Vitamin B_{12}: Experiments Concerning the Origin of Its Molecular Structure**

By Albert Eschenmoser*

Following the chemical synthesis of vitamin B_{12}, a search was begun for a potentially biomimetic "dark" variant of the photochemical A/D-secocorrin → corrin cycloisomerization, the central ring-closure step in one of the two cobyric acid syntheses. Significantly, not just one but a whole family of such variants was discovered. According to what is currently known, one of these variants can indeed be regarded as a chemical model for the reaction path followed by Nature in the biosynthetic construction of the corrin ring. These chemical studies of vitamin B_{12} biosynthesis had revealed that the A/D-ring junction, regarded as the main obstacle to a chemical vitamin B_{12} synthesis at the outset, is in fact a structural element that is formed readily and in a variety of ways from structurally appropriate precursors. More recent investigations have shown that the same holds for other specific structural elements of the vitamin B_{12} molecule, including the characteristic arrangement of double bonds in the corrin chromophore, the special dimension of the macrocyclic ring of the corrin ligand, the specific attachment of the nucleotide loop to the propionic acid side chain of ring D, and the characteristic constitutional arrangement of the side chains around the ligand periphery (which vitamin B_{12} shares with all uroporphinoid cofactors). All these outwardly complex structural elements are found to "self-assemble" with surprising ease under structurally appropriate preconditions; the amount of "external instruction" required for their formation turns out to be surprisingly small in view of the complexity and specificity of these structural elements. We view these findings as steps on the way toward a chemical rationalization of the vitamin B_{12} structure. The goal is to arrive experimentally at a perception of the biomolecule's intrinsic potential for structural self-assembly. This potential, together with the specific type of reactivity related to the biological function, is considered to be responsible for the biomolecule having been chosen by natural selection. The chemical rationalization of the structure of biomolecules is an objective of organic natural product chemistry. The field of natural product synthesis provides appropriate conceptual and methodological tools to approach this objective experimentally.

1. Introduction: Concerning the Origin of Cofactors and the Emergence of Biosynthetic Pathways

The (organic) cofactors occupy an exquisite position with respect to structure and function among the low-molecular-weight natural products. Their diverse and sometimes quite unusual structures, often occurring in families, are distinguished by their disposition to special types of reactivity. In partnerships between cofactors and specific proteins these dispositions are expressed and functionally exploited to a high degree of perfection with respect to both efficiency and selectivity. This perfection may seem natural to biologists, but it never ceases to surprise and amaze chemists to whom it represents a source of permanent challenge. Hardly anything reveals the state and limits of our chemical knowledge and skills so clearly as the level of performance of these systems. For a chemist, the functional partnerships between cofactors and proteins represent one of those incredible accomplishments of biomolecular evolution.

[**] The preceding page shows Figure 11 of this article.

The challenge referred to above has many aspects. The focus of current interest has been on molecular structure and dynamics, that is, on the mechanism of functional interaction between substrates, cofactors, and proteins. However, alternative objectives focus on chemical rationales for the cofactors' structures, questions concerning the relationship between structure and function, the chance or necessity of their occurrence, and questions concerning their origin. Such questions are motivated not the least by the extraordinary fact that important cofactors have remained structurally unchanged over the entire course of biological evolution for which evidence is available to us. The cofactor structures appear to represent optimal molecular solutions to specific biological tasks, the "institutionalization" of which apparently occurred at an early evolutionary phase. Can experiments aimed at a deeper understanding of the molecular structure of cofactors tell us something about that early phase of biological evolution?

According to the Darwinian paradigm of molecular evolution,[1-3] the structure of functional biomolecules is the result of a process of *selection* (as opposed to a "Lamarkian" process where instructions from the environment would guide molecular construction). Selection of a particular chemical structure presumes its "*preformation*," either as a product of a biotic process or (in the extreme)

as a product of a prebiotic process. Biotic preformation schemes might include both reactions catalyzed (fortuitously) by enzymes and nonenzymic (endogenous as well as exogenous) reaction sequences. A molecular structure can—irrespective of the preformation route—be regarded as being biologically selected once the enzymic control over its biological function is genetically fixed. Involvement of an enzyme in a biotic preformation sequence implies genetic fixation of at least one step of the biosynthetic pathway. In such a case, enzymic control over the (original) synthesis of the biomolecule can be older than enzymic control over its biological function. In other variants of preformation, particularly the prebiotic ones, the opposite holds: genetic fixation of function precedes the appearance (and thus the genetic fixation) of the biosynthetic pathway.

Such efforts to classify possible ways in which biomolecules might have emerged take for granted a principle of operation of biological systems that—although this is a truism to biologists—must be mentioned here, as it is fundamental to any picture of the emergence of biochemical pathways: the synthesis of protein biocatalysts proceeds exclusively via a coding process. This not only guarantees a faithful *reproduction* of the structure of the protein itself, but also implies a *preregistration* of the protein structure. The constitution of a given protein is registered (and thus potentially fixed genetically) *before* it is formed. If a new protein, arising as the result of a mutation, fortuitously turns out to be a catalyst, lasting genetic fixation of the newly discovered catalyst requires in principle no further instruction but only replication by reproduction. Preregistration is a fundamental aspect in the ability of evolving systems to develop biosyntheses; without it, an emergence of biosynthetic pathways would be inconceivable.

In the functioning of such machinery, it is helpful to differentiate between two types of fortuitous, mutually *independent* steps which determine the route by which a biosynthetic pathway arises: the preformation step and the step at which enzymic control takes over. The latter includes the two mutually dependent processes of mutation and expression and has as a prerequisite the fortuitous catalytic activity of the protein. In the case of enzymically induced preformation, the takeover of enzymic control may coincide with the preformation step. Chemists engaged in natural product synthesis are probably in the best position to grasp the vast number as well as the nature of lucky prerequisites that must be fulfilled for a multistep biosynthesis of a complex natural product to emerge. It seems inescapable to suppose that genetic fixation in the sense of preregistration can be maintained through steps involving nonfunctional (intermediate) products before the fixation becomes final through reproduction feedback after a functional (end) product has been reached. In terms of this model, the classical suggestion of *Horowitz*[4] that biosyntheses emerge "from back to front" represents an extreme case.

If the question is posed as to which factors have determined the molecular structure of a functional biomolecule, the type of answer usually given is: the molecular structure of a biomolecule is the result of biological selection processes directed toward the optimization of the molecule's biological function. Functional optimizations occur via mutation steps and reproduction feedback, the structures of the substrates lying within the boundaries delimited by the preformation steps. Although preformation steps, whether nonenzymic or enzymic, must be determined in part by chance, they are also directed by structural factors intrinsic to the substrate molecules themselves. To this extent, these steps are amenable to chemical rationalization. The structural changes involved occur along reaction channels in what is in principle a predetermined structural "landscape." In addition to a structure-function analysis, the mapping of this landscape is the goal to be aspired to in attempting a chemical rationalization of a biomolecular structure. Chemical synthesis provides an empirical, but suitable, instrument for mapping these landscapes; indeed, we should regard such mapping as one of the objectives of natural product synthesis. In fact, ever since *Stanley Miller*'s classical experiment,[5] the mapping of such structural landscapes of potentially prebiotic organic matter has been one of the goals of prebiotic chemistry.

In principle, the structural landscapes could only be referred to as "predetermined" if we were allowed to ignore the world of catalysts. Catalysts become part of the structural landscapes in the regions of the reaction channels. Our lack of knowledge of the catalysts that may have participated in preformation steps sets stringent limits to a chemical rationalization of biomolecular structures, in addition to the limits already set by the role of chance. However, these very limitations point to an important objective that can and should be studied with the tools of natural product synthesis, namely, the systematic delimitation of the boundary separating the reactivity of biomolecules (or their precursors) from structural changes for which *structured* catalysis is a prerequisite. Such questions become particularly pertinent as one attempts to proceed ever further backward along the axis of biochemical evolution, from the region where enzymic preformation steps (presumably) dominated to the region where these steps become (necessarily) increasingly nonenzymic in nature, until finally one reaches that dark area beyond which the questions posed belong to the realm of prebiotic chemistry. Ultimately, the problems referring to that dark area are equally and primarily related to the phenomenon of catalysis; after all, the major prerequisite for self-reproduction of a (macro)molecular system is its ability to act as a specific catalyst for its own synthesis.

In chemistry and biology today the experimentally[2] and theoretically[3] supported view[1] prevails that the molecular building blocks of proteins and nucleic acids are of prebiotic origin. This view refers to the (simpler) α-amino acids, the nucleic acid bases, and the (simpler) carbohydrates. The question arises[6] whether this should also hold for the molecular structures of cofactors. Should one regard these molecules as biosynthetic "inventions" of organisms that existed early in evolutionary history, or is it more reasonable to consider the basic patterns of their structures as being of prebiotic origin? Did biological systems originally take up these structures from the environment as "vitamins" (in the original sense of the word), use them as catalysts, fix their function genetically, later under selection pressure copy them biosynthetically and, finally,

optimize them structurally? Although it would be better to pose such a question not in general terms but rather for each cofactor individually, much is in favor of the idea that emerging biological systems have been heterotrophic with respect to organic (low-molecular-weight) catalysts. It must be advantageous to a system in its critical stage of development when it can take enzymic control over a catalyst's function without having to cumulate this task with the one of first "discovering" its structure via an enzymic synthesis. Although today cofactors carry out their biological function exclusively in concert with specific proteins, many are known[7] to be catalysts themselves; in the present context, this is a pertinent property. Modern biosynthetic pathways to most cofactors appear hopelessly complex when we look at them in the context of the problem of their origin. Although it may be true that present-day biosynthetic pathways could be quite different from their archaic predecessors, the argument is best illustrated by using adenine as an example. Along with *Miller*'s experiment on the origin of α-amino acids,[5] the perception of the structure of adenine as a pentamer of HCN and the discovery of its direct formation from HCN by *Oró*[8] as well as, subsequently, of its photochemical formation by *Ferris* and *Orgel*[9] represent true milestones of prebiotic chemistry (Fig. 1). The structural self-assembly of the adenine molecule from HCN contrasts starkly with the complex network of enzymic reactions,[10] which Nature was, so to speak, forced to evolve for its biosynthesis. From a chemosynthetic point of view, the structure of adenine is of utmost simplicity whereas it is quite complex from the point of view of its biosynthesis; the structure is "simple" with respect to its derivation from HCN and "complex" with respect to its construction from those precursors that present-day organisms are directed to use in their biosyntheses.

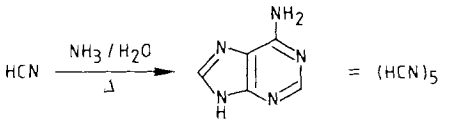

Fig. 1. Adenine, a pentamer of HCN (*J. Oró* (1960) [8]).

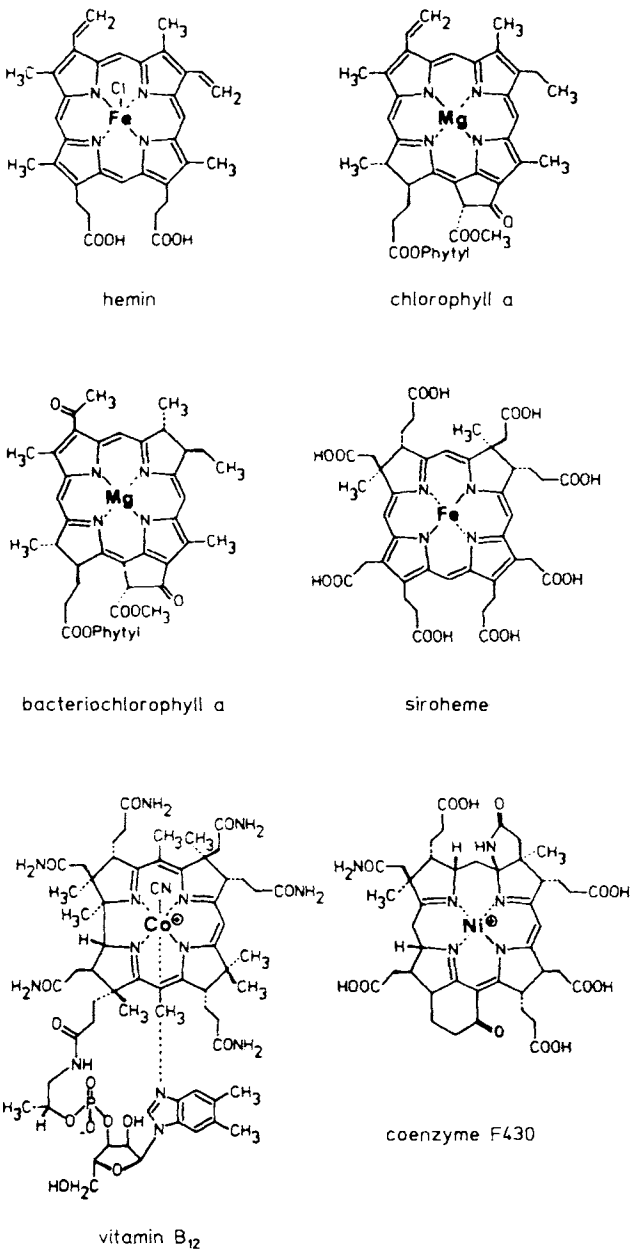

Fig. 2. Family of uroporphinoid cofactors.

The example of adenine refutes the opinion that an inquiry into the origin of cofactor structures is futile since it would be a priori impossible to draw conclusions or to study the problem experimentally. Were cofactors of prebiotic (or of otherwise nonenzymic) origin, then structural complexity of such molecules would be an apparent complexity; straightforward pathways of structural self-assembly of these structures would have to exist, and these pathways would be detectable experimentally.

The possibility that cofactor structures might be of prebiotic origin has been discussed several times in the literature.[2,6,11] In contrast to the extensive prebiotic chemistry of protein and nucleic acid building blocks,[2,11,12] however, only meager experimental results regarding potentially prebiotic routes to cofactors are available.[13]

The uroporphinoid family shown in Figure 2 occupies a special position among cofactors. Varying a single structural theme, that of uroporphyrinogen, Nature has selected a rich variety of magnificent structures which exhibit a diversity of fundamental biological functions in all kinds of organism, from microorganisms and plants to man. The diversity of form and function existing in this family is the result of selection processes for which two dimensions of structural variation were available, the central coordinated metal ion and the ligand sphere. Figure 3 indicates in abstract form the essential features, the central ion and the oxidation state of the ligand system. There is the fully unsaturated (oxidized) chromophore of the protoporphyrin iron complexes, which, in a variety of forms, are in charge of the biochemistry of molecular oxygen. Then there are the chlorin ligands of the chlorophylls, less oxidized than the porphyrins, absorbing at longer wavelength, and containing in their center a "harmless" metal ion, which, however, fulfills the crucial condition of being compatible with the ligand system's photochemistry. Finally, we have the

reduced ligand systems of the corrin of vitamin B_{12} and the (tetrahydro)corphin of coenzyme F430, whose coordination centers, cobalt and nickel, respectively, have been selected by Nature in order to gain access to the unique reactivity potential of organometallic compounds. The latter two cofactors, in particular, appear to represent exceptional examples of Nature's fine-tuning porphinoid ligands to an optimum of a cofactor's biological function; this is achieved by the appropriate choice of the size of the macrocycle, the constitution of the ligand chromophore, and the nature of the chromophore's substituents. Vitamin B_{12} is a particularly suitable target for attempting a chemical rationalization of a biomolecule's structure and for inquiring about its origin. The fact that the compound is the structurally most complex member of the uroporphinoid family should not present an obstacle; quite the opposite is true, the more complex a molecular structure, the greater the wealth of information it can potentially provide.

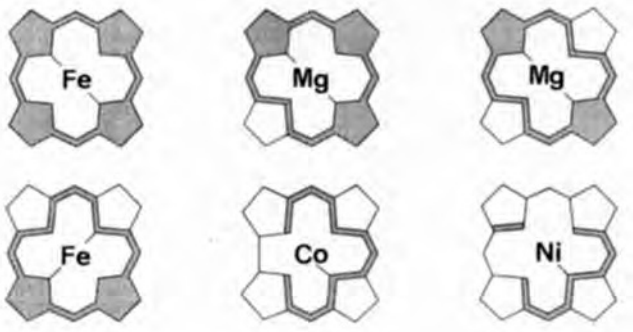

Fig. 3. Structural variability within the family of uroporphinoid cofactors (see text). The chromophore systems are indicated in grey.

The ubiquitous biological roles of uroporphinoids, together with the finding that the key step in their biosynthesis, the tetramerization of the monopyrrolic precursor porphobilinogen to give the macrocyclic uroporphyrinogens, not only occurs enzymically but also takes place under proton catalysis with great ease[14, 15] (see also Section 3.4), have already led earlier authors[16] to raise the question of a prebiotic origin of the uroporphinoid type of structure. Microbiologists[17] have expressed the opinion that corrinoids, which—according to current knowledge—are biosynthesized exclusively by microorganisms, might be functionally older than the porphyrins, since strictly anaerobic bacteria are reported to exist that produce corrinoids but apparently no porphyrins. Furthermore, it has been pointed out[17] that the corrinoid's biological task is exclusively the catalysis of biosynthetic steps, that they are not involved in energy metabolism, as the porphyrins and chlorins are.

In our laboratory, the question as to the origin of the corrin structure emerged as a consequence of our chemical studies on vitamin B_{12} biosynthesis, carried out subsequent to our work on its chemical synthesis. The next section summarizes the stages and developments that these studies have gone through.

2. From the Chemical Synthesis of Vitamin B_{12} to the Question as to the Origin of the Corrin Structure

When we look back from today's perspective at the chemical synthesis of vitamin B_{12}, we are inclined to regard that work as what would now be called "hard chemistry," in the sense that the planning and execution of these syntheses did not take into consideration at all the question as to the natural, structurally appropriate route of formation of the natural product. This means de facto, and probably rightfully so, that these syntheses were not designed in a biomimetic fashion, but this is not what is actually meant. What is meant is the more basic question concerning the structurally intrinsic reaction channels that are ultimately responsible for the very existence of a given type of natural product structure, and which often deter-

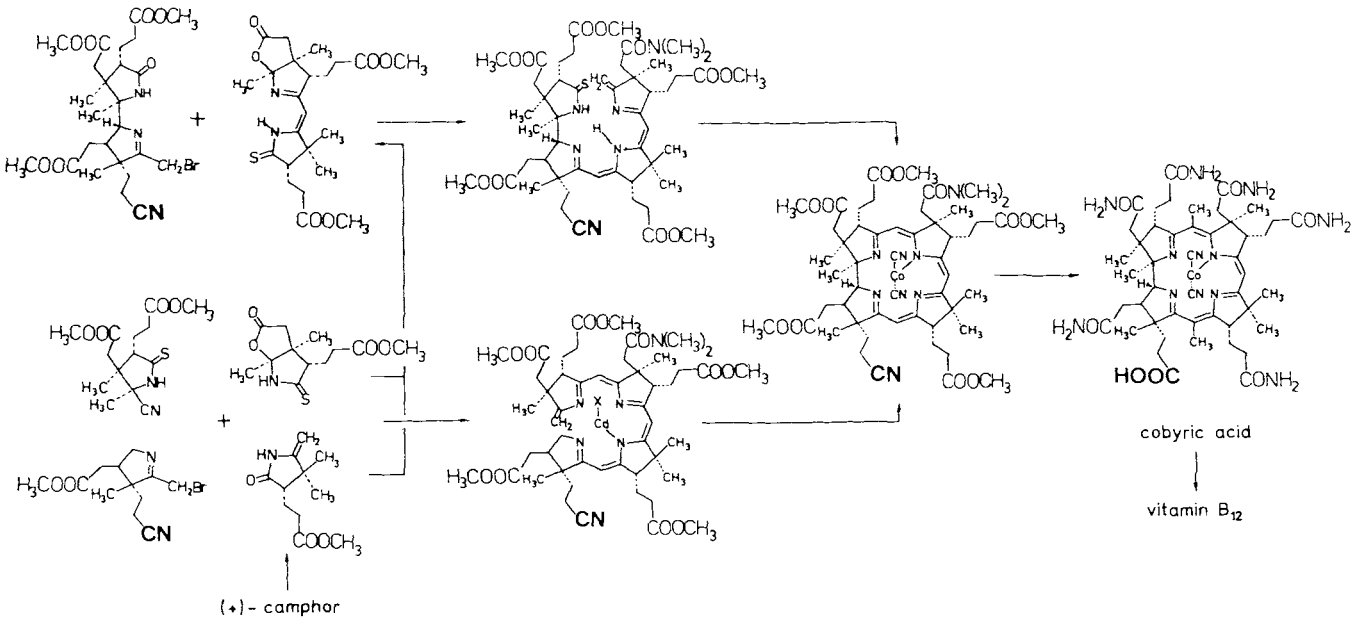

Fig. 4. Overview of the two variants for the synthesis of cobyric acid [18, 19].

mine its biosynthetic pathway (but not always, as demonstrated by the example of adenine). Nonetheless, the work on vitamin B_{12} provides an example of how research on the synthesis of a natural product, carried out originally from a chemically "hard" point of view, can lead in unexpected ways to the very questions with which this article is concerned.

The two syntheses of cobyric acid that have so far been realized are delineated schematically in Figure 4.[18,19] At the time when the Harvard group pursued the original strategy of solving the A/D-ring junction problem at the beginning of the synthesis, the Woodward–Hoffmann rules were discovered.[20] Out of the new perspective of these rules emerged at ETH the concept of a photochemical variant of the cobyric acid synthesis, the key step of which is the photoinduced ring closure of an A/D-secocorrinoid cadmium complex. The direct coupling of rings A and D was thereby accomplished in one step with high diastereoselectivity in the final phase of the synthesis (Fig. 5).[19,21] In retrospect, this photochemical A/D-secocorrin→corrin cycloisomerization proved to be the tailored solution to the problem of the A/D-ring coupling, which, for its part, had given birth to the discovery of the Woodward–Hoffmann rules.

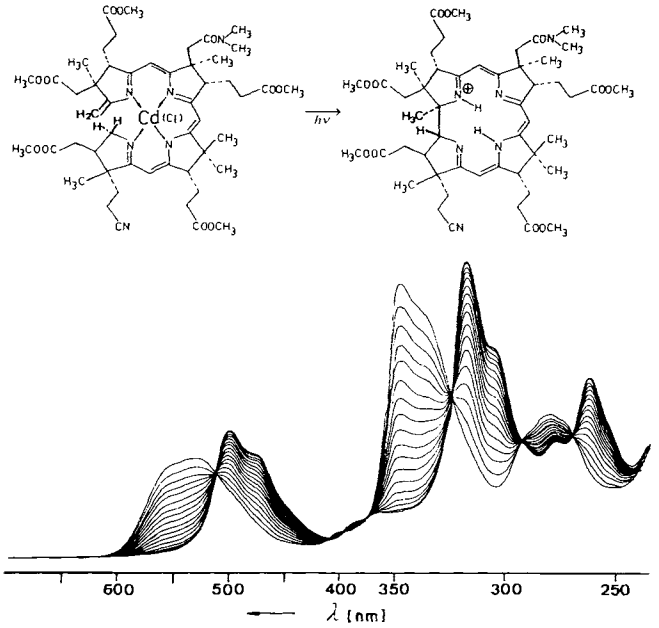

Fig. 5. Above: The A/D-secocorrin→corrin cycloisomerization step in the photochemical variant of the cobyric acid synthesis [19]. Conditions: visible *hv*, 200 W, 25 cm; in CH_3OH/HOAc/NaOAc, under argon; RT; $c \approx 10^{-4}$ mol L^{-1}. Under these conditions the cyclized cadmium(II) complex demetalates spontaneously. Below: Course of the reaction monitored by UV/VIS spectroscopy (from *W. Fuhrer* [154]).

Could there exist a dark variant of the photochemical ring-closure reaction, which might provide us with an insight into the process used by Nature to construct the corrin framework during the (in any case non-photochemical) biosynthesis of the vitamin? It was this question that directed our work for several years after completion of our studies on the chemical synthesis of vitamin B_{12}. Not just one but a whole family of such dark variants was the result of work carried out on synthetic model compounds. An overview of these reactions is presented in Figure 6.[22]

The act of photoexcitation in the photocycloisomerization of a 1-methylidene-1,19-secocorrin (e.g., cadmium, zinc, or magnesium) complex can be successfully replaced, in the case of the corresponding nickel(II) complex, by a reaction sequence consisting of (one-electron) electrochemical oxidation followed by direct reduction of the meanwhile isomerized radical cation (oxidoreductive variant, 1976[23]). The corrin complex can also be formed, however, starting from a 18,19-didehydro-1,19-secocorrin nickel(II) complex by electrochemical (two-electron) reduction in a protonating medium (reductive variant, 1975[24]). Thermal decarboxylation of the 19-carboxy derivative of a 1-methylidene-1,19-secocorrin nickel(II) complex in nonpolar medium also results in the formation of the corrin complex (decarboxylative variant, 1976[22,25]). Finally, the corresponding 19-formylsecocorrin derivative readily undergoes cyclization in the simultaneous presence of proton donors and acceptors (e.g., acetic acid/triethylamine 4 : 1 in benzene at room temperature) to give the 19-formylcorrin complex, which, in turn, undergoes smooth deformylation upon treatment with potassium hydroxide (tautomerization variant, 1977[25]). All these ring-closure variants are members of a common family of reactions; they all involve intermediates having the same type of constitution (see Fig. 6). The last two variants were worked out following the then surprising discovery of *Shemin* et al.[26] and *Scott* et al.[27] that the *meso* carbon atom between rings A and D of the uroporphyrinogen precursor is extruded during the biosynthesis of vitamin B_{12} (Fig. 7a). The cyclization of the formyl derivative demonstrated for the first time how the extrusion of a single carbon-atom equivalent from the ring-A/D region can serve a specific function in the A→D ring-coupling process and how, from a chemical standpoint, the B_{12} biosynthesis can occur in principle by transformation of a porphyrinogen-type structure to a corrin-type structure without the use of an external reducing agent (but instead by extrusion of a *meso* carbon as a carboxyl carbon).

A decisive impulse in our further search for a chemical model for the natural route of formation of the A/D-ring junction of vitamin B_{12} was imparted by a completely unexpected and very important result obtained in the laboratories of *Battersby*,[28] *G. Müller*,[29] and *Scott*.[29] In the third methylation step along the biosynthetic pathway leading from uroporphyrinogen to cobyric acid, the methyl group is introduced at the *meso* position between rings A and D, that is, at just that carbon center that is going to be extruded during subsequent biosynthetic steps. The *meso* carbon is thus extruded as a C_2 fragment along with the previously introduced methyl group, instead of as a C_1 fragment (see Fig. 7b). This discovery gave rise in our laboratory to the concept of a dihydrocorphinol→corrin rearrangement, the last variant of corrin formation shown in Figure 6. In this process, the macrocycle of a 1,20-dihydro-20-hydroxy-20-methylcorphin derivative undergoes contraction to give the macrocycle of a 19-acetylcorrin derivative (ring contraction variant, 1980[30–32]). The experimental observations are summarized in greater detail in Figure 8. It is, in particular, the stepwise reaction pathway leading

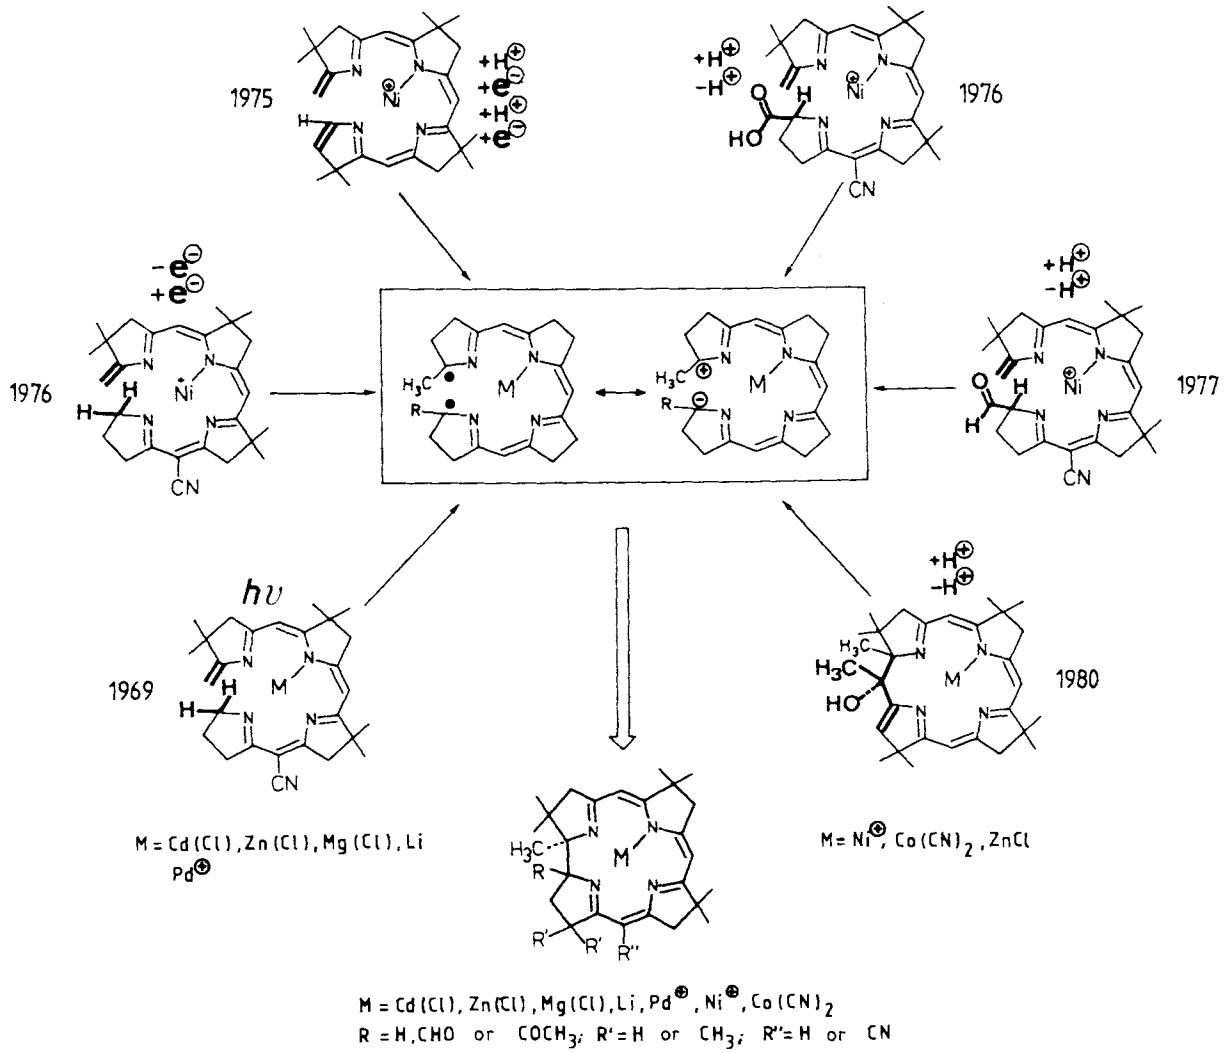

Fig. 6. Oxidoreductive [23], reductive [24], decarboxylative [25], tautomerization [25], and ring-contraction [30] variants of the photochemical A/D-secocorrin→corrin cycloisomerization [21] in synthetic model systems.

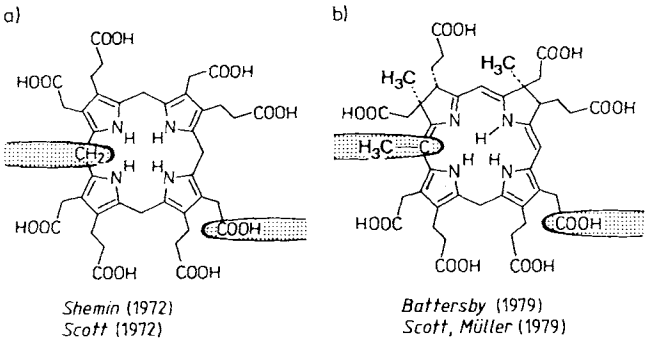

Fig. 7. Extrusion of carbon centers in the biosynthesis of vitamin B_{12} from uroporphyrinogens of type III [26–29]. For a, b see text.

to ring contraction[31] that reveals how closely related this type of corrin formation indeed is to the previously discussed cyclization of a 19-formylsecocorrin and thus to the original photochemical A/D-secocorrin→corrin cycloisomerization.

As a type of structural change, the dihydrocorphinol→corrin rearrangement is regarded in current B_{12} research[33,34] (compare Fig. 49, Section 4) as a valid model for the process by which Nature accomplishes the crucial step in the formation of the corrin system of vitamin B_{12}. In the laboratories of *Arigoni*[35] and *Battersby*[36] it has been shown experimentally that the C_2 fragment extruded during the course of biosynthesis is an acetic acid equivalent.

Thus, by transient methylation of the *meso* position between rings A and D, Nature makes use of a reaction channel leading to ring contraction, which, via intramolecular shift of π-oxidation equivalents of the chromophore system, allows the formation of the (more reduced) corrin system without the necessity of employing an external reducing agent. Among biosyntheses of low-molecular-weight natural products, the acrobatics of this sequence of reactions is probably unique. It is just such kinds of molecular complexity in the course of the biosynthesis that offer us clues as to the origin of the vitamin B_{12} structure, particularly when we study and compare the autochthonous reactivity of the type of structures that occur along the pathway leading from uroporphyrinogen to cobyric acid.

An interesting example of such autochthonous reactivity is provided by the finding made in a study of the behavior of a model dihydrocorphinol derivative lacking the critical

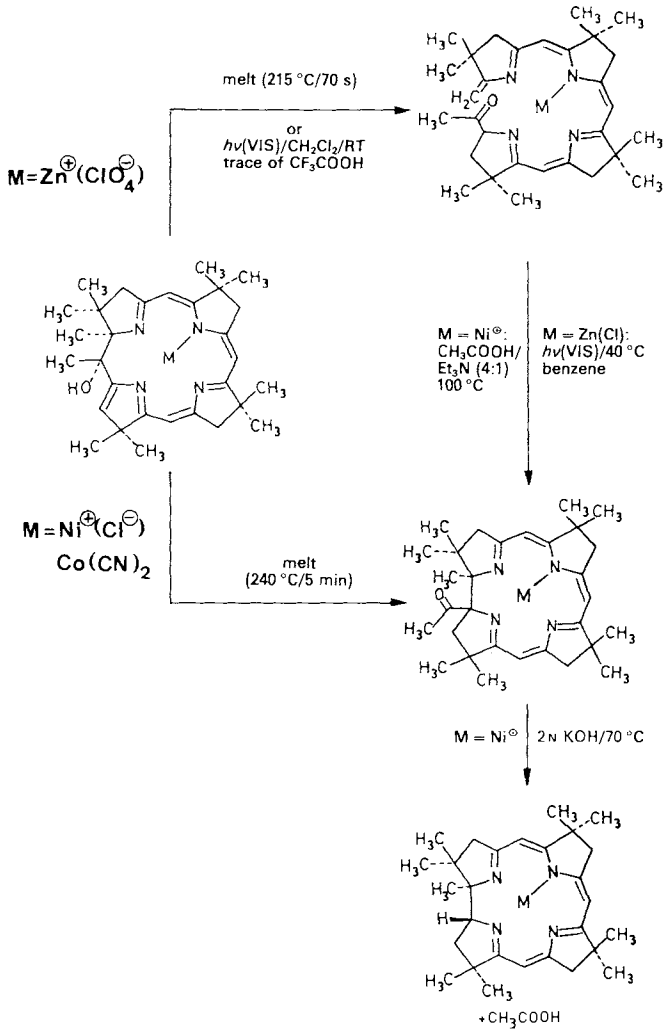

Fig. 8. The dihydrocorphinol→corrin rearrangement: synthetic model for the ring-contraction step in the biosynthesis of the corrin ring of vitamin B_{12} (*V. Rasetti* et al. [30, 31], *K. Hilpert* [32]) (cf. Fig. 27).

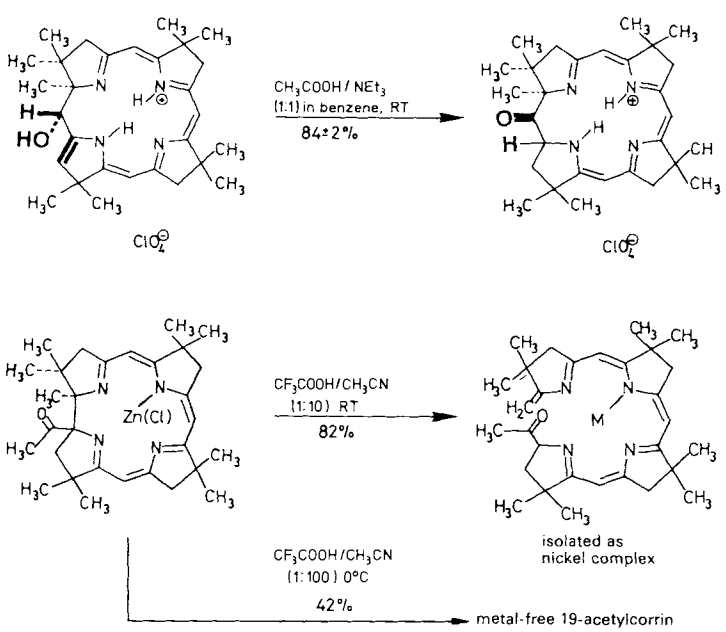

Fig. 9. Observations made in model studies on corrin biosynthesis [31] (cf. *A. Fässler* [37] and *K. Hilpert* [32]).

C-methyl group at the *meso* position between rings A and D (see Fig. 9). In contrast to the corresponding *tertiary alcohol, such a secondary* alcohol apparently has little chance to undergo the kind of ring contraction shown in Figure 8, since, under very mild reaction conditions, it undergoes irreversible tautomerization to give the 20-oxotetrahydrocorphin derivative.[31,37] This finding provides a worthy comment on the question of why Nature found it useful to transiently *C*-methylate the critical *meso* position between rings A and D in the course of developing the biosynthetic pathway to vitamin B_{12}.

The model studies on the dihydrocorphinol→corrin rearrangement have resulted in a further noteworthy finding in this connection. As also shown in Figure 9, it is the extraordinary lability of metal-free 19-acetylcorrins toward proton-induced opening of the macrocycle between rings A and D, first observed during attempted acidolytic decomplexation of a zinc(II) 19-acetylcorrin complex.[31,32] In contrast, synthetic metal-free corrins having a hydrogen atom in place of the acetyl group at position C-19 are completely stable toward such a ring opening.[38] This contrasting behavior is understandable in terms of the mechanism of ring opening in the 19-acetyl derivative. The biosynthesis of the corrin system is believed to proceed via a (potential) 19-acetyl derivative; however, it does not stop there but removes the acetyl group at position C-19 and replaces it by a proton. This fact conforms well to the above-mentioned finding.

The search for a dark variant of the photochemical A/D-secocorrin→corrin cycloisomerization led to the discovery of an entire family of alternative routes of corrin formation; the family is portrayed in Figure 6. Moreover, it led to the realization that the corrin-specific A/D-ring junction, which, at the start of the vitamin B_{12} work, had to be considered the most imposing obstacle to any chemical synthesis of vitamin B_{12}, is in fact a structural element that can form itself very readily and in a variety of ways under structurally appropriate preconditions.

In this connection, *A. W. Johnson*'s discovery[39] in the mid-1960s of the oxidative A→D cyclization of dehydrobilin derivatives to corrols and octadehydrocorrins deserves special mention.[40] We now recognize that this A→D ring-closure concept, first realized in these highly dehydrogenated systems, is relevant to the vitamin B_{12} structure in an even more comprehensive way than the pioneer of the A→D cyclization may ever have imagined. The gap in oxidation level between *Johnson*'s cyclization to octadehydrocorrins and the photochemical cyclization of A/D-secocorrins to corrins has meanwhile been bridged in our laboratory[41,42] and in that of *Montforts*.[43] The results, summarized in Figure 10, show that it is possible to carry out A→D cyclizations for a total of five different corrinoid oxidation states. These findings document the extraordinarily broad constitutional and mechanistic scope of approaches to the carbon/nitrogen skeleton of the corrin structure via A→D ring closure.

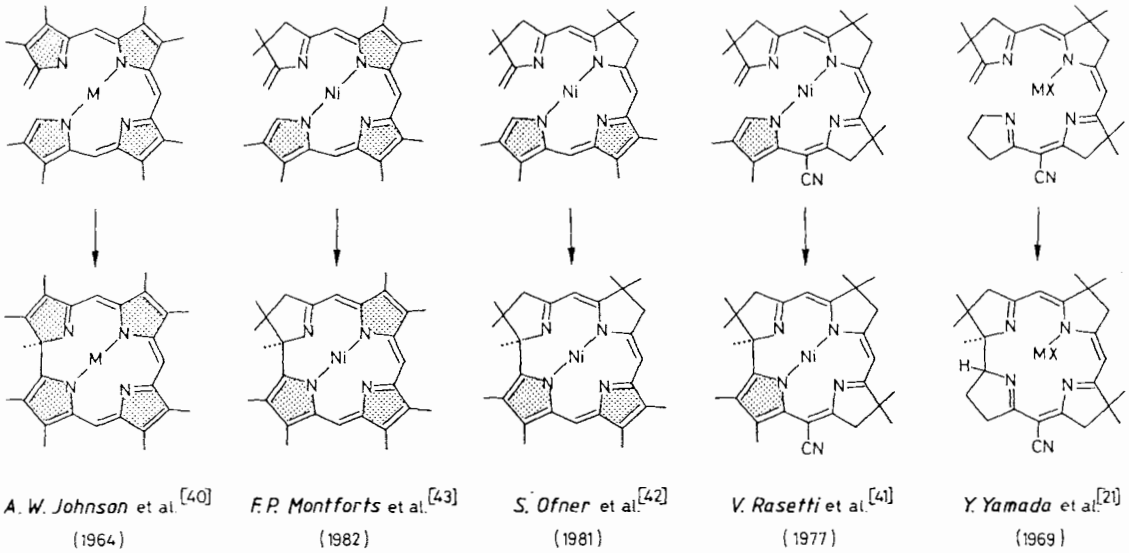

Fig. 10. A→D cyclizations to corrinoids in model systems whose ligand systems exhibit different degrees of dehydrogenation and methylation.

Figure 11 is an attempt to summarize schematically all reported cases in which an A→D cyclization was used in order to transform synthetic substrates into products having a corrinoid structure.[44] The direct coupling of two rings can be accomplished under diverse reaction conditions, largely independent of both the degree of methylation of the ligand periphery and the degree of dehydrogenation of the chromophore. *This schematic diagram might well be said to symbolize the demystification of the vitamin B_{12} structure by chemical synthesis.* The corrin-specific A/D-ring junction of the vitamin B_{12} molecule is a structural element that, under appropriate preconditions, self-assembles so to speak in a preprogramed way.

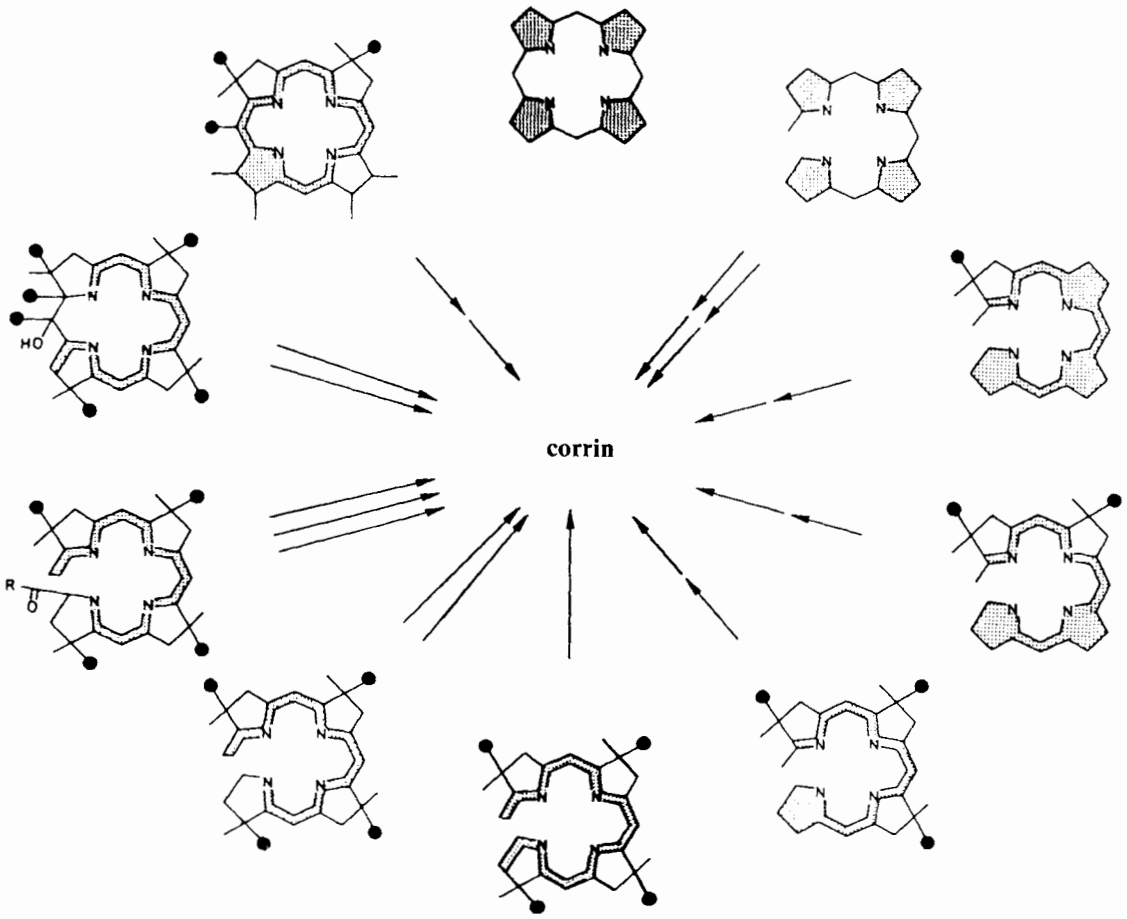

Fig. 11. Overview of the types of A→D cyclizations to corrinoids so far realized [44].

Are other structural elements of vitamin B_{12} similar to the A/D-ring junction in this respect? Do, for example, the characteristic arrangement of double bonds in the corrin chromophore, the pattern of *C*-methylation of the ligand periphery, the configuration of the ligand periphery, and the specific attachment of the nucleotide chain to the corrin ligand also represent structural elements that readily form under structurally appropriate preconditions? Or, in other words, is the outward complexity of the vitamin B_{12} molecule only a deceptive appearance?

The incisive change in our attitude toward the vitamin B_{12} structure evidenced by questions of this kind has led us to go as far as to envisage the extreme possibility of a prebiotic origin of the corrin structure.[45] Do reaction conditions exist that will, via a self-directing sequence of reactions (e.g., tautomerization, complexation, ring-opening, and ring-closing), convert a porphyrinogen into a corrin complex? Such a question (see Fig. 12) presupposes the occurrence of *reversible* protonation steps, which would have to replace the *irreversible* (but regioselective) *C*-methylation steps of B_{12} biosynthesis; electrophilic *C*-methylations (by adenosylmethionine) and *C*-protonations are isoelectronic processes. Possible intermediates would be metal complexes in which the double bonds of the chromophore system are arranged in a corrinoid (or corphinoid) fashion, with the carbon/nitrogen skeleton still being unchanged (see Fig. 12). The target product would be a corrin complex, one among constitutional and stereochemical isomers, which would correspond in constitution and configuration to cobyrinic acid with protons replacing the *C*-methyl groups around the periphery (a "protocobyrinic acid").

It was the pursuit of this question that ultimately led us to the experiments discussed in the next section.

3. Synthetic Analysis of Specific Structural Elements of the Vitamin B_{12} Molecule

This four-part section deals with experimental results and insights that we regard as way stations along the road toward a chemical rationalization of the structure of vitamin B_{12}. Some of the structural elements characteristic of vitamin B_{12} are found to be self-assembling in the sense that the amount of "external instruction" required for their formation under structurally appropriate preconditions is surprisingly small in view of the complexity and specificity of these structural elements. The investigations carried out so far have focused on the characteristic arrangement of double bonds in the corrin chromophore, the special dimension of the corrin macrocycle, the specific attachment of the nucleotide loop to the propionic acid side chain of ring D, and the arrangement of side chains around the ligand periphery. Most of these investigations have been carried out on synthetic model systems.

3.1. The Corrin Chromophore: Its Specific Arrangement of Double Bonds

At the start of this work, virtually nothing was known about the reaction behavior of porphyrinogen-type structures with respect to the problems raised in Figure 12.[46] The use of a fully symmetric model substrate in the exploratory investigations was therefore deemed advisable; the model of choice was the readily accessible octaethylporphyrinogen.

Our earlier work on the synthesis of corphin derivatives[47] provided us with a background of experience that proved to be crucial in designing and carrying out these investigations. *Corphins* are hexahydroporphinoid ligands

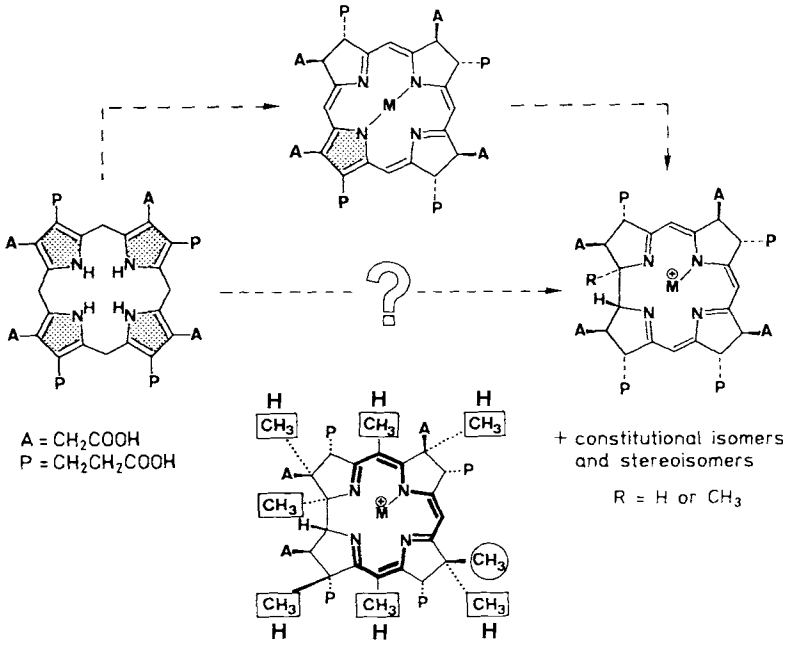

Fig. 12. Do reaction conditions exist that would transform uroporphyrinogens into (peripherally nonmethylated) corrin complexes?

which have a corrin-like chromophore but possess the carbon/nitrogen skeleton of the porphins (see Fig. 13). They form transition-metal complexes whose stabilities are similar to those of the corrins;[47,48] this gave rise to the expectation that complexes of their monopyrrolic tautomers, the *pyrrocorphins*,[49] might exist as the corresponding *C*-protonated corphin complexes in protonating media.

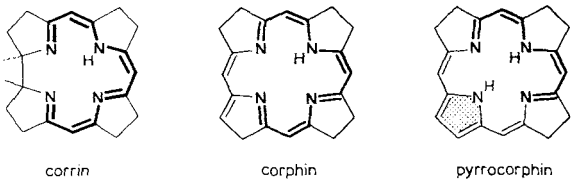

Fig. 13. Three types of chromophores.

The translation of the overall problem formulated in Figure 12 into a less demanding but experimentally more directly accessible question is depicted in Figure 14. What is the position of the tautomeric equilibrium between the tetrapyrrolic arrangement of double bonds in a porphyrinogen and the arrangement in its corphinoid (quasi-corrinoid) counterpart? Does it lie on the side of the tetrapyrrole in the absence of metal ions and on the side of the corphinic (quasi-corrinic) ligand in their presence? In other words, is it possible to force a porphyrinogen-type structure to undergo transformation to a corphin-type (or pyrrocorphin-type) structure by imposing on it a complexing metal ion?

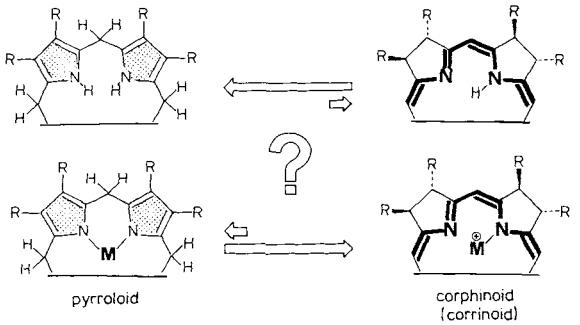

Fig. 14. Can a porphyrinogen be transformed into a corphin by imposing on the system a complexing metal ion?

The answer to this question followed a tortuous road.[50-53] This was due above all to the fact that both octaethylporphyrinogen and its tautomers are extremely prone to undergo autooxidative dehydrogenation upon exposure to oxygen, especially in basic medium. Success was finally achieved by the use of a basic and, insofar as possible, nonpolar medium—rather than a protonating medium, as originally thought. Figure 15 summarizes what we regard as the most advanced accomplishments; they were achieved following exploratory experiments with zinc(II),[50] cobalt(II),[51] and nickel(II).[52] Reaction of octaethylporphyrinogen with a mixture of 1,5,7-triazabicyclo[4.4.0]dec-5-ene ("TBD") and its iodomagnesium salt in a nonpolar solvent such as xylene in a sealed tube with strict exclusion of air resulted in tautomerization and complexation to afford a mixture of diastereomeric magnesium pyrrocorphinate complexes in nearly quantitative yield. Careful demetalation of the products with acetic acid gave the mixture of octaethylpyrrocorphins represented by HPLC 1 in Figure 15.[54-56] A ternary mixture of the three thermodynamically most stable diastereomers *ttttt*, *tttct*, and *tctct*[54] can be obtained by incorporation of an equilibration step (short treatment with magnesium bromide in moist benzene) between the tautomerization/complexation step and the demetalation step (compare HPLC 2). If the entire mixture of diastereomeric, metal-free pyrrocorphins (HPLC 1) is subjected to tautomerizing conditions (pyridine/acetic acid) with strict exclusion of air, (nearly) complete tautomerization back to octaethylporphyrinogen occurs.[53,56]

From a preparative viewpoint the discovery of the porphyrinogen→pyrrocorphin tautomerization opened up a simple and direct approach to the new type of structure represented by this hexahydroporphyrin.[56,57] The configuration of the majority of the diastereomeric octaethylpyrrocorphins appearing in the HPLCs of Figure 15 has been elucidated (X-ray structure analysis, usually of the nickel(II) complex;[58,59] autooxidative dehydrogenation to nickel(II) isobacterio- and nickel(II) bacteriochlorinates[56,57]). By metalation of metal-free pyrrocorphins it is possible to obtain nickel(II) pyrrocorphinates as well as the corresponding cobalt(II), iron(II), and copper(II) complexes, without epimerization.[56,57] Nickel(II) pyrrocorphinates may also be obtained directly by complexation-tautomerization of octaethylporphyrinogen with nickel(II) acetate and TBD in xylene.[53]

The experimental answer to the question as to the relative thermodynamic stability of the pyrrocorphin ligand system versus the tetrapyrrolic porphyrinogen is summarized in Figure 16. In the absence of complexing metal ions, the porphyrinogen is thermodynamically more stable than the pyrrocorphin; in the presence of a complexing metal ion and a base, on the other hand, the equilibrium

porphyrinogen + metal salt + base ⇌
pyrrocorphinate complex + salt

lies on the side of the pyrrocorphinate. Isolation of the unstable metal-free pyrrocorphin by demetalation of the magnesium(II) pyrrocorphinate is only successful because, in this special case, the acidolytic decomplexation can be achieved under *kinetic control*.

Pyrrocorphinate complexes undergo reversible protonation by protic acids in nonpolar medium to give the corresponding corphinate complexes, which are easily detected by UV/VIS spectroscopy (see, e.g., Fig. 17[56]). The regioselectivity of this C-protonation is associated with the specific formation of a (complexed) chromophore system, which, in the region of the five-membered rings, is identical with the (complexed) chromophore system of a corrin. Since the tautomeric equilibrium between a *metal-free pyrrocorphin* and a *metal-free corphin* lies on the side of the pyrrocorphin, the corphin too is thermodynamically less stable than its porphyrinogen tautomer.

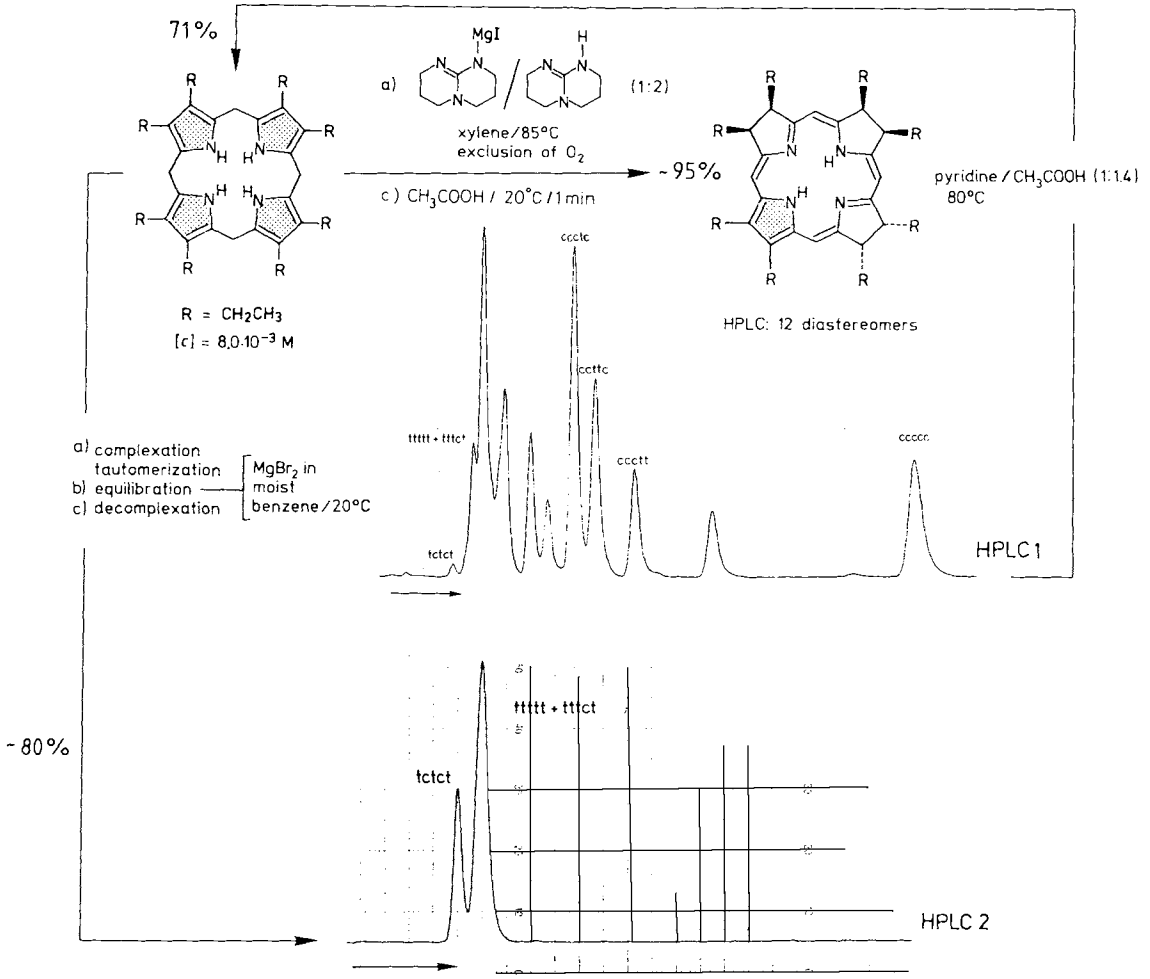

Fig. 15. The porphyrinogen→pyrrocorphin tautomerization [53, 54] (cf. *C. Angst* [50], *R. Waditschatka* [56]). Configurational designation of diastereomers: starting at ring A (above left) and proceeding in a clockwise direction (*c*=*cis*, *t*=*trans*).

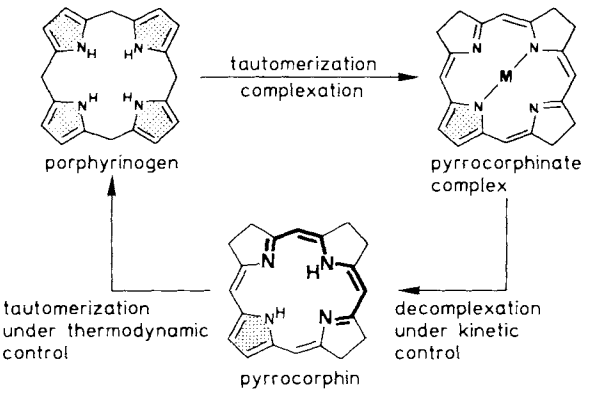

Fig. 16. In the absence of metal ions, a porphyrinogen is thermodynamically more stable than the corresponding pyrrocorphin (and corphin).

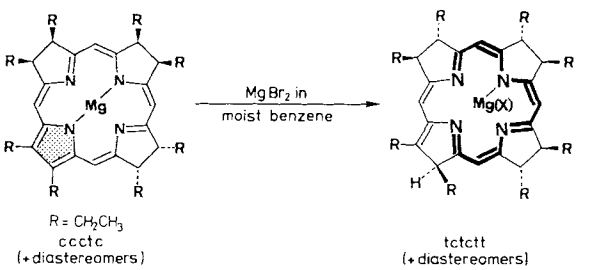

Fig. 17. In protonating medium, pyrrocorphin complexes are present as corphin complexes [56].

In the context of a chemical rationalization of the vitamin B_{12} structure, the experimentally established connection between the porphyrinogen-type structure and the isomeric hexahydroporphinoid ligand systems of pyrrocorphins and corphins affords an insight into the thermodynamic status of the corrin chromophore: *Within the family of hexahydroporphinoid ligand systems, the corphinic (or corrinic) arrangement of double bonds in the chromophore corresponds to a thermodynamically favored arrangement if the ligand is present in complexed form* (Fig. 18). The corrin chromophore is not a complex structural element that presupposes correspondingly complex pathways of formation. Quite to the contrary, the specific arrangement of double bonds in the macrocycle is in a sense a self-constituting structural element since it can form spontaneously under structurally appropriate preconditions.

How can the arrangement of double bonds in a tetrapyrrolic porphyrinogen be transformed into the thermodynamically less stable corphinic arrangement without complexation? An answer is provided by the biosynthesis of vitamin B_{12}: by electrophilic *C*-methylation of one periph-

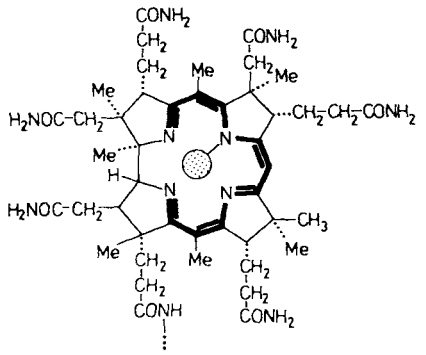

Fig. 18. "Within the family of hexahydroporphinoid ligand systems, the corphinic (or corrinic) arrangement of double bonds in the chromophore corresponds to a thermodynamically favored arrangement if the ligand is present in complexed form."

eral position of each of the four pyrrole rings! Of the eight biosynthetic methylation steps, the sequence of the six crucial ones is now known, as a result of important experimental studies carried out in the laboratories of *Battersby*[60,61] and *Scott* and *G. Müller*.[62] This sequence reveals that the biosynthetic pathway involves intermediates that are pyrrocorphins and corphins, respectively,[33,34,61] or at least very close tautomers thereof (compare Fig. 49, Section 4). Chemically, interesting parallels indeed exist between the two strategies, the biosynthetic pathway on the one hand and the porphyrinogen→pyrrocorphin tautomerization induced by complexation on the other; both achieve the transformation of a porphyrinogen to the thermodynamically less stable corphin.

The relationship of *C*-protonation and electrophilic *C*-methylation as isoelectronic processes is not only relevant in terms of classification, but it also has a counterpart in the actual chemistry of pyrrocorphins: Treatment of magnesium(II), zinc(II), or even nickel(II) complexes with methyl iodide results in regioselective *C*-methylation on the periphery of the pyrrolic ring to give the corresponding corphinate complexes.[56,63-65] Thus, pyrrocorphinates have emerged as substrates that make the (long sought[39,66]) *biomimetic* *C*-methylation of hydroporphinoids possible.

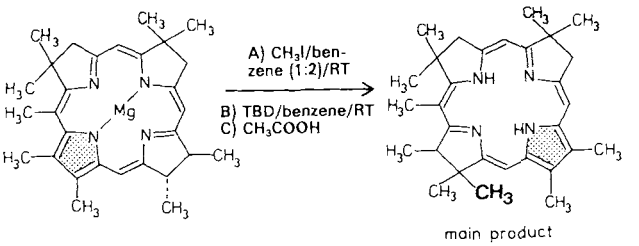

Fig. 19. Peripheral *C*-methylation of a magnesium pyrrocorphinate [67] (cf. *C. Leumann* [65]).

Figure 19 shows an example in which a synthetic model, a pyrrocorphinate bearing a methyl group at the *meso* position between rings A and D, was used to study the effect of this methyl group on the course of peripheral *C*-methylation.[32,65,67] Later, it was found that pyrrocorphinates, although the most reactive, are not necessarily the only type of substrate capable of undergoing biomimetic *C*-methylation. In general, systems containing a mixed pyrrolic-vinamidinic[68] chromophore that is not macrocyclically conjugated can undergo this type of reaction with high and predictable regioselectivity. Figure 20 shows an example involving the synthetic model of a type of chromophore that is assumed to occur along the biosynthetic pathway

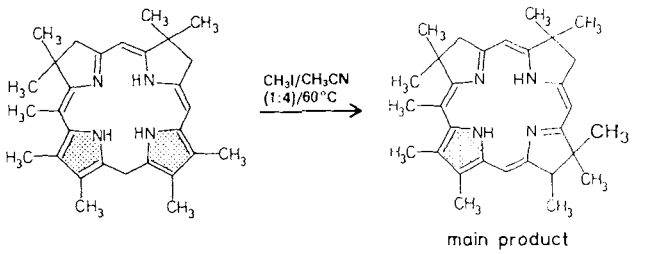

Fig. 20. Biomimetic *C*-methylation of a metal-free dipyrrolic pyrrocorphin tautomer [67] (cf. *C. Leumann* [65]).

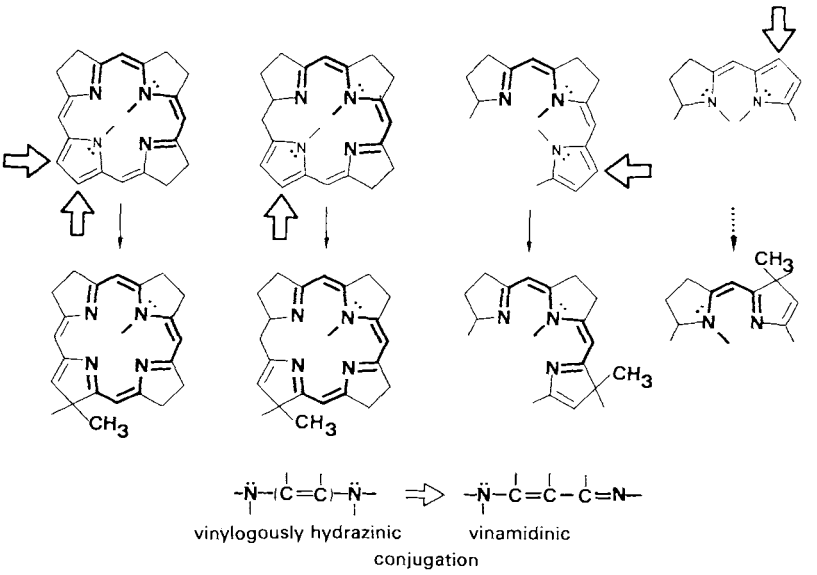

Fig. 21. Constitutional criteria related to the regioselectivity of the C-methylation of pyrrolic-vinamidinic chromophore systems [67].

leading to cobyric acid.[69] Common to all successfully tested chromophores is the presence of two NH electron pairs belonging to the π system and mutually conjugated in a vinylogously hydrazinic (i.e., potentially destabilizing) fashion. *C*-methylation results in the transformation of this system to one displaying vinamidinic (i.e., stabilizing) conjugation, in which an NH electron pair is linearly conjugated with an electrophilic ketimine group. This argument provides a way of interpreting the course of the reaction and allows predictions to be made concerning its regioselectivity. A schematic illustration is presented in Figure 21.[67]

3.2. The Corrin Ring: Its Contracted Dimension Compared with the Corphin Ring

In connection with our experiments aimed at finding a porphyrinogen→pyrrocorphin transformation in the presence of nickel(II) salts, *C. Kratky* (Institut für Physikalische Chemie, Universität Graz) carried out for us X-ray structure analyses of two diastereomeric nickel(II) hexahydroporphinates in order to confirm their constitution and determine their configuration. This work led to the discovery of an unexpected phenomenon, namely, the conformational coupling of the hydropyrrolic rings in these complexes.[52] After the existence of this phenomenon was confirmed for two diastereomeric nickel(II) isobacteriochlorinates of known structure,[70] we pursued systematic investigations in close collaboration with *C. Kratky*. The experimental data and insights thereby obtained are of general importance for the chemistry of hydroporphinoid metal complexes.[59] In particular, we believe that these insights contribute to a deeper understanding of the structure of vitamin B_{12}.

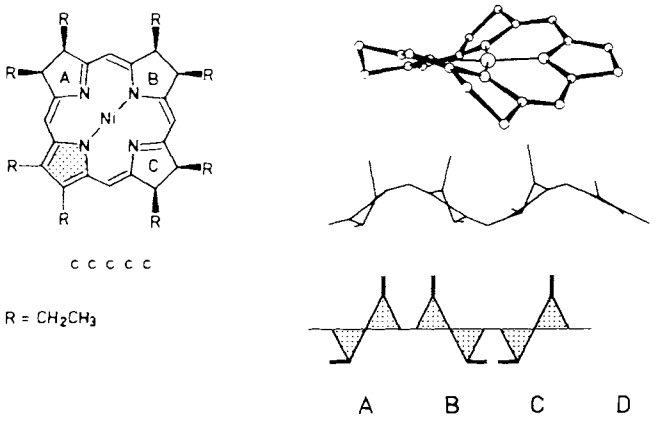

Fig. 22. X-ray structure analysis of nickel(II) *ccccc*-octaethylpyrrocorphinate (*C. Kratky* et al. [59]). Ruffling of the ligand system [71] and conformational coupling of the hydropyrrolic rings.

Figure 22 shows the X-ray crystal structure of nickel(II) *ccccc*-octaethylpyrrocorphinate, which is representative of all available crystal structures of tetra- and hexahydroporphinoid nickel(II) complexes.[55,59] The ligand system of the planar-tetracoordinated, diamagnetic nickel(II) complex is not planar but instead exhibits a saddle-shaped deformation ("ruffling") with approximate S_4 symmetry. Each of the four *meso* carbon atoms lies, on the average, 0.74 Å alternatingly above and below an equatorial plane roughly defined by the four nitrogen centers and the metal coordination center. The three hydropyrrolic five-membered rings are in half-chair conformations, resulting in quasi-equatorial and quasi-axial positions for the peripheral substituents of these rings, as revealed by the cylindrical projection[71] of the structure. The three half-chairs are conformationally coupled with each other in the sense that their puckering alternates in such a way as to parallel the wave form of the saddle-shaped ligand periphery (W conformation of the half-chair ensemble,[59] see Figs. 22 and 29.)

The phenomenon of ligand ruffling in this system is by no means the result of crystal packing factors. This is documented in Figure 23, in which the cylindrical projections of the crystal structures of nickel(II) pyrrocorphinates, structurally isomeric hexahydroporphinates, isobacteriochlorinates, and a nickel(II) bacteriochlorinate are compared.[59] Moreover, the saddle-shaped conformation is not an intrinsic property of the ligands but rather a consequence of their coordination to the central ion, as shown by the X-ray structure data for a metal-free octaethylpyrrocorphin and two octaethylisobacteriochlorins.[59] The ligand system of nickel(II) *ccccc*-octaethylpyrrocorphinate has been shown to exhibit an S_4-like deformation in solution (CS_2) as well. The conformational heterotopicity of constitutionally homotopic *meso* vinyl protons, which results from the saddle-shaped conformation, can be observed in the ^{1}H-NMR spectrum below -40 °C.[55]

Ligand ruffling was first observed by *Meyer*[72] in an X-ray structure analysis of one of the two dimorphic forms of nickel(II) octaethylporphinate and was first interpreted by *Hoard*[73] for this example. More recently, it has also been studied intensively by *Ibers* and his co-workers[74] for nickel(II) di- and tetrahydroporphinates. *Ibers'* data and our own results reveal the following correlation: the "steepness" of the ligand ruffling increases with decreasing Ni–N bond lengths. This finding is in accord with the idea of a nickel(II) ion that seeks to satisfy its electrophilicity in the square-planar environment by drawing the four nitrogen centers in the coordination plane closer to it, thereby increasing the strengths of the bonds involved in this coordination. The ligand system, in particular that of hexahydroporphinoids, whose flexibility is greater than that of porphyrins, tolerates this process by ruffling, thereby allowing the size of the inner coordination hole to be diminished. The increase in coordination bonding energy is viewed to be balanced by the increase in the strain energy of the ligand system.

The ligand ruffling process is schematically depicted by the geometric model in Figure 24.[75] Coplanar, concentric circles of constant circumference undergo deformation, forming saddle-shaped surfaces of *increasing steepness* and, at the same time, resulting in the *increasing convergence* of four equidistant points (representing the four nitrogen centers) toward the center (representing the coordination center) of the original circle, the points remaining in a common plane.

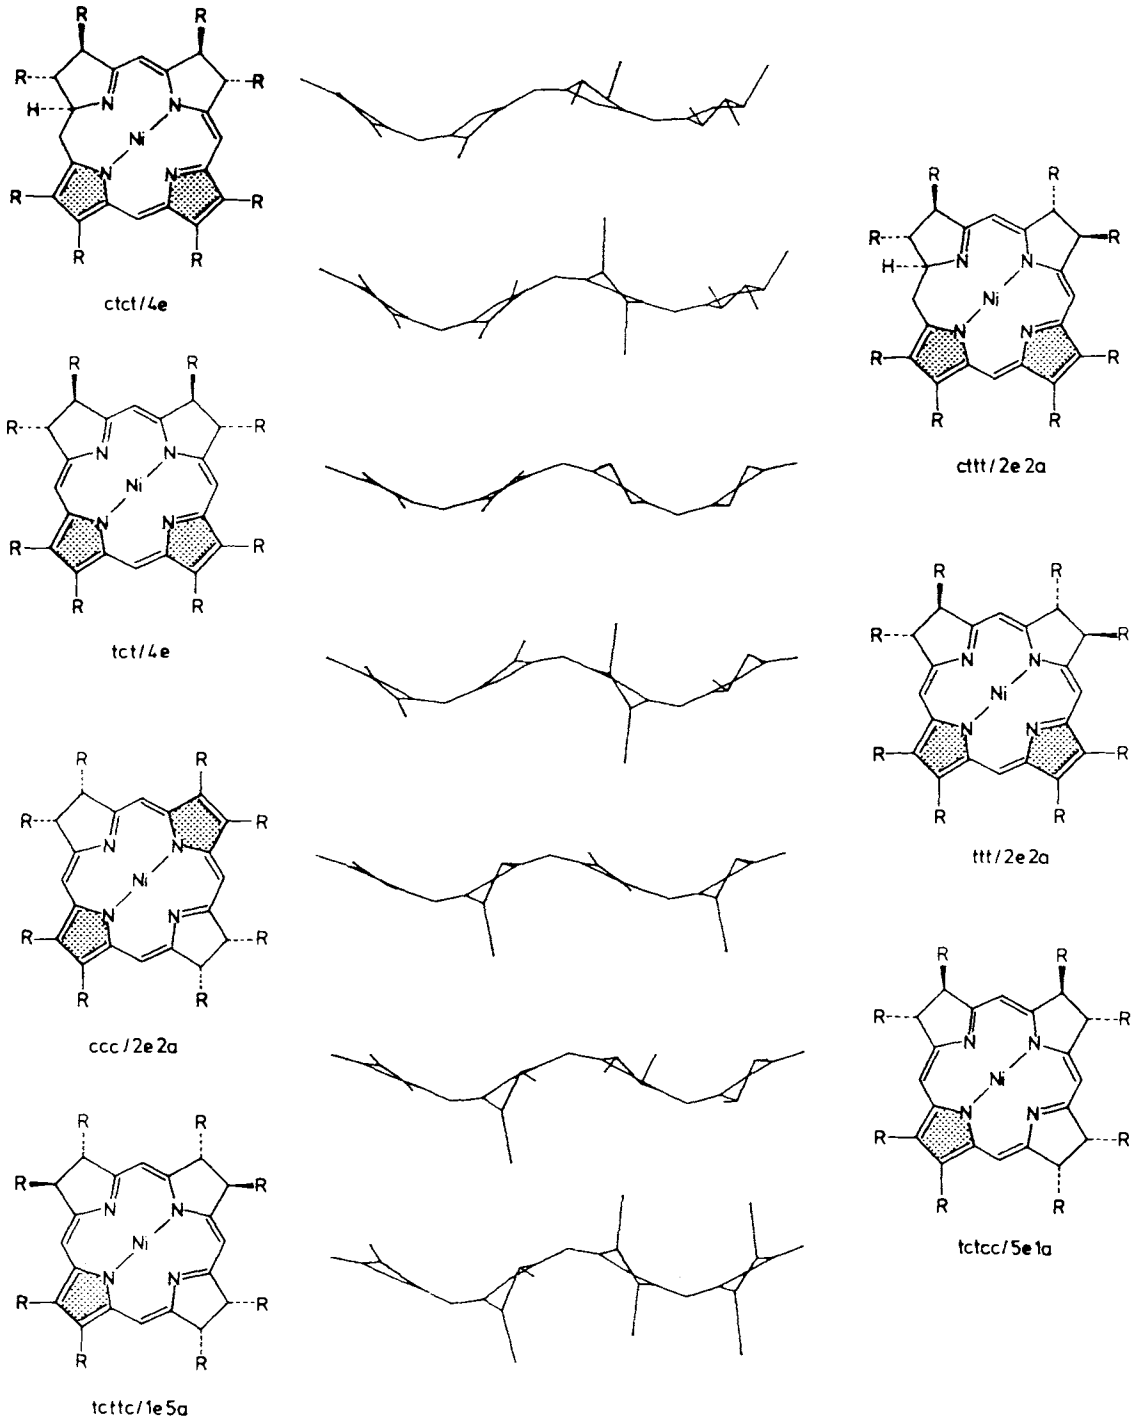

Fig. 23. X-ray structure analyses (cylindrical projections [71]) of hexahydro- and tetrahydroporphinoid nickel(II) complexes (*C. Kratky* et al. [59]).

The relationship between the "steepness" of ligand ruffling and metal-nitrogen bond length is clearly documented by comparison of the structural data for the pyrrocorphinate complexes of nickel(II), cobalt(II), and copper(II) (Fig. 25). The conspicuous inverse relationship between the steepness of the ligand ruffling and the mean length of the four M–N bonds is of significance because the chromophores in the three complexes are identical. Of particular interest is the finding that the pyridinato cobalt(II) pyrrocorphinate complex, despite its additional axial ligands, still exhibits appreciable ligand ruffling.[56,59]

According to all the structural data currently available to us, the (square-planar-complexed) nickel(II) ion (and, similarly, the cobalt(II) ion) is too small-sized for the coordination hole of hydroporphinoid ligand systems. On the other hand, the coordination hole of corrinoid ligands appears to conform well to the spatial demands of the nickel(II) ion, as clearly shown, for example, by the X-ray structure data in Figure 26. The two complexes in Figure 26 have identical chromophore systems; they differ only in the dimensions of their coordination holes. In the case of the (tetradehydro)corrinoid complex, hardly any ligand

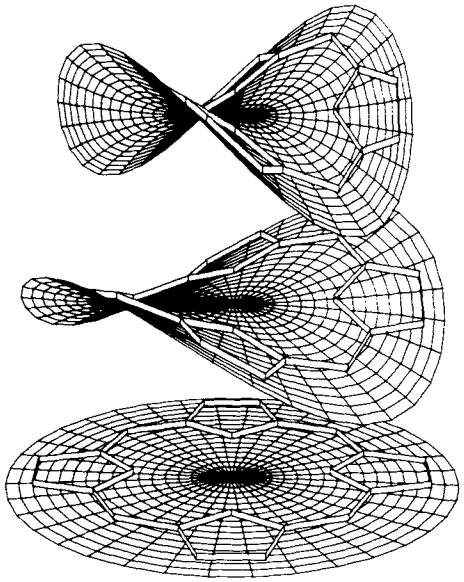

Fig. 24. Geometric model of the ruffling of the ligand periphery of hydroporphinoid nickel(II) complexes by nickel(II)-induced contraction of the inner coordination hole (*C. Kratky* et al. [59], cf. footnote [75]).

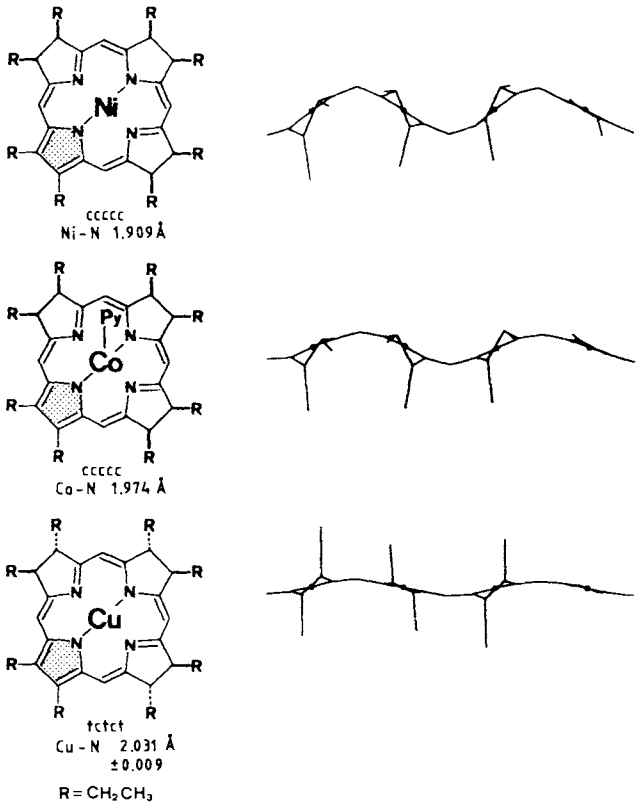

Fig. 25. Increasing "steepness" of the ligand ruffling in pyrrocorphinates is associated with decreasing metal-nitrogen bond lengths [56, 59]. Py in the cobalt complex signifies pyridine; Co-N(Py) 2.161 Å, Co is located 0.09 Å above the plane defined by the four N atoms.

ruffling is apparent, whereas it is appreciable for the hexahydroporphinate. The mean value of the four Ni–N bond lengths in the corrinoid complex is less than the statistical value (1.88 Å[159]) of Ni–N bond lengths in nickel(II) complexes exhibiting square-planar coordination, whereas the mean value of the four Ni–N bond lengths of all hydroporphinoid nickel(II) complexes so far investigated lies above this value. The corresponding value for a synthetic nickel(II) corrinate complex[76] is 1.874 Å.[77]

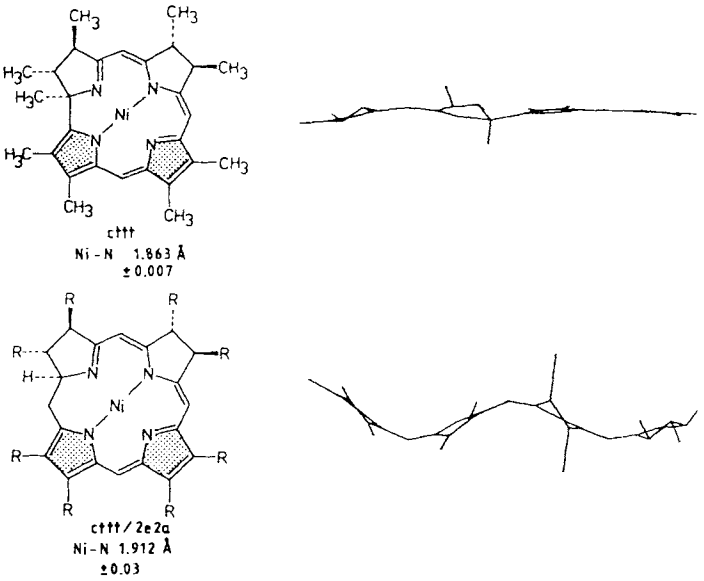

Fig. 26. The ligand system of a *corrinoid* nickel(II) complex exhibits no ruffling [50, 59]. R = ethyl.

If the interpretation of the structural data determined for hydroporphinoid and corrinoid complexes and their thermodynamic implications are correct, then a corphinoid nickel(II) complex should be expected to rearrange to a corrinoid complex, provided that a reaction pathway is made available. This, in fact, has been done in the case of the biosynthetic model discussed in Section 2, the dihydrocorphinol→corrin rearrangement (see Fig. 8). In one of the variants (Fig. 27), the crystalline complexes of both nickel(II) and dicyanocobalt(III) undergo ring contraction upon melting to give the corresponding 19-acetylcorrin complexes. Even though the difference in overall bonding energy due to the change in functional groups alone might favor product formation, the two ring contractions provide a fitting chemical illustration for the thermodynamic interpretation of the structural data.[78]

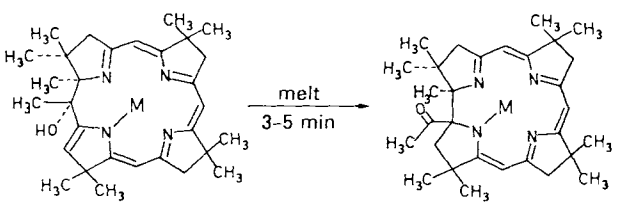

Fig. 27. Thermally induced ring contraction of corphinoid complexes to the corresponding corrin complexes (*Rasetti* et al. [30], cf. also Fig. 8).

Not only the constitution of the corrin chromophore, but also the specific size of the macrocyclic ring in corrin complexes is recognized to be a thermodynamically fa-

vored structural element: *The coordination hole in the (ring-contracted) corrin ligand is spatially better suited for the optimal coordination of metal ions such as nickel(II) and cobalt(II) than the (too large) coordination hole of corphin ligands* (Fig. 28). Apart from the importance that the specific dimension of the corrin ring has for the functional properties of the vitamin B_{12} structure (cf. Section 5), the fitting size of this ring for complexation is certainly responsible for the ease with which corrinoid structures form (see Fig. 11).

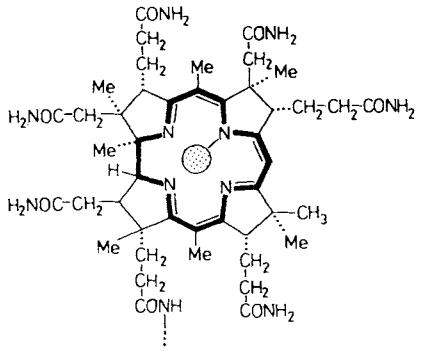

Fig. 28. In terms of the coordination of the metal ion by the macrocyclic ligand system, nickel(II) and cobalt(II) corrin complexes are thermodynamically more stable than the corresponding corphin complexes.

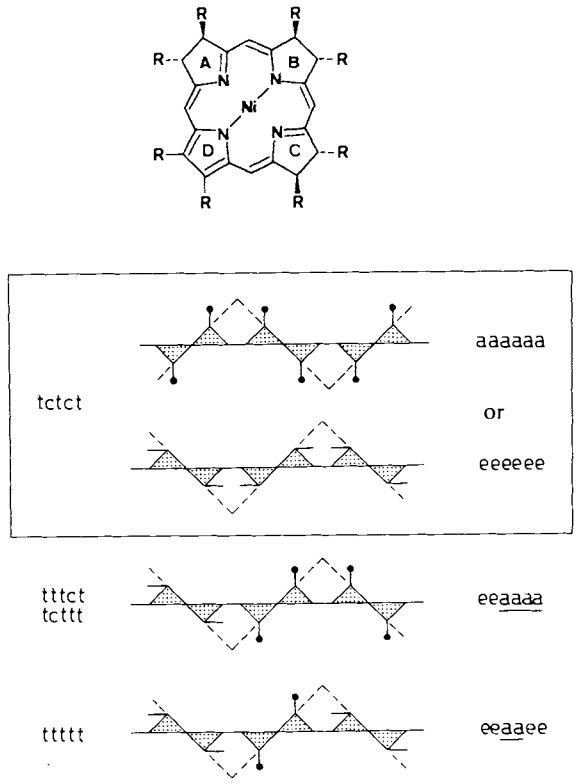

Fig. 29. As a result of the conformational coupling of the hydropyrrolic rings, the *tctct* configuration of substituents on the ligand periphery represents, of all possible configurations, the thermodynamically most stable configuration for nickel(II) pyrrocorphinates. R = ethyl.

If the ligand ruffling and the accompanying increase in coordination bond strength amounts to a stabilization of a hydroporphinoid nickel(II) complex, then the W-form conformation of the half-chair ensemble of hydropyrrolic rings (paralleling the wave form of the saddle-shaped periphery) must correspond to the energetically favored conformation, insofar as it permits maximal contraction of the coordination hole. This implies, in turn, that, of the three diastereomers of a constitutionally symmetrical pyrrocorphinate having a *trans* arrangement of all vicinal substituents (*ttttt*, *tttct*, and *tctct*; cf. Fig. 15), the *tctct* diastereomer must be the thermodynamically most stable one. The reason for this is that in the W conformation of the ring ensemble, all ring substituents exist in a uniform quasi-equatorial conformation (or a uniform quasi-axial conformation) when these substituents are in the *tctct* configuration (see Fig. 29). A variety of experimental findings are available which confirm this remarkable control of the configuration at the ligand periphery by the central nickel(II) ion; they indirectly contribute to the coherence of the interpretation given above. Two of these experiments will be briefly discussed below.

In equilibrium mixtures of octaethylpyrrocorphins or their metal complexes, the three diastereomers *ttttt*, *tttct*,[79] and *tctct* should be present in the statistical ratio of 1 : 2 : 1, since, in contrast to substituents in vicinal positions, there is no mutual steric interaction between substituents on neighboring rings flanking a common *meso* position. Indeed, this was essentially observed to be the case in product mixtures of porphyrinogen→pyrrocorphin tautomerization experiments that included the equilibration step (cf. Fig. 15). On the other hand, Figure 30 shows the result of an experiment[80] in which the pure *tttct* diastereomer[56] of nickel(II) octaethylpyrrocorphinate was subjected to configurational equilibration (occurring via double C-protonation). The product distribution, as determined by HPLC, reveals an 87% predominance of the *tctct* diastereomer. The analogous experiment performed with the palladium(II) complex led to a product mixture in which the *tctct* diastereomer predominated to a lesser extent. This result is plausible since the "larger" palladium(II) ion is expected to induce ligand ruffling only weakly, if at all.[56,57,59]

The other experiment involves the recently discovered coenzyme F430 from methogenic bacteria,[81] the corphinoid structure of which was elucidated in our laboratory together with *Pfaltz* and *Jaun* in collaboration with *Thauer* (Marburg).[82] It was known that this coenzyme undergoes structural change upon extraction from the bacteria at raised temperature, whereas no change occurs upon extraction at 0 °C in the presence of neutral salts.[83] This phenomenon has been studied[84] and Figure 31 presents the results. Upon heating in a neutral buffer solution, pure coenzyme F430 undergoes equilibration to afford a ternary mixture of products, in which the diastereomer of the natural coenzyme that is doubly epimerized in ring C predominates to the extent of 88%. Model considerations require (owing to steric hindrance of the quasi-equatorial position of the propionic acid chain by the neighboring carbonyl group) and ^{1}H-NMR analyses confirm that the two substituents in ring C affected by the double epimerization adopt the quasi-diaxial conformation, both in the natural coenzyme and in its 12-*epi*-13-*epi* diastereomers—a very

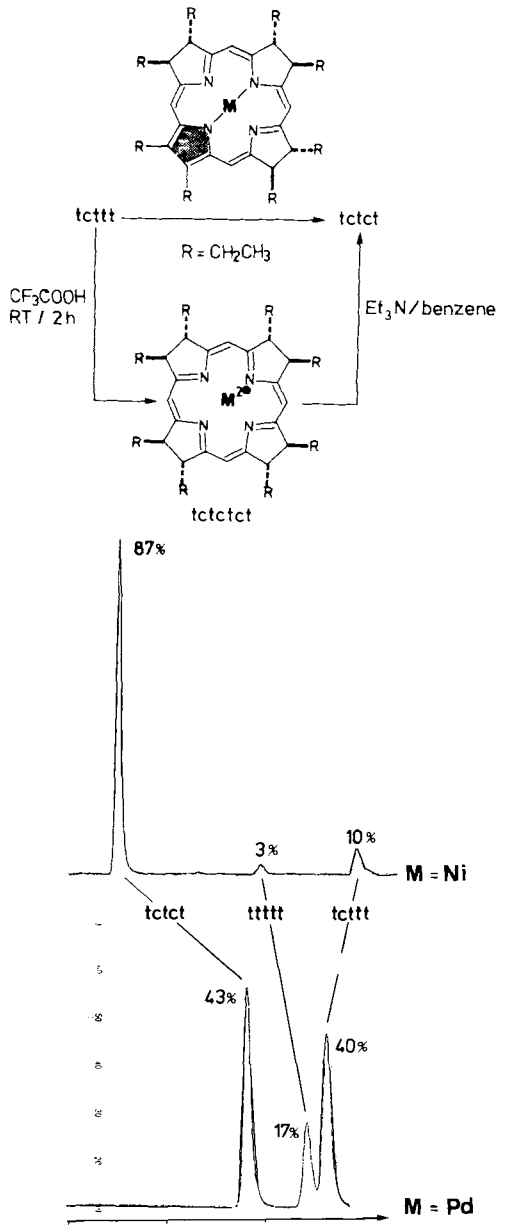

Fig. 30. Acid-catalyzed isomerization of nickel(II) *tcttt*-octaethylpyrrocorphinate to the *tctct* diastereomer [59] (*R. Waditschatka* [56]).

unusual situation, indeed. However, ^{1}H-NMR spectroscopy also reveals that the ensemble conformation of the hydropyrrolic five-membered rings present in the natural coenzyme clearly disobeys the W-form rule, which was established for hydroporphinoid nickel(II) complexes (see above). This rule is broken because the two substituents on ring C are not allowed (for the steric reasons already discussed) to occupy quasi-diequatorial positions. The double epimerization of these two substituents resolves the dilemma: since the two ring-C substituents have to remain quasi-diaxial, the epimerization induces an inversion of the half-chair of ring C and thereby generates the W conformation of the ring ensemble.

In light of the above interpretation, the configurational instability of coenzyme F430 provides a superb example of the importance of the spatial coordination demands of the central ion in influencing the configuration of substituents on the periphery of a hydroporphinoid ligand system.

3.3. The Nucleotide Ligand: Its Specific Attachment to Ring D of the Corrin Ligand

To discover that the A/D-ring junction and the ring size of the corrin ligand as well as the specific arrangement of the double bonds of its chromophore are all thermodynamically favored and largely self-assembling structural elements had come as an inspiring experience to us. Otherwise, we would probably never have dared to invest time and energy in seeking to answer a question such as that posed in this section.

In the vitamin B_{12} molecule, a nucleotide ligand forms a 19-membered loop on the bottom side of the corrin plane extending from cobalt, via the building blocks 5,6-dimethylbenzimidazole, α-D-ribose-3-phosphate, and D-1-amino-2-propanol, to the carboxyl function on the propionic acid side chain of ring D[85] (cf., e.g., Fig. 2). Constitutionally similar propionamide side chains are found on the bottom side of the vitamin B_{12} molecule on each of the four hydropyrrolic five-membered rings. Thus, the specific attachment of the nucleotide chain to ring D represents a

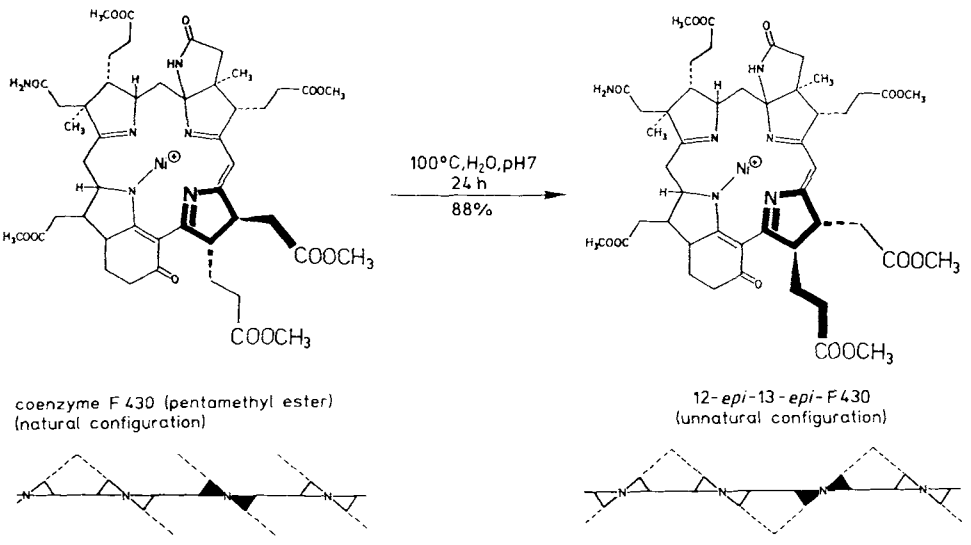

Fig. 31. The diepimerization of coenzyme F430 on the periphery of ring C is a consequence of the contraction of the coordination hole induced by the nickel(II) ion (*A. Pfaltz* et al. [84]).

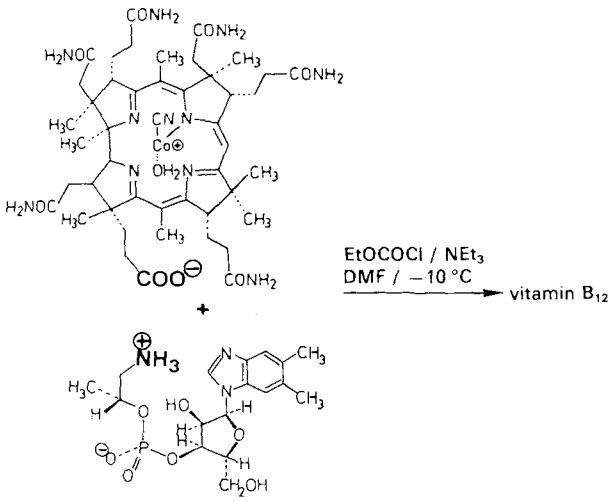

Fig. 32. Transformation of cobyric acid to vitamin B_{12} in the chemical semisynthesis [86] and total synthesis [18].

structural element whose formation ought to require a corresponding external "instruction." Indeed, at the time the chemical synthesis of vitamin B_{12} was planned, it was clear from the very beginning and in both laboratories then involved that this particular carboxyl function on ring D (=f-carboxyl function) had to be present in a constitutional form that is different from the other six carboxyl functions throughout the entire course of the synthesis (as the nitrile; cf. Fig. 4). Only in this way would it be possible to reach cobyric acid, the compulsive intermediate along the synthetic road leading to vitamin B_{12} (cf. Fig. 32 and Ref. [86]). In an undifferentiated derivative (e.g., the heptamethyl ester of cobyrinic acid or "cobester"), it would no longer be possible to attack selectively the f-carboxyl function by reaction with an external nucleophile. This was experimentally confirmed later, for example by the results obtained in the partial ammonolysis of cobester[87] (see Fig. 33).

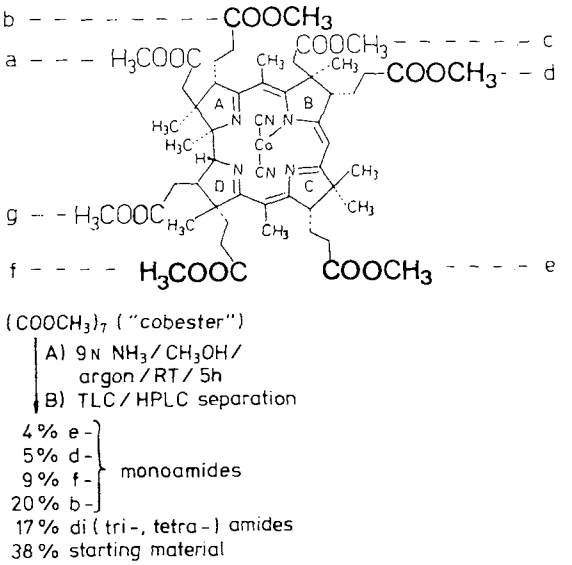

Fig. 33. Product mixture from the partial ammonolysis of the heptamethyl ester of cobyrinic acid ("cobester") (*H. Maag* [87]).

Out of the change in attitude toward the vitamin B_{12} structure came a question that (unfortunately) was totally beyond our conceptual horizon at the time the vitamin B_{12} synthesis was planned: *Is the specific attachment of the nucleotide ligand to ring D also a potentially self-assembling structural element of vitamin B_{12}?*

Once this question is posed, it is easy to recognize a unique possibility of how the nucleotide chain could be linked selectively to the f-carboxyl function, without the necessity of having this carboxyl function exist in a form different from all others. This possibility is illustrated in Figure 34.

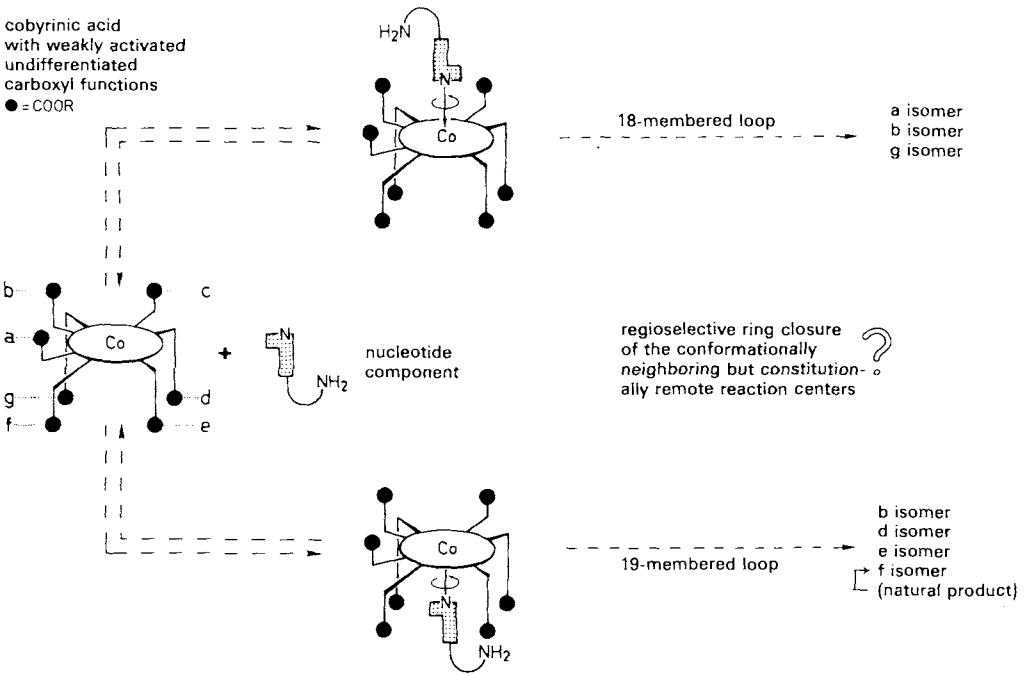

Fig. 34. Working hypothesis for the nucleotide-attachment reactions of cobyrinic acid derivatives containing undifferentiated carboxyl functions.

Consider a solution of the free nucleotide building block and a suitably activated (undifferentiated) cobyrinic acid derivative in which an equilibrium is established between the respective components of two pairs of isomeric cobalt/nucleotide complexes. In one pair, the nucleotide NH_2 group is complexed to the cobalt from either above or below the corrin plane; in the other pair (see Fig. 34), the free nitrogen of benzimidazole is the complexing ligand center. Whereas the first pair possesses no opportunities for undergoing intramolecular reactions, this is not true for the pair having a complexed imidazole nitrogen. In the component with the imidazole complexed from below, there exists a 19-membered precyclic relationship between the (free) NH_2 group of the nucleotide chain and each of the four propionic acid side chains; in principle, intramolecular amide formation can take place with each of them. An analogous (albeit 18-membered) relationship exists in the other component between the NH_2 group and the three acetic acid carboxyl functions.

If one assumes that the natural nucleotide loop (that is, the one attached to the f-carboxyl function) is the most stable one among the four (or seven) constitutionally isomeric loops, and if one further assumes that this stability maximum is due to an optimal conformation along the chain of the 19-membered nucleotide loop, then the conformation adopted by the f-propionic acid chain and the nucleotide chain in the corresponding precyclic complex should be similar to that in the cyclized complex. The nucleotide NH_2 group and the f-carboxyl function in the precyclic complex should statistically be in spatial proximity (Fig. 35), and the kinetics of the ring closures might reflect the thermodynamics of the isomeric nucleotide loops. An experimental observation of such regioselective amide formation due to the conformational neighborhood of reaction centers would, however, require a specially balanced activation of the (seven) carboxyl groups: this activation should be strong enough for *intramolecular* (conformationally assisted) amide formation to proceed, but, at the same time, it should be weak enough so that *intermolecular* (and therefore nonselective) amide formation does not occur.

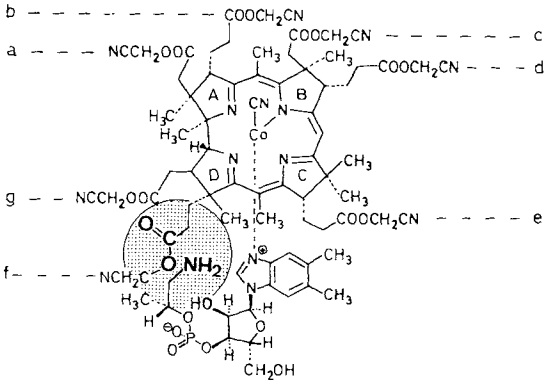

Fig. 35. Does the amino group of the nucleotide component in this complex of the heptakis(cyanomethyl) ester of cobyrinic acid react most rapidly with the f-carboxyl function?

The actual experiments fulfilled these expectations to an extent that was surprising to us (see Figs. 36–39).[88] Since this work has not yet been published, it will be described here in somewhat greater detail.

The question as to a suitable form of activation for the seven carboxyl functions of cobyrinic acid (so as not to differentiate them) happened to be solved straightaway by the use of the heptakis(cyanomethyl) ester of cobyrinic

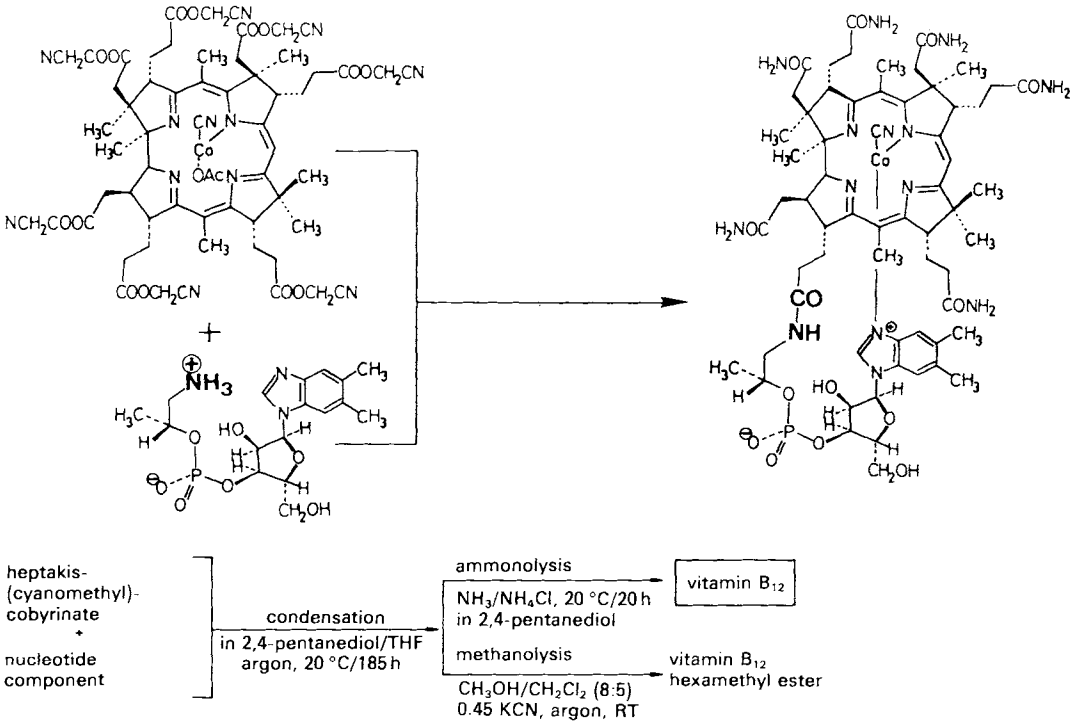

Fig. 36. The nucleotide-attachment reaction of the heptakis(cyanomethyl)ester of cobyrinic acid and direct subsequent ammonolysis (or methanolysis) leads selectively to vitamin B_{12} (or the hexamethyl ester of vitamin B_{12}) (*G. Bartels* et al. [88]).

acid,[89] after it was realized that the reactivity of the simple heptamethylester was insufficient. In order to render the cobalt(III) coordination center reactive (capable of undergoing rapid ligand exchange), the acetato-cyano form of the complex was prepared; it was obtained as an α/β mixture of diastereomers by treatment of the dicyano cobalt(III) form (which does not readily exchange ligands) with acetic acid. Later in the work, it was realized that the two diastereomers are just sufficiently stable to allow their chromatographic separation and thereby their use as pure epimers in nucleotide-attachment experiments.

When ca. 0.04 M degassed solutions of the heptakis(cyanomethyl) ester of (β or α)-acetato-(α or β)-cyanocobalt(III) cobyrinic acid and 1.5 molar equivalents of the free nucleotide component[90] (Fig. 36) in pentane-2,4-diol/tetrahydrofuran (1:1) (molecular sieves, argon, room temperature) were allowed to stand for one week, ca. 50% conversion took place, leading, after immediately following ammonolysis of the reaction mixtures, to products that, according to HPLC (see Fig. 37), mainly consisted of roughly equal amounts of only two components, vitamin B_{12} and the starting material (in the form of its ammonolysis product, the heptamide of cobyrinic acid). In the experiment corresponding to Figure 37, the product (neutral at pH 2.5) was first separated from the (positively charged) heptamide of the starting material, then purified by reversed-phase chromatography, and finally, after crystallization, identified as vitamin B_{12} by comparison of its HPLC behavior as well as its UV/VIS, CD, IR, and ^{1}H-NMR spectra with those of authentic material. In another experiment, in which the heptakis(cyanomethyl) ester of configurationally pure α-acetato-β-cyano cobalt(III) cobyrinic acid (ca. 50 μmol) was used and the mixture of starting material and product obtained by ammonolysis was not separated electrophoretically but rather by reversed-phase chromatography,[91] spectroscopically pure, crystalline vitamin B_{12} was isolated in 41% yield (Fig. 36).

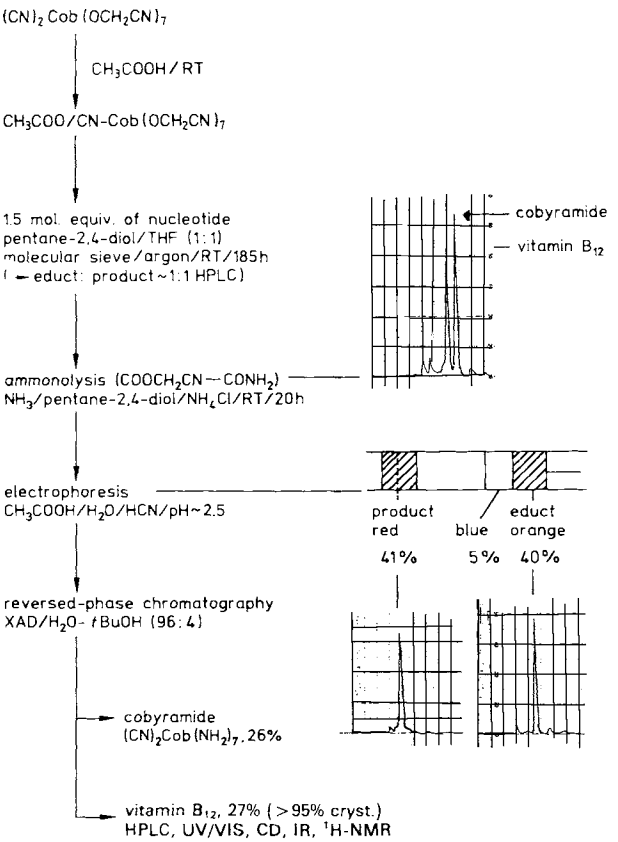

Fig. 37. Nucleotide-attachment reaction of the heptakis(cyanomethyl) ester of cobyrinic acid: HPLC of a crude product (after ammonolysis) and HPLC [91] of the two main components after separation of the crude products by electrophoresis [88].

In order to have an easier access to the information of whether and to what extent isomeric nucleotide-attachment products are formed under such reaction conditions, experiments were carried out in which the (sensitive) cyanomethyl esters of the reaction mixture components were not trapped by ammonolysis but rather by (cyanide-catalyzed) methanolysis. Both the product and the starting material components were thereby obtained as stable methyl esters (instead of amides), which are both soluble in organic solvents and readily crystallizable. Figure 38a shows the result of such an experiment starting from an α,β-diastereomeric mixture of starting materials. The two HPLCs reveal the composition of the reaction mixture immediately before and after the methanolysis. The two methanolysis products are the heptamethyl ester of cobyrinic acid[92] and the previously unknown vitamin B_{12} hexamethyl ester (cf. Fig. 36). Both products were obtained in crystalline form after chromatographic separation and repurification[93] and identified spectroscopically. For direct comparison, authentic B_{12} hexamethyl ester was prepared by semisynthesis starting from cobyrinic f-acid hexamethyl ester.[94] The minor fraction appearing after the product peak in the (second) HPLC of Figure 38a was thoroughly checked to determine whether the isomeric B_{12} hexamethyl esters might also be present. The material turned out to consist of a complex mixture[95] in which the e-iso-B_{12} hexamethyl ester (nucleotide chain on the ring-C propionic acid chain) was present, if at all, in an amount corresponding to less than 1% yield.[96]

Figure 38b shows an experiment that provides simple and convincing proof for the validity of the expectation that the regioselective attachment of the nucleotide chain takes place intramolecularly after precomplexation. The two chromatograms show the results (after methanolysis) of two nearly identical parallel experiments[97] that differed in only one respect; one of the two reaction solutions was in vapor contact with a solution of acetone cyanohydrin in acetonitrile (a source of trace amounts of gaseous HCN). The color of this reaction solution changed within ca. 10 min from red (acetato-cyano form of the starting complex) to violet (dicyano form), whereas the color of the other reaction solution remained unchanged. As revealed by a comparison of the HPLCs of the two reaction mixtures (see Fig. 38b), the presence of trace amounts of HCN results in nearly complete suppression of product formation,[98] the dicyano form of the starting complex being stable toward ligand exchange under the reaction conditions.

The regioselectivity of the nucleotide attachment can be observed most clearly during the first half of reaction, after which the rate of conversion markedly decreases. If the reaction is pushed beyond this first stage, side reactions

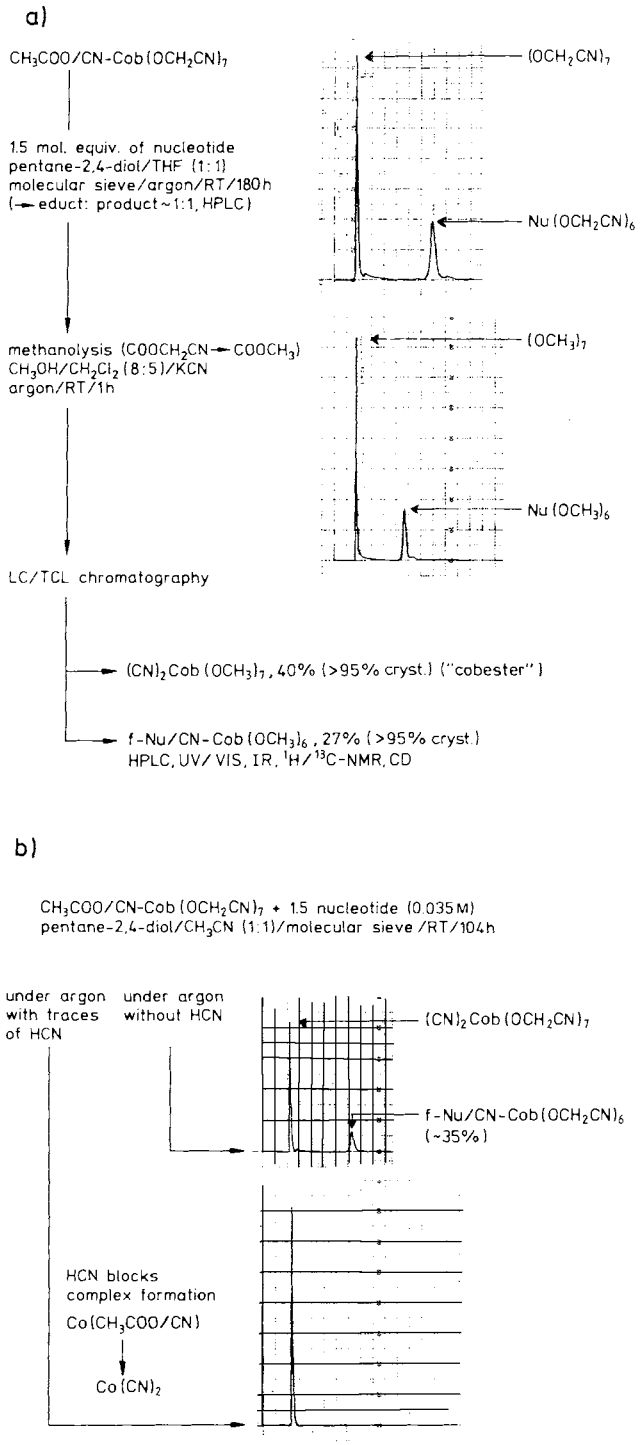

Fig. 38. Nucleotide-attachment reaction of the heptakis(cyanomethyl) ester of cobyrinic acid: a) HPLC of the crude product before and after methanolysis. b) HPLC of the crude product (before methanolysis) of a reaction in the absence and in the presence of HCN in the reaction mixture [88].

begin to become important. It was initially thought that the $\alpha \rightarrow \beta$ exchange of the axial ligands in the acetato-cyano complex (originally postulated to occur rapidly) may take place too slowly under the conditions of the nucleotide attachment. However, experiments with the two configurationally uniform complexes provided only partial support for this interpretation: although the starting material/product ratios turned out to be complementary, e.g., 1:2 (starting from the α-acetato diastereomer) and 2:1 (from the β-acetato diastereomer), an all-or-none result was obtained in none of the experiments. The factors limiting both the conversion and the uniformity of the reaction course include, besides oxidations and disproportionations, the great propensity of the seven (or six) reactive cyanomethyl ester groups in both starting material *and* product to undergo transesterification with hydroxyl-containing components of the reaction medium or hydrolysis with traces of water.[95]

We interpret the kinetic regioselectivity of the nucleotide-attachment reaction of the heptakis(cyanomethyl) ester of cobyrinic acid, in the sense of the original working hypothesis, by the assertion that *the nucleotide loop to the propionic acid side chain of ring D of the vitamin B_{12} structure represents, of all possible regioisomers, the thermodynamically most stable loop* (Fig. 39). This statement has also been subjected (subsequently) to direct experimental test. By means of potentiometric pH measurements, *Kräutler*[99] determined the equilibrium constants for the intramolecular nucleotide complexation of the four iso-B_{12} hexamethyl esters (b, d, e, and f isomers, prepared by semisynthesis) and found the highest value for the f isomer. Furthermore, in a (preliminary) molecular modeling study, *K. Müller*[100] concluded that, of the four vitamin B_{12} isomers, the natural f isomer is expected to be the lowest in energy.

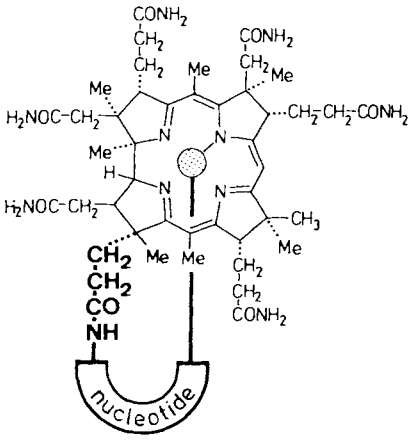

Fig. 39. The nucleotide loop in vitamin B_{12} containing the propionic side chain of ring D is the thermodynamically most stable nucleotide loop of all (four or seven) isomeric possibilities.

The findings discussed here teach us not to view the nucleotide loop of the vitamin B_{12} structure exclusively from a functional point of view. It is as though the vitamin B_{12} structure possessed an intramolecular code capable of directing the formation of a linkage between the corrin nucleus and the nucleotide chain selectively to the propionacyl group of ring D without need for external instruction. Also this structural element of the vitamin B_{12} molecule, the ring-D attachment of the nucleotide chain, is capable of self-assembly.

The present-day biosynthesis of vitamin B_{12} apparently makes no use of this capability. According to present knowledge,[101] the construction of the nucleotide loop occurs via a multistep sequence of reactions, in which the f-propionic acid side chain is converted into its 2-hydroxy-

propyl amide form and thus differentiated constitutionally from all the other carboxyl functions. This should not be surprising, since such a differentiation may well be the simplest solution for enzymes.

3.4. The Ligand Periphery: The Thermodynamic Favoring of the Type-III Arrangement of Substituents in Uroporphyrinogen-Type Structures

An analysis of the structure of vitamin B_{12} as attempted in this article should not omit a discussion of the uroporphyrinogen structures. One of these uroporphyrinogens, namely, type III, is the parent compound involved in the biosynthesis of all known porphinoid cofactors[102] (Fig. 40). Furthermore, the route via porphyrinogens is also chemically an efficient and structurally appropriate approach to the chromophore systems of these biomolecules (see Section 3.1). The central process of all porphinoid biosyntheses, the "tetrameroidization"[103] of the monopyrrolic precursor porphobilinogen, is what we might call a

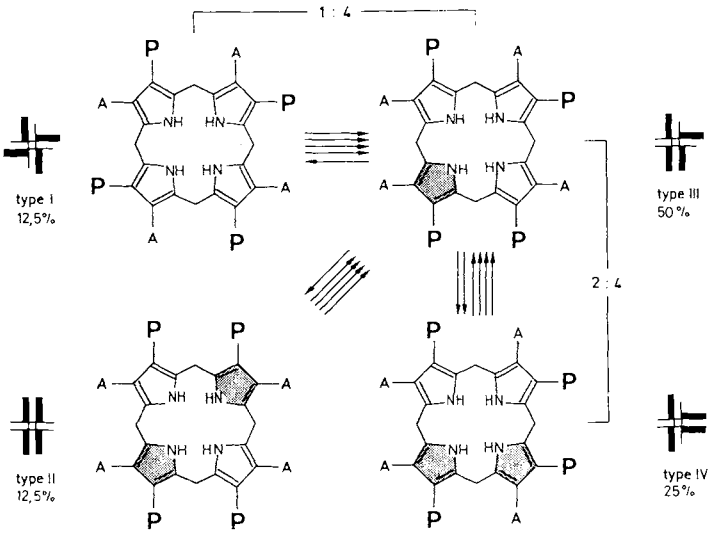

Fig. 41. Statistical favoring of the type-III constitution in the ensemble of the four isomeric uroporphyrinogens [14, 15, 106]. The arrangement of substituents in the grey regions deviates from type I.

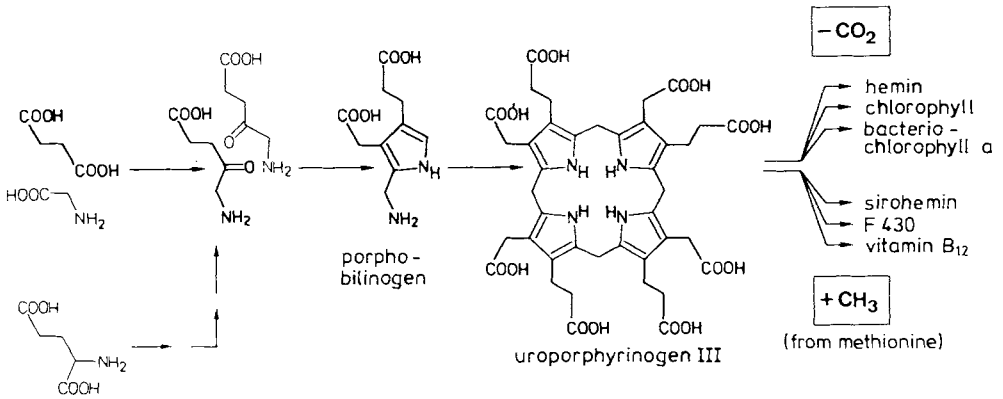

Fig. 40. Overview of the early stages in the biosynthesis of uroporphinoids [102, 104].

typical "chemomimetic" biosynthetic step insofar as such coupling of four porphobilinogen building blocks can also take place nonenzymically in the presence of acids with great ease.[14, 15] The salient feature of the *enzymically* controlled process is the diversion of the reaction sequence toward the selective formation of uroporphyrinogen type III.[104] This deviation from the straight reaction path to uroporphyrinogen type I (Fig. 41) is mechanistically complex, requiring an additional enzyme. The *nonenzymic* process most rapidly produces the type-I structure, but, under the influence of acids, the reaction course readily becomes thermodynamically controlled through isomerizations of the carbon framework to form a mixture of the four constitutionally isomeric uroporphyrinogens (types I–IV) in roughly the statistically expected ratio[14, 15, 106] of 1 : 1 : 4 : 2 (see *Mauzerall*'s[15] indirect analysis of such a reaction mixture[105]).

The statistical distribution of the four uroporphyrinogen isomers in equilibrium presupposes the (plausible) enthalpic equivalence of the isomers; the distribution is due to the isomers' differences in molecular symmetry, as visualized in Figure 41.[106] The equilibration can proceed via numerous reaction pathways, which are mechanistically related to one another. The diversity of pathways is due to the reversibility of a group of reactions, the prototype of which is the acid-catalyzed, electrophilic α-hydroxyalkylation of pyrroles by aldehydes.

The statistically favored isomer present in greatest amount in the equilibrium mixture of the four uroporphyrinogens is the biological isomer. A coincidence? Although this question is one of those that produce interpretations and not answers, this biomimetic chemosynthesis, or "chemomimetic" biosynthesis, of the uroporphyrinogen-type structure is a provocative phenomenon. Nature's enzymic acrobatics for selectively constructing the uroporphyrinogen (type-III) structure would certainly fit the idea of a biosynthesis that had to adapt itself to the structure of a nonenzymically preformed cofactor that was functionally already under enzymic control. This picture implies that the biological function was established for the *major product* (or a biologically functional derivative thereof) derived from a uroporphyrinogen mixture preformed under statistical control. Such a rationalization[16, 107] for the existence of the type-III structure of natural porphinoids would seem acceptable if, from a chemical perspective, the idea of a prebiotic origin of the uroporphyrinogen-type struc-

ture could be given "the green light." Experimentally, there is little experience that would be relevant in this connection apart from the finding that the nonenzymic simulation of the self-condensation of aminolevulinic acid was shown to proceed mainly in the wrong direction, leading only to a very small extent to porphobilinogen.[108, 109] Recently, however, as part of an extensive investigation of the chemistry of α-amino nitriles, a study was carried out in our laboratory that deals directly with potentially prebiotic routes to uroporphyrinogens. The results of this study, recently reported in detail,[110] are summarized in Figures 42 to 44.

A remarkably close structural connection exists between the nitrile form of glutamic acid and the monopyrrole derivative desaminomethylporphobilinogen, a connection that

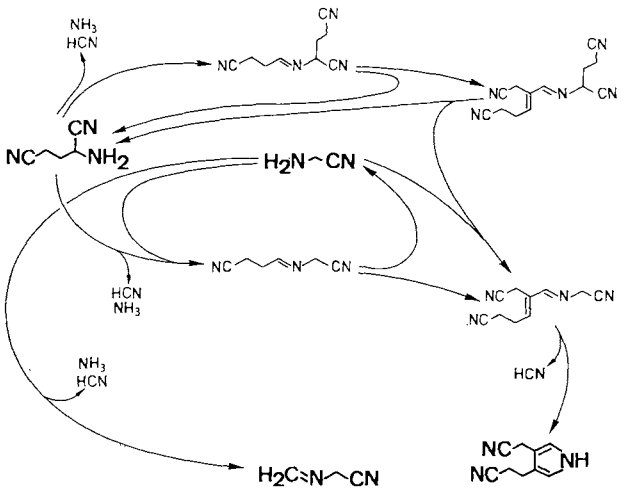

Fig. 42. General scheme for the formation of desaminomethylporphobilinogendinitrile from glutaminedinitrile and glycinenitrile [110] (cf. *G. Bold* [155]).

is evidenced in the existence of experimentally established reaction pathways linking glutaminedinitrile, glycinenitrile, and the dinitrile form of the pyrrole derivative. These reaction pathways exist as a consequence of the ability of α-amino nitriles to react as aldehyde imine derivatives; they are thereby capable of undergoing thermal coupling (with loss of HCN and NH_3) to give dimeroid or mixed imine derivatives. In the presence of weak bases in nonaqueous medium, such imine derivatives of glutaminedinitrile readily undergo condensation reactions analogous to aldol reactions. The condensation product formed from one glycine and two glutamine building blocks can thermally eliminate HCN to give (via electrocyclic ring closure of a carbenoid or ylidic intermediate) the pyrrole derivative. When this product is heated together with the trimer of *N*-methylideneglycinenitrile in acetonitrile with strict exclusion of oxygen in the presence of, for example, montmorillonite as catalyst, a mixture of the four isomeric uroporphyrinogenoctanitriles (types I–IV) is formed in high yield. The HPLC of the *crude product* of such a reaction (Fig. 43) reveals the statistical ratio of 1 : 1 : 4 : 2 for the four isomers. The efficiency of this complex reaction process is indeed extraordinary; even at a starting material concentration of 10^{-6} M (corresponding to 1 mg in ca. 5 L of acetonitrile!), the distribution is still detectable by HPLC.[111]

The nitrile forms of the four uroporphyrinogens show up in this study as a consequence of the imposed constraints decided upon in carrying out our investigation on α-amino nitriles. These not only include the exclusion of molecular oxygen[1,2] but also of water. Much of the specific reactivity of α-amino nitriles is obviated by the presence of water—insofar as this leads to hydrolysis of the nitrile group. The chemistry of α-amino nitriles has been largely unexplored, despite the fact that the *Strecker* α-am-

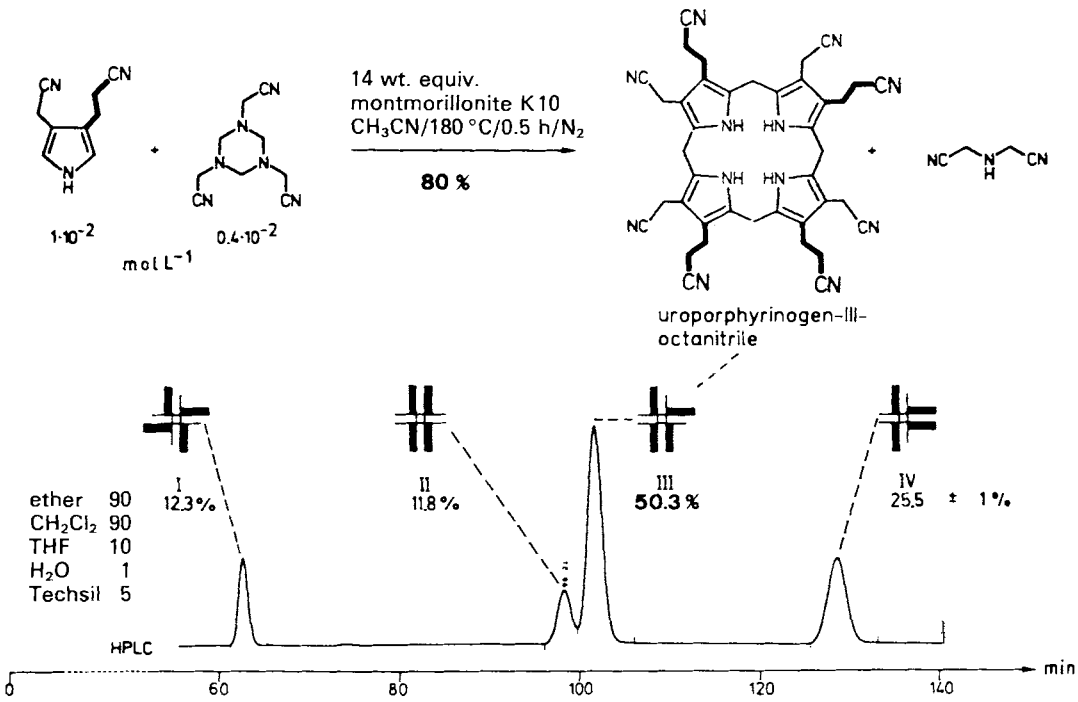

Fig. 43. "Tetrameroidization" of desaminomethylporphobilinogendinitrile with trimeric *N*-methylideneglycinenitrile in the presence of montmorillonite: HPLC of the crude product [110] (cf. *C. Lehmann* [111]).

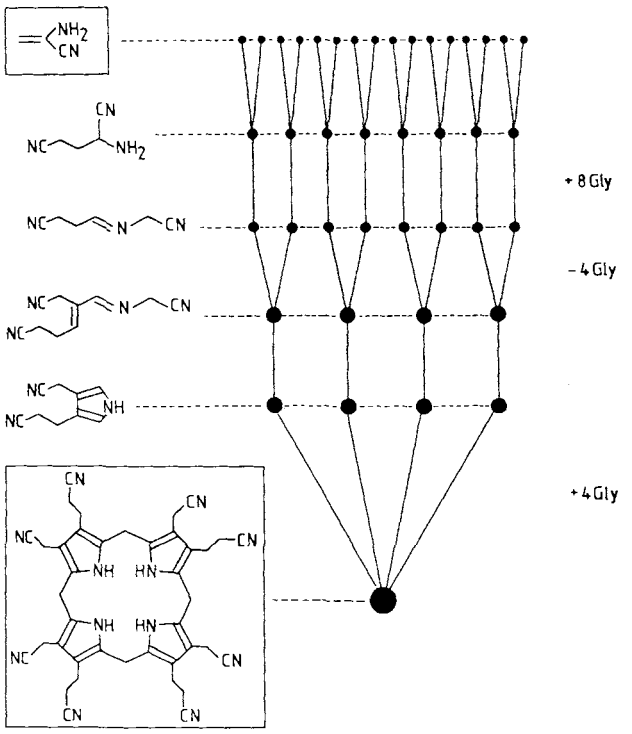

Fig. 44. Overview of the formation of uroporphyrinogenoctanitrile (type III) from 2-aminopropenenitrile (*G. Ksander* et al. [110]).

ino acid synthesis[112] has been carried out for over one hundred years and *Miller*'s experiments on the potentially prebiotic formation of α-amino acids[5] were first performed over three decades ago. In both cases, the primary interest relates to the hydrolysis products, the α-amino acids, and not to the unstable amino nitrile intermediates.

Figure 44 emphasizes the oligomeroidization aspect of the reaction sequence leading from glutaminedinitrile (or a photochemical precursor thereof[113]) all the way to uroporphyrinogenoctanitrile. This aspect is also characteristic for the biosynthesis of uroporphyrinogen (Fig. 40[102, 114]). In molecular synthesis, an oligomeroidization route is quite generally the strategy of choice if large molecules are to be built with a minimum number of precursors and steps. Not only biopolymers but also uroporphinoids provide examples.

With the ensembles of starting materials and reaction types outlined in Figures 42–44, alternative pathways undoubtedly exist that will lead to uroporphyrinogenoctanitrile percursors (including the nitrile form of porphobilinogen). In the "amino nitrile pathway" studied so far, glutaminedinitrile appears as the "natural" precursor of the uroporphyrinogen structure. The fact that one of the two known biosynthetic pathways to aminolevulinic acid starts from glutamic acid[115, 116] is noteworthy in this context.

To achieve the porphyrinogen→pyrrocorphin tautomerization (see Section 3.1) with uroporphyrinogenoctanitriles is somewhat more difficult than with the model octaethylporphyrinogen, because, under the reaction conditions found to be effective (see Fig. 45), not only the correspond-

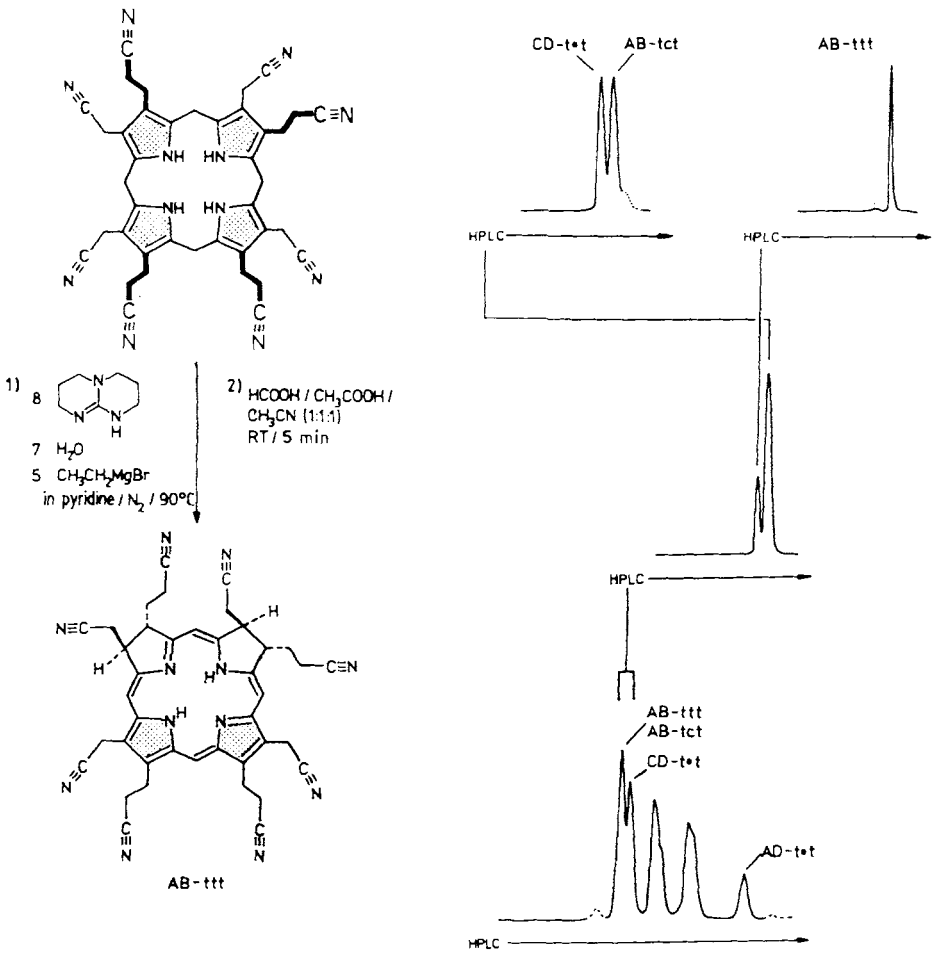

Fig. 45. One-step formation of 2,7-bis(desmethyl)sirohydrochlorinoctanitrile from uroporphyrinogenoctanitrile (*T. Früh* [117]). Conditions of HPLC (top to bottom): CH_2Cl_2/THF/H_2O (500:40:1), Techsil (SiO_2); ether/THF/H_2O (200:100:3), Partisil 10; AcOEt/pentane/H_2O (350:200:3), Techsil (SiO_2). AB-*ttt* was obtained in crystalline form and characterized by ^{1}H-NMR, UV/VIS, and FAB-MS data.

ing pyrrocorphins but also the corresponding isobacteriochlorins are formed (in roughly equal amounts), the latter by didehydrogenation. For the special case of the uroporphyrinogenoctanitrile type III, we undertook the isolation and spectroscopic identification of the constitutionally and configurationally pure AB-*ttt* isobacteriochlorin derivative; the isolation out of the complex mixture of isobacteriochlorin isomers was achieved by means of a three-step HPLC procedure[117] (see Fig. 45). We were motivated by the fact that this particular isomer corresponds to the ligand system of the natural sirohydrochlorin with respect to both its constitution and its configuration (see Fig. 46). The constitutional difference, apart from the nitrile form, lies in rings A and B, which bear protons in the places where the natural product has methyl groups. The iron(II) complex of sirohydrochlorin is the cofactor of sulfite and nitrite reductases[118] and, as a dihydro derivative, sirohydrochlorin is an intermediate in the biosynthesis of vitamin B_{12}.[69] *Thus, it is possible to reach the chromophore type of the simplest of the porphinoid coenzymes, starting from glutaminedinitrile and glycinenitrile, by means of a reaction sequence comprising a total of only five steps.*[119]

Too few of the experiments that seem desirable (both within and beyond the framework of constraints referred to above) have been carried out for making a concluding comment on the question as to whether—from the point of view of chemistry—the proposal of a prebiotic origin of the uroporphyrinogen-type structure is justified. However, in our opinion, the results shown in Figures 42 to 46 mean that we are given a "green light" to further thinking in this direction. Therefore, a chemical rationalization of the vitamin B_{12} structure must include—whatever the preformation steps between uroporphyrinogen and vitamin B_{12} may have been—the following statement concerning the specific constitution of the ligand periphery: *The arrangement of (modified) acetic acid and propionic acid side chains around the periphery of the vitamin B_{12} structure (as well as of all other uroporphinoid cofactor structures) corresponds to the thermodynamically favored arrangement in the structure type of the four isomeric uroporphyrinogens* (Fig. 47).

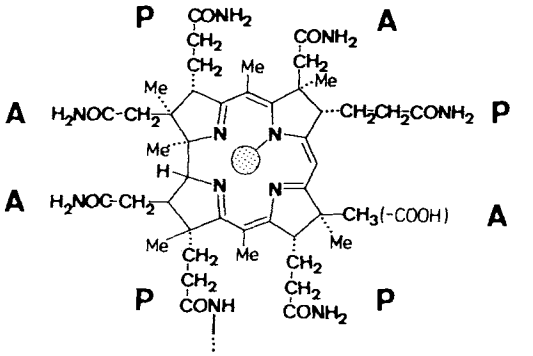

Fig. 47. The constitution of the ligand periphery of vitamin B_{12} reflects the statistically favored arrangement of the peripheral substituents for the four isomeric uroporphyrinogens.

4. Structure and Function

In the previous sections, we have dealt with synthetic aspects of the vitamin B_{12} structure, that is, essentially with preformation "chances," and omitted consideration of its function, the ultimately decisive criterion for its biological selection. The biological part of the function, its effect on and importance to the network of metabolic reactions, cannot be treated here. Instead, questions concerning the relationships between structure and molecular function for this cofactor will be dealt with—albeit in a fragmentary way. Despite the diversity of its enzymic reactions,[120] as an object of structure/function analysis, coenzyme B_{12} may well represent a lucky case among all the other coenzymes. As *Halpern*[121] was probably the first to point out clearly (see quotation in Fig. 48), the diverse molecular functions of coenzyme B_{12} can be summarized in terms of one generalized function, which consists in the coenzyme structure serving as a molecular reservoir for the dissociative generation of an alkyl radical (the 5′-adenosyl radical). The prevailing view at present is that this radical is the true catalytically active species in the B_{12}-catalyzed rearrangement reactions.[120-122] The cobalt-carbon bond of adenosylcobalamine (dissociation enthalpy of approximately 31 kcal mol^{-1} in ethylene glycol[121,123-125]) is evidently sufficiently strong for the coenzyme to be stable in the absence of light, but, at the same time, sufficiently weak that acceleration of dissociation by several orders of magnitude is possible merely by association of the coenzyme with B_{12}-enzyme proteins and with substrates.[126] It is this protein- and substrate-controlled acceleration of the reversible homolysis of the cobalt-carbon bond, that—above all other properties—a structure/function analysis of the coenzyme B_{12} structure must explain.

This problem has been recently approached by several research groups using theoretical,[127] kinetic,[121] spectroscopic,[128] and structural[129] methods. At present, attempts to interpret the phenomenon focus on an allegedly specific conformational flexibility of the corrin ligand, which should enable it to modulate, in a protein- and substrate-induced manner, the dissociation enthalpy of the cobalt-carbon bond. In reply to their question, "Why does Nature not use the porphyrin ligand in vitamin B_{12}?," *Halpern* et al.[130] have given the answer, supported by experimental data, that such flexibility is lacking in the porphyrin ligand.

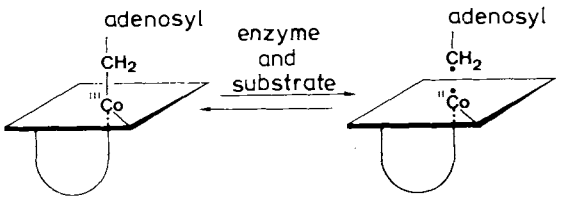

Fig. 48. Quotation from *J. Halpern* [121]: "Coenzyme B_{12} fulfills its biochemical role by serving as a *free radical reservoir* from which 5'-deoxyadenosyl radicals are reversibly released, just as oxyhemoglobin serves as a reservoir for the storage and reversible release of oxygen."

What alternative cofactor structures should be considered in analyzing the functional optimization of the vitamin B_{12} structure? The biosynthesis of vitamin B_{12} points to a clear answer. The structure type of a *corphinic* coenzyme B_{12} analogue stands out among all others. In terms of their charge and π-bond structure, corrins and corphins are (essentially) isoelectronic ligand systems. Nonetheless, B_{12} biosynthesis, in proceeding via a corphin intermediate (or a very close relative thereof)[33, 34] to cobyric acid (Fig. 49), involves a complex series of enzymic processes for the sake of transforming the 16-membered macrocycle of a (potential) corphin ligand system into the 15-membered ring of the corrin system. Such an additional investment of biosynthetic reaction steps must have functional reasons, quite apart from the aspects treated in Sections 2 and 3.2. An analysis of the cofactor structure should reveal these reasons.

A specific opportunity for our laboratory to make an experimental contribution to this problem consists in directly comparing the structural and chemical properties of cobalt

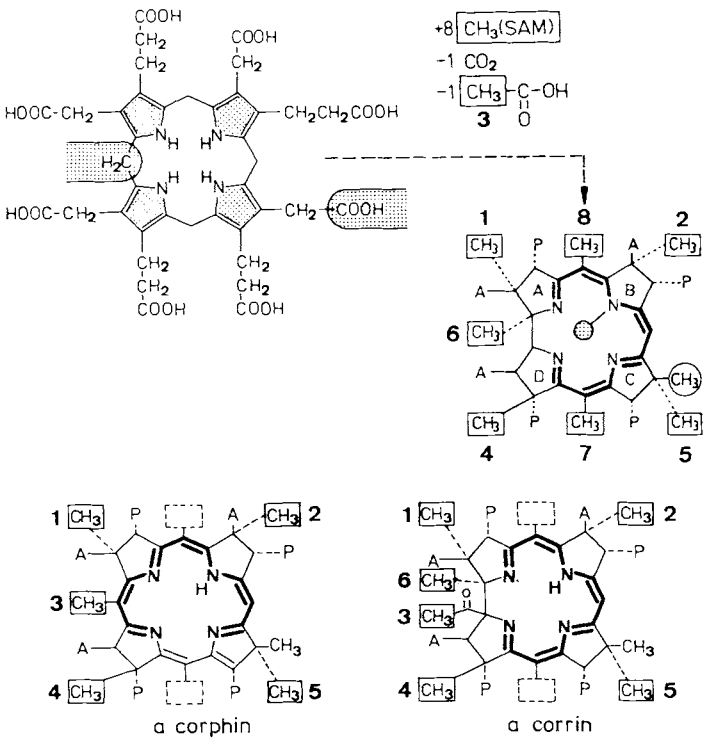

Fig. 49. Overview of the sequence of C-methylation steps in the biosynthesis of vitamin B_{12} (*A. R. Battersby* et al. [33, 60, 61], *I. A. Scott, G. Müller* et al. [34, 62]). SAM = *S*-adenosylmethionine.

complexes of the synthetic corrin and corphin models displayed in Figure 50, which we had prepared for other purposes in the course of earlier work.[47, 48, 76, 131] In addition, our investigations on hydrocorphinoid nickel(II) complexes have proved to be especially informative; we recently carried out such studies in connection with our work on the chemistry of coenzyme F430 (see Figure 54).[37, 132, 133] In fact, the discovery of this uroporphinoid nickel-containing cofactor with its unique hydrocorphinoid structure[81, 82] has in many respects stimulated our efforts and deepened our insight into the ligand-specific properties of corrin complexes.

Fig. 50. Synthetic model complexes for comparison of the properties of cobalt(III,II,I) complexes of corphin [47, 48] and corrin [76, 131] (*K. Zimmermann* et al. [140]).

Since the very start of our work on the synthesis of corrins[76, 134] and during all phases of this investigation, nickel(II) corrin complexes have served as model systems in developing the methodology of synthetic corrin chemistry. The reason has been the recurring experience that corrin complexes of divalent nickel exhibit an especially "simple chemistry." They resist decomplexation by all common demetalation methods (including reaction with KCN); they are stable toward light; they are always monocationic and tetracoordinated regardless of the counterion; they are diamagnetic in common solvents (including the relatively nucleophilic ones, such as acetonitrile and methanol) and are therefore accessible to normal ^{1}H- and ^{13}C-NMR spectroscopy, and their UV/VIS spectra are largely solvent independent. All findings indicate that the electrophilicity of the nickel(II)ion in corrin complexes is "saturated" by the equatorial coordination and that there is no observable residual electrophilicity in an axial direction. In contrast, the nickel(II) (hexafluorophosphate or perchlorate) complex shown in Figure 51, which was synthesized as a model of coenzyme F430,[37, 132] is a prime example of a corphinoid nickel(II) complex containing an electrophilically unsaturated nickel ion. Although the complex is diamagnetic (tetracoordinated) in dichloromethane, it is paramagnetic in the nucleophilic solvents acetonitrile and methanol. The nickel(II) ion is electrophilic in the axial direction, a property that is reflected preparatively in the finding that the complex reacts smoothly with potassium thiocyanate to give a neutral, covalent isothiocyanato complex, whose nickel(II) ion is pentacoordinated in (highly dilute) dichloromethane solution and hexacoordinated in the crystal

(Fig. 51). The X-ray crystal structure analysis of the isothiocyanato complex reveals a noteworthy structure, namely, a centrosymmetric (racemic) dimer in which the ligand-bound nitrile group of a given molecule serves as a sixth ligand for the nickel ion of an enantiomorphic partner molecule[133] (Fig. 51).

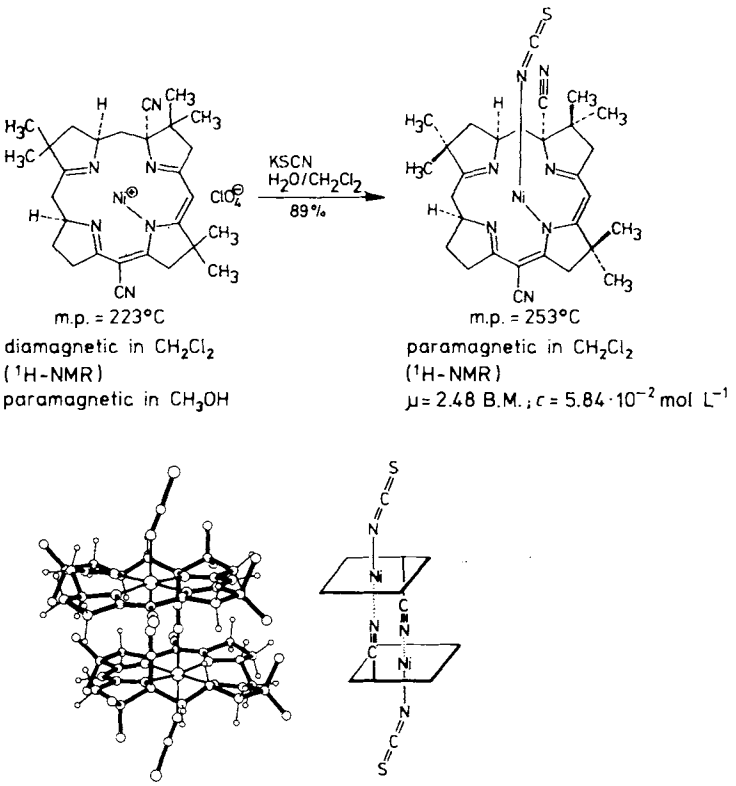

Fig. 51. Synthetic model for the coenzyme F430 from methanogenic bacteria; reactivity of the nickel(II) ion in the direction of axial coordination [132] (cf. *A. Fässler* [37] (see text).

In terms of the analysis presented in Section 3.2 concerning the structure of corphinoid nickel(II) complexes, there can be no doubt that an important cause of the difference in electrophilicity of nickel in corrin and (hydro)corphin complexes lies in the difference in the dimension of the coordination hole in the two types of ligand. A contracted, steeply ruffled ligand conformation is to be assumed for the tetracoordinated complex of Figure 51 in dichloromethane solution[135] and the strain energy due to this ruffling is to be assumed to take part in causing the residual axial electrophilicity of the nickel ion. The coherence of this qualitative picture is further confirmed by the structural data of Figure 52. Hexacoordination suppresses the propensity of the nickel(II) ion to contract the coordination hole and thereby to increase the strength of its equatorial coordination. Correspondingly, the conformation of the ligand reveals no sign of ruffling.[132]

In addition to the spatial factor, also the nitrile group attached to the chromophore contributes to the electrophilicity of the nickel ion in the F430 model complex. This nitrile group stands for the acyl substituent sitting at the corresponding position of the natural coenzyme. The effect of such a chromophore-bonded nitrile group is illustrated by the trends observed in the magnetic and electrochemical data obtained for the nickel(II) complexes shown in Figure 53. The nitrile group is evidently capable of causing a (dihydro)corphin complex, but not a corrin complex, to undergo hexacoordination (in methanolic solution). The A/D-secocorrin complex also shown provides, for comparison, a nickel complex whose central ion is not subject to the spatial coordination constraints of a macrocycle.

Of all corrinic and corphinic nickel(II) model complexes whose electrochemical reduction potentials have been determined in our laboratory by *Kräutler*[23b, 133] and *Jaun*,[133] the F430 model undergoes reduction most readily (compare the reduction in tetrahydrofuran, a solvent of low nucleophilicity). Recently, *Jaun* and *Pfaltz*[136] were able to show by ESR spectroscopy that the one-electron reduction of coenzyme F430 (in the form of its pentamethyl ester) is not ligand-centered—as suggested for the nickel(II) corrin complex[23b]—but metal-centered; i.e., it leads to the nickel(I) complex of F430. More recently, these authors, in studying the reductive chemistry of the pentamethyl ester of coenzyme F430, discovered a F430-catalyzed, reductive cleavage of *S*-methylsulfonium salts to give methane.[137] All this evidence points strongly to a central biological function of the nickel(I) form of coenzyme F430.

That a nickel(II) ion should be at the coordination center of a porphinoid cofactor that fulfills a coenzymic function in Nature was, at the time of its discovery, a surprise for us, because we had been conditioned by years of experience with chemically totally inert nickel(II) corrin complexes and by the sharp contrast between the chemically "boring" tetracoordinated nickel ion and the "so interesting" hexacoordinated cobalt ion. From our present standpoint, however, it is just this nickel coenzyme from methanogenic bacteria that has afforded—through its novel ligand structure—a deeper insight into the structure/function relationship of coenzyme B_{12} (Fig. 54). A monovalent, tetrahydrocorphinoid ligand system, whose coordination hole is too large for a (monocationic) nickel(II) ion and whose chromophore system is further substituted with an (electrophilic) acyl group (Fig. 54) is Nature's answer to the problem of selecting a cofactor structure from among uroporphinoid ligands that contains a firmly (macrocyclically) coordinated and yet electrophilic nickel(II) ion.[138] What particular property of the cobalt ion was selected for in the case of the corrin system? Taking the F430 structure as a reference may well facilitate answering this question. Figure 55 indicates how.

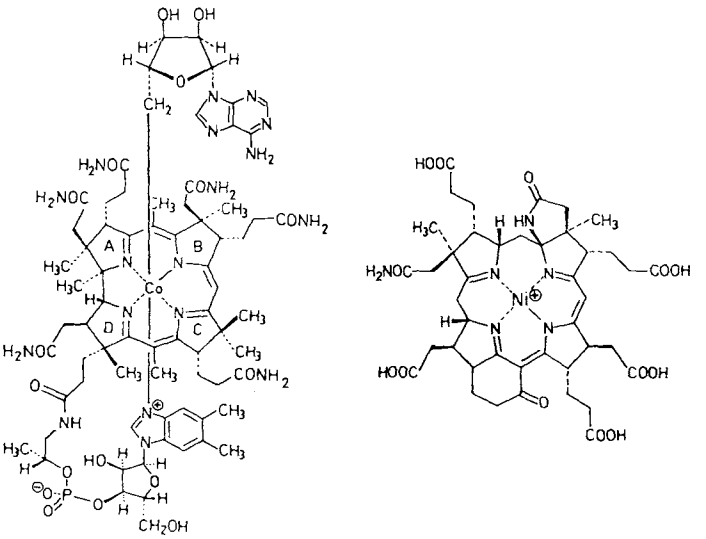

Fig. 54. Coenzyme B_{12} (left) and coenzyme F430 (right).

Extending the trend observed for the coordination number of nickel(II) complexes[139] (see Fig. 53) to the uniformly hexacoordinated cobalt(III) complexes leads to the following expectation: The binding energy of axial ligands in cobalt(III) *corrinate* complexes (ceteris paribus) should be weaker than that in cobalt(III) *corphinate* complexes and a dissociative ligand exchange via pentacoordinated cobalt(III) should occur more rapidly in *corrinate* complexes than in *corphinate* complexes. Ligand exchange occurring with a change in valence state via pentacoordi-

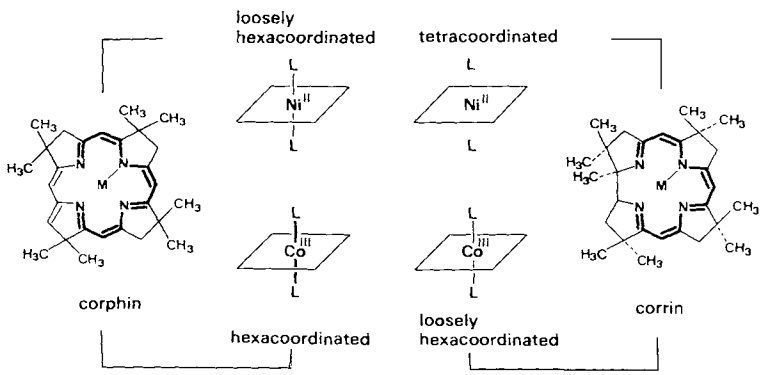

Fig. 55. A prognosis concerning the properties of axial ligands in cobalt(III) complexes of corphin and corrin.

nated cobalt(II) (e.g., the reversible homolysis of a cobalt–carbon bond) is more difficult to assess, but—compare the saddle-shaped ligand conformation of the pyridinato cobalt(II) pyrrocorphinate in Figure 25—should also be faster for *corrinates*.

The results obtained in a current study concerning the chemistry of synthetic model systems, e.g., the octamethylcorphinates and heptamethylcorrinates shown in Figure 50,[140] are only of a qualitative nature so far: The dicyanocobalt(III) *corphinate* is more stable toward acidolytic decyanidation (e.g., by silica gel during thin layer chromatography) than the dicyanocobalt(III) *corrinate*. The methylcobalt(III) corphinate complex is more difficult to prepare by Co^{I} methylation than the corresponding corrin complex; this is, first and foremost, due to the fact that the method of initial $Co^{III} \rightarrow Co^{I}$ reduction, e.g., with $NaBH_4$, which is so unproblematic with corrins, leads, in the case of corphinates, primarily to reduction of the ligand chromophore. Methylcobalt corphinate (perchlorate) eventually could be prepared under carefully controlled conditions by electrochemical $Co^{II} \rightarrow Co^{I}$ reduction in the presence of CH_3I;[141] it is—like the corresponding corrinate—a very sensitive compound. The methyl-transfer[142] equilibrium

$$CH_3Co^{III}(H_2O)\text{–corphinate} + Co^{II}(H_2O)\text{–corrinate} \rightleftharpoons Co^{II}(H_2O)\text{–corphinate} + CH_3Co^{III}(H_2O)\text{–corrinate}$$

(in methanol, 27 °C, exclusion of air and light[143]) favors the methylcobalt corphinate by a ratio of ca. 3:1. Noteworthy for the cobalt(II)(aquo) complexes is the observation that, in contrast to corrinates (and in analogy to the nickel(II) complexes), the UV/VIS spectrum of the Co^{II} corphinate is solvent dependent. Co^{II} corphinates are apparently hexacoordinated in nucleophilic solvents, whereas Co^{II} corrinates are pentacoordinated.[144]

Even these few qualitative observations concerning the properties of cobalt in a corphinate ligand indicate that the expectations depicted in Figure 55 are generally valid, but that one should not expect a significantly higher dissociation energy for a cobalt-alkyl bond in a corphinate compared with a corrinate. Of great interest would be a systematic comparison of corphins and corrins with respect to the kinetics of the ligand exchange reaction of cobalt(III) complexes proceeding dissociatively via cobalt(III), -(II), or -(I); the high rate of ligand exchange of vitamin B_{12} derivatives[145] may be a pertinent property in this connection. To get to the heart of the problem, it would seem desirable to construct a corphinic analogue of coenzyme B_{12} (including the nucleotide loop) derived from uroporphyrinogen (type III) via a chemical or a biosynthetic route.

5. Outlook

The experimental findings discussed in the four parts of Section 3 indicate that four characteristic structural elements of the vitamin B_{12} molecule represent thermodynamically favored structural fragments. However, a central goal of the investigation, namely, to discover reaction conditions under which a porphyrinogen transforms itself into a corrin (see Fig. 12), has not yet been attained. The important first hurdle along this way, the porphyrinogen → pyrrocorphin transformation, has been taken, and, moreover, a model for the final step, namely, the dihydrocorphinol → corrin ring contraction, has been found; however it has so far not been possible to connect the two. The outcome of extensive model studies makes us believe that it may be indispensable to carry out the search in the uroporphyrinogen series itself rather than in oversimplified model systems. In this context, an aspect emerges that must be considered to be part of the task of rationalizing the vitamin B_{12} structure: to give a rationale for the specific *site* of the corrinic direct ring junction. Rings A and D are the site of this direct ring junction, not the ring pairs A/B, B/C, or C/D (Fig. 56). This structural feature is just as specific for the vitamin B_{12} molecule as the corrin ring itself. Should we consider this feature as being merely fortuitous, or as related to function, or as a consequence of the preformation process? The contention upon which the chemical rationalization of cofactor structures is based would tend to disconnect this feature from the role of chance and does not rule out a priori a dependence on function, but, above all, assumes that this feature of the B_{12} structure is a specific consequence of structurally intrinsic factors. Once this point of view is taken, an attractive and, moreover, experimentally accessible possibility appears (Fig. 56): *Is the site of direct ring junction related to the fact that, in the uroporphyrinogen (type III), only the meso position between rings A and D has two flanking acetic acid side chains?*

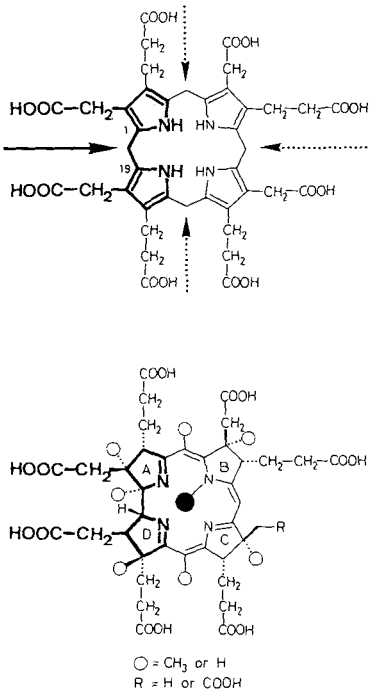

Fig. 56. Is there a relationship between the site of direct ring junction in the corrin ligand of vitamin B_{12} and the fact that in uroporphyrinogen (type III) only the *meso* position between rings A and D has two flanking acetic acid side chains?

Addressing this question experimentally is the next task in our synthetic analysis of the structure of vitamin B_{12}. The underlying working hypothesis, namely, the structural element in question is to be related to the preformation process and is therefore amenable to chemical rationalization, is typical of the overall approach used in this analysis. In each step, this approach can justify itself again and again only by producing experimental results that create a deeper insight into the architecture of the vitamin B_{12} molecule. The porphyrinogen→pyrrocorphin tautomerization and the regioselective nucleotide attachment reaction provide pertinent examples.

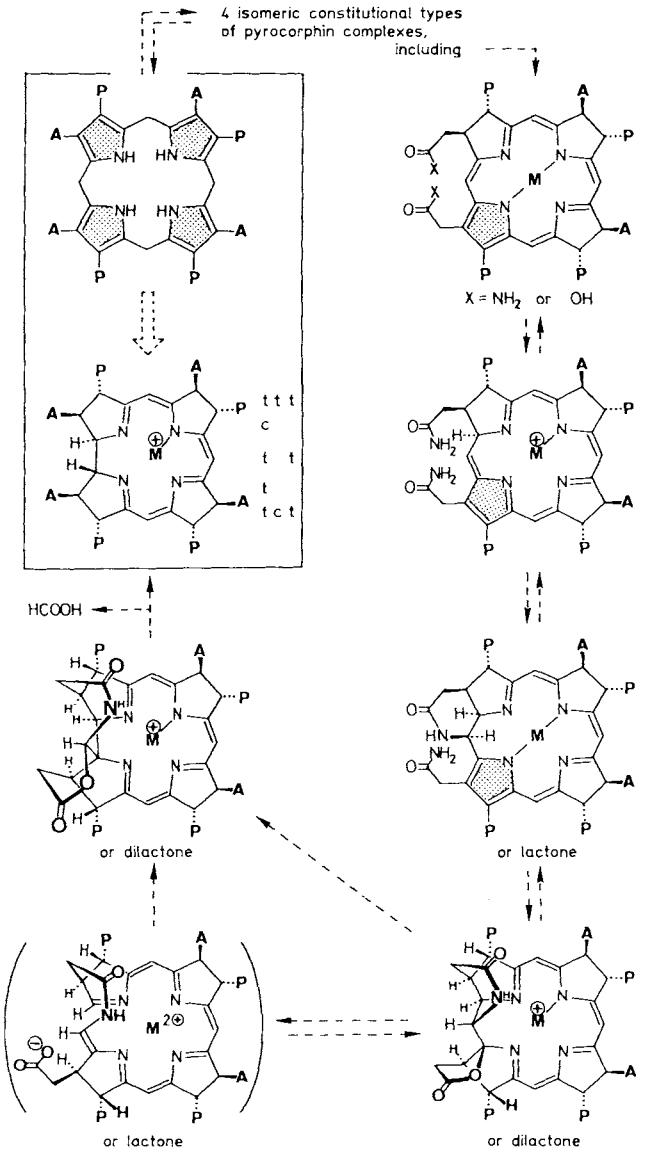

Fig. 57. Hypothesis for a regio- and stereoselective pathway from uroporphyrinogen (type III) to a proton analogue of cobyrinic acid.

Figure 57 summarizes a detailed *working hypothesis*. It integrates the wealth of observations made in our model studies (see Sections 2, 3.1, and 3.2), especially on the dihydrocorphinol→corrin transformation (Fig. 8). The proposed sequence of steps is believed to correspond to a reaction channel that connects uroporphyrinogen type III with proton analogues (Fig. 56) of cobyrinic acid regioselectively as well as diastereoselectively, and might require, in addition to a metal ion, only (unstructured) acid/base catalysis for this transformation. All steps of the reaction sequence prior to the ring-contraction step are expected to be reversible, thus making regioselection of the A/D structural region feasible. A (reversible) key step is the functionalization of the *meso* position between rings A and D by formation of a six-membered ring lactam (or lactone) group after protonation of the angular position C-1[146] (or C-19) of a pyrrocorphinate that has a pyrrolic ring D (or ring A). The ring-contraction step[30] is envisaged to occur as a dyotropic[147] 1,2-migration of antiperiplanar groups within a corphinoid lactam-lactone (or dilactone) to give the corrinoid isomer. The six-membered lactam (or lactone) ring thereby serves as a "*clamp*" which prevents a dissociative reaction course[31] or makes such a process reversible. As in the model of the dihydrocorphinol→19-acetylcorrin rearrangement (Fig. 27), the driving force for the ring contraction is supposed to be the contracting influence of a centrally coordinated metal ion (Section 3.2).

The hypothesis not only aims at a possible rationalization of the *topical* but also of the *configurational* aspect of the direct ring junction of the vitamin B_{12} structure. The steric course of the overall reaction occurring in the A/D region is viewed to be directed by the constitutional and configurational constraints of the (concerted) contraction step[148] and corresponds in all respects (protons in place of methyl groups!) to the specific configuration of vitamin B_{12} in the region of rings A and D (*trans-cis-trans-trans-trans*). If the substituents in the *peri* positions of the A/B, B/C, and C/D regions of the macrocycle are allowed to have the *trans* or *cis* configuration[149] but the vicinal substituents only the thermodynamically more stable *trans* arrangement (cf. Fig. 15), then, from among a total of 2048 racemic variants (4 constitutional types, each with 512 diastereomers), the reaction sequence formally selects eight diastereomers of one single constitution, all of which display the corrinic direct ring junction specifically between rings A and D.[150]

The numerous questions that we would very much like to address experimentally to an "urocorrin complex" such as the one shown in Figure 57 include the following one: Of the two acetic acid side chains in rings B and C, is it the latter—as would seem mechanistically reasonable[151]—that could be selectively decarboxylated? This question refers to a structural element of the vitamin B_{12} molecule not considered in our analysis of the cofactor structure so far.

The *biosynthesis* of cobyrinic acid from uroporphyrinogen (type III) occurs via a reaction sequence that, instead of (reversible) *C*-protonations, involves isoelectronic (irreversible) *C*-methylations, the sequence of which[60-62] does not correspond, however, to the protonation steps postulated in the hypothetical reaction scheme of Figure 57. Nonetheless, the way in which the two flanking acetic acid carboxyl functions can be integrated into the reaction pathway of the ring contraction prompts the question as to whether both these groups might be involved in the ring-

contraction process of vitamin B_{12} biosynthesis in a way not previously considered.[152] The course of the biosynthetic ring contraction has so far been traced only indirectly; the current notions concerning the details of this process[33,34,61,62] are mainly based on the chemical model, the dihydrocorphinol→19-acetylcorrin ring contraction.[30,31] With the structural formulas of Figure 58, we would like to indicate a way in which that ring-contraction principle might be realized in the biosynthesis.[153]

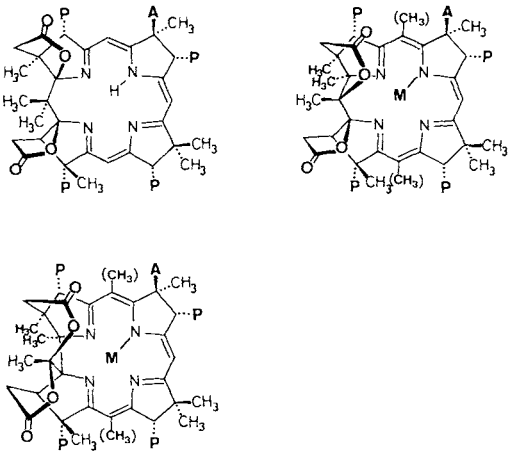

Fig. 58. Hypothetical intermediates along the route of ring contraction in the biosynthesis of vitamin B_{12}. M = H or metal ion.

The project of "chemically rationalizing the vitamin B_{12} structure" aims ultimately at providing chemical reasons for the fact that this specific molecular structure has been biologically selected as a cofactor. The search for relationships between structure and function represents one part, the mechanistic one, of this endeavor. It does not need to be further emphasized that this part will require consideration of the structure of the proteins involved in exercising this function. The other part, the synthetic one so to say, is to arrive experimentally at a perception of the biomolecule's intrinsic potential for structural self-assembly, the attempt to identify the structural factors that played a part in determining the course of its preformation steps—regardless of whether they ultimately were prebiotic or biotic. Whether, to what extent, and in what manner the prerequisites of steps leading to such a self-assembly include the assistance of enzymic catalysis is part of the overall problem. The challenge posed by the complexity of this cofactor's structure has caused two directions of research to come together and to complement each other in a synergistic manner, namely, the systematic mapping of the biosynthetic pathway on the one side, and the chemical search for the structure's potential for self-assembly on the other. The way in which this convergence takes place in this special case should perhaps be considered as a guide to how it may be possible—in concert with studies on structure/function relationships—to arrive at rational concepts concerning the origin of cofactor structures. Regardless of how far away one is from valid concepts of this kind, whatever their form and significance might assume or demand, the path leading in that direction along strictly experimental grounds is bound to result in a deeper understanding of the structures of biomolecules. Research in natural product synthesis is of crucial importance in following this path. The ultimate goal is an insight into the principles that govern the molecular architecture of biomolecules and a chemically founded view regarding the nature and extent of their structural predestination.

The following doctoral and postdoctoral researchers (in chronological order) have taken part, since the mid-1970s, in the work described here or in related work: Bernhard Kräutler, Andreas Pfaltz, Reinhard Neier, René Nordmann, Vittorio Rasetti, Christof Angst, Silvio Ofner, Beat Zehnder, René Lattmann, Kurt Hilpert, Alexander Fässler, Rudolf Waditschatka, Rolf Nussberger, Guido Bold, Christian Leumann, Thomas Früh, Christian Lehmann, Ulrich Kämpfen, Fritz Kreppelt, André Kobelt, Wlodzimierz Iwanowski, Kaspar Zimmermann (Doktoranden); Franz-Peter Montforts, Paul Naab, Masuhiro Kajiwara, Engelbert Zass, James Rigby, Gary Ksander, Reinhard Schwesinger, Jon Eigill Johansen, Mitsunori Ono, Virginia Piermattie, Günter Bartels, John Norman Lewis, Katsuhiko Inomata, Anthony Davis, Douglas Livingston, Karl Grubmayr, Jean-Christophe Plaquevent, Susan Thomas, Sundeep Dugar, Wolf-Ulrich Nickel, Michael Göbel, Jerome Hayes (Postdoktoranden).

I would like to express my deep appreciation and gratitude to all my former and present collaborators. Their contributions and achievements, their knowledge and skills, and their enthusiasm have often greatly inspired me. I would like to extend my special thanks to my scientific colleague and friend Dr. Jakob Schreiber, a member of our research group since the beginning, without whose autochthonous genius in experimental and instrumental matters our work would have been much more difficult if not impossible. I express my gratitude to Dorothee Felix, the "good spirit" of our group, for her continual help and faithful cooperation. I would also like to emphasize the names of my former Doktoranden and current Privatdozenten Bernhard Kräutler and Andreas Pfaltz, whose special competence in the areas of corrin and corphin chemistry have decisively enriched the research of our group. Our group has been particularly lucky to have as members the married couple Dr. Engelbert and Hermine Zass-Gächter; I would like to express to both my high opinion of their work as well as my gratitude. The numerous X-ray structure analyses that have been so crucial in our work were all performed in the laboratory of Privatdozent Dr. Christoph Kratky (Institut für Physikalische Chemie der Universität Graz); I owe him thanks for a very fruitful collaboration.

Our work was generously supported by the Schweitzerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung, by Ciba-Geigy AG in Basel, and by Firmenich & Co. in Geneva.

[44] One-step arrows correspond to cyclization steps that lead directly to corrins or corrin complexes; two-step arrows stand for reaction sequences in which the cyclization step results in the formation of a dehydro derivative of a corrin, which then is (or would have to be) subjected to reduction (or hydrogenation) to give the corrin. Parallel arrows indicate that several variants of the reaction are known. The literature quotations for the types of cyclization included in the figure are presented in the text, with the exception of the first variant at the above left (C. Leumann, A. Eschenmoser, *J. Chem. Soc. Chem. Commun. 1984*, 583); see also C. Angst, C. Kratky, A. Eschenmoser, *Angew. Chem. 93* (1981) 275; *Angew. Chem. Int. Ed. Engl. 20* (1981) 263.

[46] An exception is provided by the observation reported by *H. W. Whitlock, Jr.*, and *D. H. Buchanan* (*Tetrahedron Lett. 1969*, 3711) that, in CH_3COOD, the hydrogen atoms of all four *meso*-methylene groups of octaethylporphyrinogen are rapidly replaced by deuterium. *U. Eisner* (*J. Chem. Soc. 1957*, 3461) assigned a reduction product obtained from iron(II) octaethylchlorinate to a pyrrocorphin-type constitution; however, subsequent work in our laboratory proved this assignment to be incorrect [50, 52]. The sole characterized derivative having a pyrrocorphinate structure was a palladium(II) complex prepared by *N. Müller* and *H. H. Inhoffen* (unpublished results, cf. N. Müller, *Dissertation*, Technische Universität Braunschweig 1969).

[143] The equilibrium position was determined for the corresponding trideuteriomethyl derivatives by ^{2}H-NMR spectroscopy after workup of the equilibrium mixtures with methanolic HCN in the presence of air ($Co^{II} \rightarrow Co^{III}(CN)_2$).

[144] The following cobalt(II) corrinate complexes investigated by X-ray analysis display pentacoordination at the cobalt(II) ion. The heptamethyl ester of iodocobalt(II) cobyrinic acid [92]: E. Edmond, D. Crowfoot Hodgkin (details not published), *cf. D. Crowfoot Hodgkin in* B. Zagalak, W. Friedrich (Eds.): *Vitamin B_{12}*, de Gruyter, Berlin 1979, p. 19, and review by J. P. Glusker in D. Dolphin (Ed.): *B_{12}, Vol. 1*, Wiley, New York 1982, p. 23. The heptamethyl ester of aquacobalt(II) cobyrinic acid perchlorate: B. Kräutler, W. Keller, M. Hughes, C. Caderas, C. Kratky, *J. Chem. Soc. Chem. Commun. 1987*, 1678. Cobalt(II) cobalamine: personal communication Priv.-Doz. Dr. *B. Kräutler*.

[145] Cf. P. Schulthess, D. Ammann, W. Simon, C. Caderas, R. Stepánek, B. Kräutler, *Helv. Chim. Acta 67* (1984) 1026.

[146] Compare the complexation/tautomerization of octaethylporphyrinogen to a hexahydroporphinate complex, the formation of which presupposes a protonation of the C-1 position of the chromophore system [50, 52].

[147] M. Reetz, *Angew. Chem. 84* (1972) 161; *Angew. Chem. Int. Ed. Engl. 11* (1972) 129.

[148] Only when (assuming the β configuration of the acetic acid chain at C-2) the protonation at C-1 (ring A) occurs in the α position is a six-membered lactam (or lactone) ring formed on the β side, and only when the proton at C-18 (ring D) likewise enters from the α side does the acyloxy function of the five-membered lactone ring (in the β position) end up antiperiplanar to the C–C bond migrating on ring contraction. Under thermodynamic control, vicinal substituents (e.g., in pyrrocorphinates, Fig. 15) always exhibit the *trans* configuration. The subsequent deformylation step leads to a 1,19-*trans*-corrin complex [30] (cf. Fig. 8); 1,19-*cis*-corrin complexes are unknown; the synthesis of such a complex had been attempted at the time (A→B ring-closure method [76]), but was unsuccessful (M. Roth, *Dissertation No. 4668*, ETH Zürich 1971, p. 116–123).

[149] The following finding [51] is relevant for this question: The complexation/tautomerization (occurring with dehydrogenation) of octaethylporphyrinogens in the presence of cobalt(II) ions has afforded mainly two diastereomeric isobacteriochlorins (*ttt* and *tct*) with the *ttt* isomer as the major product (ca. 2:1).

[150] All vicinal substituents in *trans* arrangement, A/D configuration sequence *tctt* or *tttct*; under these preconditions, the *peri*-configuration sequence only can be either *ttc*, *tct*, *ctt*, or *ccc*.

[151] Of all the positions allylic to the chromophore system in a corrin complex, the positions *C-8* (ring B) and *C-12* (ring C) are most easily deprotonated (cf. D. Bormann, A. Fischli, R. Keese, A. Eschenmoser, *Angew. Chem. 79* (1967) 867; *Angew. Chem. Int. Ed. Engl. 6* (1967) 868.

[152] *Uzar* and *Battersby* [60] have considered a different kind of involvement of the ring-D acetic acid chain.

[153] Figure 58 implies that the C-1 methyl group would be introduced via a prior α-methylation of the *meso* position C-20. This methylation mode corresponds to the (nucleophilic) reactivity expected for a corphin chromophore. The dyotropic migration of the methyl group to the C-1 position would convert a 1,19-*cis*-homocorrinate into a (presumably more stable, cf. [37] pp.82–86) 1,19-*trans*-homocorrinate and thereby create the configurational preconditions for a subsequent ring contraction via dyotropic migration.

Natural Fats and Oils—Renewable Raw Materials for the Chemical Industry

By Horst Baumann, Matthias Bühler, Heinz Fochem, Frank Hirsinger, Hans Zoebelein, and Jürgen Falbe*

Since last century, the supply of raw materials for the chemical industry has undergone a radical change. Whereas at the beginning of the nineteenth century the demand for basic chemicals was satisfied entirely by renewable raw materials, from about 1850 the chemical industry came to rely increasingly upon coal. In the 1940's, mineral oil started to become increasingly important, and during the past thirty years it has remained by far as the most important source of raw materials. Renewable raw materials are likely to become important again in the future, as the choice of raw materials is now of great significance not only for economic reasons by influencing competitiveness, but also because this choice largely determines the properties of the derivatives produced and their ecological effects. Following the two oil crises of the 1970's, there is also now a growing awareness of the limits of raw material resources, and against the continuing background of agricultural surpluses, chemists are again showing an increasing interest in renewable raw materials. Since the end of the seventies, the Bundesministerium für Forschung und Technologie (Ministry of Research and Technology of the Federal Republic of Germany) has supported research projects on renewable raw materials in universities and in industry. For the chemical industry the use of natural products as raw materials opens up a wider spectrum of synthetic methods and finished products, some of which are not accessible by petrochemical routes.

1. Introduction

Mineral oil is at present the most important source of raw materials for the chemical industry. Natural gas, coal and renewable raw materials are used to a much lesser extent for this purpose. However, in the future this situation will change quite significantly. Natural products which are already processed by the chemical industry and used in many fields of application include in particular sugar, starch, cellulose, proteins and natural fats and oils. Many of the products thus obtained cannot be produced economically by petrochemical routes.

Table 1 gives a summary of the present consumption of renewable raw materials. The largest share is taken up by oils and fats of vegetable and animal origin. These alone have a wide range of chemical applications (Table 2) which is scarcely less than that of petrochemicals.

2. Economic Aspects

2.1. Demand

World production of oils and fats in 1985 was about 68.2 million tonnes, of which only 9.5 million tonnes (14%) was used for chemicals. 80% of the world production was used in foodstuffs and 6% in animal feeds. Taking the consumption of oils and fats in the EEC countries in 1985 as an example, an analysis of the market structure shows that, of

Table 1. Present consumption of biological raw materials by the chemical industry (estimated).

Raw material	German Federal Republic	EEC	World
	k tonnes/yr		
Sugar	15	65	800
Starch	115	390	1750
Cellulose	220	600	5014
Oils and fats	700	2700	9500

Table 2. Areas of application of oils and fats in the chemical industry.

Fatty acids and derivatives	→	Plastics; metal soaps; washing and cleaning agents; soaps; cosmetics; alkyd resins; dyestuffs; textile, leather and paper industries; rubbers; lubricants
Methyl esters of fatty acids	→	Cosmetics; washing and cleaning agents
Glycerol and derivatives	→	Cosmetics; toothpastes; pharmaceuticals; foodstuffs; lacquers; plastics; synthetic resins; tobacco; explosives; cellulose processing
Fatty alcohols and derivatives	→	Washing and cleaning agents; cosmetics; textile, leather and paper industries; mineral oil additives
Fatty amines and derivatives	→	Fabric conditioners; mining; road-making; biocides; textile and fiber industries; mineral oil additives
Drying oils	→	Lacquers; dyestuffs; varnishes; linoleum
Neutral oil derivatives	→	Soaps

[**] The figure on the preceding page shows some examples of renewable raw materials (clockwise from top center): soybeans, rapeseeds, castor beans, linseed, jojoba seeds, and sunflower seeds; the center of the picture shows part of a coconut palm with fruit.

the total consumption of 2.7 million tonnes, about 2.2 million tonnes (80%) consisted of raw materials which contain fatty acids with 16, 18 or higher numbers of carbon atoms. In this latter class, animal fats accounted for about 1.4 million tonnes (64%) consisting mainly of tallow and other non-edible animal fats, which find valuable applications with the help of chemistry.

Vegetable oils and fats with a chain length of at least C_{16} accounted for a further 800000 tonnes. These were mainly imported directly from third world countries. For example, rapeseed oil and castor oil came from Eastern Europe, Brazil and India. Other raw materials were imported in the form of oil fruits or seeds (linseed, soybean) from Canada, the USA, Brazil and Argentina. From EEC sources came sunflower oil and rapeseed oil with a low erucic acid content, the estimated total of these being almost 300000 tonnes.

For animal products the share coming from EEC sources was only 300000–400000 tonnes. The main sources of imports were the USA, Canada, Australia and New Zealand. Oils and fats with shorter chains, e.g. C_{12} and C_{14}, are nearly all imported in the form of coconut and palm kernel oil from South East Asian countries.

The present agricultural surpluses also lead to the possibility of using EEC butter as a raw material in the chemical industry. However, the particular distribution of fatty acids in butter calls for new process technologies, and appropriate research programs have already been started. Olive oil is also a surplus product, especially since the entry of Spain and Portugal into the EEC, and here, too, there are interesting possible industrial uses. However, butter and olive oil can only be introduced as chemical raw materials if they continue to be available at moderate costs over a long period.

2.2. Price Variations

Oils and fats are traded as commodities in international raw materials markets such as those in Chicago and Kuala Lumpur and are consequently subject to daily price fluctuations. The chemical process industry attempts to average out these fluctuations by its policies of buying and storing materials. As examples of market price trends for natural oils and fats, Figure 1 shows prices covering the period 1962 to 1987 for the US tallow "Bleachable Fancy" and for coconut oil, compared with naphtha as an example of a petrochemical raw material. Despite a few marked price jumps, the average annual rates of increase over the past 25 years (based on prices in DM) for coconut oil (2.20%/yr) and tallow (2.15%/yr) are below the overall rate of inflation, and are much lower than the average rate of increase for petrochemical products. These trends are likely to continue.

3. Raw Materials for the Oleochemical Industry

3.1. Animal Oils and Fats

Animal oils and fats have already been used for many years as raw materials in the oleochemical industry. Figure 2 summarizes the fatty acids composition of pork fat, beef fat and butter. It can be seen that animal oils and fats are made up chiefly of saturated and mono-unsaturated C_{16} and C_{18} fatty acids. Butter also contains some fatty acids with shorter chain lengths.

Under EEC regulations with regard to waste disposal (which are incorporated into the waste disposal regulations of the Federal Republic of Germany), tallow products arise unavoidably from abattoir wastes, and are used

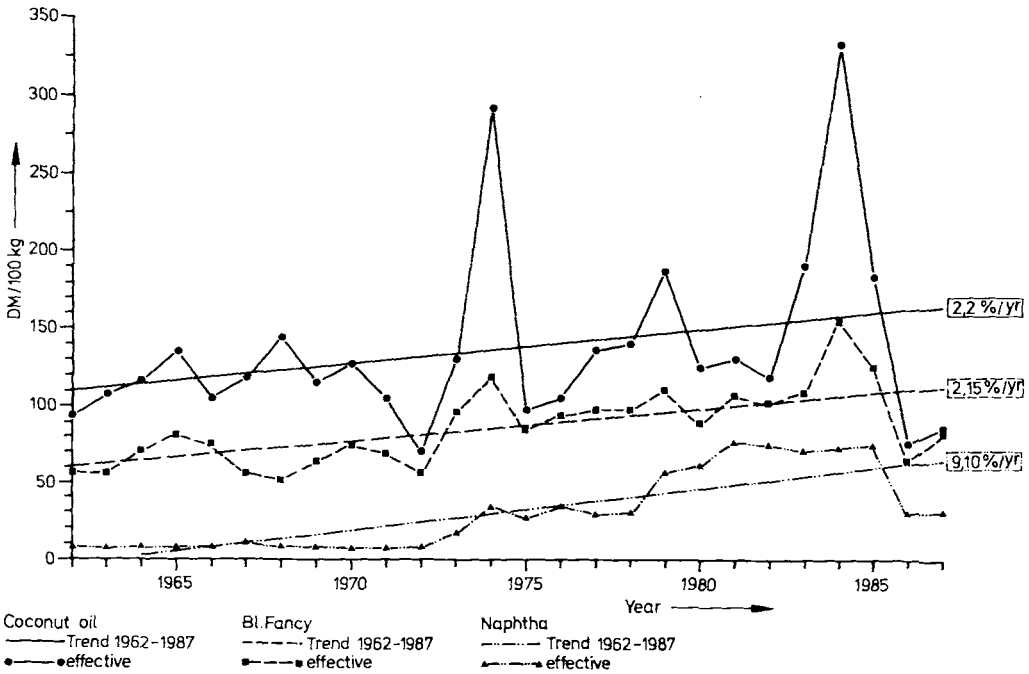

Fig. 1. Variation in price of coconut oil, US tallow ("Bleachable Fancy), and naphtha (1962-1987).

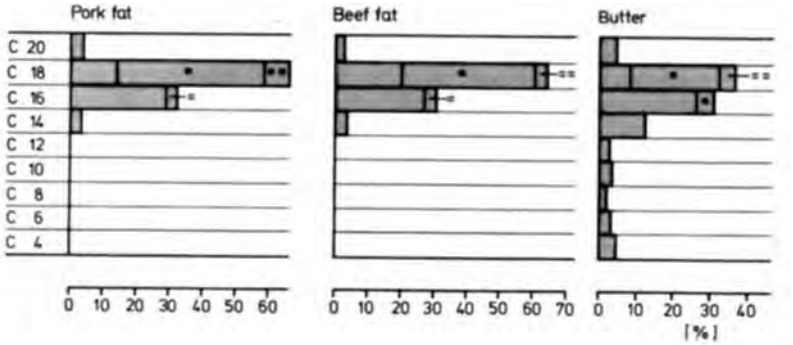

= Number of double bonds in the fatty acid chain

Fig. 2. Fatty acid composition of some animal fats.

profitably in animal feeds and in the soap and oleochemical industry.

Figure 3 summarizes the world production of individual types of animal oils and fats and also the use of tallow divided into edible and non-edible products.

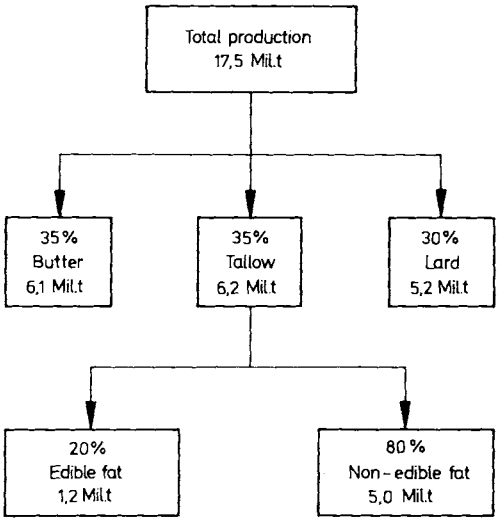

Fig. 3. World production of animal fats and oils (1985).

Because tallows unsuitable for human consumption are comparatively cheap and fairly consistent in their fatty acids composition, which is important for chemical derivatization processes, animal oils and fats now constitute the largest share of renewable raw materials used industrially.

$CH_3-(CH_2)_{14}-COOH$ **1**

$CH_3-(CH_2)_{16}-COOH$ **2**

$CH_3-(CH_2)_7-\underset{cis}{CH=CH}-(CH_2)_7-COOH$ **3**

Lard and tallow are the principal sources of the saturated and mono-unsaturated fatty acids palmitic **1**, stearic **2** and oleic acids **3**. However, vegetable oils and fats are also becoming increasingly important in this area (cf. Section 3.3.1).

3.2. Marine Animal Oils and Fats

Oils and fats from marine animals contain, in addition to C_{16} and C_{18} fatty acids, larger quantities of polyunsaturated C_{20} and C_{22} fatty acids (see Fig. 4). Up to the 1970's, sperm whale oil was of considerable importance for certain areas in which oleochemicals are used. However, as a result of legislation to protect endangered species, it has no longer been permissible, since January 1, 1982, to import these types of oils into the EEC.[1]

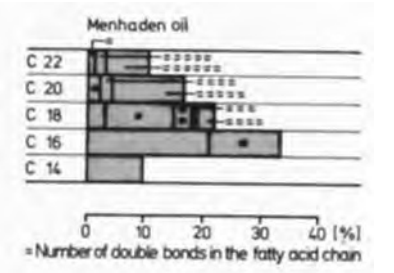

Fig. 4. Fatty acid composition of menhaden oil as an example of marine animal fats and oils.

3.3. Vegetable Oils and Fats

3.3.1. Sources and Importance

World production of vegetable oils and fats in 1985 was 49.4 million tonnes, which represents almost a fourfold increase since 1950. By contrast, world production of animal oils and fats increased by a factor of only two during the same period (Table 3).

Table 3. World production of natural oils and fats in M tonnes.

Year	Vegetable oils and fats	Animal oils and fats (including marine animal oils)	Total
1950	13.9	9.3	23.2
1960	18.6	13.6	32.2
1970	26.2	13.9	40.1
1980	43.2	17.3	60.5
1985	49.4	18.8	68.2

Figure 5 shows the countries which are most important as exporters of vegetable oils and fats. Soya is grown chiefly in the USA, Brazil and China, while palm oil comes

	Soybeans		Cotton seeds		Castor beans

	Ground nuts		Linseed		Olives

Fig. 5. Chief exporters of renewable fat raw materials.

mainly from Indonesia, Malaysia and other South East Asian countries. Table 4 gives an overview.

The data given in Table 5 for the predicted future production of important vegetable oils and fats indicate that the greatest increase is expected for palm oil. The predictions are based on the areas of existing plantations, planned areas for further cultivation, and maximization of the oil content of the crops through breeding. For soybean oil a rapid growth in production is also expected up to 1995 taking into account the EEC's declared intention of achieving increased crop production in the EEC as well as in Brazil and Argentina.

Table 4. Production of renewable raw materials in M tonnes listed according to products and countries (1985).

Product	Important producers	Amount
Soybeans	USA/Brazil/China	14.7
Rape/rape-seed	India/Canada/Europe/China	5.5
Sunflower seeds	East & South Europe/Central & South America	6.2

1995	19	18	6	8.2

3.3.2. Composition and Biogenesis of Vegetable Oils and Fats

The storage of oils and fats in plants occurs mainly in seeds and fruits. Table 6 summarizes the broad spectrum of vegetable fatty acids.

There is no indication that evolution has led to the preferential formation of one or another particular fatty acid in a certain species of plants. Within a species the pattern of fatty acids shows little variation. Consequently, the fatty acid composition of seeds has assumed great taxonomic importance for classifying plant species and families.[2]

Table 6. Fatty acids contents [%] in the seed oil of common oil crops. The column headings "m : n" signify: m = number of carbon atoms, n = number of double bonds. 18 : 1 = oleic acid **3** (+isomers); 18 : 2 = linoleic acid **13** (+isomers); 22 : 1 = erucic acid (+isomers).

Extensive studies by *Pohl* and *Wagner*[3] have established certain well-defined trends in the formation of fat reserves in plants. In the Bacteriophyta there is a strong preference for fatty acids with C_{14} and C_{16} chains. In the Rhodophyta, on the other hand, a preponderance of C_{20} fatty acids has been established in the course of their evolution. Lastly, in the Spermatophyta one finds a preference for C_{18} fatty acids. This evolutionary trend in the biosynthesis of fatty acids is also reflected in the phylogenesis of plants, e.g. in the maturing seeds of soybean and rapeseed.[4,5]

According to *Röbbelen* and *Thies*,[6] the evolutionary strategy in plant biosynthesis of fatty acids is directed towards the biochemical necessity of keeping the melting points of the oils as low as possible, sometimes by introducing double bonds or by conversion into the *cis* isomers (see Fig. 6). This strategy also appears to be one of the reasons why plants, in contrast to animals, have developed such a great variety in the formation of unusual fatty acids (see Fig. 7).

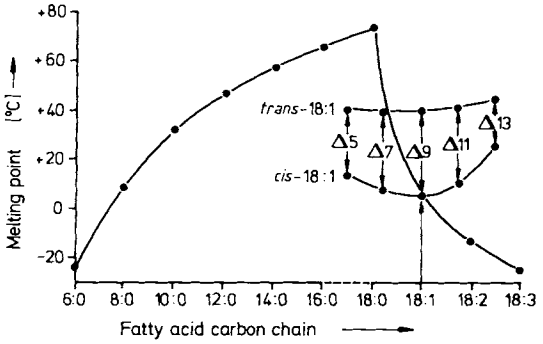

Fig. 6. Dependence of the melting points of synthetic triglycerides on the structure of their constituent fatty acids. The increase in melting point with increasing length of the carbon chain can be compensated by the incorporation of double bonds. *Cis*-isomers have lower melting points than *trans*-isomers (according to data quoted by *Gunstone* (1979) and Henkel KGaA (1971) and cited by *Röbbelen* and *Thies* [6]).

3.3.3. New Sources of Vegetable Oils

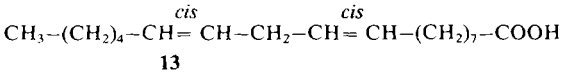
Extensive crop research programs have been undertaken to meet the increase in demand for renewable resources as well as to improve existing products. For this, both conventional breeding techniques and newer biotechnological methods are being used. Some of the most important characteristics typically aimed at in such work are as follows:

- consistent germination,
- predictable growth pattern,
- growth little affected by length of day (neutral photoperiodicity),
- consistent ripening,
- resistance to plant diseases and pests,
- a fatty acid distribution of interest for oleochemistry,

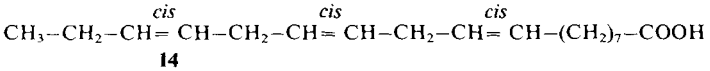
- oils and fats with functional groups,
- a high content of a single fatty acid,
- waxes in vegetable oils and fats.

3.3.3.1. Breeding Work with Existing Oil Crops

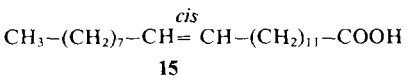
Plant breeding programs are able to increase the productivity of oil crops, in both a quantitative and a qualitative sense, through mutation, selection and recombination of appropriate phenotypes. In both annual and perennial plants, plant breeding has succeeded in increasing the oil yields by raising the harvest index (introduction of dwarf types) or by using the heterosis effect (production of hybrid varieties). Examples of such successes are the introduction of hybrid varieties of sunflowers and the development of short-stemmed varieties of linseed and dwarf types of coconut palm.



13



14



15

Table 7. Oil content and oil yield for various oil plants.

Species	Oil content [%]	Oil yield kg oil/ha/year
Oil palm	25	3000
Olive	15	800
Soybean	18	400
Groundnut	50	600
Rape	38	950

Table 8. Fatty acids content in the seed oil of various genotypes of safflower.

Genotype	18 : 1 [%]	18 : 2 [%]
F F	10-15	75-80
F f*	15-20	70-75
F f	18-35	60-75
f f*	35-50	42-54
f* f*	55-63	30-40
f f	64-83	12-30

Nevertheless, different oil crops vary widely in their productivity as measured by their oil yields (see Table 7). For example, the oil palm produces almost three times as much oil per hectare as does rape. The quality of the oil, too, which is determined by the chain lengths and degree of saturation of the fatty acids, varies between individual types of oil crops. In annual plants C_{18} fatty acids with one, two or three double bonds dominate. Groundnut oil and olive oil contain chiefly oleic acid **3**, while in sunflower oil and poppy seed oil the dominant acid is linoleic acid **13**, in flax seed (linseed) oil it is linolenic acid **14**, and in rapeseed oil it is normally erucic acid **15** (Table 6).

It has been possible through selective breeding to change the fatty acid pattern of rapeseed oil so that the erucic acid content nowadays is reduced to 3%. Doubts expressed from the standpoint of nutritional physiology concerning the unlimited use of rapeseed oil in human nutrition have thereby been overcome. The reduction in the content of erucic acid was caused by a spontaneous mutation resulting in genetic blocking of the uptake of two additional C_2 units by oleic acid.[7] Rape of low erucic acid content known in North America as canola quality has been grown worldwide since 1975.

In other plants, too, the quality of the oil has been improved. In safflower, for example, experimental mutagenesis has succeeded in altering the genes so that the mutant produces 80% of oleic acid instead of normally 80% of linoleic acid (Tables 6 and 8).

A further example indicating how oil quality in plants can be altered is given by new sunflower varieties recently selected for high contents of oleic acid. In such new varieties an enzymatic system normally responsible for the desaturation of oleic acid to linoleic acid is genetically blocked, resulting in an oleic acid content of up to 90% (Table 6).[8,9]

3.3.3.2. New Oil-Bearing Plants

Table 9 lists a selection of oil crops which might be used as new sources of raw materials. None of these has gained greater commercial importance. Most of them were identified in extensive screening studies carried out by the United States Department of Agriculture (USDA) at the Northern Regional Research Center, Peoria, Illinois, in the course of which the seed composition of about 8000 plant species was analyzed.[9-11]

Although the chemical analysis of the seeds was a comparatively simple task, the agricultural and economic eval-

uation of these potential new raw materials encountered considerable problems, since it was often necessary to take into account complex factors, e.g. the plants' architecture, indehiscence of seed, and the possible toxicity of by-products. Some new oil-bearing plants useful for the oleochemical industry and the composition of their oils are described below.

Cuphea: Various species of *Cuphea* have been recognized since the late 1950's as potential oil crops.[12] Investigations on the cultivation and economics of these plants were started in 1975,[13-15] but practical methods for growing them as a large scale crop have not yet been successfully developed. *Cuphea* is especially attractive for oleochemistry, as this annual plant is suitable for cultivation in the southern countries of the temperate zone. It has an almost ideal fatty acids composition. Several species of *Cuphea* contain large amounts of different medium chain fatty acids in the oil of their seeds. These substances could be useful for the oleochemical industry as tailored raw materials;[12] they can be obtained from *Cuphea* in a purity and quality previously unknown and could find uses in all those areas of application where coconut oil and palm oil are now being used. The presence of high fractions of C_8 and C_{10} fatty acids also offers possibilities in the oleochemical industry for synthesizing molecules based on C_8 units, e.g. dioctyl phthalate.

Euphorbia lathyris: This plant of the spurge family has been considered mainly as a possible source of industrial hydrocarbons.[16, 17] Its use as an oil-bearing plant is a comparatively recent development.[18] Its oil content of 50% is exceptionally high, with also an unusually high proportion of oleic acid (80–90%). It also satisfies the main economic criteria for a future agricultural crop.

Euphorbia lagascae: This plant is gaining increasing importance[19] because the oil from its seeds contains a large amount (60–80%) of epoxy fatty acids. It therefore provides a completely new type of oil raw material, which could open up many new applications.

Coriandrum sativum: This is a well known herb of the Umbelliferae family which synthesizes up to about 80% of petroselinic acid in the oil of its seeds.[19] This acid can be transformed by ozonolysis into lauric and adipic acid (see Section 4.2.1.2).

Calendula: The oil from the seeds of the well known ornamental *Calendula officinalis* (marigold) contains up to 55% of calendulic acid,[18] a C_{18} fatty acid with three conjugated double bonds.

Limnanthes alba: Meadowfoam, a new oil-bearing plant from the north western USA,[20, 21] contains in the oil of its seeds about 95% of long chain fatty acids, of which about 62% is $C_{20:1}$. These fatty acids have potential uses in the manufacture of cosmetics, e.g. as substitutes for sperm whale oil.

Crambe: Crambe abyssinica, a wild species of the *Cruciferae* family which comes from Ethiopia, has already been cultivated over large areas in the southern states of the USA and in Canada. The erucic acid (**15**) content is about 60%. Cultivation experiments in the Federal Republic of Germany indicate that *Crambe* can be used as an alternative to rapeseed with high erucic acid content. This could provide an answer to the problem of genetic impurities caused by inadequate isolation of rapeseed strains with high and low erucic acid contents.[22-24]

Jojoba: Jojoba wax, which already has many uses, mainly in cosmetics, is obtained from the nuts of the jojoba scrub *Simmondsia chinensis*, a native perennial of the desert regions of north western Mexico and the south western USA. Throughout the world there exist about 20000 ha of jojoba plantations.[25] The oil from the seeds is a liquid wax similar to sperm whale oil.

