed to the effective hard-sphere model for spheres, where the Debye length is added to the real size of spheres. This model is consistent with the Derjaguin–Landau–Verwey–Overbeek theory (DLVO theory) on colloidal stability.[12]

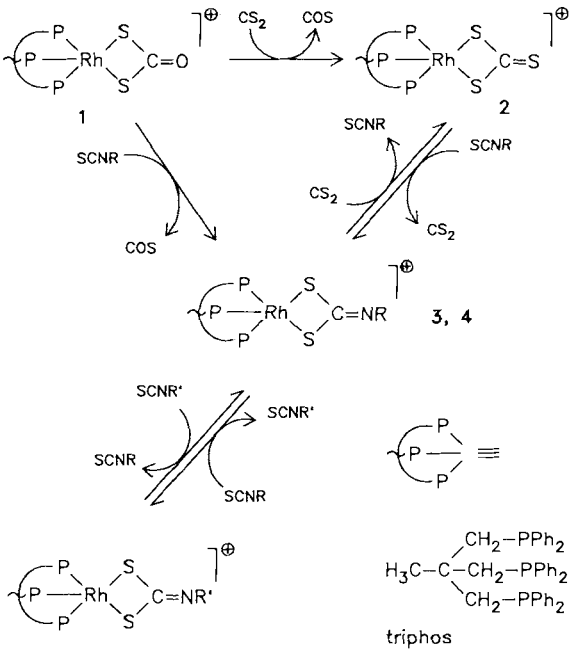
Metathesis of CS_2-Like Heteroallenes on 1,1-Dithio Complexes of Rhodium(III)

By *Claudio Bianchini,* Andrea Meli,* and *Franco Vizza*

A reaction of both technological and scientific relevance is the metal-assisted metathesis of unsaturated molecules such as alkenes,[1] alkynes,[2] and nitriles.[3] It is now generally recognized that the rupture and formation of chemical bonds within metallocyclic intermediates are important mechanistic steps of these reactions. Here we report on a new type of metal-promoted metathesis reaction which involves as unsaturated substrates CS_2-like heteroallene molecules (Scheme 1).



Scheme 1. The anions BPh_3^- are omitted. **3**, R = Ph; **4**, R = Et.

The dithiocarbonate complex **1**[4] reacts immediately in CH_2Cl_2 at room temperature with an equimolar amount of CS_2 to give, in quantitative yield, trithiocarbonate **2**[5] (red crystals) and COS. By treatment of **2** with a twofold excess of SCNR (R = Ph, Et), the dithiocarboimidic acid derivatives **3**, R = Ph,[6] and **4**, R = Et,[7] are precipitated as deep violet crystals, and CS_2 is evolved. The latter reactions are reversible; i.e., the addition of a twofold excess of CS_2 to **3** or **4** leads to quantitative formation of **2** and liberates the organoisothiocyanate. Alternatively, **3** and **4** can be directly obtained by reacting **1** with equimolar amounts of SCNPh or SCNEt, respectively. These isothiocyanates are also metathesized by the rhodium system, the only reaction condition being a twofold excess of the appropriate isothiocyanate.

Compound **1** and the related derivatives **2**, **3**, and **4** are coordinatively and electronically unsaturated complexes. The two sulfur atoms, although capable of transferring electron density to rhodium via π interaction, do not adequately satisfy the electron requirement of the metal,

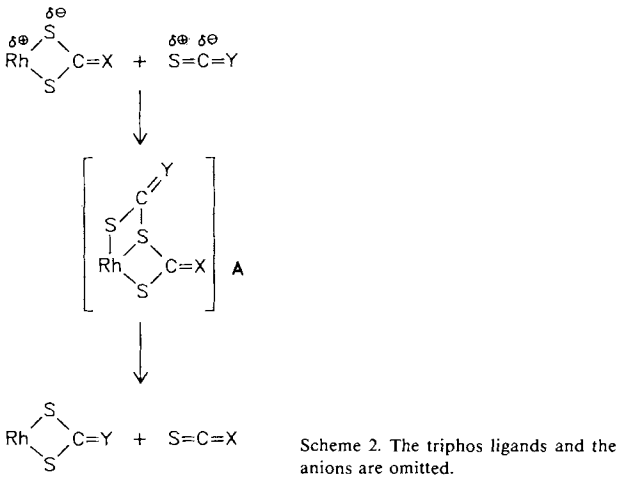
which therefore still remains an electrophilic center.[8] Indeed, all of these compounds contain polarized Rh–S linkages which can promote the heterolytic activation of H_2.[8] In addition, **1** tends to eliminate CO or COS either photochemically[9] or thermally.[10] When COS is eliminated, the [(triphos)RhS]$^{\oplus}$ fragment dimerizes to give [(triphos)Rh(μ-S)$_2$Rh(triphos)]$^{2\oplus}$.[9, 11] Although to a lesser extent, **2**, **3**, and **4** exhibit the same tendency to chelotropically eliminate heteroallene moieties from the RhSC(X)S rings (X = S, NR).[10]

In view of these results and considerations, a reasonable mechanistic interpretation of the reactions in Scheme 1 is shown in Scheme 2. This mechanism involves the formation of intermediary metallocycles of type **A** via [2+2] cycloadditions.[12] The extrusion of one of the two heteroallene moieties of the intermediates **A** completes the reactions. These can be monitored by ^{31}P-NMR spectroscopy.[13]



Scheme 2. The triphos ligands and the anions are omitted.

The replacement of the COS fragment in **1** by CS_2 or SCNR appears as the most favored reaction pathway, being quantitatively achieved by equimolar amounts of the latter coreactants. By contrast, **2** and **3** (or **4**) seem to have comparable thermodynamic stabilities. Their quantitative interconversion occurs only when large excesses of CS_2 or SCNR are used, whereas stoichiometric reactions give equimolar mixtures of **2** and **3** (or **4**). In nice agreement with the apparent, minor stability of the dithiocarbonate complex **1**, complexes **2** and **3** (or **4**) are not converted into **1** even when treated with a large excess of COS.

Experimental Procedure

2: Neat CS_2 (0.06 mL, 1 mmol) was added to a solution of **1** (1.14 g, 1 mmol) in 30 mL of CH_2Cl_2. There was an immediate color change from red brown to brilliant red and, simultaneously, COS evolution. Addition of ethanol (40 mL) gave red crystals of **2**, which were collected by filtration and washed with ethanol and petroleum ether; yield 95%.

3, **4**: Dark violet crystals of **3** and **4** were obtained in excellent yields (ca. 95%) following the same procedure as above but replacing CS_2 with SCNR (R = Ph, Et). Alternatively, **2** was treated in CH_2Cl_2 with a twofold excess of SCNR and worked up as above. The interconversion between **3** and **4** was simply achieved by adding an excess of SCNEt or SCNPh to a CH_2Cl_2 solution of **3** or **4**, respectively.

The formation of COS, CS_2, and SCNR in the course of the reactions was determined by GC. Correct elemental analyses were found for all of the products here described.

Reactions of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ with Electrophilic Complexes of Copper and Gold. Synthesis of the Pd_4 Cluster $[Pd_4(\mu\text{-Cl})_2(\mu\text{-dppm})_4](PF_6)_2 \cdot 2(CH_3)_2CO$**

By *Pierre Braunstein,* Michael A. Luke, Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*

The rich chemistry of the binuclear complexes $[M_2(\mu\text{-dppm})_2X_2]$ (M = Pd and/or Pt; X = Cl, Br, or I; dppm = *P,P'*-methylenebis(diphenylphosphane) has been widely studied.[1] However, most of the investigations have been concerned with the formation of A-frame complexes via insertion of small molecules, e.g., CO, SO_2, or RCN, into the M–M bond or with their reactivity toward nucleophilic metal reagents, e.g., carbonylmetalates.[2] Two recent publications have described the reactions of such diplatinum complexes, as exemplified by $[Pt_2(\mu\text{-dppm})_2Cl_2]$, toward electrophilic metal reagents.[3] In both cases, the expected complexes of the A-frame type were obtained. This prompted us to present some new results involving the reaction of the analogous dipalladium complex **1** with copper and gold complexes. In the reactions with copper complexes, we unexpectedly isolated the novel, tetranuclear palladium cluster complexes **2a** and **2b**. The X-ray crystal structure of **2a** revealed a 10-membered ring structure, unprecedented in this class of compounds.

When the solution resulting from the reaction of $[(PPh_3)CuBr]_4$ and $TlPF_6$ in tetrahydrofuran (THF) was added to a suspension of **1** in THF (Cu : **1** = 1 : 1), the solu-

tion rapidly turned red accompanied by the formation of a small amount of white precipitate (CuCl). After filtration and removal of the solvent, a red powder was obtained. Layering an acetone solution of this mixture with pentane yielded red crystals of **2a** in ca. 40% yield. The identity and structure of **2a** was established by an X-ray diffraction study.[4] Complex **2a** crystallizes as an acetone solvate; the cations are centrosymmetrical (crystallographically imposed symmetry). Figure 1 shows a rectangular array for the four Pd atoms with the two shorter Pd–Pd distances (2.594(2) Å) being consistent with a metal–metal bond. Each Pd atom is in a distorted square-planar environment determined by two P atoms from dppm ligands, one Cl atom, and one other Pd atom. All four sides of the Pd_4 rectangle are bridged by dppm ligands. It is noteworthy that the Pd–P bonds have different lengths. The dppm ligands bridging the longer sides form much longer bonds (2.350(6) and 2.353(7) Å) than those bridging the shorter sides (2.220(5) and 2.229(6) Å). This difference is possibly due to both steric and electronic factors arising from the *trans* influence of the Pd–Pd bond and the bulk of the phenyl substituents. The longer sides of the metal array (3.742(3) Å) are also bridged by two chlorine atoms in an almost symmetrical fashion. The spectroscopic data[6] of **2a** are consistent with its solid-state structure.

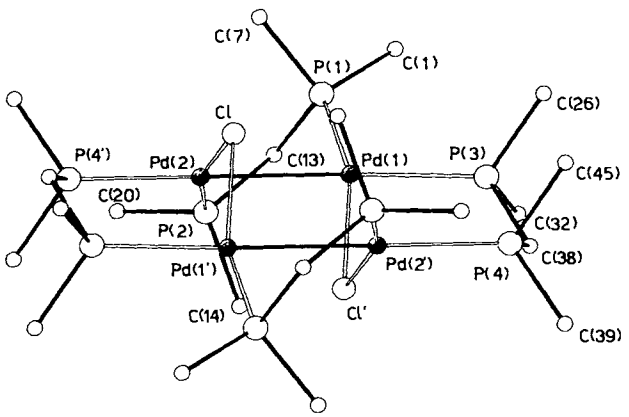

Fig. 1. Molecular structure of the cation of **2a**. Important bond distances [Å] and angles [°]: Pd1-Pd2 2.594(2), Pd1-Pd2' 3.742(3), Pd2-Cl 2.391(5), Pd1-Cl' 2.422(4), Pd1-P1 2.220(5), Pd2-P2 2.229(6), Pd1-P3 2.350(6), Pd2'-P4 2.353(7); Pd2-Cl-Pd1' 102.1(2), P1-Pd1-P3 104.0(2), P3-Pd1-Cl' 91.0(2), P1-Pd1-Cl' 158.0(2), Pd2-Pd1-P3 174.1(2), Cl'-Pd1-Pd2 84.3(2), P1-Pd1-Pd2 81.5(2), Pd1-Pd2-Cl 80.7(2), Cl-Pd2-P4' 91.2(2), P4'-Pd2-P2 105.2(3), P2-Pd2-Pd1 83.0(2), P2-Pd2-Cl 163.5(2), Pd1-Pd2-P4' 171.4(2). The 16 phenyl groups are each represented by their *ipso* carbon atom.

We found that the $BF_4^{\ominus}$ salt **2b** could be readily synthesized from **1** and $[Cu(CH_3CN)_4]BF_4$ (1 : 1). The choice of solvent appears to play a crucial role in determining the rate and selectivity of the reaction; in particular, the use of CH_2Cl_2 gave **2b** in virtually quantitative yield. The stoichiometry of the reagents is also of vital importance, since a slight excess of the copper reagent results in the formation of another complex, **3**. Indeed, the use of a threefold excess of $[Cu(CH_3CN)_4]BF_4$ resulted in the quantitative formation of **3**. Complex **3** is also formed from the reaction of **1** with two equivalents of $AgBF_4$ in CH_3CN.

Reaction of **1** with $[(PPh_3)AuCl]$ and $TlPF_6$, instead of with $[(PPh_3)CuBr]_4$ and $TlPF_6$, resulted in an extremely oily mixture of phosphane-containing cluster compounds ($^{31}P\{^1H\}$-NMR evidence). Despite extensive efforts, no solid material could be isolated. Since no precipitate was formed, the gold must be complexed in some form or other. The $^{31}P\{^1H\}$-NMR data of the product obtained from the reaction of **1** with $[(C_2H_5)_2SAuCl]$ reveal that all four phosphane atoms of the dppm ligands are now chemically and magnetically nonequivalent. Presumably, the Au atom has inserted into a Pd–P bond.[7] This reaction emphasizes the greater lability of the Pd–P compared with the Pt–P bond, since with the diplatinum precursor an A-frame structure was observed in which AuCl bridges the Pt–Pt bond.[3b]

Our results illustrate that the main driving force in the reactions of **1** with copper reagents is the precipitation of CuCl, thus leaving a vacant site on the palladium center. If no other suitable ligands are present in the reaction medium, this unit then dimerizes to give the tetranuclear palladium cluster. This is supported by the observation that the reaction of **1** with **3** leads to the formation of **2b** (1 : 1 molar ratio, CH_2Cl_2, 25°C, 2 h, 90% yield based on $^{31}P\{^1H\}$-NMR). These results also illustrate that in certain systems the isolobal analogy between group 11 metal complexes does not always guarantee similar reactivity.

IR (Nujol): $\tilde{\nu}=2285$ w (C≡N), 1075 s, br ($BF_4^\ominus$) cm^{-1}. Satisfactory elemental analyses were obtained for all complexes.

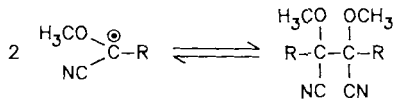
[7] The ^{1}H- and ^{31}P{^{1}H}-NMR data are consistent with a *triangulo* $Pd_2Au(\mu\text{-dppm})_2$ structure in which the dppm ligands span Pd–Au and Pd–Pd bonds, giving rise to patterns previously encountered in related heterometallic clusters synthesized in this laboratory [2a, d].

The Effect of Solvent on the Stability of mero-Substituted Alkyl Radicals**

By *Hans-Dieter Beckhaus* and *Christoph Rüchardt**

In analogy to the stabilization of carbenium ions by electron-donating substituents (donors) and of carbanions by electron-withdrawing substituents (acceptors), a particularly strong stabilization of radicals by pairs of substituents having opposite polarity ("captodative"- or "mero"-substituted) has been postulated to occur.[1] The experimental testing of this concept[2] on several examples did not lead to evidence for more than an additive effect of the substituents on lowering the enthalpy of formation of radicals of this type, e.g. **1a**, **b**.[3] Moreover, theoretical studies[4] do not allow conclusions to be drawn concerning a particularly strong stabilization of captodative-substituted radicals. Indeed, ab initio calculations showed that the effect of the substituents on tetracoordinated carbon atoms can give rise to changes in energy that are similar to those observed for radicals. This was also established experimentally by determining the strengths of C–C bonds.[5] The interaction of two geminal substituents with the σ-electron framework is about as strong as that with the unpaired electron (π system) of the radical.

Accordingly, a discussion of the effect of substituents on radicals cannot be restricted to only electron resonance phenomena. Nonetheless, a dramatic increase in "mero stabilization" by polar solvents was recently suggested on the basis of the resonance between substituents having opposite polarities at a radical center, which formally leads to charge-separated structures.[6] Calculations by an INDO-UHF-SCRF method indicated a reduction in energy of the radical **1c** by approximately 30 kcal/mol on going from a nonpolar (dielectric constant $\varepsilon=1$) to a polar ($\varepsilon=80$) medium.[6] The suggestion of such an enormous solvent effect motivated us to test this postulate experimentally.



1 **2**

a, R = C_6H_5; **b**, R = t-C_4H_9; **c**, R = H

We therefore studied the effect of solvent on the homolysis of the symmetrically hexasubstituted ethanes **2a** and **2b** to give the radicals **1a** and **1b**, respectively. Using the ESR method described earlier,[3] we determined the position of the equilibrium between **2a** and **1a** as well as the reaction enthalpy and entropy of dissociation (ΔH_r and ΔS_r, respectively) from its temperature dependence between 140 and 200°C. A stabilization of the radicals by amounts of the order calculated for **1c** should reduce the reaction enthalpy in polar solvents ($\varepsilon=80$) by up to 60 kcal/mol. However, the results of the measurements revealed no significant effect of the solvent on the dissociation (Table 1). The formation of the radicals is no more favored in ethylene glycol [$\varepsilon(100°C)=25.6$][7] and in succinic anhydride [$\varepsilon(60°C)=50$][7] than in the less polar diphenyl ether ($\varepsilon\approx3$). The agreement of the reaction enthalpy ΔH_r with the enthalpy of activation $\Delta H^{\neq}$[3] measured earlier in mesitylene supports the reliability of the results. This is unequivocal evidence in disfavor of the postulated increase in the "mero stabilization" by polar solvents, even when one takes into account that the polarity of the solvent at the temperatures of measurement is somewhat lower. The use of solvents of still higher polarity was not possible owing to technical problems in the ESR measurements. In order to also include a highly polar solvent in the investigation, we determined the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of the thermal dissociation of **2b** by ki-

Table 1. Thermodynamic reaction and activation parameters for the formation of α-cyano-α-methoxyalkyl radicals **1** by homolytic dissociation of the dimers **2** in different solvents (with standard deviation; for the method of measurement, see [3] and [8]).

netic differential scanning calorimetry (DSC) measurement[8] at 100–150 °C in *N*-methylacetamide [ε = 70 (150 °C), 110 (100 °C)].[9] In order to suppress the back reaction, we added the usual[3] 20% of thiophenol as radical trap. The activation data determined were in excellent agreement with those obtained in the nonpolar medium (mesitylene/thiophenol 8 : 2) (Table 1).

These results unequivocally rule out a "mero stabilization" of α-cyano-α-methoxyalkyl and -benzyl radicals by polar solvents. The findings show that semiempirical calculations or simple resonance rules do not allow general conclusions to be drawn concerning the relationship between the structure and stability of radicals. An experimental test is also required.

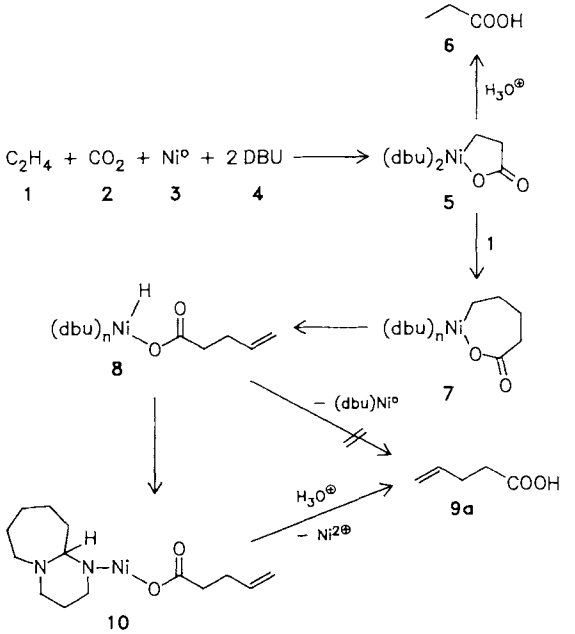
A 1-Oxa-2-nickela-5-cyclopentanone from Ethene and Carbon Dioxide: Preparation, Structure, and Reactivity

By *Heinz Hoberg,* Yolande Peres, Carl Krüger,* and *Yi-Hung Tsay*

Heterocycles containing metal atoms in the ring are of increasing importance.[1] Metallacycles have been prepared from CO_2 and compounds containing C–X multiple bonds (X = C, O, NR) in the presence of transition-metal complexes.[2] The ligands so far used have been chelating ligands, which promote the 1 : 1 couplings at nickel(0) complexes but largely suppress subsequent reactions.[3] 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) has been employed to carry out C–C bond formation between CO_2 and ethene as well as styrene at Ni^0 complexes with the formation of unsaturated carboxylic acids.[4] However, it has not been possible so far to isolate intermediates involved in these reactions, which are important for catalytic processes. We have now succeeded in isolating in 70% yield a 1 : 1 coupling product, the metallacycle **5**, formed from ethene **1** and CO_2 **2** at a Ni^0 complex **3** in the presence of DBU **4** (Scheme 1)[5] and in determining its structure. In addition, we have investigated the subsequent reactions of **5** with systems containing CC double bonds (Scheme 2). The results have provided insights into the course of the reactions of alkenes with CO_2 at nickel complexes.[4]



Scheme 1. Ni^0 = [Ni(cod)$_2$], cod = 1,5-cyclooctadiene.

It was not possible from the IR spectrum of **5** to determine which N atoms of the two DBU ligands are bonded to the Ni atom; i.e., the question whether **5** is a 16-, 18-, or 20-electron complex could not be answered. An X-ray crystal structure analysis of **5**[6] (Fig. 1), however, revealed that it is a 16-electron complex with square-planar coordination of the Ni atom, in which two N atoms of the DBU ligands occupy neighboring coordination positions and the carboxylate moiety is bound to the metal through both a Ni–O bond and a relatively short Ni–C(sp^3) bond.[7] A strong *trans* effect of the Ni–C23 bond is revealed by a large Ni–N distance to one of the two DBU ligands. Because of the planarity of the metallacycle (torsion angle O1-C21-C22-C23: 2.8°), nonbonding interactions between the Ni atom and the H atoms at C22 (Ni–H 3.6 Å) and C23 (Ni–H 2.4 Å) are not possible.

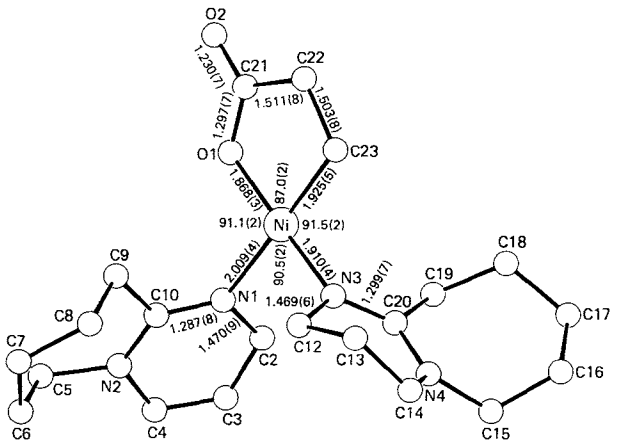


Fig. 1. Crystal structure of **5** with the most important bond lengths [Å] and angles [°] [6].

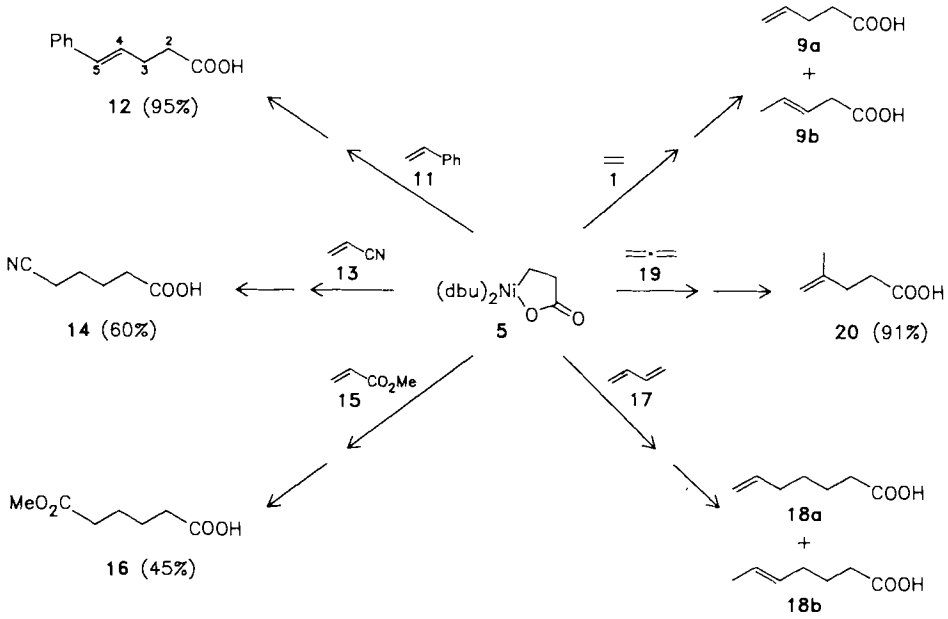
[*] Prof. Dr. H. Hoberg, Dr. Y. Peres, Prof. Dr. C. Krüger [+], Dr. Y.-H. Tsay [+]
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr 1 (FRG)

[+] X-ray crystal structure analysis.

Complex **5** exhibits properties characteristic for an organometallic compound. Thus, hydrolysis yields, as expected, propionic acid **6** (85%, identified as the methyl ester, see Scheme 1). The Ni-C bond is available for insertion reactions with systems containing CC double bonds; the products obtained after acid hydrolysis are shown in Scheme 2.[8]



Scheme 2. Products, after acid hydrolysis, of the reactions of **5** with systems containing C=C bonds. Yields based on **5**.

For example, **5** reacts with ethene **1** with formation of the linear, unsaturated carboxylic acids **9** (together 79%, **9a** : **9b** = 1 : 2; (*E*)-**9a** : (*Z*)-**9a** = 3 : 2), with styrene **11** with regioselective C-C bond formation to give **12**, with acrylonitrile **13** to give **14**, with methyl acrylate **15** to give **16**, with 1,3-butadiene **17** to give a mixture of the acids **18** (together 10%, **18a** : **18b** = 2 : 1), and with allene **19** to give the branched carboxylic acid **20**. It is noteworthy that **5** reacts with both **1** and **11** to give products in which the double bond of the starting material is still present. For this reason, **5** can be regarded as a model complex for a possible intermediate involved in catalysis.

The formation of *n*-pentenoic acid **9a** from **1** and **2** presumably occurs by the mechanism shown in Scheme 1. Following C-C coupling of **1** with **2** to give **5**, a second molecule of **1** is inserted, with ring expansion, to give **7**; subsequent β-H elimination results in the formation of the NiH species **8**. The reductive elimination to give the carboxylic acid **9a** accompanied by regeneration of the starting Ni^0 complex, which is important for a catalytic course of the reaction, is not possible; instead, Ni-H addition to the DBU CN double bond occurs with formation of the catalytically inactive complex **10**. Acid hydrolysis results in cleavage of the Ni carboxylate **10** to the *n*-pentenoic acid **9a**.

The synthesis of **5** represents the first isolation of an intermediate involved in the reaction of CO_2 with alkenes and has allowed its subsequent reactions to be investigated. That these C-C couplings have so far only taken place stoichiometrically and not catalytically is due to the DBU ligand. With other ligands, it should be possible to carry out the catalytic reaction of alkenes with CO_2 to give unsaturated carboxylic acids.

[5] *Experimental procedure* for **5**: **4** (6 mL, 39 mmol) was added to [Ni(cod)$_2$] [9] (3.54 g, 12.9 mmol) in 100 mL of tetrahydrofuran (THF) at −78°C in a 200-mL steel autoclave. CO_2 (ca. 15 bar) and ethene (ca. 30 bar) were then admitted. The stirred reaction mixture was gradually warmed to 40°C and kept at this temperature for ca. 90 h. Approximately 50 mL of THF was distilled under vacuum from the cooled solution and replaced with ca. 60 mL of diethyl ether. The resulting precipitate was filtered, washed with ether, and dried in vacuum. Yield: 3.64 g (60%) **5**. After cooling the filtrate to 0°C, additional **5** crystallized in the form of well-shaped crystals (0.425 g, 7%).—IR (KBr): 1560—1650 cm^{-1} (C=O overlapped by C=N bands), correct elemental analysis, m.p. = 92°C (dec.).
[6] **5** crystallizes in the space group $P2_1/n$, $a = 10.958(1)$, $b = 12.198(2)$, $c = 18.101(2)$ Å, $\beta = 90.81°$, $V = 2419$ Å^3, $Z = 4$, $\mu(Mo_{K\alpha}) = 8.3$ cm^{-1}, $\rho_{calcd} = 1.29$ g cm^{-3}, 5889 measured reflections ($\pm h$, $+k$, $+l$), 5458 unique reflections, 2900 observed ($I > 2\sigma(I)$), 258 refined parameters, $R = 0.059$, $R_w = 0.062$. Two molecules of THF in the unit cell, disordered around a center of inversion. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52379, the names of the authors, and the journal citation.
[7] Compound **5** does not react (via the Ni-C bond) with typical electrophiles such as aldehydes, ketones, and imines to give insertion products.
[8] *Experimental procedure* for **12**: Styrene **11** (5 mL, 40 mmol) was added to **5** (1.76 g, 4.04 mmol) in 100 mL of THF and the reaction mixture was then warmed to 60°C for ca. 30 h. The THF was then distilled off and the residue was hydrolyzed with ca. 20 mL of 2 N H_2SO_4 and extracted with ether. The ether phase was shaken several times with 1 N NaOH, the aqueous phase was acidified again with 2 N H_2SO_4, and the carboxylic acid was extracted with ether. The ether phase was dried over $MgSO_4$ and the ether was distilled off. The residue is analytically pure **12**. Yield: 0.404 g (95%).—m.p. = 80°C, MS: *m/z* 176 ($M^{\oplus}$). ^{1}H-NMR (200 MHz, $CDCl_3$, TMS, 20°C): $\delta = 7.30$ (d, 5H, Ph-H), 6.45 (d, 1H, 5-H), 6.22 (m,

1 H, 4-H), 2.55 (m, 4 H, 2,3-H; $J(2,3)=15.8$ Hz).—The other reactions of **5** shown in Scheme 2 were carried out analogously (no optimization). In each case, the reaction products were converted into the methyl esters with CH_3OH/HCl. The characterization and quantification of the ester was carried out by GC or by GC-MS (reference compounds).

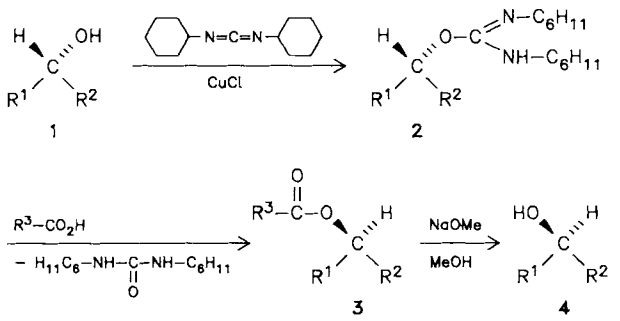
Inversion of the Configuration of Secondary Alcohols via Isourea Ethers Prepared in situ

By *Johannes Kaulen**

Procedures for the inversion of the configuration of secondary alcohols,[1] e.g., the Mitsunobu procedure for "inverting esterification,"[1a,b] are of considerable preparative interest. Such methods can be employed to establish the correct stereochemistry of secondary alcohols in those cases where the direct synthesis only leads to the undesired, "false" stereoisomer. In connection with the resolution of racemates, inversion procedures are also of interest as a way of utilizing the undesired enantiomer, thereby making chiral synthesis more economical. We have now found that the esterification of secondary alcohols via isourea ethers,[2] which has been known in principle for many years, offers a new, simple procedure for the inversion of the configuration of alcohols.[3]



The secondary alcohol **1** (as the pure enantiomer or diastereomer) is converted in situ into the isourea ether **2** by addition to dicyclohexylcarbodiimide. When **2**, without isolation, is allowed to react further with carboxylic acids in a one-pot procedure, the esters **3** are obtained in a smooth reaction; the dicyclohexylurea that is formed simultaneously can be removed by filtration.

We have been able to show, for the first time, that the esterification proceeds with practically complete inversion of the configuration, so that the ester **3** has the opposite configuration of the alcohol **1** ("inverting esterification"). Saponification of the ester **3** leads to ready formation of the inverted alcohol **4**.

The new procedure can be applied to a variety of secondary alcohols, high enantiomeric excesses and good yields[4] being obtained in every case (Table 1). Small amounts of the corresponding olefins are sometimes formed as by-products.

Of the carboxylic acids used to carry out the "inverting esterification," formic acid proved to be particularly useful, but other carboxylic acids can be employed as well.

Table 1. "Inverting esterification" of secondary alcohols. All inverted esters **3** and alcohols **4** were formed with >99% *ee* (or, if applicable, >99% *de*).

Alcohol **1**	Conditions **2**→**3** [a]	Invert. ester **3** R^3 [b]	Yield **1**→**3** [%]	Invert. alcohol **4** [b]	Yield **3**→**4** [%]
1a	A	CH_3	66	**4a**	90
1a	A	H	83		
1b	B	H	50	**4b**	91
1c	B	H	80	**4c**	90
1c	B	$CH{=}CH_2$	51		
1c	B	$C(CH_3){=}CH_2$	64		
1d	C	H	75	**4d**	90

[a] A: dioxane, 100°C, 20 h; B: toluene, 110°C, 20 h; C: dioxane, 110°C, 20 h. [b] The structures were established by IR and ^{1}H-NMR spectroscopy. The chemical purity was checked by capillary gas chromatography. The determination of the enantiomeric purity was carried out by measuring the optical rotations or, in cases in which other centers of asymmetry are present in the molecule, by capillary gas chromatographic separation of the diastereomers.

When acrylic acid or methacrylic acid is used, the inverted acrylates and methacrylates, respectively, are obtained directly and can be polymerized to yield optically active polymers.

Dioxane and especially toluene are particularly advantageous as solvents for the esterification; chlorinated solvents are unsuitable, since mainly exchange of the hydroxyl group for chlorine occurs in such solvents.

Owing to the mild reaction conditions, the simple workup, and the relatively inexpensive reagents, the "inverting esterification" via isourea ethers promises to be an interesting alternative to the known inversion procedures.

General Experimental Procedure

2 [2]: **1** (0.5 mol) was allowed to stir with dicyclohexylcarbodiimide (0.6 mol) and copper(I) chloride (50 mg) for 3 d in the absence of moisture at room temperature [5]. Solid, high-melting alcohols were allowed to stir in a small amount of anhydrous dioxane for 3 d at 40–50°C.

3: Crude **2** (0.5 mol) was dissolved in 200 mL of dry solvent (preferably toluene) and the carboxylic acid (0.6 mol, preferably formic acid) was added to the stirred solution at room temperature. The resulting mixture was heated at

reflux for 20 h and allowed to cool, and the nearly quantitatively precipitated dicyclohexylurea was filtered off and washed with a small amount of dichloromethane. The combined organic phases were concentrated in vacuum and the residue was dissolved in ether. The ether solution was washed with $NaHCO_3$ solution to a final pH of 7 and then dried over Na_2SO_4 and concentrated once again. The crude **3** was purified by distillation (or by column chromatography).

4: **3** (0.5 mol) was allowed to stir in 250 mL of methanol with 5 mL of 30% $NaOCH_3$ for 12 h. After concentration in vacuum, the residue was distilled without further workup.

Example: Neomenthyl formate **3c**: The isourea ether **2c** obtained from (−)-menthol **1c** (156 g, 1.0 mol) and dicyclohexylcarbodiimide (248 g, 1.2 mol) was allowed to stir with 45 mL (1.2 mol) of formic acid in 400 mL of dry toluene for 20 h at 110 °C. The reaction mixture was then worked up according to the general procedure described above. After distillation, 147 g (80%) of **3c** was obtained, b.p. = 52–60 °C/0.25 mbar, $[\alpha]_D^{20} = +51.9°$ (neat) ($[\alpha]_D^{20} = +51°$ [6]).

Structure Elucidation of a New Icosapeptide from Human Semen**

By *Klaus Schneider, Josef Reiner,* and *Gerhard Spiteller**

The Edman degradation as modified by *Chang* and *Wittmann-Liebold* has proved extremely useful in the structure elucidation of peptides.[1] The only disadvantage of this method is the uncertainty in determining the *C* terminus, since, once the peptide has been degraded to two or three residues, the extraction of the hydantoin can result in partial loss of the remaining peptide. Therefore, at the very least, an amino-acid determination is necessary.

This determination may no longer be necessary when the exact molecular weight of the peptide is known; the molecular weight, in turn, can be determined by "soft ionization methods."[2] However, the amount of sample required increases greatly with increasing molecular weight (by a factor of approximately 10 in going from mass 1500 to mass 2500). In our experience, the amounts of small, unknown peptides thus required are hardly obtainable.

In order to investigate peptides having molecular weights between 2000 and 3000 dalton, which we isolate from biological material, we employ the following strategy: We carry out tryptic and chymotryptic cleavage of the peptide, separate the fragments by HPLC (since the highest degree of purity possible is necessary for subsequent sequencing by MS), and then determine the molecular weights of these fragments by LSIMS.[***] Only in optimal cases—usually when the peptide has a molecular weight of < 1000 dalton—is a direct and unequivocal structure derivation of the fragments appearing in the LSIMS spectrum possible. Only a very small amount of the sample used for the LSIMS measurement (ca. 1 μg) is consumed. So far, the remainder of the sample had been discarded. We have now found, however, that the remainder of the sample can be eluted unchanged from the target and separated from the matrix substance (glycerol) by HPLC. Part of the remaining sample is then treated with a drop of CH_3OH/2 N HCl. After 12 h standing, all COOH and all $CONH_2$ groups have been converted into $COOCH_3$ groups. An LSIMS determination of this sample gives the number of COOH and $CONH_2$ groups originally present. The greater part of the remaining sample is subject to sequencing by double Edman degradation according to the modified procedure of *Chang* and *Wittmann-Liebold* et al.[3] Each cleaved amino-acid fragment is subjected to both thin-layer chromatography and HPLC (to be certain of the results). The recovered sample can, if necessary, be used for determination of the *N* terminus by dansylation. Either an LSIMS analysis of the whole peptide[4] or hydrolytic cleavage of the peptide followed by determination of the derivatized *N*-terminal amino acids by HPLC is possible.

The application of the procedure outlined above is exemplified by the sequencing of a new 20-amino-acid peptide that we isolated in 300-μg amounts from human semen. Determination of the molecular weight of the whole peptide by LSIMS was not successful. The amount of sample used for the measurement was approximately 20 μg.

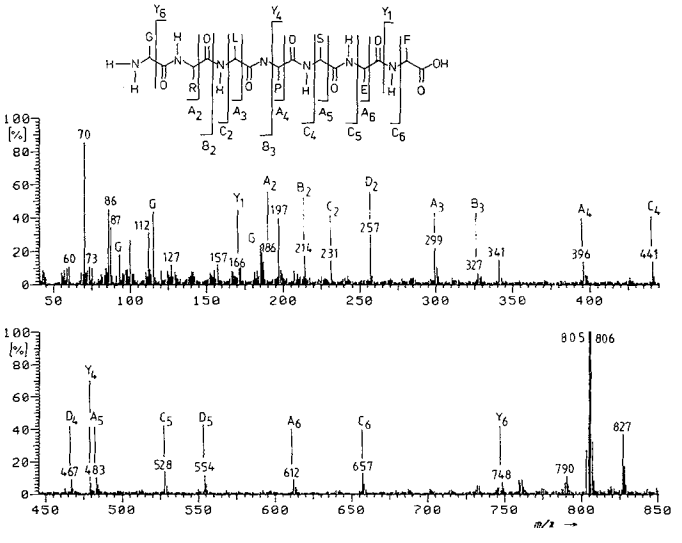

Fig. 1. LSI mass spectrum of positive ions of the fragment C1: Gly-Arg-Leu-Pro-Ser-Glu-Phe; in the one-letter code, G-R-L-P-S-E-F, m/z 805 = $MH^{\oplus}$. The signals marked with "G" are due to the matrix material (glycerol). The peptide fragment ions (A_n ... Z_n) are denoted according to the system of *Roepstorff* et al. [7]. In the scheme above the spectrum, the one-letter code applies only to the side chains of the amino acids.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

[***] LSIMS = liquid secondary ion mass spectrometry. In this method, charged molecules are ejected from a liquid matrix by bombardment with Cs^+, thereby making mass spectrometry possible. FAB mass spectrometry functions similarly, Xe atoms, instead of Cs^+, being used.

In order to analyze the peptide mass spectrometrically, we therefore cleaved it with trypsin and chymotrypsin. (Carboxamidomethylation[5] and reaction with cyanogen bromide[6] in order to modify the SH groups and to cleave the peptide chain on the carboxyl side of a methionine residue were unsuccessful). After tryptic digestion, separation by RP-HPLC yielded three fragments (T1, T2, and T3), whereas the chymotryptic digestion gave only two fragments (C1 and C2).

The LSI mass spectrum of C1 (Fig. 1) showed, in addition to the pronounced $MH^{\oplus}$ ion of mass m/z 805, intense fragments that made it possible to derive the sequence up to the *N*-terminal dipeptide of mass 231. There are only two possibilities for this remaining peptide in terms of amino-acid sequence: namely, (1) Asn-Val or Val-Asn or (2) Gly-Arg or Arg-Gly.

In order to distinguish between the four possibilities, the peptide fragment C1 was treated, as described above, with a drop of CH_3OH/2 N HCl. An LSIMS analysis of the reaction product (Fig. 2) gave the number of COOH and $CONH_2$ groups originally present from the shift of the molecular weight from mass 805 to mass 833. This demonstrates the presence of two ester groups.

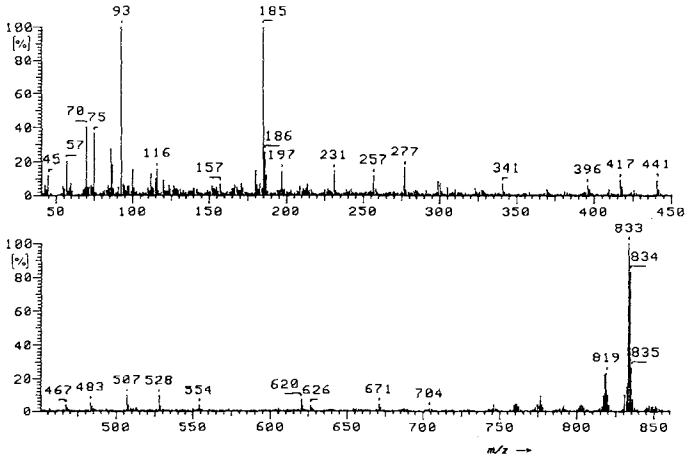

Fig. 2. LSI mass spectrum of positive ions of the fragment C1, treated with MeOH/2 N HCl; m/z 833 = $MH^{\oplus}$. The ions m/z 93 and m/z 185 are due to the matrix material (glycerol).

This finding rules out the end groups Asn-Val and Val-Asn. In order to distinguish between Gly-Arg and Arg-Gly, the end group was determined with dansyl chloride (Dns-Cl)[8] and the resulting Dns derivative determined by HPLC. Reaction of the hydrolysate with Dns-Cl made it possible to distinguish between the two possible amino acids of equal molecular weight, leucine and isoleucine (by HPLC). Therefore, the sequence for C1 was determined to be Gly-Arg-Leu-Pro-Ser-Glu-Phe.

Although the LSI mass spectrum of the fragment C2 showed a molecular ion of mass m/z 1412, a sequence analysis from the spectrum was not possible owing to the lack of sufficient sequence-specific ions.

Also in the case of the tryptic fragments T1 and T2 it was only possible with LSIMS to determine the molecular weights (Figs. 3 and 4). The fragment T3, no molecular ion of which could be obtained by LSIMS, yielded two secondary fragments upon chymotryptic digestion: CT1 is identical with C1; for CT2, having the mass 927, the LSI mass spectrum (Fig. 5) revealed several sequence-specific ions, but their intensities were too small for a structure der-

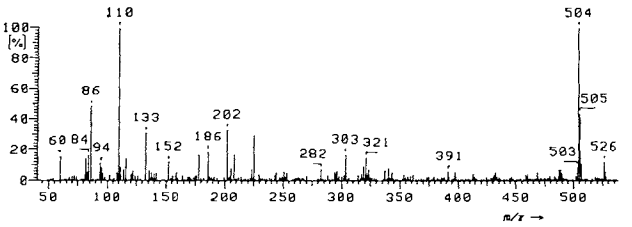

Fig. 3. LSI mass spectrum of positive ions of the fragment T1: Gly-Gln-His-Tyr; m/z 504 = $MH^{\oplus}$, m/z 526 = $MNa^{\oplus}$; glycerol background subtracted.

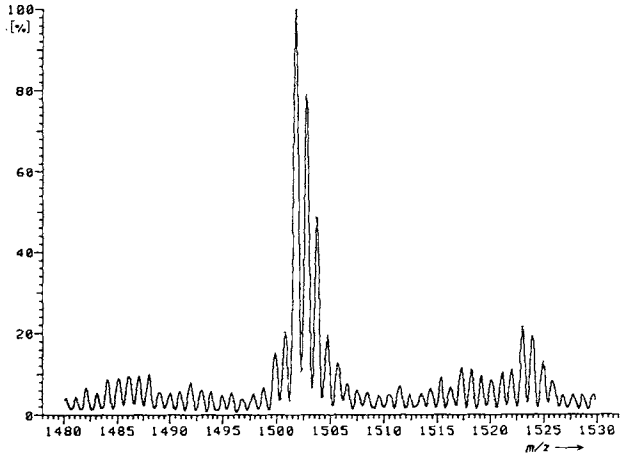

Fig. 4. LSI mass spectrum of the molecular ion region of the fragment T3: m/z 1501 = $MH^{\oplus}$: Leu-Pro-Ser-Glu-Phe-Ser-Gln-Phe-Pro-His-Gly-Ala-Gly-Lys. The amount of sample used in the measurement was approximately 5 μg.

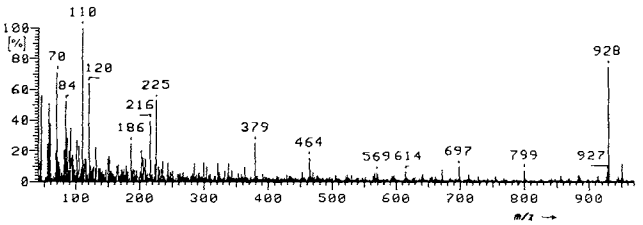

Fig. 5. LSI mass spectrum of positive ions of the fragment CT2: Ser-Glu-Phe-Pro-His-Gly-Ala-Gly-Lys; m/z 928 = $MH^{\oplus}$; glycerol background subtracted.

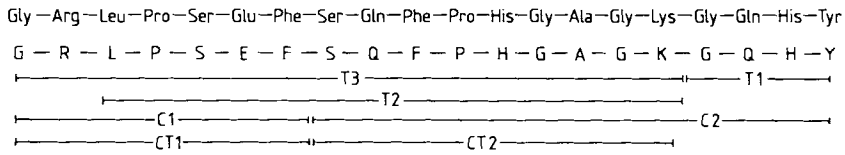
ivation. The sequence of the peptide CT2 was therefore determined by means of the manual microsequencing method of *Chang*[9] to be Ser-Gln-Phe-Pro-His-Gly-Ala-Gly-Lys and that of the partial fragment T1 to be Gly-Gln-His-Tyr.

The chymotryptic digestion of T2 yielded a fragment of mass m/z 591 (CT3) and the already known fragment CT2 of mass m/z 927.

CT3 has the sequence Leu-Pro-Ser-Glu-Phe and thus, except for the absence of the *N*-terminal dipeptide Gly-Arg, the same sequence as C1 and CT1. Therefore, the fragment T3 is only an incompletely tryptic-digested peptide.

If the molecular weights of the chymotryptic fragments C1 (mass 804) and C2 (mass 1412) are added, one obtains, after subtraction of 18 amu (= mass of H_2O) a molecular



Scheme 1. Structure of the new icosapeptide. For fragments, see text. Second line: one-letter code.

weight of 2198 for the peptide. The same mass is obtained from the fragments of the tryptic digestion T3 = CT1 (*M* 804) + CT2 (*M* 927) and T1 (*M* 503) after subtraction of 2 × 18. The structure shown in Scheme 1 is thereby obtained for the peptide. Analogous structures are unknown.

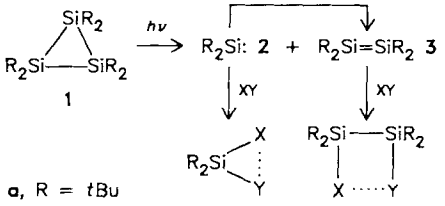
Phosphasilirenes, Three-Membered Rings Containing PC Double Bonds**

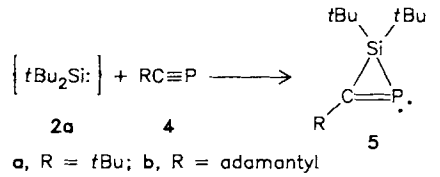
By *Annemarie Schäfer, Manfred Weidenbruch,* Wolfgang Saak,* and *Siegfried Pohl*

The photolysis of cyclotrisilanes **1** leads to cleavage of two Si–Si bonds to give a mixture of silanediyls (silylenes) **2** and disilenes **3**, which, for appropriate patterns of substitution, is completely transformed to **3**.[1,2] In the case of



compounds **3** that are thermally less stable, compounds **2** and **3** can be simultaneously or individually trapped by means of a variety of insertion and addition reactions.[3]

For example, di-*tert*-butylsilanediyl **2a**, obtained by irradiation of hexa-*tert*-butylcyclotrisilane **1a**,[4] undergoes [2 + 1] addition to the triple bond of nitriles (XY = RC≡N) to give azasilirenes, which, presumably owing to high ring



strain, undergo spontaneous dimerization to give 1,4- or 1,3-diaza-2,5-disila-1(6),3-cyclohexadienes.[5] Because the C=P bond is significantly longer than the C=N bond, addition of **2a** to phospha-alkynes[6] should lead to less strained and therefore more stable three-membered rings.

Irradiation of **1a** and the phospha-alkynes **4a**[7] and **4b**[8] in a molar ratio of 1 : 2 (in order, if possible, to trap the disilene **3a** in addition to **2a**) gives, in a surprisingly straightforward fashion, the phosphasilirenes **5a** and **5b**,[9] the first three-membered ring compounds containing a PC double bond.

The three-membered ring compounds **5** differ significantly from the formally similar "side-on"- bonded complexes of **4a** and platinum(0).[10] The differing bonding is reflected in the ^{31}P-NMR spectra: The signals for **5a** ($\delta = 274.0$) and **5b** (272.6) appear in the region characteristic of phospha-alkenes, whereas the "phosphaplatinacyclopropenes" give rise to values ($\delta \approx -55$[11]) typical of phospha-alkynes.[6]

Reaction of **5b** with [W(CO)$_5$(thf)] results in replacement of tetrahydrofuran (THF) and formation of the crystalline complex **6**.[12] The X-ray structure analysis of **6**[13] (Fig. 1) confirms the three-membered ring structure. The PC dis-

tance (168.6 pm) is typical of phospha-alkenes.[6] Within the three-membered ring, the smallest bond angle is at silicon, the largest at carbon. Together with the remarkably short C1–Si distance, the values found here establish the great similarity between the phosphasilirenes and the silirenes (silacyclopropenes), for which similar structural parameters have been measured.[14] The formation and structure of **5** thus provide a further example of the analogy between the reaction behavior of phospha-alkynes and that of acetylenes.[10]

Experimental Procedures

5a: Irradiation of **4a** (0.23 g, 2.3 mmol) and **1a** (0.50 g, 1.17 mmol) in 80 mL of *n*-hexane with a high-pressure mercury lamp (Heraeus TQ 150) led, within 1.5 h, to quantitative conversion. After distillation of the *n*-hexane, **5a** could be isolated as a bright yellow, unstable oil by HPLC (RP 18, acetonitrile as eluent).

5b: Analogously, irradiation of **4b** (0.65 g, 3.65 mmol) and **1a** (0.75 g, 1.76 mmol) in 80 mL of *n*-hexane for 3 h gave a product mixture, from which **5b** could be separated nearly quantitatively (based on **2a**) by HPLC (Polygosil 60, *n*-hexane) or column chromatography (silica gel 60, petroleum ether, 40–60 °C).

6: $W(CO)_6$ (2.4 g, 6.9 mmol) in 80 mL of THF was irradiated until approximately 80% of the amount of CO necessary to form $[W(CO)_5(thf)]$ had evolved and was removed. Compound **5b**, prepared from **4b** (0.97 g, 5.4 mmol) and **1a** (1.10 g, 2.6 mmol) in 80 mL of *n*-hexane, was then added to this solution and the resulting mixture was stirred for 30 min at room temperature. The solvent was removed under vacuum, petroleum ether 40–60 °C was added, and $W(CO)_6$ was filtered off. Yellow crystals of **6** formed from the reddish brown solution at −18 °C. These were recrystallized twice from pentane. Yield: 0.91 g (55% based on **2a**), dec. > 140 °C.

Synthesis and Chirality of Sixfold-Bridged Triple-Decker Phanes**

By *Norbert Sendhoff, Karl-Heinz Weissbarth,* and *Fritz Vögtle**

The few triple-decker phanes described so far were constructed either via several steps or from preformed cyclic partial structures.[1,2a] We describe here the first one-step synthesis, starting from open-chain educts, of the first sixfold bridged[2b] triple-decker cyclophanes **4**.

The recently achieved one-step multiple bridging[3] made it reasonable to attempt the synthesis of such triple-decker compounds from the partial structures constituting the three layers. Our earlier experiences[4] with steric factors indicated that the synthesis of the phane **3**, augmented with *meta*-phenylene rings, should be most promising. Moreover, the readily available and readily soluble *meta*-functionalized educts **1** and **2** could be employed in this synthesis.

The first reactions of **1** and **2a** carried out according to the dilution principle and "one-pot" procedures or the corresponding reactions of the components **5** and **6**, which do not contain spacers, in dimethylformamide (determined earlier to be the best solvent[3]), however, did not afford detectable amounts of the triple-decker compounds **3** and **4** or **7**, respectively. In preliminary experiments, therefore, the model reaction **2a** + **2b** → **8**[5] and the corresponding cyclization leading to the *meta*-/*para*-substituted double-decker phane **9** were optimized so that, in addition to a simple procedure, a relatively high yield was obtained [37% **8**, m.p. > 300 °C, $R_F = 0.6$ (CH_2Cl_2/CCl_4 1:1); 11% **9**, m.p. > 300 °C, $R_F = 0.5$ (CH_2Cl_2/cyclohexane 7:3)]. Decisive factors proved to be choosing the solvent mixture benzene/ethanol (2:1) and working at a not too high dilution.[6] These findings indicate that such multiple bond formations require exactly tailor-made reaction conditions in each case.

The first attempted application of the one-pot procedures worked out for the double-decker phanes to the sixfold bridge formation starting from **1**[3] and **2a** gave two chromatographically readily separable crystalline substances in a molar ratio of 1:2, together in 6% yield. The expected isomer **4**[7] having C_2 symmetry (a C_2 axis), m.p. > 300 °C, correlates with the following ^{1}H-NMR data: (CD_2Cl_2, 400 MHz): $\delta = 2.9$–3.7 (8 d, $J = 14.5$ Hz, 16H, CH_2; 2 dd, $J = 14.5$ and 5.6 Hz, 8H, CH_2), 6.05–7.8 (8 s,

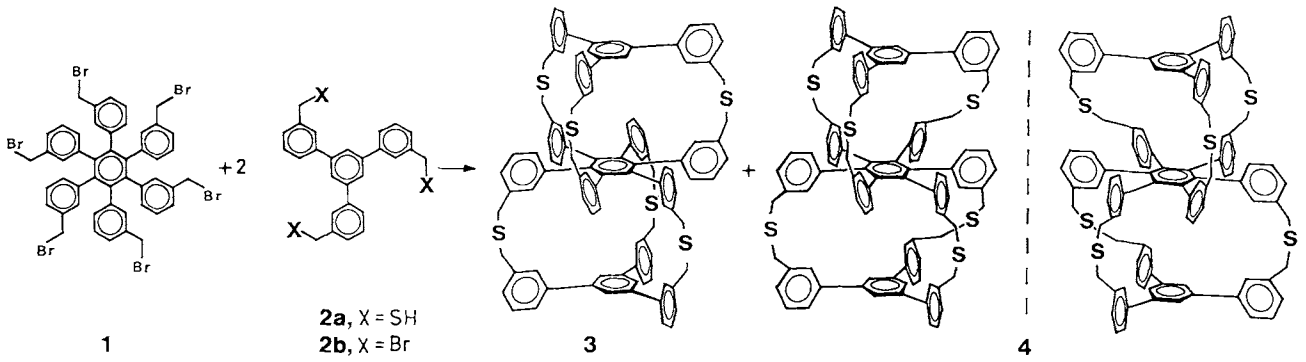
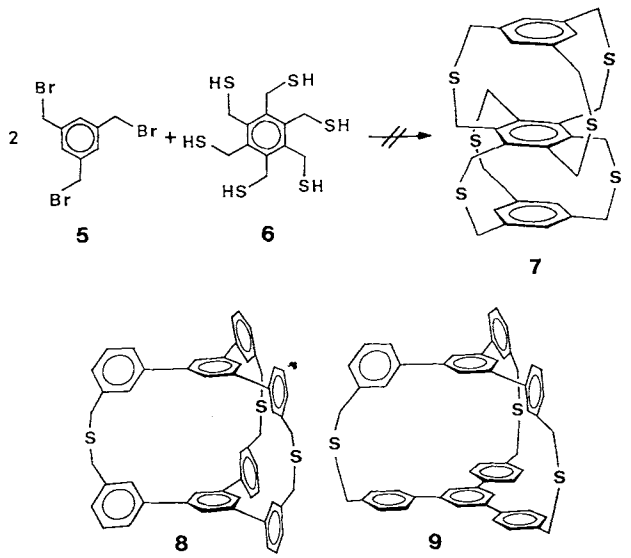
[**] This work was supported by the Fonds der Chemischen Industrie and by Degussa (supply of palladium dichloride). We thank Dr. *J. Peter-Katalinic*, Institut für Physiologische Chemie der Universität Bonn, Dr. *C. Wünsche*, Bayer AG, Wuppertal, and Prof. Dr. *H. Schwarz*, Technische Universität Berlin, for the mass spectra.





12 d, $J=8$ Hz, 6 t, $J=8$ Hz, 54 H, aromat. H).[8] FAB mass spectrometry gave a correct $[M\mathrm{H}]^{\oplus}$ ion peak for **4** ($m/z=1496$).[9]

Analysis of models reveals that the triple-decker **4**—despite the absence of chiral centers and in contrast to **3**—is helically chiral. Indeed, attempted chromatographic separations (HPLC) on Okamoto column material[10] were successful (eluent: *n*-hexane/methanol/2-propanol 3:1:0.6): the (−)-enantiomer is bound less strongly to the (+)-PTrMA column material than the (+)-enantiomer. Figure 1 shows the circular dichroism spectra of the enriched enantiomers of **4** obtained in this way (Cotton effect at $\lambda=252$ nm).[11]

The following optical rotations were obtained for the enriched enantiomers: $M^{22}_{436}=+271.97$, $[\alpha]^{22}_{436}=+18.18$ (in $CHCl_3$, $c=0.27$) and $M^{22}_{436}=-84.43$, $[\alpha]^{22}_{436}=-2.09$ (in $CHCl_3$, $c=0.48$).[11]

This study shows that "multilayered" molecules of this size and number of bridges may be easily prepared, characterized, and manipulated, when the steric requirements are already taken into consideration in designing the structure. Compounds **3** and **4** provide the largest molecular cavities in triple-decker cyclophanes so far. The simple synthesis opens up the possibility of preparing new cavities for the inclusion of guests in neighboring compartments and of synthesizing even higher oligo deckers.

Experimental Procedure

3[8] and **4**: **1** (2.00 g, 1.80 mmol) [3a], **2a** (1.63 g, 3.60 mmol) [3a], and Cs_2CO_3 (3.70 g, 11.3 mmol) were heated at reflux in 400 mL of benzene and 200 mL of ethanol in a 1-L flask (without dilution apparatus!) for 8 h. The reaction mixture was then evaporated to dryness and the residue was dissolved in dichloromethane. The resulting solution was refluxed for 3 h and then filtered while still hot. Column chromatographic separation of the nearly colorless, powdery mixture on silica gel (0.063–0.1 mm) with dichloromethane/cyclohexane 7:3 gave the two isomers **3** ($R_F=0.6$) [8] and **4** ($R_F=0.23$) in 2 and 4% yield, respectively. Compound **3** was further purified by repeated chromatography on a silica gel column with dichloromethane/cyclohexane 1:1 ($R_F=0.26$). **4**: MS: $[M\mathrm{H}]^{\oplus}=1496$.

[6] J. Fastrez, *Tetrahedron Lett. 27* (1987) 419.

[7] The formation of isomers was expected since earlier attempts had led to isomeric double-decker structures by means of fourfold bridging [4].

[8] We tentatively [9] assign the other cyclization product, m.p. > 300 °C, on the basis of the ^{1}H-NMR spectrum [(CD_2Cl_2, 400 MHz): $\delta = 3.6$ (m, br., CH_2), 3.7 (m, CH_2), 7.0 (s, aromat. H), 7.3–7.5 (m, aromat. H)] to the constitution **3** having D_{3h} symmetry. The ^{1}H-NMR spectra of **3**, but not of **4**, show a broad and a sharp CH_2 absorption at 20 °C, which we ascribe to a slow CH_2–S–CH_2 rotation.

[9] Despite repeated attempts, no $M^{\oplus}$ peak for **3** could be obtained.

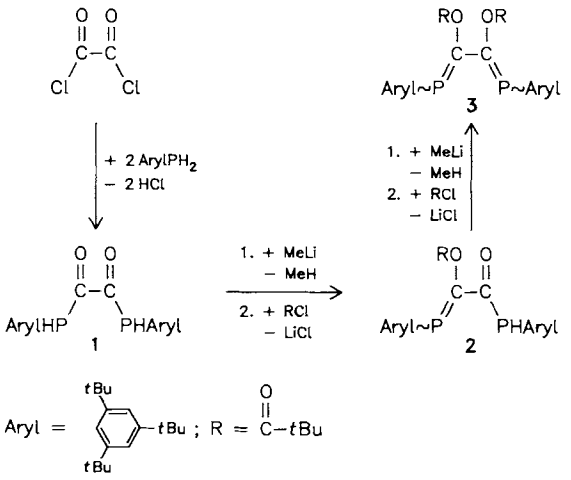
[10] a) Y. Okamoto, H. Urakawa, K. Ohta, H. Yuki, *Macromolecules 11* (1978) 719; b) Y. Okamoto, S. Henda, I. Okamoto, H. Yuki, S. Murata, R. Noyori, H. Takaya, *J. Am. Chem. Soc. 103* (1981) 6971; c) K. Meurer, A. Aigner, F. Vögtle, *J. Inclusion Phenom. 3* (1985) 51; d) F. Vögtle, J. Struck, H. Puff, P. Woller, H. Reuter, *J. Chem. Soc. Chem. Commun. 1986*, 1248.

[11] Since the separation on a preparative column was not successful, it had to be repeated several times on an analytical column (over three months). The (+) enantiomer was purified several times and can be regarded as highly enriched.

1,4-Diphospha-1,3-butadienes**

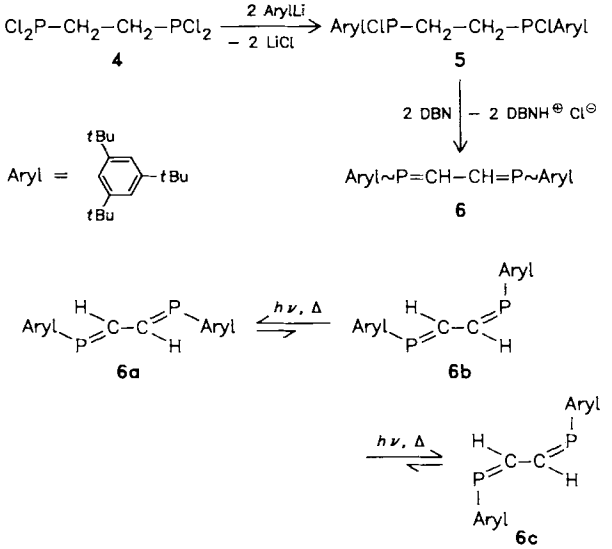
By *Rolf Appel,** *Johannes Hünerbein,* and *Nikolaos Siabalis*

Phosphacarbadienes are of interest because, owing to the similar behavior of the PC and the CC double bond, they can undergo a variety of pericyclic reactions such as the Cope rearrangement and cycloadditions.[1] Of the four possible diphospha-1,3-butadienes, derivatives of the 1,3- and 2,3-diphospha-1,3-butadienes are known at present.[2–4] Earlier attempts to obtain a missing member of this



series, the open-chain 1,4-diphospha-1,3-butadiene, by reaction of oxalyl chloride with disilylphosphanes led only to 1,2-dihydro-1,2-phosphete derivatives (diphosphacyclobutenes)[2] as a result of intramolecular [2+2] cycloaddition. These are also formed in the high-temperature reaction of cyclophosphanes with alkynes[5–7] and upon reaction of dichlorophosphanes with phosphirenes.[8] We have now found that the cycloaddition that occurs when the oxalyl chloride method is used can be suppressed by the introduction of 2,4,6-tri-*tert*-butyl moieties at the P atoms.

The reaction, carried out at −60 °C in *n*-pentane with the reactants in a 1:2 molar ratio, leads initially to the oxalic acid diphosphide **1** as a violet powder. It can be converted into its lithium enolate by reaction with methyllithium in tetrahydrofuran (THF) at −60 °C. The enolate, in turn, reacts with pivaloyl chloride to give the 1,4-diphospha-1-butene. Repetition of this sequence of reactions at room temperature leads to the 1,4-diphospha-1,3-butadiene derivative **3**. It is precipitated by addition of acetonitrile and recrystallized from toluene/acetonitrile (1:2). The structure of **3** (correct elemental analysis) is supported by the NMR, MS, and IR spectroscopic data.[9]



We prepared the *C*-unsubstituted 1,4-diphospha-1,3-butadiene **6** by reaction of ethylenebis(dichlorophosphane) **4** with 2,4,6-tri-*tert*-butylphenyllithium in a molar ratio of 1:2 at −80 °C in THF. The compound **5** thereby obtained can be dehydrochlorinated at −40 °C with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN). Compound **6** is obtained as a mixture of the stereoisomers **6a** (*E,E*) and **6b** (*E,Z*), which can be separated by fractional crystallization from toluene. The isomer **6c** (*Z,Z*) is exclusively formed from **6b** upon irradiation ($\lambda = 254$ nm) or warming in benzene (60 °C). The assignment of the three isomers (which gave appropriate IR and MS data as well as correct elemental analyses) to the proposed structures is based on the NMR spectroscopic data,[14] taking into consideration the information available for similarly substituted phosphaalkenes.[10–13] The ^{1}H-NMR spectrum of **6b** shows the typical pattern of an ABXY system, which, upon phosphorus decoupling, is reduced to a doublet of doublets with 14.4 Hz for the $^3J_{HH}$ coupling constant. The other coupling constants, which could not be determined from the experimental spectra, were determined by simulation.[14]

The 1,4-diphospha-1,3-butadienes are suitable as ligands for σ-coordinated complexes with transition metals.[15] Attempts to carry out pericyclic reactions with maleic anhydride, acetylene dicarboxylate esters, dimethylbutadiene, or cyclopentadiene were unsuccessful.[15]

Synthesis and Structure of a Stable Iodoselenide**

By *Wolf-Walther du Mont,* Silvia Kubiniok, Karl Peters,* and *Hans-Georg von Schnering*

Stable binary compounds between selenium and iodine, elements having very similar electronegativities, have not been characterized so far; the system selenium–iodine is only characterized by a eutectic.[1,2] Diorganosulfides and -selenides react with iodine to give only charge-transfer adducts. The formation of iodo(phenyl)selenide as a reactive intermediate has been suggested to occur during C–C bond formation and accompanying cyclization of 1,5-dienes using the recommended Toshimitsu reagent, diphenyldiselane/iodine,[3] but it has not been possible to isolate this species.[4]

Similar behavior is found in the system tellurium–phosphorus, for which we were able to shift telluration/detelluration and dismutation equilibria in favor of the formation of compounds containing Te–P bonds and to slow down the attainment of the equilibria by the introduction of bulky substituents.[5] It thus appeared promising to exploit steric factors to activate a compound containing Se–Se bonds in such a way that reaction with iodine should lead to the formation of products containing Se–I bonds.

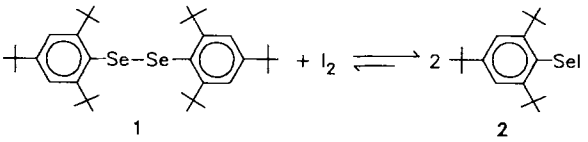
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The bulkiest compound containing a Se–Se bond, which, in addition, exhibits the highest barrier to rotation around the Se–Se bond, is bis(2,4,6-tri-*tert*-butylphenyl)diselane **1**,[6,7] which is obtained by oxidation of lithium 2,4,6-tri-*tert*-butylphenylselenide with oxygen.[8] Whereas the diselane is quite stable upon exposure to air, it is rapidly attacked by iodine with the formation of 2,4,6-tri-*tert*-butylphenyl(iodo)selenide **2**. The formation of **2** is practically quantitative if an excess of iodine is used. Compound **2** is obtained in pure form as anthracite-black crystals by recrystallization, m.p. = 156°C (dec.).[9]



1 2

In the solid state, the iodoselenide **2** is present as a monomer with a bent C–Se–I structural unit (97.5°) (Fig. 1). Significant intermolecular Se···I, Se···Se, or I···I contacts do not exist.[10] The arylseleno moiety of **2** exhibits deviations from planarity—which are characteristic of

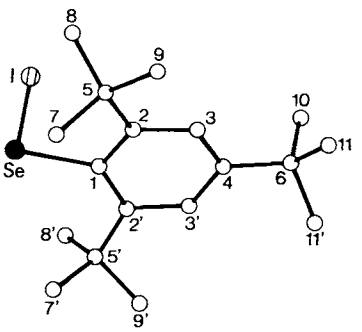


Fig. 1. Crystal structure of **2** (hydrogen atoms omitted). The compound forms orthorhombic crystals, space group *Pnma*, $a=1160.9(3)$, $b=1541.3(4)$, $c=1078.8(3)$ pm; $Z=4$, $\rho_{calcd}=1.553$ g cm^{-3}, 1808 *hkl* with $F>3\sigma(F)$, $R=0.027$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52420, the names of the authors, and the journal citation.

2,4,6-tri-*tert*-butylphenyl-substituted systems.[11] The Se–I distance (252.9 pm) is in good agreement with the value expected for a Se–I single bond[12] and is slightly longer than the bond in *Passmore*'s cationic species containing iodine of coordination number 1.[1,2b]

When crystals of **2** are dissolved in benzene or in aliphatic hydrocarbons, re-dismutation occurs to a small extent, which is confirmed by the ^{1}H-NMR spectra (integrals of the signals of **1** approximately 10–15% those of **2**; the equilibrium is established within only a few minutes after dissolving the crystals in benzene), ^{13}C-NMR spectra,[9] ^{77}Se-NMR spectra,[9] and UV/VIS spectra (in cyclopentane: weak absorption at 538 nm, I_2). The equilibrium constants for the dismutation of diselane **1** with iodine to give the iodoselenide **2** can thereby be estimated to be approximately 10^2 mol^2 L^{-2}. The attainment of the dismutation equilibrium is slow compared with the time scales of ^{1}H-, ^{13}C-, and ^{77}Se-NMR measurement.[9] The attainment of the

dismutation equilibrium between diphenyldiselane/iodine and iodo(phenyl)selenide, on the other hand, is rapid at room temperature on the 80-MHz ^{1}H-NMR and 75-MHz ^{13}C-NMR time scales.[13] This clearly explains why it is easy to overlook iodoselenide in equilibria when following, by NMR spectroscopy, the reactions of diselanes with iodine.

The ability to control, by means of the substituents, the dismutation of compounds containing Se–Se bonds with those containing I–I bonds and the surprising stability of **2**, the first base-free iodoselenide to be isolated in pure form, should also make it possible, in the future, to better characterize mechanistically the reactions in the system chalcogen/iodine.

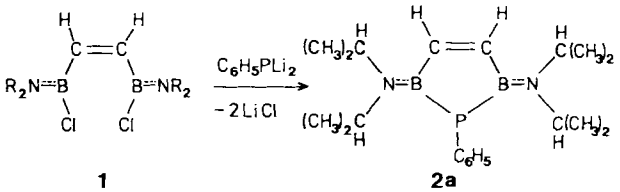
Synthesis and Structure of a 2,5-Dihydro-1*H*-1,2,5-phosphadiborole Derivative**

By *Matthias Driess, Hans Pritzkow*, and *Walter Siebert**

Dedicated to Professor Reinhard Schliebs on the occasion of his 60th birthday

2,5-Dihydro-1*H*-1,2,5-phosphadiboroles such as **2** are of interest because of possible boron–phosphorus interactions. Attempts to synthesize them by substitution of the sulfur in a 2,5-dihydro-1,2,5-thiadiborole derivative[1] or by insertion of phenylphosphanediyl into the B–B bond of the 1,2-dihydro-1,2-diborete[2] (HC)$_2$(*i*Pr$_2$NB)$_2$, however, have been unsuccessful,[3] as was the reaction of 1,2-bis(dichloroboryl)ethene with tris(trimethylsilyl)phosphane.[4] We have now succeeded in synthesizing the first 2,5-dihydro-1*H*-1,2,5-phosphadiboroles. Reaction of (*Z*)-1,2-bis[chloro(diisopropylamino)boryl]ethene **1a** (R = *i*Pr) with dilithium phenylphosphide leads to **2a**.[5] Similarly, the corresponding derivatives of **2a** are prepared starting from **1b** (R = Et) and **1c** (R = Me).



1 **2a**

Compound **2a** is a colorless, crystalline substance with an extremely unpleasant smell. It undergoes only slow decomposition in air. In solution, it reacts with oxygen, exchanging C_6H_5P for O to give the corresponding 2,5-dihydro-1*H*-1,2,5-oxadiborole derivative. The ^{1}H- and ^{13}C-NMR data of **2a** are characterized by long-range PH and PC couplings, respectively,[6] which was confirmed by ^{1}H/^{1}H double resonance and ^{13}C DEPT NMR experiments. As in the case of phosphinoboranes,[7] the different $^4J_{PH}$ and $^3J_{PC}$ coupling constants between phosphorus and the methine hydrogens and methine carbon atoms, respectively, of the diisopropylamino groups can be interpreted in terms of the *Z*/*E* arrangement with respect to the BN π bond. Assuming that the relation $J_E > J_Z$ is valid for alkenes, the signal at lower field (δ = 4.09) can be assigned to the "*E* methine proton" of the diisopropylamino group.[7]

Compound **2a** exhibits temperature-dependent ^{1}H-NMR spectra. At 283 K in [D$_8$]toluene, a doublet at δ = 0.86 as well as a broad signal at δ = 0.65 are observed for the methyl protons. Lowering the temperature results in the appearance of four doublets at 223 K (two doublets for the methyl protons of both the (*E*) and the (*Z*) isopropyl groups). We ascribe these dynamic effects to a lowered barrier of inversion at the pyramidal phosphorus atom. At still lower temperature, the rigid configuration of the phosphorus gives rise to diastereotopism of all four methyl groups of a diisopropylamino group. At raised temperature (up to 400 K), on the other hand, only two anisochronous sets of methyl groups are present owing to rapid

[*] Prof. Dr. W. Siebert, M. Driess, Dr. H. Pritzkow

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

inversion at phosphorus. An estimation of the free energy of activation for the inversion at phosphorus from the coalescence temperature, according to the doublet analysis method,[8] gives, as in the case of phosphole,[9] 10–15 kcal mol^{-1}. The observation of two multiplets for the methine protons of the diisopropylamino groups up to 380 K shows that the rotation around the BN bond is hindered. The broad ^{11}B-NMR signal is found at $\delta = 47.7$ (halfwidth $w_{1/2} = 320$ Hz). In the $^{31}P\{^1H\}$-NMR spectrum, a singlet is observed at $\delta = -124.6$ ($w_{1/2} = 120$ Hz). The chemical shift indicates a significant s character of the lone pair of electrons at phosphorus and provides further spectroscopic evidence for its nonplanar coordination, which is confirmed by the X-ray structure analysis (Fig. 1).[10]

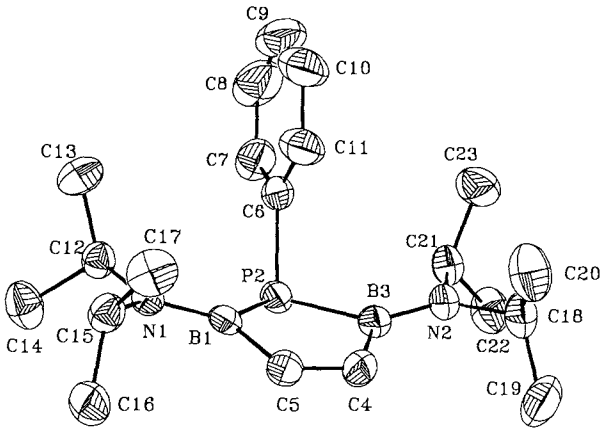

Fig. 1. Crystal structure of **2a** (thermal ellipsoids at 40% probability). Important distances [Å] and angles [°]: P-B 1.949(2), B-C 1.557(2), C-C 1.344(2), B-N 1.391(2), P-C 1.840(1); B-P-B 88.8(1), C-P-B 103.5(1), P-B-C 107.5(1), B-C-C 116.3(1).

The molecule has an approximate plane of symmetry through the phosphorus atom and the phenyl ring perpendicular to the five-membered ring, which is nonplanar. The angle between the planes B1-P2-B3 and B1-B3-C4-C5 is 17°. The phosphorus atom is located 0.4 Å above the plane B1-B3-C4-C5 and is pyramidally coordinated (sum of angles 295.9°).

Concerning the Structure of Benzene**

By *Otto Ermer**

The structure of benzene constituted one of the central problems of early organic chemistry which eventually culminated in the question whether its equilibrium geometry corresponds to a planar regular hexagon of symmetry D_{6h} or to a likewise planar D_{3h} (Kekulé) structure with localized alternating CC double and single bonds. It is claimed in many text books of organic chemistry that experimental proof for the equilateral D_{6h} structure of benzene derives from X-ray crystallography.[1] We deem it appropriate to point out in this communication that this is *not* true.

The atomic positions originating from the X-ray (and neutron) diffraction analysis of crystalline benzene are *averaged* over space and time and are compatible not only with a crystallographically ordered D_{6h} model of benzene, but also with a disordered D_{3h} model corresponding to a superposition of benzene molecules rotated with respect to each other by 60° around the three-fold axis (Fig. 1). The disorder may either be static or dynamic: In the first case, we would deal with a statistical distribution of both molecular orientations disregarding the crystallographic symmetry requirements, in the second instance with a rapid inter-

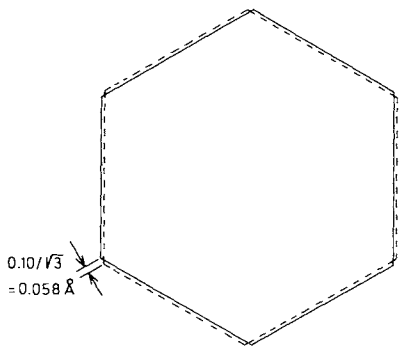

Fig. 1. Disorder model of benzene with localized single and double bonds. Both D_{3h} Kekulé structures are rotated with respect to each other by 60° around the threefold axis; C–C and C=C bond lengths of 1.45 and 1.35 Å, respectively, assumed.

conversion (relative to the measuring time of usually many hours) of D_{3h} forms *via* the D_{6h} form corresponding to a symmetric double minimum potential. Dynamic disorder could also be due to a hindered rotation of the benzene molecules around the three-fold axis. Benzene crystallizes in the space group *Pbca* with four molecules in the unit cell;[2] it is pointed out that the ensuing molecular centrosymmetry is again merely an *averaged* structural property. D_{6h} symmetry is present in the crystal not exactly, yet to a very good degree of approximation.

Assuming a difference of 0.10 Å between the C–C and C=C bond lengths in the D_{3h} model, it is evident from Figure 1 that the superimposed carbon atoms are only $0.05/\sin 60° = 0.058$ Å apart. This small separation is far below the resolving power of an X-ray diffraction measurement. By cooling, it is sometimes possible to induce an ordering process in crystals which are disordered at higher temperatures. However, this may by no means always be achieved. Yet even in this case, there remains a possibility to uncover a disorder through an analysis of the temperature dependence of the crystallographic temperature factors. To this end, however, the disorder contribution to the temperature factors must be large enough. The CC bond length difference of the present example of 0.10 Å corresponds to a disorder contribution of only $(0.025/\sin 60°)^2 = 0.0008$ Å^2, much too small to allow safe conclusions with respect to a possible disorder even at very low temperatures. The consideration of the hydrogen atoms within a neutron diffraction experiment, for example, would not help much to improve the situation. In addition, the well-known experimental difficulties complicating the derivation of reliable temperature motion parameters from diffraction measurements are entirely neglected in this discussion! The quantitative analysis of the size and orientation of the anisotropic temperature factor tensors, e.g. in terms of rigid-body motions, may also provide insight into disorder phenomena of the present kind.[3] Nonetheless, in the extreme case of benzene such methods, too, are not capable of proving the absence of disorder.

Our experimental knowledge about the symmetry of the benzene molecule derives from the vibrational spectroscopic measurements (short-time spectroscopy) of *C. K. Ingold* et al. of more than 50 years ago.[4] The decision in favor of the D_{6h} structure is largely based on the analysis of selection rules: For example, no violations of the mutual exclusion rule are perceptible when comparing the infrared and Raman spectra of gaseous benzene. This indicates the presence of a molecular center of symmetry incompatible with the D_{3h} model. The D_{6h} equilibrium structure is also supported by the following simple consideration: A frequency of 1309 cm^{-1} is commonly assigned to the CC stretching vibration corresponding to the transition $D_{6h} \rightarrow D_{3h}$ (B_{2u} species).[5] Assuming a double minimum potential with D_{3h} minima, such a large B_{2u} frequency would require an unacceptably high D_{6h} barrier in order to achieve a correspondingly high curvature of the potential at the minima. Since at most a *very shallow* double minimum could be reasonably envisaged, it follows that in actual fact a relatively steep single minimum potential with D_{6h} minimum geometry must be present. On the whole, it may be stated that although the vibrational spectroscopic data of benzene (and deuteriated species)[4,5] provide strong indications in favor of the D_{6h} equilibrium geometry, they may not be regarded an irrefutable *proof* for this structure.

We have seen that although the X-ray and neutron diffraction results of crystalline benzene (and of many benzene derivatives) are compatible with the D_{6h} model, they do not allow one to discard the D_{3h} model. The analysis of the electron diffraction data of gaseous benzene confronts us with a similar dilemma since the resolving power of this method is in principle not better than about 0.1 Å; for interatomic distances differing by less than 0.1 Å only a weighted average can be measured.[6,7] This is due to zero-point vibrations which are responsible for the relatively broad maxima in the one-dimensional distance distributions. The presence of a shallow double minimum would also lead to analytical difficulties.[6] Finally, the structural information on benzene remains which may be extracted from rotational spectra. It turns out, however, that the D_{6h} and D_{3h} models cannot be distinguished by this method either.[8] Therefore, for the derivation of a quantitative structural model of benzene, i.e. in particular the CC bond length, by means of crystal X-ray and neutron diffraction, gas-electron diffraction, and gas-rotational spectroscopy (moments of inertia), D_{6h} symmetry has to be *assumed*. We are therefore faced with the rather remarkable situation that the experimental values of one of the most important structural quantities of organic chemistry originate from experimental techniques incapable of resolving the D_{6h}/D_{3h} symmetry problem of benzene. Under the (substantiated) *assumption* of D_{6h} symmetry the following selected values for the CC bond length of benzene have been determined: Crystal X-ray diffraction at 270 K, 1.377(10) Å (average value of three crystallographically independent distances; corrected for libration, 1.392 Å);[2a] crystal neutron diffraction at 138 K, 1.393(7) Å (average value; corrected for libration, 1.398 Å);[2b] gas-electron diffraction, $r_\alpha^0 = 1.3959(19)$, $r_g = 1.3992(8)$ Å;[9] gas-rotational spectroscopy (with vibrational coupling), $r_0 = 1.3964(2)$,[10] $r_z = 1.3967(9)$ Å.[9-11] An experimental r_e structure (vibrationless equilibrium structure of minimal potential energy) of benzene has as yet not been reported.

A few years ago, doppler-free electronic spectra of benzene with completely resolved rotational lines were recorded for the first time; this could not be accomplished previously, either by Raman or infrared spectroscopy.[12] In principle, it should be possible to decide between D_{6h} and D_{3h} symmetry with the help of the intensities of the rotational lines which depend on nuclear spin statistical factors. Although it is conceivable that the statistical intensity effects are indistinguishably similar for both cases, this is unlikely. The statistical weights of the D_{6h} model are in good accord with the observed line intensities; however, the statistical analysis for the D_{3h} model has not as yet been performed.[13a] Photoelectron spectra are of rather little value as regards the present benzene problem. For example, no conclusions may be drawn from the PE band locations since it can be shown that the π ionization energies of the D_{6h} and D_{3h} models, respectively, are practically the same.[13b] NMR data are of no help either; room temperature ^{1}H-NMR measurements of benzene molecules oriented in liquid crystals give sharp lines without *ortho* H–H couplings being observable.[14] This merely allows one to conclude that the average lifetime of an eventual D_{3h} minimum structure is at most 10^{-4} s, corresponding to $\Delta G^{\neq}_{max} \approx 12$ kcal mol^{-1}.[13c]

In view of the fact that the D_{6h}/D_{3h} structural problem of benzene is not strictly solved, enhanced significance is to be assigned to theoretical calculations on a reliable quantum-mechanical basis. Such calculations yield the optimal D_{6h} structure of benzene energetically more favorable than sensible D_{3h} structures and reproduce well the (positive) force constant and frequency of the B_{2u} CC

stretching vibration, in accord with a one-minimum potential.[15]

The present discussion is relevant not only in the context of the geometrical structure of benzene, it has even more general implications in connection with questions as to the CC bond length alternation and double bond localization (and the related aromaticity problems), respectively, in annulenes of arbitrary ring size, bridged annulenes, and polycyclic π systems with condensed rings. In particular, this holds for analyses of such problems by means of routine X-ray diffraction studies: *Caution is obviously called for!*[3, 16]

[7] The one-dimensional distance distributions resulting from electron diffraction analyses may be compared to one-dimensional Patterson functions. From single crystal X-ray and neutron diffraction measurements one obtains three-dimensional Patterson functions (vector density distributions), such that in the absence of disorder and the usually sufficiently high reflection orders no resolution problems are encountered.

A collection of benzene calculations which almost always *presuppose* D_{6h} symmetry, may be found with R. S. Mulliken, W. C. Ermler: *Polyatomic Molecules (Results of ab initio Calculations)*, Academic Press, New York 1981, p. 331. Theoretical interpretations of the benzene structure have recently sparked off controversy which is of some interest in the present context: N. C. Baird, *J. Org. Chem. 51* (1986) 3907; P. C. Hiberty, S. S. Shaik, G. Ohanessian, J.-M. Lefour, *ibid. 51* (1986) 3908; S. S. Shaik, P. C. Hiberty, J.-M. Lefour, G. Ohanessian, *J. Am. Chem. Soc. 109* (1987) 363. Finally some very recent quantum-mechanical calculations are pointed out which throw new light on the electronic structure of benzene: D. L. Cooper, J. Gerratt, M. Raimondi, *Nature London 323* (1986) 699; however, a critical reply has already appeared: W. H. E. Schwarz, *Nachr. Chem. Tech. Lab. 35* (1987) 178; see also P. A. Schultz, R. P. Messmer, *Phys. Rev. Lett. 58* (1987) 2416.—For demonstration purposes, a geometry optimization of benzene on a good quantum-mechanical basis would be desirable which starts out from a D_{3h} geometry with markedly different, alternating C–C and C=C bond lengths, and which shows smooth convergence towards the D_{6h} minimum. Newton-Raphson procedures should be applied for this optimization and the minimum nature of the optimal D_{6h} structure should be clearly assessed by diagonalization of the second-derivative matrix of the potential energy. At least for didactical purposes, such a calculation which is not documented in the literature, would be useful.

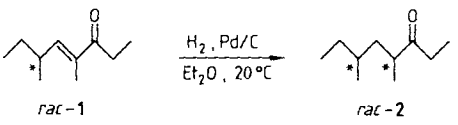
The Absolute Configuration of the Ant Alarm Pheromone Manicone**

By *Hans Jürgen Bestmann,* Athula B. Attygalle, Jürgen Glasbrenner, Roland Riemer,* and *Otto Vostrowsky*

Manicone, (4*E*)-4,6-dimethyl-4-octen-3-one **1**, had been identified 15 years ago as an active pheromone constituent of the mandibular glands in two North American species of ants *Manica mutica* and *M. bradleyi* (Hymenoptera: Formicidae).[2] However, the absolute configuration of this chiral natural product was not determined. We have also been able to identify **1** as the main pheromone (2–3 μg/insect) in the mandibular gland secretion of the only known Euroasiatic Manica species, *Manica rubida* Latr.[3, 4] Assignment of the configuration of the chiral ketone **1** has now been accomplished, in an indirect way, by means of complexation gas chromatography[5] on a chiral phase. In total, only ten insects were required in order to elucidate the stereochemistry of **1**. The method employed is outlined below.

Hydrogenation of the double bond of synthetic, racemic manicone, *rac*-**1**, with Pd/activated carbon led to the formation of a new chiral center; as a result two diastereomeric pairs of dihydromanicone, *rac*-**2**, were produced. These four isomers could be separated by complexation gas chromatography[5] on nickel(II) bis[3-heptafluorobutyryl-(1*R*)-camphorate] (Fig. 1A).[6] *rac*-**1** could not be separated.



The same reaction was carried out with natural manicone **1**. The constituents of two heads of *M. rubida* female workers were hydrogenated by reaction gas chromatography (solid sample injector,[1] H_2 as carrier gas, 1% Pd catalyst in the GC injection block) and the dihydromanicone **2** thus formed was isolated, after GC separation, in cooled

[**] Pheromones, Part 61. This work was supported by the Deutsche Forschungsgemeinschaft. *A. B. A.* thanks the Alexander-von-Humboldt Stiftung for a grant.—Part 60: [1].

glass capillaries.[9] The condensate was subsequently rechromatographed on an optically active Ni^{II}-phase. Only two diastereomeric hydrogenation products **2** appeared in the gas chromatogram (Fig. 1B); these corresponded to the isomers 1 and 4 in Figure 1A.

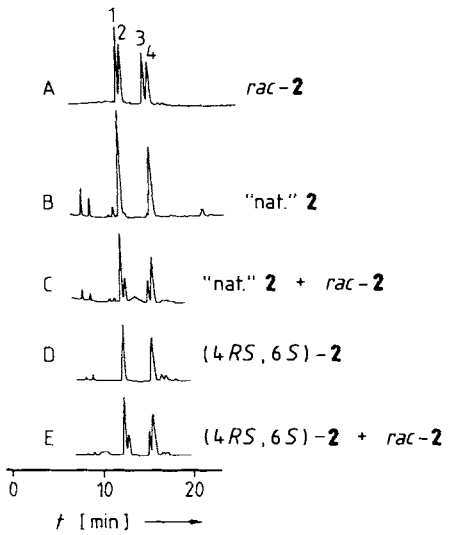

Fig. 1. Gas chromatographic separation of A) synthetic racemic dihydromanicone *rac*-**2**, B) "natural" **2**, obtained from the heads of *M. rubida* by hydrogenation, C) co-injected "natural" **2** and *rac*-**2**, D) synthetic (4*RS*,6*S*)-**2**, E) co-injected synthetic (4*RS*,6*S*)-**2** and *rac*-**2**.—Optically active GC phase: nickel(II) bis[3-heptafluorobutyryl-(1*R*)-camphorate] [5, 6]. The signals 1 and 4 correspond to the pair of diastereomers (4*RS*,6*S*)-**2**, the signals 2 and 3 correspond to (4*RS*,6*R*)-**2**.

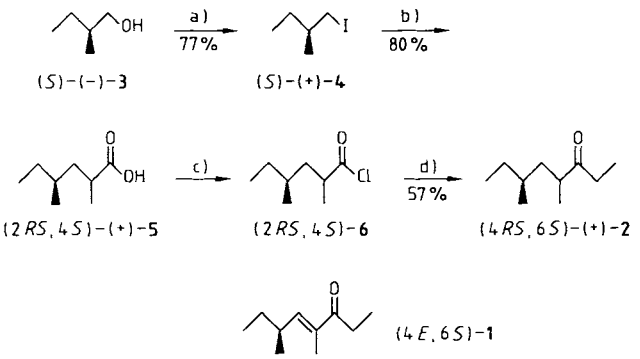
The pair of diastereomers of dihydromanicone **2**, having (*S*)-configuration on C-6 (Fig. 1D), could be synthesized, as shown in Scheme 1, starting from commercially available (*S*)-(−)-2-methylbutanol **3**, via (*S*)-(+)-2-methylbutyl iodide **4**, (2*RS*,4*S*)-(+)-2,4-dimethylhexanoic acid **5** and its chloride **6** (for analytical data and spectra of **2** and **5**,



Scheme 1. a) I_2, $P(OPh)_3$, CH_2Cl_2, 0°C, 2 h; b) CH_3–CHLi–COOLi, tetrahydrofuran/hexamethylphosphoric triamide, −15°C, 2 h; c) $SOCl_2$, $CHCl_3$, 70°C, 2 h; d) $LiCuEt_2$, ether, −78°C, 45 min.

see Table 1). This (4*RS*,6*S*)-(+)-**2** corresponded to the isomers 1 and 4 of the racemic dihydromanicone **2**, as could be demonstrated by a co-injection of the two samples into the gas chromatograph (Fig. 1E; cf. Fig. 1C). The GC-mass spectra of the synthetic diastereomeric dihydromanicones (4*RS*,6*S*)-(+)-**2** were identical to those of the hydrogenation products of racemic manicone *rac*-**1** as well as to those of the diastereomeric reduction products of natural manicone, **1**, obtained from the insect heads (Table 1).

Table 1. Physical data of (4*RS*,6*S*)-**2** and (2*RS*,4*S*)-**5** [a].

2: IR (film): $\tilde{\nu}$ = 1735 cm^{-1} (s); ^{1}H-NMR ($CDCl_3$): δ = 0.60–2.00 (m, 17H), 2.10–2.85 (m, 3H); MS (70 eV): *m/z* 156 ($M^{\oplus}$, 0.3%), 127 (2), 99 (5), 86 (52), 71 (2), 69 (4), 57 (100), 43 (12), 41 (15); $[\alpha]_D^{25}$ = +10.3° (*c* = 4.90 in pentane); b.p. 76–78°C/18 torr (Kugelrohr)

5: IR (film): $\tilde{\nu}$ = 1710 cm^{-1} (s); ^{1}H-NMR ($CDCl_3$): δ = 0.80–2.10 (m, 14H), 2.20–2.90 (m, 1H), 12.25 (s, 1H); MS (70 eV): *m/z* 144 ($M^{\oplus}$, 2), 129 (2), 126 (4), 115 (23), 101 (24), 71 (98), 74 (100); $[\alpha]_D^{25}$ = +13.3° (*c* = 6.00 in CH_3OH); b.p. 81–83°C/0.5 torr (Kugelrohr)

[a] Correct elemental analyses.

Therefore it can be concluded that manicone **1** from *M. rubida* has (*S*)-configuration at C-6 and thus is present as (4*E*,6*S*)-4,6-dimethyl-4-octen-3-one.

Reduction of 2-Enoates and Alkanoates with Carbon Monoxide or Formate, Viologens, and *Clostridium thermoaceticum* to Saturated Acids and Unsaturated and Saturated Alcohols**

By *Helmut Simon,** *Hiltrud White, Herbert Lebertz,* and *Iordanes Thanos*

All the hitherto reported biological reductions of carboxylates to aldehydes proceed via an activation of the carboxy group. The carboxylate/aldehyde pair (with $E_0' \approx -550$ mV) has a large negative redox potential. The cosubstrates or prosthetic groups usually used by reductases have redox potentials of $E_0' = -320$ mV (pyridine nucleo-

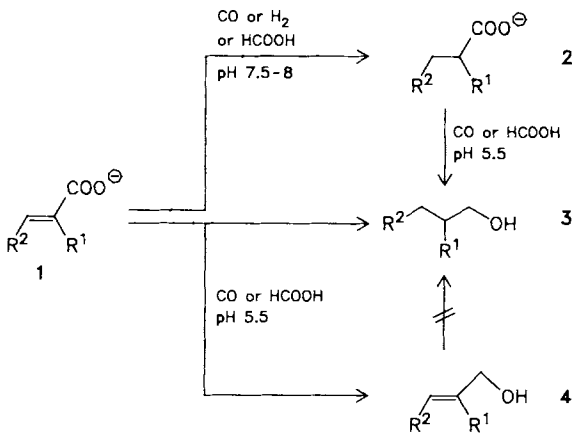
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB145) and the Fonds der Chemischen Industrie. We thank Herr *H. Leichmann* for excellent assistance and Dr. *P. Rauschenbach* and *F. Wendling* for carrying out the HPLC analyses.

tides) or up to $E_0' = -400$ mV (some flavoenzymes or iron-sulfur clusters). The activation usually consists in the formation of a thioester, which, as a rule, requires an ATP. These thioesters are reducible with NADH. We have now found a system that reduces carboxylates to alcohols and might also be preparatively useful. Due to the pH-dependence of the reduction, the undissociated acids could also be the substrates. The acids or carboxylates are apparently not activated. In this reduction the aldehyde must be an intermediate. The transition from aldehyde to alcohol is presumably catalyzed by another enzyme. Since a redox potential of -560 mV has been quoted for the carbon monoxide dehydrogenase occurring in *Clostridium thermoaceticum* which catalyzes the reaction[1]

$$CO + H_2O \longrightarrow CO_2 + 2H^{\oplus} + 2e^{\ominus}$$

we have incubated resting cells of this organism with unsaturated compounds in a CO-atmosphere. Hardly any reaction could be observed. However, if 1 mM methyl viologen is added to such a system[2] carbon monoxide is consumed and saturated and unsaturated carboxylates of diverse structures are reduced to alcohols. If no carboxylate or any other acceptor is added, then methanol is formed from the carbon monoxide (see Ref. [4]). In the case of 2-enoates the CC double bond and/or the carboxylate group can be reduced.



a, $R^1 = R^2 = CH_3$; b, $R^1 = CH_3$, $R^2 = C_6H_5$;
c, $R^1 = H$, $R^2 = CH_3-CH=CH$

Table 1 shows the large variety of substrates for the reduction of carboxylates. Both mono- as well as dicarboxylates are reduced and even such monocarboxylates as, e.g., 2-phenylbutyrate, the 2-position of which is occupied by very bulky groups. The relative rates in Table 1 should be regarded as approximate values, since not all reductions in a series were carried out in parallel experiments. The rate 100 signifies that about 30 μmol 1-propanol is formed per hour from propionate at 40°C under the given conditions.[2] At 50°C about 40 μmol per hour are formed. With *C. thermoaceticum*, reductions are also possible with hydrogen gas or formate as electron donors. Figure 1 and Table 2 show that the carboxylate group of **1a** is not attacked by any of the three reducing agents (CO, H_2, HCOOH) at pH 8.0. Due to the differing pH-dependence of the alkanoate- and enoate-reduction it is possible, e.g., to reduce an enoate at pH 7.5–8.0 with carbon monoxide first to the alkanoate **2**. After adjustment of the pH to 5.5, the saturated alcohol **3** can be obtained from **2** with formate or carbon monoxide. In this way (*R*)-2-methyl-3-phenyl-1-propanol **3b** and (*R*)-2-methyl-1-butanol **3a** can be obtained with *ee* values >95%.[5]

When an enoate **1** is reduced at pH 5.5 with CO a branching reaction ensues and a saturated alcohol **3** and

Fig. 1. pH-Dependence of the reduction of (*E*)-2-methyl-2-butenoate **1a** (30 μmol) with carbon monoxide at 40°C in the presence of 1 mM methyl viologen. **2a**, **3a**, and **4a** formed after 20 min: **2a** O—O, **3a** ●—●, **4a** ■—■.

Glutarate	1,5-Pentanediol	106
Adipate	1,6-Hexanediol	175
Benzoate	Benzyl alcohol	115
(*R,S*)-2-Phenylbutyrate	(*S*)-2-Phenyl-1-butanol [e]	30
(*R,S*)-3-Phenylbutyrate	3-Phenyl-1-butanol [f]	20
3-Butenoate	3-Buten-1-ol	15
Sorbinate **1c**	Sorbinol **4c** and (*E*)-4-Hexen-1-ol	—

[a] For better comparison, the relative rates per electron pair are given. The formation of ethanol requires two, that of 2-methyl-1-butanol from (*E*)-2-methylbutenoate three, and that of 1,4-butanediol from succinate four electron pairs. [b] The saturated alcohol can also be obtained quantitatively (see next example). [c] **3b** was obtained with the same cells from **1b** and H_2 at pH 7; >95% *ee*, since stepwise reduction **1b**→**2b**→**3b**. [d] Enantiomeric excess not determined. [e] 62% *ee*. [f] The enantiomers were formed in the ratio 65:35.

Table 2. Reduction products [μmol] obtained after 20 min at 40°C from (*E*)-2-methyl-2-butenoate **1a** (100 μmol) as a function of the reducing agents hydrogen gas or formate at pH 5.0 or 8.0 in the presence of 80 mg (dry weight) of *C. thermoaceticum*. Total volume 3.0 mL; 0.3 M buffer.

Products		**2a**		**4a**		**3a**	
pH		5.0	8.0	5.0	8.0	5.0	8.0
Reducing agent:	H_2	1.5	1.5	0.3	0.1	0.05	0.1
	Formate	7.0	1.7	7.0	0.1	4.0	0.05

an allyl alcohol derivative which is not reduced further are formed. Sorbinate **1c** could be reduced under the given conditions[2] to more than 80% to sorbic alcohol **4c**, thus demonstrating the high chemoselectivity of the reduction of enoates **1**.

The rates of reduction of (*R,S*)-**2a** and (*S*)-**2a** in a CO atmosphere are in the ratio 1.6 : 1.0. In the case of the (*R*)- and (*S*)-lactate the ratio is 1.4 : 1.0.

This means that the reduction of enoates **1** with CO, which so far has not even been described in the literature, shows a high degree of product enantioselectivity for the formation of the alkanoates **2**. The reduction of a racemic alkanoate of type **2a** or **2b** to the alcohol **3**, on the other hand, is not highly stereoselective.

The special importance of the reduction under discussion lies in the fact that neither chemical nor biocatalyzed reactions have hitherto been described by which reductions of carboxylates occur in aqueous solution. In the case of the previously described examples[6–9] it is known that either the carboxylates are activated in an intermediary step or that activation is very likely under the conditions employed.

That the carboxylates are not activated in the usual way prior to the reduction can be concluded from the following findings: 1) the reaction even takes place in phosphate-free buffers with washed, resting cells, whereby 80 mg of cells (dry weight) reduce more than 430 μmol propionate to 1-propanol. The reaction presumably ceases because the pH value, despite the buffer, drops to 4.2 due to concomitant formation of formic acid. If in the meantime the pH value of 5.5 is reestablished, up to 1520 μmol of 1-propanol can be obtained. If the activation were to be brought about by degradation of endogenous material, the cells would have to consist by more than a half of carbohydrates for the formation of 430 μmol of 1-propanol, and there would be corresponding amounts of acetate to be expected. Such an experiment however gave less than 5% of the acetate expected. In addition the enzymes necessary for the activation were not found. 2) When an ultrafiltrated crude extract is employed, from which more than 95% of all compounds with a molecular weight smaller than 5000 are removed, then almost the same rate of reduction is obtained. Furthermore, lipid membranes are not necessary since the carboxylate group is still reduced after two column chromatographic separations of the crude extract. Consequently, a reduction of acyl-CoA as in the formation of 1-butanol from butyrate, e.g. by *Clostridium acetobutylicum*,[6–8] is not involved. The substrate specificity of the acyl-CoA reductase involved is also very limited.[6] The recently observed increase in butanol formation from butyrate by *C. acetobutylicum* in the presence of CO can be rationalized by the inhibitory effect of CO on the hydrogenase. Therefore, since the reduction equivalents cannot be released in the form of H_2 they are instead consumed for the reduction of acyl-CoA.[8] Carbon monoxide reductase purified by us exhibits no alkanoate and enoate reductase activity. Consequently, the reduction of carboxylates of very different structures appears to be an hitherto unknown enzyme reaction. The reduction described by *Howe* et al.[9] of 2-(4-chlorophenyl)thiazol-4-ylacetic acid to the corresponding alcohol by different microorganisms is carried out with growing cells. The authors postulate a mechanism corresponding to that of the formation of cinnamyl alcohol, i.e. by the sequence cinnamate → cinnamoyl-CoA → cinnamaldehyde → cinnamyl alcohol. In addition, the reductions described by *Howe* et al.[9] proceed with about 1% of the rate with which, e.g., 2-phenyl-1-butanol is formed from 2-phenylbutyrate by resting cells of *C. thermoaceticum* without the supply of energy yielding substrates.

$[(\eta^5\text{-}C_5Me_5)Re(CH_3)_4]$, the First Organorhenium(V) Compound without Heteroatom Ligands**

By *Martina Flöel, Eberhardt Herdtweck, Werner Wagner, Jürgen Kulpe, Peter Härter*, and *Wolfgang A. Herrmann**

Despite a plethora of oxidation states encountered with the element rhenium, the explosive hexamethylrhenium, $Re(CH_3)_6$, has thus far remained the only homoleptic alkyl derivative of this metal.[1] The paramagnetic compound (d^1 configuration) is formed, according to *Wilkinson* et al., on reaction of trimethylaluminum with tetramethyl(oxo)rhenium and can be converted with methyllithium into the presumably square-antiprismatic Re^{V1}-dianion $[Re(CH_3)_8]^{2\ominus}$ (ESR and PE data);[2,3] however, the only species whose structure has been established unequivocally is the Re^{III}-dianion $[Re_2(CH_3)_8]^{2\ominus}$.[4] Interestingly, pentamethylrhenium is unknown, and even the so-called "trimethylrhenium" postulated by *Druce* in 1934[5a] could not be reproduced by *Gilman* et al.[5b] We have now succeeded in synthesizing **3a**, the first organorhenium(V) compound containing no heteroatom ligands.

The title compound **3a** is formed in 40–50% yield when the tetrachloro complex **2**—accessible from the trioxide **1**—is allowed to react with exactly 4.0 molar equivalents of methylmagnesium chloride in tetrahydrofuran (THF) at

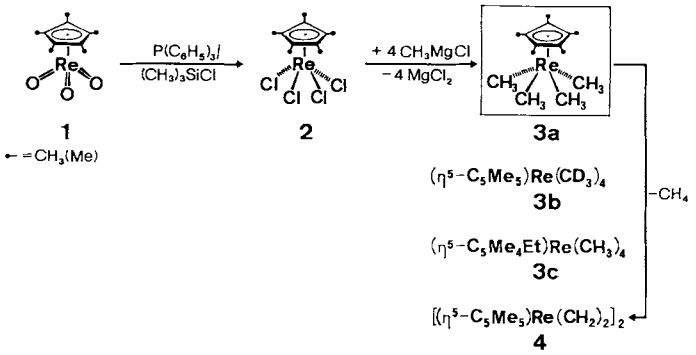
$-78\,^{\circ}C$ under scrupulous exclusion of light, air, and moisture. After purification of the crude product by column chromatography at $-30\,^{\circ}C$, low-temperature crystallization furnishes brilliant-red platelets which can be stored for some time, but only at the temperature of dry ice.



3a decomposes slowly at room temperature and very rapidly at 68 °C. The thermal decomposition is, according to a GC/MS study, determined by stepwise selective eliminations of methane; up to the decomposition point, exactly 2.0 molar equivalents of CH_4 are liberated.[6] Thereby, the mass-spectroscopically characterized dinuclear tetramethylene complex **4** is formed as coupling product of the formal monomeric precursor fragment of composition $\{(\eta^5\text{-}C_5Me_5)Re(CH_2)_2\}$.[7] At ca. 160 °C, another 0.5 equivalents of CH_4 are cleaved off. Other hydrocarbons are at most formed in only trace amounts in these thermolyses (C_2H_6 0.5%). Consequently, **3a** can be sublimed at room temperature under high vacuum only with drastic losses.

Methane is also eliminated from **3a** in solution, as confirmed by the ^{1}H-NMR signal appearing at $\delta = 0.17$ above ca. 0 °C ([D$_8$]toluene). UV irradiation of *n*-pentane solutions leads to comparable results.

Elemental analysis and the EI mass spectrum[7] confirm the empirical molecular formula $C_{14}H_{27}Re$ of **3a**. Because of the thermal sensitivity of **3a**, NMR spectra can be obtained only at low temperatures. The ^{1}H-NMR spectra show only a single, somewhat broadened signal ($\delta = 15.2$; [D$_8$]toluene, $-40\,^{\circ}C$), whose position is temperature-dependent. It could be established by control measurements that the signal is due to the ring CH_3 groups: the [D$_{12}$]-derivative **3b** synthesized in an analogous way from **2** and [D$_3$]methylmagnesium iodide (>99% D) furnished, in principle, the same ^{1}H-NMR spectrum ($\delta(CCH_3) = 17.2$, singlet; [D$_8$]toluene, $-40\,^{\circ}C$), whereas the complex **3c** afforded a correspondingly modified signal pattern.[8] The methyl groups on the metals are not traceable in the shift region $-200 \cdots +200$ ppm in any of the complexes **3**. This is true also in the case of the ^{13}C-NMR spectra, in which none of the carbon atoms bound directly to the metal atom are visible (**3a**: $\delta(CCH_3) = 56.16$; **3c**: $\delta(CCH_3) = 62.00$ and 54.00, $\delta(C_2H_5) = 41.98$ and 40.84, [D$_8$]toluene, $-80\,^{\circ}C$). Taking into consideration earlier observations on organorhenium(v) complexes[9] we rationalize these findings with the paramagnetic effects of a triplet state of the d^2 configuration of the pentavalent rhenium. In the ^{1}H-NMR spectra of the related Re^V-complex $[(\eta^5\text{-}C_5Me_5)ReCl_3CH_3]$ the CH_3 groups bound to the metal can, on the contrary, be observed; but once again the signal is strongly temperature-dependent ($\delta = 13.5$ at $-50\,^{\circ}C$ and 36.5 at $+50\,^{\circ}C$ in $CDCl_3$).[10]

With respect to the molecular structure, no reliable bond distances and angles can be given because of disorder problems, but, according to a low-temperature X-ray structure analysis (Fig. 1), crystalline **3a** has a square-pyramidal structure like $[(\eta^5\text{-}C_5Me_5)ReCl_3CH_3]$.[10] The Re–C(1...4) distances, which on average are 217(3) pm, and the CH_3,Re,CH_3 angles ($4 \times 82(1)^{\circ}$; $2 \times 136(1)^{\circ}$) correspond to those found in the dianion $[Re_2(CH_3)_8]^{2\ominus}$.[4]

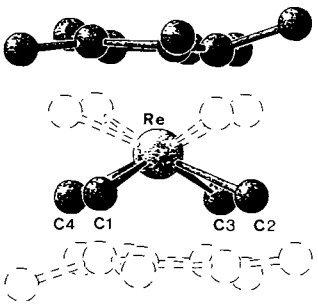


Fig. 1. Molecular structure (SCHAKAL drawing) of **3a** in the crystal (hydrogen atoms omitted; view parallel to the twofold axis [0, y, 1/4]; the same molecule rotated through 180° about Re is shown in dotted lines [11].—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-52581, the names of the authors, and the journal citation.

Experimental

3a: A solution of methylmagnesium chloride (3.48 mmol) in THF (50 mL) was treated at $-78\,^{\circ}C$ with 400 mg (0.87 mmol) of **2**. Within a few minutes, the solution turned red. After warming to $-15\,^{\circ}C$ (ice/sodium chloride) the solvent was removed at this temperature under vacuum. The residue was purified by column chromatography (silanized silica gel, 0.063–0.200 mm, Merck 77719; $-30\,^{\circ}C$), **3a** separating as a brilliant red zone on elution with *n*-pentane. Crystallization of the eluate residue (*n*-pentane) afforded analytically pure **3a** as red crystals; these decomposed spontaneously at 68 °C under inert gas in a sealed capillary; typical yields: 130–165 mg (40–50%).

Pentabenzylcyclopentadienylthallium(I): Synthesis and Structure of a "Dimeric" Organothallium Compound with Tl–Tl Interaction**

By *Herbert Schumann,* Christoph Janiak, Joachim Pickardt,* and *Ute Börner*

Cyclopentadienylthallium is valued as a mild reagent for the synthesis of difficultly isolable cyclopentadienyl derivatives of main group elements, transition metals, and lanthanoids.[1,2] In fact, some organometallic compounds with substituted cyclopentadienyl ligands can only be obtained from the corresponding cyclopentadienylthallium(I) reagents.[3] The preparative potential of these reagents is, however, limited, owing to their very different stabilities and solubilities, which depend on the ring substituents and are, in turn, also influenced by the molecular and crystal structures of the compounds. So far, however, X-ray structure analyses have been carried out only on C_5H_5Tl[4] and $(C_5Me_5)Tl$;[5] both compounds have a polymeric structure of zig-zag chains.

We have now been able for the first time to obtain a cyclopentadienylthallium(I) compound in dimeric form in the solid state, namely pentabenzylcyclopentadienylthallium(I) (**1**). Compound **1** is formed in two, reversibly interconvertible, air- and light-stable modifications upon addition of thallium ethoxide to pentabenzylcyclopentadiene in hexane[6] [Eq. (a)].

$$(C_6H_5CH_2)_5C_5H + TlOC_2H_5 \xrightarrow{-C_2H_5OH} \underset{\mathbf{1}}{[\{\eta^5\text{-}(C_6H_5CH_2)_5C_5\}Tl]} \quad (a)$$

The rapidly crystallizing needles exhibit a chain structure,[8] whereas the slowly crystallizing, thermodynamically more stable parallelepipeds exhibit a new type of structure (Fig. 1). According to an X-ray structure analysis[9] the two halves of the quasi-dimeric molecule are coupled to each other via a symmetry center between the two Tl atoms. The distance between the two Tl atoms is 3.632 Å, which is far too large for a conventional bonding. However, as in $[In_6(C_5Me_5)_6]$,[10] a bonding interaction is also essential in **1** in order to counteract an electronic repulsion of the $[(C_6H_5CH_2)_5C_5]Tl$ dipole terminals. A comparison with the interactions in d^{10}–d^{10} transition metal complexes such as Cu^I–Cu^I [11] and Au^I–Au^I complexes,[12] which had been interpreted theoretically in terms of an $s + p_z + d_{z^2}$ "mixing",[13] was called for.

The angle of 131.8° at the thallium (ring center-Tl1-Tl1*) is somewhat smaller than the Cp-Tl-Cp angle (Cp = C_5H_5 or C_5Me_5) in the polymeric compounds $(C_5H_5)Tl$ (137°)[4] and $(C_5Me_5)Tl$ (145°, mean value).[5] The C-Tl distances in **1** (Tl1-ring center 2.490 Å) are smaller than the distances in $(C_5H_5)Tl$ (3.19 Å) and $(C_5Me_5)Tl$ (2.71 Å), indicating an increased covalent character of the Cp–Tl bond in **1**. Remarkably, three of the five benzyl groups of a cyclopentadienyl ring in **1** are oriented toward the thallium atoms. The extrapolated surfaces of the total of six phenyl groups in a "dimeric" unit form a parallelepiped which envelops the two thallium atoms (Fig. 1, bottom). The smallest phenyl carbon–thallium distances are

[6] Procedure: A solution of thallium ethoxide (0.68 g, 2.70 mmol) in hexane (1 mL) was added dropwise within 15 min at room temperature to a stirred solution of pentabenzylcyclopentadiene [7] (1.40 g, 2.70 mmol) in hexane (40 mL). The solution turned yellow and a fine precipitate separated out. After a further 10 minutes' stirring the solution was allowed to stand before decanting off the clear yellow solution. After careful evaporation of the solution and cooling with ice, 0.95 g (49%) of needle-like crystals separated out. After careful evaporation of the mother liquor and subsequent storage, 0.51 g (26%) of large, yellow, parallelepipedal crystals separated out. These are also obtainable on slow recrystallization of the needles from toluene/hexane. Both modifications darken at 60°C, and soften at 80°C; the needles melt at 133–136°C, the parallelepipeds at 137–140°C. Characterization by complete elemental analysis, IR, Raman, and mass spectra. ^{1}H-NMR (C_6D_6, 25°C): $\delta = 3.93$ (d, 10 H, CH_2, $^3J(TlH) = 10.7$ Hz), 7.19 (m, 25 H, C_6H_5).

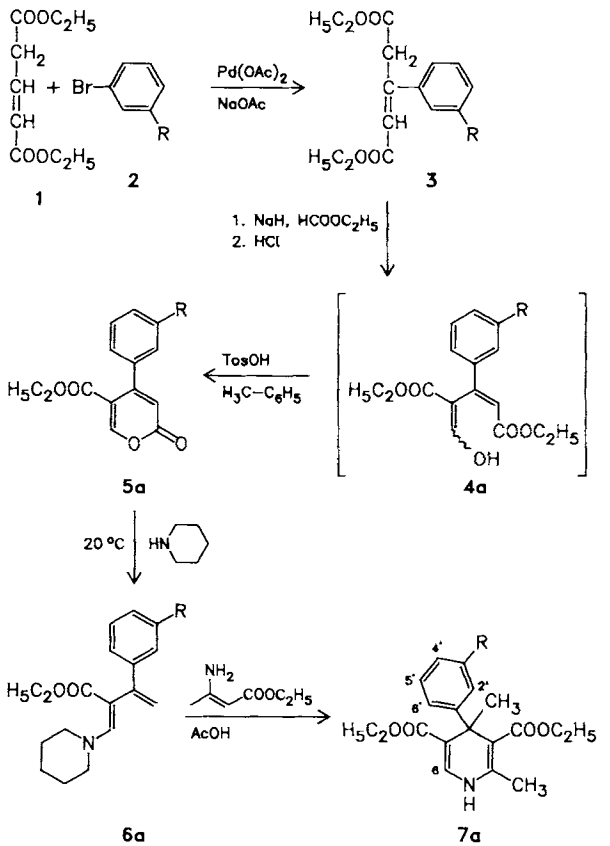
Substituted α-Pyrones as Starting Compounds for the Synthesis of 4,4-Disubstituted 1,4-Dihydropyridines

By *Vratislav Kvita** and *Hans-Peter Sauter*

Following the discovery that some 4-aryl-1,4-dihydropyridines are highly effective calcium antagonists,[1] numerous papers reporting the synthesis of derivatives of this class of substances appeared in the literature over a relatively short period of time. However, the derivatizations were for a long time restricted to the phenyl group and to C-2 and C-3 of the 1,4-dihydropyridine ring. 4,4-Disubstituted 1,4-dihydropyridines were not obtainable via the methods being used at the time.

The first synthetic method affording access to 4,4-disubstituted 1,4-dihydropyridines was that reported by *Goldmann*,[2] but even this method is not generally applicable; for instance, compounds with the mostly desired 2- or 3-nitrophenyl groups on C-4 cannot by synthesized by this method.

Starting from the α-pyrone derivative we have now obtained, via a new synthetic strategy, a 4-methyl-4-(3-nitrophenyl)-1,4-dihydropyridine which combines all the structural moieties which have previously proven to be advantageous.



a, R = NO_2; b, R = $COCH_3$; c, R = $COOC_2H_5$

The diethyl 3-(3-nitrophenyl)-2-pentenedicarboxylate **3a** was prepared from diethyl glutaconate **1** and 1-bromo-3-nitrobenzene **2a** by a Heck reaction.[3] It was then formylated to **4a** and cyclized in toluene in the presence of a catalytic amount of toluenesulfonic acid to give the diethyl 4-(3-nitrophenyl)-1,4-dihydropyridine-3,5-dicarboxylate **5a**, which was allowed to react with piperidine at room temperature to furnish, via cleavage of CO_2, ethyl 3-(3-nitrophenyl)-2-piperidinomethylene-3-butenoate **6a**.[4] This was then cyclized with ethyl 3-aminocrotonate to diethyl 2,4-dimethyl-4-(3-nitrophenyl)-1,4-dihydropyridine-3,5-dicarboxylate **7a**. Also 3-Bromoacetophenone **2b** and ethyl 3-bromobenzoate **2c** react similarly to 1-bromo-3-nitrobenzene **2a**.

Experimental

3a: A solution of **2a** (45.25 g, 0.224 mol) in dimethylformamide (DMF) (90 mL) was added dropwise within 2 h to a stirred mixture of **1** (50.22 g, 0.27 mol), palladium(II) acetate (5.03 g, 0.0224 mol), sodium acetate (20.26 g, 0.247 mol), and DMF (54 mL) at 115°C. After heating for a further 8 h at 130°C, the mixture was evaporated to dryness under vacuum and the residue taken up in CH_2Cl_2 and water. The resulting solution was filtered over Hyflo Supercel (Fluka); the CH_2Cl_2 phase was separated off, washed with water, dried over Na_2SO_4, and evaporated to dryness. Unchanged **1** was removed by distillation at 100–110°C/10^{-2} torr, and the residue then chromatographed on a column (3000 g silica gel 60, Merck; eluent CH_2Cl_2). After evaporation under vacuum there remained **3a** as a yellow oil, which soon completely crystallized. Yield 34.5 g (50%), m.p. 47°C, b.p. 170°C/10^{-2} torr (Kugelrohrofen). Correct elemental analysis. IR (CH_2Cl_2): $\tilde{\nu}$ = 1735 (s), 1715 (s), 1640 (m), 1530 (s), 1350 (s), 1180 (s). ^{1}H-NMR ($CDCl_3$): δ = 8.30 (t, 1H), 8.22 (dd, 1H), 7.76 (dd, 1H), 7.58 (t, 1H), 6.30 (s, 1H), 4.22 (q, 2H), 4.18 (s, 2H), 4.13 (q, 2H), 1.28 (t, 3H), 1.18 (t, 3H).

3b and **3c** are obtained analogously to **3a** from **1** and **2b** or **2c**: **3b**: yield 57%, viscous oil, b.p. 154°C/10^{-2} torr (Kugelrohrofen). Correct elemental analysis. IR (CH_2Cl_2): $\tilde{\nu}$ = 1730 (s), 1710 (s), 1680 (s), 1630 (m). ^{1}H-NMR ($CDCl_3$): δ = 7.99 (t, 1H), 7.90 (dd, 1H), 7.60 (dd, 1H), 7.44 (t, 1H), 6.28 (s, 1H), 4.18 (q, 2H), 4.16 (s, 2H), 4.08 (q, 2H), 2.58 (s, 3H), 1.26 (t, 3H), 1.14 (t, 3H).—**3c**: Yield 32%, viscous oil, b.p. 160°C/10^{-2} torr (Kugelrohrofen). Correct elemental analysis. IR (CH_2Cl_2): $\tilde{\nu}$ = 1720 (s), 1710 (s), 1630 (m). ^{1}H-NMR ($CDCl_3$): δ = 8.08 (t, 1H), 7.98 (dd, 1H), 7.58 (dd, 1H), 7.39 (t, 1H), 6.26 (s, 1H), 4.32 (q, 2H), 4.15 (q, 2H), 4.14 (s, 2H), 4.07 (q, 2H), 1.34 (t, 3H), 1.25 (t, 3H), 1.14 (t, 3H).

5a: A suspension of 11.7 g (0.39 mol) of NaH (80% in oil), in ether (200 mL) was treated with 55.5 g (0.75 mmol) of ethyl formate. After 2 hours' stirring a solution of **3a** (46.1 g, 0.15 mol) in ether (150 mL) was added dropwise within 2 h. After H_2-evolution had subsided (1–2 h), the reaction mixture was poured onto 300 g of ice in 60 mL of conc. HCl. The ether layer was separated off and the aqueous phase was extracted with CH_2Cl_2. The combined extracts were finally washed with water and, after drying over Na_2SO_4, evaporated to dryness. The residue was chromatographed on a column (1700 g silica gel 60, Merck; eluent CH_2Cl_2). The product **4a** was dissolved without purification in 130 mL of toluene, treated with 0.2 g of TosOH, and the solvent slowly distilled off. The solution of the residue in $CHCl_3$ was washed with 2% aqueous $NaHCO_3$, dried over $MgSO_4$, and evaporated to dryness. The (initially) oily **5a** crystallized out and was washed with Et_2O. Yield 13 g (30%), m.p. 155°C, correct elemental analysis. IR ($CHCl_3$): $\tilde{\nu}$ = 1750 (s), 1730 (s), 1630 (m), 1530 (s), 1350 (s). ^{1}H-NMR ($CDCl_3$): δ = 8.35 (s, 1H), 8.28 (m, 1H), 8.15 (m, 1H), 7.63 (m, 1H), 7.58 (m, 1H), 6.25 (s, 1H), 4.15 (q, 2H), 1.13 (t, 3H).

7a: A suspension of **5a** (1.445 g, 0.005 mol) in acetonitrile (8 mL) was treated with 0.43 g (0.005 mol) of piperidine and the mixture stirred at room temperature for 17 h. Evolution of CO_2 was accompanied by formation of **6a**, which was evaporated down at 40°C, treated with a solution of diethyl aminocrotonate (1.94 g, 0.015 mol) in acetic acid (0.3 g, 0.005 mol) and heated to 130°C for 8 h. After removal of the acetic acid under vacuum the residue was chromatographed on a column (200 g of silica gel 60 Merck; eluent acetic acid-ethyl acetate/hexane, 1:2). Yield 0.48 g (26%) of oily product that crystallized on addition of Et_2O; m.p. 153°C, yellow fluorescence at 366 nm. Correct elemental analysis. IR ($CHCl_3$): $\tilde{\nu}$ = 3400 (w), 1675 (s), 1620 (m), 1530 (s), 1350 (s). ^{1}H-NMR ($CDCl_3$): δ = 8.37 (t, H-2'), 8.14 (dt) and 7.92 (dt, H-4', H-6'), 7.53 (t, H-5'), 7.89 (s, H-6), 5.00 (s, NH), 4.21 (q, CH_2), 4.00 (m, CH_2), 2.39 (s, CH_3), 2.03 (s, CH_3), 1.35 (t, CH_3), 1.15 (t, CH_3). Due to the chirality center C-4, the protons in the two $-OCH_2-$ groups are diastereotopic. The anisochronism possible as a result of this was, however, only observed for the protons of one of the two groups ($\Delta\delta$ = 0.04 ppm) (cf. Ref. [5]).

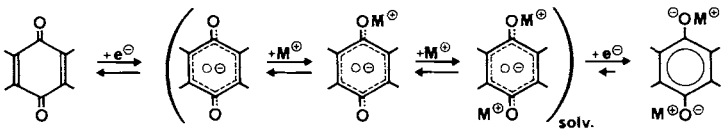
The Spin Distribution in Ion Pairs of 1-Aminoanthraquinone Radical Anion and Alkali-Metal Cations**

By *Hans Bock,* Bernhard Hierholzer,* and *Petra Schmalz*

The two-step reversible reduction of *p*-quinones in aprotic solution is greatly influenced by added metal salts;[1–3] in particular the second electron is transferred irreversibly at considerably lower potentials. This observation can be rationalized assuming complexation of metal cations $M^{\oplus}$ by the solvated semiquinone radical anion $[Q^{\odot\ominus}]_{solv}$ with formation of contact ion pair radicals $[Q^{\odot\ominus}M^{\oplus}]^{\odot}_{solv}$ and triple ion-radical cations $[M^{\oplus}Q^{\odot\ominus}M^{\oplus}]^{\odot\oplus}_{solv}$ demonstrated ESR spectroscopically, e.g. with $M^{\oplus}$ = $Li^{\oplus}$[3] (cf. Scheme 1). The total positive charge of the triple ion-radical cation $[M_2Q]^{\odot\oplus}$, in which the final reduction product, a salt of a hydroquinone dianion, is already preformed, explains both the substantial lowering of the second reduction potential as well as the irreversibility of the electron transfer.[3]



Scheme 1.

1-Aminoanthraquinone is a suitable model compound for ENDOR experiments[4] aimed to elucidate the spin distribution in the intermediary contact ion pair radicals $[Q^{\odot\ominus}M^{\oplus}]^{\odot}_{solv}$.[5,6] In dimethylformamide (DMF) with tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte it shows two reversible or quasi-reversible half-wave reduction potentials at −0.91 and −1.57 V (ΔE = 65 and 100 mV, resp.). Addition of, e.g., $LiClO_4$ or $Ba(ClO_4)_2$ influences the first half-wave potential only slightly ($\Delta\varepsilon^{1}_{1/2} \leq 0.05$ V); whereas the noticeable drop in the second half-wave potential of about 0.37 or 0.48 V to −1.20 and 1.09 V, respectively (ΔE = 120 and 130 mV, resp.) points to ion-pair formation (see Scheme 1).[2–5] The O···N distance in the peri-chelate claw of 1-aminoanthraquinone amounts to only ca. 250 pm, so that the O- and N-electron pairs interpenetrate in the preferred complex conformation in which the angle between the HNH-bisector and the six-membered ring plane (Fig. 1) will be close to 0°. In its radical anion, the electron density at the oxygen atom is increased by π-delocalization of the excess negative charge in the direction of the polarizing effective cationic charge ($M^{\oplus}$). The ESR signals of the 1-aminoanthrasemiquinone ion-pair radicals can be saturated, allowing to record highly resolved ENDOR spectra (Fig. 1)[7] and to determine the signs of the individual couplings a_H and $a_{M^{\oplus}}$ by TRIPLE experiments.[4]

[**] Electron Transfer and Ion Pair Formation, Part 4. This work was supported by the Land Hessen, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the A.-Messer Stiftung.—Parts 1-3: [1]-[3].

The ENDOR spectra (Fig. 1) of the contact ion pair radicals generated by stoichiometric alkali-metal reduction of 1-aminoanthraquinone and additionally stabilized by THF solvation, show significant differences e.g. for $X = Li^{\oplus}$ and $Cs^{\ominus}$, whose ionic radii of 60 and 170 pm, re-

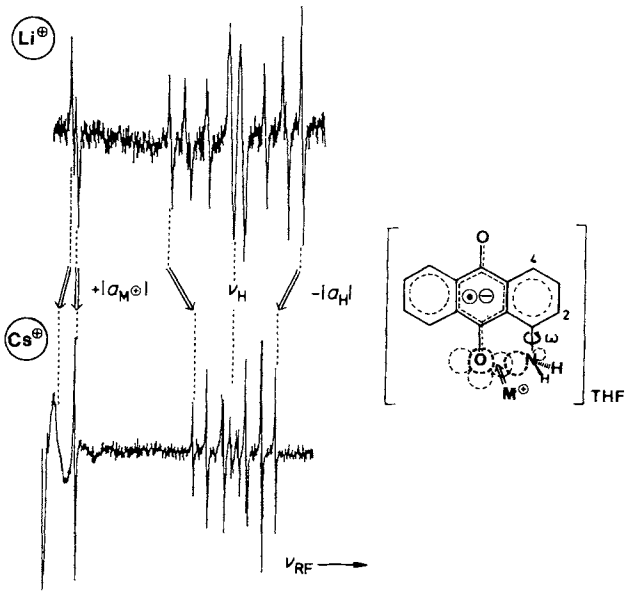

Fig. 1. ENDOR spectra of 1-aminoanthrasemiquinone ion-pair radicals with $Li^{\ominus}$ and $Cs^{\oplus}$ in tetrahydrofuran (THF) at 200 K [5].

spectively, differ the most: The spread of the ^{1}H-signal pairs about the frequency ν_H decreases, while the metal cation couplings $a_{M^{\ominus}}$ increase. Triple experiments prove[4] different signs for the couplings a_X: for all ring protons (X = H) they are, as expected, negative due to π/σ spin polarization, but positive for all added alkali-metal cations with ample hyperfine splitting constants ($X = Li^{\oplus}$, $Na^{\oplus}$, $Rb^{\oplus}$, $Cs^{\oplus}$) (cf. Ref. [4]).

The measured data yield the following information on the structure of the 1-aminoanthraquinone radical anion chelates in THF: A nitrogen coupling ($a^{14}_N = 0.06$ mT) is only observed with the nBu$_4$N$^{\oplus}$ countercation shielded by alkyl groups and, therefore, largely interaction-free,[7] i.e. when a considerable rotation of the NH_2 group favored by hydrogen bonding (Fig. 1: ω almost 90°) permits a substantial n_N/π delocalization. The positive $M^{\oplus}$ couplings suggest that the countercation is located outside the π-nodal plane and that, therefore, the N-electron pair is not rotated completely in the direction of the semiquinone oxygen atom (Fig. 1 = $0° < \omega < 90°$). This is consistent with the expectation that "docking" of the alkali cations should be energetically favored at the site of presumed highest electron density in the O,N-chelate claw, i.e. near to the semiquinone oxygen atom, but outside of the O···N axis in the π-nodal plane. All contact ion pairs investigated here should have comparable structures, as follows, e.g., from the observation that in all cases the ENDOR signals are temperature-independent.[2]

Expectedly, the ring proton couplings in the 1-aminoanthrasemiquinone radical anion chelates $[Q^{\odot\ominus}M^{\oplus}]^{\odot}_{THF}$ increase[1,4] with effective cationic charge $1/r_{M^{\oplus}}$ (Fig. 2; top). This result further supports the literature model,[4] that the charge increase on the semiquinone O-atoms due to $>C{=}O^{\delta\ominus}\cdots M^{\oplus}$ Coulomb interactions suppresses their π spin population in favor of that on the ring carbon atoms.

The dependence of the $>C{=}O^{\delta\ominus}\cdots M^{\oplus}$ Coulomb interaction on the alkali-metal cations can be demonstrated by correlation of their s spin densities $\rho_{M^{\oplus}}$ with their volumes $r^3_{M^{\oplus}}$ (Fig. 2, bottom). Based on the assumptions that the structures of all radical anion chelates dissolved in THF are comparable, and that the spin densities $\rho_{M^{\oplus}}$ of the almost spherically symmetrical chelate cations can be estimated from the McConnell analogous relationship[8a] $\rho_{M^{\oplus}} = a_{M^{\oplus}}|Q_M|^{-1}$ by inserting the ENDOR coupling constants $a_{M^{\oplus}}$ (Fig. 1) and the hyperfine splittings $|Q_M|$ of alkali metals as determined by atomic beam experiments.[8b] The resulting linear regression $\rho_{M^{\oplus}} = 0.157 + 0.0293 r^3_{M^{\oplus}}$

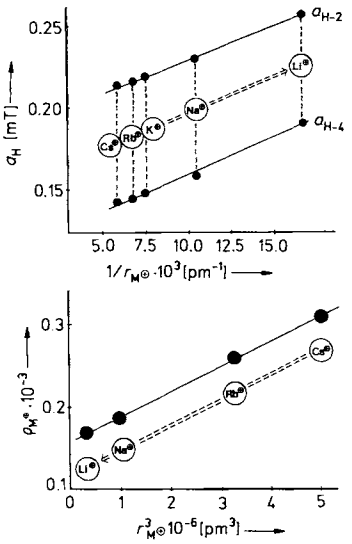

Fig. 2. Correlations of ENDOR data of the ion pairs of alkali-metal cations and 1-aminoanthraquinone radical anion. Top: ^{1}H-coupling constants of the ring protons a_{H-2} and a_{H-4} versus the effective $M^{\oplus}$ ionic charges $1/r_{M^{\oplus}}$. Bottom: $M^{\oplus}$-Spin densities $\rho_{M^{\oplus}}$ versus the cation volumes $r^3_{M^{\oplus}}$ (cf. text).

with a correlation coefficient $r = 0.999$ (Fig. 2, bottom) confirms that the transferred positive π-spin density $\rho_{M^{\oplus}}$ increases with the cation volume $r^3_{M^{\oplus}}$. According to the Coulomb interaction model $>C{=}O^{\delta\ominus}\cdots M^{\oplus}$, the spin density of the O-"docking" sites decreasing with increasing effective cationic charge from $Cs^{\oplus}$ to $Li^{\oplus}$ is the major contributing factor to this transfer.[2] Concomitantly the π-spin population of the ring carbon atoms increases, as can be demonstrated by the larger ring proton coupling constants (Fig. 1 and Fig. 2, top).

Kaiser, L. Kevan (Eds.): *Radical Ions*, Wiley-Interscience, New York 1968, p. 35f; T. E. Gough, P. R. Hindle, *Can. J. Chem. 47* (1969) 1698, 3393.

[5] For summaries of investigations on ion pairs from various view points see, e.g. a) J. M. Masnovi, J. Kochi, *J. Am. Chem. Soc. 107* (1985) 7881; b) E. S. Gould, *Acc. Chem. Res. 18* (1985) 22; c) W. Kaim, *ibid. 18* (1985) 160; d) A. Streitwieser, Jr., *ibid. 17* (1984); e) J. M. Lehn, *Pure Appl. Chem. 52* (1980) 2303; f) A. Kaifer, D. A. Gustowski, L. Echegoyen, V. J. Gatto, R. A. Schultz, T. P. Cleary, C. R. Mor, D. M. Goli, A. M. Rios, G. W. Gokel, *J. Am. Chem. Soc. 107* (1985) 1958, and references cited therein. Cf. also [4].

[6] Reducible chelate molecules with O- or N-docking sites have already been used repeatedly for ESR/ENDOR investigations on radical ion pairs. Examples are a) crown ethers with reducible π systems such as quinones (cf. [1]); b) *ortho*-quinones (cf. e.g.: J. A. Pedersen, *CRC Handbook of EPR Spectra from Quinols*, CRC Press, Boca Raton, FL, USA 1985 or [2]); c) semidiones (cf. e.g.: G. A. Russell, C. E. Osuch, *J. Am. Chem. Soc. 100* (1984) 5979 or [4]); d) N-heterocycles such as α,α'-bipyridyl (cf. e.g.: W. Kaim, *J. Am. Chem. Soc. 104* (1982) 3833, and references cited therein).

[7] 1-Aminosemianthraquinone radical anion with $n\mathrm{Bu_4N^{\oplus}}$ as, largely interaction-free, countercation can be generated electrochemically in THF/TBAP solution. THF is chosen as solvent for the ESR investigations because it favors the formation of contact ion pairs relative to more polar solvents such as DMF (cf. e.g.: K. A. M. Greber, K. S. Chen, J. K. S. Wan, *Rev. Chem. Intermed. 5* (1984) 37; E. Lesniewska-Lada, M. K. Kalinowski, *Electrochim. Acta 28* (1983) 1415, and references cited therein). The radical ion pairs $[\mathrm{M^{\oplus}Q^{\ominus\ominus}}]^{\ominus}$ are prepared in THF by reduction of 1-aminoanthraquinone on the respective alkali metal mirrors; for the preparation of Rb- and Cs-mirrors, the thermal decomposition of their azides in the presence of fine-grained iron powder proved to be advantageous. The ENDOR measurements were carried out with a Bruker 220 D spectrometer; with magnetic fields of about 3.4 kG, the frequencies $\tilde{\nu}_X$ of the individual isotopes are (rel. abundance): ^{1}H 14.46 MHz (99.98%), ^{7}Li 5.62 MHz (92.6%), ^{23}Na 3.82 MHz (100%), ^{87}Rb 4.73 MHz (27%), and ^{133}Cs 1.90 MHz (100%).

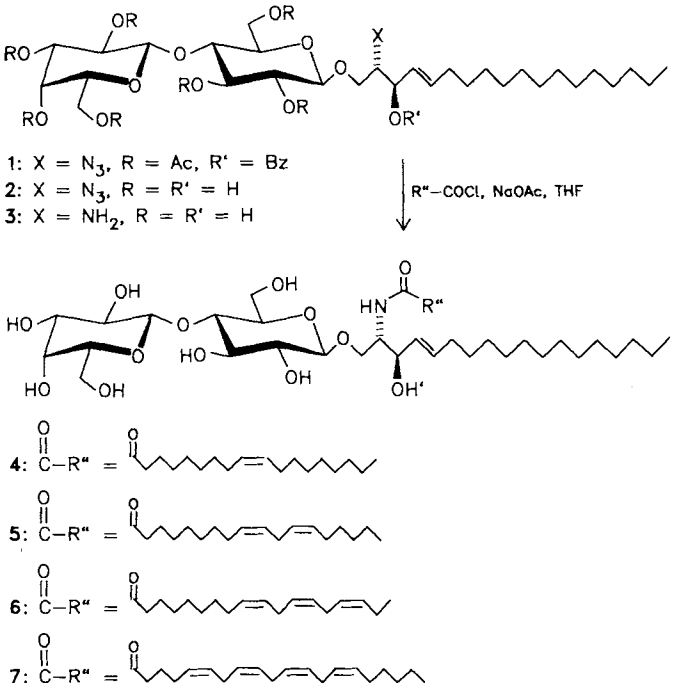
Lactosylceramides with Unsaturated Fatty Acids—Synthesis and Use in the Generation of Bilayer Membranes**

By *Richard R. Schmidt,* Thomas Bär,* and *Hans-Juergen Apell*

Dedicated to Professor Wolfgang Pfleiderer on the occasion of his 60th birthday

Glycosphingolipids are membrane building blocks, which, with their lipid moiety, the *N*-acylated sphingosine (= ceramide), participate in the formation of the outer plasma membrane bilayer. The hydrophilic carbohydrate moiety is located on the outer membrane surface, and thus can determine the specificity of interactions with cells and various biofactors.[1] C_{18}-sphingosine is the most important sphingosine base in the majority of mammalian tissues, while considerable amounts of the C_{20} homologues are found in the gangliosides of the brain. Unsubstituted and α-hydroxy fatty acids are met as *N*-acyl groups which can contain double bonds.[2]

Bilayer membranes could not be obtained with the glycosphingolipids thus far available, which are mostly chemically heterogeneous. Recently, we developed a synthetic method with which pure glycosphinolipids can be prepared in good yields.[3] Since the fatty acid is coupled with the amino group of the sphingosine moiety in the last reaction step, this synthetic method is also suitable for systems with sensitive acids. We have now used it for the synthesis of lactosyl sphingolipids containing unsaturated fatty acids which promote membrane formation and membrane fluidity.[4] Reaction of *O*-acetylated *O*-(α-lactosyl) trichloroacetimidate[5] as donor and 3-*O*-benzoylated azidosphingosine[6] as acceptor with BF_3–OEt_2 as catalyst afforded the glycoside **1**[7] (yield 85%). Competing formation of *ortho* ester could be completely suppressed by successive addition of 0.05 equivalents of catalyst. Deacylation with sodium methoxide/methanol furnished **2** in quantitative yield, and reduction of the azide group with H_2S/pyridine afforded the lactopsychosine **3**, which has already been prepared via another route.[3] The acid chlorides, which were generated with oxalyl chloride, proved to be the best for the coupling of oleic, linolic, linolenic, and arachidonic acids. Their reaction with **3** in the presence of sodium acetate in tetrahydrofuran (THF)/water led in good yields (65–74%) to the lactosylceramides **4**–**7**.[7] These can be obtained pure by peracetylation and subsequent deacetylation with Florisil[8] (**4**, **5**), or directly by reversed phase chromatography (**6**, **7**; RP_{18},[8] *n*-butanol/methanol/water, 50 : 32 : 18).[7]



To gain insights into the complexity of the cell membranes it is essential first of all to investigate the properties and modes of reaction of the individual membrane components in simple models.[9] We have therefore generated bilayer membranes with the glycosphingolipids **4**–**7** using the bilayer technique of *Müller* et al.[9, 10] and have deter-

mined the thickness of the membranes from measurements of the electrical capacity on "black films" (black bilayer membranes BLM).[11, 12] Bilayer membranes with remarkable longevity (up to several hours) and stability toward higher potentials (measurements up to 300 mV) could be obtained (surface areas 0.15 mm^2) from 3–4% solutions of **4**–**7** in *n*-decane/*n*-butanol (100:1). The specific membrane capacities measured at potentials of 10–300 mV (Table 1) lie about a factor of 1.5 above those of phosphatidylcholine membranes.[12] This can be due to the altered dielectric properties of the hydrophilic head groups in the case of the lactosylceramides, or to the bilayer being thinner due to tighter coiling and kinking of the lipid moiety. The specific membrane capacities increase with the increasing number of *cis* double bonds in the C_{18}-acid derivatives **4**–**6**, whereas, conversely, the estimated layer thickness for the lipid moiety, presumably determined by the kinking, decreases. The specific membrane capacity of the arachidonic acid derivative **7** is of the same order of magnitude as that of the oleic acid derivative **4**, i.e. the chain lengthening by two C-atoms is balanced out by about three additional *cis* double bonds.

Table 1. Specific membrane capacity (C_m) and thickness (d) of the hydrocarbon region of the bilayer membranes of lactosylceramides **4**–**7** [a].

Compound	C_m [$\mu F/cm^2$] [b]	d [nm] [c]
4	0.563 ± 0.072	3.30 ± 0.26
5	0.755 ± 0.073	2.46 ± 0.25
6	0.818 ± 0.092	2.27 ± 0.20
7	0.570 ± 0.038	3.26 ± 0.49

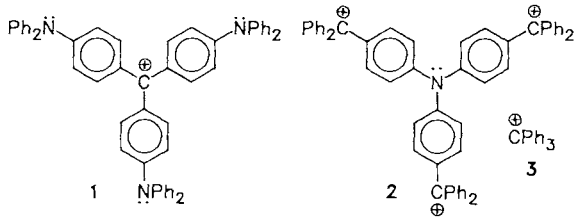
Deep-Colored, Through-Conjugated Multitriphenylmethylium Ions**

By *Dieter Hellwinkel,* Heinz Stahl,* and *Heinrich Georg Gaa*

Monocationic "conventional" triphenylmethylium dyes of the crystal violet type **1** and the tricationic "inverse" analogues **2** derivable from them by exchanging the functionalities show almost the same longest-wavelength absorptions in the electronic spectrum and have virtually the same green color.[1]



λ_{max} [nm] (lg ε):	627 (4.95)	641 (5.26)
	409 (3.27)	426 (4.35)
	(in CH_3CO_2H + 5% CF_3CO_2H)	(in CF_3CO_2H)

This can be readily explained with the aid of the characteristic HMO frontier orbital scheme for the alternating structural types shown above. The scheme is characterized by two non-bonding (n) orbitals and the weakly bonding and antibonding molecular orbitals b, a, respectively, of opposite but equal energies (Fig. 1).

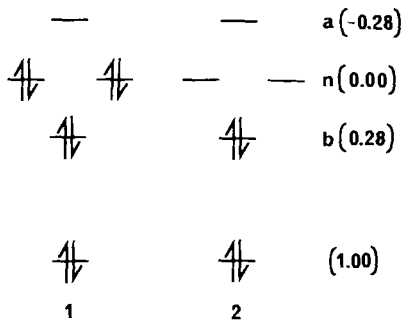


Fig. 1. Frontier orbital occupancy scheme for conventional triphenylmethylium ions **1** and their tricationic "inverse" analogues **2** in the Hückel approximation (energies in β-units).

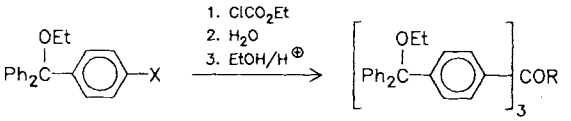
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and by BASF AG.

From the different occupancies of the frontier orbital region of the dyes of type **1** and **2** it follows that at the level of the Hückel approximation even identical longest-wavelength electron excitations are to be expected.

If the two electrons in the weakly bonding molecular orbital b are also removed, a new chromophore-type emerges, which—corresponding to a frontier excitation $1.00\beta \rightarrow b(0.28\beta)$—should absorb in the UV/VIS spectrum at a shorter wavelength than **2** [$b(0.28\beta) \rightarrow n$, $\lambda_{max} = 641$ nm], yet at a still longer wavelength than the yellow triphenylmethylium ion **3** [$1.00\beta \rightarrow n$, $\lambda_{max} = 432$ nm].[2]

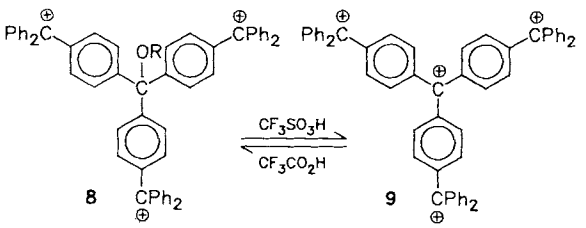
We have now transformed this idea into reality by replacing also the last N donor function in **2** by a carbenium center. Thus, we allowed the key reagent **4**,[3] accessible from benzophenone by reaction with 4-bromophenyllithium, to react, after bromine-lithium exchange to give **5**, with methyl chloroformate to give the trisether of the tetraalcohol **6**, which yielded the tetrakis(ethyl ether) **7** with ethanol.



4, X = Br; **5**, X = Li

6, R = H; **7**, R = Et

Reaction of **7** with trifluoroacetic acid afforded exclusively the yellow trication **8**, which is none other than a spacer-coupled, and thus conjugatively separated, triple tritylium system.[4] Only stronger acids such as sulfuric acid or trifluoromethanesulfonic acid can liberate from **7** or **8** the novel reddish-violet tris[4-(diphenylmethyliumyl)phenyl]methylium ion **9**, which upon dilution with trifluoroacetic acid resolvolyzes to the yellow trication **8**.



λ_{max} [nm] (lg ε): 437 (5.45) 517 (5.45)

R = Et or acid residue

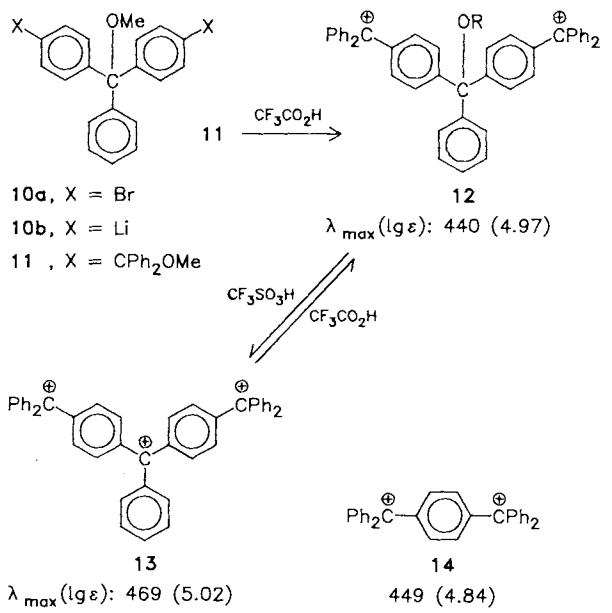


Table 1. ^{1}H-NMR data of the triphenylmethylium ions **2**, **3**, **8**, **9**, **13**, and **14** (room temperature, δ values rel. TMS), prepared from the corresponding ethers [a] with the given acids quoted under "solvent". Numbering scheme:

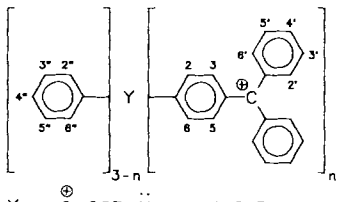

Y = ⊕C, COR, N; n = 1, 2, 3

Ion	Solvent	Charge	2′,6′ (2″,6″)	3′,5′ (3″,5″)	4′ (4″)	2,6 —	3,5 —
3	CF_3CO_2H/CD_2Cl_2 (1/1) [b]	⊕	7.77	7.95	8.34	—	—
14	$CF_3CO_2H/CF_3SO_3H/CD_2Cl_2$ (1/0.5/4) [b]	2⊕	7.92	8.07	8.50	8.03	8.03
2	CF_3CO_2D	3⊕	7.80	7.95	8.31	8.00	7.97
13	CF_3SO_3H [c]	3⊕	8.04 (8.32)	8.17 (8.35)	8.61 (**8.84**)	8.30	8.22
8	CF_3CO_2D	3⊕	7.80	7.94	8.36	7.98	8.25
9	CF_3SO_3H [c]	4⊕	8.14	8.22	**8.68**	8.57	8.38

[a] All precursors afforded correct analytical values and ^{1}H-NMR spectra. [b] Referred via $\delta(CH_2Cl_2) = 5.288$ to TMS. [c] Relative to $CDCl_2$/TMS extern.

Aside from the electronic spectrum, the 500-MHz ^{1}H-NMR spectrum[5] is especially informative regarding the structure of the tetracation **9**. For the *p*-protons of the outer phenyl groups it shows, with $\delta = 8.68$, a chemical shift value which lies well above the values hitherto observed for such protons in tritylium ions[1,6,7] (Table 1).

In a comparable way, a through-conjugated trication, the red bis[4-(diphenylmethyliumyl)phenyl]phenylmethylium ion **13** could be synthesized and characterized via the reaction of the difunctional key reagent **10b** analogous to **5** with benzophenone to give the trisether **11** and its dissolution in acids. Like **9**, the ion **13** is stable only in trifluoromethanesulfonic acid and is resolvolyzed with trifluoroacetic acid to give the yellow dication **12**. In **13** it is the *p*-proton of the phenyl group coupled to the central carbenium function which shows a record deshielding value of $\delta = 8.84$ in the ^{1}H-NMR spectrum (Table 1).

The tri- and tetra-cations **13** and **9**, respectively, are the first members of a series of novel, conjugated multitritylium systems of which we are presently synthesizing some representative examples. Hitherto, only one conjugated dication of this type, the yellow 1,4-phenylenebis(diphenylmethylium) **14**, was known.[8]

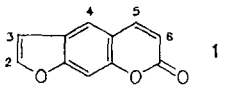
A Psoralen-Substituted Dioxetane as DNA Intercalator for Photogenotoxic Studies**

By *Waldemar Adam,* Axel Beinhauer, Roland Fischer,* and *Hermann Hauer*

The phototherapeutic action of psoralen **1**, a linearly fused furocoumarin composed of benzofuran and coumar-



1

in, in psoriasis rests on its photochemical [2+2] cycloaddition to DNA under UVA irradiation (300–400 nm).[1] These polycyclic heteroaromatic molecules intercalate into the DNA ladder and on excitation by UV radiation they cycloadd at the α-pyrone and/or furan double bonds to proximate pyrimidine bases (preferably thymine) with formation of four-membered rings. Recently we were able to show[2] that 1,2-dioxetanes (chemical sources for electronically excited states[3]) cause photochemical damage to DNA. While in isolated DNA dioxetanes induce photochemical cycloaddition, in cellular DNA their photogenotoxic action mainly derives from radical-type damage, e.g. strand breaks.[2]

The aim of this study was to bind dioxetanes chemically to psoralen, with the intention that the intercalative ability of such furocoumarins would help to transport the psoralen-bound dioxetane to the DNA. Subsequent thermal decomposition of the dioxetane would then lead to electronically excited psoralen, which should cycloadd to the DNA.

We report here on the successful synthesis, by carbonate linking,[4] of the first psoralen-substituted dioxetanes **3a–c** and on their activation parameters and excitation yields (see Table 1).

The benzofuran- and the coumarin-substituted dioxetanes **3a** and **3b**, respectively, served as model substances in the synthesis of the psoralen-substituted dioxetane **3c**. These three dioxetanes will be used as model compounds in future photobiological experiments. The corresponding phenols were prepared in 43–58% yields from the methoxy derivatives by demethylation with Me_3SiI. Reaction of the phenols with the dioxetane-substituted chloroformate **2** in the presence of stoichiometric amounts of triethylamine in

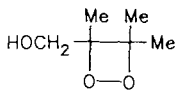
dichloromethane at 0°C led to the dioxetanes **3a–c**. These were purified by chromatography on silica gel at low temperature (−30°C). Thermolysis (ca. 75°C) of **3a–c** afforded quantitatively the ketocarbonates **4a–c** with chemiluminescence. All the new compounds **3** and **4** were completely characterized (see Table 2[5]).

The activation parameters of the dioxetanes **3a–c** (Table 1) were determined photometrically by monitoring the chemiluminescence emission under isothermal conditions.[6] Within the limits of error, the dioxetanes **3** exhibit almost the same thermal stability, which hardly differs from that of dioxetane **2** and its precursor, the hydroxymethyl(trimethyl)-1,2-dioxetane **5**.[2a, 7]



5

The excitation yields of the dioxetanes **3a–c** (Table 1) were determined photometrically using Stern-Volmer kinetics (9,10-diphenylanthracene for singlet yields and 9,10-dibromoanthracene for triplet yields).[8] In the case of **3a–c**, as in the case of **5**, the triplet excited carbonyl products predominate by a factor of 100. While **3a**, **b** furnish approximately the same triplet yields as **5**, that of the psoral-

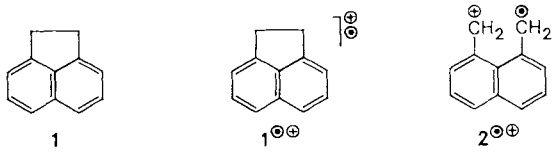
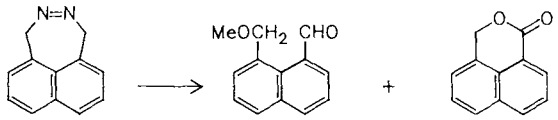
Cerium(IV)-Catalyzed Single Electron Transfer (SET) on Acenaphthene and 1,4-Dihydronaphtho-[1,8-*d,e*][1,2]diazepine: Chemical Evidence for Distinct Radical Cations**

By *Waldemar Adam,* Alicia Casado,* and *Miguel A. Miranda*

That the radical cation of acenaphthene (**1**) is naphthalenic-like (structure $\mathbf{1}^{\odot\oplus}$) rather than benzylic-like (structure $\mathbf{2}^{\odot\oplus}$) has been convincingly demonstrated by ESR and electronic spectra.[1] However, the question still is open, whether these structures rapidly interconvert and thus exhibit common chemistry, or whether a sufficiently large energy barrier separates them so that they manifest distinct chemical fates. Since a σ-π crossing obtains in the $\mathbf{1}^{\odot\oplus} \rightleftarrows \mathbf{2}^{\odot\oplus}$ interconversion, the latter behavior is anticipated. Indeed, we provide herewith experimental proof that the independently generated radical cations $\mathbf{1}^{\odot\oplus}$ and $\mathbf{2}^{\odot\oplus}$ are discrete species which undergo characteristic reactions.



1 $1^{\odot\oplus}$ $2^{\odot\oplus}$



2 3 4

The azoalkane **2**[2] was oxidized with ceric ammonium nitrate in oxygen-saturated 80% aqueous methanol at 20°C, a potent single electron transfer (SET) oxidant that proved effective for the denitrogenation of azoalkanes[3] and the cleavage of carbon–carbon bonds in 1,2-diarylethanes[4] via the corresponding radical cations. Within 5 min complete nitrogen loss ensued and upon silica gel column chromatography the previously unknown methoxy aldehyde **3**[5] could be isolated in 25% yield and the lactone **4**[6] in 18% yield. Significant is that only traces of acenaphthene-derived products were observed. Furthermore, the triphenylpyrylium tetrafluoroborate(TPT)-sensitized photolysis of azoalkane **2**, which proved successful for the denitrogenation of cyclic azoalkanes via radical cations,[7] led exclusively to the tautomeric hydrazone.

To account for the products **3** and **4**, it is postulated that the benzylic-type radical cation $\mathbf{2}^{\odot\oplus}$ intervenes, which after trapping by methanol and molecular oxygen leads to

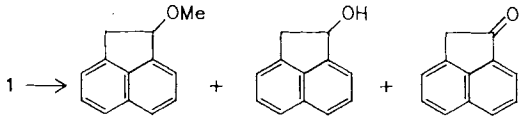
the methoxy aldehyde **3**. Trapping of the radical cation $2^{\odot\oplus}$ with water and oxygenation affords first the corresponding hydroxy aldehyde, which is further oxidized to the lactone **4** via the hemiacetal. Related chemistry was reported for the Ce(IV)-catalyzed[4] and 1,4-dicyanonaphthalene-photosensitized[8] oxidation of 1,2-diarylethanes, except that the intervening radical cation had suffered rupture of the ethane bond since trapping products of the resulting benzyl cations and radicals were observed.

Oxidation of acenaphthene (**1**) with ceric ammonium nitrate in oxygen-saturated 80% aqueous methanol furnished methyl ether **5** (14%), alcohol **6** (12%), and ketone **7** (59%), all identified by comparison of TLC retention times and spectral data with those of the authentic materials. Clearly, these products are derived from the naphthalenic-type rad-



ical cation $1^{\odot\oplus}$,[1] which deprotonates to the acenaphthyl radical. Subsequent oxygenation with molecular oxygen affords eventually ketone **7**. Alternatively, further oxidation affords the acenaphthyl cation which is nucleophilically trapped by methanol or water to generate **5** and **6**, respectively. Significant is that only traces of ring-cleavage products such as the methoxy aldehyde **3** and lactone **4** were observed.

This dichotomy in chemical behavior in the Ce(IV)-catalyzed SET-oxidation of acenaphthene (**1**) and the azoalkane **2** is indicative of the structurally distinct radical cations $1^{\odot\oplus}$ and $2^{\odot\oplus}$, respectively of the naphthalenic and

$$\mathbf{1} \xrightarrow{\text{cerium(IV)}} \mathbf{1}^{\odot\oplus} \underset{}{\overset{\text{slow}}{\rightleftharpoons}} \mathbf{2}^{\odot\oplus} \xleftarrow{\text{cerium(IV)}} \mathbf{2}$$

benzylic type. An appreciable activation barrier ($E_a \geqq 20$ kcal/mol) must separate these two species for characteristic chemistry to become observable. At first sight this seems surprising since efficient carbon–carbon bond cleavage of radical cations derived from diarylethanes,[4] and more recently benzhydryl derivatives,[9] is well documented. However, in these flexible acyclic radical cations the σ-bond to be cleaved can align itself with the aromatic moiety to generate resonance-stabilized π-type benzyl or benzhydryl radicals and cations. In the rigid naphthalenic radical cation $1^{\odot\oplus}$ the σ-bond is fixed in the plane of the aromatic system, so that overlap of the orbitals of the incipient benzylic sites with the aromatic system to form the benzylic radical cation $2^{\odot\oplus}$ is only feasible after extensive σ-bond rupture. We propose that such σ-π crossing[10] is responsible for the slow $1^{\odot\oplus} \rightleftarrows 2^{\odot\oplus}$ valence isomerization on the chemical time scale. Related cases have been extensively investigated concerning photochemical transformations under matrix isolation.[11]

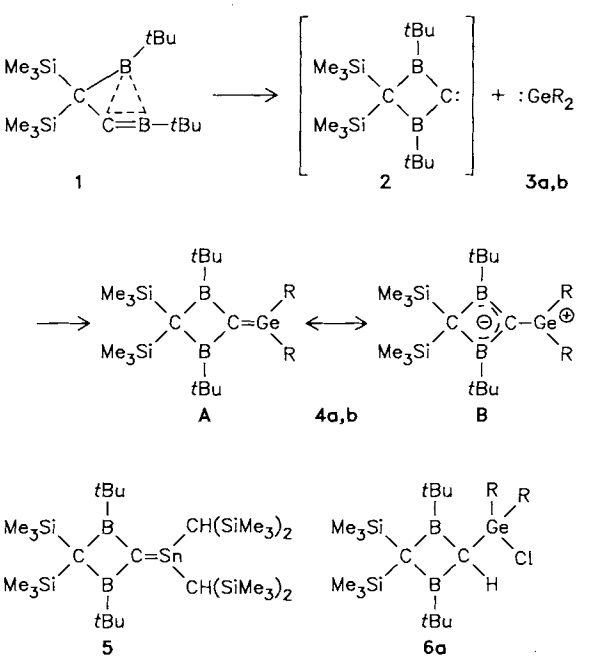
Stable Germaethenes**

By *Harald Meyer, Gerhard Baum, Werner Massa,* and *Armin Berndt**

The existence of short lived germaethenes has been demonstrated by trapping reactions.[1,2] We have now prepared stable germaethenes and characterized them spectroscopically, in one case also by a crystal structure analysis. Reaction of the electrophilic cryptocarbene **1** (**2**)[3] with the germanediylenes **3a**[4] and **3b**[5] in pentane at room temperature afforded the germaethenes **4a** and **4b**, respectively, as sole products. The lemon-yellow and pale yellow crystals of **4a** and **4b** very slowly decolorize on ex-



a, R = $N(SiMe_3)_2$; **b**, R, R = $NtBu(Si(CH_3)_2)NtBu$

posure to air (**4a** within 3d) and melt without decomposition at 167 and 183 °C, respectively. The recently described stannaethene **5**[3] decolorizes within 2 h under the same conditions and already decomposes at 133 °C. **4a** adds HCl with quantitative formation of the colorless, crystalline 1,3-diboretane **6a**.

The structures of **4a**, **4b**, and **6a** follow from their ^{1}H-, ^{13}C-, and ^{11}B-NMR spectra.[6] The tricoordinated C atoms of **4a** and **4b**, with $\delta(^{13}C) = 115$ and 93 respectively, are noticeably shielded compared to the corresponding atom in **5** ($\delta = 142$), whereas the B atoms, with $\delta(^{11}B) = 66$ and 65 respectively, exhibit almost the same chemical shift as in **5** ($\delta = 64$). They are more strongly shielded than the B atoms of the 1,3-diboretane **6a** ($\delta = 82$), thus indicating a relatively large amount of negative π charge on the B atoms and a similar ylide character (resonance formula **B**) of the CGe double bonds in **4a** and **4b** as in **5**.

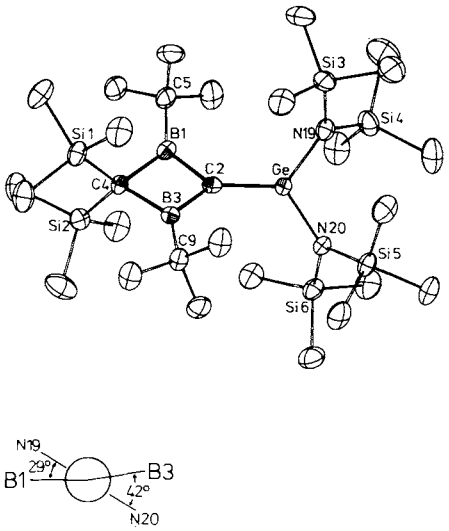

Fig. 1. Top: ORTEP drawing of the crystal structure of **4a**. The vibration ellipsoids are given at the 30% probability level. Projection onto the C2,N19,N20 plane; H atoms not shown. Important bond lengths [Å] and angles [°]: Ge-C2 1.827(4), Ge-N19 1.818(4), Ge-N20 1.835(4), B1-C2 1.534(7), B1-C4 1.626(6), B1-C5 1.586(8), B3-C2 1.523(6), B3-C4 1.628(6), B3-C9 1.604(7), C4-Si1 1.889(4), C4-Si2 1.887(5), B1···B3 2.070(7), C2···C4 2.374(5); C2-Ge-N19 125.3(2), C2-Ge-N20 124.1(2), N19-Ge-N20 110.5(2), Ge-C2-B1 138.6(4), Ge-C2-B3 135.8(4), B1-C2-B3 85.3(4), C2-B1-C4 97.4(4), B1-C4-B3 79.0(3), C4-B3-C2 97.8(4), Si1-C4-Si2 112.6(3). Torsion angle: B1-C2-Ge-N19 29.4(6), B1-C2-Ge-N20 −148.3(4), B3-C2-Ge-N19 −140.3(4), B3-C2-Ge-N20 42.0(5), Ge-C2-B1-C4 −178.9(4), Ge-C2-B3-C4 179.3(4).— Bottom: Newman projection along the C2-Ge bond.

An X-ray structure analysis[7] of **4a** (Fig. 1 top) confirmed the significance of the ylide resonance formula **B** with short distances C2-B1 (1.534(7) Å) and C2-B3 (1.523(6) Å). The distance from the germanium atom to the tricoordinated C2-atom (1.827(4) Å) is 3% longer than that calculated for $H_2C{=}GeH_2$ (1.773 Å).[8] The GeC single bond in $Ge(CH_3)_4$ (1.98 Å)[9] is 8.4% longer than in **4a**. The torsion angles B1-C2-Ge-N19 and B3-C2-Ge-N20 (Fig. 1, bottom) are 29.4(6) and 42.0(5)°, respectively, the average twist angle at the C=Ge bond is therefore 36°. The angles between the line through C2-Ge and the N19,Ge,N20 and B1,C2,B3 planes are 1.7 and 4.8°, respectively, i.e. the Ge atom is practically planar coordinated, the C2 atom slightly pyramidalized. The stannaethene **5** exhibits an average twist angle of 61° and dihedral angles of 5° and 16° respectively at the Sn and C2 atoms. Thus the germaethene **4a** is considerably less twisted than the stannaethene **5** and markedly less puckered, especially at the C atom.

Experimental:

4a: A solution of **3a** (1.42 g, 3.6 mmol) in pentane (10 mL) was treated with **1** (1.11 g, 3.6 mmol) at room temperature. After 2 d only **4a** is detectable by ^{13}C-NMR spectroscopy. It precipitates in the form of lemon-yellow crystals (m.p. 167 °C) on cooling the pentane solution to −25 °C.

Preparation of $F_4S{=}CH{-}COF$ by Isomerization of $F_5S{-}CH{=}C{=}O$**

By *Thomas Krügerke, Jürgen Buschmann, Gert Kleemann, Peter Luger,* and *Konrad Seppelt**

The alkylidene sulfur tetrafluorides $R_2C{=}SF_4$ are of special interest because of their stable, essentially nonpolar C=S double bond and their unique structure. The first compound of this type, $CH_2{=}SF_4$, was prepared in several steps from pentafluoro-λ^6-sulfanylacetic acid **1**.[1] We have

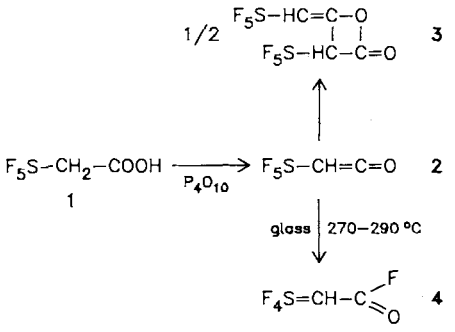
Fabeckstrasse 34-36 and Takustrasse 6, respectively, D-1000 Berlin 33

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

now synthesized two new compounds from **1** by simple reactions, namely the ketene **2** and the compound **4**, the first alkylidenesulfur tetrafluoride with a functional group.



The interesting pentafluoro-λ^6-sulfanylketene **2** is first obtained from **1** by removal of water with P_4O_{10}. **2** is stable for long periods of time at room temperature. On heating, it dimerizes to **3**, and in the presence of active fluoride, such as KF, CsF, it polymerizes to a rubbery solid. Aside from this, **2** undergoes typical double bond addition reactions for ketenes (HCl, H_2O, EtOH, Br_2). Unexpectedly, we observed **2** to thermally isomerize to fluorocarbonylmethylidenesulfur tetrafluoride (tetrafluoro-λ^6-sulfanylideneacetyl fluoride) **4** at reduced pressure in the presence of glass (not quartz).

This 1,3-fluoride migration is surprising, because a C=C double bond is given up in favor of a C=S double bond. Due to the necessity of a weakly basic catalyst (glass powder) we assume that this isomerization proceeds intermolecularly. The driving force behind the isomerization is, of course, the gain in energy on replacement of cumulation by conjugation.

That conjugation is in fact present, follows from the low-temperature crystal structure analysis (−168 °C) of this compound, which is liquid at room temperature (Fig. 1). The molecular skeleton of **4** is planar, except for the

All atoms except F1 are located on the crystallographic mirror plane.

two equatorial fluorine atoms F1 on the sulfur. Since H and COF lie in the same plane as the axial fluorine atoms F2 and F3, the structure type of the alkylidenesulfur tetrafluorides is confirmed.[1-3] The two heteroatomic double bonds are cisoid! The same structure as that found at −168 °C was also found at −40 °C. The C=S double bond in **4** (160.2 pm) is slightly longer than that in H_2C=SF_4 (155.4 pm),[3,4] as would be expected if conjugation is present. On the other hand, the central C–C bond (145.3 pm) is even shorter than the central C–C bond in butadiene (146.5 pm).[5] The CO bond is marginally shorter (117.8 pm), the CF bond somewhat longer (136.6 pm) than in H_3C–COF (118.5 and 136.2 pm).[6] For comparison: butadiene has its energetic ground state in the transoid form, whereas at −161 °C acryloyl fluoride (H_2C=CH–COF) exists 76% in the transoid form and 24% in the cisoid form.[7] Possibly, the cisoid form is favored for steric reasons: In the transoid conformation F3 and F4 would only be 187 pm apart.

