Kinetics and Stereochemistry of the $SO_4^{\odot\ominus}$-Induced Hydroxylation of Cyclohexenes in Aqueous Solution

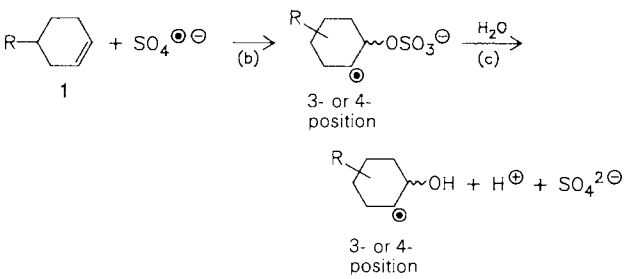
By *Günther Koltzenburg,* Eugenie Bastian,* and *Steen Steenken*

Alkyl radicals containing leaving groups such as Cl, OSO_3R, OPO_3R_2 (R = alkyl) in the β position are hydrolyzed in aqueous solution several orders of magnitude faster[1] than alkyl compounds containing the same leaving groups; e.g., $k_{hydrol}((CH_3)_2\overset{\odot}{C}CH_2Cl) = 3.5 \times 10^4\ s^{-1}$, $k_{hydrol}((CH_3)_3CCl) = 6.4 \times 10^{-3} s^{-1}$ at 22 and 15 °C, respectively.[1,2] β-Hydroxyalkyl radicals are thereby formed[1] [Eq. (a)].

$$(CH_3)_2\overset{\odot}{C}-CH_2Cl + H_2O \longrightarrow H^{\oplus} + (CH_3)_2\overset{\odot}{C}-CH_2OH + Cl^{\ominus} \quad (a)$$

Alkyl radicals containing sulfate groups in the β position are presumed to be the first intermediates in the $SO_4^{\odot\ominus}$-induced hydroxylation of olefins in aqueous solution.[3] Such reactions have found preparative applications.[4–6] Their mechanism, however, has not yet been completely determined and details of their kinetics are unknown. The possibility that an olefin radical cation[1,3] might be the first intermediate formed upon hydrolysis of the radicals in water (S_N1 mechanism) remains only speculation so long as an S_N2 mechanism, which would involve a polar transition state and thereby avoid the formation of an intermediate, cannot be ruled out. We were particularly interested in elucidating the mechanism of hydrolysis since the existence of chemical methods for the generation of short-lived olefin radical cations in water is a prerequisite for the comparative investigation of UV- or γ-radiation-initiated ionization processes of olefins and other unsaturated compounds in water.

Using pulse radiolysis and laser flash photolysis, we investigated the kinetics of the two-step reaction of $SO_4^{\odot\ominus}$ with several cyclohexenes [Eq. (b) and (c)]. The SO_4 radical



anions were generated from $S_2O_8^{2\ominus}$ either by pulse radiolysis employing a pulse length of 0.2 μs ($e_{aq}^{\ominus} + S_2O_8^{2\ominus} \longrightarrow SO_4^{\odot\ominus} + SO_4^{2\ominus}$) or by photolysis using a 20-ns flash ($S_2O_8^{2\ominus} \xrightarrow{h\nu} 2\,SO_4^{\odot\ominus}$). The formation of protons in reaction (c) was demonstrated by time-resolved conductivity measurements. Starting with low concentrations of cyclohexene, the rate of acid formation initially increases linearly with increasing concentration of cyclohexene, eventually leveling off to a plateau. From the linear part (reaction (b) rate-determining) it is possible to obtain k_b and from the plateau (reaction (c) rate-determining) k_c[7] (Table 1). We found no plateau value for α-terpineol **1d** and 2-methyl-α-terpineol **1e**, because the hydrolysis was too fast for the experimentally possible time resolution.

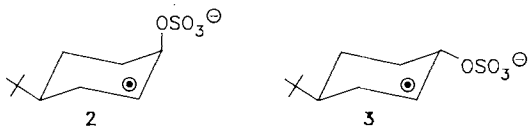
Table 1. Kinetic data for the reaction of SO_4 radical anions with cyclohexenes **1** (in O_2-free aqueous solutions at 20 °C).

	R	k_b [$M^{-1} s^{-1}$]	k_c [s^{-1}]
1a	H	1.7×10^9 [a]	3.0×10^4
1b	CH_2OH	4.3×10^9	6.5×10^3
1c	$(H_3C)_2COH$	4.6×10^9	8.4×10^3
1d	$(H_3C)_2COH$ [b]	4.6×10^9	$> 5 \times 10^6$
1e	$(H_3C)_2COH$ [c]	1.8×10^9 [a]	
		4.3×10^9 [d]	$> 5 \times 10^6$

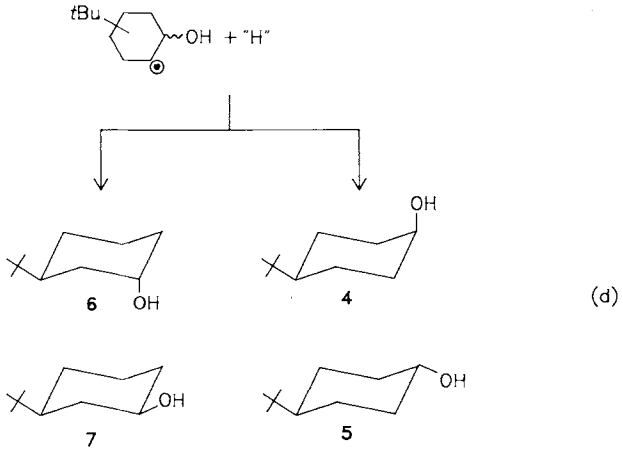
[a] In H_2O/acetonitrile 1 : 1. [b] Additional methyl group in 4-position to R. [c] Two additional methyl groups on the CC double bond. [d] In H_2O/acetonitrile 2 : 1.

The k_b values in water are close to those for diffusion-controlled reactions. In water/acetonitrile, they are somewhat smaller, pointing to a polar transition state for the $SO_4^{\odot\ominus}$ addition. Substituent and solvation effects are reflected in the k_c values. The increase of three or more orders of magnitude on going from norterpineol **1c** to α-terpineol **1d**[8–10] indicates a late transition state with pronounced charge separation.

We employed stereochemical criteria to further elucidate the reaction mechanism. The barium salts of *cis*- and *trans*-4-*tert*-butylcyclohexyl sulfate (10^{-2} M) were allowed to react with OH radicals in aqueous solution at pH 5–7 in the presence of dithiothreitol (= *threo*-1,4-dimercapto-2,3-butanediol, 5×10^{-3} M) as H donor (or at pH 3 in the presence of 10^{-2} M ascorbic acid) at room temperature. We generated the OH radicals by exposure of N_2O-saturated solutions to ^{60}Co γ-radiation. The radiation doses caused conversion of 3–10% of the substrate. Together with other H-abstraction radicals, the radical anions **2** and **3** were



formed with the conformations shown. Hydrolysis results in their conversion to β-hydroxycyclohexyl radicals [Eq. (c), R = *tert*-butyl]. They are then transformed by reaction with H donors (> 95% under our conditions) into the *tert*-butylcyclohexanols **4**–**7** [Eq. (d)].[11]



(d)

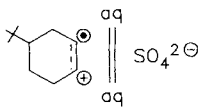
[*] Dr. G. Koltzenburg, E. Bastian, Dr. S. Steenken
Max-Planck-Institut für Strahlenchemie
Stiftstrasse 34-36, D-4330 Mülheim a. d. Ruhr 1 (FRG)

A conceivable isomerization of the β-hydroxycyclohexyl radicals before the reduction (e.g., by an $H^{\oplus}$-catalyzed 1,2 OH migration[12]) did not take place under our conditions. It requires pH values less than 1. The alcohols **4**–**7** were analyzed by GLC after extraction with ether (Table 2).

Table 2. Product composition after hydrolysis of the radicals **2** and **3** and subsequent reduction by H donors.

Radical	*tert*-Butylcyclohexanol [%]			
	4	**5**	**6**	**7**
2	38±2	4±1	52±2	6±1
3	54±2	6±1	35±2	5±1

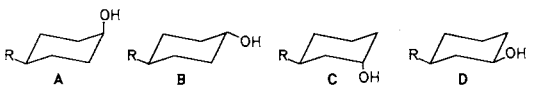
The values in Table 2 reveal that alcohols are formed with approximately 90% axial OH groups (**4** + **6**). Alcohols **5** and **6** (56±2% inversion), having *trans* configuration, predominate in the hydrolysis products of the radical **2**, having *cis* configuration. Alcohols **4** and **7** (59±2% inversion), having *cis* configuration, predominate in the hydrolysis products of the radical **3**, having *trans* configuration. The results are in clear agreement with the assumption of a largely solvent-separated 4-*tert*-butylcyclohexene radical cation/sulfate ion pair **8** as intermediate and thus point to an S_N1 mechanism.



8

Attack of water on the radical cation occurs before the sulfate group has completely departed. Therefore, the sulfate group hinders the approach of water somewhat from one side of the molecule. Otherwise, **2** and **3** afford a radical cation having the same conformation. In terms of kinetics, the attack of water competes with ion recombination and with further separation of the ions by water molecules, namely with processes for which a picosecond time scale has been measured for other cation/anion pairs.[13,14] Presumably, therefore, the radical cation of **8** has a lifetime in this range (10–100 ps). The high stereoselectivity of the water addition is remarkable when compared with the stereoselectivity observed in the direct radical hydroxylation of a cyclohexene with OH radicals (which we have studied here for the first time). As cyclohexene, the water-soluble norterpineol **1c** was used.[15] The results are summarized in Table 3.

Table 3. Product composition [%] after radical hydroxylation of **1c** in water both directly with $^{\circ}OH$ and indirectly with $SO_4^{\odot\ominus}$ followed by reduction with ascorbic acid; R = $(CH_3)_2COH$.



$^{\circ}OH$	29±1	21±1	29±1	21±1
$SO_4^{\odot\circ}$	46±2	4±1	46±2	4±1

In both cases, the hydroxylation is equally effective at either carbon of the double bond [(**C** + **D**) : (**A** + **B**) 1 : 1] and at either face of **1c** [(**A** + **D**) or (**B** + **C**)]. However, clearly evident is the high stereoselectivity in the indirect radical hydroxylation with $SO_4^{\odot\ominus}$ and the low stereoselectivity in the direct radical hydroxylation with $^{\circ}OH$ (**A** : **B**, **C** : **D**).

[7] The $SO_4^{\odot\ominus}$ addition to the CC double bond dominates, in all cases, over H abstraction from the substrate. The latter is revealed, for high concentrations of the substrate, in a relatively small, non-time-resolved conductivity jump occurring immediately after the laser flash.
[8] Methyl group effects of three or more orders of magnitude have been observed for the hydrolytic cleavage of leaving groups in the β position, for example with Cl as leaving group on alkyl radicals [1] as well as with $OCOCH_3$ [9] or OPO_3R_2 [10] as leaving group on α-alkoxyalkyl radicals.

[15] For the direct hydroxylation, N_2O-saturated aqueous solutions, containing 10^{-2} M **1c** and 10^{-2} ascorbic acid, were exposed to ^{60}Co γ-radiation; the doses used effect up to 5% conversion of **1c**. For indirect hydroxylation, the above solutions were saturated with argon and treated with ca. 20 mol% $K_2S_2O_8$, resulting in the formation of $SO_4^{\odot\ominus}$ and ascorbate radicals (in addition to $H^{\oplus}$ and $SO_4^{2\ominus}$). The ascorbate radicals do not effect hydroxylation of **1c**. The reaction solutions, after neutralization with NaOH, were analyzed directly by gas chromatography.

Isolation and Structure of $[(Fluorenone^{\odot\ominus})\{Na^{\oplus}(dme)_2\}]_2$—a Touchstone for Radical Contact Ion Pairs?**

By *Hans Bock,* Hans-Friedrich Herrmann, Dieter Fenske,* and *Helmut Goesmann*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

The formation of contact ion pairs $[M^{\oplus}A^{\ominus}]_{solv}$ in a common solvent cage involves a complex interplay of Coulombic attraction and single-ion solvation $M^{\oplus}_{solv} \cdots A^{\ominus}_{solv}$. The existence of such species, which are known to influence the course of numerous chemical and biochemical reactions,[2] has been firmly established by a variety of measurements.[1–3] Their structure in solution has been probed, for example, by ENDOR investigations[1,3] on radical salts such as that of 1-aminoanthraquinone (cf. **1**),[1] whose experimentally determined positive metal couplings indicate

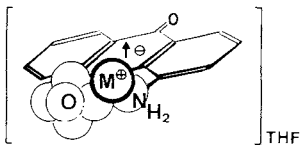
[**] Electron Transfer and Ion-Pair Formation, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 4: [1].

a π spin transfer and therefore a "docking" of the cations above the chelate plane.



1

We have now succeeded in growing deep red, metallically lustrous needles of the extremely air- and moisture-sensitive sodium salt of the fluorenone radical anion by ultrasound-activated stoichiometric reaction of sodium with fluorenone in pure dimethoxyethane at 260 K under argon followed by slow cooling of the deep red solution to 230 K.[4] The single-crystal X-ray structure analysis[5,6] (Fig. 1) revealed the presence of a dimer **2**.

those in the comparable benzophenone dianion (140.6 pm[7b]). Important structural information is provided by the dihedral angle ω(Na-O-C9-C10) = 76.3° (Fig. 1B, C): accordingly, the $Na^{\oplus}$ ion interacting most strongly with fluorenone$^{\odot\ominus}$ is situated 115 pm above the framework of the radical anion and lies about 28 pm outside of the perpendicular π_{CO} plane.

As a prototype of dimeric metal ketyls $(R_2CO^{\odot\ominus}Na^{\oplus})_2$, the ion quadruplet (fluorenone$^{\odot\ominus}Na^{\oplus})_2$ has been studied repeatedly by ESR spectroscopy,[8a] especially in methyltetrahydrofuran glasses at 100 K,[8b,c] and, on the basis of the observed zero-field (triplet) splitting, a C_{2v} geometry was eventually postulated.[8c] The structure of the tetrakis(dimethoxyethane) solvate **2** (Fig. 1) presented here further refines this prediction, although packing effects in the crystal cannot be ruled out. In solutions of higher concentration, electronic spectra indicate the formation of more highly aggregated ion clusters, especially for alkaline-earth metals,[8b] whereas, in dilute solutions, ENDOR measure-

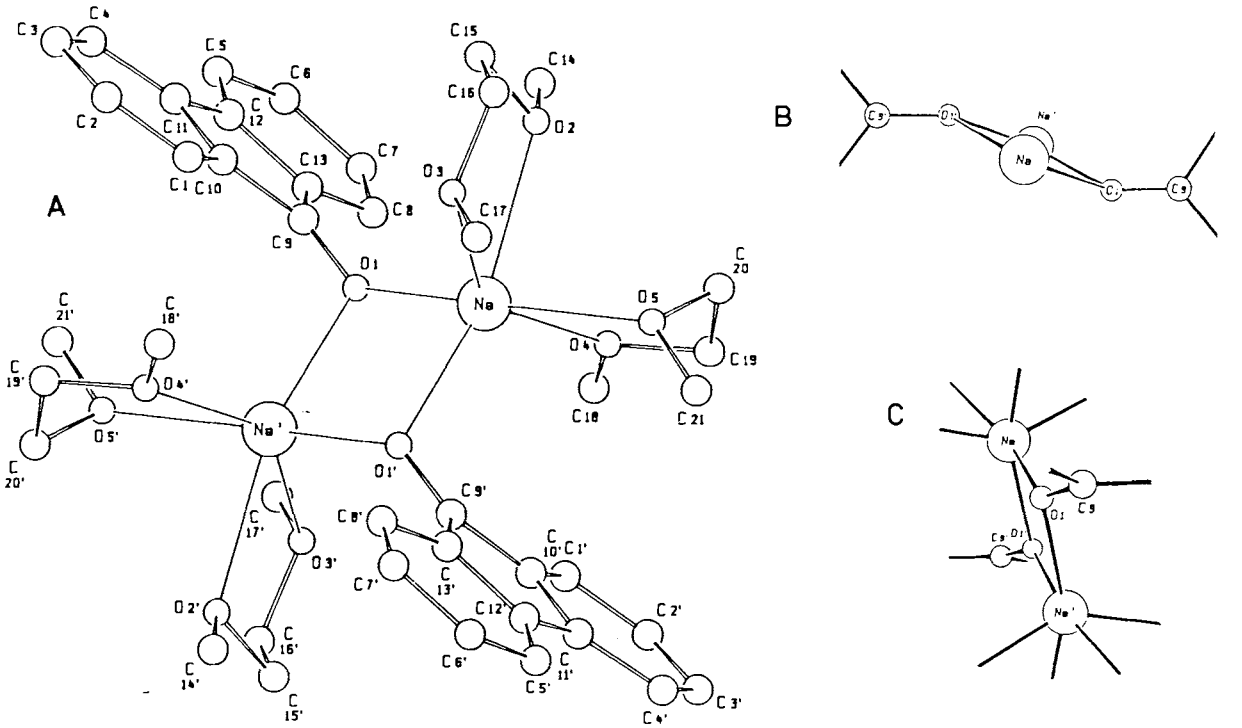


Fig. 1. Molecular structure of [(fluorenone$^{\odot\ominus}$)(Na$^{\oplus}$(dme)$_2$)]$_2$ **2** (A; H atoms omitted) as well as the cross section $Na_2O_2C_2$ perpendicular to the π planes (B) and after rotation by 90° (C). Important distances (±0.3 pm) and angles (±0.2°): Na-O1 228.1, Na-O1' 239.8, Na···Na' 335.0, O1···O1' 326.9, O1-C9 128.2; O1-Na-O1' 88.6, Na-O1-Na' 91.4, Na-O1-C9 141.0, Na'-O1-C9 117.7; Na-O1-C9-C10 76.3, Na-O1-C9-C13 73.3, Na'-O1-C9-C13 57.7. For further details see [6].

The structure of **2**, exhibiting C_i symmetry (Fig. 1A), reveals that the two [fluorenone$^{\odot\ominus}Na^{\oplus}$] moieties are linked by a planar, parallelogram-like Na_2O_2 four-membered ring (d_{NaO} 228.1 and 239.8 pm). The remaining four coordination sites of each $Na^{\oplus}$ ion are "solvated" by two dimethoxyethane molecules (d_{NaO} 245.1 to 252.4 pm). The molecular frameworks of the fluorenone radical anions, deviating slightly from planarity with the oxygens of the CO groups directed out of the plane by 8.5° ≙ 19 pm, are displaced perpendicularly to each other by approximately 100 pm about a center of inversion (Fig. 1C), and their CO axes are shifted parallel to each other by about 150 pm (Fig. 1B). As expected, the CO bonds in **2** (128.2 pm) are longer than those in neutral fluorenone (122.0 pm[7a]) and shorter than

ments prove the existence of only monomeric radical contact ion pairs (fluorenone$^{\odot\ominus}M^{\oplus})_{solv}$.[3] It should also be noted that the reduction of organic carbonyl compounds with, for example, sodium is used on a preparative scale for the synthesis of 1,2-diols HOR_2C-CR_2OH[9] and that dimers formed on the metal surface, in analogy to the generation of **2**, are presumably involved in the redox equilibria in solution.

The question posed in the title should be answered affirmatively—taking into consideration once again the complex processes involved in ion-pair formation and the possible crystallization of configurations favored by packing effects. The position of the most strongly interacting $Na^{\oplus}$ ion in the structure of **2** (Fig. 1)—above the fluorenone$^{\odot\ominus}$

framework and outside of the π_{CO} plane—is in agreement with expectations based on ESR/ENDOR measurements[3] in 10^{-5} M solutions (cf. **1**), in which partially fluxional[10] radical ion pairs are present as monomers in their respective solvent cage.

Marcus: *Ion Solvation*, Wiley, Chichester 1985, p. 218f.; c) J.-M. Lehn, *Angew. Chem. 100* (1988) 91; *Angew. Chem. Int. Ed. Engl. 27* (1988) 89; cf. references cited therein as well as in [1, 3].

[3] W. Lubitz, M. Plato, K. Möbius, R. Biehl, *J. Phys. Chem. 83* (1979) 3402, and references cited therein.

[4] *Experimental Procedure* (cf. H.-F. Herrmann, *Dissertation*, Frankfurt am Main 1988): Na (76 mg, 3.3 mmol) and sublimed fluorenone (595 mg, 3.3 mmol) were weighed into a Schlenck trap under argon at 260 K and, after evacuation (high vacuum), 30 mL of DME (dried over Na/K) was added by condensation. Following activation with ultrasound (five 5-s treatments at short intervals) and reaction for 3 d, *n*-hexane (2 mL) was condensed into the reaction mixture, which was then cooled in a cryostat to 230 K at a rate of 5°/h. The air-sensitive dark red needles of **2** (dec. >413 K), which grew within 20 h, were characterized as follows: Titration of the sodium hydroxide solution formed after hydrolysis of a weighed sample indicates a formula weight of 366 (calcd for fluorenone·Na·2DME: 383). Quenching of dried crystals (which thereby lose DME) with O_2-saturated $CDCl_3$ and integration of the NMR signal intensities gave a ratio fluorenone : DME = 1 : >1.3. A solid-state ESR spectrum ($g = 2.0034$, compared with $g = 2.00343$ reported in the literature for solutions [3]) indicates that the crystal contains fluorenone radical anions. This is further supported by the decreased IR frequency ($\tilde{\nu}$(CO) = 1540 cm^{-1}) relative to fluorenone (1600 cm^{-1}) and by the absorption spectrum in the visible ($\tilde{\nu}_{max}$ = 19000 cm^{-1}).

[5] Extensive literature search for the structures of other radical-anion salts yielded the following: In [TCNQ$^{\odot\ominus}$Rb$^{\oplus}$] (A. Hoekstra, T. Spoelder, A. Vos, *Acta Crystallogr. Sect. B 28* (1972) 14) the tetracyanoquinodimethane radical anions are stacked on top of one another. In [biphenyl]$^{\odot\ominus}$K$^{\oplus}_{solv}$] or [biphenyl$^{\odot\ominus}$Rb$^{\oplus}_{solv}$] (J. J. Mooij, A. A. K. Klaassen, E. de Boer, H. M. L. Degens, T. E. M. van den Hark, J. H. Noordik, *J. Am. Chem. Soc. 98* (1976) 680; J. H. Noordik, J. Schreurs, R. O. Gouid, J. J. Mooij, E. de Boer, *J. Phys. Chem. 82* (1978) 1105) the countercations, which are embedded in polyethers, are separated from the radical anions. Therefore, the structure presented here (Fig. 1) is presumably the first one in which interactions between the radical anion and its countercation are visible.

[6] **2**, X-ray structure analysis (180 K): space group $P1$, $Z = 1$, $a = 962.4(15)$, $b = 1071.3(15)$, $c = 1114.8(13)$ pm, $\alpha = 93.4(1)$, $\beta = 96.6(1)$, $\gamma = 112.4(1)°$, $\mu(Mo_{K\alpha}) = 0.68$ cm^{-1}. A D_{2d} geometry that deviates both from the above quoted and from the crystal structure in Figure 1 has been postulated by H. van Willigen, C. F. Mulks, *J. Chem. Phys. 76* (1981) 2135.

[9] Cf., e.g., J. March: *Advanced Organic Chemistry*, Wiley, New York 1985, p. 1110f. The reaction of fluorenone with Na affords the pinacol in 95% yield (W. E. Bachmann, *J. Am. Chem. Soc. 55* (1933) 1179).

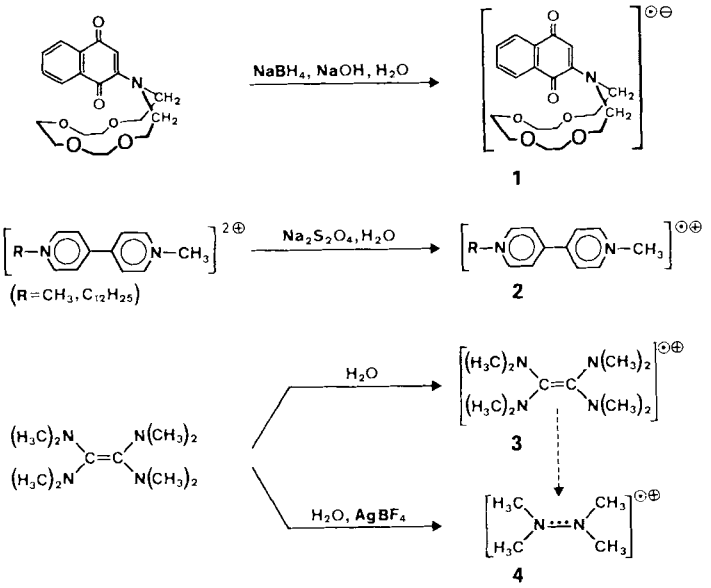
[10] For example, the 2,5-bis(trimethylsilyl)-*p*-benzosemiquinone/K$^{\oplus}$ contact ion pair, according to temperature-dependent ESR measurements attains the slow-exchange region at 223 K (P. Hänel, *Dissertation*, Universität Frankfurt am Main 1987; cf. H. Bock, B. Solouki, P. Rosmus, R. Dammel, P. Hänel, B. Hierholzer, U. Lechner-Knoblauch, H.-P. Wolf in H. Sakurai (Ed.): *Organosilicon and Bioorganosilicon Chemistry*, Ellis Horwood, Chichester 1985, p. 59f). A MNDO study (R. Dammel, *ibid.*, p. 67) yields an activation enthalpy of 30 kJ/mol and a value of 400 pm for the distance of K$^{\oplus}$ above the radical anion molecular plane at the saddle point of the fluxional motion.

ENDOR Spectroscopy in Water: Reductions and Oxidations of Organic Compounds**

By *Hans Bock** and *Bernhard Hierholzer*

Dedicated to Dr. Wolf-Dieter Luz on the occasion of his 60th birthday

Although water-free solutions are frequently advantageous for the generation, detection, and isolation[1] of radical ions and their salts, biological redox processes mostly take place in water.[2] An extension of high-resolution ENDOR spectroscopy,[3] the best method currently available for the structural elucidation of paramagnetic compounds in liquid phase, to the medium water is therefore desirable, despite the disadvantageous temperature-dependent properties of water.[4] By choosing selective one-electron-transfer reagents and working under O_2-free conditions, we have succeeded in detecting and characterizing the organic radical ions **1** to **4** in aqueous solutions by their ENDOR spectra (Fig. 1).



The experimental prerequisites for recording ENDOR spectra exhibiting an acceptable signal-to-noise ratio

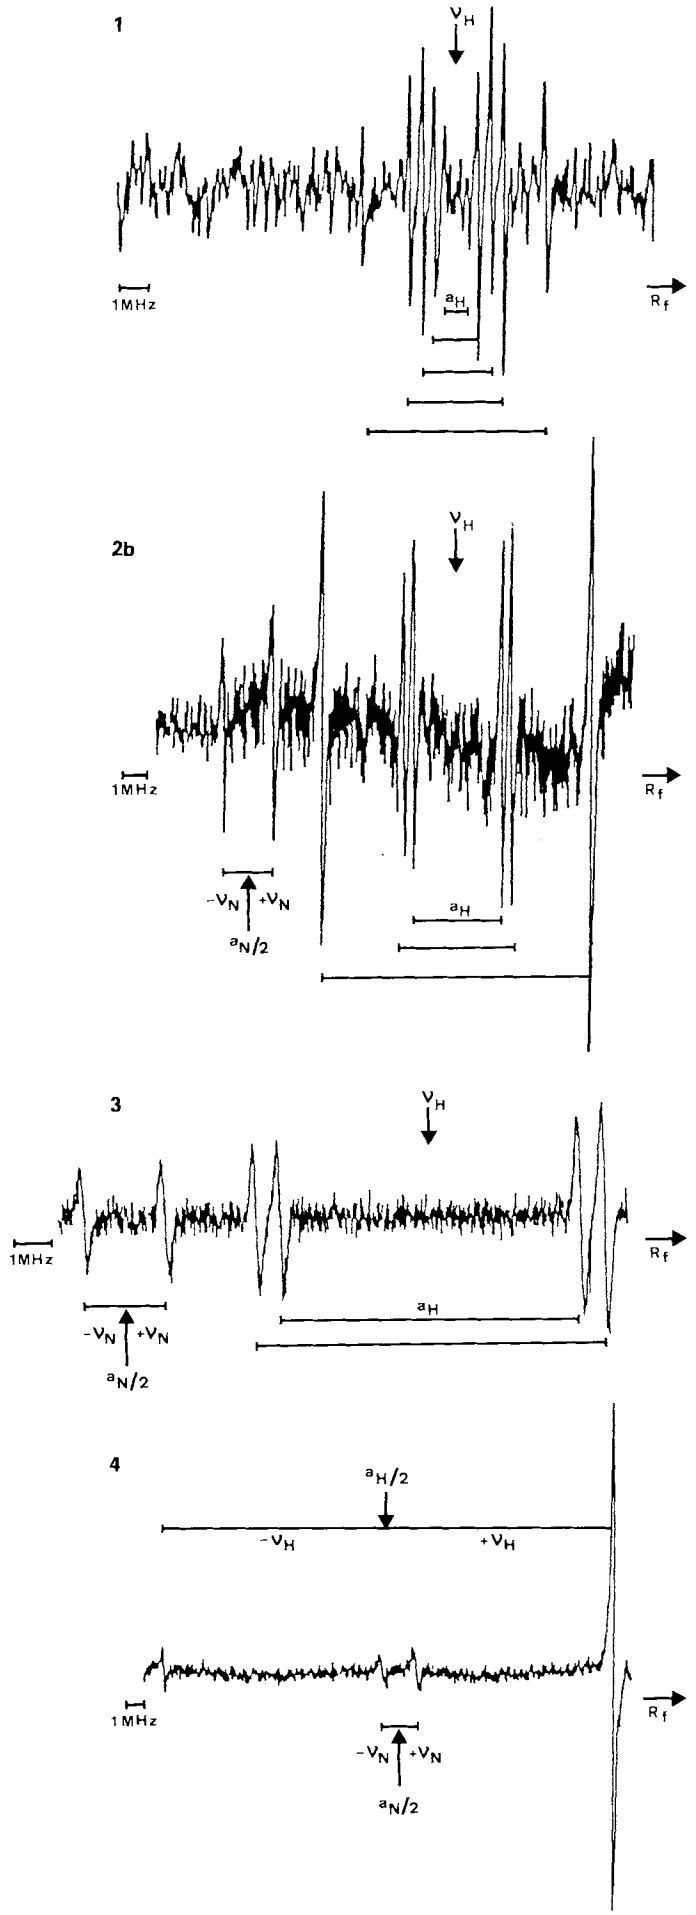
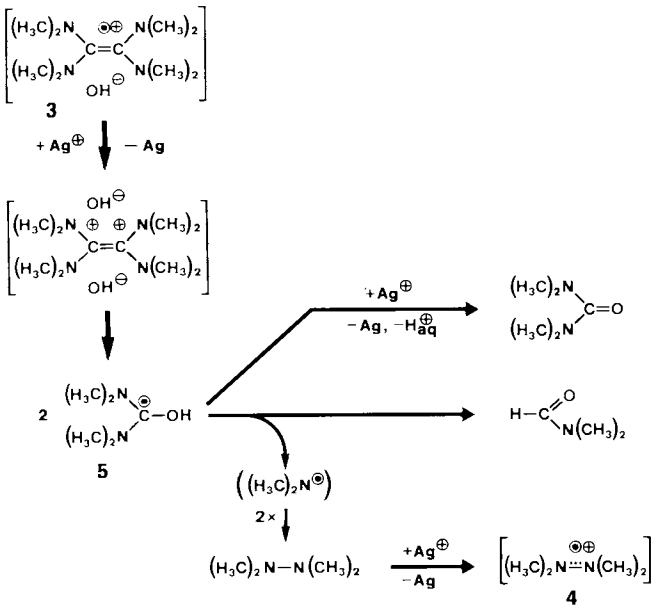
[**] Electron Transfer and Ion-Pair Formation, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Land Hessen.—Part 5: [1].



(number of scans $> 10^2$) in aqueous solutions are capillary tubes with walls of constant thickness and diameters < 1 mm as well as optimized concentrations of the redox components of $\approx 10^{-6}$ mol L^{-1}.[5] Concerning both the reactions in conductivity-pure water under argon and the assignment of the ENDOR spectra (Fig. 1), the following comments are added:

1. The ENDOR spectrum of the radical anion **1** (Fig. 1) does not show the ^{23}Na coupling observed under aprotic conditions,[6] indicating the formation of a "solvent-separated" ion pair. Because the ^1H couplings of the five ring hydrogen atoms are comparable to those of the $Cs^{\oplus}$ "contact ion pair" generated in aprotic medium, the countercations $Na^{\oplus}_{aq}$ ($r \approx 270$ pm[6]) and $Cs^{\oplus}$ ($r \approx 170$ pm[6]), surrounded by the flexible monoaza crown, cause similar π spin populations in the naphthosemiquinone radical anion. It should be further noted that the frequently used oxidation of hydroquinones with O_2 in alkaline solution, which is disadvantageous for ENDOR measurements, has been replaced by a one-electron reduction with $NaBH_4$. Generated in this way, the radical anions of biologically important quinones should also be characterizable by ENDOR spectroscopy.
2. Reduction of the dications with dithionite affords the radical cations of *N,N'*-dimethyl- (**2a**) and *N*-dodecyl-*N'*-methylviologen (**2b**). Their ENDOR coupling constants, which were determined in aqueous solution and agree with ESR literature values,[7] are identical, even though sodium dodecyl sulfate in 100-fold excess was added during the measurement of the dodecyl derivative **2b** (Fig. 1). Nonetheless, the demonstrated possibility to record ENDOR spectra of aqueous micellar solutions could be the starting point for obtaining information on aggregation and permeability of these dynamic systems by the addition of appropriate salts.
3. The electron-rich tetrakis(dimethylamino)ethene exhibits a negative oxidation potential < -0.6 V[8] and, therefore, is oxidized even by O_2-free water to the radical cation **3**. The ENDOR coupling constants of **3**[8] are in agreement with ESR values, which were measured after reduction of the dication with zinc in acetonitrile,[8] and can be interpreted in terms of a planar C_2N_4 molecular framework in which rotation around the CN axis is sterically hindered. According to our ENDOR measurements (Fig. 1), the oxidative hydrolysis of $(R_2N)_2C{=}C(NR_2)_2$, which has been the subject of controversy,[9] clearly begins with a one-electron transfer resulting in formation of the radical cation.
4. Upon addition of $AgBF_4$ to an aqueous solution of the ethene radical cation **3**, the ENDOR spectrum of the corresponding hydrazine radical cation **4** (Fig. 1 and Ref. [10]) is obtained, which can also be recorded after oxidation of tetramethylhydrazine with $AgBF_4$ in water. In addition, workup of a preparative run results in the isolation of tetramethylurea and dimethylformamide.[5] These findings suggest that the reaction proceeds by $Ag^{\oplus}$ oxidation of the ethene radical cation **3** to the dication and its nucleophilic hydrolysis to an unstable intermediate, **5**, which must be common to all the subse-

● Fig. 1. ENDOR spectra in water: radical anion **1** of the crown ether derivative 2-(1,4,7,10-tetraoxa-13-aza-13-cyclopentadecyl)-1,4-naphthoquinone at 270 K, radical cation **2b** ($R = C_{12}H_{25}$) of *N*-dodecyl-*N'*-methylviologen (with addition of sodium dodecyl sulfate in 100-fold excess) at 282 K, radical cation **3** of tetrakis(dimethylamino)ethene at 277 K, and radical cation **4** of tetramethylhydrazine at 270 K (for explanation see text).



quent products. Both the dimerization of dimethylaminyl radicals[8] and their sole formation upon γ-irradiation of tetramethylurea in a 4 K matrix[11] have been reported.

In summary, the ENDOR experiments in water described here establish the utility of this physiologically important medium for the high-resolution electron/nucleus double-resonance measurement technique and the value of the accessible information on electron-transfer reactions.

[4] Thus, the high melting point of water restricts the ENDOR "window of measurement" to 0 to 50°C, its high dipole moment is responsible for considerable dielectric losses, i.e., demands drastically reduced sample cross sections, and its small, only weakly temperature-dependent viscosity interferes with the establishment of optimal rotation correlation times [3].

[5] Cf. B. Hierholzer, *Dissertation*, Universität Frankfurt am Main 1988. The water used, which was distilled in a BIDEST quartz apparatus, degassed repeatedly at 10^{-5} mbar, and stored under argon, exhibited a conductivity of $< 10^{-7}$ Siemens cm^{-1}.

Dications Based on a Hydrotris(phosphonio)borate Skeleton**

By *Hubert Schmidbaur,* Thomas Wimmer, Gabriele Reber,* and *Gerhard Müller*

Phosphane-boranes, containing a P-B bond, are a little investigated class of compounds, despite their noteworthy properties.[1] The presence of one or more formal positive charges in immediate proximity to the boron atom leads to a reduction or even reversal ("umpolung") in the polarity of the B-H bonds. As a result, prototypes having the stoichiometries **A** and **B** are sensitive neither to oxidation nor to hydrolysis. These substances are often stable even toward aqueous acids and alkaline solutions; extremely strong bases attack the alkyl moieties.[2-7] These properties should be more pronounced in the hydrotris(phosphonio)borate dications **C**, the boron atom of which is sur-

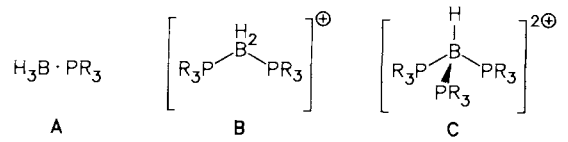
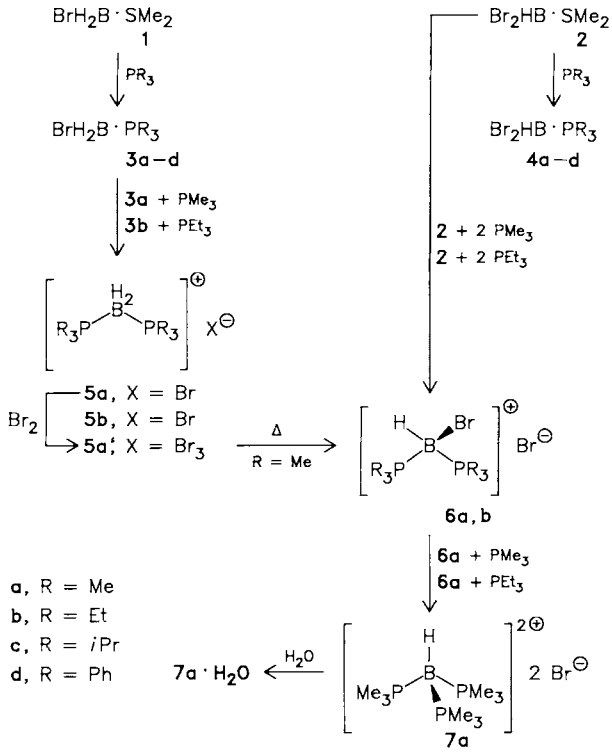
[+] X-ray structure analyses.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz-Programm), the Fonds der Chemischen Industrie, and Hoechst AG. We thank *J. Riede* for preparing the crystallographic data sets.



rounded by three phosphonium centers and only one hydrogen atom.

The investigations described here are also of interest in connection with studies on the analogous methane derivatives having one, two, or three phosphonium centers, and on the corresponding ylides,[8] as well as with attempts to use phosphane-boranes as precursors and model compounds for polymers based on boron phosphide (PB, isoelectronic with SiC).



The starting material for the synthesis of the title compounds is the adduct **1**,[9] which reacts with two equivalents of trimethyl- or triethylphosphane to give the salts **5a,b**; compound **5a** has already been well characterized.[10,11] Reaction of **5a** with bromine leads initially only to the sparingly soluble tribromide **5a'**, thereby demonstrating once again the resistance of the BH_2 unit in these molecules toward undergoing reaction. At its melting point (136 °C), **5a'** rapidly evolves HBr with formation of the salt **6a** containing a bromine-substituted boron atom. This salt and its ethyl homologue **6b** are also accessible from the adduct **2**[9] by reaction with two equivalents of PR_3.

Finally, treatment of **6a** with PMe_3 in excess affords the hydrotris(trimethylphosphonio)borate dibromide **7a**, a colorless, air-stable, readily water-soluble salt, in a slow but nearly quantitative reaction.

An X-ray crystal structure analysis was carried out on single crystals of a monohydrate, **7a** · H_2O, obtained from a mixture of dioxane, ethanol, and water (10 : 80 : 1).[12] The

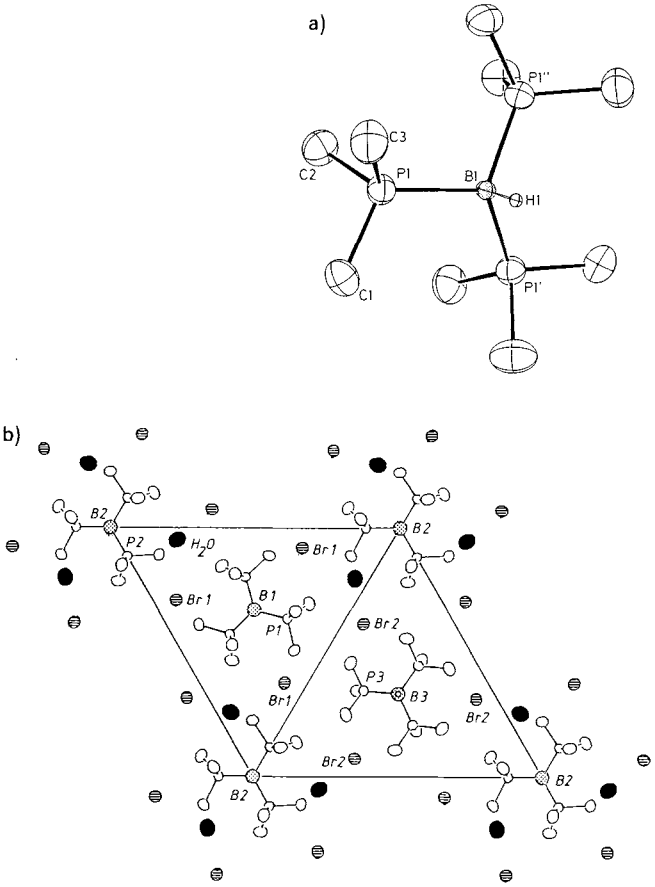


Fig. 1. a) Molecular structure of one of the three crystallographically independent dications of **7a** · H_2O (H atoms on carbons omitted). Important distances [Å] and angles [°] (for numbering see Fig. 1b): P1-B1 1.955(3), P2-B2 1.935(3), P3-B3 1.948(3); P1-B1-P1' 113.1(3), P2-B2-P2' 113.5(2), P3-B3-P3' 114.8(2). b) Arrangement of cations, anions, and hydrate water molecules in the unit cell of **7a** · H_2O (projection onto the *ab* plane).

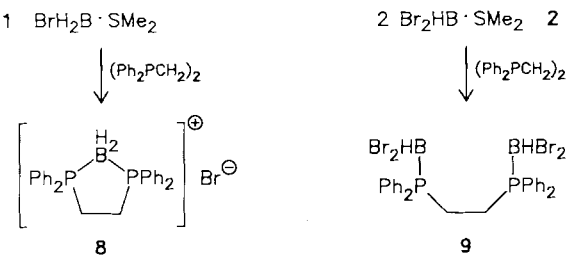
trigonal unit cell of **7a** · H_2O contains three crystallographically independent formula units (Fig. 1), which differ only with respect to conformation. Each of the cations has crystallographic C_3 symmetry. The threefold axes lie along the B–H bonds. As expected, the C–P–C angles are larger than the tetrahedral norm; the P–B distances agree with expectations. There are no directed interactions between the cations on the one hand and the anions and hydrate water molecules on the other. The ^1H-, ^{11}B-, ^{13}C-, and ^{31}P-NMR spectra, recorded in $(CD_3)_2SO$ or CD_3OD, show that the crystallographic symmetry also holds in solution; particularly noteworthy is a 1 : 3 : 3 : 1 quartet in the $^{11}B\{^1H\}$-NMR spectrum with $^1J(BP) = 95$ Hz, $\delta = -47.1$.

Even under stronger conditions, **6b** does not react with PEt_3. Presumably, steric factors are mainly responsible for this finding, since reaction of the Me_2S precursors **1** and **2** with the more bulky phosphanes $PiPr_3$ or PPh_3 results only in formation of the adducts **3c,d** or **4c,d**, respectively. Surprisingly, treatment of **6a** with PEt_3 for long reaction times also gives **7a**, thereby demonstrating the reversibility of the reaction. The poor solubility of **7a** is certainly one of the reasons for the equilibrium being shifted toward the symmetric tris(phosphonio)borate salt.

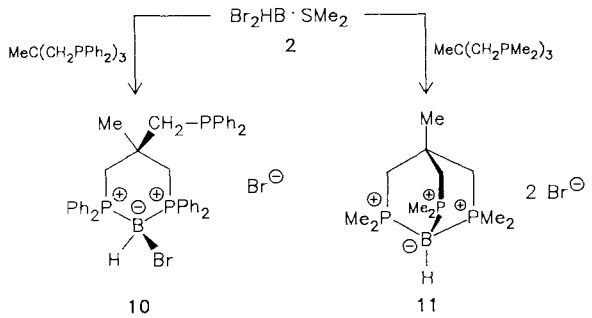
The salt **8** and the adduct **9** may be prepared by reaction of **1** and **2**, respectively, with the sterically less demanding chelate ligand "Diphos". Similarly, the sixfold phenyl-substituted ligand "Tripod" reacts with **2** to give



8 9

only the chelate compound **10** containing one noncoordinated PPh_2 function (^{31}P-NMR), instead of the desired cage compound (cf. **11**). Presumably, this finding also is due to steric factors. Use of the spatially less congested hexamethyl analogue of "Tripod" allows facile formation of the salt **11** of a bicyclic dication.

The identity and structure of this new type of phosphane-borane were readily established[13] by the unambiguous analytical and spectroscopic data as well as by an X-ray structure analysis.[14]



10 11

Compound **11** is poorly soluble in water; the solutions are stable. The NMR spectra (in methanol) are in agreement with a cation structure having C_{3v} symmetry. The cation of **10**, on the other hand, has no symmetry and shows the corresponding signal splittings. The vibrational spectra are each characterized, among other peaks, by a ν(BH) absorption (**10**, 2410; **11**, 2492 cm^{-1}).

Although the dications in the unit cell of crystalline **11** (orthorhombic, space group $P2_12_12_1$, $Z=4$), which have quinuclidine-like configurations, have no crystallographic symmetry, the deviations from point group C_3 are minimal (Fig. 2). The P–B distances correspond to those in **7a** · H_2O, but the P–B–P angles are, on the average, 102.8° and thus appreciably smaller than in the non-cagelike analogue (113.8°). The counterions ($2\,Br^{\ominus}$) have no discrete contacts with the cations. The crystals are solvate-free. In alkaline D_2O, the boron-bound H atom of **7a** and **11** is exchanged against deuterium, indicating protic character.

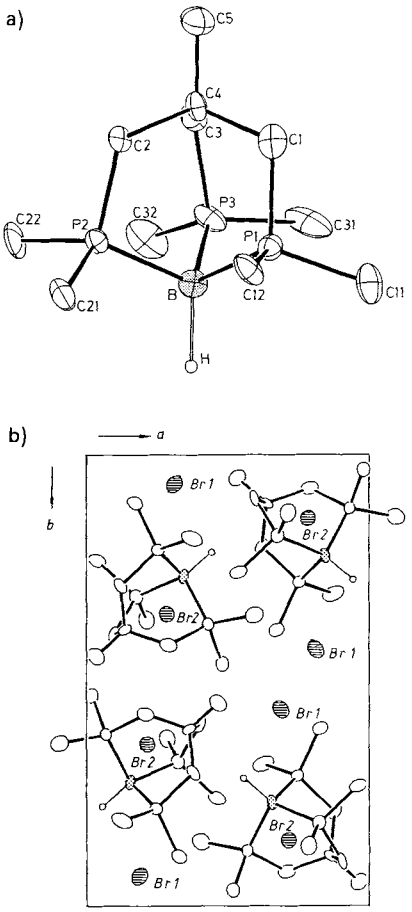


Fig. 2. a) Molecular structure of the dication of **11a** (H atoms on carbons omitted). Important distances [Å] and angles [°]: P1-B 1.94(1), P2-B 1.96(1), P3-B 1.97(1); P1-B-P2 101.3(5), P1-B-P3 104.6(5), P2-B-P3 102.4(5). b) Arrangement of cations and anions of **11a** in the unit cell (projection onto the *ab* plane).

Experimental Procedure

5a: A solution of **1** (3.87 g, 25.0 mmol) in benzene (50 mL) was combined at 5°C with PMe_3 (3.80 g, 50.0 mmol) [15]. After stirring for 1 h at 20°C, the reaction solution was filtered and the product was washed with benzene and dried under vacuum. Yield 5.33 g (87%), m.p. 254°C.

5b: A solution of **1** (3.87 g, 25 mmol) and PEt_3 (5.91 g, 50 mmol) in benzene (50 mL) was allowed to stand at 20°C for 24 h. Yield 7.20 g (88%), m.p. 160°C. ^{31}P-NMR (MeOH): $\delta=13.5$ (q, $J=92$ Hz). ^{11}B-NMR (MeOH): $\delta=-58.3$ (t, $J=92$ Hz). IR (KBr): 2410, 2379 cm^{-1} (νBH_2).

5a': Bromine (1.05 mL, 20.0 mmol) in a small amount of $CHCl_3$ was added dropwise to a suspension of **5a** (4.90 g, 20.0 mmol) in $CHCl_3$ (250 mL). An orange precipitate formed. Yield 7.62 g (94%), m.p. 136°C (dec.).

6a: **5a'** (8.09 g, 20.0 mmol) was heated to 140°C, resulting in the evolution of HBr gas. The colorless melt cake was dissolved in EtOH and the product was precipitated by addition of Et_2O. Yield 5.11 g (79%), m.p. 242°C.—The same product was obtained from **2** (5.84 g, 25 mmol) and PMe_3 (3.80 g, 50 mmol) in benzene (50 mL) at 5–20°C (5 d). Yield 4.05 g (50%). ^{1}H-NMR ([D$_6$]DMSO, 25°C): $\delta=1.80$ ("d", $N=12$ Hz, CH_3). ^{13}C-NMR (EtOH, 25°C): $\delta=6.6$ ("d", $N=56$ Hz, CH_3). ^{11}B-NMR (EtOH): $\delta=-38.9$ (t, $J=91$ Hz). IR (KBr): 2435 cm^{-1} (νBH).

6b: A solution of **2** (3.51 g, 15 mmol) and PEt_3 (3.54 g, 30 mmol) in toluene (25 mL) was refluxed for 5 d. Yield 3.86 g (63%), m.p. 180°C. ^{31}P-NMR (MeOH): $\delta=5.5$ (q, $J=92$ Hz). IR (KBr): 2412 cm^{-1} (νBH).

7a: A colorless precipitate formed over 20 d from **6a** (6.48 g, 20 mmol) and PMe_3 (1.52 g, 20 mmol) in acetonitrile (200 mL) at 20°C. Yield 4.08 g (51%), m.p. 224°C. ^{1}H-NMR ([D$_6$]DMSO): $\delta=1.98$ ("d", $N=12$ Hz, CH_3). ^{13}C-NMR (EtOH): $\delta=12.5$ ("d", $N=47$ Hz, CH_3). ^{31}P-NMR (EtOH): $\delta=-9.8$ Hz (q, $J=94$ Hz). ^{11}B{^{1}H}-NMR (EtOH): $\delta=-47.1$ (q, $J=95$ Hz); (D_2O, ^{1}H-coupled): $\delta=-47.4$ (quin, J(PB)=J(BH)=94 Hz). IR (KBr): 2393 cm^{-1} (νBH).

8: Prepared from $(Ph_2PCH_2)_2$ (7.97 g, 20 mmol) and **1** (3.10 g, 20 mmol) in benzene (50 mL). Yield 5.53 g (56%), m.p. 254°C. ^{1}H-NMR ($CDCl_3$): $\delta=3.30$ ("d", $N=10$ Hz, CH_2); 7.60 (m, Ph). IR (KBr): 2478, 2431 cm^{-1} (νBH_2).

9: Prepared from **2** (2.34 g, 10 mmol) and $(Ph_2PCH_2)_2$ (3.98 g, 10 mmol) in benzene (50 mL). Yield 2.02 g (55%), m.p. 198°C. ^{1}H-NMR ([D$_6$]acetone): $\delta=3.06$ ("d", $N=5$ Hz, CH_2); 7.75 (m, Ph). IR (KBr): 2485 cm^{-1} (νBH).

10: Prepared by refluxing a solution of $MeC(CH_2PPh_2)_3$ (3.12 g, 5.0 mmol) and **2** (1.16 g, 5.0 mmol) in toluene (50 mL) for 6 h. Yield 3.38 g (85%), m.p. 252°C. ^{1}H-NMR ([D$_6$]DMSO): $\delta=0.87$ (s, Me); 3.40 (m, CH_2); 3.69 (t, $J=13$ Hz, CH_2); 7.3–8.0 (m, Ph). ^{31}P-NMR ([D$_6$]DMSO): $\delta=-6.1$ (br, P_2B); -27.7 (s, P). IR (KBr): 2410 cm^{-1} (νBH).

11: Prepared by allowing a solution of $MeC(CH_2PMe_2)_3$ (1.26 g, 5.0 mmol) and **2** (1.16 g, 5.0 mmol) in toluene (140 mL) to react for 16 h at 20°C. Yield 1.72 g (81%), m.p. 342–345°C (dec., recrystallized from EtOH/MeOH (9 : 1)). ^{1}H-NMR (D_3COD): $\delta=1.47$ (q, $J=4$, CMe); 2.07 ("d", $N=12$ Hz, PMe); 2.56 ("d", $N=13$ Hz, CH_2). ^{13}C-NMR (D_3COD): $\delta=13.47$ (m, $N=52$ Hz, PMe); 31.15 (m, $N=42$ Hz, CH_2); 34.26 (q, $J=14$ Hz, *C*Me); 36.25 (s, C*Me*).

^{31}P-NMR (D_3COD): $\delta = 15.0$ (q, $J = 92$ Hz). ^{11}B-NMR (D_3COD): $\delta = -53.5$ (q, $J = 90$ Hz). IR (KBr): 2492 cm^{-1} (νBH).

Dedicated to Professor Ulrich Wannagat on the occasion of his 65th birthday

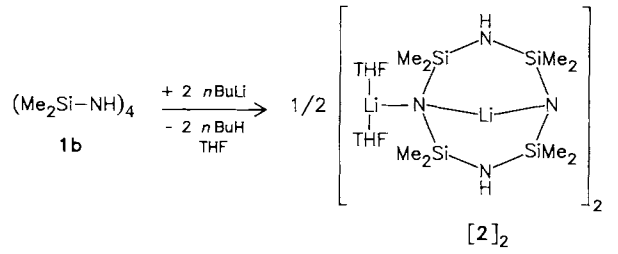
The ammonolysis of dichlorodimethylsilane leads to formation of the corresponding cyclotrisilazane **1a** and cyclotetrasilazane **1b**.[1-3]

$$n\,Me_2SiCl_2 + 3n\,NH_3 \longrightarrow (Me_2Si{-}NH)_n + 2n\,NH_4Cl$$

1a, n = 3
1b, n = 4

The reaction behavior of the six-membered ring compound **1a** has recently been the subject of intensive studies.[2] In contrast, no reactions of the eight-membered ring compound **1b** with retention of the ring moiety[4] have been reported since its first synthesis some forty years ago.[1] All attempts to carry out substitution reactions with **1b** have led to formation of isomeric six- and four-membered rings.[4]

Assuming that **1b** isomerizes according to the same rules as **1a**,[2,5] we prepared the dilithium compound **2**.[6] An X-ray structure analysis (single crystals grown from THF) provided information about the ring size and the site of second lithiation (Fig. 1).



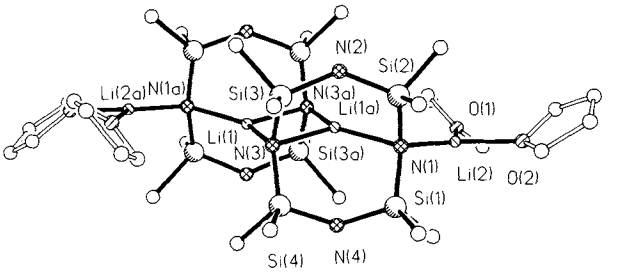


Fig. 1. Molecular structure of the dimer $[2]_2$ of **2** in the crystal (symmetry-independent atoms indicated); symmetry $\bar{1}$. Selected bond lengths [pm] and angles [°]: Si1-N1 168.3(3), N1-Si2 168.6(2), Si2-N2 174.1(2), N2-Si3 175.5(3), Si3-N3 168.7(2), N3-Si4 168.6(3), Si4-N4 174.4(2), N4-Si1 173.2(3), N1-Li2 195.0(6), N3-Li1 210.8(5), N3-Li1a 215.6(6), N1-Li1a 217.3(5), Li2-O1 192.5(5), Li2-O2 193.5(6); Si1-N1-Si2 135.6(1), Si2-N2-Si3 130.6(2), Si3-N3-Si4 130.3(1), Si4-N4-Si1 132.0(2), N1-Li1a-N3 144.7(3), N3-Li1-N3a 104.9(2), Li1-N3-Li1a 75.1(2).

2 crystallizes as the dimer $[2]_2$. The eight-membered rings are bound via a perpendicularly oriented planar, symmetrical $(LiN)_2$ four-membered ring. Li1 and Li1a are not, however, located over the centroids of the eight-membered rings: Li1a is nearer to N2 while Li1 is nearer to N2a; the distance is 241 pm in each case, whereas the distance between Li1a and N4 and between Li1 and N4a is 288 pm. Li1a and Li1 are each bound to two oppositely disposed N atoms of an eight-membered ring, namely with N1 and N3 and with N1a and N3a, respectively. The Li atoms of the four-membered ring are thus threefold coordinated. Li2 and Li2a are each coordinated to two THF molecules. The (H)N–Si bonds are systematically 5–7 pm longer than the (Li)N–Si bonds; this is consistent with ab initio calculations[7] on $(H_3Si)_2NH$ (Si–N calcd. 176 pm) and $(H_3Si)_2N^{\ominus}$ (Si–N calcd. 165 pm).

2 reacts with fluorosilanes, e.g. with $F_3SiC_6H_5$, in the molar ratio 1 : 2 to give disubstituted ("monomeric") products containing an eight-membered ring.[8]

Reaction in the molar ratio 1 : 1 leads to a derivative **4** of the novel bicyclic system 1,3,5,7-tetraaza-2,4,6,8,9-pentasilabicyclo[3.3.1]nonane (Fig. 2).[9] The N2–N4–Si2–Si3 and N2–N4–Si4–Si1 planes of the two six-membered rings are inclined towards each other. N2, Si1, N1, Si4, and N4 are coplanar, whereas N3 of the second six-membered ring is bent towards the bridging atom Si5, so that N3, Si2, N4, Si5, N2, and Si3 form a tub-shaped moiety.

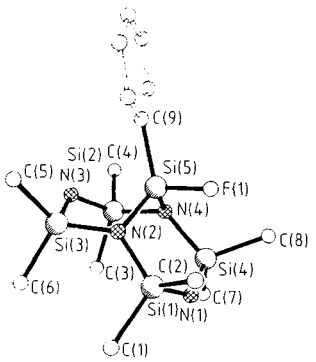

Fig. 2. Molecular structure of **3** in the crystal. Selected bond lengths [pm] and angles [°]: N1-Si1 174.7(15), Si1-N2 173.5(7), N2-Si3 175.3(7), Si3-N3 172.8(13), N3-Si2 172.8(7), Si2-N4 174.3(5), N4-Si4 175.8(8), Si4-N1 171.8(16), N2-Si5 173.2(13), Si5-N4 172.4(12), Si5-F1 160.4(5); Si1-N1-Si4 133.9(5), Si2-N3-Si3 127.1(5), Si1-N2-Si3 131.2(5), Si1-N2-Si5 111.5(6), Si3-N2-Si5 107.5(4), Si2-N4-Si4 126.4(5), Si2-N4-Si5 108.9(6), Si4-N4-Si5 110.8(4), N2-Si5-N4 106.1(5).

Experimental

A solution of **1b** (0.01 mol) in hexane (100 mL) was treated with 0.02 mol of nC_4H_9Li (15% in hexane) in a three-necked flask fitted with an internal thermometer. For complete cleavage of butane, the sludge was heated under reflux for 2 h. THF was then added until the lithium salt dissolved at the boiling temperature. **2** crystallized out at room temperature. For the synthesis of **3** and **4** the solution of **2** was cooled to −20°C. After slow dropwise addition of 0.02 mol and 0.01 mol of $PhSiF_3$, respectively, the solutions were warmed to room temperature for 2 h (^{19}F-NMR monitoring). After removal of lithium fluoride, **3** and **4** crystallized out from the solutions: yields 4.5 g (92%) **2**, 4.8 g (84%) **3**, 2.6 g (63%) **4**.

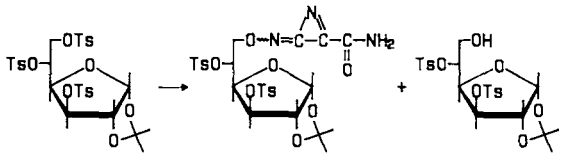
Azirineimine as a Structural Unit in the Side Chain of a Hexofuranose**

By *Wolfgang Meyer zu Reckendorf** and *Norbert Schultz*

A series of theoretical papers on the origin of life in the universe consider reactions of hydrogen cyanide and its derivatives. Azirineimine is discussed as a possible stable intermediate in the formation of peptides from hydrogen cyanide.[1] We obtained a derivative of this previously unknown compound in a completely surprising way.

All previous attempts to lengthen the chain of carbohydrates or to synthesize branched-chain compounds by reaction of sulfonic acid esters with cyanides have failed because the nucleophilicity of the cyanide ion is too low. Only *Grewe* and *Rockstroh*[2] were able to synthesize a D-glucose-6-carbonitrile from 1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-glucofuranose and KCN. However, since this reaction proceeds via the 5,6-epoxide and therefore does not seem to be applicable to compounds without neighboring hydroxy groups, we chose 1,2-*O*-isopropylidene-3,5,6-tri-*O*-*p*-toluenesulfonyl-α-D-glucofuranose **1**[3] for experiments to investigate the reaction capability of the sulfonic acid esters in more detail. Upon reaction of **1** with KCN and tetrabutylammonium chloride in nitromethane/water under phase-transfer conditions[4] (2 d at 50°C) and subsequent chromatographic separation we obtained—besides some unchanged starting material, the hydrolysis product **3**, and difficultly isolable byproducts—a crystalline compound of the composition $C_{26}H_{29}N_3O_{11}S_2$ as the main product (15%), which proved to be the azirineimine derivative **2**.



Ts = *p*-toluenesulfonyl.

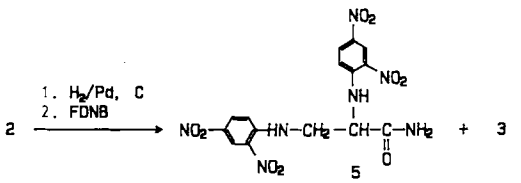
The coupling of the new side chain to C-6 followed from the catalytic hydrogenation of **2** (Pd/carbon/MeOH, 10 h), which led to **3**, and from the NMR spectroscopic data (see Table 1). Isotope labeling experiments afforded unequivocal proof of the structure. Contrary to expectation, in the synthesis with KC^{15}N a product was formed whose molecular weight was greater by only one mass unit. The ^{1}H-NMR spectrum of the compound **2a** shows the two H/^{15}N couplings characteristic for amide groups, which are confirmed in the ^{15}N-NMR spectrum, as well as the H/H' coupling which is not visible in the proton spectrum of the unlabeled substance **2**.[6] The ^{13}C-NMR spectrum, as already known from that of [^{15}N]acetamide,[7] shows a ^{13}C/^{15}N coupling with the amide carbon atom and a ^{13}C/^{15}N coupling with the neighboring C-atom. The structure of the remaining [CN$_2$] group was still unclear at this point.

The product **2b**, which is obtained by synthesis with $^{13}CH_3NO_2$ and KCN, has a molecular weight increased by two mass units. Two C-atoms characterized by two very intense signals in the ^{13}C-NMR spectrum mutually couple with the unusually large coupling constant of $^1J_{^{13}C/^{13}C} = 100.8$ Hz. Accordingly, they form a chain together with the amide carbon. The absorption at relatively high field is thus due to the azirine.

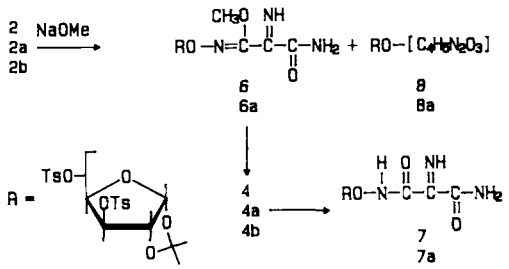
To obtain chemical proof of the structure we investigated the catalytic hydrogenation of **2** in more detail and, after reaction with 1-fluoro-2,4-dinitrobenzene (FDNB), were able to isolate 2,3-bis(2,4-dinitrophenylamino)propionic acid amide **5** in 5% yield.



When **2** was allowed to react with $NaHCO_3$ in acetone, the isomeric compound **4** was formed in 70% yield. This substance, which is also present in small amounts in the nitromethane-water reaction mixture, differs markedly from **2** in the chromatogram as well as in its melting point and its optical rotation. Since the IR, ^{1}H-NMR and ^{13}C-NMR data (including the couplings of the ^{15}N nucleus with the investigated nuclei) as well as the mass spectra and elemental analyses of **2** and **4** agree in all essential points, these two compounds can be distinguished only with respect to the geometry of the exocyclic nitrogen atom. Although only slightly deviating values are found in the spectra of the ^{13}C-enriched substances, **2b** and **4b**, both for the couplings of the two C atoms of the azirine ring as well as for the coupling of these atoms to the amide C atom, they nevertheless prove that the two C atoms form a chain with the amide carbon also in the case of **4**. Such isomeric structures have already been reported in the literature.[8]

On attempting to open the azirine ring of the compound **2** with 0.015 M sodium methoxide solution, the geometric isomer **4** was formed once again as the main product after 2 days (37 °C). A significantly stronger polar product with a molecular weight increased by 32 mass units and showing a signal for the methoxy group in the ^{1}H- and ^{13}C-NMR spectra proved to be the methanol addition product **6**.

Two substances were formed on layer-chromatographic work-up of **6**. One had an even lower, the other a considerably higher relative migration rate than **6**. The latter turned out to be the isomer **4** formed by elimination of methanol, which could also be obtained from **6** directly by reaction with methoxide.



The compound with the smallest R_f value has a molecular weight 18 mass units higher than that of **2**. According to the analytical and spectroscopic data this compound is the hydrolysis product **7**, which is clearly recognizable in the ^{1}H-NMR spectrum of the $CO^{15}NH_2$-labeled substance.

On strongly heating **2** in a sodium methoxide solution the reaction time is reduced to about 1 h, but a further by-product **8** is formed which is only slightly less polar than the starting compound **2**. It has a molecular weight of only one mass unit higher than **6**, and the elemental analysis indicates hydrolysis of the imine function. The structure of **8** has not yet been elucidated.

$^{\ominus}O-N=CH-CH=NO_2^{\ominus}$ **9**

The mechanism of formation of the azirineimine is still unclear. In the first step, nitromethane could form the condensation product **9**;[9] how **9** reacts with KCN, however, remains a matter of speculation.

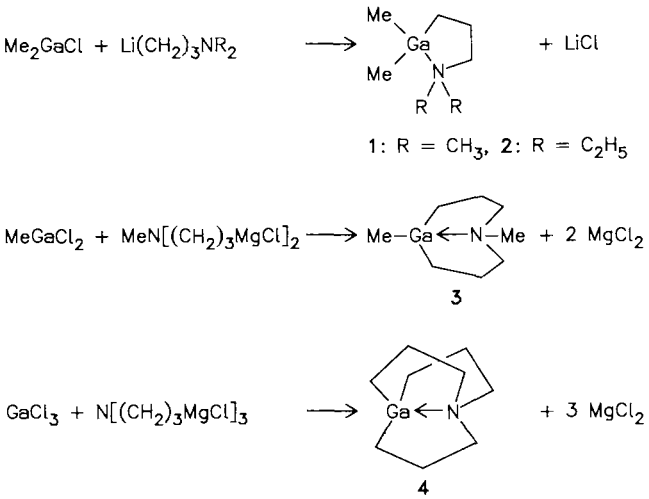
Intramolecularly Stabilized Organogallium Compounds**

By *Herbert Schumann,* Uwe Hartmann, Andreas Dietrich,* and *Joachim Pickardt*

Organometallic compounds are gaining increasing importance in the production of thin films and epitactic layers. Thus, for example, both trimethylgallium as well as its less sensitive adducts with amines and other bases are used for the gas-phase separation of gallium arsenide.[1] In our studies in this area we have prepared the interesting new intramolecularly base-stabilized organogallium compounds **1**–**4** by reaction of dimethylgallium chloride with 3-dimethylamino- or 3-diethylaminopropyllithium,[2] of methylgallium dichloride with 3,3′-methyliminobis(propylmagnesium chloride) or of gallium trichloride with 3,3′,3″-nitrilotris(propylmagnesium chloride).[3]



Compounds **1**–**4** are colorless solids which are only slowly attacked by atmospheric oxygen. They are very soluble in ethers and in aliphatic and aromatic hydrocarbons. **1** melts without decomposition at 49 °C under a vapor pressure of 230 Pa. It boils at 192 °C at normal pressure and can be sublimed under vacuum at room temperature; at 270 °C it decomposes with separation of gallium. **2** melts at 43–45 °C. **3** already melts at 34 °C and is just as stable as **1**.[4]

The X-ray structure analysis of **4** shows that the gallium atom is surrounded trigonal-monopyramidally by three CH_2 groups and the amine nitrogen (Fig. 1).[5] The GaC_3 moiety is trigonal planar with angles of 120° at the gallium. The electron deficiency of the metal atom is balanced by the intramolecular coordinative bonding of the nitrogen atom situated at the apex of the pyramid (Ga–N distance 209.5(2) pm). The Ga–N distance lies between that in **5** (197.9(3) pm)[6] and that in the pure donor–acceptor complex **6** (220(3) pm)[7] and, due to the ring strain in the molecular frame-work, is somewhat longer than the sum of the covalent radii of Ga and N (195 pm).

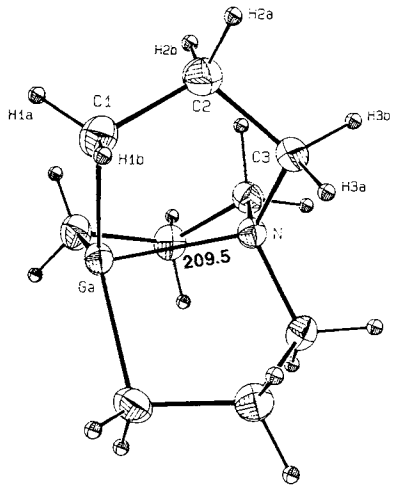

Fig. 1. Crystal structure of 4. Selected bond lengths [pm] and angles [°] (standard deviations in parentheses): Ga-Cl 199.8(2), Ga-N 209.5(2), C1-C2 153.9(2), C2-C3 153.0(2), C3-N 148.6(2); C1-Ga-N 89.2(1), C3-N-Ga 105.2(1), C1-Ga-C1′ 120.0, C3-N-C3′ 113.3(2).

Since the distance of the gallium atom from the nitrogen atom of the neighboring molecule is 409 pm, and an additional intermolecular donor–acceptor interaction can be ruled out, the gallium on this coordinatively unprotected underside of the pyramid should be prone to nucleophilic attack. In the triorganogallium-amine complexes free of steric strain that have so far been investigated X-ray crystallographically, the gallium is coordinated in a distorted tetrahedral fashion with C-Ga-C angles of 116.7° in **6**,[7] 116.6(3)° in **7**[8] and 115.9(4)° in [$Me_3Ga\cdot$(urotropine)].[9] The Ga-C distances (199.8(2) pm) are in good agreement with those in **6** (199.8(4)[7]) and **7** (199(1)[8]).

Experimental

1: A suspension of $Li(CH_2)_3NMe_2$ (1.5 g, 16 mmol) in pentane (15 mL) was treated dropwise at −78°C in the course of 15 min with a solution of 2.16 g (16 mmol) of Me_2GaCl in 15 mL of pentane. After thawing and 24 hours' stirring at 20°C, the mixture was allowed to stand and the clear solution decanted off. After removal of the solvent the residue was sublimed in a vacuum. Yield 2.1 g (71%). ^{1}H-NMR (C_6D_6, 25°C): $\delta = -0.16$ (s, 6H, $(H_3C)_2Ga$), 0.57 (t, 2H, $-CH_2Ga$, $^3J = 7.01$ Hz), 1.70 (tt, 2H, $-CH_2-$, $^{3,3}J = 7.01$, 6.31 Hz), 1.86 (s, 6H, $(H_3C)_2N$), 1.98 (t, 2H, $-CH_2N$, $^3J = 6.31$ Hz); ^{13}C-NMR (C_6D_6, 25°C): $\delta = -6.15$ (s, $(H_3C)_2Ga$), 9.33 (s, $-CH_2Ga$), 24.35 (s, $-CH_2-$), 45.87 (s, $(H_3C)_2N$), 63.96 (s, $-CH_2N$).

4: The Grignard reagent obtained from 4.9 g (20 mmol) of $N[(CH_2)_3Cl]_3$ and 1.6 g (66 mmol) of Mg in 60 mL of THF and 3.5 g (20 mmol) of $GaCl_3$, dissolved in 60 mL of THF, were added dropwise and synchronously over 3 h into 350 mL of toluene at 60°C. The mixture was then heated under reflux for 2 h, ca. 250 mL of the solvent removed by distillation, and the $MgCl_2$ that separated out was filtered off over a frit. The solution was evaporated to dryness. Sublimation of the residue at 40-60°C under vacuum furnished 0.92 g (22%) of colorless needles of **4**. M.p. 54°C. ^{1}H NMR (C_6D_6, 25°C): $\delta = 0.59$ (t, 6H, $-CH_2Ga$, $^3J = 6.34$ Hz), 1.76 (tt, 6H, $-CH_2-$, $^{3,3}J = 6.34$, 5.72 Hz), 2.14 (t, 6H, $-CH_2N$, $^3J = 5.72$ Hz); ^{13}C NMR (C_6D_6, 25°C): $\delta = 9.84$ (s, $-CH_2Ga$), 26.50 (s, $-CH_2-$), 57.02 (s, $-CH_2N$).

Tris(thioxanthen-9-ylidene)cyclopropane, and Its Radical Cation and Dication**

By *Toyonari Sugimoto, Yohji Misaki, Tohru Kajita, Toshio Nagatomi, Zen-ichi Yoshida,** and *Jun Yamauchi**

[3]Radialene (trimethylenecyclopropane), a hydrocarbon composed of a three-membered carbocycle and three exocyclic double bonds, can possess one pair of degenerate highest occupied molecular orbitals (HOMOs) if one assumes it to have C_3 symmetry or higher. Introduction of electron-donating groups into the exocyclic double bonds raises the energy of the HOMOs, and makes the [3]radialene more oxidizable. If the resulting dication has a triplet ground state, the molecule could serve as donor component for the production of donor-acceptor type organic ferromagnets,[1] which are currently attracting a great deal of interest. Indeed, tris(diaminomethylene)cyclopropane has already been proposed by *Miller*, *Epstein* et al. as a promising donor.[2] In spite of much interest in the electron-donating [3]radialenes, to our knowledge there has so far been no report on their synthesis.[3] In this paper we wish to report the first synthesis of **1**, an oxidizable [3]radialene with three electron-donating thioxanthenylidene

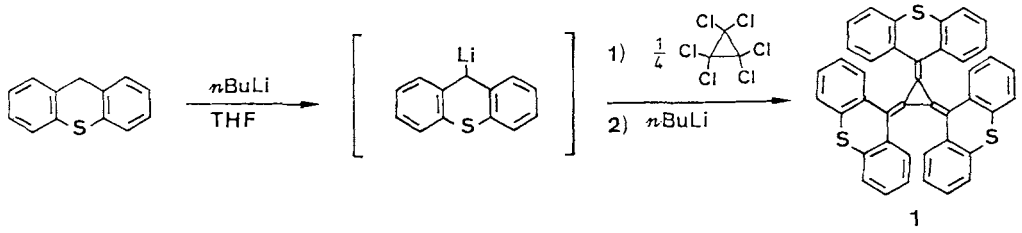

Scheme 1.

groups, and the characterization of its radical cation $\mathbf{1}^{\odot\oplus}$ and dication $\mathbf{1}^{2\oplus}$ by ESR spectroscopy.

A THF solution of thioxanthene[4] was treated with an equimolar amount of *n*-BuLi (1.6 M hexane solution) at −70°C. The resultant dark red solution of lithium thioxanthenide was treated with 1/4 molar equivalent of hexachlorocyclopropane[5] and then with an equimolar amount of *n*-BuLi (Scheme 1). The reaction mixture was stirred for 30 min at −70°C and then warmed to room temperature. After purification of the reaction mixture by column chromatography (silica gel; dichloromethane/hexane (1:4)), and then recrystallization from dichloromethane/acetone/methanol, **1** was obtained as blue crystals (m.p. 269–270°C) in 21% yield.[6] The electronic spectrum of **1** in CH_2Cl_2 showed four absorption maxima at $\lambda = 252$ ($\log\varepsilon = 4.72$), 328 (4.10), 392 (3.48) and 600 nm (4.48).[7] The ^{13}C-NMR spectrum in $CDCl_3$ showed eight signals at $\delta = 116.6$, 119.9, 124.8, 125.1, 127.1, 130.4, 132.7 and 134.9,[8] suggesting that **1** has approximately C_3 symmetry in solution. The cyclic voltammogram of **1** measured in dichloromethane[9] was composed of two pairs of reversible waves at +0.67 and +0.80 V vs. Ag/AgCl, each of which corresponds to a one-electron transfer process.[10] On the other hand, in PhCN solvent only one irreversible wave involving simultaneous transfer of two electrons, was observed at +0.70 V.

By electrochemical oxidation at constant potential, or more conveniently by chemical oxidation with $Tl(CF_3CO_2)_3$, $\mathbf{1}^{\odot\oplus}$ and $\mathbf{1}^{2\oplus}$ were generated or isolated, and characterized by ESR spectroscopy. The degassed CH_2Cl_2 solution of **1** in contact with excess $Tl(CF_3CO_2)_3$ at −78°C showed only a 600-nm absorption band due to **1** itself. At ca. −40°C the band gradually decreased and a new 536-nm band due to $\mathbf{1}^{\odot\oplus}$ increased. On raising the temperature further to −10 to 0°C the 536-nm band rapidly vanished and another new 630-nm band due to $\mathbf{1}^{2\oplus}$ appeared, which was not subject to change in the temperature range. The temperature-dependent formation of $\mathbf{1}^{\odot\oplus}$ and $\mathbf{1}^{2\oplus}$ was also monitored ESR spectroscopically. The first observed ESR spectrum of $\mathbf{1}^{\odot\oplus}$ was composed of quintet lines with ca. 0.23 mT splitting at a relatively large *g* value ($g_{iso} = 2.00638$).[11] On the other hand, for $\mathbf{1}^{2\oplus}$ one sharp ESR signal with a linewidth of 0.40 mT appeared at $g = 2.00414$ whose intensity decreased with lowering temperature (−30 to −100°C) in frozen 1,2,3-trichloropropane,[12] thus suggesting the possibility that $\mathbf{1}^{2\oplus}$ is a thermally accessible triplet. To substantiate this conjecture, isolation of $\mathbf{1}^{2\oplus}$ was attempted, and the $CF_3CO_2^{\ominus}$ salt ($\mathbf{1}^{2\oplus}\cdot 2CF_3CO_2^{\ominus}$) was successfully obtained as a dark blue solid (m.p. 65–66°C).[13] This solid exhibited one slightly broad (linewidth = 0.55 mT) ESR signal with $g = 2.00353$ at 25°C. At −196°C the spectrum exhibited fine structure together with simultaneous appearance of a half-field resonance signal at 164.8 mT (see Fig. 1). From analysis of the spectrum, D, one of the zero-field splitting parameters,

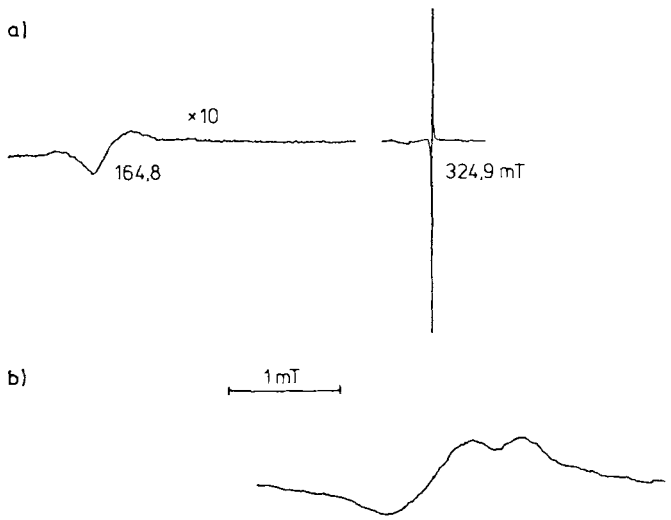

Fig. 1. ESR spectrum of $\mathbf{1}^{2\oplus}\cdot 2CF_3CO_2^{\ominus}$ at −196°C. a) The complete spectrum (the half-field resonance ($\Delta m_s = \pm 2$) signal was measured with tenfold amplification). b) The width-expansion of the central signal at 324.9 mT.

was determined to be ca. 0.7 mT. This very small value strongly suggests that the two unpaired electrons are far removed from each other and probably are located on the three thioxanthenylidene groups. From the similar temperature-dependence of the central broad signal to that of the frozen solution experiment, it was shown that the ground state of $\mathbf{1}^{2\oplus}$ is certainly a singlet and the triplet state lies only 0.07 eV higher in energy.

As is discussed for pentaarylcyclopentadienyl cations, whose ground state is a singlet with a triplet lying 0.002–0.04 eV higher,[14] it seems to be likely also for $\mathbf{1}^{2\oplus}$ that the singlet is favored because the large π electron system decreases electron correlation and the complex structure allows easy symmetry-lowering distortion. However, by choosing appropriate electron-donating substituents other than thioxanthenylidene, a ground state triplet might be produced for dicationic species of the new [3]radialenes.

[6] The mass spectrometric and elemental analysis of **1** gave satisfactory results.
[7] The UV/VIS absorption spectra of tris(2,6-di-*tert*-butyl-4-oxocyclohexadienylidene)- and tris(fluorenylidene)cyclopropanes also revealed absorptions extending into the long wavelength region of 600-800 nm.
[8] The two signals at $\delta = 116.6$ and 119.9 were assigned to the two exocyclic carbons of the three-membered ring.
[9] Cyclovoltammetry in dichloromethane or benzonitrile containing 0.1 M $(n\text{Bu})_4\text{NClO}_4$ as supporting electrolyte, platinum working electrode and counter electrode, and standard Ag/AgCl reference electrode (scan rate: 50 mV/s).
[10] The number of transferred electrons in each step was determined from the dependence of the peak currents on sample concentrations (A. J. Bard, L. R. Faulkner, *Electrochemical Methods: Fundamentals and Applications*; Wiley: New York, 1980, p. 218).
[11] A detailed analysis of the spectrum will be reported elsewhere.
[12] $\mathbf{1}^{2\oplus}$ could also be prepared in 1,2,3-trichloropropane (m.p. -14°C) at -10 to 0°C. Immediately thereafter the solution was frozen.
[13] Although the salt isolated was expected to be pure it gradually decomposed. Consequently, the purity of the salt used in the ESR measurement was not checked by magnetic susceptibility measurements but by the ESR counting method using a stable radical TMPOL (2,2,6,6-tetramethylpiperidin-4-ol-1-oxyl) as a standard. The purity was estimated to be >90%. The error inherent in this method was of the order of about ten percent. On the other hand, we could not isolate the pure $CF_3CO_2^{\ominus}$ salt of $\mathbf{1}^{\odot\oplus}$; it was always contaminated with the salt of $\mathbf{1}^{2\oplus}$.

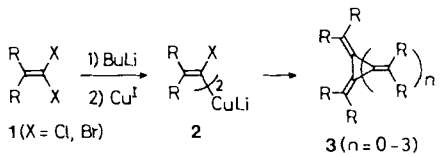
Tris(fluoren-9-ylidene)cyclopropane, a Novel [3]Radialene

By *Masahiko Iyoda,* Hiroyuki Otani,* and *Masaji Oda*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

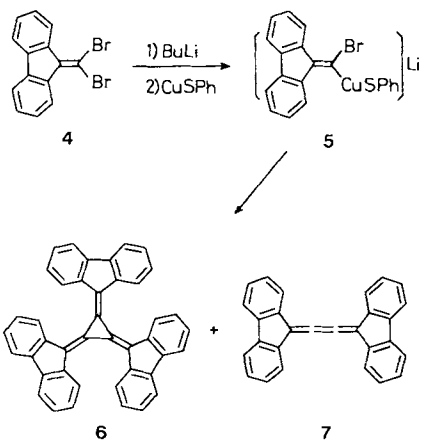
Radialenes (polymethylenecycloalkanes) have received considerable attention from both theorists and experimentalists,[1] because they display a particular arrangement of π-electrons and because they can serve as electron donors and acceptors.[2] However, the synthetic methodology for access to these molecules is still very limited and many compounds containing the radialene framework have not yet been synthesized.

We recently reported a novel method for preparing the radialenes **3** by cyclooligomerization of the ate-type complexes **2**, which were obtained from **1**.[3] We report here on



the synthesis and properties of tris(fluoren-9-ylidene)cyclopropane **6** by cyclotrimerization of the ate-type complex **5**, which was obtained from 9-(dibromomethylene)-fluorene **4**.

Reactions of the known metal methylidenecarbenoids were reported to give only dimerized butatrienes like **7** or their metal complexes via coupling of the corresponding carbenoids and/or carbenes.[4] However, reaction of the ate-type complex generated from lithium carbenoid with an appropriate copper(I) complex proceeds formally as a cyclooligomerization of the carbene center.



Thus, treatment of **4** with one equivalent of butyllithium (THF, below -90°C), followed by addition of one equivalent of copper(I) phenylthiolate[5] furnished the mixed cuprate **5**. When the solution was allowed to warm to ambient temperature and stirred for 24 h, the desired [3]radialene **6**[6] was obtained in 22% yield, together with the butatriene **7** in 58% yield.[7] With 0.5 equivalents of $CuI \cdot PBu_3$ or $CuBr \cdot SMe_2$ as the Cu^{I} complex, the [3]radialene **6** was formed in 2-3% yield, together with **7** (76-85%); with CuCN, however, the main product was **7** with only trace amounts of **6**.

The reaction of the ate-type complex, derived from **4**, with $CuI \cdot PBu_3$ in the presence of **7** gave the [3]radialene **6** in 3% yield, and no improvement in the yield of **6** was observed. Therefore, addition of the methylidenecarbene to **7** can be ruled out for the formation of **6**. Although the structure and the state of aggregation of the ate-type complex are still uncertain, trimerization of the complex **5** plays an important role in the formation of **6**. Interestingly, neither [4]- nor [5]radialenes were isolated in this reaction, and a steric factor may contribute to oligomerization of carbenoids. In agreement with this steric effect, the copper carbenoid derived from 1,1-dibromo-2-methylpropene forms the corresponding [4]- and [5]radialenes,[3b] and the copper carbenoid derived from 1,1-dibromo-2,2-diphenylethylene results in the formation of octaphenyl[4]radialene.[3a]

The [3]radialene **6** thus obtained is very stable and crystallizes from hexane/dichloromethane in the form of reddish-black crystals with metallic luster, which show no melting point up to 300°C. The electronic spectrum shows a broad, strong absorption tailing at 800 nm, corresponding to the deep-blue color in solution. The ^{1}H- and ^{13}C-NMR spectra reflect its highly symmetrical structure, although molecular models show that **6** cannot have a planar structure with D_{3h}-symmetry. We suggest a propeller-like structure with D_3-symmetry, in analogy with the twisted conformation of 9,9′-bifluorenylidene.[8]

The ethylene, butadiene and butatriene derivatives **8**, **9** and **7**, respectively, can be readily reduced with alkali metals to give stable dianions.[9] Therefore, **6** can be expected to form the dianion **10** by electrochemical reduction. Cy-

clovoltammetry of **6** displays two reversible one-electron reduction steps, shown in Figure 1. Under analogous con-

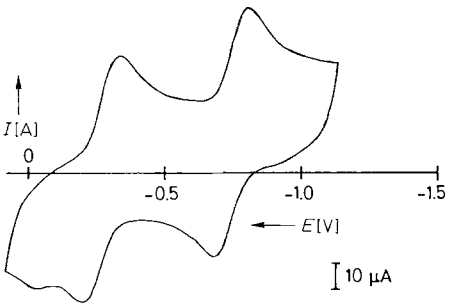

Fig. 1. Cyclovoltammogram of **6**. $c = 3.8 \times 10^{-4}$ M, *N,N*-dimethylformamide/0.1 M tetrabutylammonium perchlorate vs Ag/AgCl reference electrode [12]; scan rate 244 mVs^{-1}.

ditions, compounds **7**, **8**[10] and **9** show similar stepwise, reversible reduction to the corresponding dianions (Table 1). A remarkable feature of these reduction potentials is

Table 1. First and second reduction potentials ($E^1_{1/2}$ and $E^2_{1/2}$) of **6**–**9** [a].

	$E^1_{1/2}$ [V]	$E^2_{1/2}$ [V]	$E^1_{1/2} - E^2_{1/2}$
6	−0.27	−0.75	0.48
7	−0.73	−1.15	0.42
8	−0.92	−1.44	0.52
9	−1.06	−1.39	0.33

[a] The potentials were measured under the conditions given in the caption to Figure 1.

the fact that the $E^1_{1/2}$ and $E^2_{1/2}$ values of **6** are much more positive than those of **7**, **8** and **9**. The dianion of **6** should exist in the delocalized form **10a** but can be formulated as the structure **10b** like calicene.[11] The contribution of the cyclopropenium structure **10c** may therefore explain the extremely low reduction potentials of **6**.

Is Tetrasilatetrahedrane Kinetically Stable?**

By *Shigeru Nagase** and *Mari Nakano*

Tetrahedrane (C_4H_4) has long counted among the fascinating synthetic targets, largely because of its chemical significance, high strain, and aesthetic appeal.[1] Considerable interest is currently directed toward the preparation and characterization of the silicon analogues of polycyclic carbon compounds.[2]

Clabo and *Schaefer* have recently calculated that tetrasilatetrahedrane **1** is a local minimum on the Si_4H_4 potential energy surface and is an interesting synthetic target.[3] The local minimum T_d structure of **1** is also claimed in a very recent study by *Sax* and *Kalcher*.[4] *Schoeller* et al. have indicated that the fusion of rings is unfavorable in carbon compounds but advantageous in silicon compounds such as **1**.[5] However, none of these studies has dealt with the kinetic stability of the silicon analogues.

By way of contrast, we have shown[6] that polycyclic silicon compounds having only fused three-membered rings

[**] This work was supported in part by a grant from the Ministry of Education, Science, and Culture in Japan. Calculations were carried out at the Computer Center of the Institute of Molecular Science and the Computer Room of the Faculty of Education of Yokohama National University.

are highly strained[6a,7] and subject to "bond stretch" isomerism[6b,c,8] because of relatively weak Si–Si bonds (compared with C–C bonds).[9] Ab initio calculations[10] now show that **1** isomerizes almost without a barrier, contrary to general expectation.[3-5,11]

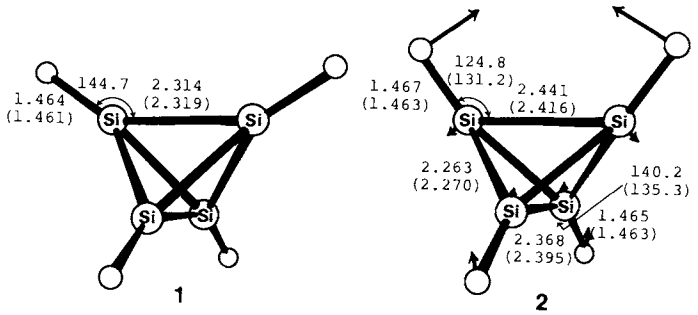

Fig. 1. Bond lengths [Å] and angles [°] of the HF/6-31G(d) and HF/6-31G(2d,p) optimized structures of **1**(T_d) and **2**(C_{2v}). HF/6-31G(2d,p) values are in parentheses. The arrows in **2** indicate the displacement vector of the reaction coordinate (the normal coordinate with an imaginary frequency) at the transition state.

Figure 1 shows the structure of **1** and a transition structure (**2**) of C_{2v} symmetry[12] (characterized by one single imaginary frequency of $325i$ cm^{-1} (a_1)) for its isomerization located at the Hartree-Fock (HF) level with the split-valence d-polarized 6-31G(d) basis set.[10] Unlike the carbon counterparts,[13] **1** and **2** are very similar. Reflecting this "early" transition state, the barrier for the isomerization of **1** is only 1.6 kcal mol^{-1}, as shown in Table 1.

Table 1. Relative Energies [kcal mol^{-1}] of **1**–**4** at various levels.

Method	**1**(T_d) [a]	**2**(C_{2v})	**3**(D_{2d})	**4**(D_{2h})
HF/6-31G(d)	0.0	1.6	−11.3	−4.2
HF/6-31G(2d,p)	0.0	0.4		
HF/6-31G(2df,p) [b]	0.0	0.4		
MP2/6-31G(d) [c]	0.0	−2.3	−39.4	−5.7
MP3/6-31G(d) [c]	0.0	−1.5	−33.5	−7.4
CI/6-31G(d) [c]	0.0	−0.4	−23.6	−4.8
CI/6-31G(d) [c, d]	0.0	−1.3	−33.4	−7.9

[a] The total energies of **1** are −1157.82123 (HF/6-31G(d)), −1157.84191 (HF/6-31G(2d,p)), −1157.85291 (HF/6-31G(2df,p)), −1158.14814 (MP2), −1158.18784 (MP3), −1158.13951 (CI), and −1158.20174 (CI) [d]. [b] Using HF/6-31G(2d,p) optimized geometries. [c] Using HF/6-31G(d) optimized geometries. [d] Values after size-consistency correction due to unlinked clusters (see Ref. [15b]).

Further inclusion of a set of d-type polarization functions on Si and a set of p-type polarization functions on H (i.e., 6-31G(2d,p) basis) brings **2** nearer to **1** and lowers the HF/6-31G(d) barrier to 0.4 kcal mol^{-1}. This barrier height was not changed at the HF level by further inclusion of a set of f-type polarization functions on Si (see HF/6-31G(2df,p) in Table 1). A zero-point correction made with the HF/6-31G(d) harmonic vibration frequencies yields a height of 0.6 kcal mol^{-1} for the classical barrier. This indicates that **1** is very unstable towards isomerization despite the fact that the lowest frequency of **1** is relatively high (277 (e) cm^{-1} at the HF/6-31G(d) level).

To confirm the findings at the HF level, the so-called HF instability problem was checked for **1** and **2** according to the procedure proposed by *Seeger* and *Pople*.[14] All positive eigenvalues of the instability matrices calculated at the HF/6-31G(d) level suggest that both **1** and **2** can be well described in the HF single-determinant treatment. Thus, the effect of electron correlation was imcorporated by means of Møller-Plesset (MP) perturbation theory up to third-order and configuration interaction (CI) calculations with all single and double excitations from the HF single-determinant in the core-frozen approximation.[15] As summarized in Table 1, electron correlation gives a lower energy for **2** than for **1** at all levels of theory.[16] This suggests that most probably **1** cannot be a minimum energy structure and, hence, is not synthesized and isolated.

Along a symmetry-allowed path, **1** collapses via **2** to a D_{2d} puckered ring structure (**3**) with all the hydrogens in axial positions.[17] As Figure 2 shows, the minimum D_{2d}

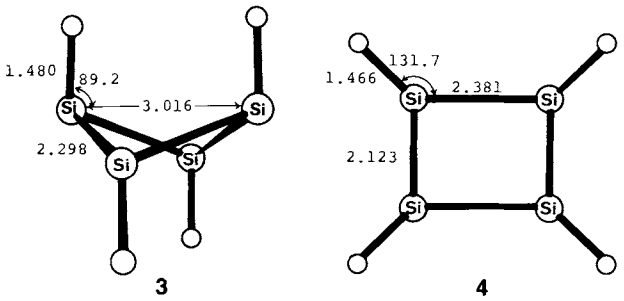

Fig. 2. Bond lengths [Å] and angles [°] of the HF/6-31G(d) optimized structures of **3**(D_{2d}) and **4**(D_{2h}).

structure can be viewed as a "two-bond stretch" isomer and is ca. 33 kcal mol^{-1} more stable than **1**, as shown in Table 1.[18] On the other hand, the symmetry-forbidden rearrangement of **1** to tetrasilacyclobutadiene **4** is ca. 8 kcal mol^{-1} exothermic. However, it should be noted that **4** has two imaginary frequencies and is not a minimum in the planar D_{2h} form.[3,4] We found that **4** leads to a nonplanar C_s structure with one axial hydrogen and three equatorial hydrogens (being 24.8 kcal mol^{-1} more stable than **1** at the CI/6-31G(d) level after size-consistency correction[15b]), as calculated very recently by *Schaefer* et al.[19]

In conclusion, the tetrahedral Si_4H_4 is unlikely to be a local minimum on the potential energy surface, in sharp contrast with the tetrahedral C_4H_4. However, it may be an interesting challenge to find out whether a proper substituent can stabilize the tetrasilatetrahedrane framework.

[7] The strain energy is as large as 141 kcal mol^{-1} in **1** [6a]. In contrast, silicon compounds consisting of four-membered rings possess consider-

ably smaller strain energies: for example, octasilacubane (being 94 kcal mol^{-1} strained) is 65 kcal mol^{-1} less strained than cubane and forms an interesting synthetic target [6a].

[8] See also P. von R. Schleyer, A. F. Sax, J. Kalcher, R. Janoschek, *Angew. Chem. 99* (1987) 374; *Angew. Chem. Int. Ed. Engl. 26* (1987) 364; P. von R. Schleyer, R. Janoschek, *Angew. Chem. 99* (1987) 1312; *Angew. Chem. Int. Ed. Engl. 26* (1987) 1267; Ref. [5].

[9] Si-Si bonds are ca. 14 kcal mol^{-1} weaker than C-C bonds: R. Walsh, *Acc. Chem. Res. 14* (1981) 246.

[10] The program used is GAUSSIAN 82 developed by *J. S. Binkley, M. J. Frisch, D. J. DeFrees, K. Rahgavachari, R. A. Whiteside, H. B. Schlegel, E. M. Fludre, J. A. Pople*, Department of Chemistry, Carnegie-Mellon University, Pittsburgh, USA. For the basis sets employed, see M. M. Francl, W. J. Pietro, W. J. Hehre, J. S. Binkley, M. S. Gordon, D. J. DeFrees, J. A. Pople, *J. Chem. Phys. 77* (1982) 3654; M. J. Frisch, J. A. Pople, J. S. Binkley, *ibid. 80* (1984) 3265.

[11] For example, see p. 90 in Ref. [1a].

[12] We also located a stationary point for a structure with D_{2d} symmetry which corresponds to the simultaneous breaking of two Si-Si bonds. This stationary point (with two Si-Si bonds stretched to 2.612 Å) was only 3.7 kcal mol^{-1} less stable than **2** at the HF/6-31G(d) level but had two imaginary frequencies; one of these frequencies was associated with distortion to **2**.

[13] H. Kollmar, F. Carrion, M. J. S. Dewar, R. C. Bingham, *J. Am. Chem. Soc. 103* (1981) 5292, and references cited therein.

[14] a) R. Seeger, J. A. Pople, *J. Chem. Phys. 66* (1977) 3045; b) for the current topics of the HF instability problem, see J. Paldus, J. Cizek, *Can. J. Chem. 63* (1985) 1803, and references cited therein.

[15] a) For MP, see J. A. Pople, J. S. Binkley, R. Seeger, *Int. J. Quantum Chem. Symp. 10* (1976) 1; b) for CI, see J. A. Pople, R. Seeger, R. Krishnan, *ibid. 11* (1977) 149.

[16] In order to check the effect of electron correlation on the geometry optimization, the structure of **1** was reoptimized at the MP2 level with the 6-31G(d) basis set. However, the resultant MP2 optimized structure (Si-Si = 2.316 and Si-H = 1.478 Å) differed little from the corresponding HF optimized structure (Si-Si = 2.314 and Si-H = 1.464 Å) and its MP2 energy (−1158.14842 au) was 2.1 kcal mol^{-1} higher than the MP2 energy of **2** calculated even on the HF/6-31G(d) optimized structure of **2**.

[17] An equatorial arrangement of the hydrogens results in a less stable minimum D_2 structure which correlates in symmetry with **4** in Figure 2. On the other hand, a C_{2v} transition structure results by arranging two hydrogens in equatorial positions and two other hydrogens in axial positions, which leads to a C_s structure as described in the text. However, it should be noted that the rearrangements of **3** to the D_2 and C_{2v} structures are both symmetry forbidden.

[18] The stability analyses of **3** and **4** show that the HF solutions (being singlet stable but non-singlet unstable [14b]) are unstable with respect to the spin density wave (SDW) solutions. This suggests that the four-membered rings of **3** and **4** have some tetraradical character (antiferromagnetic electron-spin localization onto each Si) and more sophisticated treatments of electron correlation may be essential for their relative energies. For some hexaradical character and puckering of the six-membered ring in hexasilabenzene, see S. Nagase, H. Teramae, T. Kudo, *J. Chem. Phys. 86* (1987) 4513.

1,2-Dilithioethane from Ethylene and Lithium

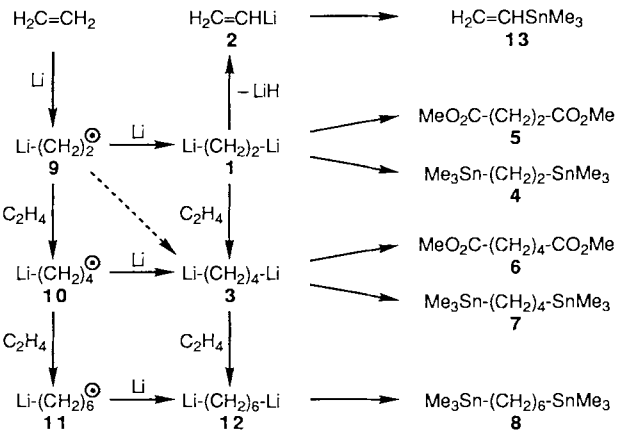
By *Nicolaas J. R. van Eikema Hommes, Friedrich Bickelhaupt,* and *Gerhard W. Klumpp**

So far, simple vicinal dilithioalkanes have eluded generation under conditions of long life.[1] On the one hand, the most accessible routes to organolithium compounds, starting from the corresponding halogen compounds, in the case of *vic*-dihaloalkanes lead to β-halolithioalkanes. These eliminate lithium halide [Eq. (a)] much faster than they exchange the halogen substituent for lithium.[2] On the other hand, calculations have shown that 1,2-dilithioethane **1** should be much less stable than an isomeric complex consisting of vinyllithium **2** and lithium hydride [Eq. (b)].[3]

$$\mathrm{HalCH_2CH_2Hal} \longrightarrow \mathrm{HalCH_2CH_2Li} \longrightarrow \mathrm{H_2C{=}CH_2 + LiHal} \quad \text{(a)}$$

$$\underset{\mathbf{1}}{\mathrm{LiCH_2CH_2Li}} \longrightarrow \underset{\mathbf{2}\cdot\mathrm{LiH}}{\mathrm{H_2C{=}CHLi\cdot LiH}} \quad \Delta H = -29.8\ \mathrm{kcal\ mol^{-1}} \quad \text{(b)}$$

In agreement with the calculational results, ethylene, in the presence of catalysts, reacts with lithium to give mainly **2** and lithium hydride.[4,5] The small amounts of 1,4-dilithiobutane **3** that are also formed may be due to addition of **1** to ethylene.[6] Recently, we were able to generate **1** by reductive coupling of two molecules of iodomethyllithium at −100 to −80 °C.[7] As expected, the elimination of lithium hydride did not occur at this temperature, and the presence of **1** could be demonstrated for the first time by stannylation. Unfortunately, this method of preparation is afflicted with the rapid destruction of **1** (presumably with the formation of ethylene [see Eq. (a)] after exchange of a lithium atom for an iodine atom from the diiodomethane used to generate iodomethyllithium); therefore, the yield of 1,2-bis(trimethylstannyl)ethane **4** is very low (0.5%).[8] We now report that **1** and **3** are formed when lithium vapor is condensed onto a glass composed of ethylene and dimethyl ether at −196 °C in the apparatus described by *Kündig* and *Perret*,[9] after which the glass is allowed to melt and the resulting solution kept at −120 °C for one hour.



The reaction mixture, consisting of a light brown supernatant and a black sediment, was treated with gaseous CO_2, worked up in the usual way, and subjected to reaction with diazomethane, giving dimethyl succinate **5** and dimethyl adipate **6**, each in ca. 8% yield based on lithium. Treatment of the reaction mixture with chlorotrimethylstannane led to **4** and 1,4-bis(trimethylstannyl)butane **7** in practically the same yield. In one experiment, a small amount of 1,6-bis(trimethylstannyl)hexane **8** could be detected. Hexamethyldistannane was the only other product formed.

Destruction of the unreacted lithium with excess *n*BuCl *before* addition of chlorotrimethylstannane had no effect on the yields of **4** and **7**. This excludes formation of **4** via the following sequence: stannylation of the β-lithioethyl radical **9**, lithium reduction of the β-(trimethylstannyl)ethyl radical thus formed, and stannylation. The presence of **1** and **3** explains the formation of the diesters **5** and **6** and the ditin compounds **4** and **7**, respectively. The following routes of formation are conceivable for **3**: (1) addition of **1** to ethylene in analogy to the known ethylen-

ation of alkyllithium compounds;[10] (2) addition of the β-lithioethyl radical **9** to ethylene to give **10**, followed by reaction of **10** with lithium.[11] Compound **3** may also (in part) result from the dimerization of **9**. The corresponding reactions of **3** and **10** with ethylene give **12** (in the case of **10** via **11**), whose presence is indicated by **8**. In agreement with the earlier results and their interpretation,[4] no **4** was isolated when the mixture of **1**, **3**, and unreacted lithium in pentane was maintained at 0°C for 30 min and then subjected to stannylation. Instead, a corresponding amount of trimethylvinylstannane **13** was found, together with **7**, present in unchanged yield. **13** is the product of stannylation of **2** formed from **1**.[12]

The formation of **1** from ethylene and lithium at a temperature much lower than the one previously required (which caused immediate elimination of lithium hydride) is a consequence of the high activity of the lithium used; i.e., in this form the reduction potential of lithium manifests itself kinetically much more strongly than is the case for lithium shavings[4a] or lithium sand.[4b]

Experimental Procedure

A steel crucible containing lithium (15 mmol) was placed in the evaporator of the Kündig-Perret apparatus. The rotating 1000-mL pear-shaped flask, cooled to −196°C, was then charged with dimethyl ether (12 g) and ethylene (140 mmol) was condensed into the flask. After reducing the pressure to 5×10^{-3} mbar, the crucible was heated to 550°C.

After ca. 30 min, the sublimation of lithium was complete. The contents of the flask were allowed to melt by warming to −120°C. The solution was kept at this temperature for one hour. Then it was cooled to −130°C and gaseous CO_2 was introduced in a rapid stream. After warming to room temperature, diethyl ether was added, the resulting mixture was shaken with several milliliters of 2 N HCl and the organic phase was dried, concentrated, and added to diazomethane in ether at 0°C. After concentration, analysis of the reaction mixture and isolation of the products were performed by gas chromatography [13]. Stannylation was carried out by adding 18 mmol of Me_3SnCl, dissolved in 50 mL of diethyl ether/pentane 1/1, to the reaction mixture at −120°C. The resulting mixture was then allowed to warm to room temperature, shaken with water, concentrated and subjected to gas chromatography for analysis and isolation of the products [13].

[6] An alternative interpretation starts from the β-lithioethyl radical **9**, which, on the one hand, can lead to **3** by addition to ethylene [11] or by dimerization and, on the other hand, can lead to **2** by donating a hydrogen atom to the radical anions formed from the catalyst. The lithium compounds formed by the latter route should finally eliminate lithium hydride.

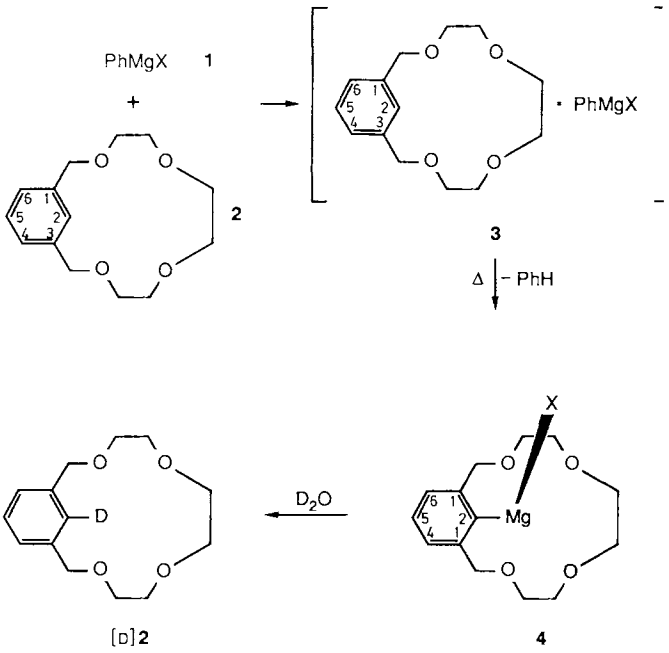
The Activation of Phenylmagnesium Compounds by Crown Ethers**

By *Peter R. Markies, Tateo Nomoto, Otto S. Akkerman, Friedrich Bickelhaupt,* Wilberth J. J. Smeets,* and *Anthony L. Spek*

Organomagnesium[1b] and organolithium[1c] compounds can be employed interchangeably in a wide range of organometallic reactions. However, certain types of reactions, such as halogen-metal exchange[2] and hydrogen-metal exchange in arenes,[3] are the exclusive province of organolithium compounds and are observed not at all—or only under special conditions—with the less reactive organomagnesium compounds.[4] We have now found that these two types of reactions indeed do occur with phenylmagnesium compounds under very mild conditions if the reactivity of these compounds is enhanced by complexation with crown ether **2**, a derivative of [15]crown-4.



Scheme 1. **a**, X = Ph; **b**, X = Br.

For example, the metalation of **2** with diphenylmagnesium **1a** to give **4a** proceeds stepwise via the complex **3a** (Scheme 1). Using an all-glass apparatus,[5] we added, with stirring, a solution of 1 mmol of **1a** in 10 mL of diethyl ether to 1 mmol of **2**; a colorless precipitate formed and was purified by decanting the mother liquor, washing with redistilled ether, and drying under vacuum. The ^{1}H-NMR spectrum,[6] as well as the HCl and EDTA titration[5] after

[**] We thank *A. J. M. Duisenberg* for collecting the X-ray data. This work was supported by the Netherlands Foundation for Chemical Research (SON) and by the Netherlands Organisation for Scientific Research (NWO) (*P. R. M., T. N., W. J. J. S., A. L. S.*).

hydrolysis, showed the composition to be **3a** · 0.75 Et_2O. Adduct **3a** was unchanged after 24 h in [D_6]benzene at room temperature. In [D_8]toluene at ca. 80 °C, on the other hand, it underwent reaction within 6 h to give **4a** and benzene quantitatively; **4a** was characterized by its ^{1}H-NMR spectrum,[6] by deuterolysis to [D]-**2**,[7] and by X-ray structure analysis.[8] Similarly, we obtained the Grignard compound **4b** from phenylmagnesium bromide **1b** and **2**; we had obtained **4b** earlier from aryl bromide **5** and magnesium.[7] The essential features of the crystal structures of **4a** (Fig. 1) and **4b**[7] are in agreement.

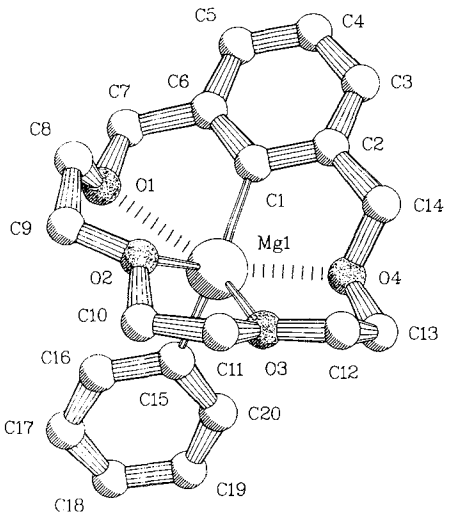

Fig. 1. PLUTON drawing of **4a** in the crystal (only one of the two nearly identical molecules is shown). Selected distances [Å] and angles [°]: Mg1-C1 2.127(4), Mg1-C15 2.154(4), Mg1-O1 2.619(3), Mg1-O2 2.183(3), Mg1-O3 2.209(3), Mg1-O4 2.335(3); C1-Mg1-C15 127.8(1), C1-Mg1-O2 111.2(1), C1-Mg1-O3 125.5(1), C15-Mg1-O2 105.6(1), C15-Mg1-O3 100.5(1), O2-Mg1-O3 71.4(1).

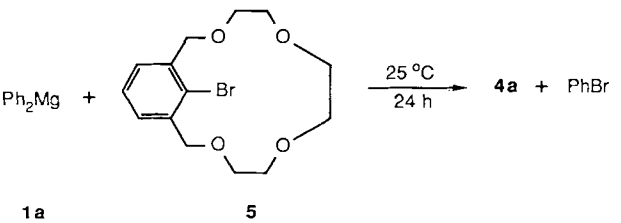
With organolithium compounds, the halogen–metal exchange occurs appreciably more readily than the hydrogen–metal exchange. The same should hold for organomagnesium compounds. Indeed, **1a** reacts with **5** to give **4a** (Scheme 2) faster than it reacts with **2**. After dissolution in [D_8]toluene, the precipitate formed initially from **1a** and **5** in diethyl ether showed immediately, even at room temperature, the ^{1}H-NMR signals of **4a** and bromobenzene; the reaction was quantitative after 24 h at room temperature.



Scheme 2.

Further investigations are necessary to elucidate the mechanism of these reactions. However, several interesting features of the reaction have already emerged: (1) The reaction **1** + **2** → **4** + benzene is certainly favored thermodynamically by the polycoordination of magnesium in **4**. (2) Steric effects play an important role, since reaction of **1a** with the next higher crown ether homologue of **2**, a derivative of [18]crown-5, under comparable conditions, does not lead to hydrogen–metal exchange. Instead, an organometallic rotaxane is formed in which nearly linear but structurally intact **1a** fills the cavity of the crown ether.[9] (3) It is tempting to speculate that, in the reaction of **1** with **2**, an important role is played not only by the carbanionic activation of the phenyl group, which occurs with certainty in the reaction of organolithium compounds, but also by the electrophilic attack of magnesium, activated by polarization of the Mg–C bond, on the benzene ring of **3**. (4) The halogen–metal exchange reveals that the reactivity of organolithium compounds is approached qualitatively but not quantitatively: organolithium reagents exchange the bromine atom in **5** at −78 °C,[10] but **1a** reacts with **5** only at room temperature. Furthermore, the direct metalation of **2** with organolithium reagents is not possible, since ethylene glycol ethers are cleaved under these conditions.[10, 11]

The reactions described here are further characteristic examples for organolithium-like behavior of organomagnesium compounds effected by polycoordination by crown ethers or cryptands; such behavior has also been observed in additions to pyridine[12a] and in ether cleavages.[9, 12b] Such reactions are not only mechanistically but also preparatively interesting, since **2** is appreciably more accessible than the bromide **5**,[7, 10] thereby allowing the facile synthesis of an organometallic compound of type **4** directly from the parent compound **2**.

β-Mannosides from β-Glucosides by Intramolecular Nucleophilic Substitution with Inversion of Configuration**

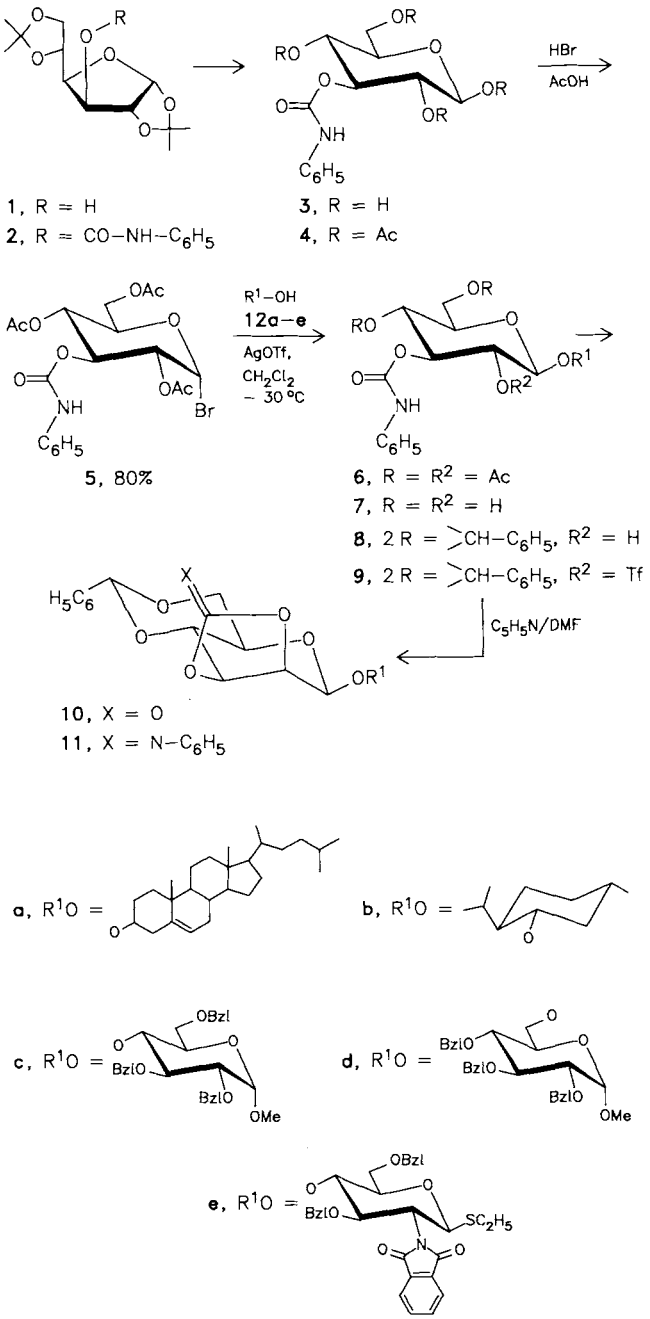
By *Horst Kunz** and *Wolfgang Günther*

Owing to their immunological as well as pharmacokinetic and pharmacodynamic properties, glycoconjugates are attracting increasing attention for the synthesis of selectively active biological substances. A central structural unit of the *N*-glycoproteins, which are widespread as serum and membrane components, is the β-mannosylchitobiose in the core region.[1]

Manβ1–4GlcNacβ1–4GlcNacβ1–Asn
core region

Of the glycoside linkages, the β-mannosidic link is especially difficult to realize, since both the anomeric effect as well as the neighboring group effects in the sense of the Koenigs–Knorr reactions favor only formation of the α-mannosides.[2] The β-mannoside syntheses described hitherto start from 2,3-carbonyl-,[3] 2-*O*-mesyl-,[4] or benzyl-protected mannosyl donors which are activated with silver silicate[5] or silver-zeolite.[6] With silver silicate as reagent, complex oligosaccharides of the *N*-glycoproteins have been synthesized. However, a satisfactory selectivity in the β-mannosidic linkage to the glucosamine is achieved only when glucosamine is employed in the form of reactive 1,6-anhydro-2-azido derivatives.[2] With 3,6-*O*-benzyl-protected *N*-acetylglucosamine derivatives, sometimes the α-mannoside is also formed exclusively by this method.[7,8] A further β-mannoside synthesis in which the benzyl-protected *N*-acetylglucosamine derivatives could be employed involves the epimerization of β-glucosides by oxidation and subsequent reduction in the 2-position.[9] Common to all these methods is that α-mannosides[3,8] or β-glucosides[9] are formed as well as the desired β-mannosides, and consequently a subsequent separation is essential.

Herein we report a method by which the β-mannosides can be obtained from the accessible β-glucosides via an inversion of configuration at C-2 by nucleophilic substitution.[10,11] The S_N2 reaction at C-2 of the glycosides is difficult because the coaxially oriented lone pair on the ring oxygen interferes. We accomplished this reaction by introduction of the oxygen nucleophile intramolecularly in the sense of a neighboring group effect. The neighboring group is formed via the *N*-phenylurethane **2** of the 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose **1**, from which the glucosyl donor **5** is synthesized via hydrolysis to **3** and acetylation to **4** by the usual reaction with HBr/glacial acetic acid (see Scheme 1).



Scheme 1. **1**→**2** [12]: H_5C_6–N=C=O; **2**→**3**: H_2SO_4/H_2O/dioxane; **3**→**4**: Ac_2O/pyridine; **6**→**7**: K_2CO_3, MeOH; **7**→**8**: H_5C_6–$CH(OMe)_2$, HBF_4/Et_2O; **8**→**9**: $(F_3CSO_2)_2O/CH_2Cl_2$/pyridine.—Tf = F_3CSO_2, C_5H_5N = pyridine.

The reactions leading to **4** proceed almost quantitatively. 2,4,6-Tri-*O*-acetyl-3-*O*-(*N*-phenylcarbamoyl)-α-D-gluco-

pyranosyl bromide **5** is obtained from **4** in 80% yield. The synthesis of the β-glucosides **6** is carried out according to the silver triflate method[13] and, without exception, leads (not optimized) to 65–80% yields. Losses arise alone by orthoester formation and associated hydrolysis (see Table 1). In no case is the α-glucoside observed.

Table 1. Synthesis of β-mannosides **10** via the inversion of glycosides **6** at C-2 according to Scheme 1.

	β-Glucoside [a]			β-Mannoside **10**		
	Yield [%]	δ(C-1) [b]		Yield [%] [c]	$[\alpha]_D^{23}$ (*c*) [d]	δ(C-1) [b]
6a	40 [e]	99.7	**10a**	65	− 91.8 (0.5)	94.3
6b	65	98.8	**10b**	80	−149.3 (1.0)	92.8
6c	67	100.1	**10c**	67	− 43.3 (1.0)	95.6
6d	69	100.7	**10d**	66	− 32.9 (1.0)	94.9
6e	82	100.1	**10e**	65	− 24.5 (1.0)	96.6
			+ **11e**	10	− 14.6 (0.5)	100.01

[a] The yields (referred to **5**) were not optimized. [b] 100.1-MHz ^{13}C-NMR ($CDCl_3$). [c] Referred to **8**, which is obtained in ca. 75% yield from the respective glucoside **6**. [d] In CH_2Cl_2. [e] Using silver 4-hydroxyvalerate [14].

In particular the sluggishly reactive acceptor **12e** (with benzyl-protective groups in the 3- and 6-position), which cannot be used for direct β-mannosylation,[7] reacts with **5** to give the desired β-glucoside **6e** in 82% yield. For conversion of the β-*gluco*-compounds **6** into the β-*manno*-compounds **10/11** the *O*-acetyl groups are removed with K_2CO_3 in methanol. In the resulting sugar **7**, the 4- and the 6-hydroxy group are protected as the benzylidene acetal (→ **8**). Both reactions proceed in 85–90% yield. The free 2-hydroxy group of the β-glucosides **8** is now activated with trifluoromethanesulfonic anhydride/pyridine for the inversion of configuration to give the isolable triflates **9**, which can be converted directly into the β-mannosides **10** by heating to 75°C in pyridine/dimethylformamide. This inversion at C-2 proceeds smoothly and without side reactions because the intramolecular attack of the carbamoyl oxygen is favored entropically. It initially affords a mixture of the 2,3-*O*-carbonyl-β-mannoside **10** in crude yields of ca. 90% and small amounts of the corresponding iminocarbonate **11**. The latter has been isolated for characterization in the case of the β-mannosylglucosamine derivative **11e**. The iminocarbonates can be easily converted into the carbonates **10** by mild hydrolysis. No carbohydrate derivatives other than the β-mannosides **10/11** are detectable in the thin-layer chromatogram of the reaction mixture. The *gluco*-configurated starting material **8** is completely converted, so a chromatographic isolation of the mannosides **10** was not really necessary. However, in these first syntheses it was carried out in order to obtain analytically pure β-mannosides. The yields of the inversion reactions after chromatographic separation are 65–80% based on the benzylidene-protected *gluco*-derivatives **8**. Thus, the disaccharide β-mannosyl-*N*-acetylglucosamine (with protecting groups: **10e**) contained in the core region of the *N*-glycoproteins is obtained in 75% yield, without having to separate side products with another configuration at C-1 or C-2.

The structure of the β-mannosides **10** has been confirmed ^{1}H-NMR and ^{13}C-NMR spectroscopically. Due to the 2,3-carbonate grouping the β-mannosides **10** show a remarkably large C-1/H-1 coupling with $J \approx 171$ Hz, signals shifted upfield to $\delta = 93$–96.5 for C-1 (see also Table 1), and a relatively large coupling constant $J_{1,2} \approx 3.5$ Hz in the ^{1}H-NMR spectrum.

	R	R	δ(C-1)	*J*(C-1/H-1) [Hz]
10a	−CO−		94.3	170.9
13a	H	H	98.0	157.1
10b	−CO−		92.8	172
13b	Ac	Ac	95.9	155

Removal of the CO group from **10b** under basic conditions and acetylation of the 2-OH and 3-OH groups furnishes the corresponding di-*O*-acetyl-β-mannoside **13b**, whose C-1 signal and, in particular, C-1/H-1 coupling confirm the β-mannoside structure. $J_{1,2}$ (≈ 1 Hz) in the ^{1}H-NMR spectrum of **13b** also has the small value typical for β-mannosides.

The reaction sequence shown in Scheme 1 thus enables the difficultly realizable β-mannosidic linkage to be achieved both selectively and efficiently.

Polycyclic Silylamides of Ge^{II} and Sn^{II} with Different Structures—Bis(germanediyl) versus Distannate**

By *Michael Veith** and *Richard Lisowsky*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

The differing coordination behavior of homologous elements in compounds of the same type can be due, inter alia, to differences in electronegativity and/or atomic size. We report here on the incorporation of two germanium(II) or tin(II) atoms respectively into the cyclodisilazane **1**; the

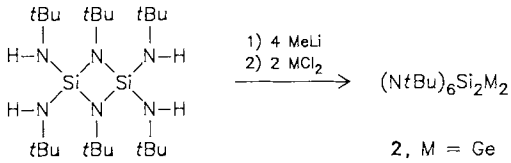
[**] Cyclic Diazastannylenes, Part 27.—Part 26: [1].

extreme differences in the structures of the products **2** and **3** are attributed to specific ring-strain effects.

Continuing on the basis of investigations into the chemistry of low valent main group elements[2] we have examined the reaction of the tetralithium salt of **1**[3] with two equivalents of the dioxane adduct of germanium dichloride and with the dichlorides of tin and lead.



$(NHtBu)_2(NtBu)_4Si_2Pb$ **4**

In the reaction with $PbCl_2$, a compound could be isolated in small yields which contained only one lead atom and, according to an elemental analysis, could be formulated as **4** (owing to its ready decomposition further physical-chemical characterization was not possible).

The compounds **2** and **3**, which are isolated in good yields, have analogous composition, have the expected molecular weights in benzene, and do not decompose in the gas phase under reduced pressure (mass spectra). The ^{1}H-NMR spectra of **2** and **3** consist of two singlets in the integral ratio 2 : 1 (Table 1).

Table 1. Some data for **2** and **3**.

The single-crystal X-ray structure analyses of **2** and **3** (Table 1) show that the structures of the two compounds are fundamentally different despite their similar composition (Fig. 1): **2** is a dispiro system with crystallographic point symmetry *mm*2 (C_{2v}) and is the first example of a species containing two isolated germanediyl units in one molecule (cf. also Refs. [4, 5]; a digermanetetrayl with both germanium atoms of formal oxidation state +1 has been described recently[6]); compound **3**, on the other hand, is a pentacycle with crystallographic point symmetry $\bar{1}$ (C_i) and with three-coordinate tin atoms. The H/Ge exchange in **1** formally proceeds with coupling of the nitrogen atoms bound to the *same* silicon atom; consequently, **2** contains two spiro centers and a linear arrangement of silicon and germanium atoms. In contrast, in the case of the formal H/Sn exchange the nitrogen atoms bridge *different* silicon atoms. The tin atoms thus come in the proximity of the nitrogen atoms N2 and N2', and, consequently, formation of an additional λ^4N-λ^3Sn bond can occur. The pentacyclic $Sn_2N_6Si_2$ skeleton can be described in terms of two face-sharing (Si_2N_2) seco-norcubane units.

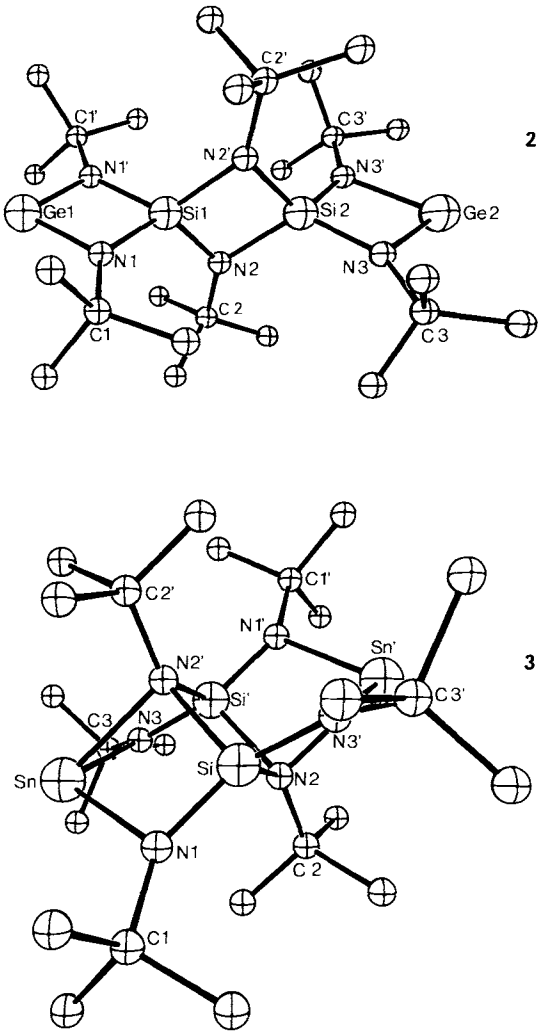

Fig. 1. Molecular structures of compounds **2** and **3**. Some (mainly averaged) bond lengths [pm] and angles [°]: **2**: N-Ge 185.6(6), N1,3-Si 173.4(3), N2-Si 174.9(1); N-Ge-N 80.9(3), N1,3-Si-N1',3' 88.0(2), N2-Si-N2' 85.9(1).—**3**: N-Sn 224.7(9), N1,3'-Si 166.8(1), N2,2'-Si 181.0(4); N1-Sn-N3 110.8(2), N1,3-Sn-N2 70.7(2), N2-Si-N2' 86.7(3), N1-Si-N3' 142.2(9) [10].

With regard to the bond lengths and angles in **2** and **3** the following special features are noteworthy (cf. Fig. 1):

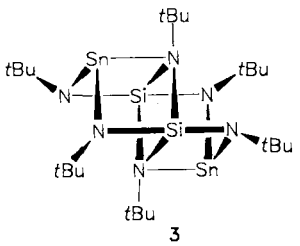
1) The Si–N distances in the central Si_2N_2 four-membered ring are, as expected, shorter in **2** than in **3**, corresponding to the different coordination numbers of N2 in **2** (three, sp^2 hybridization) and in **3** (four, sp^3).

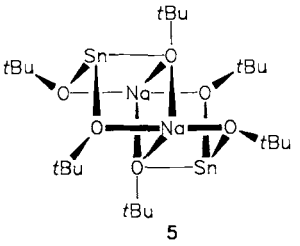
2) The Si1–N1 and Si2–N3 distances in **2** are longer than Si–N1 and Si–N3' in **3**. It can therefore be concluded that the neighboring Sn–N bond is more polar than the neighboring Ge–N bond, consistent with the higher electronegativity of the germanium compared to the tin.[7]

3) The Ge–N bond in **2** is short compared to that in the likewise monomeric bis(2,2,6,6-tetramethylpiperidino)germanium (188.5 pm);[4] this can be explained by additional p$\pi \rightarrow$pπ bonding (N$\rightarrow$Ge). All the Sn–N bonds in **3** are

about the same length; their length compares very well with those of typical λ^3Sn-λ^4N bonds such as are found in $Sn_4(NtBu)_4$ (Sn–N = 220.2 pm).[8]

The N1-Si-N3′ bond angle in **3** (Fig. 1) is extremely large for a four-coordinate silicon atom, thus indicating large steric constraints. **3** is isoelectronic and isostructural with sodium *tert*-butoxystannate **5**.[9] However, whereas





sodium as electropositive element can cope relatively well with the imposed strain in **5** (O-Na-O angle: axial 177.9(2)°, equatorial 103.3(2)°), the electronegative silicon in **3** would prefer a tetrahedral geometry (for comparison: N1-Si-N3′ 142.2°, N2-Si-N2′ 86.7°).

The different structures of **2** and **3** may be directly related to the aforementioned constraints. Since the germanium atom has a smaller radius than the tin atom, the distortion at the silicon atom in **3** should increase on formal exchange of Sn by Ge. The system is apparently no longer stable and changes to the dispiro compound **2**, even though the germanium thereby achieves the electronically less favorable coordination number two.

Experimental

A solution of **1** (1.8 g, 3.7 mmol) [3] in 20 mL hexane/20 mL diethyl ether was treated dropwise with 9.9 mL (15 mmol) of a 1.5 M solution of methyllithium in diethyl ether. After heating under reflux for 3 h the solution was cooled to −78°C and treated with 1.7 g (7.4 mmol) of germanium dichloride-dioxane adduct, [11] 1.4 g (7.4 mmol) of anhydrous tin(II) chloride or 2.06 g (7.4 mmol) of lead(II) chloride, respectively. The reaction mixture was then warmed to room temperature and stirred for a further 4 h. In all three cases the solvent was removed under high vacuum and the resulting residue recrystallized from toluene. Yields: 1.86 g (71%) pale yellow crystals of **2** (150°C, decomp.), 1.63 g (61%) orange-yellow crystals of **3** (decomp. 200°C), and 0.38 g (15%) deep-red crystals of **4**.

The Enzymic Interconversion of Isobutyryl and *n*-Butyrylcarba(dethia)-Coenzyme A: A Coenzyme-B_{12}-dependent Carbon Skeleton Rearrangement**

By *Günther Brendelberger, János Rétey,** *Doreen M. Ashworth, Kevin Reynolds, Frances Willenbrock,* and *John A. Robinson**

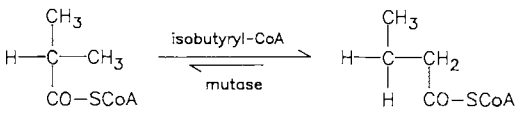
Dedicated to Professor Theodor Wieland on the occasion of his 75th birthday

Coenzyme B_{12} has one of the most complex structures[1] amongst the known coenzymes and in association with various proteins is able to promote several rearrangement reactions that until recently were without clear chemical precedence. Amongst these are three well known carbon skeleton rearrangements[2] in which an organic moiety and a hydrogen atom exchange positions on adjacent carbon atoms [Eq. (a)]. The mechanism of these rearrangements is

(a)

R = CO–SCoA methylmalonyl-CoA mutase
R = $CHNH_2$–COOH glutamate mutase
R = C(=CH_2)–COOH methyl itaconate mutase

still incompletely understood. Recently, evidence was presented for the existence of a novel rearrangement, occurring in the polyether antibiotic producing organism *Streptomyces cinnamonensis*, which involves the interconversion of isobutyryl-CoA **1** and *n*-butyryl-CoA **2**[3] [Eq. (b)]. We describe here evidence that this represents a new type of coenzyme-B_{12}-dependent enzymic rearrangement.



(b)

1 2

It was shown recently that synthetic methylmalonyl-dethia(carba)-coenzyme A (with CH_2CoA partial structure) is an excellent substrate for methylmalonyl-CoA mutase from *Propionibacterium shermanii*.[4] Such CH_2-CoA

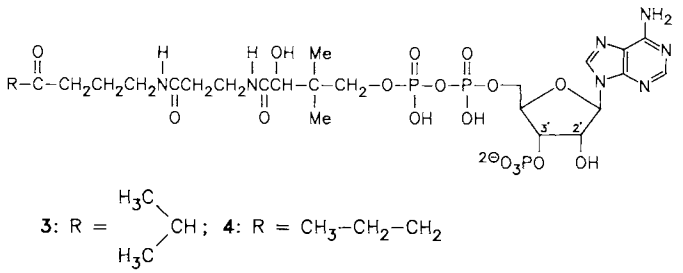
W.*, and *J. A. R.*). *G. B.* thanks the Land Baden-Württemberg for a scholarship for graduate students. We are grateful to Dr. *M. Spraul*, Bruker Analytische Meßtechnik GmbH, Rheinstetten/Karlsruhe for the 500-MHz ^{1}H-NMR spectrum.

analogues, unlike their thioester counterparts, are stable to hydrolysis and can be used for mechanistic investigations.[5] In view of this, isobutyryl-CH_2CoA **3** was prepared, starting from isopropyl vinyl ketone,[6] and following the same reaction sequence described already for the synthesis of propionyl-CH_2-CoA.[4] The ^{1}H-NMR spectrum[7] of the product, after chromatography, revealed also the presence, to the extent of about 15%, of the isobutyryl-CH_2-iso-CoA (2′-phospho-CH_2-CoA) isomer, which should not be transformed by the enzyme.



3: R = H_3C–CH(–CH_3)–; **4**: R = CH_3–CH_2–CH_2–

After **3** (5 mg) was incubated, in the presence of coenzyme B_{12} (20 μM),[8] with an ammonium sulfate fraction of a cell-free extract from *Streptomyces cinnamonensis*[9] (ca. 30 mg protein, Tris/HCl buffer, pH 7.3, 30 °C, 60 min), the protein was precipitated by acid and removed, and the products were chromatographed on DE-32 cellulose.

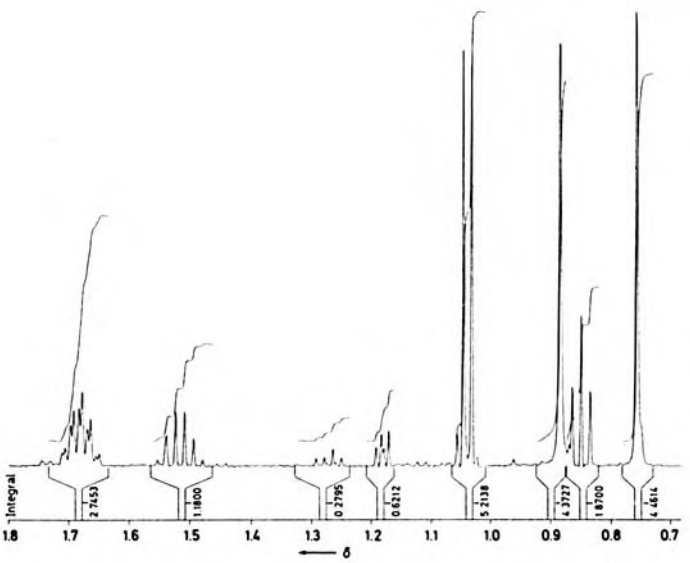


Fig. 1. Part of the 500-MHz ^{1}H-NMR spectrum of the enzymically obtained equilibrium mixture of isobutyryl- (**3**) and *n*-butyryl-carba(dethia)-coenzyme A **4** in deuterium oxide. The triplet and the sextet at $\delta = 0.85$ and 1.52, respectively, arise from the *n*-butyryl portion of **4**, while the two slightly resolved quintets at around $\delta = 1.68$ can be assigned to the middle one of the three adjacent methylene groups of the CH_2CoA moiety in each of **3** and **4** (see structural formulas).

Figure 1 shows a portion of the 500-MHz ^{1}H-NMR spectrum of these materials (3.8 mg). Clearly assignable are the signals from both isobutyryl-CH_2CoA **3** and *n*-butyryl-CH_2CoA **4**,[10] in the ratio 60:40. After taking account of the unreacted[11] isobutyryl-CH_2-iso-CoA (≈8%), the equilibrium ratio of iso- and *n*-butyryl species was 56.5:43.5.[12]

In separate incubations with the *Streptomycetes* extract, the conversion of (1-^{13}C)*n*-butyryl-CoA **2*** into (1-^{13}C)isobutyryl-CoA **1*** could also be detected,[13] and this activity was completely dependent upon the addition of coenzyme-B_{12} to the assay. The same *Streptomyces* extract was also shown to catalyze the rearrangement of methylmalonyl-CH_2CoA to succinyl-CH_2CoA, with the additional decarboxylation of about half the substrate to propionyl-CH_2CoA. However, neither isobutyryl-CH_2CoA nor isobutyryl-SCoA was a substrate for highly purified methylmalonyl-CoA mutase from *P. shermanii*. Whether or not the methylmalonyl-CoA mutase and isobutyryl-CoA mutase activities from *Streptomyces cinnamonensis* are promoted by the same protein is not yet clear. Antibodies raised against the methylmalonyl-CoA mutase from *P. shermanii* failed to inhibit the isobutyryl-*n*-butyryl-CoA rearrangement, although the same antibodies showed a clear reaction with the methylmalonyl-CoA mutase from *Streptomyces cinnamonensis* as seen on a Western Blot (immunoblot) analysis.[14]

It seems most likely that in an evolutionary sense the methylmalonyl-CoA mutase and isobutyryl-CoA mutase will be very closely related, perhaps by a mutation in the active site, in which a basic amino acid residue (for binding $COO^\ominus$) is changed to a lipophilic one (for binding CH_3).

Isolated, Complex Zintl Molecules in the Gas Phase**

By *Andreas Hartmann* and *Konrad G. Weil**

Intermetallic molecules can be prepared in many different ways. For example, they are formed in high yields by aggregation from the gas phase; they are detected by electron collision ionization and subsequent mass selection. Studies of this sort have been reported, inter alia, by *Martin*.[1] Small, mostly diatomic intermetallic molecules have been detected mass spectrometrically by several groups, and their results have been reviewed in detail by *Gingerich*.[2]

We are especially interested in establishing whether even larger intermetallic aggregates can occur in equilibrium vapors. In the past few years we have carried out a series of mass spectrometric investigations on the composition of vapors over alkali metal/antimony and alkali metal/bismuth mixtures and have in this connection reported on two classes of intermetallic compounds:

a) predominately ionic molecules like Cs_2Sb_2 and Cs_2Sb_4[3]
b) cluster-like alkali-metal-rich particles such as Na_6Sb_4[4] and Cs_6Sb_4[5]

The molecules mentioned under a) can be regarded as aggregates of cesium ions and $(Sb_2)^{2\ominus}$ dumbbells or square-planar $(Sb_4)^{2\ominus}$ ions, while the particles mentioned under b) can be interpreted as alkali-metal octahedra arranged around a tetrahedral Sb_4 nucleus.

We now report on a further class of intermetallic molecules which we will describe as ternary and quaternary isolated Zintl molecules. For investigating the molecular beam emerging from a Knudsen cell we used a sector field mass spectrometer (VG Micromass MM-30K), modified by the incorporation of an ion-counting system and a Hall probe. It was possible to ease the manipulation of the complex spectrometer system still further by incorporating microprocessor controlling with a personal computer (Olivetti M24) and software developed by us.

The controlling of the electromagnet and of the ion counting unit are crucial in facilitating the computer-controlled detection and processing of the mass spectrometric signals. In order to avoid as far as possible any fragmentation effects during the ionization, electrons with an energy of ≤ 12 eV were used.

We investigated alloys of the following components:

cesium/indium/antimony	(2/1/3)
cesium/tin/antimony	(1/1/3)
cesium/tin/antimony/bismuth	(1/1/2/1)

The mixtures corresponding to the compositions shown in parentheses were prepared in a glovebox and sealed in evacuated quartz glass ampules. The ampules were opened under argon and a part of the regulus was transferred to a steel Knudsen cell, which was immediately placed in the mass spectrometer and evacuated. Depending on the combination of elements investigated, the signals of $Cs^{\oplus}$, $Sb_2^{\oplus}$, $Sb_4^{\oplus}$, $Bi^{\oplus}$, $Bi_2^{\oplus}$ and of the monomeric and dimeric ions of indium and tin dominate in the mass spectra. Moreover, molecules corresponding to the known intermetallic compounds of the ternary system cesium/antimony/bismuth are found as minority species. As examples for the identification of ternary molecules Figure 1 shows a section of the mass spectrum that was obtained from vapor over the cesium/indium/antimony mixture. The spectra for Cs_2InSb_3 and Cs_2Sb_4 calculated from the natural isotopic ratios are shown under the mass spectrum in the region $740 \leq m/z \leq 758$ after computer subtraction of background signals. It is immediately apparent that the assignment is unequivocal.

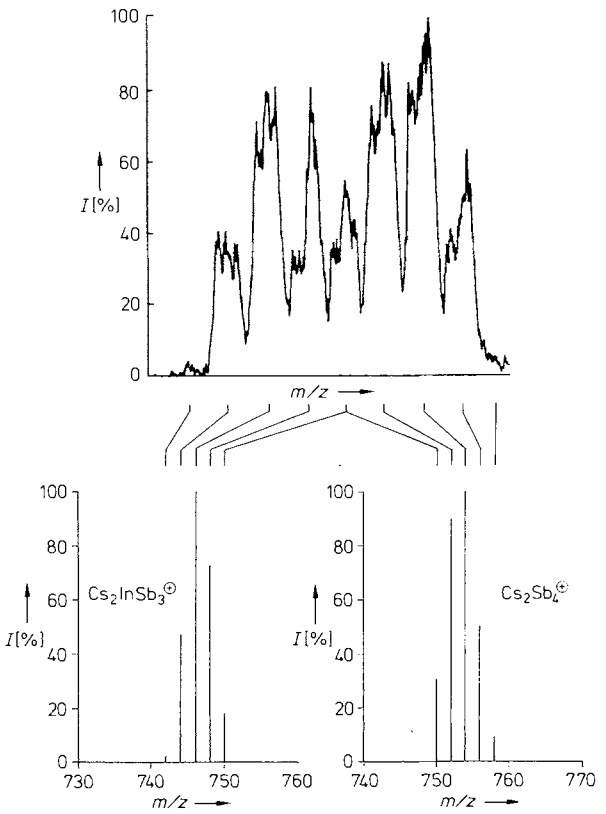

Fig. 1. Comparison of measured and calculated mass spectra for the vapor over a cesium/indium/antimony mixture at $T = 994$ K in the range $740 \leq m/z \leq 758$. I = relative intensity, referred to strongest signal.

The other ternary and quaternary compounds listed in Table 1 could be similarly assigned. The large number of natural tin isotopes makes the identification of tin-containing molecules difficult, since the neighboring mass signals in the mass range under consideration cannot be completely resolved. The comparison between calculated and measured mass spectra nevertheless leads to an unequivocal assignment, as shown for the example $CsSnSb_3$ in Figure 2. The ionization energies of the intermetallic molecules are, as far as they are known, also listed in Table 1. In addition, all the molecules mentioned in Table 1 show a significant shutter effect, thus evidencing their origin from within the Knudsen cell.

The compounds contain aggregates such as $(InSb_3)^{2\ominus}$, $(SnSb_3)^{\ominus}$, $(SnBiSb_2)^{\ominus}$, $(SnBi_2Sb)^{\ominus}$, and $(Sn_2Sb_2)^{2\ominus}$, isoelec-

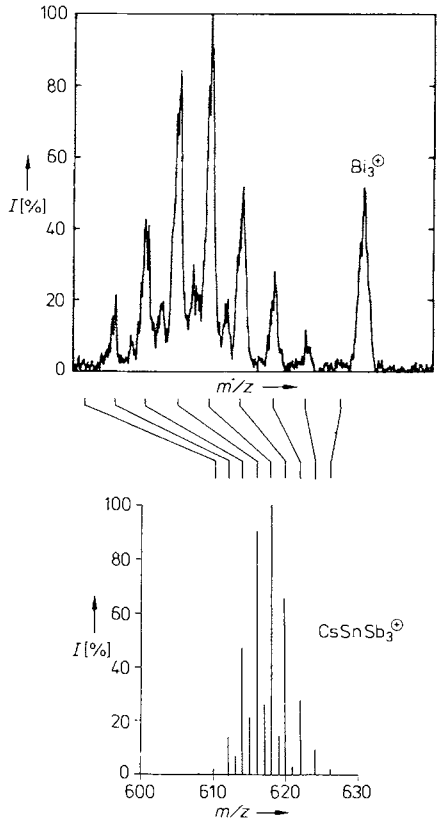

Fig. 2. Comparison of the measured and calculated mass spectra for the vapor over a cesium/tin/antimony mixture at $T = 779$ K in the range $610 \leqslant m/z \leqslant 630$. For clarity only signals with even m/z values are assigned. The signal at $m/z = 627$ contains the signal of $Bi_3^{\oplus}$ as background signal from previous experiments.

tronic with Sb_4 and with one or two $Cs^{\oplus}$ ions respectively for charge equalization.

The incorporation of heteroatoms (In, Sn) into tetrahedral Sb_4-units, not known in the solid state, is thereby made possible, at least formally, by the alkali metals transferring an appropriate number of electrons to the elements of the third and fourth main groups, respectively, such that these satisfy the (8-N) rule. Hence the above-mentioned molecules can be classified according to the concept of *Zintl, Klemm,* and *Busmann*.[6]

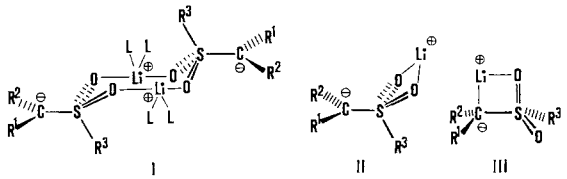
A Monomeric Potassium Salt of Bis(trimethylsilyl)methyl Phenyl Sulfone and the Determination of the $^1J(^{13}C,^{29}Si)$ Coupling Constants of Si-Stabilized "Carbanions"**

By *Hans-Joachim Gais,* Jürgen Vollhardt,* and *Carl Krüger*

Dedicated to Professor Ulrich Wannagat on the occasion of his 65th birthday

Crystal structure analyses of dimeric lithium salts of type **I** have afforded important insights into the nature of the stabilization of a carbanion by a sulfonyl group.[1] The structure of their asymmetric α-sulfonyl carbanions ($R^1 \neq R^2$) is essentially that postulated, e.g., in dimethyl sulfoxide solution[2] and calculated in the gas phase.[3a,b] Accordingly, coulombic interaction and negative anionic hyperconjugation ($n_C - \sigma^*_{SR^3}$)[3c] appear to be the dominant mechanisms of charge stabilization.



Alkali-metal salts of sulfones in dilute tetrahydrofuran solution (10^{-3} M), however, are not *dimeric* but rather *monomeric* contact ion pairs.[4] Ab initio calculations revealed two monomers (types **II** and **III**) for lithiomethyl methyl sulfone. Type **II** exhibits clear similarities to **I**, whereas **III** is completely different.[3b] What is the structure of monomeric contact ion pairs of metalated sulfones and how reliable are the calculated structures?[5] We hoped that the yet missing crystal structure of such a monomeric species might provide at least a partial answer to this question. We describe here the crystal structure analysis of the monomeric potassium·18-crown-6 salt of bis(trimethylsilyl)methyl phenyl sulfone, **1**, and we report, for the first time, the determination of the $^1J(^{13}C^{29}Si)$ coupling constants in "α-silyl carbanions".

The potassium salt **1** was obtained by metalation of bis(trimethylsilyl)methyl phenyl sulfone with potassium bis(trimethylsilyl)amide in diethyl ether in the presence of an equimolar amount of 18-crown-6. We selected this chelate ligand in order to suppress the dimerization, and the choice of potassium instead of lithium was expected to reveal the possible structural effect of the counterion.

The crystal structure analysis shows that **1**[6] is a monomer of type **II**; i.e., the potassium ion is bonded only to the sulfonyl O atoms of the anion (Figs. 1 and 2). The potassium ion is further coordinated by six O atoms of the

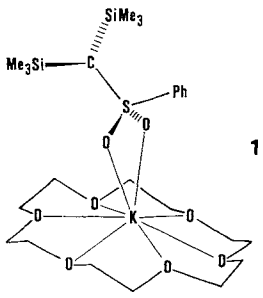
crown ether. The anionic atom C1, which is located outside the coordination sphere of the potassium ion, is coordinated in a nearly planar fashion.



1

Fig. 1. Spatial representation of **1**.

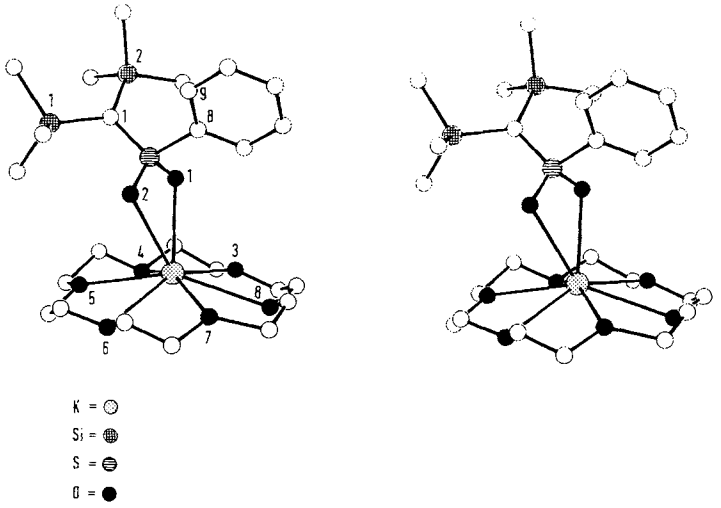


Fig. 2. Stereoprojection of the molecular structure of **1** (H atoms omitted). Important distances [Å] and angles [°]: C1-S 1.648(4), S-O1 1.473(3), S-O2 1.458(3), S-C8 1.802(4), C1-Si1 1.826(4), C1-Si2 1.875(7), K-O1 2.787(3), K-O2 2.880(3), K-O3-K-O8 2.774(4)-2.911(5); O1-K-O2 50.7(1), O1-S-O2 112.0(2), C8-S-C1 109.6(2), Si1-C1-Si2 124.0(2), Si1-C1-S 117.0(2), Si2-C1-S 118.7(2); C8-S-C1-Si1 −116.0, C8-S-C1-Si2 69.6, C1-S-C8-C9 34.3, O1-S-C1-Si2 −45.0, O2-S-C1-Si1 −1.0.

The anion has a conformation in which the lone pair on C1 is *gauche* to the two sulfonyl O atoms; however, it is rotated by ca. 23° from the ideal position[1d] for an $n_C-\sigma^*_{SPh}$ interaction. A similar finding was also made for the dimeric 1,*o*-dilithium salt of bis(trimethylsilyl)methyl phenyl sulfone **10**[7] (Table 1), which still exhibits the characteristic structural element of **I**.[7a] The length of the C1–S bond in bis(trimethylsilyl)methyl phenyl sulfone (1.747 Å)[7a] is decreased by 0.1 Å in **1** (1.648 Å), whereas the S–O bonds are only slightly longer in **1**. *There are no fundamental differences in the structures of the α-sulfonyl carbanions of* **1**, **I**, **II**, *and dimeric* **10**.

The $^1J(^{13}C^1H^\alpha)$ values have proven to be valuable probes of the structures of "carbanions" and ylides in solution:[8] sp^2 hybridization of the anionic C atom correlates with a positive Δ^1J(C,H) value and sp^3 hybridization with a negative value relative to the protonated precursor.[9] The same might hold for the $^1J(^{13}C,^{29}Si)$ coupling[10] in the synthetically important and structurally interesting "α-silyl carbanions",[11] e.g., **1** and α-silyl ylides.[12] In addition, this coupling might provide information on the C^α–Si bond.

Trimethylsilylmethyllithium **2**, which displays C–Li bonds in the crystal and whose anionic C atom is sp^3-hybridized,[13] is characterized by a solvent-dependent decrease in ^1J(C,Si) and ^1J(C,H). In contrast, ^1J(C,Si) increases relative to the protonated precursor for the Si- and S-stabilized "monocarbanions" so far investigated (Table 1). For the lithiated thioethers **3** and **4**,[14a] Δ^1J(C,Si) is smaller than for the SO-stabilized species **5**, **6a–d**, and **7**. Furthermore, the decrease in ^1J(C,H) is significantly less for **3** and **4** than, for example, for lithiomethyl phenyl sulfide, whose anionic C atom is sp^3-hybridized and which exhibits a C–Li bond.[8b,15] In the case of $^6Li/^{13}C$-labeled **4**, no C,Li coupling was observed down to −100 °C in THF; owing to the possibility of rapid exchange even at low temperatures, however, it is not possible to rule out the existence of C–Li bonds. Only a crystal structure analysis can reveal whether, in **3** and **4**, the anionic C atom exhibits partial planarity. In contrast, the SO-stabilized lithium salts **5**,[14b] **6a**,[16,1e] **6b**, and **7**, as well as the phosphazenium salts **6c** and **6d**, are characterized by a marked increase in *both* coupling constants: in the crystal, C1 of **6a** is coordinated in a nearly planar fashion,[1e] and this may be assumed to hold for **5**, **6b–d**, and **7** as well. The Δ^1J

Table 1. $^1J(^{13}C,^{29}Si)$ and $^1J(^{13}C,^1H)$ values of "α-silyl carbanions" and deviations from the corresponding values of the protonated compounds [a].

[a] J and ΔJ in Hz; sign of J not determined. [b] Solvent/temperature [°C]/concentration [mol L^{-1}]. [c] 20 MHz. [d] 100 MHz. [e] 75 MHz. [f] X = $\{[(Me_2N)_3P{=}N]_3P{=}NHtBu\}^\oplus$. [g] Y = [18]crown-6.

values for **6a** in THF and dimethyl sulfoxide are nearly identical, and no C,Li coupling was found for $^6Li/^{13}C$-labeled **6a** down to $-100°C$ in THF; in contrast to lithiated sulfoximines,[17c,d] C-Li bonds in lithiated sulfoxides[17a,b] and sulfones have thus far not been observed.[21] Interestingly, $^1J(C,Si)$ and $^1J(C,H)$ for the phosphazenium salts **6c** and **6d**, prepared by quantitative deprotonation of (triphenylsilyl)- and (trimethylsilyl)methyl phenyl sulfone, respectively, with the phosphazene base $[(Me_2N)_3P{=}N]_3P{=}NtBu$,[18] show a somewhat stronger increase than for the lithium salts **6a** and **6b**.

That the silyl group in **6b** and most likely in the other "α-silyl carbanions" acts as a strong stabilizing group is shown by the acidity of (triphenylsilyl)methyl phenyl sulfone, which is 7.7 pK_a units greater than that of methyl phenyl sulfone.[19,2] An increase in $^1J(C,Si)$ is also found for the doubly Me_3Si-substituted potassium and lithium salts **1** and **8**, respectively, the lithiosulfoximine **9**, and the 1,*o*-dilithio sulfone **10**; in the crystal, Cl of **1** and **10** is coordinated in a nearly planar fashion. However, sp^2 hybridization alone cannot explain the high, positive $\Delta^1J(C,Si)$ values of the Si/S-stabilized "carbanions", as shown by the smaller Δ^1J values of +15.0 Hz (*E*)/ +16.9 Hz (*Z*) for $Me_3SiC(=CHPh)SO_2Ph$ relative to $Me_3SiCH(CH_2Ph)SO_2Ph$. Finally, the lithiation of the monolithium salt **6a** to give the 1,1-dilithium salt **11** is accompanied by a decrease in $^1J(C,Si)$; at least two lithium ions are bound to each dianionic C atom of **11** in the crystal *and* in solution.[20]

Photolytic Cluster Synthesis: Synthesis and Structure of $[\{(Ph_3P)Au\}_7Mo(CO)_3]OH$**

By *Georg Beuter* and *Joachim Strähle**

In continuation of our studies on the controlled decomposition of azido complexes[1,2] we have also directed our attention to the photochemical degradation of $[(Ph_3P)AuN_3]$. Whereas most azido complexes undergo cleavage at the N_α-N_β bond with formation, e.g., of nitrido, nitrene, or phosphoraneimine complexes, on irradiation of $[(Ph_3P)AuN_3]$ the azide group is reductively eliminated with formation of $(Ph_3P)Au$ radicals, which subsequently unite to form gold clusters. In the presence of carbonyl-transition-metal complexes, heteronuclear metal clusters are formed. As first result of these investigations we report here on the new cluster $[\{(Ph_3P)Au\}_7Mo(CO)_3]^{\oplus}$ **1**, which can also be regarded as a half-sandwich complex of molybdenum(0) in which the C_6H_6 ligand is replaced by a previously unknown icosahedral $\{(Ph_3P)Au\}_7^{\oplus}$ fragment. Most of the gold clusters already known[3] were obtained by reduction of phosphanegold(I) halides $[(R_3P)AuX]$.

$$7[(Ph_3P)AuN_3] + [Mo(CO)_6] + H_2O \longrightarrow [\{(Ph_3P)Au\}_7Mo(CO)_3]^{\oplus}OH^{\ominus} + 3CO + 9N_2 + HN_3 \quad \text{(a)}$$

1 · $OH^{\ominus}$

For the synthesis of **1** [Eq. (a)] a mixture of $[(Ph_3P)AuN_3]$ and excess $[Mo(CO)_6]$ in THF is irradiated for ca. 12 h; after removal of the solvent the residue is taken up in CH_2Cl_2 and the reaction products separated by column chromatography.[4] The new cluster **1** crystallizes as $[(Ph_3PAu)_7Mo(CO)_3]^{\oplus}OH^{\ominus}$ in the form of air-stable red platelets.

The counterion $OH^{\ominus}$ was identified by X-ray structure analysis.[5] It arises as result of hydrolysis. If $[Mo(CO)_6]$ is not used in excess, then predominantly homonuclear gold

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

complexes that have not yet been fully characterized are formed. The IR spectrum of **1** shows two CO stretching vibrations at 1835 and 1895 cm^{-1} characteristic for the local symmetry C_{3v}. The low frequencies point to a pronounced donor behavior of the $\{(Ph_3P)Au\}_7$ residue.

Gold clusters with more than seven Au atoms are characterized by their having a central Au atom and, as a rule, they can be derived from a centered icosahedron.[3,6] A remarkable feature is that the bonds from the central atom to the peripheral Au atoms are always distinctly stronger than the bonds between the peripheral Au atoms. In the cationic cluster **1** (Fig. 1) the seven Au atoms form an icosahedral fragment with Au–Au distances between 283.8 and 303.1 pm, as are typical for bonds between peripheral Au atoms.[6] The Mo atom replaces the central Au atom of the homonuclear Au cluster and is about equidistant from all seven Au atoms (277.1–286.0 pm). With regard to its structure, the Au_7Mo skeleton has so far no analogue among the homonuclear Au_8 clusters.

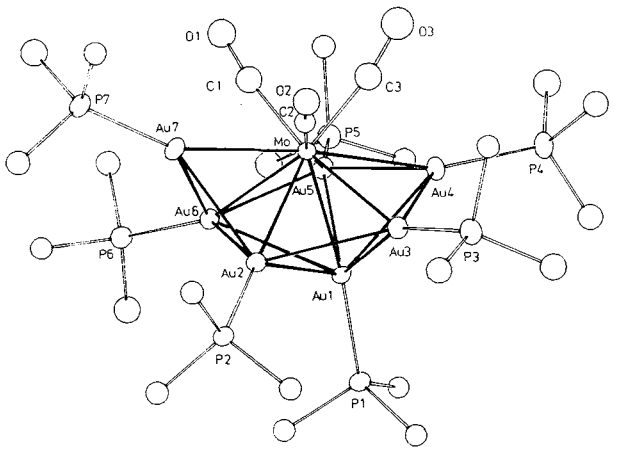

Fig. 1. Structure of **1** in the crystal of $\mathbf{1}\cdot OH^{\ominus}$. Of the phenyl groups of the phosphane ligands, only the bridgehead atoms are shown. Important bond lengths [pm] and angles [°]: Au-Au 283.80(9)–303.09(2), Mo-Au 277.11(1)–285.97(2), Au-P 228.65(4)–234.21(4), Mo-C1 197.4(2), Mo-C2 194.6(2), Mo-C3 193.8(2), C1-O1 119.1(2), C2-O2 120.1(2), C3-O3 121.2(2); Mo-C1-O1 171.8(2), Mo-C2-O2 176.3(1), Mo-C3-O3 168.5(2), C1-Mo-C2 96.90(8), C1-Mo-C3 79.49(8), C2-Mo-C3 78.14(8).

Most of the known hetero-metal-gold clusters contain isolated $(R_3P)Au$ fragments.[6,7] Two of the few examples of clusters with Au–Au bonds and a central hetero-metal atom are $[Au_6Pt(CC\text{-}t\text{Bu})(PPh_3)_7]^{\oplus}$[8] and $[\{(Ph_3P)Au\}_8Pt]^{2\oplus}$.[9] In neither case, however, can the Au_n skeleton be derived from an icosahedron.

The Mo–C–O groups in **1** are slightly bent, presumably for steric reasons; their C atoms are closer to the atoms Au4 and Au7 (C1–Au7 = 265.8(2), C2–Au7 = 280.5(2), C3–Au4 = 248.1(2) pm).

Assuming that the Mo atom has the oxidation state 0 and that only the electrons of the Au atoms contribute to the metal–metal bonds, then there are six electrons available for the skeletal bonding, as is also the case in toroidal Au clusters[3,6] and in the pentagonal-bipyramidal $[Au(PPh_3)]_7^{\oplus}$ cluster.[10] With these six electrons the Mo atom achieves a stable 18-electron configuration.

The cluster synthesis by reductive elimination of azide groups developed by us has the advantage over previously described reduction methods that only N_2 is formed as oxidation product. By variation of the phosphane ligands and the carbonyl components this method should provide access to a wide variety of clusters. Moreover, it can be extended to $[(Ph_3P)_2CuN_3]_2$.

Helicates: Tetra- and Pentanuclear Double Helix Complexes of Cu^I and Poly(bipyridine) Strands**

By *Jean-Marie Lehn** and *Annie Rigault*

Dedicated to Professor Edgar Lederer on the occasion of his 80th birthday

The design of molecular species undergoing self-assembling into a well-defined structure opens ways to the spontaneous but directed generation of an organized supramolecular entity, following an "Aufbau plan" contained in the structural elements whose interaction leads to the association process. Such systems may display positive cooperativity and represent prototypes of molecular amplification devices, if, once initiated, the subsequent steps of the assembling process are facilitated.[1] The formation of the double helix of nucleic acids is a cooperative self-assembling of a supramolecular structure held together by the hydrogen bonds between the complementary nucleic bases. In general terms, such properties may be displayed by polytopic receptor molecules in which interaction between the subunits or substrate binding to them, occurs in a way so that each association step sets the stage for the following one.

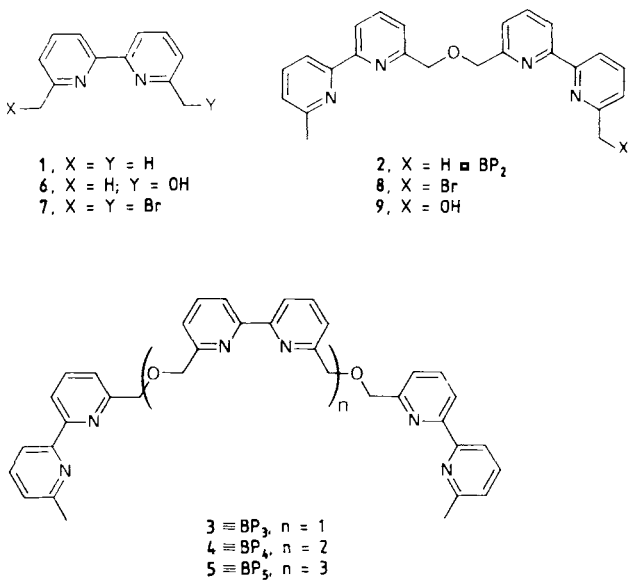
[**] We thank Dr. *Jack Harrowfield* and Dr. *Jay Siegel* for their contribution to the initial stages of this work, which was supported by the CNRS and, in part, by ORIS Industrie.

In continuation of our studies on quaterpyridine pQP[2] we have recently shown that the acyclic ligands BP_2, **2**[3] and BP_3, **3**[3] containing two and three bpy[3] subunits (derived from 6,6′-dimethyl-2,2′-bipyridine **1**) bind Cu^I ions so as to form respectively dinuclear or trinuclear *double stranded helicate* complexes in which two ligand molecules wrap around two or three Cu^I ions (one per bpy site of each ligand) which hold the strands together. The structures of the dinuclear $[Cu_2(pQP)_2]^{2\oplus}$,[2] trinuclear $[Cu_3(BP_3)_2]^{3\oplus}$[3] and dinuclear $[Cu_2(BP_2)_2]^{2\oplus}$[4] complexes were confirmed by X-ray crystallography.[5]

In order to further explore this ability of polybipyridine ligands to spontaneously assemble into double helix complexes, we have synthesized and studied the Cu^I binding properties of the next two members of the series, namely BP_4 **4** and BP_5 **5**, respectively.



Treatment of the monohydroxymethyl bipyridine derivative **6**[3] with NaH in tetrahydrofuran (THF) at room temperature for 30 min, followed by addition of one equivalent of the bis(bromomethyl) compound **7**[6] and heating at reflux for 3 h gave a mixture from which chromatography on silica (eluent 1% $MeOH/CH_2Cl_2$) enabled isolation of the monobromomethyl dimeric compound **8** in 45% yield (m.p. 152–155 °C) together with 15% of the trimeric substance **3**[3] and 30% of recovered **7**. Reaction of **8** with sodium acetate (in dimethylformamide, 140 °C, 12 h) followed by hydrolysis with NaOH (methanol/water (9/1), 30 min reflux) gave the monohydroxymethyl compound **9** (m.p. 178 °C, 80% yield). Treatment of **9** with one equivalent of potassium *tert*-butoxide in THF (room temperature, 30 min) followed by addition of one equivalent of **8** and heating to reflux for 12 h, gave a precipitate of the tetrameric substance **4** in 65% yield (m.p. > 260 °C). Similar treatment of **9**, followed by addition of 0.5 equivalent of the dibromide **7**[6] and heating at reflux for 3 h gave a precipitate of practically pure pentameric compound **5** in 68% yield (m.p. > 260 °C). The new compounds **4**, **5**, **8**, and **9** gave spectral (^{1}H-NMR, ^{13}C-NMR, FAB-MS) and microanalytical data in agreement with the assigned structures.

Compound **4** and even more so **5** have very low solubility in most common organic solvents. They are however readily soluble in acidic aqueous or organic solution at pH < 2, in which they are protonated. The 400-MHz NMR spectrum of BP_5 **5** measured under such conditions is shown in Figure 1.

The two compounds BP_4 and BP_5 are linear repetitive polybipyridine ligands, which, in view of the rich coordination chemistry of the bpy subunit, should be able to form polynuclear complexes with numerous metal ions. We have at present mainly investigated the complexation of Cu^I ions, which are known to bind bpy units in a distorted tetrahedral geometry, as found both in the case of the parent substance 6,6′-dimethyl-bpy **1**[7] and in the crystal structures of the double helicates formed with BP_3[3] and BP_4.[4]

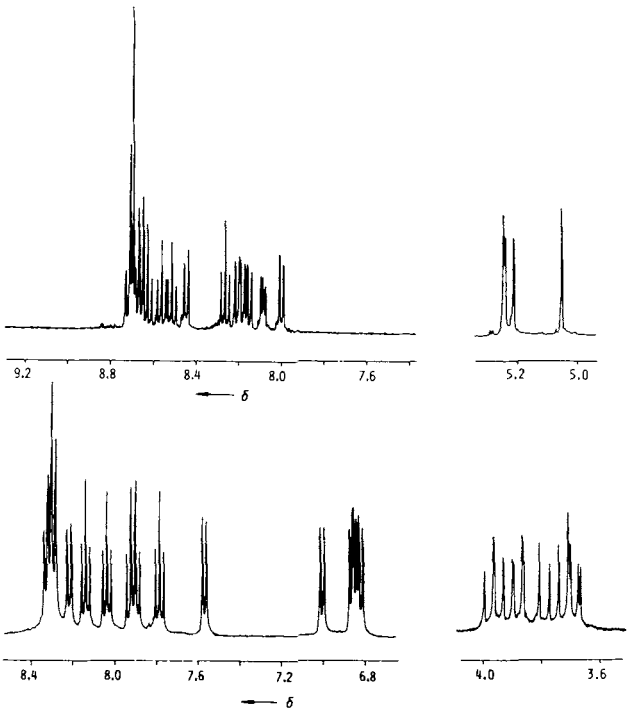


Fig. 1. 400-MHz ^{1}H-NMR spectra of the ligand BP_5 **5** (top) in [D$_6$]acetone + 10% CF_3COOD, and of the complex $[Cu_5(BP_5)_2][CF_3SO_3]_5$ in [D$_3$]acetonitrile (bottom); the signals of the CH_2 protons ($\delta = 3.5$–5.5) are shown with an expanded scale compared to those of the bipyridine protons ($\delta = 6.8$–8.8); the CH_3 signals are not shown.

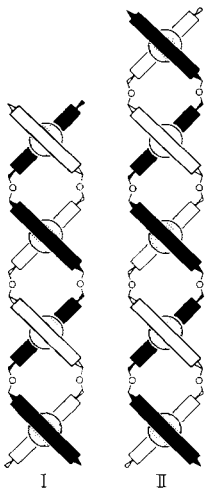
The Cu^I complexes of BP_4 **4** and BP_5 **5** have been prepared either by addition of a slight excess of an acetonitrile solution of a Cu^I salt (perchlorate, trifluoroacetate, trifluoromethanesulfonate) to a solution/suspension of the ligand in chloroform, or by addition of an aqueous solution of a Cu^{II} salt to a suspension of the ligand in acetonitrile followed by reduction with a slight excess of aqueous hydrazine. The formation of the Cu^I complexes is quantitative and results in the immediate appearance of the deep orange-red color characteristic of $[Cu^I(bpy)_2]^{\oplus}$ and related species.[7] The complexes were crystallized from 50% aqueous acetonitrile as deep-red needles. They are very stable toward oxygen. Their solubility depends on the counteranions, the triflates being soluble in organic solvents such as CH_3CN and $CHCl_3$. Their electronic absorptions correspond to those expected for Cu^I(bpy)-complexes (see Ref. [3] and references cited therein). Titration of the ligands by $[Cu(CH_3CN)_4]BF_4$ monitored by the absorption at 449 nm gave the compositions $[Cu_4(BP_4)_2][BF_4]_4$ and $[Cu_5(BP_5)_2][BF_4]_5$ for the complexes of BP_4 and BP_5 respectively. The following absorption coefficients have been measured

at $\lambda_{max} = 449$ nm under the same conditions (solvent $CH_3CN/H_2O = 4/1$; 20°C): $\varepsilon = 4800$, 10300, 14500, 18900, and 22300 (±10%) for the complexes formed respectively by ligands **1**, BP_2 **2**, BP_3 **3**, BP_4 **4**, and BP_5 **5** with $CuCF_3SO_3$; these values agree with the number of sites present in each complex.

The ^{1}H-NMR spectra of the complexes are very different from those of the ligands, the changes observed being similar to those found on going from BP_3 **3** to $[Cu_3(BP_3)_2](CF_3CO_2)_3$.[3] On complex formation, the bpy proton signals are shifted markedly upfield and, most importantly, the CH_2OCH_2 protons which appear as singlets in the free ligands, shift upfield by more than 1 ppm and split into overlapping AB patterns (Fig. 1, bottom). Thus, the CH_2 protons have become nonequivalent in the complexes and lie in the shielding regions of the bipyridine groups. Furthermore, addition of the optically active NMR shift reagent (Eu(tfc)$_3$ [tfc = 3-(trifluoromethylhydroxymethylene)-(+)-camphorato] to a solution of the complexes formed by BP_4 and BP_5 in CD_3CN, led to splitting of some proton NMR signals, demonstrating the presence of two diastereomeric species; consequently, the complexes must have a chiral structure.

By analogy with the earlier spectral and structural results on the trinuclear Cu^I complex of BP_3 **3**,[3] these properties indicate that the Cu^I complexes of BP_4 and BP_5 are tetranuclear and pentanuclear *double-stranded helicates* of Cu^I, designated by ds-$\mathscr{H}[Cu_4(BP_4)_2]^{4\oplus}$ and ds-$\mathscr{H}[Cu_5(CP_5)_2]^{5\oplus}$.[8] Their overall shape is that of *inorganic double helices*, schematically represented by **I** and **II** and presenting about 2 and 2.5 turns respectively. Their total length may be estimated to lie around 22 Å and 27 Å respectively; they thus are *self-organized nanostructures*, and represent entries into the field of functional nanoscale species and molecular devices.[1] Their structural features should be analogous to those of the trinuclear complex of BP_3 **3**;[3] more accurate data have to await crystal structure determination. From the point of view of coordination chemistry, they represent polynuclear complexes containing a string of metal ions.



I II

The present results extend the earlier ones[3] and show that inorganic double helices can indeed be generated on the basis of the structural design developed. Further chain length extension will lead to even larger organized nanostructures, eventually up to polymeric repetitive ligands and to double helical polymeric complexes. Numerous studies may be envisaged from the organic, inorganic, physical and biochemical points of view such as: subunit modification, complexation of various other metal ions, binding cooperativity, dynamics of double helix wrapping and unwrapping, interaction with DNA double helices, self-organization and amplification devices, etc.

[8] The spectroscopic data unequivocally rule out a polymeric complex, which in itself would be very interesting.

Methyl 4-Hydroxy-5-iodo-2,3-dimethoxy-6-methylbenzoate: The Aromatic Fragment of Calichemicin $\gamma^I_{1\alpha}$. Synthesis, X-Ray Crystallographic Analysis, and Properties**

By *K. C. Nicolaou,* T. Ebata, N. A. Stylianides, R. D. Groneberg,* and *P. J. Carrol*

The calichemicins are a new class of naturally occurring compounds with potent biological activities recently isolated by a Lederle group.[1] One of the most prominent members of this class is calichemicin $\gamma^I_{1\alpha}$ **1** isolated from *Micromonospora echinospora ssp. calichencis*. The biological profile of **1** includes: (1) subpicogram potency against gram-positive bacteria, and, in the biochemical induction assay, (2) very high potency against a number of animal tumor models and (3) cleavage of double-stranded DNA with minimal concurrent single-stranded breakage.[1,2] The aromatic fragment of this important biomolecule with its high degree of substitution and unusual pattern presents an interesting synthetic and stereochemical problem due to steric congestion and potential out-of-plane orientations of certain of its appendages. Herein we report (a) the first synthesis of this calichemicin $\gamma^I_{1\alpha}$ fragment as its methyl ester **2**, (b) its spontaneous resolution by crystallization into pure enantiomeric forms, (c) X-ray crystallographic

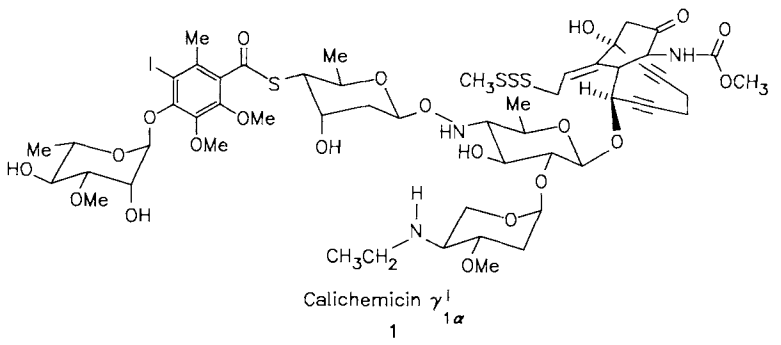
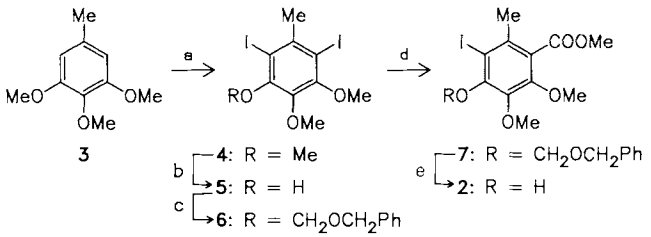
[**] This work was supported by Lederle Laboratories, Pearl River, NY, and by the University of Pennsylvania. Stimulating and helpful discussions with Dr. *May Lee* and Dr. *Ving Lee* (Lederle Laboratories), Dr. *David Eaton* (Du Pont de Nemours, Experimental Station, Wilmington, DE), Dr. *R. Huffman* (Indiana University), Prof. *Jay Siegel* (University of California, San Diego), and Prof. *Kurt Mislow* (Princeton University) are acknowledged. We also thank Dr. *George Furst* and *John Dykins* of our Department for their excellent NMR and mass spectroscopic assistance and useful comments.



analysis of both enantiomers, and (d) the properties of **2**, including its second harmonic generation (SHG) activity.

For the synthesis of the aromatic segment **2**, we started with 3,4,5-trimethoxytoluene **3** and proceeded as outlined in Scheme 1. Thus, **3** was diiodinated under Suzuki conditions[3] to afford diiodide **4** in 93% yield. Selective monodemethylation of **4** using boron trichloride led to compound **5** (58%), which was then benzyloxymethylated under standard conditions to afford compound **6** in quantitative yield.

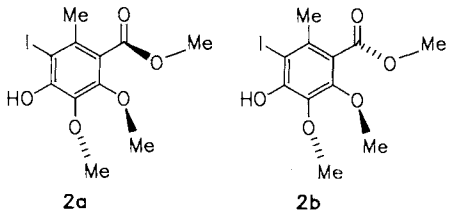
Catalytic methoxycarbonylation of **6** under the conditions of *Dolle* et al.[4] furnished the methyl benzoate **7** as the major product (44% yield, accompanied by ca. 11% regioisomer and 6% diester.) Finally, deprotection of **7** under acidic conditions followed by flash chromatography led to the desired calichemicin $\gamma^{I}_{1\alpha}$ fragment **2** in 89% yield as a crystalline solid. Recrystallization from chloroform–petroleum ether afforded colorless monoclinic crys-



Scheme 1. Synthesis of compound **2**. Reagents and conditions: (a) 1.1 equiv. I_2, 0.56 equiv. HIO_4, AcOH, 53 °C, 24 h, 93%; (b) 6.0 equiv. Et_3N, CO atmosphere, DMSO/MeOH (2:1), 70 °C, 24 h, 44% (plus ca. 11% regioisomer plus 6% dimethyl ester); (e) conc. HCl, MeOH, 25 °C, 7 h, 89%. Spectral data of compound **2**: ^{1}H-NMR (250 MHz, $CDCl_3$): $\delta = 6.42$ (s, 1H, OH), 3.88, 3.87, 3.84 (3s, each 3H, OCH_3), 2.32 (s, 3H, CH_3); ^{13}C-NMR (125.0 MHz, $CDCl_3$): $\delta = 167.8$, 150.4, 149.6, 136.5, 134.0, 121.8, 84.0, 61.3, 61.0, 52.4, 25.2; IR ($CHCl_3$): $\tilde{\nu}_{max} = 3519$ (m), 3040 (w), 3020 (m), 2960 (m), 1730 (s), 1575 (m), 1465 (s), 1428 (m), 1364 (m), 1270 (s), 1234 (m), 1099 (m) cm^{-1}; UV (MeOH): $\lambda_{max} = 214$ nm; MS, calculated for $C_{11}H_{14}O_5I$ $[M+H]^{\oplus}$ 352.9886, found $[M+H]^{\oplus}$ 352.9848.

tals (m.p. 134–135 °C). Spectral data for authentic **2** obtained by degradation of calichemicin $\gamma^{I}_{1\alpha}$ **1** were in agreement with those for synthetic **2**, thus proving the identity of the two samples.[5]

Restricting the stereogenic elements in **2** to the three axes C1-COOMe, C2-OMe, and C3-OMe (assuming that the hydroxyl hydrogen lies on the plane of the benzene ring and is H-bonded to the C-3 oxygen), one recognizes the possibility of four diastereomeric pairs, of which only **2a** and **2b** (Scheme 2) need to be seriously considered.[6] MM2 calculations (MacroModel)[7] on **2a** and **2b** placed them rather close in energy. An X-ray crystallographic analysis of **2** was undertaken, therefore, in order to shed light on this stereochemical question. Interestingly, it was



Scheme 2. Two of the four possible diastereomeric pairs of **2** (enantiomers not shown).

found that the crystals obtained as described above were a statistical mixture of two types, each containing pure enantiomer of **2a**.[8]

Table 1. Summary of X-ray data [a].

Crystal No.	I	II
Measured reflections	2654	2702
Reflections used in refinement $[F_0^2 > 3\sigma(F_0^2)]$	2232	2223
c_1	102.7	93.2
c_2	174.3	166.0
R, R_w ((*R,R,R*)-**2a**)	0.023, 0.028	0.030, 0.036 [b]
R, R_w ((*S,S,S*)-**2a**)	0.027, 0.032 [b]	0.019, 0.023

[a] Crystals of **2** were subjected to X-ray diffraction structure determination using an Enraf-Nonius CAD4 diffractometer. $C_{11}H_{13}O_5I$, $M_r = 352.13$, monoclinic, $P2_1$, $a = 8.568(2)$, $b = 6.189(2)$, $c = 12.375(5)$ Å, $\beta = 99.68(3)°$, $V = 646.9$ Å^3, $Z = 2$, $\rho_{calcd} = 1.808$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.071073$ Å, $\mu = 24.5$ cm^{-1}. Data collection was performed for reflection classes *hkl*, *hkl*, $\overline{hkl}$, and $\overline{hkl}$ to provide Friedel pairs of monoclinic data. The absolute configuration was determined by including anomalous dispersion terms in the scattering factors. Data were corrected for Lorentz and polarization effects and a numerical absorption correction was applied. The structure was solved by Patterson methods followed by weighted Fourier syntheses. Hydrogen atoms were found from a subsequent difference Fourier map, but were not refined. Refinement was performed by full-matrix least squares to minimize $\Sigma w(|F_0|^2 - |F_c|^2)$ with $w = 1/(1 + [(F_0 - c_1)/c_1]^2)$. All crystals examined revealed acentric crystal lattices. Further details of the crystal structure determination are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), on quoting the full literature citation. [b] The fit for the molecule of opposite configuration is not as good, as indicated by the R, R_w values.

Table 1 summarizes the results for two of the structure determinations. Crystal I contained the (*R,R,R*) enantiomer and crystal II the (*S,S,S*) enantiomer of **2a** as determined from the R and R_w values. Figure 1 displays an ORTEP representation of (*R,R,R*)-**2a** and (*S,S,S*)-**2a**. Figure 2 shows an ORTEP drawing of the unit cell of (*R,R,R*)-**2a**.

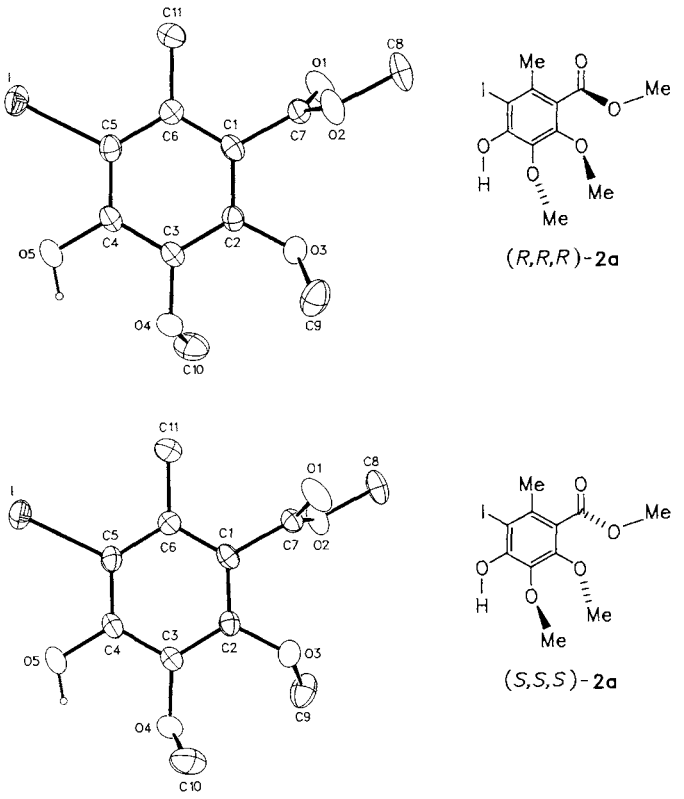


Fig. 1. Molecular structure of (*R,R,R*)-**2a** and (*S,S,S*)-**2a** (ORTEP). Intermolecular hydrogen bonds: O5···O1 2.757 Å, O5-HO5 0.885 Å, HO5···O1 2.045 Å, ∢O5-HO5···O1 140.3°. Intramolecular hydrogen bonds: HO5···O4 2.240 Å, ∢O5-HO5···O4 114.9°. The moiety O4-C3-C4-O5-HO5 is planar within 0.02 Å. Torsion angles [°]: C2-C1-C7-O1 101.0(4), C3-C2-O3-C9 −65.2(5), C6-C1-C7-O1 −76.4(4), C2-C3-O4-C10 −72.0(5), C2-C1-C7-O2 −80.1(4), C4-C3-O4-C10 108.8(4), C6-C1-C7-O2 102.5(4), C3-C4-O5-HO5 3.2(5), C1-C2-O3-C9 119.2(4), C5-C4-O5-HO5 −179.3(3).

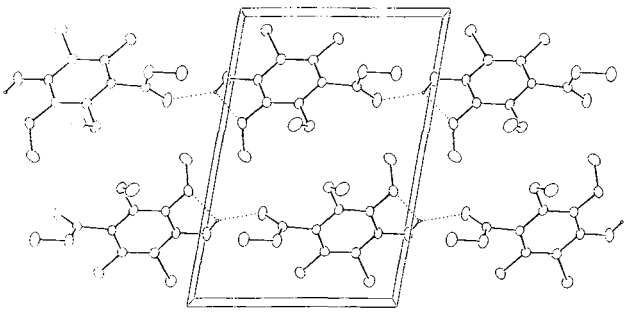

Fig. 2. Unit cell of (*R,R,R*)-**2a** (ORTEP).

In the crystal lattice, the molecules line up in parallel rows with the carbonyl of one molecule facing the free hydroxyl group of the next molecule. The hydroxyl hydrogen atom participates in (1) a weak intermolecular hydrogen bond with the carbonyl oxygen (O1) of a neighboring molecule and (2) a weak intramolecular interaction with methoxy oxygen O4.

Measurements on methanolic solutions of selected crystals of **2a** revealed no optical rotation, thus indicating racemization upon dissolution. It appears, therefore, that special crystal packing forces are responsible for the observed spontaneous resolution of the two enantiomers of **2a** upon crystallization.

Based on the observation of the acentric nature of the crystal lattice of compound **2** and the presence of donor-acceptor substituents on this aromatic system, we were encouraged to investigate its second harmonic generation (SHG) activity.[9] Indeed, the SHG activity of **2** is ca. 50% of that of urea.[10] The crowded aromatic system represents a new concept in the development of SHG-active materials and may prove useful in the preparation of more potent compounds by suitable substituent manipulation on the ring.

In conclusion, we have synthesized, by a short and efficient route, the aromatic segment (**2**) of calichemicin $\gamma^{I}_{1\alpha}$, which was found to crystallize spontaneously into pure enantiomeric forms, (*S,S,S*)-**2a** and (*R,R,R*)-**2a**. X-ray crystallographic studies revealed the acentric nature of the crystal lattice and parallel rows of molecules arranged in a head-to-tail fashion. The phenolic hydrogen was found to be simultaneously engaged in both intramolecular and intermolecular H-bonding. Finally, we have demonstrated that this class of compounds may hold considerable promise as SHG materials.[11]

Pentadienyl, a More Reactive and More Strongly Bound Ligand Than Cyclopentadienyl**

By *Enrique Meléndez, Atta M. Arif, Manfred L. Ziegler,** and *Richard D. Ernst**

Cyclopentadienyl ligands have proven to be invaluable to the field of organometallic chemistry, in large part due

[**] This work was supported by the National Science Foundation (USA).

to their robust binding to metals, which allows them to function as superb "stabilizing ligands".[1] It has recently become clear that the open pentadienyl ligands also have much promise. Despite arguments that these open ligands could be both more strongly bound and more reactive than their cyclic counterparts,[2] there has to date been no evidence demonstrating such stronger binding, and in an early review it was even concluded that metal-pentadienyl bonding seemed generally weaker.[3] In fact, direct comparisons between seemingly similar "open metallocene" and metallocene systems are not possible due to their differing steric and symmetry environments, and further complications may result from differing spin configurations. In order to circumvent such problems, and therefore to allow for more direct comparisons, we have synthesized a series of "half-open metallocenes", namely, $[M(C_5H_5)(\text{pentadienyl})]$ (M = Cr, Fe, $Co^{\oplus}$, Ru, Os)[4] and $[M(C_5H_5)(\text{pentadienyl})(L)]$ (M = Ti, V, L = phosphane; M = Cr, L = CO)[4,5] in which the above complications have been eliminated. Herein we report details for the "half-open titanocenes", and the unusual observation that, relative to the C_5H_5 ligands in these complexes, the metal-pentadienyl linkages are indeed more reactive, readily taking part in potentially useful carbon-carbon bond-forming reactions, despite the fact that the pentadienyl ligands are surprisingly more strongly bound than the "stabilizing" cyclopentadienyl ligands.

The syntheses of the desired complexes are carried out as in Equation (a), leading to the isolation of analytically

$$\underset{\mathbf{1}}{[Ti(C_5H_5)Cl_2(thf)_2]} + L + 2KL' \xrightarrow{THF} \underset{\mathbf{2}}{[Ti(C_5H_5)LL']} \qquad (a)$$

a, $L' = C_5H_7$, L = PEt_3; **b**, $L' = 2,4\text{-}Me_2C_5H_5$, L = PMe_3, PEt

pure products in reasonable yields. Treatment of the PEt_3 complexes with $P(OMe)_3$ leads to the corresponding phosphite compounds, e.g., $[Ti(C_5H_5)(C_5H_7)P(OMe)_3]$.

In order to compare the pentadienyl and cyclopentadienyl bonding in these species, a single-crystal X-ray diffraction study was undertaken for **2b**, L = PEt_3 (Fig. 1).[6]

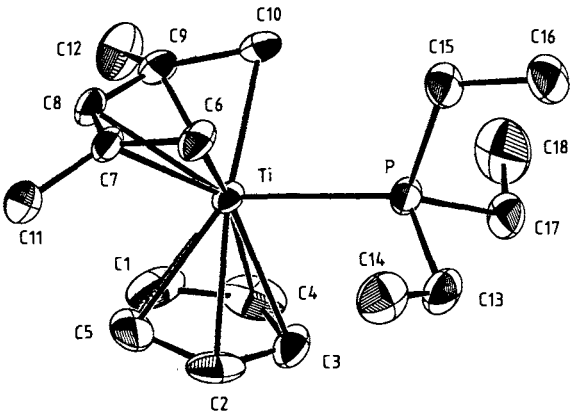

Fig. 1. Perspective view of **2b**, L = PEt_3.

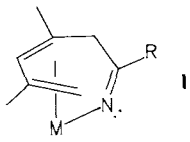
Quite unlike some pentadienyl complexes of chromium, iron, cobalt, and ruthenium, the $Ti\text{-}C_{pentadienyl}$ bonds are dramatically shorter (0.106(5) Å) than the $Ti\text{-}C_{cyclopentadienyl}$ bonds, averaging 2.240(3) vs. 2.346(4) Å, respectively. A similar observation has been made for the complex $[V(C_5H_5)(C_5H_7)PEt_3]$. Hence, it becomes clear that metal-pentadienyl bonding for at least titanium and vanadium is inherently and surprisingly stronger than that for the "stabilizing" cyclopentadienyl ligand, and in complexes such as $[M(2,4\text{-}Me_2C_5H_5)_2]$ (M = Ti, V), one can surmise that this is not simply the result of differing spin configurations.[7]

Despite its remarkably strong binding to titanium, the pentadienyl ligand has retained its greater chemical reactivity relative to cyclopentadienyl. Thus, treatment of **2b**, L = PEt_3, with CH_3CN was expected to bring about a coupling reaction, producing a complex ligand such as in **I**. In



I

fact, such a species, **3**, was isolated in an analytically pure state, and an X-ray diffraction study demonstrated that indeed pentadienyl-acetonitrile coupling had taken place (Fig. 2).[6] Notably, the former pentadienyl portion rearranged to a sickle configuration apparently prior to the coupling step, and a dimeric product resulted via N_2Ti_2 ring formation and loss of PEt_3. Our early studies indicate that pentadienyl ligands are reasonably prone to engage in such coupling reactions and the resulting carbon-carbon bond constructions appear to offer practical applications.[8]

$[\{Ti(C_5H_5)(Me_3C_6H_5N)\}_2]$ **3**

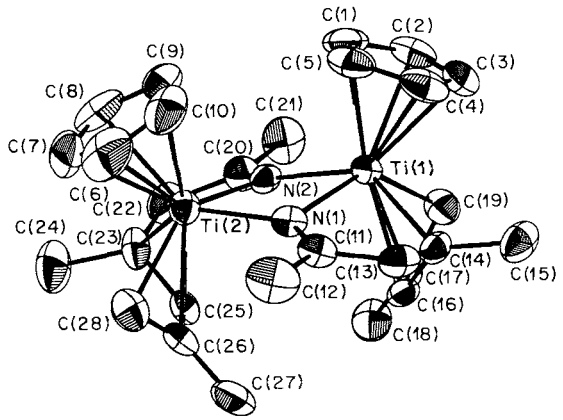


Fig. 2. Perspective view of **3**.

Since metal-pentadienyl and metal-cyclopentadienyl bonding had been found to be so similar for chromium, iron, the cobalt cation, and ruthenium,[2c,4c] there was no reason previously to expect titanium and vanadium to be any different, and shorter V-C bond distances in $[V(2,4\text{-}Me_2C_5H_5)_2]$ compared with $[V(C_5H_5)_2]$ could readily be considered to be an artifact of their differing spin configurations. The isolation of "half-open titanocenes" and "half-open vanadocenes" has now led to a resolution of this problem, with the surprising result that for at least titanium and vanadium, the open ligand may be more strongly bound than even cyclopentadienyl, and this may well account in part for the high thermal stability of "open titanocenes"[9] relative to the unstable complexes $[Ti(C_5H_5)_2]$ and even $[Ti(C_5Me_5)_2]$.[10] While it appears re-

markable that such a strongly bound ligand would be so reactive, it is possible to reconcile these seemingly contradictory observations. The key to this is the extra resonance stabilization experienced by the aromatic cyclopentadienyl unit, which may be regarded as a factor imparting a greater relative tendency to resist change. This readily translates into both a greater reluctance of this ligand to undergo disruption of its π system through coupling reactions (which are, however, known in some cases[11]) and a weaker metal-ligand bonding interaction. Thus, the lower reactivity of the cyclopentadienyl ligand in this case is a reflection of its inherent stability, rather than the strength of its binding to the metal center. However, if one were to deal with a process involving the complete removal of the π ligands, it would be expected that the cyclopentadienyl unit should be lost more readily.[12] Additional experimental and theoretical studies are underway to gain further insight into these observations.

Experimental Procedure

2b, L = PEt_3: A blue-green solution of 1.0 g (3.1 mmol) **1** in 50 mL of THF was cooled under nitrogen to −78 °C and 0.90 mL (6.2 mmol) of PEt_3 was added, yielding a dark-blue solution. To this solution was slowly added 0.9 g (6.6 mmol) of the potassium salt of the 2,4-dimethylpentadienyl anion dissolved in 50 mL of THF, after which the mixture was stirred for 2 h at −78 °C, resulting in a brown solution. The reaction mixture was allowed to warm to room temperature and stirred for about 6 h. The solvent was removed in vacuo and the crude product extracted with several portions of hexane and filtered on a coarse frit. The greenish-brown hexane solution was concentrated under reduced pressure and cooled to −78 °C, yielding a red, air-sensitive crystalline product. Complete IR data (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3170 (m), 1563 (m), 1304 (mw), 1261 (s), 1170 (sh), 1155 (mw), 975 (w), 889 (w), 797 (s).—^{1}H-NMR: δ = 6.01 (s, 1 H), 5.02 (d, 5 H, J = 1 Hz), 1.83 (s, 8 H), 1.26 (m, 6 H), 0.71 (m, 9 H), −0.85 (t, 2 H, J = 6 Hz).—^{13}C-NMR: δ = 112.46 (d, 1 C, J = 156 Hz), 101.37 (s, 2 C), 100.60 (d, 5 C, J = 170 Hz), 53.89 (t, 2 C, J = 150 Hz), 30.91 (q, 3 C, J = 134 Hz), 18.69 (t, 2 C, J = 126 Hz), 7.94 (q, 2 C, J = 128 Hz).—^{31}P-NMR: δ = 41.28.—Correct C,H analysis.

3: To a solution of 0.40 g (1.22 mmol) **2b**, L = PEt_3, in 30 mL of hexane at room temperature was added 0.20 mL (3.6 mmol) of CH_3CN dropwise. Reaction began immediately with the formation of a dard-red solution, followed by the precipitation of an oily dark-brown solid. Upon completion of the addition, the dark-red reaction mixture was stirred for an additional 30 min. Cooling the solution to −78 °C for ca. 12 h yielded a dark-brown air-sensitive product. After removing the supernatant solution, the crystalline product was dried in vacuo. Complete IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3170 (m), 1629 (s), 1563 (m), 1311 (mw), 1261 (ms), 1172 (mw), 1157 (m), 977 (w), 890 (m), 800 (s) cm^{-1}.—^{1}H-NMR: δ = 0.89 (d, 1 H, J = 5 Hz), 1.16 (s, 3 H), 1.31 (s, 3 H), 1.52 (d, 1 H, J = 5 Hz), 2.04 (s, 3 H), 2.17 (d, J = 20 Hz), 2.76 (d, 1 H, J = 20 Hz), 5.23 (s, 1 H), 5.89 (s, 5 H).—^{13}C-NMR: d = 21.93 (q, 1 C, J = 122 Hz), 26.37 (q, 1 C, J = 120 Hz), 26.76 (q, 1 C, J = 125 Hz), 60.58 (t, 1 C, J = 124 Hz), 69.97 (t, 1 C, J = 136 Hz), 76.53 (s, 1 C), 111.74 (d, 5 C, J = 170 Hz), 122.33 (d, 1 C, J = 158 Hz), 133.98 (s, 1 C), 174.74 (s, 1 C).—Correct elemental analysis (C, H, N, Ti).

[7] To establish the validity of such a comparison, one can note that even though "open ferrocenes" possess *longer* Fe-C bonds than those of ferrocene, MO studies indicate that the Fe-pentadienyl bonding is actually slightly *stronger*, indicating that the lower stability of the free pentadienyl unit can lead to stronger metal bonding even at slightly longer distances. In a molecule such as **2b**, L = PEt_3, in which the M-pentadienyl bonds are dramatically *shorter* relative to C_5H_5, one must conclude that pentadienyl is more strongly bound, which is quite reasonable given that overlap and steric effects, which could hinder metal-pentadienyl bonding relative to metal-C_5H_5 bonding, should be less important for larger metals such as titanium and vanadium. See M. C. Böhm, M. Eckert-Maksić, R. D. Ernst, D. R. Wilson, R. Gleiter, *J. Am. Chem. Soc. 104* (1982) 2699.

Phase Transformations of Lithium Nitride under Pressure

By *Heinz Jürgen Beister,* Sabine Haag, Rüdiger Kniep, Klaus Strössner,* and *Karl Syassen*

Of the binary compounds A_3B of the alkali metals (A = Li, Na, K, Rb, Cs) with an element of the nitrogen group (B = N, P, As, Sb, Bi), lithium nitride Li_3N is unique in that it is so far the only known nitride of the alkali metals. The compound is made up of planar Li_2N-layers and pure Li layers (Fig. 1), and is known to be a rapid conduc-

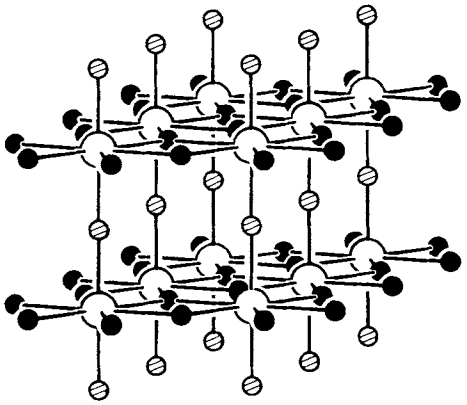

Fig. 1. The crystal structure of α-Li_3N. Large circles: nitrogen; small circles (black or shaded): lithium.

tor of lithium ions;[1,2] its conductivity is caused by lithium vacancies within the Li_2N layers. Due to the elongated cavities between the Li_2N layers the structure of Li_3N is very loosely packed, and, consequently, it could be expected to undergo a pressure-induced phase transformation. Indeed, the first indications of such a transformation have been provided by a recent ^{7}Li-NMR investigation.[3]

Fragments of a Li_3N single crystal grown by the Czochralski method[4] were used for a series of pressure experiments. It was visually established that the red transparent sample became dark opaque at 0.6 ± 0.05 GPa in a pressure cell with diamond window[5] (pressure measurement by the ruby luminescence method[6]). Optical absorption measurements in the region of about 1.85–2.30 eV (Fig. 2)

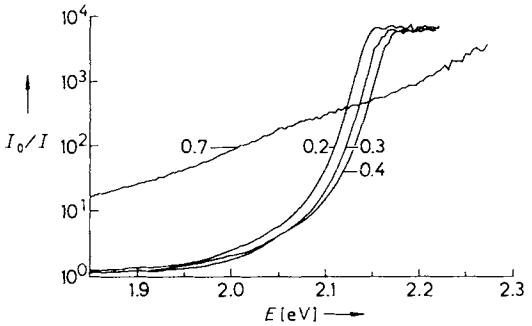

Fig. 2. Absorption spectra (unpolarized light, incident light // c axis) of Li_3N at various pressures p. Given is the inverse transmission I_0/I for samples of about 30 μm thick. p in GPa.

on the normal pressure phase α-Li_3N ($p < 0.6$ GPa) show that the absorption edge shifts to higher energies with increasing pressure. In the high-pressure phase β-Li_3N ($p > 0.6$ GPa) the absorption increases with increasing energy, but has little structure in the spectral range investigated. Raman measurements and X-ray powder investigations show that β-Li_3N is stable up to at least 8 GPa.

Larger amounts (0.3 g) of β-Li_3N were prepared in a Belt apparatus in a graphite crucible at room temperature and 4 GPa in 15 h. After release of pressure the high-pressure phase remained metastable. The results of differential thermal analyses (heating) and subsequent X-ray powder investigations provide evidence for the exothermal transformation of β-Li_3N into α-Li_3N above 200 °C. The X-ray powder diagram of β-Li_3N obtained by the Guinier method ($Cu_{K\alpha}$ radiation, film technique, evaluation with micrometer and densitometer) indicated a hexagonal structure.[7] A more accurate determination of the lattice constants by a least squares calculation gave a c/a ratio of 1.78, thus indicating a structure of the Na_3As type.[8] The X-ray powder diagram calculated for β-Li_3N with the atomic parameters of Na_3As[9] agrees with the observed values for reflection positions and intensities. Thus β-Li_3N and Li_3P are isotypic (Na_3As structure[8]). The crystallographic data of α-Li_3N[10] and β-Li_3N are listed in Table 1.

The crystal structure of β-Li_3N (Fig. 3) consists of planar layers of hexagonal symmetry with a composition $Li_{3/3}N_{3/3} \equiv LiN$ (Li–N distance in the layers 205.5 pm). The layers are stacked in the sequence ABAB ... in the 001 direction. Each nitrogen atom binds two further lithium atoms at a distance of 209.5 pm above and below the plane, thus completing its first coordination sphere to give

Table 1. Crystallographic data for α-Li_3N [10] and β-Li_3N.

	α-Li_3N	β-Li_3N
Space group	$P6/mmm$	$P6_3/mmc$
Lattice parameters [pm]	$a = 364.8(1)$	$a = 355.2(1)$
	$c = 387.5(1)$	$c = 631.1(3)$
Z	1	2
V [pm^3]	44.659×10^6	68.956×10^6
ρ_{calcd} [mg mm^{-3}]	1.295	1.677
Point positions N	1(a) 0, 0, 0	2(c) 1/3, 2/3, 1/4
Li(1)	1(b) 0, 0, 1/2	2(b) 0, 0, 1/4
Li(2)	2(c) 1/3, 2/3, 0	4(f) 1/3, 2/3, 0.583

a trigonal bipyramid $Li_2NLi_{3/3}$. As a result of the interpenetration of the Li_3N layer packets each nitrogen atom in a second coordination sphere is additionally coordinated trigonal prismatically by six lithium atoms further away (231.3 pm). Thus, altogether each nitrogen atom is surrounded by a fully capped trigonal prismatic array of lithium atoms.

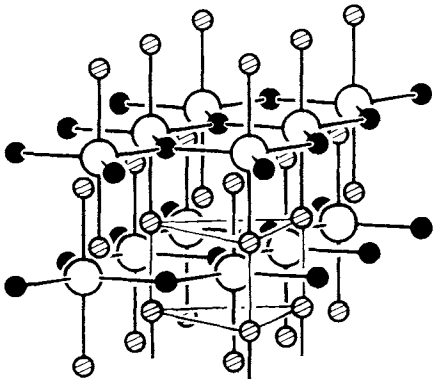

Fig. 3. The crystal structure of β-Li_3N. Large circles: nitrogen; small circles (black or shaded): lithium. The trigonal prismatic coordination in the second sphere is outlined for a nitrogen atom.

Figure 4 shows the relationship between the structure types α-Li_3N and Na_3As. For the transformation of α-Li_3N into β-Li_3N (Na_3As-type) the Li–N bonds marked with ≈ have to be opened and the layer packets shifted towards

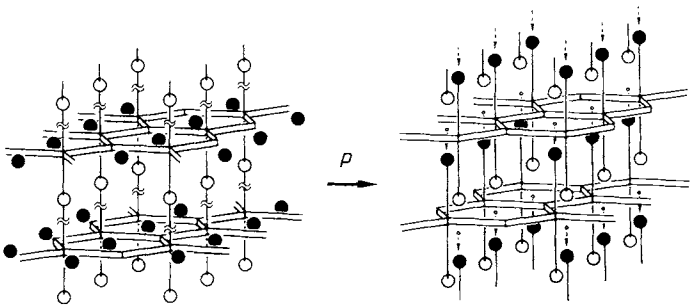

Fig. 4. Structural relationship between α-Li_3N and β-Li_3N. The Li_3N_3 structural unit is represented schematically and simply as a hexagonal network. The small dots indicate the positions from which the lithium atoms have to be shifted in the direction of the arrow. For further details see text.

each other such that the packing of the nitrogen atoms changes from a simple hexagonal arrangement (α-Li_3N) into a hexagonal closest packing arrangement (β-Li_3N). The lithium atoms shown in black then have to be merely

shifted in the direction of the nitrogen atoms of the neighboring layer.

Since the phase transformation takes place at the relatively low pressure of 0.6 GPa, it can hardly be ruled out that at least a partial transformation of α-Li_3N into β-Li_3N takes place on preparing powdered samples by grinding in a mortar, so that X-ray powder photographs of α-Li_3N always show small amounts of β-Li_3N. The observation of "additional reflections" in Li_3N powders was first reported in the literature more than a decade ago.[11]

Depressurized Li_3N samples which had previously been subjected to pressures of more than 10 GPa were investigated by the Gandolfi technique.[12] In one case an X-ray powder diagram was obtained whose reflections were consistent with a cubic structure with extinctions corresponding to an F-centered lattice (observed reflections 111, 200, 220, 311; $a = 427.3(2)$ pm; $Cu_{K\alpha}$ radiation). It is assumed that the highest pressure phase of Li_3N crystallizes in the Li_3Bi-type structure.[13] Dimorphism between Na_3As- and Li_3Bi-type structures is also observed in some higher homologues of Li_3N, e.g. in K_3Bi[14] and Li_3Sb.[13]

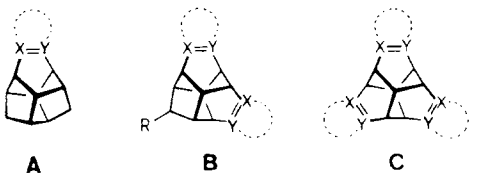
Functionalized, Enantiomerically Pure [2.1.1]-, [2.2.1]-, and [2.2.2]-Triblattanes**

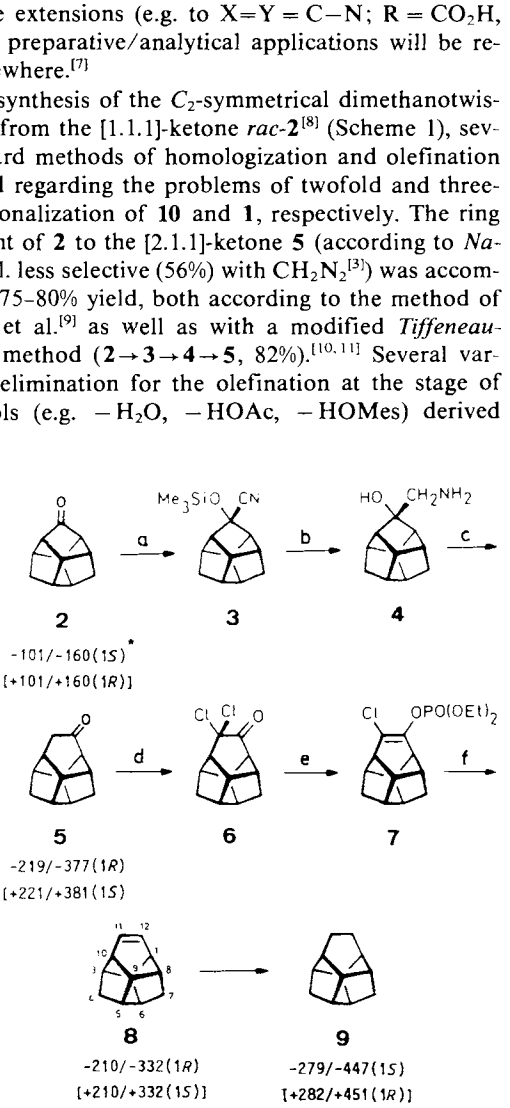
By *Hermann Müller, Johann-Peter Melder, Wolf-Dieter Fessner, Dieter Hunkler, Hans Fritz,* and *Horst Prinzbach**

We have developed an efficient scheme for the synthesis and resolution of the gyrochiral, D_3-symmetric trishomocubanetrione **1**.[1] Target compounds for which compound **1** should prove useful as starting material include not only the already known D_3-symmetric 1,4,7-trisexomethylene- and 1,4,7-trispiro-derivatives[1] and 1,4,7-triscarbocations,[2] but also variously functionalized as well as variously (hetero)benzoid annelated [2.1.1]- (**A**), [2.2.1]- (**B**) and [2.2.2]-triblattanes (**C**).[3,4] Such structural entities are of interest,



inter alia, as synthetic intermediates for the study of intramolecular interactions[5] between their characteristically oriented X=Y chromophores, because of their chiroptic properties,[3] and because of their potential as "chiralica". Herein we present efficient methods for the synthesis of the prototypical, enantiomerically pure structural entities **A**, **B** and **C** with homonuclear X=Y units (HC=CH, C_6H_4). Their PE, ORD and X-ray structure analyses,[6] preparative extensions (e.g. to X=Y = C–N; R = CO_2H, NH_2), and preparative/analytical applications will be reported elsewhere.[7]

For the synthesis of the C_2-symmetrical dimethanotwistene *rac*-**8** from the [1.1.1]-ketone *rac*-**2**[8] (Scheme 1), several standard methods of homologization and olefination were tested regarding the problems of twofold and threefold functionalization of **10** and **1**, respectively. The ring enlargement of **2** to the [2.1.1]-ketone **5** (according to *Nakazaki* et al. less selective (56%) with CH_2N_2[3]) was accomplished in 75–80% yield, both according to the method of *Schöllkopf* et al.[9] as well as with a modified *Tiffeneau-Demjanov* method (**2**→**3**→**4**→**5**, 82%).[10,11] Several variants of β-elimination for the olefination at the stage of the alcohols (e.g. $-H_2O$, –HOAc, –HOMes) derived



Scheme 1. The numbers quoted here and in the other schemes refer to specific rotations of the pure enantiomers measured at $\lambda = 587$ nm in cyclohexane or chloroform, respectively (**10**, **17**).

from the ketone **5** proved to be unproductive (the same holds true for attempts with the diols and triols derived from the diketone **12** and the triketone **16**, respectively). We therefore attempted olefination according to the methods of *Bamford, Stevens* and *Shapiro*, of *Fetizon* et al.,[12] and of *Perkow* and *Bianchini* et al.[13] The ^{1}H- and ^{13}C-NMR spectra of the waxy solid substance *rac*-**8** (*rac*-pentacyclo[6.4.0.0^{2,6}.0^{3,10}.0^{5,9}]dodec-11-ene, λ_{max}(cyclohexane) = 210 nm (ε = 1220))[11], isolated according to the last method in 80–85% yield (based on **5**), showed the expected seven and six signals, respectively, for C_2-symmetry (Table 1). The enantiomers of **2**, separated by the method of *Eaton* and *Leipzig*,[14] analogously furnished (+)-**8** and (−)-**8**, thus also establishing their absolute configuration. Hydrogenation of (+)-**8** and (−)-**8** yielded enantiomerically pure (+)- and (−)-[2.1.1]-triblattane **9**, respectively; (−)-**9** has already been described as an optically enriched sample.[3]

Table 1. Melting points, ^{1}H-NMR spectra ($CDCl_3$, 400 MHz) and ^{13}C-NMR spectra ($CDCl_3$, 100.6 MHz) of selected compounds.