3.3.3.3. Biotechnological Methods for Producing New Oil Raw Materials

Conventional plant breeding methods are limited by the extent of the gene pool achievable by cross-breeding within a plant species. The methods of biotechnology now make it possible to introduce new genetic material across the natural barriers of plant species.

Plant cell cultures: For many species of plants it is possible by techniques similar to those used for microorganisms, to grow sterile pieces of tissue on a culture medium containing phytohormones (cytokinins, auxins) giving an undifferentiated growth of cells (callus culture). By this means one can propagate and grow the genetically defined tissue of the original plant. By suitably modifying the hormone treatment the formation of branching nodules can be induced and the entire plant can thus be regenerated.[26-28] It is also possible to cultivate plant cells in liquid media.[29] Regenerable plant tissue cultures can be used both for transformation experiments with isolated DNA and for the selection of mutants. Following exposure to chemical or physical mutagens, appropriate selection methods can be used to recognize cells with the desired properties. Thus, by adding a herbicide to the tissue culture medium, cells with resistance to this herbicide can be selected which then can be regenerated to intact plants.[30] Hence it is possible to shorten breeding programs by many years.

Tissue culture techniques have already been used in breeding programs on oil palms.[31, 32] A ten-year breeding program using plant tissue cultures has resulted in about 10000 oil palms being grown from these for palm oil production in Malaysia. Initial studies have already shown that the oil yield per hectare from these plantations is 30% higher than previously, and there is an increase in the amounts of oleic, linoleic or palmitic acids present depending on the different cell lines used.[33]

Protoplast fusion: If plant tissue is treated in a suitable environment with cell wall degrading enzymes such as cellulases, hemicellulases or pectinases, round single cells surrounded only by the cell membrane, so-called protoplasts, are formed which can be used to regenerate whole plants by suitable treatment.[34]

Under the influence of high frequency alternating fields,[35] or in the presence of polyethylene glycol[36] or dimethyl sulfoxide,[37] it is possible to fuse protoplasts of different species which cannot be cross-bred by conventional methods. In cases where these methods succeed, the cell nuclei can not only be caused to fuse, but combination between other information carriers (plastides and mitochondria) which are present in the cells can also be ef-

fected. However, despite the high hopes held out for these techniques, they have so far failed to achieve a breakthrough in plant breeding, as the few hybrid varieties successfully regenerated have proved to be infertile.[38,39]

Specific gene transfer methods: Many different methods are available for specifically transferring genetic material into plant cells. These include the direct transformation of plant cell protoplasts using isolated DNA,[40,41] and the use of gene vectors such as genetically modified Ti plasmids from *Agrobacterium tumefaciens*[42] or plant-pathogenic DNA viruses.[43] Such techniques have already been used successfully to obtain resistance to herbicides[44,45] and viruses[46] in plants. Other proposed applications of genetic manipulation techniques in plant breeding are to control plant physiological processes such as photosynthesis or photorespiration, to influence nitrogen fixation by plants, or to cause changes in the type and proportions of substances present in plants.

Specific gene transfer methods are now being used to alter the content and the distribution patterns of fatty acids in oil-bearing plants.[47] The similarity between the biosynthetic routes for fatty acids in these plants and in prokaryotic microorganisms has turned out to be an advantage. The biosynthesis is catalyzed by seven enzymes, all of which can be isolated.[48,49] The individual concentrations of these enzymes can in principle be altered by way of genetic engineering techniques. However, the details of how the enzymatic steps are regulated are not yet fully understood. Furthermore, the various reactions take place in different plant compartments, and no method is yet known whereby specific genetic information can be expressed in a distinct part of the plant. The use of molecular genetics to modify oil-bearing plants or other types of plants is therefore a rather long-term prospect for the future.[50]

3.4. Oils and Fats from Microorganisms

3.4.1. Microbial Oils (Single Cell Oils)

The methods of biotechnology not only play an important part in developing new sources of vegetable oils as raw materials, but are also used in optimizing the amounts and composition of fatty acids present in fat-storing microorganisms. The ability to store fat is especially common in eukaryotic microorganisms such as yeasts, molds and algae, and its possible application as a basis for oil production was considered as early as the 1940's.[51] The fat content can be as much as 70% of the cells' dry weight. Its distribution pattern of fatty acids is generally similar to that found in commonly used raw materials such as soybean oil and tallow.[52-56]

The production process is similar to those generally used for manufacturing bakers' yeast or single cell protein. This is followed by a further step to separate the fat by solvent extraction.[57] However, the efficiency of the overall biotransformation from the carbohydrate fermentation feedstock to fat, a highly reduced substance, is relatively low (about 20%). Consequently the economic viability of processes of this kind is limited by the cost of the feedstock.[58] Up to now, there have been few reports of fat-storing microorganisms which can grow on cheap feedstocks such as methane or methanol. The higher the value of the end product, the less important is the price of the feedstock as a determining factor for the economics of the process. This is shown in the case of an oil rich in γ-linolenic acid, a potential raw material for the pharmaceutical industry. Its manufacture by the fermentation of purified glucose-containing substrates using the mold *Mucor sp.* was recently started on a production scale of 220 m^3.[59]

3.4.2. Waxes

Microbial and enzymatic systems have been described which can be used in the biotechnical synthesis of waxes, i.e. esters of long chain fatty acids with fatty alcohols, as substitutes for sperm whale oil and jojoba wax. Using the algal species *Euglena gracilis*, the change from aerobic to anaerobic growth conditions leads to a wax content of up to 50% of the cells' dry weight.[60,61] In the manufacture of substitutes for sperm whale oil using the bacterium *Acinetobacter sp.*, the effects of substrate chain length and concentration on the degree of saturation and chain length distribution in the product has been investigated in detail.[62-64]

Waxes can also be produced enzymatically by using lipases for esterifying fatty alcohols with fatty acids. This must be carried out under conditions which favor the synthesis and inhibit the hydrolysis (see Section 4.3.1). Isolated enzymes and also dried cell material can be used in such processes.[65,66]

3.4.3. Unusual Microbial Lipids

Archaebacteria which survive under extreme conditions (e.g. 60°C and pH values of 2) synthesize membrane lipids which have so far not been found in other microorgan-

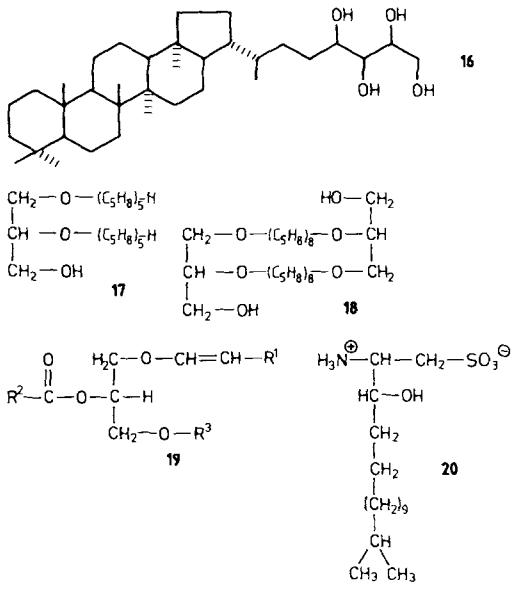

Fig. 8. Structures of unusual microbial lipids. **16**: tetrahydroxybacteriohopan (THBH) [70]; **17**: glycerol dialkyl ether (C_5H_8: isoprene unit); **18**: cyclic diglycerol dialkylene tetraether (C_5H_8: isoprene unit) [68]; **19**: alkenyl ether lipid (R^1, R^2 = alkyl, R^3 = phosphatidyl) [72]; **20**: capnin (sulfolipid) [73].

isms.[67-69] These glycerol ethers (cf. **17**-**19**) consist basically of polyisoprene chains with terminal ether linkages to either one or two glycerol molecules. Other substances found in archaebacteria include hopanoids, bacterial derivatives of steroids such as **16**, which are currently the object of intensive studies (see Fig. 8).[69-71]

The alkenyl ether lipids **19**[72] found in anaerobic organisms and the sulfolipid capnin **20** from the bacterium *Capnocytophaga*[73] (see Fig. 8) may offer hints to new types of surfactants (biosurfactants[74]) or to new applications.

4. Reactions of Oils and Fats

The limitations of oils and fats as chemical feedstocks have up to now been regarded as unavoidable. Factors contributing to these limitations are:

- the predominance of unsaturated fatty acids with chain lengths in the range C_{16} to C_{22}, and especially of C_{18}, combined with the absence of unsaturated C_8 to C_{14} fatty acids in natural sources, and
- the fact that a mixture of fatty acids is usually present, necessitating separation processes.

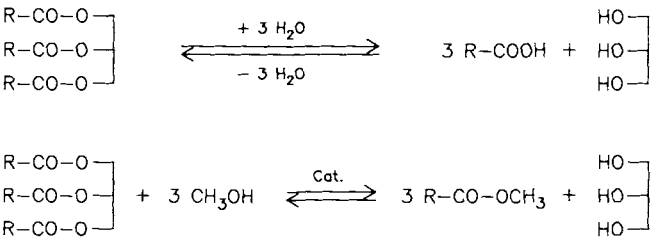
Due to these limitations, more than 90% of oleochemical reactions have been those occurring at the fatty acid carboxy groups, while less than 10% have involved rearrangements of the acid chain.[75] However, future progress will be along the lines of these latter types of reactions with their potential for considerably extending the range of compounds obtainable from oils and fats. Such progress is essential for a growth in the use of oils and fats as renewable raw materials.

Industrial and academic research in oleochemistry is becoming increasingly directed towards demonstrating new possibilities for reactions involving the hydrocarbon chains of fatty acids, especially at the CC double bonds in unsaturated fatty acids. In the following discussion, emphasis is put on reactions involving fatty acid hydrocarbon chains including biotechnological processes. "Classical" oleochemical reactions at the fatty acid carboxy group and the products which result from them are described only briefly as an introduction to this survey.

4.1. Reactions at the Carboxy Function of Oils and Fats

4.1.1. Hydrolysis and Methanolysis of Fats

Hydrolysis by steam[76] or transesterification with methanol transforms oils and fats into the basic compounds of oleochemistry, i.e. the fatty acids or their methyl esters and glycerol. The hydrolysis is carried out in continuously operating reaction columns at 250 °C and pressures between 2×10^6 and 6×10^6 Pa (20-60 bar). In the countercurrent flow method, the glycerol which is formed is extracted continuously from the equilibrium mixture using water, yielding 98% hydrolysis in a single pass. No catalyst is needed (Scheme 1).



Scheme 1. Equilibria in the hydrolysis and methanolysis of fats. Cat. = catalyst.

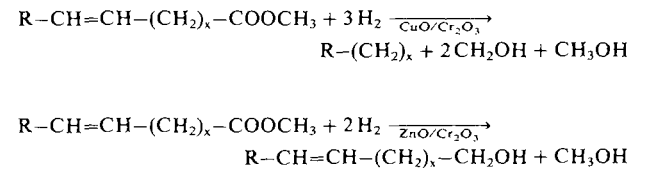
The alkaline hydrolysis of fats to give alkali soaps, which historically marked the beginning of industrial fats chemistry, is now only of minor importance. It is now preferred to make soaps by neutralization of the fatty acids.[77]

The alkali-catalyzed transesterification of oils and fats with methanol to give fatty acid methyl esters and glycerol is likewise carried out in continuously operating reaction columns, at 240 °C and 10^7 Pa (100 bar)[78] (Scheme 1).

As an alternative to this, alkali-catalyzed esterification of fatty acids with methanol is carried out at 250 °C and about 10^6 Pa (10 bar) in counter-flow reaction columns.

4.1.2. High-Pressure Hydrogenation of Fatty Acid Methyl Esters, Fatty Acids and Fats

Methyl esters of fatty acids are chiefly significant as intermediate products. Their most important downstream reaction is high pressure hydrogenation to form fatty alcohols, i.e. linear primary aliphatic alcohols with chain lengths C_8 to C_{22}. Fatty acid methyl esters are hydrogenated at temperatures of 200-250 °C and hydrogen pressures of 2.5×10^7 to 3×10^7 Pa (250-300 bar) using solid mixed metal oxide catalysts. By choosing mixed catalysts of suitable composition the reaction can be controlled so that the double bond in unsaturated fatty acid esters is not hydrogenated. Catalysts containing copper (e.g. copper chromite) give saturated fatty alcohols, while special catalysts containing zinc preserve the double bonds in the starting compounds and give unsaturated fatty alcohols such as oleyl alcohol[78] (Scheme 2).



Scheme 2. Catalytic hydrogenation of fatty acid methyl esters to fatty alcohols.

Whereas long chain saturated alcohols can also be manufactured industrially from petrochemical feedstocks (by Ziegler synthesis,[79] oxo reactions,[80] oxidation of paraffins[80] or Fischer-Tropsch synthesis[81]), this is not possible for unsaturated fatty alcohols. High-pressure hydrogenation of unsaturated fatty acid methyl esters is the only

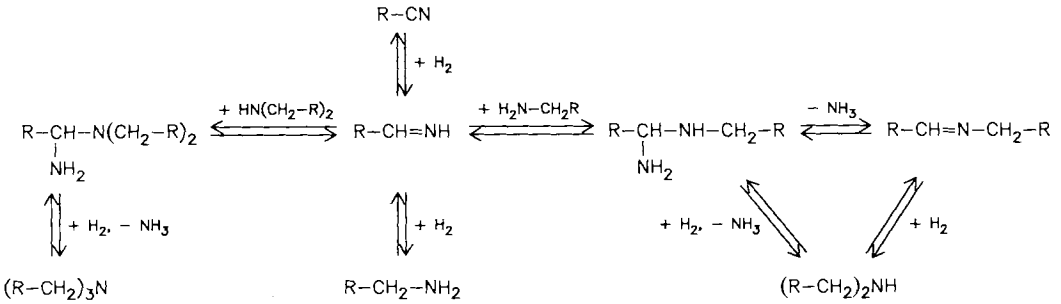
technically feasible route for synthesizing these compounds.

Fatty alcohols can be produced under certain conditions by high-pressure hydrogenation of fatty acids[78,82] and triglycerides.[83] The direct hydrogenation of fats to fatty alcohols appears attractive as a short route. Instead of glycerol as the co-product 1,2-propanediol is formed in this reaction.

Glycerol which arises as the co-product (10–15%) in the hydrolysis or transesterification of fats finds uses either as such or in the form of derivatives—mainly glycerol esters and polyglycerol esters of inorganic or carboxylic acids.

4.1.3. Synthesis of Fatty Amines

Another important class of basic oleochemicals are the fatty amines. They are obtained by reacting fatty acids with ammonia, which gives the amides and the nitriles as intermediates; the latter are then hydrogenated with a nickel catalyst to the fatty amines.[84] By adding ammonia or a secondary amine during the hydrogenation of the nitriles, the reaction can be controlled to give primary, secondary or tertiary amines (Scheme 3).

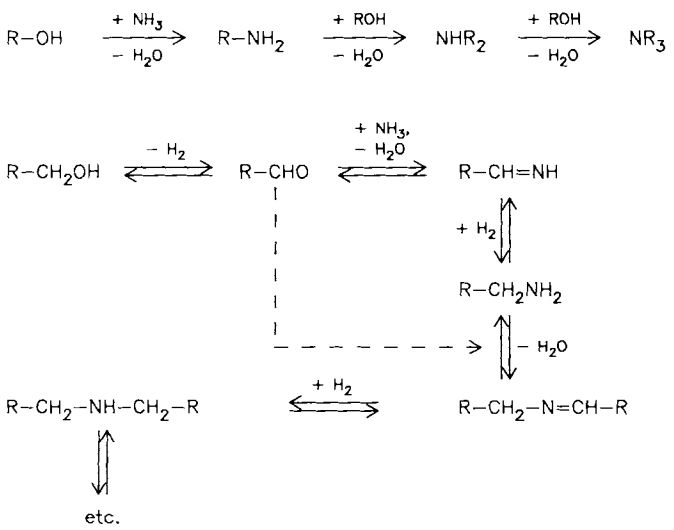


Scheme 3. Fatty amines from fatty acids via the fatty acid amides and fatty acid nitriles.

A more recent method makes possible the production of the nitriles in a single step directly from the fat also using ammonia.[85] Fatty amines are also formed in a one-step process from fatty acids or their methyl esters, using ammonia or lower amines under hydrogenating conditions with a hydrogen pressure of 2.5×10^7 Pa (250 bar) and with oxide catalysts.[86]

Another industrial process for producing fatty amines starts with fatty alcohols which are reacted with ammonia or short chain alkyl or dialkyl amines at 210–280 °C in the presence of dehydrogenation catalysts (Scheme 4).[87]

The oleochemicals mentioned above provide the basis for manufacturing a wide range of fat derivatives. The most important of these are listed in Table 10 (see overleaf).



Scheme 4. Fatty amines from fatty alcohols.

4.2. Reactions Involving the Fatty Acid Hydrocarbon Chain

As has already been mentioned, in addition to reactions at the carboxy group, rearrangements in the hydrocarbon chain of fatty acids are becoming increasingly important in oleochemistry. Through these the spectrum of chemical products that are based on raw materials from renewable sources is being greatly widened. Table 11 (see overleaf) gives a survey of the many reactions that are possible, only a fraction of which have yet been studied scientifically. Of those reactions which have been investigated in detail, the following account includes only the ones of greatest importance in oleochemistry with indications concerning any still unresolved problems.

4.2.1. Reactions of Unsaturated Fatty Acid Chains

Because of their high reactivity the double bonds in unsaturated fatty acids offer a favorable position of attack for reactions in the fatty acid chain.

4.2.1.1. Hydrogenation

The nickel-catalyzed hydrogenation of the double bonded positions in unsaturated fatty substances is used extensively in industry to improve stability and color and to raise the melting point of unsaturated fat derivatives.[88,89]

The problem of achieving selective hydrogenation in unsaturated fatty acids with several double bonds has so far only been partly solved. An example is the conversion of linolenic **14** and linoleic acids **13** to oleic acid **3**, without unwanted positional or *cis-trans* isomerizations occurring at the same time. Heterogeneous metal catalysts whose use

Table 10. Important fat derivatives and products made from fatty acids contained in new oil-bearing plants.

Starting material	Reaction (Reactants)	Derivative
Fatty acids	Amidation (NH_3, alkanolamines)	Fatty acid (alkanol)amides
	Esterification (long-chain alcohols, glycerol, polyols)	Fatty acid esters ("wax esters", partial glycerides, polyolesters)
	Ethoxylation, propoxylation	Fatty acid polyglycol esters
Fatty acid methyl esters	Amidation (NH_3, alkanolamines)	Fatty acid (alkanol)amides
	Ester rearrangement (long-chain alcohols, glycerol, polyols)	Fatty acid esters ("wax esters", partial glycerides, polyesters)
Fatty alcohols	Ethoxylation, propoxylation	Fatty alcohol polyglycol ethers [a]
	Formation of sulfates	Fatty alcohol sulfates
	Production of phosphates (P_2O_5 or (poly-)phosphoric acid)	Alkyl phosphates
Fatty amines	Ethoxylation, propoxylation	Fatty amine polyglycol ethers
	Alkylation (CH_3Cl or dimethyl sulfate)	Quaternary ammonium compounds
	Alkylation ($ClCH_2COOH$)	Betaines (amphoteric surfactants)
	Oxidation	Fatty amine oxides

[a] Products: Sulfation to fatty alcohol polyglycol ether sulfates; reaction with P_2O_5 or (poly-)phosphoric acid to give fatty alcohol polyglycol ether phosphates; reaction with $ClCH_2COOH$ to give alkyl ether carboxylic acids; reaction with alkyl chlorides to give polyalkylene glycol dialkyl ethers.

is preferred in technical processes have not yet led to satisfactory results.[90,91] Homogeneous catalysts based on complexes of precious metals could offer a solution to the problem, if a method could be found for recovering and recycling these expensive catalysts. Possibilities which have been investigated are immobilization of the homogeneous catalyst on a support or the use of microdispersed catalyst systems such as colloids, clusters, or soluble polymer chelates; the last of these seems to offer good prospects.[92]

The olefin reactions that are described in the following sections are found to proceed with little or no formation of by-products only if starting materials of technically consistent quality are available including sufficiently pure oleic acid obtained by optimal selective hydrogenation. Oleic acid which is obtained from fatty acid mixtures by physical separation methods[93,94] contains only about 70% of *cis*-9-octadecenoic acid.

An alternative method for producing pure alkenecarboxylic acids is by catalytic dehydrogenation of saturated fatty acids. However, no suitable process has yet been developed for carrying this out on an industrial scale. Biotechnology may provide a solution to this problem.

The selective dehydrogenation of saturated fatty acids could extend the spectrum of available unsaturated fatty acids beyond the narrow range occurring naturally (mainly C_{18} and C_{22} acids) thereby providing a broader foundation for olefin chemistry based on syntheses from alkenecarboxylic acids.

Table 11. Reactions of unsaturated and saturated fatty acid chains.

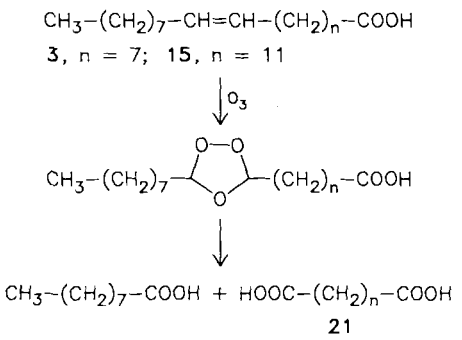
Type of reaction	Reaction products	Topics for further research
Unsaturated chain:		
Hydrogenation	Saturated fatty acids	Selective hydrogenation of fatty acids with several double bonds
Epoxidation	Epoxyacids	—
Hydroformylation	Aldehyde carboxylic acids	Improving selectivity and linearity
Hydrocarboxylation	Dicarboxylic acids	Improving selectivity and linearity
Koch synthesis	Highly branched dicarboxylic acids	—
Metathesis	Mono- and dicarboxylic acids	Catalyst optimization, increasing the proportion of substrate to catalyst
Oxidative scission	Mono- and dicarboxylic acids	Oxidizing agents other than ozone
Diels-Alder reaction	Cyclic di- and tricarboxylic acids	Use of non-activated dienophiles
Ene reaction	Branched di- and tricarboxylic acids	Use of non-activated enophiles
Ane reaction	Branched fatty acids	Not yet investigated for fatty acids
Dimerization	Long-chain di- and tricarboxylic acids	Catalyst optimization, elucidation of the reaction mechanism and structure of reaction products
Scission of ricinoleic acid		Access to other fatty acids with the β-hydroxyalkene structure
- by alkalis - thermally	Sebacic acid, 2-octanol 10-Undecenoic acid, n-heptanal	
Hydrozirconation	ω-Substituted fatty acids	Optimization of catalyst system
Saturated chain:		
Chlorination	Chloroacids	(Regio-)selectivity
Sulfochlorination	Sulfoacids	(Regio-)selectivity
Sulfoxidation	Sulfoacids	(Regio-)selectivity
Catalytic oxidation	Hydroxyacids, oxoacids	Reaction so far unsuccessful
Catalytic dehydrogenation	Unsaturated fatty acids	
Sulfonation	α-Sulfoacids	—
Guerbet reaction	α-Alkylalkanols	Optimization of the catalyst
Claisen condensation	α-Alkyl-β-oxoesters	—

4.2.1.2. *Oxidative Scission*

The double bond in unsaturated fatty acids provides a point of attack for oxidative scission. In the ozonolysis of unsaturated fatty acids, which is a highly selective reaction, ozonides are formed initially.[95] These can undergo scission either reductively to mono- and dialdehydes, or oxidatively to mono- and dicarboxylic acids.[96]

By the oxidative route, oleic acid **3** gives nonanoic acid (pelargonic acid) and nonane-1,9-dioic acid (azelaic acid **21**, n = 7), while erucic acid **15** gives pelargonic acid and brassylic acid (tridecane-1,13-dioic acid) **21**, n = 11 (Scheme 5). Petroselinic acid **12**, which constitutes about

80% of coriander oil (see Section 3.3.2), can be split by this route to give lauric acid and adipic acid.[97]

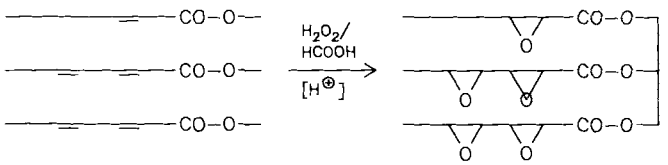


Scheme 5. Ozonolysis of unsaturated fatty acids (**3**: oleic acid; **15**: erucic acid).

The only industrial application of ozonolysis up to now is in the large scale production of azelaic acid from oleic acid;[98] azelaic acid is used in the textile fiber and plastics industries. Wider use of ozonolysis is still hindered by a number of technical and economic problems. Although some important advances have been made in this respect in recent years,[96] the alternative processes which have so far been investigated, involving diols or hydroxyoxo acids as intermediates have not succeeded in replacing the ozonolysis route.[99-101] Metal complex catalyzed direct oxidation methods, using ruthenium complexes for example, offer another possible approach to this problem.[101]

4.2.1.3. Epoxidation

Epoxidation is one of the most important addition reactions occurring at the double bond in unsaturated fatty compounds. The best method for unsaturated fatty acid esters is the *in situ* performic acid process. Scheme 6 shows



Scheme 6. Epoxidation of unsaturated fatty materials.

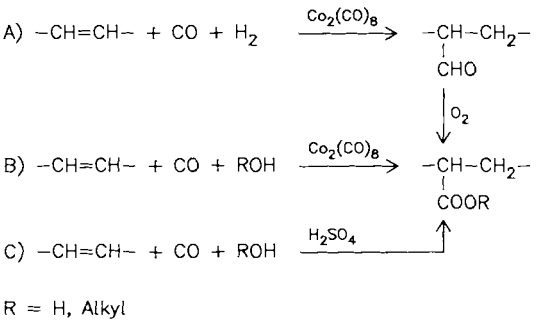
the application to a triglyceride. Methyl oleate is allowed to react in an analogous fashion to this to give 9,10-epoxystearic acid methyl ester.[102] The oxirane groups in epoxidated fatty compounds react readily with nucleophilic reagents. Opening up the epoxide ring leads to a large number of products, as summarized in Table 12. In particular, detailed studies have been carried out on ring opening in epoxyesters of fatty acids and in epoxyalcohols using mono-alcohols or polyols; by means of these reactions a wide range of alkoxy alcohols (fatty ether alcohols) and corresponding polyols can be synthesized. These are especially suitable for manufacturing polyurethane foams and molding resins with interesting properties for technological applications.[103]

Table 12. Reactions possible with fatty acids having an epoxy group.

HX	Name of partial structure
H_2	Alcohol
H_2O	Diol
ROH	Alkoxy alcohol ("ether alcohol")
RCOOH	Hydroxy ester ("ester alcohol")
$RCONH_2$	*N*-hydroxyalkylamide
H_2S	Mercapto alcohol
R_2NH	Amino alcohol
HCN	Hydroxynitrile
HCl	Chlorohydrin
$NaHSO_3$	Sodium hydroxysulfonate

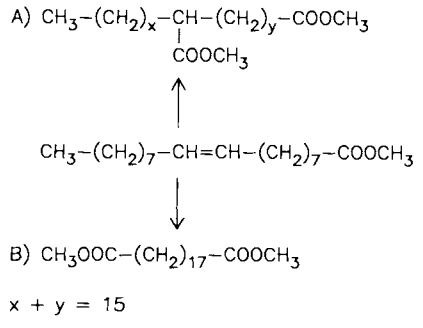
4.2.1.4. Carboxylation

The three types of reactions which are most suitable for the addition of carbon monoxide at the double bond in unsaturated fat derivatives are hydroformylation (oxo synthesis),[80] hydrocarboxylation (Reppe reaction)[80, 104, 105] and the Koch synthesis (Scheme 7).[80]



Scheme 7. Production of carboxylic acids by carbonylation reactions. A: hydroformylation with oxidation; B: hydrocarboxylation; C: Koch reaction.

Hydroformylation using transition metal complexes forms a formyl group which can then be hydrogenated to give a hydroxy group or oxidized to a carboxy group. In protonic solvents such as water or methanol, the carbonyl group is added as a carboxy function. By this hydrocarboxylation reaction, carboxylic acids or their derivatives are formed.[80, 106] Hydroformylation and hydrocarboxylation are catalyzed by $Co_2(CO)_8$ and carbonyl hydrides of metals of the eighth subgroup. These catalysts favor isomerization at the double bond. Because of this, the products of this reaction are mixtures of the various chain positional isomers. However, these reactions can be controlled by the addition of suitable complex ligands. Thus, for example, methyl oleate reacts with carbon monoxide and water in the presence of rhodium triphenylphosphane to give exclusively products hydroformylated at the 9 and 10 positions[107, 108], whereas hydrocarboxylation of the methyl esters of oleic or erucic acids using cobalt/4-picoline as the catalyst yields up to 50-60% of linear C_{19} or C_{23} dicarboxylic acid diesters (Scheme 8).[109] In the Koch synthesis, strong acids are used as catalysts. The carbonium ions formed as the primary reaction products isomerize very rapidly, with the results that the carbon chain undergoes

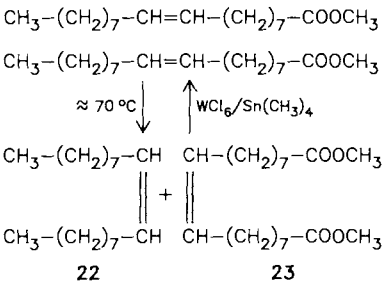


Scheme 8. Hydrocarboxymethylation of methyl oleate. A: in the presence of rhodium/triphenylphosphane. B: in the presence of cobalt/4-picoline.

rearrangement, yielding a mixture of isomers with a high proportion of α-branched dicarboxylic acids.[80]

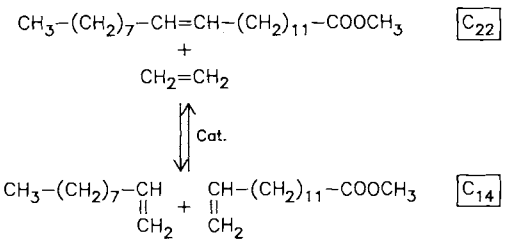
4.2.1.5. *Olefin Metathesis*

Olefin metathesis is a bond rearrangement reaction catalyzed by certain transition metal compounds (molybdenum, tungsten or rhenium).[110] The reaction can also be applied to unsaturated fatty acid esters.[111] The self-metathesis of methyl oleate, carried out by means of the catalyst system tungsten(VI) chloride/tetramethyltin results in the highly selective formation of 9-octadecene **22** and 9-octadecene-1,18-dicarboxylic acid dimethyl ester **23**, in an equilibrium mixture with the starting ester (Scheme 9). Co-



Scheme 9. Self-metathesis of methyl oleate.

metathesis of the methyl esters of oleic or erucic acids with short-chain olefins such as ethene or 2-butene results in the synthesis of unsaturated fatty acid methyl esters with chain lengths C_{10} to C_{15} and the corresponding olefins (Scheme 10).[112] Industrial application of this interesting oleochemical reaction path is at present still hindered by the poor efficiency of the expensive catalyst. At present the

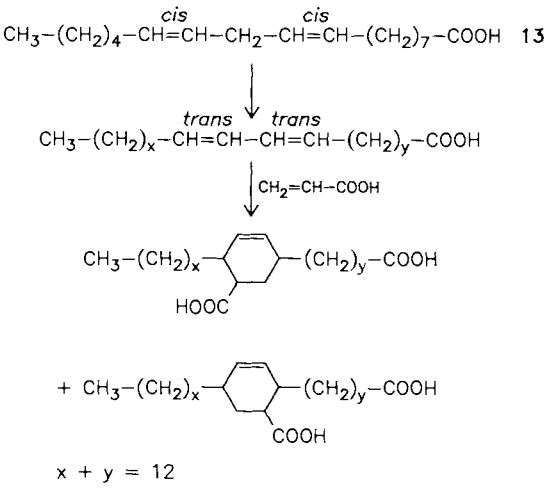


Scheme 10. Metathesis of erucic acid methyl ester and ethene. Cat. = catalyst (see text).

conversion of 150 mol of ester needs 1 mol of the tungsten compound used as catalyst. For this reason it is essential to look for new catalyst systems which are more effective.

4.2.1.6. *Diels–Alder and Ene Reactions*

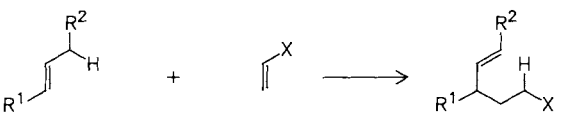
Addition reactions of isolated and conjugated double bond systems are also often used for introducing ring systems or alkyl branching groups into fatty acids. Unsaturated fatty acids with two double bonds, such as linoleic acid **13**, undergo Diels–Alder reactions with appropriately substituted dienophiles after isomerizing to a conjugated fatty acid. Thus, isomerized linoleic acid, at temperatures above 100 °C, forms adducts with maleic anhydride, fumaric acid, acrylic acid and other dienophiles with activated double bonds (Scheme 11).[113–118] In order to synthe-



Scheme 11. Diels–Alder reaction of isomerized linoleic acid ("conjugated fatty acid") and acrylic acid.

size Diels–Alder adducts the conjugated double bonds must be in the *trans,trans* form.[119] The desired configuration of the double bonds can be induced by means of an isomerization catalyst, e.g. iodine or sulfur.

Unsaturated fatty acids such as oleic acid can undergo an ene reaction at temperatures above 220 °C with maleic anhydride or other compounds having activated double bonds (Scheme 12).[120, 121] It is suitable for introducing

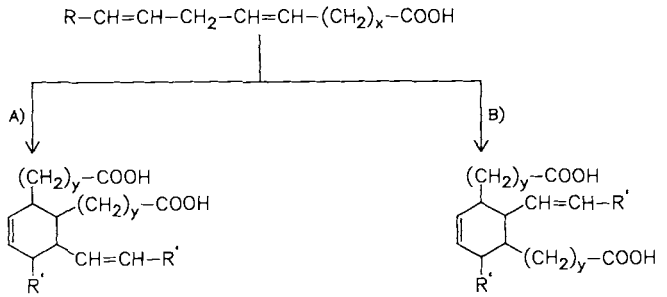


Scheme 12. Ene reaction of oleochemical compounds.

side chains containing hetero functions such as –COOR or –CN into unsaturated fatty compounds with retention of the double bond shifted across a carbon atom. Only a few examples are known so far of Diels–Alder and ene reactions of unsaturated fatty acids with unactivated dienophiles and enophiles.

4.2.1.7. *Fatty Acid Dimerization*

C_{18} fatty acids with one or more double bonds undergo dimerization at 210–250°C in the presence of layer silicate catalysts such as montmorillonite, giving a complex mixture of C_{36} dicarboxylic acids (Scheme 13).[122] This fatty

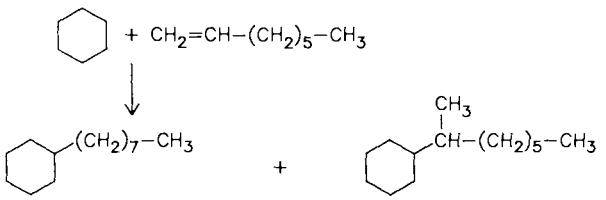


Scheme 13. Dimerization of C_{18} fatty acids by Diels–Alder reaction, schematic. For conditions see text. A: head/head reaction; B: head/tail reaction. In the products $y = x$, $R' = RCH_2$ or $y = x + 1$, $R' = R$.

acid dimerization is assumed to result from a Diels–Alder addition of oleic acid to linoleic acid. The conjugate linoleic acid dimerizes with formation of a cyclohexene ring. However, from the fact that acyclic aliphatic structures also appear it can be inferred[123] that ene reactions and reactions through carbocation intermediates also occur. An industrially important application of dimer acids is the manufacture of hot melts, printing inks and curing agents for epoxy resins.

4.2.1.8. *Free Radical Reactions*

Alkanes add to olefins at temperatures of about 400°C in a thermally initiated free radical reaction, e.g. cyclohexane adds to acrylic acid esters or to 1-octene (Scheme 14).[124, 125] This "direct substituting addition" reaction

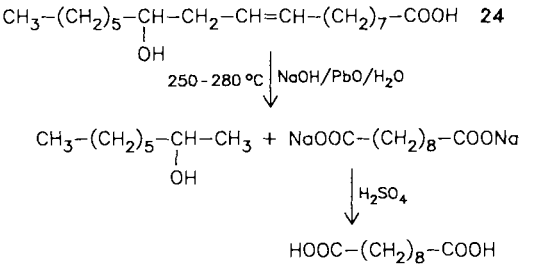


Scheme 14. "Ane reaction" of cyclohexane with 1-octene. By-products are 2-, 3-, and 4-octene.

is called an "ane reaction" by analogy with the ene reaction to which it is related. Its extension to fatty acids offers a potentially interesting topic for research.

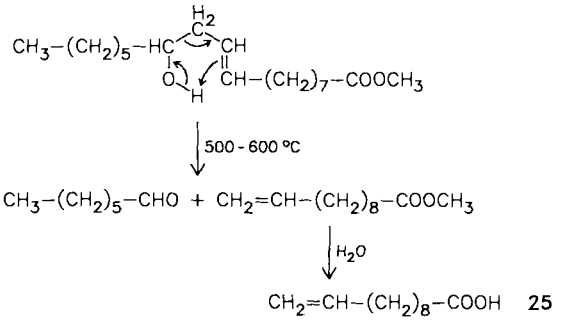
4.2.1.9. *Scission and Rearrangement Reactions*

The β-hydroxyalkene structure exemplified by *cis*-12-hydroxy-9-octadecenoic acid (ricinoleic acid) **24**, which is the principal fatty acid in castor oil, can undergo a variety of scission and rearrangement reactions. Heating ricinoleic acid to 250–280°C with excess alkali under oxidizing conditions in the presence of catalytic amounts of calcium or lead compounds causes scission, with formation of sebacic acid (decane diacid) and 2-octanol (Scheme 15).[126–129] Sebacic acid is an important starting material in the manufacture of plasticizers, lubricants, polyesters, and polyamides.



Scheme 15. Synthesis of sebacic acid by alkaline cleavage of ricinoleic acid **24**.

Thermal scission of ricinoleic acid methyl ester at 500–600°C produces 10-undecenoic acid (undecylene acid) **25** and heptanal (enanthaldehyde) (Scheme 16).[130] This scission reaction is of general validity for β-hydroxyolefins in which the OH group is free to interact unhindered with the π-electrons of the double bond. 10-Undecenoic acid is valuable as a starting material for the manufacture of Nylon 11 ("Rilsan") which proceeds via 11-bromoundecanoic acid and 11-aminoundecanoic acid as intermediates.[131]



Scheme 16. Synthesis of 10-undecenoic acid **25** by thermal cleavage of methyl ricinoleate.

Ricinoleic acid undergoes rearrangement at 250°C over a palladium contact catalyst to give 12-oxostearic acid by shifting of the double bond and the formation of an enol structure as an intermediate.[132] In the presence of manganese salts as catalysts, 12-oxostearic acid can be made to undergo oxidative scission to mono- and dicarboxylic acids.[133]

4.2.2. *Substitution Reactions in the Alkyl Chain of Saturated Aliphatic Fatty Acids*

Whereas in unsaturated fatty acids the double bonds, because of their high reactivity, allow specific reactions to be carried out on the fatty acid hydrocarbon chain, this is not the case for saturated fatty acid chains. Here the methylene groups—apart from that at the α position—have

little reactivity and the differences in reactivity from one methylene group to another are small. Consequently, the substituents that are introduced are randomly distributed along the entire fatty acid chain. Substitution reactions of this type include the free radical chlorination, sulfochlorination and sulfoxidation of fatty acids and their esters.

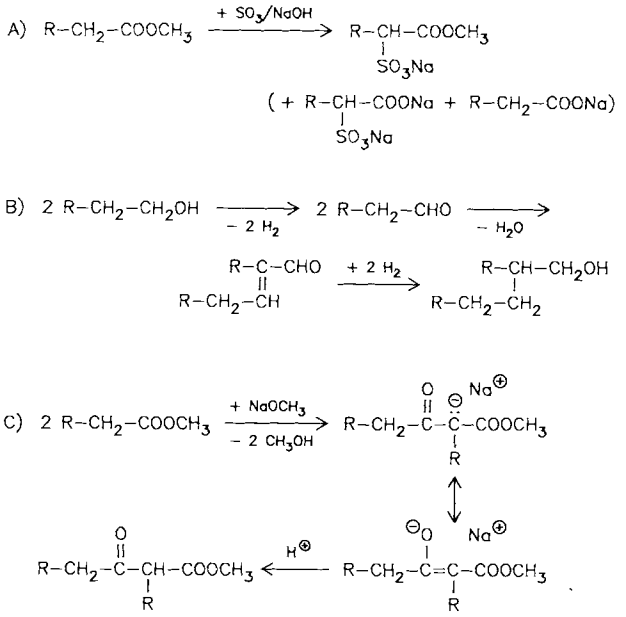
The light-induced chlorination of fatty acids and fatty acid esters leads to an essentially uniform distribution of chlorine substituents in the methylene groups of the fatty acid chain. However, α and ω substitutions occur only to a small extent or not at all.[134] The same is also true for the sulfochlorination (reaction with sulfur dioxide and chlorine leading to the introduction of SO_2Cl groups)[135] and the sulfoxidation of fatty acids and fatty acid esters (reaction with sulfur dioxide and oxygen with introduction of SO_3H groups).[136, 137]

Success in finding methods for carrying out selective substitution reactions on the alkyl chain of fatty acids would considerably widen the spectrum of compounds available through fats chemistry and with it the range of uses. Possibilities to be considered include electrostatic alignment of reagent molecules relative to protonated fatty acid molecules[138-143] and partial shielding by adsorption on inert surfaces or retention in zeolites.[143]

Except for α substitution, which can be achieved easily, only a few starting points have so far been found which offer approaches to selective substitution.[138-146] The utilization of a strongly acidic medium and the addition of a free radical trapping agent have the effect of directing chlorination predominantly into the α position.[147] This reaction is an extension of the well-known Hell-Volhard-Zelinsky reaction for α-bromination of fatty acids. Adsorbing fatty acids on aluminum oxide produces an orientation of their molecules resulting in preferential chlorination at the last and penultimate carbon atoms of the fatty acid chain.[141, 142] The chlorination of fatty acids by *N*-haloamines using a free radical initiator occurs with high selectivity at the penultimate carbon atom of the fatty acid chain.[138, 148-152] Specific substitution at the end carbon atom can also be achieved by hydrozirconation.[153] In this reaction, zirconium hydrides in the form of complexes are added at the double bond position of unsaturated fatty acids; by a repeated process of elimination and reattachment of the zirconium hydride, the zirconium substituent migrates to the ω position, where it can be replaced by any desired electrophilic reagent.[154]

Substitution of saturated fatty acids and fatty acid esters at the α position is, by contrast, relatively easy and specific. Some examples of this are the following:

- The ionic sulfonation of fatty acid methyl esters using SO_3, leading to α-sulfonated esters ("ester sulfonates") (Scheme 17A).[155-157] Ester sulfonates represent an oleochemical alternative to the petrochemicals-based surfactant alkylbenzene sulfonate.
- The Guerbet reaction,[158, 159] i.e. the alkali-catalyzed self-condensation of two molecules of a fatty alcohol to form a molecule of an α-alkyl branched dimeric alcohol (the Guerbet alcohol). This reaction probably takes place via an aldol condensation of the aldehyde formed as an intermediate (Scheme 17B).[160]
- The Claisen condensation of two molecules of a fatty acid methyl ester, which leads to the formation of an α-alkyl-β-oxoester of the fatty acid (Scheme 17C).[161]



Scheme 17. Reactions of the saturated fatty acid chain: A: sulfoxidation; B: Guerbet reaction; C: Claisen condensation of fatty acid methyl esters.

Most of the reactions discussed in this connection are typical of those on which industrial oleochemistry is based. Reactions such as these are essential for the manufacture of chemical products from renewable raw materials.

4.3. Biologically Catalyzed Reactions

Biochemical reactions provide pathways for carrying out already known chemical rearrangements such as hydrolysis or esterification under mild conditions, thus saving energy and preventing the products from thermal deterioration. Additionally, biochemical processes give rise to possibilities for the manufacture of new oleochemical products.

4.3.1. Reactions Involving the Ester Group

During the past few years the applications of enzymatic catalysis and bioreactor technology to the basic reactions of oleochemistry, namely hydrolysis, esterification and transesterification have been intensively studied.[162, 163]

As is predicted by thermodynamic calculations, the hydrolysis of triglycerides has an exceptionally small reaction enthalpy with the result that the splitting of fat as an equilibrium reaction (Scheme 1) is easily reversed under suitable reaction conditions to ester synthesis or transesterification.[164] Such reactions are catalyzed by enzymes of the ester hydrolases class (E.C. 3.1.1), namely the lipases. The enzymes act preferentially on substrates insoluble in water, so that the reaction occurs at the interface between the lipophilic and hydrophilic phases.[165]

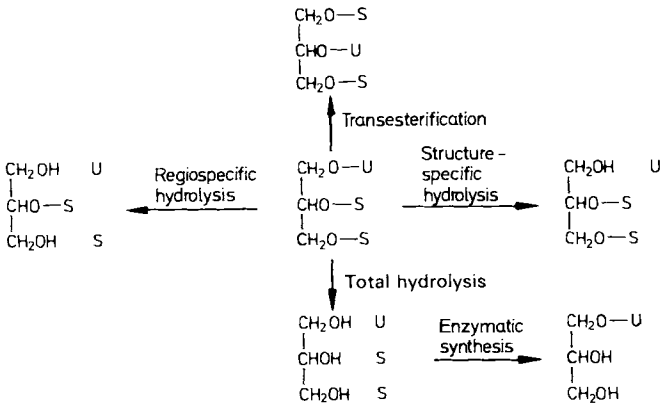


Fig. 9. Enzymatic fat splitting, transesterification, and ester synthesis. U = *cis*-9-alkenoic acid ("Δ^9-unsaturated fatty acid"), S = saturated fatty acid.

Lipases are technically available from animal, plant and microbial sources. They have different specificities with regard to the structure or chain length of the fatty acids undergoing splitting or esterification, or with regard to the position of the hydrolyzed or formed ester bond of the glycerol molecule[166, 167] (Fig. 9). They are therefore particularly suitable for the synthesis of optically active compounds and for isolating specific fatty acids. However, chemical reactions such as intramolecular exchange of acyl groups and the interfacial properties of the substrates and reaction products can interfere with these enzymatic specificities.

4.3.1.1. Enzymatic Splitting of Fats

It was suggested as long ago as the beginning of this century that castor bean seeds might be used industrially for the hydrolysis of fats and oils.[168] It is only recently, however, that interest has again grown in the lipase-catalyzed splitting of fats.[162]

A lipase for use in an industrial splitting process should act nonselectively on the ester bonds in the triglyceride causing hydrolysis of each of them with approximately equal reaction rates. Furthermore, it should be thermally stable. An enzyme which meets these requirements quite well is obtained from *Candida cylindracea*. Other lipases suitable for this purpose, with particular regard to their thermal stability, have been investigated.[169]

Various experimental reactor devices for the enzymatic splitting of fats have been described such as stirred tank reactors,[162] tubular reactors,[170] and membrane reactors.[171] Approximate cost calculations for a stirred tank reactor process show that the catalyst accounts for the greatest share of the costs. The product-specific costs of the catalyst can be considerably reduced by using more efficient manufacturing techniques and by stabilization and recovery of the lipase after the reaction. Even so, enzymatic splitting of fats cannot yet compete with conventional methods, despite the possibility of saving energy.

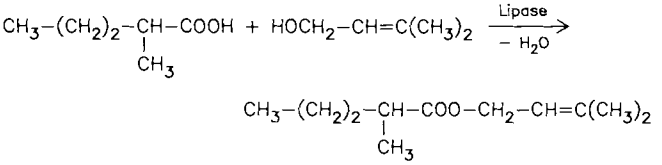
Enzymatic processes can be expected to show the greatest advantage when a complete breakdown of the material is not necessary or when the objective is to produce special fatty acids making use of the specificity or selectivity of lipases. In Japan, about 8000 tonnes of fatty acids have been produced enzymatically each year since 1983 for the manufacture of soap. A process which has been used in Japan since 1985 for producing unsaturated fatty acids on a tonnage scale with a purity of up to 99% combines enzymatic splitting with special procedures for product recovery.[172] The highly purified fatty acids are under investigation for applications in the cosmetic, pharmaceutical, and electronic fields.

4.3.1.2. Transesterification

In contrast to chemical methods, the use of lipases with regiospecificity for the 1 and 3 positions allows defined exchanges of the fatty acids in triglycerides. By this means, fats with a specified melting behavior can be synthesized, as is required for the manufacture of cocoa butter substitutes, margarine, butterfat and cooking fat.[173, 174] It is also possible to increase the half-life of the enzymes by immobilization techniques, thus reducing catalyst costs.[175]

4.3.1.3. Ester Synthesis

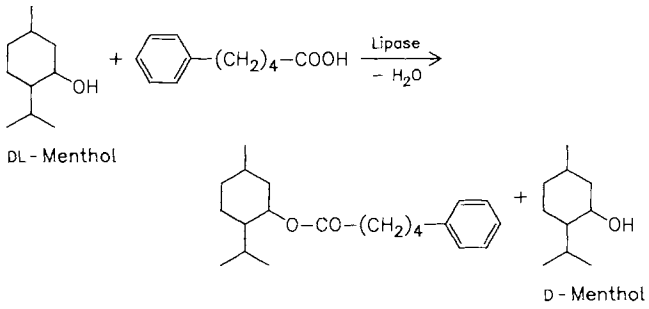
The reversibility of the enzyme-catalyzed hydrolysis of fats was demonstrated as early as 1900 by esterifying butyric acid and ethanol with a lipase-containing pancreas extract.[176] There has been further detailed development work on the enzymatic synthesis of esters during the past two decades. The ability of the various lipases to catalyze esterification reactions varies very widely for different reactants.[163, 177] Whereas tertiary alcohols and sugar alcohols undergo little or no reaction, it has been possible to synthesize the corresponding esters from many different terpene alcohols, giving products which are important in perfumery. The esterification of 2-methylpentanoic acid with prenyl alcohol has been found to give 98% conversion (Scheme 18). Enzymatic syntheses of wax-type esters and ester oligomers from dicarboxylic acids and diols also gave up to 90% conversion.[178] Sugar esters can also be obtained by enzymatic catalysis in aqueous and organic media. They are used as emulsifiers for foodstuffs.[179, 180]



Scheme 18. Lipase-catalyzed synthesis of 2-methylpentanoic acid prenyl ester.

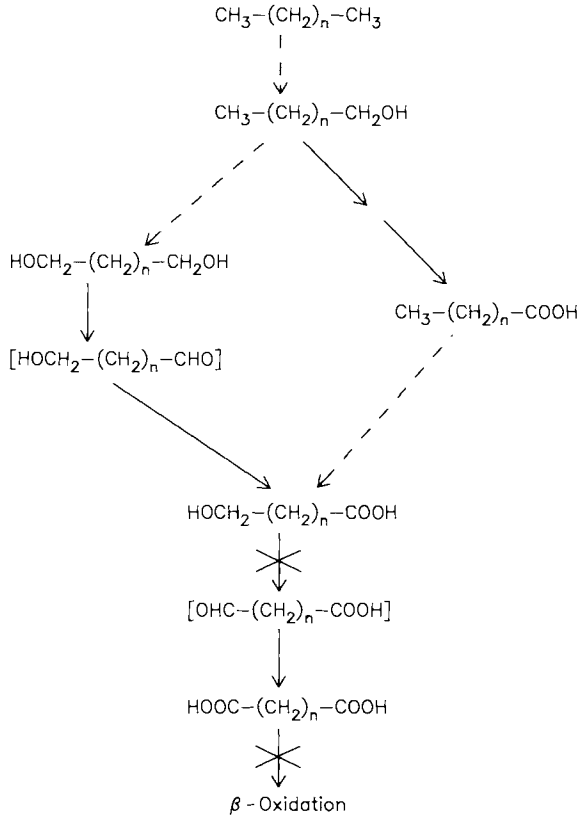
In recent years, the synthetic potential of lipases has been broadened by using them in non-aqueous and nonpolar solvents. They are increasingly used for synthesizing chiral esters (Scheme 19),[181, 182] which are potential intermediates for fine chemicals and pharmaceuticals.

Another possible area of application for lipase-catalyzed esterifications is in the production of pure monoglycerides, which are important emulsifiers and stabilizers used in foodstuffs, pharmaceuticals and cosmetics.[183]



Scheme 19. Stereoselective esterification of DL-menthol with 5-phenylpentanoic acid: only L-menthol is converted into the ester. D-Menthol remains behind.

Of the several possible reaction pathways for obtaining fatty acid glycerides, namely the partial hydrolysis of triglycerides, the transesterification of triglycerides with alcohols, the glycerolysis of triglycerides and the synthesis from glycerol and fatty acids, only the last two are useful for preparing pure monoglycerides.[163] The main enzymatic method which has been studied is the esterification of fatty acids with glycerol. Continuous reaction in a membrane bioreactor using lipases adsorbed onto membranes gave mixtures of mono- and diglycerides.[184] A mixture of glycerides containing 95% of the monooleate and 5% of the dioleate was successfully synthesized in the presence of a lipase obtained from *Penicillium cyclopium* with 50% conversion of oleic acid.[185]



Scheme 20. Microbial transformation of alkanes to dicarboxylic acids [50]. Catalysis by oxygenases (---) or dehydrogenases (——); hypothetical intermediates in square brackets; x: block mutants of technical interest.

4.3.2. *Biotransformations of Fatty Acids*

Besides the reactions involving the carboxy group, biotechnical processes also open up possibilities for carrying out specific reactions at non-activated positions in the fatty acid chain. Here the biotechnological use of isolated enzyme systems is of only limited importance, owing to the complex structure of enzymic redox systems compared with hydrolytic systems.

4.3.2.1. *Oxidative Transformations*

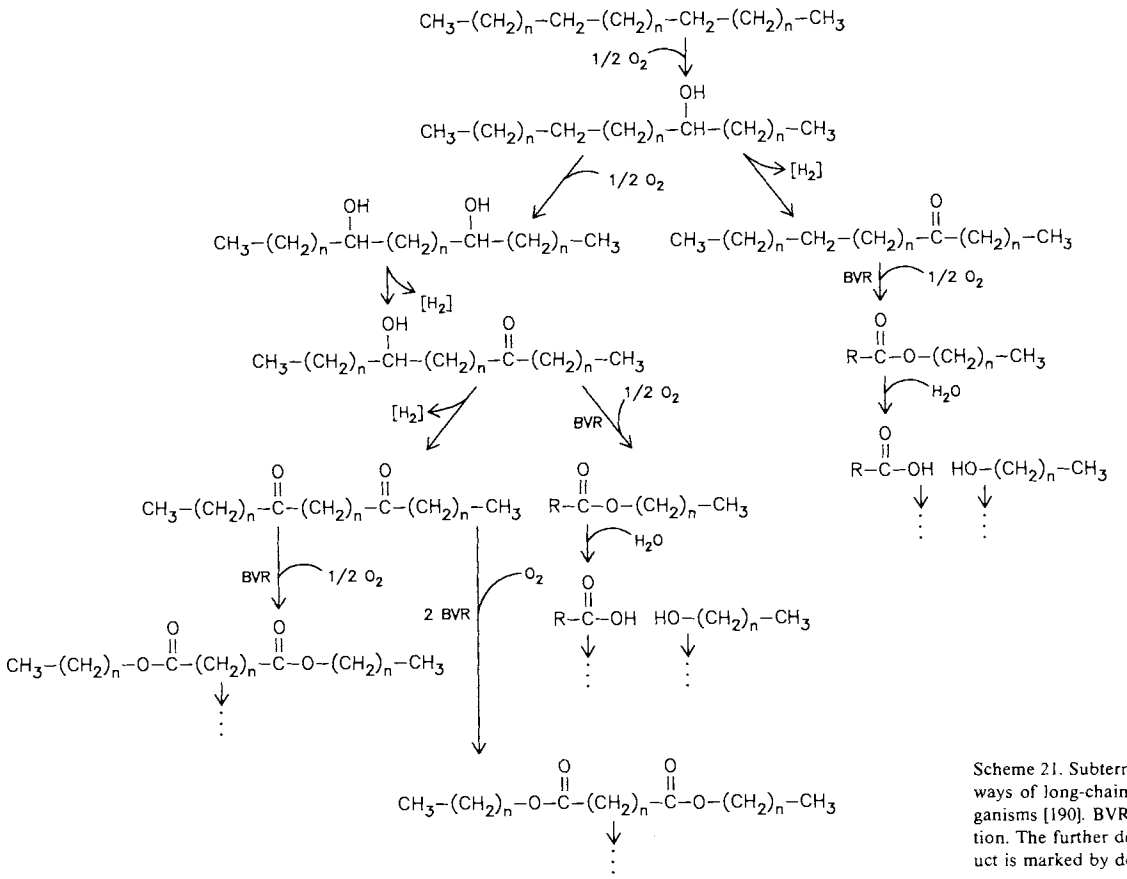
Oxidation of fatty acids at the terminal position leads to dicarboxylic acids, which are technically important as monomers for polymer manufacture and as intermediates for making bleaching agents. The diterminal microbial oxidation of unbranched alkanes and alkenes to give mono- and dicarboxylic acids using bacteria and especially yeasts has been thoroughly investigated. The metabolic pathway of this transformation proceeds via fatty acids and ω-hydroxyacids as intermediates. Subsequently, breakdown of fatty acids by β-oxidation can occur (Scheme 20).[186]

Whereas it has been possible to obtain yields of dicarboxylic acids at concentrations up to 140 g/L of fermentation liquid from alkanes using yeast, the yields of dicarboxylic acids from fatty acids have been considerably less up to now.[188] In order to develop an economical process, whether by fermentation or in the bioreactor after immobilization of the cells, highly efficient microorganisms are required in which the ability to break down fatty acids by β-oxidation has been eliminated as far as possible. A fermentation process for producing tridecane-1,13-dioic acid (brassylic acid **21**, n = 11) by terminal oxidation of tridecane is already being used on an industrial scale in Japan.[189]

The oxidation reactions that are described below have not yet been carried out on a technical scale, but they indicate the potential of microbial fatty acid transformations. Subterminal oxidation of one or more of the methylene groups in *n*-alkanes gives secondary alcohols and the corresponding ketones, which then undergo further metabolization to fatty acids (Scheme 21). Transformations of this kind have been described for a wide variety of bacteria, yeasts and molds.[190]

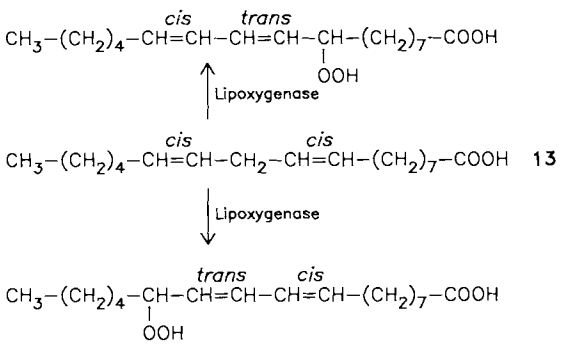
Hydroxylation as the initial enzymatic step can be catalyzed in these reactions as in terminal oxidation by monooxygenases, which are enzyme systems based on cytochrome P450.[186] Hydroxylation can also be achieved by addition of water to double bonds. Such reactions using various bacteria under anaerobic conditions have been described for Δ^9-unsaturated fatty acids and fatty alcohols.[191–193]

Unsaturated fatty acids containing a *cis,cis*-1,4-pentadienyl group undergo specific oxidation by the enzyme lipoxygenase, with a regiospecificity and/or stereospecificity which differs according to the source of the enzyme, in the presence of oxygen, to yield *cis,trans* conjugated monohydroperoxides (Scheme 22).[194, 195] The compounds thus obtained lead in turn to a range of further products and



Scheme 21. Subterminal degradation pathways of long-chain *n*-alkanes by microorganisms [190]. BVR = Baeyer-Villiger reaction. The further degradation of the product is marked by dots.

are of considerable interest for synthesizing prostaglandins and prostaglandin precursors.[196-198] The lipoxygenase for such reactions can be provided either as the crude product obtained by roasting soybean meal or as the immobilized enzyme.[199]



Scheme 22. Oxidation of linoleic acid **13** by lipoxygenase. The product composition—9- and/or 13-hydroperoxide—varies with the source of the enzyme.

Desaturation of fatty acids in microorganisms and in higher organisms has been investigated in detail.[200] In eukaryotic organisms, the reaction is catalyzed by a membrane-associated enzyme system.[201]

4.3.2.2. *Reductive Transformations*

Fatty alcohols are widely distributed in nature as components of waxes. Their biosynthesis involves the reduction of activated fatty acids in several steps by cofactor-dependent enzyme systems which are usually attached to membranes.[202] Consequently, technical processes for the bioreduction of fatty acids to fatty alcohols can only be carried out using intact microorganisms, as it is still uneconomic at present to use isolated enzymes for complex reaction sequences with the necessary regeneration of cofactors. A quantitative study of the use of enriched isolated enzyme material derived from various microorganisms and plants indicated that the biochemical potential of this conversion process is probably insufficient.[50]

The hydrogenation of unsaturated fatty acids using anaerobic microorganisms has only been demonstrated qualitatively in most cases so far.[203] Linoleic acid has been converted to *trans*-11-octadecenoic acid using several different bacterial strains.[204] By using a rumen bacterium, linolenic and linoleic acids were converted to *cis*-15-octadecenoic acid and stearic acid respectively, with yields of 85%.[205] Up to now there has been little or no investigation of the enzyme systems involved.[206]

4.3.3. *Biotransformations of Other Fat Components*

Biotransformations of glycerol, the co-product from the splitting and transesterification of fats, and the use of sterols which occur as minor components of fats with considerable economic potential, will be only briefly discussed here.

4.3.3.1. Glycerol

Glycerol can often replace glucose or other carbohydrates as a carbon and energy source in fermentation processes. Numerous fermentation products obtained from glycerol have been reported, such as bioemulsifiers,[207] flocculating agents,[208] and celluloses.[209]

Glycerol has been converted on a laboratory scale into various products of higher added value such as dihydroxyacetone,[210] glycerol-2,3-dihydroxypropylaldehyde,[211] 1,3-propanediol,[212] 3-hydroxypropylaldehyde and 3-hydroxypropionic acid[213] using in some cases bioreactors with immobilized cells.[214] For dihydroxyacetone yields of up to 149 g per liter of culture medium have been reported.

4.3.3.2. Sterols

Sterols are obtained from oils and fats used in industry, which contain up to about 0.35% of sterols.[215] With an annual consumption of 9.5 million tonnes of oils and fats in the chemical industry, the potential supply of raw materials in the form of sterols is therefore about 33 000 tonnes. Sterols are used mainly in manufacturing steroid derivatives, especially corticosteroids, for pharmaceutical purposes.[216-223]

5. Future Prospects

Oils and fats of plant and animal origin offer possibilities for providing chemistry with a wealth of reaction products which will be of great value in the future. Successful applications in this field will reduce the present over-dependence on petrochemical feedstocks and will give rise to new synthetic routes. The chemical possibilities of renewable oils and fats are still very far from being fully exploited. Interdisciplinary collaboration involving chemistry, biotechnology, plant breeding and agriculture is necessary to extend the successful applications of this technology.

The authors wish to acknowledge the contributions by Dr. G. Lück, Mr. K. Siekmann, and Dr. K. Schumann to this work.

The Use of Light in the Study of Interfacial Electrochemical Reactions

The Use of Light in the Study of Interfacial Electrochemical Reactions

Heinz Gerischer*

Spectroscopic analysis techniques have become particularly important in the study of interfacial electrochemical processes since it has become possible to increase their sensitivity to the extent where changes occurring in the absorption of light by fractions of monolayers can be detected. At the same time the development of new techniques in surface physics, though most of these can only be used in ultra-high vacuum, has also had a considerable influence on electrochemistry since it has enabled studies to be carried out on electrodes after transfer to UHV. The availability of well-defined semiconductors in which photocurrents can be generated by the absorption of light has led to the development of photoelectrochemical methods that can be used for the study of electrode reactions at semiconductors or at metal surfaces which are covered with a semiconducting film. Finally, it has been observed during the study of semiconductor electrodes that redox reactions at an electrode can result in the generation of luminescence. This, in turn, can lead to important information on the mechanism of the charge transfer process. These recent developments are reviewed in the present article.

1. Introduction

Classical investigation techniques in electrochemistry have usually depended on the analysis of quantitative and time-dependent relationships between current and potential to characterize equilibrium conditions and reaction rates of electrode processes. The kinetics of many processes could be deduced from the response of parameters measured in amplitude and time during a modulation of one of these variables. Relatively little information, however, can be obtained in this way about the influence of structural factors, intermediate products, or changes in the electrode that occur during such a reaction. Insight into the structural properties of surfaces and their behavior or into molecular processes can only be attained by the use of spectroscopic methods. Since the quantitative changes that occur on a surface are minute when measured on an absolute scale, the use of such spectroscopic techniques only became possible with the development of instrumentation with exceedingly high sensitivities. This problem is common both to electrochemistry and to surface studies performed in vacuum or in the gas phase. The development of new measurement techniques in surface physics has thus made a considerable contribution to the fact that the use of spectroscopic methods has today become indispensable in the characterization of electrochemical processes. The presence of a liquid phase at the electrode surface, however, causes severe restrictions in the use of such techniques since the majority of them involve the use of ultra-high vacuum or very low gas pressures. Many of these new techniques can consequently be used only in ex-situ measurements, which necessitates that the conditions at the electrode surface be stable on transfer to UHV.

[**] The previous page shows Figure 10 of this article.

The use of semiconductors and insulators as electrode materials gave a new impetus to the application of light to electrochemical processes. The absorption of light by these materials can lead to dramatic changes in their electronic properties which also influence their electrochemical reactivity. Photocurrents are produced, whose intensities and spectral dependences provide information on the relationships between the electronic properties of the solid and the electrochemical reactions. This article will attempt to describe these techniques together with a series of examples without, however, attempting to be completely comprehensive. The choice of examples is a personal selection taken largely from work carried out in the institute in which the author has worked for the past two decades.

2. Principles of the Usage of Light as an Analytic Tool

As in classical spectroscopy, the absorption of light at electrodes can be used to detect any changes occurring therein. Since most electrode materials possess metallic properties and themselves absorb light very strongly, one must normally work in the reflection mode, in which the reflected light intensity is dependent upon the angle of incidence and the direction of polarization of the incoming light. It is therefore necessary to be able to recognize the reflection from the "pure" surface and to derive information from the changes in this reflection. Historically, this was first achieved in ellipsometry,[1] where the thicknesses of light-transparent films were measured from the changes in phase and amplitude of polarized light reflected by the metal. This method, which can be used in-situ, achieves even today an unsurpassable accuracy in the determination of thin transparent layers, if their optical properties are well known.[2-4] On the other hand, for films which are less well characterized or which are absorbing, the method is extremely tedious and the analysis very time-consuming,

especially in cases where the optical properties of a film are not homogeneous. The less exact, but rather quicker method of direct measurement of absorption of reflected light is therefore more frequently used.

Considerable advances have recently been made in the measurement of absorption of IR light. Many metals have an extremely high reflectivity in the infrared region; thus, despite the low extinction coefficients of molecular vibrational excitation, one can observe the production and presence of adsorbed molecules in the reflection mode even at very low coverages. The excitation must, however, occur at a frequency where the solution is transparent and the extinction coefficient of the adsorbed species must not be too low.[5,6] The sensitivities of such optical methods may be increased by orders of magnitude if the absorption wavelength or the surface coverage is dependent upon the field strength and thus enables the absorption to be reproducibly modulated by periodic variation of the electrode potential. In the visible and UV regions, for which very sensitive detectors are available, changes in reflectivity of even 10^{-6} can be measured with the help of the lock-in technique.[7,8] At these wavelengths, the reflectivity of metal surfaces can be altered by the electrode potential due to the modification of the electron density at the surface.[9,10]

Another technique that can, however, achieve high sensitivity only on certain metals, is that of increased Raman scattering by rough metal surfaces, first observed at electrodes by *Fleischmann, Hendra* et al.[11] With the help of surface-enhanced Raman effects molecules adsorbed on the metals gold, silver and copper have been detected in very low concentrations,[12] which would not have been possible with normal Raman scattering.

At wavelengths where the electrolyte precludes the use of these methods due to its own absorption properties, information can, instead, be obtained by transferring the electrode to a vacuum (ex-situ methods[13,14,15]). Electron diffraction techniques and photoelectron spectroscopic methods from surface physics using X-rays, synchrotron radiation or electron beams may then be employed in the surface analysis provided that no alterations are made to the structure or composition of the surface by the transfer to an ultra-high vacuum.

Absorption of light can also lead to variations of the electrochemical behavior of the electrode itself. This can be seen in metals when excited electrons attain enough energy to enter a neighboring phase (photoelectron emission[16,17]). Such reactivity resulting from absorption of light is even more marked in the case of semiconductors.[18,19] Here, the oxidation or reduction properties which these materials possess as a result of the production of minority electronic carriers, i.e. electron holes in n-type semiconductors or conduction electrons in p-type semiconductors, are changed to such an extent that new charge transfer processes become possible at the phase boundary with the electrolyte. These may be detected by the appearance of photocurrents whose intensities and spectral behavior yield information regarding the properties of the electrode and the processes occurring at the phase boundary. It may be added that semiconductor electrodes also allow redox reactions of excited molecules adsorbed at the phase boundary to be studied (spectral sensitization[20]), a procedure which has been used for more than a hundred years in photography.[21]

Finally, the emission of light may also occur as a consequence of an electrochemical reaction, when such a reaction gives rise to electronically excited states. One example of this is the electroluminescence of semiconductor electrodes which is produced by the injection of minority carriers.[22-24] From such observations, information concerning energetic relationships during electron transfer processes can be acquired. Such data have recently even been obtained from light emitted by metal electrodes.[25]

3. Spectroscopic Methods

The spectroscopic determination of reaction products in solution which have been produced by electrode reactions is one of the most important analytical techniques. For the investigation of short-lived intermediates thin-layer cells with transparent electrodes have been developed. The electrodes are generally composed of either thin evaporated metal layers or transparent, heavily doped oxide layers (tin or indium oxides, for example, or a mixture of these components). However, only those methods which yield direct information on processes occurring at the surface of an electrode will be considered here. In the case of compact electrodes which are not transparent to light these measurements are carried out in the reflection mode. These types of investigations may be carried out in-situ if the electrolyte is transparent to light in the particular region of the spectrum used. Otherwise, the electrode must be removed from the electrolyte and transferred to a vacuum or to an inert gas atmosphere (ex-situ methods). Examples of both procedures will be given in the following.

3.1. Infrared Reflectance Spectroscopy

IR spectroscopy has only recently begun to be used in electrochemistry. This is largely due to the disturbing absorptions of the electrolyte layers next to the electrode and the relatively low sensitivity of previous IR detectors. *Bewick, Pons* et al. were the first to overcome these difficulties, using very thin electrolyte layers between the electrode and an IR-transparent window together with a modulation of the electrode potential by periodic potential stepping.[26] This procedure is called "Electrochemically Modulated Infra Red Spectroscopy (EMIRS)". By changing the potential, either a change in coverage is induced or, as is often the case, the absorption frequency of a vibrational excitation is shifted to other wavelengths as a result of the electric field produced at the electrode and the corresponding change in bond strength. Thus, a modulation of the reflected light intensity as a result of variation in absorption can, with the help of the lock-in amplifier technique, be detected with very high accuracy. The relative change in reflectivity, $\Delta R/R$, is usually measured during this process. With the help of Fourier transform spectroscopy it has become possible to record spectra in the IR region relatively quickly[27,28] and, by averaging over many repetitions, to considerably improve the signal-to-noise ra-

tio, thereby allowing difference spectra to be constructed at various potentials. This procedure is referred to as "Subtractively Normalized Interfacial FTIR Spectroscopy (SNIFTIRS)".

Since the electric vector of the light parallel to the surface of metallic conductors in the IR region goes to zero, the selection rule valid in reflectance spectroscopy in the IR region is that only vibrations with an electric moment normal to the surface can be excited. Only for such vibrations can the change of the electric field in the Helmholtz double layer influence the bond strength involved and hence the position of the absorption maximum. For this reason, linearly polarized light with a vector normal to the surface, i.e. p-polarized light, with an angle of incidence between 45° and 70° is used for such measurements. From a comparison between the reflection of p- and s-polarized light one can determine which signals are due to adsorbed molecules, since molecules in the solution, being uniformly distributed in orientation, absorb both polarizations to the same degree. By modulating the polarization angles between s and p the signal originating from the surface can be separated from the background absorption of the electrolyte. This procedure can be carried out with a dispersive monochromator or by using a Fourier transform system.[29,30]

The principles of such a system are shown schematically in Figure 1. The sensitivity of IR reflectance spectroscopy is limited by the sensitivity of the detectors. Changes in reflectivity in the order of 10^{-3} are necessary to obtain a measurable effect. This implies that one largely detects materials that adsorb in rather high coverages on the electrode. These need not necessarily be the species that dictate the reaction mechanism—they can also, of course, be by-products that only slowly undergo further reaction and thus play no decisive role in determining the overall reaction rate.

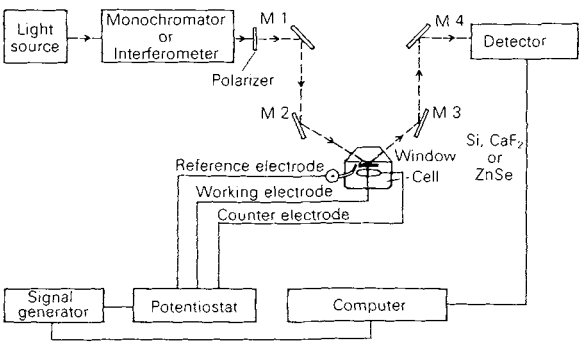

Fig. 1. Block diagram of the system used for measuring the spectra of reflected light at a given or modulated electrode potential. M = mirror.

As an example let us consider the oxidation of methanol, formaldehyde and formic acid at noble metal electrodes. From cyclic current-potential curves it was concluded that an intermediate product was produced which was very strongly adsorbed at the electrode surface. This intermediate blocks the course of the reaction until at higher anodic potentials it can be displaced by chemisorbed oxygen and thus oxidized to CO_2. It was believed to be either the COH or the HCO radical.[31,32] Spectroscopically, however, only adsorbed CO was detected on these noble metal

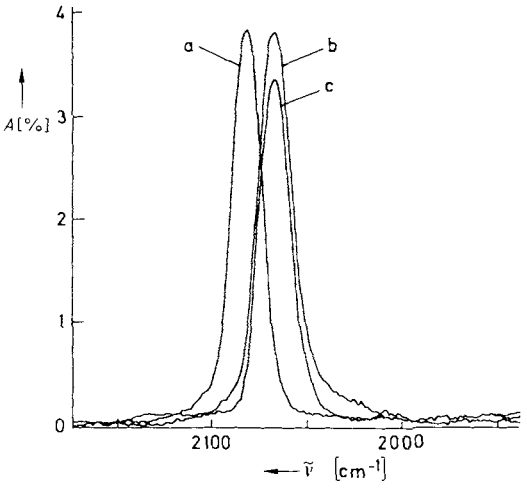

Fig. 2. IR absorption spectra of CO adsorbed on platinum at 86% coverage (Θ) in 0.5 M H_2SO_4: a) solution saturated with CO; b) + 1 M CH_3OH at $U = 0.4$ V; c) + 0.1 M HCOOH at $U = 0.3$ V; after *Kunimatsu* [34]. A = absorption. U measured versus a reversible hydrogen electrode (RHE) in the same electrolyte.

electrodes.[33,34] Figure 2 shows spectra measured for a platinum electrode that has been in contact for a certain length of time with methanol or formic acid at a specific anodic potential. For comparison, the spectrum of directly adsorbed CO is also shown. Aside from a slight shift in the position of the absorption band, indicative of the fact that the molecule is in a different environment, it has exactly the same profile and almost the same intensity as the above. This absorption band can be attributed to linearly adsorbed CO.[35] Figure 3 shows the changes occurring in the spectrum with increasing CO coverage, the CO being generated as an intermediate in the oxidation of CH_3OH.[34]

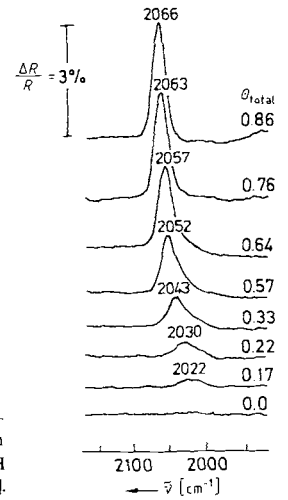

Fig. 3. Absorption spectra for various coverages (Θ) of CO adsorbed on platinum and formed during the oxidation of CH_3OH at $U = 0.4$ V (RHE); after *Kunimatsu* [34].

Other techniques have shown, however, that an intermediate is produced on the surface which blocks three adsorption sites, whereas adsorbed CO needs only one adsorption site. With the help of mass spectroscopic techniques it has recently been conclusively shown that the COH radical is present as an intermediate.[36] This discrepancy could be due to the fact that the mass spectroscopic

experiment was carried out at rather lower methanol concentrations, where sufficient adsorption sites were available for the COH radical, which requires three sites.[37] CO is preferentially produced at higher concentrations of CH_3OH. The spectroscopic evidence for adsorbed COH has still to be demonstrated.

IR spectroscopy of electrodes is still in the process of further development and one can certainly expect that significant information on reaction mechanisms will be acquired with the use of this technique.

3.2. Reflectance Spectroscopy in the Visible and Ultraviolet Regions

Very sensitive detectors are available for measurements in the UV and visible regions of the spectrum. Changes in reflectivity in the order of $\Delta R/R = 10^6$ can be measured. The first experiments of this nature were carried out by *Koch* and *Scaife*, who recorded spectra at various potentials during the growth of an oxide layer on Pt.[38] The introduction of modulation spectroscopy with the electrode potential as the modulated parameter, a technique first applied by *Seraphin* to the study of semiconductor band structure,[39] significantly increased the sensitivity that could be obtained. These techniques even allow the behavior of electrons at a metal surface in the electric field of the Helmholtz double layer and the interaction of this field with various ions or solution molecules in the double layer to be studied.[8,40,41]

Some processes in which the origins of the changes in reflectivity are easily recognized will be given here as examples. Figure 4 shows the changes occurring in the reflectance spectra of a single crystal silver surface which occur as a result of the development of a surface complex with molecules from the solution.[42,43] A repetitive anodic polarization of the silver surface is used to generate this complex, during each pulse of which a monolayer of silver chloride is built up in the chloride-containing electrolyte. On reduction, this leaves behind active silver atoms on the surface. These silver atoms form very stable surface complexes with pyridine or pyrazine which cannot be destroyed any more by reduction over a wide potential range. Figure 4 shows the difference spectrum obtained by subtraction of the reflectance spectrum taken before the cycling treatment. It is clear that a broad absorption band is visible for each of the complexes generated in this way. One knows that the complexes formed between these molecules and the silver ions in solution are transparent to light at these wavelengths. The new absorption band arises as a result of a charge transfer process between the molecular complex and the metal electronic levels. The change in reflectivity is in the order of a few per cent. This extraordinarily large amount for a single monolayer can only be explained by assuming that in this optical transition a strong interaction with the metal occurs.

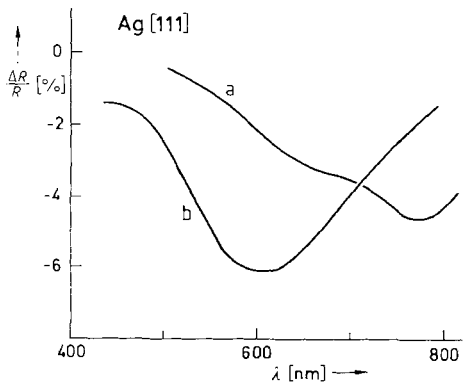

Fig. 4. Normalized electroreflectance spectra using p-polarized light for (a) pyridine and (b) pyrazine adsorbed on an activated single crystal silver surface. Modulation potential 0.5 V; after *Kolb* et al. [42, 43].

A further example demonstrating the high sensitivity that can be achieved by potential modulation is given in Figure 5a.[44] In this figure is shown the electroreflectance spectrum of *p*-nitroaniline which is strongly adsorbed on a platinum surface. The considerable difference between s- and p-polarized light may clearly be seen. In the case of s-polarized light, with the electric field vector parallel to the surface, there is no change in reflectivity on modulating the potential by ±50 mV, whereas for p-polarized light two clear maxima are produced. These maxima are not produced at the absorption maxima of the molecules in question. The maximum at 436 nm lies on the shoulder of the *p*-nitroaniline absorption band. The absorption band is considerably shifted by the change in the electric field in

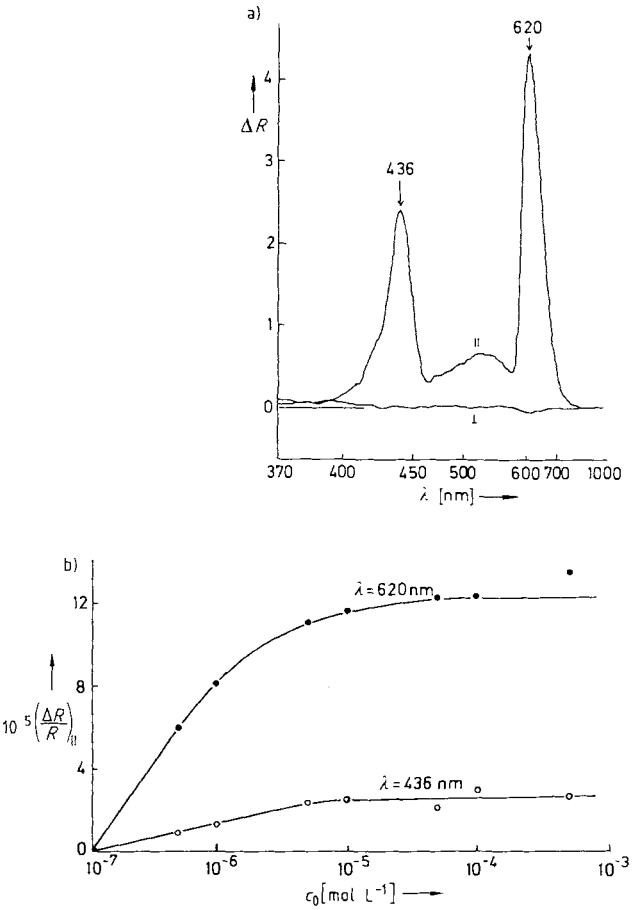

Fig. 5. a) Electroreflectance spectra of *p*-nitroaniline on a Pt electrode in 0.5 M Na_2SO_4 + 5×10^{-5} M $H_2NC_6H_4NO_2$ for p(||)- and s(⊥)-polarized light. Modulation potential: 0.1 V. ΔR in relative units ($\Delta R/R$ approximately 10^{-5} per unit). b) Normalized electroreflectance intensities of the two maxima in (a) as a function of the concentration (c_0) of *p*-nitroaniline in the solution; after *Plieth* et al. [44].

the Helmholtz double layer as a result of the fact that these electronic transitions in the molecules have an electric moment normal to the surface (Stark Effect). The maximum at 620 nm may be attributed to the build-up of aggregates of molecules on the surface. As shown in Figure 5b adsorption isotherms may be obtained from the intensity of these signals measured as a function of the concentration of molecules in the solution.

Very marked effects are observed when a second metal is deposited onto a metal electrode. The optical constants of the metal surface are, in this case, dramatically changed. Of particular interest are those systems in which adsorption of the first monolayer yields an ordered phase structure, a situation often observed on single crystal surfaces. This occurs at potentials which are more positive than the actual deposition potential of the bulk metal (underpotential deposition).[45] From the reflection spectra, one can also see how the bulk properties of a new phase are developed on deposition of successive monolayers. As an example of this, measurements made for the deposition of silver on a Cu[111] single crystal surface are presented in Figure 6.[46] The potential dependent reflectance spectrum with a potential modulation of 300 mV in a specific potential region is shown first for the pure copper and then for deposition of various thicknesses of silver. Of the changes which occur in the reflectance spectrum, the minimum occurring at 3.8 eV which first becomes visible at coverages of more than three monolayers is especially interesting.

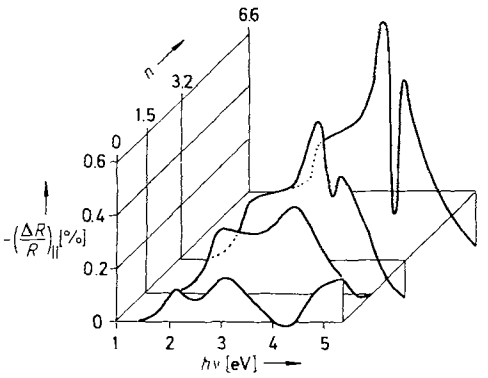

Fig. 6. Electroreflectance spectra of p-polarized light from a copper[111] surface before and after the deposition of various amounts of silver in 0.5 M H_2SO_4. Modulation potential 0.3 V (after *Kolb* et al. [46]). n = Number of atomic layers.

This minimum is typical of the excitation of bulk plasmons in the silver and shows that at these thicknesses the electronic system of the silver film already begins to show the properties of bulk silver. At thicknesses of over six monolayers the deposited layer exhibits practically the properties of the bulk metal.

3.3. Raman Reflectance Spectroscopy

Since the normal Raman effect is extremely weak, the observation of Raman lines for adsorbed molecules appeared at first rather a hopeless expectation. As already mentioned, an enhancement of Raman scattering from the surface rendering this effect measurable was first observed by *Fleischmann* and *Hendra* et al.[111] This enhancement can be up to 10^6 times greater than the original signal.[112] This phenomenon is termed "Surface Enhanced Raman Spectroscopy (SERS)" and is observed in this magnitude on only a few metals, e.g. silver, gold and copper. It occurs in connection with a plasmon resonance in the electronic systems of these metals at wavelengths at which strong absorption does not yet occur. This leads to a substantial increase in the electronic field strength on the surface under the influence of the electromagnetic field of the light. Since an excitation of this resonance is not allowed on a smooth surface, a surface roughening either by cyclic dissolution/deposition of the metal or by formation of metal clusters must precede. There must also be a very strong interaction between the adsorbed molecule and the surface, if the observed enhancement is to be explained.[47] The SERS effect is very clearly visible on colloid particles of the above mentioned metals.[48,49]

The origin of this phenomenon is, in fact, not fully understood in detail. Its restriction to only a few metals unfortunately prohibits general application, and detailed structural information on the positions of adsorbed molecules on the surface is also lost as a result of the necessary surface roughening involved. The possibility that a vibration-spectroscopic method of molecule characterization with visible light may become possible with this technique is, however, exceedingly attractive and lends impetus to the undertaking of further intensive research in this area.

The classical system in which this phenomenon has been thoroughly investigated in detail is the adsorption of pyridine at silver surfaces. Figure 7 shows a comparison between two Raman spectra, one taken from molecules in solution (Fig. 7a), the other from molecules adsorbed at a silver surface (Fig. 7b).[42] The topmost spectrum taken from pyridine in solution is recorded from ca. 6×10^{13} molecules, i.e. from that amount of pyridine to be found in the volume of solution through which the laser beam is passed. The lower Raman spectrum is taken from a single crystal silver surface, which, in order to produce an adsorbed complex of the type described above, was subjected to five oxidation-reduction cycles, thus generating activated silver atoms. If one assumes that a monolayer of pyridine molecules exists on the surface, then in this case only 10^{11} molecules should be affected by the laser beam. This difference and a comparison of the signal intensities indicate that the Raman scattering from the molecules adsorbed on the surface is a factor of 10^4 times greater than that from the molecules in the solution. One must also take into consideration the fact that in all probability not all of the molecules to be found on the surface take part in this scattering phenomenon. Furthermore, the surface roughening can be increased to such an extent that an increase in the Raman signal by as much as two more orders of magnitude can be achieved.[42]

Complementary experiments performed on colloid particles have also produced very informative results.[50] It has been observed here that fluorescence from adsorbed molecules can be almost totally repressed and the energy involved transferred to Raman scattering. This has the advantage that individual vibration lines, which otherwise would not be recognized in the broad fluorescence spec-

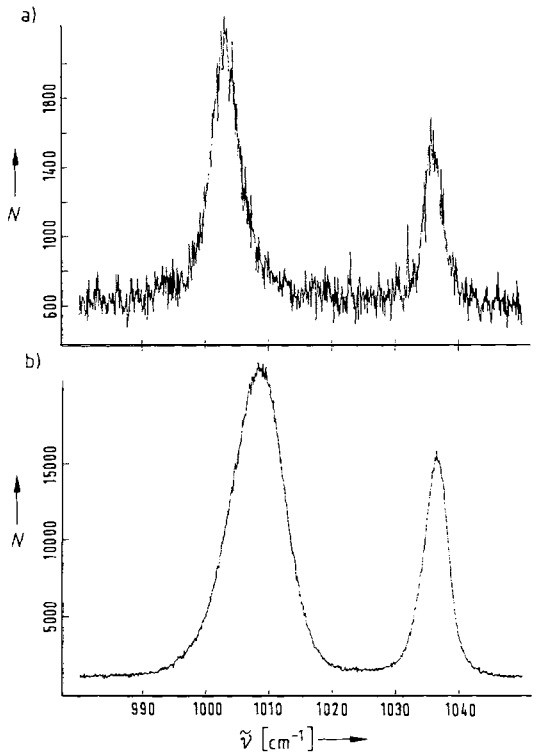

Fig. 7. Raman spectra of pyridine. a) From a solution of 0.05 M pyridine + 1 M KCl. b) After adsorption at an Ag[111] surface, activated by five oxidation/reduction cycles (after *Pettinger* et al. [42]). N = intensity, $\tilde{\nu}$ = Raman frequency.

trum, now become visible. A very sensitive technique is thus obtained for the characterization of specific molecules, a technique which looks especially promising for the study of biological molecules.[51]

3.4. Photoelectron Spectroscopy

As mentioned above, the most important spectroscopic methods used in surface physics, which deal with the energy spectrum of reflected electrons or electrons emitted from the surface, can only be used ex-situ. The electrode must therefore be transferred from the electrochemical system to a vacuum chamber. Figure 8 shows one type of setup which allows transfer in either direction to be carried out with a minimum of delay.[52] Such systems have been used to determine changes occurring in the surface structure as a result of adsorption or reaction with the electrolyte. Two examples of this will be given in the following.

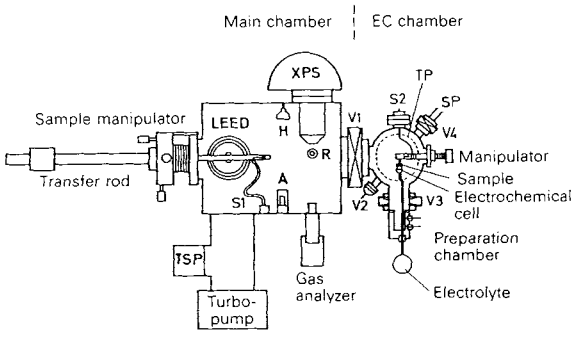

Fig. 8. Sketch of the apparatus used for investigation of electrodes in ultra-high vacuum by LEED or XPS [52]. A = ion source, H = halogen lamp, X = X-ray tube, S = sample support, V = valve, SP = sorption pump, TSP = thermosorption pump.

It has long been known from capacitance measurements carried out on electrodes in the absence of Faradaic currents that certain ions specifically adsorb on metal surfaces and can thus considerably alter the structure of the double layer. This is especially true of the halide ions, which can become strongly bonded to many metal surfaces through a partial transfer of electrons. These adsorbed ions can be directly detected with the help of photoelectron spectroscopy. The results of ion adsorption from a cesium bromide solution on gold electrodes will be discussed as an example. The electrolyte flows almost completely away from a very smooth gold electrode when the electrode is taken out of the solution. Only those ions bound by chemical or electrostatic forces to the surface remain attached. When such a surface is transferred to a ultra-high vacuum and exposed to X-rays of specific wavelength, electrons whose energies may be analyzed by detectors are released into the vacuum. From their kinetic energy and the excitation energy of the X-rays, which is well known, the energy levels from which the electrons originate can be calculated.

Figure 9 shows the concentration of the adsorbed bromide and cesium ions which remain on the electrode surface as a function of the potential at which the electrodes are taken out of the electrolyte. It may be seen that at very negative potentials only cesium is adsorbed whereas on going towards more positive potentials, bromide is adsorbed in ever increasing amounts. The point of zero charge, U_0, and the $Cs^{\oplus}$ coverage in an electrolyte in which specific adsorption of the anion does not occur are also shown in the diagram. This point of zero charge is the potential at which no excess charge would normally be found on the surface. It should be noted that the bromide adsorption first begins at quite negative potentials relative to U_0 and

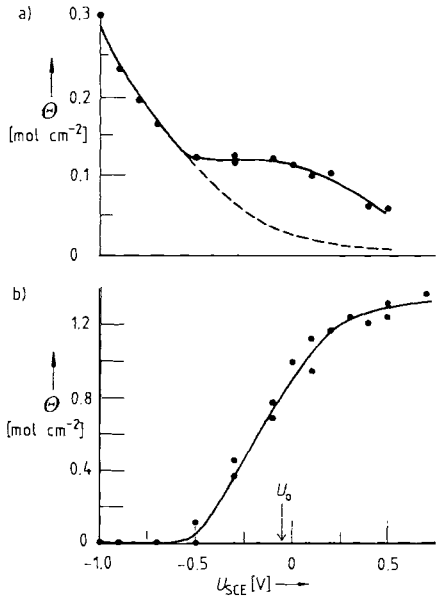

Fig. 9. Ions [a) $Cs^{\oplus}$; b) $Br^{\ominus}$] present in the electric double layer of a gold electrode after withdrawal at various potentials from a 0.01 M CsBr solution (XPS of the Cs $3d_{5/2}$ and Br $3p_{3/2}$ electrons). Dashed curve: amount of $Cs^{\oplus}$ measured using a 0.005 M Cs_2SO_4 solution; U_0 = point of zero charge in the sulfate solution (after *Kolb* et al. [53]).

that cesium ions may still be found on the surface even when it is positively charged. The bromide ions are attached to the surface not only by electrostatic forces but also by additional chemical interactions. The increase in concentration of bromide ions at the surface results in a coadsorption of cesium ions. The picture that had previously been indirectly built up from thermodynamic investigations is thus confirmed analytically.

A second example is given to illustrate the changes in chemical composition that occur in a solid during oxidation. Figure 10 shows photoelectron spectra taken from a

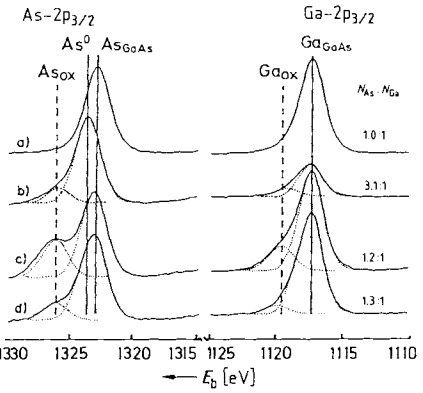

Fig. 10. Photoelectron spectra of [110] n-GaAs electrodes after various treatments [54]; AlK_α radiation; E_b = bonding energy. a) Well defined surface after tempering in UHV. b)–d) After passing 60 mC/cm² in 0.1 M NH_4BF_4 at anodic potentials of 0.7 V (vs. Ag/AgCl) under illumination: b) at pH 2 (addition of $HClO_4$); c) at pH 10 (addition of NH_4OH); d) at pH 13 (addition of NaOH).

gallium arsenide single crystal before and after oxidation.[52,54] The photoelectron spectra of the 2p-core electrons from As and Ga in the solid state after various methods of pretreatment are shown. The spectra taken from a well-defined surface after tempering (Fig. 10a) show the position of the electron energy levels, E_b, and their corresponding intensities, N, in a well-ordered crystal lattice. A spectrum obtained after oxidation in an acidic medium shows a considerable difference in the intensity ratio between the Ga and As signals (Fig. 10b). The As signal is also shifted towards higher binding energies for electrons, which may be attributed to the presence of As–As bonds in elementary As. (In gallium arsenide, arsenic has an excess negative charge which somewhat reduces the binding energy.) It therefore can be concluded that in acidic media the arsenic content is increased whereas the gallium is preferentially oxidized forming a soluble complex. This is a result of the lower electron affinity of the gallium in this bond. Figure 10c shows the spectra obtained after treatment in a weakly alkaline medium. In this case no change is observed in the gallium:arsenic ratio. Both materials are apparently oxidized to more or less the same extent. On removal of the electrolyte from the electrode, however, a part of the oxidized material remains in an oxidized state on the surface. This can be seen from the shift of both signals towards higher binding energies. Clearly the difference in electron affinity observed in the experiments described above is compensated for in alkaline solutions by the strong tendency of arsenic to form acidic compounds with oxygen.[54]

It was also observed that the oxidation of arsenic could be promoted in acidic solutions by the application of high anodic potentials which then lead to only a slight increase of the As concentration at the surface. A more careful analysis of various core level spectra has shown that the As enrichment is not limited only to the topmost layer of the metal but rather also stretches into the bulk of the crystal, so that a porous coverage of clusters of arsenic atoms is obtained.[54] Such processes are extremely important in the surface treatment of semiconductor devices.

The entire range of analytical techniques in surface physics may, of course, be applied to the electrode surface when the electrode may first be transferred to a ultra-high vacuum. For instance, EXAFS may be used to determine interatomic distances in noncrystalline ordered regions or to determine the position of adsorbed atoms or molecules on a surface.[55] Such information may also be obtained from the X-ray fluorescence seen when standing waves are generated on a surface with the use of synchrotron radiation.[56] Many new developments are taking place in this field from which one can expect to obtain very detailed information about bonding on surfaces in the future.

4. Photocurrents as a Means of Detection

Photocurrents may be observed when the absorption of light leads either to the setting free of mobile charge carriers in a solid or to ionization of atoms or molecules. In a metallic conductor where a great many mobile charge carriers already exist, the effect of absorption of light is almost impossible to detect, especially since the lifetime of the excited state is extremely short. Only when they lead to electron emission to a neighboring phase from which the charge carriers may be extracted can photocurrents be observed. Quite another situation exists in the case of semiconductors and insulators. The lifetime of an excited state is much longer here because of the existence of a band gap in their electronic systems. In addition to this, electric fields can exist in the bulk of these materials which can hinder the recombination of excited electrons with vacant energy states, the so-called electron holes or "holes", by spatially separating the two species. An analogous situation occurs for the ionization of atoms or molecules if these come under the influence of an electric field, as often happens at an interface.

If light having a quantum energy greater than the band gap energy, E_{gap}, of the semiconductor is absorbed in its bulk, pairs of conducting electrons and electron holes are generated. This is shown in Figure 11, in the energy band diagram of an n-type semiconductor. If an anodic potential is applied to the semiconductor, i.e. an excess positive charge is present, then in an n-type semiconductor a depletion layer of electrons is produced generating an electric field just under the surface. The holes formed have a specific lifetime during which they can diffuse toward the interface so long as this is within their average diffusion range. On reaching the space charge layer they are drawn to the surface by the electric field there, shown in Figure

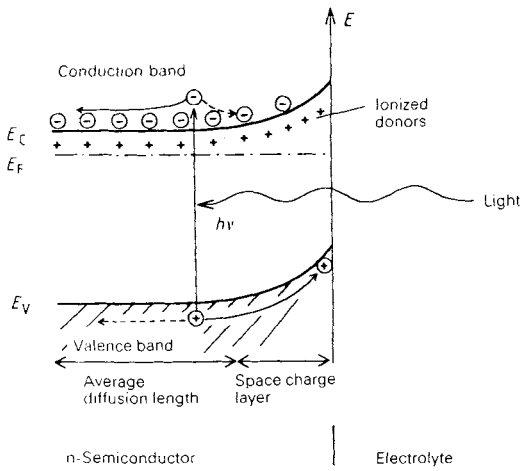

Fig. 11. Energy diagram showing the generation of photocurrents in an n-type semiconductor on application of a positive potential. E_C, E_V = position of the conduction and valence bands, resp.; E_F = Fermi level. The electric field at the interface is shown as a bending of the band edges. ⊖ = conduction electron; ⊕ = hole (defect electron).

11 as a band bending, whereas the conduction electrons are held at a distance from the surface. In this way recombination of the two species is prevented and measurable photocurrents are thus generated in semiconductors. The quantum yield obtained depends upon the properties of the solid, in particular its absorption coefficient of light and the average diffusion length of the holes. At sufficiently high anodic potentials it can reach a maximum quite close to unity.[57-59] In the following, some examples will be given of processes which have been detected by means of photocurrents.

4.1. Photooxidation of Semiconductors

It has been shown that oxidative dissolution of semiconductors occurs as a result of an enrichment of holes at the interface with an electrolyte.[60] Electron holes are simply bonding quantum states of the solid state lattice from which electrons are missing. They therefore weaken the bond strength between neighboring atoms. If such a hole reaches the surface of a solid, it acts as an ideal reaction partner for nucleophilic reagents. Consequently, p-type conductors in contact with an aqueous electrolyte are very easily oxidized on application of an anodic potential since not only nucleophilic reagents such as anions but also water molecules are present in such electrolytes. In the case of n-type conductors, exposure to light is necessary in order to form such holes. On application of anodic potentials they are drawn towards the surface, and the photocurrent observed can be taken as a measure of the decomposition rate.

Certain peculiarities are observed in the quantum yields of the photocurrents measured for germanium and silicon electrodes which provide further information on the mechanisms of these reactions. It can be shown that with these materials, the photocurrent produced can be higher than the quantum yield for production of holes would permit. In the case of silicon, which will be considered here in more detail, this increase in the quantum yield in aqueous electrolytes is only observed when $F^{\ominus}$ ions are present,[61-63] as shown in Figure 12a. In the presence of fluoride, the species $[SiF_6]^{2\ominus}$ is produced as a soluble reaction product.

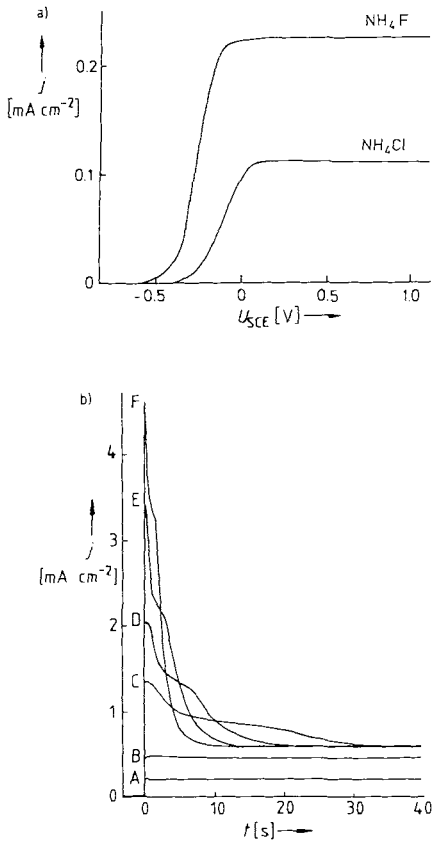

Fig. 12. (a) Photocurrent-potential curves for an n-type silicon electrode in 1 M NH_4F and 1 M NH_4Cl (pH 4.5); j = photocurrent density. b) Time decay of the photocurrents in an n-type silicon electrode in 0.13 M NH_4F (pH 4) at various light intensities: A) 0.3 mW; B) 0.7 mW; C) 2.2 mW; D) 3.6 mW; E) 6 mW; F) 8.8 mW.

In all other electrolytes, films of sparingly soluble or insoluble oxides are formed. When the silicon can react directly with the fluoride ions, the quantum yield is twice as great as in the presence of the oxide (see Fig. 12a). This is also visible in the behavior of the photocurrent when the light intensity is increased to such an extent that the rate of formation of the fluoride complex is no longer rate-determining. The photocurrent-time curves for various light intensities at constant potential in a fluoride-containing solution illustrate this effect (Fig. 12b). At higher intensities a decrease in current is observed after a short period of time, at first to about half of the original value and then to lower values. When the oxide layer reaches a certain limiting thickness the current is only limited by the dissolution rate of the oxide. A more detailed analysis has shown that, at lower light intensities and at the start of the experiment, the photocurrent is twice as great as would be generated exclusively by the transport of holes to the surface. This may be explained by assuming that of the four oxidation steps leading from Si^0 to Si^{IV}, only two are dependent on the presence of a hole as reaction partner for $F^{\ominus}$ ions. The other two steps result from interactions of surface atoms with $F^{\ominus}$ ions in which electrons are injected into the conduction band from the previously produced intermediates

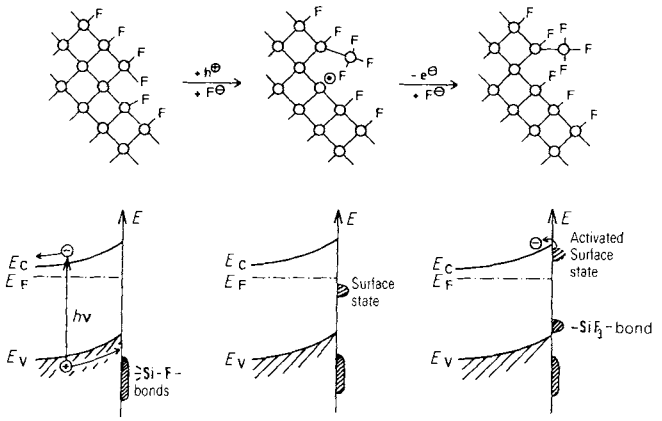

Fig. 13. Oxidation of a silicon electrode in fluoride solution. Top: reaction profile in a 2-dimensional bond scheme. Bottom: the corresponding electron energy terms in an energy band diagram [63]. $h^{\oplus}$ = Defect electron.

which contain an unpaired electron. The reaction path for the two steps is illustrated in Figure 13 (top). The bottom half of the figure also shows how the injection of an electron from the energy level of the unpaired electron in the intermediate product can be explained. An analogous mechanism may be described for the two subsequent steps, which lead to the formation of SiF_4.[63]

If the surface is covered with an oxide layer so that the $F^{\ominus}$ ions can no longer come into direct contact with the Si surface, then further growth of the oxide requires four holes. In the case of germanium, where the oxide is more soluble in acidic and alkaline solutions and the band gap is smaller, this two-step oxidation mechanism with electron injection into the conduction band can even be observed in its reaction with $OH^{\ominus}$ ions.[64] In the case of semiconductors with larger band gaps such as GaAs, GaP, CdS, and ZnO, electron injection from intermediate states is not observed, since in these materials the electrons are so strongly bound even in the radical-like intermediates that the electron cannot be excited to the level of the conduction band by thermal activation.[57]

4.2. Photooxidation of Organic Compounds

Electrons in the conduction band and holes in the valence band have a particular energy value with respect to an electrolyte. Their reactivity towards an electrolyte can thus be described energetically by a type of redox potential. Redox potentials are a measure of the electron affinity of a redox system. The more positive their value, the greater the affinity for, and hence the greater the tendency to take up, electrons, or the lower the tendency to give up electrons. The redox potential may be correlated with the work function involved in taking an electron from a solid phase to a vacuum; the higher the work function, then the greater the electron affinity. The unoccupied states in the valence band of a semiconductor, i.e. the holes, have, therefore, a much greater electron affinity than the unoccupied states in the conduction band. With the help of various techniques, which will not be described in detail here, it is possible to relate the band edges of a semiconductor to the scale of redox potentials of electrolytes.[17-19,65,66]

Figure 14 shows such a scheme for a series of semiconductors. The list of redox potentials—all referred to the normal hydrogen electrode (NHE)—is given in reverse order to that normally used in electrochemistry in order to show that we are concerned here with a thermodynamic scale for electron affinities. If the zero on this scale is put equal to the vacuum then it would lie at about −4.5 V (cf. the right-hand scale in Fig. 14). It can clearly be seen that electronic levels in the conduction and valence bands of various semiconductors have very different redox potentials. The lower down the valence band lies, the more oxidizing are its holes. The higher the level of the conduction band, then the greater the reducing strength of the electrons it contains. On the other hand, extraction of electrons from the valence band, i.e. injection of holes, requires the presence of a redox system with a redox potential lower than the band edge of the valence band and similarly, injection of electrons into the conduction band can only occur from a redox system whose redox potential lies higher than the edge of the conduction band.

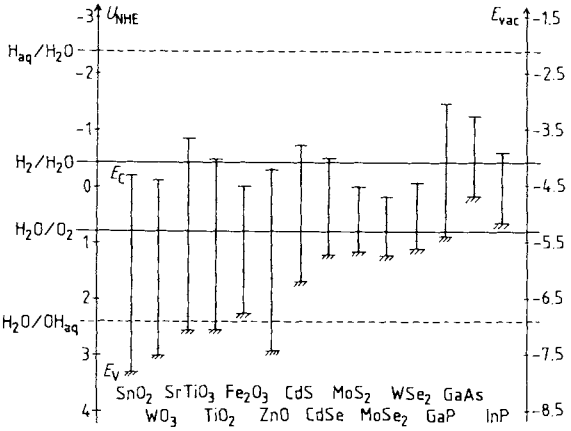

Fig. 14. Positions of the band edges of various semiconductors (at pH 7) in the scale of redox potentials, referred to the NHE (left), and to the vacuum level over the electrolyte (right).

From the position of the valence band edges of the semiconductors shown in Figure 14, it can be seen that holes in the valence band have, in general, a very strong oxidizing capability. This constitutes the energetic explanation for the photodecomposition of semiconductors considered above. If, however, species are present in the electrolyte which react with holes, i.e. which can be oxidized by them, then these reactions compete with the decomposition process and in some cases can completely prevent its occurrence. This is one of the most important factors in the operation of photoelectrochemical solar cells.[67-69]

It is therefore not surprising that organic materials can be oxidized by contact with semiconductors in which holes are generated. If it is desired to measure the competition between the oxidation of a redox system and the anodic decomposition of a semiconductor, however, then it is necessary to carry out analysis of the reaction products in the electrolyte and to determine the weight loss in the semiconductor. Such questions will not be dealt with in detail here but instead, a peculiarity in the photocurrent magnitude will be considered, which gives some insight into the

mechanism of the particular reaction. An increase in the quantum yield of the photocurrent measured in the oxidation of some organic materials analogous to that seen in the previously described oxidation of silicon (Section 4.1) was observed here. This has been found in the case of organic acids, aldehydes and alcohols.[70–72]

As an example, we will consider the oxidation of formic acid on the n-type semiconductor, ZnO. Figure 15 shows that the photocurrent, which reaches a constant value at the anodic potentials applied, increases even further on addition of formic acid. The oxidation of formic acid also occurs in two steps. The $HCOO^{\odot}$ radical is first produced with loss of a proton. An electron hole is necessary for this to occur. The radical can be further oxidized by donation of an electron to the conduction band, thereby doubling the value of the quantum yield. An increase of a factor of two is not quite achieved in Figure 15. This is because the competing photoreactions, such as oxidation of water which also require holes, cannot be completely prevented.

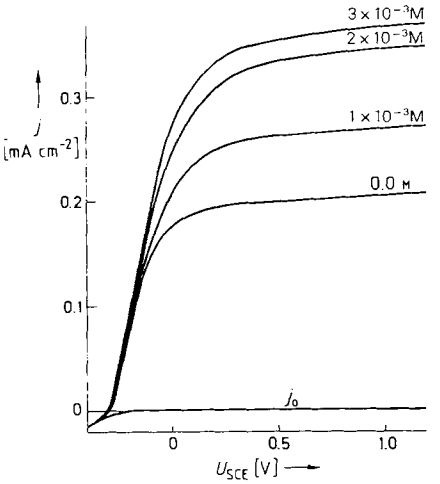

Fig. 15. Photocurrent-potential curves from n-ZnO electrodes in 0.5 M $NaClO_4$ (pH 4) with and without the addition of formic acid in three different concentrations. The dark current density j_0 was chosen as the zero point of the current density scale.

Comparison of the energetic relationships in the redox reactions of the individual steps with the redox properties of the electrons in the valence and conduction bands clearly indicates that the loss of an electron in the second step is, energetically, highly probable. The redox potential of the net reaction with two charge transfers is well known. The first oxidation step, which leads to production of the radical, requires a greater amount of energy and has, thus, a correspondingly higher, i.e. more positive, redox potential. This extra energy required is released again in the second stage, which has, therefore, a more negative redox potential. The redox potentials for the net and partial reactions of formic acid, formaldehyde and methanol are shown in Figure 16 relative to the position of the band edge of ZnO. The redox potentials for the partial reactions which are not known have been deduced from thermodynamic data on the formation energy of the radical in the gas phase. Despite the inaccuracies involved, the resulting picture clearly shows that generation of a hole is required

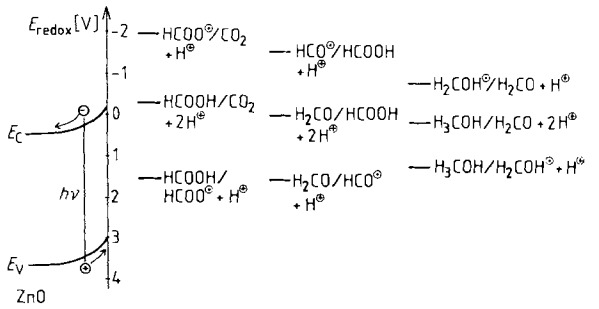

Fig. 16. Positions of the redox potentials for the total and partial reactions of the oxidation of formic acid, formaldehyde, and methanol.

for initiation of the first step, but that the intermediate product possesses enough excess energy to complete the oxidation reaction. The second step, having a redox potential near the conduction band can subsequently take place by the faster electron injection process. A similar explanation may be given for the analogous results obtained for the oxidation of methanol and formaldehyde.[70, 71, 73]

The extraordinary oxidizing properties of holes in semiconductors whose valence bands lie very far down on the redox potential scale shown in Figure 14 have, indeed, practical consequences. They yield, for instance, an explanation as to why pigments, such as TiO_2, may very easily photooxidize and decompose organic materials, such as binding species on exposure to light.

4.3. Passivating Films on Metals

Passivation of metals towards corrosion is a result of the formation of protective films on the metal, usually oxides, which prevent or slow down further attack by the oxidizing agent. These layers possess semiconductor properties and are, sometimes, insulators. When light is absorbed by these films under simultaneous application of an electric potential, photocurrents may be produced. Since they are often very thin, only a fraction of the light is usually absorbed. The transmitted light is partially reflected from the metal and can also contribute to the photocurrent. As a result of the very small film thickness, only a limited space charge is developed in layers of low conductivity, and the electric field extends over the entire film. Even when the film is an insulator, photocurrents can be produced by application of an electric potential, if mobile charge carriers are set free by the absorption of light. Figure 17 shows the conditions necessary for this to occur, by mean of an energy band di-

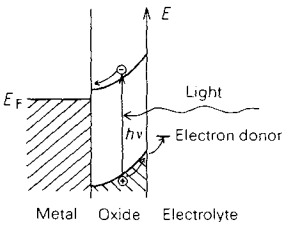

Fig. 17. Electron energy diagram showing the generation of a photocurrent in a semiconducting or an insulating film on a metal.

agram. In this diagram the electric field strength in the film corresponds to the slope of the band edges. A positive slope, in this scheme, implies a negative field. The photocurrent spectrum which may be determined can be used as a means of characterizing the film.[74-76]

As one of the many examples of such phenomena, measurements on tin will be described here.[77] Corrosion of tin in alkaline solution is only partially prevented by the formation of an oxide layer. The photocurrent which is observed is superimposed on a large dark current and must therefore be distinguished from the latter with the use of modulated illumination and the lock-in technique. In spite of this, the technique allows very high sensitivities to be achieved.

A continuous cyclic current-potential curve is shown in Figure 18a alongside the corresponding photocurrents recorded at constant wavelengths. Both the nature and the thickness of the layer are altered during the potential cycle, as is the current density. The dark current shows a large hysteresis. The photocurrent, on the other hand, has a completely different potential dependence from that of the dark current. It indicates the presence of two potential regions in each of which the film shows different properties. This is most clearly seen when the photocurrent is observed in only a particular region during a potential cycle after the electrode has reached a steady state. Curves B and C of Figure 18a illustrate this. The onset of the photocurrent occurs at different potentials.

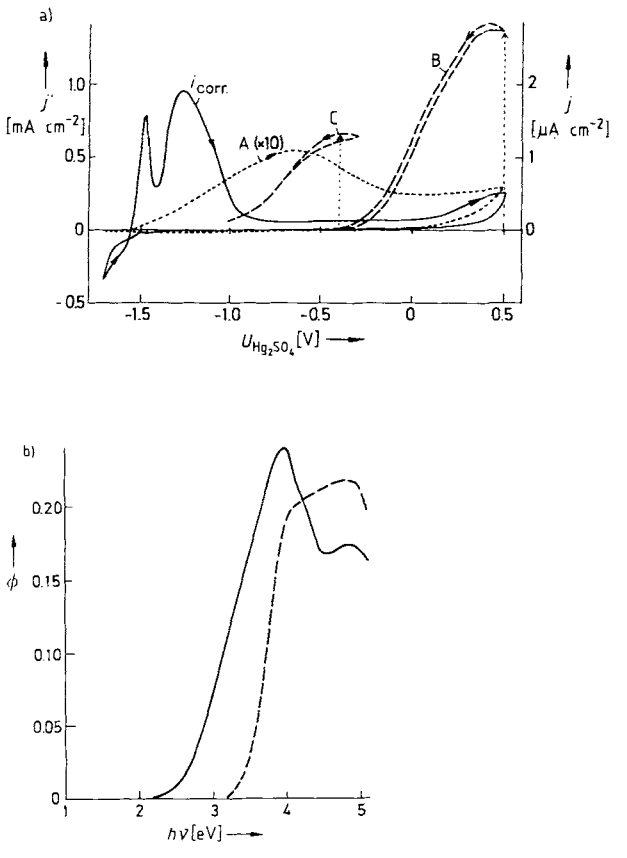

Fig. 18. a) Cyclic current-potential curves for a tin electrode in 1 M KOH solution. Full curve: current measured in the dark; dashed curves: photocurrents measured under illumination by light with a wavelength of $\lambda = 350$ nm A) cycling between -1.6 and $+0.5$ V (vs. Hg/Hg_2SO_4, 1 N H_2SO_4; B) cycling from $+0.5$ V to -0.5 V from an initial potential of $+0.5$ V; C) cycling between -0.4 V and -1.0 V from an initial potential of -0.4 V; [77]. j = photocurrent density; j' = corrosion current density. b) Photocurrent spectra as function of the irradiating energy. Full curve: in the presence of a passivating film on Sn, produced at $+0.5$ V; dashed curve: from an SnO_2 layer produced by chemical vapor deposition on steel at 400 °C. ϕ = Quantum yield.

The photocurrent spectra are also different from one potential region to the other, though the differences are not so marked and indicate only differences in the amount of hydroxide and the number of defects in the films, both of which are dependent on the formation conditions. Figure 18b shows the photocurrent spectrum of a film produced at 0.5 V (corresponding to curve B of Fig. 18a). For comparison, the photocurrent spectrum of an SnO_2 layer produced by chemical vapor deposition is also shown. This layer, produced at 400 °C, has a more well ordered structure and absorption first begins at much higher quantum energy values of the light. The large shift towards longer wavelengths, for the absorption edge of the passive layer, is indicative of the large number of electronic defects in the less well ordered structure.

The information obtainable from such photocurrent spectra is, however, limited. For a more exact chemical and electron-energy analysis of the film it is necessary to use techniques taken from surface physics, which can only be used ex-situ, as already described in Section 3.4.

4.4. Sensitization of Semiconductors

A semiconductor can be made sensitive to light at wavelengths at which it does not usually absorb light by the adsorption of certain substances at its surface. If these species can transfer charge to the semiconductor from an excited state and an electric field is present at the interface, which prevents a back-reaction occurring, then photocurrents are generated whose spectra illustrate the absorption properties of these adsorbed materials.[20,78,79] Dyes are frequently used for this purpose since the quantum yield with respect to incoming light reaches higher values only when the adsorbate has a high extinction coefficient. Ideal substrates are those semiconductors which are transparent to visible light, such as ZnO[80] or TiO_2.[81] Figure 19 illustrates the principles of this type of charge transfer in the energy diagram of a semiconductor on whose surface such molecules are adsorbed. It is assumed here that in the excited state an electron is present in what was formerly the lowest unoccupied level of the unexcited molecule (LUMO) and that the level now unoccupied is that which was previously the highest occupied molecular orbital

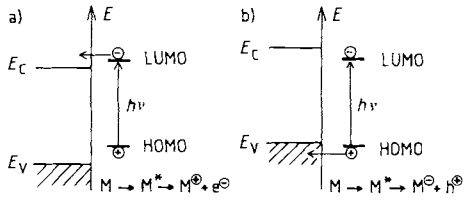

Fig. 19. Energy correlations for the charge transfer occurring between electronically excited molecules and semiconductors: a) electron injection in the conduction band; b) removal of electrons from the valence band = injection of holes.

(HOMO). Figure 19 shows the two possible mechanisms by which the semiconductor may be made responsive to light. In Figure 19a is illustrated the most common case, where the LUMO lies above the edge of the conduction band and a photooxidation is therefore possible by electron injection. A more infrequent mechanism is shown in Figure 19b in which the HOMO now lies below the valence band edge thus enabling a photoreduction of the adsorbed molecule to occur by injection of holes. In order to measure the photocurrent the semiconductor must be polarized in the reverse direction since otherwise the dyes could be either oxidized or reduced in the dark period, or a fast recombination reaction could take place. This means that in case (a) an n-type conductor and in case (b) a p-type conductor is necessary for the charge injection.

The silver halides are also semiconductors in their electronic behavior, though their conductivity in the dark is due to the mobility of the silver ions in the crystal lattice. This property introduces difficulties in the measurement of the electronic photocurrents but the use of the lock-in technique has helped to alleviate this, and has made sensitization measurements on silver halide crystals possible.[82,83] Figure 20 shows a comparison between the sensitized photocurrent spectrum of a thin AgCl single crystal sheet and that of the absorption spectrum of the dye used. The photocurrent spectrum is quite similar to the absorption spectrum but somewhat broader and shifted towards longer wavelengths. The latter is a result of the interaction between the electronically excited molecule and the crystal. Without going into detail, this example is intended to show that this phenomenon, which plays such an important role in the field of photography, can also be observed with electrochemical techniques. The quantum yield in photography is, admittedly, generally rather higher than that obtained in electrochemical experiments since in photographic emulsions the electrons injected from silver ions are very quickly captured on interstitial sites. The silver atoms thus produced form the nuclei necessary for photographic development by grouping together in clusters. This process cannot, however, be seen in a photocurrent since the current is interrupted by the capture of the electrons. Photoelectrochemical measurements are therefore carried out with crystals that have been doped and which have no silver ions in interstitial sites but only silver-ion vacancies.[83] This enables various dyes to be tested for their energetic position and their effectiveness in charge transfer without the need to involve the complicated photographic developing process.

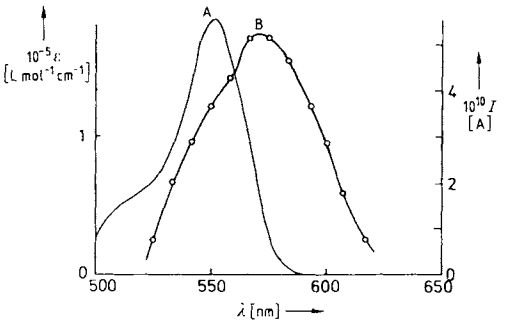

Fig. 20. A) Absorption spectrum (ε) of rhodamine B in 0.1 M $NaClO_4$ and B) the sensitized photocurrent I from a rhodium β-sensitized AgCl crystal (doped with $CdCl_2$) [83].

5. Luminescence as a Means of Detection

When a redox reaction takes place very far from equilibrium, i.e. at very high overpotentials, excited electronic states can be generated by the electron transfer. The consequent dissipation of energy is usually radiationless as the excess energy is transferred to vibrational energy or other heat sinks. In some cases, however, radiation of energy does occur. This may be seen particularly clearly at semiconductor electrodes if an excited state is produced by injection of minority carriers.[22-24] Visible light has, however, also recently been observed to radiate from metal electrodes when the corresponding redox reaction occurs at very high overpotentials.[25]

5.1. Luminescence at Semiconductor Electrodes

From the energy correlations made for photooxidation at semiconductors (see Fig. 14 in Section 4.2) it is clear that an oxidizing species can inject holes only when its redox potential is similar to or more positive than that of the redox potential of the valence band edge. In the same way, a reducing species can only inject electrons if its redox potential is the same or more negative than the redox potential of the conduction band edge. What would happen then if a hole were injected into an n-type conductor? As long as the n-type conductor remains anodically polarized, its conducting electrons are kept at a distance from the surface. The injection of holes into the surface then leads to corrosion of the semiconductor, usually without a current flowing. A reduction current can normally first be observed when the applied potential no longer keeps the electrons away from the surface or actually leads to accumulation of electrons on the surface. Thermodynamically speaking, the reduction then takes place at a very high overpotential, which is higher the bigger the band gap of the semiconductor. There are, thus, two possible mechanisms for the reduction process; these are shown in Figure 21.

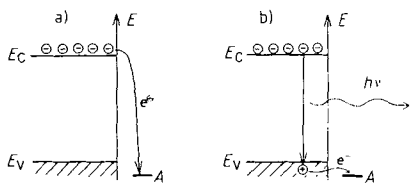

Fig. 21. Two possible mechanisms for the reduction of an electron acceptor at a semiconductor. When the acceptor A injects holes (case b), luminescence can occur.

a) The electrons can be directly transferred to the acceptor in the electrolyte. The excess energy is taken up by the acceptor and the surrounding solution mainly as vibrational energy and subsequently dissipated as heat. The rate

of electron transfer is then determined by the Franck-Condon factors governing the excitation of these vibrations.
b) Despite the presence of electrons at the surface, holes may still be injected which can then recombine with the electrons. This recombination normally takes place as a radiationless process at the interface. It can, however, also result in a radiative emission of the excess energy, which in the case of semiconductors can be observed under illumination as photoluminescence.

Experiments on n-type conductors for which photoluminescence is known to occur has shown that luminescence is very often observed when very strongly oxidizing redox systems are reduced.[22-24] Figure 22a illustrates an example of this. In the upper region the current-potential curve for the reduction of $Fe(CN)_6^{3\ominus}$ at n-gallium phosphide is given.[84] Also shown is the variation of the luminescence with applied potential. Figure 22b shows the spectrum of the luminescent light. The potential, U_{fb}, at which there is no excess charge on the semiconductor is indicated; this is the so-called flat band potential. At this potential the concentration of electrons at the surface is equal to that in the bulk. At more positive potentials electrons are prevented from reaching the surface; at more negative potentials the surface is enriched with electrons. It may be seen that the reduction current flows before this potential is actually reached. Thus, despite the potential barrier, electrons are able to reach the surface in sufficient numbers, and recombine there with injected holes. Luminescence can, however, only be seen close to the flat band potential, U_{fb}, and increases rapidly beyond this potential.

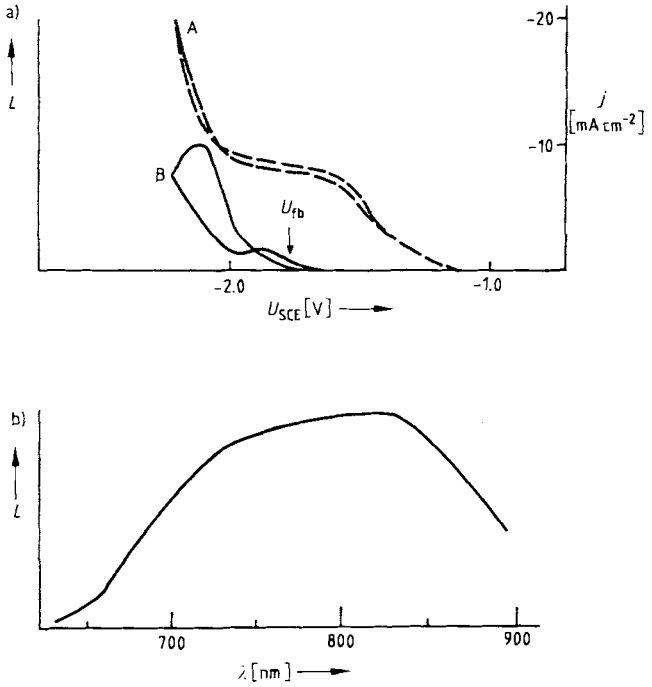

Fig. 22. The reduction of $[Fe(CN)_6]^{3\ominus}$ at an n-GaP electrode in 1 M KOH. a) Current-potential curve and potential dependence of the luminescence ina 0.1 M $[Fe(CN)_6]^{3\ominus}$ solution (the hysteresis is attributed to a chemical change taking place on the surface). b) Corresponding luminescence spectrum [84]. L = luminescence in relative units.

Recombination at the surface is apparently radiationless. When, however, holes can diffuse into the interior of the semiconductor before they are captured by recombination at the surface, luminescence results. At potentials more cathodic than the flat band potential, electrons accumulate at the surface. An electric field is thereby generated which draws the holes towards the bulk of the semiconductor and the intensity of the luminescence is further increased. The luminescence spectrum thus observed corresponds to that of the luminescence produced when the semiconductor is exposed to light of an energy which is absorbed by its bulk.[84]

This indicates that the mechanism of electron transfer is that described in case (b) above (cf. Fig. 21b), which is in agreement with the theoretical assumption that electron transfer occurs preferentially between energy levels of equal energy.[85-87] The increase in luminescence in the potential region cathodic of the flat band potential shows this very clearly; despite the increasing concentration of electrons at the surface which should facilitate mechanism (a), the luminescence continues to increase since more holes can diffuse into the bulk.

5.2. Luminescence from Metal Electrodes

There is no gap in the upper energy bands of a metal where conduction occurs; they overlap each other. Because of this, excited electronic states have a very short lifetime. A recombination involving radiation is, therefore, highly improbable. A radiation of excess energy can, however, be observed in experiments with injection of electrons to the metal from vacuum—the so-called inverse photoemission.[88] The injection currents in these experiments are small. Much larger currents can be achieved in electrochemical reactions. The question, then, is whether such luminescence can also be observed at electrochemical electrodes at sufficiently high overpotentials.

Since the overpotentials that can be reached are limited by the decomposition potentials of the solution involved, water is not an ideal medium for such experiments. They are therefore usually carried out in nonaqueous electrolytes. It has been shown that emission of light does actually occur during oxidation of a redox system with a very negative redox potential at very positive potentials[89] and during reduction of a redox system with a very positive redox potential at very negative potentials.[90,91] Such experiments can usually only be carried out with noble metal electrodes which do not corrode at the very high redox potentials necessary. They show that the electron transfer between metal and redox system at very high overpotentials leads to excited electronic states in the metal which correspond either to electrons in energy levels far above the Fermi level or to holes far below it. These states can release their excess energy as radiation. Figure 23 illustrates these possibilities in an energy diagram. On the right-hand side is shown the energy distribution of the electron levels of the compound to be oxidized (Fig. 23a) or reduced (Fig. 23b) and on the left-hand side the energy levels in the metal that are occupied or vacated in the electron transfer. The dissipation of energy after electron transfer takes place to an overwhelming extent by a radiationless elec-

tron-electron or electron-phonon interaction; the experiment shows, however, that transitions involving radiation of energy also occur.

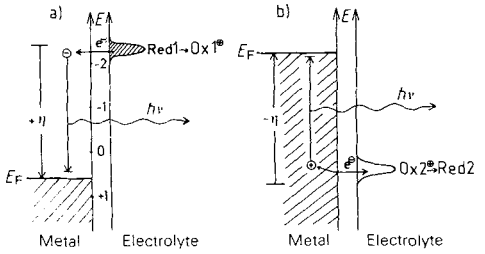

Fig. 23. Principles of the generation of luminescence by (a) electron injection and (b) hole injection when a redox reaction takes place at a metal electrode at high overpotentials. η = Energy difference between the redox potential—of the compound to be oxidized or reduced—and the Fermi level of the electrode metal.

Figure 24 shows spectra corresponding to the light radiated at various potentials in the experiment shown in Figure 23a.[92] It may be seen that, as predicted by this model, the radiation is shifted to shorter wavelengths, i.e. higher energies, as the overpotential is increased. The model of equipotential electron transfer is thus also experimentally established for metal electrodes.

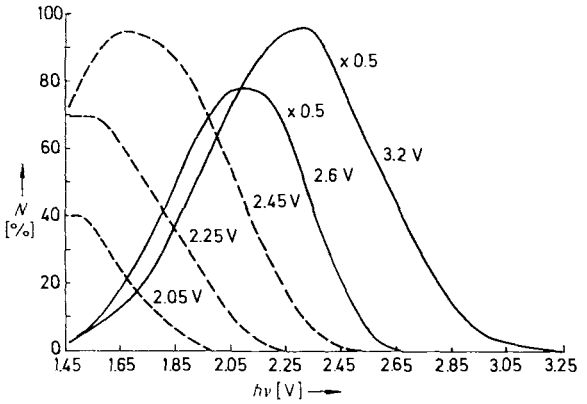

Fig. 24. Luminescence spectra produced on injection of electrons from the reduced *trans*-stilbene (0.02 M) in a solution of acetonitrile and 0.2 M $(C_4H_9)_4NPF_6$ at the indicated potentials. Full curves are for gold electrodes, dashed curves for silver electrodes (after *McIntyre* [92]). N = Intensity.

6. Future Trends

The results obtained with the spectroscopic methods described above have made a significant contribution to the understanding of both the mechanistic pathways of electrochemical processes and the influence exerted by the electronic properties of the electrode in these reactions. Another equally important factor in the understanding of electrode properties is the role played by their surface structures. To obtain information on this topic it is necessary to carry out experiments on well-defined single crystal surfaces. The development of UHV techniques and the methods of analysis made possible with their use has allowed considerable progress also to be made in this field. The structure of electrode surfaces may be determined on transfer to UHV by electron diffraction techniques such as LEED (Low Energy Electron Diffraction) or RHEED (Reflective High Energy Electron Diffraction).[15,93] The separation between individual atoms and their nearest neighbors can be determined with the help of EXAFS (Extended X-ray Absorption Fine Structure). This can even be carried out on electrodes in-situ.[94] The X-ray fluorescence from atoms in an adsorbed film on a well-prepared single crystal surface can be used to determine their exact separation from the surface and their exact position on the electrode surface. The adsorbed layer is made to fluoresce in the field of an X-ray standing wave which can be produced with the use of synchrotron radiation. This technique may also be applied in-situ.[56] Finally, great hopes are held for the use of scanning tunneling microscopy (STM) in the determination of the surface structure of electrodes, particularly if it is possible to apply this technique in-situ, i.e. with the electrode still in the electrolyte. Such studies are at present being carried out in various laboratories.

Despite all the complications of the electrochemical system, the use of interdisciplinary techniques as described above indicates the direction which should be taken to achieve a deeper understanding of reaction routes on an atomic or molecular level. This should also prove extremely fruitful for the many complex technical applications of electrochemistry.

The author wishes to express his thanks to Dr. Teresa A. Twomey, at present a Alexander-von-Humboldt fellow at the Fritz-Haber-Institut der Max-Planck-Gesellschaft in Berlin, for translating the original German text into English.

Flexibility and Rigidity of Proteins and Protein-Pigment Complexes**

By Robert Huber

Proteins may be rigid or flexible to various degrees as required for optimal function. Flexibility of large parts of a protein, which rearrange or move, is particularly interesting and will be discussed in this article. We differentiate between several categories, although the boundaries between them are diffuse: flexibility of peptide segments, order-disorder transitions of spatially contiguous regions, and domain motions. The domains may be flexibly linked to allow rather unrestricted motions or the motions may be constrained to certain modes. The various categories of large-scale flexibility will be illustrated with the following examples: (1) Small protein proteinase inhibitors are rather rigid molecules which provide binding surfaces complementary to their cognate proteases but show also limited segmental flexibility and adaptation. (2) Large plasma proteinase inhibitors exhibit large conformational changes after interaction with proteases probably for regulatory purposes. (3) Pancreatic serine proteases employ a disorder-order transition of their activation domain as a means to regulate enzymic activity. (4) Immunoglobulins show rather unrestricted and also hinged domain motions in different parts of the molecule probably to allow binding to antigens in different arrangements. (5) Citrate synthase adopts open and closed forms by a hinged domain motion to bind substrates and release products and to perform the catalytic condensation reaction, respectively. (6) Riboflavin synthase, a bifunctional multienzyme complex, catalyzes two consecutive reactions by means of two subunits, α and β. The β-subunits form a shell, in which the α-subunits are enclosed. Diffusional motion of the catalytic intermediates is therefore restricted. In addition, rearrangement of the *N*-terminal segment occurs during the assembly of the β-subunit. In contrast, rigidity is dominant in the structures of the light-harvesting complexes and the photosynthetic reaction centers involved in photosynthetic light reactions. These are large protein-pigment complexes in which the proteins serve as matrices to hold the pigments in the appropriate conformation and relative arrangement. Since motion would contribute to deactivation of the photoexcited states of the pigments and diminish the efficiency of light-energy and electron transfer, the functional role of rigidity is easy to rationalize for these proteins.

1. Introduction

The term molecular flexibility is not well-defined but is picturesque and used often in reference to vibrations, disorder, or structural adaptation of molecules. These are quite diverse physical phenomena, but all are determined by the nature and three-dimensional arrangement of the atoms of the molecules and the force field in which the atoms move.

Many physical and chemical properties of molecules depend on their dynamic properties, which have been studied by a variety of theoretical and experimental approaches. Such studies have led to a very detailed understanding of structure and dynamics of many small molecules. However, theoretical approaches to understanding the flexibility of proteins by analysis of the normal modes of vibrations or by molecular dynamics suffer from both fundamental and computational problems, owing to the very large number of atoms and internal vibrational degrees of freedom, the lack of precise knowledge of the potential energy for displacement from the equilibrium atomic positions, and the breakdown of the harmonic approximation in normal-mode analysis. In addition, the effects of the solvent cannot be neglected and add to the complexity of the system. Despite these limitations, some useful information about macromolecules has been obtained by theoretical approaches.[1-5]

Similarly, experimental approaches in the case of complex protein molecules provide usually only partial and approximate insights. These are nevertheless most welcome in view of the importance of dynamic properties for protein function. It seems likely that essentially any interaction of proteins with small or large ligands involves some structural adaptation: be it enzymic reactions, where chemical bonds are formed or broken or groups of atoms transferred, be it rearrangements of domains in proteins or of subunits in oligomeric proteins occurring in a cycle of reactions, motion is essential. Even in structural proteins, such as viral capsid proteins, flexibility of parts is important for the assembly process.[6]

On the other hand, the constituent groups of atoms are as densely packed in protein molecules as in crystals, indicating quasi-crystallinity and rigidity. Steric complementarity intimately related to rigidity is indeed the basis for precise protein-ligand interaction. Thus it is important to recognize that both flexibility and rigidity are general

[**] The preceding page shows Figure 8c of this article.

properties of protein molecules and that one or the other apparently dominates in each particular case.

To illustrate this, a number of proteins with various kinds and degrees of flexibility, as well as their functional significance and the underlying structural features, will be discussed and compared with particularly rigid proteins. The selection of examples and aspects is somewhat arbitrary but will emphasize flexibility involving the movement or rearrangement of large parts of proteins. Small-scale flexibility at the level of amino acid side chains is also functionally important but occurs universally and seems less interesting in an attempt to document the versatility of proteins.

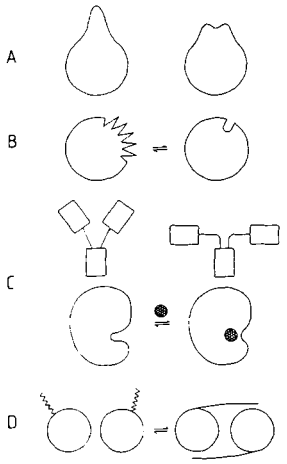

Fig. 1. Types of large-scale flexibility: A) segmental flexibility; B) order-disorder transition; C) free and hinged domain motion; D) rearrangement in subunits during assembly.

Figure 1 illustrates the various kinds of flexibility observed in proteins and discussed in the examples below. Flexibility occurs at the level of amino acid side chains, polypeptide segments, or domains. Flexibility of large parts of a protein might serve a regulatory purpose, allow binding to epitopes in different geometric arrangements, generate an active site, or stabilize oligomeric association.

2. Segmental Flexibility

Small protein proteinase inhibitors are particularly stable protein molecules by a variety of criteria. Basic pancreatic trypsin inhibitor (BPTI), a representative of this class of proteins, is thermally very stable and a high proportion of the main-chain amide hydrogen atoms do not undergo exchange in D_2O as shown by ^{1}H-NMR[7,8] and neutron diffraction studies.[9] However, NMR studies have also shown that BPTI undergoes very substantial structural fluctuations as revealed by the observation of flipping of aromatic amino acid side chains located in the interior of the protein molecule.[10] This is a process requiring high activation energies and activation volumes and indicates that large fluctuations of energy and void volume occur in the protein even at room temperature.

X-ray diffraction techniques are unable to provide information about such activated processes, which are rare and very fast and do not measurably influence the crystal structure observed as an average in time and space. However, X-ray diffraction data do bear information on the positions and the temperature factors (or, better, disorder factors) of the atoms. The latter are measures of the average deviation from the equilibrium positions. They help to differentiate rigid and "flexible" parts of a protein, but do not distinguish between the quite different physical phenomena of thermal mobility and static disorder. In addition to temperature factors, the analysis of different crystal forms of the same protein may help to define flexible parts, since, in contrast to the rigid parts, they are readily distorted by crystal lattice forces (Fig. 2).

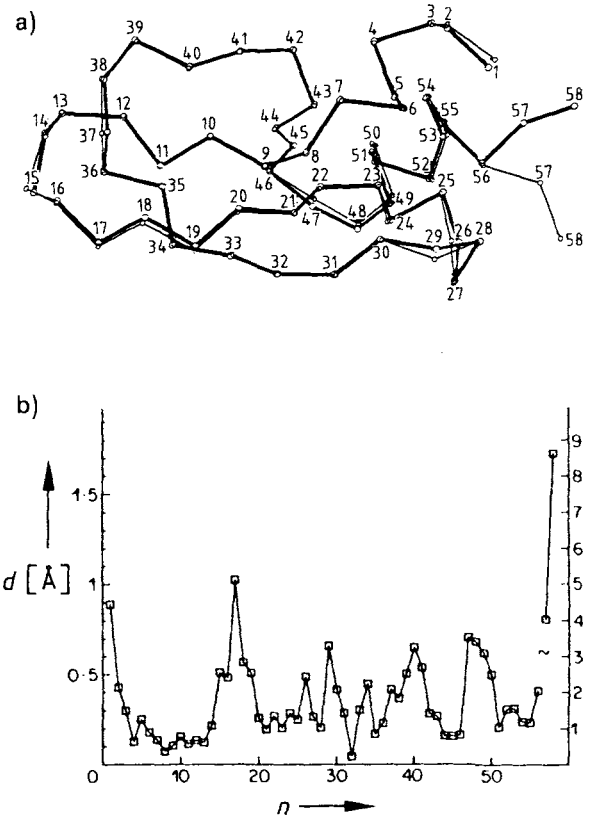

Fig. 2. Comparison of two different crystal forms of BPTI. a) Overlay of the C^α atomic positions; b) their positional deviations [11]. n = position, d = deviation (the right ordinate refers to residues 56, 57).

In the case of BPTI, both experiments, the analysis of temperature factors and the comparison of different crystal forms[11] showed enhanced flexibility of the segment around lysine 18. This segment is involved in binding to proteases and undergoes slight rearrangements upon complex formation to improve the stereochemical fit of the interacting surfaces (see Fig. 10 in Ref. [12]). Segmental flexibility is functionally relevant in this case. Similar phenomena have been found in the family of ovomucoids and secretory inhibitors.[13,14] It has been observed that the segment of the inhibitor buried in the complex shows much lower temperature factors in the complex than in the free state (see Fig. 11a in Ref. [13] and Fig. 5 in Ref. [14]).

The structural adaptations upon complex formation are small and not at variance with the notion of preformed

steric complementarity between small protease inhibitors and their cognate proteases. In accord with this notion, all inhibitors of serine proteases, even those with unrelated polypeptide chain folds show a closely similar conformation of the protease binding segment.[15, 16]

The consistent picture of structure and function of small protein inhibitors of serine proteases does not hold for α_1 protease inhibitor, the major serine protease inhibitor in mammalian blood. It is a much larger molecule and functions differently in at least one respect: proteases specifically cleave the susceptible peptide bonds in both small and large inhibitors, but the cleaved species are active only in the small inhibitors, where the new chain ends remain in close proximity as recent crystal structure analyses of cleaved ovomucoid inhibitors have shown (Fig. 3a).[17] In-

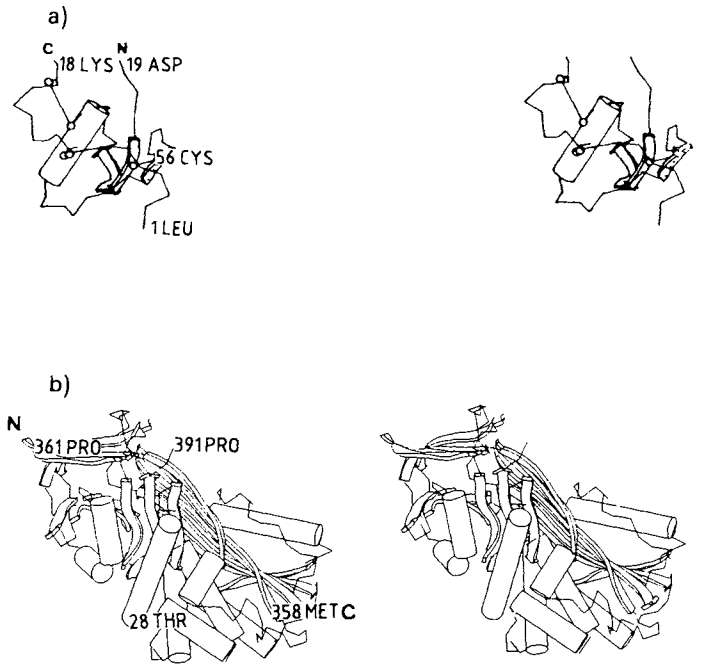

Fig. 3. a) Stereodrawing of the cleaved form of Japanese quail ovomucoid inhibitor OMJPQ. The new *N*- and *C*-termini (N and C) at residues 18 and 19 produced by proteolytic cleavage remain in close proximity [17]. b) Stereodrawing of the cleaved form of α_1 protease inhibitor. The new chain ends (N and C) at residues 359 and 358 are located on opposite ends of the molecule [19].

teraction of the cleaved species with proteases leads to resynthesis of the susceptible peptide bond.[18] In contrast, the cleaved species of α_1 protease inhibitor is inactive. An analysis of the crystal and molecular structure of α_1 protease inhibitor has provided an interpretation in molecular terms.[19] The structure of α_1 protease inhibitor cleaved at Met358–Ser359 showed a compact molecule with a very high proportion of well-ordered secondary structure. Surprisingly, the new chain termini Met358 and Ser359 were found on opposite ends of the molecule, separated by about 70 Å and incorporated in two β-sheets (Fig. 3b). Although the structure of the intact α_1 protease inhibitor is not yet known, it is clear that it is rather different since Met358 and Ser359 are covalently bonded in this species. In accord with this notion, a number of observations suggest that cleavage of the Met358–Ser359 bond is accompanied by very substantial alterations in structure, stability,

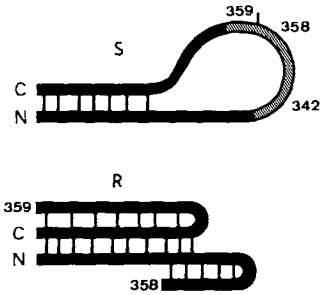

Fig. 4. In the intact form of the α_1 protease inhibitor, the segment around 358–359 is believed to be exceptionally exposed and in a strained conformation (S). Upon limited proteolysis, the molecule relaxes to the crystallographically observed compact form (R), shown in Fig. 3b.

and physiological properties (Fig. 4).[20] The intact protein species may be regarded as a strained form (S), which relaxes after limited proteolysis to form R. Conformational strain may accumulate in the Met358–Ser359 peptide bond and lead to exceptional affinity toward serine proteases.

α_1 protease inhibitor is a member of a large family of proteins to which serine protease inhibitors in serum and other proteins with quite different functions belong.[21] Other members of this family, at least those with inhibitor function, probably have similar structures and functional properties. Conformational strain may also apply to α_2 macroglobulin, another plasma protease inhibitor, though unrelated to α_1 protease inhibitor.[22] It may explain the unusual proteolytic susceptibility of a particular segment, the bait region.

3. Order–Disorder Transition

The target molecules of the natural serine protease inhibitors, the serine proteases, show a different kind of flexibility. Serine proteases are synthesized as proenzymes, which are activated by limited proteolysis.[23, 24] The corresponding structural, thermodynamic, and kinetic data have been analyzed in great detail.[25] Figure 5a summarizes the results obtained through comparison of the structures of trypsinogen, trypsin, and their complexes with BPTI. In the proenzyme trypsinogen a part of the molecule, called the activation domain, is disordered. It becomes ordered upon conversion to trypsin. The trigger for this event is the formation of a salt linkage between an aspartate residue and the *N*-terminus liberated by the activation cleavage. The activation domain is involved in substrate binding, which requires an ordered state. The catalytic inefficiency of trypsinogen is therefore due to inefficient substrate binding. Very strong ligands like BPTI are able to bind to trypsinogen and induce a disorder–order transition of the activation domain without activation cleavage at the expense of a part of the energy of interaction.

Other systems involving biological macromolecules that show an order–disorder transition have been characterized at the atomic level although in less detail than the serine protease system. Similar to the serine proteases there is a disorder–order transition that occurs when prophospholipase is converted into the active enzyme phospholipase.[26] A substantial part of the C_H2 domain (one of the constant domains of the heavy (H) chain) of the *C*-terminal frag-

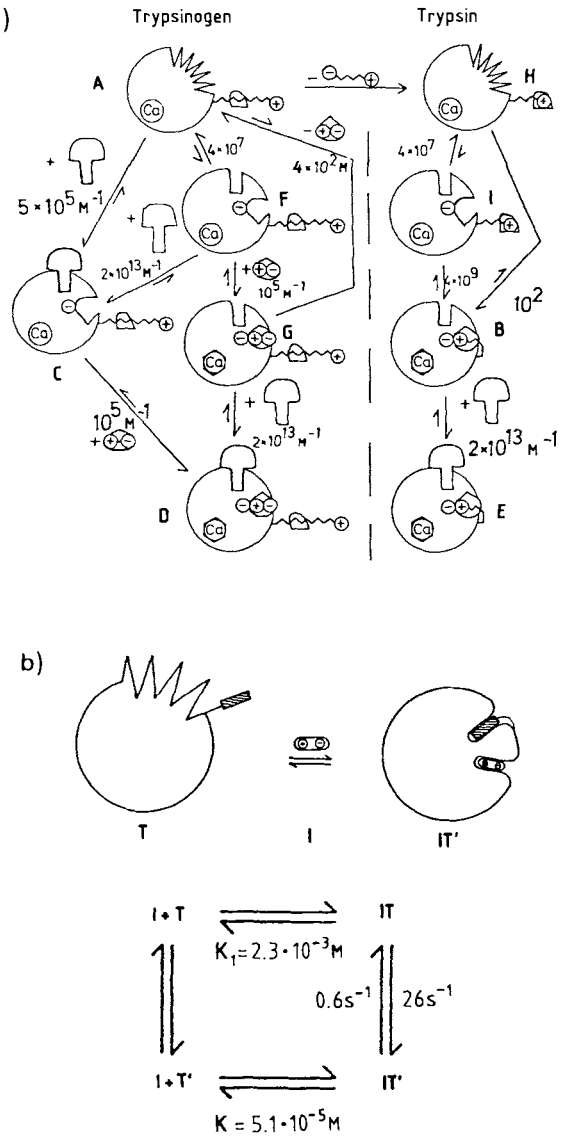

Fig. 5. Schemes of the structures and thermodynamics of the system trypsinogen/trypsin/BPTI/activation peptide. a) In trypsinogen the activation domain is disordered (**A**), but becomes ordered (**B**) after cleavage of the *N*-terminal peptide (**A**→**H**). The newly liberated *N*-terminus interacts strongly with the trypsin moiety (**B**). **B** forms a very strong complex with BPTI (**E**). Trypsinogen also forms a complex with BPTI (**C**) in which the activation domain is ordered. This complex is much weaker than **E** but is strongly stabilized by interaction with an exogenous peptide simulating the *N*-terminus of trypsin (**D**). States **A**–**E** have been crystallographically observed and the corresponding association or equilibrium constants have been characterized (large numbers). The other states and corresponding association and equilibrium constants are hypothetical (small numbers) [25]. b) The simple system of trypsinogen with covalently linked *p*-guanidinobenzoate (**T**). The activation domain becomes ordered and the binding pocket for the ligand *p*-guanidinobenzoate is formed in the presence of the exogenous peptide (**I**). Structure, thermodynamics, and kinetics of this system have been analyzed [25, 71]. These data indicate a relatively slow isomerization step with a rate constant of 26 s^{-1} from a loose **IT** complex to the stable **IT'** species; this step is probably associated with the rigidification process.

ment (Fc) of immunoglobulins is disordered.[27] It has been suggested that some of the disordered segments in immunoglobulins are involved in effector functions. In tobacco mosaic virus (TMV), the polypeptide chain in contact with the ribonucleic acid (RNA) is ordered in the intact virus[28] but disordered in the empty protein disk[29] suggesting that a disorder–order transition of this region of the coat protein accompanies the process of viral assembly. The disorder–order transition of flexible *N*-terminal "arm" regions of selected coat-protein subunits also seems to be involved in the assembly of tomato bushy stunt virus and other small icosahedral viruses.[30]

So far the unspecific term "disorder" has been used to describe the state of the activation domain in trypsinogen, indicating only that this region does not contribute significantly to the X-ray diffraction pattern of the crystal. This behavior could be caused by either "static" or "dynamic" disorder, which break the perfect arrangement of the crystalline lattice. Static disorder may be defined by the existence of different conformers of the molecule located at different sites in the crystal lattice, while dynamic disorder would imply a single conformer with large thermal fluctuations. The temperature dependence of these two models is expected to be quite different, so that a series of diffraction experiments at different temperatures may discriminate between them. Low-temperature diffraction studies of protein crystals are difficult but have been carried out with trypsinogen crystals.[31] These show that even at the temperature of liquid nitrogen the activation domain of trypsinogen does not contribute to X-ray scattering. This suggests that static disorder is predominant. We conclude that the activation domain exists in a number of different conformations of comparable stability. Transitions between these conformers may occur readily at room temperature, and the equilibrium of the conformers may be shifted by weak external forces like crystal packing, one conformer being thereby selectively stabilized. This is indeed the case in α-chymotrypsinogen, a serine protease proenzyme related to trypsinogen. Two different crystal forms have been analyzed, one of which was found to have two independent molecules in the asymmetric unit.[32–34] All three molecules experience different crystal packing forces, which have little effect on the rigid parts of the molecular structures but distort the flexible activation domain and stabilize different conformers. These studies confirm the general conclusions drawn from the studies on trypsinogen and reveal another facet of the enigmatic term disorder. A deeper understanding of the physical basis of the experimental findings may be brought to light by molecular dynamics calculations of the trypsinogen–trypsin system which are currently in progress.[35]

X-ray crystallographic experiments at different temperatures are able to differentiate between dynamic and static disorder in the above-mentioned sense and in the latter case to define a lower limit for the number of conformers. However, the term "static disorder" is somewhat confusing, since transitions between the conformers may occur depending on temperature. Diffraction experiments cannot reveal rates and energies of dynamic processes. This is the domain of spectroscopy. In the case of trypsinogen, perturbed angular γ-correlation spectroscopy has been applied and, indeed, has shown transitions in the nanosecond range at room temperature which are frozen at low temperature.[36,37] The conclusion drawn from the crystallographic and spectroscopic experiments is that the activation domain fluctuates rapidly at room temperature between conformers of nearly equal stability. In addition to this motion, the atoms vibrate about their equilibrium positions in the different conformers. Such properties are

characteristic of liquids but surely apply only to disordered regions of a protein (for a critical general discussion see Ref. [38]).

4. Domain Motion

So far structural and functional aspects of flexibility and disorder in relatively small parts of proteins have been discussed. We now turn to proteins where very large parts (domains) move relative to others as rigid bodies. The changes in conformation that accompany or allow such motions are usually limited to short segments or single peptide units, called hinges. Glycine amino acid residues are very common in hinge regions, possibly because the absence of a side chain imposes less restrictions on conformation. Similarly, glycine residues very often mark the boundaries between ordered and disordered segments in the protein systems discussed in Section 3.

Probably the best-defined example of a protein with rather unrestricted domain motions is the immunoglobulin molecule. Immunoglobulins of the class G (IgG) are symmetrical dimers of two heavy chains (H) and two light chains (L). Amino acid sequence studies had suggested long before crystal structures became available that the H and L chains are linear arrangements of four and two, respectively, structurally related domains. Consistent with this notion were the observations that the segments connecting the domains are preferentially cleaved by proteolytic enzymes to liberate stable fragments which retain partial functions of the intact molecule.

Hydrodynamic, spectroscopic, and electron microscopic studies provided evidence for extensive flexibility of the immunoglobulin molecule,[39-42] but it required crystallographic studies to confirm the domain motif of immunoglobulin structure and to reveal the potential modes of motion at the atomic level (Fig. 6).[43] It was found that closely related IgG fragments analyzed in different crystal forms differ in the relative arrangement of the pairs of domains (modules). The arrangement of the (V_H-V_L) module (V domains are variable domains) relative to the (C_H1-C_L) module within the arms of the antigen-binding fragment (Fab) shows variations up to 60° in elbow angle. The relative orientation of the Fab arms is even more variable, from maximal extension (T-shape) to almost parallel arrangement, as suggested by electron micrographs. The structure of the Fc fragment, the stem part of the immunoglobulin molecule is more constant, but the orientations of the C_H2 domain relative to the C_H3 domain vary by 5° to 10° in different crystalline environments. In a fortunate case, crystallographic experiments allowed direct observation of flexibility between Fab and Fc, because crystals of an intact immunoglobulin and its $(Fab)_2$ fragment, which lacks Fc, were available.[44] Both crystals show a very similar distribution of X-ray diffraction intensities even at low resolution. This observation proves disorder of the Fc part in the crystalline state and shows that it is predominantly static as defined above. If the Fc part were dynamically disordered, oscillating about a single equilibrium position, the diffraction patterns of intact IgG and the $(Fab)_2$ fragment should be different, at least at low resolution.

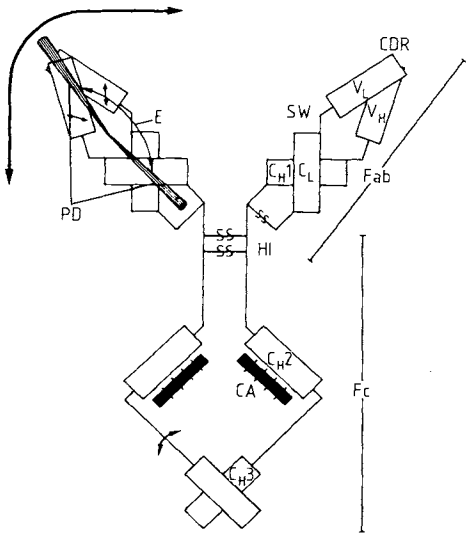

Fig. 6. Scheme of an immunoglobulin molecule of the IgG class. It is a symmetrical dimer assembled from two heavy and two light chains, which are folded into four and two domains, respectively. The V_H-V_L module forms the antigen-combining site by its complementarity-determining regions (CDR). There is flexibility in the relative arrangement of modules and domains. The extent is indicated by the lengths of the double headed arrows. E = elbow, HI = hinge, SW = switch, CA = carbohydrate, PD = pseudo diads.

A flexible linkage of the Fab parts to the Fc stem has functional importance as shown by IgG variants in which the hinge segment linking Fab and Fc is shortened by a deletion. These are defective in some of the biological functions associated with the Fc part (for a review of these functions see Ref. [44b]). This relates to the interesting issue of cooperation between the different functions of the Fab and Fc parts, namely, antigen binding and effector functions, respectively. The covalent association of Fab and Fc links these functions in space, while the relative flexibility of these segments imposes little restrictions on the reactivity of Fab and Fc with other macromolecules. Flexibility is impaired in the hingeless IgG variants, and binding sites on Fc might be concealed by the Fab part. There are no functional data that support the existence of cooperative effects other than those mentioned. Structural flexibility is inconsistent with the idea of signal transmission between Fab and Fc unless a conformer with a rigid arrangement of the Fab and Fc parts exists.[45] However, signal transmission between the (V_H-V_L) and (C_H1-C_L) modules within the Fab part has been shown by a number of experiments. The (V_H-V_L) and (C_H1-C_L) modules are separated by the switch peptides, which allow elbow bending and the formation or breakage of longitudinal V_H–C_H1 noncovalent interactions. The recently suggested distortion of the V_H-V_L module by antigen binding could act as a trigger, altering the elbow angle and the contact with the C_H1-C_L module.[46]

A number of other proteins are known which have covalently but flexibly linked domains, including protein A[27,47] and ovomucoid protease inhibitors.[14,18] Structural studies have been performed on proteolytic fragments of these proteins. These studies and the functional properties of the fragments indicate that the fragments retain their structure and thermal stability in the intact molecules and suggest a lack of significant interaction between the do-

mains. As deduced from repeating amino acid sequences it is likely that a similar scheme of construction holds for the main protein components of the cytoskeleton (spectrin)[48] and the extracellular matrix (fibronectin and laminin).[49] These proteins form a network of domains which have specific binding sites for other cellular components and may serve to organize these components in space.

Motion of the Fab parts of immunoglobulins relative to each other and to the Fc part is quite free, since the long extended connecting segments impose little steric restrictions. Elbow bending within the Fab parts is more restricted owing to the double linkage of (V_H-V_L) and (C_H-C_L) modules. This latter type of domain motion leads to flexibility in some enzymes, where domains oscillate through a small angular range.

Citrate synthase, the condensing enzyme, is a well-characterized example in structural and functional terms.[50-52] Citrate synthase is a dimeric molecule. Each subunit is folded into a large and a small domain as shown by crystal structural studies of liganded and unliganded enzyme forms. The unliganded enzyme form has a deep cleft between the large and small domains. The small domain is folded from a contiguous chain segment and doubly linked to the large domain. In the molecular form having bound product, i.e., citrate and coenzyme A (CoA), the cleft between the large and the small domain is closed, enclosing the product molecules (Fig. 7). A very similar closed form is found when the substrate and a co-substrate analogue, i.e., oxaloacetate and acetonyl-CoA, are bound. The difference between open and closed forms may, to a first approximation, be described by a rigid body rotation of about 18° of the small domain relative to the large domain. The right packing of the closed form of the enzyme suggests that it represents a stable conformation which prevails also in solution. However, an ensemble of open forms may exist in solution of which the one seen in the crystals is favored by crystal packing. From a detailed analysis of the structures it appears most likely that catalysis proceeds in the closed form, while substrate uptake and product release occur in the open form, where the substrate binding site is accessible to solvent. It is not surprising that the condensation reaction between oxaloacetate and acetyl-CoA is favored in the solvent-free environment of the closed form of citrate synthase where both substrates are in close proximity. In addition to this general effect of proximity and desolvation, there are specific residues involved in catalysis, of which His274 deserves special mention. It is adjacent to Gly275, which is at the domain rotation axis and undergoes a dramatic change in conformation between open and closed form. It appears that the interaction of His274 with the substrate might trigger the conformational transition to the closed form which is then stabilized by a multitude of substrate-protein interactions. The presence of a glycine residue at the domain boundary is in line with previously discussed cases. When the two closed forms of citrate synthase, which have product and substrate bound, respectively, are compared, numerous differences in the internal structure of the small domains are observed. The enzyme structure responds evidently to the state of the catalytic reaction and the binding requirements of the reaction intermediates. This type of flexibility

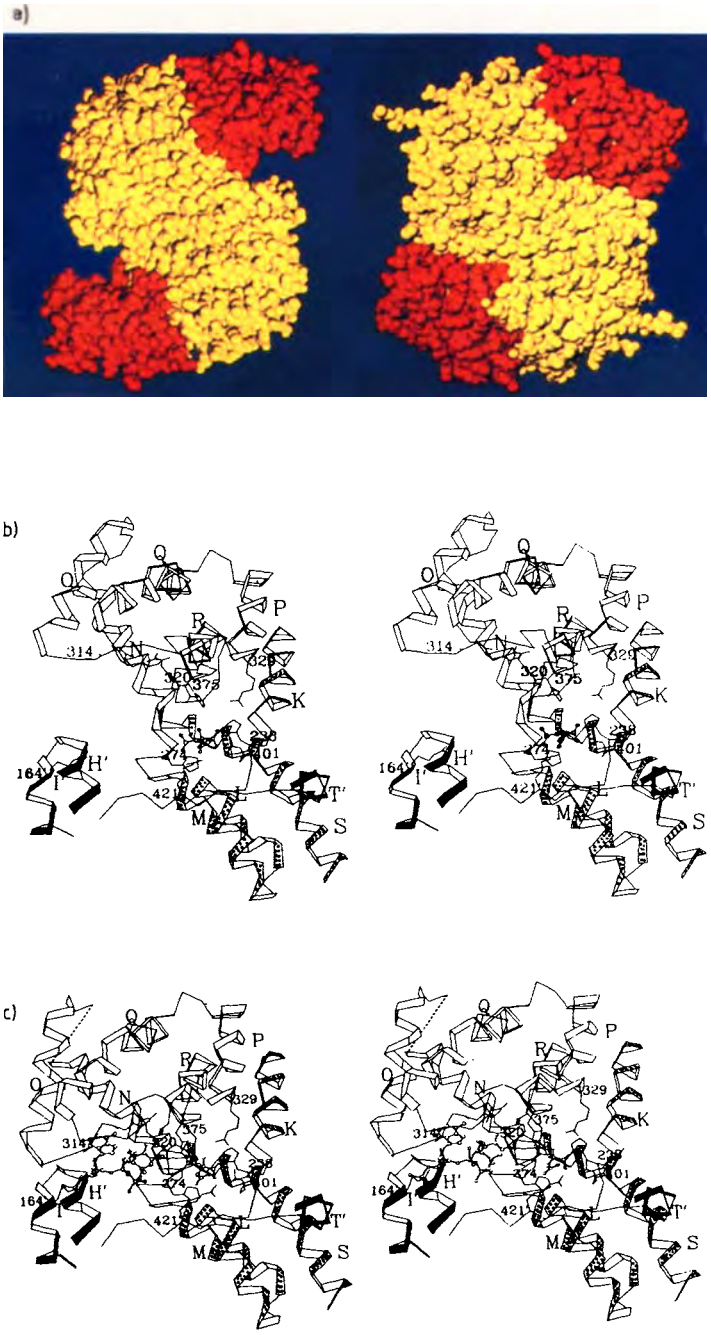

Fig. 7. a) Space-filling representation of open (left) and closed (right) forms of citrate synthase. The small and large domains are red and yellow, respectively. b) Stereodrawings of the open form of citrate synthase in the vicinity of the ligand citrate. c) Stereodrawing of the closed form with product citrate and coenzyme A bound. The binding site of coenzyme A is generated in the closed form by residues of the small domain (open ribbon) and the large domains of both subunits (dotted and filled ribbons). The filled ribbons represent diad-related subunits [50-52]).

is related to the subtle conformational changes seen in small protease inhibitors when bound to proteases.

A domain motion generating the open and closed forms seen in citrate synthase has been found and defined in detail in a few other proteins, aspartate aminotransferase,[53,54] alcohol dehydrogenase,[55] hexokinase,[56] and adenylate kinase[57] and is likely to occur in arabinose binding protein[58] and glyceraldehydephosphate dehydrogenase.[59]

5. Flexibility in Subunit Assembly

It is not surprising that flexibility plays an important role not only in the interaction of protein domains of a single polypeptide chain but also in the assembly of oligomers. The development of favorable contacts between the subunits drives the association. Polypeptide segments exposed in the isolated subunits become buried in the aggregate and will respond to this dramatic change in environment. One type of response we have already seen in the disorder-order transition in TMV assembly, where direct observations of both states, the empty disc and the intact virus, have been possible. Another type of response is seen in the spherical viruses, where the chemically identical protein subunits are in not exactly identical positions in the icosahedral capsid.[60] In an icosahedron sixty units may occupy equivalent positions. In $T=3$ particles the 3×60 protein subunits are arranged in equivalent triples of quasi-equivalent molecules. Quasi-equivalence is reflected in distinct differences in the protein subunits, namely in the form of the relative arrangement of two globular domains. They may adopt one of two different relative orientations depending on the subunit's location with respect to the icosahedral symmetry.

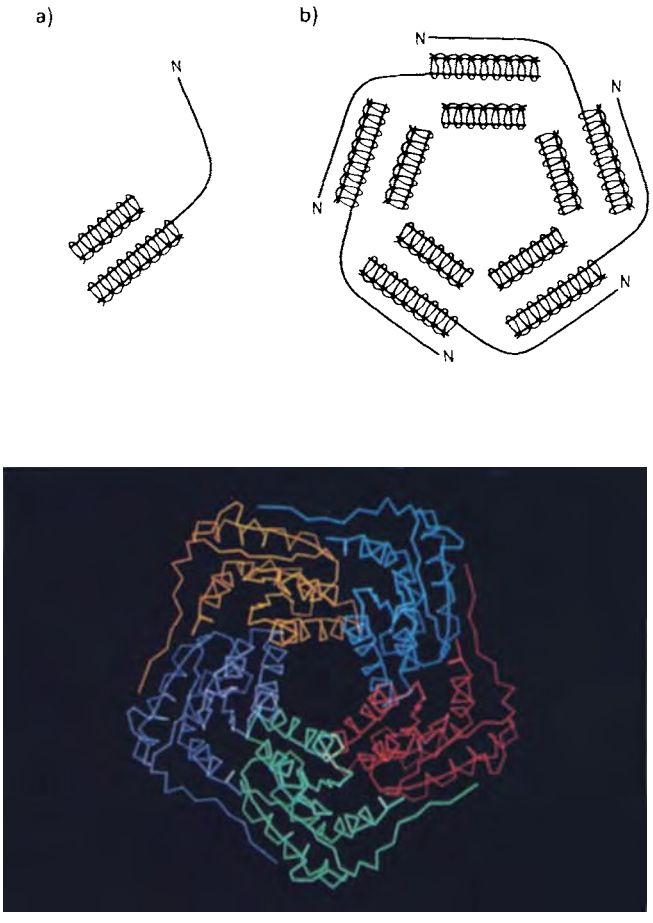

Fig. 8. a) Folding of a β-subunit of heavy riboflavin synthase. It consists of a four-stranded central β-sheet flanked on either side by two α-helices. Only the upper pair of α-helices is shown. b) The *N*-terminal segment projects away, but is attached to the β-sheet of a neighboring subunit in the pentamer. c) The observed C$^{\alpha}$ carbon position in the pentamer [61, 62]. The five subunits are color-coded.

In other cases polypeptide segments project away from the globular part of a protein subunit but are associated with a neighboring subunit in the aggregate. It is likely that these segments are disordered or in an alternative conformation in the isolated subunits. The arm segments of the icosahedral viruses described earlier are one example of this type of flexibility. A recent example is the bifunctional multienzyme complex riboflavin synthase.[61,62]

Riboflavin synthase consists of two chemically different subunits. Sixty β-subunits form a capsid with icosahedral symmetry. Three α-subunits occupy the central cavity. The β-subunit is folded into a globular body consisting of a four-stranded β-sheet and four α-helices, two on either side of the β-sheet. The *N*-terminal segment of about ten residues stretches away from the globule and is attached as the outer fifth strand to the β-sheet of a neighboring subunit in the pentamer. This occurs in a cyclic manner (Fig. 8). Although the structure of the isolated subunit is unknown, it is likely that the *N*-terminal segment is flexible, since its conformation is not supported by secondary structural interactions. Assembly of the subunits in the pentamer therefore involves rearrangement and stabilization of the *N*-terminal polypeptide strand.

6. Rigidity

I now close the circle in the discussion of the dual aspects of flexibility and rigidity in proteins. We might have lost sight of the fact that proteins provide a spatial framework to bind ligands, turn over substrates, and accommodate prosthetic groups and pigments. These functions require a quite precise geometrical arrangement of the interacting groups. To demonstrate this, any of the examples presented under the aspect of flexibility could have been chosen, since, in all cases, well-defined complementary surfaces play an important role in the interaction with ligands or macromolecules. Yet these surfaces often require some flexibility to adapt to the desolvation and change in environment. However, there exists a class of proteins where rigidity is dominant and flexibility would lead to wasteful side reactions. These are protein-pigment complexes involved in the transfer of light energy and electrons in photosynthesis. Their substrates and products are massless or very small (photons and electrons) and the reactions are intramolecular. I have therefore chosen two examples from this system to emphasize the functional significance of rigidity.

Light collection and light energy transfer in the peripheral light-harvesting complexes (phycobilisomes) of cyanobacteria occurs by a three-dimensional array of open-chain tetrapyrrole (bilin) chromophores.[63,64] The excitation energy is funneled into the photosynthetic membrane where it is trapped and converted into an electron flow across the membrane by the reaction centers of the photosystems. The energy transfer within the light-harvesting complexes, taking place by an inductive resonance mechanism, is very fast and occurs with minimal loss of energy and a quantum efficiency close to one. The electromagnetic coupling of the chromophores and the energy-transfer times are governed by distances and orientations. Motion would interfere with efficient coupling and slow down the energy

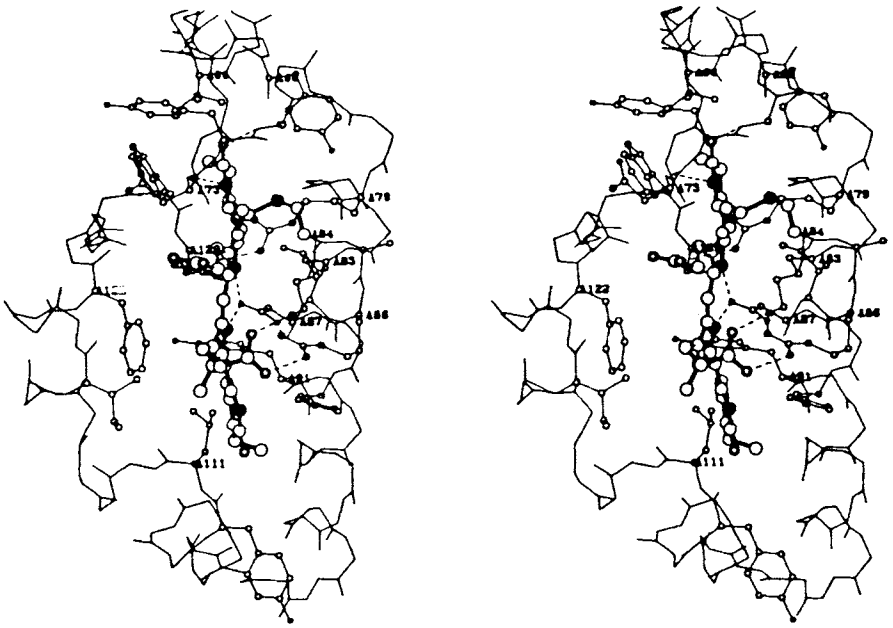

Fig. 9. Stereodrawing of the dihydrobiliverdin chromophore A84 and its environment in C-phycocyanin. Polar and charge-charge interactions of Asp A87 with the central pyrrolic nitrogens and of Arg A79, Lys A83, and Arg A86 with the propionic acid side chains form a network of bonds sequestering the chromophore in the protein matrix [65-67].

transfer, so that loss of the excitation energy by fluorescence emission could occur. In the intact complexes the energy-transfer time is several orders of magnitude shorter than the intrinsic fluorescence lifetime. Another mechanism of deexcitation would involve photochemical rearrangements of the excited chromophores. Open-chain tetrapyrrole systems indeed have this capacity and undergo photochemical isomerization as pigments in the plant photoreceptor phytochrome. In the phycobilisome components the pigments are rigidly held by hydrogen bonding interactions with charged groups of the proteins (Fig. 9). These forces are strongly directed and oppose motions leading to weaker coupling and to isomerizations.[65-67]

Similar considerations apply to the very fast electron transfer steps in the reaction centers of the photosystem, in which the excitation energy provided by the light-harvesting systems drives electrons from a primary donor to a primary acceptor.[68] Detailed structural data are available for the reaction center of a purple bacterium, *Rhodopseudomonas viridis*.[69,70] A special pair of bacteriochlorophyll chromophores is excited and ejects an electron, which is transferred to a primary electron acceptor, a quinone, via a chain of bacteriochlorophyll and bacteriopheophytin pigments. As in the light-harvesting systems, the quantum efficiency of this process is close to one. Processes such as deexcitation by fluorescence emission do not occur to a significant extent, because the electron transfer is orders of magnitude faster owing to the appropriate overlap of the electronic orbitals of the electron-conducting elements. To achieve this, the molecules must be held precisely by the

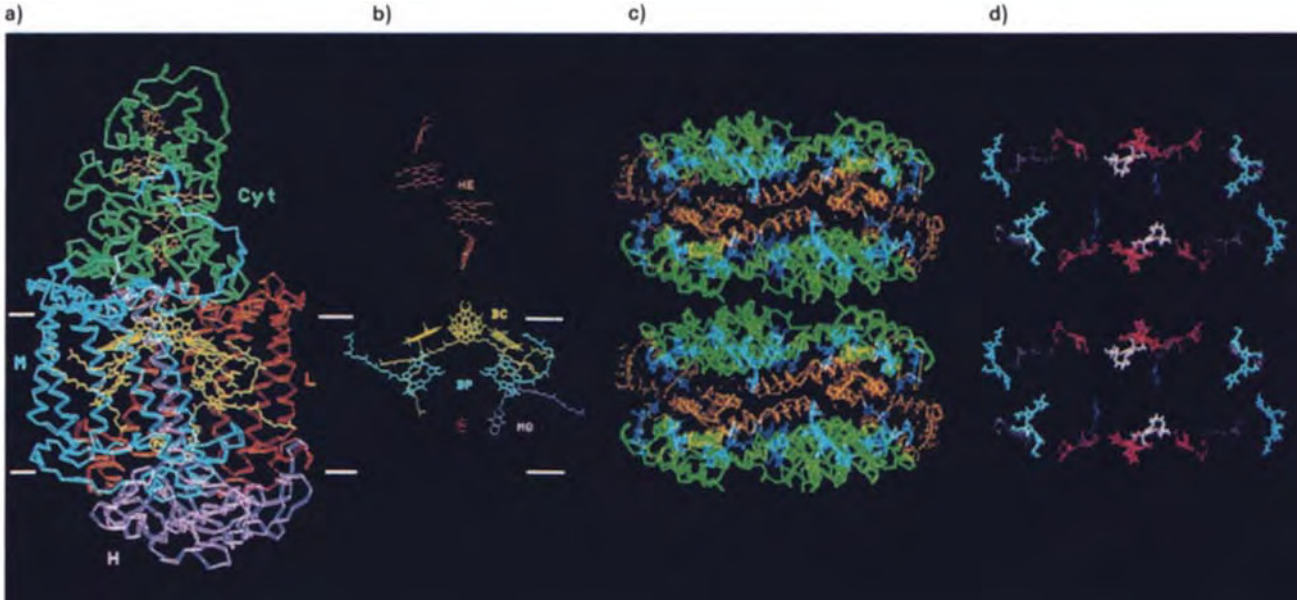

Fig. 10. a) C$^{\alpha}$-chain ribbon drawing of the reaction center protein-pigment complex. The four protein components are color-coded: green, cytochrome (Cyt); blue, M-subunit; brown, L-subunit; violet, H-subunit; yellow, pigments. b) The isolated pigments of the protein-pigment complex: brown, hemes; yellow, special pair of bacteriochlorophylls and accessory bacteriochlorophyll; blue, bacteriopheophytin; violet, menaquinone-9 (MQ); red, Fe. The presumable position of the photosynthetic membrane is indicated [69, 70]. c, d) For a comparison of sizes, three stacked hexamers of C-phycocyanin and the associated tetrapyrrole pigments are shown. This aggregate resembles an antenna of a phycobilisome organelle. The protein components of C-phycocyanin are color-coded: brown, α-subunit; green, β-subunit; blue and violet, different tetrapyrrole chromophores.

protein matrix. Photochemical isomerizations as a mechanism of deexcitation are unlikely in the cyclic bacteriochlorophyll systems, in contrast to the tetrapyrrole systems in the light-harvesting complexes. But the electron transfer might be retarded through the drag of a moving electron exerted on ions or dipolar mobile molecules, in particular water. The fast electron transfer steps indeed occur remote from water by carriers embedded in a hydrophobic protein matrix which is integrated in a membrane (Fig. 10). The energy of activation of the electron-transfer processes is very low and they are even faster at low temperatures, proving that nuclear motions are not required.

The cyclic electron transfer of photosynthesis also involves a number of slower steps not considered in this context, which require nuclear motions, rearrangements, and diffusional processes and therefore activation energy.

7. Conclusion

It was the intention of this article to point out certain aspects of rigidity and flexibility with respect to structure and function of a number of protein systems and to demonstrate the dual nature of proteins as passive, rigid matrices and as active, mobile participants in chemical reactions, respectively. The kinds of flexibility are as diverse and complex as the chemical reactions themselves. It was not and could not be the intention to describe the selected systems in detail. Instead, the article represents a selective view and the interested reader is referred to the original publications for further information.

Dr. W. S. Bennett made valuable suggestions to improve the manuscript in form and substance.

Supramolecular Chemistry—Scope and Perspectives Molecules, Supermolecules, and Molecular Devices (Nobel Lecture)**

By Jean-Marie Lehn*

Supramolecular chemistry is the chemistry of the intermolecular bond, covering the structures and functions of the entities formed by association of two or more chemical species. Molecular recognition in the supermolecules formed by receptor-substrate binding rests on the principles of molecular complementarity, as found in spherical and tetrahedral recognition, linear recognition by coreceptors, metalloreceptors, amphiphilic receptors, and anion coordination. Supramolecular catalysis by receptors bearing reactive groups effects bond cleavage reactions as well as synthetic bond formation via cocatalysis. Lipophilic receptor molecules act as selective carriers for various substrates and make it possible to set up coupled transport processes linked to electron and proton gradients or to light. Whereas endoreceptors bind substrates in molecular cavities by convergent interactions, exoreceptors rely on interactions between the surfaces of the receptor and the substrate; thus new types of receptors, such as the metallonucleates, may be designed. In combination with polymolecular assemblies, receptors, carriers, and catalysts may lead to molecular and supramolecular devices, defined as structurally organized and functionally integrated chemical systems built on supramolecular architectures. Their recognition, transfer, and transformation features are analyzed specifically from the point of view of molecular devices that would operate via photons, electrons, or ions, thus defining fields of molecular photonics, electronics, and ionics. Introduction of photosensitive groups yields photoactive receptors for the design of light-conversion and charge-separation centers. Redox-active polyolefinic chains represent molecular wires for electron transfer through membranes. Tubular mesophases formed by stacking of suitable macrocyclic receptors may lead to ion channels. Molecular self-assembling occurs with acyclic ligands that form complexes of double-helical structure. Such developments in molecular and supramolecular design and engineering open perspectives towards the realization of molecular photonic, electronic, and ionic devices that would perform highly selective recognition, reaction, and transfer operations for signal and information processing at the molecular level.

1. From Molecular to Supramolecular Chemistry

Molecular chemistry, the chemistry of the covalent bond, is concerned with uncovering and mastering the rules that govern the structures, properties, and transformations of molecular species.

Supramolecular chemistry may be defined as "chemistry beyond the molecule," bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces. Its development requires the use of all resources of molecular chemistry combined with the designed manipulation of noncovalent interactions so as to form supramolecular entities, supermolecules possessing features as well defined as those of molecules themselves. One may say that supermolecules are to molecules and the intermolecular bond what molecules are to atoms and the covalent bond.

Basic concepts, terminology, and definitions of supramolecular chemistry were introduced earlier[1-3] and will only be summarized here. Section 2.3 provides a brief account of the origins and initial developments of our work which led to the formulation of supramolecular chemistry. Molecular associations have been recognized and studied for a long time[4] and the term "Übermoleküle," i.e., supermolecules, was introduced already in the mid-1930s to describe entities of higher organization resulting from the association of coordinatively saturated species.[5] The partners of a supramolecular species have been named *molecular receptor* and *substrate*,[1,2,65] the substrate being usually the smaller component whose binding is being sought. This terminology conveys the relation to biological receptors and substrates for which *Paul Ehrlich* stated that molecules do not act if they are not bound ("Corpora non agunt nisi fixata"). The widely employed term of *ligand* seemed less appropriate in view of its many unspecific uses for either partner in a complex.

Molecular interactions form the basis of the highly specific recognition, reaction, transport, regulation, etc. pro-

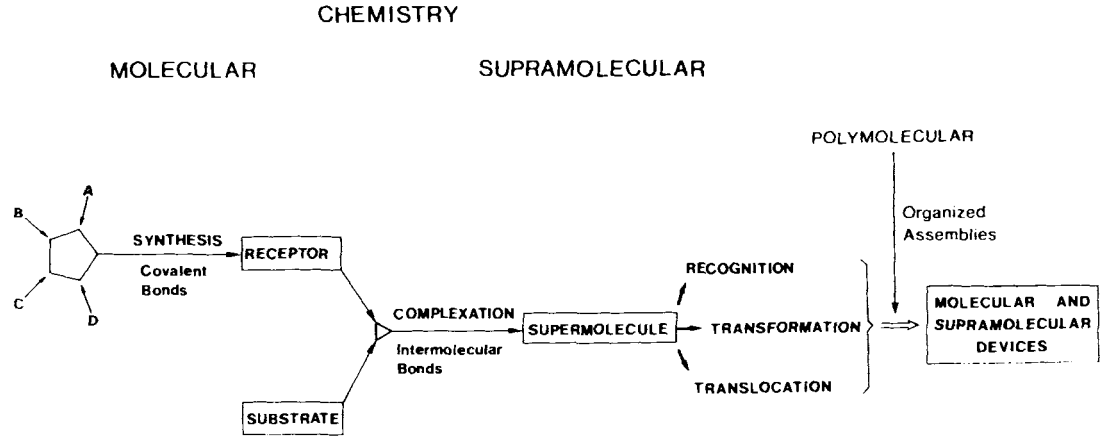
cesses that occur in biology, such as substrate binding to a receptor protein, enzymatic reactions, assembling of protein-protein complexes, immunological antigen-antibody association, intermolecular reading, translation and transcription of the genetic code, signal induction by neurotransmitters, and cellular recognition. The design of artificial, abiotic receptor molecules capable of displaying processes of highest efficiency and selectivity requires the correct manipulation of the energetic and stereochemical features of the noncovalent, intermolecular forces (electrostatic interactions, hydrogen bonding, van der Waals forces, etc.) within a defined molecular architecture. In doing so, the chemist may find inspiration in the ingenuity of biological events and encouragement in the demonstration that such high efficiencies, selectivities, and rates can indeed be attained. However, chemistry is not limited to systems similar to those found in biology, but is free to create novel species and to invent processes.

Emphasis will bear on conceptual framework, classes of compounds, and types of processes. Considering the vast literature that has developed, the topics of various meetings and symposia, etc., there is no possibility here to do justice to the numerous results obtained, all the more to provide an exhaustive account of this field of science. Supramolecular chemistry, the designed chemistry of the intermolecular bond, is rapidly expanding at the frontiers of molecular science with physical and biological phenomena.

2. Molecular Recognition

2.1. Recognition, Information, Complementarity

Molecular recognition has been defined as a process involving *both binding* and *selection* of substrate(s) by a given



Scheme 1. From molecular to supramolecular chemistry: molecules, supermolecules, molecular and supramolecular devices.

Binding of a substrate σ to its receptor ρ yields the supermolecule ρσ and involves a molecular recognition process. If, in addition to binding sites, the receptor also bears reactive functions, it may effect a chemical transformation on the bound substrate, thus behaving as a supramolecular reagent or catalyst. A lipophilic, membrane-soluble receptor may act as a carrier effecting the translocation of the bound substrate. Thus, *molecular recognition, transformation,* and *translocation* represent the basic functions of supramolecular species. More complex functions may result from the interplay of several binding subunits in a polytopic coreceptor. In association with organized polymolecular assemblies and phases (layers, membranes, vesicles, liquid crystals, etc.), functional supermolecules may lead to the development of *molecular devices.* This article describes these various aspects of supramolecular chemistry (see Scheme 1) and sketches some lines of future development (for earlier general presentations see Refs. [1-3, 6-9]). The results discussed here, taken mainly from our own work, have been completed by references to other studies, in order to draw a broader picture of this rapidly evolving field of research.

receptor molecule, as well as possibly a specific *function.*[11] Mere binding is not recognition, although it is often taken as such. One may say that recognition is binding with a purpose, like receptors are ligands with a purpose. It implies a structurally well-defined pattern of intermolecular interactions.

Binding of σ to ρ forms a supermolecule characterized by its thermodynamic and kinetic stability and selectivity, i.e., by the amount of energy and of information brought into operation. Molecular recognition thus is a question of *information storage* and *read out* at the supramolecular level. Information may be stored in the architecture of the ligand, in its binding sites (nature, number, arrangement) and in the ligand layer surrounding bound σ; it is read out at the rate of formation and dissociation of the supermolecule. Molecular recognition thus corresponds to optimal information content of ρ for a given σ.[11] This amounts to a generalized *double complementarity principle* extending over energetical (electronic) as well as geometrical features, the celebrated "lock and key," steric fit concept enunciated by *Emil Fischer* in 1894.[10] Enhanced recognition beyond that provided by a single equilibrium step may

be achieved by multistep recognition and coupling to an irreversible process.[11]

The ideas of molecular recognition and of receptor chemistry have been penetrating chemistry more and more over the last fifteen years, namely in view of their bioorganic implications, but more generally for their significance in intermolecular chemistry and in chemical selectivity.[1-3,6-9,12-21]

2.2. Molecular Receptors—Design Principles

Receptor chemistry, the chemistry of artificial receptor molecules, may be considered a generalized coordination chemistry, not limited to transition-metal ions but extending to all types of substrates: cationic, anionic, or neutral species of organic, inorganic, or biological nature.

In order to achieve high recognition it is desirable that receptor and substrate be in contact over a large area. This occurs when ρ is able to wrap around its guest so as to establish numerous noncovalent binding interactions and to sense its molecular size, shape, and architecture. It is the case for receptor molecules that contain intramolecular cavities into which the substrate may fit, thus yielding an inclusion complex, a *cryptate*. In such concave receptors the cavity is lined with binding sites directed towards the bound species; they are endopolarophilic[1] and *convergent*, and may be termed *endoreceptors* (see also Section 7).

Macropolycyclic structures meet the requirements for designing artificial receptors: they are large (macro) and may therefore contain cavities and clefts of appropriate size and shape; they possess numerous branches, bridges, and connections (polycyclic) that allow the construction of a given architecture endowed with desired dynamic features; they allow the arrangement of structural groups, binding sites, and reactive functions.

The balance between rigidity and flexibility is of particular importance for the dynamic properties of ρ and of σ. Although high recognition may be achieved with rigidly organized receptors, processes of exchange, regulation, cooperativity, and allostery require a built-in flexibility so that ρ may adapt and respond to changes. Flexibility is of great importance in biological receptor–substrate interactions, where adaptation is often required for regulation to occur. Such designed dynamics are more difficult to control than mere rigidity, and recent developments in computer-assisted molecular design methods, allowing the exploration of both structural and dynamical features, may greatly help.[22] Receptor design thus covers both static and dynamic features of macropolycyclic structures.

The stability and selectivity of σ binding result from the set of interaction sites in ρ and may be structurally translated into *accumulation* (or collection) and *organization* (or orientation), i.e., bringing together binding sites and arranging them in a suitable pattern. Model computations on $(NH_3)_n$ clusters of different geometries have shown that collection involves appreciably larger energies than changes in orientation.[23] One may note that these intersite repulsions are built into a polydentate ligand in the course of synthesis.

We have studied receptors belonging to various classes of macropolycyclic structures (macrocycles, macrobicycles, cylindrical and spherical macrotricycles, etc.), expanding progressively our initial work on macrobicyclic cationic cryptates into the investigation of the structures and functions of supermolecules presenting molecular recognition, catalysis, and transport processes.

2.3. Initial Studies. Spherical Recognition in Cryptate Complexes

The simplest recognition process is that of spherical substrates; these are either positively charged metal cations (alkali, alkaline-earth, lanthanoid ions) or the negative halide anions.

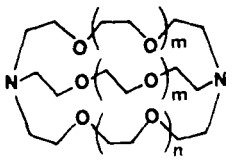
During the last 20 years, the complexation chemistry of alkali cations developed rapidly with the discovery of several classes of more or less powerful and selective ligands: natural[24] or synthetic[25,26] macrocycles (such as valinomycin, [18]crown-6, and spherands) as well as macropolycyclic cryptands and cryptospherands.[1,6,9,26,27] It is the design and study of alkali-metal cryptates that started our work which developed into supramolecular chemistry.

It may be suitable at this stage to recount briefly the *origins of our work*, trying to trace the initial motivations and the emergence of the first lines of research. In the course of the year 1966, my interest for the processes occurring in the nervous system led me to wonder how a chemist might contribute to the study of these highest biological functions. The electrical events in nerve cells rest on changes in the distributions of sodium and potassium ions across the membrane. This seemed a possible entry into the field, since it had just been shown that the cyclodepsipeptide valinomycin,[24c] whose structure and synthesis had been reported,[24d] was able to mediate potassium ion transport in mitochondria.[24e] These results[24d,e] made me think that suitably designed synthetic cyclopeptides or analogues could provide means of monitoring cation distribution and transport across membranes. Such properties were also displayed by other neutral antibiotics[24f] of the enniatin and actin[24g] groups, and were found to be due to selective complex formation with alkali-metal cations,[24h-l] thus making these substances *ionophores*.[24m] However, since cation complexation might also represent a means of increasing the reactivity of the counteranion (anion activation),[6,35] it became desirable to envisage molecules which would be chemically less reactive than cyclic peptides.[*] Thus, when the cation binding properties of macrocyclic polyethers (crown ethers) were reported by *Charles Pe-*

[*] Earlier observations had suggested that polyethers interact with alkali cations. See, for instance, H. C. Brown, E. J. Mead, P. A. Tierney, *J. Am. Chem. Soc. 79* (1957) 5400; J. L. Down, J. Lewis, B. Moore, G. Wilkinson, *J. Chem. Soc. 1959*, 3767; suggestions had also been made for the design of organic ligands, see R. J. P. Williams, *The Analyst (London) 78* (1953) 586; *Q. Rev. Chem. Soc. 24* (1970) 331.

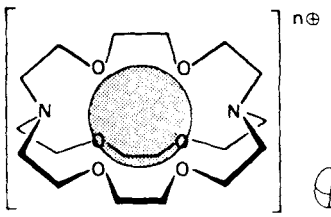
[**] To name this new class of chemical entities, a term rooted in Greek and Latin, which would also be equally suggestive in French, English, German, and possibly (!) other languages, was sought; "cryptates" appeared particularly suitable for designating a complex in which the cation was contained inside the molecular cavity, the crypt, of the ligand termed "cryptand."

dersen,[25a] these substances were perceived as combining the complexing ability of the macrocyclic antibiotics with the chemical stability of ether functions. Meanwhile, it had also become clear that compounds containing a three-dimensional, spheroidal cavity, surrounding entirely the bound ion, should form stronger complexes than the rather flat macrocycles; thus emerged the idea of designing macrobicyclic ligands.

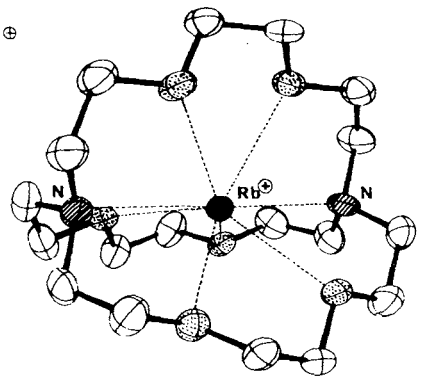


1 = [2.1.1]: m=0, n=1
2 = [2.2.1]: m=1, n=0
3 = [2.2.2]: m=n=1

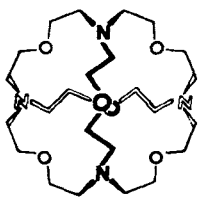
Work started in October 1967 yielded the first such ligand **3** ("[2.2.2]") in the fall of 1968; its very strong binding of potassium ions was noted at once and a cryptate structure was assigned to the complex obtained, allowing us also to envisage its potential use for anion activation and for cation transport.[29a][**] Other ligands such as **1** and **2** and larger ones were synthesized and numerous cryptates were obtained.[29b] Their structure was confirmed by crystal structure determinations of a number of complexes, such as the rubidium cryptate of **3**, **4b**,[29c] and their stability constants were measured.[28]



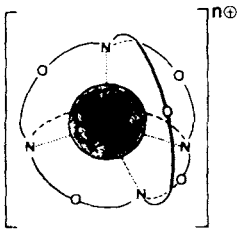
4a



4b



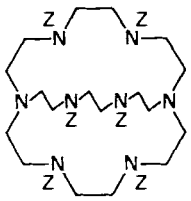
5



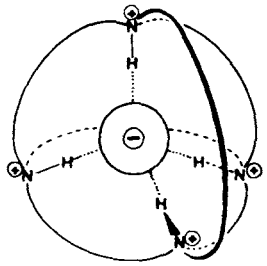
6

The problem of spherical recognition is that of selecting a given spherical ion from among a collection of different spheres of same charge. Thus, the macrobicyclic cryptands **1**–**3** form highly stable and selective cryptates $[M^{n\oplus} \subset (\text{cryptand})]$ **4a**, such as **4b**, with the cation whose size is complementary to the size of the cavity; i.e., $Li^{\oplus}$, $Na^{\oplus}$, and $K^{\oplus}$ for **1**, **2**, and **3**, respectively.[28a, 29a] Others display high selectivity for alkali versus alkaline-earth cations.[28b] Thus, recognition features equal to or higher than those of natural macrocyclic ligands may be achieved. The spherical macrotricyclic cryptand **5** binds strongly and selectively the larger spherical cations, giving a strong $Cs^{\oplus}$ complex, as in **6**.[30]

Anion cryptates are formed by the protonated polyamines **7**[31] and **5**[32] with the spherical halide anions $F^{\ominus}$ and $Cl^{\ominus}$, respectively. **5**-4 $H^{\oplus}$ binds $Cl^{\ominus}$ very strongly and very selectively compared with $Br^{\ominus}$ and other types of anions, giving the $[Cl^{\ominus} \subset (\mathbf{5}\text{-}4H^{\oplus})]$ cryptate **8**. Quaternary ammonium derivatives of such type of macrotricycles free of oxygen also bind spherical anions.[33]



7, Z=H



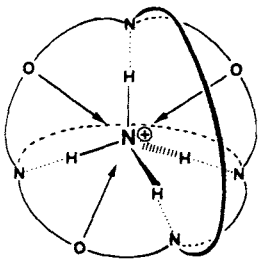
8

Thus, cryptands **1**–**3** and **5** as well as related compounds display *spherical recognition* of appropriate cations and anions. Their complexation properties result from their macropolycyclic nature and define a *cryptate effect* characterized by high stability and selectivity, slow exchange rates, and efficient shielding of the bound substrate from the environment.

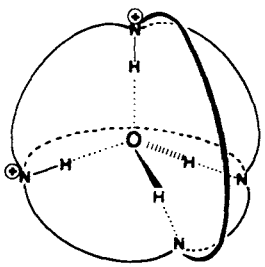
As a consequence of these features, cryptate formation strongly influences physical properties and chemical reactivity. Numerous effects have been brought about and studied in detail, such as stabilization of alkalides and electrides,[34] dissociation of ion pairs, anion activation, isotope separation, and toxic metal binding. These results will not be described here and reviews may be found in Refs. [6, 35–38].

2.4. Tetrahedral Recognition

Selective binding of a tetrahedral substrate requires the construction of a receptor molecule possessing a tetrahedral recognition site, as realized in the macrotricycle **5**, which contains four nitrogen and six oxygen binding sites located, respectively, at the corners of a tetrahedron and of an octahedron.[30] Indeed, **5** forms an exceptionally stable and selective cryptate $[NH_4^{\oplus} \subset \mathbf{5}]$ **9**, with the tetrahedral $NH_4^{\oplus}$ cation, due to the high degree of structural and energetical complementarity. $NH_4^{\oplus}$ has the size and shape for fitting into the cavity of **5** and forming a tetrahedral array of $^{\oplus}N-H\cdots N$ hydrogen bonds with the four nitrogen sites.[39] As a result of its very strong binding, the pK_a of the $NH_4^{\oplus}$ cryptate is about six units higher than that of free $NH_4^{\oplus}$, indicating how much strong binding may affect the properties of the substrate. It also indicates that similar effects exist in enzyme active sites and in biological receptor-substrate binding.



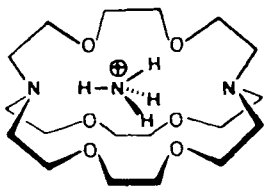
9



10

The unusual protonation features of **5** in aqueous solution (high pK_a for double protonation, very slow exchange) and ^{17}O-NMR studies led to the formulation of a water cryptate $[H_2O \subset (\mathbf{5}\text{-}2H^{\oplus})]$ **10** with the diprotonated macrotricycle.[2,6,40] The facilitation of the second protonation of **5** represents a *positive cooperativity*, in which the first proton and the effector molecule water set the stage both structurally and energetically for the fixation of a second proton.

Considering together the three cryptates $[NH_4^{\oplus} \subset \mathbf{5}]$ **9**, $[H_2O \subset (\mathbf{5}\text{-}2H^{\oplus})]$ **10**, and $[Cl^{\ominus} \subset (\mathbf{5}\text{-}4H^{\oplus})]$ **8**, it is seen that the spherical macrotricycle **5** is a molecular receptor possessing a *tetrahedral recognition site* in which the substrates are bound in a tetrahedral array of hydrogen bonds. It represents a state of the art illustration of the molecular engineering involved in abiotic receptor chemistry. Since it binds a tetrahedral cation $NH_4^{\oplus}$, a bent neutral molecule H_2O, or a spherical anion $Cl^{\ominus}$ when unprotonated, diprotonated, or tetraprotonated, respectively, the macrotricyclic cryptand **5** behaves like a sort of molecular chameleon responding to pH changes in the medium!

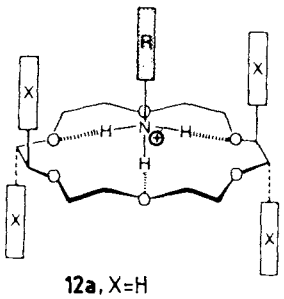


11

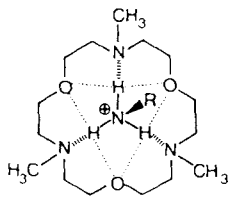
The macrobicycle **3** also binds $NH_4^{\oplus}$, forming cryptate **11**. The dynamic properties of **11** compared with **9** reflect the receptor-substrate binding complementarity: whereas $NH_4^{\oplus}$ is firmly held inside the cavity in **9**, it undergoes internal rotation in **11**.[41]

2.5. Recognition of Ammonium Ions and Related Substrates

In view of the important role played by substituted ammonium ions in chemistry and in biology, the development of receptor molecules capable of recognizing such substrates is of special interest. Macrocyclic polyethers bind primary ammonium ions by anchoring the $NH_3^{\oplus}$ group into their circular cavity via three $^{\oplus}N-H\cdots O$ hydrogen bonds as shown in **12**;[12-15,25,42] however, they complex alkali cations such as $K^{\oplus}$ more strongly. Selective binding of $R-NH_3^{\oplus}$ may be achieved by extending the results obtained for $NH_4^{\oplus}$ complexation by **5** and making use of the oxa-aza macrocycles[15,43] developed in the course of the synthesis of cryptands.[29a,b,30] Indeed, the triazamacrocycle [18]-N_3O_3,[*] which forms a complementary array of three $^{\oplus}N-H\cdots N$ bonds, **13**, selects $R-NH_3^{\oplus}$ over $K^{\oplus}$ and is thus a receptor unit for this functional group.[43]



12a, X=H
12b, X=$CO_2^{\ominus}$
12c, X=CONYY'



13

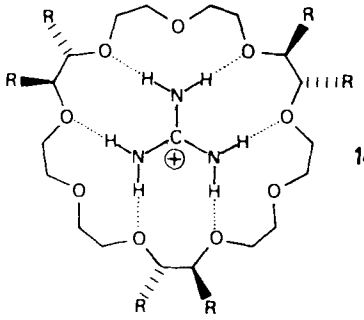
A great variety of macrocyclic polyethers have been shown to bind $R-NH_3^{\oplus}$ molecules with structural and chiral selectivity.[12,13,42] Particularly strong binding is shown by the tetracarboxylate **12b**, which conserves the desirable, basic [18]-O_6 ring and adds electrostatic interactions, thus forming the most stable metal-ion and ammonium complexes of any polyether macrocycle.[44] Very marked *central discrimination* is observed in favor of primary ammonium ions compared with more highly substituted ones; it allows preferential binding of biologically active ions such as noradrenaline or norephedrine compared with their *N*-methylated derivatives adrenaline and ephedrine.[44]

Modulation of the complexation features of **12** by varying the side groups X so as to make use of specific interactions (electrostatic, H-bonding, charge transfer, lipophilic) between X and the R group of the centrally bound $R-NH_3^{\oplus}$ substrate, brings about *lateral discrimination* effects. This also represents a general way of modeling interactions present in biological receptor-substrate complexes, such as that occurring between nicotinamide and tryptophane.[45] One may thus attach to **12** amino-acid residues (leading to "parallel peptides"[44] as in **12c**), nucleic acid bases or nucleosides, saccharides, etc.