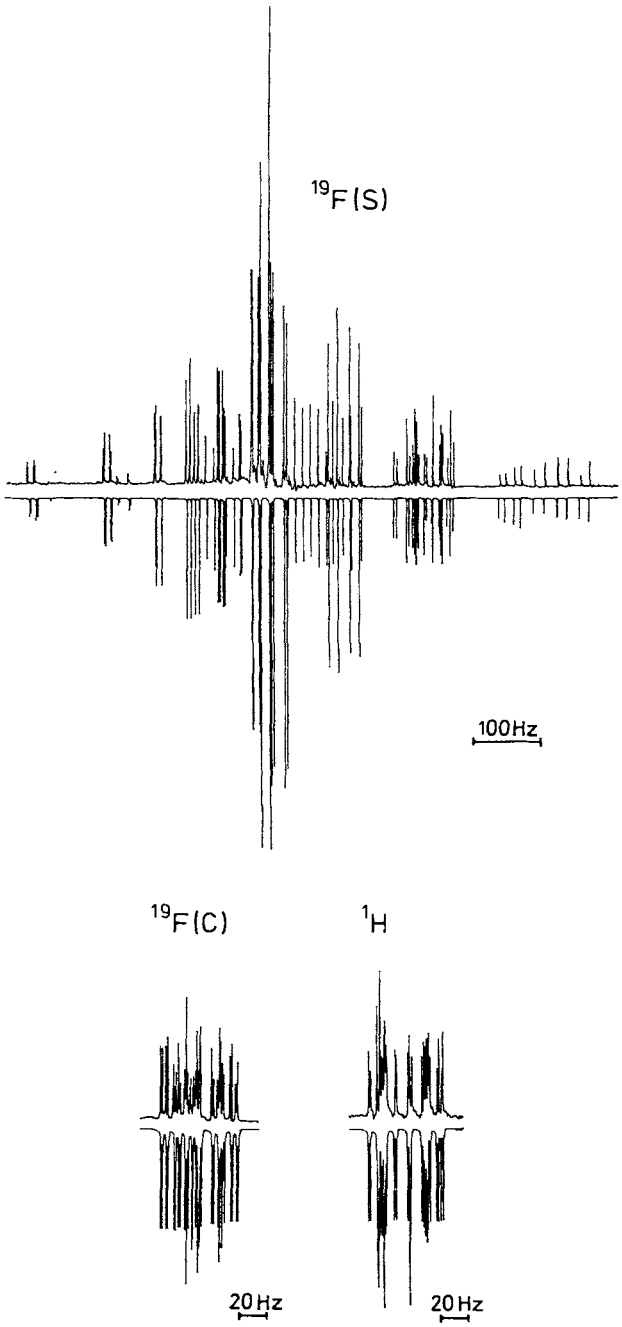


Fig. 2. ^{19}F- and ^{1}H-NMR spectra of F_4S=CH–COF **4** at +25 °C, 84.25 and 90 MHz, respectively, CD_3CN. Top: measured spectrum; bottom: simulation with the following values: A_2BCDX spectrum: $\delta F_A = 60.9$, $\delta F_B = 59.1$, $\delta F_C = 57.0$, $\delta F_D = 42.9$, $\delta H_{(X)} = 4.4$; $J_{AB} = 165.3$, $J_{AC} = 165.9$, $J_{AD} = -4.2$, $J_{BC} = 11.7$, $J_{BD} = -34.2$, $J_{CD} = -14.1$, $J_{AX} = 8.2$, $J_{BX} = -11.1$, $J_{CX} = -38.8$, $J_{DX} = -1.3$ Hz.

A striking feature is that the angle between the equatorial fluorine atoms is markedly larger (101.71°) than in $H_2C{=}SF_4$ (96.6°),[3] while the angle between the axial fluorine atoms is nearly the same in both compounds. It can be concluded from these results that there is a reduction in the π-electron density at the C=S double bond in the equatorial plane.

The complex ^{19}F- and ^1H-nuclear resonance spectra, which are temperature-independent between −130 and +100°C (Fig. 2), reveal the presence of a rigid C=S bond, since torsion about this bonding axis and Berry pseudorotation of the fluorine atoms on the fivefold coordinated sulfur atom would be coupled processes. There are also no indications of a freezable rotation of the COF group.[8] In the case of acryloyl fluoride the rotation of this group is frozen out at −154°C ($\Delta H^{\neq} = 23.8$ kJ/mol).[6]

Experimental

2: A vertically oriented heatable glass tube was loosely packed with Siccapent, P_4O_{10}/sand mixture and P_4O_{10}. The tube was heated with a temperature gradient from 60°C (top) to 160°C (bottom). 15 g of **1** was sublimed at the top of the system and pumped through the tube within two days (10^{-1} mbar) and frozen out at −196°C. Vacuum condensation at −100°C furnished 10.6 g (70%) of pure **2** as a colorless liquid, b.p. 47°C. MS (80 eV): *m/z* 168 ($M^{\oplus}$, 100%). IR (gaseous): $\tilde{\nu}$ = 3135 (w), 2177 (s), 1325 (w), 878 (vs), 720 (m) cm^{-1}. ^{19}F-NMR: AB_4X spectrum $\delta_A = 80.2$, $\delta_B = 88.7$, $J_{AB} = 152.7$ Hz. ^1H-NMR: $\delta = 5.5$ ($J(H\text{-}F_B) = 5.7$ Hz).

4: 2 g of **2** was passed at ca. 10^{-1} bar through a tube packed with glass chips heated to 270–290°C and finally frozen out. Vacuum condensation at −78°C and fractional crystallization at −70°C afforded 1 g (50%) of pure **4**. Colorless liquid, m.p. −29°C. MS (80 eV): *m/z* 168 ($M^{\oplus}$, 56%). IR (gaseous): $\tilde{\nu}$ = 3154 (vw), 1859 (vs), 1818 (m), 1372 (s), 1254 (vw), 1155 (s), 1116 (m), 1089 (m), 932 (s), 860 (vs), 798 (s), 791 (w), 678 (w), 614 (w), 582 (w) cm^{-1}.

[8] The finding that the NMR spectra remain unchanged over the whole temperature range can be interpreted in three ways: 1) The conjugated molecular system is still rigid and flat even at +100°C (unlikely). 2) The COF group still rotates freely even at −140°C (equally unlikely). 3) The difference in energy between the cisoid form and all other conformations is so large that these are present in only smallest amounts in the equilibrium. Hence the NMR signals remain *almost* unchanged on freezing-in the COF rotation.

[9] A 0.3-mm-thick glass capillary was filled to ca. 3 mm high with **4** by vacuum condensation. Low-temperature differential thermal analysis up to −140°C showed no transformation apart from the melting point. The crystals were grown directly on a Siemens four-circle diffractometer according to a method already described in the literature [10]. For the intensity measurement, the sample was cooled to −168°C. **4**, $P2_1/m$, $a = 570.3(3)$, $b = 575.8(3)$, $c = 917.4(4)$ pm, $\beta = 125.35(3)°$, $Z = 2$, $\rho_{calc} = 2.258$ g cm^{-3} at −168°C, 1252 measured reflections up to $2\theta = 72°$, 1207 reflections with $I \geq 2\sigma(I)$, 56 parameters, $R = 0.037$, $R_w = 0.041$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52440, the names of the authors, and the journal citation.

BOOK REVIEWS

EXAFS: Basic Principles and Data Analysis (Volume 9 in the series **Inorganic Chemistry Concepts**). By *B. K. Theo*. Springer, Berlin 1986. xviii, 349 pp., bound, DM 188.00.—ISBN 3-540-15833-2

Despite the growth of interest in fine structure X-ray spectroscopy (EXAFS), which is due to the availability of synchrotron radiation, there has hitherto been no easily accessible introduction to this topic. This book should now fill that gap.

The author's strategy, based on his considerable experience of experimental and theoretical work, is to lead the reader from fundamental principles and simple analysis of data to more advanced theories and complex calculations. This approach is especially welcome, as it offers both beginners and specialists an appropriate choice of entry points into the material presented. The text and diagrams are very clear, and the derivations of the formulae can be followed without too much effort.

Of the book's eight chapters, the first two introduce the properties of X-rays and electrons, their interactions with matter, the elementary theory of EXAFS, and the analysis of data. In the third chapter the EXAFS parameters (phase shift and E_0) are discussed qualitatively and represented graphically. This is especially useful for beginners wishing to develop a feeling for the technique. The next two chapters present the generalized theory and its refinements (including L-edges), lifetime effects, and in particular static and dynamic disorder effects. Chapter 6 covers practical data analysis and most aspects of filtering, curve fitting and phase information. This is followed by a chapter on theoretical amplitudes and phase functions. The final chapter presents a good review of multiple scattering effects and the determination of bond angles. Information on edge characteristics, Victoreen coefficients, fluorescence yields, scattering amplitudes and phases is contained in seven appendixes.

The book has only two weaknesses, which could easily be remedied in a later edition. It is to be regretted that experimental aspects are not mentioned at all, especially since the book "EXAFS Spectroscopy: Techniques and Applications" (edited by *B. K. Theo* and *D. C. Joy*, 1981) is already out of date. Secondly, the book should include some insight into, and a feeling for, factors such as energy resolution, harmonic contamination, and detector limita-

tions, which affect the quality of the experimental results; this would be especially useful for beginners and non-specialists. On p. 23 it is promised that "details of various experimental methods will be discussed elsewhere", but unfortunately "elsewhere" turns out to be outside this book. Another drawback is that the bibliography, which contains more literature references than are cited in the text—in itself a plus point—gives no indication as to the literature sources actually used in the text. A comment preceding each of these citations would have served the purpose.

Finally, there is a criticism which is addressed more to the publisher than to the author. Only purists would object to the use of the shorter American spellings, but in this age of word processing systems with in-built correction of errors the Springer Press might easily have avoided errors like "revolutionalize" or "parameterization", especially when one takes into consideration the price of this book.

Despite these minor details, the book can be highly recommended, not only to those who use EXAFS or would like to use it, but also to all physicists, chemists and biochemists who are looking for a work of reference which will give them a feeling for this technique and its capabilities and limitations.

M. Koch [NB 808 IE]
EMBL Outstation Hamburg (FRG)

Chemie der Hauptgruppenelemente - Stand und Erwartung (Leopoldina Symposium, Halle GDR, October 9-12, 1985). Edited by *G. Fritz, R. Hoppe,* and *K. Issleib*. Wissenschaftliche Verlagsgesellschaft, Stuttgart 1985. vi, 397 pp. (Nova Acta Leopoldina, New Series no. 264), paperback, DM 36.00.—ISBN 0369-5034

The papers collected together in this volume were presented at a symposium whose purpose was to give an overview of the current situation in the chemistry of the main group elements, and to evaluate the developments reported. In the preface the editors explain that for several reasons it was not possible to treat the whole of the chemistry of the main group elements in a uniform way. The choice of contributors resulted in certain topics being emphasized, but also gave benefits in depth of treatment.

The first quarter of the book is devoted to phosphorus chemistry, with special emphasis on low coordination numbers and on the formation and breaking of phosphorus-phosphorus bonds. It is fascinating to note how rapidly the chemistry of phosphorus with coordination numbers one and two, e.g. in pericyclic reactions, is developing: more is now known about Cope rearrangements in phospha-compounds than in thia-compounds. Equally interesting are the analogies between the nucleophilic degradation of phosphorus and sulfur compounds, e.g. the cleavage of cyclophosphanes by phosphinite to give phosphinyl phosphide, which is related to the formation of thiosulfate by the reaction of elemental sulfur with sulfite. In these phosphorus reactions ^{31}P-NMR spectroscopy might contribute further to an understanding of the chain breaking and reforming steps. Some recent results (on alkylidynephosphanes) lead one to expect that connections between the chemistry of main group elements and that of transition metals in high oxidation states will become more important in the future. Such connections are apparent, for example, in the reactions of 2,2-dimethylpropylidynephosphane (a Becker phosphaalkyne) with 2,2-dimethylpropylidynetri(*tert*-butoxy)tungsten (Schrock carbyne complex), or with $TaCl_5$, giving a polycyclic cation $(t\mathrm{BuCP})_6\mathrm{P}^{\oplus}$ of the 1,3,5-triphosphatris(homocyclopropenylium) type.

The next part of the book contains papers on solid state structural chemistry, with the emphasis on oxides and Zintl phases, these areas of inorganic chemistry being neatly brought together under the title "Zintl phases as complex ligands".

The second part of the book contains four papers on sulfur chemistry, and two each on boron chemistry and on metals in low oxidation states. The book concludes with four papers concerned with silicon. A neat link with synthetic organic chemistry is forged here, in the discussion on acyllithium reagents.

A three-day symposium cannot, of course, cover everything in the chemistry of main group elements which is currently of special interest. Nevertheless, important trends such as reactive species, low coordination numbers and novel types of multiple bonds formed by phosphorus, sulfur and boron to carbon or nitrogen, the effects of "inert" electron lone pairs in main group heavy elements, cluster compounds, and molecular aggregates are all treated by means of numerous examples.

This book, which contains the texts of 26 plenary lectures (three of them, by *J. D. Corbett, N. N. Greenwood,* and *D. Seyferth,* being in English), and consists of 400 pages with nearly 800 literature references, gives a very up-to-date survey of the basic research activities of well-known inorganic chemists of the German-speaking world. Its price is very reasonable (almost comparable in that respect to the inexpensive volumes 100, 200, and 300 of the expensive Journal of Organometallic Chemistry), and this readable and very useful volume can therefore be recommended for purchase even by advanced undergraduate and post-graduate students who are familiar with reading German, to increase the depth of their knowledge of inorganic chemistry.

Organometallic Intramolecular-coordination Compounds. By *I. Omae*. Elsevier, Amsterdam 1986. x, 402 pp., bound, HFl 250.00.—ISBN 0-444-42584-5

The author has assembled together in this book a series of review articles on the topic defined in the title, setting out to bring them up to date with the latest situation (as at the editorial deadline of the end of 1984). He expresses the hope that his book will be useful to undergraduate students, graduate students and research workers. It is arranged in eight chapters followed by two appendixes (1. The Periodic Table and Electronegativity, 2. Atomic masses, van der Waals radii, and Covalent radii) and a subject index.

Chapter 1 deals with general considerations. According to the definition of *Bähr* (1955), organometallic intramolecular complexes are compounds in which a metal atom is covalently bonded to an alkyl or aryl group having a donor atom as a substituent, and also forms a coordinative bond to that donor atom, giving a chelate ring. Such intramolecular complexes are here further classified according to the nature of the donor center. Following an account of the history of such compounds, their general properties are discussed, including ring size, structure, and the types of reactions which produce them.

The chapters which follow relate to the various types of donor centers involved in the coordinative bond. Thus, for

example, Chapter 2 deals with many different chelate complexes containing a metal-nitrogen bond as part of the organometallic ring.

The subdivision of the chapters does not follow a uniform pattern. Chapter 2 (85 pp.) is divided into ten sections according to the classification of the nitrogen-containing ligands. This chapter ends, as do all the others, with a section entitled "Concluding remarks" and a comprehensive bibliography.

Chapters 3, 4 and 6 (phosphorus, arsenic and sulfur compounds respectively) are, in contrast, subdivided according to the size of the chelate ring.

Chapter 5 (43 pp.) has yet a further different construction. First there is a coarse division into carbonyl-oxygen ligands and alkoxy-oxygen ligands, which are then further subdivided according to the compound type of the ligand (e.g. dicarboxylic acid esters, monocarboxylic acid esters, ketones, amides), the relevant complexes in each case being listed according to the type of formation reaction.

Chapter 7 (8 pp.) is devoted to halogen compounds as ligands, and lastly Chapter 8 (126 pp.) to π-complexes, subdivided into vinylene, π-allyl, cyclopentadienyl and aryl compounds.

The individual chapters list compounds, structures and reactions in the style which is familiar from the "Annual Surveys" in the Journal of Organometallic Chemistry. Consequently the book has, taken as a whole, the character of a rather heterogeneous collection of review articles.

A preliminary glance through the book produces a quite favorable impression. The direct reproduction method used for the text allows rapid publication, thus ensuring coverage of very recent literature, and hence topicality. On closer study, however, the initial good impression fades rather quickly. The numerous typographical errors are especially noticeable and tiresome, and where these occur in formulae or equations they often alter the meaning, demanding great vigilance on the part of the reader.

A similar degree of carelessness is, regrettably, also found in the text. Thus, for example, on p. 12 the following comment is made concerning a manganese-nitrogen interatomic distance: "The ability for ring formation of the compounds varies with type of metal and coordinating atom. Where the metal is manganese and the coordinating atom is nitrogen, the metal-nitrogen bond length of, e.g., (tetracarbonyl)-*N,N*-dimethylbenzylamine-manganese 1-33 is 2.139 Å (the sum of the covalent radii ($1.18(r(\mathrm{Mn})+0.7(r(\mathrm{N})=1.88$ Å [68])); therefore, the coordination bond is strong because the length is only 0.26 Å longer than the sum of covalent radii." The author could have spared himself this nonsensical interpretation if he had carefully read the original paper, since the Mn-N distance is there discussed correctly.

Also the author has had some difficulties with the nomenclature of these chelate complexes. This may be excusable with complicated compounds, but ought not to arise with substances such as $AgPF_6$ ("silver hexafluorophosphine"). There are, too, many other places in the book where chemical expressions are carelessly used. Hydrogen halides, carbon monoxide and the benzyl group are all described as "leaving groups" in the formation of chelate rings (p. 17), despite the fact that this term, as used in organic chemistry, is properly defined. Again, the author refers to the decarbonylation of acyl- and arylcarbonyl complexes as two types of "eliminations" (p. 23). On p. 25, chelate-forming reactions of the same type are differentiated under the headings "Insertions" and "Condensations". Phosphanes, amines and "acetylacetone" (by which is meant the acetylacetonate ligand) are regarded by the author as donor ligands of similar strengths (p. 29).

The title of the book is, in this reviewer's opinion, now an outdated terminology. *Bähr* in his definition distinguishes between covalent and coordinative bonding. We now know, however, that so-called coordinative bonds are also covalent in nature. The author's use of the term "intramolecular complex" also leads him to define an "intermolecular complex". This does not mean a complex of several nuclei bridged by ligands, but on the other hand a mono-nuclear compound with, for example, two terminal η^1-nitrogen ligands (pp. 15, 57).

Because of the existence of these many inaccuracies (the list of which could easily be extended), one would definitely not wish to see this book used by "undergraduate and graduate students". In view of its specialized nature this is, in any case, not likely. This leaves only the "research workers" as a potential readership for the book. It is not suited for use as a textbook-type monograph, for the reasons which have been given. For someone beginning work in the field of "organometallic intramolecular complexes" the extensive bibliography (about 1500 references) will certainly be welcome as a means of quick access to the original literature. However, contrary to the author's claims there are significant gaps in the coverage, especially on three-membered ring complexes. Consequently, neither can it be regarded as a reference book on organometallic intramolecular complexes with complete coverage of the literature up to the end of 1984. In view of the shortage of resources in many libraries, avoiding the purchase of this book would not cause much hardship.

Inorganic Solid Fluorides. Chemistry and Physics. Edited by *P. Hagenmüller*. Academic Press, New York 1985. xv, 628 pp., bound, $99.00.—ISBN 0-12-313380-X

This book sets out to collect together knowledge about the preparation and the chemical and physical properties of inorganic solid fluorides. The inclusion of contributions from theoreticians underlines the intention that the book should have an interdisciplinary character, and thus be equally useful from the viewpoints of the solid state chemist and the solid state physicist.

The book consists of 21 chapters as follows: *P. Hagenmüller* General Trends; *J. Grannec, L. Lozano* Preparative Methods; *D. Babel, A. Tressaud* Crystal Chemistry of Fluorides; *B. L. Chamberland* The Crystal Chemistry of Transition Metal Oxyfluorides; *C. R. A. Catlow* Defects in Solid Fluorides; *R. Hoppe* High Oxidation States in Fluorine Chemistry; *J. Videau, J. Portier* Fluoride Glasses; *N. Watanabe, H. Touhara, T. Nakajima, N. Bartlett, T. Mallouk, H. Selig* Fluorine Intercalation Compounds of Graphite; *J.-M. Dance, A. Tressaud* Ferro- and Ferrimagnetism in Fluorides; *G. Ferey, M. Leblanc, R. DePape, J. Pannetier* Competing Spin Interaction and Frustration Effects in Fluorides; *A. Tressaud* Electronic Conduction in Fluorides; *J. M. Réau, J. Crannec* Fast Fluorine Ion Conductors; *J. Ravez* Nonlinear Properties of Fluorides; *C. Fauassier* Optical Properties of Fluorides; *T. Oi, K. Miyauchi, J.-M. Dance* Fluorides for Electrochromic Devices; *G. Villeneuve* Nuclear Magnetic Resonance of Fluofides; *P. B. Fabritchnyi* Mössbauer Spectroscopy of Fluorine Compounds; *D. Reinen, J.-M. Dance* Local and Cooperative Effects in the Electron Paramagnetic Resonance Spectra of

Transition Metal Fluorides; *C. A. Baud* Fluorine Chemistry and Biomineralization; *J. Portier* Fluorine Chemistry and Energy; *J. B. Cochet-Muchy, J. Portier* Industrial Use of Inorganic Fluorides.

An introductory chapter by the editor is followed by a detailed description of methods for synthesizing fluorides, dealing with gas phase reactions, reactions in solution, solid reactions, and syntheses under high pressure. There is also a section discussing the most important crystal growing techniques.

A large part of the book (185 pages) is occupied by Chapters 3 and 4, which discuss the structural chemistry of fluorides and oxyfluorides. For each class of molecular formula or type of structure (e.g. binary fluorides MF_2, MF_3, MF_5), numerous compounds are listed in the form of tables and discussed from a structural standpoint, illustrated by many figures to clarify the discussion. The chapter on oxyfluorides discusses important structures such as those of the pyrochlorite, garnet and scheelite types, and deals with the molecular formula classes MOF, MO_2F, AMO_2F and many others.

A short section on defects in fluorides (e.g. in CaF_2) is followed by Chapter 6, in which *R. Hoppe* reports on fluorides containing elements in "high" oxidation states. In addition to describing such exotic representatives of these compounds as Cs_2CuF_6, AuF_6, AuF_5 and XeF_6, this chapter explains to the reader the problems that arise in understanding the occurrence of compounds of this type and their interrelationships. Chapter 7 discusses the most important fluoride glasses and surveys the properties of these materials. Graphite fluorides and intercalation compounds of binary and ternary fluorides in graphite are dealt with in Chapter 8, with the emphasis on preparation and characterization (by ^{13}C-NMR); their applications (e.g. in lithium batteries) are also discussed.

Chapters 9–15 are concerned mainly with physical properties. *J.-M. Dance* and *A. Tressaud* discuss fluorides with ferromagnetic and ferrimagnetic ordering; *G. Ferey* and co-authors are concerned with fluoro-manganates, -niccolates and -ferrates, which show hysteresis behavior. Chapter 11 deals briefly with semiconducting and (one- and two-dimensional) metallic fluorides. Chapter 12, in contrast, treats good fluoride ion electrical conductors in considerable detail; as well as describing such compounds, the ways of optimizing fluoride ion mobility, and the mechanism of conduction are included.

Chapters 13–15 are very brief, and show that fluorides include some materials with piezoelectric, pyroelectric or ferroelectric properties, or with color centers.

The next three chapters are concerned with physical methods used to study fluorides. *Villeneuve*'s contribution includes some interesting results (from NMR spectra) concerning diffusion of fluoride ions and chemical bonding in fluorides. The importance of EPR spectroscopy in investigating the local properties at paramagnetic centers is explained with the help of examples by *D. Reinen* and *J.-M. Dance*. The chapter by *C. A. Baud* is mainly concerned with the mineralizing effect of fluoride ions on biological apatite. The two concluding chapters review the importance of fluorides in energy technology and industrial production.

Verdict: This book has not been written for students; it is suitable for research workers who are concerned with substances in the solid state, in the broadest sense. The contributions come from authors with a very wide range of research interests, with the natural result that the contents of the chapters do not always have a lot in common with each other—sometimes the only link is that fluorine compounds are discussed. Nevertheless, the book is more than a good collection of original papers, since some of the more topical chapters, containing some of their authors' own ideas, extend well beyond what can be found in journal articles. Unfortunately some of these chapters are quite short owing to limited space. It would have been advantageous to omit from the articles on fluoride-specific aspects some trivial matters which are already adequately covered by numerous books (e.g. crystal growing techniques). From the same point of view one might also have considered leaving out the chapters on topics such as industrial applications and energy technology, which merely serve to extend the research worker's general knowledge.

In summary, the book is recommended for all libraries, and also for individual research workers, though many of the latter will be deterred by its high price.

The Generation and Characterization of Molecules by Neutralization-Reionization Mass Spectrometry (NRMS)

New Analytical Methods (33)

By Johan K. Terlouw and Helmut Schwarz*

Dedicated to Professor John H. Beynon FRS

The diluted gas phase within a mass spectrometer is ideally suited for performing collision experiments of fast moving ions with thermalized target atoms. One important reaction which can be brought about with a given cation is its selective reduction, i.e. its neutralization. This allows the synthesis in tailored experiments of a variety of unusual chemical species, which because of intermolecular processes cannot be prepared or studied in solution or in a matrix. Among the molecules which have been generated in this way are hypervalent species (Rydberg radicals) like $H_3^{\odot}$, van der Waals complexes like He_2, mono- or disubstituted acetylene derivatives XC≡CY (X = H, Y = OH, NH_2; X = Y = OH, NH_2), and elusive compounds like carbonic acid (H_2CO_3) or carbamic acid (NH_2CO_2H). Collision experiments can also be used advantageously for the structural analysis of the *neutral molecule N* generated in unimolecular dissociation reactions of the type $m_1^{\oplus} \rightarrow m_2^{\oplus} + N$. The dissociation of ionized aniline for example yields, besides $C_5H_6^{\odot\oplus}$ cations, neutral isocyanic acid, HNC, and not cyanic acid, HCN. The technique of *Neutralization Reionization Mass Spectrometry* (NRMS) is performed in the diluted gas phase, a medium where intermolecular interactions are entirely absent. The method may therefore increasingly be applied to the study of molecular species whose reactivity precludes their characterization in matrices. Molecules in specific excited states and fragments of organometallic compounds with unsaturated valencies are two examples of systems which could fruitfully be studied.

1. Introduction

Quite a few molecular species can only be generated in the gas phase because in solution or even in the solid state intramolecular interactions will make them unstable and lead to isomerization, polymerization or dissociation.[1] Mass spectrometric techniques are commonly employed to study the chemistry of ions in the gas phase and the past ten years have seen an impressive development in methods[2] for the tailor-made generation and characterization of solitary ions with unusual structures and/or intriguing properties. As early as 1966–1968 *Lavertu* et al.[4a] and *Devienne*[4b] demonstrated that the gas phase is also an ideal medium for the mass spectrometric generation of *neutral* molecules by reduction of the corresponding cations. However, the scope of their fundamental collision experiments was not widely recognized and more than ten years passed before the technique of *Neutralization Reionization Mass Spectrometry* (NRMS) was rediscovered by several research groups.[5] This led quickly to the realization that NRMS is a new methodological asset to physical organic chemistry. The discussion of some highlights and typical

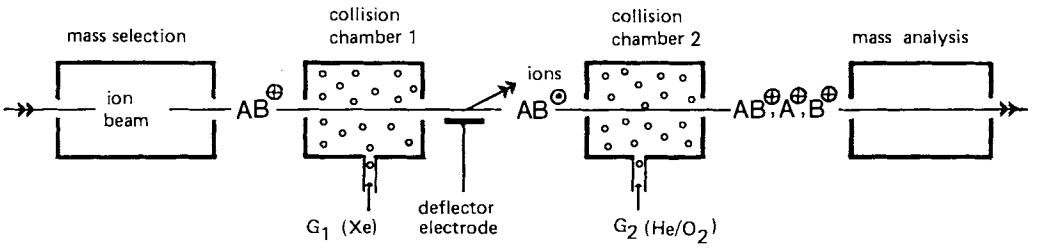
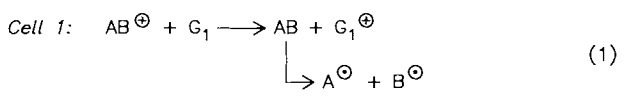
examples of results recently obtained with this technique forms the theme of this article. We shall not go into a detailed discussion of the more fundamental aspects of the method and the questions which arise with the interpretation of the spectra. These are the subject of recent review articles by *Wesdemiotis* and *McLafferty*[6a] and *Holmes*.[6b]

A neutralization-reionization experiment consists of the following steps (see Scheme 1):

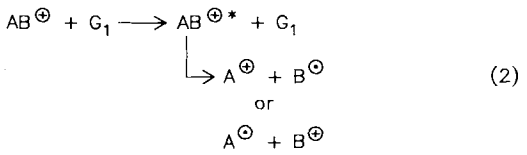


Scheme 1. Schematic diagram of an NRMS experiment.

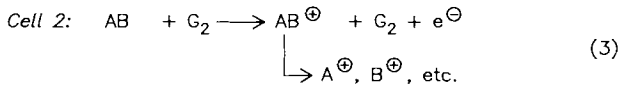
1) A given open- or closed-shell cation $AB^{\oplus}$ is generated in a mass spectrometer using one of the accepted methods and its structure is determined.[7]
2) Upon acceleration (typically to 8 kV translational energy) and mass selection the ions $AB^{\oplus}$ enter a collision gas chamber 1 (Cell 1) where electron-capture from a target gas G_1 results in their reduction to the neutral species AB [Eqn. (1)]. All $AB^{\oplus}$ ions which have not been neutralized and also (the minor fraction of) their ionic dissociation products [Eqn. (2)] are removed from the beam by a charged deflector electrode. The only species which enter the second collision gas chamber (Cell 2) are therefore the neutral molecules AB (having the momentum of $AB^{\oplus}$) and their uncharged dissociation products $A^{\odot}$ and $B^{\odot}$ (having the momentum of $A^{\oplus}$ and $B^{\oplus}$).
3) The fast moving neutrals AB are reionized by collision with a target gas G_2 in the second chamber [Eqn. (3)]. This oxidation step should be performed in such a way that not only molecular ions $AB^{\oplus}$, but also charged fragments are generated. The spectrum of the latter can conveniently be registered and serves to characterize the structure of $AB^{\oplus}$. Upon its generation in cell 1 it takes ca. 10^{-6} s for a given neutral AB, which is not necessarily in its ground state, to reach the reionization cell. The presence of a signal $AB^{\oplus}$ in a NRM spectrum



(1)



(2)



(3)

therefore signifies that the neutral has remained an intact, stable species for $> 10^{-6}$ s.

The cross sections of reactions (1) and (3) and also the lifetimes and electronic states of the reaction products AB and $AB^{\oplus}$ are highly dependent on the nature of the target gases G_1 and G_2 used. For neutralization [Eqn. (1)] *McLafferty* et al.,[5c,d,6a,8a] following the Porter group,[5b] preferentially use metal vapors (Hg, Na), whereas *Holmes*, *Terlouw*, and *Burgers* et al.[5e,f,g,h,6b] have introduced the use of xenon. This inert gas not only allows an efficient electron transfer but it is also more easily manipulated than metal vapors. When metals are used whose ionization energy (*IE*) is much lower than that of AB the charge exchange process of Equation (1) yields highly excited neutral species AB*. Their lifetime *t* can become so much shorter than that of AB that during the transit time required to reach the reionization cell (10^{-7}–10^{-5} s, dependent on the experimental setup) they completely decompose into $A^{\odot}$ and $B^{\odot}$. The NRM spectrum then only shows the signals $A^{\oplus}$ and $B^{\oplus}$ of the reionized dissociation products. However, an efficient neutralization does not require that $IE(G_1) < IE(AB)$; electron transfer upon collision as shown in Equation (1) also readily occurs if $IE(G_1) > IE(AB)$, as is the case with Xe whose *IE* (12.1 eV) is larger than that of most organic molecules. In such neutralization experiments the energy deficit (a few eV) is taken from the translational energy (typically 8000 eV) of the fast moving $AB^{\oplus}$ ions.

For reionization [Eqn. (3)], O_2 seems to have the highest efficiency. This could be related to the formation of $O_2^{\ominus}$ in the electron transfer process. Helium is also frequently used for reionization especially when a high yield of structurally characteristic fragment ions is desired.

Finally, it should be mentioned that instrumentation has been developed in which the intensity of the beam of neutrals AB is sampled as a function of scattering angle. Important structural and spectroscopic data can be derived from the resulting beam profiles including the kinetic energy released by dissociation of AB*. This method—Neutralized Ion Beam Spectroscopy—has been introduced by *Porter* et al.[5b] and it has proved of great value for the characterization of many interesting molecules (hypervalent species, van der Waals clusters, etc.).

2. Hypervalent Molecules (Rydberg Radicals) $XH_2^{\odot}$ (X = H, CH_3, NH_2, OH, F, Cl)

The unorthodox binding properties of hypervalent molecules, i.e. species having more valence electrons than pre-

scribed by the octet rule, have always fascinated chemists and physicists. For the majority of these molecules the electronic ground state is repulsive towards the dissociation products [Eqns. (4) and (5)] but as metastable molecules in highly excited (Rydberg) states they do have a definite lifetime. Leading theoreticians have predicted that the lifetime of these $XH_2^{\odot}$ radicals will increase greatly with substitution of H by D and also with the formation of clusters of $XH_2^{\odot}$ with XH molecules. This will be illustrated by some instructive examples.

$$XH_2^{\odot} \longrightarrow XH + H^{\odot} \quad (4)$$

$$XH_2^{\odot} \longrightarrow X^{\odot} + H_2 \quad (5)$$

The triatomic hydrogen radical $H_3^{\odot}$[9] has been investigated theoretically and experimentally for more than 40 years. The radical is considered to have a repulsive ground state ($H_3^{\odot} \rightarrow H_2 + H^{\odot}$) but, as pointed out by *Herzberg* et al.[9a] it should have a lifetime $t \geq 10^{-8}$ s in some of its excited states. Indeed, the first NRMS experiments on $H_3^{\oplus}$[4b,5a] clearly showed that $H_3^{\odot}$ exists in long-lived states. In subsequent studies the Porter group[10] was able to show that, dependent on the nature of the reducing agent, electron transfer to $H_3^{\oplus}$ according to Equation (6) yields $H_3^{\odot}$ in either its dissociative ground state $2p^2E'$ or the electronically excited dissociative $2s^2A_1'$, and metastable $2p^2A_2''$ states. In particular, $H_3^{\odot}$ molecules populating the nonrotating (N = K = O) level of the $2p^2A_2''$ state were observed to have an appreciable lifetime (87 μs). In going from $H_3^{\oplus}$ to $D_3^{\oplus}$ the lifetime (but not the yield) of neutral species in the metastable $2p^2A_2''$ state greatly increases: e.g. $H_3^{\odot}$ and $D_3^{\odot}$ in the 1,1 rotational level have lifetimes of 3×10^{-11} and 1.7×10^{-7} s, respectively. The $H_3^{\odot}$ radical in its $2p^2A_2''$ state was estimated to have an ionization energy of 4.1 eV.

$$H_3^{\oplus} \xrightarrow{Mg} H_3^{\odot}\ (2\ p^2E') \qquad H_3^{\oplus} \xrightarrow{K} H_3^{\odot}\ (2\ p^2A_2'') \quad (6)$$

Early calculations[11] predict that the $CH_5^{\odot}$ radical is not a minimum on the $CH_5^{\odot}$ hypersurface but that it spontaneously decomposes into $CH_4/H^{\odot}$ or $CH_3^{\odot}/H_2$. This agrees well with the findings of *Porter* et al.,[10c,12] who were not able to detect a signal corresponding to a stable $CH_5^{\odot}$ neutral in their NR spectra; the perdeuterated analogue was estimated to have a lifetime $t < 10^{-8}$ s. Surprisingly, however, *Beynon* et al.[13] in a very recent communication report that the $CH_5^{\odot}$ radical is a stable species with a lifetime $t > 3.9 \times 10^{-7}$ s and an ionization energy of 8.0 ± 0.5 eV. The sources of disagreement between the two experimental results are not yet understood.[*]

The ammonium radical $NH_4^{\odot}$ has also been the subject of numerous experimental and theoretical investigations.[14] Following *Herzberg*'s identification of its visible emission spectrum[15] in 1981, *Porter* et al.[5b,10c,12,16] (see also Refs. [17], [18]) have reported a comprehensive study of this radical from which the following conclusions can be drawn:

1) The $NH_4^{\odot}$ radical (produced by reduction of $NH_4^{\oplus}$ with various metals) has too short a lifetime for its detection with the presently available techniques. This is also the case with the labeled radicals $NH_3D^{\odot}$, $NH_2D_2^{\odot}$ and $NHD_3^{\odot}$ which undergo a very fast loss of $H^{\odot}$. For the perdeuterated radical $ND_4^{\odot}$, however, an undissociated state ($t > 10^{-6}$ s) could be observed, consistent with a tunneling dissociation mechanism for the preferential fast loss of $H^{\odot}$ from the isotopically mixed radicals.

   $$NH_{4-x}D_x^{\odot} \longrightarrow NH_{3-x}D_x + H^{\odot} \quad (x = 1, 2, 3)$$

   The ionization energy of $ND_4^{\odot}$ derived from these experiments is 4.73 eV, close to that predicted by an X_{α} calculation for $NH_4^{\odot}$ (4.85 eV).[17] Should it be possible to stabilize $NH_4^{\odot}$ in a condensed state a compound would become available with interesting metallic properties.[18]
2) For clusters of the type $NH_4(NH_3)_n^{\odot}$ (n = 1–3) and their deuterated analogues stable radicals with $t > 10^{-6}$ s could be obtained by neutralization of the corresponding ionic clusters with potassium. The *IE* of the $NH_4(NH_3)_n^{\odot}$ species decreases drastically with increasing n (n = 0, *IE* = 4.73 eV; n = 1, *IE* = 4.0 eV; n = 3, *IE* = 2.5 eV!).
3) The behavior of the $CH_3NH_3(NH_3)_n^{\odot}$ (n = 0, 1) system closely resembles that of the parent system $NH_4(NH_3)_n^{\odot}$. Substituting all hydrogens in $CH_3NH_3^{\odot}$ by deuterium ($\rightarrow CD_3ND_3^{\odot}$) and/or clustering with an NH_3 molecule significantly increases the lifetime of the neutralized species. The observed ionization energies are 4.3 eV for $CH_3NH_3^{\odot}$ and 3.9 eV for $CH_3NH_3(NH_3)^{\odot}$.

Another fascinating question in this area is the possible existence of the $H_3O^{\odot}$ (oxonium) radical. It has engaged the attention of many a theoretician and experimentalist over the past 25 years[12,19] and the most important results can be summarized as follows: *Gellene* and *Porter*[19] have elegantly demonstrated that neutralization of $D_3O^{\oplus}$ with K vapor produces $D_3O^{\odot}$ in a distribution of dissociative and metastable states with $t > 6 \times 10^{-7}$ s. Upon substitution of D by H the lifetime of the metastable state decreases rapidly (cf. the $NH_4^{\odot}$ system) and neither $H_3O^{\odot}$ nor $HD_2O^{\odot}$ could be observed, i.e. $t < 7 \times 10^{-8}$ s. The stabilizing effect of an H_2O molecule on the $H_3O^{\odot}$ radical is reflected in the increased lifetime of the oxonium monohydrate $H_3O(H_2O)^{\odot}$ which was observed to exist in metastable states for several H/D isotopic variants: $t\ [H_3O(H_2O)^{\odot}] = 2 \times 10^{-7}$ s and $t\ [D_3O(D_2O)^{\odot}] > 7 \times 10^{-7}$ s. The ionization energy is also lowered: *IE* $[D_3O(D_2O)^{\odot}] \geq 3.4$ eV, whereas *IE* $[D_3O^{\odot}] = 4.3 \pm 0.1$ eV.

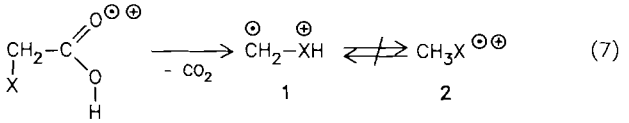
Isotope effects were also employed for increasing the lifetime of the dihydrogen fluoride radical. $H_2F^{\odot}$ has too brief a lifetime for observation, whereas $D_2F^{\odot}$, produced by the reduction of $D_2F^{\oplus}$ with Na, has a lifetime of over 4×10^{-7} s.[20] Quite unexpected isotope effects were observed by *McLafferty* et al.[21] in the NR mass spectra of chloronium ions. Their findings that the life spans of the

[*] Other recent experiments strongly indicate that both $CH_5^{\odot}$ and $CD_5^{\odot}$ are unstable, separating with a large kinetic energy release into $CH_4/H^{\odot}$ and $CD_4/D^{\odot}$ (*J. L. Holmes*, private communication).

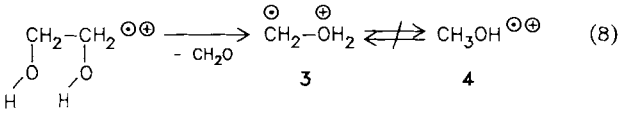
deuterated species follow the order $HDCl^{\odot} \gg H_2Cl^{\odot} > D_2Cl^{\odot}$ and that the spectra strongly depend on the chemical ionization conditions under which the primary ions, $HDCl^{\oplus}$, $H_2Cl^{\oplus}$ and $D_2Cl^{\oplus}$, respectively, are generated led the authors to the suggestion of an exothermic isomerization $H-Cl-H^{\oplus} \rightarrow H-H-Cl^{\oplus}$ prior to neutralization. The neutralization would then lead to a stable chloronium radical $H-H-Cl^{\odot}$, whereas the neutralization of $HClH^{\oplus}$ does not lead to a stable $HClH^{\odot}$ radical. Although this model explains the experimental results, it is at variance with state-of-the-art ab initio calculations[22] which exclude an *exothermic* isomerization $H-Cl-H^{\oplus} \rightarrow H-H-Cl^{\oplus}$. The global minimum on the $H_2Cl^{\oplus}$ hypersurface corresponds to an $H-Cl-H^{\oplus}$ structure with $H-H-Cl^{\oplus}$ at least 80 kcal/mol higher in energy. The radical hypersurface so far shows only one minimum corresponding to $H-Cl-H^{\odot}$ (C_{2v}). Possibly the neutralization populates Rydberg-states, which were not taken into account either in the interpretation of experiments[21] or in the ab initio calculations.[22]

3. Ylides CH_2XH (X = NH_2, OH, Cl, F) and Betaines CH_2CH_2XH (X = NH_2, OH)

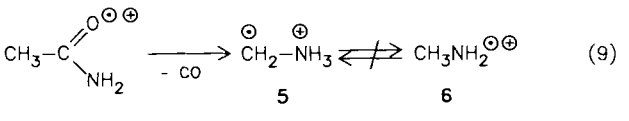
The accessibility of ylide cations in the gas phase through dissociative ionization [Eqns. (7)-(9)] or through ion-molecule reactions [Eqn. (10)] has been demonstrated several times over the past few years.[23] Frequently, radical cations **1**, **3**, **5** and many others turn out to be more stable than their tautomers of more conventional structure (**2**, **4**, **6**), from which, moreover, they are separated by significant energy barriers.



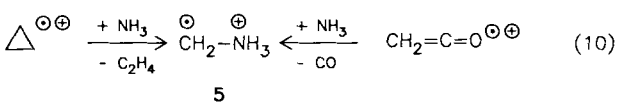
X = F, Cl (7)



(8)



(9)



(10)

It goes without saying that NRMS opens an interesting route from the easily accessible radical cations to the *neutral* ylides.[24] And last but not least, this is attractive because many ylides are fundamentally inapproachable in other ways. The NRMS experiment, however, also has its pitfalls. In the first place, the neutralization probably takes place in the form of a near-vertical process; if the geometries of the ion and the neutral differ the latter is therefore not generated in its ground state. Further high level ab initio calculations[25] point to low stabilities of *neutral* ylides such as CH_2OH_2, CH_2ClH or hydrogen bonded isomers like H_2CHF against decomposition into CH_2 and HX (12, 4 and 7 kcal/mol, respectively). Also the same evidence points to low barriers against isomerization $CH_2XH \rightarrow CH_3X$ (X = OH, Cl, F; barriers < 1, 11, 1.5 kcal/mol, respectively). The chances of producing ylides of this kind through gas-phase neutralization of the corresponding ylide ions therefore appear slim,[26] and indeed the Holmes-Terlouw group[27] did not succeed in producing stable neutrals of the CH_2XH (X = F, Cl, OH) type. The signal for CH_2XH found by *Wesdemiotis* et al.[5c,28] in the NR mass spectra of $CH_2XH^{\oplus}$ was shown by *Holmes, Terlouw* et al.[27] to originate, at least in part, from isotope interferences and the presence of conventional CH_3X species.

In the neutralization reionization mass spectra of the distonic[*] ions $\overset{\odot}{C}H_2-CH_2-\overset{\oplus}{O}H_2$ and $\overset{\odot}{C}H_2-CH_2-\overset{\oplus}{N}H_3$ signals are observed at *m/z* 46 ($C_2H_6O^{\odot\oplus}$) and *m/z* 45 ($C_2H_7N^{\odot\oplus}$), respectively.[30] These signals cannot be assigned to $[CH_3CH_2OH]^{\odot\oplus}$ and $[CH_3CH_2NH_2]^{\odot\oplus}$, respectively, since fragment ions characteristic of α-cleavage in ionized ethanol and ethylamine are not present in the NRM spectra. The authors propose that the species produced upon neutralization with Hg are either betaines ($CH_2CH_2OH_2$/$CH_2CH_2NH_3$) or complexes of ethene with H_2O and NH_3, respectively. Irrespective of the actual structures these unusual neutral species must have a lifetime of over 10^{-6} s.

4. Rare Gas Dimers X_2 (X = He, Ne, Ar)

In a detailed study, *Gellene* and *Porter*[31] have shown that rare gas dimer ions $X_2^{\odot\oplus}$ (X = He, Ne, Ar, generated by ion/molecule reactions in a high pressure ion source) react with potassium to yield neutral dimers X_2^* in their first excited singlet ($^1\Sigma_u^+$) and triplet state ($^3\Sigma_u^+$). From the analysis of the beam profiles and additional spectroscopic evidence it follows that both states decay radiatively into the essentially repulsive ground state. The triplet state, however, is sufficiently stable to enable its radiative lifetime to be estimated, viz. He_2^* $t > 3.2 \times 10^{-6}$ s; Ne_2^* $t > 7.2 \times 10^{-6}$ s; Ar_2^* $t > 2.1 \times 10^{-6}$ s. Ion beam attenuation cross sections are particularly large for $He_2^{\oplus}$ and $Ne_2^{\oplus}$ (250 and 180 Å^2, respectively), indicating that electron transfer from K [Eqn. (11)] is very efficient. The relatively intense molecular beams of He_2^* and Ne_2^* thus produced have ca. 18.0 and 16.5 eV of electronic energy, respectively. They may find applications in the investigation of energy transfer reactions.

$$X_2^{\odot\oplus} + K(g) \longrightarrow X_2^* + K^{\oplus} \quad (11)$$

X = He, Ne, Ar

[*] Distonic radical ions are defined [29] as species in which the charge and spin are "located" on different atoms.

5. Neutral Molecules which Cannot Exist in Solution

A prime reason for the attention which the NRMS technique has recently received is its successful application in the gas phase synthesis of small molecules which in solution have an extremely short lifetime only because intermolecular reactions promote their fast conversion into more stable isomers or derivatives. As prototypal examples thereof, long sought after acetylene derivatives, further carbonic acid, carbamic acid, and some acetaldehyde isomers are presented.

Decarbonylation of the radical cations of propiolic acid **7**,[32] its amide **10**,[33] squaric acid **13**[5h] and its derivatives **16** and **19**[5h] yield the substituted acetylene radical cations **8**, **11**, **14**, **17**, and **20**, respectively, whose structures could be unambiguously characterized. An example is presented in Figure 1 where it is seen that the partial collisional activation mass spectrum of ion **11** contains a structure-characteristic signal at *m/z* 16 ($NH_2^{\oplus}$) which is absent in the spectra of all other $C_2H_3N^{\oplus}$ isomeric ions. Upon neutralization, all of the above ions yield stable molecules. Their

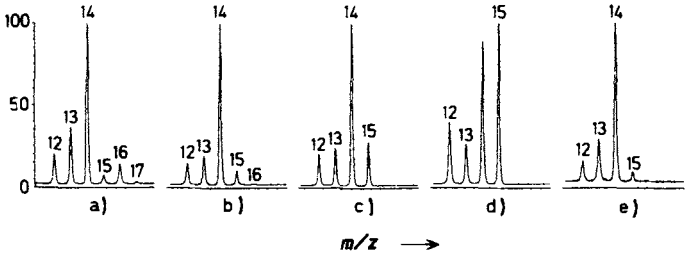


Fig. 1. Collision activation spectra (sections with *m/z* 12 to *m/z* 17) of $C_2H_3N^{\odot\oplus}$ isomers. a) $HC{\equiv}CNH_2^{\odot\oplus}$ **11** [generated according to Eqn. (13)], b) $H_2C{=}C{=}NH^{\odot\oplus}$ (from *n*-$C_3H_7CN^{\odot\oplus}$), c) $H_3CCN^{\odot\oplus}$, d) $H_3CNC^{\odot\oplus}$, e) $H_2C{=}N{=}CH$ (from *n*-$C_4H_9NC^{\odot\oplus}$).

reionization spectra leave no doubt (compare, e.g., the NR spectra of $CH_2{=}C{=}O^{\odot\oplus}$ and $HC{\equiv}COH^{\odot\oplus}$ shown in Fig. 2) that we are dealing with the long sought after acetylene

$$H{-}C{\equiv}C{-}\overset{\overset{O}{\|}}{C}{-}OH^{\odot\oplus} \xrightarrow[-\,CO]{} H{-}C{\equiv}C{-}OH^{\odot\oplus} \longrightarrow H{-}C{\equiv}C{-}OH \quad (12)$$
7 8 9

$$H{-}C{\equiv}C{-}\overset{\overset{O}{\|}}{C}{-}NH_2^{\odot\oplus} \xrightarrow[-\,CO]{} H{-}C{\equiv}C{-}NH_2^{\odot\oplus} \longrightarrow H{-}C{\equiv}C{-}NH_2 \quad (13)$$
10 11 12

$$\xrightarrow[-\,2\,CO]{} H_2N{-}C{\equiv}C{-}NH_2^{\odot\oplus} \longrightarrow H_2N{-}C{\equiv}C{-}NH_2 \quad (16)$$
19 20 21

derivatives $XC{\equiv}CY$ (X = H, OH, NH_2; Y = OH, NH_2). Some of these are of general interest like ethynylamine, **12**, which may play a role in interstellar chemistry.[34] Considering the theoretical predictions that the barriers for *unimolecular* isomerization and decomposition are quite high, it is not really surprising that these acetylene derivatives can so easily be generated in the gas phase. Finally, it should be mentioned that apart from their reduction to the neutral molecules **9** and **12**, ions **8** and **11** can also be oxidized to their respective dications[32,33] under "charge stripping" conditions.[36]

Statements of the kind that "carbonic acid, $(HO)_2CO$, and carbamic acid, NH_2CO_2H, cannot exist in the free state"[37] are warranted in so far as it has not been possible to prepare these molecules as stable species in solution.

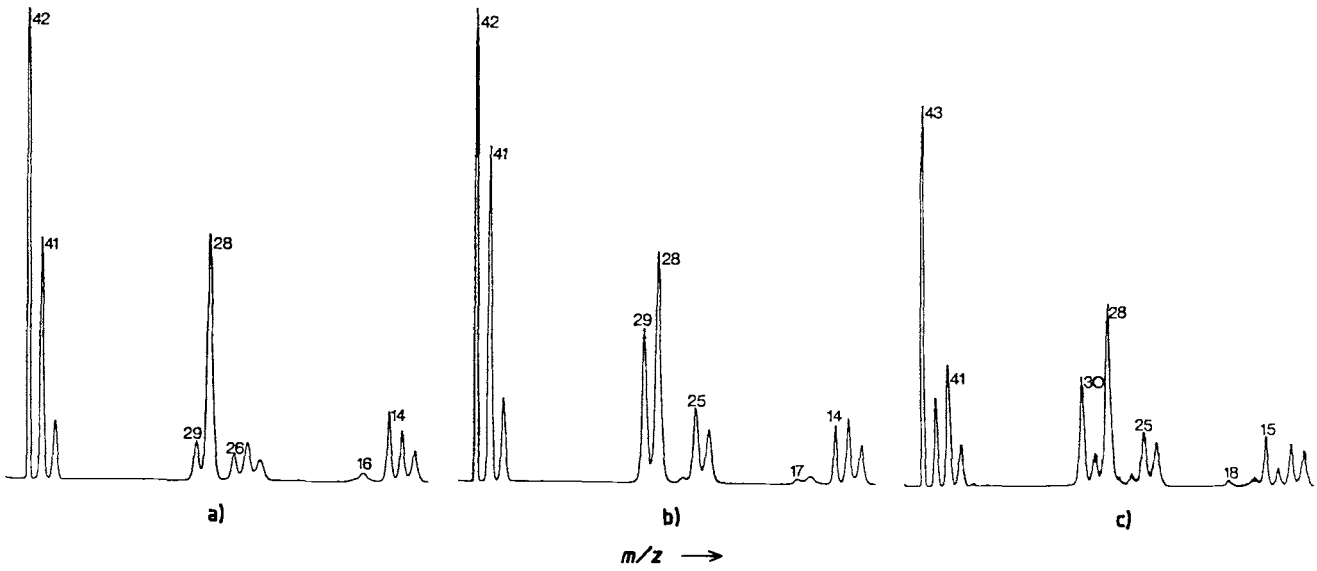

Fig. 2. NRMS of a) $H_2C{=}C{=}O^{\odot\oplus}$, b) $HC{\equiv}COH^{\odot\oplus}$ **8** [generated according to Eqn. (12)], c) $HC{\equiv}COD^{\odot\oplus}$ (generated by decarbonylation of $HC{\equiv}CCO_2D^{\odot\oplus}$): Xe was used for the neutralization and He for the reionization.

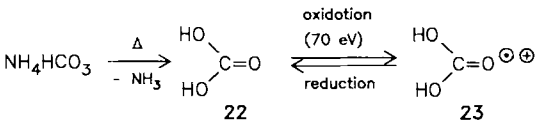
This is not due to an inherent instability of these molecules but rather to the fact that, in solution, acid/base or solvent catalysis promotes a rapid decomposition and, in the case of H_2CO_3, also deprotonation into the bicarbonate ion [Eqn. (17), (18)].

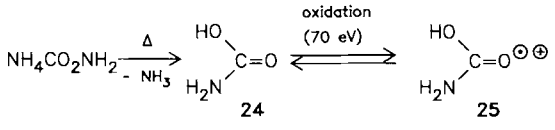
$$CO_{2aq} + H_2O \rightleftharpoons [H_2CO_{3aq}] \rightleftharpoons HCO^{\ominus}_{3aq} + H^{\oplus}_{aq} \quad (17)$$

$$CO_{2aq} + NH_{3aq} \rightleftharpoons [H_2NCO_2H_{aq}] \quad (18)$$

In the gas phase, however, quite a different situation obtains: the unimolecular dissociation of H_2CO_3 and H_2NCO_2H into $CO_2 + H_2O$ and $CO_2 + NH_3$ respectively, is predicted by *ab initio* MO studies[38] to be hampered by significant energy barriers (>40 kcal/mol), and thus the free acids should both exist as stable molecules. Indeed, recent reports[39] describe the successful preparation [Eqns. (19), (20)] and chararacterization of both acids and their radical cations in the diluted gas phase: ionization by 70 eV electrons in a mass spectrometer of the gaseous decomposition products from gently heated (T = ca. 120°C) samples of finely powdered ammonium hydrogencarbonate and ammonium carbamate yield signals at *m/z* 62.00002 and 61.01604 Dalton, respectively. These exact mass values are only compatible with the elemental compositions CH_2O_3 and CH_3NO_2, respectively. The experiments further show[39] that the *m/z 62 and m/z 61 ions must originate from the direct ionization of the corresponding neutral molecules*. That the ions have the structure of ionized carbonic acid and carbamic acid (**23** and **25**), respectively, follows from their dissociation characteristics. These further show that, analogously to the neutral counterparts, decomposition or isomerization in the ions is thwarted by sizeable energy barriers. NRMS experiments show that the neutral acids **22** and **24** can readily be regenerated by reduction of the ions **23** and **25** in the gas phase [Eqn. (19), (20)]. The NR mass spectra are only compatible with the structures **22**–**25**.



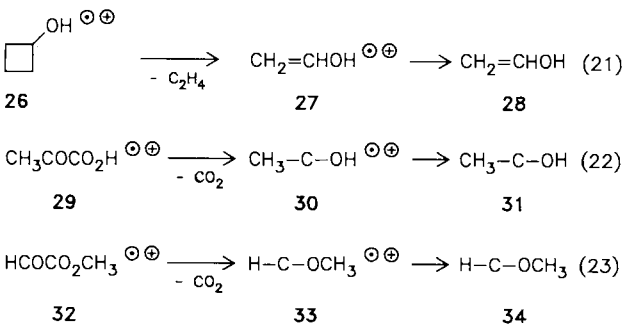
(19)



(20)

Vinyl alcohol **28** and hydroxymethylcarbene **31**, two isomers of acetaldehyde, are not accessible as pure species in solution.[40,41d] In the gas phase, however, they can readily be generated by the reduction of their radical cations **27** and **30**.[6] Ions **27** and **30** and also other $C_2H_4O^{\odot\oplus}$ isomers, like the methoxycarbene cation **33**,[41d] are separated by high isomerization barriers and they are accessible from various precursor molecules.[41] As a result a direct route is available for the generation of several neutral isomers on the C_2H_4O hypersurface.

Similarly, the reduction of "closed-shell" ions $M^{\oplus}$ [Eqn. (24)] in the gas phase provides a convenient route



(21)

(22)

(23)

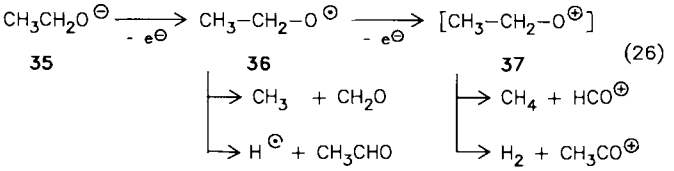
to the formation of free radicals $M^{\odot}$. The following list of radicals generated and characterized by NRMS may illustrate the scope of the method: $CH_3^{\odot}$,[28a,42] $C_2H_5^{\odot}$,[42] $C_3H_7^{\odot}$,[30] $C_4H_9^{\odot}$,[8a] $C_7H_9^{\odot}$ (toluene + $H^{\odot}$),[5c] $CH_2NH_2^{\odot}$,[8b] $CH_2OH^{\odot}$,[28,42] $CH_2F^{\odot}$,[27] $CH_2Cl^{\odot}$,[8b,27] $CH(CH_3)OH^{\odot}$,[6] $CH_2CH_2OH^{\odot}$,[6] $CH(CH_3)NH_2^{\odot}$,[30] $CH_2CH_2NH_2^{\odot}$,[30] $CH_2(CH_2)_3OH^{\odot}$,[30] $HCO^{\odot}$,[5f,43] $CH_3CO^{\odot}$,[5c,15,28] and $CO_2H^{\odot}$.[5f,28]

$$M^{\oplus} \underset{\text{oxidation}}{\overset{\text{reduction}}{\rightleftharpoons}} M^{\odot} \quad (24)$$

Another possibility for the generation of radicals in the gas phase is the *oxidation* of anions via the spontaneous or collision-induced loss of an electron [Eqn. (25)].[5g,44]

$$AB^{\ominus} (+ G_1) \longrightarrow AB^{\odot} + e^{\ominus} (+ G_1) \quad (25)$$

Starting from the easily accessible alkoxide ion $RO^{\ominus}$ (R = C_1 to C_3-alkyl) it indeed proved to be possible in collision processes to first generate alkoxy radicals by removal of an electron and subsequently to ionize these.



(26)

A typical example is shown in Equation 26 where it is seen that β-cleavage is the preferred dissociation pathway of the intermediate alkoxy radicals **36**. In contrast, the oxenium ions **37** mainly decompose via a 1,1 elimination of H_2 and CH_4. These reactions occur so rapidly that intact oxenium ions are not detected.

6. The Characterization of Neutral Molecules *N* in the Dissociation of Ions $m_1^{\oplus} \rightarrow m_2^{\oplus} + N$

Until recently the question of the structure of the neutral species *N* generated in the unimolecular dissociation of ions $m_1^{\oplus}$ [Eqn. (27)] has received relatively little attention. One reason is that the neutral eliminated often is a small molecule whose structure is not in doubt because only a single isomer exists (e.g. H_2O, $CH_3^{\odot}$, CH_4, CO_2 etc.). Secondly, it is often tacitly assumed (although this is by no means prescribed by theory) that metastable ions dissociate into the thermodynamically most stable products, thus making the question redundant whether energetically less favored neutral species would be (co)-generated. The most important reason perhaps is that, whereas a whole armoury of techniques is available to investigate the struc-

ture of the ions $m_1^{\oplus}$ and $m_2^{\oplus}$,[2,7,36] until recently the structure of N could, given a few exceptions,[45] only be determined indirectly. A recently developed variant of the NRMS technique, CIDI, the collision induced dissociative ionization of neutral molecules,[46] removes this obstacle and it is now possible to obtain a quick answer to mechanistic problems where the structure of the neutral is uncertain.

A CIDI experiment is performed with the instrumental setup for NRMS (Scheme 1) but without using collision gas chamber 1. A small fraction of the beam of fast moving mass selected ions $m_1^{\oplus}$ under investigation will dissociate unimolecularly [Eqn. (27)] during the flight to collision

$$m_1^{\oplus} \longrightarrow m_2^{\oplus} + N \qquad (27)$$

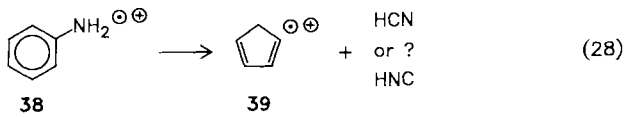
chamber 2. Upon arrival at the charged deflector electrode all ions, i.e. $m_1^{\oplus}$ and the *ionic* dissociation products $m_2^{\oplus}$, are deflected away so that the only species entering the collision chamber are the fast moving neutrals, N. These have a translational energy $E_N = (N/m_1) \times E_{m1}$ (in which E_{m1} is the translational energy, typically 8 kV, of the primary ions $m_1^{\oplus}$).

Within the cell the neutrals are ionized by collision with thermalized inert gas molecules and since we are dealing with an isolated system the energy required for ionization ($IE_{(N)}$) is taken from the translational energy of N, leading to $E_{N^{\oplus}} = E_N - IE_{(N)}$. Thus it is in principle possible to derive $IE_{(N)}$ from an accurate measurement of $E_{N^{\oplus}}$ using the procedures commonly employed for measuring the IE of cations in "charge stripping" experiments ($m^{\oplus} \rightarrow m^{2\oplus} + e^{\ominus}$).[36]

Upon collision part of the ionized neutrals dissociate and the spectrum of ionic dissociation products, which can conveniently be registered with the mass spectrometer, is used to characterize the structure of N. The following three examples from the recent literature may serve to illustrate the potential of the method.

6.1. HCN versus HNC

The major reaction observed for metastable aniline radical cations **38**, $C_6H_5NH_2^{\odot\oplus} \rightarrow C_5H_6^{\odot\oplus} + CHN$, is shown in Equation (28). Earlier work[47] clearly showed that the product ion generated is the cyclopentadiene radical cation **39**, whereas the neutral was presumed to be HCN rather than HNC on the basis of its greater thermodynamic stability.[48]



38 **39** (28)

A thorough analysis of the thermochemistry and the appearance energies obtained for reaction (28) allowed *Lifshitz* et al.[49] to conclude that dissociation of **38** yields HNC and not the thermodynamically more stable (by ca. 15 kcal/mol[50]) isomer HCN. This has been proposed earlier[51] on the basis of "chemical plausibility".

The result of the CIDI experiments[46] shown in Figure 3 provides unambiguous experimental evidence that the above proposal is correct: HCN (generated from e.g. ionized pyridine) and HNC (generated from **38**) yield strongly different CIDI spectra with signals in the m/z 12–16 region characteristic of the structure of the two isomers. Thus, it is readily shown that HNC is generated upon dissociation of **38**.

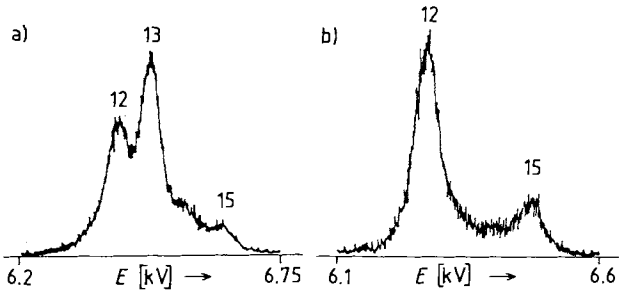


Fig. 3. CIDI spectra of a) HCN (generated from pyridine$^{\odot\ominus}$) and b) HNC (generated from aniline$^{\odot\oplus}$ **38**).

The method was successfully applied to similar cases and it could be established that the radical cations of pyrazole,[52] imidazole,[52] benzonitrile,[53] and benzyl cyanide[53] all eliminate HCN exclusively; in the case of benzonitrile and benzyl cyanide this confirms earlier proposals.[54,55]

6.2. $CH_3O^{\odot}$ versus $CH_2OH^{\odot}$

There is no doubt that the $C_2H_3O^{\oplus}$ ion generated in the unimolecular dissociation of ionized methyl acetate, $CH_3COOCH_3^{\odot\oplus}$, is the acetyl cation, $CH_3CO^{\oplus}$.[56] However, the question of the structure of the neutral generated in this reaction, which could be either the methoxy- ($CH_3O^{\odot}$) or the hydroxymethyl ($CH_2OH^{\odot}$) radical, was not settled until recently.

Results of CIDI experiments reported from several laboratories[42,44,53,57-61] were interpreted differently and for some time a confusing picture existed. However, there now seems to be a consensus that $CH_3O^{\odot}$ and $CH_2OH^{\odot}$ radicals are both generated in the above reaction, in a ratio of ca. 4:1. Whereas $CH_3O^{\odot}$ can readily be generated from $CH_3CO_2CH_3^{\odot\oplus}$ by a simple α-cleavage, a more complex mechanism must be associated with the formation of $CH_2OH^{\odot}$, which is the more stable radical by ca. 10 kcal/mol. The $CH_2OH^{\odot}$ radicals do not originate from isomerization of initially formed $CH_3O^{\odot}$ radicals[42] but are formed from methylacetate molecular ions which have undergone an extensive skeletal rearrangement. As shown in a recent ab initio molecular orbital study[62] the minimal energy requirement path for the dissociation of $CH_3COOCH_3^{\odot\oplus}$ **40** involves isomerization into the distonic ion **41** to yield the hydrogen bridged complex **42**. This ion (probably in its first excited state $^2A''$) then serves as the precursor to the formation of $CH_3CO^{\oplus}$ and $CH_2OH^{\odot}$ by direct bond cleavage (Fig. 4). This multistep pathway

$$CH_3CO_2CH_3^{\odot\oplus} \longrightarrow CH_3CO^{\oplus}/CH_2OH^{\odot}$$

is calculated to be energetically favored over the direct dissociation of **40** into $CH_3CO^{\oplus}/CH_3O^{\odot}$ by ca. 4–5 kcal/mol. The latter is entropically favored and may therefore predominate in the decomposition of methyl acetate ions of higher internal energies.

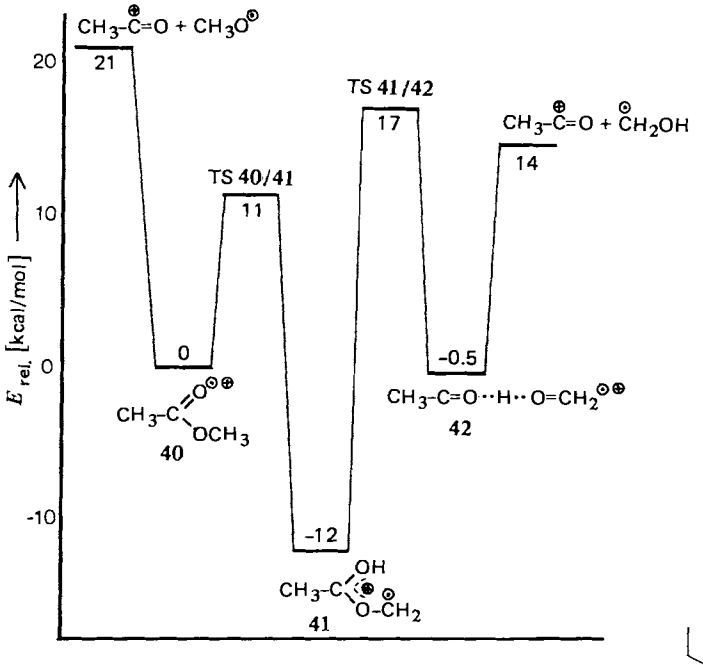

Fig. 4. Minimal energy pathway for the isomerization and decomposition of $CH_3CO_2CH_3^{\odot\oplus}$ **40** (MP2/6-31G(d)//3-21G+ZPE). Relative energies given in kcal/mol. TS = transition structure.

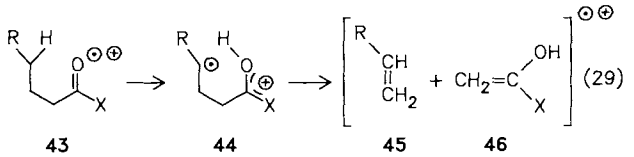
6.3. CH_3COOH versus $CH_2=C(OH)_2$

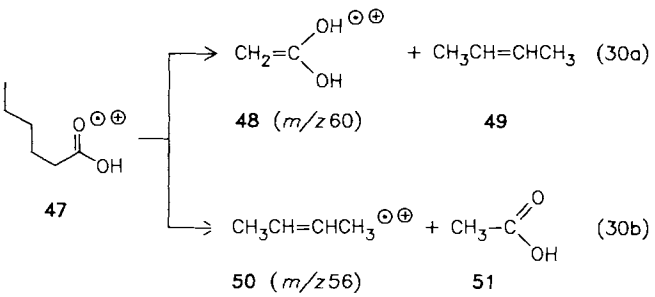
Because of its widespread occurrence in organic mass spectrometry the McLafferty rearrangement [Eqn. (29)] has been studied extensively.[63] Following the transfer of a γ-hydrogen to the positively charged acceptor group (e.g. a carbonyl group; **43** → **44**) dissociation into a radical cation



(**46**) and a neutral molecule (**45**) occurs by cleavage of the C_α–C_β bond. Energetic factors (Stevenson-Audier rule) determine which of the two fragments carries the charge.

In this context an interesting case has recently been uncovered[64] which could lead to a reinterpretation of the mechanism of the McLafferty rearrangement.

The mass spectrum of *n*-hexanoic acid **47** displays peaks at *m/z* 60 ($C_2H_4O_2^{\odot\oplus}$) and *m/z* 56 ($C_4H_8^{\odot\oplus}$) which formally are the results of a McLafferty rearrangement. A field ionization kinetics study[65] had already shown that the product ion distribution *m/z* 60 versus *m/z* 56 was strongly dependent on the lifetime *t* (and thus the internal energy) of the precursor ions **47**: ions of low internal energy mainly dissociate into *m/z* 56 ions, i.e. via a McLafferty rearrangement accompanied with transfer of the charge, **47** → $C_4H_8^{\odot\oplus}$ + $C_2H_4O_2$ [Eqn. (30b)]. Apparently the complementary process in which the charge is retained, **47** → $C_2H_4O_2^{\odot\oplus}$ + C_4H_8 [Eqn. (30a)], is thermodynamically less favored. The $C_2H_4O_2^{\odot\oplus}$ product ion generated in this reaction was shown in a CA study to be **48**, the enol of acetic acid radical cation, and the neutral probably has the 2-butene structure, **49**.[66] Thermochemical considerations[64] make it plausible that the reaction **47** → $C_4H_8^{\odot\oplus}$ + $C_2H_4O_2$ can only effectively compete with the process **47** → **48** + **49** [Eqn. (30a)] if its dissociation products are ionized 2-butene, **50**, and neutral acetic acid, **51** [Eqn. (30b)]. CIDI experiments established that the neutral generated from **47** is indeed acetic acid, **51**, and not its enol. This implies that the simple mechanism based on Equation (29) can be ruled out. Combining the results of the CIDI experiments with those of labeling studies[65] one is led to the conclusion[64] that the McLafferty rearrangement is a reaction in which the final dissociation step is preceded by an *intramolecularly catalyzed isomerization* of the dissociation products via long-lived *ion-dipole* and *hydrogen-bridged intermediate ions*. Thus the distonic ion **44** does *not* serve as the direct precursor for the formation of **45** and **46**.



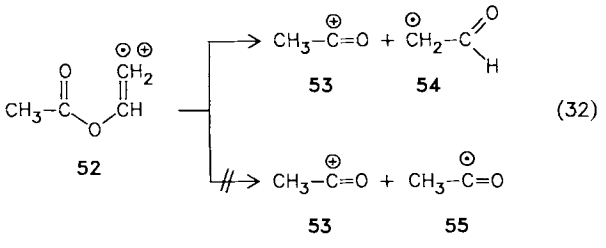
6.4. The $C_2H_3O^{\odot}$ Radicals $CH_2CHO^{\odot}$ and $CH_3CO^{\odot}$[67]

Lossing and *Holmes*[68] have shown that the measurement of the appearance energy (*AE*) of the ionic fragment $A^{\oplus}$ in the dissociative ionization of AB [Eqn. (31a)] can lead to an accurate heat of formation (ΔH_f^0) for the neutral $B^{\odot}$ via Equation (31b) provided $\Delta H^0_{f,A^{\oplus}}$ and $\Delta H^0_{f,AB}$ are well established.

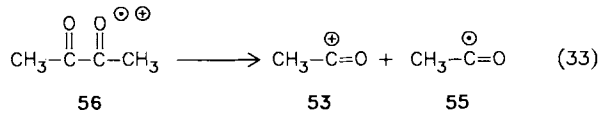
$$AB + e^{\ominus} \longrightarrow A^{\oplus} + B^{\odot} + 2e^{\ominus} \quad (31a)$$

$$\Delta H^0_{f,B^{\odot}} = AE(A^{\oplus}) + H^0_{f,AB} - H^0_{f,A^{\oplus}} \quad (31b)$$

In this way it could be decided which structure the $C_2H_3O^{\odot}$ radical has, which is formed according to Equation (32). That the ΔH_f^0 value of the $C_2H_3O^{\odot}$ radical derived from such a measurement for the dissociation of **52** [Eqn. (32)] does indeed correspond with the oxyallyl radical **54** and not with the (thermodynamically more stable) acetyl radical **55** follows from a comparison of its CIDI spectrum (Fig. 5a) with that of acetyl radicals (Fig. 5b) generated via Equation (33).[44a] Whereas ionization of $CH_3CO^{\odot}$ produces the stable $CH_3CO^{\oplus}$ cation (*m/z* 43), $CH_2CHO^{\odot}$ yields $CH_2CHO^{\oplus}$ ions which, in agreement with theoretical calculations,[69] are unstable and largely dissociate (Fig. 5a).



(32)



(33)

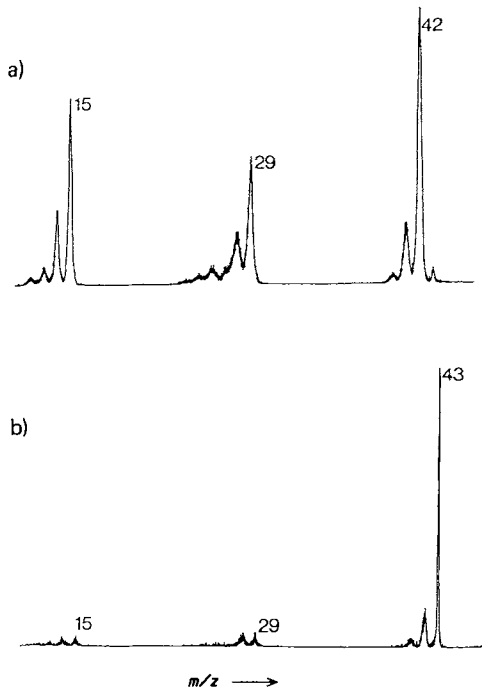


Fig. 5. CIDI spectra of a) $CH_2CHO^{\odot}$ **54** (generated from **52**) and b) $CH_3CO^{\odot}$ **55** (generated from **56**). O_2 was used for the ionization.

7. Outlook

NRMS is a relatively young and promising method for generating and characterizing neutral molecules from cations or anions. It has a greater potential than could be shown in the limited scope of this paper. We refer the reader therefore to the extensive reviews by *Porter*,[5b] *McLafferty*,[6a] and *Holmes*.[6b] We might briefly point out a few interesting fields of investigation.

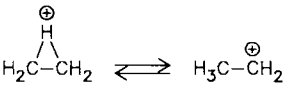
7.1. Generating Neutrals in Excited States

Reduction of $AB^{\oplus}$ by a metal M with an ionization energy lower than the electron affinity of $AB^{\oplus}$ leads to AB* neutrals excited to levels optically inaccessible due to selection rules. Different sets of levels can be populated by a judicious choice of M as was shown for CH_n^* species obtained in various spin states by neutralization of $CH_n^{\oplus}$ with Na or K atoms in the gas phase.[70]

7.2. Distinguishing Isomeric Ions

Many ions cannot be uniquely characterized by straightforward mass spectrometry. This may be due to too flat a potential hypersurface resulting in a set of equilibrating structures or to the experimental methods discriminating only weakly between isomers. An example of the first category is the $C_2H_5^{\oplus}$ problem (open versus bridged structure). Localizing the site of protonation of substituted aromatics in the gas phase is a typical case of the second category.

When ions are neutralized the geometry is largely frozen because rearrangements occur rarely in the neutrals as compared with ionic species. The radical decompositions may therefore allow conclusions as to the structure of the precursor ion. In this way it was shown for the $C_2H_5^{\oplus}$ case that reaction (34) has a ΔG^0 of 0.8 ± 0.1 kcal/mol[5h,71] and also that electron impact ionization of C_2H_5I generates ionic species **57** and **58** in the ratio 2 : 1.[6]

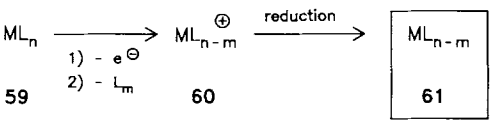


(34)

Equally promising are the first experiments[6,72] for establishing the site of protonation of substituted aromatics by NRMS.

7.3. Electronically Unsaturated Fragments of Organometallic Compounds

Organometallic compounds of the type **59** readily produce ionic fragments **60** through dissociative gas phase ionization [Eqn. (35)]. These are to be considered as coordinatively unsaturated and NRMS experiments on **60** should establish whether *neutral* compounds of type **61** have sufficiently long lifetimes to allow investigation. Results with $Fe(CO)_5$ and $CoNO(CO)_3$[73] justify cautious optimism in the direction of so far inaccessible, ligand-deficient organometallic compounds.



(35)

7.4. Addendum (July 1, 1987)

The NRMS technique has been successfully applied in the first "synthesis" of stable molecules of the type $FeCH_x$ (x = 0–3), species which may well serve as intermediates in homogenous and heterogeneous catalytic reactions.[74]

The radicals $NH_2O^{\odot}$ and $NHOH^{\odot}$, which may play a role in a catalytic cycle destroying ozone in stratospheric chemistry, and also their cations have been unambiguously characterized as stable species in the gas phase.[75] It is also reported in this study that metastable $CH_3CONHOH^{\odot\oplus}$ ions dissociate into $CH_3CO^{\oplus}$ and $NH_2O^{\odot}$ (not $NHOH^{\odot}$). Thus there is an interesting analogy with the behavior of $CH_3COOCH_3^{\odot\oplus}$ discussed in Section 6.2, i.e. the generation of $CH_3CO^{\oplus}/CH_3O^{\odot}$ versus $CH_3CO^{\oplus}/CH_2OH^{\odot}$.

Neutralization of the radical cations of fulminic acid (HCNO) and isocyanic acid (HNCO), compounds which have played a significant role in the historical development of chemistry (concept of isomerism), yields highly structure characteristic NR mass spectra.[76] Finally the first observation has been reported of the imino methyl radical ($HCNH^{\odot}$), a species of astrochemical interest.[77]

The continuous financial support of our work by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der Technischen Universität Berlin is gratefully acknowledged. We are indebted to our co-workers and the colleagues mentioned in the text for valuable contributions, helpful comments, and moral support in the preparation of this article.

[26] This does not obtain for the ylides CH_2NH_3, CH_2PH_3 and CH_2SH_2 which theory predicts to exist in potential wells of sufficient depth that it may be expected that the excited neutral species generated by vertical neutralization in a NRMS experiment will not rapidly dissociate into CH_2/X ($X = NH_3$, PH_3, SH_2) or isomerize into CH_3X. Indeed, *McLafferty* et al. [5c 27] have been able to generate CH_2NH_3 from $CH_2NH_3^{\oplus\odot}$ in NRMS experiments.

Liquid Crystalline Polymers

By Heino Finkelmann*

The liquid crystalline behavior of low molecular weight compounds has been known for more than a century; synthetic polymers have been manufactured on a large scale for several decades, but just recently it was found possible to produce polymers using the structural principles of liquid crystalline compounds. The resulting materials have, as expected, unusual properties. Numerous applications, not only in opto-electronics, are already anticipated for such materials.

1. Introduction

Technological progress is directly linked to the demand for specific and efficient materials. Particularly, in the area of macromolecular chemistry, developments in the past few years have shown that specific modification of molecular structure can lead to materials with new potential applications. Alone for linear macromolecules, the number of possibilities for varying the molecular structure is almost inexhaustable. One can vary the chemical constitution of the monomer units of homo- and copolymers or introduce groups with specific chemical, photochemical or pharmacological characteristics. The possibilities are particularly intriguing in the case of block copolymers, whose microphase-separated blocks can lead to ordered super structures.

But polymer behavior is not only determined by molecular architecture; much more crucial is the physical state in which the macromolecular compound exists. For this reason, the crystalline (or partly crystalline) state, the liquid, isotropic melt, and the glassy, amorphous state have been intensively studied in the past decade. In the case of high molecular weight compounds, the gaseous state is not achievable without decomposition.

This list of possible physical states of a polymer is, however, still far from complete. For almost a century, it has been known that certain low molecular weight compounds do not transform directly into the isotropic melt at their melting point.[1] Under constant pressure and within a defined temperature range, these compounds exist in a state, which on the one hand has the low viscosity of liquids, and on the other displays the physical anisotropic characteristics of a crystalline solid. This aggregate phase is known as the liquid crystalline phase, and the substances which form such phases are known as liquid crystals. The liquid crystalline phase of low molecular weight compounds has been intensively researched in the past twenty years, especially after it was discovered that the unusual physical properties of liquid crystals could be exploited in the field of opto-electronics.[2]

It is obvious to pursue the question of whether macromolecular substances could have liquid crystalline phases. The combination of polymer-specific characteristics with the anisotropic, physical characteristics of the liquid crystalline state promises not only interesting novel materials but also opens up new, multi-faceted theoretical, experimental and technological aspects. The chemist is thereby not only faced with constructing specific molecular structures but also with producing a defined physical state of the material.

The intention of this article is to show, with a knowledge of the structural principles of low molecular weight liquid crystals (Section 2), how various types of polymers with potentially liquid crystalline phases can be synthesized (Section 3). Each structural type shows in specific ways the liquid crystalline phase and the properties of the polymer. In Sections 4 to 6, the peculiarities of selected examples will be outlined and their properties and application perspectives will be discussed.

2. The Liquid Crystalline Phase

If an isobaric line is drawn through the phase diagram of a liquid crystal (dashed line in Fig. 1), one finds at lower temperatures ($T < T_m$) the crystalline phase which is characterized by a three-dimensional, long-range positional order of the molecule's center of mass in the crystalline lattice. Furthermore, in non-spherically symmetric molecules, the superior molecular axes, which are usually the longest molecular axes, are oriented with respect to each other

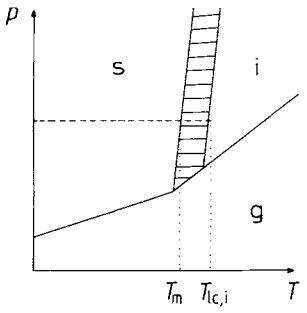

Fig. 1. pT diagram of a substance which shows a liquid crystalline phase (dashed area). s = crystalline; i = isotropic; g = gas; T_m = melting point; $T_{lc,i}$ = liquid crystalline-isotropic phase transformation temperature.

Stefan-Meier-Strasse 31, D-7800 Freiburg (FRG)

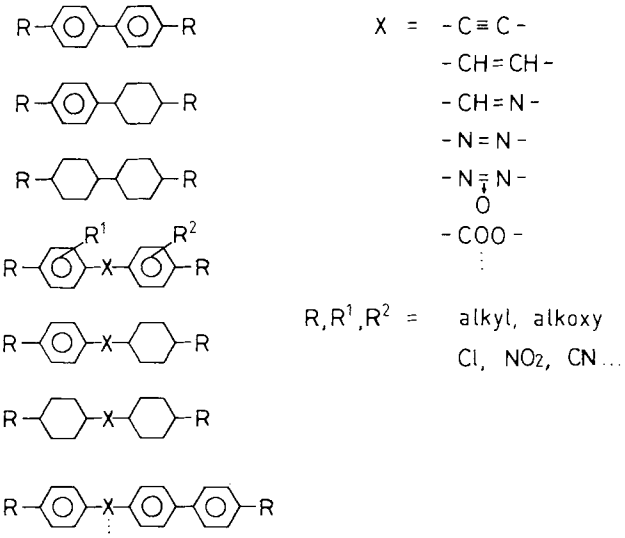
(long-range orientational order of the longitudinal molecular axes). With non-cubic crystals, the positional and orientational long-range order lead to anisotropic physical properties.

At the melting point T_m, the long-range orientational order as well as the long-range positional order for most organic compounds are lost and a melt results in which only short-range ordering between the molecules exists. The physical properties are independent of direction (isotropic).

The long-range orientational and positional order of the molecule need not always spontaneously and completely disappear at the melting point. A step-wise decay with increasing temperature of the long-range positional order in the first, second or third dimension and finally the long-range orientational order can also lead to an isotropic melt. Hence, in the temperature range $T_m < T < T_{l.c.i.}$, aggregate phases (dashed area in Fig. 1) which show a reduced long-range ordering with respect to the crystalline phase can exist between the crystalline phase and the isotropic phase. The loss of long-range positional order in at least one dimension means, however, that the solid phase has been lost and a liquid exists. The existence of long-range positional order and/or long-range orientational order of the molecules leads, on the other hand, to the anisotropic physical characteristics typical for crystals with non-cubic symmetry. This aggregate phase is therefore known as the "liquid crystalline phase."

Systematic investigations have proven that the liquid crystalline phase is found only in those substances whose molecules have a pronounced shape anisometry. They are rod- or disk-shaped molecules. Changes in conformation should not substantially affect the shape anisometry; therefore, a relatively rigid molecular structure is required. Molecules which satisfy these structural principles are known as mesogenic molecules or compounds with mesogenic groups. Simple basic structures of low molar mass, rod-shaped mesogenic compounds are given in Table 1.[3] The various liquid crystalline phases are differentiated with respect to the state of order and the ordering possibilities of the rod- and disc-shaped molecules. The most important of these types for rod-shaped molecules are summarized in Figure 2. The phase structure is determined by the chemical constitution of the mesogenic group and its substituents. In general, for a homologous series of a class of mesogenic compounds, the development of the highly-ordered smectic phase increases with increasing chain length of the flexible substituent located at the end of the longitudinal axis of the mesogen.[3]

Table 1. Selected examples of some basic structures of liquid crystalline compounds with rod-shaped molecular structure.



3. Liquid Crystalline Polymers

The existence of the liquid crystalline state requires rigid, shape-anisometric molecules. With the knowledge of these structural principles the construction of polymers with potential liquid crystalline properties is immediately obvious. The macromolecule as a whole must either have a rigid rod-like or disk-like structure or contain mesogenic groups as monomer units. Polymers whose total structures are mesogenic are only achievable when the polymer itself is rod-shaped, for example via a rigid, helical secondary structure. On the other hand, numerous structures are conceivable for polymers with mesogenic groups as monomer units, whereby one can differentiate between two fundamentally different types (Fig. 3):

1. Those in which the mesogenic groups are located in the polymer main chain. These polymers are known as liquid crystalline main chain polymers (see Section 4).
2. Those in which the mesogenic groups are attached to the polymer main chain in a side-chain-like manner. Such polymers are known as liquid crystalline side chain polymers (see Section 5).

Liquid crystalline side chain elastomers are dealt with in Section 6.

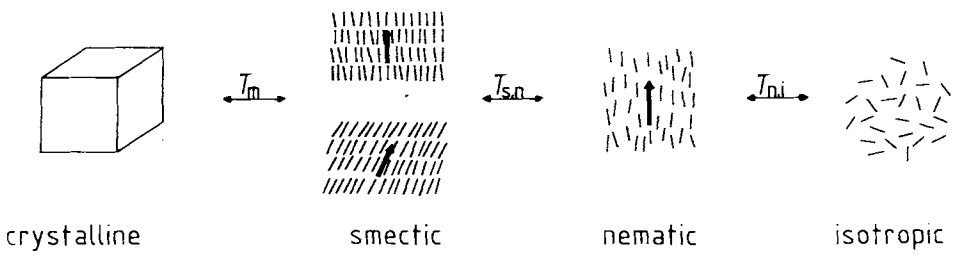


Fig. 2. Phase sequence of a liquid crystalline substance. The arrow shows the preferred direction of the orientation of the long axes of the rod-shaped molecules.

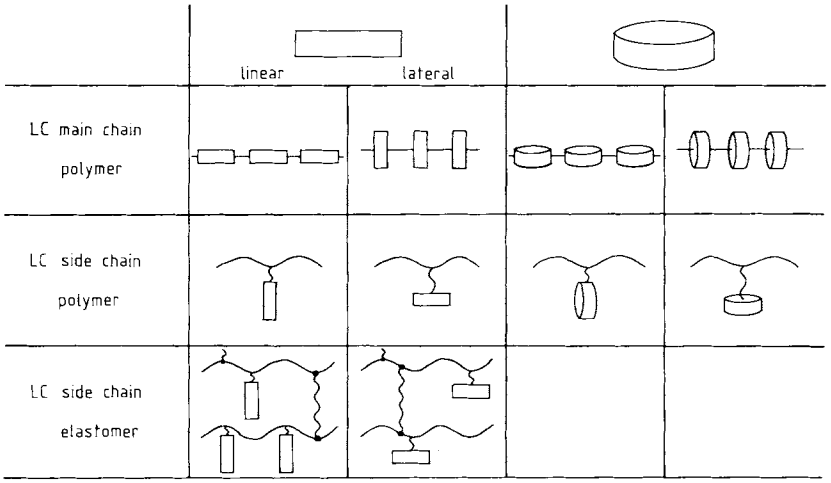

Fig. 3. Types of liquid crystalline polymers derived from rod-shaped and from disk-shaped mesogenic molecules. LC = liquid crystalline.

In comparison to low molar mass liquid crystals, attachment of the mesogenic groups to the polymer generally restricts the translational and rotational motions of the mesogenic groups. Therefore an influence on the temperature range of existence and a change in the physical properties of the liquid crystalline phase is to be directly expected. From the list of possible polymer types given in Figure 3, polymers which contain rod-shaped, mesogenic groups have been synthesized and intensively investigated in the past few years.[4] Polymers with disk-shaped monomer units could only recently be synthesized.[5,6] The same is true for combinations of liquid crystalline main and side chain polymers[7-9] and other structural variations.[8]

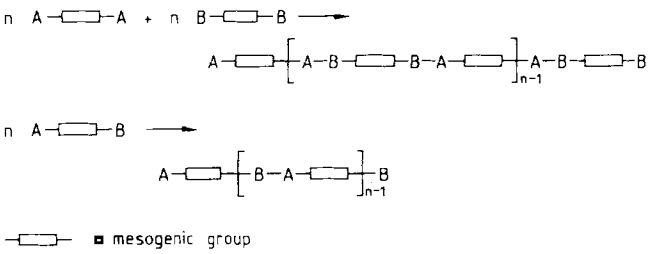
In the following, therefore, only selected examples of the synthesis of simple polymers with rod-shaped mesogenic groups in the main or side chain will be discussed. In addition, their characteristic properties and scope of application will be outlined.

4. Liquid Crystalline Main Chain Polymers

4.1. Synthesis and Structure

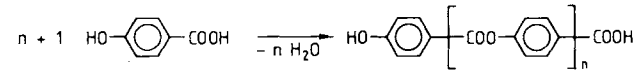
As shown schematically in Figure 3, the longitudinal axis of a mesogenic element can be laterally or linearly bound to a macromolecule. In the first case, rotations about the transverse axis and in the second case, rotations about the longitudinal axis of the individual mesogenic groups within the main chain are restricted due to polymerization. While linear attachment yields a more or less rigid main chain, with lateral attachment a chain flexibility (at least perpendicular to the mesogenic group) comparable to that of conventional polymers should result. Of these two structural variations, almost exclusively polymers with linearly-attached mesogenic groups have thus far been synthesized. The lateral attachment of mesogenic groups has only recently been described for two examples.[10]

There is a wide variety of possible polycondensation reactions for the synthesis of linear main chain polymers. In the simplest case, already known low molar mass liquid crystals[3] are functionalized with groups able to undergo polycondensation (Scheme 1). This leads to polymers which can be derived from simple basic types of mesogenic groups as shown in Table 1. Polycondensation reactions yielding polyesters, polyamides and polyethers are the most preferred reactions.



Scheme 1.

The direct, linear, rigid attachment of mesogenic groups, however, leads to problems. Beginning with a low degree of polymerization r ($r < 10$), the liquid crystalline-isotropic phase transformation temperature is quickly shifted to higher temperature with increasing r. This is due to the high anisometry of the molecule. Similarly, the melting point rises to above the decomposition temperature of the compound. As a result, the liquid crystalline phase often cannot be reached in the case of oligomers. A typical example is the polyester of 4-hydroxybenzoic acid:[11]



Although the low molar mass phenyl benzoates represent an important class of liquid crystals, the polymers of 4-hydroxybenzoic acid or analogous polycondensates of terephthalic acid and hydroquinone decompose before melting and are processable only as powders via a sintering method.

In order to obtain the liquid crystalline state with these types of polymers, there are three possible ways of modifying the rigid, rod-shaped basic structure[14,15] to decrease the melting point temperature:

1. The linearity of the macromolecule can be reduced by a less symmetric comonomer unit or a voluminous aromatic side group.
2. The rigid mesogenic groups are attached via a "flexible spacer," for example an alkyl or alkoxy chain. With increasing length of the flexible chain between the mesogenic groups, not only is the melting point of the polymer lowered, but the mesogenic groups have an increasing tendency to order in a layer-like manner. Above a specific length of the flexible spacer, which is dependent on the structure of the polymer, the development of a smectic phase can occur.
3. Linear macromolecules are substituted laterally with mesogenic groups via a flexible chain. These groups behave as "chemically-bound solvent molecules" and thereby reduce the polymer–polymer interactions and hence the melting point.

A few examples arbitrarily selected from the several polymers already synthesized are listed in Table 2.

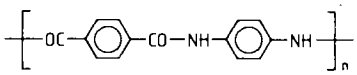
	[21]
	[22]

Decreasing the melting temperature results in the lowering of the liquid crystalline-isotropic phase transformation temperature. Through suitable combinations of different monomer units, an adjustment of a desired phase transition temperature is possible.

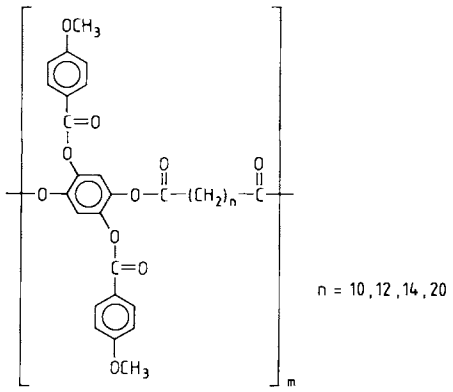
Liquid crystalline main chain polymers build, in general, a nematic phase above the melting point. An ordering of the monomer units into a smectic layered structure is prevented, especially in the case of statistically irregular copolymers which are composed of two or more different monomer units. In analogy to low molar mass liquid crystals, the development of the nematic phase is favored over that of the higher ordered smectic phase only after flexible spacers of increasing length have been introduced between the mesogens.

The liquid crystalline phase can also be realized with non-melting, rigid, rod-shaped polymers when a suitable solvent is added to reduce the melting point. This behavior was theoretically predicted in 1949 by *Onsager*[23] and in 1956 by *Flory*.[24] Rod-shaped macromolecules favor the development of nematic phases above a certain ratio of the length of the longitudinal molecular axis (or of the statistical chain segment length) to the length of the transverse axis in solution above a defined concentration of the macromolecule. The suitable solvent is in many cases problematic. Polyesters, for example, are often only soluble in substituted phenols. The most well-known polymer which forms a liquid crystalline phase only in solution is Kevlar (Du Pont).[25] In concentrated sulfuric acid, it forms a nematic phase.



Polymers with laterally-ordered mesogenic molecules in the polymer main chain are an interesting structural variation of the liquid crystalline main chain polymer. With these polymers, the mesogenic group can rotate only about its short molecular axis; rotation about the longitudinal axis is impossible. This restriction of motion has consequences on the nematic phase structure, which will be discussed later with the corresponding side-chain polymers (Section 5). Furthermore, for this type of polymer, the anisometry of the mesogenic unit does not increase with increasing r, so that the length of the macromolecule should not influence the liquid crystalline phase behavior. Only one such polymer has thus far been synthesized which has a liquid crystalline phase.[10] This phase structure has however not yet been clarified.

The characterization of liquid crystalline main chain polymers continues to be problematic. The polydispersity of polymers and copolymers leads to very broad phase transitions. Due to this multicomponent system, isotropic, liquid crystalline and crystalline phases can exist simultaneously. In spite of that, homogeneous polymers with nematic and smectic phases can be clearly identified and character-



ized.[4] The liquid crystalline phase leads to unusual properties, which will be discussed in the following by considering a model.

4.2. Properties

In the ideal case of the fully rigid polymer main chain, the longitudinal axes of the macromolecules are ordered more or less parallel to one another in the nematic melt. The state of order of this long-range orientation is described through the order parameter

$$S = 3/2(\overline{\cos^2\theta} - 1/3)$$

where the angle θ gives the deviation of the longitudinal axis of the molecule from the preferred direction of the longitudinal axes of all the molecules. For $S = 1$, all molecules are ordered exactly parallel to one another, and for the isotropic melt, $S = 0$. The preferred direction of the orientation of the longitudinal molecular axes is called the director (director = symmetry axis of the orientation distribution function of the longitudinal molecular axes). The position of the director oscillates due to thermal fluctuations within a probe so that over the macroscopic dimension of the probe, no single direction of the director develops. If, however, the polymer is exposed to a shear gradient and, for example, spun through a nozzle, a macroscopically singular orientation of the director—here in the fiber direction—can be obtained (see Fig. 4). If vitrification results upon cooling the flow-oriented polymer, the macroscopically ordered nematic structure is maintained in the glassy state. If this (ideally nematic) glass has the chains ordered fully parallel ($S = 1$), and if the degree of polymerization is high (towards infinity), then a mechanical strength in the fiber direction results due to the strength of the covalent bonds in the direction of the longitudinal molecular axis. The van der Waals interactions between the polymer chains then determine the mechanical properties perpendicular to the fiber direction.

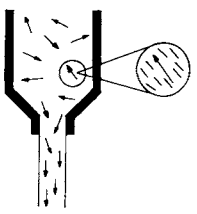


Fig. 4. Flow-orientation process of a liquid crystalline main chain polymer. → = director.

In reality, unusually high mechanical properties in the fiber direction have been found for these polymers; however, the theoretically possible values have not been reached.[15] The reason lies in the imperfect orientation of the director, a degree of order which is less than one ($S < 1$), and the finite molecular weight of the polymer which leads to defects. In addition, most polymers of this type crystallize. Theoretically, this should not reduce the mechanical characteristics of the above model, but apparently the crystallization does heavily influence the mechanical behavior due to defect structures.

Further technological interest in these polymers is based on the lower viscosity of the nematic phase as compared to the isotropic phase.[26] The cause lies in the orientation of the polymer in a shear gradient and in an anisotropic flow process which can no longer be described by one viscosity coefficient.

Due to these unusual mechanical and rheological properties, a series of liquid crystalline main chain polymers has recently become commercially available. Besides their outstanding mechanical properties,[15] they are distinguished by their dimensional stability with a very low thermal expansion coefficient, high temperature stability and low inflammability. Their possible areas of application extend therefore from fibers and composites to injection moulded parts of high tolerance with high thermal stability. Tolerance and thermal stability of electronic and optical components are critical material demands which could be fulfilled by liquid crystalline main chain polymers.

5. Liquid Crystalline Side Chain Polymers

5.1. Synthesis and Structure

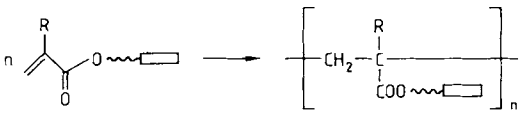
In liquid crystalline side chain polymers, the mesogenic molecules are bound as side-chains, usually via a flexible spacer to a desired polymer main chain (Fig. 3). With rod-shaped mesogenic molecules, it is significant whether the liquid crystalline molecule is attached to the macromolecule along its longitudinal or transverse axis. Lateral (with respect to the longitudinal molecular axis) substituents considerably lower the stability of the liquid crystalline state,[27] while linear substituents are, in general, necessary for the existence of the liquid crystalline state.[3] In addition, motions of the mesogens are influenced differently depending on their linkage to the backbone; this will be discussed in detail later.

For the synthesis of liquid crystalline side chain polymers, each of the known low molar mass liquid crystalline molecules can in principle be supplied with functional groups through substitution reactions and then converted into a polymer.

The active species of initiation and chain growth reactions of ionic, radical, insertion and group transfer polymerizations must be carefully selected with respect to the chemical constitution of the mesogenic groups, which lim-

its in most cases the choice of the type of polymerization. No polymerizable liquid crystal has yet been synthesized which can be converted into a high molecular weight polymer through ionic polymerization. Termination reactions in ionic polymerization lead only to oligomeric products.[28, 29] On the other hand, ionic polymerization is of interest because it enables the study of the influence of the tacticity of the polymer main chain on the liquid crystalline phase behavior. This question has yet to be clarified.

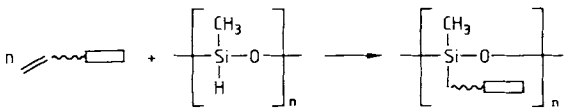
Most polymers have thus far been synthesized by radical polymerization.[4] Mesogenic compounds which are esterified with acrylic, methacrylic or chloracrylic acid[30] on the terminal or lateral substituent of the mesogenic group are converted without problem into high molecular weight products via radical polymerization under usual experimental conditions (Scheme 2).



R = H, CH_3, Cl

Scheme 2.

Reactions analogous to polymerizations[31] such as the addition of liquid crystals with terminal C=C double bonds on the mesogenic group to poly[oxy(methylsilylene)], (Scheme 3) afford access to liquid crystalline polysiloxanes.[32-34]



Scheme 3.

These platinum compound-catalyzed reactions have high reaction turnover and can be used to synthesize copolymers using monomer mixtures. Finally, liquid crystalline side chain polymers can be synthesized by polycondensation reactions[35] and group transfer reactions.[36]

Based on experience collected thus far, a few simple predictions can be made concerning the expected liquid crystalline phase of a liquid crystalline side chain polymer which is to be synthesized:

1. The conversion of monomers into a polymer leaves the anisometry of the mesogenic groups unchanged. This is contrary to the liquid crystalline main chain polymers with linearly-ordered mesogenic groups. The specific volume of the material, however, is lowered by polymerization; that is, the packing density of the mesogenic groups increases. Consequently, polymerization shifts the liquid crystalline-isotropic phase transformation to higher temperatures, in analogy to the increase in the packing density of low molar mass compounds with increasing pressure. This effect as a function of the degree of polymerization r of a polymer is shown schematically in Figure 5. The phase transition temperatures shift considerably in the oligomer region ($r < 10$), while for $r > 100$, dependence on the degree of polymerization is in general no longer observed.[37]

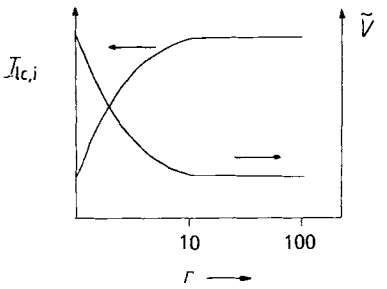


Fig. 5. Dependence of the liquid crystalline-isotropic phase transformation temperature $T_{lc,i}$ and of the specific volume $\tilde{V}$ on the degree of polymerization r of the liquid crystalline side-chain polymer.

2. In general, the attachment of the mesogenic groups on a polymer main chain tends to lead to the development of the highly ordered smectic phase. The known dependence of the polymorphology of the liquid crystalline phases on the substituents of the mesogenic groups for low molar mass liquid crystals is essentially valid also for polymers. With increasing length of the terminal, flexible substituent, development of the smectic phase is favored. This is found, however, only for polymers with flexible spacers which have a minimum length of three to four atoms within the chain. With shorter spacers, packing problems often lead to no liquid crystalline phase, or the polymer main chain forces a smectic ordering of the mesogenic side groups. Under these conditions, nematic phases are in general not found in spite of the short-chain substituents on the mesogenic groups.[38]

A further, theoretically interesting aspect is, as mentioned above, the manner in which the mesogenic group is attached to the polymer main chain. Rotation of the mesogenic group about the longitudinal axis is possible with linear attachment of the mesogenic groups and the spacers, while it is prevented by lateral attachment. Therefore, specific motions which influence the phase structure can be affected by polymer fixation. This is exemplified by the following nematic phase: For low molecular weight liquid crystals, the rather "board-shaped" molecules can be thought of as cylindrically symmetric because they rotate nearly unrestricted about their longitudinal axis. A uniaxial phase structure results from the long-range orientational order of the cylindrically symmetric longitudinal molecular axes. If now the rotation about the longitudinal axis is prevented by the lateral attachment of the mesogenic groups to the polymer main chain, the molecular shape can no longer be thought of as cylindrically symmetric. The molecule structure must be considered as being "board-like." In 1970, it was theoretically predicted[39] that with restricted rotation about the longitudinal axes, the short molecular axes could also develop long-range orientational order to one another. The result is a macroscopically biaxial nematic phase. However, because of the low rotational barrier potential, a biaxial nematic phase for low molar mass liquid crystals has not yet been demonstrated, although it does exist in polymers with laterally-

attached mesogenic groups.[40] Figure 6 shows a photograph, taken under the polarizing microscope, of a biaxial nematic polymer between two surface parallel glass plates. Through changes in the position of the director, which is essentially determined by orientation effects of the polymer at the boundary surface, a characteristic texture of the interference pattern under crossed polarizers results. This texture differs in appearance from that of the uniaxial nematic phase and can be used to identify the phase. This example demonstrates that through the attachment of the liquid crystalline molecule, specific motions can be influenced, resulting not only in new phase structures but also theoretically interesting ones.

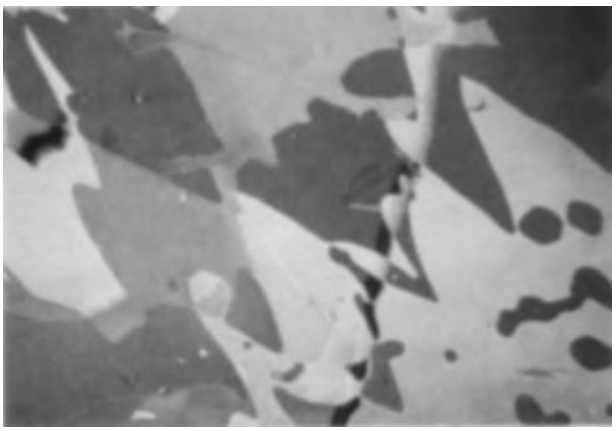

Fig. 6. Photographs, taken under the polarizing microscope, of the biaxially nematic polymer poly[1-{11-[2,5-bis(*p*-anisoyloxy)phenyl]undecyloxycarbonyl}-1-methylethylene] (crossed polarizers, magnification 40×). Original colors: mainly red-violet, light-brown, lime-green.

5.2. Properties

Although the anisotropic phase structure of liquid crystalline main chain polymers results from the long-range ordering of the main chain, only the mesogenic side groups determine the phase structure of side chain polymers. Thus the polymer main chain does not itself need to have long-range ordering. The local chain conformation must only be consistent with the liquid crystalline phase structure of the side chains. For example, a deformed polymer coil in the nematic phase was ascertained to have an axial length of 1.5 times its radius of gyration.[41] As a result, these polymers are similar to conventional amorphous polymers in their mechanical characteristics. They do not show the unusual mechanical properties of liquid crystalline main chain polymers.

Of special interest is the phase behavior of these polymers when the liquid crystalline melt is cooled to lower temperatures. This is shown schematically in Figure 7, in which the order parameter S is given as a function of temperature. With decreasing temperature, the long-range orientational order of the mesogenic side chain continually increases until a defined temperature $T_{g,lc}$ below which it then remains constant. Thermodynamic studies show that at this temperature, the liquid crystalline melt transforms into the glassy state. Optical[38] and NMR spectroscopic

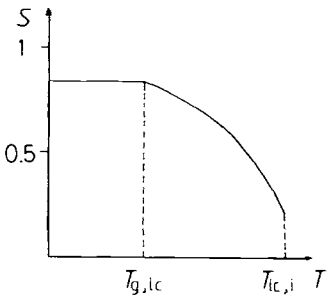

Fig. 7. Order parameter S as a function of temperature for a liquid crystalline side-chain polymer. $T_{g,lc}$ = glass transition temperature; $T_{lc,i}$ = liquid crystalline-isotropic phase transformation temperature.

measurements[42] show that the liquid crystalline structure remains unchanged in the glassy phase. Therefore it is possible to produce *anisotropic glasses* which display a nematic or smectic structure depending on the type of polymer. The glass transition temperature $T_{g,lc}$ essentially depends on the chemical constitution of the polymer main chain.

A further important aspect is the influence of an electric or magnetic field on the position of the director in the liquid crystalline phase.[43–45] In analogy to modern electrooptical display elements of low molar mass liquid crystals, the position of the director can be changed and macroscopically ordered by the application of an external field. In the ordered phase, the optical properties of the polymer correspond to that of a single crystal of the same dimension. By cooling the polymer into the glassy state, this ordered state is permanently frozen in.[46]

The combination of these characteristics—the glassy state and anisotropic physical characteristics—introduces broad application perspectives for these polymers as optical components in linear and non-linear optics.[47] Furthermore, optical memory (storage) elements which can utilize changes in the most diverse physical properties can be realized. As an example, a recording element which gives high resolution suitable for holographic photographs is shown in Figure 8.[48] A uniformly ordered polymer in the

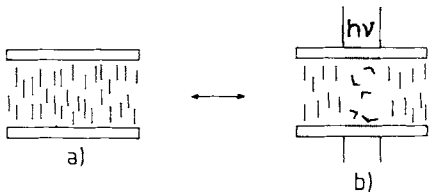

Fig. 8. Recording element with a liquid crystalline side-chain polymer. a) A uniformly ordered polymer in the glassy state; b) a linear *trans*-dye compound isomerized by light radiation into the bent *cis*-form.

glassy state (Fig. 8a) contains a dye which can undergo *trans-cis* isomerization. The glassy polymer is warmed into the liquid crystalline state by exposure to a laser for a short time, and simultaneously the linear *trans*-dye isomerizes to the bent *cis*-dye (Fig. 8b). Due to the bent conformation of the dye, the local ordering of the phase within the radiated area is reduced, thus changing the anisotropic optical

properties. After irradiation, the polymer returns to the glassy state and the given information is permanently stored. It can be retrieved by a minimal laser output. The process is reversible (for example, via a thermal reverse reaction to the *trans*-dye in the glassy state, in which the local state of order of the phase remains unaffected).

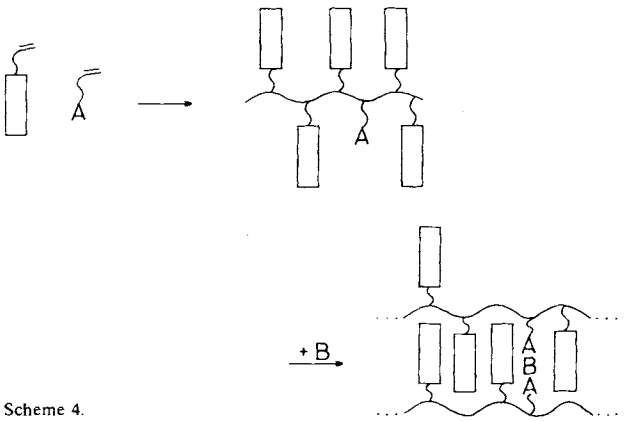
A completely different application follows from the anisotropic properties of the polymer and its negligible vapor pressure at high temperatures. As stationary phases in gas chromatography such polymers lead to higher separation efficiencies than conventional materials.[49,50]

6. Liquid Crystalline Elastomers

6.1. Synthesis and Structure

In the liquid crystalline melt above the glass temperature, the linear polymer main chains of the liquid crystalline side chain polymers can move among themselves through translational diffusion. If the linear chains are made into a polymer network by a chemical cross-linking reaction, this translational diffusion is prevented. Disregarding the cross-linkage sites, however, the high flexibility of the chain segments remains in spite of the cross-linking. In addition, the mesogenic molecules which are attached to the network are not prevented from building liquid crystalline phase structures. The networks now show, on the one hand, the anisotropic phase behavior characteristic of low molar mass liquid crystals and, on the other, the nondeformability and rubber elasticity characteristic of conventional elastomers.[51,52]

Liquid crystalline elastomers can be prepared by usual procedures in macromolecular chemistry, but the synthesis of defined networks is extremely difficult. The currently known liquid crystalline elastomers have been synthesized by simple, statistical copolymerization or by statistical polymerization-analogous addition reactions with multifunctional cross-linking molecules. Another simple method is the copolymerization of a mesogenic monomer with a functionalized comonomer to give a linear liquid crystalline copolymer, which in a second reaction step with cross-linking agent B is transformed into a network (Scheme 4).[53]



Scheme 4.

6.2. Properties

Elastomers with nematic and smectic phases are known which show the same dependence of the liquid crystalline phase on the chemical structure of the monomer units as the linear liquid crystalline polymers. At the glass transition temperature $T_{g,lc}$ the elastomer freezes into a glass with the liquid crystalline structure.

Of special importance are the mechanical properties of the elastomers. They behave at higher temperatures in the isotropic phase like conventional rubbers, whereas below the isotropic-liquid crystalline phase transformation the mechanical properties are direction dependent. If one considers an undeformed elastomer in the liquid crystalline phase, the preferred direction of the mesogenic side groups varies due to thermal fluctuations, as it does in low molar mass liquid crystals and linear liquid crystalline polymers (Fig. 9). If the elastomer is mechanically deformed by a retractive force, then one obtains a macroscopic ordering of the mesogenic side groups. The orientation of the mesogenic side groups in the direction of the force is determined by the linkage between the mesogenic groups and the network.[54] It has thus far been observed that, depending on the length of the linkage of the flexible spacer, the preferred direction of the longitudinal axes of the mesogenic groups is either parallel to or perpendicular to the deformation axis; other angular positions are not found.

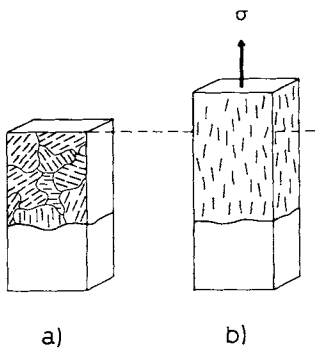


Fig. 9. Orientation of the director of a liquid crystalline elastomer through a mechanical stress σ. a) In the unstressed state, the orientation of the director is non-uniform; b) through mechanical deformation, the director is uniformly ordered. The optical characteristics of the sample correspond to that of a single crystal of the same dimensions.

The elastomer is comparable in its optical properties to a single crystal of the same dimension. A reorientation results from a change in the direction of the stress, in which the direction of the stress and the direction of the long-range orientational order are always directly related. Therefore mechanical deformation of the elastomers has the same influence on the orientation of the liquid crystalline molecules as an electric or magnetic field has on the orientation of low molar mass liquid crystals and linear liquid crystalline polymers.

Combination of the properties of anisotropic phase structure, rubber elasticity and the ability to orient the op-

tical axis through mechanical deformation results in a new class of materials whose scope of application extends beyond the area of optics. For example, thin anisotropic films can be used as separation membranes. Other detailed studies on these new materials are therefore not only of theoretical interest with respect to the interaction between a deformed polymer network and the liquid crystalline phase structure, but also provide the basis for new applications.

7. Summary and Outlook

Liquid crystalline phases always require a rigid, rod- or disk-shaped mesogenic element. The introduction of these structural elements into a polymer main chain or as side groups on the monomer unit of a macromolecule enables the synthesis of polymers which build thermodynamically stable liquid crystalline phases within a defined temperature range. In the liquid crystalline phase, the main chain segments or the mesogenic side groups which are structurally similar to low molar mass liquid crystals show long-range orientational and positional order. The liquid crystalline structure can be frozen into the glassy state of the polymer, thus enabling the preparation of glasses with anisotropic physical properties.

The examples given in this article represent only a small number of the wide spectrum of realizable or conceivable liquid crystalline polymers. The intended aim of this article has been to point out that the combination of those properties specific to polymers with the anisotropic properties of liquid crystalline structures enables the synthesis of a wide variety of new materials. The liquid crystalline polymers not only offer possibilities for new types of application. The interplay between anisotropic phase structure and the properties of the macromolecular system provides the chemist, physical chemist and physicist with many interesting theoretical and experimental problems which remain to be solved.

harge Transfer and Radical Ions in Photochemistry**

By Jochen Mattay*

Bimolecular photoreactions usually occur via several steps involving "complex-type" intermediates (excimers or exciplexes). Although physical chemists have investigated them for nearly thirty years (*Förster*, *Weller*), and postulated their existence in numerous publications, it is only in the last decade that evidence for an exciplex intermediate in cycloadditions (*Caldwell*) has been obtained, thereby establishing the link between spectroscopy and synthetic photochemistry. Since then, many investigations have confirmed the role of exciplexes as intermediates in bimolecular photoreactions. The photochemically induced charge transfer from a donor to an acceptor substrate determines not only the bond strengths in the primary exciplex but also influences—via the charge-transfer nature of the complex—the structure of the exciplex and thereby the selectivity of subsequent reactions. Such chemical processes between the donor and the acceptor prevent the reverse transfer of electrons, which usually results in regeneration of the starting materials, thereby only causing the dissipation of energy and occasionally—under specific conditions—the generation of molecules of the starting material in the triplet state. Ionic photodissociation also reduces the probability of a reverse transfer of electrons. This process, which produces solvated radical ions, is promoted by polar solvents and salt effects, particularly special salt effects. By this means it is possible to generate specific radical cations from, for example, alkenes and dienes and to study their reactions. Although in some areas, for example physical and biophysical chemistry, discussions of single electron transfer (SET) processes have long been found in the basic textbooks, organic chemistry lags far behind, although—and this is shown by the numerous recent publications—organic chemists are also aware of the fundamental importance of these processes. In this connection photochemistry plays a central role, since its instruments make it possible to carry out specific SET processes, to analyze them, and to use them in chemical reactions.

1. Introduction

"One of the simplest elementary processes in solution is the exchange of an electron between two chemical substrates." This statement by *Eberson*[1] is of fundamental importance for many areas of chemistry.[2–6] In this elementary process, bonds are neither broken nor formed. However, the transfer of an electron has important consequences for the chemical reactivity of the compounds.[1] For example, a nucleophilic reagent R–Nu is transformed by oxidation (i.e., the loss of an electron) into an electrophile. Correspondingly, the reduction of an electrophilic substrate enhances its nucleophilic character. Electron transfer therefore leads to "umpolung" (Fig. 1) with all its consequences for the ensuing reactions.

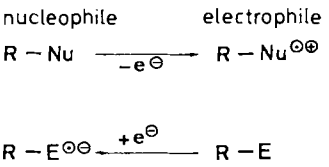

Fig. 1. Umpolung by means of electron transfer.

The importance of electron transfer in photochemistry has been known ever since the fundamental work of *Weller* et al.[7] and, for example, the studies of *Marcus*[8] and *Hush*,[9] but it was not until the 1970s that numerous groups began to approach the problem experimentally. These investigations paralleled the development of highly time-resolved methods of transient analysis, such as laser flash spectroscopy, which made possible the study of chemical processes in the ns[10–13] and ps[13–16] region, and chemically induced dynamic nuclear polarization (CIDNP),[17] which can also be applied in a time-dependent manner.[18,19] Occasionally, time-resolved ESR spectroscopy[13,20] and, most recently, time-resolved Raman spectroscopy[21] have been used. These modern analytical methods can be used to obtain information about the types of reactive intermediates and their kinetics. Simultaneously, interest has been growing in organic syntheses that proceed via electron-transfer processes.[22–24]

2. Basic Principles

2.1. Energetics

Why is there so much activity in the field of photochemistry at the moment? Because specific photochemically initiated electron-transfer processes can be used to carry out chemical reactions involving radical ions in homogeneous solution, and these reactions, in turn, can be studied by the modern analytical techniques mentioned above. Photo-

excitation of electron-acceptor (A) or electron-donor (D) substrates leads to well-defined changes in their redox properties (Fig. 2). For example, the donor properties of D

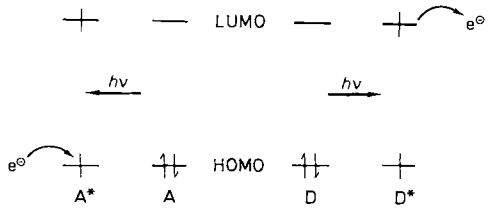

Fig. 2. Photochemical excitation and redox properties of donor (D) and acceptor (A) molecules.

increase proportionally to the excitation energy ($\Delta E(D^*)=h\nu$); i.e., the ionization energy, $IP(D)$, is reduced by the promotion of an electron from the HOMO to the LUMO [Eq. (a)]. The electron affinity of the acceptor, $EA(A)$, behaves similarly [Eq. (b)].[7,25] Electron transfer

$$IP(D^*)=IP(D)-\Delta E(D^*) \quad (a)$$
$$EA(A^*)=EA(A)+\Delta E(A^*) \quad (b)$$

between donor and acceptor substrates should therefore occur more easily after photochemical excitation of one of the reacting species[7] if either $IP(D^*)<EA(A)$ or $IP(D)<EA(A^*)$ holds true (Fig. 3).

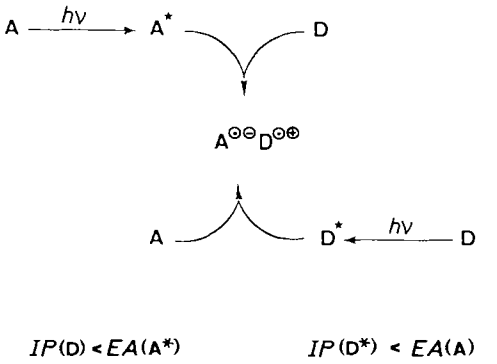

Fig. 3. Photochemically induced electron transfer between donor and acceptor molecules.

Simple energy considerations such as this clarify the dependence of the electron transfer on electronic conditions in the participating substrates. IP and EA are valid only for the gas phase. However, since the oxidation and reduction potentials ($E^{ox}_{1/2}(D)$ and $E^{red}_{1/2}(A)$), which are the corresponding parameters in solution, are easily obtained experimentally[26] and are linearly related to IP and EA, respectively,[27] the conditions for electron transfer between D and A after irradiation can be formulated as follows:

$$\Delta G(A_s^{\odot\ominus}D_s^{\odot\oplus})=F[E^{ox}_{1/2}(D)-E^{red}_{1/2}(A)]-\Delta E_{excit}+\Delta E_{coul} \quad (c)$$

In Equation (c)—the Weller equation—$E^{ox}_{1/2}(D)$ and $E^{red}_{1/2}(A)$ are the oxidation potential of the donor and the reduction potential of the acceptor, respectively, measured in acetonitrile; ΔE_{excit} is the excitation energy of the electronically excited species, and ΔE_{coul} the coulomb interaction energy of the two radical ions at a distance a from one another in a given solvent.[28,29] The exact value of ΔE_{coul} is obtained, according to the Born equation, from Equation (d).[29] With $F=96489$ C, $e=1.602\times10^{-19}$ C,

$$\Delta E_{coul}=\frac{eN}{4\pi\varepsilon_0 a}\left[\frac{1}{\varepsilon}-\frac{2}{37.5}\right] \quad (d)$$

$\varepsilon_0=8.854\times10^{-12}$ CV^{-1} m^{-1}, and $N=6.023\times10^{23}$ mol^{-1}, one obtains the free energy of formation (ΔG) of the solvent-separated radical-ion pair $A_s^{\odot\ominus}D_s^{\odot\oplus}$(SSIP) in a solvent with dielectric constant ε. In general, the distance a for a solvent-separated radical-ion pair is taken as 0.7 nm. The Weller equation therefore allows an estimate, to a first approximation, as to whether electron transfer within a donor-acceptor system is thermodynamically allowed (ΔG negative, exergonic process) or not (ΔG positive, endergonic process). In addition, it shows that the electron-transfer process can be decisively influenced by the polarity of the solvent as well as by the electronic properties of the reacting species. This gives the chemist a number of ways to direct reactions involving radical ions in a desired fashion.

2.2. Radical-Ion Pairs, Exciplexes

While the fate of a donor-acceptor pair in the exergonic region of electron transfer ($\Delta G<0$, Eq. (c)) appears at first glance to be straightforward—namely, the preferred formation of radical-ion pairs—this is not true for the endergonic region. In addition to energy transfer,[6] an exciplex (i.e., a complex in an excited state) may be formed, especially when the energy of the excited species (sensitizer) is greater than the excitation energy of the second species (for the possibility of energy transfer via exciplex intermediates, see, for example, *Kavarnos* and *Turro*[6]). Figure 4

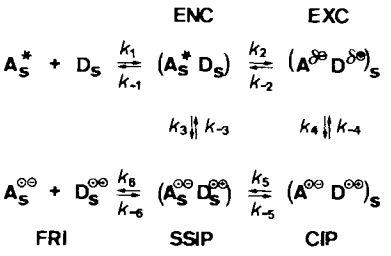

Fig. 4. General kinetic scheme for photochemically induced electron transfer in donor-acceptor systems (according to [30]). ENC complex = collision complex; EXC = exciplex; CIP = contact ion pair; SSIP = solvent-separated radical-ion pair; FRI = free radical ions.

shows various quenching processes that an excited acceptor molecule A* can undergo with a donor molecule D in the ground state (spin multiplicities as well as subsequent processes, e.g., the formation of triplet and product molecules, are not considered here for reasons of simplicity).[30] The path characterized by k_3 shows the direct formation of the SSIP from the collision complex in the exergonic region. However, the electron transfer is also possible via an exciplex intermediate (k_2, k_4, k_5). This possibility

is supported by the observation that, in contrast to the expectations based on the Marcus theory,[8] reductions in the rate constants for electron transfers in highly exergonic regions have not been observed.[30] Recently, however, *Miller, Closs* et al.[31] found clear evidence for the so-called "Marcus inverted region" in intramolecular electron-transfer processes.

According to *Weller* et al.,[27,32,33] exciplexes form because of a coupling of a local excited state with the so-called charge-transfer (CT) state [(e) and (f)]. The weight-

$$(A^*D) \longleftrightarrow (AD^*) \longleftrightarrow (A^{\ominus}D^{\oplus}) \quad \text{(e)}$$

$$\psi = c_1\psi(A^*D) + c_2\psi(AD^*) + c_3\psi(A^{\ominus}D^{\oplus}) \quad \text{(f)}$$

ing of the wave function $\psi(A^{\ominus}D^{\oplus})$ determines the CT character of the exciplex. For $c_3 > c_1$ and c_2, the wave function corresponds to a highly polar exciplex which can easily dissociate in polar solvents to form solvated radical ions (ionic photodissociation[34]). In the extreme case $c_3 \gg c_1$ and c_2, the exciplex can be considered as a contact ion pair.[29]

Exciplexes are often discussed as intermediates in photochemical reactions;[25,35-37] this is also the case for several photochemical reactions of arenes and carbonyl compounds which have been investigated in our laboratory.[38-45] If such an exciplex exhibits a bathochromic shift in emission compared with the monomer luminescence[27,46] (Fig. 5), then the experimental detection of a

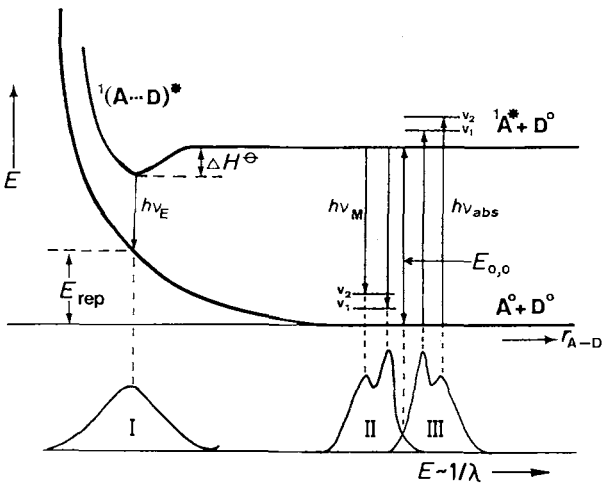

Fig. 5. Schematic potential curves for the formation of exciplexes (from [27]). $\Delta H^{\ominus}$ = enthalpy of exciplex formation; $h\nu_E/h\nu_M$ = emission energy of exciplex/monomer; E_{rep} = repulsion energy in the ground state; v_i = vibrational quantum number. I/II = fluorescence of the exciplex/monomer, III = absorption of the monomer.

reactive intermediate in a photochemical reaction is relatively simple. For example, *Caldwell et al.*[47] were able to quench the 9-phenanthrenecarbonitrile–anethole exciplex specifically with dimethyl acetylenedicarboxylate (quenching of $h\nu_E$, but not $h\nu_M$; cf. Fig. 5) and thereby demonstrate the reactive character of this intermediate. Similar examples have been described by other authors.[35,36,38,39]

Although the observation of exciplex emission is not the rule,[22] the existence of exciplexes and their role as reactive intermediates is nowadays unchallenged. Numerous studies have shown that indirect evidence can also be found. For example, reversibly formed exciplexes have been recognized by the biexponential decay of their monomer luminescence.[48] Similarly, the deviation of fluorescence or phosphorescence quenching from Rehm–Weller behavior [correlation between $\log k_q$ and ΔG: k_q = rate constant for the bimolecular quenching process; ΔG = reaction free energy of the electron transfer, given by Equation (c)] indicates the existence of additional intermediates.[40,41,44,45] Further examples are found in numerous reviews.[6,23,25,32,34-37,43]

2.3. Aim and Scope of This Article

In our studies of the photochemistry of donor–acceptor systems, we have been able to show that reaction selectivity is strongly influenced by photochemically induced charge transfer.[40-45,49,50] Reactions involving radical ions and those involving exciplex intermediates follow different paths. However, the reactions of the latter species are also determined by the degree of charge transfer (i.e., the reactivity of highly polar exciplexes is different from that of weakly polar species). The reaction free energy for the electron transfer (ΔG) calculated from the Weller equation has proved to be an excellent ordering criterion.[41-43,45] In the following discussion, we will present some examples chosen from our own work which demonstrate this correlation between reaction selectivity and ΔG values. Examples from other areas will make the general validity of this ΔG correlation clear. With the help of transient analysis methods, the intermediates involved can be detected and their kinetics investigated. It will be shown in detail how, for example, the equilibrium between contact ion pairs (CIP) and solvent-separated ion pairs (SSIP) or free radical ions (FRI) can be influenced by the suitable choice of the reaction medium and how the course of the reaction can thereby be directed. Borderline cases such as the involvement of ternary complexes in photoreactions will be discussed. This article is restricted to the photochemistry of electron donor–acceptor systems. The generation of radical ions by photoionization[51] will not be dealt with here. Readers who are interested in electron transfer processes in microheterogeneous systems, as well as in the relationship between energy transfer and electron transfer, are referred to other reviews.[5,6,22,52-54] Furthermore, reactions of radical ions in homogeneous solution have been reviewed by *Chanon* et al.,[22] *Farid* et al.,[23] and *Mariano*.[24]

3. The Concept

3.1. Photochemically Induced Charge Transfer, Intermediates, and the Course of Reaction

Table 1 shows, in a simplified manner, possible intermediates and the course of reaction for photoreactions between electron-donor and electron-acceptor molecules. This scheme was developed for the reactions between arenes and alkenes,[42,43] but has, as we shall see, proved valid for other systems. The decisive criterion for the

course of the reaction is the type of intermediate and hence the degree of charge transfer, which can be correlated with the reaction free energy for the formation of SSIPs. A positive or negative ΔG value [calculated by means of Eq. (c)] should show, to a first approximation, whether the formation of SSIPs is allowed or not, i.e.,

Table 1. Photoreactions of electron donor-acceptor systems.

Reaction	ΔG	Intermediate		Product	Example
Donor-acceptor reaction A + D	>0	$(AD)^*_\chi$	nonpolar exciplex	[AD]	cycloaddition
		$(A^{\delta\ominus}D^{\delta\oplus})_\chi$	polar	[AD]'	
	$\lesssim 0$	$(A^{\odot\ominus}D^{\odot\oplus})_\chi$	CIP	[AD]''	
Reactions of radical ions (A)D + D'	$\lesssim 0$	$(A^{\odot\ominus}_\chi D^{\odot\oplus}_\chi)$	SSIP	[DD']	cycloaddition, nucleophilic addition
		$A^{\odot\ominus}_\chi D^{\odot\oplus}_\chi$	FRI		

whether free, or at least solvent-separated, radical ions (pairs) are preferentially formed, assuming that the polarity of the reaction medium suffices for the solvation of the individual species.

The situation in the endergonic region of electron transfer is more complicated. A calculation of the free energy of formation of the exciplex is only possible when molecular parameters such as dipole moment, the radius, and the separation between the components are known.[29] Although these values are not usually known, Equation (c) offers a way out of the dilemma. Figure 6 shows curves for

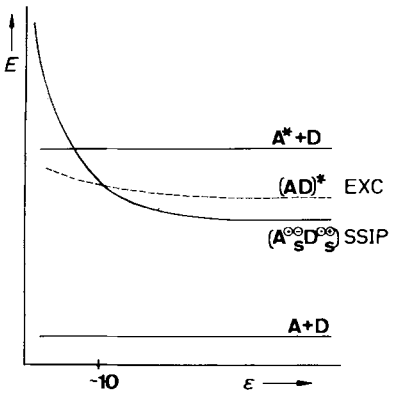

Fig. 6. Dependence of exciplex and SSIP potentials on the dielectric constant (ε) of the solvent (from [55]).

the potential of an exciplex and an SSIP as a function of the polarity of the solvent, as expressed by the dielectric constant ε. Since the curves cross in the region of $\varepsilon \lesssim 10$,[55] the experimentally easily obtainable ΔG(SSIP) value can be used as an approximate estimate of the exciplex free energy. Equation (c) therefore makes it possible to estimate the CT character of an exciplex [cf. Eqs. (e) and (f)]. This method is particularly useful when the correlations with ΔG values for electron transfer are carried out within a substrate series, since the parameters that determine the exciplex energy depend on the type of molecule.

3.2. Influencing Charge Transfer by Solvent Polarity and Salt Effects (Transient Analysis Studies)

The reaction medium plays a decisive part in processes that occur via polar intermediates.[56,57] According to Equations (c) and (d), for example, the formation of solvent-separated ion pairs in acetonitrile ($\varepsilon = 37.5$) is favored by 0.98 eV (=94.4 kJ mol^{-1}) over that in *n*-hexane ($\varepsilon = 1.89$). Ionic photodissociation of donor-acceptor pairs[34] to solvated radical ions therefore requires a polar solvent. The influence of the solvent can often be followed by transient analysis because of the specific UV/VIS absorption of the intermediates involved.

Fluorenone **1** is particularly well suited as an acceptor for such studies since the concentration, solvent, temperature, and cation-radius dependence of the absorption spectra of pairs formed from metal cations and fluorenone radical anions are already known from earlier work.[58,59] The effect of solvent and of added salts on the photoreactions of fluorenone with the electron-rich alkenes **2** and **3** is shown in Figures 7 and 8, respectively.[60] Whereas the formation of solvated radical ions is favored in polar sol-

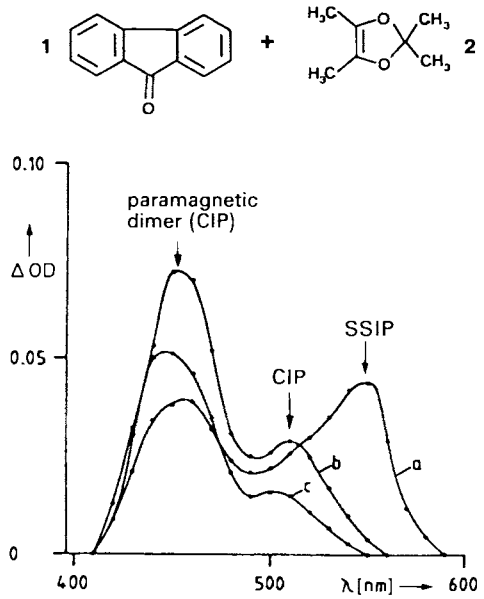

Fig. 7. Transient absorption spectra (ΔOD = absorption difference) 100 μs after flash photolytic excitation of **1** in the presence of tetramethyl-1,3-dioxole **2** in various solvents (from [60]). a) Acetonitrile. b) Benzene. c) Cyclohexane.

vents, only contact ion pairs or paramagnetic dimers could be observed in nonpolar media. It should be noted, in particular, that electron transfer from electron-rich alkenes to **1** even takes place in nonpolar solvents through the formation of contact ion pairs.

Following the fundamental work of *Hughes*, *Ingold* et al.[62] and *Winstein* et al.,[63] salt effects have been frequently investigated in organic chemistry.[57] The so-called normal salt effect is largely determined by the ionic strength; the departure from the "normal" behavior of the reaction rate at low salt concentrations has been called the special salt effect by *Winstein* et al.[63] This effect is presumably due to an ion exchange process that causes a shift in the equilibrium between the SSIP and the CIP. Whereas

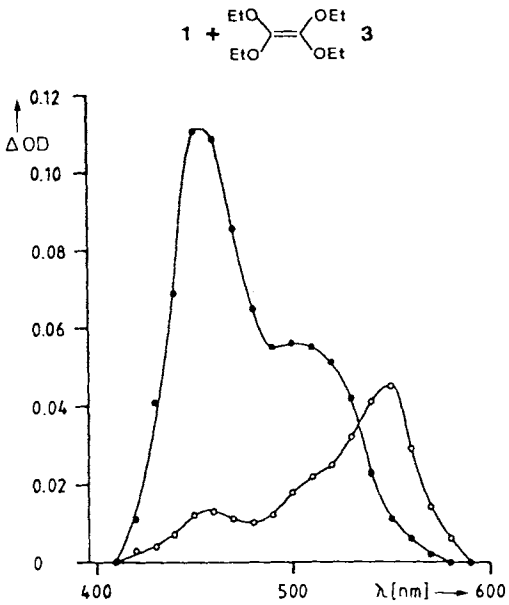

Fig. 8. Dependence of the transient spectra on added lithium perchlorate 100 μs after flash photolytic excitation of **1** in the presence of **3** in acetonitrile—special salt effect (from [60]). ○, no $LiClO_4$; ●, 0.1 M $LiClO_4$.

the long-wavelength absorption at ca. 550 nm in Figure 8 can be ascribed to the SSIP formed by $\mathbf{1}^{\odot\ominus}$ and $\mathbf{3}^{\odot\oplus}$, the addition of lithium perchlorate brings about the formation of a new ion pair (consisting of $\mathbf{1}^{\odot\ominus}$ and $Li^{\oplus}$). The hypsochromic shift of the absorption shows that this species is a contact ion pair [Eq. (g)]. The special salt effect can

$$(A_s^{\odot\ominus} D_s^{\odot\oplus}) + Li^{\oplus} \rightleftharpoons (A^{\odot\ominus} Li^{\oplus})_s + D_s^{\odot\oplus} \qquad (g)$$

therefore be used to influence the equilibrium between the SSIP and the CIP.

The separation between $A^{\odot\ominus}$ and $D^{\odot\oplus}$ makes for a longer lifetime for the radical ions, since the reverse transfer of electrons clearly takes longer. For example, using the benzophenone–alkene and benzil–alkene systems, we could extend the lifetimes by a factor of 15 (as determined by laser flash spectroscopy) by the addition of lithium perchlorate.[44,64] In addition, the special salt effect occasionally results in a greater yield of radical ions.[44,64] In the investigations of the systems so far mentioned, only the formation and decay of the long-wavelength-absorbing radical anions could be followed spectroscopically. Simultaneous analysis of both radical-ion species is possible using *p*-chloranil **4** as the acceptor and 2-methoxy-1,1-diphenylethene **5** as the donor,[44,65] because of their favorable absorption characteristics (Fig. 9). Both the radical anion $\mathbf{4}^{\odot\ominus}$ and the radical cation $\mathbf{5}^{\odot\oplus}$ decay with second-order kinetics and have almost identical lifetimes in the microsecond region, as expected for a reverse transfer of electrons. The addition of lithium perchlorate increases the lifetime by a factor of 10 without affecting the coupling of the two radical ions (Table 2).

Table 2. Effect of $LiClO_4$ on the lifetimes $\tau_{1/2}$ of $\mathbf{4}^{\odot\ominus}$ and $\mathbf{5}^{\odot\oplus}$.

λ [nm]	$\tau_{1/2}$ [μs]	
	without $LiClO_4$	1 M $LiClO_4$
450	0.9	8.9
600	1.3	11.2

Further transient analysis methods such as ESR spectroscopy using in situ photolysis conditions[40,45] can yield information about the structure of the radical-ion intermediates involved but provide little information about their dynamics. It should be noted that salt effects in photochemically induced electron-transfer processes have been investigated by other groups. For example, *Goodman* and *Peters*[66] were able to show, with the help of picosecond laser flash spectroscopy, that both the electron back transfer and the dissociation of contact ion pairs formed between *trans*-stilbene and electron-poor alkenes could be accelerated by the addition of salts. However, these effects,

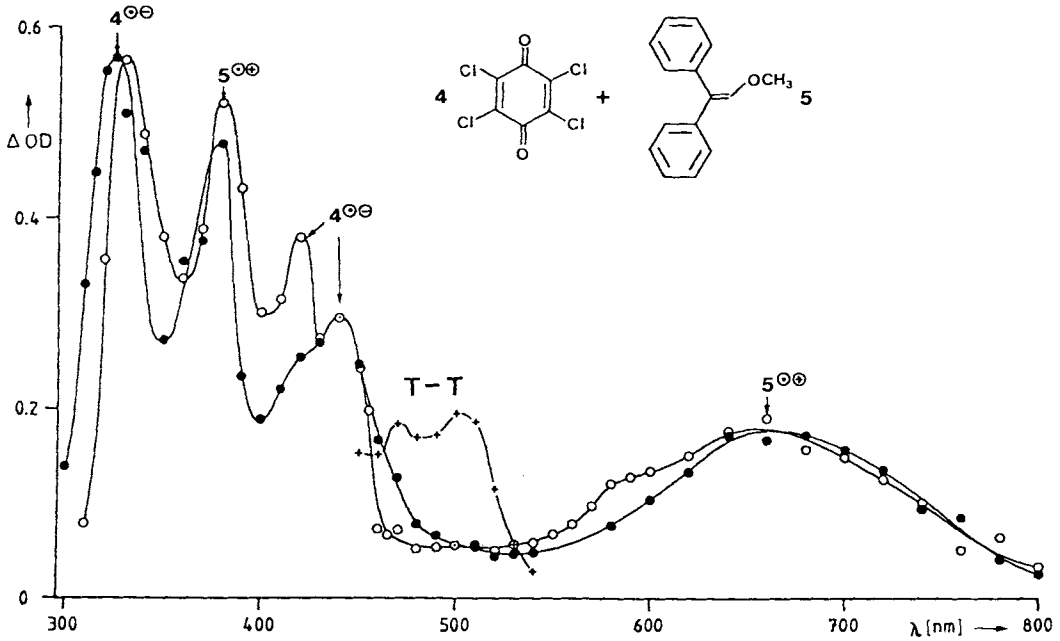

Fig. 9. Transient absorption spectra of **4** and **5** in acetonitrile 50 ns (+, T-T = absorption) and 800 ns after the start of the laser flash (from [44, 61]). ●, no $LiClO_4$; ○, 1 M $LiClO_4$.

ascribed to ionic strength, affect the dissociation more strongly, so that ion-pair separation predominates. *Goodson* and *Schuster*[67] found, moreover, that exciplexes in nonpolar solvents could also dissociate into free radical ions upon addition of ammonium salts. This effect was ascribed to the formation of larger salt aggregates. The same authors showed, in later work, that the lifetimes of 1,4-naphthalenedicarbonitrile radical anions could be dramatically increased by the addition of magnesium salts owing to the formation of complexes.[68] *Masnovi* and *Kochi*[69] investigated, in detail, the dynamic behavior of ion pairs formed by the CT excitation of electron donor-acceptor complexes formed between anthracene and tetranitromethane, and observed both normal and special salt effects in the presence of tetra-*n*-butylammonium trinitromethanide and tetra-*n*-butylammonium perchlorate.

In conclusion, it has been established that solvents and salts strongly influence the ionic dissociation of photochemically excited electron donor-acceptor pairs. Electron acceptors (for example, mixtures of carbonyl compounds or arenecarbonitriles and metal salts) are therefore suitable catalysts for chemical reactions that proceed via radical cations [Eq. (h)].[50,61]

$$A + D \xrightarrow{h\nu} (A^{\delta\ominus}D^{\delta\oplus})_s \xrightarrow{Li^{\oplus}} (A^{\ominus\ominus}Li^{\oplus})_s + D_s^{\oplus\oplus} \xrightarrow{D'} \text{product} \qquad \text{(h)}$$

4. Photochemical Reactions between Donor and Acceptor Compounds

Photoreactions between donor and acceptor molecules proceed mostly via exciplex intermediates (see Section 2.2). A scheme by which numerous reactions can be classified is shown in Figure 10 (cf. Table 1). According to this

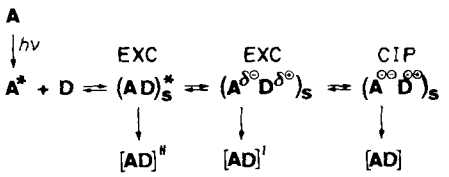

Fig. 10. Reaction between donor and acceptor molecules via exciplex and contact-ion-pair intermediates (alternatively, excitation of the donor is possible)—cf. Table 1.

scheme, the amount of charge transfer determines the type of intermediate and thereby the way in which the reaction proceeds. This concept will be exemplified by the photochemical reaction between arenes and alkenes. Three types of intermediates can be distinguished: polar and nonpolar exciplexes react to give cycloadducts, although with different degrees of selectivity; exciplexes having complete charge transfer (contact ion pairs)[29] usually show a different reaction behavior—if suitably substituted, they undergo heterolytic bond fission to form radical pairs, which then couple with one another ("substitution"), or they decay via the formation of triplet states. Dissociation into solvated radical ions and their synthetic use will be dealt with in Sections 5.1–5.3.

4.1. Photoreactions of Benzene and Monosubstituted Benzenes with Alkenes

4.1.1. The α,α,α-Trifluorotoluene Example

Discussion of the mechanism of the cycloaddition of alkenes **7** to photochemically excited benzene or its derivatives **6** has been carried on ever since the discovery of *ortho* cycloaddition[70–73] (to **9**) and *meta* cycloaddition[74,75] (to **8**).[76] On the basis of the results of various groups, we have been able to show, during the last few years, that the exciplex mechanism most fully explains the current experimental results, especially since it accounts for cycloaddition as well as substitution (to **11** and **12**) (Fig. 11).[42,43]

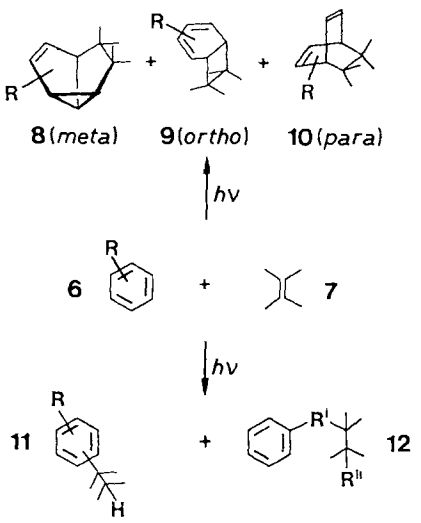

Fig. 11. Photoreactions of arenes with alkenes.

The photoreaction of α,α,α-trifluorotoluene **13** with alkenes results in the formation of all these product types in good yields (50–72%) (Fig. 12).[41] It should be noted that *para* cycloaddition (to **10**) is seldom observed and that **10** in some cases is formed from the *ortho* adducts **9** via secondary photochemical processes.[43]

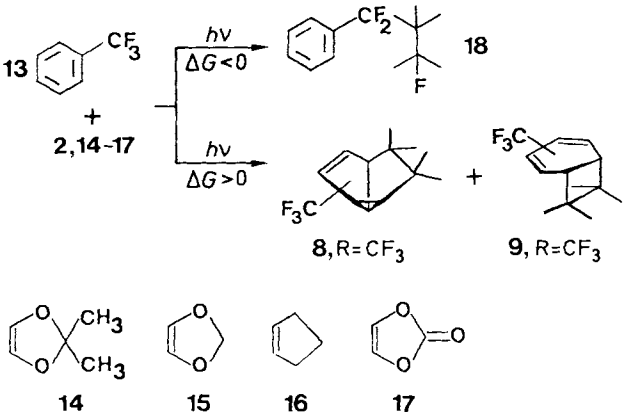

Fig. 12. Photoreactions of **13** with alkenes. Note that in the system **13/17** the alkene **17** acts as an acceptor (Table 3).

Table 3. Preferred reaction type in the photoreaction of **13** with the olefins **2** and **14**-**17** as a function of the oxidation potential of the olefin and ΔG [Eq. (c)] [a].

Olefin	$E_{1/2}$ [V]	ΔG [eV] [b]	Substitution	Cycloaddition
2	0.42	−0.23	+	−
14	0.69	+0.04	+	−
15	0.76	+0.11	+	+
16	1.83	+1.18	−	+
17	−2.64	+1.72	−	+

[a] $E^{red}_{1/2}(\mathbf{13}) = -3.18$ V, $E^{ox}_{1/2}(\mathbf{13}) = 2.91$ V, $\Delta E_{excit} = 4.65$ eV. [b] In dioxane.

After electronic excitation, **13** preferentially forms the substitution products **18** with electron-rich alkenes such as **2** and **14**. With electron-poor reactants such as **16** and **17**, on the other hand, cycloaddition to give **8**, R = CF_3, is mainly observed (Table 3). This trend is reflected in the oxidation potentials of the alkenes. The free energies of electron transfer calculated from Equation (c) show clearly that only substitution will be observed at $\Delta G \approx 0$ in the exergonic region and only cycloaddition in the endergonic region. The reaction of **13** with **15** occupies an intermediate position with respect to both selectivity and charge transfer. In line with its small positive ΔG value (in dioxane, $\varepsilon = 2.2$), the exciplex is very polar (for indirect evidence see Ref. [41]), and, in addition to forming the substitution product **18**, forms mainly the *ortho* and *meta* cycloadducts **8** and **9** (R = CF_3), respectively. According to Equations (c) and (d), the electron transfer for this system should be exergonic in a solvent of $\varepsilon > 3$. Indeed, the cycloaddition is completely suppressed when the photoreaction is carried out in solvents more polar than dioxane (Fig. 13). Only the formation of the substitution products

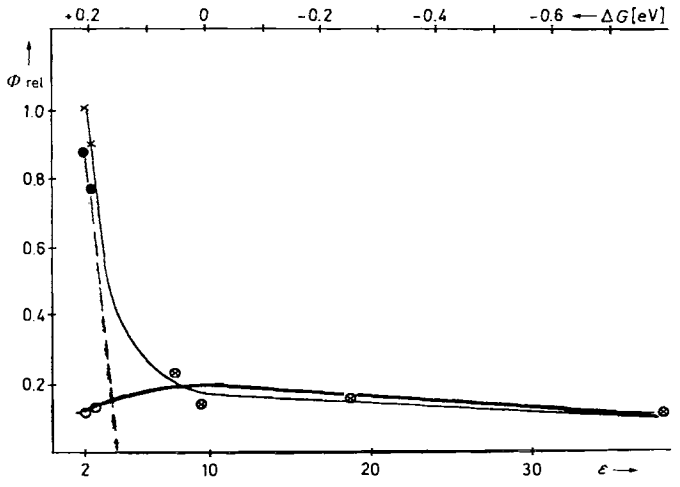

Fig. 13. Reaction selectivity (as measured by product quantum yield Φ_{rel}) as a function of the dielectric constant (ε) in the photoreaction between **13** and **15**. × = overall yield; ○ = yield of **18**; ● = yield of **8** and **9** (R = CF_3).

18 is observed. This "special" solvent effect is overlaid by the "normal" effect; i.e., the product formation is suppressed in favor of ionic photodissociation in polar media—an effect that is observed with all reactions in the exergonic region of electron transfer. The Weller equation, with the inclusion of the coulomb term [Eq. (d)], can therefore be used to control reaction selectivity.

The mechanism that best describes the relationship between photochemically induced charge transfer and the course of the reaction is shown in Figure 14. The key to the

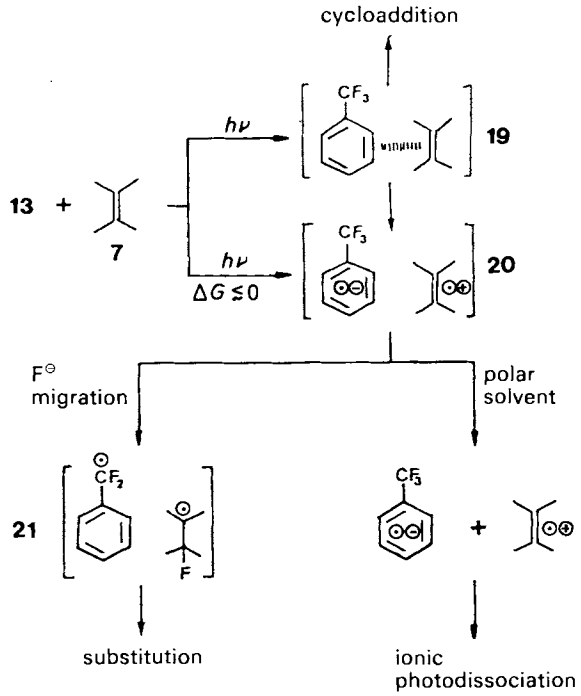

Fig. 14. Mechanism of the reactions of **13** with alkenes.

reaction is the intermediate. For $\Delta G > 0$, cycloaddition occurs via an exciplex **19**. Only when $\Delta G < 0$ is a CIP, **20**, formed; **20** either dissociates in polar media or undergoes heterolytic bond breaking to form a radical pair **21**, which in turn, finally recombines to form substitution products.

4.1.2. *Generalization of the ΔG Correlation*

Figure 15 shows the correlation between mode selectivity (substitution, *ortho* and *meta* cycloaddition) and the ΔG values for the electron transfer, as exemplified by the photoreaction of benzene **6**, R = H, with alkenes **7**.[42]

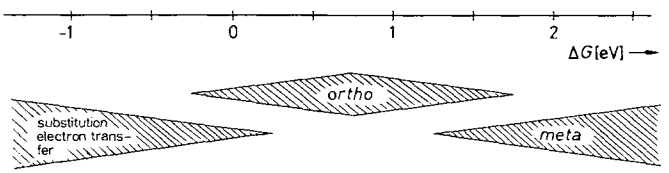

Fig. 15. Mode selectivity as a function of the free energy of electron transfer in the photoreactions of **6**, R = H, with alkenes **7**.

Relatively polar exciplexes (characterized by $\Delta G \lesssim 1.5$ eV) preferentially form *ortho* cycloadducts, while *meta* cycloaddition is mainly observed between reactants with $\Delta G \gtrsim 1.5$ eV). Similar correlations can be established for other arenes.[42] In the case of benzonitrile, for example, even cycloaddition to the nitrile group can be included. One must however always be aware of the empiri-

cal character of these correlations; i.e., their validity may be confined to only a series of related compounds.[42,43]

The classification of photocycloadditions of alkenes to arenes by means of the type of intermediate corresponding to the ΔG value also allows some connections to be drawn concerning stereo- and regioselectivity. Equation (c) can be used, for example, to determine which reagent acts as donor and which as acceptor. In many systems vinylene carbonate is an acceptor since the following relation is valid:[41-43,77]

$$\Delta G(17 = \text{A, arene} = \text{D}) < \Delta G(17 = \text{D, arene} = \text{A})$$

The electronic interactions between the components of such intermediates influence the stereochemical course of the cycloaddition in a dramatic fashion[43] (Fig. 16). Further aspects of the stereo- and regioselectivity have been discussed comprehensively elsewhere.[42,43]

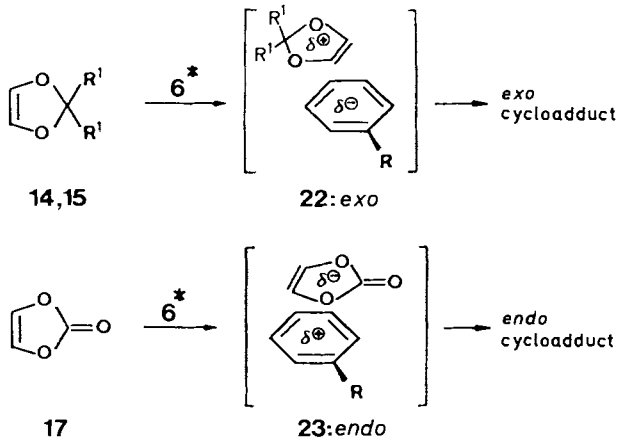

Fig. 16. Direction of electron transfer and selectivity in the photocycloadditions of 1,3-dioxole derivatives **14**, **15**, and **17** to arenes.

4.2. Photoreactions of Multiply Substituted Benzenes and Higher Arenes

The photoreactions of higher, especially acceptor-substituted, arenes with donor substrates have been investigated often. Usually, systems have been dealt with in which electron transfer is thermodynamically allowed according to Equation (c) and which accordingly yield preferentially substitution products. Some typical examples will be presented in the following discussion.

4.2.1. Reactions of Excited Acceptor Arenes

As we have already demonstrated in the case of simply substituted benzene derivatives, the substitution products are not formed by direct coupling of the radical-ion species of the contact ion pairs. In most cases the reaction occurs via a number of steps involving the heterolytic splitting off of an electrofugal or nucleofugal group and the final recombination of the radicals thus formed (exceptions include the reactions of **34** and **35** and of anthracene and *N,N*-dimethylaniline, see below). Very frequently, deprotonation of the radical cation by the radical anion is observed [Eq. (i)]. The first evidence for such a reaction was found in the 1970s by *McCullough* and co-workers[78,79] and by *Arnold* et al.[89] in the photoreactions of arene carbonitriles with alkenes as well as by *Ohashi* et al.[81] and later *Albini* et al.[82] in the corresponding reactions

$$A + DH \xrightarrow{h\nu} (A^{\ominus\ominus}DH^{\oplus\oplus}) \longrightarrow (HA^{\bullet}D^{\bullet}) \longrightarrow HA-D \qquad (i)$$

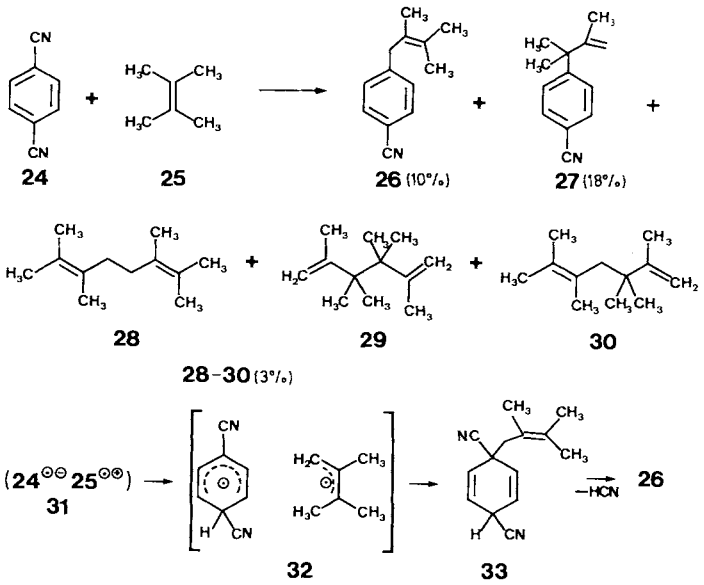

Fig. 17. Photoreaction of **24** with **25** in acetonitrile.

with alkylarenes as electron donors. Photoexcitation of terephthalodinitrile **24** in the presence of 2,3-dimethyl-2-butene **25** results in the formation of the dimerization products of **25** (**28**-**30**),[80] in addition to the substitution products **26** and **27**. The free energies calculated according to Equation (c) for radical-pair formation are -0.96 eV and thus support a mechanism involving electron and subsequent proton transfer to give **31** and **32**, respectively, as the key steps (Fig. 17). Compound **26** is presumably formed via **33**.

The corresponding reactions of 1,4-naphthalenedicarbonitrile[80] and 9-phenanthrenecarbonitrile[83] give similar results. *Mizuno*, *Otsuji* et al. were able to transform these variable-yield photosubstitution reactions into efficient allylation methods by the introduction of the trimethylsilyl group (which is easily split off as a cation) into the olefinic reagent[84,85] (Fig. 18).

Albini et al. have studied in detail the photoreactions of arenecarbonitriles with alkylbenzenes.[82,86] Also in these cases, the first step is photochemically induced electron transfer with the formation of a radical-ion pair, which

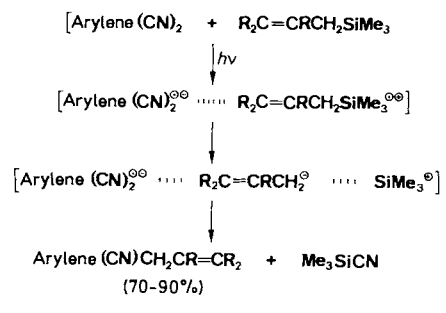

Fig. 18. Photochemical allylation of arenedicarbonitriles with allylsilanes.

then generally undergoes deprotonation and subsequent recombination of the radicals. With peralkylated toluene or dibenzyl derivatives, for which no proton transfer is possible, they even observed heterolytic fission of a C–C bond.[86] The high stereoselectivity of the addition of cumene **35** to 1,4-naphthalenedicarbonitrile **34** to give the products **36** and **37** (Fig. 19) indicates that the reactions

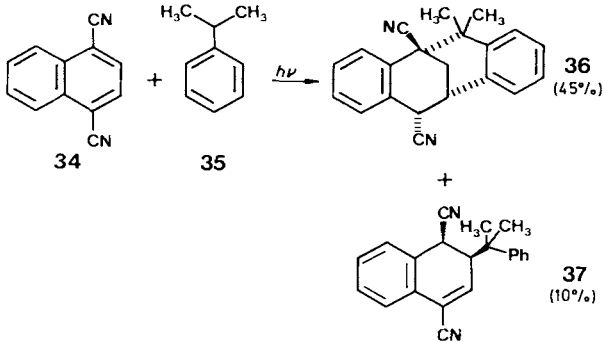

Fig. 19. Photochemical addition of **35** to **34**.

occur within the solvent cage and consequently by means of radical-ion pairs or radical pairs. Only dissociated radicals undergo the typical reactions of free and non-correlated intermediates. The ΔG values calculated by the Weller equation indicate once again that an exergonic electron transfer takes place.[87]

Because of their low oxidation potentials, amines are often used as donor components in photochemical electron-transfer reactions (see also Section 4.3) and also in reactions with excited acceptor arenes. For example, electronically excited anthracene reacts with *N,N*-dimethylaniline, by direct coupling of the radical ions, to give 9-(4′-dimethylaminophenyl)-9,10-dihydroanthracene in 70% yield along with small amounts of dimerization and H addition products.[88] In contrast, *trans*-stilbene reacts with triethylamine via a multistep series of electron and proton transfers to give disproportionation and recombination products (cage reactions) as well as symmetrical dimerization products (escape reactions).[89]

4.2.2. Reactions of Excited Donor Arenes

In 1974 *McCullough* et al.[90] reported on the photoreactions of naphthalene **38** with acrylonitrile **39**, which gave, together with the cycloadduct **40**, the substitution products **41** (Fig. 20). In polar solvents, such as acetonitrile, the electron transfer should, according to Equation (c), be thermodynamically allowed (for the redox potentials and excitation energies, see Refs. [42, 90]). Here again one can assume the formation of an ion pair followed by a proton transfer to the acrylonitrile radical anion (either from the solvent or, with other donor arenes such as indene, from the corresponding radical cation). This assumption is supported by the catalytic effect of protic solvents and isotopic labeling experiments.[90] For weaker donors, such as anthracene and phenanthrene, the electron transfer is endergonic and hence no substitution products are formed.[91]

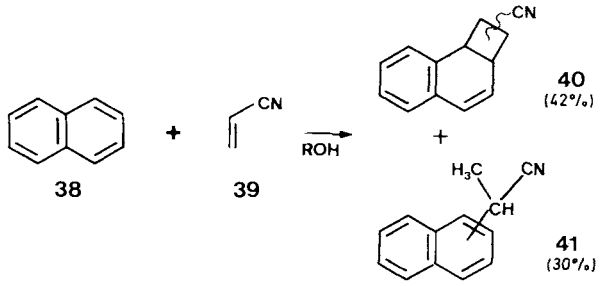

Fig. 20. Cycloaddition and substitution in the photoreaction of **38** with **39**.

Kochi, Rentzepis et al. have carried out comprehensive studies on the role of ion pairs in the photoreactions of CT complexes.[92,93] Irradiation in the long-wavelength absorption bands of CT complexes of 9-substituted anthracenes **42** and tetranitromethane **43** results, in accordance with the Mulliken theory,[95] in a fast electron transfer ($t < 25$ ps) with the formation of a radical-ion pair. Within a few ps the tetranitromethylide fragments. Ionic and radical coupling follow in two slower steps to form **44** and the final product **45**, respectively (Fig. 21). The corresponding steps apply to the nitration of methoxybenzenes[96] and alkenes.[94]

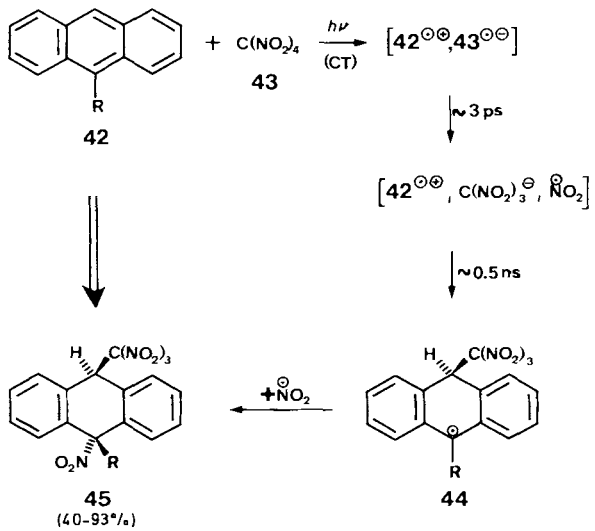

Fig. 21. Ionic coupling within a contact ion pair and radical coupling via free radicals in the photoreactions of **42** and **43**.

With tetracyanoethylene (TCNE), the anthracenes **42** form no products.[93] Transient analyses in the ps region, however, clearly show the formation of ion pairs. A proton transfer from $\mathbf{42}^{\odot\oplus}$ to $TCNE^{\odot\ominus}$ or the formation of Diels–Alder dimers apparently cannot compete with the rapid back transfer of electrons. On the other hand, the system **38**/*N*-methyldihydrotriazoledione is reactive: *Sheridan* et al.[97] were able to show, however, that here the long-wavelength-absorbing alkene component was excited and formed, from the triplet or singlet state, a contact ion pair with **38** as donor. This gave a Diels–Alder adduct in 40% yield. The same photochemical Diels–Alder reaction was observed when the CT complex was directly excited.

Sundberg has a reported, in a comprehensive review,[99] on chloroacetamide cyclization in aromatic systems in

which the initiating step is a photochemically induced electron transfer and which, in other variations, leads to lactam formation.

4.3. Photoreactions of Carbonyl Compounds with Alkenes, Alkylbenzenes, and Amines

The photoreactions of carbonyl compounds have been studied in detail since the early days of photochemistry.[99,100] In particular, the [2+2] cycloaddition with alkenes, which leads to oxetanes **48** (Paterno-Büchi reaction), has assumed great synthetic importance[100-102] although, depending on the substituents, a number of by-products (**46**, **47**, **49**, **50**) can be formed (Fig. 22).

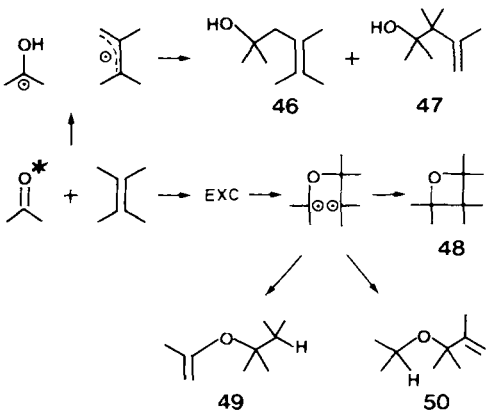

Fig. 22. Products of photoreactions of ketones with alkenes.

In general, the exciplex-diradical mechanism[100] is used to explain the reaction behavior of simple alkenes. However, owing to the ready accessibility of very electron-rich alkenes such as **2**, **14**, and **15**, electron-transfer processes have recently been shown to occur as well.[40,44,45,49] Whereas with "normal" alkenes a large number of products are often observed[100] (Fig. 22), the photochemically induced electron transfer can act as a "regulator" for reactions with electron-rich alkenes. Upon photoexcitation, biacetyl **54** reacts with ketene acetal **53** to form exclusively the oxetane **51**.[45,49] Trapping experiments with the radical cation $\mathbf{53}^{\odot\oplus}$ indicate an electron transfer as the primary photochemical step. The components of the contact ion pair, which show high spin densities at their radical centers, recombine through the radical positions to form first a zwitterion **59** and then **51** (the most important resonance structures of the radical ions taking part are given in Fig. 23). Since **53** and **54** also undergo an aldol-type cycloaddition (via dipolar intermediates) to give the other regioisomeric oxetane **52**,[49,103] the reaction here involves "umpolung" of the reactivity of a carbonyl group by means of photochemically induced electron transfer.[49]

The extremely electron-rich alkenes **2** and **55** show another type of reaction behavior. Because of the allylic hydrogen, $\mathbf{2}^{\odot\oplus}$ and $\mathbf{55}^{\odot\oplus}$, respectively, are deprotonated by $\mathbf{54}^{\odot\ominus}$ with the formation of a radical pair, which then recombines to give the reaction products **57** and **58** [see also Eq. (i)].[40,45] The dependence of the ratio (**57** + **58**) : **56** on

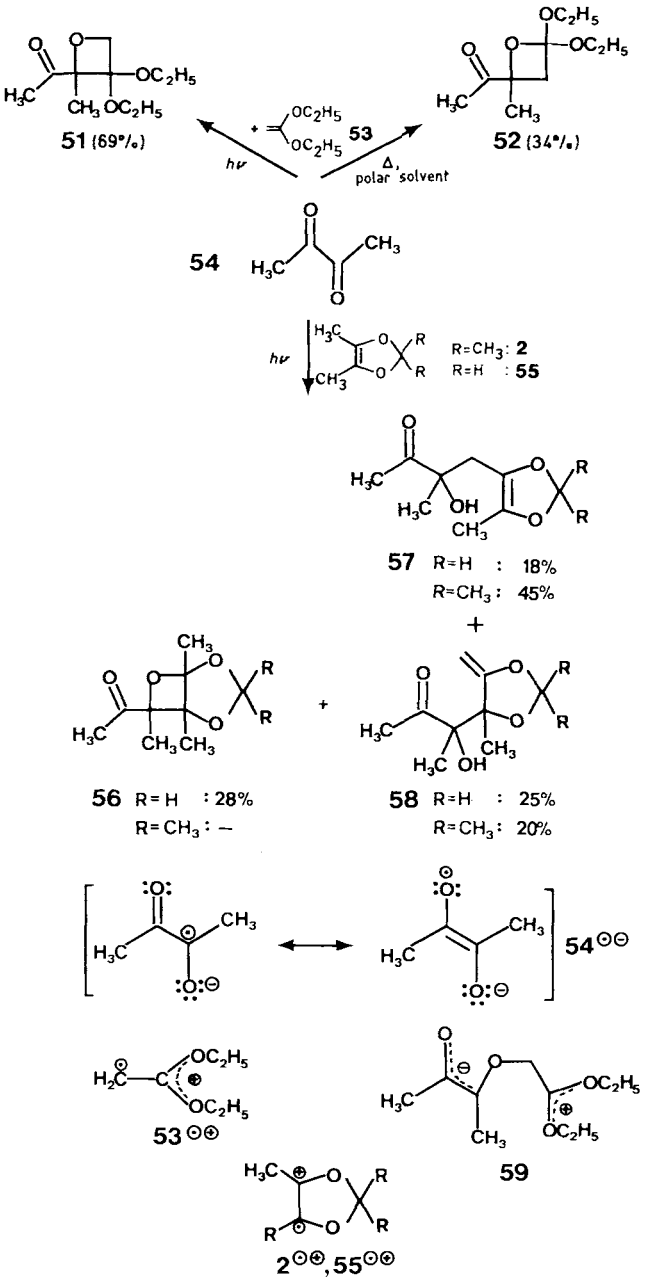

Fig. 23. Photoreactions of **54** with electron-rich alkenes.

the oxidation potential of the alkene and transient analysis investigations by means of ESR spectroscopy support this extended mechanism for the photoreactions between carbonyl compounds and alkenes.[40,45]

In an article summarizing recent results, *Wagner* et al.[104] have described the influence of charge transfer on the photoreactions of phenyl ketones with alkyl benzenes as donors. The ketones react via both the $n\pi^*$ and the $\pi\pi^*$ states by means of a CT mechanism in which the extent of the charge and electron transfer is determined by the electrochemical redox potentials of the species involved. Although $n\pi^*$ and $\pi\pi^*$ states are the same in this respect, they show different reaction behaviors because of the different structures of the exciplexes involved. In addition, H abstraction (the initiating step in the formation of a photoreduction product) can change from a one-step (H transfer) to a two-step ($e^{\ominus}$ and $H^{\oplus}$ transfer) mechanism (cf. the

photoreactions of **54** with **2** and **55**, Fig. 23, and Refs. [40, 45]).