8: m.p. 84–86 °C; ^{1}H-NMR (250 MHz): δ = 6.14 (m, 11-, 12-H), 2.20–2.25 (m, 1-, 10-H; m, 3-, 8-H), 1.68 (m, 5-, 6-H), 1.56 (m, 2-, 9-H), 1.48 and 1.28 (AB, 4,4-, 7,7-H$_2$); ^{13}C-NMR: δ = 130.2 (C-11, -12), 50.1 (C-1, -10), 47.3 (C-5, -6), 44.2 (C-3, -8), 36.1 (C-2, -9), 33.6 (C-4, -7)

14: m.p. 47–48 °C; ^{1}H-NMR (250 MHz): δ = 6.35 (ddd, 8-, 13-H), 6.07 (ddd, 7-, 12-H), 2.44 (t, 6-, 11-H), 1.90 (m, 3-, 5-H), 1.80 (t, 1-, 9-H), 1.56 (br. s, 4,4-H$_2$), 1.34 (br. q, 2-, 10-H); ^{13}C-NMR: δ = 133.8 (C-8, -13), 129.1 (C-7, -12), 48.2 (C-3, -5), 46.9 (C-6, -11), 45.1 (C-1, -9), 36.2 (C-4), 29.5 (C-2, -10)

18: m.p. 106–107 °C; ^{1}H-NMR (250 MHz): δ = 6.42 (m, 6 H, H$_{olef.}$), 1.97 (m, 6 H, H$_{aliph.}$), 0.95 (br. q, 2 H, 2-, 11-H); ^{13}C-NMR: δ = 134.3 (6 C), 47.1 (6 C), 20.8 (2 C)

21: ^{1}H-NMR: δ = 3.31 (t, 4-, 8-, 14-H), 3.20 (t, 5-, 9-, 13-H), 2.83 (br. t, 1-, 3-, 7-H), 2.18 (m, 6-, 10-, 11-, 12-H), 1.97 (br. q, 2-H); ^{13}C-NMR: δ = 54.6 (C-4, -8, -14), 48.6 (C-5, -9, -13), 36.0 (C-6, -10, -12), 33.0 (C-2), 29.9 (C-11), 29.7 (C-1, -3, -7)

22: m.p. 189–190 °C; ^{1}H-NMR (250 MHz): δ = 3.46 (t, 1 H), 3.42 (t, 1 H), 3.28 (t, 1 H), 3.24 (t, 1 H), 3.12 (br. t, 2 H), 3.03 (br. t, 1 H), 2.98 (br. t, 1 H), 2.90 (br. t, 1 H), 1.99–2.15 (m, 4 H), 1.94 (br. t, 1 H); ^{13}C-NMR: δ = 54.5, 54.2, 54.1, 49.5, 49.2, 49.0, 35.7, 35.4, 34.9, 31.6, 30.7, 30.6 (2 C), 29.9

23: m.p. 100–101 °C; ^{1}H-NMR: δ = 7.20 (m, 4 H), 2.73 (d, 1-, 10-H), 2.43 (m, 5-, 6-H), 1.90 (br. q, 2-, 9-H), 1.80 (m, 3-, 8-H), 1.63 and 1.47 (AB, 4,4-, 7,7-H$_2$); ^{13}C-NMR: δ = 140.3 (C-11, -12), 125.6 (C-3′, -6′*), 124.4 (C-4′, -5′*), 49.6 (C-5, -6), 47.8 (C-1, -10), 46.4 (C-3, -8), 37.4 (C-2, -9), 34.0 (C-4, -7)

24: m.p. 59–60 °C; ^{1}H-NMR: δ = 7.10–7.19 (m, 4 H), 6.39 (br. t, 13-H), 6.18 (br. t, 12-H), 2.93 (br. d, 6-H), 2.58 (br. t, 11-H), 2.30 (d, 9-H), 2.06 (m, 3-H), 1.93 (m, 5-H), 1.80 (br. t, 1-H), 1.71 and 1.65 (AB, 4,4-H$_2$), 1.62 (m, 2-, 10-H); ^{13}C-NMR: δ = 143.2, 139.9 (C-7, C-8), 133.5 (C-13), 129.7 (C-12), 125.6 (C-3′, -4′), 124.8, 123.4 (C-5′, C-6′), 50.8 (C-6), 49.1 (C-9), 48.0 (C-3), 47.4 (C-5), 46.6 (C-11), 43.9 (C-1), 36.5 (C-4), 31.5, 30.9 (C-2, C-10)

25: m.p. 209–210 °C; ^{1}H-NMR: δ = 7.20 (m, 6 H), 7.08 (m, 2 H), 3.06 (br. d, 6-, 11-H), 2.30 (br. d, 1-, 9-H), 2.08 (m, 3-, 5-H), 1.90 (br. q, 2-, 10-H), 1.82 (m, 4,4-H$_2$); ^{13}C-NMR: δ = 142.5, 139.8 (C-7, -12, C-8, -13), 126.0, 125.8 (C-4′, -4″, C-5′, -5″), 125.0 (C-6′, -6″), 123.4 (C-3′, -3″), 50.4 (C-6, -11), 47.4 (C-1, -9), 47.2 (C-3, -5), 36.9 (C-4), 32.8 (C-2, -10)

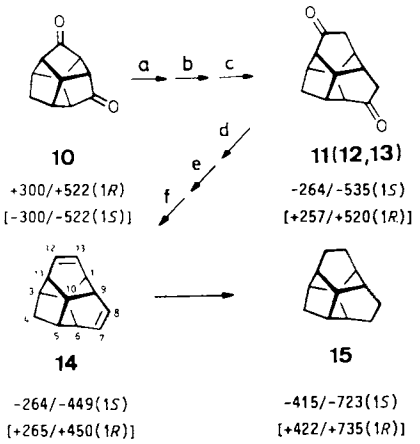
26: m.p. 91–93 °C; ^{1}H-NMR: δ = 7.17 (br. s, 4 H), 6.48 (td, 9-, 14-H), 6.44 (td, 8-, 13-H), 2.50 (d, 3-, 6-H), 2.12 (br. t, 1-, 10-H), 1.90 (br. t, 7-, 12-H), 1.27 (br. q, 2-, 11-H); ^{13}C-NMR: δ = 143.8 (C-4, -5), 134.4 (C-9, -14), 133.6 (C-8, -13), 125.3 (C-4′, -5′), 123.8 (C-3′, -6′), 50.4 (C-3, -6), 46.7 (C-7, -12), 45.2 (C-1, -10), 22.8 (C-2, -11)

27: m.p. 178–179 °C; ^{1}H-NMR: δ = 7.22 (m, 4 H), 7.15 (m, 2 H), 7.10 (m, 2 H), 6.51 (m, 13-, 14-H), 2.63 (d, 3-, 10-H), 2.42 (d, 6-, 7-H), 2.05 (m, 1-, 12-H), 1.57 (br. q, 2-, 11-H); ^{13}C-NMR: δ = 143.5, 142.9 (C-4, -9, C-5, -8), 133.7 (C-13, -14), 125.7, 124.5, 125.6 (C-4′, -5″, C-5′, -4″, C-6′, -3″), 123.8 (C-3′, -6″), 50.0 (C-3, -10), 48.6 (C-6, -7), 44.9 (C-1, -12), 24.7 (C-2, -11)

28: m.p. 215–216 °C; ^{1}H-NMR: δ = 7.23 (m, 6 H), 7.17 (m, 6 H), 2.57 (br. d, 6 H), 1.90 (br. q, 2 H); ^{13}C-NMR: δ = 142.7 (6 *ipso*-C), 125.9 (6 *m*-C), 124.0 (6 *o*-C), 48.4 (6 C), 26.7 (2 C)

30: m.p. > 370 °C; ^{1}H-NMR: δ = 8.11 (m, 6 H), 7.80 (m, 6 H), 3.34 (dd, 6 H), 2.87 (br. q, 2 H); ^{13}C-NMR: δ = 155.5 (C-4, -5, -8, -9, -13, -14), 142.2 (6 *ipso*-C), 129.6 (6 *o*-C), 129.1 (6 *m*-C), 47.4 (6 C), 28.2 (2 C)

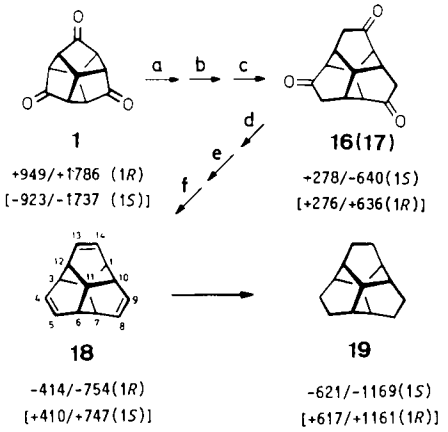
Because of the relatively rapid formation of higher triblattanes,[3] the CH_2N_2-variant was a priori not taken into consideration for the single ring enlargement of the two cyclopentanone rings in the [1.1.1]-diketone *rac*-**10**[15] which was required on the route to the C_2-symmetric methanoditwistadiene *rac*-**14**. Via the intermediates isolated analogously to **3**/**4** (reaction steps a and b in Scheme 2) in test runs,[11] an impressive yield of 75% of a mixture of the three [2.2.1]-diketones **11** (C_2; *rac*-pentacyclo[7.4.0.0^{2,6}.0^{3,11}.0^{5,10}]trideca-7,12-dione), **12** (C_2; -8,13-dione) and **13** (C_1; -7,13-dione) was achieved. Pure **11** (m.p. 175–176 °C, 18–20%) could be isolated from the product



Scheme 2.

mixture by chromatography and pure **12** (m.p. 183–184 °C, 25 °C) by crystallization. The twofold olefination also presented no problems. After extensive preliminary experimentation with pure diketone *rac*-**11**, pure tetrachloro-derivative (step d) and pure bisenol ester (step e), an average yield of 75% of crystalline *rac*-**14** (*rac*-pentacyclo[7.4.0.0^{2,6}.0^{3,11}.0^{5,10}]trideca-7,12-diene) was finally achieved on using the mixture of diketones **11**–**13** via the Perkow route, suitably modified at the chlorination stage (steps d–f).[11] The C_2-symmetry of **14** is confirmed by the ^{1}H-/^{13}C-NMR spectra (Table 1, $J_{1,2} = J_{2,3} = J_{2,6} = 6.0$, $J_{3,4} = 1.5$, $J_{5,6} \approx 0$, $J_{6,7} = 7.0$, $J_{7,8} = 8.0$, $J_{8,9} = 7.0$ Hz; λ_{max}(cyclohexane) = 215 nm (δ = 2720)). After efficient enantiomeric separation of *rac*-**10** with (*R*,*R*)-2,3-butanediol,[1] the pure enantiomers (+)- and (−)-**14** could be prepared and their absolute configuration be confirmed by hydrogenation to (+)- and (−)-**15**, respectively[13] (15% optically pure (−)-**15** has already been described; [α] = −58.6, calculated −404[3]).

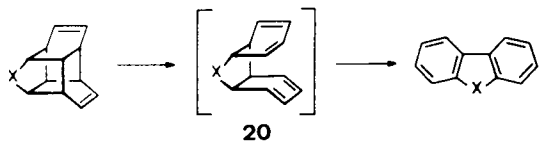
A key role in our studies with the unsaturated [2.2.2]triblattanes is played by the D_3-symmetrical $(CH)_{14}$[16] tritwistatriene **18**. The preparative demands associated therefore with the synthesis of **18** from the [1.1.1]triketone **1** could be largely fulfilled (Scheme 3): both the steps a–c leading to the threefold homologization of *rac*-**1**, which afford a 1:2 mixture (53%) of the chromatographically separated triketones **16** (C_3; *rac*-pentacyclo[8.4.0.0^{2,7}.0^{3,12}.0^{6,11}]tetradeca-4,8,14-trione, m.p. 245–247 °C, 17%) and **17** (C_1; -4,8,13-trione, m.p. 236–237 °C, 36%), as well as the steps d–f for the threefold olefination carried out with the ketone mixture according to the Perkow method, which is the only suitable method here, are reduced to economical one-pot reactions. The latter steps had been optimized to an overall yield of 68% using the pure triketones **16** and **17**,



Scheme 3.

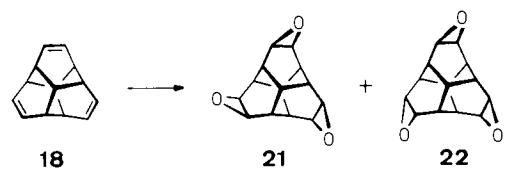
the two hexachlorotriketones (step d) and trisenol esters (step e). The yield of crystalline *rac*-**18**[11] (*rac*-pentacyclo[8.4.0.0^{2,7}.0^{3,12}.0^{6,11}]tetradeca-4,8,13-triene, λ_{max}(cyclohexane) = 216 nm (ε = 4240)), based on *rac*-**1**, is an impressive 36% for at least 21 functional changes. The antipodes (+)-**18** and (−)-**18** obtained from the triketones (+)-**1** and (−)-**1** or (+)-**16(17)** and (−)-**16(17)**, respectively, have been correlated by hydrogenation with (+)-**19** and (−)-**19**, respectively, (the known (−)-**19** had an optical purity of 44%; [α] = −250, calculated −567[3]).

The D_3-symmetry of **18** is confirmed by only three ^{1}H- and ^{13}C-NMR signals (Table 1, $J_{1,2}$ = 7.5, $J_{1,14}$ = 4.5 Hz). Despite a strain energy of 49.1 kcal mol^{-1} (force field calculation, MM2; 45.9 (47.7) kcal mol^{-1} for **8** (**14**)), **18** is thermally very stable; it slowly changes on heating in benzene (ca. 10^{-2} M) above 200°C; under dehydrogenating conditions (over Pd/C), mainly phenanthrene (X = HC=CH) (up to 75%) is formed—presumably via [4+2]-cycloreversion (**20**, Scheme 4, cf. basketene and ansaradiene).[17] In an analogous way, **14** furnishes fluorene (X = CH_2) in ca. 75% yield.

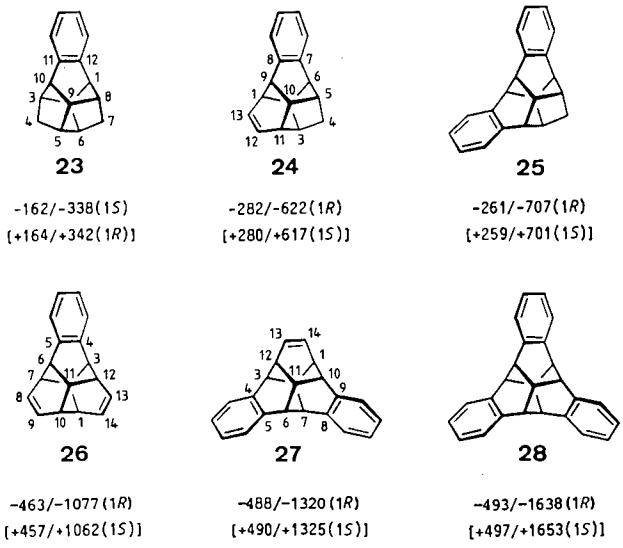


Scheme 4. Isomerization of **14** and **18** over Pd/C.

The preparatively important, in its details still unclear tendency of the [2.2.2]-triblattane skeleton to undergo (acid-catalyzed) isomerization[3] manifests itself in the perepoxidation of *rac*-**18**: even with carbamic peracids, byproducts and secondary products are formed besides the trioxides *rac*-**21** and *rac*-**22** (about 60% as a ca. 1:10 mixture, Table 1).[18]



The C=C or C=O functions in the [2.1.1]-, [2.2.1]-, and [2.2.2]-triblattanes presented here can be used in the usual way for the annelation of benzoid or heterobenzoid rings. Thus, the benzoannelated derivatives **23**, **24** and **25** or **26**–**28** could be prepared in good to very good yields from the enantiomerically pure olefins **8**, **14** and **18** via the tetrachlorothiophene dioxide adducts (Table 1).



Scheme 5. Benzoannelated derivatives of **8**, **14** and **18**.

The conversion of the ketones **5**, **11** and **17** into the single, double, and triple α-diketones, respectively, presented difficulties. The α-diketones, finally set free by ozonolysis from the respective α-methylene derivatives, proved to be increasingly unstable in the order single > double > triple, but nevertheless could be trapped with *o*-phenylenediamine, e.g. the hexaketone **29** as triquinoxaline **30**, albeit in drastically decreasing yield (95%, 56%, 9%) (Table 1).

BOOK REVIEWS

Organic Chemistry—in Color, and Good

Organic Chemistry. By *K. P. C. Vollhardt*. W. H. Freeman, Oxford 1987. xxii, 1275 pp. + index, paperback, £ 18.95/bound, £ 49.95.—ISBN 0-7167-1915-0/0-7167-1786-1

This textbook by a competent author is evidence of the enormous advantage inherent in a first edition, where, in contrast to revisions of already established textbooks, one is not encumbered with outdated ideas in previous editions which are now getting on in years. Thus, modern organic chemistry terminology and methods (e.g. stereoselective synthesis and retrosynthesis) and instrumental analysis (^1H and ^{13}C NMR) are given adequate coverage rather than being squeezed into whatever space is available. Furthermore, the choice of content is, as a matter of course, up to date, as it is not necessary to clear out unwanted material. The organization chosen here, based on functional groups and their reactions, has been proved by experience to be especially useful, and is a welcome feature. Each chapter deals first with the nomenclature of the relevant class of compounds, followed by structure and physical properties; their reactions and mechanisms are then discussed alongside each other. Each chapter contains a summary of the most important experimental findings. The exercises included are up to the most modern standard as regards selection and type of examples.

The elaborate four color printing, which the author refers to with some pride as having great didactic value ("learning simplified by the use of color"), does in fact seem to be justified. For example, nucleophiles are represented in red and electrophiles in blue, while radicals and leaving groups are shown in green, thus enabling one to see at a glance where the individual fragments of a newly formed molecule have come from. In stereochemistry colors are used to denote the sequence of substitutions according to the Cahn-Ingold-Prelog rules, and in spectroscopy the assignment of individual signals to the corresponding molecular fragments is clearly indicated by using the same color for both. In this consistent use of color it has not always been possible to avoid the risk of gaudiness (e.g. on pages 272 and 1041), but one has to accept this in view of the undeniable advantages of the technique. The typeface is clear and the structural formulas are spaciously set out, and this too is a commendable feature from a learning standpoint. The careful (possibly computer-aided?) processing of the text makes it difficult to detect printing errors, and in any case it would be petty to list them in a work of this quality.

The treatment of spectroscopy is outstandingly good, including both the introduction to the physical fundamentals and the applications to organic chemistry, generously illustrated by reproducing spectra of excellent quality. However, the contribution brought to the understanding of the subject by a photograph of a commercial (NMR) spectrometer, which after all appears as nothing more than a "black box"—decorated, of course, by the inclusion of a pretty female assistant—must remain the author's own secret.

Some examples of the small number of inaccuracies are as follows: the chlorophyll formula (p. 1040) is incorrect (as, incidentally, it also is in *Streitwieser* and *Heathcock*'s "Organic Chemistry"); enantiomerically pure amino acids are obtainable not only by cleavage of racemates and by enzymic synthesis (pp. 1240f.), but also of course by enantioselective synthesis; in connection with the 95% photochemical conversion of norbornadiene (p. 594), it should have been mentioned that a sensitizer was needed; in describing the elegant photoreaction using the matrix isolation technique (p. 1164), it would have been better to formulate a starting material that does not release any cyclobutadiene-complexing CO_2 when irradiated. Or are these points merely splitting hairs? The author's concern with completeness sometimes results in including equations of complex reactions with scarcely any explanation, e.g. in

[*] Editor's comment: But not in ANGEWANDTE CHEMIE, where electron lone pairs are represented by a pair of dots so as to avoid confusion with negative charges—a point which time and again gives cause for discussion.

that of squalene to give a steroid system (p. 492), or that of bioluminescence (pp. 329–330); this is too much of a good thing, and is unlikely to be understood by the student.

The subdivision and choice of titles in some of the chapters call for comment. It seems strange that in Chapter 2, which is entitled "Molecules lacking functional groups", the subsection which follows defines functional groups. In the title of Chapter 17, carboxylic acids are grouped together with the introduction to IR spectroscopy, whose use is by no means restricted to carboxylic acids, while in that of Chapter 18, carboxylic acid derivatives are grouped with the introduction to the equally general topic of mass spectrometry. It would have been better to include these spectroscopic techniques in Chapter 10, which has been reserved for NMR spectroscopy. Even the statement that "... at strategic points throughout the book, the important spectroscopic techniques ... are introduced" does not excuse this arrangement of topics. It is unlikely that any reader will consume this book like a detective novel, starting at page 1 and continuing through to page 1275.

Are there any topics in a work of this length which have been treated too briefly? In the description of electrocyclic reactions, although the distinction between *conrotatory* and *disrotatory* movements is pointed out, the fact that corresponding photochemical and thermal reactions have different stereochemistry is described merely as "curious"; the concepts of orbital symmetry are not explained, but the reader is referred to more advanced papers on the subject. The description of aromaticity according to the Hückel model is quite confusing and lacks conviction. It would have been desirable to include the mnemonic devices introduced by *Frost* and *Musulin* (for Hückel type arenes) and by *Zimmermann* (for Möbius type arenes), which are so useful to organic chemists. At the same time, however, special mention must be made of the very successful detailed treatment of aromatic substitution and of spectroscopic evidence for aromaticity (UV, IR, NMR). From the organic chemist's viewpoint, it would have been useful to augment the satisfying and appropriately detailed coverage of natural products chemistry with a discussion of biochemical questions such as photosynthesis and the respiratory chain, not only because topics such as these are now included in examinations, but, even more importantly, because the discipline of organic chemistry will in the future undoubtedly have (as formerly) a much greater biochemical bias.

These desirable extensions of the work need to be balanced by suggestions as to what might be taken out. Perhaps with the aim of addressing scientists of other specializations, and also possibly arising from the different structure of the education system in the USA, some chapters start from an astonishingly low level (e.g. in the discussion of stereochemistry, or in the introduction to NMR spectroscopy: "... discrete spin packets ... which are also called **quanta** of energy"), but quickly advance to a treatment of appropriate depth. Some shortening would be possible here by raising the starting level and sacrificing some of the section on general chemistry, since the book, by virtue of its declared aim, content and length, is in any case unsuitable for non-chemists.

To these critical comments, some of which are merely personal views, one may add two further sources of annoyance: 1) It is quite incomprehensible why, in a completely new textbook, which after all has been written for the 1990s, consistent use is not made of the SI system of units set up in the early seventies (e.g. kJ/mol rather than kcal/mol). Already in some monographs it is regarded as superfluous to continue including kcal/mol units in parentheses after the kJ/mol units; where this practice is still followed, it is because the older generation undoubtedly still thinks in kcal units. 2) The practice of showing only covalent bonds as dashes, while electron lone pairs are shown as a pair of dots, is now unusual,[*] at least in organic chemistry, and is also unjustified, since the latter electrons too have their spins paired. Representing electrons by dots can indeed sometimes have a confusing effect, as in the formulas of the 1,2-diketones at the top of p. 1008 (the comment on p. 16 that "The writing of electron-dot structures can be cumbersome ..." is meant in a different context, but nevertheless, how true!).

The criticisms made here should not be allowed to detract from the excellent overall impression of the book, but are meant rather as suggestions for a revised edition to follow. The book deserves to be classed as *excellent*, and if the justification for publishing a new textbook is that it should be better than all its predecessors, then "Vollhardt" is, in this reviewer's opinion, very close to reaching that goal! It is to be hoped that a German translation of this textbook will soon appear, even though one might expect today's chemists and chemistry students to have an adequate knowledge of English. Using "Vollhardt" should enable the student to progress, in many aspects of chemistry, through the intermediate examinations and on to the final degree.

PS: Unfortunately, a 'study guide', 'solutions manual,' and "overhead transparencies" were not available when this review was written.

The Chemistry of Inorganic Homo- and Heterocycles. Vol. 1 and 2. Edited by *I. Haiduc* and *D. B. Sowerby*. Academic Press, New York 1987. Vol. 1: xxiv, pp. 1–416, xi, hard cover, individual volume price: £ 60.00.—ISBN 0-12-655775-6; Vol. 2: xxiv, pp. 417–877, xi, hard cover, individual volume price: £ 65.00.—ISBN 0-12-655776-4 (price for two-volume set: £ 104.50)

This two volume work is a comprehensive and much needed review of the title area covering the years 1969–1979. It includes some thirty chapters of varying lengths by an impressive selection of widely recognized authors. Even a cursory glance through the chapter headings will reveal that inorganic ring systems constitute a truly vast area of research. The preface offers reasons for restricting the survey to the period 1969–1979. The main reasons for this are that earlier work was covered by the 1970, two-volume, work "The Chemistry of Inorganic Ring Systems" by *I. Haiduc*. Also, work since 1980 will be covered in a series of annual surveys in "Reviews in Inorganic Chemistry". It should be added that many chapters contain more modern references than 1979 so that many of the more significant recent developments are included. Page number restrictions were also cited for the limitation of the survey to a 10 year period. Valid though all these reasons are, one suspects that many potential individual buyers will be put off by the combination of the inevitably high price and the fact that 1979 is a long time ago as far as chemistry is concerned.

The work is divided into two volumes. In Volume 1, the major emphasis is on compounds involving Main Group 3 and 4 elements. Almost inevitably these rings and cages include some of the main group 5 or 6 elements. However, the main coverage of the rings and cages of these groups is emphasized in Volume 2. The material in Volume 1 involves sixteen chapters. The first five of these deal with various types of rings involving boron. Not surprisingly, Chapter 2 on boron–nitrogen heterocycles by *Maringgele* is by far the most extensive, occupying over 80 pages and over 400 references. In contrast, Chapter 3 by *Sowerby* on boron–phosphorus and boron–arsenic heterocycles involves only six pages and just over twenty references. Their relative lengths accurately reflect the amounts of activity in both fields and will undoubtedly call attention to the lack of existence of several types of B–P and B–As heterocycles which are well known for the B–N analogues. Chapters 4 and 5 by *Haiduc* and *Siebert* deal with B–O and B–S/Se cyclic systems. There is significant overlap between these and review articles covering similar compounds published in 1982 and 1983. Chapter 6 by *Cesari* and *Cucinella* covers the fascinating aluminum–nitrogen rings and cages. Surprisingly, the few known gallium and indium analogue compounds are not mentioned. There are also three short chapters dealing with the homocycles of (i) boron (Ch. 1, *Haiduc*), (ii) germanium and related compounds (Ch. 12, *Haiduc* and *Drägen*) and (iii) tin (Ch. 14, *Harrison*). A somewhat longer chapter (7) by *Hengge* and *Hassler* on silicon homocycles is comprehensive up to 1982. An interesting aspect of this chapter involves the amount of space given to cyclotrisilanes. In the period since it was written, there has been more activity involving these compounds, because they are precursors for the disilenes.

Four chapters, Nos. 8–11, cover silicon heterocycles. The longest (Ch. 8) by *Klingebiel* deals with silicon–nitrogen compounds. The following chapter by *Fritz* and *Härer* covers the phosphorus–silicon analogues and is much shorter, although there has been a considerable amount of work published in the area more recently. The subsequent chapter (10) on Si–O heterocycles by *Chvalovsky* covers material up to 1982 and contains considerable tabular material. This method of presentation, though hardly easy to read, is necessitated by the huge literature (936 references) of the area. In contrast, the corresponding silicon–sulfur compounds (Ch. 11, *Haiduc*) includes only 56 references. The remaining chapters in this volume, 13–15 and 16, cover germanium and tin heterocycles. Chapter 13 covers all germanium heterocycles whereas the more extensive work on tin merits two chapters; one, chapter 16 by *Veith*, on Sn–N and Sn–P and a further one, chapter 17 by *Mathiasch* on tin chalcogenides. These two chapters along with Chapter 6 on Al–N compounds provide convincing proof that main group compounds display a most fascinating variety of molecular architecture and reactivity.

The second volume opens with a chapter (17, *Haiduc*) on nitrogen homocycles. This is predictably short owing to the instability of the compounds. However, the corresponding phosphorus compounds, covered in Chapter 18 by *Baudler* and *Glinka*, involves some 200 references. This chapter, in contrast to some others, is considerably more up to date and contains numerous references from 1983 and 1984. The three following chapters cover the vast area of P–N cyclic compounds. Chapter 19 by *Keat* involves P(III)–N cyclics, Chapter 20 by *Allen* and Chapter 21 by *Schmidpeter* deal with cyclophosph(v)azanes with various phosphorus coordination numbers. Chapter 20 involves over 1000 references alone which the author has managed to squeeze into less than 200 pages. Summary tables for structural data are also provided. A welcome feature of all three chapters is that they contain many references from 1981 and 1982. More recent work is generally available in reviews named in the bibliography. Two somewhat shorter chapters, 22 by *Durif* and 23 by *Sowerby*, cover P–O, P–S, and P–Se rings and cages. These include a considerable amount of structural data as well as numerous references from the early eighties. Chapter 24, by *Haiduc*, treats cycloarsanes, in addition to arsenic heterocycles, and their antimony and bismuth analogues are covered in Chapters 23 and 26 by *Sowerby*. The literature on sulfur homocycles in Chapter 27 by *Steudel* involves some 160 references. The fascinating structures and chemistry of these sulfur species is made very current by the notes added in proof which even include some 1986 references! Equally interesting, but less investigated, are their selenium analogues in Chapter 28 by *Steudel* and *Strauss*. Many important references up to 1986 are also given. Sulfur–nitrogen heterocycles are ably reviewed by *Chivers* in Chapter 29. References from 1984 are included as an integral part of the text. The degree of activity in the area can be gauged from the large number of citations. A much shorter final chapter by *Haiduc* on S–O, Se–O and Se–N heterocycles completes the text.

In summary, these two volumes along with their 1970 precursor represent the classic reference work in the field of inorganic heterocycles. The presentation is excellent, generally error free, and the contents comprehensive within its limits. It could be argued, however, that some of the ring structures involving lithium hetero compounds would fall within the definition outlined by the editors. The style is also uniform despite coming from some twenty-five different authors. The only serious criticism of the work is the fact that many chapters are now out of date although some, particularly those dealing with sulfur compounds, are quite current. This drawback aside, the work is a most valuable one and is indispensible to anyone working in this field.

Industrielle Aromatenchemie. Rohstoffe, Verfahren, Produkte. By *H.-G. Franck* and *J. W. Stadelhofer*. Springer, Berlin 1987. xiv, 504 pp., bound, DM 128.00.—ISBN 3-540-18146-6

The main factors which shaped the development of the chemical industry after the second world war can be reduced to one very simple common denominator: essentially it flourished due to the availability of cheap aliphatic raw materials for petrochemicals, which led to a spectacular growth in aliphatic chemistry throughout the world. Insofar as the production of large-volume chemicals is now becoming less and less economically attractive for the traditional chemical manufacturing countries, with high-value chemical products coming into the foreground instead, the former supremacy of aliphatic chemicals is being eroded in favor of arenes. Consequently the chemical industry's field of interest is in a sense reverting to its beginnings in the mid-19th century, when the industry took as

its starting point the manufacture of dyestuffs based on the arenes present in coal-tar. In view of this situation the appearance on the market of a competently written book on industrial arene chemistry must be regarded as a welcome development, satisfying a need which has already been felt for a considerable time. Arenes and the products derived from them, which already make up almost a third of basic organic chemicals, have here at last received the comprehensive treatment which they deserve.

After a historical introduction the volume continues by discussing the nature of aromaticity, leading to the modern definition of the term "aromatic" and the boundaries of its applicability. This is followed by a very detailed chapter on sources of feedstocks, emphasizing the special importance of coal-tar and of the products obtained from the catalytic cracking and vapor phase pyrolysis of hydrocarbons. Future possibilities for making increased use of renewable raw materials as alternative feedstocks for arenes are touched on briefly.

The chapters which follow describe the properties of key arenes with reference to their manufacture and uses. The book deals first with the so-called BTX arenes, which come at the top of the production scale in megatonnes per year. These are followed by the poly(alkyl)benzenes, naphthalene, alkylnaphthalenes, anthracene and the rest of the polycyclic arenes. A separate chapter is devoted to the manufacture and uses of carbon-based products made from mixtures of condensed arenes. The final part of the book deals with the manufacture and uses of aromatic heterocycles. These chapters show strikingly that in addition to bulk chemicals with annual production figures of many millions of tonnes, such as ethyl benzene, styrene, cumene, phenol, phthalic anhydride and terephthalic acid derivatives, the field of arene chemistry also includes a large number of well-known products of the chemical, pharmaceuticals, dyestuffs and plant protection industries. Furthermore, other areas of application are discussed, some of them especially topical and others with future potential, e.g. the production of fibers of high carbon content from mesophases of pitch, the use of diisopropylnaphthalenes as solvents for NCR ("no carbon required") duplicating papers, extraction of cellulose from wood using anthraquinone, the manufacture of synthetic pyrethroid insecticides, and the use of a magnesium-anthracene complex as an intermediate in the manufacture of the hydrogen-storing medium magnesium hydride—to name only a few representative examples. A work such as this must, of course, also include a chapter on toxicology and environmental protection. This is augmented by a list giving toxicities and threshold limit values for the most important arenes.

The choice of material and the presentation of the chemical and technical details enable the reader to make a critical evaluation not only of the methods of manufacture in current use, but also of the numerous specialized applications. Economic aspects of arene chemistry are not neglected: data on production in different regions of the world, and on the distribution of the principal uses between the various business sectors, are given for the most important arenes and their derivatives. In a book of this kind the chemical process schemes are an important criterion of quality, and indeed they constitute a sort of touchstone for the technically biased chemist and the process engineer. The instructive, uniformly styled schematic diagrams effectively bring out the essential features of the production processes. In keeping with the textbook character of the work, literature references for further reading are listed in an appendix, classified according to the individual chapters.

Altogether, considering all aspects—text, figures and quality of production—this is a pleasing book, and even at a price which is by no means low, it will definitely find a wide readership in industry, universities, business and administration.

Advances in Electrophoresis. Vol. 1. Edited by *A. Chrambach, M. J. Dunn* and *B. J. Radola*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. ix, 441 pp., bound, DM 154.00.—ISBN 3-527-26741-7/0-89573-669-1 (ISSN 0932-3031)

In their preface the editors tackle the problem that is doubtless uppermost in their minds: why they have brought into the world a series which is planned to appear annually, yet—and this is admitted—predominantly contains review articles that have already been published in a similar form in the relevant journals. *Advances in Electrophoresis* is intended as a "review bank", written by experts to help overcome problems which arise from contradictory reports given by various specialists. This aim is not achieved, at least with this volume, and indeed cannot be achieved, for to do so would require the detail needed for practical work to be investigated far more thoroughly. Even in a "cookery-book"—and this is not the aim—this would hardly be possible in reality without continually "stepping on people's toes". In addition, it would first be necessary to introduce binding international definitions and test criteria, DIN-standards of electrophoresis, so to speak, by which results could be judged.

The second aim, to bring together fields of research whose publications would otherwise have to be laboriously collected from many journals, appears by contrast to be a sensible one, and as Volume 1 exemplifies, achievable. The third aim, to indicate the most important of the many, varied applications of electrophoretic methods, and their potential for solving the reader's own research problems (sometimes overestimated, sometimes underestimated), is likewise achievable.

The fourth aim, that the collected reviews should be useful to interested people who have no time to follow the original literature, is commendable. However, there are too many annoying citation errors, and significant references are simply missing, quite apart from factual errors, so this is not really a substitute for reading the original literature. For the attentive reader this shortcoming is remedied to some extent by the fact that the first two articles contain significant (avoidable!) overlaps, so that in the end one finds all the relevant literature references at least once. It is also irritating that in the introduction to the important article on two-dimensional electrophoresis, with its numerous modifications and promising applications which are well described, the historical development is evaluated in a misleading way, even though all the relevant papers are quoted. Those seeking a more accurate picture should therefore take good note of the year of each publication! In any case, not all of the contributions included here are unreservedly suitable as "key references" (the fifth aim in the preface); they could easily lead to a (most irksome) propagation of errors. After all, anyone unacquainted with

the subject will undoubtedly be keen to have review articles by experts to lean on, and on which they can rely (!).

In *Advances in Electrophoresis*, a "balanced mixture" of review articles is to appear, dealing with both methods and applications. From this point of view Volume 1 is a good beginning, with contributions from *M. J. Dunn:* "Two-dimensional polyacrylamide gel electrophoresis" (109 pages, 587 references); *C. R. Merril:* "Detection of proteins separated by electrophoresis" (28 pp., 98 references); *J. M. Gershoni:* "Protein blotting: a tool for the analytical biochemist" (32 pp., 148 references); *Nancy C. Stellwagen:* "Electrophoresis of DNA in agarose and polyacrylamide gels" (49 pp., 155 references); *K. Takeo:* "Affinity electrophoresis" (48 pp., 207 references); *P. Gebauer, V. Dolnik, M. Demel* and *P. Boček:* "Recent trends in capillary isotachophoresis" (76 pp., 239 references); *R. Horuk:* "Preparative polyacrylamide gel electrophoresis of proteins" (17 pp., 30 references); *J. S. Sutton:* "Red cell enzyme markers in forensic science: methods of separation and some important applications" (46 pp., 141 references). The index, so important for a book of this sort, contains ca. 1000 entries (11 pp.), and is therefore adequate for practical use. The numerous, well-reproduced figures and tables are informative throughout.

All in all, the idea of this series as a collection of review articles on various aspects of electrophoresis is a promising one, though the beginning is somewhat clumsy. DM 154.00 is a princely price, for which the editors are of course not responsible; however, with the good presentation overall (and a Coomassie-blue colored band at its head!), it seems justified.

Volker Neuhoff [NB 902 IE]
Max-Planck Institut für experimentelle Medizin,
Göttingen (FRG)

Protein Engineering. Edited by *D. L. Oxender* and *C. F. Fox.* Alan R. Liss, New York 1987. xvii, 365 pp., bound, $ 36.00.—ISBN 0-8451-4300-X

This book, consisting of 30 separate articles, provides the reader with an excellent survey of theoretical and practical aspects of protein structure and stability, and the effects obtained by introducing structural modifications. Our present understanding of structure-activity relationships is mainly based on protein structure determinations by X-ray analysis and (more recently) by high resolution NMR spectroscopy. These two techniques are treated in the first section of the book, which also includes a chapter on the possibilities for theoretically predicting structural modifications produced by mutagenesis. The section which follows consists of seven articles, which on the one hand describe techniques for mutagenesis and for isolating recombinant and mutant proteins, and on the other hand indicate the possibilities for using suitably modified proteins to investigate the principles of protein chain folding and structure. The third section deals, in nine articles, with basic aspects of the structure and stability of proteins in aqueous solution. Several articles are devoted to the hydrophobic effect, hydrogen bonding and amphiphilic structures, and their fundamental importance to stability and chain folding of proteins is clearly explained, taking account of the most up to date views. Other articles in this section describe the application of these principles to peptidomimetics and protein design, e.g. in synthesizing artificial amphiphilic oligopeptides with calcitonic activity. The final section of the book contains eleven articles describing, for example, experiments on regiospecific mutagenesis of individual proteins. These articles have two main objectives: on the one hand to extend understanding of the principles underlying the stability of the native form of a protein with its specific chain folding, and on the other hand to clarify the mechanism of enzymic activity at the molecular level.

This book is an excellent introduction to "protein engineering". The individual articles are, without exception, written by acknowledged experts in their fields. They are well coordinated, and cover in appropriate detail all the important aspects of this area of research. Where there is a small amount of overlapping, as is necessary for a coherent treatment of the topics, this is not a serious drawback, and it is not usually possible to avoid it completely in a collection of individual articles. Detailed descriptions of particular techniques have been deliberately omitted in favor of stressing fundamental principles and experimental procedures of general validity. The adoption of this philosophy will ensure that, even several years hence, this book will not have become much out of date. It is intended mainly for advanced students and non-specialists. Nevertheless, it is undoubtedly also of great value to the expert, whether his background is in biochemistry, biophysics or genetics. Finally, the price of $ 36.00 makes the book attractive.

Franz X. Schmid [NB 893 IE]
Institut für Biophysik und Biophysikalische Chemie
der Universität Regensburg (FRG)

The Chemistry of the Metal-Carbon Bond. Vol. 4: The Use of Organometallic Compounds in Organic Synthesis. Edited by *F. R. Hartley.* Wiley, Chichester 1987. xiv, 1349 pp., bound, $ 420.00.—ISBN 0-471-90888-6

This is (provisionally) the final volume in the series "The Chemistry of the Metal-Carbon Bond", and is aimed primarily at the organic chemist. A clear-cut distinction from Volumes 2 ("The Nature and Cleavage of Carbon-Metal Bonds") and 3 ("Carbon-Carbon Bond Formation using Organometallic Compounds") is not discernible, and according to the editor was also not intended. Those who are interested in the reactivity of organometallic compounds and also wish to use them in organic synthesis would therefore do well to consult not only the present Volume 4, but also Volumes 2 and 3, in order (hopefully) to find what they require.

The contents are divided into two parts, approximately equal in their coverage. The first is concerned with the preparation of main-group metal compounds, and their use in organic synthesis. The first two chapters, on organo-alkali metals (mainly Li; 157 pp., 1247 references) and organoalkaline earth metals (mainly Mg; 148 pp., 539 references) therefore have a broad field to cover, as might be expected. In this section particularly, the material is often presented in tabular form, which undoubtedly makes an overview easier to obtain. Chapters 3-6 are devoted to the synthesis and uses of organoboranes (102 pp., 625 references), organo-aluminum compounds (62 pp., 281 references), organothallium(III) compounds (66 pp., 325 references) and organo-silicon compounds (82 pp., 455 references). In general, the literature is surveyed up to 1984, and so here too it struggles along behind the year of publication, though not so glaringly as in some chapters of the previous volumes. It is not obvious why organo-tin compounds, which are be-

coming more and more important for organic synthesis, are not treated in conjunction with the analogous silicon compounds, but quite separately, in volume 3. This would certainly have been a help in demonstrating the advantages and disadvantages of the use of the two classes of compounds.

Part 2 is devoted exclusively to the use (not the preparation) of certain families of organo-transition metal compounds. Fortunately the individual chapters were almost without exception written by very competent authors, which has been of very great benefit to the quality. The first chapter deals with organo-iron compounds (107 pp., 303 references), and makes brief mention of their significance as electron-transfer catalysts. There is some overlap here with the later chapter on the use of transition metal-stabilized carbocations (90 pp., 151 references), but this is acceptable. Between the two lie expositions of organometallic complexes of rhodium (86 pp., 551 references) and nickel (69 pp., 363 references); here too, some overlap with individual chapters of Volume 3 can be discerned. Chapters 11 ("Hydrogenation", 69 pp., 665 references) and 12 ("Mechanism of homogeneous hydrogenation", 23 pp., 90 references) are devoted to the use of organometallic compounds as hydrogenation catalysts, in which it is not only homogeneous and heterogeneous hydrogenations with H_2 that are discussed, but also catalytic hydrogen transfer, and—though only briefly—enantioselective hydrogenations with the aid of chiral metal complexes. The final chapter deals with the activation of C–H bonds in saturated hydrocarbons, including considerations of biochemical aspects (88 pp., 295 references) and of the fixation of catalytically active organometallic compounds onto oxide and metal supports (62 pp., 479 references). The volume ends with a detailed author index, and a rather less detailed subject index. Whether a continuation volume will follow, to fill the gaps that still exist at the moment, seems to be undecided at present.

Collecting the material presented up till now must have been a herculean task, and the editors earn great respect for it. Apart from the arrangement of the individual chapters, which is not always successful, the presentation of results is almost without exception very effective. It is not only the price, however, that stands in the way of the distribution of this four-volume work, but also the fact that the even more comprehensive work "Comprehensive Organometallic Chemistry" appeared shortly before it. Whether Hartley/Patai can compete with this remains to be seen.

Helmut Werner [NB 903 IE]
Institut für Anorganische Chemie
der Universität Würzburg (FRG)

The Chemistry of the Actinide Elements. 2nd Edition. Edited by *J. J. Katz, G. T. Seaborg,* and *L. R. Morss.* Chapman and Hall, London 1986. Volume 1: xii, pp. 1–886, bound. Volume 2: xii, pp. 887–1674, bound. Price per volume £ 95.00.—ISBN 0-412-10550-0 and 0-412-27370-5

The first edition preceding this two-volume work (published in 1957 and authored by *J. J. Katz* and *G. T. Seaborg* only) dates from the pioneering years of research on the transuranium elements and has since then become by far the best known textbook on the chemistry of the actinide elements. Thirty years ago, not only was the final element of the actinide series (in the sense of *Seaborg*'s now well-established "actinide hypothesis") missing, but also the existence of the preceding element, nobelium, had not yet been fully confirmed. Now, however, in addition to No and Lr, the transactinides with atomic numbers 104 to 110 have also been made. The new edition, notwithstanding its unaltered title, includes not only the 15 elements Ac to Lr but all the translawrencium elements as well.

Without considering the elements Ac, Th, Pa and U (which together account for 430 pages of the present work), *C. Keller* had still managed in 1971 to describe the chemistry of the transuranium elements in a single volume of 675 pages. Obviously the progress which has taken place in almost every sector of actinide chemistry has necessitated a restructuring of the old Katz/Seaborg version (506 pages), into a well-composed collection of 24 chapters written by 33 acknowledged experts from the USA and Western Europe. One of the four European authors is the late *Fritz Weigel* (of the University of Munich).

The very comprehensive division of the material into Part I, which is a systematic description of the individual elements, and Part II which is focusing on specific properties and classes of compounds, respectively, of all the actinides, not only follows the structure of *Keller*'s book, but is already discernible in the 1st Edition. The three editors have themselves written the historically oriented introduction (Chapter 1, 11 pages), along with several other chapters, including one of particular versatility (Chapter 14, 74 pages: Summary and Comparative Aspects of the Actinides). This chapter is intended to be an introduction to Part II, and contains short sub-sections on such varied topics as naturally occurring transuranium elements, superconductivity, oxidation states, organometallic compounds, nuclear reactor wastes, biological effects, and the toxicology of actinide compounds. For non-specialists Chapter 14 might in fact serve as a guide to other parts of both volumes.

More than half of Part I is occupied by Chapters 5 (uranium, 274 pages, by *F. Weigel*) and 7 (plutonium, 388 pages, by *F. Weigel, J. J. Katz,* and *G. T. Seaborg*). These chapters deal in great detail with aspects of high importance for nuclear technology, e.g. the extraction of uranium and plutonium, and chemical reprocessing of nuclear fuels. Separation techniques are described in this chapter too, and are also treated in detail in chapter 21. Some compilations of data in the form of tables extending over several pages, e.g. on structural parameters of selected intermetallic uranium compounds (pages 235 to 241), are perhaps out of place in a book which is intended to also attract a non-specialist readership. The transeinsteinium elements, with atomic numbers 100 to 109, are treated collectively in Chapter 13 (by *R. J. Silva,* 32 pages), while the final chapter (Chapter 24, by *G. T. Seaborg* and *O. L. Keller, Jr.,* 25 pages), is devoted to "elements of the future", including the so-called superheavy elements.

Organoactinide chemistry, which was virtually non-existent in 1957, is here given considerable space, mainly in Part II. For some reason the authors of Chapter 22 (*T. J. Marks* and *A. Streitwieser*) and Chapter 23 (*T. J. Marks*), focus mainly on the 82 pages of these two chapters, on selected, and probably exemplaric, aspects of thorium and uranium chemistry. However, chapters 3, 5, 7, 14, 18, and 20 also each include several pages on organometallic compounds, and some transuranium elements finally feature here. Quite a lot of repetition has crept in here, e.g. on page 368, as a consequence of the renaming of allyl complexes to "allenyl complexes". Other instances of overlap-

ping between chapters in Parts I and II may be found, where the material at the two locations is not mutually complementary.

Nevertheless, the chapters in Part II all deal with important topics: (optical) spectra of the free atoms and ions (Chapter 15, *M. S. Fred* and *J. Blaise*) and of ions in compounds (Chapter 16, *W. T. Carnall* and *H. M. Crosswhite*), thermodynamic and magnetic properties (Chapters 17 and 18, by *L. R. Morss* and by *N. M. Edelstein* and *J. Goffart*, respectively), the metallic state (Chapter 19, *M. V. Nevitt* and *M. B. Brodsky*), structural chemistry (Chapter 20, *J. H. Burns*), and solution chemistry and ionic reaction kinetics (Chapter 21, *S. Ahrland*). Analytical chemistry has not been considered however.

Thermodynamic data of the highly radioactive actinide compounds, which are very difficult to determine, have rarely been presented before as systematically and comprehensively as in Chapter 17. Chapter 18 contains a short introduction to the quantitative magnetochemistry of systems with strong spin-orbit coupling and similarly large crystal field interactions, which appears suitable even for teaching purposes; even special treatments of magnetochemistry seldom include a chapter comparable to this. Chapter 19 deals with systems involving non-localized (itinerant) f-electrons and heavy fermions, two related concepts which are now the subject of intensive studies, and of relevance for an understanding of superconductivity. (One comes across references to the superconducting properties of actinide compounds in several of the chapters). Chapter 20, on structural chemistry, is organized too rigidly along classical lines, and does not mention any modern structural concepts such as those dealing with the coordinative saturation of f-element ions, nor has the structural chemistry of complexes with macrocyclic and/or large polycyclic ligands been considered, a subject of paramount interest at the present time. The only example given, in the section on actinyl complexes, is the "superphthalocyanine" complex formed by template reaction of five phthalodinitrile molecules with the uranyl cation, its structure having been elucidated as long ago as 1975. This structure is presented once more, under its systematic name, in Chapter 5 (page 385), where e.g. crown ether complexes and their structures are also briefly discussed. The section on organometallic compounds in Chapter 20 fails to take into account a number of recent developments (e.g. the uranium complexes with arene ligands which have been reported since 1971), and could, in view of the detailed coverage provided in Chapters 22 and 23, probably be omitted without creating a great loss.

The very comprehensive indexes provided at the end of each of the two volumes (59 pages of author index and 44 of subject index in total) are usually effective in directing one to the desired material (despite there being sometimes not enough cross-references). Admittedly though, in the case of the famous prehistoric nuclear reactor of Gabun, one needs to know the key word "Oklo", or must instead track it down in Chapter 14 (under actinide elements of natural origin). If one is interested in finding examples of 8-coordinate cubic actinide complexes, a ligand arrangement known to be highly unfavorable for d-transition metal ions, some more searching is needed before one finds help in Chapter 18 (page 1373), where the magnetic properties resulting from the special crystal field splitting of the cubic $[U(NCS)_8]^{4-}$ ion is mentioned, and also in Chapter 20 (pages 1447 and 1458). Appendix I (nuclear magnetic dipole and electric quadrupole moments) might lead one into a fruitless search for NMR spectroscopic data, since the first successful ^{235}U NMR experiment carried out in 1983 is nowhere mentioned. Even in Appendix II, with its extensive tables of nuclear properties, we still do not find a chart of common nuclides for atomic numbers ≥ 89, nor *Seaborg*'s popular "coastal landscape" which allegorically depicts the relative stabilities of the heaviest elements. Apart from the inclusion of numerous molecular and crystal structures, the second edition is less richly illustrated than the first, which contained, for example, a color chart showing the colors of individual actinide ions, and full-page photographs of laboratories especially equipped for work on transuranium elements.

Despite the above comments, the transition from the classical Katz/Seaborg to the completely restructured version of this second edition has already reached a remarkably high standard in its first appearance. The books will certainly find their way into every good-sized chemistry library, and will be consulted frequently. The three editors conclude their preface by expressing the hope that this new edition might also serve as a valuable source of information to all those responsible for making far-reaching decisions on the production of nuclear energy and the control of nuclear weapons.

Transition Metals in the Synthesis and Functionalization of Indoles

New Synthetic Methods (72)

By Louis S. Hegedus*

The use of transition-metal complexes as reagents for the synthesis of complex organic compounds has been under development for at least several decades, and many extraordinary organic transformations of profound potential have been realized. However, adoption of this chemistry by the practicing synthetic organic chemist has been inordinately slow, and only now are transition-metal reagents beginning to achieve their rightful place in the arsenal of organic synthesis. Several factors contributed to the initial reluctance of synthetic organic chemists to use organometallic reagents. Lacking education and experience in the ways of elements having d electrons, synthetic chemists viewed organometallic processes as something mysterious and unpredictable, and not to be discussed in polite society. Organometallic chemists did not help matters by advertising their latest advances as useful synthetic methodology, but restricting their studies to very simple organic systems lacking any serious functionality (e.g., the "methyl, ethyl, butyl, futile" syndrome). Happily, things have changed. Organometallic chemists have turned their attention to more complex systems, and more recently trained organic chemists have benefited from exposure to the application of transition metals. This combination has set the stage for major advances in the use of transition metals in the synthesis of complex organic compounds. This review deals with one aspect of this area, the use of transition metals in the synthesis of indoles.

1. Introduction

The indole nucleus **1** is common to a large number and a wide variety of biologically active natural and unnatural compounds,[1] and the synthesis and functionalization of indoles has been the object of research for over one hundred years, beginning with synthetic studies of indole-based dyes.[2] Among the many more recent synthetic targets have been the pharmacologically active ergot alkaloids **2**,[3] the antitumor agents ellipticine **3**[4] and mitomycin C **4**,[5] and the considerably more complex "dimeric" indole alkaloids such as vincristine and vinblastine.[6]

Until very recently, indole syntheses relied primarily on well-established methods such as the Fischer indole synthesis, the Madelung cyclization of *N*-acyl-*o*-toluidines, the reductive cyclization of *o*-nitrobenzyl ketones, the Batcho–Leimgruber synthesis of indoles from *o*-nitrotoluenes and dimethylformamide acetal, and the Gassman synthesis of indoles from *N*-halo anilines.[7] All of these approaches involve "classic" organic synthetic methodology and display typical "organic" reactivity patterns and selectivities. Similarly, functionalization of existing indole ring systems relied heavily on well-established electrophilic substitution reactions, typical reactions for π-electron-rich systems.[8]

With the advent and continuing refinement of transition-metal-assisted organic synthetic methodology,[9] a number of new and potentially quite versatile methods for both the synthesis and the functionalization of indoles have been developed. This new methodology is the subject of this review.

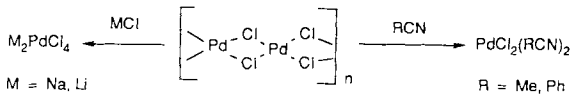
Virtually all organic functional groups will coordinate to some transition metal, producing either stable complexes or unstable, but reactive, organometallic intermediates. This complexation is usually quite specific, permitting the activation of a single functional group in the presence of other quite similar ones, thereby reducing the need for protecting groups. Once complexed, the reactivity of the organic functional group is governed by the chemistry of the metal, and the normal reactivity patterns of the functional group are often dramatically altered. Since most transition metals also have associated with them ancillary "spectator" ligands which do not participate directly in reactions at the coordinated functional group but do affect the overall reactivity of the system, it is often possible to "fine-tune" the reactivity of the complexed species. These features, exemplified by the transition-metal-assisted indole syntheses presented below, permit the use of unconventional starting materials with unusual reactivity patterns to produce complex organic compounds with a high degree of efficiency and selectivity.

2. Palladium Complexes in the Synthesis of Indoles

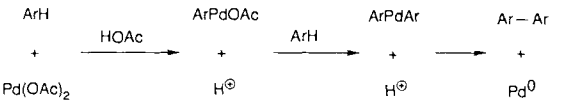
Palladium complexes have been used in the synthesis of organic compounds for over twenty years, starting with the commercially important Wacker process for the oxidation of ethylene to acetaldehyde.[10] A number of palladium complexes are commercially available and can be used as catalysts or catalyst precursors without further processing. Hence, a wide variety of palladium-assisted organic reactions has been developed and applied to the synthesis of complex organic molecules, including indoles. Palladium exists in two stable oxidation states—Pd^{II} and Pd^0—and, as usual, the chemistry of these differs substantially with regard to both substrate specificity and type of reaction promoted.

2.1. Palladium(II) Complex Chemistry

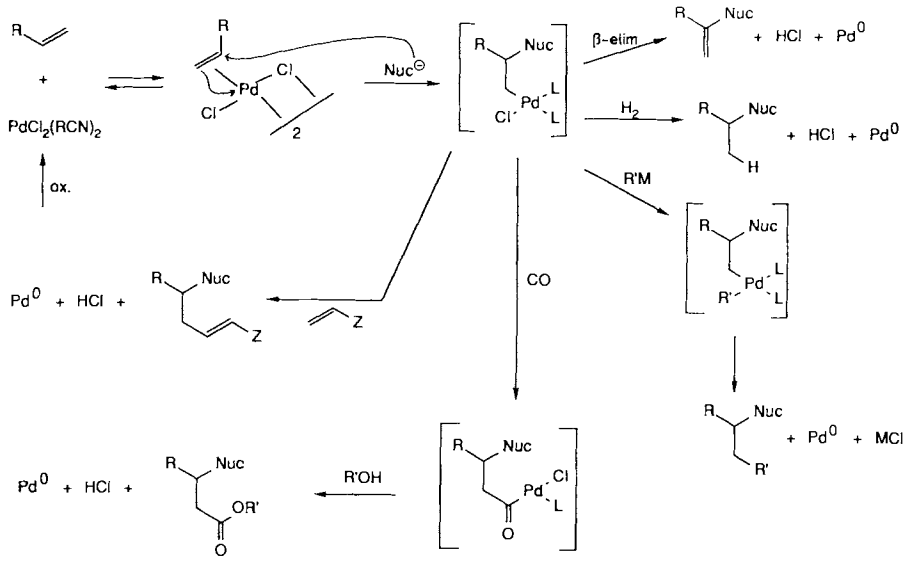
Palladium(II) salts are moderate to strong electrophiles, depending on the counterion. Commercially available salts are $Pd(OAc)_2$, $Pd(CF_3CO_2)_2$, and $[PdCl_2]_n$. The former two are relatively soluble in organic solvents, but $[PdCl_2]_n$ is a chloro-bridged polymer which is quite insoluble. It does form soluble solvates with nitriles or "ate" complexes with lithium or sodium chloride, and it is in these soluble forms that it is normally used in organic synthesis.



Palladium(II) complexes are electrophiles, and they complex and activate π-electron-rich organic compounds. Arenes are directly metalated by $Pd(OAc)_2$ or $Pd(CF_3CO_2)_2$, forming σ-arylpalladium(II) complexes in a typical electrophilic aromatic substitution. Arenes can be coupled to give biphenyls by treatment with $Pd(OAc)_2$ in acetic acid, in a process that probably involves two successive substitutions followed by a reductive elimination. Unfortunately, this process has not yet been developed into an efficient catalytic one (Ar = aryl).



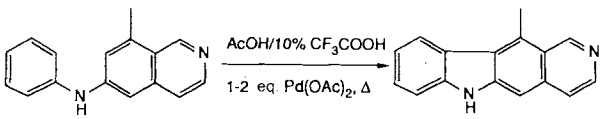
Olefins rapidly and reversibly complex to $PdCl_2$, forming relatively stable but reactive π-olefin complexes. Once complexed, the olefin becomes generally reactive toward *nucleophilic* attack—a reversal of normal olefin reactivity—forming a carbon–nucleophile bond and a palladium(II)–carbon σ bond (Scheme 1). Nucleophiles ranging from $Cl^\ominus$ to $Ph^\ominus$ react, spanning a range of 10^{36} in basicity. Most nucleophiles attack at the more-substituted olefin position. The σ-alkylpalladium(II) complex is generally not stable and can only be isolated in unusual cases. However, it is highly reactive and undergoes transformations typical of σ-alkylpalladium(II) species, regardless of the method of formation. Thus β-hydride elimination ensues at temperatures above about 0 °C, giving the formal product of nucleophilic substitution. Hydrogenolysis (> −20 °C, 1 atm H_2) produces the formal product of nucleophilic addition. Transmetalation from a main-group organometallic—Sn, Hg, Cu, Tl—produces a dialkylpalladium(II) complex which can undergo reductive elimination resulting in overall difunctionalization of the olefin. Difunctionalization of the olefin also results from insertion of carbon monoxide or olefins. The regiochemistry of olefin insertion is governed by steric rather than electronic factors, and alkylation at the less-substituted olefin terminus usually predominates in intermolecular insertion processes. Note that all of these processes produce Pd^0 in the final step, while Pd^{II} is required for the olefin-activation step. Reoxidation of Pd^0 to Pd^{II} is thus required for *catalytic* processes. Oxidants such as $CuCl_2/O_2$, benzoquinone, and $K_2S_2O_8$ are most commonly used for this purpose, the choice of oxidants being dictated by the reactant and product compatibility. All of these processes have been used in the synthesis and functionalization of indoles and will be discussed below.



Scheme 1. Reactions of nucleophiles with palladium(II) complexes. Nuc = Cl, OH, AcO, R_2N (from R_2NH), $HC(CO_2R)_2$, Ph; Z = H, R, Ph, CN, CO_2Me, OR, NHAc; L = RCN (not always drawn).

2.1.1. *Coupling of Arenes by Palladation*

Although the coupling of arenes by direct palladation is not an efficient process, it has been used in several cases to synthesize functionalized indole ring systems. The early studies involved the coupling of substituted diphenylamines. Although one to two equivalents of palladium(II) acetate were required, reasonable yields of carbazoles were obtained.[11] Ellipticine **3** was made by this process.[12] Although the yield of the coupling was low, the directness of the approach made it competitive with other synthetic routes.

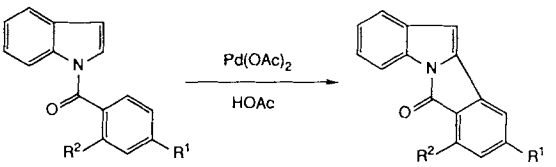


3, 25%

Indole itself undergoes direct palladation at the 2- and 3-positions. This has been used to make fused-ring indole systems—e.g., **5**,[13] **6**, and **7**[14]—as well as to introduce olefinic side chains at the 3-position (cf. **8**) or at the 2-position in 3-methylindole.[15–17] Carbonylation at the 3-position has also been achieved by this method, carbon monoxide being inserted rather than an olefin.[18] Unfortunately, all of these processes require virtually stoichiometric amounts of $Pd(OAc)_2$ even when suitable reoxidants are present, and efficient catalysis has not yet been achieved in these systems.

Finally, in a remarkable reaction, $Pd(OAc)_2$ catalyzed a single-electron-transfer process which combined 4,*N*,*N*-trimethylaniline with tetrahydrofuran to produce dihydroindole **9**.[19] Iodobenzene served as the reoxidant. This unusual process was not general.

Although direct aromatic palladation remains a catalytically inefficient process, palladium(II) is an efficient catalyst for the olefination and alkylation of thallated indoles,



R^1 = H, Cl, Me; R^2 = H, Me, Cl

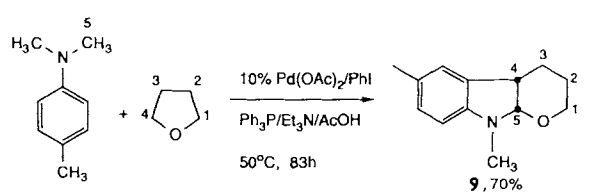
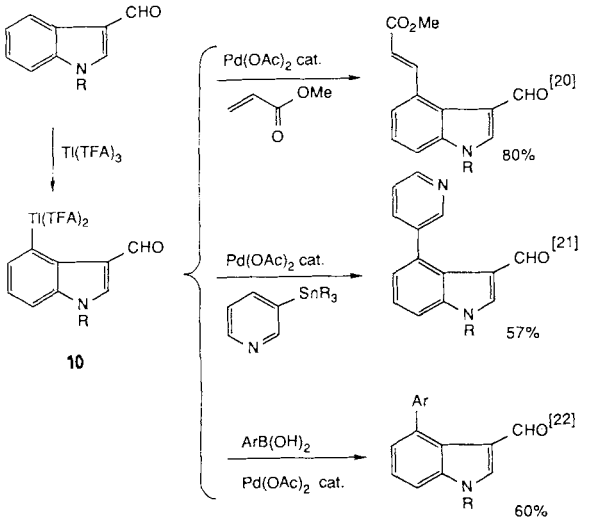
X = CN, CO_2Me, Ph

8, 40-70%



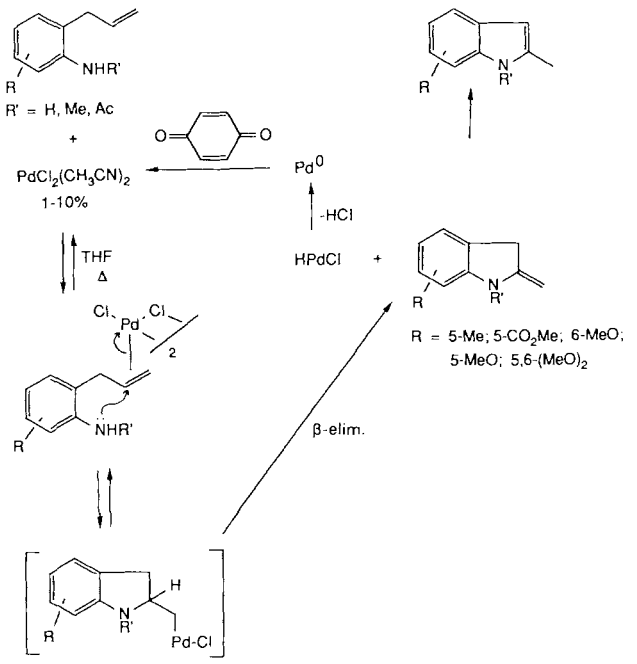
9, 70%

via a transmetalation-insertion-elimination process (Scheme 1). Thus, indole-3-carbaldehyde underwent thallation primarily at the 4-position (→ **10**). In the presence of a $Pd(OAc)_2$ as catalyst, transmetalation to palladium, followed by olefin insertion or reductive elimination, ensued producing 4-alkylated indoles in modest yield (R = CO_2Me, H). Thallium(III) probably serves as the reoxidant for palladium(0). This is a synthetically important reaction for ergot alkaloid synthesis, since ergots require substitution in the normally unreactive 4-position of the indole ring system (TFA = trifluoroacetyl; cat. = catalytic amount).



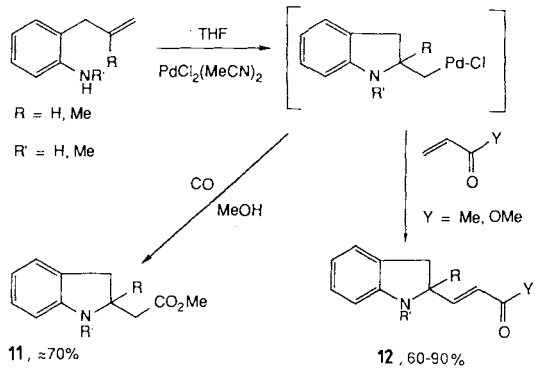
2.1.2. *Palladium(II)-Catalyzed Amination of Olefins*

Palladium(II) chloride catalyzes the amination of olefins (cf. Scheme 1). When the amine and the olefin are in the same molecule, cyclization to give nitrogen heterocycles occurs. *o*-Allylanilines were efficiently converted into 2-methylindoles using palladium(II) catalysis and benzoquinone as reoxidant[23,24] (Scheme 2). The process was

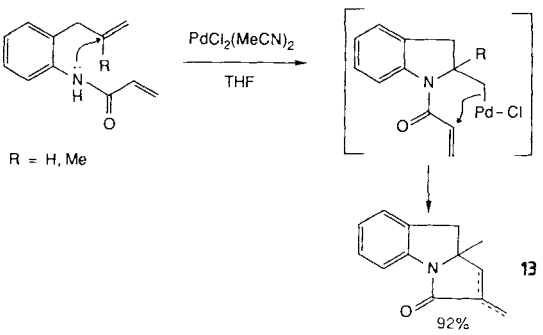


Scheme 2. Palladium(II)-catalyzed cyclization of allylanilines to 2-methylindoles.

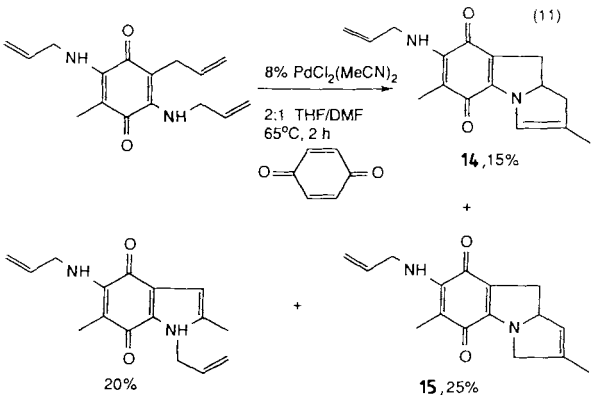
thought to involve coordination of the olefin to Pd^{II} followed by intramolecular amination. As expected, attack occurred at the more-substituted position of the olefin, forming the indole ring and an unstable σ-alkylpalladium complex. β-Hydrogen elimination followed by olefin rearrangement produced the indole. When β-hydrogen elimination was suppressed, either by blocking with an alkyl group, or by careful control of conditions, insertion of CO or an olefin ensued, leading to more complex indoles such



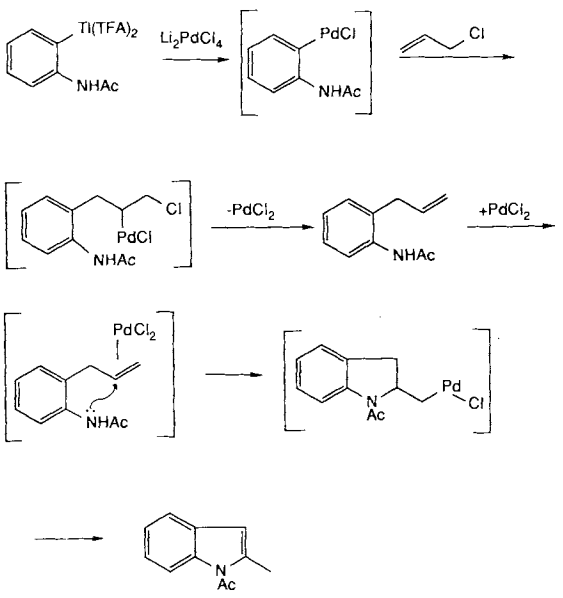
as **11** and **12**.[25] When the olefin was also incorporated into the starting aniline, pyrroloindoles such as **13** were formed efficiently.[25,26] This process was used in the syn-



thesis of pyrroloindolequinones such as **14** and **15**, which are related to mitomycin C **4**.[27]

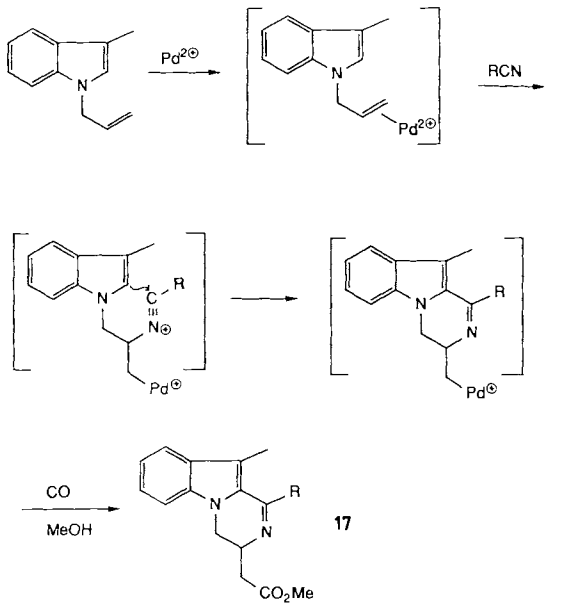


Indoles such as **16** were also produced in a stoichiometric reaction involving most of the processes described in Scheme 1, including transmetalation, insertion, elimination, and amination of olefins.[28]



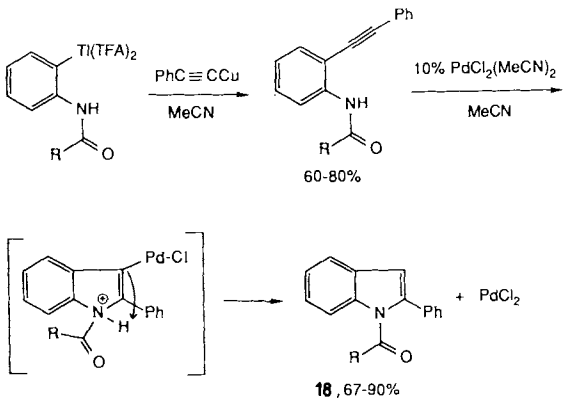
16, 45%

Palladium-assisted amination of olefins was also used to *N*-alkylate indole with olefins, giving *N*-alkylindoles upon reduction, N-vinylindoles upon β-elimination, and 3-(1-indolyl)propionic esters upon carbonylation.[29] This was a stoichiometric process since conditions to carry out the Pd^0 to Pd^{II} redox chemistry in the presence of indole anion could not be found. The strongly electrophilic $Pd(CH_3CN)_4(BF_4)_2$ promoted a Ritter-like reaction between *N*-allyl-3-methylindole and nitriles, giving pyrazino[1,2-*a*]indoles such as **17**.[30] While interesting, this process was neither efficient nor general.



R = Me, 34%; Et, 47%; Ph, 35%

In contrast to alkenes, alkyne aminations assisted by palladium(II) are much less common, primarily because of facile alkyne oligomerization reactions which occur. However, *o*-alkynylated anilides were successfully cyclized to indoles such as **18** by $PdCl_2(MeCN)_2$.[31] The mechanism

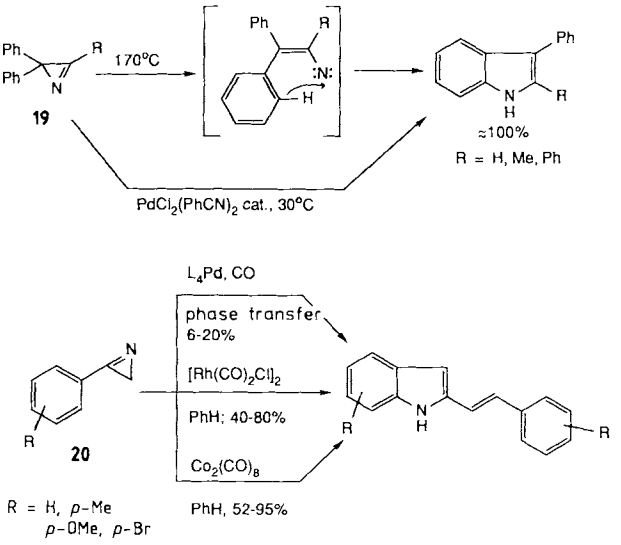


18, 67-90%

must be somewhat different from that observed with olefins, since the σ-vinylpalladium(II) intermediate cannot undergo β-hydride elimination, and protolytic cleavage of the Pd–C bond is assumed. Acetylenedicarboxylates were annelated to anilines to give indole-2,3-dicarboxylic acids in an electron-transfer process requiring stoichiometric amounts of palladium.[32]

2.1.3. Palladium(II)-Catalyzed (and Other Metal-Catalyzed) Reaction of Azirines

Thermolysis of phenylazirines **19** at temperatures above 170 °C produced indoles, presumably via a nitrene intermediate. Palladium(II) chloride catalyzed this process, permitting it to ensue at 30 °C.[33] Rhodium(I), palladium(0),



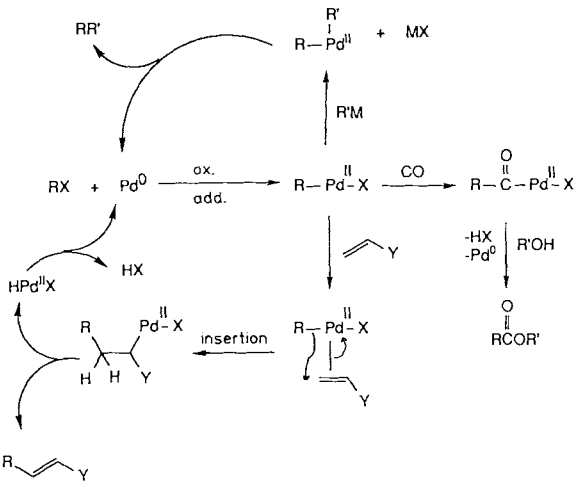
and cobalt(0) complexes catalyzed a puzzling dimerization of azirines **20** to produce indoles in variable yields.[34-36]

2.2. Palladium(0) (and Nickel(0)) Complex Chemistry

While palladium(II) salts are electrophilic reagents which react with olefins and arenes, palladium(0) complexes are strong nucleophiles and are most reactive toward organic halides. The two most common, commercially available complexes for palladium(0) catalysis are $Pd(PPh_3)_4$ and $Pd(dba)_2$ (dba = dibenzylideneacetone),

which is converted into $Pd(PPh_3)_4$ when treated with triphenyl phosphane. Both of these have been extensively used as catalysts in organic synthesis. However, it is frequently more convenient to generate palladium(0) catalysts in situ, by reducing palladium(II) catalyst precursors. Thus, treatment of $Pd(PPh_3)_2Cl_2$ with diisobutylaluminum hydride or with CO or triethylamine (see below) will generate the catalytically active Pd^0 species "PdL_n". Perhaps the most extensively used palladium(0) catalyst precursor, however, is palladium(II) acetate, which is readily reduced in situ by a range of compounds including carbon monoxide, olefins, phosphanes, and tertiary aliphatic amines such as triethyl- or tri-*n*-butylamine.[37] This causes some confusion in the literature, since palladium(0) catalysis is involved but palladium(II) acetate appears in all the equations. Invariably, some reducing agent is present in these systems, and palladium(0) catalysis is indeed involved.

The typical reaction of Pd^0 complexes is the "oxidative addition" of organic halides, wherein the Pd^0 complex is formally oxidized to a σ-alkylpalladium(II) halide complex and the "oxidizing agent" (RX) adds to the metal (Scheme 3). This reaction is limited to halides lacking β hydrogens,

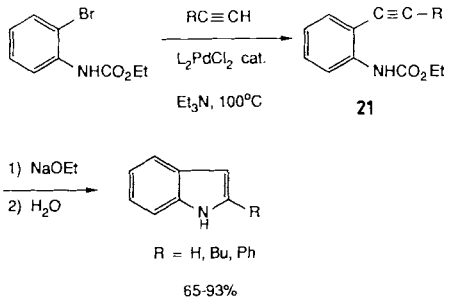


Scheme 3. Palladium(0)-catalyzed reactions of organic halides.

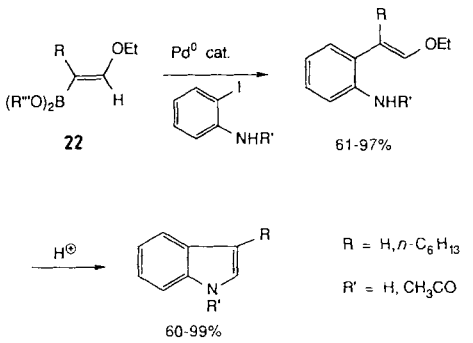
since β-hydride elimination (cf. Scheme 1) prevents the further use of these complexes. The most common substrates are aryl, vinyl, benzyl, and allyl halides. The order of halide reactivity is I > Br ≫ Cl, and iodides will often react in the absence of phosphane ligands while bromides require a phosphane. Chlorides generally are not useful. This "oxidative addition" produces a σ-alkylpalladium(II) complex which undergoes all the reactions described in Scheme 1 for σ-alkylpalladium(II) species produced by nucleophilic attack on olefins. The most extensively used reactions are transmetalation from main-group organometallics, and insertion of CO or olefins. These reactions are summarized in Scheme 3. These processes all re-form Pd^0, which can reenter the catalytic cycle directly, in contrast to Pd^{II}-catalyzed reactions, which require an additional oxidant. This feature, in conjunction with recent advances which permit very high catalyst turnover[38] and very mild conditions,[39] accounts for the extensive use of Pd^0 catalysis in the syntheses and functionalizations discussed below.

2.2.1. Palladium(0)-Catalyzed Alkynylation of Bromoanilines

o-Alkynylanilines such as **21**, made by palladium(0)-catalyzed coupling of alkynes with *o*-haloaniline precursors,[40,41] are readily cyclized to indoles. (Note that a Pd^{II} complex is the precatalyst which is reduced to Pd^0 by triethylamine.) In a related process, hydroboration of

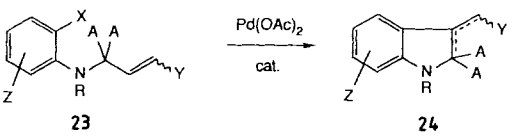


ethoxyacetylene gave a vinylborane, **22**, which underwent Pd^0-catalyzed oxidative addition/transmetalation to produce an indole precursor.[42]



2.2.2. Palladium(0)-Catalyzed Cyclization of 2-Halogenated N-Allyl-, N-Vinyl-, or N-Arylanilines to Indoles

o-Bromoanilines are easily *N*-allylated, producing substrates ideally suited for a Pd^0-catalyzed oxidative addition/olefin insertion approach to the indole ring system. As a consequence, this route has been extensively developed. Both activated[43,44] and simple olefins[45] inserted effi-



A	R	X	Y	Z	24, Yield [%]

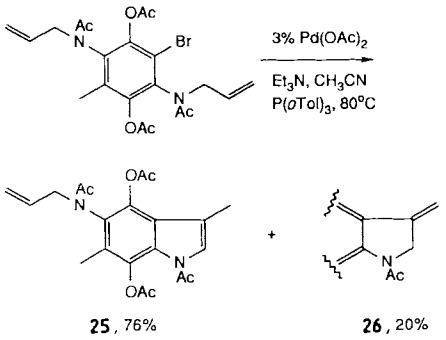
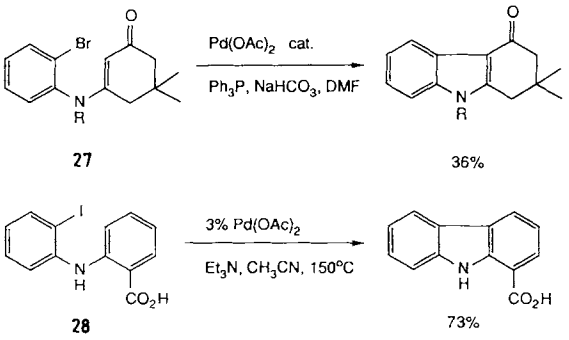
H	Ac	Br	CO_2Me	H	73
H	H	I	H	5-Me 5,6-$(MeO)_2$ 5-CO_2Me H	50–87

ciently. The insertion product **23** of simple olefins gave good yields of indoles **24** with catalytic amounts of palladium. This cyclization was even effective with highly substituted arenes and was used to synthesize indolequinones via **25** and **26**.[46] Carbazoles were produced in low yields from 3-anilinocyclohexenones such as **27** (R = H, Et)[47]



25, 76% **26**, 20%

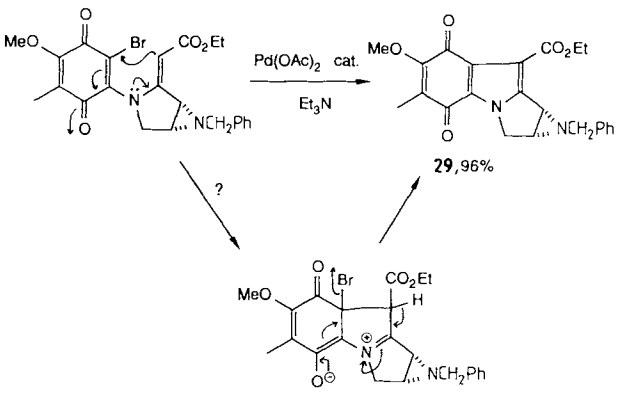
and in good yield from diphenylamines such as **28**[48] utilizing similar oxidative addition/insertion chemistry. Mi-



27 36%

28 73%

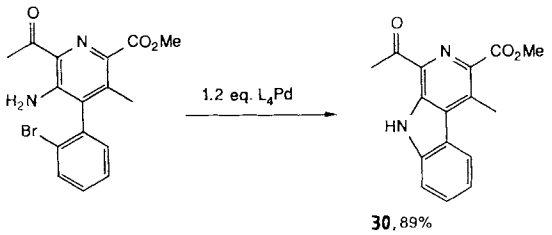
tomycin analogues (cf. **29**) were prepared very efficiently by the same process,[49,50] although the last cyclization also occurred in the absence of a Pd catalyst. Carbazoles such



29, 96%

as **30** were also produced by an intramolecular amination of an aryl halide.[51-53] This process required 1.2 equivalents of Pd^0 complex (L = Ph_3P) and its mechanism is not yet understood.

In contrast to nickel(II) salts, which differ dramatically from palladium(II) salts in their chemistry, nickel(0) complexes closely resemble palladium(0) complexes in their reaction chemistry. Thus nickel(0) complexes can also be



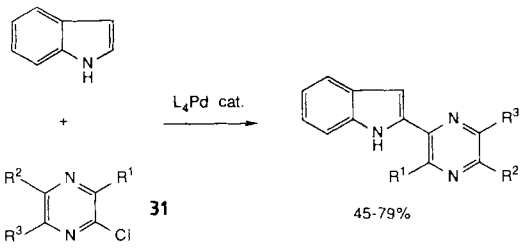
30, 89%

used to cyclize *N*-allyl-2-haloanilines to indoles, although the yields obtained are somewhat lower.[54-59]

The regioselectivity of intramolecular olefin insertion processes warrants comment. As noted in Section 2.1, the regioselectivity in the intermolecular insertion process is strongly governed by steric rather than electronic factors, and alkylation at the less-substituted terminus of the olefin predominates regardless of the electronic nature of the olefin substituents. In intramolecular processes, the effects of developing ring strain may well override those of olefin substituents, making the site of alkylation (e.g., ring size) difficult to predict.

2.2.3. *Palladium(0)-Catalyzed Functionalization of Indoles*

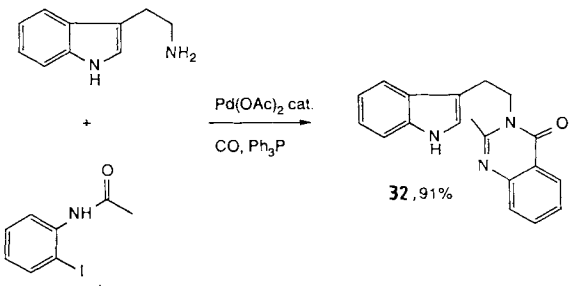
Palladium(0) catalysis has also been used extensively to functionalize indoles. Chloropyrazines **31** coupled to the 2-position of indole in the presence of Pd(0), probably by



31 45-79%

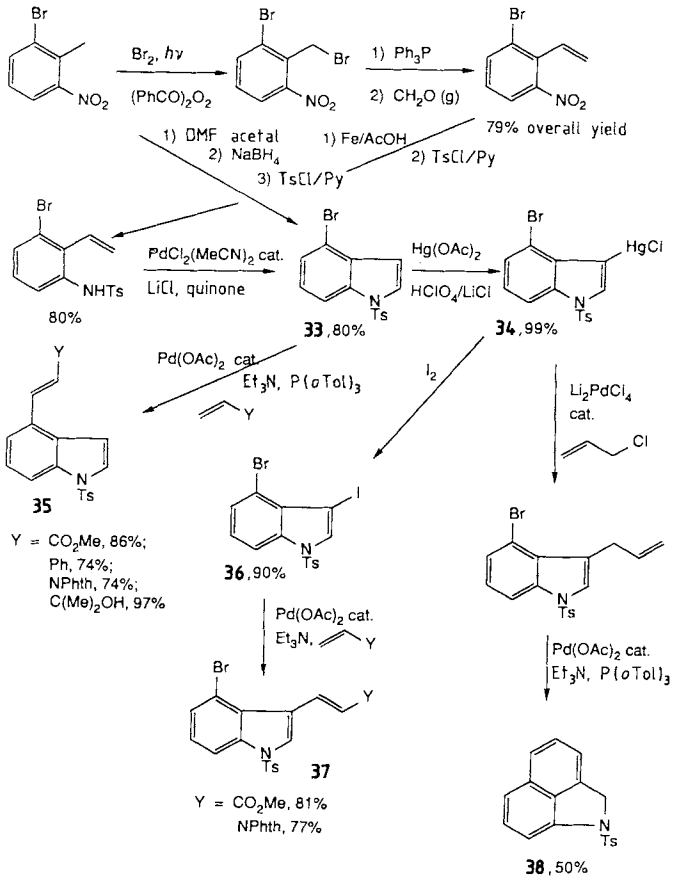
R^1, R^3 = Me, Et, *i*Pr, Ph, H; R^2 = H, Ph

an oxidative addition/insertion process.[60] The 3-aminoethyl side chains of indoles were elaborated by a Pd^0-catalyzed carbonylation, for example with ring closure to give **32**.[61]



32, 91%

Palladium(0)-catalyzed reactions of haloindoles are among the most synthetically useful processes and have been extensively developed for application in the synthesis of 3,4-disubstituted indole ring systems including ergot alkaloids (see Section 2.2.4). Introduction of functionality at the 4-position of indole using conventional electrophilic indole chemistry is difficult, since the 1-, 2-, and 3-posi-

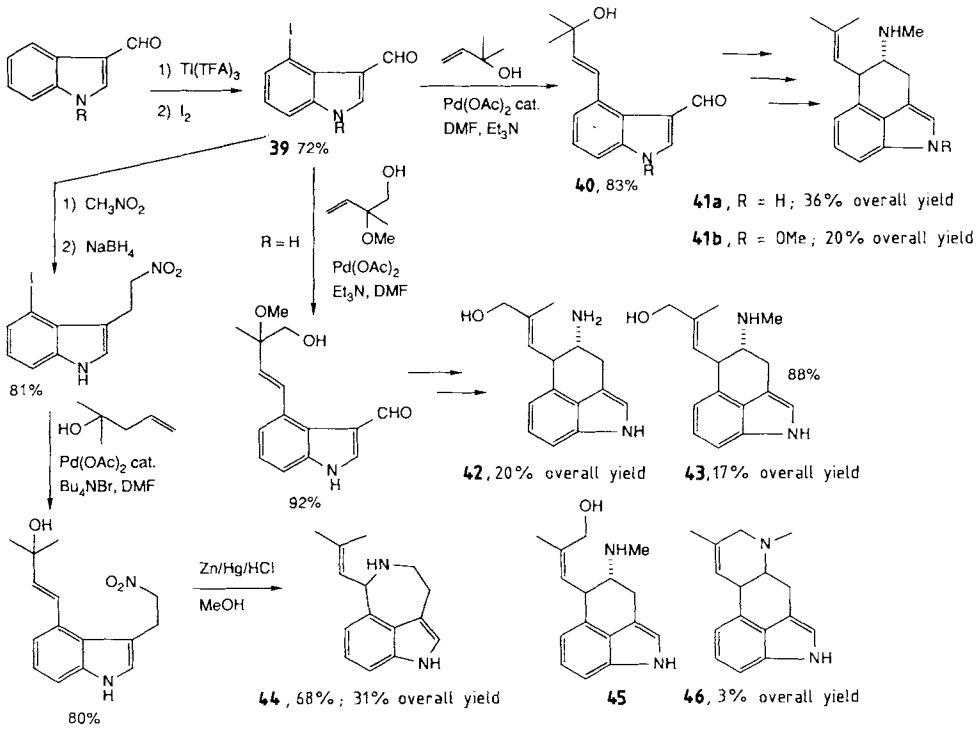


Scheme 4. Palladium(0)-catalyzed synthesis of 3- and 4-substituted indoles. NPhth (cf. **35** and **37**) = phthalylimido, Py = pyridine.

tions are considerably more reactive. Scheme 4 shows one approach to the introduction of functionality at the 3- and 4-positions of indoles.[62] The key compound in all these transformations is 4-bromo-*N*-tosylindole **33**, prepared in good yield by Pd^{II}-catalyzed cyclization of the appropriate *N*-tosyl-*o*-vinylaniline, or, more recently, by the DMF-acetal/reduction/tosylation approach. Compound **33** reacted in typical aryl halide fashion in the Pd^0-catalyzed oxidative addition/insertion process to produce 4-alkylated indoles **35** in excellent yield. Direct electrophilic mercuration at the 3-position produced **34**, which was readily iodinated to give 4-bromo-3-iodoindole **36**. The same Pd^0-catalyzed process permitted facile alkylation of the 3-position as well (cf. **37**). Complete discrimination between the bromide, which requires a phosphane to react, and the iodide, which reacts in the absence of a phosphane, was possible by appropriate choice of conditions. The mercurioindole **34** also underwent a facile Pd^{II}-catalyzed transmetalation/insertion process to give the 3-allyl-4-bromoindole. Cyclization to tricyclic compound **38** was catalyzed by palladium(0). Although **38** had the tricyclic ring system found in ergot alkaloids, rearrangement of the indole to the more stable naphthalene made this specific compound of little synthetic interest. 7-Substituted indoles were available by a related route involving thallation/iodination of the 7-position of an indole followed by Pd^0-catalyzed oxidative addition/olefin insertion.[63,64]

2.2.4. *Palladium Catalysis in the Synthesis of Ergot Alkaloids*

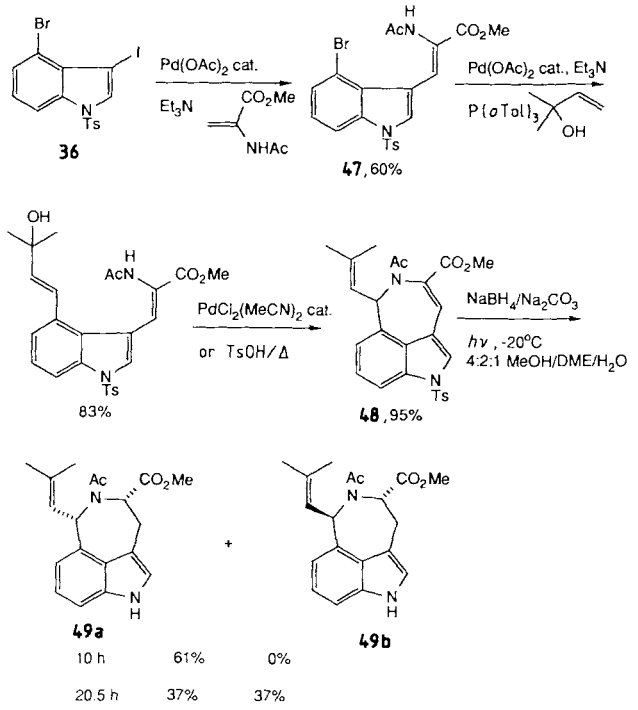
After many years of development, palladium catalysis is finally finding its way into mainstream organic synthesis. Its utility is evident from the ergot syntheses discussed below, as are its limitations. When properly applied, however, palladium catalysis can result in very short and efficient synthetic approaches to complex organic compounds. A fine example of this is seen in Scheme 5, wherein Pd^0-catalyzed functionalization of the 4-position of the indole nucleus provided the key intermediate **39** for the synthesis of



Scheme 5. Palladium-catalyzed synthesis of clavine alkaloids, which belong to the ergot alkaloids. The yields of **39** and **40** refer to R = H, OMe.

a number of ergot alkaloids such as (±)-6,7-secoagroclavine **41a** (via **40**),[65] (±)-1-methoxy-6,7-secoagroclavine **41b**,[66] (±)-norchanoclavine I **42**, (±)-chanoclavine I **43**,[67] (±)-aurantioclavine **44**,[68] (±)-isochanoclavine **45**, and (±)-agroclavine **46**.[67] These all rely on the formyl-directed thallation of indole-3-carbaldehyde, followed by iodination with iodine to give the iodide **39** and Pd^0-catalyzed introduction of the appropriate side chain at the 4-position. The remaining steps involve conventional organic chemistry.

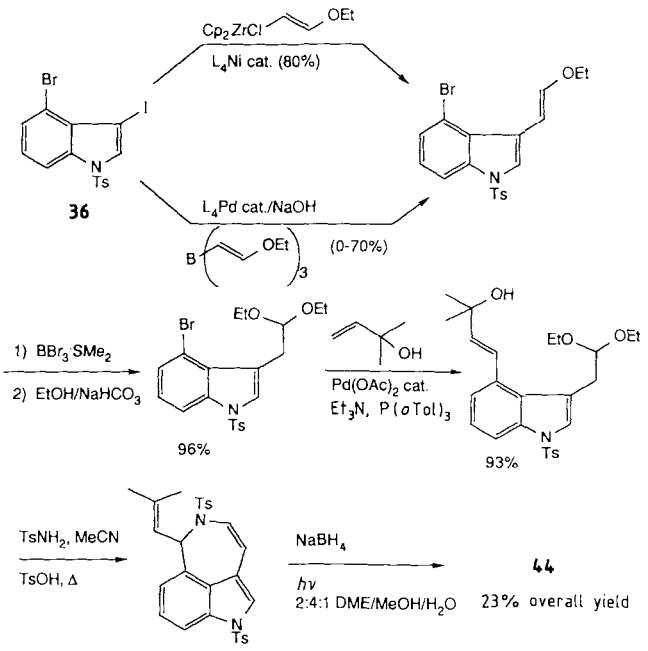
An even more extensive use of palladium catalysis is seen in the total synthesis of the methyl ester of (±)-*N*-acetylclavicipitic acid **49**,[69] which involves as key steps Pd^{II}-catalyzed formation of the indole ring, Pd^0-catalyzed introduction of both C-ring side-chain precursors, and Pd^{II}-catalyzed formation of the seven-membered ring (Scheme 6). This twelve-step synthesis in 18% overall yield from commercially available starting materials is quite efficient.



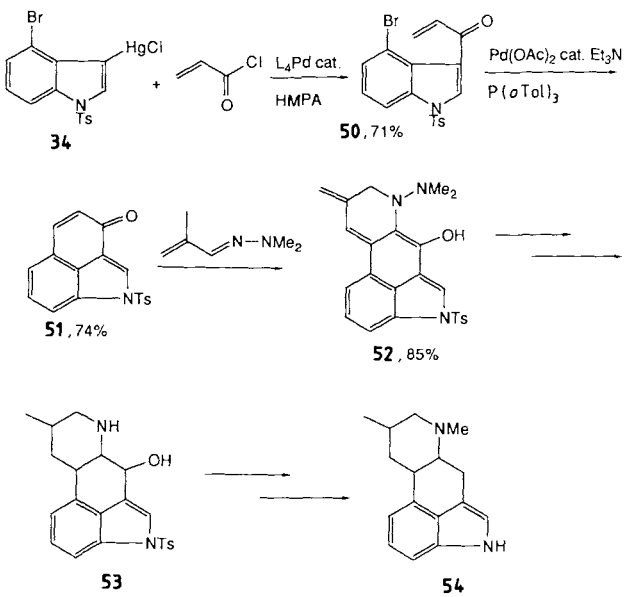
Scheme 6. Palladium-catalyzed synthesis of the methyl ester of (±)-*N*-acetylclavicipitic acid, **49**. Only the isomer shown here is formed from compound **47**.

A related approach was used in the total synthesis of (±)-aurantioclavine **44** (Scheme 7).[70] In this case, oxidative addition to Ni^0 followed by transmetalation from Zr^{IV} proved more reliable than Pd^0-catalyzed oxidative addition/transmetalation from boron for introduction of the enol ether at the 3-position. Pd^0-catalyzed introduction of the 4-alkyl group, followed by acid-catalyzed condensation/cyclization and photolytic reductive decarbonylation, completed the synthesis of compound **44**.

A potential approach to tetracyclic ergot alkaloids involving extensive palladium catalysis is shown in Scheme 8.[71] Acylation of the 3-mercurioindole **34** by acryloyl chloride using Pd^0-catalyzed oxidative addition/transmetalation to give **50**, followed by Pd^0-catalyzed cyclization,



Scheme 7. Palladium-catalyzed synthesis of (±)-aurantioclavine **44**.



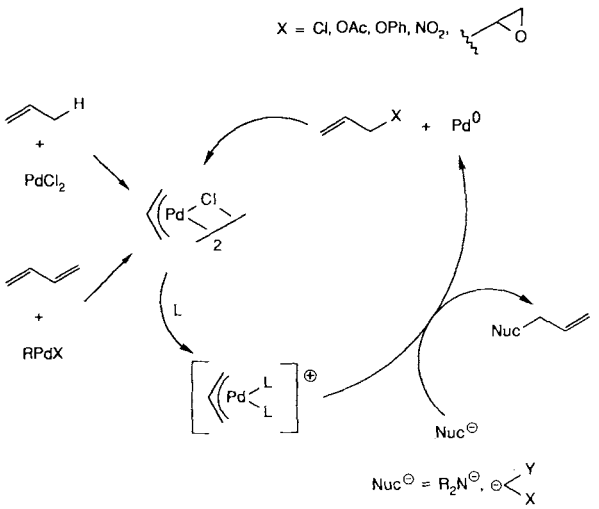
Scheme 8. Palladium-catalyzed synthesis of tetracyclic ergot alkaloids such as **54**. The reaction of **51** was carried out without solvent.

produced tricyclic intermediate **51**, which was prevented from rearranging to the naphthalene (cf. **38** in Scheme 4) by the position of the carbonyl group. Cycloaddition of **51** to an azadiene produced the proper ergot alkaloid skeleton, **52**, in a highly oxidized state. Reduction and removal of heteroatoms are required to produce the proper ergot ring system.

2.3. π-Allylpalladium Complexes in the Synthesis and Functionalization of Indoles

π-Allylpalladium(II) complexes can be prepared by proton abstraction from olefin palladium(II) complexes, by in-

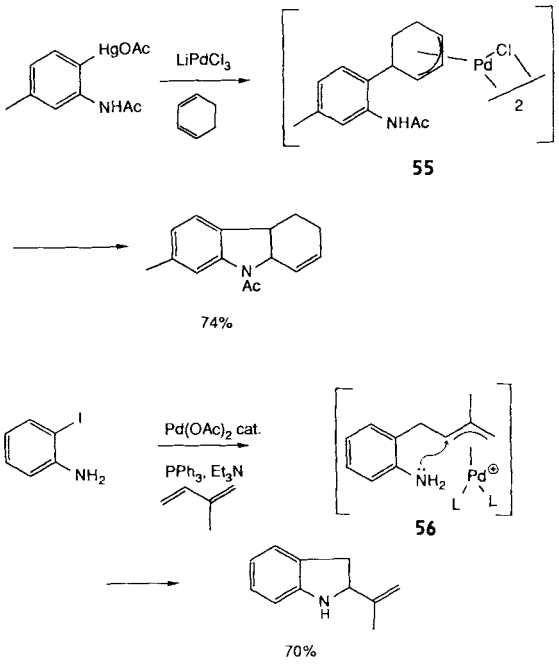
sertion of dienes into σ-alkylpalladium(II) complexes, or by oxidative addition of allylic substrates to palladium(0) complexes. They are yellow, air-stable crystalline solids, quite stable to a variety of reactive species. In the presence of good donor ligands (usually phosphanes), however, these complexes become generally reactive toward nucleophiles such as amines or stabilized carbanions, resulting in allylation of these nucleophiles and production of Pd^0 species (Scheme 9). This forms the basis of a very useful Pd^0-



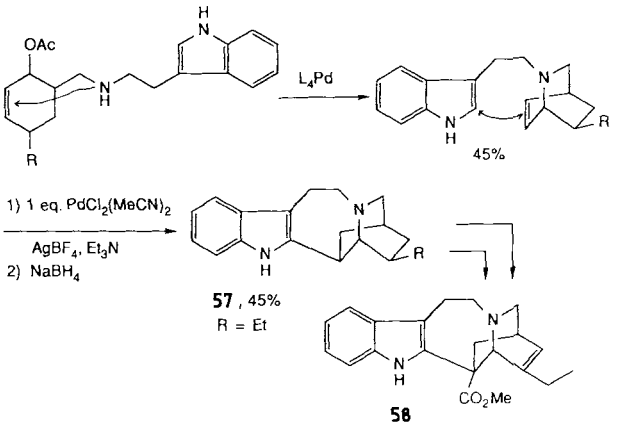
Scheme 9. Synthesis and reactions of π-allylpalladium(II) complexes.

catalyzed allylic activation process which has been extensively developed for use in organic synthesis. Some of these applications involve indoles and are presented below.

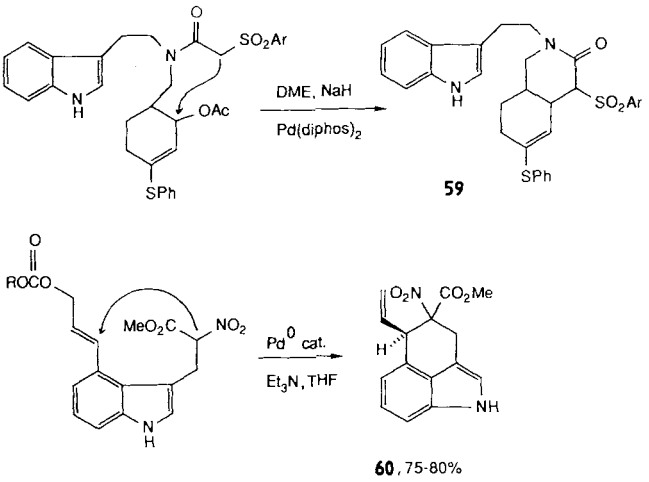
Formation of the indole ring via π-allylpalladium(II) intermediates—e.g., **55**[72] and **56**[73]—is relatively uncom-



mon. These two examples involve diene insertion into σ-arylpalladium(II) species. π-Allylpalladium(II) chemistry is more commonly used to elaborate existing indole ring systems. The isoquinuclidine ring of ibogamine **57**[76] and cantharanthine **58**[77] were synthesized by a Pd^0-catalyzed



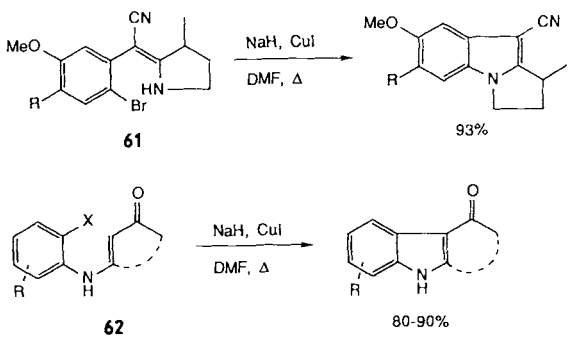
allylic amination.[74-77] Alkylation at the indole 2-position was accomplished using palladium(II) activation.[78] Other indole alkaloid syntheses have used Pd^0-catalyzed allylic alkylation to elaborate nonindolic heterocyclic rings such as **59** and **60**.[78]



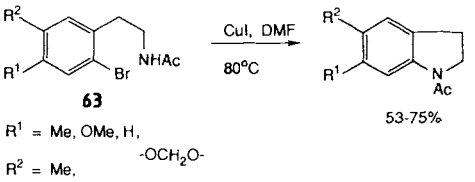
3. Other Transition Metals in the Synthesis and Functionalization of Indoles

3.1. Copper(I)-Catalyzed Cyclization and Condensation

Although palladium is by far the most extensively used transition metal for the synthesis and functionalization of indoles, many others have found at least limited use in this

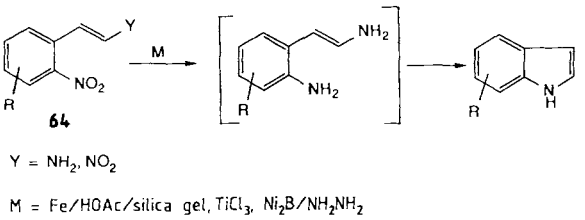


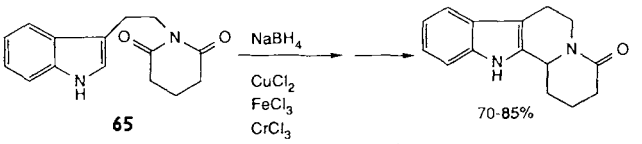
regard. For instance, copper(I) salts have long been known to catalyze the reactions of nucleophiles with aromatic halides (e.g., the Hurtley reaction). With appropriate substrates, indoles can be formed. Thus *o*-haloaryl enamines, such as **61**, R = Me, OMe, H,[81] and **62**,[82] cyclized to indoles in the presence of copper(I) iodide in excellent yield. Under similar conditions enolates condensed with *o*-iodoaniline to produce indoles.[83] *o*-Haloacetamides (e.g. **63**[84]) also cyclized to indole derivatives under these conditions. Copper(I) oxide catalyzed the cyclization of *o*-isocyanophenylacetones to indoles.[85–87]

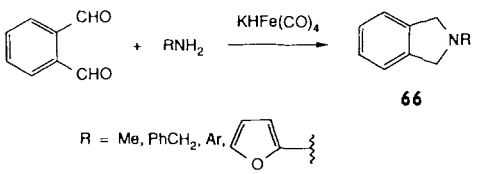


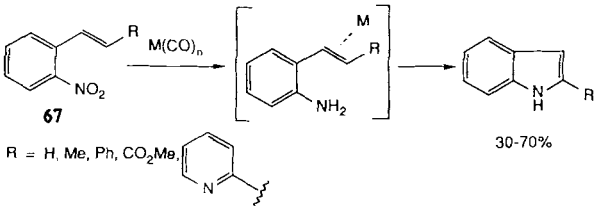
3.2. Reductive Cyclizations using Low-Valent Transition-Metal Compounds

A number of indole syntheses use low-valent transition metals to reduce aromatic nitro groups to amines, which can then cyclize with electrophilic groups in the *ortho* position to form indoles. These typically involve *o*-nitroaryl enamines (cf. **64**) and reducing agents such as iron(0),[88] titanium(III) chloride,[89] or nickel boride.[90] Tryptamine





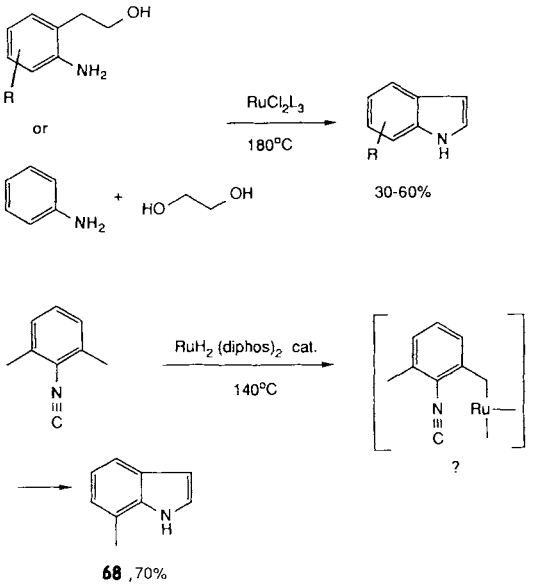




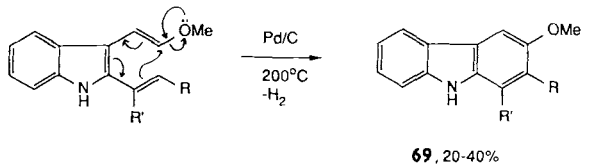
derivatives such as **65** were reductively cyclized to β-carbolines by $NaBH_4$ and copper(II), iron(III), or chromium(III) halides.[91] Dihydroisoindoles **66** were produced in excellent yield by the $KHFe(CO)_4$-promoted reductive amination of *o*-dialdehydes.[92] Finally, *o*-nitrostyrenes such as **67** were reductively cyclized to indoles by metal carbonyls, in a process which must involve olefin activation by the metal, as well as nitro group reduction.[93]

3.3. Ruthenium(II)- or Palladium-Catalyzed Oxidative Cyclization

Ruthenium(II) chloride-catalyzed oxidation of alcohols has been used to form indoles in modest yield, although the conditions are somewhat severe.[94–96] 2,6-Dimethylphenyl isocyanide was converted into 7-methylindole **68** in

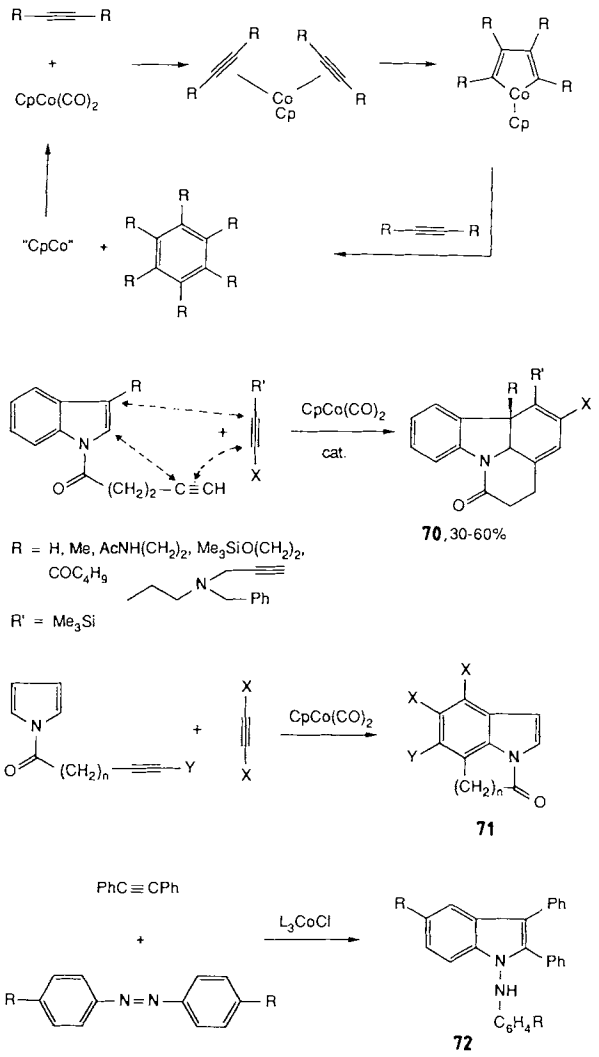


a process which must have involved C–H activation by the ruthenium (four catalytic cycles per $[RuH_2(diphos)_2]$).[97] Palladium on carbon catalyzed oxidative cyclization to **69**.[98]



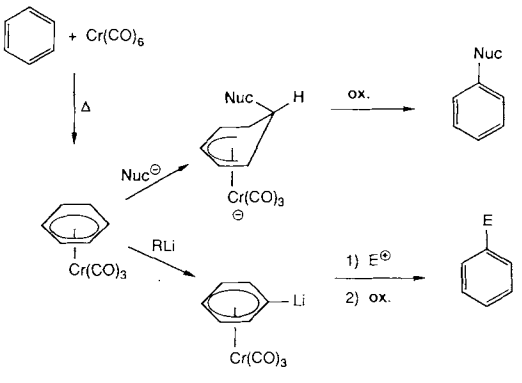
3.4. Cobalt-Catalyzed Cyclotrimerization Reactions

The cobalt(I)-catalyzed cyclotrimerization of alkynes and cocyclotrimerization of alkynes and alkenes have been extensively developed for use in organic synthesis.[99] The synthesis of compounds **70**[100] and **71**[101] exemplify the use of the latter in the synthesis of indoles. Cobalt(I) complexes also catalyzed the addition of alkynes to diazenes to produce *N*-aminoindoles **72**.[102]

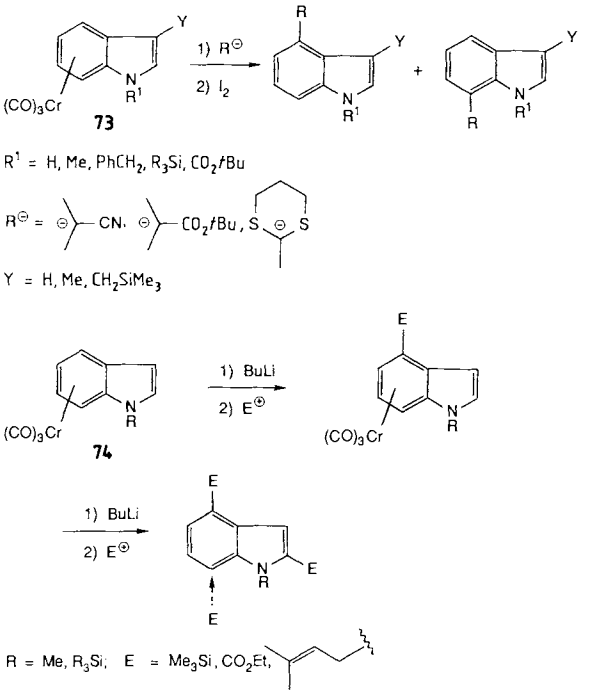


3.5. Arenechromium Tricarbonyl Complexes in Indole Chemistry

Arenes readily form η^6 complexes with chromium hexacarbonyl usually by simply heating the two together. Once complexed to the chromium tricarbonyl fragment, the arene becomes reactive toward nucleophilic attack and toward ring lithiation, the effect of the $Cr(CO)_3$ fragment being comparable to having introduced a nitro group. Thus, direct nucleophilic aromatic substitution and lithiation becomes feasible. This feature has been used to introduce functionality at normally unreactive positions of the indole ring system.



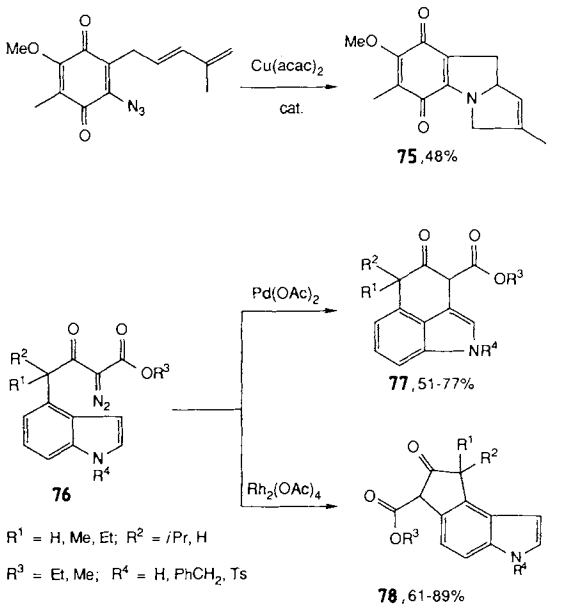
This chemistry allowed 5-chlorodihydroindoles to be converted into 5-methoxydihydroindoles by nucleophilic substitution of chloride by methoxide,[103] and complexed indoles (**73**) were alkylated in the 4- and 7-positions (major and minor product, respectively) by carbanions.[104, 105]



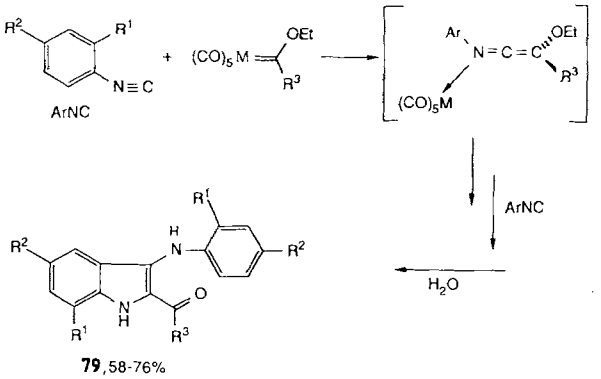
Lithiation of complexed indoles (**74**) occurred at the 4-position when the *N*-substituent was large, but at the 2-, 4-, and 7-positions when it was small.[106, 107]

3.6. Miscellaneous Indole Syntheses

The copper-catalyzed decomposition of aryl azides to produce nitrenes has been used to synthesize a number of pyrroloindolequinones (such as **75**).[108] The site of inser-



tion of carbenes generated by transition-metal-catalyzed decomposition of α-diazoesters such as **76** depended strongly on the catalyst (cf. **77** and **78**).[109] Aryl isocyanides combined with carbene complexes (M = Cr, Mo, W) to produce indoles, via ketenimine complexes **79**.[110,111]



79, 58-76%

4. Outlook

Although most of the fundamental organometallic reaction chemistry utilized in the synthesis of indoles has been known for at least a decade, only recently have these fundamental processes been applied to complex multifunctional organic substrates with the serious intent of accomplishing the total synthesis of a natural product. This extension to more complex systems has vividly brought into focus both the power and the limitations of organometallic chemistry in the synthesis of complex organic compounds. A decade ago only inorganic and "organometallic" chemists ventured into the transition series to find useful organic transformations. Today, transition metals are common in synthetic organic chemistry, and new transition-metal-catalyzed transformations of organic substrates are readily adopted by synthetic chemists. This is expected to continue.

Our research in the area of palladium catalysis in the synthesis and functionalization of indoles was supported by the National Science Foundation and the National Institutes of General Medical Sciences of the Public Health Service, whom we gratefully acknowledge.

Molecular Organometallic Chemistry on Surfaces: Reactivity of Metal Carbonyls on Metal Oxides

By H. Henry Lamb, Bruce C. Gates, and Helmut Knözinger*

Metal carbonyls react on metal oxide surfaces to give a wide range of structures analogous to those of known compounds. The reactions leading to formation of surface-bound metal carbonyls are explained by known molecular organometallic chemistry and the functional group chemistry of the surfaces. The reaction classes include formation of acid–base adducts as the oxygen of a carbonyl group donates an electron pair to a Lewis acidic center; nucleophilic attack at CO ligands by basic surface hydroxyl groups or $O^{2\ominus}$ ions; ion-pair formation by deprotonation of hydrido carbonyls to give carbonylate ions; interaction of bifunctional complexes with surface acid–base pair sites such as $\{Mg^{2\oplus}O^{2\ominus}\}$; and oxidative addition of surface hydroxyl groups to metal clusters. The reactions of surface-bound organometallic species include redox condensation and cluster formation on basic surfaces (paralleling the reactions in basic solution) as well as oxidation of mononuclear metal complexes and oxidative fragmentation of metal clusters by reaction with surface hydroxyl groups. Most supported metal carbonyls are unstable at high temperatures, but some, including osmium carbonyl cluster anions on the basic MgO surface, are strongly stabilized in the presence of CO and are precursors of catalysts for CO hydrogenation at 550 K.

1. Introduction

Organometallic chemistry has been extended to the surfaces of metal oxides. The chemistry of analogues of molecular metal carbonyls and related species on metal oxides such as silica, γ-alumina, and magnesia is becoming understood in a detail approaching that attainable in solution chemistry, provided that the surface organometallics are characterized by such techniques as IR, NMR, and EXAFS (extended X-ray absorption fine structure) spectroscopy. Elucidation of this surface chemistry is leading to new understanding of the structures and reactivities of oxide surfaces and to the preparation of new surface structures of interest as catalysts. Carbonyls of the Group VIII metals are the most thoroughly investigated of these surface species. The surface organometallic chemistry is consistent with the known molecular chemistry of the metal carbonyls in solution and with the functional group chemistry of the metal oxide surfaces, particularly the acid–base chemistry of OH groups, $O^{2\ominus}$ ions, and Lewis acidic centers such as $Al^{3\oplus}$ and $Mg^{2\oplus}$.

Knowledge of the organometallic chemistry of molecular metal carbonyls on metal oxide supports is leading to new surface structures and catalysts and to better understanding of conventional supported metal catalysts. This review is concerned with the synthesis and reactivity of well-defined surface-bound transition metal carbonyls on silica, alumina, and magnesia, prototype supports for metal catalysts. Reactions leading to the formation of poorly defined structures, often mixtures, are not considered here. The notation used is given in Table 1. Prototype reactions characterizing the adsorption of metal carbonyls on metal oxides are summarized in Table 2. These and related reactions are discussed in detail following a brief summary of the surface chemistry of the metal oxides. The important high-temperature reactions of surface-bound metal carbonyls are also examined, including the oxidative fragmentation of metal clusters to yield groupings of covalently bound subcarbonyl complexes and the reductive carbonylation of metal ions on basic supports to yield metal clusters.

2. Nature and Reactivity of Metal Oxide Surfaces

High-surface-area, microporous metal oxides are used widely as supports for catalysts incorporating highly dispersed metal aggregates (or crystallites). Silica, alumina, and magnesia are commonly used catalyst supports representative of a wide range of surface acid–base properties. Although structure and bonding within the bulk vary greatly among the oxides, there are similarities in their surface chemistries since all the surfaces incorporate hydroxyl groups. The acid–base character of these groups depends on the metal oxide and its pretreatment, typically ranging from mildly Brønsted acidic for silica to strongly Brønsted basic for magnesia. Aprotic functional groups (e.g., $Al^{3\oplus}$ and $O^{2\ominus}$) are also present on surfaces pretreated at elevated temperatures (> 473 K) in vacuo. Regulation of the concentration of surface hydroxyl groups by variation of the pretreatment temperature is the most straightforward and useful method of controlling the surface properties of a metal oxide.

Table 1. Notation used to represent surface-bound organometallic species.

Notation	Meaning	Examples
{AB}	Denotes species terminating the bulk solid	$\{Mg^{2\oplus}O^{2\ominus}\}$, magnesia surface ion pairs; $\{Al^{3\oplus}-OH\}$ or {Al–OH}, surface hydroxyl groups of alumina
[Organometallic complex]/metal oxide, [OMC]/MO	Denotes supported organometallic complex for which the details of the local interaction with the surface are unknown or uncertain	$[Rh_6(CO)_{16}]/Al_2O_3$, hexarhodium carbonyl absorbed on alumina; $[Os_{10}C(CO)_{24}]^{2\ominus}/MgO$, decaosmium carbide carbonyl ionically bound to magnesia
OMC···{AB}	Denotes a well-established local chemical interaction between a ligand of the organometallic complex and a surface group	$[CpW(CO)_2CO^{\ominus}\cdots\{Mg^{2\oplus}(OH)^{\ominus}\}]$, surface-bound $[CpW(CO)_3]^{\ominus}$ ion-paired through a CO ligand with a surface $Mg^{2\oplus}$ ion
Transition metal (TM)/MO or TM-on-MO	Denotes a supported metal incorporating aggregates or crystallites of the metal on the support	Rh/Al_2O_3, Rh crystallites supported on alumina

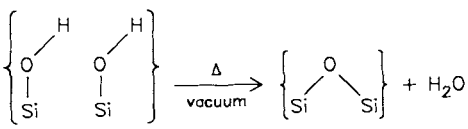
Table 2. Molecular metal carbonyls on metal oxide surfaces: prototype syntheses and surface structures.

Synthesis reaction	Adsorbates	Surface structure	Metal oxide [a] SiO_2	Al_2O_3 [b]	MgO
Adduct formation via a bridging CO ligand, involving:					
a) Lewis acidic centers	$[CpFe(\mu_3\text{-}CO)]_4$	$[Cp_4Fe_4(\mu_3\text{-}CO)_3(\mu_3\text{-}CO\cdots\{M^{n\oplus}\})]$	—	HD	—
b) Brønsted acidic centers (H-bond donors)	$Co_2(CO)_8$	$[Co_2(CO)_7(\mu_2\text{-}CO\cdots\{HO-M\})]$	PD	—	—
Nucleophilic attack at a CO ligand, involving:					
a) basic surface hydroxyl groups	$Fe_3(CO)_{12}$	$[HFe_3(CO)_{10}(\mu_2\text{-}CO)]^{\ominus}\{M^{n\oplus}\}$	—	H	H
	$Fe(CO)_5$ [c]	$[HFe_3(CO)_{10}(\mu_2\text{-}CO)]^{\ominus}\{M^{n\oplus}\}$	—	H	H
b) $O^{2\ominus}$ ions of $\{M^{n\oplus}O^{2\ominus}\}$ acid-base pairs	$Fe(CO)_5$	$[Fe(CO)_4(CO_2)^{\ominus}\cdots\{M^{n\oplus}\}]$	—	—	HD
Deprotonation of hydrido carbonyls, involving:					
a) basic surface hydroxyl groups	$[H_4Os_4(CO)_{12}]$	$[H_{4-x}Os_4(CO)_{12}]^{x\ominus}\{M^{n\oplus}\}$ $x = 1$ or 2	—	PD	PD
b) $O^{2\ominus}$ ions of $\{M^{n\oplus}O^{2\ominus}\}$ acid-base pairs	$[HWCp(CO)_3]$	$[CpW(CO)_2CO^{\ominus}\cdots\{M^{n\oplus}(OH^{\ominus})\}]$	—	—	HD
Bifunctional interaction with surface acid-base pairs, involving:					
a) promoted migratory insertion of CO	$[CH_3Mn(CO)_5]$		—	PD, HD	—
b) hydrido carbonyls as H-bond donors	$[H_2Os(CO)_4]$		—	PD	PD, HD
Oxidative addition of hydroxyl groups to give covalently bound metal clusters	$Os_3(CO)_{12}$	$[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OM\}]$	H, PD	H, PD	H [d]

[a] H, PD, and HD refer to a fully hydroxylated, partially dehydroxylated, and highly dehydroxylated metal oxide, respectively. [b] η and γ phases. [c] $[HFe(CO)_4]^{\ominus}$ is suggested to be the initial surface species formed. [d] The magnesia surface in these cases was highly contaminated with adsorbed CO_2 (surface carbonates).

2.1. Silica[1-3]

Amorphous SiO_2 is often regarded as chemically inert relative to other common metal oxide supports. Weakly acidic hydroxyl groups are usually inferred to be the most reactive native surface species. The building blocks of silica are linked SiO_4 tetrahedra, with each O atom bridging two Si atoms. Bonding within the solid is covalent. At the fully hydrated surface, the bulk structure is terminated by hydroxyl (silanol) groups {Si–OH}. Two types of these groups are usually distinguished: (1) isolated groups giving rise to a sharp IR absorption at 3750 cm^{-1} and (2) hydrogen-bonded vicinal groups identified by a broader band in the 3550-cm^{-1} region. Fully hydrated samples, calcined at temperatures below 473 K, may contain geminal groups, $\{Si(OH)_2\}$. Heating in vacuum removes the vicinal groups by dehydroxylation, i.e., condensation to form H_2O and surface Si-O-Si linkages:



(1)

Complete removal of the surface hydroxyl groups requires treatment at temperatures above 973 K in vacuo and is inferred to result in significant changes in surface morphology.

The surface hydroxyl groups of silica are weakly Brønsted acidic. Hydrogen bonding involving isolated hydroxyl groups results in a decrease in the intensity of the 3750-cm^{-1} ν_{OH} absorption and the appearance of a broad band at lower frequency; the shift relative to the 3750-cm^{-1} band, $\Delta\nu_{OH}$, is indicative of the strength of the interaction and is typically 100–200 cm^{-1}. Strong bases, such as ammonia and amines, are protonated by surface silanol groups. Aprotic sites, present after dehydroxylation at 873–1025 K, are suggested to be highly strained Si-O linkages. Such groups have been identified by IR spectroscopy[4] and inferred to serve as weak Lewis acidic centers.[5]

2.2. Transition Aluminas

Transition aluminas, the most commonly used supports for metal catalysts, are defective, metastable solids formed from aluminum hydroxide as it is heated; at temperatures exceeding about 1400 K, the transition aluminas are converted into stable, crystalline α-Al_2O_3. Two closely related transition aluminas, η-Al_2O_3 and γ-Al_2O_3, which incorporate $Al^{3\oplus}$ ions in both tetrahedral and octahedral coordination, display a wide range of surface acid-base properties that depend on the degree of thermal activation.[6] Acidic and basic sites and acid-base pair sites on the aluminas have been identified by spectroscopic characterization of adsorbed probe molecules.

Both η- and γ-Al_2O_3 have defect spinel structures with cubic close-packed oxygen sublattices; the Al sublattice in each is highly disordered, and irregular occupation of the tetrahedral interstices results in a tetragonal distortion of the spinel structure. There is a higher occupancy of tetrahedral cation positions in γ-Al_2O_3 and a higher density of stacking faults in the oxygen sublattice of η-Al_2O_3. Crystallites are terminated by anion layers, and on the basis of an electrostatics argument, these surface layers are inferred to be occupied by hydroxyl groups. In modeling the alumina surfaces, *Knözinger* and *Ratnasamy*[6] considered the (100), (111), and (110) planes of the spinel lattice and proposed five coordination environments for hydroxyl groups. This estimate of the number of chemically distinct hydroxyls is in agreement with IR spectra.[7]

Heating fully hydroxylated η- or γ-Al_2O_3 in vacuo to temperatures above 473 K results in the evolution of water and elimination of surface hydroxyl groups. This dehydroxylation process leads to the formation of a coordinatively unsaturated $O^{2\ominus}$ ion and an adjacent surface anion vacancy (Fig. 1). Assuming a close-packed (111) surface plane, the anion vacancy is expected to expose either two five-coordinate $Al^{3\oplus}$ ions or one three-coordinate $Al^{3\oplus}$ ion.[6] Thus, during the dehydroxylation process, both Lewis acidic and Lewis basic sites are created.

The acid-base properties have been examined by titration[8] and by the adsorption of organic probe molecules and characterization of the surface species by IR and NMR spectroscopy.[1] The hydroxyl groups of η- and γ-Al_2O_3 act as hydrogen-bond donors to adsorbed benzene, although the interaction is generally weaker than that observed for silica, suggesting very weak Brønsted acidity. IR spectra of adsorbed nitriles and pyridine reveal surface

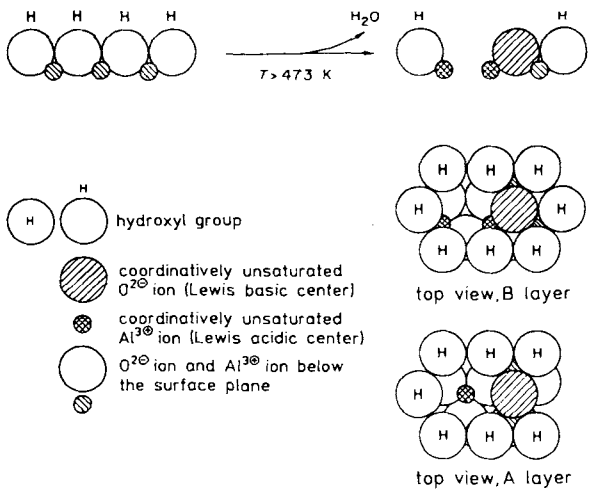


Fig. 1. Schematic representation of the dehydroxylation process for (111) surface planes of the η- and γ-Al_2O_3 structures, showing two possible configurations of the Lewis acid-base sites formed.

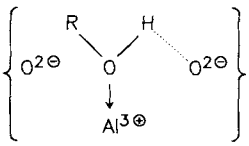
Lewis acidic sites.[7] Shifts in the N-H stretching frequency of adsorbed pyrrole provide evidence of strongly basic sites on transition aluminas,[9] but on this basis alone one cannot differentiate between $O^{2\ominus}$ ions and hydroxyl groups as the basic sites. Bifunctional adsorbate molecules interact with acid-base pair sites on these surfaces. For example, dissociative chemisorption of alcohols has been suggested to occur through the precursor state **I**.[2, 10, 11]



I

2.3. Magnesia

MgO has the simple rock salt structure, with octahedral coordination of magnesium and oxygen. Ab-initio molecular orbital calculations indicate that the electronic structure is highly ionic, with the $Mg^{2\oplus}O^{2\ominus}$ formalism being an accurate representation of both the bulk and surface structures.[12] The lattice is commonly envisioned to terminate in (100) planes incorporating five-coordinate (5C) $Mg^{2\oplus}$ and $O^{2\ominus}$ ions (Fig. 2). This model appears to be physically

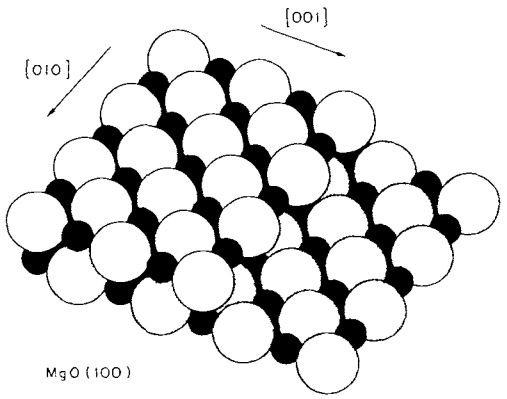


Fig. 2. Space-filling model of the MgO (100) plane, showing a unit atomic step in the [001] direction which exposes a portion of the MgO (200) plane.

accurate for MgO smoke, which may be regarded as a model crystalline metal oxide support. The (100) surface of MgO is electrically neutral, and the presence of surface hydroxyl groups need not be postulated, but *Anderson* et al.[13] demonstrated that hydroxyl groups are present on surfaces of polycrystalline MgO derived from $Mg(OH)_2$. Two absorptions assigned to hydroxyl groups were discerned by IR spectroscopy of samples treated in vacuo at 673–1073 K, and, on the assumption that the surface layers consist of (100) planes, two distinct environments for hydroxyl groups were postulated (Fig. 3).[13] Type A hydroxyl

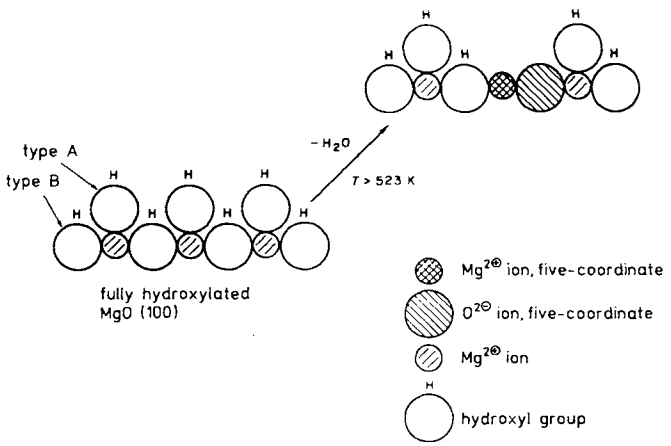

Fig. 3. Simple model of MgO dehydroxylation based on the work of *Anderson* et al. [13], who considered only the MgO (100) plane.

groups occupy the sixth coordination site of a surface $Mg^{2\oplus}$ ion and are associated with the "free" or isolated O–H vibration observed at 3740–3750 cm^{-1}. Type B hydroxyl groups may be formally derived from the protonation of surface $O^{2\ominus}$ ions. The proton could bridge (or hydrogen bond) to neighboring $O^{2\ominus}$ ions on the surface, consistent with the broad absorption observed at 3610 cm^{-1}. The dehydroxylation of this surface layer is expected to proceed by the combination of a type A hydroxyl group with the proton of a type B group to form a water molecule which desorbs, exposing a $\{Mg^{2\oplus}O^{2\ominus}\}$ 5C ion pair (Fig. 3).

The surface chemistry of MgO is dominated by its basicity. Numerous organic Brønsted acids have been shown to chemisorb to form surface-bound carbanions and surface hydroxyl groups.[14,15] These adsorbates are inferred to react dissociatively with surface ion pairs:

$$\{Mg^{2\oplus}O^{2\ominus}\} + XH \longrightarrow \begin{matrix} X^{\ominus} & H^{\oplus} \\ | & | \\ \{Mg^{2\oplus}O^{2\ominus}\} \end{matrix} \qquad (2)$$

The unique nature of highly dehydroxylated MgO originates in its high strength as a solid base, capable of deprotonating even very weak Brønsted acids such as NH_3 ($pK_a = 36$), propene ($pK_a = 35$), and acetylene ($pK_a = 25$); even the heterolytic dissociative adsorption of dihydrogen on polycrystalline MgO has been reported.

Highly coordinatively unsaturated sites appear to be required for the dissociative chemisorption of weak Brønsted acids on MgO.[14] Three- and four-coordinate $Mg^{2\oplus}$ and $O^{2\ominus}$ ions have been detected on the surfaces of polycrystalline MgO, derived from $Mg(OH)_2$, after activation at 1073 K; these sites have been characterized by ultraviolet–visible diffuse reflectance spectroscopy[16] and photoluminescence spectroscopy.[17] The ratio $\{Mg^{2\oplus}O^{2\ominus}\}(5C) : \{Mg^{2\oplus}O^{2\ominus}\}(4C) : \{Mg^{2\oplus}O^{2\ominus}\}(3C)$ has been estimated to be approximately 90 : 10 : 1.[14] The locations of the 4C and 3C sites remain in doubt, but they have been suggested to be at edges and corners of (100) planes.

The surfaces of MgO powders incorporate reducing sites in addition to the sites associated with strong basicity.[18] These are apparently defect sites, possibly surface cation vacancies. The paramagnetic surface species formed from CO adsorbed on highly dehydroxylated MgO have been thoroughly characterized by IR, ESR, and UV/VIS spectroscopy. The chemistry of the reducing sites and that of the basic sites of MgO are inferred to be closely related, since the dissociative adsorption of Brønsted acids blocks the reactivity of the reducing sites.[15a,18c]

3. Chemisorption of Metal Carbonyls on Metal Oxide Surfaces

This section is a summary of the reactions of metal carbonyls with metal oxide surfaces. The reaction classes (Table 2) all have well-established precedents in solution organometallic chemistry.

3.1. Formation of Acid–Base Adducts

One of the simplest chemisorption modes of a metal carbonyl on a metal oxide involves the formation of a Lewis acid–base adduct, the basic oxygen of a carbonyl group interacting with a coordinatively unsaturated metal ion of the surface. Adduct formation is anticipated for binary metal carbonyls adsorbed on dehydroxylated η- and γ-Al_2O_3 (because of the presence of strong Lewis acidic sites) and has been proposed for $M(CO)_6$ (M = Cr, Mo, W) complexes adsorbed on alumina, for example.[19]

This chemistry is well illustrated by the results of *Tessier-Youngs* et al.,[20] who investigated the adsorption of polynuclear carbonyl complexes of iron and nickel on highly dehydroxylated alumina films in a series designed to yield stable *O*-bound surface adducts. Each of the adsorbates chosen for the experiments, $[CpFe(CO)]_4$, $[Cp_3Ni_3(CO)_2]$, and $[CpNi(CO)]_2$, contains only bridging carbonyl groups and would be expected to form adducts readily with surface Lewis acidic centers. These molecules also are expected to have relatively low susceptibilities to nucleophilic attack, which minimizes a possible side reaction, discussed Section 3.2. The carbonyl complexes were deposited on alumina films from solution by evaporation of the solvent (benzene or dichloromethane). Formation of adducts with surface $Al^{3\oplus}$ ions was monitored by IR spectroscopy.

Tessier-Youngs et al. found that $[CpFe(CO)]_4$ forms the most stable adduct with the alumina surface, the proposed structure being shown in Figure 4. The redshift of the IR band assigned to a triply bridging carbonyl ligand of this

complex, bound through its oxygen atom to a surface $Al^{3\oplus}$ ion, is 185 cm^{-1} (compared with shifts of 102 and 257 cm^{-1} observed for the presumably analogous $Al(C_2H_5)_3$ and $AlBr_3$ adducts, respectively). Not surprisingly, the complex could be recovered from the surface by washing with pyridine. A complication in this investigation was that a significant fraction of the complexes were not molecularly dispersed, but instead formed crystallites on the alumina surface during the evaporation of the solvent.

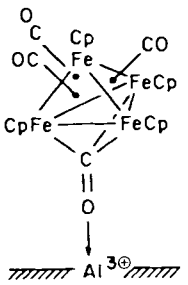

Fig. 4. Proposed structure of adduct formed by the chemisorption of $[CpFe(CO)]_4$ on highly dehydroxylated γ-Al_2O_3 [20].

The chemistry of adduct formation may, alternatively, involve simple hydrogen bonding at the surface and can therefore occur on any of the metal oxides. For example, when $Co_2(CO)_8$ is sublimed onto SiO_2 in the presence of 6.7 kPa of CO, the resulting surface species is the molecularly adsorbed dimer, apparently hydrogen-bonded to silanol groups via bridging carbonyl ligands. The hypothesis of weak hydrogen bonding is supported by the observation of characteristic shifts of IR absorptions in both the ν_{OH} and ν_{CO} regions.[21] When $Co_2(CO)_8$ is sublimed onto SiO_2 (pretreated at 673 K in vacuo) without added CO, $Co_4(CO)_{12}$ forms as the predominant organometallic surface species, as shown by the IR spectrum in the ν_{CO} region. The surface reaction is inhibited by CO, as suggested by Equation (3).

$$2\,Co_2(CO)_8 \longrightarrow Co_4(CO)_{12}/SiO_2 + 4\,CO \qquad (3)$$

3.2. Nucleophilic Attack at a CO Ligand

Adsorption of $Fe(CO)_5$ vapor on highly dehydroxylated MgO (pretreated in vacuo at 1073 K) results in formation of the surface complex $[Fe(CO)_4(CO_2)^{2\ominus}\cdots\{Mg^{2\oplus}\}]$[22a] (Fig. 5), demonstrating that the influence of surface hydration on the reactivity of adsorbed metal carbonyls can be substantial. The novel $[Fe(CO)_4(CO_2)^{2\ominus}\cdots\{Mg^{2\oplus}\}]$ structure was found to be consistent with a complete analysis of the CO and CO_2 stretching bands after ^{13}CO enrichment of the surface species. Similar structures have been proposed

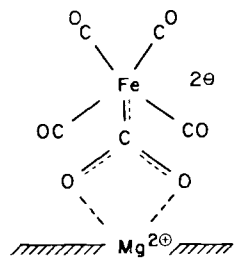

Fig. 5. Schematic representation of the surface structure formed by chemisorption of $Fe(CO)_5$ on highly dehydroxylated magnesia [22a].

for the surface species derived from the adsorption of $M(CO)_6$ (M = Cr, Mo, W) and $Ni(CO)_4$ on the highly dehydroxylated surface of MgO.[22b,c] The bent CO_2 moiety results from the interaction of a carbonyl ligand with a $\{Mg^{2\oplus}O^{2\ominus}\}$ pair. The basic $O^{2\ominus}$ ion evidently acts as a nucleophile toward coordinated CO, and the structure is stabilized by interaction with the neighboring $Mg^{2\oplus}$ ion. As evidenced by the IR data, at least two chemically distinct ion-pair sites are involved in $Fe(CO)_5$ adsorption. Closely related chemistry is discussed in Section 3.4 in the context of interactions of bifunctional organometallic reactants with surface acid–base pair sites. It is evident that the reaction classes listed in Table 2 overlap.

Binary metal carbonyls also react with basic surface hydroxyl groups of alumina and magnesia to form surface-bound anions, the reactivity being analogous to that of metal carbonyls with hydroxide ion in solution:

$$M'_x(CO)_y + \{M^{n\oplus}-OH\} \longrightarrow [HM'_x(CO)_{y-1}]^{\ominus}\{M^{n\oplus}\} + CO_2 \qquad (4)$$

Hugues et al.,[23a] who investigated the adsorption of iron carbonyls on the surfaces of hydrated η- and γ-Al_2O_3 and MgO, concluded that the adsorption of $Fe_3(CO)_{12}$ from hexanes at room temperature results in ionically bound $[HFe_3(CO)_{11}]^{\ominus}$, as evidenced by IR, ^1H NMR, and UV/VIS spectroscopy (Fig. 6). The surface-bound cluster

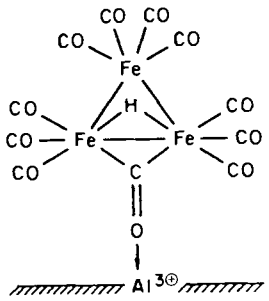

Fig. 6. Structure suggested by *Hugues* et al. [23a] for surface-bound $[HFe_3(CO)_{11}]^{\ominus}$ on η- and γ-Al_2O_3.

could be removed from the surfaces by ion exchange but not by washing with hydrocarbon, halocarbon, or alcohol solvents alone. Extractions with Et_4NCl in CH_2Cl_2 resulted in 60–70% yields of $[Et_4N][HFe_3(CO)_{11}]$. Since only little CO_2 was evolved (ca. 0.05 molecules per cluster) and IR data indicated the formation of surface bicarbonate ions, the following stoichiometry was suggested for chemisorption on alumina:

$$Fe_3(CO)_{12} + 2\{Al^{3\oplus}-OH\} \longrightarrow [HFe_3(CO)_{11}]^{\ominus}\{Al^{3\oplus}\} + \{(Al^{3\oplus})(HCO_3)^{\ominus}\} \qquad (5)$$

An alternative route to the formation of $[HFe_3(CO)_{11}]^{\ominus}$ from $Fe_3(CO)_{12}$ on γ-Al_2O_3 is indicated by results of *Hanson* et al.,[23b] who observed an inhibition of the reaction by CO and the formation of $Fe(CO)_5$ during the adsorption process. Disproportionation reactions of the type reported by *Hieber*[23c] were invoked to explain these results.

Hugues et al.[23a] found that the adsorption of $Fe(CO)_5$ on hydrated η- and γ-Al_2O_3 and hydrated MgO also results in the formation of surface-bound $[HFe_3(CO)_{11}]^{\ominus}$. This result is not surprising, since $Fe(CO)_5$ reacts in aqueous

amine solution at 353 K to give $[HFe_3(CO)_{11}]^{\ominus}$. The initial reaction of $Fe(CO)_5$ with the basic surface sites of alumina should parallel that suggested for $Fe_3(CO)_{12}$:

$$Fe(CO)_5 + 2\{Al^{3\oplus}-OH\} \longrightarrow [HFe(CO)_4]^{\ominus}\{Al^{3\oplus}\} + \{(Al^{3\oplus})(HCO_3)^{\ominus}\} \quad (6)$$

Apparently the chemistry on fully hydroxylated MgO is nearly the same. There are several plausible stoichiometries for subsequent redox condensation processes resulting in the trinuclear cluster anion (see Section 3.4 for an example involving the Os analogue), but since no gas evolution data are available, the stoichiometry of the surface-mediated condensation remains to be determined.

3.3. Deprotonation of Hydrido Carbonyls

One of the most easily defined acid–base reactions that occurs on metal oxide surfaces is the deprotonation of hydrido carbonyl complexes. The reaction class provides one of the most straightforward and easily applied routes for the preparation of molecularly dispersed organometallics on basic surfaces such as those of alumina and magnesia.

The adsorption of weakly acidic hydrido carbonyl clusters on partially dehydroxylated γ-Al_2O_3 results in the formation of surface-bound carbonylate anions. The clusters are believed to be deprotonated by reaction with basic surface hydroxyl groups, in analogy to their reactivity with hydroxide ion in solution.[24] $[H_4Os_4(CO)_{12}]$ ($pK_a = 12.0$ (CH_3OH)[24]), $[H_2RuOs_3(CO)_{13}]$, $[H_4RuOs_3(CO)_{12}]$, and $[H_4Ru_4(CO)_{12}]$ ($pK_a = 11.9$ (CH_3OH)[24]) are all deprotonated when brought into contact with alumina from hydrocarbon solvents.[25] In these experiments, the solids were typically separated from the adsorbate solution by filtration, rather than by evaporation of the solvent, and washed exhaustively. This procedure maximizes the likelihood of direct bonding to the surface and minimizes the likelihood of formation of crystallites of adsorbate on the surface. For example, when $[H_4Os_4(CO)_{12}]$ is adsorbed from refluxing hexanes onto γ-Al_2O_3 pretreated at 673 K, the resulting species is $[H_3Os_4(CO)_{12}]^{\ominus}$, ionically bound to the surface.[25a] The IR spectrum of the surface species (obtained in air) agrees closely with that of $[(Ph_3P)_2N][H_3Os_4(CO)_{12}]$ (Fig. 7), suggesting that, at least in the presence of co-adsorbed (atmospheric) moisture, $[H_3Os_4(CO)_{12}]^{\ominus}$ does not interact through specific chemical bonding with surface $Al^{3\oplus}$ counterions. $[H_3Os_4(CO)_{12}]^{\ominus}$ could be extracted from the surface by ion exchange with $(Ph_3P)_2NCl$ in CH_2Cl_2, but no osmium carbonyls were removed by washing with CH_2Cl_2 alone. Analogous results were obtained when the hydrido metal clusters $[H_2RuOs_3(CO)_{13}]$[25b,c] and $[H_4Ru_4(CO)_{12}]$[25d] were adsorbed on γ-Al_2O_3.

Since the chemistry of MgO is dominated by its strong basicity, the deprotonation of hydrido carbonyls occurs most readily on this surface. Hydrido carbonyl complexes and clusters of Os,[26,27] W,[28] Ru,[25d] and Re[29] chemisorb dissociatively on MgO. The chemisorption of $[H_4Os_4(CO)_{12}]$ on highly dehydroxylated MgO powder (pretreated in vacuo at 1073 K) leads not only to formation of adsorbed $[H_3Os_4(CO)_{12}]^{\ominus}$, the predominant organometallic surface species, but also to adsorbed $[H_2Os_4(CO)_{12}]^{2\ominus}$, as indicated by IR[27a] and ^{13}C NMR spectra[27b] of the surface structures. These anions could be removed from the surface by cation metathesis with $(Ph_3P)_2NCl$ in dry CH_2Cl_2, acetone, or 2-propanol. The formation of the dianion by deprotonation underscores the strong basicity of highly dehydroxylated MgO; even treatment of $[H_4Os_4(CO)_{12}]$ with excess KOH in methanol yields only $[H_3Os_4(CO)_{12}]^{\ominus}$.[30]

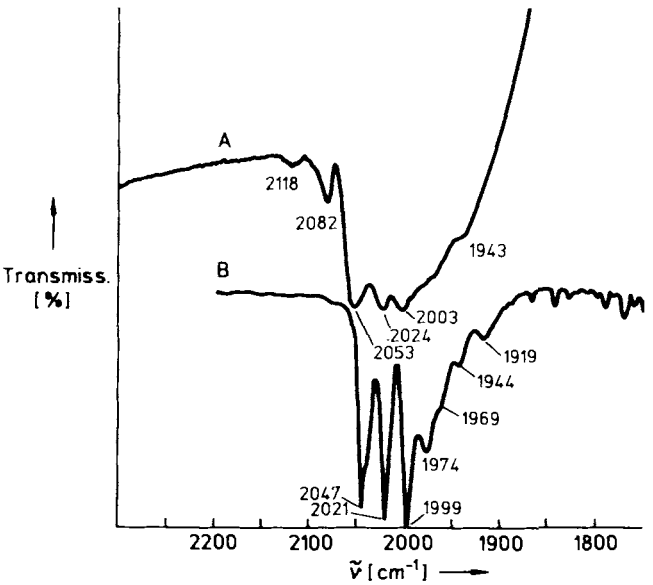

Fig. 7. Comparison of the ν_{CO} bands of surface-bound $[H_3Os_4(CO)_{12}]^{\ominus}$ on γ-Al_2O_3 (A) and the complex $[(Ph_3P)_2N][H_3Os_4(CO)_{12}]$ in CH_2Cl_2 (B) [25a].

The dissociative chemisorption of hydrido carbonyl complexes on highly dehydroxylated MgO can also result in well-defined surface ion pairs. The adsorption of $[HWCp(CO)_3]$ ($pK_a = 9.0$ (CH_3OH)[24]) from dry hexanes or toluene at room temperature results in the formation of surface-bound $[CpW(CO)_3]^{\ominus}$, paired with a surface $Mg^{2\oplus}$ ion:[28]

$$[HWCp(CO)_3] + \{Mg^{2\oplus}O^{2\ominus}\} \longrightarrow [CpW(CO)_2CO^{\ominus}\cdots\{Mg^{2\oplus}(OH^{\ominus})\}] \quad (7)$$

Three IR bands of approximately equal intensity are observed for the complex in the ν_{CO} region, with the low-frequency band at 1711 cm^{-1} indicating a direct $W\text{-}CO\cdots\{Mg^{2\oplus}\}$ interaction. $[CpW(CO)_3]^{\ominus}$ can be extracted from the solid by cation metathesis with $(Ph_3P)_2Cl$ in CH_2Cl_2. The $W\text{-}CO\cdots\{Mg^{2\oplus}\}$ interaction is analogous to that characterizing the tight ion pairs observed for $[CpM(CO)_3]^{\ominus}$ (M = Cr, Mo, W) with $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$,[31] $Mg^{2\oplus}$(Mo),[32] and $Al^{3\oplus}$(W)[33] in THF solution; the ν_{CO} IR absorptions of the surface species are listed with those of the soluble analogues in Table 3. Figure 8, left, shows a model for the structure of $[CpW(CO)_3]^{\ominus}$ on MgO; the crystal structure of $[(py)_4Mg\{CpMo(CO)_3\}_2]$ (Fig. 8, right) suggests that a magnesium–carbonyl oxygen bonding distance of approximately 0.20 nm should be expected.[32a] The contact ion pairing of $[CpW(CO)_3]^{\ominus}$ complexes with surface $Mg^{2\oplus}$ ions represents the first well-characterized example

Table 3. IR spectroscopic data for surface-bound $[CpW(CO)_3]^{\ominus}$ and analogous contact ion pairs in solution.

Species	ν(CO) [cm^{-1}]			Ref.

of this interaction for a surface-bound carbonylate anion. Carbonylate anions appear to be excellent probes of the coordination environment of surface cations, much as they have proved to be useful probes of the coordination of alkali metal ions in solution.[34]

3.4. Bifunctional Interactions

Chemisorption of certain organic molecules (e.g., alcohols) on dehydroxylated metal oxide surfaces is believed to involve bifunctional interactions with surface acid–base pairs. Metal complexes can also interact simultaneously with neighboring surface acidic and basic centers owing to the involvement of multiple chemical functionalities (i.e., the metal center and ligands). For example, *Shriver*, *Burwell*, and co-workers used $[(CH_3)Mn(CO)_5]$ and $[CpFe(CH_3)(CO)_2]$ as probes for acid–base pairs on alumina surfaces,[35,36] since "diphilic" Lewis acids such as $AlBr_3$ were known to promote methyl migration in these complexes. *Correa* et al.[35] found that when $[(CH_3)Mn(CO)_5]$ is deposited from pentane solution onto partially dehydroxylated or highly dehydroxylated alumina, an immediate color change occurs, and the IR spectrum of the surface species (obtained after evaporation of the solvent) is in close agreement with that of the $[(CH_3CO)Mn(CO)_4]\cdot AlBr_3$ adduct. Gas evolution during adsorption was negligible. Similar results were obtained for the adsorption of $[CpFe(CH_3)(CO)_2]$. The structure illustrated in Figure 9 was proposed for the surface-bound acyl derivative $[Mn(CO)_4(COCH_3)\{O-Al\}]$. These findings are good evidence for the presence of adjacent Lewis acidic and basic centers on the alumina surface, clearly demonstrating the utility of employing organometallic complexes as probes of metal oxide surface structure and reactivity.

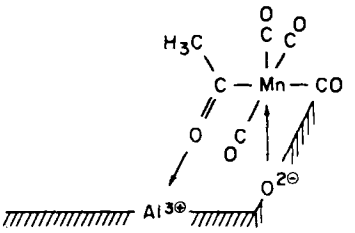

Fig. 9. Schematic representation of the proposed structure of the acyl complex derived from $[CH_3Mn(CO)_5]$ adsorbed on the γ-Al_2O_3 surface [36].

The adsorption of $[H_2Os(CO)_4]$ on the surfaces of SiO_2, Al_2O_3, and MgO has been investigated with the goal of comparing these surfaces on the basis of the acid–base chemistry of adsorption.[26,27] The expected deprotonation product of $[H_2Os(CO)_4]$ adsorption on basic metal oxides is $[HOs(CO)_4]^{\ominus}$, which has been shown to form ion pairs with alkali-metal ions in THF.[26] Adsorption of the weakly acidic $[H_2Os(CO)_4]$ ($pK_a = 14.7$ (CH_3OH)[24]) on the metal oxides was effected from hexanes at room temperature. Adsorption on SiO_2 was weak and reversible (physisorption). In contrast, on MgO and γ-Al_2O_3 pretreated at 1073 and 773 K, respectively, the complex was chemisorbed; the IR band pattern of the parent complex was strongly perturbed, and low-frequency absorptions appeared which are attributable to $Os-CO\cdots\{M^{n\oplus}\}$ interactions. The pattern of the IR bands is similar for $[H_2Os(CO)_4]$ adsorbed on magnesia and on alumina (Fig. 10); however, on magnesia the strong high-wavenumber bands (assigned to terminal carbonyl ligands) appear at lower wavenumbers relative to those of the alumina-supported complex. Significantly, the relative positions of the weak low-wavenumber bands (assigned to isobridging carbonyls, $Os-CO\cdots\{M^{n\oplus}\}$) are re-

versed. Consistent with these results, the ^{13}C NMR spectrum of the MgO-supported complex showed carbonyl groups in two distinct environments, in a 3 : 1 ratio.[27b] Extraction of the species from the MgO surface with $(Ph_3P)_2NCl$ in CH_2Cl_2 resulted in the isolation of $[(Ph_3P)_2N][HOs_3(CO)_{11}]$. The formation of the trinuclear cluster anion is consistent with a redox condensation reaction known from solution chemistry:

$$2[H_2Os(CO)_4] + [HOs(CO)_4]^{\ominus} \longrightarrow [HOs_3(CO)_{11}]^{\ominus} + CO + 2H_2 \quad (8)$$

In contrast, treatment of the structure formed from adsorption of $[H_2Os(CO)_4]$ on γ-Al_2O_3 with $(Ph_3P)_2NCl$ in CH_2Cl_2 yielded predominantly $[H_2Os(CO)_4]$ with only a trace of $[HOs_3(CO)_{11}]^{\ominus}$.

A model for the surface structures formed from $[H_2Os(CO)_4]$ adsorption on the polar alumina and magnesia surfaces is illustrated in Figure 11. The chemistry ob-

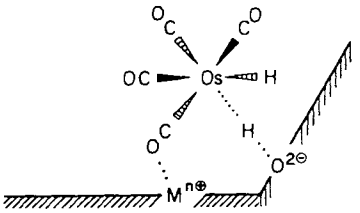

Fig. 11. Proposed structure of surface species formed from the chemisorption of $[H_2Os(CO)_4]$ on highly dehydroxylated MgO and γ-Al_2O_3.

served in the extraction experiments (consistent with the IR spectrum of the surface species) indicates that the Os–H···{$O^{2\ominus}$} interaction (H-bond donation) dominates on MgO, leading to deprotonation and formation of $[HOs(CO)_4]^{\ominus}$. On alumina the interaction with basic sites is weak, the Os–CO···{$Al^{3\oplus}$} interaction dominates, and $[H_2Os(CO)_4]$ is released from the surface by extraction. However, acid–base pairs are evidently the adsorption sites for the hydrido carbonyl on both metal oxide surfaces. Because their reactions are easily monitored with IR spectroscopy and they can engage in a variety of simple acid–base interactions, metal carbonyls are proving to be excellent probes of metal oxide surfaces.

3.5. Oxidative Addition of Surface Hydroxyl Groups

A reaction class common to metal carbonyl clusters adsorbed on hydroxylated metal oxide surfaces is the oxidative addition of surface hydroxyl groups. This chemistry was established for $Os_3(CO)_{12}$ on silica and alumina in early work by *Basset, Psaro, Ugo*, and co-workers.[37] $Os_3(CO)_{12}$ is simply physisorbed from CH_2Cl_2 onto silica surfaces pretreated at 300 and at 773 K, but upon heating to 423 K under argon, the cluster reacts to give covalently bound $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OSi}\}]$. Two CO molecules are evolved per cluster, with only negligible H_2 production. This stoichiometry is consistent with the simple oxidative addition of a surface hydroxyl group to the cluster:

$$Os_3(CO)_{12} + \{Si{-}OH\} \longrightarrow [(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OSi}\}] + 2CO \quad (9)$$

The reaction is most facile on hydrated silica surfaces with high concentrations of hydroxyl groups. A triosmium cluster with two labile nitrile ligands, $[Os_3(CO)_{10}(CH_3CN)_2]$, also chemisorbs on silica at room temperature to form $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OSi}\}]$; this observation suggests that the thermal treatment of physisorbed $Os_3(CO)_{12}$ serves to labilize the CO ligands, thereby facilitating its chemisorption. The suggested structure of the chemisorbed Os_3 cluster is analogous to that of the crystallographically characterized $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OSiEt}_3)]$[38] (Fig. 12) and of related soluble analogues. The oxidative addition of HX molecules (where X has unshared electron pairs) to $M_3(CO)_{12}$ clusters generally results in structures which have bridging hydrides and bridging X groups.[39]

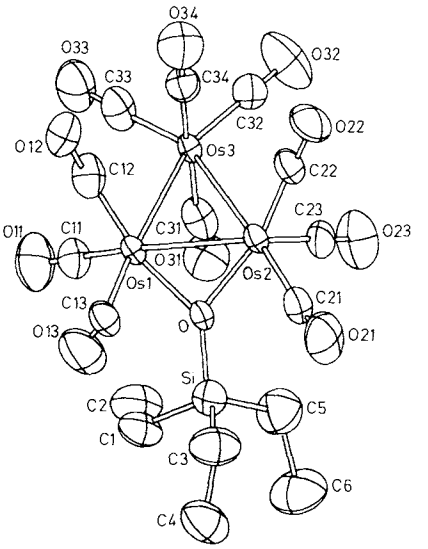

Fig. 12. Molecular structure of $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OSiEt}_3)]$, a soluble analogue of covalently bound supported triosmium clusters [38].

The reactivity of $Ru_3(CO)_{12}$ with the silica surface is similar to that of $Os_3(CO)_{12}$, resulting in the species $[(\mu\text{-H})Ru_3(CO)_{10}\{\mu\text{-O}-\text{Si}\}]$,[40] but this surface-bound cluster is unstable and decomposes even under synthesis conditions.

The surface hydroxyl groups of transition aluminas react similarly to the hydroxyl groups on silica.[37,41] Physisorbed $Os_3(CO)_{12}$ is converted into covalently bound $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OAl}\}]$ at 353–373 K under argon or in vacuo; this surface species is formed on both fully hydroxylated and partially dehydroxylated η-Al_2O_3 surfaces (the latter pretreated at 673 K). Concomitant with the formation of $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OAl}\}]$, two molecules of CO are evolved per $Os_3(CO)_{12}$ cluster. The IR spectrum of the supported cluster is closely similar to that of $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OSi}\}]$ and that of the analogue $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-OSiEt}_3)]$ (cf. Fig. 12).[38] The surface-bound cluster has also been prepared by direct reaction of $Os_3(CO)_{12}$ in refluxing *n*-octane solution with γ-Al_2O_3.[41]

$[Os_3(CO)_{10}(C_6H_8)]$ and $[Os_3(CO)_{10}(CH_3CN)_2]$ also chemisorb at room temperature on hydroxylated alumina to form $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-OAl}\}]$. The alumina-supported cluster has been characterized by Raman[42] and extended X-ray absorption fine structure (EXAFS) spectroscopy[43] and observed by high-resolution transmission electron mi-

croscopy.[44] The EXAFS analysis of *Duivenvoorden* et al.[43b] is consistent with the proposed structure of the supported cluster, yielding the structural parameters given in Table 4. *Cook* et al.[43a] found that a bis-oxygen species

such as $[Os_3(CO)_{10}(\mu\text{-}OH)\{\mu\text{-}OAl\}]$ provided a slightly better fit to their EXAFS data than a structure with a single bridging oxygen, and it was suggested[43c] that the Raman data[42] provide evidence of such a structure. However, the formation of such a surface-bound species from $Os_3(CO)_{12}$ should require the oxidative addition of two HX surface groups:

$$Os_3(CO)_{12} + H_2O + \{Al\text{–}OH\} \longrightarrow [Os_3(CO)_{10}(\mu\text{-}OH)\{\mu\text{-}OAl\}] + 2\,CO + H_2 \quad (10)$$

Since *Psaro* et al.[37a] measured only negligible H_2 evolution accompanying the formation of the alumina-supported Os_3 cluster, the original formulation of $[\mu\text{-}HOs_3(CO)_{10}\{\mu\text{-}OAl\}]$ appears to be preferable.

The wide range of characterization methods applied to these samples is exemplary; most informative are the data characterizing the surface stoichiometry, the IR spectra (giving an excellent fingerprint for comparison with the molecular analogues), and the EXAFS data, giving precise structural information.

Oxidative addition involving $Os_3(CO)_{12}$ and the surface hydroxyl groups of hydroxylated MgO also takes place, as on SiO_2 and Al_2O_3, but only when the MgO surface is contaminated with adsorbed CO_2 (which forms surface carbonates at the basic sites); otherwise anion formation occurs.[45]

3.6. Summary

These results provide evidence of the various reactivities of the metal oxide surfaces toward adsorbing metal carbonyls. The silica surface is relatively unreactive toward binary and hydrido metal carbonyls adsorbed under mild conditions. In many cases, simple physisorption occurs. Since a strong chemical interaction with the support is a prerequisite for incorporating isolated molecular complexes for use as catalysts or catalyst precursors, the metal carbonyl/SiO_2 combination is usually not advantageous. Reactions of metal carbonyls with silica under more vigorous conditions, however, can lead to the oxidative addition of surface hydroxyl groups to the adsorbing metal carbonyl. Occasionally, these reactions lead to well-characterized surface-bound complexes, e.g., $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OSi\}]$, but often the products are ill-defined mixtures of surface species.

The reactivity of alumina with metal carbonyls is more complex and varied than that of silica, reflecting the complex nature of the alumina surface, with its Lewis acidic and Lewis basic centers in addition to hydroxyl groups. The surface hydroxyl groups of hydrated alumina are basic in character and react with adsorbed binary metal carbonyls via nucleophilic attack at coordinated CO and with hydrido carbonyls via deprotonation to yield surface-bound carbonylate anions. Alumina surfaces expose $Al^{3\oplus}$ ions, which form adducts with electron-pair donors such as complexes incorporating bridging carbonyl groups, and the acid–base pairs on the surface may interact cooperatively with organometallic reagents. Oxidative addition of surface hydroxyl groups also occurs, as on silica, to yield covalently bound metal clusters.

The reactivity of the MgO surface is dominated by its basicity. Even weakly acidic hydrido metal carbonyls are deprotonated on MgO, and a wide variety of surface-bound anions are thus formed. $M\text{–}CO\cdots\{Mg^{2\oplus}\}$ interactions are important for mononuclear carbonylates and may influence the reactivity of the supported carbonyl anions. Acid–base pairs have been identified as adsorption sites for hydrido carbonyls on MgO (as on γ-Al_2O_3). On MgO surfaces contaminated with adsorbed CO_2, the formation of surface-bound clusters resulting from oxidative addition of hydroxyl groups occurs, as on silica and alumina.

4. Oxidation–Reduction and Fragmentation–Condensation Reactions of Supported Metal Carbonyls

The simple chemisorption of metal carbonyls on metal oxide surfaces discussed in the preceding section was often characterized by one surface reaction giving a single, relatively well-defined surface species. In this section we broaden the scope of surface reactions to emphasize the more complex transformations that occur when supported metal carbonyls are subjected to severe thermal conditions. These reactions often lead to changes in the nuclearity of the surface organometallic species (i.e., aggregation or fragmentation), which are often accompanied by changes in metal oxidation state.

Typically, the thermal activation (or decarbonylation) of an adsorbed metal carbonyl leads to oxidation of the transition metal center via a redox process involving the oxidative addition of surface hydroxyl groups:

$$M'(CO)_x + n\{M\text{–}OH\} \longrightarrow [M'(CO)_{x-y}\{O\text{–}M\}] + \frac{n}{2}H_2 + y\,CO \quad (11)$$

When supported metal clusters are the precursors, fragmentation of the metal framework generally occurs with oxidation of the metal centers. Occasionally, the oxidative fragmentation of chemisorbed metal clusters has been inferred to produce more-or-less unique groupings (or en-

sembles) of low-valent mononuclear surface complexes. Because of the complexity of the reaction sequences, however, the potential for producing mixtures of surface species is great. Only for certain metal carbonyl–metal oxide combinations (in narrow ranges of conditions) are unique surface species obtained.

On basic metal oxide surfaces (e.g., magnesia, alumina), the oxidative fragmentation process can be reversed. Examples are provided by reactions (12) and (13).

$$[Os(CO)_2\{O-Mg\}_4]^{2\ominus} \xrightarrow{CO+H_2} [Os_{10}C(CO)_{24}]^{2\ominus}/MgO \quad (12)$$

$$[Rh(CO)_2\{O-Al\}\{HO-Al\}] \xrightarrow{CO+H_2O} [Rh_6(CO)_{16}]/Al_2O_3 \quad (13)$$

These reactions closely parallel the reductive carbonylation of metal salts in basic solution—an important synthetic route to anionic metal carbonyl clusters.[46] Redox condensation reactions, which are implicated in the reductive carbonylation process, also occur, involving low-valent mononuclear metal carbonyls adsorbed on basic metal oxides. As in solution, such reactions lead to the formation of high-nuclearity molecular metal clusters. As a consequence of these base-promoted condensation processes, the surface organometallic chemistry on basic metal oxides can be molecular chemistry even at elevated temperatures in the presence of $CO + H_2$.

4.1. Oxidation of Supported Mononuclear Metal Carbonyls by Surface Hydroxyl Groups

Burwell, *Brenner*, and co-workers[36,47] employed gas evolution measurements to investigate the stoichiometry of the thermal decomposition of $Mo(CO)_6$ deposited on γ-Al_2O_3. Surface hydroxyl groups play a key role in the surface chemistry, oxidizing the supported metal carbonyl; the average oxidation state of Mo in the decarbonylated products depends directly on the degree of hydroxylation of the alumina. $Mo(CO)_6$ was deposited from pentane solution onto the support, and the complex was inferred to be physically adsorbed. Thermal activation of $Mo(CO)_6$ on partially dehydroxylated γ-Al_2O_3 in He at temperatures up to 373 K results in CO evolution but does not lead to oxidation of the Mo centers. However, activation of $Mo(CO)_6/\gamma$-Al_2O_3 at temperatures above 423 K results in further decarbonylation with concomitant oxidation of the Mo. H_2 and CH_4 are produced, the process evidently initiated by the oxidative addition of surface hydroxyl groups to zerovalent Mo species. From the stoichiometry of these reactions, the average oxidation state of Mo in materials activated at 573 K is indicated to be +2, but the materials are apparently nonuniform, since, after activation at temperatures above 473 K, Mo^V ions were detected by electron paramagnetic resonance (EPR) spectroscopy. Further heating increases the average Mo oxidation state to +3 and then approximately +6. Additional details of this complicated surface chemistry have been elucidated by IR spectroscopy.[19b] Mixtures of surface species are formed, and the spectra do not allow simple interpretations.

By avoiding the oxidation of the zerovalent Mo in the form of $Mo(CO)_6$, it may be possible to prepare metallic molybdenum-on-alumina. A sample prepared using a highly dehydroxylated γ-Al_2O_3 (pretreated at 1223 K) was activated to give material that was inferred to incorporate largely zerovalent Mo; exposure of this material to H_2 at 923 K was inferred to result in supported crystallites of metallic Mo,[36] but this interpretation is controversial.

Brenner et al.[48] established the generality of the redox reactions between surface hydroxyl groups and adsorbed metal carbonyls. The oxidation reactions are common to many metal carbonyls on typical metal oxide supports, but identification and thorough characterization of stable subcarbonyl intermediates have been reported only rarely; typically, during the decomposition of supported metal carbonyls, a mixture of species is present. However, simple surface chemistry is observed occasionally, as exemplified by the decomposition of chemisorbed $[HRe(CO)_5]$ on MgO, which proceeds through the formation of a single covalently bound tricarbonyl species, $[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$.

Kirlin et al.[49] investigated the thermal decarbonylation of $[HRe(CO)_5]/MgO$ in flowing He and in flowing H_2. $[HRe(CO)_5]$ is weakly chemisorbed on MgO; interaction with basic surface groups [see (14)] apparently leads to the incipient deprotonation of the following complex:

$$[HRe(CO)_5]/MgO \longrightarrow [(CO)_5Re\cdots H\cdots\{O^{2\ominus}Mg^{2\oplus}\}] \quad (14)$$

The conversion of this species into the complex $[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$ at 353 K was established by IR spectroscopy. The covalently bound surface complex was suggested to be equivalent to the well-characterized tricarbonyl species derived from the decomposition of $[H_2Re_3(CO)_{12}]^{\ominus}/MgO$.[29] Although there was no net change in *formal* oxidation state, the oxidative addition of a surface hydroxyl group was suggested to result in a Re–O bond to the surface:

$$[HRe(CO)_5] + 3\{Mg-OH\} \xrightarrow[H_2 \text{ or } He]{353\ K} [Re(CO)_3\{O-Mg\}\{HO-Mg\}_2] + H_2 + 2CO \quad (15)$$

$[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$ decomposes at temperatures above 523 K under H_2 or He to give surface species having no ν_{CO} IR absorptions.

4.2. Condensation of Supported Mononuclear Complexes to Give Surface-Bound Molecular Metal Clusters

It is clear from the preceding discussion that attempts to free metal coordination sites by thermal decarbonylation of oxide-supported metal carbonyls often fail because of oxidation of the metal centers by surface hydroxyl groups. This complication, inherent to the activation of metal carbonyls supported on typical metal oxides, has frustrated efforts to use supported molecular metal carbonyls as catalysts. However, in the case of CO hydrogenation and related reactions, high partial pressures of CO can be employed to inhibit decarbonylation (and oxidation) and stabilize the supported clusters. Unfortunately, in most cases, the neutral metal carbonyls are volatile, and the metals are gradually lost from the catalyst.

The key to stabilizing surface-bound molecular metal carbonyls at high temperatures is to use them in the presence of CO and to use basic metal oxide supports such as magnesia, which provide the opportunity to prepare a wide variety of ionically bound carbonylates. Moreover, anionic metal carbonyls are effective homogeneous catalysts or catalyst precursors for alkene hydroformylation, alcohol homologation, the water-gas shift reaction, and other reactions involving CO as a reactant.[50] Until recently, little was known about the reactivity or catalytic activity of metal carbonyls on basic supports under CO or $CO + H_2$ atmospheres at elevated temperatures. However, one should anticipate parallels to the chemistry of metal carbonyls in basic solution. This subject is developed below on the basis of the surface organometallic chemistry of species derived from $[H_2Os(CO)_4]$ chemisorbed on magnesia. In analogy to the reactivity of metal carbonyls in basic solution, a rich chemistry of molecular cluster growth on basic supports is now emerging.

$[H_2Os(CO)_4]$ chemisorbs on MgO to produce surface species described as surface-bound $[HOs(CO)_4]^{\ominus}$; the dominant adsorbate–surface interaction involves a hydride ligand and a basic surface group ($O^{2\ominus}$ ion or hydroxyl group), leading to incipient deprotonation of the complex (Section 3.4). As demonstrated by the extraction of the surface species with $(Ph_3P)_2NCl$ in CH_2Cl_2 to give $[(Ph_3P)_2N][HOs_3(CO)_{11}]$, the supported complexes are susceptible to redox condensation involving $[H_2Os(CO)_4]$ and its conjugate base. The condensation of the supported mononuclear carbonyls to yield anionic clusters bound to the MgO surface is therefore to be expected.

Indeed, samples prepared by adsorption of $[H_2Os(CO)_4]$ on magnesia (pretreated at 673 K) heated at 548 K under 1 MPa of $CO + H_2$ in 1:3 (molar) ratio (conditions under which the catalytic hydrogenation of CO occurs) for more than two days yielded materials incorporating $[H_3Os_4(CO)_{12}]^{\ominus}$ and $[Os_{10}C(CO)_{24}]^{2\ominus}$ as the predominant surface species.[26] Spectroscopic characterization of the samples after reaction gave evidence for the presence of molecular surface-bound clusters, but not metal particles. $[H_3Os_4(CO)_{12}]^{\ominus}$ was extracted from the solids by cation metathesis with $(CH_3)_4NCl$ in 2-propanol. The reddish-brown carbido cluster $[Os_{10}C(CO)_{24}]^{2\ominus}$ remained on the MgO surface after extraction, as evidenced by the IR and UV/VIS spectra of the solid. Elemental analysis of samples before and after reaction indicated that 30% of the osmium initially present had been lost, presumably as the volatile $[H_2Os(CO)_4]$ or as other neutral carbonyls.

The condensation of the original supported mononuclear metal complexes was monitored by high-pressure IR spectroscopy.[51] As in the previous experiments, the sample was heated from 300 to 548 K under flowing 1:1 CO/H_2 at 1 MPa. The initial IR spectrum recorded at 548 K (Fig. 13A) is in excellent agreement with that of surface-bound $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) clusters on MgO (Fig. 13B); limited spectroscopic evidence suggests the formation of $[HOs_3(CO)_{11}]^{\ominus}$ as an intermediate condensation product at lower temperatures. (The formation of surface-bound $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) appears to be analogous to the reaction of $[HRu_3(CO)_{11}]^{\ominus}$ in solution in the presence of H_2 to yield $[H_2Ru_4(CO)_{12}]^{2\ominus}$.[52]) As the $CO:H_2$ molar ratio of the feed mixture was changed to 1:3, the IR bands characteristic of $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) decreased in intensity with time, and a band appeared which was tentatively assigned to $[Os_6(CO)_{18}]^{2\ominus}$, a likely intermediate in the formation of the ultimate product, $[Os_{10}C(CO)_{24}]^{2\ominus}$.[53] Similar results were obtained in an experiment with a sample initially incorporating $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) derived from the adsorption of $H_4Os_4(CO)_{12}$ (Section 3.3).

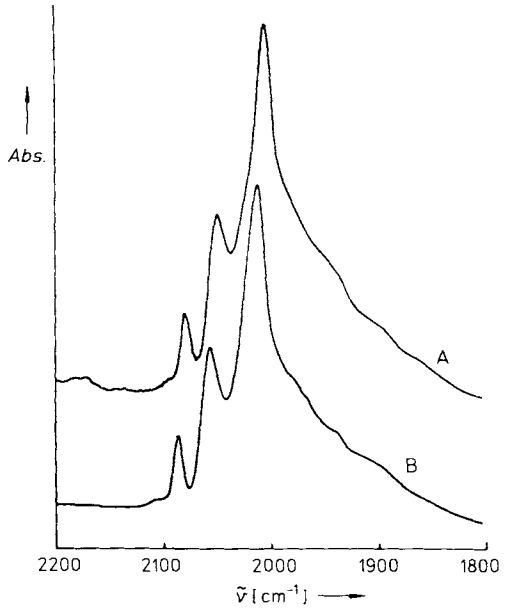

Fig. 13. Comparison of the ν_{CO} bands of surface-bound $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) on magnesia derived from chemisorbed $[H_2Os(CO)_4]$ by heating to 548 K under 1 MPa of equimolar $CO + H_2$ (spectrum recorded initially under these conditions) (A) and from the products of the dissociative chemisorption of $[H_4Os_4(CO)_{12}]$ after heating to 473 K under 100 kPa of equimolar $CO + H_2$ (spectrum recorded in vacuo at 300 K) (B).

The observation of $[Os_{10}C(CO)_{24}]^{2\ominus}$ and the tetranuclear hydrido osmium carbonyl anions as the predominant surface species after long reaction times reflects the thermodynamic stability of these clusters under the chosen conditions. The ultimate synthesis of $[Os_{10}C(CO)_{24}]^{2\ominus}$ on the basic MgO surface at high temperatures parallels its synthesis in solution via condensation of lower-nuclearity osmium carbonyls under reducing conditions.[53] The relative stability of the $[H_{4-n}Os_4(CO)_{12}]^{n\ominus}$ (n = 1, 2) clusters is attributed to the high H_2 partial pressures employed and their influence on the equilibrium; the neutral cluster $[H_4Os_4(CO)_{12}]$ has been demonstrated to be the most stable hydrido carbonyl cluster of osmium under similar conditions in solution.[54] The tetranuclear cluster anions have also been observed to form from $Os_6(CO)_{18}$ on MgO.[27c]

In summary, the combination of stable osmium carbonyls with the basic magnesia support allows the extension of the rich molecular chemistry of cluster growth in basic media to surfaces.

4.3. Oxidative Fragmentation of Supported Metal Clusters and Aggregates

This section begins with descriptions of the syntheses of stable mononuclear surface complexes by the oxidative

fragmentation of supported metal clusters, $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OM\}]$ (M = Si, Al, Mg), $[Rh_6(CO)_{16}]/Al_2O_3$, and $[H_2Re_3(CO)_{12}]^{\ominus}/MgO$. Evidence is presented for the existence of ensembles consisting of three mononuclear metal complexes originating from the decomposition of the trinuclear Os and Re clusters. Next, the surface organometallic chemistry of the rhenium-on-alumina system is described as a basis for developing the parallels between the oxidative fragmentation of supported molecular metal clusters and the disruption of small supported aggregates of metal resulting from exposure to CO.

4.3.1. Oxidative Fragmentation of Supported Metal Carbonyl Clusters

Having established the potential for forming stable low-valent subcarbonyl species via the decarbonylation of supported mononuclear carbonyls (Section 4.1), we now turn to the more complex process of oxidative fragmentation of surface-bound metal clusters. Because the metal atoms in supported clusters are initially associated, the thermal decomposition of these species provides the opportunity to synthesize ensembles of subcarbonyl complexes covalently bound to a metal oxide surface. A prerequisite for the synthesis of uniform isolated ensembles is the initial chemisorption of a metal cluster precursor, the goal being to create ensembles having the nuclearity of the cluster. For certain metals (e.g., Rh, Os, Re), the low-valent mononuclear complexes formed by the thermal decomposition of supported metal clusters provide excellent models for the surface structures formed by the analogous CO-initiated oxidative fragmentation of highly dispersed supported metal particles (Section 4.3.2). *Robbins*[55] has proposed that the rhodium(I) dicarbonyl species formed by the disruption of small alumina-supported Rh aggregates remain clustered on the support, the process being analogous to the formation of ensembles by the decomposition of metal clusters.

As described in Section 3.5, $Os_3(CO)_{12}$ reacts with silica, alumina, and magnesia at 333–423 K (the temperature depending on the support and the preparation) to give the surface-bound cluster $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OM\}]$ (M = Si, Al, Mg). Treatment of the supported trinuclear clusters in vacuo or under inert gases at elevated temperatures leads to fragmentation and oxidation to form mononuclear Os^{II} complexes.[37,40,41,45] The temperature required to induce fragmentation depends on the metal oxide support and its pretreatment.

The oxidative fragmentation of $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OAl\}]$ has been investigated by a number of research groups. Treatment of $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OAl\}]$ at temperatures above 373 K in vacuo or under an inert atmosphere induces the irreversible breakup of the triosmium cluster and the formation of mononuclear Os^{II} subcarbonyl complexes bound to the alumina surface.[37,41] *Psaro* et al.[37] found that 3 molecules of H_2 and 1.6 molecules of CO per cluster were evolved upon heating $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OAl\}]$ in argon from 373 to 423 K; the oxidative addition of surface hydroxyl groups (as indicated by the H_2 evolution) occurs concomitantly with the fragmentation of the supported cluster. The H_2 evolution and X-ray photoelectron spectroscopy measurements[44a] are consistent with the formation of Os^{II} surface species. On the basis of the IR spectrum of the surface species (typically, three ν_{CO} bands are observed at 2120–2130, 2030–2050, and 1940–1970 cm^{-1}) and a comparison of the spectrum to those of molecular analogues such as $[Os(CO)_3X_2]_2$ (X = Cl, Br, I) and $[Os(CO)_2I_2]$, the surface composition was inferred to be a mixture of di- and tricarbonyl complexes covalently attached to the alumina surface by Os–O–Al bonds. On the basis of changes in the relative intensities of the IR bands, *Knözinger* and *Zhao*[41b] proposed that the proportions of the di- and tricarbonyl species depend on the severity of the thermal treatment and that the interconversion of the two subcarbonyl species is reversible:

$$[Os(CO)_3L\{O-Al\}_2] \rightleftharpoons [Os(CO)_2L\{O-Al\}_2] + CO \qquad (16)$$
$$L = \{O^{2\ominus}\} \text{ or } \{OH^{\ominus}\}$$

The structure of the mononuclear species resulting from the treatment of $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OAl\}]$ at 423 K in vacuo for five hours has recently been elucidated by EXAFS spectroscopy[43b] (Table 4). The average M–CO coordination number was found to be 2.8, consistent with a mixture of osmium di- and tricarbonyl species. On the average, three oxygen back-scatterers at a distance of 0.217 nm are associated with each osmium complex, consistent with a hypothetical surface species $[Os(CO)_n\{O-Al\}_2\{HO-Al\}]$ (n = 2, 3). Back-scattering suggestive of direct Os–Os bonds was absent. A structural model of a tricarbonyl species situated in a threefold hollow of an alumina surface layer of close-packed $O^{2\ominus}$ ions and hydroxyl groups is presented in Figure 14; analysis of the relative intensities of the IR bands allows additional insight into the local geometry of the carbonyl ligands.[41b]

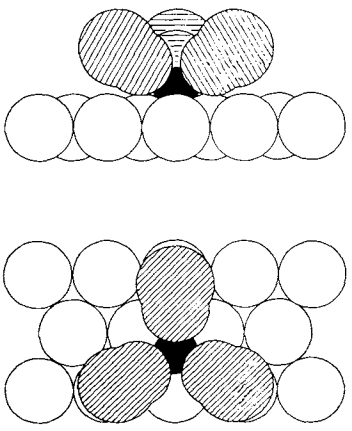

Fig. 14. Suggested model of an Os^{II} tricarbonyl site on a close-packed surface layer of γ-Al_2O_3. Top: Side view. Bottom: top view.

Similar surface complexes are formed by the decomposition of the surface-bound triosmium clusters on silica and magnesia, but there are differences in the surface organometallic chemistry. On silica there is some evidence for intermediate $[HOs(CO)_3\{O-Si\}\{HO-Si\}]$ species, which may be converted (with evolution of H_2) into $[Os(CO)_3\{O-Si\}_2]$ or $[Os(CO)_3\{O-Si\}_2\{HO-Si\}]$.[40] There is

also evidence, in contrast to observations made with alumina-supported samples, that vacuum treatment at temperatures above 523 K produces aggregates of supported Os metal.[40,43a] Also, only on silica has the apparent re-formation of the original surface-bound trinuclear cluster by treatment of the subcarbonyl complexes with CO + H_2O at elevated temperatures been observed.[40,43a] *Psaro* et al.[45b] observed that on magnesia the interconversion of the di- and tricarbonyl species was inhibited. Also, the formation of a unique Os^{II} dicarbonyl complex has been inferred;[45] the proposed structure of this species is illustrated in Figure 15. This highly stable complex forms by the oxidation of magnesia-supported triosmium clusters in the presence of O_2. Its formulation as $[Os(CO)_2\{O-Mg\}_4]^{2\ominus}$ was based on the agreement between the IR spectrum of the surface species and that of the molecular analogues $[Os(CO)_2X_4]^{2\ominus}$ (X = Cl, Br, I).

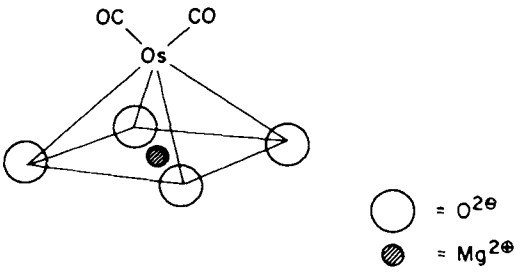

Fig. 15. Proposed structure of $[Os(CO)_2\{OMg\}_4]^{2\ominus}$ [45a].

Well-characterized Rh^I geminal dicarbonyl species are formed by the oxidative fragmentation of $[Rh_6(CO)_{16}]$ on η- and on γ-Al_2O_3.[56] $[Rh_6(CO)_{16}]$ interacts only weakly with the aluminas pretreated at 773 K. However, upon exposure of adsorbed $Rh_6(CO)_{16}$ to small quantities of water (sufficient to hydroxylate the surface completely) at 298 K, the cluster undergoes oxidative fragmentation to yield Rh^I geminal dicarbonyl species anchored to the alumina surface. At the same time, H_2 is evolved (0.5 molecules of H_2 per $Rh_6(CO)_{16}$ cluster). The dicarbonyl complex was suggested to be a 16-electron species, having a square-planar configuration with one covalent Rh–O bond and a single hydroxyl donor ligand. The intensity of the ν_{CO} bands assigned to the dicarbonyl species increased on subsequent exposure of the sample to 40 kPa of CO, which implies that other, totally decarbonylated Rh species (e.g., Rh^{III} ions) had also formed as a result of the fragmentation of $Rh_6(CO)_{16}$. *Basset* et al.[56b] suggested that a mixture of $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$ and $[Rh(H)_2\{O-Al\}\{HO-Al\}]$ complexes form by the breakup of $Rh_6(CO)_{16}/Al_2O_3$ under these conditions, accounting for the observed H_2 evolution (less than required for formation of $Rh^I(CO)_2$ complexes alone) and the CO uptake. The facile fragmentation of $Rh_6(CO)_{16}/Al_2O_3$ is apparently initiated by the electrophilic attack of surface protons at the zerovalent metal centers.

The rhodium dicarbonyl complex decomposes upon treatment at 413 K in vacuo. The exact nature of the Rh species present after complete decarbonylation has not been established; however, the material was reported to chemisorb H_2 (1.2 H/Rh), suggestive of the formation of very small rhodium aggregates or, as *Basset* et al.[56b] proposed, rhodium hydride complexes. The reduction of the Rh^I subcarbonyl species may have occurred via the oxidation of a CO ligand:

$$Rh^I(CO)_2 \longrightarrow Rh^0 + CO + CO_2 \qquad (17)$$

Exposure of the decarbonylated sample to CO at room temperature resulted in the reappearance of the IR bands assigned to the $Rh^I(CO)_2$ species. The regeneration of $Rh_6(CO)_{16}/Al_2O_3$ from $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$ by exposure to CO + H_2O at 298 K is discussed in Section 4.4.

$[Rh(CO)_2Cl]_2$ has been proposed as a molecular analogue of the $Rh^I(CO)_2$ species on alumina. Several researchers have investigated the chemisorbed dimer on alumina as a model for Rh^I geminal dicarbonyl sites produced by the oxidative fragmentation of supported Rh clusters and by the CO-initiated disruption of alumina-supported Rh crystallites (discussed in detail below).[55,56a,57] $[Rh(CO)_2Cl]_2$ chemisorbs on hydroxylated γ-Al_2O_3 by the following reaction:

$$[Rh(CO)_2Cl]_2 + 2\{Al-OH\} \longrightarrow 2[Rh(CO)_2\{O-Al\}] + 2HCl \qquad (18)$$

The IR spectrum of the resulting surface species has the characteristic two-band pattern typically assigned to $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$. *Robbins*[55] used IR, solid-state ^{13}C NMR, and EPR spectroscopy to characterize the surface species. A strong doublet (2098 and 2026 cm^{-1}) was observed in the ν_{CO} IR spectrum, consistent with previous observations. The ^{13}C NMR spectrum (recorded with magic-angle spinning) displayed a doublet centered at $\delta = 180.9$ downfield of tetramethylsilane, indicating the presence of only terminal CO ligands; the splitting can be ascribed to ^{103}Rh–^{13}C coupling. Low-temperature EPR spectroscopy gave no evidence of paramagnetic Rh centers, consistent with the presence of d^8 Rh^I species.

The oxidative fragmentation of trirhenium clusters supported on γ-Al_2O_3 and on MgO has also been demonstrated. The products of the decomposition of $[H_2Re_3(CO)_{12}]^{\ominus}$ on magnesia have been characterized by IR, UV/VIS, and EXAFS spectroscopy.[29,49] The structure of the mononuclear complex $[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$, formed by thermal decomposition of $[H_2Re_3(CO)_{12}]^{\ominus}$/MgO in H_2 or in He at 498 K, is illustrated in Figure 16. The subcarbonyl complex was found to be stable (as assessed by IR spectroscopy) at 523 K in H_2 or He.

Evidence for the formation of ensembles of mononuclear Os and Re complexes resulting from the oxidative fragmentation of the surface-bound $[(\mu\text{-}H)Os_3\{CO\}_{10}\{\mu\text{-}O-Al\}]$ and $[H_2Re_3(CO)_{12}]^{\ominus}$/MgO clusters, respectively, comes primarily from transmission electron microscopy (TEM) in the former case[44] and from the results of a structure-sensitive catalytic test reaction (cyclopropane hydrogenolysis)[58] and EXAFS[49] in the latter.

The existence of ensembles of three Os^{II} complexes resulting from the decomposition of $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}O-Al\}]$ was first suggested on the basis of electron micro-

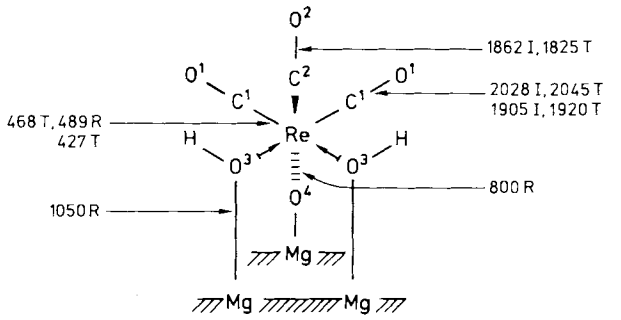

Fig. 16. Structure of rhenium tricarbonyl sites on magnesia as inferred from ν_{CO} IR (I), ν_{Re-O} Raman (R), and inelastic electron tunneling (T) data [29].

graphs of the supported osmium species showing extremely uniform scattering centers less than 1.0 nm in size.[44a] A more detailed high-resolution TEM study of the ensembles was reported by *Schwank* et al.[44b] who observed uniform scattering centers approximately 0.6 nm in size for a sample of $[(\mu\text{-H})Os_3(CO)_{10}\{\mu\text{-O-Al}\}]$ decomposed in argon at 473 K. Because of the size and uniformity of the scattering centers and their resistance to sintering under the electron beam, the surface species were inferred to be groupings of three divalent Os complexes. Further evidence of the presence of small groupings of osmium atoms derived from the oxidative fragmentation of triosmium clusters on alumina and on silica comes from attempts to model the IR spectra of the Os^{II} di- and tricarbonyl species. *Cook* et al.[43a] found that the mixed-isotope ($^{12}CO/^{13}CO$) vibrational spectra of these surface species could not be accounted for by isolated (vibrationally decoupled) $Os(CO)_3$ and $Os(CO)_2$ units. These researchers and others[59] have suggested the retention of direct Os–Os bonding within the supported ensembles. For example, *Collier* et al.[59] derived materials from $Os_3(CO)_{12}$ on alumina that were evidently present in an ill-defined aggregated form rather than as molecularly dispersed clusters.[37b] In this case, it was proposed that groupings containing roughly 12 Os atoms resulted from the decomposition of the supported organometallic precursor at 423 K in He; the ν_{CO} IR spectrum of the material was similar to the spectra reported by others[37,41] for mixtures of Os^{II} di- and tricarbonyl complexes on alumina, and the presence of these species on the surface (as part of a complex mixture) is considered likely.

The presence of groupings of three $[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$ complexes following the oxidative fragmentation of $[H_2Re_3(CO)_{12}]^{\ominus}/MgO$ in H_2 or in He has been inferred from the catalytic properties of these materials.[58] Isolated $[Re(CO)_3\{O-Mg\}\{HO-Mg\}_2]$ complexes derived from $[HRe(CO)_5]$ chemisorbed on MgO (Section 4.1) are the precursors of catalysts for propene hydrogenation but not for cyclopropane hydrogenolysis. In contrast, materials derived from the decomposition of $[H_2Re_3(CO)_{12}]^{\ominus}/MgO$ (presumably to give trinuclear ensembles) were effective catalysts for both hydrogenation and hydrogenolysis. Hydrogenolysis is generally classed as a structure-sensitive catalytic reaction requiring the cooperative action of two or more neighboring metal centers.[60]

4.3.2. CO-Induced Fragmentation and Oxidation of Supported Metal Aggregates

The oxidative fragmentation of supported metal clusters, discussed above, further illustrates the pronounced tendency of surface hydroxyl groups to add oxidatively to zerovalent metal centers. A similar oxidative fragmentation process has been proposed to account for the formation of $Rh^{I}(CO)_2$ species when highly dispersed rhodium-on-alumina is brought into contact with CO at 298 K.[61] The breakup of small metal aggregates by CO is not surprising in light of the established tendency of CO to fragment high-nuclearity metal clusters in solution.[46] The CO-induced fragmentation and oxidation of supported Re[49] and Os[62] aggregates to give low-valent mononuclear subcarbonyl species have also been proposed. Obviously, the generation of metal carbonyl intermediates is plausible under such circumstances, and the surface organometallic chemistry described above indicates that these might readily react with surface hydroxyl groups to produce the oxide-bound metal carbonyl complexes typically observed.

Supported rhodium catalysts have received a great deal of attention recently; some of these materials are catalysts for the selective formation of oxygenated products in synthesis gas conversion.[63] The problem of the nature and origin of the dicarbonyl species typically observed following CO chemisorption on highly dispersed rhodium-on-alumina has a long history.[55]

van't Blik et al.[61] investigated a series of rhodium-on-alumina catalysts derived from $\gamma\text{-}Al_2O_3$ impregnated with aqueous $RhCl_3$. Employing temperature-programmed reduction and EPR and X-ray photoelectron spectroscopy, they established that more than 95% of the rhodium in a sample containing 0.57 wt% Rh was reduced to the zerovalent state by treatment with H_2 at 593 K for one hour. The supported Rh aggregates chemisorbed H_2 at 298 K to the extent of 1.7 H atoms/Rh atom, which implies that the rhodium was highly dispersed.

EXAFS spectroscopy was used to characterize the metallic rhodium structures. The average Rh–Rh coordination number was 3.7, which is suggestive of small rhodium entities (the Rh–Rh coordination number of $Rh_6(CO)_{16}$, for example, is 4), but the average Rh–Rh distance was close to that characterizing bulk rhodium metal. Backscattering due to oxygen atoms was observed, with the scatterers placed at an average distance from Rh of 0.274 nm with an average Rh–O coordination number of 1.9. The authors suggested that the oxygen scatterers were associated with the support, since the Rh–O distance was longer than would be expected for a rhodium oxide phase, and other evidence indicated the essentially complete reduction of the rhodium.

The interaction of CO with these ultradispersed rhodium aggregates illustrates the ability of CO to fragment small "naked" clusters of supported metal atoms. CO chemisorption measurements at 298 K gave a value of 1.9 CO molecules/Rh atom, suggesting the formation of a dicarbonyl species. The inference is supported by a comparison of the IR spectrum observed following adsorption of CO with that reported by *Basset* et al. for $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$[56] and by others for geminal di-

carbonyl species derived from alumina-supported Rh;[64] the spectra are quite similar, with strong, sharp bands at approximately 2095 and 2025 cm^{-1}.

van't Blik et al.[61] provided additional characterization of the dicarbonyl surface species by EXAFS spectroscopy and X-ray photoelectron spectroscopy (XPS). By XPS the Rh $3d_{5/2}$ binding energy of a rhodium-on-alumina sample, reduced and exposed to CO in a pretreatment chamber integral with the spectrometer, was found to be equivalent, within experimental error, to that measured for $[Rh(CO)_2Cl]_2$, in which rhodium is in the +1 oxidation state. Analysis of data from in-situ EXAFS measurements indicated an average of 1.8 CO ligands per rhodium atom. Significantly, no Rh nearest neighbors were observed (at least at bonding distances); instead, oxygen backscatterers were identified at a distance of 0.212 nm, which implies oxidation of the rhodium. These results confirm that CO adsorption led to the oxidative fragmentation of the bare metal aggregates present initially.

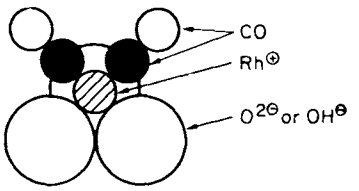

Fig. 17. Structure of Rh^I geminal dicarbonyl sites on γ-Al_2O_3 suggested by *van't Blik* et al. [61].

The structure suggested by *van't Blik* et al. for the geminal dicarbonyl species on alumina is shown in Figure 17. The Rh^I ions are proposed to exist as five-coordinate 18-electron species, associated with the threefold hollows of a close-packed surface layer of oxide ions and hydroxyl groups, in contrast to the 16-electron square-planar configuration suggested by *Robbins*[55] and *Basset* et al.[56] The structural inference of *van't Blik* et al. is based on the EXAFS finding of an average Rh–O coordination number of 3.1.

The interaction of CO with small alumina-supported rhodium aggregates has been monitored over a wide temperature range by in-situ IR spectroscopy.[65] At 77 K the spectra indicate only the presence of CO adsorbed on Rh crystallites. However, at temperatures greater than about 100 K the Rh^I dicarbonyl species is formed. These results suggest that, as expected, the oxidative fragmentation of the supported Rh aggregates is an activated process.

Robbins[55] suggested that the $Rh^I(CO)_2$ complexes remain clustered on the γ-Al_2O_3 surface following particle breakup, consistent with the formation of ensembles from the oxidative fragmentation of supported metal clusters. This view is confirmed in part by transmission electron micrographs showing 0.5–3.0-nm scattering centers after exposure of highly dispersed rhodium-on-alumina catalysts to CO.[64b,65a] However, apparently unlike the Os ensembles described above, the $Rh^I(CO)_2$ species are vibrationally decoupled.[66]

The formation of $Rh^I(CO)_2$ species by the exposure of ultradispersed alumina-supported rhodium aggregates to CO may be explained by considering the well-known tendency of CO to fragment high-nuclearity rhodium clusters in solution and the facile nature of the oxidative addition of hydroxyl groups to zerovalent metal centers. Although the detailed mechanism of the CO-induced oxidation and fragmentation of alumina-supported rhodium aggregates remains in doubt, the analogy to the oxidative fragmentation of $Rh_6(CO)_{16}/Al_2O_3$ is strong. The complementary paths taken by *Basset* and co-workers (who investigated molecular carbonyl clusters) and *van't Blik* and co-workers (who approached a problem in conventional heterogeneous catalysis) demonstrate the excellent consistency between the surface chemistry of conventionally derived supported metal catalysts and the surface organometallic chemistry of supported metal carbonyls. We believe that this work portends a rapid consolidation of the heretofore seemingly disparate fields of surface organometallic chemistry and classical heterogeneous catalysis.

4.4. Reductive Carbonylation of Supported Metal Ions

The oxidative fragmentation of supported molecular metal clusters characterizes the surface organometallic chemistry in the absence of a stabilizing CO atmosphere. However, especially on basic metal oxide surfaces, the low-valent mononuclear metal complexes formed by cluster fragmentation can be reductively carbonylated to regenerate supported molecular clusters, and sometimes this chemistry leads to simple, efficient cluster syntheses.[45c,67,70] The molecular clusters formed usually do not reflect the nuclearity of the original cluster precursor, which suggests a high mobility of the surface reaction intermediates. Generally it appears that the thermodynamically favored molecular cluster is produced; the precise nature and state of aggregation of the precursor complexes appear to be of little importance. Consistent with this view, it was established that surface-bound molecular clusters of Os and Ru are prepared in high yield by the reductive carbonylation of surface structures formed by aqueous impregnation of magnesia with H_2OsCl_6 and $RuCl_3$, respectively.[67] There are clear parallels between reductive carbonylation in basic solution and on basic metal oxide surfaces; in both cases, redox condensation reactions are expected to play a central role. This chemistry is illustrated below with a focus on the synthesis of supported molecular clusters from covalently bound metal carbonyl complexes and supported metal halide salts.

$Rh_6(CO)_{16}/Al_2O_3$ is regenerated from the species $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$ by treatment with $CO + H_2O$ at 298 K and atmospheric pressure.[56] Under optimum conditions, the yield of $Rh_6(CO)_{16}$ is high; the molecular cluster can be extracted from the surface with chloroform. However, when the partial pressure of CO is less than ca. 20 kPa, large Rh crystallites form, as observed by electron microscopy. It was inferred[56b] that $[Rh(CO)_4]^{\ominus}$, a strong nucleophile in typical solvents, was possibly the key intermediate in the reductive carbonylation process. The complex process was suggested to be initiated by the nucleophilic attack of adsorbed H_2O on $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$, generating mobile mononuclear carbonylrhodate ions:

$$[Rh(CO)_2\{O-Al\}\{HO-Al\}] + H_2O \xrightarrow{CO} [Rh(CO)_4]^{\ominus} + \{H^{\oplus}\} + 2\{HO-Al\} + CO_2 \quad (19)$$

Redox condensation to form adsorbed $Rh_6(CO)_{16}$ could then plausibly occur following nucleophilic attack of $[Rh(CO)_4]^{\ominus}$ on a $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$ complex. These hypothetical steps are consistent with metal-metal bond formation being initiated by the generation of carbonyl complexes in different oxidation states.

The reductive carbonylation of Rh ions in the supercages of large-pore zeolites has also been reported.[68] Polynuclear carbonyls are formed by the treatment of Rh^{III} ions in hydrated zeolite Y with $CO + H_2$ at 298 K; molecular Rh carbonyl clusters in zeolite Y are apparently stable at 523 K and 3 MPa ($CO : H_2 = 1 : 2$).

Similar chemistry was observed under more severe conditions by *Deeba* et al.,[45a] who investigated the behavior of materials derived from $Os_3(CO)_{12}$ adsorbed on MgO pretreated at 473 K. The basicity of MgO pretreated in this manner is severely reduced by strongly adsorbed CO_2 (surface carbonates). $[(\mu\text{-}H)Os_3(CO)_{10}\{\mu\text{-}OMg\}]$ was inferred to be the predominant surface species present initially. When the supported triosmium cluster was exposed to air under ambient conditions, a mononuclear surface species formulated as $[Os(CO)_2\{O-Mg\}_4]^{2\ominus}$ (cf. Fig. 15) was formed (see Section 4.3.1). When a sample initially incorporating this surface species was used as a catalyst for CO hydrogenation (573 K, 0.7 MPa, $CO : H_2 = 1 : 4$), molecular osmium carbonyl clusters formed, as evidenced by the IR spectrum of the used catalyst; these clusters are now recognized to be $[Os_{10}C(CO)_{24}]^{2\ominus}$.[26] The decaosmium cluster was evidently produced by reductive carbonylation of the Os^{II} complexes originally present, and this process likely coincided with the development of strong surface basicity under the synthesis conditions. This hypothesis is confirmed by the formation of $[Os_{10}C(CO)_{24}]^{2\ominus}$ from $[H_2Os(CO)_4]$/MgO (Section 4.2).

$[Os_{10}C(CO)_{24}]^{2\ominus}$/MgO has also been synthesized efficiently from MgO impregnated with aqueous H_2OsCl_6 and exposed to CO or $CO + H_2$ at 548 K and 100 kPa.[67] The reactions were monitored by in-situ IR spectroscopy, and Os^{II} subcarbonyls on MgO were observed as intermediate products. By ion exchange with $(Ph_3P)_2NCl$ in acetone, $[(Ph_3P)_2N]_2[Os_{10}C(CO)_{24}]$ was extracted from samples that had been treated with $CO + H_2$ at 548 K and 100 kPa for 5 h; 60–70% of the Os could be removed in this manner. Confirmation of the surface structure was obtained from UV/VIS and EXAFS spectroscopy; and electron microscopy of samples prepared by the surface synthesis gave no evidence of scattering centers larger than 1.0 nm.[69] The surface-mediated synthesis of $[Os_{10}C(CO)_{24}]^{2\ominus}$ and the analogous preparation of $[Ru_6C(CO)_{16}]^{2\ominus}$ from $RuCl_3$-on-magnesia[67] represent the first syntheses of high-nuclearity Ru and Os clusters by reductive carbonylation of metal salts.

In summary, basic metal oxide supports, incorporating highly nucleophilic surface hydroxyl groups, facilitate the formation of molecular metal carbonyl clusters by reductive carbonylation. $[Os_{10}C(CO)_{24}]^{2\ominus}$ and $[Ru_6C(CO)_{16}]^{2\ominus}$/MgO are even produced (in low yields) from the supported metals under conditions of catalytic CO hydrogenation,[67] suggesting that these molecular metal clusters may be the thermodynamically favored surface species under these extreme conditions. Even when the surface-bound molecular clusters are not the most stable surface species, their likely presence in small concentrations (especially on highly ba-

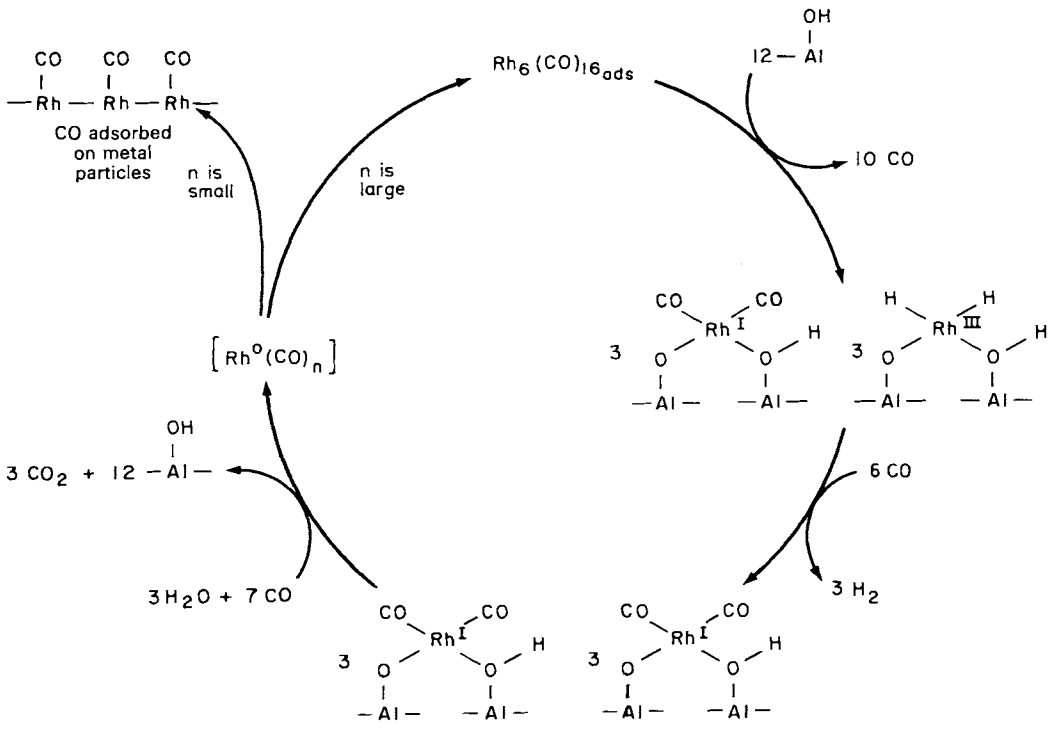

Fig. 18. Catalytic cycle for the water-gas shift reaction ($CO + H_2O \rightleftharpoons CO_2 + H_2$), which is proposed to involve only molecular rhodium complexes on alumina when the partial pressure of CO is maintained in excess of 20 kPa and the CO/H_2O ratio is high [56b].

sic supports like magnesia) suggests a heretofore unexpected role of molecular metal clusters in catalysis of carbonylation reactions. A catalytic cycle (Fig. 18) has been proposed by *Basset* et al. for the water gas shift reaction involving molecular Rh carbonyls on alumina under mild conditions.[56b] Key steps in the hypothetical process have been verified, including the oxidative fragmentation of $Rh_6(CO)_{16}/Al_2O_3$ and its regeneration by the reductive carbonylation of $[Rh(CO)_2\{O-Al\}\{HO-Al\}]$ complexes.

5. Summary and Outlook

The subject of "molecular" chemistry of transition-metal carbonyls on metal oxide surfaces has developed dramatically in just the preceding several years. The chemistry is consistent with that of molecular metal carbonyls in solution, being influenced strongly by the nature of the support, especially the acid-base properties. Some syntheses of organometallic compounds on supports are simpler and more efficient than conventional solution syntheses; we anticipate a rapid growth in the application of surface-mediated organometallic synthesis.[45c, 67, 70] Some "molecular" organometallic species on surfaces are stable even at temperatures approaching 600 K and some have demonstrated catalytic activity. The understanding of this chemistry is developing rapidly, benefiting from surface characterization techniques such as IR, NMR, and EXAFS spectroscopy. There is a compelling opportunity to exploit organometallic chemistry for the creation of materials with novel surface structures and new catalytic properties.[71] These novel catalysts may be expected to include (1) stable surface-bound metal complexes and clusters; (2) unique supported metal aggregates with framework nuclearities the same as those of precursor metal clusters; and (3) ensembles of metal ions on surfaces, with nuclearities tailored to meet the requirements for particular structure-sensitive reactions.

Molecular Mechanisms of Biomineralization in the Formation of Calcified Shells

By Gottfried Krampitz* and Gabriele Graser

Biological calcification processes (calcification, biomineralization) occur in microorganisms, in plants, and in the animal kingdom. Under physiological conditions, the results of mineral deposition in biological systems can be seen in the formation of bones, teeth, mollusc shells, egg shells, pearls, and corals. There are, however, also pathological aspects of biomineralization, including the formation of kidney stones (renal calculus), gallstones (biliary calculus), intravasal depositions (atherosclerosis, calcinosis). Abnormal mineralization processes (demineralization) can be found, e.g., in bone resorption (osteoporosis) and caries. A detailed knowledge of the molecular mechanisms of biomineralization could help considerably toward solving some of the problems encountered in orthopedics, urology, cardiovascular science, dentistry and veterinary medicine. Research in biomineralization is always interdisciplinary. In this article the typical interactions between mineral phase and organic matrix will be demonstrated using two examples—mollusc shells and egg shells.