Binding of metal-amine complexes $[M(NH_3)_n]^{m\oplus}$ to macrocyclic polyethers via $N-H\cdots O$ interactions with the NH_3 groups, leads to a variety of supramolecular species of "supercomplex type" by second-sphere coordination.[46] As with $R-NH_3^{\oplus}$ substrates, binding to aza-oxa or polyaza macrocycles (see **13**) may also be expected. Strong complexation by macrocycles bearing negative charges (such as **12b** or the hexacarboxylate in **14**[47]) should make it possible to induce various processes between centrally bound metal-amine species and lateral groups X in **12** (energy and electron transfer, chemical reaction, etc.).

Receptor sites for secondary and tertiary ammonium groups are also of interest. $R_2NH_2^{\oplus}$ ions bind to the [12]-N_2O_2 macrocycle via two hydrogen bonds.[48] The case of quaternary ammonium ions will be considered below.

[*] The designation gives the ring size in brackets followed by the kind and number of heteroatoms.



14, R=$CO_2^{\ominus}$

The guanidinium cation binds to [27]-O_9 macrocycles through an array of six H-bonds,[49] yielding a particularly stable complex **14** with a hexacarboxylate receptor, which also binds the imidazolium ion.[49a]

3. Anion Coordination Chemistry and the Recognition of Anionic Substrates

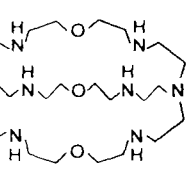
Although anionic species play a very important role in chemistry and in biology, their complexation chemistry went unrecognized as a specific field of research, while the complexation of metal ions and, more recently, cationic molecules was extensively studied. The coordination chemistry of anions may be expected to yield a great variety of novel structures and properties of both chemical and biological significance.[2,6,32] To this end, anion receptor molecules and binding subunits for anionic functional groups have to be devised. Research has been increasingly active along these lines in recent years and anion coordination chemistry is progressively building up.[8,9,50]

Positively charged or neutral electron-deficient groups may serve as interaction sites for anion binding. Ammonium and guanidinium units, which form $^{\oplus}N-H\cdots X^{\ominus}$ bonds, have mainly been used, but neutral polar hydrogen bonds (e.g., with $-NHCO-$ or $-COOH$ functions), electron-deficient centers (boron, tin, etc.), or metal-ion centers in complexes also interact with anions.

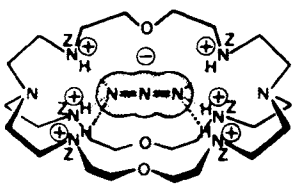
Polyammonium macrocycles and macropolycycles have been studied most extensively as anion receptor molecules. They bind a variety of anionic species (inorganic anions, carboxylates, phosphates, etc.) with stabilities and selectivities resulting from both electrostatic and structural effects.

Strong and selective complexes of the spherical halide anions are formed by macrobicyclic and by spherical macrotricyclic polyammonium receptors such as the protonated forms of **5**[32] (see **8**), of bis-tren **15**,[51] and of related compounds.[50,52]

The hexaprotonated form of bis-tren, **15**-6$H^{\oplus}$, complexes various monoatomic and polyatomic anions.[51] The crystal structures of four such anion cryptates (Fig. 1) provide a unique series of anion coordination patterns.[51b] The spherical halide ions are not complementary to the ellipsoidal receptor cavity and distort the structure, $F^{\ominus}$ being bound in a tetrahedral array of $N-H\cdots F^{\ominus}$ bonds and $Cl^{\ominus}$ and $Br^{\ominus}$ having octahedral coordination. The linear triatomic anion $N_3^{\ominus}$ has a shape and size complementary to the cavity of **15**-6$H^{\oplus}$ and is bound inside by a pyramidal array of three H-bonds to each terminal nitrogen, forming the cryptate $[N_3^{\ominus}\subset(\mathbf{15}\text{-}6H^{\oplus})]$ **16**. Thus, **15**-6$H^{\oplus}$ is a molecular receptor recognizing linear triatomic species such as $N_3^{\ominus}$, which is indeed bound much more strongly than other singly charged anions.



15



16

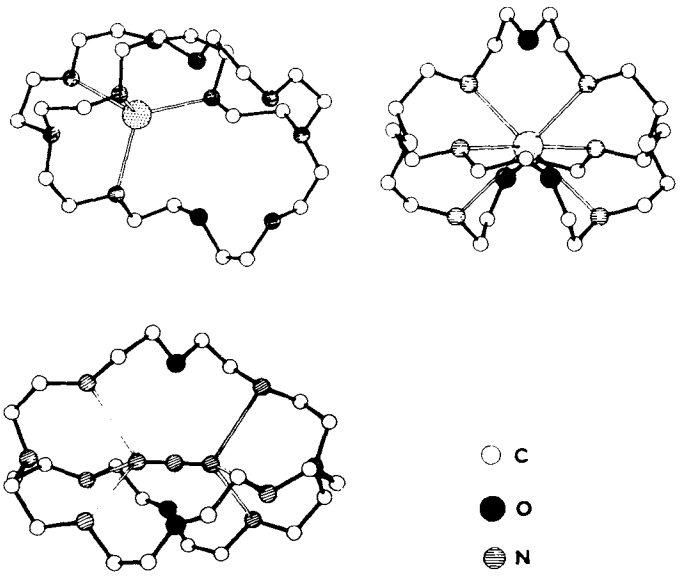


Fig. 1. Crystal structures of the anion cryptates formed by the hexaprotonated receptor molecule **15**-6$H^{\oplus}$ with fluoride (upper left), chloride (upper right), and azide (below) anions [51b].

Carboxylates and *phosphates* bind to polyammonium macrocycles with stabilities and selectivities determined by structure and charge of the two partners.[50,51,53-57] The design of receptor units for these functional groups is of much interest since they serve as anchoring sites for numerous biological substrates. Thus, strong complexes are obtained with macrobicyclic polyammonium pockets in which carboxylate (formate, acetate, oxalate, etc.) and phosphate groups interact with several ammonium sites.[51] The guanidinium group, which serves as a binding site in biological receptors, may form two H-bonds with carboxylate and phosphate functions and has been introduced into acyclic[58] and macrocyclic[59] structures. Binding units mimicking that of vancomycin are being sought.[60]

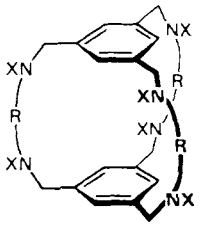
Complexation of complex anions of transition metals such as the hexacyanides $M(CN)_6^{n\ominus}$ yields second-coordination-sphere complexes, *supercomplexes*,[53a] and affects markedly their electrochemical[61,62] and photochemical[63] properties. Of special interest is the strong binding of adenosine mono-, di-, and triphosphate (AMP, ADP, and

ATP) and related compounds that play a very important biological role.[55-57]

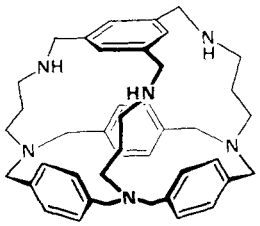
Cascade-type binding[64] of anionic species occurs when a ligand first binds metal ions, which then serve as interaction sites for an anion. Such processes occur for instance in lipophilic cation/anion pairs[65] and with Cu^{II} complexes of bis-tren **15** and of macrocyclic polyamines.[66]

Heteronuclear NMR studies give information about the electronic effects induced by anion complexation as found for chloride cryptates.[67]

Complexation of various molecular anions by other types of macrocyclic ligands have been reported,[50] in particular with cyclophane-type compounds. Two such receptors of defined binding geometries are represented by the protonated forms of the macropolycycles **17**[68] and **18**.[69]



17, X=H, R=$(CH_2)_3$



18

Anion coordination chemistry has thus made very significant progress in recent years. The development of other receptor molecules possessing well-defined geometrical and binding features will make it possible to further refine the requirements for anion recognition, so as to yield highly stable and selective anion complexes with characteristic coordination patterns. Theoretical studies may be of much help in the design of anion receptors and in the a priori estimation of binding features, as recently illustrated by the calculation of the relative affinity of **5**-4H$^{\oplus}$ for chloride and bromide ions.[70]

4. Coreceptor Molecules and Multiple Recognition

Once binding units for specific groups have been identified, one may consider combining several of them within the same macropolycyclic architecture. Thus are formed polytopic coreceptor molecules containing several discrete binding subunits which may cooperate for the simultaneous complexation of several substrates or of a multiply bound (polyhapto) polyfunctional species. Suitable modification would yield cocatalysts or cocarriers performing a reaction or a transport on the bound substrate(s). Furthermore, because of their ability to perform multiple recognition and because of the mutual effects of binding site occupation, such coreceptors provide entries into higher forms of molecular behavior such as cooperativity, allostery, and regulation, as well as communication or signal transfer, if a species is released or taken up. Basic ideas and definitions concerning coreceptor molecules have been presented in more detail elsewhere.[7]

The simplest class of coreceptors is that containing two binding subunits, ditopic coreceptors, which may belong to different structural types. Combination of chelating, tripodal, and macrocyclic fragments yields macrocyclic, axial or lateral macrobicyclic, or cylindrical macrotricyclic structures (Fig. 2). Depending on the nature of these units, the resulting coreceptors may bind metal ions, organic molecules, or both.

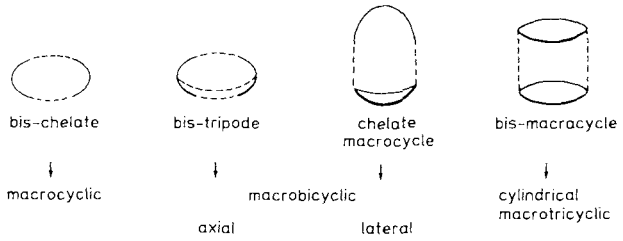


Fig. 2. Combination of chelating, tripodal, and cyclic subunits into ditopic coreceptors of macrocyclic, axial and lateral macrobicyclic, and cylindrical macrotricyclic types.

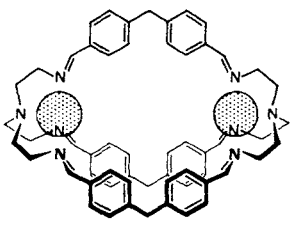
4.1. Dinuclear and Polynuclear Metal-Ion Cryptates

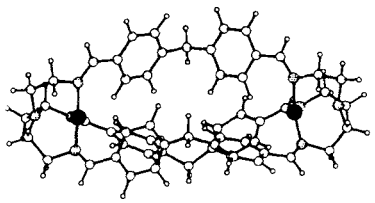
Coreceptor molecules containing two or more binding subunits for metal ions form dinuclear or polynuclear cryptates in which the arrangement of the metal ions is determined by the macropolycyclic structure. Such complexes may present a multitude of new properties, such as interactions between cations, electrochemical and photochemical processes, and fixation of bridging substrates, which are of interest both for bioinorganic modeling and for multicenter-multielectron reactions and catalysis.

Dinuclear cryptates of ligands belonging to all structural types shown in Figure 2 have been obtained. This vast area will only be illustrated here by a few recent examples (for more details and references see earlier reviews[64,71]).

Axial macrobicyclic ligands give dinuclear cryptates such as the Cu_2^I complex **19** formed by a large hexaimine structure obtained in a one-step multiple condensation reaction; its crystal structure is shown in **20**.[72]



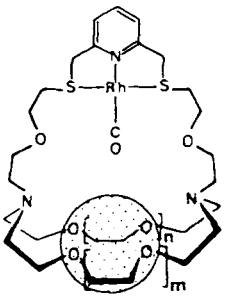
19



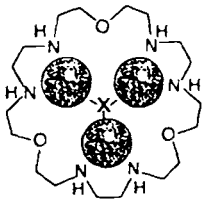
20

Lateral macrobicycles are dissymmetric by construction and make it possible to arrange metal centers of different properties in the same ligand. Thus, complexes of type **21** combine a redox center and a Lewis acid center for activation of a bound substrate.[73]

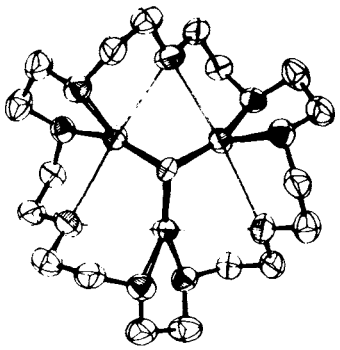
"*Cluster cryptates*" may be formed by assembling of metal ions and bridging species inside the molecular cavity of polytopic receptors. Thus, in the Cu_3^{II} complex **22** (crystal structure **23**) a bis-μ_3-hydroxo, triscopper(II) group is bound in the cavity of a tritopic macrocycle.[74] Modeling of biological iron-sulfur cluster sites may employ inclusion into appropriate macrocyclic cavities.[75]

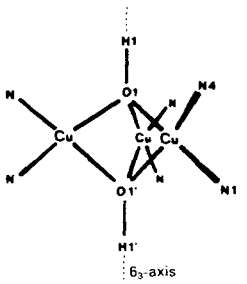


21, m,n=0,1



22



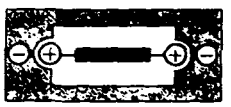


23

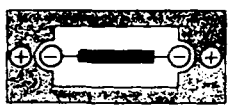
This inorganic aspect of supramolecular species represents in itself a field of research in which many novel structures and reactivities await to be discovered.

4.2. Linear Recognition of Molecular Length by Ditopic Coreceptors

Receptor molecules possessing two binding subunits located at the two poles of the structure will complex preferentially substrates bearing two appropriate functional groups at a distance compatible with the separation of the subunits. This distance complementarity amounts to a recognition of molecular length of the substrate by the receptor. Such *linear molecular recognition* of dicationic and dianionic substrates corresponds to the binding modes illustrated by **24** and **25**.

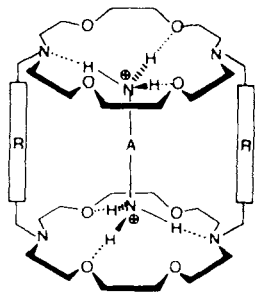


24

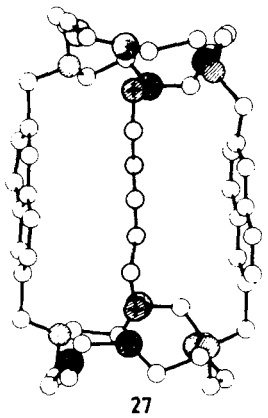


25

Incorporation of macrocyclic subunits that bind $NH_3^{\oplus}$ groups (see above) into cylindrical macrotricyclic[76] and macrotetracyclic[77] structures yields ditopic coreceptors that form molecular cryptates such as **26** with terminal *diammonium cations* $^{\oplus}H_3N-(CH_2)_n-NH_3^{\oplus}$. In the resulting supermolecules the substrate is located in the central molecular cavity and anchored by its two $NH_3^{\oplus}$ groups in the macrocyclic binding sites, as shown by the crystal structure **27** (**26** with R = NA and A = $(CH_2)_5$).[78] Changing the length of the bridges R in **26** modifies the binding selectivity in favor of the substrate of complementary length. NMR relaxation data have also shown that optimal partners present similar molecular motions in the receptor-substrate pair. Thus, complementarity in the supramolecular species expresses itself in both steric *and* dynamic fit.[79]

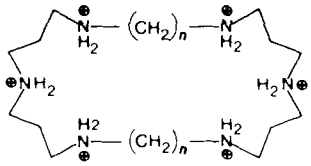


26, R=P,NA,BP,TP

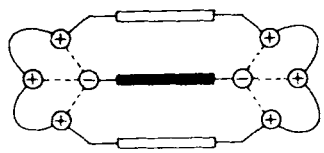


27

Dianionic substrates, such as the alkyl dicarboxylates $^{\ominus}O_2C-(CH_2)_n-CO_2^{\ominus}$, are bound with length discrimination by ditopic macrocycles such as **28**. These receptors contain two triammonium groups as binding subunits interacting with the terminal carboxylate functions, via a pattern schematically shown in **29**.[80]



28, n=7,10



29

Thus, for both the terminal diammonium and dicarboxylate substrates, selective binding by the appropriate receptors describes a linear recognition process based on length complementarity in a ditopic binding mode. Important biological species, such as polyamines, amino-acid and peptide diamines, and dicarboxylates, may also be bound selectively.

Numerous variations in the nature of the binding subunits or of the bridges linking them, are conceivable and may be tailored to specific complexation properties (see, for instance, Refs. [15, 81]). The development of *heterotopic receptors* may allow the binding of ion pairs[82] or zwitterionic species.[83]

Studies on *dynamic coupling*[79,84] between a receptor and a substrate are of much interest. Dynamic features of supermolecules correspond on the intermolecular level to the internal conformational motions present in molecules themselves and define molecular recognition processes by their dynamics in addition to their structural aspects.

4.3. Heterotopic Coreceptors: Speleands, Amphiphilic Receptors

Combination of binding subunits of different nature yields heterotopic receptors that may bind substrates by in-

teracting simultaneously with cationic and anionic neutral sites, making use of electrostatic and van der Waals forces as well as of solvophobic effects.

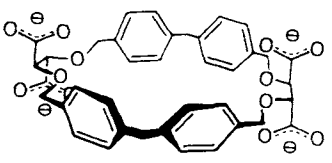
The natural cyclodextrins were the first receptor molecules whose binding properties towards organic molecules yielded a wealth of results on physical and chemical features of molecular complexation.[21,85]

Numerous types of synthetic macrocyclic receptors that contain various organic groups and polar functions have been developed in recent years. They complex both charged and uncharged organic substrates. Although the results obtained often describe mere binding rather than actual recognition, they have provided a large body of data that make it possible to analyze the basic features of molecular complexation and the properties of structural fragments to be used in receptor design. We describe here mainly some of our own results in this area, referring the reader to specific reviews of the subject.[20,86]

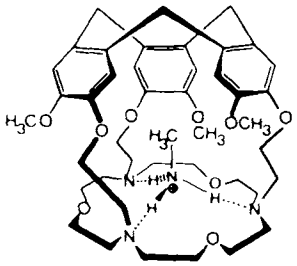
Synergetical operation of electrostatic and hydrophobic effects may occur in *amphiphilic receptors* combining charged polar sites with organic residues, which shield the polar sites from solvation and increase electrostatic forces. Such macropolycyclic structures containing polar binding subunits maintained by apolar shaping components, termed *speleands*, yield molecular cryptates *(speleates)* by substrate binding.[87]

Thus, macrocycle **30**, incorporating four carboxylate groups and two diphenylmethane units,[88] not only forms very stable complexes with primary ammonium ions, but also strongly binds secondary, tertiary, and quaternary ammonium substrates. In particular, it complexes *acetylcholine*, giving information about the type of interactions that may play a role in biological acetylcholine receptors, such as the combination of negative charges with hydrophobic walls. Similar effects operate in other anionic receptors complexing quaternary ammonium cations.[86a,89] Extensive studies have been conducted on the complexation of heterocyclic ammonium ions such as diquat by macrocyclic polyether receptors.[90]

The $CH_3-NH_3^{\oplus}$ cation forms a selective speleate **31** by binding to the [18]-N_3O_3 subunit of a macropolycycle maintained by a cyclotriveratrylene shaping component. The tight intramolecular cavity efficiently excludes larger substrates.[87,91]



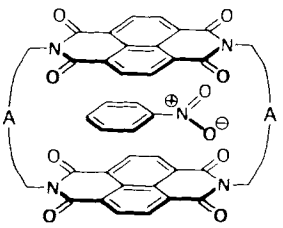
30



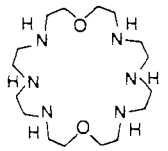
31

Amphiphilic binding also occurs for molecular anionic substrates.[20,86,92] Charged heterocyclic ring systems, such as those derived from the pyridinium group, represent an efficient way to introduce simultaneously electrostatic interactions, hydrophobic effects, structure, and rigidity into a molecular receptor; in addition they may be electroactive and photoactive.[93] Even single planar units such as diazapyrenium dications bind flat organic anions remarkably well in aqueous solution, using electrostatic interactions as well as hydrophobic stacking.[93] A macrocycle containing four pyridinium sites was found to strongly complex organic anions.[94]

Receptors of *cyclointercaland* type, which incorporate intercalating units into a macrocyclic system, are of interest for both the binding of small molecules and their own (selective) interaction with nucleic acids. A *cyclo-bisintercaland* has been found to form an intercalative molecular cryptate **32** in which a nitrobenzene molecule is inserted between the two planar subunits of the receptor.[95] Such receptors are well suited for the recognition of substrates presenting flat shapes and become of special interest if intercalating dyes are incorporated.[96]



32, A=$(CH_2)_8$



33

Fitting the macrocyclic polyamine **33** with a side chain bearing a 9-aminoacridine group yields a coreceptor that may display both anion binding, via the polyammonium subunit and stacking interaction via the intercalating dye. It interacts with both the triphosphate and the adenine groups of ATP and provides in addition a catalytic site for its hydrolysis (see Section 5.2).[97]

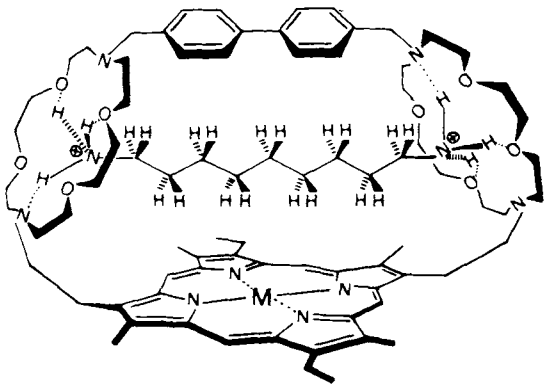
Flat aromatic heterocyclic units bearing lateral acid and amide functional groups function as receptors that perform size and shape recognition of complementary substrates within their molecular cleft.[17b] Receptor units containing heterocyclic groups such as 2,6-diaminopyridine[98a] or a nucleic acid base combined with an intercalator[98b] may lead to recognition of nucleotides via base-pairing.[98c]

The spherically shaped *cryptophanes* allow the study of recognition between neutral receptors and substrates and, in particular, the effect of molecular shape and volume complementarity on selectivity.[99]

4.4. Multiple Recognition in Metalloreceptors

Metalloreceptors are heterotopic coreceptors that are able to bind both metal ions and organic molecules by means of substrate-specific units.

Porphyrin and α,α'-bipyridine (bipy) groups have been introduced as metal-ion binding units in macropolycyclic coreceptors containing also macrocyclic sites for anchoring $NH_3^{\oplus}$ groups.[64,71,100] These receptors form mixed-substrate supermolecules by simultaneously binding metal ions and diammonium cations as shown in **34**. Metalloreceptors, and the supermolecules that they form, thus open



34, M=Zn

up a vast area for the study of interactions and reactions between co-bound organic and inorganic species. In view of the number of metal-ion complexes known and of the various potential molecular substrates, numerous types of metalloreceptors may be imagined which would be of interest as abiotic chemical species or as bioinorganic model systems.[101]

5. Supramolecular Reactivity and Catalysis

Reactivity and catalysis represent major features of the functional properties of supramolecular systems. Molecular receptors bearing appropriate reactive groups in addition to binding sites may complex a substrate (with given stability, selectivity, and kinetic features), react with it (with given rate, selectivity, and turnover), and release the products, thus regenerating the reagent for a new cycle (Fig. 3).

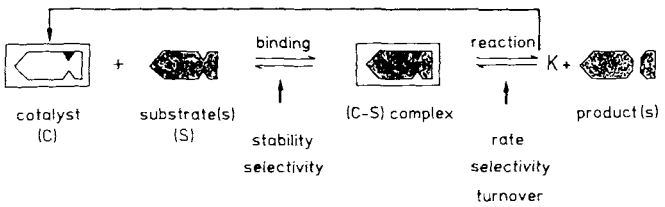


Fig. 3. Schematic representation of the supramolecular catalysis process.

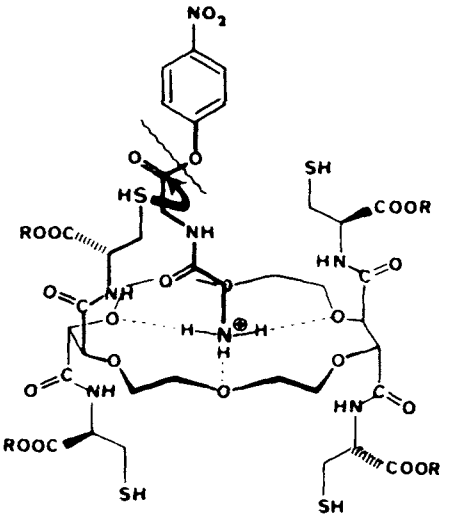
Supramolecular reactivity and catalysis thus involve two main steps: *binding* which selects the substrate and *transformation* of the bound species into products within the supermolecule formed. Both steps take part in the molecular *recognition* of the *productive* substrate and require the correct molecular information in the reactive receptor.[1] Compared to molecular catalysis, a binding step is involved that selects the substrate and precedes the reaction itself.

The design of efficient and selective supramolecular reagents and catalysts may give mechanistic insight into the elementary steps of catalysis, provide new types of chemical reagents, and effect reactions that reveal factors contributing to enzymatic catalysis. This has led to numerous investigations, which have made use mainly of reagents based on functionalized α-cyclodextrin, macrocyclic polyethers, and cyclophanes.[85, 102, 103]

5.1. Catalysis by Reactive Cation Receptor Molecules

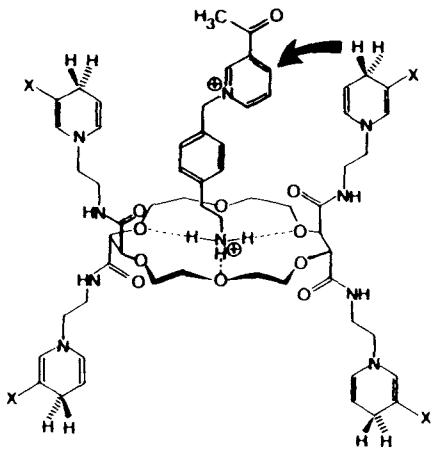
Ester cleavage processes have been most frequently investigated in enzyme model studies. Macrocyclic polyethers fitted with side chains bearing thiol groups cleave activated esters with marked rate enhancements and chiral discrimination between optically active substrates.[104–106] The tetra-L-cysteinyl derivative of macrocycle **12c** binds *p*-nitrophenyl (PNP) esters of amino acids and peptides, and reacts with the bound species, releasing *p*-nitrophenol as shown in **35**.[105] The reaction displays (1) substrate selec-



35, R=CH_3

tivity with (2) marked rate enhancements in favor of dipeptide ester substrates, (3) inhibition by complexable metal cations that displace the bound substrate, (4) high chiral recognition between enantiomeric dipeptide esters, and (5) slow but definite catalytic turnover.

Binding of pyridinium substrates to a macrocycle of type **12c** bearing 1,4-dihydropyridyl side chains led to enhanced rates of *hydrogen transfer* from dihydropyridine to pyridinium within the supramolecular species **36** formed. The first-order intracomplex reaction was inhibited and became bimolecular on displacement of the bound substrate by complexable cations.[107]



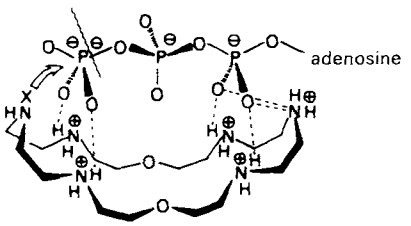
36, X=CONH*n*Bu

Activation and orientation by binding was observed for the hydrolysis of *O*-acetylhydroxylamine. $CH_3COONH_3^{\oplus}$ forms such a stable complex with the macrocyclic tetracarboxylate **12b** that it remains protonated and bound even at neutral pH, despite the low pK_a of the free species (ca. 2.15). As a consequence, its hydrolysis is accelerated and exclusively gives acetate and hydroxylamine, whereas in the presence of $K^{\oplus}$ ions, which displace the substrate, the latter rearranges to acetylhydroxamic acid, $CH_3CONH-OH$ (ca. 50%).[108] Thus, strong binding may be sufficient for markedly accelerating a reaction and affecting its course, a result that also bears on enzyme-catalyzed reactions.

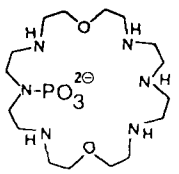
5.2. Catalysis by Reactive Anion Receptor Molecules

The development of anion coordination chemistry and anion receptor molecules has made it possible to perform molecular catalysis on anionic substrates of chemical and biochemical interest, such as adenosine triphosphate (ATP).

ATP hydrolysis was found to be catalyzed by a number of protonated macrocyclic polyamines. In particular, [24]-N_6O_2 **33** strongly binds ATP and markedly accelerates its hydrolysis to ADP and inorganic phosphate over a wide pH range.[109] The reaction presents first-order kinetics and is catalytic with turnover. It proceeds via initial formation of a complex between ATP and protonated **33**, followed by an intracomplex reaction which may involve a combination of acid, electrostatic, and nucleophilic catalysis. Structure **37** represents one possible binding mode of the ATP–**33** complex and indicates how cleavage of the terminal phosphoryl groups might take place. A transient intermediate, identified as phosphoramidate **38**, is formed by



37



38

phosphorylation of the macrocycle by ATP and is subsequently hydrolyzed. Studies with analogues of ATP indicated that the mechanism was dissociative in character within a preassociative scheme resulting from receptor–substrate binding.[110] In this process, catalyst **33** presents prototypical ATPase activity; i.e., it behaves as a proto-ATPase.

5.3. Cocatalysis: Catalysis of Synthetic Reactions

A further step lies in the design of systems capable of inducing *bond formation* rather than bond cleavage, thus effecting *synthetic* reactions as compared to degradative ones. To this end, the presence of several binding and reactive groups is essential. Such is the case for coreceptor molecules in which subunits may cooperate for substrate binding and transformation.[7] They should be able to perform *cocatalysis* by bringing together substrate(s) and cofactor(s) and mediating reactions between them within the supramolecular structure (Fig. 4).

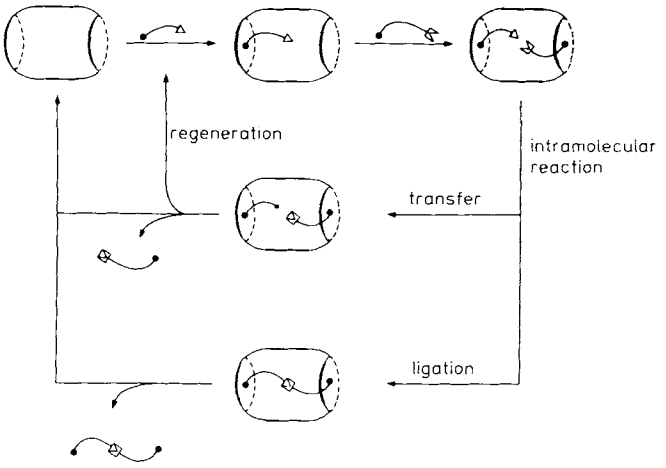


Fig. 4. Schematic illustration of cocatalysis processes: group transfer and ligation reactions occurring within the supramolecular complex formed by the binding of substrates to the two macrocyclic subunits of a macrotricyclic coreceptor molecule.

A process of this type has been realized recently.[111] Indeed, when the same macrocycle **33** used in the studies of ATP hydrolysis was employed as catalyst for the hydrolysis of acetylphosphate ($AcP = CH_3COOPO_3^{2\ominus}$), it was found to mediate the *synthesis of pyrophosphate* from AcP. Substrate consumption was accelerated and catalytic with turnover. The results obtained agree with a catalytic cycle involving the following steps: (1) substrate AcP binding by the protonated molecular catalyst **33**; (2) phosphorylation of **33** within the supramolecular complex, giving the phosphorylated intermediate PN **38**; (3) binding of the substrate $HPO_4^{2\ominus}$ (P); (4) phosphoryl transfer from PN to P with formation of pyrophosphate PP (Fig. 5); (5) release of the product and of the free catalyst for a new cycle.

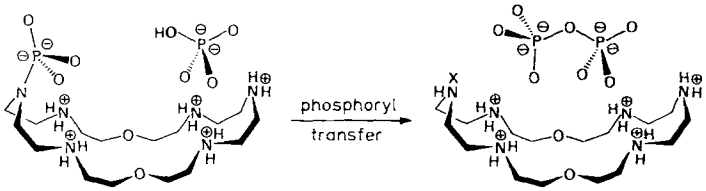

Fig. 5. Cocatalysis: pyrophosphate synthesis by phosphoryl transfer mediated by macrocycle **33** via the phosphorylated intermediate **38**.

The fact that **33** is a ditopic coreceptor containing two diethylenetriamine subunits is of special significance for both PN and PP formation. These subunits may cooperate in binding AcP and activating it for phosphoryl transfer via the ammonium sites, in providing an unprotonated nitrogen site for PN formation, and in mediating phosphoryl transfer from PN to P. Thus **33** would combine electrostatic and nucleophilic catalysis in a defined structural ar-

rangement suitable for PP synthesis via two successive phosphoryl transfers, displaying protokinase-type activity (Fig. 5). This bond-making process extends supramolecular reactivity to cocatalysis, mediating *synthetic reactions* within the supramolecular entities formed by coreceptor molecules. The formation of PP when ATP is hydrolyzed by **33** in the presence of divalent metal ions has also been reported.[112]

Functionalized macrocyclic polyethers were used for peptide bond formation in two successive intracomplex steps[113] and a macrobicyclic cyclophane bearing a thiazolium group was shown to effect supramolecular catalysis of the benzoin condensation of two benzaldehyde molecules.[114]

The systems described in this section possess the properties that define supramolecular reactivity and catalysis: substrate recognition, reaction within the supermolecule, rate acceleration, inhibition by competitively bound species, structural and chiral selectivity, and catalytic turnover. Many other types of processes may be imagined. Thus, supramolecular catalysis of the hydrolysis of unactivated esters and of amides presents a challenge[115] that chemistry has met in natural enzymatic reagents but not yet in abiotic catalysts. Designing modified enzymes by chemical mutation,[116] or by protein engineering,[117] and producing catalytic proteins by antibody induction[118] represent biochemical approaches to artificial catalysts. Of particular interest is the development of supramolecular catalysts performing synthetic reactions that create new bonds rather than cleave them. By virtue of their multiple binding features, coreceptors open the way to the design of cocatalysts for ligation, metallocatalysis, and cofactor reactions, which act on two or more co-bound and spatially oriented substrates.

Supramolecular catalysts are by nature *abiotic* reagents, chemical catalysts that may perform the same *overall* processes as enzymes, without following the detailed pathway by which the enzymes actually realize them. This chemistry may develop reagents effecting highly efficient and selective processes that enzymes do not perform or realizing enzymatic ones under conditions in which enzymes do not operate.

6. Transport Processes and Carrier Design

The organic chemistry of membrane transport processes and carrier molecules has only recently been developed, although the physico-chemical features and the biological importance of transport processes have long been recognized. The design and synthesis of receptor molecules binding selectively organic and inorganic substrates made available a range of compounds which, if made membrane soluble, could become carrier molecules and induce selective transport by rendering membranes permeable to the bound species. Thus, transport represents one of the basic functional features of supramolecular species together with recognition and catalysis.[2, 103, 119, 120]

The chemistry of transport systems comprises three main aspects: to design transport effectors, to devise transport processes, and to investigate their applications in chemistry and in biology. Selective membrane permeability may be induced either by *carrier molecules* or by *transmembrane channels* (Fig. 6).

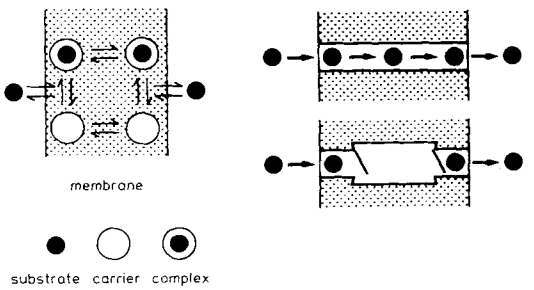

Fig. 6. Left: Transport processes: carrier-mediated. Right: Channel (above), gated channel (below).

6.1. Carrier-mediated Transport

Carrier-mediated transport consists in the transfer of a substrate across a membrane, facilitated by a carrier molecule. The four-step cyclic process (association, dissociation, forward and back-diffusions; Fig. 6) is a *physical catalysis* effecting a translocation of the substrate like chemical catalysis effects a transformation into products. The carrier is the transport catalyst and the active species is the carrier–substrate supermolecule. Transport is a three-phase process, whereas homogeneous chemical and phase-transfer catalyses are single phase and two-phase, respectively.

Carrier design is the major feature of the organic chemistry of membrane transport since the carrier determines the nature of the substrate, the physico-chemical features (rate, selectivity), and the type of process (facilitated diffusion, coupling to gradients and flows of other species, active transport). The carrier must be highly selective, present appropriate exchange rates and lipophilic/hydrophilic balance, and bear functional groups suitable for flow coupling. The transport process depends also on the nature of the membrane, the concentrations in the three phases, and the other species present. More detailed considerations on the internal and external factors that affect transport processes may be found in earlier reports.[1, 103, 120, 121]

Our initial work on the *transport of amino acids*, dipeptides, and acetylcholine through a liquid membrane employed simple lipophilic surfactant-type carriers. It was aimed at the physical organic chemistry of transport processes, exploring various situations of transport coupled to flows of protons, cations, or anions in concentration and pH gradients.[122]

Selective *transport of metal cations*, mainly of alkali cations, has been a major field of investigation, spurred by the numerous cation receptors of natural or synthetic origin that are able to function as cation carriers.[24, 103, 119–121, 123, 124]

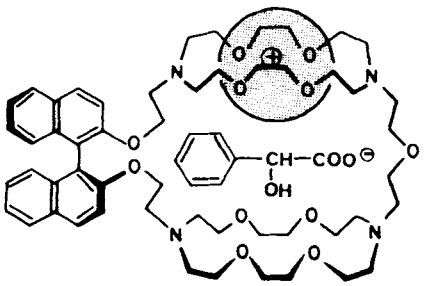
Cryptands of type **1**–**3** and derivatives thereof carry alkali cations,[125] even under conditions where natural or synthetic macrocycles are inefficient. The selectivities observed depend on the structure of the ligand, the nature of the cation, and the type of co-transported counteranion. Designed structural changes allow the transformation of a

cation receptor into a cation carrier.[120, 125] The results obtained with cryptands indicated that there was an optimal complex stability and phase-transfer equilibrium for highest transport rates.[125] Combined with data for various other carriers and cations, they gave a bell-shaped dependence of transport rates on extraction equilibrium (see Fig. 3 in Ref. [120]), with low rates for too small or too large (carrier saturation) extraction and highest rates for half-filled carriers.[120, 125] Kinetic analyses allowed the experimental results to be related to the dependence of transport rates and selectivities on carrier properties.[124, 126, 127] Detailed studies of the transport of $K^{\oplus}$ and $Na^{\oplus}$ by lipophilic derivatives of **2** and **3** in vesicles bore on the efficiency, the selectivity, and the mechanism of the processes.[128]

Modifying the nature of the binding sites makes it possible to selectively transport other cations, such as toxic metal ions. Macrocyclic polyethers can carry organic primary ammonium cations, in particular physiologically active ones.[129] The nature of the counterion and the concentrations of species strongly influence rates of transport and may affect its selectivity.[120, 125]

Anion transport may be effected by lipophilic ammonium ions or by metal complexes[120, 130] acting as anion receptors. Progress in anion coordination chemistry should provide a range of anion carriers that will help to develop this area of transport chemistry. The selective transport of carboxylates and phosphates is of great interest. Some results, references, and suggestions have already been given.[120, 131]

Cation–anion cotransport was effected by a chiral macrotricyclic cryptand that carried simultaneously an alkali cation and a mandelate anion (see **39**).[82] Employing together a cation and an anion carrier should give rise to *synergetic transport* with double selection, by facilitating the flow of both components of a salt (see the electron-cation symport below).



39

Selective transport of amino acids occurs with a macrotricycle containing an internal phosphoric acid group[83b] and with a convergent dicarboxylic acid receptor.[83c] *Neutral* molecules are carried between two organic phases through a water layer by water-soluble receptors containing a lipophilic cavity.[92b, 132]

It is clear that numerous facilitated transport processes may still be set up, especially for anions, salts, or neutral molecules and that the active research in receptor chemistry will make available a variety of carrier molecules. Of special interest are those transport effectors, derived from coreceptors, that allow coupled transport (*cotransport*) to be performed.

6.2. Coupled Transport Processes

A major goal in transport chemistry is to design carriers and processes that involve the coupled flow of two (or more) species either in the same (symport) or in opposite (antiport) direction. Such parallel or antiparallel vectorial processes make it possible to set up pumped systems in which a species is carried in the potential created by physico-chemical gradients of electrons (redox gradient), protons (pH gradient), or other species (concentration gradient). To this end, either two or more individual carriers for different species may be used simultaneously or the appropriate subunits may be introduced into a single species, a *cocarrier*.

6.2.1. Electron-Coupled Transport in a Redox Gradient

Electron–cation symport has been realized in a double carrier process where the coupled, parallel transport of electrons and metal cations was mediated simultaneously by an electron carrier and by a selective cation carrier.[133] The transport of electrons by a nickel complex in a redox gradient was the electron pump for driving the selective transport of $K^{\oplus}$ ions by a macrocyclic polyether (Fig. 7).

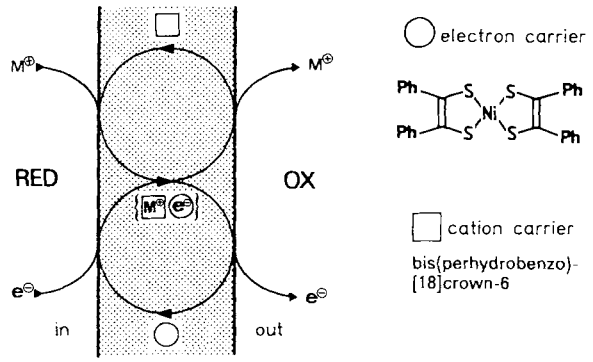


Fig. 7. Electron-cation coupled transport: a redox-driven electron-cation symport consisting of an electron carrier (nickel complex) and a selective cation carrier (macrocyclic polyether). RED, potassium dithionite; OX, $Na_3[Fe(CN_6)]$ [133].

The process has the following features: active $K^{\oplus}$ transport and coupled electron flow; two cooperating carriers acting synergetically; a redox pump; a selection process by the cation carrier; regulation by the cation/carrier pair. This system represents a prototype for the design of other multicarrier coupled transport processes. Electron transport with quinone carriers involves a ($2e^{\ominus}$, $2H^{\oplus}$) symport.[134, 135]

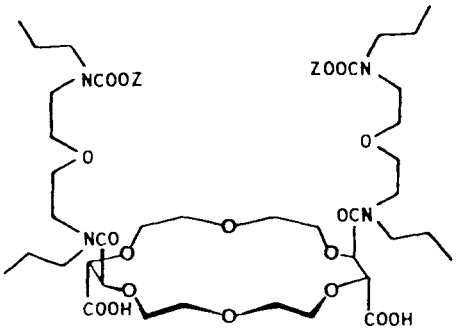
Electron–anion antiports have been realized for instance with carriers such as ferrocene or alkylviologens.[136] The latter have been used extensively in light-driven systems and in studies on solar energy conversion.

6.2.2. Proton-Coupled Transport in a pH Gradient

Carriers bearing negatively charged groups may effect cation antiport across membranes, so that if one cation is a proton, a proton pump may be set up in a pH gradient.

This has been realized for alkali cations with natural or synthetic carboxylate-bearing ionophores.[137]

A case of special interest is that of the transport of divalent ions such as calcium versus monovalent ones. The lipophilic carrier **40**, containing a *single* cation receptor site and *two* ionizable carboxylic acid groups, was found to transport selectively $Ca^{2\oplus}$ in the dicarboxylate form and



40, $Z = CH_2C_6H_5$

$K^{\oplus}$ when monoionized, thus allowing pH control of the process. This striking change in transport features involves *pH regulation* of $Ca^{2\oplus}/K^{\oplus}$ selectivity in a competitive ($Ca^{2\oplus}$, $K^{\oplus}$) symport coupled to ($Ca^{2\oplus}$, $2H^{\oplus}$) and ($K^{\oplus}$, $H^{\oplus}$) antiport in a pH gradient, which provides a proton pump (Fig. 8).[138]

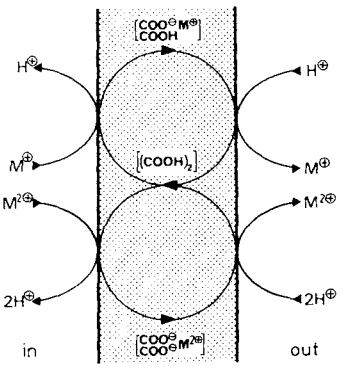


Fig. 8. A competitive divalent/monovalent cation symport coupled to $M^{2\oplus}/2H^{\oplus}$ and $M^{\oplus}/H^{\oplus}$ antiport in a pH gradient by a macrocyclic carrier such as **40**; the state of the carrier is indicated as diprotonated, $[(CO_2H)_2]$, or complexed, $[(CO_2^{\ominus})_2, M^{2\oplus}]$ and $[(CO_2H)(CO_2^{\ominus}), M^{\oplus}]$.

This system demonstrates how carrier design allows transport processes to be endowed with regulation of rates and selectivity, as well as coupling to energy sources, for transport of a species against it own concentration gradient.

6.2.3. *Light-Coupled Transport Processes*

Light-driven transport may be brought about by photogeneration of a species that will induce the process or perturb it.

This has been achieved in a *light-induced electron transport* process involving the proflavine-sensitized photogeneration of reduced methylviologen, $MV^{\oplus}$, which transfers electrons to a quinone-type carrier contained in the membrane.[135] Light-driven (electron, cation) symport occurs when combining this system with the (nickel complex, macrocycle) process described above.[139] The increased lipophilicity of reduced viologens facilitates electron and phase transfer.[140] Such processes are also of interest for solar energy storage systems where electron-permeable membranes separate the reductive and oxidative components. Photocontrol of ion extraction and transport has been realized with macrocyclic ligands that undergo a structural change upon irradiation, resulting in two forms having different ion affinities.[141]

The results obtained on coupled transport processes stress the role of cocarrier systems capable of transporting several substrates with coupling to physical and chemical energy sources.

6.3. Transfer via Transmembrane Channels

Transmembrane channels represent a special type of multi-unit effector allowing the passage of ions or of molecules through membranes by a flow or site-to-site hopping mechanism. They play an important role in biological transport. Natural and synthetic peptide channels (gramicidin A, alamethicin) for cations have been studied.[142, 143]

Artificial *cation channels* would provide fundamental information on the mechanism of cation flow and channel conduction. A solid-state model of cation transfer inside a channel is provided by the crystal structure of the KBr complex of **12c** ($Y = Y' = CH_3$), which contains stacks of macrocycles with cations located alternately inside and above a macrocyclic unit, like a frozen picture of cation propagation through the "channel" defined by the stack.[144]

A polymeric stack of macrocycles has been synthesized[145] and a cyclodextrin-based model of a half-channel has been reported.[146] A derivative of monensin, an acyclic polyether ionophore, forms lithium channels in vesicles,[147] which may be sealed by diammonium salts.[148]

Cylindrical macrotricycles such as **26** (substrate removed) represent the basic unit of a cation channel based on stacks of linked macrocycles; they bind alkali cations,[149] and cation jumping processes between the top and bottom rings have been observed.[150] Theoretical studies give insight into the molecular dynamics[151] of ion transport and the energy profiles[152] in cation channels.

Electron channels, as transmembrane wires, represent the channel-type counterpart to the mobile electron carriers discussed above and will be considered in Section 9.2. *Anion channels* may also be envisaged.

Thus, several types of studies directed towards the development of artificial ion channels and the understanding of ion motion in channels are being carried out. These effectors deserve and will receive increased attention, in view also of their potential role in molecular ionics (see Section 9.2).

A further step in channel design must involve the introduction of (proton-, ion-, redox-, or light-activated) *gates and control elements* for regulating opening and closing, rates, and selectivity. In this respect, one may note that ionizable groups on mobile carriers (as in **40**, see Section 6.2.2) correspond, for these effectors, to the gating mechanisms in channels.

In conclusion, transport studies open ways to numerous developments of this chemically and biologically most important function, such as effector design, analysis of elementary steps and mechanisms, coupling to chemical potentials, energy and signal transduction, models of biological transport processes, construction of vesicular microreactors and artificial cells, with a variety of possible applications, for instance in separation and purification or in batteries and systems for artificial photosynthesis.

By the introduction of polytopic features, which may include selective binding subunits as well as gating components for flow regulation, the design of cocarriers and of artificial molecular channels should add another dimension to the chemistry of the effectors and mechanisms of transport processes.

7. From Endoreceptors to Exoreceptors

The design of receptor molecules has mainly relied on macrocyclic or macropolycyclic architectures (see above) and/or on rigid spacers or templates (see, for instance, Refs. [17b, 26, 76–79, 81b, 83c]) that allow binding sites to be positioned on the walls of molecular cavities or clefts in such a way that they converge towards the bound substrate. The latter is more or less completely surrounded by the receptor, forming an *inclusion* complex. This widely used principle of *convergence* defines a convergent or *endo-supramolecular chemistry* with endoreceptors effecting endo-recognition. Biological analogies are found in the active sites of enzymes where a small substrate binds inside a cavity of a large protein molecule.

The opposite point of view would be to make use of an external *surface* with protuberances and depressions, rather than an internal cavity, as substrate receiving site. This would amount to the passage from a convergent to a *divergent* or *exo-supramolecular chemistry* and from endo- to *exoreceptors*. Receptor–substrate binding then occurs by surface-to-surface interaction, which may be termed *affixion* and symbolized by // or by the mathematical symbol of intersection $\cap$ (if there is notable interpenetration of the surfaces),[153] $[\rho // \sigma]$ and $[\rho \cap \sigma]$, respectively. *Exo-recognition* with strong and selective binding requires a large enough contact area and a sufficient number of interactions as well as geometrical and site (electronic) complementarity between the surfaces of ρ and σ. Such a mode of binding finds biological analogies in protein–protein interactions, for instance at the antibody–antigen interface where the immunological recognition processes occur.[154]

One may note that exo-recognition includes recognition between (rather large) bodies of similar size as well as recognition at interfaces with monolayers, films, membranes, cell walls, etc.

7.1. Metallo-Exoreceptors. Metallonucleates

In order to reinforce the binding strength, one may think of introducing one or more interaction *poles*, for instance, electrical charges, generating strong electrostatic forces. Such could be the case for a metal complex whose central cation would be the electrostatic pole and whose external surface could bear functional groups containing the molecular information required for recognizing the partner. In addition, the metal cation provides a further way of organizing the structure by virtue of its coordination geometry (tetrahedral, square-planar, octahedral, etc.), which leads to a given arrangement of the external interaction sites (Fig. 9).

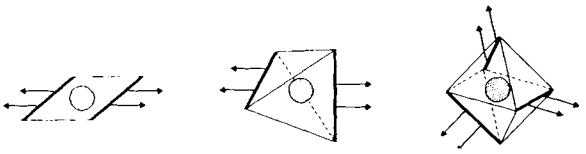

Fig. 9. Schematic representation of the arrangement of external interaction sites (arrows) around a metal ion of given coordination geometry (planar, tetrahedral, octahedral) in mononuclear metallo-exoreceptors.

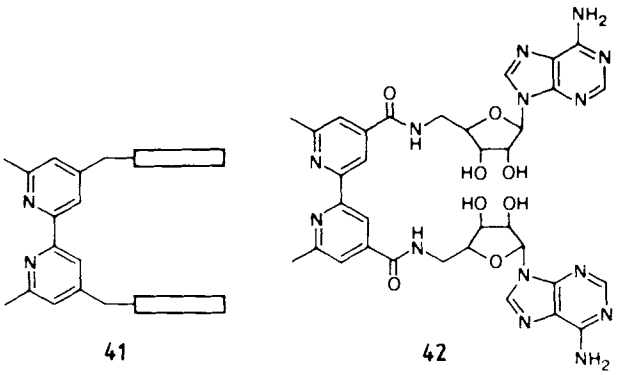
As a first approach to receptor design along these lines, specific groups, selected for their information content, have been attached to functionalized α,α'-bipyridines, giving ligands of type **41**, which form metal complexes of defined geometry and physico-chemical properties. With nucleosides, species such as the bis-adenosine derivative **42**



41 **42**

are obtained.[155] The resulting positively charged, *metallonucleate* complexes should interact strongly and selectively with the negatively charged oligonucleotides and nucleic acids, the fixation site depending on the nature and disposition of the external nucleosides. Double-helical metallonucleates[155] may be derived from the helicates described below. Numerous variations may be imagined for the external groups (intercalators, amino acids, oligopeptides, reactive functions) so as to yield metal complexes displaying selective fixation and reactivity (chemical, photochemical) determined by the nature of the attached sites.

7.2. Molecular Morphogenesis

The design of exoreceptors requires means of generating defined external molecular shapes. This may be achieved

in a number of ways, namely by stepwise synthesis of molecular architectures or by assembling on metal templates that impose a given coordination geometry, as noted in the preceding section.

Another approach to such controlled molecular morphogenesis is provided by the generation of globular molecules such as the "starburst dendrimers"[156] and the "arborols,"[157] based on branched structures formed via cascade processes. Starting from a given core, it may be possible to produce a molecule of given size and external shape. On the polymolecular level, this may be related to the generation of shapes and structures in two-dimensional lipid monolayers[158] and in aggregates of amphiphilic molecules[159] (see also Section 8).

8. From Supermolecules to Polymolecular Assemblies

Molecular chemistry is the domain of (more or less) independent *single* molecules. *Supramolecular chemistry* may be divided into two broad, partially overlapping areas: (1) *supermolecules* are well-defined *oligo*molecular species that result from the intermolecular association of a few components (a receptor and its substrate(s)) following a built-in "Aufbau" scheme based on the principles of molecular recognition; (2) *molecular assemblies* are polymolecular systems that result from the spontaneous association of a nondefined number of components into a specific phase having more or less well-defined microscopic organization and macroscopic characteristics depending on its nature (layers, membranes, vesicles, micelles, mesomorphic phases, etc.[160]).

Continuous progress is being made in the design of synthetic molecular assemblies, based on a growing understanding of the relations between the features of the molecular components (structure, sites for intermolecular binding, etc.), the characteristics of the processes which lead to their association and the supramolecular properties of the resulting polymolecular assembly.

Molecular organization, self-assembling and cooperation, construction of multilayer films,[161-164] generation of defined aggregate morphologies,[159] etc. make it possible to build up supramolecular architectures. The polymerization of the molecular subunits has been a major step in increasing control over the structural properties of the polymolecular system.[165,166] Incorporating suitable groups or components may yield functional assemblies capable of performing operations such as energy, electron or ion transfer, information storage, and signal transduction.[160,162,167,168] The combination of receptors, carriers, and catalysts, handling electrons and ions as discussed above, with polymolecular organized assemblies opens the way to the design of what may be termed *molecular* and *supramolecular devices*, and to the elaboration of chemical microreactors and artificial cells.

One may also note that polymolecular assemblies define *surfaces* on which and through which processes occur, a feature that again stresses the interest of designing exoreceptors operating at the interfaces, in addition to endoreceptors embedded in the bulk of the membranes.

9. Molecular and Supramolecular Devices

Molecular devices may be defined as structurally organized and functionally integrated chemical systems built into supramolecular architectures. The development of such devices requires the design of molecular components (effectors) performing a given function and suitable for incorporation into an organized array such as that provided by the different types of polymolecular assemblies (see Section 8). The components may be photo-, electro-, iono-, magneto-, thermo-, mechano-, or chemoactive, depending on whether they handle photons, electrons, or ions, respond to magnetic fields or to heat, undergo changes in mechanical properties, or perform a chemical reaction. A major requirement would be that these components, and the devices that they bring about, perform their function(s) at the *molecular* and *supramolecular* levels as distinct from the bulk material.

Molecular receptors, reagents, catalysts, carriers, and channels are potential effectors that may generate, detect, process, and transfer signals by making use of the three-dimensional information storage and read-out capacity operating in molecular recognition and of the substrate transformation and translocation processes conveyed by reactivity and transport. Coupling and regulation may occur if the effectors contain several subunits that can interact, influence each other, and respond to external stimuli such as light, electricity, heat, and pressure.

The nature of the mediator (substrate) on which molecular devices operate defines fields of molecular photonics, molecular electronics, and molecular ionics. Their development requires the design of effectors that handle these mediators and the examination of their potential use as components of molecular devices. We shall now examine specific features of molecular receptors, carriers, and reagents from this point of view.

9.1. Supramolecular Photochemistry and Molecular Photonics

The formation of supramolecular entities from photoactive and/or electroactive components may be expected to perturb the ground-state and excited-state properties of the individual species, giving rise to novel properties that define a *supramolecular photochemistry* and *electrochemistry*.

Thus, a number of processes may take place within supramolecular systems, modulated by the arrangement of the bound units as determined by the organizing receptor: photoinduced energy migration, charge separation by electron or proton transfer, perturbation of optical transitions and polarizabilities, modification of redox potentials in ground or excited states, photoregulation of binding properties, selective photochemical reactions, etc.

Supramolecular photochemistry, like catalysis, may involve three steps: binding of substrate and receptor, mediating a photochemical process, followed by either restoration of the initial state for a new cycle or by a chemical reaction[169] (Fig. 10). The photophysical and photochemical features of supramolecular entities form a vast area of investigation into processes occurring at the level of intermolecular organization.

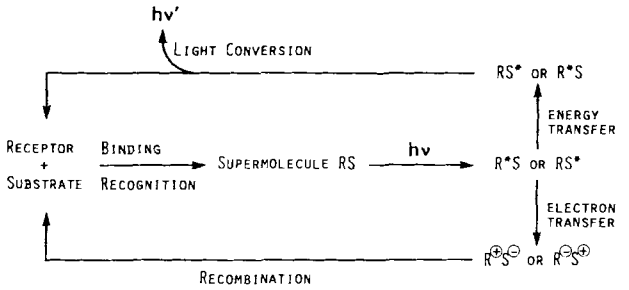


Fig. 10. Representation of the processes involved in supramolecular photochemistry. Generation of R*S, RS*, $R^{\oplus}S^{\ominus}$, or $R^{\ominus}S^{\oplus}$ may be followed by a chemical reaction.

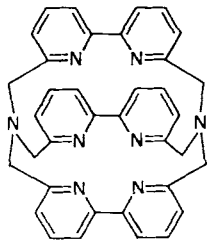
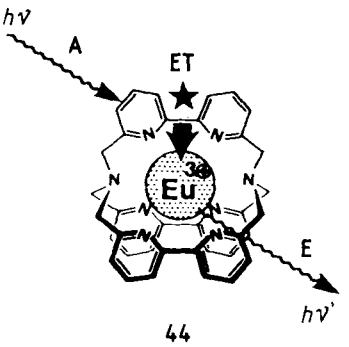
9.1.1. Light Conversion by Energy Transfer

A light conversion molecular device may be realized by an Absorption-Energy-Transfer-Emission (A-ET-E) process in which light absorption by a receptor molecule is followed by intramolecular energy transfer to a bound substrate which then emits. This occurs in the europium(III) and terbium(III) cryptates of the macrobicyclic ligand [bipy·bipy·bipy] **43**.[170] UV light absorbed by the bipy groups is transferred to the lanthanoid cation bound in the molecular cavity, and released in the form of visible lanthanoid emission via an A-ET-E process, as shown in **44**.[171] These Eu^{III} and Tb^{III} complexes display a bright



43



44

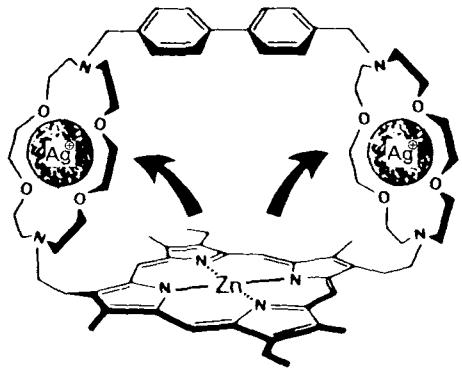
luminescence in aqueous solution, whereas the free ions do not emit under the same conditions. Numerous applications may be envisaged for such substances, in particular as luminescent probes for monoclonal antibodies, nucleic acids, and membranes.

Photophysical processes occurring in macrocyclic,[172] cryptate,[173] and molecular[174, 175] complexes have been investigated.

9.1.2. Photoinduced Electron Transfer in Photoactive Coreceptor Molecules

The photogeneration of charge-separated states is of interest both for inducing photocatalytic reactions (e.g., for artificial photosynthesis) and for the transfer of photosignals (e.g., though a membrane). It may be realized in D-PS-A systems in which excitation of a photosensitizer PS, followed by two electron transfers from a donor D to an acceptor A, yields $D^{\oplus}$-PS-$A^{\ominus}$. Numerous systems of this type are being studied in many laboratories from the standpoint of modeling photosynthetic centers.

The D, A units may be metal coordination centers. Thus, binding of silver ions to the lateral macrocycles of coreceptors containing porphyrin groups as photosensitizers introduces electron-acceptor sites, as shown in **45**. This results in quenching of the singlet excited state of the Zn-porphyrin center by an efficient intracomplex electron transfer, leading to charge separation and generating a porphyrinium cation of long half-life.[176]



45

Systems performing photoinduced electron transfer processes represent components for *light-to-electron conversion devices*. The light-activated electron transport mentioned above[135] also belongs to this general type.

9.1.3. Photoinduced Reactions in Supramolecular Species

The binding of a substrate to a receptor molecule may affect the photochemical reactivity of either or both species, orienting the course of a reaction or giving rise to novel transformations.

Complexation of coordination compounds may make it possible to control their photochemical behavior via the structure of the supramolecular species formed. Thus, the photoaquation of the $[Co(CN)_6]^{3\ominus}$ anion is markedly affected by binding to polyammonium macrocycles. The results agree with the formation of supramolecular species, in which binding to the receptor hinders some $CN^{\ominus}$ groups from escaping when the Co-CN bonds are temporarily broken following light excitation.[63] It thus appears possible to orient the photosubstitution reactions of transition-metal complexes by using appropriate receptor molecules. Such effects may be general, applying to complex cations as well as to complex anions, and providing an approach to the control of photochemical reactions via formation of defined supramolecular structures.[169, 177, 178]

Structural or conformational changes photoproduced in receptor molecules affect their binding properties, thus causing release or uptake of a species, as occurs in macrocyclic ligands containing light-sensitive groups.[141, 172] Such effects may be used to generate protonic or ionic photosignals in *light-to-ion conversion* devices.

9.1.4. Nonlinear Optical Properties of Supramolecular Species

Substances presenting a large electronic polarizability are likely to yield materials displaying large macroscopic

optical nonlinearities.[179] This is the case for push-pull compounds possessing electron donor and acceptor units. The potential nonlinear optical (NLO) properties of materials based on metal complexes and supramolecular species have been pointed out recently.[179b] The D-PS-A systems investigated for their ability to yield charge-separated states possess such features; they may be metallic or molecular complexes.

Ion-dependent optical changes produced by indicator ligands[180] might lead to cation control of nonlinear optical properties.

Molecular electron-donor-acceptor complexes could present NLO effects since they possess polarized ground states and undergo (partial) intermolecular charge separation on excitation. It is possible to more or less finely tune their polarization, polarizability, extent of charge transfer, absorption bands, etc. by many variations in basic structural types as well as in substituents (see, for instance, Refs. [174, 179c]).

The results discussed above provide illustrations and incentives for further studies of photoeffects brought about by the formation of supramolecular species.

In a broader perspective, such investigations may lead to the development of *photoactive molecular devices*, based on photoinduced energy migration, electron transfer, substrate release, or chemical transformation in supermolecules. Thus would be brought together molecular design, intermolecular bonding, and supramolecular architectures with photophysical, photochemical, and optical properties, building up a kind of *molecular photonics*.

9.2. Molecular Electronic Devices

More and more attention is being given to *molecular electronics* and to the possibility of developing electronic devices that would operate at the molecular level.[3, 181] Molecular rectifiers, transistors, and photodiodes have been envisaged, the latter requiring features such as those of charge-transfer states in organic molecules, in metal complexes, and in D-PS-A systems discussed in Section 9.1.2 (see also references in Ref. [182]).

Among the basic components of electronic circuitry at the molecular level, a unit of fundamental importance is a connector or junction allowing electron flow to take place between different parts of the system, i.e., a *molecular wire*.

An approach to such a unit is represented by the *caroviologens*, vinylogous derivatives of methylviologen that combine the features of the carotenoids and of the viologens.[182] They present features required for a molecular wire: a conjugated polyene chain for electron conduction; terminal electroactive and hydrosoluble pyridinium groups for reversible electron exchange; a length sufficient for spanning typical molecular supporting elements such as a monolayer or bilayer membrane.

Caroviologens have been incorporated into sodium dihexadecyl phosphate vesicles. The data obtained agree with a structural model in which the caroviologens of sufficient length span the bilayer membrane, the pyridinium sites being close to the negatively charged outer and inner surfaces of the vesicles and the polyene chain crossing the lipidic interior of the membrane (Fig. 11). These and other functionalized membranes are being tested in processes in which the caroviologen would function as a continuous, transmembrane electron channel, i.e., a genuine molecular wire. With respect to electron transport by means of redox-active mobile carrier molecules (see Section 6.2.1), the caroviologens represent electron channels, in analogy to cation channels and cation carriers. They portray a first approach to molecular wires, and several modifications concerning the end groups and the chain may be envisaged.[183] For instance, coupling with photoactive groups could yield photoresponsive electron channels, as well as charge separation and signal-transfer devices. Combination with other polymolecular supports, such as polymeric layers or mesomorphic phases, as well as with other components, might make it possible to assemble nanocircuits and more complex molecular electronic systems.

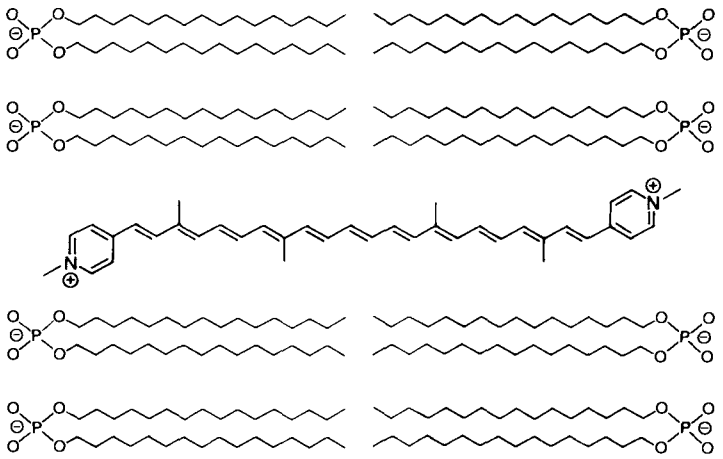


Fig. 11. Transmembrane incorporation of a caroviologen into sodium dihexadecylphosphate vesicles.

Redox modification of an electroactive receptor or carrier molecule leads to changes in binding and transport properties, thus causing release or uptake of the substrate, in a way analogous to the photoeffects discussed above. To this end, redox couples such as disulfide/dithiol[184, 185a] and quinone/hydroquinone[185] have been introduced into receptor molecules and shown to modify their substrate-binding features. Complexation of metal hexacyanides $[M(CN)_6]^{n\ominus}$ by polyammonium macrocycles markedly perturbs their redox properties.[61] These electrochemical features resulting from receptor-substrate association define a *supramolecular electrochemistry*. The mutual effects of redox changes and binding strength in a receptor-substrate pair may make it possible to achieve electrocontrol of complexation and, conversely, to modify redox properties by binding (see also next section).

9.3. Molecular Ionic Devices

The numerous receptor, reagent, and carrier molecules capable of handling inorganic and organic ions are potential components of molecular and supramolecular *ionic devices* that would function via highly selective recognition, reaction, and transport processes with coupling to external factors and regulation. Such components and the devices

that they may build up form the basis of a field of *molecular ionics*, the field of systems operating with ionic species as support for signal and information storage, processing, and transfer. In view of the size and mass of ions, ionic devices may be expected to perform more slowly than electronic devices. However, ions have a very high information content by virtue of their multiple molecular (charge, size, shape, structure) and supramolecular (binding geometry, strength and selectivity) features. Molecular ionics appears to offer a promising field of research which may already draw from a vast amount of knowledge and data on ion-processing by natural and synthetic receptors and carriers.

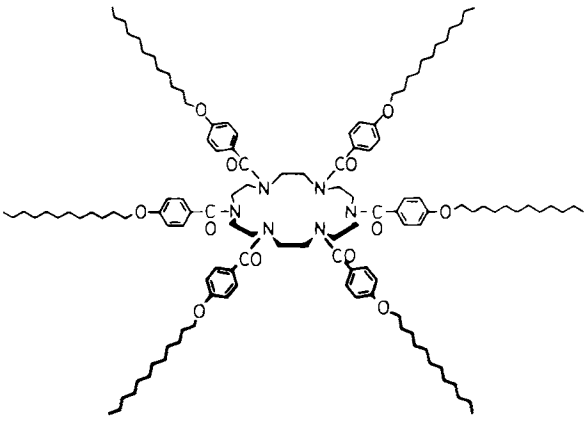
Selective ion receptors represent basic units for ionic transmitters or detectors; selective ion carriers correspond to ionic transducers. These units may be fitted with triggers and switches sensitive to external physical (light, electricity, heat, pressure) or chemical (other binding species, regulating sites) stimuli for connection and activation.

Binding or transport and triggering may be performed by separate species, each having a specific function, as in multiple carrier transport systems (see Section 6.2).[133] This allows a variety of combinations between photo- or electroactive components and different receptors or carriers. On the other hand, light- and redox-sensitive groups have been incorporated into receptors and carriers and shown to affect binding and transport properties (see Refs. [141, 172, 184, 185] and references therein). Coreceptors and cocarriers provide means for regulation via cofactors, co-bound species that modulate the interaction with the substrate. Thus, a simple ionizable group such as a carboxylic acid function represents a *proton switch* and leads to gated receptors and carriers responding to pH changes, as seen for instance in the regulation of transport selectivity by **40**.[138]

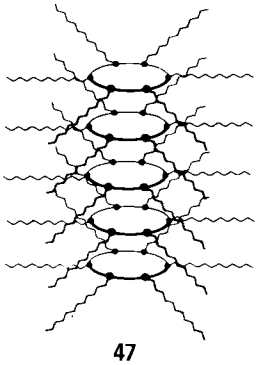
The main problem is the generally insufficient changes brought about in most systems by the switching process. It is worth stressing that proton-triggered yes/no or +/− switches are potentially contained in the ability of polyamine receptors and carriers to bind and transport cations when unprotonated and anions when protonated; also, zwitterions such as amino acids may change from bound to unbound or conversely when they undergo charge inversion as a function of pH. Molecular *protonic devices* thus represent a particularly interesting special case of ionic devices. A proton-conducting channel would be a *proton wire*.

Functional molecular assemblies provide ways of organizing molecular devices and of introducing regulation and cooperative processes which may induce a much steeper response of the system to the stimuli. Vesicles have been fitted with functional units,[168] for instance with a $Li^{\oplus}$ ion channel that may be sealed.[147, 148] Liquid crystals consisting of macrocyclic molecules bearing mesogenic groups, such as **46**, form *tubular mesophases*, composed of stacked rings as in **47**, which may lead to the development of phase-dependent ion-conducting channels.[186, 187] Cooperativity and self-assembly may also be designed directly into the molecular components (see next section).

Biological information and signals are carried by ionic and molecular species ($Na^{\oplus}$, $K^{\oplus}$, $Ca^{2\oplus}$, acetylcholine, cyclic AMP, etc.). Polytopic metalloproteins such as calcium-binding proteins[188] perform complicated tasks of detecting, processing, and transferring ionic signals. These biological functions give confidence and inspiration for the development of molecular ionics.



46



47

One may note that ion receptors, channels, switches, and gates have been considered within a potential European research project on "Ionic Adaptative Computers." Applications such as selective chemical sensors based on molecular recognition are already well advanced.[121]

9.4. Molecular Self-Assembling

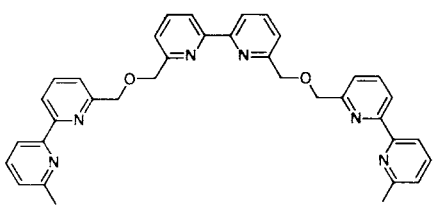
Self-assembling and multiple binding with positive cooperativity are processes of spontaneous molecular organization that also allow *amplification molecular devices* to be envisaged. Such phenomena are well documented in biology, but much less so in chemistry. By virtue of their multiple binding subunits, polytopic coreceptors may display self-assembling if substrate binding to one receptor molecule generates binding sites that induce association with another one.

Positive cooperativity in substrate binding is more difficult to set up than negative cooperativity. However, both effects are of interest for regulation processes. Cooperativity is found in the unusual facilitation of the second protonation of **5** by a water effector molecule as in **10**.[40] Allosteric effects on cation binding to macrocyclic polyethers have been studied by inducing conformational changes via a remote site,[17a] and subunit cooperativity occurs in a dimeric porphyrin.[189]

The spontaneous formation of the double helix of nucleic acids represents the self-assembling of a supramole-

cular structure induced by the pattern of intermolecular interactions provided by the complementary nucleic bases. It involves recognition and positive cooperativity in base-pairing.[190]

Such self-assembling has recently been shown to occur in repetitive chain ligands, acyclic coreceptors containing several identical binding sites arranged linearly. Based on earlier work with a "quaterpyridine" ligand, oligo-bipyridine chain ligands incorporating two to five bipy groups were designed. By treatment with Cu^{I} ions they underwent a spontaneous assembling into *double-stranded helicates* containing two ligand molecules and one Cu^{I} ion per bipy site of each ligand, the two receptor strands being wrapped around the metal ions which hold them together. Thus, the tris-bipy ligand **48** forms the trinuclear complex **49**, whose



48

49

crystal structure has been determined, confirming that it is indeed an *inorganic double helix*.[191] The results obtained indicate that the process occurs probably with positive cooperativity, binding of a Cu^{I} ion with two ligands facilitating complexation of the next one. Furthermore, it appears that in a mixture of ligands containing different numbers of bipy units, pairing occurs preferentially between the *same* ligands, thus performing *self-self recognition*. This spontaneous formation of an organized structure of intermolecular type opens ways to the design and study of self-assembling systems presenting cooperativity, regulation, and amplification features. Catalytic reactions, gated channels, and phase changes represent other processes that might be used for inducing amplification effects.

Various further developments may be envisaged along organic, inorganic, and biochemical lines. Thus, if substituents are introduced at the *para* positions of the six pyridine units in **48**, treatment with Cu^{I} should form an inorganic double helix bearing twelve outwardly directed functional groups. [155]

Designed self-assembling rests on the elaboration of molecular components that will spontaneously undergo organization into a desired supramolecular architecture. Such control of self-organization at the molecular level is a field of major interest in molecular design and engineering, which may be expected to become a subject of increasing activity.

9.5. Chemionics

Components and molecular devices such as molecular wires, channels, resistors, rectifiers, diodes, and photosensitive elements might be assembled into nanocircuits and combined with organized polymolecular assemblies to yield systems capable ultimately of performing functions of detection, storage, processing, amplification, and transfer of signals and information by means of various mediators (photons, electrons, protons, metal cations, anions, molecules) with coupling and regulation.[3,8,181,182,192]

Molecular photonics, electronics, and ionics represent three areas of this intriguing and rather futuristic field of chemistry which may be termed "*chemionics*"[3,8]—the design and operation of photonic, electronic, and ionic components, devices, circuitry, and systems for signal and information processing at the molecular level. Such perspectives lie, of course, in the distant future,[193] but along the way they could yield numerous spin-offs and they do represent ultimate goals towards which work may already be planned and realized.

10. Conclusion

The present text was aimed at presenting the scope, providing illustration, and exploring perspectives of supramolecular chemistry. Its conceptual framework has been progressively laid down and the very active research on molecular recognition, catalysis, and transport, together with extension to molecular surfaces and polymolecular assemblies, is building up a vast body of knowledge on molecular behavior at the supramolecular level. It is clear that much basic chemistry remains to be done on the design and realization of numerous other systems and processes that await to be imagined. The results obtained may also be analyzed in the view of developing components for molecular devices that would perform highly selective functions of recognition, transformation, transfer, regulation, and communication, and allow signal and information processing. This implies operation via intermolecular interactions and incorporation of the *time* dimension into recognition events. One may note that such functions have analogies with features of expert systems, thus linking processes of artificial intelligence and molecular behavior.

These developments in molecular and supramolecular science and engineering offer exciting perspectives at the frontiers of chemistry with physics and biology. Of course, even with past achievements and present activities, extrapolations and predictions can only be tentative; yet, on such an occasion for the celebration of chemistry, it appears justified to try looking out into the future, for

"He (or she) who sits at the bottom of a well to contemplate the sky, will find it small"
(*Han Yu*, 768-824).

I wish to thank very warmly my collaborators at the Université Louis Pasteur in Strasbourg and at the Collège de France in Paris, whose skill, dedication, and enthusiasm allowed the work described here to be realized. Starting with B. Dietrich and J.-P. Sauvage, they are too numerous to be named here, but they have all contributed to the common goal. I also wish to acknowledge the fruitful collaboration with a number of laboratories in various countries, beginning with the crystal structure determinations of cryptates by Raymond Weiss and his group and extending over various areas of structural and coordination chemistry, electrochemistry,

photochemistry, and biochemistry. Finally, I thank the Université Louis Pasteur, the Collège de France, and the Centre National de la Recherche Scientifique for providing the intellectual environment and the financial support for our work.

[23] An idea about the respective role of collection and orientation may be gained from examining the energies calculated for a series of $[Li(NH_3)_n]^{\oplus}$ complexes and of the corresponding $(NH_3)_n$ units in the identical geometry. In the presence of $Li^{\oplus}$ the formation energies of the complexes are obtained at the optimized $Li^{\oplus}\cdots NH_3$ distances. When $Li^{\oplus}$ is removed and the NH_3 molecules are kept at the same position, the energies calculated are for the formation of the coordination shell alone. These energies represent the repulsion between the NH_3 groups; they are a measure of the intersite repulsive energy for bringing together two, three, or four amine binding sites into a polydentate ligand of same coordination geometry. *Results*, $(NH_3)_n$, geometry (repulsive energy [kcal/mol]): $(NH_3)_2$, linear (−2.4), bent (−3.8); $(NH_3)_3$, trigonal (−9.1), pyramidal (−10.8); $(NH_3)_4$, tetrahedral (−20.8). Thus, the total collection energies are appreciably larger than the organization energies represented by the changes from one geometry to another, linear to bent (1.4 kcal/mol) or trigonal to pyramidal (1.7 kcal/mol). Ab initio computations performed with a set of Gaussian-type basis functions, contracted into a double set with polarization; J.-M. Lehn, R. Ventavoli, unpublished results; see also: R. Ventavoli, 3è Cycle Thesis, Université Louis Pasteur, Strasbourg 1972.

Molecular Architecture and Function of Polymeric Oriented Systems: Models for the Study of Organization, Surface Recognition, and Dynamics of Biomembranes**

By Helmut Ringsdorf,* Bernhard Schlarb, and Joachim Venzmer

The Part and the Whole. The principle of self-organization for the creation of functional units is not an invention of modern natural sciences. It was already a basic idea of the ancient philosophies in Asia and Europe: only the mutuality of the parts creates the whole and its ability to function. Translated into the language of chemistry this means: the self-organization of molecules leads to supramolecular systems and is responsible for their functions. Thermotropic and lyotropic liquid crystals are such functional units, formed by self-organization. As highly oriented systems, they exhibit new properties. The importance of lyotropic liquid crystals for the life sciences has been known for a long time. They are a prerequisite for the development of life and the ability of cells to function. In materials science this concept of *function through organization* led to the development of new liquid-crystalline materials. From the point of view of macromolecular chemistry, this review tries to combine these two different fields and especially hopes to stimulate their interaction and joint treatment. To exemplify this, the molecular architecture of polymeric organized systems will be discussed. Polymeric liquid crystals combine the ability to undergo spontaneous self-organization—typical of liquid-crystalline phases—with the polymer-specific property of stabilizing these ordered states. As new materials, polymeric liquid crystals have already been investigated intensively. As model systems for biomembranes as well as for the simulation of biomembrane processes, they so far have been little discussed. The intention of this review article is to show that polymer science is able to contribute to the simulation of cellular processes such as the stabilization of biomembranes, specific surface recognition, or even the "uncorking" of cells. Polymer science, having an old tradition as an interdisciplinary field, can no longer restrict itself to common plastics. Attempts to reach new horizons have already begun. The borderland between liquid crystals and cells will certainly play an important role. Basic requirements to work in this frontier area between organic chemistry, membrane biology, life science, and materials science will be the delight in scientific adventures as well as the courage to go ahead. The most important prerequisite will be the willingness to cooperate with disciplines which so far have not really accepted each other. From this point of view, this review does not aim at giving defined answers. It wants instead to encourage the scientific venture: too often we cling to painfully acquired knowledge, fearing adventures.

To the question of what he was up to at the moment, Mr. K. answered: "I'm hard at work preparing my next error"
Bertolt Brecht[1]

1. Introduction: Polymer Science Today—Ancient Roots, Young Branches?[2]

1.1. Tradition and Innovation in Science

Two decisive aspects in the field of science are tradition and innovation. Tradition is the basis, for it is the cumulation of wisdom in the body of knowledge. To know what a subject is all about and to control it creates self-confidence, thus paving the way for innovations. Innovation is the adventure, since with the challenge comes the risk of calling into question (or even losing) one's own scientific identity, gained through tradition.

Persisting in tradition without innovation, however, soon leads to tiresome routine, to the science of yesterday: the longing for new adventures withers and dies.[3] On the other hand, pure innovation harbors the danger of superficiality. The sum of knowledge is immense and growing! Tradition and solid, successful work are honored and admired. Nevertheless, science can only be justified by a challenge, and demands the willingness to give up long-held classical or traditional views[4] in the attempt to discover new horizons.

1.2. One Example to Introduce the Topic: Order versus Chaos

Only a few years ago, it was still difficult to bring the evolution of life in line with the basic laws of physics. Ac-

[**] The preceding page shows Figure 24.

cording to the principles of classical thermodynamics, disorder in the world was supposed to increase constantly. All controlled functional processes should therefore end one fine day; all order should dissipate. During the big bang, when the world evolved from chaos, there was no order at all. So how could organized structures, living organisms, develop from this start?[5]

It was a stormy development in the field of nonequilibrium phenomena that helped to resolve this dilemma. During the last few decades, the term self-organization has been synonymous with theories developed in various disciplines that deal with the further development, dynamics, and differentiation of systems. On the borderland between chemistry and biology, these include, in particular, concepts for the development of highly complicated organic molecules and the role they play in the evolution of biological information in a prebiotic world.[6b] Even the somewhat new overlapping discipline of synergetics,[6] with its concepts of ordered, self-organized, and collective behavior, had its share in this process.

The fascinating phenomena of self-organization, which can be observed in physical, chemical, and biological systems (either near to or far from thermodynamical equilibrium), are characterized by great variety and complexity. A large number of molecules organize spontaneously, eventually exhibiting well-organized behavior on the macroscopic scale. The variety of organized states ranges from relatively simple spatial or chronological forms of organization all the way to the complicated interaction between order and function in biological systems. Over the last few years, the phenomenon of self-organization has developed into a subject of interdisciplinary research with overlapping topics.[5,6]

1.3. From Polymeric Liquid Crystals to Functional Biomembrane Models?

Right from its very beginnings, polymer science was a field on the borderland between chemistry and physics, i.e., between two classical disciplines. Thus, scientists in this field had to dare to make innovations. It was no less a man than *Hermann Staudinger* who experienced this. It is highly instructive to observe how at the height of his creativity in the field of organic chemistry, he left his traditional field of work to enter the frontier between chemistry and physics in order to tackle the problems of macromolecular chemistry.[7] In the meantime, macromolecular chemistry, too, has become a classical discipline, a mature science, with all the advantages and handicaps of maturity. Harvest is plentiful, the results are abundant—but one has to ask: where is the future, where are the adventures?

Modern materials science once developed out of the interaction between metallurgy, ceramics, and macromolecular technology, and in the jubilee issue of *Angewandte Chemie* in honor of the 100th anniversary of *Hermann Staudinger*'s birth, the old "Geheimrat" *Hermann Mark* asked the question of what direction polymer science was about to take:[2] Is it going in the direction of life science? Is it possible to reduce polymer science, cell biology, and medicine to a common denominator? So from that point of view, polymer science finds itself not only on the borderland between chemistry and physics, but also between materials science and life science (Fig. 1).

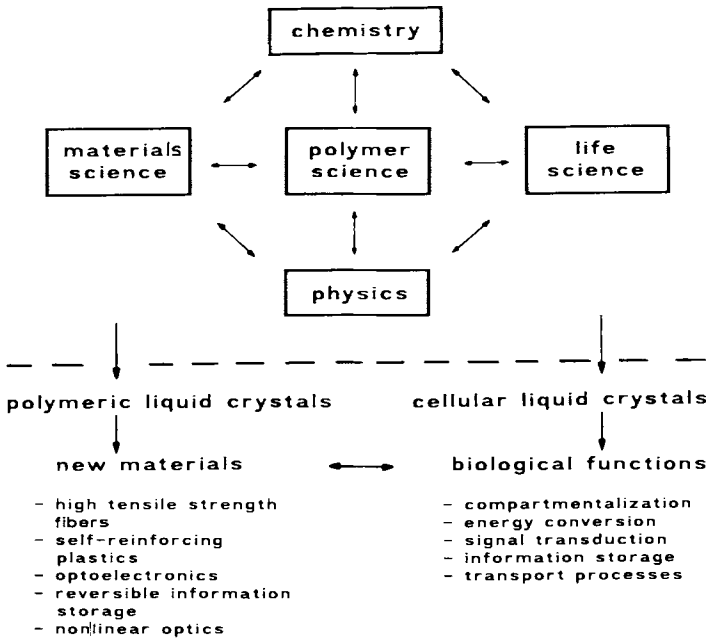

Fig. 1. Polymer science as an interdisciplinary field of science.

Taking self-organization and the molecular architecture of macromolecular systems as examples, this article aims to show that these fields of science can no longer be dealt with separately. In this review, the biological macromolecules of the cell such as polysaccharides or nucleic acids are not discussed as such. Molecular biology today is able to understand the central role which these polymers play in life science. But it has to be pointed out that their functions are based in all cases on the combination of molecular mobility and high order. This is achieved by their incorporation into membranes, by self-organization in solution, or by orientation at cell surfaces. These are combinations of properties which are typical of liquid-crystalline behavior. Thus, liquid crystals are chosen as *one* principal example of self-organizing systems, which are important for materials science as well as for life science (Fig. 1).

It was not by chance that, about 50 years ago, *J. D. Bernal* called the cell itself a natural liquid crystal, based on the knowledge of that time.[8] Liquid crystals really feature a behavior which is considered to be typical of a living cell: they react to a large number of stimulations such as light, sound, mechanical pressure, heat, and electric and magnetic fields as well as to changes in the chemical environment. The significance of cellular liquid crystals has been accepted for quite a long time. The significance of low-molecular-weight and of polymeric liquid crystals is on its way to becoming widely accepted. However, although the basic principles of self-organization are the same for both cellular and technical liquid crystals, only on rare occasions have they been looked at together.[9]

But what about the molecular architecture of the building blocks of self-organizing systems such as synthetic and biological liquid crystals and what about the structure of the resulting highly oriented supramolecular systems?

How does the molecular architecture relate to the functions of these materials? A hint as to possible answers to this problem will be given in an overview in Section 2. The goal is to stimulate interest in the overlapping fields of synthetic and biological liquid crystals in the broadest sense (cf. Fig. 2). In Section 3, thermotropic and lyotropic mesogens will briefly be defined and exemplified. Section 4 will show that scientists today are learning, step by step, what Mother Nature has long since known, namely to stabilize ultrathin, organized membranes and to functionalize them. Sections 5 and 6 will then concentrate on the connection between structure, function, and organization in biomembrane models. Even though the subject is still in its infancy, it is fascinating to observe how chemistry, physics, and membrane biology have to cooperate in order to mimic surface reactions (Section 5) and dynamic processes of biomembranes (Section 6).

Endocytosis and exocytosis, patching and capping—foreign words to chemists? Corkscrews for corked lipo somes?—a funny, maybe even nonscientific question? They originate from biology and are used on the borderland of polymer science between liquid crystals and the cell, an area of research which is only just beginning. The willingness to closely cooperate with adjacent disciplines, which hitherto have often been ignorant of one another,[10] will be a basic requirement to go ahead in this field. From that point of view, this article can neither be a perfect summary nor a presentation of detailed research results. To give definite answers is out of the question. It is simply meant to encourage innovations and scientific ventures: much too often we cling to our own knowledge out of the fear of new adventures.[11]

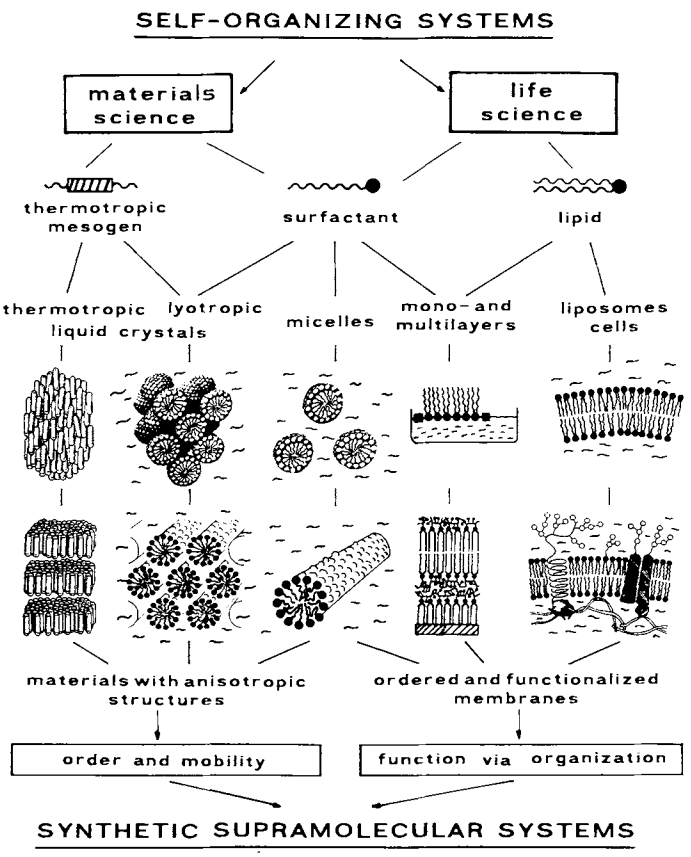

Fig. 2. Self-organization and supramolecular systems [12] in materials science and life science. The supramolecular structures range from simple nematic liquid crystals to complex biomembranes.

2. Self-Organization and Formation of Supramolecular Systems

Order and mobility are two basic principles of Mother Nature. On a molecular level two extreme cases can be found: the perfect order of crystals, in which the molecules exhibit almost no mobility at all, and the disordered state in gases and liquids, which exhibit randomness of highly mobile molecules. Both principles, order and mobility, are combined in liquid-crystalline phases. Although there are many possibilities for self-organization, the molecular basis is almost always simple: form-anisotropic or amphiphilic molecules make up the simplest building blocks. These already suffice—as shown in Figure 2—to construct a broad range of substances able to form supramolecular systems,[12] from thermotropic and lyotropic liquid crystals and the manifold micellar systems up to the highly ordered membranes in liposomes and cells.

In materials science, the significance of liquid crystals and micellar systems has long been known; it is based on exactly that combination of order and mobility in form-anisotropic molecules, leading to anisotropic (i.e., direction-dependent) properties of their materials and solutions.

From the life sciences we know that no life would be possible without the lipids' self-organization into bilayers within the cell membrane. In this case, too, order and mobility are related to the structure of functional units formed by lipids and proteins. In all cases, the functions of such supramolecular systems, formed by aggregation, are based on their organization.

The self-organization and the construction of supramolecular systems is an interdisciplinary area which cannot be understood without the cooperation of different fields of science: chemistry alone does not fulfill that task nor does physics or biology. Over the last few years it has been possible to observe an increase in the number of studies which reveal the connection between synthetic and cellular liquid crystals and in which a mutual understanding opens up new perspectives. Macromolecular chemistry may play an important role in this context. On the one hand, macromolecules can stabilize organized systems without hampering their mobility. On the other hand, it is well known in macromolecular chemistry that creative curiosity for new compounds leads to new properties due to novel structures.

3. Molecular Architecture of Synthetic Self-Organizing Structures—or How to Attract Molecules to Form Supramolecular Systems

3.1. Structure and Properties of Thermotropic Polymeric Liquid Crystals

Numerous organic compounds with a rigid, rodlike molecular geometry (mesogens) do not directly go from the

crystalline into the isotropic state when they melt. Instead, they form intermediate liquid-crystalline phases (Fig. 3),[13] known as mesophases. These mesophases combine the order of the crystal with the mobility of the isotropic liquid. The parallel orientation of the longitudinal molecular axes is common to all mesophases (long-range orientational order). Two major classes can be distinguished: nematic (molecular centers distributed isotropically) and smectic (molecular centers organized in layers) phases. The individual smectic phases are further subdivided[14] into phases with or without tilt of the mesogens in the direction of the normal to the smectic layer. The molecules can either be in a disordered state within the respective layers or show different states of order. On the one hand, the driving forces

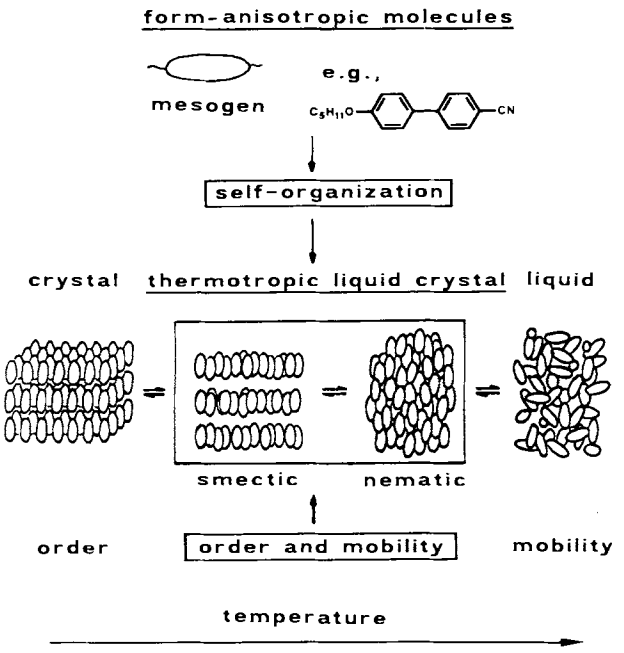

Fig. 3. Structure and phase behavior of thermotropic liquid crystals.

for the formation of mesophases are the anisotropic dispersion interactions[15] caused by the form-anisotropy of the mesogens. On the other hand, there are the steric repulsion forces[16] which are also orientation dependent.

The mesophases of rod-shaped compounds had been known for almost 100 years[17] when, in 1977, the discotic liquid-crystalline phases of disc-shaped molecules were found by *Chandrasekhar* et al.[18]. One can distinguish between a nematic discotic phase and several columnar discotic phases.[19] In the latter, molecular discs form stacks which, in turn, are organized in a two-dimensional lattice (cf. Fig. 5). These investigations reopened the game of molecular design of liquid-crystalline systems. So, additional phases were found: tubular,[20] pyramidic,[21] phasmidic,[22] and sanidic[23] phases. However, it still remains uncertain whether this is only a funny nomenclature or whether these are really new phases.

The development in the field of polymeric liquid crystals[24] started with polymers whose stiff main chain as a whole functions as the mesogen. Such polymers form liquid-crystalline phases either in solution[25] or in the melt.[26] At present, they are used as high-tensile-strength fibers (e.g., Kevlar®) or as thermoplastically processable, self-reinforcing plastics (e.g., Xydar®, Vectra®, Ultrax®).

Parallel to these industrial developments, numerous studies have been carried out in the area of basic research during the last ten years. They have dealt with the incorporation of rod-shaped mesogenic groups, known from low-molecular-weight liquid crystals, into polymers. This incorporation is either carried out by connecting the mesogenic groups via flexible spacers,[27] thus forming semiflexible liquid-crystalline (LC) main-chain polymers[28] (type B, Fig. 4) or, as in the case of the LC side-group polymers, by fixing the mesogens via flexible spacers to the polymer backbone[29] (type A, Fig. 4). Both types of liquid-crystalline polymers were, and still are, intensively investigated. Their structure-property relationships are discussed in numerous monographs[30] and reviews.[31]

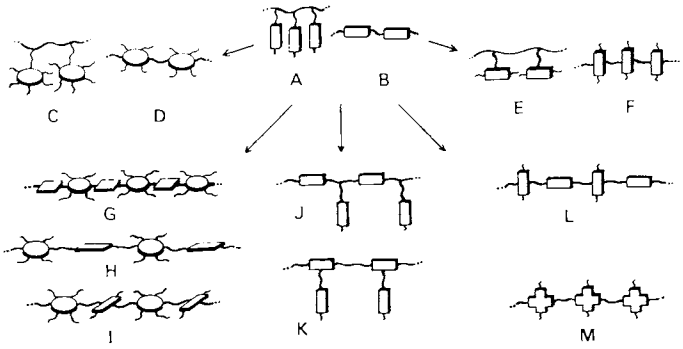

Fig. 4. Molecular architecture of polymeric liquid crystals: A) side-group polymers; B) main-chain polymers; C) discotic side-group polymers [32]; D) discotic main-chain polymers [33]; E) side-group polymers with laterally fixed mesogens [34, 35]; F) main-chain polymers with laterally linked mesogens [35]; G, H, I) combined disc-rod polymers, i.e., combinations of disc- and rod-shaped mesogens [23, 36, 37]; J, K) combined main-chain/side-group polymers [38]; L) polymers with laterally and terminally linked mesogenic groups; M) polymers with cross-shaped mesogenic groups [35].

From these two "classical" types (A and B), variations of the macromolecular architecture of liquid-crystalline polymers have recently been carried out. They are illustrated schematically in Figure 4.

On the one hand, it is possible to realize discotic phases, as observed in the case of low-molecular-weight liquid crystals, by using side-group[32] (type C) and main-chain[33] (type D) polymers. On the other hand, it is, of course, also possible to incorporate rod-shaped mesogens in different ways than in the two classical types A and B: examples are side-group polymers[34,35] (type E) as well as main-chain polymers[35] (type F) with laterally fixed mesogens. These strange-looking architectures do not prevent the formation of liquid-crystalline phases. As far as polymers of type E are concerned, the limited rotation of the mesogenic groups around their longitudinal axes leads to the formation of biaxial nematic phases.[34a-c] These phases have not been observed yet with low-molecular-weight liquid crystals. The third group of structural variations makes use of a well-known principle in polymer chemistry, which is rarely used in the field of liquid-crystalline materials: the com-

binations of different structural elements and different building principles to design one macromolecule. This includes the different combinations of rod- and disc-shaped mesogens[23, 36, 37] (types G, H, and I) and the combination of the structural principles of the two classical types of liquid-crystalline polymers (types A and B) in the combined main-chain/side-group polymers[38] (types J and K). Furthermore, the polymers with cross-shaped mesogens[35] (type M) should be mentioned, as well as the idea of combining laterally and terminally connected mesogenic groups (type L), which has not yet been realized.

Here only two examples are given to illustrate the structure-property relationships of such new polymeric liquid crystals. Figure 5 shows a discotic main-chain polymer[33a, b] of type D. This one features a columnar phase which can be mechanically oriented and frozen below the glass transition temperature. It is noteworthy that this polymer forms a highly ordered D_{ho} phase. Thus, the polymer chains do not disturb the packing of the discs.

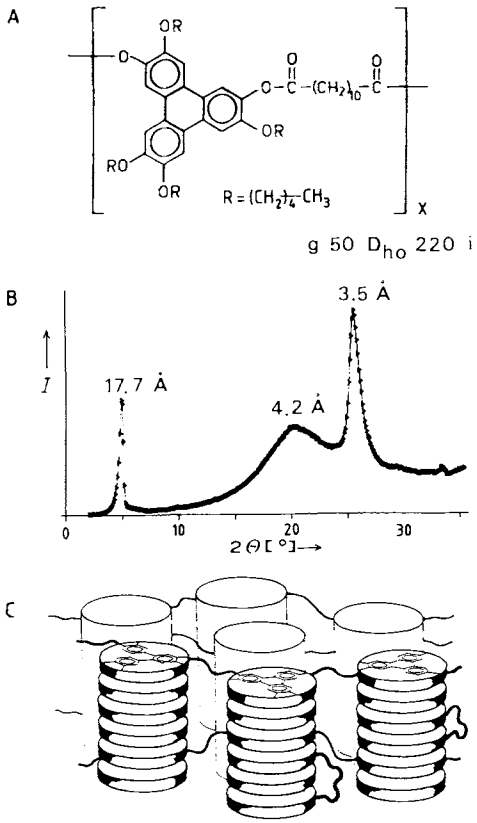

Fig. 5. A) Chemical structure and phase behavior of a discotic main-chain polymer with triphenylene moieties as core of the discogen [33a] (g = *g*lassy; D_{ho} = *d*iscotic *h*exagonal *o*rdered; i = *i*sotropic). B) X-ray scattering diagram (λ = 1.54 Å) of the polymer (I = scattering intensity, θ = scattering angle) [33b]. The scattering maxima are given by the Bragg spacings and can be interpreted in analogy to the values found for low-molecular-weight triphenylene derivatives [19b] as follows: 17.7 Å corresponds to the columnar distance in the hexagonal lattice; 4.2 Å corresponds to the nonoriented liquid-like arrangement of the alkyl chains; 3.5 Å corresponds to the constant distance of the triphenylene cores in the column. C) Structural model for the D_{ho} phase of the discotic main-chain polymer based on results from X-ray measurements of mechanically oriented samples [33b]. The columns are perpendicular to the stretching direction.

In Figure 6, a combined main-chain/side-group liquid-crystalline polyester of type J (A) is compared to one of type K (B). Depending on the point of attachment of the mesogenic side group, either mostly smectic (A) or nematic (B) mesophases are observed.

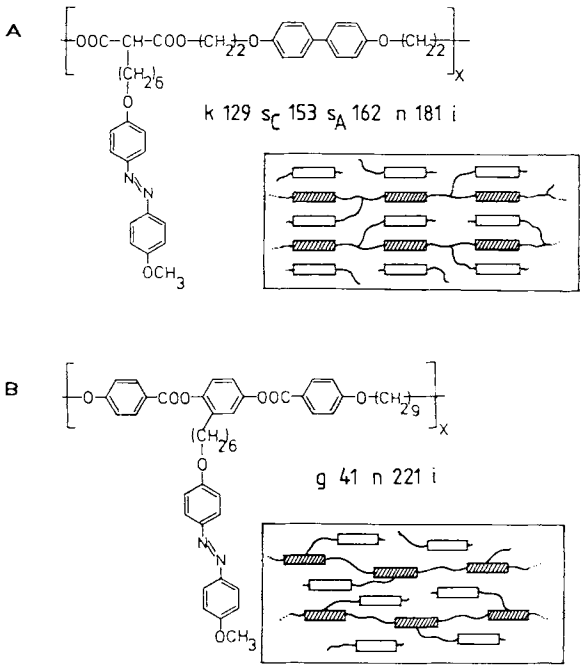

Fig. 6. Chemical structure, phase behavior, and structural models of the mesophase of combined main-chain/side-group liquid-crystal polymers. A) The attachment of the mesogenic groups to the flexible spacer of the polymalonate main chain [38a] favors smectic mesophases (s). B) The attachment of the mesogenic side groups directly to the polyester main-chain mesogens [38b] leads to broad nematic phases (n).

3.2. Structural Variations in Micellar and Lyotropic Liquid-Crystalline Systems

Contrary to thermotropic ones, lyotropic liquid-crystalline systems always consist of at least two components. One of them is a solvent, which plays a crucial role in determining order and mobility. The state of lyotropic liquid crystallinity is not primarily achieved by a change in temperature, but, as shown in Figure 7, by a change in solvent content.[39]

With decreasing solvent content, molecules that are isotropically dispersed at lower concentrations only form aggregates. These aggregates organize into nematic phases or into the more ordered lamellar (comparable to the thermotropic smectic phases), columnar, and cubic mesophases. Nematic phases differ from the isotropic solution by the long-range orientational order of the aggregates only, lamellar and columnar phases additionally by a long-range positional order of the aggregate centers in one or two dimensions; cubic phases merely show a long-range positional order in three dimensions. On further decreasing the solvent content, solvent-free crystals are formed—often via solvent-containing crystals. As typical of amphiphiles, lyotropic mesogens are composed of soluble (solvatophilic) and insoluble (solvatophobic) moieties within one molecule. Fatty acid salts and long-chain alkyl ammonium salts are representatives of this type of structure. In aqueous solution, they aggregate—if their concentration lies above

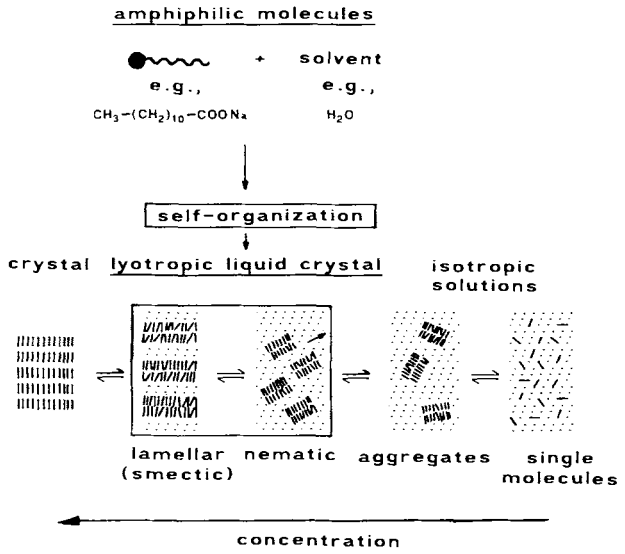

Fig. 7. Structure and phase behavior of lyotropic liquid crystals.

the critical micelle concentration (CMC)—to micelles, which may be spherical, cylindrical, or plate-shaped (Fig. 8).

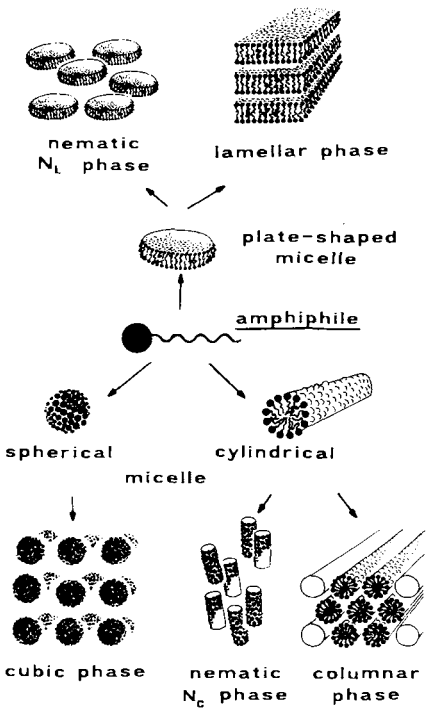

Fig. 8. Aggregation of amphiphiles to form micelles of various shapes and the formation of lyotropic mesophases from these micelles.

For spherical micelles, intermicellar interactions lead to cubic mesophases; for cylindrical micelles, to nematic N_C as well as to columnar mesophases. Plate-shaped micelles can form an additional type of nematic phase (N_L) and further a lamellar mesophase.[40] Thus, the different types of lyotropic mesophases are not directly determined by the structure of the single molecule (mesogen)—as is the case of thermotropic systems—but by the structure of the micelle[41] or the aggregate. The structure of the micelle, however, depends on several factors, such as temperature, concentration, and the structure of the amphiphile itself. The latter refers, in particular, to the hydrophobic-hydrophilic balance between the head group and the alkyl chain as well as to the geometry of the amphiphile.[42] Most of the amphiphiles form micelles of different shapes and thus often several types of lyotropic mesophases.

It is mainly this complexity of the aggregation behavior that has stimulated the syntheses of various types of amphiphilic compounds. So as to get to specific supramolecular systems, one now tries to influence the shape, size, and stability of the aggregates through molecular architecture of low-molecular-weight and polymeric amphiphiles. Two different approaches have been taken so far (Fig. 9).

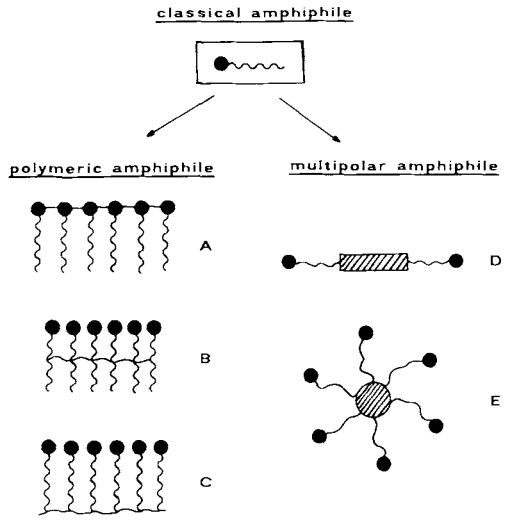

Fig. 9. Molecular architecture of polymeric (A, B, C) and multipolar amphiphiles (D, E).

The first approach starts from polymeric amphiphiles. Although they have long been known, the relationship between their structure and mesophase behavior has hardly been investigated. As depicted in Figure 9, amphiphiles can be synthesized with the polymerizable unit in the head group, in the hydrophobic chain, or attached to its end. Their polymerization leads to polymers of type A, B, or C, with the mobility of the amphiphiles, which are now fixed by the polymer, being extremely different from that of the monomeric compounds. As a consequence, aggregation and mesophase behavior may also change. In view of the few examples known,[43] hardly any changes have been observed as to the type of mesophase—not so as to the concentration and temperature ranges which were largely extended through polymerization. This is demonstrated by the amphiphilic polymer of type C shown in Figure 10.[43a]

Monomer **1** and the respective polymer only form lamellar phases in water. The monomer exhibits lyotropic liquid-crystalline behavior within a concentration range of 65–88 wt%, whereas the polymer exhibits such behavior in the range of 37–100 wt%. The maximum clearing tempera-

ture of the lyotropic mesophase of the monomer is 87 °C, that of the lyotropic mesophase of the polymer, however, 185 °C.

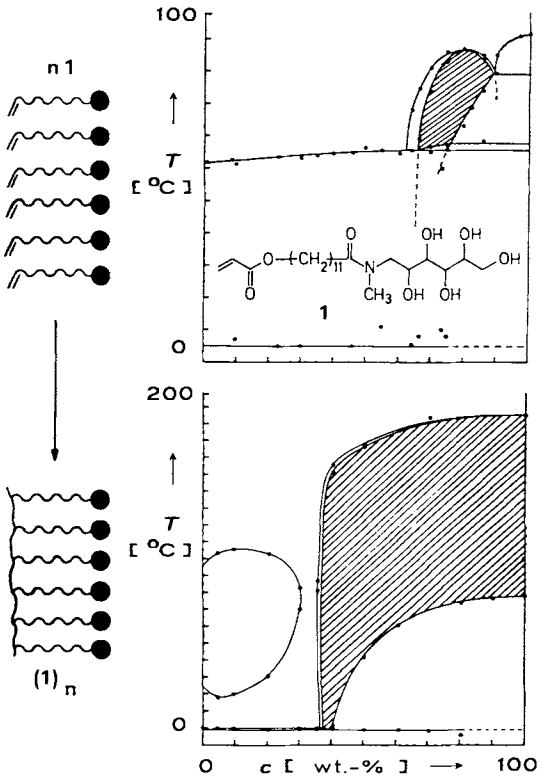

Fig. 10. Extension of the concentration and temperature ranges of the lyotropic mesophases (hatched) of **1** due to polymerization [43a].

The second approach to achieve a specific type of mesophase starts from amphiphiles of novel structure. These new structures combine the molecular design of thermotropic and lyotropic mesogens (see Section 3.3), i.e., the form-anisotropy of thermotropic liquid crystals (rod- and disc-shaped) with the amphiphilic character of lyotropic liquid crystals (see Fig. 9, types D and E). Some examples are shown in Figure 11. If, for instance, the alkyl chains of rod-shaped thermotropic liquid crystals are replaced by hydrophilic chains,[43i,k,44] rod-shaped bipolar amphiphiles result (e.g., **2** and **3**). In water, compound **2** forms only platelike aggregates, which arrange into a lamellar or smectic phase in a concentration range of 53–84 wt% at temperatures between 8.7 °C and 33.5 °C.[43i] As for the rod-shaped amphiphiles **2** and **3**, disc-shaped multipolar amphiphiles (e.g., **4**–**7**) are obtained by introducing hydrophilic chains into discotic molecules such as benzene or triphenylene derivatives. The amidation of the triphenylene-hexayl hexaester **8** with amino alcohols to form hexaamides,[47] e.g., **7** (Fig. 12), provides a simple reaction that involves this transformation of a thermotropic discotic liquid crystal to a lyotropic discotic liquid crystal. In this case, the structural similarity between the thermotropic discotic mesogen and the new lyotropic discotic mesogen is responsible for the same type of mesophase, namely, the columnar one. The lyotropic mesophase is formed by cylindrical aggregates present in the isotropic solution.

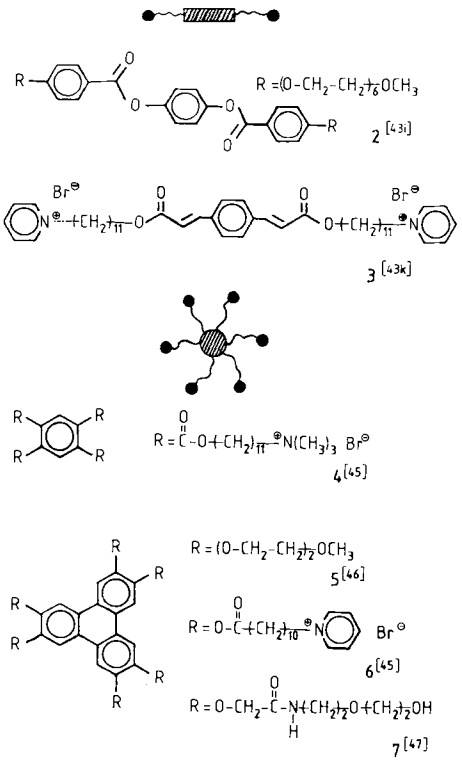

Fig. 11. Examples of multipolar amphiphiles (types D and E from Fig. 9).

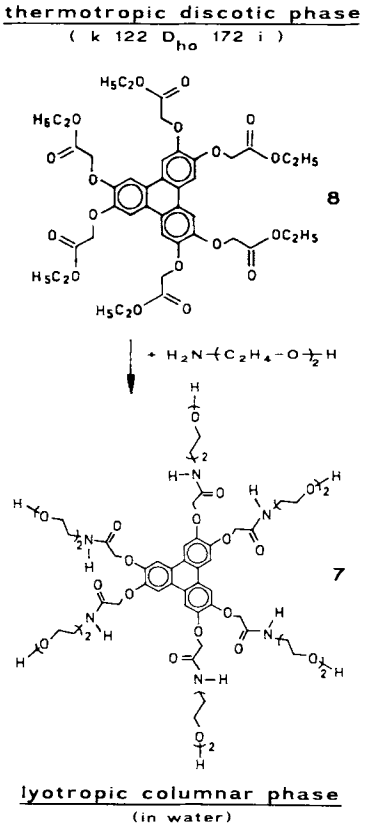

Fig. 12. Transformation of a thermotropic discotic mesogen to a multipolar amphiphile [47] (k = crystalline). Distances between the columns in the thermotropic phase (cf. Fig. 5C) at 140 °C, 19.2 Å; in the aqueous lyotropic phase (cf. Fig. 8) at 20 °C and 60 wt%, 28 Å.

3.3. Amphotropic Systems—All-round Compounds

In lyotropic mesophases, the combination of order and mobility can be achieved by using a solvent. The formation of thermotropic liquid-crystalline phases is based on the temperature-induced mobility of form-anisotropic molecules in the melt.

Amphotropic molecules (Greek: ampho = both, in two ways; trepein = align, direct) are compounds which can be organized according to at least two different principles owing to their structural properties. Figure 13 illustrates this using an example from the field of liquid crystals.

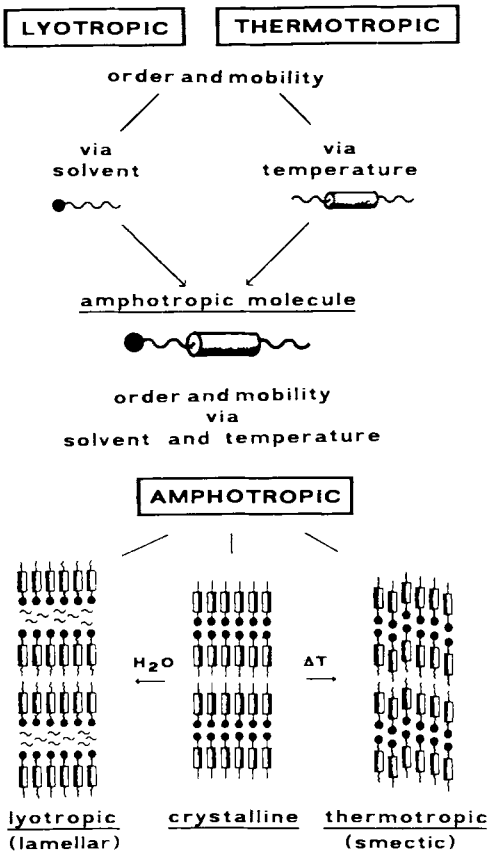

Fig. 13. Schematic representation of an amphotropic system.

Although the term amphotropic liquid crystal has not been used so far, there are many examples of amphotropic behavior:[39b, 43a, 48] some phospholipids,[48a] alkylated monosaccharides,[48b, c] and amphiphilic metal salts[39b, 48d] not only form lyotropic but also thermotropic mesophases. As regards their molecular structure, these molecules are normal amphiphiles. However, they reveal amphotropic behavior.

The range of amphotropic compounds can be considerably increased by the additional incorporation of typical thermotropic liquid-crystal building blocks (rod- or disc-shaped) into amphiphiles. *Kunitake* et al. have investigated a large number of amphiphilic substances which contain rod-shaped mesogens in the hydrophobic chains (e.g., biphenyl, azobenzene, diphenylazomethine moieties).[48e] Apart from various ordered structures in the aqueous phase, thermotropic liquid-crystalline behavior was observed for some of these compounds. Moreover, some polymers also show amphotropic properties.[43a, 48f, g, h] For example, it is possible to organize modified hydroxycellulose derivatives[48f, g] and various polyisocyanates,[48h] not only lyotropically, but also thermotropically.

As for amphotropic molecules, promising perspectives turn up in the field of Langmuir-Blodgett (LB) multilayers.[49, 50] A large number of possible technical applications of these ordered layer systems are nowadays a focal point of discussion. They could be used, for example, as electron beam resists[51] and photoresists,[52] in nonlinear optics (NLO),[53] in the field of reversible information storage,[54] and in the development of bio- and immunosensors.[55, 82]

LB multilayers show—owing to the stepwise transfer mechanism—a well-defined layer structure in the vertical direction. However, within each individual layer, the amphiphiles form two-dimensional lattices with a distinct domain structure (Fig. 14).

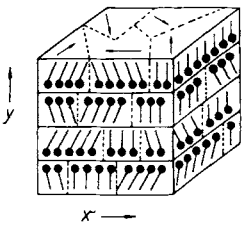

Fig. 14. Structure of LB multilayers: perfectly ordered layers in vertical direction y; irregular domain structure in horizontal direction x.

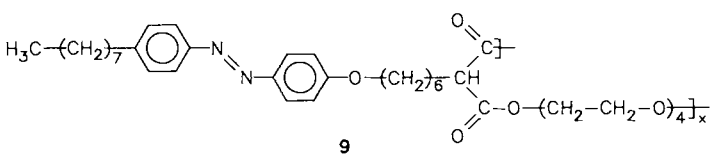
The crystalline packing of the molecules in the individual layers and the related severe limitation of the molecular mobility have so far not allowed a subsequent, specific manipulation of the molecular order. It has not yet been possible to obtain homogeneous, domain-free (i.e., uniformly oriented) lipid layers. Indeed, it is possible to induce a slight mobility of the molecules and thus a minute change in orientation by heating the multilayers within a certain temperature range. The melting of the layers, however, usually leads to the irreversible collapse of order.[56] On the one hand, amphotropic molecules are amphiphiles, i.e., capable of building up LB multilayers. On the other hand, they are thermotropic liquid crystals owing to the incorporation of mesogenic building blocks. Thus, amphotropic molecules could be used as an approach to introduce mobility within the individual layers, necessary for the subsequent manipulation process. The orientation of the molecules in the individual layers could then, for example, be carried out by means of electric or magnetic fields (Fig. 15).

Mesogen-containing amphiphiles have already been investigated in multilayers.[57] The example discussed here demonstrates that it is indeed possible to introduce thermal mobility in multilayers by using amphotropic molecules. The polymeric malonate **9** contains azobenzene



9

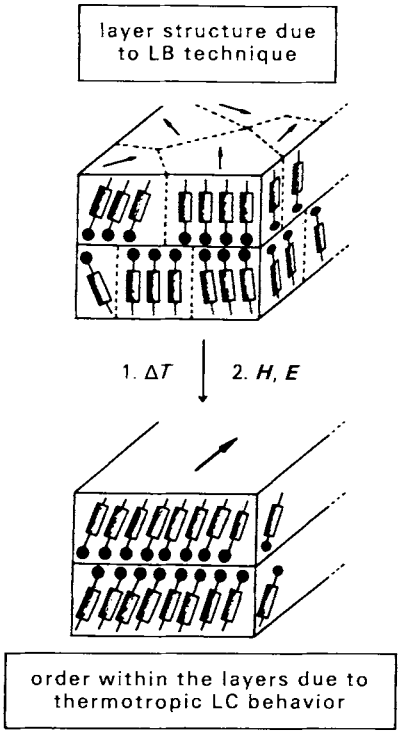


Fig. 15. LB multilayers made from amphotropic molecules: orientation within the layers by electric (*E*) or magnetic (*H*) fields in the mobile LC phase.

moieties as mesogens and an ethylene glycol main chain as the hydrophilic part.[58] In bulk, the polyester **9** is liquid crystalline (g - 275 55i). At the gas/water interface it forms a solid-analogous monolayer, which can be transferred onto solid substrates by means of the LB technique. The organization of the layers has been demonstrated by using small angle X-ray scattering (Fig. 16).

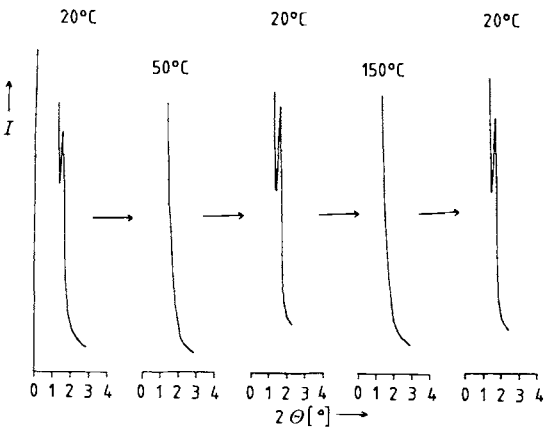

Fig. 16. Temperature-dependent small angle X-ray scattering of 30 layers of the polymer **9** on a polyethylene-therephthalate support: layer structure reappears at 20°C after melting above 50°C.

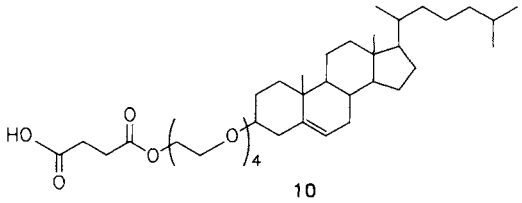
If the temperature is increased to about 50°C, the scattering reflex in the X-ray diagram disappears. The multilayer melts and the highly ordered structure is lost. It is decisive, however, that the capacity to reorientate is maintained: after cooling to 20°C, the scattering reflex reappears with its original intensity. Even after heating to 150°C, the multilayer structure reassembles at room temperature. The incorporation of mesogenic building blocks into the amphiphilic system and their fixation to the polymer seems to prevent a direct isotropic melting. Although the layer correlation is lost, the parallel alignment of the polymer-fixed mesogenic amphiphiles is maintained (cf. Fig. 13).

The field of molecular engineering of thermotropic and lyotropic liquid crystals is broad. The search for compounds capable of self-organization and formation of specific supramolecular structures will lead to numerous new classes of substances. The first examples have already been described.[48d, 59]

One compound that is capable of self-organization in manifold ways—and thus amphotropic—is the cholesterol derivative **10**. Its different possibilities of orientation are described in Figure 17.[60]



Owing to its form-anisotropy, this compound forms a thermotropic mesophase of the type "bilayer smectic S_A" between −28°C and 113°C (g −28 S_A 113 i). If it is slowly cooled, the substance solidifies at −28°C in the form of an anisotropic glass which does not crystallize even after a long period of annealing.

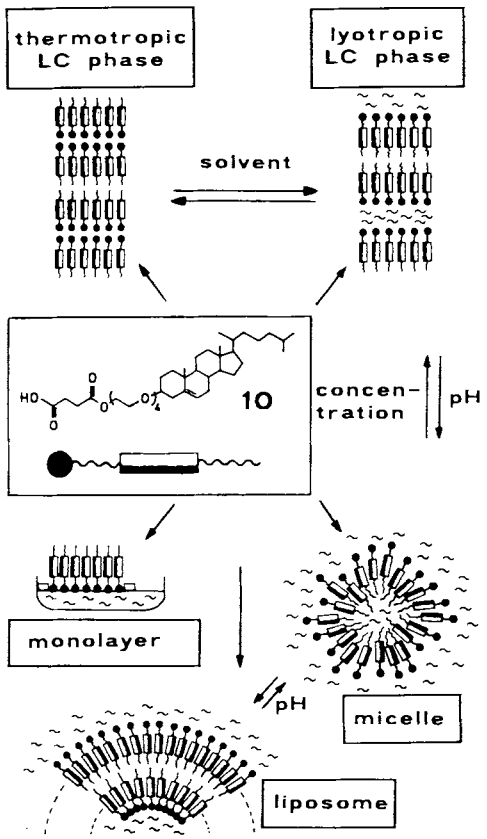


Fig. 17. Example of an amphotropic system: various ways of self-organization of the cholesterol derivative **10** [60].

Since the cholesterol derivative **10** is also an amphiphile, it can form numerous supramolecular structures in aqueous media: lyotropic LC phases, liposomes, micelles, and ordered monolayers. A lyotropic lamellar phase can be obtained by swelling in water or even in absolute diethylene glycol. In both media, spherically closed lipid bilayers (liposomes) develop spontaneously from the lamellar phase after further dilution. The formation of liposomes was demonstrated by means of entrapment of a water-soluble fluorescent marker as well as by phase contrast and electron microscopy. In addition, pH variations lead to the reversible formation of micelles. With a value of 1.6×10^{-3} mol L^{-1} (pH = 9.3), its CMC is in the range of normal surfactants. Drying of the aqueous aggregates leads back to the thermotropic liquid crystal.

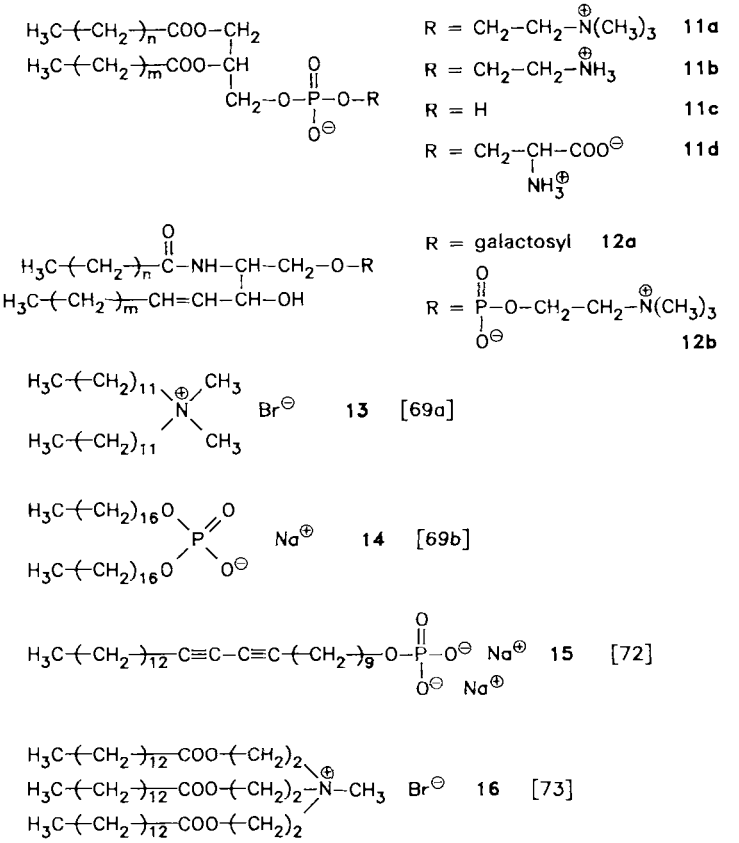
As vesicle-forming molecules, ethylene oxide cholesterol derivatives[60,61] possess an atypical structure, since the hydrophobic portion of bilayer-forming lipids usually consists of fatty acid chains. The molecular architecture of these "normal" lipids will be dealt with in greater detail in the next section.

3.4. Lipids as Bilayer-Forming Amphiphiles

Whereas the micelle-forming amphiphiles discussed in Section 3.2 still show a rather high solubility in water (CMC about 10^{-3} mol L^{-1}), it is a lot lower for membrane-forming lipids (CMC about 10^{-8} mol L^{-1}). Lipid molecules, i.e., double-chain amphiphiles, are the basic building blocks of all biological membranes.[62,63] Their self-organization in water is the result of the hydrophobic effect,[64] as is the case with surfactants, and depends also on the relative proportion of hydrophobicity and hydrophilicity of the lipid, as well as on its geometry.[42]

The phase diagram of a mixture of water with a typical lecithin lipid such as dipalmitoylphosphatidylcholine (DPPC) features the lipid bilayer as the basic structure over a very broad temperature and concentration range.[65] Depending on the water content, homogeneous, smectic phases of parallel lipid bilayers (lyotropic phases) and heterogeneous dispersions of multilamellar or single-walled liposomes can be observed. For low water content and high temperature, other lyotropic liquid-crystalline phases exist, such as the hexagonal, the cubic, and the ribbon phase.

In accordance with the importance of lipids for the formation of biomembranes, Nature is equipped with a wide range of possibilities in order to vary the molecular architecture of its membrane-forming amphiphiles (Scheme 1). Most of the natural lipids are zwitterionic (e.g., lecithin **11a** or ethanolamine **11b**) or negatively charged (e.g., phosphatidic acid **11c** or phosphatidylserine **11d**). There are also uncharged lipid structures found in Nature (e.g., glycolipids[66] such as **12a**). Not only the head-group structure but also the hydrophobic region is varied to a large extent. Depending on whether rigid or fluid membranes are needed, either saturated or unsaturated fatty acid chains are incorporated, respectively. Hydrogen bonds between the head groups, as, for example, in the case of sphingolipids (e.g., **12**), lead to an additional stabilization of the membrane.[67]



Scheme 1. Examples of natural and synthetic bilayer-forming amphiphiles.

Many of the lipids occurring in Nature have been synthesized.[68] In 1977, *Kunitake* et al. described fully synthetic amphiphiles having simple structures, which, just like natural lipids, are capable of forming bilayer membranes. Typical examples are the quaternary ammonium salts (e.g., **13**) and dialkyl phosphates (e.g., **14**) with two long chains.[69] The idea that even such simple amphiphilic structures can form bilayer membranes soon resulted in a large arsenal of artificial membrane-forming lipids.[70] These also include chiral compounds,[71] as they usually occur in Nature. Apart from the double-chain "classical" lipids discussed so far, synthetic bilayer-forming amphiphiles with only one (e.g., **15**[72]) or three (e.g., **16**[73]) hydrophobic alkyl chains also exist. Furthermore, there are membrane-spanning lipids; some of these bipolar amphiphiles will be presented in Section 4.7.

4. Stabilization and Surface Variation of Model Membranes

4.1. The Architecture of Biomembranes[74,75]

A decisive step in the development of the early forms of life was the self-organization of amphiphiles to form plasma membranes. It is unknown which principles led to the formation of macromolecules from purines, pyrimidines, or amino acids, but their self-replication would not have been possible without the protective shell of the lipid membrane. The cell membrane plays an important role in all essential biological phenomena. These include prob-

lems related to biological transport, energy metabolism, cell division, and macromolecular synthesis. The cell surface, in particular, is of significant importance as regards many aspects of cell biology, immunology, and cell-cell interaction as well as cell differentiation and the transformation of normal cells into malignant ones.

The biomembrane can be divided into three layers that are connected with one another: glycocalix, protein-lipid bilayer, and cytoskeleton (Fig. 18). The middle, protein-containing lipid bilayer is the component which indeed separates the cell into compartments.[76] Furthermore, it functions as an active filter and participates in motion and transport processes.

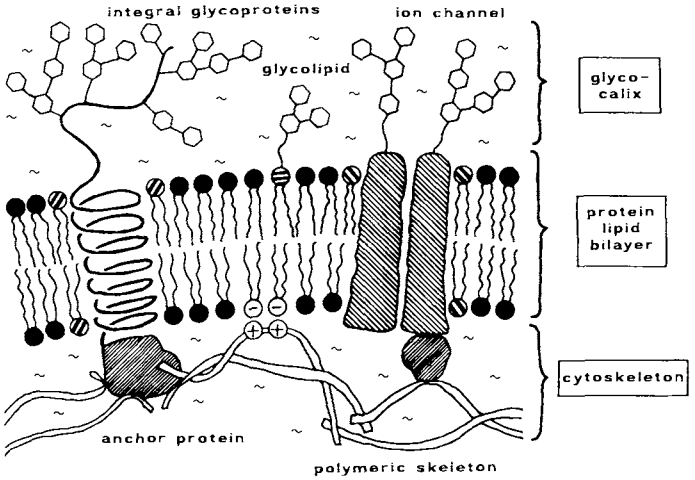


Fig. 18. Schematic representation of a biomembrane. The three layers are the glycocalix, the protein-lipid bilayer, and the cytoskeleton.

Outside, the phospholipid membrane is coated by a carbohydrate-rich layer, the glycocalix. It mainly consists of the oligosaccharide head groups of the glycoproteins and glycolipids, which are usually incorporated into the membrane. The glycocalix determines the surface recognition of cells: the oligosaccharide side chains, for example, are antigenic determinants in reactions of the immune system (see Section 5). In the case of plant cells, the glycocalix usually occurs as a solid, closed cell wall, in which the sugar groups (polysaccharides) additionally act as a skeleton (see Section 4.8.1). In the case of bacteria, the polysaccharide chains are cross-linked by oligopeptide chains. Thus, they form an extremely stable murein coat which represents one single macromolecule.

In animal cells, the stabilization of the cell membrane is mainly achieved by the cytoskeleton, which is linked to the inner side of the central lipid bilayer (see Section 4.8.2). From the point of view of polymer science, the cytoskeleton, in particular, as a polymeric network, represents an ideal basis for simulation experiments: reversible cross-linking, fixing of networks to membranes, dynamical processes in gels—these are all processes the cell constantly carries out in manifold ways.

To get a deeper insight into the structure-function relationships of biomembranes, a large number of bioorganic investigations are necessary. This is therefore an attractive and broad field of activity for synthetic chemists. However, natural membranes show a high complexity. Thus, in order to study the properties of individual membrane components, it is necessary to concentrate, at first, on simple model membranes having a defined chemical composition.

4.2. Model Membranes as Supramolecular Systems

In order to study the structure-property relationships of individual membrane components (lipids or proteins) at a supramolecular level, one has to rely on model membranes. On the one hand, they can provide information about the physical properties of membranes that only consist of lipids (pure or in mixture). On the other hand, in reconstitution experiments, membrane proteins can be incorporated into a physically and chemically defined surrounding. Then, the activity of the individual membrane proteins can be studied. Figure 19 gives a survey of the commonly used model membrane systems.

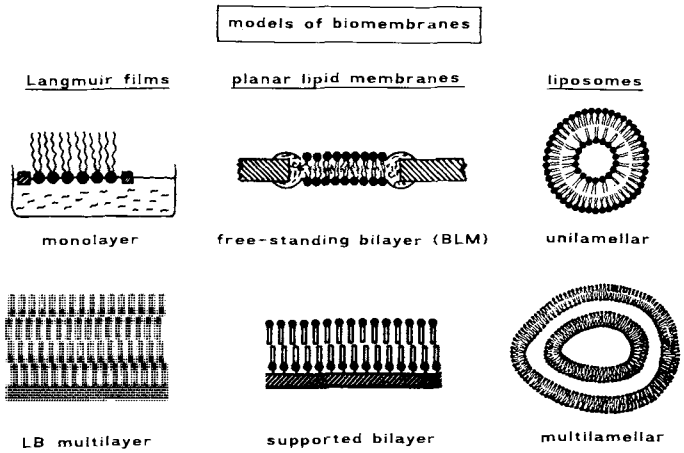

Fig. 19. Commonly used model membranes.

The spreading of a lipid at a gas/water interface leads to the formation of monolayers.[49c, 77] Formally, they represent only one-half of the lipid bilayer of a cell membrane. Thus, the monomolecular films—compared with other model membranes—seem to be the least similar to biomembranes. Nevertheless, investigations of monolayers supply precise information about the molecular packing and orientation of amphiphiles which cannot be gained from other model membranes. With the help of a film balance, monomolecular films can be characterized in the form of surface pressure-area diagrams (isotherms). This is a very sensitive method which responds to the slightest change in the structure of lipids. By means of isotherms, it is possible to gain information not only as to the orientation behavior of amphiphiles, their mobility in membranes, but also as regards the interactions with substances dissolved in the subphase (e.g., proteins; see Sections 5.2 and 5.3). Furthermore, by using a fluorescence microscope, phase-separation processes within the monolayer can be visualized.[78]

Highly ordered, ultrathin Langmuir-Blodgett (LB) films are obtained by transferring monolayers onto solid substrates.[49, 50, 79] As model membranes, multilayers are less

interesting. They seem to be technically more important as functional ultrathin films (see Section 3.3).

Planar lipid bilayers resemble much more the structure of biological membranes. They can be prepared either as free-standing black lipid membranes or as supported planar membranes. Black lipid membranes (BLMs)[80] are lipid bilayers which span a hole in a separating wall between two aqueous compartments. That is why they are ideal to carry out electrical measurements from which conclusions can be drawn as regards membrane capacity, thickness, and resistance. Thus, they are often used to study transport processes (e.g., of ions) through lipid membranes.[81] Supported planar membranes permit the use of measuring methods that cannot be applied to other model membranes.[82] If, for instance, such a planar membrane is fixed on a quartz substrate, one can detect fluorescence probes by means of TIRF spectroscopy (TIRF: total internal reflection fluorescence) only when they are close to the surface of the lipid bilayer. Therefore, such supported membranes are especially suitable for the investigation of surface recognition reactions.[82, 83, 163b]

Liposomes (vesicles)[84] are spherically closed lipid bilayers, which, in analogy to the cell membrane, enclose an aqueous compartment. Vesicles can be prepared by numerous methods,[84h, 85] which lead to the formation of completely different vesicle systems. These differ in diameter (between 20 nm and 100 μm) as well as in the number of bilayers. The sonication of lipid suspensions in water, for example, leads to small unilamellar vesicles (SUV, 20–100 nm). The swelling of lipid films, however, leads to uni- or multilamellar vesicles of the size of a cell. Liposomes are suitable for a large number of biophysical and biochemical investigations: e.g., for the measurement of membrane permeability,[84a] for the reconstitution of active membrane proteins,[86] and for the study of surface recognition reactions[84d, e] or dynamic membrane processes.[155] Furthermore, the possible use of liposomes as drug carriers is also being discussed.[87, 144a]

The five following sections (Sections 4.3 to 4.8) mainly deal with liposomes as model membranes. Apart from their surface variations, strategies for the preparation of polymerized liposomes are also discussed. On the one hand, these attempts should lead to more stable model membranes; on the other hand, they should help to simulate the stabilizing elements of the biomembrane.

4.3. Surface Variation of Model Membranes

In addition to direct variations of the membrane components, chemical surface variations of the cell membrane also play an important role in Nature: the generation of asymmetrical membranes or variations of the glycocalix are important examples. In model membranes, the molecular architecture of lipids can subsequently be varied within the supramolecular structure by means of chemical reactions. Such reactions in ordered systems are of interest because the highly organized lipid matrix represents a medium to control them. Differences in the course of these reactions, compared with the ones in isotropic solution, are caused by the orientation or the local concentration of the molecules involved.[88] Such reactions can be regarded not only as models for the transformation of lipids within biomembranes, but also, more generally, as models of enzymatic catalysis.[89] If vesicles are used as model membranes, a separation into different reaction sites[70e] (entrapped volume, hydrophobic interior of the membrane, membrane surface, aqueous outer volume), i.e., a spatial division of reaction partners, has to be considered. Thus, vesicles have been used, for example, to study artificial photosynthetic processes.[90] Moreover, the formation of spherically closed lipid bilayers by using reactive lipid molecules allows reactions to be carried out with water-soluble agents located only at the outer membrane surface. Thus, vesicle membranes with an asymmetrical distribution of head groups can be prepared.[70c, 90a] In the following examples, some reactions taking place at the surface of ordered membranes are illustrated.

The transformation of a negatively charged membrane surface to a positively charged one, under mild conditions, has been investigated in monolayers.[91] The maleic acid monoamide **17** with a carboxylic acid head group was used as an anionic reactive lipid. Under acidic conditions, the *cis* carboxyl group of **17** catalyzes the intramolecular hydrolysis of the amide bond.[92] In the course of this process, the dioctadecylammonium ion is formed. In order to observe the cleavage process, **17** was spread onto an acidic subphase. The isotherms of the acid, as well as that of the ammonium salt formed by the cleavage of the amide bond, are shown in Figure 20.

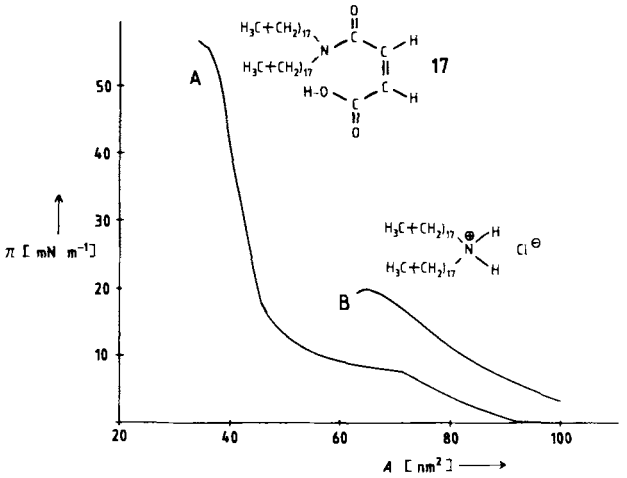

Fig. 20. Variation of the head-group charge in a monolayer [91]. A) Isotherm of the maleic acid amide **17** ($T = 31$ °C, pH of the subphase = 2). B) Isotherm of a monolayer from the amide **17** after head-group cleavage with the formation of the corresonding ammonium salt. The cleavage was achieved by leaving the film for 14 h at 0 mN m^{-1} and 31 °C on the acidic subphase (pH = 2). π = surface pressure, A = area per molecule.

Apart from a liquid-analogous phase, **17** also features a solid-analogous phase (curve A). In contrast, the isotherm of the product, the ammonium salt, shows only a liquid-analogous film (curve B). This behavior is in good agreement with the isotherm of a reference sample of dioctadecylamine. The formation of this amine in the monolayer was also demonstrated by means of thin layer chromatography and by mass spectrometry. The intramolecular

cleavage of the head group of this compound depends on its structure; it does not take place in the case of the analogous succinic acid monoamide of dioctadecylamine.

The variation of membrane properties can also be achieved photochemically;[93,94] some examples are summarized in Figure 21. The alteration of the membrane per-

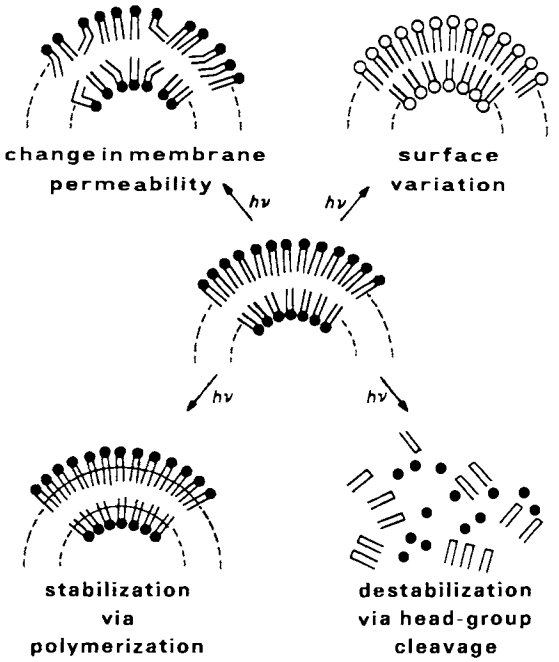

Fig. 21. Possibilities for the photochemical variation of membrane properties.

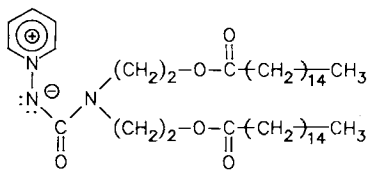
meability by means of the photochemical *cis-trans* isomerization of amphiphilic dyes has already been described.[94] The stabilization of model membranes via photochemically initiated polymerization reactions will be described in Section 4.5.1.

The photochemical variation and destabilization of the surface of monolayers and liposomes has been investigated by using lipids containing a zwitterionic photoreactive *N*-(1-pyridinio)amidate head group[95] (e.g., **18**).



18

Upon UV irradiation, these ylides can undergo ring expansion to give the isomeric 1,2-diazepines, or their head group can be cleaved, thus forming pyridine and an intermediary nitrene.[96] In liposomes composed of **18**, the photoreaction leads to the formation of 1,2-diazepine in high yield (Fig. 22).

Although the hydrophilicity of the diazepine formed in the head group is rather low, the vesicles neither aggregate nor precipitate during the photoreaction. However, these diazepine liposomes are metastable and can therefore be destroyed by mechanical stress such as shearing forces. A

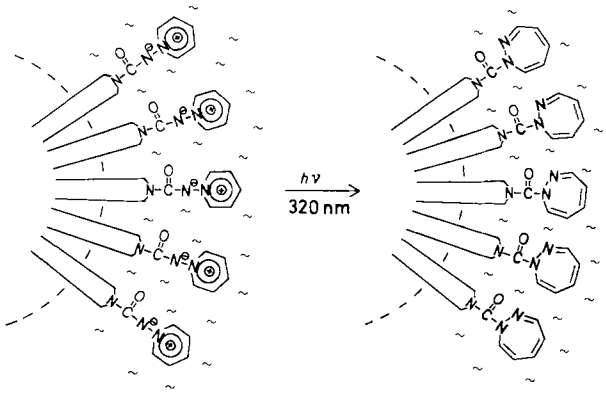


Fig. 22. Photochemical reaction of *N*-(1-pyridinio)amidate head groups forming diazepines in liposomal membranes: reduction of the head-group hydrophilicity [95].

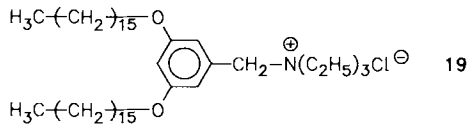
subsequent reformation of vesicles from the isolated photoproduct is not possible. Thus, vesicle membranes composed of molecules that are not able to form such supramolecular systems by themselves can be generated by means of photochemical variation within the supramolecular system.

In a different photoreaction, lipid **19** is destroyed upon photolysis of its quaternary benzylammonium head group.[97] UV irradiation of **19** in monolayers and lipo-



19

somes mainly leads to the formation of the corresponding toluene derivative.[93a] The ordered membranes then collapse and form crystals (Fig. 23).

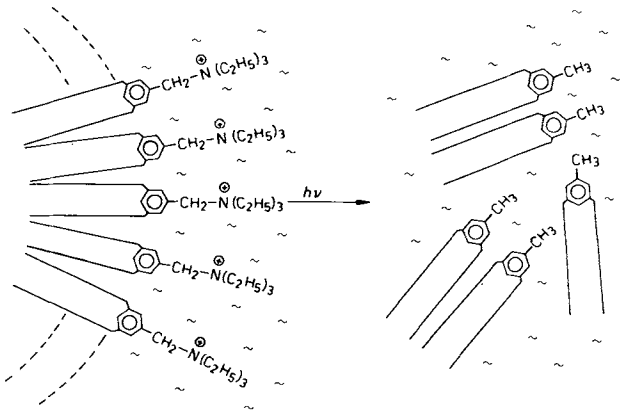


Fig. 23. Photochemical destruction of liposomes made from benzylammonium lipids [93a].

This process has also been studied in giant liposomes by means of phase contrast microscopy.[93a] Upon extended irradiation (about 40 s) the formation of crystallites is observed. A short irradiation (about 2 s), which does not result in a quantitative conversion of the reactive head groups, leads to the detachment of small liposomes from the larger ones. This process will again be dealt with briefly in Section 6.2 (Fig. 61).

4.4. Strategies for the Stabilization of Model Membranes

In the last few years, numerous methods to stabilize model membranes have been developed, mainly by using polymeric systems. A survey of the possible molecular architectures of stabilized liposomes is given in Figure 24.

The polymerization of lipids before or after their orientation in model membranes has been studied most intensively (see Section 4.5). As an alternative, the polycondensation of lipid molecules has also been described (see Section 4.6). Apart from such covalent binding reactions of lipid molecules, other possibilities to stabilize lipid bilayers are based on the noncovalent binding of polymers to the membrane surface (see Section 4.8). One method to achieve stabilization without using polymers involves the incorporation of membrane-spanning lipids into the bilayer (see Section 4.7).

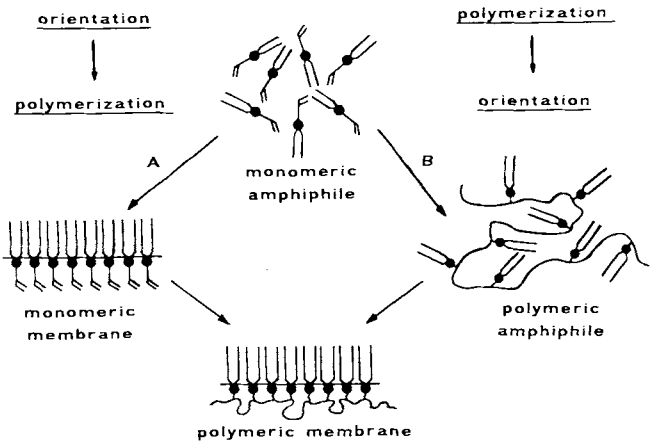

Fig. 25. Strategies for the preparation of polymeric model membranes. A) Orientation of the monomers in model membranes with subsequent polymerization. B) Polymerization of the monomers in isotropic solution and subsequent orientation of the polymeric amphiphiles.

4.5. Ordered Membranes from Monomeric and Prepolymerized Amphiphiles

Two approaches, schematically shown in Figure 25, have been used to prepare ordered polymeric model membranes. On the one hand, polymerizable amphiphiles can be used to build up monomeric model membranes, which can then be converted into polymeric ones (approach A). On the other hand, the use of oligomeric amphiphiles or the incorporation of spacer groups into the polymeric amphiphile to decouple the disordered polymer chain from the ordered membrane allows the formation of membranes from prepolymerized amphiphiles (approach B).[98]

4.5.1. Polymerizable Lipids

The polymerization behavior of amphiphiles with polymerizable units was first studied in monomolecular films.[99] In 1979, the formation of polymerized vesicles by using a lipid containing butadiyne units was mentioned for the first time.[100] In the meantime, many polymerizable groups have been incorporated into various lipid structures (see Scheme 2) to prepare polymerized liposomes.

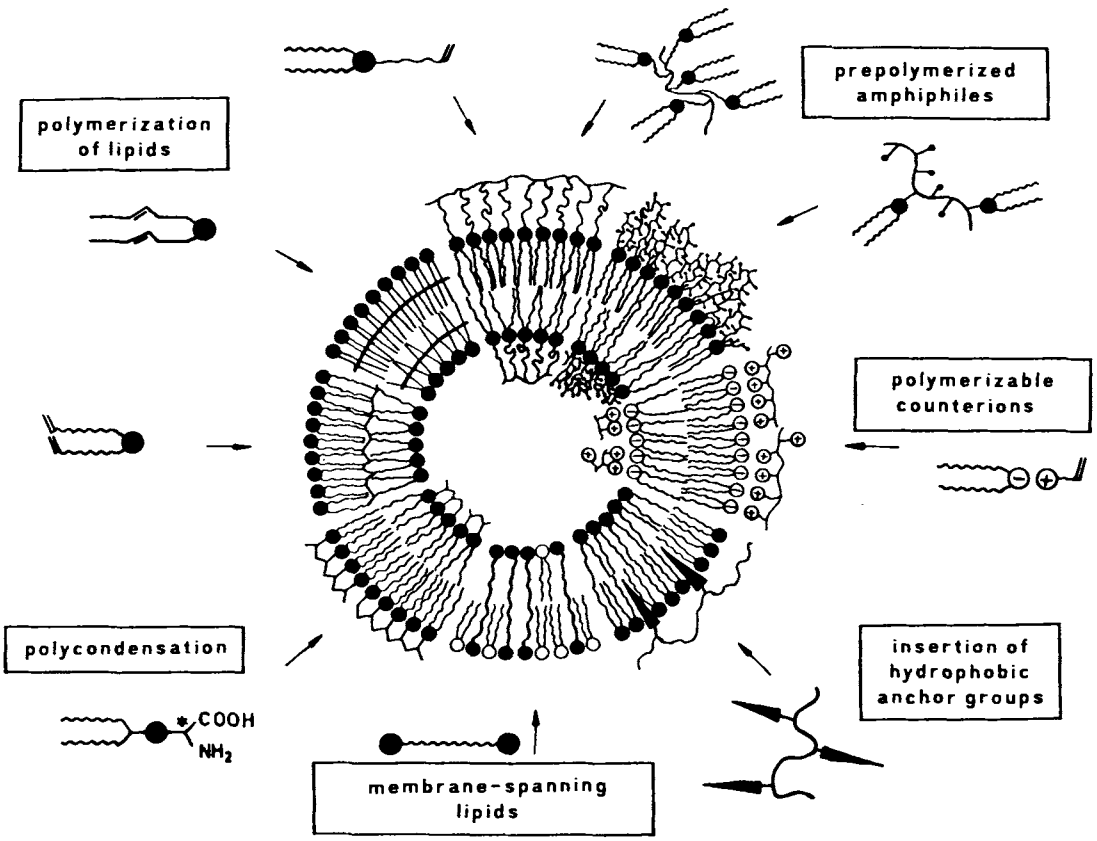

Fig. 24. Strategies for the stabilization of lipid bilayer membranes.

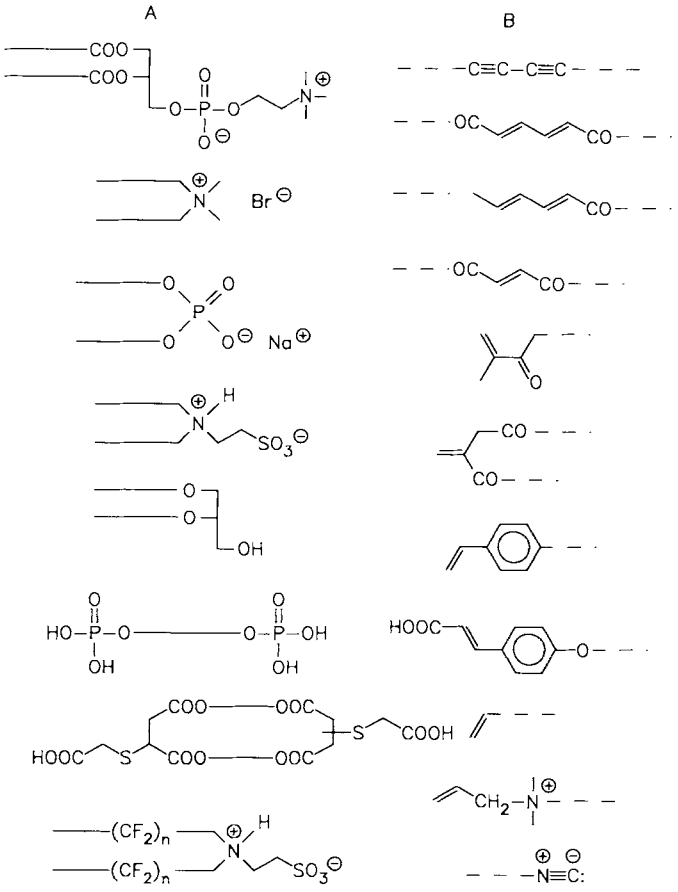
Scheme 3 shows only a few characteristic examples from the large number of polymerizable lipids.



Scheme 2. Building blocks of polymerizable lipids: A) lipid structures; B) polymerizable groups.

The game of structural variations of polymerizable amphiphiles (lipids, surfactants) and their use in monolayers, liposomes, and multilayers have enriched the monomeric and polymeric landscape and given rise to new hopes. These compounds and their perspectives of application will not be discussed further, since quite a few reviews on that topic already exist.[114]

4.5.2. *Model Membranes from Prepolymerized Amphiphiles*

A more recent concept for the preparation of polymeric membranes is based on the use of amphiphiles which have already been polymerized. At first sight, it seems surprising that this approach was taken much later than that via monomers. The problem with prepolymerized amphiphiles is the two-dimensional orientation of a three-dimensional polymer coil: An individual, motile molecule can easily be incorporated into a membrane. For a polymer-fixed molecule, however, its incorporation as a cooperative process is more complicated. Two different pathways can be followed to organize the membrane-forming alkyl chains of a polymer into ordered mono- or bilayers, despite the unordered structure of the polymer chain. On the one hand, polymers with low degrees of polymerization can be used. On the other hand, the incorporation of flexible spacers allows the decoupling of the different motion and organization processes taking place between the alkyl chains and the polymer main chain. Nature commonly uses the spacer concept, especially when functional groups with high mobility have to be kept close together. Already used for pharmacologically active polymers,[115] a similar concept has also been applied to the synthesis of liquid-crystalline polymers.[28,29] As regards polymeric amphiphiles, there exist three different possibilities as to the incorporation of a spacer group (Fig. 26).[116]

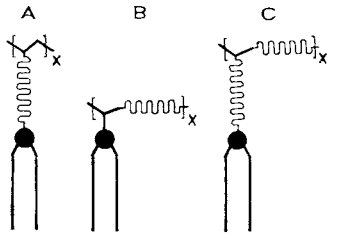


Fig. 26. Three possible ways to introduce hydrophilic spacer groups into polymeric amphiphiles [116a]: A) side-group spacer; B) main-chain spacer; C) main-chain and side-group spacer.

Homopolymers with side-group spacers (A) have been synthesized from lipids containing a hydrophilic spacer group between the membrane-forming amphiphilic part and the polymerizable unit. By means of copolymerization of simple lipids with hydrophilic comonomers, amphiphilic copolymers with main-chain spacers (B) can be prepared. The combination of both spacer types (C) can be realized by the copolymerization of spacer-containing lipids with hydrophilic comonomers.[116] The formation of polymeric model membranes by using such amphiphilic spacer-containing copolymers is illustrated in Figure 27.

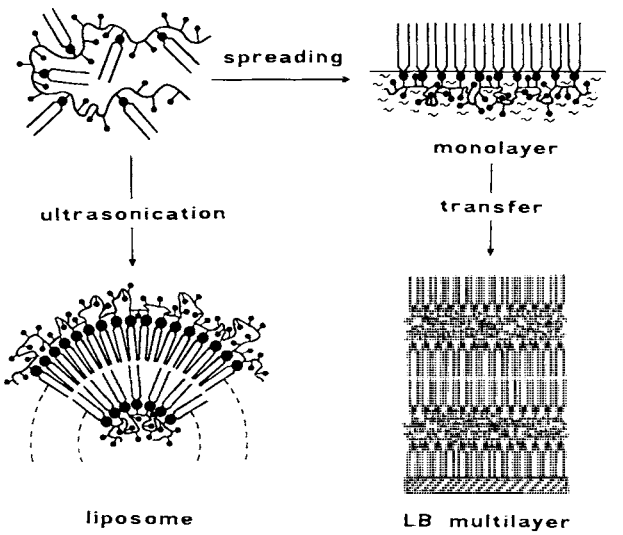

Fig. 27. Preparation of polymeric model membranes from copolymers containing hydrophilic comonomers.

The preparation of vesicles from prepolymerized lipids has so far only been described for homopolymers with

side-group spacers (type A, Fig. 26).[98] In addition, the self-organization of a polyionene as a vesicle membrane has also been discussed.[98a]

Fendler et al. described the copolymerization of maleic acid derivatives (e.g., **31**) with isotropically dissolved acrylonitrile as comonomer.[90a, 111] This kind of copolymerization also leads to the formation of polymers with main-chain spacers.

It is possible to prepare and investigate highly ordered stable monolayers by spreading the prepolymerized lipids (Fig. 27). They can also be used for the preparation of polymeric LB films via transfer onto solid substrates according to the LB technique.[116–119]

Scheme 4 shows some of the monomers from which amphiphilic homo- and copolymers with main-chain, side-group, or combined spacers have been synthesized. A fur-

ther interesting system consists of alternating copolymers made from maleic anhydride (e.g., with long-chain vinyl ethers or olefins), which have been investigated, in particular, by *Hodge* et al.[119]

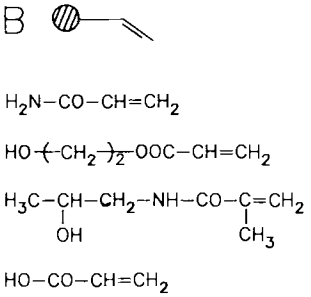
B



Scheme 4. A) Polymerizable lipids; B) hydrophilic comonomers for the synthesis of spacer-containing amphiphilic copolymers.

The necessity of introducing a decoupling spacer becomes obvious when looking at the isotherms of the monomeric and polymerized spacer-free lipid **34** (Fig. 28). The

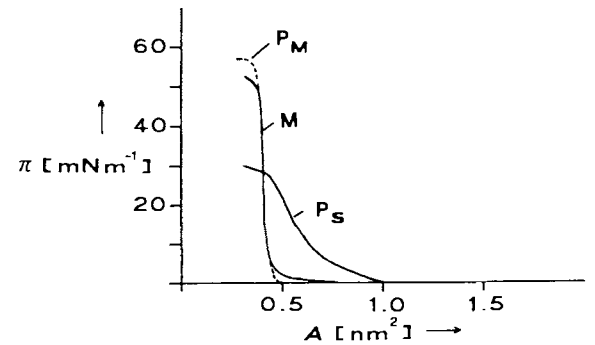


Fig. 28. Comparison of the isotherms of the spacer-free monomeric lipid **34** with its polymers [116a]. M) Monomeric lipid forms a highly ordered monolayer with a solid-analogous phase. P_M) Polymerization in the ordered monolayer leads to a slightly increased stability of the solid-analogous phase. P_S) Upon spreading of the polymer after polymerization in isotropic solution, only a liquid-analogous phase is formed. π = surface pressure, A = area per molecule.

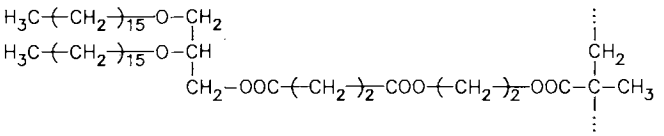
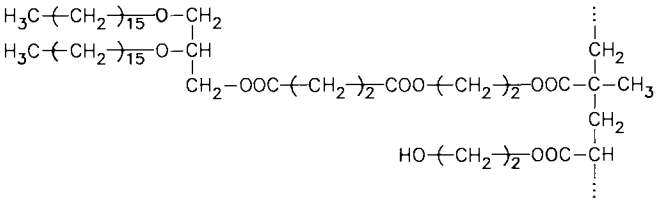
monomeric lipid **34** forms a stable film with solid-analogous packing (curve M). After polymerization in the ordered monolayer, the isotherm exhibits a similar behavior, showing a slightly increased stability of the film (curve P_M). If, however, this spacer-free lipid is polymerized in isotropic solution and then spread, it is no longer capable of forming a highly ordered solid-analogous film (curve P_S). Here, an important role should be played by the molecular weight as well as the tacticity:[118c, 120] The isotherm of a lipid polymerized in isotropic solution should show a similar behavior to that of a monomeric lipid when a small degree of polymerization and a high fraction of syndiotactic units are used.

The isotherms in Figure 29 show that it is possible to maintain mobility and orientability of the alkyl side chains of a copolymer with a main-chain spacer. Whereas the monomeric lipid **35** with a short side-group spacer exhibits a liquid- and a solid-analogous phase (Fig. 29A), the corresponding polymer **37**, prepolymerized in solution, can



37



38

only form a solid-analogous phase (Fig. 29B). After the polymerization of the lipid in the head-group region, the mobility of the alkyl chains is extremely hindered. However, it is recovered by incorporating hydrophilic comonomer units. Indeed, the introduction of an equimolar amount of hydroxyethylacrylate as hydrophilic comonomer (**38**) already suffices to give rise to a liquid-analogous phase (Fig. 29C).

In ordered multilayers, the polymerization of amphiphiles[121] usually leads to the formation of defects.[52, 122] An elegant way to avoid defects induced by polymerization is to prepare LB films from prepolymerized amphiphiles. In Figure 30, the example of copolymer **39** illustrates in how far the content of hydrophilic comonomer influences the structure of LB multilayers. By means of small angle X-ray scattering, it has been shown that the spacings between the individual layers increase with increasing comonomer content.[116a] Furthermore, an increased portion of hydroxyethylacrylate allows a higher layer correlation.

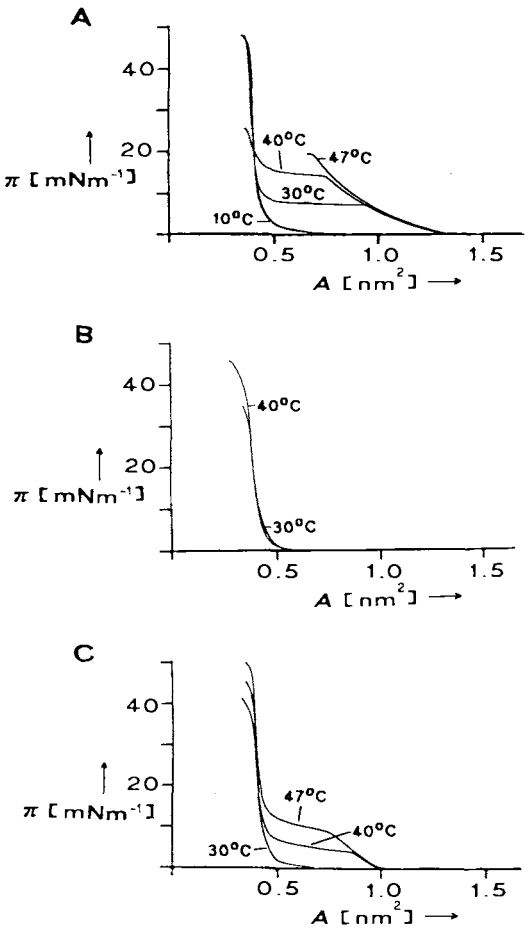


Fig. 29. Isotherms of the monomeric methacrylate **35** and its homo- and copolymers [116a]. A) The monomer **35** with a short side-group spacer forms temperature-dependent liquid- and solid-analogous phases. B) The homopolymeric methacrylate **37** (= $(\mathbf{35})_n$) is only capable of forming solid-analogous phases. C) The statistical 1:1 copolymer **38** from lipid **35** with hydroxyethylacrylate as main-chain spacer forms temperature-dependent liquid- and solid-analogous phases. π = surface pressure, A = area per molecule.

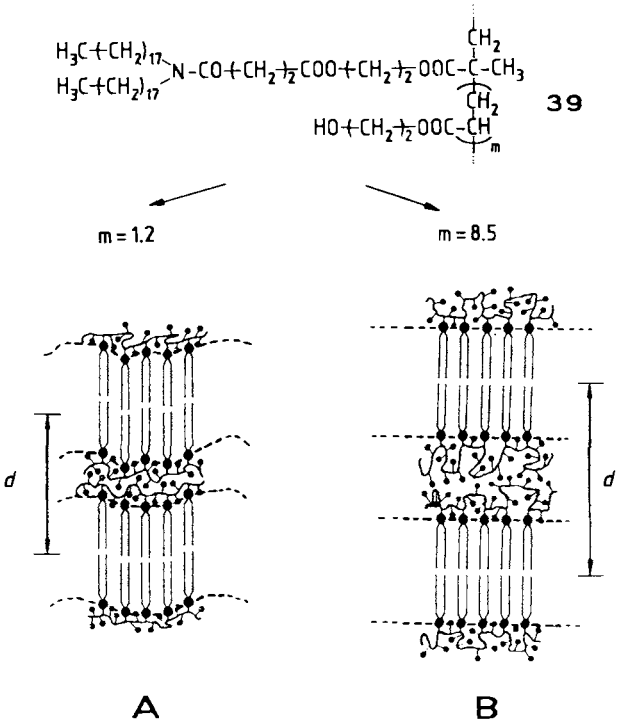

Fig. 30. Multilayers from the amphiphilic copolymer **39**. Schematic representation of the layer thickness d and the layer correlation depending on comonomer contents [116a]. A) Hydroxyethylacrylate content $m = 1.2$ (short hydrophilic main-chain spacer); small distance between layers, poor layer correlation. B) Hydroxyethylacrylate content $m = 8.5$ (long hydrophilic main-chain spacer); larger distance between layers, good layer correlation.

4.6. Polypeptide Liposomes—Bilayers from Polycondensable Lipids

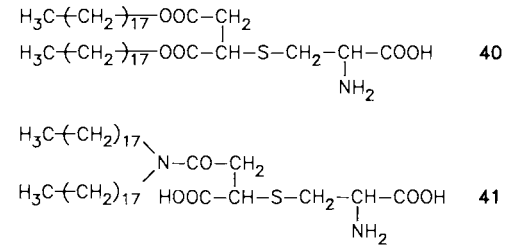
Considering the interest placed in liposomes as drug carrier systems,[87,114a] the idea of building up stabilized but biologically degradable systems looks exciting. The first attempts to prepare biodegradable polymerized liposomes have been described by *Regen* et al. They have used a reversibly polymerizable dimercaptolecithin[105] (cf. lipid **24**, Scheme 3). In this context, polypeptide liposomes seem to be promising.

Up to now, only a few papers exist on polycondensation reactions in ordered systems. The first one was published as early as 1948 by *Katchalsky* et al. It describes the condensation of octadecyl or hexadecyl esters of glycine and alanine in *LB* multilayers.[123] By simply allowing the films to stand, the corresponding polypeptides could be obtained within the films via aminolysis of the esters. In an isotropic solution, no reaction takes place under comparable mild conditions. Thus, the increased reactivity of the amphiphiles in the multilayers is presumably due to their orientation. *Fukuda* et al. later resumed these investigations.[124] Other attempts to achieve a polycondensation in ordered systems are the cross-linking of long-chain urea derivatives with formaldehyde[125] and of glycolipids with epichlorohydrin or divinylsulfone.[126]

The aminolysis of long-chain amino acid esters has also been tried in vesicle membranes. However, the transformation of free amino groups to amide groups leads to a decrease in the hydrophilicity of the lipid head groups to such an extent that the liposomes precipitate.[127] If long-chain Leuchs anhydrides are used for the polycondensation in vesicle membranes, neither educts nor products are capable of forming vesicles. Thus, it is necessary to use mixed membranes with lipids such as the phosphatidylcholine DPPC.[128]

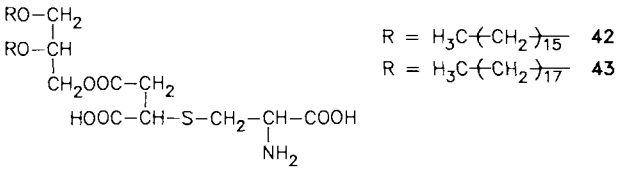
To prepare stable polypeptide liposomes, amino dicarboxylic acid lipids have been introduced by *Neumann* et al.[129] Some examples of polycondensable amino acid and amino dicarboxylic acid lipids are the compounds **40** and **41**–**45**. Liposomes prepared by using the lipids **41**–**45** remain in solution after polycondensation, owing to the additional hydrophilic carboxyl group (Fig. 31).

The lipids **40**–**45** were synthesized by the addition of cysteine or homocysteine to maleic acid derivatives. In water, they form vesicles upon ultrasonication. Furthermore, giant vesicles can be obtained from the glycerine ether derivatives **42**–**45** by means of swelling. The polycondensation of liposomes was achieved by sonicating the lipids **41**–**45** in the presence of a water-soluble carbodiimide at pH = 6.5. The formation of amide bonds, under these conditions, was confirmed by FTIR spectroscopy. Vapor-pressure osmometry reveals that oligopeptides with a mean de-



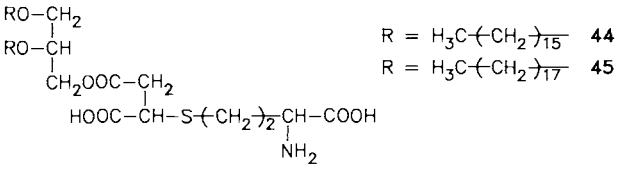
40

41



42

43



44

45

gree of polymerization of 4 are formed by the polycondensation reaction.

In order to characterize the permeability of the monomeric and oligomeric amino acid vesicles, the release of entrapped markers was measured.[129b] The twofold negatively charged fluorescent dye 6-carboxyfluorescein (6-CF) as well as [^{3}H]glucose were used as markers. The monomeric liposomes feature a remarkably small permeability towards these two markers. By using the relatively bulky, charged 6-CF, for example, less than 0.1% release is measured within 30 h at room temperature. The permeability is remarkably higher after polycondensation; however, it is still rather low: after 30 h, these vesicles lose about 1.5% of 6-CF. The diffusion through the membrane is much faster for the uncharged marker compared with the charged 6-CF. The release behavior of monomeric and polycondensed vesicles from lipid **43** is exemplified in Figure 32.

As a comparison, the release kinetics of distearoylphosphatidylcholine (DSPC) vesicles is also given. This lipid was chosen since, just like the monomeric and condensed amino acid lipids, it is in the gel state at room temperature.

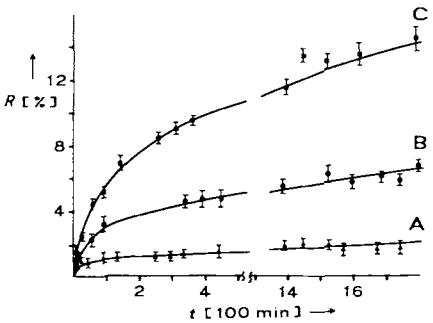


Fig. 32. Release of [^{3}H]glucose from amino acid liposomes (24 °C) [129b]. A) Liposomes made from the monomeric amino acid lipid **43**. B) Peptide liposomes made from the lipid **43**. C) Liposomes made from DSPC.

Figure 32 shows that monomeric amino acid liposomes exhibit a low permeability even when [^{3}H]glucose is used as a marker; their release rate is the lowest found for monomeric vesicles. In this case, too, the permeability is increased by the polycondensation; i.e., the packing density of the lipids is impaired by the oligopeptide formation. Nevertheless, the release rates of polycondensed liposomes are clearly below those of DSPC vesicles.

By means of sonication, isolated oligopeptides can also be used to prepare liposomes, analogously to the use of prepolymerized amphiphiles (see Section 4.5.2). The peptides of the lipids **42**–**45**, together with cholesterol, are even capable of forming giant liposomes.

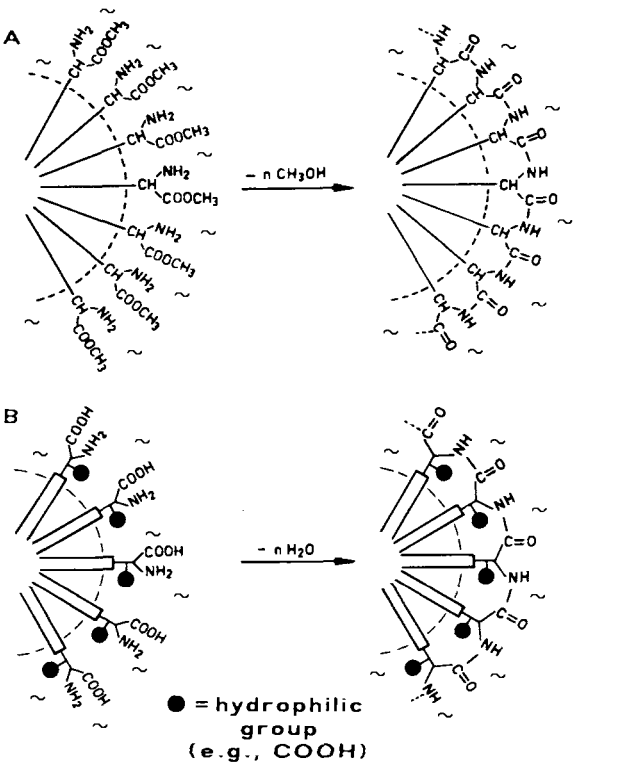

Fig. 31. Formation of peptide liposomes. A) Aminolysis of amino acid esters: reduction of the head-group hydrophilicity leads to the precipitation of liposomes [127]. B) Polycondensation of aminodicarboxylic acids: owing to the additional hydrophilic head group (COOH), such peptide liposomes remain in solution [129].

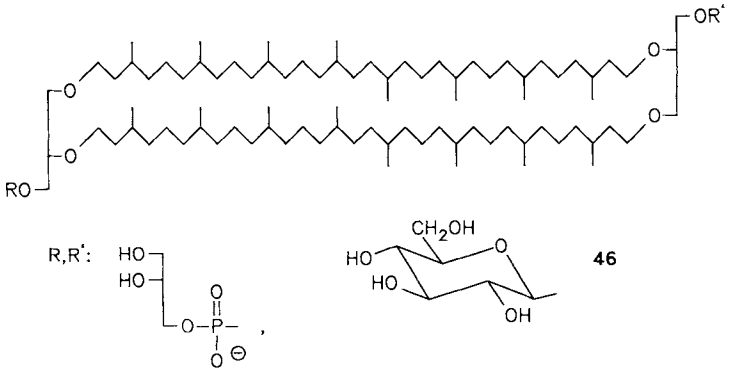
4.7. Stabilization by Means of Membrane-Spanning, Polymerizable Lipids

In archebacteria Nature offers an interesting example of membranes with high stability. They survive under extreme conditions and are therefore able to fill ecological niches. Thermophilic archebacteria thrive at temperatures up to 110 °C, acidophilic bacteria at pH values around 1, and halophilic ones even in saturated sodium chloride solution. Owing to their adaption to unusual habitats, the membrane components of these microorganisms also exhibit unusual structures.[130] The most important membrane lipid fraction is composed of membrane-spanning bipolar lipids (e.g., **46**). They consist of two isoprenoid diphytanyl (C_{40}) chains which are connected via acid-stable ether linkages to form macrocyclic glycerol tetraethers.

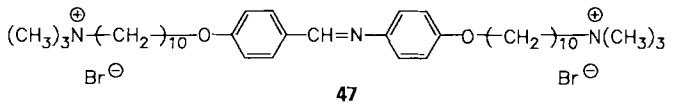


46

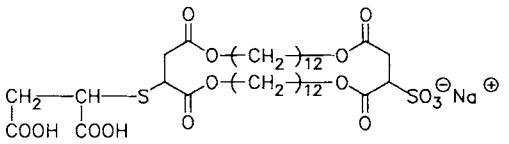
An asymmetrical structure of the bacterial membrane can be achieved with macrocycles carrying two different head groups. Commonly occurring polar head groups are phosphatidylglycerol and mono- or oligosaccharides. Some representatives of these archebacteria do not even possess a cell wall. Thus, the cell membrane is the only barrier towards the aggressive external environment.

Synthetic analogues of the membrane-spanning lipids of archebacteria have been prepared (e.g., **47**–**52**).

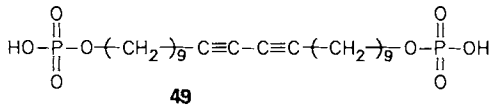
Okahata and *Kunitake* succeeded in preparing monolayer vesicle membranes by using a single-chain bipolar ammonium salt like **47**.[44] The term "bola amphiphile" was used by *Fuhrhop* et al. to describe numerous vesicle-forming bipolar, double-chain (macrocyclic) lipids (e.g., **48**).[131]



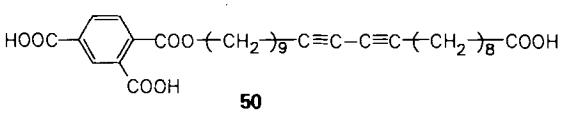
47



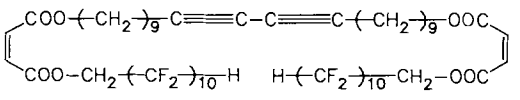
48



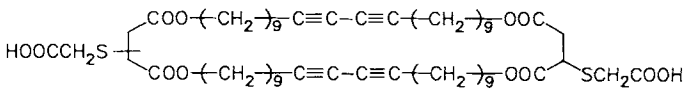
49



50



51



52

Polymerizable bipolar amphiphiles containing butadiyne units, such as **49**–**52**, were introduced by *Bader* et al.[132] In the presence of cholesterol, the single-chain bipolar amphiphile **49** forms vesicle membranes which can be polymerized by UV irradiation at 0 °C.[132a] By using the macrocyclic dicarboxylic acid **52**, small unilamellar vesicles as well as giant liposomes can be obtained. They are in the liquid state and exhibit no phase transition to the solid-analogous state down to a temperature of 4 °C. Since the topochemical polymerization of butadiynes takes place only in the solid-analogous phase,[164] it is not possible to polymerize vesicles of the macrocycle **52**.

Asymmetrical vesicle membranes can be obtained by using the bipolar amphiphiles **48** and **50**, bearing head groups of different size, since the smaller and bigger head groups will preferably point inwards and outwards, respectively, in small liposomes of asymmetrical amphiphiles (Fig. 33). This concept was first used by *Fuhrhop* et al.[131b]

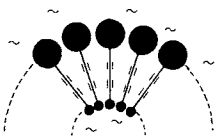


Fig. 33. Asymmetrical membranes of small, unilamellar vesicles made from membrane-spanning butadiyne lipids with head groups of different sizes [132b].

From **50**, vesicles can be prepared by sonication in the presence of 20–30 mol% of an amine (*N*-methylmorpholine, cyclohexylamine). The packing of **50** meets the requirements for a topochemical polymerization. Upon UV irradiation at 0 °C, the clear, colorless vesicle solution of **50** can be polymerized, forming a deep blue solution.[132b] The bulky trimellitic acid head group is located preferentially at the outside of the vesicle. This was proven by NMR experiments using the line-broadening effect of externally added $Mn^{2\oplus}$ ions on the signals of the aromatic protons.

Although liposomes made from a single lipid species are useful in studying basic membrane properties, those made from mixtures of structurally different lipids are a closer match to the complexity of natural systems. One can expect that mixed membranes prepared with membrane-spanning amphiphiles and conventional lipids should show a higher stability, as is schematically pointed out in Section 4.4 (Fig. 24). This stabilizing effect corresponds to that of archebacterial membranes and can also be compared to that of integral proteins. Indeed, electron microscopy reveals that mixed liposomes, made from the membrane-spanning macrocyclic amphiphile **52** and dimyristoylphosphatidylcholine (DMPC) (1:1), have homogeneously mixed membranes.[132b] Differences as to head groups or chain lengths do not result in phase separation (no DMPC domains can be seen by means of their ripple structures; cf. Section 4.8.1, Fig. 39, and Section 6.3.2, Fig.

64). Moreover, the thermal stability of these vesicles is increased by the membrane-spanning component. This has been demonstrated by temperature-dependent measurements of their permeability using 6-CF as an entrapped fluorescent marker.[132b]

4.8. "Liposomes in a Net"—Stabilization of Model Membranes by Polymeric Skeletons

Whereas model membranes can be stabilized by polymerization or polycondensation, i.e., by connecting the lipid molecules covalently, Nature makes use of completely different strategies to stabilize its membranes. Polymeric frames that are attached to the biomembrane provide it with flexibility and stability. Depending on the type of cell, these supporting elements differ considerably. Usually, they are attached to only one side of the membrane. Typical representatives are the cytoskeleton of erythrocytes and the cell walls of plant cells and bacteria.

Can model membranes be stabilized analogously to biomembranes by using polymeric frames?

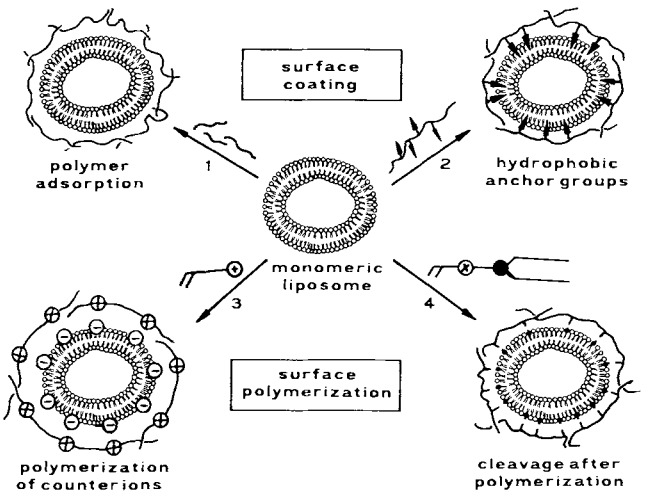

Fig. 34. Possible ways to prepare "liposomes in a net."

The four ways to bind polymers to liposomal membranes, shown in Figure 34, which are also common in Nature, are summarized as follows:

1. Water-soluble polymers can be adsorbed to vesicle membranes by means of hydrophilic or ionic interactions. Examples are the stabilization of lecithin vesicles by the adsorption of carboxymethyl chitin[133] as well as the binding of polylysine to negatively charged vesicle surfaces.[134] *Tirrell* et al. investigated the interaction between synthetic polyelectrolytes and liposomal membranes.[135]
2. Water-soluble polymers can be hydrophobized by modification with fatty acids or cholesterol. By inserting the hydrophobic anchor groups into membranes, these micellar, water-soluble, polymeric amphiphiles can be attached to membrane surfaces. *Sunamoto* et al. made use of this method in order to stabilize liposomes by coating them with hydrophobized polysaccharides.[136] These "artificial cell walls" will be dealt with in greater detail in Section 4.8.1.
3. In order to fix polyelectrolytes to membrane surfaces, charged monomers can be linked to the membrane-forming lipids via ionic forces. The subsequent "matrix polymerization" then proceeds at the membrane surface.[137] The introduction of polymerizable counterions only at the inside of vesicles leads to the formation of polymeric networks attached to the inner membrane surface. Such "artificial cytoskeletons" will be discussed in Section 4.8.2.
4. Liposomes might also be prepared from polymerizable lipids which carry a cleavable spacer (X) between the lipid part and the polymerizable group. The covalent linkage between the liposomal membrane and the enveloping polymer net can be split by the subsequent cleavage of that spacer. Such systems have not been realized yet.

4.8.1. Artificial Cell Walls or Wigs for Liposomes

To simulate the cell wall of plants, water-soluble polymers can be anchored in membranes via hydrophobic residues (Fig. 35). The driving force for the insertion of the anchor groups is the gain in free energy resulting from the transition from a dynamic, micellar system with partially solvent-exposed alkyl chains to a system in which the hydrophobic residues lie in the hydrophobic interior of the membrane.

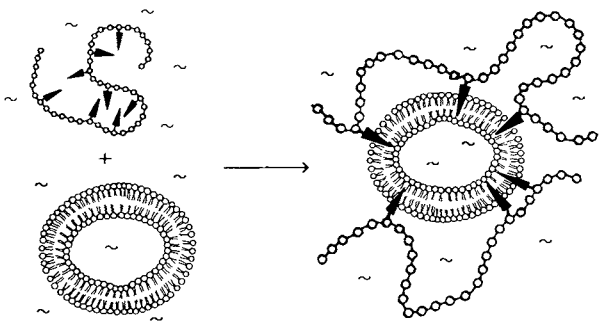

Fig. 35. Schematic drawing of the interaction of a liposomal membrane with a micellar polymer with hydrophobic anchor groups.

Examples of such interactions between polymers and membranes have been known for some time: The adsorption of synthetic polymers with hydrophobic anchor groups to cell membranes, for example, was described as early as 1964.[138] The first experiments with *O*-stearoyl derivatives of the polysaccharide dextran followed soon after.[139] *Wolf* et al. used similar polymers to study the lateral diffusion of polymers incorporated or attached to BLMs and cells.[140] In 1984 *Sunamoto* et al. introduced polysaccharide-coated liposomes as carrier systems for drugs.[136, 141] These are small, uni- or multilamellar vesicles, coated with palmitoyl- or cholesteryl-derivatized polysaccharides (pullulan, amylopectin). These asymmetrically coated liposomes feature a decreased permeability for 6-CF and an increased stability towards enzymatic de-

gradation by phospholipase D. *Kobayashi* et al. described mixed liposomes made from DPPC and synthetic *O*-octadecyl dextran.[142]

The coating of liposomes with polymers is of interest not only as regards the increase in stability, but also as regards surface variation. For example, it was demonstrated that a polysaccharide coating of liposomes leads to an altered distribution in the body.[136, 141, 143] Recently, even fragments of monoclonal antibodies were attached to a polysaccharide in addition to the hydrophobic anchor groups.[144] In vitro, the resulting "immunoliposomes" are bound to specific cells to a higher extent than the corresponding antibody-free liposomes.

Hydrophobized polysaccharides interact also with BLMs. Indeed, *Möllerfeld* et al. observed a dramatic increase in the mechanical stability of BLMs made from glycerol monoleate.[145] All other membrane properties, such as the transport of the lipophilic ion dipicrylamine, however, are influenced only slightly by this method of stabilization.

So far, attempts to simulate an artificial cell wall have only been made as regards the BLM and small vesicle model systems. However, for a direct observation of the insertion process of the anchor groups and its consequent effects on the membrane (e.g., morphological changes in the system), one has to use giant liposomes[146] as model membranes. These are form-flexible and can be observed with a light microscope. For these measurements, a temperature-controlled flow chamber[148] has been constructed, in which giant liposomes (ca. 20 μm in diameter) are prepared directly by swelling a lipid film. By using a syringe, the medium can be exchanged or additional components can be injected (Fig. 36).

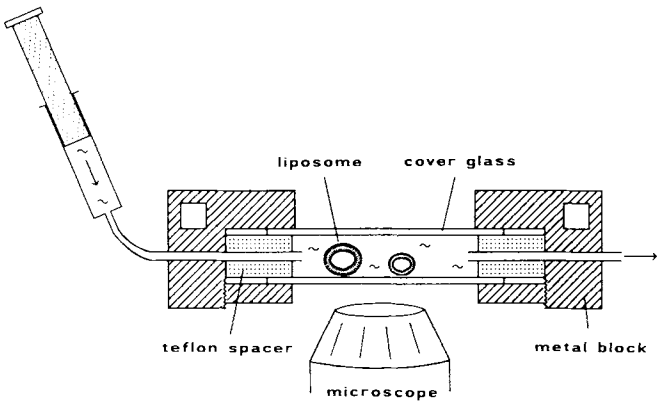

Fig. 36. Construction of the flow chamber for the observation of giant liposomes (schematic cross sectional view). The volume is 200 μL; the metal block is temperature-controlled. With the help of a syringe the medium can be gradually exchanged. Observations are carried out by using an inverse microscope (phase contrast and epifluorescence).

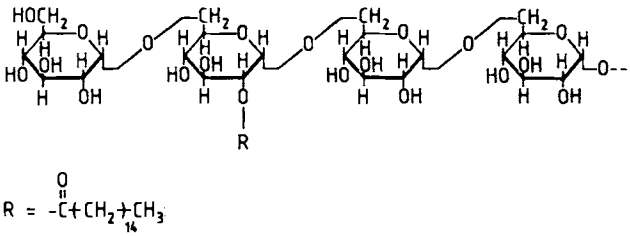
A series of amphiphilic polymers consisting of *O*-palmitoyl derivatives of the natural, linear polysaccharide dextran have been synthesized[60] (Fig. 37).

When a solution of one of those amphiphilic polymers is added to a preparation of giant liposomes, above a critical concentration, a significant morphological change can be observed: tubelike liposomes become constricted. In the course of this process structures resembling strings of pearls develop along the original longitudinal axis of the liposome (Fig. 38). These morphological changes are due to the insertion of the hydrophobic anchor groups into the bilayer. On the one hand, the unmodified dextran, without hydrophobic residues, shows no effect. On the other hand, a clearly membrane-associated fluorescence can be observed when a hydrophobized and fluorescence-labeled dextran is used. The critical concentration, above which these "strings of pearls" are formed, decreases with increasing degree of substitution and increasing molecular weight of the dextran derivative.[147] The formation of structures resembling strings of pearls is shown in Figure 38 together with a schematic representation of the insertion process.



$R = -\overset{O}{\overset{\|}{C}}-CH_2-(CH_2)_{14}-CH_3$

Fig. 37. *O*-Palmitoyldextrans [60] with mean molecular weights ranging from 43000 to 160000 and degrees of substitution between 3 and 6 mol% were used for the studies of giant liposomes described in the text. These dextrans have 15 to 40 anchor groups per polymer chain.

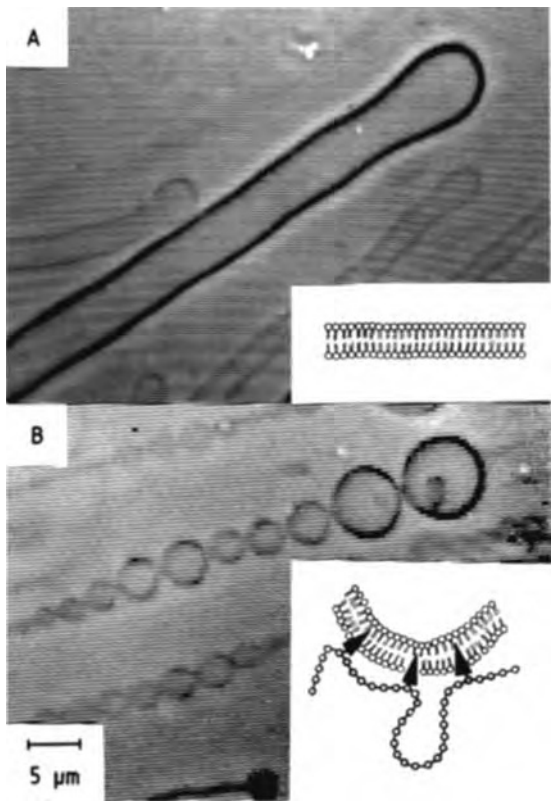


Fig. 38. Morphological change of a tubelike liposome owing to the interaction with a hydrophobized dextran (phase contrast micrograph and schematic explanation) [60, 147]. A) Before injection of the micellar polymer. B) After the injection.

According to these observations, the insertion of the anchor groups only in the outer half of the membrane induces a curvature (see Section 6.2) which leads to the formation of the "string of pearls." This is obviously a case of a polymer effect: Unsubstituted dextrans do not induce this process, whereas it occurs with octyl glucoside only at concentrations which are five orders of magnitude higher. This polymer effect is based on the fact that the locally high concentration of the anchor groups leads to a cooperative insertion into small membrane regions.

A similar kind of constriction process plays an important role in Nature in receptor-mediated endocytosis. In this case, the attachment of the protein clathrin to the inside of the cell membrane leads to the formation of "coated pits" and to the consequent detachment of "coated vesicles." They have an important transport function in the uptake of LDL (low-density lipoproteins).[149] These types of biomembrane processes will be discussed in detail in Section 6.2.

By means of freeze fracture electron microscopy,[150] it is possible to directly demonstrate the insertion of the hydrophobic anchor groups into the outer membrane of DMPC liposomes.[60, 147] By using this method, surface structures of membranes can be observed with a transmission electron microscope. Upon annealing between the pretransition and the main transition, typical ordered structures develop in liposomes from natural lecithins.[151] Owing to their appearance, they are called ripple phases. A liposomal membrane made from pure DMPC exhibits homogeneous ripple spacings of 12 ± 2 nm. Small amounts of impurities in the membrane already lead to a significant disturbance of these ripple structures.[152] Figure 39 explicitly illustrates the insertion of the hydrophobic anchor groups by means of the interaction between a hydrophobized polyvinylpyrrolidone derivative and DMPC liposomes.[60] The outer surface of the liposome shows a disturbed and widened ripple structure. However, the inner membrane surfaces of the multilamellar vesicle, which are made visible by the fracture, exhibit the perfect, original ripple structure of pure DMPC. This demonstrates that the added amphiphilic polymers, as schematically shown in Figure 35, only interact with the outer liposome surface and cannot penetrate through the membrane. A further attempt to insert amphiphilic compounds into liposomal membranes is described in Section 5.4.

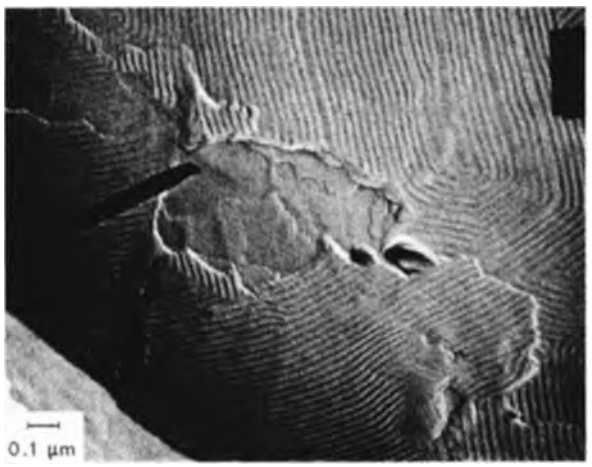

Fig. 39. Freeze fracture electron micrograph [204] of a multilamellar DMPC liposome after the interaction with a hydrophobized polyvinylpyrrolidone derivative; widened and disturbed ripple structure in the outer surface; undisturbed ripple structure of pure DMPC in the inner membrane layers [60].

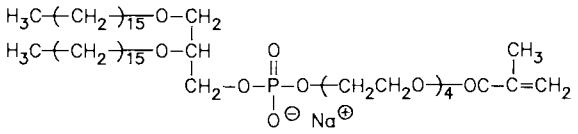
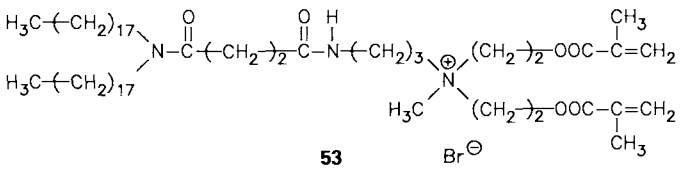
4.8.2. Cytoskeleton Models or the Stabilization from Inside

In animal cells, the highly structured interior is spanned by a three-dimensional protein network, namely, the cytoskeleton. Among other functions, it serves as a static skeleton of the cell, thus maintaining its shape and stabilizing the plasma membrane. A typical example for the stabilizing function of the cytoskeleton is the spectrin network of erythrocytes.[153] Here, the combination of stability and flexibility is achieved by a two-dimensional protein network which is coupled to the lipid/protein bilayer (cf. Fig. 18). The protein network consists of filamentous spectrin molecules. Tetramers of this protein are cross-linked by another protein, actin. Some of these actin molecules are fixed to the cytoplasmic end of an integral membrane protein (Band III) by an anchor protein, known as ankyrin. A similar coupling of the cytoskeleton probably exists to the membrane-spanning protein glycophorin.[153a] Furthermore, it is assumed that the spectrin molecules are bound to negatively charged lipids in the inner-membrane leaflet by electrostatic forces.[154]

Because of the high complexity of the interaction between plasma membrane and cytoskeleton, it is hardly possible to understand the mechanical and structural properties of erythrocyte membranes without parallel model investigations. A simple model of an erythrocyte membrane was prepared from a mixture of DMPC and the polymerizable lipid **36b**.[154, 155] Here, the polymerizable methacrylate unit is kept in the aqueous phase by the hydrophilic tetraethylene oxide spacer[98b] (see Section 4.5.2).



36b



53

The polymerization of such mixed liposomes leads to the formation of linear macromolecules at both membrane surfaces. By using a mixture of **36b** and lipid **53**, which contains two polymerizable units in the head-group region, cross-linked macrolipids are obtained. This leads to the formation of polymeric networks at both bilayer leaflets (Fig. 40).

An even better approach to simulate the cytoskeleton of the cell is a liposome, in which polymeric networks are

only inside the vesicles. It is possible either to attach two-dimensional networks to the inner membrane surface or to fill the interior of vesicles with three-dimensional cross-linked polymeric gels. Such three-dimensional networks,

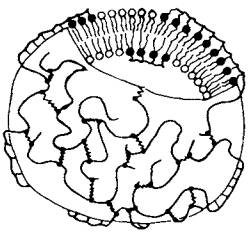


Fig. 40. Schematic drawing of a mixed liposome composed of polymerized lipids which are embedded in the monomeric lipid matrix. Additionally, the polymer chains are connected with one another forming a polymer network [155].

which span the complete interior of liposomes, are readily accessible by the polymerization of liposome-encapsulated hydrophilic monomers. By using this method, cross-linked polyacrylamide gels in the aqueous interior of liposomes have been prepared.[156] After destroying the lipid bilayer by addition of a surfactant, the size of the gel particles, as determined by light scattering and electron microscopy, remains nearly unchanged.

Two-dimensional polymeric networks that are attached only to the inner or the outer surface of the vesicle membrane via electrostatic interactions can be prepared by the exchange of the counterions at the outside of SUVs.[157] This is shown schematically in Figure 41.

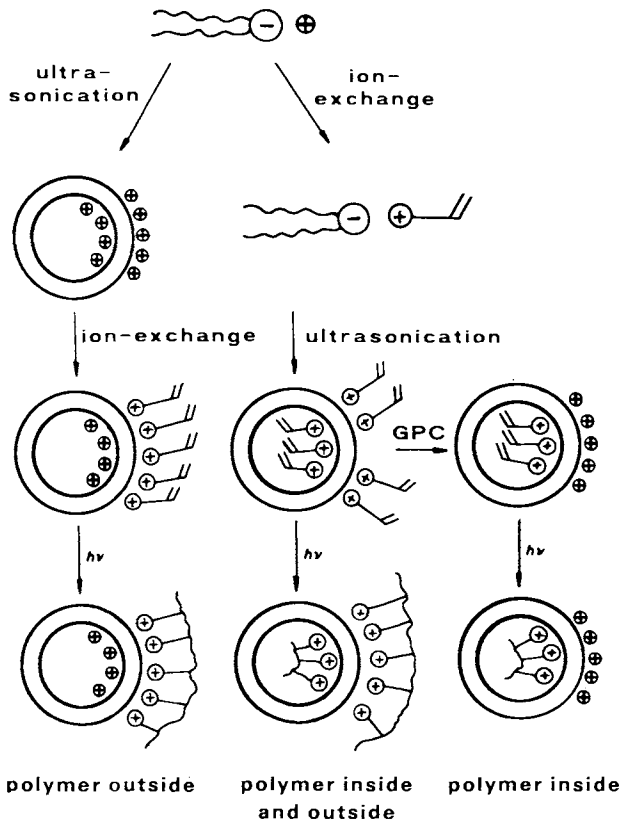

Fig. 41. Preparation of vesicle membranes with asymmetrically or symmetrically bound polyelectrolytes from lipids with polymerizable counterions [157]. GPC = gel permeation chromatography.

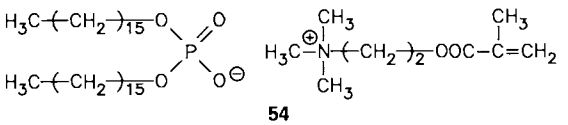
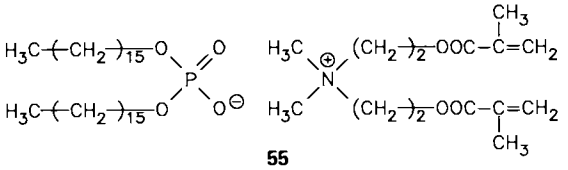
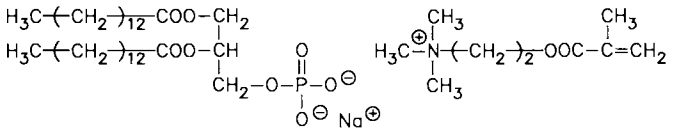
To realize this concept, the salts **54**–**57**, prepared from anionic lipids and polymerizable counterions, were used.[157] In the case of **54** and **56**, choline methacrylate is



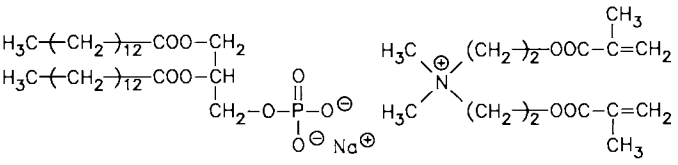
54



55



56



57

bound as a counterion to negatively charged lipids (dihexadecyl phosphate or the anion of dimyristoylphosphatidic acid (DMPA)). This leads to linear polymer chains. Additionally, the salts **55** and **57**, with a counterion bearing two polymerizable groups, were used to prepare polymeric networks. The different routes to prepare vesicles with ionically linked polymers made with these lipids, as shown in Figure 41, are discussed briefly below.