Amines have also been used as powerful electron donors in photoreactions with ketones. An early example[105,106] is shown in Equation (j). *Seebach* et al.[107] were able to use

$$Ph_2CO + H_2NCH_3 \xrightarrow{h\nu} [Ph_2CO^{\ominus\ominus}H_2NCH_3^{\oplus\oplus}] \longrightarrow [Ph_2\overset{\ominus}{C}OH\ H\overset{\oplus}{N}CH_3] \longrightarrow Ph_2C(OH)C(OH)CPh_2 + HNCH_2 \quad (j)$$

this method for an asymmetric photopinacol reaction. The involvement of contact ion pairs was examined in detail by *Peters* et al.[108] The preparative applications of this reaction have been discussed elsewhere.[24,106]

Quinones are powerful oxidizing agents, particularly after photoexcitation, and their reactions have been frequently described.[100,109] Here, the photoreactions of 1,4-naphthoquinones **60** with 1,1-diarylethenes, such as **61**, should be briefly mentioned, since a direct dependence of the course of the reaction on the ΔG values of the electron transfer similar to that found in the case of α,α,α-trifluorotoluene (Section 4.1.1) has been observed (Fig. 24).[110]

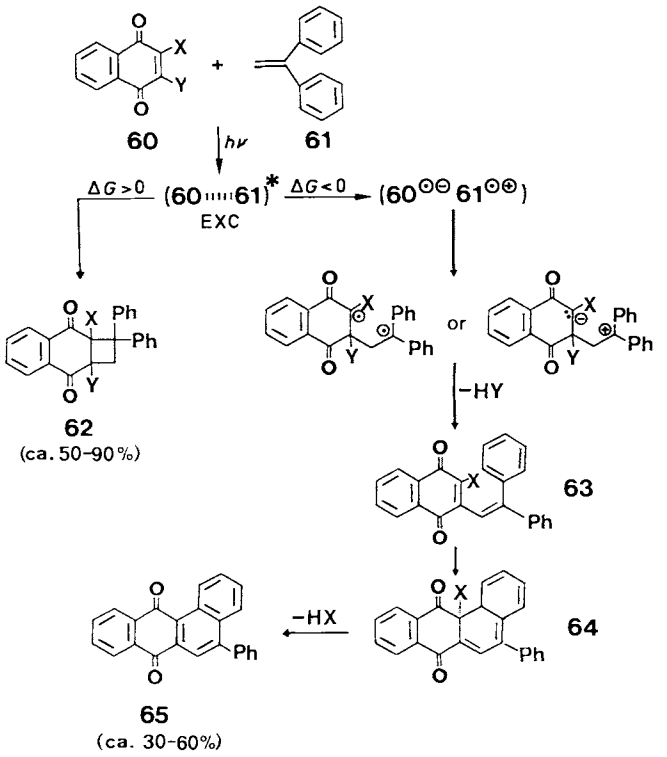

Fig. 24. Charge transfer and the course of reaction in photoreactions of **60** with 1,1-diphenylethene **61**.

Electronically excited naphthoquinones **60** form two types of products with 1,1-diarylethenes of type **61**. The cyclobutanes **62** are formed only when electron transfer is endergonic according to Equation (c), probably via exciplex intermediates. For thermodynamically allowed electron transfer, one observes the formation of the ethene adducts **63** exclusively. The presumed intermediacy of contact ion pairs and diradicals or zwitterions is supported by CIDNP studies. A subsequent photoreaction, via **64**, makes physiologically interesting benz[*a*]anthraquinones such as **65** available by means of this route.

4.4. Photoreactions of Phthalimides

Besides ketones, other carbonyl compounds such as carboxylic acids and their derivatives are of photochemical interest.[111-114] We will restrict ourselves here to the photoreactions of *N*-methylphthalimides **66** with alkenes **7**; the selectivity of these reactions is similarly determined by charge transfer (from the alkene to the imide) and the products are of synthetic interest.

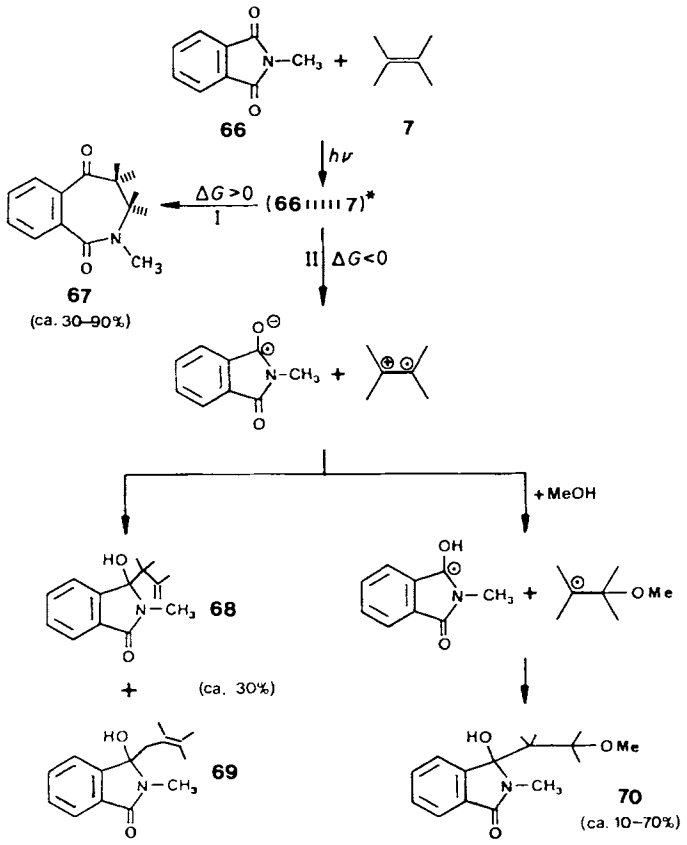

Fig. 25. Addition and reduction in the photoreactions of **66** with alkenes **7**.

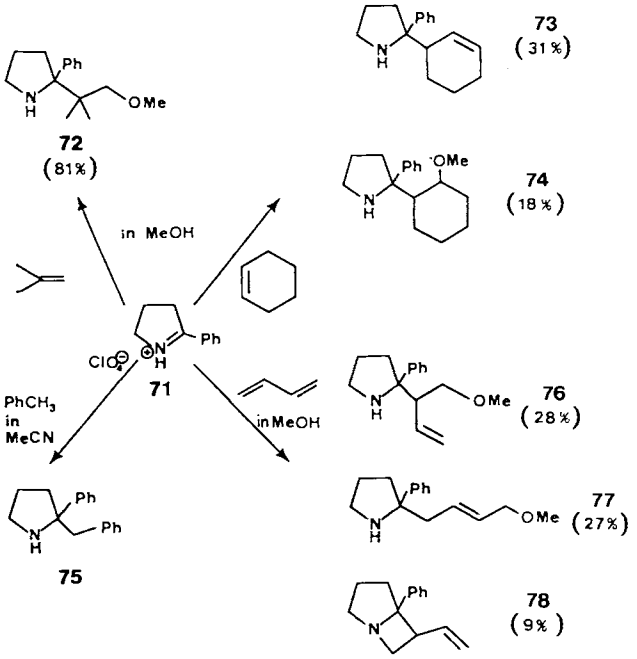
In their fundamental work, *Mazzocchi* et al.[115] investigated the photoreactions of **66** with various alkenes **7**. Two types of reaction were observed (Fig. 25); the regio- and stereospecific addition of the alkenes to a carbonyl group of **66** with ring expansion to the dihydrobenzazepinediones **67**[116] (I) and the photoreduction to **68** and **69**, which, in the presence of methanol, leads to **70**[115] (II). The ΔG values, calculated according to Equation (c), clearly demonstrate the regulatory effect of electron transfer: in the endergonic region only the $(\sigma^2+\pi^2)$ addition (I) was observed and in the exergonic region only the photoreduction (II). Trapping experiments with methanol as a nucleophile confirmed the existence of radical-ion intermediates. Only recently have *Mazzocchi* et al. been able to show, with intramolecular systems, that, here too, a direct coupling of the radical ions of the contact ion pair is possible through their radical centers.[117] The synthetic potential of such intramolecular reactions, which produce annelated dihydrobenzazepinediones or macrocyclic spiro com-

pounds, has recently been demonstrated by *Kubo* et al.[118] and *Machida* et al.[119] Other synthetic applications have been described in reviews by *Kanaoka*,[112] *Mazzocchi*,[113] and *Coyle*.[114]

4.5. Photoreactions of Alkylideneammonium Salts

Alkylideneammonium salts such as **71** are powerful electron acceptors even in their ground states. This property should be enhanced in the excited state. Indeed, photochemical electron-transfer processes have even been observed with simple alkenes;[120] they lead to products such as **72**–**78**.

In Figure 26, the probable mechanism is shown; the initiating step is the transfer of an electron from a donor molecule to an alkylideneammonium salt **71** with the formation of an α-aminoradical–radical-cation pair. This recombines either directly through the radical positions or after trapping of the radical cation by nucleophiles (e.g., methanol). The values of ΔG for the electron transfer, calculated



mechanism:

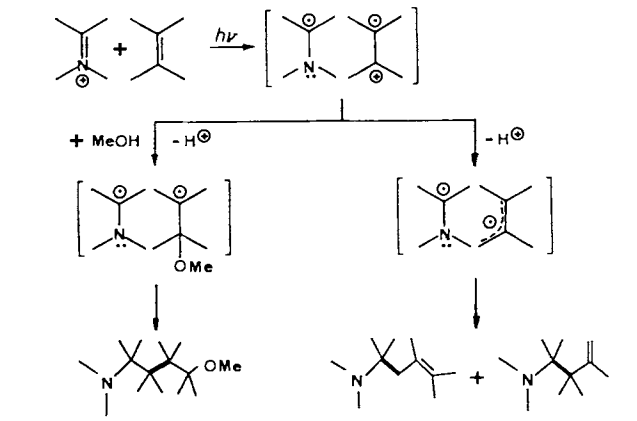


Fig. 26. Photoreactions of alkylideneammonium

from Equation (c), can once again be used as a criterion for the course of the reaction.[120, 121]

This method gives access to a large variety of *N*-heterocycles.[24, 120] The synthetic potential of the already widely used alkylideneammonium salts is thereby enormously increased (see, for example, Refs. [122–124]).

As has already been shown in Section 4.2.1, suitably substituted radical cations can easily split off electrofugal groups with the formation of a radical; the simplest case is deprotonation [see Eq. (i)]. *Mariano* et al. were able to transform this procedure into an efficient method for the allylation of alkylideneammonium salts by means of allylsilanes.[125] An intramolecular variant of this method to form structural units of the isoquinoline alkaloids is shown in Figure 27.[126]

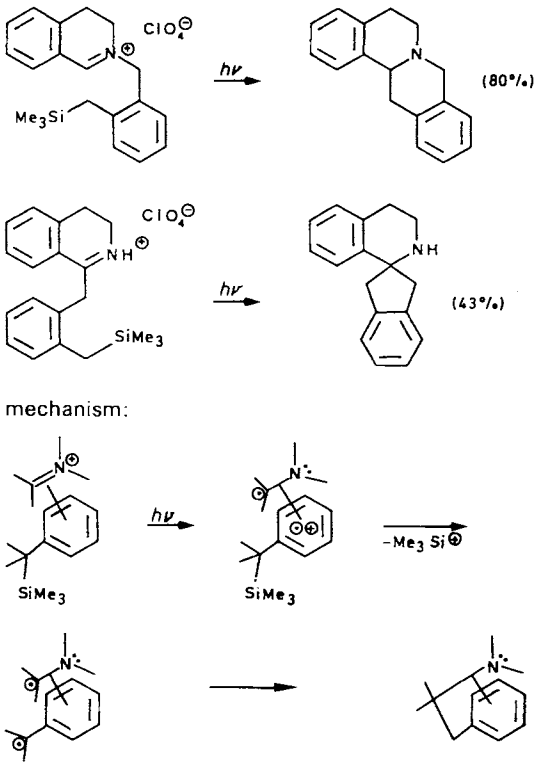

Fig. 27. "Diradical cyclization method" for the synthesis of isoquinoline alkaloid building blocks.

5. Reactions of the Radical Cations of Alkenes and Dienes

In polar solvents the components of a contact ion pair can be "separated" by solvation to form either a solvent-separated radical-ion pair or free radical ions. This process may be enhanced by the salt effect; in some cases the lifetime and the yield can be greatly increased by ion-exchange reactions [special salt effect: see also Section 3.2 and Eq. (g)]. This hindering of the back electron transfer often allows, for the first time, the directed production of radical ions and thereby makes possible the study of their reactions without the involvement of the radical-ion partner, i.e., without chemical reaction [Eq. (h), Fig. 28].

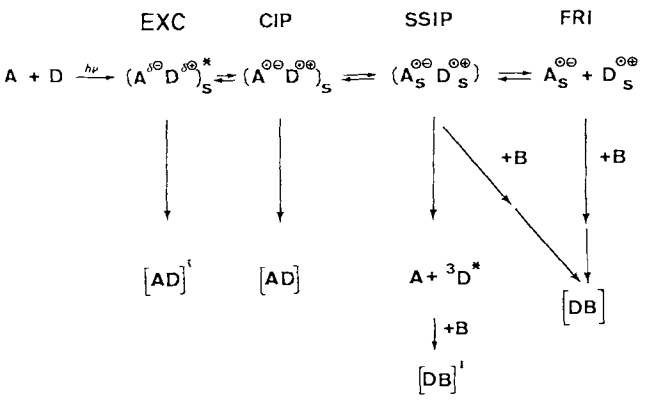

Fig. 28. Intermediates and the course of reaction in electron-transfer processes between donor and acceptor molecules. For abbreviations, see caption to Figure 4.

The following discussion will be restricted to the reactions of radical cations, in particular those of alkenes and dienes.

5.1. Dimerization and Cycloaddition

5.1.1. Reactions of Alkenes

Among the first examples of photochemically induced reactions of alkene radical cations was that of the dimerization of *N*-vinylcarbazole **79**, first discovered by *Ellinger*[127] and later thoroughly investigated by *Ledwith* (Fig. 29).[128,129] The decisive steps are the oxidation of the alkene to a radical cation **79a**$^{\odot\oplus}$ by electron acceptors such as *p*-chloranil **4** or halogenated aromatic ketones (primary electron transfer) and the reduction of an acyclic radical-ionic dimer **80a** or a cyclobutane radical ion **81a**$^{\odot\oplus}$ (secondary electron transfer). Since the quantum yield in these reactions is greater than 100% (maximum value of Φ: 66), a chain reaction is involved (I in Fig. 30) in which the secondary transfer takes place from monomer **79a** to the dimer **80a** or **81a**$^{\odot\oplus}$. The same is true for the enol ether **79b** and the aryl derivative **79c**, although here, because of the lower quantum yield, the chain length must be less.[132] A detailed analysis of the kinetics and thermodynamics of the elementary processes can be found in *Evans* et al.[132]

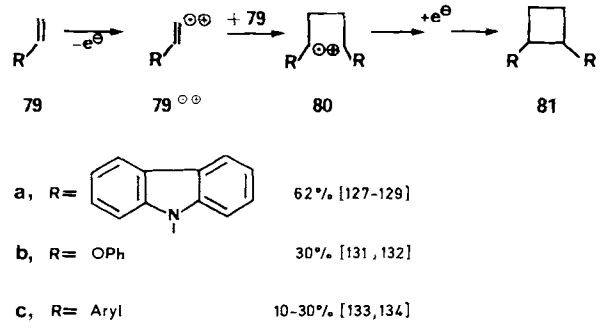

Fig. 29. Dimerization of alkenes via radical cations.

Other dimerizations have been described by *Farid* et al.,[130] *Arnold* et al.,[135] *Pac* et al.,[136,137] and others.[23,24] The regioselectivity of these reactions is generally greater than that of the corresponding triplet reactions involving diradical intermediates, which mostly yield mixtures of regioisomers.[23] Differences in the stereoselectivity have also been observed: for example, 1,3-dioxole **15** dimerizes in an energy-transfer reaction under triplet conditions to give a mixture of *endo*- and *exo*-bis(methylenedioxy)cyclobutanes in the ratio 0.6 : 1,[38] whereas, in a reaction via **15**$^{\odot\oplus}$, the stereoisomer ratio becomes *endo* : *exo* = 1.5 : 1.[51,56] Another mechanism has also been discussed which one can call "electron-transfer sensitization"[138] (II in Fig. 30). Here, the secondary electron transfer takes place between the product radical cation and the radical anion of the acceptor. Since the acceptor is thereby regenerated, it can also be viewed as the sensitizer (Sens in Fig. 30). This mechanism plays a role in many electron-transfer reactions, often in modified form such as the so-called "triplex mechanism."[39,137,139] Quantum yields below 100% are a necessary but not sufficient criterion for mechanism II, since, because of the complex kinetics, a single inefficient elementary process can drastically reduce the quantum yield in mechanism I. Comparison experiments should therefore be carried out with thermal electron acceptors, e.g., ammoniumyl salts $R_3N^{\odot\oplus}X^{\ominus}$,[129,140] for which a chain process is clearly involved. A further criterion in the case

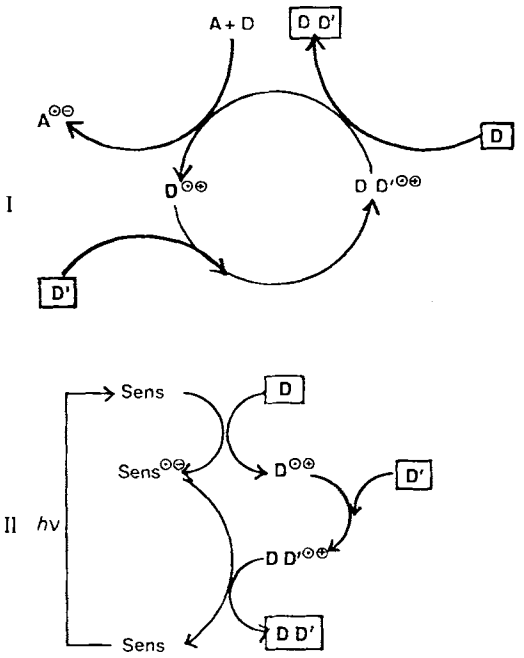

Fig. 30. Chain mechanism (I) and electron-transfer sensitization (II) in radical-cation-catalyzed reactions.

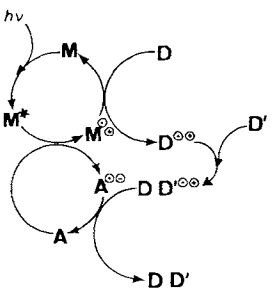

Fig. 31. Redox photosensitization according to *Pac* et al. [136] (M = mediator for "hole transfer," e.g., phenanthrene).

of mechanism I would be chain initiation by means of an independently generated intermediate (for example, by electrolysis).

In some cases the efficiency of the dimerization of alkenes by means of radical cations can be increased by the use of a mediator ("hole transfer"). This mechanism has been investigated by several Japanese groups[136, 141-143] and, according to *Pac* et al.,[136] can be classified as "redox photosensitization" (Fig. 31)—cf. also Ref. [137].

In a fundamental study, *Farid* et al.[144] demonstrated the different reactivities of radical-ion pairs and free radical ions in the dimerization of 1,1-diphenylethene **61** to give the cyclobutane **84** and the "(4+2) dimer" **87** (Fig. 32).

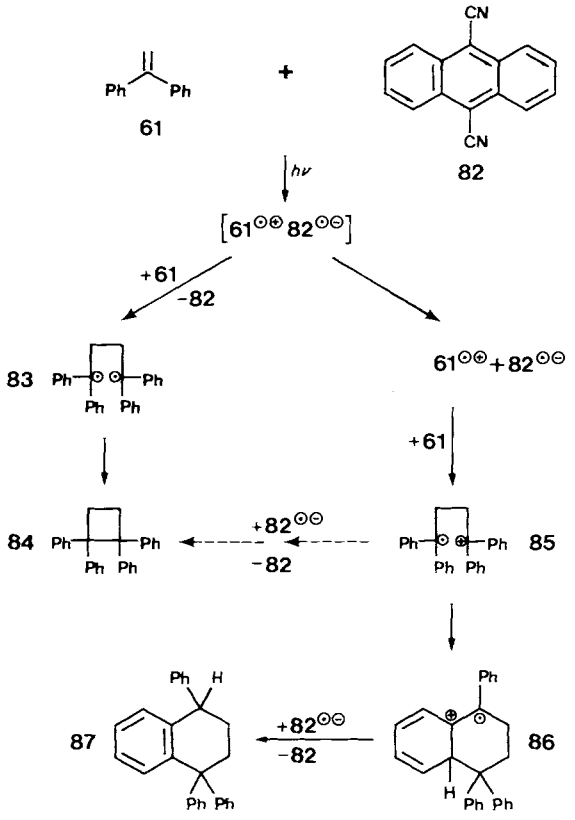

Fig. 32. Electron-transfer-sensitized dimerization of **61** via radical-ion pairs or free radicals to give **84** or [4+2] dimers **87**, respectively.

The initially formed contact ion pair [**61**$^{\odot\oplus}$**82**$^{\odot\ominus}$] reacts further, by the formation of a C–C bond with a neutral alkene **61** and subsequent back electron transfer, to give the 1,4-diradical **83**, which cyclizes to give **84**. This course of reaction largely parallels the triplex mechanism.[39, 137, 139] If, on the other hand, the radical-ion pairs are separated by solvation, the reaction takes a totally different course. In this case, reaction of **61** gives an acyclic radical-cation adduct, **85**, which, because of its longer life, cyclizes to give first the radical-ionic [4+2] dimer **86** and then **87** by means of back electron transfer. Concentration-dependence experiments (higher concentrations of **61** favor the cage reaction giving **84**) and quenching experiments with radical-cation traps support this mechanism.

After the first radical-cation-catalyzed dimerizations of alkenes, there soon followed examples of mixed cycloadditions.[130, 145, 146] A decisive criterion for selectivity is the specific oxidation of only one of the reaction species (Fig. 33), which can be easily accomplished by means of Equation (c). In the most favorable case, the conditions of Equation (k) should apply; i.e., only the oxidation of D

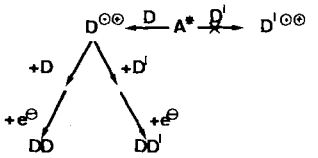

Fig. 33. Possible reaction paths in radical-cation-catalyzed reactions between various donor compounds when only one reactant is oxidized, i.e., when Equations (k) and (l) are satisfied.

$$\Delta G(A^{\odot\ominus}D^{\odot\oplus}) < O < \Delta G(A^{\odot\ominus}D'^{\odot\oplus}) \quad (k)$$

should be thermodynamically allowed. With a sufficiently high concentration of the reaction species D', it is often possible to suppress the undesired dimerization to DD. In the less favorable case, i.e., when both reacting species can undergo oxidation (only Equation (l) is valid), the dimerization to DD can at least be minimized by the optimal choice of concentrations[146] (see also Section 5.1.2). Since the reactions occur via several steps, the course of the reaction can be influenced by other effects, e.g., stabilization of acyclic intermediates by appropriate substituents, the effects of counterion, or even other mechanisms (cf. Section 5.1.2).

$$E^{ox}_{1/2}(D) < E^{ox}_{1/2}(D') \quad (l)$$

5.1.2. Reactions of Dienes (Diels–Alder Reactions)

One of the most important reactions of dienes is the Diels–Alder reaction.[147] Its scope of application, however, is limited by one of the fundamental rules of thermal $(4\pi+2\pi)$ cycloadditions: namely, a sufficiently high reaction rate is only achieved if the frontier orbitals of the starting materials (HOMO and LUMO) are energetically close.[147-149] Such ideal conditions are not always fulfilled, and there has therefore been no lack of attempts to find improvements for Diels–Alder reactions that yield poor results. Examples include reactions under high-pressure conditions,[150-152] catalysis by Lewis acids,[153-155] and the exploitation of the hydrophobic effect for reactions in aqueous media.[156, 157]

A further approach makes use of the following principle: oxidation of one of the reacting species results in an increase in the frontier-orbital interaction, which should in turn lead to an acceleration of the Diels–Alder reaction. As *Freeman* et al.[167b] and *Hammond* et al.[167c] have shown, the radiation-induced dimerization of cyclohexadiene, reported by *Schenck* et al.,[167a] can be explained in this way. A similar effect was also observed by *Mizuno* et al.[158] in the Diels–Alder reaction of furan with indene in the presence of naphthalenecarbonitriles as photochemical electron acceptors; this reaction probably occurs by means of mechanism II (Fig. 30). Later, *Bauld* et al.[159] applied this principle to thermal electron acceptors and coined the term "cation-radical catalyzed Diels–Alder reaction"; this

reaction is based on a chain mechanism (Fig. 30, I). According to theoretical considerations, the radical-cation-catalyzed Diels–Alder reaction should obey the "principle of role selectivity," which states that the cycloaddition ockurs preferably by means of the radical cation of the dienophile.[160] Since then, many groups have concerned themselves with this problem. Although no comprehensive picture has yet emerged, some of the mechanistic aspects will be dealt with here since they are directly related to the subject of this review (cf. Section 3).

The dimerization of simple dienes to Diels–Alder adducts via photochemically generated radical cations does not usually present any great difficulties as long as the diene is oxidizable, which, in turn, can be estimated from Equation (c). One exception is 2-acetoxy-1,3-cyclohexadiene (see Fig. 39 and accompanying text). Various acceptors have been used: arenecarbonitriles,[139, 161, 162] ketones and quinones in the presence of lithium perchlorate (special salt effect),[61, 65, 162–164] and pyrylium salts.[61, 65, 162–165]

The dimerization of 1,3-cyclohexadiene **88** has been investigated under various conditions (Fig. 34, Table 4). Under thermal conditions, in spite of long reaction times, the [4+2] dimers **89** and **90** are formed only in poor yield.[166, 167] The dimerization is only better under high-pressure conditions (up to 7 kbar); however, the cyclobutane adducts **91** and **92** as well as some acyclic dimers, formed by nonconcerted processes, are also produced.[168] The dimerization by means of radical-cation catalysis, on the other hand, occurs very efficiently to give, preferentially, the Diels–Alder adducts **89** and **90**.[61, 65, 139, 159, 162–165]

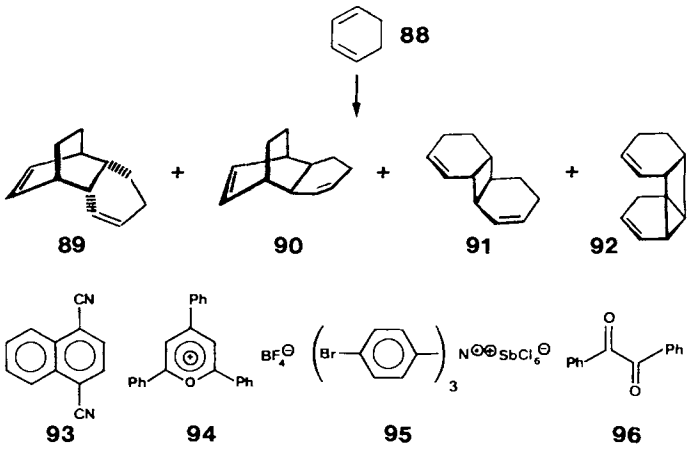

Fig. 34. Dimerization of **88** under thermal conditions and energy- and electron-transfer conditions. **93–96**: electron-acceptor molecules. See also Table 4.

Here, it is unimportant whether one employs thermal acceptors via a chain mechanism (Table 4, No. 8) or whether one uses photochemical acceptors (Nos. 5–7). Only the stereoselectivity (*endo/exo* ratio) changes, which indicates that different mechanisms are operating. It should be noted that the dimerization under energy-transfer conditions yields mainly the cyclobutane adducts **91** and **92** (No. 2, 3).[139, 166, 167]

The question of the validity of the "role selectivity" of radical-cation-catalyzed Diels–Alder reactions cannot be answered by product studies of the dimerization of dienes. For example, the mixed cycloaddition between **88** and 1,3-dioxole **15** provided clear evidence that the Diels–Alder reaction can take place via either the radical cation of the dienophile (here **15**) or the radical cation of the diene (here **88**).[162] Whereas the reaction via $\mathbf{15}^{\odot\oplus}$ forms the *endo* isomer **97** preferentially, both reaction paths are almost equally important in the corresponding cycloaddition via $\mathbf{88}^{\odot\oplus}$ (Fig. 35).

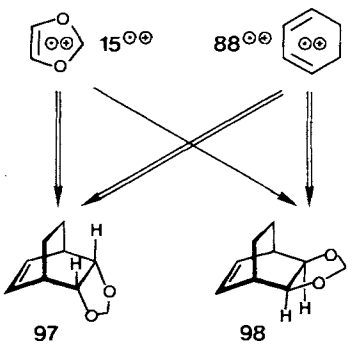

Fig. 35. Reaction paths in the radical-cation-catalyzed Diels–Alder reaction between **88** and **15** (⇒ preferred, → less preferred).

This shows at least that the cycloaddition via the diene radical cation cannot be concerted. The results obtained for the reactions between furan **99** and indene **100**[158, 163] or 1,4-dioxene **103**[163] confirm a multistep mechanism in which the cycloadduct **101** as well as the substitution products **102** and **104** are formed via acyclic radical-ion intermediates (Fig. 36).

Other authors have also found clear evidence for a multistep mechanism: *Gross* et al.[169] in the case of the dimerization of 1,3-butadiene to 4-vinylcyclohexene in the gas phase, which he investigated by means of the collision-activated decomposition (CAD) method in a tandem mass spectrometer; and recently *Roth* et al.[179] in the case of the

dimerization of spiro[2.4]heptadiene in solution, which he studied by means of CIDNP techniques.

We have observed different selectivities for contact ion pairs, on the one hand, and solvent-separated ion pairs or free radical ions, on the other hand, in the dimerization of 1,3-cyclohexadienes.[163] A high concentration of the diene and the absence of salts favor the formation of both the cyclobutanes **91** and **92** and the *exo* Diels–Alder adduct **90** even in polar solvents (20% conversion, I in Fig. 37). Addition of lithium perchlorate or a low concentration of the diene, however, result in preferential formation of the *endo* Diels–Alder adduct **89** (II in Fig. 37).

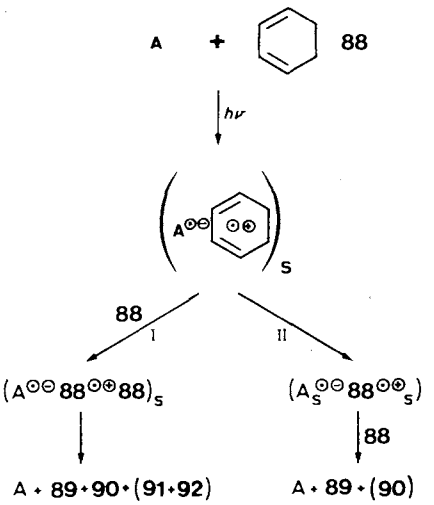

Fig. 37. Dimerization of **88** via contact ion pairs (exciplexes) (I) or via solvated radical ions (II). A: **4** and **93** ($LiClO_4$), **94**; main product **89**.

These effects are even more pronounced in the dimerization of 1-acetoxy-1,3-cyclohexadiene to the corresponding [2+2] and [4+2] adducts. Quenching experiments using 1,2,4-trimethoxybenzene (TMB, $E^{ox}_{1/2} = 0.82$ V versus Ag/$AgNO_3$ in CH_3CN[163]) and methanol confirm our assumption of the involvement of differently solvated radical-ion pairs: both TMB and methanol efficiently quench the type-II reaction but affect the type-I reaction involving contact ion pairs (or exciplexes according to *Weller*, cf. Section 2.2) far less. We have observed similar effects in the dimerization of 1-acetoxy-1,3-cyclohexadiene.

The mechanism described here for the dimerization of dienes via photochemically induced charge transfer resembles the one proposed by *Farid* et al.[144] for the dimerization of 1,1-diphenylethene **61**.[144] Whether so-called triplex intermediates are involved in this case, as suggested by *Schuster* et al.,[139] cannot be decided at present. We also observed the involvement of ternary complexes, in a different context,[39] either as reactive intermediates or simply as transition states; such complexes therefore appear to have general significance in photochemistry.[33, 137, 139, 144]

The stereoselectivity in radical-cation-catalyzed Diels–Alder reactions can also be influenced in other ways, e.g., by the choice of the acceptor (Fig. 38, Table 5). The radi-

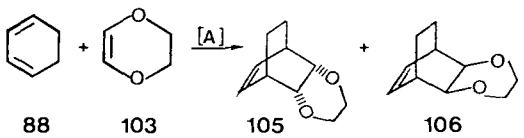

Fig. 38. Diels–Alder reaction between **88** and **103**.

Table 5. Influence of acceptor on the product ratio in the reaction of **88** with **103**.

A	Method	105 : 106	Yield [%]
95	Δ	2 : 1	29% (+40% **89** + **90**)
94	$h\nu$, S_1	10 : 1	29% (+50% **89** + **90**)

cal-cation chain mechanism in the presence of **95** shows only a small *endo* selectivity to form **105**; the selectivity is increased by the use of the photochemical electron acceptor **94** (under singlet conditions). Here, also, an electron-transfer process is probably involved, as is shown by quenching experiments with 1,2,4-trimethoxybenzene,[163, 171] which, because of its low oxidation potential (see above) can trap radical-cation intermediates. On the other hand, a smaller *endo* selectivity is observed under triplet conditions with chloranil **4** as sensitizer. Whether in this case a Diels–Alder reaction via energy transfer is operating or whether contact ion pairs are involved, as we have observed in the dimerization of 1,3-cyclohexadiene (see Fig. 37 and accompanying text), is not yet known.

Although the radical-cation-catalyzed Diels–Alder reaction can take place via various reaction mechanisms, whose relationships are not yet fully understood, radical-cation catalysis offers a new possibility for influencing selectivity and, in addition, often makes it possible to carry out, for the first time, reactions that are impossible under thermal conditions. For example, no Diels–Alder addition occurs between **88** and **103** (Fig. 38) even under high pressure.[172]

Also noteworthy is the so-called triplex mechanism,[39, 137, 139] which could, in the future, offer a further

method of directing selectivity: here, a highly polar exciplex, which does not dissociate in nonpolar solvents into radical ions, is trapped by a second donor molecule with the formation of the product [possibly via a ternary complex as reactive intermediate, see Eq. (m)]. Such exciplexes

$$A + D \xrightarrow{h\nu} [A\cdots D]^* \xrightarrow{D'} [A\cdots D\cdots D']^* \longrightarrow A + DD' \qquad (m)$$

are characterized by relatively strong bonding energies (up to 80 kJ mol^{-1}), a marked CT character (cf. Section 3.1), and a high dipole moment.[33, 39, 175, 176] They are often structured, as, for example, our studies in the field of arene photochemistry have shown, and have a decisive influence on the course of the reaction.[43] By this means it should be possible, even for the [2+2] and [4+2] cycloadditions, to make use of the different diastereomeric interactions in the exciplex formation to direct the reaction. Recently *Lemaire* et al.[177] reported very successful applications—using charge-transfer complexes, however.

Further cycloadditions of 1,3-cyclohexadienes have been investigated by *Bauld* et al.[173] and *Steckhan* et al.[165] as well as in our own laboratory[61, 163, 164, 174] with special emphasis on the correlation between substitution and mechanism, on the one hand, and efficiency and selectivity, on the other. 1-Acetoxy-1,3-cyclohexadiene **107** dimerizes, with high efficiency, to give the Diels-Alder adducts **109** and **110** (A = **94**, 47%; A = **4**, 63%). In contrast, the corresponding reaction of the isomer **111** proceeds very unselectively and in low yield, affording products similar to those obtained in the triplet-sensitized reaction (energy-transfer conditions) (Fig. 39). Assuming a multistep mechanism, a substituent at position 1 of the allylic unit (**108**) stabilizes acyclic radical-ion intermediates more efficiently than one in position 2 (**112**). Consequently, the cycloaddition of **111** and **103** to form the Diels-Alder adducts **114** and **115** (yield: 45%) now competes efficiently with the dimerization of **111**. The carboxonium ion structure of the intermediate **113** apparently favors this mixed reaction.

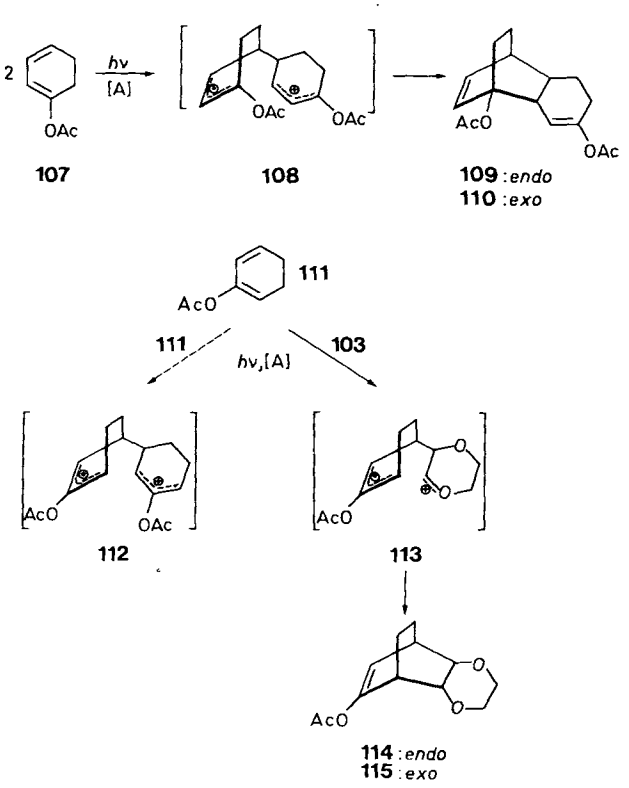

Fig. 39. Dimerizations and cycloadditions of **107** and **111**. A: **1** ($LiClO_4$), **4** ($LiClO_4$), **93** ($LiClO_4$), **94**; main products, **109** and **114**.

5.2. Reactions with Nucleophiles

Alkene radical cations can be captured in nucleophilic solvents as neutral products. This process has been extensively investigated by *Arnold* et al. and extended to the counterpart, i.e., the reactions of the corresponding radical anions with electrophiles[135, 178] (Fig. 40). For example,

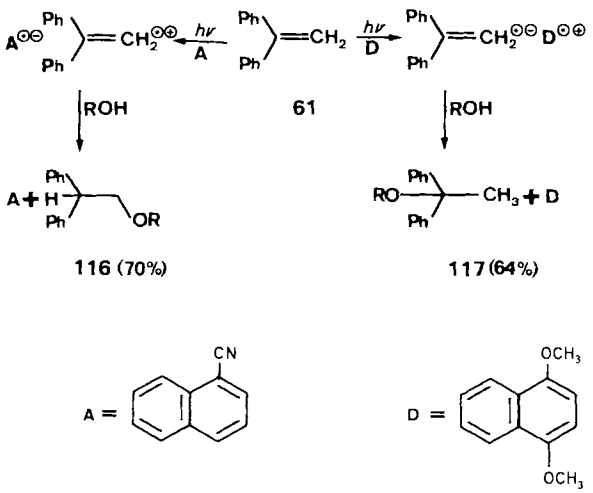

Fig. 40. Reactions of photochemically generated radical cations and anions with alcohols.

whereas the radical cation generated from **61** by electron-transfer sensitization reacts with an alcohol to give the anti-Markovnikov product **116**, the corresponding radical anion shows normal behavior, giving **117**.

Other solvents can also react as nucleophiles with alkene radical cations: e.g., the acyclic radical-ion intermediate in the dimerization of enol ethers can be captured by acetonitrile with the formation of pyridine derivatives.[132] Nitromethane acts, in addition, as an oxygen-transfer agent.[179] Finally, *Arnold* et al. applied this method to other alkene radical-cation capture reactions of synthetic interest, such as the photosensitized cyanidation of alkenes.[180] Other examples can be found in the reviews by *Farid* et al.[23] and *Mariano*.[24]

Attempts to capture radical cations with nucleophiles are not always successful. We have found differences in the reactivity of 1,3-dioxole radical cations on the one hand with $OH^{\ominus}$ and $HPO_4^{2\ominus}$ and on the other with alcohols.[51, 181] Whereas the charged nucleophiles reacted, in part, with the radical cations to form neutral products, this did not occur with alcohols. Although *Arnold* et al. were successful in similar experiments[80, 178] and thus clearly conflicting results have been obtained, there is an interesting parallel between our results and the theoretical considerations of *Pross*.[182] According to the latter, a direct attack

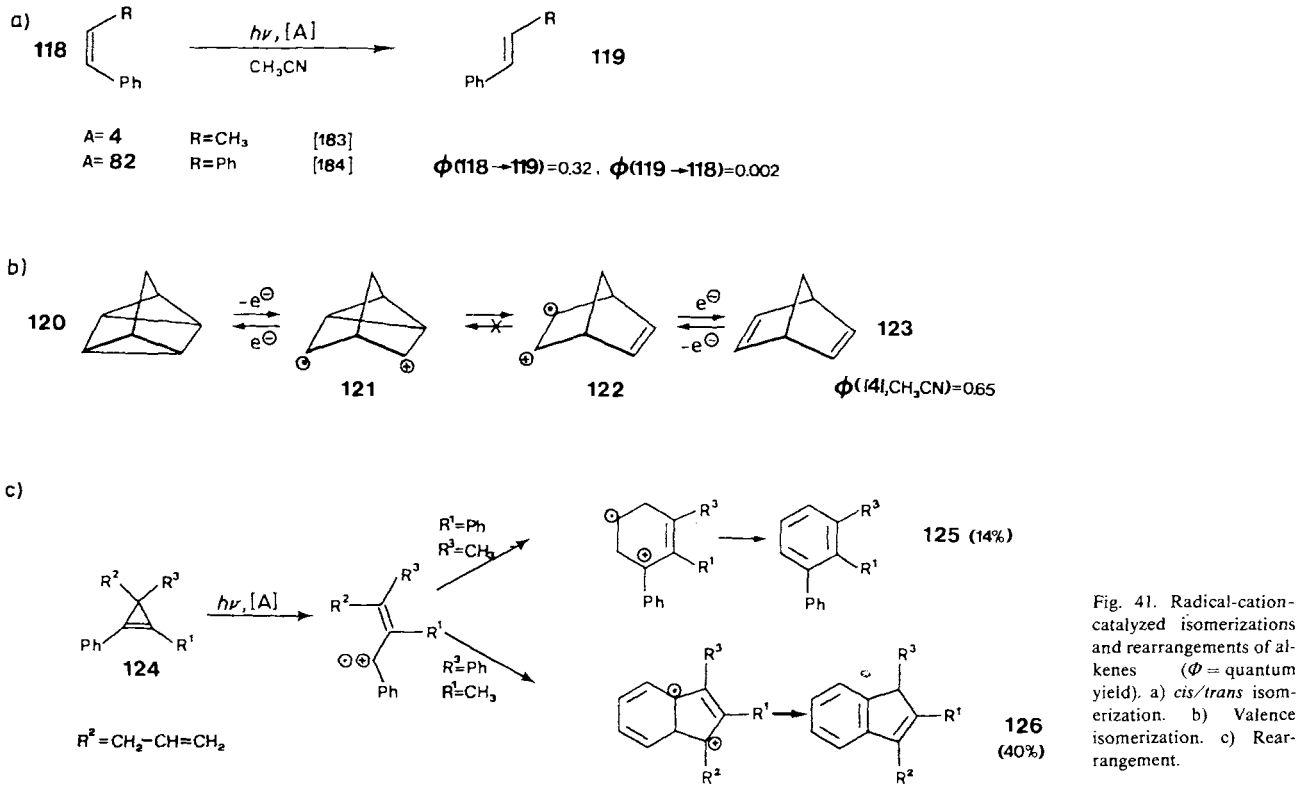

Fig. 41. Radical-cation-catalyzed isomerizations and rearrangements of alkenes (Φ = quantum yield). a) *cis/trans* isomerization. b) Valence isomerization. c) Rearrangement.

of a nucleophile on a radical cation is "forbidden" and therefore has a high activation energy.

5.3. Isomerization and Rearrangement

Since the double-bond character of the alkene has been removed in the radical cation, isomerization and rearrangements are observed, as in the case of the corresponding photoreactions involving energy transfer. Recently, the *cis/trans* isomerization of alkenes has been intensively studied. In Figure 41a, two examples are shown, both of which occur by means of a chain reaction.[183, 184] Increased solvent polarity and the addition of salts increase the efficiency of this isomerization and thus confirm that the mechanism involves solvated radical ions.[184] Here again, the analogous reaction via alkene radical anions is known, but it occurs via an electron-transfer sensitization (cf. II in Fig. 30).[185]

Valence isomerizations by means of radical cations have been observed with Dewar benzene,[186] in the intramolecular cycloaddition of "cage compounds,"[187, 188] and in the norbornadiene (**123**)/quadricyclane (**120**) system.[189–191] The latter, in particular, is of fundamental importance in connection with the storage of solar energy and has therefore been intensively investigated. The valence-isomeric radical cations **121** and **122** can be distinguished by CIDNP methods (Fig. 41b).[189, 190] The energetically unfavorable isomerization **123** → **120** can only be achieved by means of strong electron acceptors. In such a case, the contact ion pair dissociates with the formation of **123** in a triplet state, which then isomerizes to **120**[190] [Eq. (n), cf. Section 5.4).

$$A + \mathbf{123} \xrightarrow{h\nu} (A^{\ominus\ominus}\ \mathbf{123}^{\oplus\oplus}) \longrightarrow A + {}^3\mathbf{123}^* \longrightarrow \mathbf{120} \qquad (n)$$

Two examples of the rearrangement of cyclopropene derivatives (**124**) via radical cations, leading to the formation of **125** and **126**, are shown in Figure 41c.[192] The corresponding energy-transfer reactions, on the other hand, lead to intramolecular [2+2] cycloadducts (triplet) or indene derivatives via the intermediate formation of carbenes (singlet). *Roth* et al.[193] and *Gassman* et al.[194] have reported on the rearrangements of bicyclopropenyl- and bicyclo[1.1.0]butane derivatives.

5.4. Back Electron Transfer with the Formation of Triplets

According to *Weller*,[30] back electron transfer can occur from various intermediates. For example, a contact ion pair in the singlet state should give the starting material predominantly in the singlet (ground) state unless intersystem crossing by means of a hyperfine mechanism can compete with the dissociation of the radical-ion pair. Whereas this process takes place rapidly (ns region), the back electron transfer by recombination of the radical ions takes place slowly (μs region) and gives, corresponding to the number of spin sublevels, 75% of the starting material in the triplet state. Triplet formation is favored by back electron transfer when the energy of the radical-ion pair lies higher than the triplet energy of one of the starting materials. *Farid* et al.[195] have reported such an example in the electron-transfer-sensitized reactions of methyl 1,2-diphenylcyclopropene-3-carboxylate. In nonpolar solvents, it reacts with 9,10-anthracenedicarbonitrile to form the *exo*-Diels–Alder adduct via a luminescent exciplex, whereas in acetonitrile the cyclopropene dimerizes to give an *anti*-tricyclo[3.1.0.0^{2,4}]hexane derivative by means of a back-electron-transfer triplet mechanism.

We have observed similar effects in the photoreactions of electron-poor arenes with 1,3-dioxoles, which often, in the exergonic region of electron transfer, also formed dioxole dimers.[42] Here, solvent polarity plays a decisive role since it strongly affects the energy of the ion pairs [Eqs. (c) and (d)] in a different way than it does the triplet energy of the reactants. The studies of *Bauld* et al.[196] on the dimerization of 1,3-cyclohexadiene **88** and 2,4-dimethyl-1,3-pentadiene in different solvents can be interpreted on this basis. In dichloromethane ($\varepsilon = 8.9$) the proportion of cyclobutane, which is formed via the triplet reaction path according to *Bauld*, is dramatically increased in comparison to the amount formed in acetonitrile ($\varepsilon = 37.5$). Sometimes, however, the specific interaction between the radical ions and the solvent can also influence the competition between the radical-ion and the triplet reaction paths.[196] When sensitizers that are also strong electron acceptors are used, on the other hand, the involvement of differently solvated radical ions (CIP or SSIP) may also lead to the product ratios observed here (cf. Section 5.1.1 and 5.1.2).

6. Conclusions and Prospects

The electrochemical redox potentials and electronic excitation energies of reactants as well as the polarity of the reaction medium determine the amount of charge transfer between electron-donor and electron-acceptor compounds. The free energies of formation calculated according to the Weller equation [Eq. (c)] for solvent-separated radical-ion pairs have proved to be suitable as criteria for the estimation of photochemically induced charge transfer. In the exergonic region of electron transfer, solvated radical ions are formed preferentially after the excitation of donor–acceptor systems (Fig. 42, left). Back electron transfer, already reduced in this way, can be further suppressed by means of salt effects (particularly the special salt effect). This gives rise to new possibilities in the generation of radical ions and the study of their reactions. Impressive proof of this is provided by examples from the currently intensively investigated field of radical-cation-catalyzed cycloadditions of olefins and dienes. Interactions with the acceptor radical anion—either via differently solvated radical ion pairs or by means of the so-called triplex mechanism—the influence of counterions, and the participation of triplet reaction paths can alter the course of the reaction markedly, particularly the stereoselectivity. In this, and in the fact that many reactions are only possible under the conditions of radical-cation catalysis, lies the synthetic potential of these new methods.

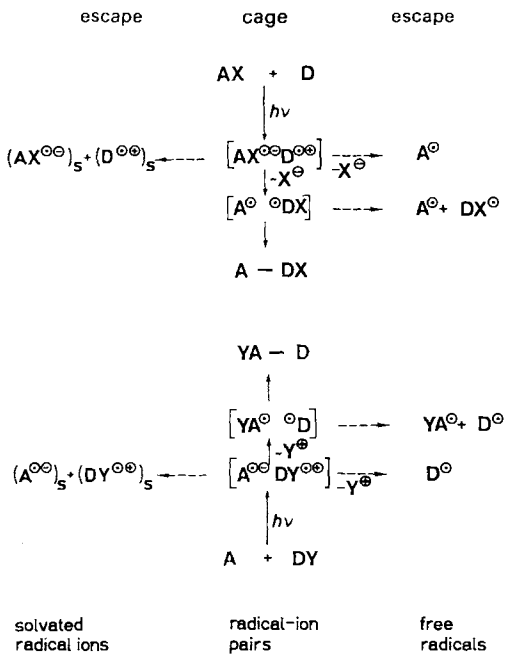

Fig. 42. "Cage" and "escape" processes in photochemical electron-transfer reactions between donor and acceptor molecules.

A further possible method of hindering the back transfer of electrons is offered by the reactions of donor and acceptor radical ions among themselves. In the most common cases, these reactions are initiated by the heterolytic splitting off of a nucleofugal or electrofugal group (Fig. 42, middle). The recombination of the radicals thus formed terminates the process. If the recombination is prevented by the choice of suitable substrates, then a new method for the generation of free radicals by means of photochemically induced electron transfer is obtained[197] (Fig. 42, right).

In the endergonic region, the free energies of electron transfer can be used to estimate the CT character and to determine the direction of the charge transfer within the exciplex. The ΔG values calculated by means of Equation (c) correlate, at least within a substrate series, with the course of the reaction (Figs. 10 and 15). In other words, photochemically induced charge transfer has a regulatory effect on the reactions between electron-donor and electron-acceptor molecules. Here also, it is possible to influence charge transfer and stereoselectivity by a suitable choice of reaction medium.

Many photoreactions in which charge transfer has a decisive influence on the course of the reaction could not be dealt with in this article. These include the diverse photoreactions of metal coordination compounds,[2-6, 22, 198-201] the photoreactions involved in the extensive studies of the storage of solar energy[5] (this area has recently been reviewed by *Fendler*[202]), and many other organic reactions.[6, 24]

The progress made in the field of photochemistry would not have been possible without interaction between individual chemical disciplines. This is particularly true for the study of electron-transfer processes, which play a decisive role in many areas of chemistry, whether they be in biological, inorganic, or organic systems, or whether they take place under thermal conditions or under the influence of light. The enormous increase, in recent years, in the number of publications dealing with electron-transfer processes is less a sign of a short-lived fashion than an indication of growing awareness of chemists that the questions concerning these processes need to be answered. The development of more refined analytical methods, the investigation of fundamental questions such as the applicability of the Marcus theory or Weller's empirical relationship to the kinetics of electron transfer, and synthetic studies by

preparatively oriented organic chemists will give a further impulse to research in this important area.

The personal work referred to here has only been possible thanks to the enthusiastic help of my co-workers Karl Buchkremer, Dr. Joachim Gersdorf, Christel Dittmer, Jürgen Mertes, Gisela Trampe, and Gabi Weber and the cooperation of colleagues working in other areas. I would specially like to thank Dr. H. Görner and Dr. S. Steenken (Max-Planck-Institut für Strahlenchemie, Mülheim) for help with the fundamental transient-analysis studies and Dr. J. Runsink (RWTH Aachen) for help with the NMR analyses. I thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous financial help and, finally, Bayer and BASF for gifts of materials.

How Chemistry and Physics Meet in the Solid State

By Roald Hoffmann*

To make sense of the marvelous electronic properties of the solid state, chemists must learn the language of solid-state physics, of band structures. An attempt is made here to demystify that language, drawing explicit parallels to well-known concepts in theoretical chemistry. To the joint search of physicists and chemists for understanding of the bonding in extended systems, the chemist brings a great deal of intuition and some simple but powerful notions. Most important among these is the idea of a bond, and the use of frontier-orbital arguments. How to find localized bonds among all those maximally delocalized bands? Interpretative constructs, such as the density of states, the decomposition of these densities, and crystal orbital overlap populations, allow a recovery of bonds, a finding of the frontier orbitals that control structure and reactivity in extended systems as well as discrete molecules.

Introduction

There is no need to provide an *apologia pro vita sua* for solid-state chemistry. Macromolecules extended in one, two, or three dimensions, of biological or natural origin, or synthetics, fill the world around us. Metals, alloys, and composites, be they copper or bronze or ceramics, have played a pivotal, shaping role in our culture. Mineral structures form the base of the paint that colors our walls, and the glass through which we look at the outside world. Organic polymers, be they nylon or wool, clothe us. New materials—ternary inorganic superconductors, conducting organic polymers—exhibit unusual electric and magnetic properties, promise to shape the technology of the future. Solid-state chemistry is important, alive, and growing.

Given the vitality and attractiveness of the field, I take some risk in listing some minor problems that I perceive at the interfaces of solid-state chemistry with physics and with the rest of chemistry. This is done not with the intent to find fault, but constructively—the remainder of this paper tries to resolve some of these perceived difficulties.

What is most interesting about many of the new materials are their electrical and magnetic properties. Chemists have to learn to measure these properties, not only to make the new materials and determine their structures. The history of the compounds that are at the center of today's exciting developments in high-temperature superconductivity makes this point very well. And they must be able to reason intelligently about the electronic structure of the compounds they make, so that they may understand how these properties and structures may be tuned. Here's the first problem then, for such an understanding of solids perforce must involve the language of modern solid-state physics, of band theory. That language is generally not part of the education of chemists. It should be.

I suspect that physicists don't think that chemists have much to tell them about bonding in the solid state. I would disagree. Chemists have built up a great deal of understanding, in the intuitive language of simple covalent or ionic bonding, of the structure of solids. The chemist's viewpoint is often local. Chemists are especially good at seeing bonds or clusters, and our literature and memory are especially well-developed, so that we can immediately think of a hundred structures or molecules related to the compound under study. From much empirical experience, a little simple theory, chemists have gained much intuitive knowledge of the what, how, and why molecules hold together. To put it as provocatively as I can, our physicist friends know better than we how to calculate the electronic structure of a molecule or solid, but often they do not *understand* it as well as we do, with all the epistemological complexity of meaning that "understanding" something involves.

Chemists need not enter a dialogue with physicists with any inferiority feelings at all; the experience of molecular chemistry is tremendously useful in interpreting complex electronic structure. (Another reason not to feel inferior: until you synthesize that molecule, no one can study its properties. The synthetic chemist is quite in control.) This is not to say that it will not take some effort to overcome the skepticism of physicists as to the likelihood that chemists can teach them something about bonding.

Another interface is that between solid-state chemistry, often inorganic, and molecular chemistry, both organic and inorganic. With one exception, the theoretical concepts that have served solid-state chemists well have not been "molecular." At the risk of oversimplification, the most important of these concepts have been the idea that one has ions (electrostatic forces, Madelung energies) and that these ions have a size (ionic radii, packing considerations). The success of these simple notions has led solid-state chemists to use these concepts even in cases where there is substantial covalency. What can be wrong with an idea that works, that explains structure and properties? What is wrong, or can be wrong, is that application of such concepts may draw that field, that group of scientists, away from the heart of chemistry. At the heart of chemistry, let there be no doubt, is the molecule! My personal feeling is that if there is a choice among explanations in solid-state chemistry, one must choose the explanation which permits a connection between the structure at hand

and some discrete molecule, organic or inorganic. Making connections has inherent scientific value. It also makes "political" sense. Again, if I might express myself provocatively, I would say that many solid-state chemists have isolated themselves (no wonder that their organic or even inorganic colleagues aren't interested in what they do) by choosing not to see bonds in their materials.

Which, or course, brings me to the exception: the marvelous and useful Zintl concept. The simple notion, introduced by *Zintl* and popularized by *Klemm*, *Busmann*, *Herbert Schäfer*, and others,[1] is that in some compounds A_xB_y, where A is very electropositive relative to a main-group element B, one could just think, that's all, think that the A atoms transfer their electrons to the B atoms, which then use them to form bonds. This very simple idea, in my opinion, is the single most important theoretical concept (and how not very theoretical it is!) in solid-state chemistry of this century. And it is so important, not just because it explains so much chemistry, but especially because it builds a bridge between solid-state chemistry and organic or main-group chemistry.

The three problems I have identified, and let me repeat that I think they are relatively minor ones for a lively field, are (1) some lack of knowledge (therefore fear) of solid-state physics language on the part of chemists, (2) insufficient appreciation of the chemists' intuitive feeling for bonding on the part of physicists, and (3) not enough reaching out for connections with molecular chemistry on the part of solid-state chemists. The characterization of these as problems represents a generalization on my part, with the associated danger that any generalization carries. Typologies and generalizations often point not so much to reality as to the weakness of the mind that proposes them.

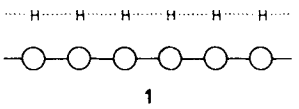
What can a theoretical chemist contribute to the amelioration of these problems, if they indeed are real ones? A theoretical *chemist* can, in fact, do very much. With his or her firm knowledge of solid-state physics (which he should, in principle, have, but often doesn't) *and* his feeling for bonding and the marvelous bounty of structures that he knows his chemical colleagues have made, the theoretical chemist should be in a wonderful position to serve as a bridge between chemistry and physics. We should certainly be able to help with point (1) above, showing our colleagues that band theory is easy. Points (2) and (3) are more difficult. We need to push our experimental colleagues to see bonds, clusters, molecular patterns in new species. But, they can see these patterns, without our help, better than we do. And to convince physicists that chemists are good for anything except making molecules, that chemists in fact understand what the electrons in molecules and solids are doing—that will take some doing.

In fact, the effort has been under way from the theoretical side for some time. I would like to mention here especially the contributions of *Jeremy Burdett*,[2,3] who is responsible for the first new ideas on what determines solid-state structures since the pioneering contribution of *Pauling*, and of *Myung-Hwan Whangbo*,[4,5] whose analysis of the bonding in low-dimensional materials such as the niobium selenides, tetrathiafulvalene-type organic conductors, and molybdenum bronzes has contributed much to our knowledge of the balance of delocalization and electron repulsion in conducting solids. On the side of physics, let me mention the work of several individuals who have shown an unusual sensitivity to chemistry and chemical ways of thinking: *Jacques Friedel*, *Walter A. Harrison*, *Volker Heine*, *James C. Phillips*, *Ole Krogh Andersen*, and *David W. Bullett*.

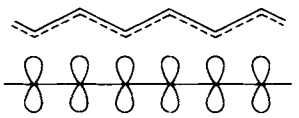
In this paper, I would like to work mainly on point (1) mentioned above, the teaching, to chemists, of some of the language of band theory.[6-8] As many connections as possible to our traditional ways of thinking about chemical bonding will be made—it is this aspect which should be of interest to any physicists who might read this article. The approach will be simple, indeed, oversimplified in part. Where detailed computational results are displayed, they will be of the extended Hückel type, or of its solid-state analogue, the tight-binding method with overlap.

Orbitals and Bands in One Dimension

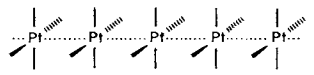
It's usually easier to work with small, simple things, and one-dimensional infinite systems are particularly easy to visualize.[2-5] Much of the physics of three-dimensional solids is there in one dimension. Let's begin with a chain of equally spaced H atoms, **1**, or the isomorphic π-system of a non-bond-alternating, delocalized polyene **2**, stretched out for the moment. And we will progress to a stack of Pt^{II} square-planar complexes, **3**, $[Pt(CN)_4]^{2\ominus}$ or a model $[PtH_4]^{2\ominus}$.



1

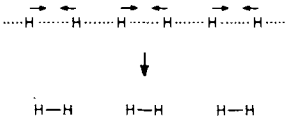


2



3

A digression here: every chemist would have an intuitive feeling for what that model chain of hydrogen atoms, **1**, would do if we were to release it from the prison of its theoretical construction. At ambient pressure, it would form a chain of hydrogen molecules, **4**. This simple bond-

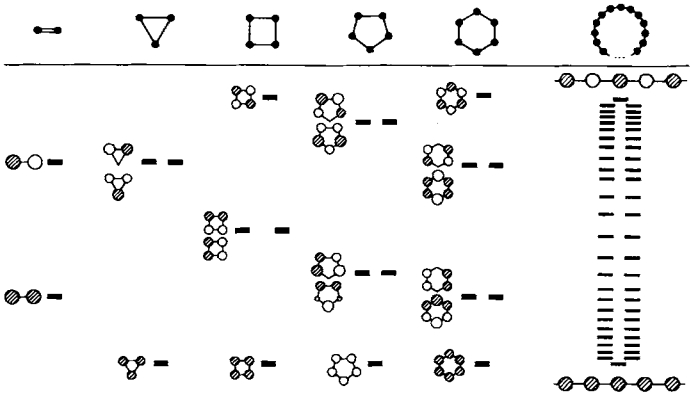


4

forming process could be analyzed by the physicist (we will do it soon) by calculating a band for the equally

spaced polymer, then seeing that it's subject to an instability, called a Peierls distortion. Other words around that characterization would be strong electron-phonon coupling, a pairing distortion, or a $2k_F$ instability. And the physicist would come to the conclusion that the initially equally spaced H polymer would form a chain of hydrogen molecules. I mention this thought process here to make the point, which I will do again and again, that the chemist's intuition is really excellent. But we must bring the languages of our sister sciences into correspondence. Incidentally, whether distortion **4** will take place at 2 Mbar is not obvious, an open question.

Let's return to our chain of equally spaced H atoms. It turns out to be computationally convenient to think of that chain as an imperceptibly bent segment of a large ring (this is called applying cyclic boundary conditions). The orbitals of medium-sized rings on the way to that very large one are quite well known. They are shown in **5**.

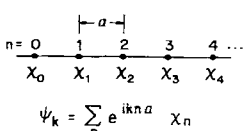


5

For a hydrogen molecule (or ethylene) there is a bonding $\sigma_g(\pi)$ below an antibonding $\sigma_u^*(\pi^*)$. For cyclic H_3 or cyclopropenyl we have one orbital below two degenerate ones; for cyclobutadiene the familiar one below two below one, and so on. Except for the lowest (and occasionally the highest) level, the orbitals come in degenerate pairs. The number of nodes increases as one rises in energy. We'd expect the same for an infinite polymer—the lowest level nodeless, the highest with the maximum number of nodes. In between, the levels should come in pairs, with a growing number of nodes. The chemist's representation of that band for the polymer is given at right in **5**.

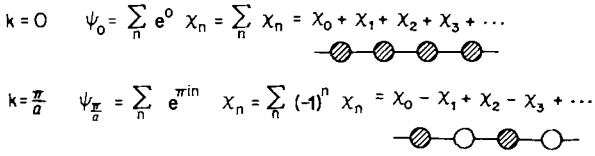
Bloch Functions, k, Band Structures

There is a better way to write out all these orbitals, making use of the translational symmetry. If we have a lattice whose points are labeled by an index n = 0, 1, 2, 3, 4, etc., as shown in **6**, and if on each lattice point there is a basis function (a H 1s orbital), χ_0, χ_1, χ_2, etc., then the appropriate symmetry-adapted linear combinations ψ (remember translation is just as good a symmetry operation as any other one we know) are given in **6**. Here a is the lattice spacing (the unit cell being in one dimension) and k is an index which labels which irreducible representation of the translation group ψ transforms as. We will see in a moment that k is much more, but for now, k is just an index for an irreducible representation, just like a, e_1, and e_2 in C_5 are labels.



6

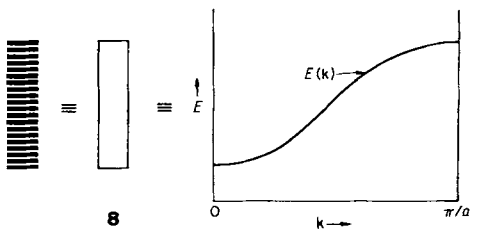
The process of symmetry adaptation is called in the solid-state physics trade "forming Bloch functions."[3,5,6,8] To reassure a chemist that one is getting what one expects from **5**, let's see what combinations are generated for two specific values of k, k = 0 and k = π/a (see **7**). Referring



7

back to **5**, we see that the wave function corresponding to k = 0 is the most bonding one, the one for k = π/a the top of the band. For other values of k we get a neat description of the other levels in the band. So k counts nodes as well. The larger the absolute value of k, the more nodes one has in the wave function. But one has to be careful—there is a range of k and if one goes outside of it, one doesn't get a new wave function, but repeats an old one. The unique values of k are in the interval $-\pi/a \leq k < \pi/a$ or $|k| \leq \pi/a$. This is called the first Brillouin zone, the range of unique k.

How many values of k are there? As many as the number of translations in the crystal, or, alternatively, as many as there are microscopic unit cells in the macroscopic crystal. So let us say Avogadro's number (N_A), give or take a few. There is an energy level for each value of k (actually a degenerate pair of levels for each pair of positive and negative k values). There is an easily proved theorem that $E(k) = E(-k)$. Most representations of $E(k)$ do not give the redundant $E(-k)$, but plot $E(|k|)$ and label it as $E(k)$). Also, the allowed values of k are equally spaced in the space of k, which is called reciprocal or momentum space. The relationship between $k = 1/\lambda$ and momentum derives from the de Broglie relationship $\lambda = h/p$. Remarkably, k is not only a symmetry label and a node counter, but it is also a wave vector, and so measures momentum.



8

So what a chemist draws as a band in **5**, repeated at left in **8** (and the chemist tires and draws ≈20 lines or just a

block instead of N_A lines), the physicist will alternatively draw as an $E(k)$ vs. k diagram at right in **8**. Recall that k is quantized, and there is a finite but large number of levels in the diagram at right. The reason it looks continuous is that this is a fine "dot matrix" printer—there are N_A points jammed in there, and so it's no wonder we see a line.

Graphs of $E(k)$ vs. k are called band structures. You can be sure that they can be much more complicated than this simple one, but no matter how complicated, they can be understood.

Band Width

One very important feature of a band is its *dispersion*, or *band width*, the difference in energy between the highest and lowest levels in the band. What determines the width of bands? The same thing that determines the splitting of levels in a "dimer," ethylene or H_2, namely, the overlap between the interacting orbitals (in the polymer the overlap is that between neighboring unit cells). The greater the overlap between neighbors, the greater the band width. Figure 1 illustrates this in detail for a chain of H atoms

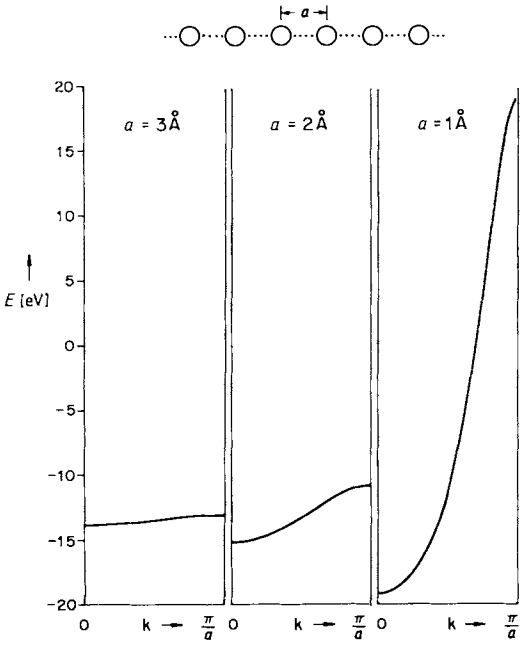


Fig. 1. The band structure of a chain of H atoms spaced 3, 2, and 1 Å apart. The energy of an isolated H atom is −13.6 eV.

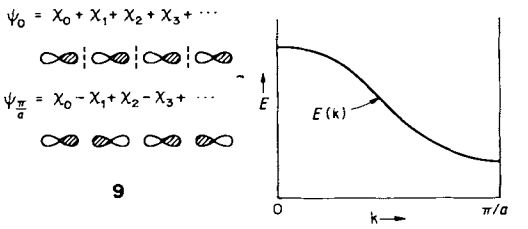
spaced 3, 2, and 1 Å apart. That the bands extend unsymmetrically around their "origin," the energy of a free H atom at −13.6 eV, is a consequence of the inclusion of overlap in the calculations. For two levels, a dimer, the energies are given by Equation (a). The bonding E_+ combi-

$$E_{\pm} = \frac{H_{AA} \pm H_{AB}}{1 \pm S_{AB}} \qquad (a)$$

nation is less stabilized than the antibonding one E_- is destabilized. There are nontrivial consequences in chemistry, for this is the source of four-electron repulsions and steric effects in one-electron theories.[8] A similar effect of overlap is responsible for the bands "spreading up" in Figure 1.

See How They Run

Another interesting feature of bands is how they "run." The lovely mathematical algorithm **6** applies in general; it does not say anything about the energy of the orbitals at the center of the zone (k = 0) relative to those at the edge (k = π/a). For a chain of H atoms it is clear that $E(k=0) < E(k=\pi/a)$. But consider a chain of p functions, **9**. The same combinations are given to us by the transla-



9

tional symmetry, but now it is clearly k = 0 which is high energy, the most antibonding way to put together a chain of p orbitals.

The band of s functions for the hydrogen chain "runs up," the band of p orbitals "runs down" (from zone center to zone edge). In general, it is the topology of orbital interactions which determines which way bands run.

Let me mention here an organic analogue to make one feel comfortable with this idea. Consider the through-space interaction of the three π bonds in **10** and **11**. The

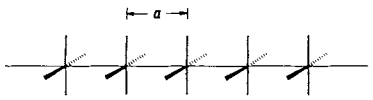
10 **11**

threefold symmetry of each molecule says that there must be an a and an e combination of the π bonds. And the theory of group representations gives us the symmetry-adapted linear combinations: for a, $\chi_1+\chi_2+\chi_3$; for e (one choice of an infinity), $\chi_1-2\chi_2+\chi_3$ and $\chi_1-\chi_3$, where χ_1 is the π orbital of double bond 1, etc. But there is nothing in the group theory that tells us whether a is lower than e in energy. For that, one needs chemistry or physics. It is easy to conclude from an evaluation of the orbital topologies that a is below e in **10**, but the reverse is true in **11**. To summarize: *band width is set by inter-unit-cell overlap, and the way the bands run is determined by the topology of that overlap.*

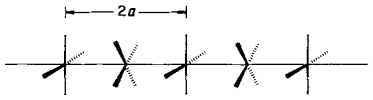
An Eclipsed Stack of Pt^{II} Square-Planar Complexes

Let us test the knowledge we have acquired on an example a little more complicated than a chain of hydrogen atoms. This is an eclipsed stack of square-planar d^8 PtL_4 complexes, **12**. The normal tetracyanoplatinates (e.g.,

$K_2[Pt(CN)_4]$) indeed show such stacking in the solid state, at the relatively uninteresting Pt–Pt separation of ≈ 3.3 Å.



12



13

More exciting are the partially oxidized materials, such as $K_2[Pt(CN)_4Cl_{0.3}]$ and $K_2[Pt(CN)_4(FHF)_{0.25}]$. These are also stacked, but staggered, **13**, with a much shorter Pt–Pt contact of 2.7–3.0 Å. The Pt–Pt distance had been shown to be inversely related to the degree of oxidation of Pt.[9]

The real test of understanding is prediction. So, let's try to predict the approximate band structure of **12** and **13** without a calculation, just using the general principles we have at hand. Let's not worry about the nature of the ligand L—it is usually $CN^{\ominus}$, but since it is only the square-planar feature which is likely to be essential, let's imagine a theoretician's generic ligand, $H^{\ominus}$. And let's begin with **12**, because the unit cell in it is the chemical PtL_4 unit, whereas in **13** it is doubled, $[(PtL_4)_2]$.

One always begins with the monomer. What are its frontier levels? The classical crystal field or molecular orbital

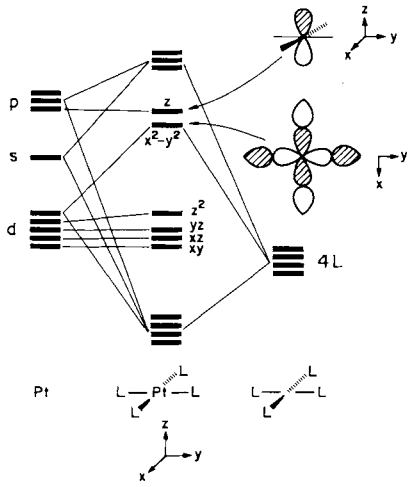


Fig. 2. Molecular-orbital derivation of the frontier orbitals of a square-planar PtL_4 complex.

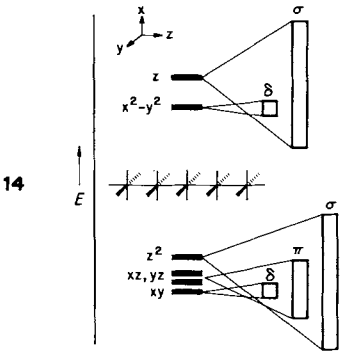
picture of a square-planar complex (Fig. 2) leads to a four-below-one splitting of the d block.[8] For 16 electrons we have d_{z^2}, d_{xz}, d_{yz}, and d_{xy} occupied and $d_{x^2-y^2}$ empty. Competing with the ligand-field-destabilized $d_{x^2-y^2}$ orbital for being the lowest unoccupied molecular orbital (LUMO) of the molecule is the metal p_z. These two orbitals can be manipulated in understandable ways: π-acceptors push p_z down, π-donors push it up. Better σ-donors push $d_{x^2-y^2}$ up.

We form the polymer. Each MO of the monomer generates a band. There may (will) be some further symmetry-conditioned mixing between orbitals of the same symmetry in the polymer (e.g., s and p_z and d_{z^2} are of different symmetry in the monomer, but certain of their polymer MOs are of the same symmetry). But a good start is made by ignoring that secondary mixing, and just developing a band from each monomer level independently.

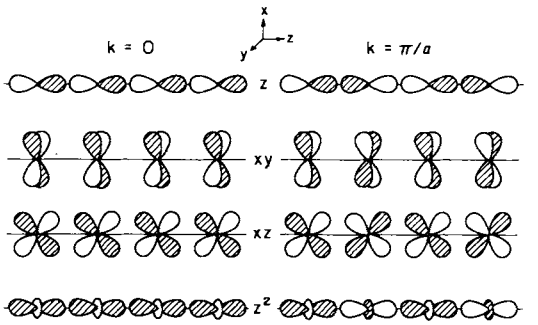
First, a chemist's judgment of the band widths that will develop (see **14**): the bands that will arise from d_{z^2} and p_z

14



will be wide, those from d_{xz} and d_{yz} of medium width, those from $d_{x^2-y^2}$ and d_{xy} narrow. This characterization follows from the realization that the first set of interactions (p_z, d_{z^2}) is σ type, thus has a large overlap between unit cells. The d_{xz}, d_{yz} set has a medium π overlap, and the d_{xy} and $d_{x^2-y^2}$ orbitals (the latter of course has a ligand admixture, but that doesn't change its symmetry) are δ.

It is also easy to see how the bands run. Let's write out the Bloch functions at the zone center ($k=0$) and zone edge ($k=\pi/a$). Only one of the π and δ functions is represented in **15**. The moment one writes these down, one sees

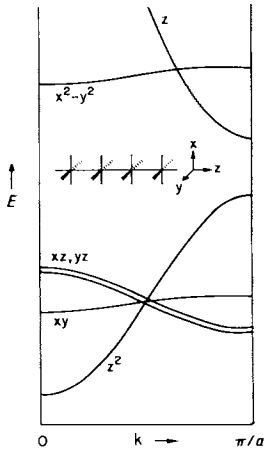


15

that the d_{z^2} and d_{xy} bands will run "up" from the zone center (the $k=0$ combination is the most bonding) while the d_z and d_{xy} bands will run "down" (the $k=0$ combination is the most antibonding).

The predicted band structure, merging considerations of band width and orbital topology, is that of **16**. To make a real estimate of band width, one would need an actual calculation of the various overlaps, and these in turn would depend on the Pt–Pt separation.

The actual band structure, as it emerges from an extended Hückel calculation at Pt–Pt = 3.0 Å, is shown in



16

Figure 3. It matches our expectations very precisely. There are, of course, bands below and above the frontier orbitals discussed—these are Pt–H σ and σ* orbitals.

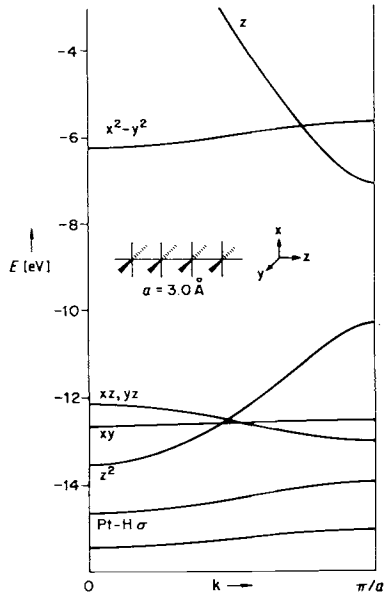


Fig. 3. Computed band structure of an eclipsed $[PtH_4]^{2\ominus}$ stack, spaced at 3 Å. The orbital marked d_{xz}, d_{yz} is doubly degenerate.

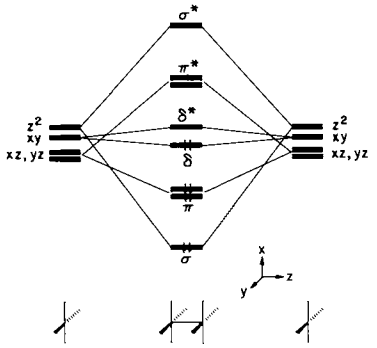
To make a connection with molecular chemistry: the construction of **16**, an approximate band structure for a cyanoplatinate stack, involves no new physics, no new chemistry, no new mathematics beyond what every chemist already knows for one of the most beautiful ideas of modern chemistry—*Cotton*'s construct of the metal–metal quadruple bond.[10] If we are asked to explain quadruple bonding, for instance in $[Re_2Cl_8]^{2\ominus}$, what we do is to draw **17**. We form bonding and antibonding combinations from the $d_{z^2}(\sigma)$, $d_{xz},d_{yz}(\pi)$, and $d_{x^2-y^2}(\delta)$ frontier orbitals of each $ReCl_4^{\ominus}$ fragment. And we split σ from σ* by more than π from π*, which in turn is split more than δ and δ*. What goes on in the infinite solid is precisely the same thing. True, there are a few more levels, but the translational symmetry helps us out with that. It's really easy to



17

write down the symmetry-adapted linear combinations, the Bloch functions.

The Fermi Level

It's important to know how many electrons one has in one's molecule. Fe^{II} has a different chemistry from Fe^{III}, and $CR_3^{\oplus}$ carbocations are different from CR_3 radicals and $CR_3^{\ominus}$ anions. In the case of $[Re_2Cl_8]^{2\ominus}$, the archetypical quadruple bond, we have formally Re^{III}, d^4, i.e., a total of eight electrons to put into the frontier orbitals of the dimer level scheme, **17**. They fill the σ, two π, and the δ level for the explicit quadruple bond. What about the $[\{PtH_4\}^{2\ominus}]_\infty$ polymer **12**? Each monomer is d^8. If there are N_A unit cells, there will be N_A levels in each band. And each level has a place for two electrons. So the first four bands are filled, the xy, xz, yz, and z^2 bands. The Fermi level, the highest occupied molecular orbital (HOMO), is at the very top of the z^2 band. (Strictly speaking, there is another thermodynamic definition of the Fermi level, appropriate both to metals and semiconductors,[6] but here we will use the simple equivalence of the Fermi level with the HOMO.)

Is there a bond between the platinums in this $[\{PtH_4\}^{2\ominus}]_\infty$ polymer? We haven't introduced, yet, a formal description of the bonding properties of an orbital or a band, but a glance at **15** and **16** will show that the bottom of *each* band, be it made up of z^2, xz, yz, or xy, is bonding, and the top antibonding. Filling a band completely, just like filling bonding and antibonding orbitals in a dimer (think of He_2, think of the sequence N_2, O_2, F_2, Ne_2) provides no net bonding. In fact, it gives net antibonding. So why does the unoxidized PtL_4 chain stack? It could be van der Waals attractions, not in our quantum chemistry at this primitive level. I think there is also a contribution of orbital interaction, i.e., real bonding, involving the mixing of the z^2 and z bands.[11] We will return to this soon.

The band structure gives a ready explanation for why the Pt–Pt separation decreases on oxidation. A typical degree of oxidation is 0.3 electron per Pt.[9] These electrons must come from the top of the z^2 band. The degree of oxidation specifies that 15% of that band is empty. The states vacated are not innocent of bonding. They are strongly Pt–Pt σ antibonding. So it's no wonder that removing these electrons results in the formation of a partial Pt–Pt bond.

The oxidized material also has its Fermi level in a band; i.e., there is a zero band gap between filled and empty levels. The unoxidized cyanoplatinates have a substantial

gap—they are semiconductors or insulators. The oxidized materials are good low-dimensional conductors, which is a substantial part of what makes them interesting to physicists.[9, 11]

In general, conductivity is not a simple phenomenon to explain, and there may be several mechanisms impeding the motion of electrons in a material.[6] A prerequisite for having a good electronic conductor is to have the Fermi level cut one or more bands (soon we will use the language of density of states to say this more precisely). One has to beware, however, (1) of distortions which open up gaps at the Fermi level and (2) of very narrow bands cut by the Fermi level, for these will lead to localized states and not to good conductivity.[4, 6]

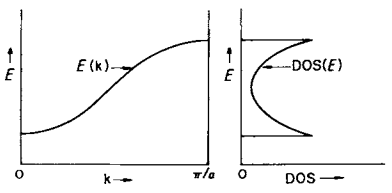
Density of States

We have already remarked that in the solid, a very large molecule, one has to deal with a very large number of levels or states. If there are n atomic orbitals (basis functions) in the unit cell generating n molecular orbitals, and if in our macroscopic crystal there are N unit cells (N is a number that approaches N_A), then we will have N·n crystal levels. Many of these are occupied and, roughly speaking, they are jammed into the same energy interval in which we find the molecular or unit cell levels. In a discrete molecule we are able to single out one orbital or a small subgroup of orbitals (HOMO, LUMO) as being the frontier, or valence, orbitals of the molecule, responsible for its geometry, reactivity, etc. There is no way in the world that a single level among the myriad N·n orbitals of the crystal will have the power to direct a geometry or reactivity.

There is, however, a way to retrieve a frontier orbital language in the solid state. We cannot think about a single level, but perhaps we can talk about bunches of levels. There are many ways to group levels, but one pretty obvious one is to look at all the levels in a given energy interval. The density of states (DOS) is defined by (b). For a

$$\mathrm{DOS}(E)\,\mathrm{d}E = \text{number of levels between } E \text{ and } E+\mathrm{d}E \qquad \text{(b)}$$

simple band of a chain of hydrogen atoms, the DOS curve takes on the shape of **18**. Note that because the levels are equally spaced along the k axis, and because the E(k)



18

curve, the band structure, has a simple cosine curve shape, there are more states in a given energy interval at the top and bottom of this band. In general, DOS(E) is proportional to the inverse of the slope of E(k) vs. k, or to put it into plain English, the flatter the band, the greater the density of states at that energy.

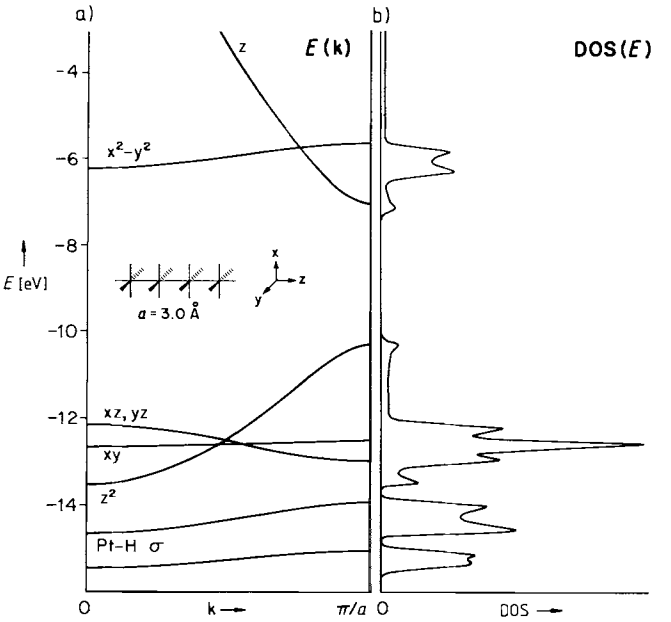


Fig. 4. a) Band structure and b) density of states (DOS) for an eclipsed $[PtH_4]^{2\ominus}$ stack. The DOS curves are broadened so that the two-peaked shape of the xy peak in the DOS is not resolved.

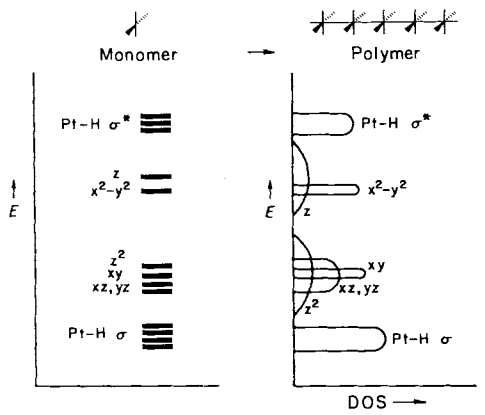
The shapes of DOS curves are predictable from the band structures. Figure 4 shows the DOS curve for the $[PtH_4]^{2\ominus}$ chain. It could have been sketched from the band structure at left. In general, the detailed construction of these is a job best left for computers. The density-of-states curve counts levels. The integral of DOS up to the Fermi level is the total number of occupied MOs. Multiplied by two, it's the total number of electrons. So, the DOS curves plot the distribution of electrons in energy.

One important aspect of the DOS curves is that they represent a return from reciprocal space, the space of k, to real space. The DOS is an average over the Brillouin zone, over all k that might give molecular orbitals at the specified energy. The advantage here is largely psychological. If I may be permitted to generalize, I think chemists (with the exception of crystallographers) by and large feel themselves uncomfortable in reciprocal space. They'd rather return to, and think in, real space.

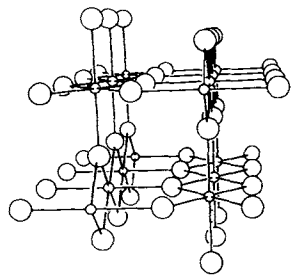
There is another aspect of the return to real space that is significant: *chemists can sketch the DOS of any material, approximately, intuitively*. All that's involved is a knowledge of the atoms, their approximate ionization potentials and electronegativities, and some judgment as to the extent of inter-unit-cell overlap (usually apparent from the structure).

Let's take the $[\{PtH_4\}^{2\ominus}]_\infty$ polymer as an example. The monomer units are clearly intact in the polymer. At intermediate monomer–monomer separations (e.g., 3 Å) the major inter-unit-cell overlap is between d_{z^2} and p_z orbitals. Next is the d_{xz}, d_{yz} π-type overlap; all other interactions are likely to be small. **19** is a sketch of what we would expect. In **19**, I haven't been careful in drawing the integrated areas commensurate with the actual total number of states, nor have I put in the two-peaked nature of the DOS each level generates—all I want to do is to convey the rough spread of each band. Compare **19** to Figure 4.



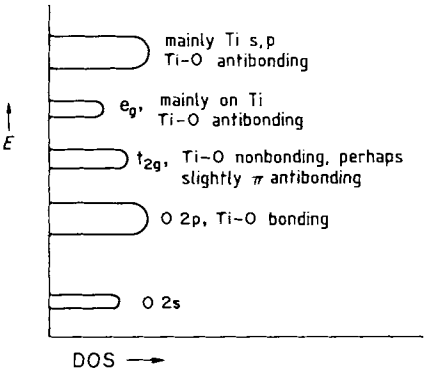
19

This was easy, because the polymer was built up of molecular monomer units. Let's try something inherently three-dimensional. The rutile structure is a relatively common type. As **20** shows, the rutile structure has a nice oc-



20

tahedral environment of each metal center, each ligand (e.g., O) bound to three metals. There are infinite chains of edge-sharing MO_6 octahedra running in one direction in the crystal, but the metal–metal separation is always relatively long.[12] There are no monomer units here, just an infinite assembly. Yet there are quite identifiable octahedral sites. At each, the metal d block must split into t_{2g} and e_g combinations, the classic three-below-two crystal field splitting. The only other thing we need is to realize that O has quite distinct 2s and 2p levels, and that there is no effective O–O or Ti–Ti interaction in this crystal. We expect something like **21**.



21

Note that the writing down of the approximate DOS curve is done *bypassing* the band structure calculation *per se*. Not that that band structure is very complicated. But it is three-dimensional, and our exercises so far have been easy, in one dimension. So the computed band structure (Fig. 5) will seem complex. The number of bands is doubled (i.e., twelve O 2p, six t_{2g} bands), simply because the unit cell contains two formula units, $[(TiO_2)_2]$. There is not one reciprocal space variable, but several lines ($\Gamma \rightarrow X$, $X \rightarrow M$, etc.) which refer to directions in the three-dimensional Brillouin zone. These complications of moving from one dimension to three we will soon approach. If we glance at the DOS, we see that it does resemble the expectations of **21**. There are well-separated O 2s, O 2p, Ti t_{2g}, and e_g bands.[12]

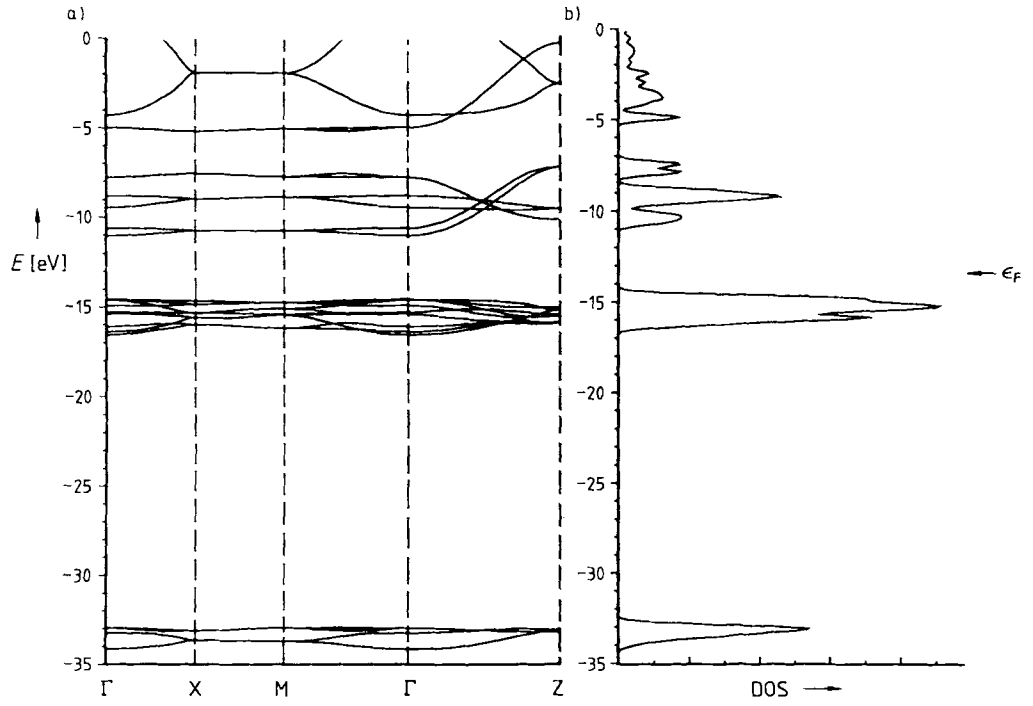


Fig. 5. a) Band structure and b) density of states for rutile, TiO_2. The two Ti–O distances are 2.04 Å (2×), 2.07 Å (4×) in the assumed structure.

Would you like to try something a little (but not much) more challenging? Attempt to construct the DOS of the new superconductors based on the La_2CuO_4 and $YBa_2Cu_3O_7$ structures. And when you have done so, and found that these should be conductors, reflect on how that doesn't allow you yet, did not allow anyone, to predict that compounds slightly off these stoichiometries would be remarkable superconductors.

The chemists' ability to write down approximate density-of-states curves should not be slighted. It gives us tremendous power, and qualitative understanding, an obvious connection to local, chemical viewpoints such as the crystal or ligand field model. I want to mention here one solid-state chemist, *John B. Goodenough*, who has shown over the years, and especially in his prescient book,[13] just how good the chemist's approximate construction of band structures can be.

In **19** and **21**, the qualitative DOS diagrams for $[PtH_4]^{2\ominus}$ and TiO_2, there is, however, much more than a guess at a DOS. There is a chemical characterization of the localization in real space of the states (are they on Pt, on H; on Ti, on O), and a specification of their bonding properties (Pt–H bonding, antibonding, nonbonding, etc.). The chemist sees right away, or asks—where in space are the electrons? Where are the bonds? There must be a way that these inherently chemical, local questions can be answered, even if the crystal molecular orbitals, the Bloch functions, delocalize the electrons over the entire crystal.

Where Are the Electrons?

One of the interesting tensions in chemistry is between the desire to assign electrons to specific centers, deriving from an atomic, electrostatic view of atoms in a molecule, and the knowledge that electrons are not as localized as we would like them to be. Let's take the two-center molecular orbital of Equation (c), where χ_1 is on center 1 and χ_2 on center 2, and let's assume centers 1 and 2 are not identical, and that χ_1 and χ_2 are normalized, but not orthogonal.

$$\psi = c_1\chi_1 + c_2\chi_2 \qquad \text{(c)}$$

The distribution of an electron in this MO is given by ψ^2. ψ should be normalized, so that Equation (d) is valid,

$$1 = \int \psi^2 \, d\tau = \int (c_1\chi_1 + c_2\chi_2)^2 \, d\tau = c_1^2 + c_2^2 + 2c_1c_2S_{12} \qquad \text{(d)}$$

where S_{12} is the overlap integral between χ_1 and χ_2. This is how one electron in ψ is distributed. Now it's obvious that c_1^2 of it is to be assigned to center 1, c_2^2 to center 2. $2c_1c_2S_{12}$ is clearly a quantity that is associated with interaction. It's called the overlap population, and we will soon relate it to the bond order. But what are we to do if we persist in wanting to divide up the electron density between centers 1 and 2? We want all the parts to add up to 1 and $c_1^2 + c_2^2$ won't do. We must assign, somehow, the "overlap density" $2c_1c_2S_{12}$ to the two centers. *Mulliken* suggested (and that's why we call this a Mulliken population analysis[14]) a democratic solution, splitting $2c_1c_2S_{12}$ equally between centers 1 and 2. Thus center 1 is assigned $c_1^2 + c_1c_2S_{12}$, center 2 $c_2^2 + c_1c_2S_{12}$, and the sum is guaranteed to add up to 1. It should be realized that the Mulliken prescription for partitioning the overlap density, while uniquely defined, is quite arbitrary.

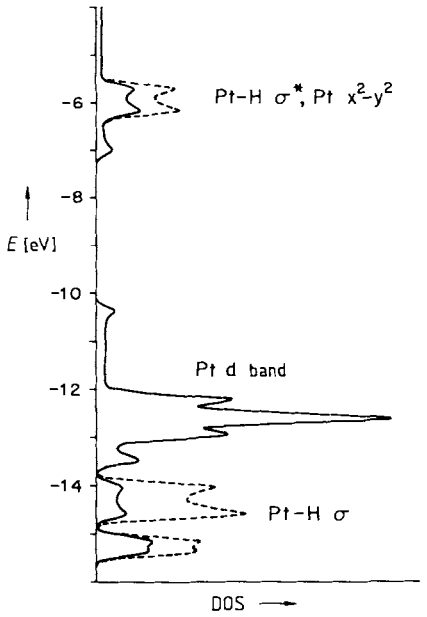

Fig. 6. The solid line is the Pt contribution to the total DOS (dashed line) of an eclipsed $[PtH_4]^{2\ominus}$ stack. What is not on Pt is on the four H's.

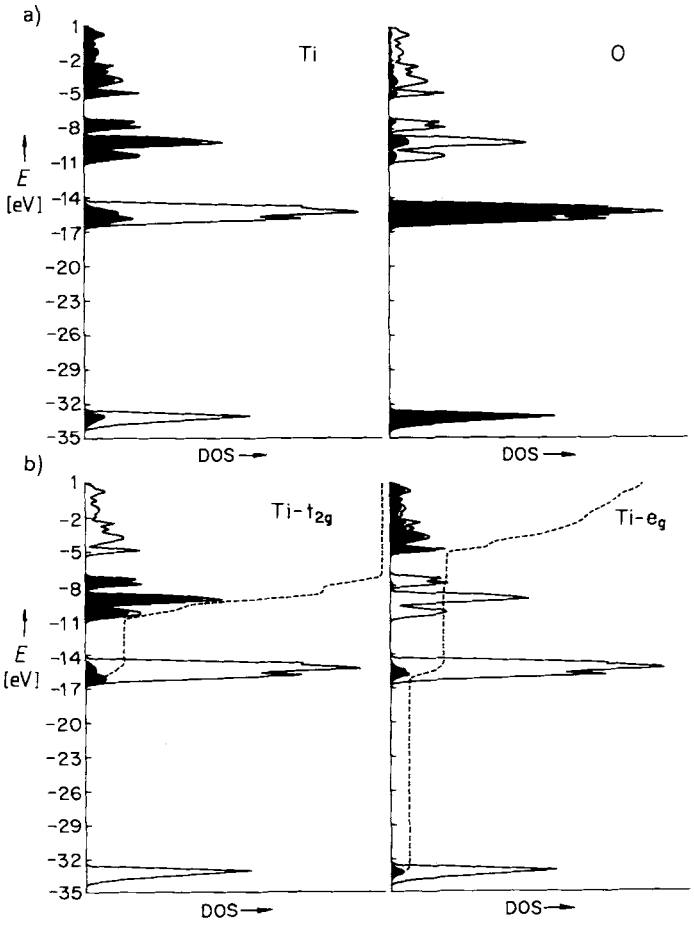

Fig. 7. a) Contributions of Ti and O (dark area) to the total DOS (solid line) of rutile, TiO_2. b) The t_{2g} and e_g Ti contributions (dark area); their integration (on a scale of 0 to 100%) is given by the dashed line.

What a computer does is just a little more involved, for it sums these contributions for each atomic orbital on a given center (there are several), over each occupied MO (there may be many). And in the crystal, it does it for several k points in the Brillouin zone, and then returns to real space by averaging over these.[15] The net result is a partitioning of the total DOS into contributions to it by either atoms or orbitals. In the solid-state trade these are often called "projections of the DOS" or "local DOS." Whatever they're called, they divide up the DOS among the atoms. The integral of these projections up to the Fermi level then gives the total electron density on a given atom or in a specified orbital. Then, by reference to some standard density, a charge can be assigned.

Figures 6 and 7 give the partitioning of the electron density between Pt and H in the $[PtH_4]^{2\ominus}$ stack, and between Ti and O in rutile. Everything is as **19** and **21** predict, as the chemist knows it should be—the lower orbitals are localized in the more electronegative ligands (H or O), the higher ones on the metal.

Do we want more specific information? In TiO_2 we might want to see the crystal field argument upheld. So we ask for the contributions of the three orbitals that make up the t_{2g} (d_{xz}, d_{yz}, d_{xy} in a local coordinate system) and the two orbitals that make up the e_g (d_{z^2}, $d_{x^2-y^2}$) set. This is also shown in Figure 7. Note the very clear separation of the t_{2g} and e_g orbitals. The e_g set has a small amount of density in the O 2s and 2p bands (σ bonding) and the t_{2g} set in the O 2p band (π bonding). Each metal orbital type (t_{2g} or e_g) is spread out into a band, but the memory of the near octahedral local crystal field is very clear.

In $[PtH_4]^{2\ominus}$ we could ask the computer to give us the d_{z^2} contribution to the DOS, or the p_z part (Fig. 8). If we look at the z component of the DOS in $[PtH_4]^{2\ominus}$, we see a small contribution in the top of the z^2 band. This is easiest picked up by the integral in Figure 8b. The dotted line is a simple integration, like an NMR integration. It counts, on a scale of 0 to 100% at the top, what percent of the specified orbital is filled at a given energy. At the Fermi level in unoxidized $[PtH_4]^{2\ominus}$, about 4% of the z states are filled.

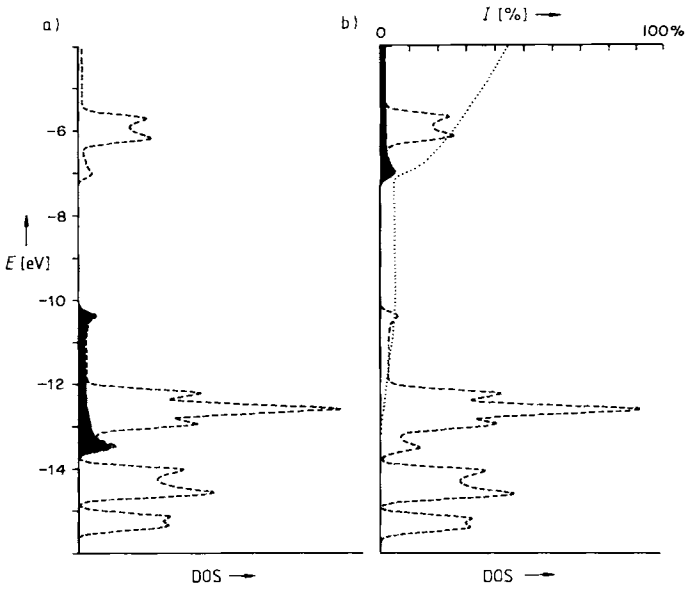

Fig. 8. a) d_{z^2} and b) p_z contributions (dark area) to the total DOS (dashed line) of an eclipsed $[PtH_4]^{2\ominus}$ stack. The dotted line is an integration I of the p_z orbital contribution.

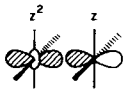
How does this come about? There are two ways to talk about this. Locally, the donor function of one monomer (d_{z^2}) can interact with the acceptor function (p_z) of its neighbor (**22**). The overlap is good, but the energy match is



22

poor.[8] So the interaction is small, but it's there. Alternatively, one could think about interaction of the Bloch functions, or symmetry-adapted z and z^2 crystal orbitals. At $k=0$ and $k=\pi/a$, they don't mix. But at every interior point in the Brillouin zone, the symmetry group of ψ is isomorphic to C_{4v},[15] and both z and z^2-Bloch functions transform as a_1. So they mix. Some small bonding is provided by this mixing. But it is really small. When the stack is oxidized, the loss of this bonding (which would lengthen the Pt-Pt contact) is overcome by the loss of Pt-Pt antibonding that is a consequence of the vacated orbitals being at the top of the z^2 band.

We have seen that we can locate the electrons in the crystal. But ...

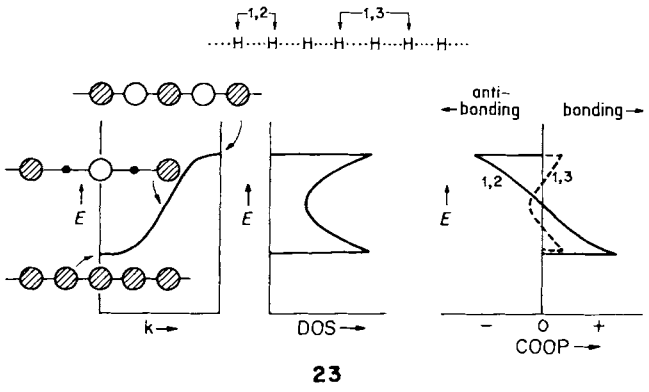
Where Are the Bonds?

Local bonding considerations (see **19**, **21**) trivially lead us to assign bonding characteristics to certain orbitals and, therefore, bands. There must be a way to find these bonds in the bands that a fully delocalized calculation gives.

It's possible to extend the idea of an overlap population to a crystal. Recall that in the integration of ψ^2 for a two-center orbital, $2c_1c_2S_{12}$ was a characteristic of bonding. If the overlap integral is taken as positive (and it can always be arranged so), then this quantity scales as we expect of a bond order: it is positive (bonding) if c_1 and c_2 are of the same sign, and negative if c_1 and c_2 are of opposite sign. And the magnitude of the "Mulliken overlap population," for that is what $2c_ic_jS_{ij}$ (summed over all orbitals on the two atoms, over all occupied MOs) is called, depends on c_i, c_j, and S_{ij}.

Now we move into the solid. An obvious procedure is to take all the states in a certain energy interval and interrogate them as to their bonding proclivities, measured by the Mulliken overlap population, $2c_ic_jS_{ij}$.[14] What we are defining is an overlap-population-weighted density of states. The beginning of the obvious acronym (OPWDOS) unfortunately has been preempted by another common usage in solid-state physics. For that reason we have called this quantity COOP (pronounced "co-op") for crystal orbital overlap population.[16] The suggestion of orbitals working together to make bonds in the crystal is not accidental.

To get a feeling for this quantity, let's think what a COOP curve for a hydrogen chain looks like. The simple band structure and DOS were given earlier; they are repeated with the COOP curve in **23**.



23

To calculate a COOP curve, one has to specify a bond. Let's take the nearest-neighbor 1,2 interaction. The bottom of the band is 1,2 bonding, the middle nonbonding, the top antibonding. The COOP curve obviously has the shape shown at right in **23**. But not all COOP curves look that way. If we specify the 1,3 next-nearest-neighbor bond (silly for a linear chain, not so silly if the chain is kinked), then the bottom *and* the top of the band are 1,3 bonding, the middle antibonding. That curve, the dotted line in the drawing, is different in shape. And, of course, its magnitude is much smaller, because of the rapid decrease of S_{ij} with distance.

Note the general characteristics of COOP curves—positive regions which are bonding, negative regions which are antibonding. The amplitudes of these curves depend on the number of states in that energy interval, the magnitude of the coupling overlap, and the size of the coefficients in the MOs.

The integral of the COOP curve up to the Fermi level is the total overlap population of the specified bond. This points us to another way of thinking of the DOS and COOP curves. These are the differential versions of electron number and bond order indices in the crystal. The integral of the DOS to the Fermi level gives the total number of electrons, the integral of the COOP curve gives the total overlap population, which is not identical to the bond order but which scales like it. It is the closest a theoretician can get to that ill-defined but fantastically useful simple concept of a bond order.

To move to something a little more complicated than the hydrogen or polyene chain, let's examine the COOP curves for the $[PtH_4]^{2\ominus}$ chain. Figure 9 shows both the Pt-H and Pt-Pt COOP curves. The DOS curve for the polymer is also drawn. The characterization of certain bonds as bonding or antibonding is obvious, and matches fully the expectations of the approximate sketch **19**. (1) The bands at -14 and -15 eV are Pt-H σ bonding, the band at -6 eV Pt-H antibonding (this is the crystal-field-destabilized $d_{x^2-y^2}$ orbital). (2) It is no surprise that the mass of d-block levels between -10 and -13 eV doesn't contribute anything to Pt-H bonding. But of course it is these orbitals which are involved in Pt-Pt bonding. The rather complex structure of the -10 to -13 eV region is easily understood by thinking of it as a superposition of σ ($d_{z^2}-d_{z^2}$), π ((d_{xz},d_{yz})$-$(d_{xz},d_{yz})), and δ ($d_{xy}-d_{xy}$) bonding and antibonding, as shown in **24**. Each type of bonding generates a band, the bottom of which is bonding and the top antibonding (see **15** and Fig. 3). (3) The δ contribution to the COOP is small, because of the poor overlap involved. The large Pt-Pt bonding region at -7 eV is due to the bottom of the Pt z band.

We now have a clear representation of the Pt-H and Pt-Pt bonding properties as a function of energy. If we are presented with an oxidized material, then the consequences of the oxidation on the bonding are crystal clear from Figure 9. Removing electrons from the top of the z^2 band at ≈ -10 eV takes them from orbitals that are Pt-Pt antibonding and Pt-H nonbonding. So we expect the Pt-Pt separation, the stacking distance, to decrease, as it does.

The tuning of electron counts is one of the strategies of the solid-state chemists. Elements can be substituted, atoms intercalated, nonstoichiometries enhanced. Oxidation and reduction, in solid-state chemistry as in ordinary molecular solution chemistry, are about as characteristic (but experimentally not always trivial) chemical activities

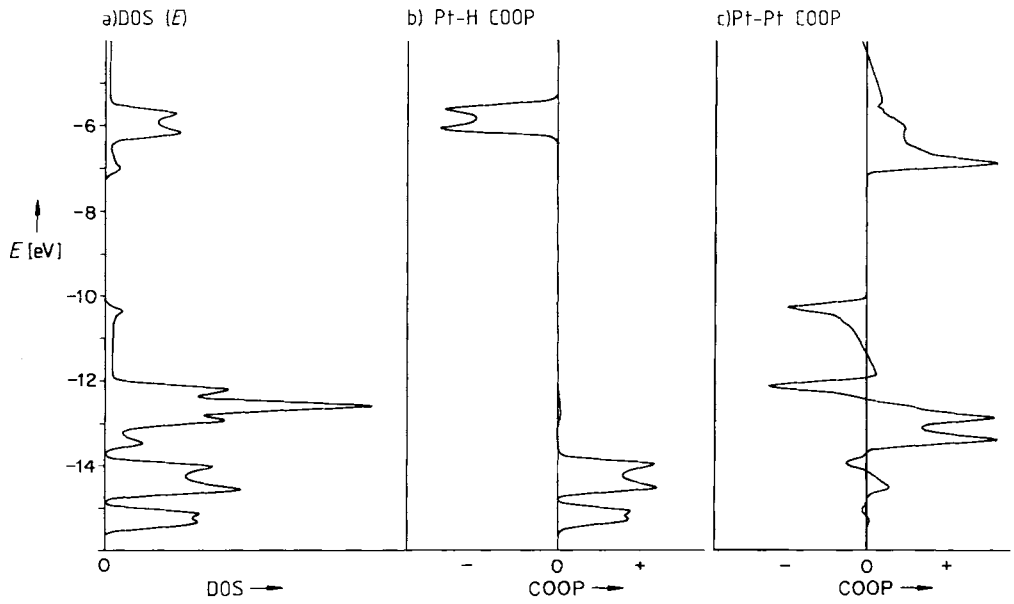


Fig. 9. Total density of states (a), and Pt-H (b) and Pt-Pt (c) crystal orbital overlap population curves for the eclipsed $[PtH_4]^{2\ominus}$ stack.

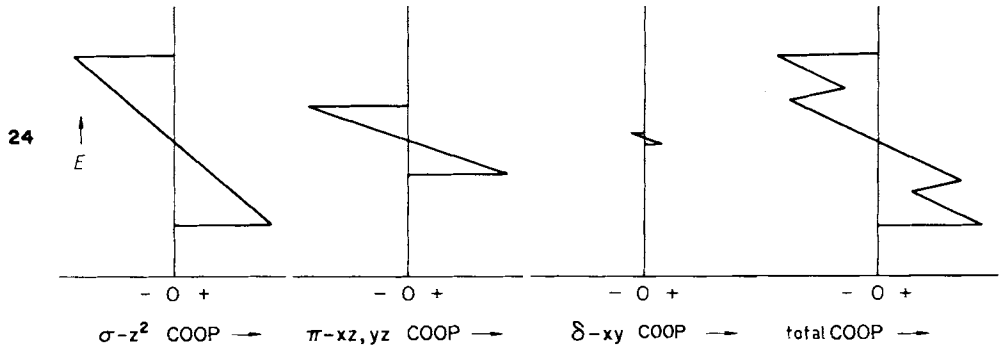
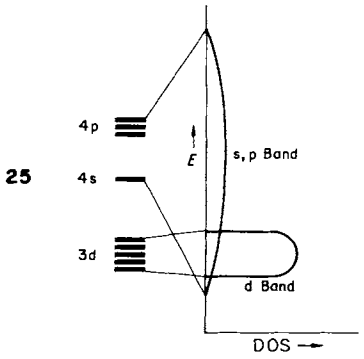


as one can conceive. The conclusions we reached for the Pt–Pt chain were simple, easily anticipated. Other cases are guaranteed to be more complicated. The COOP curves allow one, at a glance, to reach conclusions about the local effects on bond length (will bonds be weaker, stronger) upon oxidation or reduction.

We showed earlier a band structure for rutile (Fig. 5b, repeated in Fig. 10a). The corresponding COOP curve for the Ti–O bond (Fig. 10b) is extremely simple. Note the bonding in the lower, oxygen bands, and antibonding in the e_g crystal-field-destabilized orbital. The t_{2g} is, as expected, Ti–O "π-antibonding."

Let's try our hand at predicting the DOS for something quite different from $[PtH_4]^{2\ominus}$ or TiO_2, namely, a bulk transition metal, the face-centered cubic Ni structure. Each metal atom has as its valence orbitals 3d, 4s, and 4p, ordered in energy approximately as at the left in **25**. Each will spread out into a band. We can make some judgment as to the width of the bands from the overlap. The s,p orbitals are diffuse, their overlap will be large, and a wide band will result. They also mix with each other extensively. The d orbitals are contracted, and so will give rise to a relatively narrow band.

The computed DOS for bulk Ni (bypassing the actual band structure) is shown in Figure 11, along with the Ni s and p contributions to that DOS. What is not s or p is d. The general features of **25** are reproduced. At the Fermi level, a substantial part of the s band is occupied, so that the calculated[17] Ni configuration is $d^{9.15}s^{0.62}p^{0.23}$.



What would one expect of the COOP curve for bulk Ni? As a first approximation we could generate the COOP curve for each band separately (**26a**, **b**). Each band in **25** has a lower Ni–Ni bonding part, an upper Ni–Ni antibonding part. The composite is **26c**. The computed COOP curve is in Figure 12. The expectations of **26c** are met reasonably well.

A metal–metal COOP curve like that of **26c** or Figure 12 is expected for any transition metal. The energy levels

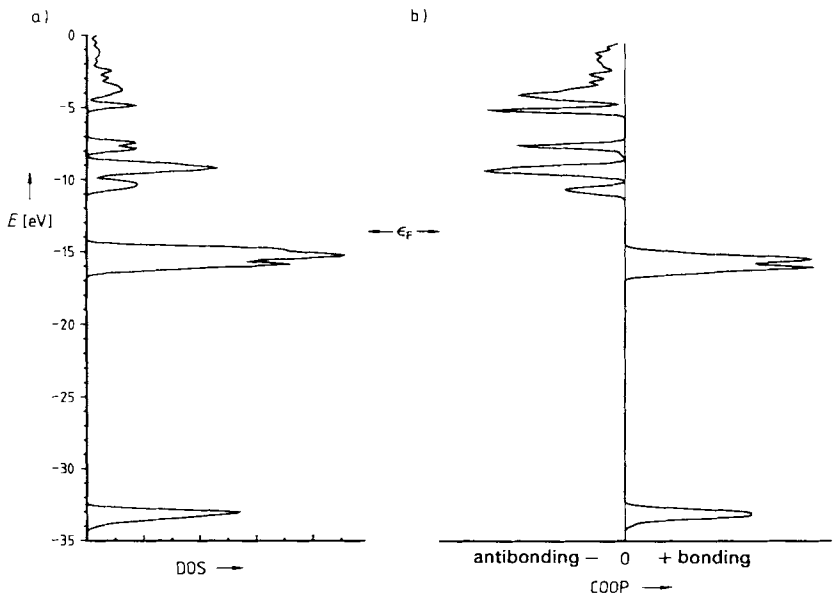


Fig. 10. a) DOS and b) Ti–O COOP for rutile.

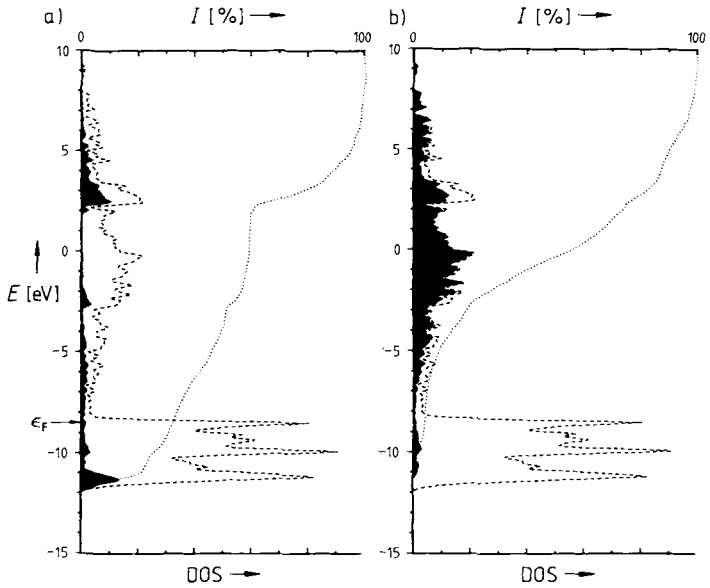

Fig. 11. Total DOS (dashed line) and 4s (a) and 4p (b) contributions to it in bulk Ni. The dotted line is an integration of the occupation of a specified orbital, on a scale of 0 to 100% given at top.

might be shifted up, they might be shifted down, but their bonding characteristics are likely to be the same. If we assume that a similar band structure and COOP curve hold for all metals (in the solid-state trade this would be called the rigid band model), then Figure 12 gains tremendous power. It summarizes, simply, the cohesive energies of all metals. As one moves across the transition series, the M–M overlap population (which is clearly related to the binding or cohesive energy) will increase, peaking at about six electrons per metal (Cr, Mo, W). Then it will decrease toward the end of the transition series and rise again for small s,p electron counts. For more than 14 electrons, a metal is unlikely; the net overlap population for such high coordination becomes negative. Molecular allotropes with lower coordination are favored. There is much more to cohesive energies and the metal–nonmetal transition than this, but

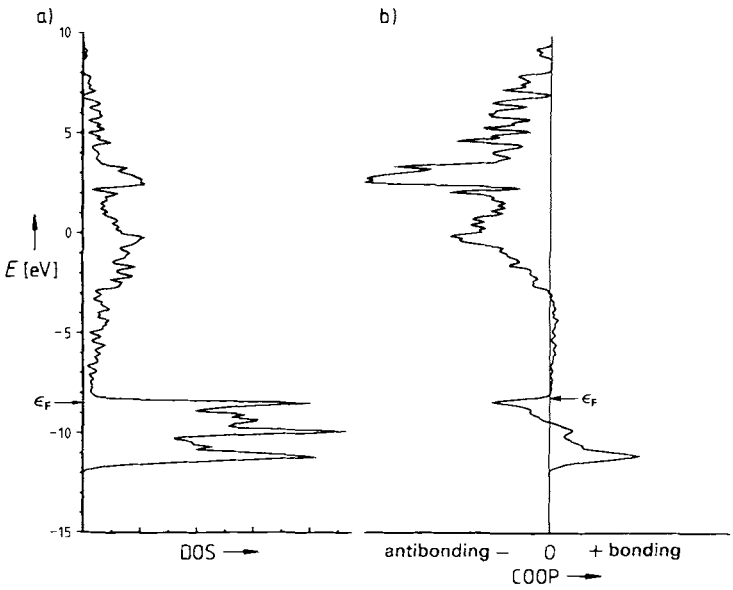

Fig. 12. a) The total DOS and b) nearest-neighbor Ni–Ni COOP in bulk Ni.

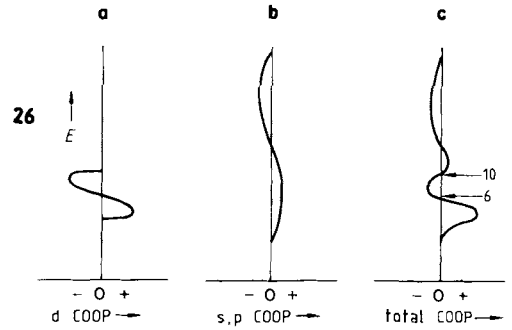


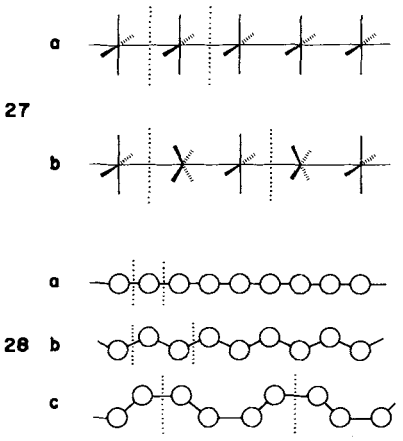
there is much physics and chemistry that flows from the simple construction of **26**.

With a little effort, we have constructed the tools—density of states, its decompositions, the crystal orbital overlap population—which allow us to move from a complicated, completely delocalized set of crystal orbitals or Bloch functions to the localized, chemical description. There is no mystery in this motion. In fact, what I hope I have shown here is just how much power there is in the chemists' concepts. The construction of the *approximate* DOS and bonding characteristics of a $[\{PtH_4\}^{2\ominus}]_\infty$ polymer, or rutile, or bulk Ni, is really easy.

Of course, there is much more to solid-state physics than band structures. The mechanism of conductivity, the remarkable phenomenon of superconductivity, the multitude of electric and magnetic phenomena that are special to the solid state, for these one needs the tools and ingenuity of physics.[6] But as for *bonding* in the solid state, I think (some will disagree) there is nothing new, only a different language.

More Than One Electronic Unit in the Unit Cell: Folding Bands

The oxidized cyanoplatinates are not eclipsed (**27a**), but staggered (**27b**). A polyene is not a simple linear chain, **28a**, but, of course, at least *s-trans* or zigzag, **28b**. Or it could be *s-cis*, **28c**. And obviously that does not exhaust the possibility of arrangements. Nature always seems to

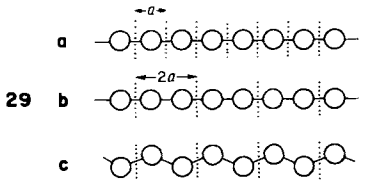


find one we haven't thought of. In **27a** and **28a**, the unit cell contains one basic electronic unit, $[PtH_4]^{2\ominus}$ and a CH group, respectively. In **27b** and **28b**, the unit is doubled, approximately so in unit cell dimension, exactly so in

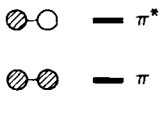
chemical composition. In **28c**, we have four CH units per unit cell. A purely physical approach might say each is a case unto itself. A chemist is likely to say that probably not much has changed on doubling or quadrupling or multiplying by 17 the contents of a unit cell. If the geometrical distortions of the basic electronic unit that is being repeated are not large, it is likely that any electronic characteristics of that unit are preserved.

The number of bands in a band structure is equal to the number of molecular orbitals in the unit cell. So if the unit cell contains 17 times as many atoms as the basic unit, it will contain 17 times as many bands. The band structure may look messy. The chemist's feeling that the "17-mer" is a small perturbation on the basic electronic unit can be used to simplify a complex calculation. Let's see how this goes, first for the polyene chain, then for the $[\{PtH_4\}^{2\ominus}]_\infty$ polymer.

28a, **b**, and **c** differ from each other not just in the number of CH entities in the unit cell, but also in their geometry. Let's take these one at a time. First prepare for the distortion from **28a** to **28b** by doubling the unit cell, and then, subsequently, distorting. This sequence of actions is indicated in **29**.

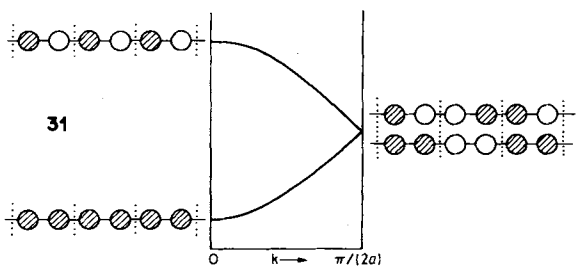


Suppose we construct the orbitals of **29b**, the doubled unit cell polymer, by the standard prescription: (1) get MOs in unit cell, (2) form Bloch functions from them. Within the unit cell the MOs of the dimer are π and π^*, **30**.



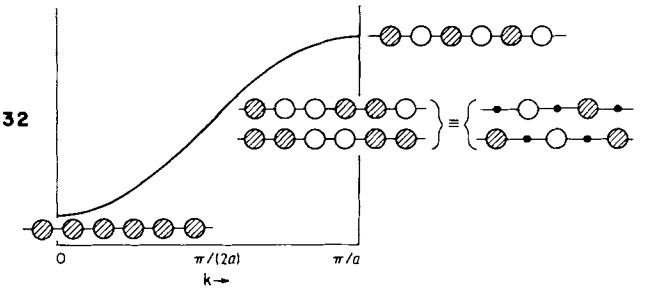
30

Each of these spreads out into a band, that of the π "running up," that of π^* "running down," **31**. The orbitals are written out explicitly at the zone boundaries in **31**. This



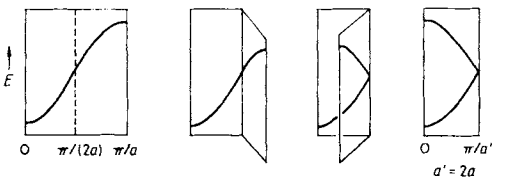
allows one to see that the top of the π band and the bottom of the π^* band, both at $k = \pi/2a$, are precisely degenerate. There is no bond alternation in this polyene (yet), and the two orbitals may have been constructed in a different way, but they obviously have the same nodal structure—one node every two centers.

If we now detach ourselves from this viewpoint and go back and construct the orbitals of the one CH per unit cell linear chain **29a**, we get **32**. The Brillouin zone in **29b** is half as long as it is here, because the unit cell is twice as long.



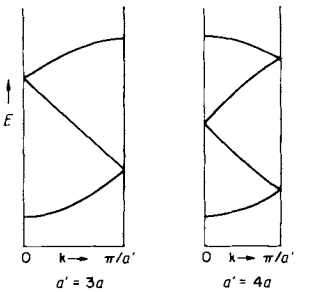
At this point, the realization hits us that, of course, the orbitals of these polymers are the same. The polymers are identical, it is only some peculiar quirk that made us choose one CH unit as the unit cell in one case, two CH units in the other. I have presented the two constructions independently to make explicit the identity of the orbitals.

What we have is two ways of presenting the same orbitals. Band structure **31**, with two bands, is identical to **32**, with one band. All that has happened is that the band of the minimal polymer, one CH per unit cell, has been "folded back" in **32**. The process is shown in **33**.[18]



33

The process can be continued. If the unit cell is tripled, the band will fold as in **34a**. If it is quadrupled, we get **34b**, and so on. However, the point of all this is not just



34

redundancy, seeing the same thing in different ways. There are two important consequences or utilizations of this folding. First, if a unit cell contains more than one electronic unit (and this happens often), then a realization of that fact, and the attendant multiplication of bands (remember

32 → **31**, **34a**, or **34b**), allows a chemist to simplify in his or her mind the analysis. The multiplicity of bands is a consequence of an enlargement of the unit cell. By reversing, in our minds in a model calculation, the folding process, by unfolding, we can go back to the most fundamental electronic act—the true monomer.

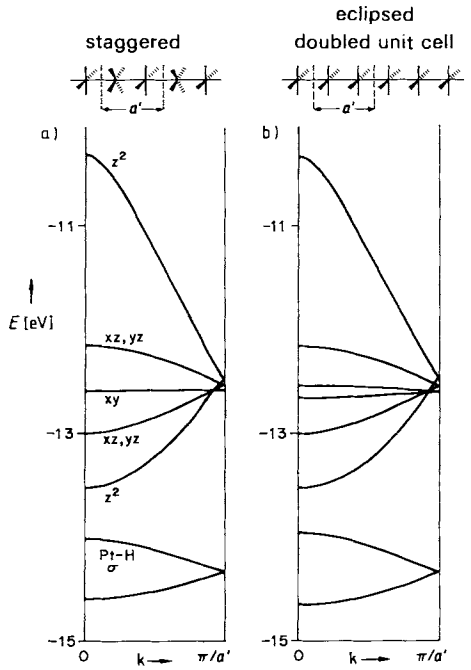


Fig. 13. The band structure of a staggered $[PtH_4]^{2\ominus}$ stack (a), compared with the folded-back band structure of an eclipsed stack, two $[PtH_4]^{2\ominus}$ in a unit cell (b).

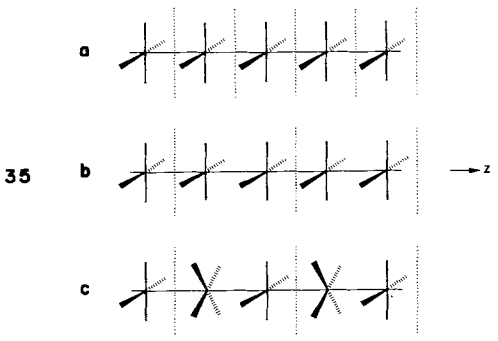
To illustrate this point, let me show the band structure of the *staggered* $[PtH_4]^{2\ominus}$ chain, **27b**. This is done in Figure 13a. There are twice as many bands in this region as there are in the case of the eclipsed monomer (the xy band is doubly degenerate). This is no surprise; the unit cell in the staggered polymer is $[\{PtH_4\}^{2\ominus}]_2$. But it's possible to understand Figure 13 as a small perturbation on the eclipsed polymer. Imagine the thought process **35a** → **35b** → **35c**, i.e., doubling the unit cell in an eclipsed polymer and then rotating every other unit by 45° around the z axis. To go



from **35a** to **35b** is trivial, a simple folding back. The result is shown in Figure 13b. Figures 13a and 13b are nearly identical. There is a small difference in the xy band, which is doubled, nondegenerate, in the folded-back eclipsed polymer (Fig. 13b), but degenerate in the staggered polymer. What happened here could be stated in two ways, both the consequence of the fact that a real rotation intervenes between **35b** and **35c**. From a group-theoretical point of view, the staggered polymer has a new, higher symmetry element, an eightfold rotation-reflection axis. Higher symmetry means more degeneracies. It is easy to see that the two combinations, **36**, are degenerate.

Except for this minor wrinkle, the band structures of the folded-back eclipsed polymer and the staggered one are very, very similar. That allows us to reverse the argument, to *understand* the staggered one in terms of the eclipsed one plus the here minor perturbation of rotation of every second unit.

The chemist's intuition is that the eclipsed and staggered polymers *can't* be very different. At least until the ligands start bumping into each other, and for such steric effects there is, in turn, much further intuition. The band structures may look different, for one polymer has one, the other two basic electronic units in the cell. Chemically, however, they should be similar, and we can see this by returning from reciprocal space to real space. Figure 14, comparing the DOS of the staggered (Fig. 14a) and eclipsed (Fig. 14b) polymers, shows just how alike they are in their distribution of levels in energy.

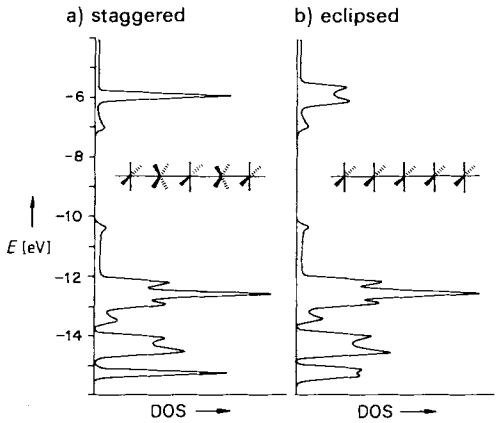


Fig. 14. A comparison of the DOS of staggered (a) and eclipsed (b) $[PtH_4]^{2\ominus}$ stacks.

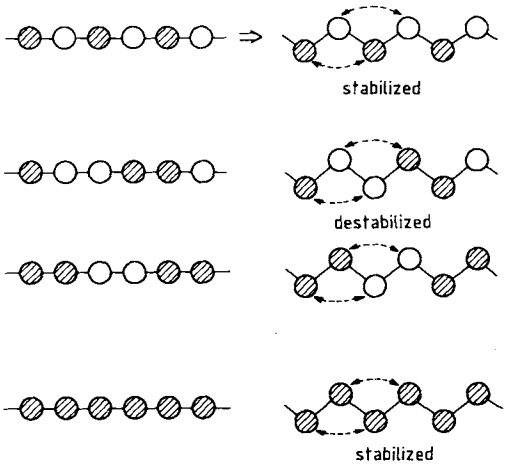
There is another reason for feeling at home with the folding process. The folding-back construction may be a prerequisite to understanding a chemically significant distortion of the polymer. To illustrate this point, we return to the polyene **29**. To go from **29a** to **29b** involves no distortion. However, **29b** is a way point, a preparation for a real distortion to the more realistic "kinked" chain, **29c**. It behooves us to analyze the process stepwise if we are to understand the levels of **29c**.

Of course, nothing much happens to the π system of the polymer on going from **29a**,**b** to **29c**. If the nearest-neighbor distances are kept constant, then the first real change is

in the 1,3 interactions. These are unlikely to be large in a polyene, since the π overlap falls off very quickly past the bonding region. We can estimate what will happen by writing down some explicit points in the band, and deciding whether the 1,3 interaction that is turned on is stabilizing or destabilizing. This is done in **37**. Of course, in a real CH



37

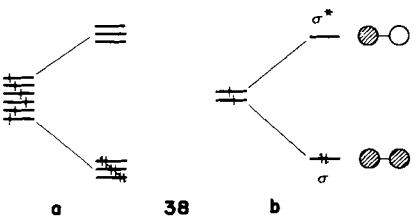
polymer this kinking distortion is very much a real thing, but that has nothing to do with the π system, it's a result of strain.

However, there is another distortion which the polyene can and does undergo. This is double-bond localization, an example of the very important Peierls distortion, the solid-state analogue of the Jahn–Teller effect.

Making Bonds in a Crystal

When a chemist sees a molecular structure which contains several free radicals, orbitals with unpaired electrons, his inclination is to predict that such a structure will undergo a geometry change in which electrons will pair up, forming bonds. It is this reasoning, so obvious as to seem almost subconscious, which is behind the chemist's intuition that a chain of hydrogen atoms will collapse into a chain of hydrogen molecules.

If we translate that intuition into a molecular orbital picture, we have **38a**, a bunch (here six) of radicals forming bonds. That process of bond formation follows the H_2 paradigm, **38b**, i.e., in the process of making each bond a level goes down, a level goes up, and two electrons are stabilized by occupying the lower, bonding orbital.



a **38** b

In solid-state physics, bond formation has not stood at center stage, as it has in chemistry. The reasons for this are obvious: the most interesting developments in solid-state physics have been around metals and alloys, and in these often close-packed or nearly close-packed substances, by and large localized chemical viewpoints have seemed irrelevant. For another large group of materials, ionic solids, it also seemed useless to think of bonds. My contention is that there is a range of bonding, including what are usually called metallic, covalent, and ionic solids, and that there is, in fact, substantial overlap between seemingly divergent frameworks of describing the bonding in these three types of crystals. I will take the view that the covalent approach is central and look for bonds when others wouldn't think they're there. One reason for tolerating such foolhardiness might be that the other approaches (metallic, ionic) have had their day—why not give this one a chance? A second reason, one I've mentioned earlier, is that, in thinking and talking about bonds in the crystal, one makes a psychologically valuable connection to molecular chemistry.

To return to our discussion of molecular and solid-state bond formation, let's pursue the trivial chemical perspective of the beginning of this section. The guiding principle, implicit in **38**, is: *Maximize bonding*. There may be impediments to bonding: electron repulsions, steric effects, i.e., the impossibility of two radicals to reach within bonding distance of each other. Obviously, the stable state is a compromise—some bonding may have to be weakened to strengthen some other bonding. But, in general, a system will distort so as to make bonds out of radical sites. Or to translate this into the language of densities of states: *maximizing bonding in the solid state is connected to lowering the DOS at the Fermi level, moving bonding states to lower energy, antibonding ones to high energy.*

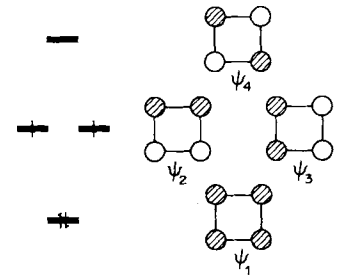
The Peierls Distortion

In considerations of the solid state, a natural starting point is high symmetry—a linear chain, a cubic or close-packed three-dimensional lattice. The orbitals of the highly symmetrical, idealized structures are easy to obtain, but they often do not correspond to situations of maximum bonding. These are less symmetrical, deformations of the simplest, archetype structure.

The chemist's experience is usually the reverse, beginning from localized structures. However, there is one piece of experience we have that matches the way of thinking of the solid-state physicist. This is the Jahn–Teller effect,[19] and it's worthwhile to show its working by a simple example.

The Hückel π MOs of a square-planar cyclobutadiene are well known. They are the one-below-two-below-one set shown in **39**.

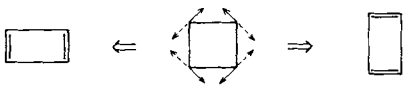
39



We have a typical Jahn–Teller situation—two electrons in two degenerate orbitals. (Of course, we need worry

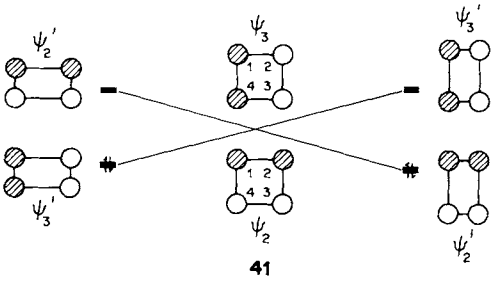
about the various states that arise from this occupation, and the Jahn-Teller theorem really applies to only one.[19] The Jahn-Teller theorem says that such a situation necessitates a large interaction of vibrational and electronic motion. It states that there must be at least one normal mode of vibration which will break the degeneracy and lower the energy of the system (and, of course, lower its symmetry). It even specifies which vibrations would accomplish this.

In the case at hand the most effective normal mode is illustrated in **40**. It lowers the symmetry from D_{4h} to D_{2h}, and, to use chemical language, localizes double bonds.



40

The orbital workings of this Jahn-Teller distortion are easy to see. **41** illustrates how the degeneracy of the e orbital is broken in the two phases of the vibration. On forming the rectangle as at right in **40** or **41**, ψ_2 is stabilized:

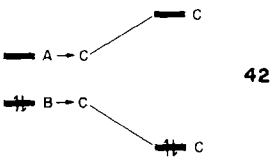


41

the 1-2 and 3-4 interactions, which were bonding in the square, are increased; the 1-4 and 2-3 interactions, which were antibonding, are decreased by the deformation. The reverse is true for ψ_3—it is destabilized by the distortion at right. If we follow the opposite phase of the vibration (to the left in **40** or **41**), ψ_3 is stabilized, ψ_2 destabilized.

The essence of the Jahn-Teller theorem is revealed here: a symmetry-lowering deformation breaks an orbital degeneracy, stabilizing one orbital, destabilizing another. Note the phenomenological correspondence to **38** in the previous section.

One doesn't need a real degeneracy to benefit from this effect. Consider a nondegenerate two-level system, **42**,



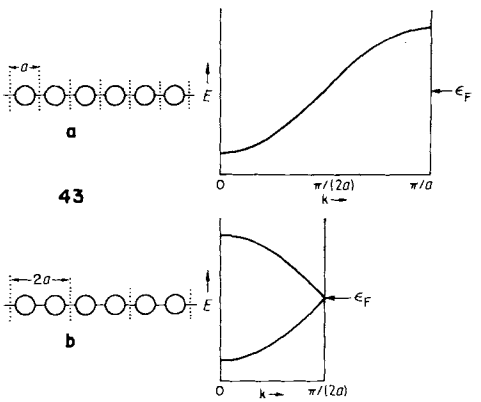
42

with the two levels of different symmetry (here labeled A and B) in one geometry. If a vibration lowers the symmetry so that these two levels transform as the same irreducible representation (call it C), then they will interact, mix, repel each other. For two electrons, the system will be stabilized. The technical name of this effect is a second-order Jahn-Teller deformation.[19]

The essence of the Jahn-Teller effect, first or second order, is: a high-symmetry geometry generates a degeneracy or near degeneracy, which can be broken, with stabilization, by a symmetry-lowering deformation. Note a further point: the level degeneracy is not enough by itself—one needs the right electron count. The cyclobutadiene (or any square) situation of **39** will be stabilized by a D_{2h} deformation for three, four, or five electrons, but not for two or six (e.g., $S_4^{2\oplus}$).

This framework we can take over to the solid. There is degeneracy and near degeneracy for any partially filled band. The degeneracy is that already mentioned, for $E(k)=E(-k)$ for any k in the zone. The near degeneracy is, of course, for k's just above or just below the specified Fermi level. For any such partially filled band there is, in principle, available a deformation which will lower the energy of the system. In the jargon of the trade one says that the partial filling leads to an electron-phonon coupling which opens up a gap just at the Fermi level. This is the Peierls distortion,[20] the solid-state counterpart of the Jahn-Teller effect.

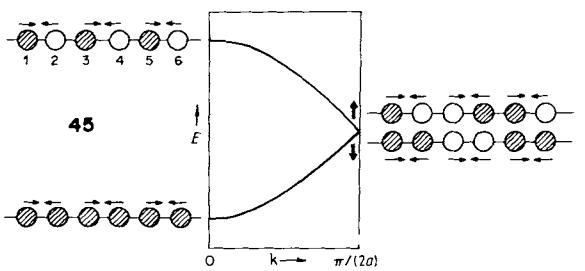
Let's see how this works on a chain of hydrogen atoms (or a polyene). The original chain has one orbital per unit cell, **43a**, and an associated simple band. We prepare it for



deformation by doubling the unit cell, **43b**. The band is typically folded. The Fermi level is halfway up the band—the band has room for two electrons per orbital, but for H or CH we have one electron per orbital.

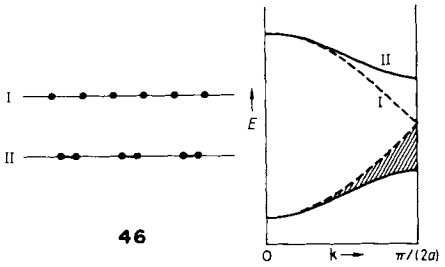
44

The phonon or lattice vibration mode that couples most effectively with the electronic motions is the symmetric pairing vibration, **44**. Let's examine what it does to typical orbitals at the bottom, middle (Fermi level), and top of the band, **45**.



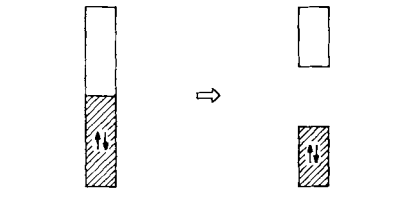
At the bottom and top of the band nothing happens. What is gained (lost) in increased 1-2, 3-4, 5-6, etc. bonding (antibonding) is lost (gained) in decreased 2-3, 4-5, 6-7, etc. bonding (antibonding). But in the middle of the band, at the Fermi level, the effects are dramatic. One of the degenerate levels there is stabilized by the distortion, the other destabilized. Note the phenomenological similarity to what happened for cyclobutadiene.

The action does not take place just at the Fermi level, but in a second-order way the stabilization "penetrates" into the zone. It does fall off with k, a consequence of the way perturbation theory works. A schematic representation of what happens is shown in **46** (I and II represent the



46

chain before and after the distortion). A net stabilization of the system occurs for any Fermi level, but obviously it is maximal for the half-filled band, and it is at the ε_F that the band gap is opened up. If we were to summarize what happens in block form, we'd get **47**. Note the resemblance to **38**.



47

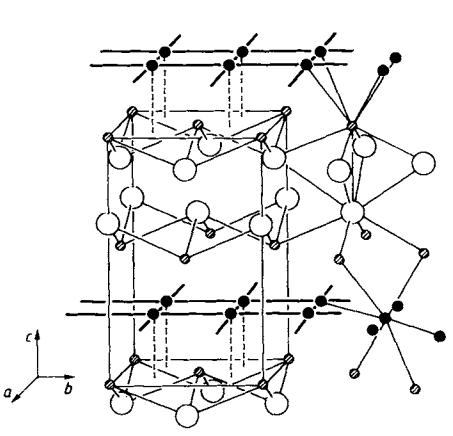
The polyene case (today it would be called polyacetylene) is especially interesting, for some years ago it occasioned a great deal of discussion. Would an infinite polyene localize (**48**)? Eventually, *Salem* and *Longuet-Higgins* demonstrated that it would.[21] Polyacetylenes are an exciting field of modern research.[22] Pure polyacetylene is not a conductor. When it is doped, either partially filling the upper band in **45** or emptying the lower, it becomes a superb conductor.

48

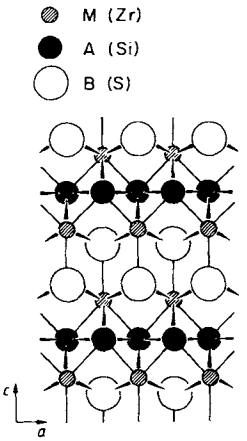
There are many beautiful intricacies of the first- and second-order and low- or high-spin Peierls distortion, and for these the reader is referred to the very accessible review by *Whangbo*.[5]

The Peierls distortion plays a crucial role in determining the structure of solids in general; the one-dimensional pairing distortion is only one simple example of its workings. Let's move up in dimensionality.

One ubiquitous ternary structure is that of PbFCl (ZrSiS, BiOCl, Co_2Sb, Fe_2As).[23,24] We'll call it MAB here, because in the phases of interest to us the first element is often a transition metal, the other components, A, B, often main-group elements. **49** shows one view of this structure, **50** another.



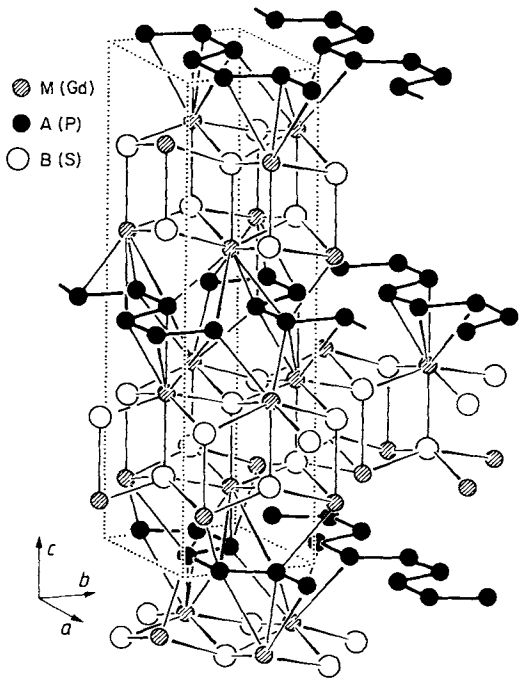
49



50

In this structure we see two associated square nets of M and B atoms, separated by a square-net layer of A's. The A layer is twice as dense as the others, hence the MAB stoichiometry. Most interesting, from a Zintl viewpoint, is a consequence of that A layer density, a short A-A contact, typically 2.5 Å for Si. This is definitely in the range of some bonding. There are no short B-B contacts.

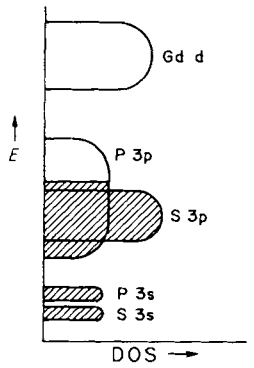
Some compounds in this series in fact retain this structure. Others distort. It is easy to see why. Take GdPS. If we assign normal oxidation states of $Gd^{3\oplus}$ and $S^{2\ominus}$, we come to a formal charge of $P^{\ominus}$ on the dense-packed P net. From a Zintl viewpoint, $P^{\ominus}$ is like S and so should form two bonds per P. This is exactly what it does. The GdPS struc-



51

ture[25] is shown in **51**, which is drawn after the beautiful representation of *Hulliger* et al.[25] Note the P–P *cis* chains in this elegant structure.

From the point of view of a band structure calculation one might also expect bond formation, a distortion of the square net. **52** shows a qualitative DOS diagram for GdPS.



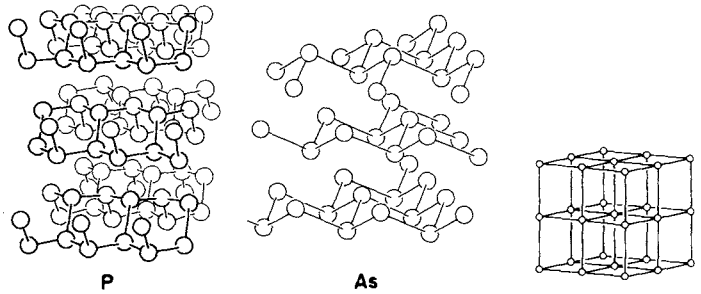
52

What goes into the construction of this diagram is a judgment as to the electronegativities (Gd < P < S). And the structural information that there are short P–P interactions in the undistorted square net, but no short S–S contacts. With the normal oxidation states of $Gd^{3\oplus}$ and $S^{2\ominus}$ one comes to $P^{\ominus}$, as stated above. This means the P 3p band is 2/3 filled. The Fermi level is expected to fall in a region of a large DOS, as **52** shows. A distortion should follow.

The details of what actually happens are presented elsewhere.[24] The situation is intricate; the observed structure is only one likely way for the parent structure to stabilize—there are others. **53** shows some possibilities suggested by *Hulliger* et al.[25] CeAsS chooses **53c**.[26] Nor is the range of geometrical possibilities of the MAB phases exhausted by these. Other deformations are possible; many of them can be rationalized in terms of second-order Peierls distortions in the solid.[24]

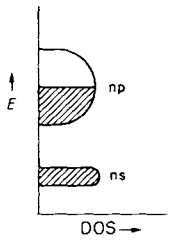
An interesting three-dimensional instance of a Peierls distortion at work (from one point of view) is the derivation of the observed structures of elemental arsenic and black phosphorus from a cubic lattice. This treatment is due to *Burdett* and co-workers.[2,27] The two structures are shown in their usual representation in **54**. It turns out that they can be easily related to a simple cubic structure, **55**.

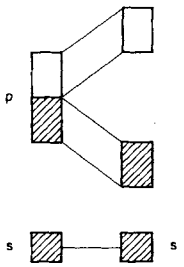
The DOS associated with the band structure of **55**, with one element of the fifth main group per lattice site must



54 **55**

have the block form **56**. There are five electrons per atom, so if the s band is completely filled, we have a half-filled p band. The detailed DOS is given elsewhere.[27] What is significant here is what we see without calculations, namely, a half-filled band. This system is a good candidate for a Peierls distortion. One pairing up of all the atoms along the x, y, and z directions will provide the maximum stabilization, indicated schematically in **57**.

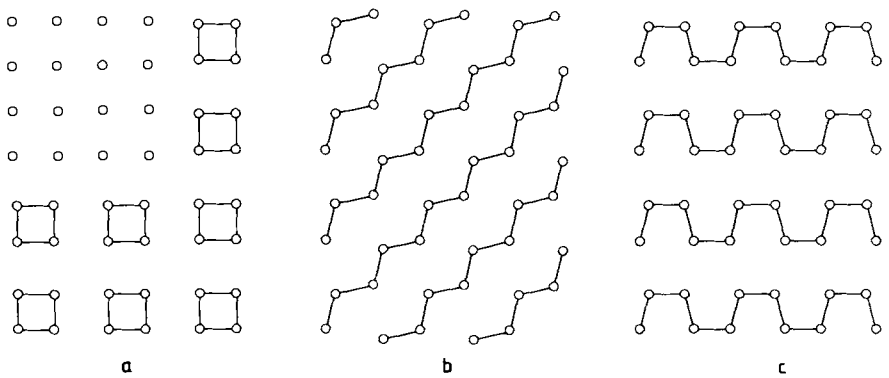




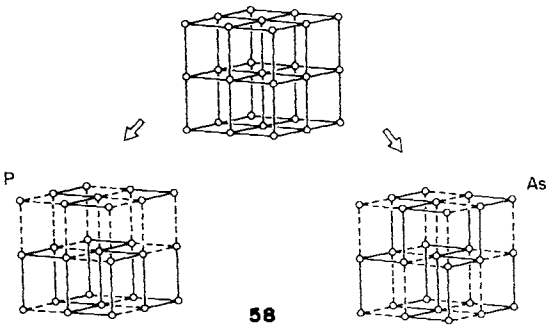
56 **57**

Burdett, *McLarnan*, and *Haaland*[27a,c] have shown that there are no less than 36 different ways to so distort. Two of these correspond to black phosphorus and arsenic, **58**. There are other possibilities.

There is one aspect of the outcome of a Peierls distortion, the creation of a gap at the Fermi level, that might be taken from the last case as being typical, but which is not necessarily so. In one dimension one can always find a Peierls distortion to create a gap. In three dimensions, atoms are much more tightly linked together. In some cases a stabilizing deformation leads to the formation of a real band gap, to an insulator or semiconductor. In other cases, a deformation is effective in producing bonds, pull-



53



58

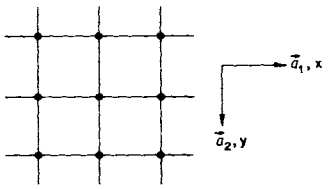
ing some states down from the Fermi level region. But because of the three-dimensional linkage it may not be possible to remove all the states from the Fermi level region. Some DOS remains there; the material may still be a conductor.

The applications discussed in this section make it clear that one must know, at least approximately, the band structure (and the consequent DOS) of two- and three-dimensional materials before one can make sense of their marvelous geometrical richness. The band structures that we have discussed in detail have been one-dimensional. Now let's look more carefully at what happens as we increase dimensionality.

More Dimensions

Most materials are two- or three-dimensional, and while one dimension is fun, we must eventually leave it for higher dimensionality. Nothing much new happens, except that we must treat $\vec{k}$ as a vector, with components in reciprocal space, and the Brillouin zone is now a two- or three-dimensional area or volume.[6, 15]

To introduce some of these ideas, let's begin with a square lattice, **59**, defined by the translation vectors $\vec{a}_1$ and

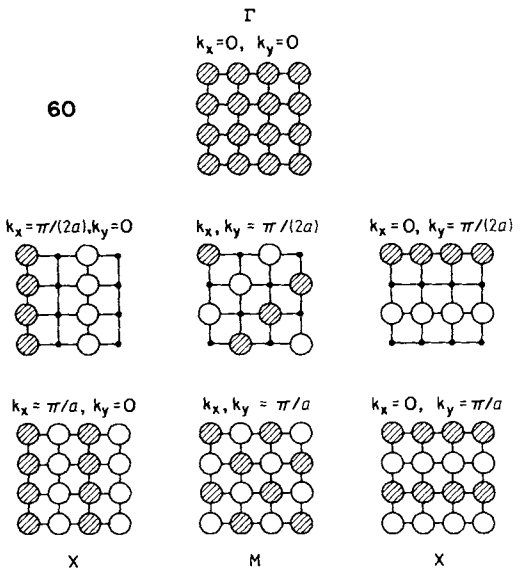


59

$\vec{a}_2$. Suppose there is an H 1s orbital on each lattice site. It turns out that the Schrödinger equation in the crystal factors into separate wave equations along the x and y axes, each of them identical to the one-dimensional equation for a linear chain. There is a k_x and a k_y, the range of each is $0 \leq |k_x|, |k_y| \leq \pi/a$ ($a = |\vec{a}_1| = |\vec{a}_2|$). Some typical solutions are shown in **60**.

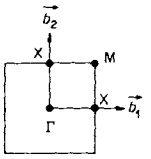
The construction of these is obvious. What the construction also shows, very clearly, is the vector nature of k. Consider the $(k_x, k_y) = (\pi/2a, \pi/2a)$ and $(\pi/a, \pi/a)$ solutions. A look at them reveals that they are waves running along a direction which is the vector sum of k_x and k_y, i.e., on a diagonal. The wavelength is inversely proportional to the magnitude of that vector.

The space of k here is defined by two vectors $\vec{b}_1$ and $\vec{b}_2$, and the range of allowed k, the Brillouin zone, is a square.



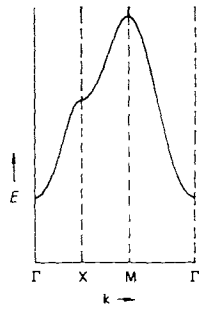
60

Certain special values of k are given names: $\Gamma = (0,0)$ is the zone center, $X = (\pi/a, 0) = (0, \pi/a)$, $M = (\pi/a, \pi/a)$. These are shown in **61**, and the specific solutions for Γ, X, M were so labeled in **60**.



61

It is difficult to show the energy levels, $E(\vec{k})$ for all $\vec{k}$. So what one typically does is to illustrate the evolution of E along certain lines in the Brillouin zone. Some obvious ones are $\Gamma \rightarrow X$, $\Gamma \rightarrow M$, $X \rightarrow M$. From **60** it is clear that M is the highest energy wave function, and that X is pretty much nonbonding, since it has as many bonding interactions (along y) as it does antibonding ones (along x). So we would expect the band structure to look like **62**. A computed band structure and DOS for a hydrogen lattice with $a = 2.0$ Å (Fig. 15) confirms our expectations.



62

The chemist would expect the chessboard of H atoms to distort into one of H_2 molecules (an interesting problem is how many different ways there are to accomplish this). The large peak in the DOS for the half-filled H square-lattice band would make the physicist think of a lattice vibration that would create a gap at ε_F. Any pairwise deformation will do that.

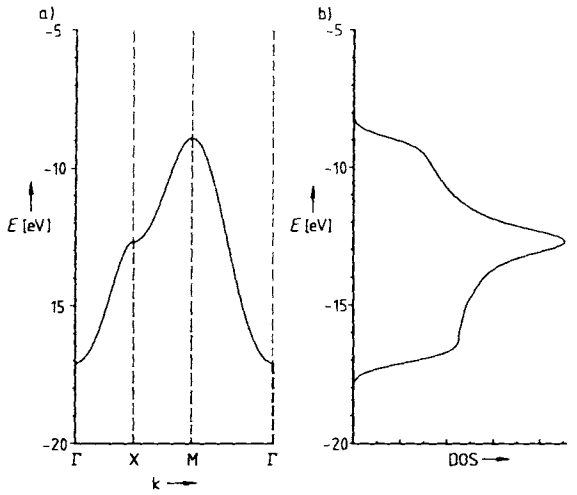


Fig. 15. a) The band structure and b) DOS of a square lattice of H atoms; H-H separation 2.0 Å.

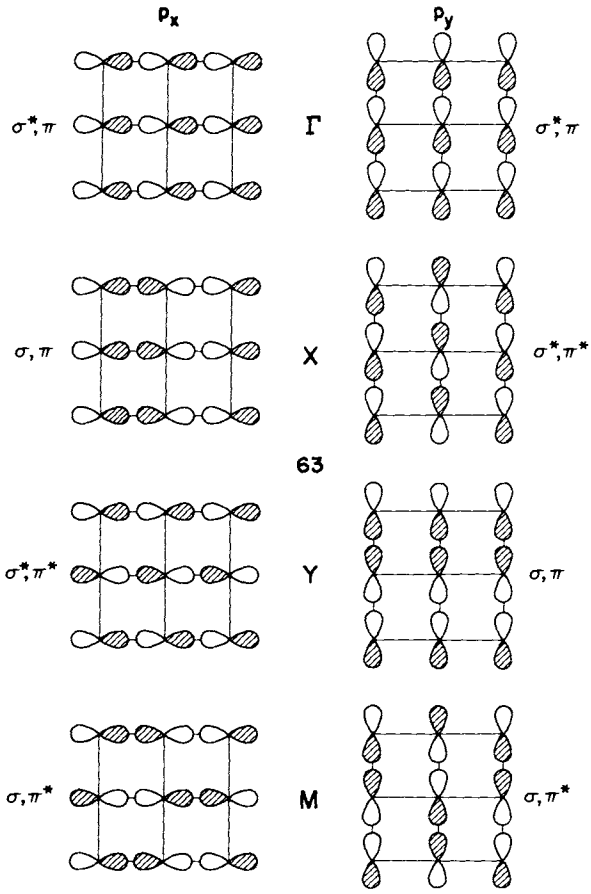
Let's now put some p orbitals on the square lattice, with the direction perpendicular to the lattice taken as z. The p_z orbitals will be separated from p_y and p_x by their symmetry. Reflection in the plane of the lattice remains a good symmetry operation at all k. The $p_z(z)$ orbitals will give a band structure similar to that of the s orbitals, for the topology of the interaction of these orbitals is similar. This is why in the one-dimensional case we could talk at one and the same time about chains of H atoms and polyenes.

The p_x and p_y orbitals present a somewhat different problem. Shown in **63** are the symmetry-adapted combinations of each at Γ, X, Y, and M. (Y is by symmetry equivalent to X; the difference is just in the propagation along x or y.) Each crystal orbital can be characterized by the p, p σ or π bonding present. Thus at Γ the x and y combinations are σ antibonding and π bonding; at X they are σ and π bonding (one of them), and σ and π antibonding (the other). At M they are both σ bonding, π antibonding. It is also clear that the x,y combinations are degenerate at Γ and M (and it turns out along the line Γ→M, but for that one needs a little group theory[15]) and nondegenerate at X and Y (and everywhere else in the Brillouin zone).

Putting in the estimate that σ bonding is more important than π bonding, one can order these special symmetry points of the Brillouin zone in energy, and draw a qualitative band structure (Fig. 16). The actual appearance of any



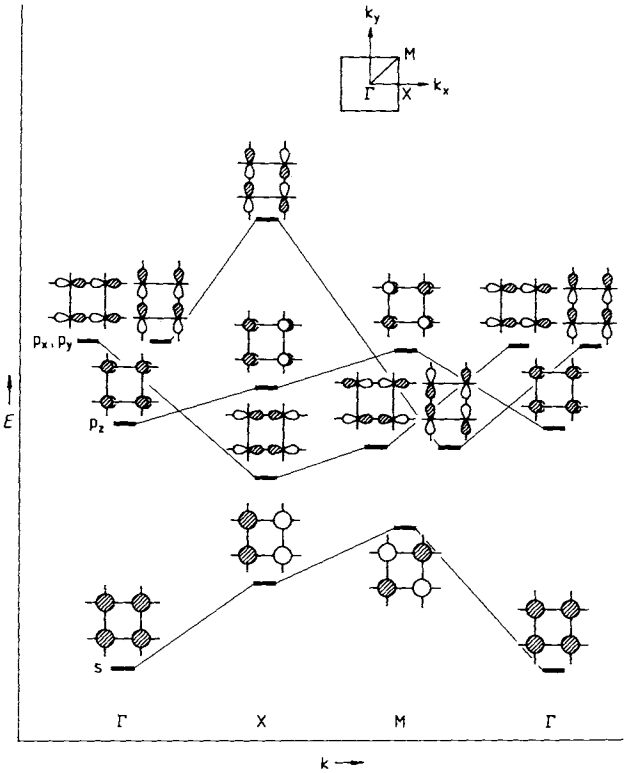


Fig. 16. Schematic band structure of a planar square lattice of atoms bearing ns and np orbitals. The s and p levels have a large enough separation that the s and p bands do not overlap.

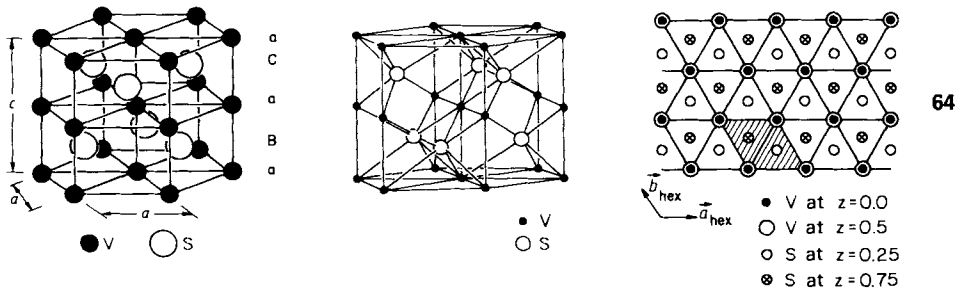
real band structure (e.g., the P net in GdPS discussed in the last section) will depend on the lattice spacing. Band dispersions will increase with short contacts, and complications due to s,p mixing will arise. Roughly, however, *any* square lattice, be it the P net in GdPS,[24] a square overlayer of S atoms adsorbed on Ni(100),[28a] the oxygen and lead nets in litharge,[28b] a Si layer in $BaPdSi_3$,[28c] will have these orbitals.

Three dimensions really introduce little new, except for the complexities of drawing and the wonders of group theory in the 230 space groups. The s, p, and d bands of a cubic lattice, or of face-centered or body-centered close-packed structures, are particularly easy to construct.

Let's look at a three-dimensional case of some complexity, the NiAs→MnP→NiP distortion.[29] First, the chemical



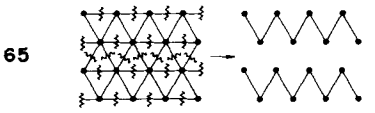
64

motivation. The NiAs structure is one of the most common AB structures, with over a hundred well-characterized materials crystallizing in this type. The structure, shown in three different ways in **64**, consists of hexagonal close-packed layers which alternate metal and non-metal atoms. To be specific, let's discuss the VS representative. The structure contains a hexagonal layer of vanadium atoms at $z=0$, then a layer of sulfur atoms at $z=1/4$, then a second layer of metal atoms at $z=1/2$, superimposable on the one at $z=0$, and, finally, a second layer of main group atoms at $z=3/4$. The pattern is repeated along the c direction to generate a three-dimensional stacking of the type aBaCaBaC. It should not be imagined, however, that this is a layered compound; it is a tightly connected three-dimensional array. The axial V–V separation is 2.94 Å; the V–V contacts within the hexagonal net are longer (3.33 Å).[29]

In terms of local coordination, each sulfur sits at the center of a trigonal prism of vanadiums, which in turn are octahedrally coordinated by six sulfurs. The V–S distances are typical of coordination compounds and, while there is no S–S bonding, the sulfurs are in contact with each other.

This is the structure of stoichiometric VS at high temperatures (>550°C). At room temperature, the structure is a lower symmetry, an orthorhombic MnP one. The same structural transition is triggered by a subtle change in stoichiometry in VS_x, by lowering x from 1 at room temperature.[30]

The MnP structure is a small but significant perturbation on the NiAs type. Most (but not all) of the motion takes place in the plane perpendicular to the hexagonal axis. The net effect in each hexagonal net is to break it up into zigzag chains, as in **65**. The isolation of the chains is



65

exaggerated: the short V–V contact emphasized in **65** changes from 3.33 Å to 2.76 Å, but the V–V distance perpendicular to the plane (not indicated in **65**) is not much longer (2.94 Å).

Still further distortions can take place. In NiP, the chains of Ni and P atoms discernible in the MnP structure break up into Ni_2 and P_2 pairs. For phosphides, it is experimentally clear that the number of available electrons tunes the transition from one structural type to another. Nine or ten valence electrons favor the NiAs structure (for phosphides), 11 to 14 the MnP, and a greater number of electrons prefers the NiP alternative. For the arsenides this trend is less clear.

The details of these fascinating transformations are given elsewhere.[29] It is clear that any discussion must begin with the band structure of the "aristotype," NiAs (here computed for VS). This is presented in Figure 17.

A veritable spaghetti diagram this, seemingly beyond the powers of comprehension of any human being. Why not abdicate understanding, just let the computer spew these bands out and accept (or distrust) them? No, that's too

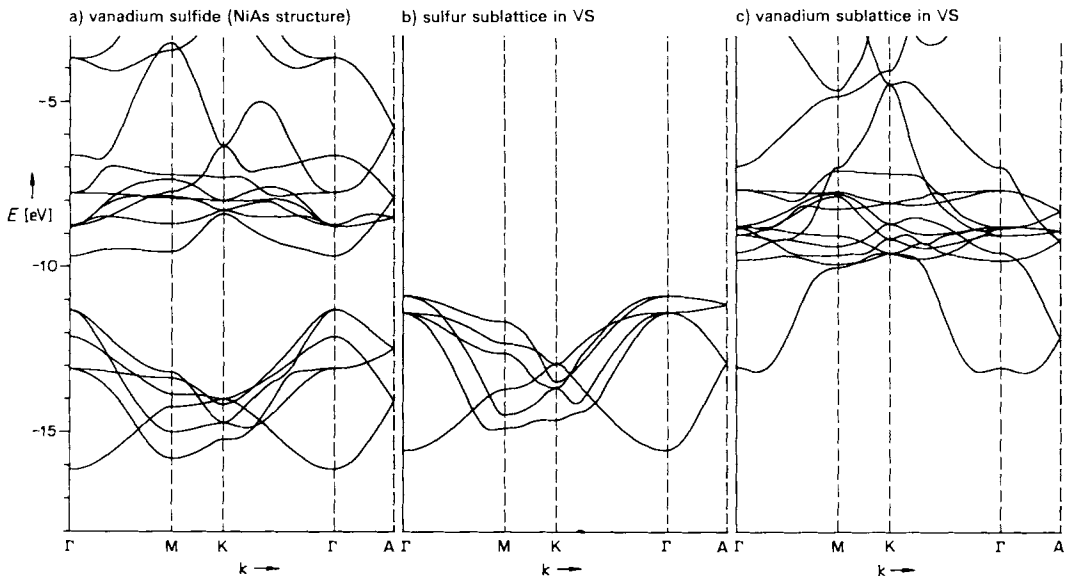


Fig. 17. The band structure for VS in the NiAs structure (a), together with the band structures of its S (b) and V (c) sublattices.

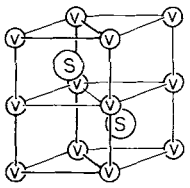
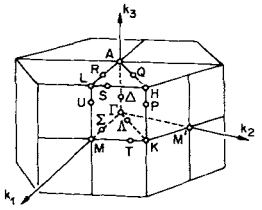
easy a way out. We *can* understand much of this diagram.

First, the general aspects. The hexagonal unit cell is shown in **66**. It contains two formula units V_2S_2. That tells us immediately that we should expect $4\times2=8$ sulfur bands, two 3s separated from six 3p. And $9\times2=18$ vanadium bands, of which 10, the 3d block, should be lowest.



66

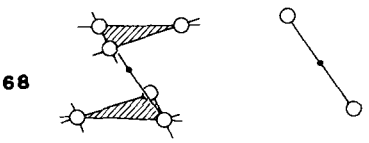


67

The Brillouin zone (**67**) has some special points labeled in it. There are conventions for this labeling.[6, 15] The zone is, of course, three-dimensional. The band structure (Fig. 17) shows the evolution of the levels along several directions in the zone. Count the levels in Figure 17a to confirm the presence of six low-lying bands (which a decomposition of the DOS shows to be mainly S 3p) and ten V 3d bands. The two S 3s bands are below the energy window of the drawing. At some special points in the Brillouin zone there are degeneracies, so one should pick a general point to count bands.

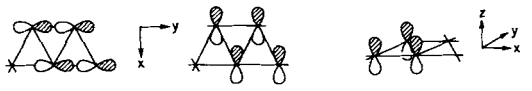
A feeling that this structure is made up of simpler components can be pursued by decomposing it into V and S sublattices (Fig. 17b,c). Note the relatively narrow V d bands around -8 to -9 eV. There is metal-metal bonding in the V sublattice; the widths of the V s,p bands show this. There are also changes in the V d bands on entering the composite VS lattice. A chemist would look for the local t_{2g}-e_g splitting, characteristic of vanadium's octahedral environment.

Each of these component band structures could be understood in further detail.[31] Take the S 3p substructure at Γ. The unit cell contains two S atoms, redrawn in a two-



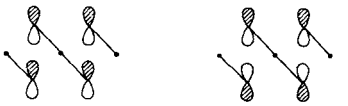
68

dimensional slice of the lattice in **68** to emphasize the inversion symmetry. **69**–**71** are representative x,y and z com-



69 **70** **71**

binations of one S two-dimensional hexagonal layer at Γ. Obviously, x and y are degenerate, and the x,y combination should be above z—the former is locally σ antibonding, the latter π bonding. Now combine two layers. The x,y layer Bloch functions will interact less (π overlap) than the z functions (σ antibonding for the Γ point, **72**). These



72

qualitative considerations (x,y above z, the z bands split more than the x,y bands) are clearly visible in the positioning of the S 3p bands in Figures 17b and 17a.