1. Introduction

Biological calcification processes are of wide occurrence in nature. They occur in microorganisms, in plants, in the animal kingdom and in humans. The results of mineral deposition under physiological conditions can be seen in the formation of bones, teeth, shell material (mollusc shells, egg shells), coccoliths, corals, pearls, etc. The variety of biomineralizates can best be expressed by the fact that, alone, approximately 128000 species of molluscs exist. The majority of them (Conchifera) produce shells and capsules from $CaCO_3$ having different sizes, shapes and color patterns.[1] There are, however, also pathological aspects of biomineralization, e.g. the formation of body stones (kidney, gall-bladder), atherosclerosis. Processes of demineralization (bone resorption, caries) must be regarded as abnormal biomineralization processes.

Biomineralization can be defined as a sequence of events whereby living organisms produce minerals which crystallize and add together to form hard pieces. In spite of their various forms and functions all biomineralizates are formed according to the same principle. The hard pieces are composed of organic and inorganic substances. The organic components are, as a rule, proteins (e.g. collagen, dentin, elastin, conchiolin). Proteoglycans and lipids have been detected, but their function is still unclear. The inorganic (mineralized) components can be found in crystallized form. Although at least twenty different skeletal minerals have thus far been reported to exist in living organisms,[2,3] only four are generally found: aragonite, calcite, hydroxyapatite, and opal.[3] The remaining kinds of minerals are either trace constituents or occur only in a few special species.[4]

Most of the research to date in the field of biomineralization can be classified under the following headings:

1. Morphological studies of the complex relationships between mineral phase and organic macromolecules (matrix).
2. Investigations on the chemical composition of mineralized tissue and minerals.
3. Exploration of ion-transport mechanisms in cellular systems and of mineral deposition on organic substrates.[5]

Despite numerous and diverse studies, our knowledge of the molecular mechanisms of biological calcification is still superficial. Surprisingly, comparatively little is known about the synthesis of organic macromolecules that participate in the processes of biomineralization. The various aspects and problems of biomineralization can be solved and explained only by interdisciplinary cooperation (chemistry, biochemistry, molecular genetics, physical chemistry, physics, biophysics, mineralogy, crystallography, geology, orthopedics, dentistry, cardiovascular science, urology, veterinary medicine, agricultural sciences, nutrition etc.).

In the following an outline is given—using the examples of mollusc shells and egg shells—of the state of our knowledge of the structure and chemical composition of biomineralizates and of our concept of the interactions between organic phase and inorganic crystals. Particular emphasis is placed on the properties of macromolecules which are involved in the formation of biomineralizates and on their functions and their ability to bind calcium.

2. Mechanisms of Biomineralization

Our concepts of biological calcification are based on the assumption that an organic matrix determines the mineralogical and crystallographic properties of the inorganic phase. Nevertheless, opinions on the types and functions of a matrix are divided. The matrix hypothesis implies that

[*] Prof. Dr. G. Krampitz, Dr. G. Graser

Physiologie und Hygiene der Haustiere, Universität Bonn
Katzenburgweg 7-9, D-5300 Bonn 1 (FRG)

processes of epitaxis[*] play a predominant role, while the compartment hypothesis regards the formation of ordered matrix compartments as being crucial.

2.1. Matrix Hypothesis

This hypothesis (cf. Fig. 1) has been developed from studies on calcified tissues. It was observed that the nucleation and orientated growth of a substance can take

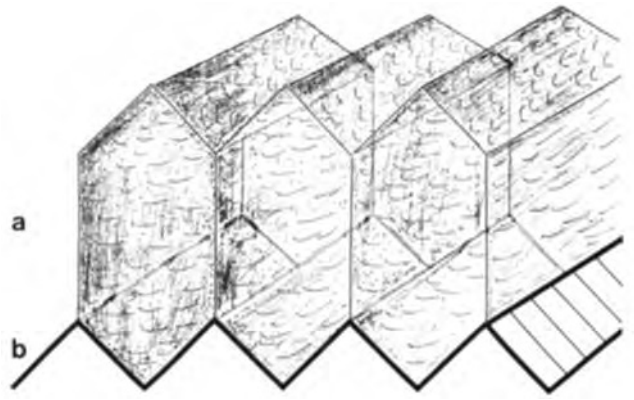

Fig. 1. The matrix hypothesis (simplified model). By its structure, the reactive matrix (b) of organic material determines the form and size of the deposited inorganic crystals (a). In this way a regular growth of the crystals is achieved.

place on the surface of another substance if both have some crystallographic parameter in common. The structure of the substrate-phase dictates the orientation of the superimposed phase. Applied to biomineralization, the organic matrix plays the role of the substrate, i.e. the directing matrix. Nucleation and growth of the inorganic biocrystals take place on the surface of the organic support. The lattice of the nucleate of the growing phase should be dependent on the atomic distances within active centers of the organic matrix. The size and, to some extent, the shape of the growing biocrystals are determined by the matrix. There is no clear understanding about the nature of the functional groups which induce the nucleation, but the simplicity of the matrix hypothesis is attractive.[7] This hypothesis is supported by results obtained from studies on mollusc shells:[8]

1. From the behavior of transplants one could derive that there are calcite-specific and aragonite-specific (conchiolin)matrices within this group of invertebrates.[9, 10]
2. There is a dependence of the orthorhombic *b*-axis in plates of mother of pearl on the direction of the individual fibrils of the conchiolin "membranes" of pelecypodes[11] and a dependence of the *a*-axis on the direction of the "trabecular cords" in the "membranes" of *Nautilus pompilus*.[12, 13]

[*] Epitaxis is defined as a process by which two chemically and/or structurally different crystalline phases grow together. An epitactic system consists of a host crystal (substrate), on which a secondary crystal has developed [6].

2.2. Compartment Hypothesis

Column-like macroprisms of the exterior side of the prism layer of *Pinna nobilis* and *Mytilis edulis* are composed of crystallites which are completely covered with an organic layer.[14, 16] This led to the idea of a hollow space formed by the organic substance ("compartment"),[7, 9] in which the crystallite is formed and in which its habit is shaped by the surrounding organic envelopes. The compartment (cf. Fig. 2) hypothesis negates the existence of reactive matrices.[9]

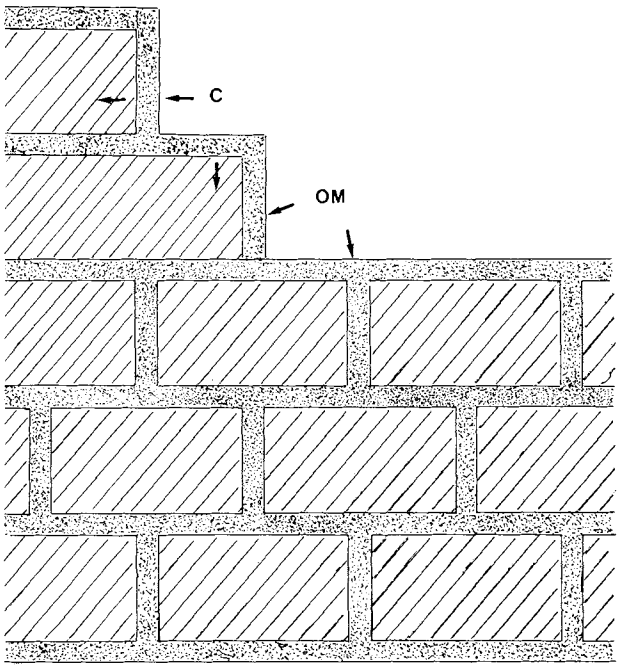

Fig. 2. Compartment hypothesis (simplified model). The mode of synthesis of this type of biomineralizate is also referred to as the "brick-wall" model in which the crystals (C) are compared with bricks and the organic material (OM) with mortar. A reactive matrix is not assumed. The growth of the crystals is irregular, as, e.g. in mother of pearl.

A decision as to whether or not the matrix or the compartment hypothesis applies in invertebrates or in vertebrates or whether both hypotheses must be taken into account has been impossible to make as yet.

2.3. Role of Cells in Biomineralization

A discussion of the cellular aspects of biomineralization immediately poses the question of which evolutionary processes have led to this biological phenomenon. The following points should be considered: The calcium ion is one of the pharmacologically most significant ions. All normal cellular processes can be interrupted by unphysiological $Ca^{2\oplus}$-concentrations. Hence, the intracellular calcium ion concentration is very carefully adjusted in the range of 10^{-6} to 10^{-7} mol/L, and therefore a surprisingly large number of cells deposit intracellular minerals which are rich in calcium.

Since $Ca^{2\oplus}$ in concentrations $> 10^{-6}$ mol/L has a toxic effect on living cells, these ions must be eliminated. There are several possibilities: on conversion from the ionized form into a non-ionized Ca-compound, insoluble substances are often formed. These can either be precipitated within the cell and its compartments or leave the cell as crystals. In other cases the precipitation occurs extracellularly (cf. Fig. 3). The appearance of extracellularly deposited Ca-compounds is nothing else but a detoxification process. It is therefore not surprising that, e.g., in mollusc shells, but also in avian egg shells, various metal-compounds can be detected apart from $CaCO_3$, albeit in trace quantities.[17] It cannot be ignored that the calcification products have originally been formed extracellularly. Moreover they represent a protection for single cells (coccoliths) and for molluscs. The formation of egg shells can be seen as an elimination mechanism for $Ca^{2\oplus}$ and concomitantly as a protection for the vulnerable egg. The evolution from exoskeleton to endoskeleton is then "only" a step from a stiff armor to a somewhat more elastic skeleton of the vertebrates.[17]

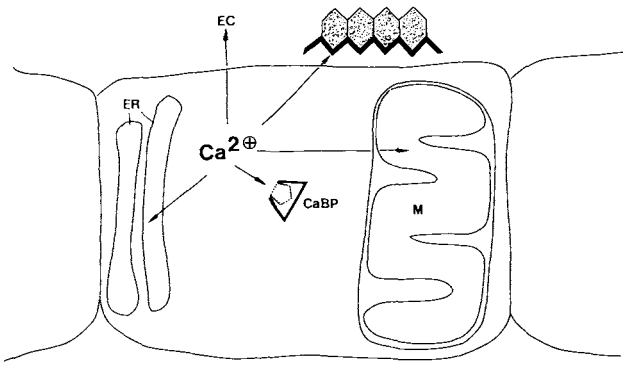

Fig. 3. Biomineralization as cellular detoxifying process. In the cytoplasm the $Ca^{2\oplus}$ concentration is precisely regulated. An excess of $Ca^{2\oplus}$ can be removed intracellulary by Ca-binding proteins (CaBP), storage in mitochondria (M) and in the endoplasmic reticulum (ER), as well as by transport into the extracellular compartment (EC). Insoluble Ca-compounds can crystallize out extracellularly if a suitable matrix is secreted concomitantly.

The contemporary processes of calcification take place in mineral-producing cells. Calcium phosphates—mainly as "inorganic calcium phosphate" $Ca_9(PO_4)_6$—are synthesized in the inner compartment of mitochondria. Amorphous calcium phosphate normally changes autocatalytically into hydroxyapatite if it is not stabilized by $Mg^{2\oplus}$ and ATP within the cells. Stabilized amorphous calcium phosphate is said to be able to cross intracellular membranes in order to serve at other sites of the cell or its surface as a precursor for larger and more stable mineral forms (hydroxyapatite).[18-20]

In unicellular organisms, e.g. protozoa *(Spirostonum ambiguum)*, the formation of $CaCO_3$ is very closely associated with the function of the vacuoles of the Golgi apparatus.[21] In the Golgi apparatus, globular structures (spherical clusters) having a diameter of 0.1 to 1.0 μm are formed, which are then secreted from the cell.[22] Presumably, during special periods of the cell activity, osteocytes and other vertebrate cells produce similar spherical structures, which consist of accumulations of mineralized filaments.[22]

2.4. Bindung of $Ca^{2\oplus}$ to Proteins

Prerequisite for calcification is the possibility to concentrate $Ca^{2\oplus}$ on the organic matrix. In this context Ca-binding properties, especially of the matrix-proteins, are discussed, but there are numerous open questions concerning binding sites. Of the amino acids (and sulfated sugars), whose Ca-binding capacity is known, only a few could actually be of importance in the Ca-binding proteins of biomineralizates. Figure 4 gives an overview.

2.4.1. Binding to Amino Acids with Free Carboxy Groups

Numerous Ca-binding proteins from biomineralizates contain a characteristically unusually high proportion of glutamic and aspartic acids. Although the ability of aminodicarboxylic acids to bind $Ca^{2\oplus}$ has long been known, there arises the question, whether the high proportions of these amino acids in Ca-binding proteins suffices to explain the Ca-binding property. There are proteins which are rich in aspartic and glutamic acids, but do not bind $Ca^{2\oplus}$.[23]

The shell matrices of various species of molluscs contain a high proportion of aspartic acid, as has been shown by amino acid analysis of the HCl-hydrolyzates. On the basis of these findings, a particular amino acid sequence $(Asp-X-)_n$ has been postulated, in which aspartic acid and predominantly serine or glycine residues (X) are arranged alternately, and which should be responsible for the Ca-binding.[24] It is still unclear whether asparagine is hydrolyzed by HCl into aspartate and ammonia. A definite proof, one way or the other, can only be presented after a complete amino acid sequence analysis, which has not been published as yet. For the above mentioned reasons this postulate has been a matter of controversy.[25-28]

In contrast, the strong Ca-binding amino acid γ-carboxyglutamic acid is found in numerous biomineralizates of vertebrates, e.g. in bones,[29] tooth cement and dentin,[30] calcified epiphyseal cartilage,[31] calcified tendons,[32] atherosclerotic plaques, sclerodermia, dermatomyosia and local calciphylaxia.[33] Furthermore, γ-carboxyglutamic acid has been detected as a building block of prothrombin and other proteins of the blood coagulation-system.[34,35] This amino acid has not been found up to now in calcified tissues of invertebrates.[36]

2.4.2. Binding to Phosphorylated Amino Acids

O-Phosphoserine, *O*-phosphothreonine and γ-glutamyl phosphate are also able to bind $Ca^{2\oplus}$. However, thus far it has only been possible to detect these amino acids in biomineralizates of vertebrates.[30,37] It seems that these amino acids do not occur in egg shells and mollusc shells.

Free SH-, OH-, amino- and amido-groups of protein building blocks as well as the spatial structures of polypeptides[38-56] could be essential for the Ca-binding ability of some proteins in biomineralizates. In the formation of mollusc shells and egg shells, however, they play only a subordinate role.

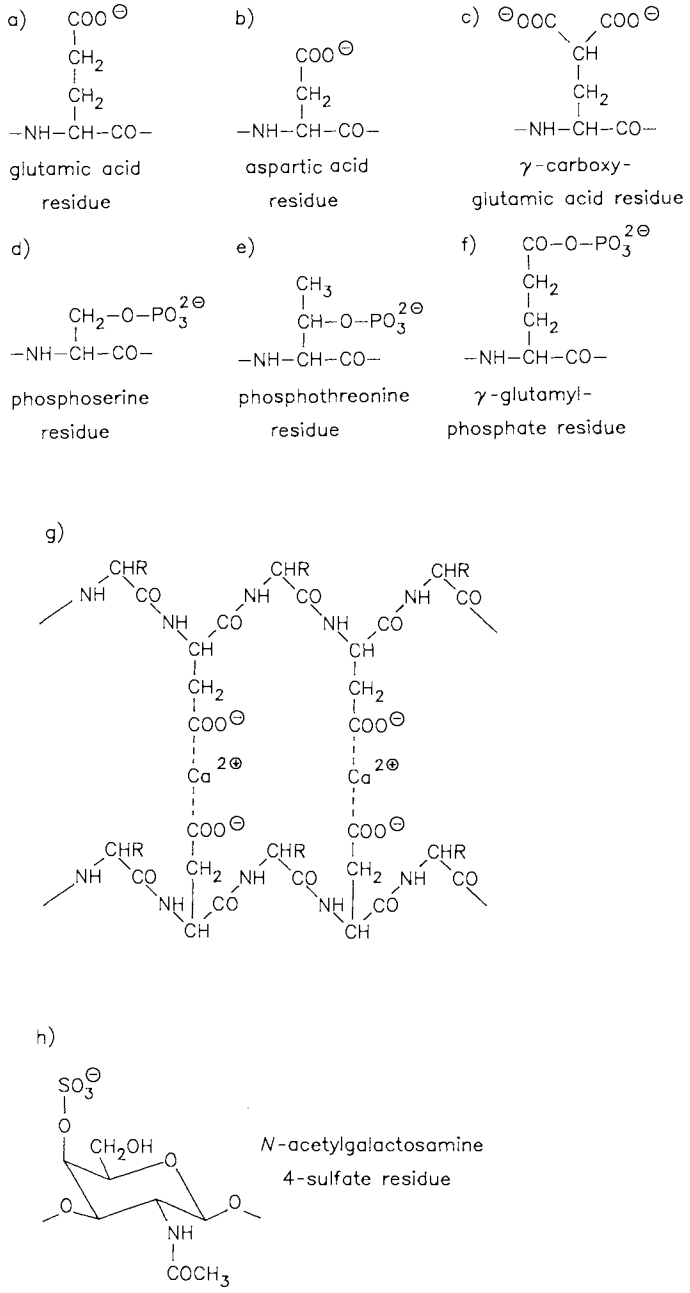

Fig. 4. Ca-binding in organic matrices. A local concentration of $Ca^{2\oplus}$ as prerequisite for crystallization is achieved by appropriate building blocks of proteins and glycoproteins (or proteoglycans) of the matrix. Typical Ca-binders are given in a)-f); they are amino acids in the peptide with negatively charged side chains. By frequent repetition of these building blocks in the polypeptide chain, the Ca concentration can be increased. g) Indicates the possibility of Ca-binding by aspartic acid residues opposite to each other. However, a Ca-binding by neighboring aspartic acid residues is also conceivable (R = H ≙ glycine residue, R = CH_2OH ≙ serine residue). An analogous situation can be constructed for glutamic acid residues. Ca-binding by aspartate has been discussed in connection with the formation of mollusc shells (see text). h) Reflects the possible mode of Ca-binding in avian egg shells. In contrast to examples a)-g) a Ca-binding by sulfated sugars or sugar derivatives is involved here.

2.4.3. Binding to Sulfated Sugars

The Ca-binding properties of the matrices of calcified shells rest primarily on sulfated sugars,[25,26,57] which are building blocks of oligo- or polysaccharides attached to polypeptides.[28,58]

3. Importance of the Matrix in Biomineralizates

Biochemical and micromorphological studies have clearly underscored the importance of matrix components as essential factors for biomineralization processes. The concept of an organic matrix (in each hard part) is based on the hypothesis of a control of deposition of insoluble inorganic material by macromolecular organic components (see Section 2.1). The term "matrix = uterus" is derived from mater and expresses that something is built or formed at a fixed place or in a defined medium. The criteria for a real matrix include:

1. Existence of the matrix before the formation of the product.
2. Participation of the matrix in its formation.
3. Spatial inclusion of the product by the matrix.

Matrices from hard parts are macromolecular polyions; these are primarily proteins and glycoproteins. Occasionally strong basic polycations and polyuronic acids are also observed.[5]

The chemistry of the organic matrices of invertebrates has received greater attention in the last decade. From these studies, functions of the matrices of invertebrate shells can also be derived:[59]

1. Crystal nucleation.
2. Limitation of crystal growth.
3. Crystal orientation.
4. Connection of crystals and crystal layers (influences physical behavior of the shell).

It has been assumed from studies on a large number of organic matrices that the precipitation of calcium ions and phosphate ions from solutions[60-66] by "heterogenous" nucleation is initiated or accelerated by organic matrices.[67-69] Since the mineral is normally deposited in the extracellular space, this observation can contribute to our understanding of the way in which the mineral phase is formed and where it is deposited. Therefore, it was supposed—in analogy to nucleation phenomena in organic chemistry—that such organization of the matrix is an essential characteristic for a matrix, which can influence the rate of crystal formation. This supposition led to inquiries into the chemical structure of the matrices with the aim of explaining relationships between structure and calcification ability. Despite great effort, however, the role of the components of calcifying matrices is still uncertain.[59]

Organic matrices are also detectable in mollusc shells and egg shells. They are found in the biocrystalline layer, i.e. in the real biomineralizate. As already mentioned, it appears that the crystal modification of $CaCO_3$ (calcite, aragonite, etc.) is controlled primarily by the chemical structure of the organic matrix in the corresponding crystal layer.

Although the inorganic components of the shells have been well studied, there is still a considerable lack of information on the chemical structures, and especially about the molecular functions and the synthesis of the (organic) matrix-components and their regulation mechanisms. The

organic matrix of mollusc shells and avian egg shells can easily be prepared by dissolution of $CaCO_3$ crystals (e.g. with EDTA solutions). A fraction that is highly soluble and a fraction that is insoluble in aqueous systems are obtained. The concentration of the total matrix of mollusc shell amounts to 0.01 to 10% depending on the species.[70]

4. Biomineralization Processes in the Formation of Mollusc Shells

4.1. Soluble Matrix

It is assumed that the soluble matrix occurs intracrystalline,[25,71,72] while the insoluble matrix is always localized intercrystalline. The concentration of the soluble matrix components varies remarkably depending on the species of animals (14% to 64% of the total matrix).[26]

The extraction and, in part, purification of a soluble matrix component of *Mercenaria mercenaria* was first reported as late as 1972.[25] It is a water-soluble glycoprotein (M_r ca. 160 kDalton) which is evenly distributed within the shell and exhibits strong negative charges (ester sulfates).[73] The amino acid composition of this sulfated glycoprotein essentially corresponds also to the composition of the insoluble matrix of other mollusc shells (see Refs. [25, 26, 74, 75]).

There is still no information available on the quantity and the relative molecular masses of soluble matrix proteins.[76,77] From our recent observations it can be concluded that, depending upon the age of the shell, very different protein profiles can occur upon gel filtration. The M_r values range from <30 to >5000 kDalton. In freshly shucked oyster shells only two groups of soluble shell proteins (5000 and 500 kDalton) occur. When these proteins are treated with sodium dodecyl sulfate (SDS) solutions they dissociate into subunits (each ca. 15 kDalton) whose amino acid compositions are nearly identical in all the mollusc species studied so far. Accordingly, these high molecular weight, soluble matrix protein aggregates are made up of only a few subunits. The existence of genes which code for 5000-kDalton proteins is very unlikely.[77]

Soluble matrix-proteins bind $Ca^{2\oplus}$ easily. This is understandable because its isoelectric point (I.P.) is about 2. Bicarbonate ions, however, decompose under these conditions into CO_2 and H_2O. Consequently, soluble matrix-proteins cannot be regarded as $CaCO_3$-forming agents. Furthermore, sulfates as well as ester sulfates, are considered as "crystal poisons" (e.g. for $CaCO_3$ crystals). An alternative explanation to circumvent these difficulties of interpretation has been offered by *Wheeler* et al.[78] The soluble, acidic shell proteins could terminate the process of shell formation. These proteins can easily intercept "excessive" amounts of Ca ions; $Ca^{2\oplus}$ ions are then not available for crystal formation. Ca ions that are already excreted cannot be picked up again by a steep $Ca^{2\oplus}$-gradient in the mucosal cells of the mantle epithelium. These ions remain bound to proteins and their charges are thereby neutralized.

Protein chemical studies on fossil mollusc shells are difficult to judge. Very different influences may have altered shell proteins over long periods of time. Therefore, it is never quite clear whether the material examined stems from components of the soluble or the insoluble matrix. Such fossil proteins are often soluble. Even though $CaCO_3$ layers may protect shell proteins from decomposition processes to a certain degree, it is doubtful whether, e.g., after 80 million years glycoproteins are still preserved in their original structure.[79] In this context a thesis has been suggested that during the source of evolution the repeating amino acid sequences $(-Asp-X-)_n$ have been well preserved. This thesis assumes that aspartic acid is the most frequently occurring amino acid next to glycine in shell proteins. This view is based on the assumption that the Ca-binding in soluble shell proteins is determined by the β-carboxy group of aspartic acid.

Other research workers suggest that it is not aspartate,[25,80-82] but asparagine, which has been detected by partial sequence analysis. The repeating sequence in shell protein may rather correspond to $(-Asn-X-)_n$. The Ca-binding is then explained by the presence of ester sulfate.

In spite of various reservations against studies on fossil peptides it is still understandable that the prevailing amino acid sequences are preserved in well conserved fossil oyster shells *(Ostrea carrissima, Lopha diluvianus, Lopha marshi)*. This points to only a small frequency of mutation of the corresponding genes; at the same time it is recognizable that $CaCO_3$ shells have protected "their" proteins from decomposition. Only some amino acid residues differ from the basic pattern. This could be dependent on evolutive or diagenetic processes.[81,82]

Besides the typical soluble shell proteins, polyphenol oxidases have been detected in the soluble matrix of *Crassostrea gigas, Strombus aureus*[59,83] and *Mercenaria mercenaria*.[84] Substrates for these enzymes (tyrosine and other phenolic substances) could be identified in shell matrices. It is possible that the effect of polyphenol oxidases is connected with aggregation or polymerization processes in the insoluble matrix.[83]

4.2. Insoluble Matrix (Conchiolin)

Conchiolin (Span. concha = mussel) has often been described as a group of proteins with an occasionally significant polysaccharide content. The latter seems to be species dependent.[71,80,85] The term "insoluble matrix" has been introduced during the last decade, but it is misleading. Conchiolin can be converted into a soluble form (see Section 5.2.2).

Conchiolin has a high affinity for lipid-staining agents (e.g. sudan black),[86,87] although even after thorough extraction with chloroform-methanol or diethyl ether, no reduced stain and no presence of lipids in the extracts have been detectable.[26] Probably the sudan-black color is due rather to a pigment distribution than to a chemical reaction. Perhaps it is connected with a predominance of aliphatic amino acids in conchiolin.

Studies on conchiolin are relatively scarce. The reason for this is the difficulty of solubilizing this material under mild conditions to give soluble proteins (polypeptides).

Therefore, most studies on the structures of conchiolin have been limited to amino acid data, IR spectra[88] and X-ray diffraction patterns.[85] It can be concluded that antiparallel pleated-sheet structures seem to be predominant.[85] Besides these, low ordered structures have also been reported.[28]

Promising efforts to extract proteins stepwise soon slowed down in the early stages.[89] It has been argued that dissolution of conchiolin proteins by means of aggressive reagents (NaOH, HCl, HCOOH)[89,90] may cause undesirable side-reactions (transformation of lysine into ornithine, deamination reactions, random partial hydrolysis etc.). That conchiolin of oyster shells can be cleaved reproducibly into subunits by SDS-containing solutions was first reported by our working group in 1986.[76] Accordingly, conchiolin is made up of a relatively low number of polypeptides (75 and 40 kDalton). These subunits contain different quantities of sulfated oligosaccharides. From these structures, subunits having I.P. values between >9.3 and 3.1 are derived. Subunits with I.P. values >7.0 simultaneously bind $Ca^{2\oplus}$ and $HCO_3^{\ominus}$. Therefore, they could be regarded as initiation factors of shell formation. Conchiolin subunits with I.P. values <7.0 may rather participate together with soluble matrix proteins in the termination of shell formation. Intact conchiolin of oyster shells in aqueous suspension has an I.P. value of ca. 8.5 and simultaneously binds $Ca^{2\oplus}$ and $HCO_3^{\ominus}$. Sulfate and phosphate ions prevent this binding.[91]

Anti-conchiolin sera not only react positively with soluble proteins of oyster shells, but also with the proteins of the soluble and insoluble matrix of egg shells.[58,76,77,92] This is indicative of relationships between the protein structures of egg shells and mollusc shells.

4.3. Molecular Mechanisms of Mollusc Shell Formation

Based on all the information now available on shell formation in molluscs, the following hypothesis can be proposed: The synthesis of soluble precursor proteins of the shell matrix seems to be localized in the hepatopancreas. Modification reactions of the soluble precursor proteins of the shell (polypeptides), i.e. additions of sulfated oligosaccharides may first take place after transportation into the mantle epithelium. Polypeptides, which occur in the soluble matrix, have relative molecular masses of about 15 kDalton, while polypeptides in the insoluble matrix (conchiolin) have M_r values in the range of ca. 75 kDalton and 40 kDalton.[76]

Figure 5 shows the structure of the mollusc shell. Matrix subunits are accumulated in mucosal cells of the mantle epithelium. $Ca^{2\oplus}$, $HCO_3^{\ominus}$ and conchiolin are excreted into the extrapallial fluid. It is not known whether the aggregation of conchiolin subunits is already accomplished in the mucosal cells or after secretion. The inorganic composition of the extrapallial fluid of marine molluscs is different from that of seawater. In the extrapallial fluid of freshwater molluscs there is less $Ca^{2\oplus}$, but more $HCO_3^{\ominus}$ than in marine molluscs. Furthermore, seasonal fluctuations in the composition of this secretion, and fluctuations which are dependent on physiological conditions of the animal have

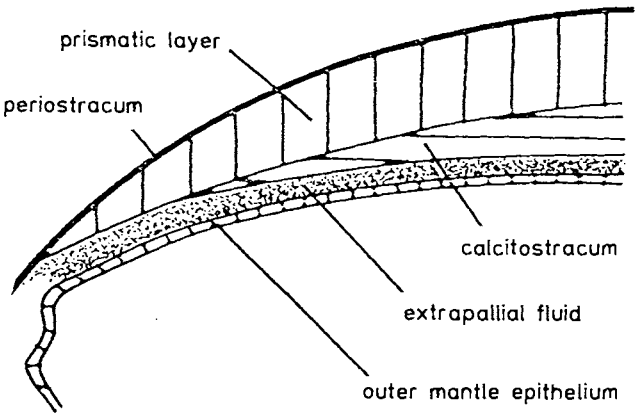

Fig. 5. Structure of the mollusc shell. The prismatic layer and the calcitostracum are made up of biocrystallites. The mantle epithelium secretes the extrapallial fluid (contains all the components for biomineralization). The periostracum is the outer layer of the mollusc shell.

been reported.[26] The contents of organic components have so far rarely been examined.

It must be assumed that aggregates of conchiolin bind $Ca^{2\oplus}$ and $HCO_3^{\ominus}$ simultaneously in vivo, as has been established in vitro.[80] At pH>8.0, precipitation of $CaCO_3$ as primary crystals might be initiated by this mechanism. Since the extrapallial fluid is supersaturated with $Ca^{2\oplus}$ and $HCO_3^{\ominus}$, it is reasonable to assume that further crystal formation is driven by kinetic forces.

Probably the termination of the crystallization process depends on components of the soluble matrix. These are proteoglycan-like, highly-sulfated macromolecules which could serve as Ca scavengers (see Section 5.4). In this way, there is the possibility of separating $Ca^{2\oplus}$ from the reaction with $HCO_3^{\ominus}$. Another function of these substances is understandable in the following context. Proteoglycans are able to inhibit the formation of calcium phosphate crystals[93,94] and calcium oxalate crystals.[56,95,96] The inhibitory effect is explained in terms of simple physical phenomena which are due to interactions of proteoglycans with already existing crystals. These crystals are protected by proteoglycans from a further accumulation of crystals.[93] Moreover high molecular proteoglycans are more effective than the subunits. Depolymerization of high molecular aggregates reduces or even prevents the inhibition effect.[97] Proteolytic enzymes of lysosomal origin are responsible for the deaggregation of high molecular weight proteoglycans, which results in calcification of cartilage.[93,98-103]

Whether both inhibition mechanisms occur during the termination phase of the formation of mollusc shells has not yet been investigated. Nothing is known so far on the regulation of the synthesis of matrix polypeptides and the control of modification reactions. It is possible that hormone-dependent regulation mechanisms exist.[104]

5. Biomineralization Processes in the Formation of Egg Shells

5.1. Function of the Egg Shell

Calcareous egg shells are found in all species of birds, in several reptiles, in monotremata, and in some gastro-

pods.[59, 70] The calcified egg shells protect the contents of the egg from mechanical effects during the extrauterine incubation and permit the exchange of water and gases through the pores. Furthermore, the egg shell prevents desiccation of the egg and the growing embryo in animals, which live in arid areas, particularly in the tropics and subtropics. On the other hand, the relatively thin shell permits exchange of temperature during the incubation period even at very low environmental temperatures (penguins). Eventually the calcareous egg shell is used as a Ca-reservoir for the construction of the embryonic skeleton.[105, 106]

The avian egg shell is morphologically divided into three layers (Fig. 6):

1. Membrana testacea.
2. Biocrystalline layer.
3. Tegmentum (cuticula).

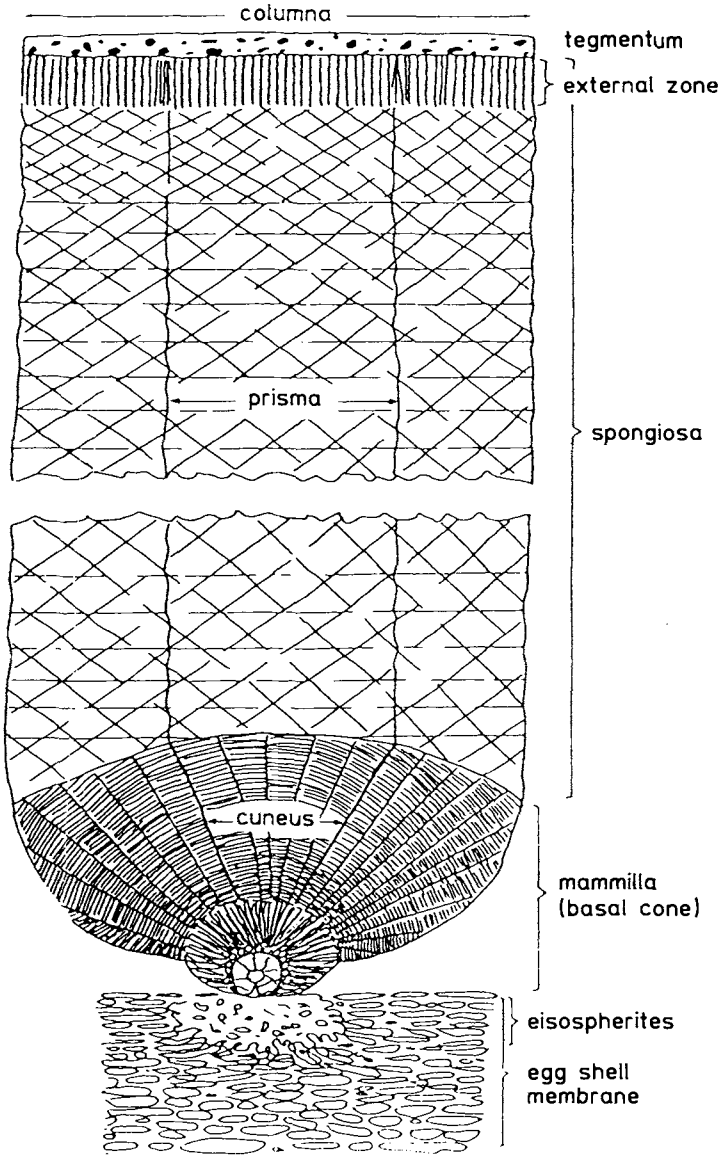

Fig. 6. Structure of the egg shell. The egg-shell membrane (membrana testacea, MT; netlike system of cysteine-rich fiber proteins) serves as elastic support for the process of shell formation. The biocrystallite layer includes the mammilla and spongiosa region as well as the external zone. The tegmentum is the outer layer of the egg shell. Columna, prisma and cuneus describe horizontal limitations of smaller units (biocrystallites) and biocrystals.

5.1.1. *Membrana testacea*

The membrana testacea (MT) of avian egg shells seems to be necessary for the construction of the biocrystalline layer. Under appropriate experimental conditions no egg shell is formed when the membrana testacea is omitted.[107] It is generally accepted that the initial processes of calcification (egg-shell formation) is localized in the mammillary layer of the shell.[105]

The MT can be divided mechanically into two net-like layers. Its biological function is primarily regarded as a filter (microorganisms).

The predominant components of the MT consist of proteins, a very low proportion of which (6%) is soluble in aqueous systems. So far there is considerable uncertainty about the characteristics of insoluble MT proteins.[50, 108–110] Some authors regard them as keratins or ovokeratins;[111] other authors disagree, because the insoluble MT proteins are distinctly different in structure, amino acid composition,[112] and solubility behavior[113] compared to classical keratins. Some consider MT proteins as collagen-like proteins because of the presence of hydroxyproline and hydroxylysine.[114] Others claim to have found elastin-like proteins in the MT.[115]

As long as it is not possible to seggregate MT proteins into soluble subunits under mild conditions and to fractionate these and carefully examine the individual proteins (polypeptides), no further insights can be expected. In this direction experiments have been carried out to study the possibility of an attack of nucleophilic reagents, e.g. $CN^{\ominus}$, on the S atoms of the sterically accessible disulfide bridges. Structure analyses of the fragments (M_r about 3 kDalton) revealed that about 45% of the intact MT is made up of cysteine-rich proteins. The remaining proteins of the MT are linked to sulfated oligosaccharide moieties.[116] Glucose, mannose, xylose, sialic acid[112] and hexosamines[110] were identified as building blocks. Uronic acids seem to be absent.[117] The presence of lipids in MT has been reported[118, 119] (mono-, di- and triacylglycerines, free fatty acids, cholesterol and cholesterol esters, and phospho- and sphingolipids).

Since the MT does not bind any Ca ions it has not been regarded as a factor of the initial phase of calcification. Probably the mesh-system of the MT functions as a support for $CaCO_3$ crystals.[120]

We assume that soluble precursor polypeptides of the MT are synthesized in the liver and in the isthmus section of the laying tract.[82] These precursors are presumably stored in the isthmus portion, from which they are secreted to form aggregates of fiber-like structures.[59] It should be mentioned that soluble precursor polypeptides of cysteine-rich feather proteins are also synthesized in the liver.[127]

5.1.2. *Tegmentum (cuticula)*

The avian egg shell is covered by a cuticula (tegmentum), which is made up of two layers. The tegmentum of freshly layed eggs has a reddish fluorescence, which depends on a so called "ooporphyrin". These layers are es-

sentially composed of glycoproteins. They do not participate in the calcification of the shell.

5.2. Organic Matrix of Avian Egg Shells

The biocrystallite layer of avian egg shell, like mollusc shells, contains organic compounds which collectively have been described as an organic matrix. It consists of a protein–oligo(poly)saccharide complex with a low content of lipids and water.[115] Glucosamine, galactosamine, mannose and fucose have been identified as building blocks of the oligo- or polysaccharides. The presence of chondroitin sulfate A and dermatan sulfate has also been reported.[117] Sialic acids are said to occur in small amounts. The evidence for matrix proteins in avian egg shells rests on amino acid analyses after HCl-hydrolysis of the organic matrix.

The organic matrix of egg shells can be likewise divided into a soluble and a water-insoluble fraction after dissolution of the mineral phase.

5.2.1. Soluble Matrix

Because of their high solubility in water and aqueous salt solutions, those macromolecules of the organic shell matrix have been studied preferentially. Shells of freshly layed eggs, similarly as freshly shucked oyster-shells, yield two groups of soluble protein-containing macromolecules (5000 and 500 kDalton). In hot SDS solution, both high molecular aggregates fall apart into relatively small subunits of about 15 kDalton.[77] With increasing age of egg shell smaller fragments appear (<30 kDalton). The I.P. of these subunits is in the range of 2.2 and enables these substances to bind $Ca^{2\oplus}$. This typical subunit (of about 15 kDalton) contains highly sulfated oligosaccharides, which are attached to the polypeptide structure. Functionally, this 15 kDalton-subunit of the soluble matrix is regarded as a termination factor of shell formation,[58] even though not every observation on shell formation can be explained in this way only.

Another soluble component of the shell matrix is carbonic anhydrase (carbonate-dehydratase) which occurs in the chicken egg shell in the form of two active isoenzymes (M_r ca. 28 kDalton). This enzyme catalyzes the reversible reaction

$$CO_2 + HOH \rightleftharpoons H^{\oplus} + HCO_3^{\ominus}$$

This is probably the primary function of this matrix enzyme, even though it concomitantly exhibits an esterase-activity.[106, 123, 124] The same enzyme occurs in the shell gland of laying hens. Its activity depends on the laying cycle. During molting a low activity is observed in the shell gland,[125, 126] which is influenced by progesterone.[127, 128] The shell gland enzyme is closely related with the formation of the biocrystallite layer of the shell, since acetazolamide and other sulfonamides, as inhibitors of carbonic anhydrase, also reduce the rate of shell formation.

The functions of the shell enzyme probably include the provision of hydrogen carbonate for calcification processes, and also the local dissolution of the shell. Through this phenomenon, which is often observed in the form of resorption-craters in hatched eggs[75, 105, 129–131] calcium of the biocrystalline layer can be provided for the construction of the embryonic skeleton.[59] Participation of carbonic anhydrase in the termination process of the shell formation is very likely. When carbonic anhydrase catalyzes the reaction

$$H_2CO_3 \rightleftharpoons H_2O + CO_2$$

there is no more $HCO_3^{\ominus}$ available for the formation of $CaCO_3$. The presence of so-called globular inclusions in $CaCO_3$ crystals of the egg shell and perhaps pore formation in the egg shell are due to gaseous CO_2.

5.2.2. Insoluble Matrix

The insoluble matrix of egg shells has scarcely been studied as yet. It was merely known that it must be composed of proteins and polysaccharides with low contents of water and lipids.[115]

From our studies on conchiolin,[91] it could be established that the insoluble matrix of egg shells is able to bind $Ca^{2\oplus}$ and $HCO_3^{\ominus}$ simultaneously.[92] The insoluble matrix has a pH of ca. 8.5 in aqueous suspension. This can help to explain the binding properties for $Ca^{2\oplus}$ and $HCO_3^{\ominus}$ and, thus, how primary crystals are formed.

Analogous to studies on conchiolin[76] the insoluble matrix of chicken egg shells could be split by treatment with SDS into subunits and then fractionated.[58] Remarkably, the insoluble matrix of egg shell is made up of only a few polypeptides (discovered so far: 50, 16 and 14 kDalton). However, there are multiple modifications of these polypeptides due to sulfated oligosaccharides, which influence the binding capability for $HCO_3^{\ominus}$. All modified subunits bind $Ca^{2\oplus}$. Nevertheless, only such subunits with I.P. values of >7.0 have an additional affinity for $HCO_3^{\ominus}$.

Subunits of the insoluble matrix of egg shells react positively with anti-conchiolin sera; also positive immunoreactions of anti-shell-matrix sera and subunits of conchiolin have been reported.[58, 77] Anti-shell-matrix sera react very strongly with the cytosol of mucosa cells of the chicken shell gland. This demonstrates the occurrence of components of shell matrix in these cells only.[58]

5.3. Synthesis of Shell Proteins

According to our own studies, soluble precursor polypeptides of egg shell matrix are synthesized in the liver.[58] The primary products of the synthesis include only a few soluble polypeptides (detected so far: 60, 40, 14, 12 kDalton), which are modified in subsequent reactions (limited proteolysis, polysaccharide addition, oligosaccharide addition, and sulfation reactions). The modification steps could take place in the liver or in the shell gland. The transportation of the primary products or secondary products proceeds from the liver through the blood to the shell gland. The modification reactions should occur, at latest, in the shell gland. Two sorts of secondary products exist. The same 12-kDalton polypeptide is attached to sulfated

polysaccharide molecules, which then aggregate to form suprastructures (ca. 5000 kDalton) and resemble proteoglycans. These structures correspond to the soluble matrix. It is unknown whether aggregates or subunits of matrix are accumulated or secreted by mucosal cells of the shell gland. Probably the 50- and the 14-kDalton polypeptides (insoluble matrix) are only slightly modified (oligosaccharide units, no sulfation), stored, and secreted from the mucosal cells. Presumably only modified subunits are secreted since no shell-protein aggregates are detectable in the uterine secretion. Such polypeptides also aggregate to form suprastructures at latest on contact with fibrils of the membrana testacea. These suprastructures correspond to the insoluble matrix (cf. Fig. 7).

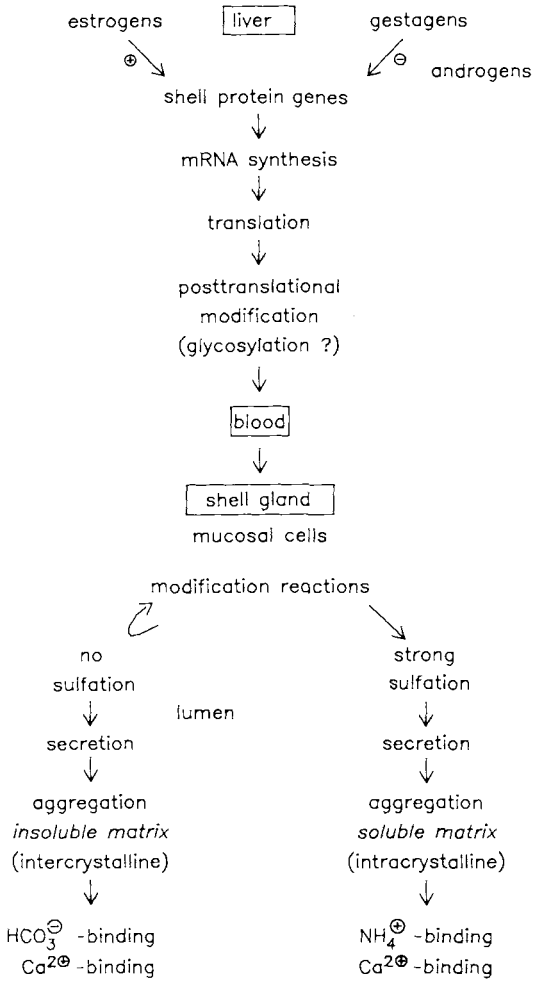

Fig. 7. Schematic representation of egg-shell protein synthesis (for details see text).

A very important question here concerns the regulation mechanisms of the hepatic synthesis of precursor polypeptides of the egg-shell matrix. We have worked on this problem because it is of practical importance and could help to answer questions relating to the formation of thin chicken egg shells (cracked eggs). Present experimental results show that the hepatic shell protein synthesis depends on the estrogen status and functional mechanisms of the liver. Antiestrogens, e.g. tamoxifen, inhibit shell protein synthesis as do androgens, gestagens, and typical liver poisons (α-amanitin and phalloidin).[77] There are direct correlations between high estrogen levels in laying hens and liver damage. Animals with high laying rates and high estrogen production frequently suffer from fatty-liver hemorrhagia syndrome.[132] This is already a pathological situation. Additional adminisitration of estrogens (17β-estradiol or diethylstilbestrol) to animals with high laying rates results in massive liver damage and terminates egg production and the synthesis of shell protein precursors in the liver.[133] These observations can help to explain the reasons for the formation of thin chicken egg shells.

5.4. Molecular Mechanisms of Egg Shell Formation

Although there is little information available about the molecular mechanisms of the formation of egg shells, we will nevertheless try to construct a working hypothesis. All of the components necessary for the formation of the egg shell are accumulated in the shell gland prior to secretion. It is not clear, whether the individual components are stored for a longer period of time in the mucosal cells (MC) of this gland. A signal for the secretion of these substances is apparently triggered by a mechanical stimulation through rotation of the shell-free egg in the gland. This effect can be induced, e.g., with a ping-pong ball whose surface is covered with a layer of membrana testacea. The thus prepared ping-pong balls must not be fixed in the shell gland. Under these conditions (rotating ping pong ball), the deposition of a shell occurs on an artificial support.[107]

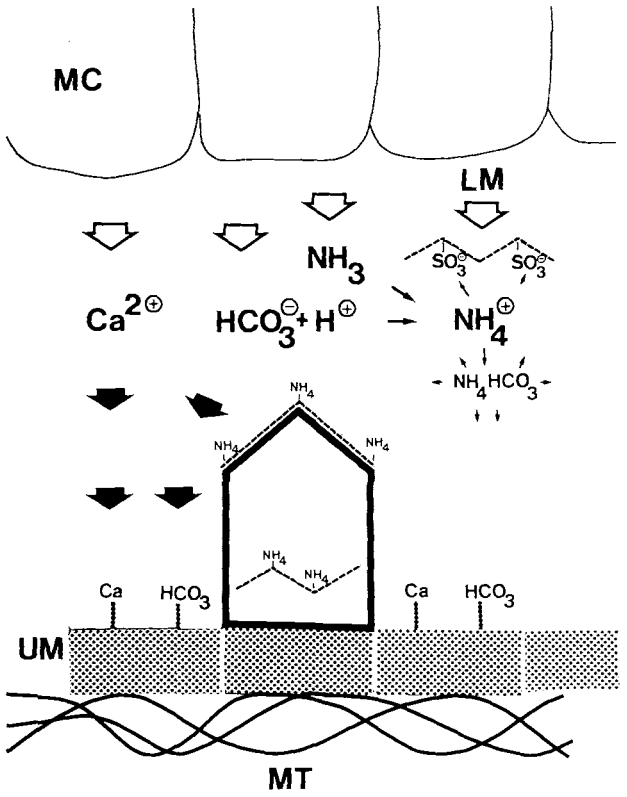

Fig. 8. Molecular mechanisms of shell formation: Initiation phase. Mucosal cells (MC) of the shell gland secrete $Ca^{2\oplus}$, $HCO_3^{\ominus}$, aggregates of the insoluble matrix (UM), aggregates of the soluble matrix (LM) and NH_3. First of all the UM is deposited on the egg shell membrane (MT) and simultaneously binds calcium and hydrogencarbonate ions. Primary crystals ($CaCO_3$) and $H^{\oplus}$ are formed. Protons react with NH_3 to give $NH_4^{\oplus}$. Ammonium ions are bound by sulfate groups of the LM and by hydrogencarbonate ions.

It must be assumed that subunits of insoluble matrix (UM) are first deposited on the membrana testacea (MT) and form the insoluble matrix. These aggregates are able to bind $Ca^{2\oplus}$ and $HCO_3^{\ominus}$ (pH > 8.0) simultaneously, and to form primary crystals (Fig. 8). This is only possible, when the protons that are formed can be eliminated. Ammonia can possibly serve as proton scavenger. Ammonia is produced in relatively high concentrations during shell formation.[134,135] Adenosine-deaminase has been identified as an ammonia producing enzyme in the shell gland. This enzyme obviously deaminates adenosine (uric acid is the final product of protein metabolism in birds) and eliminates NH_3 through the laying tract. Besides NH_3, other poisons, e.g. Be, Hg, Cd, are removed from the organism[136] by egg deposition. NH_3 intercepts protons according to the following equation:

$$Ca^{2\oplus} + HCO_3^{\ominus} + NH_3 \longrightarrow CaCO_3 + NH_4^{\oplus}$$

A reabsorption of $NH_4^{\oplus}$ by mucosal cells is possible but very difficult. Therefore $NH_4^{\oplus}$ must remain at the site of calcification. The situation is understandable if the soluble matrix (LM) is included in this reaction. The soluble matrix produces large quantities of ammonia after HCl hydrolysis (at least 60–80% of the ninhydrin-positive substances of LM). Obviously LM binds $NH_4^{\oplus}$ by means of its large number of ester sulfate residues. Probably a further but smaller portion of $NH_4^{\oplus}$ reacts with $HCO_3^{\ominus}$ to form NH_4HCO_3; this reaction helps to stabilize a slight alkaline milieu and thereby creates favorable conditions for the formation of $CaCO_3$ crystals (pH > 8.0). In addition, the intracrystalline presence of soluble matrix can be explained. The insoluble matrix is always intercrystalline (cf. Fig. 9). Since the proteins of the soluble and insoluble matrices have very similar amino acid compositions, it is very likely that they have similar amino acid sequences. At the positions which determine the crystal shape the sequences may be identical.[*]

Presumably the insoluble matrix is deposited at the latest, when a transition from one morphological layer of the shell to another is necessary, e.g. within the mammilla and within the spongiosa layer (see also Fig. 6).

The termination of egg shell formation is probably initiated by the action of carbonic anhydrase, which forms gaseous CO_2 from H_2CO_3 (Fig. 10). Therefore $HCO_3^{\ominus}$ is available for $CaCO_3$ formation; the interception of $H^{\oplus}$ is unnecessary. This means, that the secretion of NH_3 is not necessary any more. Excess of $Ca^{2\oplus}$ can be bound by the sulfate groups, while a reabsorption of $Ca^{2\oplus}$ by mucosal cells against a steep $Ca^{2\oplus}$-gradient is not possible. The formation of gaseous CO_2 is likely; this might help to explain the occurrence of globular inclusions in $CaCO_3$ crystals. It is still uncertain, however, whether pore formation is due to the production of CO_2. Pores and carbonic anhydrase have been found in egg shells, whereas both are absent in mollusc shells.

[*] Determination of the sequence is very difficult, because the fragmentation is scarcely reproducible. Shell proteins cannot be hydrolyzed by any proteolytic enzymes known thus far. A fragmentation by appropriate chemical reactions is also impossible, because the requisite amino acids (e.g. methionine) do not occur in these proteins.

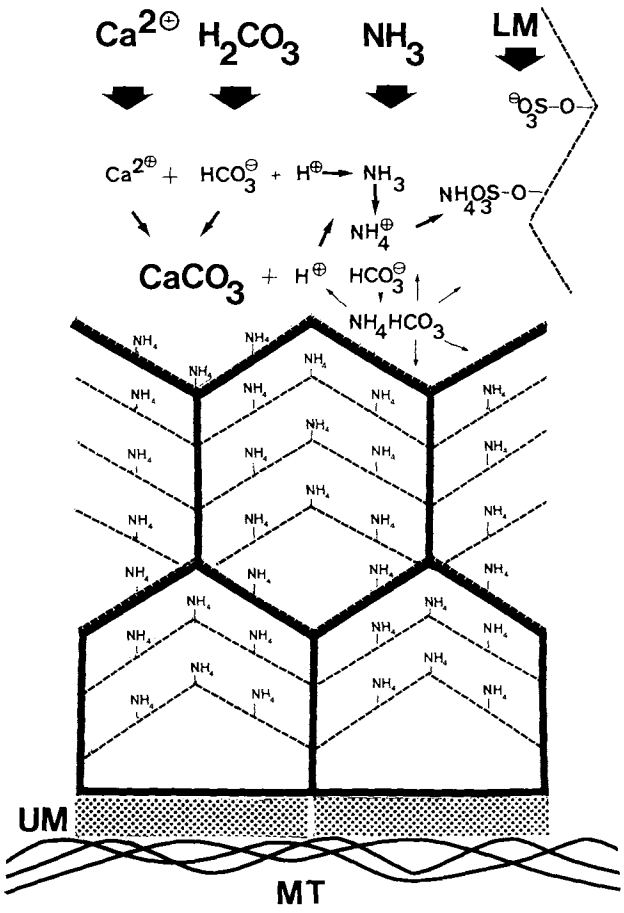

Fig. 9. Molecular mechanisms of shell formation: Elongation phase. The process outlined in Figure 8 continues and leads to crystal growth with intracrystalline inclusion of the soluble membrane (LM) (after reaction with $NH_4^{\oplus}$). The insoluble membrane UM is presumably deposited between crystalline layers (see Fig. 2).

A reduced synthesis of shell proteins automatically leads—according to the above mentioned hypothesis—to a decreased binding of $NH_4^{\oplus}$ to the soluble matrix, even when sufficient amounts of $Ca^{2\oplus}$ and $HCO_3^{\ominus}$ are present. Protons can be only insufficiently intercepted by NH_3, even when a small portion of $NH_4^{\oplus}$ is formed. $HCO_3^{\ominus}$ is then not available at the site of crystal formation. Protons in excess dissolve already existing $CaCO_3$ crystals.

A decreased synthesis of shell proteins results in thin egg shells (cracked egg syndrome). As a supervisory system, the estrogen status controls the rate of synthesis of shell proteins[133] and of carbonic anhydrase,[127] and eventually the shell formation. It is thus clear why the egg shell quality cannot be improved merely by feeding laying hens a diet high in calcium.[137]

The molecular mechanisms of mollusc shell formation may be similar to those described for egg shell formation. Not very much is known about the synthesis of mollusc shell proteins and their regulation.

6. Summary and Prospects

Biomineralization processes are widespread in nature. They differ from geological mineralization processes by

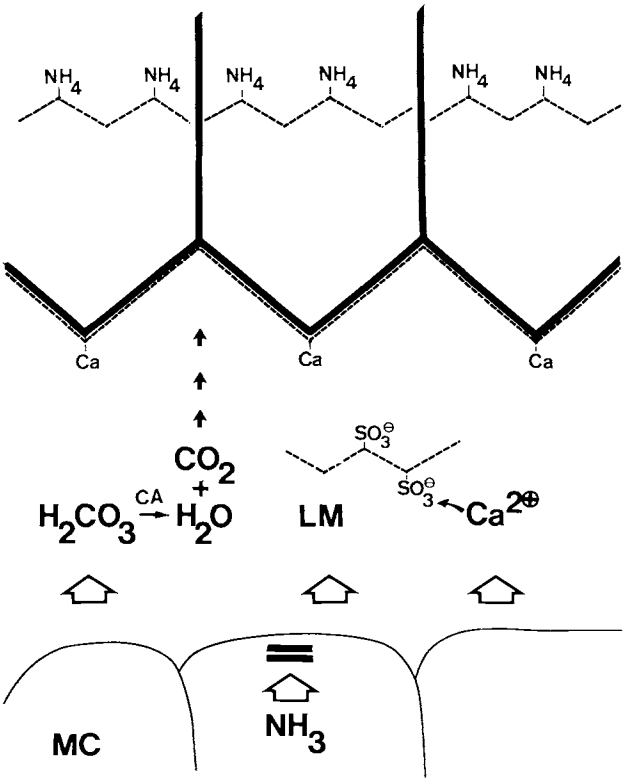

Fig. 10. Molecular mechanisms of shell formation: Termination phase. The mucosal cells (MC) of the shell gland first terminate the secretion of NH_3. In the lumen of the shell gland, secreted carbonic anhydrase (CA) forms gaseous CO_2, while excess Ca ions are bound by sulfate groups of the soluble membrane (LM). This leads to the termination of the secretion process (for details see text).

the existence of organic matrices. Organic matrices frequently include proteins (collagen, dentin, conchiolin, etc.); occasionally they are made up exclusively of polysaccharides (coccoliths). Inorganic crystals are deposited on a matrix (mineral phase), their form and dimensions being determined by the structure of the matrix. The matrix components can, in some cases, be separated into a water-soluble fraction and an insoluble part.

Biological calcification processes may have originally developed from a detoxification mechanism. The Ca ion concentration is carefully regulated because of its pharmacological effects in living cells. An excess of $Ca^{2\oplus}$ is removed from the cytoplasm and transported preferentially into the extracellular space. Appropriate counterions (phosphates, bicarbonate, rarely sulfates) react with $Ca^{2\oplus}$ to form depositions. They can be found to form exoskeletons (mollusc shells) or endoskeletons (vertebrates).

Using the example of egg shell formation, the interactions of organic matrix components with $Ca^{2\oplus}$, $HCO_3^{\ominus}$, and NH_3 can be demonstrated. In this case soluble matrix-precursors (polypeptides) are synthesized in the liver, whereas the secretion of the matrix proteins together with $Ca^{2\oplus}$, $HCO_3^{\ominus}$ and NH_3 takes place in the shell gland of the laying tract. NH_3 serves as proton interceptor and is bound as $NH_4^{\oplus}$ by the ester sulfate residues of the soluble matrix. The latter is intracrystalline. The rate of synthesis is regulated by the estrogen status. A high estrogen level causes liver damage. Decreased liver-function reduces the rate of synthesis and results in thin egg shells. The synthesis of soluble matrix precursors in the liver is regulated by a normal estrogen level and is dependent on a well-functioning liver. These findings should be born in mind in all future animal-breeding programs.

There is already the possibility of examining the structure of shell matrix genes in detail by means of a "gene-library" of the chicken genome. From these studies, information on possible mutations could be obtained.

Our studies mentioned here were generously supported by the Deutsche Forschungsgemeinschaft.

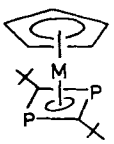
1,4-Diphospha-2-rhodacyclopentadiene—an Isolable Intermediate in the Metal-Induced Cyclodimerization of *tert*-Butylphosphaacetylene**

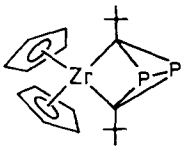
By *Paul Binger,* Bruno Biedenbach, Richard Mynott, Carl Krüger, Peter Betz,* and *Manfred Regitz*

Cyclodimerizations of *tert*-butylphosphaacetylene **3** in the coordination sphere of a metal atom have only recently been reported. Depending on the metal, one obtains either the 1,3-diphosphacyclobutadiene complexes **1**[1,2] (M = Co, Rh) or the 1,3-diphosphabicyclo[1.1.0]butanediyl complex **2**.[3] 1,4-Diphospha-2-metallacyclopentadienes, formed by oxidative coupling of two phosphaalkynes at the metal center, have been postulated as intermediates in these reactions.[1b] We have now succeeded in isolating and characterizing such a species for the first time. This species was shown to undergo transformation to a corresponding 1,3-diphosphacyclobutadiene complex in solution.



1

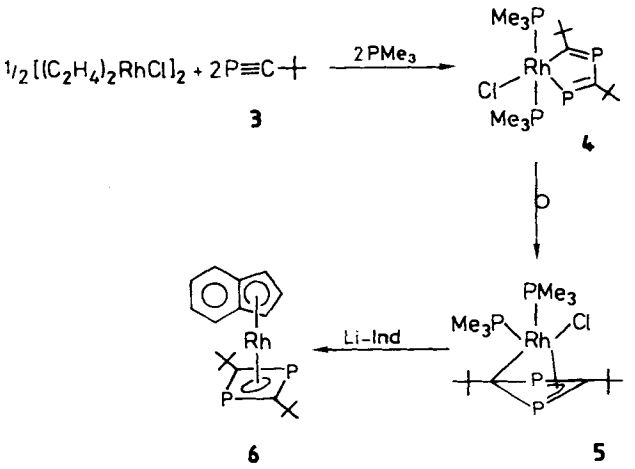
M= Co,Rh



2

Reaction of $[(C_2H_4)_2RhCl]_2$ with trimethylphosphane and *tert*-butylphosphaacetylene **3** in a molar ratio of 1:4:4 at 0°C resulted in the formation of a 1:2 mixture (^{31}P NMR) of the two rhodium complexes **4** and **5**, which could be separated by extraction with pentane and ether. The known rhodium complex $[(Me_3P)_2RhCl]_2$[4] is presumably formed as an intermediate in this reaction, but it was not isolated.

The X-ray crystal structure analyses of the two new rhodium complexes show that **4** is a chlorobis(trimethylphosphane)-1,4-diphospha-2-rhodacyclopentadiene derivative and that **5** is the corresponding 1,3-diphosphacyclobutadiene derivative.[5] The structure of **4** (Fig. 1, top) is



3 **4** **5** **6**

best described as a distorted octahedron, whose base is defined by the atoms P1, C5, Cl, and a fourth, vacant coordination site; the apices are occupied by P3 and P3*. The heterocycle lies in the crystallographic mirror plane of the molecule. The P1–C1 and P2–C5 distances (1.685(4) and 1.710(4) Å, respectively) fall in the range for PC double-bond distances.[6] The Rh–P1 and Rh–C5 distances (2.235(1) and 1.980(3) Å, respectively) also agree with expectations. Furthermore, the spectroscopic data (MS, ^{31}P and ^{13}C NMR)[7] are in agreement with this structure.

Complex **5** has a distorted tetrahedral structure (Fig. 1, bottom). The P_2C_2 four-membered ring is nonplanar, forming a dihedral angle of 5.1° between the two CP_2 planes. Whereas the bonds Rh–P1 and Rh–P2 are roughly of the same length (2.381(1) and 2.397(1) Å, respectively), the distance Rh–C1 (2.179(3) Å) is markedly shorter than Rh–C6 (2.307(3) Å, *trans* effect of the chlorine atom). In agreement with these findings, two sharp multiplets at $\delta = 84.5$ and 149.8 are observed for C1 and C6 in the ^{13}C NMR spectrum of **5**;[7] i.e., no rotation of the ring is apparent at 40°C. A slow exchange of C1 and C6 could only be demonstrated by ^{13}C 2D NMR exchange spectroscopy.[8] The large difference in the chemical shifts of the ring C atoms[9] and the spin–spin coupling constants[7] show that the bonding of the P_2C_2 ring to the Rh atom is best described as η^1,η^2 bonding.

By reaction with indenyllithium, complex **5** can be transformed into the known complex[10] η^4-(2,4-*tert*-butyl-1,3-diphosphacyclobutadiene)-η^5-indenylrhodium **6** (12 h stirring at 20°C in THF, yield 60%; ^{31}P NMR: $\delta = 35.6$ (d, $J_{Rh,P} = 31.3$ Hz)). It can also be shown by ^{31}P and ^{13}C NMR spectroscopy that complex **4** slowly rearranges to **5** in solution at room temperature (in 24 h, 40%). Thus, 1,4-diphospha-2-metallacyclopentadienes are clearly intermediates in the η^4-diphosphacyclobutadiene–metal complex formation (e.g., of **1**). Even the synthesis of the zirconium compound **2** can be interpreted quite well in terms of this intermediate.

Experimental Procedure

$[(C_2H_4)_2RhCl]_2$ (3.24 g, 8.3 mmol) was dissolved in 100 mL of THF at 0°C and trimethylphosphane (2.57 g, 34 mmol) was added to the solution, which was then stirred for 1 h at 0°C. Compound **3** (3.3 g, 33 mmol) dissolved in 30 mL of THF was then added dropwise over 2 h and the resulting reaction solution was stirred for an additional 2 h. All volatiles were removed at 10^{-2}

torr, the residue was extracted with 60 mL of pentane, and the filtered solution was concentrated to one-half of its original volume and then diluted with 15 mL of diethyl ether. Cooling the solution to −60°C resulted in the crystallization of **4** (0.68 g, 8.4%; reddish-brown crystals). The solid residue of the pentane extraction was dissolved in 50 mL of diethyl ether, filtered through Al_2O_3, and kept at −20°C for 24 h. Orange crystals of **5** were thereby obtained (2.3 g, 28%, dec. >146°C).

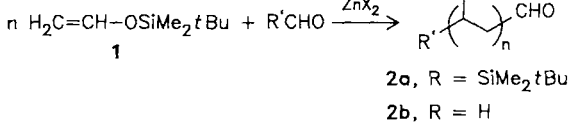
Synthesis of Oligomeric and Polymeric Monosaccharides by Aldol Group-Transfer Polymerization**

By *Günter Wulff,* Paul Birnbrich,* and *Achim Hansen*

Following the earlier described group-transfer polymerization of acrylates,[1,2] an aldol group-transfer polymerization (aldol-GTP), involving the Lewis acid-catalyzed reaction of trialkylsilyl vinyl ethers **1** with aldehydes, has recently been reported[3] (see Scheme 1). Cleavage of the silyl groups affords oligomeric or polymeric polyvinyl alcohols **2b**.



1

2a, R = $SiMe_2tBu$
2b, R = H

We have now succeeded in carrying out an aldol-GTP on the enediolate 2-phenyl-1,3,2-dioxaborole **5** producing oligomeric and polymeric monosaccharides (see also Ref. [2a], p. 74). The dioxaborole **5** was originally prepared via an anthracene adduct through retro-Diels–Alder reaction.[4,5] Now, it can be obtained more readily from 2-phenyl-1,3,2-dioxaborolane **3** (prepared from phenylboronic acid and ethylene glycol) by photochlorination with sulfuryl chloride to give the monochloro derivative **4** and sub-

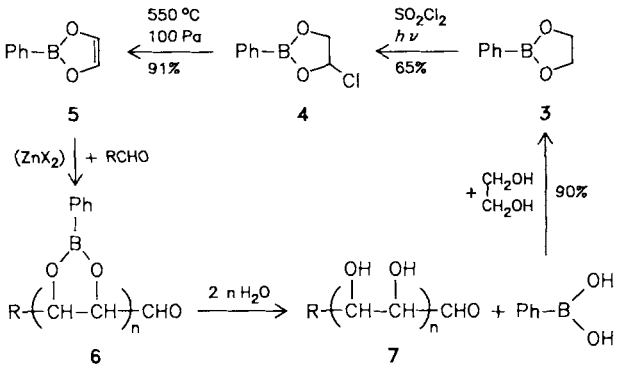
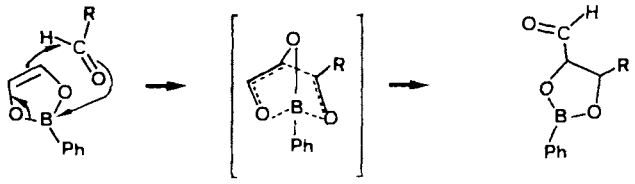
sequent thermal elimination of HCl. Dioxaborole **5**, prepared in this manner, contains trace amounts of HCl; however, this is advantageous for catalyzing the aldol-GTP reaction and does not initiate cationic polymerization.



The heterocycle **5** undergoes an aldol reaction with an aldehyde to give, initially, the mono- and diaddition products, both of which could be isolated.[4,5] In both cases, the reaction products still contain a reactive aldehyde group. As a result, in the presence of excess **5**, the reaction directly leads, without addition of a catalyst, to oligomeric and polymeric products **6**.[6] Compound **5** reacts with aldehydes much faster than with silyl enol ethers **1**. This acceleration of the reaction rate may be attributed to the participation of the boron atom in the transition state of the reaction (see Scheme 1). The reaction rate is significantly enhanced by the addition of zinc halides.



Scheme 1.

The terminal aldehyde group in the polymers **6** and **7** is present in equilibrium with pyranoid and furanoid hemiacetals, as was shown previously for diaddition products.[4,5] However, it can also react as an aldehyde, for example with 2,4-dinitrophenylhydrazine to give the corresponding hydrazone derivative. Furthermore, addition of new monomer, even after several hours, leads to a continuation of the polymerization, resulting in the formation of a high-molecular-weight polymer having monomodal molecular weight distribution; therefore, this process can be described, according to the definition of *M. Szwarc* et al.,[7] as a living polymerization.

Preliminary investigations on the constitution of the polymers indicate that exchange processes occur in the boron-containing polymer **6**. The five-membered 1,3,2-dioxaborolane structures are partially transformed into the six-membered 1,3,2-dioxaborinane structures, similar to the earlier observations made by *R. Köster* et al.[8] in the case of ethylboronates of sugar alcohols. In analogy with the results obtained in the low-molecular-weight range,[5] presumably the chains in the deprotected polymers **7** primarily contain isotactic and heterotactic triads. In the polyvinyl alcohols **2**, on the other hand, a random arrangement is found.

As shown in Table 1, the molecular weight can be controlled by the ratio of initiator to monomer, suggesting the occurrence of a transfer-free polymerization. Furthermore, the polydispersity indices of the polymers (Table 1) reveal a largely non-terminated polymerization. Polymers having molecular weights between 700 and 130000 were prepared. Both mono- and dialdehydes can be employed as initiators, the former producing monofunctional macromers, the later producing bifunctional telechelics. Both types of polymers can be used as building blocks for the construction of complex polymeric materials. This holds particularly true for unsaturated oligomers (Table 1, entries 1 and 2).

The boronic acids can be cleaved hydrolytically from the oligomers and polymers if the phenylboronic acid is removed from the equilibrium. The phenylboronic acid can be reused, so that, in principle, it is possible to synthesize the products **7**[6] starting from ethylene glycol. These are oligomeric or polymeric monosaccharides and can be used directly as macromers or telechelics. Interestingly, the higher-molecular-weight products are no longer water-soluble, as has already been shown for the products obtained by polymerization of vinylene carbonate followed by removal of carbonic acid.[9]

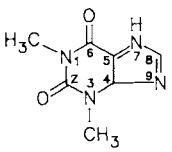
Trimethylplatinum-Theophylline Hexamer: A Novel Pt_6 Heterocycle Containing Both Pt-N and Pt-O Bonds**

By *Jörg Lorberth*, Werner Massa, Mohy E.-Essawi,* and *Lilian Labib*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

In the trimethylplatinum series $[Me_3Pt-X]_n$, the only known compound for $n=1$ is $[Me_3PtC_5H_5]$.[1] Several 1,3-diketone complexes containing Pt-O and Pt-C bonds are known for $n=2$;[2,3] no compounds are known for $n=3$. The largest number of compounds have been reported for $n=4$; these have "cubane-like" frameworks in which halogens, pseudohalogens, and similar ligands bridge three Pt atoms; examples have been reported for X = Cl,[4,5] Br,[6] I,[7,8] N_3,[9] SCN,[10] OH,[11] and SCH_3.[12,13]

Trimeric units have been postulated for trimethylplatinum complexes of the anion of the pharmacologically active purine base theophylline (Hthp) on the basis of NMR



Theophylline (Hthp)

spectroscopic data and osmometrically determined molecular weights.[14] Using modified conditions, we have obtained crystals of Me_3Pt-thp·$2CHCl_3$; its X-ray structure analysis[19] surprisingly revealed the following novel structure: Trimethylplatinum-theophylline is present as hexameric units having symmetry $\bar{3}$ (C_{3i}), in which one Me_3Pt group is coordinated in a *cis* fashion by N7 and N9 of neighboring purine molecules; a Pt-O bond to O6 of a guanine framework completes the distorted octahedral coordination of the Pt atoms. The extent of the slight octahedral distortion is revealed by the "*cis*" bond angles of 82-98° and the "*trans*" bond angles of 172-177° (Fig. 1).

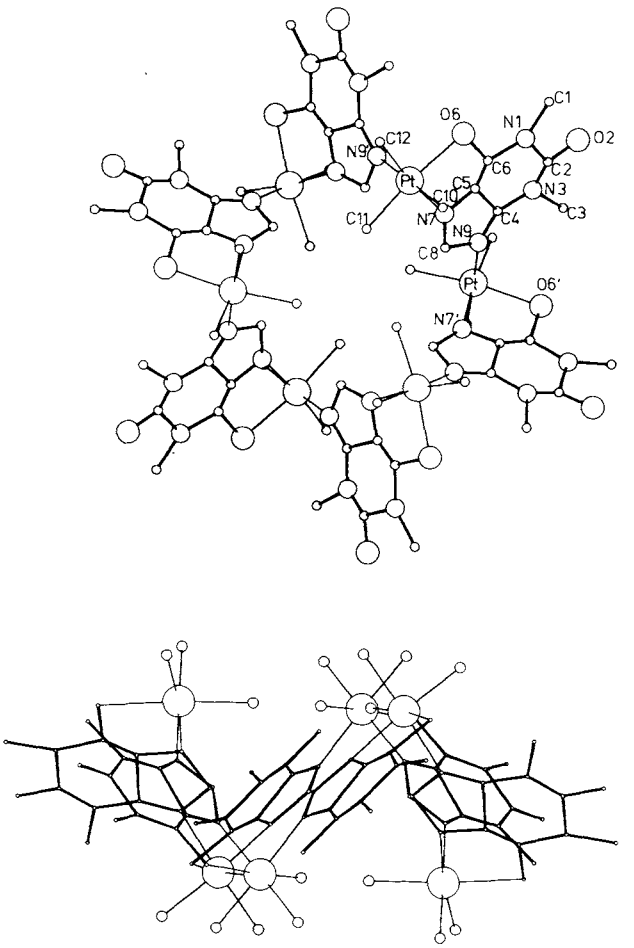


Fig. 1. Molecular structure of the hexamer $[Me_3Pt\text{-thp}]_6$ of $[Me_3Pt\text{-thp}]_6 \cdot 12CHCl_3$. Top: View along the $\bar{3}$ axis (arbitrary atomic radii). Bottom: Side view of the molecule. Important bond lengths [pm] and angles [°]: Pt-N9 221(2), Pt-N7′ 217(2), Pt-O6′ 234(2), Pt-C10 205(2), Pt-C11 207(2), Pt-C12 207(3), N1-C1 148(3), N1-C2 141(3), C2-O2 122(3), C2-N3 139(3), N3-C3 148(3), N3-C4 141(3), C4-N9 133(3), C4-C5 136(3), C5-C6 140(3), C6-O6 129(3), C5-N7 137(3), N7-C8 137(3), C8-N9 138(2), C6-N1 137(3); N9-Pt-N7′ 85.3(6), N9-Pt-O6′ 92.5(7), N9-Pt-C11 94.2(8), N9-Pt-C12 91.2(9), N9-Pt-C10 175.8(9), N7′-Pt-O6′ 78.8(7).

The Pt-N distances (217 and 221 pm) and Pt-O distance (234 pm) are in the range expected from comparable $[Me_3Pt-X]_4$ tetramers (Table 1); the Pt-C distances (205-207 pm) are nearly identical with those in the tetramers. A side view of the hexamer in Figure 1, bottom, shows more clearly the salient features of this structure: the six thp ligands are oriented by a *cis*-arrangement of neighboring guanine rings (as observed in the complexation of Pt^{II} complexes by DNA) and, additionally, by a Pt-O bond (which completes the octahedral coordination of the Pt^{IV} atom) in such a way that they lie in a layer with three Me_3Pt groups on either side.

The presence of a Pt-O bond in addition to the expected Pt-N bonds is new: even in cases where this should, in

principle, be possible for Pt^{IV} atoms, e.g., in a *trans*-$[(NH_3)_2Pt^{IV}$(1-methylcytosine)] complex,[15] chelate ring formation through nitrogen atoms is observed exclusively; this problem has been discussed in detail.[16] Chelate complexes of titanocene with xanthine[17] and theophylline[18] show, in the case of xanthine, the unique presence of two N,O-coordinated as well as one N,Cl-coordinated titanocene group, whereas, for theophylline, only a 1 : 1 complex with titanocene (N7-O6 coordination) is formed.

Experimental Procedure

An aqueous solution (20 mL) containing the potassium salt of theophylline (0.38 g, 0.17 mmol) was added dropwise at room temperature to a solution of $[Me_3Pt(H_2O)_3]_2SO_4$ (0.5 g, 0.086 mmol) in 20 mL of water. The resulting solution was refluxed for 5 h and then filtered. The filtrate was concentrated under vacuum and the solid, white residue was recrystallized from dry acetonitrile. White crystals, m.p. >215°C (dec.), were obtained. Yield: ca. 50%. For the X-ray crystal structure analysis, a small sample was recrystallized from dry $CHCl_3$.

[19] Crystal structure determination of $C_{10}H_{16}N_4O_2Pt \cdot 2CHCl_3$: space group $R\bar{3}$, $a = 2220.7(8)$, $c = 2231.4(9)$ pm, $Z = 18$, 1322 unique reflections with $F_0 > 5\sigma$ were measured on a four-circle diffractometer (CAD4, Enraf-Nonius) with $Mo_{K\alpha}$ radiation at 163 K; no absorption correction ($\mu = 70.9$ cm^{-1}). Application of anisotropic temperature factors for Pt and Cl (136 parameters, H atoms omitted) gave residual indices of $R = 0.054$, $R_w = 0.049$ ($w = 1/\sigma^2(F_0)$). Despite the low temperature of measurement, the two $CHCl_3$ molecules exhibit in part very high temperature factors, indicating the existence of disorder, which may have affected the results of the refinement. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53 187, the names of the authors, and the journal citation.

Naked Molecule Chemistry: Different Bonding Modes of CO to FeX_2**

By *Ian R. Beattie,* Susan D. McDermott, Elizabeth A. Mathews, Keith R. Millington,* and *Andrew D. Willson*

It is well established that many metal halides isolated in inert gas matrices can interact with dopants such as CO to give species showing ν_{CO} in the IR spectrum to *high* frequency of the isolated CO molecule. *Hauge* et al.[1] have summarized much of this work by showing how $\Delta\nu_{CO}$ (the shift of ν_{CO} in the "complex" from that of free CO) varies as a function of the formal metal charge divided by the square of the "metal to CO distance". Similar data have recently been given for CO on metal oxide surfaces.[2]

When iron(II) halides are cocondensed at 12 K with argon doped with CO, bands are present in the IR spectrum to high frequency of free CO. There are also metal halogen vibrations to low frequency of that of the halide isolated in pure argon. Noting that CO is known to give complexes with the (expected) impurities H_2O[3] or HX,[4] our spectra at low dopant concentrations (1 mol% CO in Ar) show additional features at 2175 cm^{-1} (Cl) and 2169 cm^{-1} (Br). The band for the iodide is apparently too close to the impurity bands for reliable observation. The precise position of these bands and the number of features observed is dependent on dopant concentration.

On annealing these matrices at temperatures of the order of 20 K, major changes occur in the spectra of the chloride, bromide, and iodide. In each case one principal band is observed in the ν_{CO} region characteristic of metal carbonyl halide formation: 2111 (Cl), 2103 (Br), 2088 cm^{-1} (I). The precise position of the bands is again to some extent dependent on dopant concentration. There are also two less-intense bands in the 600-cm^{-1} region (609 and 584 cm^{-1} in the chloride), the higher-frequency band being narrow while that to lower frequency is broader and shows indications of resolution into a doublet in some spectra. The frequency region below 500 cm^{-1} is complex and will be discussed in detail elsewhere.

Isotopic substitution using ^{13}CO gave the expected frequency shift for the ν_{CO} bands. The bands near 600 cm^{-1} both shifted by ca. 15 cm^{-1}, suggesting they are M–C–O

deformation modes. This frequency region is clear of other vibrations and represents a *useful test for the presence of metal carbonyl halides in such systems.*

Partial isotopic substitution ($^{12}CO:{}^{13}CO$ ca. 1:1) suggested for the ν_{CO} region the presence of one degenerate vibration in the parent (all ^{12}CO) compound.[5] Unfortunately, because of the relatively high frequencies of the carbonyl bands, this region is partially obscured by the intense free ^{13}CO band. Attempts to eliminate all free CO by annealing at 35 K using a krypton matrix were not successful. In 20:1:1 Ar:^{12}CO:^{13}CO, however, the narrow δ_{MCO} band at 609 cm^{-1} gave a quintet (Fig. 1). For *trans*-

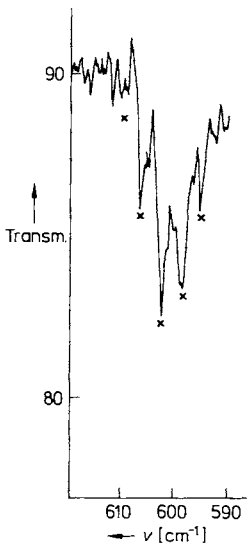

Fig. 1. Effect of ca. 50% ^{13}C isotopic enrichment on 609-cm^{-1} band. × positions for equally spaced quintet.

$[Fe(CO)_4Cl_2]$ the out-of-plane deformation of the planar D_{4h} $Fe(CO)_4$ residue would be of a_{2u} symmetry. In the absence of coupling this nondegenerate vibration must result in a quintet for a 1:1 $^{12}CO:{}^{13}CO$ isotopic ratio. There is strong evidence that molecular $FeCl_2$ is linear[6] so that acquisition of four CO molecules leads to the *trans* adduct if this linearity is retained. The only previously known isomer is the *cis* form.

The bands observed by us for *trans*-$[Fe(CO)_4I_2]$—e_u 2084, a_{2u} 612, e_u 598 cm^{-1}—are close to those proposed for the same compound produced by photolysis of *cis*-$[Fe(CO)_4I_2]$.[7,8] However, our assignments reverse those in the literature for the δ_{MCO} modes. (We also note that in one case the b_{1g} mode is reported as IR active.)

Our results suggest that the initial $FeX_2 \cdot n\,CO$ species at low dopant concentrations has an n value of less than 4.[9] Annealing enables migration of the CO molecules to occur giving a species which can then reorganize to give the iron carbonyl halide. If $FeCl_2$ is cocondensed with *pure* CO, the "π complex" is formed even at 9 K.

It is instructive to contrast the ease of reaction of CO and the *isolated* FeI_2 molecule with a *synthetic* method for *cis*-$[Fe(CO)_4I_2]$ which recommends treatment of FeI_2 with CO at 110 atm for 10 h.[10]

There is no clear-cut evidence for π species containing less than four carbonyl groups. Nor is there evidence for "π-acceptor" behavior with FeF_2. It is possible that the sharp differentiation between the fluoride and the other halides is associated with the spin changes necessary in forming the π adduct and with the "harder" metal center. Certainly the shift of the antisymmetric stretching frequency of FeF_2 from 731 cm^{-1} in Ar to 587 cm^{-1} in CO suggests a strong interaction with CO. A complication in such experiments is the variation in intensity of ν_{CO} with frequency.[7,11]

At least three types of linear CO interaction can occur, the boundaries between them not being clear:

1. van der Waals: high-frequency ν_{CO}[*]; no observed M-C-O skeletal modes. Example: $BF_3 \cdot CO$ with $d(B\text{-}C) = 2.886$ Å[12] and ν_{CO} in an argon matrix at 2150 cm^{-1}.[13]
2. "σ-bonded": high-frequency ν_{CO}; M-C-O skeletal modes present. Example: $AuCl \cdot CO$ with $d(Au\text{-}C) = 1.93$ Å[14] and ν_{CO} in the region of 2157 cm^{-1}.
3. "π-acceptor": lower-frequency ν_{CO}; M-C-O skeletal modes present. Example: $Ni(CO)_4$ with $d(Ni\text{-}C) = 1.84$ Å[15] and ν_{CO} at 2058 cm^{-1}.

Matrix isolation represents a sensitive method for studying such interactions. In particular it may be possible to examine the relationship between van der Waals, σ-bonded, and π-acceptor species by systematically varying the acceptor. It should also be possible to examine the number of CO molecules interacting on one center and possibly dipole-dipole or phonon interactions. $CrF_3 \cdot n\,CO$ would seem to be an appropriate model for the study of surface chromium atoms on $\alpha\text{-}Cr_2O_3$ where the (001) faces at 298 K show a single IR peak for CO, varying from 2185 to 2170 cm^{-1}.[16] Finally, such studies may be relevant to the occurrence of bond-stretch isomers.[17]

[*] In all cases there is a kinematic increase of ν_{CO} on coordination which depends on the effective mass of the acceptor and the M-C force constant.

Modification of Hydrophobic and Polar Interactions by Charged Groups in Synthetic Host-Guest Complexes**

By *Hans-Jörg Schneider** and *Thomas Blatter*

The quantification of noncovalent interactions plays an important role in understanding biological processes at the molecular level (for example, for the recognition between substrate and receptor) as well as in planning modifications of enzymes by genetic engineering. Synthetic host-guest complexes, by allowing structurally defined changes in a largely fixed environment, provide a way of obtaining information about the individual interactions. Herein we report on the complexation behavior of cyclobisdiphenylmethane compounds of types **A** and **B** in aqueous solution. In contrast to the earlier investigated,[1] structurally analogous macrocycle **C**, structures **A** and **B** do not have positive charges on the inner surface of the cavity, but instead negative charges that are distant from the binding center.[2]

Scheme 1. Complexation energies ΔG^0 [kJ mol^{-1}] and selected CIS values [−ppm] of host **A** in D_2O/CD_3OD (80:20). The complexation constants of **3**/**B** were not determined, since the complex is not soluble in water.

The macrocyclic host compounds **A** and **B** are accessible by reaction of the corresponding tetraazacyclobisdiphenylmethane compounds with 1,3-benzenedisulfonyl dihalide and phthalic anhydride, respectively.[3] The cavities of **A** and **C** should have similar geometries, also with respect to the sp^3 hybridization of the N atoms. Indeed, similar results are obtained even for **A** and **B**, although somewhat different conformations are expected for the carboamide **B**. Measurements of the equilibrium constants K were carried out using ^{1}H-NMR-shift titrations with **1** and its naphthalene derivatives **2**–**4** (Scheme 1) as well as computer fitting according to reported procedures.[4] For a positively charged substrate like trimethyldinaphthylammonium ion **3** in methanol/water (20:80 v/v), the K values were, as expected, large compared with electroneutral naphthalene **1** and larger still compared with the negatively charged guest molecule **4**. The contributions of the attractive and repulsive electrostatic interactions, ca. 3 kJ mol^{-1} (ΔG^0 comparison **3/1** for host **A**, Scheme 1) and ca. 4 kJ mol^{-1} (**1/4**, host **A**), respectively, are relatively constant. Comparison of these values with the corresponding ΔG^0 values for the complexation of the same substrate with host **C**, which, while analogous in structure, carries positive charges in the ring, reveals larger ΔG differences of 12 (comparison **3/1**) and 6 kJ mol^{-1} (**1/4**), as expected owing to the greater proximity of the host and guest charges.

The complexation-induced ^{1}H NMR shifts obtained by nonlinear curve fitting (CIS, see Scheme 1 for selected values), which show the expected shielding effects,[5] indicate the pseudoequatorial inclusion of the substrates **1**–**4** in the cavity of **A** and **B**, whereby the ring-current effect of both the host and the guest molecule dominates. The considerably smaller CIS values obtained with the anionic host compounds **A** and **B** in comparison with the shifts observed with the host **C**[1c,5] support our conclusion[5] that the effect of the electric field due to the charges cannot be neglected.[1b] To compare the complexation behavior, it is important to note that the absence of NMR effects due to the anionic phenyl side groups in **A** and **B** (CIS < 0.01 ppm) rules out a significant involvement of these groups through lipophilic interaction with the substrate.

Unexpected results were obtained upon comparing the binding constants K of naphthalene **1** with **A** and **C**; the K value for **A** is five times smaller than that for compound **C**,[1c] which contains four positively charged N atoms on the surface of the cavity. The presence of these four ammonium centers in **C**—which, in addition, make the macrocycle water-soluble—should lead to a *reduction* instead of an increase in the complexation constants, since the ammonium centers are much more hydrophilic[6] than the neutral nitrogen atoms in **A** (and **B**) and since the binding of hydrocarbons to **1** is mainly due to hydrophobic interactions. Moreover, dispersive lipophilic interactions should be assisted rather than weakened by neutral nitrogen atoms. Investigations using other neutral substrates, such as **2**, confirm the unexpected order of stability (Scheme 1), although in these cases smaller differences are possible owing to hydrogen bonds and polar groups. Aza host compounds containing $-NH_2^{\oplus}$ instead of $-NMe_2^{\oplus}$ units exhibit similar complexation constants. Apparently, in contrast to previous assumptions, one should consider the possibility of increased hydrophobic interactions, and possibly special ion-π-system interactions,[2b] instead of hydrophilic interactions, in the vicinity of charged groups.

Transformation of η^1-Nitrosyl to η^2-Hydroxylaminyl Ligands in the Reduction of [Mo(NO)$_2$('S$_4$')] to [Mo(η^2-NH$_2$O)(NO)('S$_4$')]: A Model Reaction for a Partial Step in the Enzymatic [$NO_3^\ominus \rightarrow NH_3$] Conversion**

By *Dieter Sellmann,* Bernd Seubert, Matthias Moll,* and *Falk Knoch*

The transition-metal-catalyzed activation and reduction of NO are important in both industrial[1a] and enzymatic reactions.[1b] In the treatment of exhaust gases, molecular nitrogen is the desired end product; the biological [$NO_3^\ominus \rightarrow NH_3$] conversion, however, avoids the formation of the energetically favored N_2 molecule, and the reduction of NO to the NH_2OH stage becomes the key step. The reduction of NO ligands to NH_2OH ligands in isolable complexes is therefore an important model reaction for understanding the biological nitrogen cycle.

The synthesis of nitrosyl complexes by use of hydroxylamine is well known[2a] and, in one case, the reversible *intramolecular* transformation of NO to NH_2O ligands has been achieved by protonation-deprotonation;[2b] the electrons involved were derived from either the NH_2O ligand or the metal center. The *intermolecular* reduction of NO to NH_2O ligands, however, has not been reported previously.[3] We have now observed such a reaction in the reduction of **1** with hydrazine according to Equation (a) (THF, 20°C, 2 h; see Experimental Procedure).

N_2 evolves and two configurational isomers of the NH_2O complex **2** are formed in equal amounts;[4] they are obtained as **2** · DMF upon recrystallization from DMF/Et_2O. The isomer shown schematically in Equation (a) was characterized by an X-ray structure analysis.[5]

Figure 1 shows that the molybdenum center is sevenfold coordinated by one oxygen, two nitrogen, and four sulfur atoms, forming a distorted pentagonal bipyramid with S3-Mo1-N2 as the main axis. The [Mo(NO)('S$_4$')] fragment of the educt **1** remains intact; the replacement of the η^1-NO ligand by a side-on-bonded η^2-NH_2O ligand leads to a further reduction in the S1-Mo1-S4 angle from 160.1(3)° in **1**[6] to 154.0(1)° in **2** · DMF. The distances in the [Mo(NH_2O)] unit clearly establish the η^2 bonding of the NH_2O ligand; the NO distance of 137.5(5) pm corresponds to a normal NO single bond.[7] One of the two H atoms forms a hydrogen bond to a DMF solvate molecule ($d_{N-H\cdots O}$ = 184.5 pm).

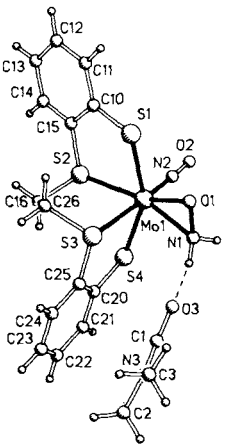

Fig. 1. Molecular structure of **2** · DMF [5].

The formation of two configurational isomers is revealed by NMR spectroscopy. The ^{13}C NMR spectrum (67.940 MHz) shows two sets of fourteen signals each for the fourteen C atoms of the ('S$_4$') ligand; they are also observed at higher temperatures (up to 60°C in [D$_8$]THF and up to 75°C in [D$_6$]DMSO), thus showing that the isomers are configurationally stable up to these temperatures. The ^{1}H NMR spectrum (Fig. 2), too, is in agreement only with the presence of two isomers: Four lines, arising from the two different AB systems, are observed for the NH_2 protons. The temperature dependence of the signals indicates exchange processes.

The ^{95}Mo NMR spectrum (17.061 MHz) exhibits only a broad ^{95}Mo signal at $\delta = -395$ (rel. $(NH_4)_6Mo_7O_{24}$) with a half-width of 760 Hz; on the one hand, the half-width presumably prevents resolution of the expected two Mo signals; on the other, it shows that the two Mo centers have very similar chemical environments and differ only in the position of the NH_2O ligand in relation to the [Mo(NO)('S$_4$')] fragment.

The 1:1 ratio of the two isomers is understandable in terms of the route of formation of **2**: the reduction **1** → **2**

[*] Prof. Dr. D. Sellmann, Dipl.-Chem. B. Seubert, Dr. M. Moll, Dr. F. Knoch

[**] ('S$_4$')$^{2\ominus}$ = 2,2'-(ethylenedithio)dibenzenethiolate.—Transition Metals with Sulfur Ligands, Part 39: This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 38: D. Sellmann, H. Kunstmann, M. Moll, F. Knoch, *Inorg. Chim. Acta*, in press.

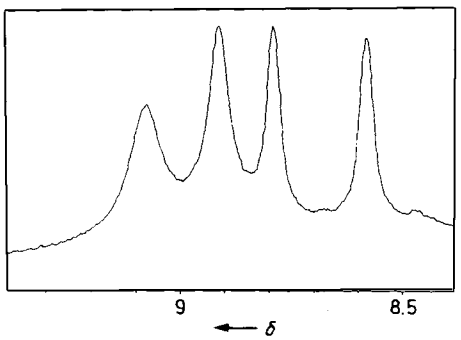

Fig. 2. δ_{NH} region of the ^1H NMR spectrum of **2** at 20°C in [D$_6$]DMSO.

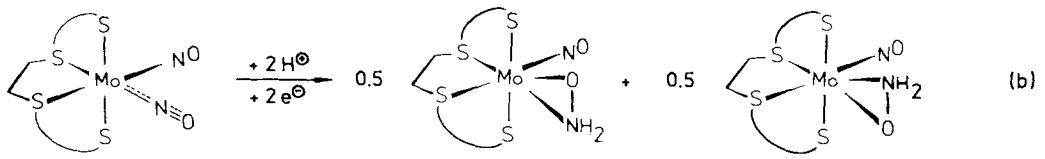
[Eq. (a)] is a proton-coupled two-electron reduction, hydrazine serving as both proton and electron source:

$$N_2H_4 \longrightarrow N_2 + 4H^{\oplus} + 4e^{\ominus}$$

Upon reduction of **1**, bending of one of the two NO ligands is expected to occur,[8] resulting in the formation of **2a** and **2b** with equal probability (Eq. (b)].



1 **2a** **2b**

Of fundamental importance for understanding the mechanism of reduction and for describing the NH_2O ligand is the question whether electrons of the metal are involved in the NO→NH_2O reduction. The ^{95}Mo shifts of **1** ($\delta = -512$) and **2** ($\delta = -395$) indicate that the reaction according to Equation (a) does not lead to a change in the oxidation state of the Mo center;[9] therefore, in both cases, it can be regarded as an Mo^{II} center. Accordingly, the 15-electron fragment [Mo(NO)('S$_4$')] is stabilized in **1** by the 3-electron donor $:\overset{\odot}{N}\equiv O:$ and in **2**, isoelectronically, by the 3-electron donor $H_2\ddot{N}-\overset{\odot}{\ddot{O}}:$, which is thus to be described as a hydroxylaminyl ligand.[10]

The transformation of **1** to **2** shows that the reduction of NO to the NH_2OH stage in metal oxidoreductases under mild conditions should be favored when the metal center is surrounded by sulfur ligands and can easily change its coordination number.

Experimental Procedure

1 (925 mg, 2.0 mmol) [11] in 70 mL of THF was allowed to react at 20°C with N_2H_4 (0.08 mL, 2.5 mmol). A clear, orange-yellow solution containing a small amount of a brown precipitate was formed over ca. 2 h accompanied by N_2 evolution (GC, MS). The solution was filtered, all volatiles were removed from the filtrate under reduced pressure, and the residue was dissolved in DMF. Addition of a layer of Et_2O (ca. 20 mL) to this yellow-brown solution and cooling to −30°C resulted, after 3 d, in the formation of amber-colored crystals. IR (KBr): $\tilde{\nu}_{NH} = 3240\ cm^{-1}$, $\tilde{\nu}_{NO} = 1635\ cm^{-1}$. FD-MS: *m/z* 468 ($M^{\oplus}$). Yield 85% (correct elemental analysis).

Mechanism of Ethylene Hydrogenation by the Molecular Hydrogen Complex $[Ir(H)_2(H_2)(PMe_2Ph)_3]^{\oplus}$—Characterization of Intermediates**

By *Eric G. Lundquist, John C. Huffman, Kirsten Folting,* and *Kenneth G. Caulton**

Facile loss of coordinated H_2 is a common characteristic of most dihydrogen (η^2-H_2) complexes.[1] While those who

[**] This work was supported by the National Science Foundation (Grant No. CHE-8707055). We thank Dr. *M. J. Hampden-Smith* for valuable advice and discussions, Johnson-Matthey for material support, and *Scott Horn* for skilled technical assistance.

investigate the structural and physical properties of these complexes might view this occurrence as a nuisance (obligatory manipulations under H_2, low temperatures, etc.), we consider it to be a convenient opportunity to access, under exceptionally mild conditions, the relatively unexplored field of unsaturated hydride complexes. Here we report on the protonation of $[IrH_3p_3]$ ($p = PMe_2Ph$) with HBF_4 to produce the cationic complex $[IrH_4p_3]^{\oplus}$,[2] which we show to contain intact H_2. This complex serves as an effective ethylene hydrogenation catalyst while, at the same time, providing an excellent opportunity to characterize and study the intermediates in a catalytic cycle.

When $[IrH_3p_3]$ is protonated with $HBF_4 \cdot OEt_2$ in CH_2Cl_2, the complex $[IrH_4p_3]^{\oplus}$ **1**[2] is formed. T_1 measurements at $-70\,^{\circ}C$ in CD_2Cl_2[3] support the interpretation that this cation is comprised of an Ir^{III} octahedron with two hydride ligands and a coordinated dihydrogen molecule. We had previously speculated[2] that this was the structure of **1** based upon chemical reactivity studies which suggested the occurrence of the equilibrium (a).

$$\underset{\mathbf{1}}{[IrH_4p_3]^{\oplus}} \underset{kk}{\rightleftharpoons} [IrH_2p_3]^{\oplus} + H_2 \qquad (a)$$

Addition[4] of excess ethylene to **1** in CH_2Cl_2 gives a 97% yield of the BF_4 salt of $[Ir(C_2H_4)_2p_3]^{\oplus}$ **2** as a cream-colored powder. The ^1H NMR spectrum[5] of this material shows resonances for two coordinated ethylene molecules and no remaining hydride ligands. The $^{13}C\{^1H\}$ NMR spectrum of a sample obtained using ^{13}C-enriched ethylene (Fig. 1), is

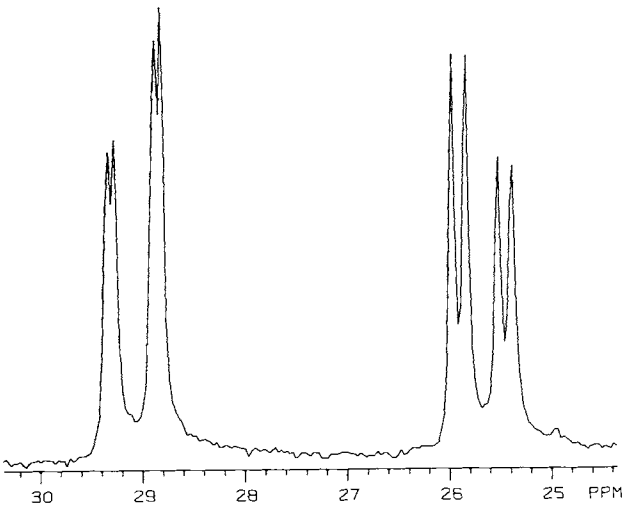

Fig. 1. $^{13}C\{^1H\}$ NMR (90 MHz, 24°C, CD_2Cl_2) of the ethylene carbons in $[Ir(^{13}C_2H_4)_2(PMe_2Ph)_3]^{\oplus}$, showing inequivalent carbons ($\delta = 29.1$ and 25.6), each of which couples to *only* one phosphorus.

invariant with temperature and, together with the $^{31}P\{^1H\}$ NMR spectrum,[5] suggests a rare,[6,7] stereochemically *rigid*, five-coordinate iridium cation with equivalent nonrotating (-80 to $+80\,^{\circ}C$) ethylene ligands: $[Ir(C_2H_4)_2p_3]^{\oplus}$ **2**. The solid-state structure determination of **2**[8] (Fig. 2) is consistent with the spectral parameters and reveals a trigonal-bipyramidal arrangement around iridium with two ethylenes and one phosphane ligand occupying the equatorial sites.

When the reaction of $[Ir(H)_2(H_2)p_3]^{\oplus}$ **1** with excess ethylene is monitored by ^1H NMR at $-50\,^{\circ}C$, *cis,mer*-

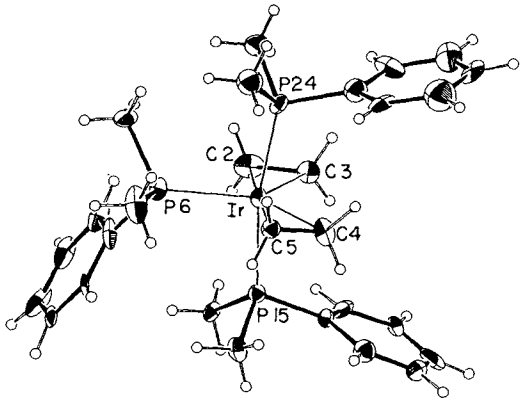

Fig. 2. The molecular structure of $[Ir(C_2H_4)_2(PMe_2Ph)_3]^{\oplus}$ (ORTEP) as the BF_4 salt [8]. Unlabeled ellipses are carbon; open circles are hydrogen. Selected distances [Å] and angles [°]: Ir-P6 2.356(5), Ir-P15 2.363(5), Ir-P24 2.351(5), Ir-C2 2.140(16), Ir-C3 2.164(16), Ir-C4 2.171(15), Ir-C5 2.166(16), C2-C3 1.401(25), C4-C5 1.427(24); P6-Ir-P15 97.11(16), P6-Ir-P24 93.47(16), P15-Ir-P24 169.41(15).

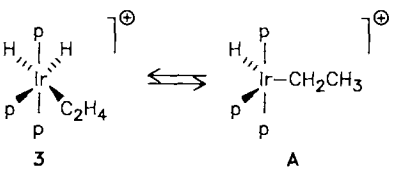
$[IrH_2(C_2H_4)p_3]^{\oplus}$ **3**, a 1:1 adduct of ethylene and $[IrH_2p_3]^{\oplus}$ (formed by loss of H_2 from **1**), can be observed.[9] Over time the resonances of **3** decrease while those of the bis-olefin complex **2** and of ethane appear. However, in the absence of excess ethylene, even at room temperature, the cationic hydrido-olefin complex **3** is stable and does not eliminate ethane. Thus, the reduction of ethylene to ethane is ethylene-promoted. The cationic complex **3** can also be generated by the reaction of **2** with H_2 [Eq. (b)]. The curious elimination of *ethylene* (not ethane) in this reaction,

$$\underset{\mathbf{2}}{[Ir(C_2H_4)_2p_3]^{\oplus}} + H_2 \longrightarrow \underset{\mathbf{3}}{\textit{cis,mer}\text{-}[IrH_2(C_2H_4)p_3]^{\oplus}} + C_2H_4 \qquad (b)$$

together with the fact that an ethylene molecule in **2** exchanges within 30 minutes with ^{13}C-labeled ethylene, implicates the equilibrium (c).[10] Thus, while **2** appears "stat-

$$\underset{\mathbf{2}}{[Ir(C_2H_4)_2p_3]^{\oplus}} \rightleftharpoons [Ir(C_2H_4)p_3]^{\oplus} + C_2H_4 \qquad (c)$$

ic" on the NMR time scale ($\Delta t < 1$ s), it shows unimolecular reactivity on the preparative time scale ($\Delta t > 1$ min). Addition of D_2 to compound **2** initially generates $[IrD_2(C_2H_4)p_3]^{\oplus}$, which shows rapid incorporation of deuterium into the ethylene and points to the rapid reversibility of reaction (d), which again involves a 16-electron $[Ir(H)(R)p_3]^{\oplus}$ species [cf. Eq. (a)].



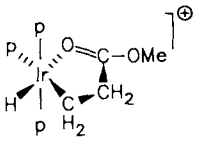
3 A (d)

Equation (d) alone, however, is not sufficient to explain the observed scrambling between *both* the hydrogens in *cis* and *trans* positions and all ethylene hydrogens of $[IrD_2(C_2H_4)p_3]^{\oplus}$, since the hydrides in **3** are stereochemically rigid. However, since **3** exchanges with D_2 (1 atm) at a rate comparable to that of reaction (d), an equilibrium

H_2-elimination from **3** must also occur [Eq. (e)].[11] Note that this equilibrium involves the same 16-electron species implicated in Equation (c).

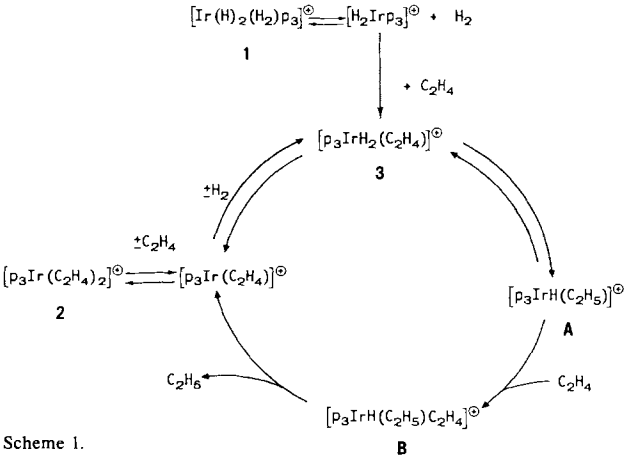
$$[IrH_2(C_2H_4)p_3]^{\oplus} \rightleftharpoons [Ir(C_2H_4)p_3]^{\oplus} + H_2 \qquad (e)$$

The product-forming hydrido-ethyl (**A**) and hydrido-ethyl ethylene (**B**) species (Scheme 1) "downstream" of reaction (d) have not been observed under a variety of conditions. However, when methyl acrylate is substituted for ethylene, the hydrido-alkyl complex **4** can be isolated in near quantitative yield.[12] This thermally stable complex serves as an ideal model for the proposed hydrido-ethyl ethylene intermediate **B**.



4

Incorporation of all the above experimental evidence leads to the catalytic cycle shown in Scheme 1 for the hydrogenation of ethylene by $[Ir(H)_2(H_2)p_3]^{\oplus}$ **1**. The $BF_4^{\ominus}$ ion



Scheme 1.

and CH_2Cl_2 also play a role as more active participants in the catalytic cycle.[13]

Synthesis, Structure, and Reactivity of $[Mn_2(\mu\text{-}H)_2(CO)_6(\mu\text{-}Ph_2PCH_2PPh_2)]$**

By *Francisco J. García Alonso, Manuel García Sanz, Victor Riera,* Miguel Angel Ruiz, Antonio Tiripicchio,** and *Marisa Tiripicchio Camellini*

Organometallic transition-metal compounds containing a formally unsaturated $M_2(\mu\text{-}H)_2$ (M = M) moiety are attractive species for the study of the reactions of small molecules at metallic centers, as suggested from the chemistry developed around $[Os_3(\mu\text{-}H)_2(CO)_{10}]$.[1] We report here the preparation, structure, and reactivity of $[Mn_2(\mu\text{-}H)_2(CO)_6(\mu\text{-dppm})]$ **1** (dppm = $Ph_2PCH_2PPh_2$). Only a few manganese analogues of **1** are known—$[Mn_2H_2(CO)_4(dppm)_2]$,[2] $[Mn_2H_2(PPh_2)(CO)_6]^{\ominus}$,[3] and $[Mn_2H_2(CO)_6(tedip)]$[4] (tedip = $(EtO)_2POP(OEt)_2$)—and their reactivity has not been explored in detail.

Reduction of $[Mn_2Cl_2(CO)_6(dppm)]$[5] with four equivalents of $Li[HBEt_3]$ in THF at 0°C affords the red-purple compound **1** in 50–60% yield. The crystal structure analysis (Fig. 1)[6] shows that the Mn–Mn distance (2.699(2) Å) is in agreement with the formal unsaturation predicted for the molecule on the basis of electron counting. Accordingly, **1** reacts under mild conditions with a variety of small molecules (see Scheme 1).

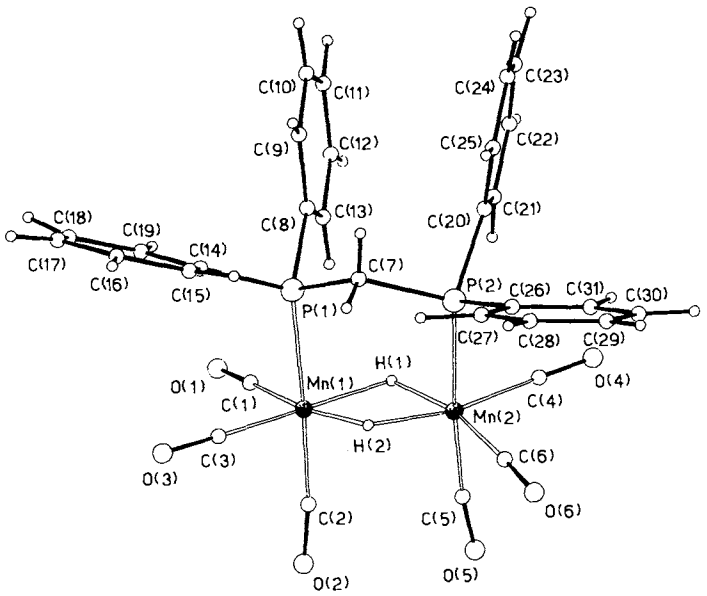

Fig. 1. Perspective view of the structure of $[Mn_2(\mu\text{-}H)_2(CO)_6(\mu\text{-dppm})]$ **1**. Selected bond lengths [Å] and angles [°]: Mn1-Mn2 2.699(2), Mn1-P1 2.308(3), Mn2-P2 2.326(3), Mn1-C1 1.784(6), Mn1-C2 1.818(6), Mn1-C3 1.791(6), Mn2-C4 1.801(6), Mn2-C5 1.804(6), Mn2-C6 1.791(5), Mn1-H1 1.76(5), Mn2-H1 1.59(5), Mn1-H2 1.81(5), Mn2-H2 1.68(5); H1-Mn1-H2 71(2), H1-Mn2-H2 78(2), Mn1-H1-Mn2 107(3), Mn1-H2-Mn2 102(2).

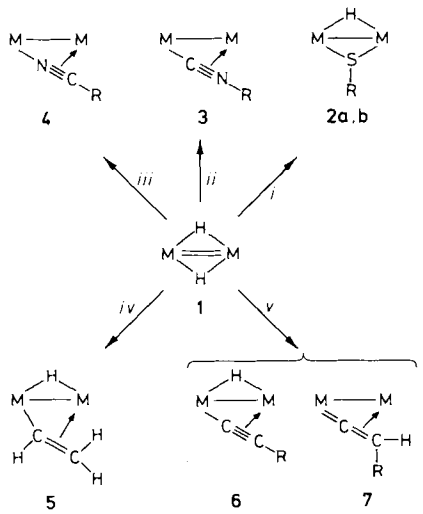
Reaction with *p*-MeC_6H_4SH results in H_2 elimination to give the μ-hydrido,μ-thiolato complex **2a**. On the other hand, reaction of **1** with *t*BuNC or MeCN results in intramolecular H_2 elimination to give the μ-σ,π-isocyanido (**3**) or -nitrilo (**4**) complexes, whereas elemental sulfur inserts into one μ-H bridge to give the μ-mercapto complex **2b**; the latter exists in solution as a mixture of two isomers, differing probably in the orientation of the S-H vector relative to the Mn_2S plane (above or below it).



Scheme 1. i: **2a** (R = *p*-MeC_6H_4), 1 equiv. *p*-MeC_6H_4SH, toluene, room temperature, 10 min; **2b** (R = H), 1 equiv. S_8, toluene, room temperature, 5 min. ii: **3** (R = *t*Bu), 1 equiv. *t*BuNC, toluene, room temperature, 5 min. iii: **4** (R = Me), MeCN (excess), toluene, room temperature, 2 h. iv: **5** C_2H_2 (excess), THF, room temperature, 4 h. v: **6** and **7** (R = *t*Bu), *t*BuC_2H (excess), THF, room temperature, 3 d.

Complex **1** also reacts with several alkynes RC_2H (R = H, Ph, *t*Bu) at room temperature, the nature and relative amounts of the products being strongly dependent on the nature of R; thus, when R = H, insertion into a Mn-H bond leads to the μ-σ,π-vinyl complex **5**, whereas for R = *t*Bu the μ-σ,π-acetylide compound **6** is the major species formed. Compounds **5** and **6** appear to be fluxional at room temperature, as concluded from their NMR spectra. Interestingly, for R = *t*Bu, a minor product **7**[7] is also obtained. Compound **7** contains a μ-σ,π-vinylidene ligand, as confirmed by an X-ray structure determination.[8]

The Influence of Polar and Steric Effects on the Selectivity of the β-Cleavage of Alkyl Radicals**

By *Kurt Klenke, Jürgen O. Metzger,** and *Stefan Lübben*

The β-cleavage of radicals plays an important role in the complex reaction mechanisms of pyrolysis, combustion, photooxidation, the thermal degradation of polymers,[1] and increasingly also in preparatively useful reactions.[2] The selectivity of the β-cleavage has been the subject of

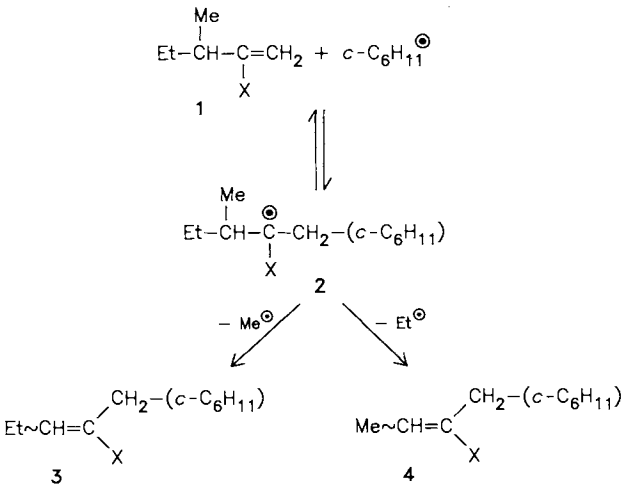
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

very few studies. We have therefore carried out experiments aimed at demonstrating the influence of polar and steric effects on the β-cleavage of alkyl radicals.

The radicals **2** were generated by addition of cyclohexyl radicals (c-$C_6H_{11}^{\odot}$) to the alkenes **1**. These fragment in an intramolecular competition reaction to give the products **3** and **4** with cleavage of methyl and ethyl radicals, respectively.[3] The polar effect of X on the selectivity of the radical cleavage can be investigated by variation of the substituents X on the radical carbon atom.[5] The products **3** and **4** are each formed as (*E*)- and (*Z*)-isomers, so that also the polar effect of X on the stereoselectivity can be measured.



a, X = COOMe; b, X = Ph; c, X = p-MeO–C_6H_4; d, X = p-Cl–C_6H_4

The results (Table 1) are in many respects surprising. The benzyl radical **2b** fragments more slowly than the methoxycarbonylalkyl radical **2a**, since **2b** is about 15 kJ/mol more stable than **2a**.[6] The selectivity of the cleavage of the more reactive radical **2a** is, however, clearly greater. The stereoselectivity is also greater. This reversal of the reactivity-selectivity principle can be explained, in analogy to the radical addition to alkenes, in terms of the polar effect of the leaving radical and of the substituents X in the alkyl radical **2**.[7] The cleavage of the more nucleophilic ethyl compared to the methyl radical is accelerated by the electron-withdrawing substituent X = COOMe. This polar effect is especially evident on considering the difference in the activation energies, which amounts to ca. 18 kJ/mol for the fragmentation of **2a** to **3a** and **4a**. The difference in the stability of the products is only ca. 8 kJ/mol.[8] The polar effect of the methoxycarbonyl group is thus about 10 kJ/mol referred to the two leaving groups in question and increases the selectivity. The converse is true in the case of the nucleophilic radical **2b**, which gives the more electron-rich alkenes **3b** and **4b**. The cleavage of nucleophilic radicals is all the more difficult the more nucleophilic they are. The cleavage of the ethyl radical is more strongly retarded than that of the methyl radical. The difference of 4.5 kJ/mol in the activation energies again makes the polar effect especially noticeable. The transition states lie ca. 3.5 kJ/mol closer together than the ground states of the products that are formed. In this case the polar effect of the phenyl group reduces the selectivity of the β-cleavage.

Table 1. β-Cleavage of the radicals **2** to give the products **3** and **4** at 350°C [3].

2	Yield [a] [mol-%]	[**4**]/[**3**] [b]	[(*E*)-**4**]/[(*Z*)-**4**]	ΔE_a [c] [kJ/mol]	A_4/A_3 [c]
a	14.7	17.8 (1.25)	3	−18.2±2	0.6±0.2
b	6.0	7.3 (0.86)	2.5	− 4.5±0.5	3.0±0.3
c	7.4	8.9 (0.95)	2.3	− 8.4±0.6	1.6±0.2
d	9.0	9.4 (0.97)	2.3	− 7.2±0.8	2.4±0.5

[a] Sum of the β-cleavage products **3** and **4** based on alkene **1** used. [b] In parenthesis: selectivity S = lg([**4**]/[**3**]). [c] $\Delta E_a = E_a(\mathbf{4}) - E_a(\mathbf{3})$; 300–450°C.

Smaller but significant effects are observable on comparing the fragmentation of the radicals **2b**, **2c** and **2d** (Table 1). The electron withdrawal by chlorine in **2d** increases the reactivity and the selectivity compared to **2b**. Surprisingly, the *p*-methoxy group in **2c** apparently reacts only through its −I effect. The selectivity of the ethyl/methyl cleavage is increased significantly compared to **2b**. This is understandable only in terms of the *p*-methoxy group having an electron-attracting effect.

The radicals **6** were obtained by the addition of cyclohexyl radicals to the alkenes **5**. These fragment in a competition reaction to give the products **7** and **8** and a methyl radical.[9] The relative effect of the substituents attached to the carbon atom at which the C–C bond is ruptured on the cleavage of the methyl radical can be determined from the ratio of the products **7** : **8**.

The fragmentation is remarkably selective (Scheme 2): the thermodynamically more stable alkene **7** is formed in only slight excess at 400°C. Normalized to the number of cleavable methyl groups, the methyl radical is even preferentially cleaved from the lesser substituted alkyl group to give the thermodynamically more unstable alkene **8**.

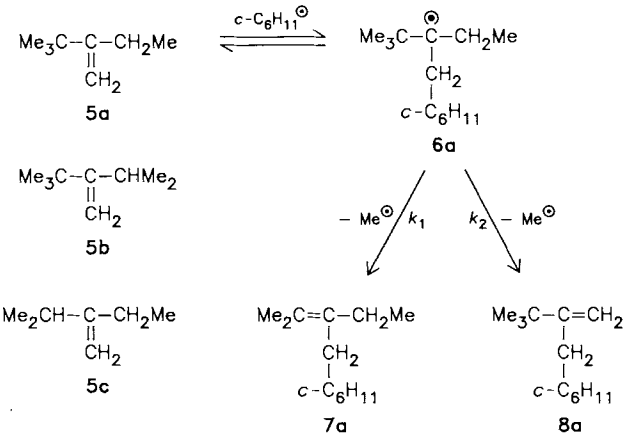


Table 2. Selectivity of the β-cleavage of the radicals **6** at 400°C.

6	[**7**] [mol-%]	[**8**] [mol-%]	$[k_2/k_1]_{norm.}$ [a]	S [b]
a	57	43	2.3	0.36
b	52	48 [c]	1.4	0.15
c	62 [c]	38	1.2	0.08

[a] Relative rate normalized to one methyl group. [b] $S = \lg k_2/k_1$. [c] (*E*)- and (*Z*)-products.

At first sight this result is surprising. One might expect that the stabler alkene is formed with higher selectivity[10] and that the cleavage of the methyl radical preferably occurs at the more substituted alkyl group. However, the result is understandable if the β-cleavage is considered from the point of view of the addition (Fig. 1). Substituents on the C atom that is attacked sterically hinder the addition.[7, 12] The free enthalpy of activation for the addition of the methyl radical to the alkene **7** is raised in comparison

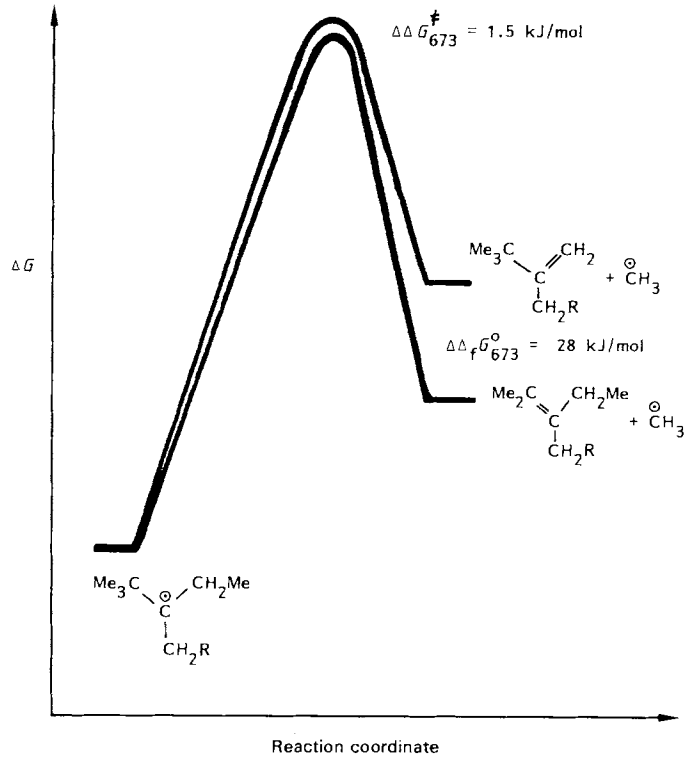

Fig. 1. Reaction coordinate of the β-cleavage of radical **6a**.

to the alkene **8** by the larger number of methyl groups on the C atom that is attacked. This means that the transition state of the β-cleavage is correspondingly also raised and the reaction retarded.[13]

The steric effects of substituents in β-cleavages should also play an important role in α-cleavages. Evidence to this effect is provided, for example, in S_H reactions of alkyltin[14] and alkylboron compounds.[15] Our results show that it is essential that polar and steric effects be taken into account as well the generally dominating influences of product stability[1] when considering the selectivity of β-cleavage.

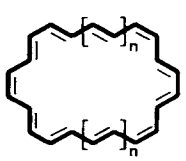
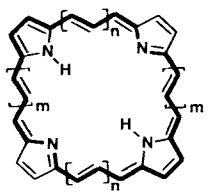
Biomimetic Synthesis of an Octavinylogous Porphyrin with an Aromatic [34]Annulene System**

By *Georg Knübel* and *Burchard Franck**

Application of the principles of natural products chemistry allows extension of the theoretically and methodologically inspiring field of annulenes[1] to higher ring systems. The series of well-defined, normal annulenes ended previously with the diatropic (aromatic) [22]annulene **2** and the paratropic (antiaromatic) [24]annulene[1] (Scheme 1). Using porphyrin biosynthesis as our model, we recently synthesized a tetravinylogous porphyrin, **7**, containing a [26]annulene system.[2a] Compound **7** displays unusual properties with possible topical applications.[3]





1, n = 0	[18]annulene	**5**, n, m = 0	[18]porphyrin
2, n = 1	[22]annulene	**6**, n = 1, m = 0	[22]porphyrin-[1.3.1.3]
3, n = 2	[26]annulene	**7**, n, m = 1	[26]porphyrin-[3.3.3.3]
4, n = 4	[34]annulene	**8**, n, m = 2	[34]porphyrin-[5.5.5.5]

Scheme 1. Structures of previously reported (above the broken line) and still unknown diatropic annulenes **1**–**4** together with the corresponding vinylogous porphyrins **5**–**8** [5].

Herein we report on the synthesis of an eightfold vinylogously enlarged porphyrin, **17**, containing a cyclic conjugated 34π-electron system. The basic structure of **17**, being a bridged diaza derivative of [34]annulene **4**, is named [34]porphyrin-[5.5.5.5] according to our nomenclature proposal.[5]

To develop a synthesis of the [34]porphyrin **17** involving as few steps as possible, we followed the pathway of porphyrin biosynthesis[6] (Scheme 2). It is known[4, 7] that porphobilinogen **9**, the biogenetic precursor of all porphyrin

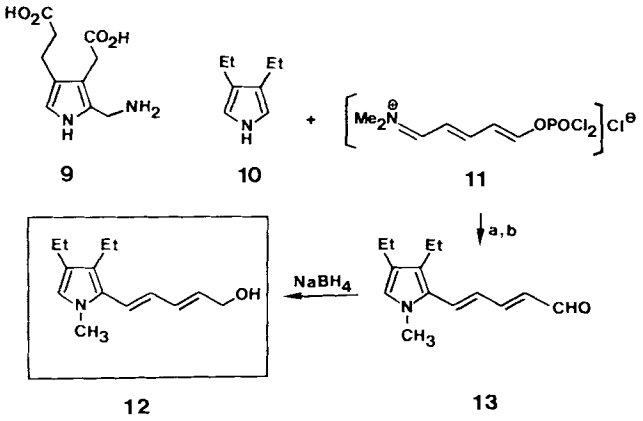
Orléansring 23, D-4400 Münster (FRG)

[**] Novel Porphyrinoids, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: [2b].

natural products, as well as similar 2-(aminomethyl)- and 2-(hydroxymethyl)pyrroles, can undergo acid-catalyzed condensation in vitro to give porphyrins.

This *biomimetic cyclotetramerization* is even suitable for the synthesis of sterically highly strained *N,N',N'',N'''*-tetraalkylated and *N,N'*-bridged porphyrinogens and porphyrins.[2b,4] Even though such condensations lead to porphyrinogens, which are (still?) unknown as natural products, these reactions are by definition[8] *biomimetic*, since they are closely related to biosynthesis.



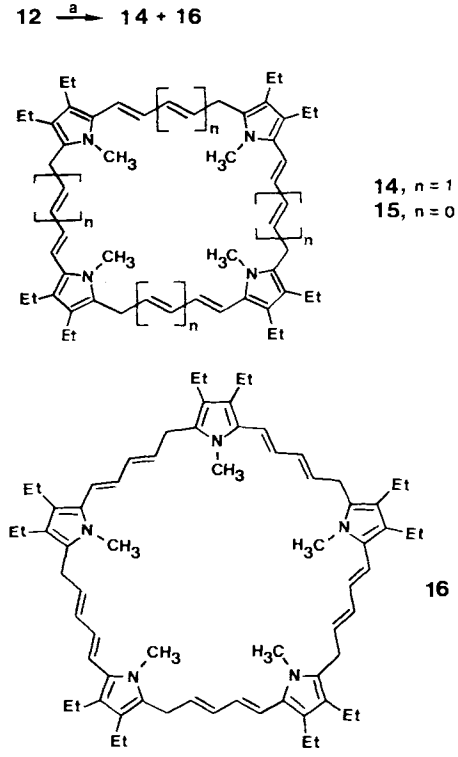
Scheme 2. Porphobilinogens **9** and synthesis of the 5-pyrrylpentadienol **12**. Reaction conditions: a) *N,N*-dimethylaminopentadienal/$POCl_3$, CH_2Cl_2, −40°C, inert gas, 4 h, 44% yield. b) NaH, dry dimethylformamide, CH_3I, 20°C, 30 min, 87% yield; **13**: m.p. 55°C.

The key building block for the biomimetic construction of a [34]porphyrin system **8** is the pyrrylpentadienol **12** (Scheme 2). Owing to its high reactivity, **12** is generated from the stable aldehyde precursor **13** by $NaBH_4$ reduction immediately prior to the acid-catalyzed condensation. Compound **13** was synthesized from 3,4-diethylpyrrole **10**[9] by doubly vinylogous Vilsmeier formylation using the complex **11**, followed by *N*-methylation.

Of decisive importance for the further synthesis of the [34]porphyrin derivative **17** was the question whether, in analogy to the porphobilinogen **9**, a derivative **12** having a doubly vinylogous side chain would also undergo acid-catalyzed condensation. The high selectivity in the biomimetic condensation of suitable monopyrroles to cyclic tetrapyrroles may be ascribed to steric interactions of substituents in the β positions of neighboring pyrrole rings.[2d,4] This effect should be strongly diminished when the bridges linking the pyrrole rings are lengthened, as in **14** and **15**.

Nonetheless, the acid-catalyzed condensation of **12** gave the colorless, cyclically nonconjugated, octavinylogous [34]porphyrinogen **14**[12] (Scheme 3). However, the yield of this reaction (4.1% based on **13**) was, as expected, smaller than that of the tetravinylogous [26]porphyrinogen **15** (27%).[2a] Still, this yield reveals a remarkable selectivity in this complex cyclization when one considers that the yield of **14** refers to a five-step synthesis—comprising reduction and four cyclization steps—and therefore represents an average yield of 53% for each reaction step.

The lesser tendency of **12** to form cyclic tetramers is also revealed in the fact that, in addition to **14**, a more slowly eluting product was isolated by flash chromatography (silica gel, cyclohexane/ethyl acetate 20 : 1) in nearly the same amount. On the basis of its mass spectrum ($M^{\oplus}$ 1005, 25%), it can be assigned the structure of a pentamer, **16**.



Scheme 3. Acid-catalyzed biomimetic condensation of the 5-pyrrylpentadienol **12**. Reaction conditions: a) *p*-toluenesulfonic acid, acetic acid, MeOH, 50°C, inert gas, 30 min; 4.1% yield; **14**, m.p. 168°C.

The cyclic conjugated target molecule **17** is so stable that the educt **14**—like the [26]porphyrinogen **15**[2a]—can be dehydrogenated by treatment with bromine. The [34]porphyrin-[5.5.5.5] was thereby obtained as the bisquaternary dibromide **17**.

	δ	J [Hz]
H^a, H^e	16.18 d	13.1
H^b, H^d	−14.27 t	13.1
H^c	17.19 t	13.1
H^f	−11.44 s	
H^g, H^h	6.04 br	
H^i, H^k	2.83 t	7.2

Scheme 4. Synthesis of the [34]porphyrin-[5.5.5.5] **17** and ^1H NMR data (in [D_6]DMSO, see Fig. 1). Reaction conditions: a) Br_2/CCl_4, polymer base (diethylaminomethylpolystyrene), 20°C, 5 h; 12.5% yield after chromatographic purification (silica gel, CH_2Cl_2/MeOH 10/1).

The [34]porphyrin **17**, which forms deep blue (λ_{max} = 664 nm) solutions, exhibits an extraordinarily large ring-current effect in the ^1H NMR spectrum (Scheme 4). The maximum shift difference $\Delta\delta$ of the resonance signals between the inner ($\delta = -14.27$) and outer protons ($\delta = 17.19$) is 31.5 ppm. This value indicates that the dia-

magnetic ring-current effect of **17** significantly surpasses the $\Delta\delta$ value (25.3 ppm)[2a] found for the analogous [26]porphyrin and that found for [18]annulene **1** (12.1 ppm).[1] The ^{1}H NMR spectrum of **17** (Fig. 1) is probably the first obtained for a non-organometallic compound in which the measured proton resonances extend over a range of more than 30 ppm. Splitting of the signals for the protons H^a, H^b, and H^c of **17** (Fig. 1a), observed only at extreme dilution, indicates a tendency toward association.

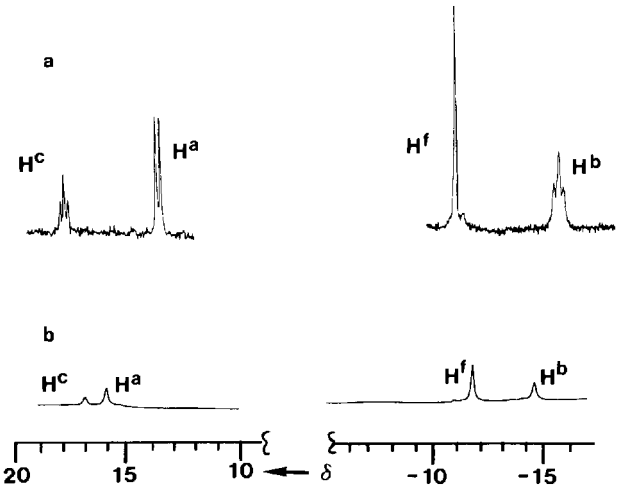


Fig. 1. 300-MHz ^{1}H NMR spectra of [34]porphyrin **17** in [D$_6$]DMSO. Concentrations: a) 0.1 g L^{-1}; b) 3.0 g L^{-1}.

The synthesis of the [34]porphyrin **17** with its high ring-current effect, characterizing its aromaticity,[10] supports—as already shown for the [26]porphyrin system—the validity of the (4n+2) rule for higher annulene systems. That the annulenes so far available exhibit diatropic behavior only in the range of 14–22 π electrons—as experimentally found and as calculated[11]—can no longer be regarded, therefore, as a limitation of the (4n+2) rule.

The diatropic behavior of the vinylogous porphyrins is appreciably more pronounced than for the annulenes. We ascribed this finding to the flattening effect of the pyrrole rings, which hinders inversions of the ring system.[2a] The present results show that this principle is so efficient that even vinylogous porphyrins having the large 34π ring system—that is, C_5 chains between the pyrrole rings—are conformationally more stable that the [18]annulene **1**.

An Antibody-Mediated Redox Reaction**

By *Kevan M. Shokat, Christian J. Leumann, Renee Sugasawara,* and *Peter G. Schultz**

The advent of monoclonal antibodies makes possible the generation of highly selective receptors to a vast number of structurally diverse ligands.[1] Recently, the high binding affinity and specificity of antibody combining sites has been exploited in the development of selective catalysts for acyl transfer,[2] carbon–carbon bond-forming,[3] and carbon–carbon bond-cleaving reactions.[4] We now report that antibody combining sites can modulate the thermodynamics of redox processes. The use of antibody specificity to alter flavin redox potentials is the first step toward developing antibodies capable of using cofactors to catalyze stereoselective reductions.

Oxidized flavin **1** and the two-electron-reduced 1,5-dihydroflavin **1a** have substantially different electronic and conformational properties.[5] The dipole moment of oxidized flavin is reduced by 40% upon two-electron reduction and the N^1 position becomes an H-bond donor.[6] In fact, the pK_a of the N^1–H bond in **1a** is 6.5, indicating it may exist largely as the anion in solution. In terms of structural differences, a bent (N^5–N^{10} axis) conformation is preferred by reduced flavin, whereas a planar form is favored by the oxidized flavin (however, the calculated energy difference between the two conformations is small, 1–2 kcal mol^{-1}).[6] Consequently, antibodies generated specifically to the oxidized flavin should preferentially bind **1** relative to 1,5-dihydroflavin **1a**. This differential stabilization of the oxidized and two-electron-reduced flavin by the

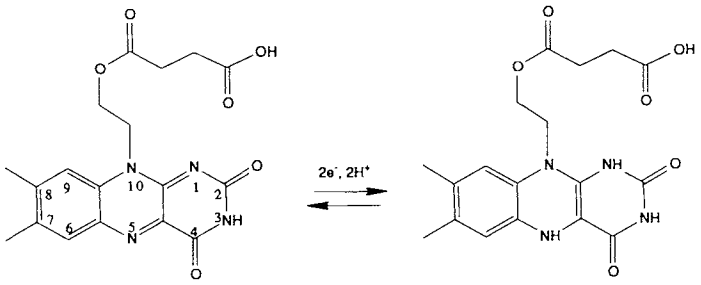
antibody (Ig) combining site should make the Ig-**1a** complex a substantially stronger reducing agent than free **1a** in solution.



1 **1a**

Periodate oxidation of riboflavin afforded 10-(formylmethyl)riboflavin, which was subsequently reduced with sodium borohydride and reacted with succinic anhydride to afford the acid **1**.[14] Hapten **1** was then coupled to the carrier proteins bovine serum albumin and keyhole limpet hemocyanin using water-soluble carbodiimide,[7] and antibodies were generated according to techniques described elsewhere.[8] Six clones were obtained and purified from mouse ascites fluid by Protein-A chromatography[9] and were judged homogeneous by sodium dodecyl sulfate polyacrylamide gel electrophoresis with Coomassie blue staining.[10]

The binding constant of flavin **1** to one of the monoclonal antibodies was determined by the method of fluorescence quenching[11] (flavin fluorescence is completely quenched upon binding to the antibody). Antibody-ligand dissociation constants of 8×10^{-9} M and 6×10^{-8} M were obtained for **1** and riboflavin, respectively.[12] The UV spectrum of **1** bound to antibody displayed a 15-nm bathochromic shift (443 to 458 nm) and a shoulder appeared at 482 nm; the 375-nm maximum did not shift appreciably. Such spectral perturbations indicate association with aromatic amino acid side chains in the antibody combining site.[13]

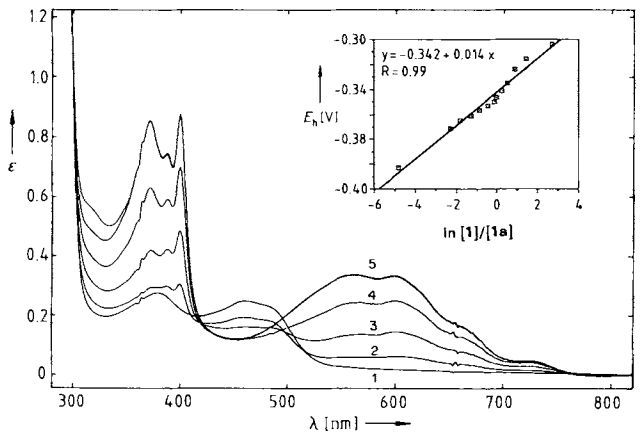


Fig. 1. Anaerobic dithionite (5 mM) titration of **1** (30 μM) bound to antibody (31 μM) in the presence of benzyl viologen (30 μM) in 0.1 M phosphate, pH 7.0; 1, **1** and oxidized benzyl viologen; 2-4, partially reduced **1** and partially reduced benzyl viologen after 0.5, 1.0, and 1.5 equivalents of dithionite were added, respectively; 5, fully reduced flavin and fully reduced benzyl viologen after 2.0 equivalents of dithionite were added. Ig concentration was determined by absorbance at 280 nm by using $E^{0.1\%}_{1cm}=1.37$ [2c]. Inset: E_h [V] vs. ln([**1**]/[**1a**]).

Reduction potentials were measured in anaerobic solutions under an atmosphere of argon by titration of flavin in the presence of redox-active dyes.[13] The antibody-**1** complex was reduced by dithionite titration in the presence of benzyl viologen (E_m(dye) = −358 mV; Fig. 1). Reduction of benzyl viologen resulted in an increase in absorbance at 598 nm where the flavin has no interfering absorption. Flavin reduction was calculated based on its decrease in absorbance at 440 nm. Using the Nernst equation [Eq. (a)],

$$E_h = E_m(\text{dye}) + \frac{RT}{nF}\ln([\text{dye}_{ox}]/[\text{dye}_{red}]) \qquad (a)$$

the potential can be directly evaluated and a plot of E_h vs. ln([flavin$_{ox}$]/[flavin$_{red}$]) allows the determination of E_m(**1**-Ig) (inset, Fig. 1). The reduction potential of flavin **1** bound to antibody is −342 mV, representing a lowering of the reduction potential (E_m(**1**) = −206 mV) by 136 mV. When the antibody-**1** complex was reduced by dithionite in the absence of benzyl viologen, no spectra associated with the protonated blue (λ_{max} = 570 nm) or the deprotonated red (λ_{max} = 480 nm) semiquinone radical species were observed. Using a thermodynamic cycle, the antibody dissociation constant for the dihydroflavin **1a** can be calculated to be 3×10^{-4} M. The antibody exhibits a more than five order of magnitude preference for binding to the oxidized over the reduced flavin.

Because the antibody-**1a** complex is a stronger reducing agent than free **1a**, compounds with reduction potentials in the range −206 to −342 mV should be reduced by Ig-**1a** but not by free **1a** in solution (inset, Fig. 2). To demonstrate this, we studied the reduction of the dye Safranine T (E_m(dye) = −289 mV). The Ig-**1** complex was stoichiometrically reduced by dithionite (no excess dithionite present) and aliquots of Safranine T were subsequently added. Oxidation of Ig-**1a** (increase in absorbance at 375 and 458 nm) occurred rapidly, whereas no absorption due to oxidized Safranine T (510 nm) was observed, indicating that antibody-bound **1a** is in fact able to reduce Safranine T (Fig. 2). Following complete flavin oxidation, O_2 was added in order to oxidize Safranine T (Fig. 2, curve 4). As expected, free **1a** is not a powerful enough reducing agent to reduce Safranine T.

In summary, an antibody binding site has been used to modulate the reduction potential of flavin **1** by preferen-

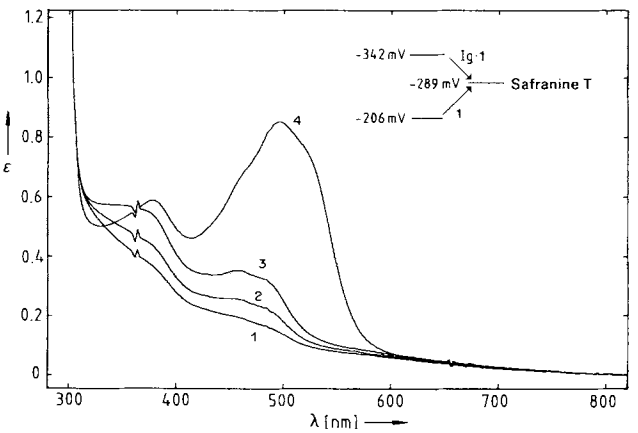

Fig. 2. Anaerobic addition of Safranine T (6 mM) to **1a** (30 μM) bound to antibody (31 μM), same conditions as Fig. 1; 1, **1a**; 2-3, partially oxidized **1a** after addition of 0.3 and 0.8 equivalents of Safranine T respectively; 4, after addition of oxygen.

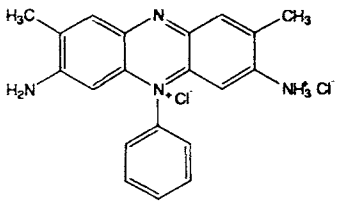

Safranine T

tially binding the oxidized form over the reduced dihydro form. The antibody–flavin complex is able to mediate redox processes not thermodynamically accessible to free flavin. Incorporation of a substrate binding site into these antibodies may lead to catalytic antibodies which can carry out stereocontrolled chemical reductions.

A Stable Bis(chelate) Analogue of the Creutz–Taube Ion**

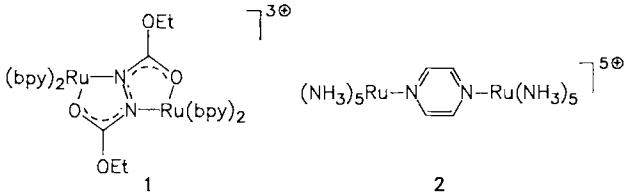
By *Wolfgang Kaim,* Volker Kasack, Herbert Binder, Eberhard Roth,* and *Jeanne Jordanov*

Since its isolation 20 years ago the electronic structure of the mixed-valence ($Ru^{II}Ru^{III}$) "Creutz–Taube ion" **2**[1] has been the subject of numerous theoretical and experimental investigations.[2–4] The controversy has focused, above all, on the extent of (de)localization between the metal centers ($Ru^{II}Ru^{III}$ or $Ru^{2.5}Ru^{2.5}$) and on the role of the bridging ligand.[2,4] Whereas delocalized mixed-valence complexes of class III-A with ruthenium ammine complex fragments have been unambiguously established in protic solvents,[2] the widely used $[Ru(bpy)_2]^{n\oplus}$ fragments, which are important in (photochemical) redox catalysis,[5] gave only mixed-valence compounds exhibiting low stability toward disproportionation ($K_c < 10^3$).[6]

$$2[Ru^{II}Ru^{III}] \overset{K_c}{\rightleftharpoons} [Ru^{II}Ru^{II}] + [Ru^{III}Ru^{III}] \qquad (a)$$

Only recently were we able to prepare binuclear compounds of this fragment which, owing to strong ligand–metal interaction, exhibit large comproportionation constants K_c;[7] however, the mixed-valence species could not be isolated because of the considerable anodic shift of the potential for metal oxidation. Nonetheless, complexes of $[Ru(bpy)_2]^{2\oplus/3\oplus}$ are soluble in aprotic media in contrast to those of $[Ru(NH_3)_n]^{2\oplus/3\oplus}$, so that complications due to acid–base equilibria and hydrogen-bonding interactions can be avoided.

By using reduced forms of very π-electron-deficient bis(chelate) ligands, we have attempted to synthesize stable bis(chelate) analogues of the Creutz–Taube ion that exhibit a high degree of delocalization. When pure N systems[8a] or when *o*- and *p*-semiquinone ligands[9] were used, however, we were able to characterize only ligand-centered (i.e., radical anion-containing) intermediates,[10a] instead of mixed-valence binuclear complexes. Herein we report on a paramagnetic binuclear complex **1** with a largely reduced diethyl azodicarboxylate (adc) bridging ligand; the spectroscopic measurements reveal that **1** can be regarded as a first true, isolable bis(chelate) analogue of the Creutz–Taube ion **2**.



1 **2**

Complex **1** is directly obtained by reaction of the bridging ligand with *cis*-$[Ru(bpy)_2Cl_2]$ in 1,2-dichloroethane (DCE); the neighboring oxidation states are accessible by reduction with Zn or by oxidation with Ag$^\oplus$. Owing to the stereogenicity of the two equivalent metal centers, *meso*/DL diastereomers should be formed;[7,9c] an effect of such isomerism on the spectroscopic data discussed here is not evident, however.

Cyclic voltammetry in DCE/0.1 M Bu_4NClO_4 shows two reversible steps at +0.38 and +0.89 V versus the saturated calomel electrode (SCE); thus, the comproportionation (stability) constant K_c [Eq. (a)] for the intermediate **1** is 4.4×10^8 (cf. $K_c=4\times10^6$ for **2**[1,2]). This high value favors the isolation of the paramagnetic species **1** and, moreover, is in agreement[7] with the large molecular orbital (MO) coefficients at N and O π centers in the lowest unoccupied MO (LUMO) of azodicarboxylic acid derivatives.[9c]

In contrast to numerous mono- and binuclear radical anion complexes of the $[Ru(bpy)_2]^{2\oplus}$ fragment,[8,9] the paramagnetic intermediate **1** does not exhibit an ESR spectrum at room temperature or at 77 K; only below about

50 K is a rhombic signal without hyperfine structure observable (Fig. 1). Very rapid relaxation is characteristic of metal-centered paramagnetic transition-metal complexes[3, 10] [Eq. (b) **A**]; also, close-lying excited states with partial ligand localization of the unpaired electron [Eq. (b)

$$[Ru^{II}(L^{2\ominus})Ru^{III}]^{3\oplus} \longleftrightarrow [Ru^{II}(L^{\bullet\ominus})Ru^{II}]^{3\oplus} \quad (b)$$

A **B**

B] may be responsible for this. The relatively small anisotropy of the glass spectrum of **1** (Fig. 1) compared with that of the Creutz-Taube ion **2** ($g = 1.346$, 2.489, 2.799; $\langle g \rangle = 2.30$[3]), which contains only inorganic co-ligands, also indicates a larger contribution of the radical anion resonance structure for **1** than for **2**.[3, 4, 11] However, this anisotropy is appreciably more pronounced than that found for the ligand-centered radicals containing $(bpy)_2Ru$[8–10, 12] which points to considerable involvement[11] of the heavy-metal center with its large spin-orbit coupling factor $(Ru^{II(III)}) = 700$–$1250\ cm^{-1}$,[4] according to formulation **A**.

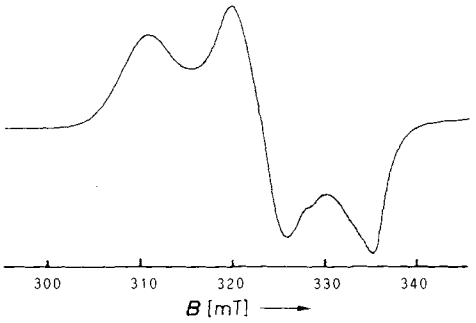

Fig. 1. X-band ESR spectrum of **1** at 3.6 K in acetone (counterions $PF_6^{\ominus}$): $g_x = 2.108$, $g_y = 2.036$, $g_z = 1.963$; $\langle g \rangle_{calcd} = 2.0364$.

In the X-ray photoelectron spectrum (−50 °C, gold foil) of **1**, as in that of the Creutz-Taube ion **2**,[4d] bands for Ru^{II} ($3d_{5/2}$: 283.0 eV) *and* Ru^{III} ($3d_{3/2}$: 290.0 eV) are observed, although they are partially overlapped by the C(1s) signal at 286.2 eV. The (2+) oxidation state, on the other hand, only exhibits a Ru^{II} ($3d_{5/2}$) band. However, this finding cannot be taken as evidence for a Ru^{II}/Ru^{III} localization, as has been discussed in detail for compound **2**.[4d]

In addition to the $d(Ru^{II}) \rightarrow \pi^*(bpy)$ charge-transfer absorption (MLCT)[13] at 450 nm,[12] the electronic spectrum of **1** shows a band with a half-width of $\Delta\nu_{1/2} = 2600\ cm^{-1}$ and an extinction coefficient of $\varepsilon = 7800\ M^{-1}\ cm^{-1}$ in the near-IR region (NIR; maximum at 1410 nm = 7100 cm^{-1}, shoulder at 1180 nm, Fig. 2). These data are very similar to the corresponding values for the Creutz-Taube ion: $\nu_{max} = 6400\ cm^{-1}$, $\varepsilon = 5000\ M^{-1}\ cm^{-1}$, $\Delta\nu_{1/2} = 1250\ cm^{-1}$,[1, 2] so that, in accordance with the formula **A**, these features may be attributed to the expected $Ru^{II} \rightarrow Ru^{III}$ intervalence transition (MMCT)[1, 2] and to an LMCT transition $\pi(adc^{2\ominus}) \rightarrow d(Ru^{III})$.

However, formulation **B** would also explain absorptions in the NIR, which would then be attributed to transitions from Ru^{II} d orbitals to the singly occupied MO of the ($adc^{\bullet\ominus}$) bridging ligand and would be split by metal-metal interactions.[9b, 10a, 12] The CT absorptions[13] of the dication [680 nm (sh; LLCT $\pi(adc^{2\ominus}) \rightarrow \pi^*(bpy)$), 527 nm (MLCT $d(Ru^{II}) \rightarrow \pi^*(bpy)$)] and of the tetracation [369 nm (MLCT $d(Ru^{II}) \rightarrow \pi^*(bpy)$)[12], 900 nm (MLCT $d(Ru^{II}) \rightarrow \pi^*(adc)$ for formula **C**, or LMCT $\pi(adc^{2\ominus}) \rightarrow d(Ru^{III})$ for formula **D**[9b])] are significantly different; values are from solutions in 1,2-dichloroethane (Fig. 2).

$$[Ru^{II}(L)Ru^{II}]^{4\oplus} \longleftrightarrow [Ru^{III}(L^{2\ominus})Ru^{III}]^{4\oplus} \quad (c)$$

C **D**

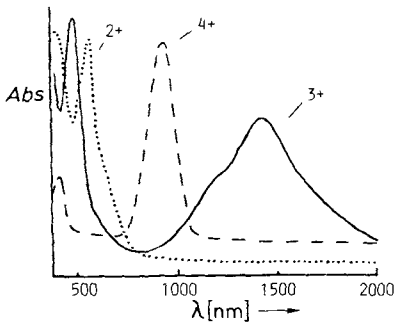

Fig. 2. Absorption spectra of **1** and of its two neighboring oxidation states in 1,2-dichloroethane (absorbance scale different for each spectrum).

The spectroscopic comparison thus shows that **1** occupies an intermediate position between the largely metal-centered, mixed-valence Creutz-Taube ion **2** and clearly ligand-centered radical complexes.[8, 10a, 12] In addition to the metal–metal interaction, the bridging ligand itself can be strongly involved in the electron delocalization, leading to the formation of extensively delocalized multimetal complexes having unusual electronic structures and remarkable physical properties.[14, 15]

Experimental Procedure

1$[PF_6]_3$: *cis*-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$ (100 mg, 0.19 mmol), diethyl diazodicarboxylate (17 mg, 0.10 mmol), and KPF_6 (70 mg, 0.38 mmol) were heated at reflux in 50 mL of 1,2-dichloroethane for 2 d. The product was precipitated from the cooled and concentrated reddish-brown solution by addition of diethyl ether and then recrystallized from acetone/diethyl ether (3 : 1) and from 1,2-dichloroethane/diethyl ether (4 : 1). Yield 30 mg (21%), correct elemental analysis (C,H,N).

The reduced (2+) oxidation state could be obtained from the (3+) ion by column chromatography on basic Al_2O_3 using acetone/water as eluent. The violet compound was recrystallized from acetone/diethyl ether (3 : 1) as the bis(hexafluorophosphate) (75%, C,H,N analysis).

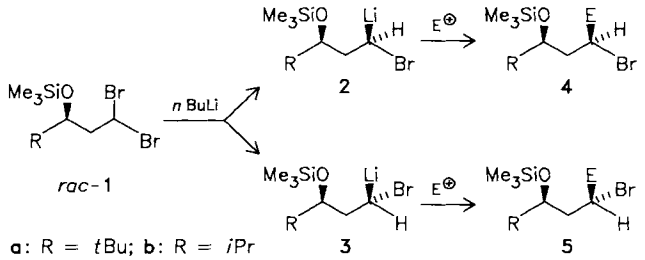
Asymmetric Induction in the Replacement of Diastereotopic Bromine Atoms by Lithium Atoms**

By *Reinhard W. Hoffmann,* Martin Bewersdorf, Klaus Ditrich, Michael Krüger,* and *Rainer Stürmer*

In memoriam Gert Köbrich 1929–1974

The formation of new chiral centers by intramolecular asymmetric induction is accomplished almost exclusively by reactions at the diastereotopic *sides* of a prochiral C=C, C=N, or C=O group.[1] The use of diastereotopic *groups* in preparative chemistry, on the other hand, has been reported in only a few special cases.[2] On cyclic systems, the selective replacement of one of two diastereotopic bromine atoms by a metal atom has long been known.[3] Herein we report on the diastereoselective replacement of one of the bromine atoms of open-chain, chiral 1,1-dibromoalkanes **1**. The investigations were carried out on racemic compounds.



a: R = *t*Bu; b: R = *i*Pr

In a typical experiment, 3.3 mmol of a 1.55 M solution of *n*-butyllithium in hexane was added dropwise to a solution of **1a** (3 mmol)[4] and acetone (6 mmol) as electrophile, $E^{\oplus}$, in 25 mL of Trapp mixture[6] at −120°C. After 1 h at < −90°C, the solution was allowed to reach room temperature and the products were hydrolyzed, affording a 94:6 mixture of the two diastereomeric epoxides **6a** in 90% yield.[5] Similar reaction using the pinacol ester of phenylboronic acid, instead of acetone, gave a 93:7 mixture of the diastereomeric boronates **7a**.[7] Addition of the carbenoids to isobutyraldehyde resulted in a 3:1 mixture of the *cis*- and *trans*-epoxides **8a** and **9a**. Each of these epoxides had a diastereomeric purity of >90:10.

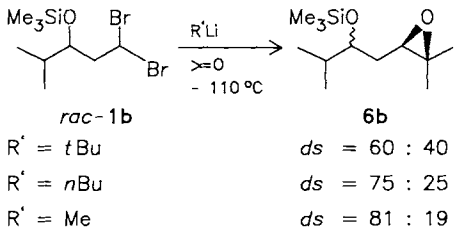
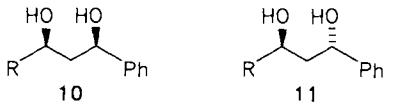
a: R = *t*Bu; b: R = *i*Pr

In the series **1b**,[4] with R = isopropyl, the results were essentially the same, although the diastereoselectivity (of **6b**–**9b**) was less[8] than in the *tert*-butyl-substituted series **1a**.

These findings indicate that the halogen–metal exchange on **1a** takes place with a diastereoselectivity of ca. 93:7 (for **1b**, 75:25), that the carbenoids **2/3** are configurationally stable at −120 to −90°C, and that they are trapped stereospecifically by the electrophiles $E^{\oplus}$ to give **4/5**. This interpretation is based on the fact that the ratio of the isomers **4/5** was independent of the nature of the trapping electrophile in the examples investigated. For a rapid epimerization of **2** and **3**, on the other hand, the product ratio **4/5** would be expected to depend on the nature of the electrophile. Thus, the halogen–metal exchange on **1** is presumably the product-determining step. Preliminary results from experiments in which the organolithium compounds were varied support this conclusion, as shown by the reaction of *rac*-**1b** to give **6b**.





Since the configuration of the product is established during the halogen–metal exchange, it is of interest to determine which of the diastereotopic bromine atoms in **1** is exchanged. To this end, the mixture of diastereomers **7a**, as well as **7b**, was oxidized with alkaline H_2O_2 to afford a mixture of the known diols[9] **10/11**. The main diastereomer in each case had the *threo* configuration **11**. Thus, the *pro-ul* bromine atom[10] in **1** is preferentially exchanged with formation of the carbenoid **2**. The (unproven) notion that coordination of the organolithium compounds to the trimethylsiloxy group might play a role in this process[3] was crucial in selecting **1** for these experiments.

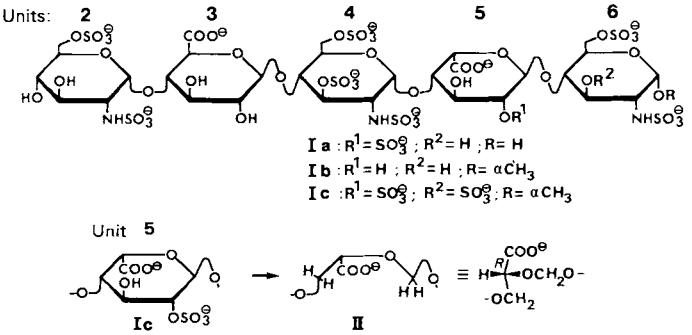
A Synthetic Heparin-like Compound which still Activates Antithrombin III although It Contains an Open Chain Fragment instead of α-L-Idopyranuronate**

By *Constant A. A. van Boeckel,* Jan E. M. Basten, Hans Lucas,* and *Sjoerd F. van Aelst*

The sulfated pentasaccharide **Ia** (Scheme 1), which is synthetically available,[1] corresponds to a unique antithrombin III (AT-III) binding region of the anticoagulant drug heparin. **Ia** catalyzes the AT-III-mediated inactivation of coagulation factor Xa (anti-Xa activity in an amidolytic assay = 590 U/mg), but not of thrombin. Recently, it has been established[2,5] that most of the charged groups in heparin fragment **Ia** participate in the AT-III-activation process. Moreover, the synthetic analogue **Ic** containing an extra 3-*O*-sulfate at unit 6 elicits higher activity (i.e. anti-Xa activity = 1270 U/mg) than the naturally occurring fragment.[3]

A special role should be ascribed to the rare, flexible carbohydrate α-L-iduronic acid (unit 5) in compound **Ia**.[4] For instance, it has been shown[5] that the carboxylate group of the α-L-idopyranuronate moiety of **Ia** is essential for AT-III activation, while the removal of its 2-*O*-sulfate substituent (Scheme 1, compound **Ib**) leads to a fourfold reduction of activity.[2b] The crucial question remains whether the presence of the complex α-L-idopyranuronate is essential for the biological activity of the heparin fragment.

To answer this question we synthesized a "ring-opened" analogue (i.e. compound **II**), in which α-L-iduronic acid (unit 5) is replaced by an (*R*)-glyceric acid -2-*O*-CH_2- moiety (2,3 *seco*-2,3-di-*nor*-α-L-iduronic acid). In addition, compound **II** contains an extra 3-*O*-sulfate group at unit 6



Scheme 1. Compound **Ia** comprises the antithrombin activating region of heparin. Compounds **Ib** and **Ic** are synthetic analogues, which are respectively less and more active than the naturally occurring derivative **Ia**. The synthetic analogue **II** is described in this communication; the α-L-iduronic acid moiety (unit 5) has been replaced by an (*R*)-glyceric acid-OCH_2-moiety.

to compensate for the drop in activity caused by the absence of the 2-*O*-sulfate group at unit 5 (see above).

A key goal in the synthesis of **II** was the preparation of a suitably protected and activated (*R*)-glyceric acid building block (i.e. compound **7**) that could be coupled via a 2-oxymethylene function to the (low reactive) 4-hydroxy group of compound **8**[3a] (see Scheme). Since this coupling reaction is formally identical to a carbohydrate glycosidic bond formation, we adopt a $BF_3 \cdot OEt_2$-catalyzed glycosidation with glycosyl fluorides[6] for coupling of the (*R*)-glyceric acid-2-*O*-CH_2F derivative **7**. The synthesis of **7** started from (*R*)-glyceric acid methyl ester **2**, which was prepared from D-serine (**1**).[7] The primary hydroxy group of **2** was protected selectively with a DMT group,[*] after which the secondary hydroxy group was methoxymethylated to give **3** in high yield. Mild acid treatment afforded compound **4**, which was allylated in a two-step procedure to provide derivative **5** in 58% overall yield. Acetolysis of **5** afforded compound **6** in quantitative yield. The latter was treated with HF/pyridine[8] to give the key building block **7** in 70% yield. Reaction of **7** with **8**, in the presence of $BF_3 \cdot OEt_2$ afforded the corresponding coupled product in 84% yield, from which the temporary allyl protective group was cleaved by $PdCl_2$ treatment to give **9** in 40% yield. The resultant aglycon **9** was then stereoselectively condensed with the known glycon **10**[1c] in 65% yield using $HgBr_2$/$Hg(CN)_2$ as promoter. The α-coupled product **12a** was first de-levulinoylated to give **12b** and then coupled to monosaccharide **11**[9] to give the fully protected pentasaccharide analogue **13** in 50% yield. Compound **13** was converted into the desired analogue **II**[10] in 22% overall yield by the following well-established[1,2c,3a,5] reaction sequence: (i) NaOH; (ii) $Me_3N \cdot SO_3$, DMF; (iii) H_2/Pd; (iv) pyridine·SO_3, H_2O; and gel permeation chromatography.

Analogue **II** displayed prominent AT-III-mediated anti-Xa activity (150 U/mg), thus proving that the biological activity of a heparin-like fragment is retained when the complex carbohydrate α-L-iduronic acid has been replaced by a linear chain that is substituted by a correctly oriented carboxylate group. Preliminary conformational analysis studies reveal that the conformational freedom of the linear moiety of **II** is restricted considerably. Thus, vicinal proton-proton coupling constants and NOE data of com-

pound **II** indicate that the glyceric acid $-OCH_2-$ moiety favors a conformation corresponding to that of the backside region (O-4, C-4, C-5, O) of α-L-idopyranuronate in the $^1C_4$ form. Taking the above mentioned results into consideration we believe that the introduction of similar "opened" carbohydrate-like moieties in other biologically active carbohydrates will find an application in broader domains of glycoconjugate research. For that purpose, asymmetrically substituted $-OCH_2O-$ acetal functions can be introduced by the methodology described in this communication.

Simple Synthesis of KDO α-Glycosides by Anomerically Selective *O*-Alkylation**

By *Richard R. Schmidt** and *Angelika Esswein*

Lipopolysaccharides (LPS) are important components of the outer membranes of gram-negative bacteria.[1] The lipophilic portion of LPS, lipid A, is responsible for anchoring the lipid in the membrane; it determines the toxic and immunostimulatory properties of LPS. Lipid A consists essentially of a β(1–6′)-linked glucosamine disaccharide containing phosphate groups at the C-1 and C-4′ atoms as well as long-chain fatty acids on the N atom and on some of the free O atoms. The hydrophilic portion of LPS consists of a complex oligosaccharide chain, which is linked through KDO (3-deoxy-D-manno-2-octulosonic acid) to the glucosamine disaccharide.[1] According to recent investigations, an α(2–6′)-glycosidic bond is present.[2] The application of the Koenigs-Knorr procedure for α-glycosidic bond formation using KDO halogenoses as glycosyl donors has often given unsatisfactory results owing to elimination of hydrogen halide and, in part, formation of β-glycoside bonds.[3] Good results were recently reported using fluoride as the leaving group.[4]

The anomerically selective *O*-alkylation reported here is an especially simple procedure for saccharide synthesis.[5,6] However, several prerequisites must be satisfied: (1) decomposition reactions in the sugar portion (particularly in the ring-open form) occurring after deprotonation of the hemiacetal hydroxyl group must be avoided; (2) the ano-

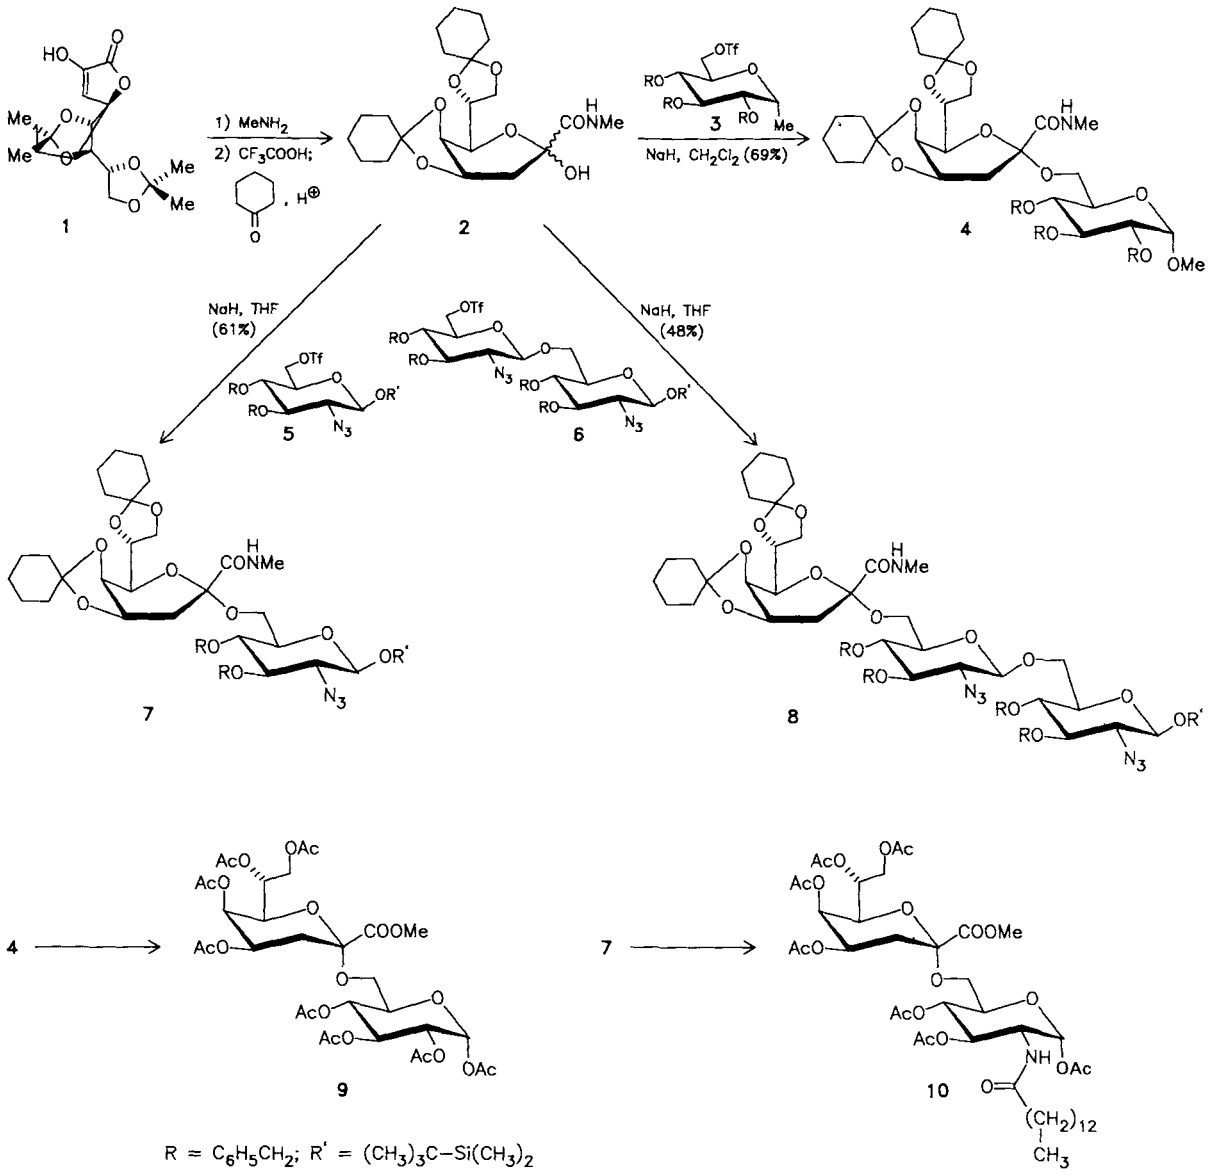
Postfach 5560, D-7750 Konstanz (FRG)

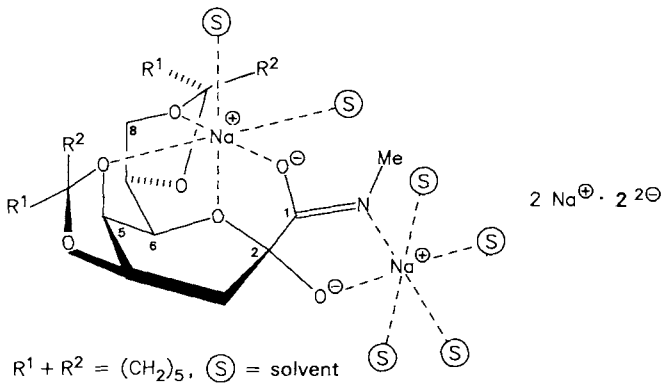
[**] Anomeric *O*-Alkylation, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: [5].



meric oxygen atom must exhibit sufficient nucleophilic reactivity; and (3) stereocontrol in the *O*-alkylation must be achieved.[6] Owing to the 1-carboxyl group and the favoring of the $^5C_2$ conformation in the 4,5,7,8-tetra-*O*-acyl-protected KDO (which is usually employed in glycoside synthesis[3]), the prerequisites are not favorably met with respect to stability and reactivity of the alkoxide intermediate and with respect to α-diastereoselectivity in the *O*-alkylation.[7]

We therefore chose the 4,5:7,8-di-*O*-cyclohexylidene derivative **2** of KDO as our starting material; this compound can be obtained in a few steps from β-lithiated α-alkoxyacrylic acid derivatives and 2,3:4,5-di-*O*-isopropylidene-D-arabinose via compound **1**.[8,9] The ^{1}H NMR data show that compound **2** exists in the boat conformation.[10] Thus, stereomodels show that, through the carboxamide group, the ring oxygen atom, and the oxygen atoms at C-5 and C-8, **2** can serve as a tetradentate chelating ligand for the complexation of a metal ion. Such complexation, accompanied by generation of the dianionic species $\mathbf{2}^{2\ominus}$ (deprotonation of the carboxamide group and of the anomeric hydroxyl group), should have a positive effect on all factors, in particular the nucleophilic reactivity and the desired α-selectivity. Indeed, addition of two equivalents of sodium hydride as base to the KDO derivative **2**, followed by addition of D-glucose-6-*O*-triflate **3** as alkylating agent, led to the isolation of the α(2–6′)-linked disaccharide **4** in 69% yield. No β-linked product was formed. To carry out a structural analysis, **4** was subjected to hydrogenolytic debenzylation, followed by acid-catalyzed cleavage of the protecting groups; per-*O*-acetylation, subsequent treatment with sodium nitrite in acetic anhydride/acetic acid, and immediate thermolysis of the resulting nitroso compound afforded the methyl ester **9**. The ^{1}H NMR data of its KDO portion agree with the corresponding data obtained for other *O*-acetylated KDO α-glycosides[3] and, moreover, satisfy the rule stated by *Unger*[11] for KDO α-glycosides.

The anomerically selective *O*-alkylation was also applied successfully to α(2–6′)-glycosidic bond formation with the glucosamine derivative **5**[9] and to α(2–6′)-glycosidic bond formation with the β(1–6′)-linked diglucosamine derivative **6**.[9] Using sodium hydride as base and THF as solvent, good yields of the desired disaccharide **7** and trisaccharide **8**, respectively, were obtained. The ^{1}H NMR data of the KDO portion of these compounds largely agree



with those of compounds **4**. To carry out a structural analysis, compound **7** was converted into the derivative **10** by amide/ester conversion, azide reduction with hydrogen sulfide/pyridine, acylation of the free amino group with myristic acid, acid-catalyzed cleavage of the cyclohexylidene and *tert*-butyldimethylsilyl groups, *O*-acetylation, hydrogenolytic debenzylation, and, once again, *O*-acetylation. The ^{1}H NMR data for the KDO portion correspond to those obtained for compound **9**.

General Experimental Procedure

4, 7, and **8**: **2** (2 mmol) was dissolved under N_2 in 50 mL of dry dichloromethane (**4**) or tetrahydrofuran (**7**, **8**) and the resulting solution was cooled to -30°C. Sodium hydride (4.2 mmol) was then added and, after 20 min, a solution of the triflate (2.2 mmol; **3**, **5**, and **6**, respectively) in 30 mL of dry dichloromethane, or tetrahydrofuran, was then slowly added dropwise. After standing for 3 h at -30°C, the solution was allowed to warm to -10 to 0°C and then stirred. The reaction was monitored by thin layer chromatography. The reaction mixture was filtered through silica gel and concentrated under vacuum, and the products were chromatographed on silica gel using petroleum ether (30–60°C)/ethyl acetate as eluent.

R_F (petroleum ether/ethyl acetate). **4** (1/1) 0.41; **7** (2/1) 0.60; **8** (2/1) 0.48.

^{1}H NMR (400 MHz, $CDCl_3$): **4**: $\delta = 4.42$ (ddd, $J_{3'eq,4'} = 3.91$, $J_{3'ax,4'} = 4.46$, $J_{4',5'} = 7.33$ Hz, 1 H, 4'-H), 4.30 (ddd, $J_{6',7'} = 6.59$, $J_{7',8'a} = 6.34$, $J_{7',8'b} = 4.88$ Hz, 1 H, 7'-H), 4.17 (dd, $J_{5',6'} = 1.95$ Hz, 1 H, 5'-H), 4.05 (dd, $J_{8'a,8'b} = 8.79$ Hz, 1 H, 8'b-H), 4.00 (dd, 1 H, 8'a-H), 3.75 (dd, 1 H, 6'-H), 2.76 (d, $J = 4.88$ Hz, 3 H, $NHCH_3$), 2.54 (dd, $J_{3'ax,3'eq} = 15.38$ Hz, 1 H, 3'ax-H), 1.90 (dd, 1 H, 3'eq-H).

7: $\delta = 4.43$ (ddd, 1 H, 4'-H), 4.31 (ddd, $J_{6',7'} = 6.34$ Hz, 1 H, 7'-H), 4.16 (dd, $J_{5',6'} = 1.95$, $J_{4',5'} = 7.08$ Hz, 1 H, 5'-H), 4.07 (dd, $J_{8'a,8'b} = 8.55$, $J_{7',8'b} = 6.35$ Hz, 1 H, 8'b-H), 3.94 (dd, $J_{7',8'a} = 5.12$ Hz, 1 H, 8'a-H), 3.74 (dd, 1 H, 6'-H), 2.75 (d, $J = 5.13$ Hz, 3 H, $NHCH_3$), 2.46 (dd, $J_{3'ax,3'eq} = 15.14$, $J_{3'ax,4'} = 5.12$ Hz, 1 H, 3'ax-H), 1.91 (dd, $J_{3'eq,4'} = 3.91$ Hz, 1 H, 3'eq-H).

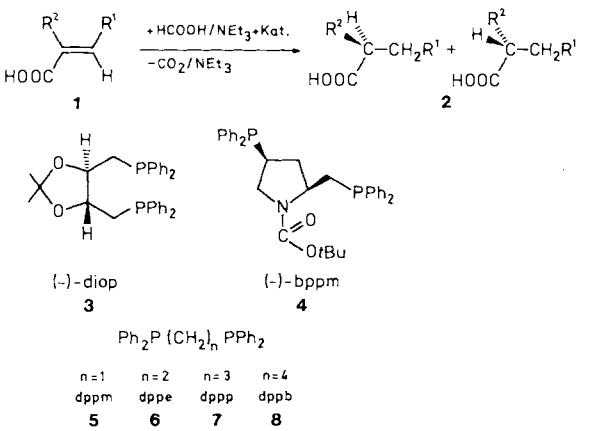
Enantioselective Catalytic Transfer-Hydrogenation of α,β-Unsaturated Carboxylic Acids with Triethylammonium Formate**

By *Henri Brunner*,* and *Walter Leitner*

The hydrogenation of prochiral olefins in the presence of optically active rhodium complexes is the most well-known enantioselective catalysis by transition metal compounds.[1] The decomposition of formic acid to hydrogen and carbon dioxide is also catalyzed by rhodium compounds.[2] We have been able to combine these two processes to provide a simple, effective alternative to the dangerous and frequently impracticable use of gaseous hydrogen. Scheme 1 shows the enantioselective transfer-hydrogenation of (*Z*)-α-acetylaminocinnamic acid **1a** and itaconic acid **1b** to **2a** and **2b**, respectively.



Scheme 1. **a**, R^1 = Ph, R^2 = NHCOMe; **b**, R^1 = H, R^2 = CH_2COOH.

In situ systems of $[Rh(cod)Cl]_2$ (cod = 1,5-cyclooctadiene) and phosphane ligands serve as catalysts, as are also used in the hydrogenation with molecular hydrogen.

Triethylammonium formate (TEAF)[3] has proven to be a useful source of hydrogen. TEAF is a commercially available azeotrope of formic acid and triethylamine (molar ratio 5 : 2).[4] Owing to its solubility in organic solvents, TEAF, in contrast to other formates, furnishes homogeneous reaction mixtures. On using dipolar aprotic solvents, under mild conditions, results are obtained which approach or even surpass those achieved with hydrogen. Even in boiling acetone or ethanol the transfer-hydrogenation leads to complete reduction of the CC double bond, albeit with optical yields of less than 10%. The highest enantiomeric excesses are achieved in DMSO (Table 1).

Table 1. Enantioselective transfer-hydrogenation of (*Z*)-α-acetylaminocinnamic acid **1a** and itaconic acid **1b** with triethylammonium formate (TEAF). The substrates were quantitatively hydrogenated [a].

Substrate	Ligand	Solvent	*T* [°C]	*ee* [%] [b] (conf.)	Number of experiments	*ee* [%] [c]
1a	**3**	DMSO	27	50.0 ± 2.1 (*R*)	10	81 [7]
1a	**4**	DMSO	45	71.7 ± 5.4 (*R*)	11	93 [9]
1a	**3**	DMF	27	37.9 (*R*)	1	
1a	**3**	MPY [d]	45	20.5 (*R*)	1	
1b	**3**	DMSO	27	49.1 ± 1.6 (*S*)	12	45 [8]
1b	**4**	DMSO	45	83.8 ± 1.2 (*S*)	5	94 [9]

[a] Determined ^{1}H-NMR spectroscopically. [b] Determined polarimetrically. Rotations of the pure hydrogenation products: (*S*)-*N*-acetylphenylalanine: $[\alpha]_D^{25} = 46.5°$ ($c = 1$, EtOH) [5], (*R*)-methylsuccinic acid: $[\alpha]_D^{25} = 15.5°$ ($c = 2.82$, EtOH) [6]. [c] For comparison: rhodium-catalyzed hydrogenation with H_2. The data refer only to substrate and ligand, not to solvent and temperature! [d] MPY = *N*-methylpyrrolidone.

In the case of **1a** the transfer-hydrogenation affords somewhat lower values, in the case of **1b**, however, similar values as the rhodium-catalyzed hydrogenation with molecular hydrogen. With the ligand **3**, the optical induction in the transfer-hydrogenation of **1b** is even higher than in the hydrogenation with molecular hydrogen. In all the cases investigated so far the preferred configuration is the same in both types of reaction. The employment of TEAF in DMSO as source of hydrogen is a substantial improvement compared to the transfer-hydrogenation with 80% aqueous formic acid recently described by us.[10]

High enantioselectivities and high reaction rates are achieved in the transfer-hydrogenation with TEAF only when ligands such as **3** or **4** are used which can form seven-membered chelate rings. With the ligands norphos[11] or prophos,[12] which form five-membered chelate rings and have proven useful in hydrogenation, only small enantiomeric excesses, usually with incomplete hydrogenation, are obtained in the transfer-hydrogenation described here. This influence of the chelate ring size is also reflected in the relative rates of reaction for the ligands **5**–**8**. When the decrease in concentration of **1b** during the catalysis is monitored via the decrease in intensity of the peaks of the methylene protons in the ^{1}H-NMR spectrum ($\delta = 6.39$ and 5.90) relative to the internal standard mesitylene ($\delta = 6.69$) curves like those shown in Figure 1 for **8** are obtained. A short induction phase is followed by a linear decrease in the substrate concentration.

A comparison of the slopes of the linear portions of the curves shows that the rate of hydrogenation is lowest with **6**. With **5** it increases by a factor of 4, with **7** by a factor of 77, and with **8** by even a factor of 128. The reason for this behavior could lie in the lack of readiness of five-membered ring forming ligands to act as so-called "dangling ligands",[13] and thus to make coordination sites free at the metal atom.

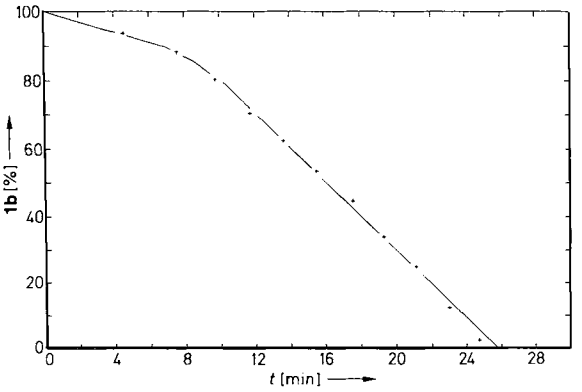

Fig. 1. ^{1}H-NMR spectroscopic monitoring of the transfer-hydrogenation of **1b** with $[Rh(cod)Cl]_2$ in the presence of the ligand **8** as catalyst (see text).

Experimental

500 mg of substrate, 0.7 mol-% of $[Rh(cod)Cl]_2$ and 1.8 mol-% of ligand were dissolved in 3.75 mL of anhydrous DMSO under an atmosphere of nitrogen. After 30 mins' stirring at the given reaction temperature (Table 1) the mixture was treated with sufficient TEAF (Merck; dried over $MgSO_4$ and distilled under N_2) to make the substrate/formic acid ratio 1 : 5. Shortly thereafter a vigorous evolution of gas was observed in the orange solution. The mixture was then stirred for 20 h, rendered alkaline with 10 mL of 2 N NaOH, and filtered. The filtrate was washed with 4 × 30 mL of ether, acidified with 6 mL of 10% HCl, and the product extracted with 4 × 50 mL of ether. After drying over $MgSO_4$ the solvent was removed and the product dried for 5 h at 40°C under vacuum. The yields were quantitative. To avoid the tedious drying necessary for the removal of DMSO residues, the ether extracts of the acid solution can be washed with 3 × 5 mL of 5% HCl. The yields are then about 75%.

Synthesis and Structure of $[NaTi(2,6\text{-}Me_2C_6H_3O)_4(py)]_2$: a Dimeric Material Containing a Novel Phenoxide Bridge**

By *Loren D. Durfee, Phillip E. Fanwick,* and *Ian P. Rothwell**

The last few years has seen a resurgence of interest in both the structure and bonding of main group element compounds.[1] In the case of the alkali metal compounds

[*] Prof. I. P. Rothwell, Dr. L. D. Durfee, Dr. P. E. Fanwick

[**] This work was supported by the US National Science Foundation.

the importance of π-bonding between metal atom and organic fragment has been an area of particular interest.[2] During our studies of the sodium amalgam reduction chemistry of titanium(IV) aryloxides,[3] we have isolated an unusual double salt of sodium and titanium which consists of a dimeric unit held together via a unique sodium phenoxide linkage.

The reduction of the tetraaryloxides $Ti(OR)_4$, R = 2,6-$iPr_2C_6H_3$ or 2,6-$Me_2C_6H_3$, with Na/Hg (1 equiv.) in THF solution yields blue-green products containing both sodium and titanium. In the case of the more bulky 2,6-diisopropylphenoxide the discrete compound

$[(2,6\text{-}iPr_2C_6H_3O)_2Ti(\mu\text{-}2,6\text{-}iPr_2C_6H_3O)_2Na(thf)_2]$ **1**

was obtained and structurally characterized.[3] However, the less bulky 2,6-dimethylphenoxide substrate was found to generate a product which was more difficult to characterize. Attempts to sequester the sodium from this latter compound by treatment with pyridine failed, leading to deep-purple solids[4] which are only sparingly soluble in hydrocarbon solvents. After numerous unsuccessful attempts, we have finally been able to obtain single crystals of **2** from hot toluene solution. A single crystal X-ray diffraction analysis of **2**[5] shows the compound to consist of a pentacoordinate titanium center surrounded by four aryloxide oxygen atoms and one pyridine nitrogen atom in an approximately trigonal-bipyramidal arrangement (Fig. 1, top). Two of the aryloxide oxygen atoms, one equatorial and one axial, then bridge to the sodium atom, giving a $[Ti(\mu\text{-}OR)_2Na]$ unit similar to that in **1**.[3] However, the σ-framework of this unit does not satisfy the serious electron deficiencies of the so far only two coordinate sodium ion. The compound overcomes this problem by forming phenoxide bridges between pairs of Na,Ti units, not through oxygen atoms, but by a π-interaction between the sodium ion of one unit and the aromatic ring of one of the phenoxide groups in a second unit (Fig. 1, bottom). The distances between the sodium ion and the carbon atoms in the π-bonded ring are all similar, varying from 2.79–2.88 Å, and are slightly longer than the distances found for sodium atoms bound to carbanionic ring systems such as cyclopentadienyl anion.[1,6] The ability of phenoxide ligands to bind in this fashion to sodium atoms is of direct relevance to previous work where it has been found difficult to account for the unusual stoichiometries obtained on alkali metal reduction of titanium phenoxides.[7]

3-Lithio-2-(*o*-lithiophenyl)naphthalenedilithium—a Tetralithio Compound with σ- and π-Bonded Lithium Atoms**

By *Rainer Benken, Werner Andres,* and *Harald Günther**

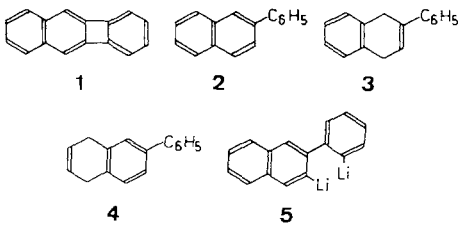
In organic monolithium compounds the metal can either be σ- or π-bonded[1]—classical examples are phenyllithium[2] and naphthalenedilithium,[3] respectively—whereas organic polylithium compounds can exhibit both types of bonding.[4] We have now, for the first time, found a tetralithio compound in which a ring-metalated dianion of an aromatic π-system occurs.

[*] Prof. Dr. H. Günther, Dipl.-Chem. R. Benken, Dipl.-Chem. W. Andres Fachbereich 8, Organische Chemie II, Universität-Gesamthochschule Postfach 101240, D-5900 Siegen (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *R. Luckenbach*, Beilstein-Institut, Frankfurt, for generous help with a literature search, Prof. Dr. *A. Maerker*, Siegen, for valuable information, and Dr. *J. Opitz*, Siegen, for the mass spectrometric investigations.

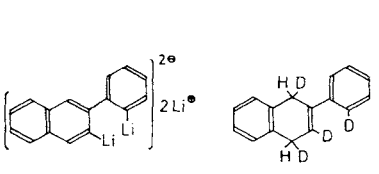
Biphenylene reacts with lithium in THF to give biphenylenedilithium in good yields, which, according to its NMR spectra is a delocalized 14π (4q+2) system.[5] The analogous reaction in the case of benzo[*b*]biphenylene **1** leads to a species which according to its ^{1}H- and ^{13}C-NMR spectrum (400 and 100 MHz, respectively, −40°C, [D$_8$]THF) has lost the C_{2v} symmetry of the hydrocarbon **1**. The ^{1}H-NMR spectrum shows two ABCD systems (δ = 1.63, 3.52, 3.12, 1.69, and 7.50, 5.97, 6.46, 5.56) with the multiplicity (d, t, t, d) typical for four neighboring benzene protons and two singlets (δ = 2.24, 2.53). The ^{13}C{^{1}H}-NMR spectrum displays two signals for quaternary carbon atoms at low field (δ = 166.6, 175.4) in addition to 14 resonances between δ = 78.8 and 161.0. A comparison of the spectra rules out the new compound being the dianion $\mathbf{2}^{2\ominus}$ of the 2-phenylnaphthalene **2**;[6] trapping experiments with H_2O, however, afford the same products which are obtained on reaction of $\mathbf{2}^{2\ominus}$ with H_2O.

Chromatographic separation on silica gel doped with $AgNO_3$ furnished 1,4-dihydro-2-phenylnaphthalene[7] **3** and the previously unknown 1,4-dihydro-6-phenylnaphthalene[8] **4** in the ratio 5 : 1. Since biphenylenedilithium is converted with opening of the four-membered ring into 2,2′-dilithiobiphenyl, the formation of 3-lithio-2-(*o*-lithiophenyl)naphthalene **5** would be expected in the case of $\mathbf{1}^{2\ominus}$, which in the reaction with H_2O, however, should only furnish **2**.

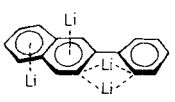


1 2 3 4 5

The experimental data, especially the high shielding for six "aromatic" protons in the ^{1}H-NMR spectrum (an ABCD system, two singlets, cf. above) are understandable if the structure **6** is assumed for the new species, which can be formed from **1** by reductive cleavage of the five-membered ring to give **5** followed by further reduction.[9] Additional findings lend support to this interpretation: 1) the chemical shifts of the strongly shielded ^{1}H and ^{13}C resonances in **6**, whose spectra were completely assigned with the help of 2D-NMR experiments of the COSY and NOESY type,[10] are very similar to those in naphthalenedilithium.[11] The downfield ^{13}C resonances (δ = 166.6, 175.4) must be those of lithiated sp^2-C atoms.[12] 3) The ^{7}Li-NMR spectrum of **6** at −100°C shows three resonances in the ratio 2 : 1 : 1 at δ = 7.26, 0.15 and −0.73,[13] which can be assigned to the σ- and π-bonded lithium



6 7



8

atoms.[14] 4) Trapping experiments with D_2O afford a [D$_4$]-1,4-dihydro-2-phenylnaphthalene, which, on the basis of its molecular mass (210.1359) and its ^{2}H-NMR spectrum with signals for two methylene-^{2}H atoms and one olefinic and one aromatic ^{2}H atom (Fig. 1) must have the structure **7**.[15]

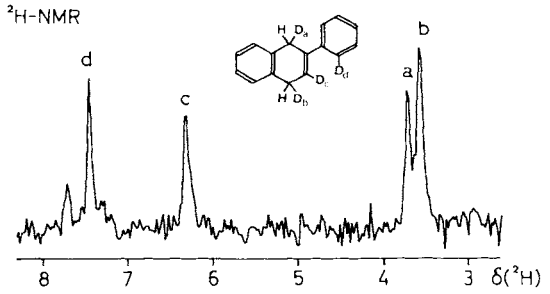


Fig. 1. 60.4-MHz ^{2}H-NMR spectrum of 1,3,4,2′[D$_4$]-1,4-dihydro-2-phenylnaphthalene **7** with ^{1}H decoupling (internal standard: tetramethylsilane). The assignment of the methylene positions a and b follows from NOE measurements for the ^{1}H-compound.

The solid-state structures found for 2,2′-dilithiobiphenyl on the one hand[16] and naphthalenedilithium on the other[3] make the structure **8** highly probable for the new Li_4-compound. Besides the ^{1}H- and ^{13}C-NMR findings, the observation that the rotation of the *ortho*-metalated phenyl ring about the C-2,C-1′ bond in **8** cannot be detected below room temperature, whereas in the dianion $\mathbf{2}^{2\ominus}$ the analogous process is first "frozen in" at −40°C on the NMR time scale, is also in agreement with this structure.[6]

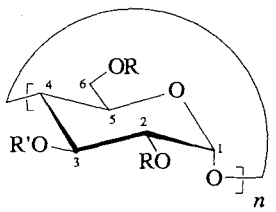
Second Sphere Coordination Adducts of Phosphane-Transition Metal Complexes with β-Cyclodextrin and its Methylated Derivative**

By *David R. Alston, Alexandra M. Z. Slawin, J. Fraser Stoddart,* David J. Williams,* and *Ryszard Zarzycki*

The second sphere coordination[1] of transition metal complexes bearing hydrophobic ligands by cyclodextrins is a relatively unexplored field.[2] Only two such supramolecular adducts have been characterized[3] structurally in the solid state by X-ray crystallography. In both cases, the hydrophobic ligand of the complex penetrates the cavity of the cyclodextrin via the wider aperture of the receptor associated with the face bearing the secondary hydroxy groups. ^{1}H-NMR spectroscopy reveals that the hydrophobic ligand also enters the cavity in solution, though unequivocal structural information regarding the preferred face[4] at which adduct formation occurs has not been obtained. A large number of transition metal complexes bearing hydrophobic trialkylphosphane ligands find applications in catalysis.[5] In addition, some are employed in the treatment of rheumatoid arthritis.[6] Our interest[1] in the second sphere coordination of transition metal complexes has led us to investigate adduct formation between trialkylphosphaneplatinum complexes and cyclodextrins and their methylated derivatives in aqueous solution. We also describe the first example of a transition metal complex adduct with a cyclodextrin in which a crystalline adduct is formed as a result of occupation of the *narrower* primary hydroxy-group-bearing face of the receptor by the substrate.



αCD: n=6; R=R'=H
βCD: n=7; R=R'=H
DMαCD: n=6; R=Me, R'=H
DMβCD: n=7; R=Me, R'=H
TMαCD: n=6; R=R'=Me

2, R=Et

In the ^{1}H-NMR spectrum of a 1:1 molar mixture of β-cyclodextrin (βCD) and *trans*-[Pt(PMe$_3$)Cl$_2$(NH$_3$)] **1**, recorded in D_2O solution (5.7 mM), the signal for the H-3 protons situated *inside* the cavity of the CD is shifted to higher frequency (0.037 ppm), relative to that observed in the spectrum of the free receptor recorded in D_2O solution. Relative to the signal in the spectrum of the free transition metal complex, an analogous shift to higher frequency (0.104 ppm) was observed for the protons of the PMe$_3$ ligand in the complex **1** in the presence of 1 mol equivalent of βCD. These results indicate that, in solution, the PMe$_3$ ligand, in common with other hydrophobic first sphere ligands, enters the cavity of the cyclodextrin. Furthermore, the associated chemical shift differences vary with the concentration of the 1:1 adduct in a manner that verifies the 1:1 stoichiometry. Quantitative treatment[7] of the concentration dependence in D_2O at 22°C afforded an average value[8] for the association constant (K_a) for adduct formation of 2950 mol^{-1} kg, corresponding to a value for the free energy of adduct formation ($-\Delta G^0$) of 19.6 kJ mol^{-1}. The K_a value is ten times higher than those so far found[3] for adduct formation between αCD and other transition metal complexes.[9] Interestingly, however, the absence of ^{1}H-NMR chemical shift changes in the spectrum of a 1:1 molar mixture of **1** and αCD shows that they do not form an adduct in D_2O solution.

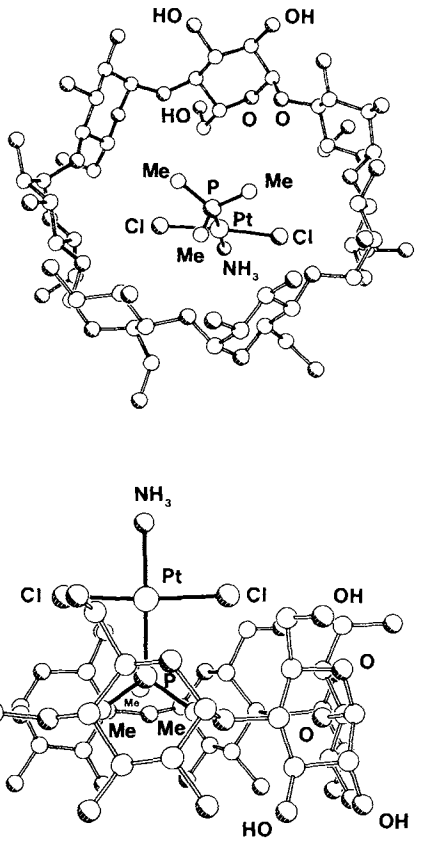

Fig. 1. Top: Structure of the adduct formed between βCD and **1** in the crystal viewed looking into the βCD face carrying the secondary hydroxy groups. Only the PMe$_3$ ligand lies in the cavity of the CD above the lower rim of primary hydroxy groups. The unresolved component of the adduct which lies within a plane parallel to the secondary hydroxy-group-bearing face, and also the peripheral water molecules, have been omitted for clarity. Bottom: In the side-on view of the adduct formed between βCD and **1** in the crystal, the degree of the penetration of the PMe$_3$ ligand of **1** into the cavity of βCD is easily discernible.—Crystal data: orthorhombic, a=19.431(7), b=24.082(12), c=32.503(11) Å, V=15209 Å^3, space group $C222_1$, Z=8, μ(Cu$_{K\alpha}$)=50 cm^{-1}, 4733 independent observed reflections with [$|F_o| \geq 3\sigma(|F_o|)$, $\theta \leq 58°$], R=0.113, R_w=0.100 [11].

Finstaking crystal-growing experiments eventually afforded[10] single crystals of the adduct of βCD and **1** suita-

ble for X-ray crystallographic analysis.[11] The X-ray crystal structure (Fig. 1) of the 1:1 adduct indicates from refinement of the occupancy of the transition metal complex that, in 57% of the adducts, the PMe_3 ligand of **1** is inserted into and bound to (Fig. 1, bottom) the narrow primary hydroxy-group-bearing face of the βCD torus. There is evidence that, in some or all of the other 43% of adducts, **1** lies within a severely disordered surface which could be forming a lid on the wider secondary hydroxy-group-bearing face of the βCD torus. Comparison of the relative internal diameters of αCD (4.7–5.2 Å)[12] and βCD (6.0–6.4 Å)[12] with the van der Waals diameter (6.0 Å) of the PMe_3 ligand on the complex account for the inability of αCD to form an adduct with **1**.

The 2,6-per-*O*-methyl derivative of βCD, dimethyl-βCD (DMβCD) is not only soluble in organic solvents, but is also ca. 10 times more soluble in water than is the parent βCD.[13] The ^{1}H-NMR spectrum of a 1:1 mixture of DMβCD and **1** (8.6 mM) recorded in D_2O reveals shifts to higher frequencies for the signals associated with H-3 (0.062 ppm) in the receptor and the PMe_3 ligand (0.034 ppm) of the substrate, indicating that adduct formation is occurring in a manner *apparently*[4] structurally analogous to that demonstrated previously for βCD. The average K_a value[14] for adduct formation, 3160 mol^{-1} kg ($-\Delta G^0$ 19.8 kJ mol^{-1} at 22°C), determined from the concentration dependence in D_2O of the chemical shift changes for the H-3 and PMe_3 signals, shows that the strength of binding is very similar to that found with the parent cyclodextrin. Moreover, the remarkable β-selectivity towards adduct formation demonstrated by **1** in its interaction with αCD and βCD in D_2O solution is also observed with the methylated derivatives: thus, DMβCD forms an adduct in D_2O solution, whereas DMαCD does *not*.

The complex, *trans*-$[Pt(PEt_3)Cl_2(NH_3)]$ **2**, bearing a larger hydrophobic PEt_3 ligand, was also shown by ^{1}H-NMR spectroscopy to form a second sphere coordination adduct with DMβCD in D_2O solution. Once again, the average K_a value[15] for adduct formation of 3190 mol^{-1} kg ($-\Delta G^0$ 19.8 kJ mol^{-1} at 22°C), matched that observed for complex **1** with the smaller PMe_3 ligand, thus implying a similar strength of binding between DMβCD and neutral square-planar platinum(II) complexes containing either PMe_3 or PEt_3 ligands.[16, 17]

The results reported in this communication have implications for the design of drug delivery systems and water-soluble catalysts.

[4] The difficulties associated with the elucidation of structural geometry by spectroscopic techniques are illustrated by the example of adduct formation with an organic substrate. The X-ray crystal structure of the 1:1 adduct between *p*-nitrophenol and αCD shows [K. Harata, *Bull. Chem. Soc. Jpn. 50* (1977) 1416] that the nitro group of the substrate enters the cavity of the receptor from the secondary hydroxy face. Similarly, ^{1}H-NMR spectroscopy indicates [Y. Inoue, Y. Takahashi, R. Chûjô, *Carbohydr. Res. 144* (1985) C9] that, in solution, the nitro group of *p*-nitrophenol penetrates the secondary hydroxy face of TMαCD during adduct formation. The X-ray crystal structure of this adduct, however, reveals [K. Harata, K. Uekama, M. Otagiri, F. Hirayama, *Bull. Chem. Soc. Jpn. 55* (1982) 3904] that, in the solid state, it is the *hydroxy* group that is inserted within the cavity, from the secondary hydroxy face.

[8] The K_a value afforded by use of H-3 in βCD as probe was 3200 mol^{-1} kg whilst that obtained from using the PMe_3 probe in complex **1** was 2700 mol^{-1} kg.

[9] K_a values for adduct formation between organic substrates and CDs in aqueous solution generally lie in the range ca. 10–10000 mol^{-1} L.

[10] βCD hydrate (215 mg, 0.18 mmol) and **1** (64 mg, 0.18 mmol) were dissolved in 30% aqueous isopropanol (8 mL) at 50°C. The hot solution was filtered and allowed to cool slowly (24 h) to room temperature in a sealed vial. Small crystals were formed and the solution was allowed to stand for a further 8 weeks, after which time the crystals had grown sufficiently to be amenable to X-ray crystallographic analysis.

[11] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The crystal was coated with epoxy resin. The structure was solved by direct methods and refined anisotropically: the high value of *R* (see caption to Fig. 1) is a consequence of the disorder in the partial occupancy transition metal complex (which constitutes a not insignificant component of the total scattering), that forms the lid on the secondary hydroxy-group-bearing face of the βCD torus. The structure also contains 5.5 both ordered and disordered water molecules occupying eleven different sites of varying occupancy around the periphery of the CD ring. Further details of these structural investigations can be obtained from the Director of the Cambridge Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[14] Using H-3 in DMβCD and the PMe_3 ligand of **1** as probes gave K_a values of 3055 and 3270 mol^{-1} kg, respectively.

[15] Using H-3 in DMβCD and CH_3 in the PEt_3 ligand of **2** as probes gave K_a values of 2270 and 4110 mol^{-1} kg, respectively.

[16] Complex **2** does not form adducts with αCD or DMαCD in D_2O solutions.

[17] It has recently been shown [P. R. Ashton, J. F. Stoddart, R. Zarzycki, *Tetrahedron Lett. 29* (1988) 2103] that adduct formation between methylated cyclodextrins and (i) neutral organic molecules, (ii) organic ammonium salts, (iii) organometallic cations, and (iv) neutral metallo-organic complexes can be probed conveniently by using fast atom bombardment mass spectrometry (FABMS). Analysis of mixtures of DMβCD with the phosphaneplatinum complexes **1** and **2** revealed primarily peaks in the FAB mass spectrum corresponding to the species [DMβCD·"$PtPR_3$"], i.e. adduct formation is occurring with the concomitant loss of one ammine and two chloride ligands. The mass spectrum of the DMβCD mixture with *trans*-$[Pt(PMe_3)_2Cl_2]$, on the other hand, revealed the presence of a peak associated with the loss of only one chloride ligand in addition to a signal arising from the 1:1 adduct [DMβCD·*trans*-$[Pt(PMe_3)_2Cl_2]$].

Induced and Non-induced Diastereoselective Intramolecular Ene Reaction of 1,6-Dienes: the Unusual Formation of *trans*-1,2-Disubstituted Cyclopentanes**

By *Lutz F. Tietze,* Uwe Beifuss, Michael Ruther, Andreas Rühlmann, Jochen Antel,* and *George M. Sheldrick*

Dedicated to Professor Heinz-Georg Wagner on the occasion of his 60th birthday

The Alder-ene reaction,[1] which for a long time was overshadowed by [4+2]-cycloadditions, has gained increasing importance in recent years.[2] By the use of modified enes[3] and enophiles[4] and activation by Lewis acids[2b] it has been possible to increase yields and selectivity considerably; thus the thermally- and Lewis-acid-induced ene reaction of 1,7-dienes bearing two electron-acceptor substituents on the enophile, e.g. **1**, yields exclusively *trans*-1,2-disubstituted cyclohexanes **2** (*trans*:*cis* > 99:1).[4] Recent STO-3G and 3-21G calculations by *Houk* et al.[5] for the reaction of propene and ethene have shown that an "envelope-like" conformation as in cyclopentane can be assumed as transition structure. It therefore follows that *trans*-disubstituted cyclohexanes are preferentially formed in intramolecular ene reactions of 1,7-dienes containing a tetramethylene chain; the cyclization of 1,6-dienes having a trimethylene chain, on the other hand, should lead via an *endo-E(ene)-syn*-orientation almost exclusively to *cis*-1,2-disubstituted cyclopentanes,[5] as has been found experimentally in a number of cases.[6] We demonstrate herein that 1,6-dienes of type **5** react highly selectively to give the *trans*-1,2-disubstituted cyclopentanes. This structural unit is found in many natural products such as prostaglandins and brefeldin. We ascribe the unexpected selectivity to the two substituents at the enophile terminus ("sp^2 geminal effect").

1 **2**

Condensation of the aldehydes **4A–C**[7] with the 1,3-dioxo compounds **3a–e** in the presence of piperidinium acetate leads, in unoptimized reactions, to the formation of the 1,6-dienes **5Aa–e**, **5Ba**, **5Ca**, and **5Cd** in 60–70% yields.[8] Varying amounts of the aldol products and the Michael adducts derived therefrom are also formed; these can be separated chromatographically. The $ZnBr_2$-catalyzed reactions of **5Aa** and **5Ab** at room temperature (1.1 mol. equiv., CH_2Cl_2, 90 min) lead almost exclusively[9a, 10] to the *trans*-1,2-disubstituted cyclopentanes **6a** and **6b** (Table 1). As expected the Lewis-acid-catalyzed reaction of **5Ad** gives predominantly the Diels–Alder adducts **14** and **15**. In addition, however, the two ene products **6d** and **7d**[9a] could also be detected. This shows, once again, that the ene reaction often displays a greater selectivity than the corresponding hetero-Diels–Alder reaction[4c] (Table 1). The amide **5Ae** does not react under the given conditions. At higher temperatures, decomposition takes place.

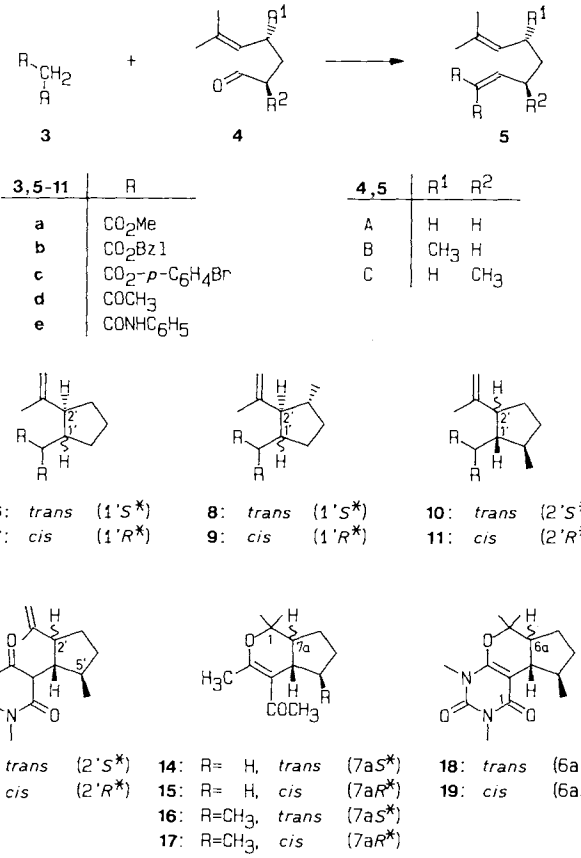

Table 1. $ZnBr_2$-catalyzed cyclization of the 1,6-dienes **5**.

Educt	Yield [%]	Products	Product ratio	*ni-de* [4a] [%]	*i-de* (*trans*) [4a] [%]	*i-de* (*cis*) [%]
5Aa	96	**6a/7a**	96.5:3.5	93.0	—	—
5Ab	89	**6b/7b**	97.5:2.5	95.0	—	—
5Ad	81	**14/15** 96:4	86.1:13.9	72.2	—	—
		6d/7d	>95:5	>90	—	—
5Ba	92	**8a/9a**	96.7:3.3	93.4	>99	>95
5Ca	91	**10a/11a**	98.2:1.8	96.4	>99	>95
5Cd	84	**16/17**	86.5:13.5	73.0	>99	>95

The asymmetric induction in the case of the ene reaction of the chiral 1,6-dienes **5Ba**[11a] and **5Ca**[11b] is especially interesting; one would expect four diastereomers to be formed. However, both the $ZnBr_2$-catalyzed cyclization of **5Ba** as well as that of **5Ca** lead only to one *trans*- and one *cis*-cyclopentane derivative in over 90% yield: **5Ba** yields **8a** and **9a** (96.7:3.3; *ni-de* = 93.4),[9a] while **5Ca** yields **10a** and **11a** (98.2:1.8; *ni-de* = 96.4)[9a] (Table 1). In both reactions the non-induced diastereoselectivity is about the same as in the reaction of the parent compound **5Aa**, whereas the induced diastereoselectivity *i-de* is >99%.

The transformation of the diketone **5Cd** is unusual. The $ZnBr_2$-catalyzed reaction leads exclusively to the two

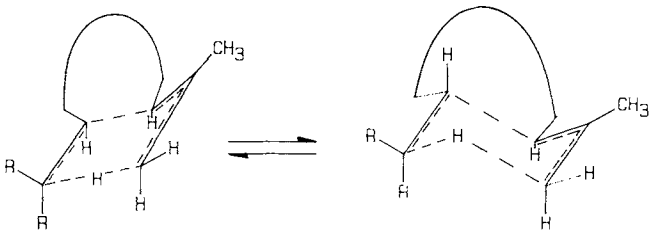
[**] Intramolecular Ene Reactions, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *R. Kummer*, BASF, for generously supplying several oxocarboxylic acid esters. — Part 5: [4e].

Diels–Alder adducts **16** and **17** in 84% yield, with the *trans*-annelated dihydropyran **16** as major product (86.5 : 13.5, Table 1), whereas in the thermal reaction (*o*-dichlorobenzene, 180 °C) the *cis*-annelated **17** predominates (**16** : **17** = 23.7 : 76.3). The *trans*-ene product **10d** is also formed thereby (**10d** : **16** + **17** = 1 : 10); the *cis*-ene product **11d** could not be detected.

The reaction of **4C** with dimethylbarbituric acid (ethylenediammonium diacetate, CCl_4/toluene = 2 : 1) proceeds as a tandem Knoevenagel-hetero-Diels–Alder[12] and -ene reaction with formation of a 4 : 1 mixture of the Diels–Alder adducts **18/19** (78.3 : 21.7; *ni-de* = 56.6; *i-de* > 98%)[9c, 9d] and the ene products **12/13** (93.7 : 6.3, *ni-de* = 87.4; *i-de* > 98%).[9b] Here also, the ene reaction is more selective than the Diels–Alder reaction. The mixture of **12** and **13** can be converted by reaction with $BF_3 \cdot OEt_2$ into **18** and **19** with retention of the diastereomeric ratio.[13]

The determination of the configuration of the ene products by NMR spectroscopy is a problem,[14] since cyclopentanes do not exist in a well-defined preferred conformation. For confirmation of the assigned structures, the *trans*-substituted cyclopentane derivative **6c** was therefore prepared by cyclization of the 1,6-diene **5Ac** and an X-ray crystal structure analysis carried out. X-ray crystal structure analyses were also carried out on the *trans*-ene product **12** and on the *cis*-Diels–Alder adduct **19**.[15]

Correlation of the ^{1}H- and ^{13}C-NMR data[16] of these compounds with the data of the other compounds enabled unequivocal assignment of all ene products except **9a**.



I II

We attribute the high non-induced diastereoselectivity of the intramolecular ene reaction of 1,6-dienes with two electron-acceptor substituents at the enophile terminus to the fact that the envelope transition structure **I** calculated for the basic reaction (cyclization of **5A** without substituents[5]) is destabilized due to *syn*-periplanar arrangement of the residues R with the neighboring substituents. This favors a chair-like transition state **II** with *exo-E(ene)-anti* orientation and 1,2-diequatorial arrangement of the chain. A reaction of the *Z*-ene is less likely according to experiments with labeled compounds;[6d] moreover, an *endo-Z(ene)-anti* transition structure is destabilized because of the geometry of the *Z*-ene. The high induced diastereoselectivity (*i-de* > 99%) in the formation of **8a** from **5Ba** is due to the strong steric interaction between the methyl groups on C-6 and C-8 during an attack of the enophile *syn* to the methyl group on C-6. (The (*ul-ul*-1,2)-process/the *Si(ene)-exo-E(ene)-anti* transition structure for **5Ba** is unfavorable.[17]) The same holds true for the formation of **10a** from **5Ca**; the attack of the ene *syn* to the methyl group on C-4 is destabilized by interaction of the methyl group on C-4 with an ester group. (The (*ul-ul*-1,2)-process/the *Si(ene)-exo-E(ene)-anti* transition structure for **5Ca** is in this case equally unfavorable.)

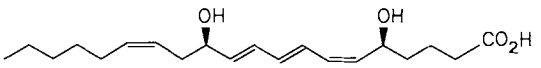
Short, Highly Enantioselective Synthesis of a Key Intermediate for the Preparation of Leucotriene B_4 and Its 14,15-Didehydro Derivative

By *Kurt Nunn, Paul Mosset, René Grée,** and *Rolf W. Saalfrank*

Leucotriene B_4 (LTB_4) **1** is the major proinflammatory product of the 5-lipoxygenase pathway in the arachidonic cascade and as such is implicated in numerous diseases.[1] Hence, the preparation of **1** and related compounds, especially labeled derivatives, is of great interest and various elegant approaches have been reported.[2,3] The purpose of this communication is to describe a short and efficient synthesis of the enantiomerically pure polyenes **6** and **8** which are key intermediates in the preparation of LTB_4[3] and 14,15-didehydro-LTB_4.[4] This new approach, which starts from the easily accessible chiral complex (−)-**2**,[5] illustrates some of the key advantages in the use of butadiene(tricarbonyl)iron complexes in organic synthesis.



1

The reaction of (−)-**2** (of known 1*R*,4*S* absolute configuration[5b]) with allenyl silane **3** (2 equiv.)[6] in the presence of $TiCl_4$ (5 equiv.)[7] at −70°C gives the homopropargyl alcohol **4** (65% yield after chromatography). The reaction is stereospecific ($de \geq 98\%$)[8] and leads only to the ψ-*endo* derivative, with the *R* configuration at the secondary alcohol function. Noteworthy is that $Fe(CO)_3$ acts here as an efficient protecting group. Under similar conditions, the free diene corresponding to **2** gives, at best, 10% of (±)-**8**.