Polymerizable counterions are introduced to the outer surface of unilamellar vesicles by exchanging $Na^{\oplus}$ against alkylammonium ions containing a methacrylate moiety. This process can be monitored by UV spectroscopy. Upon irradiation with UV light, the counterions can be polymerized at the outer membrane surface. In order to create macromolecules at the inner membrane surface, vesicles with polymerizable counterions on both sides of the lipid bilayer have to first be prepared. The polymerizable counterions at the outer membrane surface can then be replaced by $Na^{\oplus}$ by means of gel permeation chromatography (GPC). The polymerization of this vesicle system leads, in the case of lipid **55**, to a highly cross-linked polymeric network which is only attached to the inside of the vesicle membrane.

The phase transition temperature of the lipid bilayers strongly depends on the sort of counterion bound to the vesicle. Here, DMPA vesicles with a symmetrical distribution of the counterions are given as an example. Liposomes made from **56** with polymerizable counterions exhibit a phase transition temperature which is decreased to 31 °C, compared with liposomes made from the corresponding disodium salt (50 °C). By polymerization of the

cations of **56** at both membrane surfaces, the phase transition temperature is increased again.[157] Analogous results were obtained for dihexadecyl phosphate vesicles.[158] Figure 42 shows a model for the strong influence of the monomeric or the polymeric counterions on the phase transition.

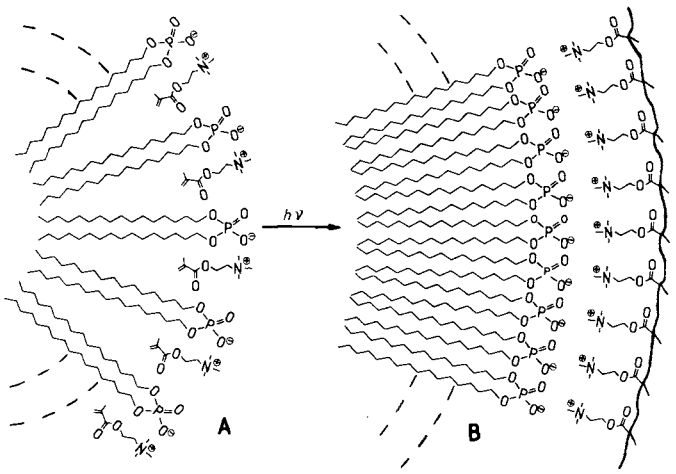


Fig. 42. Schematic drawing of the influence of choline methacrylate counterions on the packing of lipids in the membrane [158]. A) The monomeric counterions are partially inserted in the membrane, thus disturbing the packing of the lipids. B) The polymer is not inserted in the membrane, thus allowing a denser packing of the lipid molecules.

The monomeric choline methacrylate counterion thus leads to a fluidization of the membrane, owing to its partial insertion into the lipid bilayer. Since the phase transition temperature is shifted to higher values after polymerization, it can be assumed that the resulting polymer is no longer embedded in the membrane, thus allowing a denser packing of the lipid molecules. This model is also supported by results from permeability measurements.[158] Furthermore, comparative investigations of the stability of symmetrical vesicles of lipid **54** towards organic solvents were carried out using monomeric and polymeric counterions. Turbidity measurements reveal that the polymeric "liposomes in a net," in contrast with the unpolymerized counterparts, are even stable in 60% methanol.

A further step in simulating the cytoskeleton of erythrocytes is the additional fixation of an ionically fixed polymeric network to the inner membrane surface via covalently bound hydrophobic anchor groups. Such an "artificial cytoskeleton" was built up with vesicles consisting of a mixture of the lipids **53** and **54**[158] (Fig. 43). First, the polymerizable counterions are removed only from the outer vesicle surface. Then, the choline methacrylate counterions, bound to the inner membrane leaflet, are copolymerized with the cross-linking lipid **53** by means of UV irradiation. Thus, a two-dimensional polyelectrolyte network is formed at the inner-membrane surface. In addition to its electrostatic bonds, this network is fixed to the lipid bilayer via covalently linked hydrophobic anchor groups.

Comparative release measurements carried out on monomeric and polymerized vesicles using [^{3}H]glucose revealed that such an "artificial cytoskeleton" does not change the membrane permeability. Thus, it is the lipid bilayer, and not the polymeric skeleton, which indeed acts as the permeability barrier.[158] Hence, these polymerized vesicles formally behave like erythrocytes: the polymer controls their physical stability as well as their shape, whereas the lipid bilayer controls their permeability.

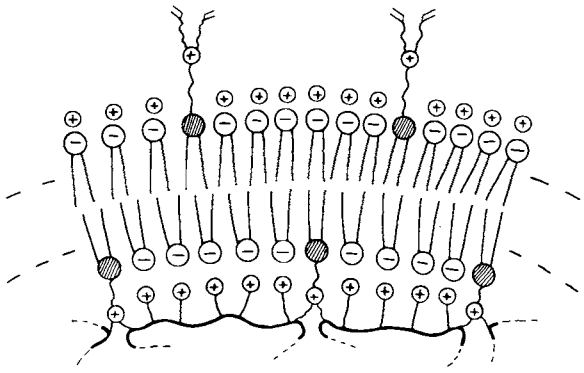

Fig. 43. "Artificial cytoskeleton" at the inner surface of vesicle membranes, prepared according to the following procedure [158]: (1) preparation of liposomes from 90 mol% of **54** (polymerizable counterions) with 10 mol% of **53** as a cross-linker (covalently bound methacrylate groups); (2) removal of the polymerizable counterions from the outer surface of the vesicle membrane via GPC; (3) copolymerization of the ionically or covalently bound methacrylates at the inner surface of the vesicle membrane.

5. The Use of Model Membranes to Study Biological Recognition Processes

The complex molecular processes in biological systems can only proceed along ordered paths if they are selectively controlled. Thus, the development of multicellular organisms can hardly be imagined without the capability of intercellular communication. The decisive step in such an information exchange is the binding of a signal molecule to a specific receptor which is usually bound to the membrane. Analogous recognition reactions are of significant importance for the immune system of vertebrates, too. The various responses of the immune system recognize and eliminate invading organisms as well as toxic substances produced by them. Because immune reactions are destructive, it is essential that they be made only in response to molecules which are foreign to the host. Without this distinction between foreign and autologous molecules, fatal autoimmune reactions would result. Therefore, biologists, biochemists, and biophysicists place great interest in the structure and the function of biological membranes as well as their interaction with signal molecules. In the course of these investigations, simple model membranes have also been used during the last few years.[82,159] In addition, the surface recognition of liposomes by target cells is of decisive importance for specific drug delivery.[87]

What kind of substances play a role in the manifold recognition reactions in Nature? The most important membrane components for surface recognition are those of the glycocalix, the glycoproteins and the glycolipids.[66] In the cell membrane, they are responsible for vital functions and properties such as cell recognition, antigenicity, histocom-

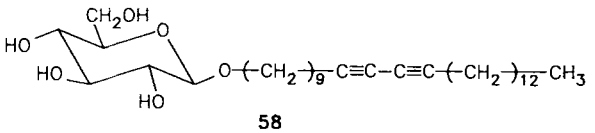
patibility, and lectin affinity. Sections 5.1, 5.3, and 5.4 will deal with the recognition of sugar structures in model membranes by means of lectins and antibodies. Moreover, the most well known and the best-investigated regulated process is the replication and transcription of DNA as well as the translation of RNA.[160] In this case, the recognition reaction is the base-coupling of nucleic acids. Model experiments in which these reactions are applied will be discussed in Section 5.2.

5.1. Reversible Sugar–Lectin Interaction with Polymerized Liposomes

Sugar structures attached to membranes can be recognized by lectins. These proteins, originally only found in plants, possess specific binding sites for certain sugars.[161] A well-studied representative is concanavalin A (Con A) which can bind α-glucopyranosides and α-mannopyranosides. It is a tetrameric protein where each subunit carries one binding site. The saturation of these binding sites with the low-molecular-weight sugars does not lead to aggregation of Con A. If, however, several of those sugar units are components of a supramolecular system such as a cell, agglutination and precipitation occurs after lectin addition. This process is reversible since the addition of a large amount of one of those pyranosides leads to the dissolution of the precipitate, thus reforming the original cell dispersion.[162]

Two principles can be used to carry out such biological recognition reactions with polymerized membrane systems. On the one hand, natural lipids with recognizable structures can be incorporated into polymeric membranes. On the other hand, polymerizable lipids with a recognizable head group can be synthesized.

Several polymerizable glycolipids with different sugar head groups were prepared a few years ago.[163] These carry a butadiyne unit as the polymerizable group in the hydrophobic chain.



58

The interaction between the glucose derivative **58** and Con A has been investigated in monolayers[163] and liposomes.[114a,b] Liposomes of **58** can be polymerized by UV irradiation, exhibiting a color change from colorless via blue to red, which is typical for butadiyne derivatives.[72,164] The experiment with Con A and sugar-bearing polymerized liposomes is schematically shown in Figure 44.

After adding Con A to a deep red solution of polymerized liposomes prepared from **58**, agglutination occurs within a few seconds: a red precipitate is formed, the supernatant becoming colorless. If, however, α-methylmannopyranoside, which binds much stronger to Con A, is then added, the precipitate is redispersed, thus leading to the original clear red solution of the liposomes. So the result is a competitive replacement of the liposomal-bound sugar groups by the soluble sugar.

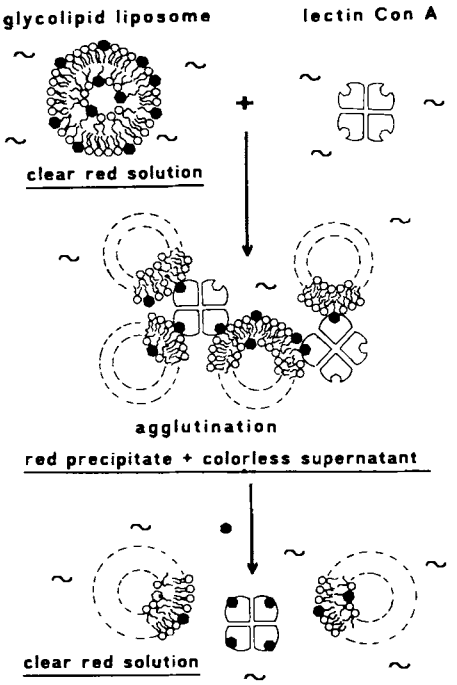


Fig. 44. Schematic representation of the reversible interaction of concanavalin A with polymerized glycolipid liposomes made from **58** [114b]. ● = sugar.

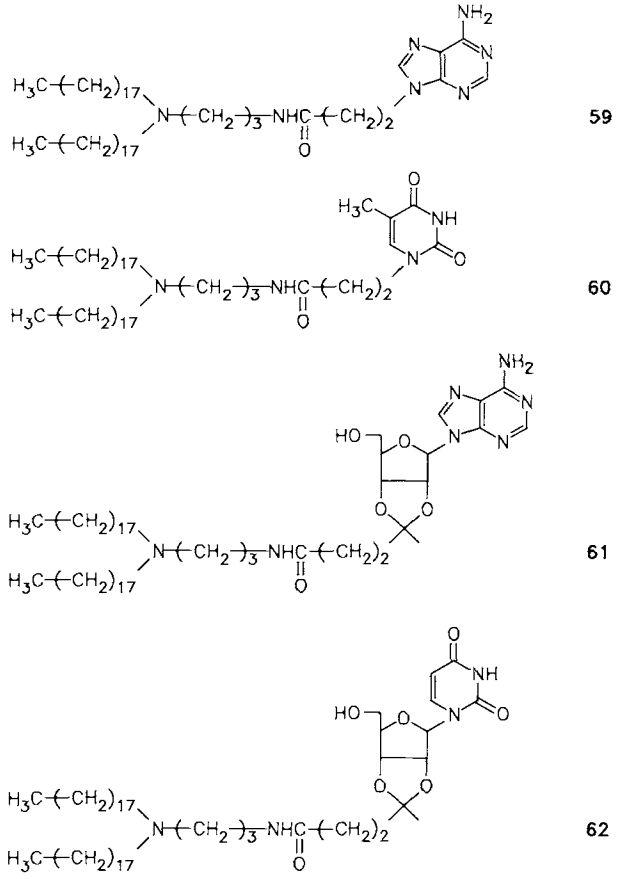
From simple qualitative experiments of this kind, one can proceed to investigations using synthetic and biologically relevant sugar structures[165] or natural glycolipids. Such model investigations gain increasing significance, for example, as regards the simulation of immunological phenomena and their medical application (affinity chemotherapy[166]).

5.2. Nucleolipid–Nucleobase Interaction in Monolayers

Another recognition reaction that occurs in Nature is the base-pairing in DNA. To learn more about the base–base interaction and the relation between structure and function, a large number of polynucleotide analogues have been synthesized.[167] The most common models are linear, uncharged polymers with nucleobases as side groups. With these polymers, specific interactions have been observed.[167,168] In none of these investigations were the nucleobases in an oriented state. In order to use the specific base-pairing in surface recognition reactions, nucleolipid monolayers and their interaction with nucleobases, dissolved in the subphase, were also recently investigated.[169] *Kornberg* et al. used such ordered nucleolipid monolayers to show that certain proteins, such as the B1 subunit of ribonucleotide reductase, are specifically bound in the form of a two-dimensional crystal.[170]

Compounds **59**–**62** are examples of new, uncharged nucleolipids, which form ordered structures like monolayers and liposomes.[169b,171] Despite their consistently big and only weakly hydrophilic head group, these nucleolipids



59

60

61

62

form stable, solid-analogous monolayers, with the nucleobase head groups dipping into the subphase. Their isotherms should be affected by the interaction of these nucleolipids with nucleobases as substratum in the aqueous phase. Figure 45 exhibits the surface-pressure behavior of the uridine lipid **62** to exemplify the influence of a monomeric nucleobase dissolved in the subphase.

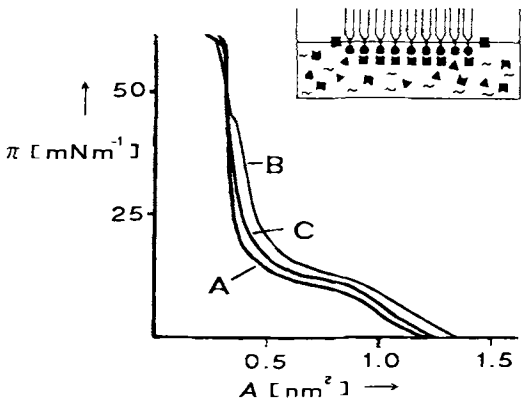


Fig. 45. Isotherms of the uridine lipid **62** on different subphases (20°C) [169b]: A) water; B) 0.01 M adenine (complementary) (■); C) 0.01 M thymine (noncomplementary) (▲). π = surface pressure, A = area per molecule.

The characteristic phase behavior of the nucleolipid **62** (curve A) is basically not changed by the dissolved nucleobases. Liquid-analogous as well as solid-analogous phases are observed, and the molecular area is slightly increased after addition of the bases. The influence of adenine (curve B), which is complementary to the nucleolipid, is slightly stronger than that of thymine (curve C).

The interaction between a nucleolipid monolayer and polymeric nucleotide bases is illustrated by means of the adenosine lipid **61** (Fig. 46). The two polynucleotides re-

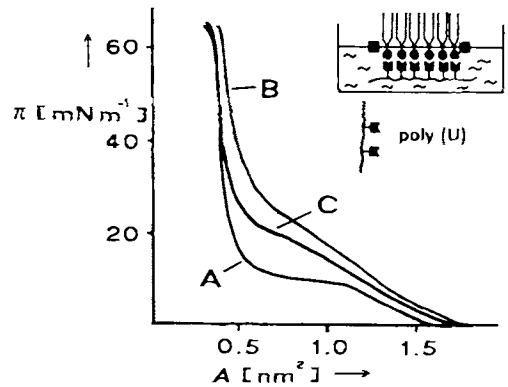

Fig. 46. Isotherms of the adenosine lipid **61** [169b] (subphase: PBS (= phosphate-buffered saline) buffer, pH 7.3, 1.5×10^{-3} M): A) in the absence of a polymeric nucleobase; B) 1.5×10^{-5} mol base L^{-1} poly(U) (complementary); C) 1.5×10^{-5} mol base L^{-1} poly(A) (noncomplementary). π = surface pressure, A = area per molecule.

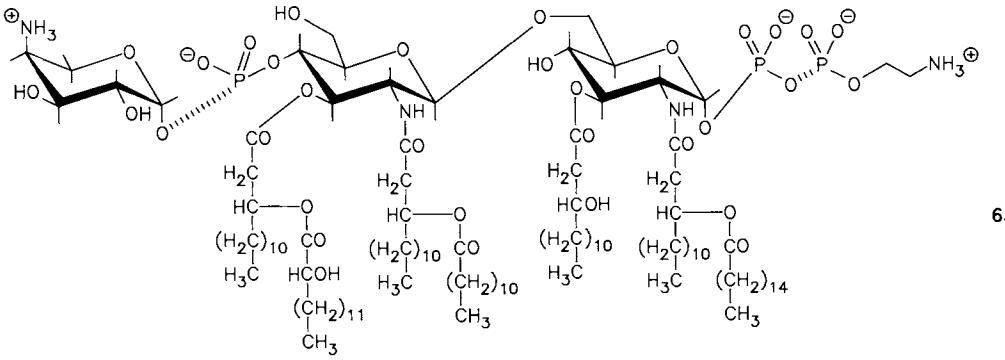
veal a noticeably different influence on the isotherms of **61** if the surface pressure exceeds 15 mN m^{-1}. As regards the noncomplementary polyadenine nucleotide poly(A), it is already expelled from the head-group region at a surface pressure of 40–50 mN m^{-1}. Thus it loses all influence on the solid-analogous packing of the monolayer (curve C). In contrast, the poly(U) base, which is complementary to the lipid head group, exhibits a considerable interaction with the monolayer (curve B) even at high surface pressures.

In the case of liposomes made with nucleolipids and the phosphatidylcholine DPPC (3 : 1), no clear interaction with monomeric nucleobases can be demonstrated. Nevertheless, a significant interaction between liposomes and polymeric nucleobases was observed. However, the hypochromicity effects (decrease of the extinction coefficient after base-coupling) display no significant difference between specific and nonspecific interaction.[169b] This may be due to the fact that the stronger ionic interaction (see Section 4.8) of the polynucleotides with DPPC is superimposed on the weaker base–base interaction.

5.3. Model Investigations of the Interaction between Bacteria and the Complement System

In humoral immune reactions, the outer membrane of gram-negative bacteria is damaged by the complement system. The resulting hydrophilic pores lead to the death of the bacterium. The complement cascade (C) consists of at least 14 serum proteins which are activated in a specific order.[172] The classical pathway of C-activation is initiated by the adsorption of the first component C1 to the surface of the bacterium. This involves the binding of the C1 subcomponent C1q to the lipid A (**63**) of the outer membrane.[173] This first step of the complement cascade can



63

also be investigated by using model membrane systems. Indeed, **63**, the lipid anchor of the lipopolysaccharide (LPS), has already been incorporated into model membranes.[174] In cooperation with the group of *Loos*, the interaction between the complement component C1q and **63** was studied in monolayers and liposomes.[175] Lipid A (**63**) consists of seven hydrophobic alkyl chains of different lengths and one hydrophilic head group made up of glucosamine units as well as phosphate and ammonium groups.[176] C1q is built up of six collagen-like triple-stranded helices which are linked together at one end (Fig. 47). The free ends carry globular head groups that function as recognition sites. The C1q molecule has a molecular weight of 410000 and consists of 18 polypeptide chains.[177]

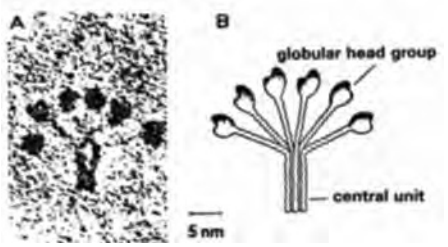


Fig. 47. A) Electron micrograph; B) schematic representation of the complement component C1q [177].

Figure 48 shows the isotherms of the purified oligomer-like **63** at different temperatures. The monolayers exhibit liquid- and solid-analogous phases and have a remarkable stability up to a temperature of 37 °C. The molecular area of about 1.3 nm^2 per molecule in the solid-analogous phase is within the range expected for a lipid with seven alkyl chains.

In order to investigate the interaction between **63** and C1q, the lipid A monolayer was kept under constant pressure while C1q was injected into the subphase. After the injection of C1q, one can clearly see a strong increase in molecular area if the monolayer is kept at a pressure of 2 mN m^{-1}, i.e., in the liquid-analogous state (Fig. 49). If, however, a higher surface pressure (20 mN m^{-1}) is applied, no change in the area per molecule is observed. In the solid-analogous state, the lipid A molecules are evidently so densely packed that the C1q head groups cannot penetrate the monolayer. For a recognition reaction to take place, not only does the specificity of the recognizable

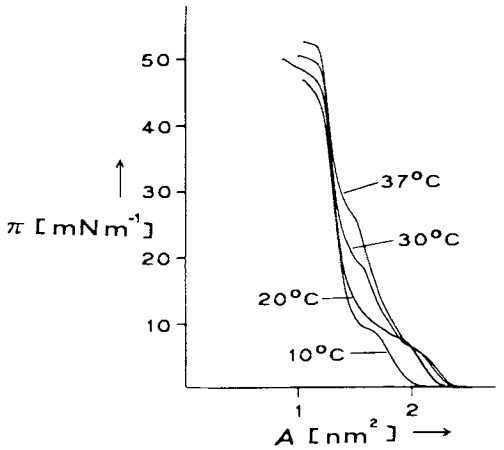

Fig. 48. Isotherms of **63** at 10, 20, 30, 37 °C (subphase: water). π = surface pressure, A = area per molecule.

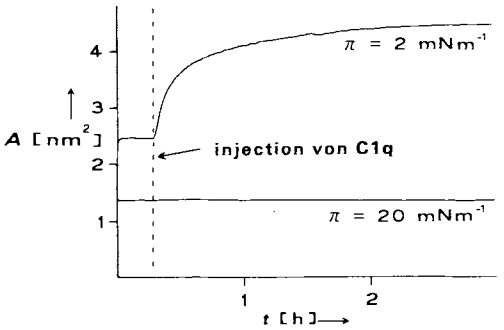

Fig. 49. Interaction of the protein C1q (1 μg mL^{-1}) with lipid A monolayers (20 °C): Injection of C1q (----) into the subphase at a constant pressure of 20 mN m^{-1} (solid-analogous phase) and 2 mN m^{-1} (liquid-analogous phase); strong interaction (expansion of the monolayer) only in the fluid state. A = area per molecule.

groups seem to be important, but also the existence of a liquid-analogous phase, common in biological membranes.[178]

The binding of C1q to lipid A monolayers was confirmed by investigations with a fluorescein-labeled anti-C1q antibody. These experiments were carried out with a film balance which was combined with a fluorescence microscope[180] (Fig. 50). Mixing diagrams of **63** and DPPC exhibit a complete miscibility of both components. However, these experiments do not give evidence as to whether the phase separation, which can be seen in Figure 50 (see also Section 6.1), already occurs owing to the adsorption

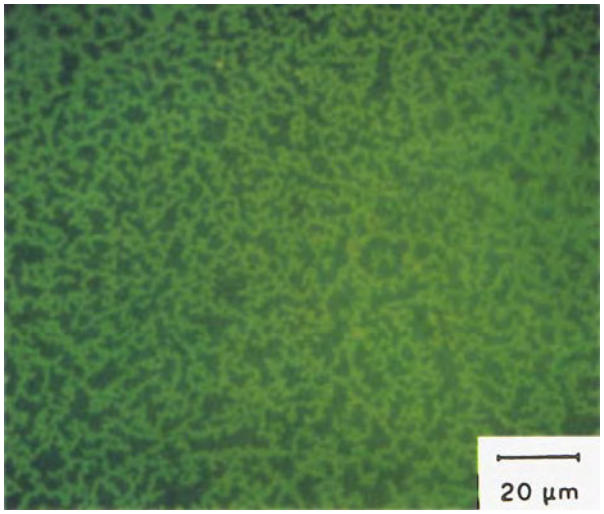

Fig. 50. Epifluorescence micrograph to show the binding of C1q to a monolayer formed from lipid A and DPPC (1:4) (cf. Fig. 51). Injection of a fluorescein-labeled antibody against C1q (anti-C1q FITC IgG [179], FITC = fluorescein isothiocyanate) into the subphase of the monolayer with bound C1q, resulted in the appearance of a fluorescence due to binding of the FITC antibody to the membrane-fixed C1q-lipid A complex.

of C1q to the lipid A monolayer, or if it is caused later by the C1q-antibody interaction.

As is known from other studies, C1q binds to **63** via its globular head-group structures. Therefore, the simplified model shown in Figure 51 can be postulated to explain the monolayer results described above.

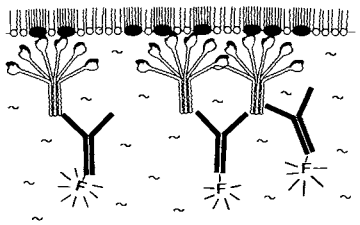

Fig. 51. Schematic representation of the adsorption of C1q to a monolayer formed from lipid A and DPPC and the binding of the fluorescein-labeled antibody. F stands for fluorescein isothiocyanate.

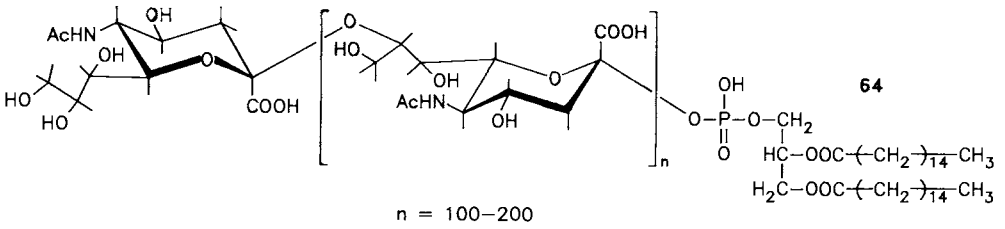
By making use of giant liposomes, it was also possible to demonstrate the interaction between C1q and **63** using FITC-labeled antibodies (for this method see Section 5.4). Here, too, it was found that, after the addition of C1q, only those liposomes containing **63** are made visible in the fluorescence microscope by the antibody.

5.4. Induction of Membrane Processes by Recognition Reactions at the Surface of Vesicles

A further example of a recognition reaction at the membrane surface is the binding of a specific antibody to its corresponding antigen at the membrane. Together with the group of *Bitter-Suermann*,[181] the polysaccharide K1 (**64**) from *E. coli* was used as a model system to investigate such surface reactions.[60]

K1 consists of α-(2-8)-linked sialic acid units[182] which are connected to a lipid residue. It belongs to the group of acidic capsular polysaccharides of the outer bacterial membrane. They are supposed to play a role in the serum and phagocytosis resistance of gram-negative bacteria.[181a] To prove the incorporation of **64** into model membranes, giant liposomes of the phosphatidylcholine DMPC were used. A micellar solution of **64** is injected into the chamber, shown in Figure 36, containing such a liposome preparation (Fig. 52A). After the insertion of the lipid anchors into the liposomal membrane (Fig. 52B, see also Section 4.8.1), the fluorescence-labeled anti-K1 antibody[181b] is added. The recognition between antigen and antibody (Fig. 52C) can be shown by means of fluorescence microscopy:



the originally diffuse fluorescence of the dissolved antibody becomes concentrated on the liposome surface.

The comparison of a phase-contrast micrograph (Fig. 53A) with the corresponding epifluorescence one (Fig.

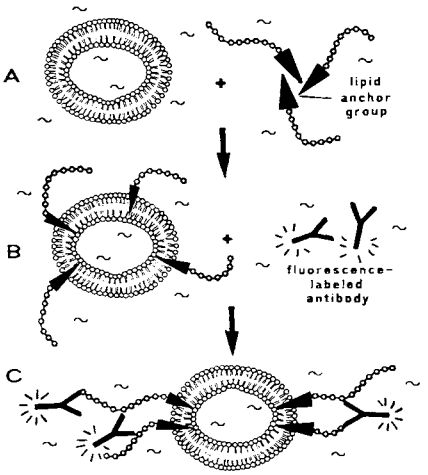


Fig. 52. Schematic representation of the experiment to prove the insertion of the capsular polysaccharide K1 (**64**) into liposomal membranes by using immunofluorescence [60]. A) Addition of a micellar solution of K1 to a liposome preparation. B) Insertion of the lipid anchor groups into the lipid bilayers; addition of the fluorescein-labeled anti-K1 antibody. C) Binding of the antibody and induction of a phase separation due to cross-linking of the K1 molecules (patching).

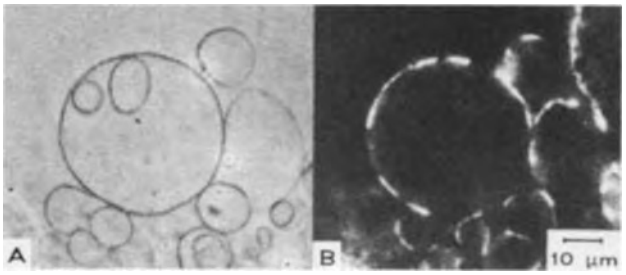

Fig. 53. Proof for the incorporation of **64** into DMPC liposomes [60]. A) Phase-contrast micrograph; B) epifluorescence micrograph of the same liposome (patching according to schematic drawing in Fig. 52C).

53B) clearly shows that the fluorescence of the antibody is associated with the membrane; i.e., **64** is detected at the membrane surface. Furthermore, it becomes evident that the fluorescence, dependent on time and concentration, is no longer distributed homogeneously in the membrane: patching[183] can be observed. It is caused by the reaction between the multivalent antigen, which is capable of lateral diffusion within the membrane, and the bivalent antibody, thus leading to a phase separation. This process might be compared to a precipitation reaction in two dimensions. Therefore, this experiment is not only an example of a recognition reaction between antigen and antibody; the final result, the clustering of one membrane component, also represents a simple membrane process (see Section 6.1).

6. Simulation of the Dynamics of Biomembranes

The dynamics of biomembranes (shape fluctuations, membrane instabilities), which is responsible for motion and transport processes, is fascinating and of great biological importance. It is a challenging task to explain cellular processes by phenomenological physical properties of the plasma membrane.[155a] The plasma membrane with its manifold functions is much more than just a passive permeability barrier which encloses cytosol from the surrounding medium. On the one hand, membrane transport proteins or ion carriers provide for a "local," ordered exchange of substances in both directions. On the other hand, dynamic processes are responsible for the important "bulky" transport through the membrane. Examples of these uptake and release processes of the cell are illustrated in Figure 54.

Cells ingest macromolecules and particles by a process called endocytosis: the substances are progressively enclosed by a small portion of the plasma membrane, which first invaginates and then pinches off to form an intracellular vesicle containing the ingested material.[185] Analogous mechanisms exist for the release of substances from the cell: as regards exocytosis, the intracellular vesicles, containing the substance to be released, fuse with the plasma membrane and open to the extracellular space. In the case of budding, bulges of the membrane to the outside are detached, whereby the substances given off remain enclosed by a lipid bilayer. This process plays a role when, for example, a virus leaves its host cell.

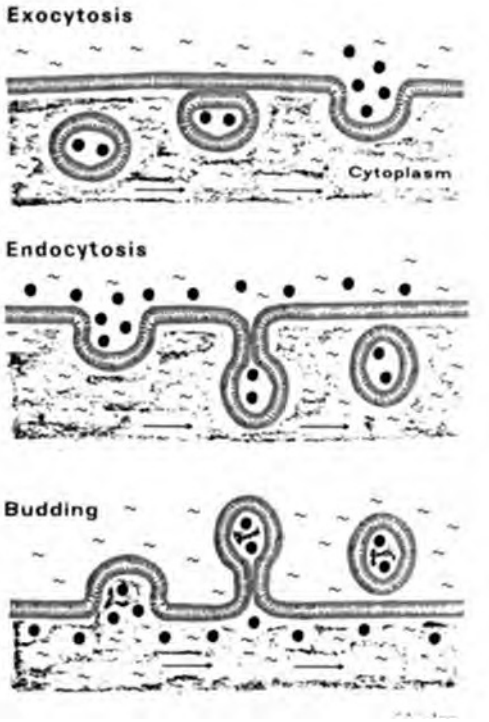

Fig. 54. Schematic drawing of three important transport processes of biological membranes [184]: exocytosis, endocytosis, and budding.

All these events require dynamic processes within the membrane, including the possibility of forming local domains in the membrane (patching and capping). In membrane biology, the mechanism of such dynamic cell processes is habitually described as extremely complex, usually involving proteins and being energy-consuming. Phase-separation phenomena, however, can be triggered off in lipid bilayers depending on counterions or temperature.[186] Simplified model membranes thus help to answer the question of what minimum requirements are necessary in a given system for a certain process to take place at all. The following sections illustrate how dynamic processes can be induced in purely synthetic, polymeric model systems in such a way that they correspond, at least formally, to biomembrane processes.

6.1. Patching and Capping in Polymerized Mixed Liposomes

Patching and capping are simple dynamic processes of the biomembrane caused by lateral diffusion. They are triggered off at the cell surface by antigen–antibody interactions and can be observed directly with a light microscope by using a fluorescence-labeled antibody.[183, 187] This is schematically shown in Figure 55. The fluorescence-labeled antibodies bind to the antigens at the cell surface (Fig. 55A) and a diffuse fluorescence, which is homogeneously distributed over the whole cell membrane, can be observed. Since the antibody molecules are bivalent, they are able to cross-link with the antigens. This soon leads to a phase separation within the membrane and thus to the fluorescent patches (Fig. 55B). An example of such a patching process in a vesicle membrane has already been described in Section 5.4. In the cell, the individual

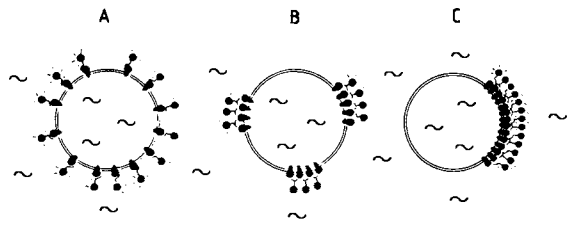

Fig. 55. Schematic drawing of the aggregation of membrane receptors induced by the binding of bifunctional fluorescence-labeled antibodies. A) Diffuse fluorescence of the homogeneously bound antibody. B) Clustering of the receptors forming fluorescent domains (patching). C) Aggregation of the domains forming a single fluorescent area (capping).

domains move, within a few minutes, to one certain area of the membrane, thus forming a cap (Fig. 55C). Whereas patching only requires lateral diffusion, it is assumed that the subsequent aggregation to one single cap is an energy-promoted process.[183, 187]

In mixed membranes of unsaturated and natural lipids, a phase separation can be induced via polymerization. This domain formation resembles the immunologically important processes of patching and capping.[188] Such experiments have been carried out with mixed giant liposomes made from the polymerizable lipid **27** (Scheme 3) and DMPC (1:1). Their membrane dynamics are made visible by the addition of a small amount of a fluorescent lipid. The liposomes composed of the monomeric components reveal complete miscibility of both lipids and the incorporated fluorescent dye, as can be seen by the diffuse fluorescence of the giant liposomes. After photopolymerization of **27** at 40°C (diffuse fluorescence still observable, Fig. 56A) and cooling down of these partially polymerized liposomes below the phase transition of the polymeric lipid, isolated areas of intense fluorescence occur (Fig. 56B).

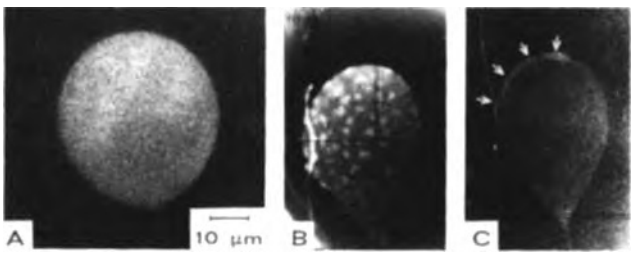

Fig. 56. Simulation of patching and capping in polymerized giant liposomes; epifluorescence micrographs of a giant liposome made from a mixture of the butadiene derivative **27** and DMPC (1:1) (0.1 mol% fluorescent lipid as marker) [188a]. A) Homogeneous fluorescence in the polymerized liposome at 40°C (above the phase transition of the polymer). B) Phase separation forming fluorescent domains in the same liposome immediately after lowering the temperature to 28°C (below the phase transition of the polymer). C) Formation of a single fluorescent cap in the same liposome after a few minutes.

This is caused by the immiscibility between the polymeric lipid, which is in the crystalline state, and the other membrane components, which are still in the fluid state. After a few minutes, the visible patches "flow" together, thus forming one single membrane cap (Fig. 56C). The time scale and appearance of these processes are completely analogous to the patching and capping observed on cell surfaces during their interaction with bivalent antibodies.

These natural biomembrane processes can thus be mimicked with striking similarity using polymeric model systems. The initiating mechanisms are, however, completely different. Nevertheless, such experiments may contribute to the understanding of the biological phenomenon. It is generally assumed that the process of capping is actively driven, thus requiring ATP. However, the results reported here provide the first experimental evidence that such a cap formation can take place passively without energy consumption.

6.2. Morphological Changes of Giant Liposomes

The transport mechanisms of endocytosis and budding involve a local bulge either to the inside or to the outside of the membrane with the subsequent detachment of a small vesicle (cf. Fig. 54). The first step of this two-stage process is a local reversible change in the spontaneous curvature of the membrane. In contrast, the second step, the detachment of the vesicle, is irreversible. Figure 57 schematically illustrates how this process is triggered off in Nature by taking erythrocytes as an example. Here a local change in the spontaneous curvature of the membrane occurs, probably due to a lateral contraction of the cytoskeleton.[154]

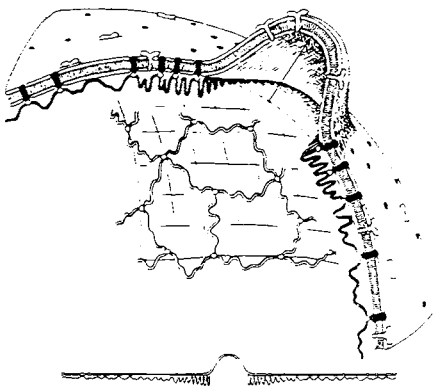

Fig. 57. Proposed pathway of triggering of endocytosis in an erythrocyte; by a local lateral contraction of the cytoskeleton, the removal of the network is expected to lead to a local change in the spontaneous curvature [154].

Protrusions caused by lateral phase separation can also occur in synthetic model systems. Figure 58A shows a giant liposome composed of a mixture of DMPC and the polymerizable spacer lipid **36b** (Scheme 4). Upon UV polymerization under a light microscope, clearly visible protrusions (Fig. 58B) develop out of the initially smooth surface. They continue to grow even after the UV light has been turned off, and their number increases with increasing amount of polymerizable lipid. This leads to the conclusion that a phase separation between the formed polymeric lipid and DMPC takes place, as shown schematically in Figure 58C.

Fairly well known examples of reversible transitions between different cell morphologies are the shape changes of erythrocytes. These can be achieved by different environmental changes such as changes in pH, temperature, and ionic strength or by the addition of drugs.[189] In the last

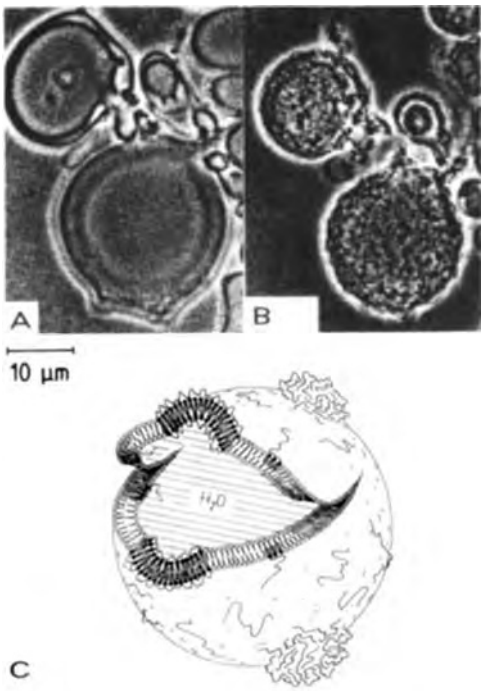

Fig. 58. Polymerization-induced protrusions in a giant liposome made from DMPC and **36b** (1:1) [154]. A) Phase-contrast micrograph of monomeric giant liposomes. B) After UV polymerization (100 s). C) Schematic representation of the microstructure of the bilayer after polymerization; lateral phase separation leads to domains of the polymeric lipid exhibiting a higher spontaneous curvature than the monomeric lipid matrix.

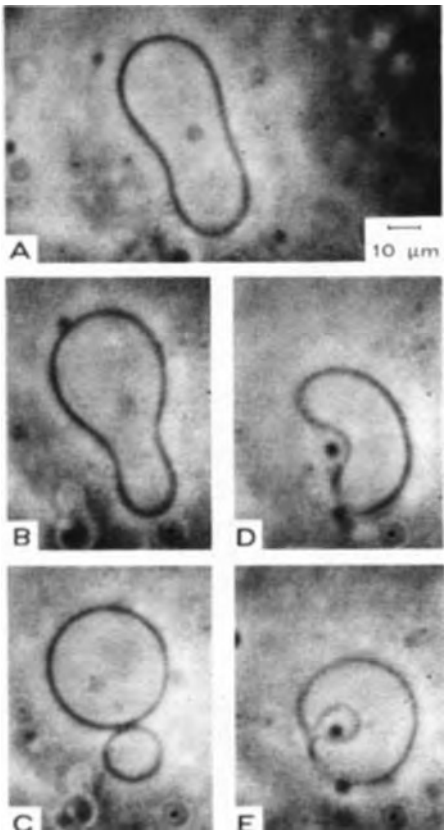

Fig. 59. Phase-contrast micrographs of temperature-induced, reversible morphology changes of a giant liposome made from the ammonium lipid **27** [155b]. A–B–C: Constriction of a discoid liposome at increasing temperature, reminiscent of exocytosis (cf. Fig. 54). A–D–E: Invagination in the same discoid liposome at decreasing temperature, reminiscent of endocytosis (cf. Fig. 54). A) 42°C; B) 42.5°C; C) 43°C; D) 41.5°C; E) 41°C.

few years, a series of theoretical studies have been published in order to explain the stability of the different cell shapes observed.[190] In this context, the model of *Svetina* and *Zeks* must be mentioned in particular.[190d] This model explains the stability of the different cell morphologies without any assumption as to the structure of the cell membrane. It is based on the idea that both leaflets of the lipid bilayer can expand and contract independently of one another. If, however, the changes in area of the two bilayer halves differ, the result is a change in the spontaneous curvature and thus a morphological change of the cell.

This concept has been confirmed by the observation of giant unilamellar liposomes.[155b] Figure 59 shows a series of reversible morphological changes of a giant vesicle made from the ammonium lipid **27**. These processes are temperature dependent and occur near the phase transition temperature (42°C). At a temperature of 42°C, the vesicle has a discoid shape (A). When the temperature is raised to 43°C, the vesicle constricts (C) via a bulge (B) to the outside. If, however, the temperature is lowered to 41°C, the opposite, i.e., a bulge to the inside, can be observed (D, E). Formally, these processes resemble budding and endocytosis and are completely reversible. By using the model of *Svetina* and *Zeks*, they can be explained in terms of a difference in the electric surface potential between the inner and outer membrane halves.[155b]

An additional example of an invagination involving a giant vesicle made from DMPC and the spacer lipid **36b** (4:1) is shown in Figure 60. In this case, however, the process is not triggered off by changing the temperature,

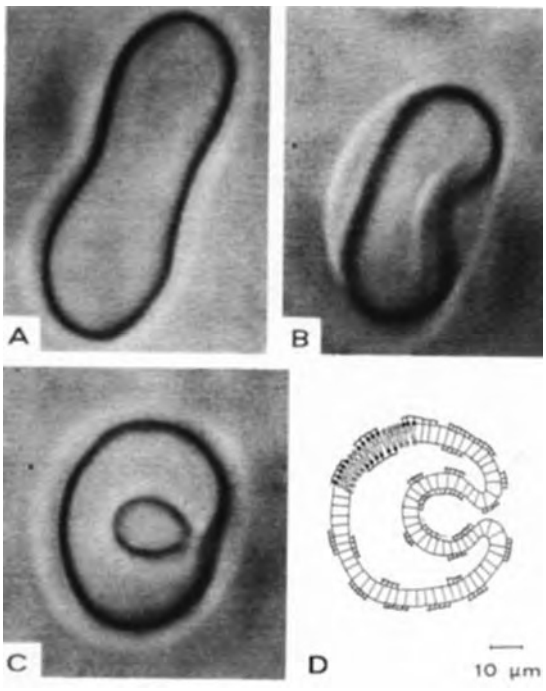

Fig. 60. Endocytosis-like shape change of a giant liposome made from DMPC and **36b** (4:1) caused by UV polymerization [155a]. A) Monomeric liposome at 29°C. B, C) Transformation occurring after 2 min of UV irradiation. D) Possible explanation for the shape transition in terms of a larger reduction of the area per lipid molecule in the outer monolayer compared with the inner leaflet. This might be due to an asymmetric distribution of **36b** which is probably preferentially distributed in the outer leaflet because of its large head group.

but by UV polymerization of one membrane component. This experiment does not lead to the protrusions of phase-separated polymer (cf. Fig. 58), because the portion of the polymerizable lipid is only 20 mol%. The membrane process observed is a bulge of the membrane to the inside, analogous to endocytosis. This can also be explained by the model of *Svetina* and *Zeks*: It can be assumed that the concentration of the spacer lipid **36b** is slightly higher in the outer membrane half than in the inner one, owing to its large head group. The polymerization going hand in hand with a decrease in area per molecule then leads to a reduction in area of the outer leaflet of the membrane, thus causing the invagination.[155a]

The experiments described show that even slight changes in the membrane or its environment may cause the morphological changes which are important for transport processes in biological systems. The second step of these processes, the irreversible detachment of smaller vesicles, however, requires more than only a change in curvature. In Section 4.3, a photoreactive system has already been presented which allows the realization of this process in model membranes. Upon short-term irradiation of interconnected, giant vesicles of the benzylammonium lipid **19**

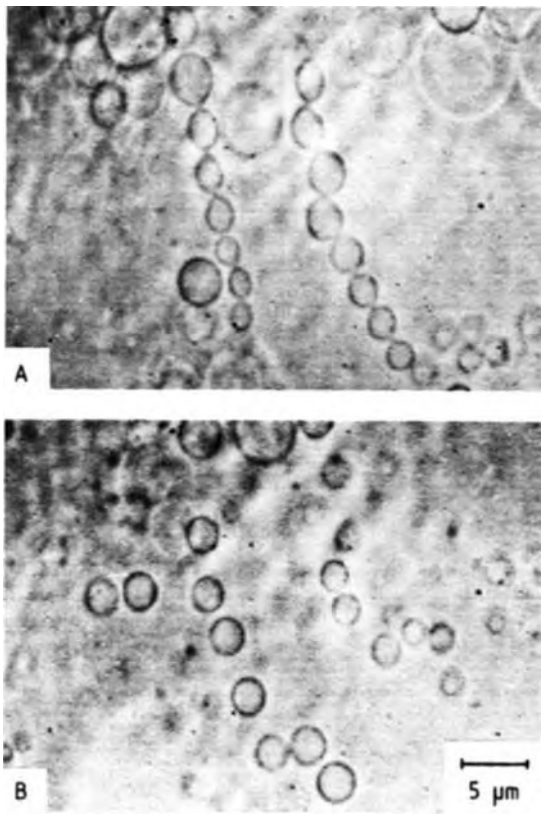

Fig. 61. Photochemically induced separation of interconnected giant liposomes made from the benzylammonium lipid **19** (cf. Fig. 23) [155b, 191]: A) before irradiation; B) after 2 s of UV irradiation.

(Fig. 61A), which resemble strings of pearls, the individual vesicles undergo separation via a photoinduced phase-separation process (Fig. 61B).[155b, 191]

6.3. Selective Opening of Phase-Separated Liposomes

6.3.1. Death of a Tumor Cell—Is Simulation Possible?

The great variety of biomembrane processes and the interaction of molecular and cellular events is reflected in a rather fascinating way in the death of a tumor cell that cannot escape from the immune system (Fig. 62).[192] The scanning electron micrograph shows the attack of an activated macrophage on a tumor cell (Fig. 62A).

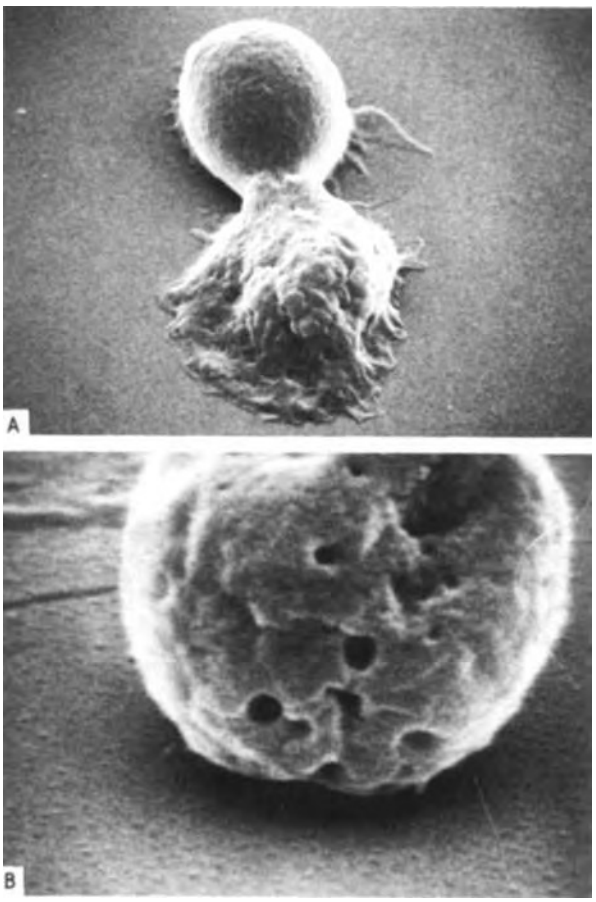

Fig. 62. Scanning electron micrograph of a tumor cell attacked by an activated macrophage [192]. A) Close contact between tumor cell (upper part) and activated macrophage (lower part). B) Holes in the membrane of the tumor cell after the attack.

On a molecular level, via antigen–antibody interaction, the macrophage recognizes the target cell and establishes a close membrane contact. Then, on a cellular level, a patching of the antigen–antibody complexes presumably takes place. In the subsequent membrane processes, which are not yet completely understood, the defense cell is able to drill holes in the originally stable membrane of the tumor cell. As a result, the cytoplasmic interior leaks out, which causes the death of the cell. What remains is a ghost cell (Fig. 62B).

Can this process be simulated? And if so, what is needed to do so? On the one hand, it is surprising that the lipid–protein bilayer does not collapse despite the visible holes. This gives evidence for its stability, the simulation of which has been discussed several times in this article. On

the other hand, the question of how these holes are created comes up. Conceivably, this occurs by means of a local process in the phase-separated membrane. One possibility could be that the macrophage tears open the tumor cell's membrane by means of a local endocytosis process of its own membrane. Another possibility is that the opening process is triggered by the macrophage and is accomplished by the cytoskeleton of the tumor cell. A further possible approach would be the lysis of membrane domains by enzymatic cleavage of the phospholipids, forming water-soluble lysophospholipids. The real course of this process is unknown.

The following sections describe the formal simulation of this process using the simple model of phase-separated polymerized liposomes.

6.3.2. *Formation of Domains in Vesicle Membranes*

Phase-separated liposomes can be used to simulate the hole formation process of the cell. In order to avoid a complete destruction of these liposomes by "uncorking," it is important that they are composed of a polymerized lipid matrix surrounding the labile domains of cleavable or nonpolymerizable lipids (Fig. 63).

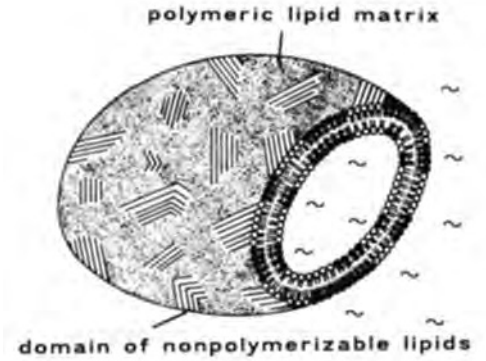

Fig. 63. Schematic drawing of a phase-separated liposome; the polymerized lipids form the stable matrix, surrounding the domains of nonpolymerizable lipids.

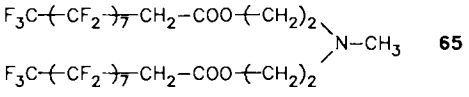
The induction of such a phase separation via polymerization has already been described in Section 6.1. Alternatively, the formation of domains can be predetermined by choosing suitable, incompatible lipid mixtures. Examples are mixtures of hydrocarbon and fluorocarbon lipids.[193] Mixed liposomes made from DMPC and the fluorocarbon amine **65** feature two phase transitions, e.g., in differential



65

scanning calorimetry (DSC) measurements. This observation clearly demonstrates that these two lipids are immiscible since these phase transition temperatures are identical with those of the corresponding pure lipids.[193a] Freeze fracture electron micrographs reveal that, indeed, phase-separated liposomes with domains of the individual lipids are formed from the lipid mixture instead of two different liposome populations. Thus, domain formation in mixed membranes prepared from DMPC and **65** (95:5) can be made directly visible (Fig. 64) by means of the ripple structure typical of lecithin liposomes (see Section 4.8.1).

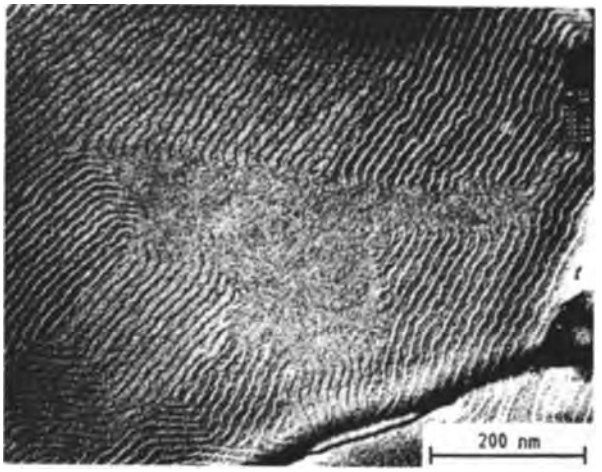


Fig. 64. Freeze fracture electron micrograph of a phase-separated liposomal membrane (95 mol% DMPC and 5 mol% fluorinated lipid **65**). The ripple structure shows the parts of the membrane composed of DMPC, surrounding a domain of the fluorinated lipid (smooth surface) [193a, 204].

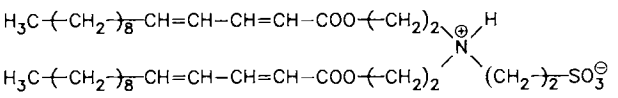
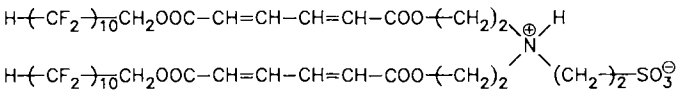
To obtain a stable polymeric matrix needed for uncorking experiments of mixed liposomes, the polymerizable lipids **66** and **67** with hydrocarbon and fluorocarbon chains, respectively, have been used.



66



67

Small unilamellar liposomes can be prepared from both lipids by means of sonication. The tightness of the polymeric matrix of vesicles formed by lipid **66** was demonstrated by time-dependent release measurements using eosin as a fluorescent marker. Figure 65 shows a comparison of the eosin release of monomeric and polymeric vesicles

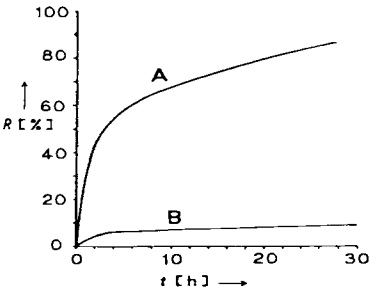


Fig. 65. Release R of eosin from vesicles (SUV) made from **66** [200]: A) monomeric; B) polymerized (5 mol% azobisisobutyronitrile, 60°C, 12 h).

made from the lipid **66**. The monomeric vesicles release half of the dye within 5 h, whereas the polymeric ones have lost only about 10% of their contents after 30 h.

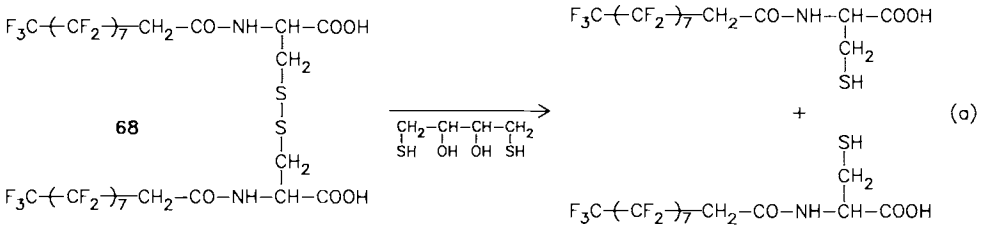
6.3.3. *Corkscrews for Corked Liposomes*[194]

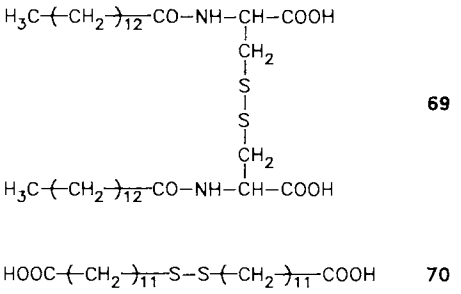
Numerous works proposing various mechanisms to destabilize membranes of liposomes have already been published. These include photochemical[94] as well as temperature-induced[195] increases in permeability or the use of pH-sensitive liposomes.[196] These investigations have exclusively been carried out with liposomes made from nonpolymerizable lipids.

In order to simulate the attack on a tumor cell by a macrophage, as shown in Figure 62, it is important not to destroy the whole liposome by membrane-destabilizing processes. Only labile domains within a stable lipid matrix should be selectively dissolved.[197] Figure 66 shows different processes that result in selective opening of such stabilized, phase-separated liposomes.

The polymeric components of these mixed liposomes form the stabilizing, shape-maintaining matrix. In order to destroy the labile domains, at least two methods are conceivable: dissolving or cleavage of the lipids. On the one hand, it is possible to dissolve the lipids of those domains with surfactants (detergents), thus forming mixed micelles, or by using organic solvents (e.g., acetone or ethanol). On the other hand, lipid cleavage through enzymatic or chemical reactions can be carried out. The enzymatic hydrolysis of phospholipids, forming lysophospholipids, by means of phospholipase A_2 (cf. Fig. 75) is the method Nature uses to synthesize and decompose membranes.[198] Several years ago, *Büschl* et al. already succeeded in transferring these reactions to polymeric model systems.[199]

The simulation of such lipid cleavage reactions by means of chemical processes offers a great number of synthetic ways to locally open the labile lipid domains in polymerized liposomes. Two principles are shown in Figure 66: head-group cleavage of double-chain lipids or chain cleavage of membrane-spanning lipids, each of them forming two surfactant molecules. To realize this concept by chemical reactions, a series of double-chain (**68**, **69**) or membrane-spanning (**70**) lipids with a disulfide group as





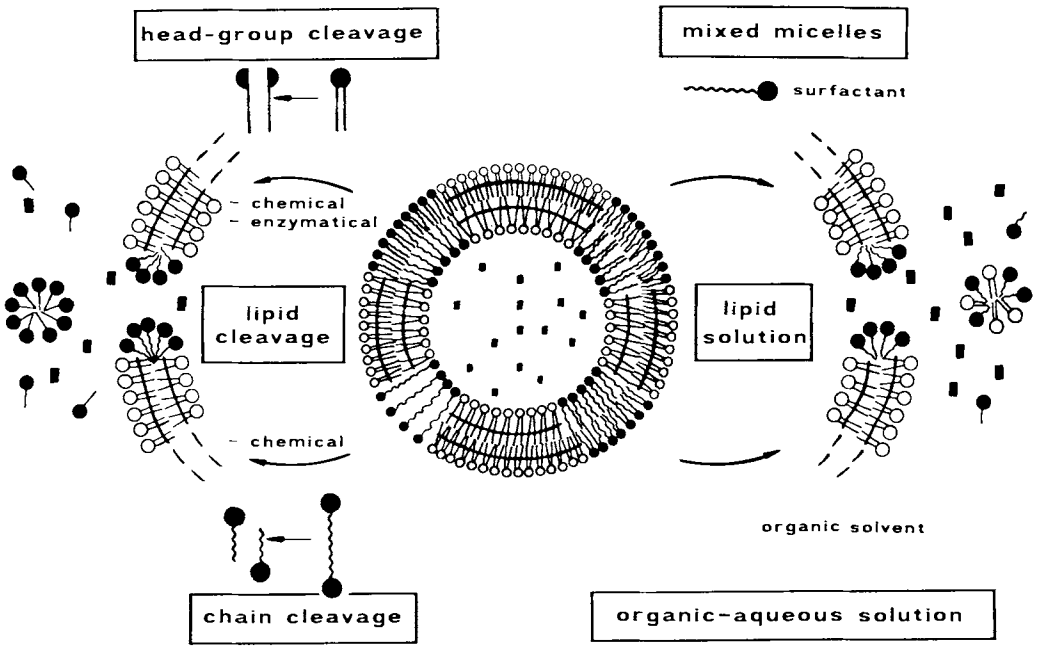


Fig. 66. Methods to uncork phase-separated liposomes composed of a stable polymeric matrix with labile domains.

cleavable unit have been synthesized.[200] The reductive cleavage of the water-insoluble disulfides—for example, with dithiothreitol (DTT)—leads to the formation of the corresponding partially water-soluble, single-chain thiols [Eq. (a)].

The cystine lipids **68** and **69** are capable of forming liposomes by sonication. The membrane-destruction process was followed by fluorescence spectroscopy using liposomes (made from **68**) containing eosin (Fig. 67). The

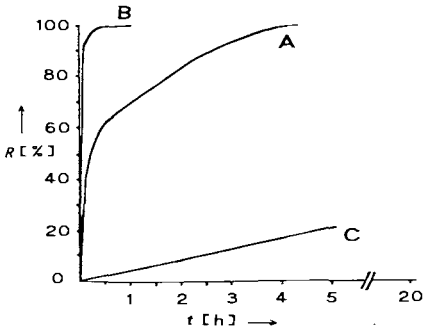

Fig. 67. Release R of eosin from vesicles (SUV) made from the fluorinated cystine derivative **68** at pH = 9 [200]. A) Cleavage of the disulfide bond by using 0.1 M Na_2SO_3. B) Cleavage by using dithiothreitol (DTT) (2 mg mL^{-1}). C) In the absence of a cleaving reagent.

cleavage process of the disulfide bonds within the cystine-lipid liposomes is much faster with DTT compared with sodium sulfite. Thus, DTT was used as a corkscrew[201] for all further opening reactions.

6.3.4. Chemical and Enzymatic Opening of Polymerized Mixed Liposomes

The combination of polymerizable taurine lipids (**66** and **67**) with cork-forming amphiphiles (**68**–**70**) results in stable polymeric liposomes with cleavable "cork" domains, as discussed in Section 6.3.3. Evidence for the opening of the labile domains in mixed liposomes was provided by electron microscopy as well as by the release of entrapped eosin.[202] Figure 68 schematically illustrates the opening process.

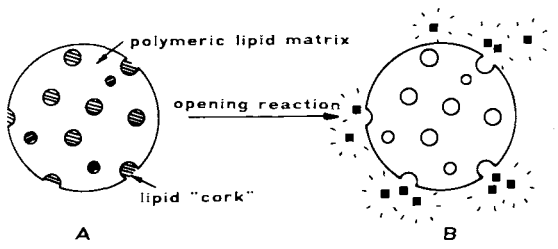

Fig. 68. Proof of the hole formation in polymerized vesicles containing labile domains. A) No fluorescence of the entrapped marker owing to self-quenching. B) Fluorescence of the released and therefore diluted marker after the hole formation in the membrane.

Head-group cleavage of lipids: In order to confirm the effect of phase separation on the release behavior of entrapped markers, liposomes with a homogeneous distribution of the cork component (i.e., not phase-separated) were studied as a comparison. Therefore, mixed liposomes from the polymerizable lipid **66** and the cystine lipid **69** (9 : 1), which form a homogeneous mixture, were used (Fig. 69).

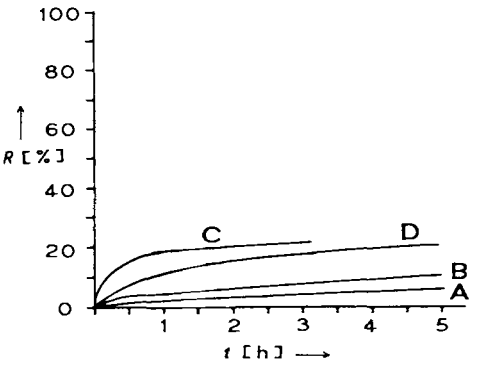

Fig. 69. Release R of eosin from domain-free vesicles (SUV) (90 mol% **66**, 10 mol% **69**, pH = 9) [200]. A) Polymerized vesicles in the absence of a cleaving reagent. B) Monomeric vesicles in the absence of a cleaving reagent. C) Polymerized vesicles after addition of DTT (1 mg mL^{-1}). D) Monomeric vesicles after addition of DTT (1 mg mL^{-1}).

In the absence of DTT as a cleavage reagent for the disulfide group of **69**, the release rates of the monomeric (curve B) and the polymerized liposomes (curve A) differ only very little. After the addition of DTT, the cleavage of the lipids does not lead to the formation of holes, because the cleavable lipids are distributed homogeneously within the membrane. The compatible lysolipids, formed during that process, cannot be pushed out of the membrane. Thus, after a short period of time, the release rates (curves C and D) are comparable to those measured without DTT (curves A and B).

A dramatic change in release behavior occurs if phase-separated liposomes from the same polymerizable lipid **66** and the domain-forming "fluorocarbon cork" **68** (9 : 1) are used (Fig. 70).

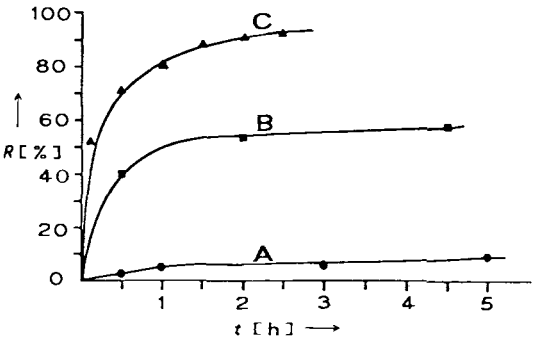

Fig. 70. Release R of eosin from phase-separated, domain-containing vesicles (SUV) (90 mol% **66**, 10 mol% **68**, pH = 9) [200]. A) Polymerized vesicles in the absence of cleaving reagent. B) Monomeric vesicles after addition of DTT (1 mg mL^{-1}). C) Polymerized vesicles after addition of DTT (1 mg mL^{-1}).

In this case, the domains of **68** are rapidly destroyed by DTT during the disulfide cleavage in unpolymerized liposomes. However, owing to the lateral diffusion of the monomeric lipids, the membrane defects are healed rather quickly. After cleavage of the whole cork component (about 1 h), the release rate (curve B) decreases to that

without DTT (curve A). After addition of DTT to the polymerized liposomes, the stiff polymeric matrix is uncorked and eosin is rapidly and almost completely released (curve C).

Is the hole formation in these experiments really similar to that which occurs in a cell (cf. Fig. 62)? It was possible to confirm this using two electron microscopy techniques. Figure 71 shows a scanning electron micrograph of a phase-separated polymeric liposome made from the taurine lipid **66** and the cleavable cystine lipid **68** before and after the destruction of the labile domains. As can be seen,

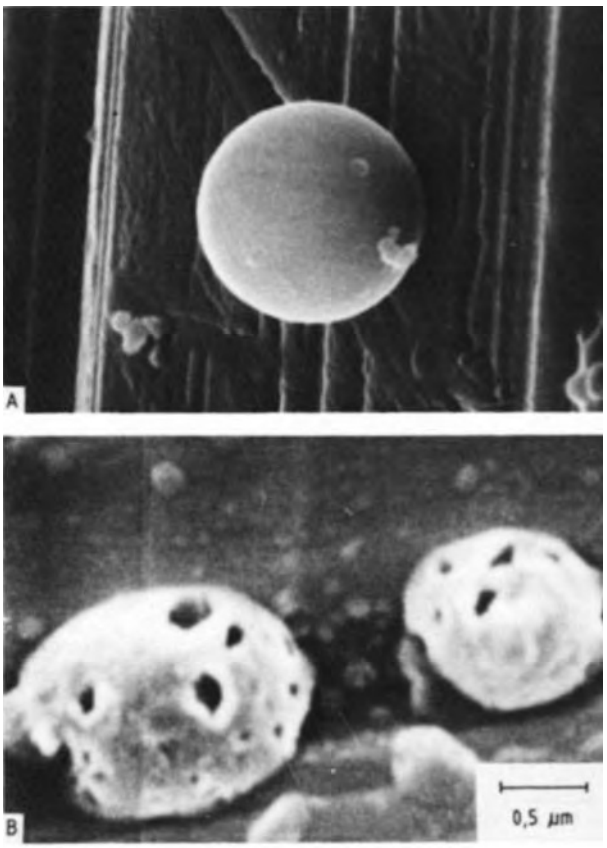

Fig. 71. Scanning electron micrograph of phase-separated, polymerized liposomes (90 mol% **66**, 10 mol% **68**) [200, 203]. A) Liposome before the cleavage reaction. B) Perforated membrane after the cleavage reaction (uncorked liposome!).

the lipid bilayers do not collapse. The function of the cytoskeleton of the cell, i.e., the stabilization of the membrane, is thus fulfilled by the polymeric matrix of the liposomes. The pore formation observed is not an artifact of the preparation technique for the scanning electron micrograph. This was proven by means of freeze fracture electron microscopy (Fig. 72). Figure 72A shows the smooth, unstructured surface of the polymeric mixed liposome before it is uncorked. In Figure 72B the membrane again features clearly visible holes after the cleavage has been carried out. The different diameters of the holes in the uncorked liposomes (Figs. 71B and 72B) are due to varying domain sizes, caused by different annealing times of the mixed liposomes before their polymerization.

Chain cleavage of lipids: All experiments discussed so far have been carried out with the cystine derivative **68** as the lipid cork. An analogous behavior has been observed with

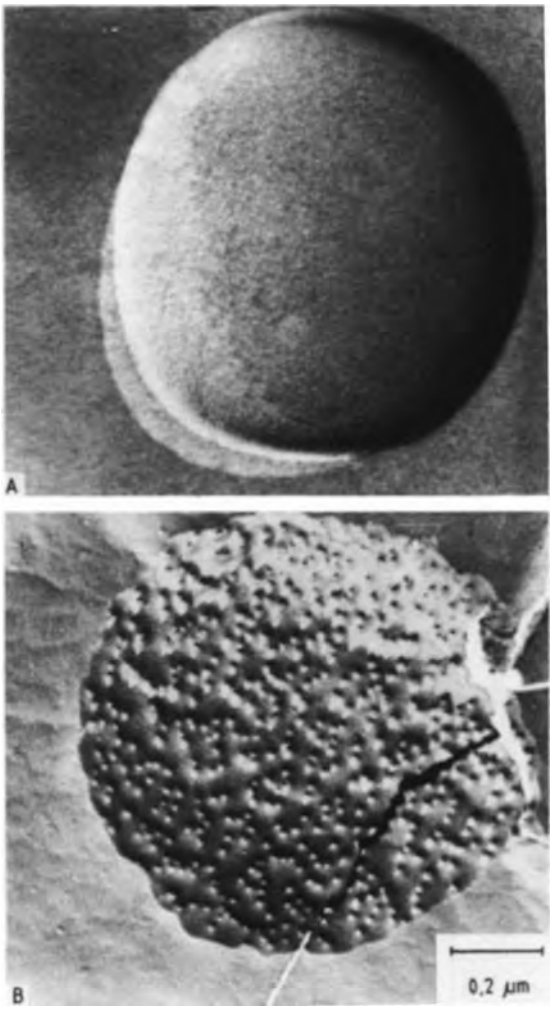

Fig. 72. Freeze fracture electron micrograph of phase-separated, polymerized liposomes [200, 204] (see caption to Fig. 71).

the bipolar disulfide amphiphile **70**. The release of eosin from phase-separated liposomes containing this cleavable lipid and the fluorinated muconic acid derivative **67** is shown in Figure 73.

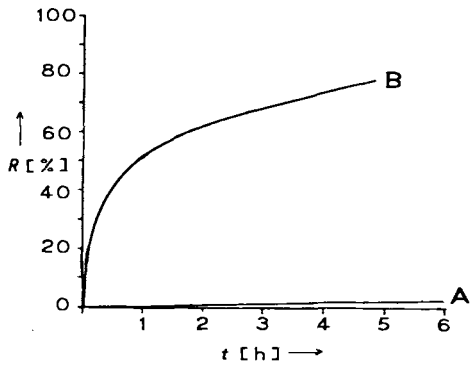

Fig. 73. Release R of eosin from phase-separated, domain-containing vesicles (SUV) (90 mol% muconic acid derivative **67**, 10 mol% disulfide **70**, pH = 9) [200]. A) Polymerized vesicles in the absence of a cleaving reagent. B) Polymerized vesicles after addition of DTT (1 mg mL^{-1}).

Polymerized vesicles with 10 mol% of the supposedly membrane-spanning cork **70** again exhibit only minor eosin release before cleavage (curve A). In this case, also, the

addition of DTT leads to a rapid release of the fluorescent marker, even though the rate is slower than that observed in the cleavage experiments with the cystine lipid **68**. This is quite understandable since the cleavage reagent does not attack the head groups; it first needs to diffuse into the membrane. However, no difference can be seen by electron microscopy between the double-chain and membrane-spanning cleavable lipid systems (Fig. 74).

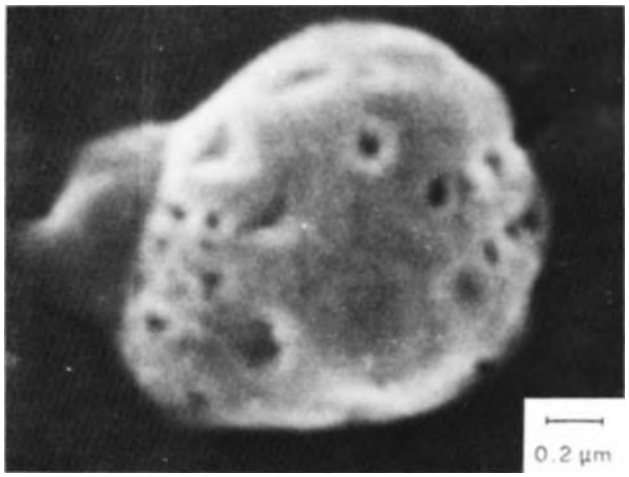

Fig. 74. Scanning electron micrograph of phase-separated, domain-containing liposomes (90 mol% **67**, 10 mol% **70**); hole formation after addition of DTT [200, 203].

Dissolving the cork without cleavage: As already illustrated schematically (Fig. 66), apart from a cleavage reaction, even the simple dissolving of the labile domains out of a polymeric matrix can lead to the formation of pores in a vesicle membrane.[200] This concept is based on the well-known fact that polymerized vesicles exhibit a higher stability towards surfactants or solvents than their monomeric analogues.[72,205]

To carry out an opening reaction by using solvents, mixed membranes made from the cationic polymerizable ammonium lipid **27** with the fluorinated amine **65** (9:1) were prepared. The dissolving of the domains formed by the fluorocarbon lipid after the addition of acetone to the solution of polymerized vesicles (1:1) was demonstrated by scanning electron microscopy. Here, too, holes are formed in the vesicle. In the course of this process, the polymerized lipid matrix again maintains its shape. In the meantime, *Tsuchida* et al. have also reported similar experiments.[206]

Enzymatic uncorking:[207] The opening reactions discussed so far proceed under nonphysiological conditions and with a relatively high concentration of cleavage reagent. The biochemical opening, in contrast, uses phospholipases and allows the process to take place under physiological conditions. Phospholipase A_2 specifically catalyzes the hydrolysis of the ester bond at the C-2 position of L-α-glycerophospholipids (Fig. 75).

This enzymatic reaction can be transferred to model membranes composed of polymerized and natural lipids. This was demonstrated first by using monolayers.[199] To investigate this cleavage reaction in liposomes,[208] mixed

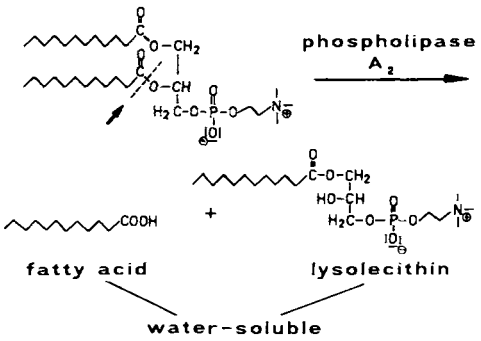

Fig. 75. Enzymatic cleavage of the C-2 ester bond of a lecithin by phospholipase A_2; the products (fatty acid and lysolecithin) are water-soluble surfactants.

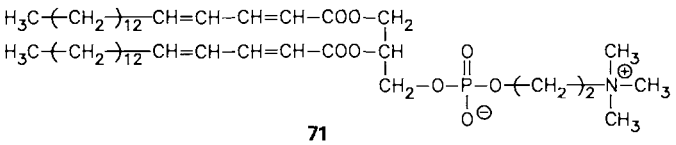
membranes of the polymerizable lecithin **71** and DPPC (1:1) were used. Here, DPPC acts as the cork, cleavable by



71

enzymes. The liposomes formed from these two lipids do not show domains since they are homogeneously miscible. Polymerization, however, induces a phase separation. It has to be pointed out that the highly specific phospholipase A_2 attacks the ester group of the dienoyl lecithin neither in the monomeric nor in the polymeric form. Indeed, liposomes prepared only from the dienoyl lecithin **71** remain tight and do not release eosin after addition of the enzyme. Thus, the release of 6-CF from mixed liposomes (Fig. 76) is clearly due only to the cleavage of the saturated lecithin (DPPC).

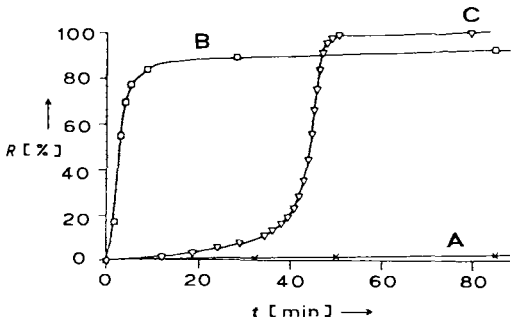


Fig. 76. Release R of 6-CF from monomeric and polymerized mixed vesicles (SUV) (50 mol% **71**, 50 mol% DPPC) [208]. A) Monomeric and polymerized vesicles in the absence of the enzyme. B) Polymerized vesicles after addition of phospholipase A_2 (30 µg mL^{-1}). C) Monomeric vesicles after addition of phospholipase A_2 (30 µg mL^{-1}).

In the absence of the enzyme, the release rate of 6-CF for the monomeric as well as the polymeric liposomes remains below 1% (curve A) during the experiment. After the addition of phospholipase A_2, a dramatic change in the release behavior occurs. The polymerized, phase-separated vesicles very rapidly lose the entrapped marker: already after 10 min, 90% of the vesicle contents are released

(curve B). In contrast, the analogous monomeric system exhibits an "incubation time" of about 40 min. In this case, too, a fast and almost complete release of the marker subsequently takes place within a few minutes (curve C). How can these different release rates be explained?

At first the 6-CF marker is only slowly released from the homogeneously mixed membrane of the monomeric liposomes. This is due to the fact that the lysolipids formed dissolve in the membrane, thus disturbing it only slowly. Since the ratio of cleavable to noncleavable lipid is 1 : 1, the membrane reaches such a high content of lysolipids and fatty acids after a certain incubation time (40 min) that the liposomes spontaneously decay, forming mixed micelles. The difference between the monomeric and the polymerized mixed system can be explained by the polymerization-induced phase separation. Experiments with monolayers of analogous systems also revealed that phospholipase A_2 attacks phase-separated membranes much faster than the corresponding homogeneous mixtures.[199] Due to phase separation, the lysolipid- and fatty-acid-rich domains are rapidly dissolved. However, the formation of a stable polymeric matrix may be impossible in these systems owing to the high contents (50 mol%) of DPPC. Thus, the polymerized liposomal membrane, too, is completely destabilized during the cleavage reaction with the formation of mixed micelles.

These concepts are supported by release measurements with mixed liposomes of the same composition but with different extents of polymerization (conversion).[208] As can be seen in Figure 77, the incubation time for the spontaneous destabilization depends on the amount of polymer in the membrane. Due to the polymerization-induced phase separation, the portion of cleavable lipid within the monomeric areas increases with increasing polymerization. Therefore, the time needed to reach the critical concentration of water-soluble products in the monomeric domains, i.e., the incubation time, depends on the extent of polymerization.

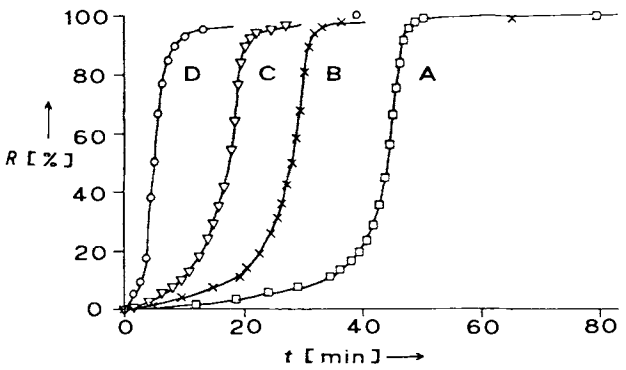

Fig. 77. Enzymatic release of 6-CF from partially polymerized vesicles (SUV) (50 mol% **71**, 50 mol% DPPC, 30 μg mL^{-1} phospholipase A_2) [208]. Dependence of the release kinetics on the extent of polymerization: A) 0%; B) 15%; C) 45%; D) 85%.

Synthetic corkscrews for cells? The experiments discussed so far show that it is indeed possible to formally simulate the biological process of local cell membrane opening by using phase-separated, partially polymerized liposomes. However, one is still miles away from the natural process. Figure 78 leads back to biological processes and does not merely show an additional polymerized liposome before and after it has been uncorked.

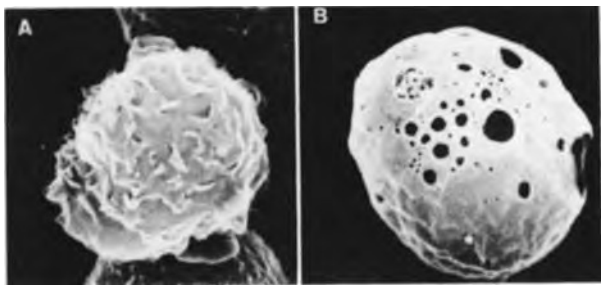

Fig. 78. Scanning electron micrograph of the hole formation in leukemia cells [209e]. A) Untreated leukemia cell. B) Leukemia cell after treatment with *O*-methyllysolecithin.

This scanning electron micrograph shows leukemia cells of a cell culture before (A) and after (B) treatment with special surfactants, namely, methyl ether derivatives of lysophospholipids which are, at present, also considered as anti-tumor agents.[209,68a] The result of the uncorking process of the cell by the synthetic lysolipid can clearly be seen. In whatever form the natural process of uncorking cells by activated macrophages (cf. Fig. 62) may proceed, it can at least be simulated in cells by using surfactants.

7. Outlook or Where to Go?

Many parts of this review are certainly incomplete. This is due partly to a lack of sufficient insight, partly to insufficient data. The reader should therefore not look at this contribution as a crystal-clear definition of facts and problems, but rather as an impulse for possible developments. This review represents an attempt, using the concept of self-organization, to jointly discuss the molecular architecture of supramolecular systems such as liquid crystals, micelles, liposomes, and biomembranes as a problem of mutual interest.[210]

The attempt to review different areas, which have traditionally been separate, is always a risky enterprise. It is impossible without generalizations and one thus, and rightly so, has to accept the eventuality of becoming superficial.[211]

On the other hand, *Georg Christoph Lichtenberg*, already 200 years ago, stated clearly: "He who understands nothing but chemistry doesn't even understand chemistry." Originally discussed in a more philosophical context, it nowadays (in times of rapidly increasing specialization) certainly holds true even for the natural sciences alone. Additionally, one has to accept that, owing to modern methods of measurements and sophisticated computer techniques, it is possible to measure to high precision and to evaluate more and more exactly: to measure and to verify is intensively taught and studied, but, too often, intuitive thinking is neglected.[212] Interdisciplinary research, however, is one way to stimulate intuition. In a refreshingly encouraging contribution, which recently appeared

in this journal, *Roald Hoffmann* describes "How Chemistry and Physics Meet in the Solid State."[211a] He stresses intuition as a strength of chemists. This frontier area of solid-state chemistry and physics can also only be tackled jointly and, like the formation and investigation of functional supramolecular systems, represents a fascinating chapter of modern materials science.

The fascination evoked in human beings by biological processes is old. The fascination of simulating these processes and transferring them into technical dimensions has just begun. The field is open and modern chemistry can offer essential contributions to it. Where to go? At present, materials science certainly can profit more from life science than vice versa. A technical analogue for biological membranes mimicking the specificity of their recognition and translocation processes has not yet been found—despite the countless varieties of synthetic polymer membranes already known. There have been many attempts to mimic the natural prototype and a few examples have been mentioned in this contribution. The breakthroughs are still missing: the knowledge is available, but innovation is a long time coming. Especially with respect to the next generation of technical membranes—switchable, functional, asymmetric, and suitable for specific and selective transport—the chemist should not leave the field of oriented supramolecular systems to the physicist and biologist alone. The physicists tend to like "too simplified" models, while biologists tend to reject all approaches which are not in accord with the "too complicated" prototypes of Mother Nature. Thus organic chemistry and macromolecular chemistry can play the important role of a mediator. One hint that this might work is given in the contribution by *J.-M. Lehn* in this issue.[12d] Molecular recognition processes for organic and inorganic compounds are a first step towards simulating highly specific recognition reactions common in biology.[12c,213] It will also be exciting to see what possibilities will be opened by the synthesis of glycolipids and glycoproteins representing tumor-specific antigens. They might be a bridge between organic chemistry and immunology.[214]

The art of synthesizing exceedingly complex molecules and characterizing them perfectly has reached dizzying heights and opens fascinating opportunities in the area of molecular engineering. But what is it good for? This art certainly will remarkably increase our chemical knowledge—but is this enough? It is not unlikely that, independent of the enormously increasing number of new synthetic compounds, the number of true innovations or innovative compounds has constantly decreased during the last few decades. In his aggressively but optimistically written contribution on "Chemical Needs and Possibilities at the End of the Century,"[215] *C. Frejacques* points out the importance of chemical systems based on self-organization. He stresses that, above and beyond the chemistry of covalent bonds, a chemistry of supramolecular systems is now emerging.

This review on the molecular architecture and function of polymeric oriented systems intends to show that such chemical systems, like their natural prototypes, may lead to functional units which can contribute to the understanding of biological processes and to the development of new materials. Both tradition and innovation are needed for that. On the borderland between the different disciplines of science, adventures are waiting. Neither uncritical optimism nor obstructive pessimism are justified. The excitement and the courage to set out for new frontiers and the willingness for close cooperation are basic prerequisites for this adventure of science. All the knowledge is available, we only have to learn to use it.

We are grateful to the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, and the Fonds der Chemischen Industrie for support of our work. And what about thanks to the coworkers? See Ref. [216]!

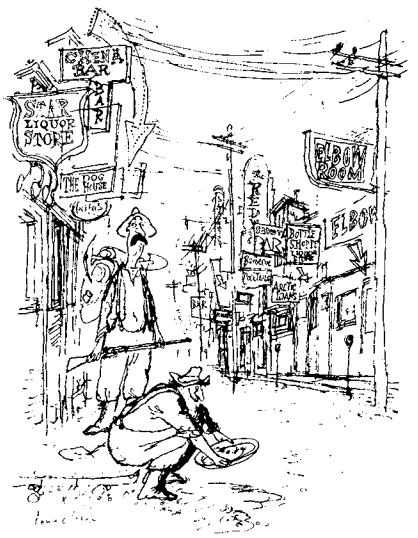
Translated by *Eva Grunwald* and Dr. *Christian Salesse*, Mainz

[1] B. Brecht: *Geschichten*, Bibliothek Suhrkamp, Frankfurt am Main 1962, p. 167. In this essay and under the heading "Hardship of the best," Mr. K. answers this question. But he certainly was a scientist! Don't you think so?

[2] H. Mark, *Angew. Chem. 93* (1981) 309; *Angew. Chem. Int. Ed. Engl. 20* (1981) 303.

[3] a) *Ronald Searle*, the scalpel-sharp British cartoonist, illustrates that even for the old gold diggers it was an absurd adventure to pan for gold by the light of the silvery neon in the main street of downtown Klondike (see [3b], p. 25):



Already in 1788 (!) *Georg Christoph Lichtenberg*, the great and critical philosopher and physicist from Göttingen, was very clear and outspoken in this respect when he characterized one of his colleagues: "... he was still hanging at his university like a wonderful chandelier without a tiny candle lit for years" (G. Ch. Lichtenberg, "*Sudelbücher*"). b) R. Searle: *From Frozen North to Filthy Lucre*, Viking Press, New York 1964.

[4] *Erwin Chargaff*, biochemist and critical essayist, depicts this as follows: "In science today smaller and smaller rooms are furnished more and more luxuriously and completely." (E. Chargaff: *Bemerkungen*, Klett-Cotta, Stuttgart 1981, p. 33).

[5] A. Dress, H. Hendrichs, G. Küppers: *Selbstorganisation - Die Entstehung von Ordnung in Natur und Gesellschaft*, Piper, München 1986.

[7] From the standpoint of the history of science, it is most interesting to see how, very often, out of controversies between different disciplines, new research areas develop. The famous and historical controversy in the twenties between the then well-established colloid science (*W. Ostwald*) and the rising macromolecular chemistry (*H. Staudinger*) is an

instructive example for that: weak interactions in the formation of aggregates (colloids) as opposed to covalently linked small molecules (macromolecules). These competitive concepts have long since inevitably fused, as perfectly demonstrated in the supramolecular systems of biological membranes. However, it is also interesting to note that—at least in Germany—colloid science did not recover from this controversy for quite a while. For at least two or three decades colloid chemistry nearly disappeared from German universities. It regained its reputation only via its industrial importance. a) H. Morawetz, *Angew. Chem. 99* (1987) 95; *Angew. Chem. Int. Ed. Engl. 26* (1987) 93; b) *Polymers. The Origins and Growth of a Science*, Wiley, Chichester 1985; c) E. Jostkleigrewe (Ed.): *Makromolekulare Chemie - Das Werk Hermann Staudingers in seiner heutigen Bedeutung*, Schnell und Steiner, München 1987.

[8] a) J. D. Barnal, *Trans. Faraday Soc. 29* (1933) 1022; b) *The Physical Basis of Life*, Routledge and Kegan, London 1951.

[9] a) G. H. Brown, J. J. Wolken: *Liquid Crystals and Biological Structures*, Academic Press, New York 1979; b) D. M. Small, *J. Colloid Interface Sci. 58* (1977) 581; c) D. Chapman in F. D. Saeva (Ed.): *Liquid Crystals: The Fourth State of Matter*, Dekker, New York 1979, p. 305; d) Y. Bouligand in L. Liebert (Ed.): *Liquid Crystals (Solid State Phys. Suppl. 14* (1978) 259).

[10] As far as the often discussed and adjured willingness of scientists to cooperate is concerned, one has to be skeptical. Again one can use the point of view of *Ronald Searle* to describe the situation: People tend to cling to the old ways; a homesteader's cabin is still his castle (see [3b], p. 14 and [4]):

[11] The courage to set out and the willingness to turn around and search for prey from a different perspective are prerequisites for the adventure of science (see [3b], p. 21):

[12] Supermolecules ("Übermolekeln") were already defined by *K. L. Wolf* in 1937 to describe associations of molecules, the function of which was based on their organization: a) K. L. Wolf, F. Frahm, H. Harms, *Z. Phys. Chem. Abt. B 36* (1937) 17; b) K. L. Wolf, R. Wolff, *Angew. Chem. 61* (1949) 191. The conception of "Supramolecular Chemistry" has been realized by *Jean-Marie Lehn* and his group during the last few years: c) J.-M. Lehn, *Science (Washington) 227* (1985) 849; d) *Angew. Chem. 100* (1988) 91; *Angew. Chem. Int. Ed. Engl. 27* (1988) 89. In this contribution the term *supramolecular systems* is not only used for small molecular complexes of single molecules, such as substrate-receptor complexes. It is also applied to large molecular aggregates (high aggregation numbers), the function of which is again based on their organization. The ideal system to exemplify this definition is the biomembrane.

Clusters of Valence Electron Poor Metals—Structure, Bonding, and Properties**

By Arndt Simon*

Metals in low oxidation states are capable of forming metal–metal bonds. An attempt has been made to classify the numerous phases and structures occurring in such metal-rich systems of valence electron poor metals in some sort of order from a rather general point of view. With this purpose in mind, clusters of these elements, their different types of interconnections, and their condensation via shared metal atoms, which finally leads to extended M–M bonded structures, are described. Interstitial atoms play an important role in stabilizing electron deficient clusters, and can actually lead to the loss of all M–M bonds. Surprising similarities emerge between apparently very different systems as the metal-rich oxides of alkali metals, the oxides, halides, and chalcogenides of d transition metals, and the halides and carbide halides of the lanthanoids.

1. Introduction

It is immediately apparent from the literature that chemists are becoming more conscious of the behavior of solids and of the interrelationships between their structure, bonding, and chemical and physical properties. Superficially analyzed, this is due to the fact that single crystal structural analysis—the development of solid state chemistry without this technique would be unthinkable—has become a routine analytical method in molecular chemistry. With this technique, one is compelled to consider additional atomic interactions present in the "extended" crystalline state that may be absent in the "molecular" state. As illustrated in the following amusing story, such additional interactions might be very special: We succeeded in solving the crystal structure of the unstable compound F_3CCSF_3, which melts at $-123\,^{\circ}C$, and found, contrary to the predicted angle of 180.0°,[2] one of 171.5° at the central carbon atom.[1] Obviously due to the influence of crystal packing forces![3] Later, calculations taking into account electronic correlation effects predicted a much larger deviation from linearity,[4] and now the experimental value was too large. Once again, packing influences? *The solid state is something very special!*

From the above it is not obvious that the last sentence is meant seriously. Naturally, an assembly of 10^{23} atoms in a crystal must have significant consequences with respect to bonding and properties like non-stoichiometry or cooperative phenomena. Besides these real peculiarities, however, there are a number of apparent ones originating from a different development of description in different fields of chemistry. The carbon suboxide C_3O_2 is not puzzling to chemists, because its conventional formulation O=C=C=C=O obeys the accepted and well-known valence rules. The formula Rb_9O_2 is more likely to raise eyebrows. Yet, the principle of bonding in both compounds is the same. Only a part of the valence electrons of C (Rb) is used for heteronuclear C–O (Rb–O) bonds, while the extra electrons are used for homonuclear C–C (Rb–Rb) bonds.

The reverse is also true. Certain bonding features in a molecule are considered most unusual, even though comparable features are quite normal in solid compounds. Thus, the carbon in the stable molecule Li_6C was believed to be hypervalent,[5,6] even though the occurrence of octahedrally coordinated carbon atoms was known to be widespread in transition metal carbides with the rock salt-type structure. The hypervalency is not required in a simple ionic formulation. With $(Li^+)_6C^{4-}(e^-)_2$ the only surprising feature is the surplus of electrons. Yet, even this feature is familiar in the case of interstitial carbides like V_2C. Again, it holds that valence electrons of V (Li) that are not used for heteronuclear V–C (Li–C) bonding are used for homonuclear V–V (Li–Li) bonds, as suggested by the 8 − n rule.[7]

The structures and properties of metal-rich compounds are well suited for illustrating the sometimes different but supplementary views in molecular and solid-state chemistry. The examples already discussed throw light on important facets of the following treatise: Metal-rich compounds contain more metal atoms than the number of free valencies of the nonmetal atoms. The excess of metal-centered valence electrons can lead to bonding, nonbonding, or even antibonding interactions between adjacent metal atoms. As a rule, these interactions are bonding with the valence electron-poor metals under discussion and therefore result in the formation of discrete metal clusters or extended M–M bonded structures.

A surprisingly uniform picture has been developed for the bonding in metal-rich alkali metal oxides, cluster compounds of d-metals, and metal-rich compounds of the lanthanoids, especially the carbide halides, allowing us to relate these seemingly different classes of compounds under one unified theme.

2. Alkali Metal Suboxides—"Cluster Metals"

The alkali metals have been considered rather boring due to their exclusive monovalency. Contrary to this, the

[**] The preceding page shows Figure 27c of this article.

previously mentioned compounds Li_6C and Rb_9O_2 indicate that metal-metal bonding occurs and results in a fascinating chemistry, even with these elements. The molecule Li_6C, which is stable toward all conceivable decomposition reactions in the gas phase, is by no means unique. Numerous comparable hypermetalated molecules (e.g., Li_3O, Li_4O, Li_5N, Na_3O, Na_4O, and Na_2OH) have been estimated to be stable and have been observed experimentally.[8] The existence of M–M bonds between alkali metal atoms should not be surprising at all, for it has long been known that vapors of these metals contain M_2 molecules. Larger homonuclear clusters are formed by high-energy ion bombardment[9] or expansion of the vapors,[10] although such homonuclear clusters have a rather low stability. If Cs vapor is expanded into an atmosphere of pure He gas, no Cs clusters are observed. The situation changes drastically when small amounts of O_2 (0.01%) are introduced into the He. A large number of homonuclear Cs_n clusters can be detected by mass spectroscopy; they are obviously formed by fractionation during the ionization process (e.g., Cs_n^{2+} with $n > 19$). On increasing the proportion of O_2, hypermetalated species like $[Cs_5O]^+$, $[Cs_7O]^+$, and $[Cs_7O_2]^+$ are formed in high concentrations.[11–13]

These findings can be summarized in the following simple way: Clusters of valence electron-poor metals have a rather low stability. They are stabilized by the insertion of heteroatoms, which leads to strong bond formation to these atoms at the expense of a further weakening of the already weak M–M bonds.

Although metal-rich solids appear to be more complicated, their bonding can be explained in a similar fashion provided one uses a sufficiently simplified description. The formulation of Li_6C as $(Li^+)_6C^{4-}(e^-)_2$ should not be taken as an ideology of chemical bonding, but as providing a simple and easily visualized counting scheme. A more detailed description tells us that in the octahedral molecule, all bonding states are occupied by ten electrons, $(3a_{1g})^2(2t_{1u})^6(4a_{1g})^2$, and that the HOMO $4a_{1g}$ has Li–Li bonding character.[6]

During the transition from the gas phase to the solid state, even the alkali metal clusters that are stabilized by interstitial nonmetal atoms are threatened with decomposition. The metals are entirely miscible with their molten halides, provided the temperature is high enough.[14, 15] The colorful and experimentally difficult cluster chemistry that results[16] is lost with decreasing temperature due to the dominance of the heteroatom bonds. This results in a phase separation and crystallization of the monohalides with their high lattice stabilities.

A small island of stability of alkali metal clusters in the solid state only exits so far in the suboxides of the heavy alkali metals, Rb and Cs,[17] although only at relatively low temperatures (Table 1). Similar compounds of the lighter metals and the higher homologs of O do not exist because of the ease of formation of the normal valence compounds M_2X.

As shown in Figure 1, the Rb and Cs suboxides contain Rb_9O_2 and $Cs_{11}O_3$ clusters, which are composed of two and three face-sharing octahedral M_6O units, respectively. They are the only constituents of the compounds Rb_9O_2 and $Cs_{11}O_3$, but occur together with a stoichiometric amount of Rb and Cs in a variety of thermally unstable phases that have even higher M:O ratios. Most of these compounds have been characterized by single crystal structural analyses. The clusters are largely decomposed in melts that have the composition of the solid phases. The decomposition follows, inter alia, from the fact that the quenching of a melt of composition Rb_7O to $-109\,^\circ C$ yields an amorphous product. Upon annealing at $-103\,^\circ C$ this product deposits crystalline metastable $Rb_{6.33}O$ but no Rb_9O_2 clusters.[25] Crystalline Rb_9O_2 is finally generated along with elemental Rb upon warming to $-90\,^\circ C$. Rb_9O_2 and $Cs_{11}O_3$ clusters do not occur in the gas phase, as has been demonstrated by mass spectroscopic investigation of the partially oxidized metal vapors.[12, 13]

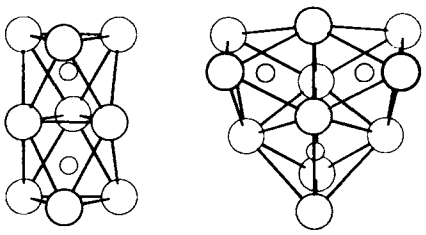

Fig. 1. Characteristic clusters Rb_9O_2 and $Cs_{11}O_3$ in Rb and Cs suboxides, respectively [17] (the large circles represent the metal atoms).

According to *Pauling*'s estimation of the ionicity based on differences in electronegativities, the O–M bonds in the Rb_9O_2 and $Cs_{11}O_3$ clusters are approximately 85% ionic. Therefore, the formulations $(Rb^+)_9(O^{2-})_2(e^-)_5$ and $(Cs^+)_{11}(O^{2-})_3(e^-)_5$ represent a rather realistic description of the bonding in these clusters. Their stability is due to strong O–M bonds, although additional (weaker) M–M bonds are essential for their existence. Model calculations using a simple Born-Mayer potential show that no stable configurations exist for the purely ionic clusters $[(Rb^+)_9(O^{2-})_2]^{5+}$ and $[(Cs^+)_{11}(O^{2-})_3]^{5+}$.[26] Such hypothetical species are unstable and lose cations. For a stable configuration, M–M bonds, i.e., additional electrons in metal centered states, are necessary, which in the electrostatic model are taken into account as a partial shielding of the positive charges. As shown in Figure 2, the energy minimum for the Rb_9O_2 cluster is reached at a global charge of

Table 1. Melting or decomposition temperature T and structural principle of alkali metal suboxides [17, 18].

Compound	T [°C]	Structural principle
Rb_9O_2	40	Rb_9O_2-Cluster
Rb_6O	− 8	$Rb_9O_2Rb_3$; three Rb atoms per Rb_9O_2 cluster
$Rb_{6.33}O$	−93 (metastable)	probably $(Rb_6O)_3Rb$; discrete Rb_6O units
$Cs_{2.78-3.19}O$	< 166	*anti*-TiI_3 type for anticipated composition Cs_3O (to be revised; additional diffuse scattering effects)
$Cs_{11}O_3$	52	$Cs_{11}O_3$ cluster
Cs_4O	ca. 12	$Cs_{11}O_3Cs$; one Cs atom per $Cs_{11}O_3$ cluster
Cs_7O	4	$Cs_{11}O_3Cs_{10}$; ten Cs atoms per $Cs_{11}O_3$ cluster
$Cs_{11}O_3Rb$	—	one Rb atom per $Cs_{11}O_3$ cluster
$Cs_{11}O_3Rb_2$	—	two Rb atoms per $Cs_{11}O_3$ cluster
$Cs_{11}O_3Rb_7$	−22	seven Rb atoms per $Cs_{11}O_3$ cluster

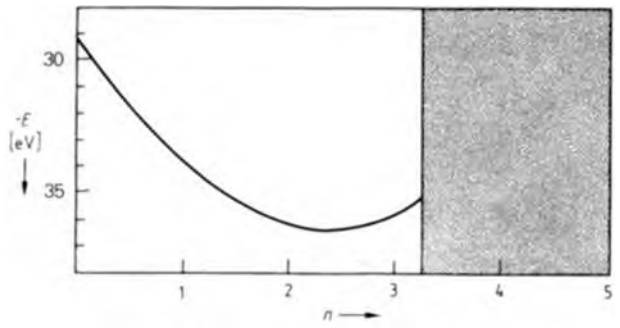

Fig. 2. Calculation of the stable configuration of the cluster $[Rb_9O_2]^{n+}$ assuming two body interactions of the kind $V_{ij}=Z_iZ_j/r_{ij}+A\cdot\exp(-r_{ij}/\rho)$ [26]. For $n>3.2$ no stable arrangement exists. In the shaded range the cluster looses a Rb atom [27].

+2.3. The incomplete shielding of the cationic charges by the additional electrons is probably associated with the anisotropic charge distribution around the Rb^+ ions, which has further interesting consequences discussed later. The vibrational states of the cluster calculated for the equilibrium configuration are in good agreement with the observed Raman spectrum of Rb_9O_2.[26] Therefore, the simple model accounts for both the static and dynamic features of the cluster.

The atomic arrangement in $Cs_{11}O_3$ (Fig. 3) is reminiscent of a molecular crystal structure exhibiting short "intramolecular" Cs-Cs distances (367–431 pm) as a consequence of the strong ionic O-Cs bonds (275–292 pm). Contrary to this, the large "intermolecular" Cs-Cs distances between the clusters, which with only one exception are longer than 500 pm, correspond to the distances in elemental Cs. $Cs_{11}O_3$ and all other alkali metal suboxides have metallic luster[29] and are good metallic conductors.[30] Thus, the electrons in M–M bonding states do not stay localized within the clusters but delocalize throughout the crystal due to the close contacts between the clusters. Accordingly, the characteristic features of the bonding in $Cs_{11}O_3$ can be described in two alternative ways, presented graphically in Figure 3: on the one hand as a "cluster metal", in which the simple ionic cores in the cesium (Cs^+) are replaced by complex ion clusters $[Cs_{11}O_3]^{5+}$ (Fig. 3, top) and, on the other, as a cesium metal that is largely contaminated with oxygen. The localization of negative charges on the O atoms and the regular arrangement of accumulated negative charge in the crystal create a lattice with regions of atomic dimensions that are repulsive to the conduction electrons. The comparison of such a void metal with a "microscopically foamed metal" might be allowed (Fig. 3, bottom).

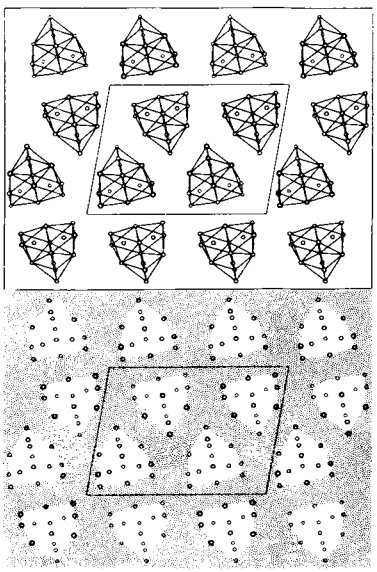

Fig. 3. Projections of the crystal structure of $Cs_{11}O_3$ [28] along [010]. The unit cell is outlined. Top: The $Cs_{11}O_3$ clusters are emphasized by interconnections between the Cs atoms. Bottom: The metallic bonding between the $Cs_{11}O_3$ clusters is emphasized (hatched) leaving repulsive regions for the conduction electrons near the O^{2-} ions (white).

Both model descriptions, the first rather chemical and molecular in character, the second rather physical and related to the quasi-infinite nature of the crystal, allow for a quantitative understanding of the properties of the alkali metal suboxides from very different viewpoints. The cluster metals Rb_9O_2 and $Cs_{11}O_3$ form "intermetallic compounds" with Rb and Cs,[17] e.g. $Rb_9O_2Rb_3$, $Cs_{11}O_3Cs_{10}$, and $Cs_{11}O_3Rb_7$ (Table 1). The molar volumes of these compounds closely correspond to the sum of the molar volumes of Rb_9O_2 and $Cs_{11}O_3$ and the atomic volumes of Rb and Cs, respectively. For example, the molar volumes of $Cs_{11}O_3Cs$ and $Cs_{11}O_3Cs_{10}$ exceed the volume of $Cs_{11}O_3$ by 69.9 and 696.5 $cm^3\ mol^{-1}$ respectively, with the volume of elemental Cs at $-50\,^\circ C$ being 69.4 $cm^3\ mol^{-1}$. Clearly, the Cs in these suboxides forms purely metallic bonds to the $Cs_{11}O_3$ cluster. In Rb-Cs mixed suboxides, under equilibrium conditions, pure $Cs_{11}O_3$ clusters are formed[17,31,32] (for example, $Cs_{11}O_3Cs_{10-x}Rb_x$, $Cs_{11}O_3Rb_{7-x}Cs_x$, and $Cs_{11}O_3Cs_{1-x}Rb_x$). It is only when there is no Cs left for the purely metallic regions between the clusters that the Rb starts to substitute Cs in the cluster itself (e.g., in $Cs_{11-x}Rb_xO_3Rb_7$ and $Cs_{11-x}Rb_xO_3$). There is evidence for the existence of K-Cs mixed suboxides that should, according to what has been said about the Rb-Cs suboxides, have the general composition $Cs_{11}O_3(Cs,K)_n$. Unfortunately, they decompose at $-60\,^\circ C$ with deposition of K_2O and only preliminary X-ray and thermal analysis data have been obtained.

Aside from these chemical aspects of the cluster metal model there emerges a number of physical aspects. Thus, for example, the temperature dependence of the specific heat[33] of $Cs_{11}O_3Cs_{10}$ closely corresponds to the sum of the appropriately scaled values of $Cs_{11}O_3$ and Cs. In particular, the separate contributions to the specific heat of the lattice vibrations of the clusters and the purely metallic regions at low temperatures are of interest. Elemental Cs shows a larger increase in the specific heat in the range $1\le T^2\le 8\,K^2$ than would be expected according to the T^3 law; this is due to the excitation of phonons of the lowest-lying acoustic branch. In the same temperature interval an anomalous increase of c_p is also found for $Cs_{11}O_3Cs_{10}$ which is caused by the excitation of vibrations of the individual isolated Cs atoms (Fig. 4). A similar, although much less pronounced behavior is found in the region $0.1\le T^2\le 1\,K^2$ (Fig. 4, inset). Here one expects excitation of the very soft vibrations of the clusters as a whole, which have more than eleven times the mass of a single Cs atom.

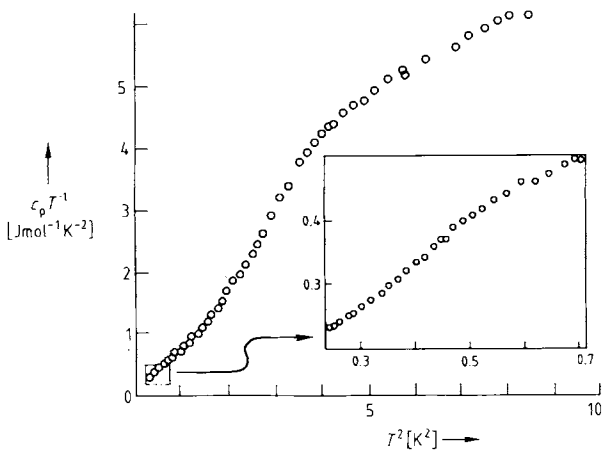

Fig. 4. Specific heat [33] of $Cs_{11}O_3Cs_{10}$ ($\triangleq Cs_7O$) as a function of T, plotted as $c_p/T = f(T^2)$ in the range $0.2 \leq T^2 \leq 9\,K^2$ (inset: $0.24 \leq T^2 \leq 0.72\,K^2$).

An additive behavior of the components in alkali metal suboxides is observed, in particular, in the electronic densities of states. At first glance, the photoelectron (PE) spectrum of $Cs_{11}O_3Cs_{10}$[34] looks like a superposition of the spectra of $Cs_{11}O_3$ and Cs (Fig. 5). All spectra exhibit densities of states at the Fermi level ($E_F = 0$ eV) as one would expect for metallic samples. In the spectrum of $Cs_{11}O_3$ the spin-orbit-split Cs 5p band is shifted by 0.5 eV to smaller binding energies compared to that of Cs, and in the spectrum of $Cs_{11}O_3Cs_{10}$ the photoemission from the 5p band is both characteristic for the $Cs_{11}O_3$ cluster and for pure Cs. The narrow O 2p band provides evidence for the localization of electrons in the O^{2-} ion, and the measured binding energy ($E_B = 2.7$ eV), which is the lowest for all oxides, is consistent with the given description of chemical bonding in terms of O^{2-} ions that are stabilized by a weak Coulomb field of surrounding cations.

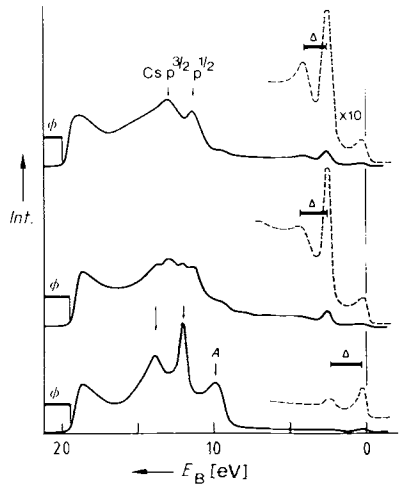

Fig. 5. PE spectra (He(I), $h\nu = 21.2$ eV) of Cs (bottom), $Cs_{11}O_3Cs_{10}$ (middle) and $Cs_{11}O_3$ (top) [34]. The binding energy E_B is referred to the Fermi level $E_F = 0$ eV (ϕ = work function, A = Auger transition $O_{III}VV$, Δ = energy loss structure $\hbar\omega$ (surface plasmon), Int. = intensity.

The measured spectrum of $Cs_{11}O_3Cs_{10}$ could stem from a heterogeneous mixture of Cs and $Cs_{11}O_3$, were it not for features of the spectrum that provide clear evidence of a homogeneous sample. Each sample has a characteristic value for the work function Φ that decreases with increasing O content and shows up as a gap between 21.2 eV (excitation energy) and the threshold of photoemission. The energy loss also changes systematically and leads to satellite structures Δ on the high-E_B side in the spectra due to reduced kinetic energies of the photoemitted electrons. The losses are caused by excitation of surface plasmons, whose energies depend on the number of quasi free electrons. The number of free electrons determined from the measured energy values for $Cs_{11}O_3$ and $Cs_{11}O_3Cs_{10}$ (5 and 14 electrons per formula unit respectively) are in excellent agreement with the simple ionic bond model explained earlier.

The PE spectroscopic investigation not only enables a quantitative proof of this model of the chemical bonding in alkali metal suboxides but also provides information of importance regarding applications and fundamental aspects. Thin composite layers of Cs_2O and Cs on Ag play an important role in the IR-sensitive S1 photocathodes that have now been manufactured for approximately fifty years.[35] The characteristic spectral response of such cathodes can be explained in terms of the presence of alkali metal suboxides ($Cs_{11}O_3$ or "Cs_2O"), which have the necessary electronic properties, namely, a low work function (approximately 1 eV compared to 2 eV for elemental Cs) and low energies of the surface plasmons (1.5 eV), which due to their decay, enhance the photoelectric yield.[36]

The small value for the plasmon energy is simply related to the low carrier concentration and intimately connected with the electron-poor nature of the alkali metals. But what is the origin of the low work function? An interesting explanation is based on the "microscopically foamed metal" model (see Fig. 3, bottom).[37] The conduction electrons in a suboxide crystal find a regular array of accumulated netative charges or "forbidden regions" and reside in narrow regions of atomic scale between the $Cs_{11}O_3$ clusters. As with extremely thin wires, quantization effects are to be expected. In fact, the estimation of such quantum size effects for $Cs_{11}O_3$ predicts a work function that is 0.9 eV lower than that for Cs. Recently, metastable de-excitation spectroscopic (MDS) investigations on cesium suboxide surfaces gave further support for such a quantum size effect.[38,39]

It is a long way from the hypermetalated molecules at the beginning of this Section to the unique electronic properties of alkali metal suboxides. The electron gas and its plasma oscillations call for a quasi-infinitely extended metal. The work function describes a surface property of a solid, and the mentioned quantum size effect is related to the unique bonding in the extended crystal. Yet, the way to molecules is not as far as it might seem. The work function is closely related to the electronegativity of atoms and to the ionization energy of molecules. Much in the same way as the work function of Cs decreases with the addition of oxygen, the ionization energy for a Cs_nO cluster in the gas phase, as a rule, is lower than for the corresponding Cs_n cluster.[11] Does the photoelectron simply experience an additional repulsion by an O^{2-} ion that acts from the interior of an isolated Cs_nO cluster or from a position be-

neath the outermost atomic layer in a suboxide crystal? Does this simple explanation of an experimental observation hold for both the crystal and the isolated molecule?

3. Discrete Clusters—Transition from Insulators to Metals

In alkali metal suboxides an extreme of cluster chemistry involving metals that are especially deficient in valence electrons is realized. The weakness of the M-M bonding in alkali metals is already apparent in the properties of cesium, which is as soft as paraffin, has a low melting point, and is easy to distill. The clusters are stabilized by interstitial atoms, and the metals lack electrons to surround the clusters by nonmetal atoms. On searching for metals with strong M-M bonds one arrives at the transition metals with approximately half-filled d-shells. These have the maximum number of electrons capable of bonding in the elements. Metals like Nb, Ta, Mo, and W are distinguished by high melting points and high values for the heats of atomization. In fact, these metals also exhibit a broad and already frequently described chemistry of metal-rich compounds.[40-59]

It is attractive to extend along the line of thoughts developed so far with a few chosen systems. Particularly suitable as model systems are compounds containing metal clusters with octahedral M_6 units. These units are surrounded by eight nonmetal atoms X above the faces (M_6X_8) or twelve X atoms above the edges (M_6X_{12}), with square coordination geometry of the X atoms at each M atom. The chemical bonding in these clusters has been repeatedly analyzed.[60] The number of M-M bonding states results in a simple way: Each M atom bonds four X atoms via s, p, and d_{xy} orbitals. In the case of the M_6X_8 cluster the remaining four d states mix to yield a fourfold degenerate valence state that bonds along the octahedral edges and leads to twelve 2 electron-2 center (2e-2c) bonds. In the case of the M_6X_{12} cluster the MX_4 planes are rotated through 45° and the corresponding d valence hybrids overlap in the octahedral faces to yield eight 2e-3c bonds.[67] Therefore, ions like $[Mo_6Cl_8]^{4+}$ and $[Nb_6Cl_{12}]^{2+}$ are effectively isoelectronic, for in both cases 20 electron pairs occupy M-X and M-M bonding states.[68]

In addition to the atoms X^i located above the edges and faces of the M_6 octahedra, there are X^a atoms located above the apices of the octahedra (Fig. 6a). In compounds such as $K_4Nb_6Cl_{18}$ ($= K_4Nb_6Cl^i_{12}Cl^a_6$)[69] or $HgMo_6Cl_{14}$ ($= HgMo_6Cl^i_8Cl^a_6$)[70] all coordination sites are occupied without any linkage between the clusters. There is a variety of different ways in which adjacent clusters can be linked, as indicated schematically for the M_6X_8 cluster in Figure 6b. For sake of clarity only bridging between two clusters is shown. Bridges between three discrete clusters are the exception, although they exist, e.g., in $Nb_6Cl_{12}I^{a-a}_{6/3}$.[71] In the condensed cluster systems discussed later, bridges between 3 or even 4 adjacent M_6 units are found.

The electronic balance and the degree of coverage of the M_6 units by X atoms critically determine the physical properties of the compounds. A total coverage always

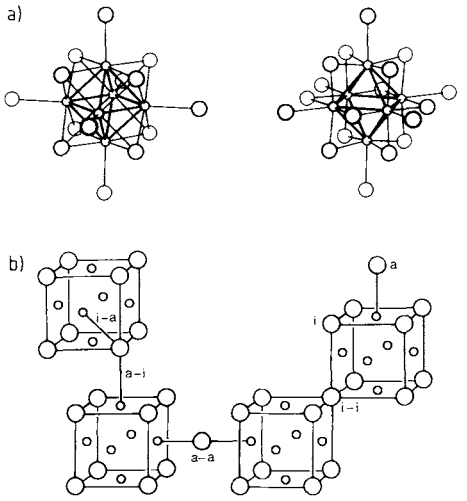

Fig. 6. a) $M_6X^i_8X^a_8$ (left) and $M_6X^i_{12}X^a_6$ clusters (right). b) Different kinds of cluster linkages via X atoms and the symbols used for their description [41]. The cube of X^i atoms is emphasized.

Table 2. Halides, halide chalcogenides and chalcogenides with Mo_6X_8 clusters; structures and properties [55] (cf. Fig. 6); the value of z indicates the number of electrons in M-M bonding states.

Compounds		Structural principle	z/Mo_6	Properties
$A_2Mo_6X_{14}$	A = Li, K, Rb, Cs, Cu; X = Cl $Cs_2Mo_6Cl_8Br_6$	$Mo_6X^i_8X^a_6$	24	insulators
AMo_6X_{14}	A = V–Ni, Zn–Hg, Sn, Pb, Mg–Ba, Eu, Yb; X = Cl	$Mo_6X^i_8X^a_6$	24	insulators
AMo_6X_{13}	A = Na, Ag; X = Cl	$Mo_6X^i_8X^a_{4/2}X^{a-a}_{2/2}$	24	insulators
Mo_6X_{12}	X = Cl, Br, I	$Mo_6X^i_8X^a_{4/2}X^{a-a}_{4/2}$	24	insulators
$Mo_6X_{10}\hat{X}$	X = Cl, Br; $\hat{X}$ = S–Te X = I; $\hat{X}$ = Se, Te	$Mo_6(X_7\hat{X})^i_8X^{a-a}_{6/2}$	24	insulators
$Mo_6X_8\hat{X}_2$	X = Br; $\hat{X}$ = S X = I; $\hat{X}$ = S, Se	$Mo_6(X_5\hat{X})^iX^{i-i}_{2/2}X^{a-a}_{6/2}$	24	insulators
$Mo_6X_6\hat{X}_3$	$Mo_6Br_6S_3$	$Mo_6X^i_4X^{i-i}_{2/2}\hat{X}^{i-a}_{2/2}X^{a-a}_{4/2}\hat{X}^{a-i}_{2/2}$	24	narrow band gap semiconductor (0.02 eV at $T < 100$ K)
$Mo_6X_2\hat{X}_6$	X = Br, I; $\hat{X}$ = S	$Mo_6X^i_2X^{i-a}_{6/2}\hat{X}^{a-i}_{6/2}$	22	metals, superconductors $T_c \approx 14$ K
$Mo_6\hat{X}_8$	$\hat{X}$ = S, Se, Te	$Mo_6\hat{X}^i_2\hat{X}^{i-a}_{6/2}\hat{X}^{a-i}_{6/2}$	20	metals, superconductors
$AMo_6\hat{X}_7$	$Cs_{0.6}Mo_6S_7$	$Mo_6X^{i-i}_{2/2}\hat{X}^{i-a}_{6/2}\hat{X}^{a-i}_{6/2}$	22	metal, superconductors $T_c \approx 8$ K

means insulating or semiconducting behavior even when the important condition for metallic conductivity, namely, partial occupation of the M–M bonding cluster states, is met. An increasing degree of cluster linkage leads to a stepwise closer approach of the M_6 units, especially if the X^i atoms are involved. Following the Herzfeld-Mott criterion,[72–74] the metallic state is finally reached, which we already met with in the bare clusters of the alkali metals. The stepwise transition from insulators to metals is immediately recognizable in the examples of Mo compounds listed in Table 2.

In the case of the valence electron poor metal Nb, the M_6X_8 cluster is found as an exception in iodides,[57–77] but is common in (chalcogenide) halides of Mo[54–58] and (halide) chalcogenides of Re.[55,78,79] There are sufficient d electrons in the halides of Mo to fill all M–M bonding states in the M_6X_8 cluster. When the halogen atoms X are successively replaced by divalent chalcogen atoms $\hat{X}$ the d electron concentration is concomitantly kept high by a stepwise reduction of the $(X,\hat{X})/Mo$ ratio. In the case of valence electron rich Re, a large portion of $\hat{X}$ atoms is needed to avoid the occupation of M–M antibonding states. The decrease in the nonmetal content in the cluster compounds of Re occurs to a lesser extent than in Mo.

The different patterns of interconnection and the increasing degree of interconnection of clusters with decreasing $(X,\hat{X})/M$ ratio are shown schematically for selected compounds in Figure 7. In the chloromolybdates, and also in the ternary molecular compound $Re_6S_4Cl_{10}$ $(= Re_6S_4^iCl_4^iCl_6^a)$,[80] discrete clusters occur. The increasing degree of interconnection via X^a atoms results in one-, two-, and three-dimensional frameworks. The salts AMo_6Cl_{13} and the compound $Re_6Se_5Cl_8$[81] contain cluster chains. The structures of the Mo dihalides[82] and of the isostructural $Re_6S_6Cl_6$[81] are made up of layers, and the complete connection of clusters in all directions according to $M_6X_8^iX_{6/2}^{a-a}$ is reached in the structures of Nb_6I_{11}[75] and the isostructural compounds $Mo_6X_{10}\hat{X}$.[83] $Li_4Re_6S_{11}$[84] is isoelectronic with the latter compounds if a full charge transfer from the Li atoms to the Re_6S_{11} clusters is assumed, which are linked as in Nb_6I_{11}. Besides simple bridges of the X^{a-a} type, polyanionic bridges have been known for a long time, as in W_6Br_{16} $(= W_6Br_8^iBr_4^a(Br_4)_{2/2}^{a-a})$ and in $K_4Re_6S_{12}$ $(= K_4Re_6S_8^iS_{4/2}^{a-a}(S_2)_{6/6}^{a-a})$.[85,86] For Re_2Te_5 $(= Re_6Te_8^i(Te_7)_{6/6}^{a-a})$ a particularly interesting structure has been found.[87,88] The bridges consist of Te_7 units containing a central Te atom with a square planar environment of Te atoms.

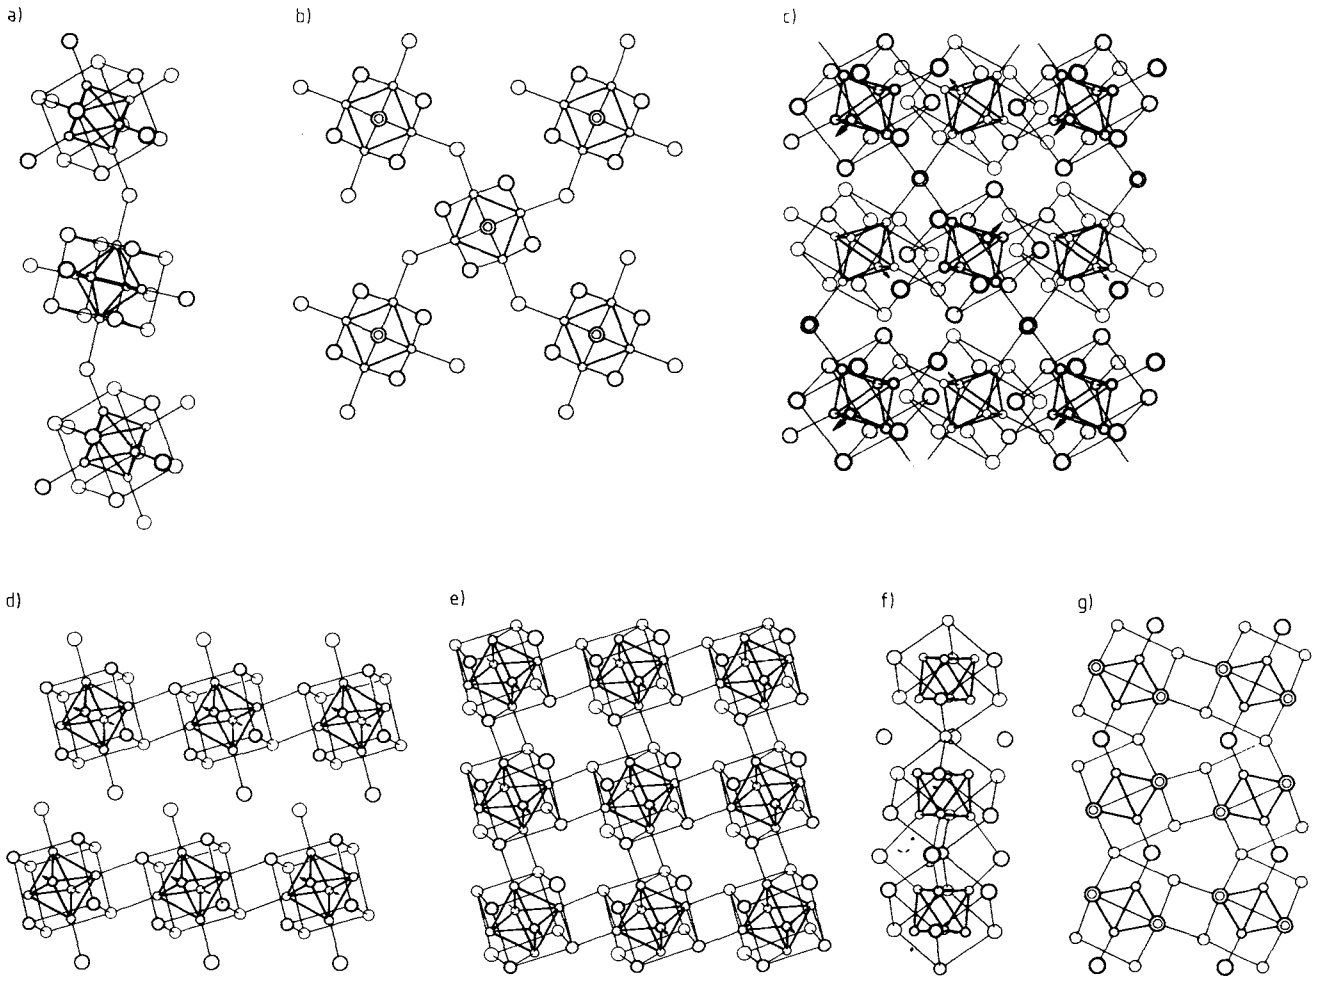

Fig. 7. Increasing connectivity of $M_6(X,\hat{X})_8^i$ clusters in halides, halide-chalcogenides and chalcogenides of the metals Nb, Mo and Re. X^{a-a} links in a) $Re_6Se_5Cl_8$ (chain), b) Mo_6Cl_{12} (layer), c) Nb_6I_{11} (network); X^{i-a} links in (d) $Re_6Se_8Cl_2$ (layer) and e) $Mo_6S_6Br_2$ (network); X^{i-i} $(+X^{i-a})$ links in f) $Mo_6Br_8S_2$ (chain) and g) $Mo_6Br_6S_3$ (layer). M, $\hat{X}$ and X atoms are drawn with increasing size (cf. Table 2 and text).

At low nonmetal contents, $(X,\hat{X})/M \leq 10$, X^{i-a} and X^{i-i} linkage becomes important. In the structure of $Re_6Se_8Cl_2$ ($= Re_6Se_4^{i}Se_4^{i-a}Cl_2^{a}$)[89] the clusters are connected via X^{i-a} bonds to form layers that are surrounded by Cl atoms and are held together via van der Waal forces. Omitting these X^{a}-type Cl atoms results in the $M_6\hat{X}_8$-type structure that consists of $M_6\hat{X}_8$ clusters connected in all directions via X^{i-a} bonds. The X^{i-i}-type interconnection always occurs via opposite atoms of the cluster and leads to linear chains. Such chains, which are van der waals bonded, are found in the structure of the compounds $Mo_6X_8\hat{X}_2$. The connection of these adjacent chains via X^{i-a} contacts results in layers as in the structure of $Mo_6Br_6S_3$. When these layers are linked via X^{i-a} contacts, the Mo-S framework of $Cs_{0.6}Mo_6S_7$ is formed. At this point, a critical limit is reached in the structural chemistry of these cluster compounds. A further reduction of the X/M ratio must lead to a condensation of the M_6 octahedra themselves.

All compounds with 24 electrons in M-M bonding states within the M_6 unit, i.e., with a fully occupied valence band, are insulators or semiconductors, even when close contacts due to interconnections via X^{i} atoms occur. In the case of $Mo_6Br_6S_3$, the energy gap is nearly closed. The gap is 0.037 eV at room temperature. A partial occupation of M-M bonding states does not, of course, result in a metal when the electrons of neighboring clusters are well separated due to X^{a-a} bridges and remain localized on the clusters. The dark green Ta_6Cl_{15} ($= Ta_6Cl_{12}^{i}Cl_{6/2}^{a-a}$)[90] or the brownish-black Nb_6I_{11} ($= Nb_6I_8^{i}I_{6/2}^{a-a}$) are insulators or semiconductors (depending where one draws the line), although only 15 and 19 electrons respectively (instead of 16 and 24) fill M-M bonding states. The description of Nb_6I_{11} as $(Nb^{5+})_6(I^{-})_{11}(e^{-})_{19}$ only serves as a unified counting scheme for electrons. It does not provide a good description of the chemical bonding. A quantitative analysis of bonding, at least within the limits of the one-electron approximation, has been performed.[91] In view of the weak electronic interaction between the clusters, the valence bands are narrow enough to describe the bonding within the MO scheme for the discrete cluster.

In compounds with such discrete units, the d electrons are only delocalized within the cluster. A partial occupation of the M-M bonding states may lead to interesting magnetic properties, which have been investigated in some depth with Nb_6I_{11}.[92-94] At low temperatures all 19 electrons in the M-M bonding states except one are spin paired. The calculated spin density distribution was also verified experimentally with polarized neutrons.[95] In a second order phase transition near 0°C the deformation pattern of the Nb_6I_8 cluster changes slightly. As a result, the states around the HOMO-LUMO gap approach each other, and when their separation becomes smaller than the spin pairing energy, one pair decouples. The phase transformation is accompanied by a change in the magnetic ground state from doublet to quartet (Fig. 8). Such spin crossover transitions should occur frequently in metal cluster compounds, since numerous closely spaced levels with M-M bonding character exist, whose energies are sensitive to small changes in the geometry of the clusters.

The compounds at the end of Table 2 combine a partial occupation of the M-M bonding states with a close approach of the clusters, which leads to broadened valence bands. These compounds are metallic. The strong electronic interactions between neighboring clusters are mainly due to the short distances between Mo and $\hat{X}$ atoms and not due to direct Mo-Mo intercluster bonding.[64] For example, the Mo-Mo distances in the structure of $Mo_6S_6Br_2$ are 272 and 273 pm within and 322.5 pm between Mo_6 octahedra. In contrast, the intracluster Mo-S distances of 240-247.5 pm are only slightly shorter than the inter-cluster Mo-S distances of 248.5 pm.[97]

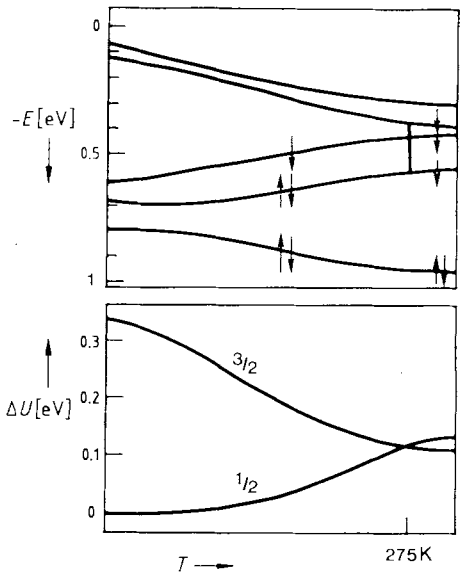

Fig. 8. Top: Changes in the one-electron energies of the highest occupied (HOMO's) and lowest unoccupied (LUMO's) d states in Nb_6I_{11} as a function of temperature (or deformation of the Nb_6 octahedron respectively) [91, 92]. When the separation of the marked states becomes equal to the spin pairing energy at 275 K the energy difference between low-spin ($S = 1/2$) and high-spin state ($S = 3/2$) disappears and a doublet-quartet transition occurs (bottom). ΔU = total energies.

Wide variations for the d electron concentration are found in the Chevrel phases $(M,M')_6(X,\hat{X})_8A_x$. One possibility for changing the electron balance is by substitution of the nonmetal atoms, as seen in the last example. Substitution of the Mo atoms by more electron-rich transition metals is also possible, and the "magic number" of 24 electrons per $(M,M')_6$ unit is reached in the semiconductors $Mo_4Ru_2Se_8$ or $Mo_2Re_4Se_8$.[98] A third possibility for varying the electronic count is the intercalation of metals A that act as electron donors. Metal atoms from the entire Periodic Table can be incorporated between the clusters. The Mo-Mo distances are a sensitive probe for the number of electrons transferred from A into the cluster. At low electron concentrations, the M_6 unit is an elongated trigonal antiprism and becomes increasingly regular as the 24 electron limit is approached.[99, 100]

The chemical and physical properties of Chevrel compounds have been covered in detail in textbooks.[101] The enormous interest in these compounds is due to the fact that Mo_6S_8Pb turned out to be a superconductor ($T_c \approx 14$ K),[102, 103] which, from the very beginning, set a new record to accessible upper critical fields ($H_{c2} \approx 60$ Tesla). Figure 9 compares Mo_6S_8Pb with the technically used superdonductors NbTi and Nb_3Sn. Incidentally, the compound initiating all the interest, Mo_6S_8Pb, already repre-

sented the nearly optimized system. In the meantime cold-drawn multifilament wires have been produced that contain thin Mo_6S_8Pb fibers in a Cu matrix.[104]

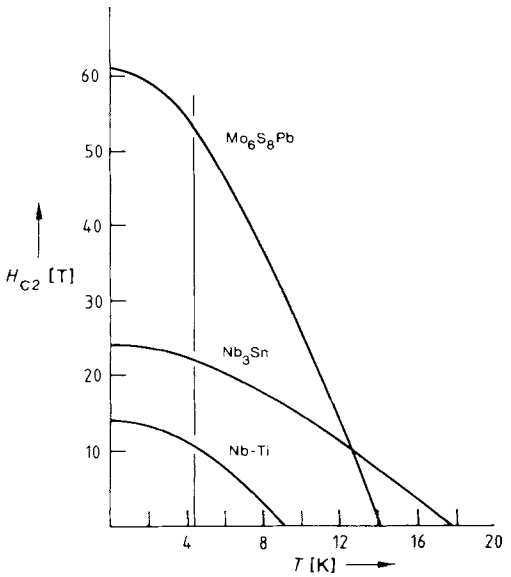

Fig. 9. Comparison of the upper critical fields H_{c2} for Mo_6S_8Pb and the technologically employed superconductors Nb-Ti and Nb_3Sn [105]. The boiling point of He (4.2 K) is marked.

Magnetic fields normally decrease the superconducting transition temperature, no matter whether the field is independent of or created by the flow of current through the wire itself. Hence, the high value of the critical field H_{c2} for Mo_6S_8Pb is of interest for any technical application of this superconductor. Moreover, the investigations carried out on Chevrel compounds have contributed significantly to our understanding of the antagonism between superconductivity and magnetism.

Superconductivity of the element Mo at $T_c < 1$ K could only be demonstrated after the metal had been purified from ppm traces of magnetic impurities, Fe in particular. In the compound Mo_6S_8Pb a contamination by 0.5 atom-% Fe suppresses superconductivity.

In contrast, large magnetic ions like those of the lanthanoids can be introduced between the clusters in a strictly ordered arrangement. The distances to the Mo atoms are large (d(Ln–Mo) > 410 pm), and their influence on the superconductivity of the phases is small. The coexistence of superconductivity and long-range magnetic order could be demonstrated in these systems for the first time.[101] The Ln sublattice (e.g., Ln = Dy, Pr, Gd, Tb) in Mo_6S_8Ln orders antiferromagnetically without affecting the superconductivity. It needs a ferromagnetic ordering of the Ln^{3+} ions, corresponding to a strong external field, to break the Cooper pairs and destroy the superconductivity. Such competition between superconductivity and magnetism is responsible for the remarkable properties of Mo_6S_8Ho, which becomes superconducting upon cooling ($T_c = 1.2$ K) and normal again at the lower temperature of 0.65 K. At this temperature, the ferromagnetic ordering of the Ho^{3+} moments occurs. Still more unusual is the behavior of $Mo_6S_{7.2}Se_{0.8}Sn_{0.25}Eu_{0.75}$ (Fig. 10).[108, 109] At $T < 1$ K the superconductivity is suppressed in a weak field of approximately 1 T, but reoccurs at higher fields. Finally, above 22 T the phase becomes a normal conductor again. This phenomenon is explained in terms of the Eu 4f electrons generating an exchange field in opposition to the external field, which it therefore compensates.

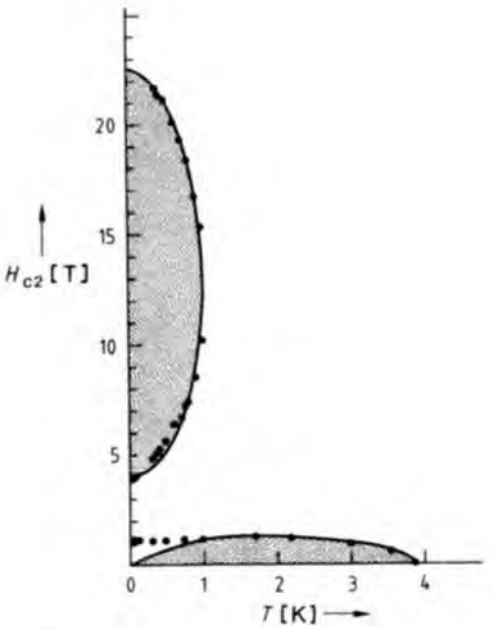

Fig. 10. Field induced superconductivity of $Mo_6S_{7.2}Se_{0.8}Sn_{0.25}Eu_{0.75}$ [108, 109]. The regions with superconductivity are shaded (lines calculated, points measured).

The intriguing physical properties of the Chevrel phases, as well as their comparatively simple crystal structures based on a primitive packing of quasi-molecular $Mo_6\hat{X}_8$ units, prompted a series of theoretical investigations in order to understand the chemical bonding in these phases.[64, 65, 110, 111] They provided evidence of strong electronic interactions between the closely spaced clusters. The transition from the local bonding scheme for the "molecule" $Mo_6\hat{X}_8$ to the band structure for the extended crystal can be illustrated in a most obvious way (Fig. 11). In the discrete regular $Mo_6\hat{X}_8$ cluster the twelve M–M bonding states lying above the M–$\hat{X}$ bonding ones are followed by the antibonding e_g, t_{1u}, a_{2g}, t_{1g}, and t_{2u} states. Their degeneracy is partly removed due to the deformations in the real clusters.

In Figure 11 the molecular orbitals (MO's) are drawn around the HOMO-LUMO gap for the real clusters in Mo_6S_8 and Mo_6S_8Pb. The interactions between the cluster systems in the extended crystal leads to a band-like broadening of all levels. Their dispersion in momentum space is shown for the symmetry direction along the threefold axis of the rhombohedral system. The bands are filled to the Fermi level, E_F.

The special arrangements of the clusters in the $M_6\hat{X}_8$ structure (Fig. 7e) allows each Mo atom to form a donor-acceptor bond with an $\hat{X}$ atom (type $X^{i\text{-}a}$) of an adjacent cluster. The bonding originates from an opening of the HOMO-LUMO gap. The M–M bonding e_g state remains

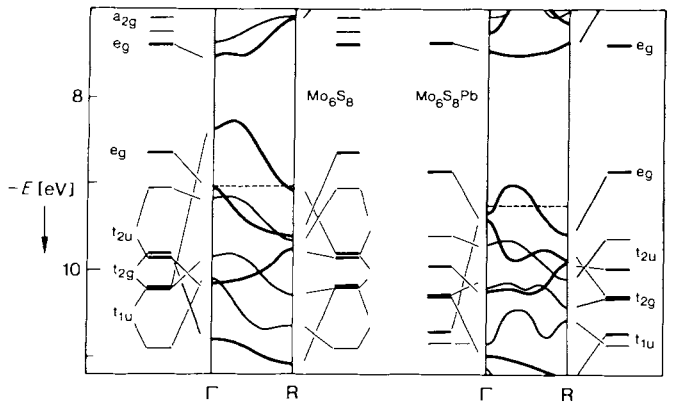

Fig. 11. MOs around the HOMO-LUMO gap for the discrete clusters in Mo_6S_8 and Mo_6S_8Pb together with the band structures for the extended crystals. The band dispersions are shown in the direction of the threefold axis of the rhombohedral system [64]. The Fermi levels are marked by dashed lines.

virtually unchanged in energy as there is hardly any overlap with the p orbitals on the $\hat{X}^{a-i}$ atom (δ bond). According to the result of a population analysis, the Mo-$\hat{X}$ bonds between clusters are essentially as strong as those within the clusters, whereas the *inter*-cluster Mo-Mo bonds have only approximately 10% of the strength of the *intra*-cluster Mo-Mo bonds. This result is fully consistent with the qualitative interpretation of the bonding presented earlier for $Mo_6S_6Br_2$ on the basis of the experimental Mo-Mo and Mo-$\hat{X}$ distances.

The self-consistent band structure calculation performed for the Chevrel phases with 20 to 23 d-electrons in M-M bonds leads to a result that is of significance to an understanding of their superconductivity. Obviously, the band scheme is not rigid but changes drastically with the electron concentration in the cluster. The conduction band, in particular, changes its shape dramatically.[112] These changes can be traced back to the antibonding interactions between e_u and the p orbitals at the $\hat{X}^{a-i}$ atom. These have π character and therefore are sensitive to changes in the intercluster distances. In the case of a filled conduction band (24 electrons) these antibonding interactions between the clusters lead to large Mo-$\hat{X}^{a-i}$ distances. The depletion of the conduction band reduces the repulsive interaction between the clusters, and as a consequence, the intercluster distances decrease and the conduction band near Γ is raised. This change is evident from a comparison of the band structure of Mo_6S_8 (20 electrons) and Mo_6S_8Pb (22 electrons).

In Mo_6S_8Pb the electrons occupy the local minimum at Γ. Vibration of the clusters as a whole changes the Mo-$\hat{X}^{a-i}$ distances and, hence, raises and lowers the conduction band near Γ. These states will fill and deplete periodically with the same rhythm of the vibrations. One might argue that the resulting strong electron–phonon coupling is essential for the superconductivity of these phases. But how is the coupling of the electrons in Cooper pairs effected? Is there a tendency for a pairwise localization of electrons in a cluster state, and do the magnetic properties of the insulating Nb_6I_{11} and the superconductivity in the metallic Mo_6S_8Pb therefore have anything in common?

4. Condensed Clusters, "Polymers" and "Oligomers"

In the previous section it was shown how stepwise lowering of the nonmetal-to-metal ratio in compounds with M_6X_8 and M_6X_{12} clusters leads to an increasing degree of bridging and, thus, to a change from insulators to semiconductors to metals. But, in the most metal-rich systems, i.e. the $Mo_6\hat{X}_8$ Chevrel phases, the relative number of $\hat{X}$ atoms is sufficiently high to occupy all inner positions of the cluster completely and even the X^a positions are all occupied by $\hat{X}$ atoms of adjacent clusters. Intercluster M-M bonding has thus far played only a subordinate role.

Further reduction of the nonmetal-to-metal ratio creates a qualitatively new situation, since not only X atoms but also M atoms now have to be shared between clusters. Such a condensation can occur via corners, edges or faces of the M_6 octahedron. In fact, numerous structures of metal-rich compounds of d metals and p elements can be interpreted in terms of condensed clusters forming the characteristic partial structures. A more comprehensive treatise of the concept has been given elsewhere.[49] In the present review, only some recent results will be summarized to illustrate the structural chemical concept, and in particular, those results will be discussed which shift emphasis from "structure" to "chemistry".

The condensation of M_6X_8 clusters via *trans*-positional corners of the M_6 octahedron is the most simple case, as the monomeric unit is kept complete in this process. The resulting chain has the composition $M_{2/2}M_4X_{8/2} = M_5X_4$. In this case the M atoms as well as the X atoms surrounding the clusters are shared between adjacent clusters. This type of cluster chain was first found in the structure of Ti_5Te_4.[113] There exists quite a number of isostructural compounds with M = V, Nb, Ta, Mo and X = S, Se, Te, As, Sb. The structure is shown as a projection along the tetragonal axis in Figure 12. The complete M_6X_8 clusters in

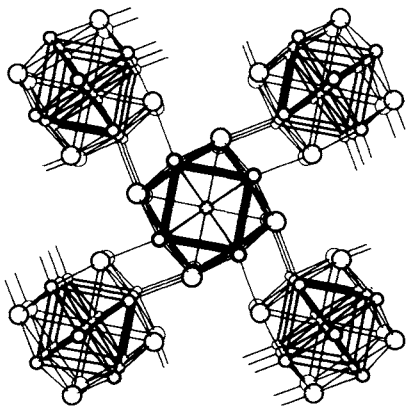

Fig. 12. Central projection of the structure of Ti_5Te_4 [113] along the tetragonal c axis. The Ti atoms (small circles) are connected by strong lines.

the chains are easily recognized. The intercluster contacts (M-X^{a-i}) are the same as those found in the Chevrel phases. Figure 13 shows, in a rather simplified way, how the bonding in the chain is derived from the bonding in the discrete cluster.[67, 114] The ordering of the d states remains,

in principle, the same in the discrete cluster as in the cluster chain structure. The four atoms in the equatorial plane of the M_6 unit are not involved in condensation. Their valence orbitals combine (2e-2c bonding) to form four bonding and four antibonding MO's respectively. In contrast, each apical M atom bonds to the atoms of two adjacent octahedron bases via four degenerate 2e-2c bonds resulting in four bonding, four nonbonding and four antibonding combinations respectively. In spite of some rather strong dispersion of the bands their origin is still recognizable, at least at low energies. Deviations from the very simplified MO scheme are mostly due to severe distortions of the clusters in the chain. The M_6 octahedra are always compressed to some degree such that the M-M distances in the octahedron bases are only slightly shorter than the intercluster distances (322 pm vs. 343 pm in Ti_5Te_4). The M-X distances between chains (d(Ti-Te) = 277 pm) are also of the same length or shorter than in the chains (277, 282, 295 pm).[113]

The M_5X_4 structure type exists with variable occupation of the M-M bonding states; Ti_5Te_4 (12 electrons) and Mo_5As_4 (18 electrons)[115] indicate the wide range of electronic balance. The experimentally established range of electron counts is in agreement with the calculated band structure (Fig. 13), which, at first glance, does not exhibit

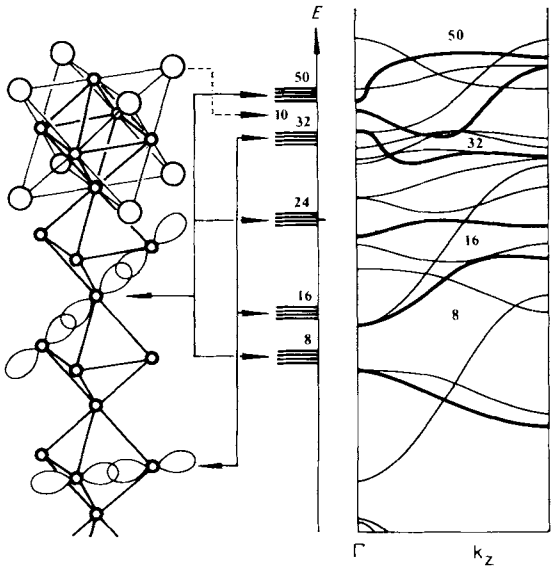

Fig. 13. Development of the band structure of a M_5X_4 chain in the [001] direction by the condensation of M_6X_8 clusters [67, 114]. The 2e-2c bond in the octahedral basis and the 2e-3c bond via the apex atom are indicated. The total number of electrons in the bands is given.

any region of low density of states. One-dimensional band structure calculations for distorted chains as in the real compounds, on the other hand, lead to electronic gaps or regions of low densities of states for the ranges 12 to 13 and 17 to 18 electrons, making the experimental observation of a certain concentration of compounds with these electron counts understandable.[116, 117]

The M_5X_4 chain is a characteristic structural component of a variety of compounds of quite different composition. The beautiful structure of $Nb_{21}S_8$[118] is shown as an example in Figure 14. The structure contains M_5X_4 chains as

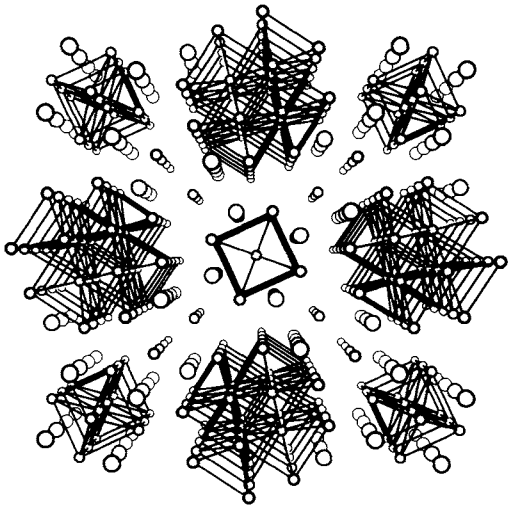

Fig. 14. Central projection of the structures of $Nb_{21}S_8$ [118] along the tetragonal c axis. The substructures derived from the M_6X_8 cluster are emphasized. Lines connect the Nb atoms.

well as parallel linear units formed by condensation of four such chains. In this process of condensation the X atoms of the single chains are largely substituted by M atoms of an adjacent chain. All Nb_6 octahedra are compressed to such a degree that the inner atoms of the unit have a cubic environment very similar to that found in the bcc structure of Nb metal. The structure gives the impression of a eutectic separation which stopped within atomic dimensions and resulted in a suspension of metallic Nb in a sulfide matrix. In fact, it is only a matter of the viewpoint one takes, whether the structures of metal-rich compounds are discussed in terms of condensed monomers or as pieces of the elemental structures cut out from the pure metals.[47] In this sense, the polycyclic arenes could equally be considered as derivatives of benzene and of graphite.

Structures are also known which are built up from M_6X_{12} clusters condensed via apices of the M_6 octahedra. In the low-temperature modification of TiO, chains occur in which the Ti_6 octahedra are condensed via *trans*-positional apices similarly as in M_5X_4 chains.[49] In NbO the clusters are condensed via all apical atoms, thus leading to a rigid three-dimensional framework with extended M-M bonding.[41] Band structure calculations impressively reveal the close relationship between the chemical bonding in the extended arrays of TiO and NbO and the bonding in a discrete M_6O_{12} unit.[119, 120] Consideration of these structures from another standpoint is helpful here: The structures of TiO and NbO almost correspond to the rock-salt type structure except for the fact that 1/6 and 1/4 of the available positions for the M and O atoms, respectively, are unoccupied. The loss of lattice energy caused by the vacancies has to be compensated for by M-M bonding. The proportion of vacancies therefore increases with the number of d electrons for M-M bonding. In the case of d^1 systems (e.g. TiN, NbC ...) the rock-salt structure is stable; the structure of the d^2 system TiO is between the rock-salt type structure and the structure of the d^3 system NbO. The conclusions drawn for metal-rich complexes in the gas phase also hold true here: if only few electrons are available for M-M bonding, then the clusters are stabilized, in

our case in the rock salt structure, by interstitial nonmetal atoms. TiO is an interesting borderline case. All clusters are empty in the structure of the low-temperature modification, but at high temperature a transition to a (statistically disordered) rock salt structure occurs.

When M_6 octahedra are condensed via apices the entire M_6X_8 and M_6X_{12} clusters remain complete and the directions of the valence orbitals are not changed significantly. The situation must change in the case of a condensation via edges or faces of the octahedra. In these systems one X atom is replaced by two or three M atoms respectively, which can only be bonded via drastically reoriented orbitals (rehybridization) compared to the discrete cluster. A correlation of the electronic band structures of extended systems of condensed clusters and the MO pictures of discrete clusters is therefore scarcely possible, and one might ask whether a description of, for example, an octahedra chain in terms of condensed clusters is meaningful. On the other hand, in recent years numerous compounds have been found which contain "polymeric" or even "oligomeric" clusters based on edge- and face-sharing M_6 octahedra. A kind of "macromolecular chemistry" with metal clusters is emerging.

Table 3. Oxomolybdates with chains of edge-sharing Mo_6 octahedra [50, 51, 53, 57]. The number z of metal centered valence electrons was derived from (a) the ionic formula, (b) from the bond-order sums Σs_i(Mo-O) for all Mo atoms [121]. **2** contains an excess of Mo in octahedral voids. Therefore, the value of z derived according to (a) is minimal.

Compounds		Interconnection of the chains	z/Mo$_4$ (a)	(b)

[a] Not calculated.

Table 3 summarizes the different crystal structures of the known reduced oxomolybdates, all of which contain chains of *trans*-edge-condensed Mo_6 octahedra. The particularly simple structure of $NaMo_4O_6$ is reproduced in Figure 15. It contains parallel chains of Mo_6 octahedra with O atoms located above all free edges (as in the M_6X_{12} cluster). The chains have the composition $Mo_{4/2}Mo_{2/2}O_2O_{8/2}$ (= Mo_4O_6). The Mo and O atoms not involved in the condensation interconnect the chains according to $Mo_4O_4^iO_2^{i-a}$ (as in rutile), and the cations occupy the cubic voids in the channels between the cluster chains. The structure is also formed with a series of other cations. Pb as cation occupies an acentric position in the cube and is coordinated in the typical pyramidal configuration of the "lone pair" Pb^{2+} ion. When the cations are In or Sr, the position of occupancy is approximately in or exactly in the cube faces respectively, and the coordination geometry is square planar. This special coordination, in conjunction with the short interactomic distances (e.g. d(In–In) = 286.3 pm), indicates that M–M bonds not only occur in the anionic part but also in the cationic part of the structure (vide infra).

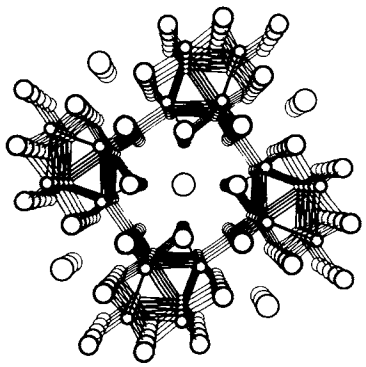

Fig. 15. Central projection of the structure of $NaMo_4O_6$ along the tetragonal c axis [122]. The Mo_6 octahedra are emphasized by strong lines. The Na^+ ions occupy the channels between the cluster chains (e.g. in the center of the drawing).

The structures of the compounds summarized in Table 3 exhibit different patterns of interconnection between the Mo_4O_6 chains. In **1**, **2**, **3**, and **5** the chains are parallel, whereas in **4** they form layers which are stacked crosswise. In **5**, in addition to the Mo_4O_6 chains there are chains of single Mo atoms and ribbons of edge-sharing Mo_4 rhomboids. These ribbons are the only structural element in $NaMo_2O_4$. The bridging O atoms in these oxomolybdates are coordinated by up to four Mo atoms, in contrast to the X atoms which bridge two discrete clusters. Oxygen atoms with trigonal and square planar or SF_4-like coordination geometries are quite common.

There are several independent ways in which the number of electrons in M–M bonding states can be estimated. The formal counting scheme via oxidation states used so far (e.g. $Na^+(Mo^{6+})_4(O^{2-})_6(e^-)_{13}$) leads to very similar results as the detailed analysis of all Mo–O distances with the aid of an empirical bond length-bond strength relationship.[121] According to this analysis 13 to 15 d electrons populate M–M bonding orbitals in the Mo_4 fragment. At high electron counts the sum of M–M bonds as determined from the Mo–Mo distances using *Pauling*'s formula is somewhat low. The logarithmic equation of *Pauling* might be too simplified for an analysis of M–M bonds between heavy transition metal atoms.[123] On the other hand, the too-low bond order sums could indicate that a portion of the d electrons have entered nonbonding or antibonding states, since chain distortions are typically found at high electron counts. For example, in **2** the Mo_6 octahedra are tilted around the common edges, leading to alternating short and long distances between the apical atoms. In **3** and **4** the apical atoms are pairwise associated and the corresponding common edge in the octahedron basis is considerably lengthened. Of course, the cation distribution in the structures as well as the interchain connections might influence these distortions. In any event, the distortions are electronically favored, as indicated from Ex-

tended Hückel (EH) calculations on an undistorted chain compared to a distorted chain as in **2**.[124]

The essential features of the band structures of compounds containing the Mo_4O_6 chains can be worked out from a one-dimensional calculation because the dispersion of the bands is small in the directions orthogonal to the chain. The decomposition of the calculated density of states into bonding and antibonding contributions for the different kinds of Mo-Mo contacts is particularly instructive. The corresponding diagrams are plotted in Figure 16. As one would expect from the crystal structure, the bonds

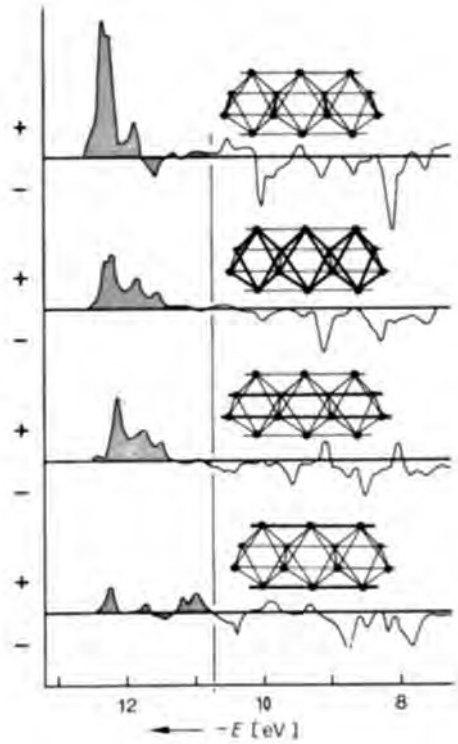

Fig. 16. COOP diagrams (crystal orbital overlap population) [161] indicating bonding (+) and antibonding (−) character of the bands for the different kinds of Mo-Mo contacts in the octahedra chain of $NaMo_4O_6$ [124]. The shaded bands are filled to the Fermi level (vertical line).

along the joined edges are the strongest and the bonds between the apical atoms the weakest. Thirteen electrons per Mo_4 fragment enter the bands without occupying antibonding states. Yet even with 15 electrons the energy balance is still good because the weakening of the bonds along the chain direction is compensated for by a strengthening of the bonds along the joined edges. At high electron counts, however, the formation of one strong bond from two weak bonds between apical atoms of adjacent octahedra leads to a decrease in energy.

The structures of the previously discussed oxomolybdates all contain quasi-infinite chains. Under weakly oxidizing conditions phases of the general composition $In_{1+x}Mo_4O_{6+2x}$ can be prepared which are built up from finite parts of the chain. X-ray crystallographic and high-resolution electron microscopic investigations indicate that many structural variations are possible.[125,126] In the structure of $In_3Mo_{11}O_{17}$, layers of clusters occur which contain five Mo_6 octahedra (Fig. 17a). The structure of $In_{11}Mo_{40}O_{62}$ is made up of alternating layers which contain clusters with four and five Mo_6 octahedra (Fig. 17b). In the electron microscope clusters of six condensed Mo_6 octahedra could also be observed (Fig. 17c), and the occurrence of diffuse and "incommensurate" superstructure reflections in X-ray diagrams of "$InMo_4O_6$" crystals furnished evidence of the existence of even longer clusters. The preparation of homogeneous phases incurs severe problems because they differ only marginally in composition. Thus, a compound which contains only clusters with five Mo_6 octahedra has the composition $In_{1.091}Mo_4O_{6.182}$ ($\triangleq In_3Mo_{11}O_{17}$); a hypothetical phase formed from clusters with six Mo_6 octahedra has the composition $In_{1.077}Mo_4O_{6.154}$. When mixtures of different layers appear as irregular patterns in the crystal a more or less continuous change of composition can occur.

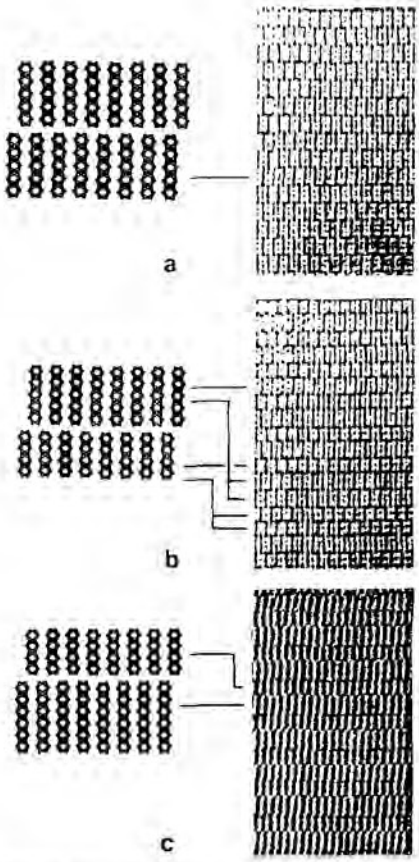

Fig. 17. High-resolution electron microscopic images of a) $In_3Mo_{11}O_{17}$ with uniform layers of $n=5$ clusters, b) $In_{11}Mo_{40}O_{62}$ exhibiting alternating layers of $n=4$ and $n=5$ clusters, respectively, and some faults indicated, and c) a phase (projected in a different direction) with layers of $n=4$, 5 and 6 in an irregular sequence [126]. The units of n edge-condensed octahedra are shown on the left-hand side.

As in the monomeric M_6X_{12} cluster, the oligomeric clusters with n edge-sharing Mo_6 octahedra are surrounded by O atoms above all free edges. The structure of $In_{11}Mo_{40}O_{62}$ therefore contains alternating layers of $Mo_{18}O_{30}$ and $Mo_{22}O_{36}$ clusters which are oriented parallel to each other and are interconnected at top and bottom according to $(Mo_{18}O_{26}O^{i-i}_{4/2})(Mo_{22}O_{32}O^{i-i}_{4/2})$. Bonds of the X^{i-a} type link the clusters within the layers. In the channels between

these clusters are suspended chains of five and six In atoms respectively.

The $Mo_{18}O_{30}$ cluster and the In_5 chain with the nearest O neighbors are shown in Figure 18. Here, we find the interesting situation where M–M bonded polycations and polyanions occur simultaneously in $In_{11}Mo_{40}O_{62}$. The In_5 chain can be formally decomposed into $2\times In^{2+}$ and $3\times In^{+}$ and can thus be described as $(In_5)^{7+}$. The summation of all In–O bond orders leads to the same ionic charge, which also corresponds to the anionic charge derived from all Mo–O distances.

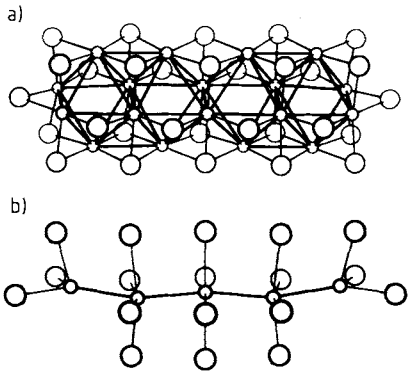

Fig. 18. a) $Mo_{18}O_{30}$ cluster in $In_{11}Mo_{40}O_{62}$ [125]. The coordination of all Mo atoms by O atoms of adjacent clusters O^{a-i} is omitted. b) $(In_5)^{7+}$ cation in $In_{11}Mo_{40}O_{62}$ with the nearest neighbor O atoms. The central In atom has an exactly planar coordination by four O atoms.

Normally, the outer two electrons of the In^+ ion are nonbonding (lone pair). In the structures of these oxomolybdates the rigid matrix of the cluster anions parallel to the In chains (Mo-Mo distances between 276 and 284 pm) forces the In^+ cations into such close proximity that the lone pair configuration is changed into two In–In bonds for each In atom. The bonds manifest themselves in the even closer approach of the atoms within the In chain (d(In–In) $\geq$ 262 pm) than required by the matrix. Thus, hitherto unknown chain-like polycations of In (and possibly other main group metals) can be stabilized by suitable anionic clusters.

The compositions of the cluster layers or, in the case of only one cluster type, the compounds $In_{1+x}Mo_4O_{6+2x}$ follow the general formula $In_{n+1}^{(n+3)+}(Mo_{4n+2}O_{6n+4})^{(n+3)-}$. The number of Mo_6 octahedra in the cluster is designated n. What values may n have?

The oligomeric clusters can be dissembled into Mo_4O_7 (top) and Mo_2O_5 (bottom) fragments, which together constitute a divided Mo_6O_{12} cluster and $n-1$ inserted Mo_4O_6 fragments (from the infinite chain). The fragment orbitals correspond to those in the monomeric cluster and in the polymeric chain. Therefore, 16 electrons (or rather 14[128]) per Mo_6O_{12} fragment and 13 to 15 electrons per Mo_4O_6 fragment can enter metal centered d states in the oligomeric clusters. Within these limits the allowed range of d-electron counts is calculated for different n and compared with the cluster electron counts derived via the anionic charges (Fig. 19). Apparently, only clusters with $n\geq 3$ are favorable in the case of the In compounds. The characteristic distortion of the $Mo_{18}O_{30}$ cluster ($n=4$) with the pairwise short distances between apical atoms, as in the infinite chains of **3** and **4** (cf. Fig. 18a), indicates a high d electron concentration. When the metal is Sn instead of In the d electron concentration is so high that, according to Figure 19, clusters with $n\leq 7$ should not occur. In fact, with Sn only the infinite chain compound has been observed so far and the Sn deficiency in $Sn_{0.9}Mo_4O_6$ can even be taken as evidence that the upper stability limit in Figure 19 should be slightly lower.

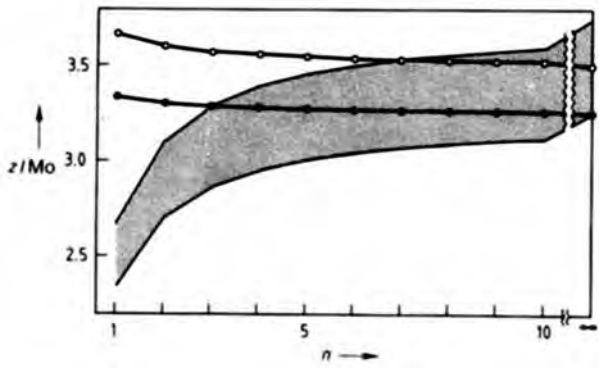

Fig. 19. Stability range for oligomeric clusters of n edge-sharing Mo_6 octahedra in the phases $A_{1+x}Mo_4O_{6+2x}$ (A = Sn (○) and In (●)). The shaded region corresponds to optimal electron concentrations. It was derived by dissembling the oligomer into a Mo_6O_{12} fragment (14–16 electrons) and $n-1$ Mo_4O_6 fragments (13–15 electrons) [127] (cf. text).

It is natural to seek for smaller oligomeric clusters with more electron poor d metals. Indeed, a variety of recently discovered reduced oxo compounds exists in the case of the neighboring element Nb. Nearly all of them have unusually complicated stoichiometries.[131] Their structures frequently contain discrete Nb_6O_{12} clusters, but so far no condensed clusters have been found. In the structure of $SrNb_8O_{14}$ (Fig. 20, bottom) the clusters are aligned in such a way that their close relation between the monomer and the polymeric chain is immediately recognizable (Fig. 20, top).

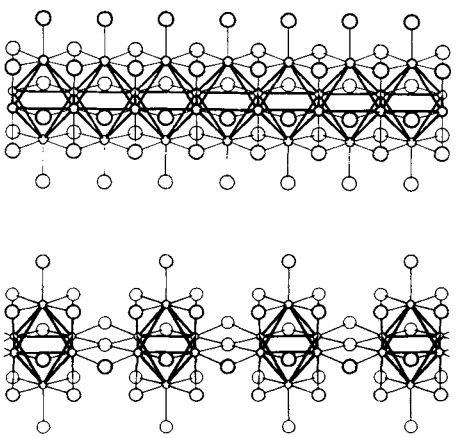

Fig. 20. Comparison of a chain of condensed Mo_6O_{12} clusters in oxomolybdates (top) and the arrangement of discrete Nb_6O_{12} clusters in the structure of $SrNb_8O_{14}$ (bottom) [133].

Table 4. Ternary molybdenum chalcogenides $A_xMo_{3n+3}\hat{X}_{3n+5}$ characterized by single crystal investigations. Those in the first group contain one individual kind of clusters with n face-condensed Mo_6 octahedra; those in the second group contain different kinds of clusters [54, 58]. In the first group the number of electrons per Mo atom, z/Mo, in M–M bonding states as derived from the composition is compared to the optimum range estimated through a fragmentation of the clusters.

n	Compound	Clusters	Charge	z/Mo Experimental	z/Mo Estimated

The chemistry of the last variant of cluster condensation, namely the condensation via faces of the M_6 octahedron is particularly impressive. Figure 21 shows the discrete $Mo_6\hat{X}_8$ cluster and the final product of the condensation of

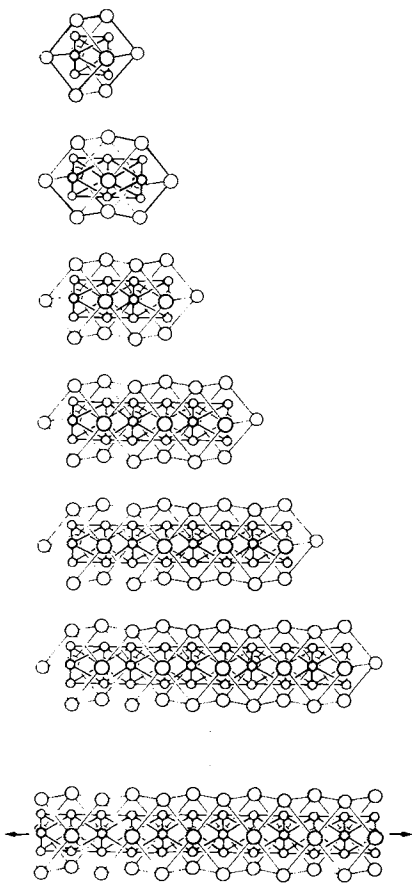

Fig. 21. Monomeric, oligomeric and polymeric clusters $Mo_{3n+3}\hat{X}_{3n+5}$ (Mo small circles) containing Mo_6 octahedra condensed via faces [54, 58]. The compositions of the clusters are $Mo_6\hat{X}_8$, $Mo_9\hat{X}_{11}$, $Mo_{12}\hat{X}_{14}$, $Mo_{18}\hat{X}_{20}$, $Mo_{24}\hat{X}_{26}$, $Mo_{30}\hat{X}_{32}$, and for the polymeric chain $Mo_3\hat{X}_3$.

such clusters via *trans*-faces of the octahedron, the $Mo_3\hat{X}_3$ chain as it occurs in the compounds $AMo_3\hat{X}_3$ with univalent elements such as A = K, Tl, etc. In the last few years, numerous compounds have been synthesized and structurally characterized[54, 58] which contain the intermediate oligomeric clusters of stepwise increasing sizes (Fig. 21). Table 4 lists some compounds which have been characterized by single crystal structure investigations.

The compounds have the general composition $A_xMo_{3n+3}\hat{X}_{3n+5}$ and can contain either one kind of cluster exclusively or different clusters together in an ordered array. The structures containing only one kind of cluster exhibit (with the exception of the Ag compounds) a particularly close relationship with the structure of the first member of the series. All compounds crystallize in the space group $R\bar{3}$ as do the Chevrel phases $A_xMo_6\hat{X}_8$: The $Mo_6\hat{X}_8$ cluster is stretched along its threefold axis, and inserted in the channels between the elongated clusters there are $n-1$ planar $Mo_3\hat{X}_3$ fragments together with the corresponding number of A atoms. This genesis of the oligomeric clusters allows for a suitable fragmentation procedure to estimate the optimal electron counts. All intra- and intercluster contacts of the $Mo_3\hat{X}_4$ fragments (top and bottom) are the same as in the Chevrel phases. Both fragments together can have 20 to 24 d electrons for M–M bonding. The number of electrons in M–M bonding states per $Mo_3\hat{X}_3$ fragment in the infinite chain is 13. Therefore the number of electrons (z) in M–M bonding states of an oligomeric cluster with n condensed Mo_6 octahedra should be within the limits $13n+7 \leq z \leq 13n+11$, where the upper limit corresponds to the closed configuration.[135] This estimate is in agreement with the results of MO calculations for the ions $[Mo_9S_{11}]^{4-}$ and $[Mo_{12}S_{14}]^{6-}$.[65] With $z = 13n+11$ and $n=2$ and 3 we get $z=37$ and $z=50$, respectively. The MO calculation gives 50 electrons in M–M bonding states for $n=3$. In the case where $n=2$ (and all clusters with even n) there is some ambiguity in the electron count due to a non-bonding state in the HOMO-LUMO gap. The cluster contains 38 electrons when this level is occupied and 36 if unoccupied.

All the examples in Table 4 have less d electrons than expected for the closed configuration. There is no ambiguity in the electron counts for the large cluster compounds with alkali metal cations; in each case four electrons are missing for the closed configuration.

Band structure calculations for the quasi infinite $^1_\infty[(Mo_3\hat{X}_3)^-]$ chain[65, 111] yield a band with very strong dispersion for the six equivalent bonds between the $Mo_3\hat{X}_3$ fragments along the chain direction. With an electron count of 13 this band is half-filled, i.e. the compounds $AMo_3\hat{X}_3$ are metals with distinctly one-dimensional character, and the Peierls distortion expected for such a system obviously occurs with the alkali metal compounds. They show a gradual transition to semiconducting behavior with decreasing temperature,[138] while the electronic coupling between the cluster chains through the Tl ions in $TlMo_3Se_3$ is apparently strong enough to suppress the metal-semiconductor transition. The compound stays metallic at low temperatures and becomes superconducting at $T<6$ K.[139]

Chemically, the one-dimensional character of these phases expresses itself in a fascinating reaction: $LiMo_3Se_3$

forms colloidal suspensions in polar solvents such as DMSO. Electron microscopic investigations reveal single $Mo_3\hat{X}_3$ chains in such systems.[140] Numerous topochemical reactions with these cluster compounds proceed without a disassembly of the entire structural framework ("soft chemistry").[141] For example, the In can be extracted from $InMo_3Se_3$ as InCl by reaction with HCl at 420 °C. Electrochemically, the residual Mo_3Se_3 can be intercalated reversibly by up to 4.5 Li.[142] Thus, Mo_3Se_3 is an interesting candidate for a solid state battery. The theoretical energy density of a Li/Mo_3Se_3 cell (referred to the volume) is nearly the same as for the widely used Li/TiS_2 cell.

The topochemical reaction described for $InMo_3Se_3$ can be exploited for the preparation of new binary and ternary molybdenum chalcogenides which are not accessible directly. Starting from $In_2Mo_{15}Se_{19}$ or $In_{\sim 3}Mo_{15}Se_{19}$, prepared directly from the elements, pure $Mo_{15}Se_{19}$ can be obtained by the removal of In.[143, 144] As the arrangement of the clusters is different in the two starting compounds, the $Mo_{15}Se_{19}$ is obtained in two modifications. The empty cluster frameworks can be reloaded by a direct reaction with metals at elevated temperatures or by electrochemical reactions (e.g. with alkali metals, Zn, Cd, Tl, Sn, Pb) and new ternary compounds are formed.

The last mentioned reactions leave the cluster framework unchanged. All attempts to disassemble the framework in a chemically controlled way have so far failed. Is such a disassembly possible and does it lead to a solution chemistry with oligomeric clusters which is offered by the defined bulk solids?

5. Clusters Containing Interstitial Atoms

Clusters with only a few valence electrons for M–M bonding can be stabilized by interstitial atoms with the consequence of a partial substitution of weak M–M bonds by strong bonds with these atoms. This conclusion drawn for clusters of alkali metals at the beginning is also valid for transition metals. The metals of the third and fourth groups form numerous cluster compounds, which are, to a great extent, isostructural with corresponding compounds of the more electron-rich neighboring metals, but differ from them by the additional atoms in the clusters of the M_6 octahedra. The list in Table 5 gives an overview of the broad spectrum of interstitial atoms and structure types known to date.

The occupation of a metal cluster center by a nonmetal atom was first demonstrated in $Nb_6I_{11}H$.[145, 155] At the same time $[Ru_6(CO)_{17}C]$[156] was prepared, and was the first molecular example containing an interstitial C atom in an M_6 octahedron. In the meantime a large variety of related organometallic compounds have been synthesized.[157, 158]

Only $Nb_6I_{11}H$ and $CsNb_6I_{11}H$ contain the M_6X_8 cluster with an interstitial atom. There is no evidence for interstitial atoms being incorporated, for example, in the clusters of the Chevrel phases, despite their electron deficiency ($M_6\hat{X}_8$: 20 electrons in M–M bonding states).

$Nb_6I_{11}H$ and $CsNb_6I_{11}H$ are formed by heating the binary and the ternary compound in H_2 respectively. Hence, the Nb_6I_8 cluster is known with and without an interstitial atom. The hydrogen is lost only in vacuum at such a high temperature that further decomposition of the residue occurs due to the formation of gaseous NbI_4. If this decomposition reaction is suppressed by sealing the sample in an H_2-permeable Nb ampoule, the hydrogenation reaction can be performed reversibly.

Table 5. Halides with interstitial atoms in M_6X_8 and M_6X_{12} clusters and their interconnection patterns together with corresponding structure types based on empty clusters.

"Empty" Cluster	"Filled" Cluster	Interconnection
Nb_6I_{11} [75]	$Nb_6I_{11}H$ [145]	$M_6X_8^iX_{6/2}^a$

$NaNb_6Cl_{15}$ [153]	$Na_xZr_6Cl_{15}Y$ (Y = B, C) [149]	$M_6X_{12}^iX_{6/2}^a$
$CsNb_6Cl_{15}$ [153]	$AZr_6Cl_{15}C$ (A = K–Cs) [154] $KZr_6Cl_{15}N$ [154] $CsZr_6Br_{15}Fe$ [147] $CsRbZr_5Cl_{15}B$ [154]	$M_6X_{12}^iX_{6/2}^a$
—	$K_2Zr_6Cl_{15}B$ [149]	$M_6X_{12}^iX_{6/2}^a$
—	$A_3Zr_6Cl_{15}Be$ (A = K, Rb) [154]	$M_6X_{12}^iX_{6/2}^a$
—	$Na_4Zr_6Cl_{16}Be$ [149]	$M_6X_{12}^iX_{4/2}^aX_2^a$

The magnetic properties of Nb_6I_{11} change drastically with the absorption of H_2. $Nb_6I_{11}H$ is nonmagnetic at low temperature, and above room temperature it exhibits a similar kind of singlet-triplet spin crossover transition as Nb_6I_{11}. Apparently, the H atom adds its electron to the electron deficient cluster system. Yet, the H atom does not play the role of a simple electron donor as is found, e.g., for the Cs atom, which lies between the clusters in $CsNb_6I_{11}$. The large difference in the electronegativities of H and Nb indicates that H is rather hydridic in nature. In fact, the calculated electron density distribution shows cumulated density at the H atom in the cluster.[159]

The solution of this apparent contradiction[91, 114, 160, 162] leads to simple general conclusions on the bonding of interstitial atoms in clusters and the meaning of "counting rules" for this case.

The interaction of the H 1s function with the fully occupied a_{1g} state of the cluster leads to a drastic lowering of the energy of this state; the antibonding combination lies well above the HOMO-LUMO gap. Therefore, the number of bonding cluster states remains unchanged, and only the number of electrons in these states is increased by the electron of the H atom. The stabilization of the cluster is not primarily due to the additional electron (in the nearly nonbonding HOMO), but to the low energy of the originally

M-M bonding a_{1g} state that becomes essentially localized at the H atom. This description of the chemical bonding for the H atom in a cluster is identical with the description of bonding in metal hydrides except for the different terms used. In NiH_x or PdH_x an "impurity band" that has strong H 1s character occurs below the conduction band formed from low-lying d band states. The additional electrons from H fill band holes at the Fermi levels.[163-165]

The transition from Nb to the more electron-deficient neighbor Zr creates a qualitatively new situation. The d electron concentration does not suffice for the formation of the M_6X_8 cluster. The number of electrons is even too low for the formation of the M_6X_{12} type cluster. Other than in the case of Nb_6I_{11}, where the cluster centers can be occupied reversibly by impurity atoms (H), interstitial atoms are a requirement for the formation of the Zr_6X_{12} unit.[166]

The Zr_6X_{12} cluster is able to incorporate a variety of atoms (cf. Table 5), with B, C, and N being the least surprising examples. The previously discussed bonding scheme for interstitial H needs only a minor extension to understand the bonding of these other interstitial atoms.[66, 168, 169] The 2s (a_{1g}) and 2p (t_{1u}) states of the central atom strongly lowers the four clusters states that have the same symmetries. The antibonding combinations are too high in energy to be reached; therefore, the relevant number of orbitals is the same as for the empty cluster. Only the number of electrons in these states is increased by the number of valence electrons of the central atom.[170] The cluster in $Zr_6I_{12}C$ has the same number of available MO's and electrons as the empty cluster in Nb_6Cl_{14}. The essential difference, though, is due to the fact that all 16 electrons in Nb_6Cl_{12} occupy M-M bonding states, whereas in the $Zr_6I_{12}C$ cluster the strong bonds between anionic C and surrounding cationic Zr atoms only allow a few direct M-M bonds.[172] It is true that the formulation $(Zr^{4+})_6(I^-)_{12}C^{4-}(e^-)_8$ ignores the covalency between Zr and C (and I), yet it yields a realistic estimate of the number of electrons involved in M-M bonding. Moreover, it links the Zr compound with simple molecules like $(Li^+)_6C^{4-}(e^-)_2$ (see Section I).

Of particular interest is the recently discovered introduction of transition metal atoms into M_6X_{12} clusters of Zr[147] and Th.[152] Figure 22 shows the cluster occupied by a Fe atom in $Th_6Br_{15}Fe$ ($= Th_6Br^i_{12}FeBr^{a\text{-}a}_{6/2}$).

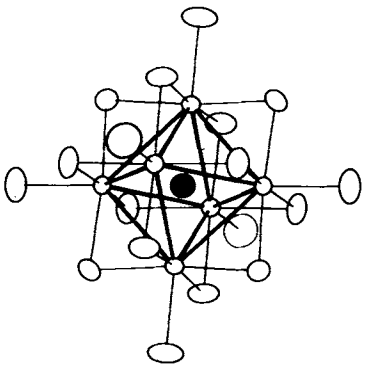

Fig. 22. $Th_6Br^i_{12}FeBr^a_6$ cluster with an interstitial Fe atom in the structure of $Th_6Br_{15}Fe$ [152]. Ellipsoids at the 90% probability level.

The chemical bonding of the 3d metal atom is described via the MO diagram for the $[Zr_6I^i_{12}FeI^a_6]^{4-}$ cluster in Figure 23. With respect to the bonding of interstitial nonmetal atoms, there are two main differences. The polarity of the bonds is smaller and reversed in direction, and the a_{1g} state is primarily Zr-Zr bonding. Furthermore, four additional electrons can be localized at the interstitial d metal atom in degenerate e_g states, which hardly interact with the states of the Zr_6 frame.

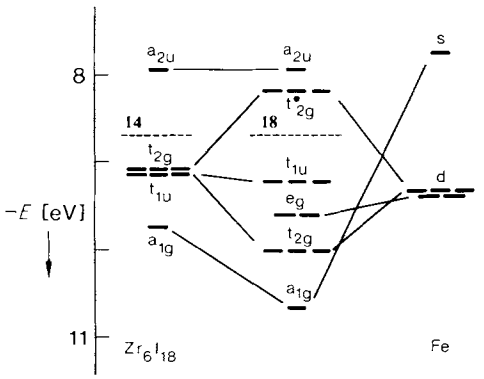

Fig. 23. MO diagram for a regular $Zr_6I^i_{12}I^a_6$ cluster with a central Fe atom [147]. The cluster with the interstitial atom contains 18 electrons up to the Fermi level (dashed line).

What criterion decides whether an element is able to contribute to the stabilization of an electron-deficient cluster as an interstitial atom? Obviously, the M_6 octahedron behaves like a microscopically small piece of metal, and therefore, the question should be, which elements form stable compounds with the bulk metal of the cluster atoms. The answer to this question gives a qualitative explanation for the fact that the electron-deficient Nb_6 unit incorporates H, while the Mo_6 octahedron does not.[173] Zr forms numerous intermetallic compounds with Be, Al, and 3d metals[175, 176] and, obviously, does not lose this ability in the case of only six Zr atoms being joined. *Miedema*'s concept of the stability of intermetallic systems[177, 178] proves helpful in the search for possible interstitial atoms, when this search is limited to atoms of appropriate size to fit into the octahedral site.[179] The comparison of $Cs_{0.3}Zr_6I_{14}Si$ (Si in the Zr octahedron[148]) and $Na(Si,Nb)Nb_{10}O_{19}$ (Si in a O_4 tetrahedron[132]) clearly indicates that the competition of different kinds of bonds (Si-Zr vs. Si-I or Si-Nb vs. Si-O) finally decides about the position of the additional atom, whether in the cluster center or between clusters.

Interstitial atoms frequently occur in discrete clusters. Even more frequently, such interstitial atoms are found in structures that can be described in terms of condensed clusters. As discussed previously, there are compounds that allow the reversible insertion of additional atoms under equilibrium conditions as well as many compounds that are only stable upon inclusion of interstitial atoms.

The Zr halides ZrCl and ZrBr[181] contain characteristic layer units X-Zr-Zr-X composed of single close-packed X and Zr layers. The units can be discussed in terms of edge-condensed Zr_6 octahedra coordinated by X atoms above all free faces (as in the M_6X_8 cluster).

The compounds reversibly absorb H_2.[182] It is remarkable that for a composition ZrX, *two* H atoms are located in each trigonally elongated Zr_6 octahedron.[183, 184] For reasons of electrostatic repulsion the X atoms move above the edges of the octahedra. Hence, the Zr/X arrangement is now related to the M_6X_{12} cluster.

The absorption of H_2 by the halides ZrX can be taken as direct chemical evidence for the deficiency of electrons in M–M bonding states. The hypothetical chalcogenides $Ta\hat{X}$, which are isoelectronic with ZrX, do not exist at all. Yet, the compound Ta_2S_2C, which has a C atom in the center of the Ta_6 octahedron (again the $\hat{X}$ atoms are above the octahedron edges), has been prepared.[186] The compounds "MX" formed with the valence electron poor metals Sc, Y, and Ln exhibit the ZrX type structure and were first thought to be binary compounds.[187–189] Later it was determined that they were stabilized by interstitial H.[52, 146, 190] Gd_2Br_2C, which is isostructural with Ta_2S_2C, has also been prepared.

An important borderline is reached with the last example. No matter what the distribution of valence electrons in Ta_2S_2C looks like, the formulation $(Ta^{5+})_2(S^{2-})_2C^{4-}(e^-)_2$ leaves electrons for M–M bonding. In contrast, all electrons are used up for strong heteroatomic bonds in Gd_2Br_2C $(=(Gd^{3+})_2(Br^-)_2C^{4-})$. The "stabilization of the clusters" by interstitial atoms has led to a decomposition of the cluster, at least if one associates M–M bonds with the term "cluster". Gd_2Br_2C is a normal simple ionic compound, like the isostructural and isoelectronic La_2O_2S.[192] What does the borderline between cluster compounds and simple salts look like?

6. d-Metal Chemistry of the Lanthanoids

All the facets of cluster compounds presented in the preceeding chapters apply to the chemistry of metal-rich halogeno compounds of the lanthanoids. The clusters exist in empty and filled, discrete and condensed forms, and the bonding ranges from M–M bonded species that may be stabilized with additional strong heteropolar bonding to interstitial atoms to species that have only ionic bonding and are simple salts. The latter still have the atomic arrangement in common with cluster compounds, yet have no electrons for M–M bonding. The compounds Gd_2Cl_3 (condensed cluster) and $Gd_7I_{12}C$ (discrete filled cluster) mark the limits of the broad spectrum.[193]

The structure of Gd_2Cl_3[195, 196] contains parallel chains of *trans* edge-sharing Gd_6 octahedra (Fig. 24) which are coordinated by Cl atoms above all free edges (as in the M_6X_8 cluster). The Gd–Gd interatomic distances along the joined edges are shorter than in elemental Gd (337 vs. 357 pm). The octahedron is extremely elongated (390 pm) and the Gd–Gd distances involving the apical atoms are 373 and 378 pm. It is clear from this that the Gd–Gd distances are much longer than in the case of the clusters of the 4d and 5d metals (d(M–M) < 300 pm) previously discussed. The larger cages with lanthanoid clusters have interesting consequences concerning the incorporation of interstitial atoms (vide infra).

The PE spectrum of Gd_2Cl_3[196] immediately affords an insight into the essentials of the chemical bonding com-

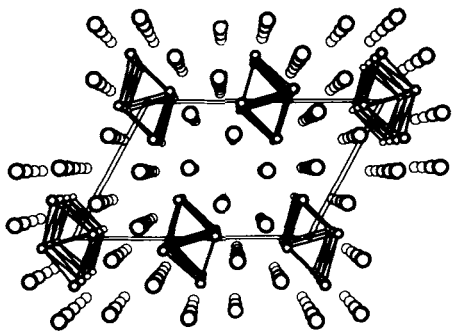

Fig. 24. Central projection of the structure of Gd_2Cl_3 [194, 195] along the monoclinic b axis. The chains of edge-sharing Gd_6 octahedra are emphasized by bold lines.

pared to that of Gd (Fig. 25). The Gd 4f band 10 eV below the Fermi level exhibits no trace of multiplet splitting and therefore corresponds to a $4f^7$ configuration as is typical for the ionic core of Gd^{3+}. The low-lying Cl 3p band gives evidence for strongly polar Gd–Cl bonds. Residual metal valence electrons are present according to the formulation $(Gd^{3+})_2(Cl^-)_3(e^-)_3$. These electrons have d character and fill M–M bonding states. Surprisingly, these electrons are localized in spite of their non-integral number per metal atom (1.5 e^-). Missing density of states at the Fermi level and the band gap of 0.85 eV determined from electrical measurements[197] are clear evidence of the electronic localization in the black compound. This result finds an interpretation from band structure calculations.[198]

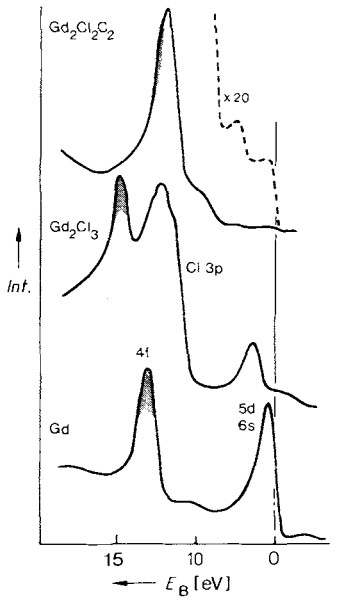

Fig. 25. PE spectra of Gd and Gd_2Cl_3, both taken with He(II) radiation (40.8 eV) [196], and of $Gd_2Cl_2C_2$ (He(I), 21.2 eV) [199]. The narrow 4f band is marked. The structures above the Fermi level ($E_B = 0$) in the spectra of Gd and Gd_2Cl_3 arise from excitations of electrons from the 4f band by the 50.3 eV satellite line.

Few valence electrons are available for M–M bonding in Gd_2Cl_3. The subchloride readily decomposes into Gd and $GdCl_3$; the enthalpy of this reaction, obtained from the

calorimetrically determined enthalpy of formation of Gd_2Cl_3, is 30 ± 15 kJ mol^{-1}.[200] Experiments on the co-crystallization of other lanthanoids in Gd_2Cl_3 indicate that only Tb is incorporated in significant amounts.[201] Obviously, the island of stability of subhalides of the lanthanoids is small.

The "stabilization" of Gd_2Cl_3 with two interstitial N atoms per Gd_6 octahedron is formally achieved in the compound Gd_2Cl_3N.[202] This step is even possible to follow structurally: According to the formulation $(Gd^{3+})_2(Cl^-)_3N^{3-}$ all electrons are removed from M-M bonding states and are now involved in strong Gd-N bonds. Nevertheless, the distances between neighboring Gd atoms are, within a few pm, the same as in Gd_2Cl_3. The mutual repulsion of the N^{3-} ions deforms the Gd_6 octahedron into two edge-sharing Gd_4 tetrahedra, each with a centered N. The Cl^- ions rearrange around the chains of tetrahedra. The Cl and N atoms together form the typical coordination polyhedron of a tricapped trigonal prism around the Gd^{3+} ion.

The band structure calculation and population analysis for Gd_2Cl_3N[198] provide a more quantitative interpretation of the bonding situation with the formulation $(Gd^{2+})_2(Cl^{0.7-})_3N^{1.8-}$ instead of the extreme ionic picture used above. However, it does not change the essential point, namely that the Gd d bands are empty and, therefore, no M-M bonds are possible. The outlined transition from Gd_2Cl_3 to Gd_2Cl_3N, however, is an unconvincingly formal one, for a topochemical reaction of this kind is not possible and the topological similarity of the two structures is more or less accidental. The jump from the black Gd_2Cl_3 to the colorless Gd_2Cl_3N is too large to see in detail what happens when the borderline between cluster systems and simple salts is crossed. The multitude of existing carbide halides of the lanthanoids allows smaller steps.

Table 6. Gd carbide halides. Crystallographically different C-C distances deviate by less than ± 5 pm from the given values. The number of electrons z (per formula unit) in M-M bonding states is derived via the ionic limit on the basis of the experimental C-C distances $((C_2)^{4-}$ and $(C_2)^{6-}$ corresponding to 130 and 145 pm, respectively).

Compound	"Linkage" of the Gd_6-Octahedra	C_n	d(C-C) [pm]	z	Ref.

Gd_3Cl_3C	network	C	—	2	[212]

Table 6 summarizes the carbide halides of Gd that have been structurally characterized. All structures contain octahedral Gd_6 units, which are discrete or condensed via edges and surrounded above all free edges (as in the M_6X_{12} cluster) by halogen atoms. A special feature, when compared to previously treated clusters, is that C_2 units are found in the octahedral voids, in addition to single C atoms. The occurrence of C and C_2 species as well as the observation of different C-C distances in the C_2 species can be used to test the electron counting scheme on a finely graded chemical scale.

$Gd_7I_{12}C$ has the same structure as $Sc_7Cl_{12}N$.[213] It contains $Gd_7I_{12}C$ clusters, whose very low d electron concentration is increased by an extra Gd atom incorporated between the clusters which acts as a three-electron donor.[214] The clusters are additionally stabilized by interstitial C atoms.

The compounds $Gd_{10}Cl_{18}C_4$ (discrete), $Gd_{10}Cl_{17}C_4$ $(= Gd_{10}Cl^i_{16}Cl^{i-i}_{2/2})$ and $Gd_{10}I_{16}C_4$ $(\cong Gd_{10}I^i_{14}I^{i-i}_{4/2})$ contain Gd_6X_{12} dimers condensed via edge sharing. C_2 groups, which are oriented parallel to each other, fill the octahedral voids (Fig. 26). The $Gd_{10}Cl_{18}C_4$ arrangement corresponds to the first step of condensation of M_6 octahedra via edges and closely follows the (empty) oligomeric clusters and chains in the reduced oxomolybdates discussed in Section 4. Even the X^{i-i} type interconnection in $Gd_{10}I_{16}C_4$ is identical to that in $In_{11}Mo_{40}O_{62}$.

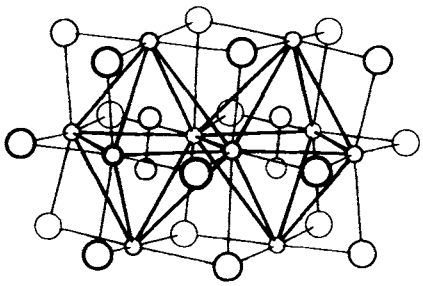

Fig. 26. $Gd_{10}Cl_{18}C_4$ unit in the structures of $Gd_{10}Cl_{18}C_4$, $Gd_{10}Cl_{17}C_4$, and $Gd_{10}I_{16}C_4$ [204-206]. Two Gd_6 octahedra centered by C_2 units are joined via a common edge and surrounded by X atoms above all free edges, as in the M_6X_{12} cluster.

The increasing degree of condensation of (C-containing) Gd_6X_{12} units via common edges of the octahedra is easy to see for the chosen examples in Figure 27. The straight chains of *trans*-edge linked Gd_6C octahedra in the structure of Gd_4I_5C (Fig. 27a) together with their immediate anionic surrounding correspond entirely to the chains in $NaMo_4O_6$. Only the connections between the chains are of a different type. The next step in cluster condensation, which involves the coupling of two parallel M_4X_6 chains with the loss of X atoms above the joined edge, has not yet been realized with empty clusters. With Gd_6C octahedra it is realized, e.g., in the structure of $Gd_6X_7C_2$ (X = Br, I) (Fig. 27b). The crystal contains parallel oriented twin chains formed from edge-sharing Gd_6C octahedra. Extension of this construction principle leads to a hypothetical series of compounds of the general composition $Gd_{2a+2}X_{2a+2}$ for the metal/halogen framework, where a is the number of condensed octahedra chains. Apart from the starting members ($a = 1$, 2), so far only the final members ($n = \infty$) have been realized in the compounds Gd_2Br_2C and $Gd_2X_2C_2$ (X = Cl, Br) (Fig. 27c). These compounds have typical layer structures with van der Waals bonds between

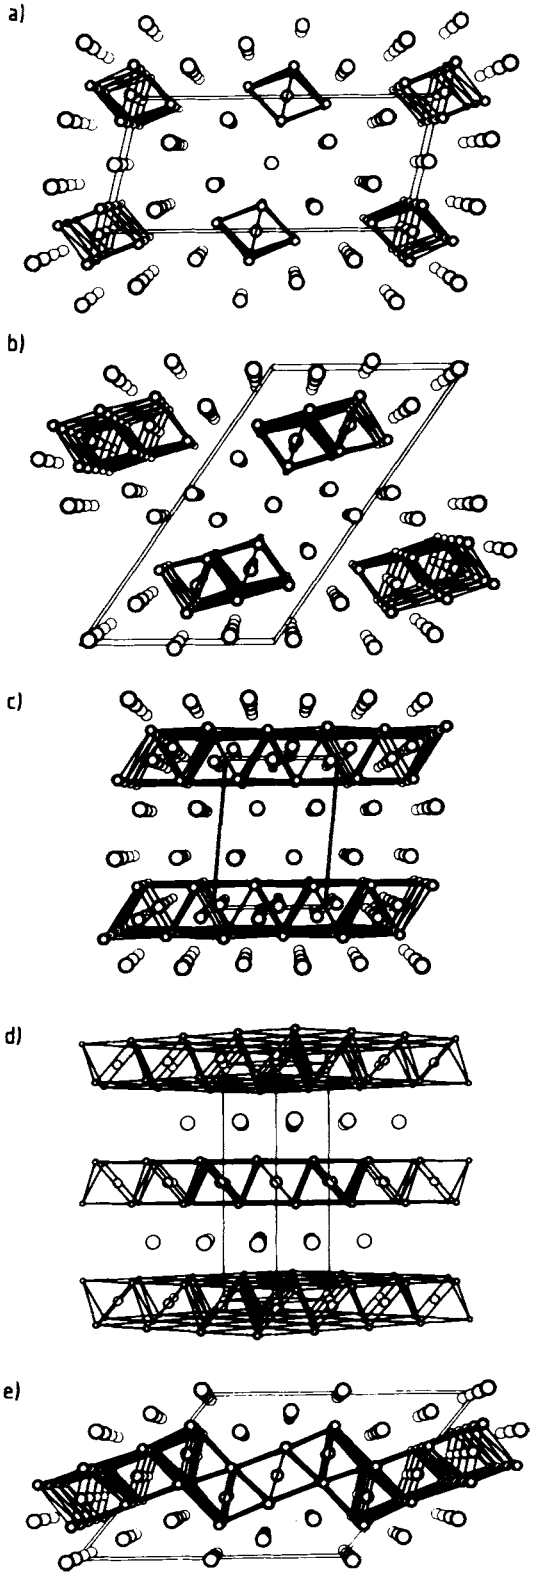

Fig. 27. Central projections along the shortest axes of a) Gd_4I_5C (octahedra chains), b) $Gd_6Br_7C_2$ (twin chains), c) $Gd_2Cl_2C_2$ (planar layers), d) Gd_2IC (planar layers), and e) $Gd_6Cl_5C_3$ (undulated layers). The frameworks of Gd_6 octahedra are outlined with bold lines (cf. Table 6).

adjacent X atom layers. In the structures of the compounds Gd_2XC (X = Cl, Br, I) the layers of octahedra are linked via X^{i-i} bridges (Fig. 27d). Finally, the structure of Gd_3Cl_3C contains a three-dimensional network of edge-sharing Gd_6C octahedra. Numerous other structural variations like the folded chains in $Gd_{12}I_{17}C_6$ or the undulated layers in $Gd_6Cl_5C_{3.0-3.5}$ (Fig. 27e) are possible. Further carbide halide variations have been identified X-ray crystallographically, but have not yet been characterized in any detail.

The way of drawing the structures of the lanthanoid carbide halides in Figure 27 has been chosen so as to relate the structures to those of the reduced d metal compounds discussed in Sections 4 and 5. One should be careful not to be mislead by the drawings, for the lines between the metal atoms might have entirely different meanings. In $NaMo_4O_6$, they indicate M-M bonds, while in the case of $Gd_2Cl_2C_2$, where there are no electrons available for M-M bond formation, they are used only to emphasize the topology of the structure.