With more, admittedly tedious, work, every aspect of these spaghetti diagrams can be understood. And, much more interestingly, so can the electronic tuning of the NiAs→MnP→NiP displacive transition.[29]

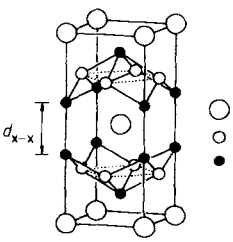
A Sample Problem: The $ThCr_2Si_2$ Structure

The preceding sections have outlined some of the theoretical tools for analysis of bonding in the solid state. To see how these ideas can be integrated, let's discuss a specific problem.

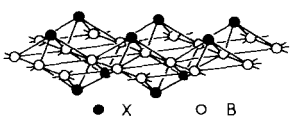
More than 400 compounds of AB_2X_2 stoichiometry adopt the $ThCr_2Si_2$ type structure,[32] but you are not likely to find any mention of these in any modern textbook of general inorganic chemistry, which just tells us something about the ascendancy of molecular inorganic chemistry, especially transition-metal organometallic chemistry, in the last three decades. However, these compounds are there, we know their structures and they have interesting properties. A is typically a rare-earth, alkaline-earth, or alkali element, B is a transition metal or main-group element, and X comes from the fifth, fourth, and occasionally third main group. Since the synthesis of AB_2X_2 with A = a rare-earth element, by *Parthé*, *Rossi*, and their co-workers, the unusual physical properties exhibited by these solids have attracted much attention. Physicists speak with enthusiasm of valence fluctuation, p-wave or heavy-fermion superconductivity and of many peculiar magnetic properties of these materials. The very structure of these materials carries much that is of interest to the chemist.

The $ThCr_2Si_2$ structure type for AB_2X_2 stoichiometry compounds is shown in **73**. It consists of B_2X_2 layers interspersed with A layers. The bonding between A and B_2X_2 layers appears largely ionic, which is why we may write the charge partitioning as $A^{2\oplus}$ and $B_2X_2^{2\ominus}$. But in the B_2X_2 layer there is indication not only of covalent B–X bonding, but also some metal–metal B–B bonding. Typical metal–metal distances are in the range of 2.7–2.9 Å.

A way to describe the B_2X_2 layers in these compounds is to imagine a perfect square-planar two-dimensional lattice of metal atoms B, above and below the fourfold hollows of which lie the main-group X atoms. This is shown in **74**.



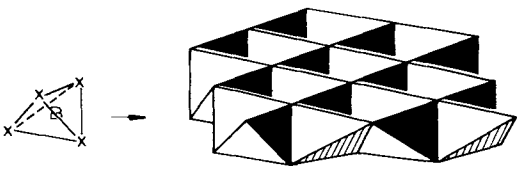
73



74

The coordination environment of the metal atom B is approximately tetrahedral in the main-group elements X, with four additional square-planar near-neighbor metal atoms B. The coordination of the X atoms is much more unusual—they reside at the apex of a square pyramid.

It may be noted here that there are alternative ways to describe the layer structure. For instance, the B_2X_2 layer may be thought of as being built up by sharing four of the six edges of a BX_4 tetrahedron by infinite extension in two dimensions, as in **75**. Such packing diagrams, or alternative ways of looking at the same structure, are inherently useful—a new view often leads to new insight. I would just introduce a very personal prejudice, voiced above, for views of structure that make as many connections as possible to other subfields of chemistry. On that basis, I would give a slight preference to **74** over **75**—the latter pulls one a little away from bonds.



75

There is a long X–X contact within the layer, but what becomes the main focus of this section is a remarkable tunable X–X contact, d_{X-X}, *between* all layers, along the edges (and across the top and bottom faces) of the tetragonal unit cell **73**. This contact is the primary geometrical variable in these structures.

Table 1. The X-X distances in some phosphide compounds of the AB_2X_2 type.

AB_2X_2	d_{X-X} [Å]	AB_2X_2	d_{X-X} [Å]
$CaCu_{1.75}P_2$	2.25	$SrCu_{1.75}P_2$	2.30
$CaNi_2P_2$	2.30		
$CaCo_2P_2$	2.45	$SrCo_2P_2$	3.42
$CaFe_2P_2$	2.71	$SrFe_2P_2$	3.43

Sometimes d_{X-X} is long, sometimes it is short. In Table 1 are shown two series of compounds studied by *Mewis*.[33] In these the cation is kept constant, and so is the main-group element, P. Only the metal varies. For reference the P–P distance in P_4 is 2.21 Å and 2.192 Å in Me_2P-PMe_2. The P–P single-bond distance in many compounds is remarkably constant at 2.19–2.26 Å. The P=P and P≡P bond lengths are around 2.03 Å and 1.87 Å, respectively. It is clear that the short distances in the $ThCr_2Si_2$ type phosphides are characteristic of a full P–P single bond. The long contacts, such as 3.43 Å, imply essentially no bonding at all. All the compounds known with a nonbonding X–X separation contain metals from the left-hand side of the periodic table. In fact, examination of all the structures reveals a trend. As one moves from left to right in the transition series, the P–P contact shortens. Clearly, there is an electronic effect at work here—a P–P bond is made or broken in the solid state. We would like to understand how and why this happens.

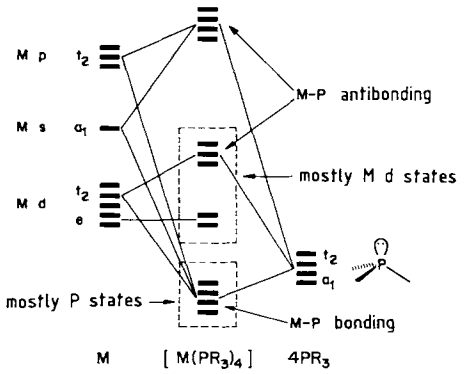
Incidentally, let's see what happens if one takes a Zintl viewpoint of these structures. The long P–P contact would be associated with a filled octet, $P^{3\ominus}$, the full P–P single bond with a $P\text{-}P^{4\ominus}$ or $P^{2\ominus}$. For a divalent $A^{2\oplus}$ we would be left with a metal in oxidation state II for the case of no P–P bond, oxidation state I for a single P–P bond. One could make some sense of the trend in terms of the energetics of the various metal oxidation states, but one way or another the Zintl picture has a difficult time with intermediate distances. How does one describe a P–P bond length of 2.72 Å? A delocalized approach has no problems with describing such partial bonding.

Chong Zheng and I[34] approached the AB_2X_2 structure, represented by a typical $BaMn_2P_2$ compound, in stages. First, we looked at a single two-dimensional $Mn_2P_2^{2\ominus}$ layer. Then, we formed a three-dimensional $Mn_2P_2^{2\ominus}$ sublattice by bringing many such layers together in the third dimension.

Consider a single $Mn_2P_2^{2\ominus}$ layer, **74**. The Mn–P distance is 2.455 Å, and the Mn–Mn distance in the square metal lattice is 2.855 Å. The latter is definitely in the metal–metal bonding range, so a wide-band, delocalized picture is inevitable. But in some hierarchy or ranking of interactions, it is clear the Mn–P bonding is stronger than Mn–Mn, so let's construct this solid conceptually or think of it in terms of first turning on Mn–P bonding, and then Mn–Mn interaction.

The local coordination environment at each Mn is approximately tetrahedral. If we had a discrete tetrahedral Mn complex, e.g., $[Mn(PR_3)_4]$, we might expect a qualitative bonding picture such as **76**. Four phosphane lone pairs, a_1+t_2 in symmetry, interact with their symmetry match, mainly Mn 4s and 4p, but also with the t_2 component of the Mn 3d set. Four orbitals, mainly on P, P–Mn σ bonding, go down. Four orbitals, mainly on Mn, P–Mn σ antibonding, go up. The Mn d block splits in the expected two-below-three way.

76



Something like this *must* happen in the solid. In addition, there are Mn–Mn bonding contacts in the layer, and these will lead to dispersion in those bands which are built up from orbitals containing substantial metal character. The combined construction is shown in Figure 18.

Can we see this local, very chemical bonding construction in a delocalized band structure? Most certainly. The calculated (extended Hückel) band structure and total den-

sity of states of a single $Mn_2P_2^{2\ominus}$ layer is illustrated in Figure 19.

The unit cell is a rhomboid of two Mn and two P atoms. P is clearly more electronegative than Mn, so we expect two mainly P 3s bands below six P 3p bands below 10 Mn 3d bands. The number of bands in Figure 19 checks. A decomposition of the DOS (Fig. 20) confirms the assignment.

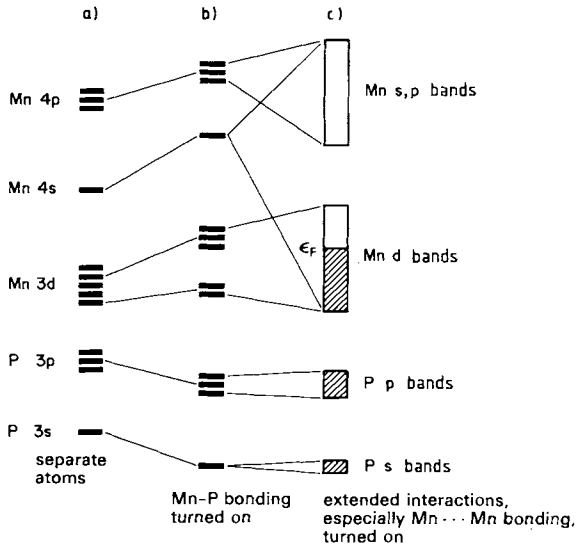


Fig. 18. A schematic picture of the $Mn_2P_2^{2\ominus}$ layer band structure is derived by first turning on local Mn-P interactions and then the two-dimensional periodicity and Mn-Mn interactions. The unit cell contains two Mn and two P atoms, so in reality each of the levels in the first two columns should be doubled.

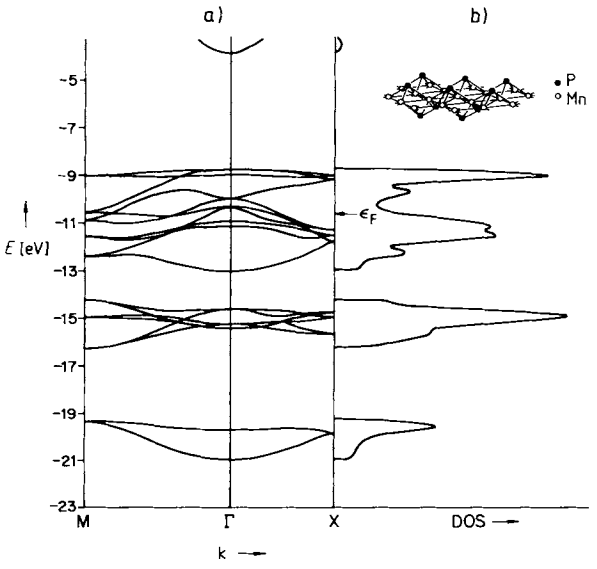

Fig. 19. a) Band structure and b) DOS of a single $Mn_2P_2^{2\ominus}$ layer.

What about the bonding characteristics predicted by the qualitative bonding scheme **76**? This is where a COOP curve is useful (Fig. 21). Note that the two lower bands (at -15 and -19 eV), which by previous decomposition were seen to be mainly P, are Mn-P bonding, whereas the mainly metal bands around -12 eV are Mn-P nonbonding. The bunch of levels at ≈ -9 eV is Mn-P antibonding—it corresponds to the crystal-field-destabilized t_2 level in **76**. The bottom of the mainly metal band is Mn-Mn bonding, the top Mn-Mn antibonding. Everything is as expected.

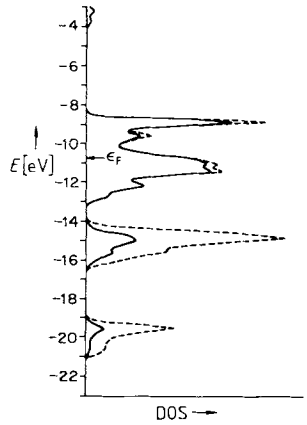

Fig. 20. Total DOS of the composite $Mn_2P_2^{2\ominus}$ layer lattice (dashed line) and the contributions of Mn orbitals to that DOS (solid line). What is not on Mn is on P.

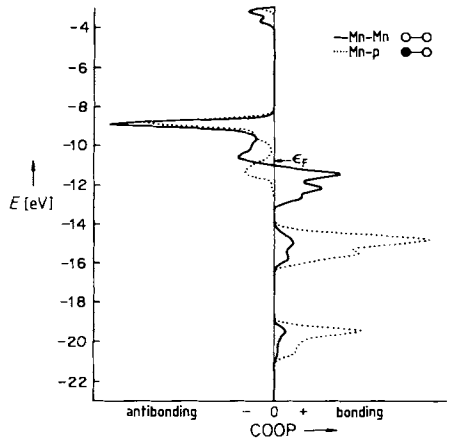

Fig. 21. Crystal orbital overlap population curves for the Mn-Mn bonds (solid line) and Mn-P bonds (dotted line) in the $Mn_2P_2^{2\ominus}$ single layer.

An interesting, slightly different approach to the bonding in the layer is obtained if we, so to speak, turn on Mn-Mn bonding first, then Mn-P bonding by "inserting" or "intercalating" a P sublattice (Fig. 22). In Figure 22a is the P sublattice. We see P 3s (around -19 eV) and P 3p (around -14 eV) bands. Both are narrow, because the P atoms are ≈ 4 Å apart. The Mn sublattice (Fig. 22b) shows a nicely dispersed density of states (DOS). The Mn-Mn separation is only 2.855 Å. Thus we have a two-dimensional metal, with a familiar wide s,p plus narrow d band pattern. The bottom part of the DOS in Figure 22b is the 3d band, the top is the lower part of the 4s,4p band. Figure 22c shows the density of states of the composite $Mn_2P_2^{2\ominus}$ layer. Note how the individual P and Mn bunches of states repel each other on forming the composite lattice. Note how part of the Mn d band stays where it is, part moves up. There is the memory, within this delocalized structure, of the local e-below-t_2 crystal field splitting. There is no more graphic way of showing that what happens in the inorganic solid is similar to what happens in an isolated inorganic molecule.

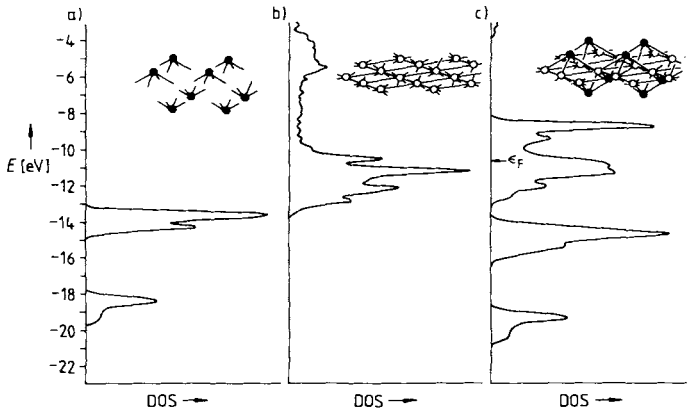

Fig. 22. Total DOS of the P sublattice (a), the Mn sublattice (b), and the composite $Mn_2P_2^{2\ominus}$ layer lattice (c).

Still another, more chemical detail. Each phosphorus in the slab is in an unusual coordination environment, at the apex of a square pyramid of Mn atoms. A chemist looks for a lone pair, **77**, pointing away from the ligands. We can

77

look for it, theoretically, by focusing on its directionality. P $3p_z$ should contribute most to this lone pair, so we interrogate the DOS for its z contribution (Fig. 23). The p_z orbital is indeed well localized, 70% of it in a band at ≈ -15 eV. Here is the lone pair.

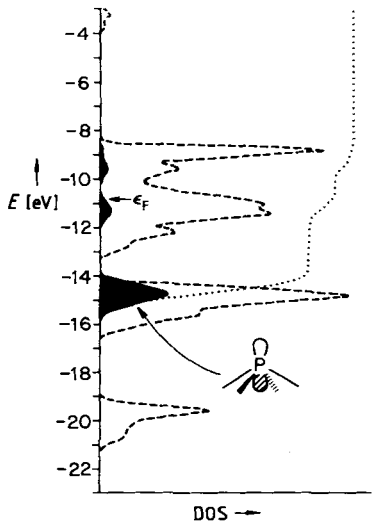

Fig. 23. Phosphorus $3p_z$ orbital contribution (dark area) to the total DOS (dashed line) of the $Mn_2P_2^{2\ominus}$ single layer. The dotted line is an integration of the dark line, on a scale of 0 to 100%.

A point that can be made here is that localization in energy space (such as we see for the P p_z projection) implies localization in real space. The easiest way to think this through is to go back to the construction of bands at the beginning of this paper. The molecular orbitals of a crystal are always completely delocalized Bloch functions. But there is a difference between what we might call symmetry-enforced delocalization (formation of Bloch functions, little overlap) and real, chemical delocalization (overlap between unit cells). The former gives rise to narrow bands, the latter to highly dispersed ones. Turning the argument around, if one sees narrow bands, that's a sign of chemical localization, where as wide bands imply real delocalization.

On to the three-dimensional solid. When the two-dimensional $Mn_2P_2^{2\ominus}$ layers are brought together to form the three-dimensional solid $Mn_2P_2^{2\ominus}$ (still without the counterions), the P $3p_z$ orbitals or lone pairs in one layer form bonding and antibonding combinations with the corresponding orbitals in the layers above or below. Figure 24

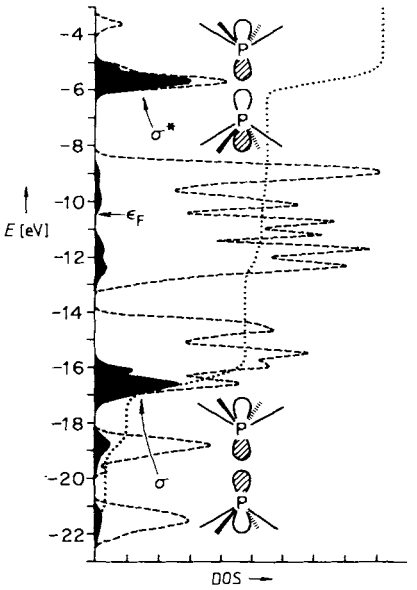

Fig. 24. Phosphorus $3p_z$ orbital contribution (dark area) to the total DOS (dashed line) of the three-dimensional $Mn_2P_2^{2\ominus}$ lattice. The phosphorus-phosphorus bond length here is 2.4 Å. The dotted line is an integration (see Fig. 23).

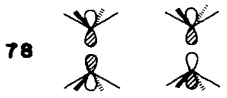
shows the P $3p_z$ density of states at an interlayer P–P distance of 2.4 Å. The wide band at -8 to -12 eV is Mn 3d. Below and above this metal band are P bands, and in these, quite well localized, are P–P σ and σ^* combinations, **78**. These bands are narrow, because the lateral P–P distance is long.

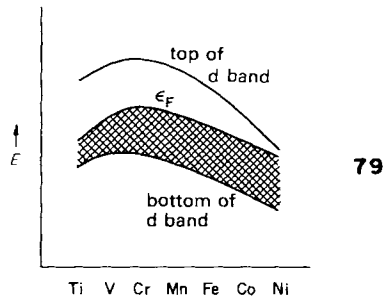


78

Perhaps it's appropriate to stop here and reflect on what has happened. There are N_A levels per atomic orbital in the solid. It's all delocalized bonding, but with our theoretical tools we have been able to see, quite localized in energy, orbitals of a diatomic molecule. The localization in energy reflects the validity of a localization in space, i.e., a bond.

If the three-dimensional calculation is repeated at different interslab or P–P distances, all that happens is that the localized P–P σ and σ^* bands occur at different energies. Their splitting decreases with increasing P–P separation, as one would expect from their respective bonding and antibonding nature.

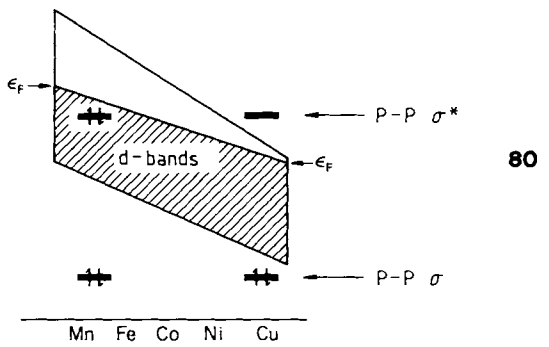
We are now in a position to explain simply the effect of the transition metal on the P-P separation. What happens when the transition metal moves to the right-hand side of the periodic table? The increased nuclear charge will be more incompletely screened and the d electrons more tightly bound. As a result, the d band comes down in energy and becomes narrower. At the same time, the band filling increases as one moves to the right in the transition series. The balance is complicated, and it is important. **79** shows the result. For details the reader is referred to the definitive work of *O. K. Andersen*.[35]



79

79 is the most important single graph of metal physics. It is analogous in its significance to the plot of the ionization potentials of atoms or diatomic molecules. At the right side of the transition series, the area of concern to us, the Fermi level falls as one moves to the right, the work function of the metal increases.

Now imagine superimposed on this variable-energy sea of electrons the P-P σ and σ^* bands for some typical, moderately bonding P-P distance, **80**. In the middle of the



80

transition series, the metal Fermi level is above the P-P σ^*. Both σ and σ^* are occupied; there is no resultant P-P bond. As P-P stretches in response, the σ^* only becomes more filled. On the right side of the transition series, the P-P σ^* is above the Fermi level of the metal, and so is unfilled. The filled P-P σ makes a P-P bond. Making the P-P distance shorter only improves this situation.

The steady, gradual variation of the P-P distance would seem to be as inconsistent with the molecular orbital model shown here as it was with the Zintl concept. This is not so. If we turn on the interaction between the P atoms and the metal layer (and we have seen before that this interaction is substantial), we will get mixing of P and Mn orbitals. The discontinuity of the above picture will be replaced by a continuous variation of the occupation of the P σ and σ^* orbitals between two and zero.

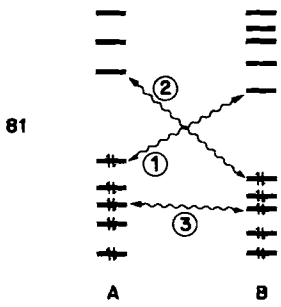
The experimentally observed trend has been explained. There is much more to the AB_2X_2 structures than I have been able to present here,[34] of course. More important than the rationalizations and predictions of the experimental facts that one is able to make in this case, is the degree of understanding one can achieve and the facility of motion between chemical and physical perspectives.

One final comment on the $ThCr_2Si_2$ structure. The reader will note that we did not use a Peierls distortion argument in the resolution of this problem. We could have done so, somewhat artificially, by choosing a structure in which the interlayer P-P separation was so large that the P-P σ and σ^* DOS came right at the Fermi level. Then a pairing distortion could have been invoked, yielding the observed bond. That, however, would have been a somewhat artificial approach. Peierls distortions are ubiquitous and important, but they're not the only way to approach bonds in the solid.

Orbital Interactions in the Solid

I have made use of frontier orbitals and orbital interactions throughout this article—the construct of densities of states restored to us the possibility of utilizing this language. Perhaps it is appropriate to make these ideas explicit.

Consider the interaction of two molecules, A and B, not an extended solid. **81** indicates, schematically, three types of interaction. ① and ② are two-electron stabilizing inter-



81

actions, ③ is a four-electron destabilizing interaction. The lines are drawn to specific orbitals, the HOMOs and LUMOs of each component. Some degree of frontier orbital control is implied here; in reality we know that all orbitals interact, and that their role is gauged by the overlap and energy factors in Equation (e).[8]

$$\Delta E = \frac{|H_{ij}|^2}{E_i^0 - E_j^0} \qquad \text{(e)}$$

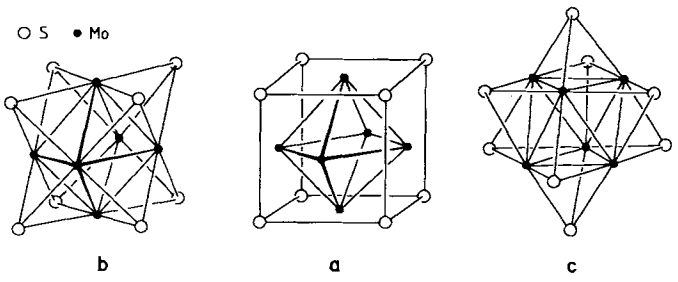
In interaction ①, A acts as a donor, B as an acceptor. In ②, their roles are reversed. The balance of real charge transfer depends on the magnitude of the two interactions, as evaluated by the above-given perturbation expression. If the energy separation $E_i^0 - E_j^0$ were dominant, then, in **81**, A would be a donor relative to B.

It should be realized that this description, while of immense interpretative power, is only a one-electron model. To analyze orbital interactions properly, in a many-electron way, is not easy. The simple picture of **81** seems to be lost; competing interaction or partition schemes have been

suggested.[36] One way to appreciate the problem a true many-electron theory has in analyzing interactions is to realize that the energy levels of A and B are not invariant to electron transfer. They change in energy depending on the charge on fragments A and B: a positive charge makes them go down, a negative charge go up. Actually realizing this, one has learned the most important correction to the simple one-electron picture.

The frontier orbital way of thinking, especially with respect to donor–acceptor interactions, is of substantial utility in the solid state. Let me give two examples here.

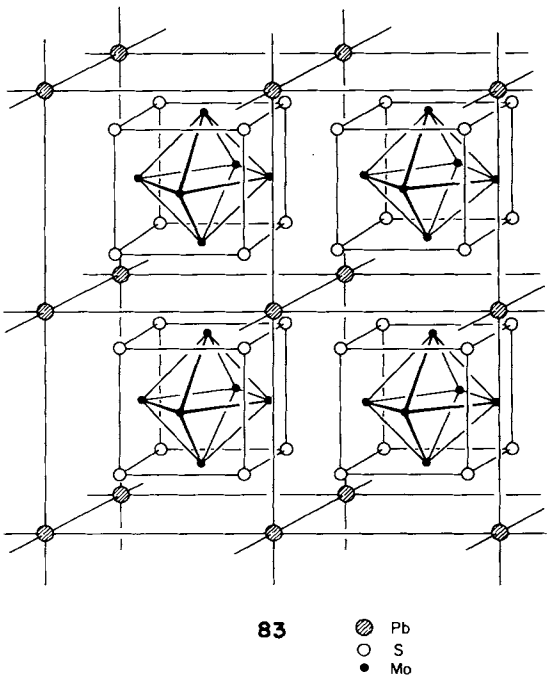
The Chevrel phases are a fascinating set of ternary molybdenum chalcogenide materials of varying dimensionality and interesting physical properties.[37] In the parent phase, epitomized by $PbMo_6S_8$, one has recognizable $[Mo_6S_8]$ clusters. In these clusters, shown in three views in **82**, sulfurs cap the eight faces of an octahedron of molyb-



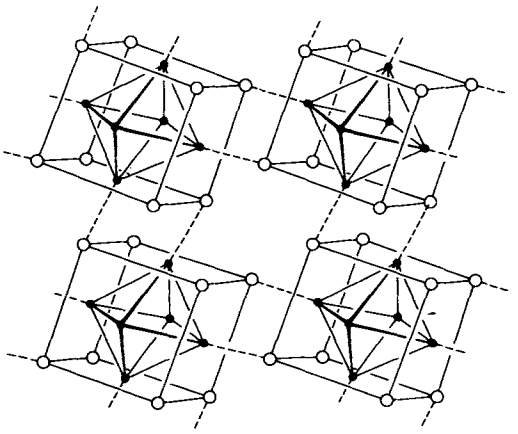
82

denums. The $[Mo_6S_8]$ clusters are then embedded in a substructure of lead cubes (this is a thought construction of the structure!), as in **83**. But the structure doesn't remain here. In every cubical cell, the $[Mo_6S_8]$ rotates by $\approx 26°$ around a cube diagonal to reach structure **84** (Pb's are missing in this drawing, for clarity).

Why? The answer is implicit in **84**. A rotation of roughly this magnitude is required to give each Mo within one unit a fifth bonding interaction with a sulfur of a cluster in the



83



84

neighboring cube. If one does a molecular orbital calculation on the isolated cluster (Fig. 25), one finds that the five lowest empty orbitals of the cluster point out, away from the molybdenums, hungry for the electron density of a neighboring sulfur.[38,39]

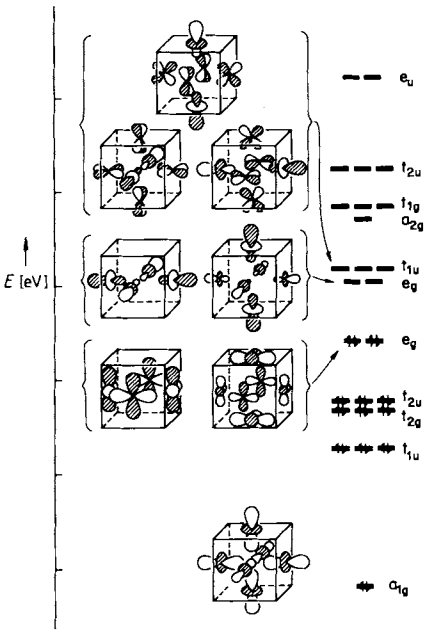


Fig. 25. The frontier orbitals of an $[Mo_6S_8]^{4\oplus}$ cluster, with some selected orbitals sketched. The lowest a_{1g} and the higher e_g and t_{1u} orbitals have substantial local z^2 character, i.e., point "out."

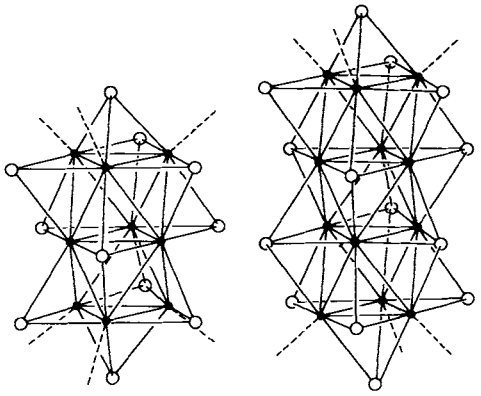
The structure of this material is driven by donor–acceptor interactions. So it is for $In_3Mo_{15}Se_{19}$ and $K_2Mo_9S_{11}$, which contain $[Mo_{12}X_{14}]$ and $[Mo_9X_{11}]$ clusters (**85**).[37] A molecular orbital calculation on each of these clusters shows prominent low-lying unfilled orbitals directed away from the terminal Mo's, just where the dashed lines are. That's how these clusters link and aggregate in their respective solid-state structures.

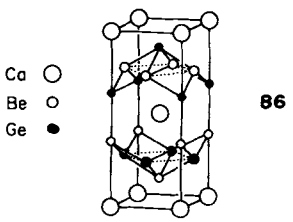
This donor–acceptor analysis of the crystal structure indicates that if one wants to "solubilize" these clusters as discrete molecular entities, one must provide an alternative, better base than the molecule itself. Only then will one get discrete $[Mo_6X_8 \cdot L_6]^q$ complexes.



85

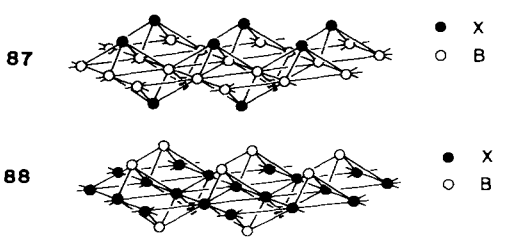
One more conclusion easily drawn from Figure 25, one applying what we know: when the clusters assemble into the lattice **83**, the five LUMOs of Figure 25 will be pushed up by interactions with neighboring cube sulfurs. All the cluster levels will spread out into bands. Will the HOMO band be broad or narrow? That band is crucial, because if you do the electron counting in $PbMo_6S_8$ you come to 22 electrons per $[Mo_6S_8]^{2\ominus}$; the top level in Figure 25 is half-filled. A glance at Figure 25 shows that the level in question, of e_g symmetry, is made up of Mo d functions which are of δ type with respect to the Mo–S external axis. Bringing in the neighboring cells will provide little dispersion for this band. The result is a high DOS at the Fermi level, one requirement (of several) for superconductivity.[40]

An interesting variation on the donor–acceptor theme in the solid is that the donor or acceptor need not be a discrete molecule, as one $[Mo_6S_8]$ cluster is toward another in the Chevrel phases. Instead, we can have electron transfer from one sublattice, one component of a structure, to another. We've already seen this in the explanation of the tuning of the X–X contact in the AB_2X_2 $ThCr_2Si_2$ structure. There the entire transition metal or B sublattice, made up of square nets, acts as a donor or acceptor, a reducing or oxidizing agent, for the X sublattice, made up of X–X pairs. A further example is provided by the remarkable $CaBe_2Ge_2$ structure, **86**.[41] In this structure one B_2X_2 layer,



86

87, is identical to the $ThCr_2Si_2$ layer. The other, **88**, has B and X components interchanging places. These layers are



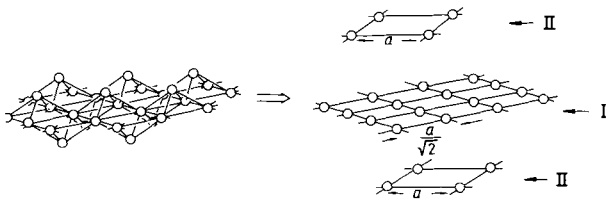
not identical, but isomeric. They will have different Fermi levels. One layer in the crystal will be a donor relative to the other. Can you reason out which will be the donor, which the acceptor layer?

What's New in the Solid?

If all the bands in a crystal are narrow (as they are in molecular and most extremely ionic solids), i.e., if there is little overlap between repeating molecular units, then there is no new bonding to speak of. But if at least some of the bands are wide, then there is delocalization, new bonding; a molecular orbital picture is necessary. This is not to say that we cannot recover, even in such a large-dispersion, delocalized situation, local bonding. The preceding sections have shown that we can see bonds. But there may be qualitatively new bonding schemes that result from substantial delocalization. Recall in organic chemistry the consequences of aromaticity, and in inorganic cluster chemistry of skeletal electron-pair counting algorithms.[42]

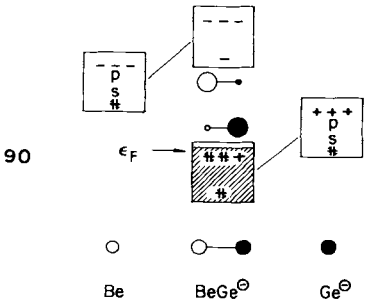
The language of orbital interactions, of perturbation theory, provides a tool that is applicable for the analysis of these highly delocalized systems, just as it works for small, discrete, molecules. For instance, take the question posed at the end of the last section. We have two isomeric two-dimensional lattices, **87** and **88**. Which will be a donor relative to the other? And which will be most stable?

These lattices are built up from two elements B and X in equal numbers, occupying two sublattices, I and II in **89**.



89

The elements are of unequal electronegativity, in the general case. In $ThCr_2Si_2$, one is a transition metal, the other a main-group element, in $CaBe_2Ge_2$ each a main-group element. Let's take, for purposes of discussion, $CaBe_2Ge_2$ as a model and write an interaction diagram, **90**, for what happens locally (Ge is more electronegative than Be). No implication as to band width is yet made—the orbital blocks are just that, blocks, indicating the rough position of the levels. The lower block of levels is obviously derived from



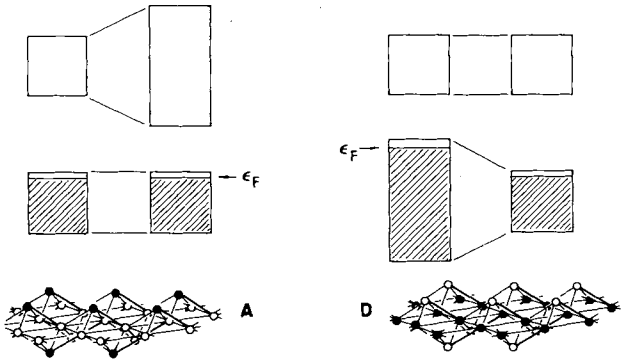
90

or localized in the orbitals of the more electronegative element. The band filling is actually appropriate to the

$CaBe_2Ge_2$ structure, i.e., $Be_2Ge_2^{2\ominus}$, or $BeGe^{\ominus}$, or seven electrons per two main-group atoms.

The orbitals develop into bands. The width of the bands depends on the inter-unit-cell overlap. The site II atoms are much farther apart from each other than the site I atoms (recall here the short metal–metal contacts in the $ThCr_2Si_2$ structure). We can say that sublattice I is more *dispersive* than sublattice II. The orbitals of atoms placed in sublattice I will form wider bands than those in sublattice II.

Now we have two choices: the more electronegative atoms can enter the less dispersive sites (lattice II) or the more dispersive sites (lattice I). The consequences are shown in **91** and **92**.



91 **92**

Which layer will be most stable and which will have the higher Fermi level depends on the electron filling. For a case such as $CaBe_2Ge_2$, or in general where the lower band is more than half-filled, the more electronegative atom will prefer the less dispersive site (**91**) and that layer will have a higher ionization potential, be a poorer donor.

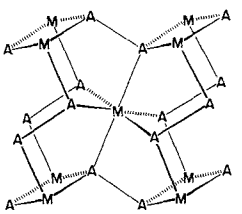
The stability conclusion bears a little elaboration. It is based on the same "overlap repulsion" argument that was behind the asymmetric splitting of hydrogen chain bands (Fig. 1). When orbitals interact, the antibonding combinations are more antibonding than the bonding ones are bonding [cf. Eq. (a)]. Filling antibonding combinations, filling the tops of widely dispersed bands, is costly in energy. Conclusions on stability, as is the case in molecular chemistry, depend strongly on the electron count. In this particular case if the lower band were less than half-filled, the conclusion would be reversed, the more electronegative element should prefer the more dispersive site.

For $ThCr_2Si_2$ AB_2X_2 structures the conclusion we reach, that the more electronegative element should enter the less dispersive site, implies that for most cases the main-group X component will prefer the less dispersive, square-pyramidal, sublattice II positions. In $CaBe_2Ge_2$, Ge is more electronegative than Be. That means the layer in which the Ge enters the more dispersive sites (the bottom layer in **86**) should be a donor relative to the upper layer.

A reasonable question to ask is the following. If one layer (the acceptor layer) in $CaBe_2Ge_2$ is more stable than the other, the donor layer, why does the $CaBe_2Ge_2$ structure form at all? Why doesn't it go into a $ThCr_2Si_2$ structure based on the acceptor layer alone? The answer lies in the balance of covalent and dative interactions; for some elements the binding energy gained in donor–acceptor *interlayer* interactions overcomes the inherent stability of one isolated layer.[41]

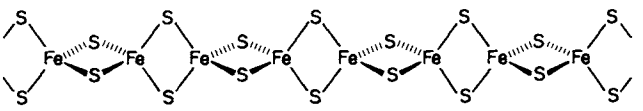
At times the perturbation introduced by delocalization may be strong enough to upset the local, more "chemical" bonding schemes. Let me sketch two examples here.

Marcasites and arsenopyrites are a common structural choice for MA_2 compounds, where M is a late transition metal and A an element of the fifth or sixth main group. The structure, **93**, is related to the rutile one, in that one can easily perceive in the structure the octahedral coordination of the metal and one-dimensional chains of edge-sharing octahedra. The ligands are now interacting, however; not isolated $O^{2\ominus}$ as in rutile, but $S_2^{2\ominus}$ or $P_2^{4\ominus}$ diatomic units in the marcasites.[43]



93

Low dimensionality characterizes another set of MS_2 sublattices, now in ternary structures of the type of $KFeS_2$ or $Na_3Fe_2S_4$.[44,45] In these molecules one finds one-dimensional MS_2 chains, consisting of edge-sharing tetrahedra (**94**).



94

In both of these structural types, characterized by their simplicity, the metal–metal separations are in the range (2.6–3.1 Å) where reasonable men, or women, might disagree whether there is much metal–metal bonding. Cases with bridging ligands are ones in which real metal–metal bonding is particularly difficult to sort out from bonding through the bridge. Certainly the metal–metal bonding doesn't look to be very strong, if it's there at all. So a chemist would certainly start out from the local metal site environment, which is strikingly simple.

One would then predict a three-below-two orbital splitting at each metal in the octahedral marcasites and a two-below-three splitting in the tetrahedral MS_2 chains. The magic electron counts for a closed-shell low-spin structure should be then d^6 for the octahedral **93**, d^4 for the tetrahedral **94**. Forming the one-dimensional chains and then the three-dimensional structure will introduce some dispersion into these bands, one might reason. But not much—appropriate electron counts for semiconducting or non-magnetic behavior should remain d^6 for **93** and d^4 for **94**.

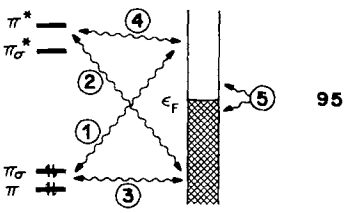
The experimental facts are as follows: the d^6 marcasites and arsenopyrites are semiconducting, but, surprisingly, so are the d^4 ones. Most of the AMS_2 structures synthesized to date feature the metal atom in configurations between

d^5 and $d^{6.5}$. The measured magnetic moments are anomalously low.

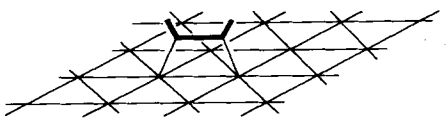
When calculations on these chains are carried out, one finds, to one's initial surprise, that the octahedral marcasite structure has a band gap at d^4 as well as d^6, and that the tetrahedral chain has a band gap at $d^{5.5}$ and not d^4. It seems that local crystal field considerations don't work. What in fact happens (and here the reader is referred to the detailed explanation in our papers[43,45]) is that the local field is a good starting point, but that further delocalizing interactions (and these are ligand-ligand and metal-ligand, and not so much metal-metal in the distance range considered) must be taken into account. The extended interactions modify the magic or gap electron counts that might be expected from just looking at the metal site symmetry.

In the preceding section, I outlined the orbital interactions that are operative in the solid state. These were the same ones as those that govern molecular geometries and reactivity. There is an interesting new feature in some solids, however. This is an interaction-induced rearrangement of the DOS around the Fermi level.

Suppose that one of the interacting orbital components is localized, with narrow bands, but it is interacting with a metallic sublattice, characterized by a reasonable DOS at the Fermi level. This is indicated schematically in **95**. Perhaps it's best to have a real example to think about. Consider an acetylene chemisorbed in low coverage on a Pt(111) surface, **96**. Here the discrete, narrow-band orbitals are the four π and π^* levels of a low-coverage acetylene layer, and the band is the Pt d band, nearly filled.[46,47]

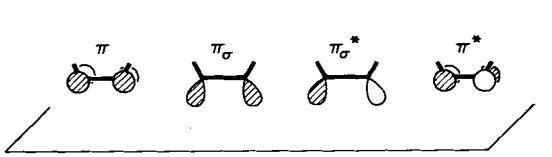


95



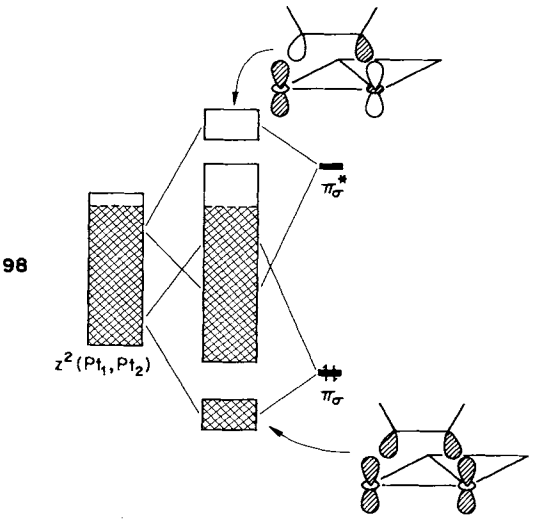
96

The most important two-electron bonding interactions that take place are between two of the acetylene π orbitals, π_σ and $\pi_\sigma{}^*$ (see **97**) and the d band. π_σ and $\pi_\sigma{}^*$ "point"



97

toward the surface, have greater overlap with metal orbitals, and they interact preferentially with different parts of the band, picking out those metal surface orbitals which have similar nodal patterns as the adsorbate. **98** shows this—in the "parallel bridging" geometry at hand the π_σ orbital interacts better with the bottom of the surface z^2 band and the $\pi_\sigma{}^*$ with the top of that band.



98

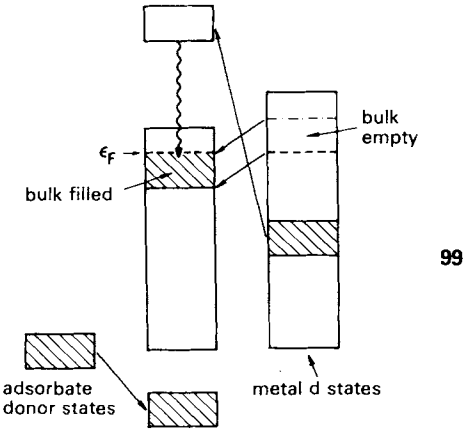
Both of these interactions are primarily of type ① and ③ (see **81** or **95**), four-electron repulsive or two-electron attractive interactions. Actually, the energetic and bonding consequences are a little complicated: the z^2-π_σ interaction would be destabilizing if the antibonding component of this interaction remained filled, below the Fermi level. In fact, many z^2-π_σ antibonding states are pushed above the Fermi level, vacated. This converts a destabilizing, four-electron interaction into a stabilizing two-electron one.

A counterpart to this interaction is ④ in **95**. Normally we would not worry about zero-electron interactions, because there is no "power" in them if there are no electrons. However, in the case of a metal with a continuous band of states, some of these levels—these are bonding combinations of $\pi_\sigma{}^*$ with the top of the z^2 band, as indicated in **98**—come below the Fermi level and are occupied. Therefore, they also contribute to bonding the adsorbate to the surface.

It should be noted that a consequence of all of these interactions is not only strengthening of metal-acetylene bonding, but also a weakening of bonding within the acetylene *and* within the metal. Interaction means delocalization, which in turn implies charge transfer. Interactions ①-④ operate to depopulate π_σ, populate $\pi_\sigma{}^*$, both actions weakening the acetylene π bond. Removing electrons from the bottom of the z^2 band and filling better the top of that band both result in a weakening of the Pt-Pt bond.

Interaction ⑤, peculiar to the solid, is a reorganization of the states around the Fermi level as a consequence of primary interactions ①-④. Consider, for instance, the levels that are pushed up above the Fermi level as a result of interaction ③, the four-electron repulsion. One way to think about this is the following: the electrons do not, in fact, go up past the Fermi level (which remains approximately constant), but are dumped at the Fermi level into levels somewhere in the solid. This is shown schematically in **99**.

But where is "somewhere"? The electrons that come in come largely from regions that are not directly involved in the bonding with the adsorbate. In the case at hand, they may come from Pt bulk levels, from Pt surface atoms not



99

involved with the acetylene, from the Pt atoms binding the acetylene, but from orbitals of these atoms not used in that binding. While the metal surface is a nice reservoir of such electrons, these electrons are not innocent of bonding. They are near the top of their respective band (see **99**), and as such are metal–metal antibonding. Thus interaction ⑤ weakens bonding in the surface. Together with the aforementioned electron transfer effects of interactions ①–④ it is responsible for adsorbate-induced surface reconstruction.

In general, non-dissociative chemisorption is a delicate balance between attractive surface–molecule bonding and the consequences of the very same interactions, which weaken bonds in the adsorbed molecule and in the surface. Dissociative chemisorption and surface reconstruction are just two extremes of one and the same phenomenon.

I have discussed an example here of a surface reaction. A more detailed analysis of the theoretical aspects of surface science will be given elsewhere.[48] I bring this example in, because I want to make the point that surface chemistry and physics is not a thing unto itself, but also part of the wondrous continuum of molecular bonding that is chemistry. Surface science, a discipline in an exciting, explosive growth phase over the last decade, occasionally neglects its connections to solid-state chemistry. It shouldn't. Solid-state chemists should also take more advantage of what surface scientists have learned. Rather interestingly, the intellectual connection between surface science and discrete molecular chemistry has remained strong, perhaps because one component of surface chemistry, the adsorbate, is patently a molecule. The cluster–surface analogy has also served to bring together the literatures of surface science and organometallic chemistry.

From the perspective of orbital interactions, surfaces by themselves, and surfaces interacting with molecules, fit perfectly into a continuum of dimensionality of solid-state chemistry and physics. They are two-dimensional, half-solid, half-molecule extended systems—the same tools of orbital analysis apply to surfaces as to other solids.

So what's new in the solid? My straw-man physicist friend thinking of superconductivity, charge and spin density waves, heavy fermions, solitons, nonlinear optical phenomena, ferromagnetism in its various guises—all the fascinating things of interest to him and that I've neglected—he might say "everything." An exaggeration of what I've said in this paper is "not much." There are interesting, novel consequences of delocalization and wide-band formation, but even these can be analyzed in the language of orbital interactions.

It would not surprise anyone if the truth were somewhere in between. It is certainly true that I've omitted, by and large, the origins of most of the physical properties of the solid, especially those like superconductivity and ferromagnetism that are peculiar to that state of matter. Chemists will have to learn much more solid-state physics than I've tried to teach here if they are to understand these observables, and they *must* understand them if they are to make rational syntheses. I have concentrated on the most chemical notion of all—the solid is a molecule, a big one, to be sure, but just a molecule. Let's try to extract from the perforce delocalized picture of Bloch functions the chemical essence, the bonds that determine the structure and reactivity of this large molecule. The bonds must be there.

My graduate students, postdoctoral associates, and senior visitors to the group are responsible both for teaching me solid-state physics and for implementing the algorithms and computer programs that have made this work possible. While in my usual way I've suppressed the computations in favor of explanations, little understanding would have come without those computations. An early contribution to our work was made by Chien-Chuen Wan, but the real computational and interpretational advances came through the work of Myung-Hwan Whangbo, Charles Wilker, Miklos Kertesz, Tim Hughbanks, Sunil Wijeyesekera, and Chong Zheng. This paper owes much to their ingenuity and perseverance. Several crucial ideas were borrowed early on from Jeremy Burdett, such as using special k point sets for properties. Contributions were also made by Christian Minot, Jean-Yves Saillard, Denis Underwood, Georges Trinquier, Santiago Alvarez, Joel Bernstein, Jerome Silvestre, Marja Zonnevylle, Ralph Wheeler, Shen-shu Sung, Wolfgang Tremel, Douglas Keszler, and Jing Li.

In the early stages of this work, very important to me was a renewed collaboration with R. B. Woodward, prompted by our joint interest in organic conductors. It was unfortunately cut short by his death in 1979. Mike Sienko and his students offered gentle encouragement by showing us the interesting structures they worked on, as did Thor Rhodin on the surface science side. It was always instructive to try to provoke John Wilkins.

Over the years my research has been steadily supported by the National Science Foundation's Chemistry Division. I owe Bill Cramer and his fellow program directors thanks for their continued support. A special role in my group's research on extended structures has been played by the Materials Science Center (MSC) at Cornell University, supported by the Materials Research Division of the National Science Foundation. The MSC's activities, especially the interdisciplinary seminars it has supported, and in general the opportunity is has offered for learning of work in other areas of science relevant to this topic, have been crucial in the development of my work. My recent surface work, briefly mentioned in the last section, has been generously supported by the Office of Naval Research.

One reason it is easy to cross disciplines at Cornell is the existence of the Physical Sciences Library, with its broad coverage of chemistry and physics. I would like to thank Ellen Thomas and her staff for her contributions here. Our drawings, a critical part of the way our research is presented, have

been beautifully made over the years by Jane Jorgensen and Elisabeth Fields. I'd like to thank Eleanor Stagg for the typing and secretarial assistance in the past, and Linda Kapitany for the present manuscript.

This manuscript was written while I held the Tage Erlander Professorship of the Swedish Science Research Council NFR. The hospitality of Professor Per Siegbahn and the staff of the Institute of Theoretical Physics of the University of Stockholm is gratefully acknowledged, as well as the assistance of Ralph Wheeler, Jing Li, and Wolfgang Tremel in the writing and computations. The comments of many people on this paper were also very useful, especially those of J. Dunitz and H.-G. von Schnering. I thank W. Tremel and H. Tremel for the German translation.

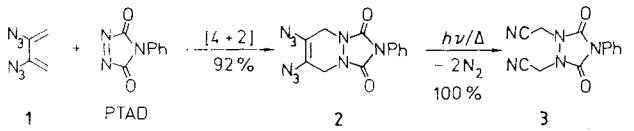
[4+2] Cycloadditions of 2,3-Diazido-1,3-butadienes: A Novel Entry to Vicinal Vinyl Diazides and 1,4-Dicyano Compounds**

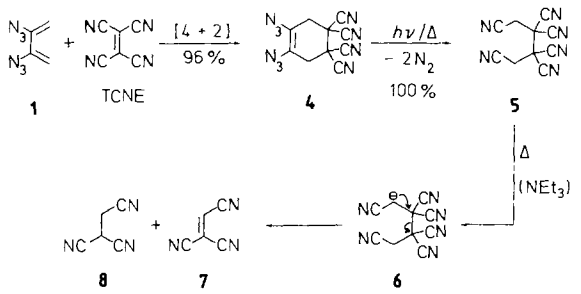
By *Klaus Banert**

Special interest attaches to the vinyl azides because of the universality of their reactions.[1] Simple methods for the synthesis of 2,3-diazido-1,3-butadienes (**1**, **9**, **10**, **13**–**16**) were reported recently[2–4] which provide access to interesting azirines and biazirinyls by photolysis or thermolysis.[3,4] In the following communication [4+2] cycloadditions of 2,3-diazido-1,3-butadienes are presented which afford a novel route to vicinal vinyl diazides and 1,4-dicyano compounds.



1 2 3

2,3-Diazido-1,3-butadiene **1** reacts with 4-phenyl-1,2,4-triazol-3,5-dione (PTAD) to give the Diels–Alder product **2**, which can be converted photolytically or thermally into the 1,4-dicyano compound **3** (Table 1).[5] Numerous examples for the decomposition of vicinal vinyl diazides to dinitriles have already been reported in the literature.[6–9] Directed syntheses, however, were hitherto only known for such vicinal diazides[10] in which two flanking, electron-attracting substituents facilitate introduction of the azide groups[9,11] or in which the azide groups are arranged *ortho* in an aromatic system.[8,12] The diazide **1** not only reacts with PTAD but also with tetracyanoethylene (TCNE), methyl tricyanoethylenecarboxylate,[13] dimethyl dicyanofumarate,[14] maleic acid anhydride, *N*-phenylmaleimide or fumaric acid dichloride in a [4+2] cycloaddition. Particularly high yields are obtained with TCNE. Initially, the vicinal vinyl diazide **4** is formed; this is then converted by photolysis or thermolysis into the hexacyano compound **5** (Table 1). These reactions, exactly like the sequence **1** + PTAD → **2** → **3**, represent a *cis* addition of two NC–CH_2 groups to an electron-deficient dienophile. On prolonged thermolysis, **5** decomposes into the fragments **7**[15] and **8**.[15] Since this cleavage is catalyzed by bases (such as NEt_3), formation of the intermediate **6** seems plausible.



1 4 5 8 7 6

Reaction of PTAD with **9**, like that with **10**, leads to the vicinal vinyl diazide **11**, which upon photolysis or thermolysis is converted into the 1,4-dicyano compound **12** (Table 1). The yield (referred to **9** or **10**) is 91%. The methyl group in the *Z*-position accelerates the cycloaddition, since **9** is more electron-rich than **1**. On the other hand, the methyl group in the *E*-position in **10** hinders a cisoid arrangement of the diene. Hence, in Diels–Alder reactions, **10** reacts more slowly than **1**. Similar differences in reaction rates are observed in the [4+2] cycloadditions of **13**–**16** with TCNE: Thus, **13** reacts much more rapidly than **14**, while

Table 1. Some physical data of the new compounds **2**–**5**, **11**, **12**, and **17**–**20**. ^{1}H-NMR at 400 and 80 MHz, ^{13}C-NMR at 100 MHz. Spectra of **2**, **3**, **11**, and **12** in $CDCl_3$; Spectra of **17**–**20** in [D_6]acetone.

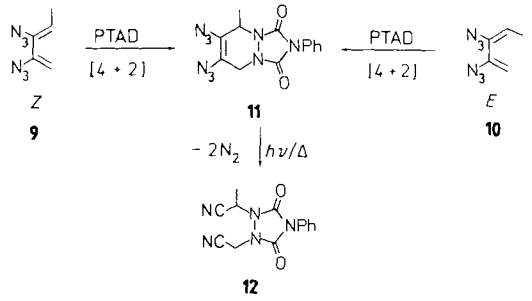
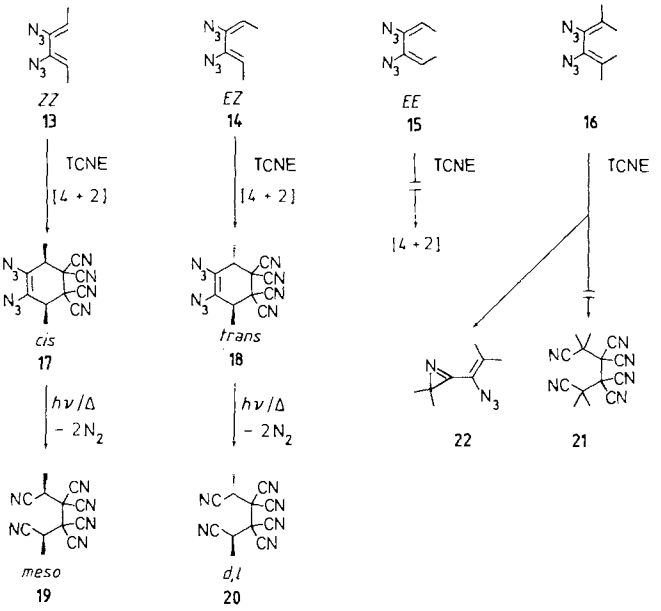
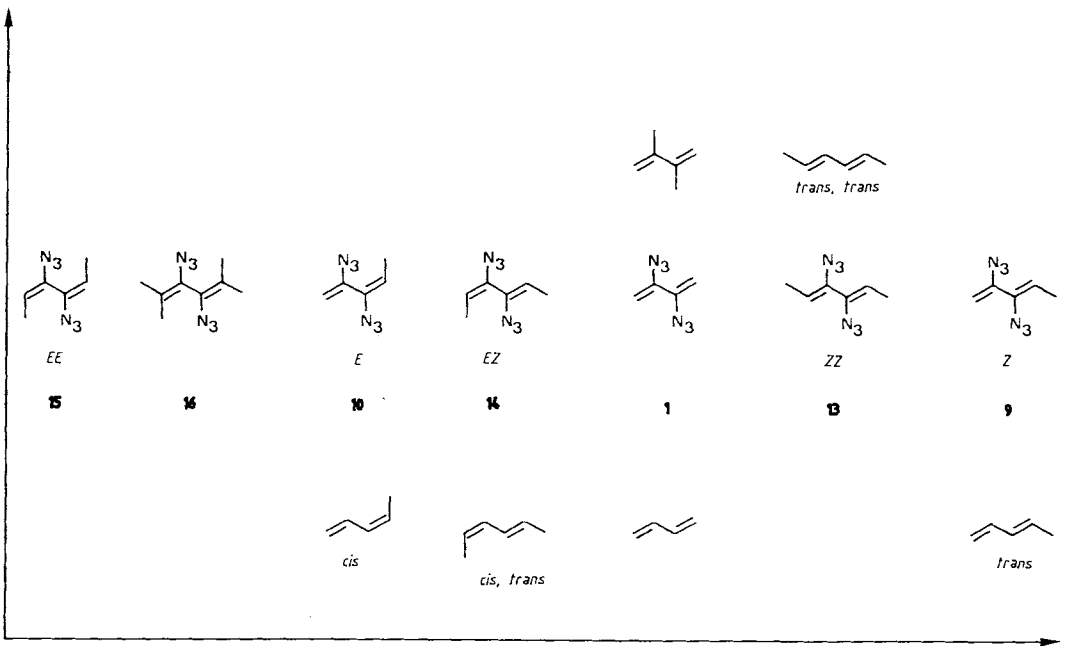
[**] Reactions of Unsaturated Azides, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft. The author thanks Frau *R. Stötzel* for assistance with some of the syntheses.—Part 3: [4].





15, like **16**, does not undergo a Diels–Alder reaction.[16, 17] The reaction **16** → **22** requires three months at room temperature. The stereospecificity of the cycloaddition to **13** and **14** is shown by the formation of the diastereomers **17** and **18** (secondary products **19** and **20**) (Table 1) with >95% *de* (NMR).

The reactivities of the dienes **1**, **9**, **10**, and **13**–**16** can be compared with one another by competition reactions, with some hydrocarbons giving a more complete picture.[18] Scheme 1 gives a qualitative comparison of the reactivities.



Scheme 1. Reactivity in [4 + 2] cycloadditions with TCNE or PTAD, qualitative comparison. The reactivity increases in the direction of the two arrows.

In the case of the azides, methyl groups in the *E*-position inhibit the [4 + 2] cycloadditions, whereas methyl groups in the *Z*-position have an accelerating effect. A comparison of the diazides with the analogous hydrocarbons shows that the additional azide groups facilitate faster Diels–Alder reactions. This effect is, however, less conspicuous than in the case of replacement of the hydrogen by methyl groups: **1** reacts more rapidly than 1,3-butadiene, but markedly more slowly than 2,3-dimethyl-1,3-butadiene. **13** occupies an unexpected position in Scheme 1. With its two activating methyl groups, **13** shows, on the one hand, a slower cycloaddition than **9** with only one such group; on the other hand, **13** reacts more slowly than the analogous hydrocarbon (*E*,*E*)-2,4-hexadiene.

The synthetic potential of 2,3-diazido-1,3-butadienes of type **1** is still not exhausted by the reactions described here. Preliminary experiments indicate that [2 + 2] cycloadditions and 1,3-dipolar cycloadditions are also possible.

Dynamic Processes on the IR Time Scale: Coalescence of CO Stretching Vibrational Bands in [(η⁴-Diene)Fe(CO)₃] Complexes

By *Friedrich-Wilhelm Grevels,* Jürgen Jacke, Werner E. Klotzbücher, Carl Krüger, Klaus Seevogel,* and *Yi-Hung Tsay*

Coalescence phenomena are often observed in NMR spectra and are routinely used for the investigation of exchange processes or fluctional molecular structures. In vibrational spectroscopy, analogous temperature-dependent changes in the band shapes can only be observed when the processes responsible for these phenomena take place on the picosecond time scale. Accordingly, the few known examples[1–5] involve conformational changes or proton transfer reactions. The possibility that rapid intramolecular rearrangements in metal complexes might also be observed by IR spectroscopy has not yet been considered. We now report on [(η⁴-organo)Fe(CO)₃] compounds[6] as the first such examples.

$LM(CO)_3$ complexes containing three equivalent CO groups exhibit two CO stretching vibrations (C_{3v}: A_1, E) in the IR spectrum, which, in the energy-factored force field model,[7] are described as in (a) by two parameters (k, i). An example is given by the CO bands of [(η⁴-trimethylenemethane)Fe(CO)₃] **1** shown in Figure 1A.

$$A_1: k + 2i - K = 0$$
$$E: k - i - K = 0 \qquad \text{(a)}$$

with

$$K = \frac{4\pi^2 c^2}{\mu_{CO} N_A} \tilde{\nu}_{CO}^2$$

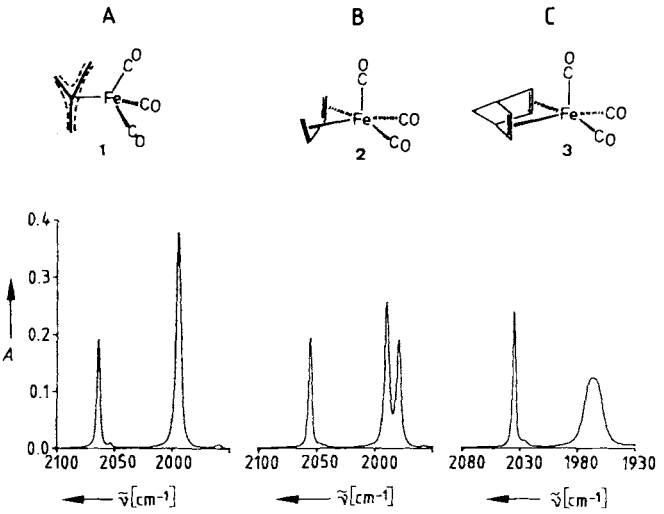

Fig. 1. CO bands of A) **1**: $\tilde{\nu}$ = 2064, 1995 cm⁻¹; B) **2**: $\tilde{\nu}$ = 2056, 1990.5, 1980 cm⁻¹; C) **3**: $\tilde{\nu}$ = 2035.5, 1967 cm⁻¹. *In* isooctane, T = 20°C, c = 0.003 mol L⁻¹, d = 100 μm. A = absorbance.

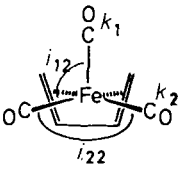
In [(η⁴-diene)Fe(CO)₃] complexes having square-pyramidal structure, the degeneracy of the out-of-phase CO stretching vibration is removed by the lowering of the symmetry to C_s, resulting in three CO bands (2 A′, A″), as described by (b). These are shown for [(η⁴-1,3-butadiene)Fe(CO)₃] **2** in Figure 1B. The Fe(CO)₃ complexes of



$$A': \begin{vmatrix} k_2 + i_{22} - K & \sqrt{2}\, i_{12} \\ \sqrt{2}\, i_{12} & k_1 - K \end{vmatrix} = 0$$
$$A'': \quad k_2 - i_{22} - K = 0 \qquad \text{b)}$$

norbornadiene (**3**) and 1,5-cyclooctadiene (**4**) belong to the few exceptions. As shown by the X-ray structure analysis of **4** (Fig. 2),[8] these complexes belong to the same square-pyramidal structure type having C_s symmetry as **2**.

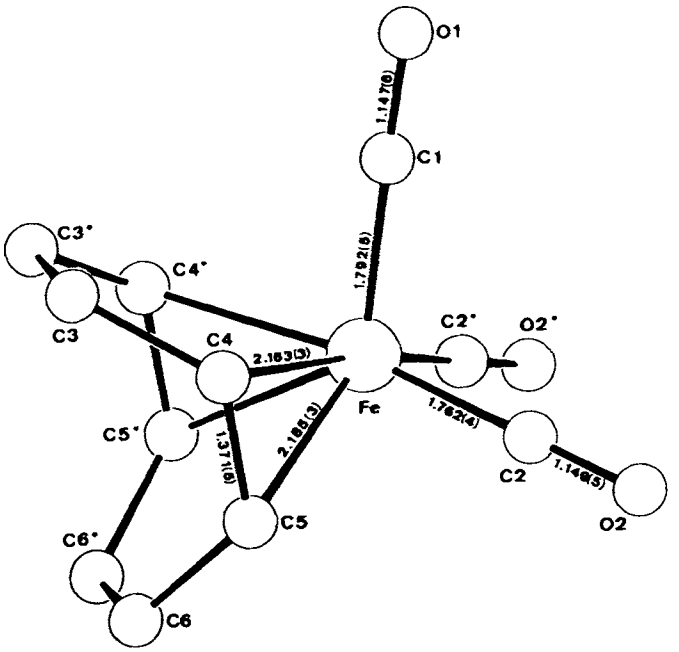

Fig. 2. Molecular structure of **4** [8]. Selected angles [°]: C1-Fe-C2 101.7(1), C2-Fe-C2* 86.6(2), C4-Fe-C4* 81.3(1), C5-Fe-C5* 78.7(1).

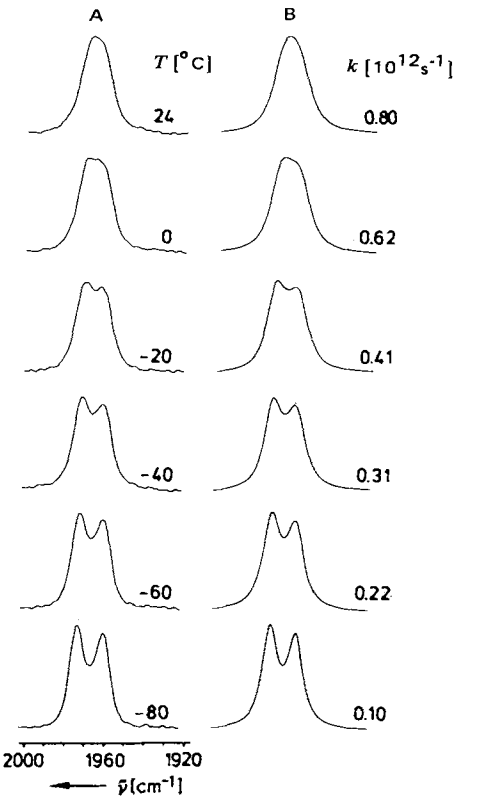

Fig. 3. Temperature-dependent IR spectrum of **3** in isooctane in the region of the two long-wavelength CO stretching bands. A) Measured [10]. B) Simulated [13].

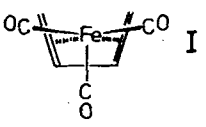
The room-temperature IR spectra of **3** and **4** exhibit only two bands in the region of the CO stretching vibrations (**3**, Fig. 1C; **4**, $\tilde{\nu}=2028$, 1959 cm^{-1}), the long-wavelength band being unusually broad (Fig. 1C). In low-temperature matrices (Ar, $T=10$–12 K), on the other hand, the expected spectrum consisting of three bands of nearly equal intensities and widths is observed in the two cases (**3**: $\tilde{\nu}=2041$, 1980, 1963.5 cm^{-1}; **4**: $\tilde{\nu}=2034$, 1977, 1956.5 cm^{-1}). In order to establish that this marked difference is not due to the effect known as "matrix splitting" (cf. $Fe(CO)_5$[9]), the spectra of **3** and **4** were also recorded in solution (isooctane) at temperatures down to $-80°C$.[10] In both cases, the long-wavelength band was observed to gradually split into two components (Fig. 3A) as the temperature was decreased. In a second series of spectra recorded at temperatures up to 80°C, the long-wavelength band was observed to become narrower and to increase in intensity ($\Delta\tilde{\nu}_{1/2}$: 17.5 cm^{-1} at 20°C, 15 cm^{-1} at 80°C).

The CO bands of **3** and **4** thus exhibit a gradual change between the types of spectra shown in Figures 1B and 1A in the temperature range between $-80°C$ (**3**: $\tilde{\nu}=2035$, 1970.5, 1958.5 cm^{-1}; **4**: $\tilde{\nu}=2027.5$, 1969, 1949.5 cm^{-1}) and $+80°C$ (**3**: $\tilde{\nu}=2035$, 1966.5 cm^{-1}; **4**: $\tilde{\nu}=2028$, 1959.5 cm^{-1}).[11] This temperature dependence in the band shape of the out-of-phase CO stretching vibrations is similar to the known coalescence of NMR signals. It can be interpreted as an equilibration of the three CO groups, assuming that the rate constant for this process lies in the range of the IR time scale. For $k_1=k_2$ and $i_{12}=i_{22}$, the expressions of (b) are transformed to those of (a); i.e., the A″ and out-of-phase A′ vibrations degenerate into the E vibration. That the fully symmetric, high-frequency vibration (in-phase A′) does not participate in this coalescence (it is transformed to the A_1 vibration)[12] is an inevitable consequence of the way in which the three CO vibrations couple [Eq. (a)].

We carried out, as a trial, a simulation of the IR bands shown in Figure 3, in analogy to two NMR signals,[13] by using rate constants of 10^{11}–10^{12} s^{-1} (Fig. 3B). These values, despite all reservations regarding the use of this procedure,[4] should at least be of the correct order of magnitude. Plotting of $\ln k$ and $\lg(k/T)$ vs. $1/T$ gave straight lines, from which the activation parameters $E_a=2.2$ kcal mol^{-1}, $\Delta H^{\neq}=1.7$ kcal mol^{-1}, and $\Delta S^{\neq}\approx 2$ cal mol^{-1} K^{-1} could be derived.[20] The value for E_a lies far below the range that is accessible by NMR spectroscopy. This finding is in agreement with the observation of only one signal for the three CO groups in the ^{13}C-NMR spectra of **3** and **4** at temperatures down to $-110°C$.[14,15]

For the $Fe(CO)_3$ complexes of conjugated dienes, on the other hand, it is known that the equilibration of the CO ligands can be followed by ^{13}C-NMR spectroscopy;[14,16] coalescence occurs in the temperature region between $-40°C$ and $-80°C$ and the activation energies are 7–12 kcal mol^{-1} (e.g., for **2**, $E_a=9.5$ kcal mol^{-1}).

The detailed mechanism of the equilibration (rotation around the metal–diene axis; pseudorotation of the $M(CO)_3$ unit)[17] is not yet clear; however, a species having the structure **I** is a plausible intermediate.[14,15] According



I

to extended Hückel calculations, this structure should be about 7 kcal mol^{-1} higher in energy than the basic structure **2**.[17] However, in the case of the norbornadiene and 1,5-cyclooctadiene complexes **3** and **4**, respectively, **I** is identical with the basic structure. This would adequately explain the unusually low activation energies.

Preliminary measurements carried out on [(η^4-cyclobutadiene)Fe(CO)$_3$] (cf. also Ref. [18]) have shown that this complex behaves similarly to **3** and **4**;[19] however, the long-wavelength, degenerate CO stretching vibration is split in this case only between -110 °C and -120 °C (in 2-methylpentane).

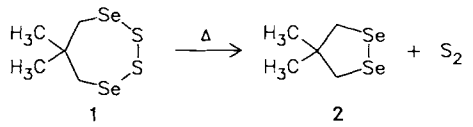
[20] *Note added in proof* (August 17, 1987): Recent measurements over a wider range of temperature (down to -140 °C, in 2-methylpentane) indicate that the value determined for E_a is too high, presumably by 0.5–1 kcal mol^{-1}.

5,5-Dimethyl-1,2-dithia-3,7-diselenacycloheptane—A Storable Source of Disulfur, S_2**

By *Max Schmidt** and *Udo Görl*

Singlet oxygen, $^1O_2$, has in principle been known for a long time; its reactivity has been intensively studied.[1,2] The interest in reactions of S_2 was first aroused much later.[3,4] In 1984, *Steliou* et al. were able to produce S_2 for the first time by a method analogous to that used for the production of $^1O_2$ from triphenylphosphane ozonide and to trap it with dienes.[5] Recently, *Steliou* has reported that reaction of 2,2′-dibenzoylbiphenyl with bis(trimethylsilyl) sulfide and boron trichloride affords 2,2′-bis(thiobenzoyl)biphenyl, which spontaneously loses S_2 with C–C coupling and formation of 9,10-diphenylphenanthrene.[6,7]

We have recently synthesized and investigated the first organosubstituted chalcogen chains of the type R–Se–S–S–Se–R.[8] The open-chain compounds are, from our experience, not suitable as a source of S_2. In sharp contrast, however, the cyclic 5,5-dimethyl-1,2-dithia-3,7-diselenacycloheptane **1** undergoes thermal decomposition with ring contraction and formation of 4,4-dimethyl-1,2-diselenacyclopentane **2** and S_2.

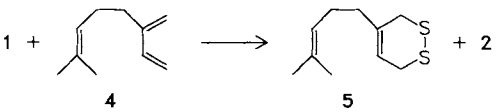


1 **2**

$HSe-CH_2-C(CH_3)_2-CH_2-SeH$ **3**

1 can be prepared from 2,2-dimethyl-1,3-propanediyl di(*p*-toluenesulfonate);[9] on reaction with sodium selenide, the latter is converted into **2**, which can be reduced with phosphorous acid (phosphinic acid)[10] to 2,2-dimethylpropane-1,3-diselenol **3**. Reaction of **3** with S_2Cl_2 then leads to elimination of HCl and formation of **1** in 70% yield as a bright-yellow solid. **1** is air-stable and soluble in the usual solvents. For prolonged storage, however, **1** should be kept at -15 to -20 °C, since it slowly decomposes to **2** and S_2 (which naturally transforms into S_8) at room temperature.

The thermal ring contraction involving cleavage of two selenium–sulfur bonds and formation of a selenium–selenium bond, which can be easily monitored ^{1}H-NMR spectroscopically, requires six days for completion when carried out in boiling toluene but only 90–240 minutes when carried out in boiling chlorobenzene. In the absence of suitable trapping reagents, S_2 is isolated—along with **2**—as S_8. The choice of reaction medium, and thus of the reaction temperature and duration of reaction, depends on the (albeit not always as high as desired) thermal stability of the S_2-adducts that are formed with the unsaturated compounds used in the reaction. Here, we shall only report on attempts to unequivocally detect S_2 by addition to the four 1,3-dienes **4**, **6**, **8**, and **10** in boiling chlorobenzene; presumably the yields can be improved by variation of the reaction time and temperature.



4 **5**

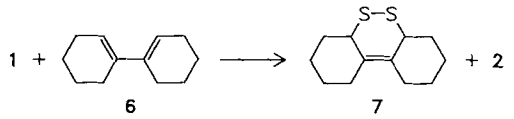
In the decomposition of **1** in the presence of myrcene **4** we obtained 4-(4-methyl-3-pentenyl)-3,6-dihydro-1,2-dithiin **5**, an antibacterial substance recently isolated from beer.[7]

Reaction of 1,1′-bicyclohexenyl **6** with **1** furnished, within 100 min, the complex **7**, 1,2,3,4,5,6,7,8,8a,10a-decahydro-9,10-dithiaphenanthrene, in 48% yield as a bright-yellow oil. In toluene the yield was only 23% after 6 d.

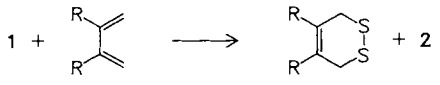
From the reaction of 2,3-dimethyl-1,3-butadiene **8** with **1** we isolated 4,5-dimethyl-3,6-dihydro-1,2-dithiin **9** as a

[*] Prof. Dr. M. Schmidt, Dr. U. Görl
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.



yellow oil in 48% yield. The diphenyl derivative **11** was obtained analogously in 54% yield from **10**.



8, R = Me **9**, R = Me
10, R = Ph **11**, R = Ph

Attempts to synthesize pure **1**, which contains two phenyl groups in place of the two methyl groups, have so far failed because of its thermal instability at room temperature. Reaction of **3**, phenyl instead of methyl, with S_2Cl_2 gives the desired product, albeit in admixture with sulfur and the sulfur-free five-membered ring. When myrcene is added to the reaction mixture, the S_2-adduct can be detected but not isolated in sufficient amounts.

Reaction of **1** with the cyclic 1,3-dienes 1,3-cyclohexadiene, 1,2,3,4,5-pentaphenyl-1,3-cyclohexadiene or 1,4-diphenyl-1,3-cyclopentadiene affords **2** again in quantitative yield; however, sulfur and hydrogen sulfide, as well as the two aromatics, benzene and 1,2,3,4,5-pentaphenylbenzene, are also formed. The cyclopentadiene derivative, in which aromatization is not possible, undergoes polymerization.

Experimental:

2: 2,2-dimethyl-1,3-propanediyl di(*p*-toluenesulfonate) [9] (20.04 g, 49.5 mmol) was added portionwise to a Na_2Se_2 solution (prepared from 14.0 g (177 mmol) of Se, 4.20 g (111 mmol) of $NaBH_4$, and 300 mL of ethanol [11]) and the mixture heated under reflux for 72 h. After filtration, the resulting red solution was treated with 200 mL of H_2O and extracted with 250 mL of $CHCl_3$. The extract was dried over $MgSO_4$. Removal of solvent and purification of the remaining red oil by column chromatography (silica gel 400 × 25 mm, room temperature, petroleum ether 30–75 °C, $R_f = 0.17$, N_2 under pressure) afforded 7.9 g of pure **2** (70%). ^{1}H-NMR (60 MHz, CS_2, TMS int.): $\delta = 1.31$ (s, 6H), 3.10 (s, 4H). Correct elemental analysis.

3: A mixture of **2** (7.9 g, 35 mmol), 10 mL of 50% H_3PO_2, and 200 mL of diethylene glycol was heated to 70–80 °C. After 45 min the resulting colorless solution was treated with 100 mL of O_2-free H_2O and the mixture distilled at normal pressure. **3** was extracted from the two-phase distillate with CS_2. After drying over $MgSO_4$ and removal of CS_2 there remained 6.36 g (79%) of **3** as a colorless, foul-smelling oil. ^{1}H-NMR (60 MHz, CS_2, TMS int.): $\delta = -0.9$ (t, 2H, $J_{HCSeH} = 8$ Hz); 1.06 (s, 6H); 2.57 (d, 4H). Correct elemental analysis.

1: Separate solutions of **3** (5.54 g, 24.1 mmol) and S_2Cl_2 (3.24 g, 24.1 mmol) in CS_2 (in each case 50 mL) were cooled to −78 °C, transferred to separate dropping funnels, and added dropwise and simultaneously with stirring into 200 mL of CS_2 at −78 °C. The resulting yellow solution was treated with 4.82 g (48.2 mmol) of triethylamine in one batch. After filtration at −78 °C and removal of solvent at $-40\,°C/10^{-3}$ torr there remained a yellow oil, which was purified by column chromatography (as in the case of **2**) ($R_f = 0.33$). 4.92 g (70%) of pure **1** (m.p. 50–51 °C) was recovered as a yellow solid. ^{1}H-NMR (60 MHz, CS_2, TMS int.): $\delta = 1.10$ (s, 6H), 3.50 (s, 4H). Correct elemental analysis.

5: A mixture of **1** (2.34 g, 8.27 mmol) and **4** (1.13 g, 8.27 mmol) in chlorobenzene (15 mL) was heated under reflux for 90 min. The solvent was removed in a water-jet vacuum and the red oil remaining was separated by column chromatography into five fractions (unchanged **4**, $R_f = 0.75$; S_8, $R_f = 0.64$; unchanged **1**, $R_f = 0.33$; **2**, $R_f = 0.17$; small amounts of **1** and **2** mixed with **5**, $R_f = 0.26$). High-pressure chromatographic separation of the latter fraction yielded 0.66 g (40%) of pure **5** as a bright-yellow oil. ^{1}H-NMR (60 MHz, $CDCl_3$, TMS int.): $\delta = 1.60$ (s, 3H); 1.68 (s, 3H); 2.06 (s, 4H); 3.03–3.33 (m, 4H); 5.07 (m, 1H); 5.72 (m, 1H). Correct elemental analysis.

7: A mixture of **1** (2.145 g, 7.34 mmol) and **6** (1.19 g, 7.34 mmol) was treated and worked-up as described for the preparation of **5**. Yield: 742 mg (48%) of **7** as a bright-yellow oil. ^{1}H-NMR (60 MHz, $CDCl_3$, TMS int.): $\delta = 0.67$–1.03 (m); 1.06–2.06 (m). Correct elemental analysis.

9: **1** (2.76 g, 9.43 mmol) was allowed to react with **8** (2.50 g, 30.3 mmol) in boiling chlorobenzene for 4 h. Excess **8** was then distilled off with the solvent at normal pressure. Column chromatography (as for **2**) and subsequent high-pressure liquid chromatography furnished 675 mg (48%) of pure **9** as a bright-yellow oil. ^{1}H-NMR (60 MHz, CS_2, TMS int.): $\delta = 1.72$ (s, 6H), 3.11 (s, 4H).

11: A mixture of **1** (5.40 g, 18.44 mmol) and **10** (3.80 g, 18.44 mmol) in chlorobenzene (30 mL) was heated under reflux for 90 min. After removal of solvent in a water-jet vacuum, column chromatography afforded 2.68 g (54%) of pure **11** as a colorless solid (m.p. 102 °C). ^{1}H-NMR (60 MHz, $CDCl_3$, TMS int.): $\delta = 3.67$ (s, 4H); 7.10–7.25 (m, 10H). Correct elemental analysis.

Synthesis of *O*-(α-Glyco)peptides by the *N*-Iodosuccinimide Procedure**

By *Horst Kessler,* Matthias Kottenhahn, Andreas Kling,* and *Cenek Kolar**

A large number of proteins found in living organisms are present as glycoconjugates; the elucidation of their structures, the understanding of their functions,[1–3] and their synthesis[4–6] still pose a challenge. One of the main difficulties is the stereoselective linking of the peptide with the carbohydrate. Glycopeptides have so far been prepared almost exclusively by modified Königs–Knorr glycosidation of protected amino acids. The remaining amino acids are subsequently added by standard methods of peptide chemistry. So far, it has not been possible to glycosidate larger peptide fragments stereoselectively in useful yields.

We report here on the use of the *N*-iodosuccinimide (NIS) procedure for the synthesis of glycosidated peptides. This procedure was developed by *Thiem* et al.[7] for the synthesis of 2-deoxy oligosaccharides. In particular, we have found that even pentapeptides react directly to give good yields of products with nearly complete diastereoselectivity.

The procedure consists in the reaction of glycals such as 3,4,6-tri-*O*-acetyl-D-glucal **1** or -galactal **2** with the hydroxyl groups of serine- or threonine-containing peptides in the presence of NIS (Scheme 1). The 2-deoxy-2-iodoglycosides thereby obtained, **3** or **4**, can be converted, via radicalic dehalogenation, into the 2-deoxyglycosides **5** or **6**, respectively.

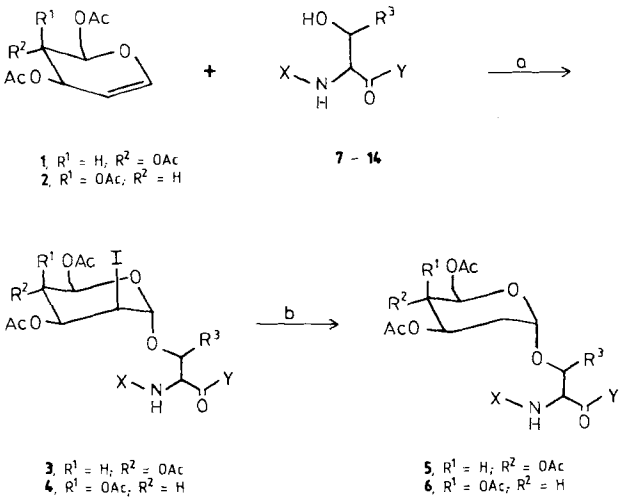

Scheme 1. The reaction of 1,2-didehydro carbohydrates with serine or threonine derivatives according to the NIS procedure followed by dehalogenation of the iodoglycopeptides. R^3 = H, CH_3; X, Y = protecting group, amino acid or peptide derivative (see Table 1). a), b): Experimental procedure, see [15] and [17], respectively.

Application of the NIS procedure has only been reported for the synthesis of di- or oligosaccharides[8] and alkylglycosides.[9] Only C-1 protected 2-deoxyglycosides have been so far prepared with 3,4,6-tri-*O*-acetyl-D-galactal **2**.[10] It is just such reactions, however, that make the method interesting, since galactose is frequently present in naturally occurring glycopeptides.

We first used **1** and **2** to carry out the glycosidation of the building blocks Fmoc-Ser-OBzl and Fmoc-Thr-OBzl, which are readily accessible by the methods of peptide chemistry.[11] Further experiments using model tripeptides and a pentapeptide demonstrate the scope of application and the possibility of using several combinations of protecting groups;[6] the Aloc,[12] Pyoc,[13] and Fmoc[14] groups served as *N*-terminal protecting groups. The yields in Table 1 show that the use of *N*-terminal Pyoc and Aloc protecting groups is not recommended in this procedure, since they give rise to side reactions owing to their chemical structure.

Particularly noteworthy are the good yields obtained in the reactions of the peptides with galactose derivatives and the high α diastereoselectivity.

The glycopeptides of types **3** and **4** thereby obtained are valuable starting materials. For example, some of them were treated with Bu_3SnH/AIBN, according to the known[16] radicalic dehalogenation procedure, to give 2-deoxyglycosides of types **5** and **6**[17] (Table 2; see also Scheme 1). The configuration at the anomeric center is completely retained during this reaction.

Table 2. 2-Deoxyglycopeptides of types **5** and **6** obtained by radical deiodination with Bu_3SnH [17]. TAD-glu = 3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl; TAD-gal = 3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactosyl.

Reactant	Product [a]		Yield [%]
3a	Fmoc-Ser(TAD-glu)-OBzl	**5a**	91
4a	Fmoc-Ser(TAD-gal)-OBzl	**6a**	84
3b	Z-Pro-Ser(TAD-glu)-Ala-OBzl	**5b**	82
4d	Z-Pro-Ser(TAD-gal)-Ala-OBzl	**6d**	92
3d	Z-Pro-Thr(TAD-glu)-Ala-OBzl	**5d**	86

[a] The purity of the synthesized compounds was determined by ^{1}H- and ^{13}C-NMR spectroscopy as well as by FAB mass spectrometry.

Of further interest is the replacement of iodine by azide or acetate. The 2-acetamido-2-deoxyglycosides are accessible from the azides (obtainable in the manno or talo configuration so far in yields of 40% by reaction of, e.g., the iodo compound **3a** with $NaN_3/(NH_4)_2Ce(NO_3)_4$).[18]

Deblocking of the glycosidated amino acids and peptides by means of available procedures[19] poses no problems.

Because of its diastereoselectivity, its high yields, and its broad scope of application, the procedure described here is well suited for the direct synthesis of glycopeptides containing various functions at C-2 of the carbohydrate. The non-naturally occurring 2-deoxyglycopeptides thereby formed are of interest as potential glycosidase inhibitors and for improving the pharmacokinetic properties of peptides.

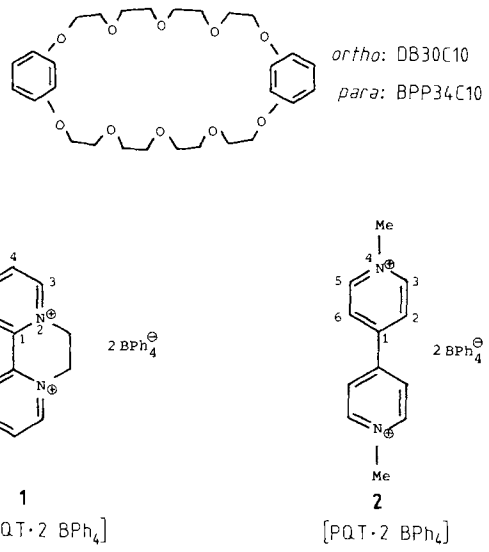
Noncovalent Bonding Interactions between Tetraphenylborate Anions and Paraquat and Diquat Dications**

By *Gwilym J. Moody, Richard K. Owusu, Alexandra M. Z. Slawin, Neil Spencer, J. Fraser Stoddart,* J. D. Ronald Thomas,* and *David J. Williams*

The observation[1] that dibenzo[30]crown-10 (DB30C10) complexes with diquat $DQT^{2\oplus}$ but not[2] with paraquat $PQT^{2\oplus}$ has led[3] to the development of an ion-selective electrode for diquat. The sensor, which is used with 2-nitrophenylphenyl ether as a plasticizing solvent mediator in a PVC matrix membrane is based on DB30C10 mixed with diquat bis(tetraphenylborate) **1**. The neutral carrier ligand improves the $DQT^{2\oplus}$-sensing quality, which is also demonstrated by **1** on its own. More recently, a constitutional isomer of DB30C10 containing 1,4-linked benzene rings, namely bisparaphenylene[34]crown-10 (BPP34C10), has been found[4] to complex with $PQT^{2\oplus}$ as well as with $DQT^{2\oplus}$. However, the $PQT^{2\oplus}$ electrode, based on **2**, is surprisingly better when BPP34C10 is absent.[3] The fact that **2** produces orange-colored membranes[5] suggested to us that there is a π–π charge-transfer interaction of the donor–acceptor type[6] between $BPh_4^{\ominus}$ and $PQT^{2\oplus}$ in **2**, in addition to major attractive interactions, involving ion-pairing,[7] and other weaker stabilizing forces arising from van der Waals and dispersive interactions.[8] We now report the confirmation of this hypothesis on the basis of an X-ray structural analysis[9] on a single red crystal[10] of **2**.



The solid-state structure reveals that the planar $PQT^{2\oplus}$ is sandwiched between two tetraphenylborate anions (Fig. 1) related to each other by a crystallographic center of symmetry which lies at the center of the Cl–Cl′ bond. One of the phenyl rings on each anion is aligned approximately parallel to (10° tilt between mean planes, Fig. 2) and partially overlapping one of the pyridinium rings of $PQT^{2\oplus}$. In the region of ring overlap, the distances of C24 and C25 from the plane of the pyridinium ring are both 3.38 Å and, conversely, those of C2 and C3 from the plane of the phenyl ring are both 3.27 Å. These contacts are consistent[11] with π–π charge-transfer interactions which give rise to the pronounced color observed in both solution[5] and the solid state. In addition to the sandwiching of $PQT^{2\oplus}$ by two anions, the space-filling representation (Fig. 3) illustrates additional edge-to-face interactions between the dication and the orthogonally disposed phenyl rings on the anions. These T-shaped arrangements of the π-electron-de-

[PQT·2PF$_6$]	—	—	—	—	—	9.36	8.83	4.73	—	—	—
2 [PQT·2BPh$_4$]	—	—	—	—	—	9.03	8.43	4.58	7.34	6.90	6.74
						(−0.33)	(−0.40)	(−0.15)	(+0.07)	(−0.01)	(−0.03)
DQT·2PF$_6$	9.23	9.09	8.59	9.49	5.69	—	—	—	—	—	—
1 [DQT·2BPh$_4$]	8.86	8.86	8.36	9.06	5.31	—	—	—	7.34	6.91	6.76
	(−0.37)	(−0.23)	(−0.23)	(−0.43)	(−0.38)				(+0.07)	(0.00)	(−0.01)

[a] The spectra were recorded at room temperature on a Bruker AM250 spectrometer using CD_2HCOCD_2H in CD_3COCD_3 as reference. The $\Delta\delta$ values (in parentheses, quoted for 0.013 M solutions) indicate the shifts with respect to the appropriate standard (nBu$_4$NBPh$_4$, [PQT·2PF$_6$], or [DQT·2PF$_6$]). The $\Delta\delta$ values for **2** represent the lowest numerical limits, since the salt starts to crystallize in the NMR tube even while the spectrum is being recorded (see [10] and [16]).

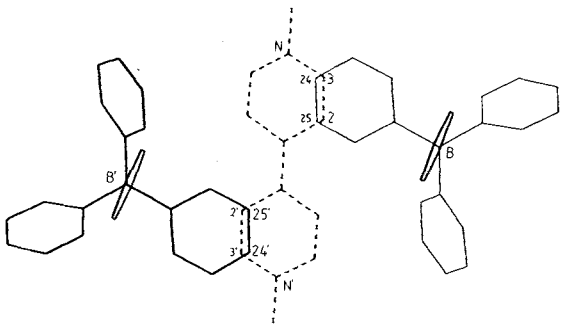

Fig. 2. Schematic representation of the overlap between the pyridinium rings of the dication $PQT^{2\oplus}$ (broken lines) and one of the phenyl rings of each anion $BPh_4^{\ominus}$ (solid lines) of **2**.

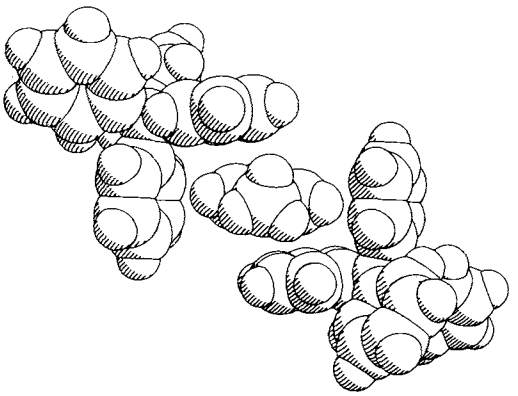

Fig. 3. Space-filling representation of the structure of paraquat bis(tetraphenylborate) **2** highlighting both face-to-face and edge-to-face interactions between the pyridinium rings of the dication and the orthogonally disposed phenyl rings of the anions.

ficient pyridinium and π-electron-rich phenyl rings, coupled with a centroid–centroid distance of 5.0 Å and the 4° inclination of the associated vector to the normal to the phenyl ring in each case, are characteristic of the geometry associated with the global potential energy minimum for two interacting aromatic rings.[11–14]

The ^{1}H-NMR chemical shift data for **1**, **2**, and reference compounds recorded in Table 1 shows that close association is maintained between the $PQT^{2\oplus}$ and $BPh_4^{\ominus}$ ions in solid **2** in acetone solution.[15] All the evidence suggests that a highly structured ternary complex involving a dication and two anions exists[16] in solution as well as in the solid state. The upfield shifts of $\Delta\delta = -0.33$ and -0.40 ppm for H-3,5 and H-2,6, respectively, in $PQT^{2\oplus}$ are compatible with the positioning (see Figs. 2 and 3) of one side of each pyridinium ring in the paratropic regions of both a parallel and an orthogonally disposed phenyl ring of $BPh_4^{\ominus}$. These upfield shifts are accompanied by small downfield shifts of the *ortho* protons of the anions: this reflects the diatropy of the encircled dication. The fact that a similar downfield shift is observed for these protons in **1** suggests that this ternary complex[16] is also a highly structured one in solution.

As a consequence of these results one can envisage a new generation of macrocyclic dianionic receptors and sensors incorporating two tetraarylborate residues.[17]

[2] This observation was made for CH_2Cl_2 solutions [1]. However, when equimolar amounts of [PQT·2PF$_6$] and DB30C10 are mixed in acetone, a faint orange coloration is observed, indicating the existence of a weak charge-transfer interaction.

[5] UV spectra of **1** ([DQT·2BPh$_4$]) and **2** ([PQT·2BPh$_4$]) recorded in acetone show absorptions associated with very broad bands that extend beyond $\lambda = 500$ nm. In the case of **1**, two shoulders are clearly identifiable at $\lambda = 380$ and 480 nm: in the case of **2**, only one shoulder could be identified at $\lambda = 360$ nm. Since neither [PQT·2PF$_6$] or [DQT·2PF$_6$] nor nBu$_4$NBF$_4$ absorb in the visible region, these absorption bands may be attributed to charge-transfer interactions (R. Foster: *Organic Charge-Transfer Complexes*, Academic Press, London 1969).

[7] Ion-pair complexation with charge-transfer interactions involving $PQT^{2\oplus}$ and inorganic anions is well established (L. A. Summers: *The Bipyridinium Herbicides*, Academic Press, New York 1980, p. 116). Ion-pair complexation involving large organometallic cations and large organic anions is also well known (for a recent example, see S. Tachiyashiki, H. Yamatera, *Inorg. Chem. 25* (1986) 3209.
[8] R. S. Mulliken, *J. Am. Chem. Soc. 74* (1952) 811; M. Meot-Ner (Mautner), *Acc. Chem. Res. 17* (1984) 186.
[9] **2**: monoclinic, $a = 9.925(2)$, $b = 14.734(3)$, $c = 17.487(5)$ Å, $\beta = 93.85(2)°$, $V = 2549$ Å^3, $P2_1/c$, $Z = 2$ (the complex possesses a center of symmetry), $\rho_{calcd} = 1.10$ g cm^{-3}. Nicolet R3m diffractometer, ω-scan, graphite monochromated $Cu_{K\alpha}$ radiation. The structure was solved by direct methods and refined anisotropically to give $R = 0.085$, $R_w = 0.095$ for 1859 independent observed reflections [$|F_o| > 3\sigma(|F_o|)$, $\theta \leq 50°$]. The R factor is high owing to slight disorder in the phenyl groups of the anion and to the presence of disordered solvent fragments. Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England) on quoting the full literature citation.
[10] *Experimental Procedure* for **2** ([PQT·2BPh$_4$]): n-Bu$_4$NBPh$_4$ (10 mg, 0.018 mmol) was dissolved in [D$_6$]acetone (0.7 mL) and the solution was added to [PQT·2PF$_6$] (4.25 mg, 0.009 mmol). The solution instantly

turned deep yellow with a slight precipitation occurring thereafter. The solution was filtered and red single crystals, suitable for X-ray investigation, grew in the filtrate within the following 24 h. M.p. = 215–220 °C (decomp.).

[11] R. O. Gould, A. M. Gray, P. Taylor, M. D. Walkinshaw, *J. Am. Chem. Soc. 107* (1985) 5921.

[12] S. K. Burley, G. A. Petsko, *Science (Washington, DC) 229* (1985) 23; *J. Am. Chem. Soc. 108* (1986) 7995.

[13] It has not escaped our attention that, in the X-ray structure of the benzene complex of a self-adjusting molecular cage containing two 1,1,1-triphenylethane units linked by three $OCH_2C{\equiv}C{-}C{\equiv}CCH_2O$ linkages (E. O'Krongley, S. R. Denmeade, M. Y. Chiang, R. Breslow, *J. Am. Chem. Soc. 107* (1985) 5544), the included benzene molecule is clamped between two phenyl residues both arranged with their edges directed toward the opposite faces of the benzene molecule.

[14] Recently, we have observed edge-to-face stacking of aromatic rings (I) in the macrocycle BPP25C7, an analogue of BPP34C10 (A. M. Z. Slawin, N. Spencer, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1987*, 1070) and (2) in a 1:2 adduct formed between $[Pt(NH_3)_4]^{2\oplus}$ and two second-sphere bicyclic polyether ligands each incorporating two 2,6-bis(hydroxymethyl)phenol residues (D. R. Alston, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, R. Zarzycki, *Angew. Chem. 99* (1987) 697, 698; *Angew. Chem. Int. Ed. Engl. 26* (1987) 692, 693. Although, in the first example, the attractive edge-to-face interactions are occurring intramolecularly, in the second example, they exist *intermolecularly* and so are more similar in type to those observed in $[PQT{\cdot}2BPh_4]$ **2** (Figs. 1–3).

[15] We have observed similar significant changes of chemical shifts of specific substrate and receptor protons *in acetone solution* when $DQT^{2\oplus}$ and $PQT^{2\oplus}$ form 1:1 inclusion complexes with DB30C10 and BPP34C10, respectively [1, 4]. It is worthy of note that the 1:1 inclusion complexes formed between numerous *water-soluble macrocyclic receptors* of the cyclophane type, incorporating either diphenylmethane or substituted diphenylmethane residues and aromatic substrates (e.g., 2,7-dihydroxynaphthalene and pyrene) also exhibit strong changes of the chemical shifts of specific protons of receptor and substrate upon complexation (K. Odashima, A. Itai, Y. Iitaka, Y. Arata, K. Koga, *Tetrahedron Lett. 21* (1980) 4347; J. Winkler, E. Coutouli-Argyropoulou, R. Leppkes, R. Breslow, *J. Am. Chem. Soc. 105* (1983) 7198; F. Diederich, K. Dick, *Angew. Chem. 95* (1983) 730; *Angew. Chem. Int. Ed. Engl. 22* (1983) 715; *Angew. Chem. Suppl. 1983*, 957; F. Diederich, D. Griebel, *J. Am. Chem. Soc. 105* (1984) 8037).

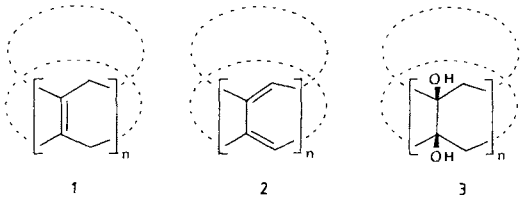
[16] In the case of $[PQT{\cdot}2BPh_4]$ **2**, a highly structured ternary complex in acetone solution is indicated by its propensity to crystallize. In the case of $[DQT{\cdot}2BPh_4]$ **1**, ^{1}H-NMR titration curves for all the $DQT^{2\oplus}$ protons obtained by adding nBu_4NBPh_4 to $[DQT{\cdot}2PF_6]$ exhibit "knees" at 2:1 molar ratios of $BPh_4^{\ominus}$ to $DQT^{2\oplus}$.

[17] The distance (6.9 Å) between C14 and C24′ (and C14′ and C24) in **2** could be bridged by, for example, an $OCH_2CH_2OCH_2CH_2O$ or an $OCH_2C{\equiv}C{-}C{\equiv}CCH_2O$ unit. Such compounds, if they can be prepared, will have obvious structural similarities with some of the macrocyclic compounds mentioned in [13] and [14].

Molecular Belts and Collars in the Making: A Hexaepoxyoctacosahydro[12]cyclacene Derivative**

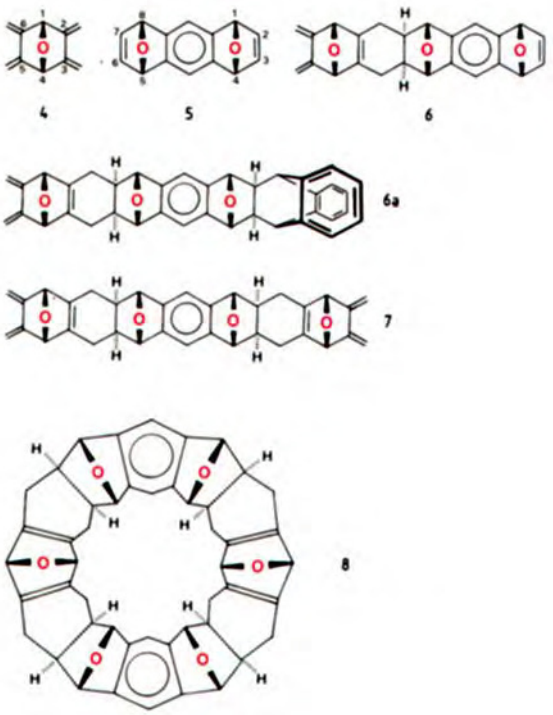
By *Franz H. Kohnke, Alexandra M. Z. Slawin, J. Fraser Stoddart,** and *David J. Williams**

For some time[1] we have been trying to prepare polyunsaturated hydrocarbons of the variety **1** wherein 1,4-cyclohexadiene rings are linked laterally to each other by means of their C=C double bonds in a belt-like manner.[2] Such compounds would provide a facile synthetic entry into a fascinating new range of molecular architectures, e.g. **2** and **3**, where compounds with intellectually-appealing



1 2 3

structures[3] promise to exhibit exciting new physical and chemical properties. The first steps towards the making of **1** where n = 12 have now been accomplished by employing repetitive Diels–Alder reactions on the readily-available[4,5] bisdiene **4** and bisdienophile **5**. Here, we disclose our synthetic strategy for the conversion (Scheme 1) of **4** and **5** via the 1:1 adduct **6** and the 2:1 adduct **7** into the hexa-



epoxyoctacosahydro[12]cyclacene derivative **8**, emphasizing the importance of (i) the choice of appropriate starting materials, e.g. **4** and **5**, with the required molecular stiffness and curvature,[6] (ii) the role of X-ray crystallography in characterizing the key intermediate **6** as its anthracene adduct **6a** and so removing any nagging doubts concerning the stereochemical options[7] that lie along the synthetic pathways, (iii) the use of high pressures in the liquid-phase[8] to promote, with acceptable efficiency, the crucial intramolecular Diels-Alder reaction[9] that leads to **8**, and (iv) the power of X-ray crystallography, not only to characterize **8** structurally but also, to reveal its exceptional ability to intercalate chloroform molecules in a layer-like manner.

The choice of 2,3,5,6-tetramethylene-7-oxabicyclo-[2.2.1]heptane **4** as one of the starting materials was based on the following features and facts: it can be prepared[4] in gram quantities from the inexpensive Diels–Alder adduct of furan and maleic anhydride: it forms[4,10,11] monoad-

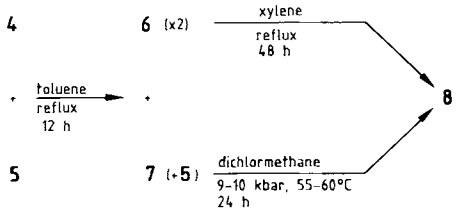

Scheme 1. Strategy for the synthesis of **8**.

ducts much faster (> 100 times) than bisadducts and so reactions can be easily controlled by varying the conditions: in its cycloadditions with bisdienophiles (e.g. benzoquinone), *one* of the two possible diastereoisomers predominates[11] overwhelmingly (e.g. > 95 : < 5). The choice of the *syn*-isomer **5** of 1,4:5,8-diepoxy-1,4,5,8-tetrahydroanthracene as the other starting material was based on the following features and facts: it can be prepared[5] in gram quantities from 1,2,4,5-tetrabromobenzene and furan; the relative configuration has been determined by an X-ray crystal structure analysis;[5] upon reaction with anthracene, only *one* of the three possible diastereoisomeric bisadducts is formed.[5] Both **4** and **5** share another two important characteristics: (i) they are rigid molecules with concave and convex surfaces; (ii) removal of the oxygen bridges at the end of a sequence of Diels–Alder reactions can usually be accomplished[5] with ease.

Inspection of molecular models revealed that, of the four possible diastereoisomeric 1 : 1 adducts which can be formed between **4** and **5**, only the two with all-*syn* oxygen atoms were candidates for macropolycyclization or macropolycyclic dimerization. Indeed, in the cycloaddition, **6** was obtained (Scheme 1) along with a bisadduct, which was assigned tentatively the relative configuration **7** on the basis of ^{1}H- and ^{13}C-NMR data, which are consistent with its C_{2v} molecular symmetry and emphasize its configurational relationship (compare chemical shifts) with **6**, whose relative configuration was established (Fig. 1) by X-ray crystallography[12] performed on the anthracene adduct **6a**. Under more forcing thermal conditions, **6** underwent (Scheme 1) macropolycyclic dimerization to give **8** in very low yield;[13] on the other hand, reaction of **7** with **5** under high pressure gave much better yields (20%) of **8** and established the stereochemistry of **7** beyond any doubt.[14] The X-ray crystal structure[12] of **8** (Fig. 2) reveals a certain structural elegance about this novel molecule with all six oxygen atoms distributed around the outer surface of the stiff molecular collar. The molecule possesses a crystallographic center of symmetry, the two benzene rings being therefore parallel with an interplanar separation of 7.9 Å. As expected, the eight *endo* methine hydrogen atoms, associated with the four benzo-fused oxanorbornene ring systems, are all directed into the center of the rigid molecular cavity. The molecules do not form continuous channels in the crystals but are arranged in parallel approximate edge-to-edge layers with the chloroform molecules sandwiched in between.[17]

The path is now clear for the production of a vast array of macropolycyclic derivatives and analogues of **8**. The synthetic intermediates provide the additional opportunity to increase the availability of rod-like molecules containing linearly-annulated rings[15] and wedge-shaped clefts and grooves.[16] Finally, answers are required to the question of the factors governing the *remote* stereoselectivities observed[18] in Diels–Alder reactions.

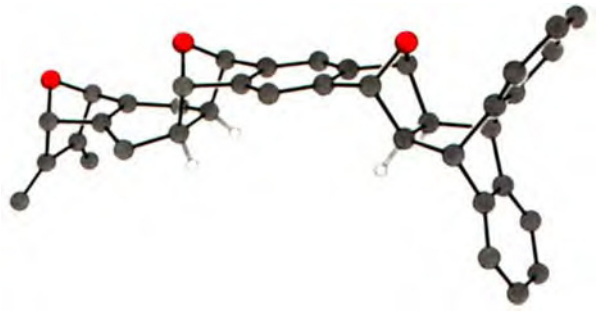

Fig. 1. Structure of **6a** in the crystal (H = white, C = gray, O = red). Crystal data: triclinic, $a = 14.399(4)$, $b = 15.220(7)$, $c = 17.274(8)$ Å, $\alpha = 86.29(4)$, $\beta = 79.63(3)$, $\gamma = 66.38(3)°$, $V = 3412$ Å^3, space group $P\bar{1}$, $Z = 4$ (2 crystallographically independent molecules, both with the same relative configuration), $\rho = 1.20$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 20$ cm^{-1}, 4582 independent reflections [$|F_0| > 3\sigma(|F_0|)$, $\theta \leq 50°$], $R = 0.14$. There are four disordered $ClCH_2CH_2Cl$ molecules in six discrete orientations included in the unit cell. For clarity, only the four methine H atoms are shown.

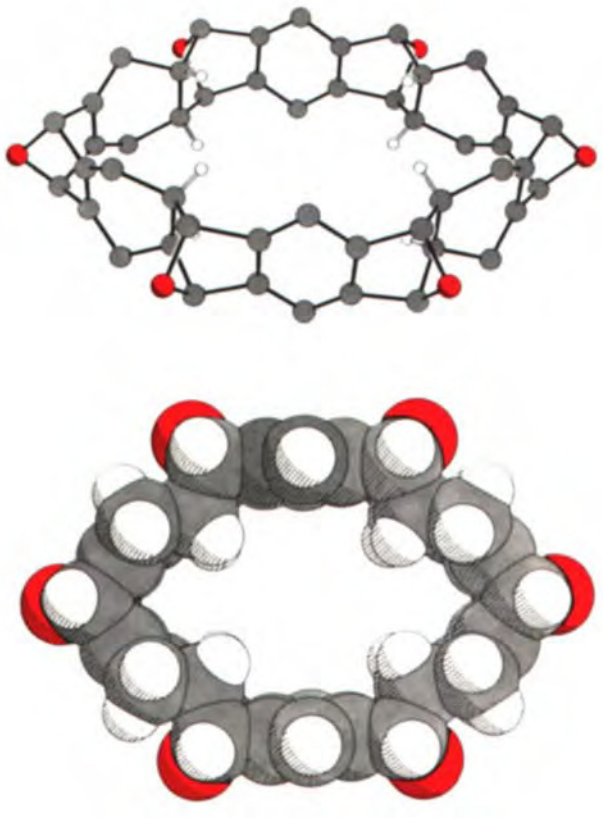

Fig. 2. Top: Structure of **8** in the crystal (H = white, C = gray, O = red). Crystal data: monoclinic, $a = 12.250(5)$, $b = 21.247(12)$, $c = 14.279(11)$ Å, $\beta = 110.59(5)°$, $V = 3479$ Å^3, space group $P2_1/c$, $Z = 2$, $\rho = 1.36$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 70$ cm^{-1}, 1689 independent reflections [$|F_0| > 3\sigma(|F_0|)$, $\theta \leq 50°$], $R = 0.196$. There are 12 disordered $CHCl_3$ molecules included in the unit cell in 16 discrete orientations. For clarity only the eight methine H atoms are shown.—Bottom: Space-filling representation of the structure of **8** (H = white, C = gray, O = red).

Experimental

6/7: The bisdiene **4** (3.37 g, 23.1 mmol) and the bisdieneophile **5** (2.43 g, 11.5 mmol) were heated under reflux (12 h) in toluene (245 mL), affording, after chromatography (SiO_2/$CHCl_3$-EtOAc-light petroleum), the 1 : 1 adduct **6** [1.0 g, 24%, recrystallized from $CHCl_3$-MeOH, m.p. > 300 °C, *m/z* (EIMS) 356; ^{1}H-NMR ($CDCl_3$): $\delta = 1.85$ (m), 2.33 (m), 2.61 (m), 4.91 (s), 4.97 (br.s), 4.98 (s), 5.08 (s), 5.63 (m), 7.02 (m), 7.08 (s) with all signals having equal intensities (2 H); ^{13}C-NMR ($CDCl_3$): $\delta = 23.7$, 43.2, 82.3, 85.1, 85.3, 100.9, 112.0, 143.1, 143.1, 143.3, 144.2, 168.6] and the 2 : 1 adduct **7** [3.63 g, 61%,

crystallized from EtOAc, m.p. >300°C, *m/z* (EIMS) 502; ^{1}H-NMR ($CDCl_3$): $\delta = 1.81$ (m, 4H), 2.33 (m, 4H), 2.61 (m, 4H), 4.92 (s, 4H), 4.97 (bs, 4H), 4.99 (s, 4H), 5.09 (s, 4H), 6.99 (s, 2H); ^{13}C-NMR ($CDCl_3$): $\delta = 25.7$, 43.2, 85.0, 85.3, 100.9, 110.2, 143.1, 144.2, 144.6].

6a: **6** (156 mg, 0.88 mmol) was heated under reflux (48 h, N_2) with anthracene (50 mg, 0.28 mmol) in xylene (5 mL); yield of the crude product: after chromatography (SiO_2/$CHCl_3$-Et_2O) 17 mg, 11%. Colorless crystals [m.p. >300°C), *m/z* (positive ion FABMS) 535 for $(M+H)^{\oplus}$] suitable for X-ray crystallography, were grown by the vapor diffusion method ($CHCl_3$-$ClCH_2CH_2Cl$-light petroleum).

8: Reaction (CH_2Cl_2, 9–10 kbar, 55–60°C, 200 h) of **7** (373 mg, 0.74 mmol) with **5** (156 mg, 0.74 mmol) yielded, after chromatography (SiO_2/$CHCl_3$-MeOH), **8** [105 mg, 20%, recrystallized from $CHCl_3$, m.p. >300°C, *m/z* (positive ion FABMS) 713 for $(M+H)^{\oplus}$; ^{1}H-NMR ($CDCl_3$): $\delta = 1.62$ (m, 4H), 2.32 (m, 8H), 2.63 (m, 8H), 4.89 (s, 8H), 5.08 (s, 4H), 6.98 (s, 4H); ^{13}C-NMR ($CDCl_3$): $\delta = 27.1$, 44.2, 84.8, 86.6, 110.1, 144.6, 152.5], which was also obtained in very low yield (3.5%) by heating **6** under reflux (48 h, N_2) in xylene. Single crystals, suitable for X-ray analysis, were obtained by slow evaporation of a chloroform solution of **8** at room temperature.

German version: *Angew. Chem. 99* (1987) 941

[1] Champions of highly speculative projects are few and far between; here, they were Dr. *R. D. Handscombe* (University of Sheffield) and Prof. *G. Stagno d'Alcontres* (University of Messina). We thank *them* for their moral support—and for their enthusiastic efforts, *all* the many postgraduate students, who over the years, have received their introduction to the research laboratory in Sheffield making starting materials for "the crazy molecule". One of the authors *(J. F. S.)* also thanks the Leverhulme Trust for the award of a Research Fellowship.

[2] Recently, some force-field calculations have been carried out (R. W. Alder, R. B. Sessions, *J. Chem. Soc. Perkin Trans. 2 1985*, 1849) on molecular belts built from cyclohexa-1,4-diene rings. Compounds of the type **1** were referred to in the above paper as [*n*]beltenes; the strain energy per 2-butene-1,2,3,4-tetrayl unit was found to decrease monotonically from [3]beltene to [12]beltene. Calculations on encapsulated complexes of small molecules led to the prediction that, in the case of acetylene, for example, [9]beltene will be the optimum molecular receptor.

[3] In looking to the future in cyclophane chemistry, *F. Vögtle* (*Top. Curr. Chem.* ("Cyclophanes II") *115* (1983) 157) has highlighted the challenge posed by the synthesis of the [*n*]cyclacenes **2**, which are also of considerable theoretical interest (S. Kivelson, O. L. Chapman, *Phys. Rev. B 28* (1983) 7236) as a class of new materials with possibly novel one-dimensional conducting properties.

[4] In the beginning, we prepared **4** in a six-step synthesis (P. Vogel, A. Florey, *Helv. Chim. Acta 57* (1974) 200) starting from dimethyl 3,4-furandicarboxylate and dimethyl acetylenedicarboxylate. More recently, the highly efficient four-step synthesis (C. Mahaim, P.-A. Carrupt, J.-P. Hagenbuch, A. Florey, P. Vogel, *Helv. Chim. Acta 63* (1980) 1149) of **4** from the Diels-Alder adduct of furan and maleic anhydride has been employed. An X-ray crystal structure analysis (F. H. Kohnke, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, unpublished results) on single crystals of the intermediate tetramethyl 7-oxabicyclo[2.2.1]heptane-2,3,5,6-tetracarboxylate has indeed confirmed that it has the all-*exo* configuration.

[5] The preparation of 1,4:5,8-diepoxy-1,4,5,8-tetrahydroanthracene from 1,2,4,5-tetrabromobenzene and furan, and the chromatographic isolation of the *syn*-isomer **5** were achieved after the kind provision (Prof. *H. Hart*, personal communication, 1986) of a detailed experimental procedure which provided some essential additional information to that already published (H. Hart, N. Raja, M. A. Meador, D. L. Ward, *J. Org. Chem. 48* (1983) 4357). Identification of the *syn*-isomer **5** in our hands followed from X-ray crystallography on single crystals of a compound isomeric with **5**. Although the crystal data we have obtained (F. H. Kohnke, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, unpublished results) are totally different to those reported in the above paper by *Hart* et al. for the *anti*-isomer of **5**, determination of the X-ray structure showed that the crystals only contain molecules of *anti* geometry. These two crystal structures must clearly represent alternative polymorphs.

[6] These principles have been capitalized upon by others (see, for example, D. J. Cram, *Science 219* (1983) 1177; H. C. Kang, A. W. Hanson, B. Eaton, V. Boekelheide, *J. Am. Chem. Soc. 107* (1985) 1979; D. J. Cram, K. D. Stewart, I. Goldberg, K. N. Trueblood, *J. Am. Chem. Soc. 107* (1985) 2574) in the synthesis of molecules with enforced cavities.—An example of a molecule similar to **8** with a rigid collar-like structure is cucurbituril which can be readily assembled (W. A. Freeman, W. L. Mock, N.-Y. Shih, *J. Am. Chem. Soc. 106* (1984) 1416) from urea, glyoxal, and formaldehyde. It forms (W. L. Mock, N.-Y. Shih, *J. Org. Chem. 48* (1983) 3618; *51* (1986) 4440) host-guest solution complexes and catalyzes (W. L. Mock, T. A. Mirra, J. P. Wepsiec, T. L. Manimaran, *J. Org. Chem. 48* (1983) 3619) 1,3-dipolar cycloadditions between appropriate substrates in a highly regioselective manner.

[7] The X-ray crystal structure analysis of **6a** (Fig. 1) not only established the stereochemistry in **6** but also demonstrated that the cycloaddition of anthracene occurs preferentially to the *exo*-face of the dienophilic C=C double bond of **6**. This strongly suggests that the 1:2 adduct formed (H. Hart, N. Raju, M. A. Meador, D. L. Ward, *J. Org. Chem. 48* (1983) 4357) between **5** and anthracene has the *exo-exo* configuration.

[8] As a result of their negative volumes of activation, Diels–Alder reactions are accelerated at high pressures (for a recent review, see N. S. Isaacs and A. V. George, *Chem. Br. 23* (1987) 47). We thank Prof. *S. V. Ley* (Imperial College) for removing any hesitation we had about employing this technique and Dr. *N. S. Isaacs* (SERC High Pressure Service Facility, University of Reading) for the superb service and help he has given us in preparing **8**.

[9] Although intramolecular Diels–Alder reactions with flexible trienes have been much studied (for a recent review, see E. Ciganek, *Org. React. 32* (1984) 1) during the last decade, their occurrence in highly rigid molecules containing diene and dienophilic units has, surprisingly, not been investigated.

[10] P.-A. Carrupt, P. Vogel, *Tetrahedron Lett. 1979*, 4533; Y. Bessiére, P. Vogel, *Helv. Chim. Acta 63* (1980) 232.

[11] A. A. Pinkerton, D. Schwarzenbach, J. H. A. Stibbard, P.-A. Carrupt, P. Vogel, *J. Am. Chem. Soc. 103* (1983) 2095; J.-M. Tornare, P. Vogel, A. A. Pinkerton, D. Schwarzenbach, *Helv. Chim. Acta 68* (1985) 2195.

[12] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). A crystal of **8** was sealed in a Lindemann capillary tube under chloroform, which was drawn away to opposite ends of the tube thus leaving the crystal in a vapor pressure of solvent: a numerical absorption correction was carried out. Both structures were solved by direct methods and refined anisotropically: the *R*-factors are high as a result of severe disorder involving included chlorinated solvents, which is particularly pronounced in the case of **8**. Further details of these structural investigations can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[13] The monoadduct **6** is unstable and undergoes polymerization. It is for this reason that we prefer to approach the synthesis of **8** via the bisadduct **7**, which can be stored for several months at −20°C in the dark without detectable decomposition.

[14] All new compounds gave satisfactory elemental analyses and spectroscopic data. We are extremely grateful to Mr. *P. R. Ashton* for obtaining EIMS and FABMS on a Kratos MS80RF spectrometer and to Dr. *C. M. Spencer* for recording high field NMR spectra on a Bruker WH400 spectrometer. We also thank Dr. *A. D. McNaught* (The Royal Society of Chemistry, London) for his freely given advice on trivial—as well as systematic—nomenclature for these new compounds.

[15] See, for example, R. O. Angus, Jr., R. P. Johnson, *J. Org. Chem. 48* (1983) 373; L. L. Miller, A. D. Thomas, C. L. Wilkins, D. A. Weil, *J. Chem. Soc. Chem. Commun. 1986*, 661.

[16] See, for example, G. A. Russell, N. K. Suleman, H. Iwamura, O. W. Webster, *J. Am. Chem. Soc. 103* (1981) 1560; E. Lipczynska-Kochany, H. Iwamura, *Chem. Lett. 1982*, 1075; C. S. Wilcox, L. M. Greer, V. Lynch, *J. Am. Chem. Soc. 109* (1987) 1865.

[17] This clathration phenomenon explains the instantaneous loss of chloroform with concomitant collapse of the crystals on removal from their mother liquor.

[18] For some excellent reviews on this topic see, W. H. Watson (Ed.): *Stereochemistry and Reactivity of Systems containing π-Electrons*, Verlag Chemie International, Deerfield Beach, FL (USA) 1983.

Triphosgene, a Crystalline Phosgene Substitute**

By *Heiner Eckert** and *Barbara Forster*

The "defusing" of dangerous and risky chemicals is exemplified here by the avoidance of the highly toxic, gaseous basic chemical phosgene ($COCl_2$) as a reagent. Liquid trichloromethyl chloroformate ($ClCO_2CCl_3$, "diphosgene"),[1] which has already been used as a phosgene substitute, has proved useful in all common phosgene reactions,[2] but, as a liquid, its transport and storage still pose considerable dangers. Bis(trichloromethyl) carbonate **1** ("triphosgene"),[3] on the other hand, is a crystalline, stable

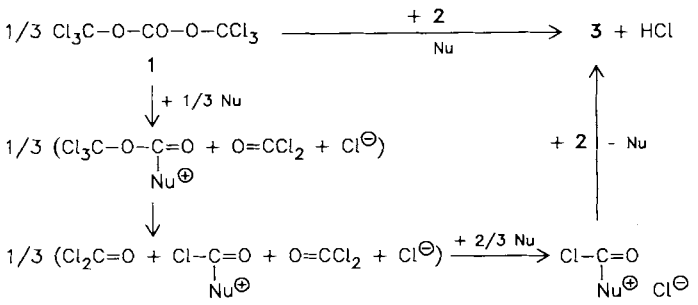
Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.



Scheme 1. Triphosgene as a phosgene substitute.

solid (m.p. = 80 °C, b.p. = 206 °C; at the boiling point, only slight decomposition to phosgene occurs[3c]), which is easy to transport and to store. Compound **1** was first prepared in 1880 by *Councler*[3a] by chlorination of dimethyl carbonate and has so far been used in reactions with primary alcohols to give esters,[3c, d] with ammonia and aniline to give ureas,[3c, d] and with aldehydes.[3b]

1/3 mol of **1** reacts under the influence of a nucleophile Nu similarly to 1 mol of phosgene, which can also arise as an intermediate (Scheme 1). Table 1 lists a selection of the reactants **2** and the products **3** thereby obtained. The auxiliary nucleophile Nu can also be identical with **2**. The functions of phosgene, e.g.,

chloroformylation	1/3 **1** + **2a**, **b** ⟶ **3a**, **b**
carbonylation	1/3 **1** + **2c–f** ⟶ **3c–f**
chlorination	1/3 **1** + **2g** ⟶ **3g**
dehydration	1/3 **1** + **2h**, **i** ⟶ **3h**, **i**

can also be performed by **1**. Good to very good yields of **3** are thereby obtained by the use of **2** in equivalent amounts in the usual solvents (dichloromethane, *o*-dichlorobenzene) or without solvent. Phosgene, on the other hand, has to be used in severalfold excess and, even in this case, the yields are often only moderate. A further advantage of **1** is that, as a solid, it can be exactly weighed out in milligram amounts. Furthermore, owing to the relatively low volatility of **1**, only the usual safety precautions are necessary.

Experimental Procedure

1: A stirred, cooled (10–20 °C cooling bath temperature) solution of dimethyl carbonate (45 g, 0.5 mol) in 250 mL of CCl_4 was irradiated with two lamps (Philips MLU 300 W). Chlorine gas was then admitted to the solution so fast that it did not leave the solution. After 28 h of net reaction (interruption of the reaction is possible), which can be followed by ^{1}H-NMR spectroscopy, the CCl_4 was removed in vacuum (200 torr); the remaining crystalline solid was dried at 0.1 torr. Yield: 143 g (97%) **1**. M.p. = 79 °C. IR (KBr): $\tilde{\nu}$ = 1820, 1175, 1115, 820 cm^{-1}. The HCl formed during the reaction is passed by means of a reflux condensor into 1.6 L of a 20% sodium carbonate solution.

Changes of Stereoselectivity in Diels-Alder Reactions by Hydrophobic Solvent Effects and by β-Cyclodextrin**

By *Hans-Jörg Schneider* and *Naresh K. Sangwan**

The possibility of controlling the course of Diels-Alder additions by the use of aqueous solvents[1] and by added cyclodextrins is currently attracting considerable interest and probably depends on an externally driven compression or packing of diene and dienophile.[2,3] After having recently been able to correlate the kinetics of such reactions for the first time with solvophobicity parameters and to demonstrate high accelerations as well as enzyme-analogue saturation kinetics with cyclodextrin,[3] we now wish to report on significant changes in the product ratios obtained in such reactions.

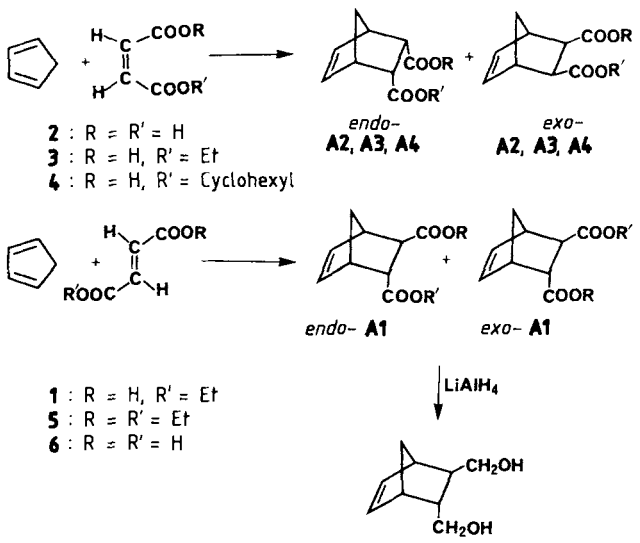

Table 1. Solvent-dependence of the diastereoselectivities (*endo/exo*-product) in Diels-Alder reactions with cyclopentadiene [a].

Dienophile	90% Dioxane 10% H_2O	MeOH	50% MeOH 50% H_2O	30% MeOH 70% H_2O	H_2O
1 [b]	—	1.10 ± 0.05	1.12 ± 0.05	—	1.10 ± 0.05
2	—	30 ± 1.5	36.5 ± 1	—	47 ± 4
3 [c]	20.5 ± 1	23.5 ± 2	39 ± 3	44 ± 4	48.5 ± 4
4	37 ± 2	—	—	60 ± 5	—

[a] In homogeneous solution at 20°C; binary solvent mixture composition given as % v/v, analysis by integration of ^{1}H-NMR signals (400-MHz measurements), whose pattern is in accord with the literature data (N. Kamezawa, K. Sakashita, K. Hayamizn, *Org. Magn. Reson. 1* (1969) 405). [b] *endo*-COOEt/*exo*-COOEt, error: deviation between two signal pair-evaluations. [c] Further measurement in 70% MeOH: 34 ± 2.

In reactions of cyclopentadiene with the maleic acid derivatives **2**–**4** we find an increase in the proportion of the *endo* products **A2** to **A4** by the use of water (Table 1). This increase is of a similar order of magnitude as that observed in earlier investigations.[1,2] Use of the particularly hydrophobic cyclohexyl ester **4** does not lead to any noticeably higher change in selectivity than **2** and **3**, thus indicating the possible increased formation in this case of associates without productive orientation of the π-systems. In contrast to earlier investigations[1,2] it was established that no micelle formation occurs even in water: at the concentrations used (e.g. 5×10^{-3} M in water) the UV extinctions obey the Lambert-Beer law, and the diastereoselectivities (*endo/exo* product) obtained in water fitted the correlation curves determined with binary solvent mixtures (Fig. 1a). This comparison of the log(*endo/exo*) values with solvophobicity parameters Sp, which are based on changes in the free energy ΔG_t^0 of transfer of hydrocarbons from the gas phase into a given solvent,[4] is to our knowledge the first quantitative description of product ratios as a function of hydrophobic solvent properties.

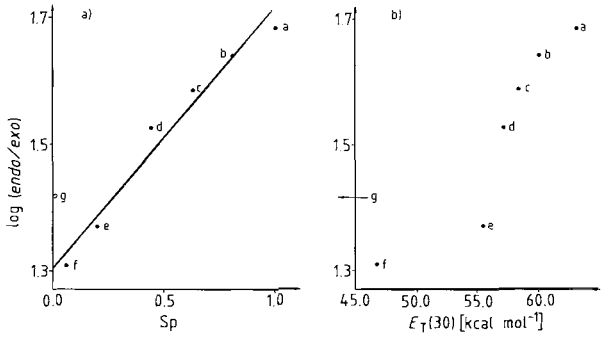

Fig. 1. a) Diastereoselectivities log(*endo/exo*) vs. solvophobicity parameter Sp for the reaction of cyclopentadiene with monoethyl maleate **3**. a: in water; b–e: 30, 50, 70, 100% methanol (v/v); f: 90% dioxane; g: hexane. b) Diastereoselectivities as a function of solvent polarity E_T(30).

The observed correlation clearly supports the aforementioned hydrophobic effect[1,2] as opposed to micelles[1c,5] being responsible for the changes in selectivity. Consistent with this finding is the observed *decrease* rather than increase in the selectivity, both on addition of surfactants as well as on increasing the concentration of starting material above its solubility in water.[2b]

In agreement with earlier results,[1b,7] the significantly poorer correlation with E_T(30)-values[8] (Fig. 1b) argues against polarity effects being the essential factors responsible for the *endo/exo*-product variations.[6] However, in order to check whether solvent polarities might play an *additional* role here,[2c] a multiple correlation for the system **3** + cyclopentadiene was carried out. A comparison of the correlations obtained and the respective errors shows that the inclusion of polarity parameters is of no significance:

with Sp alone:

$\log(endo/exo) = (0.414 \pm 0.038)\,Sp + (1.30 \pm 0.024)$

($r = 0.9835$, $\psi = 5\%$)

with E_T(30) alone:

$\log(endo/exo) = 0.0248 \pm 0.0054)\,E_T(30) + (0.113 \pm 0.306)$

($r = 0.9177$, $\psi = 24\%$)

with Sp *and* E_T(30):

$\log(endo/exo) = (0.364 \pm 0.101)\,Sp + (0.0035 \pm 0.0065)\,E_T(30) + (1.304 \pm 0.322)$

(multilinear correlation coefficient $r = 0.9850$)

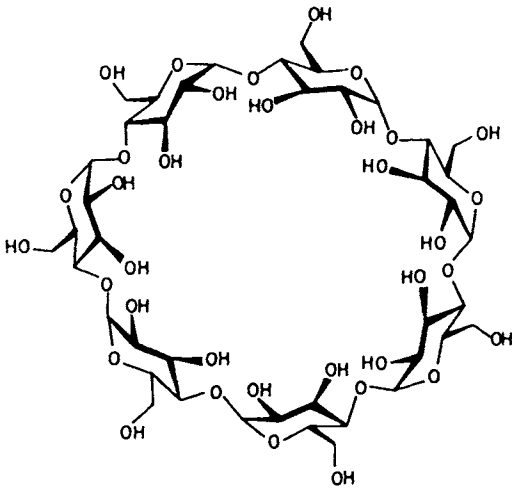
[**] Host-Guest Chemistry, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *M. H. Abraham* for stimulating discussions on the development of a solvophobicity scale, and for useful information.— Part 12: H. J. Schneider, R. Kramer, S. Kumar, U. Schneider, *31st IUPAC Congress, Sofia 1987, Proc. Org. Chem. Sect.* 189–204.

The solvent-dependence of *endo/exo* ratios recently described by *two* separate correlations for protic and aprotic solvents[1c] can also be described by *one* correlation ($r = 0.940$, $\psi = 16\%$) if Sp values—insofar as they are available—instead of $E_T(30)$ values are employed. Only the result in the extremely nonpolar solvent hexane lies significantly above the correlation curves (see Fig. 1a; hence correlation without the value in hexane), thus indicating the formation of associates by hydrogen bonding; the stereoselectivities observed in hexane usually correlate even less satisfactorily with $E_T(30)$ values (see Fig. 1b).



β-CYD

Table 2. Influence of β-cyclodextrin (β-CYD) on diastereo- and enantioselectivity in Diels–Alder reactions with cyclopentadiene.

Dienophile	H_2O Diastereoselectivity [b] (*endo/exo*-product)	0.015 M β-CYD Diastereoselectivity [b] (*endo/exo*-product)	0.015 M β-CYD Enantioselectivity *ee* [%]	
			exo-COOEt	*endo*-COOEt
1	1.10 ± 0.05	2.2 ± 0.08	8.4 ± 0.5	< 2.0
2	47 ± 4	69 ± 4	–	
3	48.5 ± 4	112 ± 5	–	
5	–	–	21.0 ± 5.5 [c]	
6	–	–	< 1	

[a] In homogeneous solution in water at 20°C. [b] For **1** *endo*-COOEt/*exo*-COOEt. [c] With [educt] = 0.001 M; with 0.003 M: 19.5 ± 1% *ee*; with which the specific rotation of the diester obtained with **5** was calculated: $[\alpha]_D^{20} = +87 \pm 2°$ (1.4% in $CHCl_3$).

The influence of cyclodextrins on diastereo- or enantioselectivities in Diels–Alder reactions has so far never been proven. Addition of maleic and fumaric acid derivatives to cyclopentadiene (Table 2) in presence of the highest possible concentration of β-cyclodextrin (0.015 M in water) show a large increase in the amount of *endo* product; this must be interpreted in terms of a more compact transition state being realized in the cavity. Noteworthy is the increase in selectivity of the reaction of the fumaric acid half ester **1**, which cannot be achieved with the use of water alone (cf. Table 1).

The asymmetric induction by the chiral cyclodextrin cavity was investigated for the addition of fumaric acid derivatives (**1**, **5**, **6**) to cyclopentadiene; in the case of the semiester **1** only the product *exo*-**A1** with *exo*-ester group could be completely analyzed. The ^{1}H-NMR spectrum of a 0.2 M solution of **1** in the presence of 0.6 M optically active 1-phenylethylamine showed pairs of signals with separations of 0.04 and 0.05 pm respectively, for the olefinic protons, from whose signal areas the enantiomeric excesses were determined[9] (Table 2). Since the product *endo*-**A1** obtained from **1** showed no splitting (not even with optically active 1-naphthylethylamine[9]), the mixture was reduced to the diol, which, like the diol obtained from the adducts with **5** and **6** in the presence of the chiral camphorato-lanthanoid shift reagent $Eu(tfc)_3$[9] [0.023 M] showed a 0.11 ppm splitting of the olefinic protons (diol concentration 0.09 M; solvent in each case $CDCl_3/CCl_4 = 15/85$). Combination of the 4.2% *ee* for the diols thus obtained from **1** with the known selectivities regarding the *exo*-COOEt compound *exo*-**A1** indicates < 2% *ee* for the isomeric *endo*-**A1** (Table 2). The enantiomeric excesses for the reaction with **5** and **6** could be determined from the area ratios of the respective diol signals in the presence of $Eu(tfc)_3$.

Whereas the enantiomeric excesses achieved in the reaction with **1** and **6** are limited by an incomplete complexation, in the case of **5** the degree of complexation must be > 90% on the basis of the corresponding kinetic analysis;[3] moreover the reaction in the complex proceeds about 70 times faster. An increase in the enantioselectivity is therefore only possible by chemical modification of the cyclodextrin.

talysis[4] in chemical industry. Synthetic and structural studies of metal clusters will not only help shed light on the important question of the development of metallic behavior[5] as a function of particle size but will also pave ways for the discovery of novel materials with unusual physical or chemical properties.

Recently, we reported the synthesis and structural characterization of a 25-atom[6] and a 38-atom[7] cluster containing gold and silver. We now wish to report the structure of a novel 37-atom cluster, the title compound **1**, formed as the AsF_6 salt upon reduction of a mixture of p-Tol_3P, Au_2O_3, $AgAsF_6$ and HBr with $NaBH_4$ in ethanol (Tol = tolyl). With 37 metal atoms, it represents the second largest structurally characterized Au–Ag cluster known (second only to **2**[7]). Other examples of metal clusters with similar nuclearities are **3**–**7**.[9–13]

$[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2\oplus}$[8] **1**
$[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{20}Cl_{14}]$[7] **2**
$[Pt_6Ni_{38}(CO)_{48}H_{6-n}]^{n\ominus}$[9] **3**, n = 4, 5
$[Ni_{38}(CO)_{42}C_6H]^{5\ominus}$[10] **4**
$[Ni_{34}Se_{22}(PPh_3)_{10}]$[11] **5**
$[Pd_{38}(CO)_{28}(PEt_3)_{12}]$[12] **6**
$[Pt_{38}(CO)_{44}]^{2\ominus}$[13] **7**

The $[P_{12}Au_{18}Ag_{19}Br_{11}]$ framework of cluster **1**, which conforms to idealized C_{3v} symmetry, is portrayed in Figure 1a. There are two types of Au atoms in the cluster: 12 on the surface and 6 in the interior. There are 12 tri(*p*-tolyl)phosphanes coordinated to the 12 peripheral Au atoms and 11 bromide ligands (six doubly bridging, four triply bridging, and one terminal) coordinated to the Ag atoms.

The metal–metal distances follow the approximate trend Au-Au (2.66–3.20 Å) ≈ Au-Ag (2.73–3.01 Å) < Ag-Ag (2.79–3.34 Å), all of which can be considered as more or less bonding. There are four groups of Ag–Ag distances: 2.79–2.94 Å for unbridged, 2.98–3.26 Å for doubly bridged, and 3.04–3.34 Å for triply bridged Ag–Ag bonds. The Ag···Ag contacts of 3.73–3.82 Å involving the one apical Ag atom (see Fig. 1b) are longer. The distances from Ag to the terminal, doubly bridging, and triply bridging Br ligands are 2.39, 2.52–2.60, and 2.62–2.81 Å, respectively.

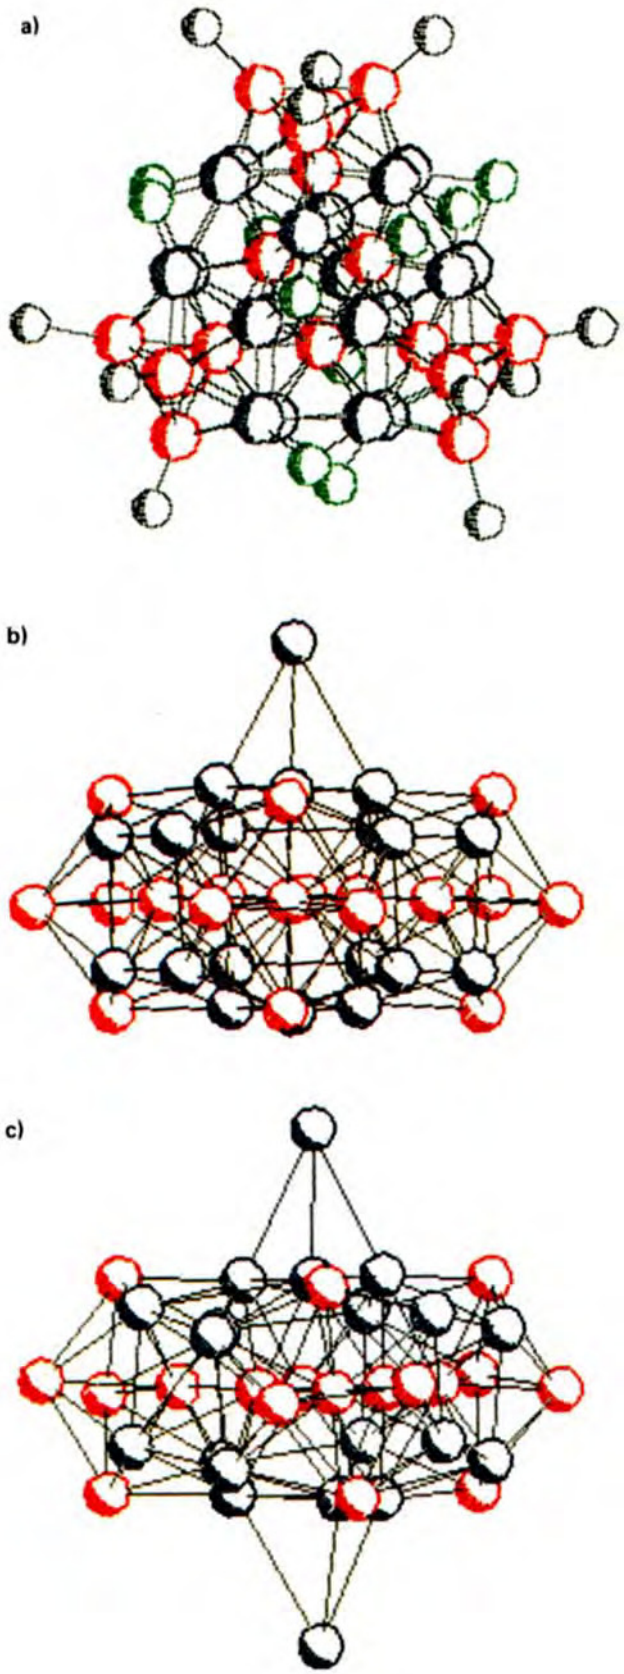

Fig. 1. a) The $[P_{12}Au_{18}Ag_{19}Br_{11}]$ framework of the 37-atom cluster **1**; Au (red), Ag (blue), Br (green), P (black). b) Side views of the metal framework of **1** and c) of **2**; Au (red), Ag (blue).

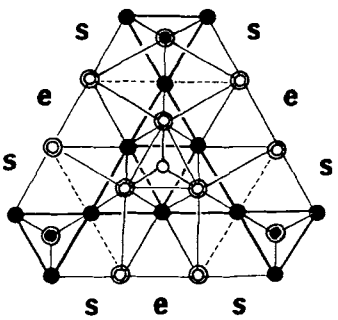

Fig. 2. A schematic representation illustrating the close packing of the metal framework of the 37-atom cluster **1**; Au ●, 2Au ⊙, Ag ○, 2Ag ◎. s = staggered, e = eclipsed.

Cluster **1** can be described in a number of ways. The most obvious description is based on close-packing of metal atoms (Fig. 2). In this description, imagine a two-dimensional close-packing of 12 Au atoms to form a v_2 triangle and three v_1 triangles sharing corners.[14] Above and below the three small triangles are six Au atoms conceptually changing the smaller triangles into trigonal bipyramids. Above the central (large) triangle are four Ag atoms arranged in a v_2 tetrahedral array. Below this trian-

gle are three Ag atoms giving rise to a v_2 tetrahedron truncated at one corner. On the three edges are 12 Ag atoms (not closest-packed), 6 above and 6 below the plane of the 12 Au atoms.

The 37-atom cluster **1** (Fig. 1b) is related to the 38-atom cluster **2** (Fig. 1c) via removal of one of the two apical $Ag^{\oplus}$ ions. The "main frame" of **1** and **2** can be approximated as a three-layer structure. More specifically, replacement of one of the two apical AgX_4 moieties (X = halogen) in cluster **2** by a μ_3-X unit gives rise to cluster **1**. In fact, if **2** is a neutral species, then **1** should be a dication, since replacement of a $[AgX_4]^{3\ominus}$ moiety by $X^{\ominus}$ decreases the charge by 2. We assume here that the 36-atom cluster framework remains unaffected by such a formal replacement.

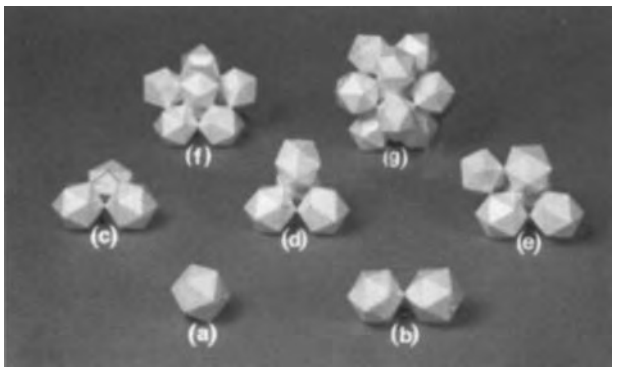

Fig. 3. Supracluster s_n formed by sharing vertices of n centered icosahedra (nuclearity in parentheses): a) s_1 (13); b) s_2 (25); c) s_3 (36); d) s_4 (46); e) s_5 (56); f) s_7 (76); g) s_{12} (127).

The most interesting structural characteristic of the 25-,[6] 37- (**1**), and 38-atom (**2**[7]) clusters is that they can be considered as being built from 13-atom, centered icosahedral cluster units (Fig. 3a). Thus, the 25-atom cluster can be considered as *two* icosahedra sharing a vertex ($2 \times 13 - 1 = 25$, Fig. 3b), the 37- and 38-atom clusters, **1** and **2**, respectively, as *three* isosahedra sharing three vertices in a cyclic manner ($3 \times 13 - 3 = 36$, Fig. 3c) plus one and two capping atoms, respectively. These considerations open up new pathways to larger metal clusters via fusion of smaller cluster units as building blocks. We shall refer to the resulting clusters as supraclusters. For example, we predict that the nuclearity of a supracluster formed by vertex-sharing of centered icosahedra is given by $13n - e$ where n is the number of the cluster units and e is the number of edges of the polyhedron formed by the centers of the icosahedral units. Thus, tetrahedral, trigonal-bipyramidal, and pentagonal-bipyramidal arrays of vertex-sharing icosahedra will give rise to nuclearities of $4 \times 13 - 6 = 46$, $5 \times 13 - 9 = 56$, and $7 \times 13 - 15 = 76$, respectively (see Fig. 3d–f). One exception to this rule is the icosahedral supracluster of I_h symmetry formed by 12 centered icosahedra sharing 30 corners. Here, the icosahedral hole created by the 12 icosahedra is filled with one atom ($12 \times 13 - 30 + 1 = 127$, Fig. 3g). Stereochemical considerations revealed that other n ($n < 13$) values are not favorable.

It is hoped that the idea of cluster of clusters in general, and the structures of the 25-, 37-, and 38-atom clusters in particular, may provide new pathways to novel high-nuclearity supraclusters via vertex-, edge-, and face-sharing and/or by close-packing of smaller cluster units as building blocks.[15, 16]

[15] Recently, *G. Schmid* and *N. Klein* (*Angew. Chem. 98* (1986) 910; *Angew. Chem. Int. Ed. Engl. 25* (1986) 922) explained their transmission electron micrographs and X-ray powder patterns by $(M_{13})_{13}$ and $(M_{13})_{\infty}$. The difference between their idea and ours is that they considered packing of spherical M_{13} cuboctahedra to form supraclusters with the following nuclearities (number of clusters in brackets): [2] $2 \times 13 = 26$, [3] $3 \times 13 = 39$, ... [13] $13 \times 13 = 169$, [∞] $13 \times 13 \times 13 \times$ ... In contrast, we considered vertex-sharing icosahedra to form supraclusters with the following nuclearities: [2] $2 \times 13 - 1 = 25$, [3] $3 \times 13 - 3 = 36$, ... [12] $12 \times 13 - 30 + 1 = 127$ ... The operational test for these two ideas will be

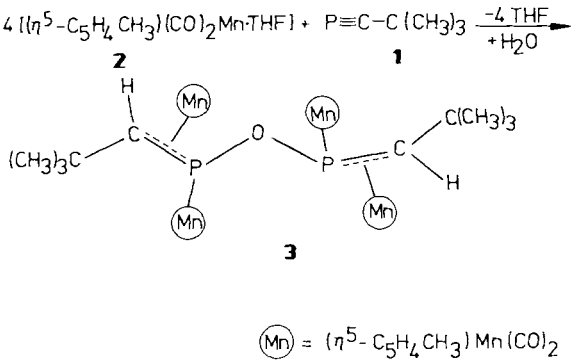
the synthesis and single-crystal structural determination of these two series of supraclusters with distinctly different nuclearities.

[16] Supracluster assemblies of icosahedral symmetry also occur in nature (e.g., viruses). See, for example, E. D. P. deRobertis, E. M. F. DeRobertis: *Cell and Molecular Biology*, 7th ed., Saunders College, Philadelphia, PA 1980, p. 119.

(2,2,8,8-Tetramethyl-5-oxa-4,6-diphospha-3,6-nonadiene)tetrakis[dicarbonyl-(methylcyclopentadienyl)manganese], the First Complexed Bis(phosphavinyl) Ether**

By *Manfred L. Ziegler,* Rainer Balles, Bernd Nuber, Gerd Becker, Helmut Schmidt, Basil Kanellakopulos,* and *Bernhard Powietzka*

The rich complexation chemistry of phosphaalkynes, especially that of 2,2-dimethylpropylidynephosphane **1**,[1] is supported by numerous examples.[2] We have now observed a novel reaction type. Reaction of **1** with the manganese complex **2** surprisingly results in formation of complex **3** (see Experimental Procedure).



This compound contains the first bis(phosphavinyl) ether ligand, to which four $(C_5H_4CH_3)Mn(CO)_2$ fragments are coordinated. The formation of this ligand can be formally understood as the addition of one molecule of H_2O to two molecules of **1**. Since the reaction was carried out in dried solvents under inert gas, the source of the water is not yet known. The reaction might involve the initial formation of a presumably very reactive complex with the solvent tetrahydrofuran (THF). In view of the diverse reactions of phosphaalkyne complexes, such secondary reactions are certainly conceivable. Unfortunately, the introduction of D_2O into the reaction mixture did not lead to unequivocal results.

The molecular ion is readily apparent in the EI and the FD mass spectra; in addition, **3** was characterized by its elemental analysis and the usual spectroscopic data,[3] as well as by X-ray structure analysis. As revealed in Figure 1, the bis(phosphavinyl) ether ligand functions as an eight-electron donor. Of the four manganese complex fragments, two are bonded to the phosphorus atoms, which thus act as phosphanes, and the other two are bonded η^2-like to the C=P double bond of the ligand.

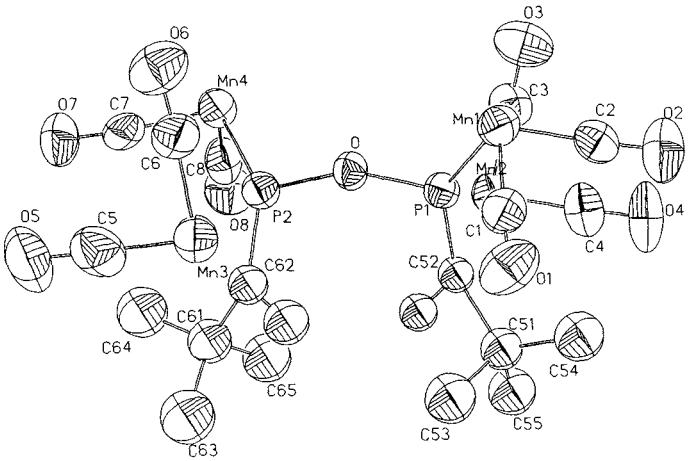


Fig. 1. Molecular crystal structure of **3**; for clarity, the methylcyclopentadienyl moieties are omitted. Selected bond lengths [pm] and angles [°]: Mn1-P1 223.6(4), Mn2-P1 240.2(3), P1-C52 171(1), Mn2-C52 215.7(9), Mn4-P2 222.6(3), Mn3-P2 243.8(3), Mn3-C62 215.6(10), P2-C62 170(1), P1-O 164.3(7), P2-O 166.5(7); O-P1-C52 107.7(7), O-P2-C62 107.2(7), P1-O-P2 154.8(7). Space group $P2_1/c$, $a=1218.6(3)$, $b=1808.2(6)$, $c=2031.4(7)$ pm, $\beta=96.66(2)°$, $Z=4$, $R_{anniso}=0.072$, $R_w=0.053$, $\rho_{calcd}=1.42$ g cm^{-3}, $F_{000}=1960$, AED2 Siemens-Stoe, graphite monochromator, $\lambda=0.7107$ Å ($Mo_{K\alpha}$), measuring range $3°\leq 2\theta\leq 60°$; $h(0/17)$, $k(0/25)$, $l(-29/29)$, 3150 measured, 3070 independent reflections with $I>2.0\sigma(I)$, $R_{merge}=0.056$. Structure solution: Patterson and differential Fourier methods, all non-hydrogen atoms refined anisotropically, H atoms calculated at ideal positions. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52488, the names of the authors, and the journal citation.

The noticeable broadening of the NMR signals prompted us to carry out magnetic measurements. They revealed a field-dependent paramagnetism for **3** between 50 K and room temperature. The magnetic moment increases monotonically between 77.6 K ($\mu_{eff}=4.57\mu_B$ per Mn) and 293.8 K (5.44). The μ_{eff} values correspond to two unpaired electrons per Mn atom. Between 20 and 1.3 K, the paramagnetism is strongly field-dependent; between 50 K and room temperature, the susceptibility obeys the Curie-Weiss law ($\theta=-53.5$ K). Since the 18-electron rule is formally valid for all manganese atoms in **3**, this finding is particularly surprising. Tetragonally or trigonally distorted coordinated Mn^I (d^6) provides a possible explanation, especially since the Mn-Mn distances (Mn1-Mn2 410.6 and Mn3-Mn4 416.0 pm) rule out the possibility of magnetic interactions.

Experimental Procedure

A solution of $[(\eta^5\text{-}C_5H_4CH_3)Mn(CO)_3]$ (1 g, 1.38 mmol) in 400 mL of THF was irradiated under inert gas in a water-cooled photolysis vessel. The evolution of CO ceased after 90 min (≈ 150 mL at 25°C). The solution of the solvent complex **2** thereby obtained was concentrated to 150 mL, cooled in a sodium chloride-ice bath, and then treated with **1** (1 g, 1.10 mmol). The mixture was stirred under constant pressure for 6 h at room temperature and the solvent was then removed in an oil-pump vacuum. The residue was dissolved in 20 mL of *n*-hexane and transferred to a column (silica gel 0.05–0.2, 40 × 2 cm, *n*-hexane). Unreacted **2** was first eluted with *n*-hexane, followed by a second, unstable, uncharacterized brown fraction with hexane/toluene (1:1) and, finally, deep orange **3** with toluene/ether (1:1). The solvent was removed and the residue was recrystallized from toluene/CH_2Cl_2 (1:1). Deep orange crystals: yield 480 mg (25%, based on the total amount of **2**), m.p. = 142–145°C.

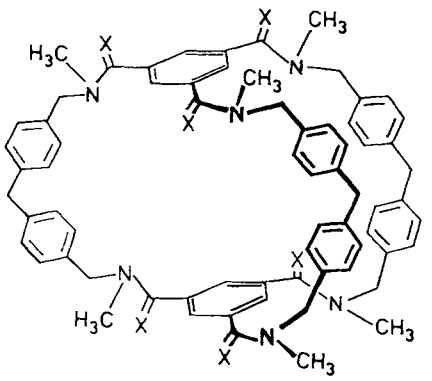
Selective Molecular Recognition and Separation of Isomeric and Partially Hydrogenated Arenes**

By *Fritz Vögtle,* Walter M. Müller, Ute Werner,* and *Hans-Willi Losensky*

Herein we describe a novel, easily obtainable, efficient host substance **1** having a symmetrical molecular structure, which owing to its large disk-shaped cavity shows remarkable, previously unobserved guest selectivities towards polycyclic arenes, partially hydrogenated and substituted arenes, in aqueous solution.[1,2]



1: X = H
2: 1·6 HCl
3: X = O

The hexamine **1**, which is readily soluble as the hydrochloride **2** in dilute hydrochloric acid, is obtained under dilution principle conditions by cyclization of 1,3,5-benzenetricarboxylic acid trichloride with 4,4′-bis(*N*-methylaminomethyl)diphenylmethane in benzene and subsequent reduction of the crude lactam **3**.[3]

The binding of guest molecules by the hydrochloride **2** was first demonstrated by fluorescence spectroscopy[4] using perylene as fluorescing guest in methanolic solution;[5] the measured data indicated an association constant of about $10^{2.5}$.

Müller* (Basel) for molecular modeling calculations, Prof. Dr. *R. H. Mitchell* (University of Columbia, Canada) for a sample of *trans*-10b,10c-dimethyl-10b,10c-dihydropyrene, Mr. *C. Schmidt* for recording the NMR spectra, Mr. *E. Gessi* for carrying out the fluorescence spectroscopy measurements, and Mrs. *S. Geskes* for valuable assistance.

Table 1. Compounds complexed and non-complexed by **1** (in D_2O/DCl).

Complexed compounds	
Acenaphthylene	Perylene
Benzo[*def*]chrysene ("1,2-Benzpyrene")	Phenanthrene
Benzo[*ghi*]perylene ("1,12-Benzperylene")	Pyrene
Fluoranthene	Triphenylene
Non-complexed compounds [a]	
Acenaphthene	3,6-Dimethylphenanthrene
Adamantane	1,2,3,4,5,6,7,8,9,10,11,12-Dodecahydrotriphenylene
Anthracene	Fluorene
Azulene	1,2,3,6,7,8-Hexahydropyrene
Benzene	Hexamethylbenzene
Chrysene	Mesitylene
Coronene	Naphthalene
cis- and *trans*-Decalin	2,6-Naphthalenedicarboxylic acid
9,10-Dihydrophenanthrene	Tetralin
trans-10b,10c-Dimethyl-10b,10c-dihydropyrene	2,3,6,7-Tetramethylanthracene
2,6-Dimethylnaphthalene	Triptycene

[a] Within the limits of detection by ^{1}H-NMR spectroscopy (200 MHz).

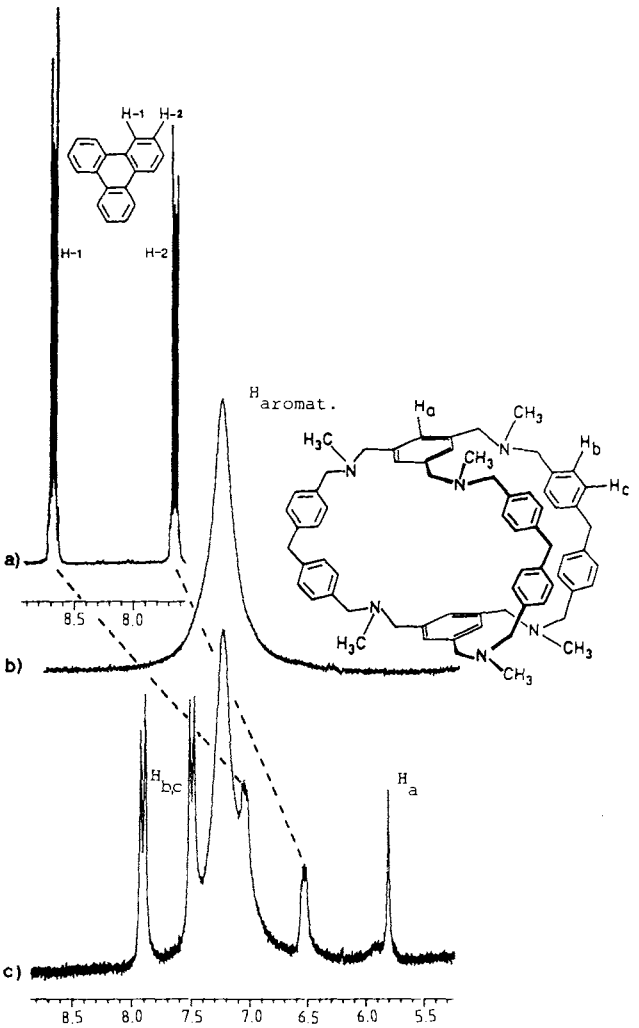

Fig. 1. ^{1}H-NMR spectra (sections; 200 MHz) [6]: a) of the guest triphenylene in CD_2Cl_2/CD_3OD (1:1); b) of the host compound **1** in D_2O/DCl; c) of the host-guest complex (**1** · triphenylene). [The guest was added in excess to a 1×10^{-2} M solution of the host (D_2O/DCl); after 30 minutes' ultrasonication the mixture was filtered.] The spectrum also shows, besides signals of H-1 and H-2 of the guest, signals of protons of the complexed *and* non-complexed host. These two kinds of host signals can be attributed to a slow establishment of the complexation/decomplexation equilibrium.

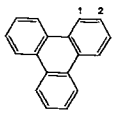
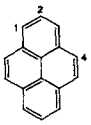
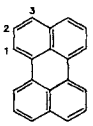
The ^{1}H-NMR absorptions of the host compound **1** are markedly broadened at room temperature/200 MHz in D_2O/DCl (Fig. 1), and become more sharply defined on increasing the temperature; the process is reversible. Addition of certain aromatic guest compounds (cf. Table 1) not only leads to drastic upfield shifts of the proton absorptions of the guests (cf. Table 2), but also to signal sharpening, splitting, and upfield (NCH_3 protons and H_a-aromatic) as well as downfield shifts ($H_{b/c}$-aromatic) of host signals. This is illustrated in Figure 1 with the example triphenylene as guest. The upfield shifts of some other guest compounds are listed in Table 2.

We explain these findings in terms of the accomodation of ideally fitting guests with complementary topology in the cavity of **1** and of the change in conformational mobility of the host molecule upon accomodating a guest. However, as Table 1 shows, there are substrates which have very little influence, if any, on the ^{1}H-NMR spectrum of the host **1**; these include substrate molecules that are too small or too large for the host's cavity and such molecules whose topology deviates widely from the flat and discoid shape of the condensed arenes.

Table 2. Some significant ^{1}H-NMR upfield shifts $\Delta\delta$ [ppm] of guest protons by the host **1** (in D_2O/DCl, 200 MHz, room temperature) [a].

Guest proton	Triphenylene	Pyrene	Perylene	Acenaphthylene
				






H-1	+1.61	+1.53	+1.01	+0.75
H-2	+1.14	+0.97	+1.24	
H-3			+1.65	– [b]
H-4		+1.52		+1.60
H-5				+1.35

[a] 0.1 mmol of the guest compound was added to 1 mL of a 1×10^{-2} M solution of the host **1** (D_2O/DCl). After 30 min ultrasonication the mixture was filtered and the filtrate investigated ^{1}H-NMR spectroscopically. [b] Masked by aromatic protons of the host.

That is, the host **1**—consistent with findings on space-filling models—preferably accomodates in its cavity guest molecules with the topology of triphenylene, pyrene, and perylene. Apparently benzene, naphthalene, azulene are too small, while coronene is too large. In contrast, all other previously synthesized host substances known to accomodate larger aromatic molecules complex even naphthalene as well as naphthalene and benzene bearing methyl substituents.[1,2]

Remarkably, phenanthrene is complexed, but the isomeric anthracene is not, a discrimination which has not been observed hitherto—not even with the cyclodextrins. The angularly annelated phenanthrene, with its unilateral "rounded off" shape would appear to find accomodation in the disk-shaped cavity more easily than linear guests. A similar sharp selection obtains in the case of benzo[*def*]chrysene and chrysene: benzo[*def*]chrysene ("1,2-benzpyrene") is complexed—this is the first reported instance—whereas complexation of the elongated chrysene is not detectable.

For partially hydrogenated arenes such as hexahydropyrene, dihydrophenanthrene, acenaphthene, and dodecahydrotriphenylene a complexation is not observed, even though the corresponding arenes fit in the host cavity.

It can be concluded from these substrate selectivities that the cavity of **1** obviously only accomodates such guests in which H atoms of the arene directly project into the rigid angle of the CH_2 group of the diphenylmethane units. Aliphatic CH_2 and CH_3 groups at the periphery of the guest molecule interfere, as demonstrated by the negative results obtained in insertion experiments with hexahydropyrene and dihydrophenanthrene, and even 2,6-dimethylnaphthalene. Adamantane and the decalins also fail to qualify as guests for the same reason.

Such a selective complexation should facilitate a preparative separation of mixtures of the substances by extraction of the potential guests dissolved in *n*-hexane with an aqueous (1×10^{-3} M) solution of the host **1** (host : guest : guest 1 : 0.75 : 0.75). The following mixtures of substances have been employed: I: phenanthrene/anthracene; II: phenanthrene/dihydrophenanthrene; III: pyrene/hexahydropyrene; IV: acenaphthylene/acenaphthene; V: triphenylene/dodecahydrotriphenylene. After the separation, the phases were investigated ^{1}H-NMR spectroscopically. (For this the hexane solution was evaporated to dryness and the residue taken up in CD_2Cl_2.) It was found, upon continuous extraction of the mixtures III and V, that the hydrocarbon (pyrene; triphenylene) is transferred to the extent of more than 70% into the aqueous phase, whereas the respective partially hydrogenated arene is not detectable in the aqueous phase by ^{1}H-NMR spectroscopy. In contrast, no noticeable liquid/liquid phase transfer is observed in the case of the mixtures I, II, and IV. We attribute this to the inferior complementary topology of these guest substances, which, nevertheless, is satisfactory enough for a solid/liquid phase transfer: in each case only the first of the given components is extracted from the crystalline mixtures I–V into the aqueous host phase with an aqueous host solution after two hours ultrasonication.[7]

Thus, to our knowledge, aromatic compounds have been preparatively separated for the first time from related compounds of similar molecular masses by selective molecular complexation. In view of these findings we posed ourselves the question whether one of the components can be selectively extracted from a solution of fluoranthene, chrysene, naphthalene, anthracene, and adamantane in paraffin-oil—as, e.g., are present in tars. Indeed, exclusively pure fluoranthene was obtained in 60% yield from such a mixture in a single extraction (several hours' stirring with the hydrochloric acid solution of **1**).

Further separations are possible by way of the selective transport of various guest compounds according to the U-tube method.[8] For example, when a solution of a 1 : 1 mixture of naphthalene/phenanthrene (4×10^{-2} mol/L of each) in *n*-hexane is placed in one limb of the U-tube, separated from neat *n*-hexane in the other limb by a layer of an aqueous-hydrochloric acid solution of **1**, after 12 hours' stirring only phenanthrene (25% of the amount initially present in the mixture) and no naphthalene could be detected in the previously "empty" (neat) *n*-hexane solution (^{1}H-NMR).

[2] Complexation of aromatic hydrocarbons containing at least three rings: see [1b].

[3] Procedure for **1-3**: A solution of 1,3,5-benzenetricarboxylic acid trichloride (4.78 g, 18.0 mmol) in anhydrous benzene (250 mL) and a solution of 4,4'-bis(*N*-methylaminomethyl)diphenylmethane (13.74 g, 54.0 mmol), also in 250 mL of anhydrous benzene, were added dropwise and simultaneously within 8 h to 2 L of anhydrous benzene at room temperature. The hydrochloride precipitate was filtered off, the filtrate evaporated to dryness, and the resulting residue thoroughly dried. For characterization the crude hexalactam **3** (20% yield) was purified by column chromatography on SiO_2 (eluent: dichloromethane/ethanol 20:1): 4% pure yield, m.p. 221-226°C. Crude **3** was heated under reflux with 90 mL of 1 M boranetetrahydrofuran solution for 7 h. Finally, the mixture was carefully hydrolyzed, the THF removed by distillation, and the residue acidified with 15% hydrochloric acid and heated under reflux for a further 2 h. The mixture was then rendered alkaline with solid sodium hydroxide and extracted five times with dichloromethane. The combined dichloromethane extracts were washed with water, dried, and evaporated to dryness. The solid residue was separated on an Al_2O_3 column (basic) with dichloromethane/ethanol (100:35) as eluent. Yield of **1**: 359 mg (2%), m.p. 78°C (decomp.). In some cases the hydrochloride **2** precipitated from the hydrochloric acid solution before neutralization; decomposition above 242°C. Correct elemental analyses and NMR and MS spectra were obtained for **1-3**.

[4] Fluorescence measurements at 20°C with a Perkin-Elmer Model 204-A. Excitation wavelength 440 nm, emission wavelength 470 nm (perylene). The concentration of the fluorescence indicator was 1×10^{-8} M, the host concentration was varied from 0 to 10^{-3} M. Methanol was used as solvent.

[5] Micelle formation could not be observed at a host concentration of 3×10^{-2} M (^{1}H-NMR measurements at various concentrations).

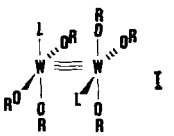
Olefinic C=C Double Bond Coordination to a M≡M Triple Bond: Bis(η^2-ethylene)hexakis(neopentyloxy)ditungsten**

By *Malcolm H. Chisholm** and *Mark Hampden-Smith*

Multiple bonds between metal atoms are reactive inorganic functional groups.[1,2] For example, the M-M triple bonds in $[Cp_2Mo_2(CO)_4]$[3] and $[M_2(OR)_6]$[4] (M = Mo or W) have been found to react with CO, alkynes, allenes, carbodiimides, diazoalkanes, and a host of other unsaturated substrates, in addition to showing reactivity toward oxidative-additions and cluster formation reactions. Notably absent from the list of substrates to be activated are N_2, H_2 and olefinic C-C double bonds. We describe here our observation of the binding of ethylene to $[W_2(ONp)_6]$ (Np = CH_2CMe_3).