Semireduction of **4** occurs smoothly using Ni/P_2 catalyst[9,10] to give a quantitative yield of **5**. In agreement with preceding results,[11] decomplexation ($Ce^{4\oplus}$, MeOH, −15°C) occurs without racemization, leading to the desired compound **6**. The optical purity of **6** is ascertained by ^{1}H-NMR using $Eu(tfc)_3$.[12] Alcohol **6** is readily converted into silyl ether **7** (tBuPh$_2$SiCl, 2 equiv.; imidazole, 4 equiv.; DMF; 0°C; 15 h; 96%). The physical data of the corresponding ethyl esters obtained by transesterification of **6** and **7**[13] are in good agreement with those described earlier,[2a,3] thus confirming the *R* absolute configuration.

On the other hand, decomplexation of **4** (same conditions as for **5**, 90% yield) gives alcohol **8** which is transformed into its silyl ether **9** (same conditions as for **6**). Both compounds are very closely related to the derivatives **10** and **11** used recently for the synthesis of 14,15-didehydro-LTB_4 and labeled LTB_4.[4]

Experimental

To a cooled (−80°C) solution of (−)-**2** (361 mg, 1.29 mmol) in anhydrous dichloromethane (10 mL) was added $TiCl_4$ (0.72 mL, 5 equiv.). After 15 minutes stirring at this temperature, allene **3** (470 mg, 2.6 mmol) was added to the red solution and the reaction mixture was stirred for 130 min at −70°C. The dark red solution was poured into a vigorously stirred mixture of ether (50 mL) and 1 N aqueous bicarbonate (50 mL). The organic layer was separated and the aqueous phase extracted twice with ether. The combined organic solutions were washed with a saturated sodium chloride solution, with distilled water, and then dried ($MgSO_4$) and concentrated. The resulting orange-red oil was subjected to flash chromatography on SiO_2 (20 g). First

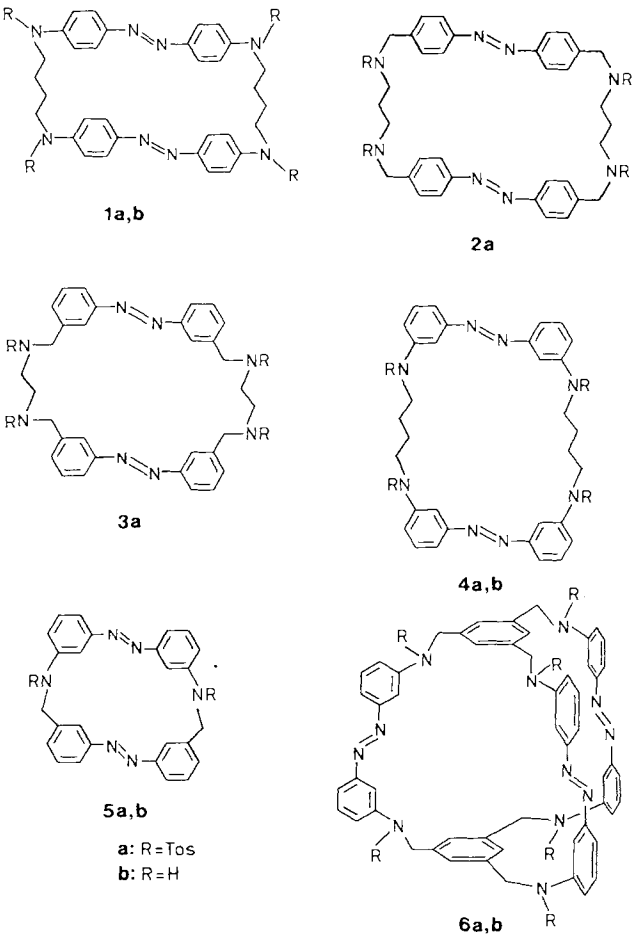
A Novel Tris(azo)macrobicyclic Molecule—Synthesis, Photochemistry, and Isomer Separation**

By *Hans-Willi Losensky, Heinz Spelthann, Albert Ehlen, Fritz Vögtle,** and *Joachim Bargon**

The reversible change of physical and chemical material properties is gaining increasing importance also in the area of host/guest chemistry[1] and the optical storage of information.[2]

We describe here for the first time the photochemically reversibly switchable azomacrocycles of type **1**–**5** and the macrobicyclic molecules **6a**, **b**, in which three azobenzene structural units are coupled in a symmetrical arrangement. The amine nitrogen atoms serve for increasing the solubility in polar or acid media.



The monocycles **1a** and **4a** containing anilide units can be prepared from the corresponding bis(tosylamino)azobenzenes and 1,4-dibromobutane. The benzylamides **2a** and **3a** are accessible from bis(bromomethyl)azobenzenes and α,ω-bis(tosylamines).[3] The cyclization of 3,3′-bis(tosylamino)azobenzene with 3,3′-bis(bromomethyl)azobenzene and 1,3,5-tris(bromomethyl)benzene, respectively, finally affords the azo compounds **5a** and **6a**.[4]

The macrocycles **3a**, **4a** and **5a** derived from 3,3′-disubstituted azobenzenes precipitate, as expected, in higher yields than the corresponding 4,4′-compounds **1a** and **2a**. In the case of the macrobicyclic molecule **6a**, the use of cesium carbonate instead of potassium carbonate leads under dilution conditions to an increase in the yield of 4 to 12% (cesium effect).[5] **6a** can thus be obtained in gram amounts from readily accessible starting materials.

In the case of aromatic/aliphatic (**1a** and **4a**) or aromatic/benzylic tosylamides (**5a** and **6a**) of azo compounds the sulfuric acid hydrolysis leads to the free amines,[4] whereas in the case of benzylic/aliphatic tosylamides (**2a** and **3a**) this method fails,[6] as also the reaction with hydrobromic acid/phenol[3b] and alkaline hydrolysis[7] or alcoholysis.[8] Apart from the cyclic amine **1b** all the new azo compounds exhibit the photochemistry of azobenzene:[9] irradiation with light of wavelength $\lambda = 313$ nm and $\lambda = 436$ nm leads to two photostationary equilibria which are interswitchable.[10]

Mirza* (Universität Bonn) for helpful discussions, Prof. Dr. *H. Rau* (Universität Stuttgart-Hohenheim) for providing an experimental procedure, and Prof. Dr. *H.-J. Schneider* (Technische Universität München) for time-resolved spectroscopic measurements.

The results of the photochemical measurements enable the following generally applicable conclusions to be drawn: a) amino groups in the 4- or 4'-position (as in **1b**) reduce the stability of the (*Z*)-isomers.[11] This phenomenon could be due to an amino-azo/imino-hydrazo tautomerism which inhibits the (*E*)→(*Z*) isomerization.[12] b) The substitution of the amino hydrogen atoms by electron withdrawing sulfonyl groups (−M effect) reverses the photoisomerization-inhibiting effect of the *p*-amino groups (cf. **1a** and **1b**). c) If the *p*-amino group is "separated" from the aromatic system by insertion of a methyl group the photochemistry of the compound in question resembles that of the unsubstituted azobenzene. d) Amino groups in the 3- or 3'-position do not appear to inhibit the photoisomerization. e) In the case of 3,3'-substituted azobenzenes of the type **3**–**5**, a stronger enrichment of the (*Z*)-isomers is generally observed than in the case of the corresponding 4,4'-substituted compounds of type **1** and **2** and the macrobicyclic molecule **6b**. This can be attributed to strain effects.

The stability of the photoisomers of the cyclic amines **4b** and **6b** suffices for the isolation of *all* possible configurational isomers (*E,E*)-**4b**, (*E,Z*)-**4b** and (*Z,Z*)-**4b** or (*E,E,E*)-**6b**, (*E,E,Z*)-**6b**, (*E,Z,Z*)-**6b** and (*Z,Z,Z*)-**6b** from a solution irradiated at the equilibrium ($\lambda = 313$ nm).[13] Figure 1 shows the absorption spectra of the photoisomers of **6b**, which can be isolated by chromatography.[14] A higher dipole moment and thus smaller R_f value can be related to an increasing degree of isomerization.[15] Table 1 lists the spectroscopic data.

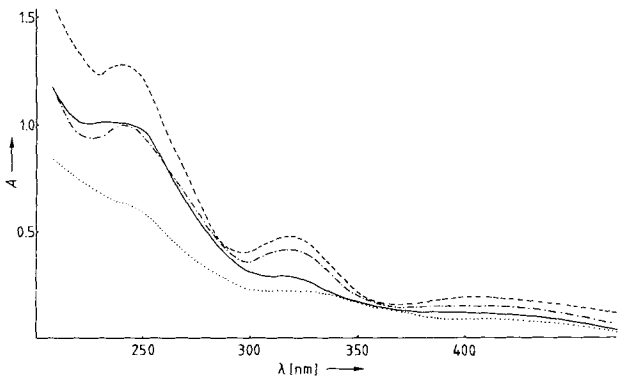

Fig. 1. UV spectra of all possible configurational isomers of the hexamine **6b**: (---) (*E,E,E*)-**6b**; (-·-·-) (*E,E,Z*)-**6b**; (——) (*E,Z,Z*)-**6b**; (·····) (*Z,Z,Z*)-**6b** [16].

Table 1. UV spectroscopic data of the configurational isomers of the macrobicyclic compound **6b** [16].

Isomers of **6b**	UV ($\log\varepsilon$)
(*E,E,E*)	209, 239, 318, 420 (4.92, 4.83, 4.42, 4.01)
(*E,E,Z*)	207, 242, 318, 420 (4.77, 4.71, 4.40, 3.87)
(*E,Z,Z*)	209, 239, 318, 432 (4.80, 4.74, 4.18, 3.81)
(*Z,Z,Z*)	212, 229, 315, 428 (4.65, 4.58, 4.11, 3.73)

The photoisomerization of the monocycle **4b** can not only be carried out in solution but also in a polymer matrix.[17] From the observation that a photoisomerization of the conformationally restricted macrobicyclic compound **6b** is possible, it can be concluded that this proceeds via an inversion mechanism.[18]

Whereas informative conclusions could hitherto only be drawn from measurements on a photostationary state,[1a] it should now be possible, as a result of the first isolation of all photoisomers of macro(bi)cyclic polyazo compounds, to study the insertion properties of (partly) isomerized azomacrocycles based on 3,3'-diaminoazobenzenes.[19]

Experimental

As example the synthesis of the hexamine **6b** is described: A suspension of 25.0 g (77 mmol) of cesium carbonate in 1 L of anhydrous dimethylformamide was treated dropwise in 7 h at room temperature with 7.80 g (15 mmol) of 3,3'-bis(tosylamino)azobenzene and 3.56 g (10 mmol) of 1,3,5-tris(bromomethyl)benzene, in each case dissolved in 250 mL of anhydrous dimethylformamide. After 2 hours' stirring the reaction mixture was evaporated to dryness under vacuum. The residue was treated with 150 mL of semiconcentrated hydrochloric acid and stirred for 12 h. The solid recovered after filtration was washed with water until neutral and then dried. The solid product mixture (ca. 10 g) was transferred to a silica gel column and eluted in the absence of light with dichloromethane/acetone (40 : 1). The fractions with R_f values of 0.35 and 0.50 were evaporated to dryness under vacuum and taken up in dichloromethane; the hexatosyl compound **6a** was filtered off as a light-yellow solid, washed with dichloromethane, and finally dried under an oil-pump vacuum: 1.08 g (12.1%), m.p. 352–354°C.

A suspension of **6a** (85 mg) in 4–5 mL of 80% (vol.-%) sulfuric acid was stirred at room temperature until a clear solution was obtained (1–2 h). This was poured onto ice (50 mL) and rendered alkaline with 5 N sodium hydroxide; the hexamine **6b** precipitated as an orange solid: 38 mg (92.7%), m.p. 350°C, decomp. above 200°C. ^{1}H-NMR and MS data were recorded. Elemental analysis and ^{1}H-NMR spectrum ($CDCl_3$) indicate inclusion of 2 moles of water per mole of **6b**.

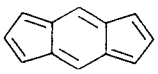
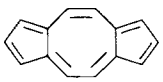
Synthesis and Structure of 2,7-Di-*tert*-butyldicyclopenta[*a*,*e*]cyclooctene**

By *Klaus Hafner,* Georg F. Thiele,* and *Carsten Mink*

Bicyclic conjugated π-electron systems with two odd-numbered rings, such as pentalene, azulene or heptalene,[1] can be viewed as annulenes bridged by a single bond. Even when an even-numbered ring is inserted between the two odd-numbered rings, the bridging bonds in all Kekulé structures remain single bonds. The only tricyclic systems of this kind reported to date are *s*-indacene **1** and a few of its derivatives, in which the substituents have a remarkable influence on the bonding behavior.[2] Comparable with the 12 π-electron system of *s*-indacene **1** is the 14π-perimeter of the dicyclopenta[*a*,*e*]cyclooctene **2**, for which π-SCF calculations indicate that the bond localization is essentially similar to that in *s*-indacene.[3] We report here on the synthesis and molecular structure of its 2,7-di-*tert*-butyl derivative **10**.



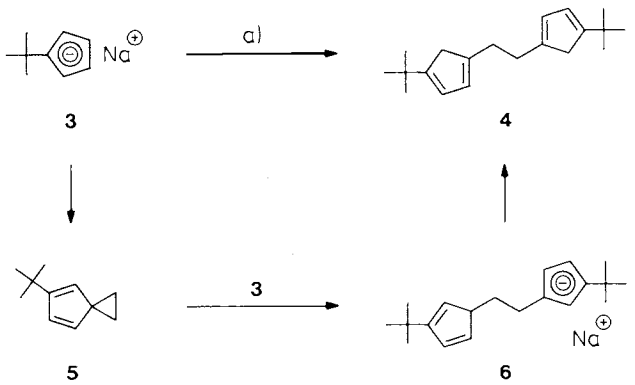
1



2

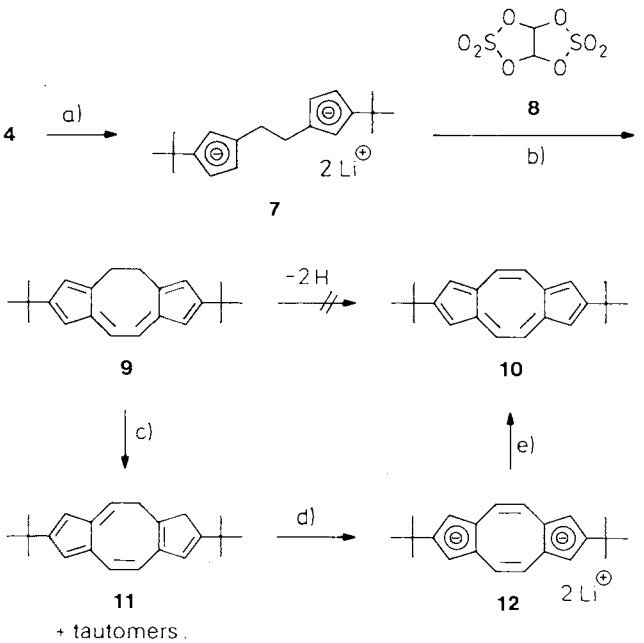
For construction of the tricyclic skeletal framework of **10** we chose the cyclizing condensation of a 1,2-dicyclopentadienylethane with a glyoxal equivalent. The selective attack of the glyoxal equivalent at the position adjacent to the ethano bridge, which is necessary for the cyclization, can be achieved by substitution of the cyclopentadienyl moiety with a sterically bulky *tert*-butyl group.[4] The corresponding 1,2-bis-(*tert*-butylcyclopentadienyl)ethane **4**[5] can be readily obtained from sodium *tert*-butylcyclopentadienide **3** and 1,2-dibromoethane (colorless oil, yield 61% (Scheme 1). The alkylation of **3** with 1,2-dibromoethane at low temperatures initially affords the spiro[4.2]heptadiene **5**,[6] whose cyclopropane ring is opened by nucleophilic attack of a second equivalent of **3** to give **6** on heating only in the presence of a crown ether.[7,8]

The cyclization of **4** to the eight-membered ring was accomplished by condensation of its dilithium salt **7** with glyoxal sulfate **8**[4,9] (Scheme 2). The bridged pentafulvadiene **9** (red-violet crystals, m.p. 174°C) is formed as the sole low molecular weight product in 9% yield. Unexpected difficulties were encountered with the introduction



Scheme 1. a) 1,2-Dibromoethane, NaH, dibenzo[18]crown-6, bis(2-methoxyethyl) ether, −30°C to 160°C, 5 h; 2. H_2O.

of a further double bond into the eight-membered ring of **9**, since all attempts to directly dehydrogenate **9** or to functionalize the methylene groups met with no success. It was possible, however, to carry out an acid-catalyzed tautomerization of **9**, which on reaction with trifluoroacetic acid at −20°C affords a tautomeric mixture (orange-yellow oil) in up to 40% yield. According to the ^{1}H-NMR spectrum the mixture contains predominantly the 3,4-dihydro isomer **11**. The driving force behind this reaction may be the decrease of the ring strain in the eight-membered ring, which, according to inspection of models, has an almost strain-free pseudo boat conformation in **11**. In contrast to **9**, compound **11** and its tautomers can be deprotonated to the dianion **12** with lithium tetramethylpiperidide. Oxidation of **12** with molecular oxygen furnishes the completely conjugated hydrocarbon **10** in 53% yield as air-stable, reddish-brown crystals (m.p. 199°C).



Scheme 2. a) *n*BuLi, TMEDA, *n*-hexane; b) THF, −70°C to 20°C; c) 1. CF_3COOH, CH_2Cl_2, −25°C, 30 min; 2. Et_3N; d) lithium tetramethylpiperidide, THF, −70°C to 20°C; e) O_2, THF, −70°C.

The ^{1}H-NMR spectrum of **10** shows a significant downfield shift of all signals compared to those of the dihydro compound **9**, thus indicating a noticeable diatropism. The

presence of only three signals in the ^{1}H-NMR spectrum and of six signals in the ^{13}C-NMR spectrum (Table 1) is consistent with a molecular structure with D_{2h} symmetry

Table 1. Spectroscopic data of **4**, **9**, and **10**. ^{1}H-NMR ($CDCl_3$, 300 MHz), ^{13}C-NMR ($CDCl_3$, 75.47 MHz), UV (*n*-hexane).

10: ^{1}H-NMR: $\delta = 1.33$ (s, 18H, *t*Bu), 6.84 (s, 4H, 1/3/6/8-H), 7.27 (s, 4H, 4/5/9/10-H); ^{13}C-NMR: $\delta = 30.22$ (q, $C(CH_3)_3$), 32.85 (s, $C(CH_3)_3$), 124.90 (d, C-1/3/6/8), 126.15 (d, C-4/5/9/10), 139.30 (s, C-3a/5a/8a/10a), 160.87 (s, C-2/7); UV: $\lambda_{max}(\lg\varepsilon) = 217$ (4.19), 324 (4.88) sh, 335 (5.02), 413 (3.51) sh, 425 (3.54) sh, 435 (3.59), 460 (3.53), 923 (1.99), 1015 (1.93) sh, 1064 (1.91) sh, 1375 nm (1.64) sh

and delocalized π-electron system. This is confirmed by the X-ray structure analysis,[10] which reveals a planar ring system with inversion center for **10** (Fig. 1). The maximum distance of the ring-C atoms from the mean plane is ±1.5 pm. The perimeter of the molecule, with CC bond lengths of about 140 pm, exhibits substantial bond equivalency, whereas the two bridges are noticeably longer (149 pm). Thus, the bridging bonds have predominantly single-bond character, as in azulene.[11]

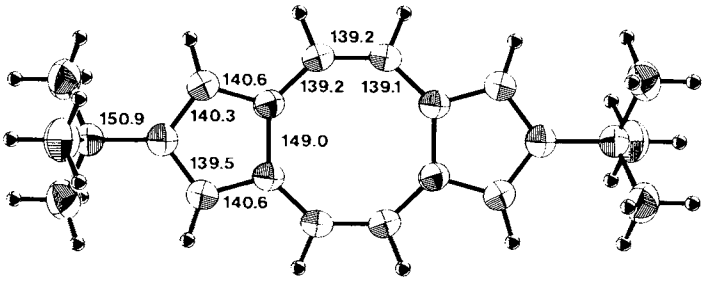

Fig. 1. Crystal structure of **10** (ORTEP, vibration ellipsoids at the 50% probability level) at room temperature with selected bond lengths [pm].

The analogy to azulene also extends to the electronic spectrum of **10**, which like that of azulene consists of three structural band systems whose extinctions decrease with increasing wavelength. Their positions compared to those of the bands of azulene, however, are strongly bathochromically shifted, so that the longest wavelength absorptions already lie in the near IR.

10 not only belongs to the few hydrocarbons with a planar eight-membered ring,[1,12] but, in addition, it is also a completely planar **14** π-electron system which has no further cyclic conjugated subunits apart from the 14 π perimeter. The molecular structure and spectroscopic properties justify the classification of **10** as a non-benzenoid aromatic hydrocarbon.

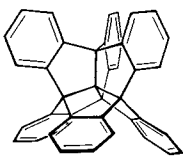
Centrohexaindan, The First Hydrocarbon with Topologically Non-Planar Molecular Structure**

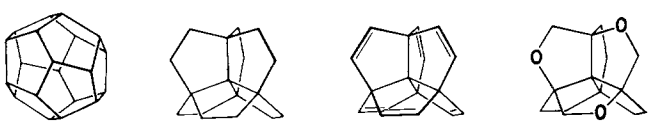
By *Dietmar Kuck** and *Andreas Schuster*

Herein we report on the synthesis of centrohexaindan **1** (hexabenzohexacyclo[5.5.2.2^{4,10}.1^{1,7}.0^{4,17}.0^{10,17}]heptadecane) and some properties of this unique hydrocarbon.



1

Like dodecahedrane **2**[1,2] among the *spherically* annelated polyquinanes, the "C_{17}-hexaquinane"[3] **3** is the most fascinating member of the *centrally* annelated so-called centropolyquinanes.[4] In contrast to **1**, however, centrohexacyclic hydrocarbons like the centrohexaquinane **3** and the corresponding hexaene **4** have not yet been synthesized, even though they are of considerable interest regarding their special ring coupling.[4–7]



2 **3** **4** **5**

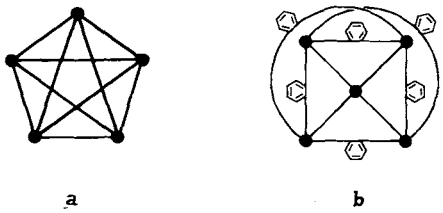
[*] Dr. D. Kuck, Dipl.-Chem. A. Schuster
Fakultät für Chemie der Universität
Universitätsstrasse 25, D-4800 Bielefeld 1 (FRG)

[**] Benzoannelated Centropolyquinanes, Part 5.—Part 4, see [13b].

The only centrohexacyclic compound known so far is the triether **5**, which was synthesized simultaneously by *Simmons* et al.[8] and *Paquette* et al.[9] Attempts to prepare **3** via a route similar to that used for the synthesis of **5** have thus far failed.[8,9] As the hexabenzo derivative of **4**, compound **1** is the first hydrocarbon with centrohexacyclic molecular structure.

The fascination of the centrohexaquinane structure of **1** lies in the annelation of six cyclopentane rings around a central C atom common to all rings.[4] The central neopentane skeleton is bridged by six *o*-phenylene groups corresponding to the six edges of a regular tetrahedron, such that the central, quaternary C atom is surrounded by four further, equivalent quaternary sp^3-C atoms[10] and therefore should exhibit ideal tetrahedral coordination.[11] Furthermore, in the ground state **1** should have prefect T_d symmetry, in analogy to the hexaene **4** calculated by *Ermer*.[6]

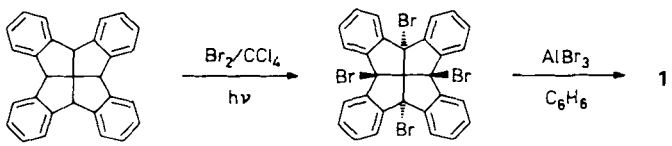
Centrohexaindan **1** combines a number of known lower benzoannelated centropolyquinane moieties (centropolyindans). Thus, in **1**, three 2,2'-spirobiindans are fused along the three space axes to give a three-dimensional cross, tribenzotriquinacene[12] and triptindan[13] (*sym*-tribenzo-[3.3.3]propellane) are condensed with each other fourfold degenerate, and, finally, **1** contains three fenestranes (tetrabenzo[5.5.5.5]fenestranes, "fenestrindans") **6**.[14] It is thus the first fenestrane substituted with carbon on all four bridgeheads.[15]



a b

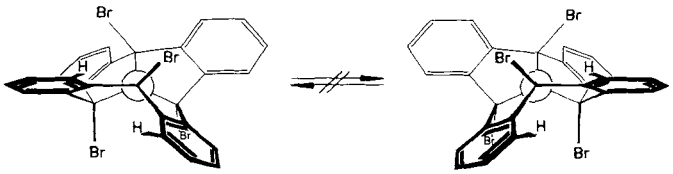
Fig. 1. a) The graph K_5. b) A graph-theory representation of **1**.

The molecular structure of **1** is also of special interest from the point of view of the graph theory.[6] Like the triether **5**, compound **1** is a topologically non-planar molecule. The complete mutual coupling of the five neopentane C atoms (vertices) via the central C–C bonds and the peripheral *o*-phenylene bridges corresponds to the *complete graphs* K_5 (Fig. 1a), whose connecting lines cannot be projected into the plane without mutual intersection (Fig. 1b).



6 7

The synthesis of **1**, based on the recently reported fenestrindan **6**, which is accessible in gram amounts in nine steps from 1,3-indandione and dibenzylideneacetone,[14] is astonishingly easy. **6** can be readily functionalized with bromine at all four bridgeheads to give the tetrabromofenestrindan **7**.[16] This is most surprising, since a high torsional strain should be generated by the pairwise *syn*-oriented bromine atoms on the bridgeheads. In actual fact the double 1,3-interaction in **7** leads to a conformation with S_4 symmetry which is static on the NMR time scale (Scheme 1). Therefore, different to the case of **6**,[14] no AA'BB' system is observed in the 300-MHz ^{1}H-NMR spectrum for the four aromatic rings, but instead an ABCX system, whereby an *ortho*-proton is in each case strongly deshielded by the neighboring benzene ring.[17]



Scheme 1. Conformers of **7**.

When **7** is heated together with four equivalents of $AlBr_3$ in benzene, fourfold C–C coupling takes place with formation of the centrohexaindan **1** in 50% overall yield! During the reaction, salt-like intermediates are formed whose structural elucidation should provide interesting details about the hitherto unknown fenestrane ions with carbenium centers at the bridgeheads.

Table 1. Spectroscopic data of centrohexaindan **1**.

MS (EI, 70 eV): $m/z = 516$ ($M^{\oplus\ominus}$, 100%), 515 (12), 439 (3), 258 ($M^{2\oplus}$, 4)

IR (KBr): $\tilde{\nu} = 3070$ (m), 3020 (m), 1470 (s), 755, 751 (s), 700 cm^{-1} (m)

^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 7.27$, 7.79 (AA'BB')

^{13}C-NMR (75.8 MHz, CD_2Cl_2): $\delta = 73.5$ (s, C^{α}), 95.4 (s, C^{centro}), 124.5 (d, C^{ortho}), 129.1 (d, C^{meta}), 148.6 (C^{ipso})

UV (*n*-heptane, $c = 4 \cdot 10^{-5}$ mol·L^{-1}): $\lambda_{max}(\varepsilon) = 276.5$ (5800), 269 (4950), 263 (3000), 257 nm (s)

The spectroscopic data of **1** are unequivocal (Table 1). Although the solubility is quite high for a compound of this molecular size ($C_{41}H_{24}$) and highly symmetrical structure compared to the lower centropolyindans,[12–14] the melting point lies well above the usual limit (420 °C). As expected the mass spectrum shows no mentionable fragmentation of the molecular skeleton. The degeneracy of all six indan units of **1** manifests itself in the NMR spectra: The ^{1}H-NMR spectrum consists of only one AA'BB' system for all twelve *ortho* and *meta* H atoms; the ^{13}C-NMR spectrum shows only five signals for the total 41 C atoms. As expected, the UV spectrum of **1** resembles those of benzoannelated centrotriquinanes and centrotetraquinanes[12–14] and gives no indication of distinct electronic interactions between the six aromatic π systems.

Experimental

7: 8.0 mL of a 1 M solution of Br_2 in CCl_4 was added dropwise to a stirred suspension of 736 mg (2.0 mmol) of **6** in 50 mL of anhydrous CCl_4. After addition of 4.0 mL of the Br_2/CCl_4 solution a homogeneous solution formed, from which, on further addition of Br_2/CCl_4, the tetrabromide **7** precipitated. For completion of the reaction, the mixture was irradiated for ca. 20 min with a photolamp (500 W). After removal of the solvent by evaporation and subsequent recrystallization of the lemon-yellow residue from toluene, 865 mg of **7** (63%) were obtained in the form of colorless needles (m.p. 341 °C).

1: A solution of **7** (500 mg, 0.73 mmol) in warm anhydrous benzene (100 mL) was treated dropwise at 40 °C within 2 h with 10.0 mL of a 0.10 M solution of $AlBr_3$ in benzene. An orange-red complex first separated out, and then redissolved on completion of the addition of $AlBr_3$. The mixture was then heated under gentle reflux for 40 h. After hydrolytic work-up and recrystallization of the light-yellow crude product from 20 mL of xylene, 300 mg of **1** (80%) were obtained in the form of colorless needles.

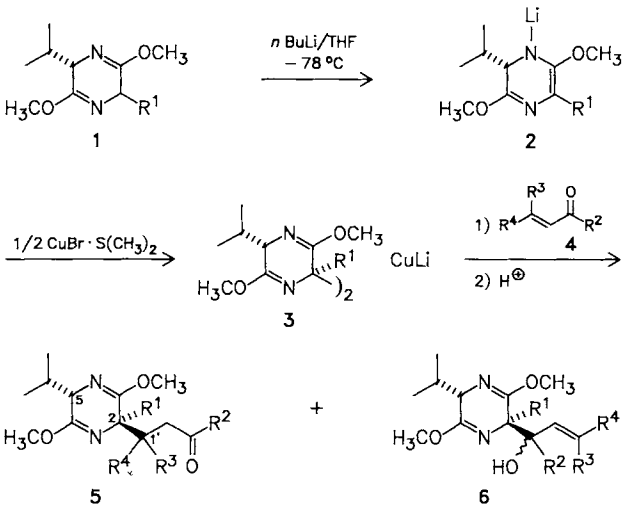
Enantio- and Diastereoselective Synthesis of Methyl (2*R*)-2-Amino-5-oxocarboxylates from Enones and Bislactim-Ether Cuprates**

By *Ulrich Schöllkopf,* Dagmar Pettig, Edda Schulze, Michael Klinge, Ernst Egert,* Bernd Benecke*, and *Mathias Noltemeyer*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Lithiated bislactim ethers **2** react with enones to give 1,2- and 1,4-adducts.[1] In our studies on the asymmetric synthesis of non-proteinogenic amino acids according to the bislactim-ether method[2] we were interested in finding an entry to 1,4-adducts of the type **5**; we therefore decided to check whether and how the lithium compounds **2** are convertible into cuprates of bislactim ethers. Numerous alkyl and alkenyl cuprates have already been described,[3] whereas very few azaenolate-cuprates have been reported.[4] Heterocyclic azaenolate-cuprates are as yet unknown. After a number of abortive attempts with such Cu^I salts, which have already proven useful for the preparation of alkyl and alkenyl cuprates,[3] we found that the bislactim-ether cuprates **3** can be obtained by reaction of **2** with $CuBr \cdot S(CH_3)_2$ in the presence of dimethyl sulfide.

The cuprate **3a** reacts highly selectively with 2-enones **4** to give 1,4-adducts; the diastereofacial selectivity at the heterocycle is extremely high (>100:1; Table 1), i.e. one obtains almost exclusively the (2*R*,5*S*) epimers of the adducts, the precursors of the corresponding D-α-amino-δ-oxocarboxylic acids (type **14**).



1–**3**: a, R^1 = H; b, R^1 = CH_3
5, **6**: R^1 = H

Table 1. Yields and configurations of the Michael adducts **5**, R^1 = H.

5	R^2	R^3	R^4	Yield [%]	(2*R*,1'*R*) : (2*R*,1'*S*) [a] [b]	5 : 6

[a] Determined by capillary chromatography and ^{13}C-NMR spectroscopy. [b] (2*S*)-epimers ≤1. [c] (2*R*) : (2*S*) > 100 : 1.

Simple cyclic enones such as cyclopentenone and cyclohexenone (**4a** and **4b**, resp.) react also with high enantiofacial selectivity at the double bond. Of four possible diastereomers, almost only the (2*R*,5*S*,1'*R*)-isomers **5a** and **5b** are formed, i.e. two stereocenters are created highly selectively at the same time. The (2*R*,1'*R*) configuration of **5b** was confirmed by an X-ray structure analysis. Cyclic enones with a substituent in the 3-position (e.g. **4d**) react with lesser enantiofacial selectivity. The same holds true for conformationally flexible acyclic enones with substituents in the 3-position (e.g. **4e** and **4f**).[5]

Reaction of **3a** with (−)-(*R*)-carvone **4h** leads because of favorable double stereoselection (matched case) and because of highly selective protonation at C-2', almost exclusively to (2*R*,1'*R*,2'*R*)-**5h**. The diastereomeric ratio is ca. 100:3:2:1. The structure of **5h** was confirmed by an X-ray analysis. With (+)-(*S*)-carvone (mismatched case) the diastereomers are formed in the ratio 10:5:1.5:1.5.

10

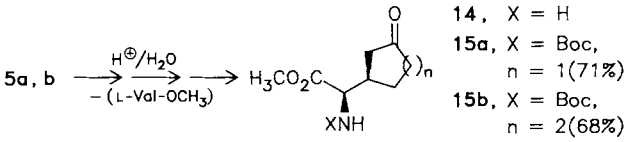
Since the carbonyl group is a particularly useful functional group, the compounds of type **5** (or **14**, cf. below) open up an entry to numerous non-proteinogenic amino acids that are stereoisomerically pure in the α- and partly also in the β-position (e.g. **14a** and **14b**). The cuprate **3a** reacts with the dienone **7** to give the 1,6-adduct **8** (together with ca. 10% 1,2-adduct), and again with high diastereoselectivity; only two diastereomers in the ratio 10:1 are detectable ^{13}C-NMR spectroscopically. Both have the (2*R*)-configuration, whereas the 1′-configuration is still unclear. Phenyl vinyl sulfone **9** also reacts with a high degree of diastereospecificity with **3a** (*de* > 98%) to give the "Michael adduct" **10**. Reaction of the lithium compound **2a** with **9**, on the other hand, furnishes only polymeric products.

As expected cuprates of type **3** can also be alkylated. Thus, reaction of **3a** and **3b** with ethyl 3-bromopropionate **11a** affords the alkylated products (2*R*,5*S*)-**12a** and **13a**, which are precursors of the corresponding (*R*)-glutamic acid derivatives, in satisfactory yields and with a remarkably high *de* value of ca. 98%. The lithium compounds **2a** and **2b** react with the bromopropionate **11a**,[7] not only with alkylation but also with elimination. 3-Bromopropionitrile **11b** reacts analogously with **3a** and **3b** to give **12b** and **13b** (*de* ca. 98%). Reaction of the lithium compound **2a** with acetonitrile leads to polymerization. The cuprates **3** are thus preferred over the lithium compounds **2** in the alkylation of the bislactim ethers if the alkylating agent is base-labile or if very high *de* values are aimed for.

12, R = H; **13**, R = CH_3

11, **12**, **13**: **a**, X = $CO_2CH_2CH_3$; **b**, X = CN

The hydrolysis of the adducts **5a** and **5b** (two equivalents of 0.25 N HCl, room temperature, 20 h) affords (besides L-Val-OMe) the diastereomerically and enantiomerically pure (2*R*,3*R*)-amino acid methyl esters **14**. These are thermolabile and therefore cannot be separated from the L-valine methyl ester by distillation. The separation can, however, be accomplished readily by chromatography at the stage of the *N*-Boc derivatives **15a**, **b**. In contrast, the hydrolysis of (2*R*,1′*S*)-**5f** leads as expected to the methyl (2*R*,3*S*)-3-(2′-furyl)-3,4-dihydro-5-methyl-pyrrolecarboxylate **16**, whose C=N bond is so regiostable that it can be purified by distillation.



14, X = H

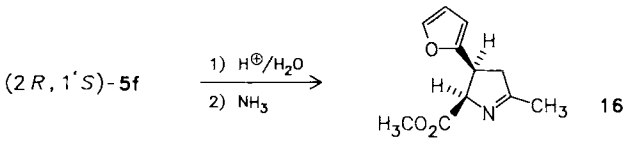
15b, X = Boc, n = 2 (68%)



16

Experimental

5 (**8**, **10**): **1a** (1.00 g, 5.45 mmol) [8] was metalated with *n*-butyllithium in THF (10 mL) at −78 °C. The solution of **2a** was then added dropwise through a Teflon tube to a solution of CuBr·$S(CH_3)_2$ [9] (0.56 g, 2.73 mmol) and $S(CH_3)_2$ (5 mL) in THF (10 mL). After 0.5 h at −30 °C the mixture was treated with a solution of **4** (or 7, **9**) (5.45 mmol) in THF (5 mL) at −70 °C and stirred for 4–16 h at this temperature. After subsequent addition of glacial acetic acid (0.33 g, 5.45 mmol) the mixture was allowed to warm to room temperature, transferred to a column of Silica gel 60 (20 g; 0.05–0.2 mm, 70–270 mesh ASTM; 200 × 60 mm^2) and eluted with ca. 500 mL of ether. After removal of solvent the residue was distilled (Kugelrohr) or chromatographed. — **5a**: b.p. 110 °C/0.05 torr, m.p. 60–61 °C; **5b**: b.p. 150 °C/0.05 torr, m.p. 95–97 °C; **5c**: b.p. 115 °C/0.05 torr, m.p. 71–72 °C; **5d**: b.p. 110 °C/0.05 torr, R_f = 0.16, ether/pentane (1:3); **5e**: (2*R*,1′*R*)-**5e**: R_f = 0.20, (2*R*,1′*S*)-**5e**: R_f = 0.14, ethyl acetate/pentane (1:6); **5f**: (2*R*,1′*R*)-**5f**: R_f = 0.07, (2*R*,1′*S*)-**5f**: R_f = 0.04, ether/pentane (1:6); **5g**: b.p. 120 °C/0.01 torr; **5h**: b.p. 120 °C/0.05 torr, m.p. 76–77 °C; **8**: R_f = 0.05, ether/pentane (1:8); **10**: R_f = 0.15, ether/pentane (1:3).

N-Boc amino acid esters **15**: A mixture of **5a** or **5b** (3.0 mmol) and 0.25 N HCl (24 mL, 6.0 mmol) was vigorously stirred for 20 h. After removal of solvent under vacuum, the residue (hydrochlorides of the amino acid esters) was treated with $CHCl_3$ (20 mL), NaCl (1.8 h) and Boc-anhydride (1.53 g, 7.0 mmol) and then with 8 mL of a saturated $NaCO_3$ solution. The mixture was heated under reflux for 3 h, the phases separated, and the aqueous phase extracted with 2 × 20 mL of ether, dried over $MgSO_4$ and the solvent removed under vacuum. The residue was chromatographed on ca. 70 g of silica gel (Silica gel 60, 500 × 15 mm^2 column, ether/pentane (1:1). — **15a**: R_f = 0.13, m.p. 104–105 °C; **15b**: R_f = 0.18, m.p. 85–86 °C.

Correct C,H analyses were obtained for all compounds.

[5] We attribute the high enantiofacial selectivity in the case of **4a** and **4b** to the rigid "transoid" enone arrangement. The situation is analogous to the Michael addition to acrylic acid esters [6]. In the case of "transoid" fixed 5,6-dihydropyran-2-one the enantiofacial selectivity at the double bond is > 90%; in the case of the open-chain, flexible crotonic acid methyl esters, however, it is only ca. 50%.

Selective INADEQUATE, a Farewell to 2D-NMR?**

By *Stefan Berger**

The INADEQUATE pulse sequence,[1] especially the two-dimensional (2D) variant,[2] is one of the most important ^{13}C-NMR methods for determining the structure of organic substances.[3] When all other modern NMR methods are of no further help, decisively important information can often be obtained with 2D-INADEQUATE. Prerequisite is a sufficient concentration of ^{13}C-disubstituted molecules, since typically 128 ^{13}C-NMR spectra must be recorded for a complete data matrix. The digital resolution in ω_2 is limited in the case of 2D-methods and makes the evaluation of C,C coupling constants over more than one bond from 2D-INADEQUATE NMR spectra[4,5] difficult.

There has been no lack of attempts in recent years to make INADEQUATE more sensitive,[6-8] but none of the improvements put forward so far can be considered as of general utility. *Kessler*[9] and *Freeman*[10] have recently indicated how 2D-methods by *frequency-selective excitation* can be reduced to the recording of a few 1D-NMR spectra. Some 2D-INADEQUATE experiments of limited application have also been reported.[11-13] In continuation of our INADEQUATE studies[4,5,14,15] we present here a generally applicable frequency-selective version of INADEQUATE which makes 2D-recordings superfluous.

Figure 1 shows the pulse sequence "SELINQUATE" in which the fourth pulse of the standard INADEQUATE sequence is replaced by a frequency-selective pulse. It is therefore not a frequency-selective excitation, but a frequency-selective transfer of coherence. Only double quantum coherence of those carbon nuclei is transferred into observable magnetization for which the frequency of the frequency-selective pulse is adjusted. We have also found that the bandwidth of the frequency-selective pulse must correspond to the C,C-coupling constant. All pulse phases remain the same as described for the original experiment,[3] but the phase of the frequency-selective pulse must be correctly adjusted in relation to the phases of the non-selective pulses as well as to the receiver phase. All known variants of the 1D-INADEQUATE experiment can also be applied to the pulse sequence in Figure 1.

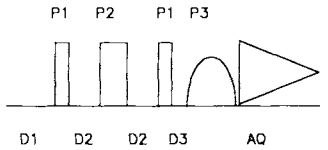

Fig. 1. Pulse sequence for SELINQUATE. D1 relaxation delay, D2 focussing delay $1/4J_{C,C}$, D3 transfer delay, P1, P2 non-selective pulses 90° and 180°, AQ acquisition time. Exact recording conditions, see [16].

The result of the pulse sequence of Figure 1 is shown in Figure 2, for the sake of simplicity in the case of *n*-propanol as example:[16] Trace (a) shows the normal ^{13}C-NMR spectrum. In traces (b-d) the frequency-selective pulse was in each case adjusted to C-3, C-2 and C-1; accordingly, in (b) only the doublet of C-2 which couples with C-3 (36.1 Hz) is observable, in (c) the doublets of C-1 and C-3 which couple with C-2 (36.1 and 34.2 Hz), and in (d) the doublet of C-2 which couples with C-1 (34.2 Hz).

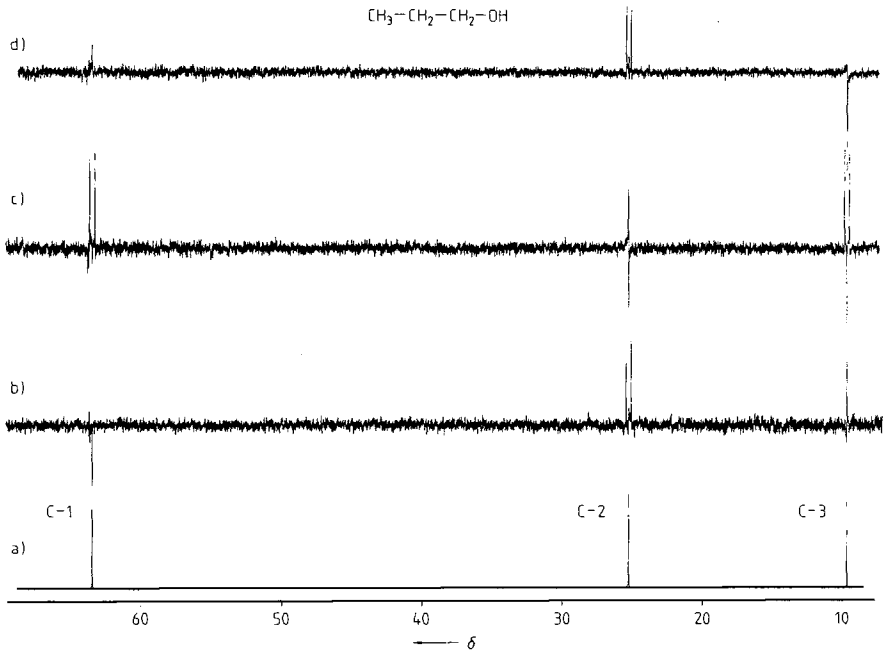

Fig. 2. ^{13}C-NMR spectra of *n*-propanol. (a) Standard ^{13}C-NMR spectrum, (b-d), Recording after pulse sequence in Fig. 1, (b) P3 adjusted to signal of C-3, (c) P3 adjusted to signal of C-2, (d) P3 adjusted to signal of C-1.

In order to obtain complete information of the coupling of all C atoms in a molecule only the recording of the ^{13}C-NMR spectra of exactly the number of differentiable carbon atoms present is necessary; moreover, this can be done with high digital resolution, so that all coupling constants can be correctly measured. The determination of

[**] This work was supported by the Fonds der Chemischen Industrie.

the structure of organic compounds is thus considerably simplified,[17] and all the more so in practice, since seldom are all C,C couplings needed but only must be proven for a few C atoms.

BOOK REVIEWS

Organic Chemistry: The Name Game. Modern Coined Terms and Their Origins. By *A. Nickon* and *E. F. Silversmith*. Pergamon Press, Oxford 1987. xii, 347 pp., bound, £ 45.00.—ISBN 0-08-035157-3; paperback, £ 18.00.—ISBN 0-08-034481-X

Named reactions are a time honored and useful feature of chemical literature and communication; the custom of *name-dropping* is at least equally old, even though it usually fails to produce the intended effect. But a *name game*?—or, more exactly, "Organic Chemistry: The Name Game", to give the recently published monograph by *Alex Nickon* and *Ernest F. Silversmith* its full title. Can the serious and sober discipline of organic chemistry be a game with words? This, and much more besides, is the theme of "The Name Game". The book, generously illustrated with excellent structural formulas, reaction schemes and other diagrams, is in the first place a collection of modern trivial names and accounts of how they originated. Developed out of a student project aimed at discovering the origins of a wide variety of expressions, the authors have based the compendium not only on an intensive study of the literature, but also on innumerable personal contacts over a period of about ten years. To limit the size of the compilation, the naming of natural products, and commercial product and brand names, are dealt with only briefly; the result is not a comprehensive index of trivial names, but instead a real book, for both serious reading and browsing. And no matter where one dips into it, fascination quickly takes hold, and one becomes absorbed in reading. To appreciate this even more fully, imagine for a moment the effect if a work of a similar kind had instead been produced in an (admittedly more comprehensive) "electronic version"!

What, then, are the origins of the names given to the many organic compounds prepared for the first time during recent years, and to newly discovered reactions? Who or what agency first coined these names, what prompted this, and what are their etymologies? Answer: the names are as varied as are the people involved in chemistry, and they reflect the personal qualities and idiosyncracies of their creators: their sense of humor (or lack of it), their vanities, their education (or its shortcomings), their knowledge of the world, or their provincialism. Nevertheless, as the authors show in the 20 chapters and six appendices of the book, it is possible to recognize certain common features and families of words and names, which together illustrate the rather childlike pleasure that chemists take in naming the objects resulting from their work. There is an abundance of names of animals; articles of apparel—especially head coverings—provide inspiration; names that clearly have their origins in children's toys, and which grown-ups (?) now have, are widespread, some of the most popular being building bricks, water-wheels and airplanes. Foodstuffs play a role to some extent. Above all, containers of every kind have a great fascination—objects into which things can be put. In due course we leave the household behind, and travel through cities and across national frontiers, even as far as the stars. In short, nothing escapes being used to form names, and inexorably there comes into being at the molecular level a more and more fully equipped micro-universe.

Furthermore, "The Name Game" shows that the number of trivial names has grown alarmingly just in recent times (and consequently the book is also very useful as a dictionary, despite the limitation on size mentioned earlier). One possible cause for this is that the standard language, i.e. the IUPAC nomenclature rules, cannot keep pace with the complexity of the structures which have been analyzed and/or synthesized. Another factor is the notorious inadequacy of this nomenclature system for describing the dynamics of chemical reactions. New developments are essential here if we are to avoid becoming completely entangled in our own special jargon. It is conceivable, for example, that for "supermolecules" (cage structures of all kinds, layered molecules) a method of nomen-

clature related to that for peptides might be used, in which the building units would be represented only by initial letters (although, of course, the problems of "branching" and "crosslinking" in the primary structures of peptides are much simpler).

Thus it can be seen that what initially at times appeared to be a collection of curiosities, even including trivia (although, just as beauty is in the eye of the beholder, so presumably the music of a name is in the ear of the listener), has now raised important and far-reaching questions. For this reason the book is also a stimulating, and often thought-provoking, contribution to the study of the language of chemistry.

The authors too must have been well aware of this aspect of the book, since some of the appendices are only meaningful in that light. Once one begins to consider the words and their meanings, one progresses very quickly from the hundredth to the thousandth. What are the origins of the expressions familiar to us? Do these words—often derived from Latin or Greek—sound better to our ears (more "euphonic") than the modern names which have been coined, sometimes making the reader or listener flinch? (on the lines of, for example, betweenanene, buckminsterfullerene—or better still, buckyball—and what if barrelene had instead been named zimmerene!). The mechanisms of (modern) word construction are by no means new. It was already common to make up composite words (acetal = acetaldehyde + alcohol; carbazole = carb + az + ole); or as an extreme example, chloramphenicol—see the book for its derivation), to use abbreviations (phthalic acid is actually (na)phthal(en)ic acid), and to make transpositions (ninhydrin from hydrindene). On the other hand, the making up of acronyms, following the modern craze for abbreviations, has recently grown to such an extent that already one can almost begin to talk in terms of a third generation of nomenclature. However, Appendix A is a mine of information on explanations and derivations of standard expressions used in organic chemistry.

It would no more be possible to translate the whole of "The Name Game" into another language than to retain its rhyming title. This is firstly because the English language, with its great differences between the spoken and written forms, lends itself much more readily to plays on words than, for example, German, and secondly because of the authors' frequent clever and imaginative use of such devices. Some nice examples are the following: "The vitamin C story began with 'ignose' and 'godnose'. Where will it end? Who knows?"; or: "Through deals made by *Alder* ..."; or: "Atrane is not something we board at a railroad station". The text abounds with puns of this sort, which, like the anecdotes, are not only intended to cause a quick smile, but are also very instructive. It is certainly true that wit or fun often lead to a much quicker and better remembered understanding of a point than does a long-winded explanation. English-speaking authors—not only when preparing textbooks or papers, but also when giving after-dinner talks (from whence, incidentally, an appreciable number of the examples in "The Name Game" seem to have originated)—use this technique more often and adeptly than we German speakers. As a general principle, when the words of one language can no longer be translated into another, this is evidence of the vitality of both words and language. One is then forced to adopt the foreign words—or remain silent.

As every competitor knows, games are not games, but are deadly earnest. In the case of the present book, whose impact depends to a large extent on correct spelling of the words, this means that it must not contain any printing or other errors. And although the authors were naturally well aware of this, some errors have nevertheless escaped their notice: *Konrad Lorenz* (in the list of Nobel prizewinners in Appendix F) is not a Dutchman, it was *Unverdorben* who isolated aniline by distillation of indigo (not Herr *Underderben*, as given in Appendix A), in *Vögtle* the umlaut has been put over the wrong letter, and so on. These are mere trifles, but the absence of an index of names must be either the final joke of the book, or a bad joke.

From time to time a plea is made for making the chemical literature more "human"—it is said to be too dry and sterile, so that one can no longer recognize the real author behind the words. It cannot be said too strongly that any such move is to be avoided. In our writing most of us are far from being great stylists, let alone literary giants, and most of our work would not gain in value by having a "humanizing" introduction included. But if now and again other books as entertaining as the all too human "Name Game" were to appear, from which one could similarly learn a surprising amount about new developments in chemistry—that would really be fine.

The Surface Scientist's Guide to Organometallic Chemistry. By *M. R. Albert* and *J. T. Yates, Jr.* American Chemical Society, Washington, DC (USA) 1987. xiii, 214 pp., bound, $ 59.95 ($ 49.95 in USA and Canada).—ISBN 0-8412-1003-9

Since the pioneering work of *Earl Muetterties*, organometallic chemistry has received increasing attention by surface chemists and surface physicists. It is therefore not surprising that the authors of this little book have dedicated it to the memory of *Muetterties*. He showed convincingly that the structures and chemical properties of chemisorption systems can be discussed in terms of the analogous interactions between transition metal centers and their ligands.

The book by *Albert* and *Yates* clearly emphasizes the importance of organometallic chemistry for the chemistry and physics of surfaces, and addresses mainly surface chemists and surface physicists. An introduction (Chapter 1), is followed in Chapter 2 (Basic Coordination Chemistry) by a concise qualitative summary of theories of chemical bonding in coordination compounds. Chapter 3 (Overview of Coordination Ligands) is the longest chapter of the book, and occupies a central position. It begins with a description of the main methods available for preparing surface complexes and ligands on well-characterized metallic surfaces in ultra-high vacuum. This is followed by a detailed discussion of the bonding situations and reactivities for 13 different classes of ligands: lone-pair donors, diatomic ligands, substituted diatomic ligands, systems with cumulenes, heteroolefins, triatomic pseudohalogens, organic chelates, nonmetal oxyanions, aromatics, heterocycles, electron deficient ligands, molecular fragments and, lastly, atomic species. The discussion points out qualitative analogies between molecular compounds and chemisorption systems, with regard to their geometric and electronic structures and their reactivity (with particular reference to catalytic reactions). In cases where there are no comparative data for ligands and surfaces, the authors draw attention to these gaps in knowledge, as potential research top-

ics of interest to surface scientists. The chapter concludes with the comment "... that most any program of surface science research could benefit greatly by using organometallic chemistry as a reference point from which to gain understanding into the more likely results that may be expected in a given surface system and to gain insight into the results that are unique to surfaces."

Chapter 4 (Bonding Sites in Clusters and their Relationship to Surface Bonding Sites) examines to what extent the description of ligand-metal bonding in complexes and clusters, in terms of orbital symmetry and orbital overlap, can be applied to chemisorption bonding. The authors emphasize the importance of relating such models to band structure calculations.

This aspect is developed in greater detail in the concluding Chapter 5 (Application of Orbital Symmetry and Orbital Overlap to Surface Band Structure Calculations), which discusses particularly the work of *Roald Hoffman* and coworkers on the application of symmetry considerations to surface bonding, taking as examples the CO/Ni(100) and H_2/Ni(111) systems. In these studies good qualitative agreement was found between calculations on metal complexes and those on simple adsorption systems.

The book contains over 400 literature references, mainly of fairly recent publications, up to and including 1985. To help overcome the well-known language problems which arise between organometallic chemists and surface scientists, an excellent glossary is included giving expressions used by specialists in both fields. The comprehensive subject index is very useful, and the book is attractively produced and almost free of printing errors.

The book, which is the only one of its kind on this topic, is fascinating to read, and it is warmly recommended to coordination chemists as well as to surface and catalysis scientists. These latter two groups will find here a wealth of stimulating ideas. For newcomers to the field, whether their interests are experimental or theoretical, the book offers an excellent start in the field of surface chemistry and physics. Certainly one wishes the authors success with this book, which will appeal to a wide readership. It should be available in all specialist libraries, and surface scientists should have it to hand at all times.

The Chemistry of the Cyclopropyl Group. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester 1987. Part 1: xii, p. 1–808, bound, £ 135.00.—ISBN 0-471-90658-1; Part 2: xii, p. 809–1739, bound, £ 135.00.—ISBN 0-471-91737-0. (Two-volume set £ 250.00.—ISBN 0-471-91738-9.)

Apart from the substantial article by *D. Wendisch* (Houben-Weyl-Müller, Volume IV/3), published in 1971, the chemistry of cyclopropane and its derivatives has scarcely been described in reviews; it is treated mainly in fragmented form in chapters and books of different emphasis, and under titles that do not explicitly refer to cyclopropane. It is therefore very pleasing that *S. Patai* has added to his successful series with two volumes in collaboration with *Z. Rappoport* that are devoted entirely to the ring of three carbon atoms.

As usual, the various topics are dealt with by different authors in independent chapters. The editors' plea to the authors was that they should not compile encyclopedias, but should place the most important developments in the foreground and not repeat in detail material that had already been reviewed. This is a demand which, of course, requires a knowledge of *all* the material, in order to make a *representative* choice, and not all the authors have succeeded in this as well as could be wished. In general, the literature is reviewed up to and including 1984; in some chapters work up to the end of 1985 is taken into account.

In the first chapter, *K. B. Wiberg* gives a brief, but extremely succinct survey of structures, energies and spectra of cyclopropanes. In the next chapter *W. Runge* deals with the chirooptical properties of cyclopropane derivatives, and presents, along with other ideas, his triad theory of optical rotations. NMR and IR spectra of cyclopropanes and cyclopropenes are covered by *D. G. Morris*. Rather than confining himself to a summary of experimental results in the area of NMR chemical shifts, he struggles with the speculations on the meaning of the data by the authors concerned, without achieving lucidity. It would have been more helpful to have indicated (as in the first chapter) that chemical shifts are only very superficially understood, but that thanks to recent work by *W. Kutzelnigg* and *M. Schindler* they can now be calculated rather precisely. On pp. 105, 118, and 153, one finds molecules that can only exist in the world of *M. C. Escher*.

Chapters 4–14 are on the following topics: the chemistry of ionized cyclopropanes in the gas phase *(H. Schwarz)*, photoelectron spectroscopy *(R. E. Ballard)*, acidity and basicity of cyclopropanes *(M. A. Battiste, J. M. Coxon)*, preparation of cyclopropyl derivatives *(T. Tsuji, S. Nishida)*, organic synthesis via cyclopropanes: principles and applications *(H.-U. Reissig)*, synthesis and reactivity of electrophilic cyclopropanes *(R. Verhé, N. De Kimpe)*, conjugative and substituent properties of the cyclopropyl group *(T. T. Tidwell)*, solvolysis of cyclopropyl-substituted derivatives *(E. C. Friedrich)*, cyclopropyl radicals, anion radicals, and anions *(G. Boche, H. M. Walborsky)*, rearrangements involving the cyclopropyl group *(J. Salaün)*, and radiation chemistry and hot atom chemistry of cyclopropane and its derivatives *(Z. B. Alfassi)*.

In Chapter 15 (electrochemistry of the cyclopropyl group, *J. Y. Becker*), the work of *S. Hünig*, which was required in connection with formulas 14, 15 (p. 926) and 82 (p. 955), is absent. Chapter 16, on the biochemistry of the cyclopropyl group *(H.-W. Liu, C. T. Walsh)*, is extraordinarily interesting, and shows the importance of the chemistry of three membered carbocycles, easily labeled "exotic", for the understanding of many reactions in living systems. *B. K. Carpenter* describes the preparation and uses of isotopically labeled derivatives; *J. F. Liebman* and *A. Greenberg* treat cyclopropanes having extra strain.

Unfortunately, Chapter 19 (bicyclo[1.1.0]butanes, *S. Hoz*) falls below the expected standard. The author stresses in the introduction that the last comprehensive article on this subject dates from 1968, and that he therefore wishes to discuss it in more detail than usual. However, this aim is reached only to a very modest extent. Results from before 1968 take up disproportionate space in the text, while a number of important recent developments are missing. Thus, in discussing the addition of tetracyanoethylene to the tetramethyl derivatives of 2,3-bismethylenebicyclo[2.1.1]hexane and 3,4-bismethylenetricyclo[3.1.0.$0^{2,6}$]hexane, the original interpretation of the large difference in rate constants between the two reactions is quoted, attributing it to orbital interactions (p. 1133). More recent experiments with the parent compounds *(P. Vogel, M. Christl)*, which trace the effect almost entirely to the steric

influence of the methyl groups, are not mentioned. For the formation of the tricyclo[2.1.0.0^{2,5}]pentan-3-one system from a cyclopropen-3-carbonyldiazomethane precursor the author presents an old example (p. 1143), without referring to the synthesis of the unsubstituted compound *(G. Maier)*, though this is rectified in Chapter 21. What justification is there for citing the preparation of 1-methylbenzvalene by the method of the benzvalene synthesis, yet not mentioning the latter *(T. J. Katz) at all*? Furthermore, this reaction type *(U. Burger)* does not represent Case D in the classification of routes of formation of the bicyclobutane skeleton, but Case F, for which the author found no examples. Nor is there a single word on the fact that benzvalene is a source of dozens of bicyclobutane derivatives which are as yet inaccessible by other routes. Why does the author satisfy himself with reporting the reaction of benzvalene with diironnonacarbonyl ($Fe_2(CO)_9$, not $Fe(CO)_9$, p. 1165), but omit the studies with iron pentacarbonyl *(R. Aumann)*? Also omitted are: the remarkable formation of a 3-oxatricyclo[3.1.0.0^{2,6}]hexane from a cyclobutene derivative under acidic conditions *(M. Regitz)*, and the reactions of 2-vinylbicyclobutane derivatives, in which the σ-system takes part, and which occur either in a concerted manner or via intermediate 2-bicyclobutylcarbinyl radicals or cations. The statements on p. 1151 about the unsubstituted cyclopropylcarbinyl cation are not only superficial, but in part simply incorrect. Fortunately, this subject is described correctly in several other chapters. Equation 86 is ahead of its time, since substrates with R = Et, Bu have not yet been examined. The lack of care is evident not only in the compilation and study of sources, but also in the presentation. One finds printing errors that distort the meaning, e.g. in Equation 31, and the structural formulas for one and the same ring system vary according to how it is shown in the original articles. The two additions to the central bicyclobutane bond of the tricyclo[4.1.0.0^{2,7}]heptane system on p. 1150 are an example. The different perspectives make the stereochemical differences and similarities hard to recognize, and even harder to understand. In some places, saving space with fewer formulas would have had the added advantage of giving a more concise account. For example, Equation 77 could have been omitted in favor of Equation 81, and the contents of Equations 136 and 140 would have been more effective if placed together.

Thanks to his own reviews, *D. Ginsburg* was able to be brief with the [*m.n.*1]propellanes. His characteristic style, so full of comparisons and metaphors, makes it entertaining to read. Chapter 21 (Cyclopropenes, *B. Halton, M. G. Banwell*) is very well researched and presented, but the laurel wreath for thoroughness must be awarded to *E. Vilsmaier*, dealing with the aminocyclopropanes. He had hardly any reviews to lean on, and therefore reached a total of about 1000 references, many of them to patents. *H. H. Wasserman, D. R. Berdahl,* and *T.-J. Lu* review the chemistry of cyclopropanones in an impressive manner. Cyclopropenyl compounds *(W. E. Billups, A. W. Moorehead)* reappear once again in Chapter 24. The few new aspects introduced could easily have been included in Chapter 21. The authors promote cyclohexylcyclopropenone to the status of a natural product (p. 1547), but the significance of this compound as a model for naturally occurring cyclopropenones is correctly described in Chapter 21.

In this two volume monograph, very carefully written chapters alternate with those that do not come up to expectations. This is mainly a criticism of the authors concerned, but the editor is also at fault, since even the addresses in the list of authors (pp. v, vi) contain errors (Hokkaido is printed incorrectly several times, Ghent University is transported to Kaiserslautern, whose name is also garbled). Despite these shortcomings, the two volumes are very useful, and they should be available to every organic chemist concerned with the chemistry of three-membered carbocycles in teaching or in research.

BMFT Materials Research Program

By Dieter Kutschke*

The Importance of Materials Research

Materials research plays a pivotal role in the research efforts of the leading industrial nations such as the United States, Japan, the United Kingdom, the USSR, France, the Federal Republic of Germany, etc. This is a natural consequence of the key function of materials in any technological and economic activity. In a system of competing economies, the best possible selection and design of materials and thus the use of improved and new materials is an entrepreneurial necessity. New and improved materials are not, as a rule, just invented, but, as has been shown in the last few decades, are the result of systematic materials research. Technological progress and the further development of industrial products and processes frequently call for the existence of high-performance materials.

In 1985, in response to this challenge, the Minister for Research and Technology of the Federal Republic of Germany launched a ten year Materials Research Program, for which the Federal Government intends to make approximately DM 1.1 billion available in research grants.

Three years after its initiation a first interim review of the progress being made within the framework of this program is now arranged. A major part of the interim review is the 1988 Materials Research Symposium due to be held at Hamm/Westphalia from September 12 to 14, 1988. No fewer than 70 reviews and specialized papers, dealing with a broad range of results from basic research to applications-oriented materials development will be presented.

Aims of the Materials Research Program

In general, the program aims at a long-term improvement in the industrial efficiency and competitiveness of the Federal Republic of Germany based on the development and use of new structural and functional materials. The intention is to mobilize the scientific and technological potential of highly qualified research groups in basic and applied research institutions together with those employed in industry, so as to solve selected research and development tasks. The basic concept is that it is the original task and responsibility of industrial enterprises to conduct R & D in order to lay the foundation of their future competitiveness. The Materials Research Program has been designed above all to help advance applications-oriented basic research of a type likely to yield results which can soon be put to use in the development of new and improvement of established materials. It is essential that existing skills and capabilities be strengthened by encouraging cooperation between scientific and industrial establishments. A concerted effort is called for in several respects: firstly, concentration on a limited number of research priorities; secondly, participation of all highly qualified research institutions in the program; and thirdly, the integration of basic research and industrial development. Such a concerted effort would open up an important, as yet largely untapped potential and would at the same time offer an opportunity for the highly efficient deployment of pro-

gram funds, by including industrial research to a large extent.

The program covers the following priority areas:

- high-performance ceramics
- powder metallurgy
- metallic high-temperature materials
- high-performance polymers
- composite materials

Cooperative research projects of the kind described above enjoy preferential support by the government: industrial enterprises, universities and research establishments are encouraged to pool their research facilities in order to jointly tackle, by sharing assignments and exchanging experience, R&D problems which are interrelated in terms of subject and function. Depending on the problem concerned, on the parties participating in the project, and on the particular circumstances, practical collaboration under such a cooperative research project can take different forms. The patterns of cooperation range from binding agreements on an exchange of R&D results to the execution of joint research work in one laboratory. Table 1 outlines a typical cooperative research project.

The costs of the cooperative research projects are shared by industry and the Ministry of Science and Technology (Bundesministerium für Forschung und Technologie, BMFT). In order to ensure the highest possible degree of efficiency in the cooperation between industry and its research partners (institutes), the firms are required to share in the expenditure incurred by the institutes. Generally speaking, the BMFT shoulders 50% of the total cost of the cooperative project. The participating industrial partners bear the remaining 50%, that is 50% of their own costs plus 50% of the expenditure incurred by the institutes.

In the past three years, cooperative projects incurring a total cost of DM 931 million have been started. The BMFT bears DM 497 million (Table 2).

Table 2. Priority areas and funds of the R&D activities within the BMFT Materials Research Program to date (in million marks).

Priority areas	Total R & D cost	BMFT share
High-performance ceramics	232	119
Powder metallurgy	96	59
High-temperature metallic materials	168	95
High-performance polymers	199	104

Total	931	497

The aim of mobilizing the scientific and technical potential has largely been realized. Closer cooperation between industry and scientific institutes at universities, the Max Planck Society, the Fraunhofer Society, the National Research Centers and the Federal Materials Testing Institute has been launched efficiently and to the mutual benefit of the private and public partners. The program is being carried out in close collaboration with the German Research Society (Deutsche Forschungsgemeinschaft, DFG), and has triggered off additional research activities. Further activities in materials research, in the form of new research programs or the foundation of new institutes, have taken place in all Federal States in the past three years. A number of EUREKA projects as well as the increased utilization of the BRITE and EURAM programs of the European Community are conducive to strengthening materials research at the European level.

Dipl.-Ing. Dieter Kutschke, born on 12 June 1930, studied engineering and chemical engineering at the Technische Hochschule Graz and Technische Hochschule Hannover from 1952–1958. Following a period of employment at Esso AG (1958–1966) he started to work in the management of the Nuclear Research Center Karlsruhe (1966–1974). He then transferred to the Federal Ministry of Research and Technology (BMFT) in 1974. Since 1985 he has been Head of the Materials Research Department.

From Carbon Beams to Diamond Films**

Ion Beam Deposition
Carbon Films
Surface Analysis

By S. R. Kasi, Y. Lifshitz, J. W. Rabalais,* and G. Lempert

1. Introduction

Diamonds have attracted mankind's attention through many centuries. The quest for synthetic artificial diamonds, as well as that of artificial gold, motivated the first experiments that led to the foundation of chemistry. Bulk diamonds were successfully produced only in 1953, however, by the ASEA group in Sweden and by the General Electric team in 1955.[1,2] A specially designed reaction vessel provided the high-temperature/high-pressure conditions needed to transform graphite, the stable carbon phase under normal conditions, to cubic diamond, the precious metastable carbon phase. Artificial bulk diamonds are now commonly used in many applications. An equally challenging goal is the deposition of diamond films on various materials, which has been the subject of intense research that started about thirty years ago and has accelerated significantly during the past few years. The interest in these films stems not from their decorative value, but from the unique set of physical properties of diamond:[1,2]

- hardest known material
- excellent electrical insulator
- best thermal conductor
- high dielectric strength
- highly transparent in the UV, visible and IR regions
- chemically inert
- resistant to oxidation and corrosion
- compatible with body tissues

Attempts to fabricate true diamond films resulted in carbon films with properties varying between those of diamond and those of graphite, within a range of many orders of magnitude.[2-7] The unique possibility of "tailoring" a combination of desired properties for a specific purpose is advantageous for a variety of applications including:[2-8]

- optical coatings suitable for hazardous environments
- protective thin films for magnetic recording materials
- heat sinks for semiconductor applications
- solid state devices
- moisture barriers
- low friction coatings for tribological applications
- hard coatings for mechanical tools
- protective coatings compatible with body tissues for medical applications

The properties of the different phases of carbon are closely related to the nature of the carbon–carbon bonds or to the electronic structure of carbon.[2,3,9] Cubic diamond has sp^3 carbon atoms and a tetrahedral structure where each carbon atom is bonded to four different carbon atoms and no "dangling bonds" exist. Graphite has sp^2 carbon atoms and a structure where each carbon atom is bonded only to three carbon atoms in a two-dimensional arrangement while the remaining p orbital forms a "dangling bond" (or a π electron band). Amorphous carbon includes a varying mixture of sp^1, sp^2, and sp^3 hybridized carbon atoms with no long range crystalline order.

Attempts to fabricate true diamond films have resulted in many deposition methods, practical processes, and films of commercial potential. Work accomplished on these topics is covered by excellent recent reviews and literature surveys.[3-5,8,10,11] Nevertheless, the understanding of the

Robertson*, University of Houston, for XRD analysis and helpful discussions. This material is based on work supported by the National Science Foundation under Grant No. DMR-8610597.

nature of these carbon films is still very limited. This is true of almost all aspects, such as film growth processes, deposition parameter-property relationships, film characterization and nomenclature. The major reason for this situation is the complex chemical-physical nature of the deposition techniques that have been used, where the ability for separating, controlling and studying the effects of individual deposition parameters is limited.

The present work reviews recent results of the first in-situ parametric investigations of the growth of diamond films under controlled UHV conditions.[10,12-15] These investigations were performed in the Houston facility[10,16] that uniquely combines a controlled, mass selected (carbon) ion beam system with a UHV deposition chamber and in-situ surface analysis techniques. The work has established several surface characterization methods for studying carbon films[14] and has addressed some fundamental problems involved in diamond film deposition, such as the possibility of growing diamond films on non-diamond substrates at room temperature, the evolution of the films at different stages of growth, effects of ion parameters (e.g. ion energy), substrate parameters (e.g. material, temperature) and ambient pressure. We first briefly summarize the previous work on "diamond-like" films, including deposition methods, main processes involved in carbon film deposition, and open questions in the field. Following a short description of the system and the diagnostic techniques, the use of various surface analysis methods for the characterization of the different carbon forms related to carbon film evolution is given. Next, the first conclusive proof for diamond growth and the different stages of diamond film evolution on different substrates at room temperature are presented. The results of some parametric studies including substrate material and substrate temperature effects follow. The summary gives the most important conclusions of this work and points to future applications.

2. Present Status of Research on Diamond-like Films

Since graphite is the most stable phase of carbon under ambient conditions,[1,2] simple thermal evaporation of carbon results in either graphitic or amorphous carbon films.[3-5] These films are undesirable because they have the properties of graphite, which is electrically conducting and has a high absorption coefficient in the visible and IR regions. The metastable nature of the diamond phase necessitates a combined high-pressure/high-temperature scheme for its formation.[1,2] Such a scheme is, however, impractical for routine thin film applications. Two alternative basic approaches have thus been adopted for diamond film deposition: a) The use of energetic species (10-1000 eV) that create localized high-temperature/high-pressure regions in the growing film called "thermal spikes".[3,6] These energetic species can be either carbon containing or other species (e.g. Ar). In the latter case a secondary beam of carbon containing species (either energetic or thermal) impinges on the substrate simultaneously with the energetic (Ar) species. b) Chemical reactions involving hydrocarbon-hydrogen gas mixtures, usually at elevated temperatures, resulting in the formation of diamond layers on different surfaces.[11]

Three main deposition techniques have thus been developed:

1) Ion beam deposition techniques[3,6] where different energetic particles (some of which contain carbon species) impinge on the substrate to be coated. IBD of carbon films was first introduced by *Aisenberg* and *Chabot*[6,17] in 1971 and highly developed by *Weissmantel* et al.[3]. Films produced by these methods are often called i-C (ion C) or DLC films (diamond-like C). Their properties vary between those of graphite and diamond and their exact structure is still in question.[3-5] Characterization of these films revealed a dominant amorphous nature and no rigorous proof for diamond formation was given, with the exception of studies carried out with mass selected ion beams.
2) Plasma techniques[4] where RF, DC or pulsed plasma decomposition of various hydrocarbon gases results in the deposition of carbon films on various substrates. The first work using these techniques was published in 1955,[18] but more rigorous work was started by *Holland* and *Ojha* in 1976;[19] since then these techniques have been adopted by many others.[4] These films usually contain large amounts of hydrogen (10%-70%) and are often called a-C : H films (amorphous carbon hydrogenated).[4,5] Though they may have properties that sometimes resemble those of diamond, they are definitely not diamond films.
3) CVD processes that use chemically active hydrocarbon fragments (ions and radicals) for the spontaneous growth of diamond material under rather metastable conditions.[11] These processes usually use a mixture of hydrocarbons and H_2 (ca. 99% H_2) excited by an external source (hot filament, RF or microwave plasma) to form the carbon films on hot (800-1000°C) substrates. Work on CVD processes was started by *Eversole*[20] and *Angus* et al.[21] and was further developed by *Derjaguin* et al.[22] in Russia and the Nirim group[11,23] in Japan.

Carbon films produced by the above processes have various useful properties, some close to that of diamond (e.g. hard, transparent, chemically inert, insulating films). Real cubic crystalline diamond films with crystal sizes of 1 μm and larger (identified by TEM, XRD, Raman spectroscopy and SEM) have been produced only by CVD techniques at practical (μm/h range) rates on hot (ca. 800°C) substrates.[11] Correlations between film properties and deposition parameters of specific systems have also been given.[3-5] Nevertheless, all of the systems described have a very complex nature where the different basic deposition parameters are very difficult to define and control and the

ADVANCED MATERIALS

pressure is in the range 10^{-4}–10 torr.[3–5] Many species with a complex, usually unknown, composition are involved in such deposition processes[3–5] (carbon atoms, ions and clusters, hydrocarbon ions and radicals, inert gas ions and atoms, energetic hydrogen species, impurity species due to residual gases, electrons, etc.). The energies of these species are not well defined and have wide distributions.[3–5] This results in non-reproducibility of the final product from the different deposition processes and limited understanding of the film growth mechanism. Examples of open questions, the answers for which are essential for the successful reproducible deposition of diamond films, are listed below:

a) Mechanisms of diamond formation—"Thermal spikes" are often suggested as a possible way of obtaining the temperature and pressure needed for diamond formation,[3–6] but their role is often doubted.[4] There is no direct proof for an alternative mechanism—that of preferential etching of graphitic or amorphous constituents by energetic hydrogen or argon species.[4,6] The role of hydrogen in the stabilization of carbon sp^3 bonds in the film by termination of "dangling bonds"[4,5] is only partly understood.
b) Crystal nucleus formation and crystal growth—What are the conditions needed for the nucleation of a diamond crystal and for its further growth on an existing diamond seed?
c) Carbon phases—What are the conditions necessary for the formation of the six known carbon phases in carbon films (graphite, cubic diamond, hexagonal diamond,[1,2] chaoite,[24] and two other carbon high pressure cubic phases[25,26])? Very often the identification of these phases in a given film is ambiguous.[3–5]
d) Growth mechanisms—What parameters determine amorphous–crystalline growth, crystalline size, epitaxy, adhesion to the substrate, surface morphology, etc.?
e) Bulk properties/structure/deposition parameters relationships are not well understood.
f) Characterization—There is no established correlation between different characterization techniques (e.g., Raman spectroscopy, TEM, XRD, and surface analysis methods). This correlation is essential for the characterization of thin ($< 1\ \mu m$) or microcrystalline (< 1000 Å) films where Raman measurements are misleading, XRD is not sensitive, and TEM is destructive and very often uncertain. Such thin films or small-crystalline material may be essential for future applications.

3. Mass Selected Ion Beam Deposition

Limited understanding of deposition phenomena due to the complex chemical-physical nature of many deposition systems is a general feature and not related to diamond film deposition only. Mass selected ion beam deposition has been suggested as a viable technique for fine control and separation of all the deposition parameters.[4,27] When combined with a UHV deposition chamber and in-situ diagnostics, it offers many advantages for deposition in general and for carbon/diamond film deposition in particular:[4,10]

- Ion source parameters: Selection of only one type of carbon bearing ion from various possibilities at a specific deposition stage, control of ion energy (e.g. 10–1000 eV), ion flux, and ion beam size over a wide range.
- Dual ion beam deposition of different species (e.g., carbon ions and hydrogen/argon ions) and simultaneous doping during (carbon) deposition.
- Target parameters (temperature, in-situ pre-deposition and post-deposition treatments, nature of target) are controlled with great flxibility.
- UHV environment provides pure films on atomically clean substrates and controlled admission of gases.
- In situ parametric investigation of film growth becomes feasible using surface diagnostic tools.

Several studies on diamond deposition using mass selected carbon ion beams have been performed prior to the work conducted in Houston,[28–35] the most important of which are those of *Chaikovskii* et al.,[28–30] *Freeman* et al.[31] and *Nelson* et al.[32] *Chaikovskii* et al.[28–30] deposited diamond films in UHV using a mass selected high intensity ion beam system, obtaining small crystalline (ca. 10–100 Å) diamond films on different substrates with ion energies of 30–100 eV at temperatures of 170–293 K. The true diamond nature of these films was established by ex-situ Auger analysis and by TEM. Large diamond crystalline inclusions (up to 50 μm size) were chaotically arranged in a finely dispersed small crystalline base. The effect of substrate temperature during deposition was also investigated and it was found that at 360 K the films were graphitic. This excellent work, which is, to the best of our knowledge, the only deposition under UHV conditions apart from the Houston work,[10,12–16] is unfortunately overlooked by later investigators.[3–5,31–35] *Freeman* et al.[31] found that diamond films could be deposited on existing diamond crystals at carbon ion energies of 900 eV and temperatures of ca. 700°C, using a mass selected carbon ion beam and a vacuum of ca. 10^{-6} torr. The moderate vacuum conditions, however, resulted in non-reproducibility of the films. *Nelson* et al.[32] showed that similar temperatures (ca. 700°C) were needed for the internal growth of existing diamonds using a mass selected high energy (several kV up to 100 kV) carbon beam under high vacuum conditions.

Rabalais et al.[10,16] have developed a unique facility that combines a mass selected carbon ion beam, UHV ($\leq 5 \times 10^{-10}$ torr) deposition environment, and several in-situ surface analysis tools. The Houston deposition system is a research facility; it has a much lower current density than the facility of *Chaikovskii* et al. (ca. 0.5 μA cm^{-2} compared to 1 mA cm^{-2}) in the energy region of 1–300 eV.

Nevertheless, the first and only rigorous in-situ parametric investigations of diamond film growth are being conducted in this facility,[10, 12-16] some results from which are summarized in this review. Complementary investigations of thicker films, produced by a more intense facility at Soreq NRC, Israel, at similar ion energies but poorer vacuum conditions are also being performed. The purpose of the current work is to understand the basic mechanisms involved in diamond film deposition by means of energetic species.

4. Surface Analysis Techniques for in-situ Investigation of Carbon Film Evolution

Differences in the electronic structure of diamond, graphite and amorphous carbon are reflected in the spectroscopic surface analysis features. Extensive work by *Rabalais* et al.[12-15] established the surface analysis data for diamond, graphite, and amorphous carbon as standards for further identification of the nature of deposited carbon films using Auger Electron Spectroscopy (AES), Electron Energy Loss Spectroscopy (EELS), Ultraviolet Photoelectron Spectroscopy (UPS), X-Ray Photoelectron Spectroscopy (XPS), Ionization Loss Spectroscopy (ILS), and X-Ray Induced Auger Spectroscopy (XAES). Published results were compared to those obtained in the Houston laboratory and missing data were complemented.

Figure 1 shows the surface analysis data obtained with AES, XPS, UPS and EELS for diamond, graphite, thermally evaporated amorphous carbon, and carbon films ca. 100 Å thick deposited on Ni(111) at room temperature by the Houston facility at ion energies in the range of 75–150 eV. EELS and UPS data for amorphous carbon are not presented. The features of the three different forms of carbon are different in all of these techniques, each of them being easily distinguishable. The differences lie in the lineshapes (e.g., in AES), the appearance or disappearance of peaks corresponding to π electrons (e.g., XPS, UPS and EELS), and the energy shift of corresponding loss peaks (e.g., XPS and EELS). It is therefore possible to identify the carbon form of the films deposited in the Houston facility.

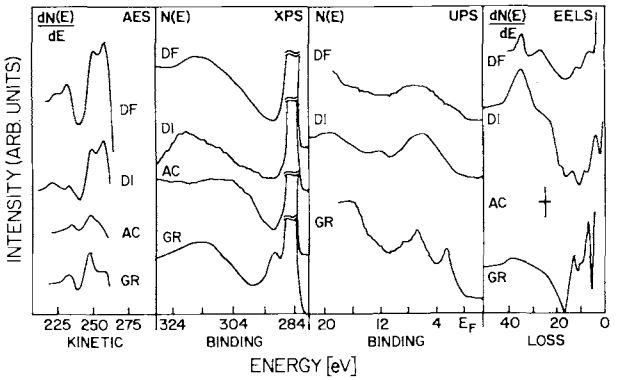

Fig. 1. Surface spectroscopic signatures of carbon in graphite (GR), amorphous carbon (AC), diamond (DI), and diamond film deposited using the Houston facility (DF), measured by AES, XPS, UPS and EELS. No information is presented for the UPS spectrum of AC. The vertical line drawn for AC in EELS indicates the energy loss position of the bulk plasmon peak. The data for GR, AC, and DI in AES, and DI in EELS are from [41] while DI in UPS is from [36].

In all four surface analysis methods, the spectra of the deposited films correspond to that of diamond and are very different from that of graphite or amorphous carbon. In the AES measurements, mild electron beam conditions are needed in order to avoid the typical electron beam damage observed for diamond surfaces.[14] Under routine experimental conditions, spectra for the electron beam damaged diamond films are measured (Fig. 2), which are

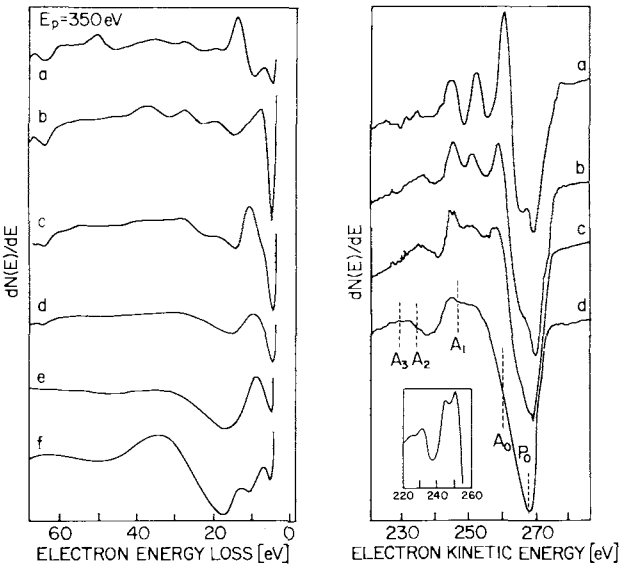

Fig. 2. Evolution of the EELS (left) and AES (right) lineshapes for 75 eV C^+ deposition on Ni(111). The doses in the EELS sequence are: a) clean Ni, b) 3×10^{15}, c) 5×10^{15}, d) 7×10^{15}, e) 9×10^{15}, and f) $>2\times10^{16}$ C^+ ions cm^{-2}. The doses in the AES are: a) 2×10^{15}, b) 6×10^{15}, c) 9×10^{15} and d) $>2\times10^{16}$ ions cm^{-2}. The inset shows an Auger electron spectrum of a diamond film subject to minimal electron beam damage.

nevertheless more similar to that of diamond than to that of graphite or amorphous carbon. The XPS spectra of the carbon films show no π electron feature at 6.7 eV from the C 1s peak and the energy of the bulk plasmon loss peak is similar to that of diamond (ca. 34 eV from the C 1s peak compared to ca. 28 eV for graphite and ca. 23 eV for amorphous carbon). The UPS spectra of the films are indicative of the typical sp^3 hybrid orbitals of diamond with no contribution in the π band region and a recession of states close to the Fermi level. The EELS spectra also exhibit the features of diamond. Additional information has also been obtained from ionization loss spectroscopy (ILS) and ellipsometry.[14]

It can thus be concluded that the short range order of the carbon films deposited at room temperature in the Houston facility is that of diamond (i.e., sp^3 hybridized

ADVANCED MATERIALS

carbon atoms). This result was reproducible on every sample tested regardless of the nature of the substrate. These films are therefore different from previously reported diamond-like carbon films (DLC's) that showed surface analysis features very different from diamond, and very similar to those of amorphous carbon.[4,5,37] The only other published data where the AES features of carbon films corresponded to diamond was that from ex-situ measurements by *Chaikovskii* et al.,[28] where the deposition conditions were very similar to those of the Houston group. In the work of the Houston group, however, several surface analysis methods were applied to establish the same result and almost all of the measurements were done in-situ. The establishment of these surface analysis data was followed by in-situ parametric investigations of the diamond film growth that are not feasible in any other existing facility.

5. Parametric Investigations of Carbon Film Growth

This section reviews results from investigations of carbon film growth that are being conducted in the Houston facility.[10,12-16]

5.1. Stages of Diamond Film Evolution

The evolution of the diamond films on atomically clean surfaces has been investigated on different materials at room temperature using the different in-situ surface analysis techniques. The three distinct stages of a) carbidic, b) graphitic, and c) diamond were observed in the film evolution on all substrates investigated. Figure 2 shows the film evolution as monitored by AES and EELS for 75 eV C^+ deposition on Ni(111). At low fluxes the impinging C^+ ions form Ni-C bonds resulting in a typical nickel carbide signature[14,38] in both the AES and EELS spectra. At higher carbon fluxes, C-C bonds begin to form and the lineshapes change accordingly. The AES and EELS nickel peak intensities start decreasing at this stage due to formation of the carbon layer. When a complete two-dimensional carbon layer is formed, the nickel lines disappear and the carbon layer gives a graphitic lineshape. This is more obvious in the EELS data since the AES lineshape at this stage still reveals some carbidic features, probably due to a contribution from the interfacial carbidic layer. At higher carbon fluxes the thicker carbon layer forms a three-dimensional short range order for which surface analysis shows the typical diamond features as discussed in the previous section.

5.2. The Role of Energy

The evolution of the carbon film was investigated by AES at different energies in the range 10–300 eV. A "phase diagram" showing the C^+ fluxes needed for the evolution of the carbidic (A), intermediate (B), and graphitic (C) stage on Ni(111) at room temperature was constructed (Fig. 3). The evolution of carbon layers is energy independent over a broad range (ca. 30–180 eV). At higher (>180 eV) or lower (<30 eV) energies, higher fluxes are required for the stabilization of the graphitic stage. The final diamond structure was not observed for energies below ca. 20 eV and is obtained only at a higher carbon flux for 300 eV. The energy threshold for diamond evolution can be interpreted in terms of the "thermal spike" theory.[3] At very low energies the ion induced "thermal spike" cannot provide the temperature-pressure conditions needed for stabilization of the diamond phase. At high energies the self-sputtering rate of carbon increases,[4,33] the net deposition rate at constant C^+ current density decreases (lower "sticking probabilities"[16]), and radiation damage may destroy the crystalline order; amorphous films are expected[33] unless the high energy deposition is performed at elevated (700–900 °C) temperatures where this damage is annealed.[31-32]

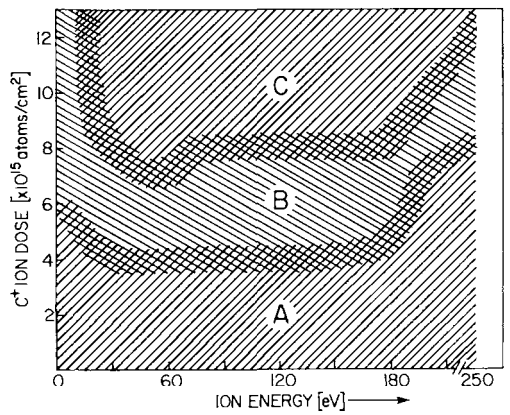

Fig. 3. Evolution of the carbon deposits monitored by AES plotted as a phase diagram of carbon ion energy and flux. Regions A, B and C correspond to deposits that have the AES lineshapes of Figure 2 (right), a, b, and c, respectively.

5.3. Substrate Structure Effects

Room temperature carbon deposition on different substrates (Ni(111), Si(100), Au, T, W, Ge and Cu) exhibited similar behavior, i.e., evolution from a carbidic through a graphitic to the final diamond stage. The carbidic stage may be important for film adhesion to the substrate. Differences in the rate of film evolution on different substrates were detected (Fig. 4), indicating the possibility of different film growth mechanisms on different substrates. The rate of the initial stages of film growth was much slower on a gold substrate than on Ni and Si, possibly due to enhanced backscattering of the C from the high Z gold substrate. The substrate material was also found to influence the temperature behavior of the films as discussed in the next section.

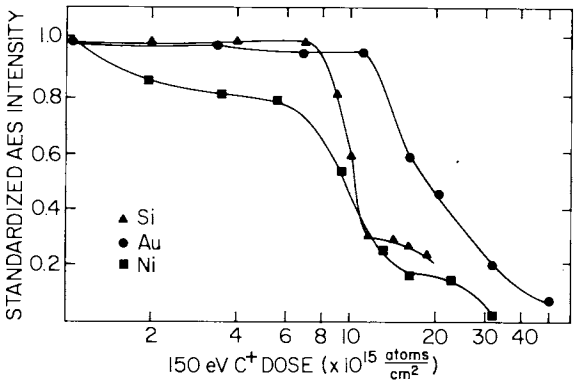

Fig. 4. Plot of the change in substrate AES peak intensity as a function of 150 eV C^+ flux. The substrate signals plotted are the Ni(61 eV), Si(92 eV), and Au(69 eV) transitions. The peak intensities are normalized to that for the clean surface.

5.4. Substrate Temperature Effects

Two kinds of temperature effects on film evolution on Ni(111) and gold were investigated, post-deposition annealing and deposition on hot substrates. The films on Ni substrates were found to be unstable under annealing. At 200°C Ni Auger lines appeared, possibly due to some Ni-C interdiffusion or film recrystallization and island formation. At temperatures exceeding 400°C carbon dissolution into the Ni associated with a graphitic transformation of the carbon was detected. This behavior is consistent with the C-Ni phase diagram.[39] Carbon ion beam deposition on the Ni substrate at 150°C resulted in graphitic films, while it was not possible to deposit carbon films on Ni at 400°C, very likely due to dissolution of C into the Ni at this temperature. Diamond films on gold were found to be much more stable under post-deposition annealing. No dissolution of the film into gold was detected, even at 875°C, although marked graphitization occurred at 650°C. Deposition of C on a gold substrate at 150°C, however, resulted in a graphitic film, similar to the results of deposition on a hot nickel substrate. This tendency to form graphitic films instead of diamond films at temperatures exceeding 100°C was also detected by *Chaikovskii* et al.[28-30] The explanation for this temperature behavior may relate to the graphite/diamond phase diagram[1,2,29] and is unclear at present.

5.5. Bulk Characterization

Bulk characterization of the diamond films is currently being performed using TEM, XRD, Raman spectroscopy, IR spectroscopy and ellipsometry. Two kinds of films are being investigated: thin (ca. 500 Å) films deposited in Houston and thick (ca. 1 μm) films deposited in Soreq NRC, Israel, under similar energy, higher current density, and poorer vacuum conditions. TEM analysis of a 500 Å diamond film deposited on Si(100) shows oriented crystals with a diameter of ca. 1000 Å. The corresponding electron diffraction pattern confirms the existence of crystals oriented with the substrate but is very complex and has not yet been resolved. The ~1 μm samples were deposited on Si(100), Si(111), Ge and Cu. They show clear interference fringes due to non-uniformity of the film thickness indicating transparency in the visible range. Ellipsometry measurements of films on Si give refractive indices that correspond to diamond. IR spectroscopy reveals very high transparency in this region as well. XRD of the carbon film on Si(111) shows a broad peak that corresponds to diamond (111) and a crystal size of ca. 50 Å. This small size may explain the absence of a sharp 1332 cm^{-1} diamond line in the Raman spectra, which are very similar to the Raman spectra of microcrystalline diamond films grown by CVD.[5] The bulk characterization of these films is still in progress; however, these preliminary results are consistent with the assumption that the films are made of a microcrystalline (20–50 Å) diamond matrix, with random inclusions of larger crystals. A similar interpretation has been given previously by *Chaikovskii*[28] and by other investigators.[3-5,40]

6. Summary and Conclusion

The most important general achievements of the work can be summarized as follows:

a) A comprehensive surface analysis procedure has been established for carbon film characterization using the AES, EELS, UPS, XPS and ILS techniques.
b) The Houston mass selected ion beam facility that combines a UHV deposition environment and in-situ surface analysis instrumentation has been established for parametric investigations of (diamond) film growth.
c) Carbon films deposited by the Houston facility have been conclusively shown, by surface analysis techniques, to have the short range diamond order. This demonstrates the feasibility of reproducible diamond film deposition using pure carbon ion beams on different substrates at room temperature (in the absence of argon or hydrogen).

In-situ parametric investigations of diamond film evolution are currently being conducted, with emphasis on film evolution, effects of ion energy, substrate temperature during deposition, post-deposition annealing, substrate features and substrate material effects, ambient pressure effects, etc. Among the most important specific results obtained are:

- The film evolution has three stages; an initial carbidic stage evolves to a final diamond structure through a graphitic stage.
- The optimal carbon ion energy range for diamond film evolution at room temperature is 30–180 eV.

ADVANCED MATERIALS

Deposition on hot (ca. 100°C and above) substrates results in graphitic films.

Substrate effects include determination of deposition rates at the initial stages and film growth modes (e.g., low deposition rates on gold) and determination of film temperature stability and the possibility of high temperature film deposition (e.g., nickel substrates are not suitable for high temperature applications unlike gold substrates).

Bulk characterization suggests that the films have the properties of diamond and that, under proper conditions, both small and large microcrystalline diamond material can be obtained.

7. Future Trends

The possibility of depositing diamond films at room temperature on different substrates has been demonstrated. These films will be useful for many applications, as mentioned in the introduction. Mass selected ion beam deposition, especially under UHV conditions, has the unique possibility of controlling and separating the different deposition parameters. These possibilities do not exist in the other deposition techniques that have a complex chemical-physical nature. Mass selected IBD can thus serve several purposes:

Parametric investigations of diamond film formation, simulating other existing deposition methods.

Development of processes with specific deposition parameters resulting in "tailored" film properties. These processes can be attempted by other deposition methods (CVD, plasma deposition, or another ion beam deposition technique) depending on economic considerations.

Actual fabrication of diamond films. Controlled, microfocused beams with in-situ flexibility of changing deposition parameters, using either dual beams for doping or successive exposures of different ions for multi-layer deposition, are most advantageous for microelectronic applications.

This review has focused specifically on diamond-film fabrication. Many arguments can, however, be extended to deposition of other materials. Mass selected ion beam deposition can therefore be applied to the development of films of a variety of materials with unique and useful properties.

ADVANCED MATERIALS

Polymeric Photoconductors—New Concepts**

Charge Carrier Transport
Amorphous Materials
Fractals

By Dietrich Haarer* and Alexander Blumen*

1. Introduction

The use of polymeric photoconductors in printing and copying techniques represents one of the most sophisticated applications of polymeric materials. However, there is a considerable lack of understanding of the basic electronic mechanisms involved in photoconduction. Recently, new theoretical concepts and improved experimental techniques have given new impetus to the complex problem of dispersive transport in polymeric photoconductors. On the experimental side one has succeeded in monitoring photocurrents over ten decades in time and the decay over many orders of magnitude. On the theoretical side one has been able to model not only the temporal disorder via random walks in continuous time but also the geometric disorder via fractals and the energetic disorder via ultrametric spaces. An introduction to these new concepts will be given and some topical aspects will be discussed in this article.

2. Historical Overview

The rapid growth of the electronic industry, and especially the almost exponential increase of the performance of its products, have mostly been attributed to technical advances in the field of single crystalline silicon devices. Yet, it was not until the mid-seventies and early eighties, that it became obvious that in the silicon technologies as well as in other domains of the electronic industry, sophisticated or so-called "intelligent" polymers have silently made an almost comparable progress. For instance, in the field of passive dielectric components the "natural polymer" paper (which had been widely used as dielectric medium in capacitors) was replaced by thin polymer films. In the field of "active applications"—here the word active is used to characterize "gain" or "electronic" mechanisms—the achievements are enormous, much beyond the expectation level set by research activities on organic molecular crystals, a typical field of research on organic materials in the sixties and seventies.

One of the best examples of this change is the development of photoconductive materials. This field originated with experiments on anthracene crystals where, for the first time, electron and hole mobilities were measured by the time-of-flight method.[1,2] From a historical standpoint it is interesting to note that in early work of the Göttingen school on the photoconductivity of color centers in alkali metal halide crystals similar techniques were employed half a century ago, using the modest experimental equipment of the time.[3] These investigations, however, were hampered by the lack of applications which was typical of most of the color center work in general. Even research on simple crystalline organic materials did not lead to any practical results, because nobody could think of ways to use anthracene or naphthalene crystals in technical devices, and because the quantum yields for charge carrier production were, at the normal electrical field strengths, on the order of 10^{-3} and therefore not attractive for applications.

It was several years after the discovery of the xerographic process based on the inorganic photoconductor selenium,[4] that the first patent on organic photoconductive systems was published.[5] Several key ingredients can, in hindsight, account for the success of polymeric photoconductors:

a) Polymeric systems can be easily fabricated in large area devices and can be produced perfect enough to withstand high electric fields (low pinhole densities).
b) The role of donor-acceptor interactions was discovered early as a key mechanism to enhance carrier production yields.

The first example of technical applications used the donor polymer polyvinylcarbazole (PVK) and the acceptor compound trinitrofluorenone (TNF) in low concentrations[5] or in a 1:1 stoichiometry.[6]

With the above-mentioned advantages of polymeric materials and with complex dye-matrix or dye-pigment systems replacing the donor-acceptor based polymers, the organic photoconductors were perfected between 1970 and 1980 to the extent that they are nowadays equivalent or superior to their inorganic counterparts. The yields for charge carrier production are on the order of ten percent,[7] depending on the limiting field strengths, and it is only the

ADVANCED MATERIALS

mobility aspect of the presently used systems which still favors inorganic materials like the chalcogenides.[8]

In spite of the large technical progress in photoconductive systems, many basic aspects of charge carrier generation and transport are still not well understood. In this article we focus on some recent experimental and theoretical aspects of charge carrier transport. Improved techniques to measure photocurrents over ten or more decades allow one to monitor the dispersive transport with previously unknown accuracy. Since the photocurrent can be determined over a wider time regime than most other properties (such as mechanical relaxation), photoconductors are a good model system for transport phenomena in disordered materials. New experimental data allow crucial tests for recent theories of non-Gaussian behavior.

From the theoretical viewpoint, the issue at stake in amorphous photoconductors is the dispersive transport, as contrasted to the familiar diffusive, Gaussian behavior. Diffusive motion, in its many facets, ranging from the transfer of heat (macroscopic) to Brownian motion (microscopic) is a well-understood phenomenon and may be modelled using the mathematical theory of Markov processes, in which the system keeps no memory of past events. Typical discrete examples are random walks on regular lattices—first introduced by *Bachelier* at the turn of the century for monitoring the fluctuations of the stock-market[9]—which nowadays comprise a vast mathematical literature.[10] Simple random walks on regular lattices of arbitrary dimensions lead to a time-independent diffusion coefficient, or, expressed differently, in the absence of a biasing field, to a linear increase in the mean squared displacement as a function of time.

In amorphous photoconductors the situation is different, since one encounters dispersive transport: the motion of the carriers through a sample becomes slower and slower with the passage of time, so that no diffusion constant in the usual sense can be defined. Here the diffusion coefficient may display an algebraic dependence on time:

$$D(t) \sim t^{\alpha - 1} \quad \text{with } \alpha < 1 \tag{a}$$

with a similar finding for the current $I(t)$ flowing in a biasing field. Such behavior is incompatible with the usual diffusion equation.

Progress in the advancement of theoretical models for dispersive transport was slow, due to the Gaussian character of most probability distribution functions put forward. Here we have to recall the overwhelming role of the "central limit theorem" of probability; under very general conditions, a sum of random variables will tend to form a normal (Gaussian) distribution when the number of elements in the sum increases. The position vector of a particle may be viewed as the sum of distance increments due to past events, say collisions. If energies, directions etc., are randomized after such events, most distributions will lead to regular diffusion. Hence, for a successful modeling of dispersive transport in such a framework one has to look for the (relatively rare) distributions for which the central limit theorem does *not* hold.

The basic theoretical problem which has to be solved for the understanding of the transport of light-generated charge carriers through an amorphous medium is to model the motion of individual carriers in a "hopping model", in which these charge carriers perform a specific type of random walk in the direction of the external electric field. In this random walk the probability for performing the next hopping process does not decay exponentially with *one* given decay constant but shows a much broader distribution. This is due to the fact that an amorphous material has rather irregular lattice spacings (geometrical disorder), which lead to large variations in energy levels (energetic disorder).

Mathematically the most important parameter characterizing the transport is the waiting time distribution, i.e., the distribution of waiting times between subsequent carrier jumps. Here a theoretical breakthrough occurred with the realization by *Scher, Lax* and *Montroll* that long tails in the waiting-time distributions $\psi(t)$ between the microscopic events can qualitatively describe the phenomenon of dispersive transport.[11,12] Such distributions lead to the so-called Lévy processes when

$$\psi(t) \sim t^{-1-\alpha} \quad \text{with } 0 < \alpha < 1 \tag{b}$$

so that the zeroth but not the first moment of the distribution $\psi(t)$ exists. This field was long considered to be a domain of mathematical curiosities.[13,14] The main technical point in investigating random walks in continuous time (CTRW) with such distributions was the realization that the basic CTRW framework developed ten years earlier by *Montroll* and *Weiss*[15] could easily incorporate these, less usual, $\psi(t)$ forms. However, although the theory developed[11,12] was successful in providing a scheme for a qualitative understanding of the dispersive transport, the nature of the microscopic parameters leading to $\psi(t)$ was at the time only conjectured.

Today we know that this is only one of the possible ways of obtaining algebraic time dependencies of $D(t)$, and that the key ingredient in the CTRW framework is the idea of temporal scaling, or of time fractals, as formulated by *Shlesinger*.[16] Other approaches that invoke scaling are based on geometrical and on energetic aspects: for the former we mention in this context fractals and percolation models and for the latter ultrametric (hierarchical) structures (UMS). All these concepts lead (for certain values of the parameters) to dispersive transport, as we discuss in the next Section.

3. New Experimental Data and Theoretical Aspects

We discuss charge carrier transport (mobility) by focussing on one of the historic hole-transport polymers, namely

polyvinylcarbazole (PVK).[17a] Here, recent experimental data have given rise to new questions concerning the general theoretical concept of transport in disordered media. The basic question is the nature of the disorder: Is it mainly geometric or mainly energetic or both?[17-20] Furthermore, which are the microscopic parameters that control the macroscopic mobility in polymeric materials?

PVK is prepared in 10 μm thick films in which both solvent and residual monomers have been removed.[17a] The polymer films are mounted between aluminum electrodes produced by vapor deposition (see Fig. 1). The top electrode is semi-transparent and allows illumination with laser pulses of a time duration of typically 10 ns and a wavelength of 337 nm (N_2 laser). At this wavelength the polymer absorption is characterized by the carbazole moiety; therefore the typical penetration depth of the light is less than 0.5 μm. The light pulse thus creates electron-hole pairs within a thin surface layer of less than 1/20 of the sample thickness. With the positive electrode as front electrode, one therefore observes photocurrents, where holes (positive charges) are transported through the 10μm-thick bulk PVK sample.

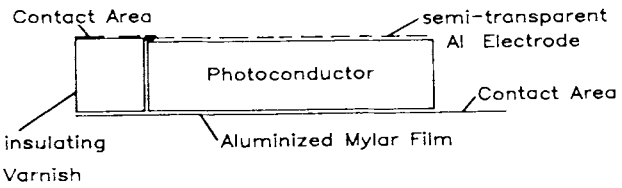

Fig. 1. Experimental arrangement for the photoconductivity measurements. The top electrode is semi-transparent aluminum. The insulating varnish prevents electrical breakthrough of the sandwich-type sample (see [17b]).

Even though the light pulse has a duration of only 10 ns and thus limits the time resolution of the experiment to the 10^{-8} s range, it triggers a photocurrent which traverses the 10μm-thick sample in roughly 10 ms and which can be experimentally monitored up to the time regime of 10 to 100 s. This wide sampling range is important for a meaningful evaluation of the experimental data.

Figures 2 and 3 show transient hole-photocurrents in PVK as a function of field and temperature taken over about nine decades in time (10 ns to 10 s) and seven or eight decades in intensity.

The gross features of the photocurrent show an initial rise time in the range of 10^{-8} s, followed by an algebraic slow decay into the 10^{-3} s time regime ($I \sim t^{\alpha-1}$, see below). At this point the first charge carriers arrive at the back electrode after having traversed the sample, and thus the slope of the photocurrent changes abruptly (to $t^{-\alpha-1}$; see below). The time at which this break in the slope occurs is called "transit time". It characterizes the macroscopic response time of the polymer sample of 10 μm thickness. For technical applications the material is some 10 μm thick and thus typical transit times are on the order of 10^{-3} to 10^{-2} s. These times are sufficiently short for technical applications in electro-photography and electroprinting.

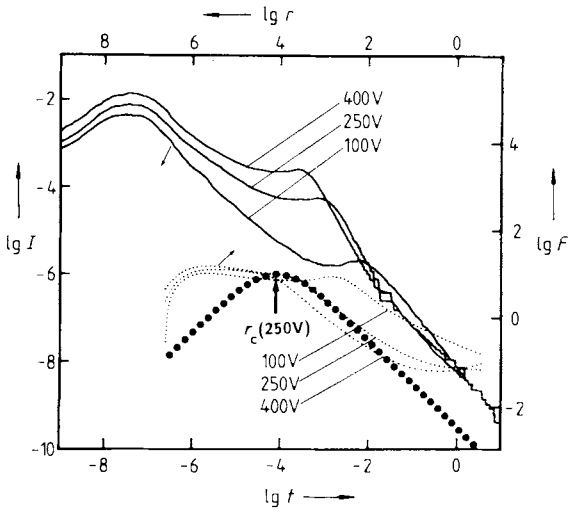

Fig. 2. Solid lines: Photocurrent of PVK (10 μm thick) at constant temperature (61.5°C) and various field strengths. Dotted lines: Analysis of rate distribution. For details see [17a].

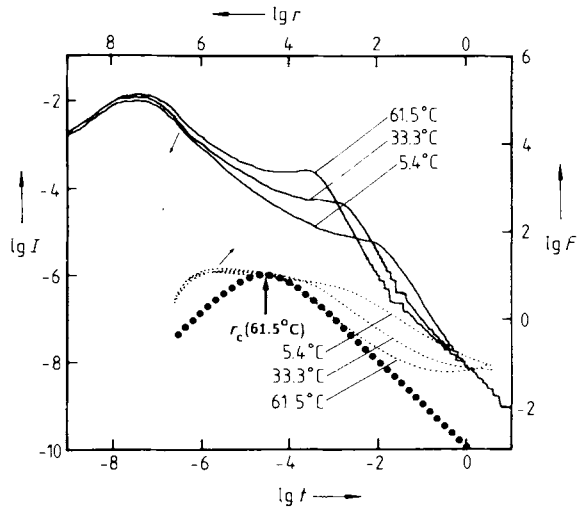

Fig. 3. Solid lines: Photocurrent of PVK (10 μm thick) at constant voltage (400 V) and various temperatures. The experimental data range over nine decades (left and lower axis). Dotted lines: Rate distributions. For details see [17a].

The difference between the data presented in Figures 2 and 3 and those published earlier (experiments on related systems) is the fact that the slope of the current (which characterizes the transport properties of the material and may be related to α) varies, as a function of time, over its full range, from 1 at short times to 0 at long times.[17a] Such a behavior can only be noticed when a sufficiently large dynamic range is monitored. If, as in many previous investigations, only four decades or less are accessible, a definite analysis to discriminate between the various microscopic processes is hardly possible.

ADVANCED MATERIALS

The analysis of the rate distribution in Figures 2 and 3[17a] is rooted in the multiple trapping (MT) formalism put forth by *Schmidlin*.[21] MT can be viewed as a phenomenological basis to characterize microscopic processes in which the main source of dispersion are energy-level fluctuations (see below). Hence, microscopic rates can be extracted from the experiment, but only when the current is monitored over many orders of magnitude in time; from measurements over nine decades one can determine rate distributions over four to five decades.[17a]

Let us remark that theoretically one usually goes the opposite way and assumes a $\psi(t)$ distribution, from which the transient currents are then calculated. This is somewhat arbitrary, but the procedure can be used to demonstrate that the current is not very sensitive to the details of the model. In fact one can show that MT and CTRW give the same result.[21–23] For a finite sample one finds[23] the following relation between the Laplace transformed current $I(u)$ and waiting-time distribution $\psi(u)$:

$$I(u) = \frac{\psi(u)}{1-\psi(u)}(1-[\psi(u)]^N) \qquad \text{(c)}$$

Nd is the thickness of the sample and d the distance between neighboring traps.

The advantage of Eq. (c) is its relatively simple structure, so that the numerical effort involved in obtaining $I(t)$ is small; only an inverse Laplace transformation is required. Our analysis[23] highlights several points, by using $\psi(t)$ forms as in Eq. (b):

1. Well inside the dispersive regime (i.e. for α around 0.5) one obtains for not-too-short times the classical Scher–Montroll behavior:[12]

$$I(t) \sim \begin{cases} t^{\alpha-1} & \text{for } t < t_T \\ t^{-\alpha-1} & \text{for } t > t_T \end{cases} \qquad \text{(d)}$$

   where t_T is the effective transit time.
2. For values of α larger than 1.0 one has, after an initial dispersive regime, Gaussian behavior.
3. The value $\alpha = 1$ is marginal; the plot of the current versus time continuously changes its slope, crossing over from dispersive to non-dispersive (Gaussian).

These findings make clear that a careful analysis of the whole current behavior is required in order to determine $\psi(t)$ from $I(t)$, since even simply structured $\psi(t)$ distributions may lead to complex $I(t)$ forms, and one cannot always rely on expressions like Eq. (d) to determine α. Moreover, up to now the microscopic mechanisms which lead to $\psi(t)$ were not discussed. The original CTRW proposition[12] was that in a chemically pure, amorphous solid the distribution of distances between the atoms gives rise to dispersive $\psi(t)$ forms, and that geometrical disorder is therefore involved. Careful computer simulations[24,25] indicate, however, that in most chemically pure solids the variation of distances can hardly lead to quite low α-values, such as $\alpha \lesssim 0.5$. The counterproposal, which leads to MT, was to invoke energetic disorder:[21,22] here the motion of the carriers is slowed down by trapping. In fact, an exponential distribution of traps[26,27] leads directly to $\psi(t)$ forms such as Eq. (b).

Due to the mathematical equivalence between CTRW and MT it is impossible to decide from a single $I(t)$ curve whether $\psi(t)$ is dominated by geometric or energetic disorder. One needs additional information. As an example, if the disorder is energetic and if the intersite transitions are thermally activated, then $\psi(t)$ will be strongly influenced by the temperature. However, the effect of temperature variation on the intersite distances is considerably smaller. As a consequence, it is very important to monitor the temperature dependence of the current. These experiments, however, are extremely difficult. On the one hand the "temperature window" in which photoconductivity experiments can be performed is rather small (typically 300 K to 400 K). At low temperatures charge carrier trapping becomes dominant and at high temperatures the polymeric materials show irreversible changes due to chemical or structural changes. On the other hand the temperature dependence of the $I(t)$ curves often does not yield a simple characteristic time exponent α (slope) if measured over a wide enough range (see Fig. 3). Here only a detailed mathematical analysis combined with measurements over more than four decades in time is sufficient to decide on the nature of the phototransport mechanism. However, measurements over such large time regimes are scarce.

The theoretical aspects of the problem are further complicated when the substrate is not chemically pure, but consists of impurity centers embedded in an inert matrix. A recent investigation used a benzotriazole derivative embedded in a polycarbonate matrix.[28] In such a situation, especially at relatively low impurity concentrations ($\lesssim 10\%$), the fluctuations in the intersite distances become very drastic. As a result, the influence of the geometric disorder may become dominant.

The prototype problem for geometric disorder in a binary mixture is percolation. In the standard model[29]—there are many variations—sites on a lattice are conducting (with probability p) or non-conducting (with probability $1-p$) and the intersite interaction is of a short-range nature (nearest neighbors only). The current flowing through the sample depends on p. For values less than a critical value p_c no current flows at all, whereas slightly above p_c one has

$$I \simeq I_0(p-p_c)^t \quad (p \gtrsim p_c) \qquad \text{(e)}$$

Here p_c depends on many details of the model (interaction range, lattice type, number of nearest neighbors), whereas t is less influenced by details, and depends mainly on the lattice dimension ($d = 2$ or 3). Note that above p_c the cur-

rent should be Gaussian (beware, however, of crossover effects near p_c). Figure 4 shows the carrier mobilities μ_T found for a mixture consisting of a charge transport component in an insulating substrate (benzotriazole in polycarbonate matrices). The experimental data seem to be consistent with the percolation picture.

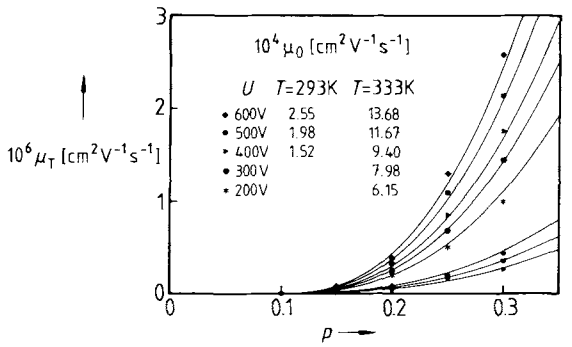

Fig. 4. The effective mobilities μ_T as a function of the benzotriazole concentration p. The μ_T data were measured at the U and T values given in the inset. All curves are fits to the percolation model, Eq. (e), with $p_c = 0.1$ and $\hat{t} = 2.5$. The resulting μ_0 values are listed in the inset.

The situation at p_c is, in the standard percolation, most interesting. Here one encounters the incipient infinite cluster on which transport is *dispersive*. This is due to the large fluctuations on connectivity at p_c, so that the incipient infinite cluster contains voids of all sizes. The structure is self-similar, or, in modern language, fractal.[14] Fractals display a subtle, lower symmetry: they are dilatationally invariant, but, in general, they lack translational symmetry.

As far as the total photocurrent is concerned, fractals can be specified by several parameters; in fact one can dispense with the stochastic intricacy of the incipient infinite cluster and model it through regular looking, deterministic fractals.[30] For diffusion on fractals one again has Eq. (a), where now α is given by:

$$\alpha = \tilde{d}/\bar{d} \tag{f}$$

$\bar{d}$ being the fractal (Hausdorff) and $\tilde{d}$ the spectral dimension of the underlying structure.[31] Use of the Einstein relation, which also holds for fractals[32,33] implies that the time dependence of the current also follows Eq. (a). In general $\tilde{d} \leqslant \bar{d}$; thus at p_c one finds $\tilde{d} \simeq 4/3$ whereas $\bar{d} = 1.9$ for $d = 2$ and $\bar{d} \simeq 2.5$ for $d = 3$.[29] Hence, the current is dispersive on percolating clusters at p_c.

It should be evident to the reader by now that the root of dispersive behavior, Eq. (a), lies in some self-similarity (scaling) of the underlying model. In the case of fractals the scaling aspect is *geometrical* (dilatation). In the CTRW model the scaling is connected to the *temporal* aspect, as expressed by Eq. (b), which is form-invariant under time-dilatation. In fact, one may use for $\psi(t)$ the Weierstrass form,[19,27] which is defined in the whole time domain:

$$\psi(t) \sim \sum_{k=1}^{\infty} (ab)^k \exp(-b^k t) \quad (a < 1,\ b < 1) \tag{g}$$

At longer times $\psi(t)$ behaves like Eq. (b), scales, and has $\alpha = \ln a / \ln b$; this prompted *Shlesinger* to call such forms time fractals.[16]

Furthermore, one may also use *energetic* self-similarity in order to obtain dispersive transport. The idea is somehow inherent in the exponential density of states, but becomes evident through model descriptions such as ultrametric spaces (UMS). Here the basic idea is to start from a Cayley tree (Bette lattice), where the tips correspond to different sites, and the energetic separation between sites is given by the length of the minimal path connecting them.[19,34] One can now show that at low temperatures the activated transport is dispersive, the parameter α being now a function of temperature, barrier-height and connectivity of the lattice.

4. Outlook

The progress that has been made recently in the theoretical description of non-Gaussian transport phenomena has created challenges for the experimentalist. It is evident that the dynamic range of most available transport data is not large enough to answer even rather basic questions such as:

- Is disorder mainly of geometric or of energetic nature?
- How well are the basic distribution functions known? (Is the trap distribution exponential, or Gaussian, or of some other type?)
- What are typical "cut-off frequencies"? Are they intrinsic or are they imposed by the nature of the experiment?

For the materials scientist the open questions are:

- What are the intrinsic limits of feasible mobilities? Can amorphous materials match the properties of crystalline materials? (Mobilities on the order of $\mu = 1$ cm^2/Vs?)
- Is the performance of polymers limited by chemical or by structural imperfections?

All of the above questions can only be dealt with if one uses modern spectroscopic tools with high time resolution. One also has to vary the materials parameters from amorphous to partially crystalline to liquid crystalline and thus utilize the flexibility offered by the wealth of organic synthetic chemistry and polymer chemistry.

Conference Reports

Organic Materials for Nonlinear Optics

The study of nonlinear optical effects in organic materials has been an active area of research for over ten years. These materials are now attracting considerable industrial interest through their potential for controlling and transforming laser radiation. The International Conference on Organic Materials for Nonlinear Optics, organized by the Royal Society of Chemistry and held at the University of Oxford, England, on 29–30 June 1988 (OMNO '88) was only one of several this year; there have already been meetings at Virginia Beach, USA, and Antibes, France, and the SPIE meeting in San Diego is yet to come. The roughly 160 delegates to OMNO '88 came from eight different countries and almost half were from industry. Its format of a single session over two days was just about right for covering the subject in depth while avoiding fatigue; the atmosphere was friendly, and the charming conference accommodation in historic Balliol College right in the center of Oxford assisted the lively evening socializing.

Fittingly, the first speaker (*J. Zyss*, CNET, France), who was among the founders of the field, spoke about the realization of one of his long-term goals, that of achieving parametric amplification in a single-crystal material. He has applied the technique as a very sensitive way of studying sub-picosecond phenomena. From his highly professional, extensively characterized and beautiful results, as well as those of *J. N. Sherwood* (Univ. of Strathclyde, UK) on crystal growth and *S. Allen*(ICI, UK) on electro-optic effects, it was apparent that second-order effects in single crystals are much better understood than any other aspect of the field. In fact, the conference heard the news that large, optical-quality crystals of 3-methyl-4-nitro-pyridine 1-oxide (POM) are now available on a commercial basis. *A. Gavezzotti* (Univ. of Milan, Italy) and *R. W. Munn* (UMIST, UK) had the design of future high-performance second-order crystalline materials in mind with their theoretical studies of molecular packing and local field effects, respectively.

Other excitement was generated by work on electro-optic effects in poled polymers. *D. R. Ulrich* (US Air Force Office of Scientific Research) gave well-reasoned arguments for his continued support of basic research in this area, and some experiments on these materials were reported by *G. R. Möhlmann* (Akzo, Netherlands) and *N. Carr* (Plessey, UK). However the most promising results were those of *J. R. Hill* (British Telecom, UK), and especially *R. Lytel* (Lockheed, USA), who appeared close to complete mastery of the technology. The electro-optic figures of merit reported are comparable with the best alternative materials, and the dispersion of dielectric constant much smaller. The major remaining task is to reduce levels of scattering.

In the area of third-order effects in conjugated polymers, there appears to have been a strategic retreat to understand the basic science. These materials, which were initially the front runners in the field, have now been faced with very effective competition from multi-quantum wells and other inorganic semiconductors materials. *P. Prasad* (SUNY, Buffalo, USA), *F. Charra* (CEN Saclay, France), *A. F. Garito* (Univ. of Pennsylvania, USA) and *D. Pugh* (Univ. of Strathclyde, UK) all attempted to understand the optical Kerr effect in terms of the interplay of molecular states, while *G. R. Meredith* (Du Pont, USA) also emphasized the contribution from cascaded second-order re-

sponse. *A. Penzkofer* (Univ. of Regensburg, FRG) reported on solution measurements of third harmonic generation. All are agreed that the effects are very fast—sub-picosecond—but *G. I. Stegeman* (Univ. of Arizona, Tucson, USA) underlined the need to consider figures of merit, which indicate that the present materials are several orders of magnitude short of usability, and require somewhat reduced attenuation and larger response. Rather than improve conjugated polymers, *K. J. McEwan* (Royal Signals & Radar Establishment, UK) tried to trade off some of the extremely high third-order response of mesogens to improve their response time and light scattering, by operating them in the isotropic phase.

Finally there were a number of talks on the general topic of Langmuir-Blodgett films. *Y. R. Shen* (Berkeley, USA) characterized the structure of monolayers on the water surface on the basis of their second harmonic generation, while *C. Bubeck* (Mainz, FRG) reported only on linear effects, mainly polarized spectroscopy, to determine the structure of deposited polymeric films. *M. C. J. Young* (Univ. of Lancaster, UK) reported some preliminary results on electro-optic response but agreed with the author of this report that optical scattering should now be the focus of applications-oriented research.

In addition to the lectures, there was a well-subscribed poster session reporting many interesting variations on the main themes discussed above, and which there is not space to review in detail here. The Proceedings of the conference are to be published by the Royal Society of Chemistry. Because of the general satisfaction all around, a further conference to be called OMNO '90 is planned in two years' time, also to be sited in Oxford.

der Universität Mainz (FRG)

European MRS Meeting in Strasbourg

Strasbourg, May 31st. No sign or poster can be seen to indicate that more than 550 highly specialized engineers and scientists from nearly all European countries and from overseas are going to meet over the next three days for an exceptional conference at the Council of Europe. Security guards routinely check the hand baggage at the entrance, a cool and impersonal climate welcomes the attendees. The atmosphere belongs to the place where European politics are handled, a place prepared for diplomatic round-table discussions rather than for the presentation of slides, transparencies and posters.

Four symposia on important aspects of materials research—high-tech ceramics, irradiation assisted processes, deep implantation and metastable alloys—were held simultaneously at the spring conference of the European Materials Research Society (E-MRS) from 31 May to 2 June 1988. "Ceramic materials research", organized by *R. Brook*, FRG, was devoted to problems of fabrication, characterization, and application of advanced ceramics and of what one could call "highly developed classical ceramics". The central topics were preparation and treatment of powders with small grain size and/or high purity (key words: "submicron powders", "zero-flaw processing"), molding processes, microstructural features caused by densification, and the resulting mechanical, thermal and electrical properties. Presentations on the mechanical testing of components, and on the statistical evaluation of flaw populations and their relevance to lifetime predictions, provoked intensive discussion; it becomes increasingly obvious that there is generally a tremendous lack of knowledge on the high-temperature behavior and on the fatigue properties of ceramics under cyclic loading. From a special session on superconductors one could form the view that the development of new compositions with higher T_c values is now stagnating, and as a result the presentations have less dramatic impact. Interest has consequently shifted to more pragmatic problems, e.g. to the preparation of well specified powders of the most promising compositions by sol-gel techniques and to the development of homogeneous microstructures with tailored grain boundaries.

The topic of the symposium on "Photon, Beam and Plasma Assisted Processing", chaired by *I. W. Boyd*, UK, and *E. F. Krimmel*, FRG, covered surface modifications of bulk materials, thin film techniques, and the preparation of high-purity powders. The compounds treated ranged from precursor materials for semiconductors and their dopants to multiply-alloyed steel. Many different deposition processes were described, and their applicability in, e.g., doping, ion beam mixing, epitaxy, recrystallization, decomposition and etching was discussed; there were also lectures on computer-assisted modeling of beam-surface interactions and characterization techniques.

Modification of semiconductors was also the most important point of interest in the session on "Deep Implant; Fundamentals and Application", directed by *G. G. Bentini*, Italy, *A. Golanski*, France, and *S. Kalbitzer*, FRG. Many lectures showed the high standard of computer simulation of ion beam interaction with matter, which can predict penetration and damage profiles in both lateral and transverse directions as a function of energy and dosage. Concerning applications, the topics were clearly governed by the interests of semiconductor research. For doping Si- or GaAs-based substrates, the trend in equipment is shifting

to large-scale MeV facilities with high current densities. Unfortunately, the topic of increasing the wear resistance of metals and ceramics by ion implantation was not addressed at all.

The symposium on "Preparation and Properties of Metastable Alloys", organized by *K. Samwer*, FRG, *M. von Allmen*, Switzerland, *J. Bottiger*, Denmark, and *B. Stritzker*, FRG, dealt with the thermodynamic aspects of metastability, the amorphization of crystals, the preparation and nucleation of undercooled liquids, the relaxation of amorphous matter, quasicrystals, ion beam modification, and the properties of metastable alloys. Although these topics seem to be rather exotic they are of high relevance not only for scientific insights but also for economic reasons; many industrial processes such as the preparation of superalloys, amorphous metals or thermodynamically impossible compounds will be able to employ such methods as powder atomization, tape casting or melt spinning to create new materials with potentially attractive properties if the basic problems of, e.g., nucleation and reaction kinetics, are understood.

Since all four symposia covered nearly every type of material from metals to ceramics, as well as all methods of preparation and characterization, all the sessions were equally attractive for the attendees. The meeting was therefore also an important opportunity to make contact with diverse groups of specialists in order to discuss new points of view and to consider unconventional strategies for solving particular problems. On the other hand, the mixing-up of related topics in four or even six parallel sessions does not permit a suitable choice of lectures without hurrying along the corridors searching out the particular room for the next session, a procedure which is even more difficult if the time schedules are not rigidly followed.

One of the advantages of this E-MRS conference was that many speakers could take part who do not normally have the opportunity to present their research in a genuinely international forum. Moreover, for many "junior scientists" Strasbourg was a very first opportunity for an international debut oral presentation before a highly expert audience; this was recognized by awards for the best presentations.

Amongst the many new competing, profit-oriented and routinely organized conferences on materials science, the merit of the annual E-MRS meeting is that it appears to be a forum specifically for European researchers—though, of course, also open to non-European attendees. The organizing committee should go on with its encouraging efforts by making further use of the charming atmosphere of the city of Strasbourg for the Fall meeting to be held on November 8–10, 1988.

Research News

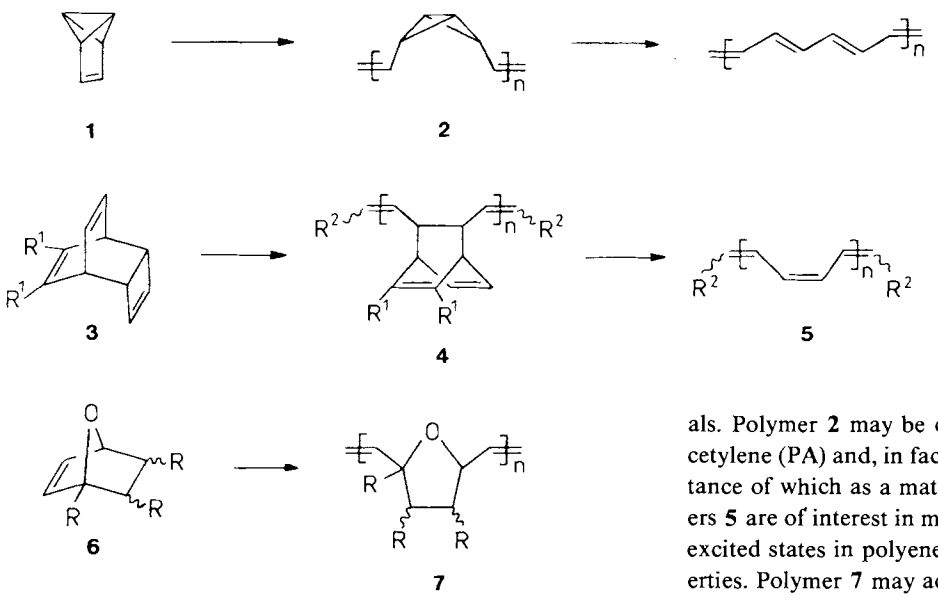
Ring Opening Metathesis Polymerization—Recent Developments

Ring opening metathesis polymerization (ROMP) originated in the late fifties and mid sixties when *Anderson*, *Dall'Asta* and *Natta* showed that strained cyclic olefins polymerize with breaking of the CC double bond in the presence of transition metal catalyst systems.[1] These observations initiated the growth of a whole area of research which is now known as ROMP, and led to the commercialization of new hydrocarbon polymers such as Vestenamer (Hüls), Norsorex (Chimie de France) and Metton (Hercules).

Research initially concentrated on the scope and mechanism of the polymerization. During this process a measure of control of microstructure and molecular weight was obtained. After several false starts[1] the consensus favoured a chain growth mechanism with an alternating metallo-carbene/metallacyclobutane as the chain carrying species. This hypothesis was fully confirmed by *Grubb*'s elegant work with titanacyclobutane initiators.[2] This work of *Grubbs* et al. also initiated an exciting new phase in this research area by establishing well-defined, living metathesis polymerization. *Osborn* et al.[3] and *Schrock* et al.[4] have also described such well defined initiators.

The catalyst acidity is critical in these polymerizations, both if monomers tend to undergo electrophilically induced rearrangements and if monomers contain nucleophilic heteroatoms which may coordinate to the metal center and lead to undesired side reactions or poisoning of the catalyst. Thus, these novel, fine-tuned initiators significantly widen the variety of monomers susceptible to ROMP. Some examples of the recent achievement in this area are briefly described.

The tungsten complex $[W(O\mathit{t}Bu)_2(2,6\text{-}\mathit{i}Pr_2C_6H_3N)(CH\mathit{t}Bu)]$ turned out to be specific enough to open the CC double bond of benzvalene **1**, while leaving the sensitive bicyclobutane moieties untouched.[5] The same complex opened



monomer **3** in a controlled manner to a set of oligomers **4**, which, after end capping and fragmentation reactions, were converted to separable polyenes **5**, with seven to fifteen double bonds.[6] Finally, a variety of substituted 7-oxanorbornenes **6** were shown to polymerize to high molecular weight compounds in the presence of $[W(OCH_2tBu)_2(CHtBu)Br_2]$, a similar tungsten catalyst. The importance of the nature of the catalyst was proven by subsequent addition of more electrophilic catalysts to polymer **7**, when complete cleavage of 1,4-epoxy units was observed.[7] These monomers may also be polymerized by ruthenium based initiators like "$RuCl_3 \cdot 3H_2O$" in the presence of water.[8]

The ROMP products **2**, **5** and **7** have entirely novel structures and are inaccessible by other methods. These polymers are not only interesting from the view-point of basic research but show remarkable properties as materials. Polymer **2** may be considered as precursor for polyacetylene (PA) and, in fact, was rearranged to PA the importance of which as a material is evident. Separated oligomers **5** are of interest in many respects, e.g. those concerning excited states in polyenes or their non-linear optical properties. Polymer **7** may act as an acyclic ionophore or as an ion permeable membrane. Thus, the new generation of ROMP catalysts has opened the way to a whole variety of novel polymers more of which might eventually gain industrial importance.

Book Reviews

Carbon Materials

Carbon—Electrochemical and Physicochemical Properties. By *K. Kinoshita*. Wiley, New York 1988. xiii, 533 pp., bound, £ 65.00.—ISBN 0-471-84802-6

Carbon materials have been used in electrochemistry for several decades, both in laboratory apparatus and in industrial plants. In many of the applications there is no competition whatever from other materials. The large potential range, wide variety of morphology, good corrosion resistance, high electrical and thermal conductivity and reasonable costs all contribute to carbon's benefit in electrochemical systems. Moreover, new types of materials such as pyrolytic graphite, glassy carbon and carbon fibers, have further extended the range of applications. However, many users today are not fully aware of the wide variety of carbons that can be produced by different manufacturing processes and—most importantly—neither do they know the individual physical and chemical properties of these forms. This lack of knowledge makes it difficult to

select the most appropriate form of carbon for any specific purpose. It seems that the main concern of the author *K. Kinoshita* is to bridge the gaps which exist in understanding the relevance of physicochemical properties to electrochemical specifications.

The book starts with a brief description of the manufacturing processes for carbon blacks, active carbons, graphite, glassy carbon and carbon fibers. Special emphasis is given to the commercial carbon blacks, i.e. channel blacks, oil-furnace blacks and thermal blacks.

The emphasis on carbon blacks continues in Chapter 2, which describes physical properties. Here the reader finds a thorough evaluation of the literature concerning crystallographic structure, surface area and porosity, morphology, heat treatment and electrical properties. The discussion in Chapter 3 focuses on the analysis of surface groups (chemical, spectroscopic and thermal analysis) and provides the basis for a better understanding of chemical reactivity, wettability and catalysis, the relevant properties for applications in electrochemistry. *K. Kinoshita* has succeeded in providing an excellent reference source on the physical, chemical and surface properties of carbons, most particularly carbon blacks. The description reflects the present state of knowledge, and will be of great use, not only to the electrochemist. It would have been desirable to use SI units consistently throughout the text. Data on the coefficient of thermal expansion, thermal conductivity and electrical resistivity in anisotropic graphite need to be corrected (pages 12 and 23).

Chapters 4 and 5 describe the chemical reactions as well as the characteristics and properties of carbon electrodes, thus helping the user to select specific carbon materials. In the section "nonporous structures" all the forms used in electrochemical studies are treated systematically, whereas in the section "porous structures" a distinction is made between flooded electrodes and gas-diffusion electrodes. Here again carbon black is shown to be a leading material and catalyst carrier, thus justifying the special emphasis accorded to it in the introductory chapters.

The author's approach of describing the electrochemical behavior of carbon separately (Chapter 6), rather than together with the individual applications proves to be advantageous. It allows the general aspects of electrochemical oxidation and electrocatalysis to be shown very clearly. The electrochemical reactivity of coal is also dealt with in Chapter 6.

After the efficient preparation in the preceding six chapters, the discussion devoted to the actual use of carbons in electrochemical systems is relatively short (Chapter 7, 80 pages). The reader may miss MnO_2 electrolysis as well as molten salt electrolysis yielding alkali metals and aluminum—the very applications that use by far the largest portion of carbon products. In addition, the application of carbon and graphite in chlor-alkali cells, including trials aimed at the introduction of an air-consuming cathode, appears to be treated too briefly. On the other hand the use of carbon in fuel cells, especially phosphoric acid fuel cells, and also in batteries is treated thoroughly. Within this section special attention is again devoted to carbon blacks. Reference is made to the extensive efforts undertaken to increase the life of carbon black electrodes by heat-treatment, and also by preventing the material from reaching critical potentials where corrosion occurs. It is made apparent to the reader that considerable efforts are still needed to clarify the dependence of electrochemical behavior on physical and chemical properties.

The patent literature is not considered in the text. Instead a list of recent patents concerning fuel cells, bipolar electrode separators and batteries dated after 1980 is given in the Appendix.

The motivation for writing this book arose at a workshop held in 1983 where experts from materials science and the electrochemistry of carbon came together. The author's intention has clearly been to provide a reference source for researchers and technologists interested in the electrochemistry and the electrochemical applications of carbon materials. This aim has been fully achieved. Skilful subject division, a thorough evaluation of the relevant literature and properly arranged tables all combine to make *Kinoshita*'s book an easily readable work of reference which can be highly recommended.

Graphite Fluorides. By *N. Watanabe, T. Nakajima* and *H. Touhara*. Elsevier, Amsterdam 1988. xi, 263 pp., bound, DFl 220.00.—ISBN 0-444-42885-2

The preparation and study of graphite fluorides goes back to the work of *O. Ruff, O. Bretschneider* and *F. Evert* (1934) and that of *W. Rüdorff* and *G. Rüdorff* (1947). The senior author of the book reviewed here, *N. Watanabe*, became interested in these graphite compounds while studying the "anode effect". It is undoubtedly this fact which has persuaded him to devote the first chapter of his book to the anode effect, which occurs at carbon anodes when they are used in molten fluoride electrolysis. *N. Watanabe* and his research group have worked continuously since 1961 on elucidating the chemistry of the graphite fluorides. He and his co-authors are ideally qualified to give a comprehensive account of the field.

Chapters 2 to 4 deal respectively with the preparation, the structure, and the surface properties and chemical properties of graphite fluorides. The experimental observations are described in detail with the help of numerous diagrams and tables. The interpretation of thermogravimetric data and of the X-ray, IR, NMR and X-ray photoelectron spectra is reported at considerable length, based mainly on the authors' own results. It has not been possible to avoid some repetition within the book; however this enhances its usefulness as a work of reference.

A considerable proportion of the book (about 100 pages) deals with technological applications. The outstanding properties of low surface energy, low bonding energy be-

tween the layers, and, most importantly, high electrochemical reactivity have contributed to the practical exploitation of graphite fluorides.

To bring lithium and fluorine together as reaction partners in an electrochemical primary battery is a worthwhile objective, because of the expected high cell e.m.f., but a fluorine partner in manageable form only became a possibility with the availability of $(C_xF)_n$ compounds. Using electrolytes in organic solvents it was found possible to attain a cell e.m.f. of 3.2 to 3.3 V. *Watanabe*'s laboratory carried out pioneering work on this development. The present state of knowledge on the electrode kinetics of graphite fluoride cathodes, and the effects of the crystallinity of the carbon, the method of preparation and the nature of the solvent in the cell are treated systematically in Chapter 5.

Chapter 6 describes how graphite fluorides are used to good effect in applying a fluoride film to aluminum. By using a graphite fluoride, or alternatively by simultaneous in-situ reaction of natural graphite and fluorine, films with large contact angles (125° for water) can be produced. In Chapter 7 the potential of $(CF)_n$ as a solid lubricant is evaluated by comparing it with graphite and MoS_2. It is noteworthy that metals and $(CF)_n$ can undergo co-deposition from certain electrolytic cells, e.g. from a Watts nickel cell, if surface active agents are added to force dispersion of the $(CF)_n$.

The final chapter summarizes the state of knowledge on C_xF, an intercalate of the acceptor type with ionically bound fluorine. The high cell e.m.f. observed for the combination of C_xF with lithium (3.9 to 4.2 V) is attributed to the release of active fluorine from the intercalate. However, at high current densities the increase of overpotential with current is steeper than for graphite fluorides.

The book does not make easy reading, due to the fact that it goes into considerable experimental detail. Nevertheless, it is indispensable for anyone whishing to gain a thorough knowledge of the preparation, properties and uses of graphite fluorides. For other readers it will be valuable as a work of reference, especially as it gives a full and up-to-date coverage of the literature.

Ferdinand von Sturm
Sigri GmbH, Meitingen (FRG)

Polymer Characterization

Polymer Microscopy. By *L. C. Sawyer* and *D. T. Grubb*. Chapman and Hall, London 1987. XIII, 303 pp., bound, £ 55.00.—ISBN 0-412-25710-6

The book "Polymer Microscopy" at least partially closes the gap between the large number of textbooks on electron and optical microscopy on the one hand and the problem oriented books about polymer morphology on the other. In general, a student of polymer science has a research problem which calls for the use of a variety of methods. It was always difficult to give him textbooks which would familiarize him with the possibilities and limits of microscopy applied to polymers, and would review what has already been done in his field of interest.

"Polymer microscopy" is not a textbook which enables the novice to avoid further reading of other books and review articles, but he (or she) will find out from the detailed reference list where additional information on a particular topic is available. An attempt has here been made to treat optical microscopy and scanning and transmission electron microscopy in one text. The result, however, is unbalanced to some extent. Whereas the treatment of electron microscopy takes most of the space, the field of optical microscopy on polymers is not sufficiently covered, even for a first introduction.

The main chapters which make the text worth reading in full, and which can also be used as a reference source, are those entitled "Specimen preparation methods" and "Polymer applications". The preparation chapter encompasses all the important stages that a sample can undergo on its way from the original state to the final specimen suitable for introducing into the microscope. Common sources of artefacts are also discussed, and some illustrations of them are reproduced. The applications chapter has to be seen in the light of a note in the authors' preface as follows: "Most of the applications come from work done by *Linda Sawyer* as a member of Celanese Research Company staff, and thus they come from the products and projects of interest to that company". Nevertheless, one does not get the impression that the idea for writing the book arose when someone had to tidy up the filling drawers in his office. The chapters are well organized, the index is very detailed, and a large number of references is listed up to 1984/85. But the statement that the text reflects the authors' experience and interests should certainly not be taken as detracting from the merit of having collected this material together.

A reader from an academic environment who has sometimes quite different problems regrets the omission of some guidance in the use of electron diffraction and dark field techniques for the investigation of polymers. These methods are very powerful when applied to semicrystalline samples to elucidate structural details or textures. The principles of these methods are explained and a few patterns are shown, but an unexperienced operator of an electron microscope who has read this text will not be able to use the instrument with the correct settings which are necessary for examining polymer specimens. And it is just this knowledge which one does not find in general textbooks on electron microscopy.

In the appendix a list of abbreviations for polymer names is given, but it does not help the reader to use the text as a reference book. For example, it is cumbersome to find out where abbreviations like LCP or NTP are introduced in the text.

The reproduction of photographs is of a high standard; some optical micrographs are even reproduced in color. The spelling of names, however, is incorrect in some cases. Obviously scientific publishing houses are not always able to reproduce special letters of foreign languages (e.g. as in Köhler, Poincaré, Michael-Lévy or the term Moiré pattern). This is irritating for a European reader. In spite of these remarks one can recommend the text to graduate students of polymer science as an introduction to the field, and to scientists as a reference book.

Mainz (FRG)

Classical Light Scattering from Polymer Solutions. By *P. Kratochvíl*. Elsevier, Amsterdam 1987. xii, 334 pp., bound, Dfl 240.00.—ISBN 0-444-42890-9

The author deals exclusively with classical light scattering by polymer solutions, in 321 pages of text. The book treats the subject at a very elementary level, and it is presumably intended as an introductory text for students. The theoretical background of classical light scattering is treated in a way which verges on the superficial, whereas the applications and experimental details are dealt with very thoroughly. The book begins with an introduction to the physical principles of light scattering. In this it already becomes apparent that *Kratochvíl*, in his concern to present the subject in the simplest possible way, is prepared to forego a proper understanding of the physics; for example, the scattering vector is not introduced as such, but is instead referred to as "parameters for describing the angular dependence of the scattered light".

The second chapter deals in minute detail with methods of measurement and sample preparation. Here the reader benefits from the author's long experience in dealing with the everyday problems which arise in light scattering. There are also detailed descriptions of the main types of light scattering photometers, most of which are nowadays only of historical interest and are no longer marketed commercially. The currently used differential refractometers are also discussed. Surprisingly, however, *Kratochvíl* makes no mention of the existence of the modern laser light scattering photometers which have now been available for about five to eight years.

The third chapter deals with "basic light scattering techniques", such as fixed angle scattering, the dissymmetry method, and the well known Zimm method for analysis of light scattering. The only one of these which is still important nowadays is the Zimm method, which is discussed at some length; the other two methods have long since been consigned to history.

The next two chapters deal with light scattering by polymers in mixed solvents and scattering by copolymers, both of which are complex and many-faceted topics. The treatment in the book is limited to a qualitative description of the physical phenomena, but presents all necessary equations.

The book concludes by discussing the importance of light scattering for polymer characterization. It is first considered in relation to other methods such as viscometry and gel permeation chromatography, followed by a discussion of the characterization of branched structures and polyelectrolytes. The final chapter is very informative and useful since some light scattering curves for industrially important polymers such as PVC, polyethylene and polyamides are presented and discussed. The reader is (quite correctly) given the impression that the light scattering measurements as opposed to sample preparation are a relatively minor part of the work; aggregation or crystallization of the samples are usually found to interfere with their molecular characterization, and need to be minimized by choosing the most suitable experimental conditions (temperature and choice of solvent).

Considerable sections of the book are long-winded and tedious to read. The book could have been significantly reduced in length by stating the ideas more precisely and without the (superfluous) digressions into the history of light scattering. Despite this, the book will be useful for anyone wishing to begin work on classical light scattering, since no other comparable work exists.

Last-minute information

More Funds for German Materials Science

In collaboration with the Fonds der Chemischen Industrie, the Federal Minister for Research and Technology (BMFT) has initiated a new support program in materials science. In the next two years selected leading research groups and talented young scientists will be awarded grants-in-aid totalling some five million marks, two million marks of which will come from the BMFT, for research in materials science.

The support program will primarily concentrate on computer simulation in materials science. In the important fields organic polymers, inorganic solids and high-performance ceramics a purposefully planned support for instruments and facilities (hardware) for six specially selected research groups (see Table 1) who already have considerable experience in these fields will hopefully contribute to a prompt and effective employment of computer simulation in materials research. This should remedy a deficiency in German basic research that has occurred because of the exceptionally rapid development in this field.

Table 1. Computer simulation in materials science: research groups already funded.

group leader	location	research topic
Hk. Müller-Buschbaum	Univ. of Kiel, Inst. of Inorg. Chem.	CAMD in solid state inorganic chemistry
R. Gruehn	Univ. of Giessen, Inst. of Inorg. and Analyt. Chem.	high resolution electron microscopy with simultaneous 2D/3D reconstructions
W. Spiess	Mainz, Max Planck Inst. for Polymer Science	polymer simulation and 2D NMR spectroscopy
D. Haarer	Univ. of Bayreuth, Physics Department	dynamic processes in polymer systems: charge carriers, color centers, micelles
J. H. Wendorff	Darmstadt, Deutsches Kunststoff-Inst.	polymer liquid crystals
G. Petzow	Stuttgart, Max Planck Inst. for Metals Research	CAD of ceramic engineering materials

The funds of this support program will also be used for providing fellowships for qualified young scientists and grants for equipment to leading scientists in the fields of macromolecular chemistry, inorganic chemistry, physical chemistry and industrial chemistry. The ear-marking of part of the funds for financing subscriptions to specialized literature, participation at scientific conferences and the compilation of information addressed to scientists engaged in materials research should lead to an improved transfer of know-how among the individual researchers. The allocation of funds will be undertaken by independent advisory committees in the individual disciplines. Each of the committees will consist of academic and industrial scientists who will assess the allocation of funds exclusively according to scientific expertise.

Further information is available on request from the Fonds der Chemischen Industrie, Karlstraße 21, D-6000 Frankfurt/Main 1, Tel. 069/2556482.

Electron Transfer and Charge Transfer: Twin Themes in Unifying the Mechanisms of Organic and Organometallic Reactions

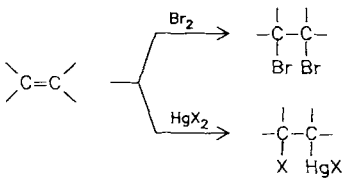
By Jay K. Kochi*

The broad varieties of organic and organometallic reactions merge into a common unifying mechanism by considering all nucleophiles and electrophiles as electron donors (D) and electron acceptors (A), respectively. Comparison of outer-sphere and inner-sphere electron transfers with the aid of Marcus theory provides the thermochemical basis for the generalized free energy relationship for electron transfer (FERET) in Equation (37) and its corollaries in Equations (43) and (44) that have wide predictive applicability to electrophilic aromatic substitutions, olefin additions, organometallic cleavages, etc. The FERET is based on the conversion of the weak nucleophile–electrophile interactions extant in the ubiquitous electron donor–acceptor (EDA) precursor complex [D,A] to the radical ion pair [$D^{\oplus}$, $A^{\ominus}$], for which the free energy change can be evaluated from the charge-transfer absorption spectra according to Mulliken theory. FERET analysis thus indicates that the charge-transfer ion pairs [$D^{\oplus}$, $A^{\ominus}$] are energetically equivalent to the transition states for nucleophile/electrophile transformations. The behavior of such ion pairs can be directly observed immediately following the irradiation of the charge-transfer bands of various EDA complexes with a 25-ps laser pulse. Such studies confirm the radical ion pair [$Arene^{\oplus}$, NO_2] as a viable intermediate in electrophilic aromatic nitration, as presented in the electron-transfer mechanism between arenes and the nitryl cation ($NO_2^{\oplus}$) electrophile.

1. Introduction

Despite the explosive developments in sophisticated methodologies for the syntheses, analyses, and structure elucidations of organic and organometallic compounds over the last forty years, the corresponding increase in our understanding of the dynamics of chemical reactions in solution is woefully lacking.[1] Indeed, the oft-repeated quip that "a reaction mechanism can never be proved—only proved wrong" characterizes the critical void in this important branch of chemistry. Thus the rates of chemical reactions cannot be predicted from the properties of the reactants and of the solvent. Heretofore, the limited means to correlate reaction rates have derived from empirical methods such as those based on the Hammett $\sigma\rho$, Brønsted $\alpha\beta$, and Dimroth-Reichardt E_T values, and then only under certain constrained circumstances. The problem is understandable if one considers the myriad reactions and reaction types that are possible with the wide variety of structures presently extant with organic and organometallic connotations. For example, let us examine a short list of such basic transformations as follows:

Olefin Addition:



(1)

(2)

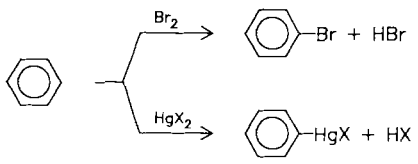
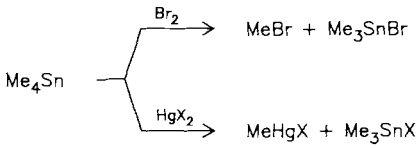
Aromatic Substitution:



(3)

(4)

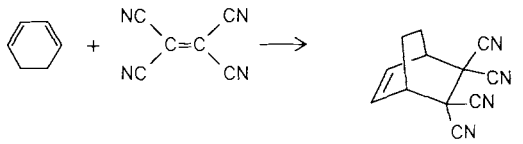
Alkylmetal Cleavage:



(5)

(6)

[4+2] Cycloaddition:

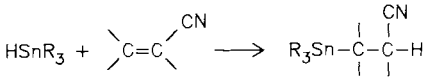


(7)

Carbonyl Addition:

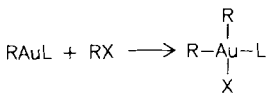
(8)

Stannane Reduction:



(9)

Oxidative Addition:



(10)

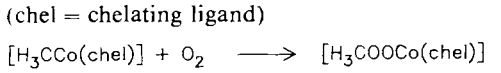
Insertion:

(11)

Carbonylation:

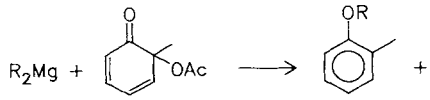
(12)

Autoxidation:
(chel = chelating ligand)



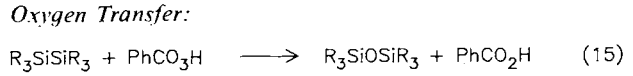
(13)

Alkylation:



(14)

Oxygen Transfer:



(15)

Are these reactions all unrelated? Or is there a common mechanistic thread that connects one set of reactants to another? For example, the treatment of alkenes, arenes, and alkylmetals with bromine [Eqs. (1), (3), and (5)] has been generally characterized as an electrophilic process. However, that is not generally considered to be the case in the Diels–Alder [4+2] cycloaddition [Eq. (7)], in the oxidative addition of an alkyl halide [Eq. (10)], or in the autoxidation of methylcobalamin [Eq. (13)]. How does one consider an insertion of sulfur dioxide into an alkyl–iron bond in Eq. (11), or, for that matter, the incorporation of an oxygen atom into a disilane [Eq. (15)]? Why does mercury(II) diacetate add readily to alkenes [oxymercuration, Eq. (2)], whereas under the same conditions the analogous dimethylmercury is unreactive.

A more detailed consideration of reactions (1)–(15) reveals that each pair of reactants consists of a relatively electron-rich component and an electron-poor one. Thus bromine, metal halides, tetracyanoethylene, nitric acid, carbonium ions, acrylonitrile, ketones, sulfur dioxide, alkyl halides, dioxygen, peroxy acids, etc. are all electron-poor acceptors by virtue of their relative ease of reduction and high electron affinities.[2] Conversely, alkenes, arenes, Grignard reagents, alkylmetals, dienes, stannanes, carbonylferrates, etc. are all electron-rich donors with relatively low ionization potentials.[3] On this basis mercury(II) diacetate is an electron acceptor, whereas dimethylmercury is an electron donor.[4] Indeed, the designation of various reactants as electron acceptors and electron donors can be carried over into a more traditional context by their description as electrophiles and nucleophiles, respectively.[5] As widespread as the latter notion is, however, this classification is qualitative and carries with it no mechanistic insight—certainly none of any quantitative predictive power.[6,7] Clearly a different approach is required.

Let us therefore consider the alternative classification of electron acceptors (A) and donors (D) as oxidants and reductants, respectively, since electron transfer as an oxidation–reduction process represents one of the simplest chemical transformations. Furthermore, the concept is well-established in inorganic chemistry in which two principal pathways for electron transfer have been identified.[8,9] In the *outer-sphere mechanism*, the coordination spheres [as pictorially represented by circles in Eqs. (16) and (17)] remain more or less intact as the donor–acceptor pair passes through the transition state [Eq. (16)]. As a result, the Marcus model for the outer-sphere transition state successfully provides the theoretical guide for the prediction of these electron-transfer rates.[10,11] By contrast, the interpenetration of the coordination spheres of the donor–acceptor pair in the *inner-sphere mechanism* presents the more compact transition state [Eq. (17)]. The shaded area

(16)

(17)

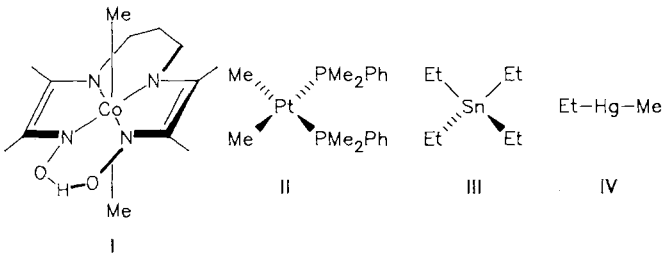
emphasizes the possibility of structural distortions, ligand bridging, etc., as additional contributions that are largely irrelevant in the simpler outer-sphere pathway. As a result, there is no general theoretical model of electron transfer for the more constrained inner-sphere pathway. This represents a serious deficiency since the vast majority of oxidation-reduction processes proceed via inner-sphere mechanisms.

2. Outer-Sphere and Inner-Sphere Mechanisms for Electron Transfer

Historically, the theories of electron transfer in chemical reactions have been developed largely from two quite separate and independent approaches. In the first approach, the evolution from inorganic chemistry of oxidation-reduction processes pertaining to transition-metal complexes has led to the Marcus theory,[10] as well as the intervalence transfer theory of *Hush*.[12] The other approach, tracing back to the charge-transfer theory of *Mulliken*, stems from organic substrates and deals mainly with electronic transitions.[13] *Mulliken*'s theory employs the intermolecular distance between donor and acceptor as the only nuclear parameter, and does not explicitly mention the changes in molecular structure attendant upon charge transfer. The Marcus approach, however, does not readily lend itself to the inclusion of the Franck-Condon factors for the donor and the acceptor. Experimentally, these two theoretical treatments have heretofore remained separate—the Marcus-Hush theory for inorganic redox and electrochemical systems and the Mulliken theory for organic acceptors—because they have lacked a common basis for comparative examination. Therefore, let us employ organometallic compounds, both as reducing agents and as electron donors, to provide such a common basis for comparing electron-transfer and charge-transfer interactions within a framework of steric effects.

2.1. Organometals as Electron Donors. Delineation of Polar and Steric Effects

We consider the four structurally diverse classes of organometals **I**–**IV** as electron donors, in which the configuration and coordination about the metal centers vary systematically from octahedral, square planar, and tetrahedral



to linear, respectively. These organometal donors are especially desirable for kinetic studies since they are all sufficiently *substitution stable* in solution to allow meaningful measurements to be made. Moreover, for these neutral donors, the work term of the reactants, w_r (consisting mainly of the electrostatic energy required to bring the reactants together), is considered to be unimportant. An additional benefit derived from the use of organometal donors lies in the transient character of many of the oxidized organometal cations. As a result, the back electron transfer is minimal, and the electron-transfer process is overall *irreversible* in these systems. Since they are relatively volatile and electron-rich compounds, the photoelectron spectra of the alkylmetals **III** and **IV** are readily accessible, and the vertical ionization potentials I_D can be accurately measured. For example, the photoelectron spectra in Figure 1 illus-

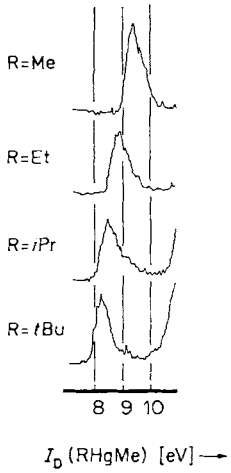


Fig. 1. He(I) photoelectron spectra of the lowest-energy bands of Me_2Hg, EtHgMe, *i*PrHgMe, and *t*BuHgMe.

trate how the lowest-energy band of a homologous series of dialkylmercurials undergoes large, systematic variations merely by branching at the α-carbon of the alkyl ligand.[14] In these alkylmetals of the main-group elements, ionization occurs from the highest occupied molecular orbital (HOMO), which has σ-bonding character; i.e., they are σ donors. Consequently, alkyl ligands exert a large dominating influence on the *ionization potentials* and the *steric properties* of alkylmetals. Both trends are illustrated in Figure 2 for the α-branched ligands (methyl, ethyl, isopropyl, and *tert*-butyl, Fig. 2a) as well as the β-branched ligands (ethyl, *n*-propyl, isobutyl, and neopentyl, Fig. 2b). Note that the steric and polar effects generally increase together in the α-branched alkyl ligands, whereas variations in the steric effect dominate in the β-branched alkyl ligands.

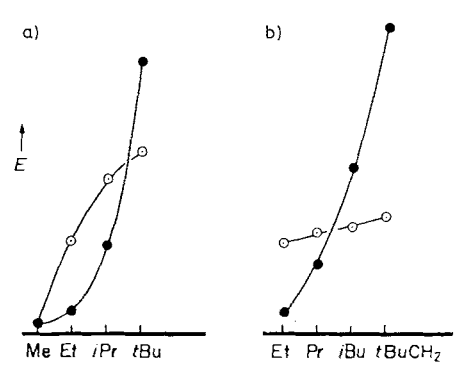

Fig. 2. Steric (●) and polar (⊙) effects of alkyl ligands with α-branching (a) and β-branching (b). Energy, *E*, in arbitrary units.

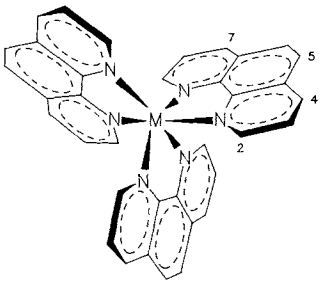
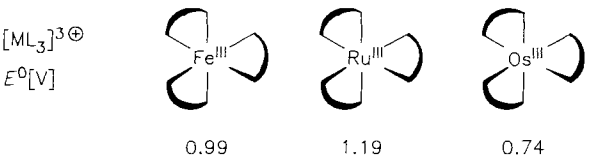
2.2. Outer-Sphere Electron Transfer from Organometal Donors

The minimal interpenetration of the coordination spheres of the reactants is inherent in any mechanistic formulation of the outer-sphere process for electron transfer [cf. Eq. (16)]. As such, steric effects provide a basic experimental criterion to establish this mechanism. Therefore, we employ the series of structurally related donors possessing the finely graded steric and polar properties described in Section 2.1 for the study of both homogeneous and heterogeneous processes for electron transfer.

2.2.1. Homogeneous Processes with Metal Oxidants

The rates of electron transfer for oxidation of the organometal donors **I**–**IV** (hereafter designated generically as RM) by a series of complexes $[ML_3]^{3\oplus}$, with $M = Fe^{III}$, Ru^{III}, Os^{III}, and L = phenanthroline or substituted phenanthroline (Scheme 1), is considered initially, since they have been previously established as outer-sphere oxidants.[15]





Scheme 1. Tris(phenanthroline) complexes as outer-sphere oxidants.

The iron(III) complexes $[FeL_3]^{3\oplus}$ cleave a variety of organometals in acetonitrile according to Equations (18) and (19).[16] The activation process for oxidative cleavage is represented by the electron-transfer step in Equation (18).

$$RM + [FeL_3]^{3\oplus} \xrightarrow{k_{Fe}} RM^{\oplus} + [FeL_3]^{2\oplus} \quad (18)$$

$$RM^{\oplus} \xrightarrow{fast} R^{\odot} + M^{\oplus} \longrightarrow \longrightarrow \cdots \quad (19)$$

The organometal cation $RM^{\oplus}$ is a transitory intermediate which subsequently undergoes a rapid fragmentation [Eq. (19)], rendering the electron transfer irreversible. For a particular iron(III) oxidant, the logarithm of the rate constant k_{Fe} for electron transfer is linearly correlated with the ionization potential I_D of the various alkylmetal donors (Fig. 3).[17] Similarly, for a particular alkylmetal donor, $\lg k_{Fe}$ for electron transfer varies linearly with the standard reduction potentials E^0 of the series of iron(III) complexes $[FeL_3]^{3\oplus}$, with L = substituted phenanthroline. In order to account for the foregoing kinetic behavior, we rely on the Marcus theory for outer-sphere electron transfer to provide the quantitative basis for establishing a free energy relationship, the Marcus equation (20),[10] where

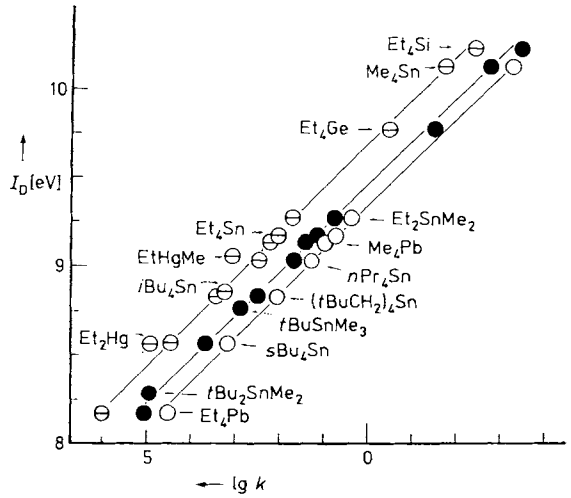


Fig. 3. Correlation of the ionization potentials of alkylmetal donors with the electron-transfer rate constant ($\lg k_{Fe}$) for $[Fe(phen)_3]^{3\oplus}$ (●), $[Fe(bpy)_3]^{3\oplus}$ (○), $[Fe(Cl\text{-}phen)_3]^{3\oplus}$ (⊖). phen = phenanthroline; bpy = bipyridine; Cl-phen = 5-chlorophenanthroline.

$$\Delta G^{\ddagger} = w_r + \Delta G_0^{\ddagger}\left[1 + \frac{\Delta G}{4\Delta G_0^{\ddagger}}\right]^2 \quad (20)$$

$\Delta G = \Delta G^0 + w_p - w_r$ and ΔG^0 is the standard free energy change accompanying electron transfer. The intrinsic barrier $\Delta G_0^{\ddagger}$ represents the activation free energy for electron transfer at $\Delta G = 0$, and w_p is the work required to separate the products. For neutral reactants such as organometals, the work term of the reactants, w_r, is considered to be nil, and the rate constants are converted to the activation free energies by $\Delta G^{\ddagger} = -RT\ln(k/Z)$, where the collision frequency Z is taken to be $3 \times 10^{10}\ M^{-1}\ s^{-1}$. In order to apply the Marcus equation to electron transfer from neutral organometals RM to the series of $[FeL_3]^{3\oplus}$ oxidants, Equation (20) can be rewritten in an alternative form [Eq. (21)],

$$\sqrt{\Delta G^{\ddagger}} = \left[\sqrt{\Delta G_0^{\ddagger}} + \frac{F}{4\sqrt{\Delta G_0^{\ddagger}}}\left(E^0_{RM} + \frac{w_p}{F}\right)\right] - \frac{F}{4\sqrt{\Delta G_0^{\ddagger}}}E^0_{Fe} \quad (21)$$

since $\Delta G^0 = F(E^0_{RM} - E^0_{Fe})$ and $w_r = 0$. E^0_{RM} and E^0_{Fe} are the standard electrode potentials of the alkylmetal and $[FeL_3]^{3\oplus}$, respectively, and F is the Faraday constant. The experimental correlation between $\sqrt{\Delta G^{\ddagger}}$ and E^0_{Fe} is linear for the various alkylmetals (Fig. 4a), and the slopes of the correlations represent $-F/(4\sqrt{\Delta G_0^{\ddagger}})$. It is important to note that the most sterically hindered alkylmetal examined, namely, tetra(neopentyl)tin, is precisely included with the other alkylmetals in the correlations shown in both Figures 3 and 4a. In other words, *alkylmetals are not distinguished from each other on the basis of their steric properties when they undergo oxidation with* $[FeL_3]^{3\oplus}$—the electron-

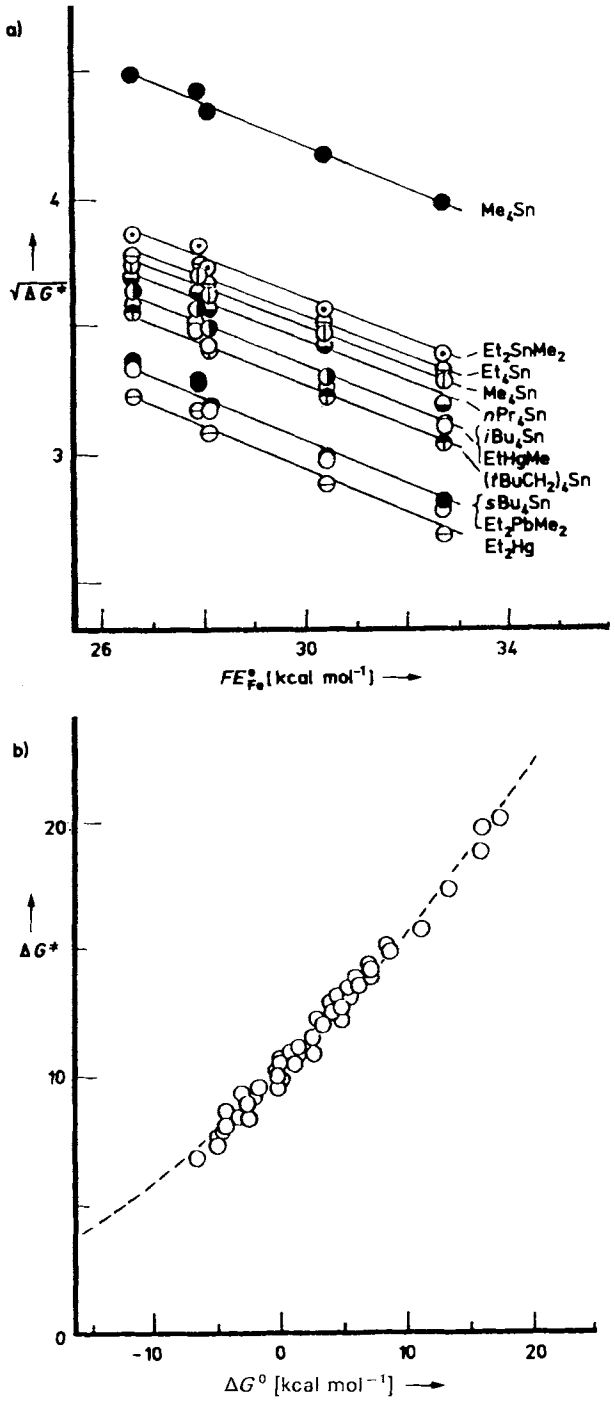

Fig. 4. Relationship of the activation free energy for electron transfer ($\Delta G^{\neq}$ [kcal mol^{-1}]) with (a) the electrode potentials of various $[FeL_3]^{3\oplus}$ according to Equation (21) and (b) the driving force according to the Marcus equation (20) (calculated for $\Delta G_0^{\neq} = 10$ kcal mol^{-1}).

donor property of the alkylmetal being the dominant factor. Such a conclusion accords with an outer-sphere mechanism for electron transfer [Eq. (18)]. The activation free energies $\Delta G^{\neq}$ obtained from the kinetics data are plotted against the driving force in Figure 4b.[17] The dashed line represents $\Delta G^{\neq}$ calculated from the Marcus equation (20) using the single value of $\Delta G_0^{\neq} = 10$ kcal mol^{-1}. Thus electron transfer from alkylmetals to $[FeL_3]^{3\oplus}$ accords well with the Marcus theory. *The absence of notable steric effects in this outer-sphere process* must be emphasized.

2.2.2. *Heterogeneous Processes at a Platinum Electrode*

The series of organometals **I**–**IV** are also readily oxidized electrochemically.[18] Thus we apply the same steric probe to the corresponding anodic process for which the analogous mechanism for electron transfer at a heterogeneous electrode [E] is represented by the electrochemical (EC) sequence shown in Equations (22) and (19).

$$RM \xrightarrow{[E]} RM^{\oplus} + e^{\ominus} \tag{22}$$

The rates of heterogeneous electron transfer in Equation (22) can be measured by two independent electrochemical methods: cyclic voltammetry (CV) and convolutive potential sweep voltammetry (CPSV). For a totally irreversible electrochemical process, the rate constant k_e for heterogeneous electron transfer at the CV peak potential E_p is given by Equation (23), where n is the number of electrons trans-

$$k_e(E_p) = 2.18[D\beta n F v/RT]^{1/2} \tag{23}$$

ferred in the rate-limiting step, v is the scan rate, β is the transfer coefficient, and the other terms have their usual significance. Equation (23) is derived from Fick's laws of diffusion together with the usual expression for the linear potential dependence of the rate constant k_e for heterogeneous electron transfer [Eq. (24)], where E^0 is the standard

$$k_e(E) = k_s \exp[(\beta n F/RT)(E - E^0)] \tag{24}$$

potential for the organometal which fixes the value of k_s. (Alternatively stated, k_s is the intrinsic rate constant for electron transfer at the equilibrium potential, i.e., $E = E^0$. It is thus related to the intrinsic barrier $\Delta G_0^{\neq}$ in Marcus theory.) The shift in the current maximum with the sweep rate accords with standard electrochemical theory,[19] and may be used with the aid of Equation (23) to determine the rate constant k_e for heterogeneous electron transfer at different values of the applied potential (driving force). The results of this analysis are shown in Figure 5 for the representative organometals **I**–**IV**.[20] The linear plots in Figure 5 correspond to the free energy relationship in Equation (24), since $\ln k_e(E) = \Delta G_e^{\neq}/RT$.

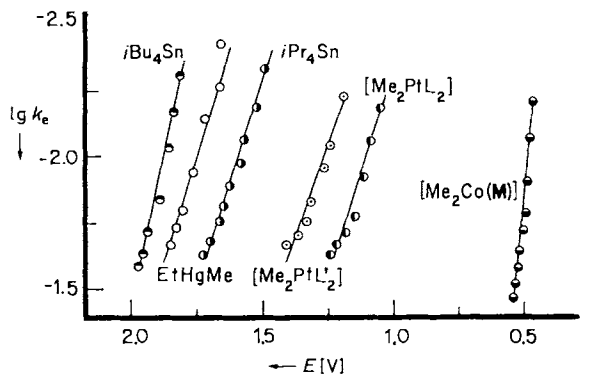

Fig. 5. Variation of the heterogeneous rate constant k_e [cm s^{-1}] with the applied potential (measured versus NaCl-SCE) for some representative organometals. **M** = macrocyclic ligand, L = PMe_2Ph; L' = $PMe_2(C_6H_4CF_3$-*p*).

2.2.3. *Comparison of Homogeneous and Heterogeneous Electron Transfers*

Let us compare the values of the rate constants k_e for the heterogeneous anodic oxidation of organometals with the rate constants k_{Fe} for the homogeneous chemical oxidation of the same organometals with $[FeL_3]^{3\oplus}$. The direct comparison of the electrochemical and chemical oxidations of organometals requires that they be evaluated at the same thermodynamic driving force; i.e., the applied electrode potential must be reasonably similar to the standard reduction potential E^0 of $[FeL_3]^{3\oplus}$. The correlation of the homogeneous and heterogeneous electron transfer, when both processes are measured under conditions of equivalent thermodynamic driving force, is presented in Figure 6.[20]

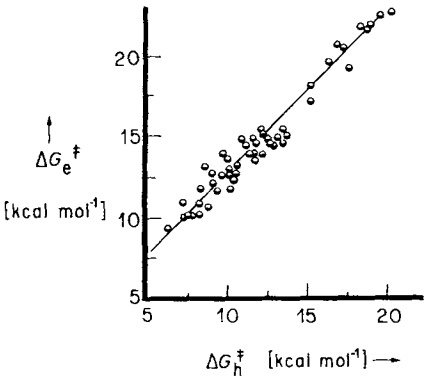

Fig. 6. Correlation of the homogeneous activation free energy $\Delta G_h^{\ddagger}$ for iron(III) oxidations and the heterogeneous activation free energy $\Delta G_e^{\ddagger}$ using the Marcus equation (20). The slope is 1.01 ± 0.03. The organometals include: $[Me_2Co(DpnH)]$, $[Me_2Co(tim)]^{\oplus}$, $[MeCo(DpnH)]^{\oplus}$, $[EtCo(DpnH)]^{\oplus}$, $[Me_2Pt(PMe_2Ph)_2]$, $[Me_2Pt\{PMe_2(C_6H_4CF_3)_2\}]$, Me_4Sn, Et_4Sn, iPr_4Sn, nBu_4Sn, iBu_4Sn, $(tBuCH_2)_4Sn$, Et_4Pb, EtHgMe, where DpnH = 2,3,9,10-tetramethyl-1,4,8,11-tetraazaundeca-1,3,8,10-tetraen-11-ol-1-olate and tim = 2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,3,8,10-tetraene.

An important feature in Figure 6 is the striking absence of steric effects arising from the organometal. Thus Figure 6 establishes the essential *unity of outer-sphere mechanisms in homogeneous and heterogeneous electron transfer from organometal donors*. Furthermore, these studies emphasize the excellent behavior of *alkylmetals as prototypical donors* for the study of electron-transfer processes, particularly with regard to their easily modulated steric and polar properties.[21] Before we exploit the latter, the structural changes that accompany electron transfer from alkylmetal donors need some consideration.

2.2.4. *Structural Significance of the Intrinsic Barrier for Organometal Donors*

In Marcus theory for outer-sphere electron transfer, the intrinsic barrier represents the activation energy for electron transfer when the driving force is zero, i.e., $\Delta G^{\ddagger} = \Delta G_0^{\ddagger}$ at $\Delta G = 0$ or at the equilibrium potential E^0 [see Eq. (20), where the reorganization energy $\lambda = 4\Delta G_0^{\ddagger}$]. Some typical values of the intrinsic barriers for the organometals **I**–**IV** are listed in Table 1.[20] It is noteworthy that $\Delta G_0^{\ddagger}$ for the octahedral macrocyclic derivative $[Me_2Co(\mathbf{M})]$ **I** is significantly less than those for either the

Table 1. Effect of organometal structure on the transfer coefficient and the intrinsic barrier.

Organometal	$\Delta G^{\ddagger}$ [kcal mol^{-1}]	β [a]	$\Delta G_0^{\ddagger}$ [kcal mol^{-1}]	$\beta^2 \Delta G_0^{\ddagger}$ [kcal mol^{-1}]
$[Me_2Co(DpnH)]$ **I** [b]	7.46	0.73	2.1 [c]	1.1
sBu_4Sn **III'**	7.65	0.31	10.0	1.0
Et_4Pb **III''**	7.68	0.28	10.0	0.8
$[Me_2Pt(PMe_2Ph)_2]$ **II**	7.69	0.27	13.0	0.9
EtHgMe **IV**	7.70	0.20	22.0	0.9

[a] Measured by cyclic voltammetry at 100 mV s^{-1} [20]. [b] DpnH in legend to Figure 6. [c] When the effect of reversibility is taken into account, the value is 6.3 kcal mol^{-1} for rate-limiting electron transfer.

tetrahedral tetraalkyltin and -lead compounds **III'** and **III''**, respectively, or the square-planar dimethylplatinum(II) complex **II**. Moreover, the linear dialkylmercurials **IV** possess the highest values of the intrinsic barrier. We believe that such large differences in $\Delta G_0^{\ddagger}$ arise largely from structural changes that can occur upon the oxidation of the organometal donor. For example, the ESR spectra of $Me_4Pb^{\oplus}$ and $Me_4Sn^{\oplus}$ in Figure 7 are characterized by

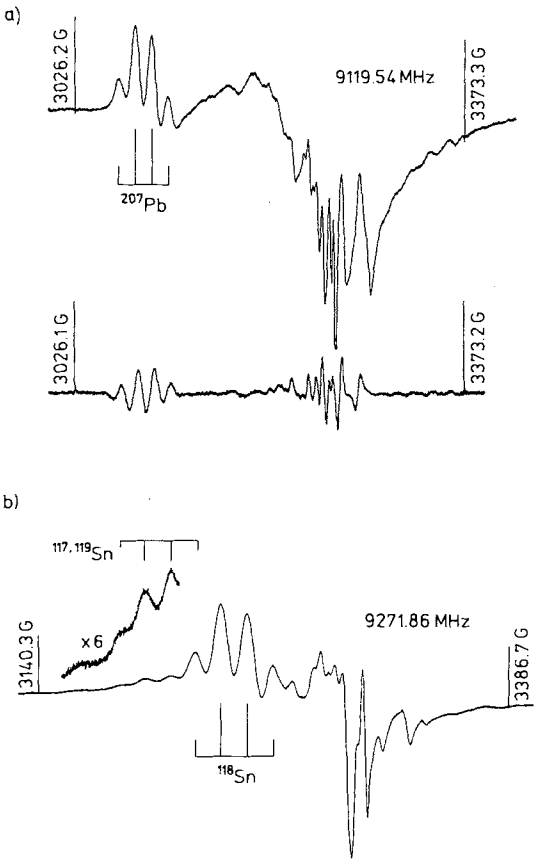

Fig. 7. a) X-band ESR spectrum of a γ-irradiated solution of 3 mol% tetramethyllead in trichlorofluoromethane at 85 K shown in first derivative (upper) and second derivative (lower). b) First-derivative ESR spectrum derived from tetramethyltin under similar conditions.

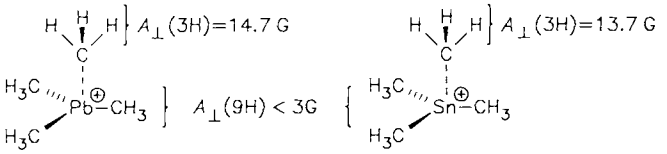
well-resolved (1:3:3:1) quartet splittings of 14.7 and 13.7 G, respectively, arising from *one unique methyl ligand*.[22] It is noteworthy that the proton hyperfine splittings from the three remaining methyl ligands are less than the spectral resolution of 2–3 G. Furthermore, in the tin

analogue, the perpendicular component of the hyperfine coupling to the naturally abundant magnetic isotopes ^{117}Sn and ^{119}Sn, with $I = 1/2$, is clearly delineated in the inset recorded at higher gain in Figure 7b. The remarkably small splitting of only 77 G is consistent with a small degree of s character in the singly occupied molecular orbital (SOMO) and indicative of a planar or near-planar metal center. Taken together, these ESR results suggest that the organometal undergoes a dramatic change in *configuration from T_d to C_{3v} symmetry attendant upon oxidation.* Judging from the similarity of the ^1H splitting and the expected larger positive g shift for the perpendicular components of $Me_4Pb^{\oplus}$, we surmise that a similar structural reorganization occurs in Me_4Pb. Accordingly, both cations are envisaged as approximating the trigonal-pyramidal structures in which the SOMO is largely localized in the dashed vertical metal-carbon bond (Scheme 2).



Scheme 2. Structures of $Me_4Pn^{\oplus}$ and $Me_4Sn^{\oplus}$ derived from their ESR spectra.

Although we were unable to obtain the ESR spectrum of the dimethylmercury cation, we infer by an extended reasoning (see Table 1) that this linear donor undergoes the largest structural change to a bent cation.

2.3. Inner-Sphere Electron Transfer from Organometal Donors

The series of organometal donors **I**–**IV** are also readily oxidized by the one-equivalent oxidant hexachloroiridate(IV) as well as by the organic acceptor tetracyanoethylene (TCNE).[17] In both cases, the rate-limiting step involves electron transfer [Eqs. (25) and (26)]. The stoichiom-

$$[IrCl_6]^{2\ominus} + RM \longrightarrow [IrCl_6]^{3\ominus} + RM^{\oplus} \quad (25)$$

$$TCNE + RM \longrightarrow TCNE^{\ominus} + RM^{\oplus} \quad (26)$$

etry of these reactions is essentially the same as that described for the trisphenanthroline-metal(III) oxidants in Equation (18).

2.3.1. Reactivity Patterns for $[IrCl_6]^{2\ominus}$ and TCNE as Oxidants

Although the patterns of reactivity for $[IrCl_6]^{2\ominus}$ and TCNE are similar, they are both quite distinct from the outer-sphere pattern established for $[FeL_3]^{3\oplus}$. The contrast is graphically illustrated in Figure 8 in which the second-order rate constants ($\lg k$) for each of the three oxidants are plotted against the ionization potentials of the same series of alkylmetal donors.[17] The uniquely linear correlation for $[Fe(phen)_3]^{3\oplus}$ is discussed in Section 2.2.1 for outer-sphere

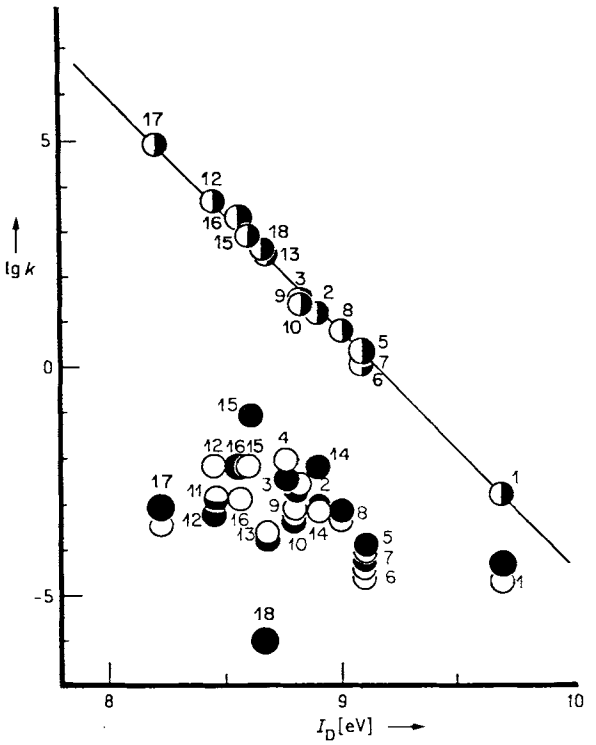


Fig. 8. Contrasting behavior of $[IrCl_6]^{2\ominus}$ (●) and TCNE (○) relative to $[Fe(phen)_3]^{3\oplus}$ (◑) in the correlation of rates of oxidation with the ionization potentials of alkylmetals: 1 = Me_4Sn, 2 = Et_4Sn, 3 = nPr_4Sn, 4 = nBu_4Sn, 5 = $EtSnMe_3$, 6 = $nPrSnMe_3$, 7 = $nBuSnMe_3$, 8 = Et_2SnMe_2, 9 = nPr_2SnMe_2, 10 = nBu_2SnMe_2, 11 = iPr_4Sn, 12 = sBu_4Sn, 13 = iBu_4Sn, 14 = $iPrSnMe_3$, 15 = $tBuSnMe_3$, 16 = iPr_2SnMe_2, 17 = tBu_2SnMe_2, 18 = $(tBuCH_2)_4Sn$ [17]. The slope of the $[Fe(phen)_3]^{3\oplus}$ correlation is $-1/2$.

oxidation. The marked deviations of all the points for $[IrCl_6]^{2\ominus}$ and TCNE from any analogous relationship is unmistakable. Furthermore, in Figure 9, the experimental values of $\Delta G^{\neq}$ for $[IrCl_6]^{2\ominus}$ and TCNE consistently fall below the solid lines representing the expected outer-sphere rates which were calculated from the Marcus equation (20) by taking into account the differences in the reorganization energies of $[IrCl_6]^{2\ominus}$ and TCNE. *With the exception of tBu_2SnMe_2 all the experimental rates are faster than the calculated values based on the Marcus outer-sphere correlation.* The magnitudes of the derivations vary from 12.5 kcal mol^{-1} for the least sterically hindered Me_4Sn to ca. 0 kcal mol^{-1} for the hindered tBu_2SnMe_2 (see Figure 2 for a qualitative expectation of steric effects). Thus among the symmetrical tetraalkyltin compounds R_4Sn, the least hindered methyl and *n*-alkyl derivatives all lie farthest from the outer-sphere correlation. Conversely, those tetraalkyltin compounds with α- and β-branched alkyl ligands consistently lie closest to the lines in Figure 9. Furthermore, the two-coordinate dialkylmercurials, which represent sterically open alkylmetals, all lie away from the outer-sphere correlation significantly beyond the tetra-*n*-alkyltin derivatives.

2.3.2. Selectivity Differences in the Oxidative Cleavage of Alkylmetals via Outer-Sphere and Inner-Sphere Pathways

The cleavage of alkyl ligands from symmetrical tetraalkyltin compounds [Eqs. (18), (25), and (26)] actually oc-

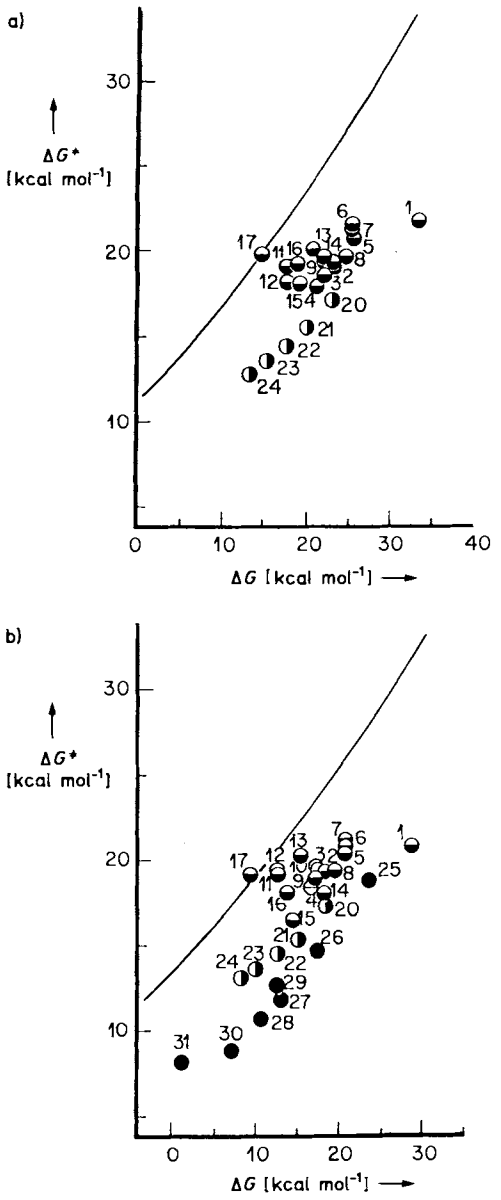

Fig. 9. Relationship between the activation free energy and the driving force for electron transfer from alkylmetals to TCNE (a) and $[IrCl_6]^{2\ominus}$ (b) according to the Marcus equation (20). Numbers 1–17 refer to alkylmetals in Figure 8: 20 = Me_4Pb, 21 = $EtPbMe_3$, 22 = Et_2PbMe_2, 23 = Et_3PbMe, 24 = Et_4Pb, 25 = Me_2Hg, 26 = EtHgMe, 27 = *i*PrHgMe, 28 = *t*BuHgMe, 29 = Et_2Hg, 30 = iPr_2Hg, 31 = tBu_2Hg. The curves are in agreement with expectations based on an outer-sphere mechanism [Eq. (20)].

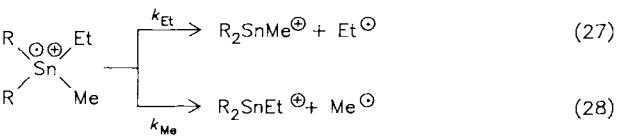
curs subsequent to the rate-limiting electron transfer. If the same cation is formed as a common intermediate, it should fragment in exactly the same manner in Equation (19) for all three processes. The selectivity S(Et/Me) for the series of unsymmetrical methylethyltin compounds represents the ratio of first-order rate constants k_{ET}/k_{Me} for the intramolecular competition in Equations (27) and (28), where R = Me, Et.[17,23]



(27)

(28)

Selectivity provides the only measure available to determine the properties of the radical-cation intermediate, $R_2SnMeEt^{\odot\oplus}$. Indeed, the grouping of S(Et/Me) in Table 2 indicates that the cation derived from $[FeL_3]^{3\oplus}$ is different from those derived from $[IrCl_6]^{2\ominus}$ and TCNE. Furthermore, the similar values of S(Et/Me) for the latter accord with a related inner-sphere process.

Table 2. Selectivity studies in the oxidative cleavage of methylethyltin compounds by $[Fe(phen)_3]^{3\oplus}$, $[IrCl_6]^{2\ominus}$ and TCNE.

Alkyltin	Oxidant/Acceptor	S(Et/Me) [a]
Et_2SnMe_2	$[Fe(phen)_3](ClO_4)_3$	27±4
	$Na_2[IrCl_6]$	11±3
	TCNE	10±3
$EtSnMe_3$	$[Fe(phen)_3](ClO_4)_3$	26±4
	$Na_2[IrCl_6]$	11±3
	TCNE	11±3
Et_3SnMe	$[Fe(phen)_3](ClO_4)_3$	[b]
	$Na_2[IrCl_6]$	11±3
	TCNE	[b]

[a] Statistically corrected in $EtSnMe_3$ and Et_3SnMe. [b] Not measurable.

2.3.3. *Steric Criterion for the Inner-Sphere Mechanism with $[IrCl_6]^{2\ominus}$ and TCNE*

The measurable effects of steric perturbation on the rates of oxidation of encumbered alkylmetals by $[IrCl_6]^{2\ominus}$ and TCNE in Figure 9 are to be clearly distinguished from the corresponding outer-sphere processes identified in Figure 3, in which steric effects exert little or no influence on the rates. Such a trend for the former must reflect steric effects that perturb the inner coordination sphere of the alkylmetal donor in the transition state for electron transfer [cf. Eq. (17)]. Indeed, *we employ this conclusion as an operational definition for the inner-sphere mechanism of electron transfer.* In the context of the Marcus formulation, the lowering of the activation barrier in an inner-sphere process could arise from the reduction of the work term w_p as a result of the strong interaction in the ionic products, e.g., $[R_4Sn^{\oplus}, [IrCl_6]^{3\ominus}]$ and $[R_4Sn^{\oplus}, TCNE^{\ominus}]$. The electrostatic potential in such an ion pair is attractive and can cause the tetraalkyltin to achieve a quasi five-coordinate configuration in the precursor complex, reminiscent of a variety of trigonal-bipyramidal structures already well-known for tin(IV) derivatives (Scheme 3).

Scheme 3. Trigonal-bipyramidal structures of tin(v) ion pairs.

The extent to which steric effects adversely affect the attainment of such intimate ion-pair structures would be reflected in an increase in the work term w_p and a concomitant diminution of the inner-sphere rate. This qualitative conclusion accords with the selectivity in Table 2 and the reactivity trend in Figure 9. However, Marcus theory does not provide a quantitative basis for evaluating the variation in the work term of such ion pairs. To obtain the latter

we now turn to the Mulliken theory of charge transfer in which the energetics of ion-pair formation evolve directly and provide quantitative information on the steric effects.

2.4. Thermochemical Formulation of Electron-Transfer Rates

Before doing so, however, let us reformulate the problem in a more general thermodynamics context, in which we consider organometals as electron donors D and the oxidants $[IrCl_6]^{2\ominus}$ and TCNE as electron acceptors A.[24]

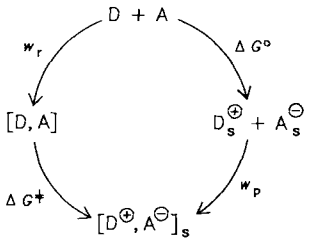
2.4.1. *Importance of the Work Term*

Electron-transfer mechanisms can be considered in the light of the standard potentials E^0 for each redox couple, i.e., E^0_{ox} for the oxidation of the donor ($D \rightarrow D^{\oplus} + e^{\ominus}$) and E^0_{red} for the reduction of the acceptor ($A + e^{\ominus} \rightarrow A^{\ominus}$). Thus the general reaction scheme for an irreversible process is represented by Equations (29),[25] in which electron transfer in the encounter complex [D,A] is rate-limiting. This scheme is particularly applicable to systems which lie in the endergonic region of the driving force (i.e., where the standard free energy change, $\Delta G^0 \gg 0$). The observed second-order rate constant k_{obs} is then given by $k_{obs} = k_{ET} K_{DA}$, where K_{DA} is the formation constant of the complex and k_{ET} is the intracomplex rate constant for electron transfer. The thermochemical cycle for an irreversible electron transfer in the highly endergonic region is schematically illustrated in Scheme 4.

$$D + A \overset{K_{DA}}{\rightleftharpoons} [D,A] \tag{29a}$$

$$[D,A] \xrightarrow{k_{ET}} [D^{\oplus}, A^{\ominus}] \tag{29b}$$

$$[D^{\oplus}, A^{\ominus}] \xrightarrow{\text{fast}} \text{products} \tag{29c}$$



Scheme 4. Thermochemical cycle for an irreversible electron transfer.

According to the thermochemical cycle in Scheme 4, the activation free energy for electron transfer $\Delta G^{\ddagger}$ in the encounter complex is given by Equation (30), where ΔG^0 corresponds to the standard free energy change of the redox process $D + A \rightarrow D^{\oplus} + A^{\ominus}$, and the work terms w_p and w_r represent the energy required to bring together the products and reactants, respectively, to within the mean separation r_{DA} in the ion pair $[D^{\oplus}, A^{\ominus}]$. The observed second-order rate constant can be expressed in terms of the activation free energy $\Delta G^{\ddagger}$ [Eq. (30)], which leads to the free energy relationship for electron transfer [Eq. (31)], where $C_1 = \lg(kT/h)$ (k = Boltzmann constant, h = Planck constant).

$$\Delta G^{\ddagger} = \Delta G^0 + w_p - w_r \tag{30}$$

$$\lg k_{obs} = -\frac{1}{2.3RT}(\Delta G^0 + w_p) + C_1 \tag{31}$$

Since the free energy change for electron transfer ΔG^0 is obtained from the standard potentials of the donor and acceptor—i.e., $\Delta G^0 = F(E^0_{ox} + E^0_{red})$—the free energy relationship (31) may be represented by an equivalent form, Equation (32), when one is dealing with a series of electron-transfer reactions with a fixed donor. Thus Equations (31) and (32) state that the observed rate constant ($\lg k_{obs}$) for electron transfer can be expressed as the sum of the standard free energy change (ΔG^0) and the work term of the products (w_p). Previous considerations of electron transfer have tended to focus only on the magnitude of ΔG^0, without explicitly taking into account the energetics of ion-pair $[D^{\oplus}, A^{\ominus}]$ formation, i.e., the work term w_p. Such an oversimplification is perhaps understandable if one considers the experimental difficulty of directly evaluating the work terms of ion pairs by the usual procedures. The problem is severely compounded by the exceedingly short lifetimes of the transient ion pairs which must be involved in irreversible electron transfer. We now discuss how the observation of charge-transfer spectra in these systems can be used to evaluate such ion-pairing energies.

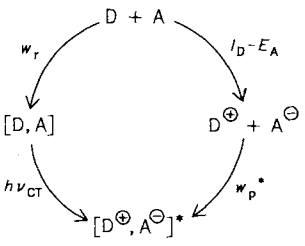
$$\lg k_{obs} = -\frac{1}{2.3RT}(FE^0_{ox} + w_p) + \text{constant} \tag{32}$$

2.4.2. *Evaluation of the Work Term from Charge-Transfer Spectra*

The intermolecular interaction leading to the precursor complex in Scheme 4 is reminiscent of the electron donor-acceptor (EDA) complexes formed between electron donors and acceptors.[26] EDA complexes are characterized by the presence of a new absorption band in the electronic spectrum. According to the Mulliken charge-transfer (CT) theory for weak EDA complexes, the absorption maximum $h\nu_{CT}$ corresponds to the vertical (Franck-Condon) transition from the neutral ground state to the polar excited state [Eq. (33)].[13] The asterisk identifies an excited ion pair with the same mean separation r_{DA} as that in the precursor or EDA complex. The thermochemical cycle for such a charge-transfer transition is schematically illustrated in Scheme 5. The vertical ionization potential of the electron donor is represented by I_D, and the electron affinity of the acceptor by E_A.

$$[D,A] \xrightarrow{h\nu_{CT}} [D^{\oplus}, A^{\ominus}]^* \tag{33}$$

The charge-transfer in Scheme 5 is akin to the adiabatic electron-transfer cycle in Scheme 4. In this case the work term w_p^* required to bring the products $D^{\oplus}$ and $A^{\ominus}$ to-



Scheme 5. Thermochemical cycle for a charge-transfer transition.

gether to the mean separation r_{DA} in the excited state is given by Equation (34), where $C_2 = E_A + w_r$; C_2 is consid-

$$w_p^* = h\nu_{CT} - I_D + C_2 \tag{34}$$

ered to be constant for a fixed acceptor.[27] In the limit of simple ion-pair interactions, the work term is largely Coulombic, i.e., $w_p^* \approx -e^2/r_{DA}$.

We can relate the work term w_p^* to that of a reference donor, w_p^{0*}, since the series of oxidations in Figure 8 involves either TCNE or $[IrCl_6]^{2\ominus}$ as the common acceptor. This comparative procedure allows the acceptor component in a given series to drop out by cancellation, and Equation (35) follows from Equation (34). In Equation

$$\Delta w_p^* = w_p^* - w_p^{0*} = \Delta h\nu_{CT} - \Delta I_D \tag{35}$$

(35), $\Delta h\nu_{CT}$ refers to the relative CT transition energy with a common acceptor, and ΔI_D is the difference in the ionization potentials of the donor and the chosen reference. Thus, by selecting a reference donor, we can express all changes in the ion-pairing energies in the CT excited state (including steric, distortional, and other effects in the D/A pair) by a single, composite energy term Δw_p^*. In so far as w_p^* is Coulombic, *the relative work term Δw_p^* measures changes in mean separation, and it is thus a reflection of steric effects*. Let us now return to the thermal electron-transfer reaction in Equation (26), for which the rate-limiting activation process has been shown to proceed from the EDA complex [Eq. (36)].[27]

$$[RM, TCNE] \xrightarrow{k} [RM^{\oplus}, TCNE^{\ominus}] \tag{36}$$

2.4.3. *Free Energy Relationship for Inner-Sphere Electron Transfer*

The variation in the driving force in Equation (36) derives from two factors: (1) the differences in the oxidation potentials of the alkylmetals and (2) the changes in the work terms in the ion pairs resulting from differences in the steric effects (i.e., mean separations r_{DA}.) The difference in the oxidation potentials is obtained from the free energy change for electron transfer (i.e., $RM \rightarrow RM^{\oplus} + e^{\ominus}$) in the outer-sphere process [see Eq. (21)]. The change in the work term is equated to Δw_p^*, determined from the CT interaction [Eq. (35)]. Thus the linear correlation in Figure 10a between the driving force and the activation free energy represents a linear free energy relationship for elec-

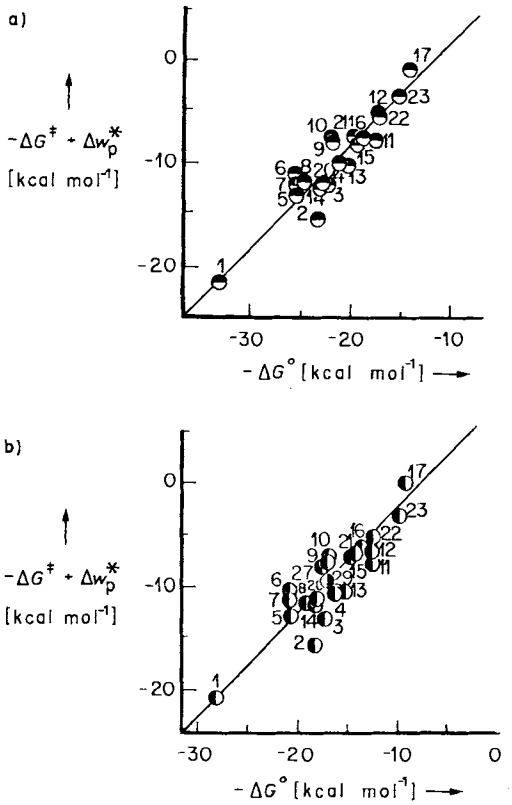


Fig. 10. Relationship between the activation free energy $\Delta G^{\ddagger}$ including the work term Δw_p^* and the driving force for electron transfer ΔG^0 to TCNE (a) and $[IrCl_6]^{2\ominus}$ (b) for alkylmetals listed in Figures 8 and 9.

tron transfer expressed as $\Delta G^{\ddagger} = \Delta G^0 + \Delta w_p^* + C_3$, where the constant C_3 represents the reference terms.[17] Furthermore, the same relationship applies to $[IrCl_6]^{2\ominus}$, as shown by the correlation in Figure 10b. (The applicability of the values of Δw_p^* obtained from TCNE to the inner-sphere oxidation with $[IrCl_6]^{2\ominus}$ is probably fortuitous. An indication of their similarity is, however, apparent from Figures 8 and 9.)

2.5. The Merging of Outer-Sphere and Inner-Sphere Mechanisms of Electron Transfer

The concepts of outer-sphere and inner-sphere electron transfer, as we have employed them, depend on the availability of various metals and alkyl ligands as highly tunable probes for steric effects. As such, we might ask how these mechanisms basically differ. One answer might focus on the properties of $RM^{\odot\oplus}$, especially with respect to selectivity in the cleavage that follows the rate-limiting electron transfer (see Table 2). Another might relate to the role of steric effects on the activation process. We suggest that both are directly related to the interaction energy in the ion pair, for which steric effects are evaluated from the CT data by means of Equation (35). According to this formulation, *outer-sphere and inner-sphere processes are largely distinguished by the magnitudes of the intermolecular separation between the donor and the acceptor in the transition states for electron transfer*. As such, there should be a continuum of activated complexes differing principally in geo-

metrical constraints, which are manifested in the context of the Marcus equation (20) by variations in the work term as well as the intrinsic barrier. In order to evaluate these contributions, let us see how they affect the free-energy correlations for outer-sphere ($[FeL_3]^{3\oplus}$) and inner-sphere (TCNE and $[IrCl_6]^{2\ominus}$) mechanisms (Fig. 4 and 10, respectively). For clarity, these correlations are redrawn and juxtaposed in Figure 11. (Note that the Brønsted slope for

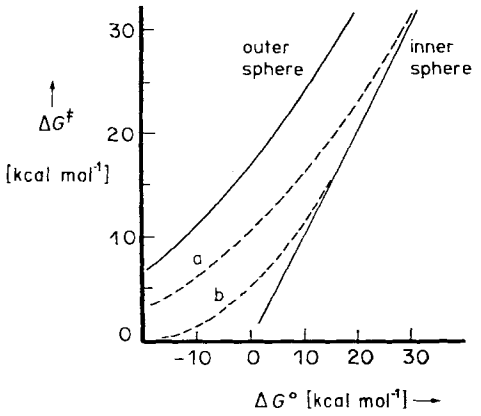

Fig. 11. The importance of the work term and the reorganization energy in the free energy correlations for outer-sphere and inner-sphere mechanisms. For details see text. The full lines correspond to the limiting cases of outer-sphere and inner-sphere mechanisms. a) Reduction of the work term w_p in the Marcus equation (20) by $\Delta w_p \approx 10$ kcal mol^{-1}; b) subsequent reduction of the intrinsic barrier by one-half.

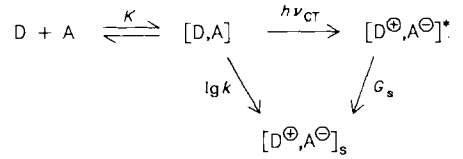
$[FeL_3]^{3\oplus}$ is effectively one-half, whereas that for both TCNE and $[IrCl_6]^{2\ominus}$ is unity.) Initially, if the work term w_p in the Marcus equation (20) is reduced by $\Delta w_p \approx 10$ kcal mol^{-1}, the new free-energy correlation follows the dashed curve a in Figure 11. Following this, if the intrinsic barrier is reduced by one-half, curve a is transformed into b, which closely follows the inner-sphere correlation. Although the choice of $\Delta w_p \approx 10$ kcal mol^{-1} and $\Delta G_0^{\ddagger}/2$ may appear arbitrary, the procedure shows that the outer-sphere correlation can be transformed to the inner-sphere correlation by suitable reductions in the work term and intrinsic barrier. Since the experimental points in Figure 9 fall between the outer- and inner-sphere limits, it is reasonable to expect that variations in w_p and $\Delta G_0^{\ddagger}$ lead to a continuum of inner-sphere and outer-sphere mechanisms. Thus, the least hindered compound Me_4Sn and the highly hindered tBu$_2$SnMe$_2$ expectedly lie at the inner- and outer-sphere limits, respectively, as depicted for both TCNE and $[IrCl_6]^{2\ominus}$ in Figure 9.

3. Generalized Free Energy Relationships for Electron Transfer (FERET)

In Section 2 we described how the variable steric and polar properties of organometal donors provide the means to predict the electron-transfer rates of both outer-sphere and inner-sphere processes. Critical to the electron-transfer kinetics is the evaluation of the work term w_p^* of the $[D^{\oplus}, A^{\ominus}]$ ion pair from the charge-transfer absorption spectra [see Eq. (34)]. Since the charge-transfer interactions derive naturally from various electron donor-acceptor pairs, let us combine the thermodynamic cycles in Schemes 4 and 5 into the composite form shown in Scheme 6, where K is



Scheme 6. Combination of the thermodynamic cycles in Schemes 4 and 5.

the formation constant of the EDA or precursor complex [D,A], and the rate of electron transfer is defined by the adiabatic rate constant k. In Scheme 6, the asterisk identifies the vertical ion pair obtained from the CT excitation; the vertical ion pair is differentiated from the adiabatic ion pair $[D^{\oplus}, A^{\ominus}]_s$ by the solvation energy G_s. Following our earlier treatment of these energy components as changes relative to a reference [see Eq. (35)], the thermodynamic cycle in Scheme 6 can be expressed as Equation (37),

$$\Delta G_r^{\ddagger} = \Delta h\nu_{CT} + \Delta G_s \tag{37}$$

where the relative rates of electron transfer (lgk/k_0) are represented by $\Delta G_r^{\ddagger}/(2.3\,RT)$ and the difference in the CT transition energies by $\Delta h\nu_{CT}$ (see Section 2.4.2). The free energy change (ΔG) for the oxidation of a donor in solution includes both the solvation term G_s for the donor cation $D^{\oplus}$ and the ionization potential (I_D) for the oxidation in the gas phase [Eq. (38)].[28] The corresponding relative

$$\Delta G = I_D + G_s \tag{38}$$

change in solvation ΔG_s for Equation (37) is evaluated independently as the difference between the gas-phase ionization potential and the oxidation potential of the donors in solution.

The validity of Scheme 6 is illustrated in Figure 12 by the excellent fit of the experimental data to the line of unit slope.[29] It must be emphasized that *this test of Equation (37) obtains from three sets of independent data.* Thus the free energy change $\Delta G_r^{\ddagger}$ is measured from the kinetics experiments, and the charge-transfer energies $\Delta h\nu_{CT}$ derive from spectral absorption measurements. The solvation change is equal to the difference between the gas-phase ionization potential I_D and the oxidation potential E_{ox}^0 in solution of the organometal donor, since the contribution from the electron acceptor cancels out in the comparative procedure for ΔG_s. For convenience the generalized free energy relationship for electron transfer in Equation (37) will be referred to hereafter by the acronym FERET.

Let us now take the charge-transfer formulation in Scheme 6 one step further and ask whether the photochemical and thermal activations of an EDA complex can actually lead to the same overall reaction. A particularly

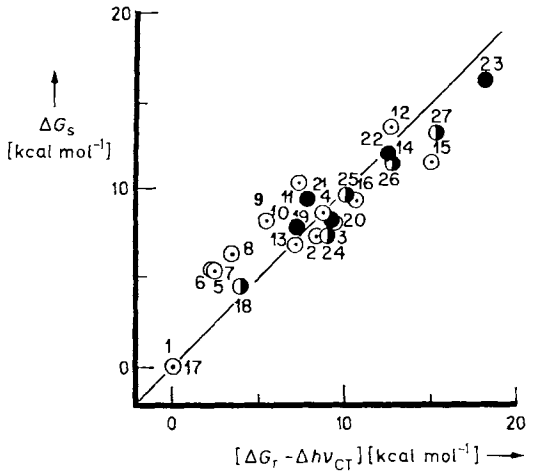


Fig. 12. FERET for the activation process for halogenolysis or insertion and the driving force for ion-pair formation as described in Equation (37): R_4Sn-I_2 (⊙), R_4Pb-TCNE (◑), and R_2Hg-TCNE (●). The dashed line drawn with unit slope represents $\Delta G_s = \Delta G_r^* - \Delta h\nu_{CT}$. 1 = Me_4Sn, 2 = Et_4Sn, 3 = nPr_4Sn, 4 = nBu_4Sn, 5 = $EtSnMe_3$, 6 = $nPrSnMe_3$, 7 = $nBuSnMe_3$, 8 = Et_2SnMe_2, 9 = nPr_2SnMe_2, 10 = nBu_2SnMe_2, 11 = iPr_2SnMe_2, 12 = tBu_2SnMe_2, 13 = Et_3SnMe, 14 = iPr_4Sn, 15 = sBu_4Sn, 16 = iBu_4Sn, 17 = Me_2Hg, 18 = EtHgMe, 19 = iPrHgMe, 20 = Et_2Hg, 21 = tBuHgMe, 22 = iPr_2Hg, 23 = tBu_2Hg, 24 = Me_4Pb, 25 = $EtPbMe_3$, 26 = Et_2PbMe_2, 27 = Et_3PbMe [29].

informative example is given by the interaction of alkylmetals with tetracyanoethylene [Eqs. (39)-(41)], in which the

$$RM + TCNE \rightleftharpoons [RM,TCNE] \quad (39)$$

$$[RM,TCNE] \xrightarrow{k} [RM^{\oplus},TCNE^{\ominus}] \quad (40)$$

$$[RM^{\oplus},TCNE^{\ominus}] \xrightarrow{\text{fast}} 1:1 \text{ adduct} \quad (41)$$

rate-limiting step for addition is given by Equation (40).[27,30] We indeed find that the *same* 1:1 adduct is produced photochemically when the CT absorption band ($\lambda_{max} = 440$ nm) is deliberately irradiated at −35°C [Eq. (42)].

$$[RM,TCNE] \xrightarrow{h\nu_{CT}} [RM^{\oplus},TCNE^{\ominus}] \longrightarrow \longrightarrow \cdots \quad (42)$$

At this low temperature, the thermal process [Eqs. (39)-(41)] is too slow to compete. Thus the observed quantum yields of unity, together with selectivities which are the same for the thermal and photochemical processes, indicate that the same ion pairs are common intermediates in Equations (40) and (42).[27] Such a direct relationship between the thermal electron transfer ($\lg k$) and the charge transfer activation ($h\nu_{CT}$) is graphically presented in Figure 13, in which ion-pairing energies of the vertical and adiabatic processes are simply represented as electrostatic terms. Thus the generalized free energy relationship in Equation (37) relates the rate of electron transfer directly to the CT transition energy of the EDA complex and the solvation energy of the ion pair.

Since the FERET correlation in Equation (37) conveys only a limited physical connotation, we replace the charge-transfer term $\Delta h\nu_{CT}$ with its equivalent in Equation (35) to obtain Equation (43).[31] The FERET in Equation (43) is a

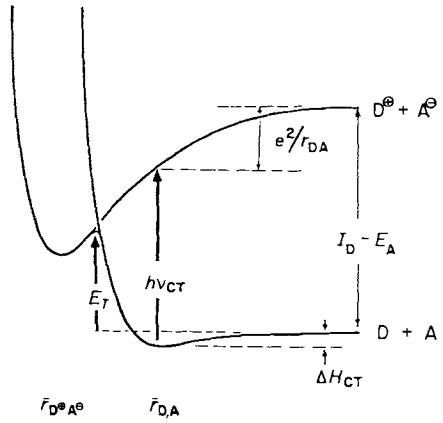

Fig. 13. The qualitative relationship between thermal (E_T) and photochemical ($h\nu_{CT}$) activation of electron transfer proceeding from the charge-transfer complex.

$$\Delta G_r^* = \Delta I_D + \Delta w_p^* + \Delta G_s \quad (43)$$

direct representation of the *electron transfer rates ($\lg k/k_0$) as a simple combination of electronic (ΔI_D), steric (Δw_p^*), and solvation terms (ΔG_s).* Alternatively, the FERET in Equation (43) can be expressed in terms of the standard free energy change ($\Delta G_r^0 = \Delta I_D + \Delta G_s$) to obtain Equation (44).

$$\Delta G_r^* = \Delta G_r^0 + \Delta w_p^* \quad (44)$$

The FERET in Equation (44) is an alternative representation of the *electron-transfer rates as a combination of the free energy change* [i.e., $\Delta G^0 = F(E_{ox}^0 + E_{red}^0)$] *and the work term of the ion pair* (Δw_p^*).

The FERET in Equation (37) together with its corollaries (43) and (44) underscores the strong energetic similarity between the CT excited state (i.e., the photochemically generated ion pair $[D^{\oplus},A^{\ominus}]^*$) and the transition state (or the adiabatic ion pair $[D^{\oplus},A^{\ominus}]_s$). The subtle balance between electronic or polar effects ΔI_D, the steric effect Δw_p, and the solvation energy ΔG_s thus determines the reactivity of electron donors, particularly with respect to solvent variation. Moreover, the prediction of electron-transfer rates derives naturally from the properties of the reactants in the gas phase (I_D,E_A) and in solution (E_{ox}^0,E_{red}^0), as well as those of the products (G_s, w_p). Most importantly, all of these energy contributions are experimentally measurable quantities.

In order to examine the applicability of this generalized free energy formulation, we now use it to resolve the critical ambiguities in some basic organic and organometallic reactions.

4. Applications of FERET to Organic and Organometallic Systems

The chemical reactions presented in Equations (1)-(7) are all examples in which EDA complexes have been actually observed as transient intermediates from the reactant donor-acceptor pairs.[5,21] Accordingly, the pertinent charge-transfer data can be applied to the generalized free energy relationships in Equations (37), (43), and (44), as described individually below.

4.1. Aromatic Substitution with Electrophiles

Halogenation and mercuration represent rather dissimilar processes for electrophilic aromatic substitution, as illustrated by the divergent trends in the relative reactivities ($\lg k/k_0$) of various arenes toward Br_2 and $Hg(O_2CCF_3)_2$ in Figure 14. Thus any mechanistic formulation of electrophilic aromatic substitution must first reconcile, in a quantitative way, such differences in arene reactivities imposed by the different electrophiles.[32] Furthermore, if the formulation is to have any generality and predictive power, it must lead to the description of the activation process for electrophilic aromatic substitution in terms of experimentally identifiable concepts. We show how the charge-transfer formulation provides physical insight into the transition state for electrophilic substitution, particularly with regard to the significance of the ρ values and the solvent effects. The CT formulation also yields a unique view into the origin of the isomeric product distributions.