The borderline separating cluster compounds and simple salts is well illustrated with Gd_2ClC. The structure is built up of close-packed layers of Gd (abc), Cl (ABC) and C atoms ($\alpha\beta\gamma$) in a cubic sequence $Ac\beta aCb\alpha cBa\gamma b\ldots$ This arrangement bears a similarity to the structure of the silver subfluoride Ag_2F,[215] a structure containing layers of condensed empty Ag_6 octahedra. In the structure of Gd_2ClC, all octahedral voids are occupied by interstitial C atoms, which stabilize the clusters. If one ignores the chemical differences between the anions in Gd_2ClC ($ABC \cong \alpha\beta\gamma$), one has the rock salt structure.

The interstitial C_2 units will commonly have C-C distances of around 145 pm, which corresponds to a shortened single bond, but the C-C distance of 130 pm found in $Gd_2X_2C_2$ (X = Cl, Br) is indicative of a double bond. In the Raman spectra, the C-C stretching vibration was observed at 1158 cm^{-1} for $Gd_{10}Cl_{18}C_4$ and 1175 cm^{-1} for both $Gd_{10}Cl_{17}C_4$ and $Gd_{12}Br_{17}C_6$. In $Gd_2Cl_2C_2$ the stretching vibration was found to be at 1578 cm^{-1}.[216] According to *Siebert*[217] the bond orders, which were derived from the corresponding force constants, are 1.2 and 1.9.

As expected, the hydrolysis[208] of $Gd_{10}Cl_{18}C_4$ with H_2O at room temperature yields a hydrocarbon mixture containing 95 mol-% C_2H_6. The unequivocal assignment of the solvolysis products to a C species in a crystal, similarly as in the case of CaC_2 is rather an exception. It has long been known that when delocalized electrons are present in the solid, the observed gas phase species need not be related to the actual units in the solid. The gases liberated in the hydrolysis of Gd_2ClC under comparable conditions (55% CH_4, 30% H_2, and 15% C_2 hydrocarbons) might still be within the range expected for the decomposition of a "methanide", although side reactions are obvious. These dominate in the case of $Gd_2Cl_2C_2$, where one finds only 15% C_2H_4 besides 45% C_2H_2 and 30% C_2H_6, as well as a certain amount of C_4 hydrocarbons.

Can the different C species in the structures of lanthanoid carbide halides be rationalized in terms of the simple concept of a stabilization of electron deficient clusters by interstitial atoms?

It has been demonstrated with the example of $Nb_6I_{11}H$ that the interstitial atom depletes the M-M bonding states of an electron deficient cluster. This effect is further enhanced in the case of the electropositive lanthanoids because the Fermi level of the metals is high with respect to

the s and p states of carbon. One only needs to check how many electrons are left with the metal atoms after bonding the X atoms. These electrons will be transferred to the empty, π, π^* and σ_p^* states of the neutral C_2 unit. In the case of $Gd_2Cl_2C_2$ ($= (Gd^{3+})_2(Cl^-)_2(C_2)^{4-}$) the framework donates four electrons to the C_2 unit. Effectively two antibonding states are not occupied and the observed short C–C distance corresponds to a double bond. In $Gd_{10}Cl_{18}C_4$ ($\cong (Gd^{3+})_5(Cl^-)_9(C_2)^{6-}$) the highest antibonding state remains unoccupied and a C–C single bond results. Finally, in Gd_2Br_2C ($= (Gd^{3+})_2(Br^-)_2(C^{4-})$ the eight electrons donated from the framework for C_2 occupy all bonding and antibonding states and only single C atoms occur. All the structures listed in Table 6 correspond to this naive counting scheme for electrons on the basis of an ionic limit in the sense of the generalized $8-n$ rule.[7]

The examples chosen to demonstrate the electron counting are special in so far as the available number of electrons from the framework corresponds exactly to the number taken up by the C_2 unit. In the more general case these numbers are different, and the excess electrons then occupy M–M bonding states. Making this balance leads to several obvious conclusions: One or more electrons per C atom in M–M bonding states are only possible when no C_2 units are present. There are also restrictions for the simultaneous presence of different C species in a compound. Thus, despite the structural similarity of Gd_2Br_2C and $Gd_2Br_2C_2$ no mixed crystals between these compounds exist, in which C^{4-} and $(C_2)^{4-}$ would be mutually exchanged. Because of a synproportionation reaction leading to $(C_2)^{6-}$, the simultaneous occurrence of these ions is not to be expected. In contrast, C^{4-} and $(C_2)^{6-}$ (as well as $(C_2)^{4-}$ and $(C_2)^{6-}$) may occur simultaneously in a compound, if the structure allows it. The range of homogenity of $Gd_6Cl_5C_{3.0-3.5}$ is rationalized in terms of a partial substitution of C^{4-} by $(C_2)^{6-}$, which proceeds until all M–M bonding states are depleted.[218]

In the previous discussions, the electron concentration in M–M bonding states was derived by assuming the ions to carry conventional formal charges (e.g., Gd^{3+} or $(C_2)^{6-}$). To avoid any misunderstanding about the relevance of such a procedure, Figure 28 (top) presents the result of a self-consistent calculation for $Gd_{10}Cl_{18}C_4$.[219] The MO's of the weakly interacting (free) C_2 units are lowered in the $Gd_{10}Cl_{18}C_4$ unit to such an extent that the π^* level falls below the Fermi level[220] and becomes occupied. The Gd 4d bands are empty. Of course, there is a significant Gd 5d contribution to the valence bands, especially by back bonding from π^* into the empty d states. But this mixing-in of d states leads to a covalency of the Gd–C and Gd–Cl bonds in the sense of the more realistic bonding description $(Gd^{1.3+})_{10}(Cl^{0.45-})_{18}(C_2^{2.4-})_2$, without any Gd–Gd bonds being present. Only the lowering of the halogen content in the compounds $Gd_{10}Cl_{17}C_4$ and $Gd_{10}I_{16}C_4$ leaves electrons with Gd and leads to the occupation of the narrow band split off from the Gd 5d block. This band has 90% d character (Fig. 28, bottom), and it is clear that it has M–M bonding character in the equitorial plane of the bioctahedron and, in particular, along the joined edge between the two octahedra. The experimentally observed shortening of this edge by 9 pm on going from $Gd_{10}Cl_{18}C_4$ to $Gd_{10}Cl_{17}C_4$ is in agreement with the result of this calculation.

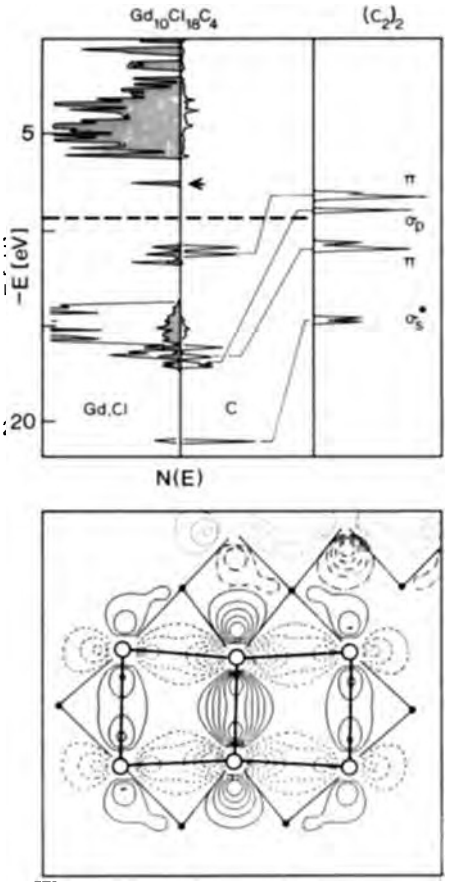

Fig. 28. Top: MO diagram of two free C_2 units arranged as in $Gd_{10}Cl_{18}C_4$ (right) and projected densities of states (Gd contribution shaded) for the unit $Gd_{10}Cl_{18}C_4$ [216, 217]. The Fermi level corresponds to the dashed line. Bottom: Representation of the discrete M–M bonding orbital above the Fermi level marked by an arrow. The orbital is drawn in the plane of the Gd_6 octahedra bases (Gd circles, Cl points). The state is singly occupied in $Gd_{10}Cl_{17}C_4$ and doubly in $Gd_{10}I_{16}C_4$.

The structures scarcely reflect that a borderline between the simple salt $Gd_{10}Cl_{18}C_4$ and the cluster compound $Gd_{10}Cl_{17}C_4$ has been passed through. The "cluster" in $Gd_{10}Cl_{18}C_4$ also results from an fcc type packing of low and highly charged anions (Cl^- and $(C_2)^{6-}$, resp.) in the ratio 9 : 1. Only the favorable octahedral voids around the highly charged anions are filled by the cations. $Gd_{10}Cl_{18}C_4$ is just a defect variant of rock salt.

The discussion shows that a simple ionic model is suitable for counting electrons in M–M bonding states. In the case of the alkali metal suboxides dealt with in Section 2 the estimated numbers were verified by physical measurements, namely by measuring the energy losses caused by these electrons. In the case of lanthanoid carbide halides, the C_n species serve as chemical checks for the correct electron balances. Physical properties, particularly the electric conductivity, are also in agreement with these balances. Metallic behavior is always observed with extended M–M bonded systems (chains, twin chains, layers, and networks) in conjunction with an excess of metal valence electrons. Insulators and semiconductors are found with discrete clusters (cf. Section 3) and in extended structures with close M–M contacts that have no electrons in the M–M bonding bands.

Only $Gd_2Cl_2C_2$ and $Gd_2Br_2C_2$ seem to be exceptions. They form golden crystals with high (two-dimensional) metallic conductivity, although all bands with M–M bonding character should be empty.

The explanation for this apparent disagreement is trivial. The statement about a filling of energy bands does not give any clue to the separation of these bands. Metallic properties might occur "accidentally" if filled valence and empty conduction bands are not separated by an energy gap.

The PE spectrum of $Gd_2Cl_2C_2$ (Fig. 25) exhibits density of states at the Fermi level. The dramatic shift of the Gd 4f band to higher energy might indicate the cause for the non-vanishing density at $E_B = 0$, namely, backbonding from occupied C_2 π^* states (valence band) into empty Gd d states (conduction band). The analysis of bonding in $Gd_2Cl_2C_2$ with the aid of EH calculations[199] verifies this interpretation. The calculated density of states (4f omitted) and the projected densities for Gd 5d (shaded) are plotted in Figure 29 (top). The character of the states at the Fermi

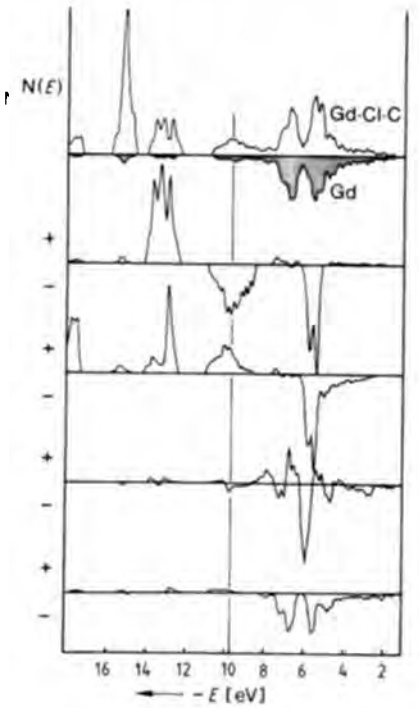

Fig. 29. Results of EH calculations for $Gd_2Cl_2C_2$ [199]. From top to bottom: total density of states and projected part of Gd 5d (shaded); COOP curves for C–C, C–Gd_{axial}, Gd_{basal}–Gd_{basal}, and Gd_{axial}–Gd_{basal} interactions, the latter in the sequence. The Fermi level is marked by the vertical line.

level are obtained from the corresponding COOP diagrams for C–C, Gd–C, and Gd–Gd interactions. As expected, they are C–C antibonding (π^*), but bonding with respect to Gd–C interactions and in particular involve those Gd atoms that are collinear with the C_2 unit. The occupation of these states is a compromise between the loosening of the C–C bonding and formation of π bonds between C and Gd. It is evident from Figure 29 that the comparatively high Gd 5d contribution to the bands at E_F is almost entirely due to the covalent Gd–C bonds and does not lead to M–M bonding. According to the population analysis, the bonding is described as $(Gd^{1.36+})_2(Cl^{0.46-})_2(C^{0.90-})_2$ and there are no electrons for Gd–Gd bonds. It should be possible to introduce weak M–M bonds (accompanied by a change from C–C double to C–C single bonding) by a chemical reduction of $Gd_2Cl_2C_2$. In fact, the compound can be intercalated, e.g., by electrochemical methods, with lithium to yield a limiting composition $Gd_2Cl_2C_2Li_{0.9}$.[208] Unfortunately, the layers become disordered during this reaction and can not be characterized structurally.

The formation and breaking of M–M bonds by means of a chemical reaction can be nicely shown with the hydride halides of the trivalent lanthanoids that are structurally closely related to $Gd_2Cl_2C_2$. Because of the strong absorption of neutrons by Gd, the diffraction studies are carried out with the isostructural Tb compounds.

TbClH has the structure of ZrBr if one considers only the TbCl framework.[189, 190, 221] Tb_6 octahedra are condensed via edges into layers, and these are surrounded by Cl atoms above the octahedral faces (as in the M_6X_8 cluster). The Tb atoms are close packed, and neutron diffraction of the deuterated compounds shows the tetrahedral voids within the Tb twin layers to be occupied by D atoms[222] (cf. Fig. 30). The compound has a range of homogeneity $TbClD_{0.67-1.00}$ due to a partial occupation of the voids.

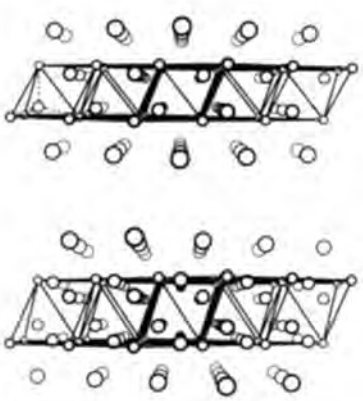

Fig. 30. Top: Characteristic part of the structure of $TbClD_{0.8}$ [223]. The D atoms are located in tetrahedral voids in the twin-layers of Tb atoms which are interconnected. Bottom: Corresponding part of the structure of $TbBrD_2$ [225] with additional occupation of the "octahedral" voids by two D atoms each. These D atoms are almost coplanar with the Tb atoms.

$TbClH_{1-x}$ looks like graphite and is a good (two-dimensional) metallic conductor, as expected from the formulation $Tb^{3+}Cl^-(H^-)_{1-x}(e^-)_{1+x}$. Heating the phase in a H_2 atmosphere topochemically leads to $TbClH_2$. A neutron diffraction study[224] showed that the Tb_6 "octahedra" are considerably elongated and filled by two H(D) atoms each. In addition, all Cl atoms are moved from positions above faces to positions above edges.

The reaction of $TbClH_{1-x}$ with H_2 is accompanied by a dramatic change in the physical properties. $TbClH_2$ forms transparent crystals and is an insulator. In $TbClH_{1-x}$ the excess valence electrons of the metal are delocalized in a band that has M–M bonding character. The reaction with H_2 results in a localization of all electrons in a narrow band that is essentially H 1s in character (the former "impurity band"). When $TbClH_2$ (and the isostructural $GdClH_2$) is heated in vacuo, hydrogen is lost and the M–M

bonds are "switched on" in a synchronized way. The resistivity of such a sample drops by several orders of magnitude with the formation of $TbClH_{1-x}$ (Fig. 31).

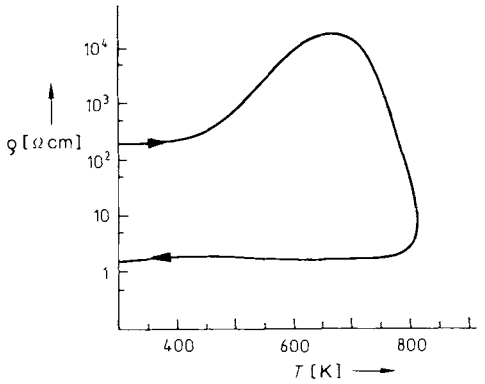

Fig. 31. Change of the electrical resistivity ϱ of a polycrystalline $GdClH_2$ pellet upon heating in vacuo [226]. $GdClH_{1-x}$ is formed, which is metallic.

Naturally, such reactions have been known for a long time. The transition from a metal to a salt is observed with the reaction of alkali metals and hydrogen. The recovery of the metal by the thermal decomposition of the hydride is also a similar reaction. The terbium example was chosen, for it demonstrates how the ideas outlined—starting from molecular clusters, their interconnection and condensation, the role of interstitial atoms, and finally the removal of any metal-metal bonding by these atoms—allow for a rather unified view of a large field. This field comprises molecules and solids, metals, and salts, and one hardly recognizes borderlines but only gradual differences.

This review article contains several, in part still unpublished, results collected by my co-workers, whose enthusiastic cooperation I gratefully acknowledge. Special thanks are due to the Fonds der Chemischen Industrie for generous long-term support of our investigations, and to I. Remón and B. Krauter for their help with the preparation of the text and drawings.

[18] All compounds with the exception of $Rb_{6.33}O$ and $Cs_{2.78-3.19}O$ have been characterized by single crystal structure investigations. The phase relationships [19] were established thermoanalytically and with the aid of a modified Guinier technique [20]. Recent investigations [21, 22] on the Cs/Cs_2O system re-establish the state of the art as it was before our own investigations. Despite the numerous experiments in our laboratory we have no evidence for the recently postulated stable Rb_3O [23,24].

[104] The wires of 1 mm thickness contain 285 superconducting filaments of 10 to 30 μm diameter. A transition temperature $T_c \approx 14$ K and critical current densities of 10^4 A cm^{-2} at 4.2 K/5 T are reached with such wires. dH_{c2}/dT ist 4 T K^{-1} [105]. The recently found high-T_C materials of the $YBa_2Cu_3O_{7-x}$ type ($T_c > 90$ K) [106] presumably allow critical fields $H_{c2} > 250$ T at 4.2 K [107]. Within half a year after the discovery of $YBa_2Cu_3O_{7-x}$ wires could be produced (0.8 mm diameter: inclusion in Ag) which stand critical current densities of 4×10^4 A cm^{-2} (*Nature 327* (1987), 356).

[112] This is due to a mixing-in of the (bonding) Mo d like t_{1u} states which are raised in energy by the interaction with low-lying (anti-bonding) X p like t_{1u} states. The conduction band states in Γ therefore are low for X = S and high for X = Te. The result is in contrast to the simple e_g conduction band model [58], which does not lead to any significant change in the conduction band energy as a function of the inter-cluster distances, because the intractions between the clusters are δ type.

[214] Single crystal investigations of $Ln_7I_{12}C$ (Ln = La, Gd, Tb, Er) [203] have met with several problems, which even have rendered an unambiguous characterization impossible: (i) Variable lattice constants indicate a range of homogeneity; (ii) the scattering density in the cluster centers varies largely, perhaps due to the presence of different interstitial atoms (cf. Tab. 5); (iii) with the exception of $Er_7I_{12}C$ the "vibrational" ellipsoids of the single Ln^{3+}-Ionen ions are extremely elongated (as in the case of $Sc_7Cl_{12}N$).

Contributions to Organo-Nickel Chemistry**

By Günther Wilke*

One hundred years of organonickel chemistry have generated a wealth of new knowledge and a history of examples of accidental discoveries which have finally led to industrial applications. The historical development is associated with the names of *Mond*, *Sabatier*, *Reppe* and *Ziegler* and, with the methods and techniques available today, many of the original discoveries and unsolved problems are attracting renewed attention. For example, 70 years were to go by before a synthesis first conceived by *Sabatier* could finally be realized. The path leading from nickel-catalyzed hydrogenation to highly enantioselective homogeneous catalysts is one of the contributions to organonickel chemistry which is described here.

1. Introduction and Historical Development

The scientist in his search for new knowledge is continually confronted with the interaction between planning and chance, the precise experiment and the unexpected results, rational thinking and intuition. This interaction is a favorite topic in science politics, and nickel is one of the few elements whose chemistry provides examples which can be regarded as pioneer achievements in chemical research and hence can provide insight into the way new knowledge evolves. For this reason, a review of the historical development accompanied by appropriate quotations and reminiscences seems a suitable introduction to the topic of this article.

100 years of "Angewandte Chemie" is almost synonymous with 100 years of organonickel chemistry. In 1890 *Mond*, *Langer*, and *Quincke*[1] reported the synthesis of "nickel carbonyl" from metallic nickel and carbon monoxide. *Mond* quickly realized the significance of this discovery and developed a technical process for purifying nickel based upon the formation and decomposition of the carbonyl. 20 years later, in an obituary for *Mond*, *Langer*[2] described the beginnings:

> "The experiments had been proceeding for some time when we discovered nickel carbonyl by accident. We treated nickel, as we had often done before, with carbon monoxide in a combustion tube and led the resulting gases into a Bunsen-burner in order to render them harmless. My assistant, who looked after these experiments, asked me to switch off the apparatus since he had to go home earlier. Some time after I had turned off the burners, I noticed that the flame of the Bunsen-burner into which the liberated gas was being led had a peculiar greenish yellow color which became more intense as the tube cooled. My first thought was that arsenic must be present in the carbon monoxide since it had been prepared from normal sulfuric acid. I therefore heated the glass tube through which the gas was led into the burner in order to obtain an arsenic mirror. The mirror was formed immediately but consisted not of arsenic but of nickel!
>
> My assistant told me later that he had often observed this flame coloration but had considered it of no importance. I mention these circumstances in such detail in order to illustrate how easily an important discovery can be overlooked and upon what insignificant details new industries are often based."

This discovery had consequences which went far beyond the creation of a new industry: a few years later *Sabatier* and *Senderens*[3] were led to attempt the preparation of volatile nickel compounds similar to $Ni(CO)_4$ using gases other than carbon monoxide. More than 40 years later, *Sabatier*[4] lectured on the background and the results before the Academy:

> "What led M. Senderens and I to develop our general direct hydrogenation method in the presence of finely divided metals and in particular of nickel?
>
> The initial objective of our research was quite a different one. A few years earlier, Ludwig Mond had managed to attach carbon monoxide directly to finely divided nickel (which he obtained by reduction of the oxide) and had prepared tetracarbonyl nickel $Ni(CO)_4$ as a well defined, volatile substance. (...)
>
> We hoped that a similar fixation would take place with other unsaturated gaseous molecules such as dinitrogen oxide, nitrogen oxide, nitrogen dioxide, ethylene, acetylene. (...)
>
> With this idea, which we later found to be incorrect, we studied the effect of ethylene upon reduced nickel.
>
> If ethylene is passed into a column of nickel in the cold nothing happens. Not much happens at 100°C, 200°C, 250°C but at 300°C the system becomes incandescent and the gas decomposes, whereby not only carbon and hydrogen are formed but also considerable amounts of *ethane*. This last compound must have been formed by hydrogenation of ethylene as the result of

[**] Including unpublished results by *A. Aradi*, *O. Behrens*, *H. Kuhn*, *T. Leven*, *J. Neuffer*, *J. Monkiewicz*, *K. R. Pörschke*, *L. Stehling*, and *K. H. Walter* and unpublished crystal structure determinations by *C. Krüger*, *E. Raabe*, and *Y.-H. Tsay*, and model calculations by *K. Angermund*. The preceding page shows Figure 19 of this article.

some special property of the nickel which caused it to act as a hydrogenation catalyst. This was subsequently confirmed in a direct experiment.

A mixture of equal volumes of hydrogen and ethylene when passed into a column of freshly reduced nickel at slightly elevated temperatures (30° to 40°C is sufficient) is converted into ethane without any by-products being formed. We then extended this hydrogenation behavior of nickel by using acetylene: a mixture of equal volumes of hydrogen and acetylene react *in the cold* with nickel to give exclusively ethylene; two volumes of hydrogen and one volume of acetylene giving one volume of ethylene.

The nickel was completely unchanged and could be used repeatedly."

During a meeting in 1912 which led to the founding of the Kaiser-Wilhelm-Institut für Kohlenforschung, *Emil Fischer* paid tribute to this discovery by *Sabatier* and *Senderens*, for which *Sabatier* had just received the Nobel Prize:[5]

"Gentlemen, a new era has begun for the chemistry of the gases and these have now moved into the constellation of catalysis. Using catalysts, some amazing conversions of hydrogen, oxygen, nitrogen, carbon monoxide can be carried out at temperatures which are many hundreds of degrees lower than that at which these gases normally react. This chapter on catalysis is unlimited and it is here that a systematic investigation promises to bring a rich reward."

75 years later, this program with which *Emil Fischer* sent the Institute on its way has, without doubt, a prophetic note and the original ideas of *Sabatier* were realized in part when we managed to prepare tris(ethylene)nickel **1**,

$[(C_2H_4)_3Ni]$ **1**

which although extremely labile can be isolated in crystalline form.[6] This discovery had been preceded by no less than 20 years of intense activity in the field of nickel chemistry.

In 1948, the 60th anniversary of the founding of this Journal, another milestone in the chemistry of nickel, was reached. *Reppe*, *Schlichting*, *Klager*, and *Toepel*[7] reported the completely unexpected discovery of the "cyclic polymerization of acetylene" to cyclooctatetraene (COT) using nickel catalysts. Well ahead of their time, the authors formulated the mechanism shown in Scheme 1.

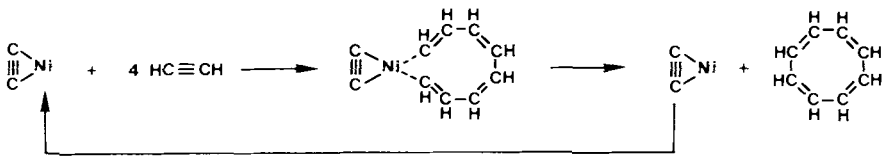
Even with hindsight, the accompanying explanation sounds surprisingly modern:

"We assume that a bond is formed consisting of a hypothetical biradical composed of four acetylene molecules, whereby both terminal radical-electrons are accepted into the 3d levels of the nickel."

This description implies what we would now describe as the formation of a metallacycle[*] by oxidative addition and its cleavage by reductive elimination. There has been much speculation concerning the mechanism of the formation of cyclooctatetraene which will not be discussed in detail here, but it is now believed that the cyclotetramerization of acetylene with a nickel catalyst does not take place in an electrocyclic manner as an example of "forbidden to allowed catalysis" but that a number of steps are involved. Recent investigations carried out both in the Mülheim Institute and by BASF in Ludwigshafen led us to suggest a mechanism involving two nickel atoms. A comparison was made using *Reppe*'s original conditions and either nickel acetylacetonate or our bis(cyclooctatetraene)dinickel $[(cot)_2Ni_2]$[10] **2** as catalyst. It turns out that in the presence of **2**, in contrast to nickel acetylacetonate, no incubation period is observed, the formation of cuprene[**] is significantly suppressed and the selectivity increases considerably. **2** is apparently the most effective catalyst known for the synthesis of cyclooctatetraene. The X-ray structural analysis of **2** shows that it is a sandwich complex in which two nickel atoms are held between two, essentially planar, cyclooctatetraene molecules[10c] (cf. Fig. 3 in Section 2). Based on this structure and the structure and chemical properties of a model—the chromium compound **3**,[11] in which a C_8H_8 chain bridges both Cr atoms, reacts further upon warming with conversion of the chain into COT which itself interacts again with both Cr-atoms—we proposed the formulation shown in Scheme 2 for the formation of COT.[11]

$[(\eta^5\text{-}C_5H_5)Cr(C_8H_8)Cr(\eta^5\text{-}C_5H_5)]$ **3**

This proposal is supported by recent experiments[12] which have led to the isolation and characterization of a



Scheme 1. The reaction mechanism for cyclooctatetraene formation as formulated by *Reppe* et al. [7].

[*] *Reppe* and *Vetter* [8] can be regarded as the fathers of the metallacycles: although they were unaware of the structure of the compound $Fe_2C_{12}H_4D_8$ which they had synthesized, a three dimensional crystal structure analysis by *Hock* and *Mills* [9] revealed the presence of a metallacycle.

[**] Cuprene is polyacetylene.

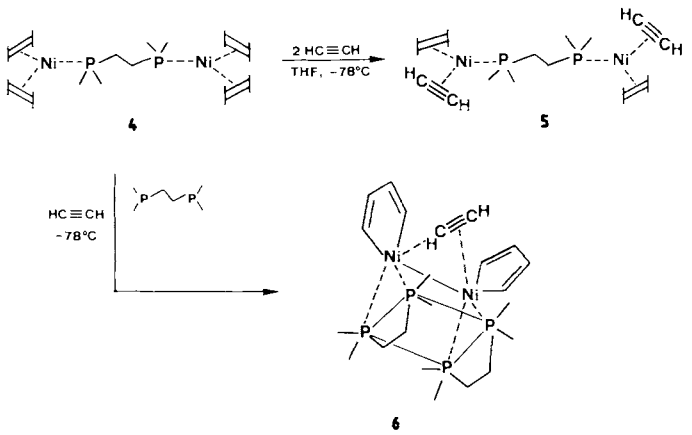
nickelacyclopentadiene complex **6** from the reaction of a nickel(0) complex with acetylene (Scheme 3).



Scheme 3. Formation of the nickelacyclopentadiene **6** from the complex **4** and acetylene by oxidative addition. Isopropyl groups are attached to the phosphorus.

Should the mechanism discussed above turn out to be correct, then we would have the interesting situation in which two metal atoms are involved in a catalytic process in a homogeneous phase and in which the product of the catalysis plays a decisive role as a ligand by holding the two Ni atoms a suitable distance apart. The incubation period mentioned above is probably associated with an initial reduction of the nickel(II) compound introduced as the catalyst.

These remarks on the third phase in the development of organonickel chemistry illustrate that modern developments have given a new actuality to discoveries made 40 years ago.

In 1953, five years after the publication of the most important aspects of the Reppe-chemistry, an initially annoying case of the failure of a routinely successful experiment occurred in the Mülheim Institute. Subsequently, however, the recognition of the reason for the failure was to become the starting point for a revolution in some areas of chemistry. For no apparent reason, the Aufbau reaction of triethylaluminum and ethylene which had been discovered by *Ziegler* and *Gellert*[13] quite unexpectedly failed. Instead of the usual higher aluminum alkyl compounds, *Holzkamp*[14] observed the formation of 1-butene. After a long search it was discovered that traces of nickel catalyzed a termination reaction after each insertion step. We described this development along with our explanation of the phenomenon in detail 15 years ago in an article in Angewandte Chemie under the title "The Nickel Effect."[15] Some recent results will be discussed in Section 4.2. The "nickel effect" was to lead step by step to the discovery of the "Ziegler catalysts."[16] These are associated by every chemist with unique scientific and economic success so that it is hardly an exaggeration to describe the development following the discovery of the "nickel effect" as revolutionary.

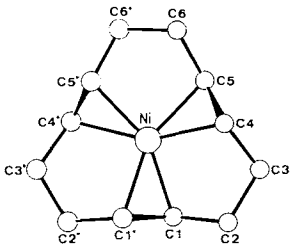
The "nickel effect" also marks the beginning of the extensive work on organonickel chemistry which developed in the Institute in Mülheim after 1959. The immediate impulse, however, came from two unrelated directions. In order to use the "nickel effect" for the continuous dimerization of ethylene to butene, it was necessary to develop a stable nickel cocatalyst. This problem was solved by treating nickel acetylacetonate in toluene with Et_2AlOEt in the presence of, for example, phenylacetylene.[14] This recipe was developed in 1954 and the desired cocatalyst was formed as a reddish orange solution. Nothing was known about its structure or even about its composition; all that mattered was that it worked. Five years later in 1959—in the meantime the cyclotrimerization of butadiene to 1,5,9-cyclododecatriene (CDT) using Ziegler catalysts had been discovered[17]—the use of this mixture, i.e. the red-orange solution, acted as the fuse for a new research strategy: the controlled oligomerization of unsaturated compounds.[18] In an attempt to develop a catalyst which would convert butadiene into a cyclic dimer instead of the cyclic trimer, experiments were carried out with various metals including nickel—*Reed*[19] having been able to dimerize butadiene with tetracarbonylnickel derivatives. To our satisfaction, the very first experiments with the "cocatalyst solution" gave 1,5-cyclooctadiene as well as cyclododecatriene. The further development in this direction will be described in Section 4.1.

The second idea led unexpectedly to a novel method for preparing transition-metal complexes. During the nickel-cocatalyzed ethylene dimerization and olefin displacement reaction, double bond isomerization had frequently been observed and we wanted to use this effect to find out which was the thermodynamically more stable isomer of cyclododecatriene. Nickel acetylacetonate was treated with Et_2AlOEt, exactly as before, in the presence of all-*trans*-cyclododecatriene. It was anticipated that the nickel produced during the reaction would cause isomerization. Instead of a precipitate of black elemental nickel, a dark red solution was formed from which an extremely air-sensitive but thermally stable, red, crystalline compound was finally isolated: the first nickel(0)-olefin complex, all-*trans*-cyclododecatrienenickel(0) **7**,[20] had been born and at the same time a general synthesis for complexes of this type had been discovered.[21]

This review of the historical development of organonickel chemistry will be followed by sections devoted to the results of our recent work with nickel complexes, their stoichiometric reactions, and their use as homogeneous catalysts.

2. Nickel(0) Complexes

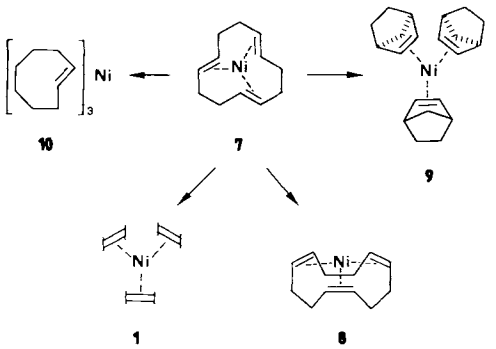
all-*trans*-Cyclododecatrienenickel(0) **7**, which has been known for over 25 years, was the first nickel(0)–olefin complex and it still attracts attention because of its structure and reactivity. The X-ray structural analysis[22] shows that the three *trans* double bonds adopt a propeller-like arrangement around the nickel atom to give a racemate in which the propeller can have a left-hand or a right-hand screw (see Fig. 1).



7

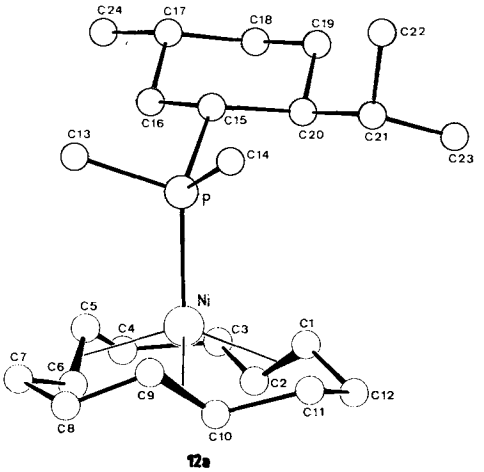
Fig. 1. The structure of all-*trans*-1,5,9-cyclododecatrienenickel(0) **7**.

The deep red color of this 16e-complex is remarkable and is presumably associated with the unusual arrangement of the double bonds. According to *R. Hoffmann* et al.,[23] the energetically most stable structure would be one in which the six C atoms of the three double bonds lie in the same plane as the nickel(0). Indeed, **7** reacts in a 1 : 1 ratio with all-*cis*-1,5,9-cyclododecatriene to give the almost colorless all-*cis*-cyclododecatrienenickel(0) **8**[24] in which the *cis*-double bonds have this arrangement. We believe that this is also the reason why the chelating ligand all-*trans*-CDT can be displaced even at low temperatures by ethylene. Similar behavior is observed for norbornene[15] and *trans*-cyclooctene.[25] The resulting tris(olefin)-16e-nickel(0) complexes **1**, **9**, and **10** (cf. Scheme 4) are also colorless, and the X-ray structural analysis of **9** confirms the coplanar geometry.[26]



Scheme 4. Tris(olefin)-16e-nickel(0) complexes, **1** and **7**–**10**.

The high reactivity and sensitivity of these 16e-complexes is of course associated with the unoccupied fourth coordination position. **7** readily adds ligands such as CO, CNR, and PR_3 as well as a hydride (see Section 4.2), and the red color disappears. For example, with Me_3P, the yellow colored complex [(Me_3P)Ni(cdt) **11** is formed. The conversion of the 16e-system into an 18e-system is accompanied by a displacement of the nickel atom out of the plane such that an almost tetrahedral coordination results, and this has been confirmed by an X-ray structural analysis of [(menthyldimethylphosphane)Ni(cdt)] **12a** (Fig. 2).[27]

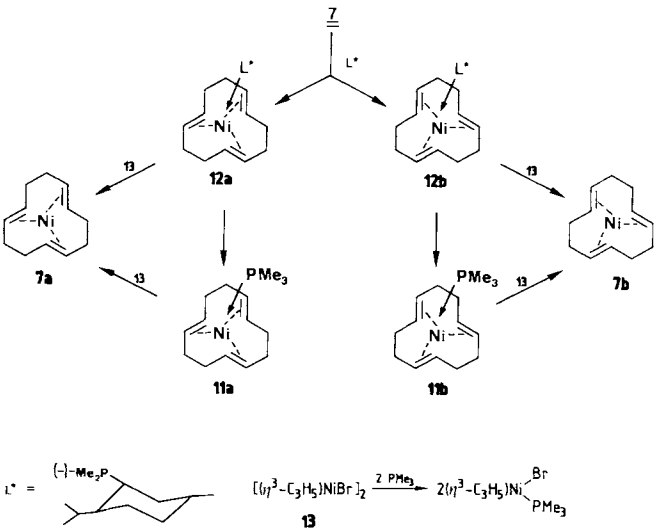


12a

Fig. 2. The structure of the adduct **12a** of menthyldimethylphosphane and [(cdt)Ni] **7**.

The fourth coordination position plays a key role in the separation of the racemate (cf. Scheme 5). We have converted **7** into the diastereomers **12a** and **12b** by a 1 : 1 reaction with menthyldimethylphosphane, separated these by recrystallization, and then displaced the optically active phosphane by reaction with PMe_3 to give the enantiomers **11a** and **11b**. The next step, the removal of the Me_3P to give the enantiomers **7a** and **7b**, created problems, which, however, were solved by treating **11a** and **11b** with the allylnickel complex **13**: at low temperatures the phosphane is transferred to **13** with liberation of **7a** and **7b**. It is also possible to go directly from **12a** and **12b**.[28]

The specific rotation of **7a** is $[\alpha]_D^{-30^\circ} = +104^\circ$. The successful separation shows that a racemization **7a** ⇌ **7b** by a simple rotation of the double bonds is not possible. The

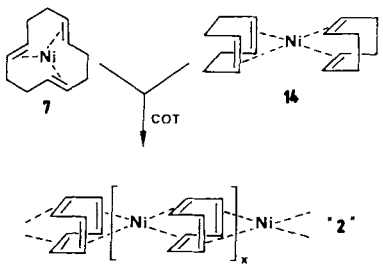


Scheme 5. Separation of the racemates of **7** and the isolation of the enantiomers **7a** and **7b**.

chirality of **7a** and **7b** has a certain similarity with that of the helicenes and they are presumably the simplest optically active transition metal complexes known.

The discovery of bis(cyclooctadiene)nickel(0) **14**[10] occurred almost simultaneously with that of 7and was prepared by a similar reduction of nickelacetylacetonate with Et_2AlOEt in the presence of 1,5-cyclooctadiene. **14** can also be easily prepared from **7** and is now used all over the world either as a stoichiometric reagent or in the preparation of catalysts. It is appropriate to mention here that we have prepared **14** in our pilot plant on a 10-kg scale with no trouble at all. Particularly effective is the reaction of nickel(II) ethoxide,[29] which we prepare by an electrochemical procedure, with Et_3Al in the presence of cyclooctadiene. **14** has now become a readily available product and its synthesis is a standard exercise with which newcomers to the Institute gain experience.

It is appropriate while discussing the olefin-nickel(0) complexes to comment further on bis(cyclooctatetraene)dinickel **2**[10] which we mentioned in Section 1. Because of its low solubility we initially regarded this complex as a polymer ("**2**"), and formulated it as such using the non-planar form of free cyclooctatetraene (Scheme 6).



Scheme 6. The initially suggested polymeric structure for **2**.

The black, metallic crystalline compound, which can be prepared in practically quantitative yield either by reduction or by a displacement reaction from **7** or **14**, has been examined by X-ray diffraction (cf. Fig. 3)[10c]: each nickel atom is bonded to two *syn*-η^3-allyl groups and the Ni-Ni distance varies between 2.719(9) and 2.947(1) Å (the nickel positions are disordered) which presumably excludes a strongly bonding Ni-Ni interaction.

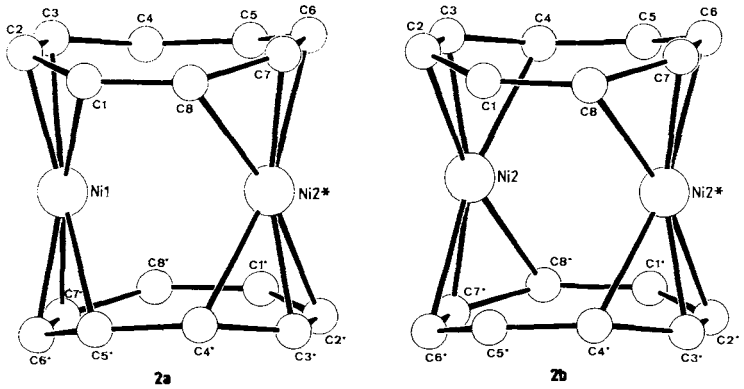


Fig. 3. The two structures of $[(cot)_2Ni_2]$ **2** (the Ni positions are disordered).

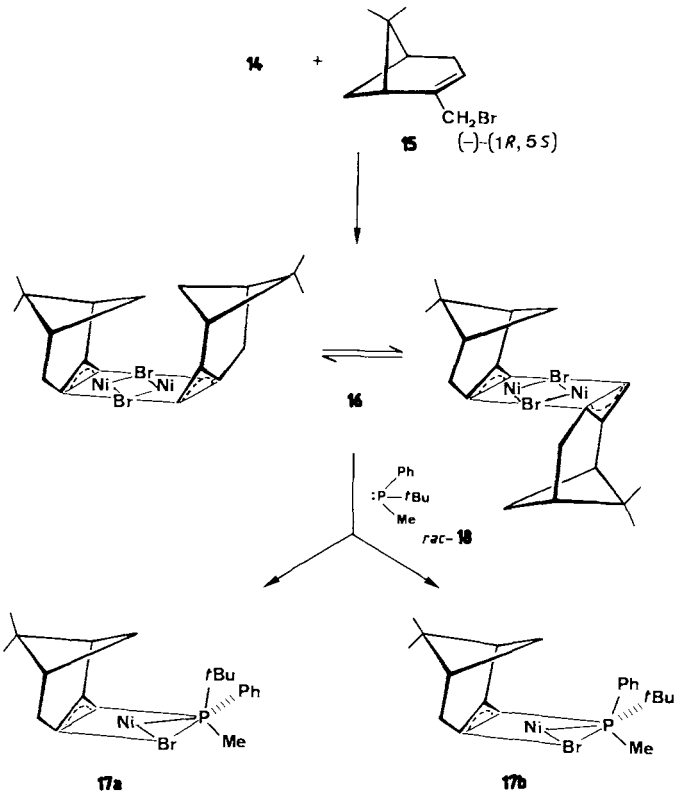
3. Stoichiometric Reactions: Oxidative Addition

The "pure" or homoleptic olefin-nickel(0) complexes have considerable synthetic potential. The driving force for these reactions is the oxidation of nickel(0) to nickel(II) and this will be illustrated in the following with a few examples.

Certain catalysts, which will be discussed in Section 4, can be easily prepared by the oxidative addition of an allyl halide to nickel(0)[30] and dimeric η^3-allylnickel halides result. *E. O. Fischer* and *G. Bürger* originally used $Ni(CO)_4$,[31] but the yields were unsatisfactory since the liberated CO can obviously interfere.[30] By using $[(cod)_2Ni]$ **14** we were able to obtain a practically quantitative yield.[30] An example is the synthesis of the rather unusual compound discussed below which later found use in a quite different area.[32]

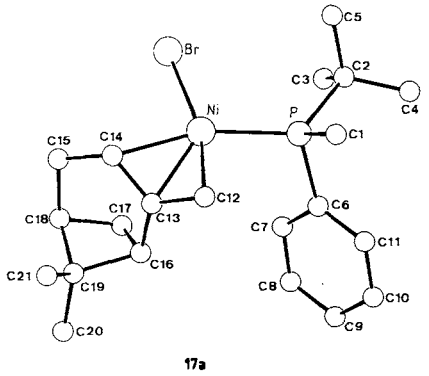
(+)-(1*R*,5*R*)-η^3-pinenylnickel bromide **16** was prepared from (−)-(1*R*,5*S*)-pinenylbromide **15** (Scheme 7) and used



Scheme 7. Reaction of the racemic Horner-phosphane *rac*-**18** with pinenylnickel bromide **16** to give the diastereomers **17a** and **17b**.

to separate Horner-phosphanes into their enantiomers by means of diastereomer formation. For example, **16**, which according to ^{1}H-NMR spectroscopy exists at −20°C in two forms, reacts with racemic *tert*-butyl(methyl)phenylphosphane *rac*-**18** in a 1:1 ratio to give the diastereomers **17a** and **17b**.

17a could be crystallized[32] and was analyzed by X-ray crystallography[33] (cf. Fig. 4). The absolute configuration turns out to be 1*R*,5*R* in the pinenyl part and *S* in the phosphane part.



17a

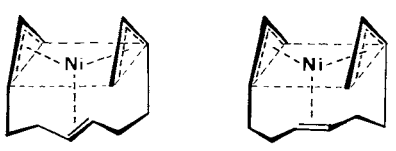
Fig. 4. The structure of the dextrorotatory complex **17a**.

The (−)-(*S*)-*tert*-butyl(methyl)phenylphosphane (−)-(*S*)-**18** can be displaced from **17a** by treatment with Me_3P and has an optical purity of 96.6%, which increases to almost 100% after one further complexation. We have used this separation procedure for a series of Horner-phosphanes of the type $PR^1R^2R^3$, and in each case the optical purity after a single crystallization lies between 60 and 96%. The example discussed above turns out to be the best, but nevertheless the method appears to be general.[32] It should also be mentioned that the preparative complexation of a Horner-phosphane to **16** can also be used analytically to determine its optical purity: the diastereomers can be distinguished in the NMR spectrum and used to measure their relative proportions.[34]

A formal oxidative addition also occurs when $[(cod)_2Ni]$ **14** is treated with butadiene at −10°C. The COD is displaced and three butadiene molecules couple together to give a C_{12}-chain which is bonded to the nickel atom by terminal η^3-allyl groups. By definition the nickel is now regarded as nickel(II). The complex $[(C_{12}H_{18})Ni]$ **19** was the first intermediate to be isolated from a catalytic cyclooligomerization reaction of butadiene.[35] It can be recrystallized from liquid butadiene and melts at +1°C. If **19** is treated with excess butadiene at elevated temperatures, the C_{12}-chain undergoes reductive elimination to give CDT. This is accompanied by the transient formation of nickel(0), which immediately undergoes a renewed oxidative addition with butadiene. Since this sequence continues repeatedly, the result is the catalytic cyclotrimerization of butadiene accompanied by a repeated change in the formal oxidation state of the nickel [$Ni^0 \rightleftharpoons Ni^{II}$].[18]

Detailed NMR-spectroscopic investigations[36] have shown that **19** exists as two stereoisomers which differ only in the arrangement of the internal double bond (Scheme 8).

Many years previous to the elucidation of these structures by NMR spectroscopy, the chemical behavior had convinced us that a C_{12}-chain is formed and that this bonds through η^3-allyl groups.[35a] The successful synthesis of bis(η^3-allyl)nickel **20** was based upon this conclusion.



19a **19b**

Scheme 8. The two stereoisomers of η^3,η^3-dodecatrienediylnickel **19**.

$[(\eta^3\text{-}C_3H_5)_2Ni]$ **20**

20, a highly volatile and reactive compound, is the simplest transition metal sandwich compound and is the prototype of the "pure" or homoleptic allyl-transition metal compounds.[37] It is mentioned here because recent structural investigations and independent ab-initio calculations have produced some interesting results and corrected some earlier misconceptions. It is hardly surprising that **20** attracted the attention of theoreticians at an early date and several groups carried out ab-initio calculations. However, it was assumed that the three C atoms and five H atoms of the allyl group lie in one plane. *F. Mark*,[38] without knowing the latest results obtained by *C. Krüger* and *R. Goddard*[38] from low temperature X-ray analysis and neutron diffraction data, found by double-ζ-ab-initio calculations that the displacement of the H atoms out of the plane of the three C atoms produces an energy minimum. The agreement between the calculated and experimental results is remarkable, as is also the stabilization of the molecule by 187 KJ/mol. Figure 5 speaks for itself.

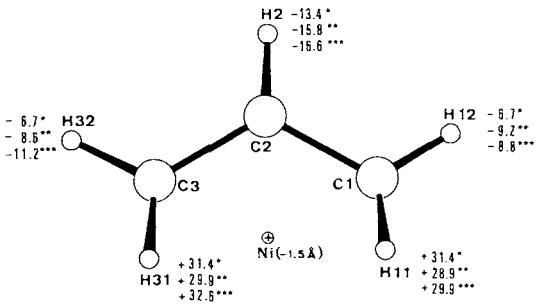


Fig. 5. The displacement of the H atoms out of the plane formed by the three C atoms of an allyl group in bis(η^3-allyl)nickel **20**. The values [°] are taken from an ab initio calculation (*), a neutron diffraction study (**), and a low-temperature X-ray structural analysis (***).

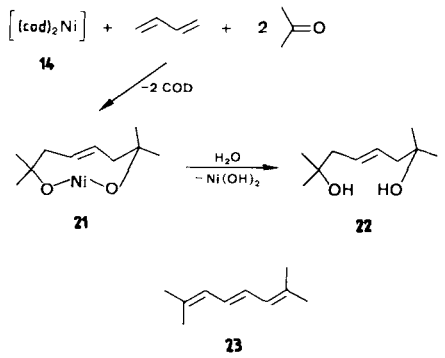
The calculations also suggest that the nickel atom has a net charge of +0.81, which is significantly higher than that calculated for a system having planar allyl groups (+0.65,[39] +0.55, and +0.485[40]).

It is appropriate to mention these results at this point since η^3-allyl systems of this type are frequently observed as intermediates in the transition metal-catalyzed reactions of 1,3-dienes.

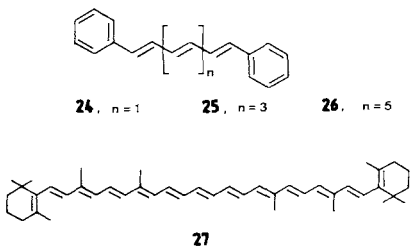
The oxidation of nickel(0) by butadiene, which we have mentioned above, takes quite a different course if the reaction is carried out in the presence of aldehydes or ketones.[41] In the simplest case of acetone, butadiene and nickel(0) (in the form of **14**) react to give a nickel dialkoxide **21** in which two equivalents of acetone are coupled with one equivalent each of butadiene and nickel (Scheme 9). Hydrolysis leads to (*E*)-2,7-dimethyl-4-octene-2,7-diol **22**, which can be easily converted by conventional dehydration into (*E*)-2,7-dimethyl-2,4,6-octatriene **23**. This nickel-induced coupling of butadiene with a carbonyl

compound forms the basis of an effective polyene synthesis.



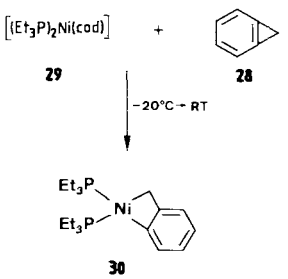
Scheme 9. The nickel-induced synthesis of the diol **22** and the triene **23**.

Analogous reactions have been used to convert benzaldehyde, cinnamaldehyde, phenylpentadienal and vitamin-A-aldehyde into the polyenes **24**–**27** (Scheme 10). Compound **27** can be regarded as a homologue of β-carotene.



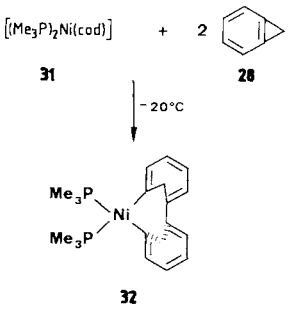
Scheme 10. The polyenes **24**–**27** prepared by reaction of butadiene with benzaldehyde, cinnamaldehyde, phenylpentadienal and vitamin-A-aldehyde, respectively.

Particularly convincing examples of the oxidative addition to nickel(0) have resulted from the investigations of the reactivity of cyclopropabenzene **28** towards Ni(0) (Scheme 11).[42] Steric factors have an obvious influence upon the reaction which can lead to completely different products. The three-membered ring opens in the reaction between **28** and $[(Et_3P)_2Ni(cod)]$ **29**, and the nickelacyclobutabenzene derivative **30** can be isolated.[43]



Scheme 11. The synthesis of the nickelacyclobutabenzene derivative **30**.

31, the methyl analogue of **29**, on the other hand, reacts under the same conditions with two equivalents of **28** to give the bismethano-bridged nickelaannulene **32** (Scheme 12).[42] The *anti* arrangement of the bridging methano-



Scheme 12. The synthesis of the nickelaannulene **32**.

group in **32** has been established by NMR spectroscopy and an X-ray structural analysis[44] (Fig. 6).

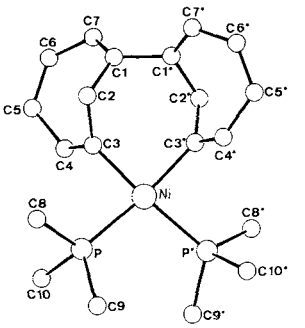


Fig. 6. The structure of the nickelaannulene **32**.

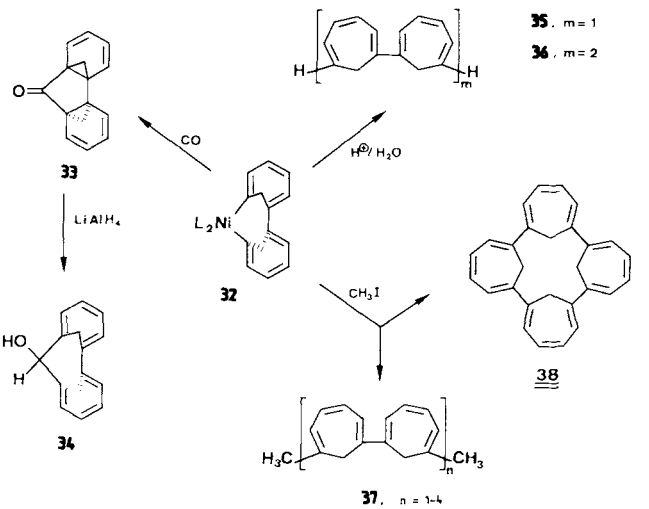
The chemistry of **32** has produced some interesting results (Scheme 13). Carbonylation leads to the ketone **33**, which has been shown by NMR-spectroscopy and an X-ray structural analysis to be a derivative of norcaradiene. Upon conversion into the alcohol **34**, the cycloheptatriene structure of **32** is re-formed.[45]

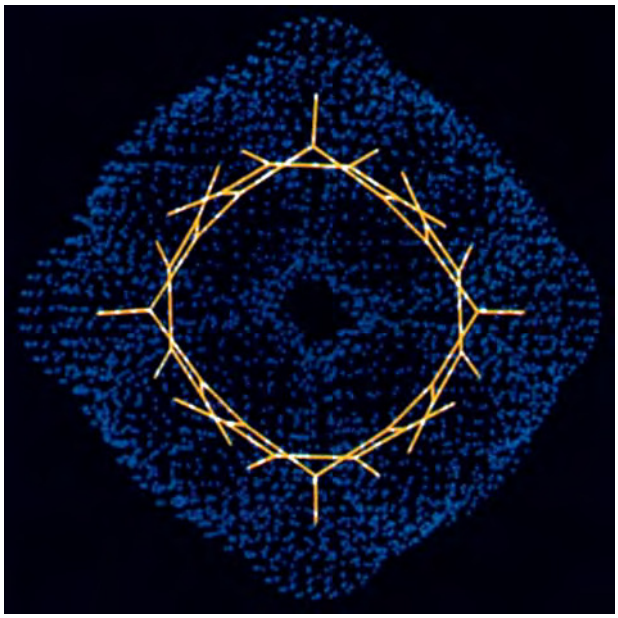
In addition to the expected product **35**, hydrolysis also produces lesser amounts of the dimer **36** indicating that **32** adopts a transient dimeric form. This tendency to dimerize or even oligomerize is also observed in the reaction with CH_3I: terminally methylated di-, tri- and tetrameric (n = 1-

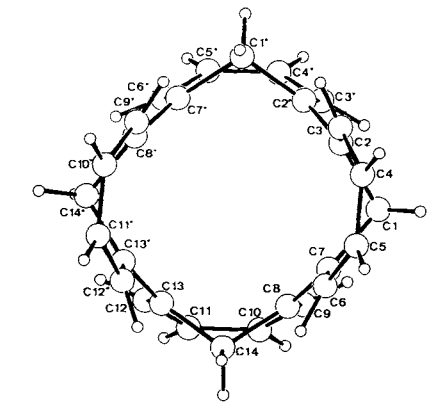


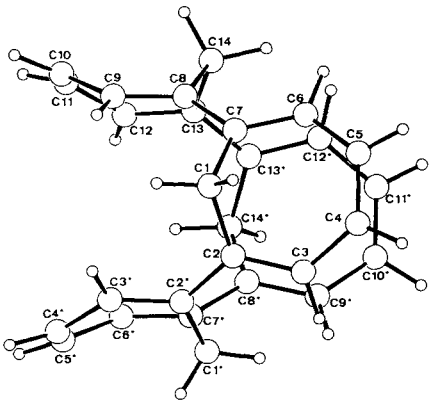
Scheme 13. The reactions of **32**, L = CH_3.

4) units are formed, i.e. the products **37** contain from two to eight coupled cycloheptatriene units.[46] The most spectacular product from this reaction, however, is the tetramethano-bridged [24]annulene **38**, which is formed as a red crystalline solid in ca. 10% yield.

An X-ray structural analysis[47] (Fig. 7) shows that **38** does not have a planar structure, as the formula would suggest, but rather has a cylindrical form.



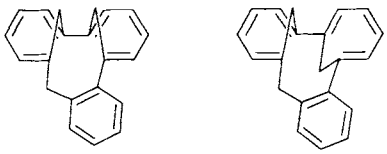




38

Fig. 7. The structure of the bridged [24]annulene **38**. Top: space-filling computer graphic representation. Middle and bottom: two views of the molecule **38**.

It is worth considering for a moment how one would synthesize **38** by conventional means. Without a doubt considerable effort would be involved, underlining the synthetic possibilities which such nickel complexes offer. However, we have not been able to prepare **38** catalytically from **28**, presumably because of a side reaction in which **32** reacts with excess **28** to give what is formally a trimer of **28** but which does not have a trismethano-bridged [18]annulene structure. During the reaction of **28** with **32**, the three-membered ring opens (in a manner similar to that discussed above for **30**) and couples with the annulene fragment of **32**. The product consists of the two isomeric hydrocarbons **39a** and **39b** (Scheme 14).[42]



39a **39b**

Scheme 14. The two stereoisomers **39a** and **39b** from the formal cyclotrimerization of **28**.

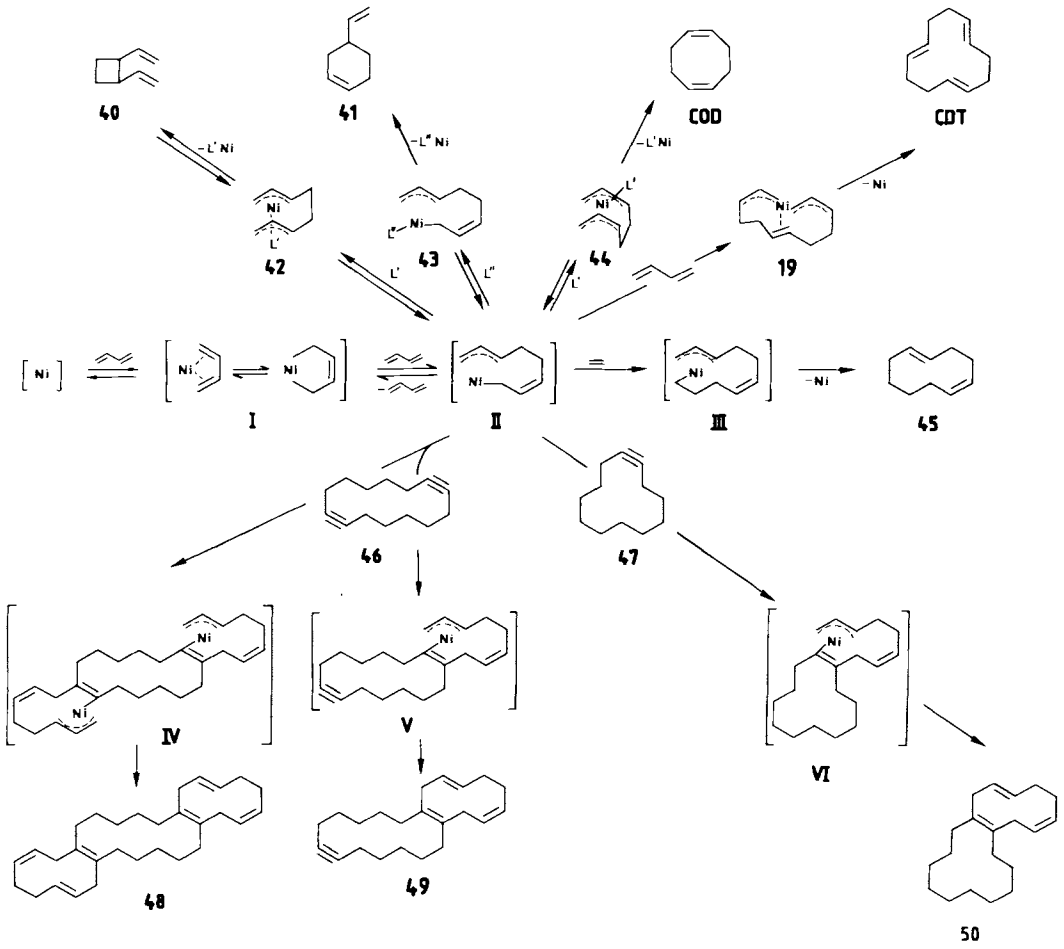
4. Catalytic Reactions

The stoichiometric reactions discussed above clearly indicate that, with the help of suitable organonickel compounds, organic syntheses can be carried out which would either be impossible or extremely tedious by conventional means. The only drawback is that the nickel is used as a stoichiometric reagent; although under suitable conditions a regeneration should be possible. This disadvantage is avoided if the nickel component acts as a catalyst and in one case, discussed below, over a million cycles have been achieved.

4.1. Cyclooligomerization

We have already mentioned a catalytic cycle which forms the basis of the cyclotrimerization of butadiene as part of the discussion of the oxidative addition of butadiene to nickel(0) or as it has been called "naked nickel".[18] Scheme 15 summarizes a number of catalytic cyclooligomerization reactions in which butadiene is one of the substrates and in which either "naked nickel" or a ligand-nickel system (LNi) are involved.

The "naked nickel", in the form of, for example [(cdt)Ni] **7** or [$(cod)_2$Ni] **14**, loses its ligands under the influence of the butadiene, and the nonisolable intermediate **I** is presumably formed in which η^4- or η^2-systems are complexed to the nickel. Further reaction occurs at low temperature ($-20°$ to $-30°C$) with butadiene to give **II**, which has also not been isolated. In the presence of ligands such as $L' = PPh_3$ or $P(OC_6H_4\text{-}o\text{-}Ph)_3$ or $L'' = P(cyclohexyl)_3$, the intermediates **42** to **44** can be isolated, while in the presence of butadiene, **19** is formed. The structures of these species have been unequivocably established by NMR spectroscopy.[36,48] It is almost certain that **19** as well as **42**–**44** are involved in the catalysis—particularly



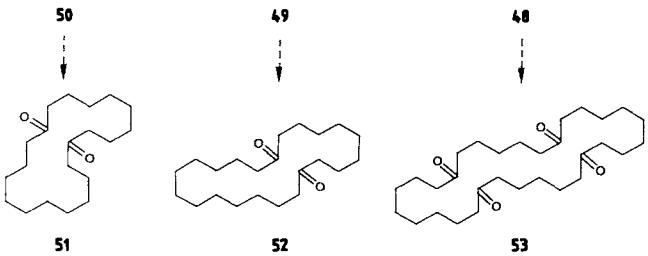
Scheme 15. The nickel-catalyzed cyclooligomerization of butadiene alone or with ethylene or cycloalkynes.

since these compounds take part in stoichiometric reductive elimination reactions to give the cyclic dimers **40**, **41** and COD as well as the cyclic trimer CDT. Related intermediates of the type **III**–**IV** are involved in the catalytic reactions of butadiene with ethylene or alkynes (here the cycloalkynes **46** and **47**) to give the cyclic oligomers **40**, **41**, COD, CDT, **45**, and **48** to **50**.[35b,49] All these products of the catalysis are formed in high yield and in principle the number of catalytic cycles should be unlimited—assuming that it were possible to guarantee the absolute purity of all the reagents involved. We have never met with a substrate specific termination reaction.

It is apparent that the catalytic syntheses leading to **48**–**50**[49c] offer a route to large ring systems. Partial hydrogenation gives bi- or tricyclic systems containing one or two tetrasubstituted double bonds. These can be cleaved by ozone to give di- or tetraketones of the 20-, 22-, and 30-membered rings **51**–**53** (Scheme 16).[49c]

1,5,9-Cyclododecatriene is produced on a large scale in various countries and is the starting material for the preparation of lauryl lactam or dodecanoic acid, which can be converted into polyamides (e.g. Vestamide and Qiana). In addition, a plant for the industrial production of 1,5-cyclooctadiene (COD) is under construction. COD is partially hydrogenated to cyclooctene and this is converted by metathesis into the polymer polyoctenamer—a rubber having interesting technical potential.

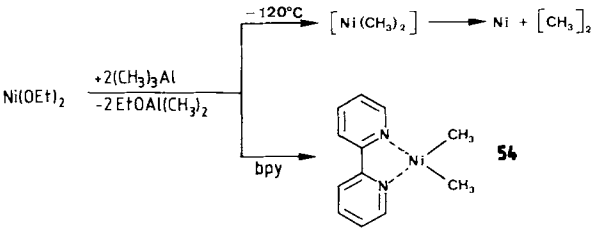
Cyclooligomerization with nickel(0) catalysts is by no means limited to dienes. Reactive monoolefins also react and intermediates in the form of nickelacyclopentane derivatives can be isolated. These can have considerable stabil-



Scheme 16. Macrocyclic ketones **51**–**53** derived from catalytically prepared di- and tricyclic systems.

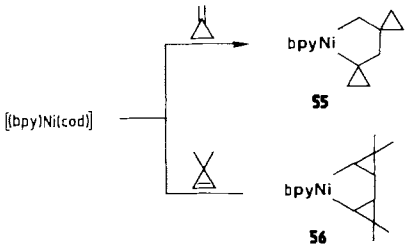
ity depending upon the nature of the associated ligands. The following example (Scheme 17) illustrates the unusual stability of the Ni–C bond in the presence of suitable ligands: whereas the reaction of nickel acetylacetonate or nickel ethoxide with $AlMe_3$ results in the immediate precipitation of elemental nickel even at $-120\,^{\circ}C$, the unstable $NiMe_2$ can be stabilized by carrying the reaction out in the

presence of, for example, α,α′-bipyridyl, and the thermally stable [(bpy)Ni(CH_3)$_2$] **54** can be isolated and can even be recrystallized from boiling benzene.[50]



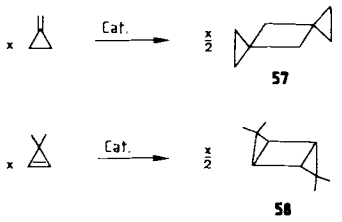
Scheme 17. Example of the ligand-induced stabilization of a Ni-C bond.

In this way it has proved possible to isolate a number of products of oxidative addition reactions involving monoolefins in the form of the nickelacyclopentane derivatives, e.g. **55** and **56**[51] (Scheme 18).



Scheme 18. Formation of the nickelacyclopentanes **55** and **56** from a nickel(0) complex and methylenecyclopropane or 3,3-dimethylcyclopropene.

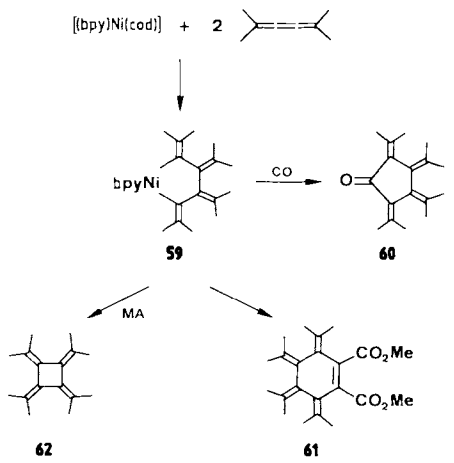
Nickelacyclopentane species of this type are probably formed during the catalytic cyclodimerization of these monoolefins (Scheme 19).[51]



Scheme 19. The catalytic cyclodimerization of methylenecyclopropane and 3,3-dimethylcyclopropene to **57** and **58**. Cat. = catalyst.

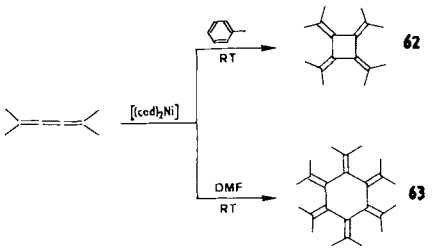
As part of another project, an interest existed in the radialenes. These were first prepared by *Iyoda* et al.[52] from dimethylhexatriene and we were able to demonstrate that it is also possible here to isolate a nickelacyclopentane derivative **59** by reaction of the hexatriene with [(bpy)Ni(cod)] (Scheme 20).[53a]

59 takes part in insertion reactions: CO reacts to give the ketone **60** and acetylenedicarboxylic acid ester gives the six-membered ring **61**. Reductive elimination to the [4]-radialene **62** can be induced in the presence of electron withdrawing species such as maleic anhydride (MA).[53a] The stoichiometric reaction can be converted into a catalytic cyclooligomerization in the presence of [(cod)$_2$Ni] (Scheme



Scheme 20. The formation of the nickelacyclopentane **59** by the oxidative addition of 2,5-dimethyl-2,3,4-hexatriene (MA = maleic anhydride).

21) and, depending upon the conditions, it is possible to obtain either the cyclodimer[53a] or the cyclotrimer.[53b]



Scheme 21. The catalytic cyclodimerization and cyclotrimerization of 2,5-dimethyl-2,3,4-hexatriene to **62** and **63**, respectively.

The catalytically prepared radialenes **62** and **63** have been investigated by X-ray methods (see Fig. 8). The four-membered ring in **62** is found to be folded, while the six-membered ring in **63** adopts a chair conformation.[54]

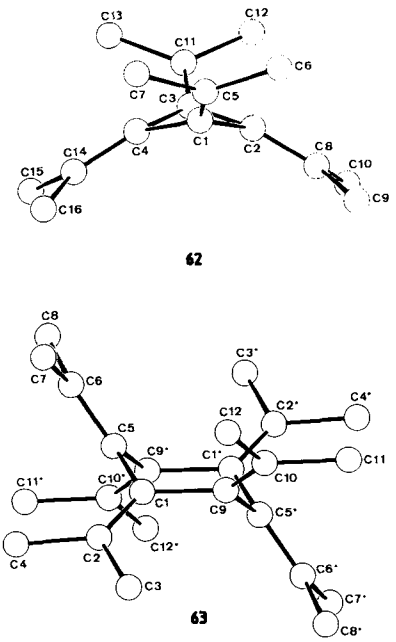


Fig. 8. The structures of the [4]- and [6]-radialenes **62** and **63**.

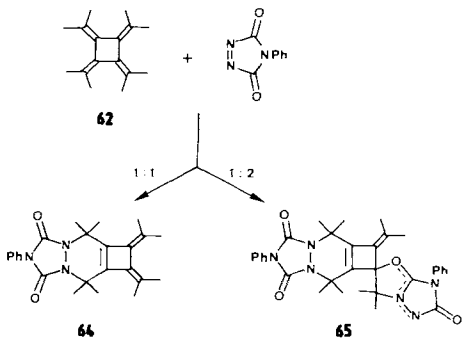
62 and **63** behave quite differently towards dienophiles (Scheme 22) and whereas **63** does not react with either tetracyanoethylene or *N*-phenyltriazoledione, **62** reacts immediately to give a 1:1 adduct. Steric hindrance apparently prevents the isopropylidene group in **63** from adopting an arrangement suitable for a Diels-Alder reaction. It should also be mentioned that **62** can react in a 1:2 manner with *N*-phenyltriazoledione—the product is not, however, a cyclobutadiene derivative. Whereas the 1:1 addition takes place in a Diels-Alder manner to give **64**, the second molecule of the dienophile reacts in an unusual manner to give **65**,[53b] which has been shown by X-ray analysis to have a betaine-like structure.[54]

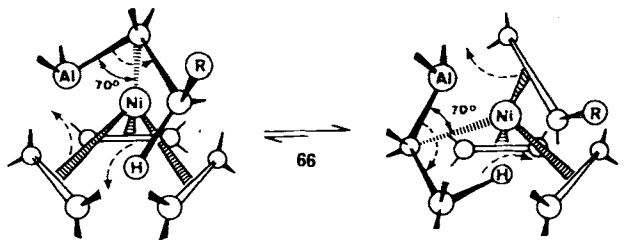


Scheme 22. Formation of a Diels-Alder adduct (**64**) and a betaine-like product (**65**) from **62**.

As far as we are aware, this is the first report of an addition of this type and it enables **64** to avoid adopting a cyclobutadiene-like structure.

4.2. The Interaction between Nickel(0) and Main Group Metal-Alkyls and -Hydrides

In 1973 we summarized for the first time the chemistry associated with the "nickel effect" (see above) and developed a model **66** based upon the assumption that in this catalytic system a key role is played by a complex involving nickel(0), the appropriate olefin and the trialkylaluminum derivative (Scheme 23).[15]



Scheme 23. A model of an intermediate in the "nickel effect".

According to this model, ethylene complexes to nickel(0) in a manner similar to that found in $[(C_2H_4)_3Ni]$ **1**. The R_3Al occupies a further coordination site and forms a three-centered bond through the α-C atom. The transalkylation of the type observed in the "nickel effect" can then occur in an electrocyclic manner.

This proposal acted as a stimulus for efforts to discover systems in which nickel(0) interacts with alkyl derivatives of main group metals. Before discussing the results, it is appropriate to mention an example of this catalytic transalkylation reaction to indicate its usefulness.[55]

$(C_8H_{17})_3Al$, which is used in the synthesis of certain tin compounds, is prepared on a technical scale by heating $(i\text{-}C_4H_9)_3Al$ with 1-octene at ca. 140°C, whereby isobutene is eliminated. However, during this purely thermal transalkylation, small amounts of undesirable higher alkyls are formed as a result of the addition of the Al-C bond to 1-octene.

The catalytic reaction, on the other hand, is carried out as shown in Scheme 24;[55] $[(cod)_2Ni]$ **14**, $(i\text{-}C_4H_9)_3Al$ and 1-octene are mixed in the ratio 5:1000:6000 and kept at −10°C. After 5 hours a quantitative reaction has occurred to give $(n\text{-}C_8H_{17})_3Al$. The catalyst can then be removed in the form of $Ni(CO)_4$ by using gaseous CO. Other α-olefins can be converted in an analogous manner.

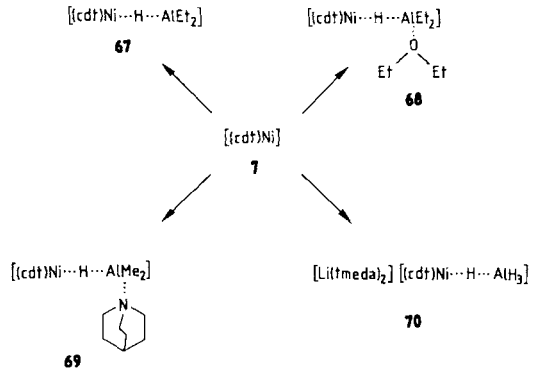
$$(i\text{-}C_4H_9)_3Al + 3\,CH_2{=}CH{-}C_6H_{13} \xrightarrow{[(cod)_2Ni]} (n\text{-}C_8H_{17})_3Al + 3\,CH_2{=}C(CH_3)_2$$

Scheme 24. The synthesis of tri-*n*-octylaluminum by nickel-catalyzed transalkylation of triisobutylaluminum.

It is of significance that we have never been able to detect an interaction between, for example, **1** and Et_3Al. If a mixture of **1** and Et_3Al is treated with C_2D_4 below −50°C, then an exchange with the C_2H_4 molecules occurs without the ethyl groups of the Et_3Al being involved, while above −50°C the "nickel effect" causes statistical scrambling of the D atoms of the C_2D_4 over all the ethyl groups and ethylene molecules. The catalytic reaction takes place, however, without it being possible to detect any complex formation[55] by NMR spectroscopy. This is not, however, adequate proof against complex formation, since, particularly in catalysis, minimal concentrations of such intermediates (or complexes) are frequently sufficient to ensure a rapid reaction.

The chemistry of the organoaluminum compounds suggests that hydrides in particular have a marked tendency to form multicentered bonds. For example, the dialkylaluminum hydrides form Al-H-Al bridges which are so stable that they are only partially cleaved by ether (see Scheme 25). It is therefore remarkable that [(cdt)Ni] **7** reacts with diethylaluminum hydride in pentane at −78°C with cleavage of the Al-H-Al bridges to give the 1:1 adduct **67**, which contains a Ni-μ-H-Al bridge.[56] In ether, a 1:1:1 adduct **68** is formed in which the fourth coordination position at the aluminum is occupied by ether.[56] Both **67** and **68** are crystalline solids but are only stable below −60°C. A 1:1 adduct is also formed between **7** and the complex derived from $(CH_3)_2AlH$ and quinuclidine.[57] **69** is also crystalline and in this case the solid is stable up to 20°C. An analogous complex **70**[58] is formed with $LiAlH_4$.

70 is an example in which the Ni atom in **7** interacts with a complex anion through a hydride bridge. Of even greater relevance to the "nickel effect" are complexes such



Scheme 25. CDT-Ni complexes **67**–**70** with Ni-μ-H-Al bridges.

as **71** to **73**, which can be prepared from **1** and in which both a C_2H_4 molecule and a hydride are bonded to nickel(0) (Scheme 26).[57]

$$[(C_2H_4)_3Ni] \longrightarrow [Na(tmeda)_2][(C_2H_4)_2Ni\cdots H\cdots AlEt_2]$$
1 **71**

$$[(C_2H_4)_3Ni] \longrightarrow [Na(thf)_6][(C_2H_4)_2Ni\cdots H\cdots AlEt_3]$$
1 **72**

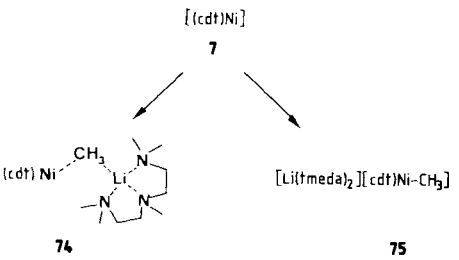
1 **73**

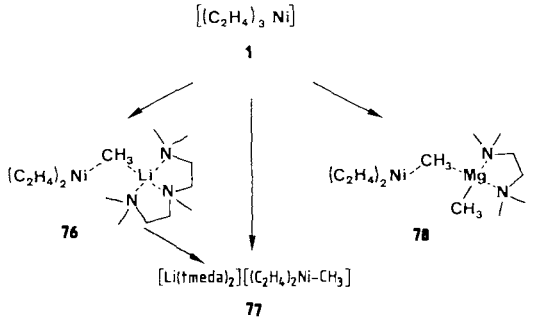
Scheme 26. Ethylene complexes **71**–**73** with Ni-μ-H-Al bridges.

In these cases the Ni atom is the anion center, while the cation is coordinated with THF or tetramethylethylenediamine (TMEDA). In **66** it is assumed that both olefinic ligands as well as the α-C atom of trialkylaluminum derivative are bonded to nickel(0). If **7** is allowed to react instead with alkyllithium compounds, then (depending upon the nature of the chelating ligand bonded to the lithium) complexes are formed which contain either a Ni-μ-C-Li bridge (**74**) or an alkyl anion (**75**) (Scheme 27).[59]



Scheme 27. The CDT-complex **74** with a Ni-μ-C-Li bridge and the ate-complex **75** derived from (CDT)Ni **7**.

The structures of the related complexes **76**–**78** derived from **1** (Scheme 28) have been determined by X-ray diffraction (Fig. 9): **76**[59] and **78**[60a] are characterized by the presence of a Ni-μ-C-Li bridge, while **77**[61] is an ion pair. **76** can be readily converted into **77**.



Scheme 28. The ethylene-nickel complexes **76** and **78** with Ni-μ-C-Li bridges and the related ate-complex **77**.

Recent results show that dialkylmagnesium compounds can be coordinated to nickel(0), but in these cases the products frequently react further—the driving force apparently being the formation of a Mg-Ni-hydride.[60b]

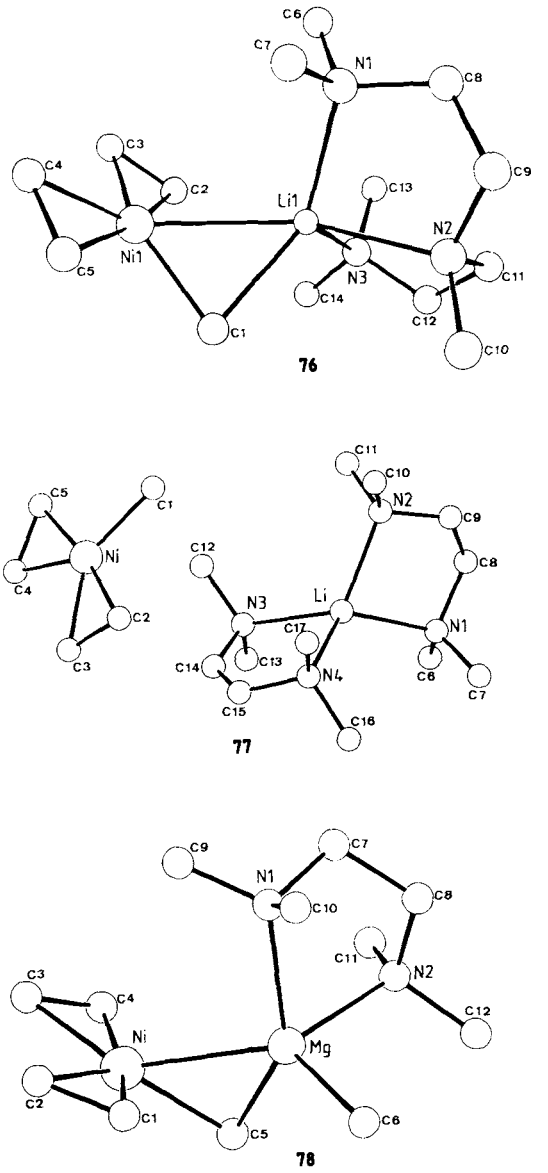


Fig. 9. The structures of the $[(C_2H_4)_2Ni]$ complexes **76** and **77** with MeLi and **78** with Me_2Mg.

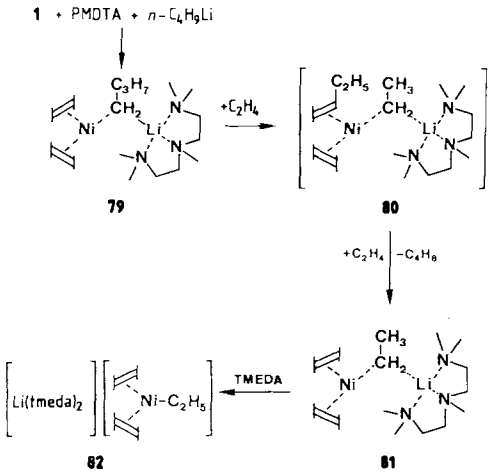
These results suggest that the interaction of alkyl derivatives and hydrides of main group metals with nickel(0) is possible as long as the M-C or M-H bonds are sufficiently polar. The polarity of the Al-C bond appears to be so low that at most only low equilibrium concentrations of an adduct are formed.

Finally, the catalytic "nickel effect" can be elegantly demonstrated with the following example (Scheme 29).[62] $[(C_2H_4)_3Ni]$ **1** reacts in the presence of pentamethyldiethylenetriamine (PMDTA) with butyllithium in ether at $-30°C$ to give **79**, in which a Ni-μ-C-Li arrangement is present. **79** reacts with ethylene to give an unstable intermediate **80**, which rearranges to **81** by transalkylation of the butyllithium to give ethyllithium and 1-butene. Displacement of the PMDTA in **81** by tetramethylethylenediamine (TMEDA) furnishes the ion-pair **82**, whose structure is analogous to that of **77**.



Scheme 29. The transalkylation of butyllithium during the "nickel-effect" (see text).

It is clear that these results do not prove the suggested mechanism for the "nickel effect", but the behavior of these model complexes is good evidence. The use of models of this type to describe catalytic processes as well as the isolation of intermediates could lead to incorrect conclusions, but, nevertheless, they are of assistance in understanding a complex catalytic cycle.

4.3. Asymmetric Catalysis and the Dimerization and Codimerization of Olefins

We described a series of catalysts based upon the η^3-allylnickel halides[30] in an article published in this Journal in 1966. This was followed in 1968 by a review of the use of ligand-modified η^3-allylnickel halide catalysts to control the course of catalytic reactions[63] and was subsequently extended to asymmetric syntheses.[64] The catalysts are prepared in a homogeneous phase by activating the 1:1 adducts of the η^3-allylnickel halide and trialkyl- or triarylphosphanes with Lewis acids such as $EtAlCl_2$. The structure of one such complex has been determined by X-ray methods (Fig. 10).[64c]

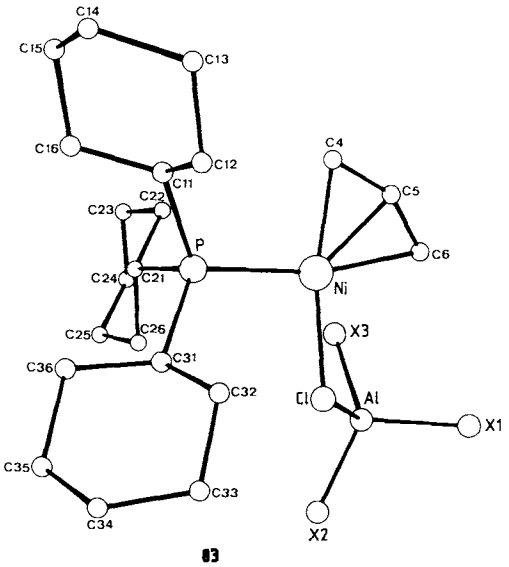


Fig. 10. The structure of a catalyst complex **83**. X1, X2, X3 = Cl or Me.

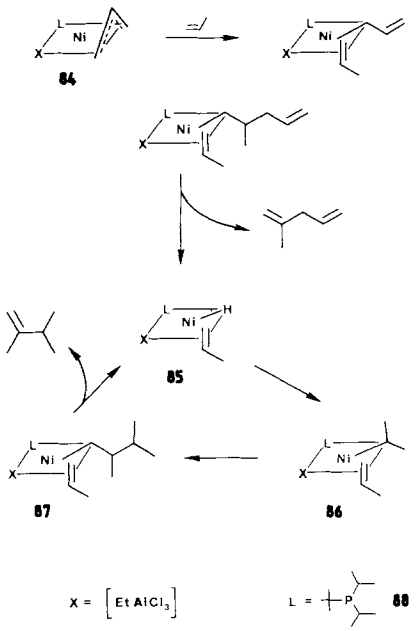
In polar solvents (CH_2Cl_2 or chlorobenzene) these catalysts dimerize olefins such as propene even at $-70°C$, whereby the structure of the dimers is dependent upon the nature of the phosphane present.[63] Although it was realized at an early date that the catalysts have a quite remarkable activity, it is only recently that we have become aware of how active they are, and experiments carried out in liquid propene and chlorobenzene suggest that they are the most active homogeneous catalysts known.[65]

It is relevant to briefly indicate the mechanism of the formation of one of the dimers of propene (Scheme 30) before discussing the latest results.



Scheme 30. The catalytic cycle for the dimerization of propene.

The η^3-allyl group in **84** has been shown to react in an initial step with propene to give the catalytically active

species—the nickel hydride **85**—with displacement of a diene. **85** then adds to propene to give the alkylnickel compound **86**, which reacts further by addition of the Ni-C bond to propene to give **87**, from which β-hydrogen transfer leads to displacement of the product (in this case 2,3-dimethyl-1-butene) with regeneration of the hydride **85**.[63]

2,3-Dimethyl-1-butene is formed preferentially in the presence of sterically demanding phosphanes such as *tert*-butyldiisopropylphosphane **88**. The initial addition of the Ni–H bond to propene takes place in a Ni→C2 manner to give an isopropylnickel species, while in the second step the Ni-C bond adds to propene in a Ni→C1 sense, and the subsequent β-H-elimination produces the branched chain dimer with regeneration of the nickel hydride **85**. Sterically less demanding phosphanes favor the formation of hexene and the methylpentenes, and 2,3-dimethyl-1-butene is only a side product.

The latest investigations[66] on the activity of the catalyst were carried out as follows: a solution of liquid propene (300 g), chlorobenzene (90 g) and $EtAlCl_2$ (0.6 g) was cooled to −45 °C and treated with 0.017 g of the complex $[(\eta^3-C_3H_5)NiX(PR_3)]$ **89**, X = Br, $PR_3 = P(iPr)_2tBu$ ($C_3 : Al : Ni \approx 7 \times 10^6 : 5 \times 10^3 : 0.5 \times 10^1$). The catalytic dimerization starts immediately and effective cooling is necessary to maintain the temperature at −45 °C. The catalysis can be stopped at will by adding NH_3. The relevant conversion data are given in Table 1.

Table 1. Catalyic dimerization of propene; for conditions see text. The conversion is calculated for 1 mol of catalyst.

Reaction time	C_3H_6 molecules per Ni atom	Conversion C_3H_6 molecules per Ni atom per s	C_6(metric tons) per mol catalyst
150 s	175000	1170	7.4
2 h	1250000	173	52.2

The activity is highest at the start of the reaction and decreases with increasing conversion: the main problem under these extreme conditions rests in the exclusion of impurities. As mentioned above, the product distribution can be controlled by varying the ligand[63] and we were therefore interested in the relationship between catalyst activity and the nature of the ligand.[66] The ligand was characterized by the ^{31}P-NMR chemical shift of the corresponding complex **89**. The catalytic reaction was stopped after 30 minutes and the catalytic activity (C_3H_6/Ni/s) was calculated from the conversion. It is remarkable, that a practically linear correlation exists between the catalyst activity and the ^{31}P-NMR chemical shift (δ) of the complexed ligand involved.[66]

As can be seen in Figure 11, trimethylphosphane and tri-*tert*-butylphosphane behave anomalously, but for different reasons. In both cases the activity is that of a phosphane-free catalyst. The PMe_3-modified catalyst **89**, X = BrAl$EtCl_2$, disproportionates to give **91**, which is inactive, and the phosphane-free species **90**, which is of only low activity (Scheme 31). The situation is somewhat different in the case of tri-*tert*-butylphosphane: the bulkiness of the ligand

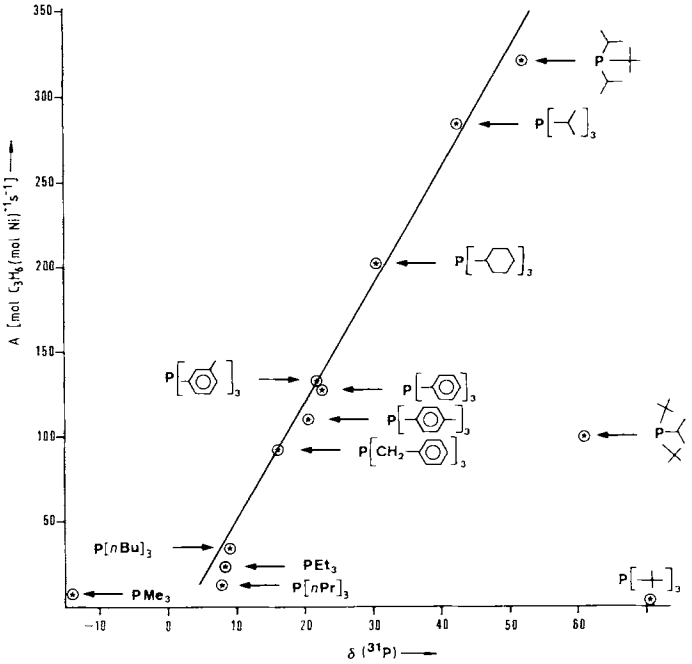


Fig. 11. The dependence of catalyst activity A on the phosphane ligand and the correlation of the activity with the $\delta(^{31}P)$-NMR values of the complexes **89**, X = BrAl$EtCl_2$, at −45 °C.

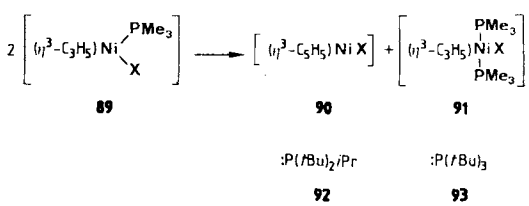
labilizes the 1 : 1 (Ni : P) adduct in solution above −78 °C, and at the reaction temperature (−45 °C) it dissociates so that the phosphane has no influence upon either the activity or the course of the reaction. The most active catalyst involves diisopropyl-*tert*-butylphosphane and is, moreover, the most selective for 2,3-dimethyl-1-butene formation. Di-*tert*-butylisopropylphosphane **92** is an exception—the corresponding complex is not noticeably dissociated but, nevertheless, the catalyst has a reduced activity. This appears to be the result of a high steric shielding which manifests itself in the formation of 2-methyl-1-pentene as the main product, i.e. the catalytic cycle proceeds through two Ni→C1 additions. In the first step, steric effects cause addition to occur in a Ni→C1-sense (in contrast to that shown in Scheme 30) to give an *n*-propylnickel species. The values in Figure 11 are based upon duplicate experiments and are reproducible.[66]

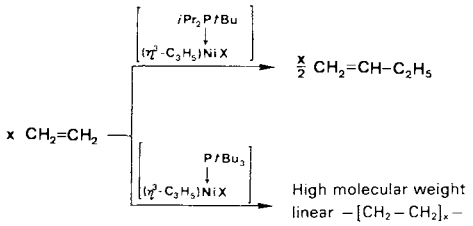
The physical basis for the essentially linear correlation between the activity and $\delta(^{31}P)$ values is not clear, but Figure 11 does show that the activity of the catalyst increases with increasing bulkiness of the modifying ligand up to a certain point beyond which a sharp decline is observed. Steric interaction within the catalyst influences both the regioselectivity and the reactivity.



Scheme 31. Disproportionation of the catalyst **89**.

It is remarkable that the most active catalyst has the highest selectivity for the formation of one of the products (in this case 2,3-dimethyl-1-butene). That activity and selectivity run parallel has also been observed in the cyclodimerization of butadiene to 1,5-cyclooctadiene[49] and a further example will be discussed later. It seems to be a general principle of catalysis that activity and selectivity are coupled.

We have already drawn attention in Figure 11 to the sudden jump in the regioselectivity on going from diisopropyl-*tert*-butylphosphane **88** to di-*tert*-butylisopropylphosphane **92**. This jump is the result of steric changes in the ligand caused by the substitution of a single H atom by a CH_3 group. A particularly impressive example of this effect is found in the catalytic conversion of ethylene: a diisopropyl-*tert*-butylphosphane-modified catalyst is highly active for the dimerization of ethylene to 1-butene. If excess tri-*tert*-butylphosphane **93** is used instead, then the product is a high molecular weight, linear polyethylene (Scheme 32).[67]

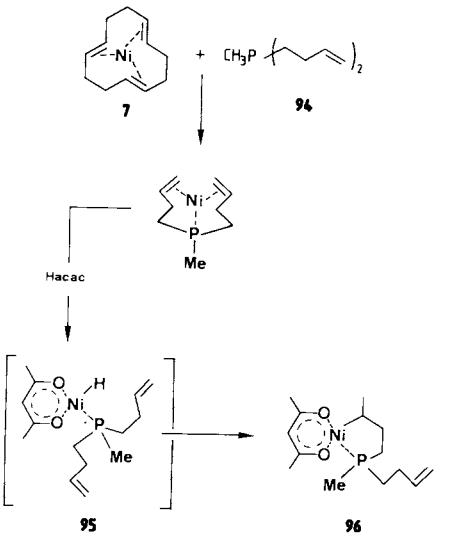


Scheme 32. The dimerization and polymerization of ethylene using a catalyst modified with **88** or **93**.

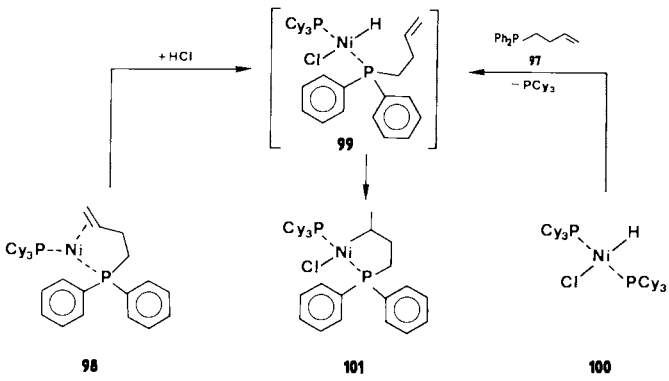
Here again, the difference in behavior is associated with the apparently small change in the steric situation associated with the substitution of a H atom by a CH_3 group. The β-H-elimination step which would lead to dimerization is apparently suppressed and instead polymerization occurs. This suggests that the more sterically demanding ligand prevents access to the required coordination position at the nickel atom. Although this explanation seems plausible, it remains speculation.

It has not proved possible to isolate the intermediate hydride **85** shown in Scheme 30—presumably it is only present in minimal concentrations in the presence of excess propene. Recent work has led to a model for the addition of a Ni-H (either as a preformed complex or as an intermediate) to an olefin[66] (cf. Scheme 33). The olefins used were di(3-butenyl)methylphosphane **94** and 3-butenyldiphenylphosphane. **94** reacts with nickel(0) (in **7**) to give a complex in which both the P atom and the C=C double bonds are complexed to the nickel atom. Protonic acids such as acetylacetone undergo an oxidative addition with this complex to give a hydride species **95**, which reacts immediately with the complexed olefin. The result is a Ni→C2 addition to give **96**. The complex **96** has been fully characterized and can be regarded as a model for an intermediate in the catalytic cycle—the alkylnickel group in **96** being equivalent to **86** in Scheme 30.

In the presence of 3-butenyldiphenylphosphane **97**, the compound **98** as well as the stable hydride **100** could be converted into the intermediate hydride species **99**, which reacts further to give **101** (Scheme 34).



Scheme 33. Di-(3-butenyl)methylphosphane **94** as a hydride trapping reagent.



Scheme 34. Trapping of a preformed (**100**) or intermediate hydride **99** with 3-butenyldiphenylphosphane **97**. Cy = cyclohexyl.

Phosphanes of the type **94** and **97** are ideal hydride-trapping reagents.[66] The NMR spectrum of the complex **96** indicates that diastereomers are present.

The use of **94** or **97** to trap a nickel-hydride species can, in principle, be applied to the catalytic reaction but the P-bonded butenyl groups react further with, for example, propene. In other words, the resulting Ni-C bond becomes itself involved in the catalytic cycle. Investigations on this problem are continuing.[66]

Catalysts containing a complex anion of the type $[EtAlCl_3]^{\ominus}$ (see Scheme 30) cannot be used in reactions involving olefins substituted by functional groups such as $-CO_2R$ or $-OR$, since these groups coordinate to the anion and bring about cleavage and deactivation of the catalyst. This can be avoided by using complex anions which resist cleavage. The $BF_4^{\ominus}$ ion has proven particularly effective. The catalyst can be prepared by reacting, for example $[(cod)_2Ni]$ **14**, $[(\eta^3\text{-}(C_3H_5)_2Ni]$ **20** or $[(C_{12}H_{18})Ni]$ **19** with HBF_4 or $[(\eta^3\text{-}C_3H_5)NiBr]_2$ **13** with $AgBF_4$, and here again phosphanes influence the direction of reaction.[68]

The dimerization of methyl acrylate using a variety of catalysts has attracted considerable attention.[69] In all cases relatively high temperatures (80–200 °C) are needed and the turnover numbers achieved are modest.

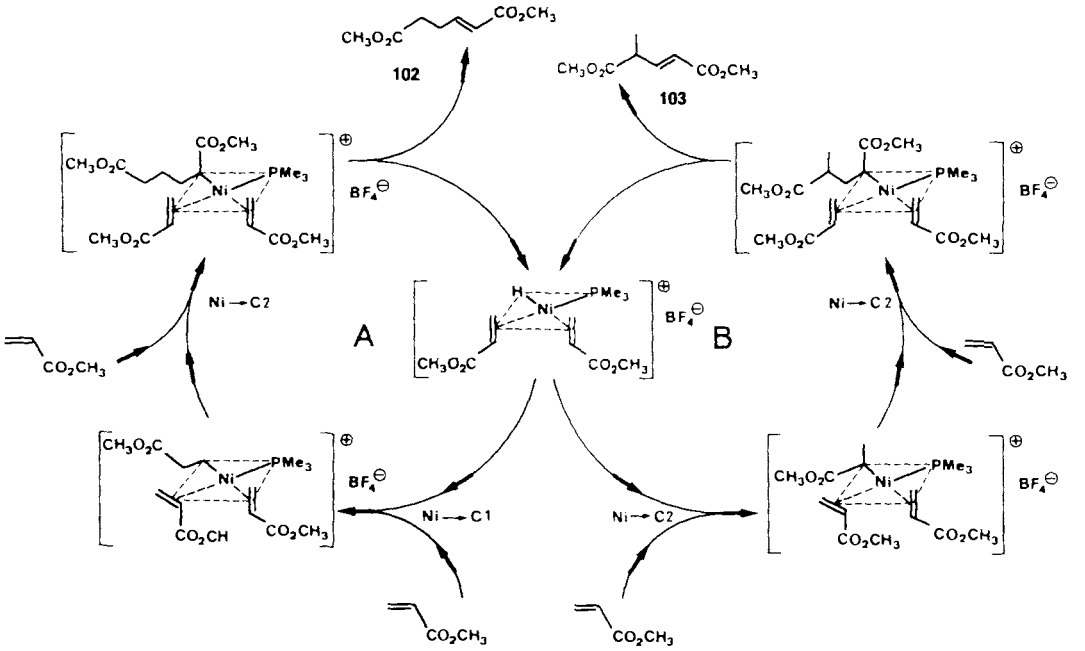
We have shown[68] that methyl acrylate can be smoothly dimerized at 0 °C using a nickel catalyst containing the $BF_4^{\ominus}$ ion and turnover numbers of 600 are easily achieved. One unusual facet is that, in contrast to the dimerization of propene, effective modification of the catalyst is achieved only in the presence of PMe_3. In this case also disproportionation leads to deactivation of the catalyst (see Scheme 31). The catalytic cycle is similar to that proposed for the dimerization of propene: cycle A is activated ten times more frequently than cycle B (Scheme 35) and as a result the dimers **102** and **103** are formed in a 10 : 1 ratio.

upon optically-pure natural products. As early as 1967 we obtained an optical induction during the codimerization of 2-butene with propene using (−)-tris(*trans*-myrtanyl)phosphane: among others (−)-*trans*-4-methyl-2-hexene was formed with an *ee* of ca. 3%.[64b]

In later work, we used the codimerization of norbornene with ethylene to give 2-*exo*-vinylnorbornane **104** (Scheme 36) as a test for the effectiveness of a particular catalyst in inducing optical activity.[64b]

The codimerization with introduction of a vinyl group is now referred to in the literature as hydrovinylation.[70]

A maximum induction was obtained in the presence of isopropyldimenthylphosphane at −70 °C and an *ee* value of 65% was obtained, i.e. 82.5% of (+)-(1*S*,2*R*,4*R*)-2-vinylnorbornane **104a** is formed. Both the selectivity and the

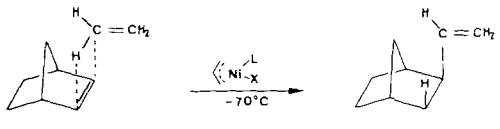


Scheme 35. The catalytic cycle for the dimerization of acrylic ester. **A**, **B** see text.

In contrast to the sequence shown in Scheme 30, the main cycle A involves an initial Ni→C1 addition which is followed by a Ni→C2 addition, whereas in cycle B both steps involve Ni→C2 additions. The absence of a ^{19}F-coupling to the ^{31}P-signal of the complexed PMe_3 in the NMR spectrum indicates that the $BF_4^{\ominus}$ ion is not coordinated to the Ni atom—coupling of this type is observed in non-dissociated model compounds.

Our activities in the field of catalyzed asymmetric synthesis stem from the idea of depositing a typical Ziegler catalyst onto finely ground optically-active quartz and to use the system to dimerize isoprene to optically-active limonene. However, before we could get round to trying this out we started to investigate homogeneous catalysts, since it had been shown that the direction of the dimerization of propene could be controlled by various modifying ligands. Optically-pure Horner-phosphanes are not easy to prepare and so we synthesized a series of phosphanes having optically-active substituents such as menthyl or myrtanyl based

activity of this catalyst were unsatisfactory, so the search for more effective ligands was continued.



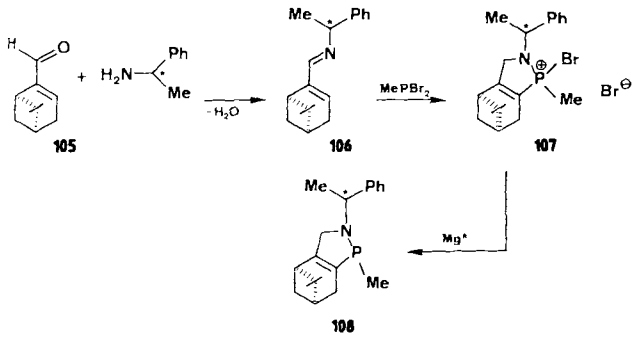
104a

Scheme 36. The hydrovinylation of norbornene with ethylene to give chiral *exo*-2-vinylnorboraane **104a**.

I have already indicated several times in this article the role which an accidental discovery can play and in the case of the further development of the catalyst, chance helped us further. Our attempts to prepare a highly rigid ligand by combining a pinene derivative, an optically active amine and a phosphorus component led to a mixtura mirabilis (^{31}P-NMR) composed of various phosphorus compounds.[71] In spite of our disappointment, a catalytic experiment was carried out with the mixture and at −70 °C

we obtained **104** with an *ee* of ca. 50% and almost 100% selectivity in a reaction whose activity was the highest we had observed.[71]

Our objective was to prepare the ligand **108** according to Scheme 37. (−)-(*R*)-myrtenal (−)-**105** was treated with (+)-(*R*)-1-phenylethylamine to give the azomethine **106**,



Scheme 37. The synthesis of the ligand **108**.

which underwent a McCormack reaction to give the salt **107**. Dehalogenation of **107** using activated magnesium (prepared by the thermal decomposition of MgH_2) led to the mixture of phosphorus compounds from which we finally isolated the component **109** responsible for the catalytic reaction.[72] **109** was isolated in crystalline form and the X-ray structural analysis (Fig. 12) showed it to be a dimeric form of **108**. The absolute configuration of all twelve chiral centers has been determined.[73]

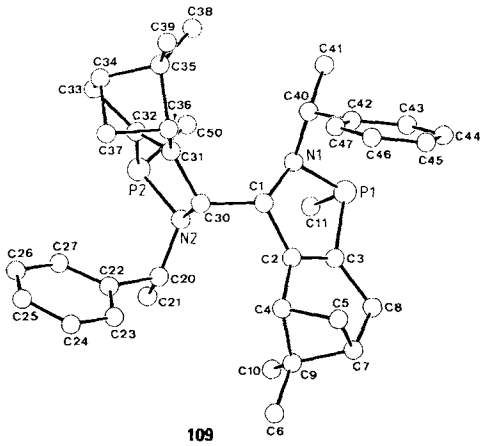


Fig. 12. The structure of the ligand **109** having an *R*-configuration at C20 and C40.

The catalyst modified with **109** produced (−)-**104** in almost quantitative yield with an *ee* of 53% and at a rate of 20000 cycles per Ni atom and hour at −65°C, i.e. the induction is modest but the activity and selectivity are excellent:[72] It should be emphasized that this catalyst does not react with norbornene alone and only very slowly with ethylene. The fast catalytic reaction occurs only when both olefins are present. This behavior is reminiscent of biocatalysts.

The enantiomeric form of **109** was prepared similarly by reaction of (+)-(*S*)-myrtenal (+)-**105** and (−)-(*S*)-1-phenylethylamine and as expected the use of this ligand led to the formation of (+)-**104**.[72]

The next step was the synthesis of the dimer **110** from (−)-(*R*)-myrtenal (−)-**105** and (−)-(*S*)-1-phenylethylamine.[72] **110** also formed crystals suitable for an X-ray structure analysis (Fig. 13).[73]

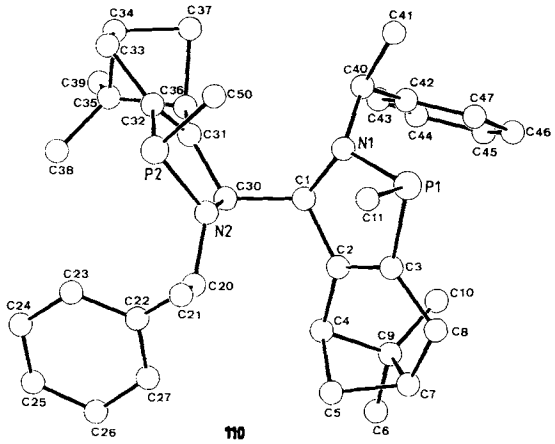

Fig. 13. The structure of ligand **110** having an *S*-configuration at C20 and C40.

The structural differences between **109** and **110** will be discussed later. The results of the catalysis with **110** were a surprise; the activity was only one hundredth of that involving **109**, and (+)-**104** was formed with an *ee* of 40%. What appeared at first glance to be only a slight change in the space-filling properties of the ligand had led to dramatic changes in the catalytic behavior.

This result induced us to try a further variation: the effect of changing the substitution at the amine, which had been unexpectedly high on going from the *R*- to the *S*-configuration, should be completely different in the presence of an isopropyl group. The resulting dimer **111** was also analyzed by X-ray diffraction (Fig. 14)[73] and used in the catalysis. At −60°C we observed ca. 1800 cycles per Ni atom and hour, but the *ee* value dropped to 26% while the yield of **104** decreased to ca. 30% and was accompanied by the formation of (*E*)- and (*Z*)-ethylidenenorbor-

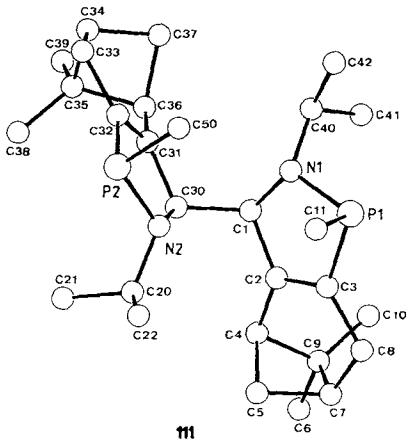

Fig. 14. Structure of the ligand **111** having isopropyl groups at N1 and N2.

nane and a vinylated dimer of norbornene. In other words, the selectivity decreases markedly, while the activity of the catalyst lies between that of systems modified with **109** or **110**.

How can we explain these experimental results? Firstly, it is necessary to compare the crystal structures. Both **109** and **110** consist of two equal parts and therefore the discussion can center initially on one of them. The two structures are similar in that the hetero five-membered rings in **109** and **110** lie in the same plane as C4, C7, and C8, while the substituents at the P and Ni atoms are arranged *trans* to each other. The CH_3 group on the P atom and the second half of the molecule, i.e. the bond C1-C30, adopt a *cis*-arrangement. A basic difference is observed in the arrangement of the substituents at the N atom relative to the $(CH_3)_2C$-bridge of the pinene group: in **109** this group occupies a position *trans* to the plane defined above, while in **110** it adopts a *cis*-position. These steric differences are the result of a difference in the induction from the *R*- and *S*-amine during the syntheses (see Fig. 15).

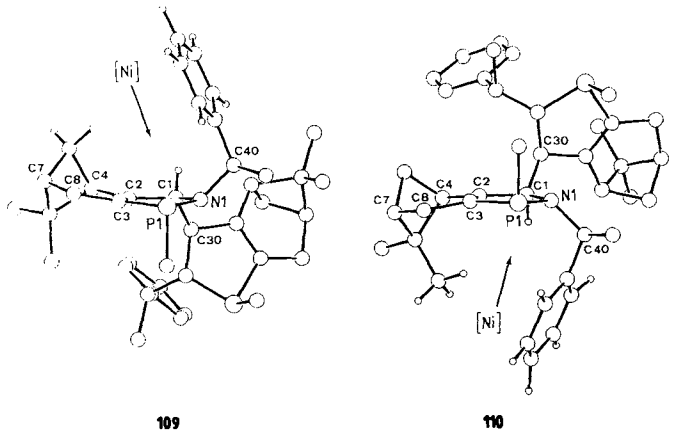

Fig. 15. The structures of the ligands **109** and **110** comparing the arrangement of the substituents in the plane defined by the five-membered heterocyclic ring and C4, C7, C8.

The interamolecular rotations have been studied using a computer simulation based on the X-ray data[74] and from this it can be seen that rotations about C1-C30 and N1-C40 are limited to ca. 50° and ca. 40°, respectively. Further rotation of the two halves of the molecule is hindered by steric effects (as is the case in atropisomers), i.e. several pairs of H atoms approach each other by less than 2 Å. The result is that **109** and **110** are relatively rigid systems.

In the catalysts the lone pairs at the P atoms form a bond to the Ni atom. The picture of the structures of **109** and **110** with incorporation of the van der Waals radii suggest that **109** can form a tunnel which can take up the Ni atom, whereas in **110** the P atom appears to be more protected—perhaps as a result of the *cis* arrangement of the $(CH_3)_2C$-bridge with respect to the substituents on the N atom.

The reduced activity of the catalyst involving **110** is then seen to be a result of the shielding of the active center. The situation resembles that discussed previously for the dimerization of propene in the presence of a catalyst modified by di-*tert*-butylisopropylphosphane **92**.

The computer simulation[74] also shows that in the nickel complex involving the ligand **109**, the 40° rotation about the N1-C40 bond causes the phenyl groups to act as a "windshield wiper" across the catalytically active center, thereby causing the H atom bonded to C43 to enter the sphere of the Ni atom, i.e. the rotation about the C40-C42 bond is also restricted (Fig. 16; for numbering see Fig. 12).

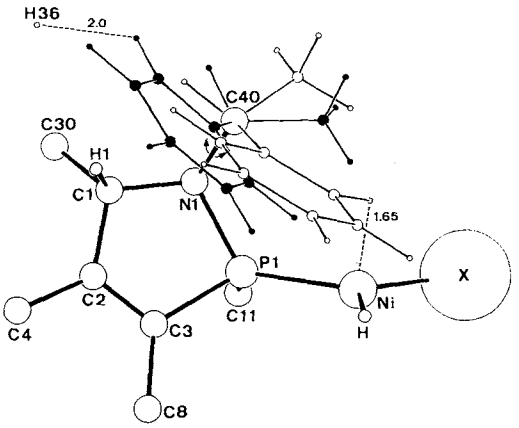

Fig. 16. A schematic representation of the rotation of the N1-C40 bond (ca. 40°). The arrangement of the substituents at N1 upon contact of the phenyl group with H36 of the second half of the molecule (phenyl group depicted by black spheres) or with the Ni atom (phenyl group depicted by white spheres).

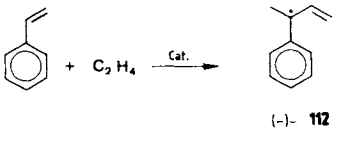
Intramolecular, directed collisions of the "windshield wiper" type between the phenyl groups and groups bonded to nickel, in as far as they are not immediately turned into translational energy, might well be expected to lead to a weakening of those bonds which are to be broken in the catalytic cycle and in this way the catalysis would be accelerated. The simulation supported suggestions are only of a preliminary nature and will need further study. We have already mentioned that a certain similarity exists between the phenomenon observed using these catalysts and those typical for biocatalysts. The similarities include the substrate selectivity as well as the sequence within the catalytic cycle. We will return to this topic after discussing a further catalytic reaction.

Recently,[72] we have investigated the hydrovinylation of styrene using a catalyst modified by the ligand **109** and to our surprise a highly selective reaction occurs to give (*R*)-(−)-3-phenyl-1-butene **112** (Scheme 38).

The interest in this hydrovinylation reaction lies both in the high selectivity and in the observation that (−)-**112** is produced at −70°C with an *ee* of 95.2%, i.e. only 2% of the second enantiomer (+)-**112** is formed.



Scheme 38. The catalytic synthesis of (−)-3-phenyl-1-butene (−)-**112**. Cat. = catalyst.

Here again, it is found that the individual components are either inactive or react only slowly with the catalyst, whereas the substrates react together with high activity. The selectivity is presumably the result of the Ni-H bond reacting more rapidly with the activated C=C bond of the styrene than with that of the ethylene. Steric effects then prevent a second styrene molecule from approaching the resulting Ni-C bond and as a result the styrene is neither oligomerized or polymerized. The much smaller ethylene molecule, however, reacts with insertion into the Ni-C bond and this is followed by β-H-elimination and displacement of **112** from the catalyst. Similar effects are observed in the hydrovinylation of norbornene. This explanation accounts for the selectivity but not for the induction.

Some insight into this problem has been obtained from a computer simulation of a complete catalytic cycle.[74] The possible pathways for the approach of a styrene molecule were simulated with incorporation of the X-ray data for **109** as well as the coordination of the H-Ni-X group to the P atom with estimated van der Waals radii for the complex anion X (Fig. 17).

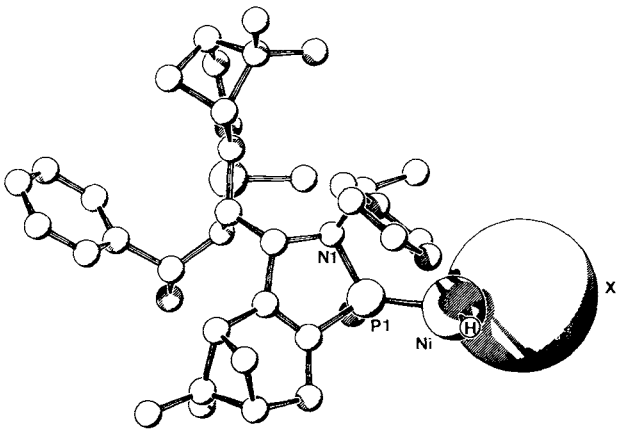


Fig. 17. A model for simulating a catalytic cycle incorporating the estimated spacial volume of the complexed anion $[EtAlCl_3]^{\ominus}$ (symbolized here as X).

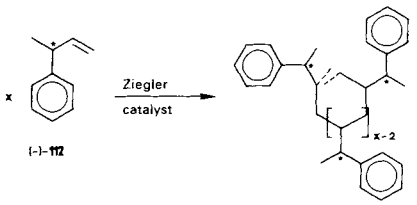
These investigations clearly show that the styrene preferentially approaches the Ni atom such that, after coordination and rotation about the complexation axis, Ni→C2 addition gives an alkylnickel species having the configuration needed for the synthesis of (−)-3-phenyl-1-butene, (−)-**112**. The subsequent addition to the ethylene and the final β-H-elimination have no further influence on the configuration of the product. The catalytic cycle has been simulated using an interactive graphics system and recorded as a video film to give an impression of the spacial properties from various perspectives. A simulation of this type does not of course mirror reality; nevertheless such pictorial representations certainly widen the chemist's conceptional horizon.

After this purely academic presentation, it should be mentioned that we have carried out the hydrovinylation of both norbornene and styrene on a 10-kg scale in our pilot plant, since both products—2-*exo*-vinylnorbornane **104** and 3-phenyl-1-butene **112**—are of interest as starting materials for further syntheses and as monomers for homopolymerization or copolymerization. Initial investigations[75] of the homopolymerization of **104** and **112** using certain Ziegler catalysts have produced polymers which decompose only above 400°C. Of particular interest is the polymer derived from (−)-**112** which is produced in an isotactic polymerization and whose orientation is controlled by both the catalyst and the chirality of the monomers (Scheme 39).



Scheme 39. The isotactic polymerization of (−)-**112**.

The polymer formed is amorphous, or at least only partially crystalline, but has an IR spectrum with remarkably sharp bands in the phenyl region. The ^{1}H-NMR solid-state spectrum is also well resolved, indicating a high regularity within the polymer. A transparent pressling formed by tempering at high temperature and pressure, rotates plane-polarized light and gives sharp Debye-Scherrer reflections, i.e. the tempering causes crystallization. Force field calculations[76] suggest that in polymeric (−)-**112**, helices can be formed which have the same configuration at the asymmetric C-atom but may be left-handed or right-handed. The identity period is made up of ca. eleven monomer units. A polymer chain containing 40 monomer units is shown in Figure 18, while Figure 19 shows a view into the left-handed helix. Both the polymerization and the structure of the polymer are the subject of ongoing investigations.

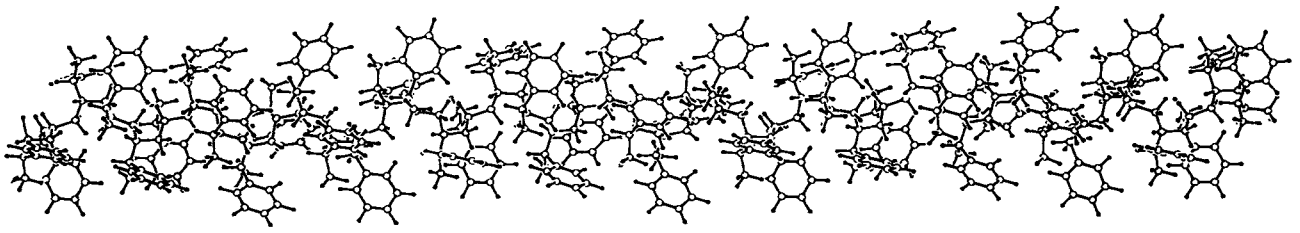


Fig. 18. Model of the polymer chain of poly-(−)-**112** based on force field calculations.

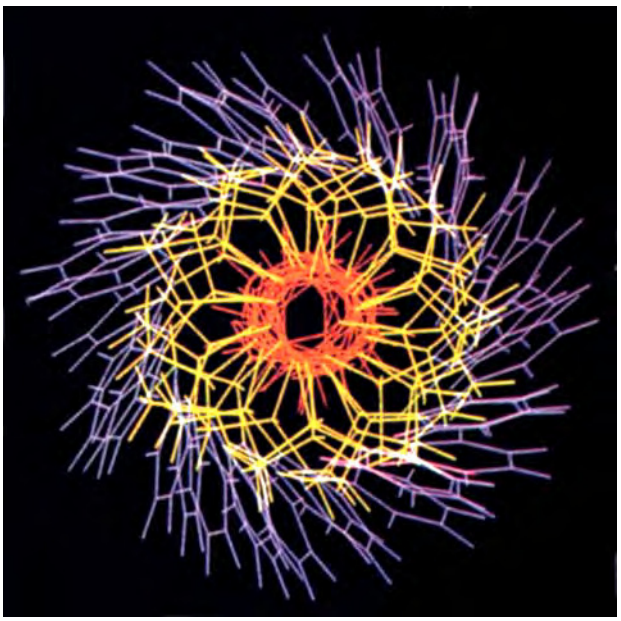

Fig. 19. A view down the helix of the computer simulated model for poly-(−)-**112**.

5. Outlook

The results described in this article indicate that the element nickel, in the form of its organometallic compounds and complexes, is able to induce a wide variety of stoichiometric and, more significantly, catalytic organic syntheses in the homogeneous phase. The highly selective and enantioselective catalytic reaction discussed above suggests some of the possibilities for further developments. In particular the incorporation of unsaturated compounds containing functional groups should open up new areas for further research. The same applies to the development of substrate-specific and enantioselective homogeneous catalysts, whereby the construction of suitable ligands using, inter alia, the principles described in this article, will play an important role—particularly since the structural permutations are practically unlimited. It can be predicted that synthetic catalysts will be developed whose properties and activities will be comparable with those of the biocatalysts. The aim will certainly not be to partially replace these but rather to develop in vitro syntheses which are not possible in vivo.

100 years of organonickel chemistry seems to be just a beginning.

Pharmaceutical Proteins**

By Dietmar Blohm,* Claus Bollschweiler, and Heinz Hillen

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

There is currently great interest in pharmaceutical proteins, and work in this area, from basic research to drug marketing, is expanding vigorously. The starting points of these developments are genetic engineering and biotechnology, which contribute to the discovery of new proteins and allow them to be produced on a worthwhile scale. Ever since the commercial introduction of insulin in 1923, of thyroid hormone in 1934, of factor VIII in 1948, and of calcitonin in 1970, hormones, serum proteins, and enzymes have been firmly established as therapeutic agents. Immunomodulators and various tissue proteins are in a turbulent phase of development as a new approach to the therapy of tumors. Increasingly, diagnostic aids now take the form of enzymes and monoclonal antibodies, and recently there has even been development of vaccines based on defined single proteins and oligopeptides. Of the more than 200 pharmaceutical proteins which have been investigated to date, more than half are undergoing research and development, about 100 are in clinical trials, and a dozen or so have already been marketed. The most important indications for them are cardiovascular disorders, tumors, autoimmune diseases, and infections. Genetically engineered proteins can be used as active substances, which are chemically and biologically exactly defined, for new drug products and in research to acquire new information on therapeutic use, based on the concept of therapy with endogenous proteins. Very recent developments have shown that proteins, either in their natural form or modified, are becoming of increasing importance for research into active substances.

1. Introduction—Definition of Terms

Active substances from medicinal herbs and other natural sources form, together with the compounds which chemists have been synthesizing for about 100 years, the backbone of drug therapy. Nevertheless, there are still many diseases which cannot be satisfactorily treated with substances derived from either of these sources.

1.1. From the Beginnings to Genetic Engineering

The active substances in many traditional medicines, such as bee-sting ointments, enzyme and snake venom products, and preparations used in "alternative medicine," are proteins, usually in the form of poorly defined mixtures. Table 1 shows some examples of proteins isolated from a wide variety of biological sources and used for

Table 1. Active proteins isolated from animals, plants, or microorganisms.

Substance	Origin	Examples of use
Aprotinin	cattle	stopping bleeding, treatment of shock
L-Asparaginase	*E. coli*	leukemia
Collagenase, Nucleases	microorganisms	healing of wounds
Dextranase	penicillium	prophylaxis of caries
Eglin	leeches	emphysema
Hirudin	leeches	prophylaxis of thrombosis
Hyaluronidase	cattle	percutaneous infiltration
Insulin	cattle/hogs	diabetes
Kallikrein	hogs	circulatory disturbances
Lysozyme	chicken eggs	bacterial infections
Thyroid hormones	cattle	metabolic disturbance
Streptokinase	streptococci	thrombolysis
Superoxide dismutase	cattle	rheumatoid arthritis
Toxins	snakes, bees, etc.	circulatory disturbances, rheumatism
Digestive enzymes, e.g., amylase, carboxy peptidase, chymotrypsin, lipase, pepsin, trypsin	cattle/hogs and, in some cases, microorganisms	digestive disturbances, healing of wounds

every type of medicinal therapy—for causal and symptomatic treatment and for prophylaxis.

Up to the late 1970s virtually the only source for endogenous substances needed for replacement therapy—for example, for deficiency of growth hormone or coagulation factor VIII—was the human body. Proteins of this type are listed in Table 2.

Table 2. Active proteins isolated from the human body (for further details, see Sections 3 and 6).

Substance	Origin	Examples of use
α1 protease inhibitor	blood	emphysema
Antithrombin III	blood	anticoagulant
Angiotensinase	placenta	high blood pressure
Factor VII, Factor VIII, Factor IX, Factor X, Fibrinogen, Thrombin	blood	blood coagulation diseases
Immunglobulins	blood	passive immunization
Interferons	blood	virus infection, tumor therapy
Plasmin	blood	thrombolysis
Serum albumin	blood	plasma replacement
Urokinase	urine	thrombolysis
Growth hormone	pituitary	dwarfism

This situation began to change in 1977, when a human hormone was synthesized for the first time using *E. coli* bacteria which had undergone gene manipulation.[90] Table 3 shows that it took less than ten years to progress from the comparatively simple somatostatin molecule to apolipoprotein B, the largest and most complicated pharmaceutical protein which can now be produced with the aid of these new methods.

Table 3. Gene cloning and expression of various complex pharmaceutical proteins (cf. Fig. 1 in Section 2.1).

Protein	AA	Structural pecularities	Successfully cloned	Ref.	Expression
Somatostatin	14	1 SS	1977	[90]	*E. coli*
Insulin	51	α and β chains, 3 SS	1979	[70]	*E. coli*
Growth hormone	191	2 SS	1979	[123]	*E. coli*
Tissue plasminogen activator	527	one- and two-chain forms, 17 SS, 3 CHO	1983	[157]	mammalian cells
Factor VIII	2332	12 SS, 25 CHO	1984	[203]	mammalian cells
Apolipoprotein B	4536	25 SS, 20 CHO	1986	[29]	

The result of these developments in method is that now more than 480 human proteins have had their primary structure elucidated by gene cloning,[183] and most of them are now available in substantial quantities by expression in host cells. This route is particularly important for substances such as interferons, interleukins, and growth factors which are often formed only in nanogram quantities in the body.

1.2. The Concept of Therapy with Endogenous Pharmaceutical Proteins

Based on these developments in molecular biology and as a result of advances in cell biology and protein chemistry, a new concept of therapy with active substances is about to become reality—the concept of therapy with endogenous active proteins.

The idea behind this concept is to supplement the research aimed at finding new active substances, the costs of which are still increasing, by the use of endogenous active proteins. At present, about 15000 chemical compounds, on average, have to be prepared and tested in order to find a new marketable therapeutic agent. In contrast, a protein that carries out the relevant function in the human body already has, by its nature, the desired biological effect. The concept essentially comprises the following three stages:

1. Discovery and preparation by gene manipulation of proteins having therapeutic potential;
2. Examination of their spectra of biological effects in vitro and in vivo;
3. Development of drug products based on these proteins and on a knowledge of their mechanisms of action.

Examples of these proteins are hormones, components in enzyme cascades, immunological mediators, and growth and differentiation factors. They are either used for therapy in the form found in nature or their structures are used as "leads" for the preparation of derivatives with improved properties.

There are no problems in the administration (e.g., in replacement treatment) of endogenous proteins which normally circulate in the blood, such as insulin and other hormones. Problems, which are largely unsolved, derive from the fact that, under physiological conditions, there is very

localized release of many active proteins, and they have short half-lives, which ensure that they have no effects on neighboring tissues or organs.

1.3. Definition

Strictly speaking, pharmaceutical proteins usually have regulatory functions in maintaining biochemical or cellular equilibria in the healthy body, and they may be involved both in pathophysiological events and in the healing process. They can be defined as proteins or polypeptides which, by reason of their natural functions in the human body, are suitable as therapeutic substances, or they are derivatives of these proteins prepared by mutagenesis or proteolysis, hybrid proteins, protein aggregates, or conjugates with other molecules.

In the wider sense, however, pharmaceutical proteins also include polyclonal and monoclonal antibodies and proteins which are derived from viruses, microorganisms, plants, or animals, and are of clinical use either directly or after modification.

It is impossible within the scope of this review to deal comprehensively with all the proteins meeting this definition. Thus, selected examples will be presented, mainly of those pharmaceutical proteins having particular importance for cardiovascular/blood and cancer/immunology indications. However, no mention is made of the various clinical aspects of pharmaceutical proteins because the pharmacology of these large molecules is very specialized—in particular, their kinetics of distribution, their protection from proteases and inhibitors (half-life), their possible antigenicity, and the fact that they cannot be administered orally.

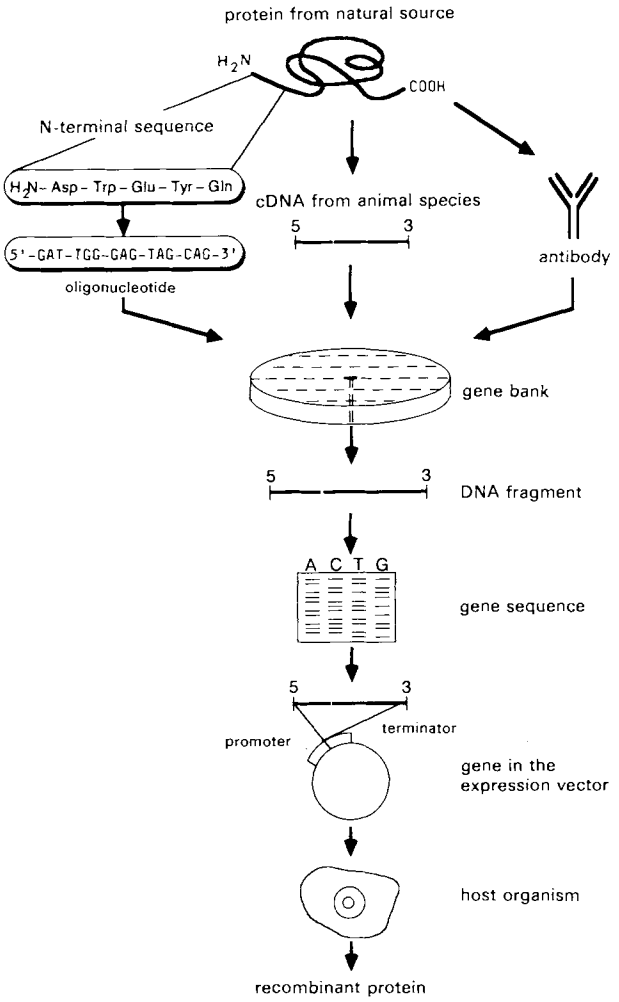

Fig. 1. Schematic summary of the gene-cloning procedure. For explanation see text.

2. Methodological Bases and Developments

The rapid developments in pharmaceutical proteins have been based primarily on the biosynthetic methods for preparation of proteins which have emerged in recent years from genetic engineering and biotechnology.[217]

The story of insulin is a particularly good illustration of these developments: although it was used clinically for the first time in 1922 by *Banting, Best,* and *Collip,* crystallized in 1926 by *Abel,* sequenced in 1955 by *Sanger,* its total synthesis published in 1963 by *Zahn, Katsoyannis,* and others, and its crystal structure elucidated in 1969 by *Crowfoot-Hodgkin*, until 1979 the only way of obtaining it was by extraction from either porcine or bovine pancreas.[70, 111]

2.1. Gene Cloning

The developments in genetic engineering in the 1970s made it possible for the first time to prepare insulin and other proteins by biosynthetic methods (for an introductory review see Ref. [28]). Nowadays, the time taken from the discovery of a protein to its preparation on a production scale has been reduced to a few years (Fig. 1).

This process usually begins with the development of straightforward biological tests for detecting the new protein. These tests are needed in order to make it possible to purify at least microgram quantities of the protein from the biological material. In favorable cases, these quantities are sufficient for the preparation of antibodies and for partial amino acid sequencing of the *N*-terminal end of the protein or fragments isolated after proteolysis. The corresponding genes are isolated from previously prepared gene banks. These are populations of recombinant host cells, usually hundreds of thousands of them, which together contain, randomly distributed, the genetic information of an organism in the form of cloned DNA fragments. Human genes for the proteins, which occur in only very small amounts, are usually isolated from cDNA banks derived from enriched messenger RNA fractions from specifically induced cell cultures or specific tissues. A variety of strategies can be used to discover the genes—for example, the use of radiolabeled DNA hybridization probes in the form of oligonucleotides whose sequence is established from the amino acid sequence and which can easily be obtained using automatic synthesizers. If the DNA fragments can be expressed in the host cells of the gene bank, it is possible to use antibodies to find the gene. The final steps are the sequencing of the DNA segment harboring the gene, and incorporation of the gene into expression vectors of suitable host cells.

The primary structure of a protein, and the information about functional domains and modifications which can be deduced from this, is now usually determined via gene cloning more rapidly than by investigation of the protein itself.

2.2. Gene Expression

Since pharmaceutical proteins are mainly extracellular, the most common modification is the attachment via nitrogen to certain asparagine residues or via oxygen to serine or threonine residues of carbohydrate chains which vary in length and are composed of either mannose and *N*-acetylglucosamine (*N*-glycosylation) or galactose and *N*-acetylgalactosamine (*O*-glycosylation). It has been shown in some cases that the glycosylation is important for transport of the protein out of the cell. In addition, there is sometimes an improvement in the solubility and resistance to proteolysis. With few exceptions, the biological activity of the protein is only slightly altered by glycosylation (but see Ref. [137]).

Proteins produced in *E. coli* bacteria are usually not glycosylated, while some glycosylations are possible in yeasts. However, only mammalian cells are suitable as host cells for the expression of proteins having complex modifications, such as γ-carboxylation of glutamyl residues, and for obtaining the same glycosylation pattern as in the human product.

Whereas genetically manipulated mammalian cell cultures rarely produce more than 50 mg of the relevant protein per liter of culture medium, it is usually possible to produce several grams per liter by use of recombinant bacteria (Fig. 2).

However, foreign proteins synthesized by bacteria are often attacked by their proteases. Proteins of low solubility may occasionally form crystalloid, denatured protein aggregates (inclusion bodies) within the cells.

2.3. Protein Chemistry

Advances in the discovery of new proteins and in retaining their biologically relevant molecular structure during purification are essentially based on developments in methods of protein chemistry. New and efficient separating materials—e.g., for HPLC, FPLC (fast protein liquid chromatography), and affinity chromatography—have considerably improved the isolation of proteins on an analytical and preparative scale. Detailed knowledge of the folding mechanisms and the structural principles assist in assessing the natural state of proteins, and this knowledge has increasingly been obtained by methods of circular dichroism and dynamic fluorescence or 2D NMR spectroscopy.

However, the renaturation of complex proteins with a high cysteine content remains a problem, particularly because of the large number of possible disulfide bridges, which are important in determining the folding of the protein and thus its biological activity.[16]

Modification of pharmaceutical proteins by chemical or genetic means—i.e., the preparation of protein derivatives ("muteins"), hybrid proteins, and protein fragments—is now performed by routine methods using in vitro mutagenesis of the relevant gene or by defined proteolysis.

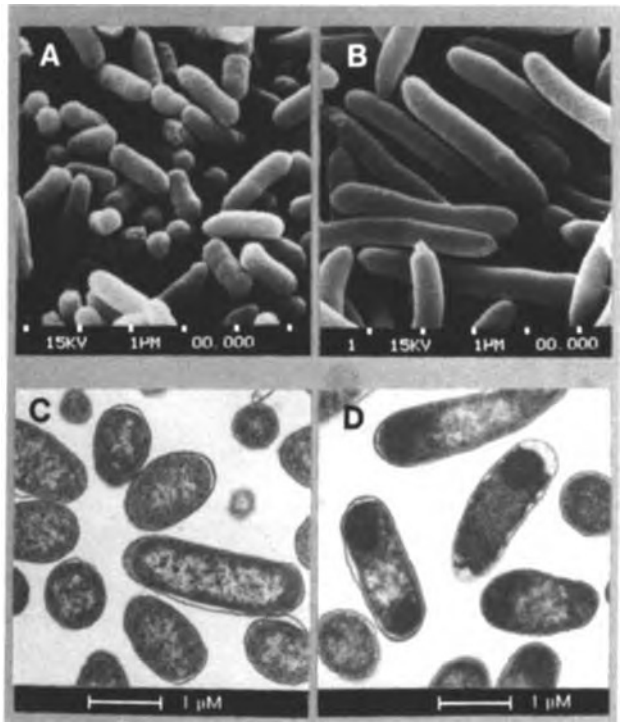

Fig. 2. *E. coli* bacteria before and after genetic manipulation A) Wild-type bacteria under the scanning electron microscope; B) TNF-producing bacteria (TNF = tumor necrosis factor; TNF remains dissolved within the cell); C) ultrathin section of wild-type bacteria; D) IFN-γ-producing bacteria (INF-γ = interferon-γ; IFN-γ forms inclusion bodies within the cell). See text for explanation.

In addition, the complete synthesis of polypeptides on polymeric supports in automatic apparatuses has recently been improved. Polypeptides having a chain length of up to 140 amino acids can be synthesized on a milligram scale in a few days.[31] Although proteins prepared in this way cannot be used as drugs because of impurities arising from side reactions, they can be used to test structural variants, which can then be produced by gene-technological methods.

3. Marketed Products

The great expectations aroused by the new methods in molecular biology were manifested in the USA back in the late 1970s by the setting up of more than 300 "gene companies" aimed at producing new pharmaceutical proteins. Many of these companies now develop their cloned proteins in cooperation with larger pharmaceutical companies, because the costs of developing a drug product are 10 to 50 times those for the research needed to prepare a protein. Examples of successful cooperation are that of Genentech with Eli Lilly for insulin and that of Genentech with Hoffmann-La Roche and of Biogen with Schering-Plough for interferon-α.

The sales of pharmaceutical proteins amounted to less than 1.5 billion US $ in 1985, scarcely 1% of world drug sales,[204] the main uses being for tumor therapy and the regulation of fibrinolysis and coagulation, and for infec-

tions, autoimmune and inflammatory diseases, hormonal disturbances, and vaccines. Market projections[5] predict for cardiovascular and antitumor agents alone a more than tenfold increase in the world sales of proteins in only four years, from about 0.2 billion DM in 1986 to more than 2.3 billion DM in 1990. It is likely that the conventional products on the market, such as animal insulins and the hepatitis B vaccines produced from inactivated viruses, will be gradually replaced by improved recombinant products.

The main advantages of recombinant products are their virtually unlimited availability, the economic aspects and, in particular, the product safety. For example, hepatitis B surface protein produced in yeast contains no viral nucleic acid (i.e., no viable particles) and consequently is far superior to vaccines produced from virions in the matter of safety. The same is true of proteins conventionally isolated from blood fractions, such as serum albumin and factor VIII, where production of them using genetically engineered microorganisms or cell cultures reduces the risk of virus infection (e.g., with hepatitis B or the AIDS virus) far below the level hitherto possible.

It is necessary to choose between classical and genetic engineering alternatives for the most economical process for preparing a pharmaceutical protein. Some of the pharmaceutical proteins now reaching the market are produced not by the recombinant DNA technique but by peptide synthesis, isolation from blood fractions, or by means of conventional cell cultures (Table 4).

In some cases, the requisite genes are not yet available, or the recombinant proteins, such as some interferons, differ slightly in structure or action from the natural forms.[170] In addition, in some cases the conventional processes are still more economical than the new biotechnological methods as is the case with human serum albumin. However, it is now possible in some cases to choose between alternative methods of gene technology.

3.1. Insulin

Insulin is an instructive example of this situation; the world demand is about 2000 kg per annum, with a market value of about 1.3 billion DM.[204] Although human insulin is less immunogenic than bovine or porcine insulin, it cannot replace the latter right away because, for many diabetics, there is no reason to change the product, which keeps diabetes well under control. Human insulin produced from porcine insulin by enzymatic amino acid replacement (i.e., semisynthetically) competes with genetically engineered human insulin, there now being at least two different processes for its production.[135]

The first step in the production of Huminsulin®, which was launched by Eli Lilly in 1982, is the separate preparation of the A and B chains in the form of fusion proteins in *E. coli* (Fig. 3a).

The individual chains are isolated and then joined together to form the active hormone via disulfide bridges produced by successive reductive thiolysis and air oxidation.

An alternative procedure starts from proinsulin, an insulin precursor (Fig. 3b). Proinsulin is likewise produced as a fusion protein in *E. coli* and is converted into human insulin by reaction with cyanogen bromide, oxidative sulfitolysis, and reductive thiolysis to give the correctly folded molecule of proinsulin, followed by treatment with trypsin and carboxypeptidase B (see Table 7).

3.2. Growth Hormone

At present, recombinant growth hormone is being used in the USA to treat several thousands of children suffering from dwarfism, a disorder brought about by a deficient endogenous production of the hormone, which is also called somatotropin. It is possible for growth to be completely normalized by administering the protein during the critical

Table 4. Examples of recently approved protein-based products on the market [a].

Protein	Product name	Company, year approved	Preparation
Calcitonin	Cibacalcin®	Ciba-Geigy, 1986	synthetic
Epidermal growth factor (EGF)	Gentel®	Zambon, 1986	
Factor VIII	Haemate®	Behringwerke (Hoechst), 1982	blood fraction

Tissue plasminogen activator (tPA)	*Actilyse®*	*Boehringer Ingelheim, 1987*	*rDNA*
Hepatitis B vaccine	Heptavax-B®	Merck & Co., 1982	blood virions,
	Gen-H-B-vax®	Merck & Co., 1986	rDNA
Insulin	Novolin®	Novo, 1982	semisynthetic
	H-Insulin®	Hoechst, 1983	semisynthetic
	Huminsulin®	Eli Lilly, 1983	rDNA
Interferon-α	Berofor®	Boehringer Ingelheim, 1983	cell culture
Interferon-α-2C	Berofor alpha 2®	Boehringer Ingelheim, 1985	rDNA
Interferon-α-2A	Roferon A®	Hoffmann-La Roche, 1986	rDNA
Interferon-α-2B	Intron A®	Schering-Plough, 1986	rDNA
Interferon-α-N1	Wellferon®	Wellcome, 1986	cell culture
Interferon-β	Fiblaferon®	Bioferon/Rentschler, 1983	cell culture
Monoclonal antibodies	Orthoclone OKT 3®	Ortho, 1986	cell culture
Secretin	Sekretolin®	Hoechst, 1982	synthetic
Streptokinase	Streptase®	Behringwerke, 1985	microbial
Somatostatin	Stilamin®	Serono, 1980	synthetic
Growth hormone	Protropin®	Genentech + KabiVitrum, 1985	rDNA
	Humatrop®	Eli Lilly, 1987	rDNA (Met-free)
	Saizen®	Serono, 1987	rDNA (Met-free)

[a] Approvals relate mainly to the Federal Republic of Germany. Further details on the proteins mentioned here are to be found in the following sections and in Tables 6-11.

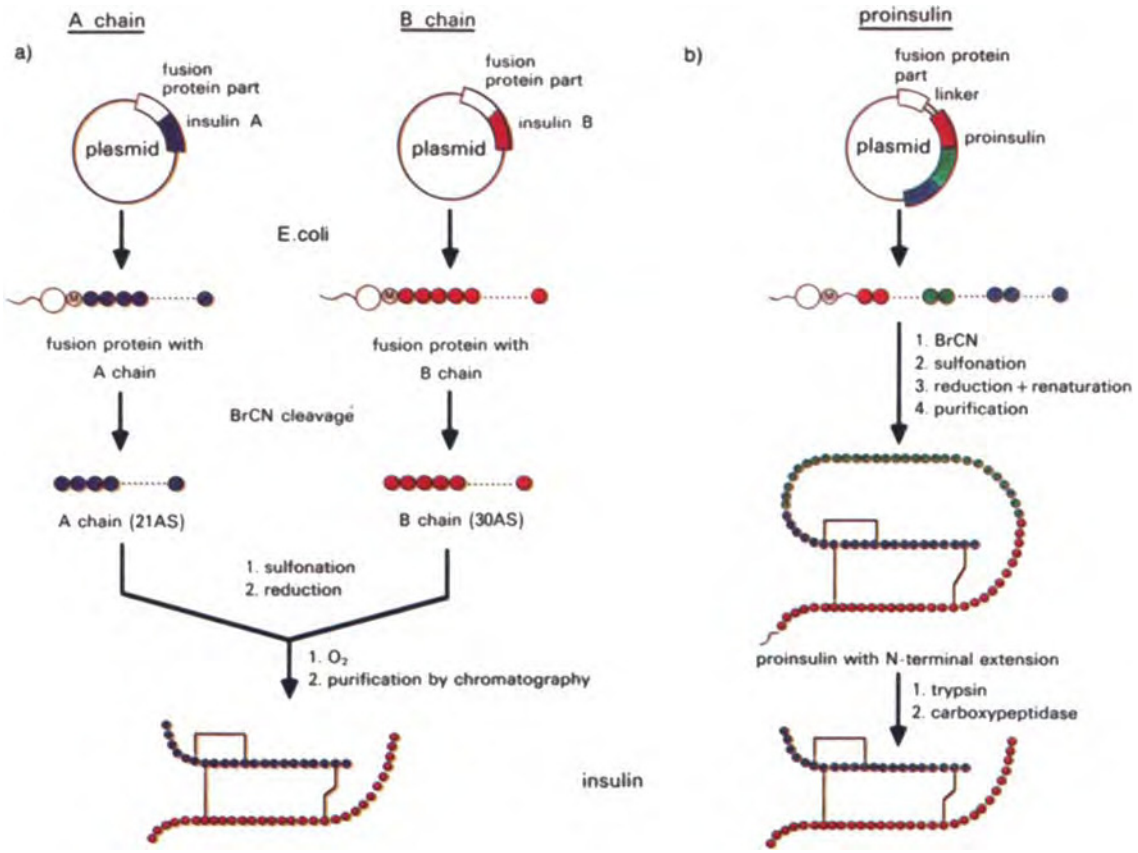

Fig. 3. Diagrammatic representation of the various genetic engineering methods for the production of insulin; see text for explanation.

years of development. Until 1985 the hormone was obtained from human pituitaries at autopsy.

This product was criticized because of the suspicion of viral contamination. Approval in 1985 of Protropin®, a human somatotropin which has an additional methionine residue at the *N*-terminal end and is produced in *E. coli* by Genentech, was rapidly followed by the Eli Lilly growth hormone Humatrop®, which contains no methionine and is thus identical with the endogenous substance.[84]

Other indications for human growth hormone, such as injuries, osteoporosis, and cachexia, are undergoing clinical trials (see Table 7).

3.3. Tissue Plasminogen Activator

Tissue plasminogen activator (tPA) is a serine protease which liberates plasmin from plasminogen and does not act until it has bound to fibrin. In contrast to streptokinase and urokinase, tPA acts on plasminogen only in the presence of fibrin, and thus can dissolve blood clots without long-lasting interference with blood coagulation.[39,210] It is a complex glycoprotein which has 17 disulfide bridges, undergoes post-translational modification, and consists of several domains to which defined functions can be assigned by examination of genetically engineered variants (Fig. 4).

Modifications in the pattern of glycosylation may also result in functional alterations in the tPA molecule. For example, it is possible in this way to increase the half-life of tPA in the blood without loss of biological activity.[113]

Indications for tPA are acute myocardial infarct and other thrombotic obstructions of vessels. With a therapeutic dose of just over 1 mg/kg body weight and 1.5 million myocardial infarcts each year in the USA alone, tPA is expected to be the "big" product giving genetically engineered pharmaceutical proteins their commercial breakthrough. Its sale has recently been approved in the USA, Canada, the Federal Republic of Germany, France, Austria, New Zealand, and the Philippines (see Table 8).

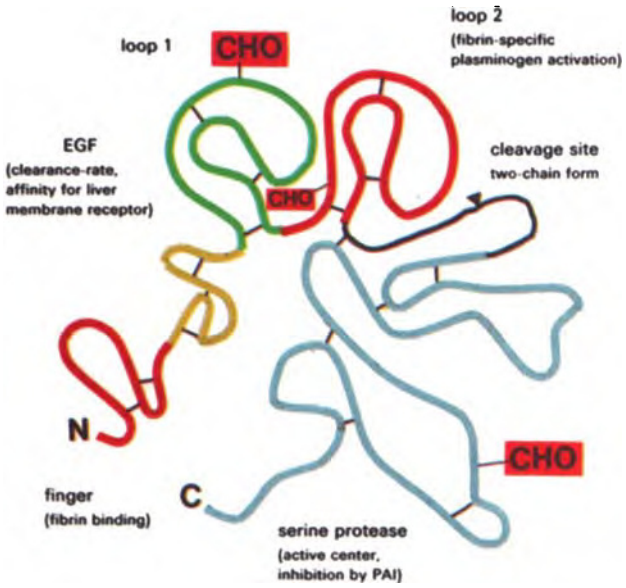

Fig. 4. Structural model of the tissue plasminogen activator (tPA) molecule: assignment of the biological functions to the domains of the protein. PAI = plasminogen activator inhibitor. EGF = epidermal growth factor. As noted at the beginning, CHO represents a carbohydrate chain.

3.4. Interferons

This group of active proteins undergoes local synthesis in picogram quantities only after induction, and it was discovered in 1957 that they have antiviral activity. They have been available in adequate quantities and high purity only since they were cloned in the early 1980s, which marked a breakthrough in gene technology methods. More than 24 natural interferons have been described to date, and these are essentially divided, according to their biological origin, into IFN-α, -β, and -γ as well as "concensus interferons" (see Table 5).

Table 5. Interferons (IFNs).

Name	Origin	Production	Stage of development	Indication
Interferon-α1 to α21	leukocytes	recombinant *E. coli*	launched (IFN-α2)	hairy cell leukemia (Kaposi sarcoma, multiple myeloma)
Interferon-β1 and β2	fibroblasts	cultured fibroblasts	launched (IFN-β1)	herpes zoster, viral encephalitis
Interferon-γ	lymphocytes	recombinant *E. coli*	clin. phase III	arthritis, leukemia
Consensus-IFN	artificial	recombinant *E. coli*	development	tumors

Interferon-β isolated from cell cultures was approved in the Federal Republic of Germany for serious viral diseases and tumors in 1983. The early expectations were great, but they have been only partially fulfilled. However, further preclinical and clinical trials on the recombinant product are in progress; these are particularly aimed, as are those on other interferons, at combinations with other active substances, especially for tumors. The best clinical results to date have been achieved with interferon-α products.[149] The first interferons produced by *E. coli* were launched in 1986 in the USA: Roferon A® of Hoffmann-La Roche and Intron A® of Schering-Plough. They differ by only one amino acid and as yet have been approved in the USA only for the treatment of the rare hairy cell leukemia. This malignant blood disease was previously incurable but about 90% of cases can now be cured by treatment with interferon-α for several months.[6]

The "immune interferon" IFN-γ is being tested for its antitumor action and recent tests have begun for the treatment of arthritis. It has a wide variety of immunological control functions and, in this respect, is more closely related to the interleukins than to the interferons, but it shares the antiviral and cytostatic activity of the latter.[211]

"Consensus" interferons are constructed by gene manipulation in order to combine sequences of the various natural types of interferons (see Table 9).

3.5. Hepatitis B Vaccines

In some countries in South-East Asia and Africa, up to 20% of the population is infected with the highly infectious hepatitis B virus, which causes jaundice and, as a late consequence of chronic infection, liver tumors. The vaccine, which has been available since 1982, is produced from virions isolated from the blood of virus carriers. In contrast, the first vaccine based on a recombinant protein, which has recently been approved for use in humans, contains the pure viral surface antigen.[105] On secretion from the genetically manipulated yeast, it spontaneously forms aggregates which substantially resemble the natural virus shell and are highly immunogenic.[206] Seroconversion rates with the new vaccine range from 80 to 100%, without there being any serious side effects or production of antibodies against yeast proteins[24] (see Table 11).

3.6. OKT3 Monoclonal Antibodies

The therapeutic uses of monoclonal antibodies (MAbs), which are mainly obtained from mouse hybridomas and thus are endogenous proteins only in the wider sense, have essentially three different aims.[102] One is the production of immunotoxins—which are molecular conjugates of MAbs with cytotoxins such as gelonin, ricin, or radionuclides. Based on the principle of drug-targeting, they are intended to attach themselves to, for example, tumor cells and selectively kill them. Immunotoxins of this type are currently undergoing initial clinical trials. The second aim is to use MAbs to act in vivo as normal antibodies. The intention is that they densely occupy the antigen-carrying cells, thus enabling them to be destroyed, particularly by the complement system and antibody-dependent cell-mediated cytotoxicity (ADCC). The third approach aims at blocking specific cell receptors in order to inhibit the biological function of these cells—e.g., T cells which are responsible for transplant rejection.

Orthoclone, OKT3®, was developed by Ortho and was the first MAb marketed for therapeutic purposes. It follows the last of the approaches mentioned, being directed against the T3 receptors of human T cells and having a strong immunosuppressant action. Where there is an acute risk of rejection, especially with kidney transplants, it is superior to conventional steroid therapy.[152] However, since it is a mouse MAb, its antigenicity makes it unsuitable for long-term therapy. It is hoped to eliminate this general disadvantage of the current MAbs by developing human MAbs[34] or producing hybrid antibodies by methods of gene technology (see Table 11).

4. Diagnostic Aids

Whereas endogenous proteins are of most interest as therapeutic agents, the greatest importance of the MAbs is as diagnostic aids, which made up about 5% of world pharmaceutical sales in 1982.[204]

MAbs are increasingly being used as components of in vitro test systems. By the middle of 1983 more than 40 MAbs from 22 different companies had already been approved in the USA as in vitro diagnostic aids. At present, in vivo uses, such as tumor imaging, still tend to be the exception.

Determinations of chorionic gonadotropin, large numbers of which are carried out with the commercially available do-it-yourself pregnancy tests, now mainly make use of MAbs. The conventional polyclonal kits are being re-

placed, especially in the area of immunology, by ELISAs, RIAs, and similar determination methods based on MAbs, because the latter have higher specificity and the MAbs can be reproducibly manufactured in virtually unlimited quantities.[182]

5. Veterinary Products

Proteins are becoming of increasing importance in veterinary medicine too, e.g., as vaccines, therapeutics, growth promoters, and diagnostic aids. The losses from livestock epidemics throughout the world amount to about 160 billion DM annually, and this has prompted intensive work on the development of, in particular, recombinant vaccines, e.g., against foot and mouth disease, which alone is the cause of more than half these losses. Bovine growth hormone is able to increase milk production by 20% or more, and porcine interferons successfully control the economically important shipping fever. In the Federal Republic of Germany alone, more than ten veterinary products based on genetically engineered proteins are already on the market.

6. Research and Development Projects

Pharmaceutical proteins provide a good example of the intermeshing of basic and applied research in molecular biology which has increased over the last ten years. The isolation of a new pharmaceutical protein usually starts with the discovery of a biological effect, for example from the observation that the supernatant from an in vitro culture of a cell line causes interesting biological reactions in another cell culture. The subsequent steps, such as characterization of the "factors," protein purification, preparation of antibodies, use of suitable animal models, and isolation of the gene, are still of the nature of basic research, but do provide a chemically defined protein for the first time. This stage is followed, as a rule, by application for a patent and preparation by gene technological methods. This arouses interest in the protein in the pharmaceutical industry. Although it is difficult to estimate the therapeutic potential of the protein at this stage, the companies have to decide whether they wish to produce it as a potential pharmaceutical protein or not. It is usually only after a company has made a recombinant protein available that further basic research reveals details of its biological function(s) and thus allows assessment of its clinical relevance—both of which are needed to justify the high costs of preclinical and clinical development of the pharmaceutical product.

It has sometimes occurred in the past that proteins have been discovered by different approaches and have appeared to be different biologically active substances and then proved to be similar or identical on comparison of the protein or DNA sequences. Thus, for example, it has slowly emerged that tumor necrosis factor, cachectin, and differentiation inhibiting factor are the same protein.

This is why the following tables include only those proteins which, while still undergoing research and development, are either in the preclinical or clinical stage of development or, at the least, chemically defined at the protein or gene level.

Given the large number of protein names and "factor" designations, synonyms have been given, if at all, only in the form of the usual abbreviations. Molecular families,[55] or polypeptides emerging as divergent by proteolysis,[176] and peptides having fewer than 30 amino acids are, as a rule, represented by only one example which has been well investigated and has important uses. Apart from a few exceptions, which are noted, all the data in the tables relate to human proteins and are merely by way of example—i.e., they only partially reflect the current state of knowledge. Further, more detailed information on the individual pharmaceutical proteins may be found in the recent reviews, to which reference is made.

6.1. Peptide Hormones

Many polypeptide hormones consist of fewer than 30 amino acids, which is the current limit below which biotechnological production processes are hardly economic because smaller peptides can, as a rule, be produced at lower cost by chemical synthesis (Table 6).

Table 6. Processes for the production of peptide hormones of various sizes.

Hormone	AA	Production process		
		chemical synthesis	extraction from tissue	gene technology
Thyrotropin-releasing factor	3	X		
Vasopressin	9	X		
LH-releasing hormone	10	X		
Secretin	27	X		
Glucagon	29	(X)	X	
Calcitonin	32	X	X	
Adrenocorticotropin	39	(X)	X	(X)
Insulin	51		X	X
Parathyroid hormone	84		X	X
Growth hormone	191		(X)	X

Some of the hormones in Tables 6 and 7 are already marketed as pharmaceuticals, and some of them have been for quite a few years. Further developments will be aimed at discovering new structural variants with improved therapeutic properties and less costly production processes.

The distinctions between hormones (Table 7), the cytokines, which are occasionally called tissue hormones (Table 9), and growth and differentiation factors (Table 10) are not sharp. For example, the molecules of the insulin family,[18] colony-stimulating factors, interleukins, and other proteins have properties which are characteristic both of hormones and of growth factors.

Many polypeptides are present in vivo as heterogeneous populations of molecules—e.g., atrial natriuretic peptide (ANF), endorphins, somatomedins, and the fertility hormones. The reasons for this are, occasionally, gene families, such as the insulin/somatomedin family, alternative splicing of the mRNA or differences in aggregation, such as with chorionic gonadotropin (HCG), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH), proteolytic processing

Table 7. Peptide hormones [a].

Protein (abbreviation)	Rev. ref.	AA	Structural peculiarities	Isolated from	Ref.	Cloned	Ref.	Example of use	Preclinical	Clinical
Adrenocorticotropin (ACTH)	[92]	39	1 ch.	—	via bovine cDNA	1980	[33]	inflammation

steps, such as with ANF and endorphins, or combinations of these possibilities. The physiological significance of these mixtures of molecules of varying biological activity, in which the spectra of action of the components overlap, for example, is largely unknown.

The molecular size of the hormone-like active proteins means that they tend to be near the limit of suitability for oral administration. Oligopeptides that have five or six, or fewer, amino acids and that are protected from peptidases, which is possible by introduction of modified amino acids, for example, are adsorbed from the digestive tract. In contrast, administration of larger polypeptides is possible only by injection or by use of delivery systems. Besides the subcutaneous insulin pump, which has to be inserted surgically, the nasal spray, and the liposome technique, other approaches now being examined are microencapsulation in biocompatible or metabolizable polymers and transmucosal administration. With respect to methodology, however, pharmaceutical proteins still have a lot to catch up on compared with the current lower-molecular-weight active

substances—at least for agents which have to be administered frequently or over long periods.

6.2. Hemostasis and Blood Proteins

Proteins having therapeutic potential for clotting and fibrinolysis indications can be roughly divided into two groups corresponding to the possibilities of treating pathological changes in hemostasis:

- coagulation-promoting proteins for conditions where there is a deficiency of clotting components or for local improvement of coagulation, or
- fibrinolytic proteins for dissolving blood clots, and anticoagulant proteins for preventing fibrin formation.

The therapeutic effect of the protein is decided by whether it acts as an activator or inhibitor, or even as an activator-inhibitor, for example, plasminogen activator-inhibitor (PAI), in the complex interactions regulating blood clotting and fibrinolysis. The functions of some proteins, such as protein C and protein S, vary widely, depending on the local situation in the blood vessel, some of them taking place on the surfaces of endothelial cells and being connected with reactions in the immune system. There are many borderline cases, so that the active proteins are to be found either in Table 8 under hemostasis, in Table 9 under immunomodulators, or in Table 10 as growth factors. Typical examples are the angiogenesis factors, such as angiogenin and fibroblast growth factors.

Development of pharmaceuticals using active proteins of these types must be based on detailed knowledge of the progress and regulation of the processes, and is thus closely tied to basic research.

In the case of human serum albumin, the annual world demand for which is currently about 100 t, with a market

value of about 1.3 billion DM,[204] the research and development is concentrated primarily on improving the biological and industrial processes for producing it using recombinant yeasts in order to be able to compete in economic terms with the conventional isolation from human blood.

Streptokinase, which is also now commercially available, is an example of the successful chemical modification of pharmaceutical proteins. The "acylated plasminogen streptokinase activator complex" (APSAC) of Beecham is distinguished from streptokinase by having less affinity for fibrinogen and a longer half-life.

6.3. Immunomodulators (Cytokines)

The immune system is, in association with the healing processes which take place following inflammation, the real source of the "natural healing powers" of the body and thus is central to the therapeutic concept of endogenous proteins. The pharmaceutical proteins that act on immunological functions include, in particular, the interferon and interleukin groups (Table 9) as well as the growth and differentiation factors (Table 10) which, as immunomodulators inter alia, control the maturation, activation, and

Table 9. Immunmodulators (cytokines) [a].

suppression of the various blood cells. Dysregulation within the immune system not only causes weakening of the body's defenses, resulting in an increased susceptibility to infection and, possibly, tumors too, but may also give rise to hyperreactivity towards autologous tissue, resulting in autoimmune diseases such as rheumatoid arthritis and multiple sclerosis.

Cells of the immune system pass through two phases of growth and differentiation which differ in character. The process of hemopoiesis initially results in bone marrow cells being converted into precursors of lymphocytes, monocytes, and granulocytes, which develop into, for example, T cells and their subpopulations, various macrophages and eosinophilic, neutrophilic, or basophilic granulocytes. Cells persisting after this first phase of growth and differentiation, called resting cells, may be activated in the case of immunological reactions to renewed proliferation and special differentiation steps. Proteins that mainly act in this second phase are listed as immunomodulators in Table 9, and proteins that control the first development phase of the immune cells or exert analogous functions on other cells are listed as growth factors in Table 10. The two groups belong together since different functions may be combined in one molecule, a good example being tumor necrosis factor (TNF). Originally isolated as a protein able to kill tumor cells selectively in vitro and in vivo, TNF has now proved to be a central immunomodulator which may act, inter alia, as a growth factor for fibroblasts, as an activator for neutrophilic granulocytes, and as an inhibitor in the differentiation of bone marrow cells to lymphocytes. The spectra of action of immunomodulators show distinct redundancies even more often than those of hormones (see Table 7). For example, TNF and interleukin-1[151] are now known to have about 30 biological effects which, for the most part, are common to both but differ quantitatively.[116] The same is true of the antiviral and cytostatic effects of interferon-α and -β.

Although they bind to the same receptor molecule on the target cell, they may trigger different cellular reactions. The biological significance of this phenomenon and the possible consequences for the development of drugs are largely unclear. Whether a cell reacts to an immunomodulator molecule or not depends equally on the presence or absence of the immunomodulator and on the presence or absence of the appropriate receptors on the target cells. In some tumor cells, for example, interferon-γ appears to influence the cytotoxic action of TNF by inducing TNF receptors and thus making the initially TNF-resistant cells sensitive. Receptors for some cytokines, such as interleukin-1 and interleukin-2, have already been isolated. Intensive work is being carried out on many others to make it possible to establish, and influence, the structural components of the receptor/ligand interaction. A requirement for structural investigations of this type is the preparation of

Table 10. Growth and differentiation factors [a].

sufficiently large protein crystals for X-ray structural analysis, and these are already available in the case of TNF, for example (Fig. 5).

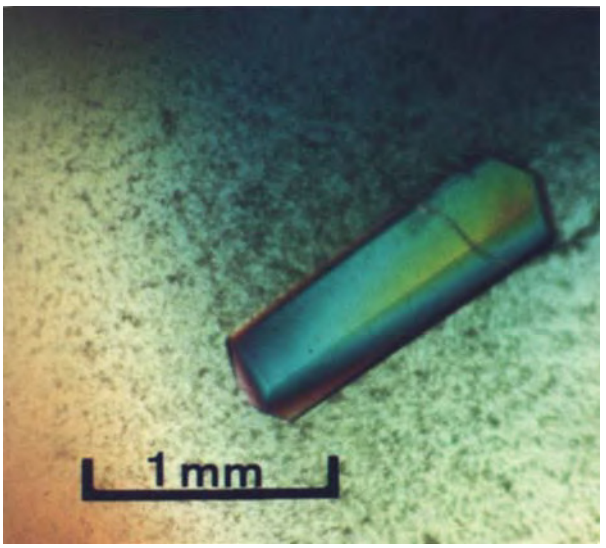

Fig. 5. Crystal of recombinant tumor necrosis factor under the polarizing microscope.

Thus, as understanding of the functioning of humoral and cell-mediated immunity increases, there is an increase in the importance not only of the soluble mediator molecules as "biological response modifiers" (BRM) for therapeutic purposes, but also of their receptors on the cell membrane and similar signal transfer molecules.

6.4. Growth and Differentiation Factors

The group of growth and differentiation factors (Table 10) includes, in particular, the colony-stimulating factors (CSFs) to which interleukin-3 and, in the wider sense, erythropoietin and erythrocyte differentiation factor also belong.[72] They are highly specific triggers of the differentiation steps in hemopoiesis. Although G-CSF activates neutrophilic granulocytes, in addition to the hemopoietic action, and GM-CSF increases the biological activity of macrophages and granulocytes, nevertheless these effects are confined to precursor and fully differentiated cells of the populations which are stimulated to differentiate by CSFs.[30] This specificity is a possible reason why the initial clinical studies, with, for example, erythropoietin on dialysis patients, and G-CSF and GM-CSF on cancer patients following chemotherapy, were so successful and were not complicated by the undesired side effects otherwise found with immunomodulators, such as fever[103] (Fig. 6).

Vastly more complicated is the development of endogenous proteins that are normally not distributed with the blood but formed locally, for example in the neighborhood of inflammations, tumors, or injuries, and display their effects only there, and are then rapidly inactivated. Typical examples are the angiogenesis factors such as angiogenin and fibroblast growth factors. Apart from wound healing, their importance is in tumor therapy, in particular, although not directly but as part of the search for antagonists or inhibitors preventing the vascularization of solid tumors and thus hindering their growth or even inducing necrosis. These proteins show that, on occasion, pharmaceutical proteins are not themselves of clinical interest but they must be available and their mode of functioning must be known in order for them to serve, for example, as test and screening systems for other proteins or low-molecular-weight active substances.

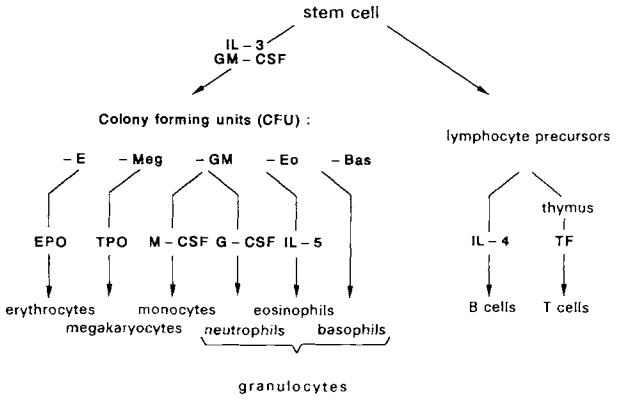

Fig. 6. Diagram showing hemopoiesis with the main sites of action of some growth and differentiation factors. Abbreviations: IL-3, -4, -5, interleukin-3, -4, -5; GM-CSF, granulocyte-macrophage colony-stimulating factor; CFU-E, -Meg, -GM, -Eo, -Bas, precursor cells for erythrocytes, megakaryocytes, granulocytes-macrophages, and eosinophilic and basophilic granulocytes; EPO, erythropoietin; TPO, thymopoietin; M-CSF, macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; TF, T-cell maturation factor (for further details see Ref. [30]).

6.5. Other Pharmaceutical Proteins

The hepatitis B surface antigen, which is already marketed as a vaccine, is included in Table 11 as a representative of many other vaccines currently under development. Genetically engineered surface proteins, or parts of these molecules, occasionally also produced by peptide synthesis, also form the basis for the development of vaccines against malaria, leprosy, meningitis, AIDS, influenza, herpes, and other infectious diseases. The first malaria and AIDS vaccines are now sufficiently advanced to have been tested on humans, but they have not proved to be sufficiently antigenic as yet.

Promising approaches to new vaccines based on anti-idiotype antibodies have recently been reported;[208] these "anti-antibodies" are directed against the antibodies previously formed in the body, and consequently have elements of the molecular structure of the original antigen. They can apparently be used in place of the antigen for vaccination.

There are great hopes that superoxide dismutase will be of use for diminishing the risk of reocclusion and necrosis following fibrinolytic treatment of myocardial infarcts, because reperfusion of tissue that has been depleted of oxygen results in the formation of O_2 radicals which are damaging to tissues.

7. Protein Purification

Apart from the few digestive enzymes that can be administered orally, at present injection is the only practica-

ble method of administering pharmaceutical proteins. This is why purification processes must be designed to meet the stringent purity requirements applying to solutions for injection. Figure 7 outlines a typical purification process for a recombinant protein from *E. coli*.

The final purification is an attempt to ensure the purity and homogeneity of the protein, usually by successive chromatography steps based on differing principles of separation, e.g., on charge, molecular weight, hydrophobicity, and other affinity properties. These separation processes are aimed at reducing the contents in the desired product of not only foreign proteins but also protein aggregates, biologically inactive isomers, and species with *N*-terminal methionine. A reliable statement about the homogeneity of a complex protein can be based only, if at all, on a combination of many results from different analytical methods. These include high-precision chemical analyses, quantitative amino acid determinations, *N*- and *C*-terminal sequencing, peptide mapping, gel electrophoreses and isoelectric focusing, in combination with spectroscopic methods and appropriate bioassays. The amounts of impurities, the most important being endotoxin, nucleic acids, and host cell proteins, tolerable per dose of active substance are usually in the picogram range, and thus at the limit of sensitivity of the currently available methods. A demonstration of the absence of viruses may be omitted for proteins produced in *E. coli*, for example, whereas great efforts must be made in this direction where the genetically modified cells used are derived from rodents or, in particular, humans.

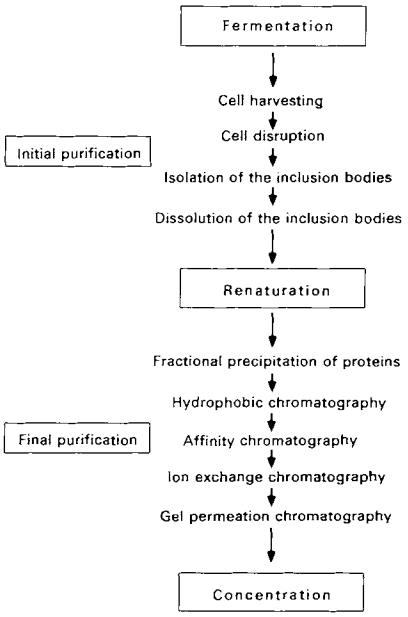

Fig. 7. Diagram of the steps in the purification of a recombinant protein produced in the form of inclusion bodies in *E. coli*.

8. Official Approval

In most countries, a staged scheme is applied to each individual protein by the authorities approving clinical trials on, or the marketing of pharmaceuticals based on, genetically engineered proteins. The requirements for this are accurate data on the purity of the protein together with preclinical investigations of the pharmacokinetics, toxicology, formulation, and biological activity in various animal models. In this connection it has to be remembered that species-specific pharmaceutical proteins in an animal model comprise a heterologous system, so that there are provisos about applying the results to humans. Where the data warrant initial clinical use, the protein is made available to physicians who, in the Federal Republic of Germany, may administer it to patients only after approval by the relevant ethical committee.

The clinical trials are conducted to determine in the first phase the dose required, in the second phase the efficacy, and in the third phase the therapeutic safety. These trials usually take three to five years, and only after this will the authority make a decision, based on the available data, about approval for marketing.

9. Patent Aspects

A plethora of questions about patent law have arisen since the results of research in genetic engineering and biotechnology have reached the level of economic decisions, and conclusive answers to these will emerge only gradually. Whereas, for example, up to 1979 it was absolutely impossible to patent microorganisms in the USA, it is now possible in most countries to protect a very wide variety of cultivated cells. This requires that the microorganism is described in such a way that those skilled in the art are able to reproduce the invention at any time and as often as required. If this is impossible, description may be replaced by deposition of the organism in a type collection accessible to the public.

Patent protection in the area of biotechnology tends at present to be limited, and efforts are being made internationally to extend and facilitate it not only by providing protection for microorganisms and results of molecular biological research (e.g., cell lines, plasmids, monoclonal antibodies), but also by improving the existing protection available for the results of breeding (e.g., for new plant varieties and animal breeds).

The importance of harmonization in the industrial property area rights is evident from the fact that, for example, in the USA and Japan a patent application can still be filed twelve and six months, respectively, after publication of the invention, whereas in the European and German proceedings any publication is immediately "prejudicial to novelty."

It will take some years for many of the questions to be answered in the courts, and only after this will it be possible to assess accurately the value of genetic engineering and biotechnological patents. The basic question of whether, in the case of a known protein which has been produced for the first time by gene manipulation, the product or only the process can be patented has been answered, for the moment, as follows: The High Court in the UK recently annulled a patent of Genentech which claimed, inter alia, comprehensive product protection for tPA, on the grounds that the patent was too broad and the substance and its use were already known.

Besides these general questions, there are many specific problems. For example, the breadth of protection conferred by a product claim for a new protein remains undetermined. Does it include genetically engineered mutants, and is it enough to replace a single amino acid, or even a nucleotide, to circumvent such a patent?

Gene patents that relate not to the protein but to the sequence of a section of human DNA and claim all the proteins, antibodies, diagnostic aids, etc. derived from it[169] have given rise to discussion about whether it is acceptable for property rights on human DNA sequences to be acquired in the course of sequencing the human genome.[174]

10. Prospects

Despite a 65-year history of the use of proteins in therapy, interest in it has perceptively increased only in recent years. The basis for this development is the enormous increase in knowledge in the biomedical disciplines which, in the last two decades, has derived from, in particular, advances in molecular biology (genetic engineering), cell biology, and protein chemistry, as well as new physicochemical measurement techniques and high-tech laboratory equipment, such as automatic analyzers and synthesizers and computers.

It now often takes less than a year for the DNA and amino acid sequences of a new protein of defined biological activity to become available. Comparison of these sequences with the several thousand already known sometimes reveals the functions and biological relationships of at least parts of the structures of these proteins. These parts of the structure, called domains, are often the structural elements responsible for biological action. Important tasks for protein chemists in the future will be to detect them in the folded protein molecule, to isolate them and stabilize their structures, and to modify them for appropriate effects. These aims are a development in the direction of "synthetic biology" and will be successfully achieved only by interdisciplinary cooperation between the molecular and cell biologists and the protein or peptide chemists and specialists in molecular modeling.

At present, most effort is still directed at finding new proteins with pharmaceutical potential. In view of the fact that there are about 30000 human genes and about 200 different tissues, i.e., mutually interacting cell types, and that the proteins suitable as pharmaceuticals are mainly extracellular proteins, each of which, in many cases, has several biological functions, it may be assumed that the number of proteins of potential use for pharmaceuticals will be in the hundreds, although hardly more than one thousand. However, it is hardly likely that the possible combinations and variations of active substances derived from them will be exhausted in the forseeable future. In addition, there is the large repertoire of "natural protein design" which is the

basis for the synthesis of antibodies in cells and which now can be artificially modified in a variety of ways.

However, work in the immediate future will be concentrated more on the clinical application of the active proteins already available, in order to make the breakthrough with new genetically engineered proteins which is now necessary after almost ten years of development in this area of molecular biology.

Thus, drug research and pharmaceutical treatment are at the beginning of an entirely new development which raises hopes of new approaches to indications as important as virus infections, inflammatory rheumatic diseases, arteriosclerosis, autoimmune diseases, and tumors.

We express our thanks to Dr. W. Heckmann for the electron micrographs and to Dr. N. Walker for the picture of the TNF crystal. The valuable assistance with the preparation of the manuscripts by M. Kern and S. Petersen-Werner is gratefully acknowledged.

Zeolites: Catalysts for Organic Syntheses

By Wolfgang Hölderich,* Michael Hesse, and Fritz Näumann

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

Zeolites have proved to be valuable technical catalysts in petrochemistry and in oil processing. The characteristic properties of zeolites, such as acidity, shape-selectivity and thermal stability also enable them to be used for highly selective synthesis in the fields of chemical intermediates and fine chemicals. This interesting area of application has grown continuously in recent years. The present article summarizes the various standard types of reaction involved in organic syntheses which can be catalyzed by zeolites; these include, inter alia, electrophilic and nucleophilic substitution reactions, isomerization of double bonds and carbon skeletons, as well as addition, elimination and hydrogenation reactions.

1. Introduction

1.1. Possible Applications

The industrial use of zeolites as catalysts started at the beginning of the 1960s with the replacement of cracking catalysts based on amorphous aluminosilicates.[1–4] Metal doped Y-zeolites proved successful as bifunctional catalysts in the field of hydrocracking.[4–7] The discovery of ZSM-5,[8] the first representative of the family of pentasil zeolites,[9,10] was a milestone in zeolite chemistry during the 1970s. The use of silicon-rich pentasil zeolites as highly acidic, extremely shape-selective and heat-stable catalysts led to new industrial petrochemical processes:[11,12] selectoforming,[13] olefin oligomerization,[15] dewaxing[4,16,17] and the MTG (methanol to gasoline) process[4,18,21] have established themselves as industrial processes alongside cracking and hydrocracking. They will probably soon be joined by the dehydrocyclization of ethane, propane or LPG (liquified petroleum gas) to arenes[14,19,20] and in the somewhat more distant future by the MTO (methanol to olefins) process.[4,21,22] A common feature in all these processes is a broad spectrum of products. However, the petrochemical industry also uses selective reactions such as the Mobil-Badger process for the alkylation of arenes,[4,23,24] the *para*-directed isomerization of xylenes[4,25] and the disproportionation[25–27] or alkylation of monosubstituted arenes.[28]

The combination of acidity and shape selectivity in the zeolite catalysts is an important factor for organic chemistry. The tendency to utilize this potential for specific, highly selective syntheses in the field of intermediates and fine chemicals has continued steadily in recent years.[29] The numerous modifications of zeolites in respect of the number and strength of acid centers, isomorphous substitution[47] and doping with metals provide an opportunity of employing catalysts that are tailored to suit the reactions desired. In this regard the experience gained in zeolite-catalyzed processes in petrochemistry offers valuable guidance.

1.2. Structure and Properties

As originally conceived, zeolites are crystalline aluminosilicates with a highly ordered crystalline structure. Cavities of a definite size are formed in the rigid, three-dimensional network composed of SiO_4- and AlO_4-tetrahedra. The lattice contains cavities of varying diameters, depending on the type of zeolite.[30] A distinction is made between large-, medium- and small-pore zeolites (Fig. 1, Table 1). In the case of large-pore Y-zeolites, for example, a cavity of this type having a diameter of 7.4 Å is formed by twelve

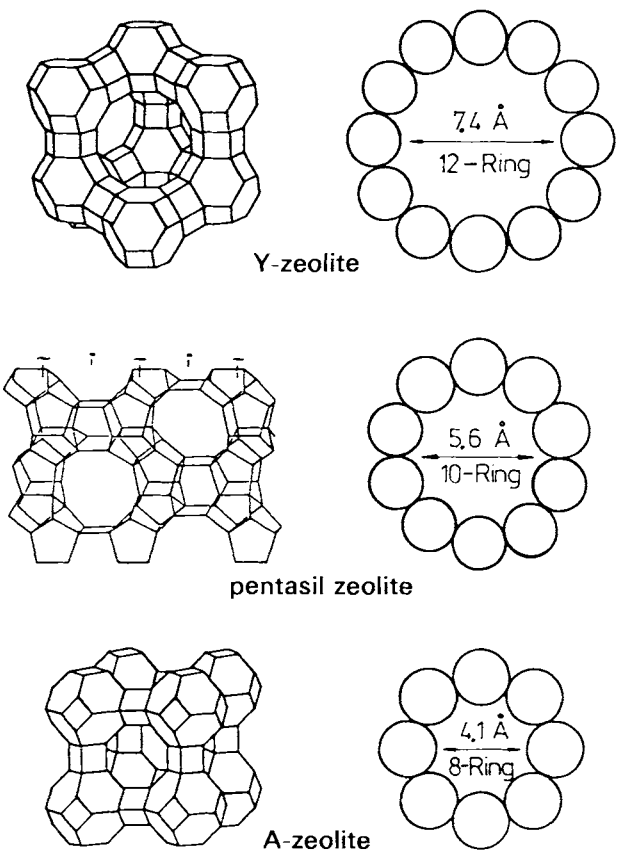

Fig. 1. Zeolite structures (see text).

Table 1. Classification of zeolites according to their pore size.

Small-pore	Ref.	Medium-pore [a]	Ref.	Large-pore	Ref.
A	[31-36]	ZSM-5	[8]	Faujasite	[31-36]
Erionite	[32-34]	ZSM-11	[32-34]	X-/Y-zeolite	[31-36]
Chabazite	[32-34]	ZSM-22	[41-44]	Mordenite	[32-34]
		NU-10	[41-44]	Offretite	[32-34]
		Theta 1	[41-44]	L	[32-34]
		ZSM-23	[42, 45, 46]	Omega	[32-34]
		ZSM-48	[32-34]	ZSM-4	[31-36]
		TS-1	[397]	ZSM-12	[31-36]
		Silicalite	[59]	Z	[102]

[a] All medium-pore zeolites are pentasil zeolites.

SiO_4 tetrahedra.[31-36] In the case of small-pore A-zeolites, eight tetrahedra form a ring of diameter 4.1 Å.[31-36] The medium-pore pentasil zeolites have a 10-ring system with an ellipsoidal tubular diameter of 5.5 Å × 5.6 Å.[8,31-40] The structural assembly of uniform channels (Fig. 2) is an advantageous special feature of the pentasil zeolites.[41-46] In contrast, the other types of zeolites contain larger cavities behind the pore openings.

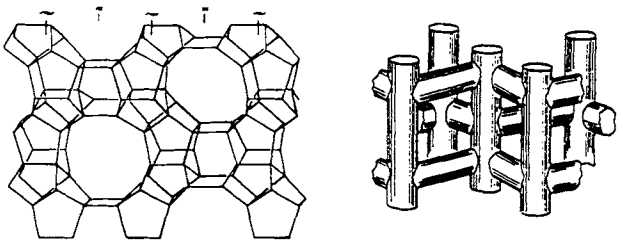

Fig. 2. Pentasil zeolites with emphasized channel system (right).

The central atoms of the tetrahedra in the zeolite lattice can be replaced in an isomorphous manner by a large number of other tri- and tetravalent atoms.[47] For example, B, Fe, Cr, Sb, As, and Ga[51-56] can be incorporated into the zeolite skeleton instead of Al, and, for example, Ge, Ti, Zr, and Hf[51-58] can be incorporated instead of Si. The pure SiO_2-pentasil zeolite (Silicalit®) is also known.[59] Isomorphous substitution results in altered lattice constants and can therefore be monitored by X-ray diffraction. In the case of some elements, such as boron, incorporation can be detected by means of MAS-NMR spectroscopy.[48,49] The nature and the extent of incorporation of the isomorphous replacement affect the catalytic properties, e.g. the acidity of the zeolites. Quantification can be attained by appropriate test reactions.[50]

The use of organic cations[31,60,61] is an important step in the hydrothermal synthesis of silicon-rich types of zeolites, whose characteristic features are high acidity, high resistance to water and acids, and high thermal stability. Amongst the large number of organic components, known as templates, which control the crystallization of new zeolite structures, the organic amines have a dominating position.[e.g. 8,31-46] Syntheses in alcohols,[54,62] ethers,[54,64] dodecylbenzenesulfonate,[65] and water[63] are also known. Further important structure-determining parameters are the Si/Al ratio[66-69] and the condition of the silicate present in the synthesis mixture, which can be described, e.g. in terms of the amount and degree of polymerization of the dissolved silicate anions.[70,71]

Zeolites are inorganic cation exchangers. Their catalytic activity is associated with the presence of acid centers in the intracrystalline surface. In their acid-form, the zeolites can be employed without further treatment as catalysts or as carrier material for active components. The following advantages of zeolite catalysts may be mentioned:

- The acid strength and number of the acid centers (Brønsted and Lewis acid centers) can be adjusted in a controlled manner during synthesis and/or by subsequent ion exchange. The acid centers can also be arranged regularly within the zeolite skeleton.[32-34,72,74-81]
- The shape selectivity means that only molecules smaller than the pore diameter of the zeolite can react with the zeolite catalyst. In addition only such molecules can be formed whose transition state geometry is smaller than the pore diameter (transition state shape selectivity).[32,33,36,82-90]

These advantageous properties make zeolites suitable for wide application in both petrochemical processes and organic syntheses of intermediates and fine chemicals:

- The most important application of zeolites is in reactions catalyzed by proton acids and Lewis acids, where the change from a homogeneous to a heterogeneous procedure brings advantages in respect of easy separation and disposal of the catalyst, avoidance of corrosion etc. In this regard, their shape selectivity has an advantageous effect on the composition of the product, e.g. on the preferred selectivity for the *p*-isomer in isomerization reactions of aromatic compounds (see Section 4).
- As carriers for active components, zeolites make it possible to increase the activity and stability of the catalyst towards steam and high temperature, e.g. by doping with rare earths.[3,72-74] Doping with suitable metals enables hydrogenation (Section 7) and oxidation (Section 8) reactions to be carried out. In all these cases the shape selectivity of the support is an additional factor controlling the reaction. The introduction of the active components can be carried out by ion exchange or by impregnation. In these cases the acid H-form of the zeolite (H-Y-zeolite, H-ZSM-5 etc.) is converted, for example, into the doped form (Ce-Y-zeolite, Pd-ZSM-5 etc.).
- The thermal stability of the zeolites permits them to be used above 150 °C. They are therefore advantageous for reactions in which the thermodynamic equilibrium requires high temperatures. At the same time carrying out the reaction at a high temperature level makes it possible to recover process heat effectively.
- Zeolite catalysts can be regenerated readily with air merely by burning off the coke, which is frequently responsible for their deactivation; after this treatment they generally regain their initial activity.

2. Substitution Reactions with Arenes

2.1. The Alkylation of Arenes

The liquid-phase Friedel-Crafts alkylation of arenes using Lewis-acid catalysts ($AlCl_3$, $FeCl_3$ or BF_3) is carried out on a large industrial scale, e.g. for the preparation of ethylbenzene. The use of such catalysts entails problems of corrosivity, toxicity, work-up and effluent pollution. This makes it desirable to replace homogeneous catalysis for electrophilic substitution reactions by heterogeneous catalysis. Furthermore, the gas phase also offers advantages in the field of process technology, such as utilization of the reaction heat.[4, 91, 92]

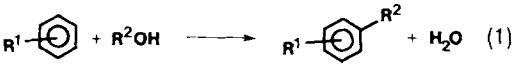
The Mobil-Badger process is an outstanding and technically proven example of the alkylation of aromatic compounds;[24, 93, 94] in the USA ethylbenzene has been produced since 1980 in a 500000 t/year plant from ethylene and benzene over phosphorus-doped ZSM-5-zeolite at approx. 400°C. In this case the shape selectivity of the medium-pore pentasil zeolite is a very important factor in the excellent product selectivity (>98% at approx. 20% benzene conversion).

Whereas ethylation ideally takes place in the gas phase, in many alkylation reactions with longer-chain alkenes it is necessary to revert to the liquid phase; as the chain length increases, cracking reactions must be expected in the gas phase. It is then preferable to use the large-pore ZSM-12-, X- and Y-zeolites.[95–98] For example, using H-ZSM-12 at 150–250°C and under pressures of up to 250 bar, isopropyltoluene (32% *p*-, 62% *m*-, and 6% *o*-isomer) or *tert*-butylethylbenzene (90% *p*-isomer and 10% *m*-isomer) are formed at a selectivity of approx. 95% at conversions exceeding 95%.[95] The high proportion of the *p*-isomer in the case of *tert*-butylethylbenzene, in comparison with isopropyltoluene, can be explained by the shape selectivity of H-ZSM-12. The crystallinity of a Y-zeolite is reduced as the result of treatment with ammonium salt, which probably increases its porosity and hence facilitates the diffusion of large molecules; a zeolite of this type produces hexadecyltoluene from toluene and *n*-hexadecene at a selectivity of 98.5% at a conversion of 94.5%,[97] whereas a large-pore, amorphous aluminosilicate only has a selectivity of 65.5% at 94% conversion.[98] The addition of SO_2 to the reaction mixture increases the activity; in the alkylation of benzene with propylene over a Ce-X-zeolite, a 96% conversion and a 96% selectivity are achieved at 120°C, compared with 53% and 90%, respectively, in the absence of SO_2.[96]

The most important selective gas phase alkylation of oligocyclic arenes is the methylation of naphthalene.[106] A 90% selectivity at 20% conversion is achieved at 460°C using H-ZSM-5. The ratio of 2-methylnaphthalene to the other isomer is 0.93 : 1. There is also preferential β-selectivity over Ce-ZSM-5 or Li-ZSM-5; the methylation of 2-methylnaphthalene gives 2,6-dimethylnaphthalene with 78% selectivity at 14% conversion. On Al_2O_3 the β-selectivity is only about half this value. This provides evidence of the shape selectivity of the zeolite.

A very important feature of the pentasil zeolites is their capacity to direct the alkylation of alkylbenzenes selectively into the *para*-position.[28] In most cases pure pentasil zeolites still do not have an adequate *p*-selectivity. However, the thermodynamically favored *m*- and *o*-isomers can be suppressed in favor of the *p*-isomers by modification, e.g. by means of metals or by adding *N*-heterocyclic compounds.[99, 100] In the methylation of toluene, 99% *p*-selectivity at 86% conversion is obtained using Mg-ZSM-5,[101] and 86% *p*-selectivity at 19% conversion is obtained using Ca-P-ZSM-5 or Mg-P-ZSM-5.[102, 103] The part played by doping in increasing *p*-selectivity is discussed comprehensively in several articles.[92, 104, 105]

Alkylation reactions of arenes containing functional groups in accordance with reaction (1) can also be carried out on zeolitic catalysts. A broad spectrum of products, consisting essentially of cresols, xylenols, anisoles and diphenyl ether, is obtained when phenol is methylated using zeolites.[107–110] The formation of the *m*-isomer, which is favored by the acidic zeolite and is difficult to separate, is inhibited by doping the zeolites with alkali or rare earth metals. The expected *p*-selectivity, as is found in the methylation of toluene, is, however, not observed. *p*-Cresol is only formed preferentially at a yield of 22% using K-Y-zeolite at 250°C. In the case of larger molecules, such as amylphenol[111] or octylphenol,[112] the reaction in the liquid phase on large-pore zeolites results preferentially in a high fraction of the *p*-isomer.



(1)

R^1 = OH, NH_2; R^2 = alkyl

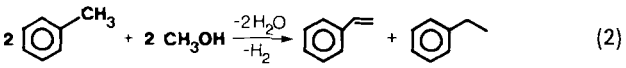
Aniline can be alkylated on faujasite zeolites both in the gas phase[113] and in the liquid phase[114] in the same way as on pentasil zeolites.[115] There is no direct advantage for either of the two types. At an MeOH/aniline molar ratio of 3 : 1 and at 350°C, the selectivity on H-ZSM-5 for toluidines is 20% at 70% conversion, but with Cs-ZSM-5 it is only 3% at 78% conversion, whereas the selectivity of *N*,*N*-dimethylaniline rises from 20% to 59%; alkali-doping increases the *N*-alkylation, whereas acid centers are responsible for *C*-alkylation.

Zeolite-catalyzed nuclear alkylation reactions afford large potential for industrial exploitation in the future as a result of their high selectivity, and the environmentally beneficial as well as energy-saving procedure.

2.2. Side-Chain Alkylation

When alkylbenzenes are alkylated, the reaction at the side chain competes with the reaction at the aromatic nucleus. In the case of alkylating agents of a small molecular size, such as methanol, medium-pore pentasil zeolites lead to selective alkylation of the nucleus, whereas large-pore zeolites, doped with alkali metals or alkaline earth metals[116–125] are employed for side-chain alkylation. The selectivity of side-chain alkylation can also be improved by an additional treatment of the zeolite catalyst with boric acid, borates or phosphates.[126, 127] The reaction of toluene with methanol or formaldehyde to yield styrene and ethylbenzene according to reaction (2) is of industrial interest; an Na-X-zeolite treated with CsOH, H_3BO_3, and LiOH

gives a 49% yield of ethylbenzene and styrene at 430 °C.[116] Doping the catalysts with subgroup elements has also been suggested,[117-119, 126, 127] although no advantage compared with the above modifications can be discerned.



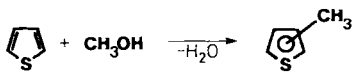
(2)

The side-chain alkylation of picolines with methanol at 400–450 °C using X- and Y-zeolites ion-exchanged with alkali metals (excepting Li) results in ethylpyridine (favored by Cs-Y) and vinylpyridine (favored by Cs-X).[131] It is characteristic that in contrast to the side-chain alkylation of toluene, alkylation also takes place in the nucleus. A 28% yield of ethylpyridine, 7% of vinylpyridine and 2% of lutidine is obtained on Cs-Y-zeolite. The Li-X- or Li-Y-zeolite leads to only nuclear alkylation. If H_2 instead of N_2 is used as the carrier gas, the content of ethylpyridine can be increased at the expense of vinylpyridine (cf. Section 2.3).

It is not yet possible to give a precise explanation of whether the selective side-chain alkylation on X-/Y-zeolites is caused by a particular arrangement of acidic and basic centers[118, 121, 123] or by an alkali metal obtained by reduction[124] or by shielding of the aromatic nucleus as the result of interaction with alkali metal ions in the zeolite cavity.[120] It is difficult to carry out these interesting reactions on an industrial scale, since under the conditions required methanol can react to give, for example, olefins and aromatic compounds. This cannot be completely prevented even by neutralizing the acidity of the zeolites.

2.3. The Alkylation of Heteroarenes

The change from homogeneous catalysis using Lewis acids to heterogeneous catalysis using zeolites can also be recommended for the alkylation of heteroaromatic compounds. For example, thiophene can be alkylated with methanol according to reaction (3) using H-ZSM-5. At 450 °C, the product contains 10% of 2-methylthiophene, 10% of 3-methylthiophene and 9% of dimethylthiophene.[128, 129] The second methylation[130] takes place preferentially in the 5-position with a yield of over 65%. Pyridines can be alkylated in the nucleus using faujasites,[131] the β-position being attacked preferentially on H-Y- or Li-Y-zeolite, and the α-position and γ-positions being attacked preferentially using Y-zeolites doped with alkaline earth metals. At 400 °C on H-Y-zeolite, 3% of α-, 12% of β-, and 3% of γ-picoline are obtained at 32% conversion, whereas on Ba-Y-zeolite 23% of α-, 4% of β-, and 8% of γ-picoline are obtained at 63% conversion (cf. Section 2.2).



(3)

The zeolite-catalyzed synthesis of alkylated heteroaromatic compounds will become important in the future for environmental reasons, even though the yield and the service life of the catalysts will have to be further improved.

2.4. The Acylation of Arenes

Like alkylation, the acylation of arenes can also be carried out using zeolitic heterogeneous catalysts. Detailed investigations of the acylation of toluene with C_1–C_{20}-carboxylic acids using Ce-Y-zeolite in the liquid phase at 150 °C have been carried out. The yield increases as the chain length of the acylating agent increases. A maximum is achieved at 96% in the case of dodecanoic acid, the *p*-isomer being present to the extent of 93%.[132]

Acylation reactions of arenes using zeolites may gain great industrial importance because of their high selectivity, especially for the production of anthraquinone from benzene and phthalic anhydride. At 350 to 550 °C, Na-X-zeolite loaded with 0.1% of Pt affords a product mixture containing 98% of anthraquinone and 2% of benzophenone.[133–135]

2.5. The Halogenation and Nitration of Arenes

Halogeno- and nitroarenes are prepared industrially in the presence of Lewis or mineral acids at 20–80 °C. A great deal of effort is being directed towards carrying out the halogenation[136–149] and the nitration[150–152] of arenes in the gas and liquid phases using aluminosilicates, especially zeolites, in order to avoid corrosion and disposal problems.

A surprising fact in the chlorination of benzene is that the substitution product chlorobenzene (CB) is obtained on Y-zeolite, whereas on ZSM-5 the addition product hexachlorocyclohexane (HCCH) is formed.[137] At 175 °C, 87% of HCCH and 13% of CB (86% conversion) are obtained on using ZSM-5. In contrast, on Y-zeolite doped with rare earth 3% of HCCH and 97% of CB (100% conversion) are obtained. Although the opposite would be expected on the basis of shape selectivity, evidently H-ZSM-5 induces a free-radical reaction which takes place mainly on the external surface and/or at the pore opening of the zeolite. X-, Y-, and L-zeolites can be employed for the chlorination of anisole,[138] toluene,[139, 140] and halogenotoluenes[141, 142] at 70–100 °C. In these cases, by virtue of the shape selectivity, the *p*/*o* ratio of isomers is higher than with conventional catalysts such as $FeCl_3$. Bromination reactions are carried out analogously.[143] In the chlorination of toluene in the gas phase, a comparison of aluminosilicate, silica gel, faujasite and montmorillonite (a layer silicate) shows that the yield of chlorotoluene achieved using the last-mentioned catalyst is 10% higher than that obtained with faujasite.[144] Since the ratio of isomers is also comparable in the case of these catalysts, the zeolite affords no advantages for the reaction compared with the less expensive layer silicates.

Investigations into the halogenation of halogenobenzenes show that Y-zeolites in which the acidity has been reduced by means of alkali exhibit a higher *p*-selectivity than the H-Y-zeolite in the liquid phase.[142] Dibromobenzene can be prepared by brominating bromobenzene or benzene on Li-faujasite; at 200 °C the conversion is 100% and the *p*-selectivity is 92%.[145] The *p*/*o* ratio is markedly higher in the case of the alkali-doped Y-zeolites than in the case of the conventional catalysts, because of steric factors

which promote the transition state for *p*-selectivity in the zeolite skeleton. Deactivation of the catalyst by HBr can be counteracted by adding $NaHCO_3$ and K-A-zeolite.[148]

Cu-faujasites are suitable for the oxidative chlorination[146,147] and bromination[145] of arenes, whereas Ca-ZSM-5 is suitable for iodination.[149] Iodobenzene is obtained with a selectivity of 97.5% at almost complete conversion.

Arenes, halogenoarenes, and alkoxyarenes are nitrated with NO_2 in the gas phase using zeolite catalysts.[150,151] For example, when chlorobenzene is nitrated on mordenite at 175°C, 10% of *o*-, 0.3% of *m*- and 33% of *p*-nitrochlorobenzene are obtained at a conversion of approx. 43%.[150] Using N_2O_4 as the nitrating agent for benzene, nitrobenzene is formed on H-ZSM-5 with a selectivity of 98% at a conversion of 64%.[151,152]

Irreversible damage is caused to the zeolites by hydrogen halides when arenes are halogenated, so that industrial application, particularly in the gas phase, appears difficult. On the other hand, nitration in the gas phase offers an advantageous alternative to homogeneous catalysis if the conversion can be increased while retaining a high degree of selectivity.

3. Substitution Reactions in Aliphatic Compounds

Nucleophilic substitution—a type of reaction frequently encountered in aliphatic chemistry—has been subjected to many investigations using zeolites, as in the case of electrophilic substitution in aromatic compounds.

3.1. The Formation of Ethers and Esters

Alcohols can be converted into ethers using a large number of zeolitic catalysts. Thus, dimethyl ether can be prepared from methanol at 80% conversion and 100% selectivity on crystalline aluminosilicate at 390°C.[154] In general, ethers are formed analogously from the corresponding alcohols.[155-157] In this case zeolites offer no advantages over montmorillonite.[153] The same applies to the conversion of diols into cyclic ethers; 1,4-butanediol is converted into THF at 100% conversion on Al-doped montmorillonite at 200°C.[157] Ethers containing functional groups are likewise accessible, as shown by the cyclization of 1,2,4-butanetriol to give tetrahydrofuran-3-ol.[158]

The zeolite-catalyzed esterification of acids with alcohols has been described many times.[159-164] For example, acetic acid and alcohols react on wide-pore H-Z-zeolite at 100°C with yields of over 93%.[162] The use of the active centers on the inner surface of the medium-pore pentasil zeolites appears to be limited to small molecules; a kinetic study of the reaction of acetic acid with butanols, catalyzed by ZSM-5, indicates that the activity corresponds only to the acid centers on the surface of the crystallite.[160,161] Transesterification using zeolites, i.e. the formation of a new ester starting from a carboxylate, is described analogously to the synthesis of esters.[165,166] For example, yields of approx. 50% are obtained at 150°C in the preparation of methyl acetate from acetic acid and methyl formate on pentasil zeolites.

In all these reactions, as in the case of homogeneous catalysis, one only achieves an equilibrium distribution, capable of being shifted by the customary methods. Since there is no necessity to change to heterogeneous catalysis for reasons of energy and environmental policy, and since an expensive change in process technology is required, industrial application will only be possible in the case of some etherification reactions in which the zeolites exhibit less coking and hence longer service lives than the conventional catalysts such as Al_2O_3, Al_2O_3/H_3PO_4 etc.