$[W_2(ONp)_6]$ can be obtained as a yellow crystalline solid by reaction of $[W_2(OtBu)_6]$ with NpOH (>6 equiv.) in hexane at 0°C. The structure of the compound is analogous to that of $[W_2(OiPr)_6]$.[5] $[W_2(ONp)_6]$ is stable in hydrocarbon solutions with respect to cluster formation for a period of days at room temperature.[6] Addition of C_2H_4 (2 equivalents) to a solution of $[W_2(ONp)_6]$ in [D_8]toluene or [D_6]-benzene leads to an immediate darkening of the solution, from pale yellow to deep yellow/brown. The ^{1}H-NMR spectrum reveals, in addition to some unreacted ethylene and $[W_2(ONp)_6]$, the formation of a 1:2 adduct, $[W_2(ONp)_6(C_2H_4)_2]$. The ^{1}H-NMR spectra require that the molecule adopts a relatively rigid structure having a C_2 axis of molecular symmetry. Specifically, there are three types of ONp ligands in the integral ratio 1:1:1 each having diastereotopic methylene protons,[7] and one ethylene moiety per $W(ONp)_3$ unit. This is consistent with a typical Lewis acid-base adduct[8] of the type shown diagrammatically by **I**, given that rotation about the M≡M bond is frozen-out. For alkoxide ligands this barrier to M≡M bond rotation is low (e.g. $\Delta G^{\ddagger} = 9.5$ kcal mol^{-1} for $[W_2(ONp)_6(HNMe_2)_2]$) and typically a "frozen-out spectrum" is only attained at very low temperatures.



I

Particularly noteworthy are the ^{1}H-NMR signals of the ethylene ligand (four multiplets, see Fig. 1). Again this is indicative of a rather rigid structure in which ethylene rotation about the metal ethylene axis is frozen-out on the NMR time-scale. Coordination of C_2H_4 thus generates an ABCD spin system, a situation rarely encountered in mononuclear complexes.[9]

In the ^{13}C-NMR spectrum (22°C, 75 MHz, [D_6]benzene), there are two resonances (at $\delta = 60.8$ and 63.8) assignable to the ethylene carbon atoms. Both signals show coupling to ^{183}W ($I = 1/2$, 14.5% natural abundance):

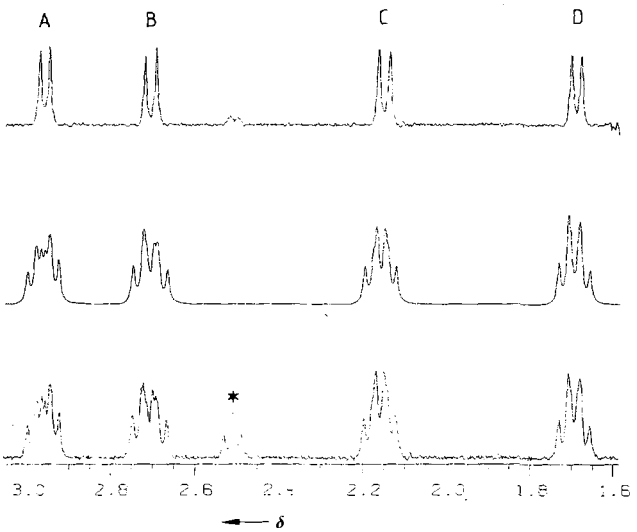


Fig. 1. Bottom: Section of a 360-MHz ^{1}H-NMR spectrum (ethylene region) of $[W_2(ONp)_6(C_2H_4)_2]$ recorded at 10°C in [D_6]benzene. The resonance marked * is due to a derivative of $[W_2(ONp)_6(C_2H_4)_2]$. Top: The ^{1}H-NMR spectrum of the ethylene region of $[W_2(ONp)_6(trans\text{-}CHD{=}CHD)_2]$ shows that statistical distribution of the three possible enantiomers and no scrambling of the label have occurred. Resonances A and D and B and C were shown to be mutually *trans*. Resonances A and C and B and D were shown to be mutually geminal in the isotopomer $[W_2(ONp)_6(CH_2{=}CD_2)_2]$. Decoupling experiments on the protio ethylene complex were employed to determine the remaining coupling constants ($^{cis}J_{AB} = 12.0$, $^{gem}J_{AC} = 6.8$, $^{trans}J_{AD} = 8.5$ Hz, $^{trans}J_{BC} = 9.5$, $^{gem}J_{BD} = 7.9$, $^{cis}J_{CD} = 10.4$ Hz) and to generate the simulated spectrum (middle).

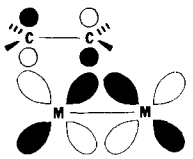
[**] This work was supported by the National Science Foundation (USA) and the Indiana University Foundation.

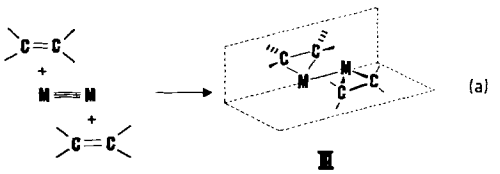
$J_{^{183}W-^{13}C} = 36$ Hz.[10] In the ^{13}C spectrum of the ^{13}C-labeled compound $[W_2(ONp)_6(*C_2H_4)_2]$ where *C represents 99 mol% ^{13}C, $^1J_{C-C} = 28$ Hz, and from the ^1H spectrum, $^1J_{H_A-C} = 150$ Hz, $^1J_{H_B-C} = 163.4$ Hz, $^1J_{H_C-C} = 146$ Hz, and $^1J_{H_D-C} = 154$ Hz.

The bisethylene adduct is formed reversibly and, over a period of days, reacts further, so that a full characterization of the compound by a single crystal X-ray study has thus far been thwarted. It is possible to formulate some satisfactory structures based on the spectroscopic requirements that: 1) the molecule has empirical formula $[W(ONp)_3(C_2H_4)]_n$ and must have C_2 symmetry; 2) there is restricted rotation about the ethylene tungsten bond. One such structure may be envisaged by analogy to **I** in which restricted ethylene rotation can be understood by a consideration of the metal to ethylene back-bonding which competes with the metal-metal triple bond. One such ethylene-W_2 interaction is diagramatically shown in **II**.



I

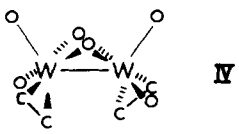
If this is the M-M π orbital formed from metal d_{xz}-d_{xz} interactions, it follows that the other ethylene will coordinate to the other metal atom at right angles to that shown in **II** so as to interact with the metal d_{yz}-d_{yz} π bond. In the limit the reaction of two C-C double bonds and one M-M triple bond, $\sigma^2\pi^4$, can be represented by Equation (a), bearing in mind that the M_2C_4 moiety is not flat but folded such that the angle between the two C_2M_2 planes is ca. 90°.



(a)

II

Another structural possibility involves two five-coordinate tungsten atoms in which the plane of ethylene coordination is perpendicular to the metal-metal bond such as is seen in $[W_2R_2(\eta^2\text{-}C_2R'_2)_2(O\mathit{i}Pr)_4]$ compounds.[11]



IV

The NMR spectra cannot reliably distinguish between **III** and **IV**, though we are inclined to favor **III** because (i) $[W_2(ONp)_6(C_2H_4)_2]$ is in fact in equilibrium with $[W_2(ONp)_6]$ and free ethylene, and (ii) in compounds of formula $[W_2R_2(\eta^2\text{-}C_2R'_2)_2(O\mathit{i}Pr)_6]$ there is rapid rotation about the W-alkyne C_2 vector. Despite this prejudice in favor of **III** it should be noted that in both **III** and **IV** the ethylene metal interaction may be termed a metallacyclopropane in contrast to **I** where the ethylene merely acts as a Lewis base. **I**, **III**, and **IV** represent limiting bonding modes and evidence in favor of a significant metallacyclopropane contribution is seen by the low value of $^1J_{C-C} = 28$ Hz in $[W_2(ONp)_6(C_2H_4)_2]$ which may be compared with $^1J_{C-C} = 67.6$ and ca. 10 Hz in ethylene[12] and cyclopropane,[13] respectively. Furthermore, from the ^1H-NMR spectrum of the compound employing $CH_2{=}CD_2$ instead of $CH_2{=}CH_2$ we can determine that the two geminal HH couplings are 7.9 and 6.8 Hz. This is significantly larger than the corresponding value for free ethylene (+2.5 Hz; $^{cis}J_{HH} = +11.7$ Hz, $^{trans}J_{HH} = +19.1$ Hz)[12] and for weakly coordinating ethylene ligands such as $[CpMn(CO)_2(C_2H_4)]$ and $[CpCr(CO)(NO)(C_2H_4)]$, where $^{gem}J_{HH}$ values fall in the range 0.5 to 1.0 Hz.[14] On the other hand, the J_{HH} values in phosphirane[15] closely resemble the values measured for $[W_2(ONp)_6(C_2H_4)_2]$.

Preparation and Structure of $[Mo_4(OMe)_2(O\mathit{i}Pr)_{10}]$; Comments on Why $[W_2(O\mathit{i}Pr)_6]$ Dimerizes, Whereas $[Mo_2(O\mathit{i}Pr)_6]$ Does Not**

By *Malcolm H. Chisholm,* Charles E. Hammond, Mark Hampden-Smith, John C. Huffmann,* and *William G. Van Der Sluys*

Our recent discovery[1] and characterization of $[W_2(O\mathit{i}Pr)_6]$ ($M{\equiv}M$) and its dimeric cluster $[W_4(O\mathit{i}Pr)_{12}]$ has led us to question why such a process does not occur for $[Mo_2(O\mathit{i}Pr)_6]$.[2] We have studied[3] the equilibrium (a) between $[W_4(O\mathit{i}Pr)_{12}]$ and $[W_2(O\mathit{i}Pr)_6]_2$ over the temperature range +20 to +38°C at six different temperatures using two different concentrations for the forward reaction and one concentration for the back reaction in $[D_8]$toluene by ^1H-NMR studies.

(a)

The tetranuclear cluster is enthalpically favored, ΔH^0, by 22 kcal mol^{-1} but entropically disfavored, ΔS^0, by 61 cal mol^{-1} K^{-1}. The activation parameters for the forward reaction, reveal $\Delta H^* = +30$ kcal mol^{-1} and $\Delta S^* = +17$ cal mol^{-1} K^{-1}, while the back reaction (dimerization) has a small enthalpy of activation, $\Delta H^* = +8$ kcal mol^{-1} but a large entropy of activation, $\Delta S^* = -44$ cal mol^{-1} K^{-1}. These activation parameters for the dimerization led us to propose that alkoxide bridge formation, as seen in

$[Mo_4(\mu\text{-}OMe)_2(\mu\text{-}O\textit{i}Pr)_2(O\textit{i}Pr)_8]$ **1**

represents an important step in cluster formation. Since in the complex $[W_4(O\textit{i}Pr)_{12}]$ there are really only two regular alkoxy bridges (two being semi-bridging[1,4] having long W···O distances of 2.59 Å) it seems that W–W bonding must make a significant contribution to the value of $\Delta H^0 = +22$ kcal mol^{-1} in favoring the cluster. The large ΔS^0 value has several components. The loss of translational entropy on combining two particles of mass of ca. 722 Daltons to give one particle of mass of ca. 1444 Daltons yields -44 cal mol^{-1} K^{-1} at 22 °C using the Sackur-Tetrode equation.[5] In addition there will be negative contributions from the loss of rotational entropy on formation of the $[W_4(O\textit{i}Pr)_{12}]$ cluster. However, it is likely that the coordinatively unsaturated $[W_2(O\textit{i}Pr)_6]$ molecule is more highly solvated, even in [D$_8$]toluene, than is its cluster, giving rise to a release of (positive) entropy for $[W_4(O\textit{i}Pr)_{12}]$ formation. Since it is known that $[W_2(OR)_6]$ compounds bind Lewis bases somewhat more strongly than related $[Mo_2(OR)_6]$ compounds[6] one is led to the conclusion that the tetranuclear compound $[Mo_4(O\textit{i}Pr)_{12}]$ might well be thermodynamically favored at lower temperatures; but at these temperatures the cluster forming reaction would be so slow that $[Mo_2(O\textit{i}Pr)_6]$ would be kinetically inert.

In an attempt to test this hypothesis we have lessened the steric demands at the $[Mo_2(O\textit{i}Pr)_6]$ center by substituting one O*i*Pr ligand by one OMe ligand. This has been achieved by controlled methanolysis [Eqn. (b)].

$$[Mo_2(O\textit{i}Pr)_6] + MeOH \xrightarrow[\text{hexane}]{22\,^\circ C} \tfrac{1}{2}[Mo_4(OMe)_2(O\textit{i}Pr)_{10}] + \textit{i}PrOH \quad (b)$$

1

The red crystalline compound **1** has a centrosymmetric molecular structure in the solid-state (Fig. 1). The rectangular Mo_4 unit has two short (2.238(1) Å) Mo–Mo distances and two long (3.344(1) Å) Mo–Mo distances, corresponding to localized Mo≡Mo bonds and non-bonding distances, respectively. The local geometry about each Mo atom consists of a distorted square planar MoO_4 unit. The four Mo–μ-O distances are essentially equivalent (Mo–O = 2.11(1) Å), while the terminal Mo–O distances (Mo–O = 1.90 Å (av)) are indicative of the retention of some Mo–O double bond character.[7] Note the Mo≡Mo bonds are unbridged by alkoxides and the molecule can be viewed as a dimer $[Mo_2(\mu\text{-}OMe)(\mu\text{-}O\textit{i}Pr)(O\textit{i}Pr)_4]_2$. In [D$_8$]toluene solution the ^{1}H-NMR spectra are indicative of a fluxional molecule and suggestive of rapid and reversible bridge opening and closing. **1** represents the first example of a structurally characterized $[Mo_4(OR)_{12}]$ compound even though the alkoxides are broken into two sets: ten O*i*Pr and two OMe ligands. What is most striking in comparing the W_4 and Mo_4 compounds supported by alkoxide ligands is that the W_4 compound $[W_4(O\textit{i}Pr)_{12}]$ clearly favors a 12-electron W_4 cluster bonding mode while the Mo_4 compound, **1**, retains the two localized Mo≡Mo bonds.

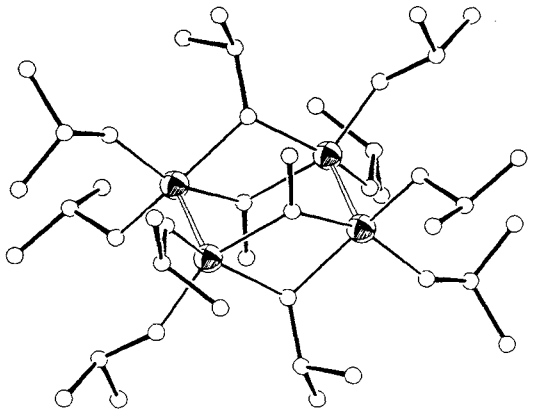

Fig. 1. Crystal structure of $[Mo_4(\mu\text{-}OMe)_2(\mu\text{-}O\textit{i}Pr)_2(O\textit{i}Pr)_8]$ **1**. The unbridged Mo≡Mo bonds (2.238(1) Å) are shown in white. The distance between the bridged Mo atoms is 3.344(1) Å; other distances: Mo-O(terminal) = 1.90(1) Å, Mo-μ-O = 2.11(1) Å.—Space group $P\bar{1}$, cell dimensions at -156 °C, $a = 10.207(4)$, $b = 10.856(4)$, $c = 9.536(3)$ Å, $\alpha = 106.63(1)$, $\beta = 78.06(2)$, $\gamma = 73.76(1)$°, $Z = 1$, $\rho_{calcd} = 1.56$ gm/cm^3 [8].

This leads us to the conclusion that the $[Mo{\equiv}Mo]^{6\oplus}$ unit is thermodynamically more stable than the the corresponding $[W{\equiv}W]^{6\oplus}$ unit with respect to cluster formation. We suggest that this finding can be attributed to core-core repulsions,[9] which has a parallel in triple-bond systems between elements of the 2nd and 3rd main groups (e.g. $2\,N_2$ vs. N_4 and $2\,P_2$ vs. P_4[10]). It is now well recognized that for compounds containing quadruple bonds $[M{\equiv}M]^{4\oplus}$ the W–W distances are longer by ca. 0.1 Å than their Mo–Mo counterparts.[11] Similarly for related $[M{\equiv}M]^{6\oplus}$-containing compounds the W–W distances are ca. 0.08 Å longer than the Mo–Mo distances.[11] In sets of related compounds the M–L distances differ by less than 0.01 Å with the W–L distances generally being shorter.[11] Consequently, for tungsten the drive to cluster formation relieves the problems of core-core repulsion relative to molybdenum for M–M bonds of high order.

Obviously this hypothesis needs considerable further elaboration, but the differences between the molecular structures of $[W_4(O\textit{i}Pr)_{12}]$ and $[Mo_4(OMe)_2(O\textit{i}Pr)_{10}]$ are most noteworthy and warrant general consideration.

Nonaphenyltristiboxane-1,5-diyl Disulfonates**

By *Robert Rüther, Friedo Huber,** and *Hans Preut*

The long known distiboxanes $(XR_3Sb)_2O$[1] may be regarded as products of the partial hydrolysis of triorganoantimony(v) compounds R_3SbX_2 (X = e.g. Cl). A hydrolysis proceeding beyond the stage of the distiboxanes and accompanied by condensation reactions takes place only under relatively drastic conditions. In such a case polymeric $(R_3SbO)_n$ is formed. Intermediates of this reaction are not known. We have now succeeded in synthesizing and characterizing for the first time the tristiboxanes $XPh_3Sb-O-SbPh_3-O-SbPh_3X$ (X = 2,4-$(NO_2)_2C_6H_3SO_3$, 2,4,6-$(NO_2)_3C_6H_2SO_3$).

Dimeric triphenylantimony oxide **1**[2,3] reacts with the free sulfonic acids **2** (molar ratio 3 : 4) in the presence of 2,2-dimethoxypropane as water-trapping reagent to give the compounds **3** [Eqn. (a)].

$$3(Ph_3SbO)_2 + 4HX \longrightarrow \underset{\mathbf{1}}{} \quad \underset{\mathbf{2a,b}}{} \qquad (a)$$

$$2XPh_3Sb-O-SbPh_3-O-SbPh_3X + 2H_2O$$

$$\underset{\mathbf{3a,b}}{}$$

a, X = 2,4-$(NO_2)_2C_6H_3SO_3$; **b**, X = 2,4,6-$(NO_2)_3C_6H_2SO_3$

3a and **3b** form yellow, air-sensitive crystals which are moderately soluble in alcohol and dimethyl sulfoxide, sparingly soluble in chloroform, and very sparingly soluble in water and hexane. The ^{1}H-NMR spectra of **3a** and **3b** exhibit several multiplets, indicating concomitant presence of various phenylantimony species in solution. Comparable observations on hexaphenyl-1λ^5,3λ^5-distiboxane-1,3-diyl disulfonates in $CHCl_3$ or acetone implicate establishment of rearrangement equilibria.[2] In analogous reactions of **1** with less acidic sulfonic acids (X = $MeSO_3$, $PhSO_3$, 4-$CH_3C_6H_4SO_3$, $HOCH_2CH_2SO_3$) mixtures of the corresponding distiboxanes and excess oxide are formed.

As previously reported,[4] the preparation and structure of the organoantimonyl(v) sulfonates are strongly influenced by the nucleophilicity of the respective sulfonate ion, while the size of the organic moiety of the sulfonate group plays only a subordinate role. Moreover, the electronic properties and the size of the organo-substituents on the antimony atom are of considerable importance.[2] Thus trimethylantimony compounds analogous to **3** cannot be synthesized, and the reaction of CF_3SO_3H with **1** leads only to the distiboxane.

The X-ray structure analysis of **3a**[5] reveals a chain of three O-coupled $SbPh_3$ units; two monodentate bonded 2,4-dinitrobenzenesulfonic acid residues function as terminal groups of this chain (Fig. 1). The trigonal-bypyrimidal

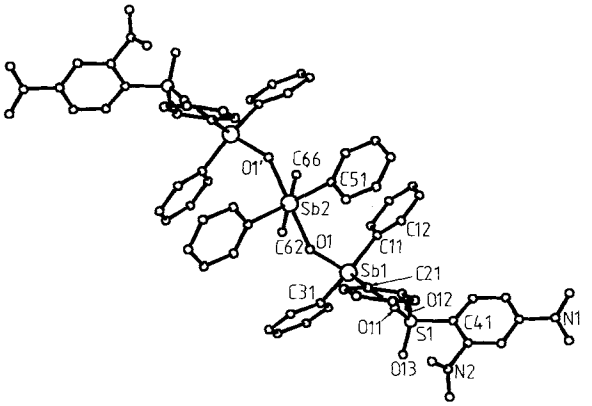

Fig. 1. Crystal structure of **3a** viewed along the C_2 axis, which runs through the atoms Sb2, C61, and C64 (ORTEP II, without H atoms); C61 and C64 are hidden by Sb2, C63 is hidden by C62. Selected bond lengths [pm] and angles [°]: Sb1-O1 192.1(4), Sb2-O1 203.5(5), Sb1-O11 250.9(5), S1-O11 145.8(5), S1-O12 143.0(7), S1-O13 144.9(7); Sb1-O1-Sb2 140.8(3), O1-Sb1-O11 174.4(2), O1-Sb2-O1' 176.8(2).

arrangement of the three equatorial phenyl groups is virtually undistorted, while the phenyl groups of the outer antimony atoms are tilted from the equatorial plane in the direction of the respective sulfonate group (mean value of the O11-Sb-C angle (C = C11, C21, C31): 82.3°), and the O1-Sb1-O11 angle of 174.4(2)° also deviates more from linearity than the O1-Sb2-O1' angle. The large Sb1-O11 distance of 250.9(5) pm (cf. Table 1), the distortion also found in other comparable compounds, and the IR data (Table 2) point to a relatively high degree of ionic character for the Sb-OSO_2 bonds.

Table 1. Typical Sb-O distances in stibonylsulfonates.

Compound	*d*(Sb-O) [pm]	Ref.
$Ph_3Sb(O_3SC_6H_5)_2$	212.8(2) and 210.6(3)	[4]
$Ph_4SbO_3SC_6H_5 \cdot H_2O$	250.6(4)	[6]
$(Ph_3SbO_3SC_6H_5)_2O$	224.7(5) and 228.0(5)	[7a]

Table 2. IR data of the compounds **3** (Nujol; $\tilde{\nu}$ in cm^{-1}).

	$\tilde{\nu}_{as}(SO_2)$	$\tilde{\nu}_{s}(SO_2)$	$\tilde{\nu}$(SO)	$\tilde{\nu}_{as}$(Sb-O-Sb)
3a	1275	1192/1185	1020	750
3b	1290	1212	1030	750

Sb-O-Sb bridges can be linear[8] or bent.[7] In **3a** the angle is 140.8(3)° and thus essentially corresponds to the values observed in bent distiboxanes.[7] Remarkable is the unsymmetric disposition of the Sb-O-Sb bridges. The Sb2-O1 distance (203.5(5) pm) corresponds to the normal Sb-O distance for a covalent bond in organoantimony(v) compounds.[9] The substantially shorter Sb1-O1 bond (192.1(4) pm) is comparable to the μ-O-Sb bonds in the previously known distiboxanes.[7,8] Substantially different μ-O-Sb bonds are also found in the Sb-O-Sb-O four-membered

ring of **1** (mean values 207.3(7) and 192.5(7) pm), which, however, can only be referred to for comparison with care because of the different orientation (apical and equatorial in **1**, apical in **3a**). The formation of unsymmetrical Sb-O-Sb bridges in **3a** can be attributed to the positive partial charge of the outer antimony atoms. This elicits a stronger interaction between metal atom and the lone pair of the bridge oxygen atom and a strengthening of the μ-O-Sb bond.

Experimental

3: A suspension of **1** (1.107 g, 1.5 mmol) [2, 4] and **2a** (0.496 g, 2 mmol) or **2b** (0.586 g, 2 mmol) in acetone (15 mL) was prepared at room temperature. After a short time a clear yellow solution formed, which, after addition of 10 mL of 2,2-dimethoxypropane, was stirred overnight and finally evaporated down under vacuum to about 10 mL. The precipitated microcrystalline, yellow powder was filtered off and washed with a small amount of ether. M.p.: **3a** 204–206 °C (decomp.); **3b** 202–206 °C (decomp.); yield **3a** 30%; **3b** 32%.

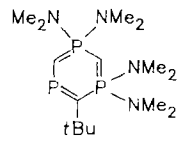
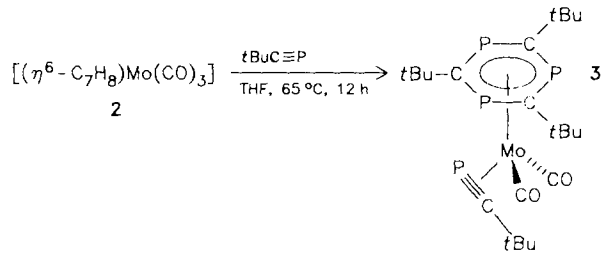
Metal-Promoted Cyclotrimerization of a λ^3-Phosphaalkyne: Formation of a Molybdenum-Coordinated 1,3,5-Triphosphabenzene**

By *Andrew R. Barron* and *Alan H. Cowley**

Despite the fact that phosphaalkynes RC≡P are isovalent with nitriles, their reaction chemistry more closely resembles that of alkynes. Phosphaalkynes thus represent excellent potential building blocks for the facile construction of a wide variety of phosphorus-containing heterocycles. This capability has been demonstrated recently by the synthesis of 1,3-diphosphacyclobutadiene complexes.[1] To the best of our knowledge, **1**, which features two λ^5-phosphorus atoms, is the sole example of a 1,3,5-triphosphabenzene derivative.[2] Since the cyclotrimerization of alkynes on transition-metal centers is well documented,[3, 4] we were prompted to investigate the corresponding chemistry of phosphaalkynes and report herein the first example of a coordinated 1,3,5-triphosphabenzene derivative.[***]



Treatment of the cycloheptatriene-molybdenum complex **2**[5] with *t*BuC≡P[6] afforded the orange, *microcrystalline* Mo complex **3**. Unfortunately, crystals of **3** were unsuitable for X-ray diffraction study.



The composition $C_{22}H_{36}MoO_2P_4$ of **3** was established by high-resolution mass spectroscopy ($M^{\oplus}$, calcd 554.0721; found 554.0712, relative intensity 23%). The medium-resolution mass spectral fragmentation pattern revealed peaks at m/z 498 (20%), 497 (19%), and 454 (7%), which correspond to the loss of two CO's, *t*Bu, and *t*BuC≡P, respectively.[7] The lowest m/z peak of significant intensity (12%) corresponds to $[Mo(tBuCP)_3]^{\oplus}$.

The IR spectrum of **3** exhibits two bands in the carbonyl region (1950 and 1890 cm^{-1}), which can be assigned to symmetric and asymmetric CO stretching, respectively. Use of these data leads to a computed[8] inter-carbonyl angle of 89 ± 3°, thus indicating a *cis* disposition of the CO ligands.

The ^{1}H-NMR spectrum of **3** (300 MHz, C_6D_6, TMS ext.) consists of two singlets at $\delta = 1.46$ and 1.30 in a 3 : 1 intensity ratio. In the $^{31}P\{^1H\}$-NMR spectrum (32.2 MHz, C_6D_6, 85% H_3PO_4, ext.) two singlets in the same intensity ratio were detected at $\delta = +25.2$ and -228.2. The high-field resonance falls in a region assigned previously to η^2-attachment of *t*BuC≡P to Mo.[9] The ^{31}P chemical shifts for uncoordinated phosphabenzenes fall in the range $\delta = 150$–300.[2, 10] Although there is no literature precedent, a ^{31}P chemical shift of $\delta = 25.2$ therefore seems plausible for an η^6-coordinated triphosphabenzene.

Experimental Procedure

3: To a solution of **2** (0.476 g, 1.75 mmol) in THF (60 mL) was added *t*BuC≡P (1.05 g, 10.5 mmol). After refluxing for 12 h, the solvent was removed (in vacuo) and the residue extracted with cyclopentane (2 × 50 mL); reduction in volume and cooling (−20 °C) gave an orange solid. Yield: 0.57 g (59%), m.p. = 83 °C (dec.).

Metal-Promoted Cyclotrimerization of a λ^3-Phosphaalkyne: Formation of Vanadium-Complexed Valence Isomers of a 1,3,5-Triphosphabenzene**

By *Roman Milczarek, Wolfgang Rüsseler, Paul Binger,* Klaus Jonas, Klaus Angermund, Carl Krüger,* and *Manfred Regitz*

tert-Butylphosphaacetylene **1** undergoes cyclodimerization on η^5-cyclopentadienyl metal complexes: Whereas reaction of **1** and cyclopentadienylbis(ethene)cobalt results in the formation of a λ^3-1,3-diphosphacyclobutadienecobalt complex with displacement of the ethene ligands,[1,2] reaction of **1** and the Cp_2Zr fragment (prepared in situ) affords a 1,3-diphosphabicyclo[1.1.0]butane-2,4-diylzirconium complex.[3] Free or complexed cyclotrimers of λ^3-phosphaacetylenes[4] were previously unknown.[***] Herein we report a metal-promoted cyclotrimerization of a λ^3-phosphaalkyne.

Reaction of *tert*-butylphosphaalkyne **1** with the naphthalenevanadium complex **2**,[5] which is a suitable source of Cp*V fragments (Cp* = η^5-pentamethylcyclopentadienyl), results in liberation of naphthalene in an exothermic reaction and formation of a new organovanadium complex as dark brown crystals having the composition $[Cp^*V(PC_tBu)_3]$ **3** (MS, elemental analysis). At room temperature, **3** readily reacts with 1 mol of CO yielding complex **4** (MS, elemental analysis) as dark green crystals.

[***] Note added by the editorial staff: A related cyclotrimerization in which a 1,3,5-triphosphabenzene derivative is formed in the coordination sphere of molybdenum is also reported in this issue: A. R. Barron, A. H. Cowley, *Angew. Chem. 99* (1987) 956; *Angew. Chem. Int. Ed. Engl. 26* (1987) 907.

The crystal structure analyses of **3** and **4** show that, in both compounds, the three phosphaalkynes are bound to the vanadium center as valence isomers of 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene (Fig. 1). The C_3P_3 ligand in complex **3** can be derived from a 1,3,5-triphosphaprismane in which no bonding interaction between P1 and C1 or between C1 and C11 (see Fig. 1, top) is present. In complex **4**, the C_3P_3 ligand is unequivocally bound as 1,3,5-triphospha-Dewar-benzene (Fig. 1, bottom).

In contrast to **4**, complex **3** exhibits dynamic behavior in solution. At 20°C, a broad signal for P-1 and P-3 at $\delta = -58.2$ is observed in the ^{31}P-NMR spectrum; only at -100°C is it split into two doublets at $\delta = +140.4$ and -234.4 ($J_{PP} = 219$ Hz). The signal for P-2, on the other hand, is temperature independent, appearing at $\delta = -130.9$ at 20°C and -135.8 at -100°C. Therefore, at room temperature a rapid valence isomerization occurs, which can be described, for example, by the structural formulas **3a** and **3b**. The small differences between the bond lengths in the C_3P_3V framework of **3a** (see caption to Fig. 1, top), however, indicate that other valence isomeric structures exist, such as those found for the structurally similar $P_7^{3\ominus}$ clusters[7] and that these must be considered for a complete description of the structural dynamics. In the ^{31}P-NMR spectrum of the carbonyl complex **4**, the P-1 and P-3 signals are observed at $\delta = -22.4$ (d, $J_{PP} = 6.0$ Hz) and that for P-2 at $\delta = +84.4$ (t); both are temperature independent.

It is remarkable that **1** and **2** react to form vanadium complexes of valence isomers of 1,3,5-triphosphabenzene, since reaction of **2** (Cp instead of Cp*) with diphenylacetylene affords a Cp vanadium complex containing π-bonded hexaphenylbenzene.[8] A possible reason for this is the strong tendency of two-coordinate phosphorus in phosphaalkenes to undergo transformation to the more stable three-coordinate form,[9] but it is not clear what role the transition metal and the Cp or Cp* ligands play.

Experimental Procedure

3: **1** (2.5 g, 25 mmol) [10] in 10 mL of THF was added to a solution of **2** (2.3 g, 7.3 mmol) [5] in 30 mL of THF at room temperature; the solution gradually heats up to boiling accompanied by a color change from dark red to brown. After stirring for 1 h at 20°C, all volatiles were removed at 0.1 torr and then most of the naphthalene was sublimed off at 20°C/0.01 torr. The residue was dissolved in 35 mL of hexane; the crystals precipitating at -78°C were filtered off and the residual naphthalene was removed at 0.001 torr. A second recrystallization from a small amount of hexane gave 1.53 g (43%) of **3** (nearly black crystals, m.p. = 121°C).

4: A solution of **3** (0.95 g, 1.95 mmol) in 15 mL of hexane absorbed 1.95 mmol of CO in 1 h at 20°C, the solution turning green. The green crystals separating out near the end of the reaction were filtered off and recrystallized from ca. 5 mL of diethyl ether at -30°C. After washing with a small amount of cold pentane and drying at 0.1 torr, 0.9 g (90%) of **4** (decomp. at 125°C) was obtained.

C–S Bond Cleavage in a π-Thiophene Ruthenium Complex**

By *Johannes W. Hachgenei* and *Robert J. Angelici**

Catalytic hydrodesulfurization (HDS), the process by which sulfur is removed from crude oil by treatment with hydrogen over a Mo-Co(γ-Al_2O_3) catalyst, is practiced industrially on a very large scale.[1] However, little is understood about the mechanism of this process, especially for the thiophene-containing organosulfur compounds, which are the most difficult to desulfurize.[2] As a model for the possible reaction of π-adsorbed thiophene with hydride hydrogen bound to the surface of the HDS catalyst, we previously[3] allowed $[Mn(CO)_3(\eta^5\text{-thiophene})](SO_3CF_3)$ to react with hydridometalates ($HFe(CO)_4^{\ominus}$ and $HW(CO)_5^{\ominus}$) and obtained the hydride adduct **1**.

$[Mn(CO)_3(\eta^4\text{-}SC_4H_5)]$ **1**

$[CpRu(\eta^5\text{-}2,5\text{-}Me_2\text{-}C_4H_2S)]PF_6$ **2**·PF_6[4]

$Na[(CH_3OCH_2CH_2O)_2AlH_2]$ **3**

$[CpRu(Me_2C_4H_3S)]$ **4**

We now find that the reaction of **2** (Cp = η-C_5H_5)[4] with hydrides ($LiAlH_4$, **3**, and $NaBHEt_3$) also results in the formation of a hydride adduct, **4**. However, an X-ray crystal structure analysis[5] of **4** (Fig. 1) shows that, in contrast to **1**, a C–S bond has been cleaved to give a butadiene

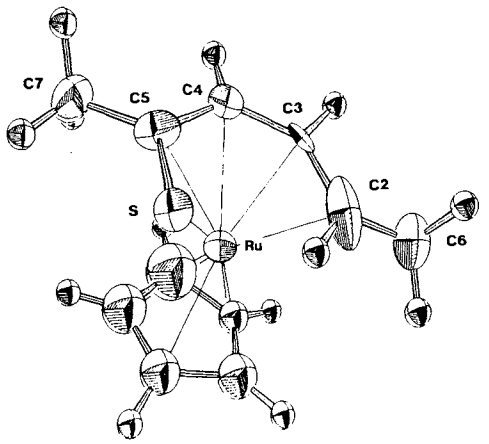

Fig. 1. Crystal structure of **4** showing 50% thermal ellipsoids. Selected bond distances [pm] and angles [°] (±2°): Ru-S 240.1(6), Ru-(C2-C5) 215-220(3), S-C5 170(2), C2-C6 129(3), C2-C3 142(4), C3-C4 140(3), C4-C5 150(3), C5-C7 151(3), Ru-C(Cp) 215-223(5), C-C (within the Cp ring) 131-147(5); C3-C2-C6 128, C2-C3-C4 138, C3-C4-C5 122, C4-C5-C7 118, C4-C5-S 121, C7-C5-S 121.

thiolate ligand. Because of disorder in the crystal,[7] the distances and angles have relatively large errors, but it is clear that the C2–S distance (315 pm) is too long for bonding and that the Ru is coordinated to all four C atoms and the sulfur of the butadiene thiolate ligand. The plane of the four C atoms (C2–C5) is at an angle of 10.7° with respect to the plane of the Cp carbons. The ^{1}H- and ^{13}C-NMR spectra are consistent with the results of the structure analysis (Table 1). Similar hydride addition to the related complexes $[CpRu(\eta^5\text{-}SC_4HR^1R^2R^3)]^{\oplus}$, where $R^1=R^2=R^3=H$ or R^1=2-Me, 3-Me, $R^2=R^3=H$ or R^1+R^2=2,3-Me_2, $R^3=H$ or $R^1+R^2+R^3$=2,3,5-Me_3, yields the analogous butadiene thiolate complexes, as indicated by their NMR spectra. Likewise, other nucleophiles, such as $SEt^{\ominus}$, $OMe^{\ominus}$, and $CH(CO_2Me)_2^{\ominus}$, give similar butadiene thiolate products[8] resulting from nucleophilic addition at a carbon adjacent to the sulfur and C–S bond cleavage. *D. Baudry* et al. report that the reaction of $[(PPh_3)_2ReH_7]$, 3,3-dimethylbutene, and furan yields the related complex $[Re(\eta^5\text{-}C_4H_5O)(PPh_3)_2(CO)]$.[9]

Table 1. NMR data of **4** (C_6D_6, 300 (^{1}H), 75.46 MHz (^{13}C)), δ values in ppm, J in Hz.

^{1}H-NMR: δ = 1.48 (d, 3H; H6), 2.29 (s, 3H; H7), 3.58 (m, 1H; H2), 4.33 (s and m, 6H; Cp and H3), 5.42 (d, 1H; H4), J(H2-H3) = 9.2, J(H2-H6) = 6.1, J(H3-H4) = 6.2

^{13}C-NMR: δ = 22.6 (q, J(CH) = 121; C7), 32.8 (q, 127; C6), 61.9 (d, 166; C2), 79.1 (d, 190; Cp), 87.7 (d, 162; C3), 91.6 (d, 161, C4), 109.9 (s; C5)

Not only do these ring-opening reactions illustrate a new type of π-thiophene reactivity, but they also provide a new model for a possible initial step in the HDS of thiophene, where surface hydride transfer to a π-adsorbed thiophene could lead directly to C–S bond cleavage. It is perhaps especially noteworthy that Ru is an excellent HDS catalyst, whereas Mn is among the worst.[10] The low HDS activity of Mn may be related to its inability to cleave the C–S bond, instead leading only to the partially saturated ring as in **1**.

Experimental Procedure

4: **2**·PF_6 (50 mg, 0.12 mmol) [4, 8] was dissolved in THF (20 mL) and treated with an equimolar amount of **3** ("Red Al," Aldrich, 3.4 M solution in toluene). The solution immediately turned intense yellow. The solvent was removed, the residue was dissolved in benzene, and the solution was chromatographed over basic Al_2O_3 (5 × 80 mm) with benzene as the eluant. Orange crystals of **4** were obtained from hexane at 0°C. The product (60% yield) was sublimed under vacuum. Correct elemental analysis—MS: m/z 280 ($M^{\oplus}$), 265 ($M^{\oplus}-CH_3$).

A Novel Heterobimetallic Asymmetric Hydrogenation Catalyst Based Upon a Chiral Rhenium Template Containing Two Phosphido Substituents**

By *Bill D. Zwick, Atta M. Arif, Alan T. Patton*, and *John A. Gladysz**

During the last decade, many pseudotetrahedral, optically active, chiral-at-metal complexes have become available.[1] Surprisingly, few if any applications in catalysis have been reported. Over the same period, terminal metal phosphide complexes, L_nMPR_2, have been shown to be excellent templates for the synthesis of binuclear bridging phosphide complexes,[2] and rhodium(I) complexes of chiral-at-backbone-carbon chelating diphosphanes have seen extensive use in catalytic asymmetric hydrogenation.[3] In this communication, we describe the combination of these *disjecta membra* to give a novel rhodium(I) asymmetric hydrogenation catalyst that contains a chiral *rhenium* in a chelating "diphosphane" backbone.[4] This structurally unique catalyst gives product enantiomeric excesses that are among the highest observed for rhodium(I) systems.

The optically active diphenylphosphide complex (+)-(*S*)-**1** ($[\alpha]^{22}_{589}$ = 220)[5] was synthesized in 89–96% yields from the tosylate complex (−)-(*S*)-[(η^5-C_5H_5)Re(NO)-

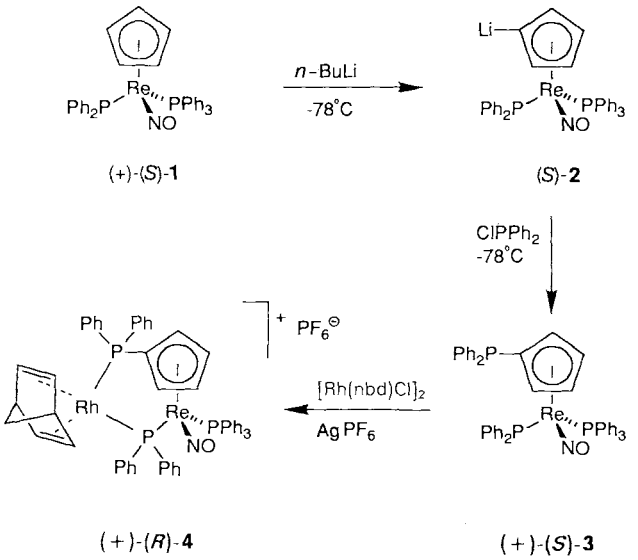
$(PPh_3)(OTs)]$[6] (>99% *ee*) by a procedure analogous to that previously reported for the racemate.[7] Reaction of (+)-(*S*)-**1** with *n*BuLi (1.1 equiv., THF, −78°C) gave a complex, (*S*)-**2**, that was stable for days at 25°C, and whose reactivity and ^{31}P-NMR spectrum[8] were consistent with the formula shown. Subsequent addition of $ClPPh_2$ (1.0 equiv., −78°C) and work-up gave the phosphidocyclopentadienyl complex (+)-(*S*)-**3** (68–89%, $[\alpha]_{589}^{22} = 216$)[5] as a THF or benzene hemisolvate. The structure of (+)-(*S*)-**3** followed readily from its ^{1}H- and ^{13}C-NMR spectra, which showed patterns characteristic of η^5-C_5H_4X ligands, and from its ^{31}P-NMR spectrum.[8]

Reaction of (+)-(*S*)-**3** with $[Rh(nbd)Cl]_2/AgPF_6$ (1.0 : 0.5 : 1.1, THF)[5,9] gave the heterobimetallic complex (+)-(*R*)-**4** (88%, $[\alpha]_{589}^{22} = 48$)[5] as a THF monosolvate after work-up. The structure of (+)-(*R*)-**4** followed readily from its spectroscopic properties. These included large J_{PRh} for both phosphide phosphorus atoms in the ^{31}P-NMR spectrum.[9] The racemic compound, (±)-**4**, was prepared by an analogous series of reactions (92% from (±)-**3**).



Complex (+)-(*R*)-**4** efficiently catalyzed the asymmetric hydrogenation (1 atm, ambient temperature) of enamide precursors to α-amino acids and esters.[10] Unoptimized turnover rates ranged from 300 to 100/h (see Scheme 1).

Scheme 1.

We sought to structurally characterize the catalyst precursor, but suitable crystals were obtained only for the solvated racemate (±)-**4**·$(CHCl_3)_2$ (deep red prisms, $CHCl_3$/hexane).[11] The five-membered chelate ring (Fig. 1) adopts

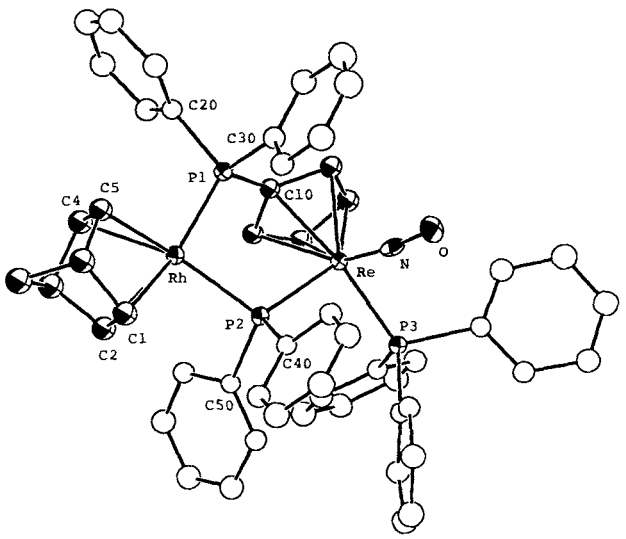

Fig. 1. Structure of the cation of (±)-**4**·$(CHCl_3)_2$. *Selected bond lengths* [Å] *and angles* [°]: Re-C10 2.217(12), Re-P1 2.487(3), Re-P3 2.392(3), Rh-P1 2.276(4), Rh-P2 2.380(3), Rh-C1 2.254(16), Rh-C2 2.258(16), Rh-C4 2.193(15), Rh-C5 2.193(15), P1-C10 1.805(13), Re-N 1.731(13); Re-P2-Rh 113.40(14), P1-Rh-P2 91.35(12), Rh-P1-C10 110.63(44), P1-C10-Re 117.09(59), C10-Re-N 112.88(46), C10-Re-P3 153.94(32), C10-Re-P2 87.42(34), C20-P1-Rh 114.78(44), C30-P1-Rh 113.30(48), C20-P1-C10 106.99(58), C30-P1-C10 106.08(60), C40-P2-Rh 102.42(42), C50-P2-Rh 108.71(40), C40-P2-Re 115.67(43), C50-P2-Re 111.39(39), Re-N-O 171.11(106), P2-Re-P3 99.55(12), P2-Re-N 99.79(38), P3-Re-N 90.81(33).

a distorted "envelope" conformation[12] in which the rhenium and *ipso*-cyclopentadienyl carbon C10 lie 0.338 Å and 0.916 Å below the P1-Rh-P2 plane. This contrasts with five-membered chelate rings in other Rh^I asymmetric hydrogenation catalysts, which adopt "half-chair"[12] (idealized C_2) conformations with one chelate atom below and another above the P-Rh-P plane.[3a,d,f,g] The PPh_3 and NO ligands occupy pseudoequatorial and pseudoaxial positions, respectively. The phenyl rings on P2 bend closer to rhodium than those on P1 (see C-P-Rh angles), most likely due to PPh_3 ligand bulk. These structural features undoubtedly contribute to the unique catalytic activity of (+)-(*R*)-**4**.

Brunner et al. have recently reported an interesting nitrogen-chelated Rh(nbd) complex that contains an asymmetric molybdenum atom in the chelate skeleton, and has briefly examined catalytic hydrosilylation reactions.[4] His study and ours should be the forerunners of a new generation of useful asymmetric catalysts based upon heterobimetallic and polymetallic complexes that contain a chiral metal.

Iodophosphonium Salts with Unusual Properties and a Structural Alternative for Halophosphoranes**

By *Wolf-Walther du Mont,* Michael Bätcher, Siegfried Pohl,* and *Wolfgang Saak*

The halogenation of tertiary phosphanes affords dihalophosphoranes, which, in the condensed phase, are present as molecules having a trigonal-bipyramidal arrangement of the substituents, **A**, or as halophosphonium halides, **B** (Fig. 1), depending on the substituent pattern at the phosphorus

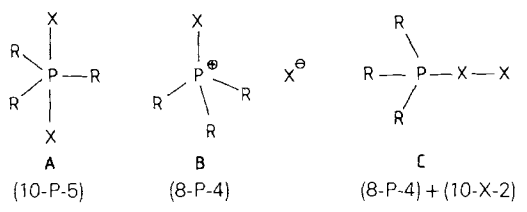

Fig. 1. Structural alternatives for the compounds R_3PX_2 [1].

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

atom.[1] In the case of iodophosphonium ions, the proposed structures and the suggestion of equilibria such as (a) are based mainly on conductivity measurements.[2, 3] Io-

$$R_3PI_2 \rightleftharpoons R_3PI^{\oplus}I^{\ominus} \quad (a)$$

dophosphonium ions are isoelectronic with the phosphane tellurides $R_3P{=}Te$, for which rapid transfer of tellurium to tertiary phosphanes is observed. We have suggested that the mechanism of this transfer involves nucleophilic attack on the tellurium atom with formation of (10-Te-2) intermediates.[4] In the correspondingly rapid transfer of $I^{\oplus}$ ions between phosphanes, (10-I-2) intermediates will be energetically favored if, despite its negative polarization, the iodine atom bonded to the phosphonium center is appreciably electrophilic.[4, 6] We have now found that ^{31}P-NMR spectroscopy provides a very sensitive method to detect the significant increase in electrophilic character of the halogen atom in going from chloro- to bromo- to iodophosphonium salts. Furthermore, the first crystal structure analysis of a diiodophosphorane shows that, in the solid state, a linear arrangement P-I-I having a (10-I-2) situation on the central iodine atom, i.e., a new structural type for halophosphoranes (Fig. 1 **C**), is present.[7]

When the reaction of tri-*tert*-butylphosphane **1** with various amounts of elemental iodine in CH_2Cl_2 is followed by ^1H- and ^{31}P-NMR spectroscopy, one observes continuous changes in the chemical shifts and the coupling constants during the addition of the iodine; separate signals for the reaction products are not observed (Table 1). After the

Table 1. ^{31}P-NMR data for the system **1**/iodine (31.91 MHz).

	Solvent	$\delta^{31}P$	$\lvert^3J(^{31}P,^1H)\rvert$ [Hz]
1	CD_2Cl_2	62.0	± 9.8
1 : I_2 = 1 : 1 (= **2**)	CD_2Cl_2	80.8	± 16.0
1 : I_2 = 1 : 1.5	CD_2Cl_2	96	± 16.8
1 : I_2 = 1 : 2 (= **3**)	CH_2Cl_2/C_6D_6	112	± 17.4
$tBu_3PI^{\oplus}I^{\ominus}$ **2B**	H_2O/D_2O	115	± 17.8
$tBu_3PI^{\oplus}BPh_4^{\ominus}$	CD_2Cl_2	110	± 18.0

"equivalence point" (**1** : I_2 = 1 : 1) is attained, the ^{31}P-NMR shift does not remain constant upon continued addition of iodine, but rather is shifted further downfield and the $^3J_{^{31}P,^1H}$ values increase still further. The 1 : 1 adduct **2** formed between **1** and iodine in water (colorless solution) exhibits ^{31}P-NMR shifts and coupling constants $^3J_{^{31}P,^1H}$ that are very close to those of the phosphonium salt $tBu_3PI^{\oplus}BPh_4^{\ominus}$ (colorless in solution and in the solid state) and differ clearly from the NMR data of the yellow solutions of **2** in CH_2Cl_2 or $CHCl_3$ (Table 1). All observations are in accord with a pronounced acceptor character of the iodine atom bonded to the phosphonium center toward soft nucleophiles ($I^{\ominus}$, PR_3, $I_3^{\ominus}$):

1. If **1** is present in excess, **2** undergoes rapid $I^{\oplus}$ exchange [Eq. (b)], so that averaged NMR shifts and coupling constants are measured.[4, 8]

$$tBu_3PI^{\oplus} + P^*tBu_3 \rightleftharpoons tBu_3P + IP^*tBu_3^{\oplus} \quad (b)$$

2. Pure **2** is characterized by a considerable iodine–iodine interaction (**2C**) in aprotic dipolar solvents and in the solid state; these interactions are the apparent cause of

the yellow color of **2** [**2** in CH_3CN: $\lambda_{max}=314$ nm ($\varepsilon=900$), tailing into the visible]. Nucleophilic attack of $I^{\ominus}$ on the iodine atom in $tBu_3PI^{\oplus}$ leads to upfield shift and a reduction in $^3J_{^{31}P,^1H}$.[9] Isolated, hydrated $tBu_3PI^{\oplus}$ and $I^{\ominus}$ ions are probably present in water (**2B**).

3. If iodine is present in excess, iodophosphonium triiodide **3** is formed.[3-5, 10] The $I_3^{\ominus}$ ion is apparently less nucleophilic than $I^{\ominus}$, so that addition of iodine to **2** in CH_2Cl_2 results in a downfield shift of the ^{31}P-NMR signal, namely toward the value for the "free" tri-*tert*-butyliodophosphonium ion [Eq. (c)].

$$\underset{\textbf{2C}}{tBu_3P{-}I{-}I} + I_2 \longrightarrow \underset{\textbf{3}}{tBu_3PI^{\oplus}I_3^{\ominus}} \qquad (c)$$

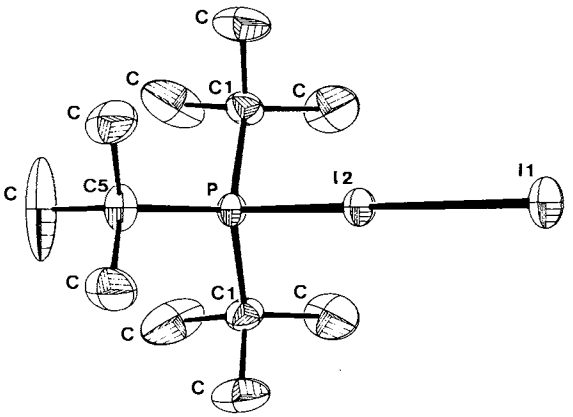

Fig. 2. Crystal structure of **2** (H atoms omitted); thermal ellipsoids at 50% probability. Selected distances [pm] and angles [°]: I1-I2 332.6(1), I2-P 246.1(2), P-C1 190.5(6), P-C5 190.1(9); I1-I2-P 177.6(1), I2-P-C1 106.3(2), I2-P-C5 105.1(3), C1-P-C5 112.5(2).

The X-ray structure analysis (Fig. 2)[11] carried out on a yellow crystal of **2** confirms the existence of significant iodine-iodine interaction in the solid state. The nearly linear P-I-I structural fragment makes **2** comparable with iodine charge-transfer complexes such as the recently described triphenylarsane diiodine.[7, 12] Since the I–I bond in solid **2** is considerably longer than in typical iodine charge-transfer complexes (d(I-I) in **2** 332.6, in Ph_3AsI_2 300.5 pm[7, 13]), **2** can be regarded as an iodophosphonium salt or as a phosphane diiodine charge-transfer complex.[14]

It remains to be shown whether, in the equilibria (a) suggested earlier,[2, 3, 15] the undissociated form R_3PI_2 is indeed present as a (10-P-5) phosphorane or instead as analogue **2** [with hypervalent (10-I-2) iodine].

Structure and Magnetic Properties of a Gadolinium Hexafluoroacetylacetonate Adduct with the Radical 4,4,5,5-tetramethyl-2-phenyl-4,5-dihydro-1*H*-imidazole 3-Oxide 1-Oxyl**

By *Cristiano Benelli, Andrea Caneschi, Dante Gatteschi,* Jean Laugier,* and *Paul Rey**

Adducts of stable organic radicals with metal ions are currently investigated[1] in order to discover novel types of magnetic interactions and also to study possible models of biologically relevant materials.

In principle, the interaction of radicals with lanthanoid ions can give rise to interesting magnetic properties, because of the high spin values of the metal ions. Indeed, although the f orbitals are relatively shielded, they can nevertheless overlap with the orbitals of the radical in a direct exchange mechanism, thus giving rise to appreciable coupling.

To our knowledge, only a few solution studies of weak interactions between nitroxides and lanthanoid ions have been reported so far,[2] but no stable adducts of a radical ligand directly bound to a lanthanoid ion have been characterized. We wish to report here the synthesis, X-ray crystal structure, and magnetic properties of the adduct formed by gadolinium(III) hexafluoroacetylacetonate, $Gd(hfac)_3$ **1**,[3] with the radical 4,4,5,5-tetramethyl-2-phenyl-4,5-dihydro-1*H*-imidazole 3-oxide 1-oxyl **2**.[4]

The X-ray crystal structure analysis[5] of $3 \cdot 0.5\,n\text{-}C_6H_{14}$, performed at room temperature, showed that the asymmetric unit consists of a discrete adduct $[Gd(hfac)_3(\mathbf{2})_2]$ and half a molecule of *n*-hexane (Fig. 1). The Gd ion is eight coordinate to six O atoms of the three hfac molecules and

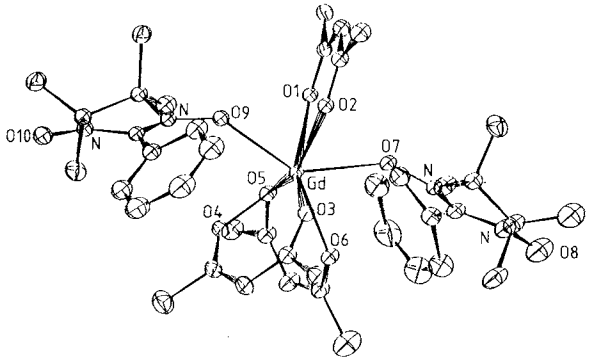

Fig. 1. Molecular structure of $3 \cdot 0.5\,n\text{-}C_6H_{14}$ (ORTEP). The atoms omitted are C atoms. Selected distances [pm] and angles [°]: Gd-O1 237.9(6), Gd-O2 238.5(4), Gd-O3 235.0(6), Gd-O4 240.3(5), Gd-O5 234.8(5), Gd-O6 237.6(5), Gd-O7 232.7(5), Gd-O9 233.7(5); O1-Gd-O9 72.2(1), O2-Gd-O9 75.0(1), O3-Gd-O9 104.1(2), O4-Gd-O9 74.2(1), O5-Gd-O9 91.1(1), O6-Gd-O9 148.1(1), O1-Gd-O7 71.0(1), O2-Gd-O7 75.7(1), O3-Gd-O7 96.3(1), O4-Gd-O7 147.5(1), O5-Gd-O7 97.8(1), O6-Gd-O7 72.7(1).

two O atoms of two different radicals **2**. The bond distances between the Gd ion and the O atoms of the bidentate ligands are in the range 234.8–240.3 pm, while the Gd–O bond distances with the two nitroxides average to 233.2 pm. The coordination polyhedron can be best described as a distorted dodecahedron, according to a procedure suggested in the literature.[6] The pseudo-S_4 axis of the dodecahedron is roughly orthogonal to the O5–O6 and O2–O9 directions. The bond distances within the nitroxides fall in the range usually found for these molecules.[7] The five-membered rings of the nitroxides are to a good approximation planar: the mean deviation of the atoms from the least-squares plane is 10 pm.

The temperature dependence of the inverse molar magnetic susceptibility χ_m^{-1} and of the product $\chi_m T$ for **3** are shown in Figure 2. The experimental points can be fitted to the Curie-Weiss law, with $\theta = 1.468(2)$ K and $C = 8.127(1)$, indicating a weak ferromagnetic interaction between Gd (spin quantum number $S = 7/2$) and the unpaired electrons

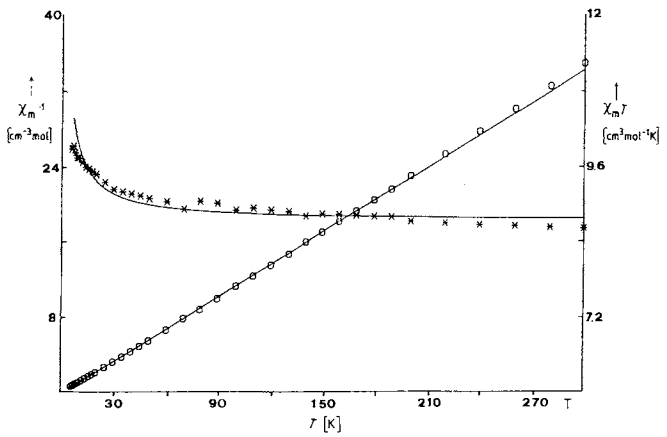

Fig. 2. Temperature dependence of the inverse molar magnetic susceptibility χ_m^{-1} (□) and of the product $\chi_m T$ (*) of **3** in the range 6–300 K.

of the two radicals ($S = 1/2$). This interpretation is confirmed by the temperature dependence of $\chi_m T$, which remains substantially constant down to ca. 20 K and increases steadily below this temperature. The $\chi_m T$ value expected for three non-interacting spins is 8.625 cm^3 mol^{-1} K, while the observed one at $T = 6$ K is $\chi_m T = 9.888$ cm^3 mol^{-1} K.

The experimental points can be fitted with a simple formula[8] which considers only isotropic exchange between gadolinium and the radicals (rad) and between the two radicals. The $\chi_m T$ curve shown in Figure 2 is calculated with the parameters $g_{Gd} = 2.010(1)$, $J_{Gd\text{-}rad} = -1.022(1)$ cm^{-1}, $J_{rad\text{-}rad} = 1.65(2)$ cm^{-1}. This result indicates a weak ferromagnetic interaction between the Gd^{III} ion and the radicals, as well as an antiferromagnetic interaction between the two radicals. The isotropic exchange may not be the only relevant mechanism of interaction and refinements might be introduced using anisotropic exchange and gadolinium zero field splitting, but anisotropic magnetic data must first become available.

In order to determine the possible orbital mechanism of interaction between the metal ions and the radicals, an angular overlap analysis can be performed using the reported matrices.[9]

In fact, the AO parameters are expected to be proportional to the square of the diatomic overlap integral S_λ ($\lambda = \sigma, \pi, \delta \ldots$) of the metal and ligand functions, and also the antiferromagnetic part of the coupling should be proportional to S_λ^2. From the AO analysis we learn that the magnetic orbital of one radical can interact with a linear combination of the f orbitals $(4z^2\text{-}x^2\text{-}y^2)x$ and $(3x^2y\text{-}y^3)$, while that of the other radical interacts with $(4z^2\text{-}x^2\text{-}y^2)y$ and $(x^3\text{-}3xy^2)$, using a reference frame with the *z* axis parallel to the pseudo-S_4 axis. This yields a weak antiferromagnetic contribution, while the interaction with the remaining six combinations of f orbitals may give ferromagnetic contributions. The experimental data show that the latter dominate.

The coupling in **3** can be best compared with manganese–radical complexes,[10] since both are ions having an S ground state. In the manganese complexes, the coupling has been found to be antiferromagnetic, with *J* of the order of 10^2 cm^{-1}. Even in the case of transition-metal ions, therefore, a direct overlap of metal and ligand orbitals does not cause a complete pairing of the spins, and the ferromagnetic contributions of the other metal orbitals become important. The reduced antiferromagnetic component in the lanthanoid ions apparently scales down the coupling, which eventually changes sign.

Experimental Procedure

$1 \cdot 2H_2O$ [3] (718.4 mg, 1 mmol) was suspended in 200 mL of hot *n*-hexane, and **2** (466.6 mg, 2 mmol) [4] was then added; after stirring for 5 min, the solution was filtered, and red-violet crystals, which analyze satisfactorily for $[Gd(hfac)_3(\mathbf{2})_2 \cdot 0.5\,n\text{-}C_6H_{14}]$ ($\mathbf{3} \cdot 0.5\,n\text{-}C_6H_{14}$), were obtained by slow evaporation at room temperature in approximately ten days.

Salicylate-Mediated Assembly of the Discrete Mixed-Valence Nonanuclear Manganese Complex $[Mn_9O_4(O_2CPh)_8(sal)_4(salH)_2(py)_4]$ ($salH_2$ = salicylic acid, py = pyridine)**

By *Cheryl Christmas, John B. Vincent, John C. Huffman, George Christou,* Hsiu-Rong Chang,* and *David N. Hendrickson*

Recent developments in Fe^{III} chemistry have established that high nuclearity (>4) complexes can be prepared with carboxylate or mixed carboxylate/amine ligation even in the expected absence of metal–metal bonds to assist aggregation. Iron complexes of this kind have been prepared by hydrolytic reactions from smaller nuclearity complexes and, to date, octanuclear[1] and undecanuclear[2] species have been structurally characterized. These units are held together by oxide and hydroxide bridges. The efforts of our own research program have been concentrated on the neighboring 3d metal Mn, and we have reported the non-hydrolytic bipyridine(bpy)-mediated conversion of trinuclear $[Mn_3O(O_2CR)_6L_3]^{0,\oplus}$ (R = Me, Ph; L = pyridine(py), H_2O) into tetranuclear species containing the non-planar $[Mn_4O_2]$ core.[3,4] We have now found that use of salicylic acid ($salH_2$) instead of bpy in these reactions leads to still higher aggregation and herein report the preparation of the remarkable nonanuclear complex **1**.

$[Mn_9O_4(O_2CPh)_8(sal)_4(salH)_2(py)_4]$ **1**

To a stirred brown solution of $[Mn_3O(O_2CPh)_6(py)_2(H_2O)]$[5] in MeCN was added solid salicylic acid (3 equiv.) under aerobic conditions. The acid soon dissolved, and the homogeneous dark brown solution was left undisturbed overnight at room temperature. The resulting black crystals of **1** were collected by filtration, washed with hexane, and dried in vacuo;[6] yield ca. 40%.

The X-ray structure[7] of **1** is shown in Figure 1. Charge considerations necessitate a mixed-valence description ($8\,Mn^{III}$, Mn^{II}) and the unique central atom Mn(1) is assigned as the Mn^{II} atom through which there is a crystallographic two-fold axis relating the two halves of the molecule. The average Mn(1)–O distances (2.312 Å) are similar to those in the eight-coordinate Mn^{II} complex $[Mn(NO_3)_4]^{2\ominus}$ (2.306 Å).[8] The eight Mn^{III} atoms are six-coordinate and are disposed in two tetranuclear $Mn_4(\mu_3\text{-}O)_2$ units, each with a butterfly structure. Figure 2a shows a stereoview of **1**; Figure 2b shows a top view of one of the $[Mn_4O_2]$-units, and it can be seen to be similar to that in discrete $[Mn_4O_2]$-containing complexes.[4] The two Mn_4O_2 units and central Mn(1) in **1** are held together via four $\mu_3\text{-}\eta^3\text{-}sal^{2\ominus}$ groups (*o*-oxidobenzoate). Peripheral ligation is by four terminal py, eight bridging $PhCO_2^{\ominus}$ (benzoate), and two bridging $salH^{\ominus}$ groups (salicylate). The latter, one at each end of the molecule, are bound only through their carboxylate functions; the OH-groups with the oxygen atoms O(60) and O(60)′ are not involved in metal ligation. This conclusion is supported by the near coplanarity between the Ph ring and its carboxylate group, and the resulting close approach of O(60) to O(51) (2.59(2) Å), suggesting a hydrogen-bonded O(60)–H···O(51) unit. A similar situation has been seen in Mo^{II} and Rh^{II} complexes containing μ-salH bridges.[9,10] Overall, the Mn_9 unit can be considered a purely inorganic example of a 'sandwich' compound not supported by metal–metal bonding and with the central Mn and two outer $[Mn_4O_2]$ units representing the three layers.

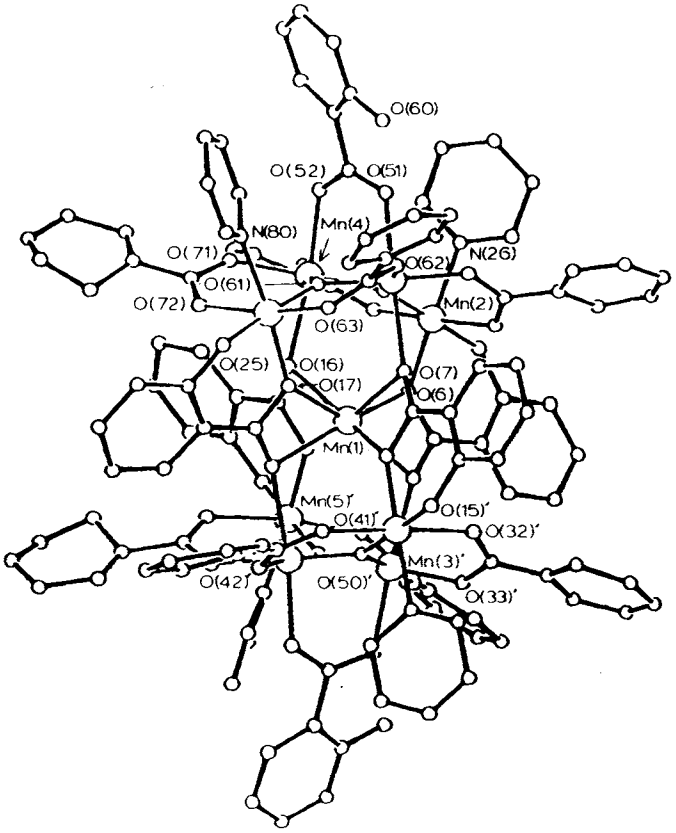

Fig. 1. Crystal structure of complex **1**. To avoid congestion, only one of each symmetry-related pair of Mn and O atoms are labeled. Primed and unprimed atoms are related by the twofold rotation axis through Mn(1). Selected atomic separations: Mn(1)–Mn(2,3,4,5), 3.814(6)–3.983(6) Å; Mn(1)–O(6,7,16,17), 2.240(14)–2.385(14) Å.

Variable temperature, solid-state magnetic susceptibility studies have been performed on powdered samples of **1** in the temperature range 300.9 K to 5.0 K. The effective magnetic moment per molecule, μ_{eff}, gradually decreases from a value of 11.82 μ_B at 300.9 K to a value of 5.83 μ_B at 5.0 K. Extensive coupling is thus indicated and attempts are in progress to elucidate the precise nature and magnitude of the magnetic interactions between the various Mn atoms of

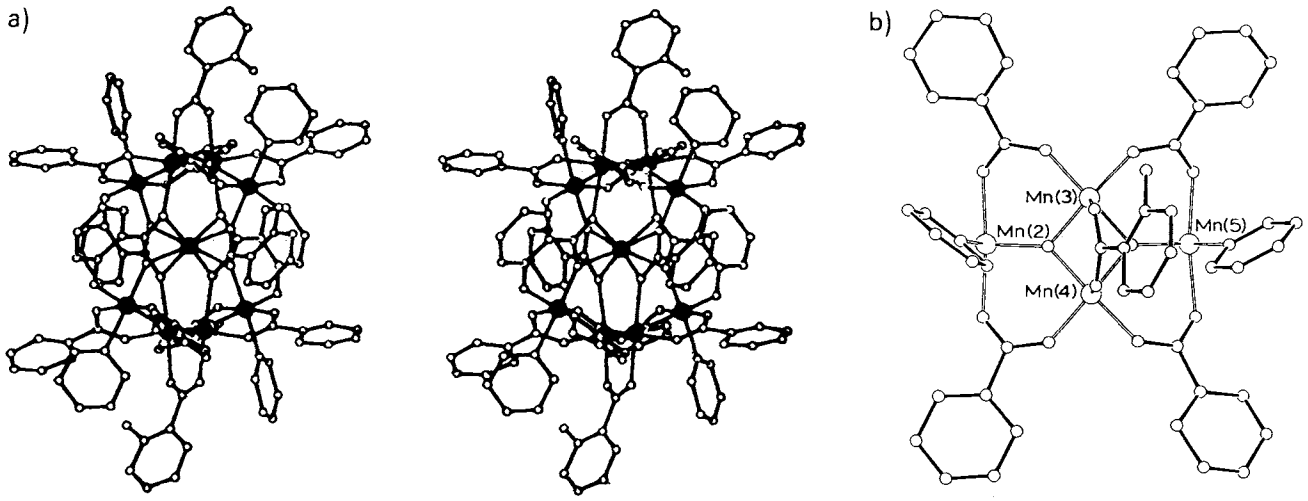

Fig. 2. a) Stereoview of the crystal structure of **1**. b) Top view of one end of complex **1** clarifying the structure of the $[Mn_4(\mu_3\text{-}O)_2]$ unit. Selected atomic separations: Mn(3)-Mn(4), 2.817(6); Mn(3)-Mn(2), 3.406(6); Mn(3)-Mn(5), 3.408(6); Mn(4)-Mn(2), 3.443(6); Mn(4)-Mn(5), 3.425(6); Mn(2)-Mn(5), 5.914(6) Å.

this complicated and relatively low symmetry molecule.[11]

In summary, trinuclear $[Mn_3O(O_2CR)_6L_3]$ complexes continue to prove useful as precursors to higher nuclearity species, and reaction with the bifunctional ligand salicylic acid leads to a convenient non-hydrolytic conversion to a discrete nonanuclear species with an unusual structure. In contrast to the octa- and undecanuclear Fe^{III} complexes, **1** is a mixed-valence compound containing Mn^{II} and Mn^{III}, as found for the recently reported hexanuclear species $[Mn_6O_2(piv)_{10}(pivH)_4]$ (pivH = pivalic acid).[12] It is interesting how these neighboring 3d metals exhibit similar, yet distinctly different, chemistry with such ligands, although it should be added that we have yet to investigate the reaction of salicylic acid with an $[Fe_3O]$-containing complex. Further studies in high nuclearity Mn/carboxylate chemistry are in progress.[13]

Synthesis and Structure of Compounds Containing Ditellurium *Side-on* Bonded to Nickel Complex Fragments

By *Massimo Di Vaira, Maurizio Peruzzini,* and *Piero Stoppioni**

There has recently been increasing interest in the chemistry of the heavier chalcogen atoms.[1] However, metal complexes containing Te ligands are extremely scarce, probably because of their instability and the limited propensity of tellurium to undergo concatenation, compared with the lighter chalcogens.[2] The Te_2 unit has been unambiguously identified so far in three compounds obtained by chance: a trimetal complex where the Te_2 unit is both terminally and *side-on* bonded[3] and two dimetal complexes where the unit is *side-on* bonded[4] or unsymmetrically[5] bridging. Stabilization of Te_2 in such compounds could be due to the presence of various shielding groups and bulky ligands. Very recently, the Te_3 cyclic unit has been identified in a tungsten carbonyl complex.[6]

We report here the synthesis of two monometal compounds containing less shielded Te_2 groups. These have been obtained by reacting a polytelluride solution and LNi^{II} fragments by a similar procedure to that already used to obtain the dinuclear Te_2 compound.[4] This may suggest a general approach to the synthesis of tellurium-rich transition-metal compounds.

The reaction of $Ni(ClO_4)_2 \cdot 6H_2O$ in the presence of the tridentate ligand 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) or bis(2-diphenylphosphinoethyl)phenylphosphane (ppp) with the stoichiometric amount of sodium telluride (prepared by reduction of tellurium with $NaBH_4$) affords the diamagnetic compounds **1** or **2**, respectively (Scheme 1), in good yield. The compounds are stable in the dark in the solid state and quite insoluble in organic solvents.

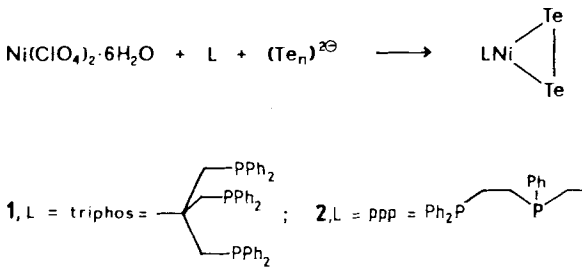
The X-ray structural investigations of **1** and **2**[7] showed that each contains one Te_2 unit coordinated as a bidentate ligand to the Ni atom, which is bound in addition by the



Scheme 1.

three P donor atoms of the L ligand. Figure 1 shows the structure of **2**. The metal atom achieves the 18-electron configuration if the Te_2 unit is considered to behave as a two-electron donor. The $NiTe_2$ fragment, which has practically identical dimensions in the two compounds, is almost perpendicular to the plane through the three P atoms (within 0.9° and 0.8° for **1** and **2**, respectively).

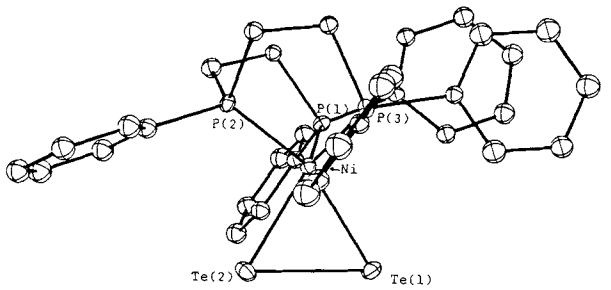


Fig. 1. Molecular structure of **2** (ORTEP). Selected bond lengths [Å] and bond angles [°]: Te1-Te2 2.668(1), Ni-Te1 2.557(2), Ni-Te2 2.555(2), Ni-P1 2.228(4), Ni-P2 2.136(3), Ni-P3 2.203(3); Te1-Ni-Te2 62.9(1), P1-Ni-P2 89.7(1), P1-Ni-P3 108.4(1), P2-Ni-P3 89.0(1).

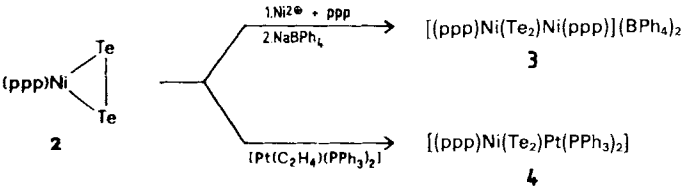
Although the Ni-Te distances in **1** and **2** (2.570(6) Å and 2.556(2) Å, respectively) are close to those (2.586(14) Å) found for the compound where the Te_2 unit is in a bridging position between two (triphos)Ni moieties,[4] the Te-Te distances in **1** and **2** (2.665(2) Å and 2.668(1) Å, respectively) are significantly shorter than that (2.802(1) Å) existing in this dimer. They compare better with the Te-Te bond length (2.686(4) Å) in the trimetal complex[3] and are slightly closer than the latter to the value for free Te_2 (2.59(2) Å),[8] probably because of the comparatively weak interactions with a single metal center.

The *side-on* coordination of the Te_2 unit should allow such a unit to react with other metal complex fragments and make it suitable for the construction of polynuclear complexes containing "naked" polytellurium ligands. Compound **2** indeed reacts with the [(ppp)Ni^{II}] moiety and with $[(PPh_3)_2Pt(C_2H_4)]$ yielding the dinuclear complexes **3** and **4**, respectively (Scheme 2), which are formed by insertion of an LM fragment (LM = (ppp)Ni or $(PPh_3)_2Pt$) into the Te-Te bond.



Scheme 2.

Experimental Procedure

All reactions and manipulations, except when otherwise stated, were carried out under purified nitrogen in the dark.

1/2: A clear red solution obtained by refluxing a stirred solution of tellurium (255 mg, 2 mmol) and $NaBH_4$ (75 mg, 2 mmol) in absolute ethanol (35 mL) for 6 h was added to a solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (365 mg, 1.0 mmol) in ethanol (10 mL) and the ligand (1.0 mmol) in THF (40 mL). The deep red crystals of compounds **1** (470 mg, 50% yield) or **2** (595 mg, 70% yield) separated out in a short time together with a small amount of light black powder; the amorphous precipitate was separated from the crystals by washing with ethanol.

3: A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (73 mg, 0.2 mmol) in ethanol (5 mL) and the ligand ppp (107 mg, 0.2 mmol) in CH_2Cl_2 (15 mL) was added to a suspension of **2** (170 mg, 0.2 mmol) in CH_2Cl_2 (25 mL); the resulting mixture was stirred for 1 h. Complex **3** (250 mg, 60% yield) was obtained as black crystals by adding $NaBPh_4$ (135 mg, 0.4 mmol) in ethanol (15 mL) and concentrating the resulting solution.

4: Solid $[(PPh_3)_2Pt(C_2H_4)]$ (150 mg, 0.2 mmol) was added to a suspension of **2** (170 mg, 0.2 mmol) in CH_2Cl_2 (25 mL) under ethylene (1 atm); the reaction mixture was allowed to stir for 30 min; compound **4** (94 mg, 30% yield) was obtained by adding benzene (10 mL) and concentrating the resulting solution under nitrogen.

All compounds gave correct elemental analyses (C, H, Ni, P, Te).

$^{31}P\{^1H\}$-NMR (32.19 MHz, CD_2Cl_2; standard: H_3PO_4 ext.): **3**: $\delta = 98.9$ (t, 1P, [NiP]), 54.5 (d, 2P, [NiP_2], $J(P\text{-}P) = 20.6$ Hz); **4**: $\delta = 109.7$ (t, 1P, [NiP]), 47.7 (d, 2P, [NiP_2], $J(P\text{-}P) = 43.8$ Hz), −5.6 (s, 2P, [PtP_2], $J(Pt\text{-}P) = 1527$ Hz).

Colloidal Bimetallic Catalysts: Pt–Au**

By *Paul A. Sermon,* John M. Thomas,* Kelei Keryou,* and *G. Robert Millward*

Two distinct but related topics constitute the subject of this communication: preparation and characterization of bimetallic colloidal sols which have not hitherto been reported; and the catalytic performance of these bimetallic particles of colloidal dimension after supporting them on graphite.

Monometallic colloidal sols are of ancient lineage[1] with those of Pt[2] and Au[3] receiving particular attention; and it has long been recognized[4] that they are potentially powerful catalysts. Effort is currently being expended in devising new ways of preparing and characterizing[5] such sols. However, as a result of their greater catalytic selectivity and resistance to poisoning, metal *alloys* are of increasing importance.[6] We have therefore explored sol routes to the preparation of bimetallic particles as they could have advantages over the traditional methods of co-impregnation, co-adsorption or co-precipitation. This approach to the production of uniform bimetallic particles of colloidal size has not, to our knowledge, been reported.

We chose $Pt_{100-x}Au_x$ ($0 < x < 100$) because of the wealth of catalytic knowledge on the respective monometallic sols[2,3] and also because, as x increases in bulk alloys of Pt and Au, the activity for hydrocarbon isomerization and hydrogenolysis decreases but activity for dehydrogenation increases.[7] These bimetallic sols were prepared by reducing mixed aqueous solutions of H_2PtCl_6 and $HAuCl_4$ (30 mg·dm^{-3} of each) with a 1% trisodium citrate solution at 373 K in a manner similar to that used for monometallic sols.[2,3,8] Their average particle sizes were found by electron microscopy to be larger than those predicted on the basis of differences in crystallographic lattice energies and surface energies. High resolution electron microscopy was used to examine the internal and surface structure[9] of these sols; the JOEL 200CX electron microscope employed having been fitted with an improved pole-piece and stage[5] with which a point-to-point resolution of 0.196 nm was achievable. The composition of the alloys was determined in two ways: *globally* by means of atomic absorption (AA) analysis of the digested sols and *locally* (2 nm diameter spot) from the intensities of the L_α X-ray emission peaks in a scanning transmission electron microscope (STEM). The catalytic activity of the colloidal particles, after they had been adsorbed onto graphite (Fluka, 99.9% purity) in a manner similar to that used recently[10] for Pt sols, was tested at 633 K in the hydrogenolysis, isomerization and dehydrogenation of *n*-butane and compared with a standard silica-supported Pt sample EuroPt.[11]

Several noteworthy features emerged. First, the individual colloidal particles possess a high degree of crystalline order (see Fig. 1a, b), with well-defined (111) and (200) planes present in sols of all compositions. Second, the size distribution of the sols at each composition is narrow (2.3 ± 0.9 nm, 4.8 ± 1.8 nm, 12.3 ± 1.4 nm, 14.3 ± 4.0 nm, and 24.7 ± 6.4 nm for $x = 0$, 10, 50, 90, and 100, respectively) and the average size increases progressively with Au content. Average radii computed from nucleation theory[12] assuming attainment of equilibrium are much smaller than measured average radii at all compositions. Third, no significant segregation of one metal with respect to the other was noted. Thus in sols prepared with the nominal composition corresponding to $x = 50$ (i.e. $Pt_{50}Au_{50}$) STEM analysis of nine individual particles of diameter 12.0 ± 0.1 nm

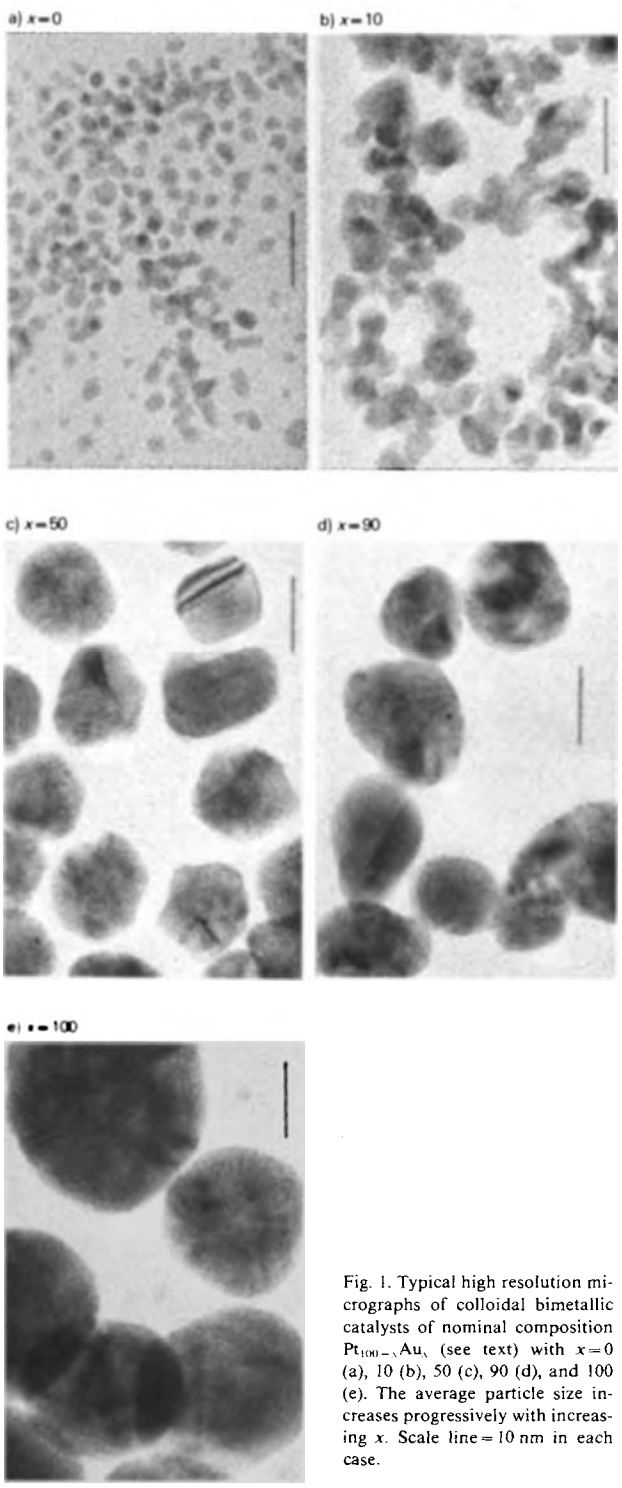

Fig. 1. Typical high resolution micrographs of colloidal bimetallic catalysts of nominal composition $Pt_{100-x}Au_x$ (see text) with $x = 0$ (a), 10 (b), 50 (c), 90 (d), and 100 (e). The average particle size increases progressively with increasing x. Scale line = 10 nm in each case.

Berger* (University of Cambridge) for his helpful assistance.

yielded an average composition corresponding to an x value of 47 ± 3. Particles in Pt-rich sols were somewhat less homogeneous than Au-rich ones. AA analysis revealed total Pt : Au ratios very close to those expected (i.e. for sols with $x = 10$, 25, and 50, Pt: Au ratios were found to be 9.0, 2.7, and 1.0, respectively).

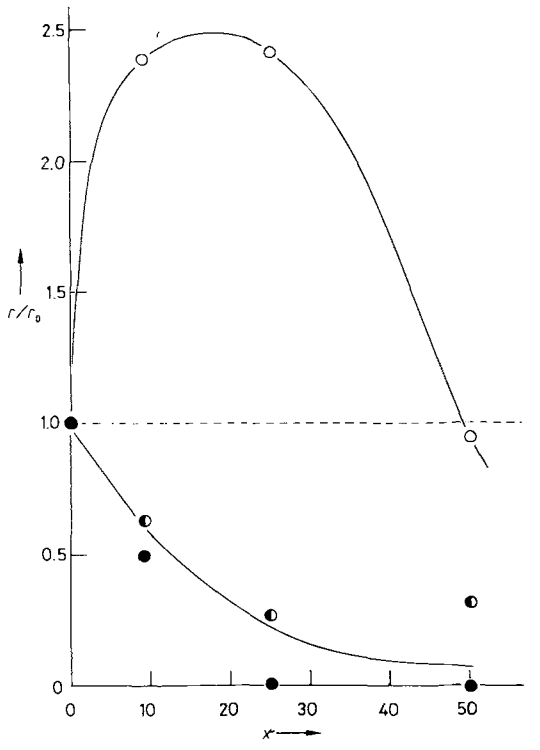

Fig. 2. Rates (r) of dehydrogenation (○), isomerization (◐), and hydrogenolysis (●) of n-butane over graphite-supported sol-derived $Pt_{100-x}Au_x$ particles relative to those exhibited when $x = 0$ (r_0).

Figure 2 shows that the activities of these supported sols towards the hydrogenolysis and isomerization of n-butane decreases steadily as their gold content increases and passes through a maximum. In broad terms these catalytic results are consistent with those for bulk Pt–Au[7] and Ni–Cu[13] alloys. As expected, addition of Au disrupts local Pt–Pt coordination thereby making the structure-sensitive hydrogenolysis[14] less favorable. However, structure-insensitive dehydrogenation, which is sustained on very small ensembles, is seen to be facilitated here. It is encouraging that these bimetallic particles of colloidal size show catalytic properties that can be related to those of the bulk alloys while at the same time offering considerable scope for fine-tuning of their specific performance. It is conceivable that alloys corresponding to the metal/metal oxide colloidal catalysts recently found[15] to be of value in the production of H_2 and O_2 from water might also be amenable to preparations of the kind adopted here.

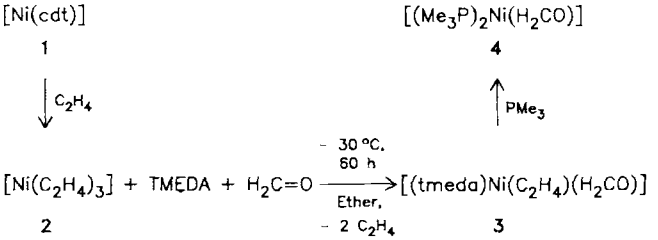
Synthesis and Structure of the Formaldehyde Complex [(tmeda)Ni(C_2H_4)(H_2CO)]**

By *Wolfgang Schröder, Klaus R. Pörschke,* Yi-Hung Tsay*, and *Carl Krüger*

Formaldehyde-transition-metal complexes[3] are attracting increasing interest[4] as conceivable intermediates of the Fischer-Tropsch synthesis,[2] but so far it has not been possible to prepare a nickel complex of this kind despite endorsing MO calculations.[3b, 5a, b] We now report a formaldehyde complex of nickel(0) which also contains π-bonded ethene.[6]

The complex [Ni(C_2H_4)$_3$], **2**,[7b] which can be prepared from (*trans,trans,trans*-1,5,9-cyclododecatriene)nickel(0) [Ni(cdt)] **1**[7a] and ethene,[7b] reacts with TMEDA (= *N,N,N',N'*-tetramethylethylenediamine)[1] and paraformaldehyde at −30 °C slowly (60 h) to give, after filtration, an orange colored solution from which orange-red crystals of the formaldehyde complex **3** separate out in up to 35% yield at −78 °C.[8] The [tmeda)Ni^0] core binds two π-ligands, if they are comparatively weak acceptors.[1]



Solid **3** is sensitive toward oxygen and is stable only below −15 °C. At −78 °C the complex dissolves readily in THF and toluene but only moderately in ether and methanol. **3** reacts with CO at −78 °C with release of all ligands

to give $Ni(CO)_4$, and with 1,5-cyclooctadiene (cod) at $-20°C$ to give $Ni(cod)_2$. Up to the decomposition temperature in solution ($-20°C$), no reaction could be detected with hydrogen, ethyne, butadiene or butyllithium; with $LiAlH_4$, decomposition with separation of nickel takes place. Removal of the tmeda ligand by reaction with a stoichiometric amount of trimethylphosphane at $-20°C$ leads to $[(Me_3P)_2Ni(H_2CO)]$ **4** (yellow crystals; 25%);[9] in contrast, reaction of $[(Ph_3P)_2Ni(C_2H_4)]$ with paraformaldehyde (20°C) leads, with liberation of hydrogen, to the carbonyl complex $[(Ph_3P)_2Ni(CO)_2]$.[3b,6] A coupling of the ethene and formaldehyde ligands with formation of an oxametallacyclopentane[3d] has not been detected.

Spectroscopically, **3** is characterized by its IR, ^{1}H-NMR and ^{13}C-NMR spectra.[10] The C=O stretching vibration of **3** ($\tilde{\nu}=1605\ cm^{-1}$) is shifted relatively little to smaller wave numbers as compared to that of free formaldehyde ($\tilde{\nu}=1746\ cm^{-1}$);[11a] consequently, a "metallaoxirane" structure[3c] can be ruled out. In the 400-MHz ^{1}H-NMR spectrum ($-110°C$) the protons of the H_2CO ligand give rise to doublets at $\delta=4.58$ and 4.23 ($^2J(H,H)=21$ Hz); in the 75.5-MHz ^{13}C-NMR spectrum ($-120°C$) a signal for the C1 atom is observed at $\delta=82.3$ (t, $J(CH)=163$ Hz).[12] For the ethene ligand, all protons as well as the two C-atoms are nonequivalent at low temperature; however, only two of the four expected ^{1}H-NMR signals were observed at $\delta=2.07$ and 1.81; the ^{13}C-resonances occur at $\delta=46.2$ and 35.8. In the low-temperature NMR spectra the tmeda ligand gives rise to four ^{1}H-NCH_3- and four ^{1}H-NCH_2-resonances as well as different resonances for all six C-atoms.[10] Above $-110°C$, the ^{1}H-resonances of the H_2CO ligand, the ^{1}H- and ^{13}C-NMR signals of the C_2H_4 ligand as well as those of the tmeda-NCH_3 and the tmeda-NCH_2 groups coalesce so that one signal each is obtained for the respective ^{1}H- (200 MHz) and ^{13}C-nuclei at $-80°C$; the signal of the NCH_3 C-atoms is still broad. Accordingly, on increasing the temperature, the H_2CO- and C_2H_4-ligands rotate about the axes between the Ni center and midpoints of the C=O and C=C bonds, respectively, and a change in the conformation of the NCH_2CH_2N bridge occurs. The low-temperature NMR spectra of **3** are consistent with the given structure, which has been found for crystalline **3** (Fig. 1).

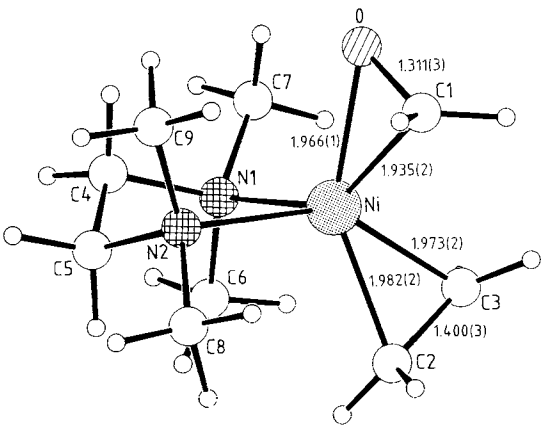

Fig. 1. Crystal structure of **3** [13].

The crystal structure analysis of **3**[13] revealed a pseudo-tetrahedral coordination of the nickel atom, whereby the geometry of the complex is defined by the midpoints (D1, D2) of the formaldehyde C=O and ethene C=C bonds (D1-Ni-D2 121.2°) and the two tmeda N-atoms. The interplanar angles are 84.2° for the Ni,N1,N2/Ni,C1,O planes, 77.9° for the Ni,N1,N2/Ni,C2,C3 planes, and 82.8° for the Ni,C1,O/Ni,C2,C3 planes. The Ni-N distances (2.144(1), 2.167(2) Å) and the Ni-C distances to the ethene ligand (1.973(2), 1.982(2) Å) as well as the C-C bond length (1.400(3) Å) of the latter are as expected.[14] The C=O bond of **3** (1.311(3) Å) is longer than that in uncomplexed formaldehyde (1.209(3) Å);[11e] its length compares with those of other formaldehyde-transition-metal complexes with short C=O bonds.[3b,f] Unlike the H_2CO-complexes of strongly oxophilic metals,[3a-c,e-g] the d^{10}-Ni complex **3** shows for the first time a short metal-carbon bond (1.935(2) Å), and a significantly longer metal-oxygen bond (1.966(1) Å). Intermolecular hydrogen bonding by interaction of the oxygen atom with methyl H-atoms of neighboring tmeda ligands (O···H 2.65-2.8 Å) must be taken into account as a contributory factor to the weak Ni-O bonding.

Trifluoromethyl Isocyanide as a Synthetic Building Block—Reaction with Trifluoroacetic Acid and with Hexafluoroacetone**

By *Dieter Lentz,* Irene Brüdgam,* and *Hans Hartl*

Trifluoromethyl isocyanide **1**[1] is of particular interest with respect to its ligand properties.[2] However, the synthesis of *N*-halomethylenetrifluoromethylamines[3] (*N*-trifluoromethyl)halomethanimines) from **1** and hydrogen halides has shown that **1** can also be used as a synthetic building block. This finding prompted us to employ **1** in two other typical isocyanide reactions.

N-Methylformamide was first prepared in 1869 by *Gautier* by the reaction of methyl isocyanide with acetic acid.[4] Its fluorinated analogue, $F_3C-NH-CHO$ **3**, on the other hand, has not been reported.

We have now succeeded in synthesizing **3** from **1**[1] and trifluoroacetic acid **2** [Eq. (a)]. Because **3** was expected to

$$\underset{\mathbf{1}}{F_3C-NC} + 2\,\underset{\mathbf{2}}{F_3C-COOH} \longrightarrow \underset{\mathbf{3}}{F_3C-NH-CHO} + (F_3CCO)_2O \quad (a)$$

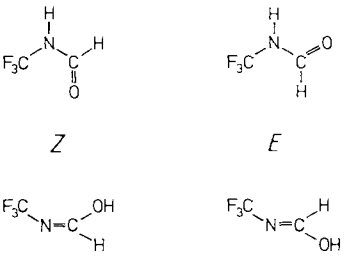
have a lower boiling point than that of *N*-methylformamide owing to the fluorine substitution, trifluoroacetic acid **2** was used as the carboxylic acid in order to facilitate the separation of **3**. Unexpectedly, in contrast to trifluoromethylamine, which already decomposes at its melting point (−21°C) to cyanogen fluoride FCN with elimination of HF,[5] **3** is surprisingly stable and can be distilled at 116°C without decomposition (for spectroscopic data see Tables 1 and 2).

Table 1. Spectroscopic data for the new compounds **3** and **7**.

3: IR (gas): $\tilde{\nu}$ = 3456 (m), 3244 (m), 3164 (m), 3051 (w), 2995 (m), 2928 (m), 2768 (w), 1762 (vs), 1744 (vs), 1502 (s), 1476 (s), 1470 (s), 1389 (s), 1302 (vs), 1253 (vs), 1200 (vs), 1176 (vs), 920 (s), 811 (w), 720 (m) cm^{-1}.—Raman (liquid): 3268 (w, br, p), 3127 (vw, p), 2934.5 (m, p), 2789 (vw, p), 1775 (w, p), 1727 (m, p), 1703 (vs, p), 1505.5 (w, p), 1408.0 (s, p), 1310 (w, p), 1255 (vw), 1159.5 (w, dp), 1031 (vw, dp), 924.5 (vs, p), 900 (vs, p), 812.5 (vs, p), 722 (vs, p), 589 (w), 552.5 (vw, dp), 474.5 (w, p), 427.5 (m, p), 375.5 (w, p), 254 (m, br), 195 (m, br) cm^{-1}.—MS (80 eV): *m/z* 113 ($M^{\oplus}$), 85 ($CF_3NH_2^{\oplus}$), 69 ($CF_3^{\oplus}$), 66 ($CF_2NH_2^{\oplus}$), 65 ($CF_2NH^{\oplus}$), 46 ($CFNH^{\oplus}$), 44 ($CH_2NO^{\oplus}$); high-resolution molecular ion: calcd. 113.0088, found 113.0086.

7: ^{19}F-NMR ([D$_6$]acetone, 84.25 MHz): δ = −50.5 (sept, J = 11.0 Hz), −51.9 (sept, J = 11.0 Hz), −54.6 (q, J = 12.8 Hz), −56.6 (q, J = 12.8 Hz), −72.3 (sept, J = 11 Hz).—^{13}C-NMR ([D$_6$]acetone, 67.925 MHz): δ = 94.9 (sept, ^2J(CF) = 37.4 Hz), 118.0 (q, ^1J(CF) = 267.0 Hz), 118.62 (q, ^1J(CF) = 267.0 Hz), 118.65 (q, ^1J(CF) = 266.3 Hz), 120.18 (q, ^1J(CF) = 290.72 Hz), 121.38 (q, ^1J(CF) = 258.1 Hz), 128.79 (s), 136.24 (s), 139.38 (q, ^3J(CF) = 8.8 Hz), 152.1 (s).—MS (80 eV): *m/z* 546 ($M^{\oplus}$, 6%), 527 ($[M-F]^{\oplus}$, 8), 477 ($[M-CF_3]^{\oplus}$, 19) and smaller fragment ions; high-resolution molecular ion: calcd. 545.9785, found 545.9746.

Besides the possibility of *E* and *Z* isomers, which have been well investigated for formamides[6] and are due to hindered rotation around the C–N bond, the possible existence of the isomeric *N*-hydroxymethylidenetrifluoromethylamine must be considered (Scheme 1).



Scheme 1. Possible structural isomers of **3**.

Table 2. NMR data for *Z*- and *E*-**3** in [D$_6$]acetone (89.55-MHz ^{1}H-, 84.25-MHz ^{19}F-, 22.49-MHz ^{13}C-NMR spectra).

	Z-3		*E*-3	
	δ	J [Hz]	δ	J [Hz]
^{1}H-NMR (−50°C)	9.29 (CH, q) 10.0 (NH, br)		9.71 (CH, d) 10.0 (NH, br)	$^3J(HH)_{trans}$ = 8.5
^{19}F-NMR (−50°C)	−57.1 (dd)	^3J(HF) = 3.7 $^4J(HF)_{trans}$ = 3.9	−55.0 (d)	^3J(HF) = 3.2
^{13}C-NMR (−90°C)	160.7 (CO)	^1J(CH) = 207.5 ^2J(CH) = 2.4	161.5 (CO)	^1J(CH) = 209.0 ^3J(CF) = 3.7
	119.0 (CF_3)	^1J(CF) = 259 ^2J(CH) = 2.4 ^3J(CH) = 11.0	120.3 (CF_3)	^1J(CF) = 258 ^2J(CH) = 2.4

A comparison of the NMR data in Table 2 with those of *N*-methylformamide[6] and *N*-methylenetrifluoromethylamines (*N*-(trifluoromethyl)methanamines)[3] shows that **3** exists primarily in the formamide form. For instance, all *N*-methylidenetrifluoromethylamines $F_3C-N=C(H)X$

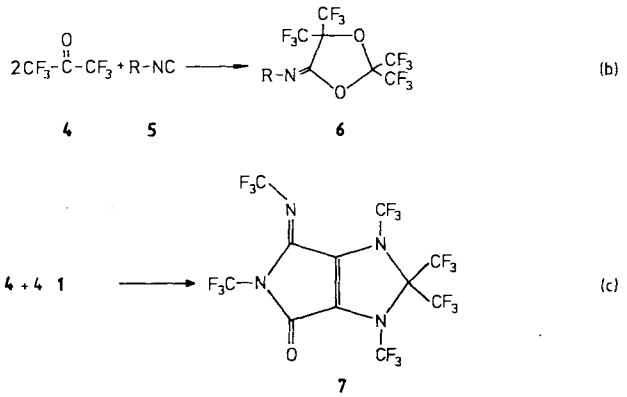
(X = F, Cl, Br), regardless of the relative orientation of the protons with respect to the CF_3 group, exhibit a coupling $^4J_{HF}$ of 1–1.5 Hz, which was not observed for the main isomers of **3**. Whereas the *Z* isomer predominates for *N*-methylformamide[6] and only the addition of the shift reagent $Eu(fod)_3$ leads to a noticeable shift in the equilibrium,[7] the relative stability of the isomers of *N*-trifluoromethylformamide is markedly solvent dependent (Table 3). In relatively nonpolar solvents, such as $CDCl_3$ or CD_2Cl_2, the *E* isomer predominates, in contrast to the case observed for the nonfluorinated compound. In [D_6]acetone, which, moreover, is a much better solvent than other solvents for **3** at low temperatures, the amount of the *Z* isomer increases dramatically. From the temperature dependence of the NMR spectra it is possible to determine the free energy of activation for the interconversion of the conformers *Z*/*E*-**3** ($\Delta G^{\neq} = 62$ kJ/mol^{-1}). The hydroxymethylidenamine form is of only minor importance. However, it can be detected in a triethylamine/[D_6]acetone solution by NMR spectroscopy.

Table 3. Ratios of the isomers of **3** in various solvents.

	% *Z*	% *E*
3	43.5	56.5
$CDCl_3$	26.3	73.7
CD_2Cl_2	26.3	73.7
[D_6]acetone	55.6	44.4

The formation of iminodioxolanes **6** from hexafluoroacetone **4** and isocyanides **5** [Eq. (b)][8] can be regarded as a typical isocyanide reaction. We were therefore surprised



when we isolated yellow crystals of **7** in high yield as sole product of the reaction of **4** with **1** [Eq. (c)]. On the basis of its spectroscopic data (Table 1) and elemental analysis, **7** has the composition $(CF_3NC)_4(CF_3)_2CO$. Despite extensive spectroscopic data, the structure of **7** could not be established. The crystal structure analysis[9] that was therefore carried out yielded a surprising result: **7** was identified as 4-oxo-1,2,2,3,5-pentakis(trifluoromethyl)-6-trifluoromethylimino-1,2,3,4,5,6-hexahydropyrrolo[3,4-d]imidazole (Fig. 1).

The two nearly planar, annelated five-membered rings (maximal deviation from the best planes 4.1 pm) form a mutual angle of 8.2(1.5)°. Both O1 and N2 lie almost in the ring plane. Only the *N*-bonded CF_3 groups are located slightly outside of the planes.

Only a few pyrrolo[3,4-*d*]imidazoles are known and these required multistep syntheses.[10] It was therefore very

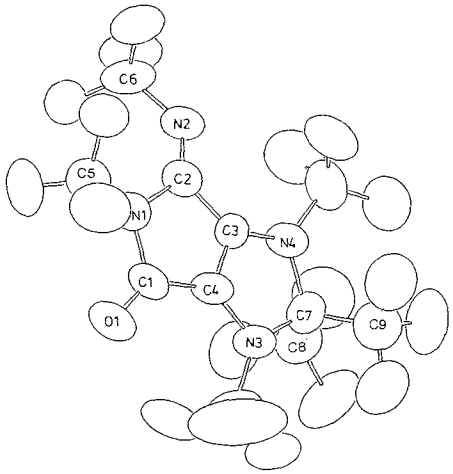


Fig. 1. Molecular structure of **7**. Important bond lengths [pm] and angles [°]: C1-N1 144(2), C1-O1 120(2), C1-C4 145(2), C2-N1 145(2), C2-N2 126(2), C2-C3 145(2), C3-N4 139(2), C3-C4 131(2), C4-N3 140(2), C7-N3 148(2), C7-N4 149(2), N1-C5 142(2), N2-C6 142(2), C-F 127–135(2); N1-C1-C4 103.9(9), C1-N1-C2 110.1(8), N1-C2-C3 102.9(9), C2-C3-C4 112.0(9), C1-C4-C3 111(1), N3-C4-C3 111(1), N4-C3-C4 110(1), C4-N3-C7 108.0(9), C3-N4-C7 108.3(9), N3-C7-N4 102.0(9), C8-C7-C9 112(1), C2-N2-C6 128(1), C2-N1-C5 127.3(9).

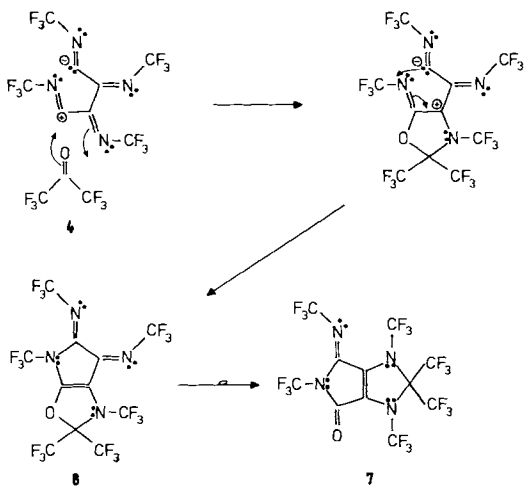
surprising to observe nearly quantitative formation of **7** from the simple starting materials **1** and **4**, a reaction involving the formation of several C–C bonds and the migration of the oxygen atom. Only speculation is possible as to the detailed mechanism of the reaction (Scheme 2). Compound **1** tends to form an α polymer $[F_3C-N=C]_n$.[11] Reaction of the oligomer of **1**, n = 4, with **4** could lead to the formation of **8**, which could then isomerize to the stable **7**; all reactions thereby occurring involve the formation of thermodynamically favored five-membered rings.



Scheme 2. Possible intermediates in the formation of **7** from **1** and **4**.

Experimental Procedure

3: Compound **1** (9.3 g, 98 mmol) was added in 14-mmol portions over 3 h to **2** (24 g, 210 mmol) in a 250-mL flask equipped with a PTFE stopcock and the reaction mixture was then stirred at room temperature. The volatile reaction products were condensed in vacuum into a 50-mL flask. Distillation through a 30-cm spinning-band column gave 5.1 g of **3** (46%); colorless liquid, b.p. = 116–118 °C, m.p. = – 16 °C. The small amount of **2** still present as an impurity could be removed by preparative gas chromatography (4-m SE 30, 15% on Chromosorb PAW, Ø = 10 mm; temperature program: 12 min 115 °C, 40°/min, 1 min 135°, 40°/min, 6 min 155 °C). In this way, 3.1 g of analytically pure **3** was obtained.

7: Compound **1** (1.5 g, 7 mmol) was condensed into a 250-mL flask equipped with a PTFE stopcock and containing **4** (0.66 g, 7 mmol). The flask was allowed to stand at room temperature. After 1-2 d, yellow crystals began to collect on the walls of the flask. At intervals of 2-3 d, 7 mmol of **1** was condensed three times into the flask. After a further 3 d of reaction, the readily volatile components (0.4 g) were distilled off at room temperature into a 100-mL flask equipped with a stopcock. Their vapor-phase IR spectrum showed exclusively the bands corresponding to unreacted **1** and **4**. The crystalline residue was dissolved in 100 mL of CH_2Cl_2. After removal of the solvent by rotory evaporation, sublimation was carried out in vacuum (10^{-2} mbar) onto a cold finger at -20°C. Yield: 3.6 g **7** (95%); yellow crystals, m.p. = 102°C.

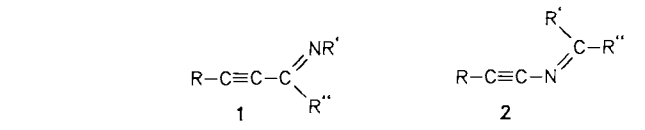
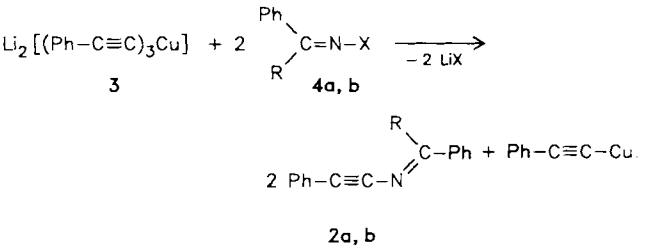
First Synthesis of *N*-Methylene-Ynamines (2-Azabut-1-en-3-ynes)**

By *Ernst-Ulrich Würthwein** and *Reinhard Weigmann*

Ynamines are highly reactive key substances for the synthesis of a great variety of acyclic and heterocyclic compounds.[1] Ynimines (iminoalkynes), wherein a C=N-function (instead of the NH_2-group as in ynamines) is bonded to a CC-triple bond, form *two* isomeric classes of compounds, of which only one, the propargylideneamines **1** (1-azabut-1-en-3-ynes), is known;[2] to our knowledge the isomeric *N*-methylene-ynamines **2** (2-azabut-1-en-3-ynes) have so far never been synthesized. We now report on an easy access to both classes of compounds, starting from alkynyl cuprates and imino derivatives.

The target molecules **2** are best prepared using alkynyl nucleophiles and imine electrophiles. The inverse strategy—alkynyl electrophiles and imine nucleophiles—yields the desired products **2** only in small amounts, because of the competing oxidative coupling of two alkynyl units to give bisalkynes; ynamines however are usually prepared using this approach. In our experience alkynyl cuprates of type **3** are the most suitable alkynyl nucleophiles.[3,4] Among the available imino compounds with electrophilic properties at the nitrogen atom, the *N*-halogenoalkylideneamines are not very useful because of their strong tendency to undergo side reactions. Better yields may be obtained using the oxime esters **4** of arenesulfonic acids,[5] which are sufficiently stable at lower temperatures.

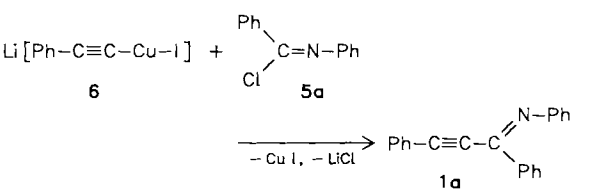




a: R = Ph, X = $OSO_2C_6H_4CH_3(p)$; **b**: R = CH_3, X = $OSO_2C_6H_5$

Reaction of **3** and **4** in diethyl ether at 20°C affords the new isolable compounds **2a** and **2b** as yellow and orange solids, respectively; they are stable in air for only a few hours.[6] In the IR spectra (KBr), the C≡C- and C=N-stretching vibrations appear at 2170-2180 and 1540-1560 cm^{-1}, respectively. The ^{13}C-NMR chemical shifts (25.15 MHz, $CDCl_3$, Standard TMS) of the three C-atoms of the C≡C−N=C-unit of **2a** are $\delta = 94.33$, 91.98, and 177.52, and thus do not show significant interaction (polarization) between the alkyne and imino part of the molecule.—Following the same procedure, alkyl, cycloalkyl, and trimethylsilyl substituted derivatives of **2** can also be synthesized, although they are generally less stable than **2a** and **2b**.

For clear analytical differentiation of the new compounds **2** from the isomers **1**, which, e.g., could have been formed by a Beckmann type rearrangement of the oxime ester **4** to the imidoyl compound **5** and subsequent coupling with **3**, we also synthesized the corresponding propargylideneamine **1a**. In analogy to a procedure described by *Bourgain* and *Normant*[2a] we obtained the stable substance **1a** upon reaction of *N*-phenylbenzimidoyl chloride **5a** with the alkynyl cuprate **6** (46%).[8] With the cuprate **3**, the yield of **1a** increases to ca. 60%; 1,4-diphenylbutadiene was identified as byproduct.



[*] Prof. Dr. E.-U. Würthwein, Dipl.-Chem. R. Weigmann
Institut für Organische Chemie der Universität
Orléansring 23, D-4400 Münster (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

If the reactions of oxime esters **4** and the cuprate **3** are carried out at 35 °C (diethyl ether, reflux) instead of 20 °C, compounds of type **1** can also be obtained (ca. 30% **1a**, together with small amounts of **2a**). Hence, the C/N regioselectivity of this reaction, leading to the isomeric products **1** and **2**, respectively, can be influenced remarkably by simple temperature control (mechanism: probably Beckman type rearrangement of an intermediate cuprate imine complex; see also Ref. [7]).

The spectroscopic data of **1a** are significantly different from those of **2a**: in the IR spectrum (KBr), the C≡C-stretching vibration is found at 2200 and the C=N-stretching vibration at 1560 cm^{-1}; thus both absorptions lie ca. 20 cm^{-1} at higher energy than those for **2a**, indicating higher bond orders in the C-C-C-N unit. The ^{13}C-NMR chemical shifts (25.15 MHz, $CDCl_3$, standard TMS) of the alkynyl carbons are 83.15 and 97.74, respectively, revealing strong polarization of the alkyne system; in analogy to the spectra of the corresponding 1-azabutadienes we assign the downfield signal to the terminal carbon atom. The absorption of the imine carbon atom is found at $\delta =$ 149.94.

According to quantum mechanical model calculations (ab initio 6-31G*//6-31G* basis set[9]) on the unsubstituted parent compounds of **1** and **2** (C_3H_3N), the isomer **1** with (*Z*)-C=N-H conformation is thermodynamically more stable ($E_{tot} = -169.70388$ a.u.) than **2** by 7.22 kcal mol^{-1}; the (*E*)-conformer of **1** is predicted to be higher in energy than the (*Z*)-form by ca. 0.8 kcal mol^{-1}. In **1** and **2** the C≡C- and C=N-bonds are almost equal in length (1.187–1.188 Å; 1.253–1.255 Å, respectively), but the charge distribution in the central skeleton of both systems is remarkably different: in **1**, both terminal atoms (N1 and C4) bear high negative charges, whereas C2 and C3 are less charged. In **2** however, alternating charge distribution is found with negative charges at N2 and C4 and positive charges at C1 and C3. This influence of the more electronegative nitrogen atom on the electron distribution in both systems is understandable from perturbation theory arguments.

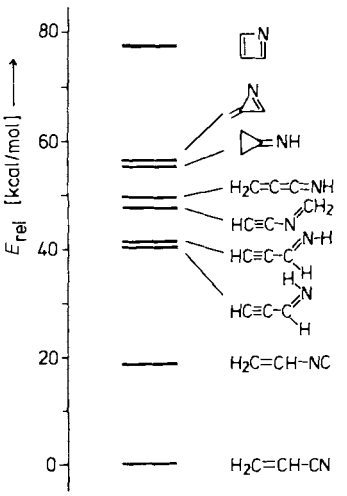


Fig. 1. Relative energies of selected C_3H_3N-isomers [kcal/mol] (ab-initio-6-31G*//6-31G*-results).

Among the substances with the molecular formula C_3H_3N there are some more interesting molecules: a comparison of the calculated total energies allows predictions to be made of the relative stabilities of these molecules (Fig. 1). The most stable isomer is acrylonitrile ($E_{tot} = -169.76801$ a.u., $E_{rel} = 0.00$ kcal mol^{-1}); vinyl isocyanide ($E_{rel} = 18.59$ kcal mol^{-1}) is clearly richer in energy. With a relative energy of more than 40 kcal mol^{-1} the unsubstituted compounds **1** and **2** have almost the high energy content of 1-azabutatriene ($E_{rel} = 49.41$ kcal mol^{-1}), probably combined with similar reactivity. The (*Z*)-form of **1** ($E_{rel} = 40.24$ kcal mol^{-1}) is the most favorable in this group of compounds, followed by the (*E*)-conformer ($E_{rel} = 41.09$ kcal mol^{-1}). **2**, with a relative energy $E_{rel} = 47.53$ kcal mol^{-1} is ca. 7 kcal mol^{-1} more energy-rich than **1**, reflecting the nitrogen perturbation on the wave function in the less favorable 2-position. The recently synthesized (as a tri-*tert*-butyl derivative) azacyclobutadiene[10] is by far the most energy-rich isomer among the closed shell molecules considered here ($E_{rel} = 77.73$ kcal mol^{-1}). The strained three-membered ring systems 2-methylene-2*H*-azirine and cyclopropenimine each assume intermediate positions ($E_{rel} = 56.07$ and 55.31 kcal mol^{-1}, respectively).

the pseudotetrahedral cation $[CpRe(NO)(CO)_2]^{\oplus}$ ($Cp = \eta^5$-C_5H_5) is possible using $NaBH_4$ in THF/H_2O. The formyl and hydroxymethyl intermediates, as well as the methyl complex, could be synthesized and characterized. In the complex $[CpRe(NO)(PPh_3)(CH_3)]$, the Re–CH_3 bond is cleaved by H–X or by X_2 (X = Cl, Br, I), resulting in the formation of $[CpRe(NO)(PPh_3)X]$ and CH_4 or CH_3X, respectively, with retention of configuration at the Re center.[2] The mechanism of these electrophilic M–C bond cleavage reactions has been suggested to involve protonation of the Re center, reductive elimination of CH_4, and rapid reaction of the 16-electron fragment with $X^{\ominus}$ to give $[CpRe(NO)(PPh_3)X]$. However, kinetic measurements have not been reported.

We recently synthesized the octahedral complex **1** (L = 1,4,7-triazacyclononane)[4] and have now found that **1** reacts with $NaBH_4$ in aqueous solution to give red, racemic **2**. Recrystallization of **2** from H_2O after addition of (1*S*)-(+)-3-bromo-8-camphorsulfonic acid monohydrate afforded enantiomerically pure **3** in 45% yield.

$[LRe(NO)(CO)_2](BF_4)_2$ **1**
$[LRe(NO)(CO)(CH_3)]BF_4$ **2**
$[LRe^*(NO)(CO)(CH_3)][(1S)\text{-}C_{10}H_{14}BrO_4S]\cdot H_2O$ **3**
$[LRe^*(NO)(CO)Cl][(1S)\text{-}C_{10}H_{14}BrO_4S]\cdot H_2O$ **4**
$\{[LRe(NO)(CO)]_2(\mu\text{-}CH_2OCH_2)\}I_2$ **5**
$[LRe(NO)(CO)(CH_2I)]BF_4$ **6**

The crystal structure analysis of **3**[5] reveals that the complex $[LRe^*(NO)(CO)(CH_3)]^{\oplus}$ has the *S* configuration[6] and that the three five-membered rings formed by the Re atom and the coordinated amine ligand have the ($\delta\delta\delta$) conformation (Fig. 1). Reaction of **3** with 1 M HCl smoothly leads to **4** and methane (> 80%) [Eq. (a)].[7]

$$[LRe^*(NO)(CO)(CH_3)]^{\oplus} + HCl \longrightarrow [LRe^*(NO)(CO)Cl]^{\oplus} + CH_4 \quad (a)$$

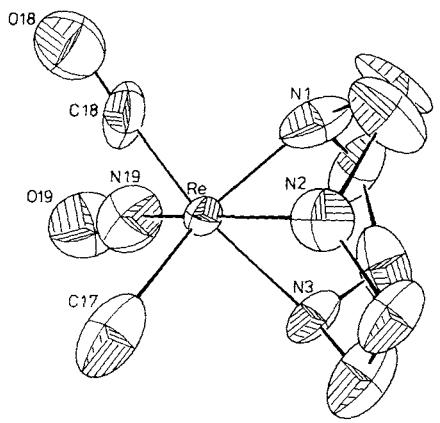

Fig. 1. Molecular structure of the cation of **3**. Selected distances [Å] and angles [°]: Re-N1 2.14(1), Re-N2 2.18(1), Re-N3 2.19(1), Re-C17 2.12(2), Re-C18 1.82(2), Re-N19 1.845(14), N19-O19 1.17(2), C18-O18 1.17(2); O19-N19-Re 173(1); O18-C18-Re 176(1).

The cation of **4** has the *R* configuration,[6] and the five-membered rings have the ($\delta\delta\delta$) conformation, as revealed by an X-ray structure analysis. Reaction (a) therefore proceeds with retention of configuration at the Re center.

From kinetic measurements of reaction (a),[8] the rate law (b) was obtained; this result is in agreement with a mechanism for which the rate-determining step is the reaction of the nucleophile $Cl^{\ominus}$ with a protonated species of the cation of **3** to give CH_4 and $[LRe(NO)(CO)Cl]^{\oplus}$ [Eqs. (c)–(e)]. If the protonation constant K_p is small ($\approx 10^{-2}$ M^{-1}), then, under the conditions selected, $K_p[H^{\oplus}] \ll 1$ and Equation (e) simplifies to Equation (b) with $k = k_1 \cdot K_0$ ($M^{-2}\ s^{-1}$).[8]

$$-d[3]/dt = k[H^{\oplus}][Cl^{\ominus}][3] \quad (b)$$

$$3 + H^{\oplus} \underset{}{\overset{K_p}{\rightleftharpoons}} [3H]^{\oplus} \quad (c)$$

$$[3H]^{\oplus} + Cl^{\ominus} \xrightarrow{k_1} [LRe(NO)(CO)Cl]^{\oplus} + CH_4 \quad (d)$$

$$-d[3]/dt = \{k_1 K_p[H^{\oplus}]/(1 + K_p[H^{\oplus}])\}[Cl^{\ominus}][3] \quad (e)$$

Interestingly, **3** does *not* react with 1 M $HClO_4$ at 25 °C if no other effective nucleophile is present; likewise, no reaction occurs at pH = 7 and 1 M $[Cl^{\ominus}]$. Reaction (a) therefore occurs only in the presence of protons *and* a suitable nucleophile. Three positions of the cation of **3** are possible sites for attack of a proton: (1) the electron-rich, low-valent Re center is protonated (formation of an Re–H species, followed by irreversible reductive elimination of CH_4 and addition of $Cl^{\ominus}$ to the 16-electron fragment formed as an intermediate; (2) Re–NO is protonated to give an Re–N(O)H species; (3) an N atom of the macrocycle is protonated after an Re–N bond is dissociatively broken. The nearly linear, extremely electron-poor Re–NO group in **3** is probably not available for the attack of $H^{\oplus}$;[9] the formation of an Re–H species and the reductive elimination of CH_4 in the rate-determining step is not in accord with the experimental rate law (moreover, the stability of **3** toward $HClO_4$ would not be explainable). We therefore propose a mechanism according to point 3 (Fig. 2), in

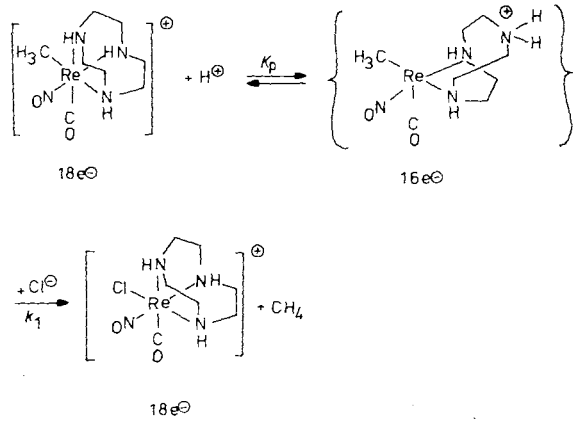

Fig. 2. Proposed mechanism for the substitution reaction (a).

which a 16-electron species is generated by acid-catalyzed cleavage of an $Re\text{-}N_{amine}$ bond. The $Re\text{-}N_{amine}$ bond involving the N atom that is *trans* to the CO ligand in **3** is the weakest. Attack of the nucleophile $Cl^{\ominus}$ and expulsion of $CH_3^{\oplus}$ (which undergoes immediate protonation) is then the rate-determining step, which is followed by rapid reformation of the $Re\text{-}N_{amine}$ bond.

Upon attempting to obtain single crystals of $[LRe(NO)(CO)(CH_3)]I$ from **2** in aqueous NaI solution exposed to the air, we surprisingly obtained, after about ten days, orange-red crystals of **5** in 40% yield. Complex **5** contains the previously unknown 2-oxapropane-1,3-diide bridge, $^{\ominus}CH_2\text{–}O\text{–}CH_2^{\oplus}$ (Fig. 3).[10]

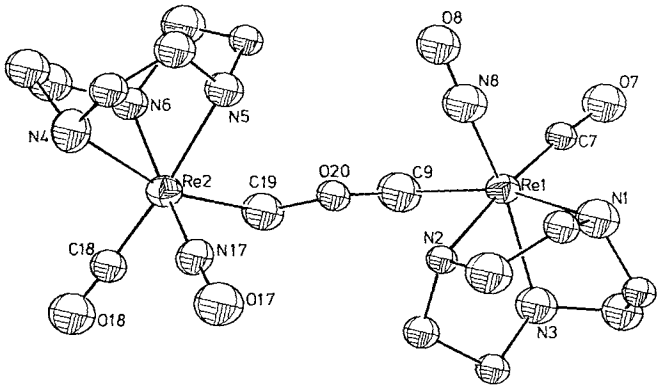

Fig. 3. Molecular structure of the cation of **5**. Selected distances [Å] and angles [°]: Re1-N2 2.19(2), Re1-N3 2.22(2), Re1-N8 1.77(3), Re1-N1 2.20(3), Re1-C7 1.83(3), Re1-C9 2.18(3), Re2-N4 2.20(3), Re2-N5 2.23(2), Re2-N6 2.09(2), Re2-N17 1.70(3), Re2-C18 1.83(2), Re2-C19 2.17(3), C19-O20 1.49(3), C9-O20 1.40(4), N8-O8 1.26(4), C7-O7 1.16(4), N17-O17 1.24(4), C18-O18 1.21(3); Re2-C19-O20 107(2), C19-O20-C9 113(2), O20-C9-Re1 111(2).

Complex **5** crystallizes in the acentric space group $P2_1$.[11] In the crystal investigated, both Re centers have the same configuration *R*,[6] and, in each case, the conformation of the coordinated 1,4,7-triazacyclononane ring is ($\lambda\lambda\lambda$). Thus, racemic resolution occurs spontaneously upon crystallization. Interestingly, the cation of **5** contains two weak N–H···O hydrogen bonds between the O atom of the bridge and one of the N–H groups of the two ligands L (N5···O20 2.98(2) Å; N2···O20 2.95(2) Å). In the solid, the cation is present as a relatively symmetrical rotamer. By examination of a model it is possible to show that an unsymmetrical rotamer of **5** can also exist which is characterized by hydrogen bonds from N2 and N6 to O20 or from N3 and N5 to O20.

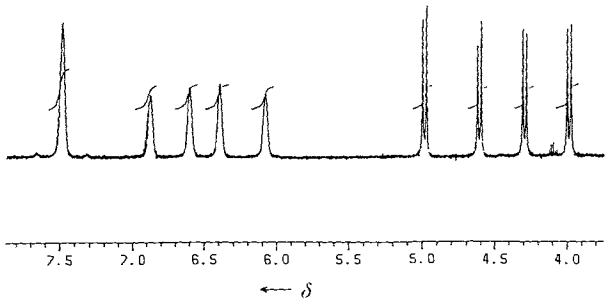

Fig. 4. Signals of the OCH_2 and NH protons in the 400.1-MHz ^{1}H-NMR spectrum of **5** in [D_6]DMSO.

The 400-MHz ^{1}H-NMR spectrum of **5** in [D_6]dimethylsulfoxide ([D_6]DMSO) (Fig. 4) exhibits chemically nonequivalent OCH_2 protons; i.e., the unsymmetrical rotamer is energetically favored in solution. Correspondingly, five N–H signals are observed, that at $\delta = 7.48$ corresponding to two protons. These signals disappear upon addition of D_2O; however, the exchange of the two H atoms whose signal appears at $\delta = 7.48$ is appreciably slower than that of the four other protons—an indication that the two weak intermolecular N–H–O hydrogen bonds are also maintained in solution.

The formation of **5** from **2** involves oxidation of the coordinated methyl group in **2**. It is known that aqueous solutions of **2** are indefinitely stable in the presence of O_2 but in the absence of iodide ions. Likewise, iodide-containing solutions of **2** are stable in the absence of O_2. Presumably, therefore, elemental iodine reacts with the Re–CH_3 unit in the first step to give Re–CH_2I (and $I^{\ominus}$), and this unit then undergoes hydrolysis in H_2O with dimerization to give **5**. The direct oxidation of **2** with I_2 (molar ratio 1 : 1) in dry ethanol gave **6**, which, in aqueous solution indeed reacts to give **5**. Complex **5** is also formed from **2** within 2–3 d after addition of I_2 dissolved in ethanol.

Experimental Procedure

2: Solid $NaBH_4$ (0.038 g, 1 mmol) was added to **1** (0.58 g, 1 mmol) [4] dissolved in 10 mL of H_2O at 20°C. Gas evolved and the solution turned red. Within 24 h, red crystals of **2** formed (ca. 75% yield). Recrystallization from CH_3CN. UV-VIS (H_2O): $\lambda = 496$ nm ($\varepsilon = 52$ L mol^{-1} cm^{-1}), 301 (423).—IR (KBr): $\tilde{\nu} = 1940$ cm^{-1} (CO), 1700 (NO).—^{1}H-NMR (400.1 MHz, CD_3CN): $\delta = 0.65$ (s, 3H; Re–CH_3), 2.70–3.50 (m, 12H; NCH_2), 4.76 (s, 1H; NH), 5.70 (s, 1H; NH), 6.10 (s, 1H; NH).—^{13}C-NMR (100.6 MHz, $CDCl_3$): $\delta = -10.2$ (Re–CH_3), 49.6–59.8 (6 signals, CH_2), 220.0 (CO).

3: (1*S*)-3-bromo-8-camphorsulfonic acid monohydrate (0.659 g, 2 mmol) dissolved in 5 mL of acetone was added to **2** (0.476 g, 1 mmol) in 10 mL of H_2O. Within 3 d, red needles of **3** crystallized (45% yield). CD spectrum (H_2O): $\Delta\varepsilon_{500\,nm} \approx -0.036$.

4: 20 mL of 37% HCl was added to **3** (0.72 g, 1 mmol) and the resulting solution was heated at reflux for 2 h. After concentration of the reaction solution to 10 mL, red crystals of **4** precipitated out within 2 d (92% yield). Recrystallization from H_2O/acetone. UV-VIS (H_2O): $\lambda = 486$ nm ($\varepsilon = 56$ L mol^{-1} cm^{-1}).—IR (KBr): $\tilde{\nu} = 1940$ cm^{-1} (CO), 1700 (NO).—CD spectrum (H_2O): $\Delta\varepsilon_{507\,nm} \approx -0.030$.

5: Method A: 5 mL of a cold, saturated aqueous solution of NaI was added to a solution of **2** (0.576 g, 1 mmol) in 10 mL of H_2O/acetone (1/1). The reaction mixture was then heated to 50°C. The resulting mixture was allowed to stand in the air, resulting in the formation, after 10 d, of orange-red crystals of **5**.

Method B: A solution of iodine (0.25 g, 1 mmol) in ethanol (5 mL) was added to a solution of **2** (0.576 g, 1 mmol) in 10 mL of H_2O. After 3 d of standing under normal atmosphere, the solution was filtered under suction to isolate crystalline **5**, which was then washed with a small amount of ether and allowed to dry in the air (yield obtained by the use of either method, 40% based on **2**.

UV-VIS (H_2O): $\lambda = 482$ nm ($\varepsilon = 89$ L mol^{-1} cm^{-1}).—IR (KBr): $\tilde{\nu} = 3060$ cm^{-1} (m, NH), 2750–2990 (br, w, CH), 1920 (s, CO), 1680 (s, NO).—^{1}H-NMR (400.1 MHz, [D_6]DMSO): $\delta = 4.98$, 4.62, 4.30, 3.99 (d, $J = 10.11$ Hz, 4H; μ-CH_2OCH_2), 6.08, 6.38, 6.62, 6.97 (s, 4H; NH), 7.48 (s, 2H; NH), 2.80–3.50 (m, 24H; NCH_2).—^{13}C-NMR (100.6 MHz, [D_6]DMSO): $\delta = 46.7$–53.8 (m; NCH_2), 71.7, 72.1 (μ-CH_2OCH_2), 220.11, 220.92 (CO).

6: I_2 (0.25 g, 1 mmol) in 10 mL of anhydrous ethanol was added under argon to a solution of **2** (0.576 g, 1 mmol) in 50 mL of anhydrous ethanol. The reaction mixture was stirred for 2 d at 22°C and the solvent was then removed. The product was washed with $CHCl_3$ and dried in the air (97% yield).

UV-VIS (CH_3CN): $\lambda = 361$ nm ($\varepsilon = 98$ L mol^{-1} cm^{-1}).—IR (KBr): $\tilde{\nu} = 1950$ cm^{-1} (s, CO), 1710 (s, NO).—^{1}H-NMR (400.1 MHz, CD_3CN): $\delta = 5.85$, 5.95, 6.11 (s, 3H; NH), 3.70, 3.87 (q, 2H; CH_2I), 2.90–3.52 (m, 12H; NCH_2).

All complexes gave correct elemental analyses (C, H, N, I, Re).

$[\{Co(Cp)_2\}\{CuI_2\}]_n$ (n = 3, 4), Cobaltocenium Iodocuprates(I) with Unusual Anion Structures**

By *Hans Hartl**

The series of compounds containing unusual iodocuprate(I) ions[1] has been extended by two examples involving cobaltocenium $[Co(Cp)]^{\oplus}$ ($Cp=\eta^5$-C_5H_5) as cation. Reaction of CuI with $[Co(Cp)_2]I$ in acetone leads to formation of the two homologous complexes, $[\{Co(Cp)_2\}\{CuI_2\}]_n$ with n = 3 (**1**) and 4 (**2**).

The tetranuclear, centrosymmetric anion $[Cu_4I_8]^{4\ominus}$ consists of two edge-linked CuI_4 tetrahedra; in addition, each tetrahedron shares a common edge with a nearly planar CuI_3 group (Fig. 1). In each case, the face of the CuI_3 unit is oriented with respect to a tetrahedral face in such a way that a strongly distorted tetrahedral coordination results for the copper atom (Cu2). This arrangement of the iodine atoms permits the following, alternative description of the anion structure: The eight iodide ions form two edge-linked trigonal bipyramids. Two of the four Cu^I ions are located at the centers of the two inner iodine tetrahedra and the two others, owing to spatial limitations, are each shifted toward a face of the two external tetrahedra. Since the I–I distances within the CuI_3 units and the CuI_4 tetrahedra are nearly identical, the Cu–I bonds in the CuI_4 tetrahedra (average 269 pm) are significantly longer than those in the CuI_3 units (254 pm). The simultaneous existence of Cu^I of coordination numbers 3 and 4 in a single anion is evidence that the transition of Cu^I from a tetrahedral hole to the planar arrangement CuI_3 is sterically easily possible; this also means, however, that Cu^I ions can migrate through the triangular faces formed by iodide ions without major deformations of the iodine framework, as is required for solid ion conductors based on iodocuprates(I).

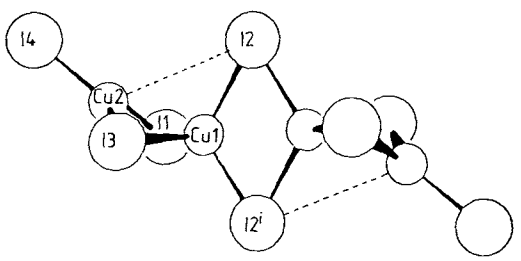

Fig. 1. Crystal structure of the anion $[Cu_4I_8]^{4\ominus}$ [5, 7]. Selected bond distances [pm] and angles [°]: Cu1-I1 270.3(3), Cu1-I2 265.3(2), Cu1-I3 276.1(2), Cu1-I2^i 269.0(3), Cu2-I1 258.0(2), Cu2-I3 255.1(2), Cu2-I4 248.6(2), Cu2···I2 408.7(3), Cu···Cu 269.0(3) and 271.0(3); I-Cu1-I 106.88(8)–118.51(9), I-Cu2-I 117.25(9), 117.62(9), 124.66(9).

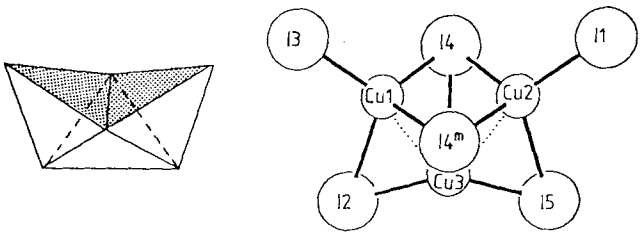

Fig. 2. Crystal structure of the anion $[Cu_3I_6]^{3\ominus}$ [6, 7]. (Left: polyhedron model. Right: Sphere model.) Selected distances [pm] and angles [°]: Cu1-I2 292.2(5), Cu1-I3 251.9(6), Cu1-I4, Cu1-I4^m 271.7(4), Cu2-I1 250.5(5), Cu2-I4, Cu2-I4^m 272.3(4), Cu2-I5 291.1(6), Cu3-I2 252.9(6), Cu3-I5 253.5(6), Cu3-I4 275.7(8), Cu3-I4^m 320.5(8), Cu3···Cu1 251.9(6), Cu3···Cu2 251.8(6), Cu1···Cu2 317.8(6); I-Cu1-I 100.1(1)–116.7(2), I-Cu2-I 100.2(1)–116.6(2), I-Cu3-I 95.3(3)–136.7(3).

The trinuclear anion $[Cu_3I_6]^{3\ominus}$ contains three face-sharing CuI_4 tetrahedra (Fig. 2). Although this structural unit has already been found as a component of an iodocuprate(I) chain $^1_\infty[Cu_3I_4]^{\ominus}$ and in the anion $[Cu_5I_7]^{2\ominus}$,[2] it was unknown as the isolated iodocuprate(I) ion. The structure of $[Cu_3I_6]^{3\ominus}$ can also be described in an alternative way: Two trigonal bipyramids formed from iodide ions are linked in such a way that they share a common iodine tetrahedron. Although the middle copper atom (Cu3) is displaced in the direction of a tetrahedral face, very short Cu–Cu distances (ca. 250 pm) result owing to the face sharing. Such short distances have been found repeatedly for comparable compounds in which this unusual face sharing of CuI_4 tetrahedra is observed (Cu–Cu distance in metallic copper: 256 pm). The short Cu–Cu distances raise the question whether Cu–Cu bonds in this anion play a role or whether the short distance is sterically forced upon the molecule by the threefold iodine bridging. By means of MO calculations on organocopper compounds, *Hoffmann* et al. have shown that bonds between Cu^I are possible by direct overlap of molecular orbitals.[3] The short Cu–Cu bonds in iodocuprates(I) might also involve indirect interactions between the metal atoms such as those assumed, for example, by *C. Haas*[4] for systems in which metal ions are surrounded by an easily polarizable medium—in this case, the iodide ions. The structures of the iodocuprates(I) are determined, above all, by the tendency of the iodine atoms to arrange themselves into the most energetically favorable spherical packings. These packings, in turn, form an easily polarizable matrix, in which the copper atoms oc-

[**] Synthesis and Structural Investigation of Iodocuprates(I), Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 6: [1].

cupy suitable holes. The nature of the packing and the occupation of the tetrahedral and triangular sites with Cu^{I} ions is influenced by the size, form, and charge distribution of the associated cations. Large cations favor, on the one hand, the formation of isolated iodocuprate(I) ions, since, by means of a kind of dilution effect, they hinder the condensation to give higher molecular units; on the other hand, large cations with low charge stabilize iodocuprate(I) ions that likewise have small charge density, i.e., a large $CuI/I^{\ominus}$ ratio and thus a high degree of condensation. Which of the two influences predominates depends on the relative concentrations and the solvent and precipitation agent employed in the synthesis. High concentrations and a large $CuI/I^{\ominus}$ ratio facilitate the crystallization of higher condensed and polymeric anions, whereas strong dilution and large cations favor the formation of lower-molecular ions. As the size of the cation decreases, the iodocuprates(I) become increasingly unstable and decompose to give the starting components CuI and iodide. An example is provided by the alkali-metal iodocuprates(I), whose stability decreases in the order $Cs^{\oplus} > Rb^{\oplus} > K^{\oplus} > Na^{\oplus}$. Due to its polarizability, the cation $[Co(Cp)_2]^{\oplus}$ is able to stabilize the relatively high negative charge of the anions $[Cu_4I_8]^{4\ominus}$ and $[Cu_3I_6]^{3\ominus}$. Electron delocalization effects or charge transfer processes of the type $Cu^{I} \rightarrow I^{\ominus} \rightarrow$ cation could play a role here. Diffuse reflection spectra and ESR measurements of iodocuprate(I) salts with other cations that are electron acceptors, e.g., *N*-methylpyridinium or dipyridiniomethane, show that such charge transfers are possible.[1b]

The packing of the anions and the cations in the crystals of both compounds confirms what has been found for all iodocuprates(I) investigated so far: The iodide partial structure and the structure of the cation are adjusted to each other in such a way that an optimal spatial packing is achieved. This simple principle of construction explains the structural variety of the iodocuprate(I) ions and suggests the possibility of obtaining other unusual structure types by suitable variation of the cation.

The cyclopentadienyl rings of the $[Co(Cp)_2]^{\oplus}$ ions are eclipsed and arranged parallel (largest dihedral angle 3.1°) in both compounds; in the different $[Co(Cp)_2]^{\oplus}$ ions of the two compounds, the distances of the cobalt atoms from the ring centers deviate by at most 2 pm from the calculated average value (163 pm); the Co-C distances are 202 ± 2 pm. Short intermolecular separations were not observed; one of the three crystallographically independent $[Co(Cp)_2]^{\oplus}$ ions in **1** is disordered.

Experimental Procedure

$[Co(Cp)_2]I$ (1.6 g, 5 mmol) and CuI (1.1 g, 6 mmol) were stirred in 150 mL of dry acetone for several hours. The reactions mixture was filtered and allowed to cool in the refrigerator (4°C), resulting in the precipitation of red-brown, column-shaped crystals of **2**. Additional **2** crystallized upon addition of $CHCl_3$. Slow addition of toluene resulted in the precipitation of **1**, in addition to **2**, with increasing dilution, in the form of thin, likewise red-brown, needle-shaped crystals. At the conclusion of the precipitation reaction, only a small amount of red-brown, leaflets of crystalline $[Co(Cp)_2]_2[CuI_3]$, containing the mononuclear, trigonal-planar anion $[CuI_3]^{2\ominus}$, were formed. Relatively pure **1** can be obtained by the addition of toluene to strongly diluted solutions containing seeding crystals of **1**.

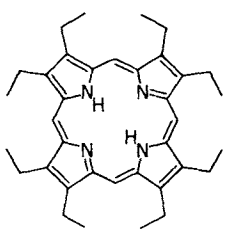
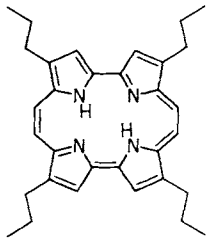
2,7,12,17-Tetrapropylporphycene—Counterpart of Octaethylporphyrin in the Porphycene Series**

By *Emanuel Vogel,* Metin Balci, Kakumanu Pramod, Peter Koch, Johann Lex,* and *Otto Ermer*

Octaethylporphyrin **1** [H_2(OEP)], first synthesized as early as 1929 by *H. Fischer*,[1] has in recent years acquired great importance as a model compound "par excellence" in the investigation of the porphyrins and metalloporphyrins.[2] In contrast to porphine and its metal complexes, whose study is impaired by solubility problems, many of the complexes derived from **1** are amenable to almost any physical and chemical investigations due to the propensity of the alkyl groups to promote solubilization and crystallization.[3] The symmetrical distribution of the substituents in **1** primarily serves to simplify the interpretation of the spectra, especially in the case of metal complexes.



1



2

The novel porphine structural isomer porphycene recently discovered in this laboratory[4] is actually more soluble than porphine, but metalloporphycenes, similarly to the metalloporphines, could hitherto only be obtained as microcrystalline powders, i.e. in a form unsuitable for X-ray structure analyses. With 2,7,12,17-tetrapropylporphycene **2**, a molecule exhibiting effective D_{2h} symmetry (NMR time scale), we now have found a porphycene derivative, which, in view of its properties, would seem predestined to play the role of a counterpart to H_2(OEP) in opening up porphycene chemistry. We report here on the syn-

The choice of a 2,7,12,17-tetraalkylporphycene – instead of the octaethylporphycene corresponding to **1** in its substitution pattern – as versatile representative of the new tetrapyrrolic macrocycle was compelling on steric grounds. As follows from model considerations on the porphycene system, 3,6- and 13,16-alkyl substitution lead to considerable non-bonding interactions between substituents, which can be expected to give rise to a more or less severe puckering of the ring skeleton and thus to perturbation of the porphycene chromophore. With the presence of four alkyl groups in the 2,7,12,17-positions, on the other hand, the planarity of the porphycene skeleton should essentially remain unaffected. The question as to what size these four alkyl groups should have in order to render the respective porphycene as comparably soluble as **1** could only be decided by experiment.

The synthesis of porphycene by reductive coupling of 5,5′-diformyl-2,2′-bipyrrole with low-valent titanium can be extended to various alkylated porphycenes. Treatment of the diformylbipyrroles **3**[5] and **4**[6] with titanium tetrachloride and activated zinc in the presence of pyridine in tetrahydrofuran (THF)[7] leads to formation of the tetraalkylporphycenes **6** and **7**, respectively (yields 2 and 4%, resp.), of which, however, even the tetraethyl compound does not have a solubility much better than that of unsubstituted porphycene. In contrast to this, the analogous synthesis of **2** from **5** represented a sort of breakthrough, for not only was **2** formed in considerably higher yield (10%), but it also exhibited a similar solubility and crystallizability as H_2(OEP). **2**, which is air-stable, affords violet needle-shaped crystals from *n*-hexane melting without decomposition at 192–194°C.

The absorption pattern and chemical shifts in the ^{1}H-NMR spectrum (300 MHz, $CDCl_3$) show that **2** is an aromatic porphycene with effective D_{2h} symmetry. The protons H-3,6,13,16 and H-9,10,19,20 of the porphycene skeleton appear as singlets ($\delta = 9.21$ and 9.62, resp.) at very low field (absorption region of corresponding porphyrin protons), whereas the N-protons give rise to a broad signal ($\delta = 3.04$) at relatively high field but are not as strongly shielded as the porphyrin N-protons ($\delta = -3$ to -4) because of the strong N–H···N hydrogen bonding. The protons of the propyl groups appear in the expected region. The simplicity of the spectrum is readily explained by a rapid NH-tautomerism in **2**, which is not noticeably slowed down even at -120°C.[8] Complementary to the ^{1}H-NMR spectrum, eight signals occur in the ^{13}C-NMR spectrum, all of which can be unequivocally assigned. Unlike the IR spectra of the porphyrins, the IR spectrum of **2** shows no NH-stretching vibration in the range of 3300–3360 cm^{-1}, thus supporting the conclusion already drawn from the ^{1}H-NMR spectrum that **2** contains strong N–H···N hydrogen bridges. As expected, **2** has a UV/VIS spectrum very similar to that of porphycene; the alkyl substitution largely manifests itself by the 1–10 nm bathochromic shift of the absorption bands.

According to an X-ray structure analysis (Fig. 1) **2** is present in the crystal as a centrosymmetric molecule with

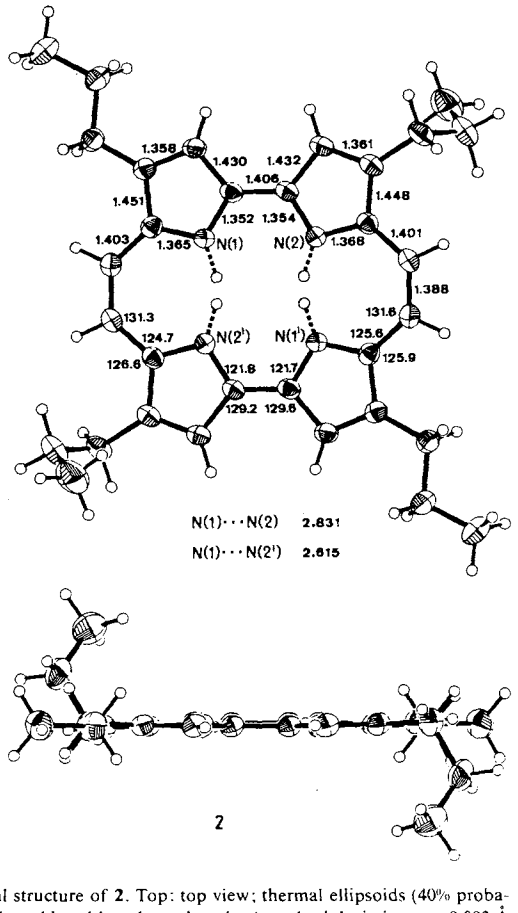

Fig. 1. Crystal structure of **2**. Top: top view; thermal ellipsoids (40% probability) and selected bond lengths and angles (standard deviations ca. 0.003 Å and 0.2°, resp.); inner hydrogen atoms disorded, see Figure 2. Bottom: side view. Crystals from *n*-hexane; monoclinic, space group $P2_1/c$, $Z=2$; $a=9.665(4)$, $b=5.343(2)$, $c=25.694(6)$ Å, $\beta=97.92(2)$°; $\rho_{calc}=1.210$ g cm^{-3}; intensity measurements on a four-circle diffractometer [room temperature, $\lambda_{Mo}=0.71069$ Å, $\theta_{Mo}(max)=27$°]; refinement (C,N anisotropic, H isotropic) including 1692 reflections with $F_0 > 4\sigma(F_0)$; $R=0.040$, $R_w=0.045$. For the two inner H atoms, four positions were refined with half-weights [9].

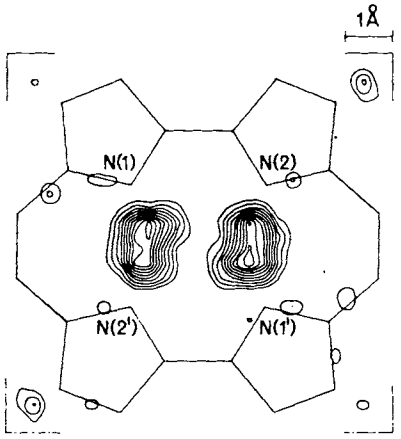

Fig. 2. Difference electron density map in the molecular plane of **2** (propyl substituents omitted). Contributions of all atoms subtracted, except inner hydrogen atoms; contours beginning with 0.05, intervals 0.025 $eÅ^{-3}$.

two pairs of conformationally different propyl groups. In accord with the model considerations, the planarity of the parent compound remains virtually unaltered in the porphycene skeleton of **2** (maximum deviation of the C- and N-atoms from the mean plane: ±0.04 Å). The propyl groups cause only slight changes in bond lengths and angles at the sites of substitution.

The electron density distribution in the N_4 nucleus of **2** (Fig. 2) indicates that the N-hydrogen atoms are partly disordered; this precludes their assignment to individual pyrrole rings. The strong N–H···N hydrogen bonds already established spectroscopically are apparently asymmetric and therefore to be described energetically by double minimum potentials. A similar behavior regarding the localization of the N-hydrogen atoms is encountered in all porphycenes structurally characterized so far (the parent compound,[4a] 2,3-dihydroporphycene,[10] and 9,10,19,20-tetrapropylporphycene[11]).

The properties of **2** would suggest the possible existence of numerous metallotetrapropylporphycenes which should have the afore-mentioned advantages over the complexes of the parent compound. Since the cavity in the porphycene system is smaller than in the porphyrin system and since the orbitals of the lone pairs on the nitrogen atoms are not optimally oriented towards the center of the molecule it was to be expected that the tendency of formation and stability of the metalloporphycenes are generally lower than those of the corresponding metalloporphyrins. Experience gathered in the meantime with complexes of unsubstituted porphycene confirm this supposition.[4a] The good agreement of the distance between N and the center of the molecule in **2** (1.920 and 1.933 Å, resp.) and the NNi distances in square-planar nickel(II) complexes (normal value: 1.95 Å),[12] as a result of which the planar diamagnetic 2,7,12,17-tetrapropylporphycenatonickel(II) **8** should be very stable, encouraged us to test the complexation of **2** with divalent nickel as metal.

The metalation of **2** with nickel was achieved unproblematically by the acetate method[2b] in that the free ligand was heated under reflux with $Ni(OAc)_2 \cdot 4H_2O$ in acetic acid. On cooling the reaction mixture, **8** crystallized out. Recrystallization from ethyl acetate/dichloromethane (1:1) furnished bluish-violet needles; m.p. >300 °C (yield 89%).

The conversion of **2** into **8** is clearly visible in the spectra. In the ^{1}H-NMR spectrum of the complex, apart from the absence of the NH resonance of **2**, a slight high-field shift of the H-3,6,13,16 and H-9,10,19,20 signals (0.4 and 0.2 ppm, resp.) is observed, while in the ^{13}C-NMR spectrum the signals of two types of quaternary C-atoms, with some certainty those of C-1,8,11,18 and C-4,5,14,15, are shifted to lower field ($\Delta\delta = 6.3$ and 9.0 ppm, resp.). Particularly convincing is the mass spectrum of **8**.

According to an X-ray structure analysis (Fig. 3), the complex **8** – like the free ligand – is centrosymmetric in the crystal; this means that the nickel atom and the nitrogen atoms are coplanar. Furthermore, the porphycene skeleton as a whole proves, to a good approximation, to be planar (maximum deviation of the heavy atoms from the mean plane ±0.04 Å). The conformations of the propyl substituents are similar to those in the free ligand. Irrespective of the overall structural similarity of **2** and **8**, the introduction of nickel into **2** obviously distorts the porphycene skeleton considerably. The complexation most strikingly affects the edge lengths of the rectangle of the N_4 nucleus.

In the free ligand **2** (Fig. 1) the distance between N(1) and N(2) is about 0.22 Å greater than that between N(1) and N(2'), whereas conversely, in the complex **8** (Fig. 3)

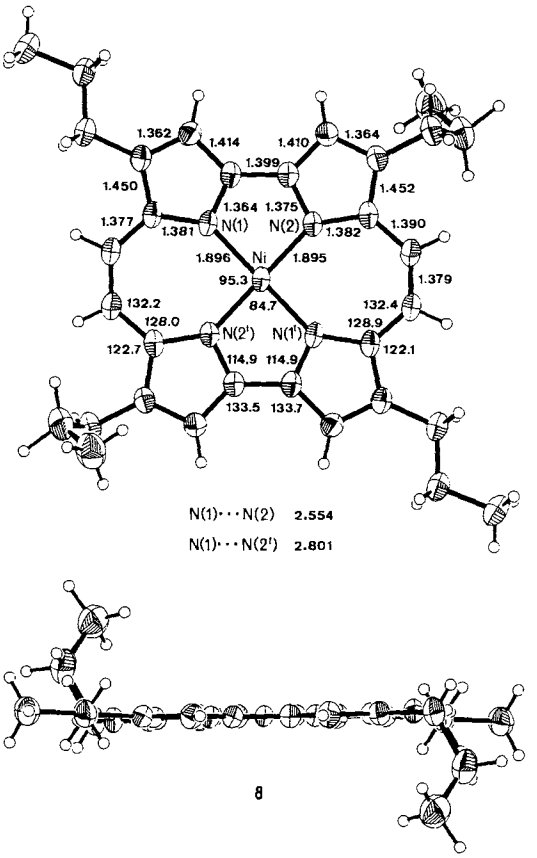

Fig. 3. Crystal structure of **8**. Same presentation as in Figure 1 (standard deviations ca. 0.004 Å and 0.3°, resp., for data involving Ni 0.002 Å and 0.1°, resp.). Crystals from dichloromethane/ethyl acetate; triclinic, space group $P\bar{1}$, $Z = 1$; $a = 5.308(1)$, $b = 9.893(1)$, $c = 12.647(2)$ Å, $\alpha = 98.97(1)$, $\beta = 94.42(2)$, $\gamma = 90.31(1)°$; $\rho_{calc} = 1.359$ g cm^{-3}; measuring conditions as for **2**; refinement (C, N anisotropic, H isotropic) including 2005 reflections with $F_0 > 4\sigma(F_0)$; $R = 0.039$, $R_w = 0.043$ [9].

the distance between N(1) and N(2') is found to be 0.25 Å greater than that between N(1) and N(2). The NiN distances (1.90 Å) are somewhat shorter than those in nickel(II)-porphyrin complexes.[13] Most likely, the geometric changes of the N_4 nucleus are to a large extent ensuing from a rotation of the pyrrole rings in the molecular plane (accompanied by considerable compression of the bond angles of the NCCN segments, Figs. 1 and 3), induced by the propensity of the metal to attain a stereoelectronically favorable square-planar coordination. The relatively long N(1)···N(2') and N(2)···N(1') distances are plausible if one takes into consideration that the two strong hydrogen bonds disappear on metalation.

In the crystal the complex **8** forms stacks of laterally displaced molecules at interplanar distances of 3.45 Å.

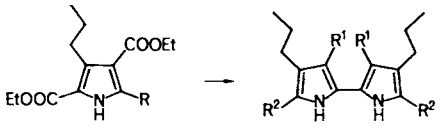
Physical data of the new compounds are listed in Table 1.

Experimental

2: 1.36 g (5 mmol) of **5** (see below) was added in one batch to a slurry of the titanium reagent (argon atmosphere), prepared from 9.5 g (50 mmol) of titanium tetrachloride and 6.55 g (100 mmol) of activated zinc in the presence of 2.5 mL of pyridine in 400 mL of tetrahydrofuran (THF), and the reaction mixture was then heated for 30 min under reflux. After hydrolysis with 125 mL of 10% aqueous potassium carbonate solution, repeated extraction with dichloromethane, and chromatography on silica gel (column: 5 × 20 cm) with dichloromethane/hexane (1:1), **2** was obtained as the only non-poly-

meric product. Recrystallization from *n*-hexane afforded fine, violet needles of m.p. 192–194 °C; yield 120 mg (10%).

5: The dipropyl derivative **5** was obtained for the first time analogously to the dimethyl derivative **3** according to the following reaction scheme [5, 14]:



9: [15] R = CH_3 — **12**: $R^1 = R^2 = COOEt$
10: R = COOH — **13**: $R^1 = R^2 = COOH$
11: R = I — **14**: $R^1 = R^2 = H$
5: $R^1 = H$, $R^2 = CHO$

9 → **10**: Br_2, SO_2Cl_2 in $CH_3COOH/HCOOH$, 0 °C, 4 h; H_2O (50–58%); **10** → **11**: KI/I_2 in $EtOH/H_2O$, 75 °C (75–77%); **11** → **12**: Cu, dimethylformamide (DMF), 20 °C, 17 h (62–71%); **12** → **13**: NaOH in $EtOH/H_2O$, 15 h reflux (96%); **13** → **14**: Sublimation at 230 °C, 0.2 torr (89%); **14** → **5**: $POCl_3$/DMF; NaOAc, H_2O (86%).

2,3-Dihydroporphycene—an Analogue of Chlorin

By *Emanuel Vogel,* Matthias Köcher, Metin Balci, Ilona Teichler, Johann Lex, Hans Schmickler,* and *Otto Ermer*

Responsible for the aromaticity of porphine, the parent compound of the porphyrins, is the presence of 18 π electrons in the main conjugation pathway (NH-bridged di-

[*] Prof. Dr. E. Vogel, Dipl.-Chem. M. Köcher, Dr. M. Balci, I. Teichler, Dr. J. Lex, Dr. H. Schmickler, Prof. Dr. O. Ermer

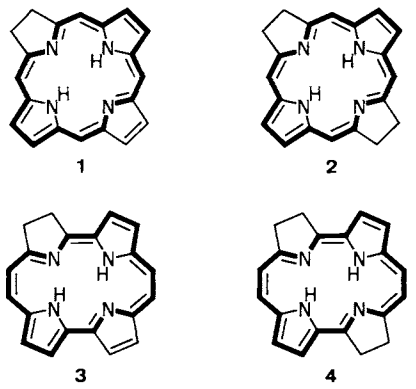
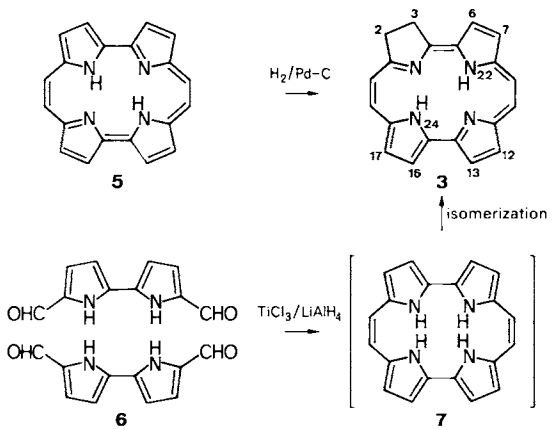
aza[18]annulene).[1] This supposition would further explain why chlorin **1**[2] – the parent system of chlorophyll – and bacteriochlorin **2**,[3] in which respectively one and two of the peripheral double bonds are hydrogenated, likewise exhibit aromatic character.



The same structural relationship formally exists between the novel porphine-isomer porphycene **5**[4] and its dihydro and tetrahydro derivatives, the compounds **3** and **4**, respectively, as in the series porphine – **1** – **2**. Having established by spectroscopic and structural investigations that porphycene and porphine exhibit essentially the same type of bonding, especially with regard to the π-electron structure, it followed that **3** and **4** should be regarded as "chlorin- and bacteriochlorin-analogues". The synthesis and properties of **3** reported in the sequel lend support to this interpretation.

Porphycene **5** (10 mg) on catalytic hydrogenation with 10% Pd/C (10 mg) in ethyl acetate (20 mL) afforded, after 45 min, a mixture consisting of 2,3-dihydroporphycene **3** (80–90%) and the starting compound **5**. Attempts to achieve complete conversion by prolonging the reaction time led to reduced yields, presumably as a result of formation of labile, more highly hydrogenated products. The isolation of **3**, which could not be accomplished by normal chromatography, was finally achieved by preparative HPLC.[5] Upon recrystallization from ethyl acetate/cyclohexane (1:1), expediently carried out with the combined products of four HPLC runs, **3** was obtained as small violet rhombs (yield 20 mg; m.p. >300°C).



Surprisingly, the synthesis of **3** can also be realized, albeit in only 1% yield, if the reductive coupling of 5,5′-diformyl-2,2′-bipyrrole **6** by low-valent titanium, which leads to porphycene **5** when titanium tetrachloride/zinc in tetrahydrofuran (THF) is used,[6] is instead carried out with titanium trichloride/lithium aluminum hydride (likewise in THF).[7,8] An explanation for this result is provided by the assumption that both titanium coupling reactions proceed via the dihydroporphycene **7** (still to be detected), and that, in the presence of titanium trichloride/lithium aluminum hydride, the prototropic rearrangement **7** → **3** is more rapid than the dehydrogenation **7** → **5**. The possibility that **3** is formed via **5** could be ruled out by control experiments.

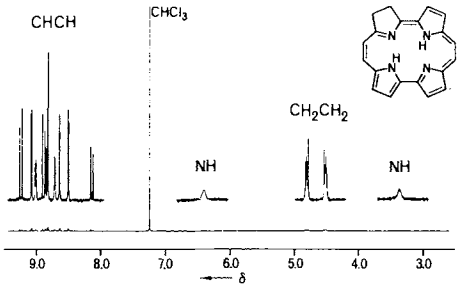


Fig. 1. ^{1}H-NMR spectrum of 2,3-dihydroporphycene **3** (300 MHz, $CDCl_3$).

The structure and the chlorin-like nature of **3** are confirmed by the spectra of the compound.[9] The ^{1}H-NMR spectrum (Fig. 1) shows: a) five AX systems in the region $\delta = 9.3$–8.2 which are easily recognizable by double resonance experiments and which by virtue of the coupling constants can be ascribed to the protons of the three pyrrolic ($J \approx 4$ Hz) and the two non-pyrrolic ($J \approx 11$ Hz) CHCH units, b) an AA′BB′ system at $\delta = 4.9$–4.6 (CH_2CH_2 protons), and c) two broad signals at $\delta = 6.45$ and 3.51 (each one N-proton; H22 and H24, resp.). Of the three AX systems of the pyrrolic protons, two are split further by coupling with an N-proton, from which it can be concluded that the N-protons each belong to a pyrrole ring. The appearance of the NH signals at relatively low field clearly indicates the presence of strong N–H···N hydrogen bonding (cf. the spectra of porphycenes[4,10]). With the aid of decoupling and NOE experiments it was possible to assign the spectrum completely (Table 1). On recording the spectrum at higher temperature (up to 75°C in C_6D_6) a noticeable broadening of the NH signals was observed, but the selective coupling of each of the N-protons to a specific pyrrolic CHCH proton pair remained unaltered. The NH tautomerism in **3** which, for geometric reasons, is presumably very rapid even at room temperature is, according to the NMR findings, apparently characterized by the fact that of the possible tautomers, predominantly one – namely **3** – is present.

Table 1. ^{1}H-NMR data (δ values and H,H coupling constants [Hz]) of 2,3-dihydroporphycene **3** (300 MHz, $CDCl_3$, saturated solution, room temperature).

	H2	H3	H6	H7	H9	H10	H12	H13	H16	H17	H19	H20	H22	H24
δ	4.64	4.94	8.91	8.54	8.90	9.24	8.64	9.08	9.03	8.75	8.91	8.24	6.45	3.51
J_{AX}			4.32		11.46		3.99		4.50		10.75			
$^4J_{A-NH}$			1.46	1.12					1.88	1.76				

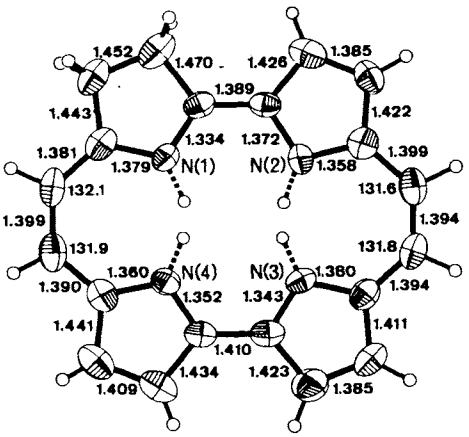
The relationship between the systems porphycene **5**/dihydroporphycene **3** and porphine/chlorin **1** manifests itself especially strikingly in the ^{1}H-NMR spectrum, for in

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1987 0570-0833/87/0909-0932 $ 02.50/0

both cases the transformation of the parent compound into the dihydro derivative results in the spectral centroid of the "arene protons" being slightly shifted to higher field [$\Delta\delta = 0.77$ (**5**/**3**) and 0.62 ppm (porphine/**1**)] and that of the N-protons being shifted downfield ($\Delta\delta = 1.83$ and 1.77 ppm).[11]

The UV/VIS spectrum of **3**, which shows three bands in the Soret region and a characteristic band pattern in the long wavelength region, is closely related to that of porphycene **5**. A pronounced increase in intensity of the longest wavelength band as in the spectrum of chlorin **1**[12] (relative to that of porphine) is not observed. Consistent with the stability and porphinoid nature of the compound, the mass spectrum (electron impact-ionization, 70 eV) exhibits $M^{\oplus}$ and $M^{2\oplus}$ as predominant peaks. The IR spectrum shows no bands for the NH stretching vibration (strong N–H···N bridges).

According to an X-ray structure analysis,[13] **3** has an almost planar ring skeleton (maximum distance of the C- and N-atoms from the central plane ± 0.09 Å; in porphycene ± 0.04 Å), like porphycene **5**, whereby the planarization of the partly hydrogenated pyrrole ring is likely to be attributed to the restricted torsional freedom about the two CN bonds.[14] The close similarity between **3** and **5** also expresses itself in other essential structural features such as the short N–H···N distances, the size of the cavity, and the widening of the CCC angles (to 132°) in the CHCH units linking the five-membered rings (Fig. 2).



N(1)···N(2)	2.843	N(2)···N(3)	2.632
N(1)···N(4)	2.668	N(3)···N(4)	2.846

Fig. 2. Crystal structure of **3**. Top: top view; thermal ellipsoids (40% probability) and selected bond lengths and angles (standard deviations ca. 0.004 Å and 0.3°, resp.); inner hydrogen atoms presumably disordered, see Figure 3. Bottom: side view.

From a difference electron density map in the plane of the molecule (Fig. 3) and from the shape of the thermal ellipsoids (Fig. 2) it can be concluded that the crystal structure of **3** is partially disordered. This affects, in particular, the two inner hydrogen atoms, which – other than is possible in solution, as shown by the ^{1}H-NMR spectrum – cannot be assigned to individual N-atoms. The electron density distribution in the N_4 nucleus would seem to indicate asymmetric hydrogen bridges, thus suggesting an NH tautomerism describable by double minimum potentials. In the case of porphycene and porphine, such potentials could in the meantime be unequivocally confirmed by solid-state ^{15}N-NMR measurements.[15]

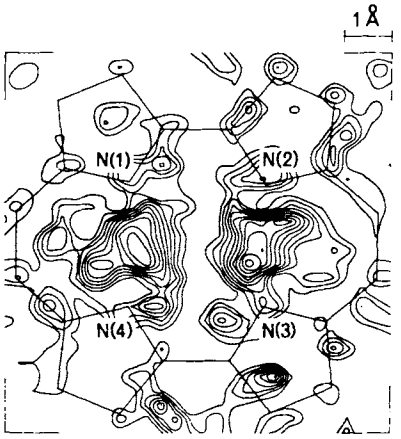


Fig. 3. Difference electron density map in the molecular plane of **3**. Contributions of all atoms subtracted except inner hydrogen atoms; contours beginning with 0.05, intervals 0.025 eÅ^{-3}.

From Figure 3 it is evident that there are a number of residual density maxima remote from atoms or chemical bonds. These maxima may be ascribed to an additional disorder effect, originating in the fact that, apart from the predominant orientation of the molecule, at least one further orientation rotated in the plane of the molecule is present. The unexpected finding that the CC single bond of the partly hydrogenated pyrrole ring is 0.09 Å shorter than normal, whereas the CC bonds of the three pyrrolic CHCH units are 0.04 Å longer than those in porphycene might be attributed to similar effects. An analysis of the anisotropic temperature factors in terms of rigid-body-motions is also in line with such an interpretation of the bond lengths.

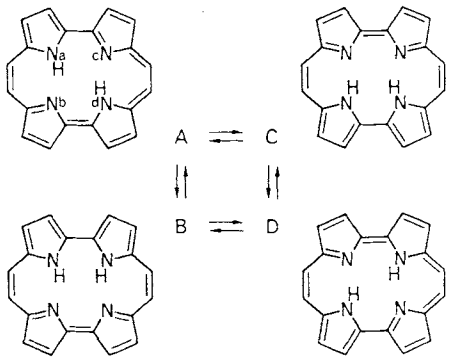
1

Scheme 1. Tautomerism of Porphine 1.