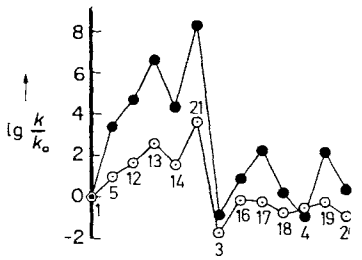

Fig. 14. Reactivities of arenes in mercuration (⊖) and bromination (●) relative to benzene(1). The following substituted benzenes were investigated. 3 = ClC_6H_5, 4 = BrC_6H_5, 5 = MeC_6H_5, 12 = *o*-$Me_2C_6H_4$, 13 = *m*-$Me_2C_6H_4$, 14 = *p*-$Me_2C_6H_4$, 16 = *o*-$ClMeC_6H_4$, 17 = *m*-$ClMeC_6H_4$, 18 = *p*-$ClMeC_6H_4$, 19 = *m*-$BrMeC_6H_4$, 20 = *p*-$BrMeC_6H_4$, 21 = 1,3,5-$Me_3C_6H_3$ [33]. $X^{\ominus} = F_3CCO_2^{\ominus}$.

4.1.1. The Charge-Transfer Correlation

The direct relationship between the relative reactivities of various arenes in electrophilic substitution and the CT transition energies is shown in Figure 15.[33] The remarkable linear correlations of the data apply equally well to mercuration, to bromination, and to chlorination. Moreover, the same relationship is applicable in solvents as diverse as dichloromethane, acetic acid, and trifluoroacetic acid. Since every line in Figure 15 is arbitrarily drawn with a slope of unity, *if all the experimental points in Figure 15 were plotted in a single figure, they would all lie on a single line.* This corresponds to the linear free energy relationship given in Equation (45), which is applicable to every electrophilic substitution process.

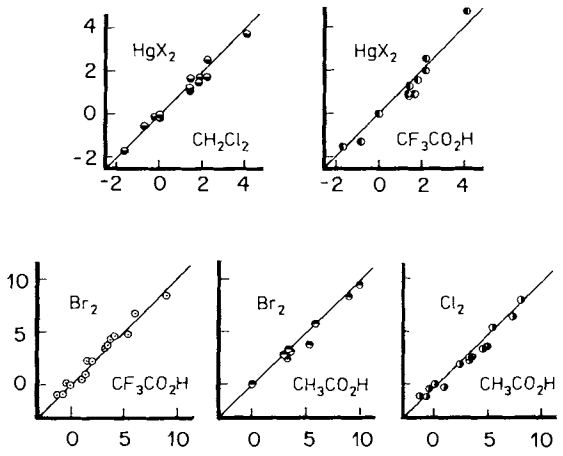

Fig. 15. The correlation of the relative reactivities of arenes with the CT transition energies in [33]. The lines are arbitrarily drawn with a slope of unity to emphasize the fit to Equation (45). Ordinate: $\lg k/k_0$. Abscissa: CT transition energies plotted as $-\Delta h\nu_{CT}/(2.3RT)$.

$$\lg \frac{k}{k_0} = -\frac{\Delta h\nu_{CT}}{2.3RT} \tag{45}$$

4.1.2. Solvent Effects

Equation (45) would represent a special case of FERET (37) for aromatic substitution if the relative solvation change ΔG_s for the donor component in Equation (37) were nil. In order to establish whether this situation actually pertains, an independent measurement of solvation changes is required. By the comparative procedure used to develop Equation (45), we need only to consider relative changes in the solvation of the aromatic cation, since the contributions from the electrophile moiety drop out by cancellation. Under these circumstances, the free energy change for solvation is represented by the difference between the gas-phase ionization potential [Eq. (46)] and the free energy change for oxidation in solution [Eq. (47)] of

$$\text{Arene} \xrightarrow{I_D} \text{Arene}^{\oplus} + e^{\ominus} \tag{46}$$

$$\text{Arene} \xrightarrow{E^0_{ox}} \text{Arene}^{\oplus}_s + e^{\ominus} \tag{47}$$

the arene, where the subscript s represents the solvated species. The correlation of the standard oxidation potentials E^0_{ox} of the aromatic hydrocarbons with the ionization potentials I_D in the gas phase is shown in Figure 16.[34] The line in the graph is described by Equation (48). The correlation coefficient of 0.975 is sufficiently high (especially since it includes 27 compounds, 12 of which are plotted in Figure 16) to ensure the validity of a linear correlation between E^0_{ox} and I_D to a confidence level of >99.9%. Thus an independent measurement of the solvation change of aromatic cations indeed accords with the prediction of the FERET in Equation (45) with $\Delta G_s \approx 0$. Thus, by taking the solvation of arene cations to be relatively constant, it follows that the vertical and adiabatic ion pairs in Scheme 6 are evaluated to be equivalent by the comparative procedure used in Equation (45).

$$E^0_{ox} = 0.71 I_D - 3.68 \tag{48}$$

It is noteworthy that the polar ion pair [Arene$^{\oplus}$, $A^{\ominus}$], when taken as a model for the transition state of electrophilic aromatic substitution, does correctly account for an otherwise inexplicable lack of sensitivity to solvent effects of the relative reactivities of various arenes, despite a strong correlation with the σ^+ parameter.[35] The *absolute* rates of electrophilic aromatic substitutions also accord with ion-pair solvation. For example, the solvation energy

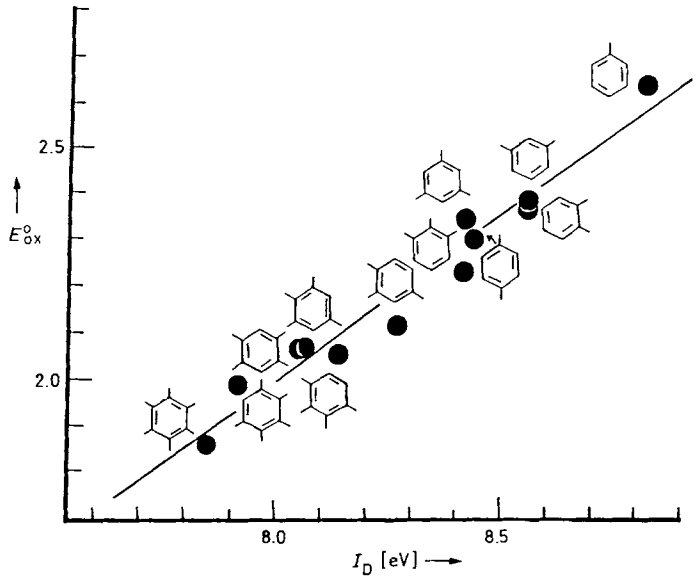

Fig. 16. Correlation of the standard oxidation potentials E^0_{ox} (in V vs. NHE) of various alkylbenzenes with the vertical ionization potentials I_D.

of aromatic cations in trifluoroacetic acid is larger than that in acetonitrile by approximately 4.6 kcal mol^{-1}, which corresponds to the difference in E^0_{ox} in these solvents. The second-order rate constant for the chlorination of benzene in trifluoroacetic acid ($k = 7 \times 10^{-3}$ M^{-1} s^{-1}) at 25°C is 1700 times larger than that in acetonitrile. This rate enhancement is equivalent to a decrease in the activation free energy of 4.4 kcal mol^{-1}, which corresponds well with the difference in solvation energy mentioned above. Although such an agreement may be fortuitous, it nonetheless underscores the importance of solvation in considering the solvent effects on the *absolute* rates of electrophilic aromatic substitution.

4.1.3. Significance of the FERET Formulation to Other Linear Free Energy Relationships

The charge-transfer formulation of electrophilic aromatic substitution leads to the conception of the transition state as an ion pair. As such, we show how the FERET formulation relates to previous linear free energy relationships which have been developed for electrophilic aromatic substitution. First, let us consider the well-known correlation [Eq. (49)] based on σ^+ substituent constants.[36]

$$\lg \frac{k}{k_0} = \rho\sigma^+ \tag{49}$$

Since the sensitivity factor ρ has been subjected to various physical interpretations, our primary task is to derive ρ from the CT data. It has been shown for a series of electrophiles and π acceptors that the CT transition energies $h\nu_{CT}$ vary linearly with the ionization potential I_D of the arene donor.[5] The relative change, as evaluated by the comparative procedure is given by Equation (50), where the slopes

$$\frac{\Delta h\nu_{CT}}{\Delta I_D} = \alpha_A \tag{50}$$

α_A are measures of the electrophile or π acceptors—varying from ca. 0.3 for $Hg(O_2CCF_3)_2$, 0.6 for 1,2,4,5-benzenetetracarbonitrile, 0.6 for Cl_2, 0.7 for Br_2 and maleic anhydride, and 0.8 for tetracyanoethylene, up to 1.0 for chloranil. The values of α_A never exceed unity. The linear free energy relationship between ΔI_D and σ^+ [Eq. (51)] has

$$\Delta I_D = -20.4\sigma^+ \tag{51}$$

been established for roughly 50 mono- and disubstituted benzenes.[33] The combination of Equations (45), (50), and (51) yields Equation (52). In other words, the electrophile-

$$\lg \frac{k}{k_0} = -16\alpha_A\sigma^+ \tag{52}$$

dependent value of ρ [Eq. (49)] is directly related to the slope of the correlation of $\Delta h\nu_{CT}$ with ΔI_D [Eq. (53)].

$$\rho = -16\alpha_A \tag{53}$$

Since $0 < \alpha_A < 1$, Equation (53) predicts that $|\rho|$ will not exceed a value of 16. Indeed, we are unaware of reports in the extant literature of $|\rho| > 16$ for any electrophilic aromatic substitution. Furthermore, the ρ values for bromination ($\rho = -12.1$) and for chlorination ($\rho = -10.0$) are readily obtained from the CT data with the aid of Equations (50) and (53). Thus, by using the values of α_A for the bromine complexes (0.7) and for the chlorine complexes (0.6), the ρ values for bromination and chlorination are $\rho = -11$ and $\rho = -9.6$, respectively. Similarly, the ρ value for mercuration (-5.7) agrees well with the calculated value of -5 based on $\alpha_A = 0.3$. Thus the absolute values of ρ, otherwise unpredictable, can be independently evaluated for various electrophiles by the use of Equation (53).

4.1.4. Variations in the Work Term

If the mean separation r_{DA} were to remain constant in a series of arenes, the relative reactivities in Equation (45) should be proportional to the differences in the ionization potentials, i.e., $\lg k/k_0 = -\Delta I_D/(2.3RT)$, since $\Delta h\nu_{CT}$ would simply be equal to ΔI_D according to Equation (35). However, a plot of the values of $\Delta I_D/(2.3RT)$ against the logarithms of the relative reactivities of arenes in bromination and mercuration shows wide scatter. The absence of any clear correlation indicates that the intrinsic donor abilities of the arenes (i.e., ΔI_D) are *alone* insufficient to account for the differences in arene reactivities in mercuration and bromination. Thus the linear correlation of $\lg k/k_0$ with $\Delta h\nu_{CT}$ in Figure 15 indicates that the work term w_p is not constant. In order to determine the effects of varying w_p, we differentiate Equation (34) to yield the slope of the correlation of $h\nu_{CT}$ and I_D [Eq. (54)]. Since the interaction

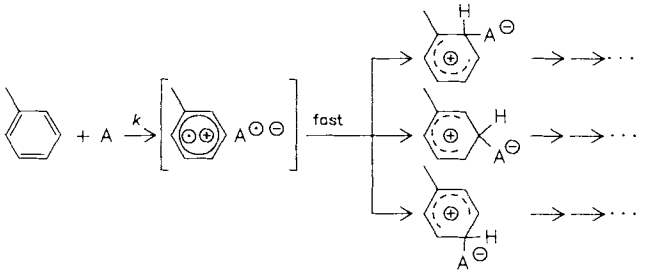
$$\alpha_A = \frac{\partial(h\nu_{CT})}{\partial I_D} = 1 + \frac{\partial w_p}{\partial I_D} \tag{54}$$

between Arene$^{\oplus}$ and A$^{\ominus}$ is attractive, the work term w_p is negative and increases with the mean separation r_{DA}. Such an increase in r_{DA} is generally accompanied by a decrease

in I_D of the substituted benzenes. As a result, the term $\partial w_p/\partial I_D$ above is negative and leads to values of α_A less than unity. Since the work term w_p in Equation (34) must also be affected by the electrophile moiety, the term $\partial w_p/\partial I_D$ is also dependent on the electrophile, as observed by the various values of α_A.[37]

4.1.5. Charge-Transfer Mechanism for Aromatic Substitution. Ion-Pair Collapse and the Isomeric Product Distribution

The various isomer distributions among meta and *para* products for the mercuration, halogenation, thallation, and nitration of monosubstituted benzenes PhZ can be separated into two groups according to whether *para* products (Z = X) or *meta* products (Z = Y) predominate. Such directive effects of the substituents X and Y have been commonly rationalized on the basis of inductive, resonance, and steric effects, the particular combination being somewhat arbitrarily chosen.[38] For example, the halogens, F, Cl, Br, and I, are classified as electron-withdrawing substituents by their values of the Hammett constants on the σ_p^0 scale and on the basis of the lower reactivity of the halobenzenes. Nevertheless, they yield predominantly *para* isomers like their more reactive counterparts, such as alkyl- and hydroxybenzenes. Such abnormalities of the halobenzenes have been troublesome to rationalize and have led to rather unsatisfactory ad hoc explanations.[39] The polar ion-pair state [Arene$^{\oplus}$, A$^{\ominus}$] as a model for the transition state avoids the ambiguous situation of reconciling reactivities and directive effects, by separating the rate-determining step from the product-forming step. Thus the rate-limiting activation process is represented by the formation of the ion pair as described in Section 3, and the product distribution is determined during the subsequent collapse of the ion pair (Scheme 7).



Scheme 7. Electrophilic aromatic substitution via a polar ion pair.

Indeed, the ion pair is prepared for bonding, since the unpaired electrons are located at the two centers that can be coupled to form the new bond. Under these circumstances, the most probable course for the collapse of [Arene$^{\oplus}$, A$^{\ominus}$] would be at the ring carbons of highest odd-electron spin density. In the benzene cation, the unpaired electron lies in the degenerate e_{1g} HOMOs, labeled S (for symmetric b_1) and A (for antisymmetric a_2). The spin density distributions for the odd electron in the benzene cation for these levels leads overall to a spin density of one-sixth at each carbon center. The symmetric orbital has a large spin density at the 1- and 4-positions, where the antisymmetric orbital has a node. The introduction of a substituent into benzene serves to remove the degeneracy of the symmetric and the antisymmetric orbitals—the electron-releasing substituent X leading to a raising of S and the electron-withdrawing substituent Y to a lowering of S, as in the energy level diagram shown in Figure 17. This assignment

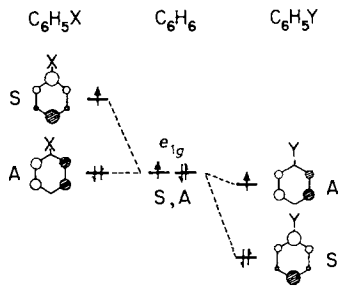


Fig. 17. Energy level diagrams for the effect of substituents on the HOMO of aromatic cations. X = electron-donating substituent, Y = electron-withdrawing substituent.

has been indeed confirmed by the analysis of the ESR spectra of various aromatic radical ions. As a result, the spin densities at the *para* and the *meta* positions of aromatic cations differ markedly, depending on whether the substituent is X or Y. In Ph–X, the HOMO is S and the increased spin density in the *para* position is at the expense of a decreased spin density in the *meta* position. In Ph–Y, the HOMO is A and the converse would apply. In order to utilize these spin densities for the prediction of the isomer distributions, we classify the substituents as either X or Y. However, the usual procedure based on some kinetic property, such as the Hammett σ constants derived from the relative reactivities ($\lg k/k_0$), is subject to changes in r_{DA} described in Section 4.1.4, and it is not an adequate criterion. Instead, we employ a more direct measure of the HOMO energy based on the ionization potential of a substituted benzene relative to benzene, as the indicator of electron release or electron withdrawal for substituents X and Y, respectively. We thus define the intrinsic electronic property of a substituent as electron-releasing or electron-withdrawing on the basis of the HOMO energy rather than the reactivity. According to this analysis, the *para*/*meta* isomer distribution would be simply predicted from the ionization potential of the monosubstituted benzene (Table 3).

Table 3. Isomer distribution for the electrophilic aromatic substitution of monosubstituted benzenes, as predicted from their ionization potentials.

Substituent	I_D	Isomer distribution
X	PhX < PhH	*para* > *ortho* ≫ *meta*
Y	PhY > PhH	*meta* > *ortho* ≫ *para*

Such a prediction is nicely borne out in Figure 18 in which the *para* and *meta* isomers obtained from a variety of electrophilic aromatic substitutions are plotted against

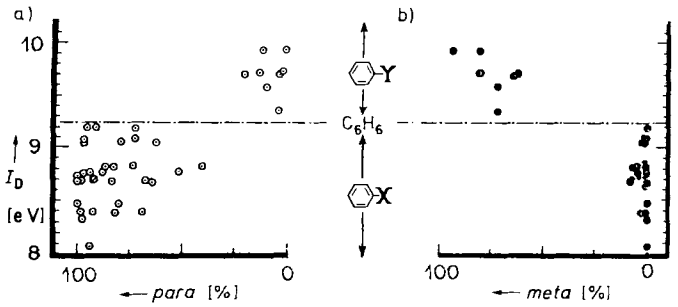

Fig. 18. The product distribution in electrophilic nitration, bromination, mercuration, and thallation among *para* isomers (a) and *meta* isomers (b) derived from monosubstituted benzenes with electron-releasing (X) and electron-withdrawing (Y) substituents, as indicated by the values of the ionization potential relative to that of benzene in [33]. Note that the halogens F, Cl, Br, and I are X substituents with $I_D = 9.18$, 9.08, 9.05, and 8.67 eV, respectively.

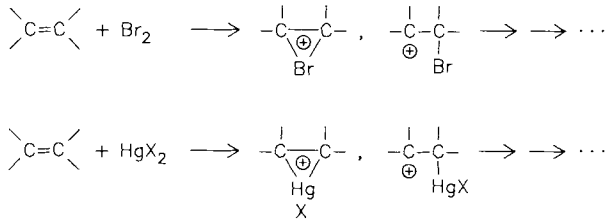
the ionization potential of the monosubstituted benzene. Four features in Figure 18 are noteworthy. First, the monosubstituted benzenes fall rather cleanly into one of two categories, i.e., heavily *para*- or heavily *meta*-producing with no arene yielding competitive amounts of each isomer. Second, the isomer distributions are determined solely by the ionization potential of the arene and are more or less independent of the electrophile. Third, the halogen substituents, F, Cl, Br, and I, are clearly to be included among the electron-releasing X, and no ad hoc explanation is required to account for the isomer distributions derived from the halobenzenes. Fourth and most importantly, there is an interesting *discontinuous transition* from *para*-producing aromatics to *meta*-producing aromatics, and vice versa, which occurs at benzene ($I_D = 9.23$ eV). All of these phenomena are in exact accord with the predictions listed in Table 3 and in Figure 17. Although the first three have been previously rationalized, the fourth phenomenon is not easily accounted for on the basis of conventional arguments. According to Figure 17, the discontinuity of the isomer distribution at benzene is caused by the splitting of the degenerate e_{1g} orbitals by the introduction of a substituent. It is noteworthy that such a splitting can arise from even minor perturbations, such as the mere replacement of hydrogen by deuterium. This extreme sensitivity is forcefully brought forth by the remarkable inequivalency of the proton splittings in the ESR spectrum of even the monodeuteriobenzene radical ion.[40]

4.2. Addition of Electrophiles to Olefins

The electrophilic addition to olefins has been one of the most widely studied processes in organic chemistry, the nature of the transition states and reactive intermediates being of considerable interest.[41] In particular, the bromination [Eq. (1)] and oxymercuration [Eq. (2) with X = OAc, OMe, etc.] of olefins have been examined extensively, and the generally accepted mechanisms involve similar intermediates (Scheme 8): π complexes (bromonium and mercurinium ions) and σ complexes (carbocations).

Despite such similar problems, however, there are significant differences in the reactivities of olefins in bromination compared with mercuration. For example, the rates of bromination generally increase with additional methyl substitution at the double bond whereas mercuration follows the opposite trend as illustrated in Figure 19. Clearly,



Scheme 8. Comparative mechanisms of bromination and oxymercuration of olefins.

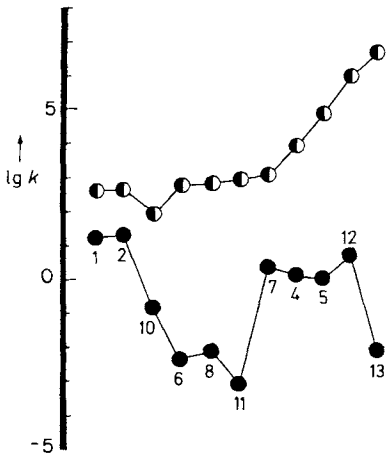


Fig. 19. Comparison of the reactivities of various olefins in oxymercuration with use of $Hg(OAc)_2$ (●) and in electrophilic bromination (◐) in methanol [42]. 1 = 1-pentene, 2 = 1-hexene, 4 = cyclohexene, 5 = cycloheptene, 6 = cyclooctene, 7 = styrene, 8 = (*Z*)-methylstyrene, 10 = 3,3-dimethyl-1-butene, 11 = (*E*)-4,4-dimethyl-2-pentene, 12 = 2-methyl-2-butene, 13 = 2,3-dimethyl-2-butene.

the reactivity patterns of the olefins are quite different for these processes—*the two generally following opposite trends*. The relative rates of bromination increase with the donor property of the olefin as measured by its ionization potential. On the other hand, the relative rates of oxymercuration show little correlation with bromination, let alone with the ionization potentials of the olefins—the most electron-rich, 2,3-dimethyl-2-butene (13 in Fig. 19), actually reacting substantially slower than the reference 1-pentene (1 in Fig. 19). Such discrepancies have been discussed in terms of differences in the rate-determining steps—that for mercuration being either the formation of π or σ complexes or the subsequent nucleophilic attack (especially by the solvent) and that for bromination being the complex formation. Generally, a combination of electronic, steric, and solvent effects has been invoked in order to understand the trends in olefin reactivity. No general mechanistic formulation has been brought forth, and the analysis of the reactive intermediates has not succeeded in explaining the significant differences in olefin reactivity between bromination and mercuration.

4.2.1. The Charge-Transfer Correlation

The relative reactivity of various olefins in electrophilic bromination, given by $\lg(k/k_0)_{Br_2}$ where k_0 refers to the reference 1-pentene, is compared directly with the relative reactivity in oxymercuration ($\lg(k/k_0)_{HgX_2}$) in Figure 20a.[42] The random, "buckshot" appearance of the plot encourages no correlation between these two electrophilic processes. However, if the work term (evaluated independently as Δw_p^* from the CT spectra according to Equation (35)) is simply included in with the relative reactivity, the remarkable transformation of the data is shown in Figure 20b. The linear correlation in Figure 20b is expressed as Equation (55). In other words, *when the work terms for the*

$$\left(\ln\frac{k}{k_0}+\frac{\Delta w_p^*}{RT}\right)_{Br_2}=\left(\ln\frac{k}{k_0}+\frac{\Delta w_p^*}{RT}\right)_{HgX_2} \qquad (55)$$

olefin-bromine and olefin-mercury(II) interactions are included, the relative reactivities of various olefins to electrophilic bromination and mercuration are identical. We interpret such an unprecedented relationship to signify that related transition states are actually involved in these apparently dissimilar processes [see Eq. (43) or (44)]. As a corollary to this conclusion, the relative reactivities in bromination and oxymercuration are expected to be the same in the absence of steric differences among olefins. Indeed, this prediction is borne out with a series of *para*-substituted styrenes that show quite similar reactivity trends in bromination and oxymercuration.[43]

4.2.2. Unity of Bromination and Oxymercuration according to FERET

The ability of the quantitative relationship in Equation (55) to successfully unify electrophilic bromination and oxymercuration is a direct consequence of FERET as generally outlined in Scheme 6. Thus the experimental correlation in Figure 20b with the work terms Δw_p^* is equivalent to the FERET with the CT energies $h\nu_{CT}$ in Equation (37), since it follows from Equation (35) that

$$[\Delta w_p^*(Br_2)-\Delta w_p^*(HgX_2)]=[\Delta h\nu_{CT}(Br_2)-\Delta h\nu_{CT}(HgX_2)]$$

for the same series of olefins with ΔI_D in common. The validity of the CT relationship depends on the ability to evaluate the work term arising from the mutual interaction of the olefin with the electrophile, be it bromine or a mercury(II) derivative. This treatment differs significantly from earlier attempts to correlate the reactivity of olefins in electrophilic additions. Although it is generally recognized that steric effects can be distinguished from polar effects in linear free-energy relationships, the approach has been largely empirical.[44] Indeed, the rate constants for bromination have been extensively analyzed in terms of Taft polar (σ^*) and steric (E_s) parameters, the relative contributions of each depending on the substitution and the topological pattern about the double bond.[45] However, in order to carry out a similar Hammett-Taft type of analysis for oxymercuration, *Pritzkow* et al.[46] were forced to employ four parameters to develop a reliable correlation. On the other hand, the direct relationship between electrophilic bromination and mercuration in Figure 20b evolves naturally from the experimental data by a purely operational approach with use of steric effects as evaluated by Equation (35).

4.3. Aromatic Substitution versus Alkene Addition

The definition of an *electrophilic reaction* forms an important pedagogical basis of organic chemistry, especially as it refers to olefin additions and aromatic substitutions.[47] It is generally recognized that alkenes are significantly more reactive than arenes in a variety of electrophilic processes. Although experimental data that allow direct quantitative comparisons between alkene and arene reactivity are scarce, there are clear indications of the problem. For example, the electrophilic chlorination of benzene ($I_D=9.23$ eV) in acetic acid proceeds slowly with a second-order rate constant of $1.54\times10^{-6}\,M^{-1}s^{-1}$, whereas the chlorination of 1-butene, which is a weaker donor ($I_D=9.63$ eV), proceeds at much faster rates even in nonpolar solvents. The electrophilic mercuration of benzene with $Hg(OAc)_2$ proceeds with a second-order rate constant of $7.5\times10^{-7}\,M^{-1}\,s^{-1}$ in acetic acid, but 1-pentene ($I_D=9.52$ eV) reacts with $Hg(OAc)_2$ in methanol more

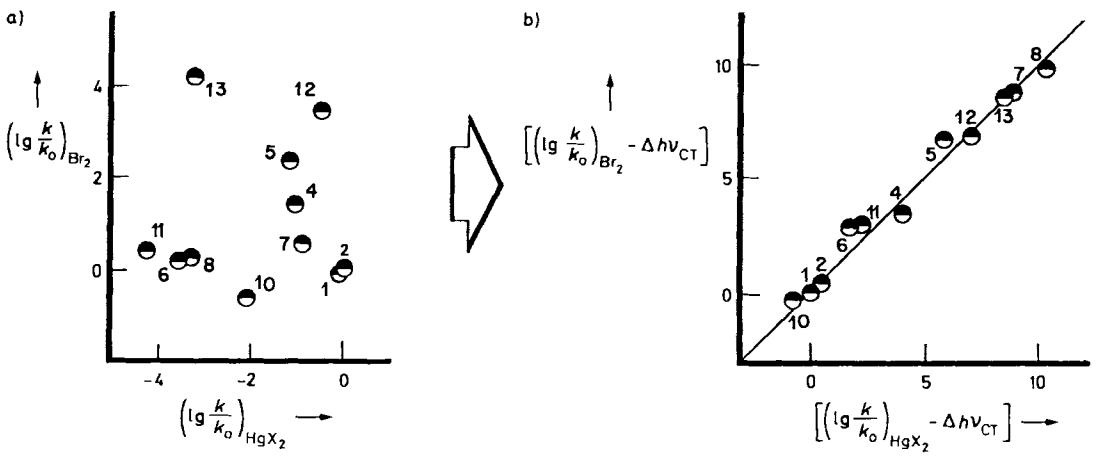

Fig. 20. Direct comparison of the relative reactivity of olefins in mercuration and bromination before (a) and after (b) inclusion of the steric effects. The line is arbitrarily drawn with a slope of unity to emphasize the fit to Equation (55). For identification of the olefins, see Figure 19 [42].

than 2×10^7 times faster than benzene. Such reactivity differences and solvent effects are difficult to assess quantitatively by the conventional mechanisms of electrophilic processes. The relative rates of various electrophilic additions and substitutions have been successfully correlated with the donor properties of substituted alkenes and arenes such as those based on the Taft σ^* constants and the Brown σ^+ constants, respectively.[32,41] Indeed, these linear free energy relationships provide considerable understanding of the influence of molecular structure on electrophilic reactivity. As successful as these empirical correlations have been for alkenes and arenes *separately*, however, no general mechanistic formulation has been brought forth to unify the concepts of electrophilic reactivity.[48] Thus no quantitative insight has been educed to relate alkene donors and arene donors with features of commonality sufficient to explain their significant differences in reactivity toward various electrophiles. Furthermore, no quantitative accounting of solvent effects in electrophilic addition and substitution is extant.

4.3.1. Charge-Transfer Correlation

Molecular bromine has served as an ideal electrophile for mechanistic studies owing to its facile reactions with both olefins and aromatic compounds. Since these reactions occur at measurable rates in a wide variety of solvents, extensive kinetic studies have been carried out on electrophilic brominations. In Figure 21a we find a direct relationship between the reactivity of alkenes and arenes in electrophilic brominations ($\lg k_{Br_2}$) and the charge-transfer transition energies ($h\nu_{CT}$) of their EDA complexes.[49] Indeed, the experimental plot shows two linear but separate correlations—the one for arenes is described by Equation (56), that for alkenes by Equation (57). The expression

$$\lg k_{Br_2} = -16 h\nu_{CT} + 55 \quad (56)$$

$$\lg k_{Br_2} = -4.1 h\nu_{CT} + 20 \quad (57)$$

for the arenes in Equation (56) merits special attention, since the slope of the correlation is remarkably close to unity when $RT\lg k_{Br_2}$ is plotted against $-\Delta h\nu_{CT}/(2.3RT)$ [cf. Eq. (45) and Fig. 15]. In other words, the reactivity of the arene in electrophilic bromination, as represented by the activation free energy $\Delta G^{\neq} = -RT\ln(k_{Br_2}/Z)$, corresponds directly to the charge-transfer transition energy in the arene–bromine complex [Eq. (58)]. However, the

$$\Delta G^{\neq} = h\nu_{CT} + \text{constant} \quad (58)$$

same does not apply to alkene bromination, as shown by the different correlation in Equation (57). Indeed, the inapplicability of Equation (58) to alkenes is reflected in the huge difference in reactivity between alkenes and arenes when they are evaluated at the same donor ability. For example, ethylene, which represents the least reactive alkene, is still more than 50 times as reactive as anisole, the most reactive arene, even after discounting the substantial difference of 32 kcal mol^{-1} in their CT donor abilities. Clearly, the CT transition energy $h\nu_{CT}$ does not provide sufficient means by itself to bridge the gap in electrophilic reactivity between alkenes and arenes. In order to understand the reactivity difference between alkenes and arenes, let us return to the FERET formulation in Scheme 6.

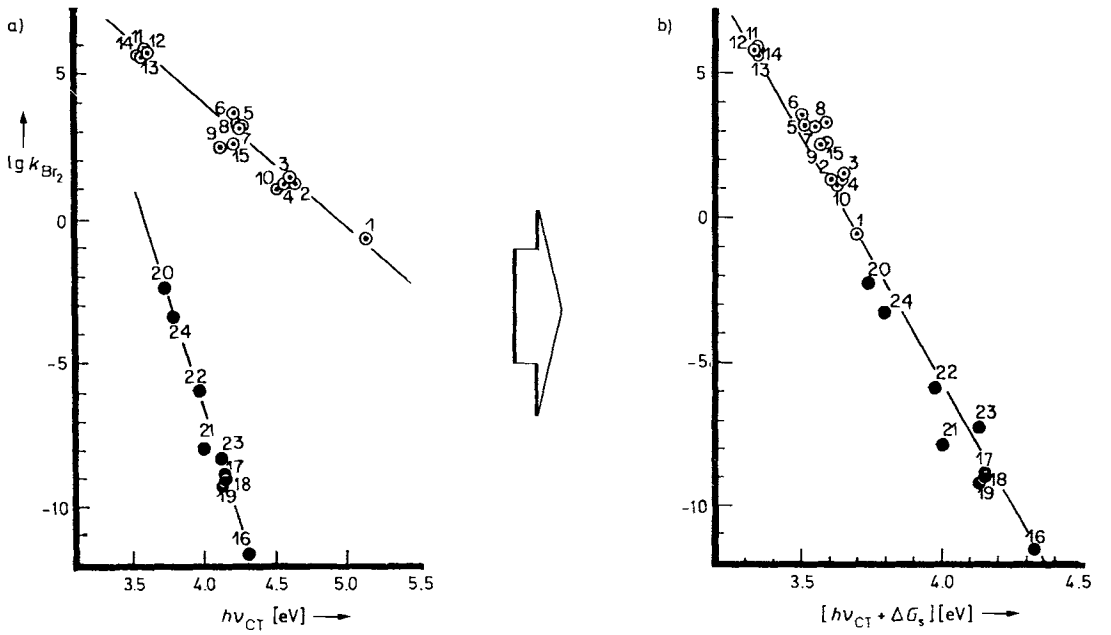

Fig. 21. a) Correlation of the logarithms of the rates k_{Br_2} [M^{-1} s^{-1}] of electrophilic bromination with the CT transition energies ($h\nu_{CT}$) of the bromine complexes of alkenes (⊙) and arenes (●): 1 = ethylene, 2 = propylene, 3 = 1-butene, 4 = 1-pentene, 5 = isobutylene, 6 = 2-methyl-1-butene, 7 = (*Z*)-2-butene, 8 = *E*-2-pentene, 9 = (*E*)-4,4-dimethyl-2-pentene, 10 = 3,3-dimethyl-1-butene, 11 = 2,3-dimethyl-2-pentene, 12 = 2,3-dimethyl-2-butene, 13 = 2,3-dimethyl-2-hexene, 14 = 2,3-dimethyl-2-heptene, 15 = cyclohexene, 16 = C_6H_6, 17 = MeC_6H_5, 18 = EtC_6H_5, 19 = $iPrC_6H_5$, 20 = $MeOC_6H_5$, 21 = *o*-$Me_2C_6H_4$, 22 = *m*-$Me_2C_6H_4$, 23 = *p*-$Me_2C_6H_4$, 24 = 1,3,5-$Me_3C_6H_3$). b) Unified correlation by FERET in Equation (60) [49]. The slope of the correlation is unity.

4.3.2. Solvation Energies of Arene Cations versus Alkene Cations

The conversion of the alkene–bromine and arene–bromine EDA complexes to their respective CT excited ion pairs $[D^{\oplus}, A^{\ominus}]^*$ occurs (Scheme 6) with minimal changes in solvation. Thus the relative donor properties of alkenes and arenes measured from the CT transitions represent essentially those in the gas phase. By contrast, the thermal activation of electrophilic brominations in solution is an adiabatic process in which the formation of the adiabatic ion pair $[D^{\oplus}, A^{\ominus}]_s$ must be accompanied by large changes in solvation. Therefore, any comparison of the reactivity of arenes and alkenes in electrophilic brominations according to this model must specifically address the question of solvation. Let us focus our attention on only the solvation change associated with the donor moiety, since the bromine acceptor is common to both systems. Indeed, for the solution process, we need consider only that energy change for the oxidation of the alkene and arene moiety, as given by the standard oxidation potentials E^0_{ox}. The latter can be measured by fast-scan cyclic voltammetry with microelectrodes [see Eq. (47)]. However, the anodic oxidation of most alkenes is irreversible even at CV scan rates of 200000 $V\,s^{-1}$ owing to the kinetic instability of their radical cations. Thus the solvation energies of the transient alkene and aromatic cations cannot be simultaneously determined by the direct method described in Equation (38). However, solvation energies can be evaluated from the free energy relationship for electron transfer such as that established for the outer-sphere oxidation of organometal donors with tris(phenanthroline)iron(III) oxidants $[FeL_3]^{3\oplus}$ [Eq. (18)]. Indeed, a detailed kinetic study of the oxidation of a series of arenes by $[FeL_3]^{3\oplus}$ establishes the outer-sphere character of the rate-limiting electron-transfer step [Eq. (59)].[50]

$$\text{ArylH} + [FeL_3]^{3\oplus} \xrightarrow{k_{Fe}} \text{ArylH}^{\oplus} + [FeL_3]^{2\oplus} \qquad (59)$$

As such, the first-order form of the Marcus free energy relationship can be used to evaluate the endergonic driving force ΔG for Equation (59). Since alkene oxidations with $[FeL_3]^{3\oplus}$ proceed in a similar manner, the difference in the driving forces for arene and alkene donors can be evaluated from the kinetics data.[49] This procedure is tantamount to the evaluation of the solvation energies of all the cations relative to that of a reference donor. We arbitrarily choose the aromatic cations as the reference, since their solvation energies are rather invariant at 2.0 eV for a series of aromatic compounds in acetonitrile (see Fig. 16). Thus the solvation energy of an alkene cation can be evaluated relative to that of an aromatic cation under isokinetic conditions, i.e., the rate at which the oxidation of an alkene is the same as that of an arene, $\Delta G^{\ddagger}(\text{Alkene}) = \Delta G^{\ddagger}(\text{Arene})$. From this we find the relative solvation energy ΔG^s_r of the alkene cation to be $\Delta G^s_r = -I_D$. The values of ΔG^s_r obtained in this manner are listed in Table 4 for the various alkenes. The relative solvation energies in acetic acid can be obtained from those evaluated in acetonitrile by using the Born model.[49] These are also listed in Table 4 together with the relative solvation energies of alkene cations in the aprotic tetrachloroethane. There is a trend for the solvation energies of transient alkene cations to vary with the substituents on the double bond. In general, the magnitude of the solvation energy is seen to decrease as the number of methyl substituents increases, approaching that of aromatic cations. Thus the solvation energies of these transient cations do reflect the degree of charge delocalization.[51]

Table 4. Solvation energies of transient alkene cations.

Alkene	I_D [eV]	ΔG^s_r [eV] MeCN	HOAc	$(ClCH_2)_2$
$H_2C{=}CH_2$	10.52	1.69	1.45	0.98

4.3.3. Unified View of the Transition States for Electrophilic Bromination of Alkenes and Arenes

The evaluation of the solvation energies of transient cations allows the donor abilities of alkenes and arenes in solution to be determined from the gas-phase data. Let us now make an analogous connection between the ion pairs generated photochemically by CT excitation and those formed thermally by an adiabatic electron transfer in solution, as presented in the thermochemical cycle in Scheme 6. Indeed, the extent to which the formation of the solvated ion pair in Scheme 6 is equivalent to the activation barrier $\Delta G^{\ddagger}$ for electrophilic bromination is then given by Equation (60). (Note the contribution from the solvation of the common bromine moiety is included in the constant term.[52])

$$RT\ln k_{Br_2} = h\nu_{CT} + \Delta G^s_r + \text{constant} \qquad (60)$$

The experimental fit of the rate data for electrophilic bromination to Equation (60) is shown in Figure 21b, which is a remarkable transformation of the two separate correlations for alkenes and arenes in Figure 21a. In other words, bromine addition to alkenes and bromine substitution of arenes are included in a single correlation, despite their distinctive stoichiometries and widely divergent rates. We interpret such an unprecedented interrelationship to signify that related transition states are involved in these otherwise disparate processes. The fit of the experimental data in Figure 21b to the line arbitrarily drawn with a slope of unity (i.e., $-(2.3\,RT)^{-1}$) emphasizes the 1 : 1 correspondence between the kinetic barrier $(-RT\ln(k_{Br_2}/Z))$ for electrophilic bromination and the energetics of ion-pair formation in solution. Although the precise structure of the

transition state is presently unknowable in detail, the correlation provided by Equation (60) indicates that the solvated ion pair is certainly a feasible model of the transition state for both alkene addition and aromatic substitution.[53] Indeed, it provides the common means to unify the very large differences in the reactivity of alkenes and arenes toward bromine in a quantitative way.

4.3.4. Significance of the CT Formulation to Other Linear Free Energy Relationships. Unity of Brown σ^+ and Taft σ^* Constants

The charge-transfer formulation in Scheme 6 for electrophilic bromination leads to the conception of the transition state as the solvated ion pair. In the general form, Equation (60) is applicable to both alkenes and arenes. As such, we show how this formulation unifies the two separate linear free energy relationships that have been previously developed independently for electrophilic additions to alkenes and for electrophilic aromatic substitutions. In particular, the rates of electrophilic aromatic substitution are well correlated by the Brown σ^+ aromatic substituent constants [Eq. (61)].[44] Likewise, the rates of electrophilic additions to alkenes approximate a similar free energy relationship based on the Taft σ^* aliphatic substituent constants [Eq. (62)].[55] Since the sensitivity factors ρ and ρ^* in

$$\lg \frac{k}{k_0} = \rho\sigma^+ \tag{61}$$

$$\lg \frac{k}{k_0} = \rho^*\sigma^* \tag{62}$$

Equations (61) and (62), respectively, have been subjected to various physical interpretations, our primary task is to relate ρ and ρ^* to the CT formulation in which the parameters bear definitive physical significance.

We begin by noting that the CT transition energy $h\nu_{CT}$ is linearly related to the ionization potentials of alkene and aromatic donors by a single correlation [Eq. (63)]. Likewise, the solvation term ΔG_r^s for alkenes in Table 4 is rather linear with the ionization potential [Eq. (64)], where

$$h\nu_{CT} = 0.7 I_D + \text{constant} \tag{63}$$

$$\Delta G_r^s = \alpha I_D + \text{constant} \tag{64}$$

α is the solvent-dependent slope of the relationship (e.g., $\alpha = 0.6$ for acetic acid). As mentioned earlier, the value of ΔG_r^s for the aromatic donors is constant irrespective of the solvent. Linear relationships have been well established for the substituent constants σ^* and σ^+ as a function of the ionization potential of the alkene and aromatic donors, respectively:[54]

alkenes: $\sigma^* = 1.1 I_D + \text{constant}$

arenes: $\sigma^+ = 1.1 I_D + \text{constant}$

The combinations of these equations with Equation (60) afford alternative forms of the free energy relationship:

alkenes: $\lg \frac{k}{k_0} = -15(0.7-\alpha)\sigma^*$

arenes: $\lg \frac{k}{k_0} = -11\sigma^+$

The comparison of these expressions with the original linear free energy relationships in Equations (61) and (62) leads to the important result that the sensitivity factors in electrophilic brominations are given by Equations (65) and (66) for alkenes and arenes, respectively.

$$\rho^* = -15(0.7-\alpha) \tag{65}$$

$$\rho = -11 \tag{66}$$

According to Equation (66), the relative reactivity of arenes in electrophilic substitution is solvent independent. The data available in the extant literature for glacial acetic acid and trifluoroacetic acid support this conclusion (Table 5). Furthermore, the solvent dependency of the electrophilic bromination of alkenes as predicted by Equation (65) accords with the experimental results in media as different as glacial acetic acid and tetrachloroethane. The calculated values of ρ and ρ^* in Table 5 show reasonable agreement with the experimental values. The agreement is especially noteworthy considering that the absolute magnitude of ρ and ρ^*, otherwise unpredictable, can be independently evaluated in different solvents. Since alkenes and arenes show common relationships between $h\nu_{CT}$ and I_D as well as between σ^* or σ^+ and I_D, the principal difference in their reactivities toward electrophilic bromination can be attributed to differences in the solvation of alkene and aromatic cations. The charge-transfer formulation, which we have outlined in Scheme 6 and expressed by the FERET in Equation (60), provides a direct and general method for evaluating the activation barriers of electrophilic brominations. The CT transition energy represents the energetics of ion-pair formation and serves as a model for the activation process when changes in solvation are explicitly taken into account. Thus the single correlation of the remarkable free energy relationship in Figure 21b underscores the conceptual unity of the activation process for both electrophilic addition to alkenes and electrophilic substitution of arenes. Moreover, the charge-transfer formulation of the activation process employs physical concepts amenable to direct molecular interpretation. Indeed, the notion of the solvation of ion pairs offers a general solution to solvent effects in electrophilic reactions. The question of whether the adiabatic ion pairs are actual intermediates along the reaction coordinate of electrophilic

Table 5. Comparison of the experimental and calculated values of ρ and ρ^* for electrophilic brominations in several solvents.

Donor	Solvent	ρ or ρ^*	
		exp.	calcd
Arenes	HOAc	−12.1 [a]	−11
Arenes	CF_3CO_2H	−12.3 [b]	−11
Alkenes	CH_3CO_2H	− 2.8 [b]	− 2.4

[a] From [32g]. [b] See [49].

brominations is, of course, not directly addressed (see Section 5). We emphasize that the charge-transfer formulation, in a more general context, relates to the electron-rich nucleophiles (such as alkenes and arenes as electron donors) and the electron-poor electrophiles (such as bromine as electron acceptors) as they were broadly envisioned by *Mulliken* in his pioneering approach to intermolecular interactions.

4.4. Halogenolysis of Alkyl-Metal Bonds

The cleavage of alkyl-metal bonds by halogens, or halogenolysis, is one of the most common reactions of organometals RM [Eq. (67)].

$$RM + X_2 \longrightarrow RX + MX \qquad (67)$$
$$X = F, Cl, Br, I$$

Such substitution reactions effected by electrophiles are basic to our understanding of a wide variety of organic syntheses via organometallic intermediates.[56] Despite extensive studies, however, there is surprisingly little quantitative information known about the structural factors important in electrophilic substitution at a carbon-metal bond. The mechanism of the electrophilic pathway is still the subject of controversy, largely revolving around the depiction of the transition state—whether it is two- or four-centered, open, cyclic, etc. Although kinetic and stereochemical probes have been extensively employed, the mechanistic difficulties have doubtlessly been exacerbated by the implicit assumption, uniformly adopted, that electrophilic processes are concerted, involving no viable intermediates. The latter is somewhat surprising in view of earlier reports of the existence of complexes between organosilanes and halogens.[57] In the cleavage of unsymmetrical alkylmetals such as tetraalkyltin Me_nSnR_{4-n} (n = 1-3) or dialkylmercury MeHgR, the selectivity S(R/Me) determines the relative rates of scission of the relevant bonds, i.e., an R-Sn bond versus a Me-Sn bond, as an intramolecular competition. Thus, iodine affords a mixture of two alkyl iodides, MeI and RI, from R_2SnMe_2 in amounts which depend upon the relative rates of cleavage [Eqs. (68) and (69)].

$$R_2SnMe_2 + I_2 \longrightarrow \begin{cases} \longrightarrow MeI + R_2SnMeI & (68) \\ \longrightarrow RI + RSnMe_2I & (69) \end{cases}$$

The selectivity, $S(R/Me) = k_R/k_{Me}$, is completely analogous to that presented for electron transfer [Eqs. (27) and (28)]. As such S(R/Me) is a measure of the intrinsic reactivity of a given alkylmetal irrespective of the substitution patterns in a series of Me_nSnR_{4-n} compounds. The solvent is known to play a large, dominating role in the iodinolysis of alkylmetals, particularly with regard to the rate and selectivity.[58] For example, the second-order rate constants for iodinolysis of tetraalkyltin compounds in acetonitrile are 10^2 to 10^3 times faster and the rate constants in tetrachloromethane 10^3 to 10^4 times slower than those obtained in dichloromethane solutions. In addition to the large sensitivity of the rates to variations in the solvent, there is a remarkable inversion in the relative rates of reactivity. For example, Et_4Sn is about ten times more reactive than Me_4Sn in dichloromethane, but the order is reversed in acetonitrile. Finally, in the iodinolysis of all tetraalkyltin compounds, there is a marked dependence of selectivity on the solvent. There are even notable reversals in selectivity with solvent polarity, e.g., $S(n\text{Bu/Me}) = 0.0040$ in acetonitrile but 1.7 in tetrachloromethane, and $S(\text{Et/Me}) = 0.11$ in acetonitrile but 6.7 in tetrachloromethane.

4.4.1. Charge-Transfer Correlation

The relative rates of iodinolysis are evaluated for various tetraalkyltins by the comparative procedure, i.e., $\Delta G_r^{\ddagger} = -2.3\,RT\lg(k/k_0)$, where k and k_0 are the rates for R_4Sn and Me_4Sn, respectively. The free-energy change ΔG_r^0 for the oxidation of a tetraalkyltin relative to Me_4Sn in solution is obtained directly from the difference in their ionization potentials in the gas phase, i.e., $\Delta G_r^0 = \alpha \Delta I_D$, where the proportionality constant α is 0.60 in acetonitrile solutions at 25 °C.[16] The accompanying change in the interaction energy ΔE of the thermal ion pair is equated to $\Delta w_p^{\ddagger}$ determined from the transition energy of the CT complex [Eq. (35)]. The striking correlation in Figure 22 with a slope of 1.0 represents a linear free energy relationship expressed as Equation (70), which is the FERET described

$$\Delta G_r^{\ddagger} = \Delta G_r^0 + \Delta w_p^{\ddagger} \qquad (70)$$

earlier in Equation (44).[54] It is important to point out that Equation (70) for alkylmetal iodinolysis obtains directly from three independent sets of experiments.

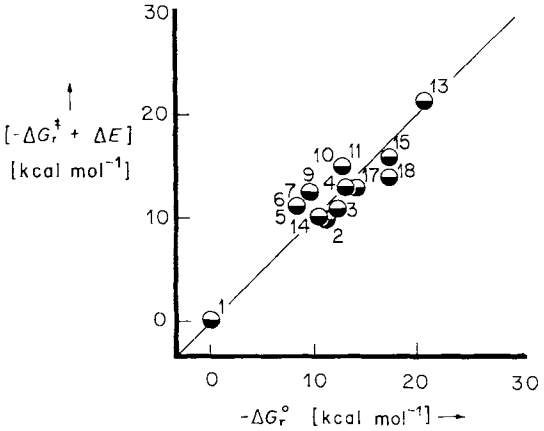

Fig. 22. The correlation of the changes in the activation free energy for iodinolysis of tetraalkyltin compounds with changes in the driving force for $[RM^{\oplus}, I_2^{\ominus}]$ formation. $\Delta E = \Delta w_p^{\ddagger}$. 1 = Me_4Sn, 2 = Et_4Sn, 3 = nPr_4Sn, 4 = nBu_4Sn, 5 = $EtSnMe_3$, 6 = $nPrSnMe_3$, 7 = $nBuSnMe_3$, 9 = Et_2SnMe_2, 10 = nPr_2SnMe_2, 11 = nBu_2SnMe_2, 13 = tBu_2SnMe_2, 14 = Et_3SnMe, 15 = iPr_4Sn, 17 = iBu_4Sn, 18 = iBu_2SnMe_2 [54].

4.4.2. FERET for the Solvent Effects in Halogenolysis

The same FERET can even be established in nonpolar solvents in which ΔG_r^0 cannot be determined. For example, the linear correlation in both Figures 23a and 23b for iodinolysis of tetraalkyltin compounds in dichloromethane and dialkylmercury compounds in tetrachloromethane, re-

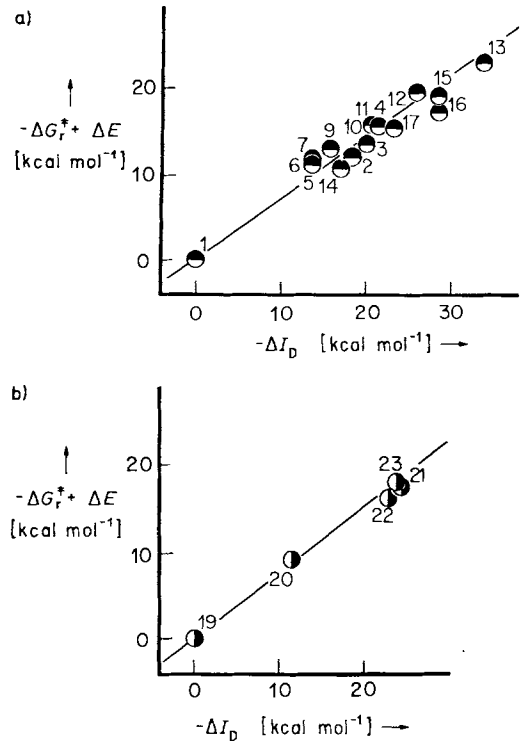

Fig. 23. Linear free energy relationships established in the iodinolysis of alkylmetals in nonpolar media. $\Delta E = \Delta w_p^{\neq}$. a) Tetraalkyltin compound in CH_2Cl_2. b) Dialkylmercury compound in CCl_4. Numbers refer to alkyltin compounds in Figure 22 (with the exception of 18) and the following alkylmercurials: 19 = Me_2Hg, 20 = EtHgMe, 21 = nPr_2Hg, 22 = nBu_2Hg, 23 = iBu_2Hg [54].

spectively, corresponds to the following linear free energy relationship:

$$\Delta G_r^{\neq} - \Delta w_p^{\neq} = \Delta G_r^0 = \alpha \Delta I_D$$

From the slopes, α is evaluated as 0.71 in dichloromethane and 0.77 in tetrachloromethane. As expected, these values are larger than $\alpha = 0.60$ in the more polar acetonitrile. Indeed, the solvent effect on the rates of iodinolysis provides an important test of FERET in dealing with the rather unusual inversion in the reactivities. Thus, the relative reactivities of various R_4Sn are obtained directly from Equation (70) [Eq. (71)].

$$-RT \ln \frac{k}{k_0} = \alpha \Delta I_D + \Delta w_p^{\neq} \qquad (71)$$

Since the variations in the relative reactivities with solvent are represented by changes in α, these are drawn in Figure 24 as a family of solid lines calculated from the FERET in Equation (71). The fit to the available experimental rate data, indicated by the shaded circles, is unmistakable.[54] In other words, a single parameter α correctly predicts the marked alteration in reactivity order of alkylmetals, which in previous treatments could only be attributed to solvent-induced changes in mechanism.[58]

4.4.3. Polarity of the Activated Complex for Halogenolysis

Since the charge-transfer formulation quantitatively accounts for the reactivities of alkylmetals in iodinolysis, we might inquire about the structural factors involved. In gen-

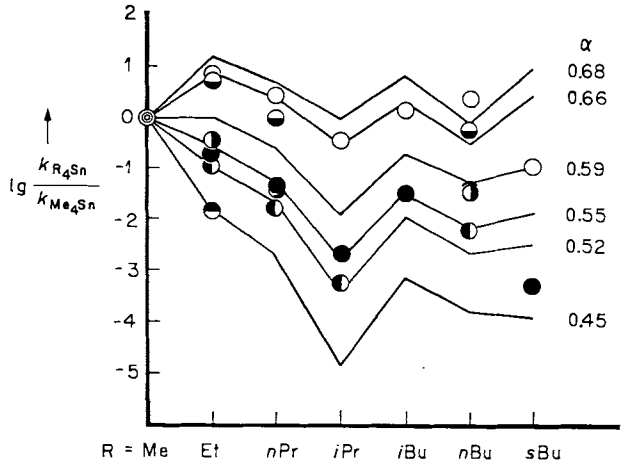

Fig. 24. Prediction of the solvent effect on the relative reactivities according to the FERET in Equation (71). The solid lines are calculated for various α in [54]. ○ = CH_2Cl_2, ◒ = PhCl, ◑ = AcOH, ● = MeCN, ◐ = MeOH, ◓ = DMF.

eral terms, $\alpha \Delta I_D$ and ΔE correspond to the electronic and steric contributions, respectively, to the activation process. The solvent effect is primarily associated with changes in the electronic effect, owing to variations in α. As the solvent increases in polarity, α decreases and steric effects become dominant—leading to $k_{Me_4Sn} > k_{Et_4Sn}$ in glacial acetic acid, acetonitrile, methanol, and dimethylformamide (Fig. 24). The reverse reactivity $k_{Me_4Sn} < k_{Et_4Sn}$ obtains in nonpolar solvents such as chlorobenzene and dichloromethane in which the electronic demand is optimized as a result of the increased values of α. The importance of solvent polarity may also be examined in another way. Thus the activation free energy, as described by the charge-transfer mechanism, relates directly to the free energy of formation of the ion pair. Consequently, the role of the solvent on the rate is largely reduced to its effect on the ion pair. Despite the lack of knowledge regarding solvent structure, we can estimate the solvation of the ion pair from a macroscopic property of the solvent.[59] Such an approach is described by the classical Kirkwood equation in which the ion pair is considered as a dipolar solute with dipole moment μ in a solvent of bulk dielectric constant ε_B. The electrostatic contribution to the chemical potential or the free energy of solvation is given by Equation (72), where $\phi(\varepsilon_B) = (\varepsilon_B - 1)/(2\varepsilon_B + 1)$ and a is the radius of the solute consid-

$$\Delta G_s = -(\mu^2/a^3)\phi(\varepsilon_B) \qquad (72)$$

ered as a sphere. In the series of alkylmetal–iodine CT complexes considered here, the reactants have no dipole moment. Accordingly, in the charge-transfer reaction, the change in the solvation term in solvents such as MeCN, EtOH, PhCl, $CHCl_3$, and Me_2CO relative to that in dichloromethane may be written as Equation (73), where $\mu^{\neq}$

$$\Delta E_s = -\Delta\Delta G_s^{\neq} = (\mu^{\neq 2}/a^3)\Delta\phi(\varepsilon_B) \qquad (73)$$

is the dipole moment in the transition state.[54] There is a more or less linear correlation of the solvation energy and the dielectric function according to Equation (73). It suggests that the slope $\mu^{\neq 2}/a^3 = 2.5$ is constant for these solvents. If, for the moment, we consider the dipolar CT so-

lute to be approximated by a sphere, then the degree of charge separation is estimated to be between 0.8 and 1. The crude model notwithstanding, this analysis of the solvent effect provides further support for the high degree of charge separation in the rate-limiting transition state for the iodinolysis of alkylmetals. These results, together with the clean linear free energy relationship in Equation (70) or its equivalent in Equation (71), provide strong evidence that the transition state for electron transfer is accurately reflected by the excited ion pair in the CT complex. As such, this conclusion forms the basis for describing the activation process for iodinolysis as electron transfer in the CT complex.

4.4.4. Selectivity and the Charge-Transfer Mechanism for Iodinolysis of Alkylmetals

The preequilibrium formation of the alkylmetal–iodine charge-transfer complex is included in the general mechanism [Eqs. (74)–(76)] for the iodinolysis of alkylmetals. The

$$RM + I_2 \overset{K_{CT}}{\rightleftharpoons} [RM, I_2] \quad (74)$$

$$[RM, I_2] \xrightarrow{k} [RM^{\oplus}, I_2^{\ominus}] \quad (75)$$

$$[RM^{\oplus}, I_2^{\ominus}] \xrightarrow{\text{fast}} RI + MI \quad (76)$$

activation process for iodinolysis is represented in Equation (75) for inner-sphere electron transfer from the alkylmetal donor to the iodine acceptor. The subsequent sequence of reactions following the CT activation process can be readily formulated on the basis of studies with other acceptors such TCNE and $[IrCl_6]^{2\ominus}$ [see Eqs. (25) and (26)].

According to Equations (74)–(76), the selectivity is determined by the cage fragmentation of the $[RM^{\oplus}, I_2^{\ominus}]$ ion pair [Eq. (76)] subsequent to the rate-limiting step. As such, an important question that evolves is: How does the nature of the ion pair affect the fragmentation pattern of the $RM^{\oplus}$ moiety leading to changes in selectivity? To answer this question, we refer to Equations (18) and (19) as well as to Equations (25) and (26), in which the selectivity was shown to decrease from 25 to 11 on going from an outer-sphere to an inner-sphere mechanism (see Table 2). Such outer-sphere and inner-sphere mechanisms are differentiated primarily by the intermolecular separation between the alkylmetal and the oxidant in the transition state for electron transfer. Extending this relationship, we consider the lower selectivities in iodinolysis to arise from selective interactions between $RM^{\oplus}$ and $I_2^{\ominus}$, which are dictated largely by steric effects. For a charge-transfer model, the alkyltin–iodine interaction can be depicted as shown in Scheme 9.[60]

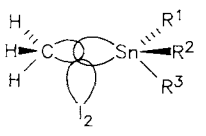
The extent of the resonance interaction is given by the relationship[61] $\xi = \xi^0 V_r$ with $V_r = V_r^0 \exp(-r^*)$, where V_r is the overlap integral and r^* is the mean separation between I_2 and alkylmetal; ξ^0 and V_r^0 are constants. The extent of the resonance interaction between I_2 and the least hindered site in the alkylmetal, i.e., the Mn–Sn bond, will lead to reductions in the selectivity S(R/Me) in the following way. We first select $[IrCl_6]^{2\ominus}$ as the reference acceptor in which the resonance interaction with the alkylmetal is taken as nil, i.e., the selectivity S_0 is determined solely by the relative bond energies D_{Me} and D_R for dissociation of $Me^{\odot}$ and $R^{\odot}$ from the alkylmetal radical cation $Me_nSnR_{4-n}^{\odot\oplus}$. The selectivity for the reference system is given by $RT \ln S_0 = D_{Me} - D_R$. For iodinolysis, the selectivity can then be represented as Equation (77) if one assumes

$$RT \ln S = RT \ln S_0 - \xi \quad (77)$$

that D_{Me} is reduced to $D_{Me} - \xi$ by the resonance interaction between $MeSnR_3^{\oplus}$ and $I_2^{\ominus}$.[54] Equation (77) can be expressed in a form which emphasizes the relationship between the selectivity and mean separation [Eq. (78)]. The

$$\ln S = -A \exp(-r^*) + B \quad (78)$$

constants are $A = \xi^0 V_r^0 / RT$ and $B = \ln S_0$. Since changes in the mean separation are a measure of the steric effect, Equation (78) indicates how the selectivity may be affected by steric effects, all within the context of the charge-transfer ion pair. In other words, a strong resonance interaction in the ion pair, mediated by the mean separation, can quantitatively account for changes in selectivity with solvent variations as described above. The cleavage of an alkyl–metal bond under these circumstances is highly reminiscent of a concerted process, more commonly referred to as an electrophilic cleavage. As a result, the two concepts become largely indistinguishable at this extreme. Indeed, the charge-transfer formulation provides new meaning to the concept of electrophilic cleavage, which has heretofore been a rather generic mechanistic description.



Scheme 9. Charge-transfer model of the alkyltin–iodine interaction.

4.4.5. Solvent Effect on the Relationship between Selectivity and Rate Constant for Halogenolysis

In the CT formulation, the perturbation by steric effects is included in the work term Δw_p^* [Eq. (35)]. The solvent effect may also be expressed as a perturbation in similar form, i.e., $RT \ln(k_m/k_n) = e^2(r_m^{-1} - r_n^{-1})$, where the subscripts m and n refer to different solvents.[54] Thus, the problem reduces to one of describing the solvent-induced change in the mean separation. A direct attack on this problem lies in the measurement of the CT transition energies in various solvents. Unfortunately, this route is experimentally unavailable owing to complications arising from the rapid rates of iodinolysis in all but the least polar solvents. The alternative approach derives from the strong influence of solvent on the intramolecular selectivity. To carry out this analysis, we introduce the term $\delta S = \ln(S_0/S)$, where S is the selectivity of a particular alkylmetal in iodinolysis and S_0 is that selectivity in a reference system (arbitrarily chosen as $[IrCl_6]^{2\ominus}$). The relationship between the changes in selectivity and mean separation, as

they are affected by solvent, can be represented by $\delta S_m/\delta S_n = \exp(r_n - r_m)$. The relationship between the rate constants and selectivities as they are affected by solvent is then expressed as Equation (79),[54] which correctly pre-

$$\ln \frac{k_m}{k_n} = (r_m r_n RT)^{-1} \ln \frac{\delta S_m}{\delta S_n} \tag{79}$$

dicts the inverse relationship between the rate constant and the selectivity in the iodinolysis of alkylmetals. Furthermore Equation (79) accords with the linear selectivity changes with the solvent dependence on the iodinolysis rates. The slope of the correlation is given by $(r_m r_n RT)^{-1}$, from which the mean value $\bar{r}_{mn}$, ranging from 3.7 Å for Et_2SnMe_2 to 4.1 Å for tBu_2SnMe_2, is evaluated. The relative magnitudes of $\bar{r}_{mn}$ for Et_2SnMe_2 and tBu_2SnMe_2 accord with qualitative expectations based on steric effects. More interestingly, the difference (0.40 eV) in ΔE for these alkylmetals, calculated from the differences in CT transition energies and ionization potentials according to Equation (35) is in surprisingly good agreement with the value (0.37 eV) evaluated from $\bar{r}_{mn}$.

4.5. Solvent Effects on Electrophile Behavior toward Organometals

The formulation of reaction mechanisms has been aided by the studies of solvent effects on the rates.[62] In many cases, the solvent variation is treated as a perturbation in which the lack of a smooth correlation with reactivity in a series of related compounds is often considered to be diagnostic of a change in mechanism.[63] For example, the large changes in reactivity, even inversions in the order of reactivity, when the medium for the halogenolysis of an alkylmetal is altered from a polar to a nonpolar solvent is illustrated in Figure 25.[31] As a result, the participation of different mechanisms has been proposed to account for such drastic changes. Such a conclusion is not required, however, since a complex pattern of solvent effects may be accommodated within the context of a single mechanism if

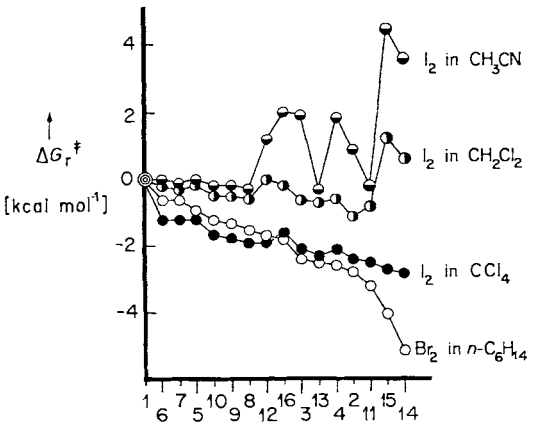


Fig. 25. The reactivity patterns in the halogenolysis of tetraalkyltin compounds in different solvents [31]. The compounds corresponding to the numbers are given in Fig. 12.

cognizance is taken of the mixing of electronic, steric, and solvation effects, as a result of solvent changes. There are several features in Figure 25 which merit special emphasis, and they may be summarized as follows: (1) Changes in reactivity resulting from structural variations in the tetraalkyltin compounds have little bearing on the solvent dependences. (2) In nonpolar solvents such as CCl_4 and hexane, the difference between brominolysis and iodinolysis is minimal. (3) The change in reactivity imposed by solvent changes can be much larger than any wrought by structural alterations of the alkyl ligands. For example, in iodinolysis the difference in the reactivity ($\Delta G^{\neq}$) of sBu_4Sn in acetonitrile and n-hexane is $RT \lg k_m/k_n = 7.2$ kcal mol^{-1}, corresponding to a rate factor of 2×10^5, whereas it is only 4.8 kcal mol^{-1} between the most reactive (sBu_4Sn) and the least reactive (Et_3SnMe) tetraalkyltin compounds in acetonitrile. (4) The change in the reactivity of alkylmetals can be as large in nonpolar solvents (hexane) as in polar solvents (acetonitrile).

4.5.1. Charge-Transfer Correlations with Solvent Variations

The free energy change for solvation ΔG_s associated with the charge-transfer process in Equation (75) is the difference between the gas-phase ionization potential I_D and the free energy change for oxidation in solution.[16] It can be evaluated directly from the FERET in Equation (37) by measuring the CT energies and halogenolysis kinetics in various solvents.[31] Indeed, the trend in ΔG_s for tetraalkyltin compounds obtained in one solvent parallels that in another, as shown by the series of striking linearities of the points in Figure 26 in which the different solvents are compared to tetrachloromethane. In other words, the solvent sensitivity of the solvation energy can be expressed simply as Equation (80), where ΔG_s^0 is taken for the reference sol-

$$\frac{\Delta G_s}{\Delta G_s^0} = \delta \tag{80}$$

vent and the δ values are the slopes in Figure 26. Since the solvation of ions is one of the least understood, but basic aspects of chemical reactions, we rely on a rather conventional model for solvation in the following analysis.

4.5.2. Solvation Energies

The modified Born equation is commonly used to estimate the free energy change associated with the solvation of simple ions.[64] As applied to the solvation energy ΔG_s of the tetraalkyltin cation, it is expressed in relative terms by Equation (81), where N is Avogadro's number, e is the

$$\Delta G_s = -\frac{N}{2} e^2 \left(1 - \frac{1}{\varepsilon}\right) \left[\frac{1}{r + r'} - \frac{1}{r_0 + r_0'}\right] \tag{81}$$

electronic charge, ε is the dielectric constant, and r and r_0 are the crystal radii of the cations $R_4Sn^{\oplus}$ and $Me_4Sn^{\oplus}$, respectively. The correction terms r' and r_0' represent the incremental changes in the corresponding radii attendant upon solvation. The solvent-induced change in ΔG_s can be

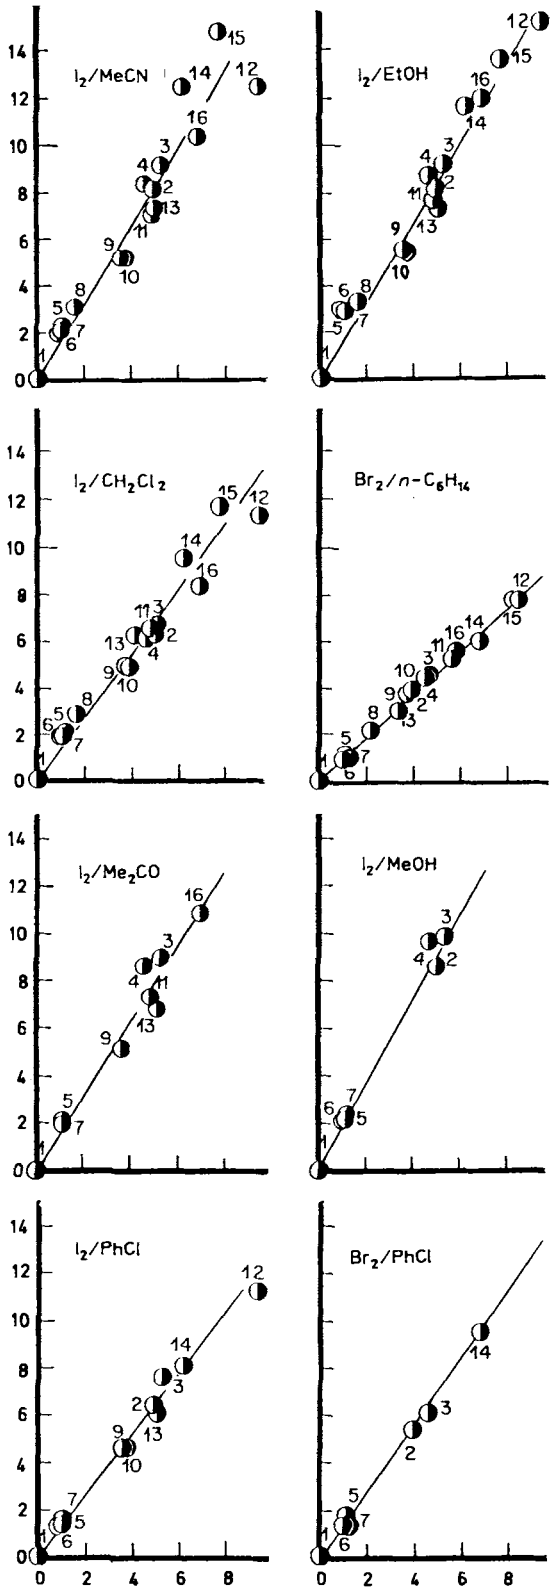

Fig. 26. Comparison of the solvation energies ($\Delta G_r^{\ddagger} - \Delta h\nu_{CT}$) [kcal mol^{-1}] obtained from the halogenolysis data for the compounds in Figure 25 according to the FERET in Equation (80) in tetrachloromethane (abscissa) with those in the solvents indicated (ordinate).

evaluated from Equation (81) relative to a reference solvent as Equation (82), where ε_0 is arbitrarily taken as the

$$\frac{\Delta G_s}{\Delta G_s^0} = \frac{1-\varepsilon^{-1}}{1-\varepsilon_0^{-1}} \qquad (82)$$

dielectric constant of tetrachloromethane. This ratio of solvation energies was represented as the slopes in Figure 26 [cf. Eq. (80)]. The reasonable agreement between the ratios calculated according to Equation (82) and the experimental ratios from Equation (80) is shown in Table 6. Although

Table 6. Comparison of the calculated ratios of the solvation energies ΔG_s in various solvents according to the Born model and the experimental values for the halogenolysis reactions given in Figure 26.

Solvent	ε	$\Delta G_s/\Delta G_s^0$ exp. I_2	Br_2	calcd
n-Hexane	1.907		0.9	0.86

MeCN	37.5	1.72		1.76

[a] Reference solvent.

neither r nor r' are known for $R_4Sn^{\oplus}$, the values of the mean separation r_{DA} in the CT complexes of tetraalkyltin and the halogen may be obtained from the Mulliken equation (34) by taking the work term to be purely Coulombic.[65] For the moment, let us assume that r_{DA} is related to $(r+r')$ by the simple additive relationship $r_{DA}+C_4=r+r'$, where C_4 is a constant, especially for the symmetrical, quasi-spherical tetraalkyltin compounds R_4Sn. Indeed, a value of $C_4=-0.75$ Å is obtained from the best fit of the Born equation (81) to the solvation energy evaluated by the FERET in Equation (37). The agreement, both in acetonitrile and in tetrachloromethane solutions, is illustrated by the fit to the line of unit slope in Figure 27. Although the choice of the Born model for solvation of $R_4Sn^{\oplus}$ may be crude, the consistency with the experimental observations based on the FERET is unmistakable.

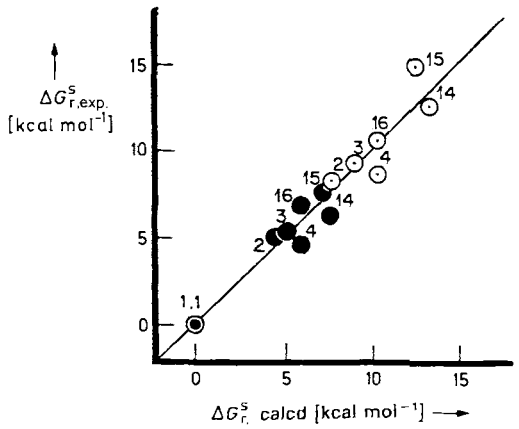

Fig. 27. Comparison of the solvation energies for symmetrical tetraalkyltin cations calculated by the Born equation (abscissa) and the experimental values obtained from Equation (80) in acetonitrile (⊙) and in tetrachloromethane (●). Note the fit to the line of unit slope. 1 = Me_4Sn, 2 = Et_4Sn, 3 = nPr_4Sn, 4 = nBu_4Sn, 14 = iPr_4Sn, 15 = sBu_4Sn, 16 = iBu_4Sn (cf. Fig. 12) [31].

4.5.3. *FERET for the Variations of Solvent and Electrophile*

The charge-transfer formulation in Equation 37 can be applied directly to the straightforward resolution of the

complex reactivity patterns which include three independent variables—namely, the changes in the donor (various alkyltin), the acceptor ($HgCl_2$, I_2, Br_2), and the solvent (CCl_4, CH_2Cl_2, CH_3OH).[66] Since the ionization potential is commonly applied to electron-transfer processes, it is plotted against the alkyltin reactivity with different acceptors for various solvents in Figure 28. No clear correlation

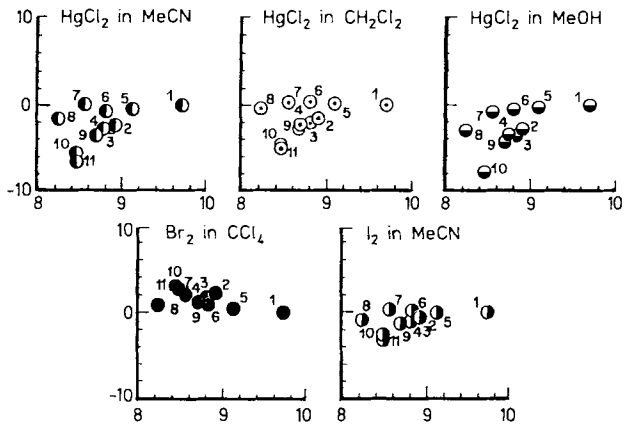

Fig. 28. Relative reactivities, as $\lg k/k_0$ (ordinate), of tetraalkyltin compounds with various electrophiles in different solvents as a function of their ionization potentials I_D [eV] (abscissa). 1 = Me_4Sn, 2 = Et_4Sn, 3 = nPr_4Sn, 4 = nBu_4Sn, 5 = $nBuSnMe_3$, 6 = nBu_2SnMe_2, 7 = iPr_2SnMe_2, 8 = tBu_2SnMe_2, 9 = iBu_4Sn, 10 = iPr_4Sn, 11 = sBu_4Sn [66].

between I_D and $\lg k/k_0$ can be discerned in any of the systems undergoing electrophilic cleavage. This is not surprising since the plot in Figure 28 is tantamount to a direct comparison of electron transfer leading to ions with that involving ion-pair formation (see Scheme 4). Figure 29 shows the new correlations of the relative reactivities after inclusion of the CT contribution by the amount $(\Delta w_p^* + \Delta G_s)$ according to the FERET in Equation (43). The striking linear correlations in Figure 29 show a remarkable transformation of the relative reactivities in Figure 28, which are severly scattered. *Indeed, if all the experimental points in Figure 29 were plotted on a single figure, they would all lie on a single line* with a slope of -16.9,

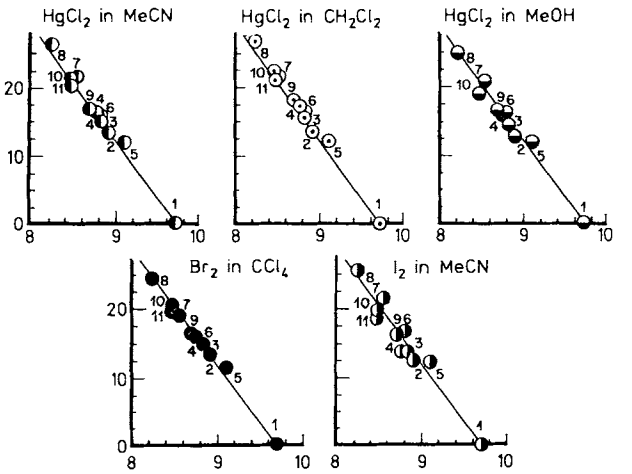

Fig. 29. Correlation of the data in Figure 28 after application of the FERET in Equation (83). Ordinate: $\lg k/k_0 + (\Delta E + \Delta G_s)/(2.3\,RT)$.

which corresponds to $-(2.3\,RT)^{-1}$ in the units used here. Since the energetics are determined from three independent measurements, namely, the ionization potential, the charge-transfer transition, and the solvation energy, these measurements are sufficient to determine completely the three variables affecting the rate of electrophilic cleavage, namely, the donor, the acceptor, and the solvent. Such a fit to the experimental data is represented by the FERET in Equation (83) [cf. Eq. (43)] as illustrated in Figure 29. This

$$-RT\ln\frac{k}{k_0} = \Delta I_D + \Delta E + \Delta G_s \qquad (83)$$

fit can hardly be fortuitous but must be taken as compelling support for the charge-transfer formulation as Equation (83). This formulation underscores the strong similarity between the CT excited state, i.e., the photochemically excited ion pair $[RM^{\oplus}, X_2^{\ominus}]^*$ and the transition state or the thermal ion pair $[RM^{\oplus}, X_2^{\ominus}]_s$ in the halogenolysis. The subtle balance between the electronic effect ΔI_D, the steric effect $\Delta E = \Delta w_p^*$, and the solvation energy ΔG_s thus determines the reactivities of alkylmetals in halogenolysis, particularly with respect to solvent variation.

4.5.4. *Charge-Transfer Mechanism for Electrophilic Cleavage of Alkylmetals by Mercury(II) Derivatives*

The preequilibrium formation of alkylmetal-mercury(II) complexes is included in the general mechanism for electrophilic cleavage [Eqs. (84)–(86)]. The activation process

$$RM + HgX_2 \overset{k_{DA}}{\rightleftharpoons} [RM,HgX_2] \qquad (84)$$

$$[RM,HgX_2] \xrightarrow{k_{ET}} [RM^{\oplus},HgX_2^{\ominus}] \qquad (85)$$

$$[RM^{\oplus},HgX_2^{\ominus}] \xrightarrow{\text{fast}} RX + RHgX \qquad (86)$$

for mercury(II) cleavages is represented in Equation (85) by the formation of the ion pair.[52] It is supported by the excellent linear correlations in Figure 29 resulting from the application of Equation (83) which directly equates the activation process for electrophilic cleavage with changes in the electronic, steric, and solvation energies for ion-pair formation. In Equations (84)–(86), the products arise subsequent to the rate-limiting electron-transfer step and are largely associated with the spontaneous fragmentation of the alkylmetal cation and recombination in the solvent cage.[67] The lability of $HgX_2^{\ominus}$ (formally a mercury(I) intermediate) accords with the facile dissociative electron capture by $HgCl_2$ to afford $Cl^{\ominus}$ and HgCl.[68]

4.6. Diels–Alder Cycloadditions with Tetracyanoethylene

Transient colors were noted in the earliest studies of the Diels–Alder reaction and ascribed to diene–dienophile complexes, then regarded as intermediates in only the vaguest sense.[69] *Andrews* and *Keefer*[70] first paid attention to the color formation and spectroscopically established the occurrence of 1 : 1 complexes between arenes and dienophiles such as maleic anhydride and benzoquinone. Transient colors have also been observed in the [2 + 2] cycloadditions of electron-rich alkenes such as aryl vinyl sulfides

and electron-poor alkenes such as tetracyanoethylene. However, the mechanistic importance of such EDA complexes has been difficult to assess quantitatively. Indeed, little or no attention has been paid to the role of EDA complexes in the majority of the mechanistic studies of either the Diels–Alder reaction or the [2+2] cycloaddition reactions. The mechanistic involvement of EDA complexes is further obscured by the kinetics dilemma as to whether they are key intermediates along the reaction pathway [Eq. (87a)] or merely innocent bystanders in an otherwise dead-end equilibrium [Eq. (87b)].

$$D + A \overset{K_{DA}}{\rightleftharpoons} [D,A] \xrightarrow{k_1} \text{adduct} \qquad (87a)$$

$$[D,A] \overset{K_{DA}}{\rightleftharpoons} D + A \xrightarrow{k_2} \text{adduct} \qquad (87b)$$

As a result, the need to accommodate EDA complexes in mechanistic considerations has generally been ignored.[71] Thus, the experimental evidence that the Diels–Alder reaction and the related [2+2] cycloadditions pass through EDA complexes has apparently had little impact on the bulk of the mechanistic output for these synthetically important reactions.[72] Since the focus heretofore has been on only the *ground-state* properties of EDA complexes in thermal cycloadditions, it is of interest to examine the role of EDA complexes from the viewpoint of their CT *excited states*.

4.6.1. The Charge-Transfer Correlation

The direct relationship between the Diels–Alder reaction of anthracene with TCNE and the transient CT absorption is illustrated in the left portion of Figure 30a, in which the second-order rate constant is plotted against the CT transition energy. The linear correlation spans a range of more than 10^6 in rates and is expressed as Equation (88),[73] with a correlation coefficient of 0.99. Such a linear relationship is strikingly akin to the FERET in Equation (56) for an electrophilic bromination that represents a distinctly *different type* of reaction. Nonetheless, the equivalence of Equations (56) and (88) establishes a common activation process for electrophilic substitution and the [4+2] cycloaddition of arene donors. Let us therefore consider the significance of the charge-transfer excited state of arene donors with various acceptors.

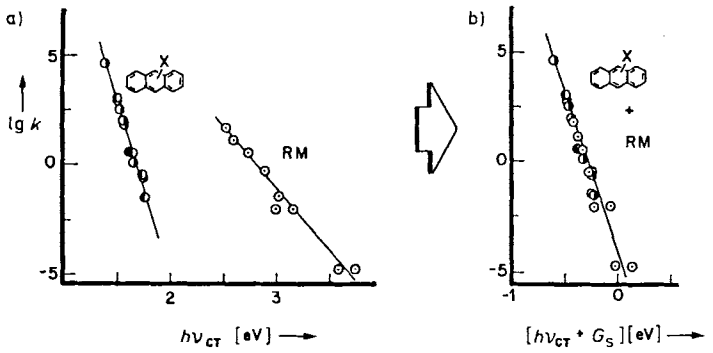

Fig. 30. a) The correlation of the logarithms of the rates ($\lg k$ [$M^{-1} s^{-1}$]) of TCNE reactions of anthracenes and alkylmetals with the charge-transfer transition energies $h\nu_{CT}$ of the EDA complexes identified in [73]. b) Unified correlation after the inclusion of solvation according to the FERET in Equation (93). X is, for example, H, 9-Me, 2-Me, 9-Et, 9-Br, 9,10-Me_2; RM = Et_nPbMe_{4-n} (n = 0–4), Me_4Sn, nBu_4Sn.

$$\lg k = -15.4 h\nu_{CT} + 26 \qquad (88)$$

4.6.2. Nature of the CT Excited State of Arene Donors

According to the Mulliken theory for weak EDA complexes of the types described for TCNE,[13] the spectral transition $h\nu_{CT}$ represents an electronic excitation from the neutral ground state to the polar excited state [Eq. (89)].

$$[\text{Arene,TCNE}] \xrightarrow{h\nu_{CT}} [\text{Arene}^{\oplus},\text{TCNE}^{\ominus}]^* \qquad (89)$$

The asterisk identifies an excited ion pair with the same mean separation r_{DA} as that in the EDA complex as described in Scheme 5. Such a Franck–Condon process can be examined directly by time-resolved picosecond spectroscopy. Thus the absorption spectra shown in Figure 31 clearly delineate the simultaneous appearance of the anthracene cation and the tetracyanoethylene anion immediately following the irradiation of the CT absorption band with a 25-ps laser pulse.[74] There is no evidence from the picosecond absorption data for either the existence of an excited state of the EDA complex or the formation of any intermediate states or species other than $Arene^{\oplus}$ and $TCNE^{\ominus}$. The electron transfer from the donor to the acceptor in the EDA complex thus effectively occurs with the absorption of a photon. Such a formulation therefore represents a direct confirmation of Mulliken theory,[13] in which excitation into the charge-transfer band of an EDA complex consisting of a relatively nonpolar ground state leads to the production of an ion pair.

4.6.3. FERET for the Diels–Alder Cycloaddition with TCNE

Based on the striking correlation shown in Figure 30a and expressed in Equation (88), we conclude that the formation of the ion pair [Eq. (89)] is tantamount to the activation process for anthracene cycloaddition to TCNE [Eq. (90)].

$$\text{Arene} + \text{TCNE} \longrightarrow [\text{Arene}^{\oplus},\text{TCNE}^{\ominus}]_s \qquad (90)$$

Taken further we suggest that the ion pair $[Arene^{\oplus},TCNE^{\ominus}]_s$ is a reasonable approximation to the transition state for the thermal Diels–Alder process. It should be noted, however, that the transition state is attained by an adiabatic process, whereas the CT excitation represents a vertical transition. As such, the CT excited ion pair in Equation (89) involves minimal changes in solvation, which occurs only in a subsequent relaxation process [Eq. (91)]. (For example, the relaxation from the Franck–Con-

$$[\text{Arene}^{\oplus},\text{TCNE}^{\ominus}]^* \xrightarrow[\text{solvent}]{\text{fast}} [\text{Arene}^{\oplus},\text{TCNE}^{\ominus}]_s \qquad (91)$$

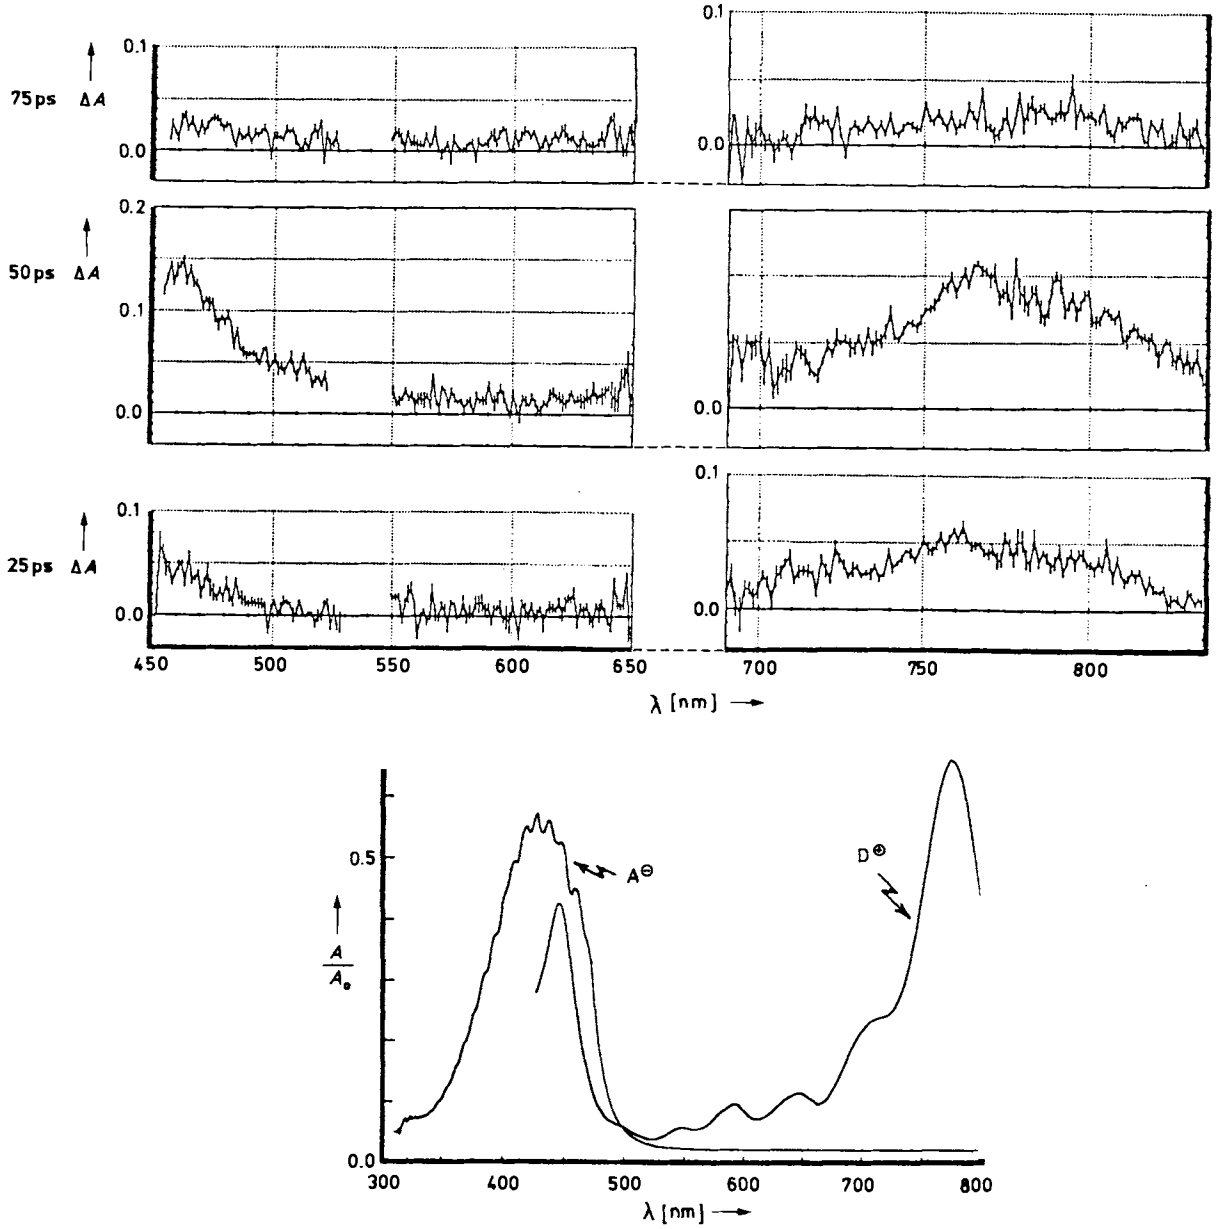

Fig. 31. Upper: Time-resolved spectra 25, 50, and 75 ps following the 532-nm, 25-ps laser pulse of the EDA complex of 9-cyanoanthracene and TCNE in CH_2Cl_2. Lower: The absorption spectra of 9-cyanoanthracene cation ($D^{\oplus}$) and tetracyanoethylene anion ($A^{\ominus}$) generated separately by spectroelectrochemical methods.

don excited state to the equilibrium fluorescent state is associated with an extraordinarily large Stokes shift of 34 kcal mol^{-1} for the toluene–benzenetetracarbonitrile EDA complex in toluene.[75]) By contrast, the formation of the polar ion pair by a thermal activation must be an adiabatic process which is accompanied by changes in solvation, as indicated by the subscript s in Equation (90). The free energy change for solvation (G_s) of anthracene cations is obtained from the gas-phase ionization potential and the reversible oxidation potential (E^0) in solution [cf. Eq. (38)]. The solvation energies are then evaluated quantitatively by use of the relationship[76] $G_s = I_D - E^0 - C$, where G_s is the free energy change in solvation relative to the neutral arene, E^0 is the standard oxidation potential of the anthracenes, and C is a constant which includes the potential of the reference electrode on the absolute scale together with the liquid junction potentials. The values of the solvation energies of the anthracene cations obtained in this manner are remarkably invariant.[77] This underscores the essential equivalence of the [Arene$^{\oplus}$,TCNE$^{\ominus}$] ion pair generated for the CT excited state [Eq. (89)] with that developed for the transition state [Eq. (90)]. Accordingly, the FERET can be expressed as Equation (92), which is equivalent to the gen-

$$\Delta G^{\neq} = h\nu_{CT} + \text{constant} \tag{92}$$

eralized free energy relationship in Equation (37) with the changes in the Arene$^{\oplus}$ solvation remaining invariant. Indeed, the extent to which the latter is true predicts that the simple FERET in Equation (92) will be applicable to all (electrophilic) aromatic reactions independent of their classification as substitution, addition, etc. As a corollary,

let us now examine the reactions of these donor–acceptor pairs in which the electrophile component is common, and solvation changes cannot be considered to be invariant.

4.6.4. *Quantitative Comparison of Anthracene Cycloaddition and Alkylmetal Insertion with TCNE as the Common Electron Acceptor*

An important test of the CT formulation for anthracene cycloaddition would be provided by demonstrating its interrelationship with the alkylmetal insertion [Eqs. (39)–(41)], particularly since the rates differ by a factor of more than 10^9. If the CT activation of the Diels–Alder reaction is valid, it must also relate directly to the activation process for alkylmetal insertion of TCNE, for which the CT interactions have already been established.[27] Such an interrelationship must be made in the teeth of the apparent diversity of the two processes shown in Figure 30a, in which the linear free energy relationship for anthracene cycloaddition differs from that for alkylmetal insertion in two important ways. First, the correlation of the alkylmetals is displaced by about 1 eV to higher energies relative to the anthracene correlation. Second, the slope of the alkylmetal correlation is quite different from the slope of the anthracene correlation, being smaller by a factor of more than 2. The correlations in Figure 30a do not specifically include solvation changes. It is clear, however, that solvation must be taken into account, since values of G_s from Equation (38)[28] in the two processes differ in significant ways. For example, G_s for the various anthracene cations is rather invariant with structure, whereas ΔG_s for the alkylmetal cations is not only structure dependent, but quite a bit larger as well.[73] If the change in solvation ΔG_s is included in the correlation, the two separate lines in Figure 30a are remarkably merged into a single line (Fig. 30b). Thus the activation processes for anthracene cycloaddition and alkylmetal insertion of TCNE are both described by a single, common relationship [Eq. (93). According to Equation

$$\Delta G^{+} = h\nu_{CT} + G_s + \text{constant} \qquad (93)$$

(93), the higher reactivity of alkylmetals relative to anthracenes derives from the larger changes in solvation during the activation process. Otherwise, there is no intrinsic difference in the activation barrier between anthracene cycloaddition and alkylmetal insertion with tetracyanoethylene.

4.6.5. *Quantitative Comparison of the Formation of Aromatic and Alkylmetal Cations in Solution*

The activation processes for anthracene cycloaddition and alkylmetal insertion with TCNE are representative of an inner-sphere mechanism for electron transfer. As such, the interaction energy w_p of the ion pairs, [Arene$^{\oplus}$,TCNE$^{\ominus}$] and [RM$^{\oplus}$,TCNE$^{\ominus}$], which is evaluated as the Coulombic work term, makes an important contribution to the activation barrier. At this juncture, the question arises as to the nature of such ion-pairs, particularly with regard to the full development of charge and the structural integrity of the component donor cation. (Note the TCNE counteranion is common to both processes.) In order to address this question, we direct our attention to the chemical oxidation of alkylmetals and aromatic compounds by the series of outer-sphere iron(III) oxidants $[FeL_3]^{3\oplus}$ with L = substituted 1,10-phenanthroline ligands [see Eqs. (18) and (59), respectively]. The second-order rate constants (k_2) of such outer-sphere electron transfers provide a means of directly comparing the energetics associated with the formation of aromatic cations, with those of alkylmetal cations, where both are formed rather free from strong counterion influences. In Figure 32a, the rate

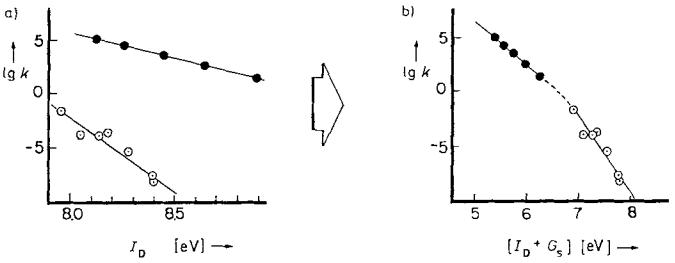

Fig. 32. Correlation of the rates of the outer-sphere oxidation with $[Fe(phen)_3]^{3\oplus}$ and the vertical ionization potentials I_D of alkylmetals (●) and aromatic compounds (⊙) before (a) and after (b) inclusion of cation solvation with the FERET in [73].

constants ($\lg k$) for the oxidations with $[Fe(phen)_3]^{3\oplus}$ are plotted against the ionization potentials of the alkylmetal and the aromatic compounds.[73] The linear correlations correspond to the relationship $\lg k = \alpha I_D + \text{constant}$, where $a = -16.9$ and -4.9 for the aromatic compounds and the alkylmetals, respectively. It is important to note that in these outer-sphere oxidations, the reactivity of a given alkylmetal is clearly more than 10^9 times greater than the reactivity of an aromatic compound with the same value of I_D. However, if the difference in cation solvation is taken into account, the reactivity of aromatic compounds follows the same trend as the alkylmetals (Fig. 32b). The resulting unity of alkylmetals and aromatic compounds in outer-sphere electron transfer can be expressed in terms of a single linear free energy relationship based on Marcus theory (compare with Section 4.3.2). At this point, however, we wish to emphasize that the dramatic effect of cation solvation in merging the outer-sphere oxidation of aromatic compounds and alkylmetals in Figure 32b is exactly the same FERET as that employed in the merging of the ion pairs in the inner-sphere mechanism in Figure 30b. Indeed, such an equality provides strong support for the CT formulation of the ion pairs [Arene$^{\oplus}$,TCNE$^{\ominus}$] and [RM$^{\oplus}$,TCNE$^{\ominus}$] as transition-state models in anthracene cycloaddition and alkylmetal insertion with tetracyanoethylene.

5. Ion Pairs [D$^{\oplus}$,A$^{\ominus}$] as Reactive Intermediates

In Section 4, we successfully demonstrated how the FERET in Equation (37) together with its corollaries (43) and (44) *quantitatively* predicts the *activation barriers* of a number of organic and organometallic reactions commonly thought of as electrophilic or nucleophilic proc-

esses. The seminal question now arises as to whether the ion pairs $[D^{\oplus}, A^{\ominus}]$ actually lie along the reaction coordinates. If so, how are such reactive intermediates related to the transition states of the electrophilic (or, equivalently, the nucleophilic) processes?

In order to address these issues let us arbitrarily select for further scrutiny only one of these processes, namely, electrophilic aromatic substitution (see Section 4.1) in which the independent evidence for the existence of the donor cation (i.e., $ArylH^{\oplus} = D^{\oplus}$)[78] facilitates its identification and the recognition of its behavior.[79] Before doing so, however, we hasten to add the caveat that the (steady-state) concentration of such a reactive intermediate is always limited in a thermal (adiabatic) process since the rate of its destruction is perforce much faster than the rate of its formation.[80] Accordingly, various indirect methods must be applied to test the viability of $[Arene^{\oplus}, A^{\ominus}]$ as a reactive intermediate in aromatic substitutions.

The traditional mechanism for aromatic substitution with an electrophile $A^{\oplus}$ is outlined in Scheme 10.[32,38]

$$ArylH + A^{\oplus} \underset{}{\overset{\text{fast}}{\rightleftharpoons}} [ArylH, A^{\oplus}] \quad \pi \text{ complex}$$

$$[ArylH, A^{\oplus}] \xrightarrow{\text{slow}} [Aryl(H)A]^{\oplus} \quad \text{Wheland intermediate}$$

$$[Aryl(H)A]^{\oplus} \xrightarrow[B]{\text{fast}} ArylA + HB^{\oplus}$$

Scheme 10. The traditional mechanism of electrophilic aromatic substitution.

Let us first reconsider one of the most important classes of aromatic substitutions, namely, nitration with $A^{\oplus} = NO_2^{\oplus}$.

5.1. Electrophilic Aromatic Nitration

The idea that charge transfer may play a key role in aromatic nitration with nitryl cations was first suggested in 1945 by *Kenner*,[81] who envisaged an initial step that "involves transference of a π-electron". Later, *Brown* postulated charge-transfer complexes as intermediates, and *Nagakura* et al. provided further theoretical support for one-electron transfer between an aromatic donor (ArylH) and an electrophile such as $NO_2^{\oplus}$.[82] Despite notable elaborations by *Pederson, Perrin, Eberson,* and others,[83] this formulation has not been widely accepted for nitration and related electrophilic aromatic substitutions.[84] As broadly conceived, the important question focuses on the activation process(es) leading up to the well-established Wheland or σ intermediate.[85] In the electron-transfer mechanism, the formation of the radical ion pair **V** is the distinctive feature (Scheme 11).

Accordingly, the properties and behavior of the intimate radical ion pair **V** are crucial to establishing its relationship with the numerous facets[86] of electrophilic aromatic nitration. For these reasons it is especially important to know whether **V** will actually lead to the appropriate Wheland intermediates, and in the amounts necessary to establish the isomer distributions commonly observed in aromatic nitrations. However, the independent proof of **V** has

$$ArylH + NO_2^{\oplus} \underset{}{\overset{\text{fast}}{\rightleftharpoons}} [ArylH, NO_2^{\oplus}] \quad \text{EDA complex}$$

$$[ArylH, NO_2^{\oplus}] \xrightarrow{\text{slow}} [ArylH^{\odot\oplus}, NO_2^{\odot}]$$

$$\mathbf{V}$$

$$\mathbf{V} \xrightarrow{\text{fast}} [Aryl(H)NO_2]^{\oplus} \quad \text{Wheland intermediate}$$

$$[Aryl(H)NO_2]^{\oplus} \xrightarrow[B]{\text{fast}} ArylNO_2 + HB^{\oplus}$$

Scheme 11. Electron-transfer mechanism of electrophilic aromatic substitution.

not been forthcoming owing to its expectedly transitory character. Thus it cannot be observed, since its rate of anihilation will always be faster than its rate of production. An alternative approach is clearly required to test the viability of the electron-transfer mechanism.

Picosecond time-resolved spectroscopy has defined the relevant photophysical and photochemical processes associated with the charge-transfer excitation of an arene complex such as anthracene with tetranitromethane (TNM).[87] As applied to benzenoid donors ArylH, the formation of the pertinent radical ion pair by charge-transfer excitation is summarized in Equations (94)–(96). All the experimental

$$ArylH + TNM \overset{K}{\rightleftharpoons} [ArylH, TNM] \quad (94)$$

$$[ArylH, TNM] \xrightarrow{h\nu_{CT}} [ArylH^{\odot\ominus}, TNM^{\odot\ominus}] \quad (95)$$

$$[ArylH^{\odot\ominus}, TNM^{\odot\ominus}] \xrightarrow{\text{fast}} [ArylH^{\odot\ominus}, NO_2^{\odot}, C(NO_2)_3^{\ominus}] \quad (96)$$

$$\mathbf{VI}$$

observations with aromatic donors and TNM indeed coincide with this formulation.[88] Thus the exposure of *p*-dimethoxybenzene (DMB) to a nitrating agent such as TNM (Fig. 33a) leads immediately to the EDA complex in Equation (94). These binary complexes are present in low steady-state concentrations owing to the limited magnitudes of K as measured by the *Benesi-Hildebrand* method.[89] Activation of the EDA complex by specific irradiation of the CT band (Fig. 33b) results in a photoinduced electron transfer [Eq. (95)] in accord with Mulliken theory.[13] The irreversible fragmentation following the electron attachment to TNM leads to the geminate triad **VI** (see Equation

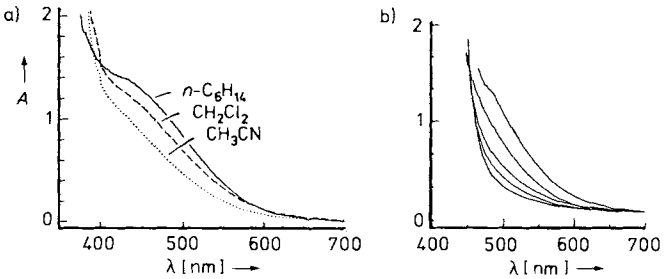

Fig. 33. a) Charge-transfer spectrum of the EDA complex of DMB and TNM in various solvents. b) Bleaching of the CT band upon constant irradiation at $\lambda > 425$ nm after (top to bottom) 0, 45, 120, 165, and 275 min.

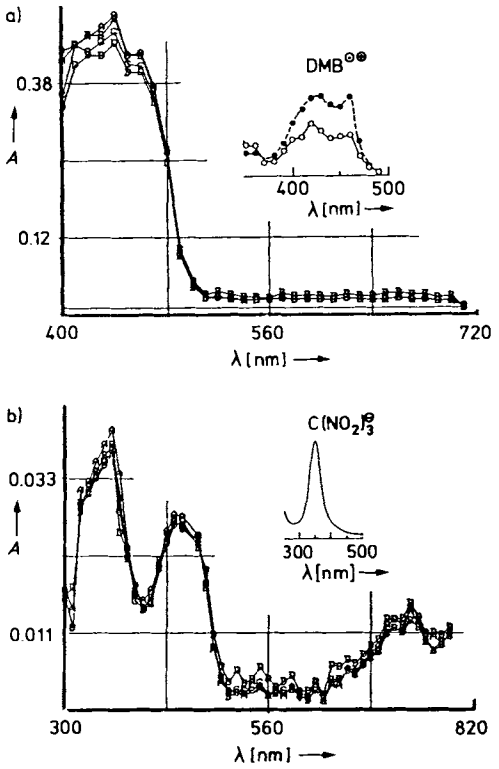

Fig. 34. Transient absorption spectra from the 25-ps laser-pulse excitation at 532 nm of the EDA complex from (a) 0.2 M DMB and 0.15 M TNM and (b) 0.1 M DMB and 0.02 M TNM in CH_2Cl_2. The insets are the absorption spectrum of (a) $DMB^{\odot\oplus}$ and (b) $C(NO_2)_3^{\ominus}$ as the tetrabutylammonium salt.

(96) and Fig. 34). The measured quantum yield of $\Phi \approx 0.5$ is similar to that ($\Phi \approx 0.7$) previously obtained for anthracene.[90] Such high quantum yields relate directly to the efficiency of geminate-triad production in Equation (96) relative to energy wastage by back electron transfer in Equation (95). Moreover, the short lifetime (<3 ps) of $TNM^{\odot\ominus}$ ensures that $ArylH^{\odot\oplus}$ and $NO_2^{\odot}$ are born as an intimate radical ion pair, initially trapped within the solvent cage, since this time scale obviates any competition from diffusional processes.[87,91] Charge-transfer excitation thus provides the experimental means to generate the intimate radical ion pair [$Aryl^{\odot\oplus}$,$NO_2^{\odot}$] **V** in sufficient concentrations and in a discrete electronic state as well as geometric configuration. In light of the fast kinetics allowed by the use of laser-flash photolytic techniques, we now focus on the pathways by which the radical ion pair collapses to nitration products.

The excellent material balance obtained in the charge-transfer nitration of DMB demands that the geminate triad **VI** proceed quantitatively to the nitration products according to Equation (97).[88]

$$\mathbf{VI} \longrightarrow ArylNO_2 + HC(NO_2)_3 \qquad (97)$$

Such a transformation must occur spontaneously with no discrimination among the reactive intermediates to accord with the absence of a deuterium kinetic isotope effect. The latter is not consistent with the collapse of **VI** as an ion pair [$ArylH^{\odot\oplus}$,$C(NO_2)_3^{\ominus}$] by proton transfer to the very weakly basic trinitromethanide. Furthermore, the presence of extra trinitromethanide (deliberately added as the tetrabutylammonium salt) exerts essentially no influence on either the course or the kinetics. Accordingly, $C(NO_2)_3^{\ominus}$ is merely an innocuous bystander insofar as the conversion of the geminate triad **VI** in Equation (97) is concerned. It follows that the disappearance of the arene radical ion must be directly related to its interaction with $NO_2^{\odot}$ [Eq. (98)].

$$\mathbf{V} \longrightarrow ArylNO_2 + H^{\oplus} \qquad (98)$$

Indeed, such radical cations have been prepared from various arenes by other experimental methods, especially electrochemical oxidation.[79] These arene radical cations are weak Brønsted acids, but they are highly susceptible to addition at the aromatic nucleus[92] [Eqs. (99) and (100)].

$$\mathbf{V} \longrightarrow Aryl(H)NO_2^{\oplus} \qquad (99)$$

$$Aryl(H)NO_2^{\oplus} \xrightarrow{k_H} ArylNO_2 + H^{\oplus} \qquad (100)$$

The σ adduct in Equation (99) is the Wheland intermediate in electrophilic nitration, which is known to show no deuterium kinetic isotope effect for k_H upon deprotonation [Eq. (100)].[93,94] The formation of the various isomeric Wheland intermediates (see Scheme 7) will occur from the collapse of the radical ion pair [Eq. (99)]. Consequently, the isomer distributions in the nitration products relate directly to the relative rates of addition to the various nuclear positions provided that the addition is irreversible and/or the adduct deprotonates rapidly. Thus the strong correlation observed between the spin densities at the various nuclear positions of $ArylH^{\odot\oplus}$ and the isomeric product distribution in aromatic nitration[33] bears directly on the mechanics of such a radical-ion-pair collapse to the Wheland intermediate.

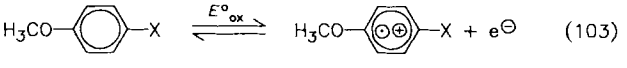
Indeed, time-resolved spectral changes of the radical cation $ArylH^{\odot\oplus}$ provide insight as to how it is formed. Thus the relatively long lifetime of the arene radical cation from DMB is sufficient to allow diffusive separation of the radical ion pair **V** to $ArylH^{\odot\oplus}$ and $NO_2^{\odot}$ as essentially "free" species [Eq. (101)].[95] The second-order process

$$\mathbf{V} \xrightarrow{>10^{-10}\,s} ArylH^{\odot\oplus} + NO_2^{\odot} \qquad (101)$$

with the rate constant k_2 for the disappearance of $DMB^{\odot\oplus}$ in Table 7 then represents the "re"-combination of these separated species to form the Wheland intermediate [Eq. (102)].

$$ArylH^{\odot\oplus} + NO_2^{\odot} \xrightarrow{k_2} Aryl(H)NO_2^{\oplus} \qquad (102)$$

For other arenes, however, the decay pattern of the spectral transients for nitration is strikingly dependent on the stability of the radical cations as measured by the one-electron oxidation potentials E^0 [Eq. (103)].[96]



(103)

The direct comparison of E^0 in Table 7 focuses on the substantial effect of substituents [Eq. (103)] on the inherent

stability of the aromatic radical cations. The decay of the spectral transients for nitration is a reflection of the stability of the aromatic radical cation. For example, the radical cation from *p*-methylanisole decays by second-order kinetics in acetonitrile, similar to the kinetic behavior of the long-lived radical cation from DMB.[88] The large difference in the rates of diffusive combination of $Aryl^{\odot\oplus}$ with $NO_2^{\ominus}$ in Table 7 (see column 4) corresponds to their rela-

Table 7. Kinetics of electron-transfer nitration of *p*-X-anisoles.

E° [V vs. SCE] [a]	X	Kinetics order [b]	k_2 [c]
1.30	Methoxy	2	1.0×10^4
1.67	Methyl	2	2.5×10^5
2.12	Fluoro	1	1.9×10^4
2.00	Chloro	1	2.4×10^4
1.78	Bromo	1	3.7×10^4

[a] In acetonitrile containing 0.1 M Bu_4NClO_4 at 25°C according to Equation (103). [b] 2° und 1° represent second- and first-order decays, respectively. [c] In units of $A^{-1}\,s^{-1}$ for second-order and s^{-1} for first-order kinetics (A = unit of absorption).

tive stabilities as measured by $\Delta E^0 = 8.5$ kcal mol^{-1} of the parent arenes (column 1). There is a further, larger gap of $\Delta E^0 = 10.4$ kcal mol^{-1} which separates the stabilities of the radical cations of *p*-methylanisole and *p*-fluoroanisole, the least reactive haloanisole. Strikingly, every member of the family of *p*-haloanisole radical cations reacts with $NO_2^{\ominus}$ by first-order kinetics (cf. Fig. 35).[96] This decay pattern

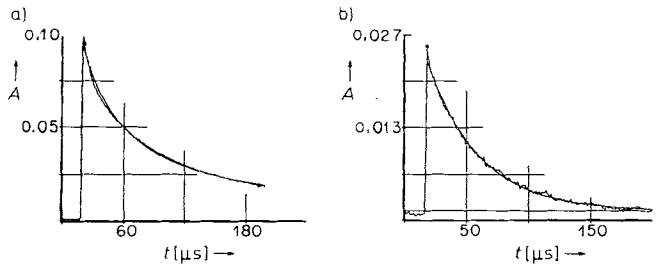


Fig. 35. Second- and first-order rate of disappearance of the radical cation from (a) *p*-methylanisole and (b) *p*-chloroanisole, respectively, as derived by CT excitation of the EDA complex from 0.2 M donor and 0.4 M TNM in acetonitrile.

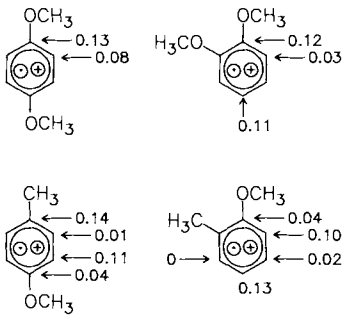
strongly suggests that the CT nitration occurs by the cage collapse of the geminate radical pair $[ArylH^{\odot\oplus}, NO_2^{\ominus}]$ in Equation (104) prior to diffusive separation, except when

$$\mathbf{VI} \xrightarrow{k_{cp}} Aryl(H)NO_2^{\oplus} + C(NO_2)_3^{\ominus} \qquad (104)$$

the anisole cation is a relatively stabilized species such as those with *p*-methyl and *p*-methoxy substituents. Such a mechanism for nitration derives from polar solvents that act selectively to preferentially separate the anion from the cation and $NO_2^{\ominus}$ in the geminate triad **VI**. The σ adduct formed in Equation (104) is the Wheland intermediate in electrophilic nitration.[38] As such, it relates directly to the classical studies of *Melander*,[93] who first established the rapid, irreversible loss of a proton from the Wheland intermediate [cf. Eq. (105)].

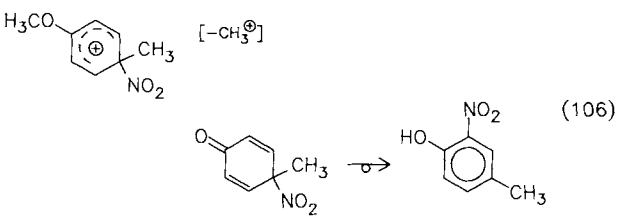
$$Aryl(H)NO_2^{\oplus} + C(NO_2)_3^{\ominus} \xrightarrow{fast} ArylNO_2 + HC(NO_2)_3 \qquad (105)$$

The isomer distributions in CT nitration are established during radical-pair collapse according to Equation (99). Since the driving force for this process is likely to be exergonic, the transition states for the formation of the relevant aromatic σ adducts in Scheme 7 will bear a strong resemblance to the aromatic radical cation. As such, the electron density in $ArylH^{\odot\oplus}$ will be an important factor in determining the positional selectivity in the aromatic ring.[33] As a first approximation, the regiospecificity in the radical-pair collapse of **V** will be determined by the sites of highest electron spin density in $ArylH^{\odot\oplus}$. The latter are determined from ESR spectra which show that these locations in the radical cations of anisole and its derivatives are concentrated at the *ortho* and *para* positions relative to the methoxy group (Scheme 12).[79]

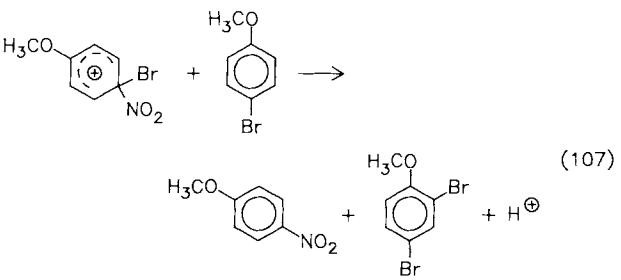


Scheme 12. Electron spin densities in the radical cations of anisole derivatives.

The isomer distributions in CT nitration are the same as those obtained by the conventional electrophilic nitrations with nitric acid.[86,96] Moreover, it is worth noting that the byproducts from CT nitration are also strongly reminiscent of the byproducts reported in electrophilic nitration. In particular, the demethylation of the methoxy group to afford nitrophenols, and the *trans*-bromination of 4-bromoanisole to afford a mixture 4-nitroanisole and 2,4-dibromoanisole are both symptomatic of radical-pair collapse at the *ipso* positions. These produce the σ adducts which are akin to the Wheland intermediates known to undergo such transformations [Eqs. (106) and (107)].



(106)



(107)

It is important to emphasize that the comparison of the behavior of various *p*-substituted anisoles shows that ion-pair collapse is strongly dependent on the stability of the radical cation, being nonexistent with the highly stabilized *p*-methoxyanisole radical cation.[88] The rates of ion-pair collapse of 4-substituted anisole cations increase in the order methyl < fluoro < chloro < bromo in line with the oxidation potentials E^0 of the parent anisole. Moreover, the rates of radical-pair collapse also increase in the same order, but with a change in the decay behavior from second-order kinetics for *p*-methylanisole to first-order kinetics for all the haloanisoles. The latter points to the importance of a geminate process for radical-pair collapse from **VI** with radical cations [see Eqs. (108)–(110)].

These studies thus underscore the strong similarity between electrophilic and charge-transfer nitration especially with regard to the spectral transients and the nitration products and byproducts. Since the latter is symptomatic of arene radical cations, the parallelism does extend to some common reactive intermediates. As such, the most *economical* formulation for electrophilic nitration would also include a pathway which is common to charge-transfer nitration, namely, via the radical ion pair **V** (Scheme 11). This mechanism differs from the conventional formulation (Scheme 10), in which the [ArylH, $NO_2^{\oplus}$] pair is directly converted into the Wheland intermediate in a single step, rather than via the radical ion pair **V**. The FERET correlation in Equation (45) has established the strong similarity in the activation barriers (i.e., energetics) for these two processes.[33] Accordingly, the problem in Scheme 11 can be considered in an alternative framework, namely, the lifetime of the radical ion pair **V**. At one extreme of a very short lifetime, the radical ion pair is tantamount to the transition state for the concerted one-step process. At the other extreme of a very long lifetime, the radical ion pair **V** is manifested by its diffusive separation. Equations (108)–(110) present this construct in a kinetics context.[85] The ef-

$$[\mathrm{ArylH},\ NO_2^{\oplus}] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\mathrm{ArylH}^{\odot\oplus},\ NO_2^{\odot}] \qquad (108)$$

$$[\mathrm{ArylH}^{\odot\oplus},\ NO_2^{\odot}] \xrightarrow{k_c} \mathrm{Aryl(H)}NO_2^{\oplus} \qquad (109)$$

$$[\mathrm{ArylH}^{\odot\oplus},\ NO_2^{\odot}] \xrightarrow{k_d} \mathrm{ArylH}^{\odot\oplus} + NO_2^{\odot} \qquad (110)$$

ficient cage collapse of the radical ion pair to the Wheland intermediate is represented by $k_c \gg k_d$. On this basis, the time scale of the "concerted" process is limited by the diffusional correlation times of $< 10^{-11}$ s. The extent to which $k_c \ll k_d$ is valid allows side reactions to compete as a result of the diffusive separation of $\mathrm{ArylH}^{\odot\oplus}$ and $NO_2^{\odot}$. The experiments with DMB clearly belong in the latter category since the evolution of nitration products takes place in the μs/ms time regime. Nonetheless, the diffusive recombination of $\mathrm{ArylH}^{\odot\oplus}$ and $NO_2^{\odot}$ pairs with the rate constant k_2 can occur in Equation (102) with very high efficiency. The competition from diffusion is represented by the cage collapse of $\mathrm{ArylH}^{\odot\oplus}$ and $NO_2^{\odot}$ in Equation (109). The radical-ion-pair formulation thus represents a unifying theme for electrophilic and charge-transfer nitration. Indeed, it can account for all the diverse experimental observations of aromatic donors with little or no ambiguity. Let us now consider a pair of aromatic substitution processes which differ primarily in the charge borne by the electrophile.

5.2. Arene Activation with Isoelectronic Mercury(II) and Thallium(III) Electrophiles

The dichotomy between the electron-transfer mechanism and the more conventional pathway for electrophilic aromatic nitration is clearly delineated in aromatic mercuration and thallation, in which the *isoelectronic* electrophiles $Hg(O_2CCF_3)_2$ and $Tl(O_2CCF_3)_2^{\oplus}$, differing only in charges, can be employed for direct comparisons. Quantitative spectrophotometric analysis has established the transient charge-transfer absorption spectra observed during mercuration and thallation to derive from the same electrophilic species as that involved in the kinetics, namely, $Hg(O_2CCF_3)_2$ and $Tl(O_2CCF_3)_2^{\oplus}$, respectively.[97] Indeed, these species form two series of arene π complexes [ArylH, $Hg(O_2CCF_3)_2$] and [ArylH, $Tl(O_2CCF_3)_2^{\oplus}$], which bear strong resemblances to each other, both in the ground state and in the CT excited state. For the mercury(II) complexes, the relevant CT transition corresponds to Equation (111), and for the thallium(III) complexes, it is given by Equation (112).

$$[\mathrm{ArylH}, Hg^{II}(O_2CCF_3)_2] \xrightarrow{h\nu_{CT}} [\mathrm{ArylH}^{\odot\ominus}, Hg^{I}(O_2CCF_3)_2^{\odot\ominus}]^* \qquad (111)$$

$$[\mathrm{ArylH}, Tl^{III}(O_2CCF_3)_2^{\oplus}] \xrightarrow{h\nu_{CT}} [\mathrm{ArylH}^{\odot\ominus}, Tl^{II}(O_2CCF_3)_2^{\odot}]^* \qquad (112)$$

Both series of π complexes share the arene cation in the form of the radical pair as the CT excited state according to expectations of Mulliken theory. The slope of 1.3 in the linear correlation of $h\nu_{CT}$ indicates that the energy of the charge-transfer excitation of the cationic π complex from $Tl(O_2CCF_3)_2^{\oplus}$ is merely ca. 30% more sensitive to changes in arene structures compared with that derived from $Hg(O_2CCF_3)_2$. Otherwise, both series of π complexes show parallel behavior in the transformation to the CT excited state. The similarity in the π complexes of $Hg(O_2CCF_3)_2$ and $Tl(O_2CCF_3)_2^{\oplus}$ with the series of sterically crowded 1,3,5-trialkylbenzenes indicates that the CT interaction is relatively long-range. The latter was confirmed by X-ray crystallography which showed a pair of long Hg–C bond distances in the η^2-bonding of the electrophilic mercury(II) to the hexamethylbenzene donor.[98] As a result, any minor difference which may exist in the steric properties of $Hg(O_2CCF_3)_2$ and $Tl(O_2CCF_3)_2^{\oplus}$ is obscured in the π complexes, both in the ground state and in the CT excited state. The kinetics studies also establish the neutral $Hg(O_2CCF_3)_2$ and the cationic $Tl(O_2CCF_3)_2^{\oplus}$ to be the principal electrophiles in mercuration and thallation, respectively. The reactivity trends in the two types of metalations can be quantitatively compared with a graded series of arenes ranging from the electron-rich pentamethylbenzene at one end to the least reactive arene, chlorobenzene, at the other extreme. The relative reactivity of an arene to elec-

trophilic metalation is represented by the activation free energy difference $\Delta G_r^{\neq} = -2.3RT\lg k/k_0$, where k represents the second-order rate constant and the subscript r refers to changes relative to that of benzene (k_0) arbitrarily chosen as the reference arene. The direct comparison between mercuration and thallation is shown in Figure 36, in which the logarithms of the ratio of second-order rate constants for mercuration are plotted against those for thallation in trifluoroacetic acid. The striking linear free energy correlations spans more than six orders of magnitude in rate with a 1 : 1 relationship, as shown by the fit of the data to the line drawn with a slope of unity. In other words, *those factors relevant to surmounting the activation barrier for mercuration are mirrored in exactly the same way during thallation* as a consequence of systematic changes in the arene donor.

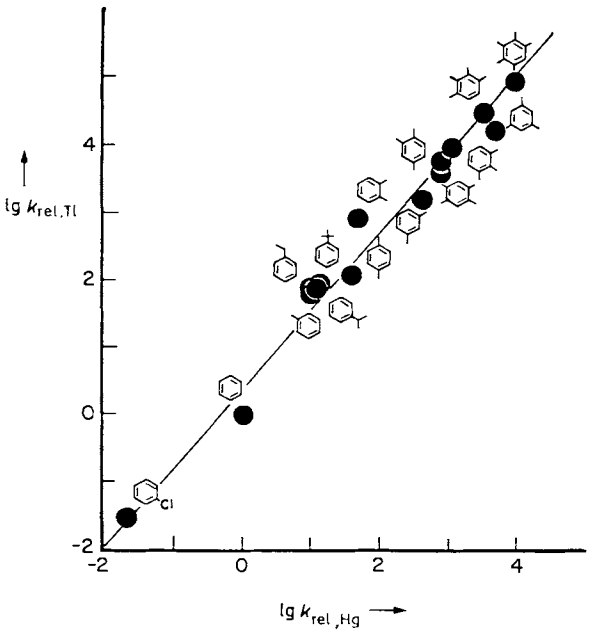


Fig. 36. Direct relationship of the relative reactivities (k_{rel}) of arenes in mercuration (abscissa) and thallation (ordinate).

The relative reactivities of arenes to metalation are represented by the activation free energy difference $\Delta G_r^{\neq}$. In the same way, the transition energy $h\nu_{CT}$ associated with the charge-transfer excitation of the π complex can be evaluated from the absorption spectrum by a similar comparative method, $\Delta h\nu_{CT} = h\nu_{CT} - h\nu_{CT}^0$, where $h\nu_{CT}^0$ is the CT transition energy of the benzene π complex.[33] The correlation of the activation barriers with the CT excitation energies shown in Figure 37 for mercury(II) clearly consists of two trends.[97] At the low end of the reactivity scale (chlorobenzene to the xylenes), a linear plot is observed for the CT transition energy with a slope of close to unity. In other words, these mercuration rates relate to the CT excited state of the π complex according to the free energy relationship described in Equation (45). On the other hand, the flat portion of the slope in Figure 37 represents the most reactive arenes (mesitylene to pentamethylbenzene) which indicates that they are all mercurated at essentially the same rate, quite independent of the donor properties as reflected in the CT transition energy of the π com-

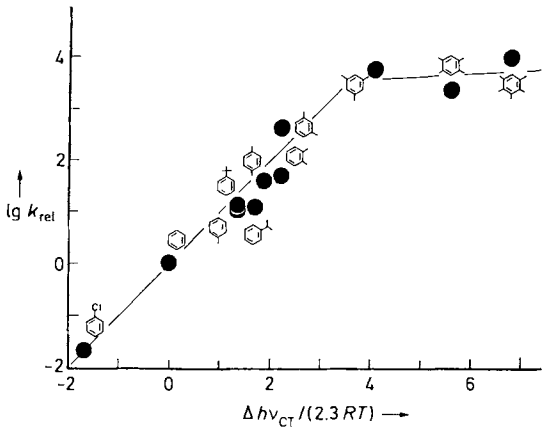

Fig. 37. Correlation of the relative reactivities (k_{rel}) of arene in mercuration with the CT transition energy according to the FERET in Equation (45). The inclined line is arbitrarily drawn with a slope of unity. $T = 25\,^{\circ}C$.

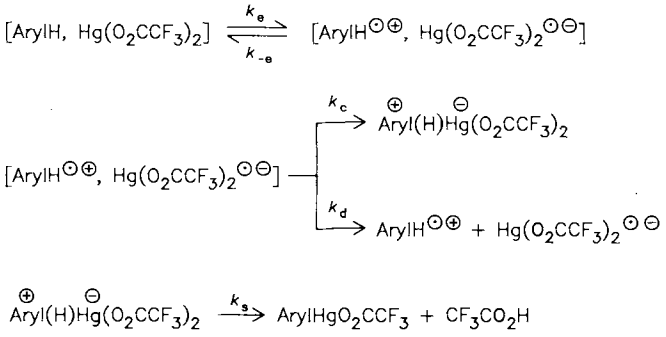
plex. This trend is also observed in the interaction of the same arenes with thallium(III). The linear free energy relationship as expressed by Equation (45) relates the activation barrier $\Delta G^{\neq}$ for aromatic substitution directly to the CT transition energy $h\nu_{CT}$ of the π complex. Since $h\nu_{CT}$ pertains to the energetics of the photoionizations in Equations (111) and (112), the correlation suggests that these arene ion pairs are reasonable approximations to the transition state for mercuration and thallation. Such a conclusion derives from the kinetics and spectral experiments with the less electron-rich arenes from chlorobenzene to the isomeric xylenes in Figure 37. Moreover, the leveling of the rates proceeding from the electron-rich arenes from mesitylene to pentamethylbenzene can be reconciled with this formulation in the following way. Consider the generalized kinetics scheme which is associated with the arene ion pair (Scheme 13).



Scheme 13. Generalized scheme for arene metalation with Hg^{II} compounds.

In Scheme 13, the activation step for electrophilic substitution proceeds from the thermal conversion ($\lg k_e$) to the arene ion pair, which is to be likened to the photoactivation of the π complex in Equation (111). The substitution-product-determining process (k_s) is then dependent on the rate constants k_c and k_d for collapse to the Wheland intermediate and diffusive separation to free ions, respectively. Since the rate constant k_d is likely to be invariant for a given electrophile and a series of structurally related arenes, the rate of aromatic substitution will be strongly mediated by the value of k_c. If, for some reason, the rate of

arene-ion-pair collapse is retarded, the competition from back electron transfer (k_{-e}) will become increasingly important. Under these circumstances, the reaction rate will no longer follow the linear free energy relationship in Equation (45). Indeed, at some point, back electron transfer will dominate (i.e., $k_{-e} \gg k_c$), and it is conceivable that little or no thermal reaction will take place. The experimental variables pertaining to (1) electronic effects, (2) steric effects, (3) solvent effects, and (4) product studies can be reconciled with Scheme 13 in terms of the facility with which such an arene ion pair collapses as follows.

(1) *Electronic effects* in the collapse of the arene ion pair can be viewed as the influence of substituents on the spin density in the singly occupied orbital (SOMO) requisite to bond formation (k_c step). For example, in mesitylene the pair collapse at any of the three unsubstituted nuclear positions is unimpeded since the SOMO is degenerate (see Fig. 38b). Similarly, the SOMOs in the cations of *p*-xylene, *m*-xylene, and pseudocumene are conducive to pair collapse at the free positions owing to the available spin densities (Fig. 38a, c, and d, respectively). By contrast, the SOMOs of the cations of durene and pentamethylbenzene have nodes at the free 3- and 6-positions (Fig. 38e and f), and collapse there is not favored. Indeed, the lack of spin density at these positions of durene and pentamethylbenzene cations, respectively, accords with the observed magnitudes of the ^1H hyperfine splittings in the ESR spectra.[99] Thus the pair collapse of durene and pentamethylbenzene cations is only favored at the already substituted *ipso* positions and is probably a reversible process. Alternatively, collapse at an unsubstituted position suffers from the promotional energy of 4–7 kcal mol^{-1} from the subjacent orbital. Such a retardation of the pair collapse of durene and pentamethylbenzene cations could account for the leveling effect depicted in Figure 37 and the attendant breakdown of the linear free energy relationship. Alternatively, it is possible to consider the latter as reflecting a change in the nature of the rate-determining step (Scheme 14).

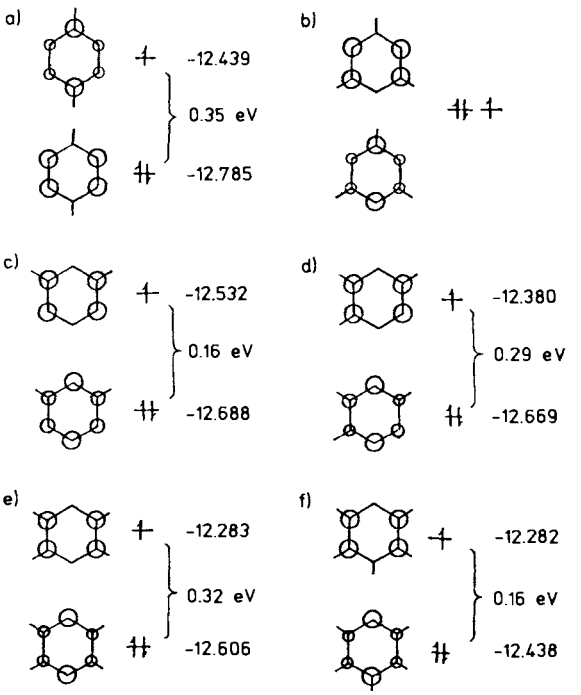


Fig. 38. The symmetries and energies of the HOMO and SOMO in the radical cations of (a) *p*-xylene, (b) mesitylene, (c) *m*-xylene, (d) pseudocumene, (e) durene, and (f) pentamethylbenzene.

$$[\mathrm{ArylH},\ Hg(O_2CCF_3)_2] \underset{k_{-\sigma}}{\overset{k_\sigma}{\rightleftharpoons}} \overset{\oplus}{\mathrm{Aryl(H)}}\overset{\ominus}{Hg}(O_2CCF_3)_2$$

$$\overset{\oplus}{\mathrm{Aryl(H)}}\overset{\ominus}{Hg}(O_2CCF_3)_2 \xrightarrow{k_s} \mathrm{ArylHgO_2CCF_3} + CF_3CO_2H$$

Scheme 14. Variation of the rate-limiting steps in arene mercuration.

If the formation of the σ complex were rate-limiting, then $k_s \gg k_{-\sigma}$. Thus the experimental rate constant is $k_{obs} = k_\sigma$, and the linear free energy relationship in Equation (45) is applicable as described above. On the other hand, if the breakup of the σ complex were rate-limiting, then $k_s \ll k_{-\sigma}$. Thus the experimental rate constant is $k_{obs} = k_s(k_\sigma/k_{-\sigma})$, and the rate of proton transfer from the σ complex is relatively slow. This situation may well lead to the observed leveling in Figure 37 as a result of compensating effects on the preequilibrium ($k_\sigma/k_{-\sigma}$) and deprotonation rate (k_s) in durene and pentamethylbenzene. However, the kinetic isotope effect for chlorobenzene is more or less the same as that for durene and pentamethylbenzene. Such an invariance of the kinetic isotope effect suggests that arene reactivity is not differentiated by the rate of proton loss from the σ adduct. We therefore conclude that a change in the rate-limiting steps in Scheme 13 is alone insufficient to account for the leveling effect in Figure 37.

(2) *Steric effects* in mercuration and thallation are manifested by the substitution rate for 1,3,5-trineopentylbenzene which is more than two orders of magnitude slower than that for mesitylene, despite their similar donor properties. Since the association constants and CT transition energies are comparable for trineopentylbenzene and mesitylene, the steric effects extant in the π complexes and in the arene ion pairs are not sufficient to account for the observed rate difference. This conclusion is also in accord with the long-range interaction observed in the X-ray structure of the crystalline complex.[98] Therefore, steric effects according to Scheme 13 arise during arene ion pair collapse (Scheme 13). In the molecular structure of the mercurated trineopentylbenzene, the heteroatom substituent occupies a position on the side opposite the aromatic ring from the pair of neighboring neopentyl groups. Thus in order for pair collapse to the σ adduct or Wheland intermediate to occur, a substantial steric barrier must be overcome to obtain a structural configuration akin to the product. Steric inhibition of aromatic substitution is even more severe in 1,3,5-tri-*tert*-butylbenzene. Although the formation of the π complex with mercury(II) and thallium(III) is comparable to that of mesitylene, the persistence of the yellow CT bands indicated that little or no thermal reaction occurred. The difficulty of attaining the σ adduct of tri-*tert*-butylbenzene is also indicated in proton exchange studies. Thus mesitylene, durene, and even pentamethylbenzene undergo efficient proton exchange in trifluoroacetic acid via an analogous intermediate.[97] Under the

same experimental conditions, no proton exchange is observed in 1,3,5-tri-*tert*-butylbenzene.

(3) *Solvent effects* in the pair collapse arise from charge stabilization by solvents with dielectric constants as different as those of trifluoroacetic acid and dichloromethane. The rates of arene mercuration are greatly increased in trifluoroacetic acid relative to those in dichloromethane—the enhancement factor being 30- to 50-fold in the second-order rate constants. However, the *relative reactivity of a series of arenes is singularly unaffected by such a change in solvent* (cf. Section 4.1.2). It is noteworthy that the arene radical ion pair, when taken as a model for the transition state of aromatic substitution, does correctly account for this otherwise inexplicable lack of solvent sensitivity on the relative reactivities of various arenes, despite the marked differences in the absolute rates. According to Scheme 13, the latter arises from the large changes in solvation which are expected to accompany the formation of the arene radical ion pair in Equation (113), since the solvation energy of the neutral precursor may be neglected in comparison with that of the ion pair.[33] However, by the comparative procedure used to develop the linear free energy relationship in Equation (45), only the relative changes in solvation of the arene cation must be considered, owing to contributions from the electrophile moiety which largely drop out by cancellation. Since the solvation energy of a series of related arene cations is relatively constant,[34] it follows for Equation (45) that the relative reactivities would be solvent independent. It is noteworthy that the latter is difficult to reconcile with reactivity changes resulting from variable transition-state structures in Scheme 10.[32]

(4) *Product studies* provide a divergent view of the arene-ion-pair collapse during mercuration and thallation. The dichotomy is most pronounced in pentamethylbenzene. Thus the treatment of pentamethylbenzene with $Hg(O_2CCF_3)_2$ affords only the nuclear substitution product pentamethylphenylmercury trifluoroacetate in high yields. No transient intermediates other than the π complex were observed in either the UV/VIS or ESR spectra. On the other hand, in the thallation of pentamethylbenzene, nuclear substitution comprised only 26%, the remainder being accounted for by side products resulting from side-chain substitution and dimer formation. Such side products are known to derive from the radical cation of pentamethylbenzene.[79] Indeed, the diversion to side products during thallation coincides with the direct observation of the arene radical cation as a transient intermediate both by UV/VIS and by ESR spectroscopy.[100] A similar dichotomy between the products of mercuration and thallation exists with durene, albeit to a lesser degree. Finally, no discrepancy is observed with mesitylene, nuclear substitution occurring exclusively in both mercuration and thallation. Such a divergence between mercuration and thallation can be reconciled by the formulation in Scheme 13 if they differ by the extent to which diffusive separation (k_d) occurs [Eq. (115)]. All factors being the same, diffusive separation of the radical pair from thallium(III) should occur more readily than that from mercury(II) owing to a significant difference in the Coulombic interactions—the arene ion being paired with the anionic $Hg^{I}(O_2CCF_3)_2^{\odot\ominus}$ in mercuration [Eq. (111)] and with the neutral $Tl^{II}(O_2CCF_3)_2^{\odot}$ in thallation [Eq. (112)]. Moreover, the same electrostatic argument provides a ready explanation for the ability of Lewis acids as additives to promote arene radical cation formation (leading to biaryls) during both mercuration and thallation of even unexceptional arenes.[101] Thus the addition of boron trifluoride (as the etherate) will foster the ionic dissociation of the uncharged $Hg(O_2CCF_3)_2$ to give the cationic $HgO_2CCF_3^{\oplus}$ and of the $Tl(O_2CCF_3)_2^{\oplus}$ monocation to give the dication $TlO_2CCF_3^{2\oplus}$. The results lead to a diminution in the Coulombic interaction in the radical pair $[ArylH^{\odot\oplus}, Hg^{I}O_2CCF_3^{\odot}]$ during mercuration and to an enhancement of the Coulombic repulsion in the radical pair $[ArylH^{\odot\oplus}, Tl^{II}O_2CCF_3^{\oplus}]$ during thallation. In both cases the increased amounts of cage escape will lead to a higher component of electron-transfer-derived products (such as biaryls). Attractive as such a simple electrostatic explanation may seem, cognizance must also be taken into account of the attendant change in the driving force for back electron transfer (k_{-e} in Scheme 13). Unfortunately, this factor cannot be evaluated at this point owing to the unavailability of the reduction potentials E^0 of these highly transient species.[102] Thus the quantitative prediction of product yields derived from Scheme 13 must await the actual measurement of these quantities. Moreover, the detailed solution of the kinetics, including the isotope effects, is likely to be even more complicated owing to rates which depend strongly on the various types of ion pairing which are likely to exist.[103] Finally, no cognizance of the spin multiplicity of the radical pairs is included in Scheme 13 and the failure to observe CIDNP during arene mercuration and thallation unfortunately leaves unanswered the question of whether singlet-triplet interconversions play a role in mediating the individual rate constants for the CT formulation.

The study of mercuration and thallation has thus provided a sharp focus on the experimental delineation of stepwise and concerted mechanisms for arene activation. The unequivocal demonstration of arene cations as key intermediates in thallation, particularly of durene and pentamethylbenzene,[97] is consistent with a stepwise (electron-transfer) mechanism for arene activation as in Scheme 13 [Eq. (113)].[104] By the same token, the singular absence of

$$[ArylH, Tl(O_2CCF_3)_2^{\oplus}] \longrightarrow [ArylH^{\odot\oplus}, Tl(O_2CCF_3)_2^{\odot}] \longrightarrow Aryl(H)Tl(O_2CCF_3)_2^{\oplus} \longrightarrow \longrightarrow \cdots \quad (113)$$

any experimental evidence for such intermediates during mercuration is directly accommodated by a concerted (electrophilic) mechanism for arene activation [Eq. (114)].

$$[ArylH, Hg(O_2CCF_3)_2] \longrightarrow Aryl^{\oplus}(H)Hg^{\ominus}(O_2CCF_3)_2 \longrightarrow \longrightarrow \cdots \quad (114)$$

The difficulty with two separate mechanisms for arene activation by mercury(II) and thallium(III) is underscored by the striking correlation in Figure 36 which shows that the *activation barriers follow identical trends*. In other words, the rate-determining processes for mercuration and thallation are similar, yet they distinctly differ in the prod-

ucts derived from the electron-rich arenes (durene and pentamethylbenzene). Such a kinetics situation commonly demands that there exists at least one intermediate which separates the activation process from the products, as in Scheme 13. This paradox can be resolved in one of two ways. *First*, the mechanistic formulation in Scheme 13 merges stepwise and concerted processes by the modulation of a pair of rate constants. According to Scheme 13, the two principal pathways are differentiated during the competition between cage collapse (k_c) and diffusive separation (k_d) of the arene ion pair. The inability to observe the arene cation (e.g., from mesitylene) could be attributed to a cage collapse to the Wheland intermediate occurring substantially faster than diffusive separation (i.e., $k_c \gg k_d$), which is tantamount to a concerted process. Likewise, the ESR observation of the arene cation would derive from a diffusive process occurring faster than collapse (i.e., $k_c \ll k_d$), which could appear as a stepwise process. Some of the structural and environmental factors which influence both rate constants have been presented in the discussion above. However, this mechanism is not without its problems since it does not as yet address the observed kinetic isotope effects in a quantitative way. *Second*, the stepwise and concerted processes for arene activation may simply represent competing pathways [Eqs. (115) and (116)],

$$[\mathrm{ArylH, Hg(O_2CCF_3)_2}] \longrightarrow [\mathrm{\overset{\oplus}{Aryl}(H)\overset{\ominus}{Hg}(O_2CCF_3)_2}]^{*} \quad (115)$$

$$[\mathrm{ArylH, Tl(O_2CCF_3)_2^{\oplus}}] \longrightarrow [\mathrm{ArylH^{\odot\oplus}, Tl(O_2CCF_3)_2^{\odot}}]^{*} \quad (116)$$

where the superscript (*) represents the activated complex. If so, those factors related to the donor properties of arenes, such as π-complex formation, CT excitation, activation barriers, are too common to both to allow any distinction between these pathways. Moreover, the common dependence on isoelectronic electrophiles, independent of charge, further obscures any difference in the transition states. This formulation thus recognizes two such dissimilar mechanisms as electron transfer and electrophilic processes in mercuration and thallation to be remarkably alike. Such kindred transition states can be theoretically accommodated within the valence bond approach to electrophile/nucleophile reactivity, as described by *Shaik* and *Pross*.[105] Crucial to the resolution of this dilemma is the understanding of the stepwise process for arene activation. Particularly germane are the microdynamics of the "intimate" arene radical ion pairs in Scheme 13, especially as they collapse or evolve to "loose" (solvent-separated) species and finally to "free" (separate) radical pairs. Indeed, the CT excitation of π complexes by a laser pulse (Section 5.1) provides access to arene radical ion pairs which can be examined directly by time-resolved spectroscopy.[87]

6. Epilogue

The merging of outer-sphere and inner-sphere mechanisms for electron transfer leads to the FERET in Equation (37) and its corollaries (43) and (44) that are applicable to a variety of organic and organometallic reactions [Eqs. (1)-(15)], otherwise referred to as electrophilic and nucleophilic processes. Critical to the FERET formulation from the thermochemical Scheme 6 is the ion pair $[D^{\oplus}, A^{\ominus}]$ as the activated complex that lies at or near the transition state for the representative electrophile/nucleophile transformations described in Section 5. Since $[D^{\oplus}, A^{\ominus}]$ arises from the weak EDA interactions inherent in the precursor complex [D, A], the evaluation of the driving force for ion-pair formation must include the work term w_p as well as the redox change $F(E^0_{ox} + E^0_{red})$. Therefore, it is important to emphasize that in any electrophile/nucleophile transformation, *the redox change is not a sufficient criterion by itself to determine whether or not electron transfer is mechanistically viable.*[106]

At one extreme of outer-sphere electron transfer at large mean separations r_{DA}, the work term w_p bears physical significance to electrostatic forces between $D^{\oplus}$ and $A^{\ominus}$, as in Marcus theory. However, at the other extreme of inner-sphere electron transfer at *very close* r_{DA}, a purely Coulombic description is no longer completely adequate (or accurate) for the interaction energy in the intimate ion pair $[D^{\oplus}, A^{\ominus}]$ (see, e.g., the treatment in Section 4.4.4). In this situation, the Mulliken treatment affords a feasible phenomenological method for the evaluation of w_p; but unfortunately it provides no physical insight into the nature and chemical properties of the ion pairs. Part of this deficiency can be made up by the examination of separate $D^{\oplus}$ and $A^{\ominus}$ which are independently generated by electron detachment from the donor and by electron attachment to the acceptor, respectively (compare, e.g., Sections 2.2.4 and 5.1).[107] Indeed, such studies have shown that significant structural changes in donors and acceptors can accompany electron transfer in a manner sufficient to allow their requisite close approach within the highly intimate ion pair. Furthermore, the radical ions $D^{\oplus}$ and $A^{\ominus}$ consistently show enhanced reactivity relative to their uncharged diamagnetic counterparts owing to the half-filled HOMO and LUMO, respectively.[108] Indeed, the spontaneous fragmentation of either $D^{\ominus}$ (e.g., $RMgX^{\oplus}$, $R_3SnH^{\oplus}$, $[CpFe(CO)_2R]^{\oplus}$, $[CH_3Co(chel)]^{\ominus}$, $R_2Mg^{\oplus}$, $R_3SiSiR_3^{\oplus}$)[109] or $A^{\ominus}$ (e.g., $Br_2^{\ominus}$, $HgX_2^{\ominus}$, $RX^{\ominus}$)[110] constitutes the single theme that unifies the diverse electrophile/nucleophile processes in Equations (1)-(15) within the common framework of charge-transfer transitions for the FERET from Scheme 6.[111] At this juncture, the contributions from additional energy terms inherent in the intimate ion pair $[D^{\oplus}, A^{\ominus}]$ with close r_{DA} cannot be experimentally evaluated. Preliminary observations of the temporal relaxation of contact ion pairs that are spontaneously generated by the laser-pulse excitation of EDA complexes encourage the further use of time-resolved spectroscopy to help to delineate this critical problem.[114] In a related context, the studies of exciplex absorptions observed in the course of diffusional quenching of excited donors and/or acceptors[115] will also doubtlessly help to delineate the properties of intimate ion pairs $[D^{\oplus}, A^{\ominus}]$ in a quantitative manner.[116]

I thank the Alexander-von-Humboldt-Stiftung for my stay at Philipps Universität Marburg with the kind hospitality of Professor Reinhard W. Hoffmann and his colleagues in Fachbereich Chemie at which this article was written. I gratefully acknowledge the numerous contributions of my

collaborators mentioned in the references and especially S. Fukuzumi, R. J. Klingler, J. M. Masnovi, and S. Sankararaman for their outstanding creative efforts. I also thank the National Science Foundation and the Robert A. Welch Foundation for financial support of this research.

[30] The formation of the 1:1 adduct in Equation (41) occurs by an initial fragmentation of $RM^{\oplus}$ and then stepwise addition to $TCNE^{\ominus}$ subsequent to the rate-limiting step in Equation (40). The process is akin to the CT-induced addition of tetranitromethane to anthracene [87].

[35] The Hammett ρ values are singularly insensitive to the solvent polarity, despite large solvent effects on the absolute rates of electrophilic substitution. This is one factor which allows the Brown σ^+ constant to be so comprehensive. By the same token, it fails to provide information about the larger solvent effects on the absolute rates. See: C. D. Johnson, *Chem. Rev. 75* (1975) 755.

[36] Although σ^+ for many substituents is effectively constant over a wide range in the variation of ρ in various electrophilic aromatic substitution, there are substituents such as F, Cl, and Br for which there is a considerable variation in σ^+ with changes in p. See J. R. Knowles, R. O. C. Norman, G. K. Radda, *J. Chem. Soc. 1960*, 4885; H. van Bekkum, P. E. Verkade, B. M. Wepster, *Recl. Trav. Chim. Pays-Bas 78* (1959) 815. The inconsistency of σ^+ constants necessitated the introduction of multiparameter extensions to the Hammett equation.

[37] For further discussion of the changes in r_{DA} and the work term w_p in the CT interaction of various donors, the reader is referred to [24].

[51] For the structural effects on some typical cation solvations, see: E. M. Arnett, H. J. Pienta, *J. Am. Chem. Soc. 102* (1980) 3329; R. Taft, J. F. Wolf, J. L. Beauchamp, G. Scorrano, E. M. Arnett, *ibid. 100* (1978) 1240, and references cited therein.

[52] a) Since the formation constants K_{DA} of these EDA complexes are small, the free energy of formation (ΔG_{DA}) of the precursor complex can be ignored in comparison with the activation barrier for the electrophilic process; b) The constant term also includes the solvation energy of aromatic cations, etc; c) For questions regarding the solvation of transition states in relation to that of stable molecular analogues, see: C. D. Ritchie, *Pure Appl. Chem. 52* (1979) 153; C. D. Ritchie, J. E. VanVerth, P. O. I. Virtanen, *J. Am. Chem. Soc. 104* (1982) 3491, and references cited therein.

[53] a) In this formulation, we do not intend to convey the notion that the configurational structure of the transition state and that of the CT excited ion pair are necessarily the same but only that the energy change in the formation of one serves as a viable model for that of the other. In more rigorous terms, Equation (60) states that alkenes and arenes are subjected to the same perturbations in electrophilic brominations as in the CT transition in the EDA complexes when changes in solvation are taken into account. It must be emphasized that the CT formulation does not require the proof that an EDA complex is (or is not) an intermediate in electrophilic brominations. For a discussion of this point, see footnotes 19 and 20 in [54]; b) The strongest kinetic evidence for the direct involvement of the EDA complex is the observation of a negative temperature coefficient; see: G. B. Sergeev, T. V. Pokolok, T. Ch'eng, *Kinet. Katal. 10* (1969) 36.

[80] For the simplified kinetics scheme: $D + A \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} [D^{\oplus}, A^{\ominus}] \xrightarrow{k_2}$ products, the steady-state concentration of the ion pair is proportional to the ratio $k_1/(k_2+k_{-1})$. For an endergonic electron transfer of the type described here, $k_{-1} \gg k_1$. K_{ET} for the preequilibrium step is k_1/k_{-1}.

[106] For an electrophile/nucleophile transformation proceeding via electron transfer as in the kinetics scheme presented in [80], the observed second-order rate constant k_{obs} is related to both the redox (pre)equilibrium (K_{ET}) and follow-up rate (k_2), i.e., $k_{obs}=K_{ET}k_2$. Accordingly, a highly endergonic electron transfer with $\Delta E^0=(E^0_{ox}+E^0_{red})\ll 0$ can be always overcome by suitably fast kinetics (k_2). See, e.g., G. S. Bodner, J. A. Gladysz, M. F. Nielsen, V. D. Parker, *J. Am. Chem. Soc. 109* (1987) 1757.

Tumor Lectinology: At the Intersection of Carbohydrate Chemistry, Biochemistry, Cell Biology, and Oncology

By Hans-Joachim Gabius*

Dedicated to Professor Friedrich Cramer on the occasion of his 65th birthday

The scientific description of lectins, a class of sugar-binding proteins distinct from both sugar-specific enzymes and antibodies, began nearly 100 years ago. The natural ligands of lectins include the sugar moieties of cell glycoproteins, glycolipids, and proteoglycans. Lectins can selectively recognize these potential information-storing or -transferring structural elements and so contribute to regulating biological processes. Plant lectins are now a well-established means of characterizing and localizing glycoconjugate-bound sugar determinants. However, work on endogenous lectins is still confronted by many open questions, whose answers require detailed experiments using a suitable model system. Tumors offer an obvious model, particularly since they allow the possible diagnostic and therapeutic uses of lectins to be explored directly. Tumor lectinology employs a broad range of methods, from the chemical synthesis of the sugar components of neoglycoproteins, and their use to seek out cellular sugar receptors with histochemical and cell-biological techniques, to the biochemical and immunological characterization of the lectins expressed by tumor cells and the use of homology analysis to find further functional domains. The outlook for clinical applications depends on the harmonious integration of these disparate disciplines in tumor lectinology.

1. Introduction

Historically, scientific attention to lectins began nearly 100 years ago with the publication of the dissertation of *Hermann Stillmark*, a doctoral student of *Rudolf Kobert* at The University of Dorpat. His work, "Ricin, a toxic ferment from the seeds of Ricinus communis and some other Euphorbiaceae",[1] was motivated by the occurrence of poisons of unknown nature in animal feeds and documented the high toxicity of the extract from *Ricinus communis*. In addition, his preparations, which by modern standards must be considered as protein mixtures, were able to cause the agglutination of red blood cells (Fig. 1). Use of this hemagglutination as an assay soon led to the discovery of further sources for extracts, thereby showing the broad distribution of such proteins. Apart from its toxicity and capacity for hemagglutination, ricin has a third property, soon put to use by *Ehrlich*: it is a potent antigen. Using ricin, in place of bacterial toxins, he provided experimental proof of the specificity of the immune reaction.[2,3]

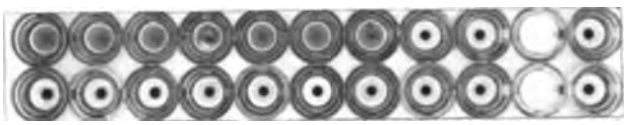

Fig. 1. Ricin-mediated hemagglutination. In the upper row, a series of increasing dilutions of ricin (1:2 to 1:612) was used. In the lower row, 0.1 M D-lactose was added to each test as a competitive inhibitor. The test at the far right in each row is a control performed without the addition of ricin; the penultimate vessels are empty.

As described in more detail elsewhere,[4,5] there followed further milestones in lectin research. In 1936, it was shown experimentally that a protein obtained from *Canavalia ensiformis* extracts causes hemagglutination by binding sugars on the erythrocytes; in 1948, certain plant proteins were found to show specificity for blood groups in hemagglutination tests.[7,8] The selectivity of different erythrocyte-agglutinating proteins obtained from plants, and so properly termed *phytohemagglutinins*, led to the introduction of the term *lectin* to distinguish between members of this class of proteins, which recognize certain molecular groups in an apparently antibody-like way, and antibodies themselves.[9] Although other terminologies were suggested, such as "receptor-specific protein",[10] these did not find general acceptance. Many of the proteins then grouped with the phytohemagglutinins were later found to be sugar-specific, and agglutinins with the same specificities were also found in other classes of organisms. In this way the foundation was laid for a more precise definition of the term *lectin*, till then used only in distinction to the term *antibody*. The definition includes sugar-binding capacity without enzymic activity together with activity in cell agglutination assays and/or precipitation of glycoconjugates. Lectins were thus specified in terms of their ligands.[11]

Compared with plant lectins, animal lectins have been investigated only recently.[12,13] The developments that have followed from the application of chemical, biochemical, and cell-biological methods will be presented in this review with particular emphasis on the possible clinical applications of endogenous lectins.

2. Can the Sugar Structures of Cell Glycoconjugates Carry Biological Information?

Sugars are generally viewed as energy-storage substances. However, as integral components of cell glycoconjugates—glycoproteins, glycolipids, and proteoglycans—they apparently perform other functions. It is attractive to suppose that the ordered arrangement of the sugar monomers in the carbohydrate part of glycoconjugates carries biological information required for the error-free performance of some recognition processes. Whereas amino acids in proteins are linked almost exclusively by peptide bonds, so that biological information can be expressed as differences between the structural units but not as differences in the types of interlinkage, sugar monomers can be linked to one another by glycosidic bonds, whose diversity opens up a great wealth of possibilities. Quite apart from the rich variety due to the location of the bond in the framework of the sugar molecule, further possibilities follow from anomerism. Even if the naturally occurring complex carbohydrate structures of glycoconjugates do not by far realize all the configurations theoretically possible (see Fig. 2), nonetheless sugar structures of relatively short sequence appear almost designed for use in information storage, as the blood groups, one example among many, conclusively demonstrate.[14–19]

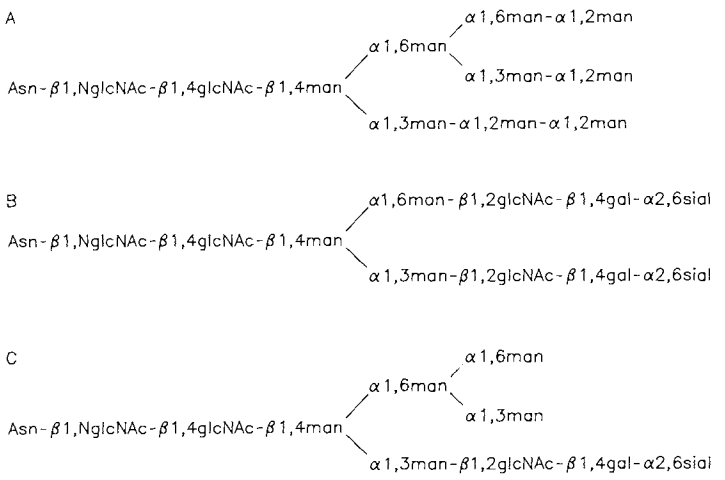

Fig. 2. Examples of the primary structure of oligosaccharides connected to the protein by *N*-glycosidic linkages via a bridging bond from *N*-acetylglucosamine to asparagine. The core part, which includes the first branching point, is identical for all three basic types. These basic types include the mannose-rich type (A), the complex type (B), and the mixed type (C), which in the peripheral parts adjacent to the core region bears elements of both the other basic types and is termed the hybrid type.

Beyond their primary structure, determined by the monomer sequence, and whose analysis has undergone significant advances in the last few years,[16–20] sugar chains can be further modified by enzymic means, such as sulfation, phosphorylation, or *O*-acetylation.[21–24] These two factors, the sequence diversity within limits set by the biosynthetic apparatus and the possibility of subsequent modifications, provide a framework underlying the immense variety of possible sugar structures. A further essential requirement for the functioning of an information-storage and -transferral device, namely, a distinct spatial organization and considerable structural rigidity, is shown to be present by conformational analysis of defined oligosaccharides and glycopeptides.[25,26] Modifications of the primary structure affect, in turn, the conformational stability. The carbohydrate part of glycoconjugates satisfies, then, the essential requirements for "coding systems" that must store and transfer information, systems that, from the moment the egg is fertilized, can cope with tasks of far-reaching importance.[27–31]

Proteins appear the most obvious partners in such recognition reactions. By definition the lectins belong to the class of proteins able to function as sugar receptors. Unlike enzymes (e.g., glycosidases or glycosyltransferases), lectins do not alter the sugar chain. The specific protein–sugar interaction between lectin and carbohydrate thus constitutes a reciprocal recognition system. Both sides of this system are open to regulation, permitting high flexibility, as shown schematically in Figure 3.

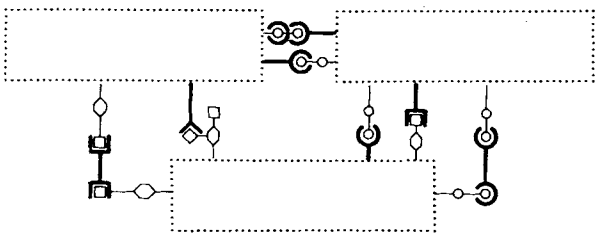

Fig. 3. Schematic illustration of a reciprocal recognition system, mediated by specific interactions between sugar ligands and cellular lectins of appropriate specificity. The lectins can also function as bridges. Large rectangles, cells; circles, mannose; squares, galactose; hexagons, *N*-acetylglucosamine; diamonds, fucose. The specific lectins, which can vary in their subspecificity, are exemplified for mannose-binding.

Although this general concept is very appealing, it should not go without remark here that carbohydrate–carbohydrate interactions have equally been documented[32,33] and that the sugar components of glycoconjugates can also serve other purposes. In glycoproteins they can influence the conformation of the protein and, by steric hindrance, protect regions of the protein surface from proteolytic degradation.[27] Glycolipids such as the sialogangliosides can modulate receptor functions by binding metal ions, without themselves (except for the sialic acid group) acting as receptors on account of their sugar structure.[34,35]

The flexibility that is required for regulatory intervention in coding systems based on sugar–protein interactions has been well documented with regard to carbohydrate structure. Apart from the availability of plant lectins as exogenous sugar receptors, the strong antigenicity of sugars was helpful in carrying out these studies.[36] Monoclonal antibodies have provided experimental means of detecting sugar epitopes and of quantifying their pattern of expression during development.[37–40] The results so obtained bear impressive witness that the pattern of sugar structures of individual glycoconjugates reflects a cell's identity during the course of differentiation. By binding to their corresponding epitopes, antibodies can spatially prevent other interactions from occurring. After the specific determi-

nants have been identified, functional studies can provide further insights into their significance.[31,41]

In a complementary approach, the sugar structures of interest can be used themselves as effectors, or they can be modified in situ. This has provided evidence for the functional significance of carbohydrate elements in such diverse processes as virus replication,[42] the regulation of cell growth in both animals and plants,[43-45] embryogenesis,[46-48] hormone distribution, and hormonally mediated signaling.[49,50] An independent approach, the use of mutant mammalian cells with genetic abnormalities in glycosylation, has provided further hints at the functional significance of the sugar part of cell glycoconjugates.[51] Taken together, these data encourage us to consider the working hypothesis to be not only attractive, but indeed plausible, namely that sugar-protein interactions involving sugar-lectin (sugar-receptor) recognition are a fundamental form of biological information transfer. However, our knowledge about the protein side of these interactions requires considerable improvement.

3. Lectins as Research Tools

Our present conception of lectins is still largely colored by the use of plant lectins as aids in biological and biochemical research. Their high selectivity for sugar structures renders them useful in studies directed at the characterization of glycoconjugates. This application presupposes that the specificity of the lectins used has been determined previously with the help of ligands of precisely defined structure, such as glycopeptides. Although there is a tendency to group together different lectins on the basis of affinity for a specific monosaccharide, exact analysis can sometimes reveal quite considerable differences in affinity within such a category.[52-54] The effort invested in gathering this further data is well repaid, because glycoconjugates of unknown fine structure can then be characterized according to their affinity as lectin ligand after gel electrophoretic separation, or they can be isolated and purified by affinity chromatography on immobilized lectins.[55-59] Work with lectins or lectin-coated carriers and cells, rather than with cell extracts, permits cell separations to be carried out, which is particularly important in hematological oncology.[58,60] The efficiency of these separations depends on such different factors as the density and mobility of the lectin ligands.[61,62]

At the level of cells and tissues lectins find application as a histological tool, with which the expression of glycoconjugate structures can be demonstrated and quantified. Examples of such applications in practical histology include the identification of certain cell types and particular functional and developmental conditions, as well as contributions to the diagnosis of tumors.[63-65]

Although plant lectins are widely used as research tools, it should not be forgotten that their presumed functions in the plant have only been roughly described.[66,67] This is true even for ricin. Just as ricin was employed in 1889, shortly after its discovery, as an antigen, on account of its potency, rather than as a sugar-binding protein, so also now, after its mechanism of toxicity has been elucidated, work with ricin centers on its application as a component of immunotoxins.[69,70] The widespread use of plant lectins as exogenous sugar receptors, however, documents their functional value and provides further support for the concept that there may be a coding system comprising endogenous lectins and their cellular ligands.

4. Neoglycoproteins as "Bloodhounds" for Endogenous Sugar Receptors

In elucidating the biological role of endogenous lectins, it is advisable to concentrate studies on established, generally accepted model systems. Those chosen should combine biological relevance with convenience in handling and a ready availability of material capable of providing satisfactory reproducibility in analysis. Tumor cells satisfy these prerequisites. In addition, the results obtained with tumor cells might be of direct clinical use. On the assumption, admittedly hypothetical but supported by the evidence presented above, that sugar-protein recognition is of significance in tumor biology, endogenous receptors for sugar structures of cell glycoconjugates are expected to provide functional markers for tumors. Such markers might serve not only as diagnostic tools or as worthwhile targets for therapeutic development in oncological practice, but they could themselves contribute to an understanding of the biological behavior of tumors.[71,72] Thus, they would provide us with more than simply a characterization of the tumor, as other types of tumor marker already do,[73] but with the further possibility of proceeding to clinically valuable judgments about such tumor properties as growth behavior, degree of differentiation, and level of malignity, as well as the capacity for metastasis.

Experimentally, appropriate reagents are used as "bloodhounds" to search for sugar-specific recognition processes involving glycoconjugates. To get some idea of the receptor capacity for sugar structures it is necessary to synthesize reagents appropriate for routine standardized use in comparative studies. A protein, chosen because it possesses no sugar component and is therefore unable itself to act as a receptor, is first conjugated synthetically with defined sugar components. The broad palette of starting substances and conjugation procedures thereby allows a wide range of precisely defined reaction products, the so-called neoglycoproteins, to be prepared.[74-76] This chemical synthesis of neoglycoproteins shows similarity to nonenzymic glycosylation of proteins, which in special cases is known to occur naturally.[77,78] Progress in the field of carbohydrate synthesis has made it possible to extend the sugar component to include even some very complex structures, thus closing the gap between the neoglycoproteins and naturally occurring—if necessary, appropriately modified—glycoconjugates.[79,80]

These neoglycoproteins open up several possibilities for the qualitative and quantitative evaluation by histochemical and cell-biological means of the pattern of sugar-specific binding capacity in comparative studies of different cell types. However, it is advisable at this stage to use the general term *sugar receptor*, because the molecular character of the individual receptors that may be involved is not

always clear. They could be endogenous lectins or, alternatively, glycosyltransferases or glycosidases, whose enzyme activity but not sugar-binding capacity is reduced in the physiological pH range. Further, some endogenous antibodies with sugar-binding specificity, as well as other proteins with sugar-binding domains, are known.[81,82] These can indeed function as lectins, but are defined operationally in terms of other functional domains, as explained in more detail in Section 6. It should also be noted that the recognition reaction responsible for detection can be influenced by the type of tissue fixation used to prepare the material and by endogenous ligands which act to inhibit the reaction.

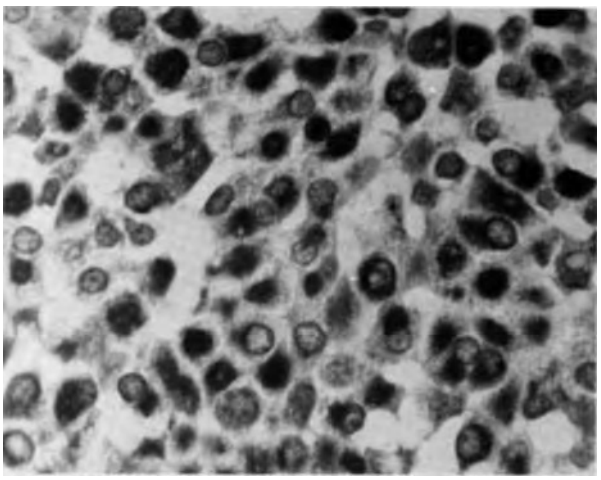

Fig. 4. Binding of labeled fucosylated albumin to cells of a poorly differentiated mucinous mammary carcinoma (magnification 600×).

For histochemistry and histopathology, appropriately labeled (e.g., "biotinylated") neoglycoproteins open the way to a more detailed analysis of endogenous sugar receptors. Biotinylation introduces a label into the carrier protein (e.g., serum albumin), thereby aiding detection. The resulting neoglycoproteins, which contain, in addition, the sugar component required for binding to the tissue section, provide complementary tools to plant lectins and sugar-specific monoclonal antibodies for use in defining a coding system based on protein-sugar interactions. The type of result obtained is exemplified in Figure 4, which shows the localization of fucose-specific receptors in a human mammary tumor of mucinous type. In control experiments, competitive inhibition with the specific sugar component prevented binding of the unmodified carrier protein, thereby proving the specificity of the interaction between the sugar part of the neoglycoprotein and the receptor in the tissue section. Comparative studies using a selection of neoglycoproteins have so far shown that analyses of this type reveal differences between normal and tumor tissues, between different types of tumor, and within a single class of tumors. This is true in particular for tumors of the breast,[83] the lung—here can be seen clearly the clinically significant differences between tumors of small-cell type and other types, and between tumor cells and inflammatory cells[84,85]—and the brain,[86,87] as shown in Table 1. Such evidence from different tumor systems shows that the use of neoglycoproteins is worth closer examination, and that their receptors are liable at least in part to dramatic regulation. A further example is provided by the course of differentiation of nonmalignant cells, for example, the different cell types during placental development (Table 2).

Table 1. Cytoplasmic binding capacity (Cp) (Σ^n) of labeled neoglycoproteins in brain tumors [a].

	−/+	+++	−/+	++	+	++

[a] All the labeled neoglycoproteins and also the β-galactoside-terminating asialofetuin were incubated with the tissue sections for 30 min at room temperature at a concentration of 10 μg mL^{-1}, except for melibiosylated albumin, which was applied for 3 h at a concentration of 100 μg mL^{-1}. [b] Abbreviations: lac = lactose, ASF = asialofetuin, mel = melibiose, man = mannose, fuc = fucose, mal = maltose. [c] M = maternal. [d] F = fetal.

To modify neoglycoproteins for use in rapid histopathological procedures, such as the surgery-associated diagnostic methods based on frozen tissue sections, the neoglycoproteins can be coupled to enzymes by means of heterobifunctional reagents in two-step procedures, thereby shortening the sequence of incubation steps prior to staining.[88] Additionally, such monoconjugates can be used to demonstrate and quantify sugar receptors. By varying the sugar component one can obtain information about the specificity of the sugar receptors involved, this feedback helping to optimize the ligand structure. "Sugar structure" is not the only variable influencing the efficiency of the neoglycoprotein; the sugar density and type of sugar–protein linkage are also important.[89–91] Taken together, these approaches provide important guidelines for research and for the subsequent biochemical purification of sugar receptors localized by histochemical procedures.

The carbohydrate portions not only of glycoproteins and glycolipids but also of proteoglycans appear to mediate important cellular functions (cell adhesion, growth control, regulation of receptor functions).[92,93] Here, too, appropriate markers can be synthesized (biotinylated polysaccharides after mild CNBr activation and aminoalkylation) to allow detection of the binding proteins involved. Standardized application of this type of marker has shown, for example, that receptors for sulfated polysaccharides are developmentally regulated[94] and are expressed differentially by different cell types.[84,94] Within a population of genetically uniform cells it is possible by use of these markers, as also by use of neoglycoproteins, to demonstrate heterogeneity both in tissue sections[83–87,94] and in tumor cells in culture.[95,96] This heterogeneity is a general phenomenon, confirmed for different parameters of tumor cells.[97a] It can be compensated for by the simultaneous application of different neoglycoproteins, whose binding specificities cover the entire cell population. This principle is decisive for precise cell characterization and for the success of therapeutic applications.

The discussion of measurements on cell populations leads us to cell-biological applications of neoglycoproteins, which include labeling by means of fluorescent dyes and the transport of chemotherapeutic agents. The latter are transported into cells via sugar-mediated binding and uptake and are released following intracellular proteolytic degradation of the carrier protein. They can then unfold their toxic activity, which can be measured at the cellular level. Their toxic effects are therefore indicative of both transport and the intracellular fate of the neoglycoprotein. Seen from another point of view, the glycosylated carrier fulfills the role of a "Trojan Horse", which smuggles the chemotherapeutic agent into the cell. The sugar component of the conjugate thus directs the fate of the conjugate, the pharmacon being exchangeable. Use of substances with a specific mode of activity—for example, amino acid analogues with aminoacyl-tRNA synthetases as target enzymes[97b]—improves further the efficiency of the conjugate. Selective uptake of neoglycoprotein–toxin conjugates via endogenous sugar receptors, the prerequisite for activity, has been demonstrated for a variety of animal and human tumor cells.[98–102] In comparison with antibodies, neoglycoproteins prove the better "Trojan Horses" in that they can be loaded synthetically with more chemotherapeutic agent, without their carrier properties being affected. It is also important for therapy that several chemotherapeutic agents applied together in this way retain their synergistic properties. For example, simultaneous application of maltosylated serum albumin complexed with *cis*-diamminedichloroplatinum(II) and lactosylated serum albumin coupled to the hemisuccinate of the phyllotoxin etoposide gave better results than those obtained by summing the results of separate applications (Table 3).

Table 3. Inhibition of [^{3}H]thymidine incorporation into human embryonic carcinoma cells by neoglyproteins conjugated to etoposide (as the hemisuccinate) or *cis*-diamminedichloroplatinum(II) (*cis*-Pt), as a model for combination therapy.

Substance	Concentration [μg mL^{-1}]	Inhibition [%]
(*cis*-Pt)-mal-BSA	1.25	1
	2.5	4
	5.0	6.5
(*cis*-Pt)-man-BSA	1.25	2
	2.5	3
	5.0	5
Etoposide-lac-BSA	7.5	8
	15	19
	30	27
(*cis*-Pt)-mal-BSA + etoposide-lac-BSA	1.25 + 7.5	28
	2.5 + 15	43
(*cis*-Pt)-man-BSA + etoposide-lac-BSA	1.25 + 7.5	22
	2.5 + 15	35

Already at this relatively low level of sugar-structure complexity, a marked increase in uptake is observed compared with use of the unmodified carrier protein.[98–102] The coupling to a carrier protein improves the pharmacokinetic properties of the therapeutic agent.[103] However,

optimizing the choice of the sugar component, which should function as a kind of postal code, should raise still further the targeting precision of the conjugate. Use of the term *therapeutic agent* signifies that, in principle, the substance brought to the target can be varied as desired. Differentiation-inducing substances such as retinoids[104] or photoactivatable dyes such as hematoporphyrin[105] can replace conventional chemotherapeutic agents. Clinical use, however, should not remain limited to local application. Therefore, the pattern of neoglycoprotein distribution in the organism, the assessment of which is now only beginning (Table 4),[106] needs to be examined more thoroughly. In this way the employment of sugars could enrich the arsenal of "drug targeting" methods presently available.[107,108] Naturally, this application is not limited to tumor cells, but can be used for any cell type and for further carrier systems such as liposomes.[109-112]

These applications show that neoglycoproteins, which were originally only conceived of as probes for sugar receptors, are also diagnostic and therapeutic tools. Furthermore, detailed molecular analysis of the receptors appears to offer much promise, especially since further functionally oriented measurements—for example, the influence of sugars on cell aggregations or on cell adhesion to sugar-coated carrier materials[113-115]—have underlined the presence of sugar receptor molecules and their functional importance.

5. Biochemical Tumor Lectinology

Conventional affinity chromatography using suitable supports and affinity ligands, whose type profoundly influences the yield of isolated lectin,[116] allows purification of endogenous lectins in relatively few steps. These analyses strengthen the conclusions drawn from the tumor-oriented application of neoglycoproteins. Moreover, the demonstrable lectin character of the isolated proteins allows us to speak of endogenous tumor lectins. The endogenous lectins isolated from different tumors display notable qualitative differences with respect to the patterns of sugar specificities, corresponding to certain components of natural glycoconjugates.[117-121] This is exemplified in Table 5 for some human tumors of differing histogenesis. An analysis of bone marrow, also shown here, indicates the differences found when tumors are compared with a mixture of nonmalignant cells. Even within a single class of tumors,

Table 4. Organ distribution of [^{125}I]neoglycoproteins in mice bearing Ehrlich tumors after 48 h [% of the injected dose per gram of tissue] [a].

[a] The relative molecular weight is stated in thousands.

in part of similar histogenesis,[122-124] qualitative differences can be observed. This also holds for tumors of the same histogenesis but different degrees of differentiation,[125] as well as for cultured lines of tumor cells of identical genetic origin but differing in cellular morphology and growth behavior.[126]

Such data indicate that the lectin pattern of tumors has a phenomenological relation to the histogenesis and cell character, though the present state of knowledge does not permit a causal relationship to be established. Three classes of tumor lectins can be discerned: Endogenous lectins are expressed in both tumor and normal tissues. Other lectins can be found in tumors and in developing tissues but not in adult tissues, a pattern defined operationally as oncofetal expression. The third group includes the lectins which cannot yet be allocated to the other groups because we lack a full catalogue of lectin expression in different normal tissues at various stages of development.[124]

As human embryonic tissue, the placenta is an appropriate research object; its various cell types exhibit developmentally dependent regulation of the expression of sugar receptors. The changes, as visualized histochemically, are reflected clearly at the biochemical level, even when analysis is limited to the whole organ.[127] Since the growth behavior of the proliferating placenta is comparable with the invasive growth of tumors, such structural analysis provides a starting point for correlation with function.

Work with tumors is open to the objection that other, nonmalignant cells contribute to the results of analysis in spite of careful preparation of the tissue. This objection can be countered by histochemical investigations employing antibodies directed against endogenous lectins[128-130] or by studies on tumor cell lines. In using these cell lines, however, it must be borne in mind that their lectin expression may depend on culture and growth conditions.[131] Further, cell lines from primary tumors represent cell populations adapted to the culture conditions. Even if they are, for this reason, not necessarily representative of the primary tumor, they nonetheless provide an important cell-biological model system.

A clinically prominent property of tumors, organotropic metastasis, can be subjected to functional studies in such model systems.[132-134] In this connection, organotropy signifies that cells from a particular type of primary tumor colonize preferentially other particular tissues and give rise to daughter growths. Some model systems comprising cells of identical genetic origin contain subpopulations of varying metastatic capacity. In such systems the differences in the patterns of endogenous lectins can be correlated with these subpopulations.[135-137] Particular lectins have already been implicated in certain functional steps of the metastatic cascade.[138, 139] Since endogenous lectins can be involved in growth regulation,[140-142] lectin expression and the associated lectin-glycoconjugate interactions presumably also play a role in promoting tumor growth. Such interactions, however, can lead to recognition and destruction of the tumor cells by cells of the immunological defense system.[124] Clearly, therefore, normal cells, with which a tumor cell is in contact from the time of its release from the parent cell mass until it colonizes a target organ, also bear endogenous lectins capable of interaction. These can help enhance metastatic organotropy.[143, 144] The recognition of cells by means of a sugar-coding system always implies mutual recognition.

Extending this concept by viewing the tumor cell in a simplified way as a normal cell that has lost its growth control and attained parasitic character,[145] one finds similar colonization mechanisms for viruses, bacteria, and parasites.[146-148] This points the way to anti-metastatic and anti-parasitic forms of treatment based on lectins.

6. Computers as "Bloodhounds" for Lectins and Lectin Functions

The physiological significance of lectins should not be viewed as restricted simply to sugar-binding and the functions associated with it. Besides the domain which defines the protein operationally as a lectin, other active domains may also determine the overall functions of any given protein. The search for these other distinct domains is facilitated by use of computer programs. Their existence can then be confirmed by direct experiment, as exemplified by the further functional domains in the slime-mold lectin discoidin I,[149, 150] in a mannose-binding protein,[151] and in the mannose-6-phosphate receptor.[152]

Proteins that are familiar to us because of other domains and their associated properties might well be included nominally among the lectins: for example, fibronectin,[153] laminin,[154] thrombospondin,[155] or the neural cell adhesion molecule NCAM.[156] The search for sugar-binding domains in yet other proteins, followed by experimental confirmation of their functional capacity, can also be helped by use of computer programs. Homology analysis starting with known sequences from lectins furnishes the initial indication of features common to parts of the sequence of lectins and proteins hitherto defined in terms of other domains. Such common sequences have been postulated for endogenous lectins and the lymphocyte IgE receptor,[157, 158] as well as the core protein of cartilage chondroitin sulfate.[159, 160] Since saccharides exhibit inhibitory effects in proliferation assays of hematopoietic stem cells dependent on the positive action of colony-stimulating factors, a homology analysis comparing sequences of these factors with lectin sequences may be limited to those lectins that function as potent inhibitors.[161] It reveals a striking homology at the hexapeptide level (Fig. 5). However, because of the lack of structural data based on X-ray analyses of protein crystals, the sugar-binding site in endogenous lectins is not adequately defined. Moreover, it might be constructed from peptide fragments which are not consecutive in the sequence. Such results of homology analysis are therefore in no way conclusive. Further information about the nature of the sugar-binding site, such as that provided by affinity labeling with photoactive sugar ligands,[163, 164] can help focus the search for sequence homologies on the relevant structural elements. Random homology fluctuations in other regions of the sequence could in this way be filtered out. In the future, computer analysis will increasingly contribute significantly to the search for structural receptors for sugars as a prerequisite for functional analysis.

Fig. 5. Sequence homologies of the granulocyte/macrophage colony-stimulating factor (A) and the multipotential colony-stimulating factor (B) with nine lectins (left, abbreviations given below). The sequence of the colony-stimulating factor (A and B) is shown nine times. Each of the two sequences was compared (using a computer program) with the sequence (not shown) of each of the nine lectins. The partial sequences of the two factors enclosed in boxes are significantly homologous with partial sequences of the lectins. These partial sequences of the lectins may be located at various sites of the molecule. No such homologies were found for some lectins. Noteworthy is the variable distribution of the homologous regions in the two factors. Abbreviations: HBP, hepatic β-galactoside-specific sugar-binding protein from rat; GALCH, β-galactoside-specific lectin from chicken; GALHU, human β-galactoside-specific lectin; GALBO, bovine β-galactoside-specific lectin; FLYLEC, β-galactoside-specific lectin from flies; RICIN B, DISCOI, PNA, β-galactoside-specific lectin from *Ricinus communis*, from the slime-mold *Dictyostelium discoideum*, and from peanuts, respectively; MANRAT, mannose-specific lectin from rat.

7. Perspectives

Does there exist a sugar-coding system involving endogenous lectins in biological recognition? This question has opened the way for ground-breaking efforts, which are likely to have a dramatic impact on future lectinology research. The resulting complex of questions includes clarification of the exact structure of receptor–ligand pairs in this system of biological recognition at both chemical and biochemical levels, as also clarification of their cellular localization and regulation at the cell-biological level. Efforts to solve these questions in the tumor model system can proceed parallel with clinical trials using lectin-based tumor diagnosis and therapy. A deepened understanding of the emerging significance of sugar–protein (lectin) interaction for growth regulation or for immune regulation—encouraged by initial data on the stimulation of cytokine release[165]—can enrich the modes of treatment available in oncological practice. The necessity for trustful interdisciplinary collaboration is both challenge and charm in this area at the intersection of carbohydrate chemistry, biochemistry, cell biology, and oncology.

I thank U. Rust for the intelligent care and great patience with which she typed the final manuscript. I am grateful to the Dr.-Mildred-Scheel-Stiftung für Krebsforschung for their financial support of the work of my research group.

New Transition Metal Clusters with Ligands from Main Groups Five and Six

By Dieter Fenske,* Johannes Ohmer, Johannes Hachgenei, and Kurt Merzweiler

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

In both physics and chemistry, increased attention is being paid to metal clusters. One reason for this attitude is furnished by the surprising results that have been obtained from studies of the preparation, structural characterization and physical and chemical properties of the clusters. Whereas investigations of cluster reactivity are at present generally limited to three- or four-membered clusters, successful syntheses of clusters with many more metal atoms have recently been designed. These substances occupy an intermediate position between solid state chemistry and the chemistry of metal complexes. This review presents a versatile method for synthesizing metal clusters: the reaction of complexes of transition metal halides with silylated compounds such as $E(SiMe_3)_2$ (E = S, Se, Te) and $E'R(SiMe_3)_2$ (R = Ph, Me, Et; E' = P, As, Sb). Although some of the compounds thus formed have already been prepared by other routes, the method affords ready access to both small and large transition metal clusters with unusual structures and valence electron concentrations; a variety of reactions in the ligand sphere are also possible.

1. Introduction

In the widest sense, a cluster is an aggregate of molecules or atoms. Many of these clusters contain metal atom groups M_n in which the metals are chemically bonded to each other. Although it is not always easy to decide whether metal-metal bonds are present, the comparison with bonding in pure metals is often made.

Metal clusters occur in discrete molecules or in units bridged by ligands. Although "isolated" clusters, lacking the protective ligand sphere, are known, the stability of aggregates of metal atoms is generally dependent on the number and type of ligands surrounding the metal framework.[1,2] As examples, consider the many known "molecular clusters" that involve CO, Cp and halide ligands.

In order to define the concept "cluster" more precisely, such compounds, consisting of an M_n cluster and ligands bound to it, are termed "metal cluster complexes". These substances have been the subject of an extraordinarily large number of studies and have been reviewed many times.[3] This review concerns itself essentially with our research since 1984.

Our interest in cluster chemistry arose from the question whether it would be possible to synthesize polynuclear complexes with phosphino derivatives of maleic anhydride as ligands, e.g. 2,3-bis(diphenylphosphino)maleic anhydride (PP). These ligands exhibit very low redox potentials;[4] as a consequence, their reaction with transition metal complexes can lead to mononuclear complexes in which (PP) is coordinated to the metal as a radical anion.[5,6] Examples of such products are:

$[(PP)^{\ominus}Co^{\oplus}(CO)_3]$ $[(PP)^{\ominus}Mn^{\oplus}(CO)_4]$ $[(PP)_2^{\ominus}M]$, $M = Pd^{2\oplus}, Pt^{2\oplus}$

Would similar electron transfer from metal to (PP) be possible in transition metal clusters containing (PP) ligands? If so, it should be possible to prepare clusters with unusual valence electron concentrations.

There are several potential routes to such compounds. The reactions of $[(PP)MCl_2]$ (M = Pd, Pt) with $[M(PPh_3)_4]$ lead to diamagnetic or paramagnetic dinuclear complexes.[7,8] We also attempted to obtain PPh-bridged complexes by the reaction of $[(PP)MCl_2]$ (M = transition metal) with $PPh(SiMe_3)_2$.

Although it has been known for years that silylated phosphanes react with transition metal halides to form polymeric products, surprisingly few authors have pursued this reaction type.[9] In contrast, a considerable number of reactions of silylated phosphanes with halides of main group elements are known, leading to products containing bonds from phosphorus to the main group element.[10] *Schäfer* et al. were able to show that this synthetic principle could be extended to transition metal halides, and they obtained a wide variety of phosphido-transition metal complexes, four- or six-membered rings bearing P functions, and also diphosphene and diphosphorus complexes of Ni and Pt.[11-13]

Correspondingly, $[(PP)NiCl_2]$ [(PP) = 2,3-bis(diphenylphosphino)-*N*-methylmaleimide)] reacts with $E'Ph(SiMe_3)_2$ (E' = P, As), forming complexes of $(PPh)_2$ or $(AsPh)_2$.[14] The formation of $(E'Ph)_2$ units bound to Ni is promoted by the migration of the $SiMe_3$ groups to the CO of maleimide. Attempts to prepare heteroatomic clusters from these complexes and $[\{MoCp(CO)_3\}_2]$ led instead to a compound of the composition $[\{MoCp(CO)_2(PPh)\}_2]$.[15]

These results show that (PP) complexes of $NiCl_2$ can react with $PPh(SiMe_3)_2$, substituting the Cl ligands. The synthesis of polynuclear metal complexes is however not observed. We therefore decided to investigate whether PR_3 complexes of transition metal halides could react with $PR(SiMe_3)_2$ to form compounds with PR bridges.

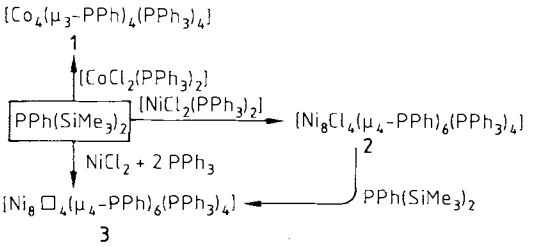
2. Clusters with E'R and E' Bridging Ligands

2.1. E' = P

Cluster compounds with ligands E'R (E' = P, As) can be prepared by various methods, e.g. the reaction of $E'RH_2$ or $E'RCl_2$ with carbonylmetals forming μ_3- or μ_4-E'R-bridged clusters.[16] We discovered a new method, the reaction of $[MCl_2(PPh_3)_2]$ (M = Co, Ni) with $PR(SiMe_3)_2$.[17] The reaction between $[CoCl_2(PPh_3)_2]$ or $[NiCl_2(PPh_3)_2]$ and $PPh(SiMe_3)_2$ in THF leads to the μ_3- or μ_4-PPh-bridged clusters **1** and **2**, respectively.[17] If $NiCl_2$, which is sparingly soluble in THF, is allowed to react with PPh_3 and $PPh(SiMe_3)_2$, a different product, the oxygen-sensitive complex **3**, is obtained; it is also formed by the reaction of **2** with an excess of $PPh(SiMe_3)_2$. Without PPh_3, the reaction of $NiCl_2$ with $PPh(SiMe_3)_2$ leads to insoluble polymeric products of unknown structure.[9] The high selectivity of the reactions is reflected in yields of **1**, **2**, and **3** of up to 90%.



Only clusters of cobalt and nickel have so far proved accessible via the reaction between $[MCl_n(PPh_3)_m]$ and $PPh(SiMe_3)_2$. The analogous reactions with $[FeCl_3(PPh_3)_2]$, $[MCl_2(PPh_3)_2]$ (M = Cu, Hg) and $[MCl(PPh_3)]$ (M = Hg, Ag, Au) lead respectively to complexes of $Fe^{2\oplus}$ and $Cu^{\oplus}$ or metallic Hg, Ag and Au. The reactions with Rh, Pd and Pt complexes have not been explored.

It can be seen that **1** (Fig. 1) consists of a tetrahedral Co_4 cluster whose four tetrahedral faces are coordinated by μ_3-PPh ligands. Each Co atom is additionally bound to the P atom of a PPh_3 ligand. The bonding parameters observed in **1** (T_d symmetry, Co-Co 256(1) pm) are in good agreement with those in a large number of known heterocubane clusters.[18]

1, which is diamagnetic, can be reversibly oxidized to $\mathbf{1}^{\ominus}$ and $\mathbf{1}^{2\oplus}$ in THF solution.[19] Consistent with this observation, **1** is oxidized by $CHCl_3$, CCl_4 or $C_2H_4Cl_2$ to $\mathbf{1}^{\oplus}Cl^{\ominus}$. **1** also reacts with CH_3COCl at temperatures above 330 K to form the paramagnetic $\mathbf{1}^{\oplus}[CoCl_3(PPh_3)]^{\ominus}$ ($\mu_{eff} = 4.55\,\mu B$ at 300 K).

2 (Fig. 1) consists of an almost regular Ni_8 cube (Ni-Ni 259–262 pm, Ni-Ni-Ni 89.6–90.3°) whose Ni atoms are coordinated alternately by PPh_3 and Cl ligands. Each face is capped by a μ_4-PPh ligand. The structure of **2** is thus comparable with $[Ni_8(CO)_8(\mu_4\text{-}PPh)_6]$, which had already been described by *Dahl* et al.[20]

The structure of **3** (Fig. 1) is similar to that of **2**. However, the Ni_8 cube in **3** is highly distorted, with Ni-Ni-Ni bond angles between 79.2 and 100.1°; this is reflected in the differing coordination of Ni1, Ni3, Ni6, Ni7 (distorted tetrahedral coordination by the P atoms of one PPh_3 and three μ_4-PPh ligands) and Ni2, Ni4, Ni5, Ni8 (coordinated only to three P atoms of the μ_4-PPh ligands).

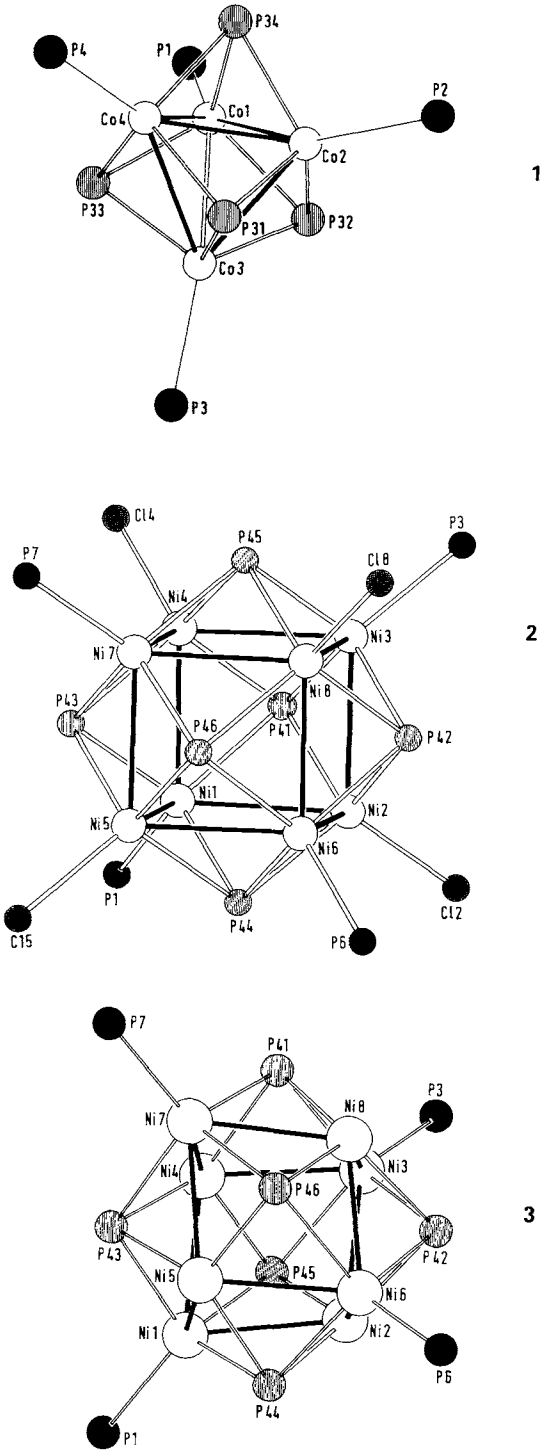


Fig. 1. Molecular structures of the clusters **1**, **2** and **3** (phenyl groups omitted). In **1**, P1–P4 and P31–P34 are the P atoms of the PPh_3 and μ_3-PPh ligands respectively. In **2** and **3**, P1–P7 and P41–P46 are the P atoms of the PPh_3 and μ_4-PPh ligands, respectively.

The usual electron counting rules indicate that Ni2, Ni4, Ni5, Ni8 are associated with 16 valence electrons, Ni1, Ni3, Ni6, Ni7 with 18. One consequence of this electron deficit may be the shortening of the face diagonals between the 16e Ni atoms to 323–325 pm and the lengthening of the distances between the 18e Ni atoms to 384–398 pm.

3 is unexpectedly stable. One reason for this may be the steric screening of the four coordinatively unsaturated Ni atoms (Ni2, Ni4, Ni5, Ni8) by six phenyl groups of the PPh_3 and PPh ligands. This crown-shaped arrangement leads to four identical free coordination sites in the molecule, with diameters restricted to 400–500 pm. Figure 2 demonstrates this for the free coordination site at Ni5 by means of a space-filling model. Further coordination of these four Ni atoms by PPh_3 ligands is no longer possible because of the steric shielding of these atoms.

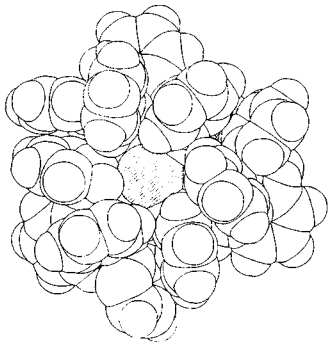

Fig. 2. Space-filling model showing a free coordination site (□) at atom Ni5 (shaded) of 3.

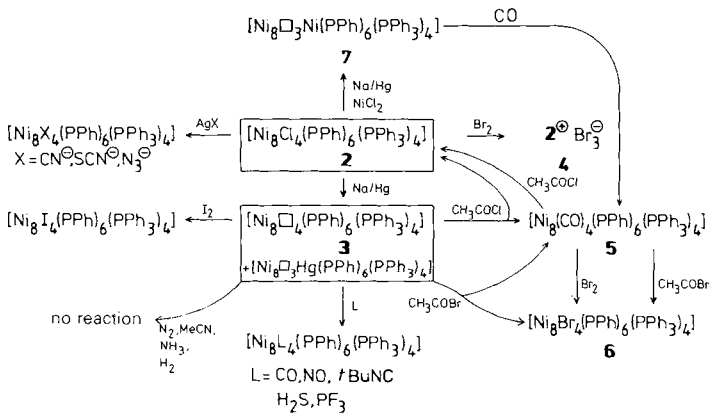
2.1.1. *Reactions of the Complexes 2 and 3*

Although the number of structurally characterized clusters is now immense, the study of their reactivity has mostly been limited to smaller clusters.[21] *Huttner* et al., for example, were able to show that trinuclear, μ_3-E'R-bridged carbonylmetal clusters (E' = N, P, As, Sb, Bi) are suitable for kinetic mechanistic studies.[22] The peripheral ligands of such clusters are susceptible to exchange by addition and subsequent elimination.

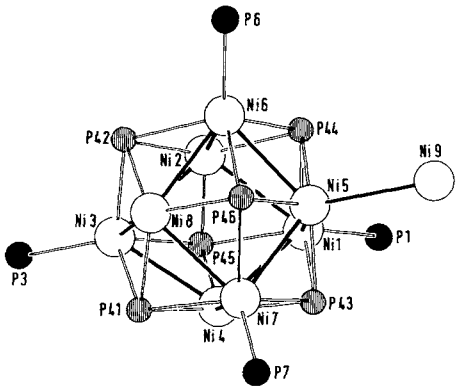
It is notable that the Ni_8-clusters 2 and 3 are also suitable for studies of substitution and addition reactions at the ligand periphery. The Cl ligands of 2 can be substituted, and neutral molecules can be added to the free coordination sites of 3. Scheme 1 summarizes the reactions carried out so far.



Scheme 1. Reactions leading to derivatives of the Ni_8 clusters.

The stability of the Ni_8 cluster framework is also illustrated by the reaction of 2 with concentrated methanolic solutions of bromine to form $2^{\oplus}Br_3^{\ominus}$ (4).

With sodium amalgam, 2 forms the coordinatively unsaturated 3. If the same reaction is carried out in the presence of solid $NiCl_2$, however, a "naked" nickel atom (presumably arising from reduction of $Ni^{2\oplus}$) is introduced into a free coordination site of 3, forming the Ni_9 cluster 7. Whereas all the vacant coordination sites in 3 display an identical form, the unoccupied sites of 7 have decreased in diameter. As a consequence, no further Ni atoms can be introduced.



7

Fig. 3. The molecular structure of 7 (phenyl groups omitted). P41–P46 and P1–P7 represent the P atoms of the μ_4-PPh and PPh_3 ligands respectively.

The structure determination of 7 (Fig. 3) shows that the bond lengths in the Ni_8 cube are comparable to those in 3. The bond length Ni5–Ni9, 268.2 pm, lies in the range of Ni–Ni single bonds. Since Ni9 is not bound to any other ligands, only its steric screening by the six phenyl groups can be responsible for the stability of 7. The long Ni···C(Ph) contacts of 326–380 pm make interactions with the π systems improbable.

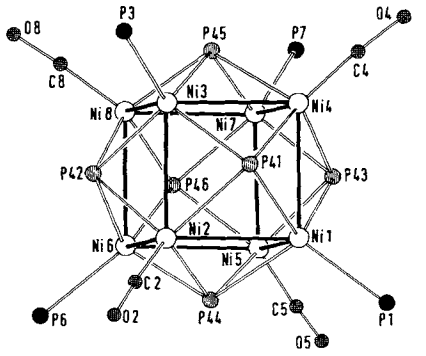
It is however possible that weak bonding interactions to three phenyl protons are involved, leading to a distorted tetrahedral coordination at Ni9 (Ni···H 247–294 pm). An NMR investigation of this hypothesis is not feasible because of the paramagnetism of 7.

By reaction of 2 with Na-amalgam we have, in the meantime, been able to isolate (besides 3) a complex which is isostructural with 7 and in which one free coordination site is occupied by an Hg atom (see Scheme 1).

Attempts to incorporate Pd, Pt and Au atoms into the free coordination site led to as yet unidentified products. The unusually large unit cells (35000–55000 $Å^3$) imply the presence of very large clusters. Other ligands (e.g. $CN^{\ominus}$, $SCN^{\ominus}$, $N_3^{\ominus}$) can be attached to the cluster by the reaction of the corresponding silver salts with 2. The alternation of PPh_3 and the newly introduced ligands is maintained, which indicates the lack of mobility of the PPh_3 groups.

The coordinatively unsaturated 3 also serves as starting material for a variety of reactions (Scheme 1). It reacts with CH_3COCl to form a mixture of 2 and 5 (Fig. 4). A possible intermediate in this reaction is an acyl complex that decomposes to form 5. 5 can also be obtained by the reaction of 7 with CO. The bromo-substituted cluster 6 is formed in the reaction of 5 with CH_3COBr.

It can further be seen from Scheme 1 that the vacant coordination sites of 3 can be occupied by ligands such as CO, *t*BuNC, H_2S, and PF_3. However, no reaction is observed with MeCN, NH_3, or H_2; no evidence for coordina-



5

Fig. 4. The structure of **5** (phenyl groups omitted). P41-P46 and P1-P7 represent the P atoms of PPh and PPh_3 ligands respectively.

tion of these molecules could be found in the solid state. Finally, N_2 does not coordinate to **3**, even under a pressure of 150 bar.

2.1.2. *Structural, Spectroscopic and Magnetic Properties of Ni_8 Clusters*

A meaningful description of bonding in clusters presupposes an understanding of the relationships between structure, physical and chemical properties, and the number of valence electrons. The structural and chemical diversity of clusters has however militated against the development of a general bonding theory. There are, though, several models that can be applied with varying degrees of success; amongst these are the 18-electron rule, Wade's rules, semi-empirical MO calculations, the topological electron counting rules of *Teo* and *Mingos*, and the isolobality principle of *Hoffmann*.[23-27]

The 18-electron rule would imply a valence electron count of 120 for clusters of cubic shape; this condition is fulfilled by e.g. $[Ni_8(CO)_8(PPh)_6]$.[20] Our cluster compounds, however, often display appreciable deviations from this criterion; if PPh_3 and $Cl^{\ominus}$ are considered 2e donors and μ_4-PPh a 4e donor, **2** and **3** contain 116 and 112 valence electrons respectively.

Table 1. Valence electron count VE and Ni-Ni, Ni-P bond lengths in $[Ni_8X_4(PPh)_6(PPh_3)_4]$.

Compound	X	VE $e^{\ominus}$	for Ni-Ni bonds	Ni-Ni [pm]	Ni-P [pm] PPh_3	Ni-P [pm] PPh
3	—	112	16	251-254	221	212-216 224-228
4	Cl	115	19	256-260	222-224	220-224
2	Cl	116	20	259-262	224-225	220-222
6	Br			259-262	224-225	220-222
5	CO	120	24	265-269	226-229	218-222

Table 1 demonstrates that the Ni-Ni bond lengths are crucially influenced by the electron count. Surprisingly, the Ni-Ni bonds are shorter when fewer electrons are available for Ni-Ni bonding. The Ni-P bonds are less sensitive in this respect.

The magnetic properties of the Ni_8 clusters are also impossible to rationalize on the basis of simple assumptions. Magnetic susceptibility measurements can however provide information as to possible coupling of electrons in the cluster. *Holm* et al. carried out such measurements some years ago for clusters of the type $[Fe_4(\mu_3\text{-}S)_4(SPh)_4]^{n\ominus}$ $(n = 2, 3)$.[28]

As would be expected, **5** (120 valence electrons) is diamagnetic and **4** (115 valence electrons) paramagnetic. It is less easy to understand the paramagnetism of **3** (112 valence electrons), **2**, and **6** (each 116 valence electrons). For instance, a temperature-dependent magnetic moment is observed for **2**: $\mu_{eff}(T) = 2.37\,\mu B$ (300 K), 2.48 (200 K), 2.54 (100 K), 2.44 (25 K), 1.86 (10 K), and 0.94 (4 K). This could be rationalized if **2** contains Ni atoms in different oxidation states $(4\,Ni^0 + 4\,Ni^{\oplus})$, the magnetic properties then corresponding to an antiferromagnetic coupling of the d^9 $(Ni^{\oplus})$ centers.

Transition metal clusters undergo reversible redox processes without altering their metal framework.[29] The clusters **2** to **6** can also be reversibly oxidized and reduced. This result is consistent with the large deviations from the 18e rule that are tolerated by **2**-**6**.

The characterization of paramagnetic clusters by NMR methods is generally difficult, because very broad signals are often observed. It is thus all the more surprising that the ^{1}H-NMR spectrum of **2** displays sharp, strongly temperature-dependent resonances. The paramagnetism causes different isotropic shifts of the phenyl protons of the μ_4-PPh and PPh_3 ligands, enabling the *o*-, *m*-, and *p*-protons to be clearly distinguished. The following shifts are observed in $CDCl_3$ in the temperature range 323-213 K: PPh_3: *o*-H 3.15-0.93, *m*-H 10.60-12.75, *p*-H 3.37-1.27; PPh: *o*-H 6.82-6.01, *m*-H 6.93-7.20, *p*-H 5.59-5.22 ppm. A plot of the shifts against temperature shows that the dependence obeys Curie's law.[30]

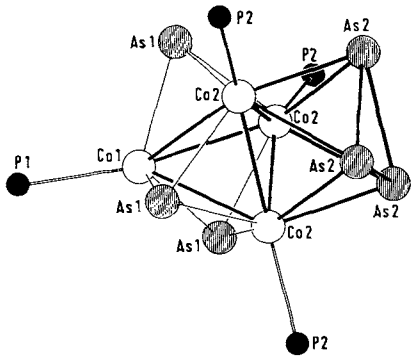
^{31}P-NMR spectra show resonance signals only for diamagnetic derivatives. The observed chemical shifts of $\delta =$ 0-20 for PR_3 and 620-640 ppm for μ_4-PPh ligands (in THF) lie in the expected ranges.[31]

The IR spectra of the compounds **2**-**7** are almost identical, except in the range 1500-2000 cm^{-1}, and have no diagnostic value.

2.2. E′ = As; Arsenic-Bridged Clusters

Attempts to extend the above synthetic principle to the reaction of $[MCl_2(PPh_3)_2]$ and $AsPh(SiMe_3)_2$ yield no evidence for the formation of complexes with bridging AsPh ligands; the reaction of $[FeCl_2(PPh_3)_2]$ with $AsPh(SiMe_3)_2$, for instance, leads only to Fe, $(AsPh)_n$, and Me_3SiCl. The reaction between $[CoCl_2(PPh_3)_2]$ and $AsPh(SiMe_3)_2$, however, leads to (apart from a little metallic cobalt) a cluster of composition $[Co_4As_6(PPh_3)_4]$ (**8**),[32] which is paramagnetic. **8** is formed in 95% yield. A crystal structure analysis (Fig. 5) reveals a Co_4 tetrahedron whose faces are capped by three μ_3-As and one μ_3-As_3 ligand. Each Co atom is additionally coordinated by one PPh_3 group.

8 (56 valence electrons) may be derived from a heterocubane cluster $[Co_4(\mu_3\text{-}As)_4(PPh_3)_4]$ in which one μ_3-As has been replaced by a μ_3-As_3 unit. Alternatively, it can be considered as a Co_3As_3 octahedron linked through one face (Co2) with a $CoAs_3$ unit. The previously known complexes of E_3' (E′ = P, As) are generally considered to be derivatives of the tetrahedral P_4 or As_4, where As or P



8

Fig. 5. Molecular structure of **8** (phenyl groups omitted). As2 represent the μ_3As_3 ligand, P1 and P2 the P atoms of the PPh_3 ligands, and As1 the μ_3As ligands. **8** displays a crystallographic threefold symmetry.

atoms have been replaced by isolobal transition metal fragments.[33,34]

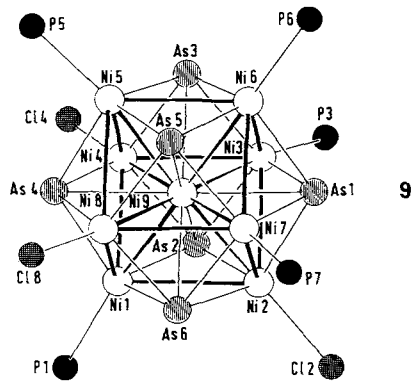
The As–As bond length within the As_3 unit (246.3 pm) is comparable with the As–As distances in As_4, $(AsPh)_6$, and $[(triphos)CoAs_3Co(triphos)]^{2\oplus}$ and is only about 10 pm longer than the As–As distance in the As_3 complexes $[As_3Co(CO)_3]$ and $[MoCpAs_3(CO)_2]$[34,35]

The formation of **8** is surprising, because it occurs at room temperature and involves the breaking of the As–C(Ph) bond. However, examples of the instability of As–C bonds have been known for a long time.[36]

Recent results confirm that $[NiCl_2(PPh_3)_2]$ also reacts with $AsPh(SiMe_3)_2$, breaking the As–C(Ph) bonds and forming As-bridged complexes. In THF the cluster **9** can be isolated.[37]

$[Ni_9Cl_3(\mu_4\text{-}As)_6(PPh_3)_5]$ **9**

Figure 6 shows that the metal atom framework of **9** consists of an Ni_8 cube, in the center of which a further Ni atom is situated. The faces of the Ni_8 cube are capped by six μ_4-As ligands, and the Ni atoms are coordinated either by $Cl^{\ominus}$ (*Ni2*, *Ni4*, *Ni8*) or PPh_3 (Ni1, Ni3, *Ni5*, *Ni6*, Ni7).



9

Fig. 6. Molecular structure of **9** (phenyl groups omitted). P1–P7 represent the P atoms of the PPh_3 ligands.

9, with 121 valence electrons, has one electron fewer than would be predicted by the 18e rule. An electron counting rule for centered metal clusters has been proposed by *Mingos*;[26a] the number of valence electrons in close-packed metal clusters should be $(12n_s + \Delta_i)$, where n_s is the number of peripheral metal atoms and Δ_i is 18 or 24 for centered cubic polyhedra. On this basis, **9** should possess 114 or 120 valence electrons.

Within the Ni_8 cube, the Ni–Ni bond lengths (277–285 pm for Ni1 to Ni8) are 40–50 pm longer than those to the central atom Ni9 (238–248 pm). In contrast, the bond lengths from the peripheral Ni atoms to the μ_4-As atoms (230–234 pm) are 30 pm shorter than the Ni9–As bonds (261–264 pm). The centered cubic cluster **9** can, like the $[Au_9(PPh_3)_8]^{\oplus}$ ion and the Rh_{14} core of the $[Rh_{14}(CO)_{25}]^{4\ominus}$ ion, be considered as a fragment of a larger centered cluster.[38,39]

Preliminary results indicate that the reaction of $[NiCl_2(PR_3)_2]$ with $AsPh(SiMe_3)_2$ can also lead to clusters with more metal atoms, formed by condensation of centered cubic clusters via common faces.

9 is interesting for another reason: analogously to **2**, it possesses three reactive Ni–Cl bonds. By breaking these bonds, it is possible to synthesize a coordinatively unsaturated complex similar to **3**. The vacant coordination sites thus formed are larger (because the μ_4-As ligands are smaller than μ_4-PPh) and thus can accommodate larger ligands.

3. S- and Se-Bridged Cluster Complexes of Cobalt and Nickel with PR_3 Ligands

The existence of the coordinatively unsaturated cluster **3** prompts the consideration whether it is possible to synthesize clusters with larger vacant coordination sites. Since these sites arise as a consequence of a steric screening of the metal atoms by peripheral ligands, several possible synthetic routes suggest themselves:

1. Substitution of PPh_3 ligands by PR_3: The reaction of $[NiCl_2(PR_3)_2]$ with $PPh(SiMe_3)_2$ leads for R = Me, Et to diphosphene complexes or clusters of unknown structure; for $R = C_4H_9$, *cyclo*-C_6H_{11}, clusters $[Ni_8\square_4(PPh)_6(PR_3)_4]$ are obtained, with properties analogous to those of **3**.

2. Substitution of PPh_3 by $E'Ph_3$ (E' = As, Sb): $[NiCl_2(E'Ph_3)_2]$ also reacts with $PPh(SiMe_3)_2$ to form clusters of the type $[Ni_8\square_4(PPh)_6(E'Ph_3)_4]$.

3. Replacement of the μ_4-PPh by μ_4-PR (R = *t*Bu, Me): The reaction of $[NiCl_2(PPh_3)_2]$ with $PR(SiMe_3)_2$ leads to complexes of unknown structure.

4. Substitution of μ_4-PPh by the less sterically demanding ligands S and Se: The compounds $E(SiMe_3)_2$ (E = S, Se, Te) react with derivatives of transition metal halides, in a manner analogous to the cleavage of the E–Si bond in $PPh(SiMe_3)_2$, to form S-, Se- and Te-substituted clusters. Although many methods are known for the synthesis of clusters with chalcogen ligands, the use of silylated chalcogenides offers easy access to transition metal clusters.[40–42]

We have so far studied the reactions of PR_3 complexes of the following metal halides with $E(SiMe_3)_2$: $MnCl_2$, $FeCl_2$, $CoCl_2$, $NiCl_2$, $PdCl_2$, $PtCl_2$, $RhCl_3$, $CuCl_2$, $HgCl_2$, "$MoCl_2$", and W_2Cl_6.