3.2. Thiols from Alcohols and Hydrogen Sulfide

Alcohols ROH react with an excess of H_2S on H-Y-, Na-Y-,[167] and L-zeolite[168] at temperatures below 300°C to give thiols ($\leq$65% yield). At higher temperatures and at a lower H_2S/alcohol ratio dialkyl sulfides are formed in yields of over 50%.[167,169-172] If sulfur is added, it is even possible to prepare dialkyl disulfides, R-S-S-R, in good yields at 310°C.[173] Here too, the chemistry of the thiols is similar to that of the alcohols and the considerations already mentioned apply in this case, the smaller market for thiols being an additional difficulty in the way of changeover, although zeolites afford better yields and service lives than conventional heterogeneous catalysts.

3.3. Amines from Alcohols and Ammonia

The methylamines obtained from methanol and NH_3 are the most important industrial products in this Section. The aim is in most cases to achieve a reaction product having a composition differing from the equilibrium distribution and containing as high a proportion as possible of monomethylamine or dimethylamine (MMA and DMA).[174-180] Thus, it is possible to reduce the proportion of trimethylamine to less than 20% when the reaction is carried out on mordenite at 350°C, but only at conversions of less than 80%.[180-181] DMA, which is particularly in demand, is produced at approx. 60% conversion with a selectivity of up to 70% on using dealuminized mordenites or erionites[182] or zeolite A and Rho.[183,184] It is not yet possible to control the reaction to give only one component, but the composition of the product mixture can be controlled better than in the classical reaction on Al_2O_3.[185,186] The synthesis of higher alkylamines, for example from NH_3 and ethanol, is also possible on H-Y- and RE-Y-zeolite[187] or from NH_3 and butanol on Na-X- and Na-Y-zeolite,[188] but only at low conversions. $EtNH_2$ is formed at 55°C and 18 bar with a selectivity of 85% at 6% conversion. The synthesis of anilines from phenols and NH_3 using ZSM-5 (if necessary doped with Cu) under pressure at 400–500°C is of industrial interest.[189-191] Selectivities to anilines of up to 99% are achieved at over 90% conversion.

Analogously to cyclic ethers, cyclic amines can be prepared from corresponding educts by elimination of H_2O or NH_3. Thus, morpholine is formed from diglycolamines.[192] Azabicyclooctane and diazabicyclooctane, respectively, are formed in accordance with reaction (4) from substi-

tuted piperidines or piperazines in yields of up to 87% using H-ZSM-5 at 400°C.[193]

(4)

R = OH, NH_2

Industrial application of the amination of alcohols on zeolitic catalysts, which is being investigated by many research groups, can be expected particularly in the case of the methylamines, if the control of the reaction in favor of MMA or DMA can be improved further.

4. Isomerization Reactions of Arenes

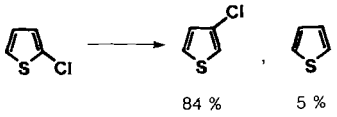
The conversion of substituted arenes into their isomers is of industrial interest and frequently serves as a model reaction for the shape selectivity of the zeolites.[50,87] An important example is the isomerization of xylenes. It is one of the processes already carried out on a large industrial scale using zeolites as catalysts. It forms the subject of numerous publications[84,194-199] and is in operation, e.g., in the UK in a 250000 t/year plant. In this instance the shape selectivity of the zeolites is utilized to increase the proportion of *p*-xylene in C_8-arene fractions.[200-202]

The principle of this reaction is applicable to a number of aromatic intermediates. The reaction generally studied is the equilibration of the *o*-compound to give a mixture of *o*-, *m*- and *p*-isomers. Examples are the isomerization of *o*-toluidine (at 340–430°C on zirconium zeolite to give 51% of *o*-, 37% of *m*- and 12% of *p*-toluidine),[203] of *o*-bromotoluene[208] or of *o*-chlorotoluene (at 250–340°C on zirconium zeolite to give 85% of *o*-, 12% of *m*- and 1.8% of *p*-chlorotoluene).[203,206] ZSM-5 is suitable for the isomerization of 3,4-dichlorotoluene to 2,5-dichlorotoluene at 310°C, and it offers advantages compared with the classical catalyst $AlCl_3$, with which six isomers are formed.[207]

A comparison of the isomerization of tolunitriles and dimethylbenzonitriles shows that, in the case of tolunitrile, the three isomers are distributed in accordance with the thermodynamic equilibrium,[205] whereas in the case of the dimethylbenzonitriles the shape selectivity results in a product distribution such that no 1,2,3-isomers or 1,3,5-isomers are formed. This limitation does not apply to trimethylbenzenes; in this case the 1,2,3-isomer and the 1,3,5-isomer are formed from 1,2,4-trimethylbenzene in a ratio between 1.3 : 1 and 2.7 : 1.[201]

The shape selectivity of the zeolites is particularly pronounced in the isomerization of substituted phenols. 2,4-Dichlorophenol reacts at 400°C on pentasil, mordenite or faujasite zeolites to give a 26% yield of 2,5-dichlorophenol.[204] The 2,5-isomer is not accessible by conventional routes by chlorinating phenol.

Isomerization reactions of heteroaromatic compounds, for example alkylthiophenes or halogenothiophenes, are also catalyzed by zeolites;[211] 2-chlorothiophene can be converted into 3-chlorothiophene according to reaction (5) using Na-ZSM-5 at 250°C, partial dechlorination taking place. The 2-chlorothiophene formed preferentially in the chlorination of thiophene can thus be converted into 3-chlorothiophene. A comprehensive review of the isomerization of halothiophenes has been published recently.[455]



(5)

Polynuclear aromatic compounds can also be isomerized using zeolites. 1-Methylnaphthalene is converted (40%) into 2-methylnaphthalene at a selectivity of 95% using H-Na-Y-zeolite at 270°C in a stream of hydrogen, but there is a loss of activity of ca. 50% in the course of 10 h.[209] 2,6-Dimethylnaphthalene in benzene solution reacts on pentasils at 350°C, with a conversion of 65% to yield a mixture of naphthalene, methylnaphthalene (6.5%) and dimethylnaphthalene isomers (42% of 1,6- and 1,5-DMN and 16% of 1,7- and 1,8-DMN).[210]

In the case of some of these reactions it must be pointed out that only equilibration takes place. Mixtures of products are always obtained in the isomerization reactions. If the isomers can be separated easily, as in the case of 2-chlorothiophene/3-chlorothiophene, it is also possible to obtain compounds which are initially only formed in small amounts. Additionally, isomerization using zeolites instead of Lewis acids offers the customary advantages of a heterogeneous process. In contrast to the isomerization of xylenes, the isomerization of functionalized aromatic compounds still awaits realization on an industrial scale. It may, however, be expected when catalyst service lives are adequate.

5. Isomerization Reactions of Aliphatic Compounds

In isomerization reactions of aliphatic compounds, a distinction must be drawn between rearrangements of the carbon skeletons, in which C–C single bonds are broken and formed, and double bond isomerization reactions, in which the carbon skeleton remains unchanged, but hydrogen atoms are shifted. The shape selectivity of the zeolites is intended to cause the reactions to take the desired path.

5.1. Double Bond Isomerization in Olefins

In the steam cracking of naphtha, after butadiene and isobutene have been removed, a C_4 fraction containing a varying proportion of 2-butene to 1-butene is obtained; this proportion can be increased as desired in an isomerization stage. The reaction can be controlled to give the desired isomer by adjusting the acidity of the catalyst and the temperature. At 175–200°C, using an acid boron pentasil, 88% of the 1-butene is converted into 2-butene in a *trans/cis* ratio of 5 : 3. Na-boron zeolite is suitable for isomerization in the reverse direction; at 450°C *trans*-2-butene is converted in a yield of 60% into 1-butene and *cis*-2-butene in a ratio of 7 : 5.[226-229] Like the isomerization of longer-chain olefins over zeolites, the isomerization of butene is the subject of numerous publications.[212-220,224,225]

If zeolites are used for double bond isomerization in linear olefins containing functional groups, it is also possible for the latter to be attacked. In the isomerization of 2-alkylacroleins into 2-methyl-2-alkenals according to reaction (6) the boron zeolite converts the terminal double bond in the 2-alkylacroleins into an internal double bond in the 2-methyl-2-alkenals, without reduction in selectivity through skeleton isomerization or reactions at the aldehyde group.[230] Ce-boron zeolite is an effective heterogeneous catalyst which, at 300°C, gives an 82% selectivity of tiglaldehyde (reaction (6), $R = CH_3$) at a conversion of 20%;[230] conventional catalysts such as S-poisoned supported Pd catalyst in the presence of H_2[231] exhibit the fundamental disadvantage of considerable formation of hydrogenation products.

(6)

R = alkyl, aryl, arylalkyl

If the olefin is substituted by an acetoxy group, the pentasil zeolites are not only capable of isomerizing the double bond, but they also produce a rearrangement through a simultaneous shift of the functional group,[233] as in the allyl rearrangement of diacetoxybutenes in accordance with reaction (7). 1,4-Diacetoxybutene is converted into 3,4-diacetoxybutene on boron and aluminum pentasils at 300°C, at a conversion of over 50%. The selectivity is 50–60%. This transformation is reversible; if 3,4-diacetoxybutene is passed over boron zeolite at 200°C, 25% of it reacts to give the 1,4-product with a selectivity of 80%. Hitherto, allyl rearrangements of this type have only been carried out in the liquid phase using SeO_2[234] or Pt or Pd halides in the presence of O_2.[235,236] The use of pentasil zeolites in the gas phase offers an alternative to this, even if the yields achieved in the former case are not always reached.

(7)

The aim of selective double bond isomerization is only attained to a limited extent, since, inter alia, mixtures of isomers are formed. The target product can, however, be obtained by removing and recycling the undesired isomers. The double bond isomerization of butenes is of industrial importance for the production of 1-butene for l-LDPE (l-low density polyethylene) and also for the production of isoprene by hydroformylation of 2-butene (cf. Section 6.2), in which zeolites offer an alternative to ion exchange resins. At present it is not possible to estimate the extent to which the isomerization of substituted olefins can be carried out on an industrial scale.

5.2. The Skeletal Rearrangement of Paraffins and Olefins

Skeletal rearrangement reactions play an important part in petrochemical cracking reactions on zeolites, a wide variety of products being obtained. In the chemistry of intermediates, however, a selective rearrangement of the carbon skeleton is the desired objective. Skeletal isomerization reactions of alkanes take place under surprisingly mild conditions over strongly acidic zeolites. A high selectivity can be achieved at a low conversion. Thus, *n*-butane is converted into isobutane at 200°C on H-Y- or La-Y-zeolite at a conversion of 15% and a selectivity of approx. 85%; propane and pentanes are formed as by-products.[215] Alkanes containing only one side chain are formed as the primary products when long-chain alkanes are isomerized using bifunctional catalysts. Thus, *n*-undecane is isomerized on Pt/Ce-Y-zeolite in a stream of hydrogen at 275°C at conversions of up to 40% into a mixture of isoundecanes, without cracking processes manifesting themselves.[221] Reactions of this type can also be used to characterize shape-selective zeolites.[87]

Another reaction of interest is the isomerization of linear olefins into branched olefins, particularly *n*-butenes into isobutene,[214] but double bond isomerization takes place as a side reaction. On Silicalite at 300°C at a conversion of 16% the yield of isobutene is only 11%.

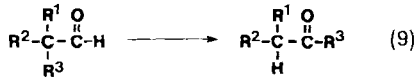
One example, even though not of commercial interest, is the complex rearrangement of tetrahydrodicyclopentadiene into adamantane in accordance with reaction (8). Selectivities of 41%, at 81% conversion, are obtained at 250°C using an La-Y-zeolite containing Pt and Co as promoters in the presence of H_2.[222,223]

(8)

With the exception of the *n*-butene/isobutene isomerization, which, however, only affords low yields, the skeletal isomerizations mentioned have no commercial importance for the chemistry of intermediates.

5.3. Skeletal Rearrangement of Compounds Containing Functional Groups

It is already evident from the allyl rearrangement of diacetoxybutenes (Section 5.2) that the skeleton of hydrocarbons containing carbonyl groups can be isomerized by pentasil zeolites without the carbonyl group being attacked. A further example is the aldehyde-ketone rearrangement according to reaction (9). Pentasils are particularly suitable for this.[240] For example, 2-phenylpropanal is converted into phenylacetone with a selectivity of 97% and a conversion of 63% at 400°C using a boron zeolite. Here too, as in other reactions,[242] iron zeolite exhibits a higher activity than boron zeolite; a selectivity of 98% at a conversion of 95% is found under the same conditions. Only a low selectivity[241] at high conversions is found with aluminum zeolite ZSM-5. In the competition between the phenyl and benzyl and methyl group, the only migration observed is, surprisingly, that of the methyl group. This could be explained by the high shape selectivity of the pentasil zeolites.



(9)

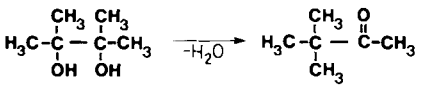
R^1–R^3 = alkyl, aryl, arylalkyl

The preparation of ketones from aldehydes is a desirable reaction, since the latter are readily accessible via the oxo synthesis. Isomerization reactions of this type using conventional catalysts composed of mixed oxides containing tin, molybdenum, and copper,[237] using cerium on aluminum oxide[238] or using an Al_2O_3 containing 10% of ZnF_2[232] are known. Only a low selectivity at satisfactory conversions is achieved in these reactions, and the best results in respect of selectivity and service life can only be obtained if steam is added. The industrial preparation of asymmetrically substituted ketones is, therefore, carried out as a condensation reaction between different organic acids followed by decarboxylation,[239] the inevitable production of symmetrically substituted ketones and carbon dioxide being a disadvantage. All these drawbacks can be avoided if zeolite catalysts are employed. As a result the potential for industrial application is high.

A reaction in which both hydrogen shifts and a migration of a methyl group take place is the rearrangement of 3,5,5-trimethylcyclohex-2-ene-1,4-dione to give trimethylhydroquinone, which occurs on H-Y-zeolite at 450°C in a stream of H_2 at a conversion of 23% and a selectivity of 50%. A conversion of 33% and a selectivity of 50% are obtained with amorphous aluminosilicates.[243] In this case the conventional catalyst is superior to the zeolite.

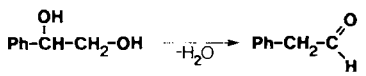
5.4. The Pinacolone Rearrangement

The dehydration of 1,2-diols using acid catalysts results in a carbonyl compound; conjugated dienes are only produced in a few cases. This applies regardless of the homogeneous or heterogeneous catalyst used. If the temperatures are raised to 400°C or higher, dienes are obtained, as can be seen from the example of the formation of isoprene from 2-methylbutanal (cf. Section 6.2).



(10)

In the pinacolone rearrangement according to reaction (10) using zeolites of the faujasite and pentasil type,[244] the carbenium ion which is formed as an intermediate is stabilized by the migration of an alkyl group. Yields between 41 and 83% are achieved at 105°C, the best performance being obtained with H-Y-zeolite. 1,2-Diols containing a primary OH group are rearranged, after dehydration, to give aldehydes. For example, phenylglycols, which can contain a wide variety of substituents in the aromatic nucleus, are converted in accordance with reaction (11) into phenyl-

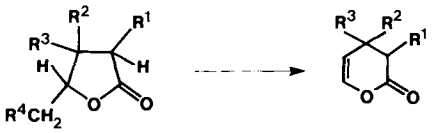


(11)

acetaldehydes on aluminum and boron pentasils at 250–300°C. The selectivity at complete conversion is between 88 and 96%.[250] In this reaction, the zeolites are superior to the amorphous metal-doped or undoped aluminum silicates, by means of which yields between 50 and 86% are attained.[245] Like phenylglycol itself, ethers and esters of the latter can be isomerized in high yields (91–96%).[250] These reactions are only of academic interest and will probably not be used in industry, since the 1,2-diols are usually prepared from the corresponding epoxides, which undergo rearrangement by zeolites to give such aldehydes too (cf. Section 5.6).

5.5. The Wagner–Meerwein Rearrangement

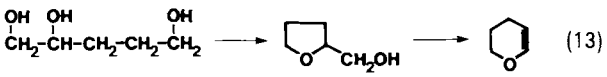
The Wagner–Meerwein or retro-pinacolone rearrangement is very closely related to the pinacolone rearrangement. The reaction of dihydro-5-(hydroxymethyl)-2-furanones on zeolites and phyllosilicates results, according to reaction (12), in 3,4-dihydro-2-pyrones, which are impor-



(12)

R^1–R^3 = alkyl; R^4 = OH, alkoxy

tant intermediates, inter alia, for insecticides.[246] It is also known[247] that 2,3-dihydro-1*H*-pyran is obtained in accordance with reaction (13) from 1,2,5-pentanetriol using

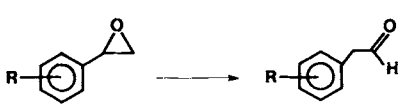


(13)

zeolites directly or via the intermediate stage of tetrahydrofurfuryl alcohol. Using a W-boron zeolite at 350°C, the pentanetriol is completely converted, and the dihydropyran is obtained with a selectivity of approx. 88%. One advantage of the zeolitic catalyst over Al_2O_3 is the fact that the dehydration and the Wagner–Meerwein rearrangement are carried out in a single reaction stage. Furthermore, the yield is markedly higher than the value of 50% achieved with Al_2O_3.[248]

5.6. The Rearrangement of Epoxides

The same considerations as for the pinacolone rearrangement (Section 5.4) apply to the opening of the epoxide ring to give aldehydes using acid, heterogeneous catalysts, such as zeolites, in the liquid or gas phase. The reaction of styrene oxide or alkyl-substituted or alkoxy-substituted styrene oxides using titanium zeolites in acetone or methanol at 30–100°C results in phenylacetaldehydes, according to reaction (14) with selectivities higher than 90%



(14)

R = alkyl, aryl, arylalkyl, halogen, haloalkyl, alkoxy, alkylthio

at conversions between 90 and 100%.[249] It is also possible to prepare phenylacetaldehydes containing a very wide variety of substituents on zeolites in the gas phase, without using solvents. Particularly attractive features of the acidic

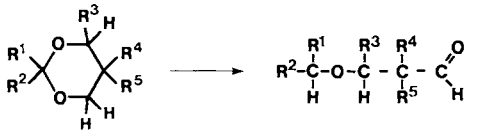
boron-, iron- and aluminum-pentasils are their high service lives and yields (>90%).[250,251]

The rearrangement of butene-1 oxide by Zn, Cd, and Ag ion-exchanged A-zeolites has also been investigated,[252] but in this case the desired butyraldehyde (55–72%) is also accompanied by a number of by-products, such as methyl ethyl ketone, *cis*- and *trans*-crotyl alcohol and 3-buten-1-ol. For the rearrangement on X-zeolite it is necessary to reduce the number of strongly acidic centers by alkali doping, as shown by the example of propylene oxide, giving acetone and propionaldehyde.[253] The formation of the acetone is catalyzed by the basic centers, while that of the propionaldehyde is catalyzed by the weakly acidic centers. Although zeolites such as faujasite catalyze the rearrangement of cyclic epoxides such as 1-methylcyclopentene oxide[254] into 2-methylcyclopentanone, methylcyclopentenol and methylcyclopentadiene are also formed in this reaction. In the case of cyclododecane oxide,[255] zeolites are inferior to Al_2O_3 catalysts doped with Pd or Rh.

Consideration of the mechanism of epoxide rearrangement over minerals and silica/alumina surfaces[256] shows that the (OH)Si-O-Al grouping acts as the active center. This model is also applicable to zeolites. There are probably opportunities for the industrial use of zeolites for the isomerization of epoxides. This is certainly already one of the established routes for the synthesis of aldehydes, since, in contrast to acid homogeneous catalysts or other acid heterogeneous catalysts, they exhibit higher selectivity, longer service lives and higher conversion rates.

5.7. The Rearrangement of Cyclic Acetals

The isomerization of 1,3-dioxanes to 3-alkoxypropionaldehydes in accordance with reaction (15) was first observed over pumice and silica gels,[257] and acid catalyst properties were considered responsible. It has also been shown, however, that basic catalysts, such as didymium oxide on SiO_2, catalyze this reaction.[258] Use of the zeolites



(15)

$R^1 = R^2 = R^4 = R^5 = H$, alkyl, alkenyl, aryl, arylalkyl, alkylaryl, arylalkenyl, alkenylaryl, heterocyclic residue; $R^3 = H$, alkyl

as acid catalysts in this reaction emphasizes once more that they are superior to the conventional catalysts;[259] their shape selectivity has a particularly advantageous effect on the yield of the long-chain neoalkanals. Selectivities of up to 90% or more at a conversion of 50–80% are achieved at 250–400°C.

5.8. The Beckmann Rearrangement

ε-Caprolactam—one of the most important fiber precursors—is mainly prepared by a Beckmann rearrangement of cyclohexanone oxime in which approx. 2.3 t of ammonium sulfate/t of lactam is inevitably formed in the oximation and rearrangement stage. If the reaction were carried out with heterogeneous acidic catalysts, this disadvantage in the rearrangement stage would be eliminated.

The Beckmann rearrangement on H-Y-zeolite was investigated as long ago as the 1960s, when the main problems were found to be the inadequate selectivity and service life of the catalyst.[260] Selectivities of not more than 80%, at an initial quantitative conversion, are achieved in benzene solution at 350°C on H-ZSM-5 with an Si/Al ratio > 1400 : 1, but even these catalysts lose 50% of their activity in the course of 12 h.[261] By-products of the reaction are hexanenitrile and cyclohexanone unsaturated derivatives thereof. The effect of the degree of replacement (H/alkali) on the service life and selectivity of alkali-doped Y-zeolites shows that the rearrangement only takes place on centers having strong Brønsted acidity, whereas nitriles are formed mainly at the alkali metal ions.[262] The rate of nitrile formation decreases in the series Li > Na > K > Cs.[263]

The service life can be improved by selectively covering the outer surface of a boron pentasil zeolite with Na ions.[264] It must, however, be pointed out that the Beckmann rearrangement of cyclohexanone oxime by means of zeolites, and similarly with other supported catalysts and ion exchangers,[265–267] does not at present, for reasons of service life and selectivity problems, constitute an alternative to the homogeneous process now practiced (96% yield).

6. Addition and Elimination Reactions

The acid-catalyzed addition reaction between olefins and polar or polarizable compounds such as acids, alcohols, water or halogens is an important fundamental reaction. Here the use of zeolites offers marked advantages; by virtue of their acidity, the zeolites accelerate the primary stage of the reaction—the formation of a carbenium ion—and it is possible to inhibit olefin polymerization which would reduce the selectivity. The reverse reaction, elimination, takes place particularly advantageously on zeolites.

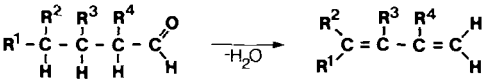
6.1. Hydration and Dehydration

Alcohols are prepared by the acid-catalyzed hydration of olefins. Catalysis with H_2SO_4 requires the additional stage of hydrolyzing the resulting sulfuric acid ester, and acid heterogeneous catalysts, such as WO_3, SiO_2/Al_2O_3 or cation exchangers, often exhibit an excessively low activity. When zeolites are used it is also necessary to accept low conversions in order to achieve high selectivities. The reaction of C_2 to C_4 olefins with water on H-ZSM-5,[268,269] H-mordenite or H-Y-zeolite,[271] and on offretite, ferrierite and erionite[272] as well as on pillared clays[273] has been described. The conversions at 100–200°C and up to 200 bar are in all cases less than 20%. Special pentasils doped with Cr and rare earths are used,[274,275] but are susceptible to rapid deactivation through coking. The reaction only appears to be of commercial interest in the case of a few cyclic alcohols, where the yields using pentasil zeolites exceed 20%.[270,276–279]

More attention is attracted to the dehydration of alcohols to olefins, which takes place in markedly better yields than the addition reaction. 100% conversion and a selectivity of over 95% are achieved using H-ZSM-5.[269,280-282] Improved selectivities are obtained in this reaction by a high Si/Al ratio in the zeolite and the addition of water, and also by the replacement of the skeletal aluminum by iron.[281] The dehydration of cyclohexanol is suggested[283] as a model reaction for the determination of zeolite activities. In addition to alkyl alcohols,[284-289] aromatic compounds are also converted, e.g. phenylethanol into styrene (95% yield at 220°C).[290] At the present time, the dehydration properties of the pentasil zeolites have found clear recognition in the MTG (methanol to gasoline) and MTO (methanol to olefin) processes, which are of industrial and scientific interest. Further industrial processes can be expected because of their wide field of application, high yields and long catalyst service lives.

6.2. The Dehydration of Aldehydes

The aldehyde-ketone rearrangement of zeolites (Section 5.3) reaches its limit in the case of aldehydes containing not only α- and β-, but also γ-hydrogen atoms. In aldehydes of this type the kinetically favored dehydration to 1,3-dienes according to reaction (16) occurs in preference to migration of the alkyl group. Enolization takes place before migration, particularly at high temperatures. The reason is probably that the enol can react further irreversibly to give the diene via the allyl isomers by 1,4-elimination of water.



(16)

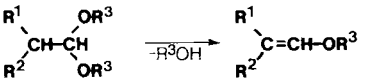
R^1-R^4 = alkyl

The preparation of dienes from aldehydes by simple dehydration is desirable, since the aldehydes are readily accessible via the oxo synthesis. Examples of catalysts used in this reaction are acids, such as phosphoric acid[291] or boron phosphates.[292-294] Steam dilution, in particular, is a disadvantage in this process. These drawbacks can be avoided if dehydration is carried out by pentasil zeolites.[295] Isoprene is obtained with a selectivity of up 95%, at 51% conversion, from 2-methylbutanal on boron zeolites at 400°C. Aluminozeolites are less suitable for this aldehyde dehydration reaction, since formation of arenes also occurs in this case. The preparation of isoprene by this process could be of commercial interest for the rubber industry and tire manufacturers.

6.3. The Addition and Elimination of Alcohols

In contrast to hydration, the direct addition of alcohols to olefins for the preparation, in particular, of mixed, substituted ethers can be carried out in good yields. This reaction is of commercial interest in regard to the production of the octane booster MTBE (methyl *tert*-butyl ether) from isobutene and methanol. Most of the papers which have appeared are therefore concerned with this synthesis.[296-299] Yields of 86% of MTBE are achieved using boron zeolite AMS-1B at approx. 100°C and 30 bar,[296] while conversions of approx. 35% with selectivities of >95% are attained using H-ZSM-5, NU-2, NU-4, and NU-10.[297,298] Higher temperatures cannot be used for this reaction owing to the formation of symmetrically substituted ethers (cf. Section 9.1). Industrially, MTBE is still produced on acid ion exchangers, since compared with these the zeolites are still inferior.

The preparation of olefins from methanol via dimethyl ether as an intermediate[4,11,20] and the rearrangement of cyclic acetals (cf. Section 5.7) demonstrate the capability of zeolites to cleave C–O bonds selectively. This fact is also utilized for the preparation of enol ethers from acetals according to reaction (17).[300,301] Yields of up to 80% or more



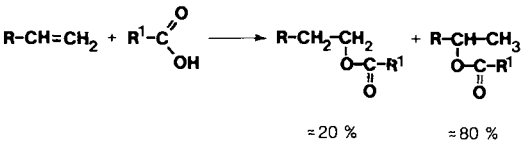
(17)

$R^1 = R^2 = H$, alkyl, aryl; R^3 = alkyl

can be achieved in this reaction within a temperature range from 270 to 340°C, if the acidity of the zeolite is suppressed or eliminated by means of alkali doping. Vinyl ethers are of considerable industrial importance both for special homopolymers and copolymers and as intermediates for organic syntheses such as the Diels-Alder reaction. They are produced industrially by the Reppe process from acetylene and an alcohol in the liquid phase. An alternative method of synthesis would be desirable at plants where acetylene is not available. The industrial use of zeolites is promising in this regard, since they are superior to the conventional catalysts (phosphates, sulfates or carbonates on a carrier).

6.4. The Addition and Elimination of Acids

The addition of acids (in most cases acetic acid) to olefins in accordance with reaction (18) is described in several patents.[302-304] However, conversions of only 30% are achieved with H-ZSM-5 and H-ZSM-12 at 150-200°C and 25 bar. In addition, mixtures of isomers are formed if asymmetrical olefins are used. Thus, 1-olefins afford the 2-carboxylates with a selectivity of 80%.[304] The use of



(18)

layer silicates in which replacement has been carried out with trivalent ions offers better results than zeolites. Yields of up to 90%, based on olefins, have been obtained.[305,306]

Dehydrohalogenation is of industrial interest, particularly in regard to the manufacture of vinyl chloride from dichloroethane; in most cases it is carried out by a thermal reaction at 500-600°C. Dehydrohalogenation in the pres-

ence of ZSM-5 or Silicalite, however, can be performed at lower temperatures.[307] At 335°C, 1,2-dichloroethane and 1,1,2-trichloroethane are converted into chloroethylene at 100% conversion and into dichloroethylene at 50% conversion, respectively. Ethylene is a by-product. Analogous reactions on offretite/erionite and Linde L[308] are described, as is also the reaction of 1,2-dichloroethane on La-H-FZ-33 leading to vinyl chloride (conversion 35%, selectivity 61%).[309] However, it appears to be difficult to carry out a process of this type on an industrial scale due to the destruction of the zeolite skeleton by HCl (cf. Section 2.5).

6.5. The Addition of S-Compounds

The acid-catalyzed reaction of olefins with H_2S furnishes thiols and thioethers.[310–312] Non-doped X- and Y-zeolites catalyze the conversion of branched olefins into tertiary thiols in high yields,[313,314] but only give moderate yields in the case of linear olefins.[312] Recourse is made in this case to RE-Y- and Cd-X-zeolites, which give conversions of >99% and selectivities >90%.[310,311] The reactions are carried out at 100–250°C and under elevated pressure (up to 250 bar). Compared with conventional acidic catalysts, zeolites give better yields and service lives.

6.6. The Addition of N-Compounds

The addition of NH_3 or amines to olefins using X- and Y-zeolites is known,[315–316] but suffers from the disadvantage of rapid deactivation. On the other hand, RE-Y-zeolites[317,318] and alumino-, ferro- and borozeolites of the pentasil type[319] afford commercially acceptable yields and service lives. Thus, in the reaction of isobutene with NH_3 at 250–300°C and a pressure of over 100 bar, a conversion into *tert*-butylamine of approx. 8–15% is achieved, with a selectivity of over 98%. The latter has hitherto been obtained by a multistage industrial process using the Ritter reaction from isobutene and hydrogen cyanide, the resulting formamide being saponified. The advantages of using zeolites are evident in this case. Compared with *tert*-butylamine, lower yields are obtained in the production of other amines such as ethylamine or isopropylamine (gradation from primary to secondary to tertiary carbenium ion). In these cases direct addition cannot compete with the conventional methods of preparation.

6.7. Carbonylation and Decarbonylation Reactions

The carbonylation of methanol on Rh- and Ir-doped X-, Y-zeolites[320–325] and H-ZSM-5[326] has been described. Conversions to AcOMe and AcOH of less than 2%, with the formation of large amounts of Me_2O, are obtained when H-ZSM-5 is used at 200–300°C and 10 bar. Co-doped pentasil zeolites, however, enable the reaction to acetic acid (9%) and methyl acetate (45%) to be carried out in acceptable yields,[327] without the addition of iodine, whereby troublesome corrosion problems are avoided. Here too, however, the addition of iodide improves the yields of acetic acid. The preparation of derivatives of the 2-hydroxy acids in yields of up to 40% from aldehydes by means of CO and an alcohol or an acid on various zeolites has been described.[328,329] It is also known that noble metal catalysts decarbonylate branched and unbranched aldehydes.[330,331] In the presence of zeolitic catalysts almost only the unbranched aldehydes contained in the mixture of aldehydes react to yield olefins; using *n*-/iso-butyraldehyde mixtures, conversions of *n*-butyraldehyde of 39–56% are achieved at selectivities of 44–73%. The reason for this behavior is the shape selectivity of the zeolites.

At the present stage of development, the synthesis of acetic acid using zeolites cannot compete with the Monsanto process, in spite of the elimination of environmental problems (iodine-free process), and, at the yields indicated, there is no industrial application for the decarbonylation of aldehydes.

6.8. Addition Reactions to Epoxides

Under mild conditions, 25–100°C, the addition reaction between water and ethylene oxide or cyclohexene oxide on H-ZSM-5 gives the corresponding diols in yields of over 90%. In this case the catalyst service life is commercially acceptable.[332,333] The catalyzed reaction of epoxides with NH_3 or amines gives ethanolamines; ethylene oxide reacts with NH_3 on A-zeolite at 110°C to give an 82% conversion into ethanolamine with a selectivity of 80%.[334] The results with faujasite zeolites and acid ion exchangers are within the same range.[335] Various asymmetric ethanolamines can be obtained analogously.[336] The cost benefit of changing the processes to zeolites is questionable, since the conventional processes operate at very high yields.

7. Reactions with Hydrogen

Hydrocracking[4–7] is one of the large-scale petrochemical processes in which zeolites are used as catalysts. Bifunctional (the hydrogenation property being achieved by deposited metals and the acidity by the zeolitic support), shape selective hydrogenation catalysts of this type are also employed for selective organic syntheses.

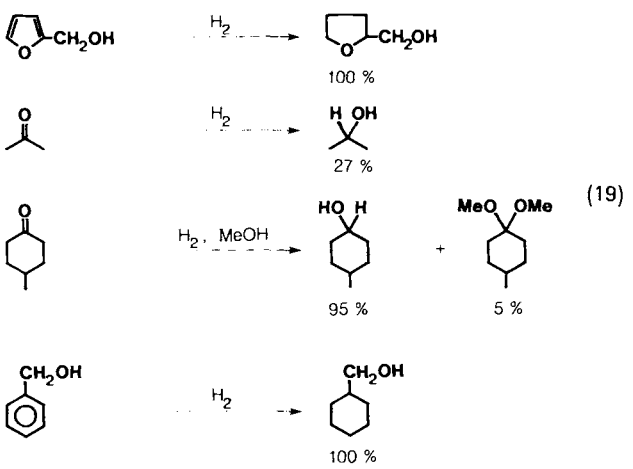
7.1. Hydrogenation and Dehydrogenation Reactions

Cyclopentene in a mixture with 4-methylcyclohexene can be hydrogenated selectively to cyclopentane by Rh-X or Rh-ZSM-11. A kinetic study shows that cyclopentene reacts 47 times as fast as 4-methylcyclohexene on Rh-ZSM-11.[337] 1-Hexene in the presence of 4,4-di-methyl-1-hexene is also hydrogenated to hexane on Pt/Cs-, Pd/Cs- or Ni/Cs-ZSM-5 or β-zeolite; because of the shape selectivity of Pd/Cs-ZSM-5, the conversion of 4,4-dimethyl-1-hexene is less than 1% at a 90% conversion of 1-hexene.[338] Ethylene employed for the manufacture of polyethylene must only contain small amounts of acetylene, Pd-Al_2O_3 being used in industry to hydrogenate the acetylene. High standards are thus set for suppressing the hydrogenation and oligomerization of ethylene. Although the activity of Pd-zeolites is somewhat less than that of the conventional

catalysts, comparable selectivities are obtained, especially with Pd-ZSM-5.[339,340]

Aromatic compounds can be hydrogenated partly or completely using zeolite catalysts. The hydrogenation of benzene is virtually the only source of cyclohexane, which is used as feedstock for ε-caprolactam. This hydrogenation is nowadays mainly carried out using nickel homogeneous catalysts. Comparisons of activity have been carried out between zeolites and non-zeolitic catalysts for the hydrogenation of aromatic compounds.[341-345] Using zeolites doped with noble metals, the catalytic activity is found to decrease in the series Pt > Rh > Ru > Ir; this is different from the activity sequence found on SiO_2-supported catalysts (Rh > Ru > Pt > Ir).[343] The partial hydrogenation of benzene to give cyclohexene on Ru-zeolites at 100–200 °C and at a H_2 pressure of 10–100 bar is described.[346] It is not apparent from this patent, however, whether the conversion and selectivity measure up to the values achieved using amorphous supports (Ru/SiO_2; 175 °C, 50 bar H_2; 56% selectivity of cyclohexene at 57% conversion).

The complete hydrogenations of furfuryl alcohol, acetone, 4-methylcyclohexanone and phenylmethyl alcohol using 5% of Ru-doped LZy52-zeolite in methanol according to reaction (19) are described.[347] At 45–55 °C, yields of up to 100% are achieved.



(19)

C_2 to C_5 alkanes can be dehydrogenated to give monoolefins on metal-doped zeolites in the presence or absence of O_2.[348-357] Propane, for example, is dehydrogenated to propylene under non-oxidizing conditions using Pt/Mg-ZSM-5 or Pt/Mn-ZSM-5; at 550 °C a conversion of 23% and a selectivity to propylene of 87% are obtained.[349] Gatheta-1-zeolite is also used for dehydrogenating C_2 to C_5-alkanes; at 600 °C the conversion of butane is 50%, but the selectivity to butenes is only 34%, the total selectivity to olefins is 63% and the remainder is composed of crack products and skeletal isomerization products.[358] A zeolite containing V, Sn, P, and alkali metals is suitable for the oxidative dehydrogenation of C_4 to C_8 monoolefins to give conjugated dienes, for example the dehydrogenation of 1-butene to 1,3-butadiene; at 400 °C a conversion of 61% and a selectivity of 91% are found.[354]

Vinylcyclohexene, which is accessible by cyclodimerization of butadiene (cf. Section 10), can be dehydrogenated oxidatively to give ethylbenzene at 210 °C, e.g. at a conversion of 99% and a selectivity of 99% using Pd-3A-zeolite. The dehydrogenation of ethylbenzene to styrene can be carried out on Na-doped, small- and large-pore zeolites in a stream of O_2.[359] The dehydrogenation of (+)-limonene to *p*-cymene also takes place at a high selectivity at 200 °C on a Pd/Ce-boron pentasil zeolite (conversion 100%, selectivity 84%); in the course of the reaction the double bonds reorient to form an aromatic system.[365] Boron pentasil zeolites[361,362] or gallium pentasil zeolites[363] doped with noble metals are employed for the bifunctionally catalyzed dehydroisomerization of *n*-butane to isobutene at 500–700 °C. Mixtures of *n*-butenes, isobutene, butadiene and isobutane are obtained. Using a Pt-boron zeolite, the maximum proportion of isobutene is approx. 27% at a conversion of 85%.[364]

Although hydrogenation with zeolite catalysts does not as yet take place with very high yields in all cases (for example the hydrogenation of benzene), it must be expected in general that hydrogenation catalysts based on shape selective carriers, such as zeolites, will become of increasing importance for the synthesis of intermediates and fine chemicals. Since dehydrogenation reactions on zeolites often produce a wide spectrum of products, industrial use of these reactions will probably be limited.

7.2. Dehydrocyclization

With the aim of obtaining more valuable products from the raw materials natural gas and petroleum, cyclization reactions of lower alkanes and olefins to aromatic hydrocarbons are being investigated. The conversion of methane to arenes is not possible for thermodynamic reasons, and, under oxidizing conditions (O_2, N_2O), the total oxidation to CO_2 always predominates.[366-369] The dehydrocyclization of ethane, on the other hand, takes place under non-oxidizing conditions at 570–620 °C on Zn/Cu-ZSM-5 or Ga-ZSM-5 at a conversion of 35% and a selectivity of 60%, the proportion of benzene in the mixture of arenes being approx. 65%.[369-371] The aromatization of propane occurs with higher yields; a conversion of 83% and a selectivity of 60% are achieved at 550 °C.[372,373] Even higher yields of arenes can be obtained if olefins are used; propylene gives 81% of aromatic products using Ga-ZSM-5, the main constituents being toluene and xylene.[374] If the raw material situation changes and the demand for arenes increases, these reactions could become commercially interesting and open up new sources of arenes.

7.3. Hydroformylation

The investigation of immobilized carbonyl-transition metal compounds for hydroformylation reactions is attracting considerable interest.[375] The classical hydroformylation of olefins on carbonylcobalt or -rhodium compounds gives mixtures of *n*-aldehydes and isoaldehydes. One aim in using hydroformylation catalysts supported on zeolites is to exploit the shape selectivity in order to shift the *n/iso*-aldehyde ratio in favor of linear isomers.[376-380] When ethylene is reacted (200 °C, 100 bar, $C_2H_4/CO/$

$H_2 = 1.5:2.1:2.5$) using a Ru-Z-zeolite, almost complete conversion is observed with the formation of approx. 12% of propionaldehyde, 36% of *n*-propanol and 12% of 2-methylbutyraldehyde; part of the Ru is removed in the form of the carbonyl complex and the spent catalyst contains ruthenium carbonyl compounds which cannot be extracted. In a further hydroformylation cycle the removal of ruthenium virtually ceases.[376] Hydroformylation over Rh-zeolites under atmospheric pressure[381-389] gives, at minimal conversion rates, *n*/iso-aldehyde ratios that do not exceed the values achieved with homogeneous catalysts.

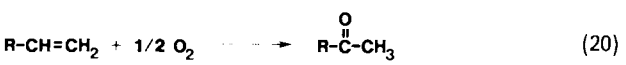
The principal problems in hydroformylation using zeolites are the occurrence of acid-catalyzed side-reactions (oligomerization or aldol condensation) and removal of the active transition metal component. Application on an industrial scale therefore appears impossible for the present.

8. Oxidation Reactions

In oxidation reactions—as also in hydrogenation and dehydrogenation reactions—zeolites assume the function of the support material for active components and influence the product spectrum by virtue of their shape selectivity.

8.1. Oxidation Reactions with Oxygen

The oxidation of lower olefins to carbonyl compounds according to reaction (20) can be carried out in the gas phase on Pd/Cu-Y-zeolites. It is essential to add water in order to ensure high selectivity and long catalyst service life. The rate of oxidation falls off as the chain length increases, as is known from the homogeneously catalyzed reaction using Pd and Cu salts.[390,391] In the oxidative acetoxylation of propylene to give allyl acetate, Pd/Cu-erionite (approx. 90% selectivity) and Pd/Cu-mordenite (approx. 70% selectivity) are superior to Pd/Cu-faujasite (approx. 40% selectivity). However, the activity and selectivity of conversion in this reaction depend on the alkali metal ion present in the zeolite before replacement by Pd and Cu.[392,393]



$$R\text{-}CH{=}CH_2 + 1/2\ O_2 \longrightarrow R\text{-}\overset{\overset{O}{\|}}{C}\text{-}CH_3 \qquad (20)$$

The selective partial oxidation of C_4 to C_{10}-hydrocarbons to maleic anhydride offers a commercially interesting alternative to the conventional process by the oxidation of benzene, 2-butene or crotonaldehyde. Maleic anhydride is obtained with a selectivity of 80% at a conversion of 17% from *n*-butane at 525°C using zeolites doped with V, P or alternatively Zn.[395]

Monochlorinated, saturated hydrocarbons can be oxyhalogenated to dihalogenated compounds over Cu-pentasil zeolite at 225–325°C;[394] chloroethane gives a 60% conversion, and the composition of the reaction mixture is 43% by volume of 1,2-dichloroethane, 40% by volume of chloroethane and 16% by volume of ethylene. As a result of the shape selectivity, more highly halogenated ethanes are not observed. The reaction can also be carried out at lower temperatures than the process using conventional catalysts, thereby avoiding the formation of vinyl chloride and separation problems associated therewith. The irreversible damage caused to the zeolite by HCl, however, makes industrial application doubtful.

A comprehensive review article on oxidation reactions, including oxidative dehydrogenation reactions over zeolites, has recently appeared.[396]

8.2. Oxidation Reactions with Peroxides

The discovery of the titanium zeolite TS-1 has enabled remarkable progress to be made in oxidation reactions with H_2O_2 in recent years.[397,398] Liquid phase epoxidation (in methanol or acetone) of olefins and diolefins[399,402] with H_2O_2 takes place over TS-1 between 0 and 80°C with selectivities of 75–96% (relative to the olefin), the conversion of H_2O_2 being in most cases complete. The principal by-product formed is a glycol monomethyl ether (in methanol) or a glycol ketal (in acetone). A great advantage of TS-1 compared with the conventional oxidation catalysts, such as OsO_4 and V_2O_5,[400] is that it is possible to use dilute aqueous peroxide solution in practically stoichiometric proportions. This reaction is of particular interest for the preparation of propylene oxide, at a selectivity of 98%, at 15°C in methanol. The side-reaction leading to glycol monomethyl ether can also be made the main reaction if the process is carried out above 100°C [reaction (21), $R = CH_3$].[401]

$$R\text{-}CH{=}CH\text{-}R^1 + H_2O_2 + CH_3OH \longrightarrow R\text{-}\underset{OH}{CH}\text{-}\underset{OCH_3}{CH}\text{-}R^1 + H_2O \qquad (21)$$

$R = R^1 = H$, alkyl, aryl, alkylaryl, cycloalkyl, alkylcycloalkyl

The direct hydroxylation of aromatic hydrocarbons by means of H_2O_2 is also possible using TS-1;[403] phenol in acetone solution gives hydroquinone at a selectivity of 92% relative to phenol or 80% relative to H_2O_2, at an H_2O_2 conversion of 100%. This process is already being carried out on an industrial scale in Italy. Further examples of its use are the hydroxylation of toluene, ethylbenzene, anisole and cresol. The tendency for the *p*-isomer to be formed preferentially and the minimization of undesired side reactions leading to multinuclear arenes are indications of the shape selectivity of the titanium zeolite. The hydroxylation of phenol can also be carried out in the presence of the aluminozeolites H-ZSM-5 or H-ZSM-11, doped with coinage metals or Fe, Co, and Ni or their homologs, with a selectivity to hydroquinone of 99%.[404]

The extension of the principle of this reaction to primary and secondary alcohols opens up new routes for the preparation of aldehydes and ketones.[405] For example, benzyl alcohol is oxidized to benzaldehyde and cyclohexanol to cyclohexanone by means of H_2O_2 in yields of approx. 90% (relative to H_2O_2) on TS-1 at 70–90°C. Reference should also be made in this connection to the conversion of hydroperoxides. Over Co-4Å-zeolite, cyclohexyl hydroperoxide is converted at 30–160°C into cyclohexanol and cyclo-

hexanone with a selectivity of over 95% at 100% conversion.[406] In contrast, Co on graphite gives a selectivity of only 82% at a peroxide conversion of 94%. The decomposition of cumene hydroperoxide to give phenol (96% selectivity) and acetone can be carried out over a mixed alumino/borozeolite at 40–60°C.[407]

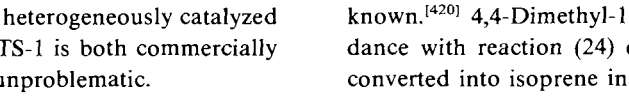
These examples justify the prediction that in the future zeolites, in particular the titanium zeolites, will find widespread application in oxidation reactions. As an alternative to the chlorohydrin route, a heterogeneously catalyzed propylene oxide process using TS-1 is both commercially attractive and environmentally unproblematic.

9. Condensation Reactions

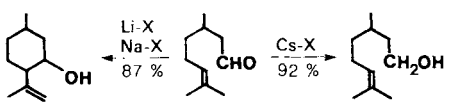
Condensation reactions are catalyzed by acids or bases. This is a suitable field for the use of zeolites, since their acidity can be easily controlled or they can be doped with bases, with the retention of their shape selectivity. In this way it is possible to adjust their catalytic properties in order to suit the desired reaction.

9.1. Aldol Condensations

The base-catalyzed or acid-catalyzed aldol condensation is a classical dehydration reaction undergone by carbonyl compounds. Over acid aluminum zeolites, acetone is converted into mesityl oxide, isobutene, phorones, mesitylene and alkylphenols.[408–412] It has been shown in a detailed investigation[411] that ZSM-5 containing iron oxide as an impurity converts acetone selectively into 2,4-dimethylphenol. The preparation of α,β-unsaturated aldehydes from formaldehyde and aldehydes in accordance with reaction (22) takes place with high selectivity using the boron zeolite H-AMS-1B.[413] For example, a 1:1 molar mixture of propanal and formaldehyde is converted at 300°C into methacrolein at a selectivity of 98% and a propanal conversion of 58%. Citronellal can react with isopropanol according to reaction (23) in a Meerwein–Ponndorf–Verley reduction at 150°C on alkali-containing X-zeolites to give isopulegol or citronellol, depending on the metal used for doping.[414]



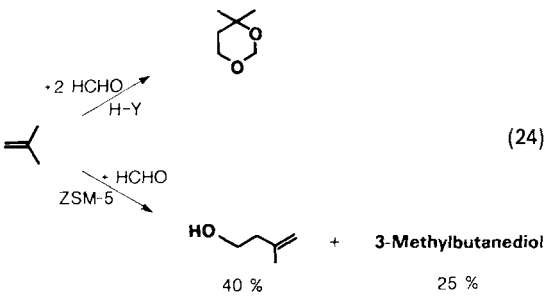
(22)



(23)

There have been many investigations of aldol condensations under hydrogenating conditions. Thus butyraldehyde is converted into 2-ethylhexanal and 2-ethylhexanol (80% conversion, >70% selectivity) on Pd/Pt–X-zeolites in the presence of H_2 and at 100–200°C.[415–417] In this case dehydration and hydrogenation take place in a single reaction step. Ketones also give hydrogenated saturated compounds in the presence of H_2;[418,419] acetone reacts with H_2 at 180°C on Pd-ZSM-5 yielding methyl isobutyl ketone with a selectivity of 98% but with a selectivity of only approx. 30% on Pd–Y,[418] the conversion in both cases being 30%. Kinetic studies[419] indicate that the condensation reaction of acetone over zeolites takes place via an intermediate attached to the surface, whereas in the case of higher ketones intermolecular dehydration predominates without the zeolite having an appreciable effect.

The reaction of olefins with formaldehyde, for example for the synthesis of isoprene from isobutene, is well known.[420] 4,4-Dimethyl-1,3-dioxane is formed in accordance with reaction (24) over large-pore zeolites, and is converted into isoprene in the second stage.[42,422] In contrast to this, the reaction according to reaction (24) on

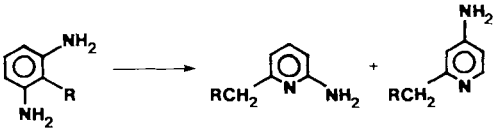


(24)

ZSM-5 or ZSM-11 (70°C, 10 bar) gives 3-methyl-3-buten-1-ol (40%) and a mixture of 3-methylbutanediols (25%) at a conversion of 50%.[423] These findings reflect the shape selectivity of the zeolites. The reaction of methyl acetate or acetic anhydride with formaldehyde over ZSM-5, giving methyl acrylate (50% yield) and acrylic acid (9% yield), offers a possible alternative to the existing method of manufacture on a large industrial scale.[424] In view of their industrial importance, further work is being carried out on both processes, since the yields are still not satisfactory at the present time.

9.2. Synthesis of Aromatic N-Heterocyclic Compounds

Classical processes for the condensation of small molecules to form N-heterocyclic compounds are markedly superior to reactions using zeolites, particularly in the case of compounds with complicated substituents.[425–428] Acetaldehyde reacts with NH_3 on H-ZSM-5 and Cd-H-ZSM-5[425] and Cd-Y[426] at 300–400°C to form picolines in yields of 20% to 60%, in a relatively unspecific manner. Acetaldehyde, formaldehyde and NH_3 give an 83% yield of a mixture of pyridine and β-picoline (molar ratio 2:1) at 450°C on zeolites.[427]



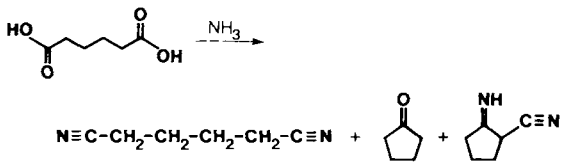
(25)

The synthesis of picolines by rearrangement of aminated arenes constitutes an interesting alternative to the reactions mentioned above. Thus, aniline can be converted into β-picoline by means of NH_3 at 500°C and elevated pressure on H-ZSM-5 (selectivity 52%, conversion 13%).[429] 1,3-

Diaminoarenes afford a mixture of 2-aminopyridines and 4-aminopyridines according to reaction (25) on ZSM-5 at 350–400 °C (selectivity 98%, conversion 40%, R = H, CH_3).[430] These compounds have hitherto only been accessible in good yields by reaction of sodamide with pyridines.

9.3. The Synthesis of Isocyanates and Nitriles

Aromatic isocyanates can be prepared from (nitromethyl)arenes,[434] and nitriles can be prepared from amides (ZSM-5, 400 °C, 85% yield) or from formaldehyde/alcohols in the presence of amines.[435,436] The preparation of aliphatic dinitriles, such as adiponitrile, from dicarboxylic acids and ammonia is carried out in the gas phase on a large industrial scale in fluidized- and fixed-bed processes. Using conventional catalysts,[431,432] the selectivity in reaction (26) is reduced as a result of cyclization to cyclopenta-



(26)

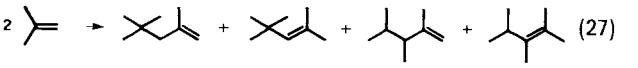
none and 2-iminocyclopentanecarbonitrile. Side reactions of this type are suppressed if, for example, a boron zeolite doped with 5.6% by weight of Na and 7.6% by weight of P is employed.[433] As shown by comparison with a catalyst based on SiO_2, the content of cyclic compounds is reduced from 6.7% to 1.4%, as a result of which the selectivity for adiponitrile is increased from 83% to 94%. The transition state shape-selectivity of the zeolite, which does not permit the cyclization reaction, is evidently responsible for this. This example shows once more the synergism of dehydration properties and shape selectivity exercised by the pentasil zeolites. The profitability of this process is increased markedly by the zeolites.

9.4. O/N Replacement in Cyclic Compounds

As is known from other acid heterogeneous catalysts, the reaction of lactones and cyclic ethers with ammonia also gives lactams or cyclic imines using zeolite catalysts.[437–441] Tetrahydrofuran is converted into pyrrolidine on H-L-zeolite with a selectivity of 91% at 350 °C or on H-Y-zeolite with a selectivity of only 82%. H-L-zeolite is not very suitable for the preparation of piperidine from tetrahydropyran.[437] Only after it has been dealuminized does this zeolite improve the catalytic activity and selectivity for the O/N exchange in the ring;[439] at 460 °C the H-L-zeolite (Si/Al = 3.2) gives a 24% conversion and a piperidine selectivity of 58%, whereas the dealuminized catalyst (Si/Al = 6.0) gives a 25% conversion and an 80% piperidine selectivity. Butyrolactone is converted into 2-pyrrolidone with a selectivity of 80–90% on Cu-Y-zeolite at 230–260 °C.[440,441] The zeolites offer an interesting alternative to conventional acid, non-shape-selective catalysts for the replacement of O by N in heterocyclic compounds.

10. Oligomerization Reactions

The only oligomerization reactions to be described here are those leading to open-chain and cyclic aliphatic hydrocarbons (cf. also Section 7.3). In general, mixtures of dimers, trimers and tetramers are formed from olefins using zeolites. The deposition of higher oligomers can, however, result in coking and deactivation of the catalyst. Isobutene can be dimerized to give trimethylpentene isomers in accordance with reaction (27) with a selectivity of up to 88% on Bi- or Pb-pentasil zeolites at 100–150 °C; migration of methyl groups also takes place.[443] Ni-ZSM-5 or Ni/Zn-ZSM-5 or ZSM-11 are suitable for the oligomerization of C_2- to C_{20}-olefins; in the case of propylene a selectivity to the dimer of 71% is achieved at almost quantitative conversion at approx. 60 °C.[442,445] C_3-olefins and C_4-olefins can be tetramerized in a two-stage process on Ni-H-ZSM-5 at 120–230 °C with a selectivity of over 60%.[444]



(27)

The selective oligomerization of lower olefins to give terminal C_8- to C_{12}-monoolefins is of interest. Hydroformylation of these monoolefins to aldehydes or alcohols yields intermediates which are used in the synthesis of surfactants and lubricants. Oligomerization reactions of this type[15] are already carried out on an industrial scale.

11. Summary and Prospects

The present exposition is intended to demonstrate the numerous possibilities in which zeolitic catalysts can be employed. It also illustrates the opportunities afforded by these shape selective acid catalysts, and emphasizes the future importance of such catalyst systems. Numerous economically interesting organic reactions, which were hitherto not feasible because of low activity, selectivity and/or service life of the catalyst, can now be commercially exploited using zeolites. It has now become easier to change from homogeneously catalyzed processes to heterogeneous catalysis if environmental and process engineering problems occur in the separation, work-up or possible recycling of the homogeneous catalyst. Existing processes can be improved merely by replacing the conventional heterogeneous catalyst.

Furthermore, publications are beginning to appear in the literature which indicate the importance of zeolite catalysts in stereochemistry[446,447] and as carriers for enzymes and microorganisms in biotechnology.[448] This opens up a wide range of new applications.

The new developments in the fields of phosphates having a zeolite structure,[449–452] artificially expanded clay minerals (so-called pillared clays)[453] and modified carbon molecular sieves[124] as well as certain crystalline cyanometalates[454] offer the possibility of combining the catalytic properties of these materials with a shape selective behavior. Solid-state chemistry will consequently provide materials which can give a new impetus to shape selective catalysis. This will enable us to proceed further along the road

leading to enzyme catalysis, the most subtle form of shape selectivity.

In our constant endeavor to look over Nature's shoulder and to learn from her, the future will certainly bring us surprises, but also insights into a deeper understanding of shape-selective catalysis. Even if we shall never quite attain the perfection of our teacher, new horizons will nevertheless open up.

The authors are grateful to Dr. H. Lermer of BASF for his helpful assistance in screening the literature and discussions leading to the preparation of Section 2.

Structure Elucidation and Artificial Intelligence

By Wolfgang Bremser*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The difference between the older and the more recent computer systems amounts, in the final analysis, to the difference between an insect and a human being. The insect comes "fully programmed" into the world—programmed by instincts which it follows without using any thought processes. On the other hand, the human being must first learn the correct behavior—however, such learning can develop an impetus all its own: becoming, indeed, proceeding from his own decision and his awareness, the human being can change his former action programs. The creation of a computer system of the x-th generation will actually far more resemble educating a child than the traditional programming of a computer.

Stanisław Lem[1]

1. Elucidation of Structure in Organic Chemistry

There is no need for any discussion concerning the increasing importance of structure elucidation in organic chemistry. During the past years, increasing emphasis has been placed not only on the classical analysis of constitution, but also on the investigation of configuration and conformation, these activities reaching their peak in the accurate imaging of entire protein structures by means of X-ray structural analysis or NMR spectroscopy. Even natural and synthetic mixtures are identified as a matter of routine, be it after previous separation, by time-dependent observation of chemical reactions or, in the case of high polymers, by sequence analysis. Finally, by measuring the isotope ratios, it is possible to retrace the history of the origin of a substance in synthetic or biological reactions with a relatively high degree of accuracy.

By means of electronics and computer control, the level of performance of modern analytic equipment has reached such an advanced stage that an abundance of accurate and highly specific data—which awaits detailed evaluation—is being generated, to a large extent fully automatically. Indeed, in our spectroscopy laboratory approximately 40 MBytes of data are handed over, each day, to our colleagues in charge of interpretation, and there await processing; this is a colossal task, which can be performed only with the aid of electronic data processing.

On the other hand, the need for detailed information about our chemical substances is also increasing daily. In the present-day political environment, with its requirements imposed by the legislature and the demands of environmental protection, as well as the high quality standard which, in the situation of fierce industrial competition, offers the only chance of survival, analytical procedures are challenged afresh every day. Moreover, an improvement of the properties of a substance is possible only by means of an accurate knowledge of the substance, and the controlled synthesis of an active substance only by means of a knowledge of the mechanism of action. It is frequently possible, by means of improved analytical data, to avoid unnecessary effort in the synthesis and testing of compounds which are unwanted, because they are inactive.

Only by the consistent application of modern computer technology in the recording and interpretation of spectroscopic data can these constantly increasing demands be met. The present article cannot and will not deal with every aspect of the problem. On the contrary the intention is to present a brief excursion into the facilities and problems of automation from the viewpoint of a modern spectroscopy laboratory, and, above all, to survey the tools which permit an "intelligent" evaluation of the raw data. In this connection, it should be borne in mind that the person commissioning a spectroscopic analysis is, in most cases, not interested in the spectrum per se, but has a direct interest in the structural information. If it proves to be possible to translate the spectroscopic parameters directly into topologies and the associated structural pictures (topograms), then a further decisive step towards the improvement of the level of performance of analytical methods has been taken.

2. Automated Recording of Spectra

Components for the fully automatic control of the recording of NMR, IR and MS spectra are nowadays included in the basic equipment of the majority of spectrometers which are commercially available. Accordingly, the experiments are designed, the measurement parameters are optimized, the desired number of runs is summed, and the data processed and printed out in standardized form on the screen or printer. The entire procedure is set up by the user in a flexible programming language and executed by the computer. In this way, it is also possible for series of experiments, such as 2D correlations, reaction kinetics,[2]

Fig. 1. An interior view of a modern spectroscopy laboratory with a high-field nuclear resonance spectrometer including an automatic sample changer in the foreground and a robot system for the automatic preparation of the substance samples in the background. A human being is intentionally employed at the intermediate monitoring stage; he inspects the solution and places it, after grading, into the changer.

daughter scans, etc., to be performed without supervision (Fig. 1).

Automatic switching-over between chemical ionization (CI) and electron impact (EI) excitation in mass spectrometry is mentioned as example of a more recent development. The CI experiment is necessary in order to determine the molecular mass and thus the overall formula with precision. This information is an important prerequisite, especially for fully automatic interpretation (see Section 10). In contrast, EI spectra supply the characteristic fragmentation of the molecule and thus the fingerprint of the structure, which is required for the library search. Switching-over between the two types of ionization during the measurement is achieved by the ACE (*A*lternate *C*hemical Ionization/*E*lectron Impact) technique. Although, in the standard method, a medium-sized aperture is used as a compromise between the small CI and the large EI slit, and the spectra produced are mixed spectra—which are not suitable for comparisons of identity—in the modification[3] developed in collaboration with an equipment manufacturer switching-over between optimal apertures takes place pneumatically. As illustrated in Figure 2, in the EI spectrum no CI components are present any longer and even in the course of a GC/MS coupling or a fractionated evaporation CI and EI spectra can be measured "simultaneously".

2.1. Automatic Sample Changers

An automatic changing of the prepared substance sample is required for a fully automatic measurement of different compounds. Automatic changers for small sample tubes (Fig. 1) in nuclear magnetic resonance and for KBr pellets in IR are nowadays included among the accessories supplied with most commercial systems, although care should be taken not to underestimate the complexity of the task with the numerous safety monitoring devices which are required. If separation techniques are carried out in advance in IR or MS, an autosampler is available, which, with its cleaning and drying cycle, can also be used for the

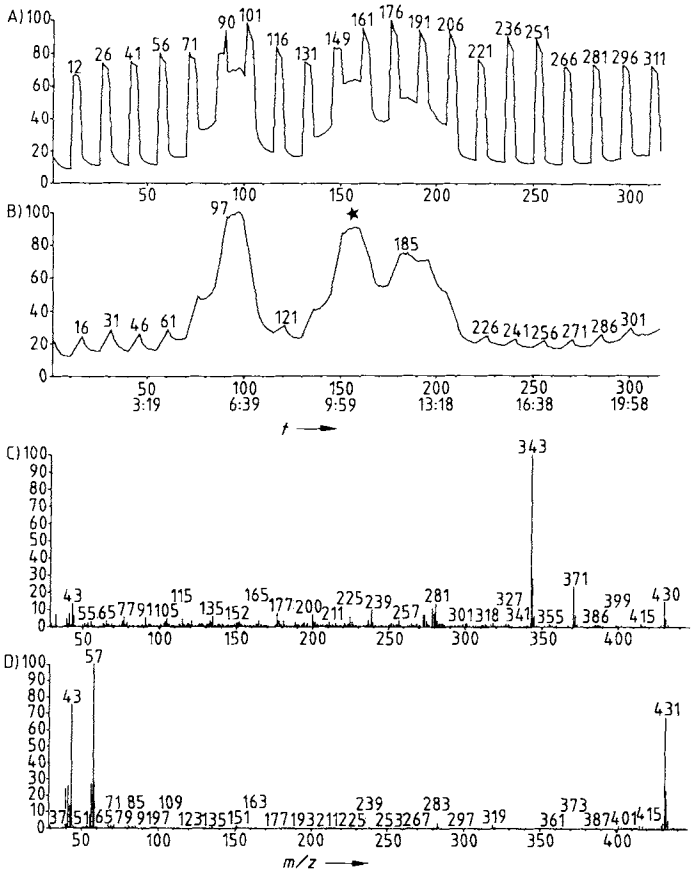

Fig. 2. Direct evaporation of a solid-sample mixture, with monitoring of the total ion current, using automatic switching-over between EI and CI. A, B) Reconstructed total ion current as a function of time. The maxima at constant intervals are due to the reactant gas ions during the CI setting. The progress of the evaporation is best reproduced by the trace B, which is derived from the ion current under EI conditions. C) EI spectra and D) CI spectra of the component which is associated with the second maximum of the evaporation profile (*). The molecular mass of 430 derived from the EI spectrum is confirmed by $(M+H)^{\oplus}$ in the CI spectrum. The EI spectrum is essentially free of impurities due to the preceding CI experiment.

filling of cells in IR.[3] In mass spectrometry, the development of automatic solid-substance charging valves (cf. AUDEVAP[4]) is in progress. Films of liquid samples on KBr windows can also be made and then inserted into the spectrometer by robots (see Fig. 3). By tireless employment, day and night and at the weekend, the automatic changers permit a large throughput of samples and an efficient utilization of the expensive spectrometers. Thus, in nuclear magnetic resonance experiments it is possible to process more than 200 samples per machine per day, and, in mass spectrometric measurements, more than 24 GC/MS couplings with an average of ten components. The information output of these systems can be processed only by resort to computer systems for the documentation and interpretation of the measured results.

2.2. Automatic Preparation of Samples

The aforementioned technical facilities for the automatic execution of the sequences of, in some cases, complicated experiments have not only relieved the burden on laboratory personnel and increased the throughput of sam-

ples but also have improved the quality of the analyses. The only significant manual work remaining is the preparation of the substance samples, especially in IR and NMR spectroscopy. And even here, it is possible to obtain a robot system, which, as a result of the flexibility of its movements and operations, can react rapidly to the required decisions associated with problems specific to certain substances.

Figure 1 shows, in the background, a robot system for the preparation of solutions for NMR spectroscopy (for details see Ref. [3]). The system can handle solid and liquid substance samples alike, from the opening of the sample vessel to the closing of the small measurement tube. Up to 100 substances can be handled in one run, which corresponds to a typical daily throughput of one employee.

In IR spectroscopy, use is made not only of an automatic system for the preparation of KBr pellets[3, 5] but also of a robot for the application of films on KBr windows (Fig. 3). The following steps are executed:

- A KBr disk is taken from the dispenser.
- The sample vessel is screwed on and the sample is pipetted onto the KBr disk, using the injection hand.
- A second KBr disk is taken from the dispenser and pressed onto the first one; the two KBr disks are then placed together with the sample film in a holder and pressed firmly together.
- The holder moves into the measurement beam of the spectrometer, and the start signal for the measurement is passed to the spectrometer. Meanwhile, the sample vessel is again screwed up and put back into position.
- After completion of the measurement, the holder travels upwards again and the measured sample is filed away. The procedure can now recommence from the start.

With this technique, it is possible for 90% of all liquid samples to be prepared and measured fully automatically;

Fig. 3. Laboratory robot (Zymark) for the preparation of films on KBr windows. A small sample tube is just being placed ready for the preparation. Left: spectrometer computer. Right: optical bench where the robot delivers the prepared KBr window.

the time required for the preparation of the robot is approximately half an hour.

By means of the robot it has thus become possible to circumvent the time-consuming filling, cleaning and drying of the standard cells and also to provide the necessary technical prerequisites for the routine recording of liquid substance samples in IR spectroscopy. In this way, the use of autosamplers with a rinsing/drying cycle[3] has been supplemented in a significant manner.

3. The Flow of Information in the Laboratory

Figure 4 shows the flow of information in an IR laboratory. The substance sample is sent by the chemist, together with a statement of the desired experiments, to the appropriate laboratory. In the case of solid state samples, the

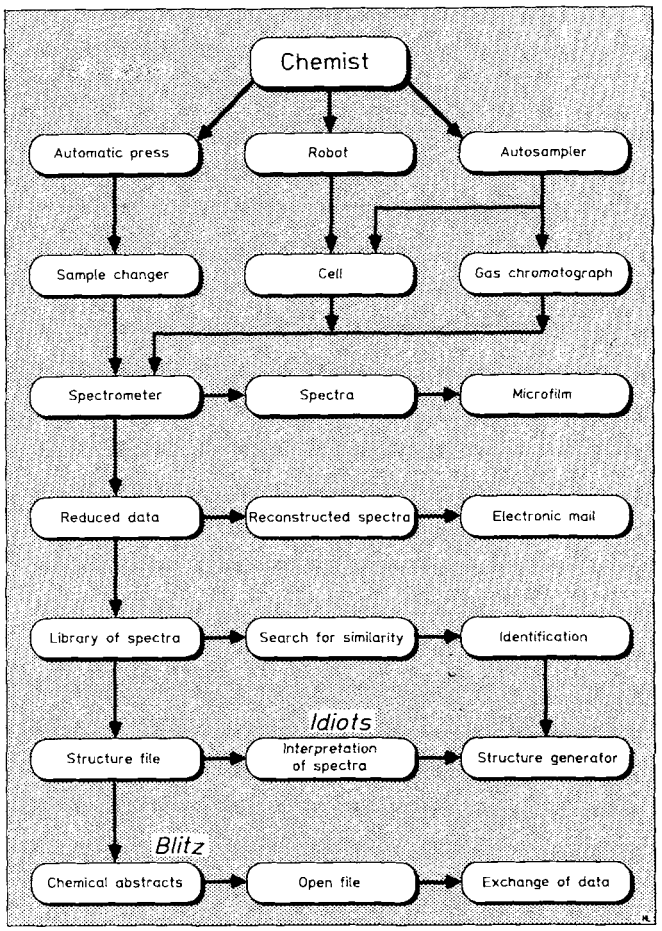

Fig. 4. The flow of information in an IR spectroscopy laboratory. A comparison of the structures present in the structure file with those of Chemical Abstracts by means of the *Blitz* system permits a decision to be made as to whether the compounds have already been published and the data sets can be cleared for exchange with partners in the development of knowledge-based expert systems.

compound is mixed with KBr, formed into pellets in an automatic press and deposited in the sample-changer wheel of the spectrometer. Liquid samples are either applied to KBr windows by the robot (see Section 2.2) or filled into a cell by means of an autosampler or introduced into the gas cell (light pipe) via a short GC column. The

automatic FT-IR spectrometer records the measurement data and plots a spectrum, which, after microfilming, is transmitted in the original to the person commissioning the investigation.

In the spectrometer computer, the data are reduced to band position, band intensity and band width, and are filed in a library of spectra. Using this condensed information, it is possible at any time to reconstruct a spectrum whose form of appearance does not differ from the original, within the limits of reproducibility. In future, the spectra will be fed directly to the chemists via LAN (=Local Area Network).

For the final evaluation, a comparison is made between the measured IR spectra and all reference data stored to date. This permits a rapid and reliable identification of unknown products. In most cases, the desired reference spectra are not present, since the substance to be analyzed is a novel type of product.

Accordingly, it is necessary to conduct a computer-assisted interpretation of the spectra,[6] whose variants will be explained in the following. The structure file is used to carry out a transformation of the spectral parameters into structure parameters and, by means of the structure generator, novel types of topological structures are proposed. These are also documented and sent to the person requesting the investigation, thus completing the analytical cycle.

4. Estimation of Chemical Shifts

As has already been stated, the spectral information $\{\nu\}$ should be capable of being directly converted into the structure information {S} desired by the person commissioning the investigation. On the other hand, the function $\{S\}=f\{\nu\}$ is just as unknown and complex as its inverse $\{\nu\}=f\{S\}$, where ν describes the entirety of the spectral parameters δ (chemical shift), J (coupling) and τ (relaxation time) and their interactions.

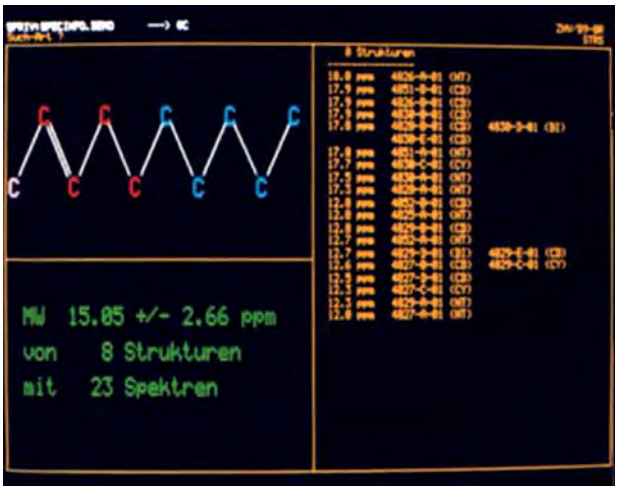

Fig. 5. Result of the search for partial structures including a methyl group at an isolated double bond. The focus is situated on the carbon shown in purple, and the range of the HOSE code with four spheres is marked in red. An evaluation of the chemical shifts derived from 23 spectra of eight structures gives a mean value of 15.05 for δ with a standard deviation of 2.66 ppm. The reference compounds listed on the right-hand side are shown, for some cases, in Figure 6.

Most appropriately, this correlation is also to be implemented in NMR spectroscopy, where, since the incremental rules of *Shoolery* et al.[7] and *Grant* et al.,[8] the relation $\delta=f(S)$ has been applied to a structural element S including the spherically surrounding α, β, γ, and δ substituents. This concept forms the basis of the HOSE code[9] with its hierarchically ordered spherical presentation (*H*ierarchically *O*rdered *S*pherical Description of *E*nvironment) of the environment. In searching for all reference data for a characteristic node in the description of the topological structure (methyl group at double bond in Fig. 5), after the desired structure has been built up the number of the node is entered, the partial structure code is computed and the corresponding entries in the index are printed out. Figure 5 shows the individual values together with the short codes for the solvent, as well as the mean value, the standard deviation and the number of reference compounds on which this estimate of the ^{13}C chemical shift is based. It emerges that the standard deviation is relatively large and the individual values can be grouped about two maxima at $\delta=12.5$ and 17.8. Inspection of the associated structures (Fig. 6) reveals that the well-known steric interactions are responsible for this: cisoid methyl groups absorb at $\delta\approx 12$ ppm and transoid ones at $\delta\approx 18$ ppm.

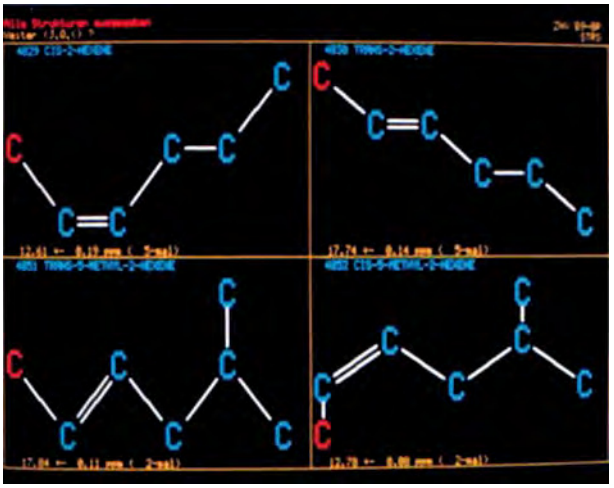

Fig. 6. Display of the first four reference compounds, indication of the atoms whose chemical shifts are sought and listing of the assigned chemical shifts. Where several spectra are recorded, mean values are indicated.

Three findings emerge from this simple example:

- Stereochemical interactions have a great effect on the physical appearance of the spectrum; the topological structure coding should therefore also include the stereochemistry (at least the configuration at double bonds). In quite general terms, it must be stated that a structure coding—if it is to serve not only for the simple objective of documentation and retrieval, but also for the explanation and modelling of physical properties—must specify the interactions in the molecule with the greatest possible accuracy.
- A pictorial recording of the interactions by means of marked structural images is in accord with the chemist's line of thinking. An expert system should not really re-

place an expert, but should serve the expert as a competent "interlocutor". Any aids necessary for making a decision about a structure should be prepared on a user-friendly basis and should provide an incentive for "browsing" through stored chemical structures, correlated with spectroscopic information for creative thought.

— If a partial structure ↔ chemical shift correlation is possible, the total spectrum can also be predicted as the sum of the partial data. However, in all cases a test of the whole set of data for multiple maxima should be carried out,[10] and double entries should be specified in the data expression. In most cases, an experienced spectroscopist can immediately decide which effect was left unaccounted for in the coding of the data; if not, browsing through the detailed data is recommended.

5. Recording of Spin–Spin Interactions

In addition to tracking down the individual items of information, the spectroscopist is also interested in the interaction between the individual parts of molecules, so as to be able to put together the components of the puzzle without ambiguity. In this connection, the spin-spin coupling is of particular importance. Figure 7 shows the search for the magnitude of a coupling between a ^{19}F atom on C4 and the carbon atom C5 of quinoline.

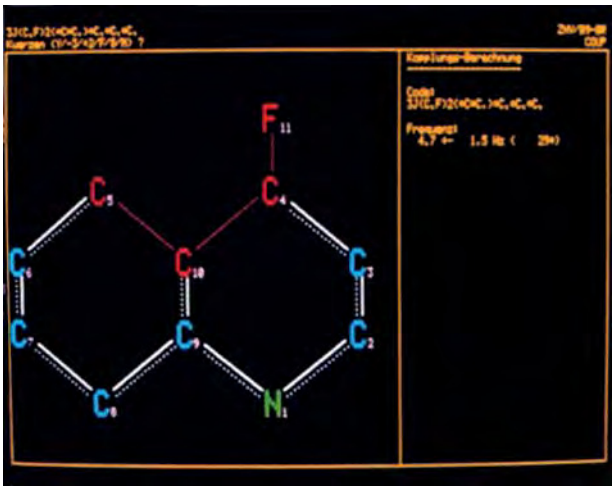

Fig. 7. Estimation of the coupling between C5 and a fluorine substituent on C4 in quinoline.

The computer supplies, as the mean value of five reference spectra, a coupling $^3J_{C,F}=4.7$ Hz with an expected range of ± 1.5 Hz. In a similar way to the above described method for estimating chemical shifts by using HOSE codes, a hierarchically ordered coupling code HOCC was developed, which describes the distance and nature of the interacting nuclei (in this case, 3J(C,F)). This is followed by the number of π electrons (in this instance two) and a precise characterization of the coupling path together with the bonds lying between the element and symbols (here *C*C.). Finally, the environment of the individual nuclei is determined in accordance with the HOSE code. The desired information can be found very quickly as

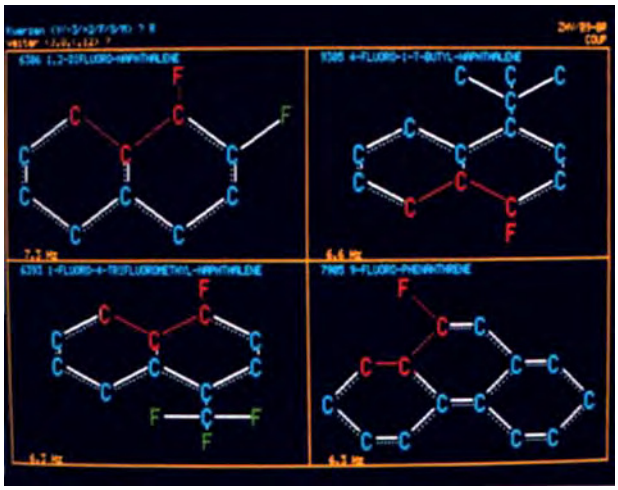

Fig. 8. Display of the first four reference compounds for the coupling searched for in Figure 7. The influence of the differing substituents is reflected in the characteristic variations of the measured coupling parameters.

an index entry under the resulting coupling code 3J(C,F)2(*C*C.)*C,*C,*C. However, if such a coupling is not described in the reference file, the search can be generalized by stepwise abbreviation, until a corresponding structure is present in the file. In this case, an inspection of the individual structures as illustrated in Figure 8 is recommended, in order to derive the best value for the specific problem. A similar example is given in Reference [3] for 4-fluoro-*N*,*N*,3-trimethylaniline.

An interaction of a specified order of magnitude is frequently observed in a spectrum. In this instance, an inspection of the reference structures proposed by the computer is likewise recommended. Thus, the coupling of 19.9 Hz measured in a ^{13}C-NMR spectrum may result from an interaction between C and F, P or D, via one or two bonds, saturated or unsaturated. Further browsing would reveal a variety of possibilities to which the expert has certainly not always given consideration and which (with the exception of $J_{C,D}$ on account of the differing pattern of splitting) cannot always be ruled out (Fig. 9).

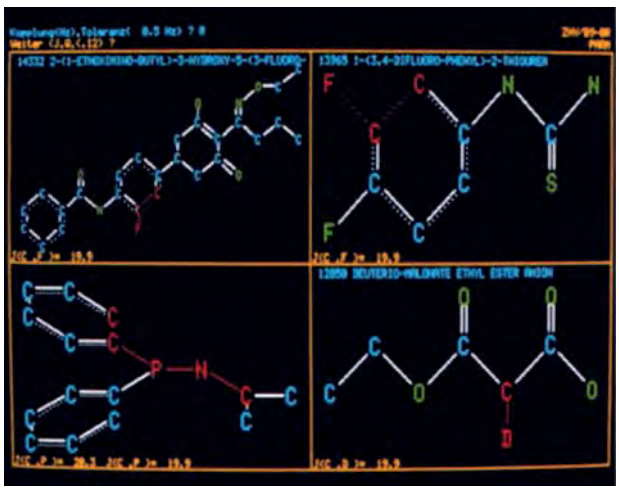

Fig. 9. Search for a coupling of 19.9 Hz, observed in a ^{13}C-NMR spectrum, with any nuclei (apart from hydrogen). The coupling path marked in the case of the first four reference compounds shows differing possibilities of interaction, which can, if desired, be restricted to specific nuclei.

6. Computation of the Spectra

As shown in Sections 4 and 5, chemical shifts and coupling constants for defined structural elements can be estimated on the basis of a reference file. If this is done for all nuclei in the molecule, a computed spectrum for an overall structure is obtained (Fig. 10).

The individual data are characterized by the standard deviation and the number of entries or a statement referring to how many spheres the abbreviation process was implemented in the course of the interpolation (INT*2), and can, at any time, be retraced to the original data in accordance with the above indicated process. Double entries (e.g. in the case of C15) result from double maxima of the total entity, which reflects steric or electronic interactions, or alternatively erroneous data.

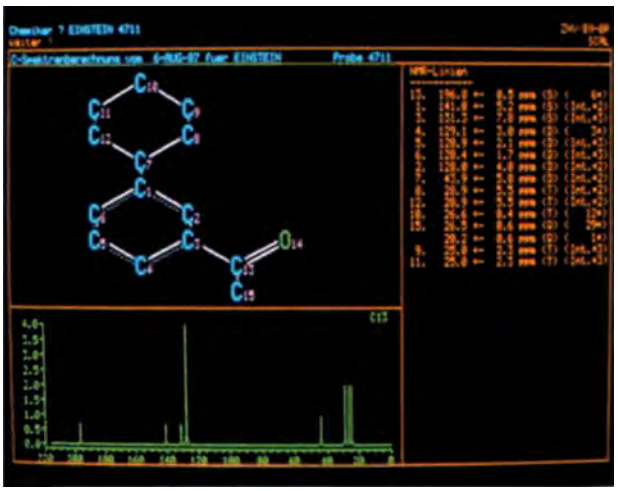

Fig. 10. Estimation of the ^{13}C-NMR spectrum of 3-cyclohexylacetophenone. The diagram shows not only the reconstructed spectrum, but also, listed on the right-hand side, the individual data which permit a good survey of the reliability of the computation. The standard format includes all essential information for subsequent documentation, and is sent to the person requesting the investigation together with the experimental results.

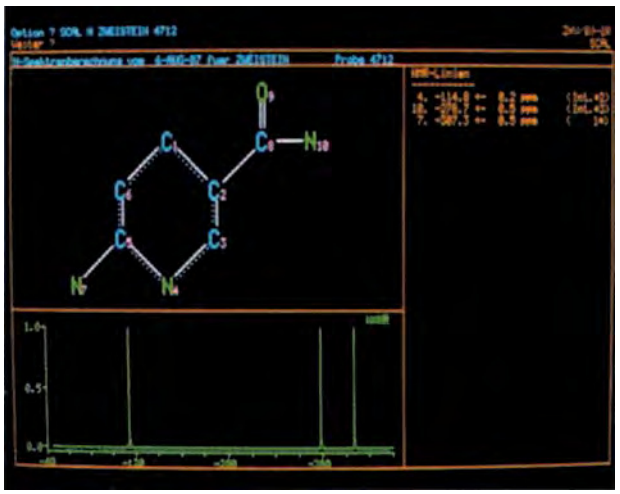

Fig. 11. Estimation of the ^{15}N-NMR spectrum of 6-aminonicotinamide on the basis of a reference file containing 1000 ^{15}N-NMR spectra [11].

This method can be applied to all nuclei, as illustrated in Figure 11 for ^{15}N, provided that the necessary structure-oriented spectral file[11] is available. In our laboratory, the data sets for ^{13}C, ^{31}P, ^{15}N, and ^{19}F are available, but in the case of ^{1}H there is as yet no assignment of the resonance frequencies, and in this instance the computation of a spectrum is possible only with difficulty in accordance with the above principle on account of the strong influence of solvation, stereochemistry and the splitting of the coupling.

On the other hand, infrared spectroscopy is not a form of atomic spectroscopy, but genuine molecular spectroscopy. In this case as well, the simulation of spectra is possible, by comparison with similar reference structures and a corresponding modification of the associated spectra. A typical result, as represented in Figure 12 for anthranilic acid hydrazide, is very promising, particularly if one compares the spectrum with the experimental spectra in the catalogs.[12]

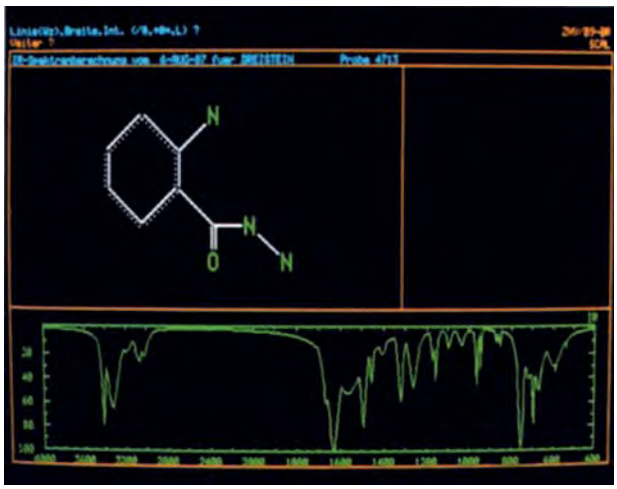

Fig. 12. Estimation of the IR spectrum of anthranilic acid hydrazide as KBr pellet.

In the simulation of mass spectra, statements are made concerning the probable sites of ionization, in the first instance on the basis of observations concerning ionization potentials. For each radical cation obtained in this manner, fragmentation and rearrangement sequences are then set up; in this procedure, each stage and each intermediate state is assessed in accordance with the physical parameters computed according to the above indicated methods.[13]

Figure 13 shows preliminary results for 3-hydroxytetrahydrofuran. The two free electron pairs on the oxygen atom come under consideration as ionization sites, whereby the radical cations **A** and **B** are obtained. The mass spectra simulated in accordance with the fragmentation mechanisms which differ for these two species are shown at the top; the superposition of the two processes gives spectrum C, which shows a very good level of agreement with the experimental data in the lower spectrum (spectrum D).

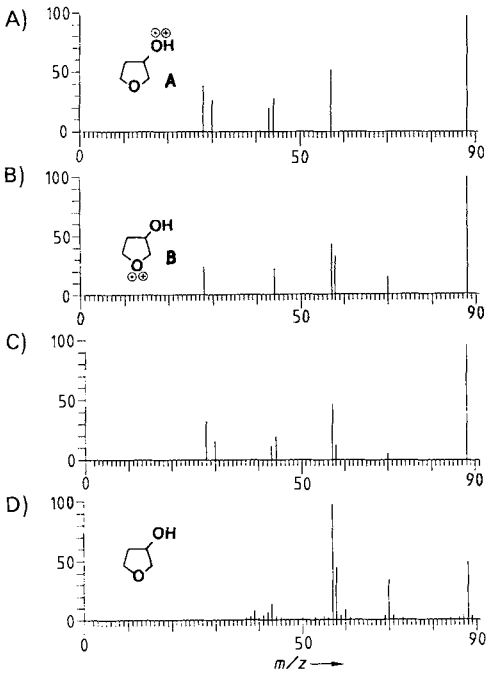

Fig. 13. Simulation of the fragmentation properties of 3-hydroxytetrahydrofuran. The two possible radical cations **A** and **B** give the partial spectra A and B, the simple combination of which yields the computed mass spectrum C. Apart from the masses at m/z 28 and 30, which were not included in the experiment (spectrum D), the physical appearance of the spectra is reproduced quite well.

7. Search for Spectra

The search for similar reference compounds can be carried out by computer in a variety of ways.[14] The method which is simplest and frequently very effective for carrying out a search for spectral patterns is the line search with reference to numbers of correlations. In the present case, a search was carried out for the features of a quartet at $\delta = 14.0$, a triplet at $\delta = 60.5$ and a singlet at $\delta = 173.1$ in a ^{13}C-NMR spectrum, using a spectral window of 0.5 ppm. The three most similar reference spectra are shown in Figure 14, with the required line positions indicated in red.

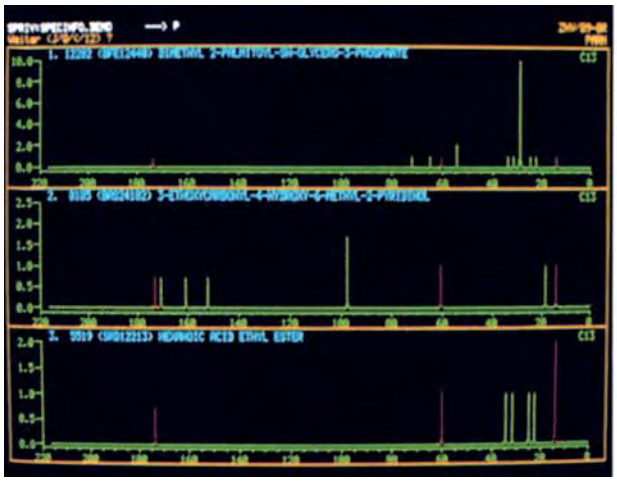

Fig. 14. The three most similar reference spectra, placed in order of increasing sum of the deviations of the chemical shifts. The signal combination required is entered in red, and the associated structures are shown in Figure 15.

More information is again provided by the associated structures (Fig. 15), which reveal that an ethyl ester could be involved. A survey of the situation is facilitated by the fact that, as a result of the assignment of the chemical shifts to the nodes of the topological matrix, the atoms with corresponding resonance frequencies can be made identifiable. In spite of this, the picture is confusing, because structures with purely random similarities at differing positions of the molecule also obscure the interrelationships. An effective suppression of this structural noise is possible by means of the partial structure analysis, as indicated in Section 8.

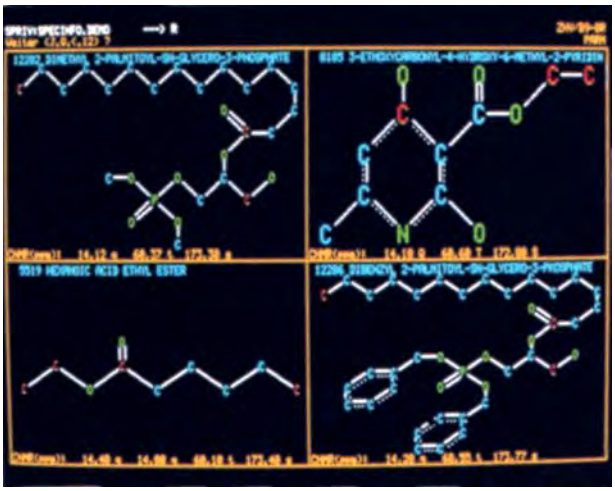

Fig. 15. The structures of the four most similar reference spectra (cf. Fig. 14) with a listing of the corresponding chemical shifts, and marking of the appropriate carbon atoms (in red).

The situation is even more difficult in IR and MS spectroscopy, where the association of spectral properties with defined structural components is possible only with difficulty. The search for IR spectra with band positions at 3305, 1255, 747, and 564 cm^{-1} (tolerance $\pm 5\ cm^{-1}$) furnishes the three most similar reference spectra shown in Figure 16. A comparison of the corresponding structures

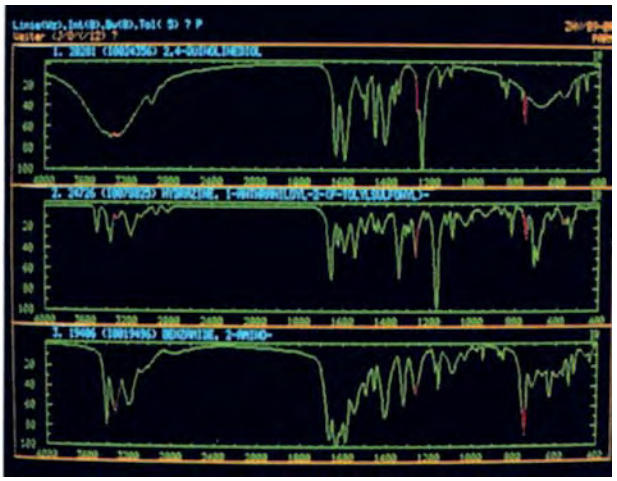

Fig. 16. The three most similar IR reference spectra, placed in order of increasing deviation of the band positions. The combination of four wave numbers which was sought is marked in red, and the associated structures are shown in Figure 17.

without marking of the common structural components is confusing (Fig. 17). In this instance, further help can be provided only by a computer analysis of the corresponding partial structures.

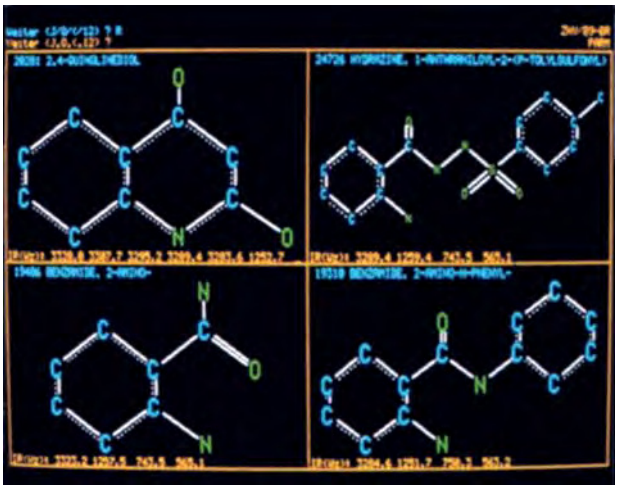

Fig. 17. The structures of the four most similar reference spectra (cf. Fig. 16) with a listing of the corresponding band positions.

8. Substructural Analysis

In substructural analysis, the structures which are found are broken down into their smallest components and are characterized in relation to their environment by means of the HOSE code (one to four spheres, according to choice). Accordingly, a topological matrix including 15 nodes would be converted into 15 HOSE codes and a specified number of HORD codes (*H*ierarchically *O*rdered *R*ing *De*scription) for the ring system. These data are generated for the desired number of structures (typically 20), combined and displayed in the form of a histogram (Fig. 18). Thereby, the information given in green (third column of figures) describes the statistical probability of finding the predetermined substructure in a total of 20 structures in the file. If the partial structure is observed more frequently (second column of figures), then the red coding exceeds the trivial standard frequency (green). This is the relevant information which defines the probability with which a specified partial structure should be present in the unknown compound, on the basis of the spectral similarities.

Fig. 18. Substructural analysis of the results of a search for ^{13}C-NMR reference spectra with the same spectral pattern (Fig. 14). The occurrence of the substructures set forth on the left-hand side is represented in the form of a histogram; in this case, the green information characterizes the standard frequency in the ^{13}C-NMR file, and the red symbols characterize the nodes going beyond that information in the data set. The first column of figures is the quotient of occurrence and standard frequency, which are then listed as individual values (second and third columns respectively).

Although far from being difficult, it is not necessary to understand the coding of the partial structures in order to use this method. The computer can indicate the substructures corresponding to the spectral patterns,[15] and can use the information in order to emphasize the conforming partial structures in the proposed structures (Figs. 15, 17) in color (Figs. 19, 20). The centers marked in red occur in 70%, and the centers marked in purple only in 35% of the best 20 reference structures. The presentation (Fig. 19) has now changed, and the structural interrelationships are more

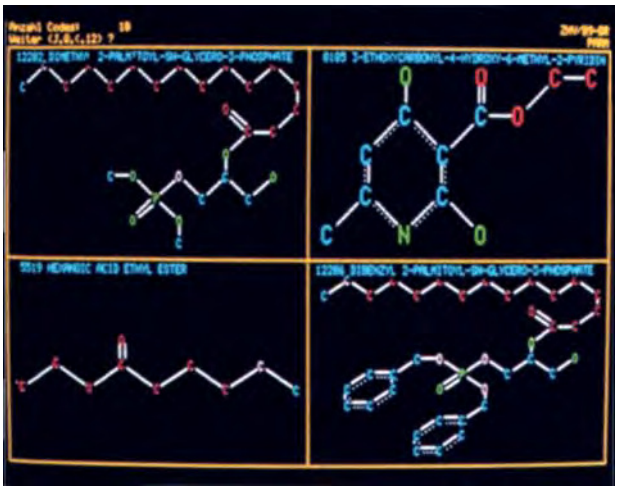

Fig. 19. Characterization of the most probable substructures on the basis of a partial structural analysis (Fig. 18, cf. Fig. 15). The most frequent nodes are marked in red, as are the bonds of the dominant ring systems. Less frequent, but significant structural components are shown in purple. The threshold magnitude for this presentation can readily be optimized in interactive dialog, in order to render the common structural elements visible.

Fig. 20. Marking of the most probable partial structures for the IR band search of Figure 16.

clearly emphasized. In the IR reference structures in particular (Fig. 20), it is now possible to discern very rapidly the common features and thus the probable structural components. There is certainly no need to add that the computer also "understands" the information which it can display, and can use that information in more extensive algorithms.

By means of the substructural analysis, it is therefore possible to convert spectral information into structural information, regardless of whether chemical shifts, band positions, masses, neutral losses,[15] couplings, splitting patterns, etc. are involved. The structural information obtained is unitary, normalized and computer-oriented. This has several advantages: it is possible to combine the results of various experiments and methods with one another. In "multidimensional spectroscopy",[15] each method contributes to the total result only with the statistically relevant, i.e. cogent findings. The structural noise is effectively suppressed. In the final proposed structure it is possible, by marking the particular methods concerned, to demonstrate which technique has confirmed which partial structural information.[15]

It is found thereby that ^{13}C-NMR spectroscopy and mass spectrometry are the most important for the elucidation of constitution, because they principally define the molecular skeleton, which the chemist usually regards as the principal characteristic of the structure. IR and ^{1}H-NMR spectroscopy, with their information about substituents and configuration, contribute to a refinement of the picture.

Following the concept of overlapping partial structures,[16] the partial structure codes may readily be combined into topological structures. Thereby, the feeding-in of additional information is permitted, and a combinatorial explosion during structure generation is restrained (see Section 9).

9. Intelligent Evaluation of Spectra

The expression "Artificial Intelligence" is defined in different ways by different authors. "Intelligence" is derived from the Latin intelligentia = concept, insight, understanding. "According to general understanding, intelligence is the superior capability (or a group of capabilities), which expresses itself in the grasping and creation of distinct and abstract relationships, and thus enables new types of situations to be coped with by problem-solving activity."[17] In this sense, the tools which we have considered so far are certainly "intel-ligent" and must simply be combined in order to solve new types of problems.

"Intelligent" systems normally possess a regulating mechanism (inference engine) and a knowledge base.[18] Let us now consider the previously discussed hypotheses from this point of view (Table 1). The library search requires a collection of reference spectra and operates on the basic principle that a relationship exists between spectrum and structure. Similar spectra should characterize similar structures, this being a simplified assumption which is not valid in all cases.

The similarity search is to a greater extent optimized with respect to the search for similar rather than identical compounds. As a matter of necessity, more degrees of freedom for deviations must be tolerated. Accordingly, in the sequential procedure *all* properties of the spectrum with respect to position, intensity, form and probability of their occurrence are compared.

Table 1. Various strategies for the elucidation of structure of differing intelligence and abstraction with the associated system of rules and knowledge base.

Method	Rule	Knowledge
Library search	Spectrum ↔ structure	Library of spectra
Similarity search	Spectrum ↔ structure	Library of spectra Tolerance
Interpretation	Partial spectrum ↔ partial structure	Rules of interpretation
Spectrum calculation	Shift ↔ chemical environment	$\delta = f(S)$
Structure elucidation	Shift ↔ chemical environment Chemical structures Spectroscopy	$S = f(\delta)$

This is implemented in an excellent way with the aid of assessment matrices (according to *Clerc* et al.[19]), but requires upstream relatively crude presearch algorithms (pre-

Fig. 21. Example of the combined interpretation of ^{1}H- and ^{13}C-NMR spectra. The possible basic structural components which were proposed on the basis of the first run may not, in this case, be unified into a consistent data set, because, apart from the ethoxy group, the partial structures which are present in the molecule have not yet been coded in the form of a rule.

liminary search and intermediate search[14]), in order to be able to undertake a search using large files containing over 50000 spectra within a reasonable time. This approach thus operates with spectroscopic expert knowledge, which defines, on the basis of experience, whether and what deviations can be tolerated. Thus, for example, the spectroscopist knows that in the ^{1}H-NMR spectra, in the event of a change of the solvent, triplets can be converted into doublets of doublets and acid protons are particularly strongly displaced. In similarity assessments, the computer should also apply this knowledge.

In the course of interpretation, subspectra are correlated with substructures. The knowledge base employed is a library of interpretation rules,[20] which define, for example, that the signals for an ethoxy group (in ethyl esters) occur in the ^{13}C-NMR spectrum at $\delta = 60.4 \pm 0.5$ (triplet) and $\delta = 14.2 \pm 0.5$ (quartet). Whenever this spectral pattern is observed, there is a high probability that an ethoxy group is present in the unknown structure, especially if further conditions, such as ^{1}H-NMR resonances at $\delta = 4.1 \pm 0.2$ (quartet, intensity 2) and 1.2 ± 0.2 (triplet, intensity 3) are fulfilled. By way of example, Figure 21 (see preceding page) shows the search for 4,6,6-trichloro-7,7,7-trifluoro-3,3-dimethylheptanoic acid ethyl ester as a fictitious unknown substance. The list of the proposed structural elements contains essential fragments of the structure sought, placed in order of decreasing probability. In a second run, the list is again processed sequentially and examined for consistency, i.e. each ^{13}C-NMR resonance may be documented only once in the correlation. In contrast to the cited instructional examples,[20] in the case of this unusual structure it is very difficult to compose the unknown from the results. The method has three essential disadvantages:

- The partial structures are predefined in the file, and only these substructures can be found by the computer. In view of the variety of feasible structural elements, the number of the presently used 1500 rules is certainly too small, but will, in practice, never become large enough. The method of substructural analysis described in Section 8 is certainly the more flexible and more promising.
- The rules were coded to a large extent manually, with reliance upon the reference spectra. This laborious process has to be periodically repeated, in order to reflect the latest state of knowledge (= the library of spectra). Rules[21] derived purely by fully automatic means from a structure-oriented library of spectra will exist in the future. This is especially true in the case of IR spectroscopy and mass spectrometry, where the relationships between partial structures and partial spectra are very complex and can be made visible only by statistical processing of the spectral material (cf. program package IDIOTS[21]).
- The probable structural fragments must be brought together by hand. As a rule, this task is time-consuming and should therefore be transferred to a computer (see Section 10). On the other hand, the expression "substructure" does not have a precise definition, and the translation of the topological fragments, which in some cases are large, in some cases small and in some cases imprecise, into the language of the structure generator presents difficulties.

While the computer interpretation yields essentially structural concepts within the meaning of "brain storming", the estimation of spectra in NMR spectroscopy is a relatively precise method. We are now at the highest level of abstraction, and, as a rule, correlate chemical shifts with chemical environments. The knowledge base, which is an index file storing the mean resonance frequencies for all chemical environments which are present, is generated entirely automatically from the spectral file, and in all cases reflects the latest state of knowledge. The application of this has already been described (Figs. 10 and 11).

The reverse process, i.e. the elucidation of structure, is the dream of the chemist and has been accomplished only in some areas. The knowledge base required in this instance is the inverted information, where, for each chemical shift, all associated chemical environments are stored. Finally, such a strategy should also take into account the basic rules of structural chemistry and spectroscopy, principally for the purpose of permitting an effective combination of the multidimensional information.

10. Fully Automatic Structure Elucidation

The essential basic components and the flow of information of a system for automatic elucidation of structures are presented with reference to the example of the program package ACCESS[16] (= *A*utomatic *C*omputer *C*orrelation and *E*valuation of *S*pectra based on *S*ubstructures) (Figs. 22 and 23). The spectral parameters (chemical shift, multiplicity, intensity, coupling) of an unknown compound are analyzed and compared with the substructure file $S = f(\delta)$. The overall formula, which can readily be obtained (especially when the number of C atoms is known) from high-resolution mass spectra, serves to eliminate substructure codes on the basis of the elemental composition. Thus, for example, there is no need to consider any $SiCH_3$

Fig. 23. Example of an automatic structure elucidation (① through ⑤) using ACCESS. The version of the program currently available cannot yet discern that, because of the interaction with the adjacent chlorine, C_9/C_{10} should exhibit different chemical shifts. A feature worthy of note is the rapid convergence of the program in only 25 s CPU.

groups, if, according to the mass spectrum or elemental analysis, no silicon is present. Alternatively, aromatic groups can be ruled out, if only three double bonds/rings are permitted on the basis of the number of hydrogen atoms.

All topologies which are at all feasible are now constructed from the partial structures which have been collected and ranked in order of their probability. With increasing molecular size and/or number of hetero atoms and double bonds, there is a combinatorial explosion, so that the hierarchical tree must be pruned at an early stage, in order to facilitate convergence. The best way for this to happen is by means of the inclusion of additional measurement results, for example by substructural analysis of the library search results in IR or MS.[15] In addition, a knowledge of the chemical reaction and the reaction partners can play an important role. In a similar way to the procedure in synthesis planning with the computer, the chemist can observe the progress of the program and take assisting action, if "nonsensical" proposals appear. Since, from the point of view of the computer, there are no nonsensical proposals, great care is required here in order to prevent wishful thinking from falsifying the information provided by the unbiased "interlocutor." However, if there is a lack of information, then the computer should be able to take account of this knowledge of the human partner.

Furthermore, it becomes evident that additional controlled experiments increase the probability of individual substructures and give these pre-eminence over the structural noise. By this means, the convergence is accelerated, and the result becomes clearer. Accordingly, it is a good idea to carry out, in advance, a library search with subsequent substructural analysis using the same data. The library search sees the spectral features in combination, and can therefore deliver more specific structural information.

The spectra of all structures proposed by the computer are computed with the aid of the shift-range file and compared with the experimental data. This generates a list—ranked in order of probability—of candidate structures, which is examined once again for conformity with the overall formula. Structures exhibiting a large deviation between computation and experiment are discarded. A

detailed inspection of the most probable structures frequently shows that further measurement data are necessary in order to achieve final clarification.

Figure 23 illustrates the progress of an automatic structure elucidation (using ACCESS) regarding the example of 4,6,6-trichloro-7,7,7-trifluoro-3,3-dimethylheptanoic acid ethyl ester. When the overall molecular formula ① has been entered, the computer determines the number of double bonds or rings. If desired, the results of other search procedures can be incorporated ②, and in this case a library search was carried out with reference to the Hash code (SAHO = *S*pectral *A*ppearance in *H*ierarchical *O*rder[14,22]) and the partial structures found were assigned a probability of 0.8 ③.

At this point, the actual search begins in an index file of the ^{13}C-NMR shift ranges for 240000 partial structures, generated from 84000 data sets of ^{13}C-NMR spectra with topological structures. The starting line position for the assembly of the structural components determined, with the aid of the structure generator, is selected by the computer itself ④. The line at $\delta = 122.4$ with the large coupling to F is clearly the most characteristic. In a first rapid run with only eight substructure codes per line, only part of the molecule is built up; some basic structural components important for a convergence are still absent. This coarse testing procedure is comparable with the "lightning chess setting" with commercial chess computers, where a superficial assessment permits a rapid overview of the complexity of the problem.

The computer switches over automatically to detailed processing of the problem with 16 substructures in each instance and a minimum probability of 1.0. Now two proposed structures follow, the second of which was discarded, on account of the great deviation (4.7 ppm) between computation and experiment. After 2 K cycles, i.e. 2000 unsuccessful attempts to synthesize a new structure, the computer went through all possibilities and interrupted its evaluation with a compilation of the result ⑤. The structure sought was correctly predicted; the alternative can readily be ruled out, on account of the resonance of C11.

11. Structural Similarity

The question of the similarity of chemical structures cannot be answered in general terms, since it is dependent upon the content of the query. Thus, the materials chemist, the pharmacist and the spectroscopist, for example, classify entirely different molecules as similar. Even the spectroscopists who are frequently specialists in one method view structural differences in relation to the distinguishing capability of their technique, and will accordingly weight similarities differently. However, a measure of structural similarity/dissimilarity as a function of the method is important, in order to select the correct experiment when additional information is required, and to take the necessary decision between alternative structures.

The basic molecular components which are most important and in most cases unchanged in syntheses are the ring systems. Ring searches[22] and the inclusion of the HORD (*H*ierarchically *O*rdered *R*ing *D*escription) ring code in the partial structural analysis[16] are necessary strategies. In the case of condensed ring systems, the CAS ring index is available, which, in modified form, is employed as a search criterion.[22] However, an analysis of the given structure from the standpoint of its characteristic fundamental components is promising. These are predefined in a library as short codes[24] and can be assessed on a basis specific to the method concerned.

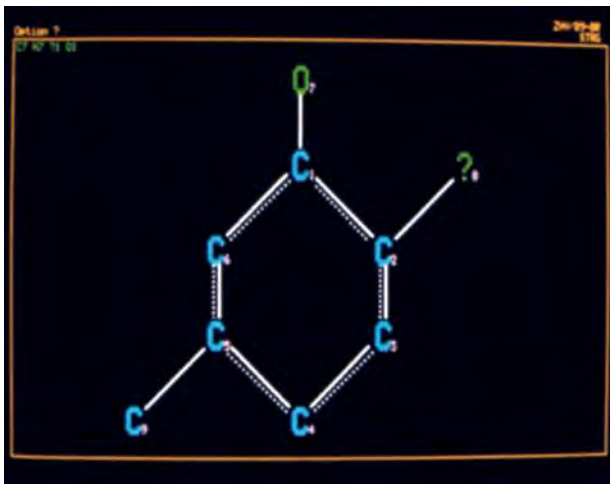

Fig. 24. Query in respect of a search for similar structures with an open substituent.

Fig. 25. Short codes [24] of a search criterion for the query in Figure 24. This control list can be edited by the experienced user prior to the search, i.e. it can be supplemented or abbreviated. Entries marked in red are already included in preceding, more specific short codes, and are therefore not taken into account in the search.

Figures 24 and 25 illustrate the procedure. The target structure 3-methylphenol with an unknown substituent in position 5 is entered and subjected to a fragment analysis

(at the present time, 240 fragments are employed). Figure 25 shows the required fundamental molecular components and their occurrence in the structure database.

The entries marked in red are redundant, because they are already included in the preceding data set, and are not searched. The resulting similar structures are shown in Figure 26. Since, at the present time, the procedure has been optimized for IR spectroscopy, all these compounds exhibit similar IR spectra, in spite of the dramatic differences in composition and constitution.

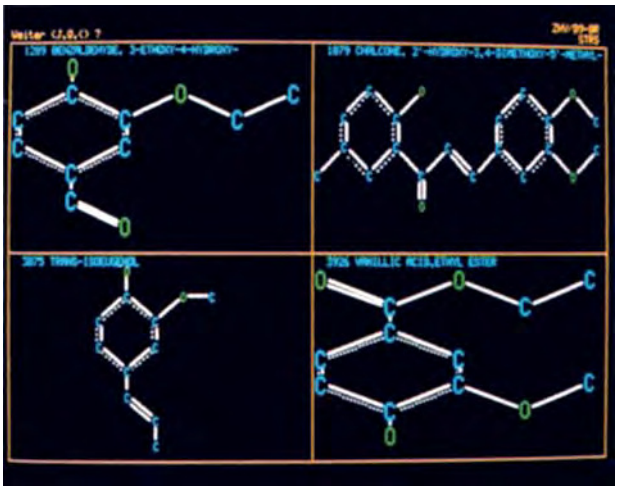

Fig. 26. Four structures which satisfy the query in Figure 24 and the automatically generated short codes in Figure 25.

12. Outlook

In spite of the difficulties which intelligent systems had in the past and still have in the interpretation of spectra, there is justification for the hope that, after the recording of spectra, they will also revolutionize the evaluation of spectra. Accordingly, in conclusion, the outlook for future development should be permitted; this might, indeed, become reality in the course of the next 5 years.

Figure 27 shows the flow of information in a spectroscopy laboratory of the future. The computers at the chemists desks are connected via LAN to the spectroscopy laboratory; the chemists send their requested analysis, including a proposed structure, direct to the Information Management System of the laboratory. Depending upon the set task and capacity, the appropriate system is selected and the sample required for the experiment is requested. After the measurement, the spectrometer checks whether the results are in accord with the structure. If so, the person requesting the investigation receives confirmation and, if desired, the spectrum as well, which he can copy into his electronic laboratory journal. If the quality standards are complied with, the data set is completed and included in the databank as knowledge base.

If discrepancies are observed between experiment and computation, the central information system SPECINFO[25] makes proposals of alternative structures, which are sent to the chemist for examination and possibly confirmed by measurements which are automatically set up. In this case, it is recommended that experiments should be carried out on the same spectrometer, since then there is no need for the sample to be transported (see Section 2). Only if the system still fails to converge must the human expert intervene and tackle the problem in partnership with the not very "creative," but extremely "hard-working" and "well-read" computer.

As has already been mentioned, a proportion of this great knowledge and experience should be transferred to a special program, which is present in the spectrometer and can directly take intelligent decisions.

The knowledge base is of decisive importance to the level of performance of the entire system. It should at the same time be broadly based and optimized for the specific problems of the working group, i.e. it should combine commercially available databanks and the organization's own measured data.

A brief overview of the commercially available reference data is given in Reference [20]. An important factor from the point of view of small laboratory units is the facility of access to ^{13}C-NMR, IR,[26] and MS databanks[27] and the corresponding expert systems via telecommunication, even though joint application with company internal information and specialist chemistry is not possible. A good compromise is frequently offered by the dedicated systems which are installed on minicomputers and which, in some cases, are supplied by instrument manufacturers directly as components of the analysis systems and, in some cases, can also be used on desk-top computers of the IBM PC type.[28] The level of performance of the programs and data files is, however, a very variable factor.[29]

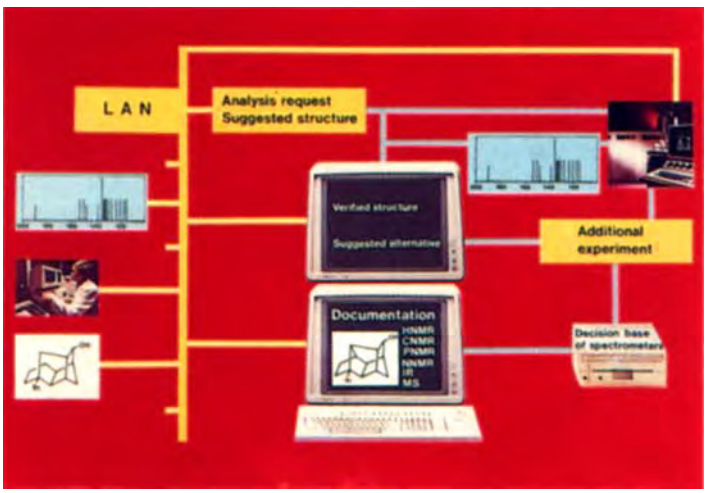

Fig. 27. Flow of information in a spectroscopy laboratory of the nineties. The individual components are essentially already available, and simply need to be combined into an operational system.

In future, increasing emphasis must be placed on the quality of these data, since erroneous data file entries lead to incorrect predictions. As *Lem* mentioned in the introduction, intelligent systems have a tendency to become independent. We shall certainly continue to experience

many, hopefully pleasant surprises while working with computers (Fig. 28).

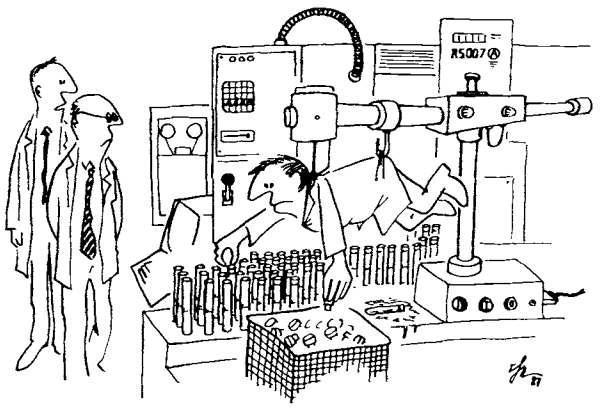

Fig. 28. "We were able to remove some initial difficulties this way."

Such an ambitious project can be pursued only in close cooperation with committed colleagues, who all made a decisive contribution to the present-day level of performance of the entire system: M. Beckmann, W. Fachinger, Prof. Dr. J. Gasteiger, A. Hardt, C. Heistermann, C. Köhler, Dr. R. Neudert, Dr. M. Passlack, R. Rupprecht, C. Schäfer, H. Wagner, and F. Wolf. We wish to express our gratitude to the research management of BASF, Prof. Dr. H. Dörfel, Dr. U. Schenck, and Dr. H. W. Schmidt, for their continuous support, and to the Bundesministerium für Forschung und Technologie and the Fachinformationszentrum Energie, Physik, Mathematik GmbH (FRG) for their financial support over many years.

$[\{Hg_3Co(C_4H_6NO)_6\}(NO_3)_2]_n$: A Macrobicyclic Bimetallic Chain Polymer Incorporating Deprotonated 2-Pyrrolidone Bridges**

By *David M. L. Goodgame,* David J. Williams,** and *Richard E. P. Winpenny*

Recently we have reported the discovery and structural characterization of complex **1**,[1] an exciting new bimetallic cationic polymer comprising contiguous 32-membered macrocycles containing Hg and Cu atoms linked by 2-pyrrolidone anions, $C_4H_6NO^{\ominus}$, and with either $NO_3^{\ominus}$ or $ClO_4^{\ominus}$ as counterions. In **1** the geometry about the Cu atom can formally be described as a severely tetragonally distorted octahedron, the $ClO_4^{\ominus}$ or $NO_3^{\ominus}$ ions being only weakly coordinated in the axial positions. We thus considered it important to investigate the influence of replacing Cu by a metal ion preferring a more rigorously octahedral geometry, e.g., Mn, Fe, Co, or Ni. To this end we have prepared an analogous Co^{II} complex, **2**,[2] though its stoichiometry differs notably from that of the Cu^{II} complex **1**. As **2** was readily obtained as good single crystals, an X-ray analysis has been carried out[3] to establish the structure of this complex and the implications of the different stoichiometry.

$[\{Hg_2Cu(C_4H_6NO)_4\}X_2]_n$ **1**, $X = NO_3^{\ominus}, ClO_4^{\ominus}$
$[\{Hg_3Co(C_4H_6NO)_6\}(NO_3)_2]_n$ **2**

The analysis has revealed the structure of **2** to be dramatically different to the contiguous 32-membered macrocyclic structure of the Cu complex **1**. Here we have a macrobicyclic chain polymer (Fig. 1). Each link of the chain is comprised of two interlocking 16-membered rings, each containing two Co, two Hg, four C, four N, and four O atoms. Alternatively, each link may be visualized as a 16-membered macrocycle with an additional $Hg(C_4H_6NO)_2$ central strut connecting adjacent Co atoms. The structure is highly symmetric, with both the Co and Hg atoms that form the central backbone lying on crystallographic centers of symmetry.

There are two nonequivalent Hg environments. One-third of the Hg atoms lie on the backbone and are centrally disposed with respect to adjacent pairs of Hg and Co atoms.[4] The remainder lie on the exterior of the chain and loosely bind the $NO_3^{\ominus}$ counterions.[5] This interaction is reflected in a noticeable bending of the associated N-Hg-N unit (175.1(2)°; cf. 180° for the central N-Hg-N units).[6]

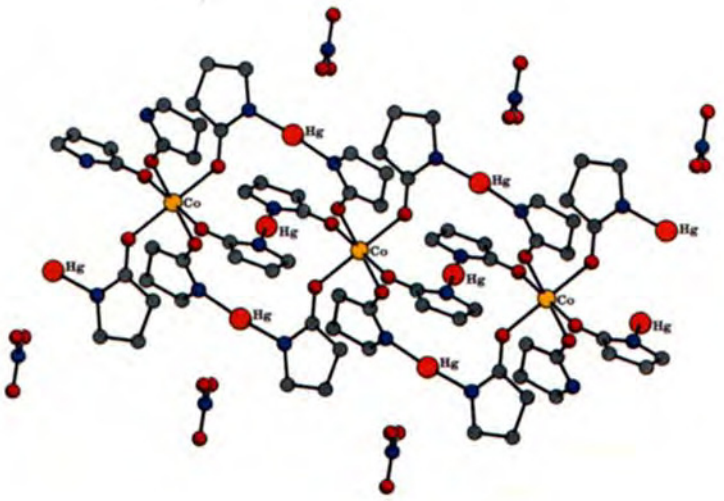

Fig. 1. Part of the contiguous macrobicyclic chain polymer formed by **2** in the crystal.

The polymer chains are not cross-linked; they are parallel[7] and lie along the crystallographic *a* direction. The $NO_3^{\ominus}$ ions are similarly aligned, occupying columns between the polymeric cations.

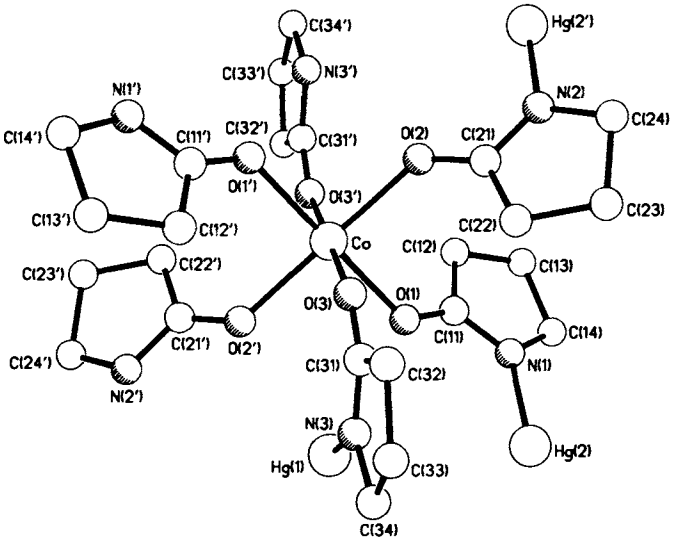

Fig. 2. The structure of **2** in the crystal. Selected bond distances and angles: Co-O(1) 2.122(5), Co-O(2) 2.120(5), Co-O(3) 2.052(7) Å; O(1)-Co-O(2) 89.8(2), O(1)-Co-O(3) 87.0(2), O(2)-Co-O(3) 94.4(2)°. O(3) is the oxygen of the 2-pyrrolidone unit that forms the central strut in the polymer chain (see Fig. 1).

As expected, the Co coordination geometry closely approaches a regular octahedron (Fig. 2). There are, however, some significant small deviations associated with Co-O bonds to the ligands that form the central strut of the chain. These result in a small axial compression as well as a slight angular distortion. This has no noticeable effect, however, on the electronic spectrum of the complex, which

[**] This work was supported by the Science and Engineering Research Council.

is unexceptional.[8] Previously[1] we considered the possible application of the polymeric complex **1** in anion exchange. Here the exclusion of nitrate from the coordination sphere of the Co leads to the anion being even more loosely bound. Also its confinement to channel-like domains in the crystal offers the potential for diffusion. Experiments to investigate this possibility are being undertaken.

[1] D. M. L. Goodgame, D. J. Williams, R. E. P. Winpenny, *Angew. Chem. 99* (1987) 1053; *Angew. Chem. Int. Ed. Engl. 26* (1987) 1044.

[2] *Experimental Procedure:* $Hg(C_4H_6NO)_2$ was made by dissolving $Hg(OAc)_2$ (2 mmol) and 2-pyrrolidone (4 mmol) in a minimum volume of methanol and reprecipitating with diethyl ether. The precipitate was then dissolved with hydrated $Co(NO_3)_2$ (1 mmol) in methanol (25 mL) and the pink solution allowed to evaporate at room temperature. Small pink, air-stable crystals for X-ray analysis formed after 3 d, yield 70%, m.p. = 170–174 °C (dec.). The compound gave a satisfactory elemental analysis. The compound was soluble in water but insoluble in dimethylformamide, alcohols, and other common organic solvents. X-ray powder diffraction photographs show the Cd^{II} homologue to be isostructural, but the Ni^{II} compound is not. To date, crystals of the latter of suitable quality for X-ray structure analysis have not been obtained.

[3] **2**: Triclinic, $a = 7.476(2)$, $b = 11.040(3)$, $c = 11.383(3)$ Å, $\alpha = 64.39(2)$, $\beta = 77.45(2)$, $\gamma = 81.95(2)°$, $V = 825$ Å^3, $P\bar{1}$, $Z = 1$, $\mu(Cu_{K\alpha}) = 310$ cm^{-1}, $\rho_{calcd} = 2.59$ g cm^{-3}. Nicolet R3m diffractometer, ω-scan, graphite-monochromated $Cu_{K\alpha}$ radiation. The structure was solved by the heavy-atom method, corrected for absorption, and refined anisotropically to give $R = 0.032$ ($R_w = 0.034$) for 2061 independent observed reflections [$\theta \leq 58°$, $|F_o| > 3\sigma(|F_o|)$]. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, Lensfield Road, Cambridge, CB2 1EW (England), by quoting the full literature citation.

[4] The central chain Co···Hg distances are 3.74 Å and the "interior" to "exterior" Hg···Hg contact distances are 3.62 Å.

[5] The approach distances of the $NO_3^{\ominus}$ oxygen atoms to the "exterior" Hg atoms in **2** are very similar to those of the $NO_3^{\ominus}$ and $ClO_4^{\ominus}$ oxygen atoms to the Hg atoms in the Cu^{II} complex **1**, with Hg(2)···O(5) = 2.855 and Hg(2)···O(4) = 2.733 Å. Interestingly, whereas all three O atoms of the $NO_3^{\ominus}$ ion in the Cu^{II} complex are involved in interactions to Hg, here only two interact.

[6] Hg(1)-N(3) = 2.041(9), Hg(2)-N(1) = 2.041(8), and Hg(2)-N(2) = 2.010(9) Å.

[7] The closest inter-polymer contact is 3.23 Å between O(6) (the nitrate oxygen not bound to Hg(2)) in one chain and C(23), a pyrrolidone carbon, in the next.

[8] Electronic spectrum of **2** by reflectance technique (Beckmann DK2 spectrometer): $\lambda = 7580$, 14000, 18520 cm^{-1}. The magnetic moment (5.1, Gouy method) and infrared spectrum of the complex are unexceptional. NMR spectrum of **2** recorded in D_2O (JEOL FX90 spectrometer) shows breakdown of the complex giving $Hg(C_4H_6NO)_2$ and $[Co(H_2O)_6]^{2\oplus}$. Interestingly, the Cu^{II} complex **1** did not dissolve in D_2O.

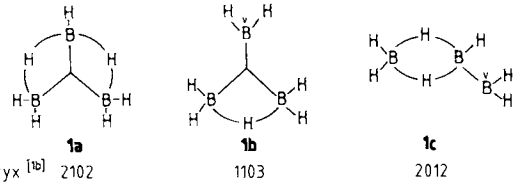
B_6H_{14}, a Dimeric B_3H_7?**

By *Bernd Brellochs* and *Herbert Binder**

The higher boranes B_4H_{10}, B_5H_9, B_5H_{11}, and $B_{10}H_{14}$ are usually prepared by pyrolysis of B_2H_6.[1] During the course of these complex reactions, the highly reactive, unstable molecules BH_3, B_3H_7, B_4H_8, and B_3H_9 are formed; with the exception of the latter species, however, they have only been identified so far by mass spectroscopy.[2] We found that the oxidation of $B_3H_8^{\ominus}$[3] with I_2 in inert solvents below −40 °C is a simple way to prepare "B_3H_7" in situ [Eqs. (a) and (b)]. The counterions are $NEt_4^{\oplus}$ or $PPh_4^{\oplus}$. B_3H_7 **1** may be described by the valence structures shown in Scheme 1.

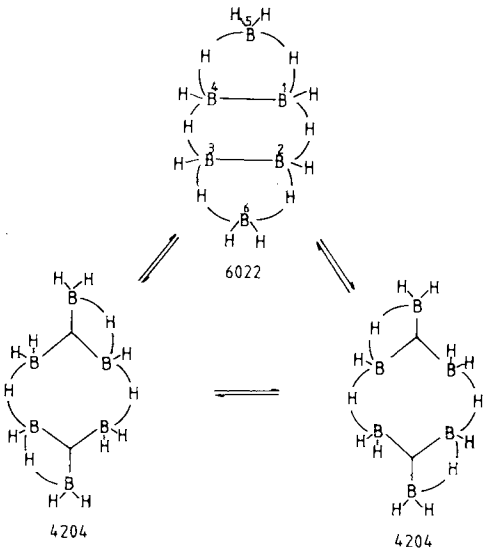
$$B_3H_8^{\ominus} + I_2 \longrightarrow B_3H_7 + HI + I^{\ominus} \quad (a)$$

$$B_3H_8^{\ominus} + HI \longrightarrow B_3H_7 + H_2 + I^{\ominus} \quad (b)$$



Scheme 1. Valence electron structures for B_3H_7 **1**. s = number of hydrogen bonds; t = number of closed two-electron three-center bonds; y = number of B-B bonds; x = additional H atoms on boron; v = free orbital.

Calculations have shown[4] that **1a** is 4.4 and 7.4 kcal mol^{-1} more stable than **1b** and **1c**, respectively; accordingly, a fluxional process is expected between **1a** and **1b**. The ^{11}B-NMR spectrum (28.88 MHz) of a solution of "B_3H_7" in CH_2Cl_2 consists of two broad, separated signals at $\delta = -10.7$ and -30.4 (intensity ratio 2:1, half-widths 180 and 172 Hz, respectively, the region of tetracoordinated boron atoms). In the $^{11}B\{^1H\}$-NMR spectrum, the half-widths of the two signals are reduced to 68 and 80 Hz, respectively. This indicates ^{11}B-^1H coupling. The ^1H-NMR spectrum (400 MHz) of "B_3H_7" in CD_2Cl_2 at −50 °C exhibits only one broad unresolved signal at $\delta = 1.38$, overall half-width 130 Hz. In the case of monomeric B_3H_7, the dynamics of the H atoms should result in the three B atoms being magnetically equivalent, in analogy to those in $B_3H_8^{\ominus}$;[5,6] thus, only one signal should be observed in the ^{11}B-NMR spectrum. The small difference in energy between **1a** and **1b**, as well as the electron sextet in **1b**, suggests that "B_3H_7" is stabilized through hydrogen bonds as B_6H_{14} **2**. The analogy to the dimerization of BH_3 to B_2H_6 is readily apparent. B_6H_{14} is formally a member of the series of *hypho*-boranes B_nH_{n+8}, whose structures may be described in terms of *Wade*'s rules with (2n + 8) skeleton electrons.[7] The examples of this class of compounds so far known are B_8H_{16}, $B_{10}H_{18}$,[8] $B_{14}H_{22}$, and $B_{15}H_{23}$;[9] the latter two examples are probably "*conjuncto*-boranes."



Scheme 2. Valence structures for B_6H_{14} **2**. The "styx" values are given once again for each structure (see caption to Scheme 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Bayer AG for the donation of chemicals.

Scheme 2 shows the probable valence structures of **2**, which would also explain the 2:1 ratio of intensities found in the ^{11}B-NMR spectrum: $B^1B^2B^3B^4 \neq B^5B^6$.

Two further observations support this interpretation. (1) The ^{11}B-NMR spectrum is independent of the solvent employed; this rules out an interaction between B_3H_7 and the solvent. (2) Since $NEt_4^{\oplus}I^{\ominus}$ precipitates in the synthesis carried out according to (a) and (b), $B_3H_7I^{\ominus}$ can also be ruled out as a product. Determination of the molecular weight by means of vapor-pressure depression, however, is not useful owing to partially dissolved $NEt_4^{\oplus}I^{\ominus}$.

Another route to **2** is via $Cl^{\ominus}$ abstraction from $B_3H_7Cl^{\ominus}$[10] with $AlCl_3$ at -45 °C in CH_2Cl_2 [Eq. (c)]. Com-

$$NEt_4^{\oplus}B_3H_7Cl^{\ominus} + AlCl_3 \longrightarrow 1/2\ \mathbf{2} + NEt_4^{\oplus}AlCl_4^{\ominus} \qquad (c)$$

pound **2** cannot be isolated from the reaction solution, however, since it decomposes upon removal of the solvent or above -40 °C to give B_4H_{10} and B_5H_9 along with H_2 [Eq. (d)]. The low stability of **2** might be due to the relatively large number of hydrogen bonds.

$$3/2\ \mathbf{2} \longrightarrow B_4H_{10} + B_5H_9 + H_2 \qquad (d)$$

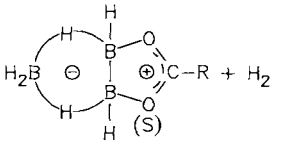
Compound **2** reacts with a series of Lewis bases at -78 °C to give the B_3H_7 adducts **3**[11] [Eq. (e)]. L–BH_3 adducts are not observed. Compound **2** reacts with some carboxylic and thiocarboxylic acids at -45 °C within a few minutes to give exclusively the bicyclic compound **4** [Eq. (f)]. (For R = Ph, it was possible to characterize **4** by an X-ray structure analysis.[12]) $NEt_4^{\oplus}BH_4^{\ominus}$ reacts with **2** to form the starting compound $NEt_4^{\oplus}B_3H_8^{\ominus}$ [Eq. (g)].

$$\mathbf{2} + 2\,L \longrightarrow 2\,L\text{–}B_3H_7\ \mathbf{3} \qquad (e)$$

L = NH_3, NMe_3, PPh_3, THF, CH_3CN

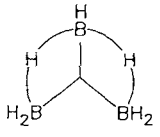
$$1/2\ \mathbf{2} + RCOOH\ (CH_3COSH) \longrightarrow \mathbf{4} + H_2 \qquad (f)$$

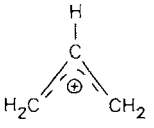
R = H, CH_3, C_2H_5, Ph



$$\mathbf{2} + 2\,BH_4^{\ominus} \longrightarrow 2\,B_3H_8^{\ominus} + B_2H_6 \qquad (g)$$

Examples (e)–(g) show that **2** presumably contains the original B_3H_7 fragments and that the linking hydrogen bonds are the reactive positions. Of particular interest is the fact that B_3H_7 can be viewed as an isoelectronic system to the allyl cation $C_3H_5^{\oplus}$ and, like this, can therefore function as a ligand in metal complexes.[13]





Experimental Procedure

a) $NEt_4(B_3H_8)$ (204 mg, 1.2 mmol) was added to a suspension of I_2 (152 mg, 0.6 mmol) in 2 mL of CH_2Cl_2 ($CHCl_3$, $C_2H_4Cl_2$, $MeNO_2$, $nPrNO_2$, or toluene) at -40 to -50 °C [14]. H_2 evolved and NEt_4I precipitated. After 1 h, only **2** was observed in the solution by ^{11}B-NMR spectroscopy. With $PPh_3(B_3H_8)$, soluble PPh_4I was formed, but **2** as well, as shown by the ^{11}B-NMR spectrum.

b) $NEt_4(B_3H_7Cl)$ (682 mg, 4 mmol) was added to a suspension of $AlCl_3$ (534 mg, 4 mmol) in CH_2Cl_2 (10 mL) at ca. -45 °C. After 6 h, only signals of **2** were still observable in the ^{11}B-NMR spectrum.

A New Type of Unsaturated *triangulo* Transition-Metal Cluster and Homogeneous Catalyst

By *Hans-Jürgen Haupt,* Peter Balsaa,* and *Ulrich Flörke*

The synthesis of $[Re_3(CO)_6(\mu_3\text{-}H)_2\{\mu\text{-}P(C_6H_5)_2\}_3]$ **2**, which has 44 cluster valence electrons (CVE), closes the gap between transition-metal clusters with 48 and 46 CVE, on the one hand, and those with 42 CVE, on the other (Fig. 1). Numerous examples of clusters with 48 CVE (three covalent M–M bonds) are known (e.g., $[M_3(CO)_{12}]$, M = Fe, Ru, Os). Those with 46 CVE (one double and two single bonds) are exemplified by at least $(NEt_4)[Re_3(CO)_9(\mu\text{-}H)_4(L)]$, L = $P(C_6H_5)_3$, C_5H_5N,[1] and $[Co_3(\mu_5\text{-}C_5Me_5)_3(\mu_3\text{-}$

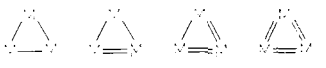

Fig. 1. Cluster valence electrons (CVE) in trinuclear transition-metal clusters fulfilling the 18-valence-electron rule for transition-metal atoms M.

$CO)_2]$.[2] An example of those with 42 CVE (three double bonds) is provided by the Re_3X_9 structural unit (X = Cl, Br, I).[3]

However, cluster **2** is not only of theoretical interest for understanding the bonding in clusters with metal-metal multiple bonds,[4] but is also of interest as a potential hydrogenation reagent. Of particular interest would be its possible suitability as a homogeneous catalyst.[5]

Cluster **2** may be prepared from the dirhenium starting clusters $[Re_2(CO)_8(PPh_3)_2]$, $[Re_2(CO)_8(\mu\text{-}H)(\mu\text{-}PPh_2)]$,[6] and $[Re_2(CO)_8(\mu\text{-}PPh_2)_2]$. To this end, the two phosphido-bridged starting clusters must be subjected to thermolysis, while, for the nonbridged starting cluster, hydrogenolysis at 210 °C proved successful [Eqs. (a)-(c)]. The two products

$$[Re_2(CO)_8(PPh_3)_2] + H_2 \rightleftharpoons 2[HRe(CO)_4PPh_3] \quad (a)$$

$$3[HRe(CO)_4PPh_3] \xrightarrow{-3CO} 3\,PhH + [Re_3(CO)_9(\mu\text{-}PPh_2)_3] \quad (b)$$

1, 48 CVE

$$[Re_3(CO)_9(\mu\text{-}PPh_2)_3] + H_2 \xrightarrow{-3CO} [Re_3(CO)_6(\mu_3\text{-}H)_2(\mu\text{-}PPh_2)_3] \quad (c)$$

2, 44 CVE

1 and **2** were identified by means of single-crystal X-ray structure analysis,[7,8] while the existence of the μ_3-hydrido bridge in **2** was shown by ^{1}H-NMR spectroscopy.

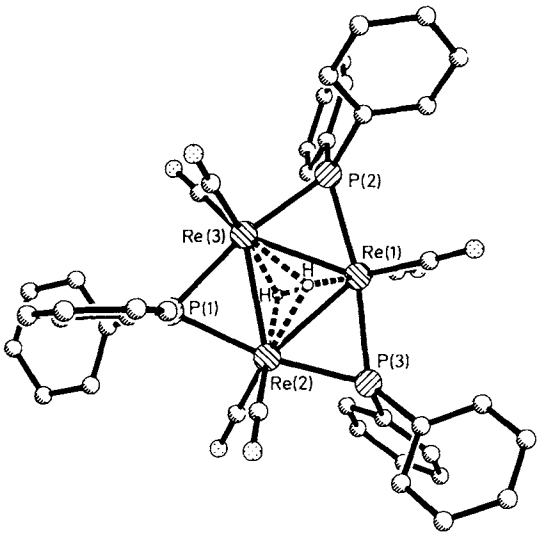

Fig. 2. Molecular structure of **2**.

Cluster **2** (Fig. 2) exhibits three comparable Re-Re bonds with multiple-bond character. This indicates that the four π electrons in the rhenium three-membered ring are not localized as shown in Figure 1. The double-bond character of the Re-Re bonds in **2** is clearly revealed by comparison of the Re-Re bond lengths of Re clusters having different CVE (Table 1) (compare also the values for Re-Re double bonds in Ref. [9]). The consequences of the short Re-Re bonds include a reduction in the Re-(μ-P)-Re bond angle by 3(1)° and a reduction in the Re-(μ-P) bond lengths. An alternative description of **2** as a system with two π electrons (analogous to the cyclopropenyl cation), which would correspond to a formulation as $[Re_3(CO)_6(\mu\text{-}PPh)_2)_3]^{2\oplus}\,2\,H^{\ominus}$, is considered less likely on the basis of the ^{1}H-NMR data, the estimated Re-H bond lengths,[8] and the behavior of **2** as a nonelectrolyte in dichloromethane.

Table 1. Selected bond lengths [pm].

Compound	CVE	d(Re-Re)	d(Re-(μ-Y))	Ref.
1	48	291.4(4) [a]	2.422(20) [b]	[7]
2	44	273.0(1)	2.369(6) [b]	[8]
$[Re_3(CO)_9(PPh_3)(\mu\text{-}H)_4]^{\ominus}$	46	279.7(1) [c]	2.481(2) [d]	[1]
		319.3(1)		
		323.4(1)	1.84 [a, e]	

[a] Mean value; [b] Y = P; [c] d(Re=Re); [d] d(Re−PPh$_3$); e) Y = H.

Phosphido bridging, such as that observed in **2**, has recently been used quite often in order to hold metals together stably.[4,10] Preliminary experiments to determine the homogeneous-catalysis properties of **2** (hydrogenation of cyclohexene in tetrahydrofuran) gave TON values [cycles h^{-1}] of 63 (20 °C) and 285 (60 °C).[11] Analysis of the activation energies of hydrogenations with these and other soluble hydridorhenium complexes will establish the prerequisites for the determination and evaluation of the catalytic activity of different types of hydrido complexes.

Experimental Procedure

Hydrogenolysis: A solution of $[Re_2(CO)_8(PPh_3)_2]$ (0.5 g, 0.45 mmol) in dry xylene (9 mL) was placed in a steel autoclave; hydrogen was then admitted at room temperature until a pressure of 2×10^5 Pa was obtained. The reaction was complete after 4 d at 210 °C. The products were separated by means of thick layer chromatography (eluant $CHCl_3$/*n*-hexane 3 : 2). **1** (0.02 g, 5%) was isolated from the red fraction and **2** (0.1 g, 26%; dec. >250 °C) from the orange-red fraction. Analytical data for **2**: $M^{\oplus}$(^{187}Re) = 1268 (150 °C vaporization temperature; 70eV-EI-MS; IR ($\tilde{\nu}_{CO}$, KBr): 1974 (s), 1938 (s) cm^{-1}; NMR ($CDCl_3$): ^{31}P{^{1}H} (standard H_3PO_4): δ = 198.2 (s, μ-P); ^{1}H: δ = 7.45 (m, 30 H, Ph), −18.20 (q, 2 H, μ_3-H), J(PH) = 7.3 Hz. Analytical data for **1**: ^{31}P{^{1}H}-NMR ($CDCl_3$): δ = 56.53 (s, μ-PPh_2), in agreement with literature value [7].

Thermolyses: $[Re_2(CO)_8(\mu\text{-}H)(\mu\text{-}PPh_2)]$ (0.08 g, 0.1 mmol) [6] in xylene (3 mL) was heated in a sealed glass tube (inner volume ca. 10 mL) for 1 d at 230 °C. The solvent was then removed under oil-pump vacuum, the remaining yellow-brown solid was dissolved in 2 mL of chloroform, and crystallization was achieved by means of the vapor-pressure equalization method ($CHCl_3$/*n*-pentane): 0.02 g (25%) of orange crystals of **2** and 0.04 g (50%) of a white crystalline mixture consisting of the starting material and $[Re_2(CO)_8(\mu\text{-}PPh_2)_2]$, which were identified by comparison of their ^{31}P-NMR data with those of authentic reference compounds. Similar treatment of $[Re_2(CO)_8(\mu\text{-}PPh_2)_2]$ (0.26 g, 0.27 mmol) also afforded **2**.

Tris(2,2'-bipyridyl-5-sulfonic acid)rhodium(III), an Improved Redox Catalyst for the Light-Induced and the Electrochemically Initiated Enzymatic Reduction of Carbonyl Compounds**

By *Marlene Franke* and *Eberhard Steckhan**

Many enzyme-catalyzed reductions require reduced nicotinamide cofactors such as NADH or NADPH as reducing equivalents. Nicotinamide cofactors also play an important role in photosynthesis for the transfer and storage of reducing equivalents. In order to use such reactions in biotechnological processes or for the transformation and storage of solar energy, it is necessary to develop simple and effective chemical, and especially photochemical, methods for the regeneration of the cofactors and, wherever possible, to couple these in situ with an NAD(P)H-dependent enzyme reaction. Enzyme-catalyzed regeneration is the most frequently used procedure.[1] Such a process, although often well-developed technologically,[2] is not optimal, because it is usually necessary to work with two enzymes, two substrates, and two products. The most advantageous procedure, which is also employed technologically, makes use of formate dehydrogenase with formate as donor; CO_2 is thereby formed as a gaseous, noninterfering product.[2] However, it is still of principal importance to develop alternative methods that do not operate with a second enzyme system. Electrochemical and photochemical procedures are possible techniques. The difficulty in solving the problem of nonenzymatic NADH regeneration consists in finding systems that are able to transfer two electrons simultaneously or a hydride ion to $NAD^{\oplus}$. One-electron transfer, however, results in formation of the NAD radical, which undergoes dimerization to form enzyme-inactive $(NAD)_2$. As a consequence, electrochemical regeneration can only be carried out by an indirect process.[3] Several research groups have shown that the indirect electrochemical regeneration of NADH can also be performed using electrochemically generated one-electron transfer agents. However, in these cases, an additional enzyme system is once again necessary.[4–6] This must be capable of accepting two electrons stepwise from the most commonly used viologen radical cations and of then transferring these electrons as a pair to $NAD^{\oplus}$. More promising seems to be the attempt to use intact microorganisms for the electromicrobial reduction.[6,7] Also for the especially interesting photochemical in situ regeneration of NAD(P)H, only one-electron transfer agents have been so far used as electron relays, which, for the above reasons, require the introduction of an additional enzyme such as ferredoxin reductase or lipoamide dehydrogenase.[8] The sensitizers used in these cases were $[Ru(bpy)_3]^{2\oplus}$ or zinc(II) *meso*-tetramethylpyridiniumporphyrin, the donors, $(NH_4)_3EDTA$ (EDTA = ethylenediaminetetraacetate) or 2-mercaptoethanol.

We showed earlier that it is possible to dispense with the use of an additional enzyme or microorganisms in the indirect electrochemical and photochemical regeneration, if electrochemically or photochemically generated and regenerated two-electron or hydride transfer agents are employed. Tris(2,2'-bipyridyl)rhodium(III), $[Rh(bpy)_3]^{3\oplus}$,[9] originally used as a redox catalyst or electron relay, however, exhibited several disadvantages. For instance, the relatively negative potential of the rhodium complex (−0.92 V vs. SCE) results in the formation of small amounts of $(NAD)_2$ by direct reduction of $NAD^{\oplus}$ at the cathode. Furthermore, the passivation of the electrode surfaces by a sparingly soluble intermediary rhodium complex occurred. We were able to solve these problems by using bipyridyl-5-sulfonic acid as ligand L. The sulfonic acid moiety in $[Rh(L_3)]^{3\oplus}$ makes the complex and its intermediates more soluble and shifts the reduction potential by almost 200 mV to more positive values ($E_p = -0.73$ V vs. Ag/AgCl). It is thereby possible to completely suppress the NAD dimerization upon electrochemical reduction of this complex in the presence of $NAD^{\oplus}$. Further improvements were achieved by adding tetraethylene glycol and by working at relatively high substrate concentrations. We carried out the electrolysis of a system that contained 0.332 mmol of the complex $[Rh(L_3)]^{3\oplus}$, 0.15 mmol of $NAD^{\oplus}$, 10.7 mg of horse liver alcohol dehydrogenase (HLADH) (16 units based on the system ethanol/acetaldehyde), 25.6 mmol of cyclohexanone, and 3 mL of tetraethylene glycol in 80 mL of Tris-H_2SO_4 buffer at pH 7.4 (Fig. 1). At a potential of −0.73 V vs. Ag/AgCl, we were able to obtain 15.2 mmol of cyclohexanol after 33 days. This corresponds to 101 cycles based on $NAD^{\oplus}$ and 46 cycles based on the rhodium complex. In this reaction, an intermediary hydrido rhodium complex is evidently involved as a hydride ion transfer agent.

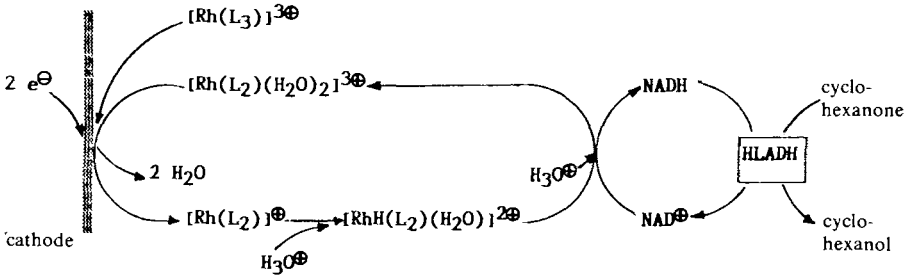

Fig. 1. Reaction scheme for the electrochemically initiated enzymatic reduction of cyclohexanone catalyzed by horse liver alcohol dehydrogenase and with tris(2,2'-bipyridyl-5-sulfonic acid)rhodium(III) $[Rh(L_3)]^{3\oplus}$ as redox catalyst.

After an induction period of several days, the rate of conversion remains constant for 20 days at approximately 0.73 mmol of cyclohexanone per day, corresponding to 4.9 cycles/day based on $NAD^{\oplus}$ and 2.2 cycles based on the redox catalyst.

Similarly, NADH can be regenerated in situ photochemically, if $[Ru(bpy)_3]^{2\oplus}$ is used as a sensitizer and 2,2,2-nitrilotriethanol (triethanolamine, TEOA) as a donor. Contrary to our former apprehension, the oxidative degradation products of TEOA do not disturb the reaction. In this way it was possible to reduce carbonyl compounds under HLADH catalysis in the presence of a catalytic amount of coenzyme in a continuous fashion (Fig. 2).

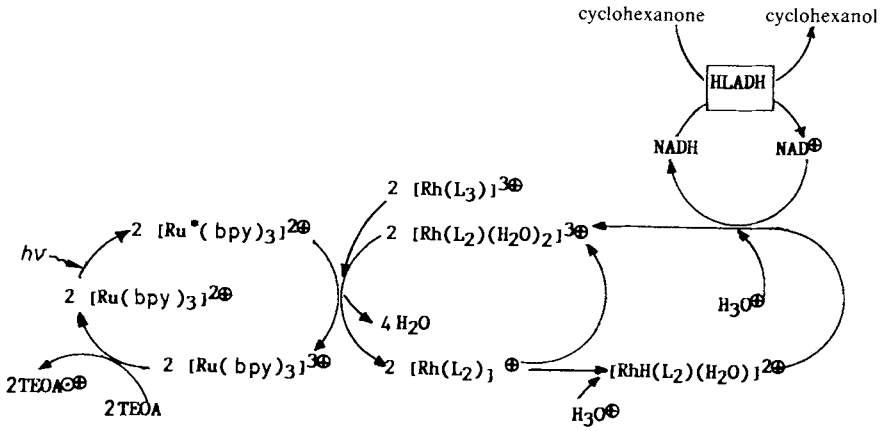

Fig. 2. Reaction scheme for the light-induced enzymatic reduction of cyclohexanone with $[Rh(L_3)]^{3\oplus}$ as electron relay.

Blank experiments with or without irradiation, in the absence of one of the components mentioned above, however, were negative. The photochemically initiated enzyme reaction (Table 1), with 11 or 12 cycles per day based on $[Rh(L_3)]^{3\oplus}$, is faster than the indirect electrochemical coenzyme regeneration by a factor of 5.

Table 1. Results of the light-induced enzymatic reduction of cyclohexanone using tris(2,2'-bipyridyl-5-sulfonic acid)rhodium(III) as electron relay [a].

No.	t [h]	Cyclohexanone [mmol]	$[Ru(bpy)_3]^{2\oplus}$ [mmol]	$[Rh(L_3)]^{3\oplus}$ [mmol]	$NAD^{\oplus}$ [mmol]	Product cyclohexanol [mmol]	Cycles based on NADH	Cycles based on $[Rh(L_3)]^{3\oplus}$
1	24	5.1	0.003	0.0114	0.022	0.128	6.0	11
2	24	5.1	0.0026	0.0167	0.032	0.204	6.3	12
	36	5.1	0.0026	0.0167	0.032	0.320	10.0	19

[a] In 50 mL of TEOA(0.42 M)/Tris-H_2SO_4 buffer at pH 7.4; irradiation with a 250-W slide projector, only $\lambda \geq 395$ nm used; 8.8 mg (15 units, No. 1) and 3.6 mg (6 units, No. 2) HLADH were used.

The time dependence of the photolysis is shown in Figure 3. After 36 h, the linear increase in the amount of cyclohexanol formed is still observed. This demonstrates that the activity of the system is fully maintained up to this length of time.

Since it was known that $[Ru(bpy)_3]^{3\oplus}$ oxidizes oxalate,[10] experiments were carried out with ammonium oxalate or formate in place of nitrilotriethanol as the effective donor to trap this Ru^{III} complex. In this case, CO_2 would be formed as an inert oxidation product. UV spectroscopic measurements showed, however, that the photochemically initiated Rh^{I} generation was too slow in these cases.

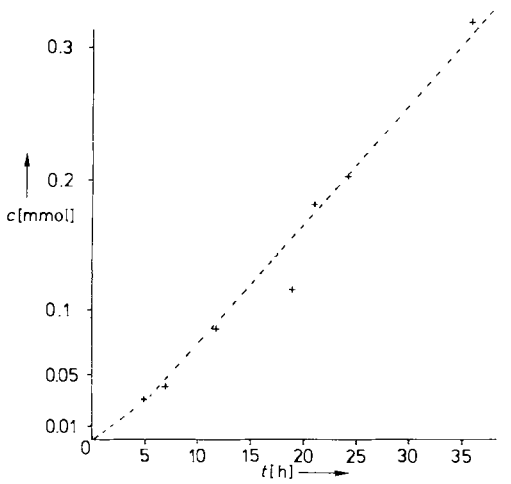

Fig. 3. Time dependence of the light-induced enzymatic reduction of cyclohexanone with $[Rh(L_3)]^{3\oplus}$ as electron relay (reaction conditions given in Table 1, No. 2). c = amount of cyclohexanol formed.

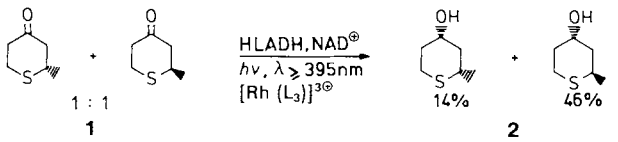
The rhodium complexes employed by us differ from other complexes in that, in their reduced form, they do not directly reduce carbonyl compounds. Thus, the stereospecificity of the enzyme can be fully exploited. In order to test this under the conditions of the photolysis, we used racemic 2-methylthiacyclohexan-4-one **1** in place of cyclohexanone. Starting from 0.003 mmol of $[Ru(bpy)_3]^{2\oplus}$, 0.174 mmol of $[Rh(L)_3]^{3\oplus}$, 0.21 mmol of $NAD^{\oplus}$, 17 units of HLADH, and 3.34 mmol of **1** in 50 mL of TEOA (0.42 M)/Tris-H_2SO_4 buffer at pH 7.4, it was possible to isolate 1.34 mmol (40% conversion) of the two diastereomeric alcohols **2** after 24 hours. This corresponds to 6.4 regenerative cycles based on the coenzyme and 7.7 cycles based on the rhodium complex. Flash chromatography (eluant *n*-hexane/ether = 3 : 7, subsequently 5 : 5) afforded initially 0.61 mmol of the (2*R*,4*S*) alcohol followed by 0.19 mmol of the (2*S*,4*S*) alcohol with specific optical rotations $[\alpha]_D$ of $+12°$ and $+3.8°$, respectively; this corresponds to an optical purity of $p = 0.81$ for the *trans* alcohol and 0.95 for the *cis* alcohol (Scheme 1). Within the limits of experimental accuracy, these results are identical with those obtained by the enzyme-catalyzed regeneration of the coenzyme.[11]



Scheme 1. Yields based on conversion (40%).

Thus, it has been shown that, for the photochemical regeneration of NADH in the presence of horse liver alcohol dehydrogenase described here, the stereospecificity of the enzyme is maintained and a direct reduction of the carbonyl compound by the reduced rhodium complex, which would circumvent the enzyme system, can be ruled out.

On the basis of these results, it should be possible to develop complexes as electron relays or redox catalysts that make possible an appreciably faster conversion.

The Copper Salt of 2-Iodo-5-methyl-*N,N'*-dicyanoquinonediimine—a Radical Anion Salt Exhibiting Metallic Conductivity down to Low Temperatures**

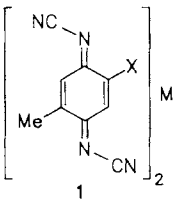
By *Peter Erk, Siegfried Hünig,* Jost Ulrich von Schütz, Hans-Peter Werner,* and *Hans Christoph Wolf*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

Organic metals whose electrical conductivity continuously increases down to very low temperatures are of particular interest, since special properties, e.g., superconductivity, are then expected. Superconductivity has so far been found for several salts containing organic radical cations.[1] We recently described the salt **1a**, the first radical-anion-containing compound whose single-crystal conductivity increases to ca. 500000 S cm^{-1} at 0.45 K.[2] It is derived from the new class of *N,N'*-dicyanoquinonediimine (DCNQI) acceptors,[3] whose 2,5-disubstituted derivatives preferentially form radical anion salts that are close-packed in segregated stacks having the stoichiometry $(DCNQI)_2M$.[4]

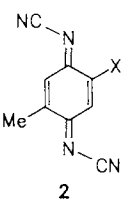
We have now investigated whether these special properties are exhibited by other 2,5-disubstituted DCNQI salts.

1. Radical anion salts of type **1**,[5] with X = Me, Cl, Br, and M = Cu[6] (except for **1a**), Ag, and alkali metals,[7] exhibit a nearly constant conductivity of $\sigma = 700$–1000 S cm^{-1} (Cu salts) and $\sigma = 100$–300 S cm^{-1} (Ag and alkali-metal salts) between 300 and 100 K. Below a phase transition (Peierls distortion) these salts undergo a transition to a semiconducting state. In addition to their high electrical conductivity, they all exhibit very similar magnetic properties.[8] Similar conductivities have meanwhile been reported for the salts **1**, X = Me, M = Cu (= **1a**), Ag, Li, Na, K, and **1**, X = Cl, M = Cu (= **1c**), Li, NH_4.[9]



1

1a, X = Me, M = Cu
1b, X = I, M = Cu
1c, X = Cl, M = Cu



2

2a, X = Me
2b, X = I

2. In contrast, the derivative **1b** surprisingly exhibits a continuous increase in conductivity down to the lowest temperatures measured (1.2 K) (Fig. 1).

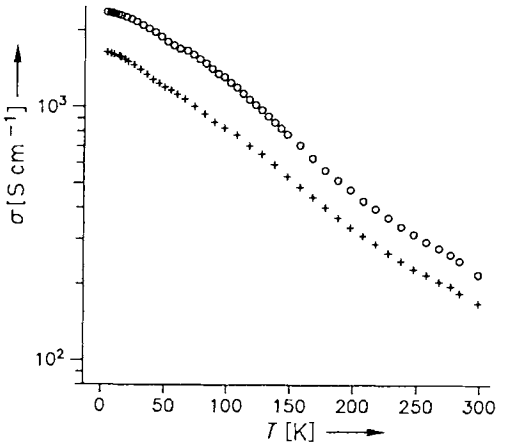


Fig. 1. Temperature dependence of the electrical conductivity of single crystals of the radical anion salt **1b**. O, + see text.

The salt **1b** was synthesized analogously to **1a**.[2] Combination of solutions of **2b**[10] and CuI in acetonitrile results in the precipitation of **1b** in the form of microcrystalline needles exhibiting a powder conductivity[11] of 0.2 S cm^{-1}.

Large single crystals of **1b** can be grown by electrolysis of **2b** and copper(II) bromide in acetonitrile (cf. Ref. [2]). A new method, which makes numerous DCNQI copper salts readily available, affords single crystals of **1b** by dipping a bright copper wire into a solution of **2b** and copper(II) bromide in acetonitrile.[12]

The single crystals of **1b** obtained in this way, which are up to 2 cm long, are indistinguishable in crystal habitus from those of **1a**. The X-ray powder diagram revealed that **1b** is isomorphous with the copper salts of the series **1**, $X = CH_3$ (= **1a**), Cl, Br,[13] so far synthesized and crystallizes in the tetragonal space group $I4_1$ (or $I4_1/a$) with the lattice constants $a = 21.687$ (± 0.003) and $c = 3.867$ (± 0.003).[14] This finding is surprising, since iodine (van der Waals radius 215 pm) is significantly larger than the other substituents of this series (CH_3 200, Br 195, Cl 180 pm).[15] In the crystal of **1a**, four molecules of **2a** are coordinated to each copper atom, and the separations of

the methyl groups (392 pm) are already less than the sum of the van der Waals radii. In the case of the iodine-substituted derivative **1b**, the van der Waals radii of the substituents also overlap.

According to Figure 1, the slope of the conductivity curve between 300 and ca. 150 K is $\sigma(T) \approx T^{-\alpha}$ ($\alpha \approx 2$); at low temperatures, the slope becomes smaller. No convergence of the conductivity is evident. The different absolute values for the two series of measurements (○, +) are due to errors in the determination of the sample dimensions.

An electron spin resonance experiment revealed no ESR signal, either in the X band (9.6 GHz) or in the Q band (35 GHz). This is in accord with the finding for **1a**; in that case, the absence of an ESR signal is explained by the extreme line broadening due to spin-orbit coupling and points to multidimensionality owing to mixed valence states of copper.[2,6-9]

In the case of **1c**, a discontinuous contraction of the lattice in the stacking direction was demonstrated for a phase transition at 210 K. The size of the substituents appears to inhibit such a contraction for **1a** without significantly perturbing the overlap of the π systems. The methyl substituents show a similar effect in the superconducting radical cation salts of tetramethyltetraselenafulvalene.[16]

We presume that the "large" van der Waals radius of the iodine substituents in **1b** causes high strain in the crystal and suppresses a Peierls distortion. At the same time, the size of iodine is responsible for a poor overlap of the π systems and thus the lower absolute conductivity at 300 K. This effect may also be ascribed, however, to a low transverse conductivity through the CN-Cu-NC bridges, since, in this case, defects in the anion stack, have a stronger effect.

The small increase in conductivity in the low-temperature region indicates that the electron-phonon interaction might be significantly increased.[17] Thus, **1b** is a potential candidate for superconductivity at even lower temperatures, if necessary under pressure. Less likely is the possibility of Cooper pair formation in the case of **1a**, which would be required for superconductivity. Its stronger increase in conductivity at low temperatures is an indication of weak electron-phonon coupling.

A New Route to *trans*-Substituted γ-Lactones**

By *Thomas Kunz* and *Hans-Ulrich Reissig**

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

The addition of nucleophiles to chiral carbonyl compounds (Cram/anti-Cram selectivity) is one of the best-studied reactions in organic chemistry. New reagents, which unequivocally attack with or without chelate control, have recently given these investigations new impetus.[1] Carbonyl compounds with functional groups in the α or β position—mostly protected hydroxyl groups—have been investigated intensively. This is not true for γ-functionalized compounds.[2] We report here on the chemo- and diastereoselective additions of organometallic reagents to the formyl group of the readily accessible chiral methyl γ-oxocarboxylates **1**,[3] which, after ring closure, afford γ-lactones with a high excess of the *trans* isomer.[4]

	R^2 = allyl	
1a, R^1 = Me	**2a**	**3a**
1b, R^1 = *i*Pr	**2b**	**3b**
1c, R^1 = Ph	**2c**	**3c**

In the reaction of allyltrimethylsilane with **1a** in the presence of Lewis acids,[5] the largest diastereoselectivity is observed with the bidentate titanium tetrachloride as acid (*trans* : *cis* = 63 : 37). $TiCl_4$ is also the most selective promoter in the case of **1b** and **1c** (*trans* : *cis* > 90 : 10) [Eq. (a), Table 1).

The ratio **2a** : **3a** is independent of whether one or two equivalents of $TiCl_4$ are used.[6] We interpret this as evidence for the formation of the seven-membered ring che-

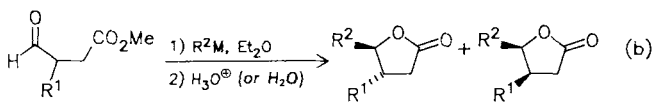
Table 1. Reaction of the aldehydes **1** with allyltrimethylsilane in the presence of Lewis acids MX_n (complexation at ca. 20°C, addition of the nucleophile at −78°C, warm-up to room temperature, treatment with acid).

1	MX_n	Yield [%]	2 : 3 [a, b]
a	$1BF_3 \cdot OEt_2$	62	52 : 48
a	$2BF_3 \cdot OEt_2$	65	59 : 41
a	$1SnCl_4$	92	58 : 42
a	$1HfCl_4$	80	59 : 41
a	$1ZrCl_4$	78	62 : 38
a	$1TiCl_4$	99	63 : 37
a	$2TiCl_4$	93	65 : 35
b	$1BF_3 \cdot OEt_2$	45	75 : 25
b	$1ZrCl_4$	63	87 : 13
b	$1TiCl_4$	69	92 : 8
c	$1BF_3 \cdot OEt_2$	75	70 : 30
c	$1ZrCl_4$	68	85 : 15
c	$1TiCl_4$	63	93 : 7

[a] Isomer ratio and assignment by high-field ^{1}H-NMR spectroscopy (cf. Refs. [4] and [12]). [b] Product distribution after kugelrohr distillation (purity ca. 90–97%); chromatography afforded samples giving satisfactory elemental analyses.

late **8**, which involves *both* carbonyl groups of **1** and *one* molecule of $TiCl_4$.[7] The formation of this chelate ring is also supported by the spectroscopic data—in particular, the significant downfield shift of the signals of both carbonyl C atoms in the ^{13}C-NMR spectrum of **1a** · $TiCl_4$.[8] The attacking nucleophile approaches **8** preferentially from the sterically less shielded face (*trans* to R^1), leading to formation of the *trans*-substituted lactone **2**. The flexibility of the seven-membered ring results in only moderate diastereoselectivity for R^1 = Me, whereas the larger substituents R^1 = *i*Pr and Ph (**1b**, **1c**) almost completely prevent *cis* attack on **8**.

With $MeTiCl_3 \cdot (OEt_2)_2$ instead of allyltrimethylsilane/$TiCl_4$ as reagent, the corresponding lactones **4** and **5** are obtained in essentially the same *trans/cis* ratio ([Eq. (b),



(b)

1a–c R^2 = Me **4** **5**

R^2 = *n*Bu **6** **7**

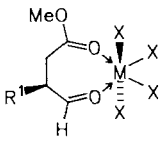
Table 2)]. This points once again to a chelate-controlled reaction at the formyl group. Better stereoselectivity is achieved with $MeTi(OiPr)_3$ and, in particular, with Me_2CuLi. In the case of these reagents, addition probably occurs without initial complexation.[9] The transfer of a butyl group is also possible, most efficiently by using the corresponding cuprate. Starting from **1a–c**, practically only the *trans*-substituted lactones **6a–c** are obtained!

Table 2. Reactions of the aldehydes **1** with other organometallic reagents R^2M.

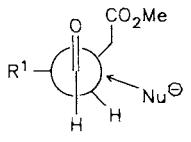
1	R^2M	Yield [%]	4 : 5 [a, b] or 6 : 7
a	$MeTiCl_3$	59	68 : 32
a	$MeTi(OiPr)_3$	60 [c]	79 : 21
a	Me_2CuLi	34	95 : 5
b	$MeTiCl_3$	74	92 : 8
c	$MeTiCl_3$	79	93 : 7
c	Me_2CuLi	53	97 : 3
a	*n*BuMgBr	39	60 : 40
a	$nBu_2Cu(CN)Li_2$	47	75 : 25
a	nBu_2CuLi	50	>95 : 5
b	nBu_2CuLi	82	>95 : 5
c	nBu_2CuLi	65	>97 : 3

[a], [b] See Table 1. [c] Purity <90%.

The stereoselectivity of the additions to aldehydes **1** can be interpreted in terms of the Felkin-Anh model[10] with the reactive conformation **9**, provided that $R^1 > CH_2CO_2Me > H$ is valid for the size of the substituents.[11] However, conformation **9** might also be fixed by chelation (cf. **8**) for reagents that exhibit less Lewis acidity.



8



9

Such *trans*-substituted γ-lactones are of importance as intermediates in synthesis and are also found as natural products (e.g., whisky lactone **6a**[12]). Since some of the aldehydes **1** are available in optically active form,[13] the concept described here may also be employed to prepare nonracemic *trans*-substituted γ-lactones.

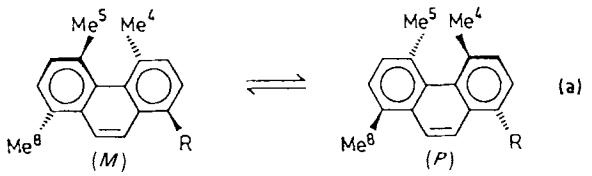
Chem. 51* (1986) 5041; b) **1a–c** have been synthesized with up to 50% *ee* by means of asymmetric catalysis: T. Kunz, H.-U. Reissig, unpublished.

How High is the Activation Barrier to Helix Inversion of 1,4,5,8-Tetrasubstituted Phenanthrenes?**

By *Albrecht Mannschreck,* Erich Gmahl, Thomas Burgemeister, Fritz Kastner,* and *Volker Sinnwell*

In 1947, the synthesis of (4,5,8-trimethyl-1-phenanthryl)acetic acid **1** and the enrichment of its (+) enantiomer were reported.[2] This kind of enantiomerism was termed isomerism of the 4,5-phenanthrene type[2] and must be considered the starting point of helicene chemistry.[3] This isomerism, described by equilibrium (a), contributed substantially to our knowledge of what is presently called molecular helicity.[4] The above enrichment of an enantiomer has been frequently cited, its significance being shown by its appearance in several textbooks.[5]



1, R = CH_2CO_2H; **2**, R = CH_2OH; **3**, R = CH(Me)OH; **4**, R = CH(CMe_3)OH

Although no information regarding the rate of racemization of (+)-**1** was given, a few optical rotations between $+0.11 \pm 0.02$ and 0.00°, measured in $CHCl_3$ with respect to time, were mentioned.[2] Since no other data on the enantiomerization of 1,4,5,8-tetrasubstituted phenanthrenes have been available until now, the above optical rotations have been used by several groups[6–10] to estimate the half-life $t_{0.5}$ at room temperature and/or $\Delta G^{\neq}$ for the inversion.

[**] Helical Phenanthrenes, Part 2. Support of this work by the Fonds der Chemischen Industrie is acknowledged. We thank Drs. *W. Fischer* and *H. Scherübl* for helpful discussions and *N. Pustet* for experimental assistance. — Part 1: [1].

The values obtained differ slightly[6–10] but are in agreement concerning the orders of magnitude ($t_{0.5} \approx 4$ h, $\Delta G^{\neq} \approx 99$ kJ mol^{-1}). These values are similar to the ones obtained for 4,5-dimethyl-9,10-dihydrophenanthrene (2.8 h, 98.4 kJ mol^{-1}, 24.8 °C, benzene).[6, 11] This result was unexpected[6] because under analogous conditions another phenanthrene derivative had shown a considerably *lower* activation barrier than the comparable 9,10-dihydrophenanthrene.[12] The $\Delta G^{\neq}$ values of 4,5-bis(acetoxymethyl)phenanthrene (75.7 kJ mol^{-1}, 24.8 °C)[7] and 4,5-dimethylphenanthrene (67 kJ mol^{-1}, 25 °C)[10] are also considerably *lower* than the value of ca. 99 kJ mol^{-1} obtained for **1**. It has been pointed out by several groups[7, 8, 10] that these differences remain to be explained. Toward the solution of these discrepancies, we report here the determination of the activation barrier to helix inversion (*M*) ⇌ (*P*) of phenanthrenes **1–4**.

Our preparation of **1** is directed toward cyclodehydrogenation as the last step (Scheme 1). This reaction was unknown at the time of the reported 20-step synthesis.[2] The primary alcohol **2** and the secondary alcohols **3** and **4** were also prepared (Scheme 1) because their $\Delta G^{\neq}$ values should be similar to that of **1**. Contrary to (*MP*)-**1** and (*MP*)-**2**, four stereoisomers of **3** and of **4** are possible ((*MP*)(*RS*)-**3** and (*MP*)(*RS*)-**4**).

The mass spectra of **1–4** were in agreement with the constitutions. The ^{1}H-NMR assignments of all aliphatic (Table 1) and aromatic protons of **1**, **2**, and **4** were obtained by nuclear Overhauser difference spectra. The HPLC peaks for the enantiomers of **1** and **2**, obtained on an optically active sorbent at −40 °C, coalesced to a single averaged peak during HPLC at +15 °C (Table 1), owing to enantiomerization.[13, 14] The melting point given in the literature (142.8–143.6 °C, corr.)[2] is close to that of our acid **1** (137.5–138.5 °C, corr.). Its UV absorption in $CHCl_3$ resembles the spectrum depicted earlier[2] (solvent not specified). The $\Delta G^{\neq}$ values for helix inversion (Table 2) were obtained by dynamic ^{1}H-NMR spectroscopy and/or thermal racemization. For the latter measurements the flow during HPLC on an optically active sorbent was stopped

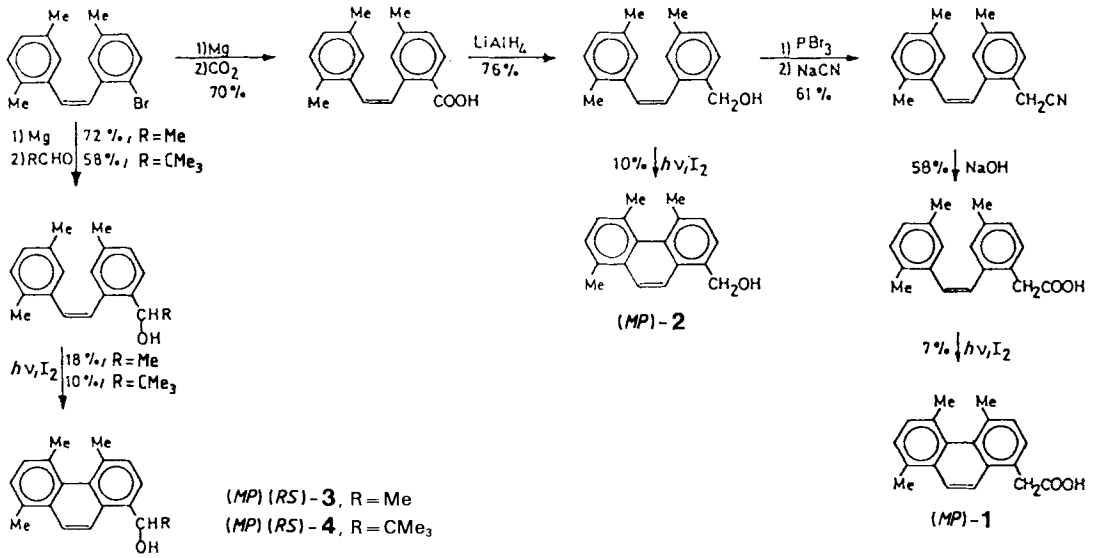

Scheme 1. Synthesis of the 1,4,5,8-tetrasubstituted phenanthrenes **1**–**4**. In most cases, the substituted stilbenes were (*E*)/(*Z*) mixtures.

when the cell of the polarimetric detector contained one enriched enantiomer. Subsequently, the cell was thermostated to a temperature suitable for on-line racemization.[14, 17, 18]

Since the known entropies of activation are not far from zero,[7, 10] it is permissible in most cases to compare $\Delta G^{\neq}$ values determined at different temperatures. The $\Delta G^{\neq}$ value of our acid **1** (78 kJ mol^{-1}, Table 2) corresponds to a half-life of enantiomerization of only 3 s at 24.8 °C and is incompatible with the above estimated values of ca. 99 kJ mol^{-1} and ca. 4 h. At the same time, our result clarifies all reported discrepancies.[6–8, 10] We have not yet been able to attempt a crystallization of the diastereomeric salts[2] of our acid **1**, since the amount available was low owing to the low yields of the cyclodehydrogenation (Scheme 1).

Our $\Delta G^{\neq}$ value for **1** is confirmed by the results for its analogues **2**–**4**. A comparison of **1** and 4,5-dimethylphenanthrene **5** or **2** and **5** shows a decrease of $\Delta G^{\neq}$ by about 10 kJ mol^{-1} (Table 2) when the 1- and 8-substituents are removed. A similar decrease of $\Delta G^{\neq}$ is found when going from 1,3,4,5,6,8-hexamethylphenanthrene **6** to 3,4,5,6-tetramethylphenanthrene **7**. These observations indicate that the interaction of the 1- and 8-substituents with the 10- and 9-hydrogens contributes significantly to the helicity of 1,4,5,8-tetrasubstituted phenanthrenes.

Table 2. $\Delta G^{\neq}$ for the helix inversion described by (a).

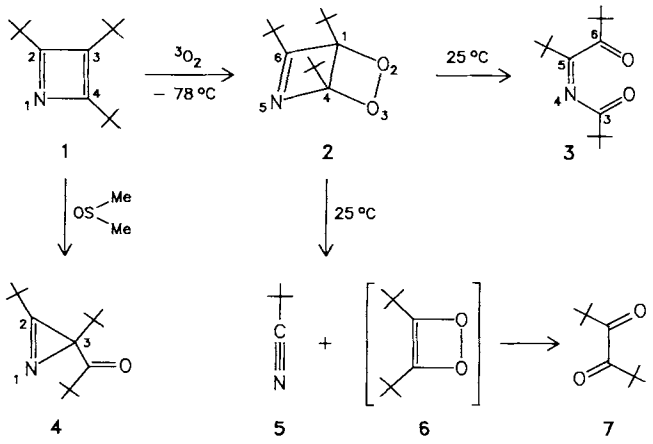
Reactivity of Tri-*tert*-butylazete**

By *Uwe Josef Vogelbacher, Martin Ledermann, Thomas Schach, Gisbert Michels, Udo Hees,* and *Manfred Regitz**

So far, only spectroscopic properties have been reported for the recently synthesized tri-*tert*-butylazete **1**, the first kinetically stabilized azacyclobutadiene.[1] We have investigated several aspects of its reactivity and report here the oxidation and hydrolytic behavior as well as the addition potential of this electronically genuine antiarene.[2]

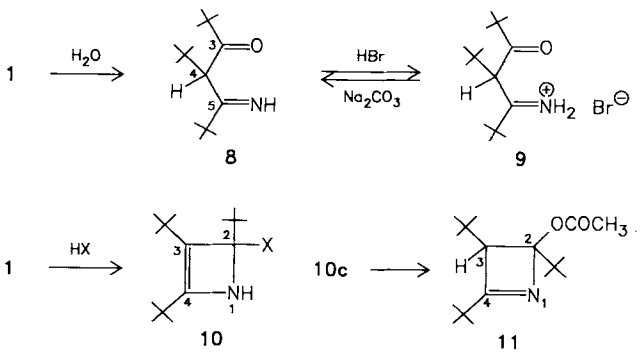
Triplet oxygen adds exclusively to the CC double bond of **1** in *n*-butane at −78 °C to give the dioxetane **2** (95%). Both in the crystalline state and in the same solvent (25 °C, half-time ≈ 4 h), the bicyclic ring opens as expected to give the dicarbonyl compound **3** (40%).



However, the cycloreversion of **2** to give the nitrile **5** and the dioxete **6** dominates over this ring opening; **6** undergoes immediate isomerization to give the α-diketone **7**. Both final products were distilled under high vacuum and identified by comparison of their ^{1}H-NMR spectra with those of authentic compounds. Surprisingly, smooth oxidation of **1** by dimethyl sulfoxide occurred at 25 °C with ring contraction to give the azirine **4**.[3] We became aware of this reaction when a sample of the azete underwent change during NMR measurements in the same solvent.[4]

Upon hydrolysis of **1** with water-saturated tetrahydrofuran (25 °C, catalytic amount of hydrochloric acid), the azomethine bond is smoothly cleaved; the β-iminoketone **8** (68%) is formed. Reaction with concentrated hydrogen bromide in the same solvent results in transformation of **8** to the iminium bromide **9** (36%), which, in turn, undergoes dehydrobromination with sodium carbonate to give **8**.

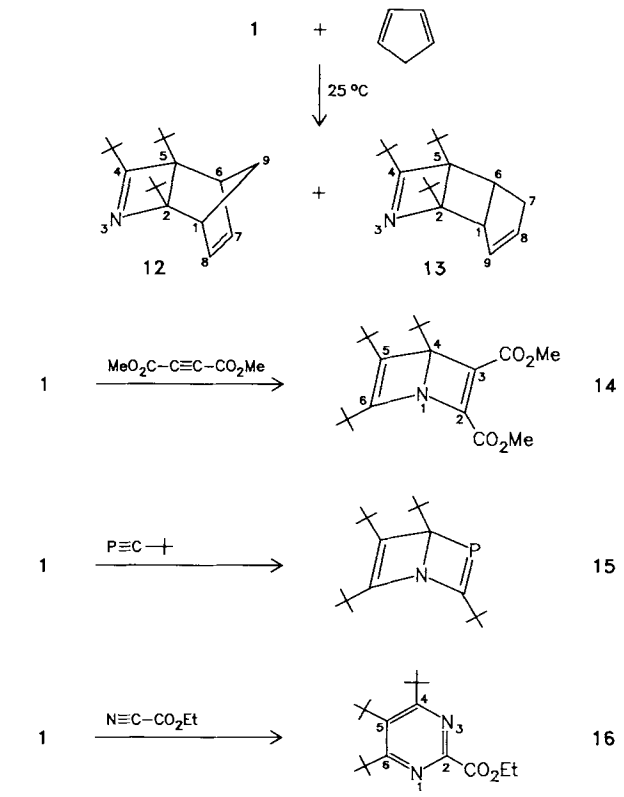
Protic nucleophiles such as methanol, dimethyl malonate, and acetic acid exclusively undergo 1,4-addition at N-1 and C-4 of **1** (25 °C, *n*-pentane or chloroform) to give the 1,2-dihydroazetes **10a–c** (81–100%);[5] the reaction is presumably initiated by *N*-protonation. In chloroform, **10c** undergoes acetic acid–catalyzed rearrangement to give the



10a: X = OMe; b: X = $CH(CO_2Me)_2$; c: X = O_2CCH_3

evidently thermodynamically more stable 2,3-dihydroazete **11**. It may be assumed that the *t*Bu groups in the 2- and 3-position are in the *trans* arrangement.

Both the 1,3-diene and the olefin character of **1** are reflected in its reactions with cyclopentadiene (25 °C, *n*-pentane). The reaction occurs exclusively at two *t*Bu-substituted carbon atoms and affords a 4:1 mixture of **12** and **13**, which may be separated by medium-pressure chromatography on silica gel (petroleum ether/ether, 4:1).



The two tricyclic compounds exhibit fundamental differences in their ^{1}H-NMR spectra in that the framework-bonded protons of **12** form an AA'MM'XX' spin system whereas those of **13** form an ABMNXY spin system (Table 1).[6]

In contrast to the reaction of **1** with cyclopentadiene, the Diels–Alder reaction with dimethyl acetylenedicarboxylate (pentane, 25 °C) takes place exclusively at a nitrogen and a neighboring carbon atom; it affords the 1-Dewarpyridine **14** (93%).[7] (2,2-Dimethylpropylidyne)phosphane,[8] a compound containing a PC triple bond, reacts

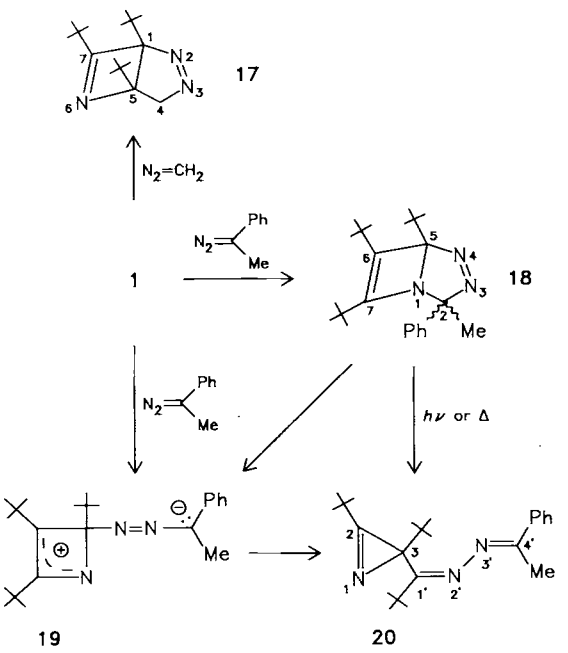
[**] Syntheses with Cyclobutadienes, Part 21. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. — Part 20: G. Michels, R. Mynott, M. Regitz, *Chem. Ber. 120* (1987), in press.

analogously with **1** to give the 1-Dewar-1,3-azaphosphinine **15** (92%). The orientation of the phosphaalkyne is established unequivocally by ^{13}C-NMR comparison of **15** with the known 2-Dewar-phosphinines.[9] Compounds containing electron-deficient CN triple bonds such as ethyl cyanoformate ("ethoxycarbonylnitrile") also add readily to **1** (dichloromethane, 25°C): Instead of a bicyclic product like **14** or **15**, the reaction affords the pyrimidine **16** (83%), formed by subsequent electrocyclic ring opening.

Depending on the size of the substituents, either the CC or the CN double bond of **1** is attacked in 1,3-dipolar cycloadditions with diazo compounds: diazomethane (ether) affords regiospecifically the dihydropyrazole **17** (81%),[10] and 1-diazo-1-phenylethane the *endo/exo* isomeric dihydrotriazoles **18** (57%, ratio 2:3);[11] in the *endo* phenyl derivative, the signal for the 7-*t*Bu group ($\delta = 0.53$) is shifted markedly to high field owing to an anisotropy effect.



In addition to the cycloadducts **18**, the azirine **20** (43%) is formed; it is also formed upon irradiation (Philips HPK 125 W) of *endo*- and *exo*-**18** in chloroform or upon warming to 80°C (neat). A crystal structure analysis has been carried out for **20**[12] which indirectly established the constitution of **18** as well. Intermediate **19** is assumed to be involved both in the azirine formation occurring in the cycloaddition and in the isomerization.

Correct elemental analyses were obtained for all the reaction products. Of particular importance for establishing the reaction centers of **1** is the presence or absence of the C=C or C=N increment, respectively, above all in the ^{13}C-NMR spectra (Table 1).

Tri-*tert*-butylcyclobutadienecarboxylic esters (**1**, C-CO_2R instead of N) are of primary interest in comparing the reactivity of **1** with other antiarenes. These esters undergo 1,4 addition and cycloaddition mainly at neighboring carbon atoms bearing ester and *t*Bu substituents.[13] The azete **1** shows corresponding behavior only toward protic nucleophiles (→ **10**). Cycloadditions take place at C-2/C-3 (→ **2**, **12**, **13**, **17**) until steric hindrance is so large that a reaction is forced to take place at N-1/C-2 (or C-4) (→ **14**, **15**, **16**, **18**).

Amino Acid Methyl Esters as Chiral Auxiliaries in Aza-Diels–Alder Reactions in Aqueous Solution**

By *Herbert Waldman**

Diels–Alder reactions make it possible to synthesize carbo- and heterocycles in a regio- and diastereoselective fashion and are therefore employed in the synthesis of natural products, for example in the de novo synthesis of carbohydrates and alkaloids.[1] To achieve higher diastereoselectivities, asymmetric Diels–Alder reactions are often carried out at low temperature (−78 °C) under Lewis acid catalysis. Of particular interest for syntheses, however, are processes that take place at higher temperatures with satisfactory stereoselectivities and allow large quantities of the products to be prepared. Uncatalyzed homo- and hetero-Diels–Alder reactions involving nonactivated dienophiles can be accelerated by carrying them out in aqueous medium.[2] *Grieco* et al. have studied aza-Diels–Alder reactions in aqueous medium with iminium ions prepared in situ from ammonium salts and aldehydes. They have shown that these reactions are diastereoselective when (*S*)-1-phenylethylamine hydrochloride is used as the ammonium salt.[3] We report here on the use of (*R*)- and (*S*)-amino acid methyl ester hydrochlorides **1**, which are readily accessible in large amounts, as chiral auxiliaries in analogous aza-Diels–Alder reactions.[4]

Amino acid methyl ester hydrochlorides **1** react with cyclopentadiene **3** and cyclohexadiene **4** in the presence of formaldehyde in THF/water at 0 °C to form the diastereomeric bicyclic aza compounds **5** and **6** (Scheme 1) in very good yields. The iminium ion **2** is assumed to be the reactive intermediate. Depending on the steric demands of the amino acid side chain, good stereoselectivities are achieved even at this reaction temperature, which is high for diastereoselective reactions (Table 1, **5a/6a–5i/6i**). The ratios of the diastereomers were determined from the 400-MHz ^{1}H-NMR spectra of the crude products.

Table 1. Yields and diastereomeric ratios in the aza-Diels–Alder reactions using (*R*)- or (*S*)-amino acid methyl ester hydrochlorides as chiral auxiliaries.

Amino acid in **1**	Diene	Compd	*T* [°C]	Diastereomeric ratio **5**:**6** or **8**:**9**	Yield [%]
(*S*)-Ile	**3**	**5a/6a**	0	93 : 7	57
(*S*)-Val	**3**	**5b/6b**	0	86 : 14	74
(*S*)-Ser	**3**	**5c/6c**	0	87 : 13	63
(*S*)-Phg	**3**	**5d/6d**	0	78 : 22	97
(*R*)-Val	**3**	**5e/6e**	0	17 : 83	69
(*R*)-Ser	**3**	**5f/6f**	0	12 : 88	66
(*R*)-Phg	**3**	**5g/6g**	0	20 : 80	90
(*S*)-Ile	**4**	**5h/6h**	25	80 : 20	35
(*R*)-Ser	**4**	**5i/6i**	25	27 : 73	40
(*R*)-Phg	**7a**	**8a/9a**	0	37 : 63	22
(*S*)-Ile	**7b**	**8b/9b**	0	71 : 29	45
(*S*)-Phg	**7b**	**8c/9c**	0	66 : 34	63
(*R*)-Ser	**7c**	**8d**=**9d**	25	—	50

The reaction of isoleucine (*S*)-Ile with **3** afforded the best stereoisomeric ratio (**5a** : **6a** = 93 : 7), which is significantly better than that obtained for (*S*)-1-phenylethylamine (80 : 20).[3] In the case of the less reactive cyclohexadiene **4**, the diastereomers (**5h/6h**) are even formed at 25 °C in a ratio of 80 : 20. The main isomers formed in these reactions, which can readily be carried out on a 30-g scale, can be obtained easily in pure form, e.g., by flash chromatography. If the (*S*)-amino acid methyl esters are used as auxiliary groups, the (1*R*,4*S*)-2-azabicycloheptenes or -octenes **5** are preferentially formed. Amino acid esters of (*R*)-configuration give preferentially the (1*S*,4*R*) isomers **6**. The configurations of these cycloadducts were established by means of NOE difference spectra.[5]

The hetero-Diels–Alder reactions can also be carried out with open-chain 1,3-dienes **7** (Scheme 2, Table 1, **8a/9a–8d**). Although the diastereoselectivities in these cases are only moderate, the substituted didehydropiperidines **8** and **9** are easy to separate by chromatography. As has already been observed for the simpler amines, the reactions with isoprene **7c** and *trans*-2-methyl-1,3-pentadiene **7b** afford only one regioisomer in each case and the reaction with *trans,trans*-2,4-hexadiene **7a** results in the formation of only one pair of diastereomers.[3]

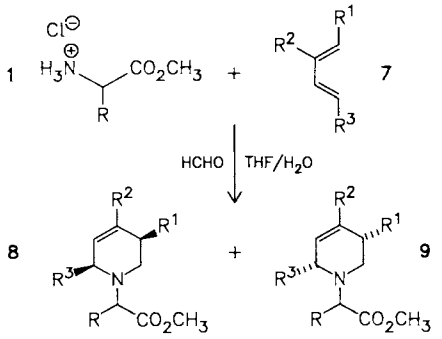
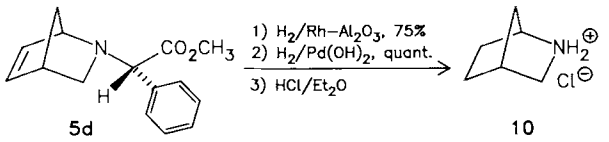
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18–20, D-6500 Mainz (FRG)

[**] This work was supported by Degussa AG and by the Fonds der Chemischen Industrie (Liebig-Stipendium). I wish to thank Prof. Dr. *Kunz*, Mainz, for his generous support.

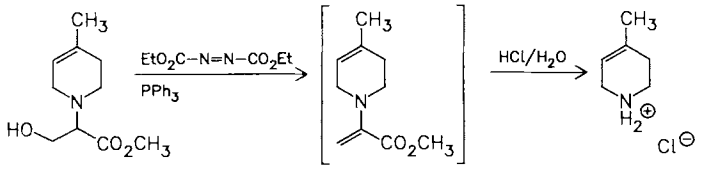


Scheme 2. **7a**, $R^1=R^3=CH_3$, $R^2=H$; **7b**, $R^1=H$, $R^2=R^3=CH_3$; **7c**, $R^1=R^3=H$, $R^2=CH_3$.

The underlying nitrogen heterocycles can be obtained in a number of ways from the cycloadducts. The benzylamine moiety in the phenylglycine derivatives (**5d/6d**, **5g/6g**, **8a/9a**, **8c/9c**) can be removed quantitatively by hydrogenolysis following selective hydrogenation of the olefinic double bond. Thus, for example, (−)-2-azabicyclo[2.2.1]octane hydrochloride **10** can be obtained in enantiomerically pure form.[6] Similarly, **8a/9a** and **8c/9c** can be converted into the corresponding piperidines.



In the case of the serine derivatives, the amino acid side chain can be removed, for example, by conversion to the enamine by means of the Mitsunobu reaction followed by its hydrolytic cleavage. For instance, the didehydropiperidinium hydrochloride **12** is obtained, albeit in achiral form, from **8d** via **11**. The double bond in the ring (allylic to N) is not attacked.



Experimental Procedure

A mixture made up of **1** (0.15 mol), **3**, **4**, or **7** (0.3 mol), water (55 mL), THF (6.5 mL), and a 35% solution of formaldehyde (19 mL, 0.22 mol formaldehyde) was stirred at the temperatures listed in Table 1 for 72 h. The reaction mixture was then diluted with 100 mL of water and extracted with ether, the pH value was adjusted to 12, and the resulting mixture was extracted three times with ether. After drying of the organic phases and evaporation of the solvent, the products were purified by distillation under high vacuum or by flash chromatography. They were characterized by ^{1}H- and ^{13}C-NMR spectroscopy as well as by elemental analysis.

Heterogeneous, Bimetallic Metathesis Catalysts by Reaction of Fischer-type Carbene Complexes with Reduced Phillips Catalyst**

By *Karin Weiss,* Wilfried Guthmann,* and *Sergio Maisuls*

Tungsten carbene complexes of the Fischer type are frequently used as model catalysts for stoichiometric metathesis reactions.[1-3] However, for catalytic metathesis reactions cocatalysts must be added to increase the activity, or the reaction temperatures should be in the range where the carbene complexes decompose. Since 1964, when *Banks* and *Bailey* discovered the metathesis of linear olefins,[4] heterogeneous metathesis catalysts have repeatedly proved to be more reactive and have been chosen for industrial processes.

We therefore tested inorganic supports such as silica or alumina as cocatalysts for Fischer-type carbene complexes, but carbene complexes were fixed only in small concentrations to alumina suspended in pentane. The metathesis activity (tested with 1-octene in hexane at 69 °C), moreover, was low. For this reason, we looked for modified inorganic supports as carriers for the carbene complexes.

Reduced Phillips catalyst, surface chromium(II) on silica,[5] abbreviated SiO_2/Cr^{II}, is thought to be the catalytically active species involved in ethylene polymerization according to the Phillips process. It contains isolated chromium atoms which are anchored through O–Si bridges and have free coordination sites for the complexation of ligands. Not only ethylene but also higher 1-olefins such as 1-octene give polymerization in high yields with SiO_2/Cr^{II} as catalyst.[6] We have now used this polymerization catalyst as an inorganic support for Cr, Mo, and W Fischer-type carbene complexes[7] (Scheme 1). Reaction of the Cr and W carbene complexes with SiO_2/Cr^{II} in pentane resulted in the evolution of an amount of CO corresponding to the cleavage of one CO ligand per coordinated Cr and W complex and more per Mo complex.

In each case, the carbene complex was used in excess (1.5 mmol per mmol Cr). The unreacted carbene complex was subsequently extracted with pentane and its amount in the eluate determined. The new bimetallic catalysts were thereby found to have a Cr:M molar ratio of 1:1.1 (M = Cr, W) and 1:1.5 (M = Mo). Thus, the Cr and W carbene complexes reacted in nearly equimolar amounts with the chromium atom of reduced Phillips catalyst. In the case of Mo, on the other hand, subsequent reactions, possibly involving cluster formation, occurred.

In principle, these bimetallic catalysts can react with alkenes in two ways:

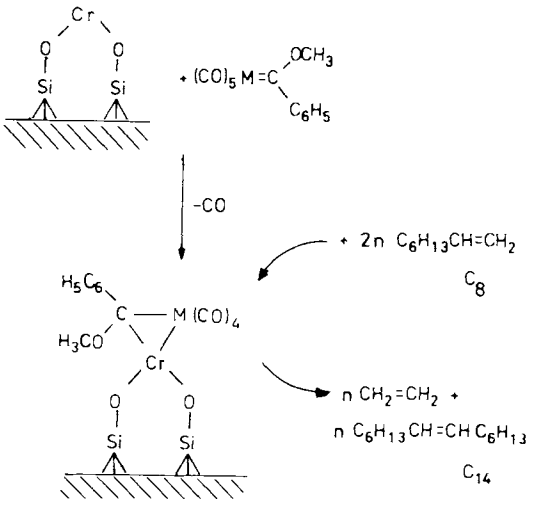
[**] Investigations of Polymerization and Metathesis Reactions, Part 11.—Part 10: K. Weiss, K. Hoffmann, *Z. Naturforsch. B42* (1987) 769.



Scheme 1. Bimetallic catalysts from reduced Phillips catalyst and carbene complexes. M = Cr, Mo, W, and 1-octene metathesis with M = Mo, W.

1. Polymerization at the carrier-bound Si–O–Cr centers.
2. Metathesis at the bound Cr, Mo, or W carbene complex fragments.

The reactivity toward 1-octene was tested in each case with a suspension of the bimetallic catalyst in refluxing hexane and the metathesis products were analyzed by gas chromatography.[8] To test for poly-1-octene, the metathesis products were distilled under high vacuum at 100 °C and the residue was investigated by IR spectroscopy. The starting carbene complexes $[(CO)_5M{=}C(OCH_3)(C_6H_5)]$, M = Cr, Mo, W, under the same conditions, in hexane solution, exhibited neither polymerization nor metathesis activity. Furthermore, no polymerization or metathesis activity toward 1-octene was observed when silica, which, except for Cr doping, had been subjected to all steps in the synthesis of SiO_2/Cr^{II}, was used as carrier for the carbene complexes (only trace amounts of the starting carbene complex were adsorbed). Polymerization or metathesis activity was not observed for the bimetallic catalyst $SiO_2/Cr/Cr$ (prepared from SiO_2/Cr^{II} and $[(CO)_5Cr{=}C(OCH_3)(C_6H_5)]$) either. We therefore conclude that the polymerization activity of the SiO_2/Cr^{II} centers is lost by reaction with the Cr carbene complex. Metathesis activity of the Cr carbene complex bound to the SiO_2/Cr^{II} centers was not expected, since Cr carbene complexes yield no catalytic metathesis reactions with unsubstituted alkenes.

Metathesis:

$$2\,C_6H_{13}CH{=}CH_2 \rightleftharpoons CH_2{=}CH_2 + \underbrace{C_6H_{13}CH{=}CHC_6H_{13}}_{C_{14}}$$

Isomerization + metathesis:

$$C_6H_{13}CH{=}CH_2 \rightleftharpoons C_5H_{11}CH{=}CH{-}CH_3$$

$$2\,C_6H_{13}CH{=}CH_2 + 2\,C_5H_{11}CH{=}CH{-}CH_3 \rightleftharpoons$$

$$\underbrace{C_6H_{13}CH{=}CHC_5H_{11}}_{C_{13}} + CH_2{=}CHCH_3$$

$$+\ \underbrace{C_6H_{13}CH{=}CHCH_3}_{C_9} + C_5H_{11}CH{=}CH_2$$

Scheme 2. Products of the metathesis of 1-octene on $SiO_2/Cr/M$ catalysts.

In contrast, $SiO_2/Cr/Mo$ and $SiO_2/Cr/W$ exhibited high metathesis activity (see Fig. 1). The amount of side products C_n (primarily C_9 and C_{13}, formed by isomerization followed by metathesis, Scheme 2) at the start of the reaction is significantly less with $SiO_2/Cr/W$ than with $SiO_2/Cr/Mo$. Possibly, these side reactions are favored by cluster formation with excess $[(CO)_5Mo{=}C(OCH_3)(C_6H_5)]$. When the concentration of 1-octene becomes less, the amount of side products of type C_n, due to isomerization and subsequent metathesis, generally increases.

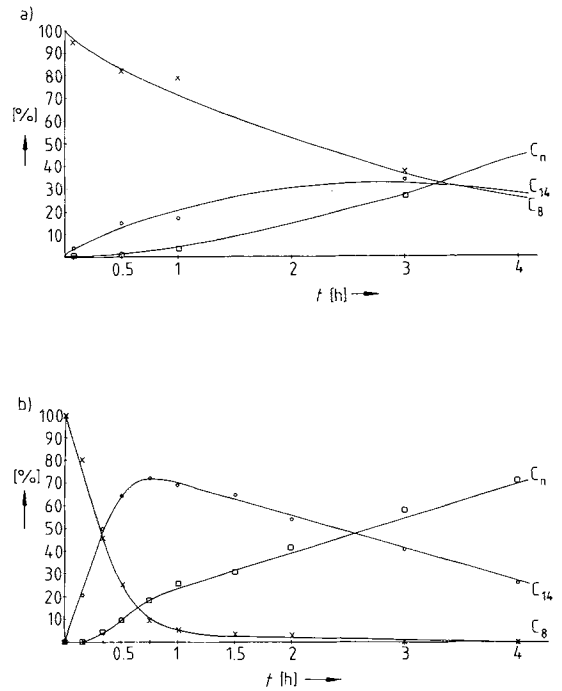


Fig. 1. Turnover/time diagrams for the metathesis of 1-octene with $SiO_2/Cr/M$ (69 °C, hexane). a) M = Mo; b) M = W.

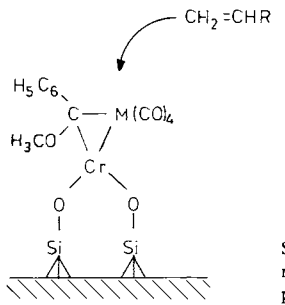
Poly-1-octenes are not formed with any of the bimetallic catalysts. This indicates that, by reaction with the carbene complexes, the originally polymerization-active SiO_2/Cr^{II} loses fully its polymerization activity. On the other hand, the Mo and W centers in the bimetallic catalysts exhibit high metathesis activity, due to the activation by the "co-catalyst" SiO_2/Cr^{II}. In order to make statements about the exact structures of these bimetallic catalysts, numerous further investigations are still required. The first FT IR investigations in diffuse reflectance from $SiO_2/Cr/W$ revealed CO absorptions of terminal CO ligands at $\tilde{\nu} = 2137$, 2094, 2075, and 2062 cm^{-1}. These absorptions might be due to a $W(CO)_4$ fragment having a positive central atom (e.g., carbyne complexes such as $[Cl(CO)_4W{\equiv}CC_6H_5]$: $\tilde{\nu}(CO) = 2123$ and 2038 cm^{-1}). Carbonyl complexes of SiO_2/Cr^{II}, on the other hand, have the most intense CO absorptions in the region around 2185 cm^{-1}.[9]

A proposed structure for $SiO_2/Cr/W$ provides a possible explanation for the especially high activity of this catalyst (Scheme 3). After having failed to prepare so far a metathesis-active bimetallic catalyst by reaction of $W(CO)_6$ with SiO_2/Cr^{II}, we believe that the carbene complex is also bound to SiO_2/Cr through the carbene ligand. The carbene complex fragment would thereby become a platform for

alkenes, the O-Cr-O fragment serving as "activating spacer" to the silica surface.