Whereas double minimum potentials have been found by dynamic NMR spectroscopy for dissolved[3] and crystalline[4,5] porphyrins the problem of tautomerism in crystalline porphine 1 has not yet been solved. Two X-ray structure analyses of 1[6,7] also indicate a double minimum potential but are contradictory with respect to the phenomenon of order or disorder of the inner hydrogen atoms.



2

Scheme 2. Tautomerism of Porphycene 2.

^{15}N-CPMAS-NMR Study of the Problem of NH Tautomerism in Crystalline Porphine and Porphycene**

By *Bernd Wehrle, Hans-Heinrich Limbach,* Matthias Köcher, Otto Ermer,* and *Emanuel Vogel**

In contrast to porphine 1 (Scheme 1) and many of its derivatives the novel porphine isomer porphycene 2[1] (Scheme 2) is distinguished by the presence of strong N–H···N hydrogen bonds and by an apparently extremely fast NH tautomerism, as indicated by the ^{1}H-NMR and IR spectra of 2. This finding agrees with model considerations because the compound can obviously be formally classified with respect to the arrangement of the N–H···N groups and the short NN distances as a double seven-membered ring H-chelate.[2] Similarly as in the case of such chelates it is also difficult to establish for 2 whether the inner H-atoms are located in a single minimum potential or whether they move along a double minimum potential. An X-ray structure analysis of 2 – although subject to some uncertainties with regard to the position of the H-atoms – indicates a multiple minimum potential.[1]

In view of the experimental[3–8] and theoretical[9] importance of NH tautomerism in the chemistry of porphyrins and related pyrrolic macrocycles we have now investigated the localization and transfer of the N-protons in 1 and 2 using variable-temperature high-resolution ^{15}N-CPMAS-NMR spectroscopy—which has already proven useful in the chemistry of macrocyles.[4,5,10,11]

Figure 1 shows a superposition of the experimental and calculated 9.12-MHz ^{15}N-CPMAS-NMR spectra of ^{15}N-enriched[13] 1 as a function of temperature. At low temperatures we observe a singlet at $\delta_{NH} = 107$ ppm for the imino and a singlet at $\delta_N = 215$ ppm for the azomethine nitrogen atoms.[14] As the temperature is raised the signals broaden and coalesce into one sharp singlet at 161 ppm. From these findings it follows that the proton transfer is very fast at room temperature, but "frozen" at low temperatures. A nitrogen atom m involved in a fast tautomeric process gives rise to a line m in the ^{15}N-NMR spectra at the position

$$\delta_m = p_m \delta_{NH} + (1 - p_m)\delta_N. \qquad (a)$$

p_m is the average proton density on atom m. The observation of only one average line at $\delta = (\delta_{NH} + \delta_N)/2$ means, therefore, that all nitrogen atoms in crystalline 1 are characterized within the margin of error by the same average proton density $p = 1/2$. This result contradicts the proposition of localized inner H-atoms,[7] but supports a disordered structure with two tautomers of almost equal energy[6] shown in Scheme 1. Such a symmetric situation is, however, the exception[4,5,10] rather than the rule, and has

been observed so far only in the case of *meso*-tetratolylporphyrin (TTP).[4, 15] In the case of triclinic *meso*-tetraphenylporphyrin (TPP) it was found by ^{15}N-CPMAS-NMR spectroscopy that the equilibrium in Scheme 1 was disturbed by crystal effects.[4] By simulation of the experimental spectra (Fig. 1) in the temperature range between 200 and 350 K an energy of activation of 39 kJ mol^{-1} and a frequency factor of 10^{11} s^{-1} were obtained for the exchange in Scheme 1. These values agree well with those found previously for dissolved TPP[3] and crystalline TTP.[4] It is still unclear as to whether the proton motion in **1** takes place along a synchronous pathway or along an asynchronous pathway via tautomers with protons on adjacent nitrogen atoms, and as to whether each inner proton migrates between only two or - as in solution[3] - between all four nitrogen atoms.

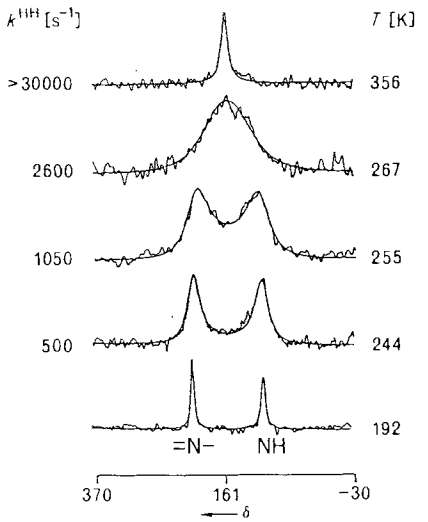

Fig. 1. Superposed experimental and calculated ^{15}N-CPMAS-NMR spectra of 95% ^{15}N-enriched porphine **1** at 9.12 MHz as a function of temperature. 3 to 6 ms CP-time, 7 kHz spectral width, 2.1 s repetition time. Reference: external $^{15}NH_4Cl$. The spectra were obtained with a Bruker CXP-100 NMR spectrometer equipped with a Doty-spinner [12] and a low temperature heat exchanger described previously [5]. k^{HH} is the rate constant of the tautomerism in a symmetric double-minimum potential. The additional simulation parameters, $W_0(N) = 57$ Hz and $W_0(NH) = 75$ Hz (halfwidth in absence of exchange) were taken from the low-temperature spectra.

A comparison of the ^{15}N-CPMAS-NMR spectra of **2** (Fig. 2) at elevated temperatures with the spectra of **1** surprisingly reveals virtually no differences, i.e. at high temperatures a very fast proton transfer apparently takes place not only in **1** but also in **2**. However, in contrast to **1**, **2** does not show line-broadening as the temperature is lowered, i.e. no "freezing" of the proton motions, but a splitting into four sharp singlets a–d, which continously drift away from each other with decreasing temperature. The upfield shift of line a (and of d) matches the downfield shift of line b (and of c). This observation proves the presence of two non-equivalent asymmetric proton transfer systems

$$ab \equiv N_aH\cdots N_b \rightleftharpoons N_a\cdots HN_b$$

and

$$dc \equiv N_dH\cdots N_c \rightleftharpoons N_d\cdots HN_c$$

in which the exchange is still fast with respect to the NMR time-scale even at 107 K. The shifts of the signals with decreasing temperature can be explained in terms of Equation (a) with an increasing proton density p_a on atom a at the expense of the proton density p_b on atom b. The same is true for the system dc, where, however, the effect is less pronounced. Since temperature-dependent proton densities are characteristic for double- or multiple-minimum potentials one can, therefore, exclude the possibility of a single minimum potential for the inner hydrogen atoms of **2**. Note that in the case of a symmetric double minimum potential the proton densities are also independent of temperature, a fact which makes it very difficult in the case of symmetric molecules in the liquid state to distinguish between single- and multiple-minimum potentials by NMR. As shown here for **2**, this distinction is possible nowadays by CPMAS-NMR spectroscopic examination of the molecules in the solid state where symmetries are generally perturbed. In order to calculate values for K_{ab} and K_{dc} in terms of Equation (a) it is necessary to assume values of the unknown quantities δ_{NH} and δ_N. Since the high-temperature ^{15}N-NMR line positions of **1** and **2** agree exactly one can take these values in approximation from **1**. Thus, we obtain from the temperature dependence of K_{ab} and K_{dc} for the tautomerism of crystalline **2** the very small reaction enthalpies $\Delta H_{ab} = 0.69$ kJ mol^{-1} and $\Delta H_{dc} = 0.2$ kJ mol^{-1}, but no entropy differences, i.e. $\Delta S_{ab} \approx \Delta S_{dc} \approx 0$. It cannot be excluded that there are also small energy differences between the two tautomers in crystalline **1** which, however, cannot be observed because of severe dynamic line-broadening when the temperature is lowered.

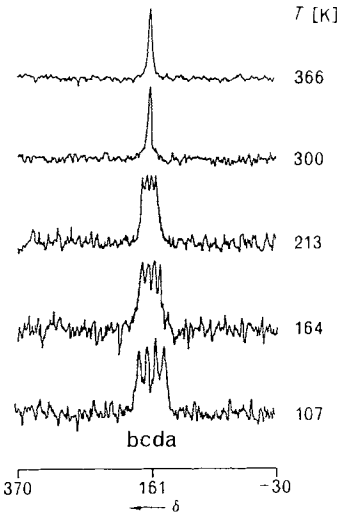

Fig. 2. ^{15}N-CPMAS-NMR spectra of 95% ^{15}N-enriched porphycene **2** at 9.12 MHz as a function of temperature. 6 ms CP-time, 5 kHz spectral width, 2.7 s repetition time. Reference: external $^{15}NH_4Cl$. Average number of scans: 1200. The low-temperature spectra were obtained with a pulse sequence for minimizing artifacts from long radiofrequency pulses [16] by which—as we find here—also acoustic ringing [17] is suppressed.

For an assignment of the nitrogen lines a–d in Figure 2 to atom positions in the unit cell two possibilities are consistent with the NMR spectra: (i) there are two non-equivalent porphycene molecules in the crystal at low temperatures, each of which contains either two equivalent ab or dc proton transfer systems, i.e. has access to only two tautomeric states; (ii) all porphycene molecules in the crystal are equivalent, but each molecule contains both proton transfer systems ab and cd, i.e. exists in all of the four fast interconverting tautomeric states A to B shown in Scheme 2. In both cases the degeneracy of the two tautomers with a

transverse arrangement and of those with a vicinal arrangement of the inner protons is removed in the crystal due to intermolecular interactions.[18] Since only one type of porphycene molecules is observed in the crystal at room temperature,[11] there is a high probability that case (ii) is realized.[19] If one further assumes that the state of lowest energy is characterized by a transverse arrangement of the inner hydrogen atoms one can, tentatively, assign the observed nitrogen lines to the atom positions shown in Scheme 2. The observation that $K_{ab}=p_b/p_a$ and $K_{dc}=p_c/p_d$ are different means that the proton motion in both proton transfer units is asynchronous. A similar situation has been found recently for a tetraaza[14]annulene derivative.[10]

We conclude that the two inner H-atoms in crystalline porphine **1** move with measurable rates in a double minimum potential which is symmetric within the margins of experimental error. In the seven-membered ring H-chelate porphycene **2** an energy barrier exists between the four NH tautomers, which, however, is very small because of the short NH···N distances. The pairwise equivalence of the tautomers is destroyed due to crystal effects. In contrast to the case of **1**, the mutual interconversion of the tautomers is, therefore, so fast that it is no longer possible to measure rate constants for the proton motion by lineshape analysis of the ^{15}N-CPMAS-NMR spectra.

[18] K_{ab} and K_{dc} are equilibrium constants in case (i). In case (ii), K_{ab} and K_{dc} are complex quantities which are related to the equilibrium constants K_{mn}, m, n = A, D of tautomerism by

$$K_{ab}=K_{AC}(1+K_{CD})/(1+K_{AB}); \quad K_{dc}=K_{AB}(1+K_{BD})/(1+K_{AC}).$$

[19] A differentiation of both cases by two-dimensional spin diffusion experiments as in the case of 5,14-dihydro-6,8,15,17-tetramethyl-5,9,14,18-tetraazadibenzo[*a,h*]cyclotetradecene(tetramethyldibenzotetraaza[14]annulene) [10] will be attempted in a future study.

BOOK REVIEWS

Ostwalds Klassiker der exakten Wissenschaften 265. Jacobus Henricus van't Hoff: Studien zur chemischen Dynamik (Etudes de dynamique chimique) 1884. Translated by *L. Dunsch*. Akademische Verlagsgesellschaft Geest & Portig, Leipzig 1985. 236 pp., paperback, DM 31.00.—

In the report "Opportunities in Chemistry" (the Pimentel Report, a successor to the Westheimer Report), published recently in the USA, the first item in a list of the most important chemical research tasks suggested for intensive study in the rest of this century is: "Understanding chemical reactivity (... clarification of factors that control the rates of reactions ... to sustain international leadership for the US at the major fundamental frontier of chemistry)". The award of the Nobel Prize for Chemistry last year to *D. Herschbach, Y. Lee* and *J. Polanyi* for their work on the dynamics of chemical reactions underlines this view of the importance of reaction kinetics.

J. H. van't Hoff's "Etudes de dynamique chimique" was published in 1884. These studies of the dynamics of chemical processes are probably the first comprehensive account of reaction kinetics. It is a happy circumstance that this classic work has now been published again (for the first time in German), and it provides a good opportunity to look back on 100 years of growth in the quantitative understanding of chemical reactions, an understanding which, as indicated above, is still open to much further improvement.

Van't Hoff's studies were published at a time when the atomic theory had become common ground to (almost) all chemists, and when thermodynamics was slowly beginning to establish a foothold in chemistry. The measurements by *Wilhemy* on the time-dependence of the inversion reaction in cane sugar, which constitute the first ever study of reaction kinetics in the modern sense, had been made about thirty years previously.

The book begins with a quantitative description of the time-scale of chemical reactions, under the following headings:

Normal reactions: unimolecular, bimolecular, multimolecular—in each case with examples of suitably chosen reactions from the known chemistry of the day, whose kinetics were carefully measured by the author and his collaborators, presented to the reader in such a way that he could follow the evaluation of the data.
Factors influencing reactions: a section which is still as relevant today as then, and from which *van't Hoff*'s working methods and experimental techniques come out especially clearly.
Applications: this section is concerned with "multimolecular" reactions and the use of rate measurements to derive reactant properties. In studying reactions of the type $4\,AsH_3 \rightarrow As_4 + 6\,H_2$, it occurred to *van't Hoff* that "the majority of these (chemical) equations give only a very distorted idea of the mechanism of the reaction ... and the actual mechanism is nearly always uni- or bimolecular". Unfortunately this point does not appear to have become more widely understood at the time.

The effect of temperature on chemical reactions, in terms of the (correct) thermodynamic expressions for temperature dependence of rate constants, is given in this section, and the essential features of the theory of thermal explosions are presented through discussion and diagrams. This too did not become a part of generally accepted knowledge until much later.

The second half of the book is concerned with chemical equilibria, vaporization equilibria, and other matters. Included here are the effects of external variables on such equilibria, and chemical affinity, topics which are still associated today with the name of *van't Hoff*. He introduced the use of twin arrows for describing a chemical equilibrium, to indicate "that the chemical reaction proceeds in two opposing directions simultaneously".

Many of *van't Hoff*'s ideas which are recorded in his "Etudes" were of a pioneering nature, and are now generally accepted knowledge, and some could have been written today. Just a few of these will be cited here, either literally or in summarized form. Time plays a special role in the chemist's thinking, it is usually not perceived. *Van't Hoff* thus concentrated on studying those reactions whose progress could be directly followed. "Reactions which occur in immediate succession or simultaneously make the process complicated, and these must be avoided in order to obtain a clearer understanding of reactions." He thereby defined a problem which still concerns reaction kineticists today. For simple reactions he states the important principle that "The progress of a chemical reaction is characterized entirely by the number of molecules whose interaction produces that reaction."

The extent to which he contributed to ideas about detailed reaction mechanisms does not emerge from the text of this book. In 1884 his papers on the size and shape of molecules had already been published ten years before. Possibly he held back from discussing this topic because conclusive experiments had only been carried out much more recently.

Since 1884 chemists have been able to obtain much further insight into the progress of chemical reactions. Numerous proposed models have been investigated, and in many cases have had to be rejected. The desire which is expressed in the Pimentel Report, perhaps almost impatiently, for more progress in "Understanding chemical reactivity", shows that *van't Hoff*'s view that "the understanding of chemical reactions has not yet been put on to such a firm basis as that of thermodynamics" is still relevant 100 years later. Nevertheless the prospects for attaining this objective have never been so good as they are today.

Herr *L. Dunsch* deserves praise for his translation, and for his explanatory notes to the German edition.

Aspects of Chemical Evolution. XVIIth Solvay Conference on Chemistry. Edited by *G. Nikolis*. Wiley, Chichester 1985. xvi, 286 pp., bound, £ 52.25.—ISBN 0-471-88405-7

The international physics and chemistry institutes founded in 1912 by the Belgian industrialist *Ernest Solvay* can be viewed as unique catalysts in the development of modern science. With a minimum of organization these famous institutes have succeeded again and again up to the present day in bringing together prominent scientists from every conceivable discipline to discuss their work, thereby providing a significant impetus for the progress of science.

The seventeenth Solvay Conference on Chemistry, which was held jointly with the US National Academy of Sciences on the occasion of the 150th anniversary of the Belgian state, was concerned with the current research situation in chemical evolution, a fundamental problem area of modern science, whose development has been greatly influenced by the theoretical work of the Director of the Solvay Institutes, Professor *I. Prigogine*.

This volume in the series "Advances in Chemical Physics" contains the lectures presented by the international experts, together with a brief look back at the history of the Solvay Institutes (*E. Amaldi* and *A. R. Ubbelohde*) and an introduction by *I. Prigogine* on the theme "Nonequilibrium Thermodynamics and Chemical Evolution". We find brilliant essays on "Atmospheric Chemistry" *(M. Nicolet)*, "The Prebiotic Synthesis of Organic Molecules and Polymers" *(S. L. Miller)*, "The Origin and Evolution of Life at the Molecular Level" *(M. Eigen)*, "Optimization of Mitochondrial Energy Conversions" *(J. W. Stucki)*, "Bifurcations and Symmetry Breaking in Far-from-Equilibrium Systems: Towards a Dynamics of Complexity" *(G. Nicolis)*, "Bifurcation in Insect Morphogenesis" *(S. A. Kauffman)*, and "Logical Description, Analysis, and Synthesis of Biological and other Networks Comprising Feedback Loops" *(R. Thomas)*. The volume also includes brief commentaries on problems of chirality, stochastic models, and oscillatory chemical systems. Altogether, this volume truly reflects the breadth of the interdisciplinary fields which are now involved in research on chemical evolution.

A Dictionary of Scientific Units. By *H. G. Jerrard* and *D. B. McNeill*. Chapman, London 1986. ix, 222 pp., paperback, £ 8.95.—ISBN 0-412-28100-7

Did you know the following?
that the name of the French physicist *Jean Baptiste Biot* (1774–1862) has been used no less than three times to describe physical quantities: 1. in the CGS electromagnetic system as the unit of electric current; 2. as a CGS unit of rotator strength, which is a quantity used in describing circular dichorism; 3. as a name for the dimensionless coefficient which characterizes heat transfer between a mobile fluid and a solid surface (now superseded by the Nusselt number)
that Kelvin is not only the name of the SI unit of temperature, but can also be used as a synonym for kilowatt-hour
that the centimeter can be an electromagnetic unit (10^9 cm = 1 henry), an electrostatic unit (9×10^{11} cm = 1 farad), or a unit of length (10^2 cm = 1 m)
that four names have been suggested for the unit of wave number: Balmer, Rydberg and Kayser for cm^{-1}, and permicron for μm^{-1}.

I did not know these facts before opening this dictionary of scientific units, dimensionless numbers, and scales of measurement. This book, having been originally published in 1963, is now appearing in its fifth edition, and contains definitions of more than 850 words, often with the addition of brief historical notes. The introduction reminds us that all non-electrical physical quantities can be defined in terms of the three fundamental mechanical quantities mass, length and time, while for electrical or magnetic quantities one additional quantity (current, permeability, or permittivity) is needed. This makes the existence of the vast number of units described in the dictionary all the more remarkable. Following the introduction there is a brief description of twelve systems that have been used in setting up units (e.g. the SI, British Imperial, and Stroud systems).

The main (dictionary) part of the book is followed by an appendix consisting of five sections: values of physical constants given to the degree of precision at present measurable; a list of committees and conferences which concern themselves with problems of standardization, each with a short paragraph on its history and responsibilities; a list of the common weights and measures units used in the USA and Great Britain; conversion tables between units of the following quantities: length, area, volume, angle, time, mass, force, power, energy (work and heat), pressure, resistance, capacitance, inductance, charge, current, potential, magnetic flux, flux density, e.m.f., magnetic field strength, light intensity, illuminance; conversion factors between units of the SI and CGS systems. Finally there follows a somewhat idiosyncratic, but nevertheless clearly arranged, bibliography.

Although the main emphasis in this dictionary is on physics, it also offers much more besides, as can be seen from this short selection of entries: Ångström, ionic strength, Miller indices, pH value, enzyme unit, Michaelis constant, osmolality, turnover number, amu (= Dalton) with the various reference masses used, Bohr magneton, quantum, clo (a unit used to specify heat transmission through a material, 1 clo = 0.154° $cm^2\ W^{-1}$), misery index (suggested by The Times for classifying rainy English summers), paper sizes (A, B, C; 0–6), pica, point (unit used in typesetting), screw threads, mesh size of sieves, trichromatic or T-coefficients (proportions of red, green and blue in a color).

I greatly enjoyed thumbing through this dictionary, but even so I must make two critical comments, the second of which is more serious than the first: 1. The authors' Anglo-Saxon origin is too evident in the book (a very detailed treatment of the "old" weights and measures units; for a unit such as the cubit only its value in inches is given). 2. Not much care has gone into preparing the index; for example, "henry" cannot be found on the given page numbers 113, 125, and 192, but appears instead on p. 188, which is not listed, "kilogram" is not on pp. 183 and 192 but instead is on p. 184, "grain" is not on p. 175 but instead on p. 177, "gauss" is not on pp. 189 and 192 but appears on the again unlisted p. 190. All of these incorrect listings relate not to the main entry for the word in question but, especially irritatingly, to the cross-references, which are sometimes much harder to find.

Despite these criticisms, I recommend this book to all those who encounter many different units in the course of their work, and also to everyone who wants to find a clearer way through the maze of units.

Molecular Beam Studies of Elementary Chemical Processes (Nobel Lecture)**

By Yuan Tseh Lee*

Introduction

Chemistry is the study of material transformations. Yet a knowledge of the rate, or time dependence, of chemical change is of critical importance for the successful synthesis of new materials and for the utilization of the energy generated by a reaction. During the past century it has become clear that all macroscopic chemical processes consist of many elementary chemical reactions that are themselves simply a series of encounters between atomic or molecular species. In order to understand the time dependence of chemical reactions, chemical kineticists have traditionally focused on sorting out all of the elementary chemical reactions involved in a macroscopic chemical process and determining their respective rates.

Our basic understanding of the relation between reactive molecular encounters and rates of reactions (formulated in terms of activation energies, E_a, and pre-exponential factors, A, as elucidated by *Arrhenius* in his rate constant expression, $k = A \cdot \exp(-E_a/RT)$), was deepened some fifty years ago following the discovery of quantum mechanics. Since a chemical reaction is fundamentally a mechanical event, involving the rearrangement of atoms and molecules during a collision, detailed information on the dynamics of simple chemical reactions could be obtained by first carrying out extensive quantum-mechanical calculations of the interaction potential as a function of interatomic distances and then computing classical trajectories based on this potential energy surface.[1] Although these initial theoretical studies were only qualitative, they heralded a new era in the field of chemical kinetics; the chemist could now, in principle, predict the dynamical course of a chemical reaction.

During the past three decades, with the development of many sophisticated experimental techniques, it has become possible to study the dynamics of elementary chemical reactions in the laboratory. For example, detailed information on the nascent quantum state distributions of simple products for some chemical reactions can be derived from the chemiluminescence spectra of reaction products obtained under single collision conditions,[2] the analysis of the threshold operating conditions of a chemical laser,[3] or the spectra obtained using various linear or nonlinear laser spectroscopic techniques.[4,5] However, when one desires to (1) control the energies of the reagents, (2) understand the dependence of chemical reactivity on molecular orientation, (3) explore the nature of reaction intermediates and their subsequent decay dynamics, and (4) identify complex reaction mechanisms involving polyatomic radical products, the crossed molecular beams technique is most suitable.[6,7]

Information derived from the measurements of angular and velocity distributions of reaction products played a crucial role in the advancement of our understanding of the dynamics of elementary chemical reactions. This and the more general investigations of chemical reactions under single collision conditions in crossed molecular beams will be the subject of this lecture.

Crossed Molecular Beams Experiments: Measurements of Angular and Velocity Distributions of Products

If the motion of individual atoms were observable during reactive collisions between molecules, it would be pos-

sible to understand exactly how a chemical reaction takes place by just following the motion of these atoms. Unfortunately, despite recent advances in microscope technology that allow us to observe the static arrangement of atoms in a solid, we are still far from being able to follow the motion of atoms in the gas phase in real time. The idea of crossed molecular beams experiments is in a sense to "visualize" the details of a chemical reaction by tracing the trajectories of the reaction products. This is done by first defining the velocities, approach angle, and other initial conditions of the reactants, and then measuring the velocity and angular distributions of the products. For example, in the investigation of reaction (a),[8] if we let F atoms and

$$F + D_2 \longrightarrow DF + D \qquad (a)$$

D_2 molecules collide at a relative energy of 1.82 kcal mol^{-1} and then measure the angular and velocity distributions of DF products, we will obtain the results shown in Figure 1.

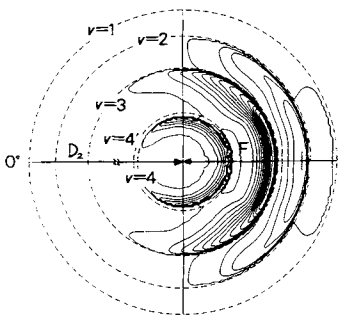

Fig. 1. Center-of-mass velocity flux contour map for reaction (a). F atoms and D_2 molecules move towards each other at a collision energy of 1.82 kcal mol^{-1}, with the F atoms moving from right to left.

This contour map shows the probability of DF products appearing at specific angles and velocities and reveals a great deal about the dynamics of the reaction. 0° corresponds to the initial direction of the F atom beam and the distance between any point and the center is the center-of-mass velocity. The strong backward peaking of DF products with respect to the initial direction of F atoms indicates that not all the collisions between F atoms and D_2 molecules produce DF product. Only those collisions in which the F atom and the two D atoms are nearly linear will react and produce DF. Apparently, if an F atom collides with a D_2 molecule from a direction perpendicular to the molecular axis of the D_2, the F atom will only bounce off elastically. The appearance of DF in several velocity bands (Fig. 1) is due to the fact that DF molecules are produced in several vibrational states (quantum number v) with different recoil velocities as indicated in the figure. Since the total energy released in every reactive encounter between F and D_2 is the same, the maximum energy available for translational motion will depend on the vibrational quantum state of DF. Because the rotational energy spread of DF products is less than the spacings of the vibrational energy levels, the recoil velocities of various vibrational states of DF products are well separated and can be identified easily.

If a crossed molecular beams study of reaction (a) is carried out using the experimental arrangement shown in Figure 2, the rate of production of DF products, dN_{DF}/dt, in

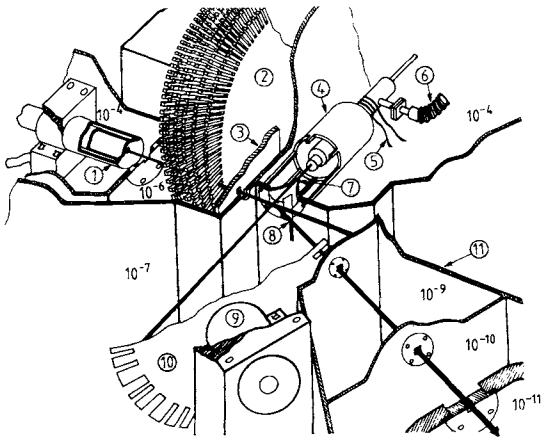

Fig. 2. Experimental arrangement for $F + D_2 \rightarrow DF + D$ and $F + H_2 \rightarrow HF + H$ reactive scattering. Pressures (in torr) for each region are indicated. Components shown by numbers are: (1) effusive F-atom beam source made of nickel, resistively heated; (2) velocity selector; (3) liquid-nitrogen-cooled cold trap; (4) D_2 or H_2 beam source, supersonic expansion; (5) heater; (6) liquid-nitrogen feed line; (7) skimmer; (8) tuning-fork chopper; (9) synchronous motor; (10) cross-correlation chopper for time-of-flight velocity analysis; (11) ultrahigh vacuum, triply differentially pumped, mass-spectrometric detector chamber.

the scattering volume defined by the crossing of two beams can be estimated from Equation (1), where n_F and n_{D_2} are

$$\frac{dN_{DF}}{dt} = n_F n_{D_2} \sigma g \Delta V \qquad (1)$$

the number densities of F atoms and D_2 molecules in the scattering region, σ, g, and ΔV are the reaction cross section, the relative velocity between F and D_2, and the scattering volume, respectively. In an experiment using a velocity-selected effusive F-atom source and a supersonic beam of D_2, the values of n_F, n_{D_2}, and ΔV are typically 10^{10} molecules cm^{-3}, 10^{12} molecules cm^{-3}, and 10^{-2} cm^3, respectively. If the relative velocity g between F and D_2 is 10^5 cm s^{-1} and the reactive cross section σ is 10^{-15} cm^2, then dN_{HF}/dt will have a value of 10^{10} molecules s^{-1}. These DF products with various recoil velocities will scatter into a range of laboratory angles. If the DF is scattered fairly evenly within 1 steradian of solid angle in the laboratory and if the movable detector which scans the angular distribution has an acceptance solid angle of 1/3000 steradian (approximately an angular width of 1° in both directions from the detector axis), the detector will receive approximately 3×10^6 DF molecules per second.

This would certainly constitute a large product signal, assuming we were able to count all of these molecules. Indeed, in a reactive scattering experiment using a beam of alkali atoms, surface ionization could be used to detect the alkali-containing product with nearly 100 percent efficiency and with high specificity. Therefore, even in the presence of a billion times more background molecules, very good signal-to-noise ratios can be obtained in a short time.

To detect the DF products, however, first it is necessary to ionize DF to $DF^{\oplus}$ by electron bombardment. The product ion can then be mass filtered and counted. The typical ionization efficiency for a molecule during the short transit time through the ionizer is about 10^{-4}. 3×10^6 DF s^{-1} reaching the detector will yield only 300 $DF^{\oplus}$ ions s^{-1}. However, this is a large enough number to allow reliable measurements of angular and velocity distributions in a relatively short time if the background count rate is not much greater. Indeed, the success of a crossed molecular beams study of such a chemical reaction depends entirely on whether the background in the mass-spectrometric detector can be reduced sufficiently.[9]

There are two sources of background molecules in the detector that one has to deal with in a crossed molecular beams experiment: the inherent background in the detector chamber and the background caused by the effusion of molecules from the collision chamber into the detector when the beams are on. The former is mainly due to outgassing from the materials used for the construction of the chamber and to limitations imposed by the performance of the ultrahigh vacuum pumping equipment. Reduction of the latter requires many stages of differential pumping using buffer chambers. 3×10^6 molecules s^{-1} entering the detector with a speed of 10^5 cm s^{-1} through a 0.3-cm^2 aperture will establish a steady-state density of only 100 molecules cm^{-3}, which is equivalent to a DF pressure of about 3×10^{-15} torr. This is four orders of magnitude lower than the pressure attainable using conventional ultrahigh vacuum techniques. Since none of the chemical compounds found in a vacuum system give ions with a mass-to-charge ratio (m/z) of 21 ($DF^{\oplus}$) in the ionization process, inherent background will not be a problem for the investigation of reaction (a) even if the ultimate pressure of the detector chamber is around 10^{-11} torr.

Suppose the partial pressure of DF background molecules in the collision chamber after the introduction of beams of F atoms and D_2 molecules reaches about 10^{-9} torr. Then three stages of differential pumping will be required to obtain a partial pressure of about 10^{-15} torr in the ionizer chamber if the partial pressure of DF is reduced by a factor of 100 in each separately pumped buffer chamber. As long as the inherent background in the detector does not contain the species to be detected, extensive differential pumping appears to be the only thing needed to make reactive scattering experiments feasible. This conclusion is unfortunately not quite correct. In order to detect the scattered products, the defining apertures, which are located on the walls of the buffer chambers of the detector, must be perfectly aligned. This limits the reduction of background that would be possible through many stages of differential pumping since some of the DF molecules in the main chamber moving along the axis of the detector will pass straight through all the defining apertures and into the detector chamber. It is important to understand that no matter how many stages of differential pumping are arranged between the collision chamber and the detector chamber, the number of these "straight through" molecules cannot be reduced.

If all the apertures on the walls of the buffer chambers and the detector chamber have the same area, A, the steady-state density of "straight through" molecules in the detector chamber, n', at a distance d from the entrance aperture of the first buffer chamber can be calculated from Equation (2), where n is the number density of background

$$n' = \frac{nA}{4\pi d^2} \tag{2}$$

molecules in the collision chamber. If d is 20 cm and A is 0.3 cm^2, Equation (3) is obtained. If the partial pressure of

$$n' = \frac{0.3}{4\pi \cdot (20)^2} n \approx 6 \times 10^{-5} n \tag{3}$$

DF background molecules in the collision chamber is 10^{-9} torr, the "straight through" molecules will create a steady-state density of 6×10^{-14} torr, which is 60 times larger than what one hopes to accomplish with three stages of differential pumping. Of course, reduction of the partial pressure of DF molecules in the collision chamber will also reduce the "straight through" background, but increasing the pumping speed in the collision chamber to reduce the partial pressure of DF by several orders of magnitude is simply not a practical solution.

Fortunately, there is a way to reduce this background without substantially increasing the pumping speed in the collision chamber. Recognizing that at a pressure of 10^{-7} torr the mean free path between molecular collisions in the collision chamber is more than 100 m, which is two orders of magnitude larger than the size of a typical scattering apparatus, one realizes that almost all of the "straight through" background will come from those molecules that bounce off the surface which is in the line-of-sight of the detector, and not from gas-phase collisions that occur in the viewing window of the detector. Installing a small liquid-helium-cooled surface opposite the detector and behind the collision region, such that the detector line-of-sight always faces a cold surface, will help to eliminate this background since the surface will trap essentially all condensable molecules that impinge on it.

Since the mid-1960s, many "universal" crossed molecular beams apparatuses have been constructed in various laboratories. Since ultrahigh vacuum equipment available twenty years ago could attain an ultimate pressure of only about 10^{-10} torr, and only two stages of differential pumping were needed to reduce the pressure from 10^{-7} torr in the collision chamber to 10^{-10} torr in the detector chamber, almost all mass-spectrometric detectors with electron-impact ionization were constructed with no more than two stages of differential pumping, the principal exceptions being those built in our laboratory.[10] The failure to recognize that for many chemical species the partial pressure in the detector chamber could be reduced well below the ultimate total pressure through additional differential pumping was part of the reason why many of these apparatuses did not perform optimally.

Direct Experimental Probing of Potential Energy Surfaces

For gaseous rare-gas systems, if the interaction potentials between the atoms are accurately known, all bulk

properties and transport phenomena can be predicted theoretically. Similarly, for a simple atom–molecule reaction, the potential energy surface, which describes the interaction potential as a function of the coordinates of the atoms, will be the basis for the understanding of the detailed dynamics of a chemical reaction.

One of the systems that has attracted extensive attention in both experimental and theoretical efforts during the last fifteen years is reaction (b). In the early 1970s, using quasi-

$$F + H_2 \longrightarrow HF + H \qquad (b)$$

classical trajectory calculations, *Muckerman* derived a semiempirical potential energy surface, known as the Muckerman V surface, which gave results in agreement with all experimental data available at that time.[11] These results included rate constants, vibrational-rotational state distributions obtained from chemical laser and chemiluminescence experiments, as well as product angular distributions obtained from experiment involving reaction (a) (see Fig. 1). The potential energy surface obtained from the ab initio quantum-mechanical calculations[12] was still rather limited at that time, but it did show many important features which were in good qualitative agreement with the Muckerman V surface.

If the Muckerman V surface were sufficiently accurate, it would be possible to carry out scattering calculations using this surface under conditions which could not be easily arranged in the laboratory. This would significantly expand the scope of our understanding of the dynamics of this system. However, the accuracy of the Muckerman V surface depends not only on the reliability of the experimental input used in the derivation of the surface, but also on the applicability of classical mechanics in treating reaction (b). This is certainly a major concern for an H-atom transfer reaction.

One-dimensional quantum calculations on the $F+H_2$ reaction, although not necessarily realistic, had in fact shown the inadequacy of classical mechanics in handling this reaction.[13,14] Quantum effects were, indeed, very important, and in all these calculations strong "resonances" were found in the dependence of reaction probability on collision energy.[15] These resonances were later shown to be due to the formation of "quasi-bound" states in the F-H-H reaction intermediate.[16,17] The $F+H_2$ surface has a barrier in the entrance channel, but there is no attractive well in the intimate region near the transition state. The quasi-bound states in the $F+H_2$ reaction are entirely dynamical in nature. Loosely speaking, the first dynamic resonance is due to the formation of a bound state which is a superposition of $F+H_2(v=0)$ and $HF(v=3)+H$ in the intimate region of chemical interaction.

The discovery of dynamical resonances in the collinear "quantal" calculations of the $F+H_2$ system provided new possibilities for probing the critical region of the potential energy surface more directly. In contrast to most other microscopic experiments, in which the influence of the potential energy surface on the final distribution of products is assessed, the experimental observation of resonances is almost equivalent to carrying out vibrational spectroscopy directly on the reaction intermediate. Thus it should offer a more stringent test of the details of the calculated potential energy surface.[16]

In a three-dimensional quantum scattering calculation of $F+H_2$ on the Muckerman V surface, *Wyatt* et al.[18] have shown that as the collision energy is increased beyond the one-dimensional resonance energy, the resonance does not just disappear but occurs at increasingly larger impact parameters. Consequently, resonances cannot be observed in an experiment in which the reaction cross section is measured as a function of collision energy. On the other hand, if the experiment is carried out at a fixed collision energy, and if the reaction probability is measured as a function of impact parameter, the resonance should be observable. Unfortunately, one has no hope of controlling or measuring the impact parameter *in* a scattering experiment. But, for reaction (b), in which the collinear configuration dominates the reactive scattering at lower collision energies, the scattering angle of HF should depend on the impact parameter. In particular, when a quasi-bound state is formed, if the average lifetime of the F-H-H intermediate is an appreciable fraction of its rotational period, HF produced from the decay of the F-H-H quasi-bound state is expected to scatter in a more forward direction compared to the strongly backward peaked HF produced by direct reaction. One of the unique and most important aspects of the measurement of product angular distributions is that one can use the rotational period of the reaction intermediate, typically 10^{-12}–10^{-13} s to judge the lifetime of the reaction intermediate.[6] If the average lifetime of the intermediate is much longer than the rotational period, the angular distribution of products will show forward–backward symmetry. On the other hand, if the lifetime is much shorter, the asymmetric angular distribution reveals the preferred molecular orientation for the chemical reaction to occur.

Experimental measurements of the laboratory angular distribution and time-of-flight velocity distributions of HF products at a collision energy of 1.84 kcal mol^{-1}, using the experimental arrangement shown in Figure 2, are shown in Figures 3 and 4. The velocity and angular distributions in the center-of-mass coordinate system derived from these experimental results are shown in Figure 5.[19] The enhanced forward peaking in the angular distribution of HF in $v=3$ is a strong indication that quasi-bound states are indeed formed in reaction (b) at this energy, and that they seem to decay exclusively into HF in the $v=3$ state.

For reaction (c), quantal collinear calculations give a very striking result. There is a sharp spike in the $HF(v=2)$

$$F + HD \longrightarrow HF + D \qquad (c)$$

reaction probability near threshold and virtually no other product is formed at higher collision energies up to 0.2 eV. The collinear calculations therefore indicate that the formation of HF in this reaction is dominated by resonant scattering while the DF product is formed by direct scattering. As shown in Figure 6, the product angular distribution of HF measured at a collision energy of 1.98 kcal mol^{-1} indeed shows that most of the signal is in the forward direction as expected, in strong contrast to the DF signal which is formed through direct scattering and is

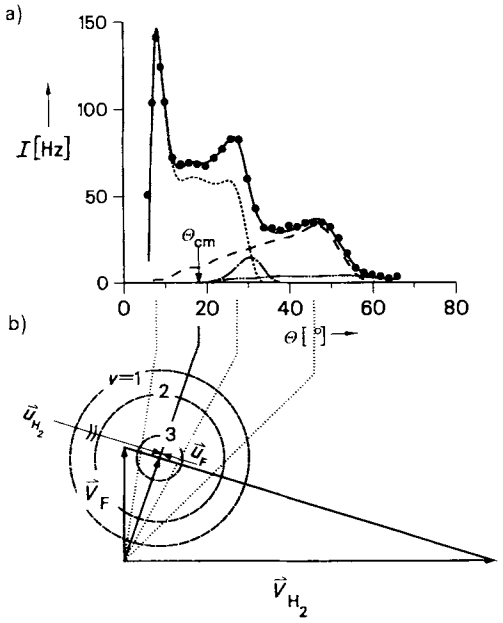

Fig. 3. a) Laboratory angular distribution for F + para-H_2, 1.84 kcal mol^{-1}. b) Velocity diagram. Both the data and calculated laboratory distributions are shown: ● data, — total calculated, — · · · — $v=1$, — — — $v=2$, ------ $v=3$, — · — $v=3'$ (from H_2 ($J=2$). I = signal intensity; Θ_{cm} = laboratory angle of the center-of-mass of the system.

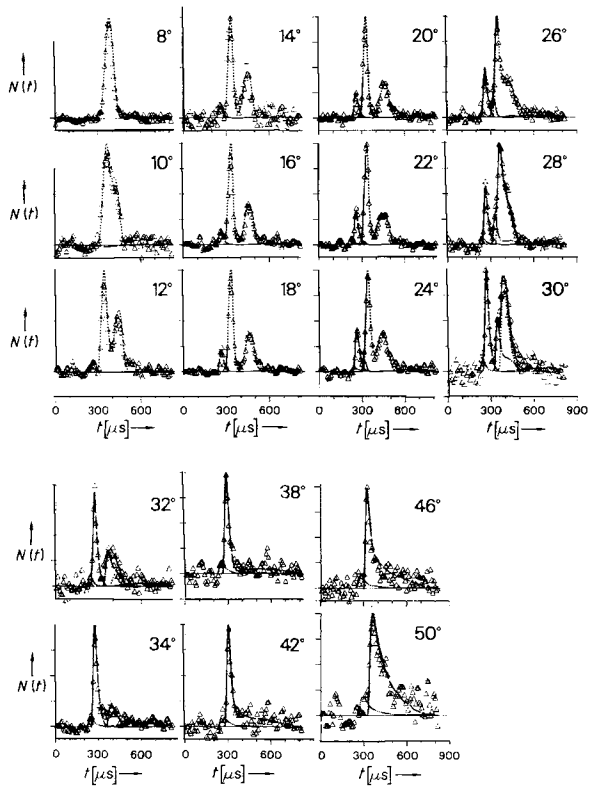

Fig. 4. Time-of-flight spectra for F + para-H_2, 1.84 kcal mol^{-1}: Δ data; for calculated curves, see caption of Fig. 3. $N(t)$ = number of product molecules in arbitrary units.

therefore mainly scattered in the backward direction. Again, the forward-peaked HF products are found to be in the $v=3$ state, rather than $v=2$, as was observed in the quantal calculations on reaction (b). This disagreement is certainly due to the shortcoming in the Muckerman V surface. These vibrationally state-specific angular distributions obtained at various collision energies for F + H_2, HD, and D_2 reactions provide a very stringent test for the ever improving potential energy surfaces obtained from ab initio quantum-mechanical calculations.

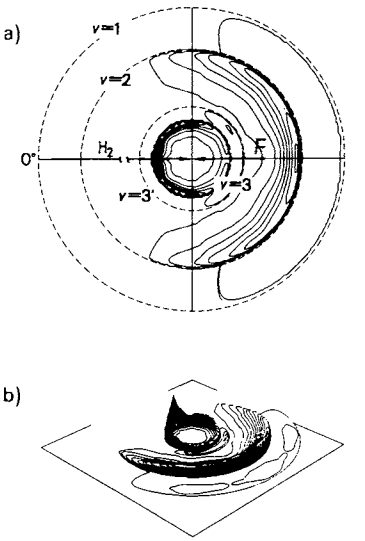

Fig. 5. a) Center-of-mass velocity flux contour map for F + para-H_2, 1.84 kcal mol^{-1}; b) three-dimensional perspective.

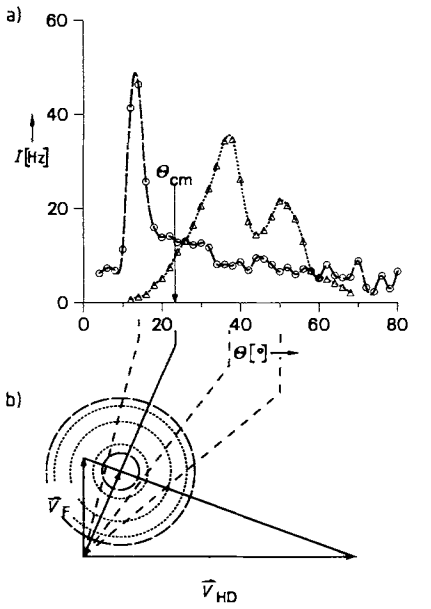

Fig. 6. Laboratory angular distribution for F + HD, at a collision energy of 1.98 kcal mol^{-1} (---O---O--- HF product, · · · · Δ · · · · Δ · · · · DF product). The Newton circles corresponding to HF and DF product are drawn with the same texture as the lines in the angular distributions. The HF($v=3$) and HF($v=2$) circles are shown, as are the $v=4$, 3, and 2 circles for DF.

There is no doubt that through meaningful comparisons with experimental results, more sophisticated and reliable ab initio quantum-mechanical calculation techniques will emerge. In the near future, ab initio calculations of potential energy surfaces and exact scattering calculations on these systems will likely provide more detailed and accurate information on simple reactive systems such as F + H_2 than one could possible learn in the laboratory. The fruit-

ful interplay of theory and experiment will then extend to more complicated systems, making chemistry a more exact science.

Exploration of New Chemistry under Single Collision Conditions

There are many mysterious phenomena in nature which have thus far defied explanation. The mystery is often due to the fact that a certain phenomenon cannot be understood based on our established knowledge or common sense.

The ease with which F_2 and I_2 react to produce electronically excited IF molecules, which relax through photon emission, was a mystery a dozen years ago.[20] A molecule-molecule reaction is supposed to have a high energy barrier and the four-center reaction producing two IF molecules, with either both in the ground state or one of them in an excited state, is a symmetry-forbidden process. The textbook mechanism has either I_2 or F_2 molecules first dissociating into atoms followed by the radical chain reactions (d) and (e). However, neither of these reactions is exothermic enough to produce electronically excited IF.

$$F + I_2 \longrightarrow IF + I \quad (d)$$
$$I + F_2 \longrightarrow IF + F \quad (e)$$

The clue that something new might be happening in this reaction was actually discovered in a crossed molecular beams study of reaction (f).[21] When we found that this

$$F + CH_3I \longrightarrow IF + CH_3 \quad (f)$$

reaction proceeded through the formation of a long-lived complex, we began to increase the collision energy to see whether it was possible to shorten the lifetime enough to make it comparable to the rotational period of the CH_3IF complex. If we could estimate the lifetime of the collision complex using the rotational period as a clock, it would be possible to evaluate the stability of this reaction intermediate using statistical theories for the unimolecular decomposition rate constants. At higher collision energies, the angular distribution of products monitored at m/z 146 ($IF^{\oplus}$) showed a peculiar feature which could not possibly be due to IF produced from the $F+CH_3I$ reaction. This was later shown to be from stable CH_3IF produced in the collision volume of the two beams which yielded additional $IF^{\oplus}$ signal after dissociative ionization.

The stable CH_3IF was in fact formed by the reaction of undissociated F_2 in our F-atom beam with CH_3I [reaction (g)]. The threshold E_0 for this reaction was found to be 11

$$CH_3I + F_2 \longrightarrow CH_3IF + F \quad (g)$$

kcal mol^{-1} as shown in Figure 7. The product angular distribution measured at a collision energy of 25.1 kcal mol^{-1} is shown in Figure 8. Since the dissociation energy of F_2 is 37 kcal mol^{-1}, the dissociation energy of $CH_3IF \rightarrow CH_3I + F$ could be as high as 26 kcal mol^{-1} (Fig. 9). This was certainly a surprising result and was entirely unsuspected.

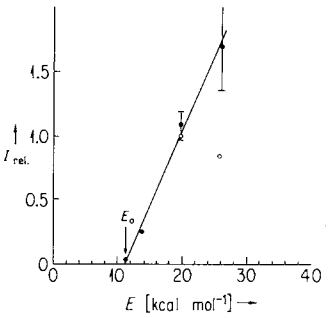

Fig. 7. The kinetic energy dependence of the production of CH_3IF in reaction (g). I_{rel} = amount of CH_3IF in arbitrary units.

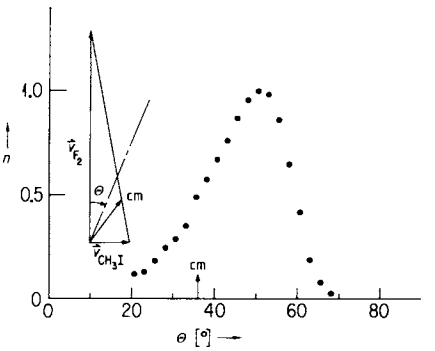

Fig. 8. Laboratory angular distribution of CH_3IF obtained in reaction (g) at a collision energy of 25.1 kcal mol^{-1}. n = number density.

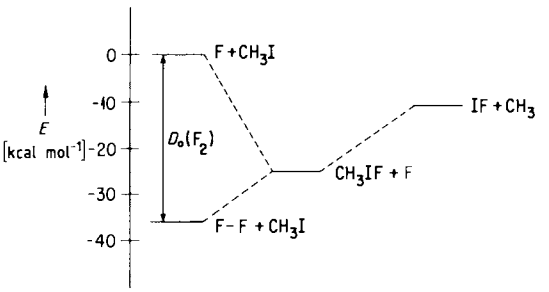

Fig. 9. Energy diagram showing the relative energy of the CH_3IF intermediate formed in reaction (f) and as a product of the endothermic reaction (g).

In the reaction of I_2 and F_2, it was not surprising that the stability of the I_2F radical is the driving force for reaction (h) to proceed. But, what amazed us most was that reaction

$$I_2 + F_2 \longrightarrow I_2F + F \quad (h)$$

(h) had a threshold of only 4 kcal mol^{-1}, and that at 7 kcal mol^{-1} reaction (i) was observed.[22] The production of I

$$I_2 + F_2 \longrightarrow I + IF + F \quad (i)$$

and IF in this reaction is most likely through the secondary decomposition of vibrationally excited I_2F radicals. Later, a careful investigation showed that the threshold energy for producing electronically excited iodofluoride, IF* [reaction (j)],[23] is identical to that for I_2F+F formation

$$I_2 + F_2 \longrightarrow IF^* + IF \quad (j)$$

[reaction (h)]. However, the formation of electronically excited IF* is only a minor channel compared to $I_2F + F$ formation. Apparently, it is a secondary encounter between the departing F atom and the terminal I atom in I_2F which produces IF*. A relatively rare sequential process during a binary collision between F_2 and I_2 is responsible for the production of electronically excited IF, not the symmetry-forbidden four-center reaction which breaks and forms two bonds simultaneously.

The fact that one can control kinetic energy precisely and carry out a synthetic study of delicate new radicals through endothermic reactions is certainly among the most dramatic features of crossed molecular beams experiments. Successful studies of the stabilities of a series of I–F-containing radicals such as HIF, ClIF, and I_2F were carried out by transferring the correct amount of kinetic energy into potential energy, just like an acrobatic performance in a circus in which an acrobat is bounced off of a plank and lands gently on the shoulder of a second acrobat who is standing on top of a third to form a fragile three-acrobat formation (Fig. 10).

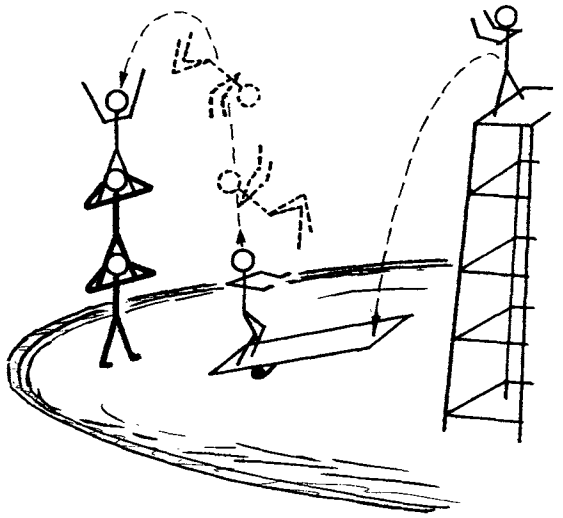

Fig. 10. An acrobat bounced off the plank converts his kinetic energy into potential energy on his way to forming a delicate three-man formation. Many delicate radicals that cannot be synthesized through exothermic channels were synthesized by this method.

The development of the seeded supersonic beam source has been largely responsible for making crossed molecular beams experiments at higher collision energies possible.[24] If a gaseous mixture is expanded into a vacuum chamber through a small nozzle with a sufficiently high stagnation pressure, all molecules, regardless of their molecular weights, attain the same average terminal speed. Consequently, the kinetic energies of molecules in the beam will be proportional to their molecular weights, and for heavier atoms or molecules a very high kinetic energy can be obtained by seeding a small fraction of heavy particles in a very light carrier gas.

Using this aerodynamic acceleration for heavier particles many interesting experiments have been carried out in our laboratory. In the collision-induced dissociation of alkali halides by rare-gas atoms,[25] it was found from classical trajectory simulations of velocity and angular distributions of the products that, for most dissociative collisions at energies near the dissociation threshold, the most efficient means of transferring translational energy into internal energy is through initial bond compression in near collinear collisions. The experimental angular and velocity distributions of $Rb^{\oplus}$ and $I^{\ominus}$ from reaction (k) at a collision

$$Xe + RbI \longrightarrow Xe + Rb^{\oplus} + I^{\ominus} \qquad (k)$$

energy of 5.97 eV are shown in Figure 11. The amount of energy transferred as measured from the final translational energy distributions of dissociated atoms agrees with the estimated initial momentum transfer to one of the atoms in the diatomic molecule using the impulse approximation.

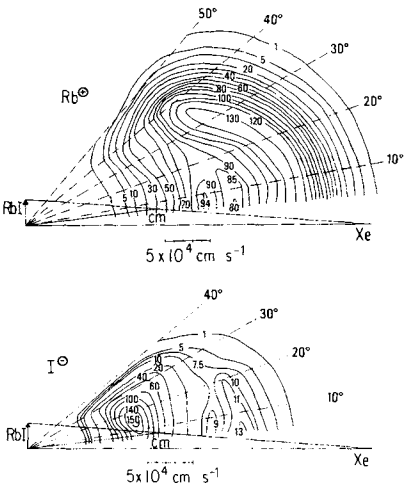

Fig. 11. Cartesian contour map of $Rb^{\oplus}$ and $I^{\ominus}$ angular and velocity distributions resulting from dissociative Xe + RbI collisions at a most probable relative collision energy of 5.97 eV.

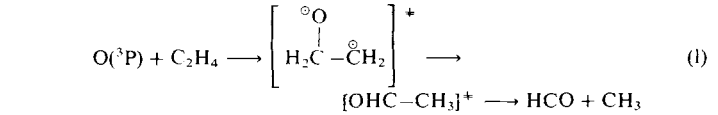
In a recent series of investigations of substantially endothermic reactions of Br atoms with *ortho-*, *meta-* and *para*-chlorotoluenes, a beam of energetic Br atoms was used to study the reactivity and dynamics of Cl-atom substitution by Br atoms.[26] The intermediates of these reactions are expected to have potential wells that are much shallower than the endothermicity of reaction. From the measurements of the translational energy dependence of the reaction cross sections and the product translational energy distributions, the extent of energy randomization among various vibrational degrees of freedom was found to be rather limited. Despite the fact that *ortho-* and *para*-chlorotoluenes react easily, no substitution was observed for *meta*-chlorotoluene, indicating that the electron density distribution on the benzene ring strongly influences the reactivity, even though dynamic factors are expected to be more important in endothermic substitution reactions.

Elucidation of Reaction Mechanisms from Product Angular and Velocity Distributions

In elementary chemical reactions involving complicated polyatomic molecules, the unraveling of the reaction

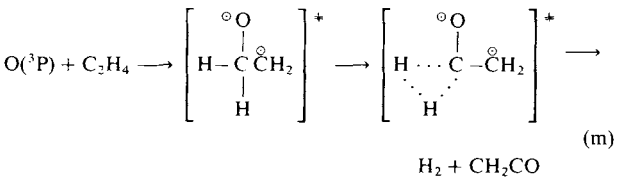
mechanism is often the most important issue. Without the positive identification of primary products, it is not possible to discuss reaction dynamics in a meaningful way. In bulk experiments, the identification of primary products has often been complicated by fast secondary reactions of primary products. Recently, advances in sensitive detection methods and time-resolved laser techniques have allowed single collision experiments to become possible even in the bulk, and complications caused by secondary collisions can be avoided. However, the positive identification of internally excited polyatomic radicals produced under single collision conditions is still a very difficult problem. Spectroscopic techniques, which are so powerful in providing state-resolved detection of atoms or diatomic molecules, are often not very useful, either because of the lack of spectroscopic information or simply because huge numbers of states are involved. The more general mass-spectrometric technique, which depends heavily on "fingerprints" of fragment ions for positive identification, also suffers from the fact that fragmentation patterns for vibrationally excited polyatomic radical products in electron-bombardment ionization are not known. This problem is especially serious because many radicals do not yield parent ions. Even if stable molecules are formed as products, the change in fragmentation patterns with increasing internal energy can be so drastic that erroneous conclusions are often reached. For example, at room temperature both ethanol (C_2H_5OH) and acetaldehyde (CH_3CHO) will yield $C_2H_5OH^{\oplus}$ and $CH_3CHO^{\oplus}$ as major ions by electron-bombardment ionization. However, since both these ions contain a very weak bond and most of the vibrational energy is retained in the ionization process, when highly vibrationally excited C_2H_5OH and CH_3CHO are ionized, even if parent ions are initially produced, they will further dissociate into $C_2H_5O^{\oplus}$ and $CH_3CO^{\oplus}$ by ejecting an H atom.[27]

The problem of product identification caused by the fragmentation of primary products during the ionization process can be overcome if product angular and velocity distributions are measured carefully in high-resolution crossed molecular beams experiments. For example, the reaction between $O(^3P)$ and C_2H_4 under single-collision conditions using a mass spectrometer to detect the products generates signals at *m/z* 43, 42, 29, 27, and 15. The fact that *m/z* 15 ($CH_3^{\oplus}$) and 29 ($HCO^{\oplus}$) are the most intense signals suggests that $CH_3 + HCO$ is the major reaction channel. This conclusion is in agreement with previous studies of the reaction of $O(^3P)$ with C_2H_4 carried out by *Cvetanovic*,[28] *Pruss* et al.,[29] and *Blumenberg* et al.[30] From the analysis of final products in a bulk experiment using photoionization detection of products with hydrogen Lyman-α (10.2 eV) radiation and electron-bombardment ionization mass spectrometry, it was concluded that formation of CH_3 and HCO, resulting from 1,2 migration of a hydrogen atom in the reaction intermediate and subsequent C-C rupture, as shown in reaction (l), provides



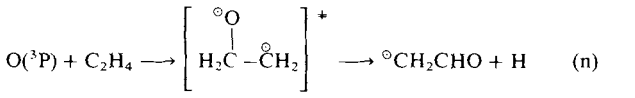
$$O(^3P) + C_2H_4 \longrightarrow \left[\begin{array}{c} {}^{\ominus}O \\ | \\ H_2C-\overset{\oplus}{C}H_2 \end{array}\right]^{*} \longrightarrow [OHC-CH_3]^{+} \longrightarrow HCO + CH_3 \qquad (l)$$

90 percent of the products. The remaining 10 percent is ketene formed by a three-center elimination of an H_2 molecule from the reaction intermediate [reaction (m)].



$$O(^3P) + C_2H_4 \longrightarrow \left[\begin{array}{c} {}^{\ominus}O \\ | \\ H-C\overset{\oplus}{C}H_2 \\ | \\ H \end{array}\right]^{*} \longrightarrow \left[\begin{array}{c} {}^{\ominus}O \\ | \\ H\cdots C-\overset{\oplus}{C}H_2 \\ \vdots \\ H \end{array}\right]^{*} \longrightarrow H_2 + CH_2CO \qquad (m)$$

The measurements of product angular distributions in a crossed molecular beams experiment,[31] as shown in Figure 12, gave strong evidence that the above conclusion was not quite correct. The fact that the intense *m/z* 42 signal and the weak *m/z* 43 signal (not shown) have the same angular distributions indicates that the substitution reaction forming vinyloxy radical occurs [reaction (n)]. The *m/z* 42



$$O(^3P) + C_2H_4 \longrightarrow \left[\begin{array}{c} {}^{\ominus}O \\ | \\ H_2C-\overset{\oplus}{C}H_2 \end{array}\right]^{*} \longrightarrow {}^{\ominus}CH_2CHO + H \qquad (n)$$

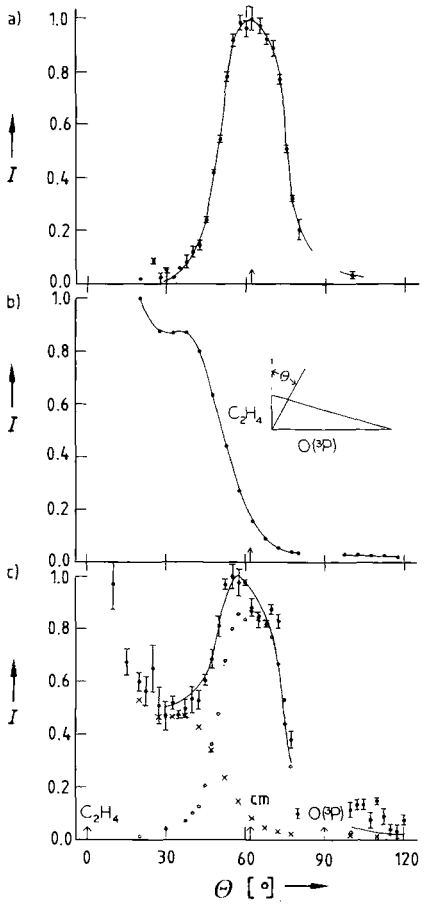


Fig. 12. Laboratory angular distributions from the reaction $O + C_2H_4$ at 10.7 kcal mol^{-1} collision energy. a) CH_2CHO product, monitored at *m/z* 42 ($C_2H_2O^{\oplus}$); b) elastic scattering of C_2H_4 monitored at *m/z* 27 ($C_2H_3^{\oplus}$); c) $CH_3^{\oplus}$ (*m/z* 15, ●), contributions from C_2H_4 and CH_2CHO are indicated by × and ○, respectively.

signal ($C_2H_2O^{\oplus}$) results from dissociative ionization of CH_2CHO product rather than from the formation of CH_2CO and H_2 [reaction (m)]. The formation of CH_2CO through the three-center elimination of a hydrogen mole-

cule is expected to release a larger amount of recoil energy and the fact that CH_2CO is recoiling from H_2 rather than from an H atom will cause the laboratory angular distribution of CH_2CO to be much broader than that of CH_2CHO. The *m/z* 15 ($CH_3^{\oplus}$) angular distribution clearly shows that in addition to reaction products, elastically scattered C_2H_4 molecules also produce $CH_3^{\oplus}$ ions during ionization. The angular distribution of scattered C_2H_4 can be unambiguously measured at *m/z* 27 ($C_2H_3^{\oplus}$). After subtracting the contribution of elastically scattered C_2H_4 from the angular distribution at *m/z* 15, it is quite clear that the residual angular distribution of reactively scattered $CH_3^{\oplus}$ has an identical angular distribution to that measured at *m/z* 43 and 42. Apparently, most of the $CH_3^{\oplus}$ from reactive scattering are also daughter ions of vinyloxy radicals, CH_2CHO. If the product channel $CH_3 + HCO$ were dominant, the angular distribution of $CH_3^{\oplus}$ would be much broader. Without the measurement of product angular or velocity distributions, which reveal the parent-daughter relations, one would not have suspected that the simple substitution reaction (n) forming vinyloxy radical is in fact the major channel.

This was certainly a shocking discovery to chemical kineticists, since the mechanism of reaction (l) was thought to be well established. The important role played by the $CH_2CHO + H$ channel was never suspected. Several recent bulk studies using various time-resolved spectroscopic techniques[32-36] have verified the major role played by the hydrogen-substitution channel indicated by the crossed molecular beams experiments. These were not strictly single-collision experiments, but all showed that the reaction channel $CH_2CHO + H$ accounted for at least half of the products.

For the reaction of oxygen atoms with benzene the story is quite similar.[37] In earlier mass-spectrometric studies of the reaction products under single-collision conditions, it was concluded that in addition to the formation of a stable addition product, CO elimination from the reaction intermediate to form C_5H_6 was another major pathway. The CO elimination mechanism was mostly based on the experimental observation that *m/z* 66 and 65 ($C_5H_6^{\oplus}$ and $C_5H_5^{\oplus}$) were the most intense signals. However, the angular distribution of products monitored at *m/z* 66 and 65 in the crossed molecular beams experiments clearly show that they are different from each other but very similar to those monitored at *m/z* 94 and 93 ($C_6H_5OH^{\oplus}$ and $C_6H_5O^{\oplus}$), respectively. Apparently, the $C_5H_5^{\oplus}$ ions observed are not from neutral C_5H_5 product, but are actually daughter ions of the phenoxy radical C_6H_5O. The fact that the very weak signals at *m/z* 94 and 93 have different angular distributions, as also reflected in the angular distributions of *m/z* 66 and 65 shown in Figure 13, is convincing evidence that the *m/z* 93 signal ($C_6H_5O^{\oplus}$) is not entirely from the dissociative ionization of the addition product, C_6H_5OH. It is the substitution reaction, in which an oxygen atom replaces a hydrogen atom in the benzene molecule, which causes the angular distribution of the phenoxy product, C_6H_5O, to be broader than that of the adduct, C_6H_5OH. The benzene ring does not seem to open up after the initial attack of an oxygen atom. The subsequent decomposition of phenoxy radicals appears to be the important ring-

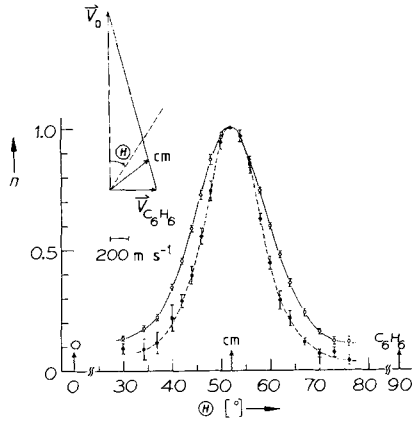

Fig. 13. Laboratory angular distributions from the reaction $O(^3P) + C_6H_6$, at a collision energy of 6.5 kcal mol^{-1}. The primary reaction products formed were C_6H_5O and C_6H_5OH, which subsequently fragmented during electron-bombardment ionization to give $C_5H_5^{\oplus}$ (*m/z* 65, ○) and $C_5H_6^{\oplus}$ (*m/z* 66, ●), respectively.

opening step. Crossed beams studies of substitution reactions of oxygen atoms with a series of halogenated benzenes[38] indeed showed that very highly vibrationally excited phenoxy radicals, produced by substituting bromine and iodine atoms in bromo- and iodobenzene with oxygen atoms, undergo decomposition to eliminate CO.

The fact that each product in a crossed molecular beams experiment has a unique angular and velocity distribution and the requirements that total mass number in a chemical reaction be conserved and that a pair of products from a given channel have the ratio of their center-of-mass recoil velocities inversely proportional to their mass ratio in order to conserve linear momentum are three of the main reasons why measurements of product angular and velocity distributions are so useful in the positive identification of reaction products, even in those cases where none of the products yield parent ions in mass-spectrometric detection.[9] In fact, there is no other general method more useful in elucidating complex gas-phase reaction mechanisms and providing information on the energetics and dynamics.

Molecular Beam Studies of Photochemical Processes

In the investigation of reaction dynamics, lasers have become increasingly important. Not only are they used extensively for the preparation of reagents and quantum-state-specific detection of products, but they have also become indispensable for the investigation of the dynamics and mechanisms of photochemical processes.

One of the more exciting applications of lasers in crossed molecular beams experiments is the control of the alignment and orientation of electronically excited orbitals before a reactive encounter. For example, in the reaction of Na with O_2,[39,40] if linearly polarized dye lasers are used to sequentially excite Na atoms from the 3S to 3P to 4D states, the electronically excited 4d orbital can be aligned along the polarization direction of the electric field vector of the lasers. Consequently, the effect of the alignment of the excited orbital on chemical reactivity can be studied in

detail by simply rotating the polarization of the lasers with respect to the relative velocity vector.

For many atom–molecule reactions that proceed directly without forming long-lived complexes, for example, $K+CH_3I$, $F+H_2$ and D_2, and $Na(4D)+O_2$, the dependence of chemical reactivity on the molecular orientation can be obtained from measurements of product angular distributions. For symmetric top molecules, control of molecular orientation in the laboratory frame is possible, and careful investigations of the orientation dependence of chemical reactivity have been carried out for many systems. The combination of laser-induced alignment of excited atomic orbitals and measurements of product angular distributions provide the first opportunity for the detailed experimental probing of the correlation between the alignment of the excited atomic orbital and the orientation of the molecule in a reactive encounter between an atom and a molecule.

The experimental arrangement for the reactive scattering of electronically excited Na with simple molecules is schematically shown in Figure 14. Because the radiative lifetimes of electronically excited Na are short, excitation and alignment have to be carried out in the intersection region of the two beams.

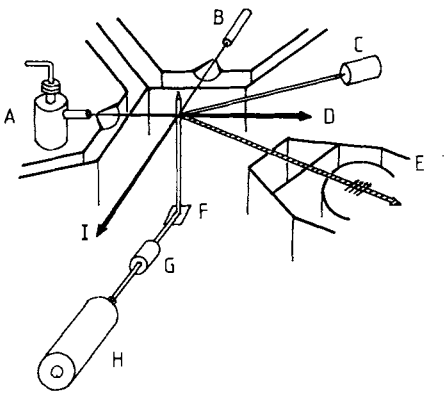

Fig. 14. Cut-out view of the experimental apparatus for the reactive scattering of electronically excited sodium atoms with various molecules. A = Na source, B = molecule source (e.g., HCl), C = fluorescence monitor, D = Na beam, E = rotating mass spectrometric detector, F = mirror, G = polarization rotator, H = dye laser, I = molecule beam.

The reaction of ground state Na atoms with O_2 [reaction (o)] is substantially endothermic. Even if Na is electroni-

$$Na(3S) + O_2 \longrightarrow NaO + O \qquad (o)$$

cally excited to the 3P state, it is still slightly endothermic, and excess translational energy in the reactants was not found to promote NaO formation in our recent experiments. Further excitation of Na from 3P to either the 4D or 5S state, which requires comparable excitation energies, makes NaO formation highly exothermic, but only Na(4D) reacts with O_2 and then only at collision energies greater than 18 kcal mol^{-1}. The NaO produced is sharply backward peaked with respect to the Na-atom beam. As in the low-energy reactive scattering of $F+D_2$ [reaction (a)], the Na(4D) and two O atoms must be lined up collinearly in order for chemical reaction to take place. Such a strict entrance channel configuration with a high threshold energy for $Na(4D)+O_2 \rightarrow NaO+O$ and the lack of chemical reactivity for Na(5S) are quite astonishing for a system in which electron transfer from Na to O_2 is expected to take place at a relatively large separation.

The 4D state of Na prepared by sequential excitation using linearly polarized lasers has an electron-density distribution similar to that of the d_{z^2} orbital in a H atom, if we take the laser polarization axis to be the z axis. Rotation of this excited 4d orbital with respect to the relative velocity vector was found to cause a strong variation in reactivity. The reactively scattered signal reaches a maximum when the d_{z^2} orbital approaches O_2 perpendicularly to the relative velocity vector (Fig. 15). The polarization dependence of products appearing at different scattering angles reflects the strong preference for the d_{z^2} orbital to be aligned perpendicularly to the O_2 molecular axis (Fig. 15b).

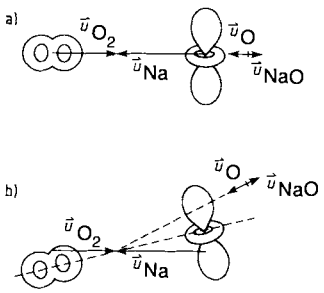

Fig. 15. From the measurements of polarization dependence at various angles, the required geometry for reaction was shown to have the Na–O–O intermediate collinear (a) so that with increasing impact parameter, the Na–O–O axis must be tilted with respect to the relative velocity vector. The Na $4d_{z^2}$ orbital remains perpendicular to the Na–O–O axis as shown (b).

These experimental observations are contrary to what one would expect from simple theoretical considerations. Because O_2 has a finite electron affinity, the $Na(4D)$–O_2 potential energy surface is expected to cross the $Na^{\oplus}$–$O_2^{\ominus}$ surface at a relatively large internuclear distance and the long-range electron transfer from Na(4D) to O_2, to form a $Na^{\oplus}O_2^{\ominus}$ intermediate, should play an important role. If this chemically activated $Na^{\oplus}O_2^{\ominus}$ complex is indeed responsible for the formation of an ionic NaO product, the reaction should proceed with a large cross section at low collision energies. Also, because the most stable structure of $Na^{\oplus}O_2^{\ominus}$ is an isosceles triangle, the angular distribution of the NaO product should show either forward peaking or forward–backward symmetry.

Apparently, this long-range electron transfer, in spite of its importance, is not the mechanism by which NaO product is formed, and may lead only to the quenching of electronically excited Na(4D) through an inelastic scattering process. It appears that only those collinear collisions that have the d_{z^2} orbital of Na(4D) aligned perpendicularly to the molecular axis can effectively avoid the long-range electron transfer. Then, with this configuration and sufficient collision energy, Na and O_2 could follow a covalent surface to reach a very short Na–O distance where the electron from Na(4D) is transferred to an electronically excited orbital of O_2 after which the complex can separate as $Na^{\oplus}O^{\ominus}$ and O.

Reaction (p) is a substantially more exothermic reaction, but it has many features which are similar to those found

$$Na(4D) + NO_2 \longrightarrow NaO + NO \qquad (p)$$

in the $Na(4D) + O_2 \rightarrow NaO + O$ reaction.[41] First of all, the high translational energy requirement, > 18 kcal mol^{-1}, for NaO product formation again indicates that the entrance channel is very restricted and is likely to be along an O–N bond. If a Na(4D) atom must approach an NO_2 molecule along an O–N bond at a high translational energy in order for a chemical reaction to occur, the orbital angular momentum between Na(4D) and NO_2 will overwhelm the molecular angular momentum of NO_2, coplanar scattering will dominate, and NaO product will be scattered in the plane of the NO_2, which also contains the relative velocity vector. In other words, when Na(4D) approaches NO_2 along the NO bond, all the forces between the interacting atoms will lie in the plane of the NO_2, and the scattered NaO will be confined to that plane. Thus, the detector, which rotates in a plane containing both the Na and NO_2 beams, can only detect those NaO products which are produced from NO_2 molecules lying in this plane at the instant when the reactions take place. In contrast to the collinear approach of Na and O_2, there is no cylindrical symmetry about the O–N axis when Na approaches NO_2 along that axis. Because of this, the reaction will depend not only on the d_{z^2} orbital alignment in the plane defined by the beams and the detector, but also on the alignment of the d_{z^2} about the relative velocity vector. This is exactly what we have observed in the laboratory. The reactivity of $Na(4D) + NO_2 \rightarrow NaO + NO$ as a function of the d_{z^2} orbital alignment with respect to the NO_2 molecule is shown in Figure 16. The most favorable approach has the d_{z^2} orbital

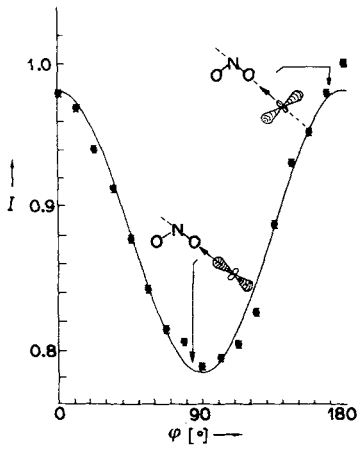

Fig. 16. Polarization dependence of the NaO signal from reaction (p). As the $4d_{z^2}$ orbital of Na was rotated in the plane which contains both beams and the detector, the signal was found to reach a maximum when the $4d_{z^2}$ orbital was perpendicular to the relative velocity vector and reached a minimum when it was parallel.

approaching the O–N axis perpendicularly and lying in the plane of the NO_2. When the alignment of the d_{z^2} orbital is rotated in the plane of the NO_2, the reactivity is reduced as the d_{z^2} orbital comes closer to being collinear with the O–N axis. When the d_{z^2} orbital is rotated out of the NO_2 plane from this collinear configuration, the reactivity decreases further and reaches a minimum when the orbital becomes perpendicular to the NO_2 plane.

The reaction of ground-state Na atoms with HCl is endothermic by 5.6 kcal mol^{-1}. Figure 17 shows the product NaCl angular distributions for Na(3S,3P,4D) at an average collision energy of 5 kcal mol^{-1}. These angular distributions were measured at m/z 23 because most of the NaCl fragments yield $Na^{\oplus}$ in the electron-bombardment ionizer.

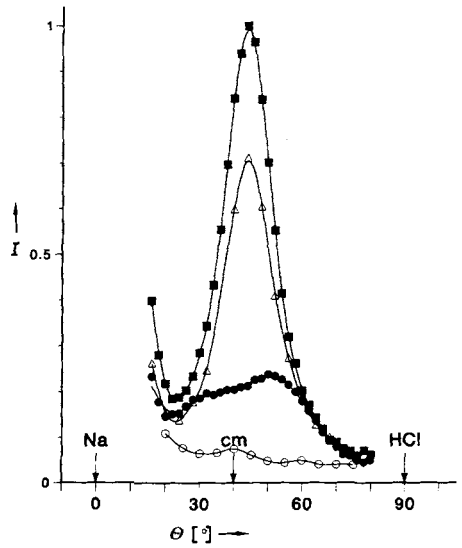

Fig. 17. Laboratory angular distributions for NaCl formed in the reactions of Na(3S) (○), Na(3P) (●), Na(4D) (■), and Na(5S) (△) with HCl at a collision energy of 5.6 kcal mol^{-1}.

The rising signal at low angles is due to elastically scattered Na atoms. The reactive cross section increases with increasing electronic energy. At the collision energy shown, the Na(3S) ground-state atoms react because the high-velocity components of each beam just barely overcome the endothermicity of the reaction. For the reaction of the Na(3P) atoms, NaCl product is observed over the full laboratory angular range possible allowing for the conservation of the momentum and total energy of the system. This implies a broad range of product translational energies, a conclusion which is supported by product velocity measurements. The same is not true of the reaction of the Na(4D) and Na(5S) states, in which the NaCl is scattered over a narrower angular range than that produced from the Na(3P) state, indicating less translational energy despite an additional 2 eV of excess energy. This is illustrated in Figure 18 in which the Na(3P) and Na(4D) angular distributions from Figure 17 have both been normalized.

These interesting results can be explained by invoking electron transfer followed by repulsion of the H atom and NaCl products. HCl is known to be dissociated by slow electrons, and has a *negative* vertical electron affinity of approximately 1 eV. For the reaction of the Na(3P) atoms, this electron transfer becomes energetically possible at 3.5 Å. This is, incidentally, the peak of the Na 3p orbital density. What the departing H atom feels is the repulsion from the Cl atom of the fully developed closed-shell NaCl molecule, and a significant impulse is given to it. In the case of the Na(4D) atoms, the crossing of the neutral and ionic potential curves (the initial point of electron transfer)

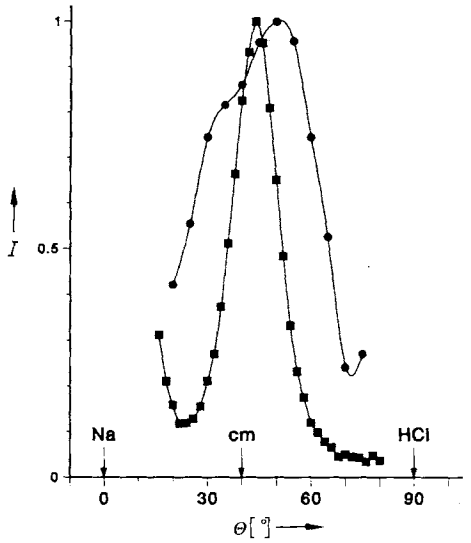

Fig. 18. NaCl angular distributions for the reactions of Na(3P) (●) and Na(4D) (■) with HCl at a collision energy of 5.6 kcal mol^{-1} from Figure 17. The peak intensity of the distribution arising from the reaction of Na(3P) is normalized to that arising from Na(4D) allowing comparison of the angular widths of the two distributions.

moves out to 7.7 Å. Thus, an electron transfers over, $HCl^{\ominus}$ dissociates, the H atom departs, and the $Na^{\oplus}$ and $Cl^{\ominus}$ are drawn together. The highly vibrationally excited NaCl cannot get rid of any of its energy as the H atom is already gone. The H atom has only felt the repulsion of the loosely bound or highly vibrationally excited NaCl. This interpretation is borne out by the polarization measurements in which the favored alignment of the Na 4d orbital for reactive signal at any laboratory detector angle is along the relative velocity vector of the system. This corresponds to pointing the 4d orbital towards the HCl, because at long range the relative velocity vector in the laboratory is from the Na to the HCl.

Such a detailed study of the dependence of reactivity on the orbital alignment and the molecular orientation is possible only by combining the crossed molecular beams method with laser excitation.

Concluding Remarks

The experimental investigation of elementary chemical reactions is presently in a very exciting period. The advancement in modern microscopic experimental methods, especially crossed molecular beams and laser technology, has made it possible to explore the dynamics and mechanisms of important elementary chemical reactions in great detail. Through the continued accumulation of detailed and reliable knowledge about elementary reactions, we will be in a better position to understand, predict, and control many time-dependent macroscopic chemical processes which are important in nature or to human society.

In addition, because of recent improvements in the accuracy of theoretical predictions based on large-scale ab initio quantum-mechanical calculations, meaningful comparisons between theoretical and experimental findings have become possible. In the remaining years of the twentieth century, there is no doubt that the experimental investigation of the dynamics and mechanisms of elementary chemical reactions will play a very important role in bridging the gap between the basic laws of mechanics and the real world of chemistry.

The experimental investigations described in this article would not have been possible without the dedicated efforts of my brilliant and enthusiastic co-workers during the past twenty years. I enjoyed working with them immensely and sharing the excitement of carrying out research together.

I entered the field of reaction dynamics in 1965 as a postdoctoral fellow in the late Bruce Mahan's group at Berkeley, and learned a lot about the art of designing and assembling a complex experimental apparatus from many scientists and supporting staff at the Lawrence Berkeley Laboratory while studying ion-molecule scattering. In February of 1967, I joined Dudley Herschbach's group at Harvard as a postdoctoral fellow. There, I was exposed to the excitement of the crossed molecular beams research and participated in the construction of a universal crossed molecular beams apparatus. Dudley's contagious enthusiasm and spectacular insight motivated not only me, but a whole generation of chemical dynamicists.

Molecular collision dynamics has been a wonderful area of research for all practitioners. This is especially true for those who were following the footsteps of pioneers and leaders of the field twenty years ago. In my early years, I was also inspired by the pioneering research work of Sheldon Datz and Ellison Taylor, Richard Bernstein, John Ross, and Ned Green, as well as the "supersonic" John Fenn. They have been most generous and caring scientists and all of us admire them. Their work is the main reason why the field of molecular beam scattering has attracted many of the best minds in the world and made it a most exciting and rewarding field.

My associations with the University of Chicago (1968–74) and with the University of California, Berkeley (1974–) have been very rewarding. I could not ask for a better environment to pursue an academic career. The stimulating colleagues and excellent facilities as shown in Figure 19 are what made these institutions so wonderful.

Fig. 19. Part of the new molecular beam laboratory at the University of California, Berkeley.

Throughout all these years, my scientific research activities have been supported continuously by the Office of Basic Energy Sciences of the Department of Energy and the Office of Naval Research. The stable and continuing support and the confidence they have shown in my research have been most important and are gratefully appreciated.

Some Concepts in Reaction Dynamics (Nobel Lecture)**

By John C. Polanyi*

The objective in this work has been one which I have shared with the two other 1986 Nobel lecturers, *D. R. Herschbach* and *Y. T. Lee*, as well as with a wide group of colleagues and co-workers who have been responsible for bringing this field to its current state. That state is summarized in the title; we now have some concepts relevant to the motions of atoms and molecules in simple reactions, and some examples of the application of these concepts. We are, however, richer in vocabulary than in literature. The great epics of reaction dynamics remain to be written. I shall confine myself to some simple stories.

1. Experimental and Theoretical Approaches

In this section I shall say something about the experimental and theoretical tools we have used, and give some indication of their origins.

Our principal experimental method has been the study of IR chemiluminescence. The most valuable theoretical tool has been, and remains, the computer integration of the classical equations of motion. Though both of these methods belong to the modern period of reaction dynamics, both have clear antecedents in earlier times.

IR chemiluminescence derives from the presence of vibrationally excited molecules in the products of reaction. Indirect evidence for the existence of such species was obtained by *M. Polanyi* and his co-workers in 1928 in the course of studies of the reactions of alkali metal atoms and halogens.[1] Following a suggestion by *Bates* and *Nicolet*[2] and by *Herzberg*,[3] *McKinley*, *Garvin*, and *Boudart*[4] looked for and found visible emission from vibrationally excited hydroxyl radicals formed in the reaction of atomic hydrogen with ozone. This finding was followed soon after by the identification, by absorption spectroscopy, of vibrational excitation in the products of the reactions of atomic oxygen with NO_2 and ClO_2.[5]

Reference [5] appeared in the year that, in collaboration with *J. K. Cashion*, we undertook to look for IR chemiluminescence from vibrationally excited hydrogen halides (and other hydrogen-containing compounds) formed in simple exchange and addition reactions. The first reaction studied was that of atomic hydrogen with molecular halogens.[6,7] IR emission was observed in the region 1.5–4.5 μm arising from the low-pressure ($\approx 10^{-1}$ torr) room temperature reaction

$$H + X_2 \longrightarrow HX^{\dagger} + X \qquad (1)$$

where X was Cl or Br.

At that date there was lively discussion of the possibility of a visible analogue of the maser, that would operate on population-inverted electronic states (a working laser was still in the future).[8] Given our interests it was natural to speculate about the properties of a vibrational laser. In our communication ("Proposal for an Infrared Maser Dependent on Vibrational Excitation")[9] we pointed to a number of virtues of such a device, of which we shall note two here.

(1) Provided that the vibrational temperature, T_V, sufficiently exceeds the rotational temperature, T_R, (both temperatures being positive, in contrast to the negative temperatures associated with population inversion in the discussions of that date), a large number of P-branch transitions will exhibit population inversion (Fig. 1). We gave the name *partial population inversion* to this phenomenon, and noted that lasing based on partial population inversion could ensue shortly after a thermal pulse (arising from a pulsed arc, or shock wave), since "partial cooling" would ensure $T_V \gg T_R$.

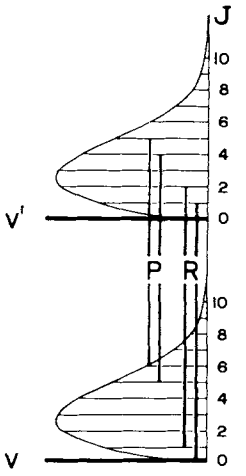

Fig. 1. "Partial population inversion"; $T_V \gg T_R$ (>0) ensures that the population in the upper state, N_u, exceeds that in the optically linked lower state, N_l for the indicated transitions (among others). The condition for lasing, $(N_u/g_u) > (N_l/g_l)$ where g is degeneracy, is only met for the P branch. (From J. C. Polanyi, *Appl. Opt. Suppl. 2* (1965) 109 [10], see also *J. Chem. Phys. 34* (1961) 347 [9b].)

(2) A chemical reaction could be used to obtain either "partial" or "complete" population inversion. We were struck by the fact that the upper atmosphere could constitute a natural laser in the IR favored by its long path length and large number of partially population-inverted transitions.[9,10]

Vibrational lasing was first achieved by *Patel* and coworkers.[11] Chemical reaction as the working material in a vibrational laser followed shortly afterward, through the work of *Pimentel* and his associates.[12] In both cases the major contribution to lasing came from partial population

inversion, as indicated by the predominance of P-branch emission.

In our first communication regarding IR chemiluminescence, we expressed the view that the method "promises to provide for the first time information concerning the distribution of vibrational and possibly rotational energy among the products of a three-center reaction."[6] This outcome was not so readily achieved.

By 1962 it was evident that reaction (1), despite the fact that it had proved to be a ready source of IR chemiluminescence, converted its heat of reaction into vibration with the modest efficiency of $\leq 50\%$.[13] This finding met with skepticism, since it was pointed out, correctly, that it implied for the reverse endothermic process that one could have so much vibration in the reagents that the reaction probability would be markedly diminished.[14] The somewhat lame reply at that date was that "though odd, it could still be the case!"[15]

Today we would surmise that it is the case since for the endothermic process $Cl + HCl \rightarrow Cl_2 + H$ a heavy particle (Cl) must approach during the brief time that the H-Cl bond remains extended; too much vibrational excitation can have the consequence that the Cl + HCl interaction is averaged over many vibrational periods, resulting in an "adiabaticity" with respect to the flow of energy into the bond to be broken. At that date the importance of the relative timing of molecular motions (though recognized for other types of inelastic encounters) had not yet been documented for chemical reactions.

It was not until 1967, with the development of the methods of "measured relaxation" (MR)[16] and "arrested relaxation" (AR)[16] that the goals established nine years earlier were truly achieved. The impediment to obtaining full quantitative data by infrared chemiluminescence, or any other means, in regard to what we have termed the "detailed rate constants", $k(V',R')$ (V' is the product vibrational excitation, and R' the product rotational excitation), has been the presence of an undetermined amount of vibrational and rotational relaxation of the reaction product prior to observation.

In the MR approach[16,17-19] this was addressed by measuring the vibrational relaxation at points along the direction of flow, and hence correcting for this effect (see Fig. 2a). In the AR method[16,18-21] relaxation, rather than being measured, was arrested to the fullest extent possible, by the rapid removal of excited products. This was achieved by complete deactivation at a surface, usually cooled in the range 20-77 K (Fig. 2b). Arrest of relaxation yielded detailed rate constants at the level $k(V',R',T')$, where T' is the translational energy distribution in the newly formed product, obtained by subtracting the initial vibrational plus rotational distributions from the total available energy.

Concurrently with the development of these IR chemiluminescence techniques, the crossed molecular beam method was established as a quantitative tool, particularly by *Herschbach* and co-workers. This method obviated problems of relaxation by conducting reaction under single-collision conditions. Since the prime measurables were product angular and translational energy distributions, by 1967 a degree of overlap existed between the approaches. It was not, however, until the incorporation of universal

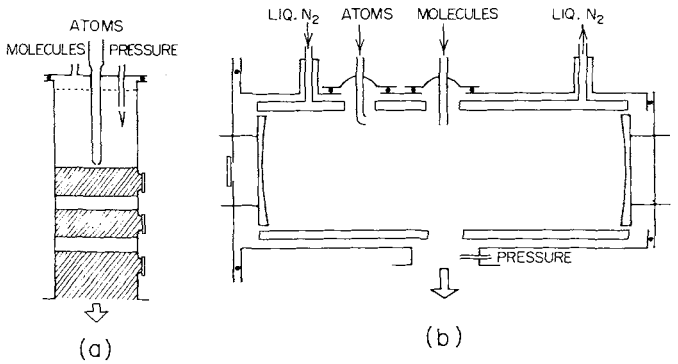

Fig. 2. a) Reaction vessel for "measured relaxation" (MR) (shaded regions indicate internal reflective coating; three sapphire windows at successive sampling points are indicated at the right); b) Reaction vessel for "arrested relaxation" (AR) shown schematically (mirrors at either end of the vessel collect IR radiation and bring it to the sapphire window at the left). (From K. G. Anlauf et al., *Discuss. Faraday Soc. 44* (1967) 183 [16].)

detectors by *Lee* and *Herschbach*, following what we have come to know as the "alkali age" of beam chemistry, that the same systems could be studied by both IR chemiluminescence and molecular beam scattering.

By the time that the first quantitative data began to appear powerful theoretical tools were available which could be used to link the potential field operating between atoms A, B, and C in a reaction

$$A + BC \longrightarrow AB + C \qquad (2)$$

to the motions of the particles. In the original work on the London equation[22] by *Eyring* and *Polanyi*[23] an attempt was made, in collaboration with *Wigner*, to solve the classical equations of motion for the reactive system A + BC. This work was taken up by *Hirschfelder* and *Wigner*,[24] but it was not until the first computer calculations of reaction dynamics by *Wall, Hiller*, and *Mazur*[25] that the full power of the approach became evident.

In parallel with *Blais* and *Bunker*,[26] we[27] employed *Wall, Hiller*, and *Mazur*'s approach in an attempt to map out the major determinants of A + BC reaction dynamics. Both groups were inspired by the proposal made by *M. G. Evans* and *M. Polanyi*,[28] over two decades earlier, that vibration in a newly formed bond might originate from the release of reaction energy as the reagents approached. Detailed computation indicated that this suggestion embodied an important kernel of truth, though the full story, as might have been expected, revealed a substantially richer range of scenarios.

2. Energy Distribution among Reaction Products

2.1. Experiment

In the MR method (see Section 1) several observation windows for recording IR chemiluminescence were located along the line of streaming flow. Provided that the observation windows were situated at distances corresponding to times during which relaxation was moderate, a simple graphical extrapolation back to zero time yielded adequate values for the relative $k(v')$ (v' is the vibrational

quantum number corresponding to the product vibrational energy V').[16,17] Detailed numerical analyses were also made, which included the effects of reaction, diffusion, flow, radiation, and collisional deactivation.[17] A model of this sort permitted, in effect, a more intelligent extrapolation to time $t=0$.

Subsequently, the flow-tube approach was applied to the determination of vibrational energy distributions in a substantial number of IR chemiluminescent reactions, particularly by *Setser* and his co-workers[29] and by *Kaufman*.[30] IR chemiluminescence experiments in flow tubes have also been extended to the elucidation of product energy distributions from ion-molecule reactions.[31]

In the AR method two uncollimated beams of reagent met in the center of a vessel, exhibiting a background pressure, with reagents flowing, of ca. 10^{-4}–10^{-5} torr. Reaction occurred at the intersection of the beams (as demonstrated in Ref. [18]). The products of reaction were transferred, following a few secondary collisions, to a deactivating surface which surrounded the reaction zone. Depending on the reagents, this surface acted as a cryo-pump, as a getter pump (trapping non-condensibles in excess condensible), or simply as an adsorber capable of bringing about complete vibrational deactivation (adsorbing product for a time sufficient to deactivate the material to its ground vibrational state, $v=0$).

The IR chemiluminescence stemming from the small fraction of molecules that emitted early in their lifetimes, was collected by gold front-surface mirrors, freshly coated for each experiment; this procedure increased the effective solid angle being viewed by almost $50\times$.[32] By this means ca. 10^{-9} torr of vibrationally excited product could be detected in one v,J (vibrotational) state, using the liquid-nitrogen-cooled PbS semiconductor detectors that became available in the late 1950s. The emission spectrum (Fig. 3) was recorded in early work on a (NaCl, then LiF) prism spectrometer, later on a grating spectrometer and (from the early 1970s; see, e.g., Ref. [33]) on a variety of Fourier transform interferometric spectrometers.

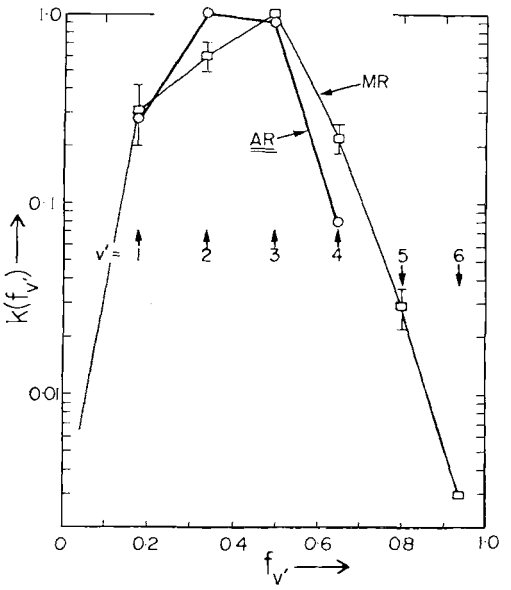

Fig. 3. Semi-logarithmic plot of the probability that a fraction $f_{v'}$ of the energy in the products of the reaction $H+Cl_2 \rightarrow HCl+Cl$ enters vibration in the newly formed bond. The data were obtained independently by the MR and AR methods, as indicated. The vibrational quantum states $v'=1$–6 correspond to the values of $f_{v'}$ indicated by arrows across the center of the figure. (From K. G. Anlauf et al., *Discuss. Faraday Soc. 44* (1967) 183 [16].)

The AR method was adopted by several laboratories, notably *N. Jonathan*'s,[34] *D. W. Setser*'s,[35] and *J. D. McDonald*'s.[36] It is characterized by molecular flow of the reactants and hence low densities in the reaction zone, permitting observation of reaction products with highly non-

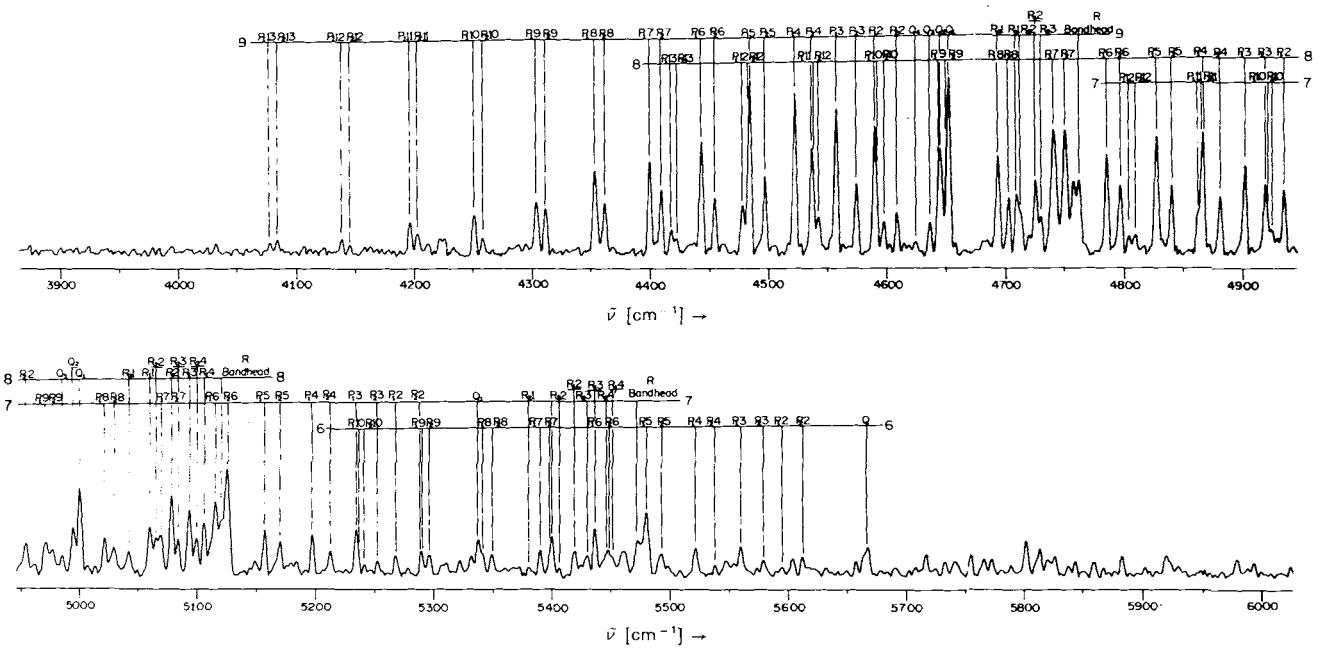

Fig. 4. First-overtone ($\Delta v'=-1$) spectrum of OH formed in the reaction $H+O_3 \rightarrow OH+O_2$, $-\Delta H_0^\circ = 77$ kcal mol^{-1}. Under arrested relaxation conditions, a continuous flow of reagents yields a steady-state distribution of $OH(v')$ that increases with v' up to the highest accessible vibrational level, $v'=9$ ($E(v'=9)=75$ kcal mol^{-1}, i.e., 3.25 eV). This spectrum was recorded by using a Fourier transform spectrometer and AR geometry; emission is from $v'=6$–9 as indicated. (From P. E. Charters et al., *J. Appl. Opt. 10* (1971) 1747 [33]; see also J. C. Polanyi, J. J. Sloan, *Int. J. Chem. Kinet. Symposium 1* (1975) 51.)

Boltzmann rotational distribution, as well as non-Boltzmann vibrational distributions.

The effectiveness of the combination of molecular flow plus rapid removal of reaction products in reducing relaxation to an insignificant amount in the majority of systems studied was indicated by the fact that the steady-state distribution observed under these conditions was in satisfactory agreement with the initial vibrational distribution obtained by the MR method (Fig. 4) and the observed rotational distribution was largely unrelaxed (Fig. 5), indicating that collisional deactivation of vibrators—generally a less efficient process—was insignificant. In the case of a few very fast reactions (notably $F+HBr \rightarrow HF+Br$[29]), $k(v')$ from MR were at variance with those from AR. At the low flows used in the AR machine it appears that reaction and deactivation were occurring within the inlets, invalidating the results;[37] in such a case the AR rotational distributions were also found to have been relaxed.[38]

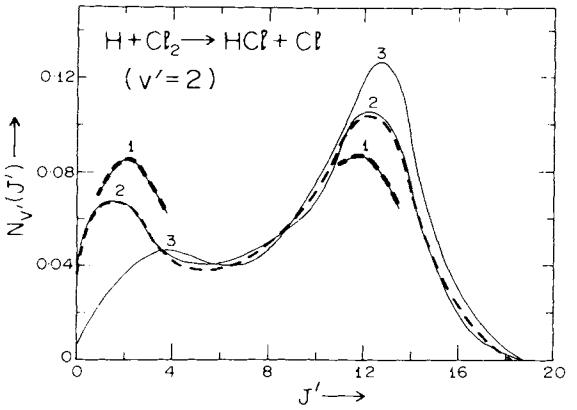

Fig. 5. Solid lines record the decreasing contribution of the peak at low J' to the observed rotational distribution (for $H+Cl_2 \rightarrow HCl(v'=2,J')+Cl$) as the pressure in the beam-crossing region is decreased (in the sequence $3 \rightarrow 2 \rightarrow 1$) in an AR vessel. The broken lines give relaxed distributions computed from 3. (Based on Fig. 1 of J. C. Polanyi, K. B. Woodall, *J. Chem. Phys. 56* (1972) 1563 [39].)

The observed rotational distributions were typically bimodal, comprising a non-thermal distribution at high rotational quantum number (high J') and a thermal distribution peaking at low J'. The contribution of the peak at low J' relative to that at high J' decreased with diminishing pressure in the reaction zone (Fig. 5). Accordingly, the low J' peak was ascribed to collisional relaxation; the relaxation mechanism being analyzed in detail.[39]

Some detailed rate constants, $k(v')$, for the reaction

$$F + H_2 \longrightarrow HF + H \qquad (3)$$

obtained by different procedures and by different workers are given in Table 1. Included among the methods used is one due to *Pimentel* and co-workers which made use of stimulated, rather than spontaneous, IR emission.[34b] This approach was an outgrowth of the first chemical laser, due to the same laboratory.[12] The laser approach[40] gave quantitative data concerning the population in the vibrational ground state $v'=0$, which previously had been unobservable. Also included in Table 1 are the findings from crossed molecular beam studies performed in *Y. T. Lee*'s laboratory.[42a] In these demanding experiments the vibrational distribution was obtained from structure in the product translation energy distribution, which was the measured quantity (the findings are for somewhat different reagent energy distributions than for the other experiments tabulated). The reaction $F+H_2 \rightarrow HF+H$ is of considerable fundamental interest since it involves only eleven electrons, and should therefore be amenable to ab initio computation (see below). The agreement between determinations of $k(v')$ is satisfactory.

When these experiments and those described below were undertaken, quantitative data regarding $k(v')$ did not exist. The prior observation of highly vibrationally excited reaction products in a number of systems, since it was a qualitative finding, left open the question of the form of $k(v')$ which could have peaked anywhere from $v'=0$ to $v'=v'_{max}$ (the highest accessible vibrational state). In fact the distributions observed by IR chemiluminescence were found to peak at intermediate v', so that the mean fraction of the available energy entering vibration in the new bond ranged from $\langle f_{v'}\rangle = 0.39$ for $H+Cl_2$, $\langle f_{v'}\rangle = 0.55$ for $H+Br_2$, $\langle f_{v'}\rangle = 0.53$ for $H+F_2$, and $\langle f_{v'}\rangle = 0.66$ for $F+H_2$ up to $\langle f_{v'}\rangle = 0.71$ for $Cl+HI$ and $\langle f_{v'}\rangle \approx 0.9$ for $H+O_3 \rightarrow OH+O_2$.

An early finding was that the product vibrational energy distribution $k(v')$ altered dramatically with isotopic substitution, but was roughly invariant if represented in the re-

Table 1. Detailed rate constants $k(v')$, for $F+H_2 \rightarrow HF(v')+H$; comparison data from various studies (with some variation in reagent collision energy).

duced form $k(f_{v'})$.[41] This is what one would expect if classical mechanics applied rather than conservation laws involving quantum states. The finding gave us courage in applying classical mechanics to these reactions (despite the fact that they were characterized by widely spaced vibrational and rotational states), and also encouraged us to record our results in a graphical form that rode roughshod over the quantized nature of $k(v',J')$.

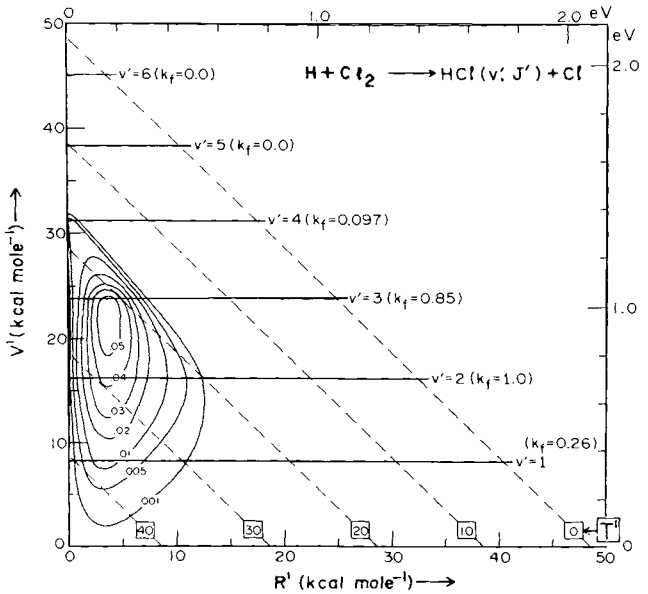

Fig. 6. "Triangle plot" for $H+Cl_2 \rightarrow HCl+Cl$ reaction showing the distribution of vibrational, rotational, and translational energy as contours of equal detailed rate constant $k(V',R',T')$. The ordinate is product vibrational energy, and the abscissa is the product rotational energy. Since the total available energy is approximately constant ($E'_{tot}=48.4$ kcal mol^{-1}), translational energy, T', given by the broken diagonal lines, increases to 34 kcal mol^{-1} at $V'=0$, $R'=0$. The rate constant $k_f \equiv k(v')=\Sigma_{J'}k(v',J')$; the subscript f denotes the "forward," exothermic, direction. Contours have been normalized to $k(v')=1.00$ where v' is the most populated vibrational level. (From K. G. Anlauf et al., *J. Chem. Phys.* *57* (1972) 1561 [19].)

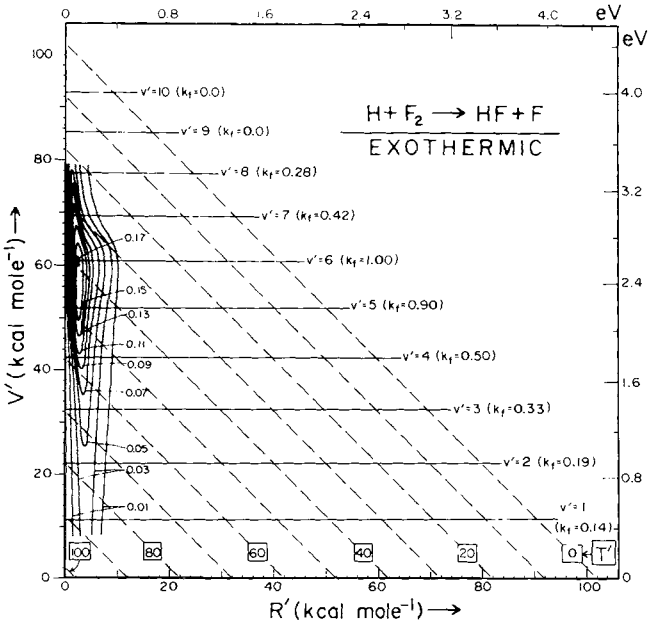

Fig. 7. Triangle plot for $H+F_2 \rightarrow HF+F$ (see caption to Fig. 6). $E'_{tot}=102$ kcal mol^{-1} for this reaction. (From J. C. Polanyi, J. J. Sloan, *J. Chem. Phys.* *57* (1972) 4988 [21].)

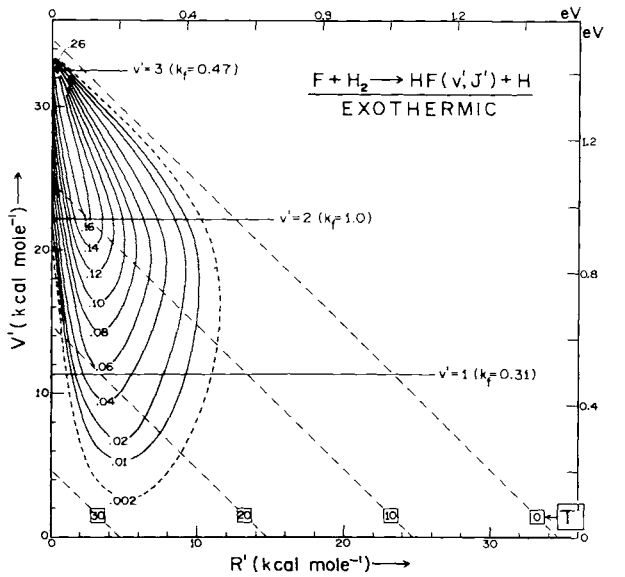

Fig. 8. Triangle plot for $F+H_2 \rightarrow HF+H$ (see caption to Fig. 6). $E'_{tot}=34.7$ kcal mol^{-1} for this reaction. (From J. C. Polanyi, K. B. Woodall, *J. Chem. Phys.* *57* (1972) 1574 [20].)

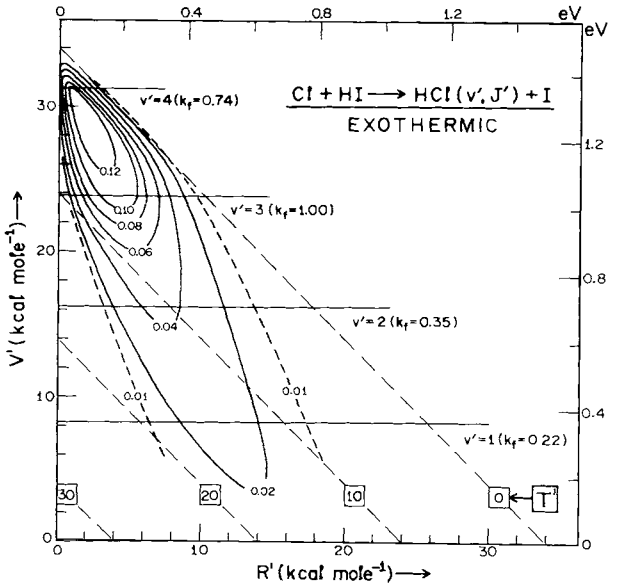

Fig. 9. Triangle plot for $Cl+HI \rightarrow HCl+I$. See caption to Fig. 6. $E'_{tot}=34$ kcal mol^{-1}. (From D. H. Maylotte et al., *J. Chem. Phys.* *57* (1972) 1547 [18].)

Four examples of the graphs that we have used (as a supplement to the tabulation of the actual $k(v',J')$ values) as an aid to the visualization of the experimentally determined product energy distributions, are shown in Figures 6–9. By interpolation between permitted combinations of V', R', and T', we obtain contours of equal $k(V',R',T')$. In these "triangle plots" contours are shown in V',R',T' space. They delineate a "hill" of detailed rate constant in that space. Portions of the hill that lie between vibrational energy states are merely included to guide the eye as to the breadth and shape of the product energy distribution over the axes corresponding to V', R', and T'. Since classical mechanics is widely used in order to interpret energy distributions, these classical "fingerprints" of differing chem-

ical reactions help us to picture contrasting types of behavior.

It is readily apparent that the first two reactions, $H+Cl_2$ and $H+F_2$ (Figs. 6 and 7), though they liberate markedly different energies, both exhibit inefficient vibrational and rotational excitation and consequently efficient translational excitation. The third reaction, $F+H_2$ (Fig. 8), gives rise to highly efficient vibrational excitation together with inefficient rotational excitation. The fourth reaction pictured, Cl+HI (Fig. 9), combines efficient vibrational excitation with exceptionally efficient rotational excitation ($\langle f_{R'}\rangle = 0.13$ for Cl+HI in contrast to $\langle f_{R'}\rangle = 0.03$ for $H+F_2$). In concurrent work, alluded to in the following section, we linked these changes in dynamics tentatively to the release of repulsive energy in systems having differing mass combination and preferred geometries of the intermediate.

The ridge of the "detailed rate constant hill" is almost vertical in the case of the first three reactions, moving out to higher R' at lower V' in the fourth of the reactions pictured (Cl+HI) (for a tabulation of mean $\langle f_{v'}\rangle$, $\langle f_{R'}\rangle$, and $\langle f_{T'}\rangle$ and for the slope of the ridge $\Delta R'/\Delta V'$ for these reactions, see Table IV of Ref. [21]). Leaving aside the dynamical implications of this distinctive behavior (see Section 2.2 below), it is noteworthy that successively lower vibrational states will exhibit marked increases in *translational* energy in the first three cases, but an overlapped "translational energy spectrum" in the fourth case. This finding was seen to have interesting implications for the crossed molecular beam chemistry in which T' (as already noted) is the prime measurable. Figure 10 gives sample distributions over $f_{T'}$ (blending rotational states into a continuum, since they cannot be resolved in molecular beam time-of-flight (TOF) studies). The reaction $H+F_2$, not pictured here, gives rise to eight well-resolved translational peaks (Fig. 5 of Ref. [21]). In the case of the $F+H_2$ reaction and its isotopic analogues, in addition to resolving these peaks by TOF, *Y. T. Lee*'s laboratory has in recent times fully characterized the angular distribution of each.[42]

The triangle plots, exemplified in Figures 6–9, constitute one way of "compacting" the substantial data embodied in $k(v',J',T')$.The information theory, pioneered by *Bernstein* and *Levine*,[43] has provided a widely used alternative method of compaction in terms of parameters which describe the deviation of the observed vibrational and rotational distributions from a statistical outcome. These deviations can be described as vibrational and rotational "surprisals." In those cases for which the surprisal is found to be a linear function of $f_{v'}$ or $f_{R'}$, not only can the data be reduced to only two constants, but extrapolations can be made. We have made use of this in our work in order to estimate the (small) fraction of product formed in the non-emitting state, $v'=0$.

Figures 11a and 11b contrasts the triangle plots for HF and DF formed in the thermal reaction $F+HD \rightarrow HF(v',J')$ or $DF(v',J')$ (+D or +H).[47] These data are included since they shed light on a source of product rotational excitation. The forces operating are very similar but are clearly substantially more effective in rotationally exciting HF (mean fraction of the available energy entering rotation is $\langle f_{R'}\rangle \approx 0.125$) than DF ($\langle f_{R'}\rangle = 0.066$). We postpone discussion to Section 2.2 below.

It is interesting to note that for the family of reactions $F+HD \rightarrow HF$, $F+HD \rightarrow DF$, $F+H_2$, and $F+D_2$, studied by IR chemiluminescence, the first reaction in the list exhibited vibrational excitation that was anomalously low as compared with classical calculation. This (together with

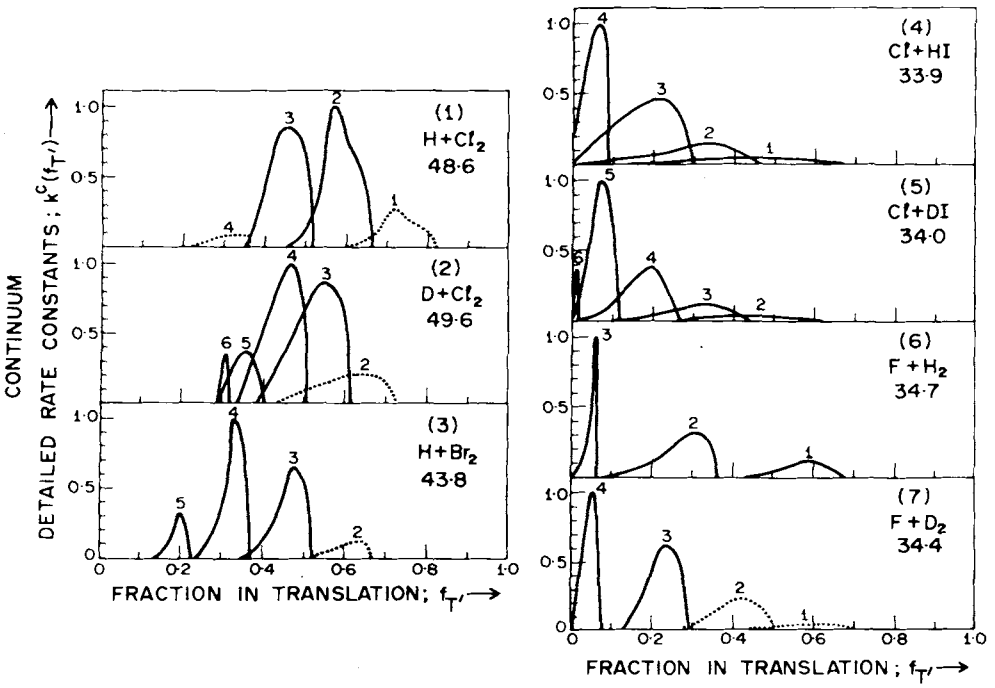

Fig. 10. Translational energy distribution ($f_{T'}$) in the products of some exchange reactions A+BC → AB+C obtained by subtracting the vibrational excitation measured by IR chemiluminescence from the total product energies (indicated in the figure). The vibrational states that contribute to the translational peaks are recorded above each peak (see text). (From K. G. Anlauf et al., *J. Chem. Phys. 53* (1970) 4091 [48a].)

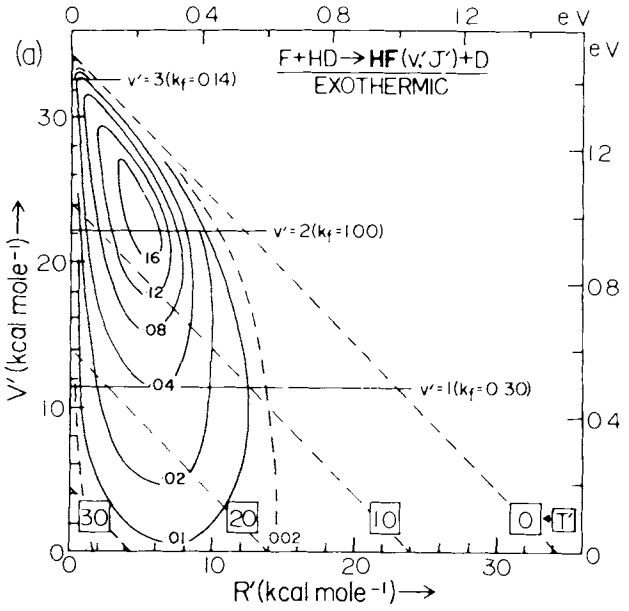

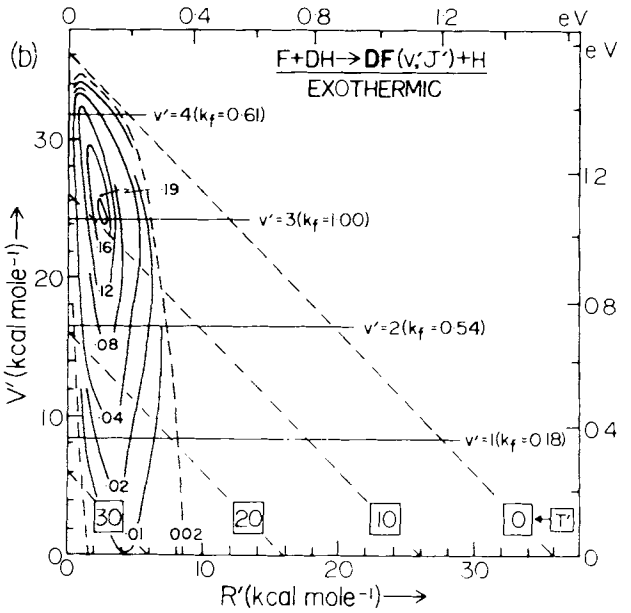

Fig. 11. Triangle plots for both branches of the F+HD exchange reaction. The total available energy in the products was taken to be $E'_{tot}=34.3$ kcal mol^{-1} for the HF product, and $E'_{tot}=36.1$ kcal mol^{-1} for DF, in calculating product translation T'. (From D. S. Perry, J. C. Polanyi, *Chem. Phys. 12* (1976) 419 [47].)

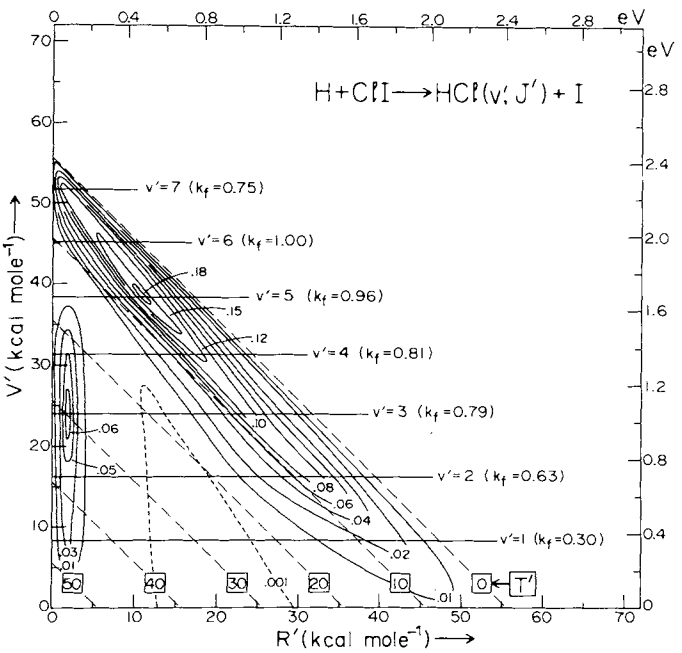

Fig. 12. Triangle plot for the reaction H+ClI → HCl+I at 300 K showing bimodality (18% of the HCl is in the low $-J'$ mode, 82% in the high $-J'$). (From M. A. Nazar, J. C. Polanyi, W. J. Skrlac, *Chem. Phys. Lett. 29* (1974) 473 [48c]; see also J. C. Polanyi, W. J. Skrlac, *Chem. Phys. 23* (1977) 167 [48d].)

the reagent-energy dependence of $k(v'=3)$ was taken to be evidence of a quantum effect at the threshold energy for formation of HF($v'=3$). Molecular beam experiments in *Y. T. Lee*'s laboratory have shown the importance of quantum effects on the dynamics of the first member of this family of reactions.[42]

Figure 12 shows the dramatic influence that atom C can have on the dynamics of a reaction A+BC → AB+C. On paper the reaction illustrated resembles H+ClY → HCl+Y, for which the detailed rate constant $k(V',R',T')$ is given in Figure 6; the difference is that the second halogen atom, Y, has been changed from Y=Cl to Y=I, with the effect on $k(V',R',T')$ recorded in Figure 12. Bimodal product energy distributions were also observed in a number of other studies[48-51] and were regarded as indicative of the existence of two types of reaction dynamics leading to the identical product (HCl in the case illustrated). This phenomenon was termed *microscopic* branching, to distinguish it from the *macroscopic* branching leading to chemically different products (see, for example, Fig. 11). As we shall indicate in Section 2.2, these two types of branching are likely to be linked.

It is interesting to consider the strengths and weaknesses of IR spectroscopy as a tool in the study of reaction dynamics. The major limitations have stemmed from the low transition probabilities in the IR, the insensitivity of IR detectors, and the lack of a sufficiently precise time scale against which to measure the vibrational and especially rotational relaxation. Substantial improvements in sensitivity have been achieved using the important new methods of laser-induced fluorescence (LIF)[44] and resonantly enhanced multiphoton ionization (REMPI).[45] However, since these make use of electronic transitions, they cannot so readily scan the full manifold of product vibrotational energy states to yield data as complete as that exemplified in Figures 7-9, which remains the most complete available.

Tunable IR lasers, combined with adequate time resolution, could give a new lease of life to the vibrotational spectroscopy of reaction products. A promising development, employing IR chemiluminescence is the introduction of time-resolved Fourier transform spectroscopy following the pulsed photolytic initiation of exchange reaction.[46]

2.2. Theory

The origin of these theoretical studies is outlined in Section 1. In the early 1960s two groups[26,27] became interested in using the computer-based classical trajectory method[25] (often called the Monte Carlo approach) to explore, for the first time, a suggestion made over two decades earlier,[28] that energy released as reagents approach is responsible for vibration in the newly formed bond.

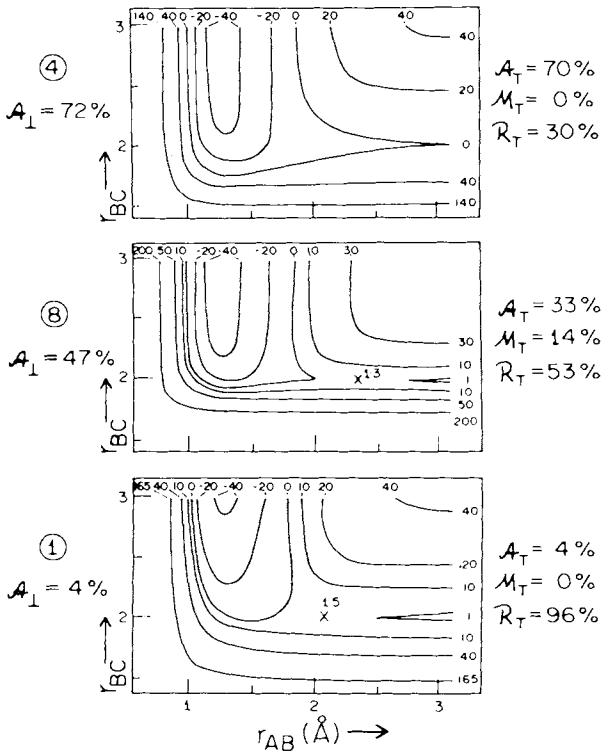

Fig. 13. Three potential-energy surfaces (PES) illustrative of the changes in potential energy as reagents A + BC (lower right) pass through collinear transition states A--B--C to form products AB + C (upper left). Contour energies are in kcal mol^{-1}; all three reactions have the same exothermicity. The PES, designated 1, 8, and 4, are arranged vertically in order of increasing "attractiveness." The PES are indexed at the left according to the percentage attractive energy release taken from a perpendicular path across the surface ($\mathscr{A}_\perp$ = 4, 47, and 72% for surfaces 1, 8, and 4). The same PES are described at the right according to the percentage attractive, mixed, and repulsive energy release, $\mathscr{A}_T$, $\mathscr{M}_T$, and $\mathscr{R}_T$, along a single collinear trajectory; this designation depends upon mass combination, which was L + HH (L = 1 amu, H = 80 amu). The barrier crest, designated x, shifts to "earlier" locations along r_{AB} as the surfaces become more attractive. (Excerpted from P. J. Kuntz et al., *J. Chem. Phys. 44* (1966) 1168 [53].)

Figure 13 shows three potential energy surfaces (PES), all of a modified London, Eyring, Polanyi, Sato (LEPS) variety,[27,52,53] selected from a wider group examined in Ref. [53]. The energy released as the reagents approached (termed the attractive energy release, and defined as $\mathscr{A}_\perp$ or $\mathscr{A}_T$,[53,54] see the caption of Fig. 13) increases as one moves upwards in the figure. There is, in related families of reaction, a concurrent diminution in the height of the energy barrier and a shift of the barrier to earlier locations along the coordinate of approach; it has proved possible to give an empirical expression to these correlations.[55,56]

In Figure 14 it can be seen that for a group of eight PES's moderate percentages of energy release along the

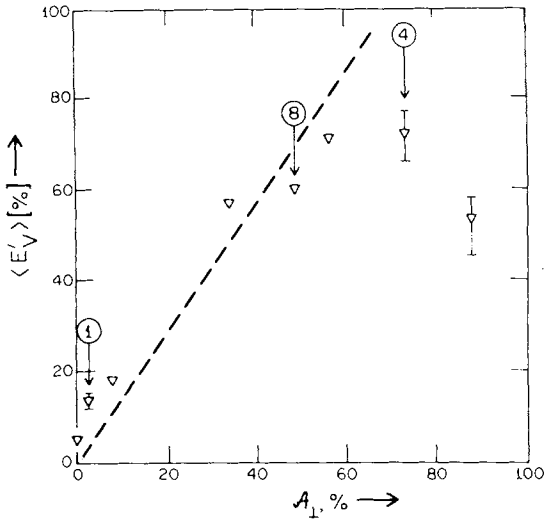

Fig. 14. Mean vibrational excitation in the products of 3D L + HH reaction on eight potential-energy hypersurfaces (PES) plotted against the perpendicular attractive energy release, $\mathscr{A}_\perp$. The collinear cuts through PES 1, 8, and 4 are to be found in the previous figure. The fall-off in $\langle E'_V \rangle$ at high $\mathscr{A}_\perp$ is due to the prevalence of secondary encounters (see text). (From P. J. Kuntz et al., *J. Chem. Phys. 44* (1966) 1168 [53].)

coordinate of approach (% $\mathscr{A}_\perp$) are converted quantitatively into product vibration, for a particular reagent mass combination (L + HH; see caption). For high % $\mathscr{A}_\perp$ the reaction moves into a new regime in which product vibration decreases with increased attractive energy release. Examination of the trajectories indicates that a transition is occurring from predominantly *direct* reaction (products once they start to separate continue to do so[57]) to *indirect* reaction in which subsequent "clutching" and "clouting" secondary encounters drain the incipient vibration out of the new bond into rotation and translation.[58,59] What we are seeing is the onset of statistical behavior, in the limit of which product vibration will receive no more than its modest equipartition allocation.

At the other end of the scale in Figure 14, where repulsive energy release predominates, the low vibrational excitation shown in the figure is by no means the rule; the observed vibrational excitation is strongly dependent on the chosen mass combination. The L + HH mass combination shown here is in fact anomalous in fulfilling the initial expectation that repulsive energy release $\mathscr{R}_\perp$ (energy released along the coordinate of separation of the PES) will be inefficiently channeled into vibration. For L + HH the attacking atom A approaches BC rapidly up to the normal bonding separation before the respulsion is released (dynamics in which r_{AB} decreases to its equilibrium separation, r^0_{AB}, and only then does r_{BC} increase, correspond on the PES to a rectilinear path). Since the repulsion operates on an already existent AB bond, vibrational excitation is indeed inefficient (left end of Fig. 14). This behavior is sufficiently atypical to be described as the "light-atom anomaly."[53]

For the more general case of a heavier attacking atom relative to the molecule under attack, the new bond is still extended ($r_{AB} > r^0_{AB}$) at the time that the bulk of the repulsion is released; we can symbolize this as A--B·C. In this case repulsion between the separating atoms B and C re-

sults in recoil of B, rather than of AB as a whole; i.e., it gives rise to efficient internal excitation of the new bond, AB.

Since the solution of the collinear equations of motion can be pictured in terms of the motion of a sliding mass across a suitably scaled and skewed representation of the PES, it is instructive to consider the characteristic path across the PES in this general case. The fact that r_{AB} decreases at the same time as r_{BC} increases (we term the energy released in this phase "mixed"; $\mathscr{M}_T$) means that the sliding mass, rather than following a rectilinear path, is cutting the corner of the PES. Instead, therefore, of approaching the exit valley from its head, it approaches the valley from the side; consequently it oscillates from side to side of the exit valley indicating that the new bond is vibrationally excited.

The proportion of the energy released during corner-cutting is clearly relevant to the efficiency with which the repulsive energy is channeled into vibration. We have routinely determined the extent of mixed energy release, $\mathscr{M}_T$, from a specimen collinear trajectory employing the appropriate mass combination and the PES in question.[10,53,60] Figure 13 shows that $\% \mathscr{M}_T$ is insignificant for **L + HH**. For other mass combinations it is so great that the points on a plot of the type shown in Figure 14 begin at substantial $\langle E'_V \rangle$, and the region of linearity prior to the falloff in $\langle E'_V \rangle$ due to the onset of indirect dynamics becomes a very short region (see the case of the heavy attacking atom in Fig. 7 of Ref. [53]).

Turning to the experimental findings of Section 2.1, it was evident that the moderate mean fractional conversion of reaction energy into product vibration, $\langle f_{V'} \rangle$, could be explained either by a highly attractive interaction leading to secondary encounters, or by predominantly one source of product rotation. The experimental data in the triangle plots of Figure 11 give persuasive evidence of the significance of this effect in the important reaction $F + H_2$. Product repulsion should be expected[47,67] on the basis of momentum conservation to give rise to decreasing $\langle f_{R'} \rangle$ in the series FH·D > FH·H > FD·D > FD·H (the dot indicated the locus of the repulsion); this is found theoretically, in 3D trajectory studies, and also experimentally (see Fig. 15). The triangle plots of Figure 11 correspond to the extremes of this range of isotopic mass combinations; $\langle f_{R'} \rangle$ for the FH·D pathway substantially exceeds that for FD·H.

Qualitative pictures of the type given in Figure 16 suggest simple models of the reactive event. Several such models are indicated in Figure 17, all of which stress the role of the forces operating along the coordinate of separation of the PES. The implications of each of these models are discussed in Ref. [59]. Despite their crudity, simple models have the important virtue that their "moving parts" are open to inspection. Model (c), called the simple harmonic model, has been used to improve our understanding of the mechanism of mixed energy release, in which a repulsive force operating between particles B and C drives an oscillator joining A to B that is under tension.[60] The model shows that for a wide range of conditions mixed energy release can play a significant role in channeling product repulsion into vibration.

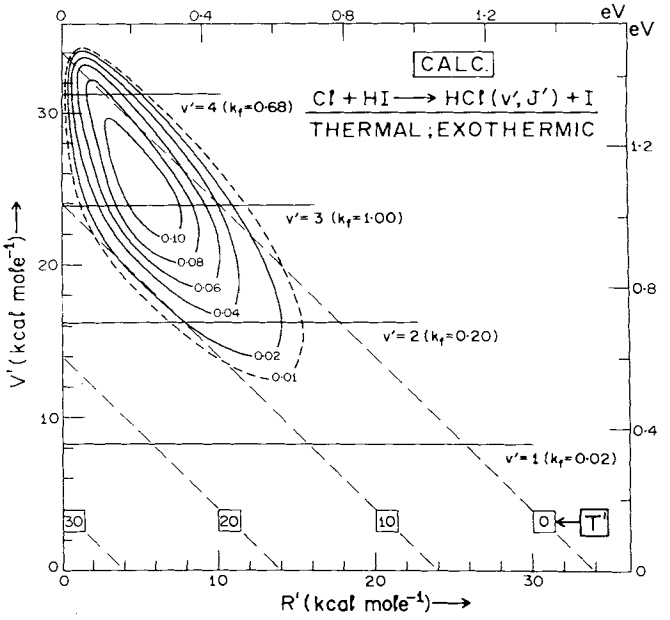

Fig. 15. Computed triangle plot for the reaction Cl + HI → HCl + I at thermal collision energies (300 K). The 3D classical trajectory method was applied to a highly repulsive PES (proposed by K. G. Anlauf et al., *J. Chem. Phys. 49* (1968) 5189 [41]; from C. A. Parr et al., *ibid. 58* (1973) 5 [61]).

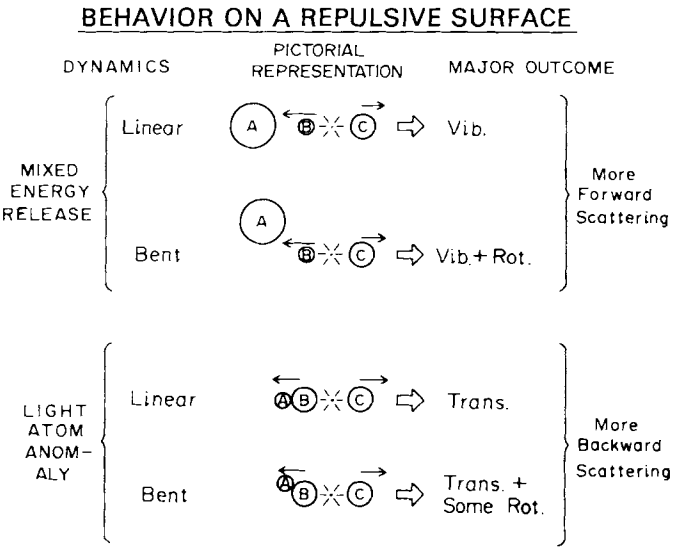

Fig. 16. Pictorial representation of contrasting types of reaction dynamics on a repulsive energy surface. "Mixed energy release" is commonly observed. "The light-atom anomaly" is observed if the attacking atom is very light. (From J. C. Polanyi, *Acc. Chem. Res. 5* (1972) 161 [58].)

Model (d), the direct interaction with product repulsion (DIPR) model,[68] sidesteps consideration of forces in the new bond by obtaining the product vibration, V', from $E'_{tot} - (R' + T')$. From the direction of recoil of atom C relative to the direction of approach of A, angular distributions can readily be generated in three dimensions (3D). The model provides a simple means to expose the link between the angular distribution of reaction products and the internal excitation, as well as the connection between these two quantities and the collision energy.

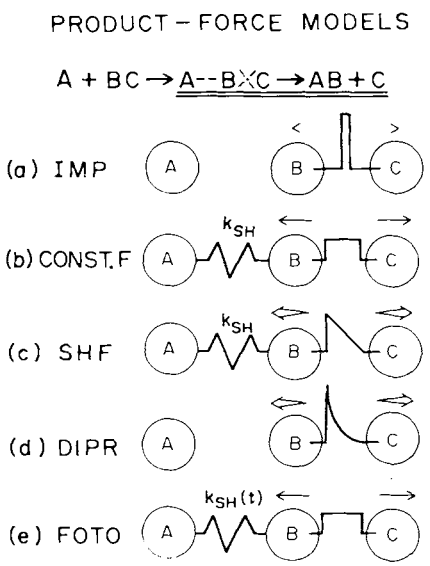

Fig. 17. Five types of simple "product-force models," which interpret product energy distributions in terms of the mode of relaxation of ABC in its retreat from the activated state → AB + C. A repulsive force is assumed to be located between the separating atoms B-C. Various assumptions are made regarding the bond A--B which is forming. a) The impulsive model (IMP); b) the constant force model (CONST. F.); c) the simple harmonic model (SHF); d) the direct interation with product repulsion (DIPR) model; e) the forced oscillation in a tightening oscillator (FOTO) model. (From J. C. Polanyi, *Faraday Discuss. Chem. Soc. 55* (1973) 389 [80].)

Findings for the DIPR model are summarized in Figure 18 (solid lines). Reading from left to right, the interactions become less repulsive (more attractive). This is achieved by systematically decreasing the repulsive impulse (the time integral of the force, $F(t)$, between B and C) which alone governs the dynamics. Since a measure of $\int F(t)\,dt$ can be obtained by a variety of means for any actual reactive PES,[47,67] the model can be applied to cases for which the results of 3D trajectory computation are known. The agreement—see the points for the more repulsive cases in Figure 18—is excellent, so long as the assumption of direct interaction remains valid.

The lessons that can be learned from Figure 18 are that strongly repulsive energy release will tend to give backward scattering of the molecular product (Θ_{mol} is substantial at 180°) coupled with moderate internal excitation, E'_{int}. As the repulsion is decreased, Θ_{mol} shifts forward and E'_{int} increases. The same effect can be achieved by increasing the reactant collision energy, since this too has the effect of decreasing the repulsive impulse $\int F(t)\,dt$.

Herschbach and co-workers have injected physical content into the DIPR model in their DIPR-DIP extension, in which the repulsive impulse is assumed to be "distributed as in photodissociation" (DIP).[69,70] The model then accounts nicely for product distributions observed in a number of reactions.[69] More recently *Zare*'s laboratory has shown how the DIPR approach can be used to understand the plane of rotation of newborn reaction products.[70]

The forced oscillation in a tightening oscillator (FOTO) model (Fig. 17e) gives a fuller rendition of the forces on a colinear PES; the B-C repulsion operates on an AB oscillator whose force constant is in the process of increasing, and whose equilibrium separation, r^0_{AB}, is decreasing. The

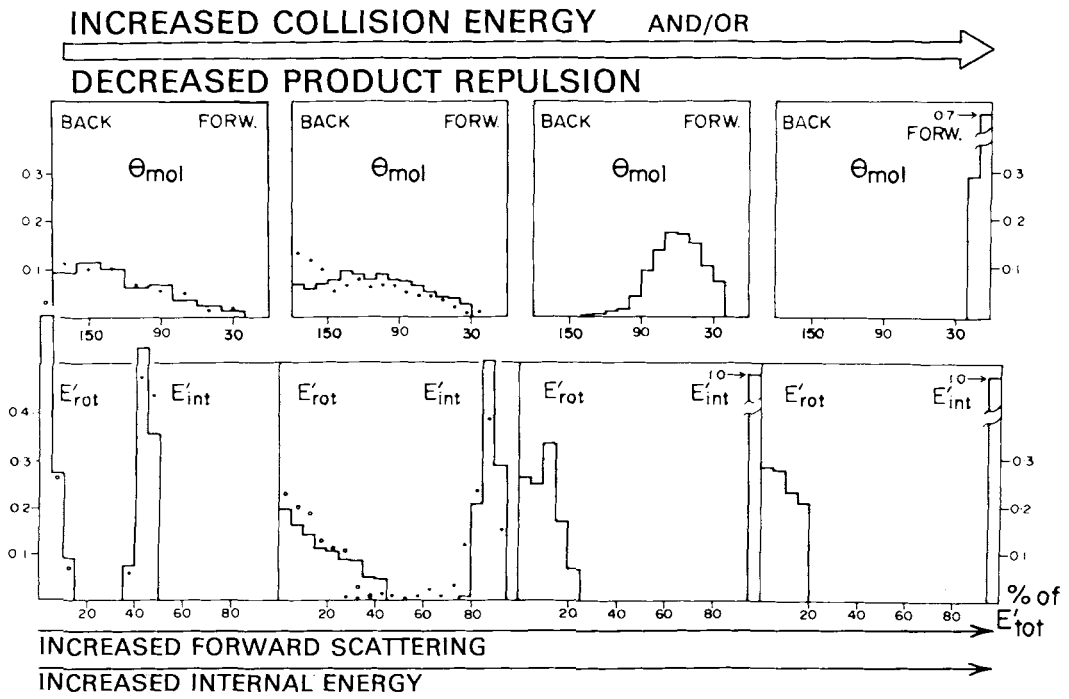

Fig. 18. Effect of repulsive energy release on product angular distribution (top row) and energy distribution (bottom row; E'_{tot} is product rotational excitation and E'_{int} is vibration plus rotation). The solid lines show the results of 3D DIPR model calculations (masses K + Br_2, energy release $E'_{tot} = 53$ kcal mol^{-1}). The total product repulsion used in the DIPR model calculations was decreased in four stages, from left to right in the figure, simulating decreased % $\mathscr{R}$, implying increased % $\mathscr{A}$. According to the DIPR model, this is mathematically equivalent to increasing the reagent collision energy, hence the dual label of the arrow at the top. The *consequences* of these changes are summarized, qualitatively, by the arrows at the foot of the figure. The dots record the distributions obtained from 3D trajectories on potential-energy hypersurfaces with comparable partitioning of the energy release. (Adapted from P. J. Kuntz et al., *J. Chem. Phys. 50* (1969) 4623 [68].)

model, which has been applied to ten reactions for which experimental or theoretical data exist, is sufficiently complete to embody analogues of the "attractive," "mixed," and "repulsive" phases of energy release.

To the extent that the rotation in a newly formed reaction product AB originates in repulsion AB·C, the rotational motion should be coplanar with the repulsive force, and B in AB should recoil away from C. This implies that the angle between the product rotational angular momentum vector, $\vec{J}'$, and the product orbital angular momentum vector, $\vec{L}'$, should be $\Theta_{J'L'} \approx 180°$ (Fig. 19). Analyses of product distributions from 3D trajectory studies[64,71] bear this out. Experimental studies of correlations between such vector attributes will add materially to the mosaic from which our picture of reaction dynamics is composed.

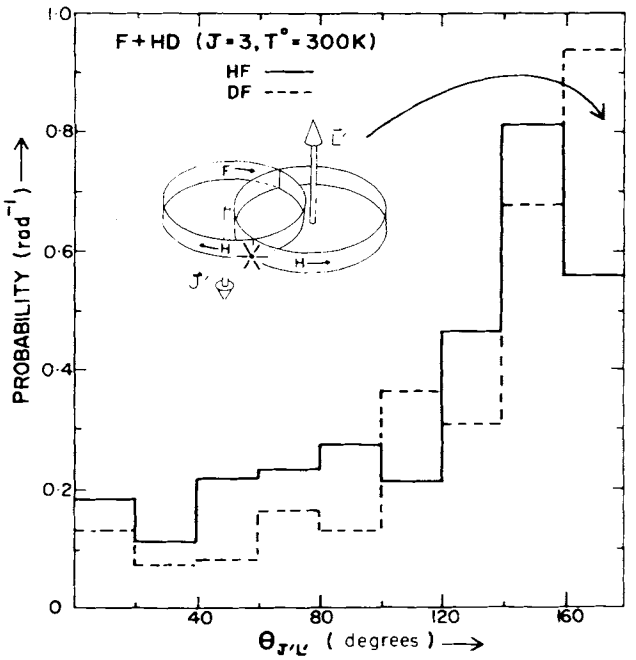

Fig. 19. Computed distribution, $\Theta_{J'L'}$, of the angle between the product rotational angular momentum, $\vec{J}'$, and orbital angular momentum, $\vec{L}'$, following repulsive energy release between the products of the reaction F+HD → HF+D (solid line) and F+HD → DF+H (broken line). At the extreme left $\Theta_{J'L'}=0$ corresponds to $\vec{J}'$ parallel to $\vec{L}'$, while at the extreme right $\Theta_{J'L'}=180°$ corresponds to the favored outcome of $\vec{J}'$ antiparallel to $\vec{L}'$.

The richer the detail in the rate constants $k(V',R',T')$, the clearer the message. The striking bimodality in the product energy distribution from H+ClI → HCl(v',J')+I recorded in Figure 12 can be ascribed to "microscopic branching"; two patterns of molecular dynamics result in the formation of the same reaction product (HCl in this example). The dynamics have been explored in 3D for reasonable PES's.[72] They are shown schematically in Figure 20. In the case of H+ClI, the migratory *microscopic* pathway (at the right of Fig. 20) is thought to dominate. This is for the same reason that *macroscopic* branching favors formation of HI rather than HCl, namely, the existence of a smaller energy barrier for approach from the I end of ICl (see Refs. [72, 73] for the greater stability of ClIH than HClI). In collisions of H with the I end of ICl that fail to yield HI, the H atom can migrate toward the Cl end of the molecule to yield highly internally excited HCl. The HCl

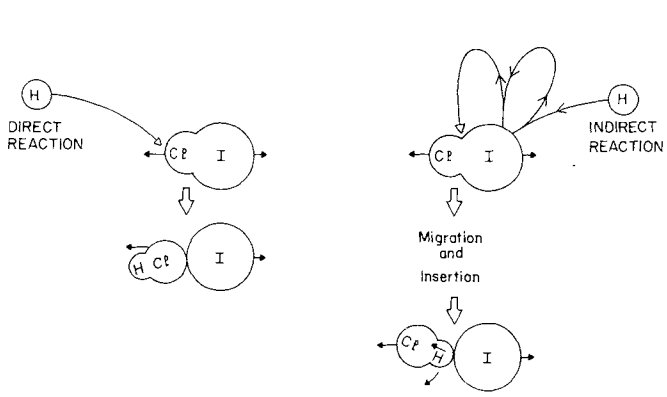

Fig. 20. Pictorial representation of the alternative dynamics—direct and indirect—in the microscopic branching underlying the bimodality of product energy distribution exemplified in Figure 12. (Based on a classical trajectory study; J. C. Polanyi et al., *Faraday Discuss. Chem. Soc.* 67 (1979) 66 [51]).

product with low internal excitation comes from H that have reacted directly at the Cl end of ClI. Since the barrier to this mode of reaction is higher, the yield (at normal reagent energies) is lower. It is evident that the relative yields of HCl and HI in *macroscopic* branching are linked to the yields of low E'_{int} and high E'_{int} HCl by way of *microscopic* branching.

Microscopic branching is though to constitute more than merely an interesting curiosity, since it can contribute to the dynamics in any case where macroscopic branching is possible—a large class of reactions. As would be expected, the importance of microscopic branching, in common with macroscopic branching, depends sensitively on the reagent energy.[49,50,74]

3. Channeling Reagent Energy into Products

3.1. Experiment

In the experiments that will now be briefly described, reagent translational, vibrational, and rotational energies were altered by simple means in order to explore the effect on the product energy distribution. To increase the collision energy we formed the atomic reagent (Cl for Cl+HI,[67,75] F for F+HCl[50] or F+D_2,[50] and H for H+Cl_2[50]) by pyrolysis, rather than using room temperature atoms as in the work described in the previous section. The effect is shown for H+Cl_2 in the triangle plot of Figure 21. Comparison with the earlier 300-K triangle plot (Fig. 6) shows marked changes. The *additional* reagent translation, ΔT, in excess of the barrier to reaction, has been channeled principally into additional product translation.

A second repository for this additional reagent energy was product rotation. (It was interesting to observe in both Cl+HI[75] and H+Cl_2[50] that this enhanced product rotation was associated with the appearance of a second maximum in the product rotational distribution, $k(J')_{v'}$, as if enhanced collision energy had led to *induced microscopic branching*.) The general finding regarding the disposition of additional reagent translation could be summarized as follows:

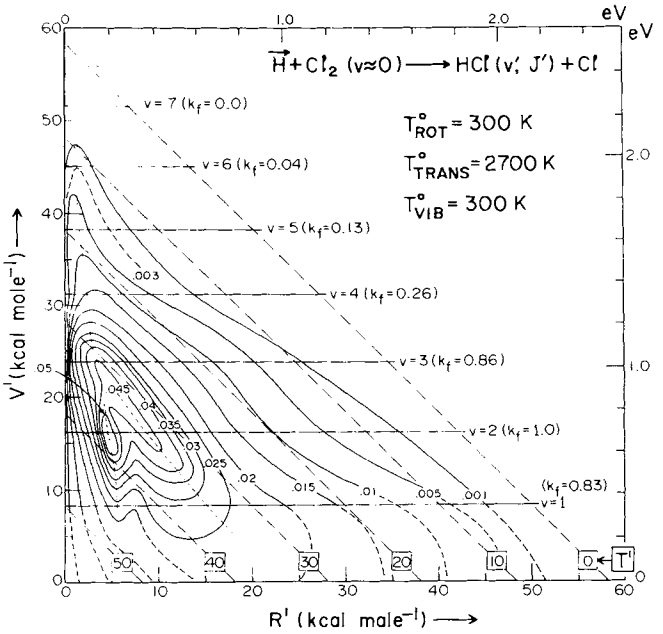

Fig. 21. Effect of enhanced reagent collision energy on the product energy distribution, i.e., experimental $k(V', R', T')$, for $H + Cl_2(v=0) \rightarrow HCl(v', J') + Cl$. Mean collision energy, $\langle T \rangle \approx 10.6$ kcal mol^{-1}. Compare $k(V', R', T')$ for room temperature reaction, in Figure 6. (From A. M. G. Ding et al., *Faraday Discuss. Chem. Soc.* 55 (1973) 252 [50].)

$$\Delta T \longrightarrow \Delta T' + \Delta R' \qquad (4)$$

This describes the average behavior; the breadth of the product energy distribution increased markedly over V', R', and T'.

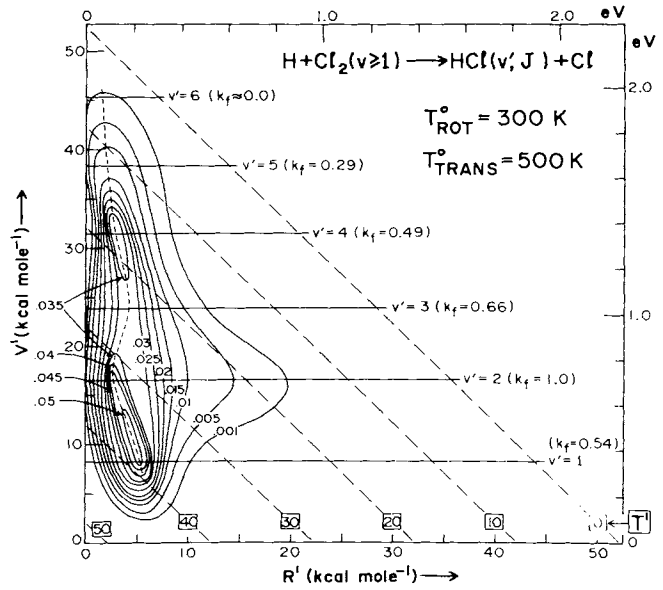

Fig. 22. Effect of enhanced reagent internal energy on the product energy distribution, i.e., experimental $k(V', R', T')$, for $H + Cl_2(v \geq 1) \rightarrow HCl(v', J') + Cl$. This result is approximate since it was obtained by subtracting the detailed rate constants for $H + Cl_2(v \approx 0) \rightarrow HCl + Cl$ from $H + Cl_2(v \geq 0) \rightarrow HCl + Cl$. Mean vibrational energy, $\langle V \rangle \approx 3.3$ kcal mol^{-1}. Compare with Figure 6. (From A. M. G. Ding et al., *Faraday Discuss. Chem. Soc.* 55 (1973) 252 [50].)

By heating the molecular species under attack and recording the change in product energy distribution (see Fig. 22), we found evidence of a similar adiabaticity, on the average, in regard to the conversion of reagent vibration into product excitation,

$$\Delta V \longrightarrow \Delta V' \qquad (5)$$

where the symbol Δ denotes energy in excess of that required for barrier crossing. As before, the breadths of the product energy distributions increased, that over V' appearing to be bimodal.

A more stringent test of this tendency toward vibrational adiabaticity was obtained using the method of IR chemiluminescence depletion (CD; Section 4.1) and IR emission. Vibrationally excited reagent, OH(v), was formed in a selected "pre-reaction." Pulses of a further reagent—Cl in the present case—were introduced, and a record was made of the depletion of chemiluminescence (at the pulsing frequency) in OH(v), as well as of the appearance of chemiluminescence in reaction product HCl(v') (Fig. 23). The reaction responsible for both emissions was

$$Cl + OH(v) \longrightarrow HCl(v') + O \qquad (6)$$

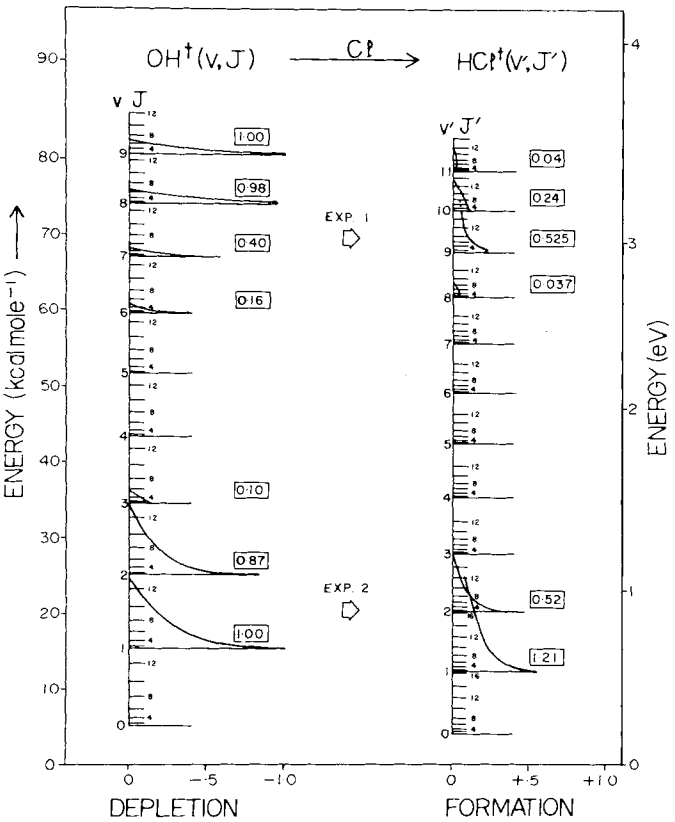

Fig. 23. Experimental evidence for the conversion of high reagent vibrational excitation into the corresponding degree of freedom of the product in the reaction $Cl + OH(v, J) \rightarrow HCl(v', J') + O$. The curves at the left show the *decrease* in population of each OH vibrotational level resulting from the introduction of Cl atoms; the curves at the right were taken from a concurrent record of the amount of HCl formed in each vibrotational level. In experiment 1 (top) the OH was formed in $v = 6$-9 by the pre-reaction $H + O_3$. In experiment 2 (bottom) the OH was formed in $v = 1$-3 by the pre-reaction $H + NO_2$. The numbers in the boxes at the left give the fractional depletions of each OH v level (summed over J), and those at the right give the corresponding information for the product HCl. (From B. A. Blackwell et al., *Chem. Phys.* 24 (1977) 25 [76].)

Using two different pre-reactions (see caption to Fig. 23), the reagent vibrational energy could be given mean values of $\langle V \rangle = 72.1$ kcal mol^{-1} or 20.5 kcal mol^{-1}. For these high vibrational energies, over 90% of the reagent vibration was found to be channeled into product vibration. Once again,

$\Delta V \longrightarrow \Delta V'$[76]

Evidence regarding the fate of reagent rotation was more fragmentary, coming from studies of the reaction $F + H_2(J)$ with J varied systematically from $0 \rightarrow 1 \rightarrow 2$.[77] A small but significant decrease was observed in the fraction of the total energy entering product vibration when $J = 0 \rightarrow 1$, followed by an increase in this fraction as $J = 1 \rightarrow 2$. This finding was in accord with an earlier less detailed study by *Coombe* and *Pimentel*.[78] As is often the case at present with the effects of reagent rotation (see Section 4.2) detailed understanding is lacking.

3.2. Theory

The nature and the origins of the approximate adiabaticity relations (4) and (5) have been discussed in a number of places.[49, 50, 54, 61, 67, 79–82] The success of the 3D classical trajectory method in describing the types of change in detailed rate constant observed experimentally (see Figs. 21 and 22) can be judged from Figure 24.[81] Figure 24b shows a computed triangle plot for the 300-K $H + F_2 \rightarrow HF(v', J') + F$ reaction at the center (see Fig. 7 for the experimental counterpart), and Figures 24c and 24a show the predictions for enhanced reagent translation (Fig. 3 in Ref. [82] has the experimental counterpart) and vibration, respectively. It is evident from inspection of Figure 24 that $\Delta T \rightarrow \Delta T' + \Delta R'$, and $\Delta V \rightarrow \Delta V'$. In addition, the increased breadths of product energy distributions over T' and R' in the former case and over V' in the latter are apparent, as also is the bimodality over V' resulting from enhanced V. (See Ref. [50] for comparable trajectory studies using parameters chosen for $H + Cl_2$.)

The origin of this adiabaticity is evident from an inspection of trajectories with and without the additional reagent energy (Fig. 25). The effect of enhanced translation is to shift the characteristic pathway across the collinear PES (used as a diagnostic of 3D behavior) toward more compressed configurations—the sliding mass impelled by its enhanced momentum along r_{AB} caroms into the corner of the PES in the region of ① in Figure 25. The compressed intermediate A·B·C, if collinear, then flies apart to give translation in AB + C, and, if bent, to give enhanced rotation in AB. For enhanced reagent vibration the most common paths to product are shifted to the region ② in Figure 25; the effect is to favor a more stretched intermediate A--B--C that pulls together along r_{AB} to give $AB(v \gg 0) + C$. The opposite phase of vibration to that pictured in Figure 25 drives the intermediate into region ①, giving rise to the low V' peak in the product distribution. Since energy released along r_{BC} has been characterized as repulsive and that along r_{AB} as attractive, we have termed these changes in dynamics *induced repulsive energy release* in the first case, and *induced attractive energy release* in the second. For a strongly exothermic reaction such as

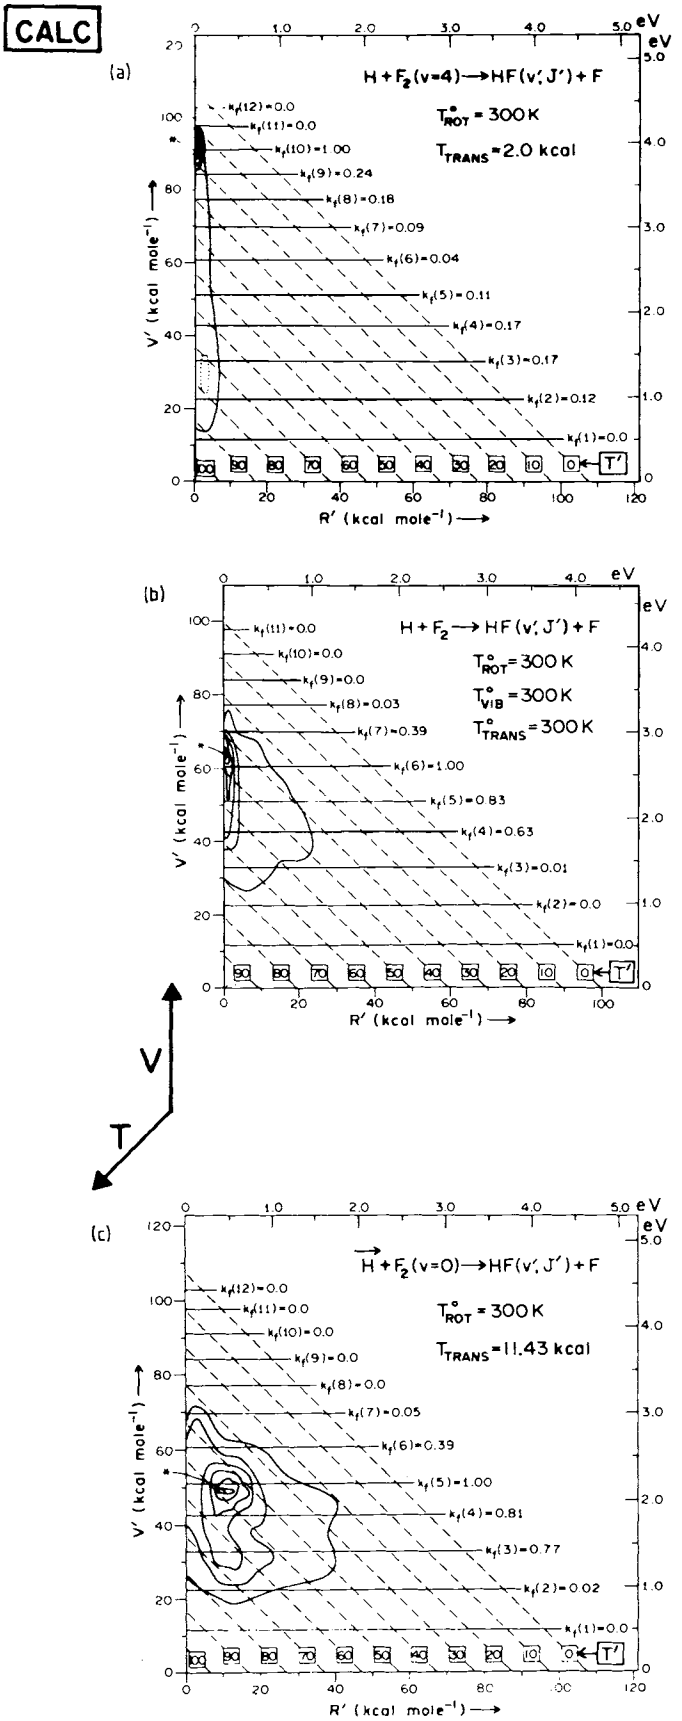

Fig. 24. Computed triangle plots for the $H + F_2 \rightarrow HF + F$ reaction. In (b) the reagents were Monte Carlo selected from a 300-K Boltzmann distribution. In (a) the F_2 reagent vibrational excitation, V, was increased to $v = 4$ (reagent collision energy 2.0 kcal mol^{-1}), and in (c) the reagent relative translational energy, T, was increased to 11.43 kcal mol^{-1} (reagent vibrational energy corresponded to $v = 0$). (From J. C. Polanyi et al., *Chem. Phys.* 9 (1975) 403 [81].)

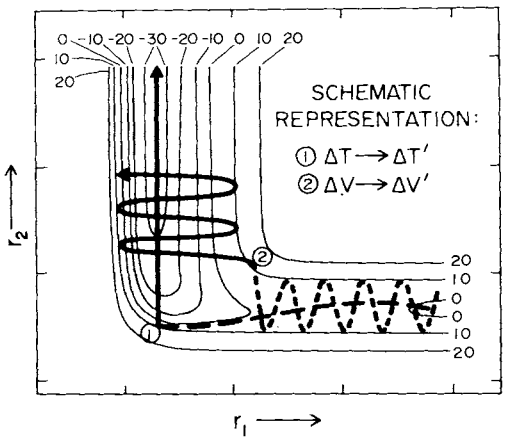

Fig. 25. Schematic representation (on a typical collinear exothermic PES) of the mechanism (1) by which "additional" reagent translation ($\Delta T \gg E_c$, where E_c is the barrier height) is channeled into "additional" product translation ($\Delta T'$), and also (2) the mechanism by which "additional" reagent vibration ($\Delta V \gg E_c$) becomes "additional" product vibration ($\Delta V'$). (These are not actual trajectories since they show neither the exothermic energy release nor the effect on that energy release of changing reagent energy; the intention, which is artificial, is to show the effect of ΔT and ΔV in isolation). (From A. M. G. Ding et al., *Faraday Discuss. Chem. Soc. 55* (1973) 252 [50].)

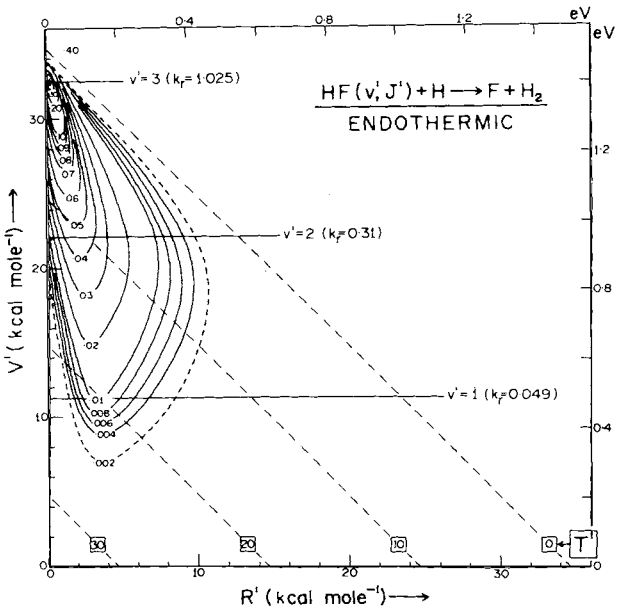

Fig. 26. Contours represent values of *reagent* vibrational, rotational, and translational energies for the endothermic reaction $HF(v',J') + H \rightarrow F + H_2$ which correspond to equal $k_r(\equiv k_{endo})$. The data were obtained by application of microscopic reversibility to the $k_f(\equiv k_{exo})$ given in Figure 8. (From J. C. Polanyi, D. C. Tardy, *J. Chem. Phys. 51* (1969) 5717 [84].)

$H + F_2$ (Fig. 24), these shifts affect not only the channeling of the *additional* reagent energy, but also the channeling of the exothermicity into product excitation, so that $(\Delta T' + \Delta R')/\Delta T$ and $\Delta V'/\Delta V$ exceed unity.[81]

4. Surmounting the Energy Barrier

4.1. Experiment

The most detailed information regarding the relative efficiency of various types of reagent motions in surmounting an energy barrier comes from the application of microscopic reversibility to detailed rate constants for forward reaction, $k_f(V',R',T')$.[83] Detailed rate constants for the reverse reaction obtained in this way, $k_r(V',R',T')$, are recorded in the triangle plot of Figure 26, where V', R', and T' are now the vibrational, rotational, and translational energies of the *reagents* for the endothermic reaction $HF(v',J') + H \rightarrow F + H_2$.[82] The total energy available for distribution is fixed by the nature of the experiment, being equal to the energy made available by the forward exothermic reaction; 34.7 kcal mol^{-1} in the case illustrated. This approach has been tested numerically by applying it to a case where $k_r(V',R',T')$ could be obtained directly from 3D trajectories or by application of microscopic reversibility; the procedures agreed with one another to approximately 10%.[85]

Inspection of Figure 26 indicates that a redistribution of 30 kcal mol^{-1} from T' into V' has the dramatic effect of increasing by ca. $10^3\times$ the rate of reaction in the endothermic direction.[58,84] Endothermic triangle plots of this type are to be found in, for example, Refs. [67, 83, 84]. In a few cases, in other laboratories, direct measurement has been made of the relative efficiency of vibration and translation in surmounting an energy barrier;[86–88] in one of these cases[88] the barrier corresponded to "substantially"[67] endothermic reaction; the reaction was $HF(v') + K \rightarrow H + KF$ (17 kcal mol^{-1} endothermic) and the effect of transferring 11 kcal mol^{-1} from reagent translation to vibration was to give an increase of $> 10^2$ in reaction rate.

The IR "chemiluminescence depletion" (CD) method, already alluded to in Section 3.1, was used to obtain a measure of the efficiency of a high degree of vibrational excitation in promoting endothermic reaction. In contrast to the microscopic reversibility procedure outlined above, by CD the vibrational energy could be varied independently of the collision energy and could be made much larger than the endothermic barrier height. The energies of one family of endothermic reactions investigated in this fashion are shown in Figure 27; $HX^{\dagger} + Y \rightarrow Y + HX$, where X = Cl or F, Y = Br or Cl, and the dagger indicates vibrational excitation.[89] An analogous study has been made of

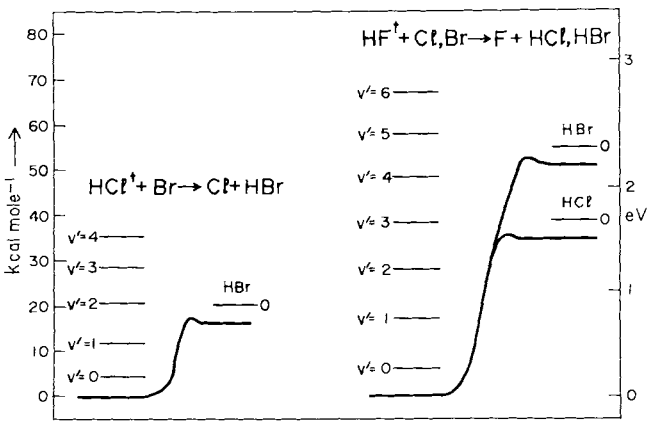

Fig. 27. Endothermicities of three reactions $HX + Y \rightarrow X + HY$; showing kcal mol^{-1} at left, eV at right, and the vibrational spacing of the relevant HX within the figure. Energy profiles are schematic. (From D. J. Douglas et al., *Chem. Phys. 13* (1976) 15.)

the endothermic reactions $HX^{\dagger} + Na \rightarrow H + NaX$, X = Cl, F.[90] For CD experiments the vibrationally excited reagent $HX^{\dagger}$ was formed in a variety of pre-reactions or in a variety of partially relaxed vibrational distributions from a single pre-reaction. The atomic reagent, Y or Na, was pulsed and a concurrent record was made of the IR chemiluminescence from $HX^{\dagger}$ (cw) and of the depletion (CD was measured on an amplifier locked to the pulsing frequency of the Y or Na beam).