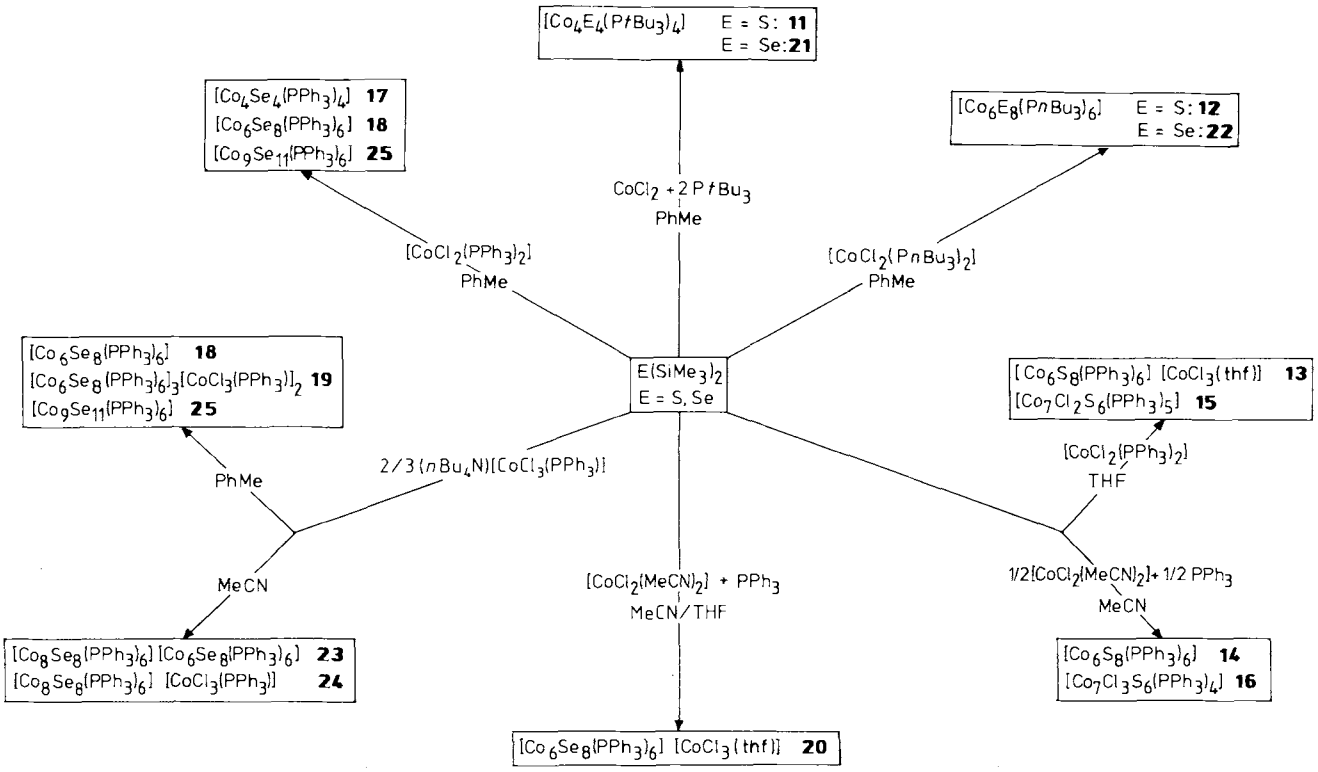
Depending on the metal and its ligands, we obtained either binary chalcogenides (Mn, Fe, Cu, Hg) or mixtures of various cluster compounds, which could be separated by fractional crystallization. Clearly, the solubility products of the chalcogenides and the stability constants of the clusters play an important role.

The IR spectra of these substances are dominated by the bands of the tertiary PR_3 ligands and are thus all practically identical. NMR spectra are difficult to obtain because of the sparing solubility and easy oxidation of the clusters in chlorinated hydrocarbons such as CH_2Cl_2 or $CHCl_3$. The information content of the spectra is anyway very limited. The identification of the products is generally dependent on crystal structure analyses.

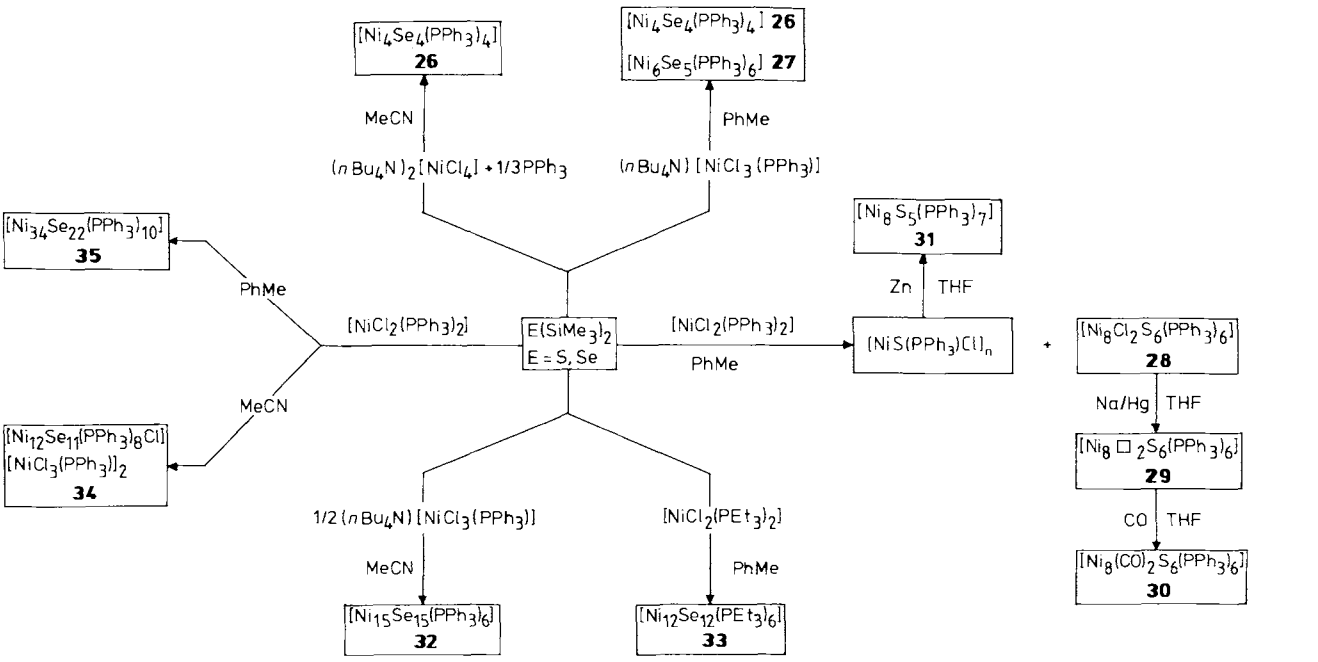
Schemes 2 and 3 summarize the cluster products that are formed in the reactions of $E(SiMe_3)_2$ (E = S, Se) with various Co and Ni complexes. By-products such as elemental Co or Ni, CoE or NiE and EPR_3 (E = S, Se; R = *n*Bu, *t*Bu, Ph) are not shown.

The following factors exert critical influence on the nature of the products:

1. The ratio M : E : PR_3.



Scheme 2. Preparative reactions for chalcogen-bridged Co clusters.



Scheme 3. Preparative reactions for chalcogen-bridged Ni clusters.

2. The solvent. The following have been used: toluene, MeCN, THF and low-melting (m.p. < 400 K) salt mixtures.

3. Conditions for crystal growth. The solubility of the products is decisively influenced by the R substituents of the PR_3 ligands. Whereas species with PPh_3-, $PtBu_3$- and $P(C_6H_{11})_3$-ligands are almost insoluble in all common solvents, the PEt_3- and $PnBu_3$-derivatives are soluble even in unpolar solvents such as heptane or ether. This initially surprising observation should enable a better control of the solubility of cluster products, and ought to make possible the spectroscopic and cyclovoltammetric studies of high molecularity clusters. It should however be stressed that mixtures of various clusters are often formed, the separation of which becomes more problematic with increasing cluster size.

The following discussion of the structures of various products is arranged according to the number of metal atoms.

3.1. M_3 and M_4 Clusters

No binuclear complexes can be isolated from the reaction between $[MCl_2(PR_3)_2]$ (M = Co, Ni) with $E(SiMe_3)_2$. The smallest cluster that we have been able to prepare so far, albeit in low yields, is the trinuclear complex $[Ni_3Cl_2S_2(PPh_3)_4]$ **10** (Fig. 7a).

In contrast, in reaction (a) with the bidentate ligand the M_3 cluster is formed in high yields. As in **10** is consists of an Ni_3 cluster in which the Ni_3 triangle (Ni-Ni 298; **10** 290–293 pm) is capped to two μ_3-Se ligands and additionally bonded to the P atoms of the bidentate phosphanes or to $Cl^{\ominus}$ and PPh_3 in **10**. $[Ni_3S_2(PEt_3)_6]^{2\oplus}$, obtained by the reaction of $[NiCl_2(PEt_3)_2]$ with H_2S, has a similar structure.[53]

$$[NiCl_2(Ph_2PCH_2CH_2PPh_2)] + Se(SiMe_3)_2 \longrightarrow [Ni_3Se_2(Ph_2PCH_2CH_2PPh_2)_3]Cl_2 \quad (a)$$

M_4E_4 heterocubane clusters (Fig. 7b) are prepared for example from $CoCl_2$, $PtBu_3$ and $E(SiMe_3)_2$ (**11** and **21**). The PPh_3-substituted compound **17**, analogous to **21**, however, is formed together with the Co_6 and Co_9 clusters **18** and **25**. The crystal structure analyses show that **11**, **17** and **21** (Fig. 7) consist of a Co_4 cluster with T_d symmetry, whose faces are capped by μ_3-S or μ_3-Se ligands. The PPh_3 ligands complete an irregular tetrahedral coordination of the metal atoms.[18,43,44]

The Co-Co bond lengths within these 60e Co_4E_4 clusters are, as would be expected, approximately equal, but they are 10–15 pm longer than in **1** (**11**: 270–272; **17**: 262–268; **21**: 264–270 pm). In contrast, in the 64e cluster **26** the four electrons in excess of the 60 electrons required by the 18e rule cause a splitting of the Ni-Ni bond lengths into four short (259–263 pm) and two long bonds (293.2, 279.1 pm). As a consequence, the Ni_4 framework is distorted towards a structure of approximately D_{2d} symmetry, as was predicted for 64e heterocubanes by *Dahl* et al.[45] Otherwise, **26** displays a structure similar to that of the Co_4 tetrahedra.

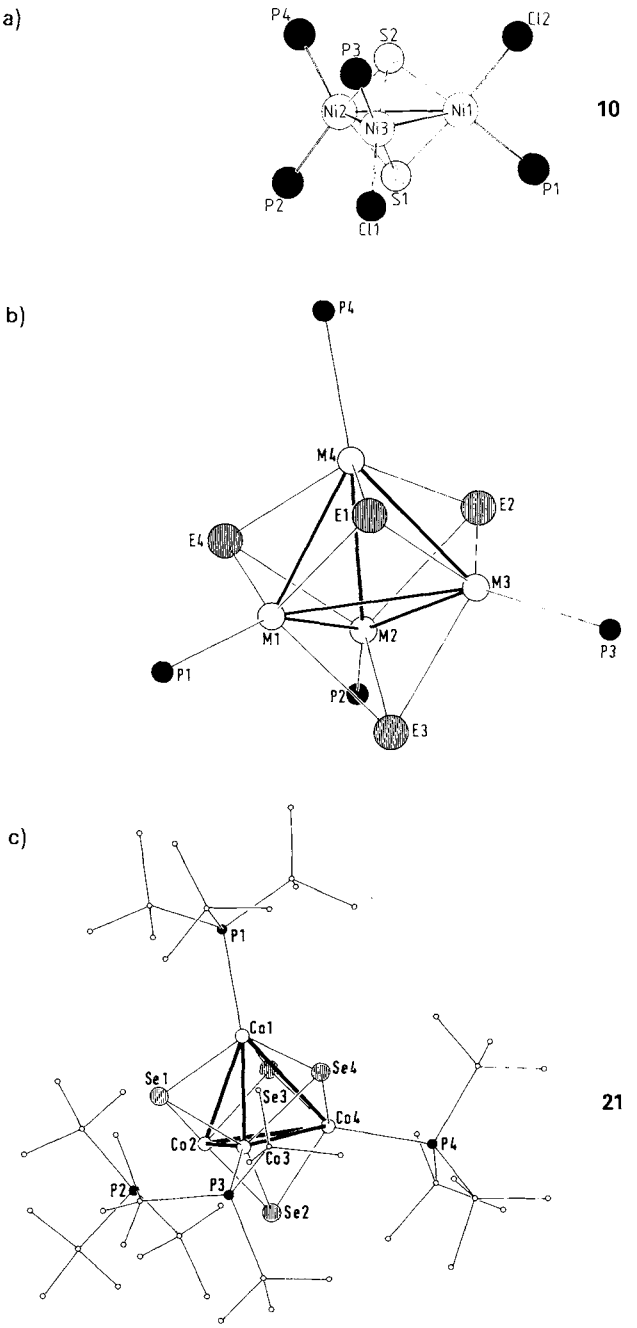


Fig. 7. a) Structure of **10** (P1–P4 are the P atoms of the PPh_3 ligands. b) Structure of the $[M_4E_4(PR_3)_4]$ framework (R groups omitted) in **11**, **17**, **21**, and **26**. c) Molecular structure of **21**.

3.2. M_6 Clusters

Not only **26** but also **27** can be isolated from the reaction of $(nBu_4N)[NiCl_3(PPh_3)]$ with $Se(SiMe_3)_2$ in toluene.[46] As can be seen from Figure 8b, **27** contains an Ni_6 prism, the faces of which are capped by two μ_3- and three μ_4-Se atoms. Each Ni atom is also coordinated by the P atom of a PPh_3 group. In the Ni_6 framework, the Ni-Ni bond lengths within the triangular faces (Ni 1,2,3 and Ni 4,5,6) are appreciably longer than those between these faces (273.0–279.8 compared to 260.2–266.3 pm). This distortion may be connected with the two electrons that the 92e cluster possesses in excess of the 90 electrons required by the 18e rule and the topological counting rules.[25]

A cluster of similar structure is the trigonal prismatic ion $[Pt_3(\mu_2\text{-}CO)_3(CO)_3]_2^{2\ominus}$,[47] although here the bonds of the Pt_3 faces (266 pm) are shorter than those between them (304 pm).

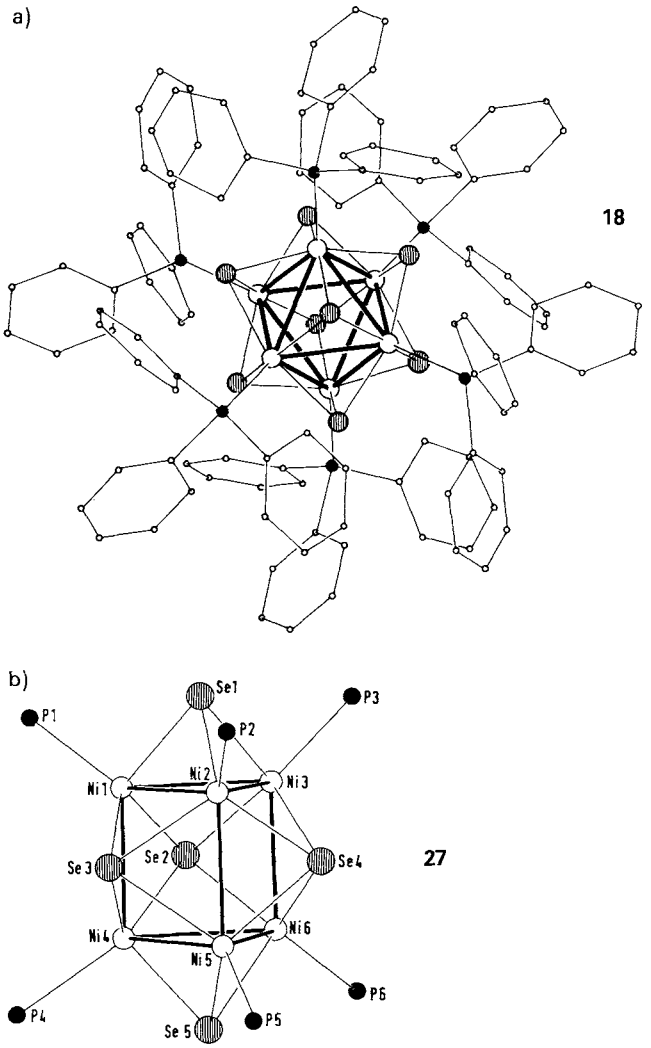

Fig. 8. a) Molecular structure of the $[Co_6E_8(PPh_3)_6]$ cluster as exemplified by **18**. b) Molecular structure of **27** (phenyl groups omitted).

We have also succeeded in preparing octahedral Co_6 clusters: the neutral compounds **12**, **14**, **18**, and **22** as well as the salts **13**, **19**, and **20**.

The basic structural principle in these compounds is illustrated in Figure 8a, using as an example **18**; an octahedron of Co atoms is capped at each triangular face by a μ_3-E ligand. The irregular tetrahedral coordination at each metal atom is completed by the P atom of a PPh_3 ligand. Table 2 compares selected bonding parameters of our Co_6 clusters[48,54] with those of the clusters $[Co_6S_8(PEt_3)_6]^{n\oplus}$ (n = 0, 1) prepared by *Cecconi* et al.[49] Four points emerge thereby:

1. All the 97e and 98e clusters possess 13 or 14 electrons more than would be expected from the 18e rule. Other electron counting rules, such as the topological rules of *Teo* et al. or *Mingos* et al.[25,26] are also unable to explain this excess of electrons. The long Co-Co distances (280–300 pm) are probably a consequence of the large number of valence electrons. Consistent with this view are the Co-Co contacts in the neutral complexes **12b**, **14**, and **18**, which are up to 10 pm longer than those in the monocations derived from them (cf., e.g., **18** and **19**). This observation implies that the one-electron oxidation of **12b**, **14**, and **18** involves the removal of the electron from an antibonding orbital. The symmetry of the clusters is unaffected by the change of valence electron number.

2. The Co-Co distances in the selenium-bridged Co octahedra **18** and **22** are appreciably longer than those in the analogous sulfur derivatives **14** and **12**. However, the nonbonding S-S or Se-Se contacts are about 50 pm less than the sum of the van der Waals' radii and could be considered weakly bonding. It is possible that the weakening of the Co-Co bonds is directly connected with the increasing interactions between the S (Se) ligands. An alternative description of all compounds in Table 2 is as cubic E_8 clusters (E = S, Se), whose E_4 faces are capped by six $Co(PPh_3)$ groups; accordingly, the Co atoms lie 42–50 pm above the E_8 cube faces. This value is clearly longer than in $[Mo_6Se_8]^{4\ominus}$ ($\pm$14.5 pm),[50] in which weak interactions between the Se ligands are also assumed to occur.

3. The PPh_3 substituted clusters display longer Co-Co bonds than the analogous derivatives with PEt_3 or $PnBu_3$ ligands.

4. The Co-E bond lengths are influenced neither by the cluster charge nor by the phosphane ligands. This implies that the bonding metal-chalcogen orbitals lie at lower energy than the Co-Co, Co-P, or E-E levels; i.e., the Co-E bonds should make an important contribution to the stability of the cluster framework.

3.3. M_7 Clusters

The reaction of $[CoCl_2(PPh_3)_2]$ or of $[CoCl_2(MeCN)_2]$ and PPh_3 with $S(SiMe_3)_2$ leads to the compounds **15** and **16**, the metal frameworks of which consist of Co_7 clusters (Fig. 9).[48]

Table 2. Averaged structural parameters for the series of isostructural clusters $[Co_6(n_3\text{-}E)_8(PR_3)_6]^{m\oplus}$ (E = S, Se; R = Et, *n*Bu, Ph; m = 0, 1).

	Co-Co [pm]	E-E [pm]	Co-E [pm]	Co-P [pm]	Co-(μ_3-E)-Co [°]	Deviation of the Co atoms from the E_4 plane [pm]
$[Co_6S_8(PEt_3)_6]^{\oplus}$	279.4	310.1	223.4	216.2	77.4	42–43
$[Co_6S_8(PEt_3)_6]$	281.7	309.5	223.3	213.8	78.2	45

16

Fig. 9. Molecular structure of **16** (phenyl groups omitted). The threefold axis is collinear with the Co3–P2 bond.

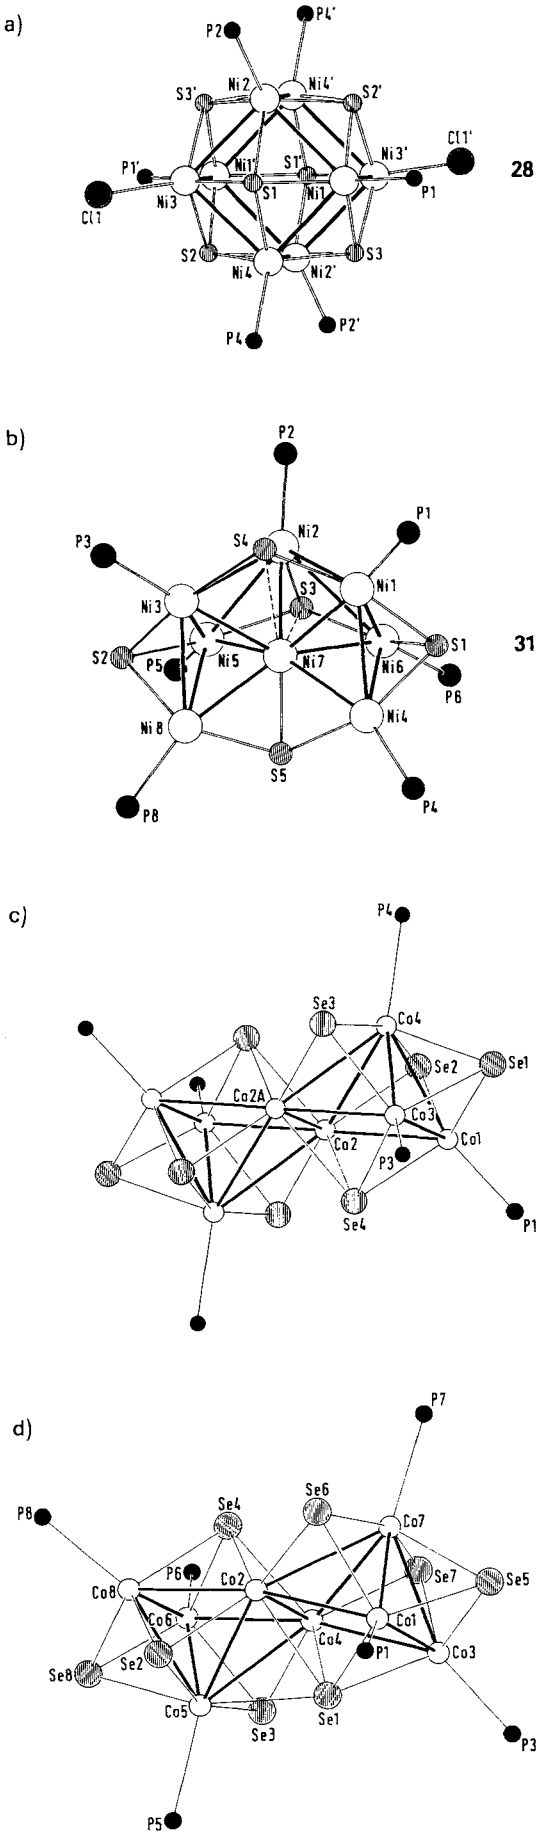
The cluster structures central to **15** and **16** can be derived from a cube by the removal of one vertex. The resulting polyhedron is thus composed of three Co_4 and four Co_3 faces; except for the triangular face Co2–Co2A–Co2B, all faces are capped by μ_4-S or μ_3-S ligands. **15** and **16** differ in that **15** has two Cl atoms coordinated to the Co_7 cluster, **16** three; the remaining Co atoms are each bound to one PPh_3 group. There are nine short Co–Co bonds (**15**: 257.4–263.7 pm; **16**: 257.1–262.2 pm) and three longer contacts within the chalcogen-free triangular face (**15**: 289.7 pm, **16**: 283.4 pm). **16** is isostructural with $[Fe_7Cl_3S_6(PEt_3)_4]$, which was prepared by *Holm* et al., and may be considered as intermediate between prismatic and cuboctahedral geometry.[51] According to the 18e rule, the paramagnetic **15** (99e) has an electron deficit of 2 and the diamagnetic **16** (98e) of 3. This is reflected in the willingness of **15** and **16** to react with CO. With **15**, a compound of formula $[Co_7(CO)_3Cl_2S_6(PPh_3)_5]$ is formed. The CO addition presumably occurs at the triangular face not occupied by S.

3.4. M_8 Clusters

Like the μ_4-PPh-containing Ni_8 clusters **2**–**7**, (Sections 2.1 and 2.1.1) **28** contains a slightly distorted Ni_8 cube ($\bar{1}$ symmetry; Fig. 10). In contrast to **2**–**7**, however, all cube faces of **28** are capped by μ_4-S ligands, and six Ni atoms (Ni1, Ni2, Ni4, Ni1′, Ni2′, Ni4′) are each bound to a PPh_3 group. The other two Ni atoms (Ni3, Ni3′) are each bound to one Cl ligand.[48] The Ni–Ni bond lengths observed in the 118e cluster **28** (266–270 pm) lie within the range given in Table 1.

When **28** is reduced with Na/Hg in THF, **29** is formed, in which two Ni atoms (Ni3 and Ni3′) are now only bound to three μ_4-S ligands. The vacant coordination sites (□) thus formed are topologically similar to those of **3**; accordingly, **29** reacts with CO, forming **30**. The addition of larger molecules has not yet been attempted. Vacant coordination sites can also arise when **28** is treated with $AgPF_6$, and the salt $[Ni_8\square_2S_6(PPh_3)_6](PF_6)_2$ can be isolated.

The reaction of $[NiCl_2(PPh_3)_2]$ with $S(SiMe_3)_2$ in THF leads to formation of **28** and a compound $[NiSPPh_3Cl]_n$, of



28

31

Fig. 10. Molecular structures of a) **28**, b) **31**, c) $[Co_8S_8(PPh_3)_6]^0$ in **23** and d) $[Co_8Se_8(PPh_3)_6]^{\oplus}$ in **24** (phenyl groups omitted).

unknown structure. The latter may be recrystallized from THF or acetone, but no single crystals have been obtained. If it is dehalogenated with Zn in THF, **31** is formed in 60% yield. Figure 10b shows this Ni_8 cluster, which consists of two trigonal bipyramids with a common edge. Apart from Ni7, all Ni atoms are bonded to a P atom of a PPh_3 ligand. Not all the faces of the polyhedron can be occupied by S atoms, because of the large size of the PPh_3 ligands. S1 and S2 are μ_3-ligands (Ni-S 211-217 pm); S5 can also be considered as a μ_3-ligand with unusual Ni-S-Ni bond angles (72.4-137.4°); S3 and S4 act as μ_4-ligands, if the weaker contacts to Ni7 are included, i.e. S3, S4 are μ_4 only when the S-Ni7 contacts are considered as bonds (Ni-S 213-219, but Ni7-S 258.6-268.8 pm). A description of the bonding in this 114e cluster is difficult because of the different Ni-Ni bond lengths (240-297 pm).[52,53,61]

The importance of the solvent is shown by the reaction of $(n\mathrm{Bu_4N})[CoCl_3(PPh_3)]$ with $Se(SiMe_3)_2$. In toluene, three products are obtained: **18**, discussed above (Section 3.2); a Co_9 cluster **25**, to be discussed below (Section 3.5); and the compound **19**. The crystal lattice of **19** contains both neutral and positively charged Co_6 polyhedra. The cationic and neutral species in the crystal cannot however be distinguished, because they are statistically distributed; the Co-Co distances in the Co_6 units are all equal and correspond to the average value of the metal-metal distances in the neutral **18** and in the ionic **20**.

If acetonitrile is used as solvent instead of toluene, the compounds **23** and **24** are obtained (Scheme 2). Crystals of **23** contain uncharged $[Co_8Se_8(PPh_3)_6]$ (Fig. 10c) and (octahedral) $[Co_6Se_8(PPh_3)_6]$ clusters. In contrast, **24** consists of the cations $[Co_8Se_8(PPh_3)_6]^{\oplus}$ (Fig. 10d) and the anions $[CoCl_3(PPh_3)]^{\ominus}$. Both Co_8 polyhedra consist of two square pyramids linked by a common edge and are mutually *trans*; their faces are capped by μ_3- or μ_4-Se ligands. The Co atoms of the pyramid bases (**23**: Co1, Co3, Co4; **24**: Co1, Co3, Co7, Co5, Co6, Co8) are bonded to PPh_3 ligands. Unlike the neutral **23**, the $[Co_8Se_8(PPh_3)_6]^{\oplus}$ cations of **24** do not possess an inversion center; the bases of the Co_5 square pyramids in **24** are thus no longer coplanar. This reduction of symmetry may have the following cause: the one-electron oxidation of the neutral **23** promotes the formation of an additional weak bond between Co5 and Se1 (258 pm) in **24**. The consequence is a mutual tilting of the Co_5 pyramids; the dihedral angle between the planes defined by Co1, Co2, Co3, Co4/Co2, Co4, Co6, Co8 in the cation of **24** is 12.5°. The association of this structural change with the loss of one electron in the oxidation of **23** to **24** is remarkable. However, the Co-Co bond lengths remain largely unaltered (244.2-279.5 pm in **23**, 247.3-279.4 pm in **24**), and are appreciably shorter than in **18**. This is consistent with the electron counts; in **18** the requirements of the 18e rule are exceeded by 14 electrons, whereas **23** (116e) and **24** (115e) approximately fulfill the predicted 114 valence electrons.

3.5. Clusters with Face-Sharing Co and Ni Octahedra

The condensation of octahedra via common vertices, edges or faces leads to cluster units of a type known since the end of the 1970's. Amongst these are the metal-rich subhalides of transition metals[55,56,58] and the Chevrel phases.[50,57,64] The preparation of $[Co_9Se_{11}(PPh_3)_6]$ (**25**) (Fig. 11a) makes clear that this structural principle can be extended to the more electron-rich transition metals.[44,46] All faces of the Co_9 cluster in **25** are capped by μ_3 or μ_4-Se ligands, and the Co atoms of the basal faces (Co1, Co4, Co9, Co6, Co7, Co8) are each additionally coordinated to one PPh_3 ligand. The Co-Co bond lengths are 271-298 pm; the shortest distances are found within the common triangular face (Co2, Co3, Co5). Clusters of similar structure are known in $[Ni_9S_9(PEt_3)_6]^{2\oplus}$ and $[Rh_9(CO)_{19}]^{2\ominus}$.[59,60] The condensation of two Co_6 octahedra clearly permits greater tolerance with respect to the valence electron count, because the 137e cluster **25** contains 17 valence electrons more than would be expected from the 18e rule.

The formation of **25** must proceed via smaller, reactive complexes. The two Co_8 clusters in **23** and **24** are tenable candidates for the precursors that are involved in the formation of the dioctahedral Co_9 cluster **25**; additional redox processes could cause the mutual tilting of the Co_5 pyramid bases to become so pronounced as to form a suitable cavity for the incorporation of a further Co atom.

Face-sharing metal atom octahedra are also observed in the Ni compounds **32** (Fig. 11b) and **33** (Fig. 11c) as well as in the dication of **34** (Fig. 11d) (see also Scheme 3). On the other hand, we have not yet succeeded in isolating a simple octahedral chalcogen-bridged Ni_6 cluster, although closely related compounds, e.g. $[Ni_3(\mu_2\text{-}CO)_3(CO)_3]_2^{2\ominus}$ are known.[47] Electronic factors are presumably responsible for this; a hypothetical "$[Ni_6Se_8(PPh_3)_6]$" would possess a total of 104 valence electrons. This would not only be 20 electrons more than expected from the 18e rule, but also six electrons more than in the analogous complex **18**, whose long Co···Co contacts (Table 2) already imply the occupation of antibonding orbitals.

The cluster dication of **34** consists of linked Ni_9Se_9 (Ni1-9, Se1-9) and Ni_3Se_2 (Ni10-12, Se10,11) units (Fig. 11d). These structural fragments were already known in the following complexes:[53,59,61]

$$[Ni_9S_9(PEt_3)_6]^{2\oplus} \quad [Ni_3Se_2(PEt_3)_6]^{2\ominus} \quad [Ni_3S_2Cp_3] \quad [Ni_3S_2Cl_2(PPh_3)_4] \quad (\mathbf{10})$$

The polyhedral faces of the dioctahedron in **34** are capped by μ_3-Se (Se1-3, Se7) and μ_4-Se (Se4-6) ligands. Se8 and Se9 are each bonded to three Ni atoms of the dioctahedron and also function as bridges to Ni11 and Ni10 respectively. The Ni-Ni bonds involving Ni9 are also relatively short (253-268 pm), whereas those within the cluster fragment Ni10-Ni11-Ni12 are rather long (283-311 pm). This might be related to weak Ni-Ni interactions between the atoms Ni10-12. The structural integrity of this Ni_3 triangle can therefore be ascribed primarily to the μ_4 and μ_3 ligands Se10 and Se11. The Se10-Se11 distance is very short (311 pm) and agrees well with the corresponding distance in the $[Ni_3Se_2(PEt_3)_6]^{2\oplus}$ cation.

Except for Ni4-6 and Ni9, all Ni atoms are coordinated by a P atom of a PPh_3 ligand, and Ni12 is additionally bonded to a Cl ligand. The topology of the Ni and Se atoms means that the cation of **23** must be regarded as an intermediate en route to more highly condensed clusters with *trans*-face-sharing metal atom octahedra. The Ni-Cl

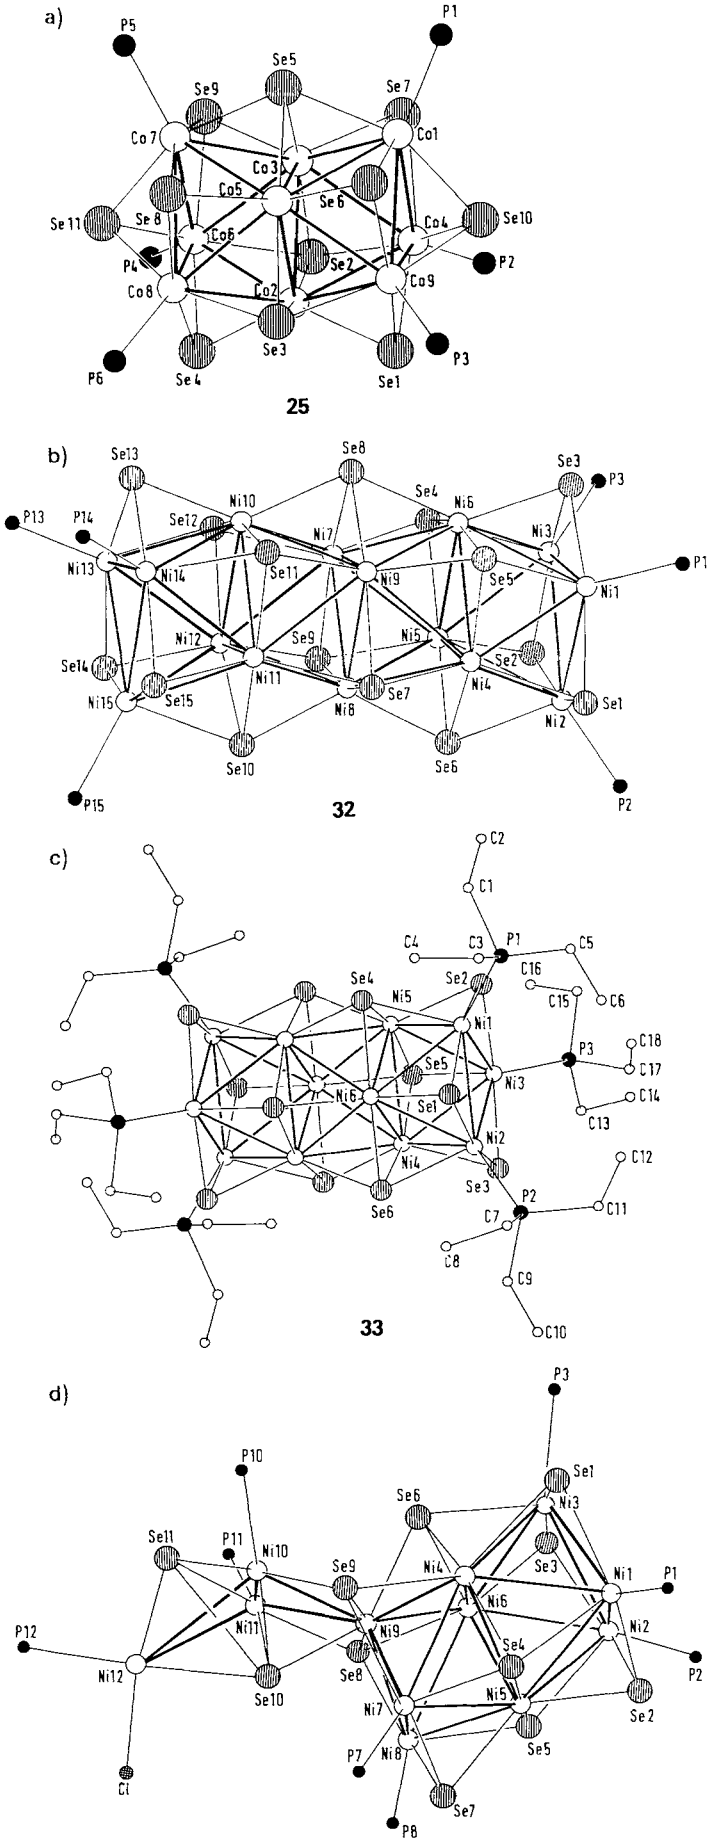


Fig. 11. Molecular structures of a) **25**, b) **32**, c) **33** and d) the dication of **34** (phenyl groups omitted in a, b and d).

bond is the reactive site of the molecule, where reaction with $Se(SiMe_3)_2$ and $[NiCl_2(PPh_3)_2]$ can promote further growth of the metal atom polyhedron.

Accordingly, **33** and **32** consist of three or four face-sharing, slightly distorted Ni_6 octahedra (Fig. 11b, c). Apart from the basal faces, all polyhedral faces of **33** and **32** are occupied by μ_3 or μ_4-Se ligands (Ni-Se: **33**, 232–244 pm; **32**, 231–249 pm). The Ni atoms of the basal faces are each bonded to a PPh_3 (**32**) or PEt_3 (**33**) group.

An alternative description of **32** and **33** is as a stacking of parallel layers (interlayer distance 216(3) pm, deviation from the plane ± 10 pm) composed of three Ni and three Se atoms. The Ni_3Se_3 planes are arranged according to an AB pattern of hexagonal close packing. (This description clearly also applies to the dioctahedra in **25** and **34**.) The Ni–Ni distances between the layers in **32**–**34** are shorter (**32**: 270–288, **33**: 272–278, **34**: 266–289 pm) than those within the Ni_3 layers (**32**: 288–301 pm, **33**: 288–297 pm, **34**: 268–313 pm). It is also observed that the Ni–Ni bonds in the outermost layers, viz. between those Ni atoms bonded to PR_3, are appreciably longer (292–301 pm) than those in the inner layers.

The structures of the Chevrel phases, such as $[Mo_{12}Se_{14}]^{2\ominus}$, $[Mo_{18}Se_{20}]^{4\ominus}$, $[Mo_{24}Se_{26}]^{6\ominus}$, or $[Mo_{30}Se_{32}]^{8\ominus}$, are governed by the same structural principle as the Ni clusters **32**–**34** and the Co compounds **18** and **25**.[57,62,63] With respect to their electron balance, however, there are considerable differences. For instance, the 222e cluster **33** and the 180e cluster **32** contain 24 and 30 electrons, respectively, more than the 18e rule would predict; in the Chevrel phases, the 18e rule is largely obeyed. Clearly, antibonding orbitals are increasingly occupied in **33** and **32**. The differences are illustrated quite distinctly by a comparison of the valence electron concentrations; whereas the Chevrel phases contain 3.33–4.33 electrons per metal atom, the Co and Ni clusters contain 6.17–6.78 or eight valence electrons per metal atom, respectively.[64]

We are certain that much larger clusters are also formed in the reactions we have described. Residues are often obtained, which from analytical results and general properties seem to possess very high molecular weights. However, the increasing insolubility makes characterization difficult. The composition of these compounds should correspond to the general formulas $[Co_{3n+3}E_{3n+5}(PR_3)_6]$ and $[Ni_{3n+3}E_{3n+3}(PR_3)_6]$ (E = S, Se; n is the number of condensed octahedra).

The valence electrons of the nickel compounds are subject to a simple counting rule: $3\times10+3\times4=42$ electrons for each Ni_3Se_3 unit plus 6×2 electrons for the terminal PPh_3 ligands.

3.6. $[Ni_{34}Se_{22}(PPh_3)_{10}]$, a Cluster with an Unusual Structure

$[Ni_{34}Se_{22}(PPh_3)_{10}]$ (**35**) crystallizes from the filtrate of the reaction of $[NiCl_2(PPh_3)_2]$ with $Se(SiMe_3)_2$. Whereas the structures of **25**, **32**, **33** and **34** can all be understood in terms of condensed octahedra, the $[Ni_{34}Se_{22}(PPh_3)_{10}]$ cluster **35** is governed by a previously unknown structural principle (Fig. 12a).[44]

The molecular structure of **35**, which possesses crystallographic $\bar{1}$ symmetry, contains a central Ni_{14} unit consisting of two staggered planar Ni_5 rings (Ni atoms shown as filled in circles in Fig. 12a) 448–456 pm apart with an Ni_4 plane (Ni9, Ni16, Ni9′, Ni16′) between them. Ni9 is disordered. The Ni_{34} polyhedron is then formally built up by adding five Ni_4 "butterfly" fragments to the pentagonal

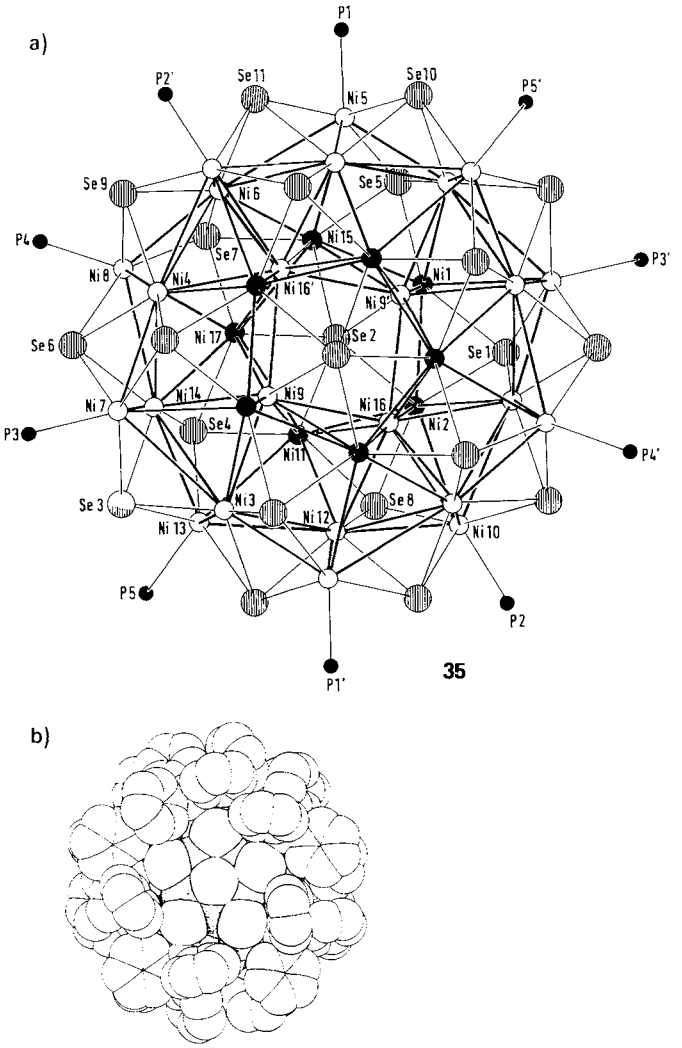

Fig. 12. a) Molecular structure of **35** (phenyl groups omitted). b) Space-filling model (H atoms omitted) of the structure of **35**. The free Ni cluster surface is the dark area.

antiprismatic Ni_{14} unit. The faces of the Ni_{34} unit are then finally capped by two μ_5-Se ligands over the Ni_5 rings and 20 μ_4-Se atoms (Ni-μ_4Se 226–246 pm, Ni-μ_5Se 236–246 pm). Additionally, ten peripheral Ni atoms (Ni5, Ni7, Ni8, Ni10, Ni13 and their symmetry equivalents) are each coordinated by one PPh_3 group. The space-filling model of **35** (Fig. 12b) demonstrates that in this way all the Ni atoms are effectively screened by the Se atoms and PPh_3 ligands.

An alternative description, which stresses the highly symmetric nature of **35**, is based on the fivefold symmetry and marked layer structure of the Ni_{34} polyhedron. The fivefold symmetry of the Ni_5 and Se_5 planes is only broken by the Ni_4 unit in the center of the cluster. This may be the reason for the disorder of Ni9 in this unit.

The cluster molecule has a diameter of about 3000 pm. The Ni–Ni distances in **35** lie in the range 236–312 pm. A description of the bonding in terms of the 18e rule is therefore impossible. **35** contains 448 valence electrons, which is in good agreement with the number predicted for M_n clusters ($n > 13$) on the basis of the Hume-Rothery rules for intermetallic phases (440–444e).[25] This shows that the properties of cluster complexes become closer to those of the metal as the number of metal atoms increases. However, it should not be forgotten that the structure of the Ni_{34} unit cannot be described in terms of principles derived from metals and intermetallic phases.

The formation of PPh_3Se is always observed in the synthesis of **35** and the compounds (except **33**) presented in Scheme 3. When large cluster molecules are formed, it may be the result of the reaction of smaller complexes with PPh_3, whereby capping μ-E ligands are extracted to form PPh_3E. The coordinatively unsaturated complexes thus generated can then react together to form metal-rich complexes.

One can only speculate about the mechanism of formation of such complex molecules. It is however a reasonable

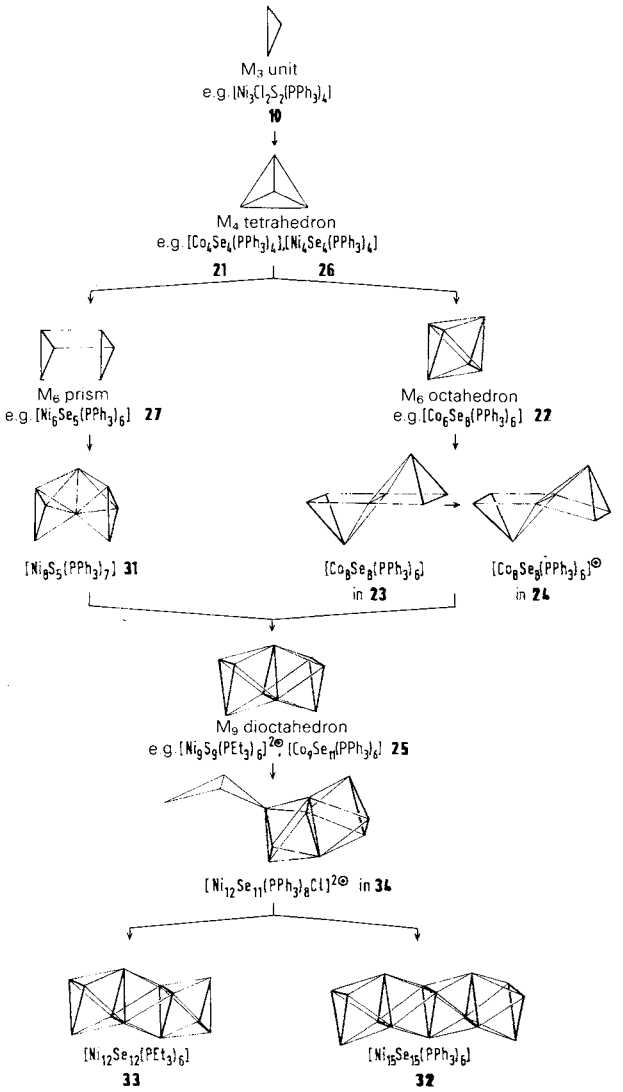

Fig. 13. Schematic representation of the metal atom frameworks of chalcogen-bridged Co and Ni clusters with terminal PR_3 ligands.

assumption that aggregation to more highly condensed compounds occurs via smaller fragments. It is not unlikely that M_3 units (M = Co, Ni) play a decisive role in our syntheses; the most direct evidence for this is the existence of **10** and of the $[Ni_3E_2(PEt_3)_6]^{2\oplus}$ cations (E = S, Se) prepared by *Cecconi* et al. It is notable that precisely such an Ni_3Se_2 unit is observed in **34**, directly linked to a "pre-condensed" group, an Ni_9 cluster (Fig. 11d) composed of three Ni_3 triangles. To demonstrate the structure-determining potential of the M_3 units, Figure 13 presents schematically the metal atom frameworks of the sulfur- and selenium-bridged Co and Ni clusters discussed here.

The starting point for this formal treatment is the M_3 unit present in **10**. The first step is the linking of this triangular unit with a fourth metal atom to form an M_4 tetrahedron (e.g. **21**, **26**). The addition of two further metal atoms leads either to a trigonal prismatic polyhedron, such as the Ni_6 prism **27**, or to an octahedron, a category to which the numerous Co_6 clusters belong. Another two-atom addition step, occurring between the two M_3 planes, leads from the Ni_6 prism to an Ni_8 polyhedron consisting of two edge-sharing trigonal bipyramids (e.g. **31**). For cobalt, this route arrives at the Co_8 clusters that are composed of two edge-sharing Co_5 square planar pyramids (e.g. **23** and **24**). The incorporation of yet another metal atom would then finally give the *trans*-face-sharing dioctahedron present in $[Ni_9S_9(PEt_3)_6]^{2\oplus}$[59] or in **25**. The stage has now been reached where three Ni_3 planes are stacked, although not exactly over each other. Further stacking processes lead via the Ni_{12} dication in **34** to the *trans*-face-sharing tri- or tetraoctahedra of **33** and **32**, respectively. The question whether the formation of **35** also proceeds via such units can probably only be answered after detailed mechanistic studies of the cluster growth.

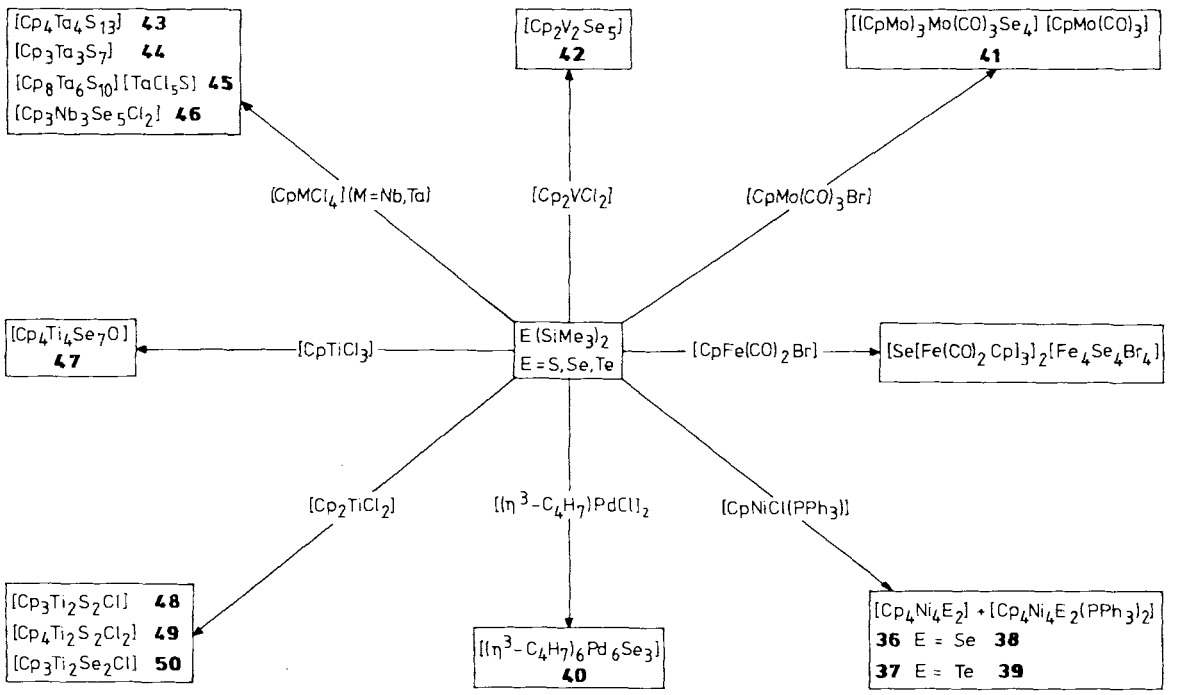
4. Chalcogen-Bridged Transition Metal Clusters with η^5-Cyclopentadienyl, μ^3-Allyl and CO Ligands

As was shown in the preceeding chapter, tertiary phosphanes are capable of promoting the synthesis of clusters of electron-rich transition metals and simultaneously of suppressing the formation of metal pnictides or chalcogenides that is always observed in the reaction of phosphane complexes of cobalt or nickel chlorides with $E(SiMe_3)_2$ (E = PPh, AsPh, S, Se).

We have now extended the synthetic principles presented above to the preparation of polynuclear complexes with Cp, allyl, and CO ligands. Preliminary results involve the reactions of cyclopentadienyl, allyl, and CO complexes of the transition metal halides with $E(SiMe_3)_2$ (E = S, Se, Te); Me_3SiCl is eliminated and a series of novel compounds (Scheme 4) are formed, the molecular structures of which are reproduced in Figures 14–21.

4.1. Chalcogen-Bridged Clusters of Electron-Rich Transition Metals

The reaction between $[CpFe(CO)_2Br]$ and $Se(SiMe_3)_2$ produces a diamagnetic compound consisting of doubly negatively charged heterocubane clusters $[Fe_4Se_4Br_4]^{2\ominus}$ and $[Se\{Fe(CO)_2Cp\}_3]^{\oplus}$ ions. The structural parameters of the Fe_4Se_4 cage are essentially similar to those of other $[Fe_4E_4X_4]^{2\ominus}$ clusters (E = S, Se; X = Cl, SPh, Br, I) as investigated by many authors;[65,66] the Fe_4 tetrahedra display two short (276.2–278.7 pm) and four long (280.2–282.5 pm) Fe–Fe distances. The $[Se\{Fe(CO)_2Cp\}_3]^{\oplus}$ cation is isolobal with $(CH_3)_3Se^{\oplus}$; it possesses an Fe_3Se moiety shaped like a compressed pyramid, with no bonding contacts between the Fe atoms (Fe···Fe 400 pm). An identical cation was recently prepared by *Herrmann* et al.[67]



Scheme 4. Reactions of $E(SiMe_3)_2$ with Cp-, allyl-, and CO-complexes of transition metal halides.

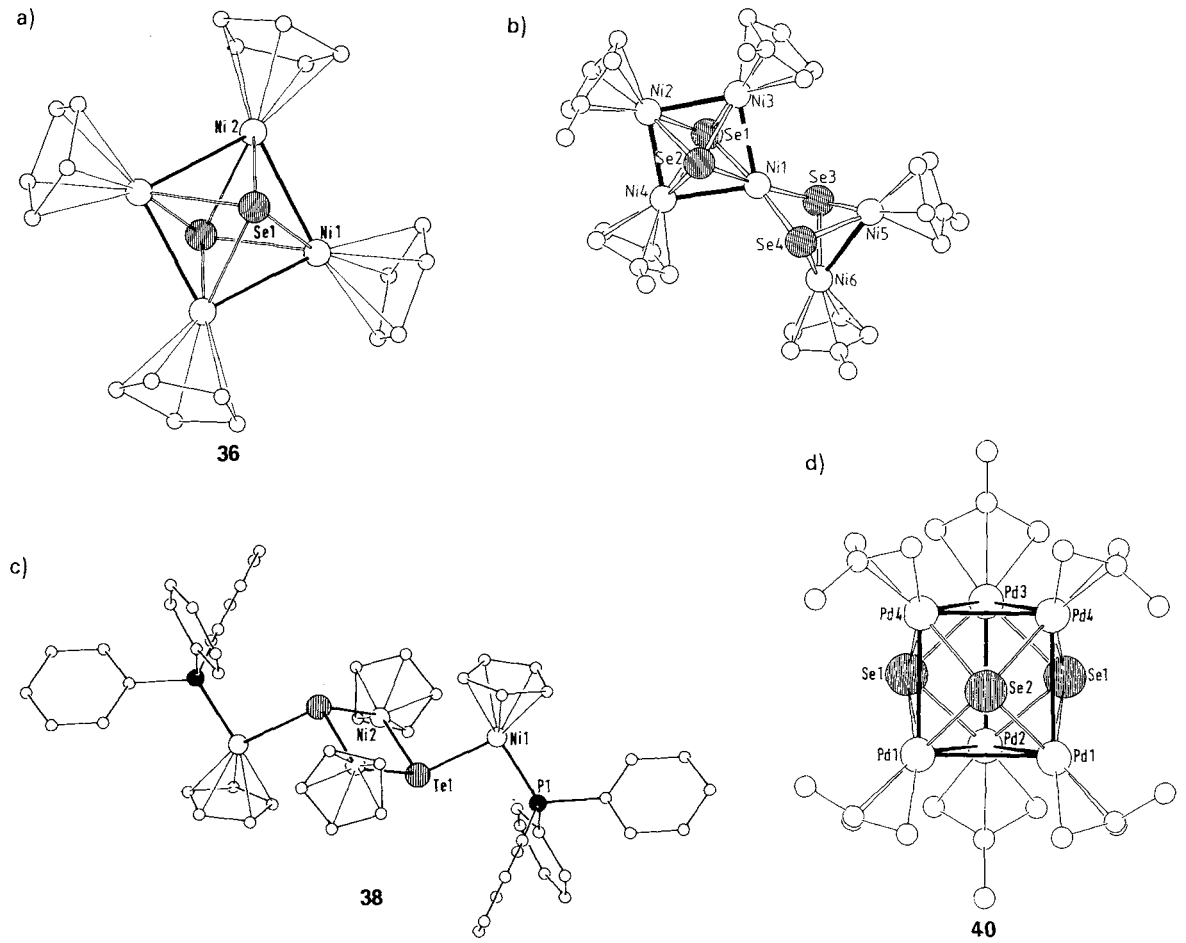


Fig. 14. Molecular structures of a) **36**, b) $[(C_5H_4Me)_5Ni_6Se_4]$, c) **38**, d) **40**, e) the cation of **41**.

Silylated chalcogens could also be used to synthesize biologically interesting complexes; this is indicated by the work of *Holm* et al.,[68] who obtained S-bridged clusters by the reaction of $[Fe_2OCl_6]^{2\ominus}$ or $[M(OEt)_5]$ (M = Nb, Ta) with $S(SiMe_3)_2$.[69,70]

As demonstrated by the synthesis of the salt **41**, a heterocubane cluster is also formed from $[CpMo(CO)_3Br]$ and $Se(SiMe_3)_2$ (Mo–Mo 294–301 pm). The cation of **41** (Fig. 14e) consists of three CpMo groups (Mo1, Mo2, Mo4), one $Mo(CO)_3$ group, and four capping Se ligands.

$E(SiMe_3)_2$ reacts with $[(\eta^3\text{-}C_3H_5)MCl]_2$ (M = Ni, Pd) to form extremely unstable, hexanuclear complexes; the S-derivatives had already been obtained by other methods.[71]

The analogous compounds with $(\eta^3\text{-}C_4H_7)$ ligands (e.g. **40**) are appreciably more stable. Analogous to the structure of $[(\eta^3\text{-}C_3H_5)_6Ni_6S_3]$, **40** contains a slightly distorted trigonal M_6 prism (Fig. 14d); the Pd_4 faces are capped by μ_4-Se ligands and the Pd atoms are each bonded to an $\eta^3\text{-}C_4H_7$ group. The Pd–Pd bond lengths within the prism are 288.4–313.2 pm, but all are considerably longer than those observed in other Pd clusters.[72]

The tetranuclear diamagnetic clusters **36** and **37** are formed in high yield from $[CpNiCl(PPh_3)]$ and $E(SiMe_3)_2$; small amounts of **38** and **39**, which are accessible from **36** and **37**, respectively, and PPh_3, are also formed. The molecular structures of **36** (Fig. 14a) and **37** consist of an almost regular Ni_4 square (crystallographic $\bar{1}$ symmetry) in which each nickel is bonded to an η^5-Cp group and two μ_4-E ligands.[73] Assuming that four Ni–Ni single bonds are present in **36** and **37**, these 68e clusters contain four electrons more than would be expected from the 18e rule. The Ni–Ni bond lengths (257 pm) lie in the expected range.[63,74] As in the Ni_3Se_2 fragment of **34**, the Se–Se contacts in **36** (303 pm) are shorter than van der Waals' contacts in selenium or $Se_8^{2\oplus}$.[75] It is possible that weak interactions between the Se ligands are responsible for this.[53,59,76]

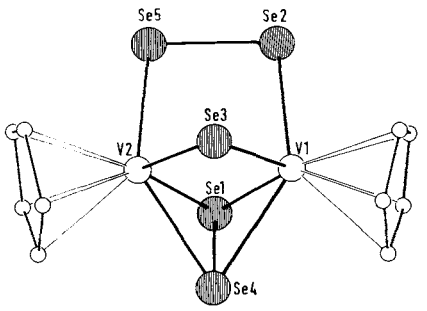
Reaction of the unstable $[(C_5H_4Me)Ni(CO)Br]$ with $Se(SiMe_3)_2$ affords the complex $[(C_5H_4Me)_5Ni_6Se_4]$. Figure 14b shows that this complex contains an Ni_4Se_2 unit analogous to **36** (Ni–Ni 250–263 pm), which is connected by two μ_3-Se bridges to a $[(C_5H_4Me)Ni]_2$ unit (Ni–Ni 253 pm). A compound isostructural with **36** in which the μ_4-Se li-

gands are replaced by μ_4-As ligands is formed on reaction of $[CpNiCl(PPh_3)]$ with $As(SiMe_3)_3$.

The structure of **38** (Fig. 14b) can be seen as a consequence of breaking all Ni–Ni bonds of **36**. Further examples of the breaking of M–M bonds have been presented by other authors.[77] **38** and **39** contain four CpNi units linked by μ_3-E ligands, the outer Ni atoms also being coordinated by PPh_3 groups. **38** and **39** are diamagnetic; each Ni atom achieves the 18 electron configuration. Correspondingly, the Ni···Ni contacts (337–382 pm in **38**, 362–398 pm in **39**) give no indication of bonding interactions.

4.2. Clusters of Electron-Deficient Transition Metals with Cp Ligands

Organometallic derivatives of the less electron-rich transition metals have been used by several authors as precursors to polynuclear complexes. Cp-substituted transition metal halides, for example, have been allowed to react with M_2E_x (M = Li, Na; E = S, Se; x = 1,2) or elemental sulfur or selenium.[78] However, it is clear that $S(SiMe_3)_2$ or $Se(SiMe_3)_2$ could also be successfully used. Thus the reaction of $[CpCrCl_2(PnBu_3)]$ with $Se(SiMe_3)_2$ furnishes the heterocubane cluster $[Cp_4Cr_4Se_4]$.[79] $[Cp_2VCl_2]$ reacts with $Se(SiMe_3)_2$ to form the diamagnetic $[Cp_2V_2Se_5]$ (**42**); *Rauchfuss* and *Rheingold* had already reported the synthesis of this complex.[80] The structure of **42** is shown in Figure 15. There are three different Se bridges: μ_2-Se (atom Se3) with V–Se 237 pm; μ-η^1-Se_2 (atoms Se2, Se5) with V–Se 245–246, Se–Se 230.2 pm; and μ-η^2-Se_2 (atoms Se1, Se4) with V–Se 252–254, Se–Se 231 pm. Examples of such bridges are also known in other complexes.[81] Compared with $[Cp_2V_2S_5]$ (V–V 266 pm), the V–V distance in **42** (277 pm) is unusually long.[80]

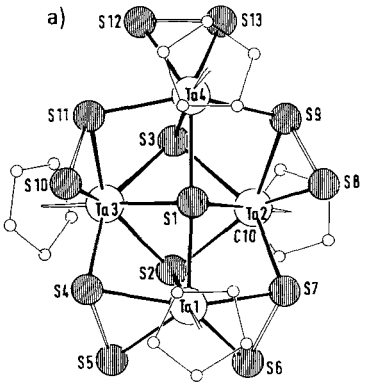


42

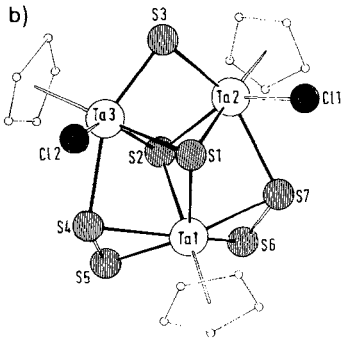
Fig. 15. Molecular structure of **42**.

Surprisingly, the Ta derivative analogous to **42** has not been prepared. Instead, the addition of a THF solution of $[CpTaCl_4]$ to $S(SiMe_3)_2$ leads to the formation of a crystalline mixture of **43** and **44**.[82] If however a THF solution of $S(SiMe_3)_2$ is allowed to diffuse into a THF solution of $[CpTaCl_4]$ the salt **45** can be isolated in high yield.

44 (Fig. 16b) contains a distorted Ta_3 triangle (Ta1···Ta2, Ta1···Ta3 360, Ta2···Ta3 324 pm) bonded to μ_3-S ligands S1 and S2 (S1–Ta 245–260, S2–Ta 251 pm). Ta1 and Ta3, and Ta1 and Ta2, are bridged by (μ-η^1,η^2)-S_2 groups (S–S 205–207, Ta1–S 248–255, Ta3–S4 and Ta2–S7 268 pm), and Ta2 is linked to Ta3 via a μ_2-S ligand S3



43



44

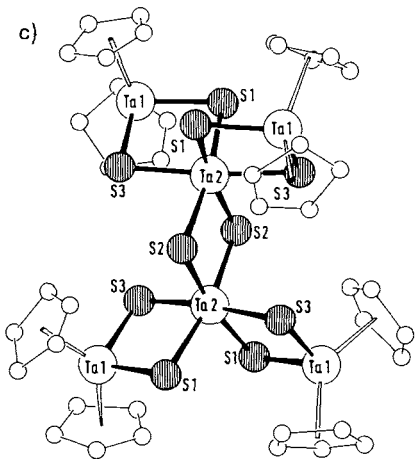


Fig. 16. Molecular structures of a) **43**, b) **44** and c) the cation of **45**.

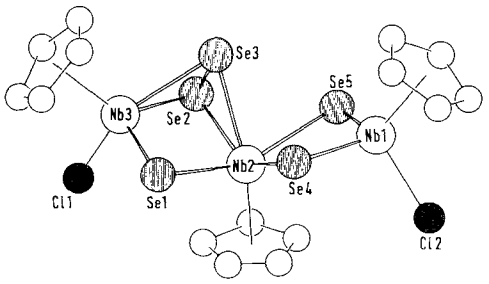
(S3–Ta 240–242 pm). Including the Cp ligands, Ta2 and Ta3 display distorted octahedral coordination and Ta1 the coordination number 7. **44** also contains two Ta–Cl bonds, which act as reactive sites with $[CpTaCl_4]$ and $S(SiMe_3)_2$ to produce the tetranuclear $[Cp_4Ta_4S_{13}]$ (**43**). A topological comparison of **44** and **43** (Fig. 16a) indicates which reorientation of ligands is necessary in this reaction. The μ_3-S (S1, S2) and μ_2-S (S3) ligands of **44** may become the μ_4 (S1) and μ_3-S (S2, S3) ligands of **43**, and Ta4 becomes linked with Ta2 and Ta3 by two (μ-η^1,η^2)-S_2 fragments. The four Ta atoms of **43** thereby acquire a strongly distorted pentagonal bipyramidal coordination geometry. Assuming that the bridges in **43** and **44** are $S_2^{2\ominus}$ and $S^{2\ominus}$, the Ta atoms in both compounds possess the formal charge +5, consistent with their diamagnetism.

The cation of **45** (Fig. 16c) contains TaS_6 octahedra (Ta2) and tetrahedral Cp_2TaS_2 groups (Ta1) linked by μ_2-S ligands (Ta–S 235–243 pm). There are no bonding contacts between Ta atoms (Ta1···Ta2 338, Ta2···Ta2 353 pm).

We have since obtained evidence that the linking of tetrahedral Cp_2TaS_2 and octahedral TaS_6 groups can also lead to more highly condensed clusters.

The individuality of the vanadium group elements can be seen particularly clearly in the reaction of $[CpNbCl_4]$ with $Se(SiMe_3)_2$. Using toluene as solvent, complexes analogous to **43**–**45** are not obtained; instead, a brown compound **46** is formed exclusively.[82]



46

Fig. 17. Molecular structure of **46**.

46 (Fig. 17) contains three differently coordinated Nb atoms. Nb1 is coordinated by η^5-Cp, Se4, Se5, and Cl2 with distorted tetrahedral geometry: Nb-C(Cp) 236.6-244.2, Nb1-Se 239 pm, Nb1-Cl2 236.6 pm. Nb3 has coordination number 5, being coordinated by η^5-Cp, Se1, Se2, Se3 and Cl1: Nb3-C(Cp) 240.1-244.0, Nb3-Se1 238.3, Nb3-Se2(Se3) 261-263, Nb3-Cl1 242.9 pm. Nb2 has coordination number 6 and is coordinated by η^5-Cp and Se1-Se5, with Nb2-C(Cp) 235.0-241.8, Nb2-Se 266.5-271.7 pm. Assuming the presence of $Cp^{\ominus}$, $Se^{2\ominus}$, $Se_2^{2\ominus}$ and $Cl^{\ominus}$ ligands, **46** must be regarded as a mixed valence compound in which Nb1 and Nb3 carry the charge +4 and Nb2 +5. Correspondingly, the compound is paramagnetic, and its ESR spectrum in $C_2H_4Cl_2$ shows the expected 10-line resonance signal ($g = 2.0047$, $a_{Nb} = 11.6$ mT).

Finally, we present some results from the reactions of $E(SiMe_3)_2$ with Cp derivatives of titanium halides. The diffusion of a THF solution of $E(SiMe_3)_2$) into a THF solution of $[Cp_2TiCl_2]$ leads in good yield to the binuclear complexes **48**-**50**.[82] **48** (Fig. 18) consists of a Cp_2Ti group bridged by two μ_2-S ligands to a CpTiCl group. Both Ti atoms thereby acquire a distorted tetrahedral coordination. Just as in the isostructural $[Cp_3Ti_2Se_2Cl]$ (**50**), the Ti-E bond lengths involving Ti2 (which is bonded to Cl1) are some 20 pm shorter than those involving Ti1 (**48**: Ti2-S 223, Ti1-S 243; **50**: Ti2-Se 237, Ti1-Se 259 pm).

The structure of **49** (Fig. 18) can be derived from two Cp_2TiCl fragments bridged by an $S_2^{2\ominus}$ group (S1-S2 208.3, Ti-S 239 pm). Although both **48** and **50** possess Ti-Cl bonds, larger clusters have not yet been synthesized.

If, on the other hand, $[CpTiCl_3]$ (in THF) is allowed to react with $Se(SiMe_3)_2$, a crystalline residue is formed, from which the tetranuclear complex $[Cp_4Ti_4Se_7O]$ (**47**) is obtained in low yield by recrystallization from $C_2H_4Cl_2$.[82] **47** consists of a Ti_4 tetrahedron (Ti···Ti 311.4-346.2 pm) with a central O atom (Ti-O 195-216 pm). The Ti atoms are six-coordinate, and the Se ligands can be classified as μ_2-Se (Se1-Ti 253 pm), μ_3-Se (Ti-Se5/Se6 260-274 pm) and Se_2 bridges spanning three Ti atoms (Se3-Se4 232, Se2-Se7 234 pm) with unequal Ti-Se distances (Ti3-Se3 263, Ti3-Se4 266, Ti1-Se3 270, Ti4-Se4 268 pm). *Rauchfuss, Rheingold* et al. have recently presented the structure of $[(MeC_5H_4)_4Ti_4S_8O_2]$, which, in contrast to **47**, contains a Ti_4 cluster coordinated by four S_2 units and a μ_2-O ligand.[83] The same authors obtained the heterocubane clusters $[(RC_5H_4)_4Ti_4S_4]$ (R = Me, *i*Pr) by the reduction of $[(RC_5H_4)TiCl_3]$ with Zn and subsequent reaction with $S(SiMe_3)_2$.[83]

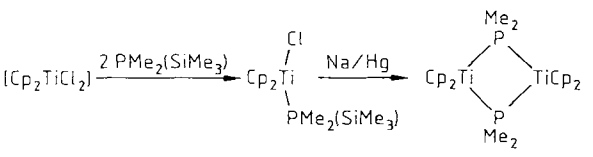
Fig. 18. Molecular structures of **47** (without Cp groups), **48**, and **49**.

5. Exploratory Reactions with $PMe_2(SiMe_3)$ and $SPh(SiMe_3)$

The reactions described above illustrate the synthetic potential of disilylated derivatives of elements of the fifth and sixth main groups. Predictably, however, monosilylated compounds (such as $PMe_2(SiMe_3)$ and $SPh(SiMe_3)$ also react with transition metal halides to form polynuclear complexes. For instance, the reaction between $PMe_2(SiMe_3)$ and $[Cp_2TiCl_2]$ leads in good yield to the highly oxygen-sensitive complex **51**,[84] in which Ti is coordinated by two η^5-Cp ligands (Ti-C(Cp) 237-241 pm), one Cl ligand (Ti-Cl 248.6 pm) and one $PMe_2(SiMe_3)$ ligand in a distorted tetrahedral geometry (Fig. 19). The silylphosphane forms an unusually long bond to Ti (Ti-P 263.9 pm).



51 **52**

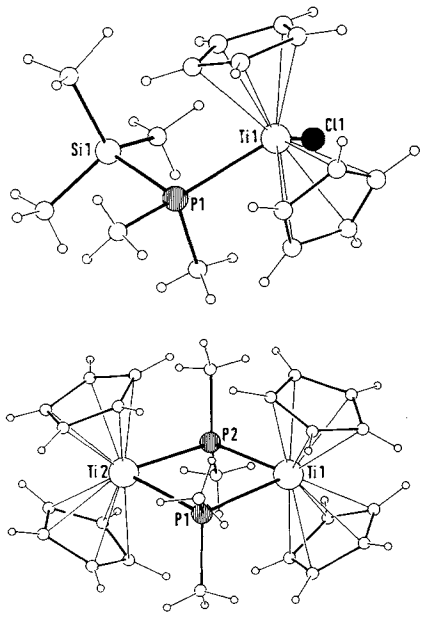


Fig. 19. Molecular structures of **51** and **52**.

This distance is markedly longer than observed in other complexes with Ti–P bonds.[85] **51**, which is paramagnetic, has 17 valence electrons. According to *Hoffmann* et al., the angle between the ligands should be determined by the d electron configuration of Ti,[86] and this is confirmed by the angle Cl1–Ti–P1, 81.2°.

In the dinuclear complex **52** (Fig. 19) each Ti is coordinated by two η^5-Cp ligands and the P atoms of the two μ_2-PMe_2 ligands. The four-membered ring Ti1, Ti2, P1, P2 is practically planar; its geometry (P1–Ti–P2 83.3°, Ti1–P–Ti2 96.1–96.8°, Ti···Ti 392 pm) corresponds well with that observed in other M_2P_2 rings lacking metal–metal bonds.[12,87] Such rings characteristically display an angle of 75–80° at the metal atom and 100–105° at the P atom. Examples are:

$[(CO)_4Mn(PH_2)]_2$: P–Mn–P 76.1°, Mn–P–Mn 103.9°
$[(diphos)Pt(PPh_2)]_2^{2\oplus}$: P–Pt–P 76.1°, Pt–P–Pt 103.9°
$[(CO)_2Rh(PtBu_2)]_2$: P–Rh–P 79.5°, Rh–P–Rh 100.5°

The 17 valence electrons of each Ti in **52** are a consequence of the two Cp ligands and the 3-electron donor PMe_2. The paramagnetism disappears at low temperatures by antiferromagnetic coupling.

Monosilylated sulfanes such as $SPh(SiMe_3)$ are also suitable for the preparation of polynuclear transition metal complexes. These complexes are however also accessible via (e.g.) the reaction of NaSPh with transition metal halides.[40,88] The reaction of $(Bu_4N)[CoCl_3(PPh_3)]$ with $SPh(SiMe_3)$ leads in practically quantitative yield to **53**.[89,90] If the neutral starting complex $[CoCl_2(PPh_3)_2]$ is used, however, then the neutral cluster **54** is formed. The

$(Bu_4N)_2[Co_4(SPh)_6Cl_4]$ **53**
$[Co_4(SPh)_6Cl_2(PPh_3)_2]$ **54**

Co atoms in **53** and **54** have the charge +2, and the complexes are thus paramagnetic. No ESR signal is observable up to a temperature of −150°C.

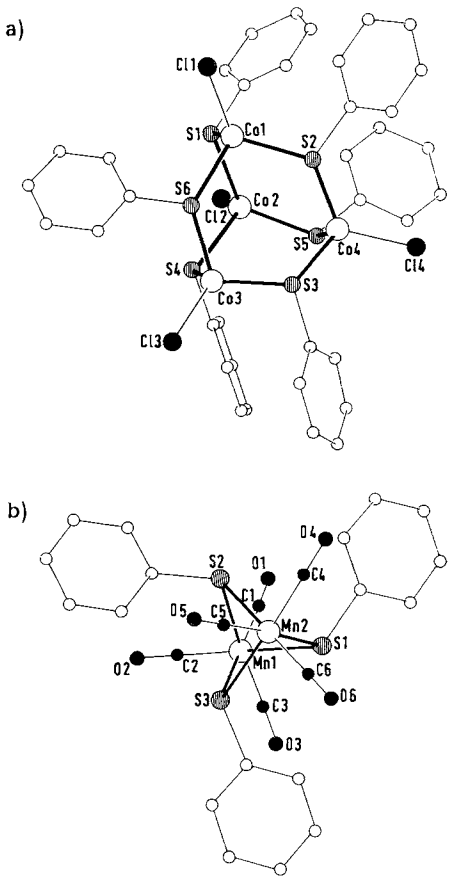

Fig. 20. Molecular structure of the anions of a) **53** and b) **55**.

The four Co atoms in the cluster anion of **53** (Fig. 20a) are linked by six μ_2-SPh bridges (Co–S 230–234 pm), forming an adamantane-like cage species in which all Co atoms display a distorted tetrahedral coordination sphere of one Cl and three SPh ligands. **53** is a representative of the commonly observed structure type $[M_4^{II}(SR)_{10-n}X_n]^{2\ominus}$ (M = Fe, Co, Cd, Zn; X = Cl, Br, SR),[91] and the Co_4 tetrahedron of **53** is slightly distorted (Co···Co 376–393 pm) in the same manner as its related species.

Attempts to substitute the Cl ligands of **53** led to a series of derivatives. However, it has not proved possible to prepare heterometallic clusters; for instance, the reaction of **53** with $NaMn(CO)_5$ leads, with exchange of the SPh ligands, to the dinuclear manganese complex **55**, the structure of which is shown in Figure 20b. The anion contains two $Mn(CO)_3$ groups bridged by three SPh ligands.[92]

$(Bu_4N)[Mn_2(SPh)_3(CO)_6]$ **55**

6. Reactions of $E(SiMe_3)_2$ (E = S, Se) with Derivatives of Main Group Halides

Silylated main group elements can serve as starting materials for the synthesis of polynuclear derivatives of those elements. An example is the reaction (b), which proceeds in good yields.

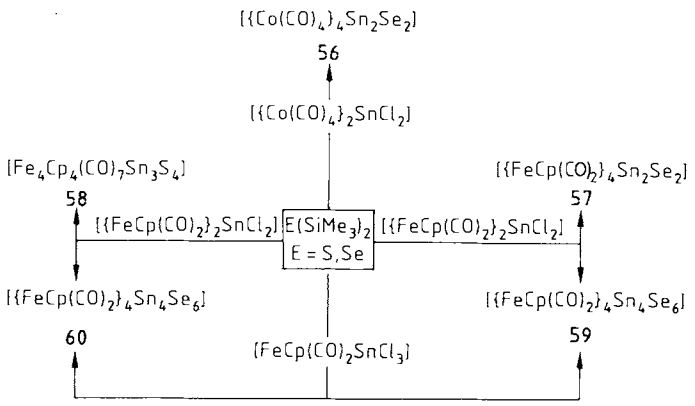
$$[Cr(CO)_5(PPh_2Cl)] + Se(SiMe_3)_2 \longrightarrow [\{Cr(CO)_5(PPh_2)\}_2Se] \qquad (b)$$

In contrast, in reaction (c) the formation of a complex iron salt, whose cation has already been described,[93] and of (as yet structurally uncharacterized) Sb–Se complexes is observed.

$$[\{FeCp(CO)_2\}_2SbCl_2][Sb_2Cl_7] + Se(SiMe_3)_2 \longrightarrow [\{FeCp(CO)_2\}_3SbCl]_2[Fe_2Cl_6] + \cdots \quad (c)$$

The reaction of $[FeCp(CO)_2BiCl_2]$ and $Se(SiMe_3)_2$ leads also to extremely insoluble products of very high molecular weight. The formation of B–Se rings is also possible, as shown in reaction (d). The B_3Se_3 complex (B–Se 193–195 pm) was generated in 80% yield (Fig. 21a).

$$[FeCp(C_5H_4BBr_2)] \cdot NEt_3 + Se(SiMe_3)_2 \longrightarrow [\{FeCp(C_5H_4B)\}_3Se_3] \quad (d)$$



The compounds **56**–**60** have been identified by crystal structure analyses: **56** and **57** (Fig. 21) consist of an Sn_2E_2 four-membered ring in which two $Co(CO)_4$ groups (**56**) or two $FeCp(CO)_2$ groups (**57**) are bonded to the Sn atoms.

59 (Fig. 21) and **60** possess an Sn_4E_6 cage with the adamantane structure, in which the Sn atoms are each bonded to three Se atoms and one $FeCp(CO)_2$ group.[94] These compounds are formed in very small quantities (5%) upon reaction of $[\{FeCp(CO)_2\}_2SnCl_2]$ with $E(SiMe_3)_2$, but in much better yield upon reaction of $E(SiMe_3)_2$ with $[FeCp(CO)_2SnCl_3]$.

The structure of the by-product **58** is particularly interesting (Fig. 21). Like the adamantane cage in **59**, **58** also contains a corrugated Sn_3S_3 six-membered ring (E = S), in which all Sn atoms are bonded to $FeCp(CO)_2$ groups (Fe1, Fe2, Fe3). S3 functions as a μ_3-bridge between Sn2, Sn3 and the Fe atom (Fe4) of an FeCp(CO) unit that is additionally bonded to Sn1.

Considerably more complicated cage structures can also be formed [e.g. **61** in reaction (e)].

$$[NiCp(PPh_3)SnCl_3] + Se(SiMe_3)_2 \longrightarrow [Sn_6Se_9Ni_5Cp_4(PPh_3)_3] \quad (e)$$

61

A description of the molecular structure of **61** (Fig. 22) could begin with an Sn_6Se_6 ring (Sn1–Sn6, Se1–Se3, Se7–Se9) in which pairs of Sn atoms (Sn1, Sn2; Sn3, Sn6; Sn4, Sn5) are linked by additional μ_3-Se bridges (Se4–Se6).

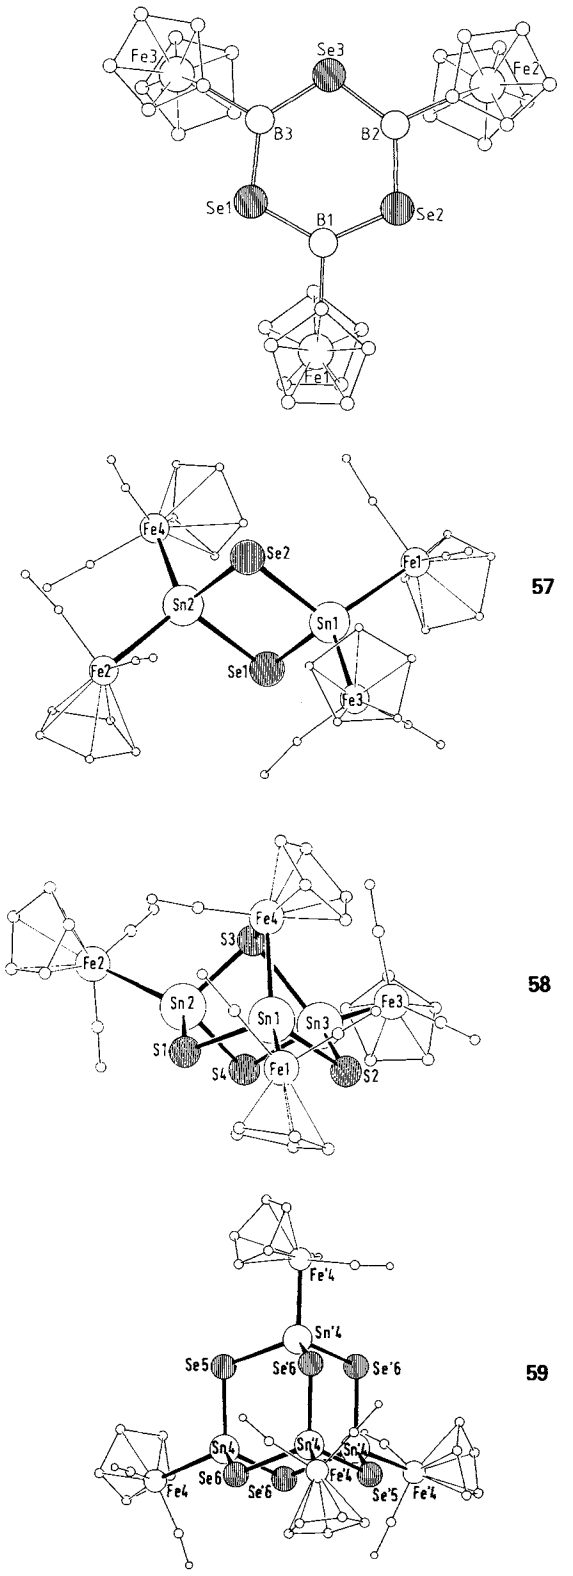


Fig. 21. Molecular structures of a) $[\{FeCp(C_5H_4B)\}_3Se_3]$, b–d) of **57**–**59**.

Se4–Se6 also function as ligands to Ni5, in the middle of the macrocycle, which is additionally bonded to a CpNi group (Ni–Ni 267.3 pm). Both Ni atoms are bridged by three Sn atoms of the twelve-membered ring (Sn1, Sn5, Sn6; Ni–Sn 249–256 pm), and the remaining Sn atoms (Sn2, Sn3, Sn4) are each bonded to the Ni atom of a terminal $CpNi(PPh_3)$ group (Ni–Sn 243–244 pm).

Fig. 22. Molecular structure of **61**.

7. Summary

The studies reported in this article demonstrate that silylated derivatives of elements of the fifth and sixth main groups can serve as starting materials for the synthesis of cluster compounds. Clearly a great deal of work remains to be done in this area. The reader will have realized that the element of chance plays an important role in many unexpected results; the deliberate synthesis of large molecular clusters will be a worthwhile goal. Such compounds, intermediates between molecular chemistry and solid state chemistry, should possess interesting physical and chemical properties.

This article presents results (some not yet published) of the following collaborators: R. Basoglu, H. Fleischer, H. Graef, K. Höffgen, A. Hollnagel, J. Magull, P. Maué, C. Persau, F. Rogel, F. Rudolpf, and L. Weisse, to whom our especial thanks are due. We are also grateful to the Institute of Crystallography at the University of Karlsruhe, where many of the structures were measured. The Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft provided generous financial support.

High Oxidation State Organometallic Chemistry, A Challenge—the Example of Rhenium**

By Wolfgang A. Herrmann*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Homogeneous catalysis as the major industrial outlet of organometallic basic research has been enjoying great benefit from organotransition metal species that promote bond forming between hydrocarbon fragments. Most of the commercially important processes that serve to produce large-volume organic feedstock chemicals such as linear α-olefins (Shell Higher Olefins Process), linear aldehydes (hydroformylation), acetaldehyde (Wacker-Hoechst), acetic acid (Monsanto), adiponitrile (DuPont hydrocyanation of butadiene) operate at low-valent metal centers. It is thus hardly surprising that by far the most part of organometallic research during the past few decades has been directed towards an understanding and the improvement of these catalytic reactions as well as towards the related stoichiometric chemistry. As a matter of consequence, our present knowledge on high-valent organotransition metal compound is comparatively shallow, nor do we know much about the chemical relationship and interconvertability of high and low oxidation states within a given class of compounds. In this article I want to point out some ostensibly challenging perspectives of future organometallic research by describing a novel class of high oxidation state organorhenium compounds as well as by speculating on possible generalizations for other transition metals.

1. Introduction

When a present days' chemistry student first encounters organometallic compounds, he may be amazed about the overwhelming diversity in composition and structures, in properties and reactivity.[1,2] On the other hand, he will no longer view them as laboratory curiosities as I did when I took my first chemistry courses at Munich twenty years ago. At that very *time of excitement*[3] the recognition of metal-metal multiple bonds (*Cotton* et al.)[4,5] and metal-carbon multiple bonds (*Fischer* et al.)[6,7] was brand-new, the catalytic merit of rhodium complexes had just been uncovered (*Alderson* et al., *Osborn* and *Wilkinson* et al.),[8,9] and *Wilke* et al. were using zerovalent 'naked' nickel to tailor cyclic oligomers from butadiene.[10] Faster and more precise structure and reactivity studies of existing compounds and catalytic cycles became escorted by novel instrumental techniques. Shortly before, *Ziegler* and *Natta*[11] had received the Nobel Prize that could be considered a first public award to young organometallic chemistry in blossom. And backstage, the Wacker process of palladium-catalyzed, highly selective oxidation of ethylene to acetaldehyde was heading towards large-scale production,[12] again demonstrating the synthetic power of the metal-to-carbon bond. Acetylene which had been pioneered by *Reppe* et al. of the Badische Anilin- & Sodafabrik back in the forties,[13] was no longer the major chemical feedstock.

Many more and not less striking examples could be brought to memory[14,15] here to support the statement that the fate and future of organometallic chemistry in those days were in the hands of the low oxidation states.[16] Since organotransition metal compounds were so successful in the construction of carbon-carbon and carbon-hydrogen bonds, the field more or less merged with organic synthesis, and metal-mediated shortcuts towards sophisticated pharmaceuticals, insecticides, and fragrances is certainly an attractive research domain that greatly relies on the expertise of both organic and organometallic chemists.[17,18]

At the same time organometallic basic research moved towards organic synthesis, with all sorts of metals and metal compounds nowadays being used by 'straight' organic chemists,[17] the gap between organometallic research and the chemistry of inorganic compounds including inorganic solid state chemistry became canyon-like. This is all the more a pity in that the recent desire for 'novel materials' (e.g., ceramics, glasses, alloys, refractory materials, 'inorganic' polymers, 'electronic materials' etc.) can only come to scientific success if we understand the structures, the bonding, and the behavior of inorganic metal compounds and combine them with organometallics.[19] In doing so, we ought to open our eyes for the metals' high oxidation states and learn how to deal with them. *Roald Hoffmann* has convincingly emphasized the future impact of solid state chemistry and physics on the rest of chemistry.[20]

This proposal is nothing that would contradict even the needs of organic chemists. Who would for instance seriously claim to understand how oxidation reactions of organic compounds really work?[21] More precisely: Which reagent is best used to oxidize a specific alkyne, olefin, or alkane? Under which circumstances is an oxo group transferred upon a hydrocarbon compound to be oxidized?

How does 'chromium peroxide' (CrO_5) work in oxidation, which is the active oxidant, what is the nature of the organometallic intermediates involved, and what does or do the mechanism(s) look like?[22-24] What are the pivotal mechanistic steps in the industrially so important SOHIO 'ammonoxidation' process for converting propylene into acrylonitrile in the presence of bismuth molybdate catalysts?[25] These are just two examples calling for a phalanx of organometallic chemists to tackle dozens of problems involving nothing less important than *oxidation chemistry*.

2. Organorhenium Compounds as Examples

Let us come up with a few details. I shall pick the element rhenium for the simple reason that we have found some unexpected compounds that promise useful applications in various fields of catalysis, not least in hydrocarbon oxidation. Moreover, the element rhenium—as a child of our century discovered as late as in 1925 by *Walther* and *Ida Noddack* in Germany—provides us with eleven different oxidation states, from +7 to −3. Rhenium may thus be viewed as an inorganic and organometallic 'chameleon', and Figure 1 amplifies on this picture.[26] Oxides and halides are expectedly at the higher range of the scale, while carbon monoxide extends the series towards the negative oxidation states, with dirhenium heptoxide/rhenium heptafluoride and tetracarbonylrhenate(−III) terminating at opposite ends. While the large body of carbonyl compounds has well been known to us organometallic chemists, we have hardly considered (simple?) oxides, halides, and oxohalides, nor have we thought of combining them with organic molecules. Still, even their structures are exciting. In dirhenium heptoxide (Re_2O_7), for example, we encounter both tetrahedral and octahedral coordination of the metal, with the so-called perrhenic acid merely being a hydrate of this oxide. Rhenium trioxide (ReO_3) forms a perovskite-type structure of hexacoordinate rhenium, with a counter ion being missing in the cavity of the cube; this d^1 compound shows metallic conductivity (!) resulting from delocalization of the d electrons. In Section 2.3 it will be shown how successive replacement of two methyl groups for each oxygen leads to interesting and useful 'organic' derivatives.

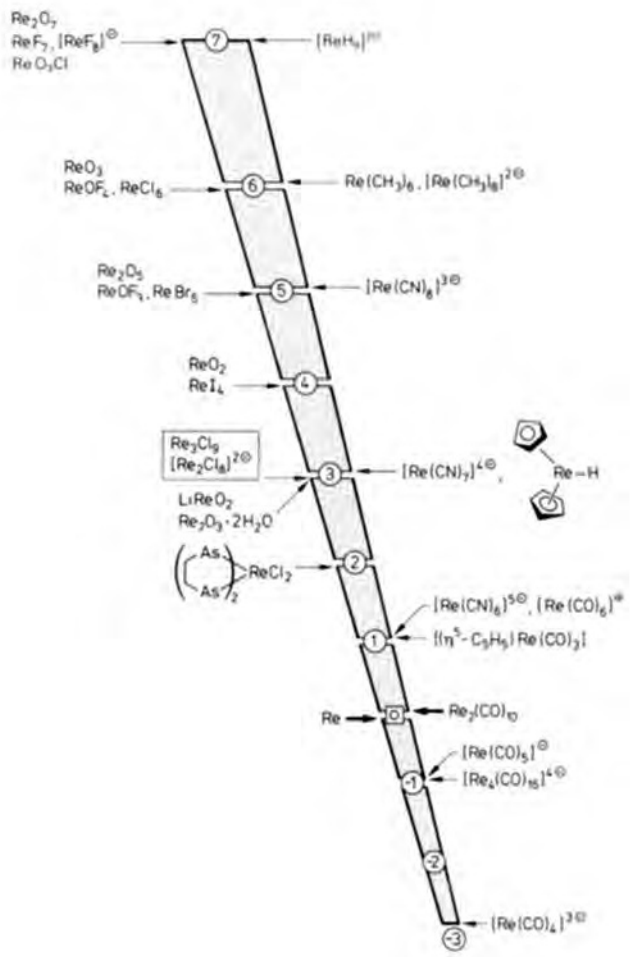

Fig. 1. Typical rhenium compounds representing oxidation states −3 to +7. The lighter homologue manganese would show up with a similar picture. A few important differences remain to be noted, however: 1. The high oxidation-state dimanganese heptoxide, Mn_2O_7, is very unstable. 2. High-valent organomanganese compounds do not exist (e.g., $[(\eta^5\text{-}C_5Me_5)MnO_3]$ and $Mn(CH_3)_6$ are unknown). 3. Manganese-manganese multiple bonds are rare (example: W. A. Herrmann, R. Serrano, J. Weichmann, *J. Organomet. Chem.* *246* (1983) C57; J. D. Korp, I. Bernal, W. A. Herrmann, R. Serrano, *Chem. Ber.* *117* (1984) 434). 4. The oxidation state +2 is the most common one in aqueous manganese chemistry, whereas only few well-defined rhenium(II) compounds have been described (e.g., $[Re_2Cl_4(PR_3)_4]$: T. J. Barder, F. A. Cotton, K. R. Dunbar, G. L. Powell, W. Schwotzer, R. A. Walton, *Inorg. Chem.* *24* (1985) 2550).

Let us come up with a few details. I shall pick the element rhenium for the simple reason that we have found some unexpected compounds that promise useful applications in various fields of catalysis, not least in hydrocarbon oxidation. Moreover, the element rhenium—as a child of our century discovered as late as in 1925 by *Walther* and *Ida Noddack* in Germany—provides us with eleven different oxidation states, from +7 to −3. Rhenium may thus be viewed as an inorganic and organometallic 'chameleon', and Figure 1 amplifies on this picture.[26] Oxides and halides are expectedly at the higher range of the scale, while carbon monoxide extends the series towards the negative oxidation states, with dirhenium heptoxide/rhenium heptafluoride and tetracarbonylrhenate(−III) terminating at opposite ends. While the large body of carbonyl compounds has well been known to us organometallic chemists, we have hardly considered (simple?) oxides, halides, and oxohalides, nor have we thought of combining them with organic molecules. Still, even their structures are exciting. In dirhenium heptoxide (Re_2O_7), for example, we encounter both tetrahedral and octahedral coordination of the metal, with the so-called perrhenic acid merely being a hydrate of this oxide. Rhenium trioxide (ReO_3) forms a perovskite-type structure of hexacoordinate rhenium, with a counter ion being missing in the cavity of the cube; this d^1 compound shows metallic conductivity (!) resulting from delocalization of the d electrons. In Section 2.3 it will be shown how successive replacement of two methyl groups for each oxygen leads to interesting and useful 'organic' derivatives.

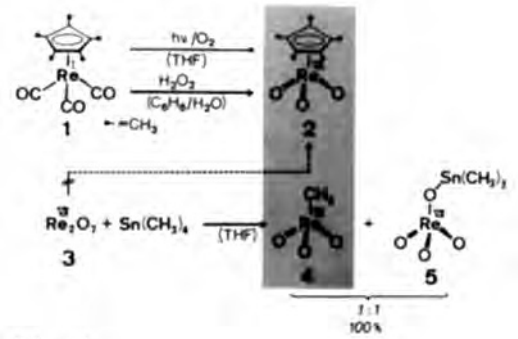
In the intermediate oxidation state range, rhenium (like molybdenum and tungsten) forms a wealth of metal–metal multiply bonded compounds such as *Geilmann*'s old 'rhenium trichloride' which in truth is a polymer in the solid state containing Re_3Cl_9 subunits.[5a] On the other hand, even methyl groups have been attached to hexavalent rhenium; *Wilkinson* has pioneered this chemistry by synthesizing the green explosion hazard hexamethylrhenium, $Re(CH_3)_6$.[27]

2.1. Trioxo(η^5-pentamethylcyclopentadienyl)rhenium(VII)

We had to learn that hydrogen peroxide does not necessarily 'chew up' the metal-attached π-aromatic ligands[28] when we treated this reagent (or *tert*-butyl hydroperoxide) with the low-valent half-sandwich carbonyl precursor compound **1** in a boiling two-phase water/benzene system. According to Scheme 1, the yellow, thermally stable product **2** containing rhenium in its highest possible oxidation state +7 is rather formed in at least 70% yield.[29] The compound can be sublimed in a high vacuum at ca. 110°C without any deterioration, and no decomposition point under normal pressure was observed up to 250°C, showing that rhenium(VII) is perfectly compatible even with otherwise oxidizable π-aromatic hydrocarbon ligands. PE spectroscopic comparison of **1** and **2** clearly revealed this difference in metal oxidation states.[30-35] Light-induced air oxidation of **1** also generates the title compound **2**, albeit less conveniently on a preparative scale and in lower yields.[30,31]

The organorhenium oxide **2** has a conventional pyramidal structure with an entirely symmetrically bonded Cp*-

[*] General remarks: All drawings of structures have been performed using the SCHAKAL program (E. Keller: *Ein Programm für die graphische Darstellung von Molekülmodellen*, Kristallographisches Institut der Universität Freiburg (FRG), 1986).—Color code: Re violet, Cl green, S yellow, P brown, O red, C black, H orange.



Scheme 1.

ligand (Cp* = η^5-C_5Me_5).[32] A space-filling model (Fig. 2, left)[*] tells us that the metal atom is effectively shielded from the upper side of the molecule while the three oxygen atoms take up most of the space on the opposite side. For this very reason, chemical reactions generally occur at the 'oxidic' part of the molecule (see Fig. 2b and Refs. [36–46]). An ^{17}O-NMR study comes to the result that the oxo ligands of compound **2** are relatively electron-rich (δ(O) = 646 ppm) while they are rather electron-deficient (δ(O) = 829 ppm, $CDCl_3$) in complex **4** (Section 2.2).

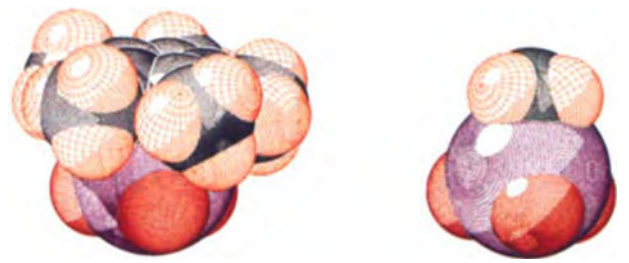


Fig. 2. Computer-generated space-filling models of the complexes [(η^5-C_5Me_5)ReO_3] **2** (left) and [CH_3ReO_3] **4** (right) correspond to an X-ray structural analysis of [(η^5-C_5Me_4Et)ReO_3] using acceptable *van der Waals* radii for rhenium (240 pm), carbon (160 pm), oxygen (140 pm), and hydrogen atoms (120 pm). For compound **4** a rhenium-methyl single bond distance of 210 pm was taken from structural data obtained for the related dinuclear derivative [$(CH_3)_4Re_2O_4$] **9a** [47].—These drawings show that the bulky π-bonded pentamethylcyclopentadienyl ligand shields the metal atom from attacking reagents on the upper side of the molecule (left) while the metal atom of compound **4** (right) is fairly exposed. It is thus understandable that compound **2** resists attachment of further ligands, whereas compound **4** forms stable adducts with such compounds (e.g., azabicyclo[2.2.2]octane, ammonia, aniline, bipyridine; see text).

2.2. Methyltrioxorhenium(VII)

We do not yet know why the parent *cyclopentadienyl* compound [(η^5-C_5H_5)ReO_3] has so far resisted all attempts at its synthesis. Neither do the oxidation reactions of Scheme 1 work in the case of [(η^5-C_5H_5)$Re(CO)_3$], nor did we succeed in making the compound from the 'right' oxidation state +7 by treating chlororheniumtrioxide (ReO_3Cl) with various cyclopentadienyl transfer reagents such as LiC_5H_5, TlC_5H_5, (C_5H_5)Sn(*n*-$C_4H_9)_3$, etc.

However, the even more interesting methyltrioxorhenium(VII), **4**, was achieved by *Kuchler* of our research group.[47] Knowing that dirhenium heptoxide and tetramethyltin are effective catalyst/cocatalyst components in olefin metathesis, even catalyzing metathesis of industrially important unsaturated carboxylic acids and nitriles under quite mild conditions,[48] he allowed these two chemicals to react in boiling tetrahydrofuran and obtained according to Scheme 1 not only colorless, completely air stable, water-soluble (!) **4** (m.p. 106 °C) but also the perrhenyl ester **5** (m.p. 213 °C, dec.); the product yields are essentially quantitative.[47] With such a simple method at hand, a whole series of high-valent organometal oxides may be opened up now, since tetramethyltin seems to be an extremely selective, non-reductive methylation reagent. No secondary reactions occur in the given example, even in the presence of a large excess of the tin reagent. *Kuchler*'s results were all the more exciting in light of the fact that compound **4** had been obtained before by *Beattie* and *Jones*[49] in small amounts by air oxidation of tetramethyloxorhenium(VI), [$(CH_3)_4ReO$], which compound in turn is difficult to make.[50a] One limitation of this synthetic strategy may, however, arise from the β-hydrogen activity of compounds [$R_2CHCH_2ReO_3$] which is evident from the reaction of Re_2O_7 with $Sn(C_2H_5)_4$ that leads to reduction of the metal with concomitant ethylene/ethane elimination.[51] Tetraphenyllead does not form the (still unknown) phenyl complex [$C_6H_5ReO_3$] with Re_2O_7 but rather the plumboxy derivative [{($C_6H_5)_3PbO$}ReO_3].[50b]

The silyl and stannyl esters [{$(CH_3)_3SiO$}ReO_3] and [{$(CH_3)_3SnO$}ReO_3], respectively, undergo reductive alkylation by aluminum alkyls to form d^1-rhenium(VI) compounds of general formulas $R_4Re_2O_4$ (e.g., **9a**) and $R_6Re_2O_3$ (e.g., **9b**; see Section 2.3).[50b,51] The latter compounds undergo oxidative cleavage with γ-picoline *N*-oxide to form the mononuclear Re^{VII} derivatives R_3ReO_2 (**9c**).[50b,51]

Replacement of the *ten*-carbon π-ligand of **2** by *one* methyl group in complex **4** must of course relieve steric crowding dramatically. Figure 2 gives a pictorial view of this issue.[50b] Evidently the metal atom is no longer buried under the surrounding ligands, so attachment of further groups at the metal should now be possible. Although investigations into the chemistry of **4** have just started, some typical reactions can already be given. Amines such as quinuclidine or 1,4-diazabicyclo[2.2.2]octane (DABCO) form stable, crystalline adducts of formulas **6a** and **6b**, respectively, demonstrating the Lewis acidity of the metal center in compound **4** (X-ray structural analysis for **6a**).[50b] These two complexes exhibit trigonal-bipyramidal geometry. Ammonia and bipyridine, however, form octahedral adducts **6c** and **6d**, respectively, the oxo ligands of

$[CH_3ReO_3]\cdot C_7H_{13}N$	$2[CH_3ReO_3]\cdot C_6H_{12}N_2$
6a	**6b**
$[CH_3ReO_3]\cdot 2NH_3$	$[CH_3ReO_3]\cdot C_{10}H_8N_2$
6c	**6d**

which are electron-rich. **4** reacts with sodium hydroxide in the presence of benzo[15]crown-5 (B15C5) according to equation (a) yielding the perrhenate **6f**, very likely via the intermediate **6e** with clean elimination of methane. **6f** has an unprecedented double-helix crystal structure.[50c]

$$[CH_3ReO_3] + NaOH \xrightarrow{B15C5} [Na(B15C5)][CH_3Re(OH)O_3] \longrightarrow [Na(B15C5)][ReO_4] + CH_4 \quad (a)$$

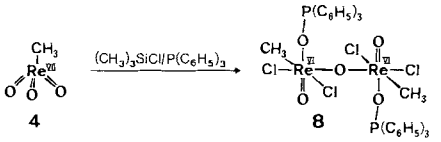
4 **6e** **6f**

Treatment of **4** with ^{17}O-labeled water should proceed along the same pathway: the intermediate **6g** would explain the observed rapid oxygen-exchange reaction.[50c]

$[CH_3ReO_3]\cdot x\,H_2O$ $[CH_3ReOCl_2]$

6g (x = 1, 2) **7**

Thionyl chloride converts **4** at low temperatures into a sensitive dark-red compound of the composition **7**, whose structure is still unknown.[50b] While a mixture of triphenylphosphane and chlorotrimethylsilane converts sterically crowded **2** reductively into the organorhenium(V) chloride **12** (see Scheme 4),[34b-d] the methyl compound **4** rather forms the dinuclear product **8** (Scheme 2) in which each metal atom has a total of six ligands, with the ReORe backbone being strictly linear (Fig. 3).[74]



Scheme 2.

Let us speculate for a moment. Scheme 1 does not comprise any redox chemistry. Hence there is no reason to assume that analogous reactions should not be feasible in related high-valent metal oxides such as V_2O_5 (possibly yielding dimers or oligomers of net composition $[CH_3VO_2]$), Cr_2O_3 (yielding a tetramer of net composition $[(CH_3)_4Cr_4O_4]$, with a cubane-type structure like the known $[(\eta^5\text{-}C_5H_5)_4Cr_4O_4]$),[53] unless the special structural features of Re_2O_7 dictate its chemistry. With only few exceptions[53-55] our knowledge of organometallic oxides mainly suffers from a lack of synthetic strategies.

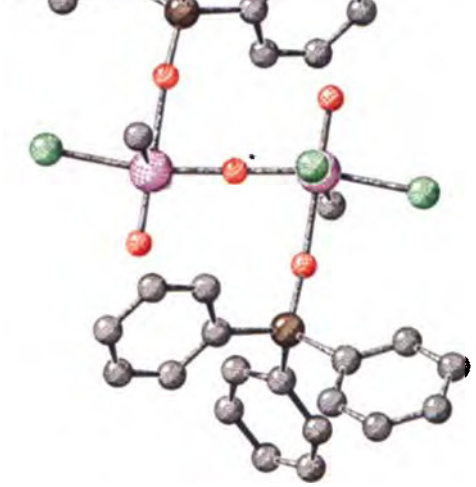


Fig. 3. Molecular structure of the dinuclear Re^{VI} complex **8**. The molecule has a center of symmetry (*) located at the central oxo bridge.

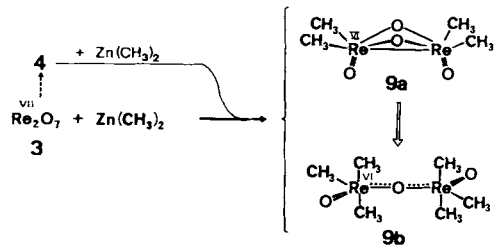
2.3. Exchange of One Oxygen for Two Methyl Groups

Dimethylzinc is generally considered by organometallic chemists to be a mild, *non-reductive* methylating reagent. This assessment does not apply, however, to its reaction with Re_2O_7 as shown in Scheme 3. In this case, the rhenium(VI) compound **9a** (Fig. 4, left; yellow, sublimable crystals; m.p. 120°C) is formed via **4**, from which it can also be made. The kinetic product **9a** is further methylated by excess dimethylzinc in a non-reductive way to the thermodynamic product **9b** (Fig. 4, right; red, sublimable needles; m.p. 88°C).[47] This last-named compound had previously only been accessible via a more tedious indirect route.[56] Only when dirheniumheptoxide **3** is treated with stoichiometric amounts of dimethylzinc (molar ratio 1/1), can the mononuclear Re^{VII} complex **4** be isolated, thus proving its intermediacy for the subsequent complexes **9a** and **9b**.[50d] This observation gives support to the expectation that phenyl and longer chain alkyl groups can be achieved in complexes of simple composition $RReO_3$ (metal-oxide substituted alkanes!) by virtue of the easily accessible organozinc compounds.



Scheme 3.

Fig. 4. Left: Molecular structure of the dinuclear Re^{VI} complex **9a**. The compound crystallizes upon vacuum sublimation in the monoclinic space group *Pn*. The hydrogen atoms have not been localized. Right: Molecular structure of the Re^{VI} complex **9b**. The diamagnetism observed for this particular organorhenium(VI) oxide is due to a 'super exchange' phenomenon typical for *linear* oxo bridges. The center of symmetry is marked with an asterix (*). The drawing was generated from the X-ray data given by *Wilkinson* et al. in Ref. [56].

If one disregards the metal-metal bond present in **9a** (259.3(< 1) pm),[47] then a strongly distorted square-pyramidal coordination geometry for rhenium is evident in the solid-state structure [two square pyramids joining the basal oxygen groups O(1) and O(2)]. Figure 5 shows how the individual dinuclear molecules are close-packed in the lattice unit cell.

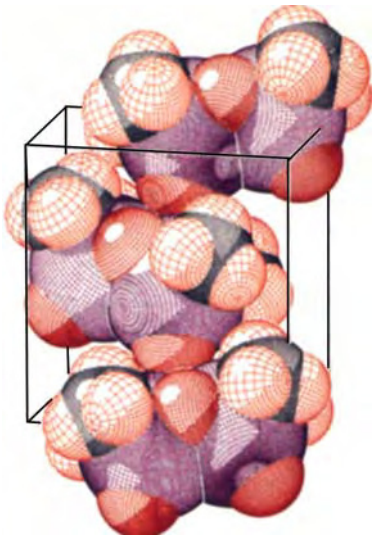


Fig. 5. Space-filling model of the unit cell of **9a**, showing that a close-packed arrangement of the individual dinuclear molecules is supported by the terminal oxo groups approaching bridging positions at neighboring molecules.

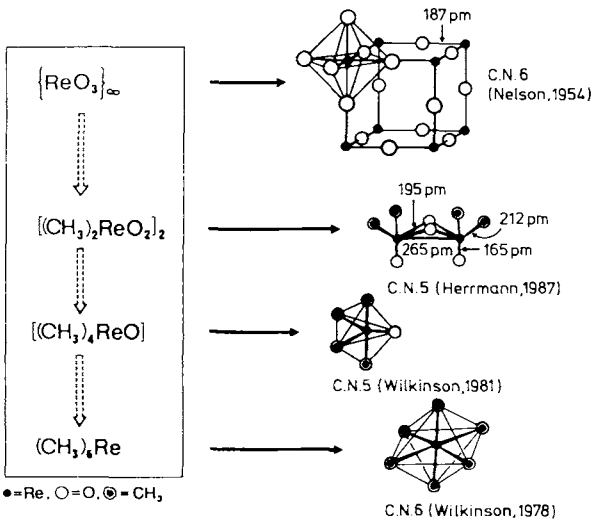

Fig. 6. From rhenium trioxide to hexamethylrhenium. In no compound of this series does the metal atom show a coordination number <5.

The novel methyl(oxo) compound **9a** can quite easily be put in the row of other, known rhenium(VI) species (Fig. 6). Rhenium trioxide is kind of a reference compound. Due to the low ligand/metal ratio of 3/1, it must have a 'polymeric' (perovskite-type) structure with several oxygen atoms joined by two metals in order to achieve an acceptable coordination number for rhenium.[26] Formal replacement of two methyl groups for one oxygen atom yields a higher ligand/metal ratio (4/1) with concomitant breakdown of the highly aggregated ReO_3 structure. This is the reason why "$(CH_3)_2ReO_2$" is just a dimer (and not paramagnetic, because of metal–metal spin pairing). Exchange of another oxygen by two more methyl groups (on paper) gives *Wilkinson*'s tetramethyl(oxo)rhenium(VI), which compound can exist as a (paramagnetic) monomer[50] since a coordination number of five has already been reached. Finally, hexamethylrhenium(VI) represents the fully methylated terminal of this series;[27] like its formal d^1-'precursor' $[(CH_3)_4ReO]$, it is paramagnetic since spin pairing is not possible.

The four compounds shown in Figure 6 form the first complete series of isovalent methyl/oxo derivatives of any transition metal. There is again no reason to assume that similar analyses will fail for other metals. Tungsten, as rhenium's uncle in the periodic table should play this game as well, e.g. $WO_3 \longrightarrow [(CH_3)_2WO_2]\,(?) \longrightarrow [(CH_3)_4WO]\,(?) \longrightarrow [(CH_3)_6W]$.[57]

When dimethylzinc reduces rhenium(VII) by one step in the reactions of Scheme 3, methyl groups appear to become oxidized at the same time since zinc is already in its highest possible oxidation state. Observation of ethane supports the idealized equation (b).

$$\underset{\mathbf{4}}{2\,[CH_3ReO_3]} + 2\,Zn(CH_3)_2 \longrightarrow \underset{\mathbf{9a}}{[(CH_3)_4Re_2O_4]} + 2\,ZnO + C_2H_6 \quad (b)$$

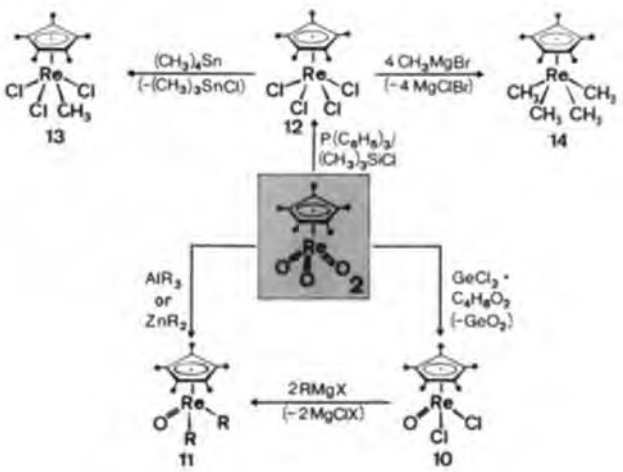
Reduction processes also come to the fore when higher tetraalkyltin reagents SnR_4 are subjected to high-valent rhenium compounds such as Re_2O_7 **3** (see Section 2.5).[58a] Derivatives of compound **9a** undergo symmetric cleavage when treated with alkaline metals M such as lithium, to give ionic products of the type

$$M^{\oplus}[R_2ReO_2]^{\ominus} \quad \mathbf{9c}$$

in which the d^2-Re^V anion has a distorted tetrahedral structure ($R = CH_2C(CH_3)_3$).[51a] Re^{VII} alkyl complexes of formulas $[R_2ReO_2Br(L)]$ (R = alkyl, L = pyridine) and $[R_3ReO_2]$ have been presented in further papers by *Hoffman* et al.[51b]

2.4. Functionalizations at Metal Oxide Fragments

Reductive processes govern the chemistry of $[(\eta^5\text{-}C_5Me_5)ReO_3]$ **2** no matter whether Lewis bases or Lewis acids are used as reagents. Typical examples are germanium dichloride (as 1,4-dioxane adduct $GeCl_2 \cdot C_4H_8O_2$) and alkylating agents such as AlR_3 or ZnR_2 that effect rather clean formation of the oxodichloro and oxodialkyl compounds **10** and **11**, respectively (Scheme 4a). These Re^V



Scheme 4a.

species are once again powerful and useful synthetic intermediates for a range of other half-sandwich complexes. Thus, treatment of the oxodichloride **10** with the reagents indicated in Figure 7 yields compounds **15a–g**, most of which have (stable) rhenium–oxygen bonds. The rhena(V)-

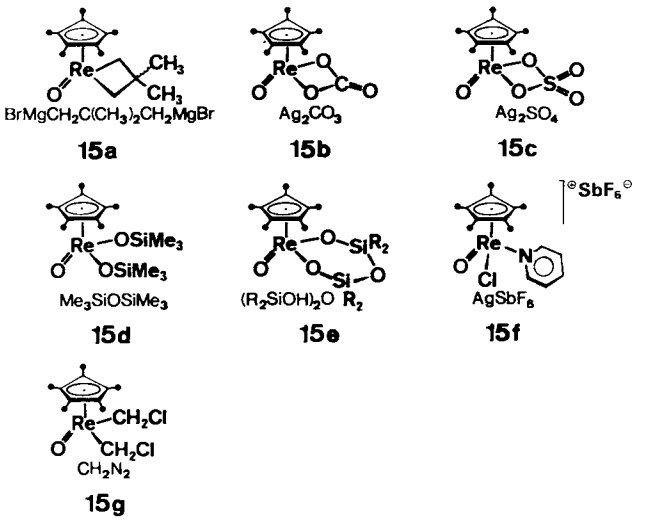


Fig. 7. Various organorhenium complexes resulting from chlorine substitution of $[(\eta^5\text{-}C_5Me_5)ReOCl_2]$ **10** by means of the reagents listed underneath the respective compounds.

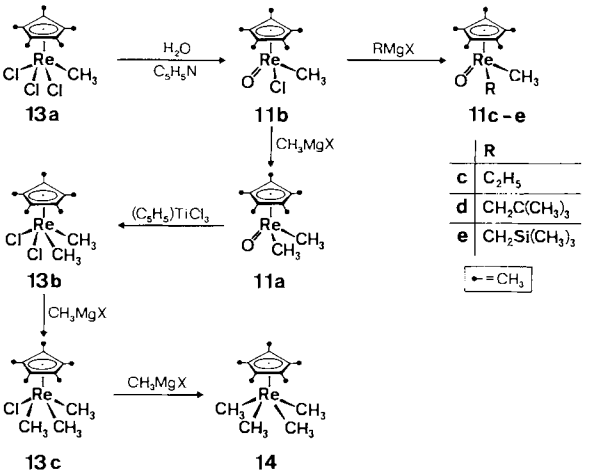
cyclobutane **15a** eliminates isobutylene, while the carbonato derivative **15b** loses carbon monoxide upon gentle heating. Sulfur dioxide is (reversibly) lost from **15c** at elevated temperature. Ionic compounds of type **15f** may serve as intermediates of chiral derivatives of general composition $[(\eta^5\text{-}C_5Me_5)Re(=O)Cl(L)]^{\oplus}$. The siloxy compound **15d** as well as the stannoxy congener $[(\eta^5\text{-}C_5Me_5)ReO(OSnMe_3)_2]$ are also *directly* available from **2** and hexamethyldisilane (or the distannane, resp.) in boiling toluene [Eqn. (c)].[58b] Compound **15e** may serve as a simple model of silica-bound organorhenium catalysts.

$$[(\eta^5\text{-}C_5Me_5)ReO_3] + (Me_3Sn)_2 \longrightarrow [(\eta^5\text{-}C_5Me_5)ReO(OSnMe_3)_2] \quad (c)$$

Other Lewis base reactions of the title compound **2** are described in Section 2.10 (Scheme 14).

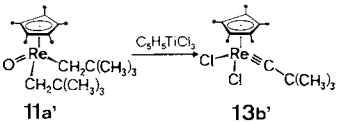
2.5. Alkylation or Reduction?

A nice comparison for alkylation *versus* reduction effected by tetramethyltin and its higher homologues is provided by the Re^V complex **12** (Scheme 4a) that now presents another very useful key compound in organorhenium chemistry.[34] Even when treated with an excess of *tetramethyl*stannane, the *mono*methylated product **13a** forms quantitatively while reduction of rhenium does not occur at all (Scheme 4a).[59] Successive methylation reactions of **13a** may be achieved, however, with dimethylzinc (*no* reduction again).[52,60] The fully methylated derivative **14** is a very water-, air-, light- and temperature-sensitive compound (stable only well below 0 °C).[61,62] The partially alkylated members **13b** and **13c** of this series are best synthesized *via* a detour (Scheme 4b): first, the chiral **11b**, which is an ideal precursor for complexes **11c–e** that contain different alkyl ligands,[52] is obtained *quantitatively* by hydrolysis (water/pyridine; molar ratio 1 : 2). The dimethyl derivative **11a** can be converted into **13b** by means of the oxophilic organotitanium(IV) reagent $[(\eta^5\text{-}C_5H_5)TiCl_3]$.[52] This route is all the more useful in that a selective methylation **13a** → **13b** does *not* work. Further stepwise methylation employing stoichiometric amounts of Grignard reagents lead according to Scheme 4b *via* (now isolable) trimethyl **13c** ultimately to the tetramethyl derivative **14**.[52]



Scheme 4b.

An interesting exception is the bis(neopentyl) derivative **11a'**, which is also isolable: upon chlorination with trichloro(η^5-cyclopentadienyl)titanium(IV) cleavage of neohexane leads to formation of the paramagnetic carbyne complex **13b'** (Scheme 4c). This undergoes a reversible



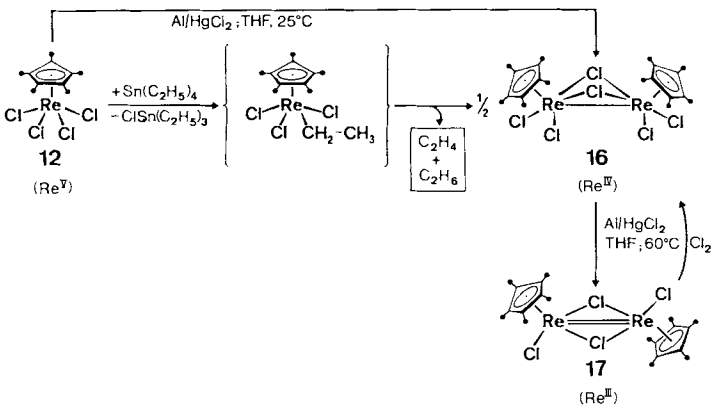
Scheme 4c.

one-electron oxidation ($E_{1/2} = 0.79$ V) and with silver hexafluoroantimonate yields the cationic, diamagnetic product $[(\eta^5\text{-}C_5Me_5)ReCl_2(\equiv C\text{–}CMe_3)]^{\oplus}[SbF_6]^{\ominus}$.[52]

All compounds of the series $[(\eta^5\text{-}C_5Me_5)ReL_4]$ are d^2-Re^V systems (L = alkyl, halogen), display singlet/triplet spin equilibria (magnetic measurements and NMR evidence),[52,59–61] and have square pyramidal crystal structures with the π-aromatic ligand always occupying the apex of the polyhedron (Fig. 8).

*Tetraethyl*stannane reacts with the tetrachloride **12** to give the dinuclear complex **16**. The ethylrhenium(V) intermediate $[(\eta^5\text{-}C_5Me_5)ReCl_3(C_2H_5)]$ (Scheme 5) is probably formed but is further *reduced* to the stable rhenium(IV) dimer of net composition $[(\eta^5\text{-}C_5Me_5)ReCl_3]$ with concomitant formation of ethylene and ethane (no hydrogen).[59] In terms of structure, the dimer **16** is related to α-$\{ReCl_4\}$ in that it also displays *two* chloro bridges between rhenium atoms. Due to the bulky five-membered ring ligand, how-

Fig. 8. All $[(\eta^5\text{-}C_5R_5)ReL_4]$ complexes have a square-pyramidal ('pianostool') geometry. The example shown here is the first homoleptic organorhenium(v) compound, tetramethyl(η^5-pentamethylcyclopentadienyl)rhenium **14**. Due to disorder phenomena, individual structural parameters cannot be given for this particular compound; average Re-C1···C4 distances 217(3) pm, average CReC angles 81(1) and 136(1)°.



Scheme 5.

ever, the polymeric chain structure of rhenium tetrachloride[26b] is cut down to dinuclear ensembles in the 'organic' derivative **16** owing to its bulky π-aromatic ligand (Fig. 9). The compound is also available from the Re^V precursor **12** by reduction with electropositive metals, preferably powdered aluminum (Scheme 5).

Fig. 9. Molecular structure of the orgahorhenium(IV) complex **16'** $[(\eta^5\text{-}C_5Me_4Et)ReCl_3]_2$. **16'** was synthesized by reduction of $[(\eta^5\text{-}C_5Me_4Et)ReCl_4]$ **12'** with $Sn(C_2H_5)_4$ or $Al/HgCl_2$. Shown is a computer-generated space-filling model that underlines the *cis* geometry of the two five-membered ring ligands. — Re-Re' 307.4(<1) pm.

The Re_2^{III} dimer **17** obtained by further reduction of **16** (and vice versa) by means of $HgCl_2$-activated aluminum (Scheme 5) is shown in Figure 10 for the sake of comparison. From the close packing of both the bridging and the terminal chloro groups around the (formal) metal–metal double bond (250.6(<1) pm), the rather low reactivity towards neutral ligands such as alkynes becomes evident.

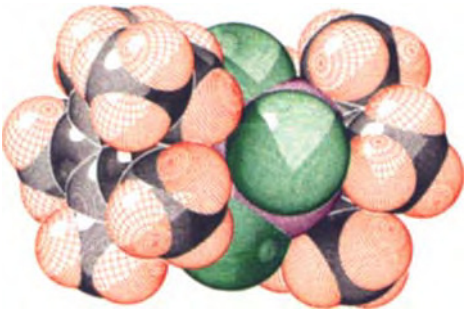


Fig. 10. Further reduction of **16'** (Fig. 9) yields the organorhenium(III) dimer $[(\eta^5\text{-}C_5Me_4Et)ReCl_2]_2$ **17'** (see also Scheme 5). The two five-membered ring ligands are parallel to each other (*trans* geometry).—Selected bond lengths [pm] and angles [°]: Re-Re' 250.6(<1), Re-Cl(terminal) 240.6(1), Re-Cl(bridge) 239.7(1) and 240.1(1); ReCl(bridge)Re' 63.0(0). The space-filling model suggests no great difference between bridging and terminal chloro ligands. A center of symmetry is located at the midpoint of the metal-metal (double) bond.

Thus, tetramethylstannane does not reduce high-valent rhenium compounds, whereas β-hydrogeno-containing tetraalkylstannanes very much do so. Consequently, these various stannanes should display distinct differences in activity when employed as cocatalysts in rhenium-containing olefin-metathesis catalysts. It is therefore difficult to understand why tetramethyl- and tetra-*n*-butylstannane are frequently used interchangeably for this purpose without too great a difference in catalyst activity and selectivity—this certainly constitutes an unsolved problem of significance.[48]

2.6. Olefin Metathesis[65]

Schrock has repeatedly pointed out that higher metal oxidation states (e.g. W^{IV}) are essential for olefin metathesis, a mechanistically interesting and commercially important process.[66] Since $Re_2O_7/Sn(CH_3)_4/Al_2O_3$ represents an effective (heterogeneous) olefin metathesis catalyst system, it appeared obvious that the methylrhenium oxide **4** would serve as a key to the understanding of this special catalyst/cocatalyst system.

As a matter of fact, **4** catalyzes both ring opening polymerization of cyclopentene and metathesis of open-chained olefins but requires aluminum trichloride and excess tetramethylstannane in order to do so.[47] The Lewis acid effect upon olefin metathesis has been emphasized by *Osborn* et al.,[67] and we believe that the Lewis acid $AlCl_3$, in our case, removes an oxygen atom of CH_3ReO_3 in order to introduce one or two more methyl groups so that the prerequisites for carbene-ligand generation via elimination of methane according to the generally assumed reaction sequence (d) are fulfilled. That this may not be a poor hypothesis is demonstrated by the fact that compound **9b** which has the higher CH_3/Re ratio of 3/1 does effect olefin metathesis, even in the absence of tetramethylstannane.[47,58a]

$$M(CH_3)_2 \longrightarrow M{=}CH_2 + CH_4 \qquad (d)$$

In the light of recent work by *Osborn* et al., it appears quite obvious that $AlCl_3$ first forms an adduct with the organometal oxide with subsequent reduction, which possibility is even more likely in that the related reaction (e) is

$$[(\eta^5\text{-}C_5Me_5)ReO_3] + Al(CH_3)_3 \longrightarrow [(\eta^5\text{-}C_5Me_5)ReO(CH_3)_2] + \cdots \quad \text{(e)}$$

2 **11a**

known.[34] We have in fact isolated a red, crystalline compound of composition $[(\eta^5\text{-}C_5Me_5)ReO(CH_3)_2]\cdot AlCl_3$ **18** at low temperature which decomposes upon warming to ca. 0 °C.[58c] By way of analogy, reductive chlorination [Eqn. (f)] of **4** with subsequent chlorine/methyl exchange by excess tetramethylstannane may not be pure fantasy. This proposal would involve oxidation state +5 at rhenium to promote olefin metathesis processes.

$$[CH_3ReO_3] + AlCl_3 \longrightarrow [CH_3ReO_2Cl_2] + \{AlOCl\} \quad \text{(f)}$$

In continuation of such considerations we have recently been able to establish a catalyst system which surpasses all previously known rhenium-containing catalysts in the *metathesis of functionalized (!) olefins*.[58a]

2.7. Oxidative Coupling of Alkynes; Model Compounds and Reality

A group at the Amsterdam Shell laboratories reported the oxidative coupling of two alkyne molecules to give furan derivatives,[68] important compounds in industry. This rather intriguing coupling reaction, in which *one* CC and *two* OC bonds are formed, also involves participation of the organorhenium(VII) oxide **2** (Scheme 6). While triphenylphosphane alone reacts with **2** with clean formation of the Re^V dimer **20** according to equation (g), the novel rhena(V)-pyrans **19** are formed as isolable compounds in the presence of alkynes, e.g. 2-butyne. These latter compounds **19** undergo double metal–carbon bond cleavage upon successive treatment with iodine.[68]

$$[(\eta^5\text{-}C_5Me_5)ReO_3] + P(C_6H_5)_3 \longrightarrow \quad \text{(g)}$$

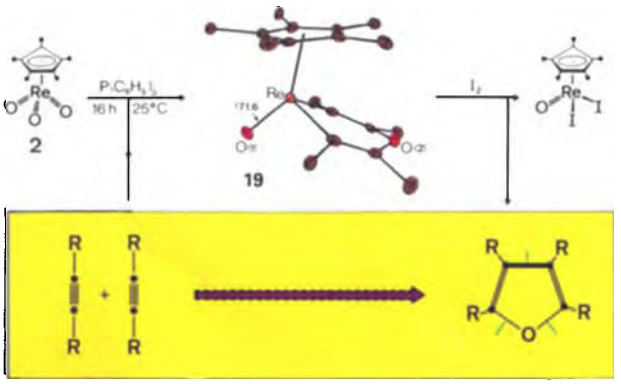
2

$$\tfrac{1}{2}[(\eta^5\text{-}C_5Me_5)ReO_2]_2 + O{=}P(C_6H_5)_3$$

20

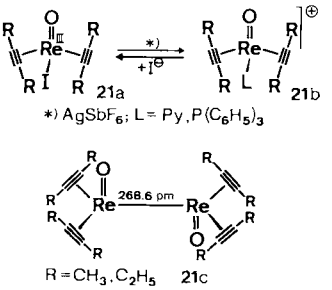
A further challenge for organometallic oxide chemistry is to carry out the oxidative coupling outlined in Scheme 6 as a *catalytic* reaction. A synthesis of pyrroles via participation of imido groups (NR) attached to rhenium should also be conceivable. An alkyne/alkyne/sulfur coupling reaction catalyzed by cyclopentadienylcobalt complexes has recently been described by *Bönnemann*.[69]

The attractive-looking synthesis of heterocycles mentioned in the preceeding paragraph warrants a better understanding of the largely unexplored interactions between alkynes and organorhenium fragments of intermediate oxidation states.



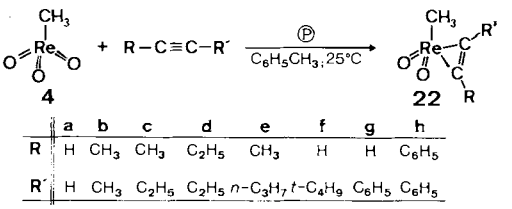
Scheme 6.

Alkynes are rarely found as ligands in organorhenium complexes, even with rhenium in low oxidation states. Probably best known are alkyne-to-vinylidene isomerizations at Re^I centers.[70] Trivalent rhenium forms several structurally simple oxidic alkyne complexes **21a**, **b**, the synthesis of which has recently been reported by *Mayer* et al. (Scheme 7).[28, 71, 72] The assignment of oxidation states is of course rather formalistic here since the alkynes seemingly act as 4e-ligands. The same problem is encountered in the case of the unprecedented Re^{II} complexes $[(RC{\equiv}CR)_4Re_2O_2]$ **21c** (characterization by means of X-ray diffraction techniques).[73]



Scheme 7.

Clean reductive substitution ($Re^{7\oplus} \rightarrow Re^{5\oplus}$) of alkynes for oxo groups occurs at methyltrioxorhenium(VII) (**4**) in the presence of polymer-bound (!) triphenylphosphane as a selective reductant. A whole range of thermally rather stable π-alkyne complexes **22** has thus been prepared according to Scheme 8.[74] The occurrence of isomers in the cases of **22c** and **22e** suggests high rotational barriers between the metal and the alkyne ligands. Even the unsubstituted acetylene ligand of compound **22a** does not exhibit fast rotation on the NMR time scale up to at least 100 °C.



Scheme 8. Ⓟ = polymer-bound $P(C_6H_5)_3$ [74].

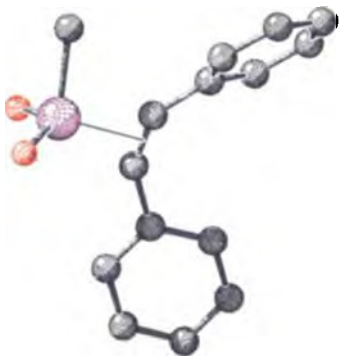


Fig. 11. Molecular structure of $[CH_3ReO_2(\eta^2\text{-}C_6H_5C{\equiv}CC_6H_5)]$ **22h**. The compound crystallizes from methylenechloride/*n*-hexane at −25°C in the monoclinic space group $P2_1/c$.—Selected bond lengths [pm] and angles [°]: Re-O 174.0(4) and 171.0(1), Re-CH_3 209.2(7), C-C(ethyne) 128.0(9); OReO 119.5(2) [74].

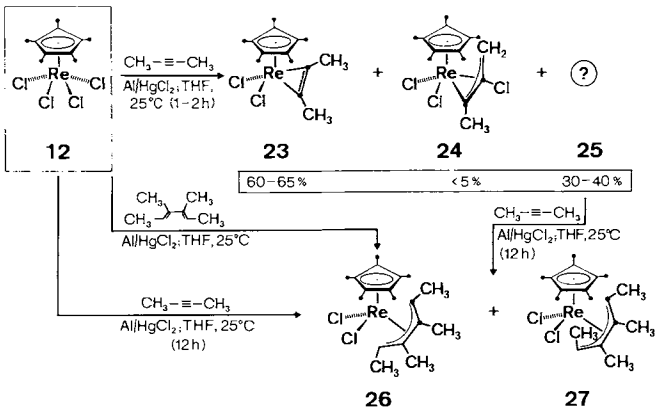
An X-ray structure of **22h** confirms the suggested structure (Fig. 11) which is in contrast with theoretical predictions.[99] Note that all attempts to synthesize the analogous compounds with a pentamethylcyclopentadienyl ligand in place of the methyl group have thus far failed. Thus the butyne-Re^{III} complex $[(\eta^5\text{-}C_5Me_5)ReO(\eta^2\text{-}MeC{\equiv}CMe)]$ (**33**) does not undergo oxidation to give (the hitherto unknown) Re^V derivative $[(\eta^5\text{-}C_5Me_5)ReO_2(\eta^2\text{-}MeC{\equiv}CMe)]$.[64a] Oxidation of **33** (R = Ph) with ferricinium salts cleanly furnished the dinuclear cation $[(\eta^5\text{-}C_5Me_5)_2Re_2(\mu\text{-}O)_2(tolan)_2]^{\oplus}$.[64a]



Scheme 9.

Further deoxidation of compounds **22** is only possible with polymer-bound triphenylphosphane under more drastic conditions, e.g., boiling toluene. The expected mononuclear Re^{III} derivatives $[CH_3ReO(\eta^2\text{-}RC{\equiv}CR)_2]$, however, are not formed, but rather the dinuclear Re^{IV} species of composition $[(\mu\text{-}O)\{CH_3ReO(\eta^2\text{-}RC{\equiv}CR)\}_2]$ (X-ray structural analysis for R = CH_3).[52]

The Re^{III} complex **23** (with 2-butyne as 4e-ligand) is accessible according to Scheme 9 by reduction of the parent Re^V compound **12**.[63,75] In terms of further chemical transformations, chlorine replacement at the stage of compound **23** by alkyl and oxo groups is particularly useful.[75]

The byproduct of the Re^V-reduction outlined in Scheme 9 is the Re^V-vinyl/carbene derivative **24**, whose unexpected composition and structure are shown in Figure 12 (left).[75] It derives from the C_4-alkyne by loss of a hydrogen atom, with concomitant metal-to-carbon chlorine transfer. The structure of **24** is best interpreted as an allylidene complex on geometrical grounds.[75] Finally, a third product **25** of unknown identity proved very useful for subsequent reductive carbon–carbon coupling processes. Thus, excess 2-butyne yields a mixture of two isomeric Re^{III}-1,3-diene complexes **26** and **27**, respectively (Scheme 9). The diene complex **26** can also be prepared under reductive conditions from **12** and 3,4-dimethyl-2,4-hexadiene.[76]

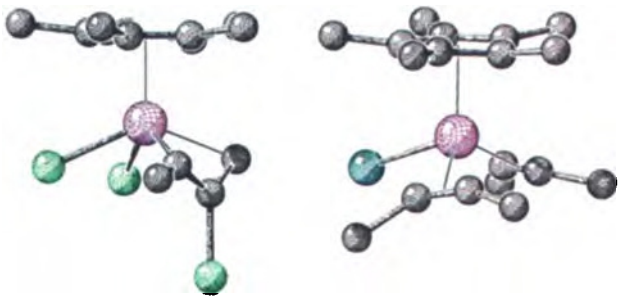


Fig. 12. Left: Molecular structure of the allylidene complex **24**. Selected bond lengths [pm] and angles [°]: Cl3-C2 178.8(3), Re-Cl1 239.1(1), Re-Cl2 241.9(1); Cl1ReCl2 82.27(3).—Right: Structure of the cationic bis(η^2-butyne) complex **29** in the crystal, Br instead of Cl (see Scheme 10).—Selected bond lengths [pm]: C≡C 136(2) and 124(2), Re-C 199(1)/201(1) and 198(2)/202(2). The crystal contains dichloromethane (1 : 1).

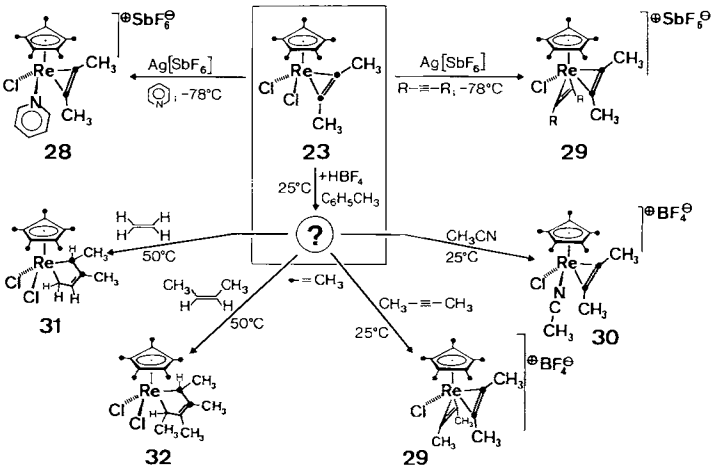
Chlorine/pyridine exchange at the stage of **23** to form compounds of type **28** is achieved by silver hexafluoroantimonate (Scheme 10). Likewise, a second alkyne may be introduced if one removes a chloride group from **23** by means of $AgSbF_6$ in the presence of the new alkyne to enter the molecule. The cationic bis(π-alkyne) complexes **29** (Fig. 12, right) exhibit free metal-to-alkyne rotations only at higher temperatures. Rotational barriers around 60 kJ mol^{-1} have been established by temperature-dependent NMR spectroscopy.[64b,75]

A synthetically useful acid catalysis effect is demonstrated by π-alkyne complexes of type **23** (d^4-Re^{III}); CC coupling processes that do not work in the absence of Brønsted acids take place when **23** is treated with traces of



Scheme 10.

HBF_4 in the presence of ethylene or *cis*-2-butene. The 1,3-diene complexes **31** and **32** (Fig. 13, left), respectively, are thus obtained in yields around 80% (Scheme 10).[76] Stoichiometric amounts of HBF_4 suffice to achieve fast chlorine substitution in the presence of acetonitrile to give the (chiral) ionic compound **30** according to Scheme 10.[76]

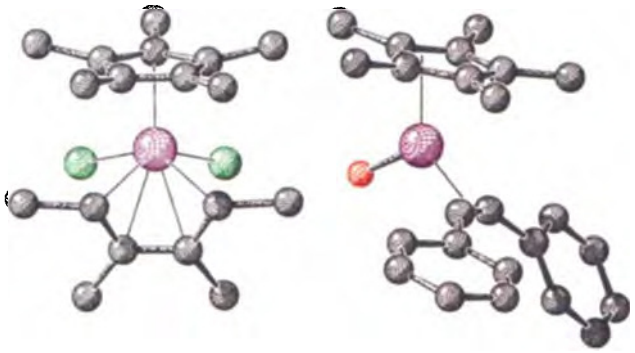


Fig. 13. Left: Structure of the 1,3-diene complex **32** in the crystal. Right: Structure of the alkyne(oxo) complex $[(\eta^5\text{-}C_5Me_5)ReO(\eta^2\text{-}C_6H_5C{\equiv}CC_6H_5)]$ **33** in the crystal.—Selected bond lengths [pm] and angles [°]: Re-O 171.0(1), C≡C 130.0(2), Re-C(alkyne) 203.0(1), 203.6(1); $C(C_6H_5)$-C-C 142.2(2) and 145.6(2).

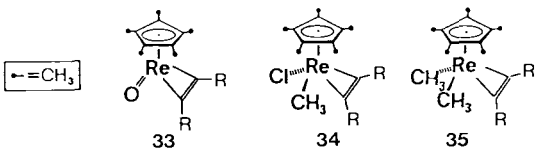
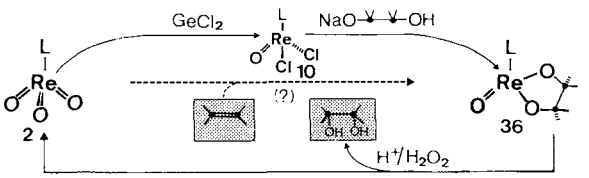
The synthetic potential of Re^{III} alkyne complexes such as **23** (also Br and I in place of Cl, and R = alkyl, aryl) is further demonstrated by their smooth hydrolysis to give novel oxo(alkyne) derivatives **33** (**33**, R = Ph, see Fig. 13, right), and by their reaction with Grignard compounds to form **34** and **35**.[63]



33 **34** **35**

2.8. The Search for Organorhenium Oxides that Oxidize Olefins

The formation of furans from rhena(v)-pyrans according to Scheme 6 constitutes an oxidative carbon–carbon coupling process during which the metal stays in oxidation state +5; in this reaction elemental iodine is the oxidizing agent.[68] Redox-neutral rhenium–oxygen bond cleavage occurs when five-membered metallocycles of type **36** are treated with Brønsted acids such as HBF_4 according to Scheme 11.[77]

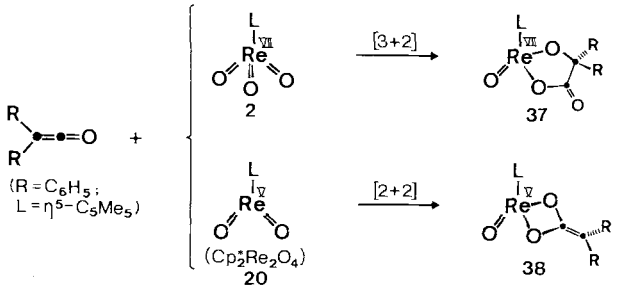


L = η^5-C_5Me_5

Scheme 11.

The metallocycles **36** may alternatively be viewed as *O,O*-glycolate complexes like those known from *Sharpless'* osmium work on the *cis* hydroxylation of olefins to 1,2-glycols.[21a,78] In spite of the fact that the osmium tetroxide used in these catalytic reactions is extremely toxic (maximum working concentration 0.002 $mg \cdot m^{-3}$!), no better replacement has been found as yet. This is a result of our rather crude general knowledge of the hydrocarbon chemistry occurring at high-valent transition metals. It may certainly be true that metals other than Os^{VIII} are inferior in oxidation power, but a 'tune up' towards the right potentials and intermediates seem possible by way of tailored auxiliary ligands. In this important area of metal-mediated oxidation chemistry, a similar development as that which occurred in low-valent coordination compounds for hydroformylation, olefin hydrogenation etc. is conceivable. Instead of the 'soft' phosphanes useful for these latter processes, the 'hard' oxo, alkoxide, and imido ligands might yield step-by-step improvements at the higher oxidation states of transition metals.

To this end, we have synthesized a number of rhenium(v) glycolates as well as their *O,N-*, *O,S-*, and *S,S* congeners.[77,79] Apart from a few exceptions, these compounds are in general thermally quite robust, but heating above the melting points effects selective oxygen–carbon bond breaking in the case of the glycolate compounds with formation of the corresponding olefins. Since $H^{\oplus}/H_2O_2$ treatment, on the other hand, cleanly gives glycols and the rhenium(VII) oxide **2** (Scheme 11), the only missing link in a catalytic cycle is direct cycloaddition of the olefins to the oxide **2**. Since activated carbon–carbon double bonds like those in ketenes undergo clean [3+2] and [2+2] cycloaddition reactions to produce compounds **37** and **38** according to Scheme 12 (X-ray characterization),[39,42] it appears just a matter of enhancing the ReO_3 core reactivity, e.g. by replacement of the C_5Me_5-ligands by more electron-withdrawing groups (e.g. CF_3), in order to reach the penultimate goal of removing the question mark from Scheme 9. This has been achieved for several derivatives of methyltrioxorhenium(VII) **4**[50b] and, at the same time, replaces the model compounds by a catalytic cycle.



(R = C_6H_5; L = η^5-C_5Me_5)

2 **37** **20** **38**

Scheme 12.

Organometallic glycolate complexes of other metals of relevance in oxidation processes have also been synthesized. Thus, the organovanadium(v) species **39**[80,81] forms the dinuclear compound **40** having a $V_2O_3C_2$ seven-membered ring geometry (Fig. 14).[82,97]

$[(\eta^5\text{-}C_5Me_5)VOCl_2]$ **39**

$[\{(\eta^5\text{-}C_5Me_5)VO\}_2(\mu\text{-}O)(\mu\text{-}OCH_2CH_2O)]$ **40**

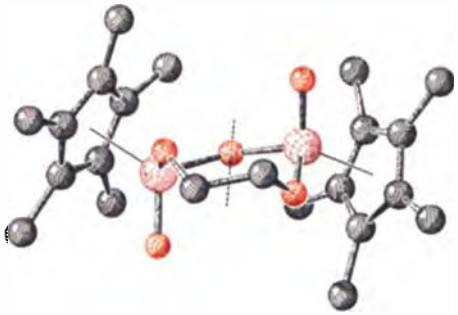


Fig. 14. Structure of the dinuclear organovanadium(v) complex **40** in the crystal. – Selected bond lengths [pm] and angles [°]: V=O 159.8(1), V-O(glycolate) 181.0(1), V-O(bridge) 177.7(1); VOV' 127.0(1).

Apart from their catalytic potential (e.g. for amine oxidation), *N,O*-metallocycles analogous to **38** provide easily accessible starting materials for the synthesis of imido complexes.[79]

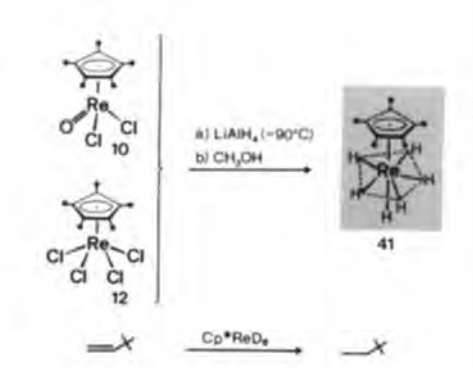
Instead of glycolate ligands other anionic chelates can be attached to rhenium(v); examples are the carbonato- and sulfato complexes **15b** and **15c**, respectively (Fig. 7).[83] Rhenium-attached oxometalates of transition metals[84] (e.g. $[Cr_2O_7]^{2\ominus}$) are presently being investigated for their potential as organometallic catalysts on oxidic metal surfaces.

2.9. New Polyhydrides of Rhenium

Despite the uniqueness of our two title compounds $[(\eta^5\text{-}C_5Me_5)ReO_3]$ (**2**) and $[CH_3ReO_3]$ (**4**), it emerges from what has been outlined in the previous chapters that rhenium chemistry resembles that of molybdenum and tungsten much more than the chemistry of any other element, with the possible exception of osmium on the right and tantalum on the left.[85] Only with these three elements, molybdenum, tungsten, and rhenium is it possible to catalyze olefin metathesis at an industrially acceptable level.[66] Beyond this 'catalysis bracket', there are numerous analogous compounds, and the reader need only be reminded of the metal-metal multiple bonded compounds comprising a major, attractive part of the chemistry of these elements.[5]

Moreover, rhenium, like molybdenum and tungsten, is compatible with hydrogen and hydrido ligands (H_2 and H, resp.) across the entire range of oxidation states.[86] Let it suffice to mention only the textbook example of nonahydridorhenate(VII), $[ReH_9]^{2\ominus}$.[87] Hydrogen atoms attached to rhenium can also be found at low oxidation states such as Re^I in the examples $[HRe(CO)_5]$ or $[H_3Re_3(CO)_{12}]$ and many other complexes.[70] As a matter of fact, the redox versatility of hydridorhenium species is a great advantage of *Felkin*'s carbon-hydrogen activation catalysts of type $[L_2ReH_7]$ ($L = PR_3$)[88] while there is a demand for further improvement of catalyst activity and selectivity.[89]

The novel neutral rhenium(VII) hydride **41** – air-stable, sublimable, thermally robust up to the melting point at 192 °C! – can be prepared in 75% yield by treatment of the Re^V-complex **10** with lithium aluminum hydride in diethylether at low temperatures and subsequent reaction of the intermediate with methanol (Scheme 13).[90] The yields of



Scheme 13.

the *mononuclear* hexahydride **41** are lower when the tetrachloride **12** is used as a starting compound; in this case the dinuclear hexahydride **42** is also formed. This synthe-

$[(\eta^5\text{-}C_5Me_5)_2Re_2H_6]$ **42**

sis is mechanistically not fully understood but it is tempting to assume that the Re^V precursor compounds **10/12** are first converted into an intermediate $[(\eta^5\text{-}C_5Me_5)ReH_4]$, which subsequently undergoes formal oxidative addition of H_2 (from $LiAlH_4/CH_3OH$). The compound has a fluctional pentagonal-bipyramidal structure (temperature-dependent NMR experiments). Neohexene is hydrogenated by **41**. When $[(\eta^5\text{-}C_5Me_5)ReD_6]$ is used, a mixture of several neohexane isotopomers (Scheme 13, bottom) is observed by GC/MS.[58a]

Both thermal (> 200 °C) and light-induced elimination of hydrogen (0 °C) from **41** yield the red-colored, air-stable, dinuclear rhenium(IV) hydride **42**. According to a low-temperature X-ray diffraction study (−100 °C), two terminal and two bridging hydrogen atoms are present on each rhenium atom of **42'** (C_5EtMe_4 instead of C_5Me_5) (Fig. 15).[91]

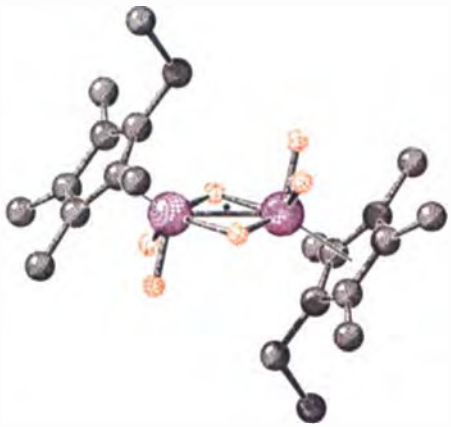


Fig. 15. Structure of the organorhenium(IV) complex bis[(μ-hydrido)dihydrido(η^5-ethyltetramethylcyclopentadienyl)rhenium](*Re≡Re*) **42'** in the crystal at −160 °C. – Re-Re distance 245.2(1) pm (triple bond).

Photolysis of **41** in the presence of trimethylphosphane, however, furnishes the derivative **43**, whereas treatment with hot carbon tetrachloride results in formation of the chloro complex **44** in a radical-type dark-reaction.[92]

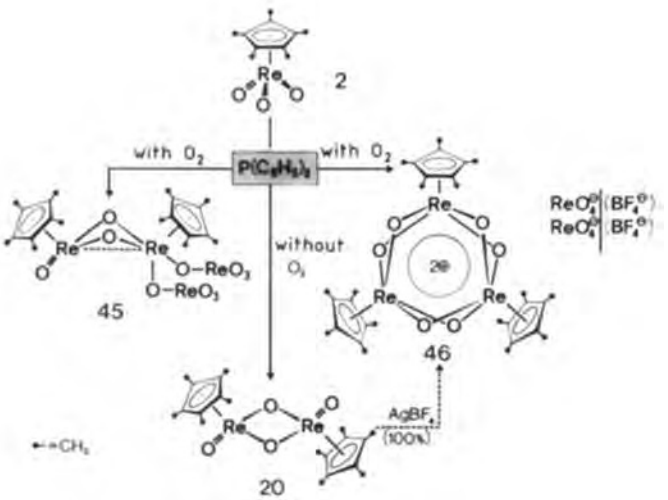
trans-$[(\eta^5\text{-}C_5Me_5)Re(H)_2(PMe_3)_2]$ **43**

$[(\eta^5\text{-}C_5Me_5)Re(\mu\text{-}H)Cl_2]_2$ **44**

2.10. How Useful is the Pentamethylcyclopentadienyl Ligand Really?

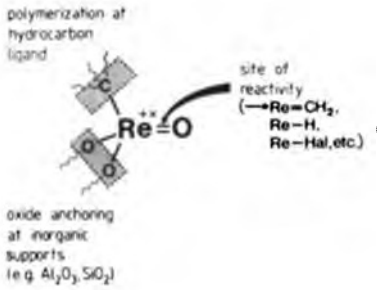
The π-bonded pentamethylcyclopentadienyl ligand was fortunately retained at the metal when *Serrano* first synthesized the title compound **2** by light-induced oxidation of the parent carbonyl precursor **1**.[30] Excellent solubility of compound **2** and of essentially all derivatives in common organic solvents enabled us to quickly develop this type of high oxidation state organorhenium chemistry after we had found that purification of the compounds could be achieved by low-temperature column chromatography on silylated silica gel. The bulky ten-carbon ring ligand prevents more complicated reactions to occur but rather directs them to the ReO_3 core.

On the other hand, cleavage of the rhenium-carbon bonds of **2** is occasionally encountered. For example, deoxygenation effected by (polymer-bound[74]) triphenylphosphane cleanly yields the synthetically useful rhenium(V) compound **20** (see Scheme 14 and Section 2.7), but only if atmospheric oxygen is strictly excluded.[34] Otherwise, partial loss of the π-aromatic ring comes to the fore, with the perrhenate groups showing up in the products. The two structurally characterized compounds **45** and **46**[93] are good examples (Scheme 14).



Scheme 14. In **45** we have the combination Re^{V}/Re^{VII}, in **46** $Re^{+5.66}/Re^{VII}$; **20** is a Re^{V}/Re^{V} complex.

These findings revealed that at some (mechanistically unknown) stage of the reaction atmospheric oxygen may split off the hydrocarbon π-ligand, which would therefore have to be replaced by better ones such as the more tightly bonded methyl group.[94] Now that we have achieved this goal by preparing methyltrioxorhenium(VII) (**4**) from Re_2O_7 and $Sn(CH_3)_4$, the entire range of compounds merits a firm place in catalysis research.[47] In this context, the alkyl ligand might be exploited for the generation of polymer chains that carry isolated metal oxides MO_x. Models for surface-anchored catalysts may be obtainable via *O,O*-chelation (Scheme 15).



Scheme 15.

2.11. Sulfur and Selenium Instead of Oxygen?

The higher homologues of oxygen — sulfur and particularly selenium — are of great interest in organic synthesis or for medical applications.[95] The hitherto unknown sulfur and selenium congeners of compounds **2** and **4** are attractive target molecules. That oxygen is in fact prone to replacement by sulfur and selenium is evident from two reactions: (i) Treatment of $[(\eta^5\text{-}C_5Me_5)ReOCl_2]$ **10** with bis(trimethylsilyl) sulfide gives the oxygen-free compound **47** among other organorhenium sulfides from which the

$(\eta^5\text{-}C_5Me_5)_2Re_2S_4$ **47** $\quad [(\eta^5\text{-}C_5Me_5)Re(O)S_4]$ **48**

main product has so far resisted separation.[96] (ii) Four sulfur atoms are transferred from $[(\eta^5\text{-}C_5H_5)_2TiS_5]$ to the same organorhenium(V) compound **10** to form the air-stable, mononuclear complex **48** in a surprisingly clean reaction (≥90% yield). The five-membered, non-planar ReS_4 ring system thus generated is evident from Figure 16.[97]

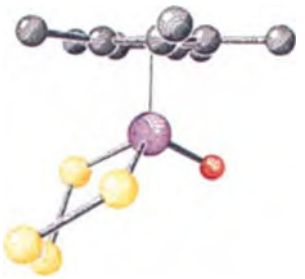


Fig. 16. Molecular structure of the ReS_4 metallacycle **48**.—Selected bond distances [pm]: Re-O 171.8(3), Re-S 226.4(1) and 224.4(2).

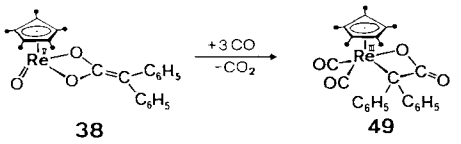
Due to the much higher catenation and cyclization tendency of sulfur and selenium over oxygen, this chemistry appears by far less predictable at present, but nevertheless presents another exciting challenge for skilled experimentalists.

2.12. Back to Monovalent Rhenium — A Play with Oxidation States

We now return to our starting point of monovalent rhenium. Conversely to its mode of formation, the title compound **2** can be reduced by carbon monoxide under pressure or by the oxophilic carbonylation reagent $[(\eta^5\text{-}C_5H_5)_2Ti(CO)_2]$ at normal pressure.[36] If there is only one terminal oxo group present, reductive carbonylation follows the overall equation (h).

$$[L_yM^x{=}O] + 3\,CO \longrightarrow [L_yM^{x-2}(CO)_2] + CO_2 \qquad (h)$$

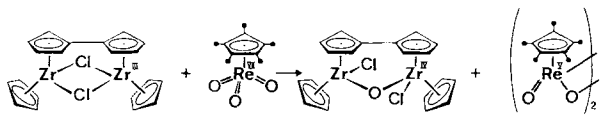
Typically, the Re^V chelate complex **38** is reduced to the Re^{III} complex **49** (X-ray characterization) with concomitant isomerization of the bidentate O,C ligand (Scheme 16).[44]



38 49

Scheme 16.

Clean redox processes also take place when the strongly reducing zirconium(III) complex **50** reacts with the organorhenium(VII) oxide **2**. The desired rhenium/zirconium oxide was unfortunately not obtained; instead, the homonuclear redox products **20** (Re^V) and **51** (Zr^{IV}; X-ray characterization) were isolated (Scheme 17).[46] The study of this type of reversible redox processes has only just begun.

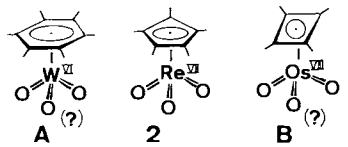


50 2 51 20

Scheme 17.

3. Pure Speculation?

Being convinced that π-aromatic ligands do in fact survive at even the highest possible oxidation states of transition metals, we may speculate about other congeners still to be discovered. If the isoelectronic principle is going to hold promise again, then benzene (or its hexamethyl derivative) should not disguise the WO_3 fragment to give (stable?) **A**. On the other hand, one should not be surprised to see a cyclobutadiene ligand in the osmium compound **B** some day (Fig. 17). At least in these two compounds, additional prerequisites for thermal stability are fulfilled: they belong to the elements of the third transition metal series that generally form more stable and less strongly oxidizing high-valent compounds than their 'lighter brothers'. Secondly, the coordination numbers are high enough to avoid kinetic lability which, for instance, would result in aggregation to dimers or oligomers. For this latter reason, the vanadium(v) compound '$[(C_5H_5)VO_2]$' announced by Russian workers[98a] turned out to be trimeric (X-ray structure of $[(\eta^5\text{-}C_5Me_5)_3V_3O_6]$[98b]).



A 2 B

Fig. 17. Organometal oxides that are isoelectronic with **2**. The tungsten and osmium compounds are as yet unknown.

4. π-Acceptor versus π-Donator Ligands: Molecular Orbital Reasoning for Stability

Bursten et al. addressed the basic question of d-electron count vs. stability of high- and low-valent piano-stool complexes.[99] To this end, they subjected the structurally analogous compounds **C** and **D** of idealized C_s symmetry to Fenske-Hall molecular orbital calculations, from which the following message becomes evident (Fig. 18):

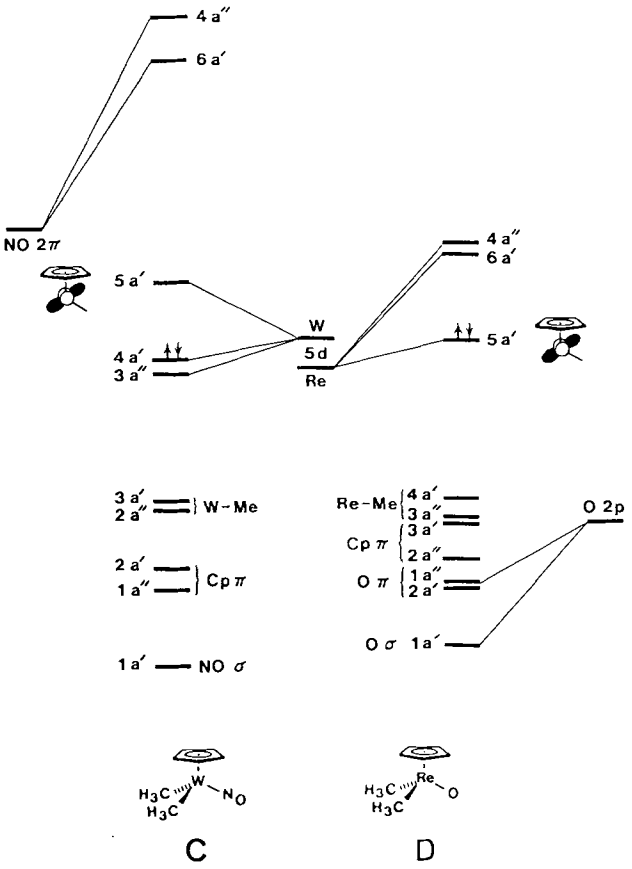


Fig. 18. Simplified molecular orbital diagram of d^4-tungsten(II) and d^2-rhenium(V) complexes **C** and **D** [99]. The neopentyl derivative $[(\eta^5\text{-}C_5H_5)W(NO)\{CH_2C(CH_3)_3\}_2]$ belonging to type **C** is a known, stable compound (P. L. Legzdins, S. J. Rettig, L. Sanchez, B. E. Bursten, M. G. Gatter, *J. Am. Chem. Soc. 107* (1985) 1411). The ring-substituted derivative $[(\eta^5\text{-}C_5Me_5)ReO(CH_3)_2]$ and a series of higher alkyl homologues have been synthesized and structurally characterized [34].

1) In the case of the nitrosyltungsten(II) complex **C** two of the metal-centered 5d orbitals are significantly stabilized as a result of an interaction (4a′ and 3a″) with the very strong π-acceptor ligand nitric oxide. By way of contrast, the 5a′ orbital remains non-bonding because the methyl ligands function only as σ-donors in the present case. The splitting of the metal 't_{2g}' orbital set amounts to 2.23 eV according to these calculations.

2) The opposite picture emerges for the rhenium(V) oxo complex **D**. Since a single oxo atom is an exceedingly good π-donator ligand (as well as a good σ-donor), it interacts with the rhenium-centered 5d orbitals to destabilize two levels by 2.36 eV (4a″ and 6a′); the nonbonding 5a′-type orbital becomes the HOMO because of the d^2 configuration of the metal atom.

Bursten et al. came to the conclusion that the stability of the 16-electron complex **C** (d^4-W^{II}) can be attributed to the nonbonding 5a′ orbital generated by the strong π-acceptor ligand NO. On the other hand, the 18-electron rule must no longer be considered in the case of high-valent organometallic complexes as in **D** (d^2-Re^V), since the d-orbital levels are generally destabilized by π-donors such as the oxo group and thus would rather remain unoccupied anyway. The entire pseudo-t_{2g} set of orbitals is destabilized when the metal atom is surrounded by *at least two oxo ligands*, with the existing compounds of type $[L_xMO_y]$ ($y \geq 2$) in fact all exhibiting d^0 configuration. However, the recently synthesized compounds of type **22** (Section 2.7) are obvious exceptions to this statement. Molecular orbital calculations of these and other catalysis-relevant transition metal oxides have already been carried out by *Goddard* et al. and *Yamaguchi* et al.[100]

5. Just at the Beginning

By no means is it of merit to make an accidental discovery. Much more important is the recognition of possible consequences that might result from serendipity. Organometallic chemistry has certainly seen many organometal oxides since *E. O. Fischer* and his group first had the cubane-type oxide $[(\eta^5\text{-}C_5H_5)_4Cr_4O_4]$ in their hands in 1960.[53a] Systematic studies have now begun in this field with the key compounds **2** and **4**. We are, as it were, just starting to learn such apparently simple things as the reaction of dirheniumheptoxide with tetramethyltin. One of the major short-term goals is to establish the relationship between redox chemistry at the metal and the reactivity of the ligands surrounding it. Any synthetic enterprise should be oriented toward new stoichiometric and catalytic hydrocarbon reactions or towards the improvement of those already known. Rhenium is certainly an ideal case for demonstrating how both low and high oxidation states are stabilized by good π-acceptor and π-donor ligands, respectively.

Further aims include the correlation of readily obtainable ^{17}O-NMR data[101] and electrochemical data with the redox processes occurring at metals attached to oxygen(s). Reduction[102] and oxidation[103] processes of great practical benefit may thus become better understood and optimized. Planned organometallic studies must be carried out in order to elucidate even simple-looking, useful reactions occurring at metal oxide structures.[104] The stage is already set for the anchorage of organometallic oxides to surfaces in order to gain more insight into the consequences of metal oxide surface effects for catalytic activity.[105] Hardly anything is known about this important issue to date; and that what is known can be quite confusing because of a lack of model substances.[106] In addition, the isomerism between dioxo- and peroxo systems $M(O)_2$ and $M(O_2)$, respectively, is of basic importance.[107]

Since this review and previous evidence[34,35,108,109] may convince us that organometallic oxides are compatible with classical "inorganic" oxides, both these areas of chemistry should converge in the near future. Suffice it to say that even bioinorganic problems also fall within the realms of high-valent organometallic oxides![110,111]

The author is greatly indebted to those co-workers who are fond of organometallic oxides. Since these scholars only happen to show up in the publications, they at least deserve being named here in appreciation of their enthusiastic, thoughtful, and skilled contributions: Dr. Tomas Cuenca, Josef K. Felixberger, Roland A. Fischer, Martina Flöel, Dr. Peter Härter, Karin A. Jung, Dr. Heinz-Josef Kneuper, Josef G. Kuchler, Dr. Ulrich Küsthardt, Jürgen Kulpe, Monika Ladwig, Dieter Marz, Dr. Babil Menjon, Dr. Jun Okuda, Dr. Rocco Paciello, Dr. Adolf Schäfer, Prof. Dr. Ricardo Serrano, Helmut Theiler, Werner Thiel, Dr. Erdmuthe Voss, Werner Wagner, and Georg Weichselbaumer. The entire research group particularly acknowledges the outstanding crystallographic performances of Dr. E. Herdtweck assisted by Pavlo Kiprof in our laboratories. Generous support comes from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the German Bundesministerium für Forschung und Technologie, Hoechst Aktiengesellschaft, Degussa AG, Hüls Aktiengesellschaft, BASF Aktiengesellschaft, Ruhrchemie AG, Alexander von Humboldt Foundation, Merck'sche Gesellschaft für Kunst und Wissenschaft e.V., the Spanish Ministery of Education and the Deutsche Akademische Austauschdienst. We express our gratitude for financial help that we have been receiving from these companies and institutions. Miss Juliane Geisler is greatfully acknowledged for the typescript of this article, Erich Krebs for the skilful drawings. The author had the privilege of being hosted as a 'Professeur Associé' by his colleagues Didier Astruc (Université de Bordeaux I) and Igor Tkatchenko (C.N.R.S. Toulouse), without whose generosity this essay may not have materialized. Of particular benefit were the stimulating discussions with Professor Jean-Marie Basset (C.N.R.S. Lyon-Villeurbanne) during his visit as an Humboldt Senior Awardee in our department. Freya and our five children are once again thanked for their patience.

[19] Metal-metal multipe bonding is featured by quite a number of simple looking inorganic compounds. For example, La_2ReO_5 and $NaNb_3O_5F$ contain multiply bonded M_2L_8 units completely analogous with $[Re_2Cl_8]^{2\ominus}$: a) K. Waltersson, *Acta Crystallogr. Sect. B 32* (1976) 1485; b) J. Köhler, A. Simon, *Angew. Chem. 98* (1986) 1011; *Angew. Chem. Int. Ed. Engl. 25* (1986) 996 and references cited therein.

[20] R. Hoffmann, *Angew. Chem. 99* (1987) 871; *Angew. Chem. Int. Ed. Engl. 26* (1987) 846.

Laser Photochemistry at Surfaces— Laser-Induced Chemical Vapor Deposition and Related Phenomena

By Karl L. Kompa*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The structural characterization of materials and the tailoring of their properties is an important area of chemical research. A new trend in this area is the recourse to lasers both for analytical as well as preparative purposes, exploiting the fact that lasers, by virtue of their properties (sharp energy, spatial and temporal resolution etc.), offer the most precise and selective interaction of energy and matter that we know. Furthermore, photochemical syntheses and material transformations can proceed "cold" and without causing damage to surface structures. Laser chemistry finds application in thin film deposition, in the formation of surface layers, as well as in (structuring) ablation or etching, and in the initiation and enforcing of reactions at surfaces. In the present paper an introduction to these new possibilities on the general basis of molecule-surface interactions is followed by a brief characterization of lasers suitable for such purposes. Thereafter, four examples are discussed: gas phase deposition from volatile organometallic compounds with photoelectric activation at the surface or photochemical activation of the gaseous species (e.g. by employing molecular beams). In this way (noble) metal contacts can be deposited on various substrates. Instead of surface deposition, nucleation can occur in the gaseous medium, yielding highly disperse powders, e.g. of silicon carbide. Finally, an etching reaction is discussed where the laser does not act as an energy source but as an analytical instrument to provide diagnostic and mechanistic information.

1. Introduction

A gaseous particle with a certain amount of kinetic energy as well as energy in internal degrees of freedom may approach a solid surface, whereby an attractive interaction via the surface potential occurs. The question now arises whether and to what extent energy is exchanged between the molecule and the surface. Figure 1 depicts the situation, showing three cases which can be investigated and distinguished experimentally.

The basic assumption in all three cases is that the possible energy transfer happens, if at all, in the direction from the molecule to the surface. The reverse case, in which energy flows out of the surface into the molecule will be considered later for a specific example (Section 6.1). Figure 1 shows first the case of elastic scattering proceeding without molecular relaxation. This might be caused by very weak interaction but also by a very short interaction time, too short to allow an energy adaptation (e.g. large kinetic energy of the scattering particle). The further examples given in Figure 1 (center and bottom) exhibit increasing energy transfer. One finally speaks of adsorption if the particle reaches the bottom of the surface potential and stays there long enough to be experimentally observable.

The important question of the detailed mechanisms of energy exchange, i.e. of the degrees of freedom involved in the molecule and in the solid will not be discussed here. Also not dealt with is the related question of whether or not excitation in certain degrees of freedom will hinder or further an adsorption. This has been the subject of numerous physical studies.[2] Instead, the further fate of the adsorbed particle will be discussed in some detail. The first point of interest here is the mobility of the adsorbate on the surface.

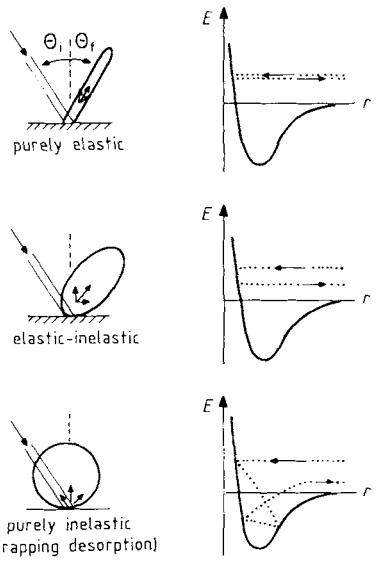

Fig. 1. Varying amounts of energy exchange in collisions of atoms or molecules with solid surfaces: Three cases with increasing interaction [1].

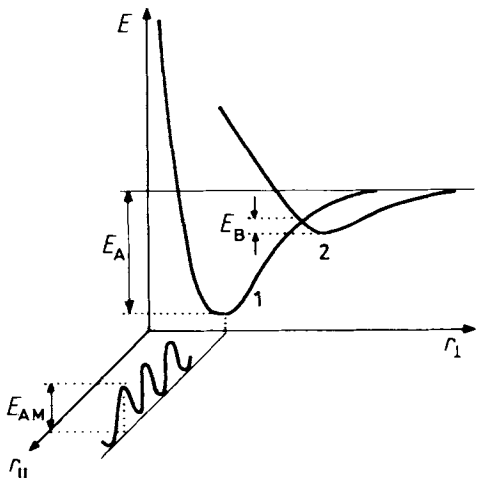

Fig. 2. Potential profile (simplified) parallel and perpendicular to the surface [3]. $r_{\parallel}$ and $r_{\perp}$: distance parallel and perpendicular to the surface, respectively.

Figure 2 shows the two different barriers which must be surmounted in the course of site changes of adsorbates on a surface. For many cases relevant to laser-CVD (laser chemical vapor deposition) such reorientations or relocations are the rule. If the deposition is continued, it can be expected, upon further energy input (radiation as well as particle impact), that the adsorbed molecule will be free to lateral diffusion and even desorption (sublimation, vaporization, photoablation). This implies that adsorption and desorption have always to be considered jointly in the study of such processes. For those interested in using laser-CVD this is a troublesome side effect, especially with regard to lateral resolution of the deposition. On the other hand, the possibility of studying the lateral motion of adsorbates without prevailing desorption is opened up by the same argument. This is then called photo-displacement spectroscopy and provides important options for studying bonding relations in adsorbates[4] (cf. Fig. 4).

Ignoring microscopic mechanisms, the sticking probability r_a (rate of adsorption) is represented by a sticking coefficient s as given in Equation (a1). This coefficient denotes the ratio of sticking particles over the sum of particles arriving at the surface [Eqn. (a3)]. Equation (a2) gives the desorption probability r_d as a function of the energy absorbed. The asterix denotes the reaction (or kinetic) order of the process.

Adsorption	$r_a = s(dn/dt)$	(a1)
Desorption	$r_d = n_s^* \exp(-E_d/RT)$	(a2)
Arrival rate at surface	$dn/dt = p(2mRT)^{-1/2}$	(a3)

The mobility of adsorbed particles will be reduced once the coverage of the surface becomes more dense; larger aggregates form which are more ponderous. In this regard it is important whether the formation of the layer starts at specified lattice sites or occurs disorderly. In the latter case island formation is possible. Special interest attaches here to the coadsorption of several components, whereby the rivalry between competitive and cooperative behavior can be observed (Fig. 3 left and right, resp.). The laws of growth of a thin layer with continuing feed from the gas phase are thus determined by the interaction of the particles impinging on the surface with the lattice of the solid and with the neighbors in the growing layer ("adsorbate interaction"). If the particle-lattice interaction dominates, a commensurable phase forms; in the other case islands are formed. If the adsorbate-adsorbate interaction dominates, vertical growth also occurs, i.e. clusters, whiskers, needles or columns appear above the surface. A homogeneous or even epitactical film formation is then excluded.

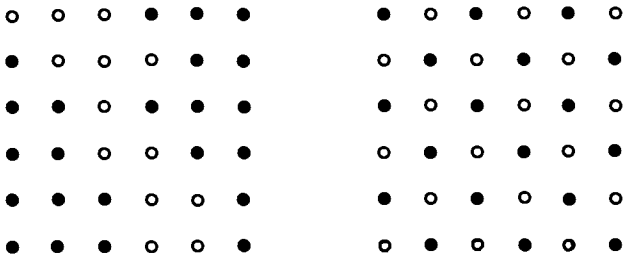

Fig. 3. Competitive (left) and cooperative (right) behavior during coadsorption of two species denoted by filled and empty circles.

Island formation and mobility of a species on a surface can also be controlling factors of the total rate of adsorbate reactions. *Ben-Shaul* et al.[5] have modeled aggregation and reaction using the Monte-Carlo simulation method (Fig. 4). One of the reactive components was assumed to be present on the surface beforehand, with lateral interaction leading to island formation. The islands grow in time and change their shape. The second reactive component can attack the islands peripherally from their boundary (although this is not beyond doubt). Hence, there is a relationship between reaction rate on the one hand, and island size and history of formation on the other, i.e. the reaction depends on the time the islands had to grow prior to arrival of the reaction partner.

In addition to the above mentioned factors, which assume the establishment of an equilibrium, in real systems other influences may be effective in inducing kinetic barriers (e.g. stabilization of thermodynamically disfavored amorphous layers).[6]

Furthermore, the influence of impurities and/or imperfect surfaces has to be taken into account. Which morphology under which conditions finally exists is thus difficult to predict, despite an understanding of the influential factors. Only experimental studies such as are described in the following sections can provide useful information in concrete cases.

As far as the desorption of a species once deposited on a surface is concerned, a simple model by *Levine* and *Zare* [see (b)] can illustrate some principal features.[7] These au-

Criterion for "cold" desorption: $\tau\nu\exp(-\xi) < 1$ (b)

(τ = duration of light pulse; ν = characteristic frequency of physisorption bond; $\xi = 2(T/T')$ = adiabaticity parameter, dependent on the characteristic times T and T' of the physisorption mode and internal mode in the free molecule)

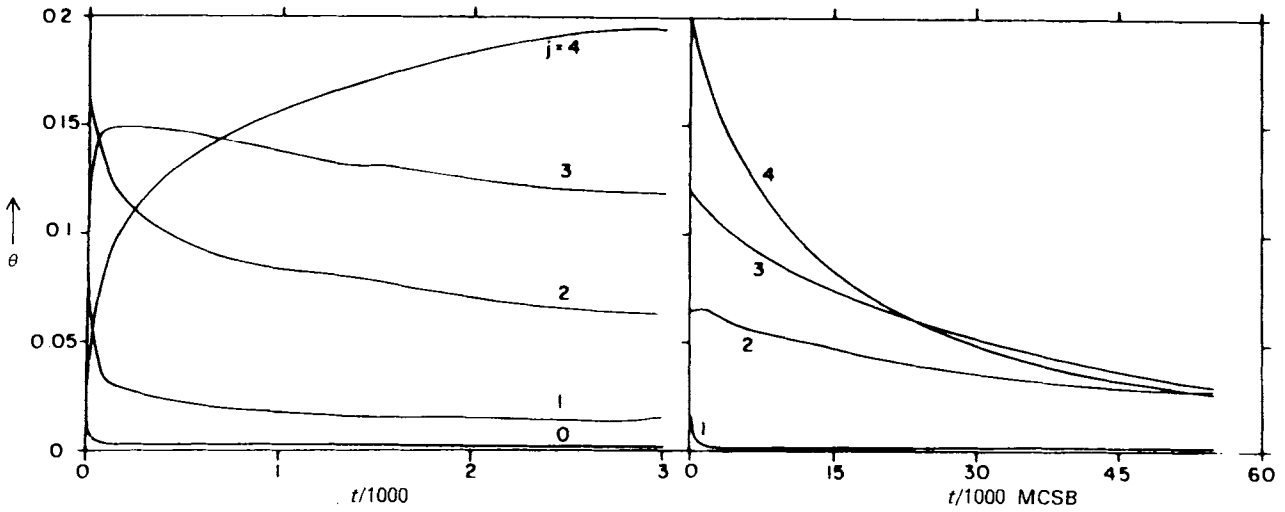

Fig. 4. Monte-Carlo simulation (MCS) of the influence of adsorbate aggregation on the kinetics of surface reactions [5]. t is given in simulation steps for species A (MCSA) and for reactions with species B (MCSB). j = 0–4 gives the number of neighbors of an atom/molecule A or B. θ is the specific coverage of the surfaces for the time of aggregation (left) and reaction (right), i.e. describes how rapid a reaction is for a given island growth.

thors have shown that the relative coupling constants, which determine the energy flow from the molecule to the surface and vice versa, the duration of the impact of laser light, and last but not least the localization of the primary energy absorption in the adsorbate or substrate are decisively important. The coupling of a molecular species to the surface by a physisorption bond is not dissimilar to the situation in a van-der-Waals-complex in the gas phase, a case for which bond-selective laser chemistry has attracted interest.[8] The important point here is that the physisorption bond acts as a bottleneck for communication between the surface and the molecule. This idea was put into quantitative terms by introducing an adiabaticity parameter ξ (exponential gap law to describe the dependence on energy mismatch), which, as shown in (b), describes the time needed to make energy flow into the physisorption bond and heat this bond sufficiently to induce bond rupture and desorption.

For the kinetics of energy transfer a balance equation (based on (b) and Fig. 5) can be derived, which describes the energy flow from the substrate into the van-der-Waals bond and from there into the adsorbed molecule with $E(t)=E_0(t)-ktf(D)$, where D denotes the energy of the bond between molecule and surface.[7] This means that the relevant rates and times decide whether a molecule will desorb internally "cold" or whether an energy-rich species before or in competition to desorption will undergo chemical changes (e.g. fragmentations). It is possible to measure the energy of the desorbing particles spectroscopically and to check the validity of this simple model.[9, 10] In the case of an energy absorption in the adsorbate rather than in the substrate (see Fig. 5) "hot" particles in particular should be desorbed, for the same reasons of blocked energy transfer to the solid. This has been confirmed experimentally—at least for some cases studied.[11]

Thus, laser flash-desorption may be used as an analytical tool to obtain a "snapshot" of the chemical nature and composition of species on a surface (unstable intermediate products, for instance, in catalytic reactions). This aspect has received special attention by *R. B. Hall* et al.[12]

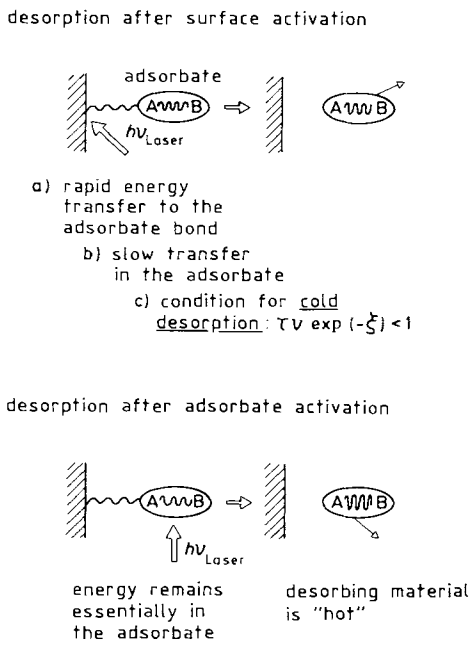

Fig. 5. Pictorial representation of laser-induced desorption without (top) and with (bottom) energy absorption in the desorbing particle [7].

It has been pointed out that the ratio of Arrhenius factor A to heating rate v and activation energy E_a determine the competing behavior of reaction and desorption. The general conclusion is that rapidly desorbing molecules will leave the surface "lukewarm" and chemically intact (examples: methanol and ethene desorption from metal surfaces[12]).

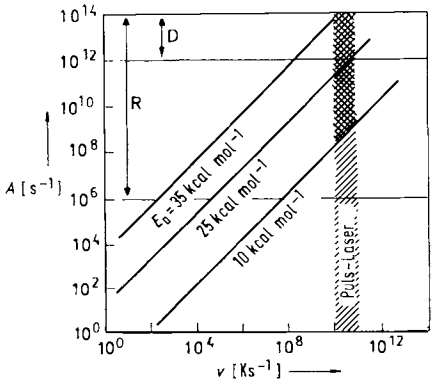

Fig. 6. Requirements for the magnitude of the pre-exponential factor A needed for a minimal yield of 1% desorption as a function of the heating rate ν. Three different activation barriers are considered. The shaded area shows the conditions under which desorption D exceeds decomposition R [12].

2. Laser-Induced Photochemical Reactions at Gas-Solid Interfaces

A deposition reaction can be activated in different ways (Fig. 7):

① By local thermal activation of the surface and transfer of energy to gaseous species adjacent to the surface.
② By photolysis in the gas phase and deposition of the products.
③ By photoelectric excitation of the solid and dissociative electron capture of gas phase particles.

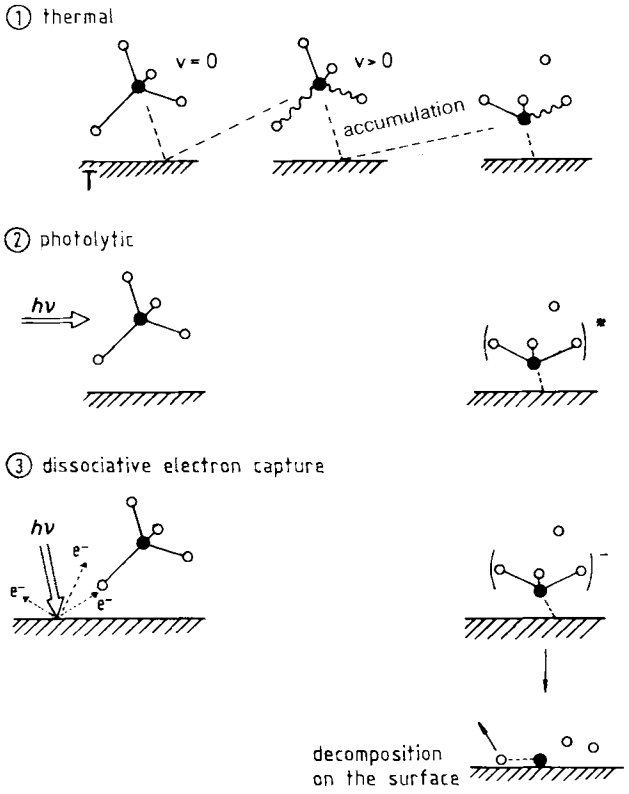

Fig. 7. Initiation of deposition by activation in the gas phase (②) or at the surface (① and ③).

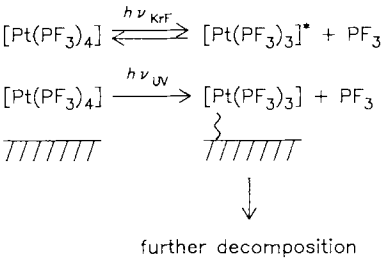
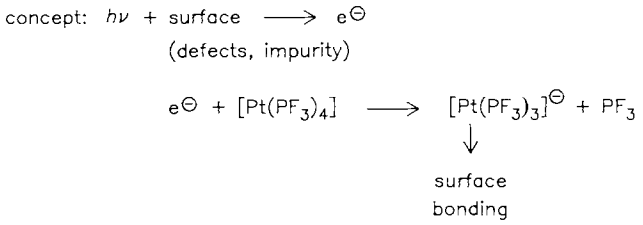
In general we thus distinguish processes in the gas phase from processes that begin in the solid. Vapor phase deposition at surfaces may be initiated by sputtering, ion- or electro-plating, chemical or plasma reduction, or anodizing, whereby the generation of active species or nucleation centers may play an important role. But let us turn to a specific example, namely noble metal deposition on different substrate materials. In this case the starting materials are volatile organometallics,[13] for example tetrakis(trifluorophosphane)platinum(0). This molecule exhibits reversible photolysis in the vapor phase (Scheme 1, top).



Scheme 1. Photolysis of the relatively volatile platinum compound $[Pt(PF_3)_4]$; it is reversible (top) in the gasphase, irreversible on surfaces (bottom).

In the vicinity of a surface, however, the ligand bond may be substituted by the surface bonding, in this way replacing one or several PF_3 groups (Scheme 1, bottom). This takes place particularly well if the $[Pt(PF_3)_n]$ fragment is negatively charged following photoelectric surface activation (see Scheme 2).



Scheme 2.

We expect first a deposition of $[Pt(PF_3)_3]$, which, presumably by dissociative chemisorption, will be converted into a pure platinum deposit. The gas column from which the local deposition is fed has a height of a few μm. By variation of the parameters a quantitative model picture of the process may be obtained. However, direct measurements of the photoeffect by UV lasers are needed (see Sections 4 and 6.4).

3. Laser Sources for Chemistry

From the extensive arsenal of lasers used in physics[14] primarily those mentioned in Figure 8 have gained importance in analytical and synthetic laser chemistry.[15]

The mode of operation of a laser can be that of an oscillator or that of an amplifier. The radiative power that is

delivered ranges (for pulsed operation) from $<10^{-6}$ W up to $>10^{12}$ W. The geometrical dimensions of the radiation path in the laser accordingly range from mm to km. Both pulsed as well as continuous operation is possible, and in the case of some lasers there are both variants. The efficiency, i.e. the ratio of emitted to absorbed (e.g. electrical) power is normally small, typically in the range $\leq 0.1\%$. There are, however, exceptions like the CO_2-laser, which can have an efficiency of $>10\%$.

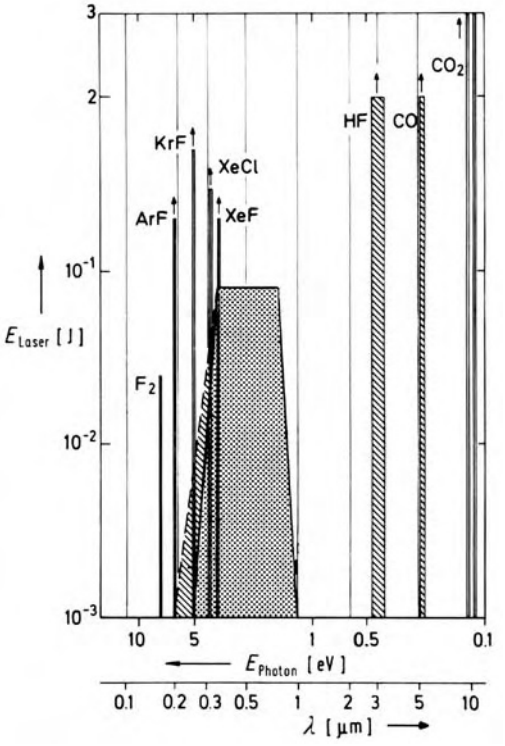


Fig. 8. Overview of the most popular types of lasers for chemistry as function of wavelength λ or photon energy E_{photon}. the cross-hatched area denotes dye lasers, the shaded area anti-Stokes-shifted or other frequency-converted dye lasers.

The photon fluxes are, in view of the many different types of laser, very different. The lasers indicated in Figure 8, which can be operated without difficulty in the power range of 100 W or above, deliver about 10^{19}–10^{21} photons per second. In molar units this amounts to 1–100 mEinstein s^{-1}. Assuming reasonable quantum yields, material conversions in the mol/min range are conceivable. For the often more important analytical applications of lasers this is irrelevant; the choice of usable laser sources here is much larger than in preparative chemistry.

The spatial coherence of laser radiation leads to ideal beam collimation—limited only by diffraction effects—and thus enables loss-free radiation transport over large distances. Here, one should not only think about laser beam transport by mirrors but also by waveguides and optical fibers. Remote laser interaction with reacting systems is in this way possible both in an analytical and a synthetic sense. If one considers for instance the use of an IR laser as a specialized heat source to bring about a reaction it should be noted that the energy can be coupled into the medium directly as radiation without being mediated through wall effects. Therefore reaction vessels are less subject to corrosion and attack.

Under certain conditions laser light is extremely monochromatic. Lasers in the visible region having frequencies of about $4\text{–}7 \times 10^{14}$ Hz have bandwidths of MHz to GHz, or relative bandwidths of up to 10^{-9}. With special stabilization measures, however, bandwidths <1 Hz have been realized. This gives a spectral purity of $\sim 10^{-15}$. As a consequence lasers can be employed as frequency and time standards.

The extreme monochromaticity, the high energy densities achievable in the focus of the beam and the possibility of generating extremely short pulses have already been mentioned above. A further brief illustration follows: Coherent radiation can be focussed to a spot size of one wavelength. With a 100 W Laser in the visible spectral region one then obtains power densities of up to 1 GW/cm^2 (for a correspondingly short time). The electrical field strength is in the MV/cm^2 to GV/cm^2 range. At such high photon densities multiphoton processes come into play—a molecule absorbs more than one photon (some times even much more) from the laser pulse. This opens up new possibilities for *nonlinear spectroscopy* and for *nonlinear photochemistry*.[16]

Depending on the frequency bandwidth[17] very short laser pulses can be generated. The record here lies at ca. 10 fs. The geometrical length of such a pulse is only 3 μm. Hence its propagation is no longer conceivable as a beam but rather as a thin film of electromagnetic energy traveling at the speed of light. Such a short pulse naturally loses its monochromaticity but exhibits a rather broad-band frequency spectrum.

A new development in the ultraviolet spectral region in the last ten years has been that of excimer lasers.[18] These have introduced a new dimension into the field of surface photochemistry since, in view of their photon energies, they not only make thermal but also electronic substrate activation possible (see Section 4). Such lasers are currently available only in the pulsed mode of operation (typical pulse durations: 10^{-8} s, repetition rates: ≥ 100 Hz, and average powers: ≥ 100 W). The more commonly used excimer lasers are listed in Figure 8.[19] There are three groups of excimer lasers, namely rare gas dimers, rare gas halides, and halogen dimers.[20] Their common feature is that the active laser materials are molecules which exist only in an excited (lasing) state and decay instantaneously once having returned to the lower (ground) state. In all technical versions of relevance here the excitation is achieved by a pulsed electrical discharge. The potential of this type of laser has not yet been fully exploited.[21]

Since a light source cannot be focussed down to spots of sizes less than their wavelength the resolution is limited to maximally 0.2 μm. This has in fact been achieved, but the field of view, as well as contrast and homogeneity of illumination are still the subject of intensive development. As has been pointed out in the preceding section, secondary changes in the deposits are frequently more limiting for a desired spatial structuring than the optical imaging parameters of the laser.

4. Photoelectrical Initiation of Vapor Phase Deposition

The possibility of initiating laser-CVD by mobilizing charges at solid surfaces has already been demonstrated in Figure 7. Of special interest here is the photoelectrical initiation of the reaction. Electron emission can be induced by elevation of temperature, by photon bombardment, and by an electric field. In the first case an increasing number of states above the fermi level is populated. The number of emitted electrons is thus proportional to the high-energy end of the Boltzmann tail, exceeding E_{vacuum}. In contrast, in the second case the emission occurs by (1) excitation via photon absorption by an electron, (2) diffusion of the electron to the surface, (3) transmission through the surface. The kinetic energy of the electron is described in terms of *Einstein*'s classical formula

$$\frac{1}{2}mv^2 = h\nu - \Phi \qquad (c)$$

A more detailed inspection shows that the work functions Φ for metals are typically, in the region of 5 eV, i.e. are accessible with the photon energies of excimer lasers. Measurements have shown that the work functions strongly depend on the adsorbate coverage and that excimer irradiation of the surface can even produce photoelectron currents which are space-charge limited. It is easy to see that the effect can be amplified by external fields and that in the limiting case even a laser-preionized plasma discharge will be obtained. This implies (Fig. 9) that the discharge remains localized and can be controlled by the path of the laser beam. In this way the spatial resolution of the deposition is more or less maintained. For comparison: If the particles to be deposited should be generated by photolysis at some distance from the surface (Fig. 7, ②) they would first have to diffuse to the surface and remain stuck there; a controlled and locally or spatially resolved formation of the deposit is then much more difficult to achieve.

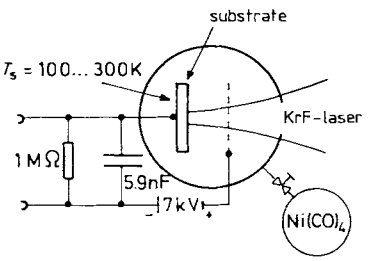

Fig. 9. Experimental scheme of photoelectrical vapor deposition, shown here for $Ni(CO)_4$. The wiring of the "diode" corresponds to one particular set of parameters discussed in [30].

For several reasons, organometallic compounds are especially suitable for such experiments with lasers: they are generally sensitive to dissociative electron capture, the range of effective electron energies ranging from mV to V. Furthermore, it is desirable that the gas-phase photolysis be reversible so that excitation in the gas remote from the surface does not lead to permanent chemical changes (see Scheme 1) and only participation of the surface leads to deposition. Besides the deposition of platinum, that of many other elements can also be realized (see Section 6.4).

5. Photochemical Deposition with Molecular Beams

Many recent papers dealing with molecule/surface interaction concern the utilization of molecular beam techniques. This type of laser-CVD is thus closely related to molecular beam epitaxy for spatially resolved materials synthesis.[22] A schematic introduction to the experimental concept is given in Figure 10. Molecular beams guarantee

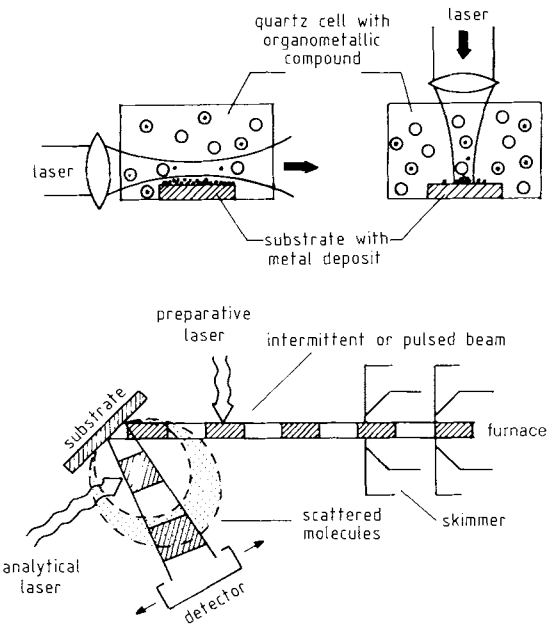

Fig. 10. Experimental setup for photochemical deposition from molecular beams (bottom) in comparison to the deposition from a static gas (top).

collision-free conditions in the gas space and thus ensure that a once excited or otherwise prepared species will not be changed due to bimolecular processes nor be withdrawn from the interaction region of the surface. One special feature compared to static gas conditions is associated with the high kinetic energy of the colliding particles which may eventually result in extremely short interaction times. Often the molecular beam is pulsed, which causes special boundary conditions for the reaction kinetics (high collision rate for a correspondingly short time).

6. Examples

The four examples discussed in the following represent a small selection from a rapidly growing and diverse field.[23] The discussion in the following sections covers a) the interaction of electronically excited carbonylnickel compounds with surfaces, b) the reactive scattering of fluorine (atomic, molecular) with copper surfaces, c) the vapor phase deposition of silicon carbide powders, and d)

the production of noble metal films for electric contacts and in particular for the metalation of non-metallic substrates. In some of these examples industrial applications are also envisaged, to which reference is made in the individual cases.

6.1. Surface Interaction of Volatile Metal Compounds

In Section 2 under item 2) the possibility of metal deposition by photolysis of suitable precursors in the gas phase and subsequent transport to the surface was addressed. As a first example the deposition of nickel from tetracarbonylnickel will be considered. The measurements were conducted under molecular beam conditions (cf. Fig. 10), which means that the beam particles undergo only a single collision with the surface. No thermal deposition is observed up to surface temperatures of >470 K; only when the beam is exposed to UV laser radiation does decomposition and formation of a nickel layer occur.

The discussion of the photochemical behavior of $Ni(CO)_4$ is based on the model by *Rösch* et al.[24] shown in Figure 11. According to this model the molecule decom-

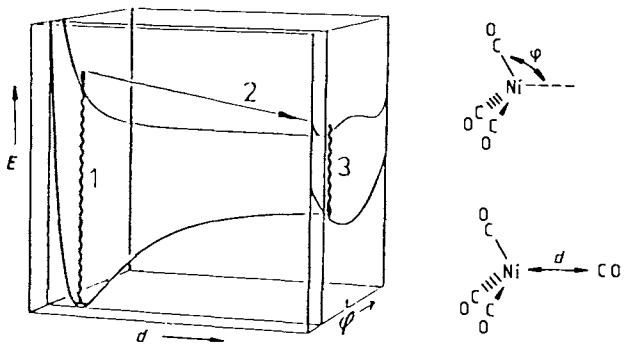

Fig. 11. Mechanism of excitation and photodissociation of $Ni(CO)_4$ showing the most important reactions [24].

poses after excitation by a XeCl laser ($\lambda = 308$ nm) in less than 10^{-10} s, losing only one of its ligands. The excess excitation energy does not lead to further bond rupture but remains in the $Ni(CO)_3$) fragment as electronic excitation. This manifests itself in a spontaneous luminescence decaying with a time constant of 15 μs. With the time of flight typically encountered in molecular beam experiments (700 m/s in the present case) and with a distance between the place of excitation and the substrate of 2.5 cm the $Ni(CO)_3$ fragments have lost most of their excitation on the way to the surface. The ground-state fragments, however, then yield a nickel film on contact with the surface which is of high quality also in a technical sense (Fig. 12).[25]

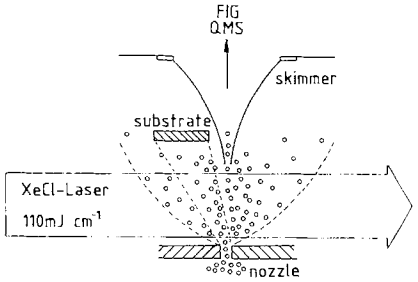

Fig. 12. Top: Schematic diagram of an apparatus for the deposition of highly pure nickel films: a pulsed $Ni(CO)_4$ molecular beam leaving the nozzle is excited with an XeCl laser. After (multistep) $Ni(CO)_4$ decomposition the nikkel atoms deposit on the substrate. The skimmer gates out the core of the molecular beam, which is thereby collimated (FIG: fast ionization gauge; QMS: quadrupole mass spectrometer). Bottom: Picture of the experiment. After emergence from the nozzle (above), the $Ni(CO)_4$ molecular beam fans out conically. Interaction with the laser pulse leads to formation of excited $Ni(CO)_3$, whose luminescence is clearly recognizable. The skimmer is faintly visible in the center.

Figure 13 again compares $Ni(CO)_4$ absorption and $Ni(CO)_3$ emission. The deposition thus proceeds as a reactive surface interaction. The removal of one ligand opens up the possibility of nickel binding to the surface. The sublimation energy set free in this process leads to dissociation of the remaining ligands. Consequently, one can speak of a surface-catalyzed deposition. The same general picture appears to be applicable in the surface decomposition of other photolysis products derived from tetrahedral or octahedral molecules.[26] A general statement about the possible dependence of the chemical nature and preconditioning of the substrate, however, cannot as yet be made on the basis of information thus far available.

It is well known that the impact of UV lasers on polyatomic molecules at elevated power densities soon leads to multiphoton excitation and ionization.[27] This possibility also has to be taken into account in the present context of UV laser photolysis of organometallic compounds. An attempt was made to clarify the question as to what extent and at what power or energy density ionic fragments form during the excitation of $Ni(CO)_4$ with excimer lasers. To this end, mass spectrometric measurements were per-

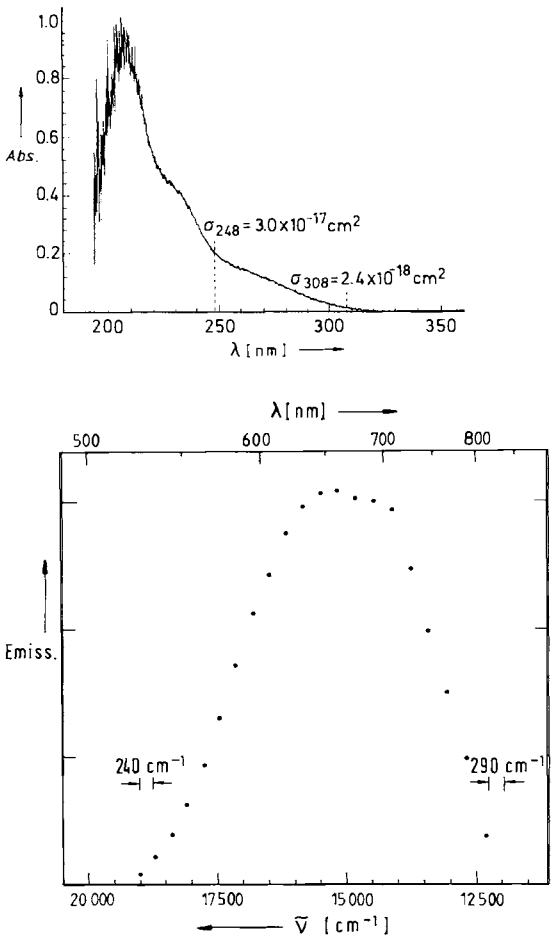

Fig. 13. Top: Absorption spectrum of $Ni(CO)_4$ at ca. 50 μbar; bottom emission spectrum of $Ni(CO)_3$ on excitation with a XeCl laser.

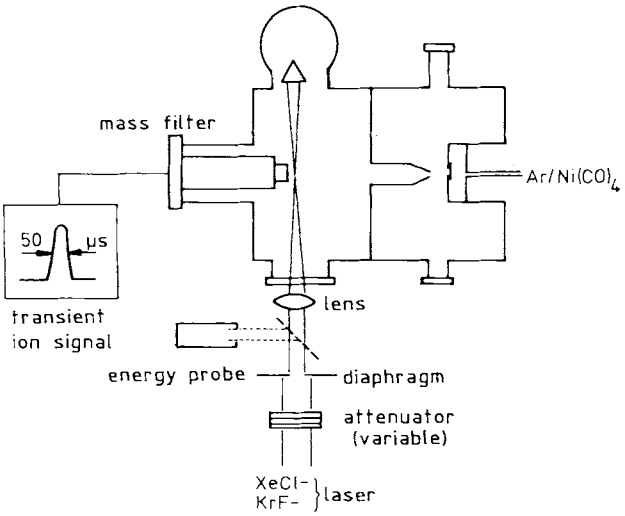
formed on $Ar/Ni(CO)_4$-molecular beams to determine the ion yield as function of laser energy. The experimental setup together with some results are shown in Figure 14.

By additional measurements in a static gas cell at low pressures the absolute concentration of $Ni^{\oplus}$ ions could be determined for the calibration of the molecular beam data. The complete pattern of fragment ions between molecular beam and static gas can be compared in this fashion. In the latter case, by varying the gas pressure also the electron capture cross section of neutral $Ni(CO)_4$ molecules can be measured. The corresponding values for two excimer laser wavelengths are $\sigma = 4.8 \times 10^{-14}$ cm² (XeCl) and $\sigma = 2.9 \times 10^{-14}$ cm² (KrF). From the plots of Figure 14, which are linear over the relevant range, it follows that the ions in the case of KrF laser radiation are formed in a 3rd order process and for the XeCl laser in a 4th order process. Also the corresponding effective cross sections have been derived from the measured data.



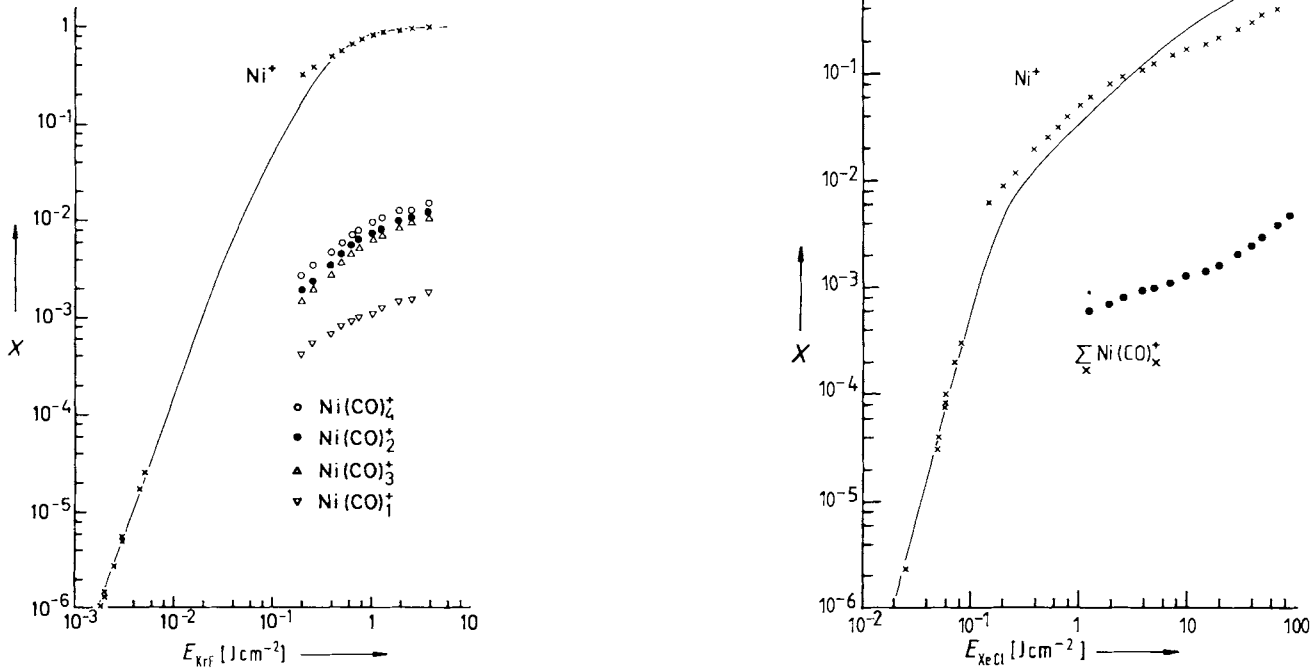


Fig. 14. Top right: Experimental arrangement for the investigation of resonance-enhanced multiphotoionization of $Ni(CO)_4$. Bottom: Comparison of calculated (unbroken curve) and mass-spectrometrically determined ion yields X on using a KrF (left) and XeCl laser (right), respectively (see also Scheme 3). E = energy flux of the KrF or XeCl laser.

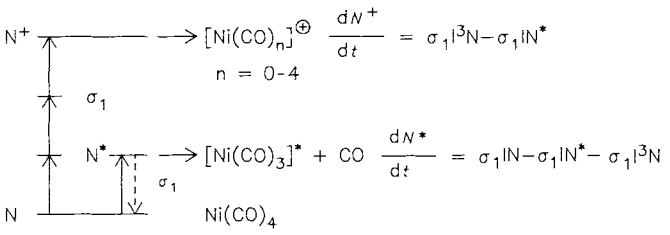
All these facets of information finally yield a kinetic model based on rate equations. Without detailed discussion, the elements of this model are reproduced in Scheme 3.



Scheme 3.

A conclusive picture is obtained if one assumes that the total excitation and ionization occurs in the mother compound and that all ionic products are formed therefrom. The $[Ni(CO)_4]^{\oplus}$ ions are then produced in a direct 3-photon process (KrF laser) and decay statistically, mainly to $Ni^{\oplus}$ and CO. The only competing channel of importance is the above mentioned process of excitation to generate $[Ni(CO)_3]^*$. This scheme resembles the situation for KrF laser photolysis. The interpretation for the corresponding behavior in the case of XeCl laser irradiation is somewhat more complicated since three competing channels have to be considered. A detailed discussion of this case is omitted here. Computational evaluation of this model yields the curves shown in Figure 14 (bottom), which are in remarkably good agreement with the experimental curves.

The special features possibly related to deposition from gas samples or molecular beams with a high degree of ionization are still subject to discussion. In this connection concepts of plasma chemistry or plasma-induced vapor phase deposition may be of interest. Attention should also be paid to a further aspect of deposition from pulsed molecular beams which is of interest both scientifically as well as with regard to industrial application. This concerns the role of clusters which are often present—depending on the experimental conditions—in molecular beams.[28,29]

In the investigations mentioned in the following section the surface where the interaction occurs was the front face of a pyroelectrical calorimeter. That is, the polyvinylidenedifluoride (PVDF) calorimeter foil was coated with a metal film (e.g. aluminum).[28,29] In this way the energy exchanged in the scattering process can be measured directly as heating or cooling of the detector. At the polymer foil a voltage is measured which is proportional to the energy content of the foil. If energy is fed into the detector foil (light, particle impact etc.) the voltage becomes more negative. The reverse is true if energy flows out of the detector. At such a metal-coated foil rare gas beams, pure and seeded with $Ni(CO)_4$, are scattered (cf. Fig. 10).

Experiments in which energy transfer to surfaces have been investigated using this same detector concept[30] generally assumed that the total amount of energy contained in the molecule is always quenched at the surface. This could not be confirmed for the systems considered here. Since the molecules are scattered at the surface they at least retain part of their kinetic energy. Moreover, it was shown that even molecules having a certain amount of internal energy often "survive". In the case of SO_2, this even included electronic excitation. In addition, not only does transfer from the molecule to the solid occur but also in the reverse direction. This means that, depending on the experimental conditions, warming or cooling of the substrate is possible. Characteristic differences exist among the rare gases as carriers, but also other parameters such as pressure in the molecular beam source and mixture ratios play a role. The calorimeter thus responds very sensitively to varying beam conditions (energy resolution better than 1 nJ).

For the beam conditions used here typically 5×10^{13} molecules or atoms in a pulse reach the detector surface and are scattered there. The average energy resolution is less than 1 meV. The time profile of the energy transfer can be determined by differentiating the signal with respect to time. The most straightforward assumption now would be that the average energy transfer for all particles is the same. This, however, as Figure 15 shows for the case of Xe, is not confirmed experimentally. Instead, the fast (early arriving) particles heat, while the slow ones cool the surface.

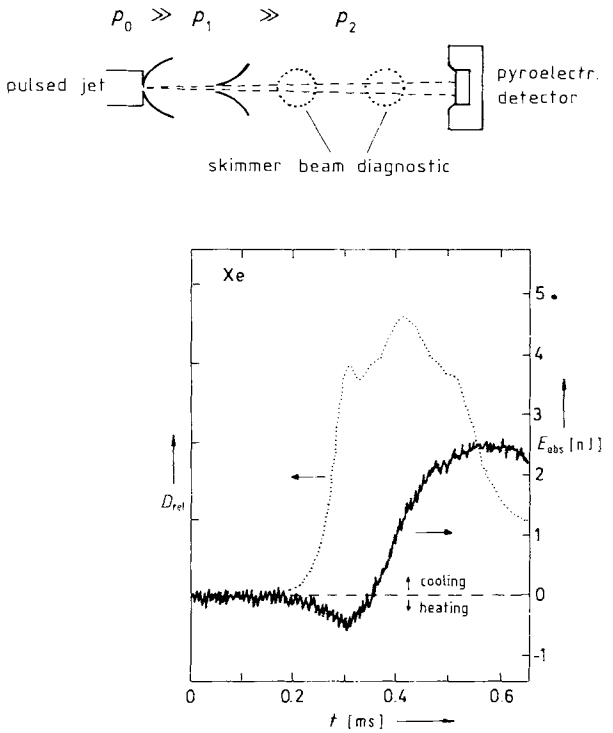


Fig. 15. Investigation of the cooling of a surface during interaction with pulsed molecular beams of specified composition. Top: Apparatus used with various detector positions. Bottom: The parts of the beam arriving early and late respectively contribute to the heating and cooling. D_{rel} = relative beam density; E_{abs} = absolute energy transfer.