Scheme 3. Structural proposal for the bimetallic catalyst $SiO_2/Cr/W$, which explains its high activity.

New Complex Cations of Aluminum(III) and Gallium(III)**

By *Alan H. Cowley,* Carl J. Carrano, Rolf L. Geerts, Richard A. Jones,** and *Christine M. Nunn*

Recently, $[MX_4]^{\ominus}$ salts of cations of the genre $[(\eta^6\text{-arene})_2M]^{\oplus}$ (M = Ga^{I}, In^{I}; X = Cl, Br) have been isolated and structurally characterized.[1] Interestingly, it has not yet been possible to synthesize cyclopentadienyl-substituted cations of the group 13 elements of the type $[(\eta^5\text{-}C_5R_5)_2M]^{\oplus}$ (M = Al^{III}, Ga^{III}, In^{III}; R = H, Me).[2] Recognizing the formal analogy between cyclopentadienyl and tris(pyrazolyl)borato ligands,[3] we were prompted to attempt the preparation of the corresponding $[HB(pz^*)_3]$-substituted cations ($[HB(pz^*)_3]^{\ominus}$ = tris(3,5-dimethyl-1-pyrazolyl)hydridoborate anion). In passing we note that the use of (pyrazolyl)borato ligands in main-group chemistry is relatively unexplored.

Treatment of $GaCl_3$ with an equimolar quantity of $K[HB(pz^*)_3]$ in THF resulted in formation of the salt **1**.

$[\{HB(pz^*)_3\}_2Ga][GaCl_4]$ **1**

The ^{71}Ga-NMR spectrum of **1** (THF, 91.54 MHz, 25°C) exhibited two sharp singlets of equal intensity at $\delta = 2.8$ ($w_{1/2} = 60$ Hz) and $\delta = 239.2$ ($w_{1/2} = 60$ Hz). The latter peak corresponds to the $[GaCl_4]^{\ominus}$ anion,[1a,4] leading to the conclusion that the former peak is due to the cation $[\{HB(pz^*)_3\}_2Ga]^{\oplus}$. This was confirmed by a single-crystal X-ray diffraction study.[5] The solid-state of **1** comprises discrete $[\{HB(pz^*)_3\}_2Ga]^{\oplus}$ and $[GaCl_4]^{\ominus}$ ions with no short interionic contacts. Within experimental error, all Ga-N bond lengths of the cation are identical and the GaN_6 geometry is close to regular octahedral (Fig. 1). The N11-N21-N31 and N41-N51-N61 planes are therefore parallel.

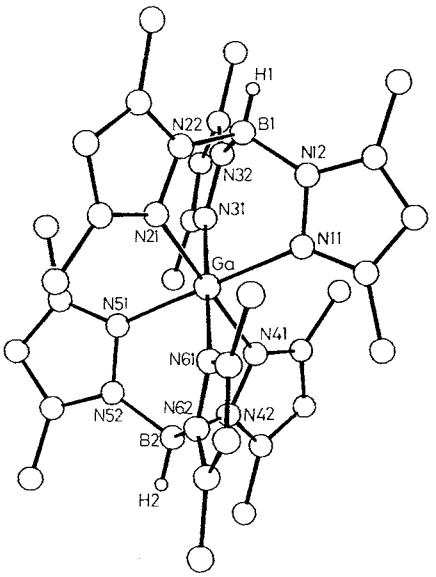

Fig. 1. Structure of **1** in the crystal. Selected bond lengths [Å]: Ga-N11 2.070(7), Ga-N21 2.066(6), Ga-N31 2.057(7), Ga-N41 2.060(6), Ga-N51 2.066(7), Ga-N61 2.064(7).

If the view is taken that the hydridotris(pyrazolyl)borate and cyclopentadienyl ligands are chemically similar, then $[\{HB(pz^*)_3\}_2Ga]^{\oplus}$ corresponds to the unknown "gallocene" cations, $[(\eta^5\text{-}C_5R_5)_2Ga]^{\oplus}$ (R = H, Me). The $[(arene)_2Ga]^{\oplus}$ cations have been shown to possess bent-sandwich structures;[1i] however, since the $[(\eta^5\text{-}C_5R_5)_2Ga]^{\oplus}$ cations feature two less electrons on the central atom, they are expected to adopt a parallel ring sandwich structure as observed for **1**.

The reaction of $K[HB(pz^*)_3]$ with $AlCl_3$ in CH_2Cl_2 proceeded similarly and afforded **2**. Unfortunately, the crys-

$[\{HB(pz^*)_3\}_2Al][AlCl_4]$ **2**

tals of **2** were not suitable for X-ray diffraction study; however, the presence of $[AlCl_4]^{\ominus}$ in solution was evident from the ^{27}Al-NMR spectrum (CH_2Cl_2, 78.21 MHz, 25°C) which exhibited a sharp singlet at $\delta = 98.5$ ($w_{1/2} = 6$ Hz).[6]

[**] This work was supported by the National Science Foundation, The Robert A. Welch Foundation, and the Texas Advanced Technology Research Program.

A second sharp singlet of equal intensity at $\delta = 6.2$ ($w_{1/2} = 12$ Hz) is attributed to the cation $[\{HB(pz^*)_3\}_2Al]^{\oplus}$.

Interestingly, the reaction of $K[HB(pz^*)_3]$ with $InCl_3$ took a different course and afforded the covalent dichloride **3**. An X-ray crystal structure determination of

$[HB(pz^*)_3]InCl_2$ **3**

$\mathbf{3} \cdot CH_3CN$[5] revealed that each indium atom is bonded to two chlorines and four nitrogens (Fig. 2). Three of the nitrogens are associated with the pyrazolylborato ligand, the fourth being from a coordination CH_3CN molecule. The binding of the $(CH_3CN)InCl_2$ moiety to the pyrazolylborate face is not symmetrical as indicated by the fact that the In–N21 distance is somewhat shorter than the other two $In-N_{pyrazolyl}$ distances.

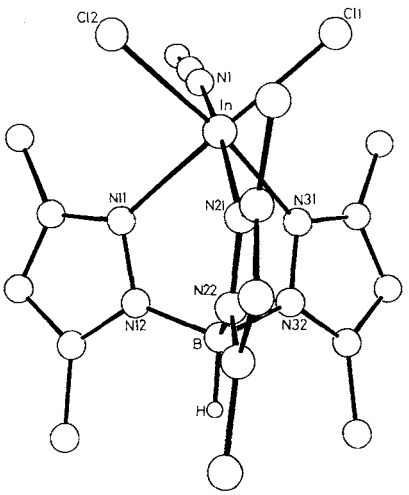

Fig. 2. Structure of **3** in the crystal. Selected bond lengths [Å]: In-Cl1 2.428(2), In-Cl2 2.429(2), In-N1 2.379(7), In-N11 2.268(4), In-N21 2.233(6), In-N31 2.249(5).

Experimental

All operations were performed under dry, oxygen-free conditions.

1: A THF (150 mL) solution of $K[HB(pz^*)_3]$ [3] (1.91 g, 5.7 mmol) was added dropwise to a THF (150 mL) solution of $GaCl_3$ (1.0 g, 5.7 mmol) at room temperature. After stirring the reaction mixture for 18 h, the solvent was removed in vacuo. The resulting solid residue was extracted with CH_2Cl_2 (2×100 mL) and filtered. Recrystallization from CH_3CN afforded colorless **1** in >80% yields. ^{1}H-NMR (90 MHz, CD_3CN, 25 °C) $\delta = 1.13$ (s, 18 H, aryl-CH_3), 2.50 (s, 18 H, aryl-CH_3), 5.90 (s, 6 H, aryl-H).

2 was prepared in the same manner as **1** except that CH_2Cl_2 was employed as the reaction solvent. Recrystallization from CH_3CN afforded colorless, microcrystalline **2** in virtually quantitative yield. ^{1}H-NMR (300.15 MHz, $CDCl_3$, 25 °C) $\delta = 1.07$ (s, 18 H, aryl-CH_3), 2.56 (s, 18 H, aryl-CH_3), 5.88 (s, 6 H, aryl-H).

3 was prepared in the same fashion as **1**. Recrystallization from CH_3CN afforded colorless, crystalline **3** in essentially quantitative yield. ^{1}H-NMR (300.15 MHz, C_6D_6, 25 °C) $\delta = 0.58$ (s, CH_3CN), 2.03 (s, 9 H, aryl-CH_3), 2.80 (s, 9 H, aryl-CH_3), 5.45 (s, 3 H, aryl-H).

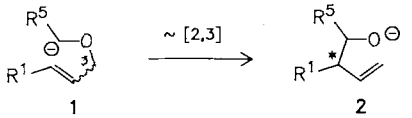
Asymmetric Induction in the [2,3] Wittig Rearrangement by Chiral Substituents in the Allyl Moiety**

By *Reinhard Brückner** and *Henning Priepke*

Recently, the Wittig rearrangement of allyloxy carbanions (**1** → **2**) has attracted renewed interest in terms of developing novel methodologies for stereoselective C–C bond formation.[1] The relative configuration of the newly formed stereogenic centers ("stereocenters") is influenced by the configuration of the double bond in the allyl ether **1** and by the R^5 moiety; the absolute configuration of the newly formed stereocenters has been controlled so far by a stereocenter at C-3 of the educt or by a chiral substituent R^5.[1,2] Here we describe two examples of high asymmetric induction by a stereocenter in the R^1 moiety.



1 **2**

In the first example, the allyl ether **3**, containing a double bond with *trans* configuration, was rearranged upon lithiation (Scheme 1).[3] Due to the influence of the chiral dioxolane ring, the new stereocenter was formed with a diastereoselectivity of 86%. The configuration of this stereocenter in the major product **4** was determined by ^{1}H-NMR spectroscopy[4] after transformation to the lactone **6**. Upon irradiation of the CH_2OH resonance of **6**, we observed a nuclear Overhauser effect (NOE) of 6% for the $CH{=}CH_2$ signal, which indicates a *cis* arrangement of the vinyl and hydroxymethyl groups. In the isomeric *trans* lactone, a corresponding NOE was not observed.[5]

The second example of the novel asymmetric induction was found when we deprotonated the allyl ether **7**,[6] containing a double bond with *cis* configuration. The Wittig rearrangement of the lithium enolate of **7** gave a 40% yield of only one homoallylic alcohol, **8**,[7] along with <2% of the other three possible stereoisomers (Scheme 2). The

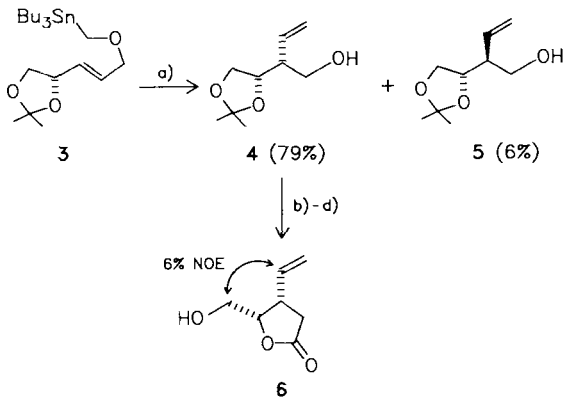
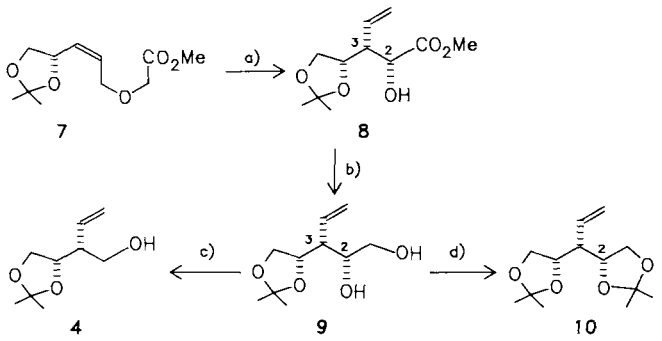


Scheme 1. a) 0.2 M in THF; +2 equiv. 1.5 M *n*BuLi in hexane, −78°C, 1 h. b) nBu$_3$P, Ph_2S_2, CH_2Cl_2, room temp., 4 h; 84%. c) LiNaphth/THF, then $ClCO_2Me$, both −78°C, 30 min; 29%. d) Ref. [5]; 49%.

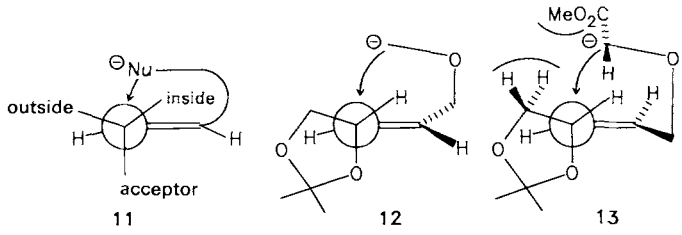
configuration of the stereocenters of **8** was determined after conversion to the diol **9**. Glycol cleavage and reduction lead to compound **4** mentioned above; hence, C-3 has the (*S*) configuration in **9** and **8**. The configuration of C-2 of **8** was obtained after transformation of the diol **9** into the bisacetonide **10**; this compound is optically inactive and displays only *one* set of signals for the *two* dioxolane rings in both the ^{1}H- and ^{13}C-NMR spectra. This means that **10** contains a symmetry plane, which, in turn, proves the (*R*) configuration of C-2 in **8**.



Scheme 2. a) 0.2 M in THF to 1.25 equiv. 0.2 M lithiumdiisopropylamide, −78°C, 30 min; then 5.5 equiv. tetramethylethylenediamine, −40°C, 3 h; 40%. b) $LiAlH_4$/THF; 92%. c) 1. $NaIO_4$/aq. MeOH, 2. $NaBH_4$/EtOH; 58%. d) $Me_2C(OMe)_2$, acetone, *p*-TsOH; 76%.

We observed the same 1,2-asymmetric induction in both Wittig rearrangements, in **3**→**4** as well as in **7**→**8**. The vinyl group of the preferred rearrangement product is *syn* to the C-O bond at the stereocenter originally present. This finding becomes plausible by examining the reaction path with the lowest-energy transition state in the frontier orbital model. For this purpose, the Wittig rearrangement is regarded as an S_N2' nucleophilic attack on an allylic ether. The crucial orbital interaction occurs between the $HOMO_{anion\ moiety}$ and the $LUMO_{allyl\ ether\ moiety}$, whereby the latter approximately can be taken as the $\pi^*_{C=C}$ orbital. The energy of the $\pi^*_{C=C}$ orbital is lowered through overlap with the adjacent allylic σ* orbitals,[8] such as are present in the dioxolane ring of **3** and **7**. The lower in energy the $\pi^*_{C=C}$ orbital thereby becomes, the better is the HOMO/LUMO interaction in the transition state and the faster is the [2,3]-sigmatropic rearrangement. Since a σ^*_{C-O} orbital is lower in energy than a σ^*_{C-C} orbital, the former lowers the $\pi^*_{C=C}$ energy more than the latter. Consequently, in the preferred transition state **11** of the Wittig rearrangement, the C-O bond of the allyl substituent is perpendicular to the plane of the double bond; of the remaining allylic substituents, the larger is found "outside" for steric reasons.

We therefore propose that **12** and **13** are transition states for the Wittig rearrangements **3**→**4** and **7**→**8**, respectively. Here, the bulky heterocycle prefers the "outside" position and the H atom the "inside" position.[9]



Cha et al. investigated the Claisen-Ireland rearrangements related to the Wittig rearrangements described here, but they found lower asymmetric inductions by the chiral dioxolanes.[10] A possible explanation is that, in the rearrangement of the neutral ketene acetal, less charge has to be stabilized in the transition state by the σ^*_{C-O} orbital than in the rearrangement of the carbanions.

Thus, the reactions **3**→**4** and **7**→**8** represent a novel stereocontrol in the Wittig rearrangement, which can be interpreted by a Felkin-Anh-type transition state **11**. Compounds **4** and **8** are needed for the synthesis of amphotericin B.

[9] The configuration of C-2 of **8** arises because in the transition state **13** the ester function gives way to the bulky dioxolane ring and therefore occupies *exclusively* the *exo* position (cf., however, Ref. [1]).—If the dioxolane ring in **13** is replaced by the smaller methyl group, i.e., in the transition state of the Wittig rearrangement of the (cis-crotyloxy)acetic ester anion, the ester function is no longer forced completely into the *exo* position. Accordingly, the hydroxy ester resulting in *this* case, contrary, to **8**, shows only a 2:1 preference for the *syn* arrangement of the hydroxyl group and the vinyl group [2b].

On the Pentaphosphacyclopentadienide Ion, $P_5^{\ominus}$**

By *Marianne Baudler,* Stilianos Akpapoglou, Dimitrios Ouzounis, Fritz Wasgestian, Bernd Meinigke, Herbert Budzikiewicz,** and *Helmut Münster*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

We recently reported on the formation of the pentaphosphacyclopentadienide ion **1** upon cleavage of white phosphorus with sodium in diethylene glycol dimethyl ether (diglyme) or with lithium dihydrogen phosphide in tetrahydrofuran (THF); in addition, other polyphosphides (in particular, $M_2^IP_{16}$, $M_3^IP_{21}$, and $M_3^IP_{19}$) were formed.[1] Compound **1** was identified by a low-field singlet in the ^{31}P-NMR spectrum ($\delta = +470.2$) and a singlet in both the ^{23}Na- and ^{7}Li-NMR spectra as well as by the Na:P ratio of 1:5 determined analytically for solutions of NaP_5. We report here further findings that have been made in the meantime concerning the formation, characterization, stability, and reactivity of **1**.

1

Preparation of a pure NaP_5 solution: The lithium salt was the first alkali-metal pentaphosphacyclopentadienide that could be obtained pure in solution.[1] In the case of the sodium compound, the other polyphosphides formed could not be separated by crystallization from diglyme. As observed by chance,[2] the formation tendency of NaP_5 in THF is significantly increased by the presence of [18]crown-6, which simultaneously favors the precipitation of other polyphosphides, so that a pure NaP_5/[18]crown-6/THF solution can be obtained;[3] NaP_5 is formed in 12% yield.

Properties and stability: The NaP_5 solutions prepared in this way are golden orange, extremely sensitive to oxidation, and stable for 7–10 days in concentrations of 10^{-2} M at room temperature. These solutions are considerably more stable than the solutions of coronand-free LiP_5 in THF.[1] Upon further concentration, NaP_5 undergoes rearrangement, in particular with formation of Na_2P_{16} and Na_3P_{21}. The addition of dimethylformamide effects stabilization, whereas hydrocarbons or active charcoal cause immediate decomposition.

Characterization. The composition and structure of **1** were corroborated by extensive spectroscopic characterization of the NaP_5/[18]crown-6/THF solutions. The ^{31}P-NMR singlet appears at somewhat higher field ($\delta = +467.2$) than in diglyme, corresponding to the larger polarity of the solvent mixture used.

The first determination of the ion mass of **1** in solution[4] was achieved by means of negative-ion FAB mass spectrometry. The use of method a) (cf. Ref. [5]) revealed, in addition to ions of the solvent mixture, a species of mass *m/z* 155 ($P_5^{\ominus}$) when the solution was warmed. This peak disappeared upon further warming, while *m/z* 62 ($P_2^{\ominus}$) increased in intensity. After averaging of the separate spectra obtained in the temperature region where *m/z* 155 appears and subtraction of the spectrum of the solvent mixture recorded under the same conditions, the difference spectrum exhibits (in addition to weak peaks corresponding to ions of the series $[(CH_2)_xO_y \pm H]^{\ominus}$, due to incomplete subtraction) only the phosphorus-containing species $P_5^{\ominus}$, $P_2^{\ominus}$, and $P_2O^{\ominus}$ (*m/z* 78, oxidation upon admission of the sample). The use of method b) (cf. Ref. [5]) resulted in the immediate transient appearance of the $P_5^{\ominus}$ ion with high intensity in addition to the matrix ions.

In the IR and Raman spectrum of the NaP_5 solution, an intense band at 815 cm^{-1} (IR) and a medium-intense polarized band at 463 cm^{-1} (Raman) are observed (in addition to the bands of the solvent mixture). These bands can be assigned to the vibrational modes E_1' and A_1', respectively, of a planar, five-atom ring of symmetry D_{5h} ($\overline{10}2m$).

The UV spectrum[6] (Fig. 1) exhibits two π–π^* bands of medium intensity at 260 and 320 nm as well as an n–π^* transition at 370 nm. When freshly prepared, dilute solutions ($c < 10^{-4}$ M) are employed, the 260-nm band shows a vibrational fine structure with maxima at 271, 266, 258, 252, 246, and 241 nm. The low intensity of the longest-wavelength vibronic maximum (271 nm) is an indication for a symmetry-forbidden transition corresponding to $^1A_1' \rightarrow {}^1E_2'$ of a 6π-electron system of the cyclopentadienide type.[7] Overall, the shape of the UV spectrum confirms the aromatic character of **1**.

Reactivity: The chemistry of **1** is characterized by analogies to and differences from that of the $C_5H_5^{\ominus}$ ion. For instance, **1** reacts with alkyl halides to form, mainly, P_7R_3

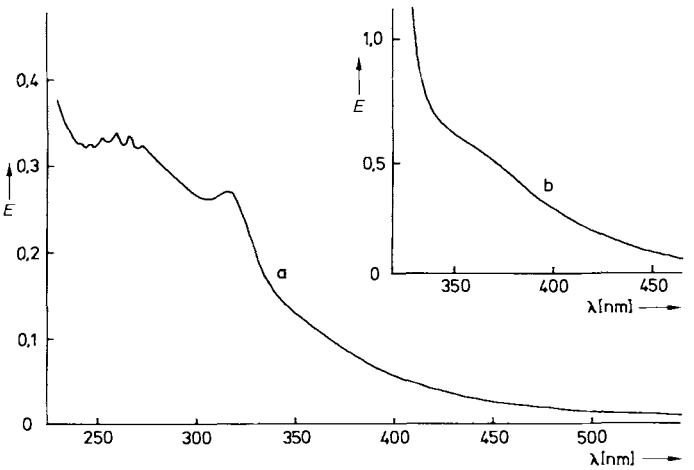

Fig. 1. Electronic spectrum of NaP_5/[18]crown-6/THF solutions; concentration of NaP_5 ca. 3×10^{-5} M (a) and 10^{-4} M (b).

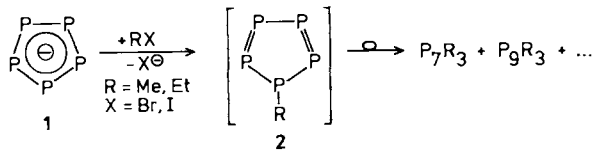
and P_9R_3. The nonaromatic primary product **2** is apparently so unstable that it spontaneously rearranges to give the thermodynamically favored alkylpolyphosphanes. No evidence for dimers of **2** was found.



1 2

$$LiP_5 + LiC_5Me_5 + FeCl_2 \xrightarrow[-2\,LiCl]{THF} [(\eta^5\text{-}P_5)Fe(\eta^5\text{-}C_5Me_5)]$$

3

Compound **1** reacts with compounds of the transition metals Fe, Ni, Rh, Mn, Cr, or Mo to form dark brown to black solids, whose insolubility and relative nonvolatility make their characterization difficult. However, black "FeP_{10}," formed immediately upon reaction with $FeCl_2$ in THF at room temperature exhibits—like **1**—an IR band at 815 cm^{-1}, which is evidence for an intact aromatic P_5 ring as structural element, since it is definitely not caused by free **1**. That a "decaphosphaferrocene" might indeed be present was further supported by direct one-pot synthesis of the mixed sandwich complex **3** (in addition to "FeP_{10}" and $[(C_5Me_5)_2Fe]$) from LiP_5, LiC_5Me_5, and $FeCl_2$;[8] **3** is identical with the compound recently obtained by *Scherer* et al.[9] by cothermolysis of $[(\eta^5\text{-}C_5Me_5)Fe(CO)_2]_2$ and P_4.

[3] *NaP_5 solution:* Freshly distilled white phosphorus (1.27 g, 0.041 g atom) in a mixture of THF (160 mL) and [18]crown-6 (5.04 g, 0.019 mol) was allowed to react under inert gas at reflux temperature with powdered sodium (0.44 g, 0.019 g atom) with stirring for 3.5 h. After standing for 24 h at room temperature, the reaction solution was separated from the sparingly soluble P-rich polyphosphides by siphoning off over a frit. Concentration to half of the original volume under oil-pump vacuum (bath temperature 55 °C, cold trap −78 °C) and renewed crystallization at −30 °C followed by filtration in the cold gave a pure, ca. 10^{-2} M NaP_5/[18]crown-6/THF solution. Additional NaP_5 can be extracted from the precipitate with boiling THF. Overall yield (by comparison of the intensity of the ^{31}P-NMR singlet with the signal of a Ph_4PCl solution of known concentration) 0.18 g (12%, based on phosphorus).

[4] The appearance of **1** in the negative ion mass spectrum of red phosphorus at 325 °C has been reported by J. T. Snodgrass, J. V. Coe, C. B. Freidhoff, K. M. McHugh, K. H. Bowen, *Chem. Phys. Lett. 122* (1985) 352.

[5] Mass spectrometer MAT-731 (acceleration voltage 8 kV, post-acceleration 7.5 kV) equipped with an 11 NF FAB ion source (Ion Tech Ltd., Teddington; 10^{-5} torr Xe, 7 kV, Cu target). The sample was admitted either by a) application of a NaP_5/[18]crown-6/THF solution, concentrated to 1/6 of its volume, onto a liquid-nitrogen-cooled target followed by slow warming in the ion source accompanied by continuous recording of the spectra or b) by mixing the concentrated solution with dibenzyl ketone as matrix at 25 °C.

[6] Cary 2300. The concentrations of the stock solutions (ca. 10^{-2} M) were estimated from the intensity of the ^{31}P-NMR singlet [3].

Synthesis and Optical Properties of Terminally Substituted Conjugated Polyenes**

By *Franz Effenberger,* Hubert Schlosser, Peter Bäuerle, Stefan Maier, Helmut Port,* and *Hans Christoph Wolf**

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The mechanisms of energy transport in molecular systems have been the subject of numerous studies in recent years.[1] Aside from investigations on the elucidation of processes involved in biological systems, e.g., in photosynthesis,[2] increasing attention has been directed to the synthesis of compounds which are suitable for the transport and storage of information on a molecular basis.[3]

Herein we report on the synthesis of conjugated polyenes of various lengths with terminal substituents whose spectroscopic properties differ from those of the polyene chains. The selective optical excitation of these model compounds and the possibility of an intramolecular energy transport are discussed on the basis of absorption, emission, and excitation spectra.

Starting from the polyene dialdehydes **1** and **7** we have synthesized, via Wittig reactions, numerous conjugated polyenes bearing the following terminal groups: 9-anthryl (A), 1-naphthyl (N) and 5,10,15,20-tetraphenylporphyrin-2-yl (TPP) as well as *p*-nitrophenyl, *p*-dimethylaminophenyl, ferrocenyl, alkoxycarbonyl, carboxy, and methyl. In the present communication, however, only those compounds shown in Schemes 1 and 2 (see overleaf) and 4,8,13,17-tetramethyl-2,4,6,8,10,12,14,16,18-eicosanonaene (TMEN) used as reference compound will be discussed.[4]

Upon Wittig reaction and purification of the products by column chromatography, the dialdehydes **1** and **7** with all-*E*-configuration initially yield *E*/*Z* isomeric mixtures in which the all-*E*-isomers dominate. The all-*E*-isomers can be enriched by recrystallization: for example, the compounds **2**-A and **3**-A,N are enriched to the extent of 100%, **3**-A,A and **3**-N,N to 99%, **3**-A,TPP to 95% and **6** to 70% in the all-*E*-form. The isomeric ratios were determined by HPLC and the respective isomers assigned by ^{1}H-NMR and UV/VIS spectroscopy.

Figure 1a shows the absorption spectra of anthracene, 5,10,15,20-tetraphenylporphyrin and TMEN, while Figure 1b shows, as selected examples, those of the polyenes **3**-A,TPP, **6** and **9**-A,A (concentrations between 10^{-6} and 10^{-4} mol L^{-1}, CH_2Cl_2, $T = 295$ K). The shapes of the spectra are concentration-independent. The anthrylpolyenes **2**-A, **8**-A, and **10**-A all show an absorption maximum at 256 nm independent of the chain length, which is not observed in the case of **1**, **7**, and TMEN, and which corresponds to the ^1B_b state[5] of anthracene. As expected, in the case of the bilaterally anthryl-substituted polyenes **3**-A,A, **9**-A,A, and **11**-A,A, the extinction coefficients of the absorption at 256 nm are doubled. In the absorption spectra of the mixed-substituted compounds **3**-A,N, **9**-A,N, and **11**-A,N a further band aside from that at 256 nm appears at 220 nm; this corresponds to the excitation of the ^1B_b

state[5] of naphthalene. The intensity ratios of the anthryl and naphthyl bands (2 : 1) of these polyenes approximately correspond to those of the free arenes anthracene and naphthalene. The spectra of **3**-A,TPP and **6** show the typical anthryl band at 256 nm, in addition to the Q bands (500–650 nm) as well as the intense Soret band (425 nm)[6] of the TPP group. The TPP bands are more or less largely superimposed by the polyene absorptions.

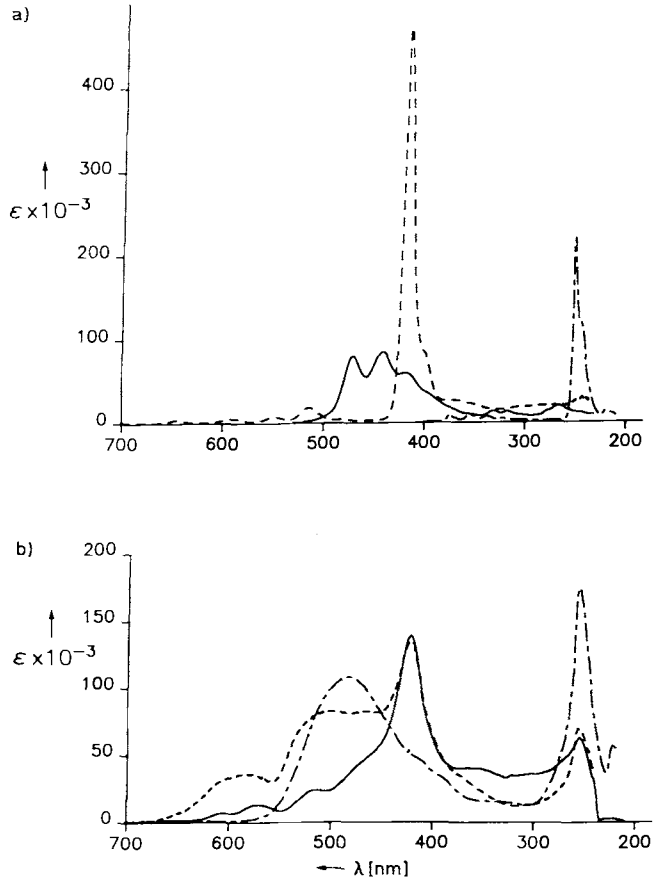

Fig. 1. Absorption spectra (CH_2Cl_2, T=295 K) of a) TMEN (——), anthracene (—·—·—), and 5,10,15,20-tetraphenylporphyrin (— — —), and of b) **3**-A,TPP (——), **6** (— — —), and **9**-A,A (—·—·—).

Evaluation of the absorption spectra accordingly reveals the not fully expected but important finding, especially as regards an application in the sense alluded to in the introduction, that a localized excitation of terminal groups is possible in the conjugated π-systems mentioned here.

In order to check whether an energy transport from an electronically excited terminal group via the conjugated polyene to another terminal group is possible we chose the compounds **3**-A,TPP and **6**, in which the absorption and emission bands of the relevant molecular moieties are adequately separated. Figures 2a and 2b show the corrected emission spectra[7] of anthracene and tetraphenylporphyrin and of **3**-A,TPP, respectively (*n*-hexane, T=180 K, excitation at 257 nm). Compared to the emission spectrum of the anthracene-tetraphenylporphyrin mixture, the emission spectrum of **3**-A,TPP shows a decrease in the anthryl emission with concomitant increase in the tetraphenylporphyrinyl emission.

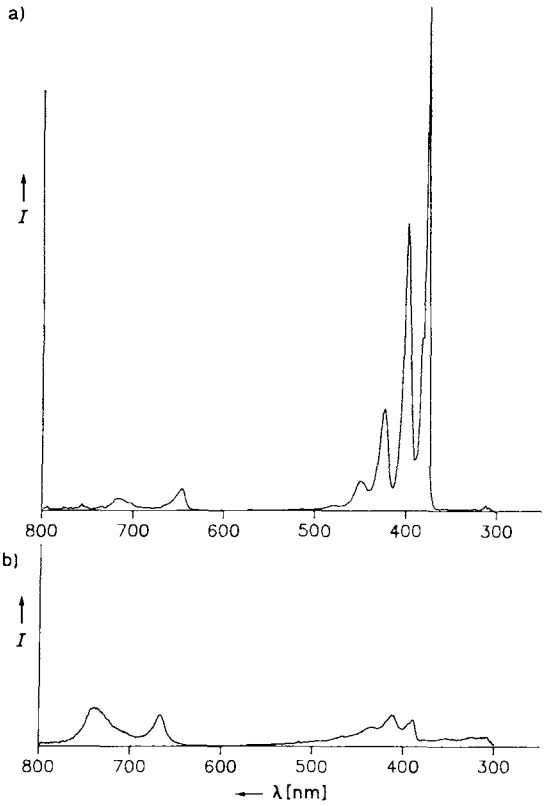

Fig. 2. Emission spectra (*n*-hexane, T=180 K, excitation at 257 nm) of a) anthracene/5,10,15,20-tetraphenylporphyrin (1/1), concentration 10^{-6} mol L^{-1} (the spectrum corresponds to a superposition of the individual spectra) and of b) **3**-A,TPP, concentration 2×10^{-5} mol L^{-1} (the origin of the weak emission between 300 and 380 nm is still unknown).

From the corrected excitation spectra of the compounds **3**-A,TPP and **6** shown in Figure 3 it clearly follows that, depending upon the excitation wavelength, the emission intensity of the TPP terminal group at 665 nm shows a

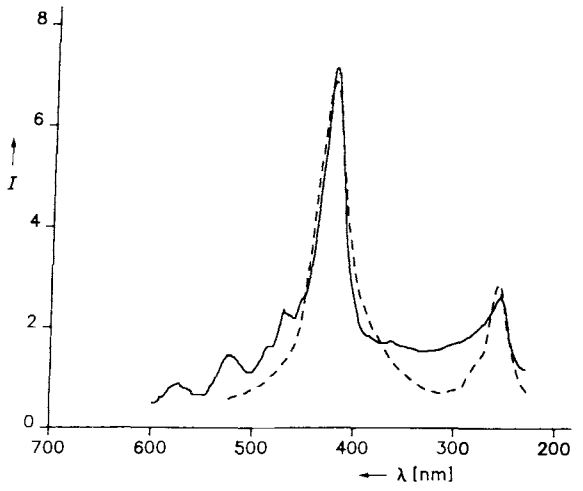

Fig. 3. Excitation spectra at T=295 K. Detection at 665 nm. **3**-A,TPP (——) and **6** (— — —).

maximum upon excitation with 256 nm, corresponding to the absorption band of the anthryl substituent. A TPP emission is not observed upon excitation in the range of

the polyene absorption of the compound **6** (at ca. 500 nm).

The time resolved measurements of the emission (picosecond laser pulse excitation, single-photon counting detection) gave no significant changes of the time constants for the growth and decay behavior of the coupled systems **3**-A,TPP and **6** compared to anthracene and tetraphenylporphyrin. The time constants for the growth are in all cases <25 ps, while those for the decay lie between 3.6 and 5.5 ns.

All the emission and excitation spectroscopic findings are consistent with an intramolecular energy transport from the excited anthryl group via the polyene chain to the TPP substituent, which then emits in competition with the anthryl group. Other known energy transfer mechanisms such as reabsorption,[8] Förster mechanism[9] or light-induced electron transfer[1] are not involved. The independence of the emission spectra on the concentration and the short growth times of the TPP emission rule out reabsorption and an intermolecular energy transfer by Förster mechanism. In the case of an intramolecular energy transfer by long distance interactions as described by *Förster* a shortening of the anthryl emission decay time should be observed, as also in the case of an electron transfer from the anthryl- to the TPP-substituent.

For an explanation of the observed energy transport we must therefore assume that the energy absorbed in the anthryl substituent leads only to partial relaxation into the anthryl S_1 state, which then emits. Occupation of an energy state delocalized over the molecule competes with this; after relaxation into the first excited singlet state of the TPP group the corresponding emission finally takes place.

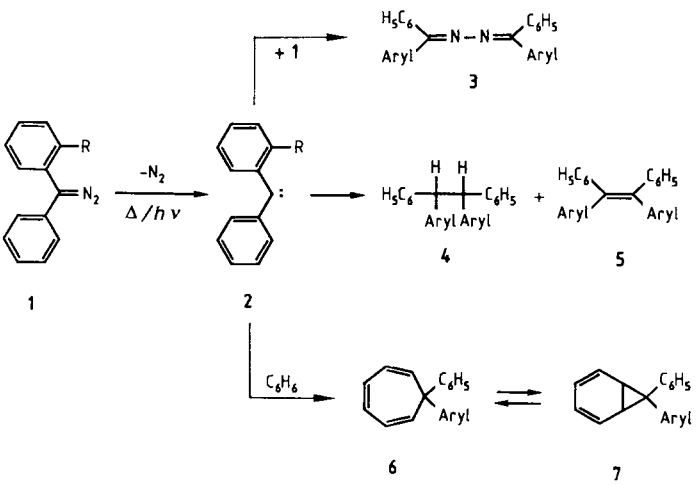
Formation of Cycloheptatriene/Norcaradiene Systems in the Decomposition of Diaryldiazomethanes in Benzene**

By *Klaus Hannemann**

Whereas numerous carbenes are known to react with benzene to form cycloheptatriene/norcaradiene systems,[1] to our knowledge this reaction has hitherto not been observed with diphenylcarbene. Benzophenone azine **3a** and small amounts of tetraphenylethane **4a** and tetraphenylethene **5a** were mainly obtained as products of the thermal and photochemical decomposition of diphenyldiazomethane **1a** (Scheme 1).[2] We have now been able to observe addition of the corresponding carbenes **2** to benzene in the thermal decomposition of diphenyldiazomethane **1a** and its *ortho*-methyl derivative **1b** and to isolate the previously unknown cycloheptatriene/norcaradiene systems **6/7** in substantial yields.[3,4]



Scheme 1. Aryl = C_6H_4R; **a**, R = H; **b**, R = CH_3.

When the diazomethanes **1** are decomposed in boiling benzene the product composition strongly depends on the concentration of the starting material. At high concentrations of **1** the reaction of the carbene **2** with its precursor **1** dominates.[2] At greater dilution, reactions of **2** with the solvent and with traces of impurities such as water and oxygen predominate.

In the thermolysis of **1b** in boiling benzene (on a preparative scale, high dilution, complete absence of moisture and oxygen) an addition product of **2b** and benzene could be isolated in 31% yield.[5] Diphenylcarbene **2a** is less reactive: under the same conditions, only 8% of the addition products **6a/7a** were obtained. The same compounds are also formed on photolysis, but the yields are lower.[6]

The NMR spectra of the compounds are consistent with a cycloheptatriene/norcaradiene equilibrium.[7] The chemical shifts of the 1,6 H and C atoms of pure cyclohepta-

trienes lie at $\delta = 5.2$–5.3 and 120–130, respectively, whereas typical norcaradienes absorb at $\delta = 2.8$–3.5 and 35–45, respectively (Table 1). The resonances of equilibrium systems lie between these values, and from their position the position of the cycloheptatriene/norcaradiene equilibrium can be estimated.[8] The addition compound of **2a** and benzene shows shifts of $\delta = 4.54$ and 96.20 for the 1,6 H and C atoms, from which it can be estimated that ca. 35% of the norcaradiene form **7a** is present in the equilibrium at room temperature. In contrast, the resonances at $\delta = 2.87$ and 42.27 for the 1,6 H and C atoms, respectively, of the addition product of **2b** and benzene show that this is present entirely as the norcaradiene **7b**. Hence, the *ortho*-methyl group influences the position of the cycloheptatriene/norcaradiene equilibrium considerably.

Engl. 10* (1971) 342. [d] ^{1}H-NMR in [D$_6$]acetone, ^{13}C-NMR in $CDCl_3$. [e] C. Ganter, J. D. Roberts, *J. Am. Chem. Soc. 88* (1966) 741.

Studies on the influence of substituents on the cycloheptatriene/norcaradiene equilibrium showed that the norcaradiene form can be stabilized by π-acceptors in position 7,[9] by incorporation of the norcaradiene in ring systems,[8b, 10] and by steric effects.[11] Electronic effects are unlikely to be responsible for the shift in the equilibrium **6** ⇌ **7** on going from **6a/7a** to **6b/7b**, since a *para*-methyl group in similar systems shows no comparable effect[9f] and the methyl group shows a +I effect (negative Hammett constant) instead of a −I effect stabilizing the norcaradiene system. The strong influence of the *ortho*-methyl group on the cycloheptatriene-norcaradiene equilibrium is therefore probably due to steric interactions and thus represents a considerable "*ortho*" effect.

The addition of diarylcarbenes to benzene opens up the possibility of systematic studies on the influences of aryl substituents on the cycloheptatriene/norcaradiene equilibrium.

Experimental

A solution of **1** in benzene was added dropwise over a period of 24 h to 250 mL of boiling anhydrous benzene under N_2; the mixture was then heated under reflux for a further 24 h. After removal of the benzene, the crude product was separated by column chromatography (silica gel, gradient elution with hexane containing 0.5–3% ethyl acetate).

a) Products of the reaction with **1a** (1.40 g, 7.21 mmol) in benzene (150 mL): 4 mg (0.7%) of biphenyl, 140 mg (8%) of **6a/7a**, 102 mg of a mixture of **4a**, **5a** and two further unidentified compounds, 78 mg (6%) of benzophenone, 770 mg (59%) of **3a**.

b) Products of the reaction with **1b** (500 mg, 2.40 mmol) in benzene (50 mL): traces of biphenyl, 55 mg (13%) of phenylcyclobutabenzene, 210 mg (34%) of **7b**, 20 mg (4%) of **4b**, 27 mg (6%), of 2-methylbenzophenone, 95 mg (20%) of **3b**.

[3] A tricarbonylchromium complex of **6a** has already been described: G. Simonneaux, G. Jaouen, R. Dabard, *Tetrahedron 36* (1980) 893. **6a** and other substituted cycloheptatrienes are also accessible via addition of diazomethanes to benzvalene after denitrogenation of the adduct and subsequent catalyzed rearrangement. We thank Prof. *M. Christl* for informing us of these unpublished results.

[4] Reviews: a) G. Maier, *Angew. Chem. 79* (1967) 446; *Angew. Chem. Int. Ed. Engl. 6* (1967) 402; b) D. Wendisch in *Houben-Weyl-Müller: Methoden der organischen Chemie, Vol. IV/3*, 4th Edit., Thieme, Stuttgart 1972, p. 509; c) H. Kessler, *ibid., Vol. V/1d*, p. 301.

[5] Aside from other products, 12% of phenylcyclobutabenzene could be isolated, which is formed by intramolecular H-abstraction and subsequent ring closure. At room temperature, cyclobutabenzene is formed in traces only; upon pyrolysis (325°C), however, it is formed in more than 50% yield. This is consistent with findings on comparable systems: H. E. Zimmermann, D. H. Paskovich, *J. Am. Chem. Soc. 86* (1964) 2149.

[6] The efficiency of the photochemical addition of carbene to benzene is temperature-dependent: photolysis of **1b** at 50°C furnished 13% of **6b/7b**, that at room temperature 10% of **6b/7b**.

C_5 Building Blocks for Terpene Syntheses: γ-Acetoxylation of (*E*)-2-Methyl-2-butenals

By *Rolf H. Fischer,* Heinz Krapf,* and *Joachim Paust*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The (*E*)-2-methyl-2-butenals **1** and **2** containing acetoxy groups are important C_5 building blocks for the synthesis of terpenes by means of the Wittig reaction. Thus, (*E*)-3-

formyl-2-butenyl acetate **1** is of industrial importance for the production of vitamin A.[1] In unilaterally protected dialdehydes, such as (*E*)-3-formyl-2-butenylidene diacetate **2**, first the free, then—after hydrolysis of the protecting group—the capped aldehyde can each be allowed to react with a different ylide.[2]

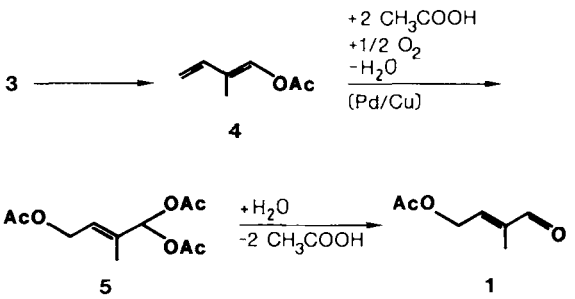
1: R^1=OAc, R^2=H
2: R^1, R^2=OAc

3

1 can either be prepared from C_1- to C_3-starting compounds such as acetylene and acetone or acetylene, formaldehyde and carbon monoxide,[1] or by functionalization of the C_5 skeleton already present in isoprene.[3] For the synthesis of **2**, only the oxidation of 3-methyl-2-butenylidene diacetate ("4,4-diacetoxy-2-methyl-2-butene") with selenium dioxide has previously been described.[2a]

An attractive starting compound for the preparation of **1** and **2** is (*E*)-2-methyl-2-butenal (tiglaldehyde) **3**, which contains all the structural elements of **1** excepting the acetoxy group and, e.g., is readily accessible from isoprene epoxide[3a] or 2-methyl-2-butenylene diacetate ("1,4-diacetoxy-2-methyl-2-butene").[4]

Attempts to convert **3** into **1** in one step by acetoxylation have thus far met with little success.[5] On the other hand, if **3** is first converted into 2-methyl-1,3-butadienyl acetate **4** with isopropenyl acetate,[6] then a method already described for the 1,4-bisacetoxylation of butadiene can be used successfully for the synthesis of **1**.[7]

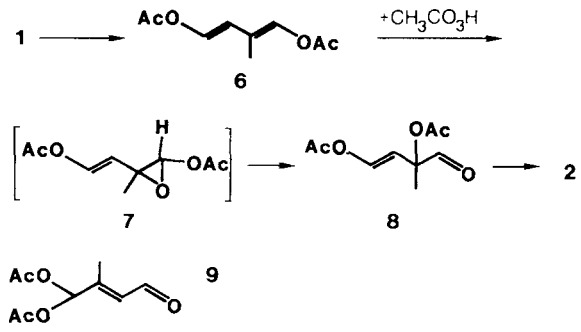


After reaction of **4** with glacial acetic acid and oxygen at 95°C in the presence of a suspension of supported Pd/Cu catalyst (5% Pd, 9% Cu on activated carbon)[8] we isolated **1** in 28% yield and (*E*)+(*Z*)-2-methyl-2-butene-1,1,4-triyl triacetate **5** in 37% yield. For the preparation of pure **1**, the reaction products, after removal of catalyst by filtration, were worked-up by hydrolysis. Although **5** is present as an (*E*)/(*Z*)-mixture (53% *E*, 47% *Z*), **1** can be isolated (yield 66%), after hydrolysis of **5**, with an (*E*)-content of 98%.

Using the same principle, other α,β-unsaturated aldehydes instead of **3**, such as 2-butenal, 3-methyl-2-butenal, and 3-formylallyl acetate ("4-acetoxy-2-butenal"), can be acetoxylated via dienyl acetates to tri- and tetraacetoxylated 2-butenes.

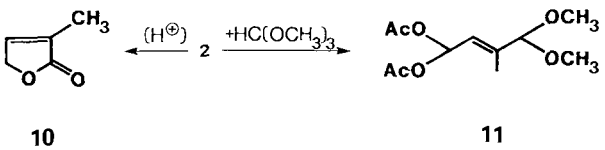
For the conversion of **1** into **2** via 2-methyl-1,3-butadienylene diacetate **6**[9] we could not use the 1,4-bisacetoxylation method: namely, the (*E*)/(*Z*)-mixture of the 1,1,4,4-tetraacetates obtained by acetoxylation of **6** could not be hydrolyzed to **2** with sufficient regioselectivity.

On the other hand, it was possible to oxidize **6** to **2** with anhydrous peracetic acid[10] at 100°C in glacial acetic acid as solvent (yield ca. 50%).[11] The (*E*)-fraction of **2** amounted to 69% and could be increased to 83% by addition of strongly acidic ion-exchangers.[12]



In the reaction of **6** with peracetic acid the methyl-substituted double bond should be epoxidized with high regioselectivity, as in the case of isoprene.[3a] The epoxide **7** formed thereby is presumably converted into **2** via the aldehyde **8** (allyl rearrangement). Consistent with this explanation is the fact that, after epoxidation of **6** with *m*-chloroperbenzoic acid in chloroform, a mixture of **8** and its (*Z*)-isomer together with **2** could be isolated and identified by ^{1}H-NMR spectroscopy.[13] The ester **9**, isomeric with **2**, was isolated as by-product (yield 2%). The (*E*)-form shown here is consistent with the ^{1}H-NMR spectrum.

Interesting secondary products are accessible from **2**: Thus, on heating with acetic acid in the presence of *p*-toluenesulfonic acid, **2** is converted into 3-methyl-2(5*H*)-furanone **10**.[14] Upon acetalization with trimethyl orthoformate the C_5 building block (*E*)-4,4-dimethoxy-3-methyl-2-butenal is formed in the form of its acylal **11**.[15]



10 **11**

Experimental

1+5: 63 g (0.5 mol) of **4** was added dropwise within 4 h at −95°C to a stirred suspension of 25 g of Pd/Cu catalyst (5% Pd, 9% Cu on activated carbon) [8a] in 600 g of glacial acetic acid in a three-necked flask fitted with a gassing stirrer; at the same time 12 L of O_2 were passed into the solution. A further 3 L of O_2 were then passed into the solution within 1 h at 95°C and stirring continued for 15 min with simultaneous passage of N_2. After cooling, the catalyst was removed by suction. According to combined GC/MS the reaction product (663 g) contained **1** and **5** together with small amounts of **3** and 1-formyl-1-methylallyl acetate ("2-acetoxy-2-methyl-3-butenal"). After fractional distillation, 20.4 g of **1**, b.p. 92–95°C/16 mbar ((*E*)/(*Z*) ratio according to GC 98:2) (28% based on **4**) and 44.9 g of **5**, b.p. 118–124°C/0.8 mbar, n_D^{20} = 1.4492 ((*E*)/(*Z*) ratio according to ^{1}H-NMR ca. 1:1) (37% based on **4**) were isolated.—^{1}H-NMR (250 MHz, $CDCl_3$, TMS int.): (*E*)-**5**: δ = 1.78 (s, CH_3, 3 H), 2.03–2.12 ($COCH_3$, 9 H), 4.66 (d, OCH_2, *J* = 6.6 Hz, 2 H), 5.86 (t, =CH−, 6.6 Hz, 1 H), 7.05 (s, −OCHO−, 1 H). (*Z*)-**5**: δ = 1.84 (s, CH_3, 3 H), 2.03–2.12 ($COCH_3$, 9 H), 4.79 (d, OCH_2, *J* = 7.0 Hz, 2 H), 5.61 (t, =CH−, *J* = 7.0 Hz, 1 H), 7.48 (s, −OCHO−, 1 H).

1: The reaction product, after removal of catalyst by filtration and addition of 29 g (1.6 mol) of H_2O, was heated under reflux for 4 h. After work-up by distillation, 48.1 g of **1** (66% based on **4**) ((*E*)/(*Z*) ratio 98:2) was obtained.

2: A suspension of 10 g of acidic ion-exchanger (®Amberlite IR-120, H-form; previously washed anhydrously with glacial acetic acid) in a solution of **6**

(184 g, 1 mol) (60% (*E,E*), 18% (*Z,E*), 17% (*E,Z*), and 5% (*Z,Z*)) and 500 g of glacial acetic acid was treated at 100±2°C within 1 h with a solution of 806 g (1.2 mol) of 11.3% anhydrous peracetic acid [10] in glacial acetic acid and then stirred a further 10 min at the same temperature. After removal of ion-exchanger from the peroxide-free solution by filtration, removal of the acetic acid (rotary evaporator, 45°C/215 mbar), and distillation (Vigreux column), 141 g of crude **2**, b.p. 86–102°C/0.9 mbar was obtained (GC analysis: 80% **2** + (*Z*)-isomer, 2% **8**, 3% (*Z*)-isomer of **8** and 6% **9**; the percentage amounts are based on peak areas in the gas chromatogram). Fractional distillation (1 m rotary band column) furnished 117 g of **2**, b.p. 79–81°C/0.1 mbar (GC purity: 97%, (*E*)/(*Z*) ratio according to ^{1}H-NMR (ratio of aldehyde protons) 83:17) (47% based on **6**) and 4 g of **9**, b.p. 87–88°C/0.15 mbar (GC purity 86%) (2% based on **6**). **2** and **9** gave correct elemental analyses.—Under the same conditions, but without ion-exchanger, 125 g of **2** ((*E*)/(*Z*)-ratio 69:31) (43% based on **6**) was obtained after fractional distillation.—^{1}H-NMR (250 MHz, $CDCl_3$, TMS int.). **2**: δ=1.90 (d, CH_3, J=1.5 Hz, 3H), 2.15 (s, $COCH_3$, 6H), 6.40 (q, d, =CH–, J=1.5 Hz, 7.7 Hz, 1H), 7.60 (d, –OCHO–, J=7.7 Hz, 1H), 9.50 (s, –CHO, 1H).—(*Z*)-form of **2**: δ=1.87 (d, CH_3, J=ca. 1.6 Hz, 3H), 2.15 (s, $COCH_3$, 6H), ca. 6.40 (q, d, =CH–, J=ca. 2 Hz, ca. 8 Hz, 1H), 7.98 (d, –OCHO–, J=8.6 Hz, 1H), 10.30 (s, –CHO, 1H).—**9**: δ=2.14 (s, $COCH_3$, 6H), 2.22 (d, CH_3, J=2 Hz, 3H), 6.19 (q, d, –CH=, J=2 Hz, 7 Hz, 1H), 7.15 (s, –OCHO–, 1H), 10.08 (d, –CHO, J=7 Hz, 1H).

[11] The epoxidation of **4**, on the other hand, proceeds less selectively under the conditions given for **2** in the experimental section. Not only the expected **1** is isolated (22%) but also 1-formyl-1-methylallyl acetate ("2-acetoxy-2-methyl-3-butenal") (23%) and a mixture of 4-hydroxy-2-methyl-2-butenylidene diacetate ("1,1-diacetoxy-4-hydroxy-2-methyl-2-butene") and **5**.
[12] Larger amounts of ion-exchanger in the epoxidation, or heating of (*Z*)-isomer containing **2** in the presence of this exchanger increase the (*E*)-fraction—albeit with losses in yield—to ca. 95%.

Synthesis and Structure of an Azastibacubane**

By *Walter Neubert, Hans Pritzkow,* and *Hans P. Latscha**

Antimony(v)-nitrogen compounds are formed only when the basicity of the nitrogen is reduced by electron-attracting groups or by mesomeric effects. Furthermore, the nitrogen-containing reaction partner must be relatively insensitive towards oxidation.[1–3] Amines, for example, react with antimony pentachloride to give, inter alia, mixed valence compounds;[4] single valence products can only be obtained if trimethylsilyl-substituted amines are used.

On allowing antimony pentachloride to react with methylbis(trimethylsilyl)amine [Eq. (a)] we obtained pale yellow crystals of **1** in good yield.

$$4\,SbCl_5 + 4((CH_3)_3Si)_2(CH_3)N \longrightarrow (CH_3NSbCl_3)_4 + 8\,(CH_3)_3SiCl \quad \text{(a)}$$

1

1 is the first compound whose cubane-like structure is entirely made up of nitrogen and antimony atoms (Fig. 1).[5] The molecule has a fourfold rotary inversion axis; the Sb–N distances are comparable with those in Sb_2N_2 four-membered rings.[2,6]

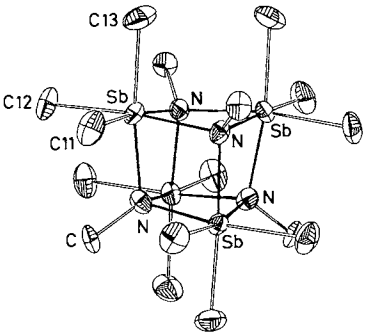

Fig. 1. Molecular structure of **1**. Important bond lengths [Å] and angles [°]: Sb–Cl 2.320–2.337(3), Sb–N 2.151–2.189(10), N–C 1.504(13); Sb–N–Sb 99.6–100.8(4), N–Sb–N 78.2–79.1(3).

Experimental

Separate solutions of equimolar amounts of $SbCl_5$ and of $((CH_3)_3Si)_2(CH_3)N$ in CH_2Cl_2 were prepared. Both were made as dilute as possible. The $SbCl_5$ solution was added dropwise and slowly at room temperature to the stirred silylamine solution. After addition was complete the mixture was heated for about 1 h under reflux. Finally, the solvent together with trimethylchlorosilane was removed from the mixture by distillation. The residue was then extracted with CH_2Cl_2. On evaporation of the extract to dryness, yellow crystals of **1** were obtained. They are soluble in aromatic and chlorinated hydrocarbons, and were purified by chromatography on silica gel (eluent cyclohexane/dichloromethane 3/1); m.p. 180°C (decomp.) yield ca. 55%.—IR spectrum (KBr pellet): $\tilde{\nu}$ [cm^{-1}]=3500–3400 (w, KBr), 3250 (w, NH), 2930 (w, ν(CH)), 2860 (w, ν(CH), 1440 (s, δ(CH)), 1410 (m, δ(CH)), 970 (s, ν(N–CH)), 780 (m), 635 (w), 530 (s, ν_{as}(SbN)), 395 (m, ν($SbCl_2$)), 330 (m, ν(SbCl), ν_s(SbN_2)).—^{1}H-NMR spectrum ($CDCl_3$, TMS as standard): δ=3.65. ^{13}C-NMR spectrum ($CDCl_3$): δ=35.9.—MS: *m/z* 984 ($M^{\oplus}$ – HCl).—Correct elemental analysis (C,H,N,Cl,Sb).

A Conjugated Bis(tetrathiafulvalene) System with Tetrathia-*s*-indacene Structure**

By *Peter Wolf, Herbert Naarmann,* and *Klaus Müllen**

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The anisotropy of the charge transport in stacked charge-transfer (CT) complexes of the tetrathiafulvalene (TTF) series[1,2] leads, below a critical temperature, to reorganizations of the crystal lattice and thus to the breakdown of "metallic" states.[3,4] The distortions in the crystal lattice can be prevented if the electron transfer between neighboring donor stacks is facilitated and the dimensionality of the conduction process thus increased. Typical examples are CT complexes of bis(ethylenedithio)tetrafulvalene, in which the increase in dimensionality results from the special, unpredictable crystal structure.[5] Another more rarely investigated strategy consists in enabling the delocalization of electrons via neighboring donor stacks by covalent bonds. Following this concept we developed donor systems of larger molecules which contain conjugatively coupled TTF units.

We describe here the dibenzo-"bis"-TFF **1c** containing a benzene unit as "conjugative bridge". The tetrathia-*s*-indacenedithione system **2** appeared to be a suitable candidate as precursor, but the parent compound **2a** (R = H) is unsuitable due to its insolubility in organic solvents.[6] The advantage of **2** is that groups which improve the solubility can be readily incorporated. As starting material for the synthesis of soluble derivatives of **1** we chose the dihydroxy compound **2b**,[7] which we (cf. Ref. [8]) etherified with 3,5-di-*tert*-butylbenzyl bromide to give **2c** (acetone, K_2CO_3, 62%; m.p. 237 °C).[9] Possible disadvantageous effects of the bulky benzyl residue on the distance of neighboring donor units within TTF stacks were put up with in favor of the easy accessibility and improved solubility of the compounds **1**.

7

a, R = H; **b**, R = OH; **c**, R = 3,5-Di-*tert*-butylbenzyloxy

The method of choice for the coupling of the readily soluble dithione **2c** to bis-TFF systems proved to be that described by *Lindsay* et al.[10,11] and previously used only for the synthesis of unsymmetrical benzotetrathiafulvalenes. A solution of the trithioorthoformate anion **3** in tetrahydrofuran (THF) was treated (argon, −78 °C) dropwise with a THF-solution of **2c** (molar ratio 2 : 1), and the dithiolate ion **4c** that was formed initially was converted by addition of methyl iodide into the bis(hexathioorthooxalate) **5c** (colorless microcrystals, m.p. 119 °C; yield 66% after chromatography on silica gel [petroleum ether/chloroform 2 : 1] and recrystallization). An attempted reaction of the anion **3** with the unsubstituted analogue **2a** yielded only unchanged **2a** and methylated **3**.

Heating of a tetrachloroethane solution of **5c** resulted in extrusion of dimethyl disulfide and formation of the desired compound (orange needles, m.p. 242 °C [decomp.]; yield 45% after chromatography on silica gel [petroleum ether/chloroform 1 : 1] and recrystallization), which is readily soluble in organic solvents. Characteristic in the NMR spectra of **1c** are the resonances of the aromatic protons ($\delta_H = 7.10$–7.30 [8 H] and 7.30–7.48 [6 H]) due to an AA'BB' and an AB_2 system, and the resonances of the fulvalenic carbon atoms ($\delta_C = 110.7$ and 112.2).

Reaction of **2c** with only one equivalent of the anion **3** and work-up as previously described affords the monothione **6c**, which is a useful starting material for further coupling reactions.

The electrochemical oxidation of **1c** leads, according to cyclovoltammetry (dichloromethane, tetraethylammonium perchlorate, Ag/AgCl reference electrode), to reversible electron transfers at +0.70 and +1.00 V. These potentials largely correspond to those of the model system dibenzo-

TFF 7, which under our conditions lie at +0.66 and +1.08 V.[12] In the ESR spectrum of the oxidatively generated radical cation $\mathbf{1c}^{\odot\oplus}$ (aluminum chloride, dichloromethane, hyperfine couplings of ^1H not resolved) the couplings of ^{32}S obtained from the satellites are of the same magnitude as those in the radical cation $7^{\odot\oplus}$.[13] Apparently the spin density in $\mathbf{1c}^{\odot\oplus}$ remains localized in a TTF unit.

Reaction of **1c** with dichlorodicyano-*p*-benzoquinone (DDQ) and with iodine, bromine and chlorine leads to the formation of CT complexes, but not, however, the attempted reaction with tetracyanoquinodimethane. In the case of the deep-green DDQ complex the composition determined by elemental analysis is 1:2, i.e. each TFF subunit binds one acceptor molecule. The IR spectrum of the complex shows a very broad, intense absorption band, which stretches from the NIR region to a wavelength of ca. 2000 cm^{-1}. This band is typical for mixed valence CT complexes with separate donor and acceptor stacks; it is generally attributed to an electron transition between neighboring donor molecules within a stack.[14]

The IR spectrum of the iodine complex of **1c** is similar, only the broad absorption band is shifted to shorter wavelengths. The composition determined by elemental analysis is, in this case, 1:1.52, i.e. 76% of the fulvenic centers are present in the oxidized state. The powder conductivity of the DDQ complex of **1c** is $10^{-8}\ \Omega^{-1}\ cm^{-1}$. This possibly reflects a greater TTF layer separation caused by the bulky substituents.

Further possibilities of the synthesis described here are the construction of higher molecular TTF systems and the variation of the substituents R, which also includes the generation of water-soluble substances.

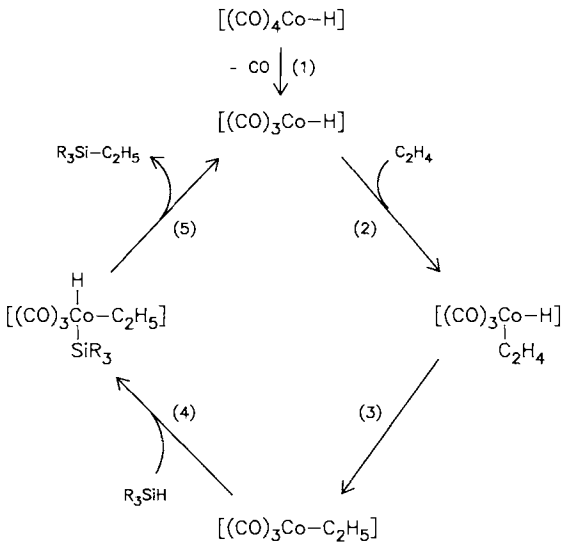
Photochemical Reaction of $[(CO)_4Co(SiEt_3)]$ with Ethylene: Implications for Cobaltcarbonyl-Catalyzed Hydrosilation of Alkenes**

By *Friedrich Seitz* and *Mark S. Wrighton**

Dedicated to Prof. Dr. Helmut Dörfel on the occasion of his 60th birthday

The commonly proposed Chalk-Harrod mechanism (Scheme 1)[1–3] for transition metal catalyzed hydrosilation of alkenes involves as the key steps the insertion of an alkene into a M–H bond [step (3)] and the reductive elimination of an alkyl and a silyl ligand to form an alkylsilane [step (5)]. Whereas the insertion of alkenes into M–H bonds is well documented,[4] the reductive elimination of an alkylsilane has only been reported for $[(CO)_4Fe(alkyl)(SiR_3)]$,[5] and this is a slow reaction at 298 K. More importantly, the mechanism in Scheme 1 cannot explain the formation of alkenylsilanes, which are frequently observed as by-products of hydrosilation reactions.[6–9]



Scheme 1. Chalk-Harrod mechanism of the catalytic hydrosilation by insertion of C_2H_4 into a M–H bond, with $[(CO)_4Co-H]$ as model example [1–3].

An alternative mechanism (Scheme 2) has been suggested for the photocatalyzed hydrosilation of alkenes using $Fe(CO)_5$,[6] $M_3(CO)_{12}$ (M = Fe, Ru, Os)[7] or $[(CO)_4Co-SiR_3]$[8] as catalysts. The key steps of this mechanism are

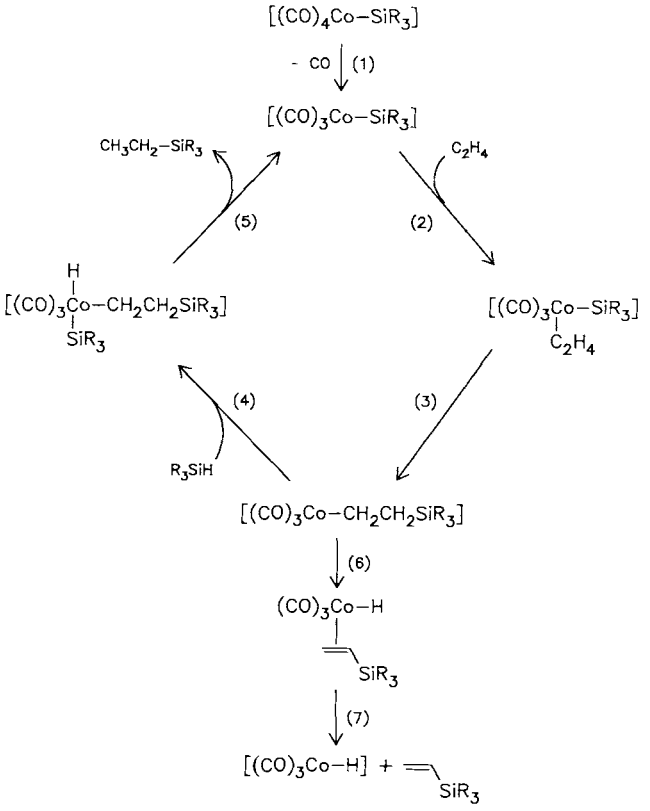
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Office of Naval Research (USA), and the National Science Foundation.

the insertion of an alkene into a M–Si bond [step (3)] and the reductive elimination of an alkyl and a hydrido ligand [step (5)]. Evidence for all steps required by this mechanism has been obtained for $[(\eta^5\text{-}C_5Me_5)(CO)_2Fe\text{-}SiR_3]$.[10] We have now extended these investigations to the complex $[(CO)_4Co\text{-}SiR_3]$, which is known to be an efficient hydrosilation catalyst under irradiation.[8]



Scheme 2. Newly proposed mechanism for the catalytic hydrosilation by insertion of C_2H_4 into a Co–Si bond (R = Et).

It has been shown[11] that near-UV photolysis of $[(CO)_4Co\text{-}SiEt_3]$ at 77 K in a methylcyclohexane (MCH) matrix yields the 16-electron complex $[(CO)_3Co\text{-}SiEt_3]$ and CO as the only species detectable by FTIR.[12] The same coordinatively unsaturated complex is obtained at 77 K, when the matrix contains ethylene. However, in this case warm-up of the matrix leads to disappearance of bands attributed to $[(CO)_3Co\text{-}SiEt_3]$ and formation of new bands at 1968 (sh) and 1961 cm^{-1}. These bands are also observed upon near-UV irradiation of a solution of $[(CO)_4Co\text{-}SiEt_3]$ and ethylene in MCH at 210 K. We attribute the bands at 1968 and 1961 cm^{-1} to $[(CO)_3(C_2H_4)Co\text{-}SiEt_3]$, formed by addition of ethylene to photogenerated $[(CO)_3Co\text{-}SiEt_3]$. Coordination of ethylene is also evidenced by ^{1}H-NMR spectroscopy.[13]

According to Scheme 2 the next step in the catalytic cycle is insertion of the coordinated alkene into the Co–Si bond [step (3)]. To investigate this reaction a solution of $[(CO)_3(C_2H_4)Co\text{-}SiEt_3]$ was slowly warmed to 298 K and monitored by FTIR. Upon warming, a reaction is observed which under the experimental conditions has a half-life of about 2 minutes at 265 K. The unexpected reaction product is the acyl complex $[(CO)_4Co\text{-}C(O)C_2H_5]$, established spectroscopically by comparison with independently synthesized material.[14] We assume that insertion into the Co–Si bond [step (3)] does indeed take place, but, since no R_3SiH necessary for step (4) is present, β-H transfer takes place instead [step (6)]. The complex obtained is expected to undergo loss of vinyl(triethyl)silane [step (7)]. Free vinyl(triethyl)silane can be detected in the reaction mixture by gas chromatography by comparison with an authentic sample. We have thus demonstrated formation of an alkenylsilane. This result is consistent with the finding that photolysis of $[(CO)_4Co\text{-}SiEt_3]$ in the presence of 1-pentene yields triethyl(pentenyl)silane[8] and the photolysis of $[(\eta^5\text{-}C_5Me_5)(CO)_2Fe\text{-}SiMe_3]$ in the presence of ethylene yields trimethyl(vinyl)silane.[10] Since we have used a large excess of ethylene the 16-electron metal complex formed in step (7) undergoes addition of ethylene, followed by insertion into the Co–H bond and addition of two molecules of CO to form $[(CO)_4Co\text{-}C(O)C_2H_5]$ [reactions (a–c)]. Consistent

$$[(CO)_3Co\text{–}H] + C_2H_4 \longrightarrow [(CO)_3Co(C_2H_4)\text{–}H] \quad \text{(a)}$$

$$[(CO)_3Co(C_2H_4)\text{–}H] \longrightarrow [(CO)_3Co\text{–}CH_2CH_3] \quad \text{(b)}$$

$$[(CO)_3Co\text{–}CH_2CH_3] + 2\,CO \longrightarrow [(CO)_4Co\text{–}C(O)CH_2CH_3] \quad \text{(c)}$$

with consumption of two molecules of CO for one metal complex, the formation of $[(CO)_4Co\text{-}C(O)C_2H_5]$ stops, once 40% of photogenerated $[(CO)_3(C_2H_4)Co\text{-}SiEt_3]$, i.e. 80% of CO, reacts. The rate-determining step in this reaction sequence appears to be the ethylene insertion into the Co–Si bond, since none of the intermediates could be observed. Insertion of ethylene into the Co–Si bond [step (3)] is the first example of insertion of an unactivated alkene into the M–Si bond of a catalytically active complex. In the presence of R_3SiH, step (7) in Scheme 2 is presumably followed by reaction of $[(CO)_3Co\text{-}H]$ with R_3SiH to regenerate $[(CO)_3Co\text{-}SiR_3]$ and H_2.

We have so far demonstrated steps (1)–(3) and (6) and (7) of Scheme 2. To obtain evidence for steps (4) and (5), we turned to $[(CO)_4Co\text{-}Me]$ as model compound for the alkyl complex $[(CO)_4Co\text{-}CH_2CH_2SiR_3]$. Due to the lability of cobalt alkyl complexes, the reactions could not be spectroscopically monitored. We therefore allowed $[(CO)_4Co\text{-}Me]$ to react with Me_3SiH and analyzed the products by ^{1}H-NMR.[15] We assume thermal CO loss occurs from $[(CO)_4Co\text{-}Me]$ giving $[(CO)_3Co\text{-}Me]$, corresponding to the intermediate $[(CO)_3Co\text{-}CH_2CH_2SiR_3]$ in Scheme 2, but also to $[(CO)_3Co\text{-}C_2H_5]$ in Scheme 1. In both cases, as well as with our model complex, the next step is oxidative addition of the silane [reaction (d)].

$$[(CO)_3Co\text{–}Me] + Me_3SiH \longrightarrow (CO)_3Co(H)(SiMe_3)\text{–}Me \quad \text{(d)}$$

In Scheme 2 this is followed by elimination of the alkyl and the hydrido ligand to yield, in the case of our model compound, CH_4 and $[(CO)_3Co\text{-}SiMe_3]$ [reaction (e)]. In

$$(CO)_3Co(H)(SiMe_3)\text{–}Me \longrightarrow CH_4 + (CO)_3Co\text{–}SiMe_3 \quad \text{(e)}$$

contrast, from Scheme 1 we would expect elimination of the silyl and the alkyl ligand to yield $SiMe_4$ and $[(CO)_3Co-H]$ [reaction (f)]. We find CH_4, not $SiMe_4$ by ^{1}H-NMR

$$(CO)_3Co(H)(SiMe_3)-Me \longrightarrow SiMe_4 + (CO)_3Co-H \qquad (f)$$

($\delta = 0.18$) and $[(CO)_4Co-SiMe_3]$ by FTIR. We cannot completely rule out the possibility that some $SiMe_4$ is also formed, but formation of CH_4 is certainly the predominant reaction.

We have thus found evidence for all steps postulated in Scheme 2. Formation of CH_4, not $SiMe_4$, in the reaction of $[(CO)_4Co-Me]$ with Me_3SiH is clearly inconsistent with the Chalk-Harrod mechanism, Scheme 1. We therefore propose the mechanism depicted in Scheme 2 for hydrosilation catalysis, at least with carbonylcobalt complexes. This new mechanism involves as key step the insertion of an olefin into a Co-Si bond.

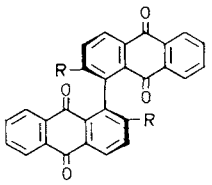
[12] IR spectroscopic data (CO stretching region) for relevant complexes [cm^{-1}]: $[(CO)_4Co-SiEt_3]$: 2089 m, 2026, 1995 s; $[(CO)_3Co-SiEt_3]$: 1957 s, 1953 s; $[(CO)_3(C_2H_4)Co-SiEt_3]$: 1968 sh, 1961 s; $[(CO)_4Co-C(O)CH_2CH_3]$: 2105 m, 2045 m, 2023 s, 2002 s.
[13] When a solution of $[(CO)_4Co-SiEt_3]$ in ethylene containing [D$_8$]toluene is irradiated, signals at $\delta = 1.15$ (m) for Et_3Si and 3.00 (s) for coordinated ethylene are observed. For the resonance of coordinated ethylene cf. Y.-M. Wuu, J. G. Bentsen, C. G. Brinkley, M. S. Wrighton, *Inorg. Chem. 26* (1987) 530.
[14] Under 1 atm of CO at 0°C, 210 mg (0.3 mmol) of $[(Ph_3P)_2N][Co(CO)_4]$ in 2 mL of THF was added to 200 mg (1.1 mmol) of $[Et_3O][BF_4]$. After stirring the solution for 15 min, the solvent was removed in vacuo. The residue was redissolved in 1 mL of methylcyclohexane. $[(Ph_3P)_2N][BF_4]$ and excess $[Et_3O][BF_4]$ was removed via filtration and the solution was used without further purification. Only signals due to $[(CO)_4Co-C(O)CH_2CH_3]$ were observed in the FTIR spectrum; cf. L. Marko, G. Bor, G. Almasy, P. Szabo, *Brennst. Chem. 44* (1963) 184.
[15] At 0°C 45 mg (0.3 mmol) of MeI was added to a solution of 70 mg (0.4 mmol) of $Na[Co(CO)_4]$ in 1 mL [D$_8$]THF. After 2 min the resulting $[(CO)_4Co-Me]$ was allowed to react with 100 mg (1.3 mmol) of Me_3SiH. The solution was stirred for 20 min at 0°C and then warmed up. Immediately after the solution reached room temperature, a ^{1}H-NMR spectrum was recorded: $\delta = 0.18$ for methane. Formation of $[(CO)_4Co-C(O)CH_3]$ accompanies formation of $[(CO)_4Co-Me]$ in the synthesis (see [14]) and the thermolysis of the $[(CO)_4Co-Me]/[(CO)_4Co-C(O)CH_3]$ mixture in the presence of Me_3SiH gives CH_3CHO in addition to CH_4 (cf. also R. W. Wegman, *Organometallics 5* (1986) 707, which shows formation of CH_3CHO from reaction of $[(CO)_3(PPh_3)Co-C(O)CH_3]$ with Et_3SiH or Ph_3SiH).

CD Spectroelectrochemistry, a Method for the Characterization of Chiral Electron Transfer Reagents and Chiral Reaction Intermediates**

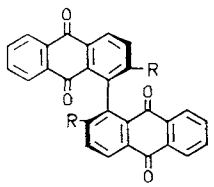
By *Jörg Daub,* Josef Salbeck,* and *Irmgard Aurbach*

The combination stereochemistry/electron transfer (ET) has so far never been dealt with in monographs on stereochemistry even though a close relationship exists between both fields.[1,2] Only a slight stereoselectivity has thus far been observed in ET reactions carried out in homogeneous solution. This holds true for diastereoselective reactions and in particular for enantioselective reactions.[3]

We now show that chiral ET reagents can be investigated by the use of chiroptic methods (here measurement of the circular dichroism) in spectroelectrochemical measurements.[4] For this purpose a thin-layer cell developed for spectrochemical investigations, which consisted of an optically transparent working electrode (OTTLE = optically transparent thin-layer electrode, indium oxide doped with tin oxide, coated on glass), a platinum disk as counter electrode and an Ag/AgCl reference electrode,[5] was mounted in the beam of a CD and UV/VIS spectrometer. By means of this instrumental coupling of potentiostatic intermediate generation and electron spectroscopic (UV/VIS) and chiroptic (CD) detection, both electrochemical as well as structural properties of chiral intermediates can be determined. Thus, a method is available which provides access to important information about the properties of chiral electron transfer compounds and about their use for enantioselective redox reactions.[6] Herein we shall outline the application of the method to the study of the axially chiral bisanthraquinone **1**.



(*R*)-**1** - (*R*)-**5**



(*S*)-**1** - (*S*)-**5**

1, R = CO_2CH_3; **2**, R = CH_3; **3**, R = $CHBr_2$; **4**, R = CHO; **5**, R = CO_2H

The enantiomeric forms of **1** are readily accessible on a preparative scale: starting from *rac*-2,2'-dimethyl-1,1'-bianthraquinone **2**, the dicarboxylic acid *rac*-**5** was prepared via *rac*-**3** and *rac*-**4**;[7] this was then separated into the two enantiomers (*R*)-(−)-**5** and (*S*)-(+)-**5**.[8] Subsequent reaction with diazomethane furnished the optically active esters (*R*)-(−)-**1** and (*S*)-(+)-**1** respectively, in good yields.[9] The optical purity of both enantiomers was determined ^{1}H-NMR spectroscopically (250 MHz): in the presence of (−)-9-(1-hydroxy-2,2,2-trifluoroethyl)anthracene as chiral auxiliary reagent the ^{1}H-NMR spectra of the enantiomers each show only the signals of one diastereomeric associate. The absolute configurations of (*R*)-(−)-**1** and (*S*)-(+)-**1** were derived from the known configurations of (*R*)-(−)-**2**, (*S*)-(+)-**2** and (*R*)-(−)-**5**, (*S*)-(+)-**5**.[10]

Universitätsstrasse 31, D-8400 Regensburg (FRG)

[**] This work was supported by the Stiftung Volkswagenwerk and the Deutsche Forschungsgemeinschaft. We thank Prof. *H. Brunner* for placing the CD spectrometer (circular dichrograph J-40A, Jasco) at our disposal and Frau *D. Andert* for instructions on the use of the apparatus.

For the electrochemical and spectroscopic measurements, **1** was dissolved in acetonitrile. Bu_4NPF_6 served as supporting electrolyte; the substrate concentration was 5.4×10^{-3} mol L^{-1}.

$$\mathbf{1} \overset{E^1}{\rightleftharpoons} \mathbf{1}^{\odot\ominus} \overset{E^2}{\rightleftharpoons} \mathbf{1}^{2(\odot\ominus)} \overset{E^3}{\rightleftharpoons} \mathbf{1}^{(\odot\ominus)2\ominus} \overset{E^4}{\rightleftharpoons} \mathbf{1}^{4\ominus} \qquad \text{(a)}$$

The cyclovoltammograms of (*S*)- and (*R*)-**1** show the reversible reaction cycle (a) with the following half-wave potentials: $E^1 = 1190$ mV; $E^2 = -1360$ mV, $E^3 \approx E^4 = -1780$ mV (Fig. 1). In the electronic spectra obtained by UV/VIS

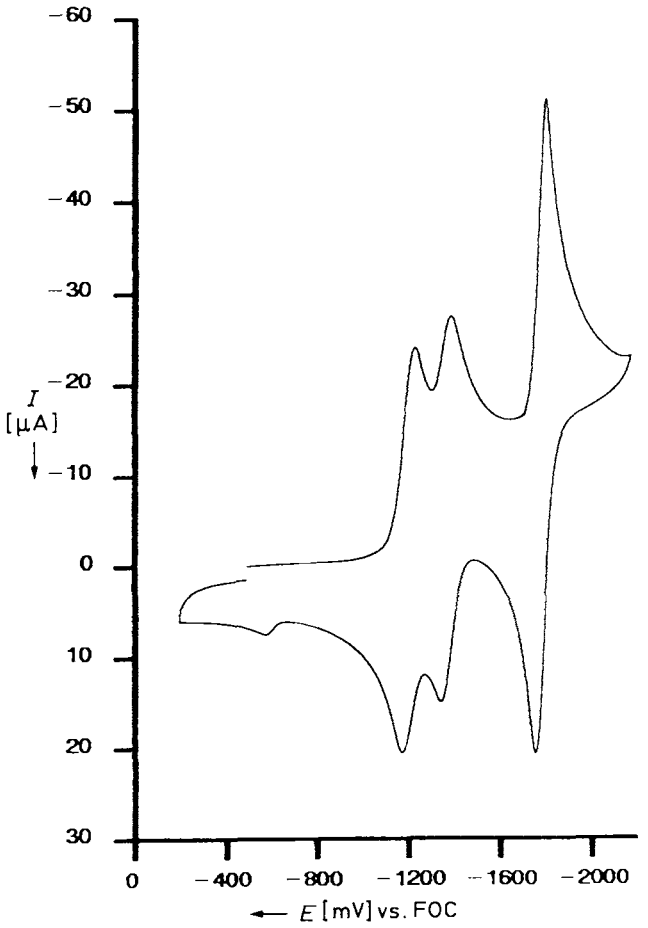

Fig. 1. Cyclovoltammogram of (*S*)-(+)-**1** in CH_3CN, $c = 5.4 \times 10^{-3}$ mol L^{-1}, scan 200 mV s^{-1}; FOC = ferrocene.

spectroelectrochemical inspection of **1** the formation of the monoanion $\mathbf{1}^{\odot\ominus}$ is recognizable only by one isosbestic point at $\lambda_{max} = 360$ nm. $\mathbf{1}^{\odot\ominus}$ is thereby formed at a stationary potential of -1275 mV. The dianion $\mathbf{1}^{2(\odot\ominus)}$ (absorptions at 403 and 614 nm, Fig. 2b) is formed at a stationary potential of -1600 mV. At a potential of -2200 mV the tetraanion $\mathbf{1}^{4\ominus}$ is then formed. Its absorption spectrum shows an intense band at $\lambda_{max} = 490$ nm with a shoulder extending to 800 nm.

The dianion $\mathbf{1}^{2(\odot\ominus)}$ is a bisradical anion (Scheme 1), as is clearly shown by comparison of its electronic spectrum (Fig. 2b) with that of 9,10-anthraquinone **6** obtained by UV/VIS spectroelectrochemistry (Fig. 3). The most intense

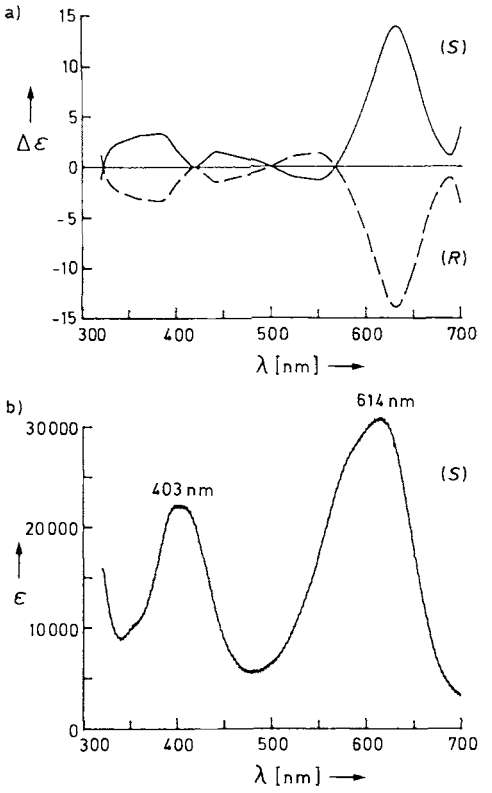

Fig. 2. Spectroelectrochemistry of (*R*)-(−)-**1** and (*S*)-(+)-**1**. a) CD spectra of the enantiomeric bisradical anions $\mathbf{1}^{2(\odot\ominus)}$. b) Electronic spectrum of (*S*)-(+)-$\mathbf{1}^{2(\odot\ominus)}$.

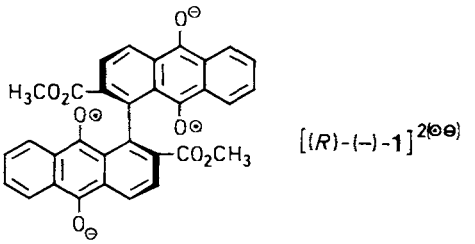

Scheme 1. $\mathbf{1}^{2(\odot\ominus)}$ as bisradical anion.

absorptions of the radical anion $\mathbf{6}^{\odot\ominus}$ appear at $\lambda_{max} = 390$, 410, and 540 nm. The dianion $\mathbf{6}^{2\ominus}$ has its most intense band at $\lambda_{max} = 480$ nm and a weaker absorption at 645 nm.

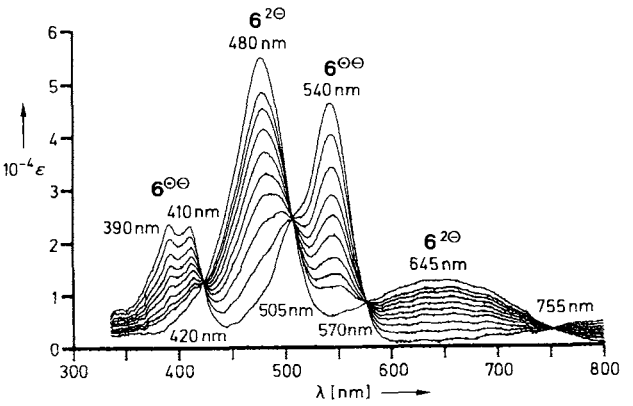

Fig. 3. UV/VIS spectroelectrochemistry of **6**. Potential range 0 to −2300 mV.

The CD spectra of electrochemically generated ions of (*R*)-(−)-**1** and (*S*)-(+)-**1** were recorded over the potential range 0 to −2200 mV. Figure 2a shows the CD spectra of both enantiomeric forms of $\mathbf{1}^{2(\odot\ominus)}$, which were generated at a stationary potential of $=-1600$ mV.[11] (*S*)-$\mathbf{1}^{2(\odot\ominus)}$ shows a positive $\Delta\varepsilon$ for the longest wavelength absorption; in the case of (*R*)-$\mathbf{1}^{2(\odot\ominus)}$ the corresponding band has a negative $\Delta\varepsilon$ value of equal intensity. The tetraanion (*S*)-(+)-$\mathbf{1}^{4\ominus}$ generated at a potential of −2200 mV has a positive $\Delta\varepsilon$ value for the intense band at $\lambda_{max}=490$ nm. A further band with positive $\Delta\varepsilon$ is observed at 630 nm.

The reaction cycle between bianthraquinone **1** and bisradical anion $\mathbf{1}^{2(\odot\ominus)}$ is electrochemically reversible over several measuring cycles. Racemization could not be observed. On the other hand, during the electrochemical formation of the tetraanion $\mathbf{1}^{4\ominus}$ with Bu_4NPF_6 as supporting electrolyte, a chemical secondary reaction can already be observed after the first cycle.[12]

$[TiSCl_4]^{2\ominus}$ and $[Ti_3O(S_2)_3Cl_6]^{2\ominus}$, a Multinuclear Complex with a Structure Typical for Clusters

By *Ulrich Müller** and *Volker Krug*

For molybdenum, a series of cluster compounds of the composition $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3X_6]^{2\ominus}$ with molybdenum in the oxidation state +IV (X = Cl, CN, S etc.) are known.[1-5] Such compounds contain metal-metal bonds, as is evident from, inter alia, the Mo-Mo distances of between 272 and 278 pm. In the case of titanium, however, far fewer cluster compounds are known. Examples are $[Cp_5Ti_5(\mu_3\text{-}S)_6]$ with bridging sulfur atoms[6] and $[Cp_6Ti_6(\mu_3\text{-}O)_8]$ with bridging oxygen atoms;[7] in these compounds the titanium has an oxidation number between +III and +IV and the Ti-Ti distances are on average 317 and 289 pm, respectively. The Ti-Ti distances in $[(MeC_5H_4)_4Ti_4S_8O_2]$ are of the same order of magnitude;[8] this compound has been described as a cluster, although according to *Cotton*'s definition[9] it should not be regarded as a cluster, since the titanium has oxidation number +IV and therefore no metal-metal bonds should be present. We report here on a further Ti^{IV} compound with a structure typical for clusters.

In the reaction of titanium tetrachloride with bis(trimethylsilyl) sulfide [Eq. (a)] a black precipitate is formed which mainly consists of $TiSCl_2$. When the precipitate is treated with a solution of tetraphenylphosphonium chloride or tetraethylammonium chloride in dichloromethane the greater part turns green or orange in color respectively; the tetrachlorothiotitanate ion **1** is formed.

$$\begin{array}{l} TiCl_4 + S(SiMe_3)_2 \longrightarrow TiSCl_2 + 2\,ClSiMe_3 \\ \qquad\qquad\qquad\qquad\quad \downarrow +2Cl^{\ominus} \\ \qquad\qquad\qquad\qquad\quad [TiSCl_4]^{2\ominus}\ \mathbf{1} \end{array} \qquad (a)$$

At the same time a small amount of the precipitate dissolves, resulting in a red solution. After addition of CCl_4, red $(PPh_4)_2[Ti_3(\mu_3\text{-}O)(\mu\text{-}S_2)_3Cl_6]$ **2a** or $(NEt_4)_2[Ti_3(\mu_3\text{-}O)(\mu\text{-}S_2)_3Cl_6]$ **2b**, respectively, crystallizes from the solution. The oxygen in the anion **2** presumably comes from the inert gas (anhydrous N_2 containing small amounts of O_2). This assumption is supported by the finding that the yield of **2** is considerably greater on repeating the experiment in an atmosphere of pure oxygen [Eq. (b)].

$$\begin{array}{l} 3\,TiCl_4 + 6\,S(SiMe_3)_2 + 3/2\,O_2 \longrightarrow \\ \qquad\qquad [Ti_3O(S_2)_3Cl_4] + 8\,ClSiMe_3 + 2\,O(SiMe_3)_2 \\ \qquad\qquad\quad \downarrow +2Cl^{\ominus} \\ \qquad\qquad [Ti_3O(S_2)_3Cl_6]^{2\ominus}\ \mathbf{2} \end{array} \qquad (b)$$

$(PPh_4)_2[TiSCl_4]$ **1a** and $(NEt_4)_2[TiSCl_4]$ **1b** can be recrystallized from warm acetonitrile. Crystalline **1a** is green, crystalline **1b** orange. **1b** crystallizes tetragonally with the $[TiSCl_4]^{2\ominus}$ ions on fourfold axes of rotation.[10] The ions have a square-pyramidal structure with a short TiS bond (211 pm) (Fig. 1). This can be interpreted in terms of a Ti-S double bond, consistent with the IR spectrum ($\nu(TiS)=530$ cm^{-1}).

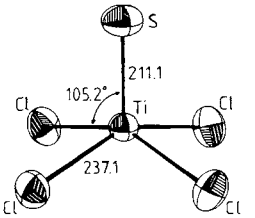

Fig. 1. Structure of the $[TiSCl_4]^{2\ominus}$ ion in the crystal of **1b**, with ellipsoids of thermal vibration (50% probability level at 22 °C). Bond lengths in pm, standard deviations: 0.2 pm.

When recrystallized from acetonitrile, **2a** contains one mol. equivalent of CH_3CN. Its structure analysis[11] reveals

[*] Prof. Dr. U. Müller, Dipl.-Chem. V. Krug
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

the same type of structure (Fig. 2) for the anion **2** as mentioned above for the case of the molybdenum compounds. The oxygen atom bridges all three titanium atoms and each pair of Ti atoms is linked via a side-on coordinated disulfide unit. The Ti-Ti distances of 314 to 318 pm are markedly greater than the Mo-Mo distances in the molybdenum clusters—as to be expected for a Ti^{IV} compound,

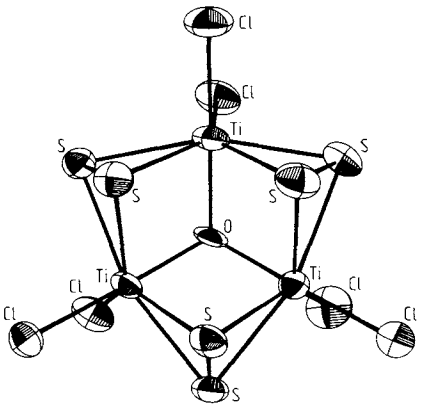

Fig. 2. Structure of the $[Ti_3O(S_2)_6Cl_6]^{2\ominus}$ ion in the crystal of **2a** · CH_3CN. Important bond lengths [pm]: Ti-Cl 231.3 to 235.7(5) (mean 232.3), Ti-S (in the plane of the Ti atoms) 250.9 to 252.4(5) (mean 252.3), remaining Ti-S 245.8 to 248.7(5) (mean 247.0), Ti-O 190 to 193(1) (mean 191.6), S-S 203.3 to 205.0(5) (mean 204.0), Ti···Ti 314.0 to 317.9 (mean 316.3); mean bond angles [°]: Ti-O-Ti 111.3(5), Cl-Ti-Cl 93.9(2), O-Ti-Cl 96.1(4) and 170.0(4).

owing to the absence of metal-metal bonds. On the other hand, however, these distances are not longer than those in the titanium clusters with Ti oxidation numbers between +III and +IV.[6,7] In the perthiotitanate Tl_2TiS_4, in which there are chains of edge-sharing octahedra, the Ti-Ti distances are 349 pm,[12] whereas in the triangular Ti_3 groups of Ti_7Cl_{16}, Ti-Ti distances of 295 pm have been found.

The Structures of 1*H*-Cyclopropabenzene and Its 1,1-Bis(triisopropylsilyl) Derivative

By *Richard Neidlein,* Detlev Christen, Volker Poignée, Roland Boese,* Dieter Bläser, Alfred Gieren,* Catalina Ruiz-Pérez,* and *Thomas Hübner*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

1*H*-Cyclopropabenzene **1a**,[1a] which has recently found increasing interest because of its reactivity and regioselectivity,[2] has also been the subject of intensive spectroscopic[1c,3] and theoretical[4] studies. X-ray structure analyses, however, have thus far only been carried out on the derivatives **1b** and **1c**.[4e,5] We have now prepared the parent compound **1a** (from 3-bromocyclohexene **2**) and the derivative **1d**, 1,1-disubstituted with the very bulky triisopropylsilyl residue,[2c,1d] and have carried out single-crystal X-ray structure analyses on both compounds[6] (**1a** at 120 K, **1d** at room temperature).

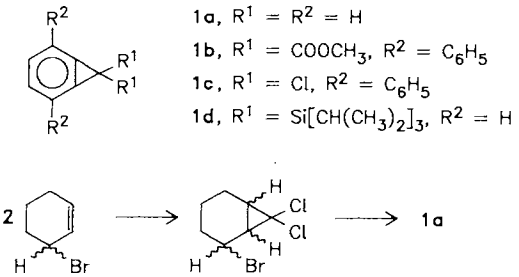

Figure 1 shows the structures of **1a** and **1d**; the bond lengths and bond angles for the 1*H*-cyclopropabenzene skeleton of **1a** and **1d** are listed together for comparison in Table 1. A significant difference (0.043 Å) appears only in the C-C bond lengths in the cyclopropene ring (C6-C7). As a result the bond angles in the cyclopropene ring differ slightly. The remaining differences in bond lengths and bond angles are not significant on taking into account the standard deviations. Both in **1a** as well as in **1d** the 1*H*-cyclopropabenzene moiety deviates from a strictly planar conformation, albeit with a different reduction in symmetry. In the case of **1a** the *mm*2 symmetry is reduced to *m*; the six-membered ring and the three-membered ring are tilted at an angle of 2.4° to each other. In **1d** there is a reduction in symmetry from *mm*2 to 2. This is induced by the bulky triisopropylsilyl groups, which, for steric reasons, are so arranged that they are interconverted into each other, not via a mirror plane but via a twofold molecular symmetry axis (Fig. 1). This symmetry continues in the 1*H*-cyclopropabenzene skeleton. The maximum deviation from an *mm*2 symmetry here, however, corresponds to a torsion angle of only 1.9°. A slight non-planarity of the 1*H*-cyclopropabenzene moiety has also been observed in the case of **1b**.[4e]

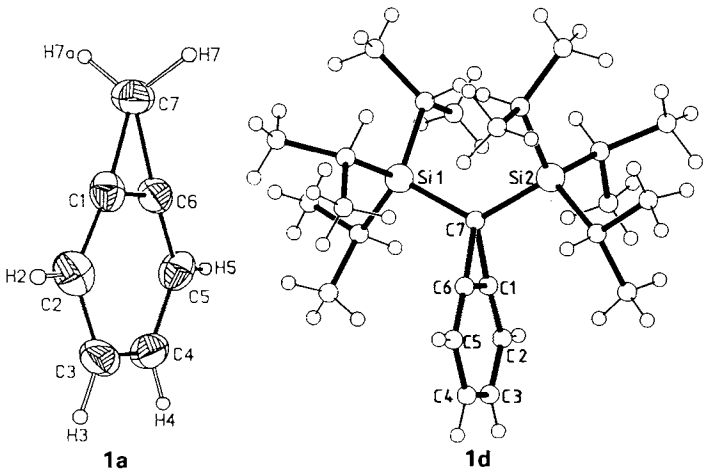

Fig. 1. Molecular structures of 1*H*-cyclopropabenzene **1a** and its derivative **1d**.

The structure of the benzene ring in **1a** and **1d** is, in principle, comparable with that in **1b** and **1c**, i.e. the angles in the benzene ring are deformed in the same manner by the annelation of the three-membered ring, and, in all cases, the C-C bond lengths give no indication of bond localization but rather of an aromatic delocalization. The C1-C6 bond is equally short in all the compounds **1**: **a**, 1.334(4); **b**, 1.333 (max. 8);[4e] **c**, 1.35(2);[5] **d**, 1.336(3) Å. The mean length of the five longer bonds in the benzene ring is also the same in **1a** (1.378) and **1d** (1.381 Å), and is 0.04 Å greater than the length of a C=C double bond. The C1-C6 bond in **1a** and **1d** is also lengthened to a similar extent compared to the C=C bond in cyclopropene.[7,8] Thus, the aromatic π-electron delocalization in the benzene ring is retained.

Table 1. Bond lengths [Å] and angles [°] averaged by the molecular symmetry of **1a** and **1d**.

	Bond lengths			Bond angles	
	1a	**1d**		**1a**	**1d**
C1-C6	1.334(4)	1.336(3)	C3-C4-C5	122.4(2)	122.4(2)
C3-C4	1.390(5)	1.379(6)	C4-C5-C6	113.2(2)	112.9(2)
C4-C5	1.387(4)	1.401(4)	C1-C6-C5	124.5(2)	124.6(1)
C5-C6	1.363(3)	1.361(2)	C1-C6-C7	63.6(1)	64.3(1)
C6-C7	1.498(3)	1.541(1)	C5-C6-C7	171.7(2)	171.0(1)
C4-H4	0.93(3)	0.90(2)	C1-C7-C6	52.8(2)	51.4(1)
C5-H5	0.94(3)	0.92(2)	C3-C4-H4	121(2)	116(1)
			C5-C4-H4	117(2)	121(1)
			C4-C5-H5	122(2)	124(1)
			C6-C5-H5	125(2)	123(1)

A comparison of **1a** and **1d** shows that the C-C bond lengths in the cyclopropene ring are strongly dependent on the substituents at the sp^3-hybridized carbon atom. That this is due to a steric effect is immediately evident upon comparison with the structure of **1b**. In **1d**, whose triisopropylsilyl groups are bulkier than the carboxy groups in **1b**, the C-C bonds are lengthened by 0.04 Å compared to those in **1a** but by only 0.02 Å compared to those in **1b**.

The C-C bonds in the cyclopropene ring of **1a** are ca. 0.02 Å shorter than those in cyclopropene,[7,8] obviously as a result of the widening of the C5-C6-C7 angle to almost 180° caused by the annelation. An X-X map of deformation energy shows a marked bonding electron density maximum for each C-C bond which is shifted from the center of the bond outwards in the case of **1a**, as would be expected for bent bonds.

Nitrogen Fixation by Borabenzene**

By *Günther Maier,* Hans Peter Reisenauer, Jochem Henkelmann,* and *Christine Kliche*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

Free borabenzene **3** (borinine[1]) is still unknown. The nearest related species so far reported is the betaine **4**, which was recently prepared by us[2] from the boracyclo-

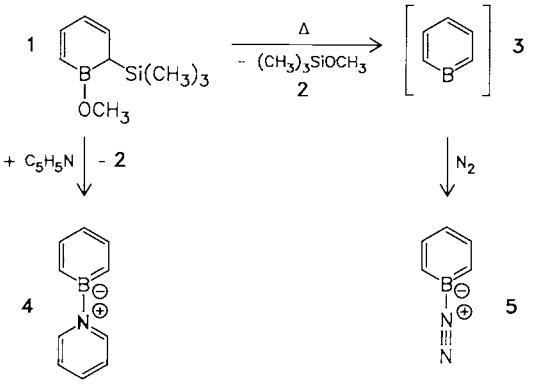
[**] Hetero π-Systems, Part 15. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 14: [5].

hexadiene **1** and pyridine using the method described by *Paetzold*.[3] It is questionable whether borabenzene occurs as an intermediate in this reaction. Presumably pyridine is first bound to the boron atom in **1** and then elimination of the ether **2** follows in a secondary reaction.

In continuation of our investigations[4] of the borabenzene[3] and boraethene problem[5] we have studied the flash-thermolytic fragmentation of **1** (770 °C; condensation of the products on a 10 K cold window), not only with argon[3,4] but also with nitrogen as carrier gas.

On changing over from argon to nitrogen, a remarkable effect was observed. When the flash thermolysis of **1** was carried out in a stream of argon only the ether **2** could be detected on the matrix support,[2,4] whereas when it was carried out in a stream of nitrogen an additional set of IR bands was recorded, the most intense of which was observed at 2197.6 cm^{-1} (Table 1). In the UV spectrum of the condensate, absorptions appear at 235, 240, and 361 nm.



The long wavelength band shows a vibrational fine structure with maxima at 315, 337, and 361 nm. We ascribe these spectroscopic data to the adduct **5** of nitrogen and borabenzene **3**. The main argument for this is the intense IR band at 2197.6 cm^{-1}. It shifts by 73.3 cm^{-1} to 2143.3 cm^{-1} when $^{15}N_2$ is used as carrier gas,[6] and can therefore be assigned to the N≡N stretching vibration (Table 1). The assignment of the other IR absorptions listed in Table 1 to **5** follows from their synchronous decrease with the disappearance of the diazonium band upon irradiation of the matrix with 366-nm light. As to whether free borabenzene **3** is formed during this decomposition reaction cannot be ascertained on the basis of the experimental findings thus far available.

Table 1. IR data (10 K, N_2 matrices) of [$^{14}N_2$]-**5** and [$^{15}N_2$]-**5**.

[$^{14}N_2$]-**5**		[$^{15}N_2$]-**5**

492.7	(0.04)	—	—

According to theoretical calculations[7] borabenzene **3** is characterized by a very low-lying σ*-MO, mainly localized on the boron atom. The resulting pronounced acceptor property is responsible for the trapping of nitrogen. From MNDO calculations[8] it follows that the nitrogen adduct **5** has an energy minimum, and that the trapping of nitrogen by borabenzene **3** is exothermic (reaction enthalpy $\Delta H = -25.2$ kcal/mol). The values for the reaction of **3** with pyridine ($\Delta H = -39.6$ kcal/mol) and with carbon monoxide[9] ($\Delta H = -73.6$ kcal/mol) are much more favorable.

The nitrogen fixation by borabenzene **3** is reminiscent of the N_α,N_β-rearrangement of diazonium salts,[10] in which the phenyl cation (isoelectronic with **3**) formed by dediazonation is capable of trapping nitrogen in the same way. The observations outlined above indicate that borabenzene **3** is formed—as hoped—in the pyrolysis of **1**. In an argon stream it does not survive the thermolysis, since owing to its extreme Lewis acidity, it is absorbed on the surface of the pyrolysis tube, where it decomposes. With nitrogen as carrier gas, borabenzene **3** can give the stable adduct **5** in competition with the wall reaction, and in this way, can be flushed through the hot tube.

The Central Propellane Bond as Polymerizable CC Single Bond: Poly(tricyclo[4.2.0.0^{2,7}]octane-1,7-diyl) — a "Poly([1.1.1]propellane)"**

By *Arnulf-Dieter Schlüter**

Small ring propellanes[1] are characterized by a special bonding geometry ("inverted tetrahedra"[2]) at the bridgehead C-atoms. They exhibit high ring strain concentrated over a few bonds,[3] an unusual electron distribution in the central σ bond,[4] and considerable reactivity.[5,6] Acceptor-

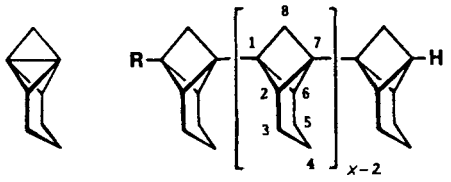
Max-Planck-Institut für Polymerforschung
Postfach 3148, D-6500 Mainz (FRG)

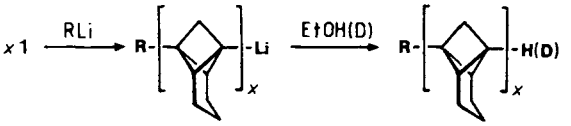
[**] I thank Prof. Dr. *G. Wegner*, Mainz, and Prof. Dr. *W. J. Feast*, Durham (UK), for their interest in and support of this work. I also wish to thank Frau Dr. *C. Böffel* for recording the solid-state NMR spectra and Herrn *K. Opitz* for help with some of the experiments.

substituted cyclopropanes and bicyclobutanes polymerize with ring-opening (cleavage of a CC single bond).[7] This poses the question whether small-ring propellanes can also undergo polymerization with ring-opening. Such a polymerization should lead, assuming exclusive cleavage of the central σ-bond, to a novel type polymer with a rigid rod-like structure.[8] Polymerization of [n.1.1]propellanes (n > 1) has occasionally been observed,[9] but neither the directed synthesis nor the structure of a "polypropellane" has thus far been described.[10] We report here on the first anionically-induced polymerization of [1.1.1]propellane **1**[11] leading to formation of the polymers **2**, whose structure could be established by solid-state ^{13}C-NMR spectroscopy.



1 **2a**, R = *t*Bu
2b, R = Ph

Reaction of monomer **1**, which is readily accessible in gram amounts, with 0.15 equivalents of *tert*-butyllithium in a small amount of hexane at 20°C led to exothermic formation of a white precipitate, to which we assign the structure **3a**. After 30 min, the mixture was treated with ethanol and filtered through a frit; the remaining precipitate was then carefully washed with hot water and hot chloroform to remove inorganic and oligomeric components. Finally, the white, powdery polymer **2a** was dried to constant weight at 10^{-6} torr and 100°C (mass balance: 50% polymeric, 46% oligomeric material). The polymer **2b** could be obtained analogously in 35% yield by reaction of **1** with phenyllithium.



3 **2**

a, R = *t*Bu ; b, R = Ph

The CP-MAS-^{13}C-NMR spectra[12] of **2b** (Fig. 1) and **2a** show as expected five well-resolved signals in the region $\delta = 20$–60; these could be assigned by special pulse techniques which enable differentiation of C atoms according to the number of H atoms bonded to them. The assignment given in Figure 1 is consistent with the ^{13}C-NMR data of **2a**, x = 1.[11] The *t*Bu and Ph terminal groups in **2a** and **2b**, respectively, give rise to very low intensity signals at $\delta \approx 30$ and 128.[13] The spectrum of **2a** shows no signals for olefinic C-atoms or signals that could be assigned to bicyclobutanes. Hence, the signal of **2b** at $\delta \approx 128$ must indeed originate from the Ph terminal group, and, what is more important, only the central bond of the propellane **1** must have been opened in the polymerization step.

By exploiting the decreasing solubility of the oligomer in THF with increasing degree of polymerization (P_n) a fraction of **2a** could be isolated whose P_n value (average number) was, according to ^{1}H-NMR integration, ca. 11. The

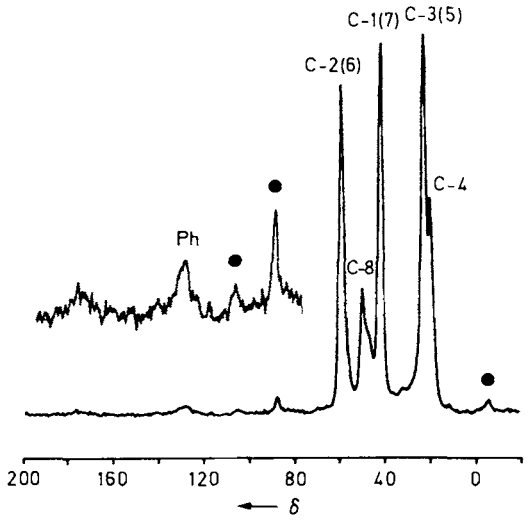


Fig. 1. CP-MAS-^{13}C-NMR spectrum (75 MHz) [12] of polymer **2b** with amplified downfield portion. The spinning side bands are indicated by black dots; the broad signal at $\delta \approx 180$ could not be assigned.

signals at $\delta = 2.29$ for 2-H and 6-H of one of the terminal repeat units are not superposed by the broad signals of the oligomeric mixture,[14] and thus enable a comparison with the intensity of the likewise unmasked *t*Bu signal. The ^{1}H- and ^{13}C-NMR spectra[14] are consistent with the given oligomeric structure, and thus further confirm the postulated polymeric structure.

A remarkable finding is that, at a P_n value of ca. 11, these rigid rods can still be readily dissolved in chloroform.[15] The rotation of the individual repeat units about the rods' axis and the folding back of the trimethylene bridges might play an important role regarding this finding. The P_n value of 11 found for the oligomer is a lower threshold value for the P_n value of the polymer **2**. We obtained direct information about the P_n value by quantitative determination of the lithium content in **3**. Atomic absorption spectroscopy gave a lithium content of 0.38% (±0.1%), which corresponds to a minimum value of P_n[16] of 17. This finding and the low intensity of the signals of the *t*Bu and Ph terminal groups, respectively, in the solid-state NMR spectra of **2a** and **2b** suggest P_n values of over 20.

The ring-opening polymerization of the propellane **1** presumably proceeds according to an anionic mechanism. This is indicated in the work-up of the lithiated species **3a** with EtOD, in which monomeric and dimeric compounds **2a**, x = 1, and **2a**, x = 2, are formed, each of which are deuteriated to more than 96% in position 7—that is, at the bridgeheads formerly bearing lithium. Furthermore, it follows from the ^{1}H-NMR spectra of all oligomers that there are two different terminal groups, likewise an indication of the postulated mechanism.

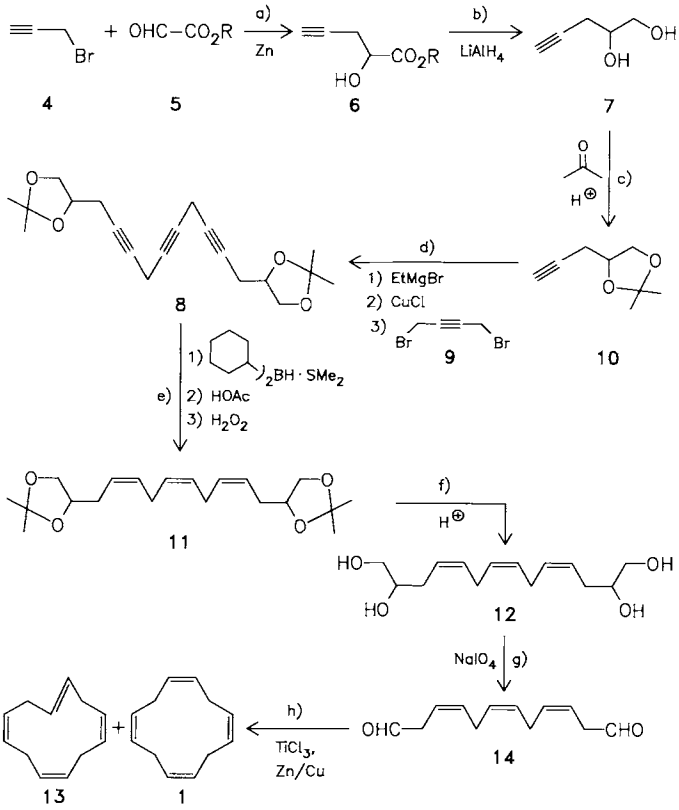
[12] Spin frequency 3.516 kHz; cross-polarization time 3 ms; in KBr; room temperature; standard: TMS external.
[13] The intensity of the signal at $\delta = 128$ representing five C atoms is only 5% of that of the C-2/C-6 signal.
[14] **2a**, $x \approx 11$: ^{1}H-NMR ($CDCl_3$, 50°C): $\delta = 0.84$ (s; CH_3), 1.15 (s; H(terminal(t)-8), 1.27 (H-8), 1.35 (s; H(t)-8), 1.43 (H-4), 1.59 (H-3(5), H(t)-3(5)), 2.16 (H-2(6)), 2.29 (poorly resolved t; H(t)-2(6)); ^{13}C-NMR ($CDCl_3$, 50°C): $\delta = 17.92$ (t; C-4), 22.56 (t; C-3, C-5), 27.76 (q; CH_3), 41.12 (s; C-1, C-7), 47.30 (t; C-8), 57.75 (d; C-2, C-6).
[15] For comparison, the solubility of quinquiphenyl, which also has a rigid structure, is already less than 0.1 g/L: W. Kern, M. Seibel, H. O. Wirth, *Makromol. Chem. 29* (1959) 165.
[16] We presume that a part of the initiator forms mixed aggregates with the lithiated species **3**. Moreover, the initiator may contain small amounts of the hydrolysis product lithium hydroxide. Both effects lead to an underestimation of the true P_n of **2**.
[17] Especially indicative are the H-8 signals: small, sharp singlets at $\delta = 1.15$ and 1.35, respectively, for both terminals.



Synthesis of all-*cis*-1,4,7,10-Cyclododecatetraene**

By *Martin Brudermüller* and *Hans Musso**

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

Reflecting on the known ability of cyclic olefins to form π-complexes such as, e.g., bis(cyclooctadiene)nickel,[1] with transition metals it seemed worthwhile trying to synthesize the title compound **1**. Depending on the conformation of the olefin and molar ratio of the reactants there are numerous possibilities for complex formation (see, e.g. **2**). Intra- and intermolecular cycloadditions of **1** are of interest; e.g. tetraasterane **3** could be formed in a double intramolecular [2+2] cycloaddition.

Scheme 1. a), b), c) Ref. [9], 30% yield of **10**.—d) 7.0 g (50 mmol) of **10** was added slowly under N_2 to a solution of ethylmagnesium bromide (55 mol) in THF (70 mL) such that the temperature did not exceed 40°C; the mixture was heated at 60°C for 45 min, allowed to cool to room temperature, and treated firstly with 150 mg of CuCl, then, after 20 min, with 4.76 (22.5 mmol) of **9** within 20 min. Finally, the mixture was heated under reflux for 16 h. After hydrolysis with NH_4Cl/KCN solution, extraction, and chromatography on SiO_2 with CH_2Cl_2 and $CHCl_3$, 6.60 g (89%) of a light-brown oil was obtained whose spectra were consistent with the constitution **8**.[17] Compound **8**, which turns black after a few hours, was immediately reduced. ^{1}H-NMR: $\delta = 1.36$ (s, 6H; CH_3), 1.44 (s, 6H; CH_3), 2.33-2.60 (m, 4H; CH_2—C≡), 3.14 (t, 4H; =CCH_2C≡), 3.75 (dd, 2H; CH_2O *trans*), 4.10 (dd, 2H; CH_2O *cis*), 4.22 (m, 2H; CHO).—e) A solution of dicyclohexylborane-dimethyl sulfide (3.2 g, 41 mmol) in THF (50 mL) was treated at 0°C with 6.9 g (82 mmol) of cyclohexene and the mixture stirred for 2 h; a solution of **8** (3.3 g, 10 mmol) in THF (10 mL) was then added dropwise at 0°C. The mixture was allowed to warm to 20°C within 2 h, stirred for a further 2 h, and treated dropwise with 16 mL of ethyl acetate. After a further 15 hours' stirring, addition of 60 mL of 5 M NaOH and 16 mL of 30% H_2O_2, work-up, and chromatography on SiO_2 with ethyl acetate and $CHCl_3$, **11** was obtained in 72% yield as a yellowish oil. ^{1}H-NMR: $\delta = 1.35$ (s, 6H; CH_3), 1.43 (s, 6H; CH_3), 2.25-2.51 (m, 4H; CH_2C=), 2.83 (t, 4H; =CCH_2C=), 3.56 (dd, 2H; CH_2O *trans*), 4.03 (dd, 2H; CH_2O *cis*), 4.12 (m, 2H; CHO), 5.34-5.57 (m, 6H; CH=).—f) After 15 hours' stirring with 3% H_2SO_4 at room temperature, extraction with ether, and chromatography with CH_2Cl_2, 1.4 g (74%) of **12** was obtained as an almost colorless oil. ^{1}H-NMR: $\delta = 2.50$ (m, 4H; CH_2C=), 2.90 (t, 4H; =CCH_2C=), 3.51 (dd, 2H; CH_2O), 3.63 (dd, 2H; CH_2O), 3.78 (m, 2H; CHO), 5.57 (m, 6H; CH=).—g) A solution of **12** (1.9 g, 7.4 mmol) in H_2O (20 mL) was treated portionwise at 0°C with a solution of $NaIO_4$ (3.2 g, 15 mmol) in H_2O (15 mL). After 1.5 h the mixture was extracted with ether and the extract dried over $MgSO_4$ and evaporated to dryness; 1.16 g (82%) **14**, IR: $\tilde{\nu} = 1720$ cm^{-1}; ^{1}H-NMR: $\delta = 9.67$ (t, 2H; CHO), 5.64 (m, 4H; C=CH), 5.38 (t, 2H; =C*H*–CH_2), 3.03 and 2.82 (m, each 4H; CH_2).—h) A mixture of $TiCl_3$ (10.3 g) and Zn/Cu couple (10.0 g) in 200 mL of DME was boiled for 1 h and then a solution of **14** (1.5 mmol) in DME (200 mL) was added dropwise over a period of 8 h. After a further 15 hours' heating under reflux and further dropwise addition of **14** under the same conditions, the final mixture was heated to boiling for 12 h, allowed to cool, and filtered over Florosil. The filtrate was evaporated down to a few mL and the residue extracted with *n*-pentane. After evaporation of the extract to 3 mL, half of the residue was separated chromatographically on a QF1 column at 95°C (injection block 200°C): **1** (retention time 69 min), 4 mg (2%), colorless liquid which solidified in the cold trap; **2** (retention time 64 min), 10 mg (4%), colorless liquid.

All-*cis*-1,4,7-cyclononatriene has a crown conformation,[2] and its photoelectron spectrum reveals a weak through-space interaction between the three double bonds (6π-electron system),[3] which according to *Winstein* can be regarded as an indication of homoaromaticity.[4] In the case of **1**, as 8π-electron system and homolog of cyclooctatetraene, the crown conformation **1''** should be unstable, and an interaction between the double bonds is highly unlikely.

Following a number of unsuccessful attempts to synthesize **1**, including even the use of the Wittig reaction,[5] we have now found that the McMurry reaction[6] is suitable for this purpose (Scheme 1).[7]

Reaction of propargyl bromide **4** and the glyoxylic acid ester **5**, $R=C_2H_5$,[8] in the presence of zinc furnishes the 2-hydroxy-4-pentynoate **6**,[9] which is reduced to the pentynediol **7**. After protection of the hydroxy groups with acetone, the acetal **10**[9] is coupled via the Grignard compound to both ends of the 1,4-dibromobutyne **9**[10] to give the triyne **8**. Hydrogenation of **8** with Lindlar catalyst does not afford the pure all-*cis*-triene **11**. This could be achieved, however, with the dicyclohexylborane-dimethyl sulfide complex;[11] the product was chromatographically >94% isomerically pure, and the ^{1}H-NMR spectra showed a *cis* configuration for all three double bonds. The protecting groups were removed hydrolytically with dilute sulfuric acid, and the tetraol **12** was cleaved with sodium periodate in water. The sensitive dialdehyde **14** could be obtained as crude product in 82% yield and sufficiently pure for cyclization. **14** was immediately added slowly and dropwise as a 7.5×10^{-3} molar dimethyloxyethane (DME) solution to a large excess of the McMurry reagent prepared from titanium trichloride and zinc/copper couple. Two cyclic tetraolefins $C_{12}H_{16}$ were formed which could be isolated analytically pure on a preparative scale by gas chromatography as colorless liquids; 4% of **13** from the front fraction and 2% of **1** from the end fraction. Both compounds show molecular ion peaks at *m/z* 160 and afford cyclododecane upon catalytic hydrogenation.

The isomer formed in lower yield and with somewhat longer retention time must be the all-*cis*-isomer **1**, since it shows a symmetric quintet for the olefin protons at $\delta=5.41$ and a triplet for the CH_2 groups at $\delta=2.98$ in the ^{1}H-NMR spectrum. Since the spectrum does not alter down to -110°C we assume that a very flexible conformer predominates in the equilibrium in which the H atoms of the CH_2 groups can very rapidly occupy homotopic sites. The fine splitting of the signals is remarkably similar to that which is observed for 1,4,7-cyclononatriene at 80°C.[2]

The other $C_{12}H_{16}$ isomer, one and a half to four times more of which is formed than 1, depending on the amounts of starting material used, is regarded as the *trans-cis*[3]-isomer **13**, since its ^{1}H-NMR spectrum shows two signals for olefin protons, a multiplet of $\delta=5.40$–5.62 corresponsing to 6 H, and a sharp q at $\delta=5.37$ for 2 H. The signal for the CH_2 groups at $\delta=2.80$–2.87 is also broadened in two regions in the ratio 1 : 1. The McMurry reaction[6] often furnishes the more stable *trans*-olefin. For example, from dodecanedial we obtained pure *trans*-cyclododecene in 76% yield.

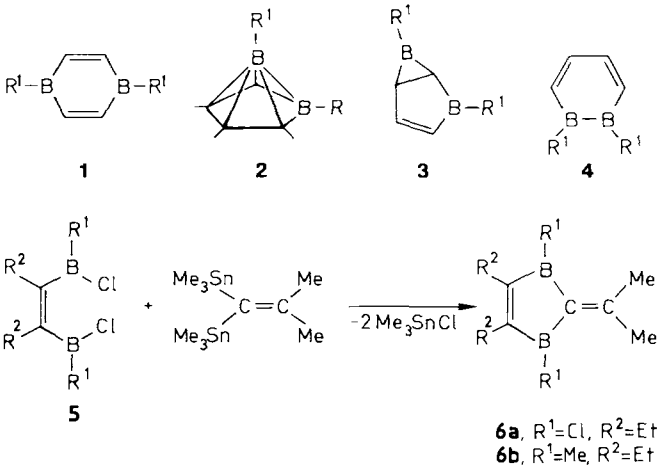
1,3-Dihydro-1,3-diborafulvene Derivatives**

By *Volker Schäfer, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

1,4-Diboracyclohexadienes **1** are stabilized by π-donor substituents (e.g. $R^1=F$, OMe) at the boron atoms, whereas when $R^1=$alkyl, rearrangement to *nido*-carbaboranes **2** takes place.[1] *Herberich* et al. recently described two further isomers, 2,6-diborabicyclo[3.1.0]hex-3-ene **3** ($R^1=NiPr_2$)[2a] and 1,2-dibora-3,5-cyclohexadiene **4** ($R^1=NMe_2$) as ligands in Ru- and Rh-complexes.[2b]



6a, $R^1=Cl$, $R^2=Et$
6b, $R^1=Me$, $R^2=Et$

Herein we report on derivatives of the novel $C_4B_2R_6$ isomer 1,3-dihydro-1,3-diborafulvene **6** which are obtained in good yields by reaction of (*Z*)-bis(dichloroboryl)alkenes **5**, $R^1=Cl$, with 1,1-bis(trimethylstannyl)-2-methyl-1-propene.[3] Substitution of the chlorine atoms in the pale yellow **6a** with Al_2Me_6 leads to the yellowish-orange derivative **6b**. The ^{13}C-NMR spectra of **6a**, **b** at 25°C contain sharp signals at $\delta=172.3$ and $\delta=154.6$, respectively, for the exocyclic olefinic C-atom. Broad signals are observed at $\delta=176$ and 179, respectively, which we assign to the C

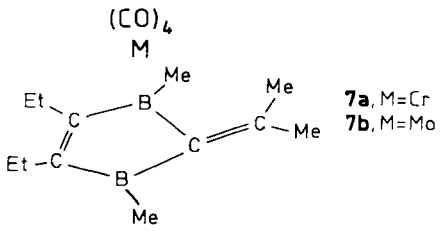
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

atoms of the ring double bonds. The signal for C2 is not observable at 25 °C because of the quadrupole effect of the two boron atoms. In the case of **6b** the signal for C2 ($\delta = 151.8$) is first observed on cooling to −45 °C; **6a** already crystallizes out at this temperature.

Prolonged heating of the air-sensitive derivative **6b** under nitrogen at 120 °C leads to rearrangement to a carbaborane whose constitution has still not been clarified.[4] As a Lewis acidic dihydrodiborafulvene, **6b** has good donor and acceptor properties for the formation of mononuclear and dinuclear complexes.[5] Typical examples are the tetracarbonylmetal complexes **7a** and **7b** formed on reaction of **6b** with $Cr(CO)_6$ and $Mo(CO)_6$, respectively. Their constitution follows from the spectroscopic data and an X-ray structure analysis of **7b**.[6]



7a, M=Cr
7b, M=Mo

Complexation of **6b** at the $M(CO)_4$ fragment results in an upfield shift of the NMR signals for the ring atoms, while the signal for C6 remains virtually unaffected (cf. [(fulvene)$Cr(CO)_3$] complexes[7a]). The donor groups coordinate the molybdenum atom in a distorted octahedral geometry with the ligands C18–O4 and C15–O1 and the double bonds C2–C6 and C4–C5 (midpoint) in one plane (Fig. 1). Prerequisite for a favorable interaction of the molybdenum atom with the π-electrons of the C2–C6 double bond

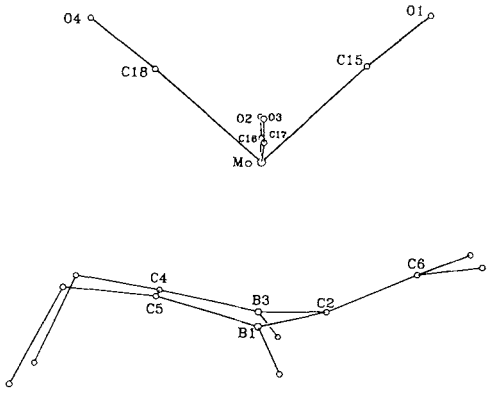


Fig. 1. Schematic representation of the crystal structure of **7b** [6]. Bond lengths [Å] and angles [°, esd 0.2°]: Mo-C2 2.324(1), Mo-C4(C5) 2.461, 2.469(2), Mo-B1(B3) 2.563, 2.546(2), Mo-C6 2.714(2), C2-C6 1.387(3), C2-C1(B3) 1.580, 1.574(3), C4-C5 1.407(3), B1(B3)-C5(C4) 1.558, 1.558(3), Mo-C15(C18) 1.994, 1.983(2), Mo-C16(C17) 2.041, 2.033(2), distances to the midpoints of the C=C bonds: Mo-(C4,C5) 2.362, Mo-(C2,C6) 2.430; C4C5B1B3/B1B3C2 20, B1B3C2/C2C6 14, C18MoC15 96.7, C16MoC17 162.7, B1C2B3 104.7, C2B3C4 105.0, B3C4C5 110.8, C4C5B1 110.2, C5B1C2 105.1; C6C2B1 125.7, C6C2B3 125.6.

is the bending at C2 (14°) and along B1B3 (20°). The distance Mo-C6 (2.71 Å) is longer than in analogous fulvene(η^6-arene)molybdenum complexes (2.37, 2.31 Å),[7b] since the donor centers (midpoint of the double bonds) are further apart because of the longer B–C bonds and the different disposition of the double bonds.

Experimental

6a: A solution of **5** (1.97 g, 8 mmol) in toluene (10 mL) was added dropwise to a solution of 1,1-bis(trimethylstannyl)-2-methyl-1-propene (3.06 g, 8 mmol) [3] in toluene (50 mL) at −10 °C. The mixture was then stirred for 2 h at 20 °C. Finally, the solvent was removed in a vacuum and **6a** (1.4 g, 77%) isolated by distillation at 55 °C/10^{-3} torr.—^{1}H-NMR (C_6D_6): $\delta = 0.96$ (t, 6H, $^3J(HH) = 7.6$ Hz), 2.15 (s, 6H), 2.28 (q, 4H); ^{11}B-NMR (C_6D_6): $\delta = 62.6$; ^{13}C-NMR ([D_8]toluene): $\delta = 14.1$ (CH_3CH_2), 21.8 (CH_2), 26.6 (CH_3C), 172.3 (C_{exo}), 176 (C4/C5, br.); EI-MS: *m/z* 228 ($M^{\oplus}$, 100%).

6b: A solution of trimethylaluminum (0.5 g, 3.5 mmol) in pentane (10 mL) was added dropwise with stirring to a solution of **6a** (0.79 g, 3.5 mmol) in pentane (10 mL) at −60 °C. The mixture was warmed to 20 °C, filtered, and the solvent removed from the filtrate in a vacuum. **6b** (0.54 g, 82%) was then recovered by distillation at 35 °C/10^{-3} torr.—^{1}H-NMR (C_6D_6): $\delta = 0.98$ (t, 6H, $^3J(HH) = 7.6$ Hz), 1.08 (s, 6H; B-CH_3), 1.99 (s, 6H), 2.34 (q, 4H); ^{11}B-NMR (C_6D_6): $\delta = 68.6$; ^{13}C-NMR ([D_8]toluene, −45 °C): $\delta = 7.4$ (B-CH_3), 14.7 (CH_3CH_2), 22.2 (CH_2CH_3), 26.4 (CCH_3), 151.8 (C2), 154.6 (C6), 179.3 (C4/5), Assignments by means of 2D-NMR measurements (^{1}H-,^{13}C-correlated) at 25 °C); EI-MS: *m/z* 188 ($M^{\oplus}$, 2.6%); 108 ($M^{\oplus} - C_5H_9B$, 53.1%).

7a: A solution of $Cr(CO)_6$ (0.26 g, 1.18 mmol) and **6b** (0.22 g, 1.17 mmol) in toluene (20 mL) was heated under reflux for 4 h. After removal of the solvent the red residue was dissolved in petroleum ether and the resulting solution chromatographed on an Al_2O_3 column (5% H_2O): 0.35 g of red **7a** (85%, m.p. 63 °C, from hexane, −35 °C). Yellow **7b** (69%, m.p. 75 °C, from hexane, −35 °C) was obtained analogously.—Spectroscopic data for **7a**: ^{11}B-NMR (C_6D_6): $\delta = 34.0$; ^{1}H-NMR (C_6D_6): $\delta = 0.91$ (s, 6H, B-CH_3), 1.05 (t, 6H, $^3J(HH) = 7.7$ Hz), 1.52 (s, 6H), 1.87 (m, 2H), 2.20 (m, 2H); ^{13}C-NMR (C_6D_6): $\delta = 3.3$ (br., B-CH_3), 15.5 (CH_3CH_2), 22.5 (CH_2CH_3), 28.1 (CCH_3), 140 (br., C4,5), 157.2 (C6), 218.0 (CO), 219.2 (2CO), 228.0 (CO). MS-EI: *m/z* 352 ($M^{\oplus}$, 3.2%), 324 ($M^{\oplus} - CO$, 4%), 296 ($M^{\oplus} - 2CO$, 3.4%), 268 ($M^{\oplus} - 3CO$, 25.3%), 240 ($M^{\oplus} - 4CO$, 81.7%). IR (ν(CO), pentane): 2026.0, 1960.0, 1936.5, 1907.5 cm^{-1}). **7b**: ^{11}B-NMR (C_6D_6): $\delta = 37.2$; ^{1}H-NMR (C_6D_6): $\delta = 0.98$ (s, 6H, B-CH_3), 1.08 (t, 6H, $^3J(HH) = 7.7$ Hz), 1.65 (s, 6H), 2.13 (m, 2H), 2.22 (m, 2H); ^{13}C-NMR (C_6D_6): $\delta = 1.35$ (br., B-CH_3), 16.1 (CH_3CH_2), 22.6 (CH_2CH_3), 28.3 (CCH_3), 138.5 (br., C4,5), 150.3 (C6), 211.1 (CO), 211.4 (2CO), 217.3 (CO); MS-EI: *m/z* 396 ($M^{\oplus}$, 34.1%), 368 ($M^{\oplus} - CO$, 54.1%), 340 ($M^{\oplus} - 2CO$, 100%), 312 ($M^{\oplus} - 3CO$, 56.5%), 284 ($M^{\oplus} - 4CO$, 11.8%). IR (ν(CO), pentane): 2029.0, 1964.0, 1920.5, 1909.5 cm^{-1}.

A New Route to Nitrile Oxides via α-Nitrosodiazo Derivatives**

By *Ghislaine Sicard, Antoine Baceiredo, Guy Crocco,* and *Guy Bertrand**

It has been known since 1889 that 1,2-bisdiazo derivatives spontaneously decompose to the corresponding alkynes—thus indicating that 1,2-biscarbenes are acetylenic in nature.[1] Recently, we have extended this concept to λ^3-phosphanes which are directly bound to a diazomethyl[2] or an azido group[3] and have been able to synthesize new heteroelement multiply bonded systems.

$$-\underset{\underset{N_2}{\|}}{C}-\underset{\underset{N_2}{\|}}{C}- \xrightarrow[-\,2\,N_2]{} -\ddot{C}-\ddot{C}- \longleftrightarrow -C\equiv C-$$

$$\gtrdot\ddot{P}-\underset{\underset{N_2}{\|}}{E} \xrightarrow[-\,N_2]{} \gtrdot\ddot{P}-\ddot{E} \longleftrightarrow \gtrdot P\equiv E \qquad E = CR, N$$

Nitrile oxides[4] can be formally considered as "nitrene oxides" α to a carbene carbon atom:[5]

$$-\ddot{C}-\ddot{N} \longrightarrow O \longleftrightarrow -C\equiv N \longrightarrow O$$

Therefore, α-nitrosodiazo derivatives are potential precursors of these species. We have already shown that the carbon-silicon bond of trimethylsilyldiazo derivatives easily reacts with activated halogen compounds.[2b] Since no phosphorus-substituted nitrile oxide was known, we first chose to study the reaction of nitrosyl chloride with the [diazo(trimethylsilyl)methyl]phosphonic acid derivative **1**.[6-8]

$$R_2P(=S)-\underset{\underset{N_2}{\|}}{C}-SiMe_3 \xrightarrow[-\,Me_3SiCl\ -\,78\,^\circ C]{+\ ClN=O} \left[R_2P(=S)-\underset{\underset{N_2}{\|}}{C}-\ddot{N}=O\right] \xrightarrow[-\,N_2]{} R_2P(=S)-C\equiv N\rightarrow O$$

1 **2** **3**

R = iPr_2N

The α-nitroso derivative **2** was not stable enough to be characterized, even at −78 °C; in contrast, the λ^5-phosphorus-substituted nitrile oxide **3**[8] was obtained in 90% isolated yield as white crystals (m.p. 60 °C, decomp.). Characteristic nitrile oxide reactivity was observed for derivative **3**. With triphenylphosphane, the nitrile **4**[8] was obtained in nearly quantitative yield, while irradiation ($\lambda = 254$ nm) gave rise to the isomeric isocyanate **5** in 71% yield.[8]

$$R_2P(=S)-C\equiv N \xleftarrow[-\,Ph_3PO]{+\,Ph_3P} \mathbf{3} \xrightarrow{h\nu} R_2P(=S)-N=C=O$$

4 **5**

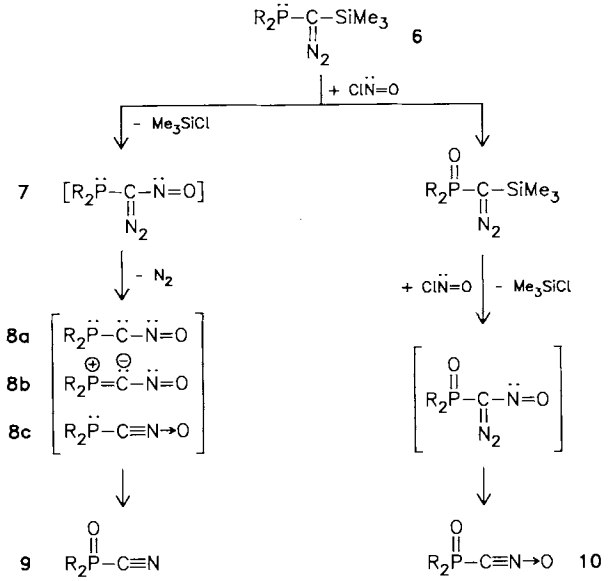
[**] We thank Dr. *I. Tkatchenko,* Dr. *Y. Dartiguenave,* and Dr. *M. Dartiguenave* (Laboratoire de Chimie de Coordination du CNRS, Toulouse) for providing us with laboratory facilities following the destruction, on March 25, 1987, of the Chemistry building of the Université Paul Sabatier.

Since α-nitroso-α-phosphino carbenes such as **8a** can be considered either as nitroso λ^5-phosphaacetylenes **8b** (formulated as zwitterion) or as λ^3-phosphinonitrile oxides **8c**, it was of interest synthesizing the diazo(nitroso) precursor **7** (analogously to **2**[7]), starting from the [diazo(trimethylsilyl)methyl]phosphane **6**.[2a] In fact, **7** appeared to be unstable as well as **8**, which spontaneously rearranged, via a 1-3 oxygen shift,[2b] to the corresponding nitrile of the phosphane oxide **9**,[8] in 75% isolated yield. A small



R = iPr_2N

amount (15% yield) of the corresponding nitrile oxide **10**[8] was also obtained, presumably resulting from oxidation of the starting material **6** followed by a subsequent reaction with a second molecule of nitrosyl chloride.

Note that in all the methods described so far for the synthesis of nitrile oxides, organic systems already containing the C-N-O sequence have been used as starting material. That the conversion of organic compounds possessing a CN single, double or triple bond into nitrile oxides or even that the introduction of an NO group into organic compounds is possible has hitherto never been clearly indicated.

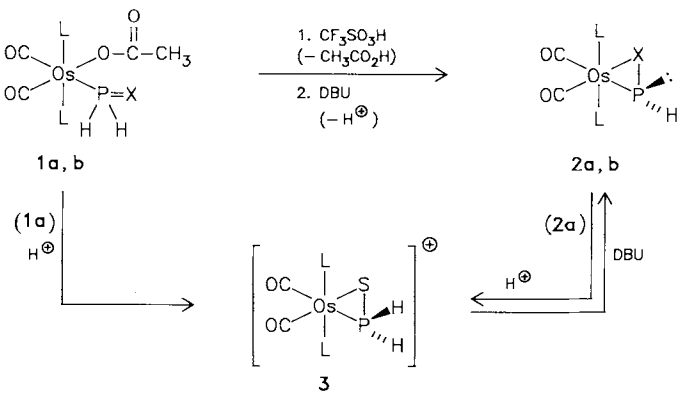
$[Os(\eta^2\text{-}PHS)(CO)_2(PPh_3)_2]$, a Stable η^2-Thioxophosphane(H−P=S)-Metal Complex**

By *D. Scott Bohle, Clifton E. F. Rickard,* and *Warren R. Roper**

A variety of reactive, small molecules such as CF_2,[1] Se_2,[2] $S_2Me^{\oplus}$,[3] PH(OMe)Ph,[4] and PC(O)CF_3[5] form stable complexes with the 16-electron fragment $[Os(CO)_2(PPh_3)_2]$. As part of our attempts to stabilize a terminal phosphanediyl (phosphinidene) complex $[L_nM{=}PR]$[5] utilizing this metal fragment we have prepared a mononuclear example of complexed η^2-thioxophosphane, H−P=S, that is, the sulfide of a terminal phosphinidene complex. This unusual ligand is the parent molecule of the class of compounds R−P=S, examples of which are found in the two binuclear complexes, $[(OC)_4Mn(\eta^2\text{-}\mu^2\text{-}PMeS)Mn(CO)_5]$,[6] and $[(C_5H_5)_2Mo_2(CO)_3(\mu\text{-}CO)(\eta^2,\mu^2\text{-}PRS)]$ ($R = C_6H_4OCH_3$).[7] Free thioxophosphanes are very reactive and their existence has been demonstrated only by matrix isolation vibrational spectroscopy[8] and by trapping experiments with dienes and alcohols.[9] Thioxophosphanes are also of interest as an extension of the emerging chemistry of R′P=A (A = CR_2, NR, and PR). Herein we report the preparation of the osmium complexes **2a** and **2b**, and the crystal structure and reactions of **2a**.

$[Os(\eta^2\text{-}PHX)(CO)_2(PPh_3)_2]$ **2a**, X = S; **2b**, X = Se

Addition of one equivalent of trifluoromethanesulfonic acid to the phosphane sulfide (or selenide) complexes **1a**, **b** (Scheme 1) followed immediately by addition of an excess of the base DBU (1,8-diazabicyclo[5.4.0]undec-7-ene), results in good yields of the η^2-thioxo- and η^2-selenoxophosphane complexes **2a** and **b**, respectively.



Scheme 1. Synthesis of **2a**, **b**. L = PPh_3; **a**, X = S; **b**, X = Se.

While attempts to isolate the cationic H_2PS complex **3** have failed, both ^{1}H- and ^{31}P-NMR spectra (Table 1) indicate that **3** is the initial product when either **1a** or **2a** is treated with strong acids. At room temperature, solutions of **3** quickly decompose. Spectroscopic data for **2a** ($\tilde{\nu}$(PH) = 2196 cm^{-1} and $^1J_{HP} = 117.5$ Hz) suggest a weakened phosphorus-hydrogen bond. However **2a**,**b** are prepared in the presence of excess base and there is no evidence for the deprotonation of **2a**,**b** under these conditions. Only very low yields (< 7%) of **2a** result when **1a** is treated directly with base.

Table 1. Selected NMR and IR spectroscopic data of **1**–**3** and **5**–**7** [a].

1a: ^{1}H: $\delta = 1.44$ (s; O_2CCH_3), 5.82 (dt, $^1J_{HP} = 374.8$, $^3J_{HP} = 7.9$; H_2PS); ^{31}P{^{1}H}: $\delta = -3.48$ (d, $^2J_{PP} = 27.7$; PPh_3), −56.29 (t, $^2J_{PP} = 27.7$; H_2PS); IR: 2050, 1969

[*] Prof. Dr. W. R. Roper, D. S. Bohle, Dr. C. E. F. Rickard
Department of Chemistry, The University of Auckland
Private Bag, Auckland (New Zealand)

[**] We thank Dr. *Jan Coddington* for assistance in obtaining NMR data; Johnson Matthey for the loan of OsO_4; and the New Zealand Universities Grants Committee for grants towards the purchase of instrumental facilities and the award of a Postgraduate Scholarship to *D. S. B.*

Both NMR spectroscopy and the reactions of **2a** suggest that there is a lone pair of electrons on the phosphorus in the HPS and HPSe ligands. The $^{31}P\{^1H\}$-NMR spectrum of **2a** indicates that there are two strongly coupled ($^2J_{PP}=285.9$ Hz), inequivalent, *trans*-triphenylphosphane ligands (Table 1). The X-ray diffraction study of **2a** (Fig. 1)[10] reveals that the phosphorus and sulfur atoms are almost coplanar with the metal and the two carbon monoxide ligands. Therefore, the inequivalence of the triphenylphosphane ligands arises from there being a lone pair on one side of this plane and a hydrogen atom on the other side. Because of the inability to distinguish phosphorus and sulfur crystallographically little can be inferred from the specific geometry of **2a** except that the phosphorus–sulfur bond length, 209.0(5) pm, is significantly longer than the average value for the thiophosphoryl phosphorus–sulfur double bond, 193 pm; in fact it is at the long end of the range (203–209 pm) associated with phosphorus–sulfur single bonds.[11] Weakened phosphorus–selenium bonding in **2b** is also implied by both the ^{31}P- and ^{77}Se-NMR spectra which show that the one bond phosphorus–selenium coupling ($^1J_{PSe}=280$ Hz) is about half of that found in **1b** ($^1J_{PSe}=531$ Hz).

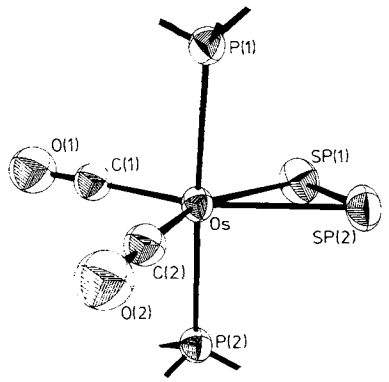

Fig. 1. Crystal structure of **2a** [10]. Because phosphorus and sulfur were not distinguished these atoms are represented by SP(1) and SP(2). Bond lengths [pm]: Os-P(1) 240.3(3), Os-P(2) 239.4(3), Os-SP(1) 245.7(3), Os-SP(2) 244.3(3), SP(1)-SP(2) 209.0(5). Bond angles [°]: SP(1)-Os-SP(2) 50.5(1), Os-SP(1)-SP(2) 64.4(1), Os-SP(2)-SP(1) 65.1(1). The phenyl rings of the triphenylphosphane ligands have been omitted for clarity.

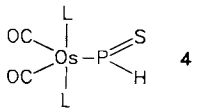
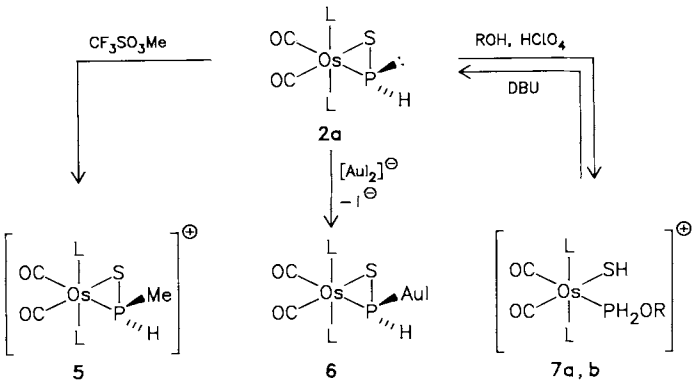
These structural and spectroscopic results suggest that the bonding in **2a,b** may be similar to that in the complexes $[Os(CO)_2(PPh_3)_2L]$, L = alkene and alkyne. Interaction of the empty π^* orbital of HPS with filled metal orbitals of the appropriate symmetry would be expected to weaken the phosphorus–sulfur bond, as observed. There is no evidence of a *monohapto* HPS interaction as depicted in **4**, although this is the geometry present in the related $R_2N-\ddot{P}=O$ complex $[(OC)_5Cr\{P(O)NR_2\}]$, R = *i*Pr.[12] Both geometries are found in phosphaalkene[13] and diphosphene[14] transition metal complexes.



4

Electrophiles readily add to the phosphorus in **2a** (Scheme 2). Stable adducts result when **1a** is treated with methyl trifluoromethanesulfonate, to give **5**, and with $[NBu_4][AuI_2]$, to give **6**. In the presence of alcohol, however, reaction with acid results in phosphorus–sulfur bond cleavage and the product, a cationic mercaptoalkylphosphinite complex, **7a,b**, is formed from overall ROH and $H^{\oplus}$ addition. This reaction is reversible and addition of base (DBU) to **7a,b** leads to abstraction of $H^{\oplus}$, loss of ROH, and return of **2a** in high yield. The HPSe complex **2b** behaves similarly when treated with acidic alcohol but the resulting product is stable only in the presence of acid. In the presence of D_2O, NMR experiments indicate that the SH protons exchange more rapidly than the $ROPH_2$ protons.



Scheme 2. Reactions of **2a**. L = PPh_3; **7a**, R = Me; **7b**, R = Et.

At low temperatures the cationic complex **5** is deprotonated rapidly with DBU to give $[Os(\eta^2\text{-}PMeS)(CO)_2(PPh_3)_2]$.[15]

Experimental

2a: **1a** (0.5 g, 0.59 mmol) in 10 mL of anhydrous THF is treated with CF_3SO_3H (0.59 mmol, 0.084 g, 0.049 mL), and to this colorless solution excess DBU (1.7 mmol, 0.25 g, 0.25 L) is immediately added. The bright yellow color of **2a** is produced instantly. The THF is removed and dichloromethane/ethanol is used to recrystallize **2a** in 63% yield (0.31 g, m.p. 188 °C). **2b** is prepared analogously (in 70% yield) from **1b**. The starting materials **1a**, **b** are prepared in three steps from $[OsCl(PH_3)(CO)(NCCH_3)(PPh_3)_2]ClO_4$ (**A**) [5, 16]: **A** (0.7 g, 0.73 mmol) and CH_3CO_2Na (1.4 g, 17.1 mmol) are heated at reflux for 20 min in 20 mL of methanol, cooled, and the product $[Os(PH_2)(\eta^2\text{-}O_2CCH_3)(CO)(PPh_3)_2]$ (**B**) (0.56 g, 0.67 mmol, 92% yield, m.p. 171 °C) is isolated by filtration and washing with water, methanol and ethanol. **B** (0.1 g) is carbonylated (dichloromethane, 300 kPa CO, 20 min, 25 °C) and the product $[Os(PH_2)(\eta^1\text{-}O_2CCH_3)(CO)_2(PPh_3)_2]$ (**C**) is recrystallized from dichloromethane/ethanol to give 0.1 g (95% yield) of white solid, m.p. 177 °C. **1a** is prepared from **C** (0.28 g, 0.32 mmol) by treating it with sulfur (1.1 equivalents, 0.35 mmol, 0.011 g) in 20 mL of benzene for 5 h. The benzene is removed in vacuo and dichloromethane/ethanol used to recrystallize **1a** (0.28 g, 98% yield, m.p. 153 °C). **1b** is prepared analogously from **C** and selenium. All isolated compounds have given satisfactory elemental analyses.

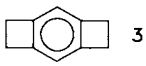
2c, $R^1 = H$, R^2 = Cl, Br, I
2d, $R^1 = H$, $R^2 = ONO_2$



3

The substituents in **2b**–**2d** give rise to reductions in symmetry and electron shifts that are not observed in the parent compound (cf. also the situation in **1**[11]). We have therefore carried out an X-ray structure analysis of **2a** (m.p. ca. −75 °C) at −170 °C and calculated the X–X deformation electron density; single crystals prepared by a

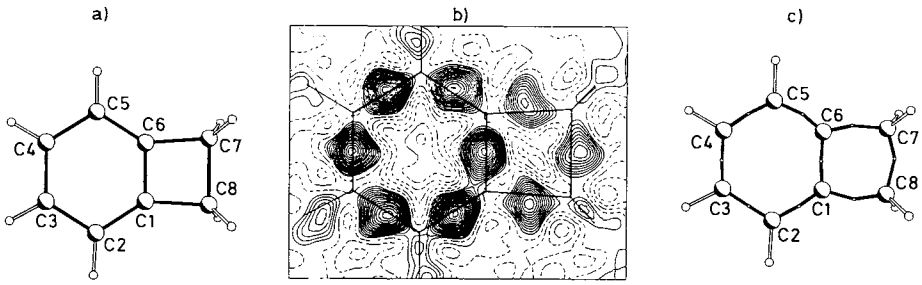


Fig. 1. a) **2a** with atomic labeling and important distances [Å] and angles [°] (standard deviations 0.001 Å and 0.1° resp.) averaged for *mm*2 symmetry (corrected values according to *Schomaker* and *Trueblood* [13] in brackets): C3-C4 1.399 (1.402), C4-C5 1.400 (1.402), C5-C6 1.385 (1.387), C6-C1 1.391 (1.395), C6-C7 1.518 (1.520), C7-C8 1.576 (1.580); C3-C4-C5 121.7, C4-C5-C6 116.0, C5-C6-C1 122.3, C5-C6-C7 144.2, C1-C6-C7 93.5, C6-C7-C8 86.5. b) X-X-deformation electron densities of **2a** in the plane of the molecule. Contour interval 0.025 eÅ^3, negative electron densities dashed, intervals 0.05 eÅ^3. c) Bond lengths [Å] and angles [°] of **2a**, calculated in each case linearly via the maximum of the deformation electron densities (estimated standard deviations about 1 in the last decimal place): C3-C4 1.40, C4-C5 1.41, C5-C6 1.40, C6-C1 1.41, C6-C7 1.56, C7-C8 1.65; C3-C4-C5 127, C4-C5-C6 124, C5-C6-C1 123, C1-C6-C7 106, C6-C7-C8 112.

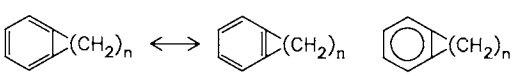
Structures and Deformation Electron Densities of 1,2-Dihydrocyclobutabenzene and 1,2,4,5-Tetrahydrodicyclobuta[*a,d*]benzene**

By *Roland Boese** and *Dieter Bläser*

X-ray crystallographic analysis of cyclopropabenzene **1** reveals no bond localization in the sense of the Kekulé resonance structures **A** or **B**, but rather a reduction in symmetry with retention of the aromatic π-electron delocalization in the benzene nucleus (**C**).[1] This trend should con-



A B C

n = 1 : 1
n = 2 : **2a**

previously described method[7] were used for the analysis.[8] A redetermination of the structure at −170 °C and calculation of the X–X deformation electron density were also carried out for **3**.[9] The results are presented in Figures 1a (**2a**) and 2a (**3**).

The molecules of **2a** and **3** in the solid state are, within the limits of error, planar. **2a** has *mm*2 symmetry, while **3** has *mmm* symmetry; the resulting symmetry element *i* is identical with the crystallographic inversion center in $P\bar{1}$.

Unlike in **1**, in **2a** and **3** there is no significant shortening of the annelated bond, and an alternation of the bonds is also not observed. In **2a** the bonds in the benzene ring adjacent to the annelated bond (C1-C2, C5-C6) are shortened (1.385 Å). Both types of σ-bonds in the cyclobutene ring in **2a** and in **3** are of equal length (1.518 Å and 1.576 Å in **2a**, 1.521 Å and 1.575 Å in **3**) and are comparable with those in 1-cyclobutene-1,2-dicarboxylic acid (1.50 Å and 1.56 Å).[10] This is consistent with the concept of bent bonds; the respective shifts of the bonding electron density maxima are clearly recognizable in Figures 1b and 2b. The angular deformation of the benzene ring in **3** is almost as large as that in **1** (C3′-C1-C2 112.1° in **3**, C1-C2-C3 113.2° in **1**), but smaller in both cases than that in

[**] We thank Herrn Prof. Dr. *W. Roth*, Universität Bochum, for generously supplying the substances.

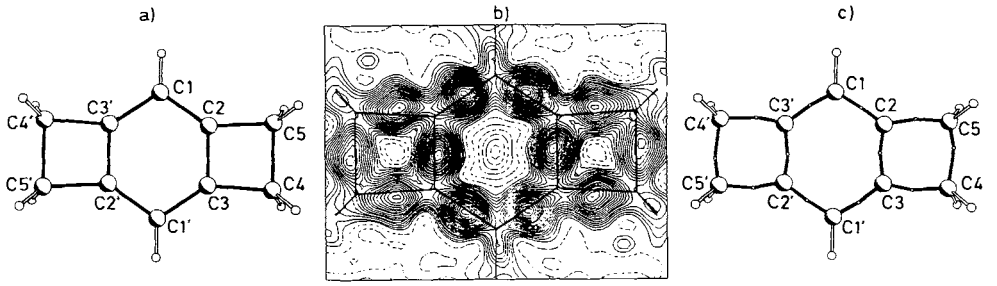

Fig. 2. a) **3**, distances and angles averaged for *mmm* symmetry, other data as for Fig. 1a: C1-C2 1.394 (1.396), C2-C3 1.399 (1.402), C2-C5 1.521 (1.522), C5-C4 1.575 (1.579); C3'-C1-C2 112.1, C1-C2-C3 124.0, C1-C2-C5 142.7, C3-C2-C5 93.4, C2-C5-C4 86.6. b) X-X deformation electron densities of **3**, other data as for Fig. 1b. c) Bond lengths and angles of **3**, other data as for Fig. 1c: C1-C2 1.40, C2-C3 1.41, C2-C5 1.53, C5-C4 1.60; C3'-C1-C2 119, C1-C2-C3 120, C3-C2-C5 107, C2-C5-C4 102.

2a (C1-C2-C3 116.0°). If, on the other hand, the angles are calculated with the assumption of bent bonds, i.e. bonds which do not correspond to the nucleus-nucleus bond axes but to lines joining the maxima of the deformation densities (Figs. 1c and 2c), angles result which compare far better with those expected for sp^2 and sp^3 hybridized C-atoms.

From Figures 1b and 2b it is clear that the ring strain of the cyclobutene ring is transferred to the annelated bond, whose bonding electron density shifts to the center of the benzene ring. This causes an outward shift of the electron densities in the neighboring bonds. As a result the C-C-C angles at C2 and C5 of **2** become smaller. Due to double annelation, the ring strain in **3** is much greater, and leads to even smaller angles (at C1 and C1'). Attempts to annelate two cyclopropene rings to a benzene ring in order to increase the ring strain still further have hitherto failed.[11] So far only the annelation of a cyclopropene ring and a cyclobutene ring to a benzene ring has been achieved.[12] Determination of the structure of this species is presently under way.

Protein Chemistry in Vogue

The last few years have seen advances in molecular biology which break new ground. Since in most cases the end product of a piece of research in molecular biology is a protein, there has also been a new upsurge of interest in protein chemistry. The importance of collaboration between molecular biologists and protein chemists can be seen by considering an example. Thus, the protein chemist begins by determining a part of the sequence, starting at the terminal NH_2 group, for a very small quantity of an unknown protein. Next the molecular biologist, using an oligodeoxynucleotide which corresponds to the sequenced portion, isolates the gene or the cDNA of the unknown protein and expresses this in a foreign organism. The recombinant protein which is thereby obtained in a sufficient quantity can now be characterized by the protein chemist (physico-chemical properties, perhaps a sequence analysis to confirm the cDNA sequence, determining the positions of any post-translational modifications such as disulfide bridging, glycosylation, or proteolytic scissions, determining secondary and tertiary structure, and identifying biological activity). The combined efforts may culminate in selective mutagenesis of the protein being studied ("protein engineering"). The techniques of protein chemistry needed in order to attain these and other objectives are described in detail in

Practical Protein Chemistry—a Handbook. Edited by *A. Darbre*. Wiley, Chichester 1986. xix, 620 pp., bound, $ 91.55.—ISBN 0-471-90673-5

The book includes chapters on affinity chromatography, disulfide bonds, fragmentation of proteins, separation of peptide and protein mixtures, X-ray crystallography, predicting likely secondary and tertiary structures, a section on analysis of glycoproteins, and, occupying a central position, several contributions on manual and automatic methods of sequence analysis. The most important methods used in protein chemistry are here summarized in a single volume by prominent experts, the only exceptions being peptide synthesis and the chemical modification of proteins, which have already been covered in detail elsewhere.

The term "protein engineering" is relatively new, but the field to which it mainly refers has been in existence since the beginnings of sequence analysis and peptide synthesis, being previously described less succinctly as "the study of protein structure and function". Protein engineering in its broadest sense means modifying the properties of proteins, e.g. their stability, specificity towards particular substrates, or enzymic activity. One must also include in this the developing field of designing new polypeptides which do not occur naturally. The current popularity of protein engineering arises from the possibility of being able, through site-directed mutagenesis, to effect any desired amino-acid exchange at any desired position on a protein chain. It is therefore not surprising that we now have the first monographs dealing with this field. The book to be discussed here is

Protein Engineering. Edited by *M. Inouye* and *R. Sarma*. Academic Press, New York 1986. xiii, 424 pp., bound, $ 49.95.—ISBN 0-12-372485-6

The work is divided into four sections. The first (Structure and Design) includes articles on the importance of data banks of protein sequences, the construction of models of biologically active polypeptides, the molecular analysis of thermophilic proteins, the total chemical synthesis of a gene for bovine rhodopsin, "surface simulation synthesis", and a particularly important chapter on the analysis of homologous tertiary structures. The second section (Mutant Analysis) deals with mutants of individual proteins; examples are the hemagglutinin of the influenza virus, bacterio-opsin, staphylococcal nuclease, and the lysozyme of the T4 bacteriophage. In the third section (Complex Systems), the protein engineering of antibody molecules deserves particular attention. The antigen binding sites of the variable regions of light and heavy chains suggest the possibility of manipulations which could lead to completely new proteins; experiments along these lines are still at an early stage. The fourth section (Applications) includes chapters on enzymic reactions in non-aqueous media, on directed transport of toxins by using monoclonal antibodies, on the production of new antibiotics, on genetic transformation of plants, and on the application of genetic engineering to bioinsecticides.

The individual contributions have undoubtedly been written by authors competent in their fields, but it must be said that the editors of the book have shown some lack of care, especially in the fourth section, in what has been included under the heading of protein engineering which is not identical with genetic engineering and biotechnology; some of the chapters are at best only marginally related to the book's title. Conversely, some topics which ought to have been covered in an introduction to this field and an account of its main features are not included, e.g. the prediction of likely protein structures and their experimental determination, the design of new proteins, and a good summary of the methods of site-directed mutagenesis (all of which are covered in another book on protein engineering, edited by *Oxender* and *Fox*). Also, some of the contributions in this monograph are not very up-to-date; a glaring example is a chapter with 50 references, of which 42 are to papers published in the 1960's and 1970's and only eight relate to the 1980's. Despite these shortcomings, the book can be recommended for the predominantly high quality of the contributions. However, newcomers to the field should begin with a better structured work than this.

Aromaticity. By *P. J. Garratt*. Wiley-Interscience, New York 1986. xi, 318 pp., bound, $ 65.00.—ISBN 0-471-80703-6

The many-faceted concept of aromaticity has had a profound effect on progress in organic chemistry from its beginnings up to the present day, involving an interplay of experiment and theory. This monograph, intended for use as a student textbook, attempts to convey something of that continuing process. The arrangement of the present work follows that of the text published by the same author 15 years ago, under the same title. After a short historical introduction, the first of the eleven chapters continues by defining the problem of aromaticity, then gives a very con-

cise introduction to the HMO and VB methods, as exemplified in the prototype molecule benzene. By way of providing a key to all that follows, Chapter 2 then gives a detailed account of the physical, chemical and theoretical differences between anti-aromatic, aromatic and non-aromatic systems, based on the example of the classical triad cyclobutadiene-benzene-cyclooctatetraene. The following chapter, which is newly introduced material, first briefly describes the chemistry of simple arenes, taking as examples the different substitution mechanisms as well as thermal and photochemical addition reactions; this is followed by a discussion of the synthesis, chemistry and properties of the valence isomers of benzene, dehydroarenes, and arenes whose structures are distorted by bridging, by sterically hindered substitutions, or by annelation of small rings. The following chapters deal with all the main classes of compounds that are connected with the concept of aromaticity: annulenes, monocyclic aromatic and anti-aromatic ions, annulenones, fulvenes and related systems. Further chapters are devoted to heterocyclic compounds—subdivided into π-excessive compounds of the pyrrole type, π-deficient compounds of the pyridine type and heterocyclic compounds with two or more heteroatoms—and polycyclic benzenoid and non-benzenoid arenes. The penultimate chapter discusses homo-aromatic and topologically related compounds such as bicycloaromatic and longicyclic ions with non-coplanar π-electron systems. The final chapter is concerned with the aromatic transition states in pericyclic reactions, and gives a concluding summary of aromaticity criteria. An adequate index is provided (14 double column pages) with cross-references, giving quick access to particular topics, though it fails to include some of the key phrases that are used frequently in the text, e.g. delocalization energy.

New passages of greater or less detail, which one only notices on close comparison with the earlier book, have been interlaced into all the chapters. These take particular account of the progress made during the past one and a half decades. The wide scope of subjects covered in the book is supported by a wealth of factual material, in particular by a large amount of magnetic, kinetic, spectroscopic and structural data. One especially welcomes the ^{13}C- and ^{1}H-NMR data, explicitly given for many molecules to establish the diatropic, paratropic or atropic character of the compounds under discussion. The persistent use of the Frost-Musulin formalism, and of *Dewar*'s PMO method for estimating delocalization energies, has to be considered as instructionally very successful. It affords the reader an easy approach, free of more severe mathematical hurdles, to these quantities, which are fundamental to an understanding of aromaticity. Reference is also made to more recent theoretical approaches to this topic. In keeping with the textbook character of the work, the references which are given at the end of each chapter are nearly all to review articles, arranged according to topics (extending up to 1986 in many cases). Sometimes, though, the lack of references to original papers is a disadvantage.

In the chapter on homo-aromaticity, insufficient account is taken of recent new knowledge, especially concerning neutral compounds. Particularly noticeable is the absence of quantitative data which are now available on aromatic stabilization or destabilization. There is no mention of anti-homo-aromaticity. The treatment of aromatic transition states, which is very relevant in the context of this book, deserved to be covered in more detail in view of its importance, which is not confined to mechanistic organic chemistry alone. Here too, it would have been desirable to include data on the order of magnitude of the energy advantage conferred by reaction routes involving aromatic transition states, compared with alternative reaction channels.

The book is written in a very readable style, and is richly illustrated by figures and clearly presented reaction schemes. Some typographical errors need to be corrected in a later edition. With regard to errors of content, only two will be mentioned here. The conversion of hexatriene to 1,3-cyclohexadiene is not a Cope rearrangement but an electrocyclic reaction. The homo-aromatic ions involved in solvolysis with retention (p. 292) are reaction intermediates, not transition states.

Despite the shortcomings mentioned here, this monograph certainly offers to advanced students, and to chemists who wish to refresh their knowledge of the whole topic of aromaticity, the quickest, most complete, and most up-to-date means of access to the subject that is now available. The book will undoubtedly be a valuable addition to every chemistry library, especially since it can also be useful as a work of reference.

The Practice of Enantiomer Separation by Capillary Gas Chromatography. By *W. A. König*. Hüthig, Heidelberg 1987. xii, 104 pp., bound, DM 48.00.—ISBN 3-7785-1324-3

The separation and quantitative analysis of enantiomers is still a difficult problem even today. One method which has been developed and perfected in recent years for this purpose is capillary gas chromatography. This little book by *König* gives a complete and easily understood account of the present state of knowledge on this topic.

It begins with a general section dealing with the principle of the technique, with the preparation of chiral coating materials for columns and that of the columns themselves, and—so far as this is known—the mechanisms whereby such columns effect separation of enantiomers. As the compounds to be separated are usually strongly polar, it is necessary in nearly all cases to prepare a derivative of the sample. The following chapters of the book describe methods for derivatization and the difficulties encountered, illustrated by many actual examples. Detailed experimental conditions for preparing the derivatives are appended to each chapter. Further sections follow in which other chromatographic techniques for separating and determining enantiomers are discussed, such as by forming metal complexes and preparing diastereomeric derivatives to achieve separation of enantiomers. The book thus provides a good survey of the different techniques for enantiomeric separation, enabling the reader to choose the best method for the problem in hand.

In this description of enantiomer separation by gas chromatography, *König* has provided a valuable aid to the experimentalist. The book's outstanding characteristics are the clear and helpful discussion of the various methods, with their advantages and disadvantages, and the relationship to practical examples, the whole book being a pleasure to read. Everyone who is at some time involved in the separation and determination of chiral substances will find this book valuable.

Gerhard Spiteller [NB 841 IE]
Laboratorium für Organische Chemie I
der Universität Bayreuth (FRG)

The Manipulation of Air-Sensitive Compounds. 2nd Edition. By *D. F. Shriver* and *M. A. Drezdzon*. Wiley, Chichester 1986. x, 326 pp., bound, $ 62.95.—ISBN 0-471-86773-X

This book, the fully updated second edition of a classic work, deals with all the currently used techniques for handling air-sensitive substances, including gases. The book is both a practical work of reference and a laboratory handbook for use in many fields of organic, inorganic, physical and analytical chemistry, and in biochemistry, materials science and solid state physics. It can be recommended not only for experts who have a considerable experimental background, but also for students and for practising scientists who are unfamiliar with these techniques.

The book is arranged in two parts: Part 1 (Chapters 1–4) describes inert gas techniques, and Part 2 (Chapters 5–10) describes vacuum work.

Chapter 1 is concerned with those inert gas techniques which can be used directly at the bench without elaborate apparatus, i.e. work under argon using manifolds, syringes, Schlenk tubes, and fritted funnels, and with flushing of apparatus and the supplying and handling of gases, etc. Chapter 2 describes glove box and glove bag techniques: providing and maintaining the inert gas atmosphere, gas locks for introducing and withdrawing samples, work using microscopes, etc. Chapter 3 deals with the purification of inert gases, including the use of chemical drying agents, freezing, adsorption, oxygen removal, and the design of gas purifying systems. Chapter 4 contains information on purifying solvents and reagents. Systems for distillation under inert gas and for storing solvents of high purity are described, as are purification methods for specific cases. Chapter 5 is devoted to classical high vacuum techniques as used particularly in preparative inorganic chemistry. The authors discuss various aspects of the design of high vacuum systems suitable for handling volatile compounds without loss of material. Out-gassing, trap-to-trap distillation (using a partial condenser), measurement of gas quantities, various types of baths for cold traps, and even a Töpler pump, are described. The sixth chapter describes the principles of construction of different types of vacuum pumps, including vacuum seals, cold traps, etc., and compares performance data. Pressure measurements and leak-finding are discussed in detail in Chapter 7, and Chapter 8 deals with ground joints, taps and valves. High vacuum systems and techniques for special purposes are treated in Chapter 9; these include tensimeters, measurement of vapor pressures, determinations of molecular weights and melting points, sample preparation methods for different spectroscopic techniques (IR, NMR etc.), filtration, storage of gases, use of break seals, and high vacuum handling of purified alkali metals. Chapter 10 is concerned with systems of metallic construction for work at higher pressures, for handling reactive fluorine compounds, or for applications requiring extreme vacuum tightness. The book concludes with six appendices which deal in turn with safety, glass-blowing techniques, plastics, metals, calculations of vapor pressures (using various empirical equations, approximations and tables), and lastly conversion factors (for pressures, flow rates, mercury data).

Since the book has been written by American authors, equipment which is commercially available from European manufacturers has in some cases not been mentioned; some examples to which this applies are dosing funnels for powdery substances, dosing funnels and fritted funnels with temperature control jackets, and sublimation apparatus suitable for air-sensitive substances (all available from Normag, Hofheim am Taunus, FRG). Considered as a whole, the book is certainly worth the price, and no laboratory in which techniques of this sort are used should be without it.

Tetrahedrane and Cyclobutadiene

By Günther Maier

Tetra-*tert*-butyltetrahedrane—a useless molecule? In the first part of this progress report an attempt is made to answer this provoking question in order that the reader can evaluate why it is worthwhile to track such an esoteric molecule. An account of the unusual properties of tetra-*tert*-butyltetrahedrane, the only tetrahedrane unequivocally identified so far, and the most highly strained saturated hydrocarbon of all, is followed by a summary of attempts to synthesize the parent compound. The emphasis in these two sections is on our own research achievements. Since any discussion of the tetrahedranes must necessarily include the corresponding cyclobutadienes, it was found appropriate to organize the article at the same time as a final account of the cyclobutadiene problem. *Masamune*[8c] characterized his excellent report in 1980 in the journal Tetrahedron as a *comma* in the history of cyclobutadiene. Meanwhile, the significant questions have been answered. The time is now ripe to replace the comma by a *full stop*.

1. Introduction

Why does the tetrahedrane molecule fascinate the organic chemist? Is it the aesthetic appeal of the topology of the tetrahedron or the hope that the unusual bonding properties of this molecule could lead to otherwise inaccessible knowledge of general importance, or is it indeed the synthetic challenge of the highly reactive—if at all capable of existence[1]—tetrahedrane, together with the sporting ambition to reach the goal first?

Let us start with the first mentioned aspect. If symmetrical objects are considered beautiful, harmonic, and inwardly balanced, this is no modern trend. Behind lies a long tradition, reaching back into antiquity. *Plato* assigned four of the five regular polyhedra described by him to what he called the elements of matter, of which the world was assumed to be composed, namely the tetrahedron to fire, the cube to earth, the octahedron to air, and the icosahedron to water. No terrestrial room was left for the fifth, the pentagonal dodecahedron (nothing material is envisaged for the "ether" (Fig. 1)). This object should serve to

Fig. 1. The Platonic solids: tetrahedron, cube, pentagonal dodecahedron (upper row); octahedron, icosahedron (lower row).—Reproduced by kind permission of the publisher from: L. Pauling, R. Hayward: *The Architecture of Molecules*, W. Freeman, San Francisco 1964.

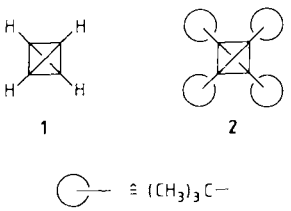
organize the universe into a beautiful whole.[2] It is easy to bridge the gap to the present day.[3] Replacing the corners of the regular polyhedra by methine groups in which three of the bonds go to neighboring ring carbon atoms and the fourth to a hydrogen atom[4] leads in the case of the first three structures of Figure 1 to the so-called "Platonic hydrocarbons", tetrahedrane, cubane, and dodecahedrane. It is now understandable why the synthetic chemist, whose daily routine surely also consists of an artistic component, finds it attractive to create these "beautiful" molecules in the laboratory. Previous efforts in this area are documented by two milestones: *Eaton* et al.[5] constructed cubane over 20 year ago. The synthesis of dodecahedrane by *Paquette* et al.[6] is much more recent.

The equating of the tetrahedron with the element fire has a chemical parallel. According to theory, tetrahedrane (**1**) is the most highly strained (fiery) of the formally saturated hydrocarbons. Therefore, it is also the most likely to satisfy the second criterion, namely to show properties that are not otherwise experimentally accessible. Any such chemical "extravagances" of tetrahedrane could by far exceed the importance of its mere synthesis. It is the purpose of this article to demonstrate whether or not the tetra-*tert*-butyl derivative (**2**) can fulfill the above-mentioned expectations.



As for the sporting ambition,[7] a piece of evidence is given here. How else could it be understood why we, in spite of discouraging predictions by the theoreticians as well as many previous unsuccessful attempts, are still engaged in finding a route to the unsubstituted tetrahedrane?

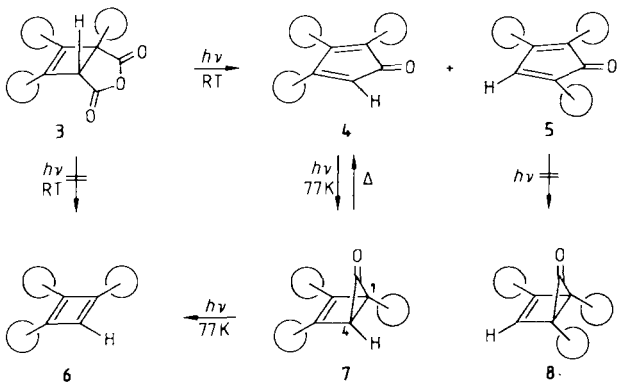
The chemistry of tetra-*tert*-butyltetrahedrane is closely associated with that of the corresponding valence isomeric cyclobutadiene. Although the present article focuses on our own work, it also includes important results from other groups, and it can be seen at the same time as a progress report on the subject tetrahedrane/cyclobutadiene.[8]

2. Tetra-*tert*-butyltetrahedrane

If only a minimal lifetime is expected of the unsubstituted tetrahedrane (**1**), it is appropriate to replace the hydrogen atoms by *tert*-butyl groups. Examples of this trick of attaining kinetic stabilization through steric hindrance of attack of external reaction partners are legion. Apart from the intermolecular effect of mutual shielding, the voluminous substituents in tetra-*tert*-butyltetrahedrane (**2**) play a second role of decisive importance for the stability. The intramolecular repulsion of the four *tert*-butyl groups is at a minimum when their mutual distance is at a maximum. This condition is fulfilled by the T_d symmetry of the tetrahedron. Any other imaginable arrangement causes the substituents to be closer to each other. The breaking of a tetrahedrane bond in **2** must equally lead to strong steric strain. In other words: the favored spherical arrangement of the four peripheral groups in **2** forces the tetrahedral geometry on the molecule. The two *tert*-butyl groups which would recede from each other on stretching a ring bond are forced back again by the other two. This "corset effect" must stabilize **2** relative to **1**. If, however, only one of the substituents in **2** is replaced by a smaller group, the situation must change drastically. Since, in general, alkyl groups lower the thermal stability of a CC bond, all tetrahedranes less highly substituted than **2** should undergo ring opening more easily than the parent molecule itself. In this context it is logical that phenyl-[9] and methyl-substituted[10] tetrahedrane derivatives remain undetectable even under matrix conditions.

2.1. Preparation

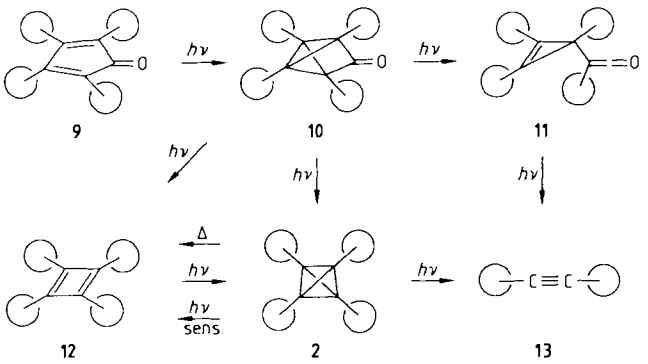
The concept for the synthesis of tetrahedrane **2** is based on our experience gained during the photochemical formation of tri-*tert*-butylcyclobutadiene (**6**) from the cyclopentadienone **4**.[8b, 11, 12] The anhydride **3** ought to be an ideal precursor for **6**. However, the photochemical cleavage at room temperature gives exclusively the two cyclopentadienones **4** and **5**.[13] In contrast to the positional isomer **5**, **4** is photolabile at 77 K and gives the desired cyclobutadiene **6**.[11] Meanwhile, the mysterious origin of the strange



temperature-dependence of the photochemical behavior of **4** has been solved:[14] irradiation of **4** at 10 K gives the housenone **7**, which subsequently is transformed into **6** via CO elimination. The thermal ring-opening of **7** to **4** already takes place at −80 °C.[15] Therefore, at room temperature the stationary concentration of **7** is so low that no formation of **6** is observable. The fact that the cyclopentadienone **5** does not undergo any photofragmentation at any temperature (room temperature, organic matrix at 77 K, or argon matrix at 10 K[16]) demonstrates the importance of the mutual orientation of the *tert*-butyl groups. Apparently, the corresponding housenone **8** is so strained

that it is either not formed by photochemical excitation, or rapidly undergoes ring opening to **5** even at 10 K. This view is supported by theoretical studies.[17] MNDO calculations give a C1–C4 distance of 1.587 Å for **7**. The corresponding bond in **8** must be longer (1.647 Å) and hence weaker.

From the above observations it may be inferred that introduction of a fourth *tert*-butyl group in **4** or **5** should drastically influence the ability to undergo photoisomerization. This expectation finally led to the successful synthesis of the tetrahedrane **2**:[18] the photochemical behavior of tetra-*tert*-butylcyclopentadienone **9** is entirely different from that of **4**. Excitation of the dienone **9** isolated in argon with 254-nm light results in exclusive criss-cross addition to give the tricyclopentanone **10** as observed by IR spectroscopy. Continued irradiation leads to carbon monoxide elimination. At the same time, the typical band of ketene **11** appears. This ketene is likewise photolabile and eliminates CO, albeit very slowly. Irradiation in an organic matrix at 77 K permits isolation of the hydrocarbons formed.



Apart from di-*tert*-butylacetylene (**13**), which is the only end product of the room temperature irradiation, *Pfriem*[18] isolated the tetrahedrane **2** as stable, colorless crystals. On heating to 135 °C, **2** is transformed into the corresponding cyclobutadiene **12**. This valence isomerization is photochemically reversible. It may be assumed, therefore, that the bicyclobutanediyl diradical primarily formed on irradiation of **10** is converted into the cyclobutadiene **12** by cleavage of the backbone bond; the cyclobutadiene then furnishes the tetrahedrane derivative **2** under the conditions of irradiation.

2 is the only isolated and unequivocally identified tetrahedrane so far.[19] The route to **2** should also be applicable to other highly strained systems. Unfortunately, however, this is not so. An examination of the differently substituted cyclopentadienones **14**–**24**[20] showed that **14**–**19** are totally unchanged by irradiation ($\lambda = 254$ nm) in argon at 10 K. Only **20**, **21**, and **22** undergo photoisomerization to the related tricyclopentanones of type **10** to an increasing extent.[20b] At least **22** undergoes the criss-cross addition about as easily as the reference substance **9**. However, no tetrahedrane derivative is detectable on subsequent CO elimination. Although the extremely bulky adamantyl residue favors tricyclopentanone formation, it may already be too large to permit the planarization of the cyclobutadiene ring necessary for decarbonylation. Apparently, it is only in the tetra-*tert*-butyl series, which also includes **23** and **24**, that everything fits nicely together.

19	trimethylsilyl		

The very different photochemical behavior of the cyclopentadienones **4**, **5**, and **9** still requires an explanation. The X-ray structure analyses carried out by *Boese* provide an indication (Fig. 2).[21]

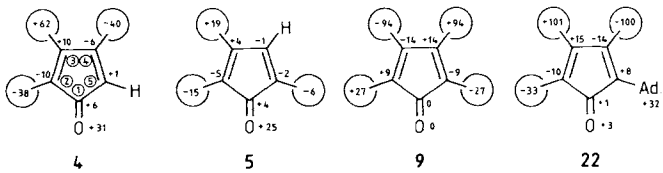

Fig. 2. Deformations [pm] of the cyclopentadienones **4**, **5**, **9**, and **22** relative to a "best" plane through the rings, determined by X-ray crystallography. +: above; −: below the plane.—The distance to the "best" plane refers, in the case of the adamantyl moiety (Ad), to C1.

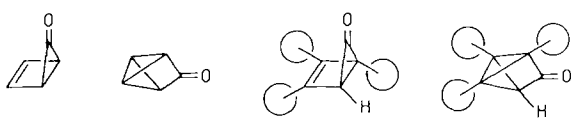
The structures demonstrate that the direction of the photochemically induced reaction is already given by the distortion of the rings in the ground state. The deviations are relatively small in the case of **5**. Therefore, no photoreaction takes place. In ketone **4**, the four *tert*-butyl groups and therefore also the neighboring ring C-atoms are in a staggered arrangement. Here, less energy is required in order to achieve photoisomerization. From the structure, one could expect a criss-cross reaction. Nevertheless, when a housenone is formed, this is because it is preferred over the tricyclopentanone on the grounds of ring strain. According to MNDO calculations,[22] the enthalpy of formation of **26** is 26.8 kcal mol^{-1} higher than that of **25**. The



introduction of three *tert*-butyl groups reduces this energy difference between **27** and **7** to 4.8 kcal mol^{-1}. It is therefore no wonder that the tricycle **27** is known; however, the

compound is completely photostable.[23] Following the trend, the tricyclopentanone **10** could already be more stable than the corresponding housenone in the tetra-*tert*-butyl series. Furthermore, the structure of **9** (Fig. 2) implies that photoexcitation should lead to the tricycle (corset effect, see above). Since the deviations are larger still in the adamantyl derivative **22**, the same reaction should be observed here, in agreement with experiment.

2.2. Structure and Spectroscopic Properties

In view of the erroneous announcements of successful syntheses of compounds with tetrahedrane structure, we endeavored to gather as many data as possible and thus prove the structure of **2** unambiguously. The first indication was given by the ^{13}C-NMR spectrum [in $CDCl_3$; three signals at $\delta = 9.27$ (ring-C), 27.16 ($C(CH_3)_3$), and 31.78 (CH_3)]. The observation that the quaternary C atoms of the *tert*-butyl groups appeared at higher field than the primary ones was a first indication of the peculiarity of **2**. The bond between the *tert*-butyl groups and the neighboring C atoms must possess a high degree of s character (as in di-*tert*-butylacetylene, **13**). The high field position of the signal for the ring carbon atoms is even more revealing. It is in exact agreement with expectations.[24] Naturally, the ^{1}H-NMR spectrum of **2** features only a single signal (even in a nematic phase[25]) at $\delta = 1.18$ ($CDCl_3$). The mass spectrum (field desorption) gives the correct molecular mass (*m/z* 276.1). The PE-spectroscopic examination by *Heilbronner* et al.[26] played an important role in the structural analysis of **2** and **12**. As required, the lowest energy band of **2** (centered at $I \approx 7.9$ eV) is a doublet due to Jahn-Teller splitting. Cyclobutadiene **12** shows a singlet at $I = 6.35$ eV.

In addition to the spectroscopic properties already reported,[25] two investigations of isotopically labeled derivatives of **2** should be mentioned. *Saunders*, for example, queried whether in the case of **2** perhaps a dynamic system of rapidly equilibrating singlet diradicals exists rather than a static molecule. Tetrahedrane derivative **2** possessing one perdeuterated *tert*-butyl group is obtainable from the cyclopentadienone **23**[20b] and the isotopic perturbation observable by ^{13}C-NMR spectroscopy was studied in this regard.[27] However, no effect over and above an "intrinsic shift" was detectable. Accordingly, **2** possesses a rigid, fixed structure. Another important point concerns the electron distribution in **2**. ^{13}C–^{13}C coupling constants can give information on this. The couplings are observable by labeling one of the *tert*-butyl groups in **2** with ^{13}C at the quaternary center. The required substance can be obtained from the dienone **24**.[20b,28] The analysis of the ^{13}C-NMR spectrum carried out by *Lüttke* et al.[29] allows the following conclusions to be drawn: the axes of the endocyclic hybrid orbitals ($sp^{5.20}$ hybrids) are bent outward by 28.4° with respect to the lines connecting the nuclei (record value for banana bonds). The bond connecting the tetrahedral corner with the *tert*-butyl group has a high degree of s character ($sp^{1.04}$ hybridization; closely related to *tert*-butylacetylene). These bond properties are in good agreement with predictions.[30–32]

The remaining spectroscopic information[25] has become less significant as a consequence of a recent X-ray structure analysis of **2**. After many unsuccessful attempts with the room-temperature modification of **2** (plastic, i.e. soft and easily deformed crystals), *Irngartinger* et al.[33] succeeded in growing a more highly ordered modification at low temperature. Recent, impressive results by *Irngartinger* et al.[34] show that this low-temperature form of **2** is "stabilized" by entrapped gases (N_2, Ar). This has allowed the solution of the structural problem. The result shown in Figure 3[33] should remove any remaining doubt about the

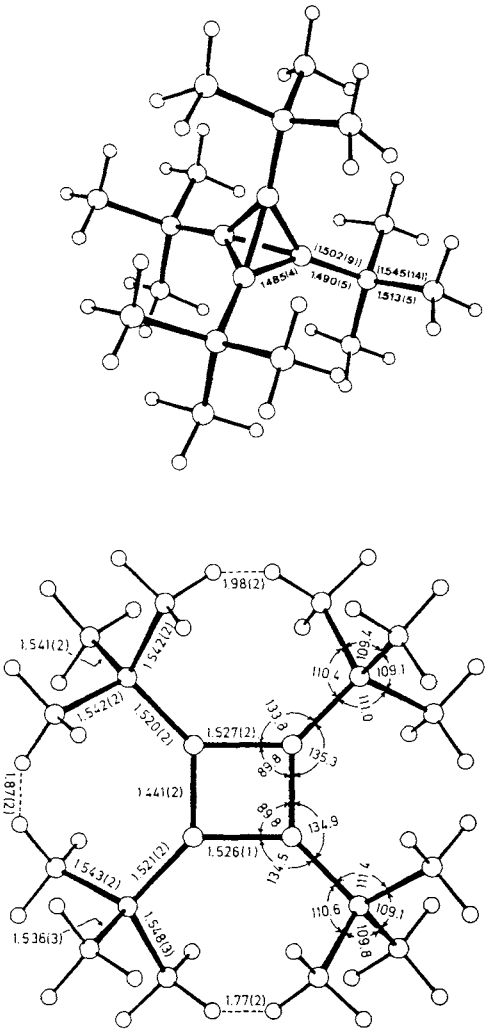


Fig. 3. Crystal structure of **2** [33] with averaged bond lengths ([Å]; deviations in parentheses; corrected values in square brackets); crystal structure of **12** at −150°C with bond lengths [Å] and angles [°].

correctness of structure **2**. The bond lengths in the tetrahedron are relatively short (average 1.485 Å;[33] 1.497 Å[34]) in comparison with normal CC single bonds (1.54 Å) as a consequence of the bending of the bonds. The deformation densities determined for the Ar-clathrate of **2** demonstrate a bending of the ring bonds by 26°.[34] The agreement with the value mentioned above (28.4°) is remarkable. Incidentally, the quantum chemically calculated bond lengths vary between 1.470 and 1.520 Å.[30,32,35,36,37] Of these, the distance originally computed by *Schulman* and *Venanzi*[30] us-

ing an ab initio method comes closest to reality. The appearance of relatively large vibrational ellipsoids of the methyl carbons could indicate that enantiomeric molecules of chiral T symmetry are disorderly arranged about the mirror plane in the crystal. *Mislow* et al.[38] has predicted such deviation from the maximal T_d symmetry to the lower T symmetry on the basis of force field calculations for the free molecule **2**. MNDO calculations have confirmed this.[36]

In this context, it is worth mentioning the curious history of the structural analysis of tetra-*tert*-butylcyclobutadiene (**12**). At room temperature, slight but nevertheless significant alternation is found (1.482 and 1.464 Å) for the ring bonds. The quaternary C atoms of the *tert*-butyl groups deviate from the ring plane by 0.37 Å above or below in an alternating fashion. Also, the four-membered ring itself is not planar but folded with a dihedral angle of 170°.[39] Whereas in other stable cyclobutadienes prepared by *Krebs*[40] and *Masamune*[41] (**65a**, **65b**, **66a**; see Section 2.5) the single bond is stretched, thereby causing a clear alternation (up to 0.26 Å),[42,43] the double bond in **12** is elongated, and therefore the difference in the bond lengths reduced. It has been argued that the stretching of the double bonds (caused by the amassing of four *tert*-butyl groups) should lead to a shortening of the single bonds and hence a nearly square structure.[44] Doubt[45] about this X-ray structure of **12** with "almost equal bond lengths in the four-membered ring" motivated *Irngartinger* to repeat the structure analysis at −150 °C.[46a] Under these conditions, the constitution given in Figure 3 results. The folding of the four-membered ring remains, also at −150 °C. However, the bond alternation is now found to be noticeably larger (0.086 Å). The strange "temperature-dependence of the structure" can be explained by disordering phenomena. The experimentally determined bonding electron density distribution in **12**[46a,b] shows bent bonds in the four-membered ring. The single bond having a lower electron density is more bent than the double bond. A part of the above-mentioned disorder is possibly still present even at −150 °C. A detailed analysis of the anisotropic displacement parameter of ring carbon atoms of **12** shows that the measured data can be reconciled with an averaging, in the sense of a superposition of two rectangular rings rotated through 90°, with the bond alternations found for the other cyclobutadienes mentioned above.[46c]

2.3. Physical Properties

Tetra-*tert*-butyltetrahedrane forms colorless crystals, stable in air and melting at 135 °C with red coloration; i.e. at this temperature **2** is transformed into the valence isomeric cyclobutadiene **12**. This high thermal stability appeared to make a tetrahedrane structure very unlikely. On the other hand, the high melting point is an expression of the high symmetry of **2**. A model based on the van der Waals radii leads to a sphere whose surface is covered with hydrogen atoms (Fig. 4). The volatility is correspondingly high: **2** sublimes very easily in a water aspirator vacuum at room temperature.

Fig. 4. Space-filling model (SCHAKAL [47]) of tetra-*tert*-butyltetrahedrane **2**. The carbon atoms of the ring skeleton are shown in red.

Of course, the ring strain of **2**, which must be an absolute record, is of most interest. There is no other molecule that could surpass tetrahedrane in terms of the strain theory postulated by *Baeyer*[48] just over 100 years ago. Theoretical calculations are in agreement with this, although at first strongly scattered expectation values between 97 and 150 kcal/mol were mentioned.[30,48-50] Using the *Franklin* increments as a reference point,[30] a comparison with the most recently calculated heat of formation of tetrahedrane[36,37,51-55] yields expected strain energies of 136 (MNDO[36]), 134 (ab initio[37]), 126 [MINDO/3[52]), and 132–134 kcal/mol (ab initio).[53-55]

What does the experiment tell? The enthalpy of combustion of **2** determined by *Månsson*[56] ($\Delta H_c^\circ = -3099.8 \pm 1.8$ kcal mol^{-1}) leads to an enthalpy of formation in the condensed phase of $\Delta H_f^\circ(c) = -10.9 \pm 1.9$ kcal mol^{-1}. The enthalpy of sublimation measured by *Rüchardt* et al.[57] ($\Delta H_{sub} = 17.1 \pm 0.8$ kcal mol^{-1}) gives an enthalpy of formation of **2** in the gas phase of $\Delta H_f^\circ(g) = +6.2 \pm 2.1$ kcal mol^{-1}. *Schleyer*'s increments[58] give a calculated enthalpy of formation for the strain free molecule $\Delta H_f^\circ(g) = -123.0$ kcal mol^{-1}. Thus, the strain enthalpy of **2** is calculated as $\Delta H_s = 129.2 \pm 2.1$ kcal/mol (541 kJ mol^{-1}). Since the *tert*-butyl groups contribute very little to the strain of **2**,[59] each ring bond in the tetrahedrane skeleton of **2** can be assigned a strain enthalpy of 21.5 kcal/mol. This is the highest value ever found.[60,61]

Because of the high strain energy, tetrahedrane **1** possesses a higher enthalpy of formation than cyclobutadiene (**29**). All theoretical calculations agree in this. Table 1 gives information on the enthalpy differences thus determined. According to force field calculations by *Mislow*,[64] the substitution by four *tert*-butyl groups in the system **2/12** causes a strong preference for the tetrahedrane form (by 43.8 kcal mol^{-1}). MNDO calculations[36] give the same result (preference by 39.2 kcal mol^{-1}; without *tert*-butyl groups $\Delta\Delta H^\circ = 45.9$ kcal mol^{-1}, i.e. **2** is only 6.7 kcal mol^{-1} higher in energy than **12**). Therefore, the driving force for the conversion **2** → **12** should be significantly weaker than for the unsubstituted parent compounds. If it was previously claimed that tetrahedrane (**1**) would isomerize to cyclobutadiene (**29**) without activation on the grounds of the thermodynamics,[49] recent calculations per-

mit somewhat more optimism. Perhaps one may expect a certain kinetic stability of **1** after all, firstly because both the synchronous ring-opening **1** → **29** and the cleavage of **1**

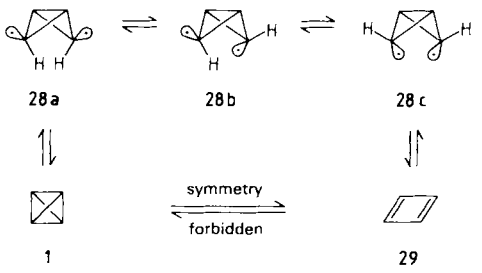

Table 1. Calculated enthalpy differences $\Delta\Delta H°$ between tetrahedrane **1** and cyclobutadiene **29**.

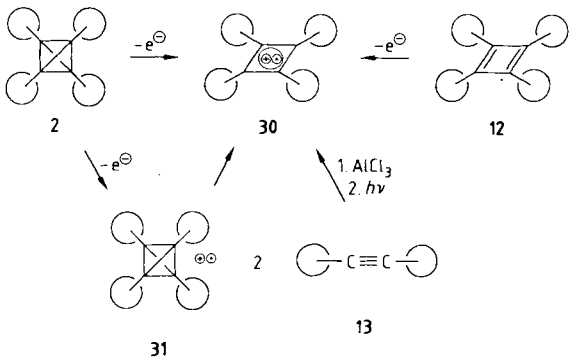
to two acetylene molecules are symmetry forbidden processes, and secondly because a noticeable barrier must be expected also for a multistep reaction via bicyclobutanediyl diradicals **28**.[37] According to *Gleiter* et al.[65] this is due to a HOMO-LUMO crossover on the way from **28a** to **28c**. The activation enthalpy $\Delta H^{\neq}$ calculated for this process spans from 10 to 50 kcal mol^{-1}.[30,36,37,49,52] Some prominent values are: 11 (MINDO/3[52]), 15 (MNDO),[36] 18 (ab initio[30]), and 30 kcal mol^{-1} (ab initio[37]). In this connection *Kollmar*[37] points out that the actual bond cleavage **1** → **28a** only requires 10 kcal mol^{-1}, and this diradical could possibly play a role as a reactive intermediate in bimolecular reactions.

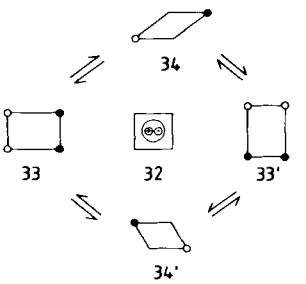
How does the fourfold substitution with *tert*-butyl groups influence the activation barrier? An activation enthalpy of 20 kcal mol^{-1} has been predicted for the process **2** → **12**.[36] The successful isolation of **2** again allows a comparison between theory and experiment for the first time. It is possible to monitor the kinetics of isomerization of the tetrahedrane **2** to cyclobutadiene **12**. The activation parameters thus derived are $\Delta G^{\neq} = 28.6 \pm 2.9$ kcal/mol, $\Delta H^{\neq} = 25.5 \pm 2.3$ kcal mol^{-1}, and $\Delta S^{\neq} = -10.3 \pm 5.8$ cal mol^{-1} K^{-1}.[25] If it is true that the activation enthalpy for the unsubstituted tetrahedrane (**1**) is about 5 kcal mol^{-1} lower,[36] then a value of about 20 kcal mol^{-1} would be expected. Given this barrier, the lifetime of **1** at −40 °C would be about 10 s.[49] From this point of view the matrix isolation of **1** does not appear hopeless.

As described in more detail in the next section, the most important chemical property of **2** is its ease of oxidation.[66] This is to be expected from the exceptionally low ionization potential of **2**[26] and is confirmed by results from chemical ionization.[67] These show that **2** is not protonated by the plasma ion, but oxidized. It was now enticing to attempt the deliberate oxidation of **2**. Several aspects were of interest: a) is the same radical cation **30** formed from both **2** and **12**? b) how high is the barrier for a possible isomerization of the radical cation **31** to **30**? c) is **30** a π or a σ radical? d) what is the structure of the cyclobutadiene radical cation? *Bock* et al.[66] succeeded in finding answers to all these questions. **2** and **12** afford the



same radical cation **30** on one-electron oxidation with aluminum chloride in dichloromethane at −70 °C. The radical cation **31** initially formed from **2** spontaneously isomerizes to **30**. As indicated by calculations, no activation barrier is expected for the conversion of **31** into **30** (**31** is a C_4 cluster with the "wrong" number of electrons). Thus, the radical cation of **2** behaves completely differently from the neutral precursor (see above). The ESR spectrum of **30** features 36 equivalent, coupled protons and four equivalent ring C atoms. The coupling constants argue for a π radical. Moreover, the values measured [$a(H_\gamma) = 0.28$ G; $a(^{13}C_\alpha) = 10.0$ G] can be taken as indications of a roof-like bending. This interpretation is supported by subsequently published work. *Hogeveen* et al.[68] have prepared the radical cation of tetramethylcyclobutadiene by treatment of 2-butyne with aluminum chloride followed by irradiation of the σ complex so formed. This method can be applied to other acetylenes.[68,69] According to *Davies* et al.[69] it is even possible to generate the radical cation **30** in sufficient quantity for ESR spectroscopic detection, starting from di-*tert*-butylacetylene (**13**). These studies also reveal that the cyclobutadiene radical cations are to be regarded as planar π radicals. The folding in the case of **30** is an exception, although it is in agreement with the structure of the electroneutral cyclobutadiene **12**. Furthermore, the bending becomes still more noticeable in the radical cation bearing four 1-adamantyl groups.[70,71]

One problem remains: inspired by the preparation of **30**, *Borden* et al.[72] carried out an ab initio calculation of the cyclobutadiene radical cation **32**. As expected, **32** is subject to Jahn-Teller distortion. The rectangular geometry **33** represents the minimum (the same is true of the radical cation of tetramethylcyclobutadiene[66,73]). The two valence isomers **33** and **33'** can be transformed into each



other via the 6 kcal mol^{-1} higher energy rhombohedral forms **34** and **34'**. In this regard the situation differs from that of cyclobutadiene itself, in which the transition state for valence isomerization is described by a square geometry (see below). Accordingly, one may very well conclude that the experimental ESR spectrum of **30**[66] is the result of exchange between two folded structures with alternating bond lengths, occurring rapidly on the ESR time-scale.

The picture is rounded off by experiments on electrochemical oxidation of **2** and **12** by *Fox* and *Hünig* et al.[74] The oxidation potentials determined by cyclic voltammetry are exceptionally low and again constitute record values for saturated and unsaturated hydrocarbons, respectively. At $E_{pa} = 0.50 \pm 0.10$ V the tetrahedrane **2** gives a radical cation **31**, which is transformed into **30** in an unmeasurably fast reaction.[66,75] **30**, in turn, is reversibly formed from cyclobutadiene **12** at $E_{1/2} = 0.15 \pm 0.10$ V. Knowing these data, we examined[76] whether **2** might be convertible into cyclobutadiene **12** in a photochemically induced electron transfer reaction.[77] In fact, **2** isomerizes smoothly and quantitatively to the cyclobutadiene **12** on irradiation in tetrahydrofuran in the presence of catalytic amounts of 9,10-dicyanoanthracene, and even in the absence of the acceptor by irradiation in benzene solution. Thus, the equilibrium **2** ⇌ **12** can be entirely displaced in one or the other direction depending on the conditions of irradiation (see Section 2.1); this is not an everyday occurrence.

2.4. Chemical Properties

In contrast to the valence isomeric cyclobutadiene **12**, tetra-*tert*-butyltetrahedrane (**2**) is insensitive to air and humidity under ordinary conditions. It is now known that only two reaction channels are open to **2**, viz. protonation and oxidation.[76,78-80] A proton can just fit in between the *tert*-butyl groups. Apart from this, all reactions start with an oxidation step, and the chemistry of **2** is characterized by the primary formation of the radical cation **30**.