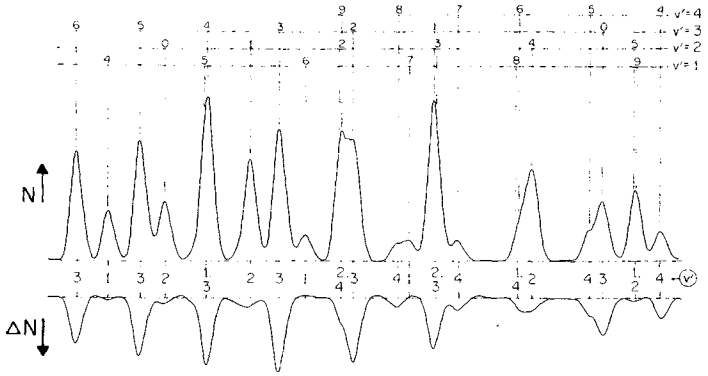

Fig. 28. A portion (20%) of the spectrum recorded in an IR chemiluminescence depletion (CD) study of the endothermic reaction $HCl(v'=1\text{-}4) + Br \rightarrow Cl + HBr$. At the top (labeled N) is the emission from the $HCl(v'=1\text{-}4)$ formed in a pre-reaction. Below (ΔN) is the concurrent record of the depletion, due to pulses of Br (trace enlarged 2.5×). The fraction $\Delta N(v')/N(v') > 0$ for $v' \geq 2$. (Excursions of ΔN above the baseline can be identified with product emission ($HBr(v=1,2)$) rather than reagent depletion.) (From D. J. Douglas et al., *J. Chem. Phys. 59* (1973) 6679 [89].)

A small portion of the concurrent spectral traces from an experiment on $HCl(v',J') + Br$[89] is given in Figure 28. The fractional depletions ($\Delta N(v',J')/N(v',J')$), which should be independent of $N(v',J')$, gave a measure of the endothermic rate constant, $k_{endo}(v',J')$. Values of $k_{endo}(v')$ (summed over J') are shown plotted against the reagent energy expressed as a fraction of the endothermic barrier height, Q^* in Figure 29.[89] The onset of k_{endo} is marked for each reaction by a threshold at the expected Q^* ($Q^* = 16.5$, 34, and 49 kcal mol^{-1} for the reactions discussed here). The reagent translational energy corresponded to 300 K; it follows that approximately 95% of the reagent energy was present as vibration. Calibrations showed that the reactive cross section for high v exceeded 1 Å^2; i.e., the collision efficiencies for reaction approached 0.1. With an analogous preponderance of vibration in the reagents of $HX^{\dagger} + Na$, the collision efficiencies approached unity.[90] We conclude that vibrational excitation is highly efficient in carrying these reactions over their endothermic energy barriers.

The CD approach was also used to map out the dependence of reaction rate on reagent rotational excitation. The results shown in Figure 30 for the endothermic processes $HX(J)_v + Na \rightarrow H + NaX$ are typical of the findings from CD. Comparable results were obtained (by a cruder approach) for the exothermic reaction $F + HCl(J)_v \rightarrow HF + Cl$.[50] There is an initial decline in reaction probability with increasing J, followed by a rise in reaction probability. Similar behavior has been noted in crossed beam experiments.[92,93] Nonetheless our knowledge of $k(J)$ leaves much to be desired.

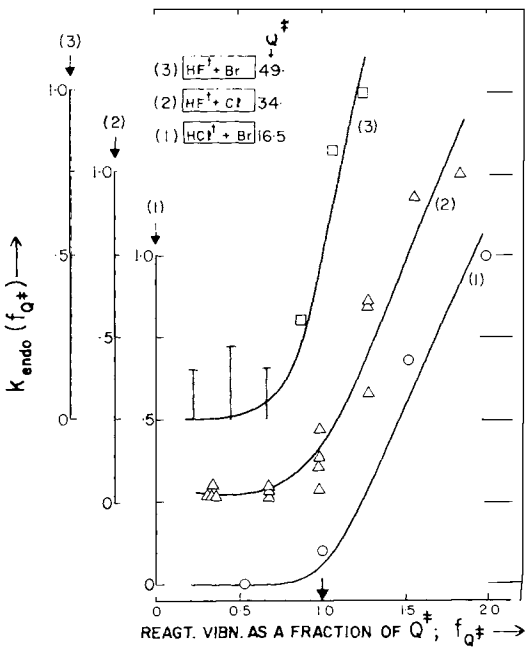

Fig. 29. Endothermic rate constant, $k_{endo}(f_{Q^*})$ is the reagent vibrational energy expressed as a fraction of the endothermicity Q^* for reactions (1)-(3). (From D. J. Douglas et al., *Chem. Phys. 13* (1976) 15.)

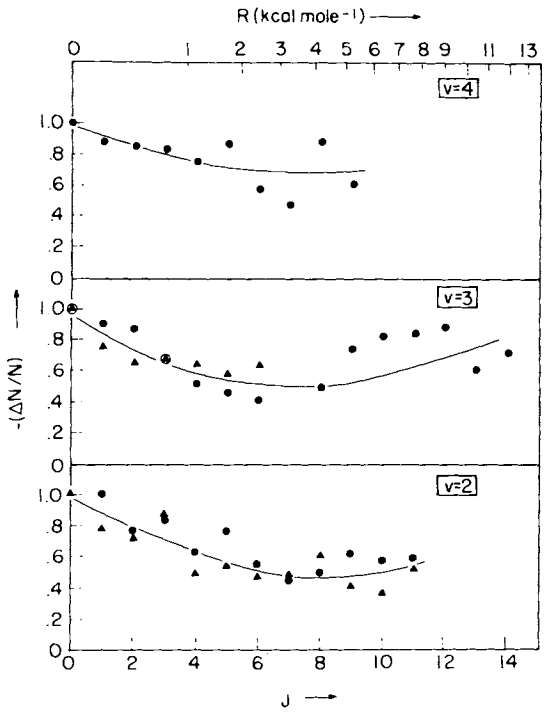

Fig. 30. Fractional depletions of individual J states of $v = 2\text{-}4$ in a CD study of the endothermic reaction $HF^{\dagger} + Na$. (From B. A. Blackwell et al., *Chem. Phys. 30* (1978) 299 [91].)

4.1. Theory

We have found it useful and revealing to link the preferred type of reagent energy distribution to the location of the energy barrier on the collinear PES (termed a "diagnostic cut" through the full hypersurface which gives the 3D dynamics). In the first approximation we have looked

for a correlation between the dynamics of barrier crossing and the location of the barrier crest relative to the point at which the entry and exit valleys of the PES may be said to meet on the collinear PES, namely, the equal-stretch configuration, ρ^*, for which $r_{AB}-r^0_{AB}=r_{BC}-r^0_{BC}$.[94] *Duff* and *Truhlar*[95] have examined an alternative definition of the point where entry and exit valleys meet, namely, the point of maximum curvature, C*, of the minimum-energy path across the collinear PES (a concept prefigured in work of *Hofacker* and *Levine*[96]). Since the two bonds change length with minimum expenditure of energy at their maximum extension, it is understandable that $\rho^* \approx C^*$.[97]

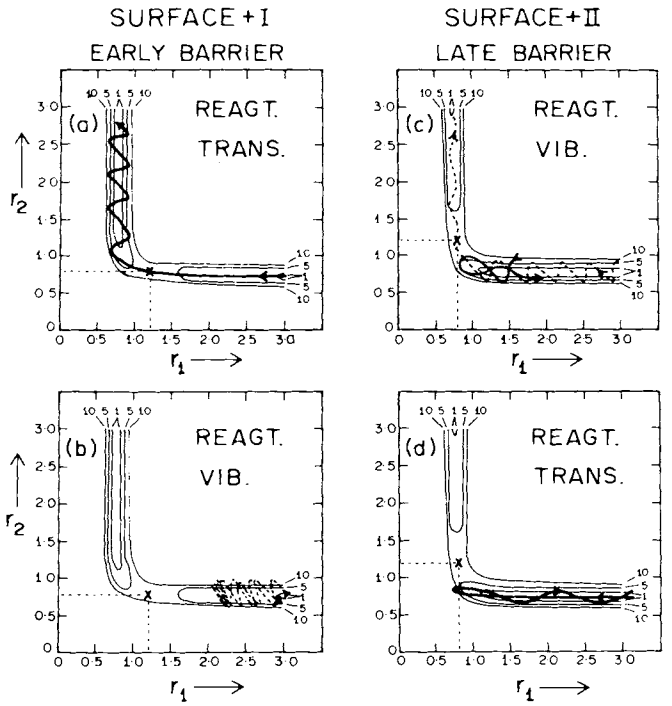

Fig. 31. At the left (a) and (b) show specimen trajectories with (a) largely reagent translation ($T=9$, $V=0$) and (b) largely reagent vibration ($T=1.5$ and $V=14.5$) on an "early barrier" surface, i.e., type I. At the right (c) and (d) show trajectories with (c) largely reagent vibration ($T=1.5$ and $V=7.5$) and (d) largely reagent translation ($T=16.0$, $V=0$). All energies are kcal mol^{-1}; reagent vibration relative to $E(v=0)$. Three equal masses, $m_A=m_B=m_C$. Positive and negative vibrational phases in solid and broken lines. Barrier heights on both surfaces I and II are 7 kcal mol^{-1}; contours are labeled in kcal/mol. (From J. C. Polanyi, W. H. Wong, *J. Chem. Phys. 51* (1969) 1439 [94].)

Figure 31 shows the dynamics characteristic of equal masses reacting across a PES with "early barrier" (surface I) at the left and "late barrier" (surface II) at the right.[44] The barrier crest was located approximately 0.03 Å ahead of ρ^* on surface I and 0.03 Å beyond ρ^* on II (these surfaces are designated +I and +II in Figure 31, since the labels −I and −II were used for potential hollows similarly displaced from ρ^*[58]). The effect of these displacements of the barrier crest upon the preferred mode of motion in the reagents was dramatic. As illustrated in Figure 32, on surface I a reagent translational energy only slightly in excess of the 7 kcal mol^{-1} barrier height gave a calculable cross section, whereas a reagent vibrational energy double the barrier height gave a reactive cross section too small to be computed in our study. The converse behavior

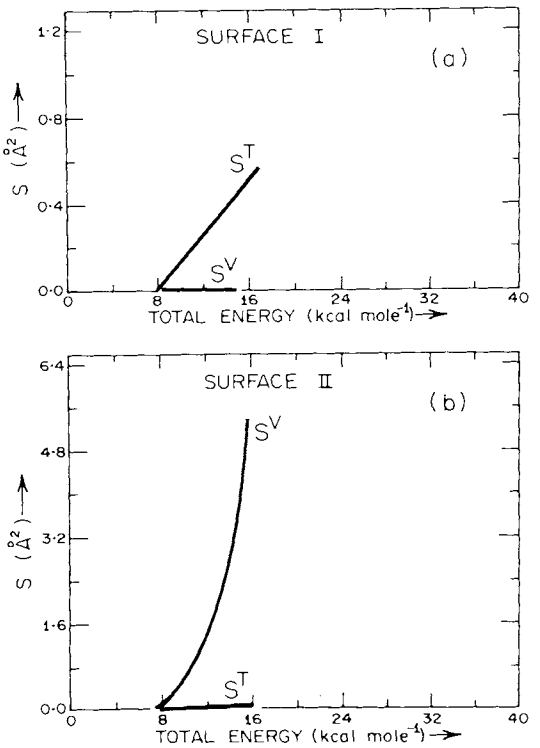

Fig. 32. a) Reactive cross sections S^T (reagent energy in translation (S^V (reagent energy in vibration, + 1.5 kcal mol^{-1} of translation) on the "early barrier" surface depicted at the left of Figure 31. b) Reactive cross sections S^T and S^V on the "late barrier" surface shown at the right of Figure 31. Three equal masses. (From J. C. Polanyi, W. H. Wong, *J. Chem. Phys. 51* (1969) 1439 [94].)

is seen to apply to surface II (Fig. 32); reagent vibrational energy (with a small amount of translation to bring the reagents together) was highly effective in giving reaction, whereas translation was without effect.

As we have remarked, these correlations are of more than empirical value; by focusing attention on certain simple attributes of the PES, we can shed light upon dominant features of the dynamics. In terms of the dynamics of the reaction A+BC the correlations noted in the preceding paragraph reduce to the proposition that a barrier predominantly along the coordinate of approach, r_{AB}, is best traversed by motion in that same coordinate, namely, reagent translation, whereas a barrier predominantly along the coordinate of separation, r_{BC}, is best traversed by motion in that coordinate, i.e., vibration in the bond under attack. The trajectories in Figure 31 (obtained by solution of the equations of motion, but capable of being pictured as the motion of a sliding mass across the PES) illustrate this; the reactive cases are (a) and (c) (early and late barriers), the nonreactive are (b) and (d) (early and late barriers once more). The effect illustrated is sufficiently striking that it may also have relevance to the dynamics of reactions involving many atoms (cf. Ref. [99]), provided that these occur by a direct pathway.

The interest of these correlations is greatly increased if we can link the form of the PES to the nature of the chemical reaction. Though unrecognized by reaction dynamicists, *Hammond*'s postulate[100] that for endothermic reactions the transition state resembles reaction products should have pointed the way to the desired connection.

In fact it was a systematic study of a considerable number of exchange reactions $A+BC \rightarrow AB+C$ in terms of both the London, Eyring, Polanyi, Sato (LEPS) and the bond-energy bond-order (BEBO) methods that led to the conclusion that for substantially exothermic reactions the barrier crest is located in the entrance valley ("early barrier") of the PES, and for substantially endothermic reactions it is in the exit valley ("late barrier").[55] From this and the dynamical study of early and late barriers, it followed (as previously surmised[101]) that the favored degree of freedom for barrier crossing in substantially exothermic reactions would be translation, whereas reagent vibration would be most effective in giving rise to substantially endothermic reaction. (In the BEBO approximation, "substantially" has the meaning ≥ 10 kcal mol^{-1}[67]).

Behavior of the type illustrated in Figure 32a, computed for the well-studied exothermic reaction $F+H_2 \rightarrow HF+H$ is shown in Ref. [64]. Behavior of the type illustrated in Figure 32b is in accord with the evidence of Section 4.1. There is, nonetheless, a clear need for comparisons of what we have termed (Fig. 32) S^T with S^V for a range of reactions and within related series of reactions.

If barrier location is to be made to any degree a quantitative index of the relative efficacy of translation and vibration in bringing about barrier crossing, the location of the barrier must be considered as it appears on a surface skewed and scaled for the appropriate masses m_A, m_B, and m_C, so that a sliding mass will correctly solve the equations of (collinear) motion.[98] The mass combination **H + HL** accentuates surface I behavior while diminishing the surface II effect, whereas **L + HH** has the converse effect. The qualitative behavior noted above remains unaltered.

A further significant refinement in understanding the controlling features of the PES takes note of the fact that in the case of a later barrier crest some part of the energy barrier is located along the coordinate of approach. This further element was included in the picture by distinguishing between type "IIS" and "IIG" barriers, where S and G differentiate late barriers approached by a sudden (S) or gradual (G) potential rise.[97] The gradual rise implies the existence of a significant fraction of the type II barrier in the coordinate of approach, with a corresponding requirement for a minimum reagent translational energy along with the (dominant) vibrational contribution.

A further dividend that accrues from the inclusion of this refinement is that it has the effect of tying in the considerations raised in this section, regarding the favored type of reagent energy for endothermic barrier crossing, with those described in Section 2.2 in regard to the channeling of exothermic energy into product degrees of freedom. The portion of the (late) barrier to endothermic reaction that extends into the coordinate of approach for "reverse" reaction is the portion of the exothermic energy release that occurs in the coordinate of separation for "forward" reaction; we are viewing the same hill from below and above. Similarly, the reagent translational energy required for endothermic reaction is related to the translational energy derived from repulsive energy release in the corresponding exothermic reaction. Since the PES is a single whole, it is to be hoped that the various indices of reactive behavior bear an evident relationship to one another.

The "indices of reactive behavior" referred to in the previous paragraph (see Sections 2.2 and 3.2) make frequent use of the collinear "diagnostic" PES. Since this allows for neither reagent nor product angular momenta, it gives no insight into the sources of product rotation (Section 2.2), nor into the channeling of reagent rotation into motion across the barrier.

The experimentally observed dependence of reaction probability on J can plausibly be explained as follows.[91] In the great majority of reactions there will be a preferred orientation for the required close approach of the attacking atom to the molecule under attack. With increased J the time that the system spends in this orientation will decrease, as will the detailed rate constant, $k(J)$. With further increase in J the preferred orientation will be recovered at short intervals during the approach of A to BC, resulting in a reversal of the downward trend in $k(J)$. At high J the attacking atom responds to an average interaction around BC; $k(J)$ would be expected to level off. There is, however, a further contributing factor at J sufficiently high that the rotational energy is significant in terms of the energy required for barrier crossing; this is the effect of rotation in carrying the system across the barrier to reaction. If the barrier is "late," this would be expected to occur largely through vibration–rotation interaction; if "early," through the component of force along r_{AB} as BC rotates into A (see Ref. [71b] for the geometry of this collision).

These scenarios are speculative. What can be said with assurance is that the ratio of time spent along the approach coordinate to the rotational period of the molecule under attack will play an important role in the outcome of a potentially reactive encounter in addition to the energy vested in rotation.

5. Future Directions

This talk has described the development of one type of "state-specified" chemistry, from which some simple lessons regarding reaction dynamics can be drawn. What we see obscurely today we shall in the future see much more clearly through the more rigorous application of state selection, an increase in the range of attributes being selected, and also an extension in the range of reactions amenable to study. All of this will add up to a maturation of the field of state-to-state chemistry.

In closing, I mention two further approaches which could assist materially in the quest for understanding of the choreography of chemical reaction. In the first, attempts are being made to observe the molecular partners while they are, so to speak, on the stage, rather than immediately prior to and following the reactive dance. This we term "transition-state spectroscopy" (TSS); it is a young but burgeoning field. In the second novel approach, the intention, stated a little grandiosely, is to have a hand in writing the script according to which the dynamics occurs; the reagents are aligned by the forces at a crystal surface and held in a fixed arrangement immediately prior to the initiation of the reaction by light, thus restricting the subsequent pattern of motion. This field of "surface aligned photochemistry" (SAP) has only very recently made its ap-

pearance. SAP may initiate reaction part way across the PES and hence is related to TSS, since the adsorbed reactants can be held together in configurations that locate them at the outset part way up the reactive barrier. In the SAP experiments performed till now the forces holding the reactants to the surface have been physisorptive.

These two approaches, TSS and SAP, will be briefly reviewed.

The impetus for transition-state spectroscopy, TSS, came from a series of theoretical studies of the effect of laser fields on reactive encounters.[102] A variety of intriguing alterations in dynamics were predicted, exemplifying in the reactive domain the effects being explored at that date for nonreactive encounters under the heading of "laser-assisted collisions." However, the laser powers thought to be required lay in the gigawatt to terawatt range (powers associated with the electrical breakdown of gases) so that the outlook for success appeared bleak.

It was pointed out that a simple alternative would be to look for emission from electronically excited transition-state configurations (ABC^{+*}).[103] (In reaction rate theory "transition states" are sets of intermediate configurations variously defined; in the spectroscopic context we use the term to denote the full range of configurations intermediate between reactants A + BC and products AB + C). An example is shown in Figure 33. In collisional line-broaden-

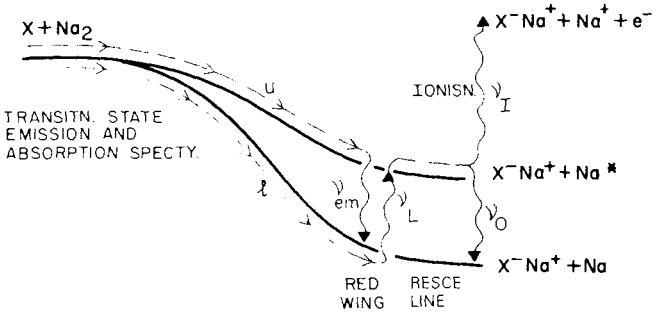

Fig. 33. Illustration of transition state emission and absorption spectroscopy (TSS), in analogy to collisional line-broadening. The reaction is $X + Na_2 \rightarrow NaX + Na^{(*)}$ (X = halogen). Reaction on the upper surface, u, leads to emission as the products separate (ν_{em} constitutes a redshifted "wing" on the D line at ν_0). Reaction on the lower surface, l, may be detected by laser absorption as products separate ($\nu_L < \nu_0$ in the illustration); absorption at ν_L may be evidenced by subsequent emission of Na* at ν_0, or by laser ionization of Na* using a second laser tuned to ν_L. (From J. C. Polanyi, *Faraday Discuss. Chem. Soc.* 67 (1979) 129 [103].)

ing of Na* + NaX the wings on the atomic line emission would be due to the approach of Na* to NaX (moving from right to left in the figure) followed by emission of frequency ν_{em}. In TSS comparable wings should be observed due to the fact that every Na* is formed by separation from NaX (moving from left to right in the figure); separation can be preceded by emission at frequency ν_{em}. A simple calculation showed that the emission intensity at a ν_{em} of ca. 1 cm^{-1} bandwidth, would total approximately 10^{-6} the chemiluminescent intensity of Na*, and that this should be measurable. Observation of wings of this intensity, having the appropriate kinetics, followed shortly thereafter.[104] Preliminary reports of similar measurements in absorption[105-107] have led to more definitive successes[108] at increasing levels of spectroscopic detail.[109]

The relative intensity of the TSS at various ν_{em} or ν_L (corrected for changing transition moment, where warranted) will yield information concerning the relative times that the absorber, ABC^+, spends at successive configurations *en route* from reagents to products.[110-112] This is precisely the information that reaction dynamicists have sought to infer from a knowledge of reagent and product motions. The more direct approach of TSS suffers from the drawback that it is a spectroscopy of two PES's rather than one, namely, the reactive PES and the optically linked PES (preferably a bound state) to which emission or absorption occurs. This complication need no more be fatal to TSS than it was to the study of stable molecules by electronic emission or absorption spectroscopy in decades past. It does however mean that as soon as our experimental virtuosity permits, we should turn our attention to the TSS of the simplest reactive systems, such as that involving only hydrogen atoms ($H + H_2 \rightarrow H_3^+ \rightarrow H_2 + H$).[111, 112]

In regard to surface aligned photochemistry (SAP) we can be brief. In the experiments performed to date[113] a submonolayer of H_2S was adsorbed in ultrahigh vacuum (UHV) on a single crystal of LiF(001), and was irradiated with ultraviolet (UV) at 193 and 222 nm coming from an excimer laser (5 mJ/pulse). At low coverage (ca. 0.01 monolayers), fast-moving $\bar{H}$ photofragments were observed to leave the surface. From their energy and angular distribution these were clearly due to the UV photolysis of H_2S still held at the surface at the instant of photofragmentation. With increasing coverage ($\gtrsim 0.1$ monolayers), the photoproducts included fast-moving $\bar{H}_2$ formed in the reaction $\bar{H} + H_2S \rightarrow \bar{H}_2 + HS$. The yield of $\bar{H}_2$ increased with coverage at a rate and to an extent that could only be explained by the reaction of photorecoiling $\bar{H}$ with *adsorbed* H_2S; accordingly the reaction is ascribed to SAP. The $\bar{H}_2$ product is fast and directional.

This is a small first step along the way to inducing reactions under conditions where the range of reagent angles-of-approach and impact parameters is restricted by surface alignment and (by choice of crystal, crystal face, and coverage) is controllable. A trajectory study[113] illustrates the simplified link between product attributes and reactive geometries that applies under these more disciplined conditions.

Even in the world of molecules the civilizing influence of modest restraints is a cause for rejoicing.

The research described here in so far as it relates to the work of my laboratory was performed over a thirty-year period at the University of Toronto. It is a pleasure to express my indebtedness to my colleagues at this University—most especially to the late Prof. D. J. LeRoy who fostered this work from its inception—and to my students and postdoctoral associates whose talents, generosity, and friendship have made this undertaking possible and fulfilling.

Ether Cleavage with Organo-Alkali-Metal Compounds and Alkali Metals

By Adalbert Maercker*

In memoriam Georg Wittig

Reactions with organo-alkali-metal compounds are mostly carried out in ether-type solvents. It has long been known that ether cleavage takes place at the same time. The mechanism of the cleavage, in particular the fact that dialkyl ethers can be decomposed by a variety of mechanisms acting simultaneously, has only become clear in the most recent investigations. The observation that even with purely aliphatic ethers a considerable amount of Wittig ether rearrangement can occur is remarkable. Unusual secondary reactions can also occur by means of which alkyl- and aryllithium compounds in ether or tetrahydrofuran yield new organolithium compounds—sometimes with rearrangement. The reactions of alkyl aryl ethers with alkali metals are also varied and five different mechanisms for them have been discussed in the literature. It is interesting, for example, that the cleavage of anisole can be directed simply by changing the solvent so that in one case only cleavage of the aryl-oxygen bond occurs and in the other almost 100% cleavage of the alkyl-oxygen bond results. The formation of biphenyl as a by-product upon cleavage of the alkyl-oxygen bond in anisole was also puzzling. This was later shown to occur not through the dimerization of phenyl radicals but via 2-methoxybiphenyl. The number of cleavage mechanisms reduces to two if one assumes two different σ*-radical anions as being intermediates in the kinetically controlled reaction. Comparison of the reactivity of thioethers and ethers reveals not only gradual but also fundamental differences—the cleavage of the thioethers is thermodynamically controlled.

1. Introduction

Review articles concerning ether cleavage, in which also cleavages with organo-alkali-metal compounds and alkali metals are thoroughly dealt with, already appeared in the literature in 1954,[1] 1965,[2] and 1967.[3,4] A later review in 1983,[5] which, however, only touched on these areas, mentioned little which was new. The present review therefore concentrates mainly on developments over the last 20 years and includes many unpublished results from our research group. Older work which has already been mentioned in the earlier reviews[1-3] will only be cited where it is considered necessary for an understanding of newly developed mechanistic concepts. Likewise, the numerous syntheses with metalated benzyl,[6] allyl,[7-12] and vinyl[13-17] ethers, in which the cleavage of the ether bond was first achieved later, using other methods, will not be dealt with here.

2. Ether Cleavage with Organo-Alkali-Metal Compounds

2.1. Primary Reactions

2.1.1. *Protophilic Cleavage*

Theoretically there are four different reaction paths available for the cleavage of any dialkyl ether with a base R″Li (Scheme 1): β-, α-, and α,β′-elimination as well as the Wittig rearrangement. The number of possibilities doubles when R≠R′. It is clear that β-, α-, and α′,β-elimination as well as β′-, α′-, and α,β′-elimination lead to the same end products, respectively, so that only the Wittig rearrangement can be differentiated by product analysis.

An example from the literature in which the ether cleavage probably takes place via a β-elimination is the reaction of 2-methoxyoctane with isopropyllithium [Eq. (1)].[18] α-Eliminations have been observed with dimethyl ether and butyl methyl ether,[19] where the undetectable methylene carbenoid intermediate either combines with the alkyllithium compounds or is trapped, in the presence of cyclohexene, as norcarane [Eq. (2)].[20] If there is a hydrogen atom on the atom adjacent to the carbenoid center, stabilization usually occurs by means of a 1,2-hydride shift (Scheme 1).[21] The first α,β′-elimination was discovered with metalated benzyl ethyl ether,[22] and the mechanism was confirmed by means of isotopic labeling [Eq. (3)].[23] The Wittig ether rearrangement[24] was first observed in the reaction of benzyl methyl ether with phenyllithium [Eq. (4)].[22]

The decomposition of diethyl ether with organolithium compounds to ethylene and lithium ethoxide has been known for a long time.[19] In the literature the α-,[19] β-,[3] and even the α′,β-elimination[25] mechanisms have been postulated (Scheme 2), although, as has been pointed out, a decision on the basis of a product analysis is not possible. In order to clarify the cleavage mechanism we have prepared the α- and the β-deuterated diethyl ethers in a high state of purity and allowed them to react with perdeu-

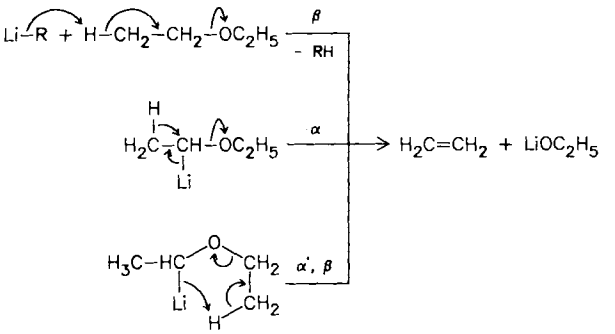
terioethyllithium.[26] Surprisingly, the two ethers are decomposed by different mechanisms. While the α-deuteriated ether undergoes exclusively β-elimination the extent of attack at the β-position in the β-deuteriated ether is reduced to 45% because of the isotope effect.[27] At the same time 10% α- and 45% α′,β-elimination are observed. Competition experiments with 1:1 mixtures of the α- and β-deuteriated diethyl ether on the one hand—in which almost exclusively the α-deuteriated ether was attacked—and α- and non-deuteriated diethyl ethers on the other—in which both ethers were decomposed in equal amounts—show that both the undeuteriated and the α-deuteriated ethers are cleaved by β-elimination.



Scheme 2. Proposed mechanisms for the decomposition of diethyl ether by organolithium compounds.

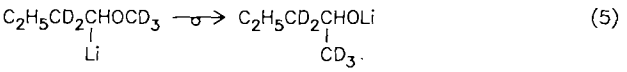
Starting from diethyl ether,[26] ethers with shorter and longer alkyl groups were now systematically investigated, so that finally, with seven further α- and/or β-deuteriated dialkyl ethers, the cleavage mechanism—even for the mixed aliphatic ethers—could be completely elucidated.[28]

With the exception of dimethyl ether, in which exclusively α-elimination occurred, all the dialkyl ethers investigated were decomposed by several mechanisms operating simultaneously, one or other mechanism being preferred depending on the substitution pattern or the position of deuteriation. The following regularities were found for the course of the reaction:[28]

If the ether contained a β-methyl group the attack of the alkyllithium compound took place overwhelmingly at the primary β-C–H bonds, presumably via E2-elimination in which proton removal probably precedes C–O bond breaking. Thus, all ethyl ethers such as diethyl ether or butyl ethyl ether undergo, almost exclusively, β-elimination at the ethoxy group. A similar situation occurs with an α-methyl group, though the reactivity is slightly less, as is evidenced by the cleavage of methyl ethyl ether, in which α-elimination from the methoxy group (ca. 40%) competes with β-elimination from the ethoxy group (ca. 60%). The isotope effect[27] in β-deuteriated ethyl methyl ether is already sufficient to allow α-elimination to become the main reaction (ca. 80%). Here deuteriation has a very similar influence to that of alkyl chain elongation. This is strikingly evident on comparing β-deuteriated ethyl methyl ether and butyl methyl ether, which exhibit almost identical cleavage patterns. Apart from dimethyl ether, where only α-elimination is possible, the highest contribution of α-elimination (90%) is found, as expected, with the combination of alkyl chain elongation and β-deuteriation in β-deuteriated butyl methyl ether. In three β-deuteriated dialkyl ethers, besides α- and β-elimination a considerable amount of α′,β-elimination could also be detected.[28]

Interestingly, whenever the α-, β-, or α′,β-elimination is hindered we find a large amount of Wittig rearrangement taking place. We have observed[28] a maximum of

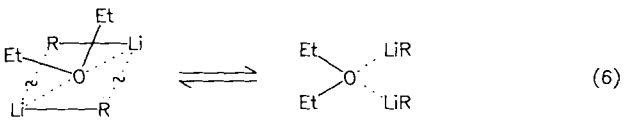
21%, for example, on using the specifically deuteriated dibutyl and butyl methyl ethers $(C_2H_5CD_2CH_2)_2O$ and $C_2H_5CD_2CH_2OCD_3$ [Eq. (5)]. Apart from in the case of di-



(5)

methyl ether, Wittig rearrangements were found to take place to a small extent with all ethers. Undeuteriated dibutyl ether as well as butyl trideuteriomethyl ether, $C_2H_5CH_2CH_2OCD_3$ still yield 12% of the product of a Wittig rearrangement. At the moment no definite statements can be made about the mechanism of this new form of the Wittig rearrangement for pure aliphatic ethers.[28]

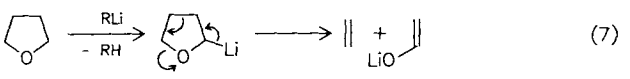
We have not yet investigated the kinetics of the cleavage reactions in detail. However, it was especially interesting to find that the temperature coefficient for the cleavage of diethyl ether with *n*-butyllithium or isobutyllithium is negative[29-31] when the reactions are carried out in *n*-heptane with equimolar amounts of the reactants. The increase in the reaction rate as the temperature is reduced from +30°C to −21°C is explained by the shifting of the solvation equilibrium (6) to the left favoring a kinetically more



(6)

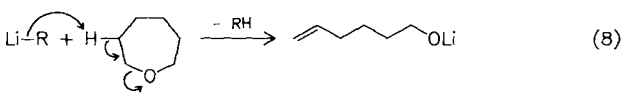
active solvate. Other simple ethers behave similarly, but not, however, mixed ethers such as *n*-butyl *tert*-butyl ether, where a positive temperature coefficient has been found for the cleavage with *n*-butyllithium.[32]

The investigations were also extended to tetrahydrofuran (THF), which behaves kinetically like the simple ethers, that is the rate of cleavage with *n*-butyllithium decreases on increasing the temperature from −20°C to +20°C.[33,34] The *mechanism* of the cleavage of THF is, however, quite different from that of the open-chain dialkyl ethers: after the α-metalation, a [π4s + π2s] cycloreversion occurs with the formation of ethylene and the enolate of acetaldehyde [Eq. (7)].[35,36] A β-hydrogen atom of the



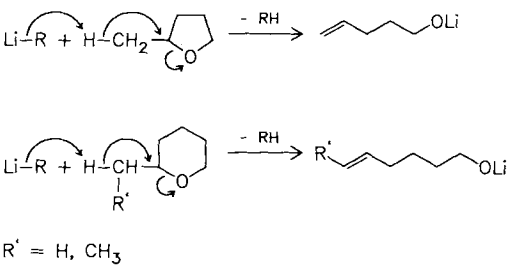
(7)

ring is not attacked, since the steric prerequisites for an E2-elimination in a five-membered ring are unfavorable. A seven-membered ring is the first which can assume the requisite geometry without difficulty [Eq. (8)].[36,37]



(8)

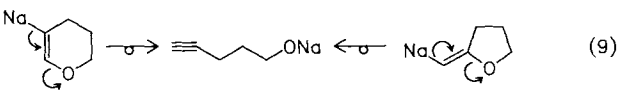
Alkyl groups in the 2-position of the five-membered ring favor a β-elimination; however, as expected, a side-chain proton is removed exclusively (Scheme 3).[36,38,39] Also in the case of 2-substituted six-membered rings the attack of



Scheme 3. β-Elimination with *n*-butyllithium in 2-alkyl-substituted THF and tetrahydropyran.

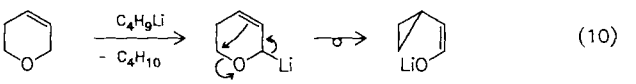
the protophile occurs exclusively on the side chain,[38] even if the methyl group is replaced by an ethyl group.[40] Interestingly, the β-elimination can be suppressed in favor of the α-elimination by using butylpotassium as base.[39]

The course of the reaction with dihydropyrans depends on the position of the double bond in the ring. Dihydropyran with the double bond in the α,β-position can be metalated, with amylsodium, at the β-vinyl position; subsequent β-elimination then leads to formation of 4-pentynolate, which is also obtained from 2-methylenetetrahydrofuran [Eq. (9)].[41] If the double bond is in the β,γ-position, metal-



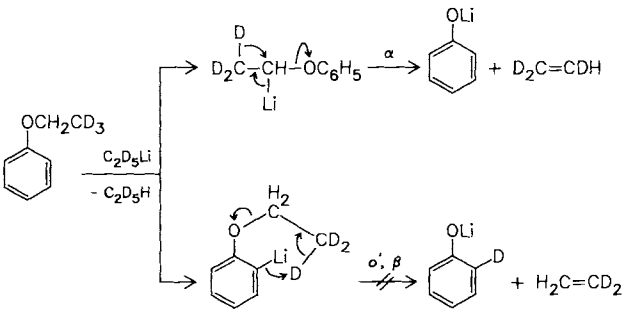
(9)

ation by *n*-butyllithium takes place in the 2-position, and subsequent rearrangement leads to a cyclopropyl-substituted enolate [Eq. (10)].[42]



(10)

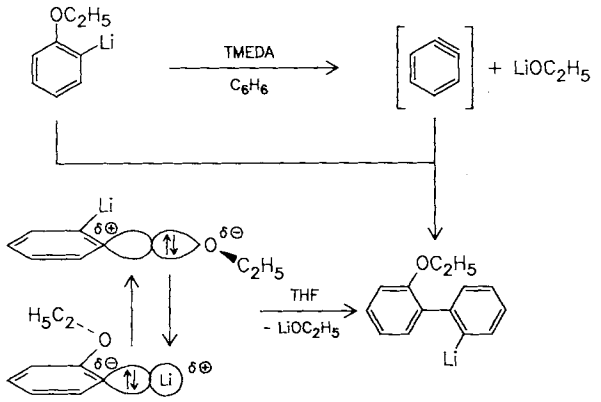
The course of the reaction of alkyl *aryl* ethers with perdeuteriated ethyllithium has been thoroughly studied, by us, using phenetole.[43] Here again, the cleavage mechanism is—as with diethyl ether[26,28]—strongly dependent on the position of deuteriation. While we were able to confirm, with α-deuteriated phenetole, the β-elimination already found by *Letsinger* et al.[23] on using propylsodium, with β-deuteriated phenetole (Scheme 4) this form of elimination could no longer be detected.[43] The main reaction is, in each case, *ortho*-metalation;[44] the *o'*,β-elimination



Scheme 4. Reaction of β-deuteriated phenetol with perdeuterioethyllithium.

(here *o'* indicates that the *o* and β positions are situated on different sides of the oxygen atom),[45] which was expected to follow, could be ruled out. This reaction does, however, take place to a small extent (16%) with 1-methoxy-2-phenoxyethane, where *inter*molecular elimination still predominates.[46]

The most interesting subsequent reaction of metalated phenetole is, undoubtedly, the condensation of two molecules of 2-ethoxyphenyllithium with elimination of lithium ethoxide, leading to 2-ethoxy-2'-lithiobiphenyl (Scheme 5).[43] The intermediate formation of dehydrobenzene, i.e. the *intra*molecular elimination of lithium ethoxide, as has been observed in the photolysis[47] of 2-methoxyphenyllithium, can be excluded with THF as the solvent.[48] Only in the presence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) in the dark was dehydrobenzene formed as an intermediate which could be trapped with anthracene with the formation of triptycene.[43] We formulate the *inter*molecular elimination of lithium alkoxide via the formation of a dimeric species (Scheme 5)



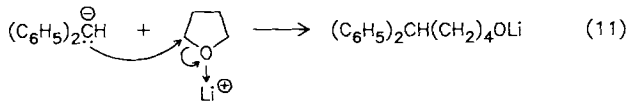
Scheme 5. Condensation reaction of metalated phenetole.

which probably first dissociates under the influence of TMEDA into a monomeric ion pair, which then undergoes reaction according to the aryne mechanism.[49]

Open-chain alkynes are formed by β-elimination from vinyl ethers,[41,50] and also from 2-chloroethyl ethers.[51,52]

2.1.2. *Nucleophilic Cleavages*

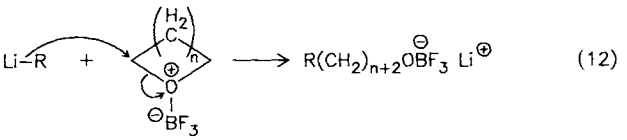
Only mesomerically stabilized, soft, organolithium compounds such as tritylithium,[53] 1,1-diphenylhexyllithium,[54] or benzhydryllithium[55,56] are capable of cleaving THF nucleophilically [Eq. (11)].



We were unable[40,57] to reproduce the corresponding reaction with ethyllithium.[35] Even benzyllithium tends to prefer protophilic cleavage;[57] however, in perdeuteriotetrahydrofuran this is so suppressed by the isotope effect[27] that nucleophilic cleavage predominates.[58,59]

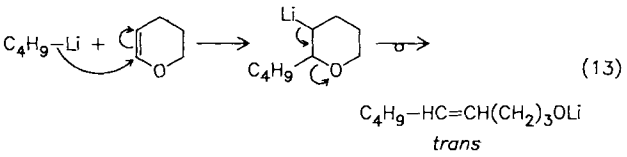
The counterion is clearly involved in the reaction, since tritylsodium reacts only in the presence of triphenylboron.[60] Radical anions of naphthalene, anthracene, and biphenyl with lithium—but not sodium—as the counterion are also able to cleave THF nucleophilically.[61]

Hard organolithium reagents, even lithium acetylides,[62] can be activated for a nucleophilic attack on THF and smaller rings, if they are used in the presence of boron trifluoride ether [Eq. (12)].[63] On changing over to organo-



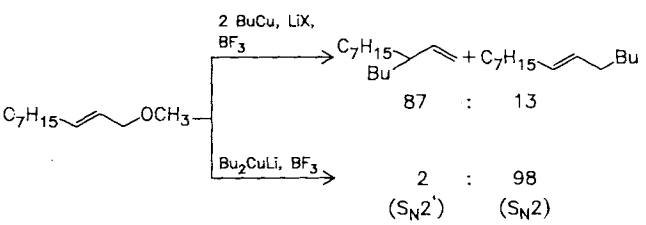
copper compounds,[64] especially in the presence of boron trifluoride,[65] there is a dramatic increase in reactivity.

Interestingly, unlike THF, tetrahydropyran is attacked nucleophilically by butyllithium without the addition of any other reagents; the yield of 1-nonanol at room temperature after 2–3 days is about 20%.[40] Tetrahydropyran is, therefore, less stable than diethyl ether towards butyllithium, although it is not attacked nucleophilically by 1,1-diphenylhexyllithium.[54] Dihydropyran, with the double bond in the α,β-position, reacts with butyllithium to give *trans*-4-nonen-1-ol [Eq. (13)].[40,66] Here, as with the open-



chain vinyl ethers,[50,54,67] an addition-elimination mechanism is probably involved. With hard bases there is competition from protophilic cleavage [cf. Eq. (9)],[50] or metalation occurs in the α-position.[13–17]

The S_N2 or S_N2' attack of organolithium compounds on allyl ethers, which takes place particularly easily,[68] is generally sterically controlled, but also dependent on the solvent used.[54] Conversion of the organolithium compounds into corresponding organocopper compounds or cuprates allows one to steer the reaction in one direction or the other (Scheme 6).[69]



Scheme 6. Influence of the organometallic compound on the course of reaction in allyl ethers.

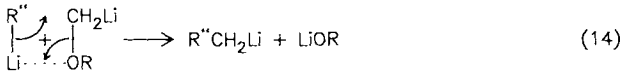
Even the methyl group in anisole can be attacked by nucleophiles,[54] although, in the case of alkyllithium compounds, only when it is twisted out of the plane of the ar-

ene ring by the presence of two *ortho*-substituents.[70, 71] With phenylcesium prepared in situ, however, we have also observed a nucleophilic attack on unsubstituted anisole.[72]

For the attack of 1,1-diphenylhexyllithium on a variety of ethers the following reactivity series is found:[54] Allyl-O > Vinyl-O > Methyl-O ≫ Aryl-O.

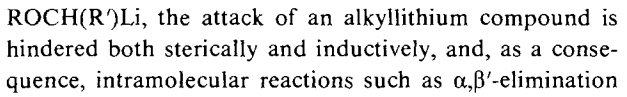
2.2. Secondary Reactions

Metalated dimethyl ether and alkyl methyl ethers metalated on the methyl group undergo an interesting secondary reaction with the unreacted organolithium compound involving a methylene insertion into the Li-C bond.[19] With hexyllithium we have observed up to ten methylene insertions.[28] Presumably this occurs via a direct attack of the alkyllithium compound R″Li on the α-metalated ether [Eq. (14)] without the formation of a free carbene intermediate.[73] This view is supported by the finding[28] that such carbene insertions are only observed with methyl ethers; in the case of secondary alkoxyalkyllithium compounds ROCH(R′)Li, the attack of an alkyllithium compound is hindered both sterically and inductively, and, as a consequence, intramolecular reactions such as α,β′-elimination and the Wittig rearrangement are much more favorable. In addition there is, in general, always the possibility of an α-elimination occurring, followed by an intramolecular 1,2-hydride shift (cf. Scheme 1B)[21]—as has been demonstrated in particular with β-deuteriated diethyl ether and β-deuteriated dibutyl ether.[28]

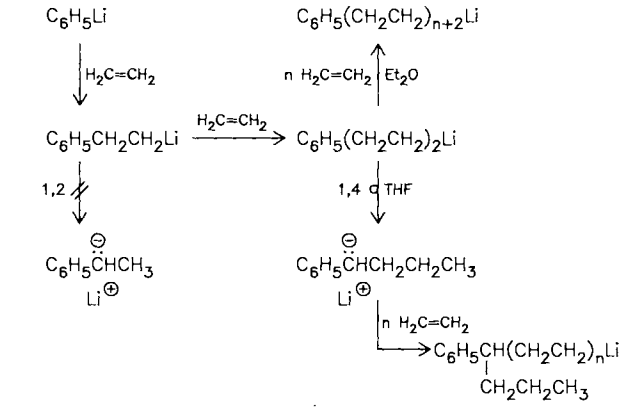


(14)

However, we have, quite accidentally,[74] also observed the gradual formation of higher homologous alkyllithium compounds during the decomposition of organolithium compounds in diethyl ether and THF. A systematic investigation[27] of this secondary reaction showed that the ethylene formed in the primary reaction inserted itself several times into the Li-C bond of the still unreacted organolithium compound [Eq. (15)]. This corresponds to a carbanion-initiated ethylene oligomerization, a reaction which was earlier[75] believed to be possible only under a pressure of several hundred atmospheres. Starting with *n*-butyllithium, up to twelve ethylene insertions could be demonstrated mass spectroscopically, and, after hydrolysis, in contrast to the reaction in dimethyl ether, only *n*-alkanes with an even number of carbon atoms were obtained.[27] The analogous reaction starting from secondary and tertiary alkyllithium compounds,[76] or from naphthalene dianions,[77] strangely comes to a halt after the insertion of one ethylene unit into the Li-C bond. Phenyllithium (Scheme 7) behaves like *n*-butyllithium but only in diethyl ether as solvent. In THF, after two insertions of ethylene into the Li-C bond a 1,4-proton shift occurs, leading to the formation of 1-phenylbutyllithium, which then either reacts further with ethylene or attacks the THF nucleophilically.[57] The intramolecular course of the reaction was confirmed in a later study.[58]

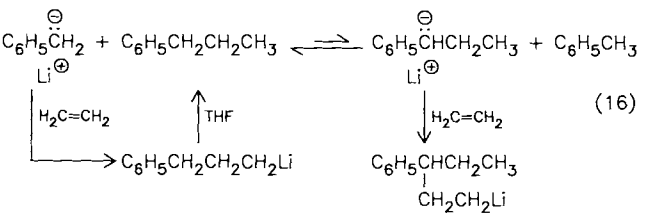


(15)



Scheme 7. Insertion of ethylene from Et_2O and THF into the Li-C bond of phenyllithium.

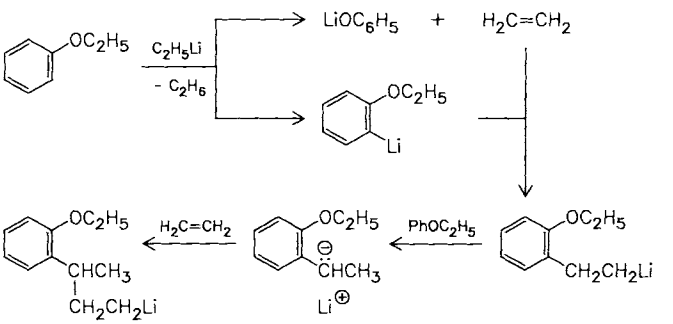
The formation of 1-phenylpropyllithium from benzyllithium and ethylene in THF, however, depends—contrary to earlier opinion[57]—on an *inter*molecular transmetalation of propylbenzene by still unchanged benzyllithium[59] and not on an *intra*molecular 1,3-proton shift [Eq. (16)].[58]



(16)

The equilibrium lies well to the left ($K^{293} = 1.1 \times 10^{-4}$), but since 1-phenylpropyllithium reacts very much faster with ethylene than benzyllithium it is continuously removed from the system, so that eventually the branched molecule is obtained as the major product of the secondary reaction.[59]

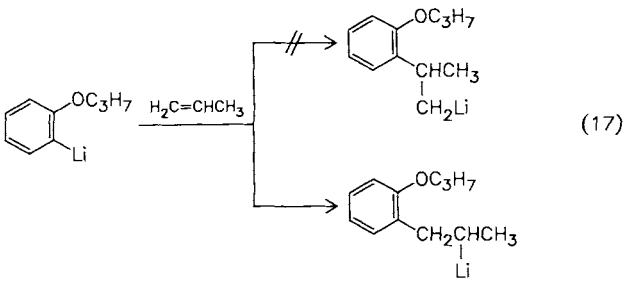
Branched products are also obtained from the decomposition of ethyllithium in phenetole.[43] Interestingly however they are derived not from ethyllithium but from *o*-ethoxyphenyllithium (Scheme 8). Here also the rearrange-



Scheme 8. Branched products from phenetole and ethyllithium.

ment of (2-(*o*-ethoxyphenyl)ethyllithium to 1-(*o*-ethoxyphenyl)ethyllithium) takes place *inter*molecularly, since neither 1,2- nor 1,3-*intra*molecular proton shifts are possible.[58]

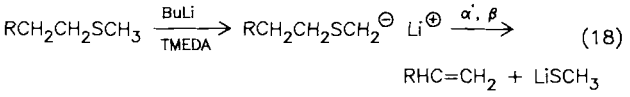
In the corresponding, extremely slow reaction of phenyl propyl ether with ethyllithium the propylene generated in the primary reaction inserts itself into the Li-C bond to give, contrary to expectations, the secondary and not the primary organolithium compound [Eq. (17)].[49]



(17)

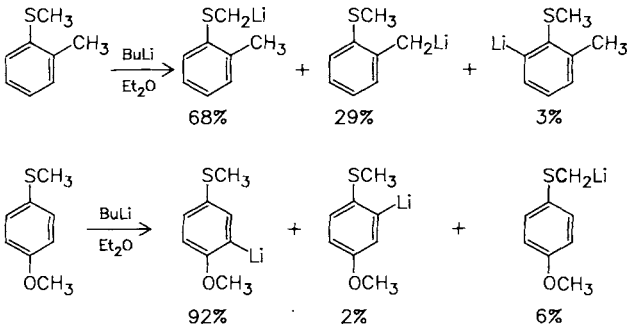
2.3. Cleavage of Thioethers

Thioethers can also be cleaved protophilically or nucleophilically, but are, however, clearly differentiated from the ethers in their reactivity. In addition, there is the possibility of a thiophilic attack, i.e. a nucleophilic attack on sulfur. What is striking is the ease with which α′,β-eliminations occur even with alkyl methyl sulfides [Eq. (18)].[78]



(18)

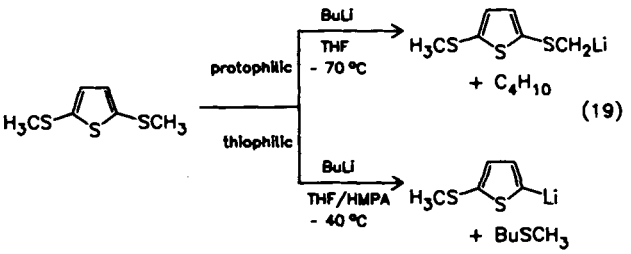
This is undoubtedly because of the higher acidity of the methylthio group, which is even higher than that of benzylic protons (Scheme 9).[79] The *ortho*-positions of an arene ring are, nevertheless, much less activated by SMe than by OMe (Scheme 9).[80]



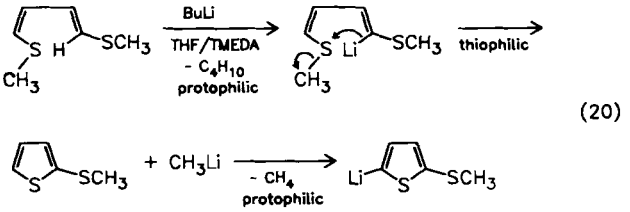
Scheme 9. Comparison of the reactivity of ArylSMe/ArylMe and ArylSMe/ArylOMe.

Protophilic and nucleophilic cleavage often occur simultaneously; with (1-methylthioethyl)benzene, for example, β-elimination, coupling, and Wittig rearrangement occur.[81]

Interestingly, in the metalation of benzyl methyl sulfide with butyllithium both the coupling reaction and the Wittig rearrangement can be suppressed by employing hexane with added TMEDA as the solvent instead of diethyl ether.[82] By varying the solvent, *n*-butyllithium can also be made to react with 2,5-bis(methylthio)thiophene, either as a thiophile or as a protophile [Eq. (19)].[83] Sometimes protophilic and thiophilic steps occur consecutively [Eq. (20)].[84,85]



(19)



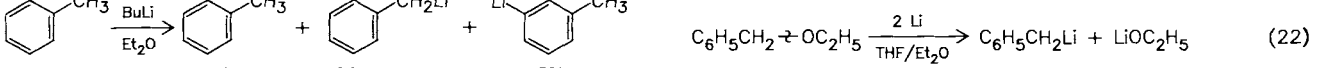
(20)

3. Ether Cleavage with Alkali Metals

3.1. Cleavage with Lithium

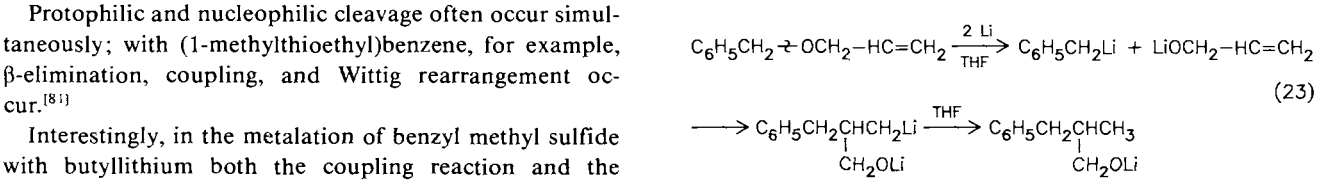
Cleavage of certain ethers such as allyl[86] and benzyl[87] ethers with lithium is very important for the synthesis of mesomerically stabilized organolithium compounds, which, because of extensive Wurtz coupling, are not readily available from the corresponding halo-compounds [Eqs. (21) and (22)].

(21)



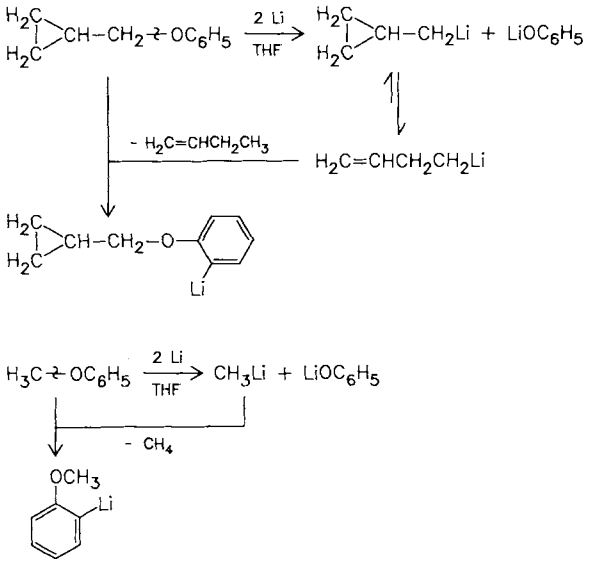
(22)

In order to establish whether the allyl- or the benzyl-oxygen bond is most easily cleaved we allowed allyl benzyl ether to react, under the same conditions, with lithium in THF.[88] Surprisingly, neither allyl- nor benzyllithium were obtained. The benzyl-oxygen bond was indeed cleaved but the benzyllithium formed as a primary product reacted with the simultaneously formed lithium allyl oxide to form an adduct [Eq. (23)][89] whose Li-C bond, as one might ex-



(23)

pect, is not stable in THF.[88] Also when the allyl group in allyl phenyl ether was replaced by a cyclopropylmethyl group, we did not isolate the initially formed alkyllithium compound in analogy to (21).[90] The homoallyllithium formed by rearrangement is, in contrast to allyllithium, so strongly basic that it deprotonates the phenyl ring of the starting material in the *ortho*-position (Scheme 10).[90] We have found a quite similar course of reaction in the case of anisole (Scheme 10).[90] The fact that this *ortho*-metalation

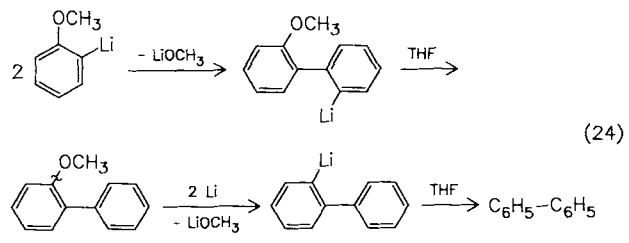


Scheme 10. *ortho*-Metalation as secondary reaction in the reaction of alkyl aryl ethers with lithium.

has not been observed before[91] is probably due to the use of hydrolytic work-up procedures. Our observations were, however, confirmed later—also in the corresponding cleavage of diphenyl ether by lithium.[92]

In order to cleave less reactive ethers it is often useful to catalyze the reaction by making use of electron transfer in the presence of biphenyl,[90-93] naphthalene,[92,93] phenanthrene,[92] or even pyridine.[94] In this way, even THF can be cleaved.[91]

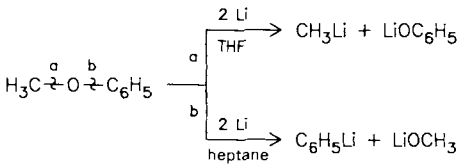
Interestingly, in the cleavage of anisole with lithium in THF we also found biphenyl, although none had been added, especially when the reaction was carried out at relatively high concentrations (>3 molar).[48] It is formed via 2-methoxybiphenyl [Eq. (24), cf. also Scheme 5], which,



(24)

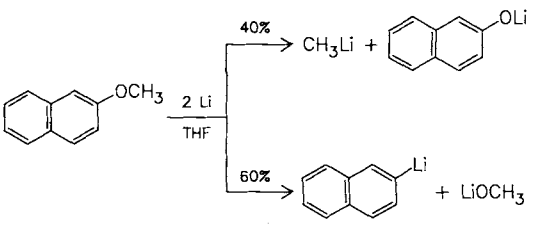
under the conditions used, suffers aryl-oxygen cleavage only, as was also demonstrated in a separate experiment.[48] Formation of an arene intermediate can be ruled out, since, when starting with 4-methyl-anisole, 3,3'-bitolyl should be found together with the 3,4'-bitolyl that is formed.[48]

As a gross simplification one can say that, under otherwise identical conditions, the degree of aryl-oxygen cleavage is higher, in general, with a more extended aromatic system. Even with anisole (Scheme 11) we do not find exclusive cleavage of the methyl-oxygen bond, although it exceeds 80%—at least in THF.[48] Just how important the solvent is, can be gauged from the observation that for anisole in heptane practically only phenyl-oxygen cleavage takes place, and that the reaction with lithium powder at room temperature only reaches 75% completion after 14 days.[72]



Scheme 11. Influence of solvent on the cleavage of anisole with lithium.

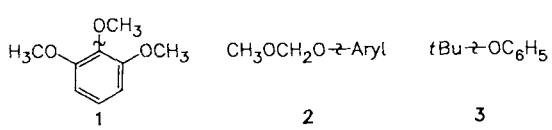
The cleavage of the methoxynaphthalenes in THF [Eq. (25)] lies, with regard to its regioselectivity, between that of



(25)

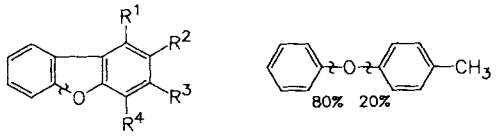
anisole and 2-methoxybiphenyl. In contrast to anisole, no metalation of the starting materials by the organolithium compounds formed was observed. This is probably because cleavage occurs much more rapidly than metalation, a fact which can be deduced from the exothermic nature of the reaction.[48] In this connection it is interesting to note[92] that diphenyl ether is only *ortho*-metalated if lithium-naphthalene is used in less than molar proportions. This might also be due to competition between cleavage and metalation.

The yield of β-naphthol in the cleavage of nerolin (2-methoxynaphthalene) in THF exceeds 90% if lithium-naphthalene is used instead of lithium.[95] Aryl-oxygen cleavage predominates—also in THF—whenever the methyl group is twisted out of the plane of the aromatic system (**1**),[48] or when it is replaced by a methoxymethyl group (**2**) or other acetal group, e.g. tetrahydropyranyl ether (Scheme 12).[96] A *tert*-butyl group has the opposite



Scheme 12. Types of compounds in which one of the C–O bonds is preferentially cleaved.

effect,[48,96] and in the case of *tert*-butyl phenyl ether (**3**), for example, alkyl-oxygen cleavage predominates to the extent of 99%.[48] The influence of structure and solvent on the regioselectivity of the cleavage will be discussed in more detail later. It should, however, be pointed out here and now that, in the case of methyl substituted dibenzofurans[97] and diphenyl ethers,[98] the bond between the unsubstituted ring and the oxygen atom is preferentially cleaved (Scheme 13).

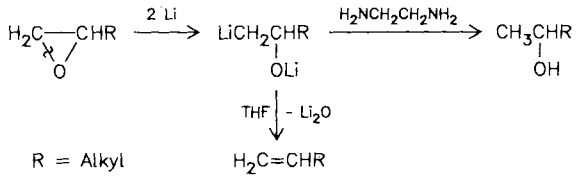


R^1, R^2, R^3, R^4 = H, CH_3

Scheme 13. Mode of cleavage in unsymmetrically substituted diaryl ethers.

The organolithium compound formed in the primary reaction naturally defies detection when the reaction is carried out in ethylenediamine,[98] ethylamine,[99] or HMPA[95,100] as a solvent.

In the cleavage of epoxides with lithium, even different products are obtained depending on whether protic or aprotic solvents are used (Scheme 14). In ethylenediamine,



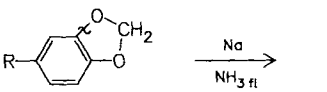
R = Alkyl

Scheme 14. Influence of solvent on the isolable products in the cleavage of epoxides with lithium.

the product of the primary reaction, a β-lithioalkoxide, is protonated to an alcohol,[101,102] whereas in boiling THF it splits off lithium oxide with the formation of the corresponding alkene.[103] Only with lithium-biphenyl or lithium-naphthalene at −80 °C has it been possible to prepare the β-lithioalkoxides unchanged and to derivatize them with nucleophiles.[93] For R = C_6H_5,[93] $CO_2C_2H_5$,[93] or C≡CH[104] the other C-O bond of the epoxide ring (not marked in Scheme 14) is broken.

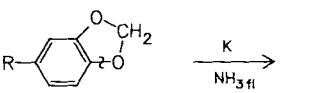
3.2. Cleavages with Higher Alkali Metals

For many years ether cleavages have been carried out with sodium or potassium in liquid ammonia[105-112] or hexamethylphosphoric acid triamide (HMPA).[113-116] Naturally, no organometallic intermediates can be isolated, since they are immediately protonated by the solvent. Alkyl aryl ethers are usually dealkylated to phenols (alkyl-oxygen cleavage); the ease of splitting off alkyl decreases along the series: $PhCH_2 > CH_3 > n$Pr, iPr.[109,116] Acetals undergo aryl-oxygen cleavage, the breaking of the bond taking place preferentially in the *meta*-position to electron releasing substituents [Eq. (26)] and in the *para*-position to electron withdrawing substituents [Eq. (27)].[107,109] The



(26a)

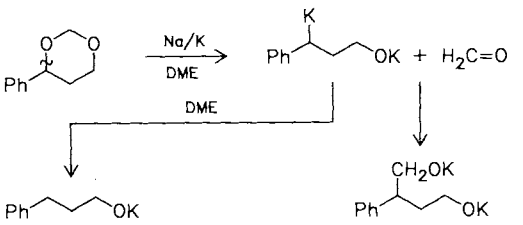
R = H, CH_3, C_3H_7, $H_2C=CHCH_2$



(26b)

R = CO_2H, $H_3C-HC=CH$

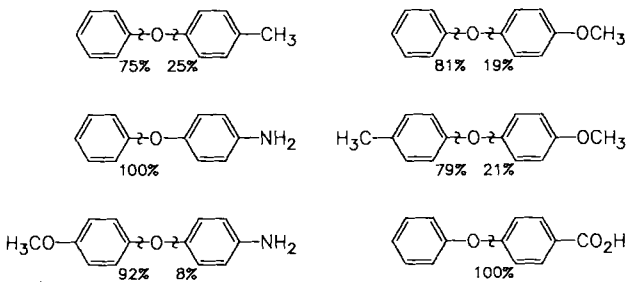
methyleneoxy group is released as formaldehyde, as shown in reaction (28) (DME = dimethoxyethane), in which the formaldehyde is incorporated, to some extent, into the primary product.[117] Open chain acetals are decomposed in a corresponding fashion.[109]



(27)

In HMPA, nerolin yields an almost 1:1 mixture of naphthalene and β-naphthol.[114] 1-Methoxynaphthalene reacts analogously with potassium in DME/THF.[95]

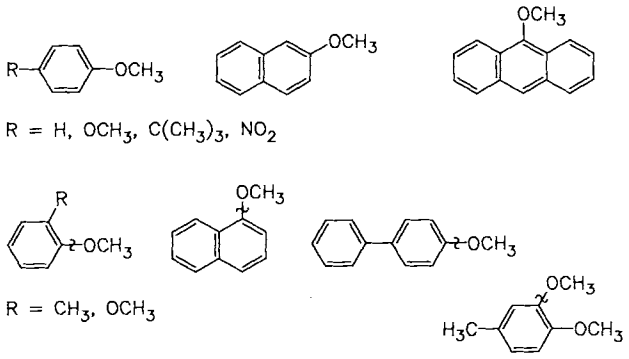
With diphenyl ethers the substituents play a role in determining the direction of cleavage (Scheme 15): electron releasing groups reduce the tendency toward bond breaking between the oxygen atom and the substituted ring in the order p-$CH_3 < p$-$OCH_3 < p$-NH_2, while electron withdrawing groups such as p-CO_2H increase it.[105,106]



Scheme 15. Influence of substituents on the mode of cleavage in diphenyl ethers.

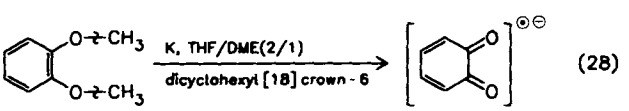
If the reactions of diaryl ethers[118] or dibenzofuran[119] with alkali metals are carried out in ether-type solvents such as DME or THF then the primarily formed radical anion can be detected by means of ESR-spectroscopy. With aryl *methyl* ethers this is not, however, always possible. Only in six of the eleven ethers investigated (Scheme 16) could we observe the ESR spectrum of the original radical anion $ArylOCH_3^{\odot\ominus}$ after reduction with potassium in THF at 170 K; in the remaining cases it was that of the corresponding cleavage product $ArylH^{\odot\ominus}$.[120]

From these findings there emerges a remarkable dependence of the stability of the primarily formed radical anion $ArylOCH_3^{\odot\ominus}$ on the bond order, calculated by the Hückel method, of the aryl-oxygen bond. As soon as the π-bond order falls below 0.19 only the ESR spectrum of the radical anion $ArylH^{\odot\ominus}$ can be observed, even at low temperatures (170 K).[120] Particularly interesting in this respect was the finding that in the decomposition of 3,4-dimethoxytoluene (4-methylveratrole) only one of the two aryl–oxygen bonds was split, namely that for which a π-bond order of 0.169 was calculated, while the other with a π-bond order of 0.196 remained unaffected.[120] A borderline case is that of 9-methoxyanthracene with a π-bond order of 0.197. Here, one can demonstrate very nicely that the stability of the radical anion is also dependent on the nature of the counterion, the ease of decomposition falling off in the order Li > Na > K > Rb > Cs. With lithium, even at low temperatures, the ESR spectrum of the anthracene radical anion $ArylH^{\odot\ominus}$ appears, while with sodium, between −110 and −30 °C, one observes the radical anion of the starting ether $ArylOCH_3^{\odot\ominus}$ and at room temperature $ArylH^{\odot\ominus}$. With potassium and cesium as counterions the radical anion of 9-methoxyanthracene is stable at room temperature for long periods and the ESR spectrum of $ArylOCH_3^{\odot\ominus}$ is then gradually replaced—more slowly with cesium than with potassium—by that of the anthracene radical anion $ArylH^{\odot\ominus}$.[120] With dibenzofuran also, it has been observed that the decomposition of the radical anion with lithium as the counterion is 25 times faster than with cesium.[119]



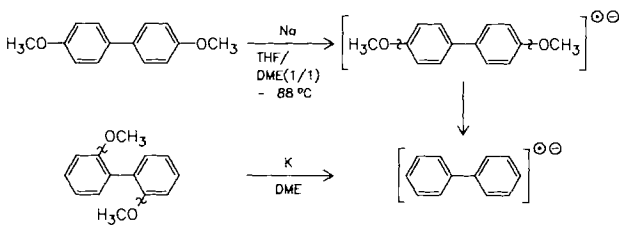
Scheme 16. ESR spectra could be obtained of the aryl methyl ethers of the first row after reduction with potassium in THF. In the case of the ethers of the second row the cleavage was too rapid.

In the presence of dicyclohexyl[18]crown-6, veratrole yields the radical anion of *o*-benzoquinone; that is, both *methyl*-oxygen bonds are cleaved [Eq. (28a)].[121]



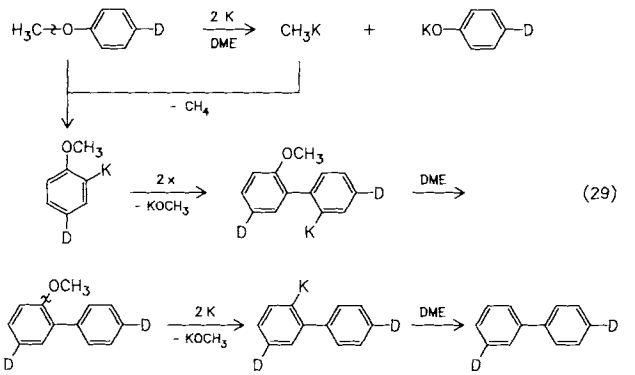
(28)

On the other hand, both *aryl*-oxygen bonds are cleaved in 4,4′- and 2,2′-dimethoxybiphenyl; the intermediate could only be detected (by ESR spectroscopy) in the case of the 4,4′-derivative (Scheme 17).[122]



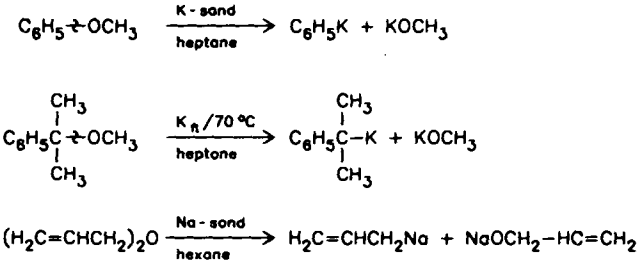
Scheme 17. Ether cleavage in methoxy-substituted biphenyls.

At first the appearance of biphenyl in the cleavage of anisole with potassium in DME was puzzling, since at that time none of the mechanisms under discussion could be reconciled with the results of the isotopic labeling experiments.[123] If the assumptions developed by us for the case of lithium can be extended to the mode of reaction of the higher alkali metals, the "strange behavior of anisole"[124] would be easily explained in terms of the mechanism shown in Equation (29). Clearly, anisole can also act as a proton donor, in place of DME, in the decomposition of the biphenylylpotassium compounds which occur as intermediates—particularly when the solvent is deuteriated. When the reaction is carried out in perdeuteriated DME, no deuterium from the solvent is found in the biphenyl that is formed.[123]



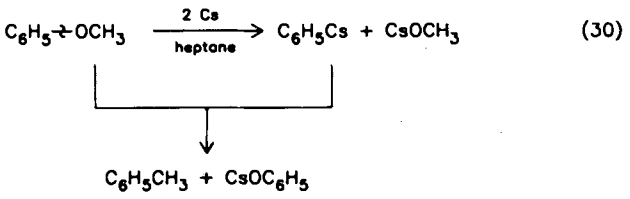
(29)

Even for the preparation of mesomerically stabilized organosodium and -potassium compounds—with the exception of benzhydryl and trityl compounds[125]—ether-type solvents such as THF and DME are not suitable, since Wurtz coupling,[125] Wittig rearrangement,[126] and other secondary reactions[127] can occur—with strongly basic compounds also protonations.[117, 125] Wittig rearrangements have also been observed in HMPA.[114] The best solvents are, therefore, aliphatic hydrocarbons such as hexane[128] and heptane;[129, 130] however, other than in THF, the cleavage of anisole this time takes place at the phenyl-oxygen bond (Scheme 18).[130]



Scheme 18. Syntheses of some organo-sodium and -potassium compounds.

In the preparation of allyl- and benzyltrimethylsilane from allyl- and benzylsodium it is obviously better, even in *n*-decane or toluene, to carry out the ether cleavage in the presence of chlorotrimethylsilane.[131] A secondary reaction, which however only takes place to a large extent at 60°C, has been observed by us in the cleavage of anisole with cesium in heptane.[72] The phenylcesium attacks the methoxy group nucleophilically with the formation of toluene and cesium phenolate [Eq. (30)].



(30)

3.3. Influences on the Direction of Cleavage in Alkyl Aryl Ethers

3.3.1. Influence of Structure

In the reduction of alkyl aryl ethers with alkali metals both the alkyl-oxygen and the aryl-oxygen bond can be broken. In most cases one observes both directions of cleavage [Eq. (31)]. In the ESR spectrum one only sees the

(31)

fragment due to aryl-oxygen cleavage—however little there is—since the phenolate formed by alkyl-oxygen cleavage forms no radical anion and therefore cannot be observed. This is why, in the reduction of anisole with potassium in DME,[123] an unimportant secondary reaction, which leads to the formation of biphenyl [see Eq. (29)], is observed in the ESR spectrum, while the main reaction—cleavage of the methyl-oxygen bond to give methylpotassium and potassium phenolate—is not. Influences on the regioselectivity of the cleavage can therefore only be studied when all the cleavage products can be analytically determined.

For this reason we have taken anisole as the starting point and varied the alkyl residue systematically, and, after carrying out the cleavage with each compound under identical conditions [lithium powder in boiling THF (2 h)], have analyzed the products by gas chromatography[48] (Table 1). It is obvious that the amount of alkyl-oxygen cleavage falls off strongly at first on going from anisole to phenetole but then rises again with isopropyl and *tert*-butyl ethers. A similar pattern is found with the corresponding naphthyl ethers except that it is shifted in favor of the aryl-oxygen cleavage, i.e. here also there is a minimum in the alkyl-oxygen cleavage with the ethyl ether (Table 2). Another important observation is that there is no connection between the rate of the reaction and the cleavage pattern. Ethyl naphthyl and isopropyl naphthyl ethers (1 : 1) react with a substoichiometric amount of lithium at approximately the same rate although they show totally different cleavage patterns.[48]

Table 1. Regioselectivity of the cleavage of alkyl phenyl ethers with lithium in THF [37].

R	% C_6H_5O–R	% C_6H_5–OR
CH_3	82	18
C_2H_5	59	41
$CH(CH_3)_2$	84	16
$C(CH_3)_3$	99	1

Table 2. Regioselectivity of the cleavage of alkyl naphthyl ethers with lithium in THF [37].

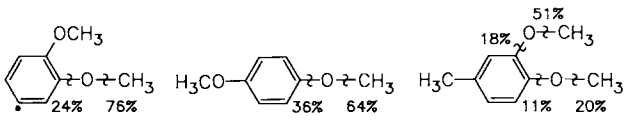
R	% Naphthyl–O–R		% Naphthyl–OR	
	α	β	α	β
CH_3	36	40	64	60
C_2H_5	2	1	98	99
$CH(CH_3)_2$	57	53	43	47
$C(CH_3)_3$	87	97	13	3

Substituents on the arene ring also influence the direction of cleavage, as can be shown in the example of the cresol ethers[48] (Table 3). The *para*-compound yields values comparable with those of anisole, whereas the extent of methyl-oxygen cleavage in the *ortho*-compound is clearly higher, and in the case of the *meta*-compound it is considerably lower.

Table 3. Influence of the position of methyl on the cleavage of cresol ethers with lithium in THF [37].

H_3C–C_6H_4–OCH_3	% C_7H_7O–CH_3	% C_7H_7–OCH_3
ortho	91	9
meta	68	32
para	79	21

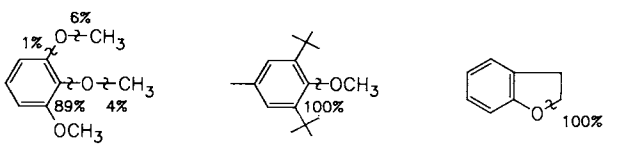
The introduction of a second methoxy group, particularly in the *para* position, leads in each case to a marked increase in the amount of cleavage of the the aryl-oxygen bond. In addition, we have shown that veratrole is cleaved faster, by a factor of 7, than anisole.[48] Particularly interesting is the influence, in 4-methylveratrole, of an additional methyl group, which favors both types of cleavage, i.e. alkyl-oxygen as well as aryl-oxygen cleavage, in the *meta* position as opposed to the *para* position (Scheme 19).[48] Of the four different types of cleavage only one could be recognized in the ESR spectrum after reaction with potassium in THF.[120]



Scheme 19. Mode of cleavage in substituted anisoles.

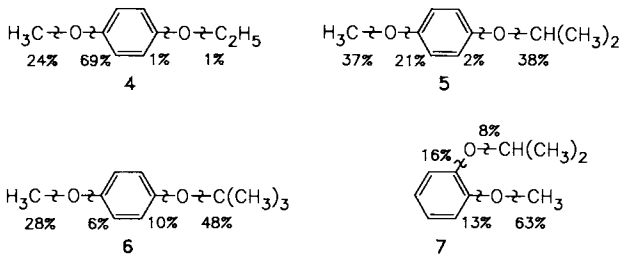
Aryl methyl ethers, whose methoxy groups are twisted out of the plane of the arene ring by two *ortho*-substituents,[132] show overwhelmingly aryl—oxygen cleavage (Scheme 20)[48]—even upon reduction with potassium in DME.[72] If, however, the orientation in the plane is fixed,

as in 2,3-dihydrobenzo[*b*]furan, alkyl-oxygen cleavage occurs exclusively, but with a much reduced reactivity (Scheme 20).[72]



Scheme 20. Steric influence on the mode of cleavage in alkyl aryl ethers.

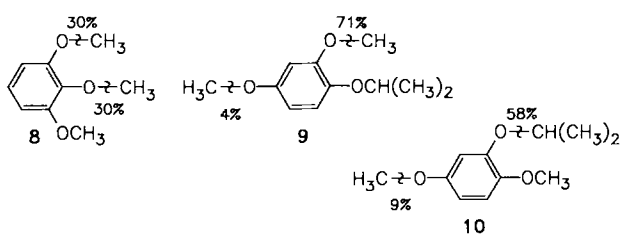
A mixture of four products—enriched by secondary products such as benzene and phenol—is obtained upon reduction of the mixed hydroquinone ethers **4**–**7** with lithium powder in THF (Scheme 21).[48] Of particular interest is the methyl isopropyl *p*-hydroquinone diether **5**, since the cleavage patterns of methyl phenyl and isopropyl phenyl ethers are very similar (cf. Table 1).



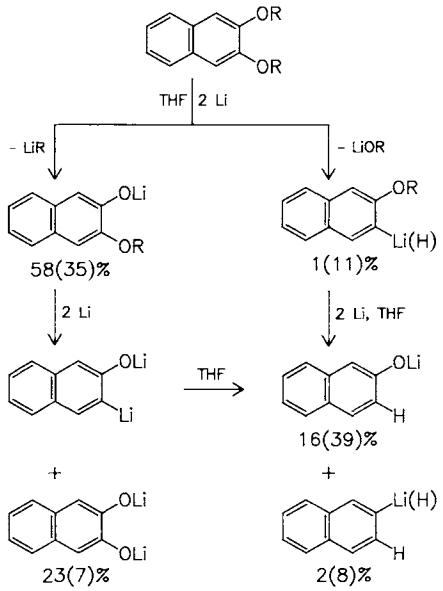
Scheme 21. Pattern of cleavage in diethers with hydroquinones as aryl component.

In fact, the two alkyl-oxygen bonds in **5** are cleaved almost to the same extent, but not so the aryl-oxygen bonds; in the case of the corresponding *o*-hydroquinone diether **7** exactly the opposite is true.[48]

With sodium in HMPA, the preferential cleavage of the methyl group in contrast to the isopropyl group had already been found, both in the case of **5** and **7**, as well as in the *m*-isomer.[116] As expected, in this solvent aryl-oxygen cleavage plays no part, so that the yield of the corresponding isopropyl half ethers of *p*-hydroquinone, pyrocatechol, and resorcinol lies between 72 and 93%.[116] In HMPA even the trimethoxybenzene **8** can be partly dealkylated; however, the two different methyl-oxygen bonds are each only cleaved to the extent of 30%.[116] In the 1,2,4-trialkoxybenzenes, the alkyl group in the 2-position is always preferentially split off—even when it is an isopropyl group (cf. **9** and **10**).[116]



With 2,3-dialkoxynaphthalene we have observed substantial further reduction of the primary reaction products (Scheme 22). β-Naphthol, however, does not undergo further cleavage, as was also shown in a separate experiment.[48]



Scheme 22. Cleavage of 2,3-dialkoxynaphthalenes. The product ratios hold true for R = $CH_3(C_2H_5)$.

3.3.2. *Influence of the Solvent*

Once it was known that the solvent had, in some cases, a large influence on the regioselectivity of cleavage[133] we undertook a systematic study of the cleavage of anisole with potassium powder and with sodium/potassium alloy in various solvents.[72] It turns out that one can alter the direction of the cleavage from pure aryl-oxygen cleavage to almost 100% alkyl-oxygen cleavage simply by changing the solvent used.

When the cleavage was carried out in heptane as solvent we were unable to find evidence of there being more than 2–3% phenol when using potassium powder or sodium/potassium alloy [Eq. (32)]. The amount of alkyl-oxygen

$$C_6D_5K + KOCD_3 \xleftarrow[98\%]{2\ K} \underset{\text{in heptane}}{C_6D_5OCD_3} \xrightarrow[2\%]{2\ K} CD_3K + KOC_6D_5 \quad (32)$$

splitting remained just as low even when the reaction temperature was raised to 60–65 °C. The objection could be raised that such traces of phenol could arise from oxidation of phenylpotassium by traces of oxygen in the reaction mixture. We therefore also analyzed the gaseous products after deuteriolysis by mass spectroscopy and indeed found traces of methane—and, starting with perdeuterioanisole, traces of CD_4.[72]

The situation is completely different when even small amounts of THF are added to the heptane (Table 4). The addition of only 1 mmol of THF per mmol of potassium increases the amount of phenol to 13%.[72] Particularly interesting is the finding that the amount of alkyl-oxygen cleavage in pure THF drops from 96% to 71% if the reaction is carried out at 65 °C instead of 20 °C.[72] DME is even more effective than THF in forcing methyl-oxygen cleav-

Table 4. Influence of increasing amounts of THF on the regioselectivity of the cleavage of 25 mmol of anisole with 25 mmol of sodium/potassium alloy in heptane at room temperature [63].

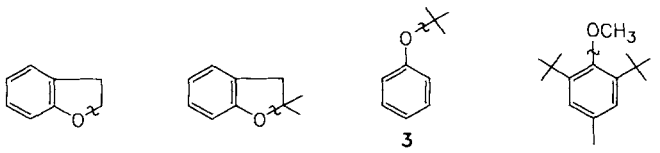
THF	% $C_6H_5O\rightarrow CH_3$	% $C_6H_5\rightarrow OCH_3$
0%	2	98
25 mmol (=7%)	13	87
50%	89	11
100%	96	4

age. In pure DME as solvent, only 1% of benzene was found after the hydrolysis.[72]

A surprising observation was made with TMEDA as solvent. Addition of 5 mmol per mmol of potassium only brought about 32% of alkyl-oxygen cleavage, and even in pure TMEDA it amounted to only 49%.[72] This finding is very important with regard to our concepts of the mechanism of ether cleavage (see Section 3.4).

A large increase in the amount of alkyl-oxygen cleavage was also found in the changeover from THF to THF/HMPA (1:1) in the cleavage of α-naphthyl decyl (from 29 to 63%) and β-naphthyl decyl ethers (from 30 to 56%) with potassium.[134] Upon cleavage of these decyl ethers with sodium, with a change from THF/biphenyl to THF/HMPA as solvent, the increase was even larger: α-naphthyl decyl ether (from 18 to 92%), β-naphthyl decyl ether (from 34 to 92%), and *p*-biphenylyl decyl ether (from 5 to 83%).[134]

There are, however, ethers whose direction of cleavage remains completely uninfluenced by the solvent (Scheme 23). Thus, 2,3-dihydrobenzo[*b*]furan, 2,3-dihydro-2,2-dimethylbenzo[*b*]furan, and *tert*-butyl phenyl ether **3** undergo pure alkyl-oxygen cleavage with potassium in all solvents—heptane, THF, DME—whereas 2,6-di-*tert*-butyl-4-methylanisole is attacked exclusively at the aryl-oxygen bond, even in DME.[72] All these ethers react extremely slowly in heptane at room temperature, even with potassium powder, so that prolonged heating at 80–90 °C is often necessary.



Scheme 23. Ethers in which the mode of cleavage is not influenced by the choice of solvent.

3.3.3. *Influence of the Metal*

In contrast to the solvent, which has a dramatic influence on the direction of cleavage of anisole, the alkali metal (lithium to rubidium) has no significant influence on the regioselectivity of the cleavage; only cesium is at variance.[72] Naturally, one finds great differences in the reactivity. However, it is astonishing that anisole reacts at all with lithium powder at room temperature in heptane, and then largely by phenyl-oxygen cleavage.

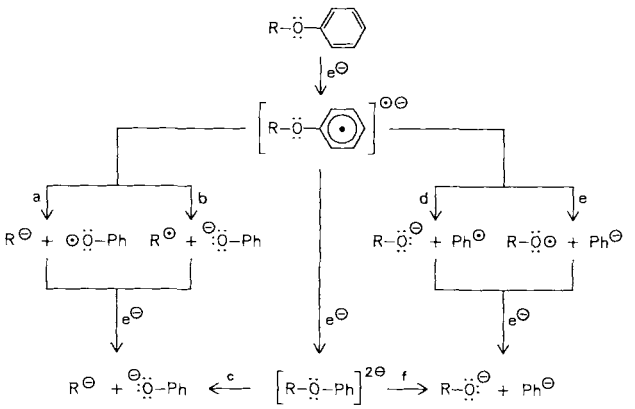
Rubidium cleaves ethers in the same way as potassium, i.e. in heptane 98:2 in favor of aryl-oxygen splitting, but in DME the ratio is 7.5:92.5.[72]

In heptane, cesium behaves like potassium only at room temperature. At 60 °C, the initially formed phenylcesium attacks the starting material nucleophilically with formation of toluene and cesium phenolate [Eq. (30)].[72] There is also a marked difference in the behavior of cesium and potassium in THF. Whereas with potassium the amount of alkyl-oxygen scission decreases from 96% to 71% as the temperature is raised from 20 °C to 65 °C, with cesium exactly the opposite is observed; the amount of methyl-oxygen cleavage increases with increasing temperature from 39% at room temperature to 62% at 60 °C.[72]

Larger differences in regioselectivity were observed in the cleavage of aryl decyl ethers with lithium, sodium, or potassium in THF, where, however, biphenyl was added as a catalyst[134] (Table 5). The large differences between the α- and β-naphthyl ethers are striking; these did not come to light in our work. Also striking is the completely different behavior of *p*-biphenylyl decyl ether. In the case of the naphthyl ethers the results with lithium and potassium are very similar, in the case of biphenylyl ethers, however, those with sodium and potassium are very similar.

3.4. Mechanistic Considerations

In the literature one finds diametrically opposed views on the mechanism of ether cleavage by alkali metals (Scheme 24). The only undisputed point is the primary for-



Scheme 24. Proposed mechanisms for the cleavage of ethers with alkali metals.

Table 5. Influence of the metal on the regioselectivity of the cleavage of various aryl decyl ethers in THF/biphenyl [125].

Metal	% Naphthyl$O\rightarrow C_{10}H_{21}$		% Naphthyl$\rightarrow OC_{10}H_{21}$		% *p*-Biphenylyl$O\rightarrow C_{10}H_{21}$	% *p*-Biphenylyl$\rightarrow OC_{10}H_{21}$
	α	β	α	β

mation of a radical anion, which in some cases has been demonstrated by ESR spectroscopy. The radical anion can collapse in four different ways (a, b, d, e) into a radical and an anion, or, before collapsing, it can take up a second electron with the formation of the corresponding dianion. The collapse of this dianion into two anions, which can also occur in two different ways (c, f), completes the spectrum of conceivable mechanisms.

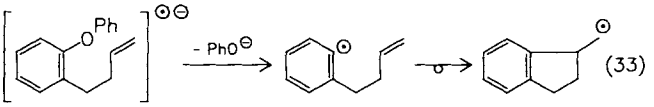
In the case of alkyl aryl ethers, of the six possibile reactions three (paths a–c) lead to alkyl–oxygen scission and three (paths d–f) to aryl–oxygen scission. With the exception of path e all the reaction mechanisms have been discussed in the literature. Confusion often arises upon introducing thermodynamic arguments—stability considerations of the products—although the course of the reaction is undoubtedly kinetically controlled.

For example, path a has been postulated for alkyl–oxygen cleavage[123] on the basis of the following argument: the phenetole radical anion is more stable than the anisole radical anion, because the ethyl anion is less stable than the methyl anion.

Path b, however, has been discussed even more often[92, 134, 135]—partly on the grounds of electrochemical findings.[136, 137] Another group of workers[116] is of the opinion that path b is followed by alkyl aryl sulfides, but not, however, by the alkyl aryl ethers, for whose cleavage path c via the dianion is required. The dianion mechanism (path c) was also favored in the older work[91, 108, 109, 114] for alkyl–oxygen cleavage as well as for the alkyl–sulfur cleavage in thioanisole,[138] which, nevertheless, is said to take path b to the extent of 10% in solvents like benzene.[138]

The dianion also enjoys great popularity as an intermediate in the aryl–oxygen cleavage by path f of diaryl ethers[118] and alkyl aryl ethers.[134]

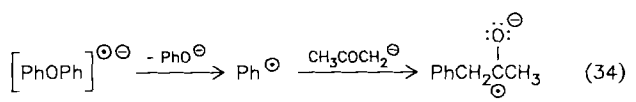
Nevertheless, the one-electron mechanism via path d has many adherents[92, 119, 123, 139]—also for the cleavage of the aryl–sulfur bond.[116, 140, 141] Through the electrochemical reduction of a suitably substituted diphenyl ether, and with the help of a cyclization reaction characteristic of radical reactions, evidence was even adduced for an intermediate aryl radical [Eq. (33)].[142]



(33)

The intermediacy of the phenyl radical was also held to be plausible in the cathodic reduction of diphenyl ether, when the dianion did not lead to cleavage.[143] The same is true for diphenyl sulfide.[144]

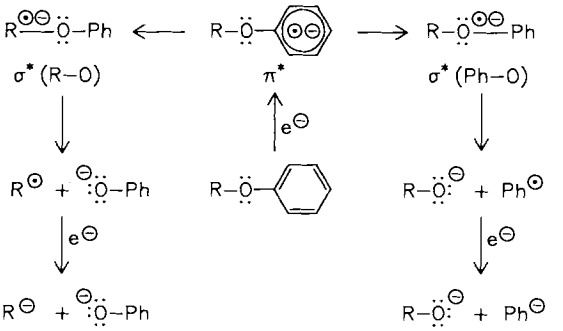
A few phenyl radicals could be trapped during the cleavage of diphenyl ether with potassium in liquid ammonia, when it was carried out in the presence of the acetone enolate anion [Eq. (34)].[139]



(34)

Unfortunately, under these conditions the cleavage of anisole did not occur.[145] The fact that up until now no aryl radicals have been demonstrated in the cleavage of alkyl aryl ethers does not, of course, mean that path d can be ruled out.

Our mechanistic propositions are shown in Scheme 25. According to this scheme there is only one mechanism for each direction of cleavage and the assumption of a dianion intermediate is not necessary. The reaction paths correspond to paths b and d in Scheme 24, but a major difference is that before the scission of the π*-radical anion a conversion into two different σ*-radical anions has been introduced. σ*-Radical anions are nowadays discussed as intermediates in a wide variety of reactions,[144, 146–152] and that formed from pentafluoroiodobenzene can even be demonstrated by means of ESR spectroscopy at 77 K.[153]



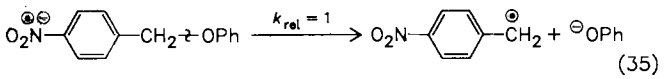
Scheme 25. Probable mechanism of the cleavage of ethers with alkali metals.

The σ*(Ph–O)-radical anion would correspond to the intermediate in an $S_{RN}1$ reaction[154, 155] between an alkoxide anion and a phenyl radical, a reaction which is not, however, observed since the corresponding σ*-orbital probably lies at too high an energy.[156] Corresponding reactions are known, on the other hand, with sulfur,[139, 140, 146, 147, 157] selenium,[158] tellurium,[158] arsenic,[148, 159] and antimony[148] analogues of alkoxides. However, in contrast to the σ*-radical anions discussed in these instances, the case of σ*(R–O) and σ*(Ph–O) radical anions is not one of two limiting mesomeric forms of one and the same radical anion but of two entirely different species of which the σ*(Ph–O) radical anion, because of the stronger—by ca. 170 kJ/mol (40 kcal/mol)—phenyl oxygen bond,[160] lies energetically much higher than the σ*(R–O) radical anion.

With thermodynamic control therefore almost exclusive alkyl–oxygen cleavage must occur, as is observed with the corresponding alkyl aryl sulfides.[161] Kinetically, however, the electron transfer π*→σ*(Ph–O) is much more favorable, probably because the oxygen forms a large barrier. This is reminiscent of the fission of certain benzyl phenyl ethers which—contrary to thermodynamic expectations—only take place unproblematically if the spin density remains on the radical which is split off ("regioconservation") [cf. Eqs. (35) and (36)].[152]

Here also, electrons cross the oxygen only with difficulty. There is much evidence that with the aryl alkyl ethers this occurs well only in a solvent separated ion-pair. Only in this way can we explain why the amount of alkyl–oxy-

gen cleavage with sodium/potassium alloy in THF drops from 96% to 71% when the temperature is raised from



(35)

(36)

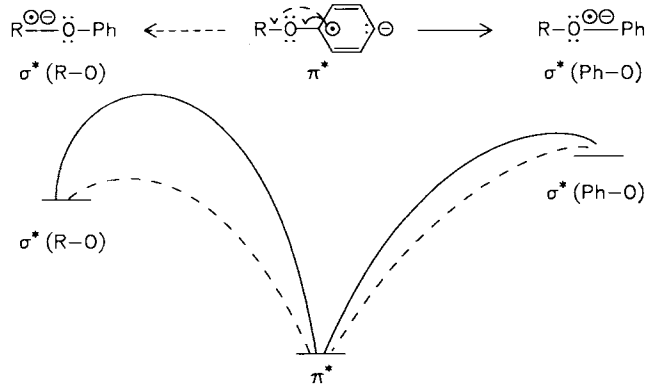
20°C to 65°C (see Section 3.3.2),[72] since it is well known that this rise in temperature reduces the number of solvent separated ion-pairs in the solution.[162] This is further supported by the finding that in TMEDA (Section 3.3.2) which has been shown not to favor the formation of solvent separated ion-pairs,[162] alkyl-oxygen cleavage does not even reach 50%.[72] Similarly, the small amount of alkyl-oxygen cleavage with cesium in THF[72] fits into this scheme since $Cs^{\oplus}$, as the largest alkali metal ion, is the one most poorly solvated by THF. The increase in alkyl-oxygen cleavage with increasing temperature,[72] however, indicates that with cesium as the counterion the $\pi^* \rightarrow \sigma^*$(R-O) electron transfer does not only take place within a solvent separated ion-pair.

The kinetic barrier can also be lowered by the addition of naphthalene[95] or biphenyl[134] as catalysts, so that the amount of alkyl-oxygen cleavage increases. The same is true when the solvent is changed to DME[72] or HMPA.[114, 116]

The transfer of electrons into the σ^*(Ph-O) orbital is also made easier by solvation of the counterion, although not to the same extent. This is particularly well illustrated in the case of 9-methoxyanthracene whose radical anion in THF is more stable with cesium as counterion than with lithium.[120]

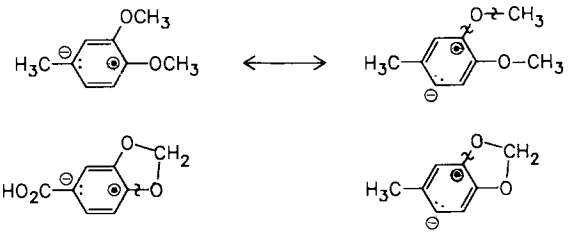
A hypothetical energy diagram for the two intramolecular electron transfers, which may possibly even take place through space,[163] is shown in Scheme 26.

Only one of the possible 18 resonance formulas[164] which can be written for the π^*-radical anion is shown in Scheme 26, but this is probably, by a wide margin, the most important one. We have established that the reaction with alkali metals takes place best—with both alkyl-oxygen and aryl-oxygen cleavage—if the spin density on the carbon atom which bears the oxygen atom is particularly



Scheme 26. Hypothetical energy diagram of the transformation of the π^* radical anion of Scheme 25 into the two σ^* radical anions. — non-polar solvent; --- readily solvating solvent.

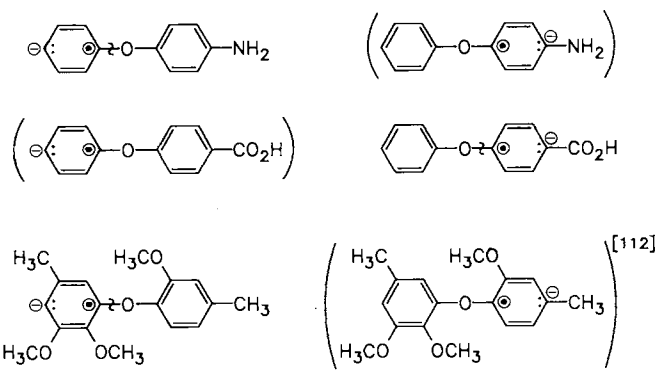
high and with it the weighting of the mesomer shown. With this as a working hypothesis it is also easy to predict the preferred direction of cleavage of bifunctional ethers. Naturally, one can calculate the relevant bond strengths quite accurately from MO-theory;[120] a glance at the essential resonance formulas (Scheme 27), however, tells us immediately which bond will be preferentially cleaved, for example, in 4-substituted *o*-hydroquinone diethers.



Scheme 27. Establishment of preferred modes of cleavage in dialkyl aryl diethers on the basis of resonance formulas.

As already mentioned in Section 3.3.1, not only the aryl-oxygen bond in 4-methylveratrole but also the *methyl*-oxygen bond *meta* to a methyl group is more easily cleaved, although it should be stronger than that of the methoxy group in the *para* position. This is also an indication that the $\pi^* \rightarrow \sigma^*$ electron transfer takes place intramolecularly and is kinetically controlled. The, at first surprising, results[116] in the cleavage of 1,2,4-trialkoxybenzenes with sodium in HMPA can be explained in the same way.

In diaryl ethers ArylOAryl',[97, 98, 105, 106] too—in contrast to the corresponding thioethers[140, 165]—the strongest bond is preferentially cleaved (Scheme 28), since electron with-



Scheme 28. Establishment of the preferred modes of cleavage in diaryl ethers on the basis of resonance formulas.

drawing substituents, which reduce the energy of the π^*-orbitals, on the one hand facilitate the entry of the electrons but on the other raise the π-bond order to the oxygen atom.

If the σ^*(Aryl-O) and σ^*(Aryl'-O) radical anions were only limiting resonance structures of one and the same species, as is the case with sulfur,[147] then the weaker aryl-oxygen bond would be cleaved preferentially.

If the aryl-oxygen bond in alkyl aryl ethers is especially weak, as when the alkyl residue, for steric reasons, is twisted out of the plane of the arene ring, then cleavage of

the aryl-oxygen bond occurs under conditions which normally lead to alkyl-oxygen scission. On the other hand, the aryl-oxygen bond may be very strong, as in 2,3-dihydrobenzo[*b*]furan, or the alkyl-oxygen bond especially weak, as in *tert*-butyl ethyl ethers, leading to alkyl-oxygen scission under all conditions.

The reason that the methyl group is always more easily split off than the ethyl group is no doubt due to the lower bond dissociation energy of the methyl-oxygen bond in anisole (239 ± 8 kJ mol^{-1} = 57 ± 2 kcal mol^{-1}),[166] as compared with the ethyl-oxygen bond in phenetole (278.8 kJ mol^{-1} = 64.0 kcal mol^{-1}),[167] which in turn affects the energy of the σ^*-orbital involved. However, there are always other influences at work; besides the energy difference between the two σ^*-orbitals, there may be, in the solvent separated ion-pair, steric factors which also play a role.

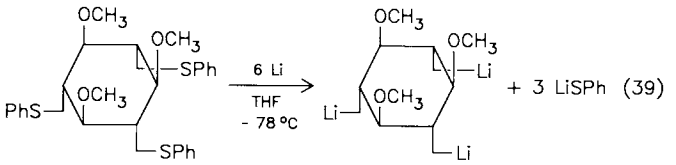
3.5. The Cleavage of Thioethers

Thioethers are more easily cleaved than ethers. Moreover, the regioselectivity is much greater; for instance alkyl phenyl sulfides are—with few exceptions[161]—almost exclusively cleaved at the alkyl-sulfur bond. This property has been exploited in the synthesis of numerous alkyllithium compounds, including bifunctional ones [Eqs. (37) and (38)].[168, 169]

$$PhCH_2O(CH_2)_3SPh \xrightarrow[\text{THF}\\ -50\,^\circ C]{2\ Li} PhCH_2O(CH_2)_3Li + LiSPh \qquad (37)$$

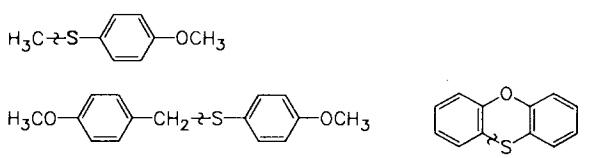
$$PhS(CH_2)_3O(CH_2)_3SPh \xrightarrow[\text{THF}]{4\ Li} Li(CH_2)_3O(CH_2)_3Li + 2\ LiSPh \qquad (38)$$

To accelerate the reaction—even in the preparation of benzylsodium or -potassium compounds[169]—naphthalene is added, or the metal is used as a dispersion. For the synthesis of allyllithium compounds from allyl phenyl sulfides, the addition of 1-dimethylaminonaphthalene instead of naphthalene is recommended, as this is easily removed from the reaction products by extraction with acid.[170] With lithium di-*tert*-butylbiphenyl,[171] even a trilithio compound could be prepared [Eq. (39)].[172]



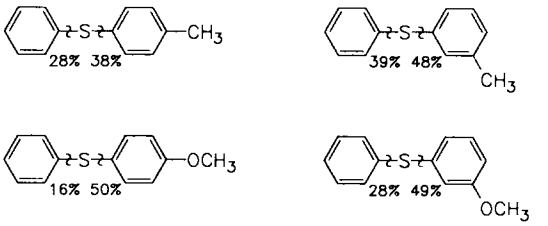
+ 3 LiSPh (39)

These and other examples[91, 116, 140, 173, 174] show that the carbon-sulfur bond can be selectively cleaved even in the presence of ether bonds (see Scheme 29).



Scheme 29. Selective cleavage of carbon-sulfur bonds in the presence of ether bonds.

Interestingly, diaryl sulfides behave quite differently to the corresponding diaryl ethers in cleavage reactions with lithium in methylamine[165] or potassium in liquid ammonia.[140] In the case of the ethers, electron releasing substituents hinder the cleavage of the substituted ring from oxygen, whereas in the case of the thioethers the sulfur-oxygen cleavage is facilitated (Scheme 30).

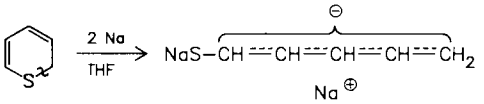


Scheme 30. Influence of substituents on the mode of cleavage in diaryl sulfides.

Naturally, under these conditions, no organometallic compound can be isolated, no more so than in cleavages with lithium or sodium in liquid ammonia.[175-177] However, lithium and sodium do not necessarily lead to the same end products (Scheme 31).[178] Even in ethereal solvents

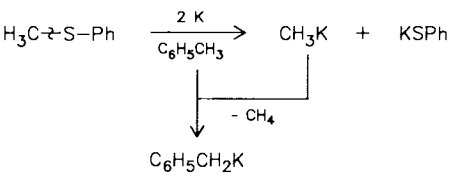
Scheme 31. Influence of the metal on the product in the cleavage of thioethers.

such as diethyl ether, DME[138, 179] or THF,[180] stable organometallic compounds are formed with sodium and potassium only in exceptional cases.[169, 181] The same is true for HMPA as a solvent.[116, 161] A beautiful example of such an exception is reaction (40).[181]



(40)

In the cleavage of thioanisole with potassium in toluene the solvent is metalated by the initially formed methylpotassium and benzylpotassium is obtained in 70% yield [Eq. (41)].[138] It should be noted that under these conditions—

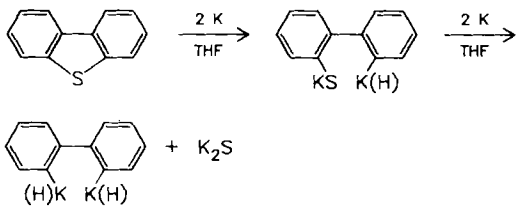


(41)

other than in the case of anisole—no cleavage of the aryl-heteroatom bond occurs. The only exception—even with HMPA as solvent—was observed as a side reaction in the dealkylation of poly(alkylthio)benzenes with sodium, although only when two or three spatially demanding alkyl-

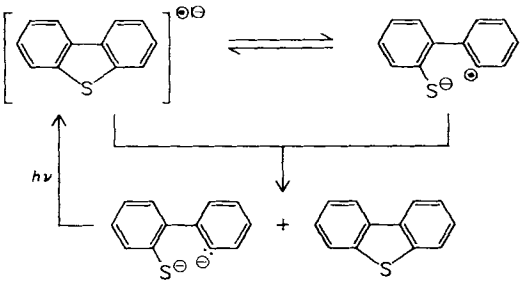
thio groups in the *ortho* position strongly interfered with one another.[161]

A further reaction, which finds no analogy in the corresponding ether cleavages, is the splitting out of K_2S from the thiophenolates which are first formed in the cleavage of mono- or diaryl sulfides, for example, in the cleavage of dibenzothiophene with potassium-naphthalene in THF [Eq. (42)].[180] The collapse of the dibenzothiophene radical



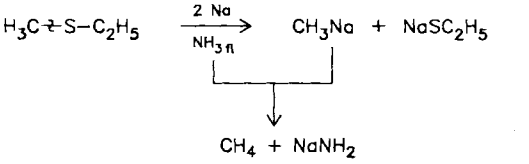
(42)

anion and its conversion into a dianion by electron transfer from another radical anion can be followed spectroscopically.[141] Especially interesting is the reconversion of the reaction products into two molecules of the original radical anion by flash photolysis [Eq. (43)].[141]



(43)

In the cleavage of dialkyl sulfides (with sodium in liquid ammonia[182, 183]), on the other hand, no sodium sulfide is formed, since the alkyl sulfides formed under these conditions are stable.[182] In the case of ethyl methyl sulfide exclusively the methyl-sulfur bond is cleaved [Eq. (44)].[183]



(44)

The easier cleavage of the dialkyl sulfides compared with that of the dialkyl ethers is remarkable, and shows that the transfer of electrons into the corresponding σ^*-orbitals can also occur without difficulty even if no π^*-orbitals are available as a means of transfer. The possibility cannot be excluded, therefore, that the formation of π^*-radical anions—at least in the case of the cleavage of alkyl aryl sulfides—is only a side reaction. What is certain, however, is that the cleavage, in contrast to the corresponding ether cleavage, is thermodynamically controlled.

I wish to thank the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie, for supporting my work, and the "Stiftung Volkswagenwerk" for financing the collaboration with Professor B. J. Herold, Lisbon, Portugal, whom I would like to thank for many ESR measurements and valuable discussions. I would also like to thank Dr. E. Bartmann, Darmstadt, for generously placing his unpublished results at my disposal. The, largely unpublished, results from my group were made possible only by the unsparing efforts of the co-workers, whose names are given in the literature citations, and to whom I would also like to convey my sincerest thanks.

Di-Grignard Compounds and Metallacycles

By Friedrich Bickelhaupt*

In memoriam Georg Wittig

Just as the by now famous Grignard reaction can be used to prepare organomagnesium halides from organic monohalides, organic dihalides can be used under certain conditions to prepare di-Grignard compounds. Difficulties are encountered in particular when the two halide functionalities are separated by only a short carbon chain (i.e. by 1–3 carbon atoms): in such cases side reactions predominate. It has however recently become possible to obtain such "short" di-Grignard compounds on a preparatively useful scale. This opens up new perspectives for the synthesis of metallacyclic compounds of other main group and transition metal elements and in particular for metallacyclobutanes. The preparation, structure and application of a selected number of di-Grignard reagents will be treated in the present review.

1. Introduction

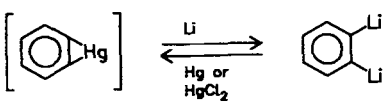
1.1. Background Perspectives

I should like at the beginning of this article to indicate in the form of a short personal note the (by no means straight) line connecting my apprenticeship in *Georg Wittig*'s laboratory in Tübingen, and the inspiration he provided, with my own work which is discussed in this review.

During his investigations on the formation and behavior of ate complexes,[1] *Wittig* had discovered the formation of a complex between phenyllithium and phenylsodium; he had shown this interaction to have a stabilizing effect on phenylsodium, which is otherwise extremely reactive.[2] The "remarkable stability" of phenylsodium in diethyl ether was interpreted in terms of the formation of diphenyllithium-sodium (or sodium diphenyllithiate) **1** [Eqn. (a)].

$$PhLi + PhNa \longrightarrow \underset{\mathbf{1}}{Na[LiPh_2]} \qquad (a)$$

The task assigned to me in the laboratory in Tübingen was to extend this concept to other combinations of alkyl and aryl derivatives of lithium and sodium. This goal was achieved, but with only a moderate degree of success.[3] When my diploma work was completed, *Wittig* thus suggested another subject for my doctoral thesis, the preparation of *ortho*-dilithiobenzene (**2**) from *ortho*-phenylenemercury (**3**)[4–6] and lithium metal in diethyl ether [Eqn. (b)].



3 **2** (b)

The fascination arising from this deep red, reactive compound[5] has never left me since, even though my active interests often involved completely different topics. Apart from its beautiful red color, the fascination of this compound stems in part from the existence of two highly polarized carbon–metal bonds in one molecule. These lie close together in space, so that one may expect them to influence each other to a high degree and thus to produce a special electronic structure and reactivity. On the other hand, the well-known synthetic potential of reactive organometallic compounds suggests that bifunctional species of this type will have many and varied applications in organic and organometallic chemistry. A simple example is provided by the retro-transformation of **2** into **3** by means of mercury, or better still mercuric chloride;[5] many other examples could be added.[5,7]

1.2. Scope of the Present Review

Organolithium and organomagnesium compounds are of approximately equal importance in preparative chemistry; they are often used interchangeably for comparable purposes. Although organolithium reagents are more reactive, this difference in reactivity is often not decisive: more often it is a question of convenience (the accessibility or the method of preparation) which determines the class of compound to be used.

This survey of bifunctional organometallic compounds will put particular emphasis on those compounds in which the metal functionalities are separated by a short chain consisting of 1, 2 or 3 carbon atoms. These types of compound are at present much more readily accessible in the Grignard series than are the corresponding organolithium reagents. For this reason, and because polylithium compounds have recently been the subject of several reviews,[8–10] the present article will deal mainly with bifunctional organomagnesium compounds.

A second limitation results from the breadth of this area. As already indicated, an important goal in the synthesis of bifunctional organolithium and organomagnesium com-

[*] Prof. Dr. F. Bickelhaupt
Scheikundig Laboratorium, Vrije Universiteit
De Boelelaan 1083, NL-1081 HV Amsterdam (The Netherlands)

pounds is the synthesis of other bifunctional derivatives and in particular the preparation of metal-containing cyclic compounds, the metallacycles. As will be shown, this goal was recognized soon after the discovery by *Grignard* of the reagents bearing his name and was intensively pursued. It is thus not surprising that the synthesis of metallacycles by such routes has led to a plethora of reactions and compounds.[11] For this reason I shall mainly concentrate in the following on results obtained by our own group; these deal in particular with aliphatic compounds and arylalkyl compounds.

2. Di-Grignard Compounds

2.1. Preparation

Of the various methods for the preparation of organomagnesium compounds,[11a,c,12] two in particular are important in the present context. The preparation starting from organic dihalides corresponds to the famous original synthesis of the Grignard reagent[13] [Eqn. (c)] and is also preparatively the most important because of the ready accessibility of the starting materials and because of the (at least in principle!) simple experimental procedure.

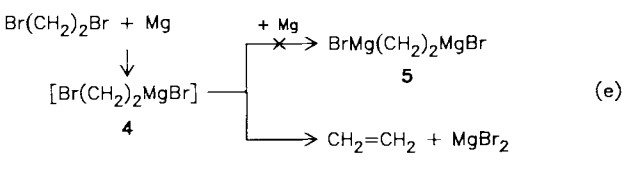
$$R-Br + Mg \xrightarrow[Et_2O]{} R-Mg-Br \qquad (c)$$

The preparation starting from organic derivatives of mercury [Eqn. (d)] should also be mentioned, since it yields very pure Grignard reagents.

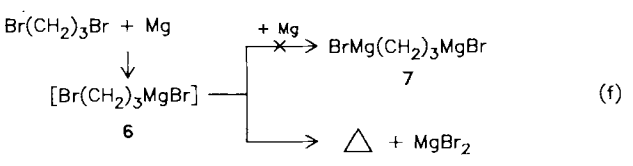
$$R-Hg-Br + Mg \longrightarrow R-Mg-Br + Mg/Hg \qquad (d)$$

2.1.1. General and Historical Remarks

After Grignard had succeeded in 1900 in preparing the first mono-Grignard reagents [Eqn. (c)], the obvious next step was to use organic dihalides to prepare the corresponding di-Grignard compounds. *Tissier* and *Grignard* in fact carried out the first investigations in this direction in the following year. That they[14] and others[15] were at first unsuccessful was not due to the concept being faulty, but to the starting materials chosen: 1,2-dibromoethane and 1,3-dibromopropane were the only readily available dibromides, but were at the same time the very two which were not suited for the desired synthesis. Instead of the hoped-for di-Grignard compounds **5** [Eqn. (e)] and **7** [Eqn. (f)], ethene and cyclopropane were obtained in high yields. It is very likely[16] that these reactions occur in two



(e)



(f)

steps, the initially-formed mono-Grignard reagents **4** and **6** very rapidly eliminating magnesium bromide.

Thus, the truism well known to every chemist showed itself to apply yet again: no product will be obtained without a (suitable) starting material! As in the present case, it is of little importance whether the required starting material is unknown or merely difficult to obtain. Higher homologues, such as the 1,5-dibromopentane (**8**), with which the Grignard reaction can readily be carried out, were in fact already known.[17] But advances towards obtaining di-Grignard compounds were made only after *J. von Braun* had in 1904 shown this compound to be readily available in pure form from the reaction between phosphorus pentabromide and benzoylpiperidine.[18]

However, this process did not occur without tension and a certain amount of drama. *J. von Braun* had certainly immediately recognized the potential of this "synthon" (as we would say today) and studied its reactivity in various directions with great success. As early as 1905, in a publication with *Steindorff*,[19] he mentioned an investigation of its reactivity "towards magnesium in absolute ethereal solution. We intend to report in the near future in more detail on the application of the Grignard reaction to 1,5-dihalogen compounds".

It is not known to me why the publication of these results was delayed. However, the first detailed study of the preparation and of several reactions of 1,5-di(bromomagnesio)pentane (or pentamethylene-1,5-bis(magnesium bromide)) (**9**) appeared only in 1907; it was published by *Grignard* and *Vignon*[20,21]

$$\underset{\mathbf{8}}{Br(CH_2)_5Br} + 2\,Mg \longrightarrow \underset{\mathbf{9}}{BrMg(CH_2)_5MgBr}$$

Grignard made it quite clear that this success was mainly due to the availability of the starting material **8**: "Malheureusement les dihalogénures intermédiaires étaient, jusqu'à ces dernières années, à peu près inaccessibles, lorsqu'en 1904, M. J. v. Braun[1] découvrit un élégant procédé d'obtention du dichloro- et du dibromopentane, ...".[20]

However, it must have been a great disappointment to *von Braun*, as he reacted swiftly and not without bitterness.[22] He first emphasized the key role of the starting material and then derived his own claim[23] from its production: "That I am carrying out such experiments (and, as the discoverer of the method by which the pentamethylenedihalogen compound first became available in larger amounts, I surely had the right to use the Grignard reaction, which has by now become common property), ...". He referred to the publication mentioned above of his intentions[19] and continued: "In the interests of both sides it is to be regretted that the references concerned have escaped the notice of the French colleagues, ..." *Von Braun* did indeed play an important part in the discovery and application of the aliphatic α,ω-di-Grignard compounds.[24] In addition, he was one of the first to use the new dihalogenoalkanes for the synthesis of a metallacycle, the (oligomeric) pentamethylenemercury;[25] however, he used sodium amalgam in its preparation, as did *Hilpert* and *Grüttner*.[26] *Grüttner* and his school, to which the well-

known *E. Krause* also belonged, then rapidly developed the preparation of metallacycles and other organoelement heterocycles using di-Grignard reagents.[27,28]

The experience gained in the course of these earlier studies and of many later ones[29] can be summarized as follows. Di-Grignard compounds can be prepared from the corresponding dihalides (generally the dibromides[12,29]) *with some care* just as well as can the mono-Grignard compounds, when the two halogens are separated by at least four carbon atoms. The necessary *precautions* involve the reaction being carried out relatively slowly, since otherwise intra- and intermolecular Wurtz coupling occurs, as is also the case for the normal Grignard reaction. It will be shown in Section 2.2.1 that the "normality" of this type of di-Grignard compound is expressed not only in its preparation but also in its properties.

In contrast, the Grignard reaction does not succeed, or the yields are very poor, when 1, 2 or 3 carbon atoms separate the halogens. These three cases will now be dealt with in more detail.

2.1.2. *Geminal Di-Grignard Compounds*

It is interesting that the simplest members of the group of "small" di-Grignard compounds are in fact exceptional in that they can be prepared in relatively good yields and have thus been known for the longest time. They were first described by *Emschwiller* in 1926,[30] and their preparation was subsequently considerably improved by *Cainelli* et al.;[31] the most important modifications made by them were to use magnesium amalgam instead of magnesium metal and to use a 1:1 mixture of ether and benzene instead of pure absolute diethyl ether.

$$CH_2X_2 \xrightarrow[Et_2O/C_6H_6]{+Mg/Hg} CH_2(MgX)_2$$

The yields of the methylene di-Grignard reagents were however still not easily reproducible and generally lay no higher than 50–60%;[31,32] the by-products were ethene, propene, cyclopropane and, particularly unwanted for organometallic syntheses, methylmagnesium halide. Better yields were obtained only in reactions which were carried out under "Barbier" conditions, i.e. when a dihalogenomethane was reacted with magnesium amalgam and the substrate (for example a ketone) in a "one-pot" synthesis.[31] We were recently able to improve the synthesis further by using diisopropyl ether as solvent. In this way the methylenedimagnesium dibromide **10** can be obtained in a reproducible yield of 80% and free from unwanted by-products.[33] It has thus become an interesting synthon for the anionic introduction of a methylene group.[34]

$$\underset{}{CH_2Br_2} \xrightarrow[iPr_2O]{+Mg/Hg} \underset{\mathbf{10}}{CH_2(MgBr)_2}$$

The excellent way in which the reaction proceeds when this method is used is even more remarkable since it is an essentially heterogeneous reaction: **10** is practically insoluble in the reaction mixture, just like the amalgam and the magnesium bromide which is formed as a by-product. On the other hand, the success of the reaction is due to exactly these circumstances: all other by-products such as (unsaturated) hydrocarbons and methylmagnesium bromide dissolve in diisopropyl ether and can be removed by simple decantation.

Still to be explained is the (intuitively somewhat unexpected) ready formation of the "1,1-di-Grignard reagent" **10** in contrast to the "1,2-reagent" **5** and the "1,3-reagent" **7**. This is probably due to differences in stability, the carbenoid mono-Grignard **11** (which must be postulated as an intermediate) being much more stable than **4** and **6**. The α-elimination of **11** to give **12** proceeds more slowly since it is enthalpically less favorable than the formation of ethene [Eq. (e)] and cyclopropane [Eq. (f)].

$$\begin{array}{l} CH_2Br_2 \\ \downarrow \\ BrCH_2MgBr \longrightarrow BrMgCH_2MgBr \\ \quad\mathbf{11} \qquad\qquad\quad \mathbf{10} \\ \downarrow \\ MgBr_2 + CH_2{:} \longrightarrow CH_2{=}CH_2 + CH_3CH{=}CH_2 + \triangle \\ \quad\quad\mathbf{12} \end{array}$$

The α-elimination can however not be completely suppressed, and is probably responsible for the formation of ethene, propene, and cyclopropane.[32] It can be reduced to a minimum by the choice of suitable reaction conditions: particularly important is that the magnesium content of the amalgam be as low as possible (0.5–1% magnesium). This results in the main drawback of the synthesis: relatively large amounts of mercury (which, of course, can be recovered) are required.

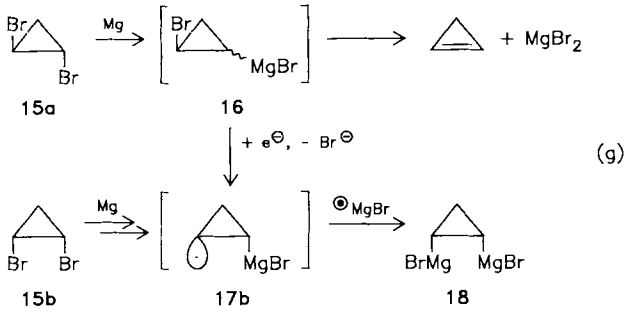
Although this procedure for the preparation of **10** is successful, in our experience it cannot (with one exception) be extended to the use of other 1,1-dibromo compounds. For example, neither 1,1-dibromoethane, 1,1-dibromoneopentane nor benzal bromide give appreciable amounts of any organomagnesium compounds in an ether/benzene solvent mixture.[35] Only trimethylsilyldibromomethane (**13**) reacts in diisopropyl ether to yield 70% of the di-Grignard compound **14**;[36] even the tin analogue of **13** gives complex product mixtures.[37]

$$\underset{\mathbf{13}}{Me_3SiCHBr_2} \xrightarrow[iPr_2O]{+Mg/Hg} \underset{\mathbf{14}}{Me_3SiCH(MgBr)_2}$$

2.1.3. *Vicinal Di-Grignard Compounds*

The preparation of compounds of this type has until now proven to be the most difficult to realize, particularly in the aliphatic series. The future prospects are also not particularly good, since the β-elimination described as an example in Equation (e) is so strongly favored both by entropy and by enthalpy that the lifetime of an intermediate such as **4** is too short for it to react in a second step with the magnesium surface to give a di-magnesium derivative such as **5**.

Success has thus been limited to cases in which it has been possible to drastically retard the rate of β-elimination. The classical example in the aliphatic series is the preparation of the *cis*-1,2-di-Grignard reagent **18** of cyclopropane by *Wiberg* and *Bartley*[38] from *trans*-1,2-dibromocyclopropane (**15a**). In this case the β-elimination from the mono-Grignard reagent **16** is made difficult by the fact that it leads to cyclopropene [Eqn. (g)]: this process doubles the already high ring strain in cyclopropane.



Various aspects of this reaction are remarkable, firstly of course the fact that **18** is formed at all. The yield is low (ca. 10–15%), the main product being the alkene (i.e. cyclopropene), as in Equation (e). The formation of the *cis*-compound **18** from the *trans*-compound **15a** is also surprising; *Wiberg* and *Bartley* assigned this structure on the basis of the carboxylation and deuterolysis of **18**, since they obtained *cis*-products in both cases. They attempted to rationalize the formation of the *cis*-structure by the formulation **19**, but presented no arguments for it.

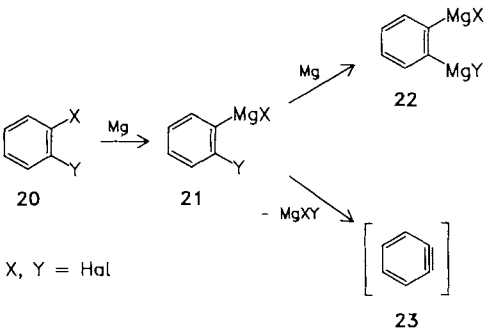
We have repeated *Wiberg*'s experiments and could in the main confirm their results.[39] In addition we were able to isolate **18** in a pure form, as it is only slightly soluble in diethyl ether. It is interesting that its solubility is increased considerably by the addition of magnesium bromide (see Section 2.2.2); this allowed us to measure the ^{1}H-NMR spectrum of **18** and thus to confirm the *cis*-structure directly. In addition we found that **18** is also formed in a comparable yield from the *cis*-dibromide **15b**. Since the cyclopropyl-magnesium bond is generally configurationally stable,[40] the *cis*-configuration of **18** is either thermodynamically more stable, which would be somewhat surprising (see however the discussion in Section 2.2.2), or the stereochemistry is determined at the stage of the configurationally flexible cyclopropyl radicals.[55] The immediate precursor for **18** is very likely **17b** [Eqn. (g)]. Theoretical calculations show that **17b** is more stable than its *trans*-isomer **17a**,[41] so that the explanation of the favored *cis*-configuration on the basis of *kinetic* factors gains credibility.

It appears questionable at present whether a simple aliphatic 1,2-dimagnesium compound such as **5** can in fact be synthesized. It is also unclear whether it would be thermally stable, since the corresponding organolithium compounds appear to decompose very readily with elimination of lithium hydride.[10]

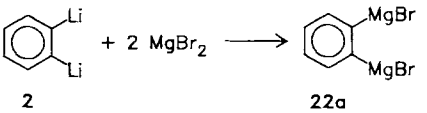
$$LiCH_2CH_2Li \longrightarrow LiCH{=}CH_2 + LiH$$

From this point of view, the stability of **18** at room temperature is probably due to two factors: firstly the lesser tendency of magnesium to split off hydride and secondly the strain already mentioned in the product of magnesium hydride elimination from **18**, which would be a Grignard derivative of cyclopropene.

It could also be expected that in the aromatic series the β-elimination from *o*-dihalogenobenzenes **20** would be made more difficult by the formation of the strained triple bond of the aryne.



The course taken by the reaction depends on the nature of the halogens X and Y. The first step (**20**→**21**) only occurs in a satisfactory manner when X = Br or I.[42,43] The mono-Grignard compound **21** can be quite stable, especially when Y = Cl or Br.[44,45] This has already been utilized for further reactions of **21**.[42–46] However, there is a more or less distinct tendency for the elimination of magnesium halide to give the aryne (e.g. **23**), as has been shown in particular by *Wittig*.[44] The di-Grignard compounds **22** can be obtained under favorable conditions from **20** (X = Y = Br,[12,47] X = I, Y = Br[48]) in 20–40% yield. This relatively poor yield can however be of preparative interest, since one can obtain bifunctional or cyclic products in a one-pot synthesis from a readily available starting material (**20**). However, pure **22a** can only be obtained via the dilithium compound **2**.[5]



2.1.4. 1,3-Di-Grignard Compounds

The chance that a 1,3-di-Grignard compound can be prepared from the dibromide [Eqn. (f)] is a priori greater than that for a 1,2-di-Grignard compound [Eqn. (e)]. The gain in enthalpy from the successfully competing elimination of magnesium bromide is probably approximately equal in both cases, but the entropy is clearly more favorable for the 1,2-elimination, particularly since the ideal combination of a strongly electrofugal group ($MgBr^{\oplus}$) and a strongly nucleofugal one ($Br^{\ominus}$) makes only small demands on the relative orientation of the groups.

In spite of this, all attempts to prepare **7** were, for a long time, unsuccessful.[15b,c] *Zelinsky* and *Gutt* were able to identify a di-Grignard compound as well as the by-product propene; however, the product was not **7** but 1,6-bis(bromomagnesio)hexane **27**,[15c] the product of a Wurtz reaction. The main product was always cyclopropane. One can generalize by saying that the formation of a three-membered ring from a 1,3-dihalide proceeds so well that it has been developed into a versatile synthesis for cyclopropanes and heterocyclopropanes; zinc and alkali metals can be used as well as magnesium.

The first preparation of **7** was achieved by *Costa* and *Whitesides* in 1977 using an indirect method via organoboron and organomercury compounds.[49]

$$CH_2{=}C{=}CH_2 \xrightarrow{B_2H_6} B(CH_2CH_2CH_2)_3B \xrightarrow{Hg(OAc)_2}$$

$$AcOHg(CH_2)_3HgOAc \xrightarrow{NaCl} ClHg(CH_2)_3HgCl \xrightarrow{CH_3Li}$$

$$CH_3Hg(CH_2)_3HgCH_3 \xrightarrow{Mg/MgBr_2}$$

$$\underset{\mathbf{7}}{BrMg(CH_2)_3MgBr} + CH_3MgBr + n\text{-}C_3H_7MgBr + \underset{\mathbf{24}}{CH_2{=}CHCH_2MgBr}$$

Although the concept of this synthesis is very elegant, it cannot to be recommended for preparative applications because of its complexity, the low yields, and the large number of organomagnesium side products; however, *Costa* and *Whitesides* were able to use **7** to prepare a silacyclobutane.[49]

A chance observation in fact finally led to a breakthrough in the direct synthesis of **7**. In our laboratory *F. A. Hartog* had been studying the Barbier reaction,[50] one goal being to trap unstable Grignard intermediates using carbonyl compounds.[51] Thus he obtained **25**, which can be interpreted as an adduct between **27** and benzophenone, in 6% yield. This indicated the possibility that the lifetime of compounds of type **26**, to which **6** [Eqn. (f)] also belongs, is short, yet long enough to permit further intermolecular reactions.

$$\underbrace{Cl(CH_2)_3Br + Mg}_{\downarrow} + Ph_2C{=}O \xrightarrow{H_2O} \underset{OH}{Ph_2C(CH_2)_3Cl}\ \mathbf{25}$$

$$\mathbf{26}\ [Cl(CH_2)_3MgBr] \xrightarrow{1)\ Ph_2C{=}O,\ 2)\ H_2O} \uparrow$$

This result, together with the demonstrated ability of **7** to exist,[49] removed the psychological barriers which had for so long prevented attempts to synthesize **7** directly from 1,3-dibromopropane.[51,52] The first ray of hope was provided by a signal at $\delta \approx 0$ to -1 ppm in the ^{1}H-NMR spectrum of the reaction mixture: it could only be due to **7**, but the yield was at first below half a percent. Variation of the dihalide, the metal and the solvent led to the procedure which gave the best results [Eq. (h)].[53]

$$Br(CH_2)_3Br \xrightarrow{+Mg} \underset{\mathbf{7}\ (30\%)}{BrMg(CH_2)_3MgBr} + \underset{\mathbf{27}\ (15\%)}{BrMg(CH_2)_6MgBr} + CH_2{=}CHCH_2MgBr + (CH_2)_3 + MgBr_2 \quad \text{(h)}$$

$$\mathbf{24}\ (0\text{–}10\%)$$

It is important for a high yield of **7** (ca. 30%) that the reaction be carried out slowly in diethyl ether using a large excess of magnesium (the latter should preferably be purified and activated by double sublimation). Such conditions can be readily achieved when the dibromopropane is added to the magnesium at room temperature over a period of 2 days in a sealed glass apparatus with an overflow system. Under these conditions, cyclopropane is still the main product. A few percent of other hydrocarbons are also present: propene (1.1%), propane (1.0%), ethene (0.6%), methane (0.4%), and ethane (0.1%). This indicates that the Grignard reaction occurs in a complex manner involving free radicals.[55] If necessary, **7** can easily be purified by treating it with THF (see Section 3).

The range of di-Grignard compounds which can be obtained directly has in this case also proven to be small. The synthesis of the 2,2-dimethyl derivative **28** is preparatively useful; though the yield is only 10–15%, the reagent is almost free from organometallic by-products and can thus be used directly for the synthesis of metallacycles; in addition, the starting material is readily available.[56]

$$BrCH_2CMe_2CH_2Br + Mg \longrightarrow \underset{\mathbf{28}}{BrMgCH_2CMe_2CH_2MgBr}$$

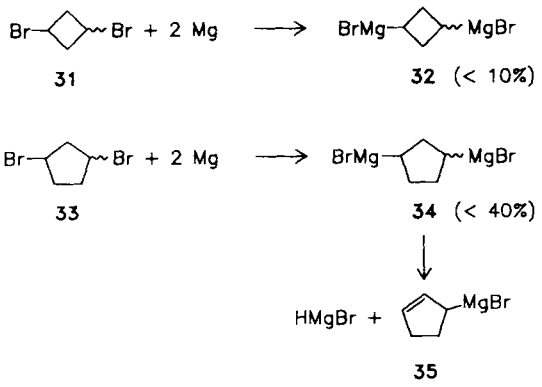
In contrast, the formation of 1,3-di-Grignard reagents does not occur satisfactorily when a hydrogen atom is present in position 2, as is shown by the example of **29** (9%). Remarkable in this reaction is the high yield (70%) of the hydrocarbon **30**, which is formed directly during the

$$BrCH_2CH(t\text{Bu})CH_2Br \xrightarrow{+\ 2\ Mg} \underset{\mathbf{29}\ (9\%)}{BrMgCH_2CH(t\text{Bu})CH_2MgBr} + \underset{\mathbf{30}\ (70\%)}{\text{[structure]}}$$

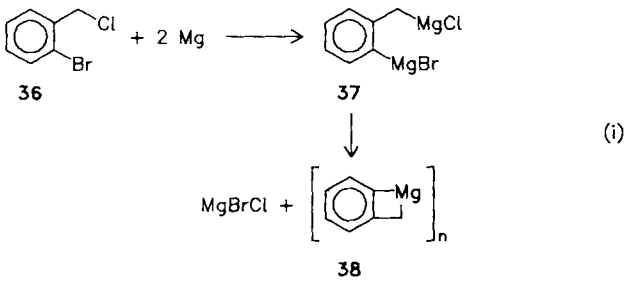
reaction and not by hydrolysis of an organomagnesium precursor.[56] We still have no completely satisfactory explanation for the formation of **30**.[52]

Similarly, our expectation that it would be possible by using the cyclic dibromides **31** and **32** to reduce the formation of three-membered rings, because of the ring strain generated in such products, and thus favor the formation of the di-Grignard compounds has regrettably not been fulfilled.[52] The products **32** and **34** were obtained in low yields, in each case together with several by-products; in addition **34** decomposes rapidly to give **35** (see also Section 2.2.2).

On the other hand, we have recently succeeded in obtaining the 1,3-di-Grignard reagent **37** in 96–100% yield by slow reaction of *ortho*-bromobenzyl chloride (**36**) with an excess of magnesium (sublimed and sieved to give a par-



ticle size <2 mesh) in THF. It disproportionates immediately according to the Schlenk equilibrium [Eqn. (l) in Section 2.2.1]. The diorganylmagnesium compound **38**, a nearly insoluble solid, is precipitated and can be easily freed from all impurities by decantation (isolated yield 85–90%) [Eqn. (i)] (see also Section 2.2.2).



(i)

2.1.5. *Summary of the Previous Results*

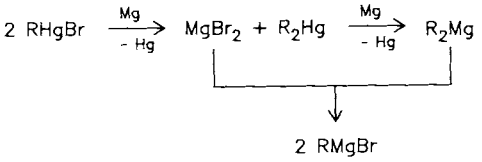
We can sum up as follows: it is possible not only to prepare "normal" di-Grignard compounds directly from the corresponding dihalides; a number of such reagents where the two magnesium atoms are separated by one or three carbon atoms is now known. However, 1,2-di-Grignard compounds are rareties, and it appears that this will continue to be the case in the foreseeable future.

2.1.6. *Di-Grignard Reagents from Mercury Compounds*

The preparation of Grignard reagents from the corresponding organomercury compounds [Eqn. (d)] is normally of no preparative importance, since the mercury compounds are themselves obtained from the Grignard compounds (with the exception of the amalgam method). This cumbersome reaction sequence can however become necessary when a Grignard reagent of high purity is required for structural studies. This is always the case when the yield for the reaction of formation from the organic halide is low; dihalides, as we have seen, very often give such low yields.

$$RBr \xrightarrow{Mg} RMgBr \xrightarrow{HgBr_2} RHgBr \xrightarrow{Mg} RMgBr$$

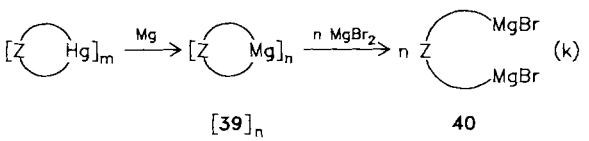
This method has two advantages: firstly the impure Grignard reagents obtained initially can be converted into stable organomercury halides which can be obtained in high purity by recrystallization. The subsequent reaction, carried out by shaking the organomercury compound in THF with an excess of magnesium metal, is slow but practically quantitative. In mechanistic terms there is probably an initial reduction to give the diorganomercury compound, which reacts with further magnesium to give the diorganomagnesium compound; the Schlenk equilibrium is then set up between the latter and the magnesium bromide formed [Eqn. (j)] (see Section 2.2).



(j)

When the substituents R are sterically demanding, the second step is sterically hindered and the reaction proceeds only as far as the diorganomercury compound.[58]

The last step in Equation (j), the ligand exchange reaction between the diorganomagnesium compound and magnesium bromide, can also be carried out separately: for example, a cyclic organomercury compound can first be converted into the magnesacycle and the latter then treated with the stoichiometric amount of magnesium bromide [Eqn. (k)].



(k)

2.2. Structure and Properties

No X-ray crystal structure determinations have yet been reported for solid di-Grignard compounds, so that the following discussion refers to solutions, mainly in THF.

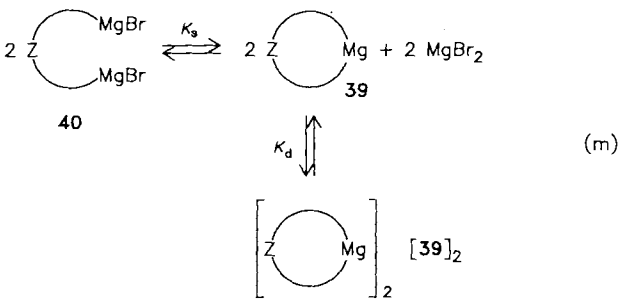
2.2.1. *"Normal" Di-Grignard Compounds*

The structure of Grignard reagents in solution is complex, since several parallel equilibria are involved.[11c] Apart from a quantitatively unimportant electrolytic dissociation, the so-called Schlenk equilibrium [Eqn. (l)] dominates; all the components of this equilibrium can form associates with themselves or with other components.

$$2\,RMgBr \overset{K}{\rightleftharpoons} R_2Mg + MgBr_2 \qquad (l)$$

The position of these equilibria depends on the organic group R, on the halide and on the solvent. Our structural investigations have been concerned mainly with bromides in THF as solvent. In this case, association is unimportant for all three components; they are monomolecular. In the bifunctional series, the same is true for the di-Grignard compound **40** and for magnesium bromide but not for the diorganomagnesium, which is in this case the magnesacycle **39**. In dilute solution, magnesacycles are either completely dimerized or at least dimerized to a large extent to

$[39]_2$. It was not possible to derive the structure and behavior of the di-Grignard compounds **39** until after the structure of $[39]_2$ was known (see Section 3) [Eqn. (m)].



(m)

The position of the equilibrium was determined by very accurate measurements of the osmotic particle number using a stationary isothermal distillation. The results are collected in Table 1 and compared with the values for ethyl magnesium bromide.

Table 1. Thermodynamic parameters of the Schlenk equilibrium in THF at 25 °C [Eqns. (l) and (m), upper part].

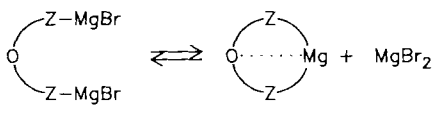
Compound	K_s	ΔH_s [kJ mol^{-1}]	ΔS_s [J mol^{-1} K^{-1}]	Ref.
EtMgBr	6.8	25.6	99.2	[59]
$BrMg(CH_2)_4MgBr$	9.3	32.6	127.6	[60]
$BrMg(CH_2)_5MgBr$	9.2	31.4	123.4	[61]

These results show that the mutual influence of the two organomagnesium functionalities is not large in the thermodynamic ground state, since they do not deviate appreciably from the values for the monofunctional model compound and show little dependence on the length of the methylene chain. This probably also means that the situation in solution is the same as that for the mono-Grignard compound. The magnesium usually binds two additional THF molecules to become tetracoordinate.[11e] Association, including that with magnesium bromide, is unimportant; we shall however see in Section 2.2.3 that the situation is very different for the "short" di-Grignard compounds.

The mono- and di-Grignards also resemble each other in diethyl ether in that in both cases the Schlenk equilibrium is shifted completely towards the side of the organomagnesium bromide.[11c,62,63]

2.2.2. *Intramolecular Coordination*

The situation is quite different when, as in **41**, the chain linking the two organomagnesium functionalities carries an oxygen atom which is able to form an intermolecular coordinative bond to the magnesium atom. In these cases



41 42

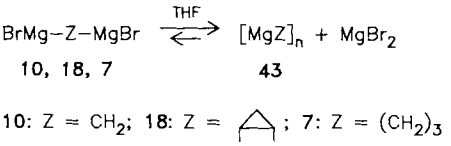
Z = $(CH_2)_3$[64]; $(CH_2)_4$[65]; o-$C_6H_4CH_2CH_2$[65]

the cyclic diorganomagnesium compound **42** is so stable (see Section 3) that the Schlenk equilibrium is shifted completely to the right-hand side (cf. **55**, **56**, and **57** in Table 2).

2.2.3. *"Short" Di-Grignard Compounds*

Di-Grignard compounds with 1, 2 or 3 carbons between the two magnesium functionalities differ in several characteristic aspects from the "normal" members of this class. These differences probably have a common origin in the relatively short distance between the charges or dipoles of the two polarized carbon–magnesium bonds. However, we have no direct information on the structure of **7**, **10**, and **18**, since their crystal structures have not been determined and no association measurements have been carried out.

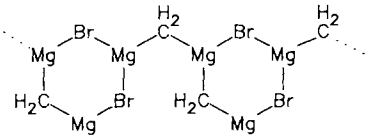
In general the solubilities of the "short" Grignard reagents are low. In THF, where the Schlenk equilibrium [Eqn. (l)] is shifted considerably to the right (see Section 2.2.1), disproportionation to the dialkylmagnesium **43** occurs; because of its oligomeric or polymeric character, the latter is practically insoluble [Eqn. (n); compare Eqn. (o)].



(n)

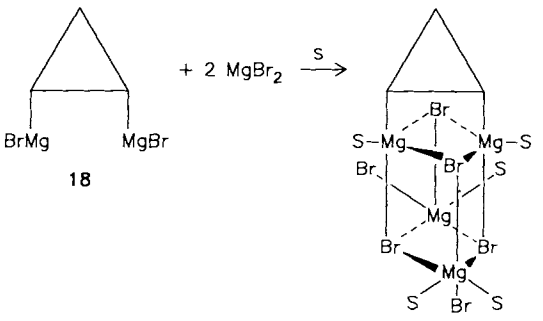
In the case of **10** this reaction does not go to completion, since magnesium bromide is apparently locked in structures such as $[CH_2Mg \cdot CH_2(MgBr)_2]_n$ (**44**) (for the sake of clarity coordinated solvent molecules have been omitted).[32,36]

$[CH_2Mg \cdot CH_2(MgBr)_2]_n$



44

In all cases, the insoluble **43** can be redissolved by the addition of an excess of magnesium bromide. This is not due to a shift of the Schlenk equilibrium (n) to the right, since in the case of **18** and 7 exactly two moles of magne-

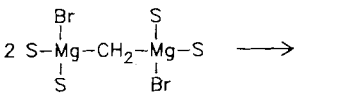


S = THF 45

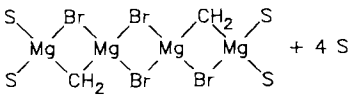
sium bromide are used; thus the formation of a complex such as **45**[39] must be assumed; analogies are known in the case of simple organomagnesium compounds.[66]

This unusually strong complex formation with magnesium bromide apparently serves to compensate for the high "concentration" of negative charge in a small space.

As has already been mentioned, the Schlenk equilibrium in diethyl ether lies far to the side of the organomagnesium bromides;[62,63] **10**, **18**, and **7** are more soluble in this solvent (where they probably have the structure depicted). However, their solubilities are still not high, particularly in the case of **18** (see Section 2.1.3). What is remarkable, and so far unexplained, is the considerable increase in the solubility of **10** in a 1:1 mixture of diethyl ether and benzene. Since the non-polar benzene normally decreases the solubility of the somewhat polar Grignard compounds, one may speculate that **10** is aggregated [Eqn. (o)] to form the dimer **46**, which has a relatively non-polar outer surface.[67]

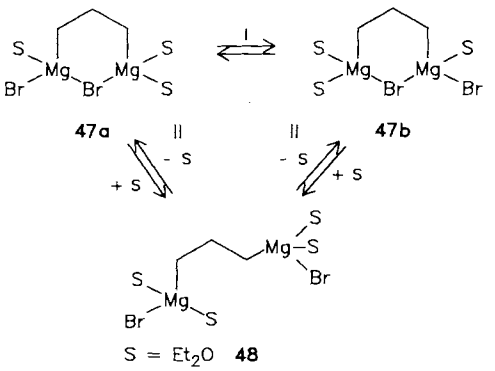


10 · 4S (o)



S = Et_2O **46**

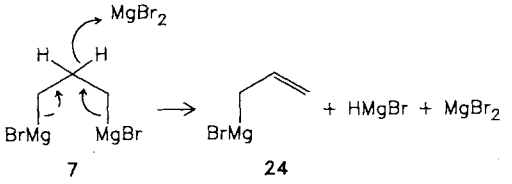
We have also observed a tendency for **7** to form charge-compensated bromine bridges in diethyl ether.[34,52] At lower temperatures, coalescence effects are observed in the proton NMR spectra; these can be interpreted as an equilibrium between the two equivalent structures **47a** and **47b** (together 90%), and **48** (10%). The ratio of **47** to **48** is temperature-independent, which means that the enthalpy difference is zero; that **47** is favored must thus be due to entropy factors ($\Delta S = -4.3$ J mol^{-1} K^{-1}), the ring formation in **47** apparently being overcompensated by the fixation of additional solvent molecules **S** in **48**.



S = Et_2O **48**

Since the two α-methylene groups in **47a** or **47b** and **48** have different chemical shifts, line shape analysis allowed us to determine the activation parameters for the equilibria I ($\Delta H^{\neq} = 21$ kJ mol^{-1}, $\Delta S^{\neq} = -109$ J mol^{-1} K^{-1}) and II ($\Delta H^{\neq} = 28$ kJ mol^{-1}, $\Delta S^{\neq} = -118$ J mol^{-1} K^{-1}). The negative entropy of activation in particular indicates that the initial steps in the rearrangement reactions involve attack by solvent molecules.

Finally, we should comment on a property of **7** which somewhat reduces its stability and usefulness. It was mentioned in Section 2.1.4 that one of the by-products in the preparation of **7** by both *Whitesides'* and our method is allylmagnesium bromide (**24**). Further studies[52,53] have shown that **24** does not arise during the formation of **7**, but is a secondary product formed from **7**.



7 **24**

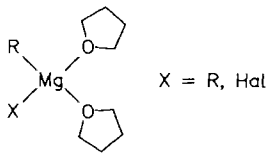
The hydrogens at carbon 2 are hydridically activated from both sides by hyperconjugation with the two electron-rich carbon-magnesium bonds, so that magnesium bromide hydride can be split off. Magnesium bromide functions here as a Lewis acid catalyst, so that the rate of decomposition of **7** depends on the concentration of $MgBr_2$. Since the presence of $MgBr_2$ is unavoidable in both syntheses, a certain amount of **24** is always present. However, when **7** is purified according to Equation (r) and is free from excess magnesium bromide, it is quite stable in solution (half-life ca. 120 days). We shall see, however, that the double hydridic activation can be a great disadvantage in some applications. The 2,2-dimethyl derivative **28** can naturally not split off hydride; it is thus quite stable and also undergoes no side reactions during chemical transformations.

3. Magnesacycles

The preparation and study of magnesacycles is important for two reasons. Firstly, they are of fundamental importance as metal-containing heterocycles: thus, for example, the question can arise as to whether a magnesacyclohexane is stable, and as to its structure. In addition, a knowledge of the structure of magnesacycles is also essential when the structures of the di-Grignard reagents (see Section 2.2) are to be studied, particularly in the most important solvent, THF. The dilemma present is that, because of the unavoidable Schlenk equilibrium (Eqns. (l) and (m)], Grignard compounds can never be obtained in a pure form in this system. This limitation does not apply to the other partner of the Schlenk equilibrium, the dialkylmagnesium compound; thus pure [**39**]$_n$ can be obtained from the corresponding mercury compound, as shown in the first step of Equation (k). A further possibility is the method discovered by *Schlenk* himself during his studies of the equilibrium reaction which bears his name:[68] this involves the removal of the magnesium bromide, formed according to Equation (l), as an insoluble dioxane complex. This method is faster and more convenient for the preparative formation of diorganomagnesium compounds,

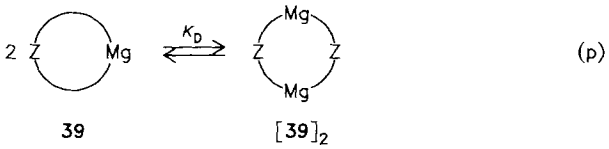
but is not to be recommended when extremely pure compounds are required for structural studies. In the case of the magnesacycles there is an additional problem: the dioxane precipitate contains not only magnesium bromide but also organomagnesium compounds (either bonded or only entrained), so that the yields of pure magnesacycles in solution are very low.

It should be remembered that all components of the Schlenk equilibrium [Eqn. (l)] are normally monomeric in THF. In the case of organomagnesium compounds the strong nucleophilicity of the THF molecule towards magnesium usually leads to the formation of a tetracoordinated, saturated species.[11c,69,70]



X = R, Hal

It was thus surprising that in the case of magnesacyclohexane an extremely strong tendency to dimerization [cf. k_D in Eqn. (p)] was observed;[63] the monomeric form could only be detected by measurements in extremely dilute solutions (0.001 to 0.02 M). The thermodynamic parameters (Table 2) were determined from the temperature-dependence of the dimerization equilibrium.



(p)

39 $[39]_2$

Table 2. Association of magnesacycles of type **39** in THF [71].

2 **39** ⇌ $[39]_2$	Z	n [a]	Ref.
49	$(CH_2)_4$	2	[60, 74]
50	$(CH_2)_5$	1-2 [b]	[61]
51	$(CH_2)_6$	2	[72]
52	$(CH_2)_9$	2	[72]
53	*o*-$C_6H_4(CH_2)_3$	1-2 [c]	[72]
54	*o*-$C_6H_4(CH_2)_2$	1	[72]
55	$(CH_2)_3O(CH_2)_3$	1	[64, 65]
56	$(CH_2)_4O(CH_2)_4$	1	[65]
57		1	[65]

[a] Association number $n = c_f : c_{osm}$, c_f being the formal concentration when 100% monomer is present and c_{osm} the particle concentration determined osmotically. [b] $\Delta H_D = -48.0 \pm 3.0$ kJ mol^{-1}, $\Delta S_D = -106.0 \pm 10.0$ J mol^{-1} K^{-1}. [c] $\Delta H_D = -48.7$ kJ mol^{-1}, $\Delta S_D = -118 \pm 12$ J mol^{-1} K^{-1}.

Two aspects of this result were extremely puzzling: 1) Why is magnesacyclohexane **50** so unstable compared to the dimer $[50]_2$, although a six-membered ring structure with tetracoordinated magnesium could be considered possible? 2) When **50** is so unstable, why does it give only the dimer without polymerizing further?

The answers are supplied by the X-ray structural analysis of $[50]_2$ (Fig. 1).[61] The compound is dimeric in the crystal. As expected, the magnesium is made tetracoordinate by the complexation of two molecules of THF. However, the geometry is not that of an ideal tetrahedron, the

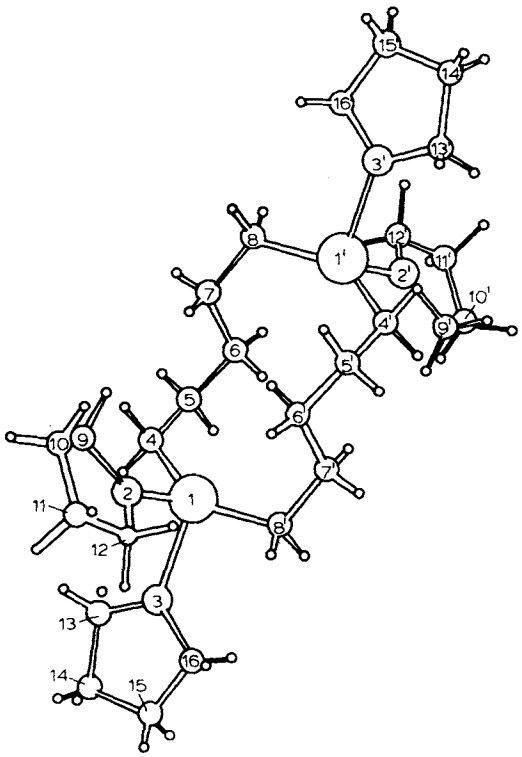


Fig. 1. X-ray crystal structure of 1,7-dimagnesacyclododecane $[50]_2$; 1 and 1′ are the magnesium atoms, 2, 3, 2′ and 3′ the oxygen atoms of the four THF molecules, 4-8 and 4′-8′ the carbons of the two pentamethylene chains, and 9-16 and 9′-16′ the carbon atoms of the four THF molecules.

C-Mg-C angle being very obtuse (141.5°). According to one's taste one can either say that the sp-hybridization of the magnesium (bond angle 180°, see zinc and mercury!) is only slightly perturbed by the ether oxygens, or that according to *Bent*'s rule[73] the magnesium uses much more s-character in the bond to carbon than in that to the more strongly electronegative oxygen.

In any case, the result is a large intraannular angle at magnesium; this cannot be accommodated in the six-membered ring of **50** without introducing strain, but becomes possible in the twelve-membered ring of $[50]_2$. The strain makes itself felt in the form of the exothermal dimerization energy of $\Delta H_D = -48$ kJ mol^{-1}. The entropy loss caused by the dimerization ($\Delta S_D = -107$ J mol^{-1} K^{-1}) compensates only partially for this effect ($\Delta G_D(25\,°C) = -16$ kJ mol^{-1}). However, as soon as the driving force of the ring strain in the six-membered ring has disappeared in the dimerization to the twelve-membered ring, the entropy component opposes any further polymerization. Evaporation of $[39]_2$ followed by slow warming in fact yields modifications of **39** [Eqn. (m)] which can be redissolved only with difficulty on shaking for a long time with THF. Apparently, the removal of the complex-forming THF has led to an extensive polymerization (to $[39]_n$).

The ring strain in **50** has also been confirmed thermochemically. Model experiments first showed that with respect to one carbon-magnesium bond, the enthalpy of reaction according to Equation (q) always has the same value ($\Delta H = -220$ kJ mol^{-1}), independent of the group R.

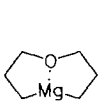
$$R_2Mg + 2CH_3COOH \longrightarrow 2RH + (CH_3COO)_2Mg \qquad (q)$$

Deviations from this standard value signalize particular effects, for example ring strain. Thus, when the position of the equilibrium $2\,\mathbf{50} \rightleftarrows [\mathbf{50}]_2$ is known the experimentally determined heat of reaction can be used to determine the ring strain in **50**, under the reasonable assumption that $[\mathbf{50}]_2$ is strain-free. The value obtained for **50** was $\Delta H = -45.4 \pm 6.5$ kJ mol^{-1}, which within the (in this case much larger) limits of error agrees with that from the association measurements ($\Delta H = -48.0 \pm 3.0$ kJ mol^{-1}; Table 2). A similar equilibrium position and ring strain was determined for the six-membered benzoannelated magnesacycle **53** (Table 2).

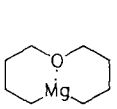
After this detailed discussion of the results for **50**, the other data in Table 2 can be readily explained. It is of course completely clear that a large C–Mg–C bond angle in a five-membered ring will generate even more strain than in a six-membered ring; it is thus not surprising that $[\mathbf{49}]_2$ in THF shows no tendency to form the monomeric five-membered ring **49**. $[\mathbf{49}]_2$ also exists as a ten-membered ring in the crystalline state.[74] We can thus assume that $[\mathbf{51}]_2$ and $[\mathbf{52}]_2$, which exist solely in the dimeric form, also contain fourteen- and twenty-membered rings, respectively. Ths complete dimerization of **52**, which would like $[\mathbf{49}]_2$ contain a ten-membered ring if monomeric, is at first surprising. A detailed analysis of the X-ray structures of $[\mathbf{49}]_2$ and $[\mathbf{50}]_2$, however, shows that the two oligomethylene chains in these compounds are sufficiently separated from each other by the two large magnesium atoms; thus, they cannot cause a transannular van der Waals repulsion. In contrast, **52** as a ten-membered ring would contain only one magnesium atom; therefore, just as for **51**, the well-known ring strain in medium-sized rings plays an unfavorable role.

It is interesting to note that the rapid exchange of bonds between magnesium and carbon or oxygen[11c] is responsible for the fact that the systems mentioned above can and must always seek out the thermodynamically most favorable state. Pure carbocycles or hetero- and metallacycles with stable ring bonds do not have this possibility, so that in such systems strain can only be determined thermochemically and not by means of the experimentally simpler association measurements.

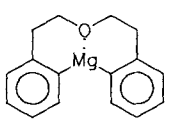
Finally, we should remark on the last four compounds in Table 2. In contrast to the general trend, they exist in a purely monomeric form. We have no completely convincing explanation for this in the case of **54**; probably the ring strain is reduced by benzocondensation (i.e. some unfavorable hydrogen interactions are no longer present; see also [74b]). In the cases of **55**, **56**, and **57** the monomeric state is clearly stabilized by intramolecular coordination (see also Section 2.2.2). Particularly informative is **56**, which without oxygen coordination would have a ten-membered ring as does **52**. While the latter is not stable as the monomer, **56** is, the reason being that it contains not a ten-membered ring but two six-membered rings.



55



56



57

The heats of the reaction with acetic acid mentioned above can also be used in conjunction with values for standard dialkylmagnesium compounds to estimate the strength of the intramolecular coordination.[65] This is however only possible to a certain degree of approximation, since compounds **55**–**57** do not have the idealized geometry mentioned above; because of the longer Mg–C and Mg–O bonds, the rings do in fact exhibit ring strain, the value of which is not known. In this manner we arrive at a lower limit of $\Delta H = 90$ and 87 kJ mol^{-1}, respectively, for the strengths of the Mg–O bonds in **55** and **56**.[65] This value lies considerably higher than that of 68 kJ mol^{-1} estimated for the magnesium–oxygen bond in $Et_2Mg \cdot 2\,THF$; it should be remembered that THF is quite a strong base toward magnesium.

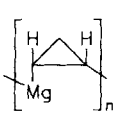
Little is known about the structures and properties of the dialkylmagnesium compounds or magnesacycles corresponding to the "short" di-Grignard compounds **10**, **18**, and **7**. They are in general only slightly soluble and appear to be oligomeric or even polymeric. This is in fact understandable, since on the basis of experience with larger systems the formation of smaller rings is extremely unlikely (Table 2).

As already mentioned in Section 2.2.3, **10** can be freed from most of the magnesium bromide by precipitation and washing, though it is not possible in this way to obtain bromine-free methylenemagnesium (**58**).[32b] However, *Ziegler* et al. have prepared **58** as a white insoluble powder by pyrolyzing dimethylmagnesium.[75]

$$n\,Mg(CH_3)_2 \xrightarrow{\Delta} n\,CH_4 + [MgCH_2]_n \quad \mathbf{58}$$

It is also worthy of mention that the bromide-containing **58** obtained by us gives better results in some applications than does **10**, for example in the synthesis of a 1,3-digermacyclobutane[32b] (see Section 4.2.5).

The dialkylmagnesium compound **59** obtained from the di-Grignard **18** also consists of a mixture of oligomers. This is suggested by the following observation: while **59** is almost insoluble in THF, it dissolves in $[D_{18}]$HMPA (hexamethylphosphoric acid triamide). The α-protons in the ^{1}H-NMR spectrum of **59** occur as a broad signal at $\delta \approx -1.7$ (signal width ca. 1 ppm). When the HMPA solution is allowed to stand for several days, a weak unsymmetrical multiplet is observed which overlaps the broad band; eventually the solution decomposes slowly with a half-life of ca. 16 days.[39,52] We assume that **59** is polymeric or highly oligomeric in the solid state; when it dissolves in HMPA, smaller oligomeric units with $n > 3$ are slowly formed.



59

The dialkylmagnesium compound **60** corresponding to the di-Grignard **7** is also fairly insoluble in THF and can be obtained in pure form when the impure **7** obtained from 1,3-dibromopropane is evaporated and the magnesium bromide washed out, together with other impurities [Eqn. (h)], using small portions of THF; large volumes of

THF cannot be used, since otherwise too much **60** will be lost as a THF-soluble complex of **7** with $MgBr_2$ (see Section 2.2.3). We thus have a preparatively simple method for the formation of very pure **7**: the pure **60**, a dry white powder obtained by decanting off the THF, is treated with one molar equivalent of magnesium bromide in diethyl ether; since in this solvent the Schlenk equilibrium lies on the side of the Grignard reagent (see Section 2.2.1), **7** is re-formed quantitatively and dissolves [Eqn. (r)].[54]

$$7 + \text{impurities} \longrightarrow \xrightarrow{THF} \longrightarrow \qquad (r)$$

$$1/n(MgCH_2CH_2CH_2)_n \xrightarrow[MgBr_2]{Et_2O} BrMg(CH_2)_3MgBr$$

60 **7**

4. Applications of Di-Grignard Compounds

4.1. "Normal" Di-Grignard Compounds

As has already been noted briefly in Sections 1.2 and 2.1.1, the direct synthesis of readily available "normal" di-Grignard compounds with four or more carbon atoms between the magnesium functionalities was used early on for the synthesis of both acyclic and more particularly cyclic compounds, especially in organometallic chemistry.[11,52] Apart from the syntheses already mentioned,[24–28] the preparation of metallacyclic transition metal compounds by the groups of *Whitesides* (Ti,[76] Pt[77]) and *Grubbs* (Pt,[78] Ni[79]) are worthy of mention as examples of more recent developments; the same holds for our own work on the synthesis of heterocycles of main group elements.[46,80]

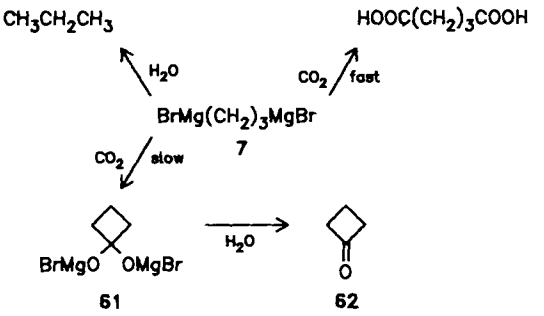
4.2. "Short" Di-Grignard Compounds

The 1,1-di-Grignard reagent **10** has been known since 1926,[30] and its application in organic synthesis has already been studied.[31,32] However, apart from one example,[81] its potential for the synthesis of organometallic reagents had not been explored. This is naturally also true for the recently prepared 1,2- and 1,3-reagents. In the following discussion we shall reverse the sequence used in Sections 2 and 3 and start with the applications of the 1,3-di-Grignard reagents **7** and **28**, since they precede those of **10** and, as will be shown, have contributed conceptually to certain developments of the chemistry of **10**.

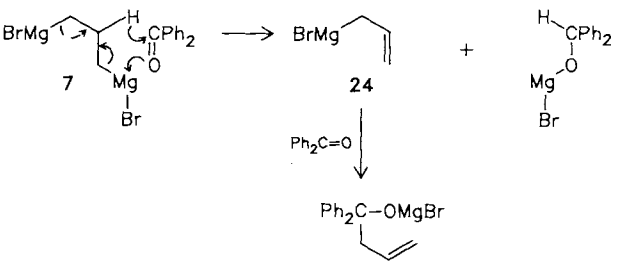
4.2.1. Organic Compounds from 1,3-Di-Grignard Compounds

We shall first refer to some applications of **7** and **28** in organic synthesis; these will show some interesting possibilities, but also clear limitations. **7** reacts readily with hard nucleophiles such as water and CO_2; as expected, propane and glutaric acid are formed.[53]

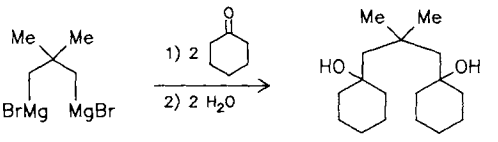
Glutaric acid is obtained as the main product only by pouring **7** onto dry ice. When, however, gaseous carbon dioxide is slowly passed into the reaction vessel, the well-known[20,24] double reaction with one molecule of CO_2 occurs, giving the magnesium salt **61** of cyclobutanone hydrate; this in turn gives cyclobutanone **62** on hydrolysis.[82] Although the yield of **62** is only ca. 30% (with respect to **7**), this method for its preparation is one of the simplest and cheapest. It is also simple to execute, since crude **7** [Eqn. (h)] can be used; **61** is the only product in the reaction mixture which is rather insoluble, so that all by-products can be decanted off prior to hydrolysis; **62** can be obtained by simple distillation after the hydrolysis of **61**.



The greatest limitation for the use of **7** is unfortunately to be found in its reactions with carbonyl compounds and in particular with ketones. Here the double hydridic activation of the β-hydrogens takes the upper hand, and for example the reaction with benzophenone yields only its reduction product benzhydrol and the tertiary alcohol 1,1-diphenyl-3-buten-1-ol, the latter arising from addition of the allyl derivative **24** (which is formed as an intermediate) to benzophenone.



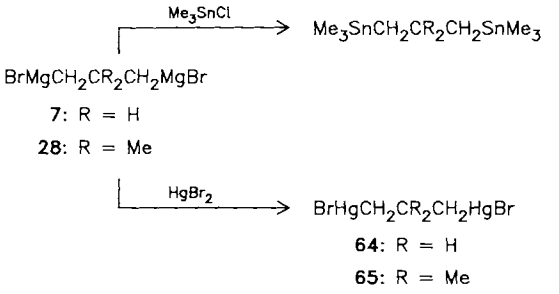
Problems of this type do not arise with **28**, as demonstrated by the reaction with cyclohexanone, which leads to the expected diol **63**.



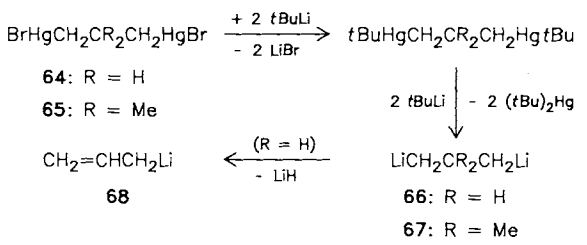
4.2.2. Acyclic 1,3-Dimetal Compounds from 1,3-Di-Grignard Compounds

The reactions of **7** and **28** with chlorotrimethylstannane and mercuric bromide are very clean, and can be used for the determination of the yields of the di-Grignards.

The 1,3-bis(bromomercurio)propanes **64** and **65** in turn offer interesting reaction possibilities, as will be shown using two examples. The two-step reaction with butyllithium afforded the 1,3-dilithiopropanes **66** and **67**,[83] which had



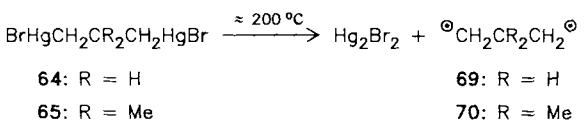
previously been found to be inaccessible by other routes.[10]

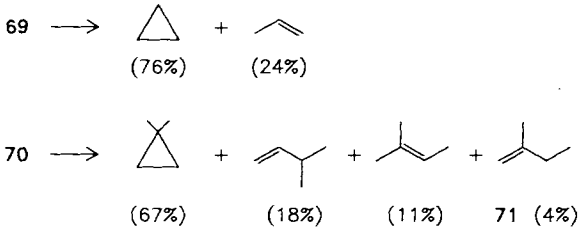


Compound **66** exhibits an even more extreme β-hydride activation than that described for **7** and splits off lithium hydride even at −60 °C to give allyllithium (**68**).

In contrast, compound **67** is extraordinarily stable for an organolithium compound in diethyl ether; according to calculations by *Schleyer* et al., this could be due to the existence of a structure with double lithium bridges.[8, 10, 84]

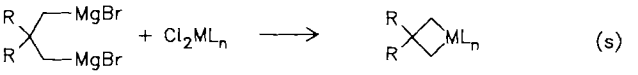
A second interesting application of **64** and **65** lies in their thermolysis; this occurs with elimination of mercurous bromide, presumably giving trimethylene (**69**) or its 2,2-dimethyl derivative **70**.[53, 85] Interestingly, the product spectrum of the diradicals obtained in this manner differs strongly from those which are normally found for **69** and **70**.[86] This applies not only to the relatively low yield of cyclopropane (or its dimethyl derivative), but also particularly to the unusual formation of **71**, which is perhaps due to a 1,2-methyl migration. A possible explanation could be that the diradicals are formed in a vibronically excited state.[85]





4.2.3. *Metallacyclobutanes from 1,3-Di-Grignard Compounds*

Metallacyclobutanes are of great interest because of their structural and bonding properties and because of their postulated or demonstrated role as catalytic intermediates in important industrial processes such as olefin metathesis.[34, 57, 87, 88] They have thus been extensively studied, although until recently no general route to these compounds was available. The proven di-Grignard route to larger rings suggests itself: as shown by Equation (s), both main group and transition metal element dichlorides **72** should in principle lead to metallacyclobutanes **73**.

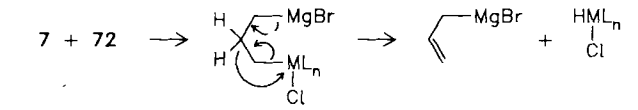


7: R = H
28: R = Me

72

73

As is so often the case, this new procedure is not so universally applicable as had been hoped. The greatest, though trivial, problem is the in some cases inherent instability of **73**, e.g. for M = Ni.[89] However, the route via Equation (s) is useful even in such a case; one can postulate with more confidence than otherwise that **73** is in fact formed and that the secondary products actually detected do arise from **73**.



74 **24** **75**

On the other hand, it can happen that the yields of **73** are low although **73** itself is in fact stable.[90] The reason is then to be found in a particularly strong activation of the β-hydrogens in the intermediate **74** by certain transition metals M. While **73** is stable, because the orientation necessary for β-elimination is not possible in the inflexible four-membered ring,[77] **74** can by rotation adopt conformations in which the elimination of **75** is readily possible. In the case of **28**, such a complication cannot occur, so that better results have been obtained using this reagent. Table 3 gives an overview of the results so far obtained.

It is outside the scope of the present review to go into details of the many interesting aspects of the various reac-

Table 3. Metallacyclobutanes of type **73** (from 1,3-di-Grignard compounds).

ML_n	R	Yield [%]	Ref.
$TiCp_2$	H	<5	[90]
$TiCp_2$	Me	89	[90]
$ZrCp_2$	H	<5	[90]
$ZrCp_2$	Me	76	[90]

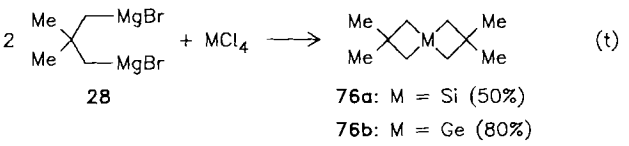
$Ni(PPh_3)_2$	Me	(unstable)	[89b]
$GeMe_2$	H	96	[54]
$GeMe_2$	Me	98	[54]
$SnMe_2$	H	10	[52, 92]
$SnMe_2$	Me	48	[52, 92]

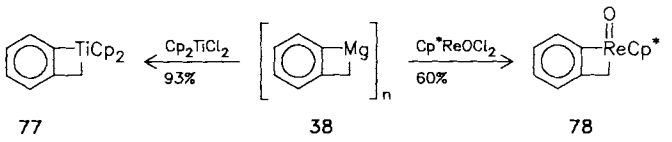
[a] A different decomposition reaction of the intermediate **74** is observed in this case [56]. [b] Cp* = C_5Me_5.

tions and compounds; here we must refer to the original literature (Table 3). We should, however, mention that many of the metallacyclobutanes in Table 3 (M = Hf, Zr, V, Re, Sn) have been prepared for the first time using this method: the hafnium compound has since been obtained by a different procedure. The gaps in Table 3 make it clear that much valuable work remains to be done in this area.