The speculation that in the case of surface cooling the respective particles have a higher kinetic energy after the collision, i.e. that the energy drawn from the solid is converted into translational energy, could not be verified. Pure rare gas pulses or rare gas/carbonylnickel pulses cool the surface all the more strongly the heavier the rare gas employed. This trend qualitatively follows the tendency for cluster formation in pulsed beams. The assumption here is that the slower part of the beam contains particles of heav-

ier mass. For a more detailed discussion of the subject of film formation from cluster beams reference should be made to the literature.[31]

6.2. Interaction of Fluorine Atomic or Molecular Beams with Copper Surfaces

The laser is an ideal tool for the quantum specific investigation of molecular systems. In physical chemistry this was first exploited in the area of the dynamics and kinetics of vapor-phase processes.[32] The development now, however, extends to chemical reactions at surfaces, too. So far, there is still only a limited number of examples, concentrating primarily on the state-specific investigation of species potentially active in catalysis.[33] A general observation is that the distribution of the energy liberated in these reactions can usually be described in terms of an equilibrium which is determined by the temperature of the surface. Strong non-equilibria as are often found in elementary chemical reactions in the gas phase have so far rarely been observed. The search for non-statistical effects in (strongly exoergic) surface reactions is therefore of special interest. As examples, reactions of fluorine with metal surfaces lend themselves to study. The products formed in such "etching" reactions are volatile under the chosen temperature conditions and can be analyzed in the gas phase by the conventional techniques of laser spectroscopy. It has already been shown that laser desorption per se can be a very fast process and is expected to provide no obstacle for the detection of non-equilibrium effects [see Eqn. (a2)].[3] Dry etching reactions of metals and semiconductors are also of practical interest and may be employed in the production of electronic devices.

To gain access to an understanding of the dynamics of this class of reactions an experimental setup following basically the concept shown in Figure 10 was used. A beam of atomic or molecular fluorine is generated in a high-vacuum vessel. This is allowed to impinge onto a single-crystal copper surface whose temperature can be varied over a large range. The reaction products a few mm above the surface are then analyzed with a tunable dye laser. In this instance, CuF shows laser induced fluorescence (LIF) bands—relevant transitions $X(^1\Sigma^+)\leftarrow B(^1\Sigma^+)$ and $X(^1\Sigma^+)\leftarrow C(^1\Pi)$—which can be used to obtain information on the state of excitation of the molecule.[34]

The relevant part of the CuF excitation spectrum is shown in Figure 16. The fluorescence intensity depends linearly on the flow of gaseous fluorine and saturation effects are not observable, i.e. the concentration of fluorine on the surface is in the sub-monolayer range. The LiF spectrum of CuF exhibits a characteristic threshold behavior. A preliminary analysis of the internal product energy distribution for three surface temperatures between 800 and 900 K yields a vibrational state population which is represented by a Boltzmann distribution. The vibrational temperature, however, considerably exceeds the surface temperature. In contrast, the rotational temperature is more or less equal to the surface temperature.

The measured energy distribution poses the question as to what extent the desorbing molecules have lost or retained the "memory" of the details of their formation. A loss of memory in this case may be equivalent to a "longer" residence time on the surface. A conclusive answer to this question is not yet possible. The Arrhenius activation energy for the desorption of CuF in the temperature range 750–900 K is 135 ± 20 kJ/mol. A proof of the mechanism involved is still lacking but may well be possible on the basis of further measurements involving a kinetic energy analysis (high resolution ring laser) of the desorbing particles.

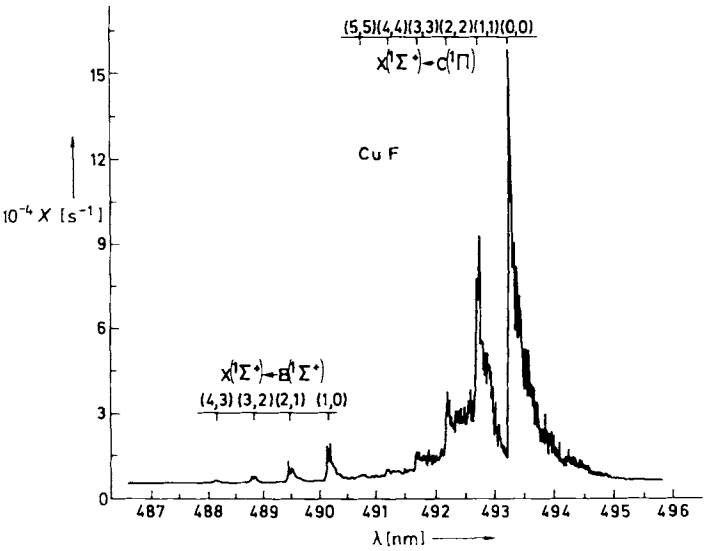

Fig. 16. Excitation spectrum of gaseous CuF formed in an etching reaction with copper at a temperature of 820 K [34]. X = count rate.

6.3. Laser Induced Powder Synthesis (Silicon Carbide)

One disadvantage of ceramic materials is their brittleness, arising from microscopic structural defects, pores, and microcracks. In contrast to metallic materials, where cracks are anealed by plastic flow, in the covalent ceramics cracks develop until rupture occurs. For high quality ceramics it is therefore necessary to avoid structural defects. To this end sinterable powders are needed which are very pure, homogeneous, of small particle size and small size distribution, and which may possibly be sintered without additives.

Powders of high purity are best produced in gas phase reaction systems since here wall effects are absent and the reagent gases can be pre-purified. It has already been demonstrated[36] that such a powder synthesis is possible by laser-induced chemical vapor deposition. In the following a special variant of this technique will be described in which the gas-phase reaction occurs in a plasma generated by gaseous breakdown in the focus of a pulsed TEA-CO_2-laser.[35] The benefit of this technique is seen in a high heating rate, the achievement of high temperatures and a well-defined reaction zone.

Other than in the case of reaction initiation by cw (= continuous wave) lasers,[36] reactions near the entrance window can be avoided without applying gas purging by choosing a wavelength of the CO_2 laser which is not (or only slightly) absorbed by the cold gas.

As first example for this type of powder synthesis silicon carbide was selected. As starting materials tetramethylsilane $Si(CH_3)_4$, hexamethyldisilane $(CH_3)_3Si\text{-}Si(CH_3)_3$ and methylsilane CH_3SiH_3 were investigated. The reagents were handled in a cyclic flow apparatus equipped with a membrane pump and a membrane filter.

The main products left in the gas phase after the reaction had occurred were methane, ethyne, ethene and propyne. The product yields amounted to 100 to 300 mg per hour. Depending on the laser pulse repetition rate (1–4 Hz) this corresponds to 3600 to 14000 laser shots with a single pulse energy of 2 J. The powders obtained still contain free carbon. According to IR spectra some $SiCH_3$, $SiCH_2Si$ groups and occasionally some SiO are also present. The $SiCH_3$ groups could be removed by heating the samples to 800–1000°C in vacuo, whereupon methane was liberated. The $SiCH_2Si$ groups remained uneffected under these conditions. This points to a reaction proceeding in two steps: After the high temperature primary reaction some (less complete) secondary product formation occurs during the cooling. Polymers are formed which are stable up to temperatures of 1000°C. Whether these polymers are favorable or disfavorable for later sintering procedures remains to be seen. Figure 17 shows an electron micrograph of a laser-produced SiC powder.

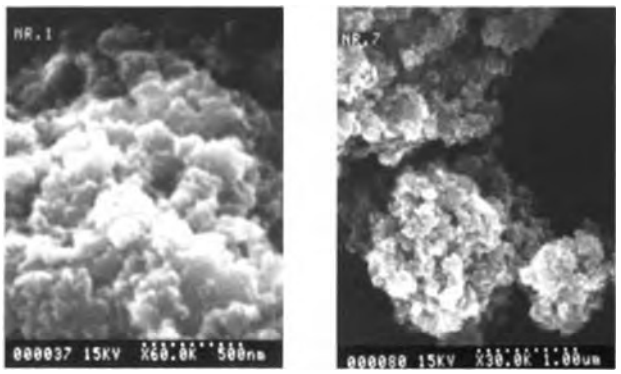

Fig. 17. Electron micrograph of SiC powder produced from hexamethyldisilane by laser radiation. Particle size: 40 to 120 nm.

To reduce the free carbon content which may be disadvantageous for later use of the powder a 0.5 nm molecular sieve was inserted into the apparatus. This fulfilled its purpose, but at the same time led to products which were pyrophoric. Since also products with Si–H bonds were now detected in the gas phase it would appear that polymers containing Si–H bonds, which react exothermally with air to give Si–O bonds, are the cause of this behavior.

At the present time experience of sintering properties is still lacking, and the question of the scaling up of the reaction still requires investigation.

6.4. Noble Metal Contacts by Laser-CVD

The photoelectric initiation of deposition processes was already introduced in Section 4. The following discussion will outline the concept in more detail and provide links to practical applications.

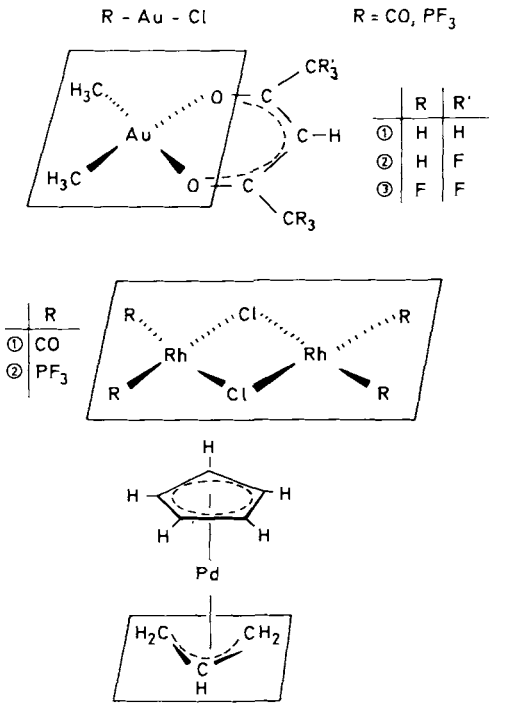

Fig. 18. Some rare metal compounds for the production of thin structured films and layers by laser-CVD [40].

Emphasis is placed here on the deposition of noble metals (gold, palladium) on metallic and non-metallic substrates. The deposition of many other elements, however, has also been investigated, e.g. that of Al, Cd, Cr, Fe, Mo, Ni, Si, W.[23] Numerous compounds such as Al_2O_3, CrMoW, CrO_x, GaAs, HgTe, HgCdTe, InP, Si_3N_4, SiC (cf. Section 6.3), SiO_2, $TiSi_2$, ZnO, and ZnSe as well as materials for high-T_c superconductors have also been deposited.[23] Nevertheless, this area of research is still at in early stage. In particular, there is a lack of data on the influence of surface defects and impurities (sometimes required to mediate sticking) and on the relationship between temperature, deposition rate and morphology of the deposit.[37]

A selection of compounds successfully used for rare metal deposition via laser activation of the surface is listed in Figure 18.[38,39,40] It could be demonstrated for some selected cases that imaging and structuring deposition is possible. For this purpose experimental setups on a pilot-plant scale have been described. These allow for quick access and interchange of samples and control of the (flowing) processing gas. Gas purging of the chamber windows helps to suppress deposits on window surfaces. So far the results obtained are still unsatisfactory as regards morphology and purity of the deposit. The limits associated with these effects may cause difficulties when thicker films (some μm) are to be fabricated. Deposition rates, process control and structural contrast, however, are basically suitable for industrial applications. Noteworthy is the possibility of forming films and ohmic contacts on ceramics and organic polymers. This can be carried out in such a way that lasers generate only the first nucleation layer on the surface, which is then strengthened by galvanic techniques.

As mentioned in Section 4 a photoelectric mechanism has been suggested for this kind of deposition. This hypothesis

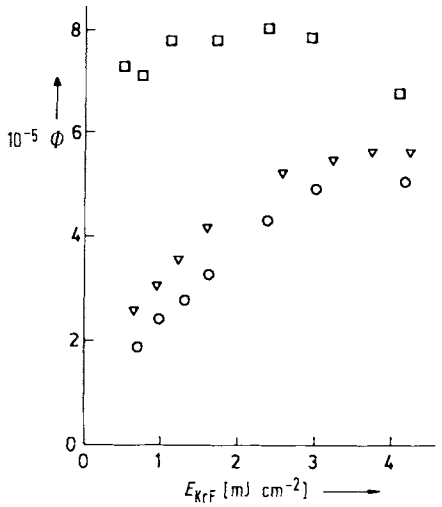

Fig. 19. Laser-induced charging and photoionization of Al with and without adsorbate coverage. Φ = quantum yield; E_{KrF} = energy density of the KrF laser. ○ clean surface. ▽ 10^{-2} mbar $Ni(CO)_4$; □ 1 mbar $Ni(CO)_4$.

could be supported by measurements of the electron yield (Fig. 19). Details of these results will not be given here, however, for lack of space. Essentially there are three different effects of the UV laser irradiation of surfaces (as a most studied example consider aluminum): 1) The quantum yield of the photoelectron emission correlates non-linearly with the energy density of the laser. 2) The quantum yield can be increased by adsorbates, e.g. $Ni(CO)_4$. 3) At higher laser energy density, ions are generated from the adsorbate.

Photo- and thermo-ionization as a general phenomenon of laser surface interaction deserves interest beyond the special case shown here. Corresponding investigations were therefore not only conducted on macroscopic surfaces but also on microscopically fine surfaces of aerosols, both in the pure form and adsorbate-covered. To achieve a desired deposition (filtration) of an aerosol from the gas phase an effective charging of the particle is necessary. To this end experiments were carried out in which for the first time aerosols were charged by pulsed laser radiation in the visible and ultraviolet spectral region.[41] Carbon aerosols (also covered with coronene adsorbates) were of primary interest, but nitrides, carbides and oxides have also been investigated.

7. Concluding Remarks

Electronic excitation, photodissociation and photoionization in the gas phase and at surfaces by pulsed UV lasers opens up new routes for the initiation, acceleration and control of gas-surface interactions. The examples discussed here are the first steps in this direction and show that lasers enable a spatially and temporally very precise impact on materials. *M. von Allmen*[6b] expressed this point in the following way: "Laser beams, in a way, might appear to be a material scientist's dream: They can deliver concentrated "pure" energy to almost any material, and they do so exactly where, when, and in the quantity desired". With laser chemical processing, material-specific factors (work functions, absorption) can be exploited and processes can be conducted under non-equilibrium conditions (photochemically, photoelectrically). Limitations emerge, but these are primarily due to a lack of availability of suitable beam handling and imaging methods.

$[Au_2Ag_4L_4]^{2\ominus}$, $[Au_2Cu_4L_4]^{2\ominus}$, $[Au_3Cu_3L_4]^{2\ominus}$, $[Cu_4L_3]^{2\ominus}$, and $[Ag_9L_6]^{3\ominus}$ (L = ethane-1,2-dithiolate)—Novel Homoleptic Complexes of the Coinage Metals, including the First Heteronuclear Metal Thiolates**

By *Gerald Henkel,* Bernt Krebs, Peter Betz, Heidrun Fietz,* and *Karlheinz Saatkamp*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Copper reacts with simple saturated thiolates to give tetranuclear complexes of the type $[M_4(SR)_6]^{2\ominus}$ containing a central cage-like *tetrahedro*-M_4-*octahedro*-(μ-S) moiety (Fig. 1a) in which copper is surrounded by a trigonal array of sulfur atoms.[1] Surprisingly, for quite a long time it proved impossible to prepare the corresponding silver thiolates. An entry to such complexes, however, was recently accomplished by suitable choice of the ligands. The isolation and characterization of $[Ag_4L'_3]^{2\ominus}$ anions (L' = $SCH_2C_6H_4CH_2S$,[1] $SC_6H_3(Me)S$[2]) now confirms the existence of tetranuclear silver thiolates.

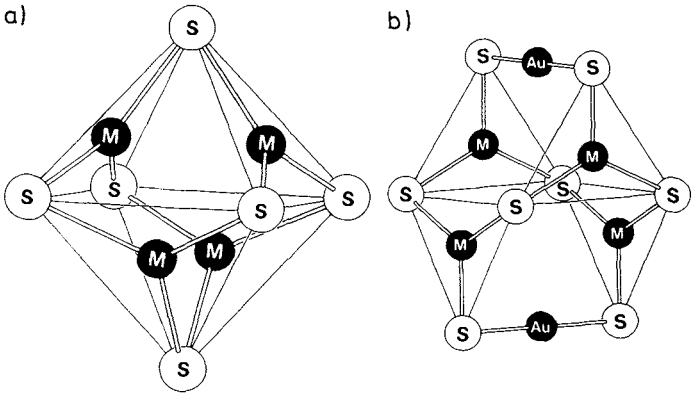

Fig. 1. The closed heavy-atom skeletons of homologous metal(I) thiolates: a) M_4S_6 cage; b) M_6S_8 cage in idealized geometries.

An interesting extension of the M_4S_6-cage occurs in the pentanuclear complex anions $[M_5(SPh)_7]^{2\ominus}$, the copper and silver variants of which are well-known.[3] Here, one metal atom is coordinated linearly by sulfur, while the other four are coordinated in a trigonal planar fashion. The resulting M_5S_7 skeleton arises from the M_4S_6 cage of the tetranuclear complex by opening of a thiolate bridge and insertion of an M–S unit.

It should be possible to extend this principle to the side of the sulfur octahedron opposite to the inserted unit and construct hexanuclear metal thiolates with the M_6S_8 cage skeleton shown in Figure 1b. A complex salt with appropriate stoichiometry, namely $[Me_4N]_2[Ag_6(SPh)_8]$ is, in fact, known;[4] however it does not contain the desired isolated hexanuclear anions, but one-dimensional infinite $[Ag_6(SPh)_8]_n^{2n\ominus}$ chains with mixed trigonal-planar and tetrahedral silver coordination.

Since chemical examples for the remarkable M_6S_8 cage were still unknown we attempted their preparation by directed cluster synthesis. It appeared meaningful to stabilize the two linear S–M–S units of the target compound by metal centers which avoid a trigonal planar coordination.

Reaction of a solution of $CuCl_2$ or $AgNO_3$ in methanol (or of CuCl in acetonitrile) with ethane-1,2-dithiolate leads initially to the formation of the homonuclear compounds **4** or **5**,[5] respectively. When the reaction solutions are subsequently allowed to react with $[Et_4N][AuBr_2]$ the desired heterohexanuclear complexes **2** and **3** or **1** are indeed formed.

We report here on the synthesis and structure of these heteronuclear (**1**–**3**) and homonuclear (**4**, **5**)[5] metal thiolates, which after addition of Ph_4PBr crystallize as complex salts **6**–**9**.

$[Au_2Ag_4(SCH_2CH_2S)_4]^{2\ominus}$ **1**
$[Au_2Cu_4(SCH_2CH_2S)_4]^{2\ominus}$ **2**
$[Au_3Cu_3(SCH_2CH_2S)_4]^{2\ominus}$ **3**
$[Cu_4(SCH_2CH_2S)_3]^{2\ominus}$ **4**
$[Ag_9(SCH_2CH_2S)_6]^{3\ominus}$ **5**
$[Ph_4P]_2[Au_2Ag_4(SCH_2CH_2S)_4]\cdot 2/3\,MeOH$ **6**
$[Ph_4P]_6[Au_2Cu_4(SCH_2CH_2S)_4]_2[Au_3Cu_3(SCH_2CH_2S)_4]\cdot 4\,MeOH$ **7**
$[Ph_4P]_2[Cu_4(SCH_2CH_2S)_3]\cdot MeOH$ **8**
$[Ph_4P]_3[Ag_9(SCH_2CH_2S)_6]\cdot 3\,MeOH$ **9**

According to the results of an X-ray structure analysis,[6] crystals of **6** consist of $Ph_4P^{\oplus}$ ions, discrete complex anions **1**, and solvate molecules (methanol). The monoclinic unit cell contains twelve anions, eight of which (**1a**) lie on general positions and four (**1b**) on twofold axes. The structures of the symmetry-independent molecules are nearly identical; the structure of **1a** is shown in Figure 2.

The hexanuclear thiolates **1** contain the M_6S_8 skeletal frameworks shown in Figure 1b (D_{2d} symmetry) in a somewhat distorted geometry. As expected gold is linearly coor-

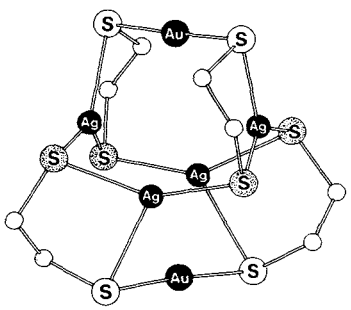

Fig. 2. Structure of the complex anion **1a** in crystals of **6** (without H atoms).

dinated, whereas silver is surrounded by a trigonal planar array of sulfur atoms. The eight sulfur atoms of the four ligands form two distorted trigonal prisms sharing a common square face (dotted atoms in Fig. 2); the edges parallel to this plane contain the two gold atoms and the triangular faces of the S_8 polyhedron are completely occupied by silver atoms. This coordination leads to a central Ag_4S_4 heterocycle, which (like the complete S_8 polyhedron) is topologically related to the A_4B_4 cage of tetrasulfur tetranitride. As in the tetranuclear copper and silver thiolates, all sulfur atoms are bound to two metal atoms. The first thiolate function of each ligand bridges two silver atoms (Ag···Ag 3.170 Å), the second couples a silver atom with a gold atom (Au···Ag 2.996 Å). The angles of the Ag–S–Ag bridges (80.8°) are on average about 6.1° larger than the angles of the Au–S–Ag bridges, which exhibit a marked asymmetry (Au–S 2.293, Ag–S 2.625 Å, averaged values). The Ag–S bonds in the heterocyclic Ag_4S_4 fragments (cf. Fig. 2) are alternately short (2.416 Å) and somewhat longer (2.488 Å).

1 is stabilized by chelate rings in which the small S···S distance of the ethane-1,2-dithiolate ligand leads to very small S–Ag–S chelate angles (average 87.8°); they are on average 53.2° (!) smaller than the S–Ag–S angles in the central cyclic Ag_4S_4 fragment. The remaining S–Ag–S angles (128.3°) lie between these extremes.

Crystals of **7**[6] contain the complex anions **2** and **3** at identical lattice sites. Since the frequency of occurrence of **2** in the crystal is twice that of **3** and two anions are present in each unit cell an ordered structure can be ruled out. In principle, **2** shows all the coordination characteristics of the analogous silver compound **1**; hence Figure 2 may also be used for reference here. The Au–S bonds in **2** (average 2.286 Å) are only slightly shorter than in **1** (average 2.293 Å), whereas the expected proportional shortening (on average 0.22 Å) of all other metal–sulfur bonds is observed on going from silver to copper. This shortening is also the reason for the likewise significant widening of the S–Cu–S chelate angle to 94.4°, and in turn leads to S–Cu–S valence angles of 133.5° in the central Cu_4S_4 cycle and thus to a decrease in the ring strain (Cu···Cu 3.149 Å), but has only a very slight influence on the second group of the exocyclic S–M–S valence angles (average 130.0°, Au···Cu 2.862 Å).

The molecular structure of the gold-rich complex anion **3** is shown in Figure 3. The M_6S_8 skeleton of this compound is a variant of the cage structure shown in Figure 1b, in which a copper atom is replaced by gold. This atom is shifted from the center of the sulfur triangle into the middle of the edge belonging to the M_4S_4 ring and thereby effects the transition from the trigonal-planar coordination of the copper atom to the linear coordination of gold. At the same time the bond to the opposite sulfur atom is ruptured and the chelate ring opens.

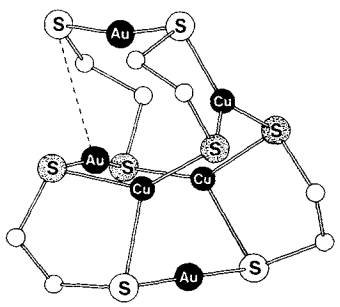

Fig. 3. Structure of the complex anion **3** in crystals of **7** (without H atoms).

The structure of **4** (point group C_3, slightly distorted) in crystals of **8**[6] is shown in Figure 4 and contains the heavy atom skeleton with copper atoms at the tetrahedral sites

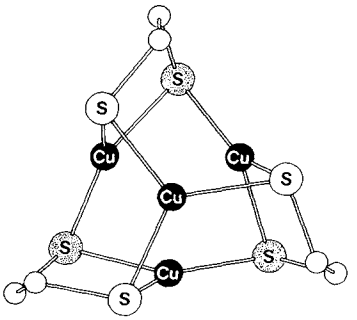

Fig. 4. Structure of the complex anion **4** in crystals of **8** (without H-atoms).

shown in Figure 1a. The coordination principle frequently found in copper–sulfur chemistry with sterically unencumbered substituents is thus observed in homoleptic ethane-1,2-dithiolate complexes, despite the short intramolecular S···S distances of the ligands. The type of ligand arrangement here is quite similar to that in the anions **10** of the related complex salts $[Ph_4P]_2 \cdot \mathbf{10} \cdot 3\,MeOH$[7a] and $[Ph_4P]_2 \cdot \mathbf{10} \cdot MeCN$.[7b] The stronger distortion of the coordination of all the copper atoms of **4** that participate in chelate rings is a direct consequence of the short "bite" (3.397 Å) of the ethane-1,2-dithiolate ligands. These copper atoms are equivalent under C_3 symmetry. Each of them shows an angle of 127.2° in their respective heterocyclic Cu_3S_3 fragment (dotted S atoms, Cu–S alternately 2.305 and 2.223 Å) besides the small valence angle of 94.9° within the chelate ring, while the third S–Cu–S valence angle (137.4°) is significantly widened. The fourth copper atom (in the center of Fig. 4) is coordinated almost regularly (valence angles 118.5(1), 119.0(1) and 121.9(1)°) by one thiolate function of all three ligands (Cu–S 2.289 Å). The average Cu–S distance is consistent with expectation (2.281 Å).

$[Cu_4(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ **10**

In contrast to the copper salts, no tetranuclear complexes are obtained in reactions of ethane-1,2-dithiolate with silver salts. Instead, and fully unexpected, the nonanuclear complex anion **5** is formed, whose structure in crystals of **9**[6] is shown in Figure 5. Here, eight silver atoms form a cubane-like metal skeleton with a further silver atom in the center. The metal cube is strongly distorted, the central silver atom being at distances of between 3.084(4) and 3.403(4) Å (mean value 3.199 Å) from its neighboring silver atoms. The six bidentate ligands are involved in chelate rings and are thus arranged such that a sulfur atom is located above the center of each edge of the silver cube. They thus define a sulfur icosahedron, which like the silver-centered cube already described is considerably distorted. The coordination of the silver atoms at the corners of the cube is distorted trigonal planar. Two opposite atoms of the cube (Ag′) are simultaneously bound to three dithiolate ligands and therefore do not participate in chelate rings. Like their trigonally coordinated neighbors

(Ag) they are unusually tolerant with regard to angle deformations. Thus, in each case one finds three different S-Ag-S valence angles (average values 101.9, 115.9 and 140.4° (Ag'), and 88.0, 130.0 and 139.7° (Ag)).

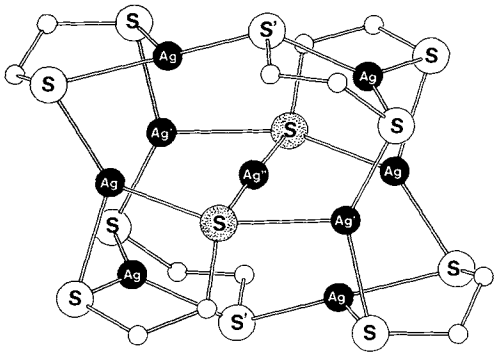

Fig. 5. Structure of the complex anion **5** in crystals of **9** (H atoms omitted).

The silver atom in the center of **5** (Ag'') is bound to two sulfur atoms (dotted atoms, S-Ag''-S 177.4(4)°), each of which additionally couples two further silver atoms at the corners of the cube. Here, we have μ_3-thiolate bridges with unusual geometry, in which the Ag-S-Ag valence angles are 76.1° if one of the silver atoms is Ag'' and on average 150.3° if the trigonal-planar coordinated silver atoms Ag and Ag' participate (for comparison: the angles of the μ_2-thiolate bridges are 114.2(4) and 119.0(3)° in the case of the atoms marked S' in Figure 5 and are on average 78.2° in the case of the other S atoms). The Ag-S distance is somewhat shorter in the case of linear coordination (average 2.478 Å) than in the trigonal-planar AgS_3 units (average 2.512 Å), in which once again the distances within the chelate rings are longer (2.546 Å) than those outside the rings (2.445 Å).

The trigonal-planar coordinated silver atoms are in part replaced by copper atoms when the methanolic solutions of the Na salts of **4** and **5** are allowed to react with each other. With a copper : silver ratio of 1 : 1, orange crystals of the composition **11** precipitate on addition of Ph_4PBr. The crystals are isotypic with crystals of **9**.

$[Ph_4P]_3[Ag_{3.9}Cu_{5.1}(SCH_2CH_2S)_6]\cdot 3\,MeOH$ **11**

The individual $[AgM_8(SCH_2CH_2S)_6]^{3\ominus}$ ions can, according to the results of an X-ray structure analysis, contain silver or copper at all metal positions at the corners of the cube. The intense wine-red colored complex salt **12** is formed at a copper : silver ratio of 5 : 2.

$[Ph_4P]_3[Ag_{2.3}Cu_{6.7}(SCH_2CH_2S)_6]\cdot 4\,MeOH$ **12**

12 crystallizes in a different lattice, presumably because of its high copper content.[7a]

The central Ag_9S_{12} fragment of the anion **5** is topologically related with the Ag_8S_{12} cage of the complex anion $[Ag_8(S_2C{=}C(CN)_2)_6]^{4\ominus}$, which contains only μ_2-sulfur atoms and no chelate rings.[8] The μ_3-S-Ag_3 unit first realized in **5** presumably owes its existence to a trigonal coordinated silver atom, which can form a long Ag-S bond of average length 2.646 Å because it is not involved in a chelate ring and therefore has two further sulfur neighbors at a distance of 2.452 Å (Ag' in Fig. 5).

Experimental

All operations were carried out under an inert gas atmosphere (N_2 or Ar) in sealed vessels. A $NaSCH_2CH_2SNa$ solution was prepared by reaction of 0.69 g (30 mmol) of sodium with 1.26 mL (15 mmol) of ethane-1,2-dithiol in 100 mL of methanol. Correct C,H analyses were obtained for the salts **6**-**9**.

6: A solution of $AgNO_3$ (0.17 g, 1 mmol) in methanol (30 mL) was treated dropwise with 10 mL of the $NaSCH_2CH_2SNa$ solution. The initially formed lemon-yellow precipitate redissolved shortly before completion of the addition. The clear reaction solution was treated dropwise with a solution of 0.24 g (0.5 mmol) of $[Et_4N][AuBr_2]$ in 20 mL of methanol and the resulting bright-yellow solution treated with 0.42 g (1 mmol) of Ph_4PBr. Within a few hours at room temperature colorless crystals separated out (yield 81%). The quality of the crystals could be improved at the expense of the yield, by using a solution of $[Et_4N][AuBr_2]$ in dimethylformamide.

7: 10 mL of the $NaSCH_2CH_2SNa$ solution was diluted to three times its volume and added dropwise to a solution of 0.10 g (1 mmol) of CuCl in 10 mL of acetonitrile. The initially formed yellow precipitate redissolved toward the end of the addition. The further steps were analogous to those for the synthesis of **6**; after a few days, **7** crystallized in the form of orange-colored crystals (42%).

8: A solution of 0.68 g (4 mmol) of $CuCl_2\cdot 2H_2O$ in 15 mL of methanol was treated dropwise with 55 mL of the $NaSCH_2CH_2SNa$ solution. The initially formed yellow precipitate redissolved on completion of the addition. Upon addition of 0.84 g (2 mmol) of Ph_4PBr, **8** crystallized in the form of orange platelets (86%).

9: A solution of 1.70 g (10 mmol) of $AgNO_3$ in methanol was treated dropwise with 67 mL of the $NaSCH_2CH_2SNa$ solution. The initially formed lemon-yellow precipitate redissolved in the course of the ensuing reaction. Upon addition of 4 mmol (1.68 g) of Ph_4PBr to the clear reaction solution, lemon-yellow needles of **9** crystallized out (95%).

Is the Molecule BOK Quasi-Linear?**

By *Pavel Rosmus**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Unlike the linear HCN[1] and LiNC molecules (linear cyanide, LiCN, is metastable),[2,3] the cyanides NaCN,[4,5] KCN,[6] and RbCN[7] possess triangular equilibrium structures in the gas phase. Several experimental and theoretical studies have established that the orbiting motion of $M^{\oplus}$ (M = Na, K, Rb) in the strongly polar structures $M^{\oplus}CN^{\ominus}$ is almost unhindered,[5-9] whereas higher barriers of isomerization have been found for HCN[10] and LiNC.[2] An unusual early onset of classical and quantum chaos has been reported[11-13] for the $K^{\oplus}$ vibrational modes of $K^{\oplus}CN^{\ominus}$.

Similar properties can be expected for the isoelectronic bivalent boron compounds, MBO, yet only the parent linear oxoborane, HBO, has been hitherto detected experimentally.[14,15] The BOK molecule—isoelectronic with KCN—has been investigated neither experimentally nor theoretically. Herein we report results obtained from ab initio Hartree-Fock calculations for the electronic ground-state potential energy surface of BOK.

The potential energy function $E(r,R,\Theta)$ of the electronic ground state of BOK was mapped in two dimensions. The BO distance r (orientation of the vector $\boldsymbol{r}$ from B to O) was kept fixed at the equilibrium distance of the BO radical ($r_{BO}=2.27697$ bohr,[17]) and both the distance R from K to the center of mass of BO and the angle Θ between r and R were varied. The potential energy functions in other cyanides have been represented in a similar way.[7,8,11-13] About 100 SCF total energies were calculated[16] in order to map the motion of the K atom in BOK. The SCF dissociation energy into the neutral fragments K + BO in their electronic ground states was calculated to be 212 kJ mol^{-1};[16] hence BOK is a stable species. In the entire region of the geometries considered (cf. Fig. 1) the molecule has a strongly ionic electron distribution $K^{\oplus}BO^{\ominus}$. The total SCF dipole moment at the global triangular equilibrium structure was calculated to be 11.67 debye; 13.54 debye and 13.59 debye were obtained for the minimum energy linear structures KBO and BOK, respectively. As in the cyanides,[7] the dominating part of the dipole moment originates from the charge separation in $K^{\oplus}$ and the moiety $BO^{\ominus}$. Since $K^{\oplus}BO^{\ominus}$ dissociates, within the Hartree-Fock approximation, into ionic fragments, the potential energy function of the electronic ground state will exhibit an avoided crossing with another electronic state, which will change the charge distribution and yield the neutral fragments. This crossing has not been considered in the present work.

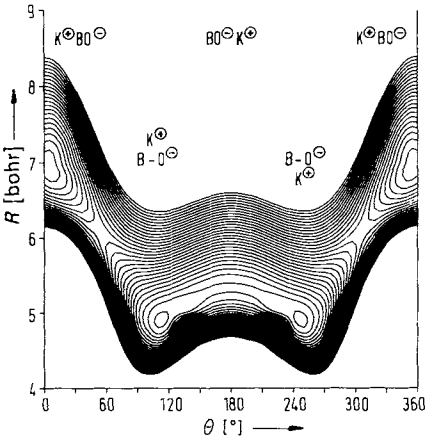

Fig. 1. Contour plot of the two-dimensional potential energy function for one orbiting period of $K^{\oplus}$ in $K^{\oplus}BO^{\ominus}$. $\Theta=0°$ for linear KBO, $\Theta=180°$ for linear BOK. The contours are plotted in 2-kJ mol^{-1} steps.

The contour plot of the potential energy surface for one orbiting period of $K^{\oplus}$ around $BO^{\ominus}$ is shown in Figure 1. The orbiting channel for $K^{\oplus}$ around $BO^{\ominus}$ can easily be recognized. The minimum energy path for $K^{\oplus}$ motion on the potential energy surface is displayed with the full line in Figure 2. This diagram shows that the linear KBO structure as calculated within the Hartree-Fock approximation represents only a local minimum separated by a barrier from the triangular global minimum with $R_{KB}=5.788$ bohr and ∢KBO 50.1° (KCN:[6] $R_{KC}=4.91\pm0.2$ bohr, ∢KCN = 76° ± 10°). Previous SCF calculations of similar quality[5,8] for KCN showed that the R_{KC} distance is reproduced to within about 6%, the KCN angle to within about 10%. It has also been shown[5] that small changes in the CN distance hardly influence either the calculated equilibrium geometry parameters or the overall picture for $K^{\oplus}$ motion around $CN^{\ominus}$. Therefore, similar accuracy for the

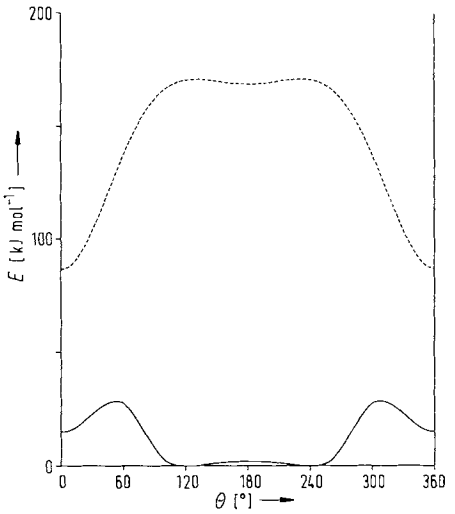

Fig. 2. The full line represents the minimum energy path of the orbiting motion of $K^{\oplus}$ on the two-dimensional potential energy function of BOK (cf. Fig. 1 and Ref. [16] for the definition of the coordinate system); the broken line corresponds to the energy path for $K^{\oplus}$ separated from the center of mass of the $BO^{\ominus}$ fragment by 9 bohr.

geometric parameters and the shape of the surface can be expected for BOK. The $K^{\oplus}$ ion approaches the $BO^{\ominus}$ fragment more closely in the BOK linear structure ($R_{OK}=4.51$ bohr) than in the KBO linear structure ($R_{KB}=5.53$ bohr) (cf. Fig. 1). Similar behavior has been found for the linear KCN and KNC structures,[5] which is due to a stronger electrostatic attraction by the more electronegative atom. At a distance of 9 bohr from the center of mass of BO, the long-range interaction potential (broken line in Fig. 2) shows that at the SCF level of theory an opposite stabilization to that at short range occurs. The $K^{\oplus}$ approach is energetically more favorable for linear $K^{\oplus}BO^{\ominus}$ geometries. The barrier height between the global minimum and the KBO local minimum has been calculated to be 30 kJ mol^{-1} (KCN: 27 kJ mol^{-1},[8] 20 kJ mol^{-1}[9]). The barrier to linearity for the BOK structure relative to the global minimum has been calculated to be only about 2 kJ mol^{-1} (KCN: 7 kJ mol^{-1},[5] 8.5 kJ mol^{-1},[8] 6 kJ mol^{-1}[9]). The SCF results indicate that the barrier between the triangular equilibrium structure and the linear BOK structure is smaller than in KCN. This could mean that even the vibrational ground state of BOK lies above this barrier and the molecule is quasi-linear—with a large zero-point-energy amplitude for the $K^{\oplus}$ bending motion.

The influence of the orbiting $K^{\oplus}$ in KCN on its photoelectron spectrum has been investigated by Green's function calculations, which showed that the first three peaks in the spectrum could be broadened by up to 1.2 eV.[18] In the linear structures KBO and BOK the highest three molecular orbitals are of σ ($-\varepsilon^{SCF}=14.28$ eV (KBO), 15.67 eV (BOK)), π (11.02 eV, 12.13 eV), and σ (8.08 eV, 8.81 eV) symmetry. The π orbital splits into two components in the triangular structure, resulting in the following orbital symmetries and energies: a′($-\varepsilon^{SCF}=15.84$ eV), a′(12.35 eV), a″(12.16 eV), and a′(7.18 eV). The SCF molecular orbital energies given in parentheses suggest that the $K^{\oplus}$ orbiting in BOK will also significantly broaden the bands in its photoelectron spectrum.

The calculated energy differences and barriers between various structures are rather small. In this situation it is difficult to find a simple explanation for the structural differences. This problem has been discussed in detail in a comparison of the LiCN and KCN structures.[8] A more accurate approach including electron correlation and the calculation of the corresponding force field would require a correct treatment of the induction and dispersion forces, which would result in very extensive computations. Even for KCN only Hartree-Fock results have been reported so far. It has been suggested,[9] however, that, as in LiCN, the inclusion of electron correlation could stabilize the KCN structure relative to the KNC structure.

In summary, it has been found that the electronic ground-state potential energy function of BOK strongly resembles that of KCN, i.e., the $K^{\oplus}$ is almost freely orbiting around $BO^{\ominus}$. The molecule is probably quasi-linear and will show an early onset of classical and quantum chaos in the $K^{\oplus}$ nuclear motion. Further investigations are necessary to compute the induction and dispersion forces in this salt more accurately.

Triazatrimetallabenzenes, a New Class of Inorganic Heterocycles; Synthesis and Structure of $[Cp^*TaN(Cl)]_3$**

By *Herbert Plenio, Herbert W. Roesky,* Mathias Noltemeyer,* and *George M. Sheldrick*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

In 1983 we reported on the synthesis and structure of $(Cl_2VN_3S_2)_x$, a triaza-1,3-dithiabenzene containing a metal atom as the sixth member of the ring.[1] In 1986 we described $[Cl_3WN_3(PPh_2)_2]$, the first cyclophosphazene in which a ring phosphorus atom is replaced by a transition-metal atom in its maximum oxidation state.[2] Further members of this class of compounds were synthesized in 1987.[3] We now report the first triazatrimetallabenzene. This compound can be regarded as the trimer of a metal nitride.

Metal nitrides of the early transition metals[4] display a wide range of structures and can exist as mononitrides, dinuclear mononitrides, trinuclear dinitrides, tetramers, and linear polymers. *R. Hoffmann* et al. thus concluded that analogies exist between transition-metal nitrides, organic polyenes, and phosphazenes and that benzene-like cyclic trimers of a nitride should be particularly stable.[5]

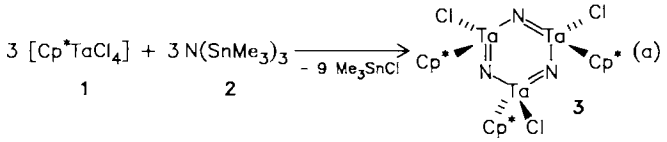
Such a compound has now been synthesized from $[Cp^*TaCl_4]$ **1** ($Cp^* = \eta^5$-C_5Me_5) and tris(trimethylstannyl)amine **2** [Eq. (a)]. Evidence for the six-membered cyclic structure of **3** is provided by the ^1H NMR spectrum, which indicates the presence of two nonequivalent pentamethylcyclopentadienyl groups ($\delta = 2.08, 2.12$) in a ratio of 1:2. In addition to the molecular ion peak (*m/z* 1095), the mass spectrum always reveals small amounts of the tetramer $[Cp^*TaN(Cl)]_4$ (*m/z* 1460). The IR spectrum exhibits a strong absorption at 960 cm^{-1}, which we ascribe to the Ta-N valence vibration.



1 2 3 (a)

Crystals of **3** suitable for an X-ray structure analysis (Fig. 1)[6] were obtained by recrystallization from toluene/hexane. The six-membered $(TaN)_3$ ring, containing tetrahedrally coordinated tantalum atoms, is not completely planar in the solid state but instead exists in a kind of boat conformation, with the atoms Ta(2), N(3), Ta(3), and N(2) lying in the same plane (±0.03 pm). Ta(1) lies 13 pm and N(1) 39 pm from this plane. The molecule has a non-crystallographic mirror plane through Cl(1), Ta(1), and N(1); two Cp* rings lie below and one lies above the $(TaN)_3$ ring plane, as expected on the basis of the NMR spectrum. The Ta-N bond lengths (average 188(2) pm) are comparable to those in $[Br_5TaNTaBr_5]^{3\ominus}$ (185 pm[7]) and lie between the values for Ta=NR (175–178 pm) and $Ta-NR_2$ (195–203 pm).[8]

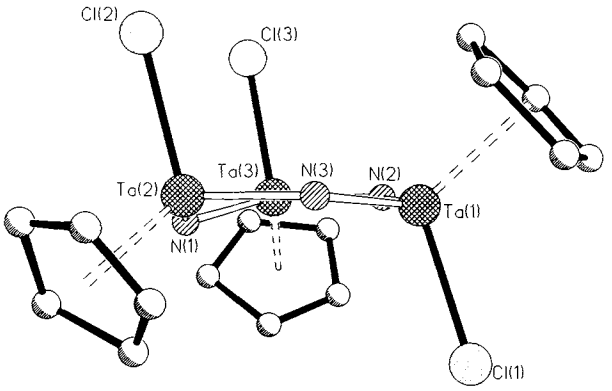


Fig. 1. Molecular structure of **3** (side view of the $(TaN)_3$ ring). Selected bond lengths [pm] and angles [°]: Ta1-N2 190(3), N2-Ta3 186(3), Ta3-N1 188(2), N1-Ta2 190(2), Ta2-N3 191(2), N3-Ta1 184(2), Ta1-Cl1 238(1), Ta2-Cl2 235(1), Ta3-Cl3 235(1), N-Ta-N (average) 109.8(10), Ta-N-Ta (average) 127.9(12), N-Ta-Cl (average) 103.6(9).

Many other triazatrimetallabenzenes should be accessible via reactions analogous to reaction (a).

Experimental Procedure

A solution of **2** (1010 mg, 2 mmol) in toluene (10 mL) was added dropwise to a stirred suspension of **1** (916 mg, 2 mmol) in dry toluene (20 mL). After stirring for 12 h at room temperature, the clear orange solution was heated at 50°C for 1 h and all volatiles were then removed under vacuum. The partly oily, partly crystalline residue was stirred with 50 mL of pentane and a crystalline solid was collected by filtration. The bright yellow product was washed several times with pentane and then dried under vacuum for 6 h. The IR, ^1H NMR, and mass spectra established its identity as **3**. Yield: 490 mg (67%).

π Complexes of an Amino-9-fluorenylideneborane**

By *Scott Helm* and *Heinrich Nöth**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

9-Fluorenylidene-2',2',6',6'-tetramethylpiperidinoborane **1**,[1] the first aminoorganylideneborane derivative,[2,3] is characterized by high reactivity of its BC double bond. Typical reactions are additions to the double bond to give amino-9-fluorenylborane derivatives as well as [2+2] and [2+3] cycloadditions.[1,4] However, π complexes of this system in which the benzo groups, the cyclopentadienylidene ring, or the BC double bond are bonded in an η^6, η^5, or η^2 fashion, respectively, have not been reported. This is due, among other things, to the fact that the fluorenyl moiety shows little tendency to form π complexes.[5]

We have now found that $TiCl_4$ and $TiBr_4$ react readily with **1** to give fluorenylidene-TiX_3 π complexes. Presumably, **2** is initially formed, since analogous compounds are obtained upon reaction of **1** with boron or phosphorus halides.[6]

The X-ray structure analysis of **3a** (Fig. 1)[7] does not show fully symmetrical η^5 bonding of the $TiCl_3$ fragment to the central five-membered ring, since the TiC distances to C7 and C8 are longer than those to C1, C2, and C13.

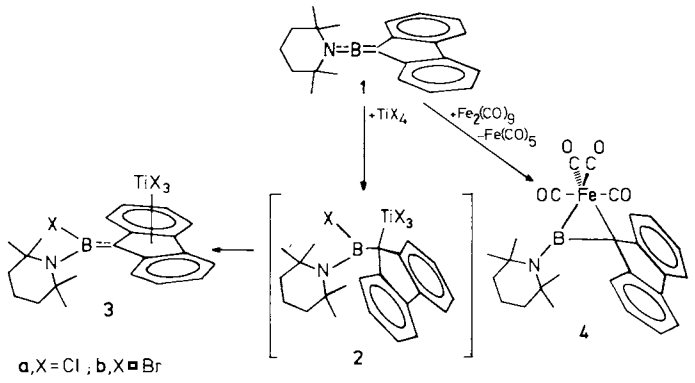

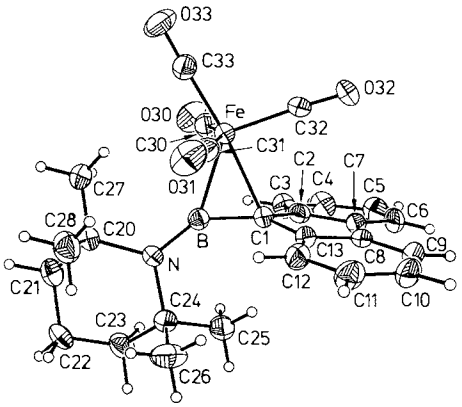

Fig. 2. Molecular structure of **4** (ORTEP). Selected bond lengths [Å] and angles [°]: Fe-B 2.125(5), Fe-C1 2.190(4), Fe-C30 1.786(5), Fe-C31 1.786(5), Fe-C32 1.820(5), Fe-C33 1.798(5), B-C1 1.518(7), B-N 1.377(6); C30-Fe-C31 151.2(2), C30-Fe-C32 104.5(2), C30-Fe-C33 85.7(2), C30-Fe-B 82.9(2), C30-Fe-C1 92.8(2), C31-Fe-C32 104.0(2), C31-Fe-B 83.4(2), C31-Fe-C1 93.4(2), C32-Fe-C33 100.2(2), C32-Fe-B 126.7(2), C32-Fe-C1 85.5(2), C33-Fe-B 133.2(2), C33-Fe-C1 174.3(2), B-Fe-C1 41.2(2), Fe-B-N 146.0(3), Fe-B-C1 71.7(2), N-B-C1 142.3, C13-C1-C2 104.3(4), Fe-C1-B 67.1(2).

However, this distortion toward η^3 coordination is still not strong enough to consider it as a purely allylic interaction of the 9-fluorenyl ligand with the $TiCl_3$ fragment.[8] The electron demand of the boron atom in **3a** is satisfied by a BN bond displaying pronounced double-bond character; this is shown in the bond lengths and in the near coplanarity of the C21-C25-N plane and the N-B-C14(C1) plane, which, in turn, forms an angle of 48.6° with the plane of the five-membered ring.

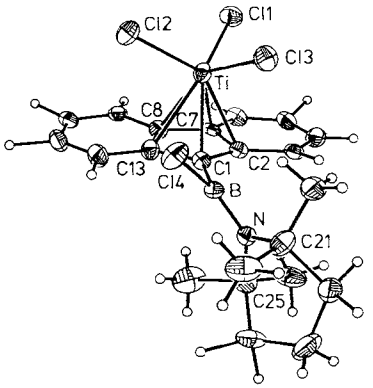

Fig. 1. Molecular structure of **3a** (ORTEP). Thermal ellipsoids at the 25% probability level. Selected bond lengths [Å] and bond angles [°]: Ti-Cl1 2.262(4), Ti-Cl2 2.213(3), Ti-Cl3 2.225(3), Ti-C1 2.27(1), Ti-C2 2.35(1), Ti-C13 2.43(1), Ti-C7 2.50(1), Ti-C8 2.52(1), B-C1 1.60(1), B-N 1.37(2), B-Cl4 1.83(1); Cl1-Ti-Cl2 101.5(1), Cl1-Ti-Cl3 98.6(1), Cl2-Ti-Cl3 104.7(1), Cl4-B-C1 110.0(8), Cl4-B-N 121.7(7), C1-B-N 128.3(9).

Reaction of **1** with nonacarbonyldiiron affords the crystalline tetracarbonyliron complex **4**, whose NMR data indicates a symmetrical molecule. The four CO groups are equivalent at room temperature on the NMR time scale; at 210 K, however, three CO groups (intensity ratio 1:1:2) become distinguishable and thus confirm the formation of a tetracarbonyliron complex. The absence of the NBC vibrational band of **1** at 1717 cm^{-1} in the IR spectrum of **4** suggests the formation of a π complex involving the BC bond. The X-ray structure analysis (Fig. 2)[9] corroborates this conclusion.

In the solid state, **4** has near C_s symmetry. The BC bond occupies an "equatorial" position in the strongly distorted trigonal-bipyramidal arrangement of the ligands around the iron atom. The bulky ligand **1** causes a reduction in the angle between the axial CO groups from 180° in $[Fe(CO)_5]$ to 151.2° in **4**. As in heterocumulene $(CO)_4Fe$ complexes,[10] which have analogous configurations, the double bond involved in the coordination is lengthened (by 0.1 Å compared with **1**), whereas the BN bond is only 0.03 Å longer (indicating that its π-bond character is only slightly changed). The C20-C24-N plane is practically parallel to the Fe-B-C1 plane (angle formed by the normals to the planes: 4.7°). Since, despite the larger covalent radius of boron, the FeB bond is shorter than the FeC bond, the boron atom apparently plays a dominating role as π acceptor and thus contributes appreciably to the stabilization of **4**. According to *Floriani* et al.,[11] the stability of heterocumulene tetracarbonyliron complexes, such as **4**, is determined by the π interaction between the C=X fragment and the metal d orbitals.

Experimental Procedure

3a, b: **1** (1.75 mg, 5.5 mmol) in toluene (10 mL) was allowed to react with an equimolar amount of TiX_4 (X = Cl, Br) in toluene (10 mL). After 1 h, the precipitated product was separated from the nearly black solution. Recrystallization from a small amount of CH_2Cl_2 at −20°C. **3a**: Yield 45%, green-black crystals, dec. >200°C; ^{11}B NMR ($CDCl_3$): δ = 38.8; ^1H NMR ($CDCl_3$): δ = 0.95, 1.67, 1.71, 1.88 (s, 3 m, 18 H; NC_9H_{18}), 7.29, 7.70, 7.74 (3 m, 8 H; $C_{13}H_8$); MS (70 eV): *m/z* 435 ([*M* − 2 Cl + 2 H], 100%). **3b**: 42%, green-black crystals, dec. >200°C; ^{11}B NMR ($CDCl_3$): δ = 39.1; ^1H NMR ($CDCl_3$): δ = 0.93, 1.54-1.76, 1.89-1.96 (s, 2 m, 18 H; NC_9H_{18}), 7.29, 7.67, 8.28 (3 m, 8 H; $C_{13}H_8$); MS (70 eV): *m/z* 394 ([*M* − $TiBr_3$], 100%).

4: Equimolar amounts of **1** and $[Fe_2(CO)_9]$ were stirred in toluene until the metal carbonyl had dissolved (16 h). The volatile components were then removed under vacuum, and the oily, reddish-brown residue was crystallized from toluene/hexane (1/3) at −20°C/−78°C. 48%, light brown crystals, m.p. 137°C. IR (hexane): $\tilde{\nu}$ = 2064, 2011, 1962, 1971 (sh) cm^{-1}; ^{11}B NMR (C_6D_6): δ = 58.5; ^1H NMR (C_6D_6): δ = 0.80, 1.33, 1.81 (s, br. m, 18 H; NC_9H_{18}), 7.15-7.74 (m, 8 H; $C_{13}H_8$); ^{13}C NMR (C_6D_6; numbering in Fig. 2): δ = 16.3 (C22), 33.2, 34.3 (C25, C26, C27, C28), 38.6, 39.2 (C21, C23), 58.7, 61.8 (C20, C24), 121.0 (C6, C9), 123.6 (C5, C10), 124.9 (C3, C12), 126.3 (C4, C11), 138.4 (C7, C8), 153.4 (C2, C13), 208.7 (CO), the signal for C1 was not observed; ^{13}C NMR (*T* = 210 K, CO region): δ = 209.4, 207.8, 206.6 (1:1:2).

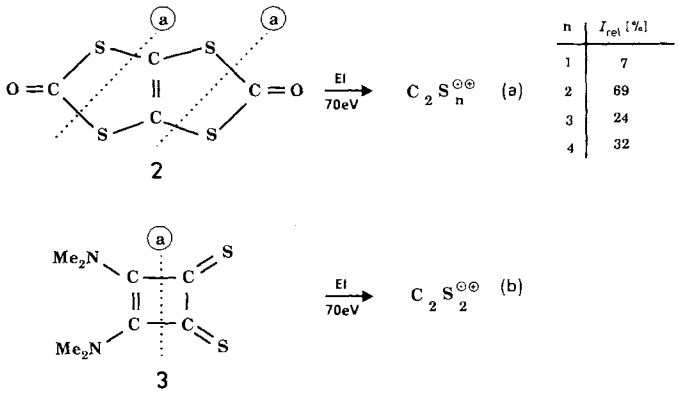
Ethylenedithione (C_2S_2): Generation and Characterization by Neutralization-Reionization Mass Spectrometry**

By *Detlev Sülzle* and *Helmut Schwarz**

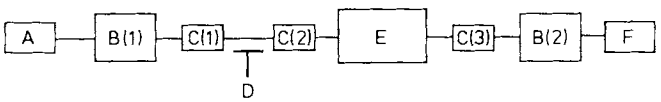
Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Theory leaves no doubt that ethylenedithione **1**, the dimer of carbon monosulfide, should be a "makeable" molecule, since it corresponds to the global minimum of the C_2S_2 hypersurface. Its decomposition into CS has, according to reliable ab initio calculations, a $\Delta H^{\ominus}$ of 39 kcal mol^{-1}.[1] However, beyond the presumed existence of $(CS)_2$ as transient component of the "LASER snow" (polymeric $(CS)_x$) in CS_2 vapor,[2] it has thus far been impossible to obtain unequivocal experimental evidence of the existence of **1**, despite all favorable prognoses. The reason for this is presumably linked with several factors: 1) **1** is stable with regard to unimolecular processes, but it may be very easily attacked by electrophiles, nucleophiles or even radicals. 2) Even if it were possible to find an inert medium there always remains the problem of a suitable precursor and optimal reaction conditions. Intermolecular interactions in a high vacuum, as occur, e.g., in a mass spectrometer, can essentially be ruled out. We report here how **1** can be prepared and characterized using the relatively new method of neutralization-reionization mass spectrometry (NRMS).[3]

Electron impact ionization (70 eV)[4] of 1,3,4,6-tetrathiapentalene-2,5-dione **2**[5] affords as most important fragments $C_2S_n^{\odot\oplus}$ [Eqn. (a)], including the interesting $C_2S_2^{\odot\oplus}$. This is also accessible by 70-eV ionization of **3**, the tetramethyl-substituted dithiodiamide of squaric acid [Eqn. (b)].[6]



The mass selection of $C_2S_2^{\odot\oplus}$ (m/z 88) using B(1)/E (Scheme 1) in a tandem experiment,[7] followed by collisional activation[8] in the third collision chamber (collision gas helium, 80% transmission) furnished by scanning B(2)



Scheme 1. Schematic diagram of the mass spectrometer setup. A = ion source, B = magnetic sector, C = collision chamber, D = deflector electrode, E = electric sector, F = ion detection.

the collisional activation (CA) mass spectrum shown in Figure 1a. Although the CA spectrum of $C_2S_2^{\odot\oplus}$ would, in principle, be consistent with the structures **4**–**7**, we presume, on the basis of the results of ab initio calculations that electron impact ionization of **2** and **3** leads via the bond ruptures indicated by ⓐ [Eqns. (a) and (b)] to the radical cation of **1**, i.e. **4**. Whereas **5** and **6** correspond neither at the UHF/3-21G/3-21G nor the UHF/6-31G*//6-31G* level to stationary points on the energy hypersurface, at the 3-21G level **7** corresponds to a transition struc-

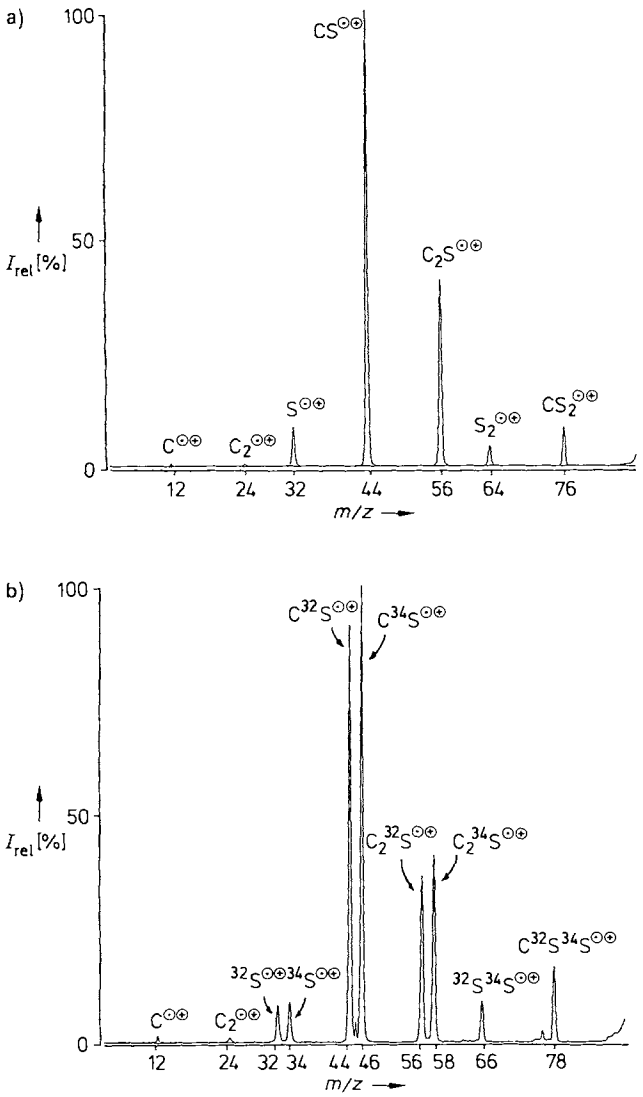

Fig. 1. CA-mass spectra a) of $C_2{}^{32}S_2^{\odot\oplus}$ (*m/z* 88), b) of $C_2{}^{32}S^{34}S^{\odot\oplus}$ (*m/z* 90).

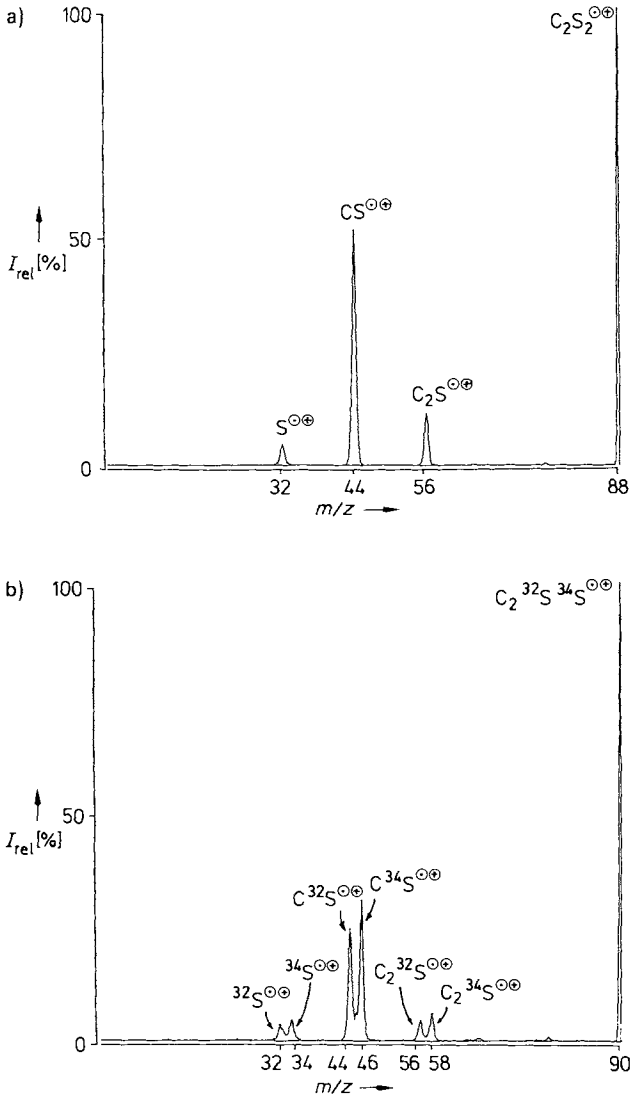

Fig. 2. NR-mass spectra (neutralization with Xe, 90% transmission *T* in the first collision chamber, reionization with O_2, 80% *T* in the second collision chamber; deflection electrode for the deflection of other ions ca. 500 V) a) of $C_2{}^{32}S_2^{\odot\oplus}$, b) of $C_2{}^{32}S^{34}S^{\odot\oplus}$.

ture for the cleavage of atomic carbon from **4**. At the distinctly better 6-31G* level, **7** corresponds to a local minimum, which, however, after taking into consideration the zero point vibration energy, lies 87.2 kcal mol^{-1} higher than the minimum calculated for **4**. Thus, **4** presumably corresponds to the global minimum on the C_2S_2 hypersurface.

Collisional activation of **4** then affords the spectrum reproduced in Figure 1a; the signal for $S_2^{\odot\oplus}$ presumably arises via the sequence $\mathbf{4} \rightarrow \mathbf{6} \rightarrow S_2^{\odot\oplus} + C_2$ or (less likely) via the intermediate $CS_2^{\odot\oplus}$. Also for the formation of this fragment, **4** would have to isomerize under the conditions of the collisional activation.

Remarkable is the isotope effect that can be gleaned from Figure 1b; according to the data ^{32}S is always preferentially cleaved as neutral particle rather than ^{34}S in the collision induced decomposition of $C_2{}^{32}S^{34}S^{\odot\oplus}$ (*m/z* 90). A convincing explanation for the strong isotope effect (up to 10%) (see also Fig. 2b) is still wanting. The signal at *m/z* 45 corresponds to the doubly charged cation $C_2{}^{32}S^{34}S^{2\oplus}$ formed by charge stripping.[9]

Can **4** not only be oxidized to the dication, but also reduced to the previously unknown neutral molecule **1**? The answer is unequivocally yes. The NMR/mass spectra (Fig. 2) not only contain very intense signals for $C_2S_2^{\odot\oplus}$ and for $C_2{}^{32}S^{34}S^{\odot\oplus}$, also the other fragments in the spectra can be readily assigned. What is the constitution of the neutral C_2S_2 thus generated, whose lifetime is at least $t \geq 0.8$ µs (determined by the time of flight from C(1) to C(2) (Scheme 1))? The neutralization is a vertical process,[3] so that if $C_2S_2^{\odot\oplus}$ is present as **4**, C_2S_2 is generated as **1**. This presumption is strengthened by the following findings: 1) The change of geometry in the transition $\mathbf{4} \rightarrow \mathbf{1}$ is, other than in the transition $\mathbf{7} \rightarrow \mathbf{8}$, relatively minor (see 6-31G* geometry parameters in the corresponding molecular structures); this could explain the unusually high fraction of $C_2S_2^{\odot\oplus}$ "survivor" signals in the NR-mass spectrum (Fig. 2a). 2) At the RHF/3-21G//3-21G level, as also at the RHF/6-31G*//6-31G* level, **1** is the most stable of all calculated C_2S_2 structures. The neutral analogues of **5** and **6** do not correspond to any stationary points, and **8** (as triplet) is around 79.4 kcal mol^{-1} less stable than the triplet state of **1** (UHF/6-31G*//6-31G* + ZPVE). Although the basis set used by us is modest in comparison to the "state-of-the-art" basis set used by *Schaefer* et al.,[1] the qualitative results lead to the same conclusions: a) the triplet state

of **1** is more stable than the singlet state; b) **1** is more stable than two monomeric CS molecules.

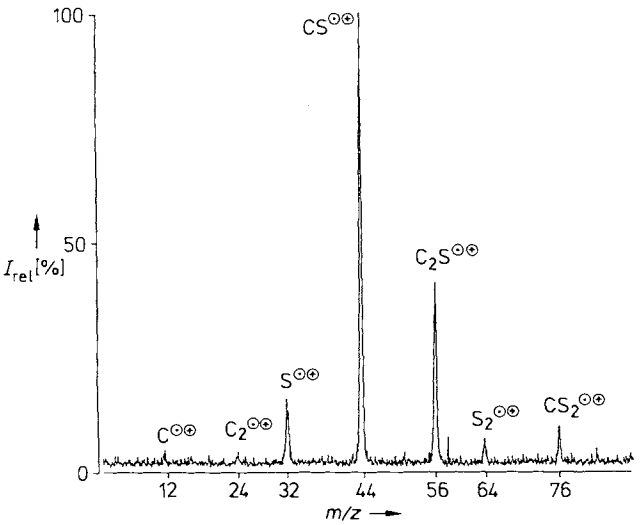

Fig. 3. CA mass spectrum of $C_2S_2^{\odot\oplus}$, generated by the sequence

$C_2S_2^{\odot\oplus} \xrightarrow[90\%\ T]{Xe} C_2S_2 \xrightarrow[80\%\ T]{O_2} C_2S_2^{\odot\oplus} \xrightarrow[80\%\ T]{He}$ products.

In view of the high yields of C_2S_2 in the neutralization step **4**→**1** we have carried out a further experiment. The ion with *m/z* 88 ($C_2S_2^{\odot\oplus}$) generated in the sequence $C_2S_2^{\odot\oplus} \rightarrow C_2S_2 \rightarrow C_2S_2^{\odot\oplus}$ was subjected, with the help of the electric sector E (Scheme 1) to a kinetic energy analysis, and the interference-free $C_2S_2^{\odot\oplus}$ beam (8 keV kinetic energy) was re-excited in the third field-free region in a collision experiment with helium (80% *T*). A CA mass spectrum thus obtained (Fig. 3) basically contains no contributions from reionized neutral particles (N), which, e.g., occur in the reaction $C_2S_2^{\odot\oplus} \rightarrow$ fragment ion + N and can lead to an uncertainty in the interpretation of ordinary NR-mass spectra. The spectrum reproduced in Figure 3 is free of these possible interferences and it is unambiguous, since it contains the characteristic fragments for **4** with the correct relative intensities (cf. Fig. 1a).

Summarizing, it can be established that *Schaefer*'s prognosis[1] "... we are convinced that C_2S_2 is a "makeable" molecule ..." has been verified by the NRMS investigations described here. Obviously other exotic molecules, e.g. the hitherto unknown dimer of carbon monoxide[1] or the only partly investigated molecules of the type $X(C)_nY$ (X, Y: free electron pairs, H_2, O, S; n = 2, 3, 4 etc.)[10] related to C_2S_2 and C_2O_2, which are of interest in astrochemistry, as well as many other transients "produced" by *Hans Bock* and his co-workers,[11] are also possibly detectable by NRMS.

The Structures of Perchloric Acid, $HClO_4$, and Its Anhydride, Cl_2O_7

By *Arndt Simon** and *Horst Borrmann*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Perchloric acid, or, more accurately, the aqueous solution of $HClO_4$, has been known since the beginning of the last century.[1] Numerous crystalline hydrates exist and nearly all of them have been structurally characterized.[2–9] A structure analysis of pure, anhydrous $HClO_4$ itself, however, which melts at −112 °C,[10] is still lacking. It has been concluded, from density measurements in particular, that the dissociation equilibrium

$$3\,HClO_4 \rightleftharpoons Cl_2O_7 + H_3O^{\oplus} + ClO_4^{\ominus}$$

responsible for the intrinsic conductivity of nonaqueous $HClO_4$[11,12] is shifted entirely to the right-hand side at low temperature due to the crystallization of the monohydrate $H_3O^{\oplus}ClO_4^{\ominus}$. In contrast, according to *Mascherpa*,[13] solid $HClO_4$ exists, but undergoes an allotropic phase transition at −103.5 °C and decomposes peritectically at −101.4 °C into the solid hydrate β-$HClO_4 \cdot 0.25\,H_2O$ and Cl_2O_7-rich melts.

Anhydrous $HClO_4$[14] exhibited thermal effects upon warming near −145 °C (exothermic) and −120 °C (endothermic) in DTA experiments. Both effects were accompanied by structural changes which are clearly recognizable in powder patterns recorded with the modified Guinier technique.[15] The low-temperature phases did not reappear upon cooling of the obviously stable form, which melts at −112 °C, and they were not observed with specially purified samples. The melting point of $HClO_4$ was always found to be near −112 °C.

After several attempts, a suitable single crystal of $HClO_4$ could be grown on a diffractometer by slow crystallization a few tenths of a degree below the melting point. The data were collected at −160 °C. The structure was solved in the acentric space group $Pca2_1$ and could be refined including

Heisenbergstr. 1, D-7000 Stuttgart 80 (FRG)

the H positions without encountering any problems.[16] The four crystallographically different $HClO_4$ molecules all exhibit the same typical distortion of the tetrahedral ClO_4 unit. Three Cl-O distances have nearly equal lengths (approx. 142 pm). The fourth is 161 pm. These distances result from a rigid body refinement.[17] Compared to the results of electron diffraction on gaseous $HClO_4$,[18] the averaged single bond Cl-O distance is approx. 3 pm shorter.

The short intramolecular O-H distances of approx. 82 pm[19] already indicate that the bridges between neighboring molecules are weak. The shortest intermolecular O···H distances are 203 pm. In spite of their weakness, these bridges play an important role in the molecular arrangement. There exist rods of H-bridged molecules (Fig. 1a) which form a closest rod packing[20] (Fig. 1b). The rods are connected via very weak H-bridges ($d(O\cdots H) \geq$ 261 pm).

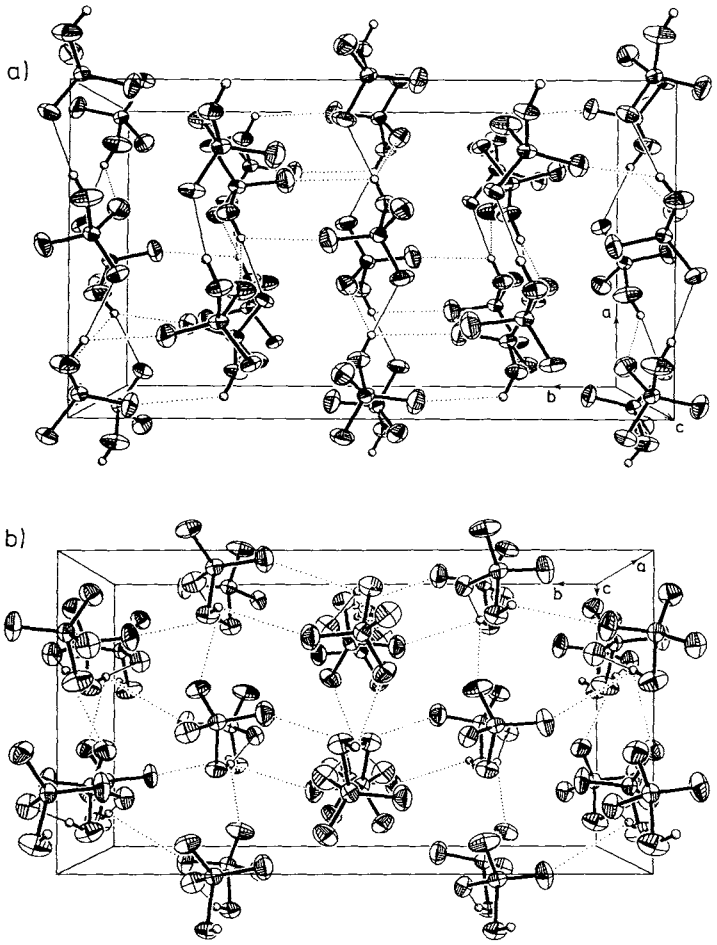

Fig. 1. Projection of the structure of $HClO_4$ onto a) (001) and b) (100). Cl and O atoms are drawn at the 70% probability level, the hydrogen atoms have an arbitrary size. The $HClO_4$ molecules are connected in chains via weak hydrogen bonding [solid lines in (a)]. The chains are arranged in a hexagonal rod packing (b) linked by weaker hydrogen bonds (dotted lines).

The structure analysis shows unambiguously that solid perchloric acid only consists of weakly interacting $HClO_4$ molecules. These are nearly identical in structure with the ClO_3F molecule (d(Cl-O) = 140.4, d(Cl-F) = 161.9 pm[21]).

The literature on the anhydride of the acid, Cl_2O_7, is also controversial about the solid state. A phase transition is said to occur at -100 °C.[22] DTA measurements on Cl_2O_7[23] showed only the effect due to melting at -92 °C. Modified Guinier diagrams, too, exhibit no sign of a phase transition. After some time of X-ray irradiation, only the strongest lines of Cl_2O_6[24] were observed with samples that slowly became yellow.

Growth of a single crystal presented similar problems as in the case of $HClO_4$. It was finally achieved with a slightly contaminated yellow sample. The structure of the compound, which crystallizes in $C2/c$, is shown as a projection along [010] in Figure 2.[25] The molecule consists of two corner-sharing ClO_4 tetrahedra and has C_2 crystallographic symmetry. The Cl-O distances corrected for librational motions of the tetrahedra are 172.3 pm for the bridging O atom and (averaged) 141.6 pm (3×) for the terminal atoms. Compared to $HClO_4$ the long "single bond" distances that involve the bridging O atom are unusual. Such long distances also occur in the Cl_2O molecule measured in the gas phase.[26]

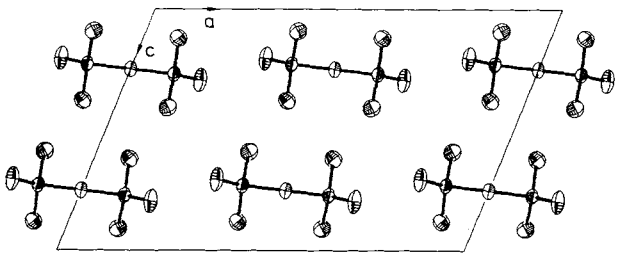

Fig. 2. The structure of Cl_2O_7 projected along [010]. The atoms are drawn at the 70% probability level.

There are significant differences between the structure of Cl_2O_7 and the recently determined structure of Mn_2O_7.[27,28] The distances with the bridging (177 pm) and terminal O atoms (159 pm) respectively do not differ to the same extent as in the structure of Mn_2O_7, and the molecules in the structure of Cl_2O_7 have nearly ideal C_{2v} symmetry. The bond angles, in particular, exhibit significant differences in both structures. The largest deviation of the angles at Mn from ideal tetrahedral is 1.8°. In contrast, in the Cl_2O_7 molecule angles between 98° and 116° occur. The Cl atom is shifted towards the plane formed by the terminal O atoms. This structural detail, as well as the large Cl-O distances for the bridging atom, possibly provides evidence of highly polar bonding in the sense of the formulation $(ClO_3^{\delta\oplus})_2O^{2\delta\ominus}$. Reference to SO_3,[29] which is isoelectronic with $ClO_3^{\oplus}$ and planar in the gas phase, might be helpful in interpreting the structure. Our arguments follow conclusions from an analysis of the distortions of tetrahedral molecules MX_4[30] in terms of ligand dissociation reaction pathways (e.g. $AlCl_4^{\ominus} \rightarrow AlCl_3 + Cl^{\ominus}$). The same kind of distortion is also obvious for $HClO_4$, which exhibits HO-Cl-O angles of between 101.1° and 106.6° without showing a bond lengthening.

In spite of the aforementioned differences the Cl_2O_7 and Mn_2O_7 structures show surprising similarities. In both, the O atoms have an approximately cubic close packed arrangement with occupied adjacent tetrahedral voids ("defect-CaF_2 structure"). Only the special choice of occupied voids is different for both compounds, and, therefore, the extent of shear deformation of the fcc arrangement differs. Whereas the monoclinic angle $\beta = 100.2°$ is near to the value of 98.1° calculated for the undistorted fcc arrange-

ment in Mn_2O_7, one finds rather large deviations ($\beta = 111.8°$ compared to 119.7°) in the case of Cl_2O_7.

A New Approach to Ionic Ozonides**

By *Werner Hesse* and *Martin Jansen**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Ionic ozonides are red, crystalline solids containing the bent molecular anion O_3^-. Only alkali-metal ozonides, which are extremely sensitive to moisture and also thermally labile, have been described so far. Their preparation is particularly difficult, since decomposition and formation reactions are both exothermic. Only recently was a solution to this preparative problem found.[1] We developed a practical procedure involving reaction of the alkali-metal hyperoxides with O_2/O_3 mixtures under controlled-temperature conditions in the sense of a self-organization, followed by extraction of the reaction products with liquid ammonia.

The preparative potential of ionic ozonides is clearly of interest to both solid-state and molecular chemistry. It has not been possible to exploit this potential, however, since, among other things, the alkali-metal salts of ionic ozonides are soluble in only a few solvents. The availability of ozonides of other cations is therefore desirable. Our experience has shown that the formation of O_3^- (from hyperoxide ions and monooxygen) is only possible for alkali-metal compounds without complications in the ozonolysis and purification of the initial products. Accordingly, we prepared the alkali-metal ozonides, which are accessible on a preparative scale, and allowed these to react with salts of the desired cation in a suitable solvent.

Our first success was the preparation of tetramethylammonium ozonide $N(CH_3)_4O_3$ from KO_3 and $N(CH_3)_4O_2$ in liquid ammonia.[2] Surprisingly, the bright red $N(CH_3)_4O_3$ is thermally more stable than all alkali-metal ozonides and does not undergo slow decomposition at room temperature as observed for the alkali-metal salts. We were unable to confirm the contradictory results obtained earlier[3] on apparently very impure samples of $N(CH_3)_4O_3$. The decomposition point (75°C) is above that of CsO_3 (53°C), the most stable ozonide previously known. In contrast to the alkali-metal ozonides, however, $N(CH_3)_4O_3$ is photochemically labile; upon exposure to sunlight, it decomposes within a few hours to give a white, not yet identified crystalline substance.

The result of the X-ray structure analysis,[4] in which all hydrogen atoms were localized and refined, is shown in Figure 1. The relationship with the CsCl structure is readily apparent. Despite this basic agreement with the structure of the alkali-metal ozonides,[1b] there is an important difference which provides an explanation for the different chemical behavior. In the alkali-metal ozonides, the O_3^- groups are arranged in such a way that the intermolecular distances are quite short (e.g., 299.2 pm for RbO_3); the terminal O atoms of each molecule, which bear most of the negative charge, are directed toward the positively polarized bridging oxygen atoms of neighboring ozonide groups. This arrangement is not observed for $N(CH_3)_4O_3$. In this case, the O_3^- dipoles are arranged in an antiferroelectric sense with the shortest intermolecular O–O distances (438.8 pm) being those between terminal oxygen atoms. These long distances, which are clearly due to the

[*] Prof. Dr. M. Jansen, Dipl.-Chem. W. Hesse

Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

larger effective radius of the $N(CH_3)_4^+$ ion compared with the alkali-metal ions, presumably rule out any significant intermolecular interactions.

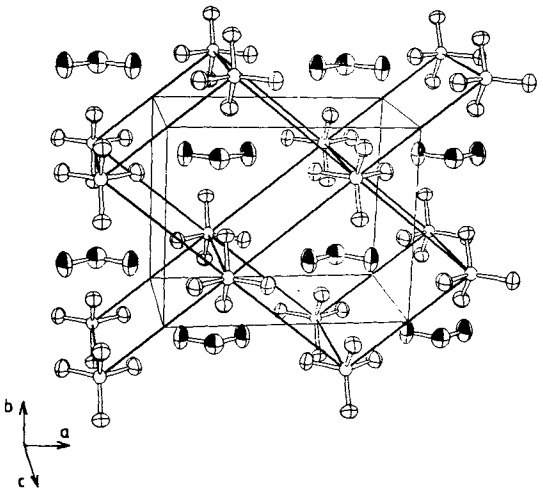

Fig. 1. Perspective drawing of the crystal structure of $N(CH_3)_4O_3$ (H atoms omitted).

The alkali-metal ozonides undergo exothermic decomposition according to the following equation:

$$AO_3 \longrightarrow AO_2 + 1/2\,O_2$$

Oxygen transport in the solid probably involves initial transfer of the oxygen atoms of the O_3^- ions to hyperoxide ions formed on the surfaces. It is easy to imagine how the larger intermolecular O–O distances in the case of $N(CH_3)_4O_3$ make this reaction more difficult and thus may explain its unexpected high thermal stability. This interpretation is supported by the fact that $N(CH_3)_4O_3$ decomposes by a mechanism different from that for the alkali-metal ozonides. MS and DTA/TG investigations indicate that the first step is an oxidative attack on the cation, resulting in exothermic formation of the white crystalline substance mentioned above, which, above ca. 100 °C, decomposes into gaseous products, identified by mass spectrometry as $N(CH_3)_3$, CO, O_2, H_2O, $(CH_3)_2O$, CH_3OH, and C_3H_7NO (possibly DMF).

The synthesis and structural elucidation of $N(CH_3)_4O_3$ demonstrate, for the first time, the stability of the O_3^- ion in the presence of cations other than alkali-metal ions. The surprisingly high stability, which is mainly determined by the intermolecular O–O distances, points the way toward the synthesis of even more stable ozonides.

[2] KO_3 and $N(CH_3)_4O_2$ (1 mol each) were each placed, with exclusion of moisture, in one leg of an H tube containing a frit. Subsequently, 15 mL of liquid ammonia was condensed onto each substance. Mixture of the red KO_3 solution and the colorless $N(CH_3)_4O_2$ solution resulted in the formation of a cloudy solution owing to precipitation of KO_2. The red $N(CH_3)_4O_3$ solution thereby obtained was decanted through the frit of the H tube to separate it from the poorly soluble KO_2. Slow evaporation of the ammonia yielded red, transparent crystals of $N(CH_3)_4O_3$ in nearly quantitative yield.

3- and 3,6-Silylated 2-Pyridinethiols: New Hindered Bidentate Ligands and Their Novel Silver and Copper Clusters**

By *Eric Block,* Michael Gernon, Hyunkyu Kang,* and *Jon Zubieta**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Thiolate ligands are of great current interest in tailor-making models for enzyme active sites, new conducting materials, and structurally unusual metal complexes.[1] We have demonstrated that the range of available thiolate ligands can be substantially increased through attachment of single or multiple silyl functions to methanethiol, ethane-1,2-dithiol, and thiophenol, affording new structures such as **1**–**5**.[2] To this list we now add 3- and 3,6-

$(Me_3Si)_3C\text{-}SH$ $Me_3SiCH(SH)CH(SH)SiMe_3$ $HSCH_2SiMe_2CH_2SH$

silylated 2-pyridinethiols **6** and **7**, respectively, which can be directedly prepared from the parent compound and which afford novel clusters with Cu^I and Ag^I. Although a characteristic feature of the chemistry of Cu^I and Ag^I with thiolate ligands is the occurrence of polymeric materials and large clusters,[1] the introduction of bulky substituents onto the thiolate unit modifies the tendency of thiolates to bridge the metal sites and allows the isolation of mononuclear or low oligomeric complexes.[3,4,5] The substituted 2-pyridinethiolate ligand presents both a bulky substituent to sterically impede the aggregation process and an addi-

tional ligating functionality, the pyridine nitrogen, which should dramatically affect the coordination geometry. The choice of R_3Si as the bulky substituent offers the additional advantage of control of size through variation of R. The complexes **8** and **9**, whose preparation and structure

$[Cu_6(SC_5H_3NSiMe_3)_6]$ **8** $[Ag_6(SC_5H_3NSiMe_3)_6]$ **9**

we report, represent unique examples of MS_2N coordination and novel examples of hexanuclear thiolate clusters for these metals. Significantly, in the absence of the bulky silyl substituent, 2-pyridinethiol itself affords only polymeric materials in reactions with Cu^I and Ag^I under conditions affording clusters with **6a**.

By the one-pot reaction of 2-pyridinethiol with lithium diisopropylamide (LDA) and addition of chlorotrimethylsilane, followed by sublimation or recrystallization of the product from benzene, **6a** can be conveniently prepared on a large scale in 55% yield.[6] Similar sequences afford **6b** (45%) and **6c** (36%); surprisingly, use of the same conditions with the more hindered *tert*-butylchlorodimethylsilane and *tert*-butylchlorodiphenylsilane gives bis-silylated compounds **7a** (52%) and **7b** (37%).[6] Treatment of **6a** with LDA followed by chlorotriethylsilane gave bis-silylated compound **7c** (28%).[6] The ^{13}C NMR data for **6**–**7**[6] is consistent with a significant structural contribution from the thioamide form. Deuteration studies are more in keeping with *S*-silylation of 2-pyridinethiol followed by C-3 deprotonation[7a] and an Si–S to Si–C shift[7b] rather than direct formation of a dilithio species.[4]

Reactions of the ligand **6a** with Cu^I or Ag^I precursors yield isomorphous structures **8** and **9**.[8] The hexanuclear complexes, as illustrated in Figure 1 for **8**, possess $2/m$ symmetry with pseudo threefold axes passing through the centroids of the two M_3S_3 rings of both structures. The overall geometry of this type of cluster is best described as a molecular paddlewheel, a structure reminiscent of the cyclophanes.[9] The central cylinder of the paddlewheel consists of the two M_3S_3 heterocyclic rings, with the $-C_5H_3N(SiMe_3)$ fragments of the ligands providing the six paddles. The M_3S_3 units are distinctly crown-shaped rather than planar and are staggered with respect to each other.

The six substituted pyridinethiolate ligands bridge the two M_3S_3 rings, alternating such that three thiolate donors

Relevant bond lengths [Å] and angles [°] for the isostructural silver complex **9** (not shown): Ag1-S1 2.479(2), Ag1-S2b 2.479(2), Ag1-N2 2.312(9), Ag2-S2 2.474(2), Ag2-N1 2.300(6), Ag1-Ag2 3.323(1); S1-Ag1-N2 117.0(2), S2-Ag2-N1 118.6(2); S2-Ag2-S1b 124.8(2); Ag1-S1-Ag1a 83.9(1), Ag2-S2-Ag2a 77.4(1).

and three pyridine donors are presented to each ring. The thiolate sulfur atoms bridge adjacent metal sites within an M_3S_3 ring, while a pyridine nitrogen completes the pseudo trigonal-planar geometry about each metal site. The distortions from idealized trigonal-planar geometry are primarily a consequence of the inequivalence of the donor groups in the MS_2N coordination sites, with no significant metal-metal interactions (Cu1···Cu2, 3.139(1) Å; Ag1···Ag2, 3.323(1) Å).

While analogous structures for anionic Cu^I and Ag^I structures of the types $[M(SR)_2]^{\ominus}$,[3] $[M_5(SR)_6]^{\ominus}$,[10–12] and $[M_5(SR)_7]^{2\ominus}$[13] have been described, neutral homoleptic complexes of Cu^I and Ag^I do not present analogous structural types,[4,5] a feature which appears to be a consequence of the pronounced tendency of Ag^I centers to participate in secondary interactions with thiolate donors, resulting in higher oligomers.[5] The substituted pyridinethiolate ligand has been designed specifically to preclude secondary interactions at the metal sites and to favor small molecular cages. The bulky $-SiMe_3$ substituent prevents close approach of additional [M(SR)] units required in the formation of large oligomers or polymeric materials, while the presence of the additional ligand functionality, the pyridine nitrogen, serves to satisfy the coordination requirements of the metal atoms, obviating the need for secondary interactions.

The structural consequences of the sterically constraining Me_3Si substituent are dramatically illustrated by a

comparison of compounds **8** and **9** with the materials isolated from reactions of Cu^I and Ag^I with the parent 2-pyridinethiolate. Although 2-pyridinethiol has been demonstrated to form a variety of molecular complexes with transition-metal cations,[14, 15] under conditions similar to those employed for the syntheses of **8** and **9**, polymeric materials are formed exclusively with Cu^I and Ag^I. The isolation of the molecular clusters **8** and **9** is thus attributed to the introduction of the steric constraints associated with the Me_3Si substituent.

Experimental Procedure

6a: A solution of 2-pyridinethiol (2.2 g, 20 mmol) in dry THF (30 mL) was added slowly under argon to a stirred THF (100 mL) solution of LDA at 0°C prepared from iPr_2NH (6.1 g, 60 mmol) and nBuLi (25 mL of 2.5 M solution; 62 mmol). The solution was stirred at 0°C for 2 h, quenched with Me_3SiCl (8.7 g, 80 mmol), and stirred for a further 6 h at room temperature. The reaction was quenched with water (5 mL) and then concentrated in vacuo. The organic residue was taken up in CH_2Cl_2 (200 mL), the organic phase was washed two times with water (100 mL), the solvent was removed under vacuum, and the yellow solid was washed with hexane and then recrystallized from benzene. Yield 2.0 g (55%); m.p. 194–195°C (after sublimation at 110°C/0.5 torr).

9: Addition of a solution of $AgNO_3$ (0.170 g, 1 mmol) in acetonitrile (10 mL) to a solution of **6a** (0.183 g, 1 mmol) in acetonitrile (10 mL), followed by triethylamine (0.101 g, 1 mmol), led to immediate formation of a white precipitate. After stirring for 15 h, the resultant solution was concentrated giving a white solid. The solid was dissolved in CH_2Cl_2 (7 mL) and filtered to remove impurities, and the filtrate was slowly diluted with acetonitrile (7 mL). After several days, pale yellow crystals were collected and recrystallized from CH_2Cl_2/CH_3OH. Yield 0.152 g (52%); dec. >200°C.

8: A procedure similar to that described above using $[Cu(CH_3CN)_4]PF_6$ in CH_3OH, followed by recrystallization from CH_2Cl_2/CH_3OH (3:1, v/v), afforded **8** as orange, block-shaped crystals. Yield 75%; dec. >190°C.

Reactions of Pentacarbonyl(trichloromethyl isocyanide)chromium**

By *Gerhard Beck* and *Wolf P. Fehlhammer**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

We have recently shown that the radical alkylation of cyano complexes opens up a surprisingly simple and efficient route to the synthesis of complex-stabilized α-haloalkyl isocyanides [Eq. (a), $CHCl_2R$ as solvent; R = H,

$$[Cr(CN)(CO)_5]^{\ominus} + ArylN_2^{\oplus} + CHCl_2R \longrightarrow [(OC)_5CrCNCCl_2R] + ArylH + N_2 \quad (a)$$

Cl].[1] The chemistry of pentacarbonyl(trichloromethyl isocyanide)chromium **1** (Scheme 1) has now revealed a surprising and unusual isocyanide reactivity together with a high mobility of the α-chloro atoms. Although it is possible, in some cases, to limit the reaction to the trichlorome-

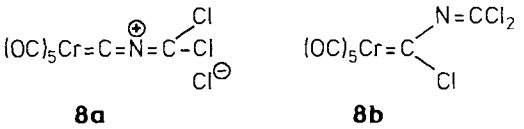
HNR_2 in excess, 2. dioxane-H_2O.—**13**, **15**: HSEt in excess, NEt_3.—**14**: $MeHN(CH_2)_2NHMe$.—**16** (R = H, Me): $HSCH_2CHRSH$, NEt_3.—**17** (n = 2, 3): $H_2N(CH_2)_nNH_2$ in excess.—**19** (R = e.g., adamantyl, $CH_2CH{=}CH_2$, CH(Me)Et, $CH_2CH_2NCCr(CO)_5$): RNH_2 in excess.

thyl group of **1** and thereby obtain new functional isocyanides (cf. point 1), most reactions occur at the two electrophilic centers (C^1, C^3) jointly; i.e., the trichloromethyl isocyanide ligand reacts like a masked azaalleniumylidene or even like a dichlorocarbene equivalent, affording a broad variety of carbene, heterocycle, and isocyanide complexes (Scheme 1).

1. Reductions of **1** proceed relatively unspecifically but the isocyano function remains intact. Reaction with zinc in aprotic medium leads to a product mixture from which the alkenyl isocyanide complexes **2** and **3** were isolated along with other products.[2,3] Similar CC coupling products are formed upon reaction of **1** with iron carbonyl. On the other hand, the main product of the reaction with cobalt carbonyl is the isocyanomethylidyne-bridged tetranuclear cluster $[(OC)_5CrCN{-}C[Co(CO)_3]_3]$ ("permetalated methyl isocyanide").[4] The replacement of Cl by H dominates in protic solvents; with PPh_3 in ethanol, this process can be stopped at the stage of the dichloromethyl isocyanide **4**; with zinc in glacial acetic acid, complete reduction to the methyl isocyanide complex **5** occurs.

Even slight changes in the reaction conditions lead to the formation of organophosphorus ligands (**6**, **7**) with interesting possible uses in synthesis: for example, **7**, which is also accessible via a different route,[5] opens up a simple approach to the synthesis of alkenyl isocyanides and diverse triphenylphosphonio-substituted five-membered heterocycles.[5,6]

2. In contrast to reducing agents or organometallic bases and phosphanes (cf. point 1), N and S nucleophiles attack the isocyanide carbon atom and simultaneously cause the departure of a chloride ion from the trichloromethyl group. Examples of such products, which are best explained as arising from one of the two isomeric forms **8** (azaallenium chloride **a** or chlorocarbene **b**) of the trichloromethyl isocyanide starting complex **1**, are the molecules **9** and **10**. The analogy between **1** and complexes of the allenylidene type $[L_nM{=}C^1{=}C^2{=}C^3R_2']$ becomes even more obvious from the identical preferences of the corresponding electrophilic centers C^1 (for O and N nucleophiles) and C^3 (for P nucleophiles).[7]



8a **8b**

An X-ray structure analysis (Fig. 1)[8] has been carried out for the deep dark-green heterobinuclear complex **10** prepared from **1** and $[Mn(CN)(Cp)(CO)_2]^{\ominus}$. It reveals the presence of a novel isocyanocarbene bridging ligand which

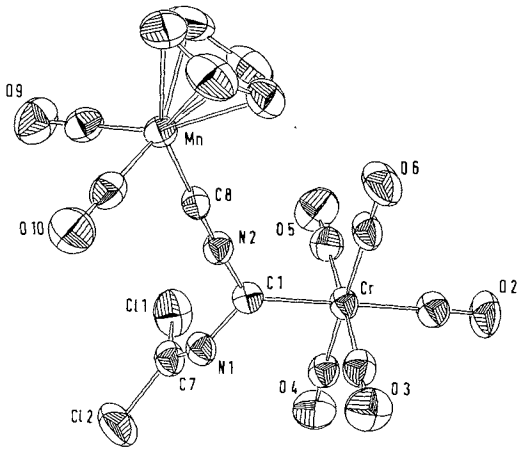


Fig. 1. Molecular structure of **10**, space group $P\bar{1}$, $a = 8.949(1)$, $b = 11.122(2)$, $c = 11.763(2)$ Å, $\alpha = 109.68(1)$, $\beta = 102.33(1)$, $\gamma = 110.22(1)°$, $V = 959.6$ Å^3, $Z = 2$, 3246 measured reflections, 2902 observed ($I > 2\sigma(I)$), 273 refined parameters, $R = 0.031$, residual electron density < 0.40 e Å^{-3}. Important bond lengths [Å] and bond angles [°]: Cr-C1 2.012(4), C1-N1 1.397(3), N1-C7 1.232(4), C1-N2 1.332(4), N2-C8 1.196(4), Mn-C8 1.796(3); C1-N1-C7 127.9(3), C1-N2-C8 172.9(4) [8].

contains both a linear and a bent CNC unit sharing the carbene carbon atom. Both forms are under current discussion in connection with the bonding in 2-azaallenium compounds[9] and imino-substituted carbene complexes.[10] Interestingly, the isocyano function, which is known for its ability to stabilize carbanions, is also most effective in carbene (carbenium) stabilization in **10**, thus confirming predictions on this matter made on the basis of MO theory.[11] On the other hand, the contribution of the dichloroisocyanide substituent to the stabilization remains small, despite its nearly perpendicular orientation with respect to the carbene plane—the N2-C1-N1-C7 torsion angle is 82.0°—which would be ideal for an $n_\pi(N1)$-$p_\pi(C1)$ bond.

3. When amine or thiol is used in excess, a second molecule of the nucleophile is incorporated into the azomethyne part of the polyfunctional ligand. In this way, the complexes **11**, **13**, and **14** are obtained. Under hydrolytic conditions, however, carbamoyl isocyanide complexes **12** can also be formed. The X-ray structure analysis of **14** (Fig. 2)[8] shows that its seven-membered ring is folded along C7–C9, a conformation also observed for metal-free triazepane derivatives.[12] In contrast to **10**, however, the again very different $C_{carbene}$–N distances are due to the constrained coplanar arrangement of the N2-C1-N1-C7 unit in the ring, which rules out an interaction of the lone pair on N1 with the $C_{carbene}$ p_z orbital.

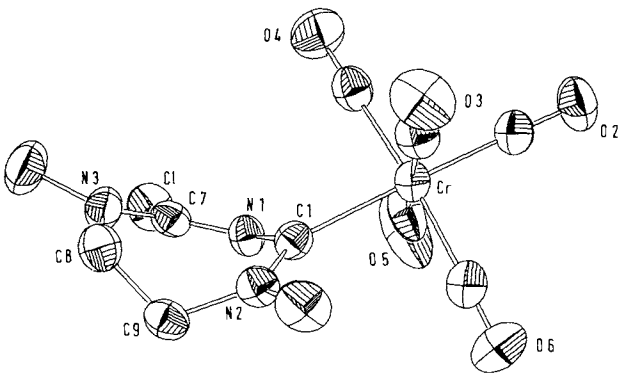

Fig. 2. Molecular structure of **14**. Yellow rhombs from chloroform (−25°C); crystal dimensions, 0.35 × 0.20 × 0.30 mm³; triclinic, space group $P\bar{1}$, $a = 8.079(4)$, $b = 9.845(5)$, $c = 10.495(4)$ Å, $\alpha = 92.32(3)$, $\beta = 110.21(3)$, $\gamma = 105.24(4)°$, $V = 749.9$ Å³, $Z = 2$, 2839 measured reflections, 2429 observed ($I > 2\sigma(I)$), 230 refined parameters, $R = 0.032$, residual electron density < 0.39 e Å^{-3}, H positions isotropically refined. Selected bond distances [Å] and bond angles [°]: Cr-C1 2.114(3), C1-N1 1.389(3), C1-N2 1.329(4), N1-C7 1.275(3), N2-C9 1.467(4); Cr-C1-N1 113.1(2), Cr-C1-N2 131.0(1).

4. Reactions with $EtSH/NEt_3$, dithiols, or primary diamines result in a further degradation of the complex-bound trichloromethyl isocyanide: in the molecules **15**–**17**, only the isocyanide carbon atom is left, i.e., $CNCCl_3$ reacts like dichlorocarbene, which as such is not available in a pentacarbonylchromium complex. In the reaction giving the dithiocarbene complex **16**, 1,3-dithiolane imine **18**

18

was isolated. Thus, at least in this case, information regarding the fate of the leaving group "$NCCl_3$" was obtained. The following reaction sequence, alternating between the electrophilic centers C^1 and C^3, thus emerges:

- "Carbene addition" of the nucleophile NuH followed by HCl elimination
- Cl/Nu substitution(s) on the dichloromethylene group
- Nucleophilic addition at C^1 once again and elimination of a carbonic acid derivative $HN{=}C(Nu)_2$

As in the synthesis of **10**, however, redox steps may be involved before or during certain stages of this reaction sequence.

5. Complex **1** also acts as a dichlorocarbene equivalent toward primary amines, effecting the spontaneous formation in high yields of a wide variety of isocyanide complexes **19**, including those containing sterically demanding, functional, chiral, or divalent isocyanide ligands (see caption to Scheme 1). We reported earlier[13] on similar interconversions of nonfunctional isocyanides, whereby an auxiliary agent ($COCl_2$) was required. It is remarkable that these complex-based isocyanide syntheses ($[L_nMC{\equiv}N{-}R] \rightarrow [L_nMC{\equiv}N{-}R']$ do not imply substitutions at the isocyanide nitrogen atom; instead, the CN triple bond is successively broken with ensuing bond formation to the newly entering amino nitrogen atom.

Experimental Procedure

7 (R = R' = Ph): First water (0.07 mL) and then triphenylphosphane (2.40 g, 9.16 mmol) were added to a vigorously stirred solution of **1** (1.00 g, 2.97 mmol) in a mixture of diethyl ether (40 mL) and acetonitrile (15 mL). Within a few minutes, small bright yellow crystals began to separate from the yellow-red solution thus formed. The crystals were collected by filtration after 1–2 h and dried under vacuum. Yield after recrystallization from dichloromethane/diethyl ether: 710 mg (45%) **7** (dec. at 170°C).

9 (2 R = $(CH_2)_4$): **1** (800 mg, 2.39 mmol) was dissolved in 30 mL of diethyl ether and the resulting solution was treated with pyrrolidine (339 mg, 4.76 mmol), resulting in the immediate formation of a white precipitate. After 24 h, the precipitate was collected and washed with a small amount of ether and all volatiles were removed under vacuum. The residue was dissolved in petroleum ether and purified by column chromatography ($l = 20$ cm, $d = 2$ cm; Merck, 0.063–0.200 mm). Elution with petroleum ether/diethyl ether (40 : 1 v/v) gave **9** as a pale yellow band; the eluate was concentrated until the onset of crystallization. At −25°C, 647 mg (73%) of bright yellow needles (m.p. 77–78°C) was obtained.

10: A solution of **1** (760 mg, 2.26 mmol) in a mixture of 20 mL of dichloromethane and 10 mL of acetonitrile was treated with $Na[Mn(CN)(Cp)(CO)_2]$ (500 mg, 2.22 mmol); the color of the reaction solution turned from yellow to red-violet. The solvent was removed, the residue was extracted with a small amount of diethyl ether, and the ether phase was chromatographed on silica gel (15 × 22-cm column). The blue fraction thereby obtained was subjected to thin layer chromatography (silica gel/petroleum ether) to remove small amounts of $[(OC)_5CrCN]_2CCl_2$ and **3**. Concentration and cooling of the petroleum ether solution to −78°C yielded **10** as green leaflets and black needles (m.p. 98–100°C).

19: In a typical experiment, **1** (650 mg, 1.93 mmol) was dissolved in 20 mL of ether and treated with an excess of primary amine; the solution was then stirred for 18 h at room temperature. The solvent was removed, the residue was extracted three times with 20 mL of petroleum ether, and the concentrated petroleum ether phases were chromatographed on silica gel (15 × 2-cm column, petroleum ether). The colorless product fraction was detected by IR spectroscopy and, after removal of the eluent, the product was sublimed (cold finger: −5°C) or purified by recrystallization from petroleum ether. Yield 50–90%.

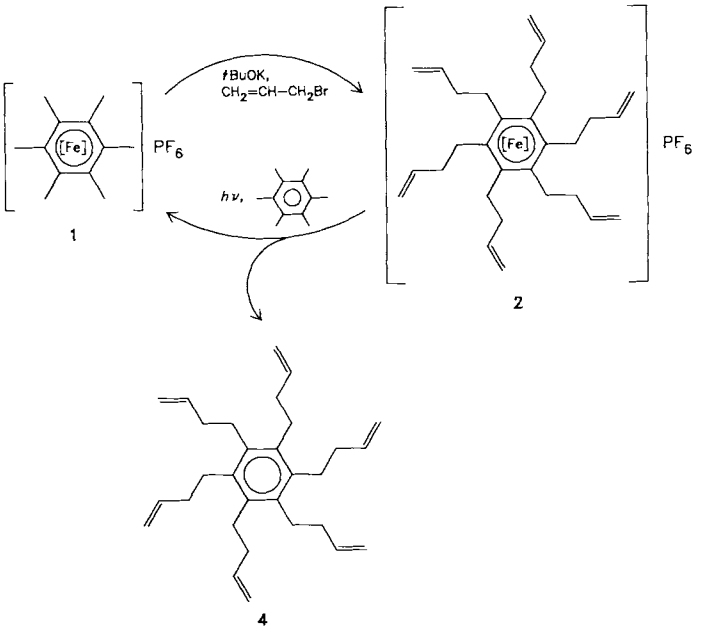
Tentacled Iron Sandwiches**

By *Françoise Moulines** and *Didier Astruc**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

The synthesis of hexasubstituted benzene derivatives has attracted attention for more than 50 years.[1-4a] Friedel-Crafts reactions were first employed, followed by the reaction of hexakis(bromomethyl)benzene or hexakis(thiomethyl)benzene[1] and the transition-metal-catalyzed trimerization of alkynes.[2] Now, we report a method providing the first hexafunctionalization of a transition-metal-arene complex in one step, and we illustrate the possibilities of chain design in a series of "tentacled" sandwich molecules containing a reversible redox center.

Hexaalkylation of $[Fe^{II}Cp(C_6Me_6)]PF_6$ **1** is known to proceed with *t*BuOK and CH_3I, giving $[Fe^{II}Cp(C_6Et_6)]PF_6$,[4a,b] but extension to higher RX fails when the alkyl chain bears β-hydrogens because dehydrohalogenation is faster than alkylation.[4c] We find that the reaction of the readily available complex **1** with *t*BuOK and allyl bromide in THF yields the hexabutenylbenzene complex **2** quantitatively (Scheme 1, 4-mmol scale).[5] Recrystallization from acetone/pentane (1/3) after chromatography on silica with CH_2Cl_2 gives yellow crystals of **2** in 75% yield. Spectroscopic and electrochemical data for **2** are given in Table 1. The Fe^{II} center[6] of **2** can be reduced with complete chemical and electrochemical reversibility



Scheme 1. [Fe] = $(\eta^5\text{-}C_5H_5)Fe^{\oplus}$.

Table 1. Spectroscopic and electrochemical data [a] of the new compounds. Correct elemental analyses were obtained for **2**–**7**.

2: ^1H NMR (CD_3CN): δ=5.8-6.1 (6H; CH=CH_2), 5.1-5.28 (12H; CH=CH_2) [b], 4.65 (5H; C_5H_5), 2.9-3 (12H; ArylCH_2), 2.35-2.45 (12H; ArylCH_2–CH_2–) [c].—^{13}C NMR (22.63 MHz, CD_3COCD_3): δ=137.7 (CH=CH_2), 116.03 (CH=CH_2), 103.9 (C_6R_6), 79.2 (C_5H_5), 35.7, 30.5 (ArylCH_2–CH_2). E^0 = −1.42 V [d]

3, mixture of stereoisomers: ^1H NMR (CD_3CN): δ=4.88, 4.87, 4.85, 4.80 (5H; C_5H_5), 4.54 (br., 6H; CHBr), 4.05, 3.9 (br., 12H; CH_2Br), 3.15-2.94 (br., 12H; ArylCH_2), 2.44, 2.25 (br., 12H; ArylCH_2–CH_2).—^{13}C NMR (22.63 MHz, $CDCl_3$): δ=103.1-103.6 (C_6R_6), 79.74, 79.58 (C_5H_5), 62.34, 52.72 (CHBr), 38.75, 37.94 (ArylCH_2–CH_2), 29.80 (CH_2Br)

4: ^1H NMR ($CDCl_3$): δ=5.89-5.98 (6H; CH=CH_2), 5.01-5.17 (12H; CH=CH_2) [c], 2.63-2.71 (12H; ArylCH_2), 2.24-2.29 (12H; ArylCH_2–CH_2) [c].—^{13}C NMR (50.3 MHz, $CDCl_3$) [e]: δ=138.4 (CH=CH_2), 136.8 (C_6R_6), 114.78 (CH=CH_2), 35.9 (ArylCH_2–CH_2), 29.7 (ArylCH_2)

5: ^1H NMR ($CDCl_3$, based on comparison with $[CH_3(CH_2)_7Si(CH_3)]_2O$): δ=4.55 (s, 5H; C_5H_5), 2.75 (br., 12H; ArylCH_2), 1.58 (br., 24H; ArylCH_2–$(CH_2)_2$), 1.27 (br., 72H; $(CH_2)_6$), 0.88 (t, 18H; CH_2–CH_3), 0.56 (br., 24H; CH_2–SiCH_2), 0.01 (36H; CH_3–Si–CH_3).—^{29}Si NMR ($CDCl_3$): δ=2.85.—^{13}C NMR (50.2 MHz, $CDCl_3$) [e]: δ=103.45 (C_6R_6), 77.9 (C_5H_5), 33.99, 32.33, 29.66, 29.59, 29.14, 22.95 ((CH_2)$_6$), 36.02, 25.22 (ArylCH_2–$(CH_2)_2$), 30.75 (ArylCH_2), 15.56, 15.50 (CH_2–Si–CH_2), 14.37 (CH_2–CH_3), 3.11 (CH_3–Si–CH_3). E^0 = −1.34 V [d]

6: ^1H NMR (CD_3COCD_3): δ=4.85 (5H; C_5H_5), 3.9 (br., 6H; OH), 3.63 (br., 12H; CH_2OH), 2.97 (br., 12H; ArylCH_2), 1.76 (br., 24H; ArylCH_2–$(CH_2)_2$.—^{13}C NMR (50.3 MHz, CD_3COCD_3) [e]: δ=104.43 (C_6H_6), 78.53 (C_5H_5), 61.49 (CH_2–OH), 30.94 (ArylCH_2), 33.77 (ArylCH_2–CH_2–CH_2), 28.84 (ArylCH_2–CH_2). E^0 = −1.475 V [f], −1.72 V [d]

7: ^{13}C NMR (22.63 MHz, $CDCl_3$): δ=166.8 (O–CO), 133.5)*p*-C of CO–C_6H_5), 133.2 (*i*-C), 129.8 (*m*-C), 128.8 (*o*-C), 102.75-103.75 (C_6R_6), 78.5 (C_5H_5), 64.4 (CH_2–O), 30.9, 29.7, 28.6 (Aryl$(CH_2)_3$). E^0 = −1.45 V [d]

8: ^{13}C NMR (50.3 MHz, $CDCl_3$) [e]: δ=173.8 (O–CO), 103.5 (C_6R_6), 81.5 (C_5H_5), 64.1 (CH_2–O), 36.6 (CO–CH_2), 33.2, 29.7, 28.13 (Aryl$(CH_2)_3$), 18.7 (CO–CH_2–CH_2), 14.0 (CH_3).—[g]

9: ^1H NMR (CD_3COCD_3): δ=3.4-3.7 (br., 18H; CH_2–OH), 2.5-2.8 (br., 12H; ArylCH_2), 1.1-1.9 (br., 24H; ArylCH_2–$(CH_2)_2$).—^{13}C NMR (22.63 MHz, CD_3OD): δ=137.7 (C_6R_6), 62.7 (CH_2OH), 34.24, 30.47, 29.23 (Aryl$(CH_2)_3$)

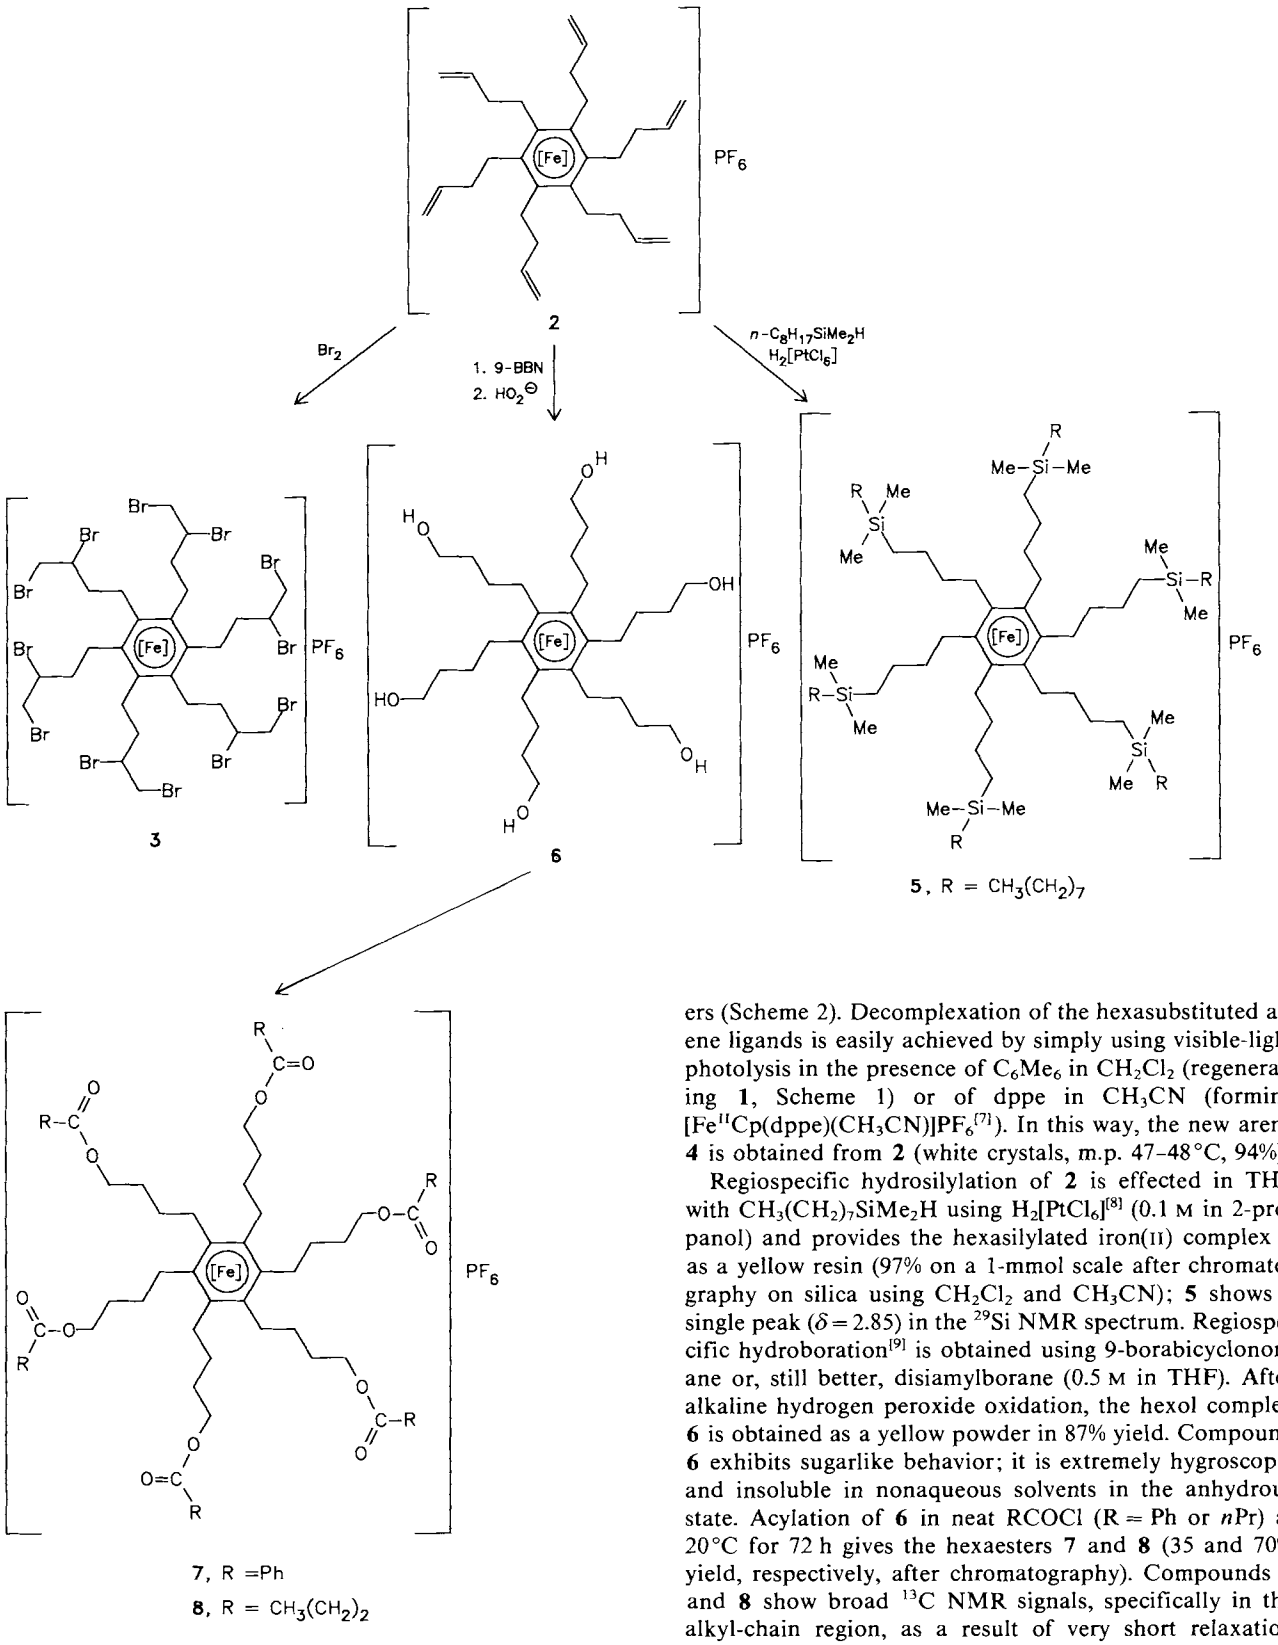
[a] 200-MHz ^1H NMR, $^{13}C\{^1H\}$ NMR, and 39.73-MHz $^{29}Si\{^1H\}$ NMR spectra with Me_4Si as standard; cyclic voltammetry vs. SCE, reversible. For **2**, **3**, and **9**, ^{13}C off resonance spectra were also recorded. [b] The ABX pattern of the terminal double bond appears by spin decoupling on the protons of the CH_2 group in β position. [c] Spin decoupling. [d] Hg or Pt cathode, dimethylformamide, 0.1 M $nBu_4N^{\oplus}BF_4^{\ominus}$. [e] INEPT and selective spin decoupling. [f] Hg cathode, aqueous 1 M LiOH. [g] The ^{13}C NMR spectra and elemental analyses indicate slight decomplexation.

[*] Ing. F. Moulines, Prof. D. Astruc
Laboratoire de Chimie Organique et Organométallique
Université de Bordeaux I
351 Cours de la Libération, F-33405 Talence Cedex (France)

[**] We thank *M. Petraud* and *B. Barbe* (CESAMO) for NMR assistance, *M.-H. Desbois* for helpful experiments, and the CNRS (ATP grant No. 959.278).

to Fe^{I} at $E^{0} = -1.42$ vs. SCE; the Fe^{I} state can also be generated using Na/Hg in THF (ESR at 77 K: $g_x = 2.0087$, $g_y = 2.0414$, $g_z = 1.8475$). On the other hand, **2** is extremely robust toward oxidation. Thus, reaction with Br_2 does not lead to decomplexation, but rather results in addition of Br_2 to the six double bonds, giving the golden hexakis(3,4-dibromobutylbenzene)(cyclopentadienyl)iron(II) complex **3** in quantitative yield as a mixture of fourteen stereoisomers (Scheme 2). Decomplexation of the hexasubstituted arene ligands is easily achieved by simply using visible-light photolysis in the presence of C_6Me_6 in CH_2Cl_2 (regenerating **1**, Scheme 1) or of dppe in CH_3CN (forming $[Fe^{II}Cp(dppe)(CH_3CN)]PF_6$[7]). In this way, the new arene **4** is obtained from **2** (white crystals, m.p. 47–48 °C, 94%).

Regiospecific hydrosilylation of **2** is effected in THF with $CH_3(CH_2)_7SiMe_2H$ using $H_2[PtCl_6]$[8] (0.1 M in 2-propanol) and provides the hexasilylated iron(II) complex **5** as a yellow resin (97% on a 1-mmol scale after chromatography on silica using CH_2Cl_2 and CH_3CN); **5** shows a single peak ($\delta = 2.85$) in the ^{29}Si NMR spectrum. Regiospecific hydroboration[9] is obtained using 9-borabicyclononane or, still better, disiamylborane (0.5 M in THF). After alkaline hydrogen peroxide oxidation, the hexol complex **6** is obtained as a yellow powder in 87% yield. Compound **6** exhibits sugarlike behavior; it is extremely hygroscopic and insoluble in nonaqueous solvents in the anhydrous state. Acylation of **6** in neat RCOCl (R = Ph or *n*Pr) at 20 °C for 72 h gives the hexaesters **7** and **8** (35 and 70% yield, respectively, after chromatography). Compounds **7** and **8** show broad ^{13}C NMR signals, specifically in the alkyl-chain region, as a result of very short relaxation times typical of structural organizations found in discotic



Scheme 2. [Fe] = $(\eta^5\text{-}C_5H_5)Fe^{\oplus}$.

liquid crystals.[10] Decomplexation of **6** can be effected as indicated above for **2** to provide the hexol $C_6[(CH_2)_3CH_2OH]_6$, **9** (white crystals, m.p. 115–120°C, 76% yield), which is hygroscopic and insoluble in nonaqueous solvents.

Phosphane-Stabilized Cu^I and Ag^I Silanes

By *Alan H. Cowley,* Tammy M. Elkins, Richard A. Jones,** and *Christine M. Nunn*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Amides,[1] phosphides,[2] and alkyls[3] of Cu^I have been prepared and found to be tetrameric in the solid state. Interestingly, the corresponding Cu^I silanes have not been reported. Silyl cuprates of the general type $[(R_3Si)_2Cu]Li$ are, of course, well known[4] and find increasing utility as organic reagents. However, such compounds are prepared in situ and structural information is unavailable. To the best of our knowledge, no compounds are known with Ag–Si bonds.[5]

Our first attempts to synthesize Cu^I silanes were not successful. Thus, the reaction of $(Me_3Si)_3SiLi$ or Ph_3SiLi with CuCl in THF solution did not result in tractable products. However, treatment of a THF solution of CuCl with one equivalent of Ph_3SiLi and three equivalents of Me_3P resulted, after recrystallization from toluene, in yellow crystals corresponding to the composition **1**. The ^{31}P NMR chemical shift for **1** ($\delta = -43.4$) is indicative of coordinated Me_3P ligands and the ^{29}Si NMR chemical shift ($\delta = -21.5$) seems reasonable for a Ph_3Si–metal moiety.[6]

$[Ph_3SiCu(PMe_3)_3]$ **1**

Department of Chemistry, The University of Texas at Austin
Austin, TX 78712 (USA)

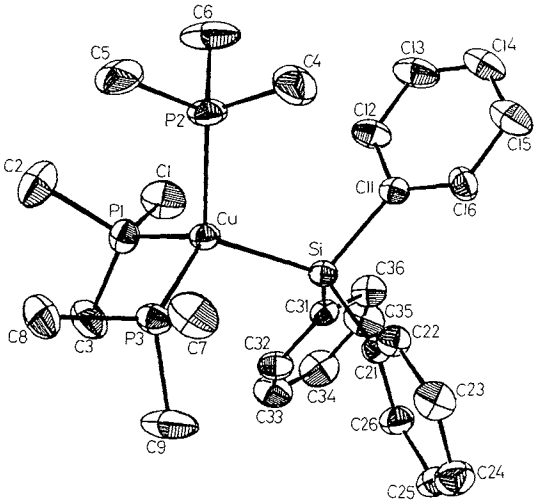

Fig. 1. Structure of **1** in the crystal. Selected bond lengths [Å] and angles [°]: Cu-Si 2.340(2), Cu-P1 2.278(3), Cu-P2 2.278(2), Cu-P3 2.273(2); P1-Cu-P2 107.0(1), P1-Cu-P3 108.11, P1-Cu-Si 112.09(7), P2-Cu-P3 105.70(8), P2-Cu-Si 111.38(8), P3-Cu-Si 112.17(8), Cu-Si-C11 113.6(2), Cu-Si-C21 114.9(2), Cu-Si-C31 117.5(3), C11-Si-C21 104.1(3), C11-Si-C31 102.8(3), C21-Si-C31 102.2(3).

An X-ray analysis[7] showed that, in the solid state, **1** (Fig. 1) consists of individual molecules with no short intermolecular contacts. The geometry around Cu is approximately tetrahedral and comprises three Me_3P ligands and a Ph_3Si group. The geometry at Si is also approximately tetrahedral. We are not aware of any previous measurement of a Cu–Si bond length, which in **1** (2.340(2) Å) is somewhat longer than the sum of the covalent radii (2.28 Å). This may be due, at least in part, to steric interactions, because the Cu–P distances are at the high end of the range established for this linkage. Moreover, the P–Cu–P and C–Si–C angles are smaller than the remainder of the bond angles at Cu and Si. It would be interesting to compare the structure of **1** with that of the isoelectronic complex $[(Me_3P)_3NiPPh_3]$.[8] Unfortunately, however, the structure of the latter has not been determined. The coordination of three Me_3P ligands in **1** provides an 18-electron configuration at Cu and avoids the formation of (presumably weak) Cu–Si–Cu three-center, two-electron bonds.

$[Ph_3SiAg(PMe_3)_3]$ **2**

A similar procedure was employed for the preparation of the analogous silver compound **2**. Unfortunately, crystals of **2** were not suitable for X-ray diffraction study. However, the ^{31}P ($\delta = -48.2$) and ^{29}Si ($\delta = -21.5$) NMR chemical shifts for **2** are very similar to those for **1**. Moreover, the ^{13}C and ^1H NMR data (see *Experimental Procedure*) are in accord with the proposed formula. Finally, the EI mass spectrum (70 eV) of **2** exhibits peaks corresponding to $(Me_3P)_3Ag$ and Ph_3Si fragments.

Experimental Procedure

1: THF solutions of Ph_3SiLi (7.02 mmol) and Me_3P (21.06 mmol) were added simultaneously to a solution of CuCl (0.7 g, 7.07 mmol) in THF (40 mL) at −78°C. The reaction mixture became yellow-brown and a small amount of black precipitate formed. After stirring the reaction mixture for 1 h at 0°C, it was warmed to 25°C and the solvent and volatiles were removed in vacuo. The resulting residue was dissolved in toluene, filtered, concentrated, and allowed to stand at −20°C. Yellow, crystalline **1** formed in 65% yield. ^1H NMR (300 MHz, C_6D_6, TMS ext.): $\delta = 0.74$ (s, 27H; Me), 7.1, 7.2, 7.7 (each br. m, 15H; C_6H_5).—$^{13}C\{^1H\}$ NMR (75.5 MHz, C_6D_6, TMS ext.): $\delta = 18.5$

(br.; Me), 125.4, 126.8, 136.6 (each s, C_6H_5).—$^{31}P\{^1H\}$ NMR (121.5 MHz, C_6D_6, 85% H_3PO_4 ext.): $\delta = -43.4$ (br. s).—^{29}Si NMR (59.6 MHz, C_6D_6, TMS ext.): $\delta = -21.5$ (s). A similar method to the foregoing was used for the preparation of yellow, crystalline **2** in 70% yield. ^1H NMR (300 MHz, C_6D_6, TMS ext.): $\delta = 0.84$ (d, 27 H, $^2J(PH) = 6.0$; Me), 7.1, 7.2, 7.9 (each m, 15 H; C_6H_5).—$^{13}C\{^1H\}$ NMR (75.5 MHz, C_6D_6, TMS ext.): $\delta = 15.7$ (d, $^1J(PC) = 5.3$ Hz; Me), 126.8, 127.1, 136.9 (each s, C_6H_5).—$^{31}P\{^1H\}$ NMR (121.5 MHz, C_6D_6, 85% H_3PO_4 ext.): $\delta = -48.2$ (br. s).—^{29}Si NMR (59.6 MHz, C_6D_6, TMS ext.): $\delta = -21.5$ (*m*). Silver-phosphorus and silver-silicon couplings were not resolved.

First Direct Evidence for Nitrile Imine–Diazo Isomerization. Synthesis of Relatively Stable *N*-Silylated Nitrile Imines**

By *Michel Granier, Antoine Baceiredo,* and *Guy Bertrand**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Transient nitrile imines, first prepared by *Huisgen* et al.,[1] have been widely used in organic synthesis. Depending on the nature of the carbon and nitrogen substituents, it has been shown by matrix spectroscopy that these 1-3 dipolar species could undergo rearrangements into carbodiimides or azines,[2] fragmentations into nitriles and nitrenes[2a] or intramolecular cyclization.[3] The possible existence of a diazomethane–nitrile imine equilibrium was reported in the sixties,[4] but was later considered to be highly controversial.[5] Nitrile imine–diazo rearrangements have been postulated[6] to explain the nature of the products obtained in the thermolysis of potential nitrile imine precursors; however, the nitrile imines have never been observed and apart from one case[6a] the resulting diazo derivatives were also not stable under the experimental conditions used. Here we wish to report the synthesis of relatively stable *N*-silylated nitrile imines and several examples of nitrile imine–diazo isomerization.

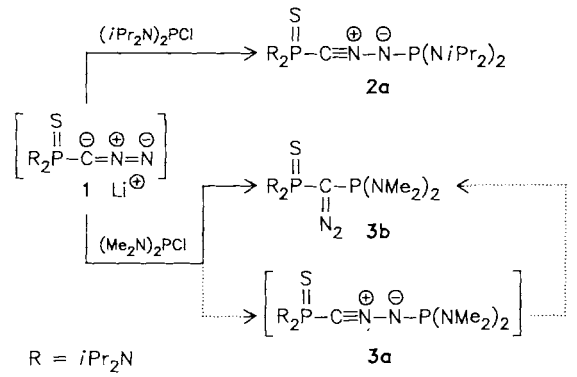
Laboratoire des Organométalliques, U.A. 477
Université Paul Sabatier
118, route de Narbonne, F-31062 Toulouse Cédex (France)

[**] We thank Drs. *I. Tkatchenko, Y. Dartiguenave* and *M. Dartiguenave* (Laboratoire de Chimie de Coordination du CNRS, Toulouse) for providing us with laboratory facilities after the destruction, on March 25, 1987, of the chemistry building at the Université Paul Sabatier.—In our previous paper on nitrile *oxides* (G. Sicard, A. Baceiredo, G. Groco, G. Bertrand, *Angew. Chem. 100* (1988) 289; *Angew. Chem. Int. Ed. Engl. 27* (1988) 301, an important literature reference should be added: H. Dahn, B. Favre, J.-P. Leresche, *Helv. Chim. Acta 56* (1973) 457.



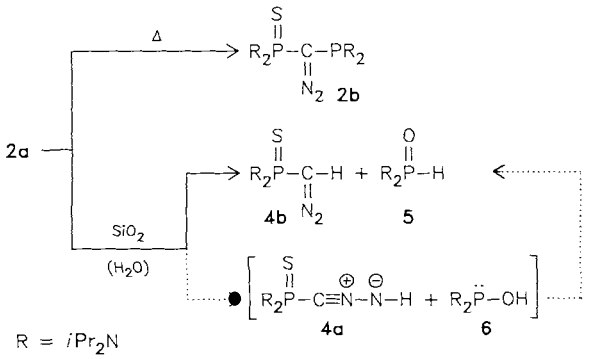
Recently, we prepared the first stable nitrile imine **2a** (m.p. 100 °C)[7] by reaction of the lithium salt of diazomethylthiophosphonic bis(diisopropylamide) **1** with chlorobis(diisopropyl)aminophosphane. In contrast, when the chlorobis(dimethylamino)phosphane was used, the diazo derivative **3b** was obtained in 87% yield and all attempts to trap the possible intermediate **3a**, even at −78 °C, failed (Table 1).

Table 1. ^{31}P-NMR and IR spectroscopic data for the nitrile imines (**a** series) and diazomethanes (**b** series). The ^{31}P-NMR spectra were recorded at 32.438 MHz in THF or $CDCl_3$, the IR spectra in THF or $CDCl_3$.

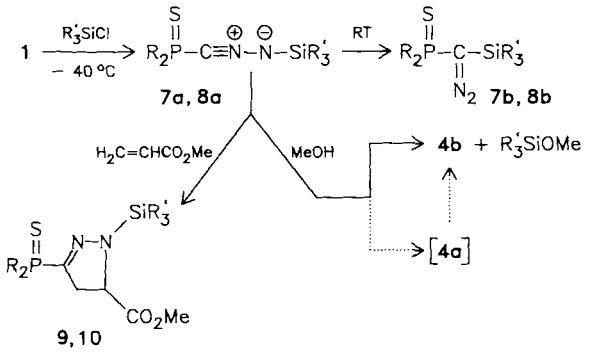
	^{31}P NMR [a] δ (J [Hz])	IR $\tilde{\nu}$ [cm^{-1}]
2a	35.4, 99.9 (5.25)	2040 (br., s)
2b	74.5, 72.8 (140.10)	2028
3b	63.4, 106.0 (104.94)	2035
4b	57.6	2080
7a	32.5	2010 (br., s)
7b	65.8	2050
8a	31.1	2120 (br., s)
8b	59.5	2100

These results might indicate that N or C substitution occurs at the diazo moiety, depending on the steric hindrance of the chlorophosphane. However, when a chloroform solution of nitrile imine **2a** is heated at 55 °C for 6 hours the phosphino(thiophosphinoyl)diazomethane **2b** is obtained in almost quantitative yield. Moreover, although **2a** is not very sensitive to water, filtration on silica gel affords diazomethylthiophosphonic bis(diisopropylamide) **4b** (82% yield) and the phosphane oxide **5** (89% yield). It is reasonable to postulate a phosphorus–nitrogen bond hydrolysis of **2a**, leading to nitrile imine **4a** and the hydroxyphosphane **6**, followed by subsequent isomerization to **4b** and **5**.

As reported by *Bock* et al.[8] and *Wentrup* et al.,[2c] *N*-silyl substituents prevent most intramolecular isomerizations.



We have therefore investigated the reaction of the lithium salt **1** with chlorotrimethylsilane and chlorotriphenylsilane.[9] After workup, we obtained the diazo derivatives **7b** (90% yield) and **8b** (82% yield), respectively. However, when the reactions were monitored by spectroscopy, the *N*-silylated nitrile imines **7a** and **8a** were characterized at $-40°C$. Compared with the spectroscopic data for the diazo derivatives (**2b**, **3b**, **4b**, **7b**, **8b**), nitrile imines (**2a**, **7a**, **8a**) show a ^{31}P-NMR chemical shift at high field and an extremely broad IR absorption (see Table 1). **7a** is only stable in solution below 0°C, but **8a** is still observable after a few hours, at room temperature. The nitrile imines **7a** and **8a** react with methylacrylate to give the expected [2+3] adducts **9** and **10**, respectively, in good yield.[10,11] With methanol the diazo compound **4b** is obtained in 92% yield along with quantitative amounts of methoxytrimethyl- and methoxytriphenylsilane. This last reaction is analogous to that observed upon filtration of **2a** over silica gel, and probably involves the primary formation of nitrile imine **4a**.



7, **9**: R = iPr_2N, R' = Me
8, **10**: R = iPr_2N, R' = Ph

These results as a whole strongly suggest that, in contrast to what is generally admitted, nitrile imines (**a** series) are the kinetic products of the electrophilic attack of diazolithium salts such as **1**, whereas the isomeric diazo derivatives (**b** series) are the thermodynamic products. The stability of nitrile imines is strongly dependent on the steric hindrance of the nitrogen substituent.

Reactivity of (*R*)-2-*tert*-Butyldihydrooxazole Derivatives Prepared from Serine and Threonine: Novel, Versatile Chiral Building Blocks

By *Dieter Seebach** and *Gerhard Stucky*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Two years ago we reported on the preparation of methyl (*R*)-2-*tert*-butyldihydrooxazole-3-carboxylate **1** from (*S*)-serine, using electrolytic decarboxylation as a key step.[1] The heterocycle **1**, and its methyl derivative **2**, prepared from (*S*)-threonine, are readily available on a 100-g scale,[2] so that their reactivity and use as chiral building blocks could be studied. A preliminary account of some surprising results of this investigation is given here.

Both olefinic carbon atoms of **1** can be caused to react with electrophiles. Lithiation at C-4 (→ **3**)[3] and addition of methyl chlorocarbonate or acetone give products **4** and **5**, respectively, while direct Vilsmeier formylation and Friedel–Crafts acetylation occur on C-5 (see compounds **6**–**10**). Hydrogenation of the double bond in the products thus obtained, **4**, **7**, and **8**, is highly stereoselective, with formation of the *cis*-disubstituted heterocycles **11**, **12**, and **13**, respectively. These results show (1) that the cyclic *N,O*-acetal **1** is quite stable under both nucleophilic and elec-

A **B**

Strong diastereofacial bias is also observed in cycloadditions to the double bond of **1**. Thus, reaction with tetracyanoethylene or osmium tetroxide or cyclopropanation (via the Simmons–Smith or Makosza reactions or by Cu^{II}-induced decomposition of ethyl diazoacetate) gave bicyclic products **14**–**19** with the *tert*-butyl group on the *exo* face (bromine/lithium exchange with the dibromocarbene adduct **18** was *endo*-selective and furnished the products **20**–**23** with electrophiles). Also, Lewis acid-catalyzed cycloaddition of 4-methyl-2-oxo-3-pentenonitrile[6] to **1** and Diels–Alder reaction of the diene **10** with maleic anhydride[7] gave the bicyclic and tricyclic products **24** and **25**, respectively, in a single diastereomeric form. Subsequent reactions such as the catalytic hydrogenation of the double bond in **25** (→**26**) and the acid-catalyzed ring opening of the oxaspiropentane derivative **23** (→**27**) were highly selective. Some of the reactions that we carried out with the 5-methyl derivative **2** are evident from the product structures **28**–**31**.

Table 1. Data of the products **4**–**31** and comments on the corresponding reactions. The yields given are those of recrystallized products. The specific rotations were measured in chloroform with a concentration of ca. 1. When the ratio of diastereoisomers (*d.r.*) is not given, the isomer illustrated in the text was formed in >50:1 ratio (high-field NMR, crude product).—TEBACl = benzyltriethylammonium chloride, LDA = lithium diisopropylamide.

Starting material	Conditions and comments	Product	Yield [%]	M.p. [°C]	$[\alpha]_D$

[a] Two isomers (7:3), epimeric at the α-CO position, readily separated by chromatography. [b] Mixture of diastereoisomers. [c] Solvent acetonitrile. [d] The crude product was directly used for the next step.

Table 1 contains the yields, melting points, and specific rotations of the products obtained from the dihydrooxazoles **1** and **2**, along with some information about the reaction conditions. All compounds were fully characterized by IR, NMR, and MS spectra and by elemental analyses. The configurational assignments rest upon NOE measurements. The surprising structure of the solvolysis product **27** was determined by X-ray diffraction.[8] Centers whose absolute configuration has not been determined with certainty so far are not specified.

A New Cubane Cluster with the $[MoFe_3S_4]^0$ Core and Possible Relevance to the Fe_3-Centers in Ferredoxins. The Synthesis, Structure and Properties of the $[Fe_3S_4(SEt)_3Mo(CO)_3]^{3\ominus}$ Anion**

By *Dimitri Coucouvanis,* Saleem Al-Ahmad, Athanasios Salifoglou, W. Richard Dunham,* and *Richard H. Sands*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Interest in the coordination chemistry of Fe/S and Fe/Mo/S clusters derives mainly from the importance of such clusters in biomolecules like the non-heme iron proteins (ferredoxins) and the nitrogenases. The former are essential for many biological electron transfer processes and the latter are involved in the catalytic reduction of small substrate molecules (N_2, H_2, C_2H_2, etc.).

The heterometallic clusters with cubane structure $[MoFe_3S_4]^{3\oplus}$ cores and have been obtained by solvolysis of the doubly-bridged double-cubane **2**.[2] The latter are formed in reactions of the clusters **3**[3] with 3,6-disubstituted catecholate ligands (R_2'cat).

[**] This research was supported by a grant from the National Institutes of Health (GM-26671).

$[MoFe_3S_4(SR)_3(R_2'cat)L]^{2\ominus}$ **1**
L = CH_3CN, DMF, DMSO

$[MoFe_3S_4(\mu_2\text{-}SR)(SR)_2(R_2'cat)]_2^{4\ominus}$ **2**

$[Mo_2Fe_7S_8(\mu_2\text{-}SR)_6(SR)_6]^{3\ominus}$ **3**

On the basis of ^{57}Fe Mössbauer isomer shift data, the clusters **1** are described[4] as formally containing $Fe^{+2.67}$ and Mo^{+3} ions. These clusters display magnetic ground states[1] ($S = 3/2$), and Mo K-edge EXAFS[5] similar to those reported for nitrogenase;[6,7] however, they are deficient in Fe content and do not qualify as stoichiometric structural analogues for the Fe/Mo/S active site. For the latter, both spectroscopic results[6] and chemical analyses[8] suggest an Fe/Mo ratio of at least 6:1. In our search for Fe/Mo/S clusters as possible structural analogues for the center in nitrogenase we have shown that a new type of Fe/Mo/S clusters (**4**) can be obtained[9] by coordination of $Mo(CO)_3$ fragments to the hexagonal faces of the $(Fe_6S_6L_6')^{n\ominus}$ prismanes.[10]

$[(Fe_6S_6L_6')(Mo(CO)_3)_2]^{n\ominus}$ **4**

These clusters, that show the same deficiency in Fe content as the $MoFe_3$ cubanes, also can be obtained (L' = Cl) by the condensation of three $[Fe_2S_2(Cl)_4]^{2\ominus}$ dimers[9e] in the presence of **5**.[11]

$[Mo(CO)_3(CH_3CN)_3]$ **5**

This reaction, which may be taking place on $Mo(CO)_3$ "template" units, prompted us to investigate the possible rearrangement of the known $[Fe_3S_4(SEt)_4]^{3\ominus}$ linear trimers **6**[12] in the presence of "$Mo(CO)_3$". The reaction of **6** (as Et_4N-salt) with **5**[11] in CH_3CN, in a 1:1 molar ratio, proceeds readily [Eqn. (a)] and the crystalline product **7**[13] is isolated in 62% yield after recrystallization from CH_3CN/ether.

$$\underset{\mathbf{6}}{[Fe_3S_4(SEt)_4]^{3\ominus}} + \mathbf{5} \longrightarrow \underset{\mathbf{7}}{[Fe_3S_4(SEt)_3Mo(CO)_3]^{3\ominus}} + 1/2\,EtSSEt \quad (a)$$

Cyclovoltammetric measurements of **7** (Pt electrode, CH_2Cl_2, vs. SCE) show two one-electron reversible waves at -0.36 V and -0.89 V that correspond to the $7^{2\ominus}/7^{3\ominus}$ and $7^{3\ominus}/7^{4\ominus}$ redox couples. The Mössbauer spectra of **7** ($T = 120$ K, vs. Fe) can be deconvoluted into two quadrupole doublets with a 2:1 intensity ratio. The isomer shift (IS) and quadrupole splitting are 0.37(2) and 0.76 mm s^{-1}, respectively, for the higher intensity doublet, and 0.46(2) and 0.95 mm s^{-1}, respectively, for the lower intensity doublet. The 2:1 site ratio, which corresponds to crystallographically imposed C_s symmetry, has already been observed previously[4] in clusters with $[MoFe_3S_4]^{3\oplus}$ cores. For FeS_4 tetrahedral units the IS values for Fe^{III} and Fe^{II} are 0.25 and 0.70 mm s^{-1}, respectively, and the change in isomer shift that accompanies an Fe valence change of 1 is ca. 0.45 mm s^{-1}. Furthermore, for a cluster with n electronically equivalent Fe atoms, a change in oxidation level of 1 would correspond roughly to a change in IS values of $1/n(0.45)$.[9e] Under these empirical rules, the average IS value of 0.40 mm s^{-1} for **7** would indicate that the Fe atoms are in a +2.67 formal oxidation state. The similarity in the Fe formal oxidation levels in the $[MoFe_3S_4]^0$ core of

7 and in the $[MoFe_3S_4]^{3\oplus}$ cores reported previously suggests that, while the latter probably contains Mo^{III}, the former contains zerovalent Mo. The C–O stretching vibrations in 7 observed at 1750 and 1864 cm^{-1} are also consistent with the presence of Mo^0 and indicate the rather poor π-accepting properties of the $[Fe_3S_4(SR)_3]^{3\ominus}$ "ligand".

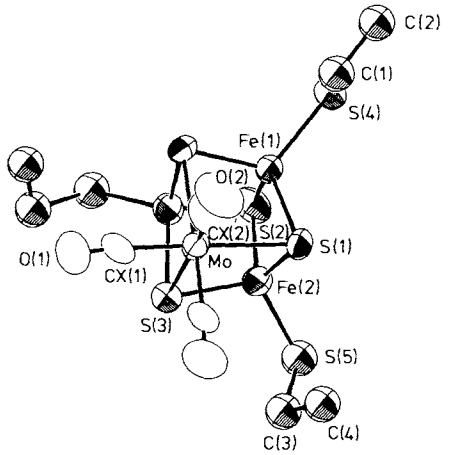

Fig. 1. Structure and atomic labeling of 7 [14]. Thermal ellipsoids as drawn by ORTEP represent the 40% probability surfaces. The thermal ellipsoids for the S(5) and C atoms of the SEt terminal ligands have been drawn smaller for clarity.

The structure of 7 has been determined[14] and the anion (Fig. 1), contains the same basic $[MoFe_3S_4]$ structural unit previously found in other similar cubane clusters.[1] A closer examination of the crystallographic data (Table 1), reveals some rather unusual structural features. In comparison to the $[MoFe_3S_4]^{3\oplus}$ cores in the clusters reported by *Holm* et al.,[1] the $[MoFe_3S_4]^0$ core in 7 has undergone a trigonal elongation that is a consequence of weak $Mo(CO)_3$–Fe_3S_4 bonding interactions that are apparent in the rather long Mo–S bonds and Mo–Fe distances in 7. The Mo–S bonds of ca. 2.63 Å are longer than the weak Mo–S bonds in the adducts **4** (L′ = Cl)[9] (ca. 2.57 Å for n = 3 and ca. 2.61 Å for n = 4). Similarly, the Mo–Fe distances in 7 (ca. 3.25 Å) are significantly longer than those in the adducts **4** (L′ = Cl): ca. 2.93 Å for n = 3 and ca. 2.99 Å for n = 4. The Mo–S and Mo–Fe bonds in 7 are too long and do not resemble those determined by EXAFS for either the Fe/Mo/S site in nitrogenase[7] or for the $[MoFe_3S_4]^{3\oplus}$ cores.[5]

We suggest that 7 can best be described as a weak complex of the $Mo(CO)_3$ unit and the $[Fe_3S_4(SR)_3]^{3\ominus}$ cluster. The latter could be considered as the first synthetic analog of one of the proposed[15] models for the reduced form of the Fe_3S_4 center in *A. vinelandii*. The $[CoFe_3S_4]$[16a] and $[ZnFe_3S_4]$[16b] cubane derivatives of the Fe_3S_4 center in *D. Gigas* ferredoxin II (Fd II) are obtained by the addition of $Co^{2\oplus}$ or $Zn^{2\oplus}$ to dithionite-reduced Fd II. The "oxidized" form of the $[CoFe_3S_4]$ derivative formally contains $[Co^{II}\,Fe^{II}Fe_2^{III}]$, shows Mössbauer parameters similar to those found for 7, and is characterized by a $S = 1/2$ ground state.

Solutions of pure 7 in CH_3CN are EPR silent at temperatures as low as 9 K. In contrast, partially oxidized solutions of 7 show an EPR spectrum characteristic of a $S = 3/2$ ground state, with signals at $g = 5.8$, 3.16 and 1.98. Preliminary analysis of the spectrum indicates $D > 0$ and an E/D ratio of 0.18. At present we are pursuing the synthesis and characterization of this oxidation product as well as of other derivatives of 7.

Table 1. Selected bond lengths [Å] and angles [°] in 7 and **1** (R = Et, R′ = Cl, L = CH_3CN).

	7		$[MoFe_3S_4(SEt)_3(Cl_4cat)(CN)]^{3\ominus}$ [a]

Convenient Routes to Di-*tert*-butylsilanediyl: Chemical, Thermal and Photochemical Generation**

By *Philip Boudjouk,** *Upasiri Samaraweera, Ratnasabapathy Sooriyakumaran, Jerzy Chrusciel,** and *Kevin R. Anderson*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

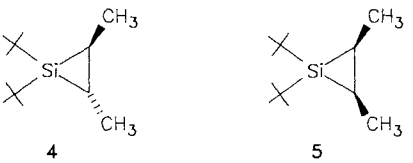
Although the chemistry of the silanediyls is well developed and of continuing interest,[1] there are few convenient methods for generating these species on a preparative scale. We had need for a variety of methods for making di-*tert*-butylsilanediyl (**2**) and in this communication we report three convenient routes for generating this intermediate, possibly in a complexed form like **8**, in high yields.[2]

2 has been proposed as a product of the photolyses of hexa-*tert*-butylcyclotrisilane[3] and di-*tert*-butylsilyldiazide.[4] We have found [Eqn. (a)] that when di-*tert*-butyldichlorosilane (**1a**) and lithium in THF in the presence of excess of triethylsilane, were irradiated with ultrasonic waves using an ultrasonic cleaning bath, the di-*tert*-butylsilanediyl insertion product 1,1,1-triethyl-2,2-di-*tert*-butyldisilane (**3**) was isolated in 60% yield.[5] The same product was obtained in comparable yields from **1b** and **1c**. This is the first example of a metal-promoted α-elimination of dihalosilanes on a preparative scale.

$$t\mathrm{Bu_2SiX_2} + \mathrm{Li} \xrightarrow{)))} [t\mathrm{Bu_2Si:}] \xrightarrow{\mathrm{Et_3SiH}} \mathrm{Et_3Si{-}SiH}t\mathrm{Bu_2} \qquad \text{(a)}$$

1a, X = Cl; **1b**, X = Br; **1c**, X = I — **2** — **3**

We have investigated the reactions of **1a** and lithium with other trapping agents and in the absence of a quenching agent. With *trans*-butene for example, 1,1-di-*tert*-butyl-*trans*-2,3-dimethylsilirane (**4**), was isolated in 65–70% yield. None of the *cis* isomer was detected by gas chromatography. When *cis*-butene was used as a trap, 1,1-di-*tert*-butyl-*cis*-2,3-dimethylsilirane was also isolated in 65–70% yield.[6] A small amount (<5%) of **4** was detected along with **5** but was understood to arise from the presence of 2–5% *trans*-butene in our samples of *cis*-butene.



4 **5**

The siliranes **4** and **5** (Table 1) are rare examples of isolable siliranes with hydrogen substituents on the ring carbon atoms. They are surprisingly stable, surviving distillation (65 °C/4 torr) and exposure to dry methanol. They are, however, very reactive towards water and oxygen. Upon thermolysis (200 °C, benzene, sealed tube) both siliranes produce di-*tert*-butylsilanediyl **2** and only one butene. The silanediyl produced in this fashion can also be trapped with Et_3SiH to give **3** in 72–84% yields.

$$\mathbf{4}\ (\mathbf{5}) \xrightarrow[C_6H_6]{200\,^\circ C} \mathbf{2} \xrightarrow{\mathrm{Et_3SiH}} \mathbf{3} + \textit{trans}\text{-butene}\ (\textit{cis}\text{-butene}) \qquad \text{(b)}$$

Table 1. Characteristic data of the compounds **4**–**7**. 90-MHz ^{1}H-NMR, 90-MHz ^{13}C-NMR and 90-MHz (**7**), 400-MHz (**4**, **5**), and 300-MHz (**6**) ^{29}Si-NMR spectra in C_6D_6 ($CDCl_3$ for **7**) with TMS as standard.

4: ^{1}H NMR: $\delta = 1.63$ (d, $J = 6$ Hz, 6H, CH_3), 1.23 (s, 18H, *t*Bu), 0.80 (m, 2H, CH); ^{13}C NMR: $\delta = 16.66$ (CCH_3), 17.4 (CCH_3), 19.7 ($C(CH_3)_3$), 30.9 ($C(CH_3)_3$); ^{29}Si NMR (benzene-d^6): $\delta = -43.92$; MS: 198 ($M^{\oplus}$, 4%), 141 ($M^{\oplus} - t$Bu, 15%). Elemental analysis was obtained on the methanol addition product.

5: ^{1}H NMR: $\delta = 1.55$ (d, $J = 6$ Hz, 6H, CCH_3), 1.23 (m, 2H, CH), 1.3, 1.13 (each s, each 9H, *t*Bu). ^{13}C NMR: $\delta = 10.02$ (CCH_3), 10.22 (CCH_3), 18.51, 20.7 ($C(CH_3)_3$), 29.91, 31.47 ($C(CH_3)_3$).—^{29}Si NMR: $\delta = -53.21$; MS: *m/z* 198 ($M^{\oplus}$, 4%), 141 ([$M^{\oplus} - t$Bu], 13)

6: ^{1}H NMR: $\delta = 1.13$ (s, 18H, *t*Bu), 0.36 (s, 18H, $SiMe_3$).—^{13}C NMR: $\delta = 184.9$ (C=C), 31.1 ($C(CH_3)_3$), 28.0 ($C(CH_3)_3$), 0.22 ($SiMe_3$).—59.6-MHz ^{29}Si NMR: $\delta = -12.78$ ($SiMe_3$), −86.16 ($SitBu_2$).—MS: *m/z* 312 ($M^{\oplus}$, 64%), 297 ([$M^{\oplus} - 15$], 11), 255 ([$M^{\oplus} - t$Bu], 76); correct C,H analysis was obtained on the methanol addition product

7: ^{1}H NMR: $\delta = 1.33$ (s, 18H, $C(CH_3)_3SiH$), 1.40 (s, 36H, tBu_2Si), 4.00 (s, 2H, SiH).—17.9-MHz ^{29}Si NMR: $\delta = -35.77$ (Si(H)*t*Bu), 31.15 (tBu_2Si).—MS: *m/z* 456 ($M^{\oplus}$), 400 ($M^{\oplus} - 56$); correct C,H analysis for $C_{24}H_{56}Si_4$

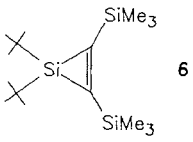
[**] This work was supported by the United States Air Force of Scientific Research (Grant No. 84-0008). *J. C.* was visiting research fellow in Fargo. The authors thank Prof. *N. Woolsey* for the ^{29}Si-NMR spectra of **6** and Prof. H. Sakurai for the ^{29}Si-NMR spectra of **7**.

These reactions are characteristic of a singlet silanediyl.[7] All silanediyls for which there is experimental[8] or theoretical[9] data indicate a singlet ground state although large groups on silicon should lead to a more nearly linear geometry and close the gap between the singlet and triplet states.[9]

When **4** or **5** is photolyzed (Rayonet, 254 nm, hexane) in methanol, di-*tert*-butylmethoxysilane is obtained in approximately 70% yield from silanediyl insertion into the O–H bond of methanol [Eq. (c)]. With triethylsilane as

$$\mathbf{4}\ (\mathbf{5}) \xrightarrow[MeOH]{h\nu} t\mathrm{Bu_2Si(H)OMe} \qquad \text{(c)}$$

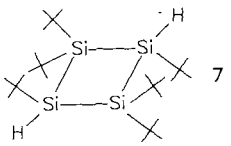
trapping agent, **3** is isolated in 72–84% yield after photolysis. In the presence of a three-fold excess of bis(trimethylsilyl)acetylene, **2** gave, as expected,[6] the silirene **6** (Table 1) which was isolated in 90% yield.



6

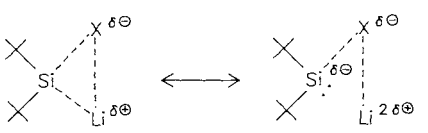
4 and **5** are the only alkylsiliranes known to be photochemically active, attributable perhaps to additional strain put on the molecule by the steric interaction between the *tert*-butyl groups on silicon and the methyl groups on the carbon atoms.

We have also examined the products of the reaction of lithium with **1a**, **1b** and **1c** in the absence of a trapping agent. To our surprise, we found that the dichloro derivative **1a** forms different products from those obtained from **1b** and **1c**. From **1a** we obtained tetra-*tert*-butyldisilane (65%) as did *Masamune*[10] and *Watanabe*,[11] but were also able to isolate for the first time the novel ring compound, *trans*-1,1,2,3,3,4-hexa-*tert*-butylcyclotetrasilane (Table 1) in 15% yield. **1b**, on the other hand, gave good yields (> 50%) of pure hexa-*tert*-butylcyclotrisilane, similar to that reported for **1c**.[3]



7

From these preliminary studies it is apparent that dihalosilanes are convenient sources of silanediyls, that the silanediyls produced from the three dihalides **1a–c** differ in their chemistry, and that free silanediyls are, at least in one or two of the three examples, probably not involved. More likely "silylenoid" species with structures like **8** are produced in which the halogen, X, plays an important role in the structure, and therefore the reactivity, of the intermediate.



8

Moreover, these results suggest that other highly hindered dihalosilanes may react with lithium to produce silanediyls in synthetically useful quantities.

Experimental

A dispersion of 0.1 g (14.3 mmol) of lithium (30% in mineral oil) and 1% sodium was washed with hexane to remove the mineral oil and treated in a flask under N_2 with anhydrous THF (5 mL), triethylsilane (3.65 g, 31.5 mmol) and di-*tert*-butyldichlorosilane (**1a**) (1.5 g, 7.1 mmol). After irradiating the reaction mixture with ultrasonic waves (Bransonic model 220, 55 kHz, 150 W) for 6 h, the THF was removed by evaporation and replaced by hexane. The hexane soluble fraction was separated from the lithium chloride by filtration and 1,1,1-triethyl-2,2-di-*tert*-butyldisilane (**3**) was isolated by preparative GC in 60% yield.

The Microwave Spectrum and Structure of the Ethylene–Sulfur Dioxide Complex**

By *Marabeth S. LaBarge, Kurt W. Hillig II*, and *Robert L. Kuczkowski**

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Ethylene and SO_2 each form complexes with a variety of species. However, there is not much information about the complex formed between them although it has been observed by mass spectrometry.[1,2] We were interested in the structure of the ethylene–SO_2 dimer in part because it might model the early stages of the classic cycloaddition reaction between ethylene and ozone. This report describes the assignment of the microwave spectrum of this complex. The structure which is deduced indicates that the SO_2 plane sits over the C_2H_4 plane, suggestive of an interaction between the π systems. The data do not discriminate between structures which place the oxygens versus the sulfur closer to the carbon atoms. While the former would resemble a precursor to 1,3-dioxa-2-thiocyclopentane, the latter would resemble a precursor to thiirane dioxide. The complex also shows evidence of tunneling between two equivalent forms.

[*] Prof. Dr. R. L. Kuczkowski, K. W. Hillig II, M. S. LaBarge
Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109 (USA)

[**] This work was supported by the National Science Foundation (Grant CHE-8614340).

The spectrum was observed with a Fourier transform microwave spectrometer.[3] The complex was formed when a mixture of 1% ethylene, 1% SO_2 and 98% neon (or argon) at total pressures of 1–2 atm expanded through a supersonic nozzle; both C_2H_4 and SO_2 were necessary to observe the spectrum. The spectrometer was equipped with Stark plates to examine transitions in an applied electric field to aid in the assignment of quantum numbers; combination differences were also helpful in some assignments.

Fifty-six transitions were assigned; selected transitions are given in Table 1. The spectrum was characterized by

Table 1. Selected rotational transitions of the C_2H_4–SO_2 complex [a].

[a] J is the rotational quantum number, K_p and K_o are the quantum numbers in the prolate and oblate limit, respectively, v is the vibrational quantum number (o-c is observed minus calculated frequencies).

doublets of unequal intensity. The μ_a transitions had splittings of 0–2 MHz, while the μ_c transitions were split by 20–63 MHz. The intensity variations and splittings indicate a tunneling motion in which the μ_c component changes its direction; the vibrational selection rule is $\Delta v=0$ for μ_a transitions and ± 1 for μ_c lines. The presence of such splitting precludes an equilibrium structure with C_2 or C_{2v} symmetry but is consistent with C_s symmetry and dipole components along the a and c inertial axes.

All of the transitions were simultaneously fit to rotational and quartic centrifugal distortion constants and an energy difference for two states, using the formalism of *Pickett*.[4] The derived constants are given in Table 2. While the frequency fit is not within experimental error (0.124 MHz rms), addition of the remaining quartic or sextic distortion terms or a P_{ac} term to account for a vibration-rotation interaction arising from the tunneling motion did not improve the fit.

An average structure for the complex can be estimated from the moments of inertia of the lower energy state. Assuming that the structures of ethylene and SO_2 do not change in the complex, the model shown in Figure 1 depends on the distance between the centers of mass of the moieties (R_{cm}) and two angles, $\theta+90°$ and $\phi+90°$, describing the angle that the ethylene and SO_2 planes make with the line between their centers of mass. For this model,

Table 2. Spectroscopic constants of the C_2H_4–SO_2 complex [a].

		$v=0$	$v=1$–$v=0$
A	[MHz]	6670.9565(27) [b]	−22.3538(18)

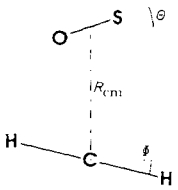

Fig. 1. Projection of Et-SO_2 onto the symmetry plane showing the definitions of R_{cm}, θ and ϕ.

the structures of ethylene and SO_2[5] predict a value for the out-of-plane moment of inertia arising from the b coordinates ($P_{bb}=1/2(I_a+I_c-I_b)$) of 65.9066 amu·Å^2 which agrees well with the observed value of 64.6073 amu·Å^2. The discrepancy is typical for weakly bonded complexes and arises from their large-amplitude motions.

The data are relatively insensitive to the sign of θ or ϕ; hence four structures are compatible with the data as shown in Figure 2. Values of $R_{cm}=3.509$ Å, $\theta=\pm 26.6°$

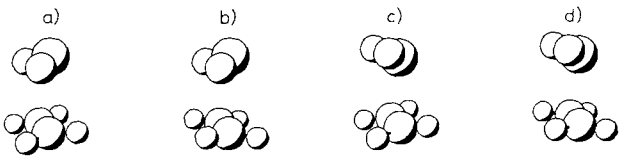

Fig. 2. Views of four conformations compatable with the rotational constants. a) $+\theta$, $-\phi$; b) $+\theta$, $+\phi$; c) $-\theta$, $-\phi$; d) $-\theta$, $+\phi$.

and $\phi=\pm 6.8°$ (taken with the same sign) give (in MHz) $A=6669$, $B=2007$, $C=1645$ while with opposite signs $A=6671$, $B=2007$, $C=1644$. Preliminary measurements of the dipole moment components ($\mu_c>\mu_a$; $\mu_b=0$) are also compatible with the orientation of the SO_2 obtained from the inertial moments. In all of the structures the C_2H_4 and SO_2 planes are more or less parallel. While this is suggestive of a HOMO–LUMO interaction, it has been pointed out that electrostatic interactions may also account for the orientational preference, even when the interaction is as large as 9 kcal as in $NMe_3 \cdot SO_2$.[6,7] The interaction between ethylene and SO_2 is probably much weaker; a dissociation energy of 426 cm^{-1} is obtained from the D_J distortion constant using the standard approximations for weak complexes.[8] It is not difficult to envisage several possible tunneling motions which could give equivalent forms and change the direction of μ_c, such as an internal rotation or flipping of the SO_2 from one side of the a axis to the other along with a concerted motion of the ethylene.[10] Since the

energy difference between the states is only 24.45 MHz, the barrier hindering the tunneling is appreciable.

At this point it is difficult to estimate how closely the average structural parameters may be to the equilibrium values. Isotopic data will be necessary to further refine the structural model, distinguish between the possible structures in Figure 2 and shed more light on the tunneling motion. The possibility of tunneling to equivalent forms by more than one pathway with different barriers also cannot be excluded without further study.

[10] Note added in proof (Sept. 22, 1988). Another assignment has been found which does not reguire a change in v and which fits to 0–10 kHz (o-c, Table 1). Since the reassignment involves only vibrational quantum numbers, the rotational constants and structural conclusions are essentially unchanged. With this assignment, the doublets arise from an internal motion where μ_c does not change direction, for example, rotation of ethylene about the C–C bond.

Solubilization of Elemental Sulfur in Water by Cationic and Anionic Surfactants**

By *Ralf Steudel** and *Gabriele Holdt*

Elemental sulfur belongs to the particularly hydrophobic substances that are neither wetted nor dissolved by water. The solubility of α-S_8 in water is 5 μg L^{-1} at 20°C[1] and is thus practically negligible. The dissolution of larger amounts of sulfur in aqueous media has so far only been accomplished by chemical reactions, e.g. oxidation or nucleophilic degradation with sulfides. We have now found that the solubility of α-S_8 in H_2O is increased by a factor of at least 5000 when neutral surfactants are present which do not alter the S_8 molecule chemically. The following amphiphilic surfactants[2] have been investigated regarding their suitability for the solubilization of sulfur:

1: "SDS", sodium dodecylsulfate [$C_{12}H_{25}SO_4Na$]
2: "Tergitol 7", sodium [4-ethyl-1-(3-ethylpentyl)octyl]sulfate [$C_{17}H_{35}SO_4Na$]
3: "CTAB", hexadecyl(trimethyl)ammonium bromide [$C_{16}H_{33}(CH_3)_3NBr$]

[**] Sulfur compounds, Part 119. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *J.-G. Kuenen* (Delft) for drawing our attention to Refs. [12] and [13]. – Part 118: D. M. Giolando, M. Papavassilion, J. Pickardt, T. B. Rauchfuss, R. Steudel, *Inorg. Chem. 27* (1988) 2596.

A mixture of excess cyclooctasulfur (α-S_8, recrystallized from CS_2; 1 mg mL^{-1}, particle size 160–200 μm), water (10–50 mL), and a known amount of surfactant was stirred for a known period of time in a flask fitted with a magnetic stirrer. Small samples (ca. 1 mL) were withdrawn from the mixture with a syringe, forced through a filter of 0.45 μm pore width,[3] and quantitatively analyzed for S_8 by high-pressure liquid chromatography using an octadecylsilane separating column.[4] Blank runs without surfactant gave no S_8 peak, since the limit of detection of our apparatus lies at ca. 0.1 μg mL^{-1}. Figure 1 shows the increase in S_8

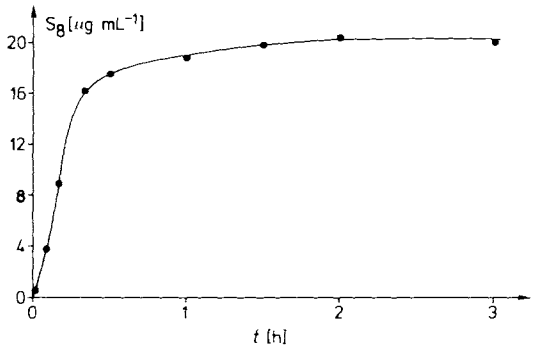

Fig. 1. Increase of S_8 concentration with time in an aqueous solution of SDS at 22°C (50 mg of **1** per mL) after mixing the components at $t = 0$.

concentration with time for the case of SDS **1** at 22°C and a surfactant concentration of 50 mg mL^{-1}. The saturation concentration reached after 90 min is 20 μg mL^{-1} S_8, i.e. 4000 times more than in pure water. With 10 mg of **1** per mL, a saturation concentration of 2.8 μg of S_8 per mL was achieved. In a completely analogous way the S_8-saturation value was also achieved within 90 minutes on using **2** or **3** (in each case 10 mg mL^{-1}); at 22°C, the values are 7.5 μg mL^{-1} in the case of **2** and 8.2 μg mL^{-1} in the case of **3**.[6] Thus, referred to the same amount of surfactant, **3** dissolves the most S_8. A saturated solution of **3** gave an S_8 concentration of 26.5 μg mL^{-1} (22°C) after 60 min—that is 5300 times the solubility in pure water.

Figure 2 shows the dependence of the S_8-saturation concentration on the surfactant concentration at 22°C. For all three surfactants investigated, similar and, in a certain range, linear functions were obtained. In the case of **1** the best fitted straight line cuts the abscissa at about 3.9 mg mL^{-1} (0.014 mol L^{-1}), i.e. a marked solubilization first

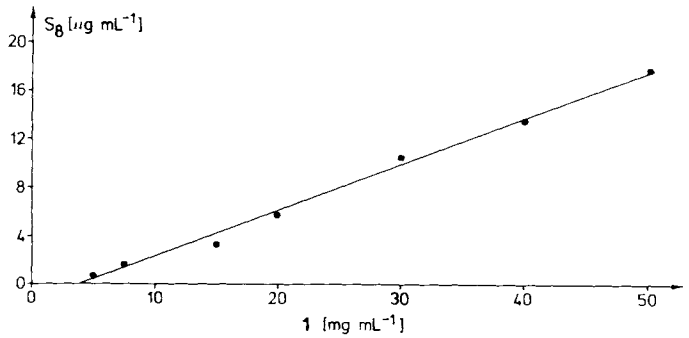

Fig. 2. S_8 saturation concentration in aqueous SDS **1** at 22°C as a function of the surfactant concentration. The best fitted straight line has the form $y = 0.38x + 3.9$ (correlation coefficient: 0.994).

takes place above this concentration, which is in good agreement with the critical concentration of **1** for micelle formation at room temperature (0.011 mol L^{-1}[7]). However, small S_8 concentrations (0.5 ± 0.2 μg mL^{-1}) were still measured with only 1 or 2 mg of **1** per mL. The absorption spectrum of an S_8-solution in aqueous Tergitol 7 **2** is very similar to the spectra of equally concentrated S_8-solutions in methanol/water (80/20 v/v)[8] and in cyclohexane; the extinctions in the range 235–300 nm for S_8 in **2** lie between those in CH_3OH/H_2O and C_6H_{12} (see Fig. 3).

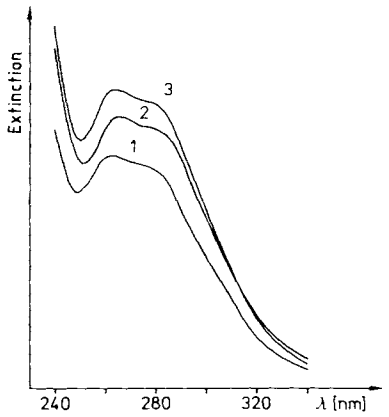

Fig. 3. UV absorption spectra of S_8 in methanol/water (80/20 v/v; 16.0 mg mL^{-1}; curve 1), in aqueous Tergitol 7 **2** (16.7 mg S_8/mL; curve 2), and in cyclohexane (17.1 mg S_8/mL; curve 3). All three spectra were measured with reference cuvettes containing the pure solvent.

As expected, the S_8-saturation concentration at constant surfactant concentration increases with increasing temperature, particularly in the range 40–60°C (see Fig. 4).

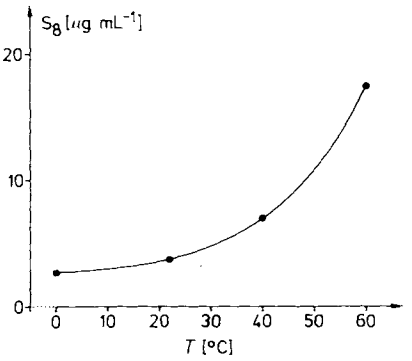

Fig. 4. Temperature-dependence of the S_8 saturation concentration in an aqueous solution of Tergitol 7 (10 mg of **2**/mL).

Above a critical concentration in water, **1**, **2** and **3** form spherical or rod-shaped micelles, the average number of particles per micelle being ca. 55 in the case of **1**.[8] The apolar hydrocarbon residues, which behave like a liquid solvent and can intercalate S_8 molecules are located in the interior of the micelle.[9] The longer the hydrocarbon chains the higher the saturation concentration, because the length of the hydrocarbon chains determines the volume of the apolar part of the micelles. The number and size of the micelles increases with increasing surfactant concentration and, accordingly, the S_8-saturation concentration increases linearly. If one assumes a micelle size of 55 anions in the case of **1** then the S_8 concentration of 0.77 μg mL^{-1} at a surfactant concentration of 5 mg mL^{-1} corresponds to ca. one molecule of S_8 in 100 micelles or to 5500 molecules of **1**. This number can be regarded as the lower limit, since those portions of the surfactant that are bound at the phase boundaries or are dissolved as monomers have been neglected in the calculation. The solubility of α-S_8 in comparable hydrocarbons such as *n*-heptane is one S_8 molecule to 700 heptane molecules at 25°C.

Exploratory experiments show that other allotopes of sulfur (e.g. S_6) can also be dissolved in aqueous surfactant solutions, although in this case a slow conversion into the more stable S_8 is observed. It can be expected that other apolar molecular compounds (e.g. white phosphorus P_4, cyclic selenium sulfides Se_xS_y, diorganosulfanes R_2S_n, sulfur–nitrogen compounds such as S_4N_4, etc.) can be dissolved in the same way in aqueous phases, so that chemical reactions of these substances in water should be accelerated considerably by surfactants.

Our findings now explain how it is possible that certain sulfur bacteria enzymatically oxidize elemental sulfur despite its insolubility at 20–25°C. These include, e.g. *Thiobacillus ferrooxidans* and *Thiobacillus thiooxidans*, which play a decisive role in bacterial ore leaching processes.[11] These organisms grow directly on sulfur particles suspended in the culture medium, from which S_8 is thereby apparently extracted, so that, on the one hand, the bacterium secretes various surfactants (e.g. hydroxy fatty acids, phosphatidylinositol, ornithine derivatives[12]), and, on the other hand, the S_8 molecules dissolves in the hydrophobic regions of the outer bacterial membranes, which resemble the surfactant micelles.[13] Probably S_8 is transported into the interior of the cell in this way, where the chemical degradation—oxidation to sulfate—takes place.

1,4-Diphosphabutatrienes

By *Gottfried Märkl** and *Peter Kreitmeier*

Whereas cumulenes **1** up to the decanonaenes (n = 8) are known[1] (although their stability decreases with increasing n) azacumulenes **2** and diazacumulenes **3** are only represented, to the best of our knowledge, by ketenimines and carbodiimides, respectively (i.e., the parent compounds with n = 1).[2] For the higher α,ω-diazacumulenes **3**, n = 2, 3, an MO study on possible mechanisms of

$R_2C{=}C{=}_nCR_2$ **1** n = 1–8

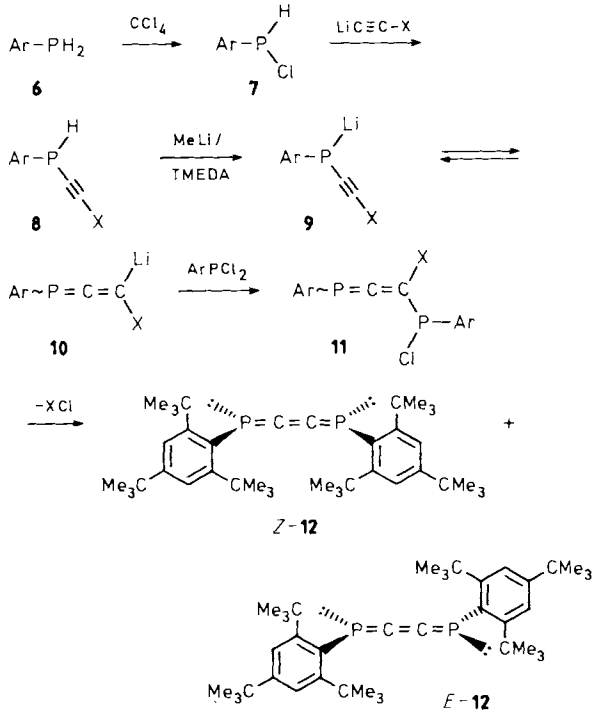
$R'N{=}C{=}_nCR_2$ **2** n = 1 $RN{=}C{=}_nNR$ **3** n = 1

$R'P{=}C{=}_nCR_2$ **4** n = 1,2 $R'P{=}C{=}_nPR'$ **5** n = 1

isomerization has been carried out.[3] In the series of phosphacumulenes **4**, so far it has been possible to prepare a number of axially chiral phosphaallenes **4**, n = 1,[4,5] as well as the first *E*/*Z*-isomeric phosphabutatrienes **4**, n = 2.[6]

The only diphosphacumulene, the axially chiral "parent compound" diphosphaallene **5**, n = 1 (R' = 2,4,6-tri-*tert*-butylphenyl) is known through the work of *Karsch* et al.,[7] *Appel* et al.,[4b] and *Yoshifuji* et al.[8] *Yoshifuji* et al. succeeded in carrying out the chromatographic separation of the two optical antipodes.[9]

Herein we report on the synthesis of the 1,4-diphosphabutatriene **12**, a compound of type **5**, n = 2. It is the next higher homologue of diphosphaallene **5**, n = 1 and, accordingly, the first *E*/*Z*-isomeric α,ω-diphosphacumulene. The synthetic route is shown in Scheme 1.

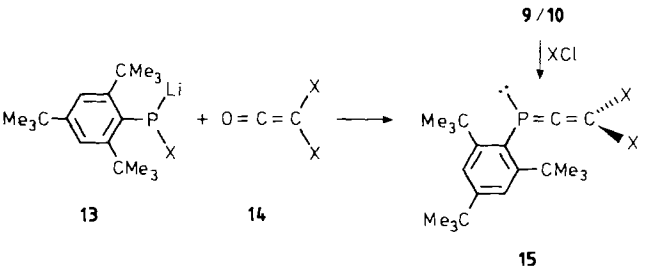


Scheme 1. Ar = 2,4,6-tri-*tert*-butylphenyl; X = trimethylsilyl.

[*] Prof. Dr. G. Märkl, Dipl.-Chem. P. Kreitmeier
Institut für Organische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (FRG)

The monochlorophosphane **7**,[10] accessible by chlorination of 2,4,6-tri-*tert*-butylphenylphosphane **6**[11] with tetrachloromethane, was first converted into the alkynylphosphane **8** (cf. Table 1).[12]

The lithium phosphide **9**, expected to be formed upon metalation of **8** with MeLi in tetramethylethylenediamine in THF (−60 to +25 °C), appears to exist in metallotropic equilibrium with the lithiated allene **10**. Reaction of **9**/**10** with trimethylchlorosilane results in formation of the bis(trimethylsilyl)phosphaallene **15** (yield 70%, cf. Table 1), whose structure was confirmed by independent synthesis from the silylphosphane **13** and bis(trimethylsilyl)ketene **14** (yield 40%). Complete shift of the equilibrium **9** ⇄ **10** toward **10** is presumably possible because direct substitution at phosphorus does not occur for steric reasons.



Reaction of **9**/**10** with 2,4,6-tri-*tert*-butyldichlorophosphane[13] in THF at −78 to +25 °C results initially in formation of the coupling product **11**, which can be isolated as a pale yellow solid but is impure owing to the partial loss of Me_3SiCl. Complete elimination of Me_3SiCl from **11** was achieved by treatment with KF/18-crown-6 in refluxing toluene. The desired 1,4-diphosphabutatriene **12** separates from the cooled solution as a yellow, finely crystalline solid which is only sparingly soluble in conventional solvents.

Table 1. Selected physical and spectroscopic data for **8**, **12**, and **15**.

8 [13]: Yield 42%; m.p. 91–93 °C (from EtOH); ^{1}H NMR ($CDCl_3$): $\delta = 0.20$ (s, $Si(CH_3)_3$), 1.44 (s, *p*-$C(CH_3)_3$), 1.76 (s, *o*-$C(CH_3)_3$), 5.81 (d, $J(P/H) = 247.4$ Hz, P–H), 7.55 (d, $J(P/H) = 2.9$ Hz, aryl-H); IR (KBr): $\tilde{\nu} = 2400$ (P–H), 2100 cm^{-1} (C≡C)

12: Yellow to orange, finely crystalline powder, yield 44%; m.p. 224–226 °C (dec.) (from toluene or tetrachloroethylene); ^{1}H NMR ($CDCl_3$, 250 MHz): *E*-**12**: $\delta = 1.34$ (s, *p*-$C(CH_3)_3$), 1.57 (s, *o*-$C(CH_3)_3$), 7.43 (s, aryl-H); *Z*-**12**: $\delta = 1.28$ (s, *p*-$C(CH_3)_3$), 1.55 (s, *o*-$C(CH_3)_3$), 7.29 (s, aryl-H); ^{31}P NMR ($CDCl_3/CHCl_3$, 101.257 Hz, 305 K): *E*-**12**: $\delta = 180.6$ (78%); *Z*-**12**: $\delta = 170.0$ (22%); (*n*-hexane): $\lambda_{max} = 213$ ($\varepsilon = 19700$), 244 (29700), 311 (3600), 387 (14700), 465 sh nm (1850); MS (70 eV): *m*/*z* 576 ($M^{\oplus\ominus}$, 70%), 520 ($[M - C_4H_8]^{\oplus\ominus}$, 10), 464 ($[520 - C_4H_8]^{\oplus\ominus}$, 10), 346 ($[Ar{-}P{=}C{=}C{-}P{-}Me]^{\oplus\ominus}$, 4), 288 ($[M/2]^{\oplus\ominus}$, 25), 575 ($[M - H]$, 69), 519 ($[575 - C_4H_8]$, 12), 463 ($[519 - C_4H_8]$, 11), 345 ($[Ar{-}P{=}C{=}C{-}P{=}CH_2]^{\oplus\ominus}$, 14), 315 ($[345 - 2CH_3]^{\oplus\ominus}$, 17), 301 ($[315 - CH_2]$, 20), 57 ($[C_4H_9]^{\oplus\ominus}$, 100)

15: Yellow, highly viscous oil; ^{1}H NMR ($CDCl_3$): $\delta = 0.22$ (s, $Si(CH_3)_3$), 1.79 (s, *o*-$C(CH_3)_3$), 1.46 (s, *p*-$C(CH_3)_3$), 7.47 (d, $J(P/H) = 2$ Hz, aryl-H); ^{31}P NMR ($CDCl_3$): $\delta = 3.84$; IR (neat): $\tilde{\nu} = 1650$, 1685 cm^{-1}; MS (70 eV): *m*/*z* 446 ($M^{\oplus\ominus}$, 11%), 276 ($[aryl\text{-}P]^{\oplus\ominus}$, 12), 261 ($[276 - {}^{\ominus}CH_3]^{\oplus}$, 10)

The formation of **12** (cf. Table 1) is essentially the result of a Wittig-Peterson-like condensation. The metallotropic rearrangement **9** → **10** suggests a novel principle for the synthesis of α,ω-diphosphacumulenes.

The ^{1}H NMR data reveal that **12** is present as an *E*/*Z*-isomeric mixture; we have assigned the *E* configuration to the main component (78%). The isomeric distribu-

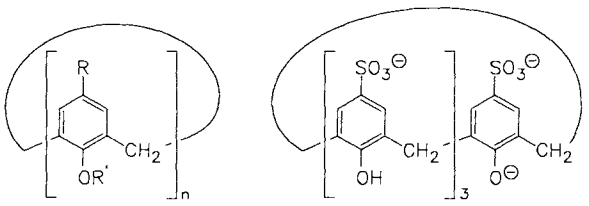
Novel Layer Structure of Sodium Calix[4]arenesulfonate Complexes—a Class of Organic Clay Mimics?**

By *Anthony W. Coleman, Simon G. Bott, S. David Morley, C. Mitchell Means, Kerry D. Robinson, Hongming Zhang,* and *Jerry L. Atwood**

Calixarenes[1] **1** have been studied primarily for their use as enzyme mimics since they have the ability to bind both organic and inorganic substrates.[2,3] Recently, water-



1 2

soluble calixarenes **1**, R = CO_2H, NO_2, SO_3H, have been prepared and successfully applied in areas of transport and selective complexation, although little is known of their structure.[4] To better understand the properties of these compounds, we prepared the sodium salt of calix[4]arenesulfonate **2** and obtained single crystals from an aqueous solution.[5] X-ray structural analysis revealed that, in the solid state, the calixarene sulfonate ion combines with sodium ions and water molecules in the ratio 1 : 5 : 12 to produce the highly ordered arrangement **2** · 5 $Na^{\oplus}$ · 12 H_2O (Fig. 1a). While at first glance this appears highly reminiscent of a bioorganic bilayer membrane,[6] the similarity to a clay is, in fact, far more compelling.

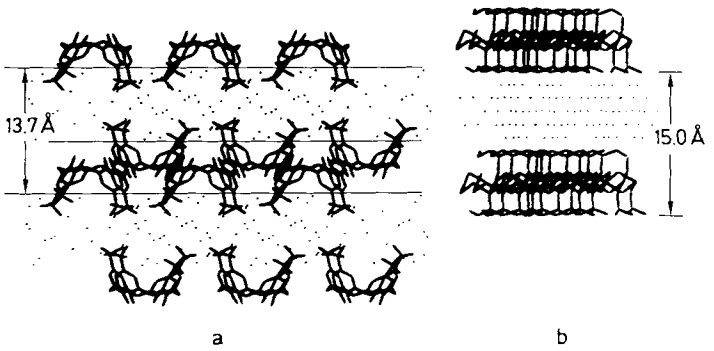


Fig. 1. a) Bilayer structure of **2** · 5 $Na^{\oplus}$ · 12 H_2O in the crystal; b) layer structure of hydrated sodium vermiculite.

The structure may be divided into organic and inorganic layers. The organic layer is formed by interlocking calixarenes in an up-down fashion, a sodium ion and a water molecule interacting simultaneously with the phenolic oxygen atoms of one calixarene and the sulfonate oxygen atoms of others. To accommodate this cation, the superacidic proton[7] of each calixarene has been removed; the resultant negatively charged oxygen atom forms a strong electrostatic bond with the sodium ion. The inorganic layer is comprised of the remaining four sodium ions and eleven water molecules. These exist in a vast hydrogen-bonded array which includes the sulfonate head groups of the calixarenes.

Upon recrystallization of sodium calix[4]arenesulfonate from acetone/water, thin plates are obtained. These tend to aggregate in sheets, but may easily be cleaved in a manner resembling micas. The X-ray structure[8] shows this to be the calix[4]arenesulfonate ion associated with five sodium ions, eight water molecules, and one acetone molecule. As with the parent compounds, **2** · 5 $Na^{\oplus}$ · 8 H_2O · Me_2CO consists of bilayers of calixarenesulfonates intercalating layers of water molecules and sodium ions. The acetone molecule, however, is a guest within the cavity of the calixarene anion,[9] with the polar carbonyl group projecting into the inorganic layer (Fig. 2).

To compare the overall layer structure with that of a clay of 2 : 1 layer type, Figure 1a shows the parent water systems, and Figure 1b the structure of hydrated sodium vermiculite.[10] The similarity is striking. Both consist of layers of covalent material with hydrated cations between. If one

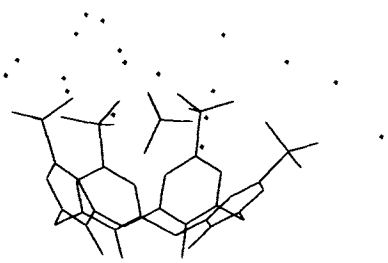

Fig. 2. Inclusion of the acetone molecule in the calixarene cavity in the calix[4]arenesulfonate complex **2** · 5 $Na^{\oplus}$ · 8 H_2O · Me_2CO. The carbonyl oxygen atom is positioned so that it projects into the polar layer.

[**] This work was supported by the U. S. National Science Foundation.

considers the sulfonate groups as part of the hydrated layer, the comparisons of Figure 1 are close. The hydrated layers are 8.3, 8.4, and 9.4 Å in the calixarene/water parent system ($2 \cdot 5\,Na^{\oplus} \cdot 12\,H_2O$), the calixarene/acetone structure ($2 \cdot 5\,Na^{\oplus} \cdot 8\,H_2O \cdot Me_2CO$), and the sodium vermiculite clay,[10] respectively. The sum of the distances between the two layers in the title calixarene materials is near 13.7 Å. This may be compared with 15.0 Å in sodium vermiculite and 14.4–15.6 Å in smectite.[11]

As with the clays, the sodium ions are exchangeable. Structural verification has been obtained for $K^{\oplus}$, $Rb^{\oplus}$, $Cs^{\oplus}$,[12] and $NH_4^{\oplus}$ analogues.[13] With the $NH_4^{\oplus}$ derivative, the displacement of water by the ammonium cations is seen, a feature also observed for clays.[14]

In conclusion, we have shown that the sodium calix[4]arenesulfonate complexes with water or water/acetone closely mimic the structural behavior of clays. However, they possess the advantage of a secondary size- and polarity-selective cavity formed by the cone of the calixarene coupled with an ease of chemical modification of the organic calixarene fragment.

[8] $2 \cdot 5\,Na^{\oplus} \cdot 8\,H_2O \cdot Me_2CO$: Colorless crystals of the compound were prepared by recrystallization of $2 \cdot 5\,Na^{\oplus} \cdot 12\,H_2O$ from an acetone/water solution. The compound belongs to the monoclinic space group $P2_1/n$ with $a = 11.05(4)$, $b = 14.157(4)$, $c = 27.162(7)$ Å, $\beta = 97.47(3)°$, $Z = 4$. Refinement based on 4724 observed reflections led to $R = 0.054$ [15].
[9] The acetone molecules are, in fact, complexed in aqueous solution by the calixarenes **2**, as shown by ^1H NMR studies. In the ratio 2 : 1 **2** : acetone, the acetone methyl resonance is found as a broad singlet at $\delta = 0.7$–0.8. This demonstrates that the methyl groups are well shielded in the vicinity of the aromatic rings. In the ratio 1 : 1, the signal is found at $\delta = 1.0$, and in the ratio 1 : 4 the chemical shift of $\delta = 1.8$ is near the uncomplexed value of $\delta = 2.05$ for **2**. The NMR experiments were performed at 19°C in D_2O on a Nicolet NT 200.

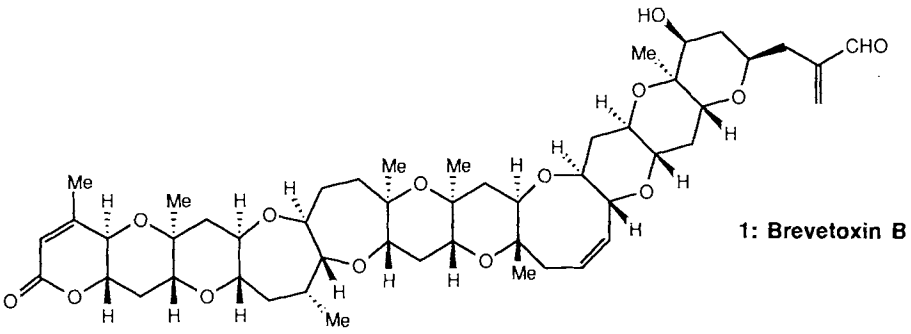
A Photolytic Entry into Oxepane Systems**

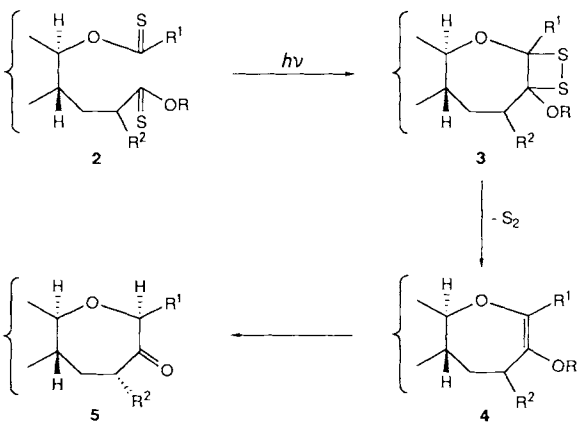
By *K. C. Nicolaou,* C.-K. Hwang,* and *D. A. Nugiel*

The oxepane ring skeleton is becoming an increasingly common structural feature of natural products, particularly those of marine origin.[1] As part of our program directed toward the total synthesis of brevetoxin B **1**,[2] and in an effort to develop general and mild methods for the construction of oxepanes,[3] we designed the strategy shown in Scheme 1 as a potential route to these systems that may be applicable to the above target. According to this strategy, the dithionoester **2** was expected to generate



1: Brevetoxin B

the 1,2-dithietane system **3** via diradical formation under photolytic conditions.[4] Expulsion of disulfur under the reaction conditions should then lead to the didehydrooxe-



Scheme 1. General strategy for the synthesis of oxepanes by photolytic cyclization of dithionoesters.

[a] Based on consumed starting material **2**. Recovered starting material: **2a**, 42%; **2b**, 43%; **2c**, 43%; **2d**, 44%; **2e**, 50%; **2f**, 35%; **2g**, 37%; **2h**, 37%.

pane **4**, which may be regioselectively hydrolyzed to afford the highly functionalized oxepane intermediate **5**.

As Table 1 shows, this idea turned out to be successful, providing a facile entry into a variety of didehydrooxepanes and oxepanes of the type present in brevetoxin B **1**. Thus, the dithionoester **2a**[5] (Table 1, entry 1, mixture of methyl epimers), upon photolysis in toluene solution (Hanovia UV lamp, 70°C, 2 h), produced didehydrooxepane **4a**[6] (mixture of methyl epimers, ca. 1 : 1, 66% yield based on 42% recovered **2a**), presumably via the corresponding 1,2-dithietane **3**.[4] Regioselective enol ether rupture and tautomerization in **4a** was induced by fluoride treatment (nBu$_4$NF, THF, 45°C, 8 h), leading to oxepane ketone **5a** as a single isomer[7] (95%). The indicated structure was tentatively assigned on the basis of NOE studies, molecular modeling, and MM2 calculations.[8] Apparently, under the reaction conditions (basic), epimerization leads to the thermodynamically most stable product. The regioselective conversion **4** → **5** was also possible with other groups R such as CH_2CCl_3 (Table 1, entry 2, removed with Zn/AcOH) or Me (Table 1, entry 3, removed with aqueous HCl). In both cases, however, an epimeric mixture of **5a** (ca. 1 : 1) was obtained which was converted by basic treatment (NaH, THF, 12 h, 95%) into the same isomer as that obtained from **4a**.

A number of comments regarding the present photoinduced cyclization **2** → **3** are in order. (1) From studies with acyclic precursors, it appears that preexisting rings in the substrates **2** are necessary for the success of this reaction. (2) Photolysis at elevated temperatures leads to cleaner reactions and higher yields as compared with lower temperatures, suggesting that thermal energy may be necessary to achieve the proper conformation for coupling to take place. (3) Several of the presumed 1,2-dithietanes **3**[4a] were detected by thin layer chromatography (yellow coloration); their isolation is currently being pursued. The potential application of this procedure to the total synthesis of brevetoxin B **1** is also in progress.

Experimental Procedure

4a: The dithionoester **2a** (390 mg, 1.0 mmol) in anhydrous toluene (200 mL) was photolyzed (Hanovia UV lamp, 450 W) at 70°C for 2 h. The solvent was removed under reduced pressure and the residue was flash chromatographed (silica, 10% ether in petroleum ether) to afford **4a** (104 mg, 66% based on consumed starting material) and recovered starting material (**2a**, 163 mg, 42%). **4a**: oil, R_F = 0.33 (silica, 10% ether in petroleum ether); IR (neat), $\tilde{\nu}_{max}$ = 1660 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$), δ = 3.85 (m, 1H, CH_2–O,

equatorial), 3.60 (m, 2H, C*H*–O), 3.30 (m, 1H, C*H*–O), 3.15 (m, 1H, CH_2–O, axial), 3.02 (m, 1H, C*H*–O), 2.75, 2.52 (2 × m, 2 × 0.5H, C*H*), 2.30–1.40 (m, 10H, CH_2), 1.25, 1.12 (2 × d, J = 7.4 Hz, 2 × 1.5H, CH–CH_3), 1.0 (m, 3H, CH_2–CH_3), 0.88 (m, 2H, CH_2–SiMe_3), 0.0 (s, 9H, SiMe_3); HRMS, calcd for $C_{18}H_{34}O_3Si$ ($M^{\oplus}$) 326.2285, found 326.2284.

5a: The didehydrooxepane system **4a** (326 mg, 1.0 mmol) in anhydrous THF (5 mL) was treated under argon with nBu$_4$NF (1.0 M solution in THF, 1.2 mL, 1.2 mmol) at ambient temperature and then stirred at 45°C for 8 h. Removal of the solvent, followed by flash column chromatography (silica, 20% ether in petroleum ether) gave **5a** (215 mg, 95%). **5a**: oil, R_F = 0.30 (silica, 20% in petroleum ether); IR (neat), $\tilde{\nu}_{max}$ = 2940, 2880, 1720 (s, ketone), 1475, 1160, 1000, 955 cm^{-1}; ^{1}H NMR (500 MHz, [D$_6$]benzene), δ = 3.90 (dd, J = 9.4, 3.6 Hz, 1H, C*H*–O), 3.70 (m, 1H, C*H*–O, equatorial), 3.25 (m, 1H, C*H*–O), 3.20 (m, 1H, CH_2–O, axial), 3.01 (m, 1H, C*H*), 2.80 (m, 1H, C*H*–O), 2.05–1.45 (m, 10H, CH_2), 1.22 (d, J = 7.4 Hz, 3H, CH–CH_3), 1.05 (t, J = 7.3 Hz, 3H, CH_2–CH_3); ^{13}C NMR (125 MHz, CDCl$_3$), δ = 217.60 (C=O), 86.95, 80.82, 80.47, 67.52, 38.79, 37.72, 35.17, 30.92, 25.66, 12.65, 16.33, 13.68; HRMS, calcd for $C_{13}H_{22}O_3$ ($M^{\oplus}$) 226.1569, found 226.1567.

[8] Irradiation of H$_a$ (structure **5a**, Table 1) produced a 17% NOE indicating a *syn* relationship for H$_a$ and H$_b$. Molecular models of **5a** suggest a pseudoequatorial position for the Me group as depicted in **5a** (rather than the opposite stereochemistry which forces the Me into a pseudoaxial orientation); MM2 calculations (MacroModel) of the energies give 40.05 kJ mol^{-1} for **5a** and 42.99 kJ mol^{-1} for its epimer, also pointing to the assigned stereochemistry.

$Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$: A New Type of Catalyst for Selective Oxidation Derived from Bismuth Oxychloride**

By *Kenneth D. M. Harris, Wataru Ueda, John M. Thomas,** and *Gallienus W. Smith*

When a 1:1:1:2 mixture of Bi_2O_3, BiOCl, CsCl and $CaCl_2$ is heated for 12 h in an open alumina or platinum container at 1073 K a new type of compound is formed. The predominant crystalline product contains single crystals suitable for structural analysis using conventional X-ray diffractometric techniques. This product (idealized formula $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$) possesses attractive properties as a catalyst for the selective oxidation of methane in O_2 ($CH_4:O_2 = 2:1$, partial pressure of CH_4 20 kPa, total flow rate 50 mL m^{-1} with N_2 as diluent up to atmospheric pressure in the temperature range 873 to 1023 K).

A typical run at 994 K results in 21.3 and 46.3 percent conversion of CH_4 and O_2 respectively, and the following product selectivities: C_2H_4, 39.5; C_2H_6, 11.6; C_3 and C_4 compounds, 3.5 and 3.9, respectively; CO, 7.6; CO_2, 25.0%; with $C_2H_4/C_2H_6 = 3.4$. Further details of the catalytic performance of this and of related materials will be given elsewhere.[1]

As with other[1] complex layered oxyhalides derived from or related to the Sillen structure[2] (for example, $NaBi_3O_4Cl_2$ and $Ca_{1.25}Bi_{1.5}O_2Cl_3$), the mechanism of catalytic selective oxidation is unclear, but likely to involve[3–5] methyl radicals.

The structure[6] of $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$ is quite novel (Fig. 1, Table 1) and exhibits interesting features including the presence of a layer which is itself structurally similar to that in CsCl with the alkali cation, as expected, in eightfold coordination. Within this layer, however, there are two types of Cs site (designated Cs1 and Cs2), both of which are only partially occupied, with fractional occupancies of 0.78 and 0.21 respectively. This layer is flanked on either side by layers of modified BiOCl with $Bi^{3\oplus}$ and $Ca^{2\oplus}$ ions occupying the same sites (subsequently designated M sites). In the crystal structure refinement, the ratio of $Bi^{3\oplus}$ and $Ca^{2\oplus}$ on these sites has been allowed to vary subject to the constraint that the total occupancy on each M site is unity.[7] The fact that the fractional occupancies of $Bi^{3\oplus}$ and $Ca^{2\oplus}$ are not 0.625 (10/16) and 0.375 (6/16) respectively for each of the M sites indicates that the $Bi^{3\oplus}$ and $Ca^{2\oplus}$ cations, whilst capable of occupying the same type of site, are not distributed at random in the modified BiOCl layers. (We note, in passing, that a tendency for non-random, supermesh arrangements involving $Bi^{3\oplus}$ and $Ca^{2\oplus}$ cations within layers of the warm superconducting compounds[8–10] of Bi/Ca/Sr/Cu/O (suggested formulas[11,12] $Bi_2Sr_{2-x}CaCu_2O_8$ and $Bi_{2+x}Ca_{1-x}Sr_2Cu_2O_{8+x}$)

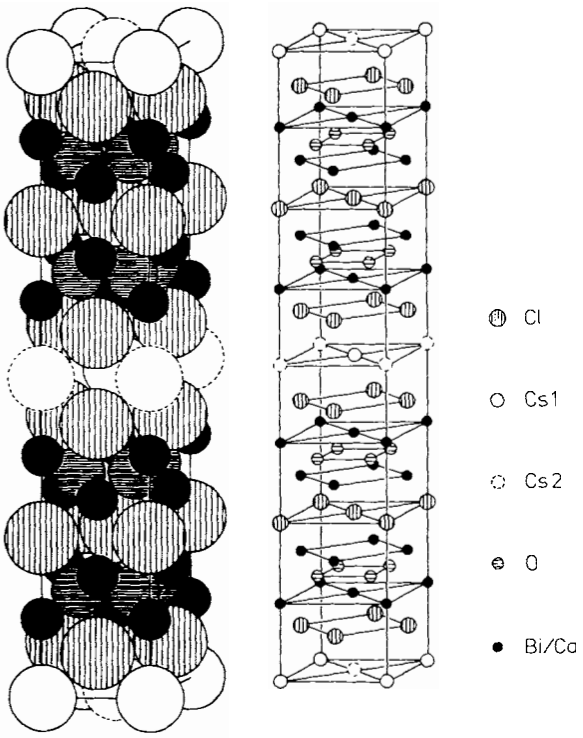

Fig. 1. Two representations of the stacking of the constituent ions in the structure of the oxidation catalyst $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$. (In b, conventional ionic radii are represented.) In the layers of modified BiOCl which are integral parts of this novel structure the $Bi^{3\oplus}$ and $Ca^{2\oplus}$ cations share the same sites but not completely at random (see text). Note also the existence of two different types of Cs site within the CsCl layers. In both of these sites the Cs is in eight-fold coordination.

Table 1. Fractional coordinates and site occupancies in $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$ (with estimated standard deviations in parentheses).

[a] Number of sites in the unit cell.

has recently been postulated by *Zhou* et al.[12] Indeed, from the magnitude of the thermal parameter quoted by *Subramanian* et al.[10] for the $Bi^{3\oplus}$ site in their 'warm' superconductor one may suspect that, in that material also, both $Bi^{3\oplus}$ and $Ca^{2\oplus}$ may tend to occupy this site.)

The new structure reported here (for $Cs_2Bi_{10}Ca_6Cl_{12}O_{16}$) is corroborated by other evidence.[13] It is not far removed, architecturally, from the rich variety of discrete structures in the so-called 'Bipox' series[14] formed from unit-cell-level intergrowths[15] of Aurivillius phases[16] and Sillen phases.

[6] Crystal structure of $Cs_{1.98}Bi_{10.02}Ca_{5.98}Cl_{12}O_{16}$: tetragonal, space group *I4/mmm*, $a = 547.71(9)$, $c = 3286.2(7)$ pm, $\rho_{calcd} = 5.53$ g cm^{-3}, $\mu = 463.19$ cm^{-1}, $F(000) = 1393.98$. Data collection at room temperature on a CAD4 diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 71.069$ pm); $1.5° < \theta < 36°$, $h = -9$, $k = 0$ to 9, $l = 0$ to 54. Numerical absorption correction applied after indexing crystal faces and using the crystal size ($0.18 \times 0.18 \times 0.01$ mm^3) which minimized R_{merge} (0.038) for the merging of equivalent reflections. (For comparison, $R_{merge} = 0.282$ with no absorption correction.) Total of 760 unique reflections measured, of which 531 (satisfying $|F| > 3\sigma(F)$) were used in refinement. Scattering factors for neutral atoms were assumed. Anisotropic thermal parameters were used finally for all atoms. $R = 0.0419$, $R_w = 0.0354$ using weight $1.6917/[\sigma^2(F) + 0.0002F^2]$. Salient data (with fractional coordinates *x/a*, *y/b*, *z/c*; and occupancies) are given in Table 1.

[7] In a given refinement job, the occupancies of the two types of Cs site and the relative $Bi^{3\oplus}/Ca^{2\oplus}$ occupancies on the M sites were refined with the thermal parameters for all of these sites fixed, while, in the following refinement job, the occupancies were fixed at these new values and the thermal parameters allowed to refine. This iterative procedure was continued until constancy of both occupancies and thermal parameters produced from successive pairs of refinement jobs was obtained for all of the Cs and M sites (see K. D. M. Harris, *Ph. D. Thesis* (1988), University of Cambridge, for further details).

[13] Briefly, the validity of the refined occupancies of Cs, Bi and Ca is supported by the three following facts. First, crystal structure refinements starting from different initial sets of occupancies produce, in all cases, the values given in Table 1, within the quoted standard deviations. Second, from the stoichiometry that follows from these occupancies (i.e. $Cs_{1.98}Bi_{10.02}Ca_{5.98}Cl_{12}O_{16}$) the net charge is 0.00, indicating that, within errors, this stoichiometry satisfies the requirement of electro-neutrality. Refinements in which the total occupancy of individual M sites are fixed at values less than unity (e.g. 0.95 or 0.90), while the $Bi^{3\oplus}/Ca^{2\oplus}$ ratio for these sites is allowed to refine, lead to stoichiometries for which the net charge is distinctly non-zero, thus vindicating our assumption that the total occupancy of each of the M sites is unity. Third, the bond valence sum (S) for the oxygen site in the structure, when computed using the parameters R_i^{Ca}, N_{Ca}, R_i^{Bi}, N_{Bi} (compiled by I. D. Brown, K. K. Wu, *Acta Crystallogr. Sect. B32* (1976) 1957) yields a value of $S = 2.04$ (theoretical value 2.00). Here

$$S = \sum_{\text{M sites}} \left(f_{Ca} \left(\frac{R_{M-O}}{R_i^{Ca}} \right)^{-N_{Ca}} + f_{Bi} \left(\frac{R_{M-O}}{R_i^{Bi}} \right)^{-N_{Bi}} \right)$$

where f_{Ca} and f_{Bi} are the fractional occupancies of $Ca^{2\oplus}$ and $Bi^{3\oplus}$ on the M site and R_{M-O} is the M–O interatomic distance.

Solid-Phase Synthesis of *O*-Glycopeptide Sequences

By *Hans Paulsen,* Gunnar Merz,* and *Udo Weichert*

Glycoproteins are of great interest owing to their numerous biological functions on cell surfaces and as enzymes, serum proteins, and mucins.[1] Glycopeptides, containing a

[*] Prof. Dr. H. Paulsen, Dipl.-Chem. G. Merz, Dipl.-Chem. U. Weichert
Institut für Organische Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

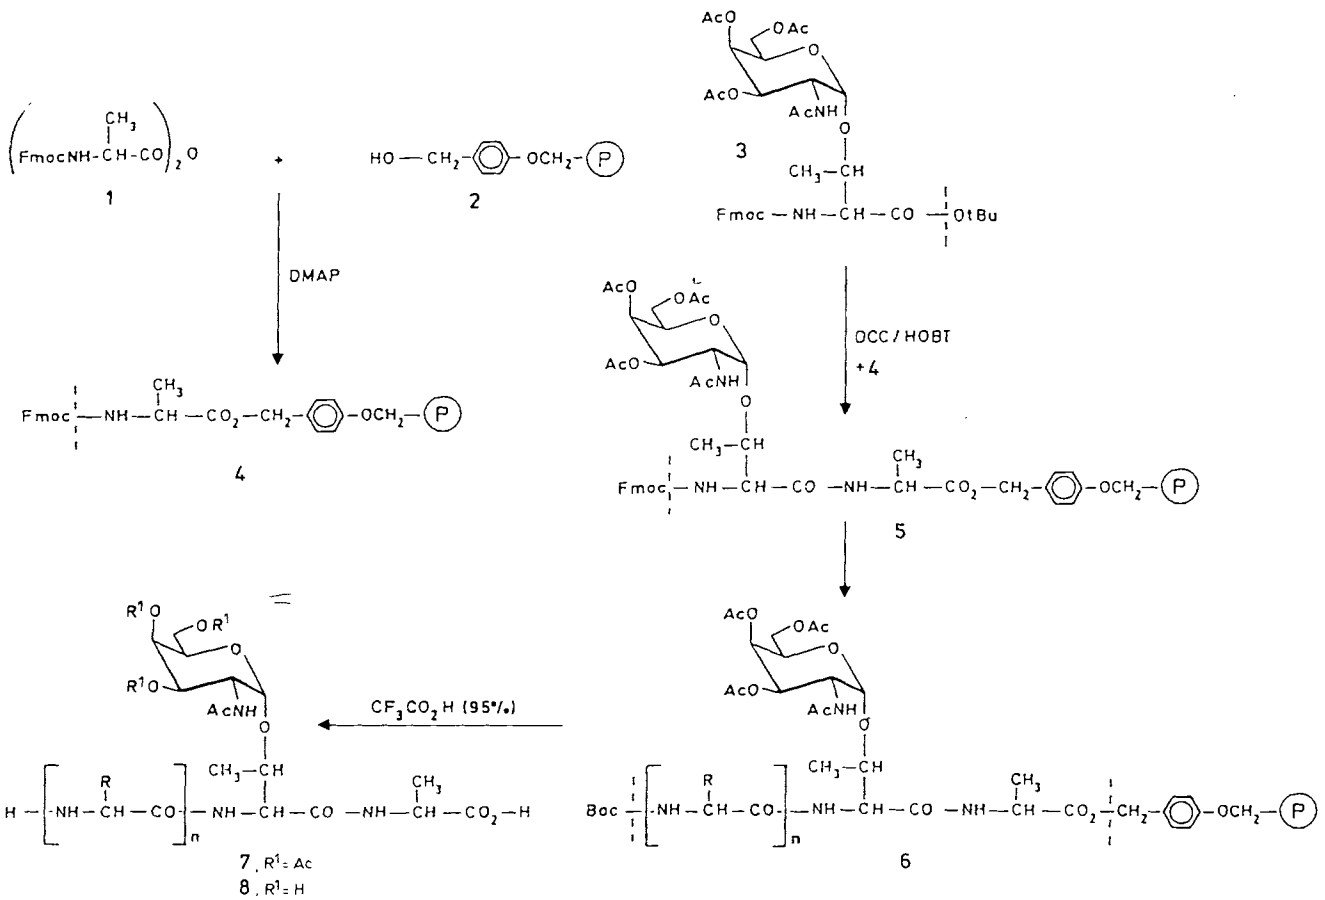
peptide moiety and a carbohydrate moiety, are desired for elucidating the functions of glycoproteins. The synthesis of such *O*-glycopeptides has so far been carried out stepwise using the standard methods of peptide coupling.[2,3] The question therefore arose whether solid-phase synthesis, developed initially for peptides,[4] might offer a quicker and simpler approach to the preparation of *O*-glycopeptides. Herein we report on several examples of this approach.

Only some of the standard methods and protecting groups of peptide chemistry are applicable to the synthesis of *O*-glycopeptides. This is due to the acid lability of the glycosidic bond between 2-acetamido-2-deoxy-D-galactose and the hydroxyl group of L-serine or L-threonine and to the facile cleavage of this bond via β-elimination under alkaline conditions. Solid-phase syntheses that involve cleavage of the peptide from the resin with HF are therefore not useful.[5] A resin bearing allyl groups, only recently described by *Kunz* et al.,[6] appears applicable since Pd-catalyzed cleavage is used. A study of the methods commonly employed in peptide chemistry revealed that a carrier resin developed by *Wang*[7] is most promising. The solid phase is a polystyrene resin containing *p*-alkoxybenzyl alcohol groups as shown in **2**. The synthesized peptides can be cleaved from this resin under mild acid conditions.

The synthetic procedure involves several steps (Scheme 1). In the first step, the symmetrical anhydride of an Fmoc-amino acid **1**[8] (3 mole equiv.) is esterified with the hydroxyl group of the anchor in **2** under mild catalysis with 4-dimethylaminopyridine[9] (0.06 mole equiv.) to give **4**. 4-Alkoxybenzyl alcohol resin (Bachem, capacity 0.45 mmol g^{-1}) was employed and, under these conditions, underwent 50% esterification. The unreacted OH groups of the resin were subsequently acetylated by reaction with acetic anhydride. An important carbohydrate-containing building block is the L-threonine glycoside **3**.[10] It contains the protecting group combination Fmoc/O*t*Bu, which has proven advantageous for solid-phase synthesis.[11]

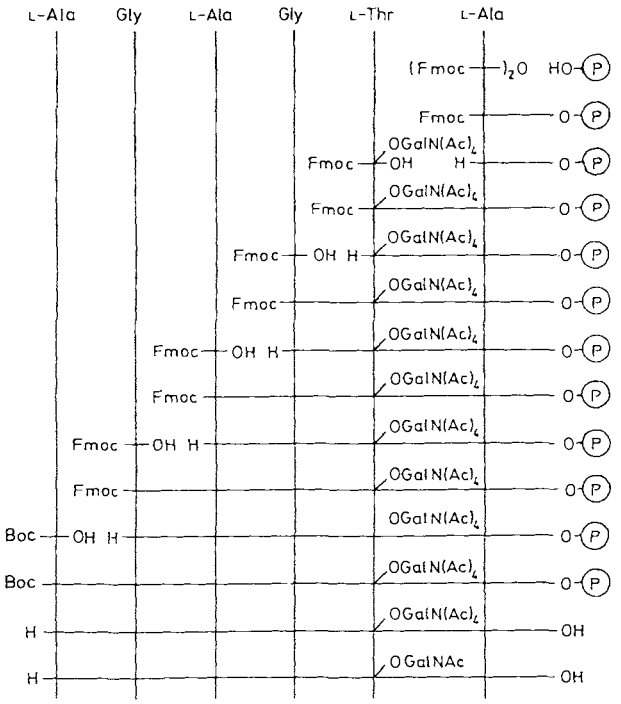
Cleavage of Fmoc in **4** and O*t*Bu in **3** and conversion of the product obtained from **3** to the *N*-hydroxybenzotriazole ester (6 mole equiv.) is followed by coupling to give **5** (reaction time 1.5 h). After deprotection of the *N*-terminus of **5** by cleavage of the Fmoc group with morpholine, further amino acids can be joined to give **6**. All coupling steps of the amino acids (6 mole equiv.) are carried out with DCC/HOBT in dimethylformamide (reaction time 1 h in each case). If a Boc-amino acid is chosen in the final step, treatment of the resin with aqueous trifluoroacetic acid (95%) results in simultaneous cleavage of both the glycopeptide from the resin and the Boc group from the *N*-terminus, thereby affording **7**. No glycoside cleavage was observed over a reaction time of 1.5 h. To accomplish complete deprotection, the acetyl groups of the carbohydrate moiety are removed with $NaOCH_3$ in methanol maintained at exactly pH 8.5. A β-elimination or racemization does not usually occur under these conditions.