A first example is provided by the spiro compounds **76** [Eqn. (t)].[93]

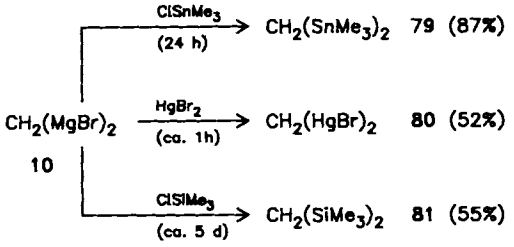


The development of new 1,3-di-Grignard reagents has opened up other possibilities. Apart from the examples to be discussed in Section 4.2.4, the reagent **38** [Eqn. (i)] should be mentioned here; it has been used as the starting material for the preparation of the new metallacyclobutabenzenes **77**[94] and **78**[91] and of corresponding derivatives with Si, Ge, Sn or Pb.[89b]

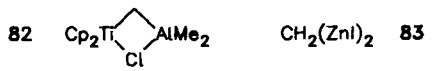


4.2.4. *The Methylene Di-Grignard Reagent*

We have already referred to the possibility of using the methylene di-Grignard reagent **10** in organic synthesis in Section 4.2.[31,32,81] Its use for the preparation of other dimetallomethanes requires only a brief mention; in some cases such compounds are available via other routes. A certain disadvantage is the markedly reduced reactivity of **10** in comparison with other Grignard compounds; thus, while the formation of **79** and **80** occurs readily, **81** is produced only slowly.[32b]



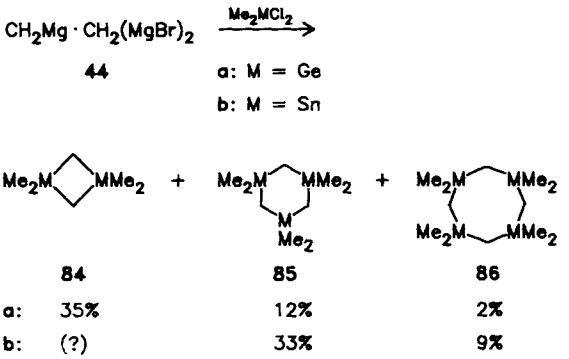
It should also be mentioned that the last ten years have seen the development of the chemistry of the 1,1-dimetal compounds ("methylene complexes") on a broad front;[10,36,95-100] in this connection the by now classical Tebbe reagent **82**[95,96] and the dizinc reagent **83**[97] are worthy of particular mention.



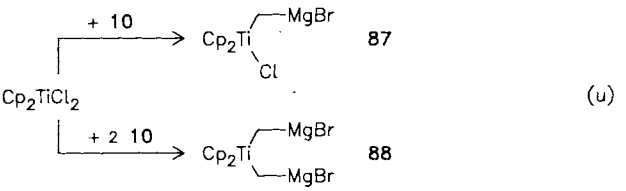
The chemistry of these compounds cannot be discussed here; there is however a certain amount of overlap with that of **10**, so that the decision as to which reagent should be used for a certain reaction is often one of small nuances and in particular of preparative availability. Developments in the coming years will show which approach is the most practical; the recently improved preparation of **10**[33] will certainly put it in a more competitive position.

4.2.5. *1,3-Dimetallacyclobutanes*

The reactions of **10** with Me_2GeCl_2 and Me_2SnCl_2 have so far been successful only in the case of the 1,3-digermacyclobutane **84a**; it is not clear whether the tin analog **84b** was not formed or whether it merely decomposed very rapidly.[32b] The use of the only slightly soluble and largely bromide-free modification **44** gave considerably better yields of the four-membered ring **84a**; the interesting higher ring-homologues **85** and **86** were also obtained.



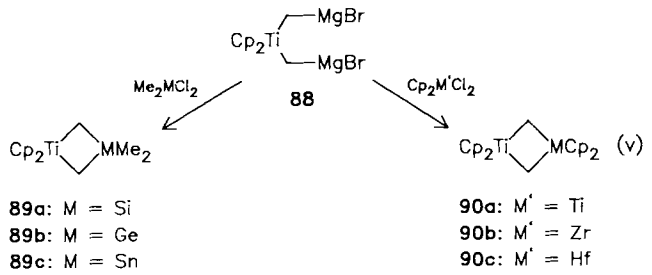
The reactions which have been studied in the most detail are those with cyclopentadienyl derivatives of titanium, zirconium, and hafnium. As the example of the titanocene dichloride [Eqn. (n)] shows, either one or both chloride functions can be allowed to react with **10**, giving the intermediates **87** and **88**, respectively.

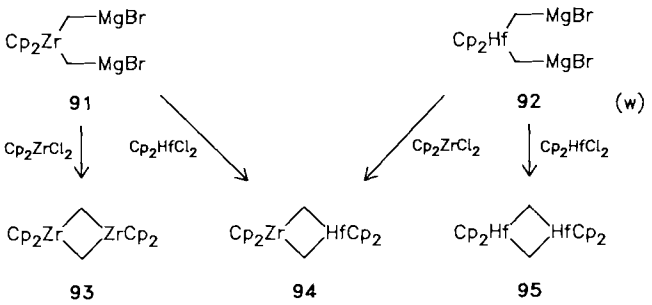


The behavior of **87** will be discussed in Section 4.2.6. Compound **88** can be regarded as a di-Grignard compound in which carbon atom 2 in **7** or **28** has been replaced by the titanocene moiety. It can be used in a completely analogous manner (see Section 4.2.3) for syntheses of four-membered rings [Eqn. (v)]. The same is probably true for **91** and **92**, which are obtained from zirconocene and hafnocene dichlorides [Eqn. (w)].[33]

Only two of the nine 1,3-dimetallacyclobutanes described in Equations (v) and (w), **89a**[101] and **90a**,[102] had previously been prepared in other ways.

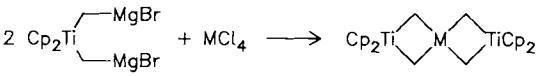
It must be noted that some of the four-membered ring compounds were obtained in only poor yields. This is for





example the case for **89c**, which, however, being a stannacyclobutane is inherently unstable (see Ref. [92]). It also applies for **94** and **95**; in these cases the reasons lie in practical difficulties such as the solubility of **91** and the presence of zirconocene dichloride as an impurity in the hafnocene analogue. We have also since been able to show that the published yields can be improved by modification of the reaction conditions (for example in the case of **95** from 3.5%[33] to 24%[37]). A discussion of the interesting spectral and bonding properties of the 1,3-metallacyclobutanes lies outside the scope of the present survey.[33]

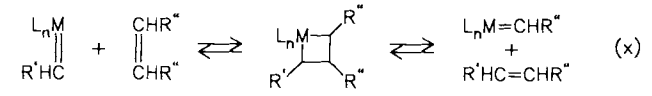
It should, however, be mentioned here that the analogy between the reagents **28** and **88** also applies to the synthesis of the spiro compounds **96**,[103] which can be described as double 1,3-dimetalla-analogues of the double metallacyclobutane **76** [Eqn. (t)].



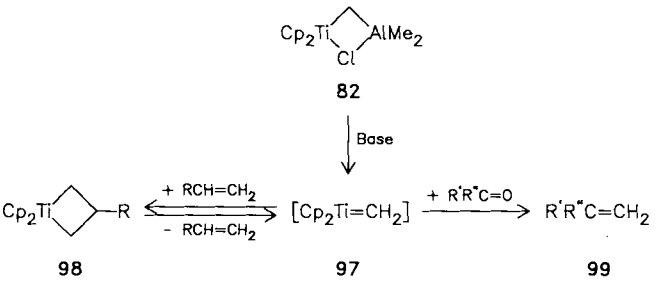
a: M = Si, b: M = Ge, c: M = Sn

4.2.6. Metallaalkenes

Metallaalkenes or metal-carbene complexes contain the structural element $L_nM{=}CR_2$ and are, like the metallacyclobutanes, objects of great interest.[87] A point of contact between the two types of compound can be found in olefin metathesis,[88] for which a mechanism according to Equation (x) is now generally accepted.



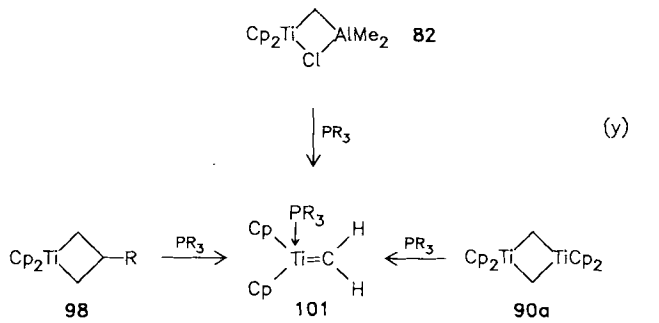
As *Tebbe* et al.[95] and *Grubbs* et al.[96] have shown, the Tebbe reagent **82** provides an easy route to the titanaethene **97**; this can, when prepared in situ, be trapped reversibly by alkenes to give titanacyclobutanes **98** or by carbonyl compounds to give 1-alkenes **99**.



The titanium/zinc compound **100**[97] obtained from the dizinc reagent **83** and compound **87** obtained by us from **10** [Eqn. (u)] undergo completely analogous reactions. Free **97** is extremely unstable and is present in only a very

$$\underbrace{XTi(Cp_2)CH_2ZnX}, \quad X = Cl \text{ or } I \qquad \mathbf{100}$$

low steady state concentration; it can, however, be stabilized at low temperatures as **101** by complexation with tertiary phosphanes. Apart from **82**[104] and **98**,[105] compound **90a** (obtained according to Equation (v)) has been shown to be a good starting material for this reaction [Eqn. (y)].



Compounds such as **82**, **87**, **100** and **90a** can thus be regarded as "precarbenes" or as metallaalkenes stabilized by other metal compounds, Me_2AlCl, MgBrCl, ZnX_2 or $Cp_2Ti{=}CH_2$ (**97**), respectively, acting as "stabilizers". Such an approach is justified not only by the reactivity of these compounds [Eqn. (y)] but also by theoretical calculations[107] and by their ^1H- and ^{13}C-NMR spectra; the carbenoid carbon and its attached protons are generally very strongly deshielded (Table 4).

Table 4. Chemical shifts of the methylene hydrogen and carbon nuclei of methylenetitanium compounds.

	Compound	$\delta(^1H)$	$\delta(^{13}C)$	Ref.
82	$\underbrace{ClTi(Cp_2)CH_2}AlMe_2$ [a]	8.49	188	[95]
100	$\underbrace{XTi(Cp_2)CH_2}ZnX$ [b]	8.32	—	[97a]
87	$\underbrace{ClTi(Cp_2)CH_2}MgBr$ [c]	2.93	—	[37]
102	$\underbrace{BrTi(Cp_2)CH_2Mg}\underbrace{CH_2Ti(Cp_2)}Br$ [b]	9.87	223.3	[37]
90a	$\underbrace{CH_2Ti(Cp_2)CH_2}TiCp_2$ [a]	8.72	235.8	[33, 102]

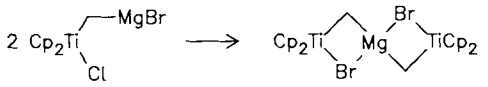
98, R = H	$\underbrace{CH_2Ti(Cp_2)CH_2}CH_2$ [b]	2.95	76.7	[32, 108]

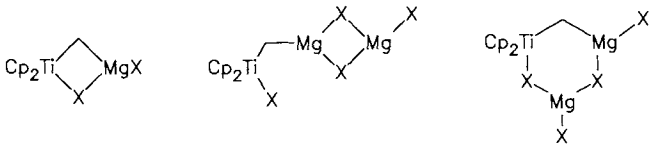
[a] In [D6]benzene. [b] In [D8]toluene. [c] In [D10]Et_2O/[D6]benzene 1:1. [d] In [D8]THF.

The different NMR behavior of **87**, the structure **87a** of which is at a first glance completely analogous to those of **82** and **100**, shows that there are still problems to be solved in this area. Very recent results[37] have surprisingly shown that **87** can be converted into **102** when a solution of **87** in ether/benzene is evaporated to dryness and the residue so obtained is dissolved in toluene.



87 **102**

Compound **102** then exhibited the expected low-field shift for the methylene protons (Table 4) and showed itself to be a very good starting material for **97**. The unexpected NMR data for **87** are probably due to the fact that in the ether/benzene solution, which contains excess magnesium halide, **87** exists as **87b** or **87c** and not as **87a** (for the sake of clarity the ether molecules are not shown; both Cl as well as Br are symbolized by X).



87a **87b** **87c**

It remains astounding that structures such as **87** and **102** are in fact relatively stable, although the differences appear subtle when one considers that bonds between magnesium and carbon or halogen normally undergo rapid exchange in ethereal solution.[11c] It is also surprising that these on paper subtle structural differences apparently have wide-reaching consequences for the bonding situation, as must be concluded from the very different NMR data for the methylene protons (Table 4). Further studies will undoubtedly shed more light on this important question.

Many of the results discussed here were obtained in our own laboratories; they are due mainly to the enthusiasm, the hard work and the great skill of my co-workers, whose names can be found in the list of references. I am very thankful to all of them, but in particular to Dr. O. S. Akkerman and Dr. C. Blomberg, who have been with me for many years, and to Mr. Gerrit Schat who supported the often extremely difficult work by his immeasurable experimental ability and passed on practical experience and traditions in the group to many generations of undergraduate and graduate students. I thank the foundation for Chemical Research in the Netherlands (S.O.N.) for supporting our work with funds from the Organization for Fundamental Scientific Research (Z.W.O.).

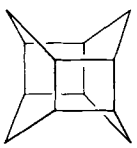
Nonacyclo[10.8.0.0^{2,11}.0^{4,9}.0^{4,19}.0^{6,17}.0^{7,16}.0^{9,14}.0^{14,19}]-icosane, a Double Tetraasterane**

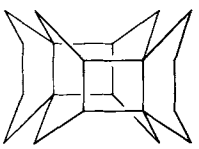
By *Volker T. Hoffmann* and *Hans Musso**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

Replacement of the cyclohexane chair-form rings in the vertical planes of the diamond lattice by boat-form rings results in the wurzite lattice. If this is also carried out on the horizontal planes, one obtains an unknown carbon modification,[1] whose smallest characteristic structural unit, the tetrasterane **1**, is known.[2] Earlier, we succeeded in enlarging **1** by the addition of two cyclohexane rings to give **2**.[3] We now report the synthesis of the double tetraasterane **9**[4] (Scheme 1).

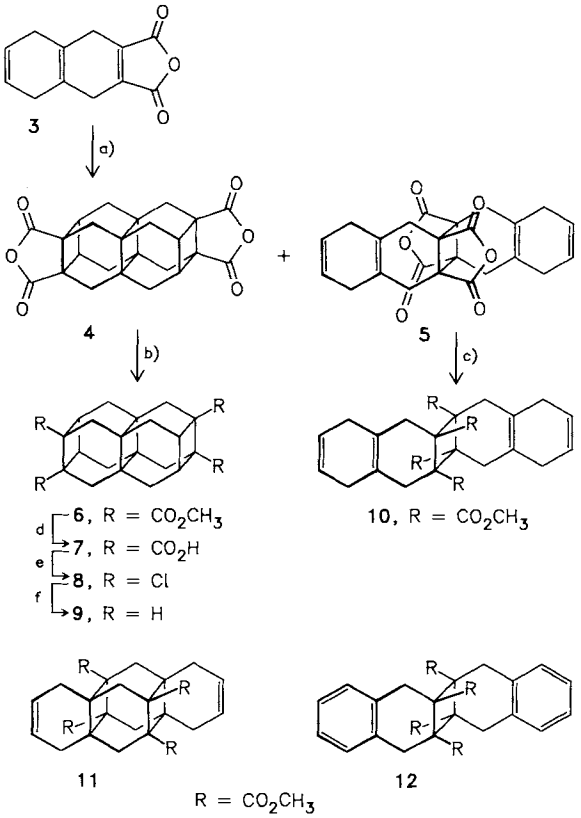


1



2

Photoexcitation of 1,4,5,8-tetrahydronaphthalene-2,3-dicarboxylic anhydride **3**[5] in dioxane with a high-pressure mercury lamp equipped with a Solidex filter in the presence of benzophenone as photosensitizer results in the formation, in approximately 8% yield, of a sparingly soluble mixture consisting of at least four dimers. Fractional sublimation of this mixture at 10^{-4} torr gave a forerun at about 250°C followed by the desired dimer **4** starting at 310°C (relative amount in the mixture, 46%; m.p. >350°C). Compound **4** was treated with methanol/acetyl chloride to convert it into the tetramethyl ester **6** (Table 1). The *anti* head-head dimer **5** undergoes sublimation already at 190–200°C and was likewise characterized as the tetramethyl ester (**10**). The structures of **6** and **10** were confirmed by X-ray crystal structure analysis.[4,6] Chromatography of the mother liquors of **10** on SiO_2 revealed the presence of two additional compounds. The faster eluting component was isolated and identified spectroscopically as the doubly aromatized derivative of **10**, namely, **12**. The more slowly eluting component could not be obtained in pure form. The tetraasterapropellane structure of **11** can be derived from its ^{1}H-NMR spectrum.



Scheme 1. a) **3** (6.8 g, 33.6 mmol), benzophenone (200 mg), dioxane (200 mL) under N_2. Philips HPK (125 W), Solidex filter, irradiated for 4 d. 560 mg (8%) **4** + **5** (see text). b) **4** (65 mg, 0.16 mmol), methanol (10 mL), acetyl chloride (1.0 mL), refluxed for 5 d, heterogeneous reaction, 69 mg (87%) **6**, m.p. = 324°C. c) **5** (200 mg, 0.48 mmol) was added to a solution containing sodium (50 mg) in methanol (15 mL) and the solution was acidified with dilute H_2SO_4. The monoester was extracted with ether and then treated with diazomethane in ether, affording 124 mg (51%) **10**, m.p. = 230°C. d) **6** (400 mg, 0.99 mmol) dissolved in 2 N NaOH (50 mL) over 30 min. The solution was then acidified with 2 N H_2SO_4, resulting in the formation of a fine, colorless precipitate, 396 mg (90%) **7**. e) A suspension of **7** (690 mg, 1.56 mmol), *N*-chlorosuccinimide (3.22 g, 24 mmol), and $Pb(OAc)_4$ (5.0 g, 6.3 mmol) in dimethylformamide/glacial acetic acid (5:1) (30 mL) was heated under N_2; the reaction occurred at 45–60°C. Workup with water and pentane and sublimation afforded 14 mg (2%) **8**, m.p. >350°C, containing a small amount of a pentachloro derivative. f) A refluxing suspension of **8** (50 mg, 0.13 mmol) in ethanol (40 mL) was treated over 3 h with sodium (3.0 g, 0.13 mmol) added in the form of small pieces. Workup with water and pentane afforded 7.0 mg (21%) **9** as colorless needles, m.p. = 230–235°C (methanol). $M^{\oplus}$ (calcd) = 264.1878, $M^{\oplus}$ (found) = 264.1885.

Alkaline hydrolysis of the tetramethyl ester **6** yields the acid **7** (90%), which, upon heating or drying, is readily converted back into the anhydride **4**. Grob degradation[7] kith lead tetraacetate and *N*-chlorosuccinimide results in the formation of a mixture consisting of three parts of the expected tetrachloride **8** and roughly one part of a pentachloro compound (mass spectrum), which cannot be completely separated by recrystallization. Dehalogenation occurs only slowly with sodium in ethanol and affords the

pure, double tetraasterane **9** in only about 21% yield as colorless needles (m.p. = 230–235 °C, methanol). Whereas **1** melts at very high temperature (Table 1) and is thermally stable at temperatures over 300 °C, heating of **9** in the injection part of a gas chromatograph at 270 °C results in the formation of two isomers; however, the structures of the isomers have not yet been determined.

Dimanganese Heptoxide for the Selective Oxidation of Organic Substrates

By *Martin Trömel** and *Manuel Russ*

Mn_2O_7 has been described as a dark red, volatile, unstable oil,[1] which, apart from its strong oxidative ability, can explode unexpectedly (for example, on contact with organic compounds or with dust from the air). There are apparently no reports on controlled oxidation reactions, although the compound has been known for over 125 years. The Mn–O bond lengths,[2] which have been determined experimentally,[3] indicate that Mn_2O_7 should be a stronger oxidizing agent than permanganate.

According to the most detailed investigation carried out so far,[4] solvents such as glacial acetic acid or CCl_4 undergo oxidation by Mn_2O_7 even at low temperature. In contrast, we have been able, by means of a special procedure, to obtain stable solutions of Mn_2O_7 in CCl_4 or 1,1,2-trifluoro-1,2,2-trichloroethane (Freon 113). Mn_2O_7, prepared by reaction of $KMnO_4$ with concentrated sulfuric acid in the presence of the solvent according to the following reaction, is immediately taken up by the organic phase:

$$2\,KMnO_4 + 2\,H_2SO_4 \longrightarrow Mn_2O_7 + 2\,KHSO_4 + H_2O$$

The stability of the solutions is probably due to the fact that oxidizable impurities and traces of water, which cause decomposition of Mn_2O_7, are removed during its formation. The deep red solutions contain approximately 100 mg of Mn_2O_7 per mL, are practically completely stable at room temperature, and, in contrast to undiluted Mn_2O_7, can be handled safely. Our investigations so far have shown that selective oxidation reactions are possible which can be carried out simply with efficient thermal control. The course of the reaction can be observed owing to the intense color of the Mn_2O_7 solution themselves. The reagent is especially suitable for use in aprotic medium.

Aliphatic and alicyclic C–C bonds, C–F and C–Cl bonds, and primary C–H bonds are not usually attacked at room temperature; the same holds true for trimethylsilyl groups.

Primary and secondary alcohols, such as **1** and **2**–**6** (Table 1), respectively, are smoothly oxidized to carboxylic acids and ketones, respectively. The reactions proceed in aprotic medium at temperatures as low as −70 °C, thereby making it possible to react thermally unstable and acid-sensitive compounds such as **2** and **5**, respectively.

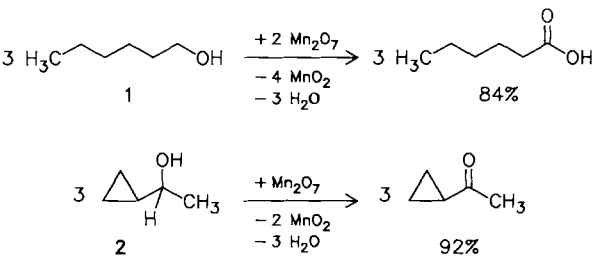

Table 1. Oxidation of selected secondary alcohols with Mn_2O_7.

	Alcohol	Product	Yield [%] [a]
3	cycloheptanol	cycloheptanone	91
4	1-cyclohexylethanol	cyclohexyl methyl ketone	88
5	1-phenylethanol	acetophenone	81
6	3-octanol	3-octanone	84

[a] Yields of isolated product.

Owing to the low temperature, the oxidation of primary alcohols such as **1** can be carried out without accompanying acetalization. Ketones formed from secondary alcohols can be easily separated by filtration from the MnO_2 precipitate. In addition, the MnO_2 binds the water formed dur-

Niederurseler Hang, D-6000 Frankfurt am Main 50 (FRG)

ing the reaction. Oxidative C–C bond cleavage does not occur at all, and tertiary C–H bonds such as those in **4** and **2** are not attacked. Phenyl and cyclopropyl groups such as those in **5** and **2**, respectively, are stable under the reaction conditions, so that the reactions occur chemoselectively and afford high yields of products.

CC double bonds, such as those in **7**–**13** (Table 2), undergo oxidative cleavage already at −80 °C with formation of the same products, albeit in high yield, as those formed by ozonolysis followed by oxidative workup. These oxidations can also be carried out selectively in the presence of aromatic systems.

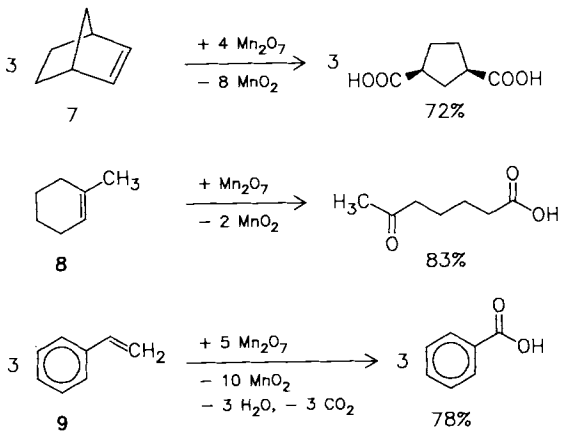

Table 2. Oxidation of selected alkenes with Mn_2O_7.

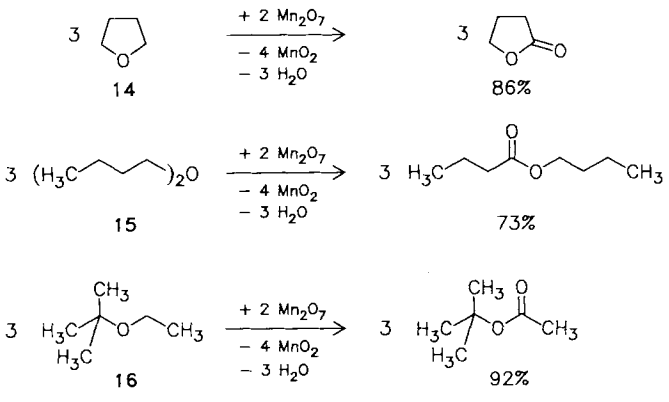
	Olefin	Product	Yield [%] [a]
10	cyclohexene	adipic acid	69
11	cycloheptene	pimelic acid	82
12	1-octene	heptanoic acid	73
13	heptadecafluoro-1-decene (H_2C=CH–C_8F_{17})	perfluorononoic acid	94

[a] Yields of isolated product.

α-Methylene groups in ethers such as **14**–**16** react at −45 °C to form lactones or esters. Aromatic systems, for example that of benzene, on the other hand, are attacked at temperatures around −20 °C.



Oxidations with dimanganese heptoxide are, without exception, complete within a short period of time (seconds or minutes) and are characterized by simple operational procedures and a smooth course of reaction. The reaction mixtures can be worked up easily without the necessity of employing extraction procedures. The resulting manganese oxide, which is easily filtered off, binds water formed during the reaction, so that the organic product can be simply isolated by evaporation of the solvent. In all reactions leading to carboxylic acids, the products are bound to the MnO_2 precipitate. They can be separated by reduction with sulfite followed by extraction (see Experimental Procedure). The extraction is unnecessary if the MnO_2 is immediately reduced in the reaction mixture by reaction with a defined mixture of solid $Na_2SO_3 \cdot 7\,H_2O$ and $Na_2S_2O_5$ or, more elegantly, with glyoxylic acid **17**.

$$MnO_2 + (HO)_2CH{-}COOH \longrightarrow Mn(COO)_2 \cdot 2\,H_2O$$

17

The carboxylic acid is thereby released and taken up by the solvent. Glyoxylic acid and the manganese oxalate formed are insoluble in the reaction medium, so that the carboxylic acid may be obtained by filtration and evaporation of the solvent. At temperatures up to approximately +15 °C, solvents such as acetone, methyl and ethyl acetate, CCl_4, Freon 113, and mixtures thereof, are suitable for the oxidations with Mn_2O_7.

In carrying out these reactions, it is important that undiluted Mn_2O_7 not be allowed to collect (e.g., by evaporation of the solvent), since, in the presence of flammable vapors, it can explode. The reactions should therefore be carried out in a stream of inert gas. Moreover, the spout of the dropping funnel should be drawn out to a point and, during prolonged addition, this should be washed with Freon 113 or CCl_4. The ground glass must not be greased.

Experimental Procedure

Preparation of a Mn_2O_7 solution: Powdered $KMnO_4$ (16.3 g) was added in portions to a stirred mixture of concentrated H_2SO_4 (24 mL) and dry CCl_4 (100 mL) in a 250-mL flask kept at 20–25 °C. The resulting reaction mixture was stirred for several hours and the deep red organic phase was then decanted from the lower layer. The solution was stored in the refrigerator at approximately 4 °C.—The procedure can also be carried out using correspondingly larger amounts of reactants (up to approximately 50 g of $KMnO_4$).

Determination of the content: 0.3 mL of the solution was added to approximately 30 mL of water and the resulting mixture was stirred. After addition of KI (1.5 g) and glacial acetic acid (p.a., 4 mL), the solution was titrated. 1 mL of 0.1 N thiosulfate solution corresponds to 2.2 mg of Mn_2O_7.

Oxidations: The reactant (7.8 mmol) in a 1:1 mixture of CCl_4 and acetone (both dry) or of methyl or ethyl acetate and Freon 113 was placed in a 100-mL three-necked flask equipped with a thermometer, a stirrer, a dropping funnel, and an inlet for inert gas. 3 to 4 mL of the solvent was required per 100 mg of the stoichiometrically required Mn_2O_7 amount to ensure easy stirring. After cooling to the reaction temperature (alcohols, −70 °C; alkenes, −80 °C; ethers, −45 °C), Mn_2O_7 in CCl_4 solution was added with stirring in a moderate stream of nitrogen or argon at such a rate that the temperature did not increase by more than 5 °C. Mn_2O_7 was thereby used in a small excess. The reaction mixture was then stirred for 5 min at the same temperature. Excess Mn_2O_7 can be removed by addition of several mL of isopropyl alcohol.

Workup of esters and ketones: After warming to room temperature, the precipitate was filtered off under suction, the filtrate was concentrated, and the crude product was purified by recrystallization or by distillation.

Workup of carboxylic acids (extractive): The MnO_2 precipitate obtained by filtration or evaporation of the solvent was combined with 20–30 mL of water and the resulting slurry was treated with $Na_2S_2O_5$ (0.95 g per 1 g of reacted Mn_2O_7). 50% aqueous H_2SO_4 was then added to the stirred mixture until full dissolution had occurred and the reaction mixture was strongly acidic. The carboxylic acid was extracted and purified according to the standard procedures.

Workup of carboxylic acids (without extraction): After completion of the reaction and warming of the reaction mixture to 0 °C, 0.97 g of $Na_2SO_3 \cdot 7\,H_2O$, 0.76 g of $Na_2S_2O_5$ (both powdered), and 1.25 mL of HCOOH (p.a.) per 1 g of Mn_2O_7 employed were added to the mixture, which was stirred at room temperature. After complete disappearance of the color (ca. 1 h), the salts were

filtered off under suction, the filtrate was concentrated, and the residue was purified by distillation or by crystallization.—Alternatively, after completion of the reaction, 0.94 g of powdered glyoxylic acid monohydrate and 1.25 mL of HCOOH (p.a.) were added per 1 g of reacted Mn_2O_7 at 0°C. The reaction mixture was then worked up as described above.

$[Fe_4Te_4(TePh)_4]^{3\ominus}$, the First Telluride-Tellurolate Complex**

By *Wolfgang Simon, Alfons Wilk, Bernt Krebs,* and *Gerald Henkel**

Complexes having cubane-like M_4X_4 frameworks and tetrahedral MX_4 centers are of considerable interest, in particular because of their widespread occurrence in iron-sulfur proteins (see, e.g., Ref. [1]). In addition to roughly 40 differently substituted sulfide-thiolate clusters of the type $[Fe_4(\mu_3\text{-}S)_4(SR)_4]^{2\ominus/3\ominus}$ (see, e.g., Ref. [2]), the ion $[Fe_4(\mu_3\text{-}Se)_4(SePh)_4]^{2\ominus}$,[3,4] the first example of a species having a selenide-selenolate ligand sphere has been reported. Tellurium-coordinated soluble cubane clusters, however, were previously unknown.

In our attempts to prepare the first members of this new class of compounds, we initially prepared the precursor **1**, which was reacted with NaHTe in acetonitrile to give the complex salt **2**, containing the cubane-like anion **3**.[5]

$[Et_4N]_2[Fe(TePh)_4]$ **1**
$[Et_4N]_3[Fe_4(\mu_3\text{-}Te)_4(TePh)_4]\cdot 2\,MeCN$ **2**
$[Fe_4(\mu_3\text{-}Te)_4(TePh)_4]^{3\ominus}$ **3**

The X-ray crystal structure analysis[6] revealed that crystals of **2** consist of $Et_4N^{\oplus}$ cations, MeCN molecules, and isolated anions **3**. The arrangement of the cations and MeCN molecules precludes unusually short intermolecular contacts between the anions of **2**. The center of **3** (Fig. 1) contains the characteristic Fe_4Te_4 cage with the cubane-like structure well known from iron-sulfide-thiolate chemistry. This cage consists of two interpenetrating distorted tetrahedra of different size, the smaller one being defined by Fe atoms and the larger one by Te atoms. They are arranged in such a way that the Te atoms are located above the centers of the faces of the iron tetrahedron.

The Fe atoms complete their coordination by each binding a tellurophenolate ligand with an average distance of 2.598 Å, thereby increasing their coordination number to 4. This results in an Fe_4Te_8 framework consisting of four $FeTe_4$ tetrahedra sharing common edges in such a way that three vertices always coincide. Very similarly constructed Fe_4Te_8 units are present in the ternary solid-state compound $Cs_7Fe_4Te_8$ reported by *Bronger* et al.[7] The analogies between soluble clusters and discrete structural units in typical solids extend beyond mere topological relationships. They are also revealed in the oxidation state of iron, which, in both the salt **2** and $Cs_7Fe_4Te_8$, has an average value of +2.25.

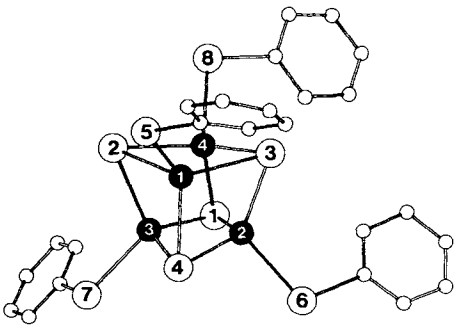

Fig. 1. Molecular structure of the anion **3** in crystals of **2** (hydrogen atoms omitted). Large empty circles, tellurium; large solid circles, iron; −120°C. Important distances [Å]: Fe_4Te_4 framework: Fe1···Fe4 2.640(1), Fe2···Fe3 2.624(2), Fe1···Fe2 2.799(2), Fe1···Fe3 2.781(2), Fe2···Fe4 2.825(2), Fe3···Fe4 2.810(1); Fe1-Te4 2.588(1), Fe2-Te3 2.564(1), Fe3-Te2 2.565(1), Fe4-Te1 2.571(1); Fe1-Te2 2.646(1), Fe1-Te3 2.627(1), Fe2-Te1 2.620(1), Fe2-Te4 2.604(1), Fe3-Te1 2.631(1), Fe3-Te4 2.640(1), Fe4-Te2 2.598(1), Fe4-Te3 2.611(1); Fe-$Te_{term.}$: Fe1-Te5 2.601(1), Fe2-Te6 2.594(2), Fe3-Te7 2.589(1), Fe4-Te8 2.606(1); Angles [°]: Fe_4Te_4 framework: Fe-Te-Fe 60.0(1) to 60.5(1) (average 60.2, 4×) and 64.3(1) to 66.2(1) (average 65.3, 8×); Te-Fe-Te 105.7(1) to 108.9(1) (average 106.8, 8×) and 116.7(1) to 119.1(1) (average 118.0, 4×); $Te_{term.}$-Fe-$Te_{br.}$ 94.3(1) to 100.0(1) (average 96.5, 4×) and 108.0(1) to 118.1(1) (average 114.4, 8×).

The magnetic properties of **2** in solution indicate the existence of antiferromagnetic coupling of the iron atoms. Based on the results of NMR spectroscopy,[5] similar magnetic properties are expected as for the corresponding sulfur-containing trianions.[8] The magnetic properties of crystalline **2** are still under investigation. Values for $Cs_7Fe_4Te_8$ are not available.

The Fe_4Te_4 framework in **3** is significantly distorted from the T_d symmetry of a regular A_4B_4 cubane system towards an idealized D_{2d} symmetry; in addition to four short Fe–Te bonds, which correspond to a set of parallel edges of an undistorted cube and which are 2.572 Å long on the average, the cluster contains eight significantly longer distances with an average value of 2.622 Å. With respect to the $\bar{4}$ axis, which passes through the center of the edges Fe1-Fe4 and Fe2-Fe3, the Fe_4 tetrahedron is clearly stretched (average edge lengths: 2×2.632, 4×2.804 Å), whereas the Te_4 tetrahedron is just as clearly compressed (average edge lengths: 4×4.169, 2×4,496 Å). Both effects are reflected in the observed compression of the overall Fe_4Te_4 cubane unit, the distances Fe1-Fe4 and Fe2-Fe3 (2.632 Å, average) being unusually short for mixed cubane clusters and approaching the iron-ligand distances.

At first sight, these findings appear to violate an empirical rule formulated by *Holm* et al.,[9] which—based on a number of sulfide-thiolate complexes—establishes a relationship between the distortion of the cubane unit and the average oxidation state of the iron atoms. In accordance with this rule, the cubane unit should be stretched along the $\bar{4}$ axis for an average oxidation state of +2.25. The compression observed here, which is also present—albeit to a smaller extent—in $Cs_7Fe_4Te_8$, might be due to electronic factors caused by the specific influence of the tellurium ligands. However, in analyzing electronically induced distortions in solids, one should note that these effects overlap with the effects due to packing. Thus, it is also possible that the molecular $\bar{4}$ axis of the thermodynami-

[1+4] Cycloaddition of a Diphosphene to Acrolein: Synthesis and Structure of a Dihydro-1,2λ^5-oxaphosphole with an Exocyclic P=P Bond**

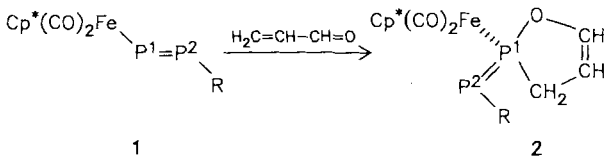
By *Lothar Weber,* Matthias Frebel,* and *Roland Boese*

Iminophosphanes **A** tend to undergo dimerization[2] and react with $(CF_3)_2CO$[3] to give three-membered heterocycles. The phosphanediyl complex **B** can also react in this "carbene-like" way with olefins and alkynes.[4] Furthermore, the cheletropic [1+4] cycloaddition of **B** to cinnamaldehyde has been reported.[4] Such behavior was previously unknown for diphosphenes **C**. Instead, these react in an "olefin-like" way with dienes, undergoing [2+4] cycloaddition.[5] We report here the cheletropic [1+4] cycloaddition of the transition-metal-substituted diphosphene **1**[6] to acrolein, an α,β-unsaturated aldehyde.

R−P=N−R′ (CO)$_5$W=PPh R−P=P−R′

A **B** **C**

Compound **1** reacts with acrolein (molar ratio 1 : 1) in benzene at 0 °C to give the dihydro-1,2λ^5-oxaphosphole **2**, which was isolated as a violet, diamagnetic, air-sensitive solid. The ^{31}P-NMR signals of **1** are shifted strongly upfield on cyclization ($\Delta\delta_{P^1} = 553.9$, $\Delta\delta_{P^2} = 581.7$ ppm). The increase in the coupling constants $^1J_{P1P2}$ from 594.2 to 727.5 Hz is in agreement with the presence of a P=P bond in **2**, but its ylide character is indicated by the marked upfield shift of P2 ($\delta = -28.2$).[7]



1 **2**

Cp* = C_5Me_5, R = 2,4,6-tBu$_3$C$_6$H$_2$

The $[(\eta^5\text{-}C_5Me_5)Fe(CO)_2]$ fragment of **2** is revealed in the IR spectrum (pentane) by two intense bands at 2018 and 1966 cm^{-1}. The X-ray crystal structure analysis of **2** (Fig. 1) shows[8] that the ring P atom P1 is coordinated in a distorted tetrahedral fashion and is part of a dihydrooxaphosphole.

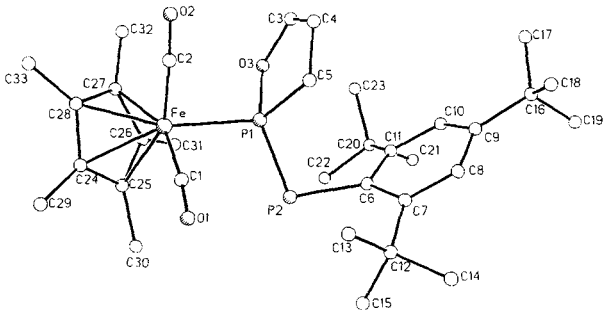


Fig. 1. Molecular structure of **2**. Selected bond lengths [pm] and angles [°]: Fe-P1 224.3(2), Fe-C1 175.0(6), Fe-C2 174.7(6), P1-P2 206.4(2), P1-O3 170.3(5), P1-C5 185.2(7), P2-C6 185.0(5), O1-C1 113.9(7), O2-C2 114.3(8), O3-C3 138.8(11), C3-C4 126.8(12), C4-C5 145.5(11); Fe-P1-P2 111.2(1), Fe-P1-O3 105.9(2), Fe-P1-C5 114.2(2), O3-P1-C5 92.0(3), P1-P2-C6 100.3(2).

The P1–P2 distance in **2** (206.4(2) pm) is significantly larger than that in **1** (202.7(1) pm). In contrast to **1**, C6 does not lie in the same plane as Fe, P1, and P2 in **2**, but is displaced by 0.485 Å out of this plane toward C5 (torsion angle Fe,P1,P2,C6 = 164.6°). The dihydrooxaphosphole ring is slightly tilted along the O3–C5 axis (dihedral angle 169.7°); it is nearly orthogonal to the Fe,P1,P2 plane (interplanar angle 94.5°). In P_2H_2, the n_+ and π orbitals have similar energies.[9] The incorporation of a strongly nucleophilic transition-metal fragment apparently increases the energy level of the n_+ so much relative to the π MO that

[**] Transition-Metal-Substituted Diphosphenes, Part 11. This work was supported by the Fonds der Chemischen Industrie.—Part 10: [1].

"carbene-like" reactions are possible.[10] Other mechanisms for the formation of **2** are also conceivable.

Experimental Procedure

0.7 mL of a solution containing freshly distilled acrolein (2 mL) in benzene (8 mL, 2.95 mmol) was added to a vigorously stirred solution of **1** (1.50 g, 2.70 mmol) in benzene (10 mL) at 0°C. The reaction mixture was then stirred for 2 h at 20°C, the red-brown solution thereby turning deep violet. All volatiles were removed in vacuum and the violet, oily residue was dissolved in pentane (20 mL). The solution was filtered and the filter cake was extracted with pentane until the extracts were colorless. The filtrate and combined extracts were concentrated to ca. 10 mL and stored at −28°C, resulting in the crystallization of violet **2**; yield 0.77 g (47%), m.p. = 151°C (dec.).—^{1}H-NMR (200 MHz, C_6D_6, 22°C): δ = 1.38 (s, 9H, *p*-*t*Bu), 1.56 (s, 15H, $C_5(CH_3)_5$), 1.86 (m, 1H, CH_2), 1.92 (s, 9H, *o*-*t*Bu), 2.01 (s, 9H, *o*-*t*Bu), 2.36 (m, 1H, CH_2), 4.73 (m, 1H, =C*H*−CH_2), 5.95 (m, 1H, =CH−O), 7.47 (d, 2H, ^4J(PH) = 4.2 Hz, *m*-H phenyl).—^{13}C{H}-NMR (C_6D_6, 22°C): δ = 9.99 (d, ^3J(PC) = 5.4 Hz, $C_5(CH_3)_5$), 31.74 (s, *p*-C(CH_3)$_3$), 33.04 (d, ^1J(PC) = 18.8 Hz, CH_2), 33.76 (dd, J(PC) = 10.8 Hz, 2.7 Hz, *o*-C(CH_3), 34.70 (s, *o*-C(CH_3)$_3$), 34.83 (s, *p*-*C*(CH_3)$_3$), 39.00 (s, *o*-*C*(CH_3)$_3$), 39.48 (s, *o*-*C*(CH_3)$_3$), 98.18 (s, $C_5(CH_3)_5$), 103.7 (s, CH_2−*C*H=), 119.69 (d, J(PC) = 3.9 Hz, *m*-C phenyl), 121.0 (d, J(PC) = 3.9 Hz, *m*-C phenyl), 138.46 (dd, J(PC) = 82.0, 20.4 Hz, *ipso*-C phenyl), 143.55 (dd, J(PC) = 7.0, 3.5 Hz, O−*C*H=), 146.93 (d, J(PC) = 4.5 Hz, *p*-C phenyl), 157.5 (d, J(PC) = 9.9 Hz, *o*-C phenyl), 157.8 (d, J(PC) = 8.4 Hz, *o*-C phenyl), 213.45 (dd, J(PC) = 18.6, 4.8 Hz, FeCO), 215.5 (d, J(PC) = 22.8 Hz, FeCO).—^{31}P{H}-NMR (C_6D_6, 22°C): δ = 162.25 (d, $^1J_{P1P2}$ = 727.5 Hz, P1), −28.2 (d, $^1J_{P1P2}$ = 727.5 Hz, P2).—IR (pentane): 2018 s, 1966 s cm^{-1} [ν(CO)].—EI/MS (Varian MAT 312); *m*/*z* 610 ($M^{\oplus}$).

Mono- and Diphosphatricyclo[3.2.1.0^{2,7}]oct-3-enes: Synthesis from 1,3- and 1,4-Dienes and a Stable Phosphaalkyne**

By *Eberhard P. O. Fuchs, Wolfgang Rösch,* and *Manfred Regitz**

Phosphaalkynes undergo regiospecific [3+2] cycloaddition with 1,3-dipoles, such as diazo compounds, azides, and nitrile oxides, to give the corresponding phospholes.[1–3] In contrast, only a few examples of Diels–Alder reactions of phosphaalkynes with cyclic 1,3-dienes are known.[4] The reaction of open-chain 1,3-dienes with the phosphaalkyne **2** is—as we report here—much more complex: it proceeds—largely independent of the ratio of reactants—with a 1:2 stoichiometry.

In order to carry out the reaction, the reactants are heated in a glass pressure vessel partly with and partly without solvent (see footnotes to Table 1) to temperatures ≥90°C. Kugelrohr distillation affords the oily 1,7-diphosphatricyclo[3.2.1.0^{2,7}]oct-3-enes **5a–d** in high yields.[5] The reactions of **1b** and **1d** with **2** each afford two isomers, the main products being **5b** and **5d**, respectively (ratio 60:40 and 90:10, respectively, as determined by ^{31}P-NMR spectroscopy). In the minor products, the sequence of the substituents R^1–R^4 is the reverse of that in **5b** and **5d**.

	R^1	R^2	R^3	R^4
a	H	H	H	H
b	H	H	Me	H
c	H	Me	Me	H
d	H	H	H	Me

The products are presumably formed by an initial Diels–Alder reaction (**1** + **2** → **3**) followed by an ene reaction of **3** with a second equivalent of **2** to give **4**,[6] which, in turn, undergoes an intramolecular [4+2] cycloaddition (**4** → **5**). In the case of **1b** and **1d**, the first step is not regiospecific, which explains the formation of the minor products. The ene reaction, in contrast, occurs specifically at the PC double bond. Steps **3** → **4** and **4** → **5** were previously unknown in the chemistry of low-coordinate phosphorus compounds. The mechanistic interpretation of the reaction **1** + **2** → **5** is also supported by the fact that the 1,4-cyclohexadienes **6a–d** react with **2** in a ratio of 1:1 under comparable conditions (see footnotes to Table 1) to give the 1-phosphatricyclo[3.2.1.0^{2,7}]oct-3-enes **8a–d** (colorless to yellow oils).

In the case of **6c** and **6d**—but not of **6b**—approximately 10% (^{31}P-NMR spectroscopy) of an isomer is formed in addition to the main products; this isomer bears the substituents in the 4,5 positions, but it could not be separated. Thus, the ene reaction with **6b** occurs exclusively, and that with **6c** and **6d** with great selectivity, at the substituted, electron-richer CC double bond. In carbon chemistry, it is known that **6a** reacts with dimethyl acety-

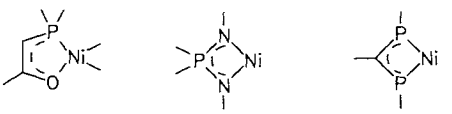
A New 1,3-Diphosphaallylnickel Complex for the Polymerization of Ethene

By *Wilhelm Keim,* Rolf Appel,* Stefan Gruppe,* and *Falk Knoch**

Dedicated to Professor Friedrich Asinger on the occasion of his 80th birthday

There have been few investigations regarding the influence of chelating ligands on the transition-metal-catalyzed formation of C–C bonds under homogeneous conditions. Noteworthy, however, is the controlling effect that has been achieved using PO bidentate ligands.[1] The size of the chelate ring plays an important role in these reactions: for example, PO complexes, **I**, oligomerize ethene selectively to give α olefins (SHOP process).[2]



I II III

Using aminobis(imino)phosphorane complexes, **II**, α olefins could be polymerized to give α,ω linkages via a novel mechanism.[3] As shown by the X-ray structure analysis of **II**, the complex contains a four-membered ring in which three electrons are distributed in a η^3-allyl-like fashion. In order to increase our understanding of chelate ligand properties and to discover new ways to carry out C–C bond formation, it seemed of interest to include phosphaalkene complexes, **III**, in our investigations, since it was known that phosphaalkenes can function as η^3-1,3-diphosphaallyl chelating ligands.[4]

Reaction of bis(1,5-cyclooctadiene)nickel with the 1,3-diphosphapropene **1** in toluene affords a catalyst, which, in situ at 70–100°C and 30 bar ethene, polymerizes ethene to give linear polyethylene ($M_r \approx 0.8 \times 10^6$). IR investigations reveal that mostly terminal double bonds are present. Activities of > 1000 mol ethene per mole of nickel per

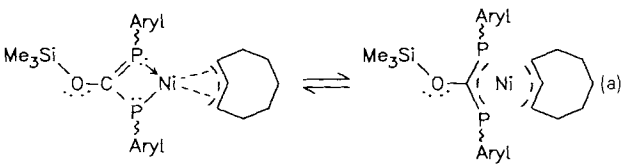
An X-ray crystal structure analysis of **2** revealed that the 1,3-diphosphapropene ligand was η^1,η^2-coordinated. This finding is supported by the different P–C and P–Ni distances and the aryl–P–C angle. According to the spectroscopic data (^{1}H- and ^{13}C-NMR)[5] recorded in solution, **2** contains an η^3-1,3-diphosphaallyl ligand, so that equilibrium (a) can be postulated:



Experimental Procedure

All reactions were carried out under argon.

2: [(cod)$_2$Ni] (5.6 g, 20.35 mmol) and **1** (13.35 g, 20.3 mmol) [6] were each dissolved in 50 mL of toluene and the solutions were cooled to −50°C. The two solutions were combined with stirring and the resulting reaction mixture was stirred at room temperature for ca. 15 h. Toluene was removed in vacuum and the oily residue was dissolved in 10 mL of CH_2Cl_2. After filtration, the filtrate was treated with acetonitrile until it became cloudy. In ca. 15 h, 4.2 g (32%) of **2** crystallized at −15°C.

Unusual Ligand Directed Regioselectivity in the Iron Catalyzed Cross Coupling of Allylic Ethers to 2-Substituted 1,3-Dienes**

By *James M. Takacs,** *Lawrence G. Anderson, G. V. Bindu Madhavan,* and *Franklin L. Seely*

Catalytic transition metal mediated carbon–carbon bond forming reactions which enable useful new types of bond constructions, or which exhibit unusual reaction selectivities, have found exceptional use in organic synthesis.[1,2] We have recently reported that soluble (bpy)Fe^0 complexes (bpy = 2,2′-bipyridine) catalyze the selective 1:1 cross coupling of 2,3-dimethyl-1,3-butadiene to allyl benzyl ether to yield (benzene, 25°C, 8 h, 80%) a 1,4-addition product.[3] This new iron catalyzed cross coupling reaction complements the known thermal ene chemistry.[4,5] We now wish to report that by judicious choice of ligand, the (L)Fe^0-catalyzed cross coupling reactions of monosubstituted 1,3-dienes with allylic ethers can be directed toward *either* 1,4-addition or toward the previously unknown 1,2-addition mode. These cross coupling reactions provide an unusually striking example of the effect that coordinated ligands can impose upon the kinetic selectivity of a catalytic metal complex.

Catalytically active soluble iron(0) complexes can be conveniently prepared in situ via reduction of Fe(acac)$_3$ with 3.1 equiv of Et_3Al in the presence of a 1,3-diene and 1.1 equiv of an appropriate ligand.[6] Allyl benzyl ether

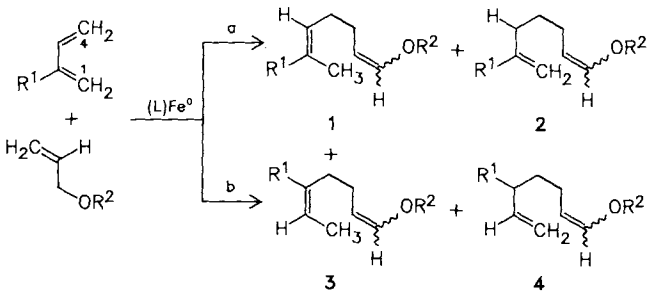
Salt Lake City, UT 84112 (USA)

[**] This work was supported by the National Institutes of Health, the Petroleum Research Fund administered by the American Chemical Society, and the University of Utah Research Committee.

reacts with isoprene (benzene, 25 °C, 3–10 h) in the presence of 5–10 mol-% of (L)Fe^0 catalysts to give a mixture of four isomeric 1:1 coupling products **1**–**4** (Scheme 1, $R^1 = CH_3$, $R^2 = CH_2Ph$). The yields lie between 30 and 90% (Table 1).[7] The product ratio is dramatically influenced by the ligands attached to the metal.

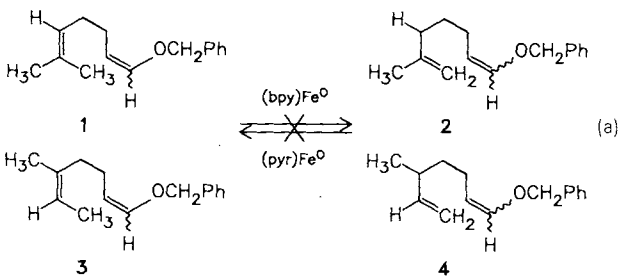


Scheme 1. Fe^0-catalyzed addition of allyl ethers to monosubstituted butadienes. a) Addition to C4; b) addition to C1. **1** and **3** are the products of 1,4-additions, **2** and **4** those of 1,2-additions.

Two unusual types of reaction selectivity are of particular interest in this process. First, the carbon–carbon bond construction is regioselective (C4- vs C1-addition) with respect to the 2-substituted 1,3-diene moiety. Secondly, we have found that within each of the addition modes the selectivity between 1,4- and 1,2-addition products can be varied (Table 1). For example, allyl benzyl ether reacts with isoprene in the presence of 10 mol-% (bpy)Fe^0 (benzene, 25 °C, 8 h) to give a mixture of enol ethers **1**–**4** in 80% yield (Table 1). In this case, about 90% of the carbon–carbon bond formation takes place at the less substituted olefin of the isoprene unit (C4-addition) to yield predominantly products **1** and **2**.[8] In comparison, the known addition of carbanion nucleophiles to the [(η^4-isoprene)$Fe(CO)_3$] complex under kinetic conditions proceeds primarily (90%) at the 3-position of the coordinated isoprene. Under thermodynamic conditions, however, the carbanion additions yield only C4-addition products and no products resulting from C1-addition are observed.[1d] Considering the products derived from the predominant C4-addition mode in the (bpy)Fe^0 catalyzed reaction, we find that greater than 70% is the 1,2-addition product **2** (**1**:**2**, 27:73). The minor coupling products **3** and **4** (< 10% yield), derived from coupling to the more substituted end of isoprene (C1-addition) are formed with little selectivity by this catalyst (**3**:**4** = 56:44). The observed reaction selectivities obtained with the (bpy)Fe^0 catalyst are not highly dependent upon the reaction medium (benzene, ether or THF) nor upon the allylic ether substituent ($R^2 = CH_2Ph$, $CH_2C_6H_{11}$, tetrahydropyranyl (THP); Table 1).

In contrast to the (bpy)Fe^0 catalyzed reaction, the C4-addition product mixture formed from the coupling of allyl benzyl ether to isoprene in the presence of 10 mol-% (pyr)Fe^0 (pyr = pyridine; in benzene, 25 °C, 10 h, 70%) is predominantly the 1,4-addition product **1** (**1**:**2** = 94:6). In the presence of this catalyst, however, the regioselectivity favoring C4- over C1-addition to isoprene is only modest (62:38). Of the isomeric products formed from the latter mode of coupling, about 70% results from the 1,2-addition mode (**3**:**4** = 24:76). Soluble iron catalysts containing 2,2′-biquinoline, 1,10-phenanthroline, or methyl substituted 1,10-phenanthroline ligands, and catalysts prepared in the absence of added ligand show product ratios of **1**–**4** similar to those of (pyr)Fe^0.[9] Table 1 lists the results.

While the origin of the catalyst selectivity cannot yet be fully resolved, preliminary experiments indicate that the isomeric products formed in the presence of these various catalysts are the result of ligand directed kinetic selectivity. We find that the isolated 1,2- and 1,4-addition products do not interconvert when subjected to active (bpy)Fe^0 or (pyr)Fe^0 catalysts [Eq. (a)]. In addition, the observed C4-



(a)

vs. C1-addition ratios parallel the relative reactivities of isoprene and 2,3-dimethyl-1,3-butadiene toward the (L)Fe^0 catalysts. Treatment of allyl benzyl ether with (bpy)Fe^0 in the presence of a large excess of an equimolar mixture of the two dienes yields a mixture of products in which the isoprene unit is incorporated with about 4:1 selectivity. The corresponding reaction catalyzed by (pyr)Fe^0 is nonselective, consistent with the low C4:C1 selectivity exhibited by this catalyst.

Structurally more complex dienes can also be employed in the coupling reaction of Scheme 1. Myrcene, 2-(2′-phenyl-2′-trimethylsilyloxyethyl)-1,3-butadiene and 2-(trimethylsilylmethyl)-1,3-butadiene yield the corresponding coupled products **1**–**4** when treated with the various (L)Fe^0 catalysts. In each case, the products corresponding

Table 1. The substrate and ligand dependency of the product distribution in the cross coupling of allylic ethers to isoprene (Scheme 1, $R^1 = CH_3$).

to isomers **1** and **3** are formed as *single trisubstituted olefin isomers* possessing the indicated *E*-geometry. The selectivity trends are similar to those observed with isoprene. For example, myrcene reacts with allyl benzyl ether in the presence of 10 mol-% (bpy)Fe^0 (benzene, 25°C, 21 h, 79%) to give an 8.0:59.2:13.7:19.1 mixture of **1-4** ($R^1 = CH_2CH_2CH{=}C(CH_3)_2$, $R^2 = CH_2Ph$), while the (pyr)Fe^0-catalyzed reaction (benzene, 25°C, 12 h, 82%) leads to a product mixture of the composition **1**:**2**:**3**:**4** = 63.3:27.1:4.4:5.2. Other dienes such as 1-vinylcyclohexene, 1,3-decadiene and 2-(α-acetoxybenzyl)-1,3-butadiene are not efficiently coupled to allyl benzyl ether under the influence of the (L)Fe^0 catalysts examined to date.

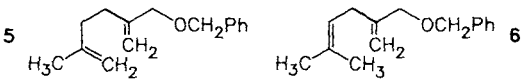
[7] Compounds **1-4** are formed as a mixture of *cis/trans* enol ethers (60:40). The ratios of **1-4** are determined by capillary gas chromatography after conversion to their ethylene acetals ($HOCH_2CH_2OH$/TsOH/THF). The ratio of isomeric products **1**:**2**:**3**:**4** does not change with the degree of conversion. Conversions are typically 60-100% after 8 h at 25°C. Cyclooligomerization of the 1,3-diene is competitive with the coupling reaction. No attempt to optimize the catalyst or reaction conditions with respect to this side reaction was made. Typically a three- to fivefold excess of 1,3-diene is employed.

[8] Similar regioselectivity has been observed in the oxidative coupling of tetrafluoroethylene to tricarbonyl(isoprene)iron(0): A. Bond, B. Lewis, M. Green, *J. Chem. Soc. Dalton Trans. 1975*, 1109.

[9] The regioselectivity of carbon-carbon bond formation with respect to the allyl ether component is also highly dependent upon the added ligand [4]. While the (bpy)Fe^0, (pyr)Fe^0, and "ligand-free" catalysts are highly selective toward the formation of products **1-4**, other (L)Fe^0 catalysts which we have examined are not. In those cases, a 30:70 mixture of 1,2- and 1,4-hydrovinylation products, **5** and **6**, can be isolated in addition to the 1,2- and 1,4-addition products, **1-4**. The ratio of addition to hydrovinylation coupling products in the reaction of allyl benzyl ether with isoprene catalyzed by (L)Fe^0 varies as a function of L; L = pyr: >95:5; bpy: >95:5; 2,2'-biquinoline: 55:45; 1,10-phenanthroline: 56:44; 2,9-dimethyl-1,10-phenanthroline: 46:54; 3,4,5,6-tetramethyl-1,10-phenanthroline: 34:66. The chemical yields cited in Table 1 are for the addition products **1-4** only.

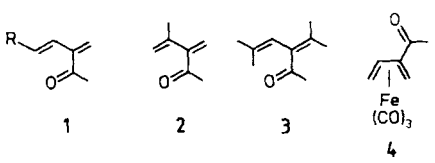


Stereoselective Synthesis of (*E*)-3-Methylene-4-alken-2-ones from Aldehydes and Methyl Vinyl Ketone and Their Spontaneous Dimerization**

By *H. M. R. Hoffmann,* Ulrike Eggert,* and *Wolfgang Poly*

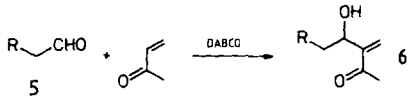
Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

3-Methylene-4-alken-2-ones of type **1** were hitherto unknown, although **2**[1] and the trimethylated derivative **3**[2] have been reported.[3,4] The parent compound **1a** (R = H)[5] has also been isolated as the stable tricarbonyliron complex **4**.[2]



We describe a facile two-step route to *E*-configurated oxodienes **1** and show that such functionalized dienes dimerize spontaneously and regioselectively.

Coupling of aldehydes **5** with methyl vinyl ketone as Michael acceptor in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO)[6] affords the 4-hydroxy-3-methylene-2-alkanones **6**, whose dehydration should furnish



the desired 3-methylene-4-alken-2-ones. However, given rotamers **6A** and **6B** and an antiperiplanar E2 transition state, both the *E*-configurated diene **1** and its *Z*-isomer **7** seem feasible as the reaction products.

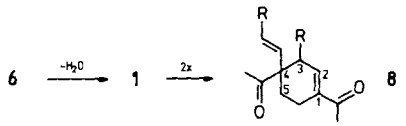
[**] DABCO-Catalyzed Coupling of Aldehydes with Activated Double Bonds, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank *N. Daude* for experimental contributions.—Part 6: [7].

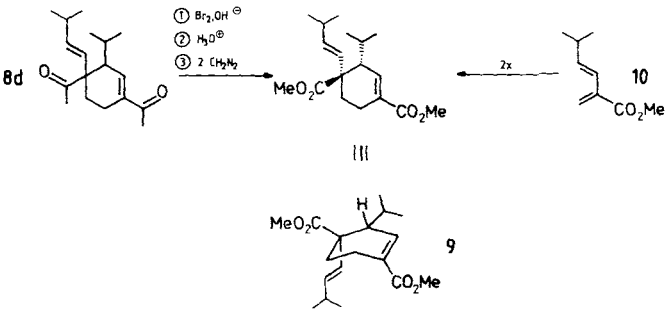
Orienting experiments showed that mild conditions were necessary in order to suppress *E/Z* isomerization, 1,5-hydrogen shifts, and other undesirable side reactions.

When the β-ketoallyl alcohols **6** were allowed to react with methanesulfonyl chloride/DABCO at 0°C to room temperature and the reaction mixture was worked up after 1 day, neither the monomer **1** nor its *Z*-isomer **7** were obtained. Instead, the functionalized 1,4-diacetylcyclohexenes **8** were isolated in good to very good yields (Table 1).



Several stereochemical features of the sequence **6**→**1**→**8** are of interest.

1. *E-Selectivity of the formation of the monomer.* All dimers **8b–i** showed an *E*-configurated exocyclic CC-double bond. No isomer with a *Z*-olefinic bond was detected. Thus, the monomer intermediate is **1** rather than **7**.
2. *Regioselectivity of dimerization.* The dimerization proceeds with unusual ease and is highly *para*-selective to give **8**. No *meta*-oriented dimers (cf. dimerization of **2**[1]) were detected.
3. *Stereochemistry of dimerization.* Column chromatography combined with ^{13}C-NMR allowed us to establish two stereochemical series, consisting of the major and the minor stereoisomer of the dimerization. Table 1 lists the diagnostic ^{13}C-NMR signals for each series. Dimer **8d** (the major stereoisomer) was subjected to a double haloform reaction giving the diacid, which was converted into the diester **9**. Comparison of the spectra (^{1}H-NMR, ^{13}C-NMR, IR) showed the diester **9** to be identical with the major stereoisomer formed in the dimerization of diene ester **10**. The dimer from the latter



reaction is probably the *endo* dimer,[7] i.e., the alkenyl side chain in **9** is *endo* with respect to a rooflike cyclohexene moiety, and the 3-isopropyl group is *trans* to the 4-methoxycarbonyl group. Thus, the dimerization of **1d** and of the other dienes **1** is moderately *endo*-selective, contrary to that of the corresponding diene esters (e.g. **10**).[7]

The DABCO-catalyzed coupling of methyl vinyl ketone with aldehydes (**5**) to give **6** and in-situ dimerization of the dehydration product **1** to functionalized 1,4-diacetylcyclohexenes **8** is thus an efficient and short procedure, which starts from inexpensive educts and creates four new σ bonds and two new unsaturated CC-bonds in convergent fashion. The products, which are formed *para*-selectively and contain a quaternary carbon, are of interest in terpene synthesis, e.g., for preparing spirocyclic compounds. The

procedure allows also for the introduction of further functionality via the aldehyde **5**.

Experimental procedure

6: Methyl vinyl ketone (7.01 g, 100 mmol), aldehyde **5** (100 mmol), and DABCO (1.68 g, 15 mmol) were dissolved in anhydrous THF (25 mL) and left at room temperature. After 7 days the solution was diluted with diethyl ether, washed with dilute hydrochloric acid and aqueous $NaHCO_3$, and dried ($MgSO_4$). The crude product was purified by chromatography on silica gel (diethyl ether–light petroleum) or distilled in a Kugelrohr apparatus.

8: The coupling product **6** (10 mmol), DABCO (3.37 g, 30 mmol) and *p*-dimethylaminopyridine (120 mg, 1 mmol) were dissolved in anhydrous CH_2Cl_2 (20 mL) and the solution cooled to 0°C. Methanesulfonyl chloride (1.37 g, 12 mmol) in anhydrous CH_2Cl_2 (10 mL) was added dropwise and the reaction mixture stirred for 24 h at room temperature. The mixture was worked up by dilution with CH_2Cl_2, washing with water (3×), drying ($MgSO_4$), and removal of the solvent. The crude mixture of stereoisomers was purified on silica gel/diethyl ether-light petroleum and—when possible—separated (cf. Table 1).

Adsorption and Curvature in Highly Dealuminated Zeolites**

By *Ronnie Thomasson, Sven Lidin,* and *Sten Andersson**

We have recently shown that the silicon and oxygen atoms in a zeolite structure like faujasite reside on a surface parallel to the periodic minimal surface, the so-called *D*-surface.[1] Extensive Ewald calculations of electrostatic point charge distributions by *von Schnering* and *Nesper* have shown that there exist equipotential surfaces in solids which in fact are periodic minimal surfaces.[2]

It has also been shown that when gases are adsorbed by zeolites, the dispersion energy contribution to the physical bond between sorbate and sorbent varies according to the geometry of the local environment. The heats of sorption in zeolite cavities can be as much as eight times larger than those found for a corresponding smooth, planar surface of the same chemical composition.[3]

The total van der Waals force between two molecules is the sum of the van der Waals forces between atoms facing each other in the two molecules. Therefore, it generally, increases with the number of atoms and their atomic numbers and thus often appears to increase with the molecular weight. It is also well known that molecules of a homologue series are adsorbed by zeolites according to their molecular weight. Further, it is found that zeolites of different structures have different heats of sorption for the same molecule at the same temperature.

The purpose of this paper is to describe the adsorption process in a zeolite with the concept of intrinsic curvature. We have already shown in earlier works that the atoms in the faujasite, cristobalite, diamond or silicon structure lie on a surface parallel to the *D*-surface.[1a] This is shown schematically in Figure 1 for a (110) plane of the structure of cristobalite. The curved line corresponds to a principal line of curvature in the *D*-surface.

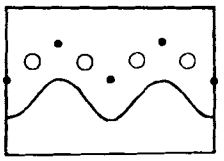

Fig. 1. (110) section of the structure of cristobalite. The small circles represent silicon atoms, and the larger circles oxygen atoms. The curve is the minimal surface D.

If we assume that this surface constitutes the path for molecules being adsorbed by a zeolite, and that such molecules move as particles, the well known equation

$$\boldsymbol{a} = \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}t} \cdot \boldsymbol{u}_T + v^2 \cdot \kappa \boldsymbol{u}_N \qquad (1)$$

holds true ($\boldsymbol{a}$ is the acceleration, $\boldsymbol{v}$ is the velocity, v is the magnitude of velocity or speed, κ is the curvature, and $\boldsymbol{u}_T$ and $\boldsymbol{u}_N$ are tangent and normal vectors, respectively. If the molecules move on principal lines of curvature, the motion is curvilinear and uniform (the force lines are orthogonal to the curve, speed is constant) there is no tangent acceleration and

$$|a| = v^2\kappa \quad \text{or} \quad F = \mathrm{m}v^2\kappa \qquad (2)$$

The curvature in Figure 1 corresponds to a principal line of curvature for the *D*-surface, and then

$$\kappa = \sqrt{-K}$$

where K is the Gaussian curvature ($K=\kappa_1\cdot\kappa_2$ and for minimal surfaces $\kappa_1 = -\kappa_2$).

F is here a van der Waals force acting on a molecule from the zeolite surface, and is strongest when K is greatest, that is on the saddle points. However, during its motion, the molecule "feels" forces from a surface element and its integral curvature.

One of the most important equations in differential geometry is the Gauss-Bonnet equation

$$\iint_{ABC} K\,\mathrm{d}s = A + B + C - \pi \qquad (3)$$

[**] This work was supported by the Swedish Research Council. We thank Dr. *Zoltan Blum* for valuable discussions.

A, B, and C are here the interior angles in a geodesic triangle (easy to find in minimal surfaces), and K is the Gaussian curvature of a point inside the triangle. The integral curvature of a unit saddle with tetrahedral boundaries for the isometric surfaces D, P, and G is $-2/3\pi$. Required here, however, is an average Gaussian curvature, which we define as follows:

$$K_{av} = \frac{\text{integral curvature}}{\text{area}}$$

We have already reported on the calculation of the cartesian coordinates and Gaussian curvatures of the D, P, and G surfaces by the numerical integration of the Weierstrass equation.[1c] The area of the minimal surface was calculated using a result from elementary differential geometry: If dA is the area of a surface element S and dA' is the Gauss map S* of S, then

$$\lim_{A \to 0} \frac{A'}{A} = K$$

thus

$$\iint dA_S = \int\int_{S^*} \frac{dA'}{K}$$

The area of the surface contained in one unit cell of the dealuminized faujasite structure of $a = 24.20$ Å becomes 2261 Å^2, and a tetrahedral saddle 47.11 Å^2. And the average curvature is

$$K_{av} = -\frac{2}{3}\frac{\pi}{47.11} = -0.0445\ \text{Å}^{-2}$$

Inside a zeolite, molecules should experience an attractive force:

$$F = \text{const} \cdot N \cdot K_{av} \qquad (4)$$

Although mass or molecular weight is useful in explaining adsorption behavior, we use here N, the number of bonding electrons per molecule, which also reflects the nature of interaction between sorbate and sorbent in the group of molecules discussed below. The formula clearly shows how bond force depends on curvature, and the physical meaning of the sign of K_{av} is whether the sorbent surface is convex (+) or concave (−). Valleys or holes in a surface attract molecules, while hills or elevations repel them.

The differential heat of adsorption (ΔH) to be calculated should be valid for small uptake when adsorbate-adsorbate interaction is negligible. The adsorbate-adsorbent interaction should be as "clean" as possible as present in hydrophobic zeolites. The expression for ΔH now includes the distance between the adsorbed molecule and the host structure (harmonic motion) and we assume that it will not vary for a series of related compounds:

$$\Delta H = \text{const}_1 \cdot N \cdot K_{av} \qquad (5)$$

Recently *Stach* et al.[5] reported accurate calorimetric measurements on the adsorption of *n*-paraffins and related compounds in a US-Ex zeolite of the faujasite type with a Si/Al ratio = 95:1.

The peculiar shapes of the enthalpy curves for small adsorbed amounts are obviously due to the fact that the first molecules interact with saddles or sites with maximum curvature. We have therefore calculated integrated enthalpies up to 0.5 mmol adsorbate per gram zeolite from the data given by *Stach* et al.[5] This concentration corresponds to slightly less than 50% occupancy of the internal interface for the faujasite structure, and slightly more than 50% for the silicalite structure.

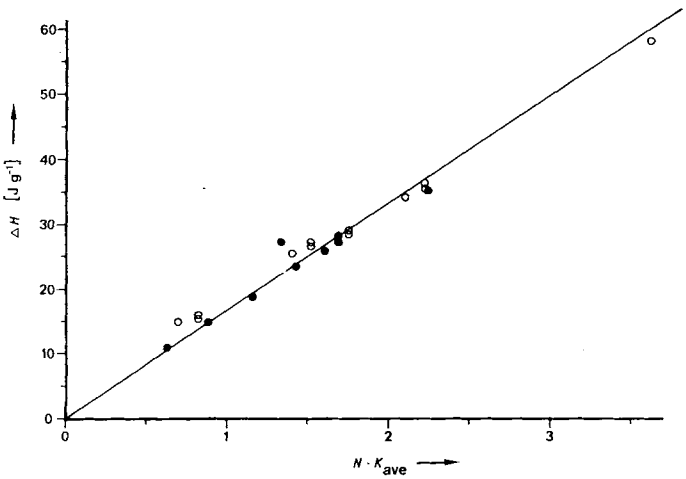

Fig. 2. Integrated heats of adsorption for various hydrocarbons vs. the product of curvature K_{av} and N (number of bonding electrons) in US-Ex and silicalite. Filled circles, in US-Ex, from left to right ethane, propane, *n*-butane, *n*-pentane, benzene, cyclohexane, *n*-hexane, *n*-hexane, *n*-octane; empty circles, in silicalite, from left to right ethene, ethane, ethane, 1-butene, *n*-butane, *n*-butane, cyclopentane, benzene, *n*-hexane, *n*-hexane, toluene, *n*-decane.

The product of N and curvature K_{av} is plotted versus ΔH in Figure 2 [cf. Eq. (5)]. *Stach* et al.[5] also made accurate measurements on the adsorption of some hydrocarbons on silicalite. This zeolite has a orthorhombic structure with ten-membered rings, for which we do not yet have a periodic minimal surface. However, with the knowledge of const_1 in Equation (5), and with known integrated ΔH and N for several different hydrocarbons, an average curvature for silicalite has been calculated to be -0.0584 Å^{-2} (see Fig. 2).

In conclusion it should be mentioned that the concept of curvature is useful for explaining why zeolites of different structures have different adsorption properties. We hope to be able to extend our studies to the ordinary alkali zeolites and their properties.

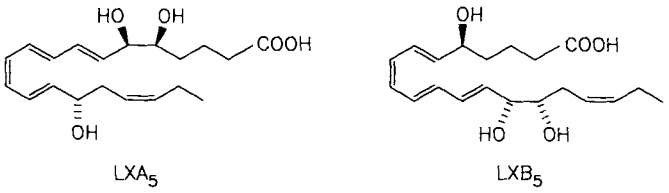
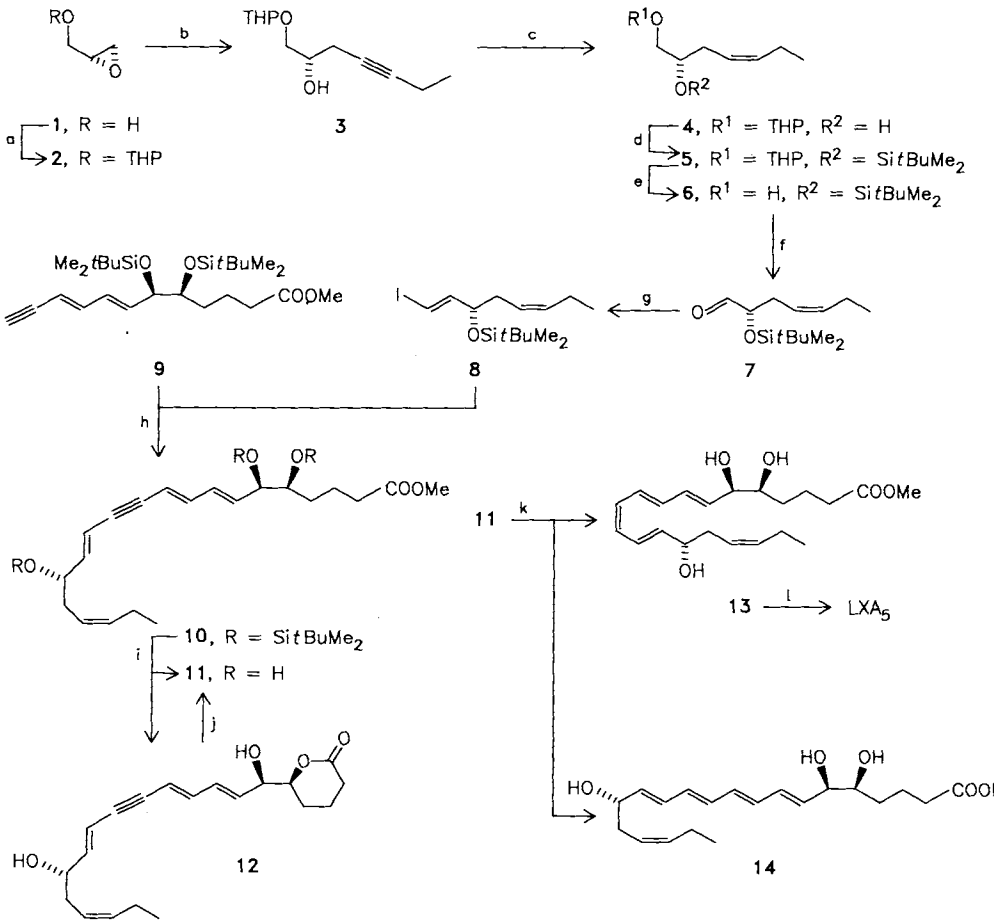
Stereocontrolled Total Synthesis of Lipoxins A_5 and B_5**

By *K. C. Nicolaou,* S. E. Webber, J. Ramphal,* and *Y. Abe*

A recent report by *Wong* et al.[1] described the isolation of lipoxins A_5 (LXA_5, 5,6,15-trihydroxy-7,9,11,13,17-eicosapentaenoic acid) and B_5 (LXB_5, 5,14,15-trihydroxy-6,8,10,12,17-eicosapentaenoic acid) from incubation mixtures of porcine leukocytes and 15-hydroperoxyeicosapentaenoic acid (15-HPEPE). In view of the current nutritional and biomedical interest[2] in eicosapentaenoic acid (EPA) and its metabolites and the minute quantities in which these substances are available from biosynthetic schemes coupled with the uncertainty regarding their precise structures and biological profiles, we undertook their total synthesis. We now report the first total synthesis of (5*S*,6*R*,15*S*)-5,6-15-trihydroxy-7,9,11,13,17-eicosapentaenoic acid (LXA_5) and (5*S*,14*R*,15*S*)-5,14,15-trihydroxy-6,8,10,12,17-eicosapentaenoic acid (LXB_5), the two structures suspected of being the natural stereoisomers by analogy to the structures of lipoxins A_4 (LXA_4)[3] and B_4 (LXB_4).[4]



The synthetic schemes for the construction of LXA_5 and LXB_5 were based on our recently established general strategy towards linear eicosanoids.[5] This efficient strategy involves Pd^0–Cu^I catalyzed coupling of terminal acetylenes with vinyl halides[6] to construct the eicosanoid skeleton and Lindlar hydrogenation to secure the *Z* olefins stereoselectively. Scheme 1 outlines the synthesis of LXA_5 starting with the readily available *R*-epoxyalcohol **1**.[7] Thus, 1-lithiobutyne reacts with the THP ether of **1** in the presence of TMEDA in THF (−78→25 °C) to afford compound **3** in 77% yield. Selective hydrogenation of the triple bond in **3** ((Lindlar catalyst, Fluka, hexane) led to olefin **4** (91%), which was transformed by standard chemistry to aldehyde **7** via intermediates **5** and **6**. The *E*-vinyl iodide **8** was then prepared from **7** using $CrCl_2$–CHI_3 according to



Scheme 1. Synthesis of LXA_5. Reagents and conditions. (a) 1.5 equiv. dihydropyran, TsOH catalyst, CH_2Cl_2, 0 °C, 2 h, 88%; (b) 5.0 equiv. 1-butyne, 1.1 equiv. *n*BuLi, 1.0 equiv. verted into **11** by exposure to Et_3N in MeOH (83%). Finally, controlled hydrogenation of **11** (Lindlar catalyst, Fluka, quinoline, CH_2Cl_2), gave LXA_5 methyl ester **13** (51%), its all-*trans* isomer **14** (9%), and unreacted starting material **11** (30%), which were separated by HPLC [reverse phase; altex-ultrasphere ODS, 5-μm particle size; MeOH : H_2O (70 : 30); 3.5 mL/min; retention times: 9.4 min (**11**); 11.6 min (**14**); 12.7 min (**13**)]. LXA_5 methyl ester **13** was found to isomerize slowly at ambient temperatures to the all-*trans* isomer **14**, a conversion which was accelerated by catalytic amounts of iodine. Hydrolysis of **13** to LXA_5 was carried out with LiOH in aqueous THF.[5a]

The synthesis of LXB_5 and its methyl ester **29** utilized the readily accessible optically active hydroxyepoxide **15**[9] and vinyl bromide **25**[10] as starting materials and proceeded along similar lines as described above for the synthesis of LXA_5. Scheme 2 summarizes the chemistry involved in this synthesis including reagents, conditions, and yields. LXB_5 methyl ester (**29**) was purified by HPLC as described above (retention time = 13 min) and was also observed to isomerize slowly to its all-*trans* isomer (**30**) at ambient temperatures, a process found to be catalyzed by trace amounts of iodine. LXB_5 itself could be generated from **29** by saponification as in the case of LXA_5. Some

The described chemistry renders these two new metabolites of eicosapentaenoic acid (EPA), LXA_5 and LXB_5, readily available and in optically active form. Comparisons of the synthetic compounds with naturally derived LXA_5 and LXB_5 and biological investigations with these compounds are currently in progress.[12]

1,8-Naphthalene-Linked Cofacial Dimeric Phthalocyanines**

By *Clifford C. Leznoff,* Herman Lam, W. Andrew Nevin, Nagao Kobayashi, Pavel Janda,* and *A. B. P. Lever*

Binuclear phthalocyanines covalently linked by five,[1,2] four,[3] two,[3] one,[4] and "−1"[5] atom bridges have been recently described. We now report new cofacial binuclear phthalocyanines **1a–d** linked by a triatomic bridge on a rigid naphthalene framework. These compounds complement 1,8-anthracene bridged porphines,[6,7] and provide entry to a new class of pillared phthalocyanines. They

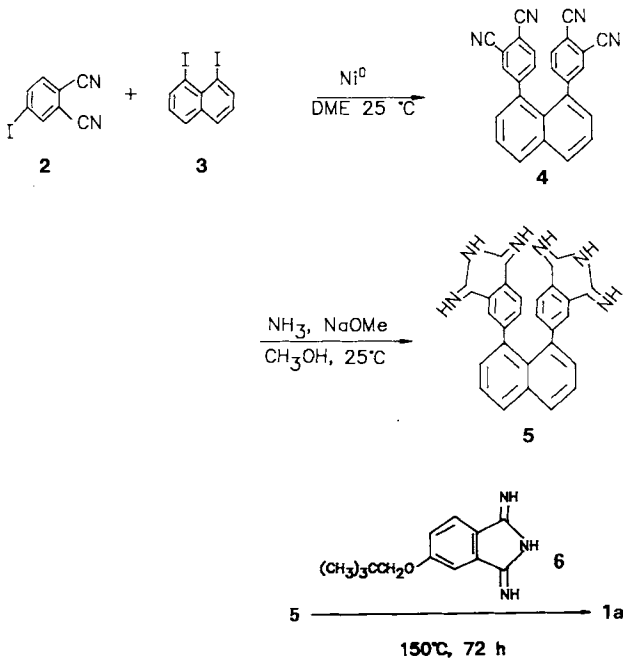
should prove of value in the photo- or electroactivation of small molecules, such as dioxygen, carbon or sulfur dioxide.

Treatment of 4-iodophthalonitrile **2** (4.0 g, 16 mmol) with 1,8-diiodonaphthalene **3** (2.0 g, 5.3 mmol) in a mixed coupling reaction, in the presence of elementary nickel powder under conditions described for homocoupling reactions[8,9] led to 1,8-bis(3,4-dicyanophenyl)naphthalene **4** (310 mg, 15.5% yield) as a mixture of *syn* and *anti* isomers due to restricted rotation about the 1,8-positions of the naphthalene nucleus. Conversion of **4** (380 mg, 1 mmol) into its dihydroisoindole **5** and a mixed condensation of **5** with the dihydroisoindole **6** prepared from 4-neopentyloxyphthalonitrile (6.0 g, 28 mmol) gave, following standard reaction conditions and chromatography,[1-5] the desired 1,8-bis-2'-(9',16',23'-trineopentyloxyphthalocyaninyl)naphthalene **1a** in 15.5% yield. The dicobalt, dicopper, and dizinc derivatives (**1b-d**) of **1a** were prepared by refluxing **1a** with $CoCl_2$, $Cu(OAc)_2$ and $Zn(OAc)_2$, respectively, as previously described.[1-5]



1a-d and **4** have been fully characterized.[10] The fast atom bombardment[11] (FAB) mass spectra **1a-d** were most informative, exhibiting parent ions as the base peak. Furthermore, no evidence of partially or half-metalated derivatives of **1b-d** were detected in their mass spectra. The ^{1}H-NMR spectrum of **1a** exhibited the upfield shifted NH protons which were absent in the spectrum of the zinc derivative **1d**.

Electrochemical and spectroelectrochemical results show that the rigid geometry of the naphthalene bridge induces important changes in the cofacial dicobalt derivative **1b**, compared with previously studied mononuclear and "clamshell" binuclear cobalt phthalocyanines.[1-4,12] The halves of the molecule of **1b** do not oxidize and reduce at the same potential, resulting in clear splitting of the redox couples. Cyclic and differential pulse voltammetry of **1b** in *o*-dichlorobenzene (0.2 M nBu_4NClO_4) revealed a series of three oxidation and four reduction waves with halfwave potentials of +0.53, +0.14, 0.00, −0.90, −1.29, −1.68, and −2.08 V vs $Fc^{\oplus}/Fc$ (Fc = ferrocene).[13,14] Comparison with the cyclic voltammogram of the mononuclear parent compound (2,9,16,23-tetrapentyloxyphthalocyaninato)cobalt CoTNPc ($E_{1/2}$ = +0.59, +0.03, −0.91, and −2.07 V in *o*-dichlorobenzene[12]) indicates splitting of the first oxidation ($L^{\oplus}/L$), and first reduction (Co^{II}/Co^{I}) couples by 140 and 390 mV, respectively. This is the first example of clearly observed splitting of the redox waves in a ring bridged binuclear metal-phthalocyanine and indicates a high degree of coupling between the halves of the molecule. Mixed valence $L^{\oplus}/L$ and Co^{II}/Co^{I} species are thus potentially available.

In contrast to **1b**, the splitting of the corresponding redox couple in the case of a so-called (−1) binuclear derivative (two phthalocyanine rings sharing a common benzene ring)[5] was less than 100 mV (shoulder) in the mixed valence Co^{II}-Co^{I} species. The reduction couples at −0.90 and −1.29 V were investigated by controlled potential electrolysis in an optically transparent thin layer electrode (OTTLE) cell utilizing a gold minigrid or platinum mesh working electrode. Stepwise reduction across each of the couples in turn gives the spectroscopic changes shown in Figure 1. Reduction over the first wave gives a green solution, with isosbestic points occurring at 322, 348, 545, 642, 664, and 760 nm (Fig. 1a). The spectrum is unlike any seen previously for a reduced cobalt-phthalocyanine, having a Q band at 650 nm. It does however exhibit a new absorption band in the region of 450–470 nm associated with metal-to-ligand charge transfer (MLCT) [Co^{I}Pc[d(xz,yz)]→π*($1b_{1u}$)Pc] of a Co^{I}Pc species,[12,15,16] as well as a blue shift and increase in intensity of the Soret band.

The second reduction at −1.29 V (Fig. 1b) gives a yellow solution, with isosbestic points at 332, 395, 566, 678, and 758 nm. The final spectrum is very similar to that of the mononuclear Co^{I}TNPc species,[12] indicating that both cobalt atoms have been reduced to Co^{I}. The spectra are fully reversible by stepwise oxidation to the initial species.

Nernst plots of the spectroelectrochemical data over each of the reductions give slopes approaching 59 mV, showing that each step involves a one-electron transfer. Thus, the product of the reduction at −0.90 V must be a mixed valence species **1e**, of mainly [Co^{II}-Co^{I}] character. The intensity of the MLCT band is only 35% of that of the fully reduced Co^{I}-Co^{I} species **1f**, so that some delocalization of the added electron over the phthalocyanine ring system may be occurring. The presence of the well resolved Q band at 650 nm, rather than ca. 710 nm, may also indicate extensive delocalization throughout the molecule. A weak absorption occurs in **1e**, in the region of 800–900 nm (Fig. 1a), absent from the spectra of both **1b** and **1f** and which may be an intervalence band. The Q band region of the spectrum of **1e** mixed valence species is very different from that observed for the −1-bridged mixed valence Co^{II}-Co^{I} compound,[5] which has a split Q band at 700 and 760 nm.

Neither of the species **1b** or **1f** exhibit ESR absorption in *o*-dichlorobenzene. Species **1e**, however, exhibits typical low spin $(dz^2)^1Co^{II}$ ESR absorption when 2-methylimidazole is added to the solution. The spectrum (g = 2.25) is very similar to that observed for the mixed valence Co^{II}/Co^{II} species of a cofacial dicobaltporphyrin[17] in the presence of *N*-methylimidazole.

In comparing these findings with those for the corresponding cofacial binuclear dicobalt porphyrins[17-20] note that the latter also show splitting of the Co^{II}/Co^{I} couple by up to 290 mV; however, unlike the phthalocyanines, no

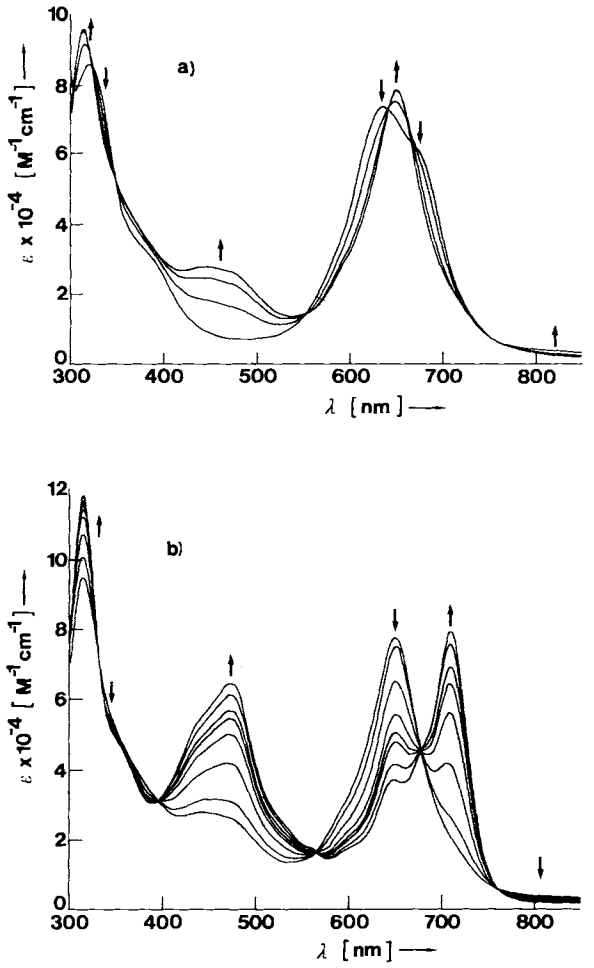


Fig. 1. Development of the electronic spectra with time (in *o*-dichlorobenzene), showing the formation of (a) the mixed valence Co^{II}-Co^{I} compound **1e**, and (b) the doubly reduced Co^{I}-Co^{I} species **1f** obtained by reduction of **1b** at potentials between -0.9 and -1.2 V, and -1.3 and -1.6 V, respectively, (vs $Fc^{\oplus}$/Fc). [**1b**] = 1×10^{-4} M, [TBAP] = 0.3 M.

distinct changes in the electronic spectra were observed for the mixed valence species.[19]

Electrocatalytic reduction of oxygen was examined at electrodes (glassy carbon and ordinary pyrolytic graphite) covered with adsorbed **1b**. Oxygen reduction occurred at -0.34 V (vs SCE, cyclic voltammogram, pH 1 to pH 13), and the limiting current corresponding to two-electron reduction of oxygen to hydrogen peroxide was observed in rotating disc experiments. Logarithmic analysis of the wave yielded a Tafel plot of -120 mV/decade, which corresponds to a charge-transfer coefficient of 0.5 and a one-electron transfer rate-determining step.

Pentacyclo[11.3.0.0^{1,5}.0^{5,9}.0^{9,13}]hexadecane ([4.5]Coronane)**

By *Lutz Fitjer** and *Ulrike Quabeck*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

As has recently been reported,[1] reaction of the dispiroketone **1** with anhydrous *p*-toluenesulfonic acid in benzene leads via a fourfold 1,2-shift to formation of the propellanone **3**. The rearrangement proceeds via the β-hydroxy carbenium ion **2** and is quantitative.

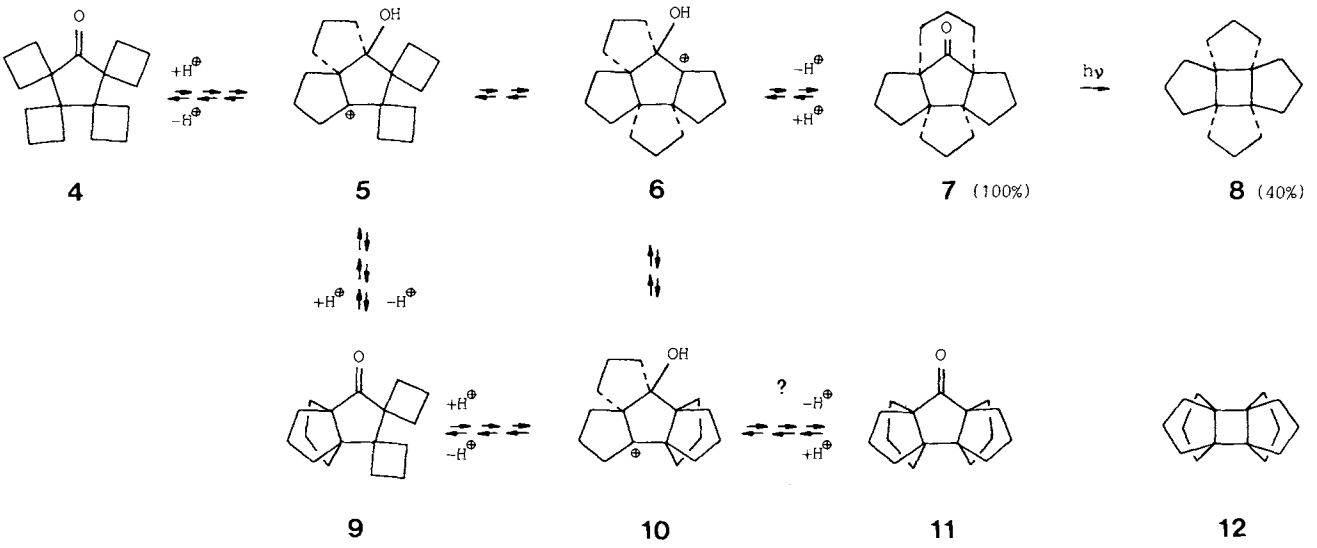
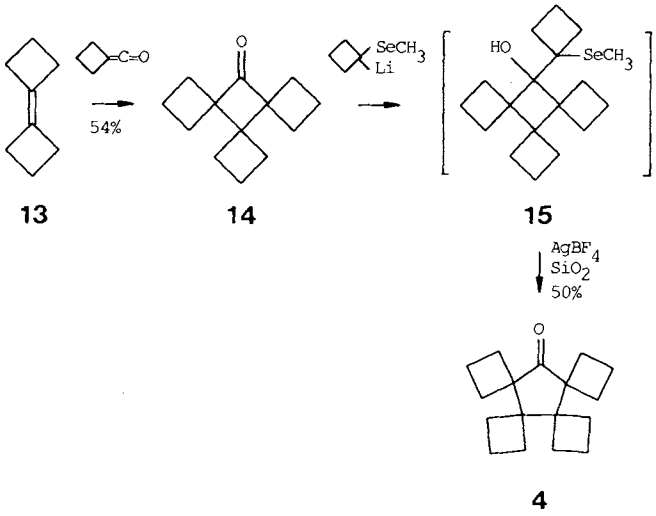
[**] Polyspiranes, Part 13, Cascade Rearrangements, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Parts 12 and 7, respectively: [3].



This finding led us to question whether the previously unknown tetraspiroketone **4** would be converted under comparable conditions into the bispropellanone **11** related to **3** (**4**→**5**→**6**(**9**)→**10**→**11**) or into the bridged pentacyclic ketone **7** (**4**→**5**→**6**→**7**). Both ketones appeared to be amenable to a photochemical decarbonylation and thus to a conversion into the novel pentacyclic hydrocarbons **12**[2] and **8** ([4.5]coronane),[3] respectively. According to force field calculations[4] **8** ($\Delta H_f^0 = -3.2$ kcal/mol) proved to be slightly favored over **12** ($\Delta H_f^0 = -0.8$ kcal/mol); however there proved to be no significant preference with regard to the rearrangement of **4** ($\Delta H_f^0 = 25.8$ kcal/mol) into **7** ($\Delta H_f^0 = -53.1$ kcal/mol) and/or **11** ($\Delta H_f^0 = -53.5$ kcal/mol). Since the boundary kinetics of a rearrangement of **4** also appeared to be difficult to estimate, we sought an experimental explanation.

The synthesis of the tetraspiroketone **4** was accomplished by cycloaddition of carbonylcyclobutane (trimethyleneketene)[5], generated in situ, to bi(cyclobutylidene) **13**[6] and subsequent ring-expansion of the trispiroketone **14** via the β-hydroxyselenide **15**.[7]



For the cycloaddition, a solution of triethylamine (0.15 mol) in bi(cyclobutylidene) **13**[6] (100 mL) was treated with cyclobutanecarboxylic acid chloride (0.10 mol) and the mixture heated for 5 h at 120°C; after washing with 2 N hydrochloric acid and saturated sodium bicarbonate solution, **14** (b.p. 76°C/0.6 torr; yield 54%)[8] was isolated by fractional distillation. Unchanged **13** (b.p. 145–148°C)[6] could be recovered as first fraction. For the homologization[9] the trispiroketone **14** (25 mmol) was added dropwise to a solution of 1-lithio-1-(methylseleno)cyclobutane (prepared from 1,1-bis(methylseleno)cyclobutane[10]) (30 mmol) in ether/pentane at −78°C, the mixture worked-up after 2 h at −78°C, and the crude β-hydroxyselenide **15** (yellow foul-smelling oil) rearranged without further purification with silver tetrafluoroborate (25 mmol) and aluminum oxide (200 mmol) in carbon tetrachloride (100 mL). **15** was completely consumed after 36 h at 20°C. Filtration and chromatography on silica gel in pentane/ether (9 : 1) afforded pure **4** (m.p. 78°C; yield 50%).[8]

As expected, the tetraspiroketone **4** proved to be unstable toward acids. A 0.25 M solution of anhydrous *p*-toluenesulfonic acid in benzene (molar ratio **4** : acid = 1 : 1) isomerized it quantitatively within 30 min at 80°C to a new ketone (b.p. 144–145°C), which, according to the ^{13}C-NMR spectrum (50.3 MHz, $CDCl_3$): $\delta = 18.30$, 25.86, 25.88, 30.01, 34.12, 37.79, 38.16 (C_{sec}), 57.47, 63.56, 222.66 (C_{quart}) was the bridged compound **7**.[8] The same ketone could also be obtained within 10 h at 80°C by reaction of Nafion-H[11] with a 0.25 M solution of **4** in benzene (w/w ratio of **4** : Nafion-H = 1 : 1). In both cases no intermediates were detectable; **7** remained unaltered on prolonging the reaction times. This does not mean, however, that **7** had to be formed in a thermodynamically controlled reaction.

For the decarbonylation, a solution of 200 mg of **7** ($\lambda_{max} = 289$ nm, $\varepsilon = 20$) in 35 mL of cyclohexane was irradiated with a 150W mercury high-pressure lamp in a Duran ring reactor. After 14 d at 20°C, 40% of **7** was consumed and a single product was formed, which was recognized by the presence of only three lines in the ^{13}C-NMR spectrum [(50.3 MHz, $CDCl_3$): $\delta = 26.54$, 35.48 (C_{sec}), 55.06 (C_{quart})] as the desired [4.5]coronane **8** (m.p. 186–188°C.[8] It is the second [m.n]coronane,[3] and, according to force field calculations,[4] has S_4 symmetry. Non-bonding interactions seem to be minimized by a slight folding of the

central ring ($\theta = 11.0°$), which cause the peripheral rings to be crossed pairwise.

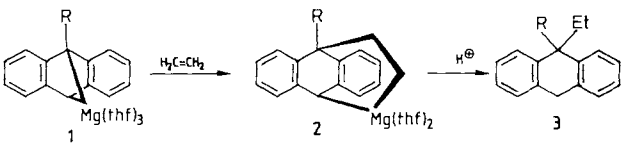
9,10-(1′-Magnesiapropano)-9,10-dihydroanthracene, Synthesis, Structure, and Reactivity**

By *Borislav Bogdanović,* Nikolaus Janke, Carl Krüger, Klaus Schlichte,* and *Joachim Treber*

The high reactivity of the Mg–C bonds in the strained metallacycle of magnesiumanthracene·3THF **1a**[1,2] and the known insertion of alkenes into the Mg–C bonds of certain Grignard compounds[3] prompted us to investigate the reaction of **1a** and its methyl derivative **1b**[4] with ethene. We report herein on the synthesis of 9,10-(1′-magnesiapropano)-9,10-dihydroanthracene·2THF **2a** and its methyl derivative **2b** from **1a** and **1b**, respectively, and ethene, as well as on the crystal structures of the new compounds and on a few reactions of **2a** with electrophiles.

When the reactions of **1a** and **1b** were carried out at 85 °C and 60 bar ethene in THF, **2a** and **2b** were obtained in 72% and 45% yields, respectively. The protolysis of **2a** afforded 9-ethyl-9,10-dihydroanthracene **3a**[5] and that of **2b** the corresponding methyl derivative **3b**. This means



a, R = H; b, R = Me

that in the case of **1b**, ethene is inserted only into the Mg–C_{tert} bond. Further insertion of ethene does not take place under the given conditions. Presumably this can be attributed to removal of ring strain in the metallacycle system upon conversion of **1** into **2** and to the resulting reduced reactivity of the Mg–C bond. Products of the insertion of ring-opened THF into the Mg–C bond of **1a**[1] and **2a** are formed in side reactions with the solvent (ca. 10%). Due to their insolubility, however, these can be readily removed from the reaction solution. The compounds **2** already lose one equivalent of THF at room temperature in toluene.

The monomeric structures of **2** could be confirmed, both by NMR investigations and structure analyses on single crystals.[6] Compounds **2a** and **2b** (Fig. 1) have com-

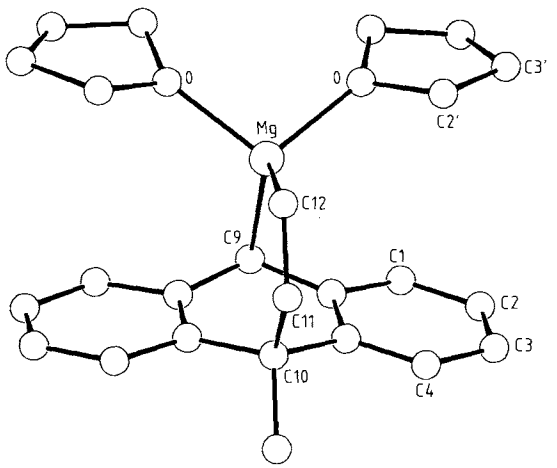


Fig. 1. Crystal structure of **2b**.

parable structures. In each case the coordination geometry about the magnesium atom is distorted tetrahedral with the metal attached via one coordination site directly to the anthracene skeleton. Moreover, a σ-Mg–C bond is also formed (mean value 2.113(9) Å). The two remaining coordination sites of the magnesium are occupied by the THF molecules, whereby the THF rings are not only puckered differently, but, depending on the molecular packing in the lattice, exhibit different torsional angles with respect to the C–Mg–O bonds. Both compounds are chiral; in **2a** there are two molecules in the asymmetric unit which differ slightly in the anthracene skeleton. The anthracene moieties of both compounds are folded along the C9–C10 vector, with the interplanar angle in **2b** being smaller (11.1°) than in **2a** (26.0°) for steric reasons (methyl group on C10).

Further metallapropano compounds analogous to **2a** are accessible by reaction of **2a** with organometal dihalides. Thus, reaction of **2a** with dichloromethylsilane or

[*] Prof. Dr. B. Bogdanović, Dr. N. Janke, Prof. Dr. C. Krüger, K. Schlichte, Dipl.-Chem. J. Treber

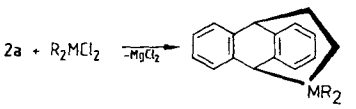
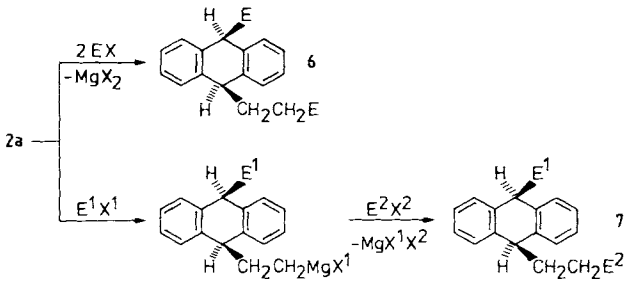
[**] Magnesium-Anthracene Systems, Part 3.—Part 2: [2].

dichlorodiphenylgermane in dioxane (20°C/5 d) leads, via elimination of $MgCl_2$, to the sila- and germapropano derivatives **4** and **5**, respectively, in 80 and 50% yield,[7] the structures of which could be deduced by comparison of the NMR spectra with those of **2a** (see *Experimental Procedure*).



4, M = Si, R = Me
5, M = Ge, R = Ph

Owing to the different Mg-C distances in **2a**, the two carbanion centers can be expected to exhibit different reactivities. Whereas **1a** is characterized by its ambivalent character,[8] **2a** behaves chemically as a "normal" diorganomagnesium compound, but with a markedly increased reactivity of the long Mg-C9 bond compared to that of the short Mg-C12 bond. Thus, **2a** can react chemoselectively with two different electrophiles E^1X^1 and E^2X^2 in succession to give 9,10-disubstituted 9,10-dihydroanthracenes **7** (Scheme 1). With electrophiles EX in excess, 9,10-disubstituted 9,10-dihydroanthracenes of type **6** are formed (Scheme 1). Since the compounds **6** and **7** are *Z*-configurated[9] (exception: reaction with CO_2 to give the *E*-dicarboxylate) it can be concluded that the Mg-C9 bond participates in the S_E reaction with retention of the configuration on C9. With one exception,[12] these are the first examples for the elucidation of the stereochemical course of S_E reactions with C-C coupling.[13]



Scheme 1. Reactants and reaction temperatures: EX = MeI (70°C) [14], EtI (20°C), Me_3SiCl (50°C), CO_2 (20°C); E^1X^1 = MeI, EtI, *i*PrBr, oxacyclobutane; $E^2X^2 = H_2O$, CO_2. All compounds **7** were prepared at 20°C.

Experimental Procedure

2a: A solution of **1a** [1] (32.5 g, 77.6 mmol) in THF (300 mL) was stirred for 3 d at 60 bar ethene pressure and 80°C in a 500-mL autoclave in the absence of air and moisture. The solution was filtered, the solvent removed, and the resulting residue stirred for 3 h in 250 mL of toluene. The pale-yellow mono-THF adduct thus obtained was filtered off, washed with toluene and pentane, and dried in a vacuum. Yield: 16.0 g (72%). Correct elemental analysis. For the crystallization 40 mL of the THF-filtrate was cooled to −78°C and the precipitated crude product separated off and dissolved in a THF/pentane mixture (1/1). After 48 h at −30°C, **2a** was obtained as pale-yellow platelet-shaped crystals.

^{13}C-NMR (7.5 MHz, [D$_8$]THF, $\delta \pm 1$ rel. TMS, ^1J(CH) ±1 in Hz): δ = 129.0 (C1; ^1J(CH) = 151.0), 117.9 (C2; 158.0), 125.5 (C3; 155.0), 119.5 (C4; 153.0), 51.7 (C9; 141.0), 51.0 (C10; 124.0), 133.3 (C11), 149.2 (C12), 44.3, −0.85 (THF C-atoms).

2b is obtained analogously from 15.79 g (36.5 mmol) of **1b** [4] in 250 mL of THF at 54 bar ethene pressure (60°C, 6 d). Yield: 4.0 g (45%). Correct elemental analysis; pale-yellow platelet shaped crystals.

Anodic Grob Fragmentation of Bicycloalkylcarboxyl Acids to Specifically Disubstituted Cycloalkenes**

By *Ralf Michaelis, Ulrich Müller,* and *Hans J. Schäfer**

Dedicated to Professor Kenneth B. Wiberg on the occasion of his 60th birthday

The anodic oxidation of carboxylates leads, depending on the reaction conditions and the structure of the carboxylic acid, to radicals (Kolbe electrolysis[1]) or—in a secondary oxidation—to carbocations (non-Kolbe electrolysis[1,2]).

We have now found that stereospecifically 3,4-disubstituted cyclopentenes can be obtained from 3-substituted 6-hydroxy-2-norbornanecarboxylic acids by non-Kolbe electrolysis (Scheme 1). The reaction course resembles that observed by *Grob* et al. in the fragmentation of norbornyl tosylates.[3] Depending on whether there is an *exo*- or *endo*-substituent in the 3-position, either a *trans*- [Eq. (a)] or a *cis*-disubstituted cyclopentene [Eq. (b)] is obtained. Of additional preparative advantage is the fact that the two substituents do not have to be the same. Table 1 shows the broad spectrum of applications of the reaction.

The starting substances were obtained in a few steps in high yield by Diels-Alder reaction and hydrolactonization

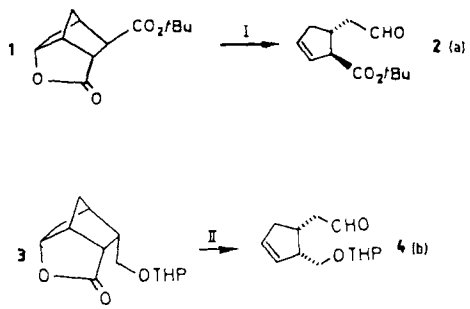

Scheme 1. I) LiOH in methanol, $-e^{\ominus}$, 0°C, graphite anode. II) KOH in acetonitrile/ethanol (5/1), $-e^{\ominus}$, 10°C, graphite anode. THF = tetrahydrofuran.

(**1**, **3**) and oxidation of the γ-lactones at a nickel hydroxide electrode[4] (**5**, **7**, **9**, **11**, **13**, **15**). **17** and **19** were obtained by α-alkylation of cyclohexanone with bromoacetate. **21** is the product of the Mn^{III}-acetate-oxidation of norbornene and subsequent oxidation of the γ-lactone.[4]

As shown in Table 1, the lactones, which open under the conditions of the non-Kolbe electrolysis to give γ-hydroxycarboxylic acids, fragment to cyclopenteneacetaldehydes (**2**, **4**). The γ-oxocarboxylic acids correspondingly form cycloalkeneacetic acids, which are isolated in the form of their methyl esters (**6**, **8**, **10**, **12**, **14**, **16**). In the case of **17** an elimination with subsequent double-bond isomerization takes place, but also here the fragmentation can be achieved—by ketalization of the carbonyl group (**19**). **21** fragments analogously.

The readily and specifically accessible products are suitable, inter alia, for the synthesis of cyclopentanoid natural products.

Experimental Procedure

The experimental procedure is described for the example **10**. A solution of **9** (0.25 g, 1.00 mmol) in methanol (50 mL) was neutralized to 100% with 1 M NaOH in methanol and electrolyzed at graphite electrodes in an undivided cell using a current density of 10 mA cm^{-2} at 0°C until consumption of 4 F mol^{-1}. The solution was then evaporated to dryness, treated with saturated NaCl solution, and extracted five times with CH_2Cl_2. After drying ($MgSO_4$) and removal of the CH_2Cl_2, 0.11 g (55%) of **10** was obtained as a colorless oil by column filtration (silica gel, petroleum ether/ether = 2/1). After acidification with conc. HCl to pH = 1 and threefold extraction with CH_2Cl_2, 0.04 g (16%) of **9** was recovered from the aqueous phase.— **10**: IR (film): $\tilde{\nu}$ [cm^{-1}] = 3040, 1720 (C=O). ^{1}H-NMR ($CDCl_3$): δ = 1.45 (s, 9H; *t*Bu), 2.06 (J = 14.4, 6.1, 4.5, 2.2 Hz, 1H; 4-H), 2.41 (J = 15.4, 8.4 Hz, 1H; 6-H), 2.58 (J = 15.4, 6.1 Hz, 1H; 6-H), 2.70 (J = 14.3, 8.5, 4.7, 2.1 Hz, 1H; 4-H), 2.87 (J = 9.5, 8.4, 6.3, 6.3, 1H; 5-H), 3.18 (J = 6.3, 4.8, 2.4 Hz, 1H; 1-H), 3.67 (s, 3H; Me), 5.65 (J = 5.8, 4.6, 2.2 Hz, 1H; 3-H), 5.78 (J = 5.8, 4.6, 2.1 Hz, 1H; 2-H). — MS (70 eV): *m/z* (%) 184 (15, $M^{\oplus} - C_4H_8$), 167 (13, $M^{\oplus} - OC_4H_9$).

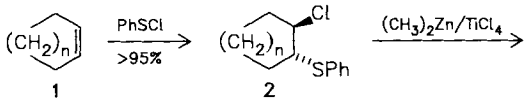
Regio- and Stereoselective Carbosulfenylation of Olefins**

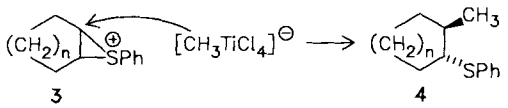
By *Manfred T. Reetz,** and *Thomas Seitz*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

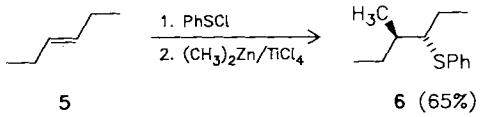
Lewis acidic organotitanium reagents[1] such as CH_3TiCl_3[2] or trichlorotitanium enolates[3] undergo C-C coupling reactions with S_N1-active alkylating agents, e.g. with tertiary or aryl-activated secondary alkyl halides. Since carbocations occur as intermediates, mixtures of enantiomers[4] or diastereomers are formed in stereochemically relevant cases.[1] However, if the alkylating agent contains a suitable neighboring group, then not only is an increased reaction rate to be expected, but also retention of configuration (double inversion).[3,5] In the following communication we report on regio- and stereoselective reactions of Lewis acidic methylmetal reagents with β-chlorosulfides, in which the sulfur residue functions as the neighboring group.[6]

When the *trans*-β-chlorosulfides **2** obtained from cyclic olefins **1** are allowed to react in a one-pot process with dimethylzinc in the presence of 20 mol-% $TiCl_4$ in dichloromethane, the C-C coupling products **4** are formed with complete *retention* of configuration.[7] The same holds true for the carbosulfenylation of the prochirally pure olefin **5** to **6**. Since $(CH_3)_2Zn$ reacts spontaneously with $TiCl_4$ to give CH_3TiCl_3 and $(CH_3)_2TiCl_2$,[2] the latter are probably the alkylating reagents. Supported by the PhS-neighboring groups they effect the formation of episulfonium ions **3**,[8] which are attacked stereospecifically by the complex counterion (e.g. $[CH_3TiCl_4]^{\ominus}$). The only by-products are the starting olefins and CH_3SPh, which are formed by nucleophilic attack at the sulfur in the episulfonium ion **3**. Besides $(CH_3)_2Zn/TiCl_4$, the more reactive $(CH_3)_3Al$ (CH_2Cl_2, 0°C, 22°C/5 h) is also an effective reagent (80% **4b**).

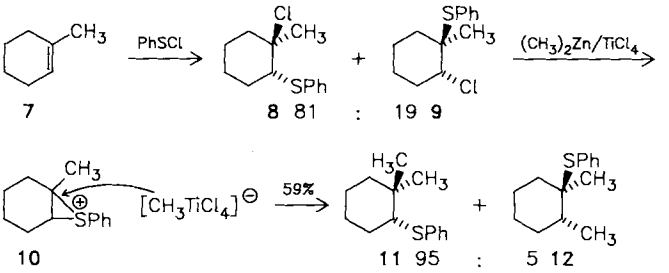


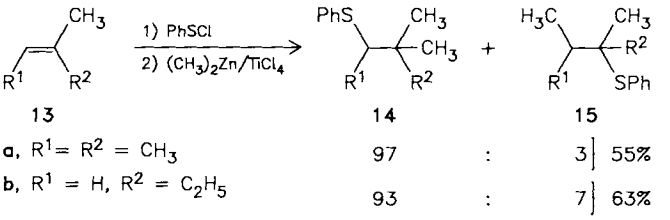


a, n = 1(78%); b, n = 2(68%); c, n = 3(50%)

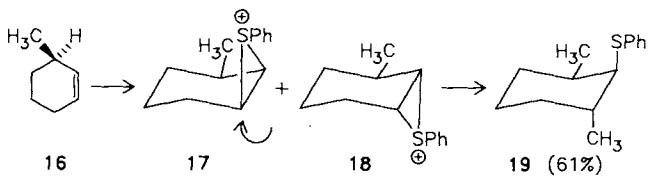


Noteworthy is the regioselectivity of the C-C coupling in the case of di- and trisubstituted olefins: the methyl group is always placed at the higher substituted C-atom. The regioselectivity of the reversible chlorosulfenylation is incomplete, but this is of no importance, since both adducts (e.g. **8**/**9**) lead to the same episulfonium ion (e.g. **10**). Charge control determines the regioselectivity of the subsequent irreversible methylation. In the case of **13a**, the use of $(CH_3)_3Al$ was also examined: the mixture **14**/**15** (97 : 3) was formed in 68% yield.





Finally, the regioselectivity as well as the 1,2-asymmetric induction in the case of α-chiral 1,2-disubstituted olefins were investigated. In the case of the cyclic olefin **16** the regioselectivity is 85% and **19** is formed with >99% diastereofacial selectivity. Probably two episulfonium ions **17** and **18** are formed in equilibrium. For stereoelectronic reasons, only **17** undergoes a *trans*-1,2-diaxial ring opening to give **19** in the chair conformation.[7]



In the case of the acyclic olefins **20** with electronegative moieties at the chiral center, the carbosulfenylations are likewise regio- and, depending on the nature of the protective group on the oxygen, stereoselective (Table 1). The regioselectivity can be explained in terms of steric and electronic effects. More difficult is an interpretation of the 1,2-asymmetric induction.[9,10] As a possible model we postulate the preferred formation and reaction of the episulfonium ion **21**, in which an electrostatic attraction between

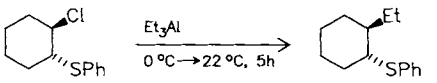
CH_3	C_2H_5	0	40	99 : 1

[a] The carbosulfenylation was carried out at the given temperatures, the methylation immediately thereafter with $(CH_3)_2Zn/TiCl_4$ at 0°C→22°C/15 h.

the positive sulfur atom and the electron-rich oxygen residue has a stabilizing effect.[11] Consistent with this hypothesis is the significantly smaller 1,2-asymmetric induction with larger protective groups which hinder this interaction. The influence of the temperature of the PhSCl addition on the stereochemistry of the subsequent methylation points to a possible equilibration of diastereomeric β-chlorosulfides.[11] The diastereoselectivity can even be reversed with the *tert*-butyldimethylsilyl protective group. The results are preparatively important, since the interplay of 1,2-asymmetric induction and *trans*-stereospecificity leads to a well-defined 1,3-stereorelation.[7]

Preliminary experiments with further organometallic reagents as well as other arylsulfenyl chlorides can be summarized as follows: ethyl moieties can be stereospecifically introduced with $AlEt_3$ (e.g. **2b**→**25**).



2b **25** (85%)

Organoaluminum reagents are less suited for allyl ethers, since, inter alia, ether cleavages occur. Cuprates such as $(CH_3)_2CuLi$ do not effect methylation. Replacement of PhSCl by 2,4,6-triisopropylphenylsulfenyl chloride leads to adducts which afford fewer by-products with $(CH_3)_2Zn/TiCl_4$ (starting olefins/CH_3SPh). For example, the adduct of cyclohexene can be methylated to the extent of 90% (82% isolated, in contrast to 68% in the case of **4b**). The bulky residue on the sulfur suppresses the undesired thiophilic attack. It remains to be seen whether these steric effects also influence regio- and stereoselectivity.[12]

Paterson, *ibid. 24* (1983) 5911).
[7] The *trans* arrangement in **4** was demonstrated ^{1}H-NMR spectroscopically. In the case of **19**, desulfurization (Raney nickel) led exclusively to the known *trans*-1,3-dimethylcyclohexane. The assignment of the compounds **23/24** was achieved as follows: after removal of the protective group on the oxygen, the sulfur residue was methylated with $(CH_3)_3OBF_4$ and an epoxide was formed stereospecifically (**23** gave the *cis*-epoxide, **24** the *trans*-isomer).

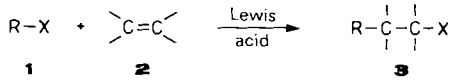
[9] Electrophilic additions to chiral olefins with electronegative substituents at the allyl position proceed stereochemically differently depending on the electrophile and substrate. For a survey of the literature on this theme as well as an attempted explanation [10] see: S. D. Kahn, W. H. Hehre, *J. Am. Chem. Soc. 109* (1987) 666.
[10] Alternative theories: K. N. Houk, S. R. Moses, Y.-D. Wu, N. G. Rondan, V. Jäger, R. Schoke, F. R. Fronczek, *J. Am. Chem. Soc. 106* (1984) 3880; K. N. Houk, M. N. Paddon-Row, N. G. Rondan, Y. D. Wu, F. K. Brown, D. C. Spellmeyer, J. T. Metz, Y. Li, R. J. Loncharid, *Science 231* (1986) 1108.
[11] Of course, **22** can also assume a conformation in which the alkoxy group is situated near the sulfur residue; this would, however, cause an unfavorable steric interaction between the methyl group and the three-membered ring. Use of the Hehre model in which the entering electrophile is guided by the alkoxy residue [9] would require a kinetically controlled reaction.
[12] *Typical procedure:* Phenylsulfenyl chloride (2.9 g, 20 mmol) is added at 0°C (or −78°C) (see Table 1) to a solution of cyclohexene (2 mL, 20 mmol) in anhydrous CH_2Cl_2 under argon until a permanantly pale-yellow colored solution is obtained (quantitative conversion). After 10 min, 5 mL of a 4 M $(CH_3)_2Zn$-solution in CH_2Cl_2 (1.9 g; 20 mmol of pure $(CH_3)_2Zn$) is syringed into the stirred reaction solution at 0°C. Upon subsequent addition of $TiCl_4$ (0.44 mL, 4 mmol) the solution turns blood red. Thereafter the solution is stirred for 15 h at room temperature. The black-brown mixture is poured into 100 mL of ice-water, treated with 2 N HCl to dissolve any precipitate, and the aqueous phase extracted several times with ether. The combined organic phases are washed with $NaHCO_3$ and NaCl solutions and dried over $MgSO_4$. After removal of the solvent the residue is distilled in a Kugelrohr (80–82°C/1 torr). Yield: 2.7 g (68%) of pure **4b**. The same procedure using 2,4,6-triisopropylsulfenyl yields, after column chromatographic purification, 82% of the analogous product.

Control of the Relative Electrophilicity of Alkylating Agents by Variation of the Lewis Acid Concentration**

By *Herbert Mayr**, *Christian Schade*, *Monika Rubow*, and *Reinhard Schneider*

Dedicated to Professor George A. Olah on the occasion of his 60th birthday

The Lewis acid-catalyzed addition of alkyl halides **1** to alkenes **2** represents a straightforward method for the formation of CC-bonds.



1 **2** **3**

When only small equilibrium concentrations of carbenium ions are generated during such reactions, the selective formation of 1 : 1 products can only be achieved if the reactants **1** ionize faster than the products **3**.[1] Other regularities result when the condition ΔG^0 (ionization) ≫ 0 is abandoned, and the foregoing rule turns out to be a special case of a more general principle.[2] We now demonstrate

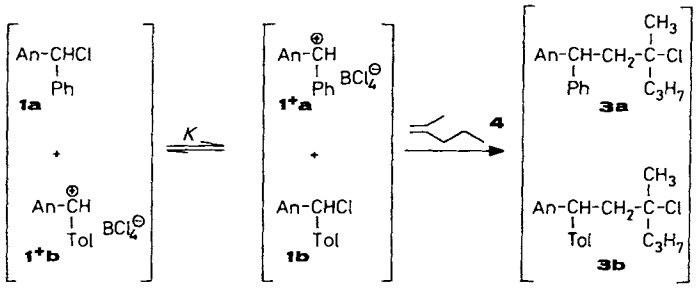
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *C. S.* thanks the Stiftung Volkswagenwerk for a Kekulé fellowship.

for a model reaction, how to invert the relative reactivities of alkylating agents by varying the concentration of the Lewis acid (see Scheme 1).



Scheme 1. An = *p*-methoxyphenyl, Tol = *p*-tolyl.

When 5 equivalents of BCl_3 (6.0 mmol) and 0.20 mmol of 2-methyl-1-pentene **4** are added successively to a solution of the diarylmethyl chlorides **1a** (0.40 mmol) and **1b** (0.80 mmol) in dichloromethane, the 1 : 1 adducts **3a** and **3b** are formed in the ratio 2.98 : 1. From this experiment, a competition constant $k_a/k_b = 7.2$ is derived,[3] which is closely similar to the ratio of the rate constants directly measured for the reactions of $\mathbf{1}^+\mathbf{a}$ and $\mathbf{1}^+\mathbf{b}$ with **4** (7.06);[4] under these conditions both diarylmethyl chlorides are fully ionized.

Reduction of the BCl_3 concentration causes a decrease of the reactivity ratio *a/b* (Fig. 1), and a value of 0.18 is achieved when 0.05 equivalents of BCl_3 are used. The less reactive carbenium ion $\mathbf{1}^+\mathbf{b}$ now reacts preferentially, because of its higher concentration in the preceding equilibrium (Curtin Hammett situation[5]). A theoretical value of 0.18 is obtained for the competition constant at low catalyst concentrations by multiplication of the ratio $k(\mathbf{1}^+\mathbf{a})/k(\mathbf{1}^+\mathbf{b})$ with the NMR spectroscopically determined equilibrium constant $K = ([\mathbf{1}^+\mathbf{a}][\mathbf{1b}])/([\mathbf{1a}][\mathbf{1}^+\mathbf{b}]) = 0.025$.

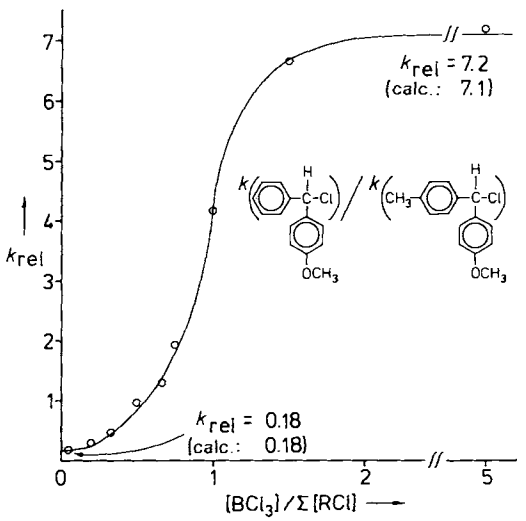


Fig. 1. Relative reactivity of the diarylmethyl chlorides **1a/b** towards 2-methyl-1-pentene in CH_2Cl_2 at −70°C as a function of the Lewis acid concentration.

In this system, the difference between the reactivities of two electrophiles increases with increasing difference of the ionization standard free enthalpies ($\Delta\Delta G^0_{ionization}$) of the two competitors. Under conditions of prevailing ionization, the *p*-phenoxy-substituted benzhydryl cation is 5400 times more reactive than the bis(*p*-methoxy)-substituted benzhydryl cation, while in presence of catalytic amounts of Lewis acid the relative reactivity is 0.016 (Fig. 2).

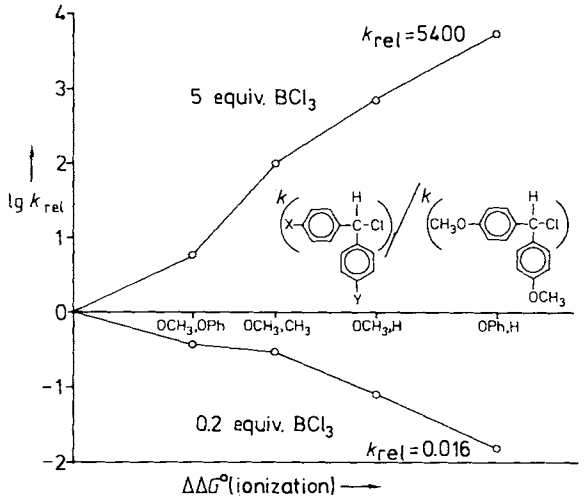

Fig. 2. Relative reactivity of *para*-substituted diarylmethyl chlorides towards 2-methyl-1-pentene in presence of catalytic amounts of Lewis Acid (bottom) and under conditions of complete ionization (top) (CH_2Cl_2/ −70°C).

A situation as described above is generally encountered in electrophilic alkylations of the type $\mathbf{1} + \mathbf{2} \rightarrow \mathbf{3}$. The $\mathbf{1}/\mathbf{1}^+$ and $\mathbf{3}/\mathbf{3}^+$ couples compete for the alkene **2**, and it depends on the magnitude of the particular competition constant, whether selective formation of $\mathbf{3}/\mathbf{3}^+$ or polymerization takes place. Hence the following rules result:

A: *If the carbenium ion* $\mathbf{1}^+$ *is less stabilized than* $\mathbf{3}^+$ [i.e. $\Delta G^0_{ionization}(\mathbf{1}) > \Delta G^0_{ionization}(\mathbf{3})$] *the selective formation of 1 : 1 products requires at least an equivalent amount of a completely ionizing Lewis acid.*

B: *If the carbenium ion* $\mathbf{1}^+$ *is better stabilized than* $\mathbf{3}^+$ [i.e. $\Delta G^0_{ionization}(\mathbf{1}) < \Delta G^0_{ionization}(\mathbf{3})$] *the 1 : 1 products are formed most selectively with (catalytic amounts of) the weakest possible Lewis acid.*

Since ΔH^0 ($\approx \Delta G^0 + \text{const.}$) of the ionization of alkyl chlorides and ΔG^+ of the corresponding solvolysis reactions are proportional to each other,[6] rule B is equivalent to the earlier alkylation rules,[1a,b] which were restricted to systems with a small degree of ionization. These rules have proven useful in the case of electrophilic carboxylations and carbonylations of alkenes[7a] and for a new cyclopropene-cyclopropenone synthesis by addition of trichloropropenylium ions to olefins.[7b]

Electrocatalytic Deposition of Polypyrrole**

By *Manfred Oberst* and *Fritz Beck**

Ever since it was demonstrated that durable films are produced on electropolymerization of pyrrole in aqueous[1] and non-aqueous[2] electrolytes, polypyrrole has been the subject of intensive study. In the past few years particular attention has been paid to reversible discharging and recharging of primarily co-deposited anions in view of a possible application as battery electrodes or in electrochromic displays (cf. Refs. [3, 4]). Other possible applications, e.g. in corrosion protection are being studied. The continuous preparation of polymer films by electrochemical deposition on slowly rotating anode cylinders has been described.[5] For the mechanism of the electrochemical deposition the primary formation of a radical cation is assumed as a direct electrode process [Reaction (a)].

$$\text{pyrrole} \longrightarrow \text{pyrrole}^{\oplus\ominus} + e^{\ominus} \qquad \text{(a)}$$

As second reaction step there follows a C–C coupling in the 2-position, either between two radical cations or between a radical cation and a neutral molecule.[6, 7] Since these dimers can (at less positive potentials) be readily further oxidized, the oxidative synthesis of the polymer proceeds according to a scheme 2+2, 2+4, 4+4, etc. When the solubility limit of the oligomers is reached a solid phase forms.

Our voltammetric measurements for the electrodeposition of polypyrrole at a rotating platinum disk electrode reveal a primary step (Fig. 1a), which is partially kinetically determined, even when using freshly distilled, highly pure pyrrole. Polypyrrole is deposited both in the region of the prewave as well as in the positive main branch. The prewave is also observed with Bu_4NBF_4 as supporting electrolyte. It is independent of the pyrrole concentration down to small values (0.01 M). From these findings we conclude that the pyrrole is reacting in the adsorbed state. A polypyrrole layer behaves thereby like platinum.

We have now surprisingly found that a bromine-catalyzed electrodeposition of polypyrrole is also possible. The current-voltage curve in the presence of 1 mM $Br^{\ominus}$ is reproduced in Figure 1b. Once again a prewave can be recognized, but at still more negative potentials. In the course of this primary step *no* film formation is observed. The deep-colored polypyrrole is already clearly recognizable at a layer thickness of 100 nm. During this prewave a polypyrrole film of about 0.5 μm thickness could have been formed. Polypyrrole first grows in the steeply rising part, which coincidentally occurs at the same potential as the prewave in Figure 1a. As experiments on large platinum sheets have shown, the current efficiency is almost 100% (referred to the theoretical value of 2.4 F/mol). The current-voltage curve in the absence of pyrrole, i.e. with 1 mM $Br^{\ominus}$ in acetonitrile (0.1 M Bu_4NBF_4 as supporting electrolyte) shows two steps in the ratio 2 : 1 (cf. Fig. 1c). Consistent with earlier measurements in acetonitrile[8, 9] we assign the first step, which appears at the same potential as the prewave in Figure 1b, to the formation of the tribromine anion [Reaction (b)].

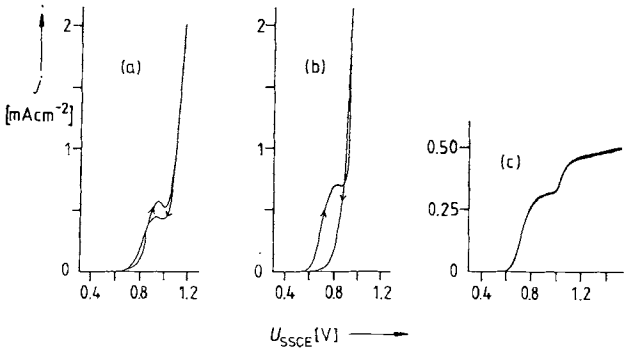

Fig. 1. Current-voltage curves at the rotating Pt-disk electrode ($A = 0.5$ cm^2 at 200 rpm and a voltage scan rate of $v_s = 2$ mV s^{-1}. Solvent: anhydrous acetonitrile; 20°C). a) Bromide-free system, 0.1 M pyrrole, 0.05 M $NaBF_4$; b) 0.1 M pyrrole, 0.1 M Bu_4NBF_4, 1 mM Bu_4NBr; c) pyrrole-free system. Potentials "U_{SSCE}" versus the calomel electrode with $NaCl_{sat}$, which is 236 mV more positive than the standard hydrogen electrode.

$$3\,Br^{\ominus} \longrightarrow [Br_3]^{\ominus} + 2e^{\ominus} \qquad \text{(b)}$$

Only in the course of the second step is free bromine formed [Reaction (c)].

$$[Br_3]^{\ominus} \longrightarrow 3/2\,Br_2 + e^{\ominus} \qquad \text{(c)}$$

The free bromine, here formulated as tribromine complex can oxidize pyrrole radical cations according to [Reaction (d)].

$$\text{pyrrole} + Br_3 \xrightarrow{k} \text{pyrrole}^{\oplus\ominus} + [Br_3]^{\ominus} \qquad \text{(d)}$$

The anion is reoxidized at the electrode. The homogeneous reaction (d) takes place in a reaction boundary layer in front of the electrode. At higher pyrrole concentrations it is quasi first order. This means that the thickness of the reaction layer can be calculated using the simple relationship

$$\rho = \sqrt{D/k} \qquad \text{(e)}$$

where D = diffusion coefficient and k = first order chemical rate constant; ρ concomitantly determines the rate of back diffusion of the $[Br_3]^{\ominus}$ to the electrode. That is, with the assumption of a rapid electrochemical partial step, there is a current amplification proportional to $\sqrt{k}$ and to the concentration of pyrrole.

When a dilute solution of bromine in acetonitrile is mixed with a solution of pyrrole in acetonitrile a sudden decoloration is observed, followed by a slow coloration to dark-green and subsequent separation of a black precipitate of pyrrole black; its formation with chemical oxidizing agents has been investigated by *Gardini*.[10]

Experiments with the rotating ring-disk electrode reveal the presence of reducible oligomeric radical cations, but no Br_2. This means that reaction (d) is rapid. Our mechanism is also supported by the finding that, in the galvanostatic deposition progressively less substance is deposited on the rotating disk with increasing speed of rotation. Since the height of the two steps in Figure 1c and that of the primary step in Figure 1b increases proportionally to $\sqrt{\omega}$ (ω = angular velocity), and thus (according to *Levich*) there is a limiting diffusion, it follows that an ever greater increasing percentage of the current is involved in the ineffective reaction (b) with increasing ω.

A homogeneous redox catalysis by electrolytically generated bromine is also observed in other electroorganic

reactions, e.g. in the anodic methoxylation of furan[11] and the anodic oxidation of propylene to propylene oxide.[12] Even pyrrole has already been electropolymerized in aqueous HBr[13] and NaBr solution.[14] In this case, however, the polymer contains considerable amounts of bromine (up to 0.8 mol Br per pyrrole unit), which may in part be covalently bound. We use bromide in only small concentration, and the polymeric product contains practically no bromine; that is, bromide is a real catalyst. *Bidan* et al. have recently reported on the polymerization of 2-bromopyrrole to polypyrrole with cleavage of HBr.[15] Under our conditions, the intermediary formation of a bromine-substitution product can, however, be ruled out on kinetic grounds.

The practical significance of the electroanalytical deposition of polypyrrole lies in the realization of higher current densities. Whereas small current densities (below 1 mA cm^{-2}), which obviously lie in the region of the primary step in Figure 1a, are usually recommended,[16] a deposition is possible at essentially higher current densities in the presence of small bromide concentrations. In this way the scan times can be substantially decreased.

cis- and *trans*-1,2-Dilithioethylene**

By *Adalbert Maercker,** *Thomas Graule,* and *Wolfgang Demuth*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

We recently found that vicinal dilithioalkenes are accessible by addition of lithium to alkynes.[1] When the reaction is carried out with open-chain alkynes in diethyl ether, insoluble *trans*-products are formed, whereas cyclooctyne affords the soluble *cis*-1,2-dilithiocyclooctene. All attempts to prepare the 'parent compounds' *cis*- and *trans*-1,2-dilithioethylene have so far failed, even though at least the *trans*-compound has been estimated calculationally to have a higher stability than methyl- and vinyllithium.[2] Inconsistent with this proposal was the finding that only one stannyl moiety in the *trans*-1,2-bis(tributylstannyl)ethylene **1** ($R = n\text{-}C_4H_9$) can be replaced by lithium upon reaction with *n*-butyllithium.[3] We are therefore of the opinion that even *n*-butyllithium is more stable than *trans*-1,2-dilithioethylene **6**.[4]

Switching over to *tert*-butyllithium for the R_3Sn/Li exchange in **1** had little hope of success, however, since the ate-complex intermediate with four *tert*-butyl groups attached to the five-coordinate tin necessary for the second exchange would be sterically too demanding. Thus, e.g., even in the case of tetramethylstannane in this way maximally two methyl groups can be replaced by *tert*-butyl residues.[5] We have therefore replaced the four-coordinate tin by two-coordinate mercury prior to the reaction with *tert*-butyllithium and thus indeed have been able to achieve a double metal-metal exchange. The compounds **6** and **7** already formed at −75 °C in diethyl ether or THF were derivatized with dimethyl sulfate, which had the advantage that the gaseous reaction products *trans*- **9** and *cis*-2-butene **10** could be driven out of the reaction mixture and quantitatively determined as *meso*- **8** and *d,l*-2,3-dibromobutane **11**, respectively, after passage into a solution of bromine in chloroform. The analysis was accomplished gas chromatographically as well as by combined GC/MS.

One could argue that the derivatization might also have proceeded stepwise, i.e. that the second Hg/Li exchange has taken place only after the introduction of the first methyl group. This argument can easily be invalidated: It could be shown that the metal-metal exchange in the presence of dimethyl sulfate functions very poorly, since *tert*-butyllithium reacts much more rapidly with dimethyl sulfate than with the mercury compounds.[6] The finding that the amount of di-*tert*-butylmercury in the reaction mixture before and after the derivatization is the same, also speaks against a mercury-lithium exchange during the addition of the dimethyl sulfate. Crystallization of the 1,2-dilithioethylenes and thus the separation from the di-*tert*-butylmercury has so far not been accomplished. No statements can be made therefore about the exact structure and degree of association of the compounds.

Interestingly, it was observed that reaction of *cis*-1,2-bis(chloromercurio)ethylene **3** containing 7% **2** at −75 °C does indeed afford the 2-butenes **10** and **9** in the ratio 93 : 7, but, after 10 min at 0 °C, the amount of *trans* product increases to 65%. This first suggested a rapid rearrangement of the *cis*-1,2-dilithioethylene **7** into the *trans*-isomer **6**.[7] In the meantime it has emerged that this *cis-trans* rearrangement **7** → **6** is only simulated due to a very much higher *kinetic* stability of **6** in comparison to **7**. Namely, *cis*-1,2-dilithioethylene **7** decomposes particularly rapidly, splitting off lithium hydride,[8] and, as expected, the lithioacetylene **12** formed thereby is immediately metalated to dilithioacetylene **14**. Not only is excess *tert*-butyllithium suitable as metalating reagent, but also the dilithioethylenes themselves. The resulting vinyllithium **13**, like the dilithioacetylene **14**, was derivatized by dimethyl sulfate, so that finally the bromination products of propene **15** and 2-butyne **16** could be detected gas chromatographically in addition to **8** and **11**. The methane formed by reaction of lithium hydride with dimethyl sulfate was detected mass spectrometrically.

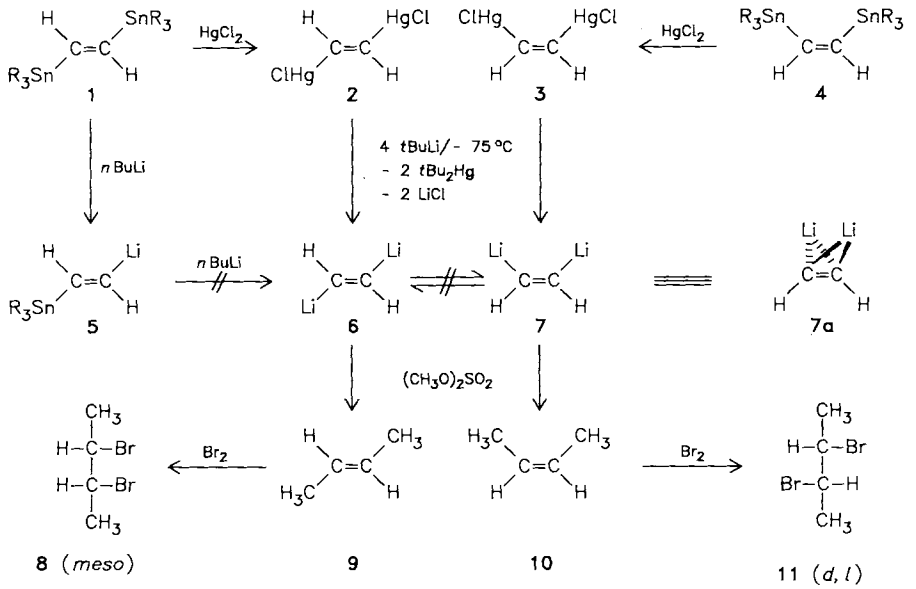
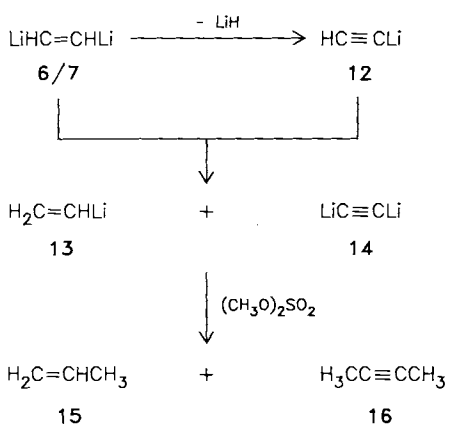
[**] Polylithium Organic Compounds, Part 6. This work was supported by the Fonds der Chemischen Industrie.—Part 5: [1].



8 (*meso*) 9 10 11 (*d, l*)

Indications that the rearrangement **6** ⇌ **7** does not take place were already provided in experiments in which *n*-decane had been added as standard. Despite varying yields it was recognizable that with increasing portions of *trans*-2-



butene **9** in the reaction mixture the overall yield of 2-butene **9** + **10** decreased, whereas the amount of propene **15** and 2-butyne **16** became greater and greater.[9]

Final proof of this conception was then possible however with the help of the isotope technique. Doubly deuteriated **2** and doubly deuteriated **3** were each prepared and allowed to react in the form of a 4 : 1 *cis-trans*-mixture consisting of [D_2]-**3** + **2** and **3** + [D_2]-**2**, respectively, with *tert*-butyllithium. In none of the cases was there any appreciable change in the isotopic composition of the *trans*-1,2-dilithioethylene **6** upon enrichment in the reaction mixture, i.e. a rearrangement **6** ⇌ **7** can be ruled out. Interestingly, in an incompletely deuteriated sample of *cis*-1,2-dilithioethylene, the deuterium is enriched; this can be attributed to an isotope effect during lithium hydride elimination (LiH > LiD). In the decomposition of an undeuteriated sample of **7** in deuteriated diethyl ether, no deuterium was incorporated in the vinyllithium **13**, i.e. the solvent is comparatively slowly decomposed.[10]

Experimental Procedure

6: 0.50 g (1.0 mmol) of **2**, prepared from **1** (R = *n*-C_4H_9) [11] by reaction with $HgCl_2$ [12], was slurried with 2.0 mL of anhydrous THF under argon in a 10 mL Schlenk tube. 2.8 mL (4.0 mmol) of a 1.44 M solution of *tert*-butyllithium in pentane (Metallgesellschaft, Frankfurt am Main) was then added to the vigorously stirred slurry (magnetic stirrer) within 15 min at −75 °C from a gas-tight syringe and the mixture stirred for a further 15 min at this temperature. Derivatization was then carried out with 0.6 g (4.76 mmol) of dimethyl sulfate in 2.0 mL of diethyl ether at −75 °C, whereby the gas formed was passed into a solution of 1.2 mmol of bromine in 10.0 mL of chloroform with *n*-decane as standard. To ensure complete transfer of the dissolved gas the reaction mixture was warmed slowly to room temperature, heated to reflux (35 °C), and a weak flow of argon passed through the apparatus for ca. 10 min. Gas chromatographic analysis revealed an overall yield of 84.3% of dibromo adducts: 9.5% ethylene (at least partly from the solvent), 14.2% propene **15**, 13.0% 2-butyne **16**, 47.3% *trans*-2-butene **9**, and 0.3% *cis*-2-butene **10**.

3, prepared from **4** (R = CH_3) [13], was allowed to react in an analogous way with *tert*-butyllithium.

The starting material for [D_2]-**2** and [D_2]-**3** was the corresponding *cis*-1,2-dideuterio-1,2-bis(trimethylstannyl)ethylene [D_2]-**4** (R = CH_3), which was prepared from dideuterioacetylene and from which the corresponding *trans*-compound [D_2]-**1** (R = CH_3) can be synthesized by photoisomerization [13].

[6] Small amounts of 2-butene are indeed also formed, but no 2-butyne, since, in contrast to 1,2-dilithioethylene, the monolithioethylene precursors do not split off lithium hydride.
[7] According to ab-initio calculations carried out in 1979 [2], **6** should be 1.4 kcal/mol less stable than **7**. The energies of the two 1,2-dilithioethylenes were therefore recently recalculated using improved methods, with the result that the *trans*-compound is now 1.6 kcal/mol more stable than the *cis*-isomer **7a**. A computerized determination of the reaction mechanism of the *cis-trans* isomerization has also been proposed. Cf. P. von R. Schleyer, E. Kaufmann, A. J. Kos, T. Clark, J. A. Pople, *Angew. Chem. 98* (1986) 164; *Angew. Chem. Int. Ed. Engl. 25* (1986) 169.
[8] The easy elimination of lithium hydride from 1,2-dilithioethylene is remarkable, since according to calculations [2] it should proceed strongly endothermally, much more unfavorably than the elimination of H_2 or Li_2, neither of which have we been able to observe. We presume that lithioacetylene initially forms a relatively stable complex with lithium hydride. This could be similar to the case of 1,2-dilithioethane, where the experimental results could also be only explained theoretically after assuming formation of an extremely stable complex of vinyllithium with lithium hydride.
[9] Some vinyllithium **13** and dilithioacetylene **14** are already formed during the synthesis at −75 °C, presumably by splitting off lithium hydride

from the second ate complex intermediate, as we have previously observed also in other Hg/Li exchange reactions [4].

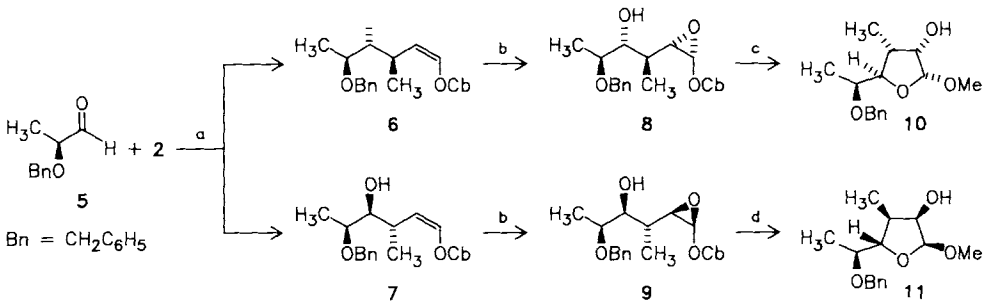
chain extension of optically active 2-oxyalkanals by a 2-hydroxy-3-methylpropanal unit **A** to give branched deoxyhexoses in three steps (including a simple diastereomer separation; Scheme 1).

(*S*)-2-Benzyloxypropanal **5**,[5,6] obtained from (*S*)-ethyl lactate, reacts with **2**[3,4] to give two enantiomerically pure (*Z*)-3,4-*anti*-adducts[7,8] **6** and **7** in the ratio 53:47 (42.5% of **6** and 37.5% of **7** after a simple chromatographic separation on silica gel). As expected, the chiral center of the aldehyde **5** does not effect a diastereofacial differentiation, since the topicity of the carbonyl attack is determined by the stereogenic α-C-atom of the racemic reagent **2**.[9]



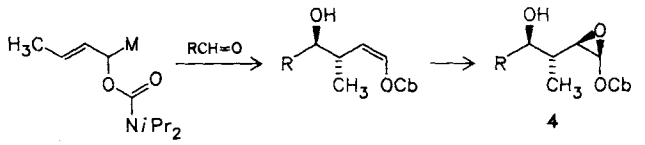
Scheme 1. a) 1.1 equiv. **2**, 16 h at −78°C, Et_2O; column chromatography (LC) on silica gel, ether/hexane. b) 1.5 equiv. *t*BuOOH [10], 2 mol% $VO(acac)_2$; 0.07 M in CH_2Cl_2, 16 h, 0→20°C; c) unpurified **8** in 5 mL of anhydrous CH_3OH and 5 mL CH_2Cl_2/mmol, 1.0 equiv. Et_3N, LC [1b]. d) As for c), but without CH_2Cl_2.

Enantioselective Synthesis of Methylfuranosides of Unnatural 3,6-Dideoxy-3-methylaldohexoses from Lactates by Homoaldol Reactions**

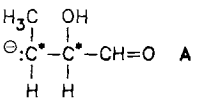
By *Dieter Hoppe,* Gerhard Tarara, Marcus Wilckens, Peter G. Jones, Dieter Schmidt,* and *John J. Stezowski*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 60th birthday

As we have recently shown,[1] simple racemic 1-oxyoxiranes of type **4** with four contiguous chiral centers are accessible with high diastereoselectivity (>98% *ds*) in only two steps by homoaldol reactions:[2] addition of the α-titanated[3] (*E*)-2-butenylcarbamate **2**[4] to prochiral aldehydes yields the *anti*-enolcarbamates **3**, which are converted via vanadyl-catalyzed oxidation into the reactive epoxides **4**. Depending on the reaction conditions, nucleophiles open the three-membered ring either at C-2 (inversion of configuration) or at C-1 (retention at C-2[1b]). We now report the



1, M = Li · tmeda
2, M = $Ti(NEt_2)_3$
Cb = $CNiPr_2$; racemates



The reaction of the more polar 4,5-*anti*-diastereomer **6** with di(*tert*-butyl) hydroperoxide via $VO(acac)_2$-catalysis[10,2a] yields the diastereomerically pure crystalline epoxide **8** (yield 92%), whose relative—and thus absolute—configuration was confirmed by an X-ray structure analysis. **7** correspondingly afforded the epoxide **9** in 97% yield. Acid-catalyzed methanolysis[1b] of the oxirane **8** at −78°C leads in 75% yield to a single methylfuranoside **10**,[12] whose α-L-*allo* configuration followed from that of the precursor **6** and comparison of the ^{1}H-NMR spectrum with that of an analogue whose structure had been confirmed by a crystal structure analysis.[1b] In the same way, the diastereomer **9** furnishes β-L-*talo*-furanoside **11** in 79% yield.

The method outlined here should be generally applicable to the de-novo synthesis[13] of 3-*C*-branched deoxyaldoses. Few steps are necessary since the terminal C-atom in the homoenolate reagent **2** is already present as a masked carbonyl group and, in addition, the (1*Z*)-substituent in the adduct **6** and **7** permits subsequent reactions that are highly stereoselective. Further advantages are the formation of anomerically pure furanosides and the chemical differentiation of all hydroxy groups. The free 2-hydroxy group in **10** and **11** allows inversion of configuration at C-2 in a few steps. Thus *ent*-**10**[14] affords the α-D-*altro*-furanoside *ent*-**12** in 65% yield by successive trifluoromethanesulfonylation, acetolysis with cesium acetate,[15,16] and hydrolysis. Correspondingly, *ent*-**11**[14] furnishes the β-D-*galacto*-furanoside *ent*-**13** (yield 67%) (Scheme 2). Table 1 contains selected physical and NMR spectroscopic data for **8**–**11** as well as *ent*-**12** and *ent*-**13**.

The only drawback of the simple racemic reagent **2** is that two diastereomers are formed in similar amounts; this disadvantage does not apply to the enantiomerically pure 1-alkylated homoenolate reagents (e.g. CH_3 for 1-H in **2**).[9,17,18]

Cobalt-Mediated [2+2+2]Cycloadditions of Alkynes to the Imidazole 4,5-Double Bond. First Synthesis of the 3*a*,7*a*-Dihydrobenzimidazole Nucleus and Its Preliminary Chemistry Including a Novel Quinoline Construction**

By *Roland Boese, Hans-Joachim Knölker,* and *K. Peter C. Vollhardt**

We recently reported that the aromatic 2,3-double bonds in indole[1] and pyrrole[2] could be activated by $(C_5H_5)Co$ to enter into [2+2+2]cycloadditions[3] with alkynes giving rise to hitherto unknown heterocycles. An application of this methodology to the imidazole nucleus was deemed significant as: 1) it provided the opportunity to test the relative reactivities of a C–C versus a C–N double bond, 2) it represented a significant expansion of the substrate pool available to this reaction, and 3) it involved a heterocycle abundant not only in ordinary natural and/or medicinal products[4] but also in two of the nucleic acid bases, adenine and guanine. Herein we describe a novel mode of

1b, (X = H_2)	[8] (85)	**2a** $R^1 = R^2 = Si(CH_3)_3$	**3b** (*anti*) (18) **3b** (*syn*) (18)
1a	[7] (91)	**2b** $R^1 = CH_2CH_3$, $R^2 = Si(CH_3)_3$	**3c** (*anti*) (22) $R^1 = CH_2CH_3$, $R^2 = Si(CH_3)_3$
1a	[7] (91)	**2c** $R^1 = OCH_3$, $R^2 = Si(CH_3)_3$	**3d** (*anti*) (25) $R^1 = OCH_3$, $R^1 = Si(CH_3)_3$
1a	[7] (91)	**2d** $R^1 = COOCH_3$, $R^2 = Si(CH_3)_3$	**3e** (*anti*) (35) $R^1 = COOCH_3$, $R^2 = Si(CH_3)_3$ **3f** (*anti*) (10) $R^1 = Si(CH_3)_3$, $R^2 = COOCH_3$

Several comments are in order to amplify our data. 1) Some optimization of the efficiency of the reaction was carried out only for **3a** leading to an improvement of the initial yield from 26% (cyclization executed at 25 °C) to 72%. We have remarked earlier[2] that variation of the reaction conditions (temperature, solvent, addition rates, substrate ratios, use of $[(C_5H_5)Co(CH_2{=}CH_2)_2]$) can affect yields dramatically, and have refrained here from such an optimization for each case of **3**. Instead, the yields reported refer to a standard set of conditions [high dilution in 1,2-dimethoxyethane, reflux (with the exception of the cyclization of **1b**, which was carried out at room temperature), irradiation with a Sylvania ELH 300W tungsten lamp], under which the starting materials **1** are unstable. 2) The reaction is extensively chemoselective, none of the other possible cyclization products[3] being observed. 3) It is similarly stereoselective, the *cis*-stereochemistry around the 4,5-imidazole bond being preserved in the novel 3*a*,7*a*-dihydrobenzimidazole product, and the metal usually (with the exception of **3b**) emerging *anti*. 4) It is also highly regioselective, the trimethylsilyl group in **3** preferring the terminal diene position, in accord with mechanistic expectations;[3] an electronic effect[9] appears to be strongly influential in the formation of **3f**. 5) The structural assignments of **3** are based on spectral data[6] in comparison with model systems,[1,2] an X-ray structural analysis of **3e** (Fig. 1),[10] and chemical transformations.

Thus, complexes **3** (and also **5**, vide infra) could be demetalated [$CuCl_2$, $CH_3OCH_2CH_2OCH_3$, H_2O, 0 °C] to the free ligands (with the exception of **3d** *anti*, vide infra) in high yield.[6] In contrast to the analogous indole-derived

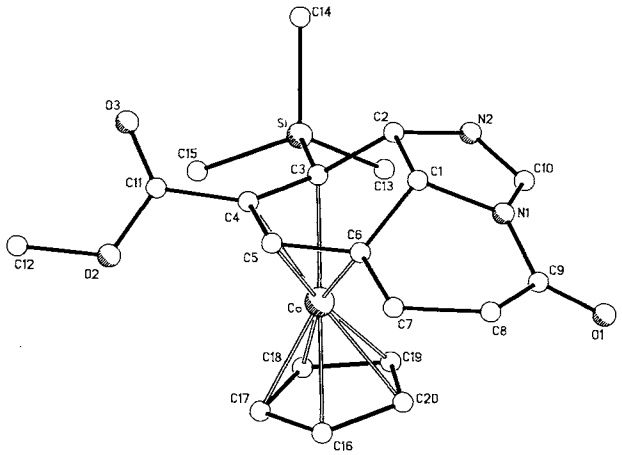

Fig. 1. Crystal structure of **3e** [10]. Important bond lengths [Å] and angles [°]: Co-C3 2.058(2), Co-C4 1.967(2), Co-C5 1.981(3), Co-C6 2.067(3), C2-C1-C6 113.8(2), C1-C2-C3 111.1(2), C2-C3-C4 116.1(2), C3-C4-C5 116.3(2), C4-C5-C6 115.9(2), C1-C6-C5 118.9(2).

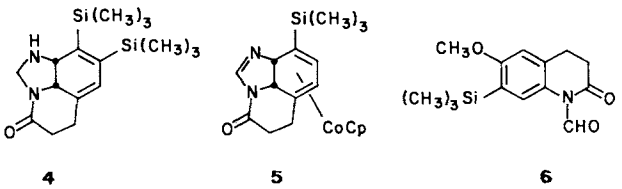
complex,[1] but in agreement with the related pyrrole system,[2] recomplexation of the free ligand derived from **3a** *anti* gave the original complex exclusively. While the new functional arrangement in **3a** *anti* is surprisingly inert to treatment with $NaBH_4$ or even $LiAlH_4$, exposure to $NaBH_4$ (2 equiv.) in 1,2-dimethoxyethane, followed by addition of $CuCl_2$ (4 equiv.)[11] in water gave rise selectively to the surprisingly stable **4** (72%).[6] Selective protodesilylation of **3a** *anti* to **5** (and also of **3f** *anti* to the analogous complex) could also be achieved [nBu_4NF, THF, 2 h, 25 °C, 91% **5**, m.p. 134 °C], a significant result in view of



4 **5** **6**

the number of related bis(trimethylsilylated) diene complexes that have become accessible by this technology.[1-3] Finally, and of clear relevance to further synthetic applications, the methoxy derivative **3d** *anti* was converted into the quinolone **6**[6] (ca. 60%), the result of a combined demetalation, aromatization, and imine hydrolysis process during which the original imidazole auxiliary is unravelled to leave a heterobicycle, constructed entirely in the cobalt-mediated step. Support for this sequence is derived from the isolation of the intermediate imine (6%) of **6** in this transformation. The generality of this process is under active investigation.

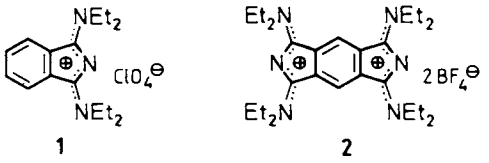
2,6-Diaza-*s*-indacenes**

By *Fritz Closs, Rudolf Gompper,* Ulrich Nagel,* and *Hans-Ulrich Wagner*

Donor and acceptor substituents in cyclopolyolefins generally reduce the HOMO-LUMO gap in (4n+2) π-systems and increase it in (4n) π-systems. This enables the synthesis of stable (4n) π-electron systems; examples are diethyl 2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate,[1] 1,3-bis(dimethylamino)-2-azapentalenes,[2,3] donor-acceptor-substituted cyclopentadienylium salts,[4,5] and azacyclopentadienylium salts.[6–8] The attachment of benzene rings to cyclopentadienylium salts naturally leads to a weakening of antiaromatic effects,[9] yet the NMR and MO data of the 1,3-bis(diethylamino)isoindolylium perchlorate **1** still show that a part of the positive charge is delocalized in the benzene ring in the sense of an 8π-electron system. This therefore raises the question of what sort of an effect the annelation of a positively charged ring element to **1**, as shown, e.g., in **2**, would have on the system. In contrast to **1**, **2** is a 10π-electron system. Its reduction ought to lead to 1,3,5,7-tetrakis(diethylamino)-2,6-diaza-*s*-indacene (**5**), a representative of the hitherto unknown class of diaza-*s*-indacenes. The Dewar resonance energies ($E^{\pi}_{ring} - E^{\pi}_{open\ chain}$ [HMO]) of *s*-indacene (1.639β), 2,6-diaza-*s*-indacene (1.738β), 1,3,5,7-tetraamino-*s*-indacene (1.700β), and 1,3,5,7-tetraamino-2,6-diaza-*s*-indacene (1.756β) show that *s*-indacene is an aromatic system and document an increase in aromaticity in **5** by the donor-acceptor effect. **5** has a very high-lying HOMO (according to HMO: 0.141β) and should thus be a strong reducing agent.



1 **2**

The convergence of the properties of donor-acceptor-substituted antiaromatic systems to those of aromatic ones also brings about, inter alia, a reduction or complete removal of the tendency to undergo double bond localization characteristic of antiaromatic systems. Evidence of this effect is provided by diethyl-2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate[10] and the 4,8-bis(dimethylamino)- and 1,3,5,7-tetra-*tert*-butyl-*s*-indacenes synthesized by *Hafner* et al.[11,12] Also in the case of 1,3,5,7-tetradonor-2,6-diacceptor-substituted *s*-indacenes, the MNDO heats of formation show that a tendency to undergo double-bond localization no longer exists. The double-bond localization parameters "λ_{max}" calculated according to the method of *Binsch* and *Heilbronner*[13,14] show the same trend: *s*-indacene (1.36), 1,3,5,7-tetraamino-*s*-indacene (1.18), 1,3,5,7-tetraamino-2,6-diaza-*s*-indacene (1.22).

The method developed earlier by us for the synthesis of **1**[6] from 1,1,3-trichloro-1*H*-isoindole opens up a route to **2** and **5**. Similarly to the conversion of phthalimide into trichloroisoindole,[15] pyromellitimide **3** can be converted into 1,1,3,5,5,7-hexachloro-2,6-diaza-1,5-dihydroindacene **4** (or into the 1,1,3,5,7,7-isomer) by heating with PCl_5/$POCl_3$ (yield of crude product almost quantitative). **4** reacts with diethyl(trimethylsilyl)amine in THF to give a blue product mixture, from which the yellow salt **2** can be separated (see Table 1) in 31% yield after treatment with sodium tetrafluoroborate/acetonitrile, stripping of the acetonitrile, addition of cold water and extraction of the aque-

ous phase with dichloromethane. Although one could expect that **2**, as a 10π-electron system, fundamentally differs from **1**, as an 8π-electron system, no significant difference is observable, at least in the electronic spectrum ($\lambda_{max}(CHCl_3)$: **1**: 375 nm; **2**: 440 nm; λ_{max} calculated according to PPP: **1**: 385 nm; **2**: 415 nm), and even the positions of the signals of H-4 and H-8 in the ^{1}H-NMR spectrum of **2** ($\delta = 8.05$) differs very little from the positions of the signals of H-4 to H-7 in **1** ($\delta = 7.96$). According to this, the interaction of the two azavinamidinium moieties in **2** appears to be relatively weak.

Table 1. Selected data of the compounds **2** and **5**–**11**.

2: m.p. = 276 °C; UV/VIS (CH_2Cl_2): $\lambda_{max}(\log\varepsilon) = 260$ nm (4.66), 269 (4.66), 326 (4.20), 352 (4.13), 420 (3.99), 434 (3.99), 440 (3.99); ^{1}H-NMR (80 MHz; CD_3CN): $\delta = 1.45$ (t; 12H, CH_2CH_3), 1.53 (t; 12H, CH_2CH_3), 4.00 (q; 8H, CH_2CH_3), 4.10 (q 8H, CH_2CH_3), 8.05 (s; 2H, H-4, H-8)

5: Violet rods with green-gold shiny surface decomp. > 120 °C; UV/VIS (hexane): $\lambda_{max} = 223$ nm, 260, 295, 306, 327, 343, 395, 609; (benzene): $\lambda_{max} = 313$ nm, 334, 376, 614; calculated according to PPP: $\lambda_{max} = 233$ nm, 249, 293, 596); ^{1}H-NMR (360 MHz; [D$_8$]THF): $\delta = 1.00$ (t; 24H, CH_2CH_3), 2.55 (q; 16H, CH_2CH_3), 7.66 (s; 2H, H-4, H-8)

6: m.p. > 350 °C; UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 337$ nm (4.37), 627 (4.16)

7: m.p. > 350 °C; UV/VIS (DMF): $\lambda_{max}(\log\varepsilon) = 314$ nm (4.62), 356 (4.52), 440 (sh), 464 (4.50), 497 (4.57), 610 (sh), 650 (4.64)

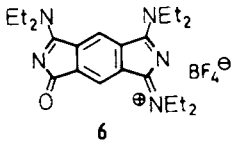
8: m.p. 295 °C; UV/VIS ($CHCl_3$): $\lambda_{max}(\log\varepsilon) = 320$ nm (4.62), 350 (sh), 375 (4.07), 390 (sh), 395 (4.09), 460 (sh), 484 (4.37), 506 (4.25), 518 (4.28)

9: m.p. > 350 °C; UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 333$ nm (4.38), 361 (4.25), 400 (sh), 484 (4.10), 507 (4.10), 545 (4.01)

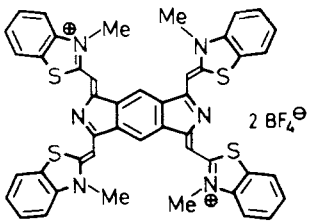
10: m.p. > 350 °C; UV/VIS (DMF): $\lambda_{max}(\log\varepsilon) = 347$ nm (sh), 362 (4.76), 394 (4.50), 419 (4.39), 520 (4.51), 543 (4.50)

11: m.p. 293 °C; λ_{max} (DMF) = *290* nm, *310*, 364, 395, 419, *490*, 520, 540, *800*, *880* (bands in italics occur in addition to the bands in **2** and **10**)

A series of colored by-products as well as **2** are formed from **4**. The violet compound **6** (see Table 1) can be separated in 3–5% yield from the mixture by column chromatography on silica gel (eluent $CHCl_3/CH_3OH$ 9 : 1).



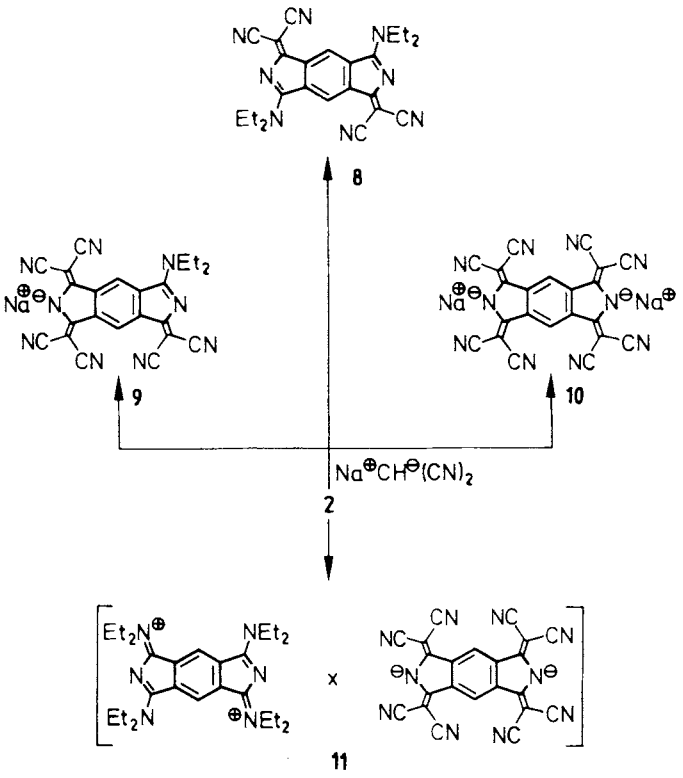
6



7

4 can also be reacted with enamines instead of with tertiary amines. If, e.g., 2,3-dimethylbenzothiazolium tetrafluoroborate is used as enamine precursor the dark green cyanine dye **7** results (see Table 1). The two chromophores of this compound are, as in the case of **2**, only weakly coupled. For comparison: the cyanine dye[16] prepared from aminoimino-1*H*-isoindole and a 2,3-dimethylbenzthiazolium salt absorbs at only about 25 nm shorter wavelength ($\lambda_{max} = 625$ nm) than **7**, which is somewhat less than the corresponding difference observed in the spectra of **2** and **1**.

2 can also be used for reactions with nucleophiles. For example, reaction with sodium malononitrile leads, depending on the molarity of the reactants, to **8**, **9** or **10** (see Table 1).



8, **9**, **10**, **2**, **11**

10, as dianion salt, is the electronic counterpart of the dication salt **2**. Combination of the aqueous solutions of **2** and **10** results in formation of the red compound **11** in 89% yield (see Table 1), which is predominantly present as the dication-dianion salt. However, **11** also partly contains radical cations, formed from **2** under the influence of **10**, as can be concluded from the UV/VIS spectrum. Namely, the bands at 800 and 880 nm also appear (in THF at 795 and 875 nm) when equimolar amounts of **2** and **5** are combined in THF.