The application of the above procedure is exemplified by the synthesis of the hexapeptides **9** and **10**. For **9**



Scheme 1. Solid-phase synthesis of *O*-glycopeptide sequences. DMAP = 4-dimethylaminopyridine, DCC = dicyclohexylcarbodiimide, HOBT = 1-hydroxybenzotriazole, Fmoc = 9-fluorenylmethoxycarbonyl, Boc = *tert*-Butyloxycarbonyl, Ⓟ = polymer.

(Scheme 2), L-alanine is first coupled to the carrier. Cleavage of the Fmoc group is followed by coupling with the glycosylated L-threonine building block. The other amino acids are then added sequentially. Completion of the reaction steps is checked using the Kaiser test.[12] After cleavage of the glycopeptide from the resin, the product is purified first on Sephadex LH20 and, after further deprotection of the sugar moiety, on Sephadex G10. With 0.25 g of resin it is possible to obtain 20 mg of hexapeptide **9** (55% based on the first amino acid to be coupled) in pure form. The sequence **9** is a partial structure of the ovine submaxillary mucin.[13]



9

Scheme 2. Solid-phase synthesis of the glycopeptide **9**, a partial structure of ovine submaxillary mucin.

The reaction steps for the synthesis of **10**, which contains two carbohydrate chains (Scheme 3), are analogous to those for **9**. Only an additional glycosylated L-threonine building block is introduced. The cleavage from the carrier and the deprotection present no difficulties. With 0.25 g of resin, it is possible to obtain 25 mg of hexapeptide **10** (48% based on the first amino acid to be coupled). The hexapeptides **9** and **10** were checked for purity using ^{1}H NMR spectroscopy, including 2D techniques. Side products or racemization of the amino acids could not be detected. The sequence **10** is a partial structure of porcine glycophorin.[14]

The procedure described here affords glycopeptides in considerably shorter time than the corresponding syntheses in solution and can be extended further. The building block **3** may also be suitable for use in an automated peptide synthesis.

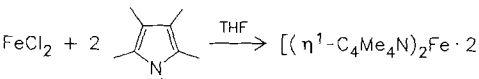
Does a 1,1′-Diazaferrocene Exist?**

By *Norbert Kuhn,* Eva-Maria Horn, Roland Boese,* and *Norbert Augart*

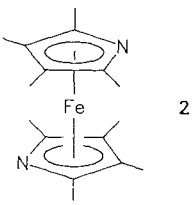
Although the formal replacement of CH groups by phosphorus atoms in ferrocene[1] recently culminated in the synthesis of "FeP_{10}",[1e] diazaferrocenes and their nitrogen-richer analogues have been considered for 20 years to be unstable.[2] The recently demonstrated stabilization of nitrogen-containing metallocenes by permethylation of the heterocyclic ring[3] prompted us to attempt the synthesis of $[(\eta^5\text{-}C_4Me_4N)_2Fe]$.

The complex **1**, accessible by reaction of $FeCl_2$ with C_4Me_4NLi in tetrahydrofuran [Eq. (a)], contains *N*-coordinated pyrrolyl ligands, as shown by the δ values for the ring C atoms in the ^{13}C NMR spectrum ($\delta = 119.81$, 113.05). Compound **1** is stable in the solid state under argon as well as in THF and toluene at $-40\,^\circ C$. At room temperature, however, it decomposes in solution within a few hours with liberation of THF; the desired 1,1′-diazaferrocene **2** could *not* be detected. The decomposition of **1**



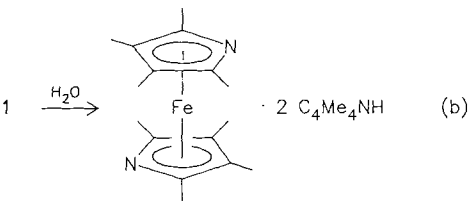
(a)

1



2

is appreciably accelerated by traces of water [Eq. (b)]. The stable adduct **3** is formed as the reaction product in useful yields.[4]



(b)

3

Complex **3** is present in the crystal as a centrosymmetric molecule (Fig. 1).[5] The η^5-pyrrole ligands, which lie in parallel planes, are arranged in a stacked fashion and the nitrogen atoms are situated in *anti* positions. Further, the η^5-pyrrole ligands are each linked through hydrogen bonds to an additional tetramethylpyrrole molecule, whose plane is nearly perpendicular (81.2°) to that of the ligand. All C_4N rings are planar within the limits of experimental error. The line joining the geometric centers of the η^5-pyrrole ligands forms an angle of 1.6° with the normal from the coordination center Fe to the average plane of the ligands, the projection of the coordination center being displaced slightly toward the nitrogen atom. The distance between the ring center and the iron atom, 1.651 Å, is in the expected range.

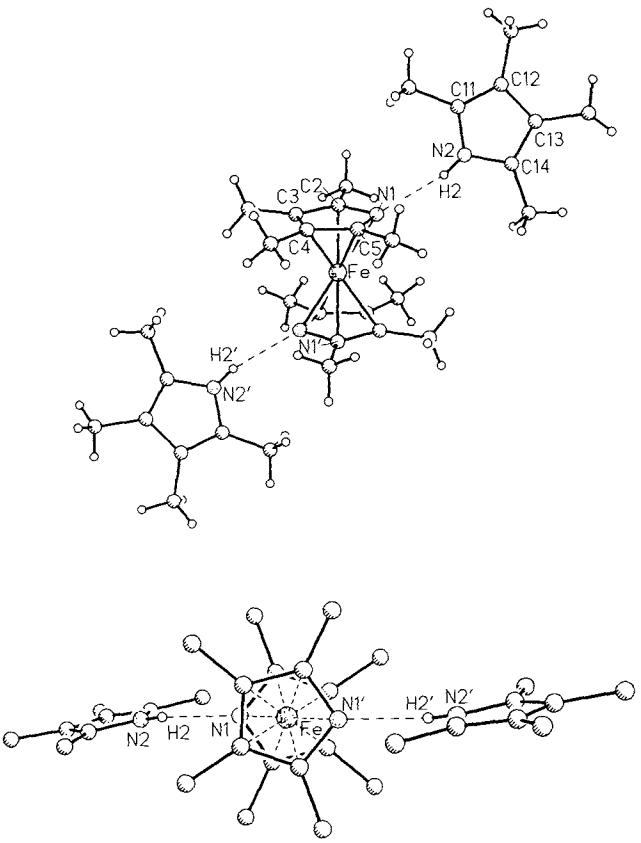


Fig. 1. Two views of the molecular structure of **3**. Selected bond lengths [Å] and bond angles [°]: Fe-N1 2.015(2), Fe-C2 2.023(3), Fe-C3 2.064(3), Fe-C4 2.066(3), Fe-C5 2.019(3), N1-C2 1.395(3), C2-C3 1.414(4), C3-C4 1.413(4), C4-C5 1.407(4), N1-C5 1.390(3), N2-C11 1.371(3), C11-C12 1.355(3), C12-C13 1.425(3), C13-C14 1.352(4), N2-C14 1.365(3), H2-N2 0.806, H2-N1 2.224, Fe-C_4N(center) 1.651; N1-C2-C3 109.8(2), C2-C3-C4 107.0(2), C3-C4-C5 106.6(2), C4-C5-N1 110.5(2), C2-N1-C5 106.2(2), N2-C11-C12 107.4(2), C11-C12-C13 107.5(2), C12-C13-C14 107.5(2), C13-C14-N2 107.7(2), C11-N2-C14 109.8(2), N1-H2-N2 163.1, C_4N(center)-N1-H2 152.7, interplanar angle [C(2-5)N1]-[C(11-14)N2] 81.2.

In the η^5-coordinated pyrrole rings, the CN and the neighboring CC bonds are ca. 0.03 and 0.06 Å longer, respectively, than those in the rings that are not directly bonded to the coordination center, whereas the CC bond opposite the nitrogen atom is slightly shorter. Also clearly revealed is the reduction of the angle at the nitrogen atom of the η^5 ligand (106.2(2), compared with 109.8(2)°), which is accompanied by an enlargement of ca. 3° in the angles at the carbon atoms neighboring the nitrogen atoms.

The hydrogen atom of the unsymmetrical hydrogen bond lies closer to the more strongly basic nitrogen atom N2 (H2-N2 0.806, H2-N1 2.224 Å); the NHN angle (163.1°) is that expected for this type of compound.[6]

[**] Heterocycles as Ligands, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. *P. Sartori* for assistance. Part 2: [9].

In solution, the ^{13}C NMR shifts of the ring atoms ($\delta = 120.56$, 113.76, 99.29, and 84.36) of **3** indicate the presence of η^5- and η^1-coordinated pyrroles. The hydrogen bonds are so stable that the η^1-pyrrole ligands cannot be exchanged at room temperature by addition of tetramethylpyrrole in excess.

The *anti* positions of the ring heteroatoms in **3** contrast to the structures of known 1,1'-diphospha- and 1,1'-diarsaferrocenes.[1b, 7] Apparently, the reduction of the charge density at the nitrogen atoms that accompanies formation of the hydrogen bonds contributes appreciably to the stability of the 1,1'-diazaferrocene system in **3**[8] and points to a possible approach for the stabilization of nitrogen-richer metallocenes.

Experimental Procedure

1: Anhydrous $FeCl_2$ (1.57 g, 12.4 mmol) and C_4Me_4NLi (2.58 g, 20 mmol), prepared from C_4Me_4NH and *n*BuLi, were stirred in 30 mL of THF for 10 min. The residue remaining after removal of the solvent under vacuum was extracted at -40°C with 20 mL of toluene. After addition of 20 mL of *n*-pentane, **1** crystallized at -78°C as an ocher-colored solid. Yield: 2.13 g (48%).—^1H NMR (60 MHz, [D$_8$]toluene, -40°C, TMS int.): $\delta = 3.50$ (m, 8H; OCH_2), 1.97 (s, 12H; C(2,5)-CH_3), 1.93 (s, 12H; C(3,4)-CH_3), 1.43 (m, 8H; CCH_2).—$^{13}C\{^1H\}$ NMR (75.43 MHz, [D$_8$]toluene, -40°C, TMS int.): $\delta = 119.81$ (C2,5), 113.05 (C3,4), 68.42 (OCH_2), 26.26 (CCH_2), 11.33 (C2,5-CH_3), 9.73 (C3,4-CH_3).—MS (70 eV): *m/z* 300 ([$M^{\oplus} - 2C_4H_8O$], fragment of highest mass).

3: **1** (2.50 g, 5.60 mmol) was dissolved in dichloromethane (30 mL) and treated with 0.2 mL of water. Complex **3** precipitated from the filtrate after 10 min and was crystallized from dichloromethane at -78°C as an orange-yellow, stable solid. Yield: 9.09 mg (59.4% based on C_4Me_4NH).—^1H NMR (60 MHz, [D$_8$]toluene, TMS int.): $\delta = 2.05$ (s, 12H; C2,5-CH_3), 1.95 (br. s, 24H; C11,12,13,14-CH_3), 1.57 (s, 12H; C3,4-CH_3), NH not observed.—$^{13}C\{^1H\}$ NMR (75.43 MHz, [D$_8$]toluene, TMS int.): $\delta = 120.56$ (C11,14), 113.76 (C12,13), 99.29 (C2,5), 84.36 (C3,4), 12.62 (C11,14-CH_3), 10.98 (C2,5-CH_3), 9.21 (C3,4-CH_3), 8.77 (C12,13-CH_3).—MS (70 eV): *m/z* 300 ([$M^{\oplus} - 2C_4Me_4NH$], fragment of highest mass).

[8] This is in accordance with the argument presented in [2]. Additional stabilization in this case is provided by the blocking of the lone pair on the nitrogen atom; worthy of note, however, is the fact that a stability maximum is attained in the series of azaferrocenes $[(C_5H_5)Fe(C_4Me_4N)]$ despite the highest nitrogen basicity: N. Kuhn, E. Zauder, unpublished.

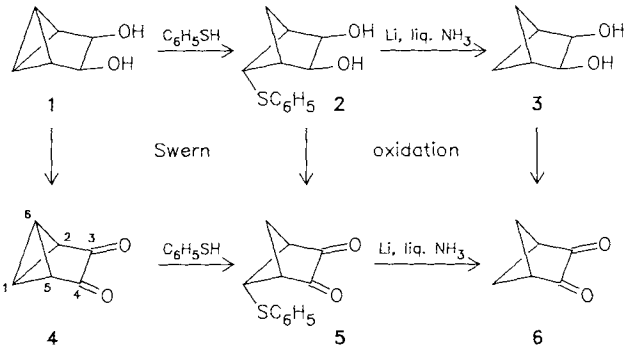
Tricyclo[3.1.0.0^{2,6}]hexanedione (the Valene of *o*-Benzoquinone), Bicyclo[2.1.1]hexane-2,3-dione, and Valenes of a Quinoxaline, of Phenazine, and of a Benzophenazine**

By *Manfred Christl** and *Arno Kraft*

α-Diketones are of interest to photochemists[1] and, along with triketones, to spectroscopists and theoretical chemists[2] as well. Further, their importance as precursors of hetero-[3] and carbocyclic[4] compounds is growing. The starting materials for the preparation of α-diketones include 1,2-diols, which can be oxidized by various reagents.[5] However, each case usually requires a search for a suitable oxidizing agent and the optimal conditions. Recently, the oxidations described by *Corey* and *Kim*,[6] *Pfitzner* and *Moffatt*,[7] and *Swern*[8] have been employed for this purpose.

Some time ago we prepared the *cis*-diol **1** from benzvalene and converted it into the cyclobutyl thioether **2**.[9a] The desulfurization of **2** to give bicyclo[2.1.1]hexane-*cis*-2,3-diol **3** has now been achieved in 70% yield.[9b]



The successful application of the Corey–Kim oxidation to a substrate[6] structurally related to **1** encouraged us to subject **1** to these conditions. Although the desired product, tricyclo[3.1.0.0^{2,6}]hexanedione **4** (16%)[11] was indeed obtained, 4-(methylthiomethoxy)tricyclo[3.1.0.0^{2,6}]hexan-3-one[11] was also formed. Swern oxidation gave pure **4** in only 41% yield (see *Experimental Procedure*). Similarly, bicyclo[2.1.1]hexane-2,3-dione **6** (45%)[12] and its 5-phenylthio derivative **5** (59%)[11] were obtained from **3** and **2**, respectively.

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

As expected,[3] treatment of **4** with the primary 1,2-diamines diaminomaleodinitrile, *o*-phenylenediamine, and 2,3-diaminonaphthalene gave the valenes **7** (50%, m.p. 209–210 °C),[11] **8** (95%, m.p. 122–125 °C),[11,13] and **9** (24%, m.p. 209–211 °C)[11] of quinoxaline-2,3-dicarbonitrile, phenazine, and benzo[*b*]phenazine, respectively. We also prepared analogues of **8** from **5** and **6**.

Whereas the ^{13}C NMR chemical shift of the bicyclobutane bridgehead carbon atoms ($\delta = 10.0$) of **4** is found in the normal region, the annelation of the pyrazine ring in **7**, a quinoxaline unit in **8**, and a benzoquinoxaline system in **9** to the tricyclo[3.1.0.0^{2,6}]hexane framework leads, as expected,[14] to considerable deshielding. The chemical shift values written above the formulas of **7**–**9** show an interesting tendency—namely, the deshielding decreases with increasing size of the aromatic system; on going from **7** to **9**, $\Delta\delta = 12.9$ ppm.

Experimental Procedure

4: Dimethyl sulfoxide (910 mg, 11.7 mmol) was added under N_2 over 3 min to a mixture of oxalyl chloride (1.27 g, 10.0 mmol) and dichloromethane (36 mL) cooled to −70 °C. The resulting, stirred solution was treated within 5 min with **1** (500 mg, 4.46 mmol) in dichloromethane (9 mL) and then stirred for 40 min at −70 °C. Subsequently, triethylamine (2.70 g, 26.7 mmol) was added to the milky mixture at this temperature. The mixture was stirred for an additional 5 min and then allowed to warm to 20 °C, affording a colorless precipitate in a yellow to dirty green solution. Silica gel (3.0 g, 0.063–0.2 mm) was added, the resulting suspension was stirred for 5 min, and the dichloromethane was then carefully removed at 20 torr. The brown residue was placed on a column already containing 5.0 g of silica gel. After elution with *tert*-butyl methyl ether (ca. 180 mL) until the column and the eluate were nearly colorless, the eluate was concentrated at 20 torr and dissolved in 3 mL of dry dichloromethane. Compound **4** was precipitated by addition of 4 mL of petroleum ether. Yield 179 mg (41%) yellow crystals, dec. 145–155 °C (in a sealed tube). IR (KBr): $\tilde{\nu} = 3140, 3125, 3080, 1755\ cm^{-1}$. UV ($CH_3CN$): $\lambda_{max}(\varepsilon) = 431$ nm (28). ^1H NMR ($CDCl_3$): $\delta = 3.13$ (t, $J_{1,2} = 2.2$ Hz; 2-H), 3.83 (t; 1-H), the assignments were made by means of the ^{13}C satellites: $J_{C\text{-}1,1\text{-}H} = 240$, $J_{1,6} = 4.5$, $J_{C\text{-}2,2\text{-}H} = 181$, $J_{2,5} = 3.7$ Hz. ^{13}C NMR ($CDCl_3$): $\delta = 10.0$ (dd, $J_{C\text{-}1,6\text{-}H} = 3$ Hz; C-1), 43.3 (dd, $J_{C\text{-}2,5\text{-}H} = 7$ Hz; C-2), 198.5 (t, $J_{C\text{-}3,1\text{-}H} = 5$ Hz; C-3).

5: The oxidation of **2** was effected according to the procedure described for **4** but with tetrahydrofuran instead of dichloromethane as solvent. The workup was not carried out by adsorption on silica gel but rather by hydrolysis with 2 N HCl and subsequent extraction with ether. Yield after dissolution in dichloromethane and precipitation with petroleum ether: 59%, m.p. 98–101 °C.

6: The oxidation of **3** was effected according to the procedure described for **4**. The workup was not carried out by adsorption on silica gel but rather by concentration of the reaction mixture in vacuo followed by treatment of the residue with ether, filtration of the ether suspension to remove the precipitate ($HEt_3N^{\oplus}Cl^{\ominus}$), concentration of the filtrate in vacuo until the onset of crystallization, and driving the crystallization to completion by addition of petroleum ether. Strict exclusion of moisture is necessary. Yield: 45%. For physical data, see [12].

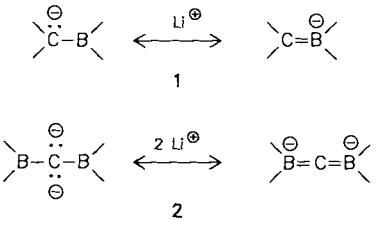
A Monomeric Diboryldilithiomethane with a 1,3-Diborataallene Structure**

By *Monika Pilz, Jürgen Allwohn, Ralf Hunold, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Boryllithioalkenes[1] are boron-stabilized[2] carbanions having the borataalkene structure **1**.[3] We have now prepared the first diboryldilithiomethane **2b** and present here data establishing its 1,3-diborataallene structure **2**.[4]



When we attempted to prepare the 1,3-diborataallene **2a** by addition of *tert*-butyllithium to **3**,[5] we obtained instead the 1,3-diborataallene **2b**, which contains a second *tert*-butyl group in place of the $CH(SiMe_3)_2$ group. The dilithium

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

salt **2b** crystallizes with two ether molecules from a pentane solution of the complex reaction mixture as yellow cubes (yield: 50%).

Upon treatment with one equivalent of cyclopentadiene (CpH), **2b** is transformed into the monoprotonated form **4**, which can be protonated with a further equivalent of CpH to give **5**. Compound **5** is also accessible directly by treatment of **2b** with CpH in excess. Thus, **2b** reacts like a dilithiomethane.

Table 1. Selected physical and spectroscopic data for **2b**, **4**, and **5**. Spectra in [D$_8$]THF (**2b**, **4**) and $CDCl_3$ (**5**).

2b: yellow crystals, m.p. 148°C (dec.), yield 50%. ^{1}H NMR: $\delta = 0.80$ (s, 18H, $C(CH_3)_3$), 2.07, 2.21 (each s, each 6H, *o*-CH_3), 2.50 (s, 6H, *p*-CH_3), 6.63 (s, 4H, *m*-H); ^{13}C NMR (−40°C): $\delta = 21.2$ (2C, *p*-CH_3), 25.1, 26.1 (each 2C, *o*-CH_3), 34.5 (6C, $C(CH_3)_3$), 127.9, 128.0 (each 2C, *m*-C), 134.2 (2C, *p*-C), 140.8, 142.6 (each 2C, *o*-C), 149.2 (br., 2C, *i*-C), 180.2 (br., 1C, CB_2); ^{11}B NMR: $\delta = 32$ ($\nu_{1/2} = 595$ Hz)

4: ^{1}H NMR: $\delta = 0.75$ (s, 18H, $C(CH_3)_3$), 1.88 (s, 18H, *o*- and *p*-CH_3), 4.56 (s, 1H, CHB_2), 5.92 (s, 4H, *m*-H); ^{13}C NMR (−40°C): $\delta = 21.6$ (q, 2C, *p*-CH_3), 25.0 (q, 4C, *o*-CH_3), 33.0 (q, 6C, $C(CH_3)_3$), 99.7 (d, 1C, CHB_2, $^1J_{C-D} = 107.3$ Hz), 125.0 (d, 4C, *m*-C), 129.5 (s, 2C, *p*-C), 136.2 (s, 4C, *o*-C), 154.4 (s, 2C, *i*-C); ^{11}B NMR: $\delta = 61$ ($\nu_{1/2} = 1071$ Hz)

5: colorless crystals, m.p. 57°C, yield: quantitative (NMR spectroscopy). ^{1}H NMR: $\delta = 1.09$ (s, 18H, $C(CH_3)_3$), 1.84 (s, 12H, *o*-CH_3), 2.31 (s, 6H, *p*-CH_3), 2.54 (s, 2H, CH_2B_2), 6.65 (s, 4H, *m*-H); ^{13}C NMR: $\delta = 21.1$ (q, 2C, *p*-CH_3), 22.6 (q, 4C, *o*-CH_3), 28.6 (q, 6C, $C(CH_3)_3$), 29.6 (br. s, 2C, $C(CH_3)_3$), 36.6 (br. t, 1C, CH_2B_2, $^1J_{C-H} = 99.3$ Hz), 127.1 (d, 4C, *m*-C), 134.8 (s, 4C, *o*-C), 135.6 (s, 2C, *p*-C), 144.0 (br. s, 2C, *i*-C); ^{11}B NMR: $\delta = 88$ ($\nu_{1/2} = 952$ Hz)

The structures of **2b**, **4**, and **5** were established from the ^{1}H, ^{13}C, and ^{11}B NMR spectra (Table 1); the structure of **2b** was corroborated by an X-ray structure analysis. In **2b**, the C atom bonded to two boron atoms is strongly deshielded ($\delta(^{13}C) = 180$) compared with the corresponding atoms in **3** (127) and **4** (100). The boron atoms ($\delta(^{11}B) = 32$) are appreciably shielded (**3**, 41 and 54; **4**, 61). Shielding of the terminal atoms and deshielding of the central atom are characteristic properties of allenes.[6] In tetra-*tert*-butylallene, the chemical shift of the central C atom is $\delta = 199.2$.[7] The (linear) chirality of **2b** is revealed by the different chemical shifts of the diastereotopic *ortho*- and *meta*-C atoms and *ortho*-methyl groups in the ^{13}C and ^{1}H NMR spectra.

The X-ray structure analysis[8] of **2b** (Fig. 1) reveals a slightly deformed 1,3-diborataallene structure with a C_2 axis through the central C atom C1. The B-C1-B′ bond angle is 168°, with the boron atoms displaced away from the center of gravity of the lithium ions. The planes B, C11, C21 and B′, C11′, C21′ form an angle of 83°. The mesityl ring is twisted by 88° with respect to the plane C1, B, C21. The B-Cl distance (145 pm) is shorter than the corresponding distance in **3** (149 pm), which has only partial BC double-bond character,[5] and similar in length to that in **1** (144 pm).[3] The lithium ions, each coordinated by one ether molecule, exhibit short distances to C1 (204 pm; in **3**, 209 pm); in addition, each displays a short distance to one boron atom (239 pm; in **3**, 249 pm). The distance to the other boron atom (272 pm) is significantly longer, whereas the distance (234 pm) to the *ipso*-C atom of the mesityl group (C11) corresponds to that in **3** (235 pm). The larger negative charge in the dianion **2b** compared with the monoanion **3** is responsible, owing to stronger attraction of the lithium ions, for the shorter distances. The tendency of the lithium ions to coordinate the *ipso*-C atom of the mesityl groups—C1, B, C11, Li lie practically in the same plane—presumably leads to the Li, C1, Li′ angle of 120° and to the deviation from orthogonality of the planes

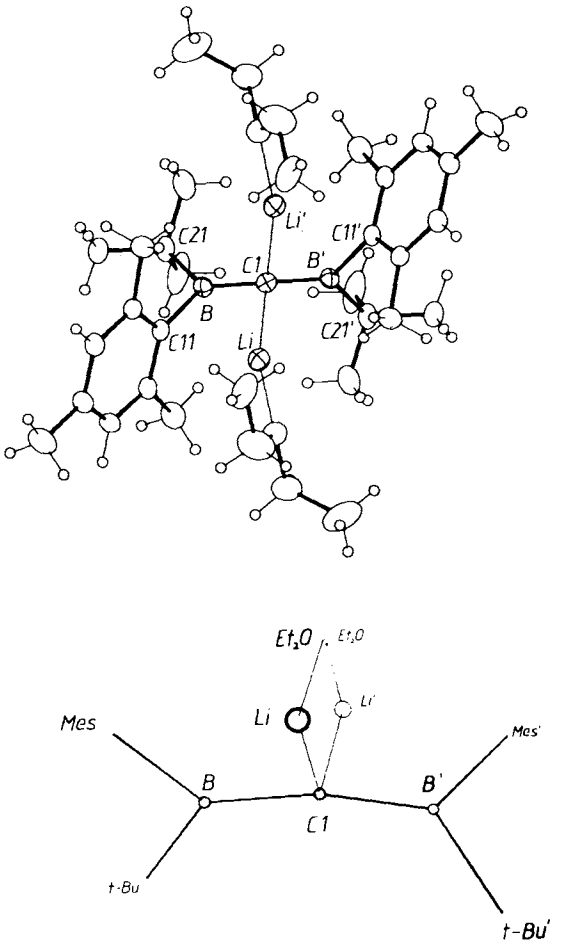

Fig. 1. Top: ORTEP drawing of the molecular structure of **2b** · 2 Et_2O, projection along the C_2 axis. Thermal ellipsoids at the 30% probability level. Bottom: Geometry of the CB_2Li_2 framework, projection roughly perpendicular to the C_2 axis. Important distances [pm] and angles [°]: C1-B 145.0(5), C1-Li 204.0(8), Li-B 239.0(8), Li-B′ 272.3(9), Li-C11 233.5(8), B-C11 164.5(6), B-C21 166.0(6); B-C1-B′ 168.4(4), Li-C1-Li′ 120.1(3), B-C1-Li 84.6(2), B-C1-Li′ 101.2(2), C1-B-C11 124.2(3), C1-B-C21 123.1(3), C11-B-C21 112.7(3).

Li, C1, Li′ and B, C1, B′, reflected in the angles B-C1-Li (84.6°) and B-C1-Li′ (101.2°). The planarity of the mesityl rings is not influenced by the coordination.

The dilithiomethane derivatives characterized so far are aggregated;[9] **2b** is the first derivative with a monomeric structure.

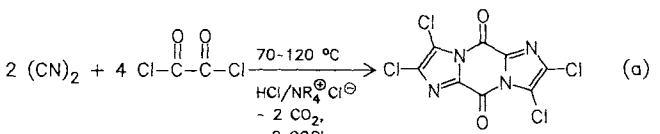
Catalytic Syntheses of Functionalized Nitrogen Heterocycles from Cyanogen**

By *Jörg Sundermeyer* and *Herbert W. Roesky**

Dedicated to Professor Wolfgang Sundermeyer on the occasion of his 60th birthday

A number of reports on novel heterocycle syntheses starting from cyanogen have appeared in this journal in recent years.[1] Using the catalyst systems HCl/Adogen® and $HBr/NBu_4^{\oplus}Br^{\ominus}$, we have now surprisingly found a simple route leading directly to the synthesis of halogenated aromatic heterocycles in good yields starting from cyanogen and oxalyl chloride or bromide.

In the presence of catalytic amounts of HCl and a quaternary ammonium chloride, cyanogen reacts with oxalyl chloride at 70–120 °C to give the tricyclic compound **1** [Eq. (a)]. Carbon dioxide and phosgene, along with small amounts of CO, are formed as gaseous reaction products.



(a)

1

Compound **1** can be regarded as an unusual head-to-tail 1,3 dimer of the ketene **2**, which has not yet been isolated in condensed phase. Indeed, $1/2\,M^{\oplus}$ is observed as the base peak in the EI mass spectrum. The ^{13}C NMR spectrum of **1** shows four signals. A reaction behavior deviating from that expected for ketene dimers[2] and the $\nu_{C=O}$ absorption at 1745 cm^{-1} in the IR spectrum corroborate the central dilactam structure. Compound **1** is cleaved by ammonia and by primary and secondary amines in an exothermic reaction, and by alcohols and water upon warming in a base-catalyzed reaction, to give in near quantitative yield two equivalents of the 4,5-dichloroimidazole-2-carboxylic acid derivatives **3a**,**c**–**e**, which are not otherwise accessible via a simple route. Compound **3a** can be decarboxylated to give **3b**. Characteristic data for these imidazoles are presented in Table 1.

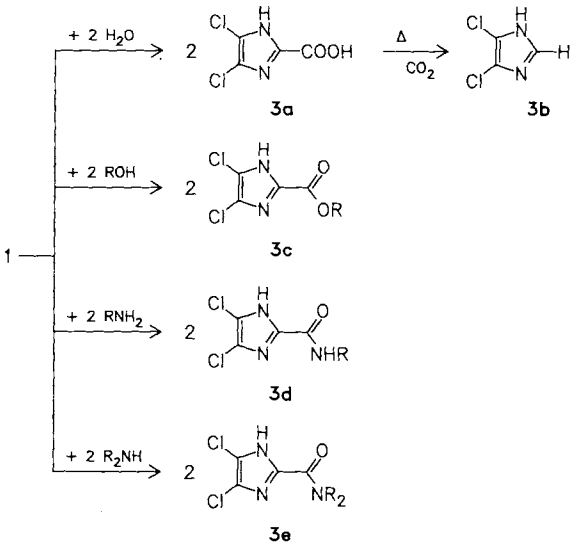


Table 1. Characteristic data for imidazoles **3a**–**e**.

3a: m.p. 160 °C (dec.); yield: 91%.—FI-MS: *m/z* 180 ($M^{\oplus\ominus}$, 50%), 136 ($[M^{\oplus\ominus}-CO_2]$, 100).—IR (Nujol): $\tilde{\nu}=2650$–3400 (ν(NH assoc.) + ν(OH)), 1600–1700 cm^{-1} (br)

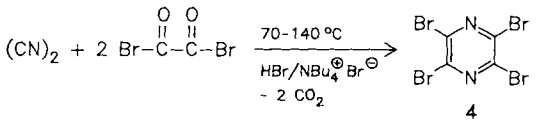
3b: m.p. 179 °C; yield: 60%.—EI-MS: *m/z* 136 ($M^{\oplus\ominus}$, 100%), 109 ($[M^{\oplus\ominus}-HCN]$, 95).—IR (Nujol): $\tilde{\nu}=2500$–$3100\ cm^{-1}$ (ν(NH assoc.)).—^1H NMR ([D6]acetone, 25 °C): $\delta=12.2$ (br; NH), 7.82 (s, 1 H)

3c (R = CH_2CF_3): m.p. 187 °C; yield: 78%.—EI-MS: *m/z* 262 ($M^{\oplus\ominus}$, 24%), 162 ($[M^{\oplus\ominus}-F_3CCH_2OH]$, 100).—IR (Nujol): $\tilde{\nu}=1740$ (ν(C=O), vs), 1160–1200 cm^{-1} (ν(C–F), vs).—^1H NMR ([D6]acetone, 25 °C): $\delta=13$ (br, NH), 4.93 (q, 2 H, $^3J_{CF}=8.7$ Hz).—^{19}F NMR ([D6]acetone, 25 °C): $\delta=-73.22$ (t, $^3J_{CF}=8.7$ Hz)

3d (R = C_6H_5): m.p. 246 °C; yield: 92%.—EI-MS: *m/z* 255 ($M^{\oplus\ominus}$, 20%), 163 ($[M^{\oplus\ominus}-C_6H_5NH]$, 10).—IR (Nujol): $\tilde{\nu}=1660\ cm^{-1}$ (ν(C=O), vs)

3e (R_2 = $CH_2CH_2OCH_2CH_2$): m.p. 218 °C, yield: 93%.—EI-MS: *m/z* 249 ($M^{\oplus\ominus}$, 10%), 163 ($[M^{\oplus\ominus}-NC_4H_8O]$, 20).—IR (Nujol): $\tilde{\nu}=1610\ cm^{-1}$ (ν(C=O), br, vs)

Remarkably, the reaction of cyanogen with oxalyl bromide under analogous catalytic conditions affords the tetrabromopyrazine **4** and carbon dioxide in over 70% yield [Eq. (b)].



(b)

4

Compound **4** exhibits a broad bactericidal activity.[3] Since the bromine atoms can undergo facile nucleophilic substitution, **4** is also of interest as a central building block in the synthesis of antitumor agents[4a] as well as of heterocycles with high electron affinity.[4b] Chloroimidazoles of type **3**, as well as the tetrabromopyrazine **4** and its derivatives, can only be prepared in poor yields, if at all, by halogenation[5] of the parent structures synthesized via classical routes.

Presumably, in both reactions (a) and (b), cyanogen first reacts with the catalyst to establish an equilibrium with the oxalimidic halide **5**, which is unstable as a free species. Compound **5** then undergoes partially irreversible reactions (*N*-acylation, ring closure, *O*-acylation, decarboxyla-

5, X = Cl, Br

tion) with oxalyl halide to give functionalized heteroarenes, the catalyst being re-formed.

Experimental Procedure

1: Anhydrous Adogen® 464 (9 g; Aldrich) and oxalyl chloride (125 mL) were dissolved in dichloromethane (220 mL) contained in a 500-mL Monel cylinder, and cyanogen (26 g) and HCl (3 g) were then condensed into the solution. This mixture was stirred for 3 d, the temperature being increased stepwise from 70 to 120°C. The autoclave was then opened and the precipitated crude product, obtained as gold-yellow crystalline platelets, was separated from soluble impurities by filtration and subsequent washing with THF. Yield 48.5 g (60% based on $(CN)_2$). Traces of $(CN)_x$ give the product a greenish-yellow color. Loss-free purification was carried out by sublimation at 300°C/10^{-1} mbar; m.p. >270°C. Compound **1** is poorly soluble in the conventional solvents.—IR (Nujol): $\tilde{\nu}$ = 1745 cm^{-1} (ν(C=O), vs).—EI-MS: *m/z* 326 ($M^{\odot\ominus}$, 24%), 162 ($1/2\,M^{\odot\ominus}$, 100), 134 ([$1/2\,M^{\odot\ominus}$ − CO], 17); FI-MS: *m/z* 326 ($M^{\odot\ominus}$), correct isotopic pattern for $C_8N_4O_2Cl_4$.—^{13}C NMR ([D$_6$]dimethyl sulfoxide, 50°C): δ = 145.9, 135.5, 131.9, 116.8.

4: Tetrabutylammonium bromide (5 g) and oxalyl bromide (53 mL) were dissolved in dichloromethane (150 mL) contained in a 300-mL Monel cylinder, and cyanogen (8 g) and HBr gas (8 g) were then condensed into the solution. This mixture was stirred for 3 d, the temperature being increased stepwise from 70 to 140°C. The autoclave was then opened and the brown reaction solution was evaporated to dryness under vacuum. Compound **4** was sublimed at 100–130°C/10^{-1} mbar from the residue remaining after evaporation. Yield: ca. 45 g white crystals (73% based on cyanogen). If necessary, **4** can be purified further by recrystallization from CH_2Cl_2/hexane or by column filtration (40 g of product on 80 g of SiO_2 (0.060–0.200 mm), elution with $CHCl_3$), m.p. 150–151°C.—IR (Nujol): $\tilde{\nu}$ = 1348 (m), 1270 (vs), 1195 (w), 1140 (s), 1035 (s), 515 (m), 468 cm^{-1} (m).—EI-MS: *m/z* 396 ($M^{\odot\oplus}$, 100%), 315 ([$M^{\odot\ominus}$ − Br], 50).—^{13}C NMR ($CDCl_3$, 25°C): δ = 139.6.

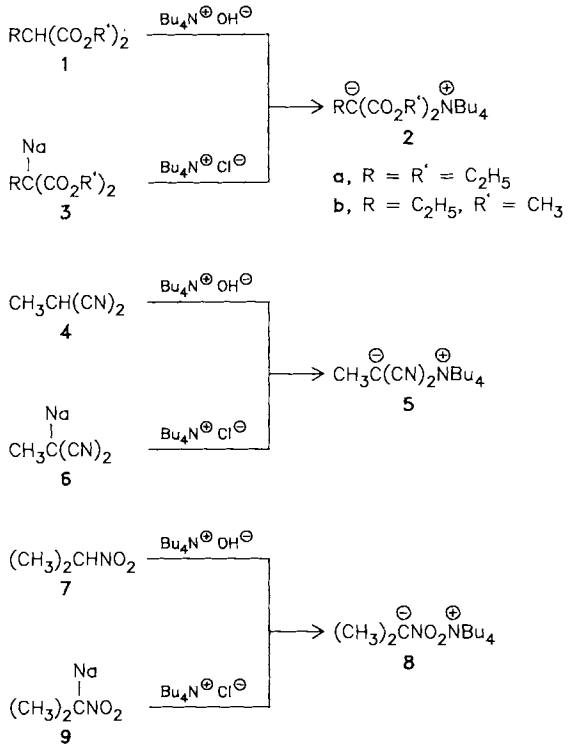
Metal-free Carbanion Salts as Initiators for the Anionic Polymerization of Acrylic and Methacrylic Acid Esters**

By *Manfred T. Reetz,* Thomas Knauf, Ulrich Minet,* and *Carsten Bingel*

The polymerization of alkyl acrylates at room temperature with quantitative formation of living polyacrylates having a narrow molecular weight distribution has only recently been made possible.[1] Reaction of alkylthiosilanes as initiators with acrylic acid esters in the presence of catalytic amounts of ZnI_2 results in a group transfer polymerization[2] with formation of polymers having M_w/M_n values (ratio of weight average molecular weight to the number average molecular weight) of < 1.3. A second and in principle quite different method uses tetrabutylammonium thiolates $Bn_4N^{\oplus}RS^{\ominus}$ as initiators.[3] This metal-free anionic polymerization requires no catalysts, but has the disadvantage that the initiators are highly nucleophilic and therefore relatively unstable, and that only oligomers with molecular weights of less than ca. 2000 can be obtained.[4] We report here on a method which overcomes both these problems.

The initiators in this new method are the resonance-stabilized, metal-free ammonium methanides[5] **2**, **5** and **8**, which are accessible either by deprotonation of the corresponding C–H acidic precursors **1**, **4** and **7**, respectively, with $Bu_4N^{\oplus}OH^{\ominus}$ or by reaction of the sodium salts **3**, **6** and **9**, respectively, with $Bu_4N^{\oplus}Cl^{\ominus}$.



These carbanion salts are either colorless oils (**2b**) or white crystals (**2a**, **5**, **8**) and have been characterized by NMR and IR spectroscopy.[6] They are storable for months in a refrigerator, but can also be handled at room temperature without problems. When acrylic acid butyl ester **10** is added dropwise to solutions of **2**, **5** or **8** in THF or toluene at room temperature, a spontaneous exothermic reaction takes place with formation of the polyacrylate **13** (>95% conversion after acidic workup of **12**).

Table 1 clearly demonstrates that the molecular weight distribution is influenced by the solvent, the initiator, and the monomer/initiator ratio (reflected in M_n (calcd)). Low, i.e. good M_w/M_n values (≤ 1.3) are achieved in particular with the malonates **2** (e.g. Nos. 1, 3, 6, 8, 10), whereas the nitromethanide **8** affords larger M_w/M_n values (≈ 2–3). Significantly, a polymer with a molecular weight of ca. 20000 and relatively narrow molecular weight distribution

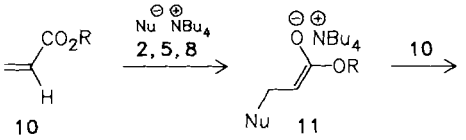
Table 1. Polymerization of butyl acrylate **10** with metal-free carbanions at room temperature [a].

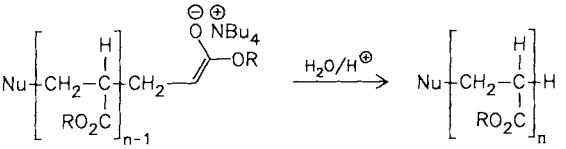
No.	Initiator	Solvent	M_n (calcd) [b] [kg mol^{-1}]	M_n (exp) [kg mol^{-1}]	M_w/M_n [c]
1	**2a**	THF	1.15	0.90	1.16
2	**2a**	THF	5.32	3.13	1.36
3	**2a**	THF	10.44	7.42	1.25
4	**2b**	THF	1.44	1.51	1.50
5	**2b**	toluene	1.44	0.64	1.37
6	**2b**	THF	5.29	5.86	1.30
7	**2b**	toluene	5.29	6.82	1.36
8	**2b**	toluene	10.41	10.92	1.30
9	**2b**	THF	20.67	17.43	1.38
10	**2b**	toluene	20.67	20.39	1.30
11	**5**	THF	1.36	0.61	1.14
12	**5**	toluene	1.36	0.71	1.61
13	**5**	THF	5.21	2.59	1.43
14	**5**	toluene	5.21	4.21	1.34
15	**8**	THF	1.37	0.85	2.71
16	**8**	toluene	1.37	1.25	2.18

[a] The temperature rises 10–25 °C during the polymerization. [b] Calculated from the ratio [monomer]/[initiator]. [c] The breadth of a molecular weight distribution can be characterized by M_w/M_n. The M_n values were determined gel-chromatographically using a standard calibration. The calibration samples were supplied by Bayer AG.

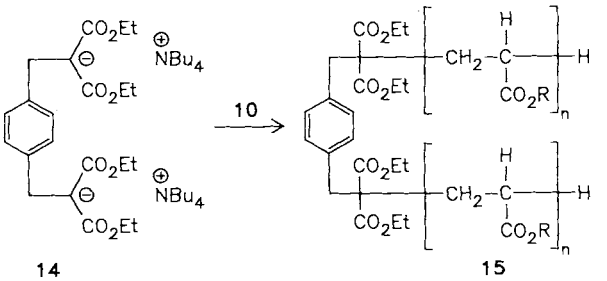
($M_w/M_n = 1.3$; No. 10) can be prepared; this is not possible with ammonium thiolates as initiators.[3]



R = n-C_4H_9



Dianions of the type **14** also initiate the polymerization of acrylic acid butyl ester (→ **15**: e.g. M_n(calcd) = 1717, M_n(exp) = 1624, $M_w/M_n = 1.1$; THF/room temperature).



Not only acrylic acid methyl and ethyl esters, but also the less reactive methacrylic acid butyl ester can be polymerized in the same way. Surprisingly, the nitro-stabilized carbanion **8** proved to be optimal in the polymerization of methacrylates (e.g. M_n(calcd) = 2090, M_n(exp) = 2050; $M_w/M_n = 1.17$; THF/room temperature).

Why can α-activated olefins such as acrylic acid alkyl esters (and even the very reactive methyl ester) be smoothly polymerized with **2**, **5** and **8** at room temperature, while such classical initiators as bulky organolithium compounds generally lead to moderate yields and high M_w/M_n values, even at low temperatures?[7] Perhaps this has to do with the fact that the typical side reactions and chain-terminating reactions like the intramolecular Claisen condensation require a metal ion for the activation of the ester function and expulsion of the alkoxide, so that this back-biting reaction[7] cannot compete in the same way in the case of the metal-free system. Relevant is the observation that polymers with a wider molecular weight distribution ($M_w/M_n > 3$) are obtained in poor yields on using the sodium or potassium salts instead of the ammonium salts **2**, **5** and **8**. In contrast to the group transfer polymerization, in which covalently bonded silyl groups migrate along the growing chain,[1,2] in the metal-free polymerization electrostatic forces between the anionic chain terminal and the ammonium counterion are expected to play an important role. Mechanistic and theoretical investigations relating to this hypothesis are presently under way.[8]

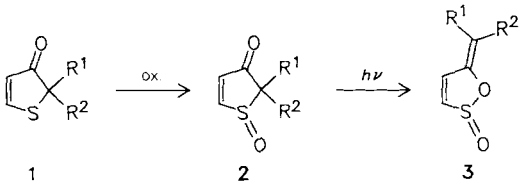
5-Isopropyliden-1,2-oxathiole 2-Oxide by Photoisomerization of 2,2-Dimethyl-3(2*H*)-thiophenone 1-Oxide

By *Ronald Kowalewski* and *Paul Margaretha**

3(2*H*)-Thiophenones **1** are cyclic enones. Upon excitation with light, **1a** forms tricyclic dimers[1] and **1b** undergoes intramolecular [2 + 2] cycloaddition to give thiatricyclooctanones.[2] We now report that the sulfoxides **2**, which are readily accessible by oxidation of the cyclic γ-ketovinyl sulfides **1**,[3] behave completely differently in light-induced reactions.



a: $R^1 = R^2 = CH_3$
b: $R^1 = COOCH_3$, $R^2 = CH_2CH{=}CH_2$

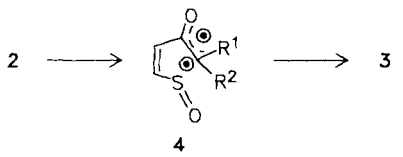
Thus, irradiation ($\lambda = 350$ nm) of **2a** in CH_3CN or CH_2Cl_2—even in the presence of an alkene, e.g. isobutene—leads selectively to 5-isopropylidene-1,2-oxathiole 2-oxide **3a** which can be isolated in 90% yield by chromatography.[4] In an analogous way, **2b** isomerizes exclusively (NMR) to **3b**, which, however, could not be isolated since it partially decomposes, both on SiO_2 as well as on Al_2O_3. Above 50 °C, re-isomerization to **2a** is observed in the case of **3a**, whereas the diene ester **3b** polymerizes. The compounds **3** were characterized by ^{1}H-NMR, ^{13}C-NMR, IR and mass spectroscopy.[5] The alternative structure of a 1,2-oxathiin-5(6*H*)-one can be ruled out by the absence of carbonyl absorptions.

In principle, in the photoisomerization of **2b** two diastereomeric esters can be formed. The selective formation of **3b**, which on the basis of the downfield shift[6] of H-4 ($\delta = 8.15$) can be assigned the depicted *E* configuration, could be attributed to destabilizing dipole-dipole interactions between the ester-O and ring-O atoms in the *Z* isomer.

In analogy to the photo-Fries rearrangement[7] of non-enolizable 1,3-diketones to enol lactones,[8] the formation of the diradical **4** by α-cleavage of the $\geqslant$C–S bond[9] can be assumed as reaction mechanism for the isomerization **2** → **3**. From the values determined for the quantum yields ($\Phi = 0.6$–0.7) it follows that **4** preferentially cyclizes to **3** and that the recombination to give **2** plays only a subordinate role.



The 1,2-oxathioles are a class of heterocycles that have rarely been studied.[10] Whereas the unsubstituted 5*H*-1,2-oxathiole 2-oxide,[11] 4-bromo-5-alkyl derivatives,[12] and the 3,4-diphenyl compound[13] have been prepared, 5-alkylidene-1,2-oxathiole 2-oxides such as **3** were hitherto unknown. These *S*- and *O*-functionalized *s-trans*-1,3-dienes **3** are now readily accessible and could prove to be interesting intermediates for organic synthesis.

The *p*-Nitrocinnamyloxycarbonyl (Noc) Moiety—an Acid-stable Amino-protecting Group Removable under Neutral Conditions for Peptide and Glycopeptide Synthesis**

By *Horst Kunz** and *Joachim März*

On attempting to synthesize glycopeptides[1] one is always confronted with a lack of protecting groups which, on the one hand, are reliably stable for handling, and, on the other, can be removed again under almost neutral conditions. Aside from the classical benzylic[2] and the two-step protecting groups,[3] the allyl esters[4] and allyloxycarbonyl protecting groups[5] fulfill these requirements the best. They can be removed from the blocked functions by palladium(0)-catalyzed allyl transfer under practically neutral conditions. Even the sensitive *O*-glycosyl-serine and *O*-glycosyl-threonine bonds remain intact.[4]

We have now modified the principle of the allyl-protecting moiety in the *p*-nitrocinnamyloxycarbonyl (Noc) protecting group such that acid-stability and tendency to crystallize are increased and a strong UV absorption ($\lambda_{max} = 310$ nm) is observed. At the same time the cleavability under neutral conditions remains unaltered. Neither the cinnamyl esters[6] nor the cinnamyloxycarbonyl group[7] fulfill these conditions because they are already attacked upon cleavage of the *tert*-butyl ester and carbamate with HCl in ether. For the preparation of a reagent for intro-

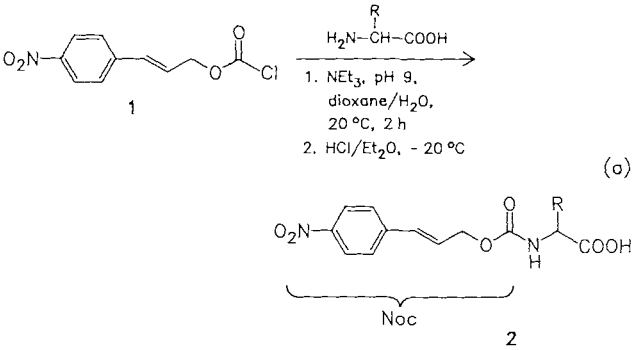

Table 1. *p*-Nitrocinnamyloxycarbonyl (Noc) amino acids **2** prepared according to Equation (a).

Compound	Amino acid	Yield [%]	M.p. [°C]	$[\alpha]_D^{22}$ ($c = 1$, $CHCl_3$)
2a	Ile	95	83	+21.0
2b	Ser	98	76	+15.2 [a]
2c	Phe	85	68	+26.8
2d	Ala	81	93-95	+ 2.3
2e	Leu	64	86	− 3.68
2f	Val	61	72	+ 8.1
2g	Asp(OH)-O*t*Bu	72	oil	+14.8

Johann-Joachim-Becher-Weg 18-20, D-6500 Mainz (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ducing the Noc group, *p*-nitrocinnamaldehyde[8] was prepared from *p*-nitrobenzaldehyde and acetaldehyde and then reduced with sodium tetrahydroborate to cinnamyl alcohol, which on reaction with phosgene furnished the *p*-nitrocinnamyl chloroformate **1**. This reacts, either as such or after conversion into the analogous *N*-hydroxysuccinimide-active ester at pH 9 (under pH-stat conditions) with amino acid salts to give, as a rule, crystalline *p*-nitrocinnamyloxycarbonyl(Noc) amino acids **2** in high yields [Eqn. (a); Table 1].

Owing to the stability of the Noc-protecting group, the Noc amino acids **2** can smoothly react with amino acid *tert*-butyl or allyl esters[9] both in the presence of ethyl-2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ) [method B in Eqn. (b)][10] as well as according to the modified carbodiimide method [method A in Eqn. (b), DCC = dicyclohexylcarbodiimide, HOBt = 1-hydroxybenzotriazole][11] to give the Noc dipeptide esters **3** (Table 2).

$$\underset{\mathbf{2}}{\text{Noc–Xaa–OH}} + \text{H–Xaa'–OR} \xrightarrow[\text{B: EEDQ, } CHCl_3,\ 20\,^\circ C,\ 8\,h]{\text{A: DCC/HOBt, } 20\,^\circ C,\ 8\,h} \underset{\mathbf{3}}{\text{Noc–Xaa–Xaa'–OR}} \quad \text{(b)}$$

Table 2. Noc dipeptide esters **3** prepared according to Equation (b).

Compound	Xaa-Xaa'	OR	Method	Yield [%]	M.p. [°C]
3a	Ile-Phe	O*t*Bu	A	93	86–89
3a	Ile-Phe	O*t*Bu	B	84	104–105
3b	Ser-Phe	O*t*Bu	B	96	54
3c	Phe-Phe	O*t*Bu	B	92	98–99
3d	Ala-Phe	O*t*Bu	B	92	65–67
3e	Val-Phe	O*t*Bu	B	97	70–72
3f	Phe-Val	OAllyl	B	93	134
3g	Phe-Ala	OAllyl	B	91	148

A comparison of the samples of **3a** prepared according to methods A and B showed that pure compounds are more easily obtained according to the EEDQ method. Therefore, the other Noc dipeptide esters **3** were prepared by this method.

Due to the acid stability of the Noc group, the *tert*-butyl esters **3a–e** can be removed with trifluoroacetic acid selectively and quantitatively within 30 min to give **4** [Eqn. (c)].

$$\underset{\mathbf{3}}{\text{Noc–Xaa–Xaa'–O}t\text{Bu}} \xrightarrow[1\,h,\ 20\,^\circ C]{CF_3COOH} \underset{\mathbf{4}}{\text{Noc–Xaa–Xaa'–OH}} \quad \text{(c)}$$

3a: 70%
3d: 90%
3e: 90%

The Noc group can be cleaved quantitatively and selectively from the compounds **3** under neutral conditions by palladium(0)-catalyzed allyl group transfer [Eq. (d)]. The reaction times are noticeably longer than in the case of the unsubstituted allyloxycarbonyl (Aloc) protecting group[5] (up to 8 hours).[12] Therefore, dimedone[5] is less suited as allyl acceptor, because it reacts further with the liberated amino components to give the enaminoketone[13] (Dche-protecting group). The practically non-carbonyl-active CH acid *N,N'*-dimethylbarbituric acid[14] (DMBS, $pK_s = 4.7$) proved to be a much more suitable allyl acceptor; its 5-(*p*-nitrocinnamyl) derivative is easy to separate from the liberated dipeptide esters **5**.

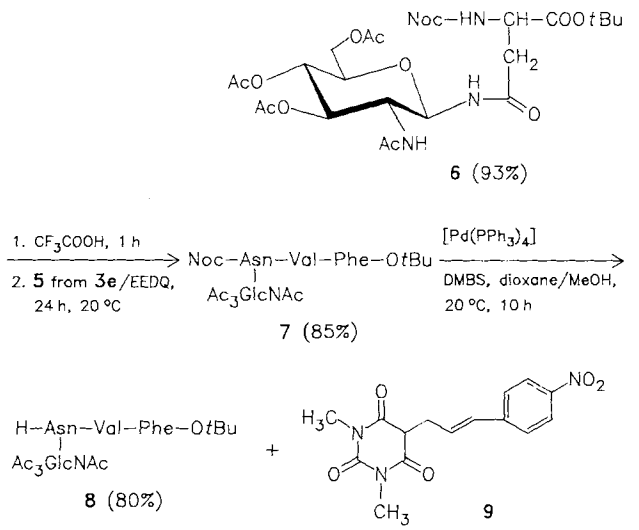
$$3 \xrightarrow[THF,\ 8\,h,\ 20\,^\circ C]{[Pd(PPh_3)_4]/DMBS} \underset{\mathbf{5}}{\text{H–Xaa–Xaa'–O}t\text{Bu}} \quad \text{(d)}$$

3a: 96%
3d: 91%
3e: 84%

Most advantageous is that the new protecting group Noc is stable towards the rhodium(I)-catalyzed isomerization and hydrolysis by which the allyl ester is selectively removed [Eqn. (e)].[9]

$$\underset{\mathbf{3f}}{\text{Noc–Phe–Val–OAllyl}} \xrightarrow[EtOH/H_2O,\ 1\,h,\ 70\,^\circ C]{[(Ph_3P)_3RhCl]} \underset{87\%}{\text{Noc–Phe–Val–OH}} \quad \text{(e)}$$

Thus, the Noc moiety is a valuable protecting group which can be removed under neutral conditions and which is even partially orthogonally stable to the protection by the unsubstituted allyl group. Its suitability in the synthesis of glycopeptides is demonstrated by the reaction sequence in Scheme 1.



Scheme 1. Use of the Noc protecting group in peptide synthesis.

The stability of the Noc group towards acids and its completely selective removal under neutral conditions are clearly demonstrated in the synthesis of **8**. The CH acid **9** ($\lambda_{max} = 277$ nm in trifluoroacetic acid), like free DMBS, can easily be separated from the *N*-deblocked glycopeptide **8**.

General procedure for 5

A solution of 1 mmol of Noc-dipeptide *tert-butyl ester* **3a–e** in 30 mL of acid-free THF (or dioxane/methanol) was treated with 0.78 mmol of *N,N'*-dimethylbarbituric acid (DMBS), 0.26 g (0.1 mmol ≙ 10 mol-%) of tetrakis(triphenylphosphane)palladium(0) and 0.26 g (1 mmol) of triphenylphosphane and the resulting mixture stirred in the dark. The *N,N'*-dimethyl-5-(*p*-nitrocinnamyl)barbituric acid **9** which precipitated was filtered off and the solvent was then removed from the filtrate by distillation in vacuo. The resulting residue was taken up in 80 mL of $CHCl_3$ and extracted four times with 0.5 N Na_2CO_3 solution. The $CHCl_3$ solution was extracted five times with 0.5 N HCl and the combined aqueous solutions were extracted once with $CHCl_3$. The aqueous phase was brought to pH 10–11 with Na_2CO_3 and extracted with 50 mL of $CHCl_3$. After drying of the $CHCl_3$ solution with $MgSO_4$ and removal of the solvent by distillation in vacuo the remaining oils were treated at −20 °C with HCl-saturated ether and immediately evaporated to dryness in vacuo. The hydrochlorides of the peptide esters **5** were recrystallized from ethyl acetate/petroleum ether or $CHCl_3$/petroleum ether.

In this way we obtained, e.g. L-valyl-L-phenylalanine *tert*-butyl ester as the hydrochloride: m.p. 173–176°C; $[\alpha]_D^{22}$ of the free ester = +3.1 (c = 1, $CHCl_3$).

A Donor Cage with Bent Tetrathiafulvalene Moiety**

By *Jorg Röhrich, Peter Wolf, Volker Enkelmann,* and *Klaus Müllen**

Upon reaction with suitable acceptors, tetrathiafulvalene (TTF) can form crystalline charge transfer (CT) complexes displaying high electrical conductivity.[1–3] Particularly attractive from the electronic point of view are derivatives with two or more phane-like[4] or chain-like[5–8] coupled TTF units, with or without conjugation. We have searched for a route to oligomeric TTF systems which can furnish chain- and/or cage-like molecules and enables the introduction of solubility-improving substituents. The readily accessible title compounds **1b,c** contain a strained donor cage with an unusually bent TTF unit.

Reaction of the 1,3-dithiole-2-thione-4,5-dithiolate **2** (as tetraethylammonium salt of the zincate)[9] with the tetrafunctional electrophilic tetrabromodurene **3a** in tetrahydrofuran (THF) provided the dithione **4a** in 65% yield. This compound is a further potential polyfulvalene precursor like the dithione **5** recently described by us,[10,11] but it is unsuitable for further reactions because of its sparing solubility. Therefore, starting from duroquinone,[12] we synthesized the dialkoxytetrabromides **3b** and **3c**,[13] which react with **2** to give the significantly more soluble dithiones **4b** and **4c**, respectively.[13]

The intramolecular coupling of **4b** or **4c** in boiling xylene in the presence of triethyl phosphite leads to formation of the macrocycles **1b** or **1c** respectively, which contain a TTF unit. There is no evidence of linear oligomers being formed; the formation of **1** does not necessitate high dilution. Characteristic in the NMR spectra of **1b,c** are the resonances of only four sp^2-hybridized C atoms and the absorption of an AB spin systems, which can be ascribed to the eight-membered ring methylene protons.[13]

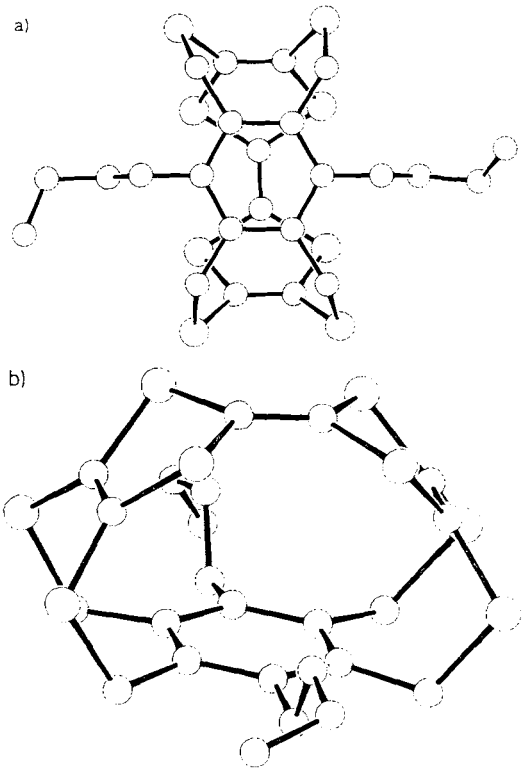

Fig. 1. Molecular structure of **1b** [14, 15]. a) Projection onto the plane of the benzene ring. b) Side view of the molecule.

The result of a crystal structure analysis is shown in Figure 1. As the view onto the plane of the benzene ring shows, the basic skeleton of the compound has approximately ideal *mm*2 (C_{2v}) symmetry, i.e. the fulvalenic double bond is located centrally above the benzene ring at a transannular distance of 391 pm. Due to the high ring strain the TTF skeleton deviates considerably from planarity. The planes defined by the sulfur atoms and the outer double bonds are inclined at angles of 49.5° and 47.6° to the central double bond. Within the accuracy of the structure analysis (0.6 pm) the benzene ring is planar, but in contrast to normal cyclophane structures the bonds to the

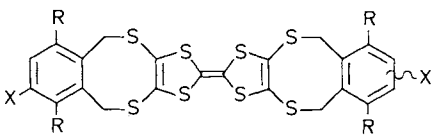
[**] This work was supported by the Bundesminister für Forschung und Technologie.

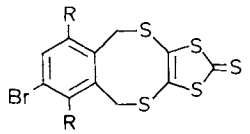
bridgehead atoms are bent outwards, i.e. away from the TTF system. The distance of these atoms from the plane of the benzene ring is 1-2 pm.

Compound **1** contains a TTF moiety which is coupled via four-S-CH_2 groups to a benzene ring, and thus can be compared with the well-known donor bis(ethylenedithio)-TTF.[16] **6a** can serve as a linear model compound for **1**,[17] but its sparing solubility impairs a spectroscopic characterization. We therefore synthesized the thione **7** from 4-bromo-3,6-dibutoxy-*o*-xylene dibromide and the dithiolate **2**. Coupling of **7** in the presence of triethyl phosphite furnishes the spectroscopically fully characterizable fulvalene **6b** as a *cis/trans* mixture.[13]

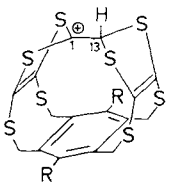


6

a: R=H; X=H
b: R=OBu; X=Br



7, R=OBu



8, R=OPr

A comparison of **1b,c** and **6b** reveals marked differences in the physical properties:

- the ^{13}C resonance of the fulvalenic centers in the cage compound **1c** ($\delta = 134.5$) is shifted noticeably downfield compared to that in the "linear" species **6b** ($\delta = 112.0$);
- the electrochemical oxidation of **6b** with cyclovoltammetric monitoring (dichloromethane, tetraethylammonium perchlorate, SCE) shows two reversible one-electron transfers at 0.52 V and 0.96 V. Under the same conditions, an electron is irreversibly removed from **1b** at 1.09 V; the secondary product can be oxidized reversibly ($E_{1/2} = 0.55$ V);
- the longest wavelength band in the absorption spectrum of **6b** ($\lambda = 303$ nm) is shifted hypsochromically compared to that of **1b** ($\lambda = 311$ nm); however, the band in the cyclic compound **1b** is less intense [**6b**: $\varepsilon = 22730$ L mol^{-1} cm^{-1}, **1b**: $\varepsilon = 8600$ L mol^{-1} cm^{-1}].

To determine the consequences of the unusual structure of **1b,c** on the reactivity we treated **1b** with gaseous hydrogen chloride and monitored the reaction ^1H- and ^{13}C-NMR spectroscopically. Protonation of the fulvalenic double bond takes place, accompanied by a change in color from yellow to red. The resulting cation **8** is stable at 0°C and displays a dynamic effect due to migration of the added proton to the neighboring C atom [$\delta(^{13}C) = 220.8$ (C-1), 60.0 (C-13); $\delta(^1H) = 4.45$ and 4.54 (two AB systems for the SCH_2 protons)].

Following the recently reported acid-catalyzed *cis/trans* isomerization of unsymmetrically substituted TTF compounds,[18] this now provides an example of the spectroscopic detection of a protonated intermediate. The protonation is reversible: neutralization of a four-days-old solution of **8** in chloroform with gaseous ammonia led to quantitative recovery of the intact cyclic compound **1b**.

The red coloration observed on protonation of **1** also occurs with other acceptors such as copper(II) triflate, dichlorocyano-*p*-benzoquinone or iodine. The ^1H-NMR and FAB-MS spectra of the copper complex furnish proof of the intact constitution of **1**; the absorption spectrum shows a characteristic long wavelength band at $\lambda = 533$ nm. This band can also be observed in a solution of **8** in dichloromethane and possibly corresponds to an intramolecular CT transition from the electron-rich benzene system to the dithiolylium fragment; it does not occur on protonation of the linear analogue **6b**.

The synthesis of **1** described here also offers the possibility of changing the size of the molecular cage with tetrafunctional electrophiles other than tetrabromodurene.

[14] Crystallographic data: Enraf-Nonius CAD-4 diffractometer, $Cu_{K\alpha}$ radiation, $\lambda = 1.5405$ Å, graphite monochromator, monoclinic, space group $P2_1/n$, $a = 11.3921(10)$, $b = 14.666(11)$, $c = 17.746(2)$ Å, $\beta = 71.537(8)°$, $\rho_{calcd} = 1.64$ g cm^{-1}, $Z = 4$, $T = 140$ K, $\mu(Cu_{K\alpha}) = 87.1$ cm^{-1}. 4546 reflections, 2841 observed [$I > 3\sigma(I)$]. Empirical absorption correction; anisotropic temperature factors for Cl [15], S, O and C excepting the terminal C atoms of the side groups, which like the H atoms were refined with isotropic temperature factors. $R = 0.051$, $R_w = 0.053$, $w = 1$, for 455 parameters. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53228, the names of the authors, and the journal citation.
[15] All bond lengths and angles have ordinary values with exception of the bonds to the terminal C atoms of the propyl moiety. This is due to a disorder which is associated with high temperature factors and a larger uncertainty of the coordinates. In each case two positions are found for the terminal CH_3 groups; in the refinement these were taken into account with a population parameter of 50%. For clarity, only one of the two orientations is shown in Figure 1. In each case the conformation of the side chains deviates considerably from an all-*trans* conformation.

After recrystallization from chloroform, the crystals of **1b** contain one molecule of $CHCl_3$ per cage molecule, which they slowly lose at room temperature. The structure analysis was therefore carried out at 140 K.

Paraformaldehyde as Possible Chirality Amplifier**

By *Christian R. Noe,* Max Knollmüller,* and *Peter Ettmayer*

Not long ago it was reported that the space probe "Giotto" had, on encountering the vapor trail of Halleys comet, discovered a short-chain polyoxymethylene, possibly deposited on silicates or graphite, as the first polymer in the universe.[1] It is well-known[2] that polyoxymethylene has a helical conformation; therefore there should be levorotatory and dextrorotatory enantiomers of such helices.

For some time we have been concerned with the role of stereoelectronic effects of the anomeric type in the chiral recognition and especially in the amplification (perpetuation) of chirality in evolution.[3] Since the helicity of polyoxymethylene is attributed to such stereoelectronic effects[4] it appeared interesting to us to carry out experiments on asymmetric induction with the help of such structures. The fundamental requirement for a role of paraformaldehyde in chirality transfer, for example from silicates to organic molecules, would be an unambiguously predictable direction of the asymmetric induction, independent of the number of oxymethylene groups.

For the preparation of model chiral oligooxymethylene compounds we used the model terpenoid carbohydrate **1**, to which we added formaldehyde and, subsequently, hydroxyacetonitrile under acid conditions at $-20°C$. The compounds **2a-d**[5] could be readily isolated from the resulting nitrile mixture by flash chromatography and then characterized and converted by reaction with phenylmagnesium bromide into the arylketones **3a-d**.

The nucleophilic methylation of prochiral carbonyl groups in **3** was chosen as model reaction for the asymmetric induction. Besides methylmagnesium iodide, also methyllithium and, in two cases, methylmagnesium iodide with zinc chloride were used for the methylation so as to be able to relativize the chelating effect on the ratio of the diastereomeric pairs (**4a-d/5a-d**). The addition to the ketone **3a** was accomplished with moderate selectivity, and the ratio of the diastereomers (**4a/5a**) could easily be determined ^{1}H-NMR analytically (see Tables 1 and 2); the absolute configuration of the end products could be determined by characterization of the cleaved tertiary alcohol.[7]

Since the induction in this case is effected by an acetalic center and therefore fundamentally stereoelectronic effects[8] should play a role, it could be expected that the direction of the induction is maintained upon introduction of oxymethylene groups.

3d	MeMgI	−40	**4d** : **5d**	2.0 : 1	95	*S*
7c	MeMgI	−40	**8c** : **9c**	1.1 : 1	95	*S*
7d	MeMgI	−40	**8d** : **9d**	1.03 : 1	95	—

of formaldehyde under acidic conditions and reacetalization) into (**4a**/**5a**).

The experiments showed that the diastereofacial selectivity of the organometal addition decreased with increasing chain length, but always had the same direction (Fig. 1).

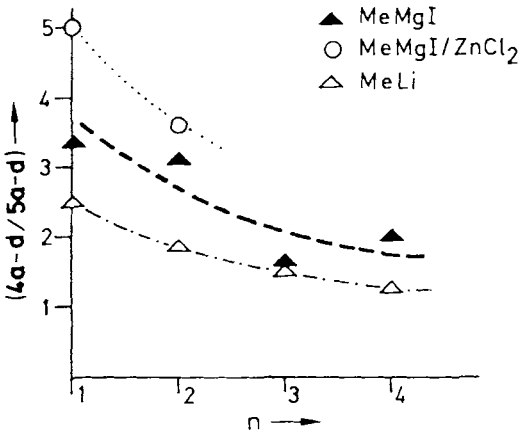

Fig. 1. Selectivity (diastereomeric ratio (**4a-d**/**5a-d**)) as a function of the number *n* of the OCH_2 members.

The shielding of the *Si* side of the prochiral carbonyl group is thus independent of the number of $O-CH_2$ units. This is consistent with the assumption illustrated in Figure 2 of a stabilized helix conformation with equal participation of all lone electron pairs and an antiperiplanar orientation of the terminal C–CO bond to that free electron pair of the neighboring acetalic oxygen which is still not involved in the anomeric interaction.

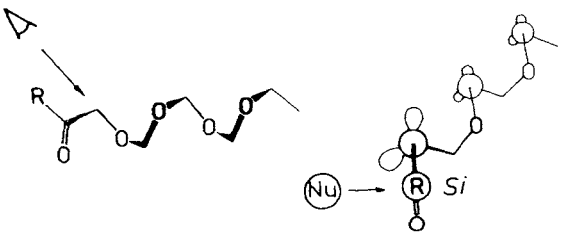

Fig. 2. Shielding of the *Si* side of the carbonyl group in **3** by the left-handed helix. R = phenyl.

The synperiplanar position of the oxygen of the carbonyl group to the acetalic oxygen corresponds to the arrangement observed in a similar compound[9] (X-ray structure analysis) and is also that conformation which is determinative in the reactions of α-alkoxycarbonyl compounds in *Cram*'s cyclic model[10] (Fig. 3).

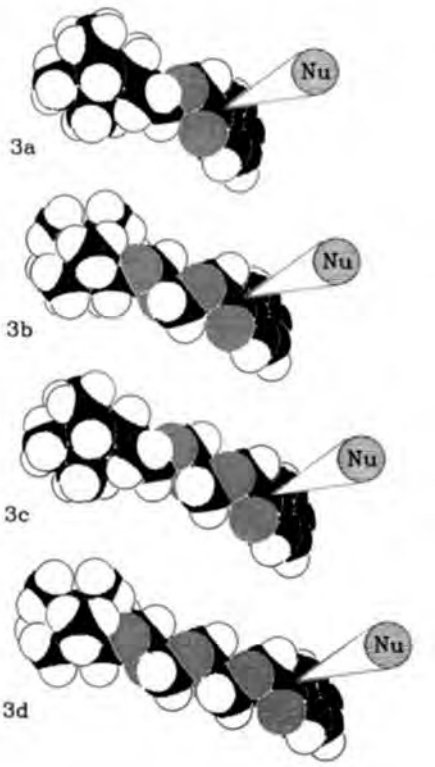

Fig. 3. Nucleophilic attack at the helix in **3**. The oxygen atoms are shaded.

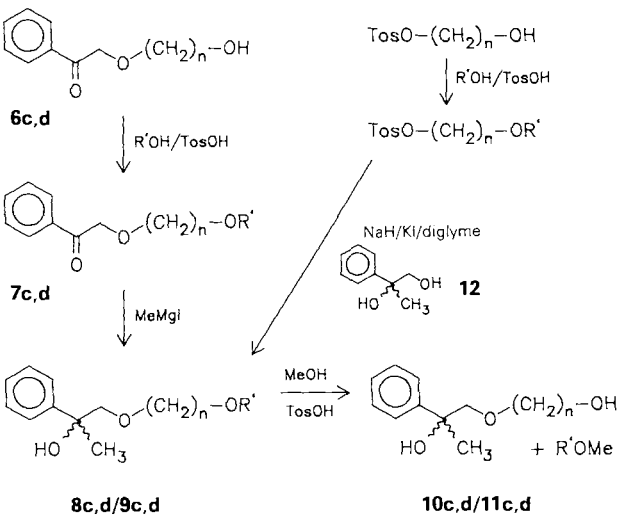
In order to exclude coincidental influences and to guarantee that the ensuing inductions are clearly attributable to the oligooxymethylene groups, the non-terminal oxygen atoms of the oxymethylene chain in the compounds **3c** and **3d** were formally replaced by CH_2 groups. The corresponding compounds **7c** and **7d** were synthesized from **6c** and **6d**, respectively,[11] and allowed to react with methylmagnesium iodide as described in the experimental section.



R'OH ≡ 1

6-**11**: **c**, n = 3; **d**, n = 5

Whereas the diastereomeric pair (**4d**/**5d**) was still clearly distinguishable in the ^{1}H-NMR spectrum (see Table 1), in the case of (**8d**/**9d**) a nuclear resonance spectroscopic assignment was no longer possible. The selectivity achieved was less than 1.5% *ee*, as shown by a comparison of the specific rotations of the liberated alcohols (**10d**/**11d**) and the reference compound (**10d**/**11d**)[12] prepared from the enriched 2-phenylpropanediol **12** ($S:R = 3.3:1 \triangleq 54\%$ *ee*). The ratio of (**8c**/**9c**) determined by 250-MHz ^{1}H-NMR[13] (1.1 : 1 ≙ 5.0% *de*) was also significantly lower than that of the corresponding oxymethylene diastereomers (**4c**/**5c**).[14]

With the experiments presented here it could be shown that an asymmetric induction with predictable direction (even with slightly decreasing selectivity with increasing chain length) is possible via an oxymethylene structure. If one considers the reaction from the formal aspect of a 1,*n*-asymmetric induction then the ratio 2 : 1 (≙ 33% *de*) found experimentally for (**4d**/**5d**) is so far the highest value known to us for a 1,10-asymmetric induction. From the point of view of a naturally related system of chiral compounds,[3] based on stereoelectronic effects, the direction of the reaction effected by a left helix corresponds fundamentally to that which is induced by an acetal group of the B family (configuration like α-L-glucose or β-D-glucose). Consequently, there is also a correlation of α-D-glucose (acetalic center of the A-type) with a dextrorotatory oxymethylene helix.

The actual occurrence of oxymethylene structures in the presence of silicates under potentially prebiotic conditions together with the predictable specificity of the enantiomerically pure helix make it seem possible that optically active paraformaldehyde has played a role in the amplification (perpetuity) of chirality in the course of chemical evolution.

Experimental

The compounds **2** to **5** (in each case **b**, **c**, **d**) were characterized ^{1}H-NMR and ^{13}C-NMR spectroscopically and by elemental analyses. For data and experimental details not mentioned in this communication see: P. Ettmayer, *Diplomarbeit*, Technische Universität Wien 1987. The compounds **6** to **11** (each **c** and **d** were characterized ^{1}H- and ^{13}C-NMR spectroscopically.

Reaction with methylmagnesium iodide: A 0.705 M solution of MeMgI (5.4 mL, 3.82 mmol) was diluted with 5 mL of ether, cooled, and treated with 0.636 mmol of ketone **3** in 10 mL of anhydrous ether. After 20 min the mixture was diluted with 10 mL of petroleum ether and extracted with 20 mL of 10% NH_4Cl solution. The organic phase was washed once with $NaHCO_3$, dried, and evaporated to dryness.

Reaction with methylmagnesium iodide and zinc chloride: A solution of ketone **3** (0.636 mmol) in anhydrous ether (10 mL) was cooled to 0°C and treated with a solution of $ZnCl_2$ (150 mg, 1.1 mmol) in anhydrous ether (10 mL). After 15 min the cloudy solution was added in bulk to a solution of 5.4 mL (3.82 mmol) of a 0.705 M MeMgI solution and 5 mL of anhydrous ether cooled to −40°C. After 20 min the heterogeneous reaction solution was diluted with 30 mL of petroleum ether and extracted with 20 mL of 10% NH_4Cl solution. The organic phase was washed once with saturated $NaHCO_3$ solution, dried, and evaporated to dryness.

Reaction with methyllithium: The reaction was carried out in ether analogously to the reaction with methylmagnesium iodide.

[5] 35.8% **2a**, 19.0% **2b**, 6.9% **2c**, 4.3% **2d**, and 11.5% **1a** were obtained. For further experimental data and ^{13}C-NMR and ^{1}H-NMR spectra of **2a** see Ref. [3].
[6] **3a** could be obtained in 70% **3b** in 72%, **3c** in 66%, and **3d** in 66% yield. According to 90-MHz ^{1}H-NMR and 22.5-MHz ^{13}C-NMR all the products are pure compounds at room temperature.
[7] a) The absolute configuration of (**4a**/**5a**) could be determined via the specific rotation of the alcohol described in the literature [7b], which was obtained from (**4a**/**5a**) by methanolysis (cleavage of the protecting group **1a** under acid conditions in methanol; b) see E. L. Eliel, J. P. Freeman, *J. Am. Chem. Soc. 74* (1952) 23.
[8] We assume that one of the free electron pairs on the acetal oxygen is stabilized exo-anomerically with the σ* orbital of the C-O bond in the ring and that the aryl ketone is so arranged that a further anomeric stabilization by n-σ* interaction of the second electron pair on the oxygen with the σ* orbital of the C-CO-aryl bonding is possible. We obtained evidence for this conformation by an X-ray structure analysis of compound **2a**.

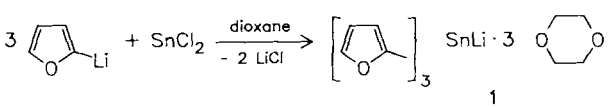
Solid State Structure of a Lithium Triorganostannate

By *Michael Veith*,* *Cornelius Ruloff*, *Volker Huch*, and *Fritz Töllner*

Dedicated to Professor Hans Bock on the occasion of his 60th birthday

Lithium triorganostannates have been used for several years for the transfer of triorganostannyl groups to electrophilic centers.[1,2] Although there is no lack of methods for their synthesis,[3] all attempts to determine their structures directly have thus far failed because the compounds were neither isolable nor crystallizable. Especially regarding mechanistic problems there are controversial discussions as to whether, e.g., the lithium atom is bound to the tin atom or an ion pair is present,[3] or when these different structures must be reckoned with. In continuation of our studies in the area of metal alkoxystannates,[4] we have now succeeded in preparing lithium tris(α-furyl)stannate **1** as the first compound of this kind in crystalline form and in investigating it by X-ray structure analysis.

For the synthesis of **1** we used α-furyllithium[5] and tin(II) chloride. The colorless crystalline platelets of **1** obtained as precipitate formally contain three dioxane molecules per lithium atom.



1

The dioxane molecules are bound with different strengths. Two of these molecules can be cleaved from the

Institut für Anorganische Chemie der Universität
D-6600 Saarbrücken (FRG)

compound (elemental analysis of the remaining product) under reduced pressure and at slightly elevated temperature (10^{-3} torr, 50°C). The chemical shifts and the coupling constants of the hydrogen atoms of the furyl moiety of **1** and the characteristics of the unit cell of **1** are collected in Table 1.

Table 1. Some ^{1}H-NMR, crystal, and structural parameters of **1**.

$C_{48}H_{66}Li_2O_{18}Sn_2$, $M_r = 1182.29$ g mol^{-1}

^{1}H NMR (furyl region only, [D$_3$]acetonitrile):
$\delta = 6.25$ (dd, $J(H_b,H_c) = 1.6$ Hz, 1H, $-O-CH=CH-CH=$),
6.33 (d, $J(H_a,H_b) = 2.9$ Hz, 1H, $-O-CH=CH-CH=$),
7.71 (d, $J(H_a,H_c) = 0.5$ Hz, 1H, $-O-CH=CH-CH=$)

Triclinic space group: $P\bar{1}$, $a = 1089(1)$, $b = 1372(1)$, $c = 1974(3)$ pm, $\alpha = 102.5(1)$, $\beta = 104.6(1)$, $\gamma = 91.25(8)°$, $V = 2775 \times 10^6$ pm^3, $Z = 2$, 7037 reflections in the range $3° < 2\theta < 50°$, 2603 classified as "not observed" ($F_0 < 4\sigma(F_0)$), 445 parameters. $R = 0.073$, $R_w = 0.084$

Figure 1 shows a drawing of the centrosymmetric anion of **1** based on the results of the X-ray structure analysis.[6] It follows therefrom that compound **1** is not to be formulated as a simple tris(furyl)lithium stannate, but as an ion

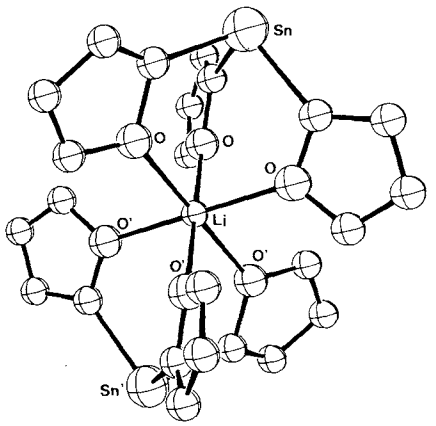

Fig. 1. Structure of the anion $[(Sn(furyl)_3Li(furyl)_3Sn]^{\ominus}$ of **1**. The unmarked atoms are C atoms. The following Li-O distances are found in the cation $[Li(dioxane)_4]^{\oplus}$: 186(3), 193(3), 193(3) and 194(3) pm. Some averaged bond lengths [pm] and angles [°] in the anion: Sn-C 218.8(9), Li-O_{eq} 209.6(9), Li-O_{ax} 229(1), C_α-C_β 136(1), C_β-C_γ 141(1), C_γ-C_δ 131(1), C_α-O 141(1), C_δ-O 138(1); C-Sn-C 96(2), O-Li-O 87-93.

pair consisting of a lithium ion coordinated by four dioxane units and a complex anion. The anion is formally formed by reaction of a lithium ion with two tris(furyl)stannate ions. Two crystallographically independent but structurally very similar anions are located with their inversion centers at the positions 0,0,0 and 0,0,0.5 of the unit cell, while the cation assumes a general position. Two further dioxane molecules are accommodated in the crystal without interacting with metal atoms; hence, the following general formula can be given for the crystalline compound **1**:

$[Li(dioxane)_4]^{\oplus}[Sn(furyl)_3Li(furyl)_3Sn]^{\ominus} \cdot 2\,dioxane$ **1**

The tin atoms have the typical pyramidal geometry for threefold coordinated tin(II) atoms,[7] with C-Sn-C angles of approximately 90°. The lithium atom in the cation $[Li(dioxane)_4]^{\oplus}$ has almost ideal tetrahedral coordination, whereas in the anion it is coordinated by a distorted octahedral array of oxygen atoms from the furyl groups. Four "equatorial" Li-O distances (mean value 209.6(9) pm) can easily be differentiated from the "two axial" distances (229(1) pm), so that the coordination geometry around the lithium atom can also be described as square planar with additional axial interaction. We attribute the observed distortion about the lithium atom in the anion of **1** not to electronic but to steric effects: on the one hand, lithium atoms normally strive for tetrahedral coordination (with an expected Li-O value of 190-195 pm)[8] and, on the other, the mutual distance of the oxygen atoms is predetermined by the specific geometry in the tris(furyl)stannate ions. The only possible alternative would appear to be the compromise found in the given structure.

Experimental

A suspension of $SnCl_2$ (1.26 g, 6.6 mol) in Et_2O (40 mL) was treated rapidly at −50°C with a solution of furyllithium (20 mmol) [5] in Et_2O (50 mL). After warming to room temperature the mixture was stirred for 8 h and filtered (to remove LiCl). After separation of volatile components by condensation there remained pale yellow crystals, which were recrystallized from 30 mL of dioxane; **1** forms colorless platelets. Yield: 1.76 g (45%).

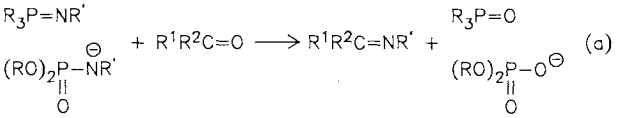
A Novel Entry to the PC-Double Bond: the "Phospha-Wittig" Reaction

By *Angela Marinetti* and *François Mathey**

The archetypal Wittig and Wittig-Horner olefinations of carbonyl compounds have less popular equivalents in nitrogen chemistry[1] [Eqn. (a)]. We therefore wondered



(a)

whether it would be possible to extend this kind of chemistry [Eqn. (a)] to phosphorus. In practice, this meant that it was necessary to have a ready and general access to phosphorus species such as **1** or **2**.

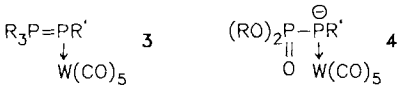
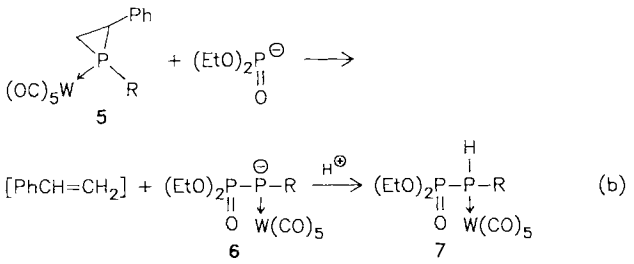
Some phosphoranylidenephosphanes (**1**) are known[2] but they appear to be stable only with very specific sets of substituents. On the other hand, to our knowledge, no anion such as **2** has been reported in the literature so far.[3] It was therefore clear to us that it was necessary to provide some extra stabilization to the dicoordinate phosphorus in order to facilitate the synthesis of **1** and **2**. Thus, we focused our work on the synthesis of the P^{II}-complexed species **3** and **4**. This was all the more tempting since we



knew that P-$W(CO)_5$ complexation had a strong stabilizing effect upon the P=C double bond,[4] which was the ultimate target of our program.

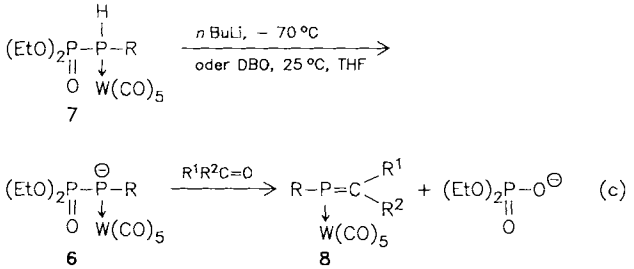
After some disappointing experiments, we discovered that it was indeed possible to prepare secondary phosphorylphosphane complexes such as **7** from the appropriate phosphirane complexes **5**[5] [Eqn. (b)].



[PhCH=CH_2] + $(EtO)_2P(O)-P^{\ominus}-R$ (**6**) $\xrightarrow{H^{\oplus}}$ $(EtO)_2P(O)-PH-R$ (**7**) (b)

a, R = Ph; b, R = Me

These stable phosphorylphosphane complexes **7** furnish the corresponding anions **6** again upon reaction with *n*BuLi or basic tertiary amines (1,4-diazabicyclo[2.2.2]octane (DBO)) in THF. These anions easily react with aldehydes and ketones to give the expected phosphaalkene complexes **8** [Eqn. (c)], which are either isolated or trapped with various reagents.



7 $\xrightarrow[\text{oder DBO, 25 °C, THF}]{n\text{BuLi, } -70\,°C}$ **6** $\xrightarrow{R^1R^2C=O}$ $R-P(W(CO)_5)=C(R^1)(R^2)$ (**8**) + $(EtO)_2P(O)-O^{\ominus}$ (c)

Some examples will illustrate the various possibilities that are offered by this scheme (important spectroscopic data of the products are listed in Table 1).

The reaction of **7a** with DBO and acetone or cyclopentanone gives the stable phosphaalkene complexes **9** and **10** [Eqns. (d) and (e)]. These complexes were purified by chromatography on silica gel with pentane.

The corresponding phosphaalkene complexes formed with aldehydes tend to be unstable; the P=C double bond was therefore allowed to react in situ with methanol or conjugated dienes [Eqns. (f)–(h)]. The phosphaalkene complex **11** was characterized in situ by ^{31}P-NMR spectroscopy. As expected, on replacing the phenyl substituent (**7a**) by a methyl substituent (**7b**), the stability of the phosphaalkene complexes decreases. Nevertheless, we were able to monitor the clean and almost quantitative formation of **15**

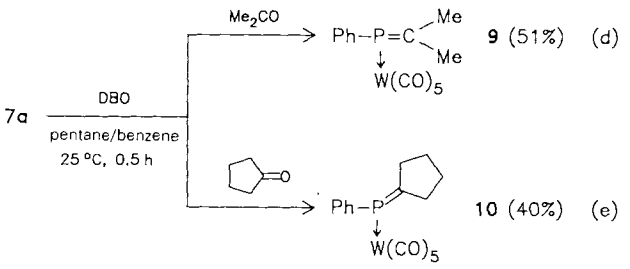


Table 1. Most important spectroscopic data of compounds **9**–**14**, **16** and **17** [a].

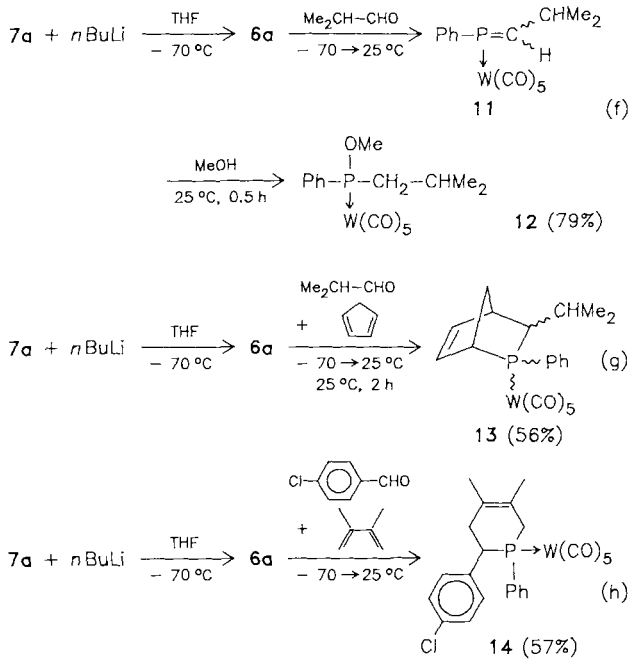
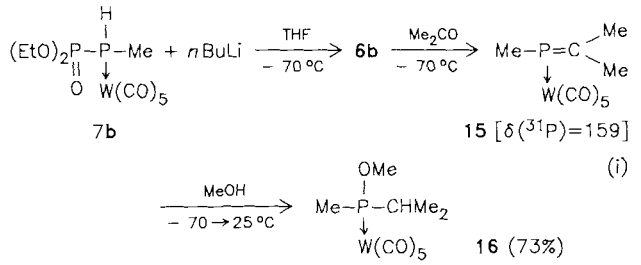
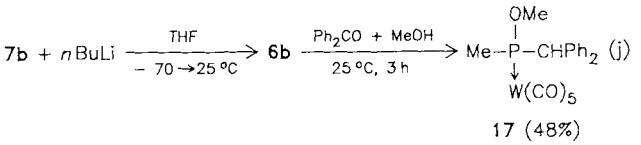
[a] 200.132-MHz ^{1}H-, 50.323-MHz ^{13}C-, 32.435-MHz ^{31}P-NMR: δ positive for downfield shifts from external 85% H_3PO_4, *J* in Hz; MS: EI, 70 eV, ^{184}W.



from **6b** and acetone by ^{31}P-NMR spectroscopy, but only the methanolysis product **16** was isolated [Eqn. (i)]. The phosphide **6b** appears to be more reactive than **6a**. In-



deed, **6b** reacts with benzophenone whereas **6a** does not [Eqn. (j)].



On the basis of this first series of examples, it is quite clear that the scope of the "phospha-Wittig" reaction is extremely wide.[6] From stable reagents such as **7** and carbonyl compounds, it is possible to prepare in a one pot reaction under mild conditions either PC single bonds, PC double bonds, or PC heterocycles.[7] Various synthetic applications of this scheme are currently under active investigation.

Experimental

9 and **10**: Complex **7a** (0.57 g, 1 mmol), the appropriate carbonyl compound (8 mmol) and DBO (0.12 g, 1 mmol) were stirred in benzene/pentane (1:2) for 0.5 h at room temperature. The reaction mixture was then directly chromatographed, as fast as possible, on a silica gel column with pentane as eluent. The final product was crystallized from pentane. **9**: yellow solid, m.p. 60°C; **10**: yellow solid, m.p. 81°C.

Trapping reactions: A solution of **7a** (or **7b**) (1 mmol) in THF was cooled to −78°C. *n*BuLi (0.7 mL, 1.6 M solution in hexane) was then added. After a few minutes, an excess of the trapping reagent (MeOH, 2,3-dimethylbutadiene or cyclopentadiene) and the carbonyl compound (1 mmol in the case of aldehydes, about 5 mmol for ketones) were added. The reaction mixture was then allowed to warm to room temperature. Reactions (f), (h) and (i) are very fast. Reactions (g) and (j) need a longer reaction time (2–3 h at room temperature). After hydrolysis, evaporation of the solvent and extraction with ether, the final product was purified by chromatography on silica gel with hexane as eluent.

An Introduction to Chemisorption and Catalysis by Metals. By *R. P. H. Gasser*. Oxford Science Publishers, Clarendon Press, Oxford 1987. xii, 260 pp., paperback, £ 12.95.—ISBN 0-19-855271-8

To write an introduction to chemisorption and catalysis by metals at the present time is no easy task, in view of the rapid developments occurring in this field. The author of this book avoids these difficulties by confining himself to an account of long-accepted facts, well established methods, and only one example of a heterogeneously catalyzed reaction. He deliberately excludes any discussion of the theory of the bonding of molecules to the surface.

The book begins with a brief description of the interaction between the adsorbate and the surface and the thermodynamics of adsorption (isotherms, isobars and heats of adsorption), such as one finds in other books of a similar kind. The reader is then prepared for the chapters which follow by a useful account of the primary processes that occur during collision (elastic and inelastic processes, energy exchange). A longer chapter is devoted to the kinetics of adsorption and desorption, including especially a discussion of sticking probability and of temperature programmed thermal desorption.

Next a short introduction to the structure of metals and surfaces, the real and reciprocal lattices, the use of the Ewald sphere, and the behavior of electrons in metals leads into an essentially qualitative treatment of low energy electron diffraction. Under the heading "Electron emission" is given a 31-page account of ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), field electron microscopy and field ion microscopy. This chapter certainly does not do justice to the present-day importance of these techniques. For example, in the treatment of UPS we find no mention of the important information that can be obtained by using polarized radiation or by measuring the angular dependence. Similarly the ways in which XPS and AES can be used are only briefly touched on. The most recent developments in field emission are not included.

The treatment of chemisorption concludes with a very brief section on modification of work functions, infrared spectroscopy and high resolution electron energy loss spectroscopy (HREELS).

Heterogeneous catalysis is introduced by referring to the theory of the transition state, and discussing selectivity and the relationship between strength of chemisorption bonding and catalytic activity; rate equations are derived for reactions involving the Langmuir-Hinshelwood and the Eley-Rideal mechanisms. The principles are illustrated by reference to the *ortho-para* interconversion in hydrogen and to hydrogen-deuterium exchange.

In a concluding chapter, as an example of the application of the methods described in the previous chapters, the catalytic oxidation of carbon monoxide on palladium and platinum is discussed with reference to model reactions under high vacuum conditions.

Anyone working in the area of adsorption and catalysis will find few new ideas in this book. New techniques which have been developed in the last few years, such as those which have become possible by using synchrotron radiation, inverse photoemission, tunneling microscopy, ion scattering and many others are not mentioned. The bibliography consists mainly of references to monographs and review articles; it covers publications up to 1981, and is thus not very up-to-date. However, the readership aimed at by the author is not the expert one mentioned above. The book originated from an introductory lecture course, and is intended for students who have mastered the fundamentals of physical chemistry and now wish to study special topics, in this case that of adsorption as the primary step in heterogeneous catalysis. These readers will find the book useful. As a textbook to accompany a course such as that mentioned it is an appropriate choice, being clearly presented, adequately illustrated, and concentrating on the essentials.

Chemicals from Coal: New Processes (Series: Critical Reports on Applied Chemistry, Vol. 14). Edited by *K. R. Payne*. Wiley, New York 1987. 114 pp., bound, $ 50.30.—ISBN 0-471-91325-1

The book "Chemicals from Coal: New Developments" appeared in 1985 as Volume 9 in the series "Critical Reports on Applied Chemistry". That first 122-page volume, edited by *K. R. Payne*, contained three articles: *J. Schulze* (Technische Universität Berlin) and *H. Gaensslen* (Lurgi GmbH) discussed the economics of coal conversion processes, and in the two following articles *J. O. H. Newman* and *G. O. Davies* of the National Coal Board (Great Britain) reported on possibilities and recent advances in obtaining chemical feedstocks from coal by pyrolysis or direct liquefaction. The same editor (but a different publisher) has now produced the book under review here, as Volume 14 of the series, under the very similar title "Chemicals from Coal: New Processes". In this volume the discussion of chemical feedstocks from coal is taken further, with five articles on coal gasification, synthesis gas chemistry, Fischer-Tropsch syntheses and the production of acetylene from calcium carbide.

In the first chapter, "Syngas via coal gasification", *B. Cornils*, formerly of Ruhrchemie and now with Hoechst, reviews the present state of the art in coal gasification technology. Starting from the thermodynamic and kinetic relationships, and the existing first-generation gasification processes (the Lurgi, Winkler, and Koppers-Totzek gasifiers), the discussion proceeds to the modern second-generation processes, some of which are still at the development stage. The process engineering principles of fixed bed, fluidized bed and entrained bed gasification processes, as well as the differences between the many new developments which are competing with each other, are clearly explained. As a possible third-generation process, the allothermal fluidized bed gasification using process heat from a high temperature nuclear reactor is discussed. This chapter is a concise but successful review of the topic by a competent author who was for some years involved in the advanced development of the Texaco gasification process.

In the second chapter, "Chemicals from coal via the carbide route", *F.-W. Kampmann* and *W. Portz* of Knapsack/

Hoechst describe the production of acetylene via calcium carbide. Only the manufacture of the carbide is described in detail. The reader learns that since 1962 the production of carbide has greatly declined throughout the world; regrettably, though, he is not told about alternative routes to acetylene, such as by partial combustion of hydrocarbons, by the Hüls process in which hydrocarbons undergo conversion in a plasma arc torch, or by similar attempts to produce acetylene in the plasma directly from coal.

Chapter 3, "Catalysis in the conversion of synthesis gas to chemicals", by *I. Wender*, and Chapter 5, "Syngas chemistry to chemical feedstock: New frontiers", by *B. Cornils*, are the most informative ones for the chemist interested in C_1 chemistry. The two chapters overlap to some extent in the topics covered, but on the other hand they complement each other through their different viewpoints and in the literature cited. *Wender*, formerly at the Pittsburgh Energy Technology Center and now an emeritus professor at the University of Pittsburgh, generally discusses methods of catalyzing reactions of carbon monoxide and C_1 compounds. Accordingly the conversion of methanol using zeolites, and the acid catalyzed Koch-Haaf synthesis of carboxylic acids from carbon monoxide, olefins and water, are addressed as well as the many different catalytic reactions using heterogeneous and homogeneous transition metal catalyst systems. Some of the reaction schemes given here for catalytic cycles do not quite correspond to the presentations found in modern textbooks of organometallic chemistry, but this does not detract from the value of the information collected together in the review. *Cornils* limits his discussion to recent developments in C_1 chemistry, such as the production of C_2 to C_4 olefins using modified Fischer-Tropsch syntheses, the dehydration of methanol using zeolites, and methods for directly synthesizing carboxylic acids, acetaldehyde, ethanol or ethylene glycol from synthesis gas. As alternatives to such direct manufacturing routes from synthesis gas, multistage processes via methanol, acetic acid, formaldehyde or oxalic acid esters as intermediates are also discussed. Further possibilities for using C_1 compounds as building blocks in synthetic routes to methyl methacrylate, vinyl acetate, styrene, heterocyclic compounds, urethanes, acrylonitrile and long chain unbranched fatty acids are also indicated.

In Chapter 4, "The Fischer-Tropsch synthesis as a source of raw materials for the chemical industry", *M. E. Dry* describes the South African plants in Sasolburg and Secunda which operate the Fischer-Tropsch synthesis. Compared with other similar articles by the same author, this review emphasizes the different spectrum of products obtained from the two variants of the Sasol process using fixed bed reactors and circulating fluid bed reactors, and the downstream industrial processing of the mixture of products obtained.

New processes for making chemicals from coal were promised in the title of the book. The reader learns something of these in Chapters 1, 3 and especially 5, but little in Chapters 2 and 4. Apart from a very few exceptions, the literature cited does not extend beyond 1984; as is unfortunately so often the case, this appears to be due to the long delay between the completion of the manuscript and the publication of the book.

For chemists and chemical engineers who wish to familiarize themselves with synthesis gas and C_1 chemistry, the book is quite useful. So long as oil and natural gas continue to be cheaply available in sufficient quantities, processes based on coal will scarcely be economic. However, the present situation in energy markets cannot blind one to the fact that eventually it will become necessary to make greater use of coal. The route via coal gasification and synthesis gas chemistry which is discussed here as a way of producing chemical feedstocks appears very promising.

Finally, a comment on the short preface by the editor: This reviewer, who happens to work in the laboratories where *Franz Fischer* did his research, was surprised by the following sentence: "The Fischer-Tropsch process was originally developed in Germany by BASF before the First World War, and was improved over the years until, by the advent of World War II, it became an important source of chemicals and fuel for the Third Reich." The 1913 BASF patent D.R.P. 293787, which first described the formation of saturated and unsaturated hydrocarbons and of oxygen-containing compounds from synthesis gas at high pressure, was certainly one of the starting points which in 1922 prompted *Fischer* and *Tropsch* at the Kaiser-Wilhelm-Institut in Mülheim to carry out their work on "Synthol", a mixture consisting mainly of oxygen-containing compounds. *Franz Fischer* himself confirmed this fact in a controversy with *Alwin Mittasch* (*Angew. Chem. 40* (1927) 164 and 166). Systematic investigation of the reaction conditions led in 1925 to a hydrocarbon synthesis carried out without increased pressure and at lower temperatures, which was patented (D.R.P. 484337 and others) and given the name Fischer-Tropsch synthesis. The history of the discovery is described by *Otto Roelen*, one of the research team involved at the time, in a paper presented and published in 1977 (*Erdöl, Kohle, Erdgas, Petrochem. 31* (1977) 524).

Multinuclear NMR. Edited by *J. Mason*. Plenum Press, New York 1987. 639 pp., bound, $ 115.00.—ISBN 0-306-42153-4

The publication of this book has been eagerly anticipated for some time in specialist circles, particularly in view of the many new and important directions of research which NMR spectroscopy has helped to stimulate in nearly every area of chemistry and in interdisciplinary fields. The 23 chapters of the book have been written by twelve authors, and the editor is herself a co-author in five of the chapters.

An explanation of the arrangement of the book's contents and the scope of the different topics treated (Chapter 1) is followed by a concise account of the fundamentals of the various NMR parameters (Chapter 2). Chapters 3–5 contain detailed discussions in turn of the chemical shift (δ), spin-spin coupling constants (^nJ), and relaxation processes. Chapters 1–5 take up about a quarter of the book. Much of what they contain is, necessarily, familiar ground, but they also bring out many aspects, especially concerning δ and J, which could otherwise only be discovered more laboriously from theoretical treatments, and might therefore remain unknown to the preparative chemist. As the title indicates, the book then continues, from Chapter 6 onwards, by dealing with the NMR parameters for the different nuclides, starting with ^1H, ^2H, and ^3H, and continuing through to the magnetically active isotopes of Cu, Ag, Au, Zn, Cd, and Hg (Chapter 21). The arrangement of the subject matter follows the groups of the Periodic System. Some important nuclides (e.g. ^1H, ^{11}B, ^{13}C, ^{19}F, ^{31}P) are only dealt with briefly, the main emphasis being on inor-

ganic and organometallic applications. These chapters vary greatly in their usefulness, as can be seen from the critical appraisal of individual chapters which follows.

Chapter 8 (^{11}B-NMR) concentrates on polyboranes, giving a clear and systematic presentation of the complex NMR spectroscopic properties of these compounds. By contrast, in Chapter 10 (^{13}C NMR), an attempt has been made to summarize an enormous quantity of data. A purely graphical presentation may be helpful for some purposes but it precludes access to detailed information. In the case of coupling constants only a few actual values are given, though unfortunately marred by an error which has been pointed out several times before: $^1J(^{13}C,^{11}B)$ in $[BMe_4]^{\ominus}$ is 39.4 Hz, not 22.0 Hz. Insufficient space (28 pages) has been given in Chapter 11 to the important nuclides ^{29}Si, (^{77}Ge), ^{119}Sn and ^{207}Pb. An error from earlier work remains uncorrected here: $\delta(^{119}Sn)$ in $Sn(C{\equiv}CH)_4$ is -356.3, not -279. Chapter 12 (^{14}N and ^{15}N NMR) is a pleasure to read. Here some important relationships between NMR parameters and structure are brought out, attention is given to the growing importance of NMR spectroscopy of solids, and reference is made to numerous recently published papers. On the other hand, in Chapter 13 the reader is in places not very well served, e.g. when ^{31}P chemical shifts are under discussion. The treatment of $\delta(^{31}P)$ values for phosphorus atoms with coordination numbers 1 and 2 is very vague. Here the reader would be well advised to refer instead to the excellent Chapter 3 (or even Chapter 14) for interpretation purposes. More confusion is added when the compound $[t\text{Bu}-P\{Cr(CO)_5\}_2]$ is assigned to the group in which phosphorus has the coordination number 2. Compound classes which have already been covered in detail in earlier review articles are given a lot of space. In Chapter 14 (^{17}O NMR) scant reference is made to boron–oxygen compounds, for which a large number of ^{17}O chemical shifts were reported in the period 1980–83 alone. In Chapter 16 ^{19}F NMR spectroscopy, in keeping with its relative importance, and in view of the existence of various review articles, some of which are now quite old, is discussed very briefly. The help which the experimental chemist is given towards interpreting his data is rather limited. For example, it is stated that in compounds with the general formula XF_n the shielding of the ^{19}F nucleus decreases with increasing n, and that this behavior is not unlike that of the ^{31}P shielding in PCl_3, $[PCl_4]^{\oplus}$, PCl_5, and $[PCl_6]^{\ominus}$ (even though the shielding increases in this case!). Chapters 19–21 (110 pages) on the NMR spectroscopy of transition metal nuclides are satisfyingly comprehensive in the information which they give. There is currently an upsurge of interest in this topic, and the data presented here will be of considerable value in helping future research. The interpretation of NMR parameters for these nuclides is very complex. It is therefore quite appropriate in view of the present state of research that in these chapters most of the pages are occupied by data and graphs.

In each chapter the arrangement of the material essentially follows a constant pattern, treating in turn chemical shifts, coupling constants and relaxation behavior. For newcomers to the field especially, this makes it easier to begin using NMR data to obtain information, and this is especially helpful when one is concerned with the less common nuclides. The structure of the book as a whole is similar to that of the work which paved the way in this field (*R. K. Harris* and *B. E. Mann* (Editors): *NMR and the Periodic Table*, Academic Press, London 1978). In this context the striking resemblance between several chapters in the two books is not solely due to the fact that parts of them have been written by the same authors. Most of the chapters include references to the applications of NMR spectroscopy of solids (sometimes under the heading "Miscellaneous"), but the great upsurge which is occurring in the development of this technique is not conveyed to the reader. The large quantity of NMR data from measurements in solution is for the most part clearly presented (in the form of tables and graphs). The last two chapters (22 and 23) have been included so as to complete the broad coverage of the book; they deal briefly with NMR spectroscopy in inorganic biochemistry, and with biomedical aspects. The effort which has been made to soften the otherwise rather abrupt conclusion of the book by including references to the literature in these two areas makes a favorable impression.

To cover multinuclear NMR in a single book was a formidable undertaking. The problem of condensing as much material as possible into a small space (for which even 639 pages is insufficient!), while maintaining the required standards of quality, topicality and breadth of coverage, has no perfect solution. Nevertheless, there are grounds for criticism when the literature coverage in the majority of the chapters extends only up to mid-1983. The cosmetic remedy of fitting in individual more recent references afterwards cannot hide this defect. If one regards this book as an attempt to organize the ever faster growing avalanche of NMR data into manageable channels, then despite certain reservations one must on balance give it a positive vote. The NMR literature market cannot at present offer any other comparable work. In view of these comments, the book is definitely a worthwhile purchase as a work of reference for chemists in academic departments and industry, whether or not NMR spectroscopy applications are in the foreground of their interests. For both undergraduate and graduate students too, this book could fill a troublesome gap, provided that the high price is not prohibitive.

Bernd Wrackmeyer [NB 884 IE]
Laboratorium für Anorganische Chemie

Inductively Coupled Plasmas in Analytical Atomic Spectrometry. Edited by *A. Montaser* and *D. W. Golightly*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. xxiii, 660 pp., bound, DM 220.00.— ISBN 3-527-26529-5/0-89573-334-X

Inductively coupled high frequency plasmas (ICPs), which were first used in the early sixties as radiation sources for emission spectrometry, by *Greenfield* in Great Britain and by *Fassel* in the United States, have developed to become the basis of a powerful analytical method for multielement determinations. ICP emission spectrometers are now available from more than fifteen manufacturers throughout the world. ICPs are also used as atom reservoirs for fluorescence spectrometry, and as ion sources for mass spectrometry, and systems for these types of measurements are also commercially available. ICP spectrometry is now used as a routine method in many analytical laboratories, together with other elemental analysis methods such as atomic absorption spectrometry (AAS), X-ray spectrometry, and electrochemical and chromatographic techniques. Its fields of application include biology and medicine, the analysis of ores, minerals, soils and ceramics, environmental analysis, and checking the purity of chemicals and of metals. This book, which is the second comprehensive treatment of ICP to appear within a short time, follow-

ing the two-volume work by *Boumans* on ICP atomic emission spectrometry, therefore meets a considerable need on the part of analysts. The editors *Montaser* and *Golightly*, by bringing together a group of eminent authors in this field, have produced an account of the fundamentals of ICP as a technique of optical emission spectrometry (OES). The book also deals with the use of ICPs as ion sources for mass spectrometry and as atom reservoirs for atomic fluorescence work.

In the introductory chapter (15 pages) a brief account is given of the important advantages which the introduction of ICP, compared with other types of electrically generated plasmas, has brought to the analysis of liquids. The chapters which follow are arranged in four parts. The first part (304 pages) deals with ICPs as radiation sources for optical emission spectrometry. This begins with a chapter on basic plasma spectroscopy rather than on analytical plasma spectrometry. Next a chapter on emission spectrometers deals with the construction and performance criteria of modern sequential and simultaneous spectrometers, together with trends for their future development. A further chapter discusses elementary aspects of high frequency generators for ICP spectrometry, and gives characteristic data on plasma torches and nebulizers. The chapter on the analytical capabilities of ICP deals with optimization techniques such as simplex procedures, the relationship between operating conditions and analytical performance. Limits of detection, quantitative analysis, and calibration in ICP-OES are treated thoroughly. The problems of choosing suitable spectral lines and of spectral interferences, which are very important in analytical practice, are clearly and concisely treated in one chapter. In a further chapter, using analytical results on actinides as an example, it is impressively demonstrated that optical ICP atomic spectrometry using high resolution spectrometers is very effective even with difficult matrices. In another chapter on the spectroscopic properties of the inductively coupled plasma, the reader is given a clear understanding and a good review of this aspect of the literature on ICP, which also is of importance to analytical chemists.

The second part (75 pages), deals with the analytical capabilities of ICPs in fields other than optical emission spectrometry. The first chapter of this section gives an account of the principles of atomic fluorescence spectrometry and the most recent results from ICP atomic fluorescence. The chapter on ICP mass spectrometry too gives an indication of future developments, and provides an insight into a technique which is now being used more and more for multielement determinations in the sub-μg/mL range of concentrations.

The third part (101 pages), on sample introduction, gives a clear description in three chapters of the various methods for generating aerosols from liquid and solid samples, and for introducing gases into the ICP. Two further chapters report on important developments such as ICPs with a gas consumption of less than 2 L/min, and ICPs which operate with gas mixtures and with gases other than argon; the development of ICPs of medium power (0.6–1 kW) and medium gas requirement ($\leq$8 L/min), which are now available from several manufacturers, is briefly touched on.

In the final part (29 pages) the analytical capabilities of ICP spectrometry are described. The reader is referred to important published work in various areas of application. Also in this part the performance of ICP spectrometry is compared with that of other atomic spectrometry techniques, such as AAS, DCP (directly coupled plasma) and X-ray spectrometry, and problem-orientated developments of ICP-related techniques are described; these topics are treated in a clear, but quite brief manner. An appendix, which is especially useful for users of the technique, lists data on prominent ICP emission lines, as published by *Winge*, *Peterson* and *Fassel*.

The information which this book on ICP spectrometry contains will certainly be greatly welcomed by the circle of analytical chemists, built up during the past fifteen years, who now use the technique. It also provides research scientists engaged in further development of ICP with a good review of the current state of the art and useful literature references. Because of its presentation and the amount of detailed information included, the book is a standard work on this important elemental analysis technique.

Intelligent Materials—A New Frontier

Functional Ceramics
Ceramic Sensors
Sensor Tuning

By Hiroaki Yanagida*

1. The Need for Intelligent Materials

The incentive for materials R&D is to achieve improvements in either manufacture or performance, or to introduce novel functions. Until very recently only the first two of these have been recognized as important. Improved manufacturing methods have led to large scale production systems. Iron and plastics are examples of progress in this direction. Research on engineering ceramics has been aimed at improving performance, in particular to give improved durability under severe conditions. There is another direction for R&D in materials, namely the introduction of novel functions. Various specialized functions have been discovered. Nonlinear electrical and/or optical behavior, various types of transducers, chemically interesting properties, etc. give rise to many types of novel devices, using what are described as functional materials.

Materials with excellent performance *and* novel functions are ideal candidates for future technology. One such class of materials is that of functional ceramics. Various functional ceramics have already been developed or are still undergoing development. Some of these have the special properties mentioned above. It may be said that no electronic devices can be constructed without ceramic components. Various novel devices have been developed using functional ceramics. These might be described in a sense as keys to the development of an advanced technological society.[1]

The ultimate functions may be those with "intelligence". There are potential demands for so-called intelligent materials. Although computers with integrated circuits are normally used to control operations or to make judgements, neither these nor any other devices containing electrical connections can be introduced into hazardous environments. Some operations or judgements therefore need to be carried out within materials which satisfy the required safety conditions. Even under non-hazardous conditions, where computers are used for complicated functions the result is often a tangle of electrical leads, a situation which has been referred to by medical electronics scientists as the "spaghetti syndrome".[2] Here again it is an advantage if some of the intelligent judgements can be made within materials. Thus there is a need for intelligent materials.

Examples of what is meant by the term intelligent are concepts such as self-recovery, self-adjustment or control, self-diagnosis, stand-by capability for detecting nonlinear onset, ability to be externally tuned, etc. These concepts seem to be realized only in living organisms, which, however, cannot survive in hostile environments, and in some senses, therefore, intelligent materials must perform better than living organisms, by being able to withstand very hos-

tile environments. Nevertheless, to achieve intelligence in materials one must learn from living organisms which are not necessarily ideally adapted, since in the modern technological age hostile conditions of previously unknown kinds are encountered. To carry out work in environments which human beings could not tolerate, robots with capabilities exceeding those of living organisms, and able to withstand such severe conditions, must be used. Living organisms lack some important sensing mechanisms, e.g. the ability to detect insufficient oxygen pressures or the presence of so toxic a gas as carbon monoxide. With the help of intelligent materials, living organisms can survive under severe conditions.

2. Functions Required from Intelligent Materials

Some of the functions that may be demanded of intelligent materials have already been mentioned above. The meanings of these functions will be explained in this section.

2.1. Self-recovery

Most materials inevitably degenerate continuously until they are no longer usable. Living organisms, on the other hand, frequently recover their original function and performance through a self-recovery mechanism. They may recover through resting, for example. A disadvantage arising from the lack of a self-recovery mechanism is seen in the case of the humidity sensor consisting of a porous ceramic semiconductor. The conductivity of the porous material usually increases with adsorption of water vapor under humid conditions, and decreases with removal of adsorbed water molecules under dry conditions. Removal is, however, very slow at room temperature. A large hysteresis loop is observed in the humidity-conductivity characteristic. A measured conductivity value will not necessarily indicate the humidity level existing at the time of the reading. In order that the water molecule adsorption sites should remain fully active one must frequently carry out a so-called cleaning operation to remove the adsorbed water molecules at high temperature. During such cleaning treatments the sensor cannot supply any information about humidity.

A few years ago we constructed a new type of ceramic humidity sensor.[3] This uses point contacts between a p-type semiconductor (copper oxide or nickel oxide) and an n-type semiconductor (zinc oxide). The voltage-current characteristic changes with humidity as shown in Figure 1. The mechanism of this device has been analyzed as follows.[3c] The amount of water adsorption in the vicinity of the hetero contacts changes with humidity, as is also found for porous humidity sensors of the usual type with homo phase contacts. Electron holes are injected from the p-type semiconductor electrode into the adsorbed water molecules, giving rise to protons in the adsorbed water phase. The positive charge is liberated at the surface of the n-type semiconductor electrode. As a consequence of this process the adsorbed water is electrolyzed. During measurements the cleaning process is always working, since the cleaning or self-recovery treatment is itself the working mechanism.

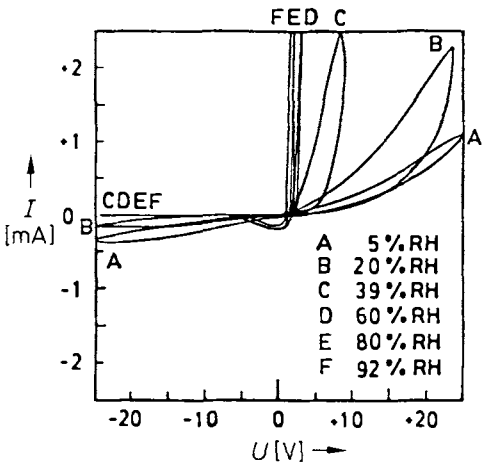

Fig. 1. Humidity dependent voltage-current characteristic changes of an intelligent humidity sensor made of hetero-contacts between copper oxide and zinc oxide [5]. RH = relative humidity.

The change from the usual porous ceramic humidity sensors to the p/n contact type discussed here is from single phase contacts to two different phase contacts. The morphology appears to be very similar in the two cases. However, the working mechanism is significantly different. Both are typical examples of two-dimensional structures,[4] as shown in Figure 2. However, the p/n contact type has greater potential than the former type, at least as far as intelligence is concerned. Table 1 gives a comparison between the usual porous type ceramic humidity sensor and the p/n contact type.

Fig. 2. Difference in structure and working mechanism between single phase contact type (left) and two phase contact type humidity sensors (right). Left is a porous zinc oxide humidity sensor and right a p/n hetero-contact type humidity sensor.

2.2. Self-adjustment or Control

The types of control systems that have been proposed are many and varied. Most of them use feedback logic with conventional electric circuits. There are, however, some self-control devices without feedback circuits, although they may still be primitive from an intelligence standpoint.

ADVANCED MATERIALS

Table 1. Comparison of two types of ceramic humidity sensors.

	porous zinc oxide humidity sensor	CuO/ZnO contact humidity sensor
structure [4]	open interface between identical materials	open interface between different materials
measurement	conductivity change	*U/I* characteristic
mechanism	protonic conduction	electrolysis of adsorbed water
hysteresis	causes problems	none, no problems
cleaning	necessary	not needed (working mechanism itself gives cleaning)
self-recovery	ineffective (frequent cleaning treatments needed)	effective

The temperature of heating elements may be roughly controlled if the resistance increases with temperature, as occurs in silicon carbide heating elements above 1000°C. The most typical self-control mechanism is seen in perovskite type ceramic (PTC) heating elements; semiconductor PTCs are well known and used in practical applications. They have very low resistivity below the transition temperature, and can be used for heating elements in this range. Above the transition temperature the resistivity begins to increase dramatically. The change in resistivity can be used to measure the temperature. The resistivity reaches a very high value, so that only a very small current passes. This constitutes a switch which does not rely on a change in contact behavior. Through the intrinsic properties of the material, the element performs simultaneously the functions of heater, temperature monitor and switch. Here again the origin of the intelligent character lies in a type of two-dimensional structure:[4] a closed interface between identical materials, with the phenomenon occurring across the interface.

2.3. Self-diagnosis

The reason why we try to improve the performance of materials is that we hope to use the materials for as long as possible. We also try to establish methods whereby the life of the materials in a particular application can be predicted. However, in a significant proportion of samples the lifetime is shorter than that predicted. We therefore need to periodically check the condition of the materials during use. One method of monitoring which can be used is to observe acoustic emission from the materials. However, it is not practicable to install acoustic emission apparatus in every application. When living organisms go wrong, they signal to others that they are in difficulties, and help from others may then relieve their problems. Although they may not have the self-recovery mechanism within themselves, they can receive help by telling others of the difficulty occurring in them. If materials could be made with such a self-diagnostic mechanism, we could take action to avert disasters caused by failures of materials. We could also avoid unnecessarily sacrificing materials through replacing them prematurely lest they should fail.

2.4. Stand-by Capability

Machines are sometimes criticized because their response is slower than that of living organisms. For example, the motion of robots is slower than that of humans. Machines are also said to be incapable of releasing stored energy as rapidly as living organisms. A flea can jump very high very quickly. Rockets, on the other hand, take off very slowly. Most machines cannot release a very high concentration of energy within a very short time. The difference is in the stand-by mechanism. There are, nevertheless, some cases where devices have an effective stand-by mechanism. Consider the mechanism of amplification in transistors. Between source and sink a large bias is applied. Unless the barrier height is reduced no significant current flows from source to sink. The barrier (or gate) works as a trigger. The humidity sensor of the p/n contact type, which was discussed earlier from the standpoint of self-recovery, may also be analyzed in terms of its stand-by capability. Under dry conditions only a very small current flows through the contacts, although there is a bias across the p/n contact, whereas in humid conditions the current increases with the adsorption of water molecules. The sensor behaves like a hungry animal waiting for food.

If materials can be equipped with a stand-by mechanism in which they wait for nonlinear onset triggered by certain signals, they become interesting candidates for use as intelligent materials.

2.5. Ability to be Externally Tuned

Sometimes we need to change the behavior or characteristics of materials from outside. We may call this "tuning" the device. This avoids having to employ a large number of different components. The most convenient form of control signal is to change an applied voltage. Various ceramic capacitors exist whose capacitance varies with the applied voltage. The optical transmission of ferroelectric ceramic films made of PLZT (lead lanthanum zirconate and titanate) can be altered by changing the applied voltage, which is known as the Kerr or Pockels effect. The p/n contact humidity sensor also works as a very selective carbon monoxide gas sensor.[5] The selectivity towards carbon monoxide arises from selective adsorption of carbon monoxide at the copper oxide surface. The capacitance of the p/n contact increases when carbon monoxide is introduced into the ambient atmosphere (nitrogen and oxygen). The sensitivity changes with the bias applied across the p/n contact as shown in Figure 3. The maximum sensitivity is obtained when the CuO side is positively biased at about 0.5 V. This effect constitutes a tuming. The chemical

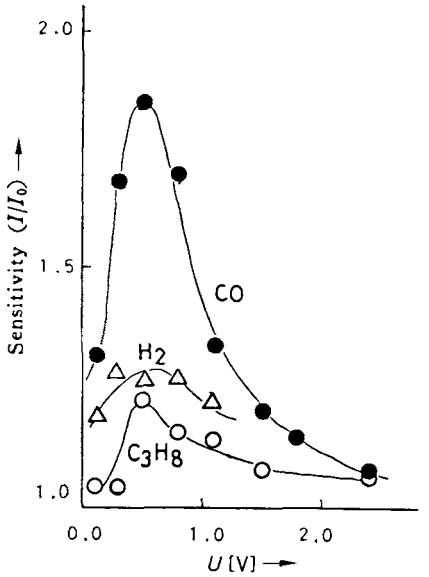

Fig. 3. Tuning of the sensitivity to carbon monoxide by bias in the CuO/ZnO contact type gas sensor [5]. ●: with CO, △: with H_2, ○: with C_3H_8; gas concentrations: 8000 ppm; temperature: 260°C.

reaction between carbon monoxide adsorbed on the positively charged copper oxide surface and oxygen adsorbed on the negatively charged zinc oxide surface, giving rise to carbon dioxide, is enhanced when the bias is greater than 0.5 V. If this explanation is correct, we have here an electric field controlling a chemical reaction.

A difficulty in applying control voltages is the need to connect leads. If the tuning is achieved by optical or magnetic means, the materials can be regarded as being more intelligent.

3. Conclusion

Intelligent materials can be developed through learning about the mechanisms in living organisms. However, we require materials that can be used in environments not tolerated by living organisms. Intelligent materials perform better than living organisms from the durability standpoint. Key functions for intelligent materials are self-recovery, self-adjustment or control, self-diagnosis, stand-by capability, and ability to be externally tuned. Some examples of intelligent materials have been discussed here. One example in which we can see self-recovery and stand-by capabilities, and ability to externally tune the behavior, is the p/n (CuO/ZnO) contact structure. Research and development on intelligent materials has only just begun. It is one of the most challenging frontiers of materials science.

From Electronic/Ionic Conductors to Superconductors: Control of Materials Properties

High T_c Perovskites
Electron/Ion Transfer
Topotactic Reactions

By Robert Schöllhorn*

1. Introduction

Modern materials science may be defined in analytical terms as the effort to understand the macroscopic properties of solids by considering their structure on the microscopic (atomic) level. The term "structure" comprises here the geometrical/crystallographic aspects, the total of electronic interactions between the atoms which constitute the material, and the lattice dynamics. In synthetic terms one major approach in materials science is the aim of "tailoring" materials with a given set of particular properties on the basis of analytical knowledge in order to meet optimally and economically the needs of specific applications. The thermal synthesis of solid compounds is usually related to a substantial structural reorganization at high temperatures. However, the properties of the products are not

ADVANCED MATERIALS

determined solely by thermodynamics, but are frequently strongly dominated by kinetic phenomena leading to non-equilibrium states. One interesting alternative route for preparing new materials that makes use of the consequences of kinetics is low temperature synthesis, which exploits the fact that metastable intermediate states can be stabilized at lower temperatures. A particular case here is the synthesis of solids at or close to ambient temperature; under specific conditions such reactions can be carried out as reversible processes. One most attractive aspect of these "topotactic" reactions is the fact that they can be used for the *modification and control of physical properties* of solid materials by isothermal chemical reactions at ambient temperature. We shall briefly outline here the principles of this concept, and illustrate through a few selected examples the potential and the problems encountered.

2. Concepts

In terms of charge carrier transport properties, solid materials can be classified by a simple scheme in three groups: 1) electronic conductors, 2) ionic conductors, and 3) mixed electronic/ionic conductors, the latter being able to transport electrons as well as ions simultaneously. A large number of solids [H] (binary or multinary phases) which have electronic conductivity together with an appropriate band structure for the uptake of additional electrons and a system of interconnected vacant lattice sites may react with mobile ions A^+ according to the following scheme:[1-3]

$$\underset{\text{electronic conductor}}{[H]} + x e^- + x A^+ \rightleftharpoons \underset{\text{electronic/ionic conductor}}{A^+[H]^{x-}} \qquad (1)$$

This electron/ion transfer process can be performed by chemical or electrochemical techniques. The electrons are taken up into the upper band level (conductivity band) of the host matrix [H] (Fig. 1), while the guest ions A^+ fill up the vacant sites in [H]. Reactions of this type are usually reversible and proceed at or close to ambient temperature while retaining the structure of the rigid matrix [H] (topotactic process). In terms of composition, inorganic host materials are mainly binary or multinary compounds of non-metals with redox-active transition metals, e.g. oxides (WO_3, MoO_2, V_2O_5 etc.), chalcogenides (TiS_2, Mo_6S_8, $NiPSe_3$ etc.) or halides ($RuCl_3$, $RuBr_3$, FeOCl etc.). Similarly a large number of organic conducting polymers (e.g. polyacetylene, polypyrrole, polyaniline etc.) have been found to undergo electron/ion transfer reactions. Non-crystalline inorganic materials with electronic conductivity, such as amorphous MoS_3, TiS_2 and V_2O_5 have also been shown to be able to act as host lattices for these reversible topotactic processes.

The structural dimensionality of the host compounds may range from three-dimensional to one-dimensional (Fig. 2), and strongly affects the reactivity in geometrical terms. Framework hosts with vacant "lattice channels" can accept only atomic guest ions (metal ions, protons) up to a critical diameter determined by the geometry of the channel system. Layered host lattices are flexible and can easily adapt to the geometry of the guest species; they may also

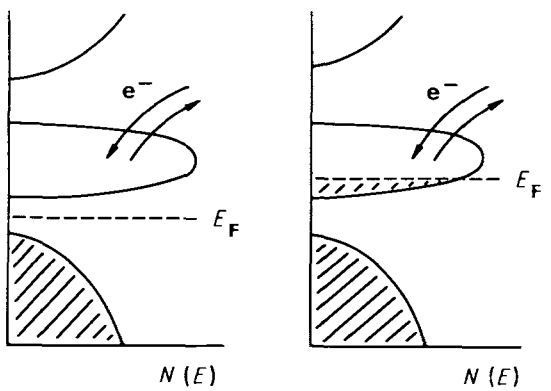

Fig. 1. Electron/ion transfer scheme for semiconducting (left) and metallic (right) materials (E_F = Fermi energy, $N(E)$ = density of states.

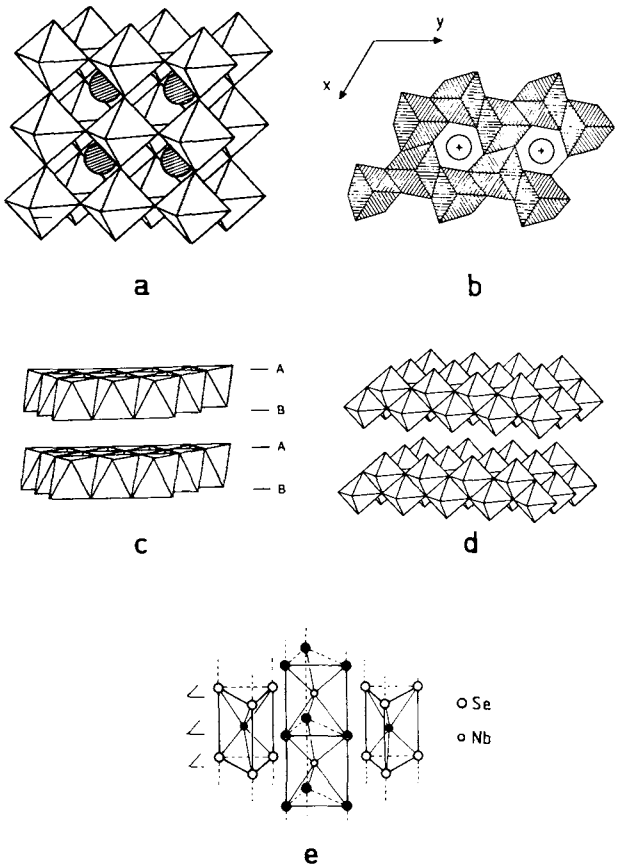

Fig. 2. Host lattices with different structural dimensionality. Framework structures: a) WO_3, b) Nb_3S_4; layered structures: c) TiS_2, d) MoO_3; chain structure: e) $NbSe_3$ (spheres in a) and b) indicate guest positions on lattice sites) [19].

intercalate organic and organometallic ions with or without neutral solvate molecules. The tremendous variety of the latter phases represents an interesting area in which molecular chemistry and solid state chemistry are closely associated. Reactions of layered host systems exhibit a number of structural peculiarities such as "staging" (partial occupation of the van der Waals gaps between the layers in an ordered sequence), "stacking" (different layer order sequence perpendicular to the basal planes), order/disorder transitions of guest or host sublattice, incommensurate phases, cooperative exchange reactions and hysteresis. Similar phenomena are observed for one-dimensional host lattices.

Reaction (1) describes the electron/ion transfer process for an "empty" conductor host lattice. Many ternary phases $A_xM_yX_z$ (M = transition metal, X = non-metal) with electronic conductivity are known, however, which are characterized by a rigid lattice framework (M_yX_z) and cations A^+ selectively mobile at ambient temperature. Many of these phases have an appropriate band structure that allows the following (reversible) electron/ion transfer process:

$$A_x^+[M_yX_z]^{x-} \rightleftharpoons M_yX_z + xA^+ + xe^- \quad (2)$$

A few examples may illustrate the reaction principles outlined above. Niobium disulfide is a metal with a layered structure related to that of the CdI_2 type, which may intercalate Li^+ ions, for example, according to equation (3). For $x = 1$ the lithium ions occupy all octahedral

$$xLi^+ + xe^- + NbS_2 \rightleftharpoons Li_x^+[NbS_2]^{x-} \quad (3)$$

sites in the van der Waals gap between the NbS_2 layer units which themselves have a negative excess charge $[NbS_2]^{1-}$ (macroanions). The intercalation of solvated ions or molecular ions (Cp_2Co^+ = cobaltocenium ion) is similarly illustrated by equations (4) and (5). An example for

$$xNa^+ + yH_2O + xe^- + NbS_2 \rightleftharpoons Na_x^+(H_2O)_y[NbS_2]^{x-} \quad (4)$$

$$xCp_2Co^+ + xe^- + NbS_2 \rightleftharpoons (Cp_2Co^+)_x[NbS_2]^{x-} \quad (5)$$

$$Cu^+[Ti_2S_4]^- \rightleftharpoons Cu^+ + e^- + Ti_2S_4 \quad (6)$$

the deintercalation of a ternary phase with a selectively mobile cation species (Cu^+) is the reaction of the metallic copper chalcogen spinel $CuTi_2S_4$ [equation (6)] that leads to the formation of $Ti_2S_4 = TiS_2$, i.e. a new modification of titanium disulfide with cubic structure (Table 1).

The reactions considered above represent electron/cation transfer processes. Only a few host lattices able to undergo the symmetrical reaction of electron/anion transfer

Table 1. Metastable binary transition metal chalcogenides prepared from ternary phases via electron/ion transfer reactions. A^+ = mobile lattice ion, D = structural dimensionality of the product.

Ternary Phase	A^{n+}	Binary Phase	D	Ref.

[equation (7), [H] = host lattice] have been found so far. Examples are graphite and conducting polymers, which are

$$[H] + xA^- \rightleftharpoons (A^-)_x[H]^{x+} + xe^- \quad (7)$$

redox amphoteric systems accessible to electron/cation as well as to electron/anion transfer. Layer charge sign transition $[H]^- \rightarrow [H]^+$ and electron/anion transfer reactions have been reported recently, however, for a series of layered transition metal hydroxide oxide phases,[4] and we shall discuss below in more detail an example of an electron/oxide ion transfer.

3. Control Functions and Potential Application

The primary chemical properties of solids that can be controlled by electron/ion transfer processes are changes in composition (type of guest species), stoichiometry (concentration of guest species), redox state, and structure. Since these reactions are performed at low temperatures the influence of kinetics becomes dominant. For this reason the reaction products are frequently metastable new phases that cannot be prepared by conventional thermal synthesis techniques. Table 1 presents a few examples of binary chalcogenides which have been obtained from ternary compounds by electrochemical or chemical oxidation. None of these phases can be synthesized from the elements with the stoichiometry or structure indicated. The (reversible) structural changes within the host matrix elements are always rather small (0.01–0.1 Å); for low dimensional host lattices with flexible matrix units (layers, chains) the geometrical separation between these units can, however, be controlled between ca. 6 and 60 Å, e.g. by intercalation of large or anisometric guest species. Lattice defect concentration and order/disorder transitions in the guest or host sublattice can be strongly influenced by the kinetics of the reaction. In layered solvated compounds significant changes in the interlayer spacing can be controlled by minor changes in the equilibrium electrolyte concentration, due to structure induced selectivity resulting from cooperative transitions.[2–4]

One most important aspect is the possibility of inducing and controlling changes in the *physical* properties of a given solid by reversible chemical reactions at ambient temperature. These changes concern in particular the elec-

ADVANCED MATERIALS

tronic properties (i.e. electronic transport, metal/semiconductor and metal/superconductor transitions, charge density waves, magnetic ordering phenomena), optical properties and ionic transport. Mechanical properties can similarly be strongly affected: the layered chalcogenide NbS_2 is a highly elastic compound with lubricant properties, whereas after intercalation even of small amounts of copper (Cu_xNbS_2) a brittle material results.

In terms of applications, electron/ion transfer reactions are of interest from various aspects. As already discussed above, they provide a wide base for the low temperature synthesis of new materials. A quite obvious application in energy storage is their use as reversible electrodes, e.g. in high energy density secondary batteries with aprotic electrolytes.[13] Galvanic cells for this purpose have been designed not only with inorganic materials but also with conducting organic polymers.[14] Changes in optical properties with the redox state have been used for the construction of passive display systems, with the advantage that the information stored is retained in the absence of an external voltage.[15] Recently a rear mirror with dimmer function for automobiles has been developed with a thin film galvanic cell around the reflector plane[16] (Fig. 3). Mixed conductor materials with redox properties can be used as sensor systems (e.g. ion-sensitive field effect transistors) and in microelectronic devices.[17] Further applications relate to the use of electronic/ionic conductors in heterogeneous catalysis, electrocatalysis, in photoelectrochemical systems[18] and for the controlled release and uptake of reagents by host solids.

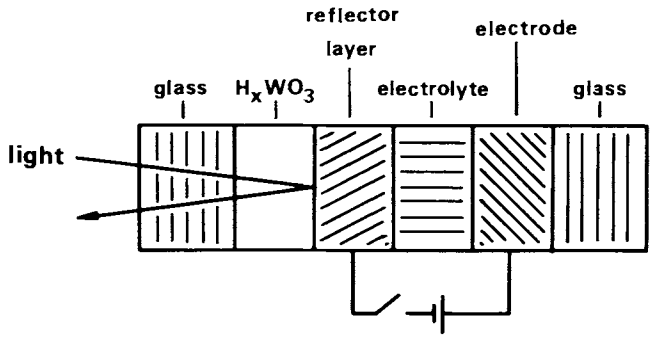

Fig. 3. Scheme of the design of a rear mirror for automobiles (cross section) with dimmer function based on the reversible formation of H_xWO_3 (see section 4) [19].

A major requirement in setting out to exploit the potential of electron/ion transfer reactions for the control of the physical properties of solid materials is the understanding of the reaction mechanism and the changes in structure and bonding with the redox state. We shall discuss in the following a few examples of systems which have recently been studied in more detail; for simplicity we will restrict the scope to atomic species as the guest ions.

4. Electron/Proton Transfer: Mechanism, Kinetics, Anisotropic Dynamics

The intercalation of hydrogen via electron/proton transfer into electronically conducting solids with the formation of hydrogen bronzes is a well known phenomenon.[1,2] These systems can be used as battery electrodes, for passive displays, for hydrogen storage, and as heterogeneous catalysts. An instructive example for the reversible changes in composition, structure and physical properties is the reaction of tungsten trioxide WO_3 (ReO_3 type framework structure, Fig. 2a):

change in stoichiometry:	$WO_3 + xH^+ + xe^- \rightleftharpoons H_x[WO_3]$
change in structure:	monoclinic $\rightleftharpoons$ tetragonal
change in electronic transport:	semiconductor $\rightleftharpoons$ metal
change in optical properties:	yellow transparent $\rightleftharpoons$ blue metallic

Similar reactions are observed for the layered binary molybdenum oxide MoO_3 (Fig. 2d). Five different phases have been identified for H_xMoO_3: I, blue orthorhombic, $0.25 \leqslant x \leqslant 0.4$; II, blue monoclinic, $0.6 \leqslant x \leqslant 0.8$; III, blue monoclinic, $0.95 \leqslant x \leqslant 1.05$; IV, red monoclinic, $1.55 \leqslant x \leqslant 1.72$ and V, green monoclinic, $x = 2.0$. The H_xMoO_3 system displays a characteristic strong kinetic influence: 1) IV and V are metastable phases with potentials lying below the equilibrium potential of H_2/H^+, 2) the reaction cycle exhibits strong hysteresis, phases II and III appear only in the oxidation cycle, which has been explained by the large changes in unit cell volume;[19] 3) the complete transformation of $H_{0.25}MoO_3$ (lower limit of phase I) back to MoO_3 is not possible at equilibrium potentials due to an electron transport threshold. MoO_3 is a wide gap semiconductor (insulator), which at first sight is in conflict with the requirement of electronic conductivity for host lattices as stated above. However, upon reduction the first phase $H_{0.2}MoO_3$ formed at the triphase boundary electronic lead/electrolyte/MoO_3 is a metal, and is thus able to transport electrons. On the way back (anodic oxidation) in the two phase region from $H_{0.2}MoO_3$ to MoO_3, the latter forms a thin layer (metal/insulator transition) blocking the electron transport across the phase boundary. Similar characteristic kinetic phenomena are frequently found in electron/ion transfer reactions of other systems.[2,19]

A further characteristic is the observation of anisotropy effects in low-dimensional host lattices, not only with respect to electronic transport but also regarding the dynamics of the mobile guest species. It is surprising to find that this applies also to proton mobility, since protons are the smallest mobile ions, and could be expected to show iso-

tropic motion independent of the host lattice dimensionality. An interesting example that has been thoroughly studied by solid state ^{1}H-NMR is provided by the layered H_xMoO_3 phases. At low hydrogen concentration ($x \approx 0.25$) hydrogen shows quasi-one-dimensional mobility between the zigzag chains of edge sharing MoO_6 octahedra that constitute the MoO_3 layer units. At intermediate hydrogen concentration ($x \approx 1$) a quasi-two-dimensional motion in the *a/c* layer planes is observed, while at high concentration ($x = 2$) three-dimensional mobility appears. The motional dimensionality of hydrogen can thus be controlled via the redox state and the corresponding stoichiometry.[20]

Early use was made of hydrogen bronzes for galvanic cells, although the reaction mechanisms were established only later. The nickel/hydroxide electrode in the Ni/Cd and Ni/Fe battery is basically an electron/proton transfer process [equation (8)]. The accessible range is $0.2 \leqslant x \leqslant 1.4$;

$$H_2NiO_2 \rightleftharpoons H_{2-x}NiO_2 + xe^- + xH^+ \quad (8)$$

the lower limit corresponding to $Ni(OH)_2$ cannot be reached in electrochemical systems for kinetic reasons, since nickel(II) hydroxide is an insulator (electron transport threshold, see above). Equation (8) represents a simplified version of the overall process; investigations on the solid state chemistry of layered hydroxide oxides have shown that the real process is far more complex.[4,21]

The first discharge region of the MnO_2 electrode in the Leclanché cell [equation (9)] is reversible and corresponds

$$MnO_2 + xH^+ + xe^- \rightleftharpoons H_xMnO_2 \quad (9)$$

to the insertion of protons into the vacant lattice channels of the rutile structure of MnO_2; however, further reduction leads to irreversible lattice transformations. Replacement of H^+ by Li^+ and the use of aprotic electrolytes have led to the development of secondary batteries (reversible cells) of the Leclanché type with higher energy density.

Topotactic electron/proton transfer reactions have also been found to occur in molecular solids, e.g. planar transition metal complexes with columnar structures and cluster halides.[22] In the latter phases long-range electron/proton transfer across insulator barriers occurs, as in certain organized biological cell components; the mechanism of this process is not yet understood.

5. Stoichiometry: Electronic and Geometrical Thresholds

An important point in the control of stoichiometry is the question of the upper intercalation limit, which can be governed either by electronic (band structure) or by steric factors. We will briefly demonstrate these aspects by using the molybdenum cluster chalcogenide Mo_6S_8 as an example.[23,24] The structure of Mo_6S_8 can be described as consisting of sulfur cubes surrounding Mo_6 octahedra. These units are interconnected via Mo-S bonding to a framework which contains "channels" of vacant sites along the rhombohedral axes. The simple valence electron counting scheme shows that the Mo_6 clusters have a deficit of four electrons in terms of metal-metal two-electron cluster bonds. This is in agreement with band structure calculations. We can now predict easily that the maximum number of electrons that can be taken up into the valence band is four [equation (10)], corresponding to an intercalation limit of four monovalent or two bivalent guest ions. This prediction on electronic grounds has turned out to be valid for all cations with small ionic radii.

$$Mo_6S_8 + 4e^- \rightleftharpoons [Mo_6S_8]^{4-} \quad (10)$$

A steric threshold appears for guest ion radii > 0.9 Å: $Cd_1Mo_6S_8$ can be obtained easily, while $Cd_2Mo_6S_8$ does not form, although the system is not saturated in electronic terms. Physical properties change significantly with stoichiometry as is shown, e.g., by the electronic transport characteristics of the lithium system:

Mo_6S_8	$Li_1Mo_6S_8$	$Li_3Mo_6S_8$	$Li_4Mo_6S_8$
metal	superconductor	metal	semiconductor

After a transfer of $4e^-$ the band is filled and the compound becomes a semiconductor.

In spite of this simple and consistent scheme, detailed investigations revealed that these transitions can be more complex. ^{7}Li-NMR studies have recently shown that in the lithium system $Li_xMo_6S_8$ at $x = 3$ partial charge transfer is observed, which has been explained by the formation of Li_3^{2+} guest ion clusters with one-electron three-center bonding; after a transfer of four electrons and transition to the semiconductor state, however, normal NMR shift values and quantitative charge transfer are found.[24]

6. Control of Isothermal Magnetic Phase Transitions: Critical Valence States

An interesting specific example of the modification of electronic properties of solids by electron/ion transfer reactions is the possibility of isothermal control of magnetic ordering states which has been observed recently for copper chromium chalcogen spinels $CuCr_2X_4$ (X = S, Se, Te).[25] The structure of these phases can be described schematically by a cubic close-packed anion lattice with Cr ions on octahedral lattice sites and Cu ions on tetrahedral sites. In terms of electron transport properties these phases are metals; the copper ions are mobile at ambient temperature. These spinels are able to intercalate additional copper ions according to equation (11). As shown in Figure 4, this reaction corresponds, e.g. for the selenide, to a one phase region with $x_{max} = 1$ (i.e. $Cu_2Cr_2Se_4$) and a contin-

ADVANCED MATERIALS

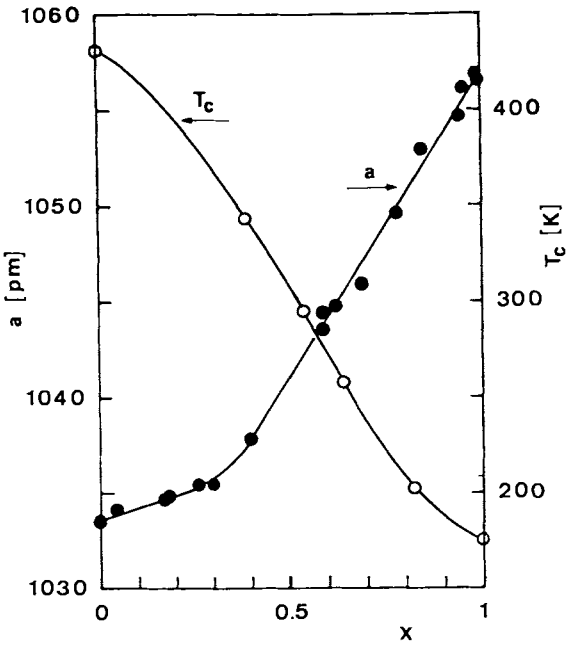

Fig. 4. $Cu_{1+x}Cr_2Se_4$: change of the cubic lattice parameter a (300 K) and Curie temperature T_c with the stoichiometry [25].

uous change in lattice parameters. $CuCr_2Se_4$ is a ferromagnetic metal at 300 K with a rather high Curie temperature T_C. Figure 4 shows the change in T_C with increasing copper content. Reaction (11) corresponds to the 300 K isotherm in Figure 4: it can be seen that at a critical value x_c an isothermal phase transition [equation (12)] from the spin-ordered magnetic state to the disordered system is observed. The reaction is reversible and represents the first example of the control of isothermal magnetic order-disorder transitions by chemical reactions at ambient temperature. In principle, this process can be used to design chemically operated magnetic switches or magnetic sensor systems indicating the redox state of a chemical reaction.

$$\underset{\substack{x=0\\ \text{ferromagnetic}\\ \text{metal}}}{CuCr_2Se_4} + x\,Cu^+ + x\,e^- \rightleftharpoons \underset{\substack{x=1\\ \text{paramagnetic}\\ \text{semiconductor}}}{Cu_{1+x}Cr_2Se_4} \qquad (11)$$

$$\text{ferromagnetic ordered state} \underset{x<x_c}{\overset{x>x_c}{\rightleftharpoons}} \text{paramagnetic state} \qquad (12)$$

In order to discuss the correlation between redox state, magnetic behavior and chemical bonding, we come back to equation (6) which concerns the reaction of the spinel $CuTi_2S_4$[7] that is obviously at variance with the chromium system. The titanium spinel can be oxidized to c-TiS_2, which is easy to understand in terms of the ionic formula [equation (13)].

$$Cu^+[Ti^{3+}Ti^{4+}(S^{2-})_4]^- \rightleftharpoons [(Ti^{4+})_2(S^{2-})_4] + Cu^+ + e^- \qquad (13)$$

Ti^{3+} is oxidized to Ti^{4+}. The formula is based on the well established fact that Cu ions in chalcogenides are invariably monovalent;[26] the metallic properties of $CuTi_2S_4$ are explained by cation mixed valence states with identical lattice positions. The equivalent reaction of the chromium spinels which should lead to cubic CrS_2 [equation (14)] is

$$Cu^+[Cr^{3+}Cr^{4+}(S^{2-})_4]^- \rightleftharpoons [(Cr^{4+})_2(S^{2-})_4] + Cu^+ + e^- \qquad (14)$$

not accessible, however. Instead, the chromium spinels may be reduced [equation (11)] with the uptake of one additional electron. Earlier polarized neutron diffraction studies[27] and recent XPS/UPS investigations[28] have now provided experimental evidence for the presence of holes in the anion p band of the copper chromium spinels $CuCr_2X_4$ and for the exclusive presence of chromium(III) in the reduced and oxidized state. The correct description of $CuCr_2Se_4$ by formal valence states is thus given by

$$Cu^+[(Cr^{3+})_2(Se^{2-})_3(Se^{\bullet-})]^-$$

This description explains the metallic properties of $CuCr_2Se_4$ by anion mixed valence. The ferromagnetic properties have been discussed in the original bonding model given above [equation (14)][29] in terms of super-exchange via excited anion states; however, this cannot easily explain the high Curie temperature. The revised model explains the strong spin coupling by super-exchange $Cr^{3+}/Se^{\bullet-}/Cr^{3+}$ via a high concentration of delocalized ground state anion holes in the valence band. The reaction mechanisms of the titanium and chromium spinels are thus quite different in terms of bonding changes. The oxidation of $CuTi_2S_4$ to c-TiS_2 is related to a conventional oxidation state change of the transition metal ions [equation (15)].

$$Ti^{3+}/Ti^{4+} \rightleftharpoons Ti^{4+}/Ti^{4+} + e^- \qquad (15)$$

The reduction of the chromium spinels is correlated with a new electron transfer mechanism via host lattice anion redox reactions equivalent to the annihilation and generation of anion p band holes:[30]

$$\underset{\text{anion mixed valence; ferromagnetic metal}}{Cu^+[(Cr^{3+})_2(X^{2-})_3(X^{\bullet-})_1]^-} \quad \begin{matrix}+x\,e^- + x\,Cu^+ \\ \text{hole generation process} \uparrow \\ \downarrow \text{hole annihilation process} \end{matrix} \quad \underset{\text{integral valence; paramagnetic semiconductor}}{(Cu^+)_2[(Cr^{3+})_2(X^{2-})_4]^{2-}}$$

The behavior of the chromium spinel phases has been rationalized recently in terms of a "critical valence state" (CVS) model.[28,30] The latter is defined for an internal redox couple M^{n+}/X^{m-} in a solid as the critical redox state, where the electron affinities E_A of the metal ion M^{n+} and the anion X^{m-} become equivalent

$$E_A(M^{n+}) \triangleq E_A(X^{m-})$$

The limiting states are given by equation (16); for low valent M^{n+} the left side is favored, with the upper band being

$$M^{n+}/X^{m-} \longleftrightarrow CVS \longleftrightarrow M^{(n-1)+}/X^{(m-1)-} \quad (16)$$

dominated by cation states, while the anion retains a closed valence shell. For high-valent M^{n+} the metal ion becomes reduced to a lower valency by electron transfer from X^{m-} (right side). The upper band is now dominated by anion states with p band holes. In chemical terms the anion loses its closed valence shell and becomes a "radical". As in molecular chemistry, where radical ions are known to tend to dimerize so as to for complete the valence shell, anion holes are frequently "dimerized" also in the solid state. Well-known examples are pyrites MS_2 with S_2^{2-} ions. In some cases, however, delocalized hole systems with metallic properties occur, e.g. $CuS=(Cu^+)_3(S_2^{2-})S^{\cdot-}$, where localized hole dimers S_2^{2-} coexist with delocalized $S^{\cdot-}$ in different lattice planes.

For the copper chromium chalcogen spinels the equilibrium is clearly above the critical valence state on the right side of equation (17). The fundamental difference in reac-

$$Cr^{4+}/X^{2-} \rightleftharpoons Cr^{3+}/X^{\cdot-} \quad (17)$$

tivity and reaction mechanism between the titanium spinel and the chromium spinels can thus be rationalized in terms of the model outlined above. An important aspect is that one can now make predictions of the reactivity of related phases.[30] To illustrate this we shall consider here only the case of a simple system. The pyrite FeS_2 is a semiconductor with a rock salt type lattice; Fe is located on the cation positions in a distorted octahedral environment, while the anisometric anions display statistical orientation so that the overall symmetry is cubic. In FeS_2 iron is above the critical valence state, i.e. $Fe^{2+}/S^{\cdot-}$. The anion holes are dimerized, resulting in $^{-}S-S^{-}$ units which explains the semiconducting properties. It should thus be possible to generate decocalized holes by electron/anion transfer, e.g. by intercalation of Li^+ ions according to equation (18) and to simultaneously achieve a semiconductor/metal transition.

$$Fe^{2+}S_2^{2-} + xLi^+ + xe^- \rightleftharpoons (Li^+)_x[Fe^{2+}(S_2^{2-})_{1-x}(S^{2-})_xS^{\cdot-}]^{x-} \quad (18)$$

7. Control of the Transition Temperature of Defect Perovskite Superconductors

The concept of controlling physical properties of materials by intercalation reactions led at a relatively early stage to studies on the modification of the critical temperature T_c of superconducting phases.[1,31-33] It has been possible to verify this concept with a variety of systems; examples that have been studied in more detail are layered transition metal dichalcogenides (e.g. NbS_2, TaS_2, $NbSe_2$) and molybdenum cluster chalcogenides Mo_6X_8 (X = S, Se). The results show that T_c can be either increased or decreased

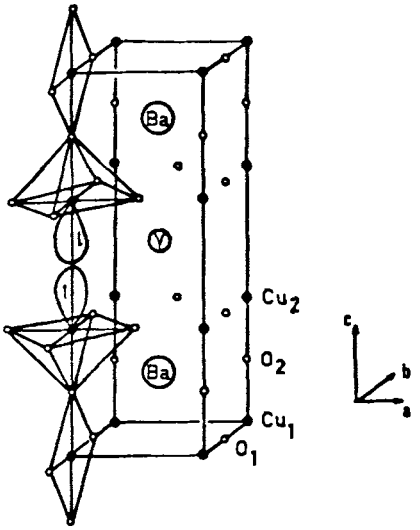

Fig. 5. Structure of the high temperature superconductor $YBa_2Cu_3O_7$ (schematic).

depending upon the band structure of the host lattice. The accessible temperature range extends from ca. 0.8 K to ca. 12 K. The recent rapid development in the area of high temperature superconductors[34] has provided a series of new materials, whose properties are of major interest also in terms of the aspects under discussion here. We shall take the quaternary copper oxide $YBa_2Cu_3O_7$ as an example for the consideration of chemical reactivity, stoichiometry, reaction mechanism, and corresponding changes in superconducting behavior.

$YBa_2Cu_3O_7$ has a defect perovskite type structure[35] (Fig. 5) with copper ions in tetragonal pyramidal (sheets in the *a*/*b* planes) and in square planar (chains in *b*/*c* planes) coordination. The simple ionic formula may be described by

$$Y^{3+}(Ba^{2+})_2(Cu^{2+})_2(Cu^{3+})_1O_7$$

Obviously a part of the copper ions is present in the unusual valence state Cu^{III}. Interatomic distances based on refined structural data suggest that Cu^{III} is primarily located in chain positions along the *b* axis, while Cu^{II} occupies positions in the *a*/*b* plane.

Investigations on the synthesis conditions revealed a significant influence of oxygen partial pressure and annealing temperature on the superconducting properties of $YBa_2Cu_3O_7$. Similar observations were made earlier on several ternary perovskite systems which show temperature and $p(O_2)$ dependent changes in oxygen stoichiometry correlated with high defect concentrations.[36] Detailed studies have shown that $YBa_2Cu_3O_7$ may react according to equation (19) with a rather broad nonstoichiometric range ($0 \leq x \leq 0.9$).[37-39] This reaction is clearly a topotactic process which is fully reversible in the range indicated. $YBa_2Cu_3O_7$ is a metal at ambient temperature, but transforms into an electronic/ionic conductor at a rather low

ADVANCED MATERIALS

temperature (ca. 300°C), where the oxygen ions become selectively mobile. Reaction (19) can similarly be performed in a galvanic cell; the oxygen intercalation and deintercalation thus correspond to an electron/anion transfer process [equation (20)]. The oxygen ions are selectively removed from the copper/oxygen chains in the basal planes of the unit cell.

$$YBa_2Cu_3O_7 \rightleftharpoons YBaCu_3O_{7-x} + x/2\,O_2 \quad (19)$$

$$YBa_2Cu_3O_7 + 2xe^- \rightleftharpoons YBa_2Cu_3O_{7-x} + xO^{2-} \quad (20)$$

The reaction discussed in equation (20) can be used to control the superconducting transition temperature of $YBa_2Cu_3O_{7-x}$ as is shown in Figure 6, which illustrates the

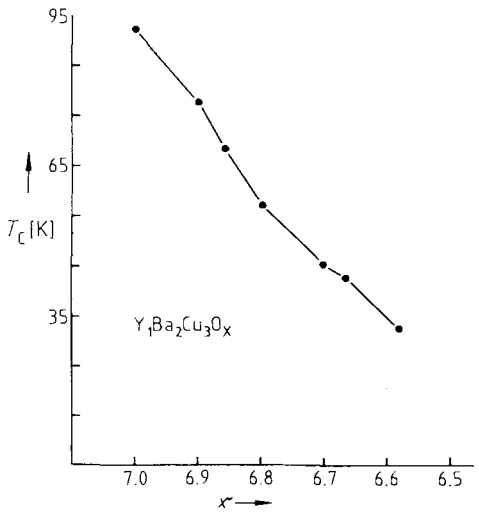

Fig. 6. Change of the superconducting transition temperature T_c of $YBa_2Cu_3O_x$ with the stoichiometry [39].

correlation between oxygen stoichiometry and T_c. By topotactic oxygen intercalation/deintercalation the transition temperature can be varied continuously between 93 K and 30 K. From $x=0$ to $x=0.5$ the lattice parameters a and b vary simultaneously with the oxygen loss such that a transition from orthorhombic to tetragonal is attained at $x=0.5$. This structural transformation is accompanied by an electronic metal/semiconductor transition: at $y=0.5$ the oxide displays semiconductor properties. In terms of chemical bonding this effect can be explained by the correlated valency changes [equation (21)]. For $x=0$ the metallic properties are related to the mixed valence system Cu^{2+}/Cu^{3+}, while at $x=0.5$ all Cu ions are bivalent, which results in semiconductor behavior.

$$\underset{\text{mixed valence metal superconductor (93 K)}}{Y^{3+}(Ba^{2+})_2(Cu^{2+})_2(Cu^{3+})O_7} \rightleftharpoons \underset{\text{integral valence semiconductor}}{Y^{3+}(Ba^{2+})_2(Cu^{2+})_3O_{6.5}} + 1/4\,O_2 \quad (21)$$

One most interesting aspect of the $YBa_2Cu_3O_{7-x}$ system is the observation that the oxygen anions become mobile at an exceptionally low temperature, which is quite unusual for a ceramic oxide with high lattice energy. In order to explain this behavior a model has been proposed recently that suggests a critical valence state situation:[30,38,39]

$$Cu^{3+}/O^{2-} \rightleftharpoons Cu^{2+}/O^{\bullet-} \quad (22)$$

i.e. the simultaneous presence of Cu^{3+} as well as $O^{\bullet-}$ (anion holes). This implies that the electron affinities of Cu^{3+} and O^{2-} are approximately equivalent; the upper band level must exhibit considerable anionic character. This model can explain the high oxygen mobility in terms of the lower activation energy of site change for a monovalent anion (Fig. 7), and the reduced effective size of $O^{\bullet-}$. As in the case of the chromium chalcogen spinels (see Section 6) the appearance of anion 2p band holes may result in strong super-exchange coupling between the Cu ions close to the Y planes inducing antiferromagnetic order (Fig. 5), which in turn would explain the absence of local magnetic moments in $YBa_2Cu_3O_7$.

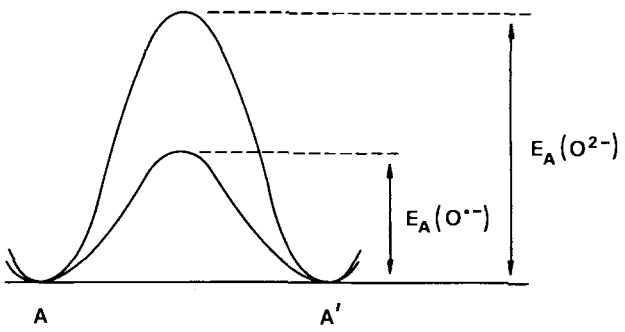

Fig. 7. Scheme of difference in activation energy E_A for site change between regular lattice sites A,A' for bivalent and monovalent oxygen anions.

With respect to the bonding situation, several other models have recently been proposed, some of them rejecting the presence of Cu^{III};[40-42] a decision in this controversial situation must await further experimental evidence.

8. Conclusions

The few examples presented in the foregoing focussed on the demonstration of the attractive potential for controlling major functional properties of solid materials by reversible chemical reactions at low temperature under isothermal conditions. One obviously critical point with respect to these systems is the level of understanding of the correlation between chemical reactivity, geometrical structure and chemical bonding, which in turn is a prerequisite for undertaking a systematic search for new systems. As

shown in the preceding sections, even seemingly simple reactions may turn out to be rather complex at various levels of description. At the same time there is an evident trend in advanced materials—when specific requirements have to be met—towards an increasing degree of complexity in terms of stoichiometry. An illustrative example is the development of superconductor materials, where high transition temperatures are one particular objective for application purposes. The first superconductors were elements with an upper T_c limit of ca. 10 K under normal pressure. The investigation of binary and ternary alloys increased T_c to as high as 23 K. Ternary compound superconductors attained ca. 40 K, and only polynary phases containing four or more different elements were found to yield transition temperatures above the boiling point of liquid nitrogen. Obviously a large number of different atomic species is required for optimal "tuning" of these phases with respect to the property desired.

It is hard to see at present how materials science, as defined in the introductory paragraph of this article, can keep pace with the progress made via the predominantly empirical traditional approach. It is apparent that both lines will coexist in the near future; what we can expect from modern materials science is the development of firm qualitative guide lines indicating more economic routes to the tailoring of solids with defined functional properties.

One additional note should be made concerning bonding concepts in inorganic solid state chemistry. In the last decade major trends in studies on metal/non-metal systems M_nX_m have been the concentration on compounds with high n/m ratio, i.e. cluster phases with metal-metal bonding, and on compounds with low n/m ratio exhibiting anion homonuclear bonding. The example of the critical valence state discussed above demonstrates that, also in the intermediate n/m range of "classical" compounds, interesting bonding situations may arise which may be correlated with specific solid state properties.

Conference Reports

Better High-Tech Ceramics by Improved Processing

The 90th Annual Meeting of the American Ceramic Society from 2–6 May in Cincinnati was, with more than 4000 participants, once again the most exciting congress event of the year for the ceramic community. The general trend towards obtaining better high-tech ceramics by improved processing resulted in a noticeable emphasis on processing steps such as powder production methods, powder handling, and on forming and sintering. In this report some special aspects illustrating the general trends will be discussed.

Powder Synthesis

The sessions on powder synthesis showed the efforts being made to produce powders of higher purity and smaller, controlled particle size. *G. M. Crosbie* et al. (Ford Motor Company, Dearborn, Michigan) reported on the synthesis of Si_3N_4 powder of outstanding purity by the reaction of $SiCl_4$ with liquid NH_3 at 0°C. The intermediate reaction product was described as "$Si(NH)_2$" which reacted further to Si_3N_4 at elevated temperatures. An optimized method to obtain a homogeneous distribution of yttria in a Si_3N_4 powder matrix yielding homogeneous densification and microstructural development was described by *A. K. Garg* and *A. L. C. DeJonghe* (University of California, Berkeley). The beneficial effect of Y_2O_3 additions to Si_3N_4 itself is well known. The additive forms a liquid phase at temperatures between 1500 and 1800°C, which results in the benefits of fast densification and satisfactory microstructural development of Si_3N_4. In the work described, a better distribution of the additive was obtained when yttrium hydroxycarbonate was precipitated from a liquid suspension on to the Si_3N_4 matrix powder and transformed into Y_2O_3 during calcining. A number of speakers described other methods which are particularly suitable for the synthesis of highly pure, monosized submicron powders, namely sol-gel technique, hydrothermal synthesis and emulsion techniques. All of them expected an enhanced sinterability and improved mechanical and physical properties due to the high purity and narrow size distribution of powders produced by these methods.

An entire session was devoted to AlN, which has a considerable potential for technical applications where its outstandingly high thermal conductivity can be used. A new method of AlN powder production was proposed by *L. D. Silverman* (Engelhard Corporation, Edison, NJ). An Al_2O_3 sol is embedded in a polymer matrix and heated in nitrogen. During heating the pyrolysis of the polymer matrix provides free carbon, which reacts at still higher temperatures with Al_2O_3 in a carbothermic reaction. In the presence of nitrogen the reacting Al_2O_3 forms AlN.

Interesting possibilities for controlled texture formation in ceramics were reported, which also have implications with regard to the anisotropy of critical currents in the new ceramic superconductors. Precursor powders consisting of faceted cubic MgO particles were converted into textured MgO ceramics by cold pressing and sintering. The existence of texture was established by a new application of EPR spectroscopy showing that after sintering the MgO (111) cubic axes are preferentially oriented along the cold pressing direction. EPR spectroscopy seems to be an important new tool for studying texturing effects in a wide range of ceramics.

Nanocrystalline Ceramics

Nanocrystalline solid bulks of strongly covalent ceramics such as SiC, Si_3N_4 and BN were synthesized and consolidated by *G. D. Soraru* et al. (University of California, Los Angeles) by the pyrolysis of organometallic polymers. The initially amorphous powders transformed into the nanocrystalline solid bulks during tempering. No information was available at the conference on the properties of these nanocrystalline materials.

Forming

D. J. Rhee and *I. A. Aksay* (University of Washington, Seattle) presented an improved understanding of the debindering of injection molded ceramic parts, which is one of the potential future methods for producing high-tech ceramics with complex shapes. Debindering in ceramic–polymer composites not only determines the properties of the residual matrix, but also the required debindering time has a decisive influence on the economic viability of the method.

Sintering and Hot Isostatic Pressing

During the Annual Meeting the three day symposium "Sintering of Advanced Ceramics" effectively summarized the present knowledge in this field. A book containing the papers presented orally or as posters will be published

soon by the American Ceramic Society. The symposium was also intended to honor Professor *Robert L. Coble* (Massachusetts Institute of Technology), who has made outstanding contributions to the field of ceramic materials development (LUCALOX). In the mid-1970's, *R. L. Coble* had stimulated a series of questions about an ideal approach to powder processing, from which the proposal for optimized programs for sintering single phase ceramics evolved. *K. Bowen* (Massachusetts Institute of Technology) summarized some of the experimental results that were subsequently obtained and concluded that the sintering programs have been a necessary stage in structuring the problem of improving the sintering process. This improves the reliability of ceramics, which is essential for the broader application of structural ceramic components. *A. G. Evans* (University of California, Santa Barbara) explained how reliability enhancement may be achieved by combining control of defects with high toughness microstructures, a problem which includes topics such as defects caused by differential densification and grain growth in the presence of pores and second phases. In electronic ceramics the reliability of the products is considerably affected by impurities which influence processing and the final properties. *P. Morris* (Bellcore, Red Bank, NJ) pointed out that most of the present ceramic materials typically contain at least several thousand ppm of impurities, due to chemical inhomogeneities present in the powdered starting materials or introduced during processing.

Impurity and Additive Control

Unintentional impurities or intentional additives were shown to result in complex chemical reactions, often involving liquid phases, which frequently cause discontinuous grain growth (see Fig. 1). A quite surprising effect of the particle size distribution on liquid phase sintering of alumina was found in the case of three alumina powders with equivalent purity levels but varying particle size distributions, which were sintered using a calcium-magnesium-aluminum silicate glass additive. Although the samples sintered to essentially identical densities, radical differences in the fired microstructure were observed. Alumina powders having a bimodal particle size distribution were observed to have the most uniform fired microstructure. Questions regarding the role of a liquid phase (often a glass) in sintering of technologically important ceramics, and also on tungsten when cofired with ceramics in multilayer ceramic packages were generally thought to be of considerable practical importance. Controlled use of impurities and additives can improve the production of, for example, electronic ceramic-metal composites. Tungsten, for example, is commonly used to form conductors in ceramic multilayer packages. During cofiring in hydrogen, densification of the tungsten was shown to be promoted by a silicate liquid that forms either in the ceramic body (typically 90% alumina) or from glass forming components added to the tungsten screen printing paste. In lead perovskite systems a controlled small change in the cation stoichiometry can lead to a substantial reduction of the sintering temperature. This is thought to be due to the formation of a liquid phase during sintering, which would be detrimental to the electronic properties if allowed to remain in the material. However, as some components of the liquid phase have relatively high vapor pressures, the liquid phase can be removed by the evaporation process. Thus, a single perovskite phase is obtained by liquid phase sintering at low temperatures.

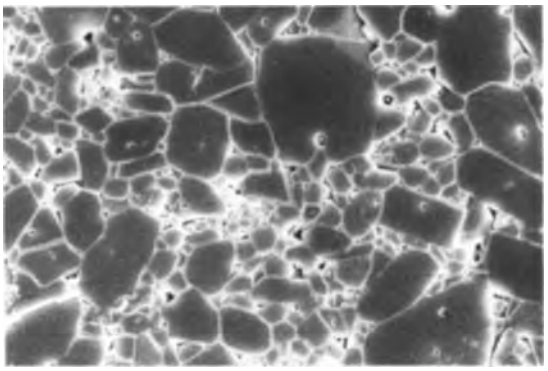

Fig. 1. Uncontrolled abnormal grain growth during sintering of MgO-doped alumina due to the presence of a small amount of liquid phase.

A considerable number of presentations dealt with sintering and hot isostatic pressing of nanoscale powders of Si_3N_4 and Si_3N_4/AlN, obtained by pyrolysis of organometallic precursors in ammonia, or described the effects of sintering aids on densification and microstructural development of SiC, Si_3N_4 and oxide ceramics. Major emphasis was put on the advantages of rare earth oxides which are increasingly used as sintering aids in high performance ceramics. The chemical stability of these oxides should theoretically result in very little oxidation reaction with the host material. In addition, the eutectic mixtures of rare earth oxides with silica have unusually high melting points, which provide a decreased tendency towards uncontrolled grain growth.

High Temperature Creep

Special sessions treated sintering and creep of two phase materials as a subject of growing importance with regard to understanding ceramic processing and improving the reliability of ceramic materials at elevated temperatures. Again, trace amounts of a second phase at grain boundaries were shown to have disastrous effects on component lifetime, since cavities that form during creep tend to propagate as cracks. The viscosity and Poisson's ratio of sintering glass/ceramic and metal pastes used in multilayer substrates can be used to predict stresses and strains produced by differential strain during sintering of composites. Meth-

ods of measuring and avoiding these strains were described by a number of authors, emphasizing the enormous amount of recent research activity in the USA in the field of ceramic composites.

The Long Road of Materials Research

A most illuminating example of the subtle and complex chemical and physical problems involved in research on existing and emerging advanced materials was presented by *M. P. Harmer* (Lehigh University, Bethlehem, PA) when he gave the keynote lecture on the perennial topic "Alumina". He commented: "Twenty-seven years have elapsed since *R. L. Coble* reported that small additions of magnesia promote the sintering of alumina to full density—the LUCALOX invention. A steady succession of papers have subsequently appeared concerning the role of the additive, and a considerable amount of controversy has surrounded this topic until today. After critically reviewing what progress has been made over that twenty-seven year period in understanding the role of MgO in the sintering of alumina, I have to conclude that, although we have come a long way in understanding the phenomenology of this classic additive effect, much still remains to be done to understand the detailed mechanisms involved at the atomic level".

Many of the talks at the 90th Annual Meeting of the American Ceramic Society suggested that *Harmer*'s statement is equally applicable to most of the other major topics of current research on the processing of advanced ceramics.

Advanced Concepts for Ceramic Toughening

A workshop on Advanced Concepts for Ceramic Toughening was held on 14–17 April 1988 at Schloss Weitenburg, FRG. The objective of the workshop was to clarify current understanding of toughening mechanisms in ceramics and to identify future patterns of work needed for the development of materials with the mechanical properties required for applications.

The meeting was divided into four sections concerned respectively with the theory of toughening mechanisms, with the role of interfaces in toughened microstructures, with the requirements of processing and with the transfer of these concepts into industrial practice. An additional discussion session was devoted to the significance of toughness for the acceptability of ceramics.

It was recognized that different sectors of the subject were at very different levels of development. Thus, work on transformation toughening had been brought to a level of maturity where significant issues remained but where the basic understanding was now sound. In contrast, work on fiber and whisker reinforcement was at a very preliminary level in terms of the understanding of the desired interface structure between the reinforcing phase and the matrix. There was in particular concern that high temperature events in toughened microstructures had received little attention and were not well understood.

Toughness and Microstructure

The majority of contributions in this session were concerned with transformation toughening and this subject was also emphasized in the discussion. The common opinion expressed in the summary was that the understanding of transformation toughening is already very high; we have a good understanding of the microstructural contributions (grain size, grain shape, glassy phase, inclusions, etc.) to the toughness. In general it is possible to tailor a microstructure towards a desired toughness.

In selecting particular items from the session, ceria-stabilized tetragonal zirconia (Ce-TZP) is seen as a new material in the group of transformation toughened zirconias. The strongly nonlinear crack diffraction curve will be a subject for many investigations in the future. The origin for the curve is the unusual transformation zone which reaches far ahead of the crack tip and whose shape and elongation are not yet understood. The crystallographic origin of this shape is probably the related transformation tensor, which is not known and which has to be investigated. The scatter of the mechanical properties, especially that of the K_{Ic} values, is dramatic and reaches from just 5 MPa m^{-1} to over 30 MPa m^{-1}. There is strong evidence for a microcrack mechanism in this material; however, the microscopic proof for this is still missing. For this material, the fracture mechanical description using only a K_{Ic} value is no longer valid and has to be replaced by a set of R-curves.

Interfaces

Compared to transformation toughening, the understanding of the role of interfaces is pretty weak. The audience agreed that experiments on the characterization of interfaces in model systems and, of course, in practical systems are missing. For most materials the fracture energies

for the interfaces are not known; thus the effect of inclusions on crack propagation cannot be predicted theoretically. In particular the characterization of interfaces at the high temperatures encountered in many applications has not been investigated and is surely a subject for the future.

Basically, a similar judgement can be made for reinforcement with ductile particles. It is already known that a certain degree of debonding at the interface between the ductile particles and the brittle matrix is wanted in order to allow an extended deformation of the particle. However, numbers such as the required percentage of debonded surface, the optimal inclusion size, the preferred level of ductility, etc. are not known and have to be measured in the future. For the technical application of ductile particle reinforcement, long term properties such as corrosion, wear, oxidation behavior, etc. have to be taken into account.

Acceptability of Ceramics

The measurements on fatigue, i.e. the degradation of strength under cyclic load, were the most exciting and impressive news in the discussion session. The fact that toughening and resistance to fatigue are contradictory targets has not been recognized until now; microstructural optimization and design have been directed only to the improvement of the K_{Ic} value. For the future, of course, microstructural design has to consider long term properties. The description of materials behavior in terms of fracture mechanics is losing its dominating importance, i.e., consideration of long crack behavior will be one part of the truth which must be supplemented by the mechanics of short cracks. Hence, fatigue, subcritical crack growth, and creep will recieve more attention.

Brittle materials have been described by one K_{Ic} value and non-linear materials by just one R curve. However, R curve measurements with different starting crack length have shown that the slope of the R curve depends on the length of the initial crack. A complete description of the materials properties thus requires the knowledge of a whole set of R curves. Materials designed with contact shielding (crack surface interactions behind the crack tip) will be very difficult to describe and many measurements must be done in the future.

Processing

The discussion of the processing session was relatively short. The wet chemistry processing routes for single phase powders are standard techniques now and will be optimized in the future. Whisker and fiber reinforced systems will require hot isostatic pressing or hot pressing for densification. However, when these materials are densified at a certain temperature they will not be able to carry load in this same temperature range (creep, oxidation etc.). Consequently, non-sintering processing routes are being developed such as gas phase infiltration, liquid phase infiltration, displacement reactions and melt-oxidation. Undoubtedly these preparation techniques will attract more attention in the future.

Applications

This session was planned to link the basic scientific aspects with industrial applications. It is obvious that there is a need in industry for more damage tolerant materials, and industry therefore welcomes the newly developed ceramics. But it has to be stated that toughness and high K_{Ic} values are not the only properties required of a material. The relationship between different properties, and the response of the behavior of a material to various microstructural modifications have to be studied. A conflicting relationship between toughness and fatigue is already visible. This is not an unusual situation in the development of materials: in metallic systems, an understanding of the properties-microstructure relationship has been a prerequisite in applying these materials safely in well designed constructions. In the future one has to study the effects of preparation conditions on the microstructures and the correlation between microstructures and properties, with toughness being one important parameter. These studies will be done in the area of basic science with feedback, however, from the applications side.

The meeting was encouraging in that it demonstrated the progress that could be made with a topic such as transformation toughening when the resources of the materials community were focussed on its solution. The meeting raised matters of real concern in respect to the possible fatigue penalty which could ensue from the use of toughening mechanisms, and in particular with respect to the absence of identified toughening mechanisms suitable for high temperature applications. The two topics were seen as a suitable basis for future research programs which could then be reported at a subsequent workshop.

ADVANCED MATERIALS

Polymer Crystals

Forty scientists from Europe, the United States and Japan were invited to Gargnano, Italy (Europhysics Conference on Advanced Topics in Polymer Science, June 19–24, 1988) to lecture on the progress achieved in topics concerning polymer morphology and kinetics in recent years. The opening session was overshadowed by the announcement of Dr. *David Sadler*'s death. Professor *Keller* (Bristol, UK) gave a memorial address, in which he paid tribute to Dr. *Sadler*'s work in many different fields of polymer science and biophysics.

Subsequently theoretical aspects of polymer crystallization were presented. These indicated the diversity of models still under discussion, ranging from tight folding (*J. D. Hoffman*, Midland, USA) via bundles (*G. Allegra*, Milan, Italy) to rough surface growth (*J. Point*, Mons, Belgium). The question of sharp folding and adjacent re-entry was also discussed, both theoretically (*E. Passaglia*, Gaithersburg, USA) and experimentally (*G. Wegner*, Mainz, FRG; *G. Ungar*, Zagreb, Yugoslavia) for *n*-alkanes. Although similar experimental techniques were used, the interpretations differed, suggesting regular fold surfaces and integer long spacings (*G. Ungar*) or, alternatively, a lack of sharp folds (*G. Wegner*).

Diversity was again demonstrated on the second day of the conference regarding the multitude of morphologies observed in polymers. A critical examination of the variety of growth habits exhibited by polymer crystals grown from dilute solution (*F. Khoury*, Gaithersburg, USA) and their crystal surface structure (*B. Lotz*, Strasbourg, France), as well as by those grown from the melt (*D. C. Bassett*, Reading, UK), provided a basis which should allow an evaluation of the different models proposed for crystal growth, as well as helping to correlate polymer morphology with mechanical properties. In this connection, two lectures presented evidence for the existence of a transition region between the crystalline and amorphous regions, both theoretically and on the basis of dielectric relaxation measurements (*D. Yoon*, San Jose, USA), as well as by thermal analysis (*B. Wunderlich*, Troy, USA).

In view of the complex morphologies observed in homopolymers, it was not surprising to find a large variety of differing observations for polymer blends in which at least one component is a crystallizable polymer. Depending on the compatibility of the components, the non-crystallizable component is generally rejected into the interlamellar regions, forming a homogeneous solution with that part of the crystallizable component which is not incorporated into the lamellae (*E. Martuscelli*, Naples, Italy), and thus strongly influencing the tensile and impact properties of the blend. Small angle X-ray and neutron scattering experiments indicated that there is a third phase near the crystal surface where crystalline order is dissipated (transition region), and from which the non-crystallizable component is excluded (*T. Russel*, San Jose, USA).

In the section on advances in experimental techniques, progress was reported particularly in vibrational spectroscopy, synchrotron radiation and high resolution electron microscopy. Synchrotron scattering was used as a technique for studying the early stages of crystallization (*A. Keller*) and crystallization kinetics (*H. Zachmann*, Hamburg, FRG). In contrast to the later stages in crystallization, where the crystal thickness is known to increase logarithmically with time, the initial process was shown to involve thickening in discrete steps (*A. Keller*). Direct imaging using high resolution electron microscopy was demonstrated to be a highly powerful technique for providing information at the molecular level in single crystals of poly(*p*-xylylene) (*E. Thomas*, Amherst, USA), in polymeric liquid crystals (*I. G. Voigt-Martin*, Mainz, FRG) and in polymeric whiskers (*H. Chanzy*, Saint Martin d'Heres, France). In all these cases a comparable stage of sophistication had been achieved with regard to information acquisition as well as image analysis. Various techniques were discussed for correctly taking account of the phases and amplitudes, thus avoiding misinterpretation of defect structures.

The final day of the conference was reserved for advances in processing and properties. This involved morphological engineering, particularly the creation of highly oriented, high modulus fibres (*A. Keller*), and processing techniques which have been developed to improve polymer properties (*J. M. Magill*, Pittsburg, USA).

From the lectures, as well as from the 42 posters that were also presented, it became clear that our understanding of polymer crystals has grown enormously in recent years.

Research News

NMR Imaging of Materials

In the past ten years NMR imaging has developed into a valuable diagnostic tool for clinical applications, because images of arbitrary cross-sections of living objects are obtained in a non-invasive fashion free of radiation hazards.[1] During the same period various efforts have been undertaken to apply NMR imaging to materials. However, for two reasons the results turned out to be of limited significance for practical applications: 1) The NMR signals of nuclei in solids are several orders of magnitude broader than those in liquids, which limits the achievable spatial resolution. Instead of a few Hertz linewidth encountered in medical applications, the resonances of solid materials are several Kilohertz wide. Because of the slow molecular mobility in solids, the anisotropy of the chemical shift and the dipole-dipole interactions of the nuclear spins are not averaged to their isotropic values as in liquids. 2) There seem to be few arguments against dissecting a dead object for analysis.

To circumvent the linewidth restriction, much attention focussed on the imaging of highly mobile species in solids, such as liquids diffused into solids, or on narrow solid-state resonances. Some representative applications are investigations of the pore size and binder distribution in green-state ceramics,[2] the distribution of liquids in polymers,[3] the oil and water contents of sand and rock,[4] and stress induced crystallization of polyisoprene rubber.[5]

To answer these questions, non-invasiveness is not a prerequisite, but for the investigation of properties dependent on the shape or function of the sample it is. Such properties are for instance nonequilibrium distributions of heat or strain, transport phenomena, and the progress and extent of chemical reactions. A few such questions have been addressed employing basically liquid state imaging techniques, for example the temperature distribution in a KBr sample,[6] the cross-linking of polyesters as a function of the flow rate of the resin, changes in viscosity, differential cross-linking before gelation, and catalyst concentration,[7] and the growth and mineralization of bones.[8]

In materials science, however, liquid-state NMR techniques are inadequate for handling the large linewidths, and special solid-state imaging techniques need to be developed. Recently two new significant approaches to solid-state imaging have been demonstrated, which rely upon line-narrowing techniques known in high resolution solid-state NMR spectroscopy.[9] 1) By homonuclear multi-pulse decoupling dipolar broadened lines can be narrowed up to a factor of 400.[10] An application of the technique is shown in Figure 1, which displays the images of a neoprene rubber annulus around a cylindrical tube of adamantane.[11] In Figure a) both, cylinder and annulus are seen. By exploiting differences of relaxation times of these two materials in the rotating frame, the rubber (b) and the adamantane (c) signals can be discriminated. The spatial resolution is about 0.25 mm. 2) Higher resolution, even in truly rigid samples, can be achieved by spinning the sample at the magic angle of 54.7° relative to the magnetic field with speeds of 3 kHz and more. If the magnetic field gradients needed for spatial resolution are rotated with the sample, basically all known imaging methods can be adapted.[12] The sample size, however, is restricted to cylinders smaller than about 12 mm in length and 6 mm in diameter. With such methods, the ultimate spatial resolution in solids is not so much restricted by the linewidth anymore, but rather by the number of nuclei producing the

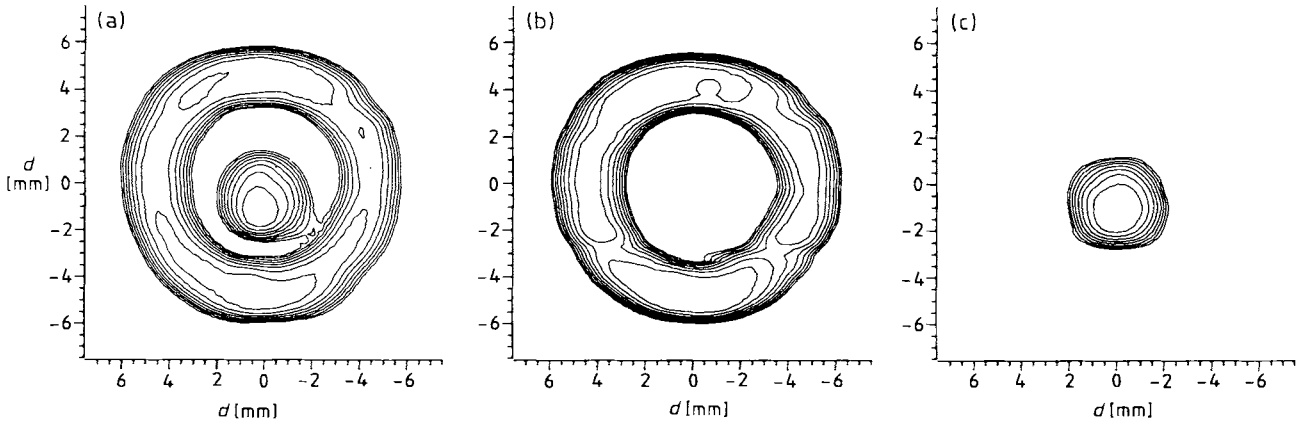

Fig. 1. Solid-state ^1H NMR image of an adamantane cylinder in a neoprene rubber annulus (a). The different molecular mobility in the two materials is exploited via the relaxation time in the rotating frame to discriminate the rubber signal (b) from the adamantane signal (c). (Adapted from ref. 11.)

signal. A practicable value is 100 μm. Thus microscopic resolution is not achievable, but other properties of solid materials varying on a macroscopic scale now seem to become amenable to investigation. Examples are the material's response to nonlinear mechanical wear, crazing, locally controlled polymerization, crystallization, and self-organization of molecular segments as well as strain, heat conductivity, convection and diffusion in composite materials.

Book Reviews

Corrosion of Materials

DECHEMA Corrosion Handbook: Corrosive Agents and their Interaction with Materials, Volume 1. Edited by *D. Behrens*. VCH, Weinheim 1987, 333 pp., bound, DM 775.00.—ISBN 3-527-26652-6

Materials scientists have developed a huge number of technically important materials based on metals, inorganic and organic compounds and composites, suitable for applications which are sometimes very specific. One criterium for choosing a material for a given technical use is its corrosion behavior. However, the prediction of corrosion properties is a rather difficult task due to the complex nature of corrosion processes, involving in a typical case a metallic substrate, a corrosive medium, the hydrodynamic properties of the medium, and the geometric properties of the construction itself. Therefore, a *Corrosion Handbook* collecting together the vast literature and knowledge in this area is highly welcome.

The DECHEMA Corrosion Handbook—a series of at least twelve volumes is planned—is a completely new English edition of the DECHEMA-Werkstoff-Tabelle. The chapters are arranged according to the aggressive media, but instead of being arranged alphabetically these are treated in an apparently random order. Each chapter, which reviews the data concerning one medium, is divided into metallic materials, non-metallic inorganic materials, organic materials and materials with special properties. In this first volume metallic materials predominate. At the beginning of each chapter all materials are classified in a table according to their corrosion properties in the given medium; following this table a detailed description of their corrosion behavior is given. Owing to the very different technical applications for the different materials in the given medium, the ratings in the table may be misleading, if the detailed description is not taken into account. For example, in the chapter "Chlorine" the material gold is classified from resistant to unsuitable due to the fact that on the one hand the contact resistance of Au contacts is high in chlorine atmospheres, whereas on the other hand Au has only limited resistance to high temperature corrosion. In the same table high alloy cast iron is classified as fairly resistant, yet in the detailed description it is stated that not much literature is available about the corrosion of this material in chlorine atmospheres, and therefore the rating is based only on very specific applications.

It is therefore essential for the user of this handbook to read and understand the detailed description and not to rely on the ratings in the well presented tables by themselves. In order to understand the data presented in the different chapters, the reader needs to have a sound background in corrosion science, as the handbook offers only very limited background information concerning the basic mechanisms of corrosion processes. As some interested users might not have this background in electrochemistry or physical chemistry of solids, the reviewer would have liked the first chapter "General remarks and instructions for use" to contain much more information than the one page can offer to the reader. In this chapter only corrosion rates are classified, by which the different materials are evaluated. There is a lengthy explanation of how to convert

rates given in g/m^2d into mm/y (with some mistakes: the symbols < and > are mixed up, the comparison of light and heavy metals is wrong), yet no information is provided concerning the different types of corrosion (general corrosion, and localized corrosion such as pitting corrosion, grain-boundary attack, crevice corrosion etc.), nor on standards used in corrosion (ASTM, DIN), typical corrosion tests, etc. Nothing is said in this chapter concerning the basic mechanisms of corrosion, e.g. the extent to which metallic corrosion is governed by anodic and cathodic reactions and the resulting electrode potentials, how the corrosion rate is calculated using polarization curves, and how corrosion can be accelerated or retarded by an external polarization or by galvanic elements (see e.g. cathodic protection potential). This is important, since in later chapters numerous electrochemical data are presented and—to give only one example—many different reference systems are used for the potential scale (potentials quoted without any reference!, potentials vs. NHE, vs. SHE, vs. H, vs. SCE etc.), which might be quite confusing for some readers. In order to avoid dangerous mistakes, it would be very helpful if this handbook had contained a chapter in which the user could find this basic information which is necessary to understand the different figures and tables. At least some textbooks or standards on corrosion should be cited, so as to provide the missing background. The same comment applies to high temperature corrosion. In later chapters different time laws are mentioned (e.g. the parabolic law), which are sometimes explained and sometimes not, and again this will provide information only to those readers who have a thorough knowledge of the corrosion field.

The next two short chapters are concerned with acetates and aluminum chloride as corrosive media. The introduction to the chapter dealing with acetates is rather long, and contains information concerning the chemistry and preparation of acetates which belongs more appropriately to a chemistry textbook. The rest of both chapters is clearly written and easy to understand, but does not contain as many diagrams as the longer chapters which follow.

The fourth chapter discusses the corrosion behavior of different materials in contact with chlorine and chlorinated water. In general, this chapter is a well written and adequately illustrated summary, including both the wet corrosion of materials in chlorine-containing electrolytes and in chlorine atmospheres, and high temperature corrosion in different chlorine-containing gases. The information is illustrated by numerous figures and tables. Considering the very different corrosion conditions (wet corrosion, atmospheric corrosion, high temperature corrosion), the distinction between these conditions could be more clear. Again, this chapter is presumably addressed to corrosion scientists with a sound background of knowledge in the field; other readers will find that the diagrams and tables are not easy to understand. Some topics in this chapter are discussed in detail (e.g. the high temperature corrosion of Ni), but there are some mistakes and ambiguous diagrams. Some examples: in Table 1 rate constants are given in cm^2/h (?); Figure 4 shows rate constants for the chlorination of Ag in mol/cm s; page 40 cites 50 K instead of 50 bar; in Table 11 the duration of the experiment is given without any unit (s?, h?) and a "theoretical rate" is mentioned, which seems to be an experimental one; in Table 21 the activity of O_2 is given in the wrong order, and Figure 52 shows a potential axis in V without mentioning any reference electrode. In the part of this chapter devoted to Ti the importance of the passivity of Ti to its corrosion resistance in Cl_2-containing media is emphasized, but the electrochemical basis of the effect of alloying Pd to Ti (acceleration of the cathodic reaction and therefore passivation) is not very clearly explained. This is one example, representative of many other instances in this handbook, of a situation where a large number of empirical facts regarding the corrosion of materials would be made much easier to understand if they were also discussed from a fundamental standpoint.

Whereas the chapter "Chlorine" is mainly concerned with high temperature and atmospheric corrosion, the fifth chapter "Fluorides" deals predominantly with the corrosion behavior in wet media and melts. The introduction is well written, short and precise. In general the same is true for the rest of this chapter, the text again being illustrated by a number of diagrams. Two reservations should be mentioned: the reference electrode for the potentials which are quoted is indicated by three different subscripts: V_H, V_{SHE}, and V_{NHE} (all three meaning the same), whereas V_{SCE} refers to a different standard. A number of the figures (e.g. 12, 20, 28) show a potential axis in "Volt" without mentioning any reference. Since there is no uniform reference system in this first volume of the Corrosion Handbook, these figures are useless, as the reader does not know to which reference the potentials refer. The second reservation refers to some statements such as "the corrosion of steel is reduced by the exclusion of oxygen" (page 114), or "the corrosion is promoted by oxygen" (page 124), which are trivial if one considers the O_2-reduction as the cathodic part of the corrosion process.

The sixth chapter deals with the corrosion properties of materials in KOH. Like the others, this chapter contains much valuable information with many illustrations. The reservations are the same as the ones mentioned above: potentials are frequently given without any reference (Figs. 1, 2, 4, 13, 22, 26, 38), and some electrochemical information is not very precise (distinction between increasing voltage and increasing anodic polarization?, page 165; negative protection potential $= -1$ V vs. which reference?, page 168). The part dealing with iron contains only a little information about the stress corrosion cracking of this material in KOH electrolytes and on the range of potentials in which the material is susceptible to this localized attack.

The last two chapters deal with steam and sulfonic acid as aggressive media. In general, both chapters are well written. The chapter "Steam" in particular contains a good introduction, and the detailed description of the corrosion behavior of the different materials is clearly arranged. The part dealing with iron discusses high temperature oxidation in depth, and contains a description of the parabolic rate law, which is missing from the chapter "Chlorine", where also parabolic rate constants are discussed. It would be much better to summarize this fundamental theory in an introductory chapter than to distribute the information over the different chapters of the handbook.

Altogether the DECHEMA Corrosion Handbook is a very valuable reference book for all engineers working in the area of corrosion, provided that the reader has a thorough knowledge of this area and is thus able to critically evaluate the information in the figures, tables and text of individual chapters. The organization of the Handbook is clear, and it is rather easy for the user to find the desired information. In addition to this, the large number of literature references cited in the Handbook (about 400 for most chapters, citations up to 1980) offers even more information to users who have to solve special corrosion problems.

Miscellanea

Photophysics of Polymers. Edited by *Charles E. Hoyle* and *John M. Torkelson*. American Chemical Society, Washington, D.C., USA 1987. 531 pp., $ 119.95.—ISBN 0-8412-1439-5

This clearly structured and nicely presented book stems from a symposium of the Division of Polymer Chemistry of the American Chemical Society which took place in Anaheim, CA, in September 1986. The book is designed to provide scientists engaged in basic and applied polymer research with a comprehensible text on polymer photophysics. The philosophy of the book is that photophysical phenomena allow one to gain an accurate picture of the properties of polymers, both in solution and in solid phases. Based on the historical development as well as on current practice, the book is divided into six main sections: 1) Overviews, 2) Polymer Dynamics and Complexation, 3) Excimer Photophysics, 4) Energy Migration, 5) Luminescent Polymerization Probes, 6) Photophysics of Silicon-Based Polymers.

On the whole, the book is a timely and most welcome addition to the literature in a field which has recently seen a strong increase of interest. In fact several works on related subjects have been published over the last few years: the monographs by *J. Guillet:* "Polymer Photophysics and Photochemistry; an Introduction to the Study of Photoprocesses in Macromolecules" (Cambridge Univ. Press, 1985) and *J. F. Rabek:* "Mechanisms of Photophysical Processes and Photochemical Reactions in Polymers; Theory and Applications" (Wiley, New York 1987) as well as the multi-author volumes: "Polymer Photophysics, Luminescence, Energy Migration and Molecular Motion in Synthetic Polymers" (edited by *D. Phillips*, Chapman and Hall, London 1985), "Photophysical and Photochemical Tools in Polymer Science: Conformation, Dynamics, Morphology" (edited by *M. A. Winnik*, NATO ASI-Series C, Vol. 182, D. Reidel, Dordrecht, Netherlands 1986) and "New Trends in the Photochemistry of Polymers" (edited by *N. S. Allen* and *J. F. Rabek*, Elsevier, London 1986). In my opinion the new book edited by *Hoyle* and *Torkelson* is extremely valuable, since it stands at the forefront of this dynamic field which offers many possibilities for future developments. The presentation is—unusually for a multi-author book!—balanced; most of the active research groups in the field are well represented. Of course, one cannot expect a book with some eighty contributors to present a unified viewpoint; however, one gets a good snapshot of the situation. Furthermore, even the camera-ready printing does not impair the presentation too much.

The individual contributions stress the application of photophysical methods to polymers, and it is indeed gratifying for a physicist to see such devoted use of physical methods in chemistry research. While most groups have realized the importance of time-resolved measurements (the contributions by the groups of *M. D. Fayer, H. F. Kauffmann* and *S. E. Webber* highlight this trend), an intimate connection between theory and experiment is—in general—still lacking. Several contributors have, in my opinion, not always been cautious in interpreting their data, and one sometimes gets the feeling that the method is over emphasized; in many cases I would welcome a comparison of photophysical results with data obtained by other physicochemical methods.

In summary, the editors have achieved their goal of providing a picture of the state-of-the-art situation in the photophysics of polymers. I view the book as a valuable addition to the library of scientists actively involved in polymer research.

Physics at Surfaces. By *A. Zangwill.* Cambridge University Press, Cambridge 1988. xiii, 454 pp., hardcover £ 40.00.—ISBN 0-521-32147-6

Physics at Surfaces is an excellent introductory book for students or other researchers interested in surface processes. It is certainly the best source of general information about the concepts and techniques of surface physics/chemistry, painting a broad-brush picture of the current state of the field and covering a broad range of topics. Characteristics of both metal and semiconductor surfaces, clean and adsorbate-covered are described. Topics such as the thermodynamics and electronic structure of surfaces, and adsorption/desorption phenomena are discussed. Several emerging, albeit not understood areas, such as metal organic chemical vapor deposition (MOCVD) and energy transfer at or near surfaces are also introduced.

There is rather comprehensive coverage of the myriad of techniques used in surface science so that the reader is exposed to the spectroscopic methods currently available and their typical applications. Necessarily, the discussion of the large number of topics is somewhat superficial. A student who would actually use one or more methods would most certainly need to read more broadly. While the bibliography serves as a good starting point for more in-depth reading, it is not comprehensive because of the large number of topics discussed in the book. Only selected examples are referenced on a given topic, e.g. the study of activated adsorption using molecular beam techniques. Therefore, if the reader or instructor of a course wishes to go beyond the text, an independent review of the literature will be necessary in many cases.

The text is also a useful overview of the developments in the field of surface chemistry for experienced researchers in surface physics and related fields. Results of experiments performed over the past two decades are synthesized into a general framework. The overview serves as a conceptual basis for the vast research encompassed in the area of surface physics and induces one to cast current work within this framework.

Overall, *Physics at Surfaces* is an excellent introduction to the emerging and developing field of surface science from which both students and experienced researchers will benefit.

Metallic Superlattices—Artificially Structured Materials. Edited by *T. Shinjo* and *T. Takada*. Elsevier, Amsterdam 1987. xii, 271 pp., bound, DFl 240.00.—ISBN 0-444-42863-1

Advances in ultrahigh-vacuum deposition techniques have made possible the sequential monolayer-by-monolayer deposition of artificially layered materials including semiconductors, metals, etc. This volume 49 of the series "Studies in Physics and Theoretical Chemistry" is a collection of review papers on artificially layered metal structures presented by several principal investigators. The majority of the authors (five out of eight) are university professors in Japan, so that the book has a somewhat eastern asian flavor, although the research activities in this field are equally spread all over the industrialized world. However, with the recent rapid growth of activity on artificially layered materials and the concomitant dramatic increase in the number of published papers, finding a book that can serve as a comprehensible text for an introductory course is particularly important. This book addresses that purpose very well, and it is to be highly recommended for that use, as well as to the individual reader seeking an introduction to one of the special topics discussed in five of the chapters.

The book consists of seven chapters: 1. Overview of metallic superlattices (*T. Shinjo*), 2. X-ray diffraction studies on metallic superlattices (*Y. Fujii*), 3. Neutron diffraction studies on metallic superlattices (*Y. Endoh, C. F. Majkrzak*), 4. Mössbauer spectroscopic studies on superlattices (*T. Shinjo*), 5. NMR studies on superlattices (*H. Yasuoka*), 6. Superconductivity in superlattices (*V. Matijasevic, M. R. Beasley*), 7. Theories on metallic superlattices (*K. Terakura*). Much credit must be given to the editors for providing an extensive list of element combinations used in layered metallic structures and a comprehensive bibliography in the appendix.

In the areas covered this fine book is close to being a state-of-the art summary of current research.

High-Resolution Solid-State NMR of Silicates and Zeolites. By *G. Engelhardt* and *D. Michel*. John Wiley & Sons, Chichester 1987. xiv, 485 pp., hardcover £ 55.00.—ISBN 0-471-91597-1

For many years solid-state NMR spectroscopy was regarded merely as a tool for specialists in the shadow of the more important magnetic resonance applications to the liquid state. This changed after novel sophisticated high-resolution techniques such as magic angle spinning (MAS) and multi-pulse experiments were developed for solid materials. Nowadays multinuclear high-resolution solid-state NMR spectroscopy is attracting increasing interest in chemistry, materials science and many other domains. The new book by *G. Engelhardt* and *D. Michel* gives a survey of one of the most important applications, i.e. that to silicates, aluminosilicates, zeolites and silicate sorbents. It is an excellent introduction to high-resolution solid-state NMR spectroscopy in general, and gives an overview of current research activities in silicate and zeolite science in particular.

The text is organized in seven chapters beginning with a short introduction to the historical background. Chapter 2 treats the basic principles of high-resolution NMR of solids. The nuclear spin interactions affecting the spectral features are described in the irreducible tensor notation, and the most important experimental techniques (MAS, cross-polarization, dipolar decoupling, multi-pulse methods) are briefly discussed. The peculiarity of adsorbed molecules is emphasized. Since detailed information about the structure of species containing silicon has been obtained from studies of the liquid state, the third chapter of the book is completely devoted to ^{29}Si NMR of silicate solutions.

The next two chapters deal with general aspects and applications of ^{29}Si and ^{27}Al NMR studies of silicates, aluminosilicates and zeolites. Experimental methods, general features of the spectra, spectral parameters and correlations with structure are discussed in Chapter 4, whereas Chapter 5 summarizes the large amount of data that have already been accumulated from studies on natural and synthetic silicate and aluminosilicate materials and zeolites. In addition to crystalline materials and especially zeolites, other materials included are glasses, layer silicates, silica polymorphs and tectoaluminosilicates.

Chapter 6 focusses on NMR studies of nuclei other than ^{29}Si and ^{27}Al in zeolites and non-zeolitic silicates. The topics covered are ^{11}B NMR studies of borosilicates and borozeolites, ^{17}O resonances of framework oxygen, NMR of charge-compensating cations, and ^{13}C and ^{1}H studies of zeolites. The final chapter is devoted to high-resolution NMR of adsorbed molecules. Adsorption on zeolites, silica surfaces, silicates and aluminosilicates, and diamagnetic and paramagnetic adsorption sites are considered. Most work discussed in this chapter deals with ^{1}H, ^{13}C, ^{15}N, and ^{129}Xe resonances.

The book as a whole is well organized and gives useful information for anyone who is interested in the wide range of applications to silicates, zeolites, and all kinds of adsorbed systems. But it is equally important for NMR spectroscopists who are already engaged in studying crystals and glasses and plan to extend their activity to new techniques and materials. Particular emphasis is given to all types of chemical information obtainable from the spectra, but the treatment is by no means confined to a purely descriptive presentation. A real advantage of this monograph is that it is readily comprehensible to chemists, while at the same time including the necessary physical background. Zeolite and silicate scientists will appreciate the wealth of literature references given in connection with the various NMR applications. Without hesitation this book may be recommended as an excellent approach to high-resolution solid-state NMR spectroscopy. It should not be considered as an alternative to *Colin Fyfe*'s "Solid-State NMR for Chemists", but as a useful supplement with emphasis on inorganic silicates and a more physico-chemical style of description.

Inorganic Thermochromism. By *K. Sone* and *Y. Fukuda*. Springer, Berlin 1987. xi, 134 pp., bound, DM 168.00.—ISBN 3-540-17662-4

The color change of chemical species with temperature is a widespread phenomenon and can be traced back to a variety of causes. The book of *Sone* and *Fukuda* concentrates mainly on the thermochromism of transition metal complexes in solution which results from changes in the crystal field. The introductory chapter defines the subject and gives some instructive examples, including the red to violet to green color change of Cr^{3+} doped α-Al_2O_3 with increasing temperature. Chapter B considers chromotropic phenomena, mainly of cobalt(II)chloro complexes, which result from the tetrahedral–octahedral interconversion and from ligand exchange reactions in various protic and aprotic solvents (including an analysis of inert salt effects). The color shift from the blue tetrahedral $CoCl_4^{2-}$ to the pink octahedral $Co(OH_2)_6^{2+}$ complex is a well known example of this category.

Chapter C concentrates on nickel(II) chelates in solution. An analysis of the spectral changes which accompany the conversion of paramagnetic octahedral, square pyramidal and tetrahedral to diamagnetic square-planar complexes is given. Interconversions of this type which depend on the donor properties of the solvent are extensively discussed. Geometrical changes of this kind may also occur within monomer-polymer equilibria. Finally isomerization reactions (nitro–nitrito) are mentioned. The next chapter is devoted to the thermochromism of copper(II) complexes. They are geometrically extremely variable as a consequence of the Jahn-Teller effect of the d^9 configurated central ion, and change their coordination sphere rather continuously from elongated octahedral or square pyramidal to square-planar—in line with corresponding color shifts.

Chapter E comprises miscellaneous chromotropic phenomena of other transition metal complexes in solution. Thermochromism may be observed, for example, in octahedral Fe^{II} or Fe^{III} complexes if the ligand strength is very near to the critical value of the ligand field parameter, which determines the transition from the high-spin to the low-spin configuration. Equally interesting is the color change which accompanies the addition of a second axial ligand to square-pyramidal $[O{V^{IV}}(acac)_2]$ complexes. The last chapter outlines the thermochromism of transition metal complexes in the solid state. After considering irreversible reactions caused by thermal dehydration, desammination and isomerization, a few examples of reversible thermochromism are presented. In particular, the compressed tetrahedral–square-planar interconversion of $Cu^{II}L_4$ complexes, which often occurs continuously with temperature, is discussed and compared with the discontinuous (but also reversible) change from a tetrahedral to an octahedral coordination in the case of Ni^{II} complexes. Finally, the fluorescence thermochromism of certain copper^{I} complexes is mentioned, and a short section describes the application of thermochromic compounds as color indicators for temperature changes.

The book under review is the first attempt to give a rather thorough description of the exciting world of thermochromism and related chromotropic phenomena in inorganic chemistry. It is easy and enjoyable to read, and will certainly be extremely informative for scientists and graduate students who are involved in the spectroscopy of transition metal complexes and compounds in solution or in the solid state. Because the authors have themselves been engated for many years in the solution chemistry of transition metal complexes, the main emphasis is laid upon this subject; the equally fascinating thermochromism of solid compounds is unfortunately not very extensively treated. Although the authors state in the preface that this was not their intention, the book would have fulfilled its purpose even more effectively if there had been a higher degree of sophistication in the discussion of the physical basis of the thermochromic properties, and an even stronger emphasis on the correlation of these properties with the electronic structures of the transition metal ions involved. However, this is a book with many merits, which can be warmly recommended to all chemists who are interested in and fascinated by color phenomena in inorganic chemistry.

ADVANCED MATERIALS

is a successful new special section of ANGEWANDTE CHEMIE. In order to strengthen it further, we offer the position of an

Associate Editor

You have an advanced degree in materials science, chemistry or physics and, perhaps, some editing experience; English is your mother tongue. You feel challenged by using the full range of your knowledge for aquiring articles, writing short news items and carefully editing texts on the varied aspects of materials research and engineering. You like to talk to scientists and you are comfortable working with tight schedules.

VCH is a major international scientific publisher with subsidiaries in Basel (Switzerland), Cambridge (United Kingdom), and New York (USA). The editorial office of ADVANCED MATERIALS/ANGEWANDTE CHEMIE is in Weinheim, a pleasant small town near Heidelberg in the southwest of Germany. A competitive salary and excellent benefits are guaranteed.

Please apply in writing and send full career details to:

VCH Verlagsgesellschaft, Personalabteilung, Postfach 101161, D-6940 Weinheim (West Germany)

Pages 1417–1592

Synthesis of the Heaviest Chemical Elements—Results and Perspectives**

By Günter Herrmann*

Dedicated to Professor Christoph Schmelzer on the occasion of his 80th birthday

All 17 artificially produced elements heavier than uranium were discovered by nuclear-chemical synthesis. The three heaviest ones—elements 107, 108 and 109—were synthesized at the heavy-ion accelerator UNILAC in Darmstadt by nuclear fusion from the heaviest stable nuclei, lead-208 and bismuth-209, and the most neutron-rich stable isotopes of chromium and iron: element 107 from bismuth-209 (atomic number $Z=83$) and chromium-54 ($Z=24$), element 108 from lead-208 ($Z=82$) and iron-58 ($Z=26$), and element 109 from bismuth-209 and iron-58. The first isotopes detected were those with mass numbers 262 ($Z=107$), 265 ($Z=108$) and 266 ($Z=109$); these nuclei are short-lived α-emitters with half-lives of 8.2 ms, 1.8 ms and 3.4 ms, respectively. The yields of these reactions are extremely small; only three atoms of element 109 have ever been observed. Experiments to synthesize element 110 have given ambiguous results. All attempts to detect the "superheavy" elements with proton numbers near $Z=114$ and neutron numbers near $N=184$ have thus far failed. These elements have been predicted theoretically, and many attempts to synthesize them have been made, e.g. at UNILAC by fusion of calcium-48 ($Z=20$) with curium-248 ($Z=96$), or by transference of protons in the collision of two very heavy nuclei such as uranium-238 ($Z=92$). Surprisingly, the heaviest known nuclei are far more stable toward spontaneous fission into two fragments than was expected, but their synthesis is strongly hindered—much more than was initially anticipated. It is this hindrance rather than the decreasing nuclear stability which seems to presently limit the extent of the periodic table: even heavier elements should be able to exist, but no way has yet been found to produce them.

1. Some Historical Remarks

Some fifty years ago the newly introduced methods of nuclear chemical-element synthesis opened up, for the first time, a way to produce new elements beyond the heaviest then known, uranium (atomic number $Z=92$). *Fermi* and his co-workers transformed numerous elements into radioactive isotopes by adding a neutron. Via subsequent β-decay—emission of an electron from the nucleus—these isotopes transform into elements with the next higher atomic number. In the case of uranium, for example, one expected the formation of element 93, i.e. capture of a neutron by uranium-238, and β-decay of the newly formed uranium-239, as follows:

$$^{238}_{92}U + {}^{1}_{0}n \longrightarrow {}^{239}_{92}U \xrightarrow{\beta^-} {}^{239}93$$

Fritz-Strassmann-Weg 2, D-6500 Mainz, and
Gesellschaft für Schwerionenforschung,
Planckstr. 1, D-6100 Darmstadt (FRG)

[**] After a paper presented at the 20th Biannual GdCh Meeting in Heidelberg on September 17, 1985.

According to the periodic table as it was understood at that time (see Fig. 1), element 93 was said to correspond to eka-rhenium in the 7th group of transition elements. And indeed, after irradiating uranium with neutrons several β-emitters were found. The difficult radiochemical analysis of this mixture, performed by *Hahn, Meitner* and *Strassmann,*[1] indicated that three chains of transuranic elements had been produced. One of them even reached as far as eka-platinum ($Z=96$). However, not all of the new β^--emitters fitted into this scheme. In 1938, during a rigorous examination of such discrepancies, *Hahn* and *Strassmann*[2] arrived at a completely unexpected conclusion, which is commemorated this year: after capture of a neutron, uranium fissions into two fragments, and the activities originally ascribed to transuranic elements rather belong to medium-heavy, known elements.[3]

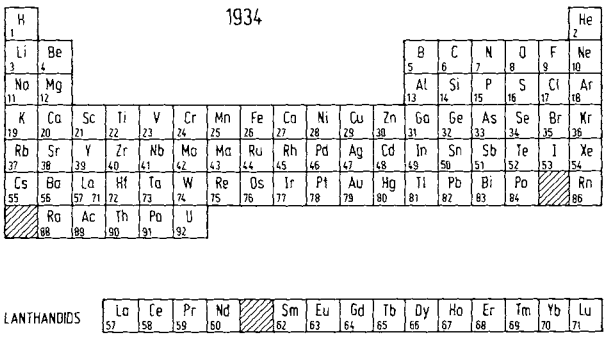

Fig. 1. The periodic table of the elements in 1934. Missing elements at that time are shown as dashed boxes. The present symbols for the elements are used, except for masurium (43).