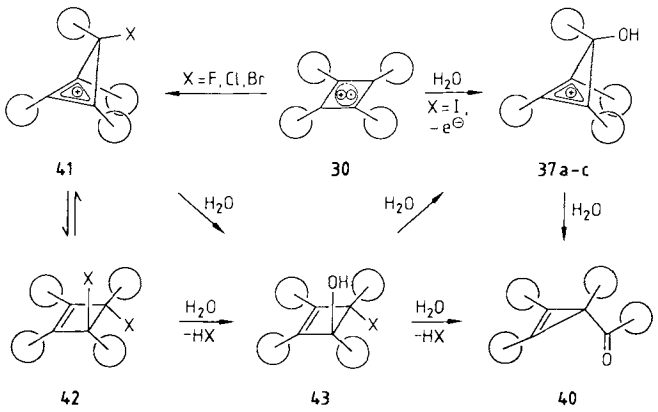
The high degree of p character of the ring bonds in **2** must result in high reactivity toward electrophiles. It has even been predicted[81] that the tetrahedrane **2** should still be protonated at pH = 16.2, i.e. in molten sodium hydroxide. Nevertheless, **2** is completely inert to aqueous hydrochloric acid. The relatively large $H_9O_4^{\oplus}$ ions[82] cannot penetrate the shield of *tert*-butyl groups (Fig. 4). Therefore, protonation of **2** is possible only with anhydrous hydrogen chloride. The same reaction is much faster for the cyclobutadiene **12**, which smoothly reacts with water to give the cyclobutenol **39**.[39] This proceeds via the homocyclopropenylium chloride **35a** which in non-polar solvents and in substance captures a chloride ion, forming an adduct **38** with covalently bonded chlorine. This type of nucleophilic attack is not possible in the case of the bromide and iodide ions. Hydrogen bromide leads only to the formation of the salt **35b**; there is no indication any more of a covalent form. The other salts **35c-g** are likewise obtained either by treatment of **2** with the corresponding acid, or by exchange of the chloride ion in **35a** or the OH group in cyclobutenol **39**. The alcohol **39** is formed again by hydrolysis of these salts.

A first indication of how to "activate" the unreactive tetrahedrane derivative **2** was obtained in the attempt to catalyze the valence isomerization **2** → **12** which requires heating to 135 °C in the absence of a catalyst. The use of $Ag^{\oplus}$ ions as a catalyst[83] did not result in the expected reaction; instead **2** was oxidized. The nature of the isolable end-product, cyclobutenol **39** or ketone **40**, depends on the reaction conditions. It has taken some effort to unravel the ensuing intricacies.[84] Silver tetrafluoroborate, silver hexafluoroantimonate, and silver perchlorate cause oxidation of **2** and **12** to the radical cation **30** (both valence isomers **2** and **12** were always employed in parallel in these experiments).

Steric shielding by the four *tert*-butyl groups hinders the immediate conversion of **30**. In this regard **30** is an ideal molecule for the study of the chemical properties of radical cations.[85] It is also understandable why **2** is an ideal precursor for **30**: ordinary reactants cannot approach the ring skeleton of **2** sufficiently. This is less serious in the oxidation. The electron can overcome a distance of up to 15 Å[86] in SET (single electron transfer) reactions. If no other suitable reagent is available, **30** reacts with traces of water, which in spite of much effort cannot be entirely removed, giving the adduct **36**. The latter can be transformed into the HO-salts **37f-h** in a second oxidation step. In fact, two equivalents of $Ag^{\oplus}$ ions are consumed as long as the hydrocarbon is added slowly to an excess of the oxidant. However, the intermediate **36** can also transfer a proton to **2** or **12**. This latter reaction occurs on inverse addition. Here, the radical cation **36** acts as an acid toward **2** or **12** still present.[87] In this manner the salts **35f-h** are formed. Hydrolysis of the hydroxy salts **37** leads to ketone

40. Also this reaction is reversible; reaction with trifluoroacetic or nitric acid results in regeneration of the salts **37e** and **37i**, respectively. This means that **40** is much more basic than ordinary ketones. In this connection, it is worth mentioning that nitric acid oxidizes the tetrahedrane **2** faster than it protonates, i.e. **37i** is formed exclusively, and not **35i**. On prolonged standing in concentrated nitric acid subsequent cleavage of **37i** gives tri-*tert*-butylcyclopropenylium nitrate and pivalic acid.

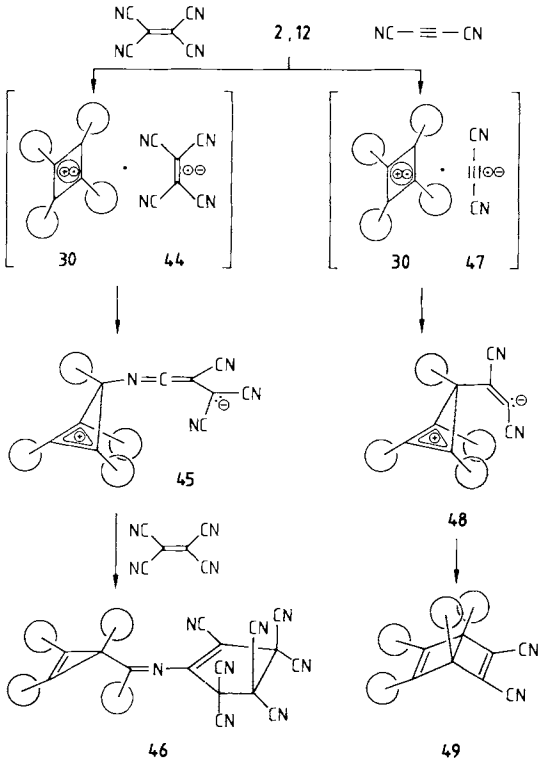
Also halogenations of **2** may be looked upon as redox reactions. The first step is again oxidation to the radical cation **30**. The subsequent course is determined by the nature of the halogen. Xenon difluoride, (dichloroiodo)-benzene (or chlorine), and pyridinium perbromide (or bromine) react with **2** to give dihalocyclobutenes **42** via **30** → **41**. The stability of the dihalocyclobutenes decreases strongly from the difluoro to the dichloro and dibromo-compound. The ketone **40** is again the hydrolysis product of the compounds of type **42**. The rate of this reaction followed by ease of ionization **42** → **41** and the subsequent addition of water to give the intermediate **43**. If traces of water are not entirely excluded, the hydroxy salts **37a–c**



are formed as well in competition to **41** during halogenation. The iodide ion is too large for an addition to **30**, and hence with iodine the hydroxy salt **37c** or the ketone **40** is obtained exclusively.

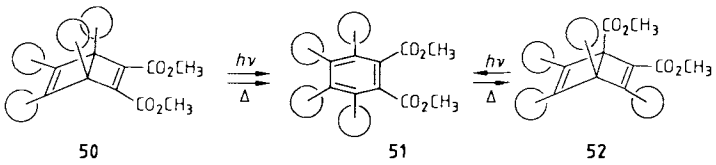
The above-mentioned properties engendered the hope that examples of Diels–Alder type reactions with radical ion pair intermediates could be found for **2** or **12**. Although the two reactions described below do not constitute a proof, they provide strong indication of such a course of reaction.[88] Both **2** and **12** give rise to the 1:2 adduct **46** with tetracyanoethylene (TCNE). This substance is a rarity with regard to structure and reactivity.[89] It may be assumed that the radical ion pair **30** · **44** is formed in the first step. Due to steric hindrance, the radical anion **44** attacks **30** with the nitrogen atom as the "spear head". The end product **46** is formed via **45** after addition of a second TCNE molecule. The "normal" Diels Alder adduct **49** can be formed analogously from **2** and **12** and dicyanoacetylene via the radical ion pair **30** · **47** and the zwitterion **48**.[90,91]

What is the evidence for the intermediate appearance of the radical ion pair **30** · **47**? It is simply the fact that while



cyclobutadiene **12** gives the Diels–Alder adduct **50** with acetylene dicarboxylic ester, tetrahedrane **2** remains unchanged under the same conditions. If, however, dicyanoacetylene is used, both **2** and **12** give the adduct **49**. The explanation is obvious: the oxidation potential of dicyanoacetylene, but not that of acetylene dicarboxylic acid esters, suffices in order to generate the radical cation **30** from **2** (and **12**).

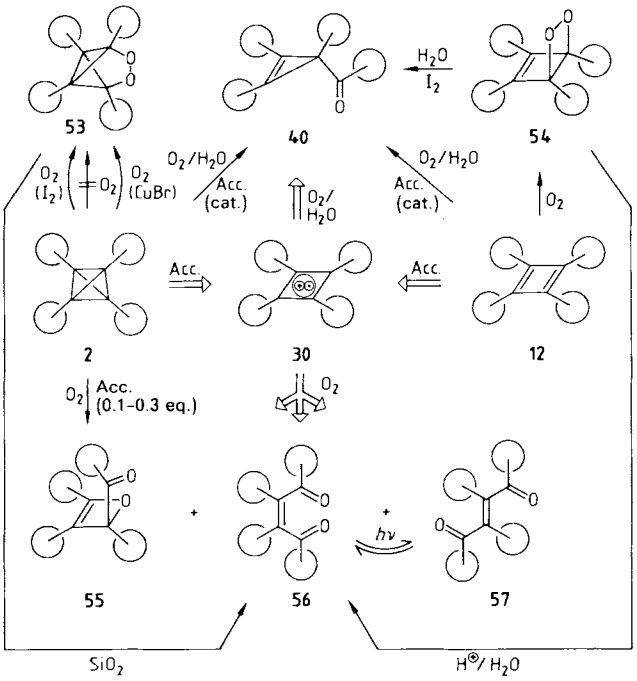
The adduct **50** also has no shortage of surprising properties.[92] The genetic connections between the valence isomers **50**, **51**, and **52** are shown in the scheme. The crucial point is the thermal isomerization of the arene **51** to the thermodynamically more stable Dewar-benzene **52**. This



reversal of stabilities relative to the habitual situation once again documents the drastic influence exerted by four directly neighboring *tert*-butyl groups.[93,94]

Autoxidation is a subject where the importance of the tetrahedrane **2** for cognition in apparently very remote areas becomes particularly clear. **2** and cyclobutadiene **12** behave entirely differently in the presence of oxygen. Furthermore, the product formation is also very sensitive to the reaction conditions: tetra-*tert*-butyltetrahedrane **2** is completely stable in air. The corresponding cyclobutadiene **12** reacts smoothly with oxygen to give the dioxetane **54**. This picture changes completely in the presence of an acceptor. Addition of 0.1–0.3 equivalents of silver

ions or iodine to an O_2-saturated solution of **2** results in the formation of at least four products, of which the oxete **55** is the major component. At least the spectra support this unusual structure. The last doubt has not yet been removed, however, for in contrast to known oxetes,[95,96] **55** is stable up to 200°C. Perhaps the accumulation of four sterically demanding groups is once again responsible.[97] The other products are the diketones **56** and **57**, which incidentally are photochemically interconvertible, and the cyclopropenyl ketone **40**. The latter is formed also when **2** is allowed to stand for several days in oxygen-saturated chloroform, and by oxidation of cyclobutadiene **12** in the presence of 0.1–0.5 equivalents of the acceptor. The use of an excess of oxygen in diiodomethane, or the addition of a trace of iodine in chloroform or carbon tetrachloride results in the exclusive formation of the cyclic peroxide **53**. This is the only product from **2** in which only one bond has been broken.



Two reactions in which the oxidation state remains unchanged should also be mentioned: chromatography of the peroxide **53** on silica gel gives rise to the diketone **56**.[80] The latter is also obtained by acid treatment of the dioxetane **54**.[97] Apparently, mineral acid catalyzes ring opening of **56** and not elimination of hydrogen peroxide to give the cyclopropenyl ketone **40**. Strangely, this is the only product when the dioxetane **54** is treated with water in the presence of iodine.

Apart from **53**, all the products of the reaction of **2** with oxygen are likely formed via the radical cation **30**. It is difficult to provide an overall picture of the branching observed in the autoxidation of **2** and **12**. Nevertheless, it will be attempted: the normal potential of oxygen [$E_{1/2}(O_2/O_2^{2\ominus}) = -0.57$,[98a] -0.8,[99] -0.83,[100] -0.94 V[98b]] is too low to oxidize **2** ($E_{pa} = 0.5$ V, see above). In order to make **2** reactive enough, a sufficiently strong acceptor is needed ($Ag^{\oplus}$ ions, iodine, TCNE, and similar acceptors). The crucial intermediate **30** is formed via **31**. At this stage oxygen is consumed, and the two radical cations **60** and **61** are formed. Ring opening of **61** leads to the open-chain intermediates **63** and **64**.[101] These are in equilibrium with **62**. All three species, **62**–**64**, can be reduced by tetra-*tert*-butyltetrahedrane **2** to **55**, **56**, and **57**. Compound **30** is regenerated in this process. Such a reaction chain can explain the rapid oxidation of **2**.

The formation of ketone **40** is more difficult to interpret. As described above, **40** can be formed from **30** by addition of water and repeated oxidation. However, another route via the oxygen adduct **60** (or **61**) is also open. In the presence of water, the adduct can give the intermediate **59** (the reverse reaction, i.e. first addition of water to **30** and then reaction of the intermediate **36** with oxygen is also possible). Reduction of **59** (by the iodide ions resulting from the oxidation of **2** with iodine, or by either **2** or **12** within the reaction chain) leads to the hydroperoxide corresponding to compound **59**. Elimination of hydrogen peroxide then gives the cyclopropenyl ketone **40**. If this purely speculative mechanism is correct, it implies that an unusual process has been discovered as follows:

$$H_2O^* + O_2 + \text{substrate} \xrightarrow{I_2} H_2O_2 + \text{substrate}\cdot O^*$$

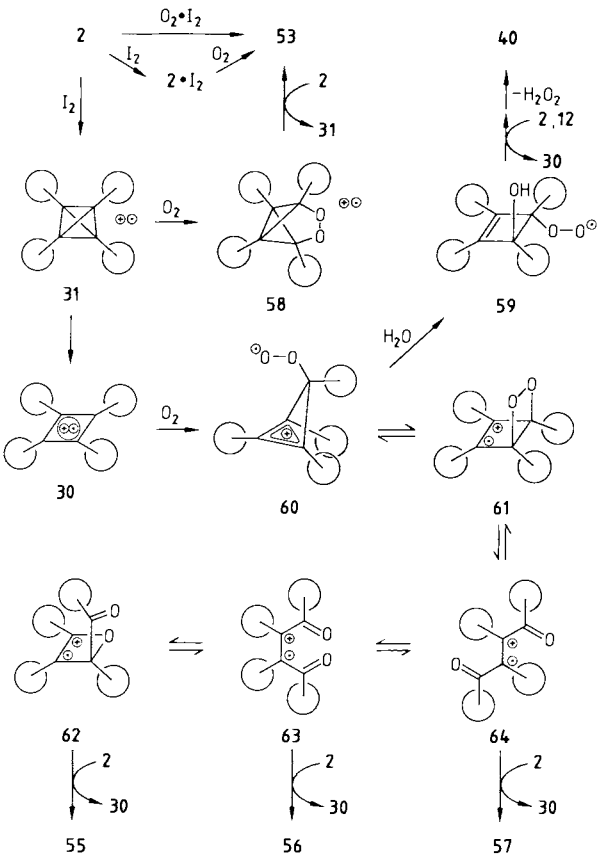
The substrate molecule is transformed into an oxidation product carrying only *one* more oxygen atom; this takes place under catalysis by iodine, which is at first consumed but reappears at the end of the reaction. The asterisk denotes that the added oxygen atom originates in the water, not in the actual oxidant (O_2).

Finally, the question of how the peroxide **53** is formed from **2** is still unanswered. Several interpretations are possible: oxygen, present in excess, captures the radical cation **31** postulated as the primary product; this requires that in contrast to the outcome of the calculations (see above) **31** possesses a finite lifetime. Reduction of the peroxide radical cation **58** could then give **53**.

Another possibility is that a charge transfer complex between **2** and iodine is formed initially; in the presence of excess oxygen the peroxide **53** would result at once.

Or perhaps the attacking oxygen is activated rather than **2**. This phenomenon is not altogether unknown.[102] This would imply that some iodine–oxygen complex is the attacking agent. This type of oxygen activation with iodine has not to our knowledge been reported in the literature.[103] There are, however, accounts of a corresponding function of transition metal–oxygen complexes.[104] Accordingly, we also treated **2** with copper(I) bromide in acetonitrile and oxygen.[105] Indeed, peroxide **53** is the exclusive product of this reaction.[76] Since **2** is inert toward copper bromide alone (the normal potential of copper(I) is strongly reduced under these conditions[105]), oxygen activation cannot be dismissed as the mechanism of the reaction **2** → **53**.

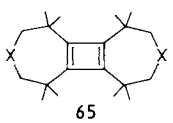
The system presented above also offers the specific possibility to elucidate the autoxidation of cyclobutadienes.[106] Presumably, dioxetane **54** is not formed via the radical cation **30** (this leads, as mentioned above, to other products), but is more likely the result of the diradicaloid



character of **12**.[107] The relevance of the results for the discussion of SET oxidations in general[108] (excitation by irradiation or addition of an oxidizing agent, trapping of the radical cation by the radical anion $O_2^{\odot\ominus}$ of triplet oxygen, possible chain reaction with radical cation catalysis) is obvious.

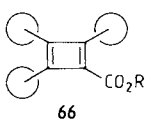
2.5. Guide to New Fields

The tetrahedrane **2** and the cyclobutadiene **12** are end members of a chain starting with the still very reactive tri-*tert*-butylcyclobutadiene **6** whose principal reaction channels have been clarified.[8b, 11, 12, 107, 109] Other members of



65

a, X = S ; b, X = CH_2

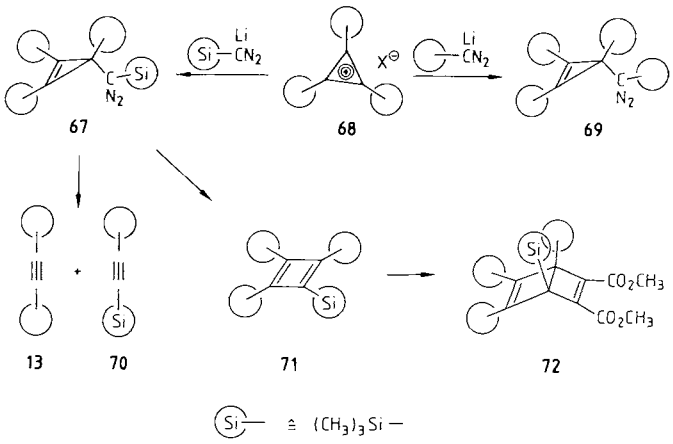


66

a, R = CH_3 ; b, R = $C(CH_3)_3$

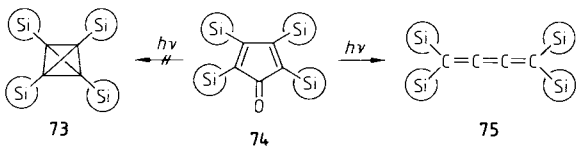
the chain include *Krebs*' stable cyclobutadienes **65a** and **65b**,[40, 43, 106, 110] *Masamune*'s ester **66a**[8c, 12] and the *tert*-butyl ester **66b** recently widely employed by *Regitz* et al.[111]

To what extent can occupying oneself with **2** still generate new questions? A few examples will illustrate this. The bottleneck in the study of **2** is still its poor accessibility. An alternative was sought in the reaction of lithiated *tert*-butyldiazomethane with the cyclopropenylium salt **68**. We have found no mention of the synthetic use of anions of alkyl-substituted diazomethanes in the literature. It is all



the more surprising, therefore, that the reaction **68** → **69** can be accomplished. The diazo compound **69** is surprisingly stable thermally [20a] and melts at 120 °C. Future experiments[112] will show whether a route to **12** and hence **2** can be found from **69**. The known[113] lithium salt of (trimethylsilyl)diazomethane reacts with **68** to give the silylated cyclopropenyldiazomethane **67**. Pyrolysis or irradiation of the latter results in fragmentation to **13** and **70**. Catalysis with copper(I) chloride and trapping with acetylenedicarboxylic acid ester allows isolation of the adduct **72**,[114] a proof for the presence of the new cyclobutadiene **71** — which itself is a potential candidate for tri-*tert*-butyl(trimethylsilyl)tetrahedrane[112] — in the crude product.

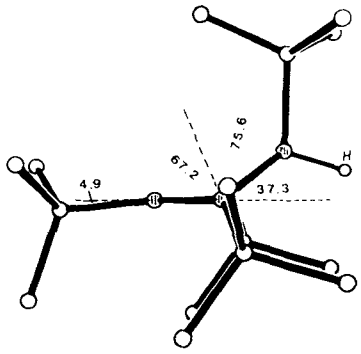
In this context, the specific utilization of trimethylsilyl residues has singled out a new synthetic concept. These substituents have the advantage to be larger still than the *tert*-butyl groups. Furthermore, they are easily eliminated and thereby permit access to the unsubstituted parent compounds (see next section). Thirdly, our own experience demonstrates that in the presence of trimethylsilyl groups polycyclic compounds are preferentially formed.[115–119] Finally, the kinetic stabilization by TMS-substituents is particularly large. However, there are disadvantages too.



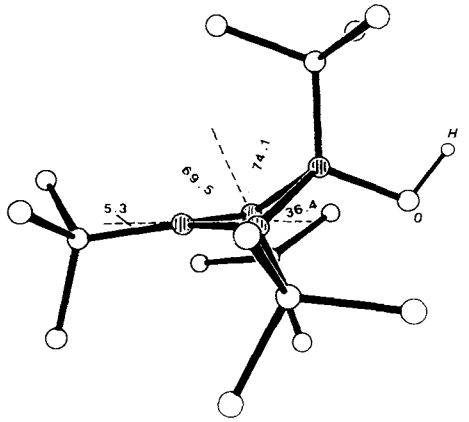
Due to the long C–Si bond, the corset effect in **73** should be weaker than that in **2**. Furthermore, silyl groups tend to rearrange. This is the reason why **74** furnishes the butatriene **75** rather than the tetrahedrane **73**.[120]

The occupation with the chemistry of **2** has also opened our eyes to some aspects of carbenium ion chemistry. Redox reactions of **2** permit the isolation of crystalline cyclobutenylium salts of the types **35** and **37** for the first time, as well as the X-ray determination of their crystal and molecular structures (Fig. 5).[84] This is of importance in connection with *Winstein*'s[121] postulate that these ions should have homoaromatic character. Numerous investigations of this point have been carried out — but all in solution.[122] The structural data now available for **35d** and **37g**[84]

(folded rings; relatively short C1-C3 distances) justify the description of these compounds as homocyclopropenylium salts in spite of the scepticism of theoreticians.[123]



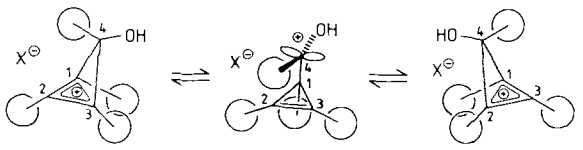
35d



37g

Fig. 5. Crystal structure (folding angle [°]) of the cyclobutenylium ions of **35d** (C1-C3 = 1.806 Å) and of **37g** (C1-C3 = 1.833 Å). C1 and C3 are the atoms at the site of folding.

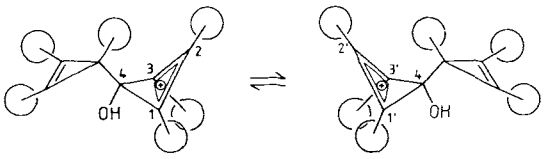
The ion **37** offers a further surprise. Its NMR spectrum is temperature-dependent as a result of a carousel rearrangement **37** ⇌ **76** ⇌ **37'**.[124]



37 **76** **37'**

It is of particular interest that, in contrast to the predictions of the Woodward-Hoffmann rules, this reaction proceeds with inversion at the migrating C-atom, i.e. the bisected transition state **76** is preferred—as predicted.[125]

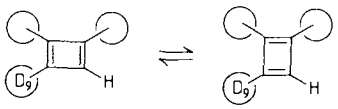
Incidentally, if the *tert*-butyl group at C1 is missing in cation **76**, the cyclopropenylmethylium system becomes an energy minimum relative to the corresponding homocyclopropenylium system; accordingly, direct observation is possible.[126] The interplay between cyclobutenylium and cyclopropenylmethylium system culminates in the dynamic behavior of the cation **77**.[127] The latter is obtainable from the diazo compound **67** via an unconventional



77 **77'**

route. Compound **77** can undergo a tandem walk rearrangement, i.e. a consecutive migration of C4 around the segment C1/C2/C3 accompanied by a mutual exchange of ring moieties in the sense **77** ⇌ **77'**. As a consequence, the carbon atom carrying the hydroxyl group migrates around six equivalent ring positions.

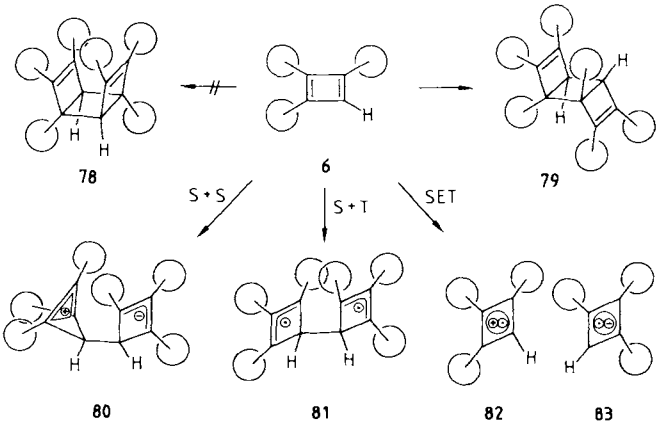
The study of the system **2/12** has also caused a small renaissance concerning our previous model molecule **6**. The consideration that *Saunder*'s isotope perturbation method, which proves a static structure for tetrahedrane, should reveal a dynamic equilibrium [D_9]-**6** ⇌ [D_9]-**6'** in the case of deuterated tri-*tert*-butylcyclobutadiene was confirmed in the first attempt.[128] The splitting found in the



[D_9]-**6** [D_9]-**6'**

^{13}C-NMR spectrum is the first direct spectroscopic proof for the postulate that cyclobutadiene is not a resonance-stabilized molecule but consists instead of a valence tautomeric equilibrium between two rectangular singlet ground state structures (a kinetic proof due to *Carpenter*[129] will be described in Section 4.1).

Another peculiarity of **6** concerns the stereochemistry of its dimerization. In contrast to previous belief,[8b] the dimer does not have the structure **78** expected from a reaction of the Diels-Alder type, but is in reality the *anti*-tricyclic compound **79**.[130] The transition **6** → **79** must be a two-step process. The first step may be either a nucleophilic addition of singlet **6** to another molecule of singlet **6** (with **80** as an intermediate), or a reaction between one molecule of singlet **6** with a thermally populated triplet **6** (with **81** as

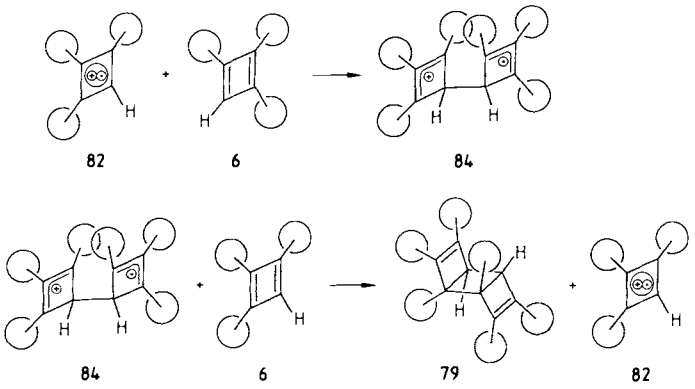


78 **6** **79**

80 **81** **82** **83**

an intermediate). Thermal activation of a singlet ground state to the excited triplet state has been reported for antiaromatic dianions.[131] Admittedly, a singlet-triplet gap of at least 12 (adiabatic triplet energy) or 29 kcal mol^{-1} (vertical energy) has been measured for **65b** by *Wirz* and *Krebs* et al.[110a] However, it cannot be excluded that the energy difference is significantly smaller in the case of **6** (e.g. due to less alternation, as in **12**). There is a third and bolder hypothesis, namely that electron transfer in a triplet excimer complex ^{3}(**6***,**6**) could generate a radical ion pair **82**·**83** and thence the dimer **79**. We know of no example of such a thermally induced "disproportionation",[132a] but it could perhaps be the result of the small HOMO-LUMO distance in **6** caused by the pseudo-Jahn–Teller distortion.

However, a chain reaction catalyzed by the radical cation **82**[85d, 132b]—as the "effectiveness" of the dimerization would suggest—cannot be ruled out either. In some way or other traces of the radical cation **82** are formed by external

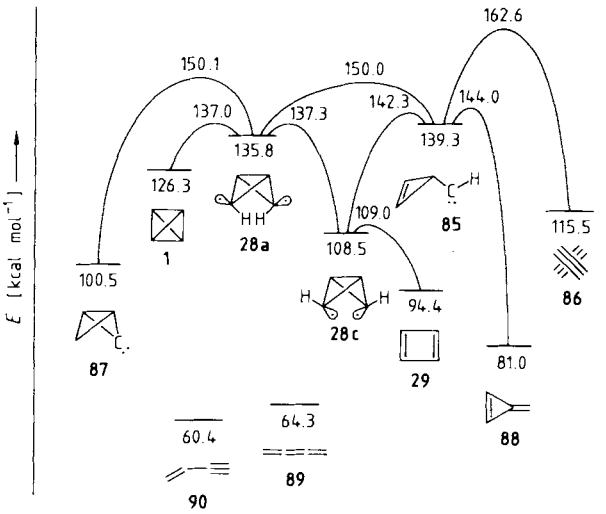


effects. This reacts with a further molecule of **6**—probably via a π-complex between the two species[132c]—to give the coupling product **84**, which undergoes a redox process with **6** again, leading to renewed liberation of a radical cation **82**.

In this context it is important to realize that, in contrast to previous experience with other cyclobutadienes,[8] **6** and **12**[133, 134] as well as *Masamune*'s ester **66a**[135] give poorly resolved ESR signals in the region expected for monoradicals. It is, unfortunately, very difficult to give an assignment of the observed signals to a particular species.

3. Unsubstituted Tetrahedrane

The risks associated with a search for the unsubstituted parent compound are obvious.[1] As briefly discussed in Section 2, the corset principle no longer applies when there are less than four substituents on the tetrahedrane skeleton. Indeed, bond breaking becomes easier than in the unsubstituted tetrahedrane if only one substituent is removed. Thus, if one hopes to synthesize less sterically demanding tetrahedranes, there is only one consequence: to dare the attempt at the wholly unsubstituted parent molecule **1**. In view of the energetic situation mentioned above, a matrix isolation appears possible. The question is whether a usable way to **1** exists. If one accepts the theoretical predictions slavishly, one need not even commence

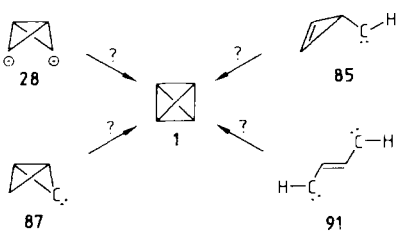


Scheme 1. Calculated [52] enthalpies of formation of the most important C_4H_4 minima and the energies of the connecting transition states.

such a project. A section of the C_4H_4 energy hypersurface is given in Scheme 1 for clarity. The calculated[52] enthalpies of formation of the C_4H_4 minima **1**, **28a**, **28c**, and **29**, and **85**–**90** as well as the barrier heights connecting them demonstrate that there is only one reasonable route to **1**, namely the one from diradical **28a**. However, isomerization to diradical **28c** can compete, having the same activation barrier. It is more difficult still to obtain **28a** in the first place. Regardless of the starting point, there are always more favorable escape routes. The only consolation in this awkward situation is the fact that the calculations only indicate the general trend, and the absolute numerical values are less meaningful. Moreover, the picture should be valid for thermally induced transitions. Electronically excited species generated by photochemical fragmentation of suitable precursors could react quite differently. In this hope, and guided by the "trimethylsilyl trick" as a method for the preparation of reactive unsubstituted tetrahedrane precursors, we have attempted to defy the difficulties.

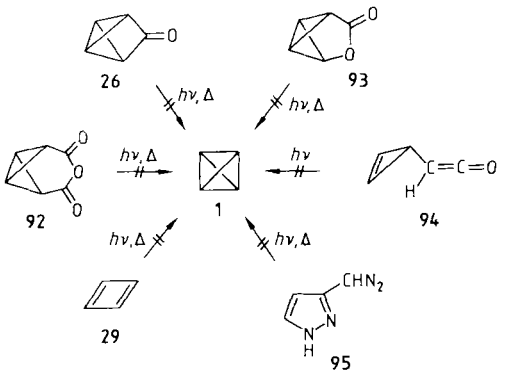
3.1. Experiments on the Preparation of Tetrahedrane

Tetrahedrane (**1**) might be formed by ring closure of **28** or by intramolecular carbene addition of **85**. As further routes the two carbenes **87** and **91** are of particular interest. Both precursors have been approached experimentally, and were claimed on the basis of labeling experiments[136–138] to dissociate into two molecules of acetylene via tetrahedrane (**1**). The precursor **87** was reportedly formed by addition of atomic carbon[136] or C_2O[136, 137] to cyclopropene, in the latter case followed by CO elimination. Dicarbene **91** or cyclopropenylcarbene **85** are considered as the

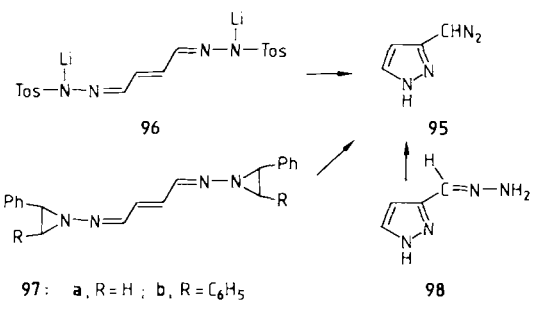


products of pyrolysis of the lithium salt **96** of the bistosylhydrazone of fumaric dialdehyde.[138]

We have endeavored to generate all the tetrahedrane precursors **28**, **85**, **87**, and **91** selectively in order to trap the expected tetrahedrane in a matrix at 10 K. It is possible to isolate the anhydride **92**[115, 139] and the ketone **26**[116, 140] by desilylation of the corresponding trimethylsilyl derivatives and then subject them to photofragmentation in a noble gas matrix at 10 K. Neither these conditions nor flash pyrolysis with matrix isolation permit the IR-spectroscopic detection of tetrahedrane (**1**) (tricyclopentanone **26** gives cyclobutadiene and cyclopentadienone **142** as well as methylenecyclobutenone **119** under these conditions).[135] If the target molecule **1** were present in the matrix, at least the strongest (calc.: 895[54] and 940[30] cm^{-1}, resp.) of the three theoretically possible IR bands ought to be recognizable. The diradical **28** might also be formed from the *Corey* lactone **93**.[141] However, **93** is photostable under matrix conditions. Flash pyrolysis does not give **1** but cyclobutadiene (**29**).[142, 143]

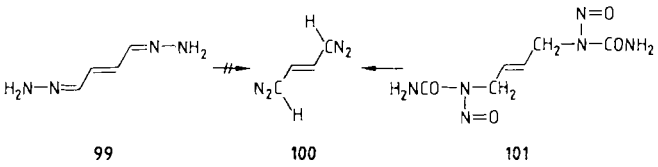


The question of the properties of dicarbene **91** remains open. In our hands, repetition of the procedure by *Rodewald* and *Lee*[138] did not show the reported result. According to our results[117] vacuum pyrolysis of the lithium salt **96** does not give any acetylene. Rather, the only spectroscopically identifiable product is 3-pyrazolyldiazomethane (**95**). An independent structure proof for **95** is given by the fact that the same substance results from the oxidation of the hydrazone **98** with MnO_2,[144] and also by vacuum pyrolysis of the bishydrazones **97a**, **b**.[145] These hydrazones, prepared by the method of *Eschenmoser*[146] have the advantage over **96** that they are obtained in analytically pure form, free of solvent, and are cleaved to the desired carbenes[147] in the same manner as the still missing cyclopropenyldiazomethane.[148]

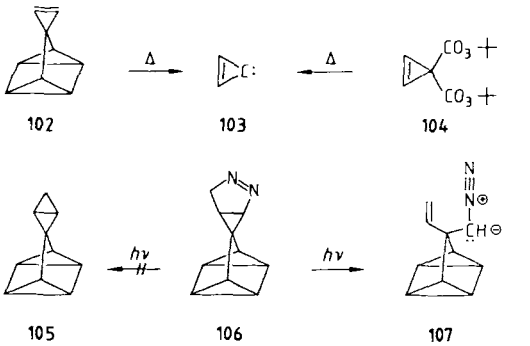


It may be concluded, therefore, that the pyrazolyldiazomethane **95** was an intermediate also in the experiments of *Rodewald* and *Lee*.[138] In these circumstances it is surprising that **95**, in contrast to the literature statement for the pyrolysis of the salt **96**, does not give any acetylene or vinylacetylene. Nevertheless, **95** is a good source of C_4H_4 species. Matrix irradiation[144] results in a complicated picture. The two thermodynamically most stable isomers (cf. Scheme 1), namely butatriene (**89**) and vinylacetylene (**90**), can be discerned in the products together with methylenecyclopropene (**88**) and acetylene (**86**).

A further procedure reported in the literature[149] and involving dehydrogenation of the bishydrazone **99** to the bisdiazo compound **100** likewise could not be reproduced by us. We[145] believe, however, to have prepared **100** as a violet substance, which is only isolable at −196 °C, starting from the urea derivative **101**. Preliminary matrix-irradiations of **100** in argon at 10 K have unfortunately yielded only acetylene.

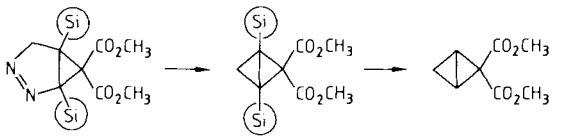


The third potential tetrahedrane precursor, viz. bicyclobutylidene (**87**), has not been mentioned so far. The enthalpy of formation of this candidate is relatively low. A problem could be that in **87** a concerted ring opening to vinylacetylene (**90**)[150a] takes precedence over the formal insertion giving tetrahedrane (**1**). There are hurdles in the practical execution too; the common procedure for carbene generation (Bamford–Stevens reaction) is prohibited for this species since the bicyclobutane ring system does not readily tolerate an sp^2-hybridized C-atom.[150b] Studies using cyclopropenylidene (**103**) as a model give an indication of the procedure to follow. This carbene was recently prepared for the first time in collaboration with *R. W. Hoffmann* by flash pyrolysis of the polycyclic **102** with subsequent matrix isolation.[151] The bisperoxy ester **104** also serves as a precursor.[152, 153] This access is not only new in principle, but also synthetically simpler.



Applying the reaction **102** → **103** to the bicyclobutylidene problem it seems logical to utilize the dihydropyrazole **106**, obtainable from **102**,[144] in the preparation of

87. However, matrix irradiation of **106** does not give the desired starting material for **87**, namely **105**, but instead the diazo compound **107**.[154] Surprisingly, the latter is unchanged by further matrix irradiation although this is in agreement with analogous observations for diazomethane itself.[155] The preparation and flash pyrolysis of the diester of bicyclobutane-2,2-bis(peroxycarboxylic acid) is a logical extension of this work[152] (cf. **104**). Access to the diester **110**[119] has in the meantime been considerably improved.[152] When heated in the presence of copper(I) bromide, **108** is converted quantitatively into **109**. The subsequent desilylation with tetra-*n*-butylammonium fluo-



108 109 110

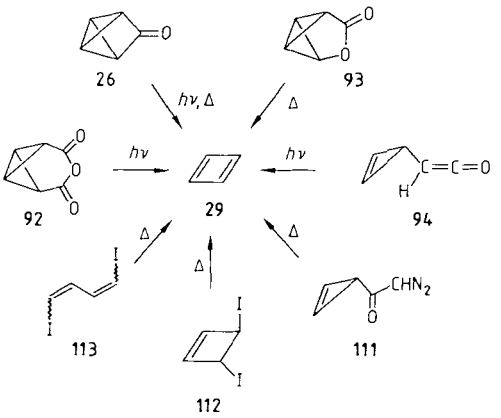
ride can be accomplished only in dioxane (but with 60–70% yield). The last step has thus far failed in that the free dicarboxylic acid—in contrast to the dianion—is not able to exist.

Summarizing: an unquestionable proof of the existence of tetrahedrane (**1**) is still wanting. The diradical **28** preferentially undergoes ring opening to cyclobutadiene (see Section 4.1). Not unexpectedly, cyclopropenylcarbene **85** avoids carbene addition to give **1**;[156] instead, ring expansion to cyclobutadiene (**29**) and ring opening to vinylacetylene (**90**) (see Section 3.2), or fragmention to two molecules of acetylene[143] occur. Presumably, the dicarbene **91** is not formed at all by decomposition of compounds of the type **96**. This is not surprising since this species should not be a minimum on the C_4H_4 energy hypersurface.[52] With regard to bicyclobutylidene (**87**) the experimental material is still too meager for a clear verdict. The catalog of negative results is easily extended: in contrast to the photoisomerization **12** → **2**, matrix irradiation of cyclobutadiene (**29**) does not furnish tetrahedrane (**1**), but mainly acetylene and a little vinylacetylene.[135, 157] This fragmentation of **29** to two molecules of acetylene is also seen in the gas-phase pyrolysis of cyclobutadiene.[135, 142] In view of these disappointing results[158, 159] it would seem reasonable to turn the synthetic efforts toward more promising goals. But the cards have not been completely outbidden yet, and there is one small consolation: at least it is known how tetrahedrane *cannot* be made.

3.2. Other C_4H_4 Isomers

Of the C_4H_4 isomers mentioned in Scheme 1, butatriene (**89**) and vinylacetylene (**90**) have been known for a long time. Both occupy energy sinks and there are many routes to these thermodynamically favored species. The three remaining bond-saturated hydrocarbons **1**, **29**, and **88** are much more interesting. If tetrahedrane itself still needs a lot of pressing, at least the efforts can be turned into success regarding cyclobutadiene (**29**) and methylenecyclopropene (**88**).

The experiment shows that almost all of the above-mentioned tetrahedrane precursors lead to cyclobutadiene (**29**) on either flash pyrolysis or matrix irradiation. The cyclopropenylketene **94** is generated either by low-temperature irradiation of diazoketone **111** in a matrix[143] or by pyrolysis of the formal adduct between **111** and hexafluoro-*o*-xylene with condensation of the fragments (**94** and hexafluoro-*o*-xylene) on the cold window.[144] The diiodides **112**[160] and **113**[161] are additional thermal precursors.[143] These results are of importance for several reasons: firstly, the existing range[8] of cyclobutadiene precursors is significantly extended; secondly, the pyrolyses demonstrate that cyclobutadiene is sufficiently long-lived in the gas phase to



survive the distance to the cold finger.[162] Thus, the unequivocal determination of the PE spectrum of cyclobutadiene starting from **93** was achieved recently.[163] Thirdly, the case of the diiodide **113** has shown that it is even possible to thermally close open-chain starting materials to a cyclobutadiene ring![142, 143]

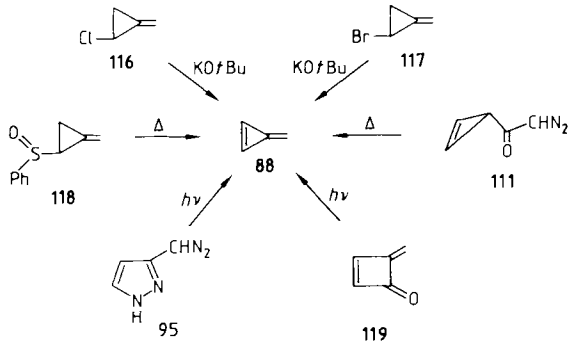
Two further examples of abortive attempts to synthesize tetrahedrane (**1**) must be cited because they were to start from "optimal" precursors. The polycycle **114** prepared by *Christl* et al.[164a] evades fragmentation in the matrix irradiation (Ar, 10 K) by an intramolecular [2+2]-photoaddition of the two double bonds (the same is true for derivatives of **114** substituted in the six-membered ring). The azo compound **115**[164b] affords only the dimer of cyclobutadiene and pyridazine after irradiation in an organic glass

114 1 115

at 77 K and thawing (irradiations in an argon matrix have not yet been attempted). As we have found earlier,[135] no **115** or even **1** can be detected in the matrix irradiation of pyridazine — formally the "most elegant" route to tetrahedrane. Only an isomerization to pyrazine is observed.

Also the preparation of methylenecyclopropene (**88**) has been a long time coming. This substance was obtained only recently by *Billups* et al.[165a] and *Staley* et al.[165b] by treatment of **116** or **117** with potassium *tert*-butoxide. The

same compound, **88**, is also obtained by gas-phase pyrolysis of the sulfoxide **118**[166] or the diazoketone **111** with condensation of the products at 10 K.[142,143] It should be noted that a band at 904 cm^{-1} previously assigned to **88**[165a] is absent when using **111** and **118** as precursors.



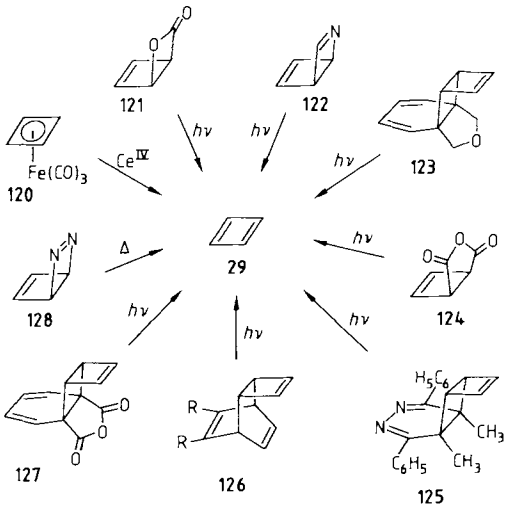
This absorption is also absent in the calculated IR spectrum.[167] Meanwhile it has become clear that the said band is not due to **88**,[168] and this is a further proof of the quality of state-of-the-art calculations of positions and intensities of IR absorptions for molecules of a reasonable size.[169] While the reaction **111**→**88** is strange enough (insertion of the carbene center in the bridgehead C–H bond followed by CO elimination), it is even more surprising that matrix irradiation of **95** likewise leads to methylenecyclopropene.[144] As the IR spectrum of **88** is now known, it is easily confirmed that also the irradiation of methylenecyclobutenone **119** gives **88** as previously reported by *Chapman*.[158] Long-time irradiation of **88** finally leads to vinylacetylene.

4. Completion of the Picture

As a supplement to the two previous reviews of the cyclobutadiene problem,[8b,8c] recent work that has not already been mentioned will be briefly outlined here. It will emerge that large segments of the cyclobutadiene theme can now be regarded as "closed".

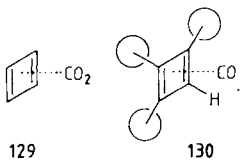
4.1. Unsubstituted Cyclobutadiene

There exists a whole range of further cyclobutadiene precursors apart from the ones mentioned in Section 3.2. The tricarbonyliron complex **120** of *Pettit*[170] is still unbeaten from the point of view of preparative chemistry. Several compounds have played an important role in the spectroscopic identification of cyclobutadiene (**29**): photo-α-pyrone **121** (*Chapman* et al.,[171] *Krantz* et al.[172]), Dewar-pyridine **122** (*Chapman* et al.[171a]), the ether **123** (*Masamune* et al.[173]), the anhydride **124** (*Maier* et al.[157,174a]), the heterocycle **125** (*Maier* et al.[174a]), adducts of the type **126** (*Maier* et al.[157]), and the polycyclic **127** (*Maier* et al.[174b]). The azo-compound **128** (*Masamune* et al.[175a]) motivated *Carpenter* et al. to investigate the automerization of cyclobutadiene.[129] It is amazing that the related azoxide[175b] furnishes no cyclobutadiene upon pyrolysis, and only traces thereof in the matrix pyrolysis.[135] The photo-



chemical cleavage of the anhydride **124** is the most convenient method for matrix isolation of cyclobutadiene, whereas it is obtained in the purest form from tricyclopentanone **26**.

The first argon matrix isolation of cyclobutadiene in 1973 by *Chapman* et al.[171] and *Krantz* et al.[172b] is now a classical experiment. However, the correct interpretation of the experimental IR results has been going on till today. A square structure was originally claimed [D_{4h} geometry allows four, and the rectangular D_{2h} seven fundamental vibrations], but this became questionable as we[157] and *Masamune* et al.[173b] demonstrated that one of the postulated cyclobutadiene bands was due to an absorption of carbon dioxide imbedded in a matrix cavity together with **29**. Subsequent isotope labeling experiments have confirmed this assumption.[172c] Such association (**129**) is reminiscent of neighboring phenomena previously postulated by us in



terms of formula **130**.[14] The square geometry of **29** was definitively ruled out when *Masamune* et al.[173c] found four bands below 2000 cm^{-1}, i.e. one more than allowed for D_{4h} symmetry. Calculations[169,176,177] support the now accepted D_{2h} symmetry.

The two lines at the highest frequency (>3000 cm^{-1}) are expectedly due to the C–H stretching vibrations. They were not recorded by *Masamune*. However, bands are observable in this region (3105, 3073 cm^{-1}) on irradiation of tricyclopentanone **26** in argon.[135] The difference spectrum (Fig. 6, see over) shows the IR spectrum of cyclobutadiene (**29**) in the upper half, and in the lower half that of its photolysis products (much acetylene (**86**) and traces of vinylacetylene (**90**)). Provided that the bands at 3105 and 3073 cm^{-1} are due to the two expected fundamental vibrations, at least six of the seven bands expected for D_{2h} symmetry are discernible in the spectrum of **29** (a seventh band at 1028 cm^{-1} is too weak for an unambiguous assignment; it would, however, correspond to the required sev-

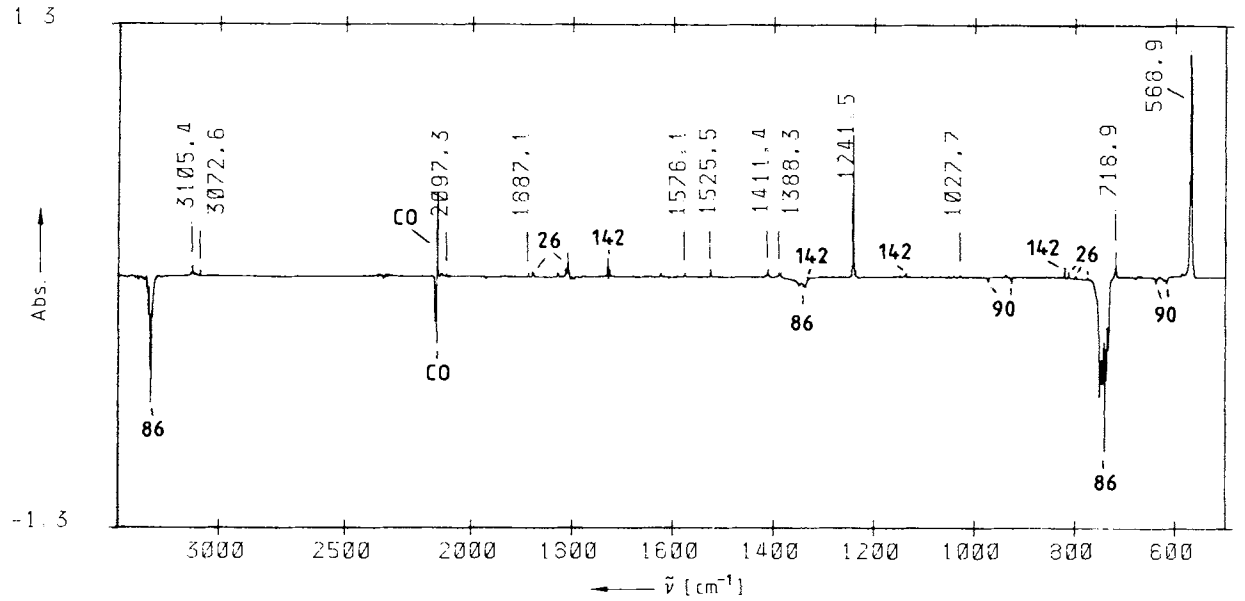


Fig. 6. IR subtraction spectra (Ar matrix, 12 K; irradiated **26** minus irradiated **29**) of cyclobutadiene (**29**) (upper part; 3.5 h irradiation of **26**, $\lambda = 254$ nm) and its photoproducts (lower part, after 3 h additional irradiation of **29** at $\lambda = 250$–420 nm).

enth absorption band at 1081 cm^{-1} (Table 2). Very weak additional absorptions at 2098, 1887, 1576, 1411, 1388, and 1386 cm^{-1} are presumably combination bands).

Table 2 demonstrates the good agreement between the measured spectrum and that calculated by *Hess* and *Schaad*[177c] for a rectangular geometry (Fig. 7).

Table 2. Comparison of experimental [135] and calculated [177c] IR spectrum of D_{2h}-cyclobutadiene [cm^{-1}] (E, relative intensity).

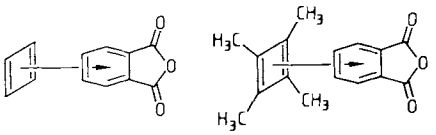
Assignment		Calculated		Experimental	
B_{1u}	ν(CH)	3299	(14.4)	3105	(4.2)
B_{2u}	ν(CH)	3279	(6.8)	3073	(1.7)
B_{1u}	ν(C=C)	1619	(1.0)	1526	(1.2)
B_{2u}	$\delta i.p.$(CH)	1293	(24.4)	1242	(25.1)
B_{1u}	$\delta i.p.$(CH)	1081	(0.6)	1028	(0.6)
B_{2u}	δ(Ring)	750	(4.4)	719	(5.7)
B_{3u}	$\delta o.o.p.$(CH)	560	(100)	569	(100)

The last flaw has also been eliminated in the meanwhile: according to the IR spectrum, *Chapman*[171b] had obtained but a single cyclobutadiene from two positionally isomeric deuterated photo-α-pyrones; the two valence isomers [D_2]-**29** and [D_2]-**29′** would have been expected for a rectangular structure. Hence it was concluded that cyclobutadiene was square. However, a comparison with the spectra calculated by *Hess*, *Schaad* et al.[169,177,178] demonstrates that here, too, an equilibrium mixture of the rectangular 1,2-D_2 and 1,4-D_2 isomers was actually present. The fact that both species were formed each time could be due to photoequilibration already in the precursors.[172d] At any rate, *Chapman* had the two valence isomeric rectangular forms of the cyclobutadiene present in his experiment already in 1973 without noticing it.

The UV spectrum of cyclobutadiene is more problematic. The handicap here is the low extinction of the expected band. We have tried several times but without success to ascertain the validity of the maximum at ca. 300 nm ($\varepsilon \leq 100$) postulated by *Masamune* et al.[173] and previously by ourselves.[174a] The band is not unequivocally documented.[157] Perhaps the inconsistencies are due to the fact that this extremely weak band is seen only in the difference spectrum,[173a] and not in the direct measurement.[135,157]

The weak band in question (300 nm; 4.13 eV) would be in good agreement with theory, which requires a forbidden transition between 338 nm (3.67 eV) and 358 nm (3.46 eV) as the longest-wavelength UV absorption band of the rectangular singlet cyclobutadiene.[179] Evidence for a relatively long-wavelength absorption of **29** is also given by the fact that cyclobutadiene is cleaved into two molecules of acetylene much faster using low energy light (Hg high-pressure lamp; range $\lambda = 250$–420 nm) than with short wavelength irradiation (Hg low-pressure lamp; $\lambda = 254$ nm; see caption to Fig. 6). Further support is given by a comparison of the UV spectra of cyclobutadienes and the "isoelectronic" cyclopentadienones: in analogy to other substituted cyclopentadienones,[180] the tetra-*tert*-butyl derivative **9** absorbs at a very long wavelength (420 nm; $\varepsilon = 186$).[18c] The corresponding cyclobutadiene **12** absorbs at 425 nm ($\varepsilon = 38$),[18c] again in agreement with other cyclobutadiene derivatives.[8c] Due to the easily polarizable π system in both classes of compounds, a hypsochromic shift is expected for the unsubstituted parent systems. In accordance with this, cyclopentadienone features a maximum at 360 nm.[181] Accordingly, a similar value is expected for cyclobutadiene (**29**).

If cyclobutadiene forms matrix "complexes" such as **129** and **130** already with CO_2 and CO,[182] particularly drastic effects must be brought about by partners that can engender a stabilizing electronic interaction. In fact, phthalic anhydride gives a yellow charge transfer complex **131** with an absorption maximum at 375 nm ($\varepsilon \approx 500$) due to interaction with **29** in either organic or argon matrices.[174b]

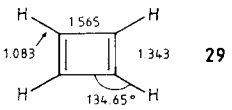


131 132

The donor-acceptor influence is even more distinct in the tetramethylcyclobutadiene complex **132**, which absorbs at 495 nm in an organic matrix,[183] and at 525 nm in argon.[184] Hence, the donor property of cyclobutadiene can be exploited in the spectroscopic identification. For example, the appearance of the complex **132** in the photocleavage of a precursor expected to yield tetramethyltetrahedrane[10d, 184] quickly destroyed that hope.

As already mentioned in Section 3.2, the photoelectron spectrum of **29** was recently recorded by *Schweig* et al.[163] The lowest vertical ionization potential is 8.24 eV, in ideal agreement with the previous indirectly determined value of 8.29 eV[185] as well as the ionization energies of substituted cyclobutadienes.[26, 186] Because the observed band is relatively sharp, whereas a square radical **32** should show first order Jahn-Teller splitting, the authors consider the appearance of the PE spectrum an independent proof for the rectangular geometry of the cyclobutadiene ring.

Thus, all information speaks for a rectangular singlet ground state of cyclobutadiene **29**. The following structural data, used in the calculation of the IR spectrum,[177c] should be rather close to reality.



29

Fig. 7. Bond lengths [Å] and angles [°] in cyclobutadiene **29** [177c].

Difficulties with the theoretical treatment of cyclobutadiene[8c] have also been removed in the meanwhile. The outcome is decidedly dependent on whether or not configuration interaction is taken into account. When it is, the singlet turns out to be favored over the triplet species, even in the case of square geometry.[187] The preference of the rectangular vis-a-vis the square arrangement of singlet cyclobutadiene is due to mixing of energetically close states (pseudo Jahn-Teller or second order Jahn-Teller effect).[8c, 188] The quintessence is: a square geometry is a minimum for triplet cyclobutadiene, but it is a transition state for the interconversion of two degenerate and rectangular singlet ground states on the singlet energy hypersurface (Fig. 8).

According to the most recent calculations, the barrier height for automerization is about 10 kcal mol^{-1} (MINDO/3: 8.1;[189] ab initio: 8.3,[190] 9.0,[179c] 9.0,[191] 13.4[188]). A similar value is also given for the difference between SS and ST cyclobutadiene (8.6,[188] 11.0,[191] 14.1[190] kcal mol^{-1}). Incidentally, a rhombohedral transition state for the RS,RS equilibration is less favorable[8c, 190, 191] than the square. Likewise, folding of RS-cyclobutadiene does not cause any gain in energy.[192, 193] Accordingly, the non-planar structure of the cyclobutadiene **12** is caused by steric repulsion between the *tert*-butyl groups. The further effect

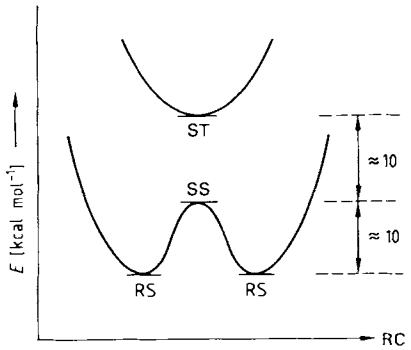


Fig. 8. Reaction diagram for interconversion of two rectangular cyclobutadienes. RS = rectangular singlet; SS = square singlet; ST = square triplet molecule.

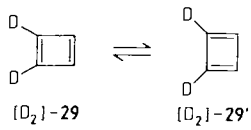
of the four sterically demanding groups, viz. the increased similarity of the bond lengths,[39, 44, 46] was discussed in Section 2.2. However, the accumulation of four voluminous substituents not only favors the tetrahedrane **2** relative to **12**, it also favors SS-**12** relative to RS-**12**. According to force field calculations by *Mislow* et al.,[64, 187] this effect is approximately equal to the RS, SS difference in unsubstituted cyclobutadiene. Therefore, it would be completely understandable if the parent compound **29** (Fig. 7) were to show a stronger alternation than the tetra-*tert*-butyl derivative **12** (Fig. 3). A further consequence is that the rate of valence isomerization and the size of the HOMO-LUMO gap will be smaller in **12** than in cyclobutadiene itself.

The high reactivity of cyclobutadiene (**29**) is often associated with its "antiaromaticity". It is difficult enough to clearly define the concept of "aromaticity",[194] and this is even more true of the determination of "antiaromaticity".[8c, 193, 195] Yet, the heuristic value of this notation cannot be denied, regardless which point of reference is used (cf. the different definitions by *Hückel*, *Dewar*, *Hess*, and *Schaad*, or *Hadden*, *Herndon*, *Trinajstic*, *Aihara*, *Randić*, and others[8b, c, 196]). The division of the "excess energy" of cyclobutadiene into two entities, namely strain energy and electronic destabilization[197, 198] is also informative. The former accounts for about 40%, the latter for 60% (e.g. the heat of formation of cyclobutadiene (Scheme 1) is composed of a strain energy of 24, and an "antiaromaticity" of 35 kcal mol^{-1}[198]). While the starting material already has a high energy content, the ready dimerization of **29** to give the *syn*-tricyclic compound (**78** without *tert*-butyl groups) is facilitated by virtue of the orbital symmetry-allowed [4+2]-cycloaddition. The preference for the *syn*-transition state is due to a secondary orbital interaction.[88a]

Thus, we have a feeling for the nature of the peculiarities of the cyclobutadiene system. The molecule has by no means lost its fascination for the theoreticians, however.[199]

The discussion of the unsubstituted cyclobutadiene will be terminated with the work of *Carpenter* et al.,[129] who in elegant kinetic studies determined the activation parameters for the valence isomerization [D_2]-**29** ⇄ [D_2]-**29**′. The cyclobutadiene is generated by thermal [4+2]-cycloreversion from 1,4-dideuterio-2,3-diazobicyclo[2.2.0]hexa-2,5-diene ([D_2]-**128**) and trapped with 3-cyanoacrylic ester in a Diels-Alder reaction. The concentration- and temperature-

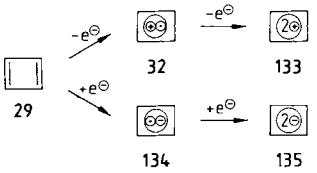
dependence of the products lead to an activation enthalpy for the valence isomerization [D$_2$]-**29** $\rightleftarrows$ [D$_2$]-**29**′ between 1.6 and 10 kcal mol^{-1} (the "classical" barrier for the RS$\rightleftarrows$SS$\rightleftarrows$RS process is 8.1–13.4 kcal mol^{-1}; see above]. Furthermore, the activation entropy so obtained is strongly negative (-17 to -32 cal mol^{-1} K^{-1}). On the basis of



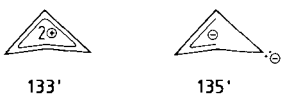
these parameters, *Carpenter*[129c] postulates that the automerization of cyclobutadiene is dominated by tunneling of the CH units. This process is believed to account for 97% of the total rate below 0°C. The demonstration of such a heavy-atom tunneling is of general importance. Scepticism about the ability of the large methine units in cyclobutadiene to tunnel has been largely removed,[189,200] if not completely so,[201] by theoretical calculations. It cannot be ruled out that tunneling of carbon atoms may play a role in other bond migrations such as in cyclooctatetraene[129c] and the unsubstituted norbornyl cation.[202]

4.2. Cyclobutadiene Dications and Dianions

In contrast to the electroneutral cyclobutadiene (**29**) (and the radical cation **32** and radical anion **134**), its dication **133** and dianion **135** should be "aromatic" according to the Hückel rule. Yet, elaborate calculations indicate that

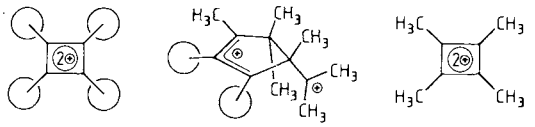


both **133**[197c,203,204] and **135**[203b,204,205] should be regarded as non-aromatic because of destabilizing 1,3-interactions. In other words, the stabilization due to cyclic delocalization is not sufficient in these doubly charged systems. Accordingly, the Hückel-type D_{4h} geometry is not to be expected. Calculations by *Schleyer* et al.[203a] indicate that the dication is folded (**133**′, D_{2d} symmetry); for the dianion a



square geometry is predicted by ab initio calculations,[204,205] but an additional vibrational analysis demonstrated that the minimum is occupied by the C_s conformation **135**′,[204] which is composed of an allyl anion and a localized negative charge.

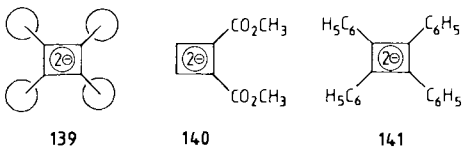
For these reasons it is understandable why the unsubstituted dication **133** has not so far been detected. The hope to generate a stable dication **136** from the hydroxy salt **37** in magic acid was not fulfilled. Presumably, **136** is formed as an intermediate but rearranges immediately to the ring-expanded dication **137**.[76] It is reasonable that a series of Wagner–Meerwein rearrangements takes preference over a cleavage into two acetylene fragments—another potential stabilizing reaction for cyclobutadiene dications.[206]



In contrast, the tetrakis(dimethylamino) derivative is a stable substance.[207b] But even alkyl groups suffice, in principle, to delocalize the positive charge. Thus, *Olah* et al.[207a] succeeded in the unambiguous identification of tetramethylcyclobutadiene dication (**138**). Folding is expected for this species too.[203a] Unfortunately, the NMR spectra allow no decision on this question. Therefore, information about the exact structure of cyclobutadiene dication is still lacking. The isolable tetrakis(dimethylamino) derivative is not a good reference substance since its charges are essentially delocalized in the substituents.[207b]

An alkyl group does not help in the case of cyclobutadiene dianions.[208] Therefore, the dianion **135** and its alkyl derivatives are unknown. In agreement with this, the cyclovoltammetric investigation[74] of tetra-*tert*-butylcyclobutadiene (**12**) gave no indication of either the dication **136** or the dianion **139**, which is also not accessible by deprotonation of the corresponding monoanion.[109b]

However, *Garratt* et al.[209] successfully used ester groups to delocalize the negative charge so extensively that the dianion **140** was stable at room temperature.

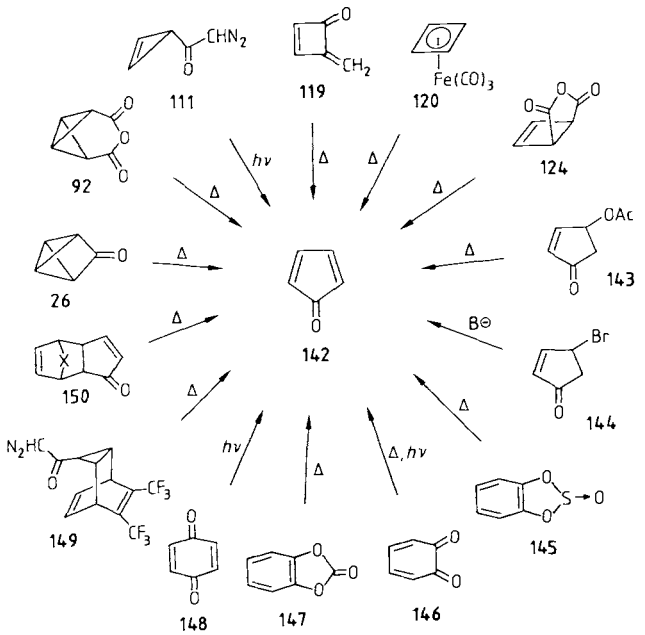


According to the authors, only 40% of the negative charge in **140** remains in the four-membered ring. pK_a measurements indicate that the dianion does not experience any "aromatic" stabilization. The same applies to the tetraphenylcyclobutadienediide **141** synthesized by *Boche* et al.[210] Again, the charge resides predominantly (64%) on the phenyl groups. This is true also for the dication.[207a] The destabilizing electron repulsion in the dianion compensates for any energy gain expected for a closed (4n + 2) π-electron system.

4.3. Cyclopentadienone

The relationship between cyclobutadiene and cyclopentadienone was pointed out in the previous review.[8b] Meanwhile, the secrets of this ring system have also been explored.[133,180,181] The unsubstituted cyclopentadienone (**142**) can be prepared from a multitude of precursors (**26**,

92, **111**, **119**, **120**, **124**, **143**–**150**). The molecule is stable in an argon matrix and behaves in the ground state like its derivatives as a normal α,β-unsaturated ketone (PE, NMR,

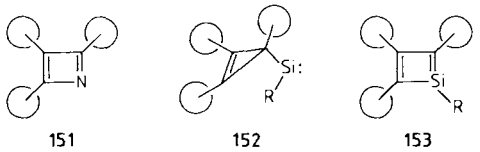


IR spectra; dipole moment; bond alternation). The resonance structures with a cyclopentadienyl cation, or a "wrongly" polarized C=O double bond hardly contribute. The unusual properties gleaned from the UV-spectra, redox behavior, and Diels–Alder reactivity are due to a strongly delocalized and hence low-lying LUMO.[211]

5. Outlook

A proof for the existence of the unsubstituted tetrahedrane (**1**) and the synthesis of modified derivatives of tetra-*tert*-butyltetrahedrane **2** are still challenges.

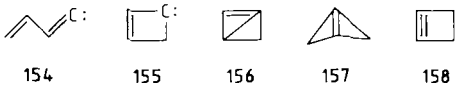
Heterocyclobutadienes and tetrahedranes will experience increasing importance in the future. There is a whole range of possibilities between the $(HC)_4$ cluster **1** and the tetrahedral structure of white phosphorus.[212] The preparation of tri-*tert*-butylazacyclobutadiene (**151**) by *Regitz* et al.[213] is a first success. Monosila-[214a] and tetrasila-deriva-



151 152 153

tives[214b,c] are further exciting targets. In this connection a rewarding object of study is silylene (silanediyl) **152**.[215] Every possible stabilization reaction is interesting, whether it is the ring-expansion to the silacyclobutadiene **153**, the ring-closure to the corresponding silatetrahedrane, or the cleavage with formation of a silaacetylene.[216]

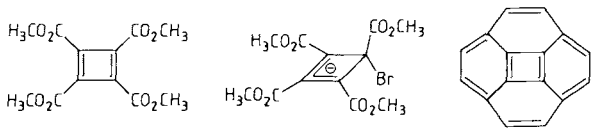
Likewise, it is not difficult to predict future activities regarding the unsubstituted C_4H_4 systems. *Dewar* et al.[52] located no less than 19, and *Hehre* and *Pople*[35] ten minima on the singlet C_4H_4 hypersurface (Scheme 1 only represents a small selection). Only four (**29**, **88**, **89**, **90**) are known today. The race for new exotic molecules will not be slow in coming, or to put it better, is already underway: upon photochemical elimination of CO from vinylpropadienone[152] one presumably obtains butadienylidene **154**, a "suppressed" C_4H_4 isomer in the global treatment.[52] The direct detection of **154** is very difficult since it immediately transforms into vinylacetylene **90** under the conditions employed. There is already some information about cyclobutenylidene (**155**). *Shevlin* et al.[217] attempted to prepare this species by reaction of cyclobutenone with atomic carbon but isolated only vinylacetylene (**90**). This was probably formed by ring cleavage of **155**. According to MINDO/3 calculations, the cleavage is faster than both ring contraction to methylenecyclopropene (**88**) and CH-insertion to give cyclobutadiene (**29**). It may be, however, that **155** is only a transition state for the ring inversion in bicyclo[1.1.0]but-1-ene (**156**). According to *Dewar* et al.,[52] the latter is one of the lowest energy minima of the 19 calculated. Thus, the matrix isolation of **156** is a logical experiment. The same is true for bicyclo[1.1.0]but-1(3)-ene (**157**) and cyclobutyne (**158**).



154 155 156 157 158

Bicyclobutene **157** is expected to have a folded structure. Its IR-spectrum has been calculated.[63] Impressive experiments by *Szeimies* et al.[218a] have already demonstrated the existence of bridged derivatives of **157**. Unfortunately, no bicyclobutenes are formed in the absence of the bridge. Only butatrienes or vinylacetylenes are detectable in such cases.[218b] The theoretical IR-spectrum of cyclobutyne (**158**) is also available.[219] The likelihood of isolating **158** is somewhat remote, however. The compound is higher in energy than tetrahedrane.[63] Perhaps it is not a minimum on the energy hypersurface at all.[52]

Two final examples will illustrate that there are always practical or theoretical facets worth investigating. It is synthetically attractive to have good access to the polyfunctional cyclobutadiene **159**, the intermediacy of which has been demonstrated previously by *Scharf* et al.[220] The treatment of 1,2-dibromocyclobutane-1,2,3,4-tetracarboxylic acid ester with potassium *tert*-butoxide at −78 °C gave the anion **160**, which on warming to room temperature gave very good yields of products (e.g. Diels–Alder adducts) formally derived from **159**.[221] On the theoretical side, one may ask how a square structure may be forced upon a cyclobutadiene. The simplest possible and hitherto "forgotten" circulene **161** could be such a molecule.[222,223] According to the method proposed by *Hess* and *Schaad*[197]



159 160 161

calculations give a molecule with D_{4h} symmetry and a resonance energy per electron (REPE) of 0.028 β.[135] Perhaps the synthesis[224] of **161** will be successful in spite of the considerable angular strain expected for this molecule.

6. Conclusion

Our present knowledge about cyclobutadiene (**29**) allows this chapter to be terminated. It is now secured textbook material.

Nobody knows whether the unsubstituted tetrahedrane (**1**) can ever be synthesized. It is easy, however, to answer the question posed in the preamble: the excitement caused by an unusual molecule such as the tetrahedrane **2** does not end with its mere synthesis. The real importance lies in the new fundamental knowledge obtainable from working with such rarities.

The study of tetra-*tert*-butyltetrahedrane has a) sharpened our feeling for the subtle influence of sterically demanding groups (favoring of otherwise impracticable synthetic routes; reversal of thermodynamic stabilities), b) led to broadly applicable concepts (corset principle, silyl-trick, formation of radical ion pairs), c) opened up access to several unknown or at least difficultly accessible classes of substances, d) allowed the isolation of crystalline derivatives of highly reactive systems, e) caused X-ray investigations with surprising results (extremely bent bonds, dependency of alternation on degree of substitution, gas inclusion compounds, structural indicators of "homoaromatic" character), f) allowed detailed insight into the behavior of radical cations, and g) made the discovery of new reaction mechanisms possible (in addition reactions, autoxidation, and cationic rearrangements). The molecules **2** and **12** have delivered non-stop record values of physical data (NMR, ionization potentials, redox potentials etc.).

Having successfully prepared the highly strained tetrahedrane **2**, any shyness toward other sterically loaded molecules disappears.[225,226] The synthetic building blocks designed for **1** and **2** (geminal diperoxy esters, lithiated diazoalkanes, etc.) may also become important in other areas of research. Finally, the work with tetrahedrane required extensive use of matrix isolation techniques in combination with photolytic and flash thermolytic fragmentations. The skills thus acquired encouraged us to transfer the methodology to many other fields, ranging from unsaturated silicon[227] and boron[228] compounds to radicals,[229] carbenes,[153] new isomers of polyhalomethanes,[230] and interstellar molecules.[231] These simple molecules open another aspect: they are small enough to allow "reliable" predictions to be made with modern computational methods and thus offer an ideal opportunity to test the quality of theoretical calculations by experimentation.[135,151,153] In brief, an originally very specific and for many outsiders "irrelevant" quest has led to many fields previously totally unknown to us and far from the primary goal. Hence, it pays off to "seek the adventure, without which science as well as life would be insipid" (*R. Criegee*).[232]

The results reported from our own research group are due to the efforts of a series of risk-taking and motivated coworkers. Their names are given in the appropriate references. I am indebted to them, as also to the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for financial support.

Paquette, *Top. Curr. Chem. 119* (1984) 1; d) Pagodane route to dodecahedrane according to *Prinzbach*: W.-D. Fessner, B. A. R. C. Murty, J. Wörth, D. Hunkler, H. Fritz, H. Prinzbach, W. D. Roth, P. von R. Schleyer, A. B. McEwen, W. F. Maier, *Angew. Chem. 99* (1987) 484; *Angew. Chem. Int. Ed. Engl. 26* (1987) 452.

[7] If the synthesis of dodecahedrane has been compared with the first ascent of Mount Everest, the air is not thinner in the case of tetrahedrane, more so in terms of the high energy content than the number of synthetic steps.

[8] a) Earlier summaries: M. R. Cava, M. J. Mitchell: *Cyclobutadiene and Related Compounds*, Academic Press, New York 1967; b) G. Maier, *Angew. Chem. 86* (1974) 491; *Angew. Chem. Int. Ed. Engl. 13* (1974) 425; c) T. Bally, S. Masamune, *Tetrahedron 36* (1980) 343; d) D. Lloyd: *Non-benzenoid Conjugated Carbocyclic Compounds*, Elsevier, Amsterdam 1984, p. 197-244. – Note: cyclobutadiene complexes and annelated systems are not discussed in the present paper.

Mayer, *ibid. 114* (1981) 3922; d) G. Maier, W. Mayer, H.-A. Freitag, H. P. Reisenauer, R. Askani, *ibid. 114* (1981) 3935; e) G. Maier, H. P. Reisenauer, *ibid. 114* (1981) 3956.

[11] G. Maier, A. Alzérreca, *Angew. Chem. 85* (1973) 1056; *Angew. Chem. Int. Ed. Engl. 12* (1973) 1015.

[12] **6** was obtained independently and simultaneously by *Masamune* et al. using another route: S. Masamune, N. Nakamura, M. Suda, H. Ona, *J. Am. Chem. Soc. 95* (1973) 8481.

[13] G. Maier, F. Bosslet, *Tetrahedron Lett. 1972*, 1025.

[14] G. Maier, U. Schäfer, W. Sauer, H. Hartan, R. Matusch, J. F. M. Oth, *Tetrahedron Lett. 1978*, 1837.

[15] W. Sauer, *Dissertation*, Universität Marburg 1977.

[16] H.-G. Hartan, *Dissertation*, Universität Marburg 1976.

[17] A. Schweig, W. Thiel, *J. Comput. Chem. 1* (1980) 129.

[18] a) G. Maier, S. Pfriem, *Angew. Chem. 90* (1978) 551; *Angew. Chem. Int. Ed. Engl. 17* (1978) 519; b) G. Maier, S. Pfriem, U. Schäfer, R. Matusch, *ibid. 90* (1978) 552 and *17* (1978) 520; c) G. Maier, S. Pfriem, U. Schäfer, K.-D. Malsch, R. Matusch, *Chem. Ber. 114* (1981) 3965.

[19] a) Almost simultaneously with the synthesis of **2** the preparation of an alleged tetralithiotetrahedrane was reported: G. Rauscher, T. Clark, D. Poppinger, P. von R. Schleyer, *Angew. Chem. 90* (1978) 306; *Angew. Chem. Int. Ed. Engl. 17* (1978) 276. A structural proof is still lacking (lithium atoms are presumed to be arranged above the planes of the carbon tetrahedron). Review of unusual structures of lithium compounds: P. von R. Schleyer, *Pure Appl. Chem. 56* (1984) 151. b) More recently it has been questioned whether the assumed structure represents an energy minimum at all: J. P. Ritchie, *J. Am. Chem. Soc. 105* (1983) 2083; R. L. Disch, J. M. Schulmann, J. P. Ritchie, *ibid. 106* (1984) 6246. c) More elaborate calculations (K. Raghavachari, P. von R. Schleyer) confirm the T_d symmetry of Li_4C_4 (see footnote [12] in H. G. von Schnering, M. Schwarz, R. Nesper, *Angew. Chem. 98* (1986) 558; *Angew. Chem. Int. Ed. Engl. 25* (1986) 566). d) Tetralithiotetrahedrane has been reported to give tetramethyltetrahedrane with methyl iodide: N. S. Zefirov, V. N. Kirin, N. M. Yur'eva, A. S. Koz'min, N. S. Kulikov, Y. N. Luzikov, *Tetrahedron Lett. 1979*, 1925. This is incorrect (N. S. Zefirov, private communication).

[20] a) G. Maier, K. A. Reuter, L. Franz, H. P. Reisenauer, *Tetrahedron Lett. 26* (1985) 1845; b) L. H. Franz, *Dissertation*, Universität Giessen 1982.

[21] R. Boese, unpublished. We are indebted to Dr. *Boese*, Universität Essen, for these structural investigations.

[22] W. Thiel, unpublished. We thank Prof. *Thiel*, Universität Wuppertal, for these data (private communication).

[23] Cf. [8c], footnote 58. In [8c], Scheme 10, the arrow should start from **22a** instead of **22b**.

[24] A chemical shift of $\delta = -15.9$ is calculated for tetrahedrane **1**: M. Schindler, W. Kutzelnigg, *J. Am. Chem. Soc. 105* (1983) 1360; application of a low-field shift of 25 ppm due to the *tert*-butyl groups gives a value of $\delta \approx 9$ for **2**. For the calculation of shielding tensors, see also J. C. Facelli, A. M. Orendt, M. S. Solum, G. Depke, D. M. Grant, J. Michl, *ibid. 108* (1986) 4268.

[25] Summary of the spectroscopic properties of **2**: G. Maier, S. Pfriem, K.-D. Malsch, H.-O. Kalinowski, K. Dehnicke, *Chem. Ber. 114* (1981) 3988.

[26] E. Heilbronner, T.-B. Jones, A. Krebs, G. Maier, K.-D. Malsch, J. Pocklington, A. Schmelzer, *J. Am. Chem. Soc. 102* (1980) 564.

It should be remembered that the equilibrium **6** ⇌ **6'** cannot be frozen out in the ^{13}C-NMR even at −185 °C, indicating an activation barrier of probably less than 2.5 kcal mol^{-1} [14]. Perhaps this low value may be due to some contribution from tunneling [129].

[147] Irradiation of **97a** or **97b** in solution gives the corresponding aziridinyl imine of cyclopropenecarbaldehyde [145], also obtainable from the analogous bistrimethylsilylated hydrazones of this aldehyde by desilylation (A. Rubo, Diplomarbeit, Giessen 1986). Attempts to obtain the unsubstituted cyclopropenyldiazomethane [148] via this route are underway.

[201] J. Michl, note in a book review, *Angew. Chem. 97* (1985) 1005. Note added in proof (February 24, 1988): Quite recently the static ^{13}C-NMR dipolar spectrum and polarized IR spectrum of vicinally ^{13}C-labeled cyclobutadiene (**29**) have been recorded. If the barrier for the automerization is ≈ 10 kcal mol^{-1} (Fig. 8), the interconversion in an argon matrix must be due to tunneling at a rate of at least 10^3 s^{-1} (*J. Michl*, private communication).

[202] The experimental findings reported by *Yannoni* et al. make a tunneling effect appear questionable: a) C. S. Yannoni, V. Macho, P. C. Myhre, *J. Am. Chem. Soc. 104* (1982) 907, 7380; b) P. C. Myhre, K. L. McLaren, C. S. Yannoni, *ibid. 107* (1985) 5294. c) According to *Dewar* et al. this effect does not play a role in the case of the 1,2-dimethyl-2-norbornyl cation [202b] but does in the case of the parent compound [202a]: M. J. S. Dewar, K. A. Merz, Jr., *ibid. 108* (1986) 5634.

Enzymic Baeyer–Villiger Oxidations by Flavin-Dependent Monooxygenases

By Christopher T. Walsh* and Y.-C. Jack Chen

There has recently been a revival of interest in microbial biochemistry. Part of this resurgence is due to the increased presence of man-made organic compounds in the biosphere and the resultant interest in microorganisms which can degrade these xenobiotic molecules. Also, advances in genetic engineering have raised the possibility of utilizing the chemical machinery of bacteria for commercial profit and social benefit. The Baeyer–Villiger reaction is a useful transformation in organic synthesis which provides chemists with a gentle means of converting ketones into esters or lactones. The reaction, however, suffers from the problems of low yield and the need, in some cases, to utilize harsh conditions. There exist bacteria, capable of growth on aliphatic molecules, that contain enzymes which can catalyze Baeyer–Villiger reactions. These enzymes, known as monooxygenases, are involved in the breakdown of acyclic and alicyclic ketones to provide simpler carbon units for further catabolism. The gamut of reactions catalyzed by some of these enzymes is remarkable. This diversity, plus their availability in pure form in quantity by genetic engineering raises the possibility that these biocatalysts can be useful as reagents in organic synthesis.

1. Introduction

The oxidation of ketones to esters and lactones by the Baeyer–Villiger reaction is a reliable and highly useful transformation in synthetic chemistry and is typically effected by a peroxide or peracid reagent.[1–3] In general, the Baeyer–Villiger reaction is conducted with peracids, and the reaction with simple peroxides proceeds in low yields or not at all because the readily formed, and often isolable, tetrahedral peroxy adducts of ketones with H_2O_2[4] or alkyl hydroperoxides are resistant to the alkyl migration step needed to generate the ester or lactone.[5–11] Some rate data are collected in Table 1.

With these few facts on the chemical Baeyer–Villiger process as backdrop, this review turns to biological Baeyer–Villiger transformations as its focus and summarizes the current knowledge on the enzymes and the cofactors and cosubstrates required for the biological counterpart.

Table 1. Rate of Baeyer–Villiger oxidations of three substrates by peroxides and peracids.

Reagent	Cyclohexanone	Cyclohexyl methyl ketone	Acetophenone
*t*BuOOH	slow	slow	slow
H_2O_2	slow	slow	slow
$C_6H_5CO_3H$	$96\text{–}158 \times 10^{-5}$ $M^{-1}\,s^{-1}$ ($CHCl_3$, 25 °C)	$11.7\text{–}14.1 \times 10^{-5}$ $M^{-1}\,s^{-1}$ ($CHCl_3$, 15 °C)	1.5×10^{-5} $M^{-1}\,s^{-1}$ ($CHCl_3$, 28 °C)
CF_3CO_3H	6.1×10^{-2} $M^{-1}\,s^{-1}$	5.7×10^{-3} $M^{-1}\,s^{-1}$ [a]	1.7×10^{-3} $M^{-1}\,s^{-1}$

[a] For isopropyl methyl ketone.

Collected in Table 2 are seven examples of transformations which appear by stoichiometry, and, in some cases, by detailed mechanistic analysis, to be enzyme-catalyzed Baeyer–Villiger reactions. The first five transformations, (a)–(e), camphor to the "1,2-campholide,"[12] 2-tridecanone to undecyl acetate,[13] progesterone to testosterone acetate,[14] cyclohexanone to ε-caprolactone,[15] and tetradecanal to tetradecanoate,[16] are all catalyzed by bacterial enzymes that have been purified to homogeneity and characterized as pure biocatalysts. As will be detailed in the next section, all five enzymes require O_2 as the cosubstrate for oxidation, contain or utilize a riboflavin-based coenzyme, and contain no transition metals. Reaction (e) is catalyzed by luminescent bacteria, and a coproduct of the oxidation of an aldehyde to an acid is a photon of blue-green light.[16] Many luminescent fish give off light by this mechanism from colonies of photobacteria harbored in specialized light organs.

The last two transformations, (f) and (g), occur in the metabolism of the hepatotoxic, carcinogenic aflatoxin mold metabolites. One involves oxygenative ring expansion of the cyclopentanone moiety to a six-membered ring lactone in the conversion of aflatoxin B to G_1. The other transformation, occurring in earlier stages of aflatoxin biogenesis, is proposed for conversion of averufin to versiconal acetate.[17] No further biochemical information is available on these latter transformations. There are dozens of other natural products and biogenetic routes to accumulating secondary plant metabolites where biological Baeyer–Villiger reactions have been postulated or are likely.

Given the observations that molecular oxygen is cosubstrate and flavin coenzymes are cofactors in the five

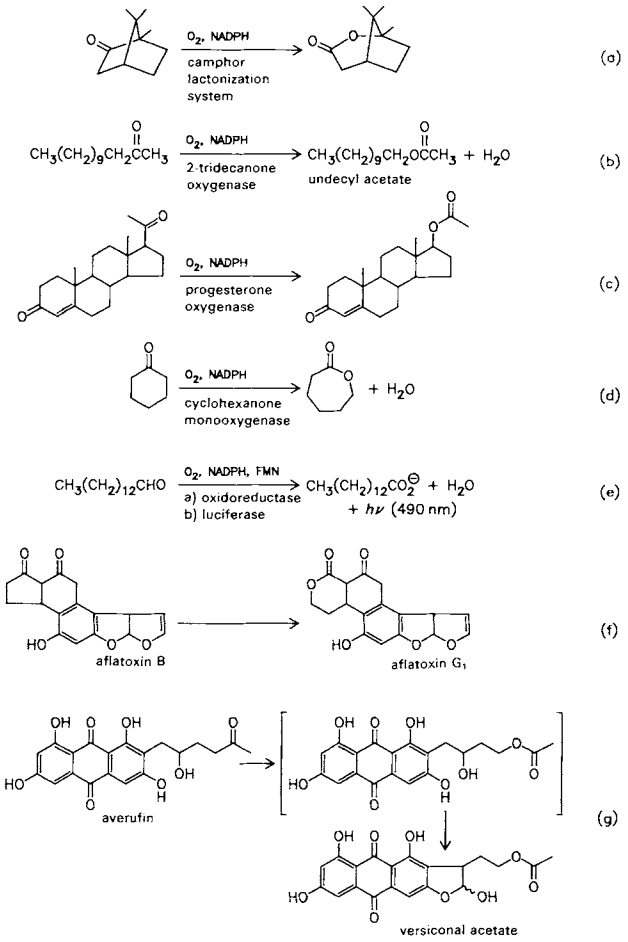
Table 2. Biological transformations effected by enzymes catalyzing Baeyer-Villiger oxidations.



Baeyer-Villiger enzymes so far purified, we briefly analyze oxygenase enzymes and their cofactor requirements in the next section.

2. Oxygenase Categories

Enzymes that reductively activate oxygen for insertion into some cosubstrate can be broadly classified as dioxygenases or monooxygenases based on whether two or only one of the oxygen atoms from O_2 is incorporated into a cosubstrate as it is transformed into product[18] (Fig. 1). Dioxygenases usually contain tightly associated iron, in heme or non-heme environments, and are exemplified by the enzymes involved in 1,4-dioxygenations in prostaglandin and leukotriene biogenesis, in aromatic ring functionalizations by microbes such as the conversion of benzene to its *cis*-1,2-dihydroxy derivative, and in oxygenative aromatic fissions of phenols and catechols in aromatic ring biodegradations. Monooxygenases, of which the Baeyer-Villiger oxygenases are a subset, show a wider range of cofactor content, and also convert one atom of O_2 into H_2O as a coproduct of the oxygenation process. To convert O_2

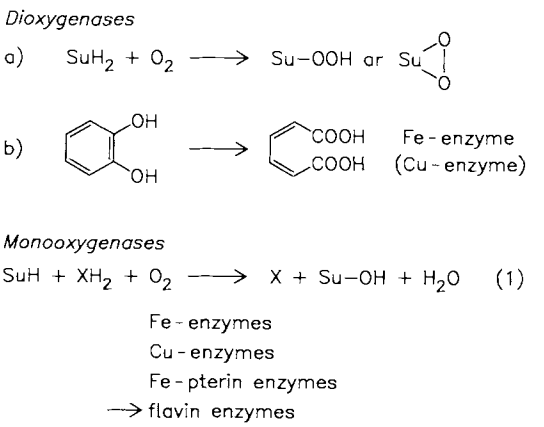


Fig. 1. The two classes of oxygenases and the reactions they catalyze. Dioxygenases require metal cofactors whereas monooxygenases utilize either metal or organic cofactors.

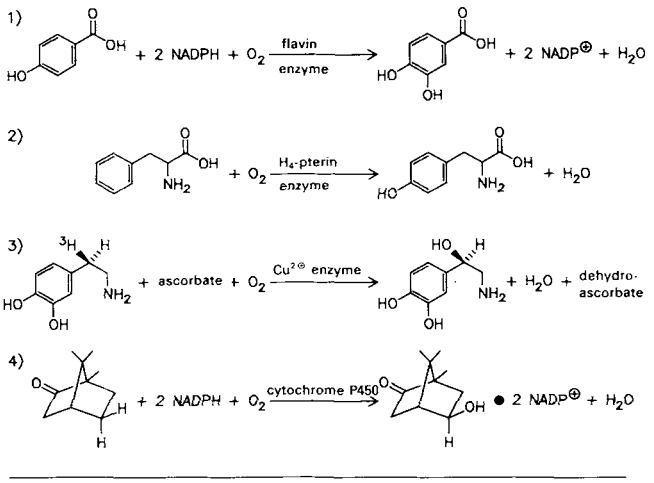
into an activated oxygen transfer reagent, monooxygenases generally use a two-electron reductant and either a redox-active transition metal (Fe, Cu) or a conjugated organic cofactor (pterin or flavin coenzyme) to facilitate passage of electrons one at a time to O_2 via an oxo-metal or oxygenated cofactor intermediate. The general stoichiometry is given by Equation 1 in Figure 1.

The four types of monooxygenases, based on the redox cofactor, are exemplified in Table 3. A typical flavoprotein monooxygenase is represented by the bacterial *p*-hydroxybenzoate hydroxylase, which produces the catecholic product by *ortho* hydroxylation of an activated aryl ring.[19] The second type using a conjugated organic cofactor is phenylalanine hydroxylase, the first enzyme in adrenergic neurotransmitter biosynthesis, which carries out a much more difficult functionalization of the unactivated phenylalanine ring, regiospecifically, to yield tyrosine. Whereas the reductant for the flavoenzyme(s) is the readily available dihydronicotinamide NADPH, the phenylalanine hydroxylase uses tetrahydrobiopterin and generates as initial product the bridgehead hydroxy pterin that is enzymically dehydrated to H_2O and the quinoid tautomer of dihydrobiopterin. Phenylalanine hydroxylase also requires one equivalent of iron in its active site to be catalytically active and it is likely that the oxygenating species may be a high-valent oxo-iron reagent in the enzyme's active site.[20] The third type of monooxygenase, a copper enzyme, is dopamine β-hydroxylase, which functions further along the same catecholamine biosynthetic pathway to convert dopamine into noradrenaline by benzylic hydroxylation.[21] Here the reductant, XH_2, is vitamin C in a biologically well-documented role for ascorbic acid. The fourth example is an iron enzyme, here a heme protein of the cytochrome P_{450} family, acting to convert camphor into the 5-*exo* alcohol at the start of the bacterial catabolic pathway for this bicyclic substrate, a regio- and stereoselective hydroxylation of an unactivated carbon site.[22]

Because the Baeyer-Villiger enzymes (Table 2) are flavoprotein monooxygenases, we focus on the catalytic capacity of this vitamin B_2-based class further. In Figure 2 are shown the coenzymically active forms of riboflavin, the 5'-monophosphate, FMN (active with luciferase), and the 5'-

Table 3. The four different classes of monooxygenases. All monooxygenases catalyze reduction of molecular oxygen to water with concomitant oxidation of a substrate molecule. The differences stem from the cofactors which are required to effect these reactions.



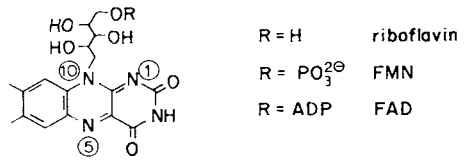


Fig. 2. Riboflavin (vitamin B_2) and coenzyme forms which are active as enzyme cofactors.

ADP ester, FAD (the predominant coenzyme form in the flavin-linked monooxygenases where it stays tightly bound to the enzyme active site through multiple catalytic turnovers). The tricyclic isoalloxazine ring system is the key locus for redox catalysis and the role of the exogenous reductant NADPH is to deliver hydride ion and reduce bound FAD to $FADH_2$, the 1,5-dihydro regioisomer.

Because $FADH_2$ (and $FMNH_2$) has a central dihydropyrazine ring, it is readily reoxidized by both one-electron (to the semiquinone radical) and two-electron routes and so can function as a two-electron/one-electron redox switch in biochemistry (Fig. 3).[22] The kinetic and thermodynamic accessibility of the semiquinone radical is the structural feature enabling rapid reaction of $FADH_2$ with O_2 to yield, by one-electron transfer, $O_2^{\ominus\ominus}$ (superoxide anion radical) and $FADH^{\ominus}$. Rapid radical recombination yields a bridgehead 4a-hydroperoxyflavin, first characterized with bacterial luciferase where its accumulation as an intermediate was detected by cryoenzymologic investigation.[23] The hydroperoxyflavin can break down intramolecularly to yield reoxidized flavin and H_2O_2 or it can undergo O–O bond fission at the active site of a specific flavoenzyme to monooxygenate, intermolecularly, a cosubstrate bound in its proximity and yield the 4a-hydroxyflavin as initial coproduct; intramolecular loss of H_2O from this pseudobase then regenerates FAD for a subsequent catalytic cycle (Fig. 4).

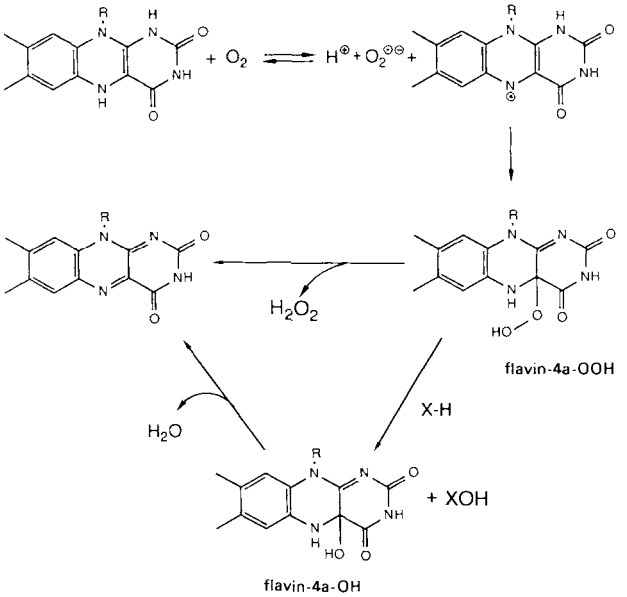

Fig. 4. Proposed reaction of reduced flavins with oxygen. The flavin hydroperoxide intermediate can either fragment to oxidized flavin and H_2O_2 or can oxygenate a cosubstrate with concomitant generation of a 4a-hydroxyflavin which then breaks down to oxidized flavin and water.

The types of substrates that undergo monooxygenation by flavoenzymes can be divided into three categories: (1) phenols are transformed into catechols; (2) heteroatom-containing compounds into the corresponding oxides; (3) ketones or aldehydes into esters or acids. This last category is our focus.

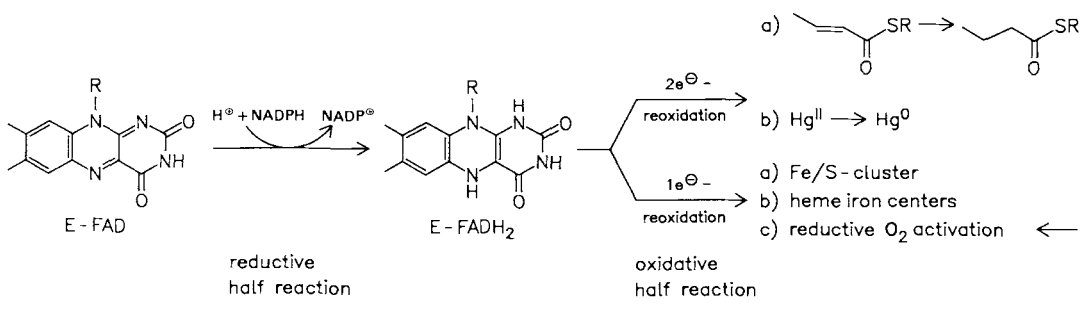

Fig. 3. The redox versatility of the flavin cofactor arises from its ability to perform both one- and two-electron transfers. E = enzyme.

3. Baeyer-Villiger Flavoprotein Monooxygenases

Although we shall focus on cyclohexanone monooxygenase as the example of the Baeyer-Villiger enzyme subjected to closest mechanistic scrutiny, we note first some contextual features of the other flavoenzymes of Table 2. *Pseudomonas* can grow on camphor as a sole carbon source, and its strategy for disconnection of the bicycloheptane skeleton to return its carbons to metabolically useful building blocks is remorselessly monooxygenative in attack. As shown in Figure 5, camphor can undergo a

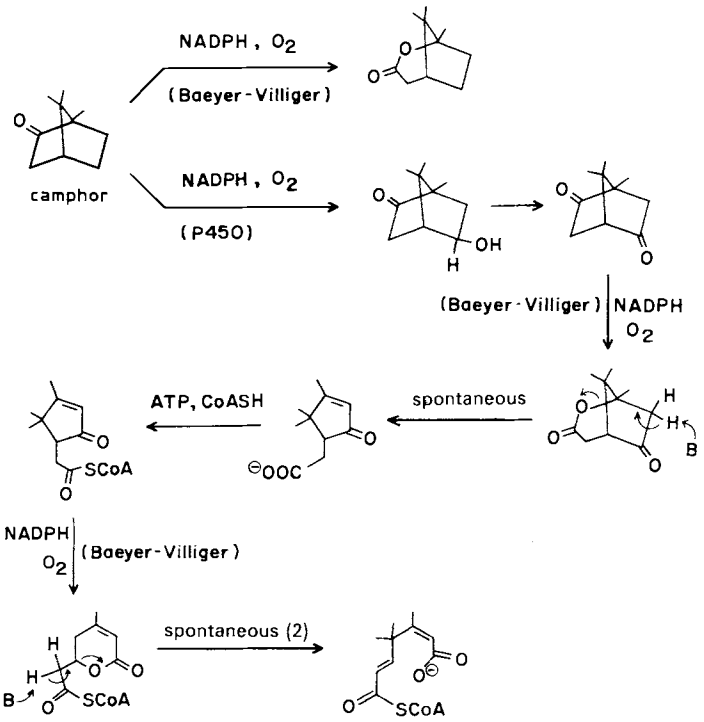

Fig. 5. The oxygenative pathway for camphor dissimilation. Initial hydroxylation by a cytochrome P_{450} monooxygenase activates the bicyclic system for subsequent fragmentation of each ring via successive Baeyer-Villiger oxidations.

Baeyer-Villiger enzymic oxygenation directly, but the major metabolic flux is by initial 5-*exo*-alcohol formation by the P_{450} camphor hydroxylase (entry 4, Table 3), oxidation of the alcohol to yield the diketone, and then Baeyer-Villiger oxidation with insertion of oxygen, as anticipated, between the carbonyl C atom and the bridgehead.[12,24,25] The resultant lactone is unstable in mild base and fragments to the monocyclic conjugated cyclopentenone with a pendant acid grouping. The acid is thioesterified with coenzyme A and then yet another Baeyer-Villiger-type flavoprotein oxygenase is brought to bear to convert the last ring by oxygenative fragmentation into acyclic metabolites. Note the key role of multiple Baeyer-Villiger enzymes in the skeletal disconnection strategy.

The 2-tridecanone oxygenase from *Pseudomonas cepacia* turns out to be a highly nonselective oxygen-insertion enzyme. It will take C_7 to C_{14} methyl ketones and convert them into the corresponding alkyl acetates. Further, it will take any other ketone isomer of tridecanone and insert oxygen into either side as exemplified (Fig. 6) by the conversion of 6-tridecanone to heptyl hexanoate and pentyl octanoate.[13] This enzyme has also been reported to act on cyclopentanone and cyclohexanone. The pure FAD-containing steroid oxygenase from *Cylindrocarpon radicicola*[26] will not only convert progesterone into testosterone acetate but also androstenedione into testolactone, with a broad specificity suggested for other 17- and 20-ketosteroids.

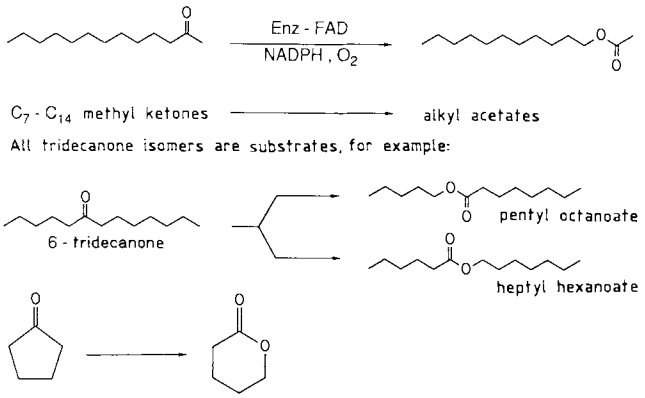

Fig. 6. Alkyl methyl ketone catabolism by *Pseudomonas cepacia* tridecanone oxygenase. Note the ability of this enzyme to insert oxygen into either side of the carbonyl moiety. This oxygenase is a dimeric flavoprotein (2 × 55 kDa); it constitutes 3% of the soluble protein in the cell. $k_{cat} = 100\ min^{-1}$.

Luciferase, in structural terms, is the best characterized of this class of flavoenzymes and has been available in homogeneous form from several photobacteria for about 20 years.[27] This enzyme is an $\alpha\beta$ dimer. However, the enzyme differs from the other flavoenzymes in that it binds FMN only weakly and requires a separate feeder enzyme to reduce free FMN to $FMNH_2$. The $FMNH_2$ then diffuses to luciferase's active site. With purified luciferase enzyme, O_2, $FMNH_2$, and tetradecanal, only a single turnover ensues (due to competing nonenzymic autoxidation of $FMNH_2$), so steady-state kinetic determinations have been difficult. The main focus in luciferase study has been on the emission of blue-green light ($\lambda_{max} = 490$ nm, quantum yield = 0.1) generated as coproduct of luciferase action. Possibly, the FMN-4a-OOH reacts with aldehyde to yield the tetrahedral adduct which then could decompose with C-H cleavage in a Baeyer-Villiger mode[28] and yield product acid and FMN-4a-OH. This route does not obviously explain light emission. *Hastings* and colleagues have suggested that the excited state of FMN-4a-OH is the initial species which can emit light directly or transfer energy to an accessory chromophore. To produce the excited FMN-4a-OH, they proposed that luciferase fragments the O-O bond via intramolecular electron transfer to yield carboxylic acid and diradical. Then "charge annihilation results in the formation of the excited state of the hydroxy flavin"[29] (Fig. 7). This type of mechanism has also been proposed by *Ghisla* and coworkers.[30,31] In model studies with N_5-ethyl-4a-hydroperoxyflavin and aldehydes, a low-quantum-yield chemiluminescence has been reported.[32]

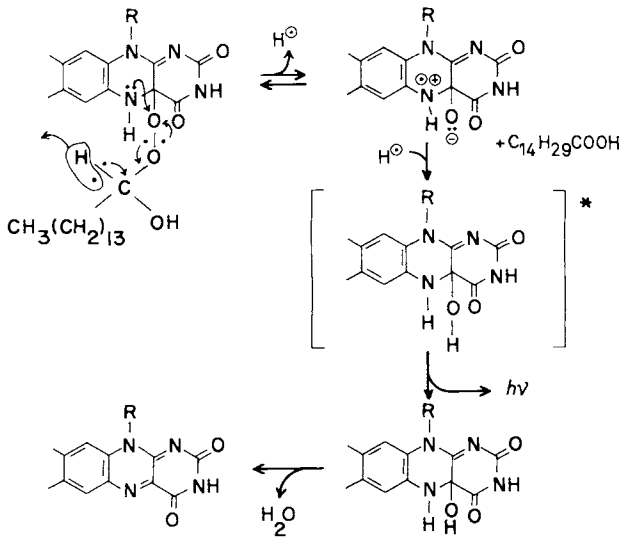

Fig. 7. A possible catalytic cycle for the bacterial luciferase reaction.

The enzyme cyclohexanone monooxygenase has been detected in soil bacteria—*Nocardia, Pseudomonas, Acinetobacteria*—that can grow on cyclohexanol as sole carbon source.[33] The key step in cyclic ketone carbon assimilation is the Baeyer-Villiger ring expansion to the seven-membered ring lactone. Subsequent enzymic hydrolysis leads to the hydroxy acid which can be processed to standard C_2 and C_4 metabolites (Fig. 8).

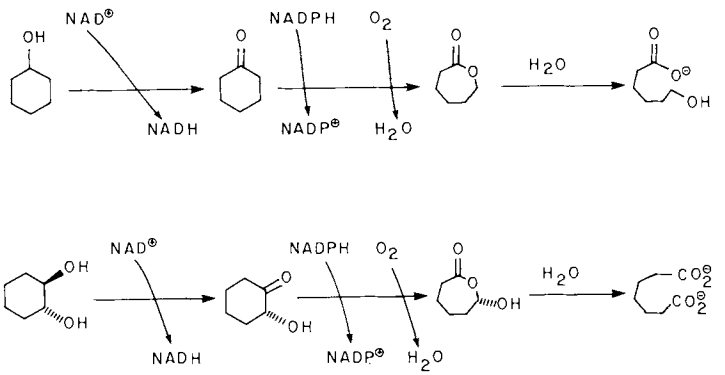

Fig. 8. Metabolic path of cyclohexanol and *trans*-1,2-cyclohexanediol catabolism in *Acinetobacteria*. Cyclohexanone monooxygenase catalyzes the second step in this pathway.

4. Properties of Cyclohexanone Monooxygenase

The enzyme was initially purified from *Acinetobacteria* and *Nocardia* by *Trudgill* et al.[15] and found to be a yellow FAD-containing enzyme of about 60000 daltons. The enzyme is active as a monomer and contains one tightly but noncovalently bound FAD per monomer. The *Acinetobacter* gene has recently been cloned and expressed in *E. coli* and the DNA sequence determined, leading to the first primary sequence of a Baeyer-Villiger enzyme.[53] Analysis of the first 50 residues at the NH_2-terminus reveals a homology to the FAD-binding domain of other flavoenzymes such as glutathione reductase, whose X-ray structure is known, where the glycine clusters represent part of an FAD nucleotide binding domain in the enzyme (Fig. 9).

Fig. 9. Sequence alignment of the FAD-binding region of cyclohexanone monooxygenase (A) and glutathione reductase from human liver (B) and *E. coli* (C). All three sites are located near the NH_2-terminus and display strong homology across species.

The optical spectrum of the enzyme is displayed in Figure 10, showing the characteristic two absorption maxima of FAD in the 375- and 450-nm region.

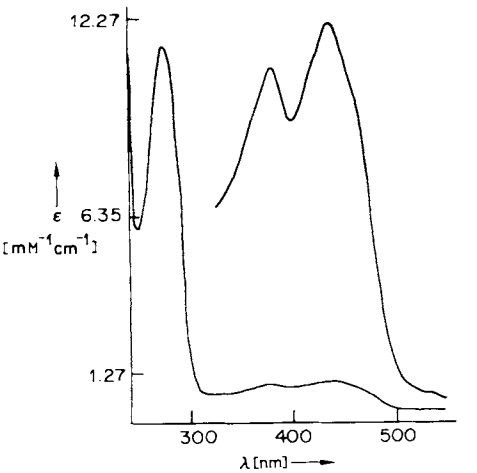

Fig. 10. UV/VIS spectrum of pure cyclohexanone monooxygenase. $\varepsilon_{450} = 11.3\ mM^{-1}\ cm^{-1}$.

Trudgill et al. established that the enzyme would process C_4 to C_8 cyclic ketones (Fig. 11)[15,33] and we have also seen cyclononanone-dependent O_2 and NADPH consumption by the pure enzyme. In fact, the enzyme shows even broader specificity, working on some acyclic ketones and aryl ketones such as acetophenone.[34] The enzyme also oxygenates camphor and fenchone and even, slowly, pregnelone.[35] On initial isolation, there is good coupling of NADPH oxidation to ketone oxygenation with only 0.3% of O_2 being reduced and appearing as H_2O_2, presumably by intramolecular breakdown of the FAD-4a-OOH in the enzyme's active site.[36] As the pure enzyme ages and perhaps denatures a bit in its active site integrity, the uncoupled oxidase rate may rise to 2-3% of the flux.

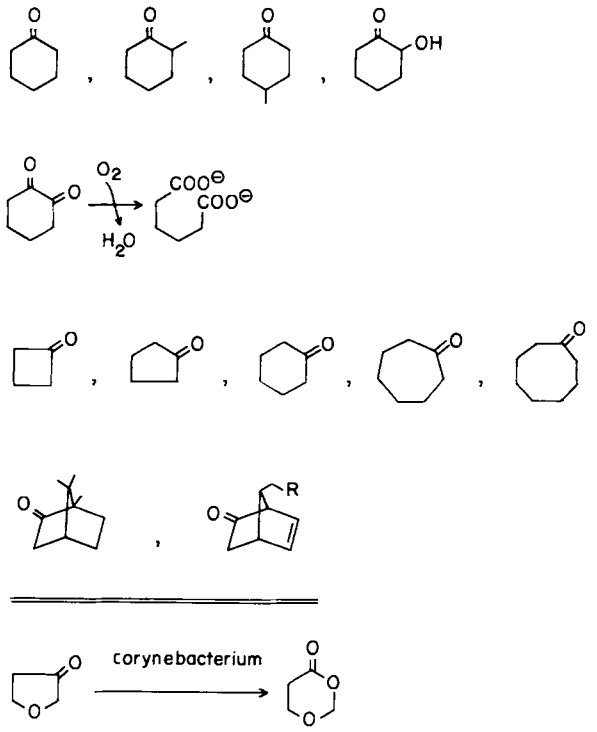

Fig. 11. Cyclic ketone substrate range for cyclohexanone monooxygenase.

4.1. A Baeyer–Villiger Biocatalyst

The migratory aptitude of the enzymic oxygen insertion process has been probed with two types of substrates. First, 2-methylcyclohexanone gives oxygen insertion only between the carbonyl group and the substituted carbon center.[37] Also, phenylacetone is converted into benzyl acetate, reflecting exclusive benzyl migration[34] in accord with the nonenzymic reaction of phenylacetone with trifluoroperacetic acid (Fig. 12). Enzymic processing of the aldehydic substrate phenylacetaldehyde results in both hydrogen and benzyl migration (2:1 hydrogen:benzyl) to yield 65% phenylacetic acid, 12% benzyl formate, and 23% benzyl alcohol. An inverted preference (7:1 to 2:1 benzyl:hydrogen) is seen with various peracids nonenzymically.[38] Aliphatic aldehydes, e.g., butyraldehyde (Fig. 12), yield only carboxylic acids with either cyclohexanone monooxygenase[34] or peroxide reagents.[7] In aldehyde oxidations by this enzyme, in contrast to luciferase, no light emission was detected. The molecular bases for these distinctions are unknown.

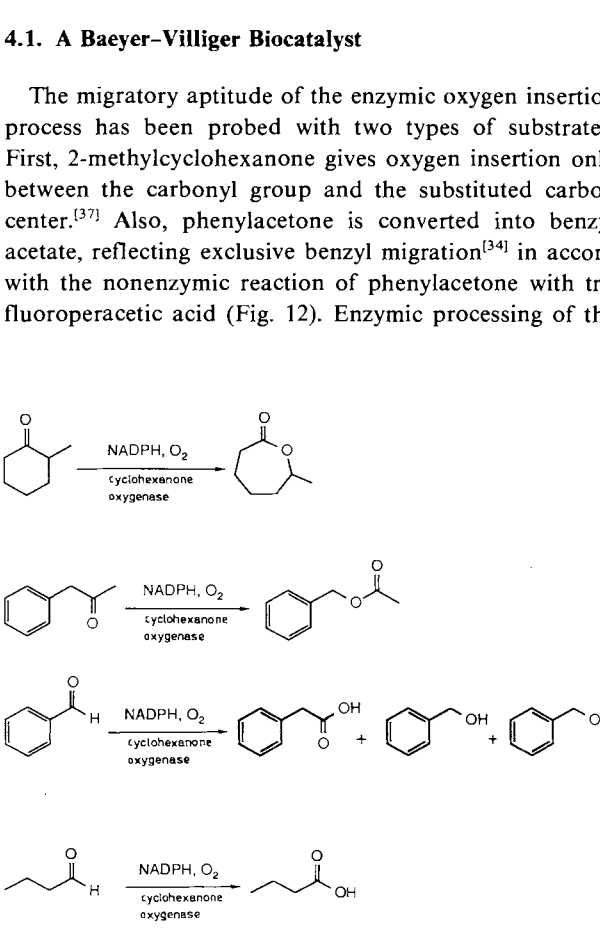

Fig. 12. Migratory aptitude of cyclohexanone monooxygenase-mediated oxygen insertion parallels that of chemical reagents such as trifluoroperacetic acid. Some inverted preferences are observed, possibly as a result of the steric constraints of the active site.

The nonenzymic Baeyer–Villiger reaction proceeds with retention of configuration at the migrating carbon center[39] (Fig. 13a). This aspect of mechanism has been probed with cyclohexanone monooxygenase using (2*R*)-[D_1]cyclohexanone; retention of stereochemical configuration in the monodeuterolactone product was confirmed by NMR spectroscopy.[37] To rule against an enolization, epoxidation, rearrangement route (Fig. 13b), 2,2,6,6-tetradeuteriocyclohexanone was incubated with enzyme and the retention of all deuteriums in the lactone product confirmed by GC/MS analysis. These data, taken in aggregate, strongly support a Baeyer–Villiger mechanism involving formation of a tetrahedral adduct at the cyclohexanone carbonyl in the active site.

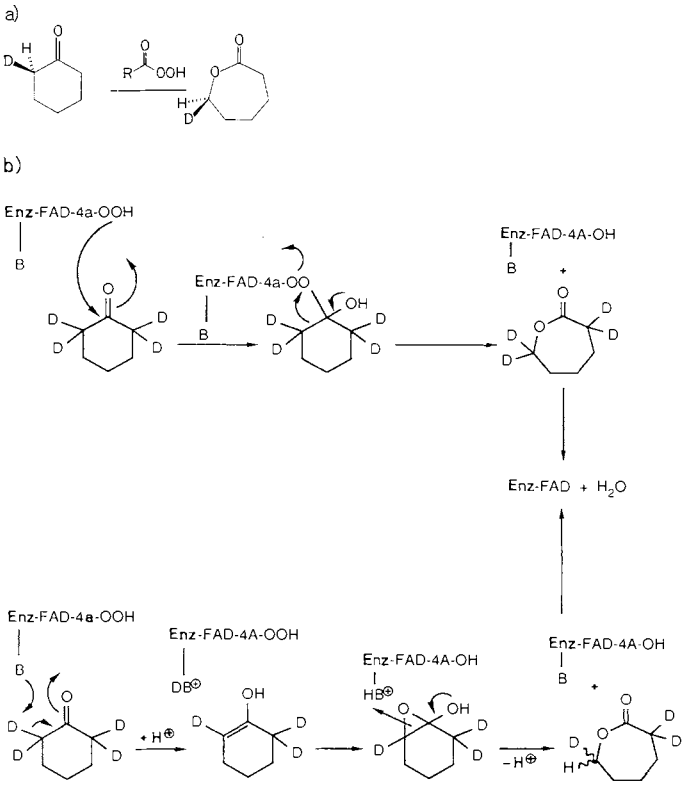

Fig. 13. a) Migration of the carbon center in the enzymic reaction proceeds with retention of stereochemical configuration in accord with the chemical Baeyer–Villiger process. b) Oxygen insertion is suggested to proceed by way of formation of a tetrahedral intermediate which breaks down to products (above). Studies with 2,2,6,6-[D_4]cyclohexanone argue against the enol epoxidation route (below).

To determine whether nascent H_2O_2 generated by two-electron reduction of O_2 might be the oxidant, we determined that incubation with $NADP^{\oplus}$, H_2O_2, cyclohexanone, and enzyme did not yield any lactone product.[40] This negative result coupled with pre-steady-state spectrophotometric kinetic studies supports the idea of an enzyme-bound FAD-4a-OOH intermediate.[41] A corresponding FMN-4a-OOH species is chemically and kinetically competent in luciferase catalysis.[23]

Thus, the mechanism shown in Figure 14 has been proposed as a minimal mechanism for cyclohexanone monooxygenase.[40] NADPH binds to and reduces the enzyme-bound FAD (E-FAD) with a very fast rate (>50000 min^{-1}). The $FADH_2$ likewise reoxidizes with O_2 much more rapidly than catalytic turnover to produce the FAD-4a-OOH. The flavin hydroperoxide can form the hydroperoxy anion (pH optimum of enzyme = 9.0) and act as nucleophile at the ketone (or aldehyde) carbonyl. The tetrahedral adduct then decomposes in the forward direction by typical Baeyer–Villiger migration of one of the carbon–carbon bonds (or the carbon–hydrogen bond for aldehydes) with fragmentation of the weak O–O bond to yield ester (or acid) and flavin-4a-OH, which returns to FAD by internal loss of H_2O.

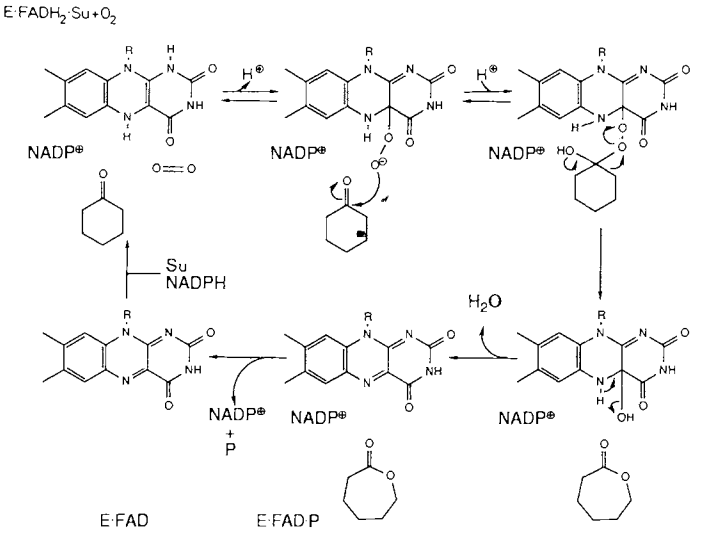

Fig. 14. Mechanistic proposal for oxygen insertion by cyclohexanone monooxygenase. Oxidation of the reduced flavin generates E-FAD-4a-OOH which serves as the oxygen donor. Elimination of water regenerates oxidized flavin for the next catalytic cycle.

One can write more elaborate variants of this mechanism in which the flavin-4a-OOH is not the actual oxygen transfer agent but rather a progenitor of a more activated species such as a flavin oxaziridine, a cyclic 4a,10a-peroxide, a flavin perepoxide, or a ring-opened flavin carbonyl oxide, to name a few (Fig. 15). However, no discrete evidence for such species has been obtained and, by Occam's razor, one stays with the peroxyflavin until proven otherwise. There is the issue of whether the flavin bridgehead hydroperoxide is a sufficiently reactive peroxide reagent. Model data from *Bruice* et al. exist at least for *N*- and *S*-oxygenation, albeit not for Baeyer–Villiger reactions.[41] For *N*- or *S*-oxygenations, the N_5-alkylflavin-4a-hydroperoxide is almost 200000 times more reactive than *tert*-butyl hydroperoxide. *Bruice* et al. have conducted structure–activity studies on these flavin hydroperoxides and find they are well-behaved in an activated peroxide–peracid series[41] where the oxygen-transfer potential of various ROOH species, including flavin-4a-OOH, is correlated with the pK_a of the leaving group alcohol.

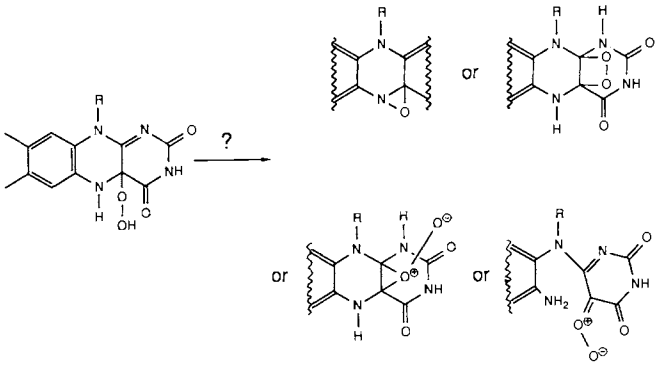

Fig. 15. Other possible flavin oxygen transfer agents derived from FAD-4a-OOH. No evidence yet exists to support these species.

4.2. Heteroatom Oxygenation by Cyclohexanone Monooxygenase

Given the reactivity of flavin-4a-OOH in model *S*- and *N*-oxygenations, one can inquire whether the flavoenzyme oxygenases capable of Baeyer–Villiger catalysis can also oxygenate such heteroatoms. Further, one expects an activated alkyl hydroperoxide equivalent to show ambident reactivity in oxygen transfer, both as initiating nucleophile at ketone carbonyls and for electrophilic transfer to nucleophilic substrates. Indeed, cyclohexanone monooxygenase will oxygenate trimethyl phosphite to trimethyl phosphate, and will also oxidize iodide ion, a classic reagent for titrimetric determination of peroxides.[42]

The enzyme is also active with sulfide substrates, processing thiacyclohexane with 88% the V_{max} of cyclohexanone ($K_m = 24$ μM).[40] If enough product sulfoxide builds up, it can be oxidized on to the sulfone. The K_m for the sulfoxide ($K_m = 170$ μM) is eightfold higher than for thiacyclohexane, and the V_{max} is 60% that of cyclohexanone (Fig. 16a).[34] This qualitatively parallels peracid oxidation of sulfides to sulfoxides with one equivalent of oxidizing reagent and to sulfones with two equivalents.[1,43] As a probe for stereoselectivity of sulfoxidation, ethyl *p*-tolyl sulfide was incubated with the enzyme and found to give 82% *S*-sulfoxide, suggesting only a 4:1 kinetic preference in enantiomeric sulfide recognition (Fig. 16b).[44] No further studies of sulfur stereochemical analysis have been reported with this oxygenase.

Initial studies to evaluate the preference of cyclohexanone monooxygenase for sulfide oxidation versus Baeyer–Villiger oxygenation utilized isomers of thiacyclohexanone. The enzyme converted 3- and 4-thiacyclohexanone exclusively into the lactone products with no detectable

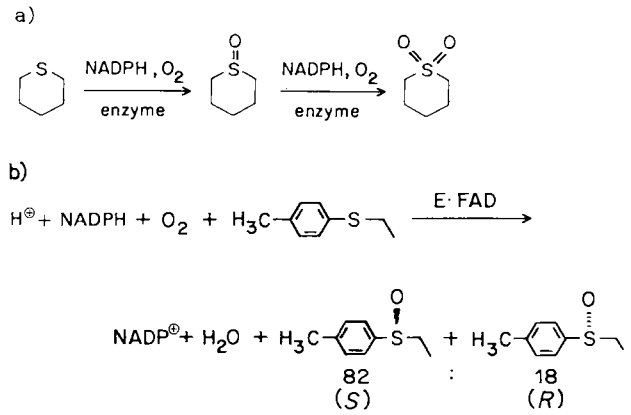

Fig. 16. a) Oxidation of sulfides to sulfones proceeds in two steps by way of the isolable sulfoxide. b) Cyclohexanone monooxygenase-mediated sulfur oxidation appears to be enantioselective as evidenced by a ca. 4 : 1 preference for generation of the (*S*)-sulfoxide.

sulfoxidation.[36] This may reflect preferential recognition of the carbonyl group in initial binding near the flavin peroxide species (Fig. 17).

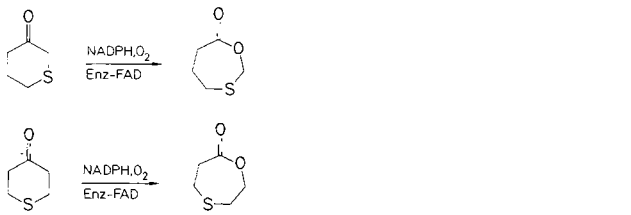

Fig. 17. Enzymic oxidation of thiacyclohexanones is regioselective with a preference for insertion of oxygen adjacent to the carbonyl.

Studies with allyl phenyl sulfide indicated smooth conversion to the sulfoxide by cyclohexanone monooxygenase with no inactivation from potential 2,3-sigmatropic rearrangement of the product allyl sulfoxide (Fig. 18a).[34] The

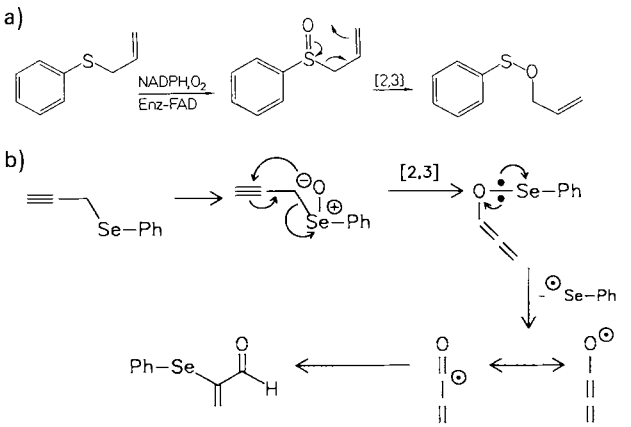

Fig. 18. a) Oxidation of allyl phenyl sulfide to the sulfoxide did not cause enzymic inactivation (from potential 2,3-sigmatropic rearrangement to an electrophilic species). b) Enzymic oxidation of phenyl propargyl selenide [45] yielded the same products of 2,3-sigmatropic rearrangement as those generated by chemical oxidation of the selenide [46].

corresponding selenide was readily oxygenated, again without detectable loss of enzyme activity. When the corresponding phenyl propargyl selenide was enzymically processed (Fig. 18b), the sole product detected was α-phenylselenoacrolein,[45] a product likely to have arisen from enzymic selenoxidation, followed by 2,3-sigmatropic rearrangement to an allenyl selenenic ester, then fragmentation and recombination to the accumulating product. This route is precedented by treatment of the same selenide with ozone in dry organic solvents.[46]

At this point, cyclohexanone monooxygenase has shown versatility in delivery of electrophilic oxygen to a variety of electron-rich heteroatom-containing substrates. To test further for nucleophilic oxygen-transfer initiation beyond the Baeyer–Villiger reaction, we analyzed for oxygen transfer to boron, specifically boronic acid substrates.[34] Both alkylboronic and arylboronic acids are smoothly converted into the corresponding alcohols (Fig. 19) via the intermediate borate esters as hydrolytically labile initial enzyme products. For example, *n*-octylboronic acid is converted into *n*-octanol and boric acid with a K_m lower than that for cyclohexanone (2.5 μM versus 6 μM) and a higher k_{cat} (580 min^{-1} versus 400 min^{-1}), making it the most efficient substrate yet detected for this oxygenase ($k_{cat}/K_m = 3.8 \times 10^6\ M^{-1}\ s^{-1}$).

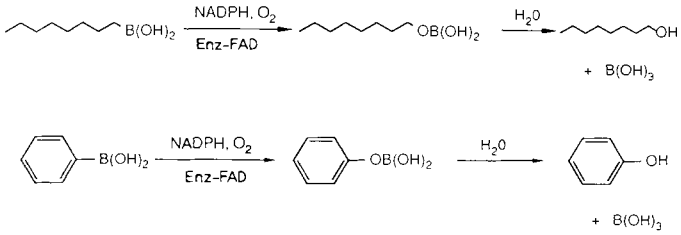

Fig. 19. Cyclohexanone monooxygenase catalyzed the first example of an enzymic boron oxidation, converting boronic acids into the corresponding alcohols.

This was the first example of any enzymic boron oxygenation and seemed likely to proceed by analogy to the Baeyer–Villiger process with attack by a flavin hydroperoxy anion on boron and then decomposition of the adduct with R group migration and O–O bond fission (Fig. 20). The reaction is so facile nonenzymically with peracids that oxygen insertion into carbon–boron bonds is used both synthetically and in organoboron quantitative analy-

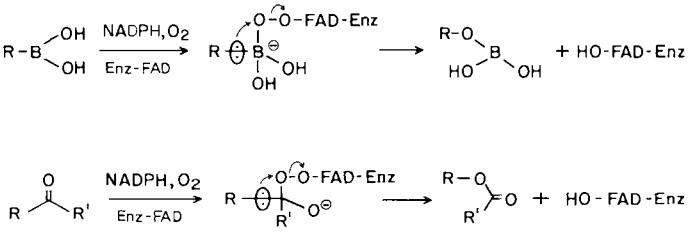

Fig. 20. Mechanistic proposal for oxidation of boronic acids by cyclohexanone monooxygenase via a tetrahedral peroxyboron adduct and alkyl or aryl group migration (top) in analogy to the Baeyer–Villiger process (bottom).

sis.[12,47] It seems that boronic acid substrates may be useful probes for *nucleophilic oxygen equivalents*.[34]

If boronic acid enzymic oxygenation proceeds by a boron equivalent to a Baeyer–Villiger process, then the R group migrating from boron to oxygen should retain stereochemical configuration. This prediction has been validated with (*S,S*)-2-methylcyclohexylboronic acid. Enzymic oxidation yielded the (*S,S*)-2-methylcyclohexanol with quantitative retention of configuration at the migrating cyclohexyl group[48] (Fig. 21). This finding parallels the results obtained for oxidation of dimethyl (*S,S*)-2-methylcyclohexylboronate with H_2O_2 in alkaline medium.[48b]

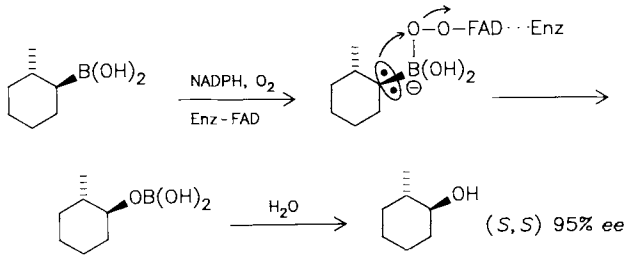

Fig. 21. The enzymic conversion of boronic acids to the borate esters proceeds with retention of stereochemical configuration at the migrating center. Incubation of (*S,S*)-2-methylcyclohexylboronic acid yields the corresponding (*S,S*)-2-methylcyclohexanol.

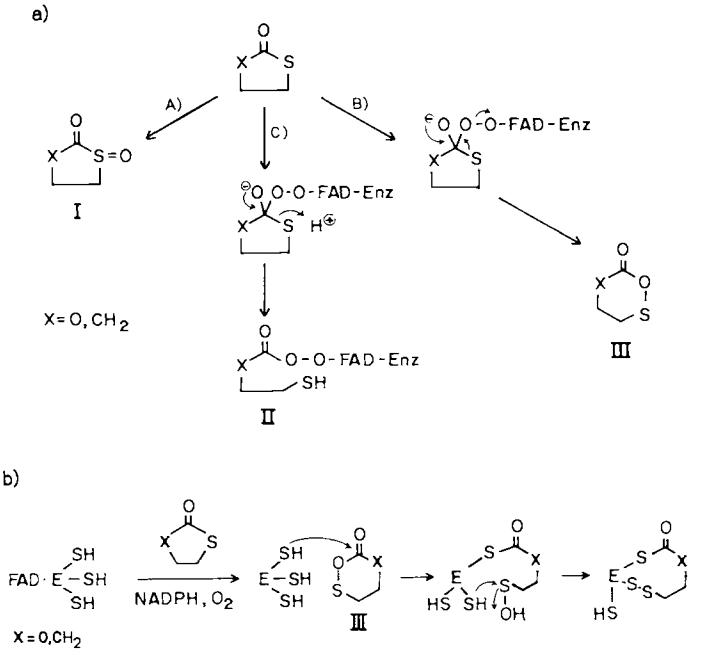

Fig. 22. a) Possible routes for enzymic inactivation by thiolactone substrates. Three pathways involving oxidation of the substrate to extremely reactive electrophilic species, **I**–**III**. b) Acylation of **III** unmasks a second electrophilic site for a cross-linking step, leading to an enzyme disulfide thioester adduct.

4.3. Enzymic Inactivation by Thiolactones and Thiocarbonates

In contrast to the 3-thia- and 4-thiacyclohexanones, cyclohexanone monooxygenase processes 2-thiacyclohexanone and in the process inactivates itself.[36] This thiacyclohexanone isomer is of course a thiolactone which itself could be a reactive acylating agent, but the inactivation of cyclohexanone monooxygenase requires NADPH and O_2 and is clearly mechanism-based. The processing of thiolactones to products is in kinetic competition with enzymic suicidal inactivation. γ-Thiobutyrolactone undergoes 33 turnovers per inactivation event while ethylenethiocarbonate yields 110 turnovers per killing event.[36] With [^{35}S]-γ-thiobutyrolactone, inactivation results in stoichiometric incorporation of one radiolabel per enzyme molecule, but the covalent adduct structure has not yet been determined. Nonetheless, one can propose three alternatives: (1) oxygen transfer to sulfur to yield an acyl sulfoxide, **I**, a known active acylating species, (2) a Baeyer–Villiger-type oxygen insertion to a mixed sulfenic carboxylic anhydride, **III**, or (3) decomposition of the tetrahedral adduct to a perester species, **II** (Fig. 22a). All routes involve generation of an activated acylating species and then uncovering of an electrophilic sulfenic acid group capable of a second cross-linking reaction with a protein residue (e.g., to form a disulfide) (Fig. 22b). This route may have some generality beyond cyclohexanone monooxygenase since thiocarbamate herbicides are known to require enzymic oxygenation in the plants by oxygenases, probably of the cytochrome P_{450} type, to yield acyl sulfoxides, isolable at low temperatures, as active herbicidal acylating agents.[49–50] There is also the possibility that some of the toxicity of the antihypertensive and diuretic agent spironolactone is due to tissue-specific (adrenal and kidney) enzymic *S*-oxygenation (Fig. 23).[51]

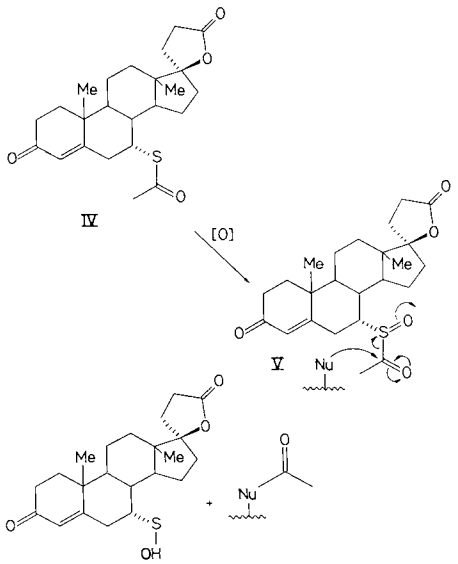

Fig. 23. Possible mode of action for the drug spironolactone **IV**. Enzyme-mediated *S*-oxygenation generates an acyl sulfoxide **V** which captures a free nucleophile to yield an acetylated molecule and an electrophilic sulfenic acid moiety.

5. Concluding Remarks

As a well-studied flavoprotein monooxygenase apparently designed as a Baeyer–Villiger catalyst to degrade cycloalkanones in bacterial metabolism,[33] cyclohexanone

monooxygenase has shown remarkable versatility as an oxygenation reagent. This enzyme has an activated FAD-4a-OOH, bound tightly in its active site, to deliver either a formal "nucleophilic" or "electrophilic" oxygen equivalent, depending on the electron-poor or electron-rich nature of the bound cosubstrate. A representative list of cyclohexanone monooxygenase substrates with K_{cat} values ranging from 50 min^{-1} to ca. 700 min^{-1} is presented in Table 4. It might seem that the enzyme can oxygenate almost any substrate that can diffuse into the active site. However, as Table 5 shows, there are some exceptions, among them 1,3-cyclohexanedione, 2-cyclohexenone, 4-phenylcyclohexanone, 2-butanone, triphenylphosphane, and such ketones as carvone, pulegone, and menthone.

The regiochemistry of Baeyer–Villiger migration has only been examined in a few cases but appears as predicted chemically. Retention of configuration of the migrating group occurs, in the two cases examined, for 2-methylcyclohexanone and for 2-cyclohexylboronic acid oxygenation. We have observed no preference in lactonization of 4-methylcyclohexanone as determined by NMR analysis after derivatization (Y.-C. J. Chen, P. Lodi, C. Walsh, unpublished results);[52] both D- and L-camphor are substrates. There is an apparent 2:1 kinetic preference for (*R*)-2- over (*S*)-2-methylcyclohexanone reacting with the enzyme.[39]

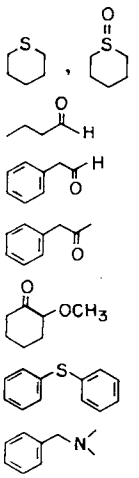
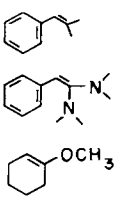
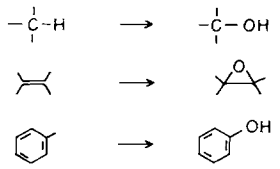
Substrates	Not substrates
		$P(OMe)_3$	PPh_3
	


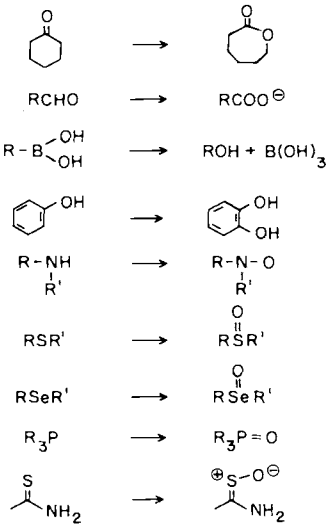


Repeated efforts to epoxidize olefinic double bonds such as that of dimethyl styrene and enols such as the methyl enol ether of cyclohexanone or an enamine, 2-phenylvinylidenebis(dimethylamine), have all failed with this enzyme (J. Latham, Y.-C. J. Chen, C. Walsh, unpublished results) and we raise the question whether the intrinsic reactivity of the enzyme-bound FAD-4a-OOH (or a reactive species derived therefrom) is sufficient for olefin epoxidations. Thus, in Table 6, we list the scope of oxygenations known to be carried out by flavin-based or iron-based monooxygenases. Below the dashed line, and well-exemplified by cyclohexanone monooxygenase, is the province of flavin-linked oxygenases. Above the line are the epoxidations of isolated double bonds and of aromatic double bonds (where the initial dihydroaromatic arene oxides rearrange unimolecularly to phenols) and the hydroxylation at unactivated sp^3 carbon centers (e.g., in camphor). To date, these constitute the exclusive province of oxo-iron enzyme reagents (and also a few oxo-copper enzymes). While flavin-dependent monooxygenases may yet be shown to epoxidize olefins, it may be that epoxidations and alkane hydroxylations require the oxo-iron enzyme biological "oxygen-guns" to be wheeled up.

Lastly, all examples yet characterized of Baeyer–Villiger enzymes are flavoproteins and it is likely one can antici-



Flavin-dependent monooxygenases



pate them to be the biological reagents for many other biological Baeyer–Villiger transformations occurring in more complex natural product structures.

Oxo-Bridged Polyiron Centers in Biology and Chemistry**

By Stephen J. Lippard*

The functions of iron in biology are often associated with heme or iron-sulfur proteins. But dioxygen transport, reduction of ribo- to deoxyribonucleotides, acid phosphatase activity, oxidation of methane to methanol, and iron storage are among the growing list of biological phenomena known or believed to be associated with a newly emerging class of proteins having oxo-bridged di- or polyiron aggregates at their metallic cores. The recognition of these iron-oxo proteins as a separate class has stimulated efforts on the part of inorganic chemists to prepare and characterize model compounds that replicate the physical properties and functions of the polymetallic protein cores. As a consequence, a variety of new oxo-bridged di-, tri-, tetra-, hexa-, octa-, and undecairon aggregates has been synthesized. These novel molecules promise not only to provide insight into the detailed characteristics of the metal centers in iron-oxo proteins, but also to serve as a focal point for preparing new materials, including oxidation catalysts and corrosion inhibitors, for the evolution of new theories to describe their physical properties, for developing new strategies for the treatment of iron-related disease, and for building links between the chemistry of the biosphere and the geosphere.

1. Introduction

Of all the transition elements, none is more prevalent in the sea or the earth's crust than iron.[1] In aqueous solution, the chemistry of iron is dominated by ferrous ($Fe^{2\oplus}$) and ferric ($Fe^{3\oplus}$) species, and its complexes are well known to undergo facile acid-base and electron transfer reactions.[2] Iron is therefore ideally suited for its many roles in biology, which include the transport and storage of dioxygen (O_2) and the catalysis of numerous reactions that utilize O_2.[1] In much of its biological chemistry, iron is chelated by a porphyrin ligand. In this form, it transports and stores O_2, in hemoglobin (Hb) and myoglobin (Mb), respectively, and catalyzes the oxidation of organic substrates, in cytochrome P-450, for example.[3] Another common source of Fe in biology are the iron-sulfur proteins, which function as electron transfer catalysts and participate in nitrogen fixation.[4] A third major class of iron-binding proteins contains neither cofactors nor sulfur clusters and includes transferrin and catechol dioxygenases.[5] The present discussion focuses on proteins in this third category that have two or more iron atoms known or thought to be linked by one or more oxygen atoms as bridging oxo, hydroxo, or alkoxo ligands. Although some of these proteins, such as ferritin and hemerythrin, have been known and studied for several decades, others have been subjects of interest only recently, as similarities among the structural and physical properties of their polyiron centers have begun to emerge.

Table 1 lists proteins currently known to contain an oxo-bridged binuclear or, in the case of ferritin, polynuclear iron center, together with their functions.[6-13] Although the properties of several of these proteins are discussed in greater detail below, some general observations are relevant in the present context. Hemerythrin (Hr), ribonucleotide reductase (RR), and methane monooxygenase (MMO) may all be comprised of the same or closely related (μ-oxo)bis(μ-carboxylato)diiron cores (Fig. 1). Their functions differ distinctly, however, Hr being a reversible oxygen carrier, whereas MMO and RR catalyze the oxidation of methane and reduction of ribonucleotides, respectively. Thus, the local protein environment may alter the properties of similar bimetallic centers to evoke the desired bio-

Table 1. Polyiron-oxo proteins: their abbreviations and biological functions.

Protein	Biological function	Occurrence	M_r	Ref.
Hemerythrin (Hr)	Oxygen transport	Marine invertebrates	108000[a]	[6]
Ribonucleotide reductase (RR)	Reduction of ribo- to deoxyribonucleotides	Animals, viruses, bacteriophages, prokaryotes	200000-300000[b]	[7, 8]
Purple acid phosphatases (PAP), uteroferrin	Unknown	Mammals, plants	35000-110000	[9]
Methane monooxygenase (MMO)	Methane oxidation	Methanotrophic bacteria	272000[c]	[10-12]
Ferritin (Ft) hemosiderin	Iron storage	Most life forms	450000	[13]

[a] Refers to the octamer. Dimers, trimers, and tetramers also exist. The molecular weight of monomeric myohemerythrin is 13900. [b] Comprised of two identical 80-90-kD and two identical 35-55-kD subunits, the former of which bind iron. In bacterial forms, these are designated B1 and B2, respectively. [c] Comprised of non-heme iron component A ($M_r = 210000$), 20-kD component B, and iron-sulfur flavoprotein component C ($M_r = 42000$). Component A has three subunits ($M_r = 54000$, 42000, 17000) present in stoichiometry $\alpha_2\beta_2\gamma_2$.

[**] In this article, "oxo-bridged" is usually taken to mean a bridging oxygen atom derived from an oxo ligand, but also refers generically to species with bridging $OH^{\ominus}$ or $OR^{\ominus}$ ligands.

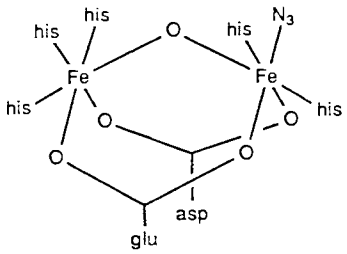

Fig. 1. Binuclear unit found in azidomet- and azidometmyohemerythrin. Similar (μ-oxo)bis(μ-carboxylato)diiron cores may occur in RR and MMO.

logical response. This phenomenon has interesting parallels in the biochemistry of other iron and copper metalloproteins.[1,14] The diiron center in Hr, like the dicopper center in hemocyanin and the iron porphyrin centers in Hb and Mb, binds O_2 reversibly, while the putative $[Fe_2O(O_2CR)_2]$ and $[Fe_2(OH)(O_2CR)_2]$ cores in RR and MMO, like the respective dicopper and iron porphyrin cores in tyrosinase and cytochrome P-450, for example, catalyze reactions involving oxygen-atom transfer steps. Uncovering the principles used by Nature to tune these centers to perform such diverse functions is a major incentive for investigating their chemistry.

Fig. 2. Hydrolysis reactions of iron(III) at 25°C, $\mu = 0$. Data were taken from Ref. [15].

Figure 2 reveals the tendency for iron(III) to hydrolyze in the physiological pH range 6–8, forming the familiar brown precipitate known as rust.[15] As a consequence, there were few well-characterized classes of soluble, oxo-bridged polyiron complexes prior to the work that is the major focus of this article. Among the better known discrete oxo-bridged polyiron complexes are the basic iron carboxylates first prepared early in this century.[16] The magnetic behavior of these trinuclear iron(III) oxo complexes (Fig. 3a) has been the subject of extensive investigations.[17–21] These compounds have recently formed the basis for a new class of alkane oxidation catalysts,[22] and many derivatives[23] and mixed-valence analogues[24] are now known. Another important species has been (μ-oxo)diiron(III) (Fig. 3b), recognized as a thermodynamically very stable entity in the hydrolytic coordination chemistry of iron.[2] Numerous complexes containing the linear $[Fe_2O]^{4\oplus}$ core have been characterized.[25,26] The molecular geometries of species depicted in Figures 1 and 3 differ significantly, however, and except for a structurally poorly characterized mineral known as ferrihydrite,[27,28] postulated as a model for the polyiron oxo core in the iron-storage protein ferritin (Ft),[29] accurate model compounds for oxo-bridged polyiron centers in biology did not exist prior to 1984.

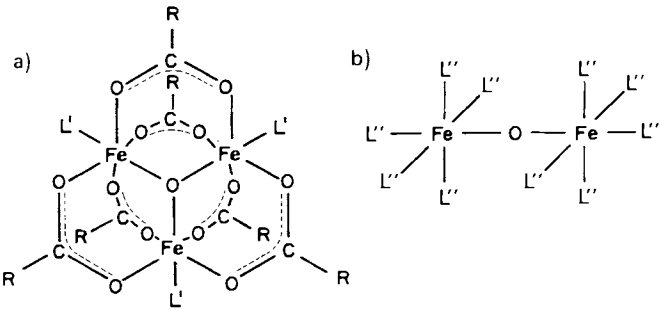

Fig. 3. Two common oxo-bridged polyiron species: a) the basic iron carboxylate structure; b) the (μ-oxo)diiron(III) structure. $L' = H_2O$, pyridine, etc.; e.g., $R = CH_3$.

In the following discussion, we first describe what is known about various members that constitute the class of iron-oxo proteins and, more importantly, what remains to be learned. Relevant iron chemistry is then described, building from simple binuclear hemerythrin model complexes to Fe_3, Fe_4, Fe_6, Fe_8, and Fe_{11} aggregates of higher nuclearity. In comparing the physical and chemical properties of well-defined inorganic complexes with those of the protein cores, we hope to learn, ultimately, "how Nature has managed to fashion a bioinorganic chemistry of rust."[30]

2. Proteins Containing Oxo-Bridged Polyiron Centers

2.1. Hemerythrin

Hemerythrins (Hr's) are the oxygen transport proteins of marine invertebrates including members of the Sipunculida, Priapulida, and Brachiopoda phyla.[6,31,32] Single- and multi-subunit forms are known and referred to as myoHr and Hr, respectively. X-ray crystal structure studies of the functionally inactive, oxidized (met) forms of myoHr and Hr have been determined, in which the dioxygen binding site is either occupied by $N_3^{\ominus}$ or vacant.[33,34] The structure of the diiron(III) center in azidometmyoHr is shown in Figure 4. The two iron atoms are bridged by an oxygen atom and two bidentate carboxylate groups from glutamate and aspartate amino acid residues. The $[Fe_2O(O_2CR)_2]^{2\oplus}$ core is further anchored to the protein by the imidazole side chains of five histidine residues, three of which occupy an octahedral face of one iron atom and two of which coordinate to the other iron atom. The sixth octahedral site on the second iron atom is filled by the azide nitrogen atom. This structure is consistent with magnetic and spectroscopic data on met forms of the protein, indicating two strongly antiferromagnetically coupled ($J \approx -134$ cm^{-1}), high-spin Fe^{III} atoms.[35]

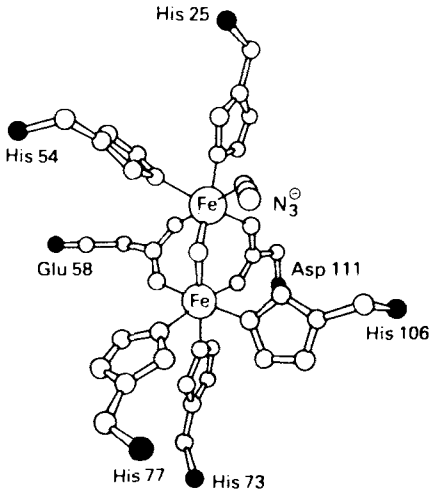

Fig. 4. Structure of the diiron center in azidometmyohemerythrin from *T. zostericola* [34] (reproduced by permission from Ref. [34]).

Magnetic susceptibility, Mössbauer, MCD (magnetic circular dichroism), EXAFS, ^{1}H-NMR, and low-resolution (3.9 Å) X-ray data on deoxy Hr suggest the presence of a $[Fe_2(OH)(O_2CR)_2]^{\oplus}$ core with one five-coordinate (Fe_A) and one six-coordinate (Fe_B) high-spin Fe^{II} center and weak antiferromagnetic coupling ($J \approx -15$ cm^{-1}).[36-40] Similar studies, including resonance Raman spectroscopic experiments, indicate that oxy Hr is best formulated as a hydroperoxy derivative of the (μ-oxo)bis(μ-carboxylato)diiron(III) core, with the hydroperoxide ligand filling the sixth coordination site of Fe_A.[4] Thus, the reversible dioxygen binding reaction of Hr may be viewed as oxidative addition and reductive elimination of O_2 to the diiron center (Fig. 5). Since dioxygen binding to *P. gouldii* Hr is pH-independent, internal proton transfer from the bridging hydroxide ligand in deoxy Hr to the hydroperoxide group in oxy Hr is postulated (Fig. 5).[41] Moreover, resonance Raman studies of oxy Hr, including ^{18}O and ^{2}H isotope substitution experiments, suggest that the proton on the hydroperoxide ligand is hydrogen bonded to the μ-oxo group. This hydrogen bond may be a key component that facilitates the kinetics of the oxygen binding reactions (see Section 3.5).

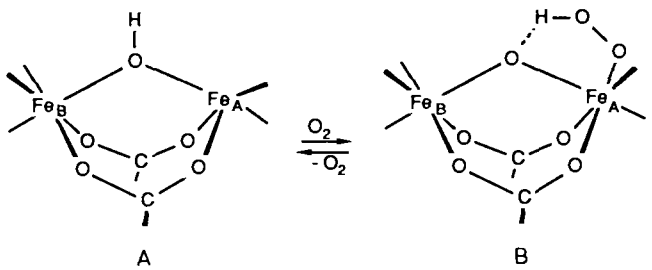

Fig. 5. Proposed model for reversible oxygen binding to hemerythrin [41]. **A** = deoxy Hr, **B** = oxy Hr.

Although the main features of the functional center in Hr are reasonably well understood, the protein continues to be a focus for physical and chemical studies because it is the prototype for other oxo-bridged diiron proteins about which much less is known. One point of interest is the existence of various redox states of Hr, for in addition to deoxy [Fe^{II},Fe^{II}], oxy [Fe^{III},Fe^{III}], and functionally inactive met [Fe^{III},Fe^{III}] Hr, several mixed-valence semimet [Fe^{II},Fe^{III}] forms are known (Fig. 6).[6] Numerous kinetic studies of electron transfer to, from, and among these forms have been reported.[6,42,43] Recent ^{1}H-NMR probes of the binuclear core have correlated chemical shifts with the extent of antiferromagnetic exchange between iron atoms in the different forms and, in particular, estimated J for semimet Hr to be ca. -20 cm^{-1}.[39] Derivatives have been prepared in which the bridging oxide atom in Hr has been replaced by sulfide or selenide, the semimet versions of which have been characterized.[44-46] The iron atoms of azidosemimet Hr have a trapped [Fe^{II},Fe^{III}] valence state on the NMR time scale (ca. 10^{-4} s) and the sulfide-bridged form of semimet Hr has the same trapped valence on the Mössbauer time scale (10^{-7} s).[39]

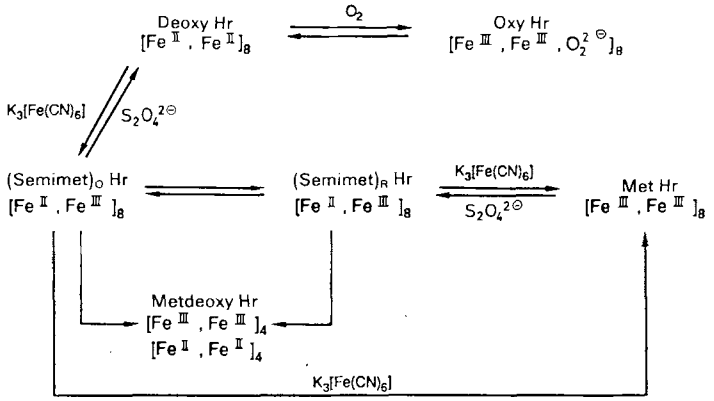

Fig. 6. Redox states of hemerythrin and their interconversion (after Ref. [6]).

The met form of Hr, very little of which is found in freshly isolated sipuncular worm erythrocytes, is unable to function in the oxygen-binding reaction (Fig. 5) unless first reduced to deoxy Hr. Recently, a cytochrome b_5 in *P. gouldii* erythrocytes was discovered, which appears to be one component of a potential system for reduction of met Hr in vivo.[47]

2.2. Ribonucleotide Reductase

Ribonucleotide reductases (RR's) catalyze the conversion of ribonucleotides to deoxyribonucleotides (Fig. 7), the first committed step in DNA biosynthesis. There are at least two major classes of this enzyme, a bacterial and cyanobacterial form that is dependent upon coenzyme B_{12}, and a form containing iron that occurs in bacteria including *Escherichia coli*, in mammals including man, and in herpes simplex and Epstein Barr viruses.[7,8,48] Although the detailed mechanism by which these enzymes catalyze reduction of the 2′ hydroxyl group of ribose is unknown, they are both believed to function by radical reactions in which $H^{\odot}$ is abstracted from the 3′ carbon atom of the sugar ring.[48,49] Adenosylcobalamin cofactors are well

known to promote such free radical reactions through homolytic cleavage of the Co-C bond.[50] The iron-containing RR enzymes have, in addition to a binuclear iron center with properties similar to the $[Fe_2O(O_2CR)_2]^{2\oplus}$ core in Hr,

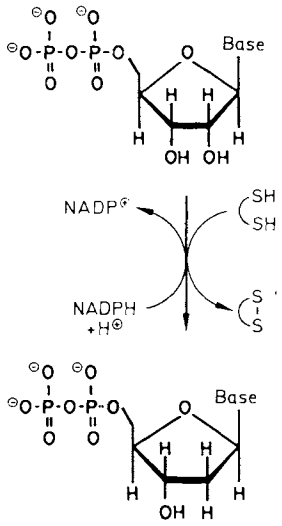

Fig. 7. Reaction catalyzed by RR.

a stable deprotonated tyrosine radical that has been implicated in the catalytic mechanism.[51] The protein is made up of two subunits, designated in the bacterial enzymes as B1 and B2. The B1 subunit ($M_r \approx 170000$) is comprised of two nearly identical protein chains, α and α′, binds substrates and allosteric effectors, and contains mercapto groups required for reducing the substrate. The B2 subunit ($M_r \approx 87000$) is made up of two identical chains, β, either one of which may contain the free radical tyrosine residue (Tyr 122)[52] and which together bind the binuclear iron unit.

Although X-ray crystallographic structural information is not yet available to define the diiron center in RR (the B2 dimer has been crystallized[53]), resonance Raman,[54] magnetic and UV/VIS spectroscopic data,[55] and Mössbauer results[56] all support an oxo-bridged diiron(III) formulation. This assignment is especially convincing, given the similarity of these properties to those of azidomet Hr and met Hr[33,34] and model complexes,[57,58] discussed in Section 3.3, having the $[Fe_2O(O_2CR)_2]^{2\oplus}$ core (Table 2).

Recent EXAFS studies of the B2 subunit obtained from a heat-inducible overproducing *E. coli* strain[59] have yielded the metrical parameters given in Table 2. Similar results were obtained in an independent study.[60] Since the shell due to the five Fe-O/Fe-N bonds around each iron other than the Fe-$O_{\mu\text{-oxo}}$ bond is 0.07 Å shorter for B2 RR than for azidomet Hr or the model compound $[Fe_2O(O_2CCH_3)_2(HBpz_3)_2]$, **2b** (see Section 3.3), one or more of the terminal nitrogen atoms in these latter two species is postulated to be replaced by hydroxide, phenolate, or carboxylate in RR. Paramagnetically shifted ^{1}H-NMR resonances observed for the B2 subunit of *E. coli* RR have been assigned to histidine ligands.[62] Taken together, these results have been interpreted in terms of the structural model shown in Figure 8.[61] Resonance Raman work on B2 RR and its ^{18}O-substituted derivative supports the presence of terminal hydroxide ligands and an Fe-O-Fe angle of 138°.[61]

Table 2. Properties of the $[Fe_2O(O_2CR)_2]^{2\oplus}$ cores of hemerythrin (Hr), ribonucleotide reductase (RR), and a model complex.
a) Structural features [34, 57, 59].

	AzidometmyoHr	RR	$[Fe_2O(O_2CCH_3)_2(HBpz_3)_2]$ **2b**
d(Fe-$O_{\mu\text{-oxo}}$) [Å]	1.80, 1.77	1.78	1.784

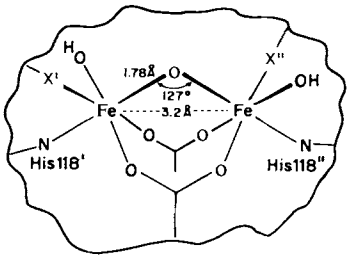

Fig. 8. Postulated structure [61] for the diiron center of RR, based on information provided in Refs. [57-62]. N represents a histidine nitrogen atom, OH, a hydroxide anion, and X, an unassigned ligand. Ligands from different subunits are designated by superscripts (′ and ″) (after Ref. [61]).

Very little is known about the role of the oxo-bridged diiron(III) center in the function of RR. Removal of iron by prolonged dialysis against chelating agents inactivates the enzyme and destroys the ESR signal of the tyrosine free radical. Both the enzymatic activity and the ESR signal can be restored upon addition of iron(II) in the presence of O_2.[49] It has been suggested that nucleotide phosphate groups might bind the binuclear $[Fe_2O]^{4\oplus}$ core, by analogy to the chemistry of model compounds,[63] but no experiments bearing on this point have been carried out. Establishing the role of iron in the catalytic function of RR is clearly an important objective. Further discussion of the inhibition of the enzyme by chelators, redox agents, or hydroxyurea, the role of such agents in chemotherapy, and other details about the formation of the tyrosine radical is available.[48,49,61]

2.3. Methane Monooxygenase

Methanotrophic bacteria, which utilize methane as their sole carbon and energy source, oxidize methane to methanol, formaldehyde, formate, and eventually carbon dioxide.[10] The initial oxidation to methanol has been shown for *Methylococcus capsulatus* (Bath) to be catalyzed by a

multicomponent methane monooxygenase (MMO). Component A of this enzyme system is comprised of three subunits, α, β, and γ, having molecular weights of 54000, 42000, and 17000, respectively, with the native protein having the stoichiometry $\alpha_2\beta_2\gamma_2$.[12] The active site of the enzyme appears to consist of a binuclear iron center capable of accessing the redox states [Fe^{II},Fe^{II}], [Fe^{II},Fe^{III}], and [Fe^{III},Fe^{III}] with midpoint potentials of -25 mV and $+350$ mV, respectively.[64] ESR studies[64] of the mixed-valence state revealed a signal showing principal g values of $g_z = 1.78$, $g_y = 1.88$, $g_x = 1.95$, values similar to those reported for semimet Hr. The ESR study also revealed a broad free radical signal at $g = 2.011$ with some partly resolved hyperfine structure. Very recent iron EXAFS data on semimet component A reveal an Fe–Fe distance of 3.41 Å and no short Fe–$O_{\mu\text{-oxo}}$ bond.[65] These results suggest that a binuclear iron core functions to promote the oxidation of methane to methanol in MMO, although considerably more work is required to establish its structure and role in the catalytic mechanism.

That Nature may have chosen a binuclear iron center to catalyze both the reduction of the hydroxyl group in ribonucleotides (RR) and oxidation of alkanes to alcohols (MMO) may be no coincidence. The latter reaction, the oxidation of saturated hydrocarbons, is of considerable industrial interest.[22]

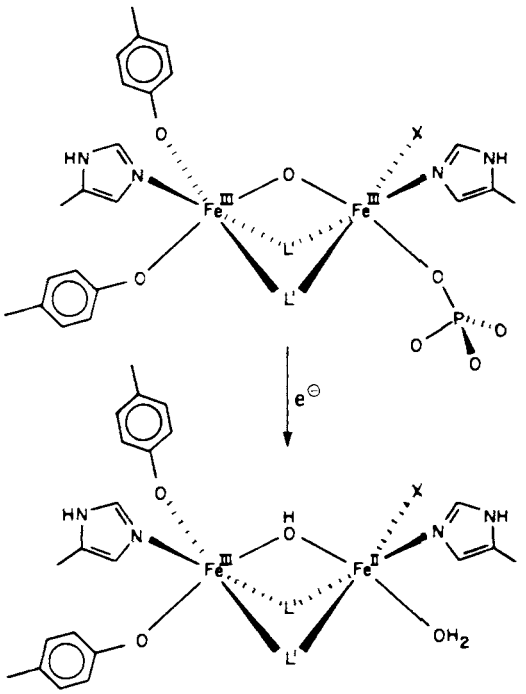

Fig. 9. Proposed structures for the oxidized, purple (top) and reduced, pink (bottom) forms of purple acid phosphatases (after Ref. [67]). L' and X are unidentified.

2.4. Purple Acid Phosphatases (Uteroferrin)

These enzymes have been isolated from a variety of microbial, plant, and animal sources. They occur in a purple ($\lambda_{max} = 550$–575 nm), catalytically inactive diiron(III) form and an enzymatically active, mixed-valence pink ($\lambda_{max} = 505$–515 nm) diiron(II,III) form.[9] Although the true biological function of the purple acid phosphatases is unknown, they catalyze the dephosphorylation of phosphoproteins and nucleotides and are assayed by their ability to hydrolyze *p*-nitrophenyl phosphate to *p*-nitrophenol and inorganic phosphate. The magnetic and ESR properties of the mixed-valence form of the enzymes obtained from beef spleen and porcine uterine fluid (uteroferrin) resemble those of semimet Hr. As a consequence, it has been suggested that the $[Fe_2O]^{3\oplus}$ core might be present in these enzymes.[66,67] From resonance Raman and ^{1}H-NMR spectroscopy, it is known that tyrosine ligands are coordinated to the binuclear iron center[67,68] at the ferric site in the mixed-valence form.[69] A tightly bound phosphate group has also been found for purple acid phosphatase (PAP), but there is presently some controversy over whether or not addition of phosphate to the reduced form is accompanied by rapid oxidation.[66,70] Recent X-ray absorption studies of this enzyme reveal an Fe···Fe distance of 3.00 Å, consistent with a bridged binuclear iron center, Fe–$O_{tyrosine}$ linkages of 1.8–1.9 Å, which prohibit positive identification of Fe–$O_{\mu\text{-oxo}}$ linkages, and an Fe···P distance of 3.06 Å assigned to a monodentate phosphate ligand.[71] From this information, the structures shown in Figure 9 have been proposed for the binuclear iron center in PAP.[67] Further work is required, however, to verify this assignment.

2.5. Ferritin

Ferritin (Ft) is a protein found in bacteria, plants, and animals. Its functions are to store iron, which it does in the form of a polyiron oxo aggregate, and to detoxify and recycle iron.[13,72,73] A related iron-storage protein is hemosiderin,[74] isolated as insoluble granules believed to arise from ferritin breakdown. Less is known about hemosiderin than Ft. Much of our knowledge about the latter is based on the X-ray crystal structure of horse spleen apoferritin, which consists of 24 subunits arranged in a hollow shell of crystallographically imposed 432 symmetry (Fig. 10). The resulting molecule of apoFt is roughly spherical with an inner diameter of 80 Å; it can store up to 4500 iron atoms. Eight hydrophilic and six hydrophobic channels are located respectively along molecular threefold and fourfold symmetry axes. The funnel-shaped hydrophilic channels, 3–4 Å wide at the protein interior and broadening outward towards the protein surface, are lined with three aspartate and three glutamate residues. Suggestions that these channels are the entry and departure routes for iron have been supported by probes with various paramagnetic metal ions.[75,76] Peptide-specific antibodies have recently been used to demonstrate that iron probably enters the core via the threefold channels and is released via the fourfold channels.[77] Details of the loading and unloading of iron from the Ft core in vivo are unknown, however, and it is even uncertain whether Fe^{II}, Fe^{III} or some combination of the two is a kinetically competent species for this process.[78]

Although crystallographic information about ferritin is available, less is known about how the iron atoms are arranged inside the hollow protein core. Five characteristic

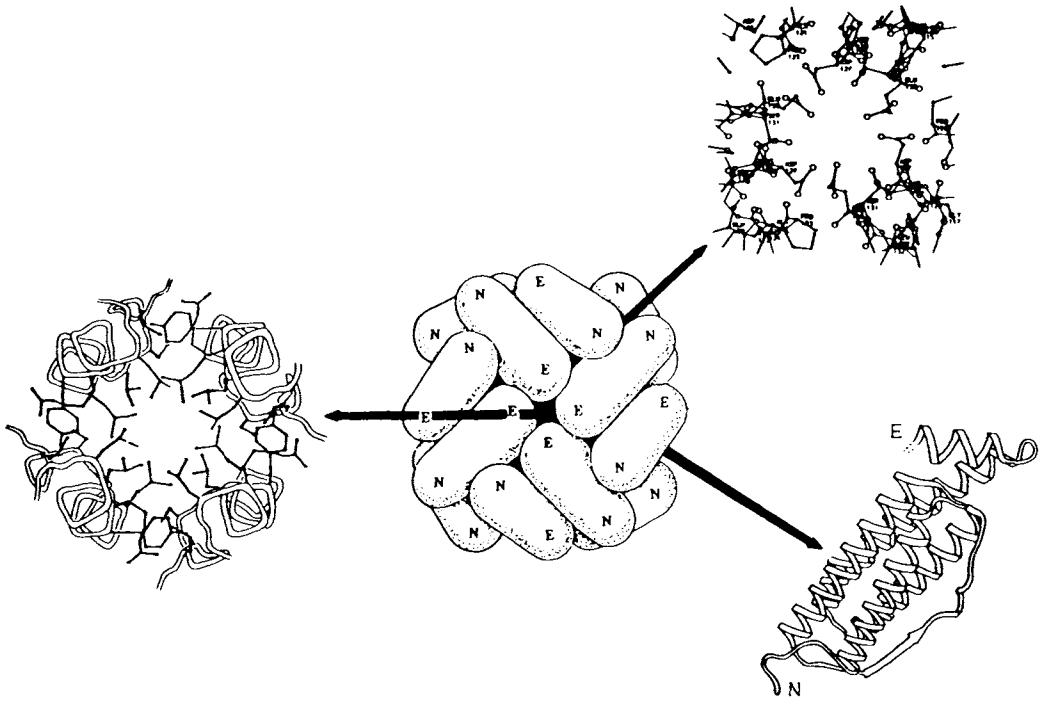

Fig. 10. Structural features of apoFt. In the center is shown the gross quaternary structure of the protein and more details on the fourfold channels (left-hand side), threefold channels (upper right), and the subunits (lower right) are also illustrated (reproduced by permission from Ref. [75]).

electron or X-ray powder diffraction rings have been observed which resemble those of the mineral ferrihydrite.[28,29] Ferrihydrite has the composition $5\,Fe_2O_3 \cdot 9\,H_2O$, but details of its structure are obscure.[27] From spectroscopic data,[79,80] it seems clear that iron in ferritin is present as polymeric (Fe-Fe distance ≈ 3.5 Å), octahedrally coordinated Fe^{III}, with oxygen donor atoms contributed by one or more of the ligands $O^{2\ominus}$, $OH^{\ominus}$, H_2O, and possibly inorganic phosphate (P_i). Variable amounts of phosphate have been found to be associated with the iron core in Ft, and early workers postulated the formula $[\{FeO(OH)\}_8\{FeO(H_2PO_4)\}]$.[81] In human thalassemic ferritin, the Fe/P_i ratio is 21.0 : 1 and, as this ratio increases, the core exhibits more crystallinity.[82] Bacterial ferritin has significantly higher amounts of inorganic phosphate, the Fe/P_i ratio being measured at 1.71 : 1.[82] Estimates of the crystallite sizes of ferritin cores range from 40 to 80 Å.[29] The variability in size, shape, and composition of the iron(III) oxo-hydroxo-phosphato species that constitute the ferritin core is perhaps not surprising in view of the function of the protein. Rapid access to and egress from the hollow core[83] might be better facilitated by a sponge-like structure comprised of small aggregates of iron atoms than by an extended three-dimensional crystalline matrix.

2.6. Other Polyiron Oxo Centers in Biology

Magnetotactic bacteria are aquatic microorganisms that orient and swim along magnetic field lines.[84] They contain crystals of magnetite, Fe_3O_4, with typical dimensions of 400 to 1200 Å, the magnetic moment of which is large enough to facilitate their orientation in the earth's magnetic field.[85] They tend to migrate downward towards the North or South Pole, depending upon the hemisphere in which they are found, ostensibly to avoid oxygen-rich surface waters. In the organism *Aquaspirillum magnetotacticum*, the iron comprises more than 2% of the total dry weight of the cell. Wrapped in a membrane, the Fe_3O_4 particles are called magnetosomes. Mössbauer spectroscopic studies revealed the presence of octahedral high-spin Fe^{II} and both tetrahedral and octahedral Fe^{III}, consistent with the inverse spinel structure of magnetite.

The presence of magnetite in magnetotactic bacteria and the less well defined ferrihydrite in biological organisms provides examples of what has been termed the biomineralization[86] of iron oxides.[87] Another illustration of this phenomenon is the deposition of the iron(III) mineral goethite, α-FeO(OH), in the teeth of marine mollusks known as limpets.[88] Magnetite also occurs in the radula teeth of chitons, in homing pigeons,[89] and in honey bees,[90] where it may also serve as a homing mechanism.[89] The diversity of structures and functions of oxo-bridged polyiron centers in biology is fascinating, and its attraction to the bioinorganic chemical community is understandable.

3. Oxo-Bridged Diiron(III) Cores

3.1. The Hydrolytic Chemistry of Iron(III)

The hydrolysis of iron(III) salts in dilute aqueous solutions has been extensively studied.[15,26,91] Equilibrium constants corresponding to the formation of some of the

known species are given in Figure 2. As the pH is raised from very acidic to conditions near neutrality, binuclear and then species of higher nuclearity form within milliseconds. At low pH, the major binuclear complex is $[(H_2O)_4Fe(OH)_2Fe(OH_2)_4]^{4\oplus}$, which contains the di(μ-hydroxo)diiron(III) core. In 0.2 M NaCl, needle-shaped polynuclears form, which laser light-scattering methods have shown to be rotational ellipsoids that achieve a polynuclearity of 21000 and 400–500 Å lengths within several days at 25 °C.[92] As the pH is raised into the neutral region, $Fe(OH)_3$ or $FeO(OH)\cdot H_2O$ precipitates. It is therefore clear that hydrated ferric ion is an unrealistic source of Fe^{III} at physiological pH in biological systems, and that either hydrated ferrous ion or a complexed form of Fe^{III}, such as found in microbial iron transport compounds called siderophores,[93] will be required.

3.2. Early Studies of the (μ-Oxo)diiron(III) Center

In the presence of chelating agents, discrete oxo-bridged polyiron complexes can be crystallized and structurally characterized. An early example was [(hedta)FeOFe(hedta)]$^{2\ominus}$, where hedta = (*N*-hydroxyethyl)ethylenediaminetriacetate, in which the two ferric centers are connected by an oxo bridge (Fe-O-Fe angle = 165.0°).[94] Numerous binuclear oxo-bridged iron(III) complexes were soon available, and their electronic structures and magnetic exchange interactions were thoroughly investigated.[26] Close scrutiny of the properties of these (μ-oxo)diiron(III) complexes revealed, however, that despite their ready synthesis by reaction (a), their physical properties did not match in

$$2[L'Fe(OH_2)]^{3\ominus} + 2OH^{\ominus} \longrightarrow [L'FeOFeL']^{4\oplus} + 3H_2O \qquad (a)$$

detail those of the diiron(III) center in the oxidized forms of hemerythrin. A critical ingredient was missing, namely, the two additional bridging carboxylate ligands.

3.3. Accurate Models for the Hemerythrin Core

Significant progress was made in the synthesis of models for azidomet Hr in 1983 by two groups working independently.[57,58] As shown in reactions (b) and (c), the (μ-oxo)bis(μ-carboxylato)diiron(III) core readily assembles from mononuclear ferric salts in the presence of water, an alkyl carboxylate salt, and a facially coordinating tridentate nitrogen donor ligand, hydrotris(1-pyrazolyl)borate ($HBpz_3^{\ominus}$) or 1,4,7-triazacyclononane (tacn) (Fig. 11). The benzoate-bridged analogue **2d**, which could not be synthesized by reaction (b), was subsequently obtained by using $(Et_4N)_2[Fe_2OCl_6]$, according to reaction (d).[57] This synthesis and several others discussed below (cf. reactions (k) and (l) in Section 5.1) have been greatly facilitated by the use of $(Et_4N)_2[Fe_2OCl_6]$, containing the "preformed" (μ-oxo)diiron(III) synthon.[95] The $[Fe_2O(O_2CR)_2]^{2\oplus}$ unit appears to be exceptionally stable, however, and can be assembled even by using basic iron acetate as the source of metal.[96] Structurally related $[M_2O(O_2CR)_2]^{n\oplus}$ centers have recently been reported for $M = Ti^{IV}$,[97] V^{III},[98] Mn^{III},[99,100] and Os^{IV}.[101]

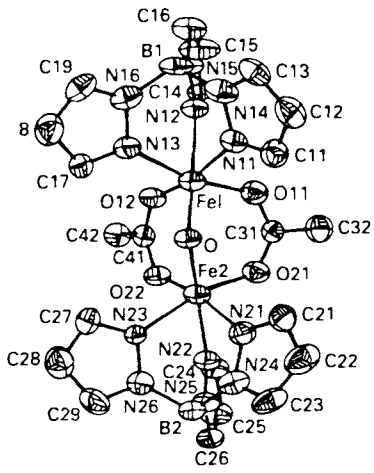
The simple binuclear iron(III) complexes are excellent models for the azidomet Hr core, as demonstrated by comparing their physical properties with those of the protein.[57,58,102] Single-crystal X-ray diffraction studies of complexes **2** and **3** revealed geometries (Fig. 12) nearly congruent with those of the azidomet forms of Hr and myoHr (Fig. 4). A significant feature of these structures is the short Fe-$O_{\mu\text{-oxo}}$ bond (ca. 1.78 Å) compared with the Fe-O distances of ca. 2.05 Å to the bridging carboxylate ligands. As a consequence, the Fe-N bond *trans* to the Fe-$O_{\mu\text{-oxo}}$ bond is lengthened (2.20 Å, compared to 2.15 Å for the *cis* Fe-N bonds), and the quadrupole splitting parameter in the Mössbauer spectrum is 1.6 mm s^{-1}. Moreover, the short Fe-$O_{\mu\text{-oxo}}$ bridge bond mediates substantial antiferromagnetic spin exchange between the two high-spin ferric centers, with coupling constants J in the range -115 to -135 cm^{-1} for the protein and model compounds. The residual paramagnetism of the complex at ambient temper-



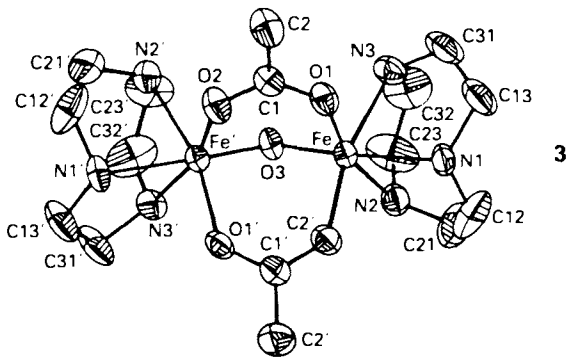


Fig. 12. Crystal structure of two model compounds, **2b** and **3**, for the active center of met Hr (cf. Fig. 4) (reproduced by permission from Ref. [30]).

ature, $\mu_{eff}/Fe \approx 1.71\,\mu_B$, gives rise to broad, characteristic ^{1}H-NMR resonances that are isotropically shifted. A resonance at $\delta = 10.5$ ppm in **2b**, assigned to the acetate methyl protons, has a counterpart in the ^{1}H-NMR spectrum of azidomet Hr which could, by analogy, be identified as broad, unresolved aspartate β-CH_2 and glutamate γ-CH_2 proton resonances.[39] Resonance Raman and IR spectroscopic studies of **2** and a derivative, in which ^{18}O had been exchanged into the bridging position, identified symmetric (ν_s) and asymmetric (ν_{as}) stretching vibrations of the $[Fe_2O]^{4\oplus}$ core at 528 and 751 cm^{-1}, respectively.[57, 103] These values are similar to those of azidomet Hr, 507 and 770 cm^{-1} (Table 2). A rich pattern of overtones has been observed upon excitation of the model complex with 4067-Å laser light.[103] Although the optical spectra (UV/VIS, near IR) of the models and proteins are in good agreement and some tentative assignments have been made,[57] the electronic spectroscopic analysis of the $[Fe_2O(O_2CR)_2]^{2\oplus}$ chromophore is not yet completely satisfactory.

An excellent model for the reduced, deoxy form of hemerythrin has been prepared according to reaction (e).[104, 105] The success of this synthesis is due at least in

$$Fe(ClO_4)_2 \cdot 6H_2O + 2\,Me_3tacn \xrightarrow[Ar]{CH_3OH} \xrightarrow[Ar]{2\,NaO_2CCH_3} [Fe_2(OH)(O_2CCH_3)_2(Me_3tacn)_2](ClO_4) \cdot H_2O \quad (e)$$

4·$ClO_4^{\ominus}$·H_2O

part to the fact that the ligand Me_3tacn (Fig. 11) is too sterically encumbered to form a mononuclear bis(chelate) iron(II) complex. The structure of **4** is similar to that of **3** (cf. Fig. 12), except that the Fe-O bond length to the bridging oxygen atom has increased to 1.99 Å, owing largely to protonation and, secondarily, to the lower charge at the metal center. Consequently, the *trans* Fe-N bond is no longer lengthened and the spin exchange coupling constant is diminished to $J = -13$ cm^{-1}.[105] This value is in good agreement with that estimated by MCD and ESR ($-13 > J > -38$ cm^{-1})[40] and by ^{1}H-NMR ($J = -15 \pm 2$ cm^{-1})[39] studies of deoxy Hr. Additional changes in the Mössbauer and electronic spectra of the reduced diiron(II), compared to the oxidized diiron(III), model compound parallel those observed in going from azidomet Hr to deoxy Hr.

Although semimet, mixed-valence diiron(II,III) forms of hemerythrin are known, it has not yet been possible to isolate and fully characterize the (μ-oxo)bis(μ-acetato)diiron(II,III) core in a model compound. Such a mixed-valence species, $[Fe_2O(O_2CCH_3)_2(Me_3tacn)_2]^{\oplus}$, has been generated electrochemically in dilute solution, however, as revealed by ESR spectroscopy.[105] Reaction (f) illustrates

$$[Fe_2(OH)(O_2CCH_3)_2(Me_3tacn)_2]^{\oplus} \xrightleftharpoons[Et_3N]{-0.29\ V} Fe^{II}Fe^{III}\ \text{species} \quad (f)$$

4

$$\xrightleftharpoons{-0.37\ V} [Fe_2O(O_2CCH_3)_2(Me_3tacn)_2]^{2\oplus}$$

5

that the $Fe^{II}Fe^{III}$ center can be obtained both from diiron(II,II) and diiron(III,III) precursors, **4** and **5**, respectively, but the redox potentials (vs. SCE) reveal that the mixed-valence species is unstable with respect to disproportionation. This behavior parallels that of the Hr proteins, the semimet forms of which also disproportionate. A small amount of triethylamine was added in reaction (f) to simplify the cyclic voltammetric waves by converting hydroxo- into oxo-bridged mixed-valence diiron(I,III) species. In the absence of added base, two closely spaced cathodic peaks appear following the oxidation of **4**. These peaks were assigned to reduction of $Fe^{II}Fe^{III}$ oxo- and hydroxo-bridged species. Controlled-potential electrolysis of **5** produced a reasonably stable species after addition of one electron. ESR studies at 9.6 K of the product revealed features at $g < 2.0$ that integrated to 65% of the value expected for one unpaired spin. The synthesis and X-ray crystal structure determination of an isolated mixed-valence model complex containing the $[Fe_2O(O_2CR)_2]^{\oplus}$ or $[Fe_2(OH)(O_2CR)_2]^{2\oplus}$ core remains an important, if formidable, objective. Two mixed-valence, phenoxo-bridged diiron(II,III) complexes have been characterized.[106, 107]

3.4. Relevance of Models to Ribonucleotide Reductase

A detailed comparison of the Mössbauer spectral parameters, magnetic spin exchange coupling constants, UV/VIS spectroscopic properties, Fe-O-Fe symmetric stretching frequency, and EXAFS spectra of ribonucleotide re-

ductase subunit B2 and the complexes **2** (Table 2) reveals many similarities, strongly suggesting that the (μ-oxo)bis(μ-carboxylato)diiron(III) core occurs in the enzyme. The presence of the bridging carboxylate groups was questioned at an early stage since, unlike Hr, which is known to have an $[Fe_2O(O_2CR)_2]^{2\oplus}$ core structure, RR readily exchanges ^{18}O into the bridging position upon equilibration with $H_2{}^{18}O$.[54] Studies with the model compounds **2** revealed ^{18}O exchange to occur at a rate comparable to that of RR, however.[57] This result is thus consistent with the triply bridged $[Fe_2O(O_2CR)_2]^{2\oplus}$ core model for RR and suggests that the failure of Hr to exchange ^{18}O into its bridging site may be due to the inaccessibility to water of the bimetallic center in that protein. A definitive structural characterization of the B2 subunit of RR to high resolution by X-ray diffraction methods is awaited with interest.

3.5. Chemistry of Diiron Centers: Possible Functional Significance

Thus far, we have compared only the physical and geometric properties of molecules containing the $[Fe_2O(O_2CR)_2]^{n\oplus}$ or $[Fe_2(OH)(O_2CR)_2]^{m\oplus}$ core with those of the proteins. In order for model chemistry to have functional significance, the reaction chemistry of the metalloprotein cores must be reproduced. In the case of hemerythrin models, this requirement includes reversible redox (electron transfer) chemistry and, most importantly, reversible binding of O_2. Additional reactions of the oxo-bridged diiron cores of biological relevance would be catalysis of the reduction of diols to monoalcohols, oxidation of hydrocarbons, and phosphate ester hydrolysis. Ligand substitution and exchange reactions are also of interest, for they help to define the parameters that control substrate molecule access to oxo-bridged diiron centers in proteins.

As previously illustrated by reaction (f), the model complexes **4** and **5** can be interconverted electrochemically. Cyclic voltammetric studies of **2b**, however, revealed decomposition to the mononuclear Fe^{II} complex $[Fe(HBpz_3)_2]$ **6**.[57] Consequently, a desirable design feature for achieving reversible electron transfer involving the $[Fe_2O(O_2CR)_2]^{2\oplus}$ core is to use ligands that either cannot form $Fe^{II}L_2$ complexes, such as the sterically bulky Me_3tacn molecule, or have a framework that ties together the triply bridged binuclear iron center, rendering it kinetically inaccessible to redox-activated decomposition. Two published attempts to achieve the latter objective have not been successful.[96, 108]

The (μ-oxo)bis(μ-carboxylato)diiron(III) core can be reversibly protonated, as shown in reaction (g), which was

$$\underset{\textbf{2b}}{[Fe_2O(O_2CCH_3)_2(HBpz_3)_2]} \xrightarrow[Et_3N]{HBF_4} \underset{\textbf{7}}{[Fe_2(OH)(O_2CCH_3)_2(HBpz_3)_2]^{\oplus}} \quad (g)$$

carried out in CH_2Cl_2/Et_2O solutions.[109] Table 3 compares the structural, magnetic, and spectroscopic properties of the diiron(III) cores in these oxo- and hydroxo-bridged complexes.[57, 109, 110] Protonation of the bridging oxygen atom results in elongation of the two Fe-O bridge bonds by ca. 0.17 Å. The corresponding reduction in Fe-O bridge bond order eliminates the structural *trans* influence on the pyrazole ring nitrogen atom *trans* to the bridging oxygen atom, and substantially diminishes the antiferromagnetic exchange interaction. The latter leads to larger isotropic shifts in the ^{1}H-NMR spectrum, while the former, which produces a much more symmetric electric field gradient at the iron atoms, markedly reduces the quadrupole splitting parameter in the Mössbauer spectrum. All of these differences serve to validate the assignment of the binuclear centers in oxidized forms of met Hr and RR as μ-oxo, rather than μ-hydroxo, carboxylate-bridged diiron(III) units.

Table 3. Comparison of structural, magnetic, and spectroscopic properties of μ-oxo and μ-hydroxo diiron(III) complexes [57, 109, 110].

Property	**2b**	**7**

It is instructive to compare the geometric features of four bridged binuclear iron complexes containing $[Fe_2O(O_2CR)_2]^{2\oplus}$, $[Fe_2(OH)(O_2CR)_2]^{3\oplus}$, or $[Fe_2(OH)(O_2CR)_2]^{\oplus}$ centers (Table 4). Protonation of the (μ-oxo)diiron(III) unit (**2b**→**7**) lengthens the bridge bonds by ca. 0.17 Å, but reduction of $[Fe_2(OH)(O_2CR)_2]^{3\oplus}$ to $[Fe_2(OH)(O_2CR)_2]^{\oplus}$ increases the bridge bond lengths by only an additional few hundredths of an angstrom (cf. **7** and **4**). Let us now consider the reversible binding of O_2 by the hemerythrin core, as represented in Figure 5. Formation of a hydrogen bond in oxy Hr between the proton on the hydroperoxy ligand and the μ-oxo oxygen atom will tend to increase the Fe-O bridge bond length from its 1.8 Å value in metazido Hr towards the ca. 1.95 Å value expected for the deoxy form of the protein. In the absence of

Table 4. Comparison of Fe-$O_{\mu\text{-oxo}}$ bond lengths (average) [Å] and Fe-$O_{\mu\text{-oxo}}$-Fe angles [°] for hemerythrin model compounds [a].

Compound	d (Fe–μ-O)	Fe-μ-O-Fe-angle

5	1.800(3)	113.2(2)
7	1.956(4)	123.1(2)
4	1.987(8)	119.7(1)

[a] Data from Refs. [57, 105, 109].

models containing the $[N_3FeO(O_2CR)_2FeN_2(O_2H)]^{\oplus}$ moiety, the Fe-O bridge bond lengths in such an internally hydrogen-bonded complex are unknown. Nevertheless, the existing models suggest such hydrogen bonding would minimize the Franck-Condon reorganizational barrier to electron transfer involved in shortening the Fe-O bridge bond during oxidative addition of the bimetallic center from diiron(II) in deoxy Hr to diiron(III) in oxy Hr (Fig. 5).

Protonation of the μ-oxo group in **2** also facilitates exchange of the bridging ligands.[63] As shown in reactions (h)-(j), the bridging carboxylate ligands exchange with perdeuterioacetic and with diphenyl phosphoric acid. Reactions (h) and (i) were readily followed by

$$\mathbf{2b} + CD_3CO_2D(\text{excess}) \xrightarrow{CD_2Cl_2} [Fe_2O(O_2CCD_3)_2(HBpz_3)_2] \quad (h)$$

$$7 + CD_3CO_2D(\text{excess}) \xrightarrow{CD_3CN} [Fe_2(OD)(O_2CCD_3)_2(HBpz_3)_2]^{\oplus} \quad (i)$$

$$\mathbf{2b} + 2(PhO)_2PO_2H \xrightarrow{CH_2Cl_2} [Fe_2O\{O_2P(OPh)_2\}_2(HBpz_3)_2] + 2CH_3CO_2H \quad (j)$$

8

^{1}H-NMR spectroscopy. Protonation of a bridging ligand, probably the μ-oxo group, is necessary for exchange to occur, since $[Fe_2(OH)(O_2CCH_3)_2(HBpz_3)_2]^{\oplus}$ **7** exchanges its bridging acetates with $(Et_4N)(O_2CCH_3)$, whereas $[Fe_2O(O_2CCH_3)_2(HBpz_3)_2]$ **2b** does not.[110] Protonation might also facilitate ^{18}O exchange into the bridging position, but information on this point is not yet available.

The diphenyl phosphate-bridged product of reaction (j), **8**, has been isolated and structurally characterized (Fig. 13).[63] The slightly larger bite distance of the bridging $(PhO)_2PO_2^{\ominus}$ ligands in this complex (2.576(7) Å, compared to 2.236(3) Å for the bridging acetate groups in **2b**[57]) leads to longer $Fe-O_{\mu\text{-oxo}}$ and Fe···Fe distances. As a consequence, the antiferromagnetic exchange interaction constant is less negative in **8** ($J = -98\ cm^{-1}$). The sensitivity of the J values to even minor changes in the geometry of the $[Fe_2O]^{4\oplus}$ core is of interest in interpreting the magnetic properties of Hr, RR, and related proteins. Exchange reactions of the $[Fe_2O(O_2CR)_2]^{2\oplus}$ core that lead to new phosphate ester- and carboxylate-bridged complexes are potentially useful as models for naturally occurring iron-phosphate interactions in biology.

Attempts to synthesize asymmetric diiron complexes of the kind $[L^3FeO(O_2CR)_2FeL^2]$, where L^3 is a tridentate and L^2 a bidentate nitrogen donor ligand, as functional models for Hr, RR, or MMO have led to tetranuclear compounds containing the $[Fe_4O_2]^{8\oplus}$ core. This chemistry is further discussed in Section 5.2. An unsymmetrical (μ-oxo)diiron(III) complex $[N_5Fe-O-FeCl_3]^{\oplus}$, where N_5 = 2-{*N*-(2-benzimidazolylmethyl)-*N'*-{2-[bis(2-benzimidazolylmethyl)-amino]ethyl}amino}ethanol (Fig. 11), has been prepared and structurally characterized.[111] Quasi-reversible cyclic voltammetric formation of the mixed-valence diiron(II,III) form was mentioned. Several other binuclear mixed-valence iron(II,III) complexes with a variety of ligands have recently been reported,[106,107,112] but their relevance to uteroferrin and semimet Hr is uncertain. Also of interest is the discovery that phenoxo-bridged diiron(III) complexes can serve as catalysts for catechol oxidation[113] and olefin epoxidation.[114] Detailed mechanisms and the relevance of this chemistry to MMO or RR remain to be established.

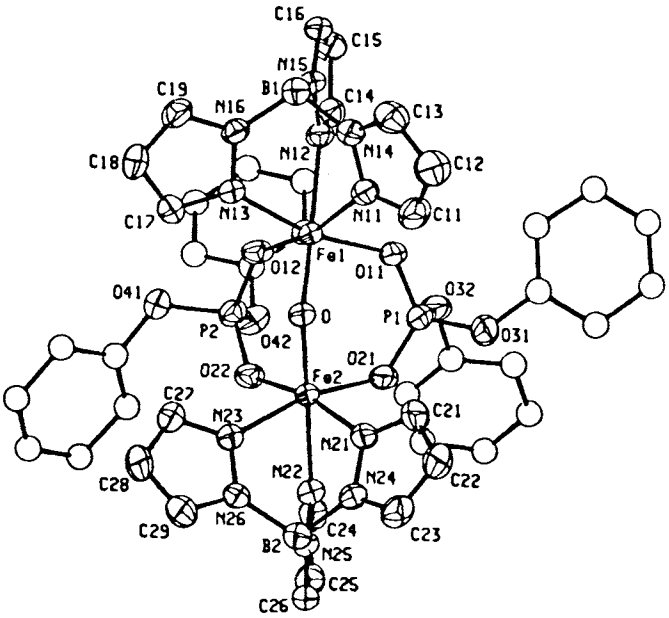

Fig. 13. Structure of **8** (reproduced by permission from Ref. [63]).

4. Oxo-Bridged Triiron(III) Systems

4.1. Basic Iron Acetates; An Equilateral Triangle of Iron Atoms[115]

Solutions of ferric ions in the presence of carboxylate salts have been known for over a century to form stable (μ_3-oxo)hexakis(μ-carboxylato)triiron(III) complexes, referred to as basic iron acetates.[16] As depicted in Figure 3, the structures of these complexes consist of an equilateral triangle of iron atoms with a triply bridging oxygen atom at its center, two bidentate bridging carboxylate ligands along each edge of the triangle, and one centripetally directed terminal ligand (L') completing the octahedral coordination sphere of each metal atom. A variety of mixed-valence, especially $Fe_2^{III}Fe^{II}$, species as well as heterometallic and sulfate-bridged analogues are also known.[23,24] In several cases, the bridging carboxylate group is part of an amino acid.[116,117] The magnetic properties of $[Fe_3O(O_2CR)_6L'_3]^{\oplus}$ complexes were extensively investigated long before their structures were known.[18,19] The three high-spin d^5 iron(III) atoms are antiferromagnetically coupled, giving rise to a total ground-state spin of $S_T = 1/2$ which determines their magnetic properties at 4.2 K. The spin exchange coupling constants J fall in the range -20 to $-40\ cm^{-1}$.[115] The magnitudes of these coupling constants are substantially smaller than observed for the binuclear $[Fe_2O]^{4\oplus}$ complexes, but larger than for

$[Fe_2(OH)(O_2CCH_3)_2(HBpz_3)_2]^{\oplus}$ **7**. The proton thus appears to be more effective at withdrawing electron density from Fe-$O_{\mu\text{-oxo}}$ bonds than a third iron(III) atom. Antiferromagnetic exchange interactions between iron(III) atoms linked both by a bridging oxygen atom and by other bridging ligands are qualitatively correlated with the Fe-$O_{\mu\text{-oxo}}$ distances,[118] although a theoretical model for this behavior remains to be developed. Vibrational spectroscopic studies of $[Fe_3O(O_2CCH_3)_6(py)_3]^{\oplus}$ and its ^{18}O and [D_5]pyridine isotopically substituted derivatives have identified in-plane ν_{as} and out-of-plane δ_s IR bands characteristic of the $[Fe_3O]^{7\oplus}$ core.[119]

Apart from structural, magnetic, and spectroscopic correlations, there has been considerable interest in mixed-valence derivatives of the basic iron acetates.[24,115] In particular, $[Fe_2^{III}Fe^{II}O(O_2CCH_3)_6L'_3]$ complexes, where L' = H_2O, pyridine, or a substituted pyridine, exhibit temperature-dependent internal electron transfer rates in the solid state. These intramolecular electron transfer reactions can be substantially influenced by dynamic disorder phenomena of the ligands L', counterions, and/or solvate molecules in the crystal lattice.[24]

4.2. An Isosceles Triangle of Iron Atoms

Although the mixed-valence forms of the basic iron acetates show distortions from an equilateral towards an isosceles triangle of iron atoms, especially at low temperatures,[120] a much more dramatic deformation of this kind was recently discovered for the $[Fe_3O]^{7\oplus}$ core in $[Fe_3O(tieo)_2(O_2CPh)_2Cl_3]\cdot 2C_6H_6$, where tieoH is 1,1,2-tris(*N*-methyl-2-imidazolyl)ethanol (Fig. 11).[121] The structure of the complex (Fig. 14) is characterized by two short Fe-$O_{\mu\text{-oxo}}$ bridge bonds of 1.865(7) Å and one long one (2.067(6) Å), while the Fe-$O_{\mu\text{-oxo}}$-Fe bond angles are also very asymmetric. Their values are 159.1(3)° for Fe1-O3-Fe2 and 100.3(3)° and 100.5(3)° for Fe1-O3-Fe3 and Fe2-O3-Fe3, respectively. Magnetization and magnetic Mössbauer studies revealed the ground state of this unusual molecule to be $S_T = 5/2$, in contrast to the value of $S_T = 1/2$ for the symmetrically bridged $[Fe_3O]^{7\oplus}$ cores described in Section 4.1. Fits of the temperature-dependent magnetic susceptibility data to a theoretical expression for isotropic spin exchange in a trinuclear Fe^{III} cluster of C_{2v} symmetry gave coupling constants $J_{12} = -55(1)\ cm^{-1}$ and $J_{13} = J_{23} = -8.0(4)\ cm^{-1}$, where the subscripts refer to the iron atom labels given in Figure 14. These J values fit the correlation of spin exchange coupling constant with Fe-O bond distance[118] and readily explain the $S_T = 5/2$ ground state of the cluster. At 4.2 K, iron atoms Fe1 and Fe2 are magnetically coupled to form a diamagnetic (S = 0) pair, leaving the magnetically isolated third, high-spin Fe3 center to account for the ground-state spin. As the temperature is raised, the magnetic moment of the trinuclear system actually decreases, due to the fact that the first excited magnetic state has $S_T = 3/2$, reaching a minimum at 60 K, before increasing towards the maximum theoretical value expected for $S_T = 15/2$.

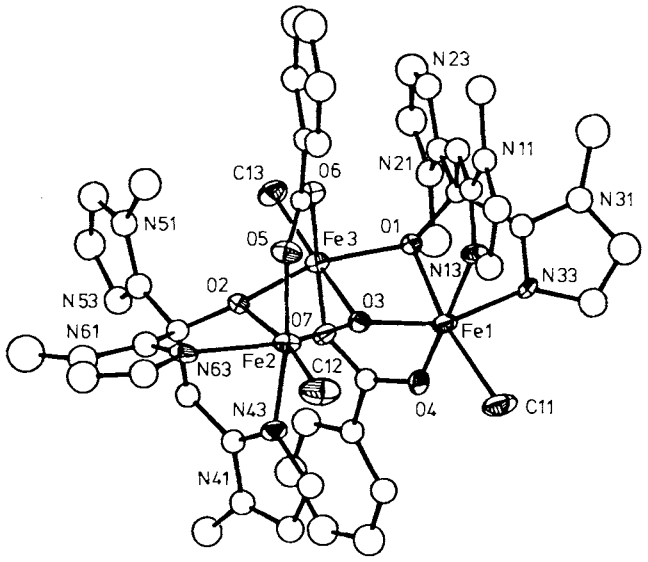

Fig. 14. Structure of $[Fe_3O(tieo)_2(O_2CPh)_2Cl_3]$ (reproduced by permission from Ref. [121]).

This example illustrates the importance of measuring the magnetic properties of polynuclear iron oxo centers over as wide a temperature range as possible, and of fitting the data to the proper theoretical model. Moreover, the unusual asymmetric $[Fe_3O]^{7\oplus}$ core, a topological isomer of the symmetric structure found in the basic iron acetates and their analogues, results from complexation by the new polyimidazole ligand, tieoH.

5. Oxo-Bridged Tetrairon(III) Complexes

5.1. Tetranuclear $[Fe_4O_2]^{8\oplus}$ Cores by Formal Dimerization of $[Fe_2O]^{4\oplus}$ Units

In order to explore chemistry of (μ-oxo)bis(μ-carboxylato)diiron(III) centers relevant to their functions in biology, it is desirable to have one or more terminal coordination sites available for ligand substitution. Attempts to achieve this goal by using KH_2Bpz_2 (Fig. 11) in place of $KHBpz_3$ in reaction (b) led instead to the novel tetranuclear complex **9** [reaction (k), R = Me, Ph], the structure of which is

$$2(Et_4N)_2[Fe_2OCl_6] + 7\,NaO_2CR + 2\,KH_2Bpz_2 \xrightarrow{MeCN} (Et_4N)[Fe_4O_2(O_2CR)_7(H_2Bpz_2)_2] + 7\,NaCl + 2\,KCl + 3\,Et_4NCl \quad \text{(k)}$$

$Et_4N \cdot$ **9**

shown in Figure 15 for R = Ph.[122] A manganese(III) analogue with seven bridging carboxylate ligands and bipyridine instead of dihydrobis(pyrazolyl)borate, $[Mn_4O_2(O_2CR)_7(bpy)_2]^{\oplus}$, has also been synthesized, attesting to the stability of the $[M_4O_2(O_2CR)_7L'_2]$ stoichiometry.[123]

A very similar $[Fe_4O_2]^{8\oplus}$ core was also obtained when bis(*N*-methyl-2-imidazolyl)methanol (bicoH, Fig. 11) was used in a parallel attempt to prepare functional models for oxo-bridged diiron(III) protein cores [reaction (l) and Fig. 16].[124] Although there are additional bridging ligands in **10**, complexes **9** and **10** have the same core structure, depicted in Scheme 1, where the curved lines represent car-

$$2(Et_4N)_2[Fe_2OCl_6] + 4\,NaO_2CPh + 4\,bicoH \xrightarrow[-2\,Et_3NHCl]{MeCN/Et_3N} [Fe_4O_2(bicoH)_2(bico)_2(O_2CPh)_4]Cl_2 + 4\,NaCl + 4\,Et_4NCl \quad (1)$$

10 · 2 Cl

boxylate ligands. This structure further illustrates the propensity of the μ-oxo ligand in the $[Fe_2O(O_2CR)_2]^{2\oplus}$ core to become triply bridging by coordination to a third iron(III) center. These reactions, to form tri- or tetranuclear aggregates, are formally depicted in Scheme 2.

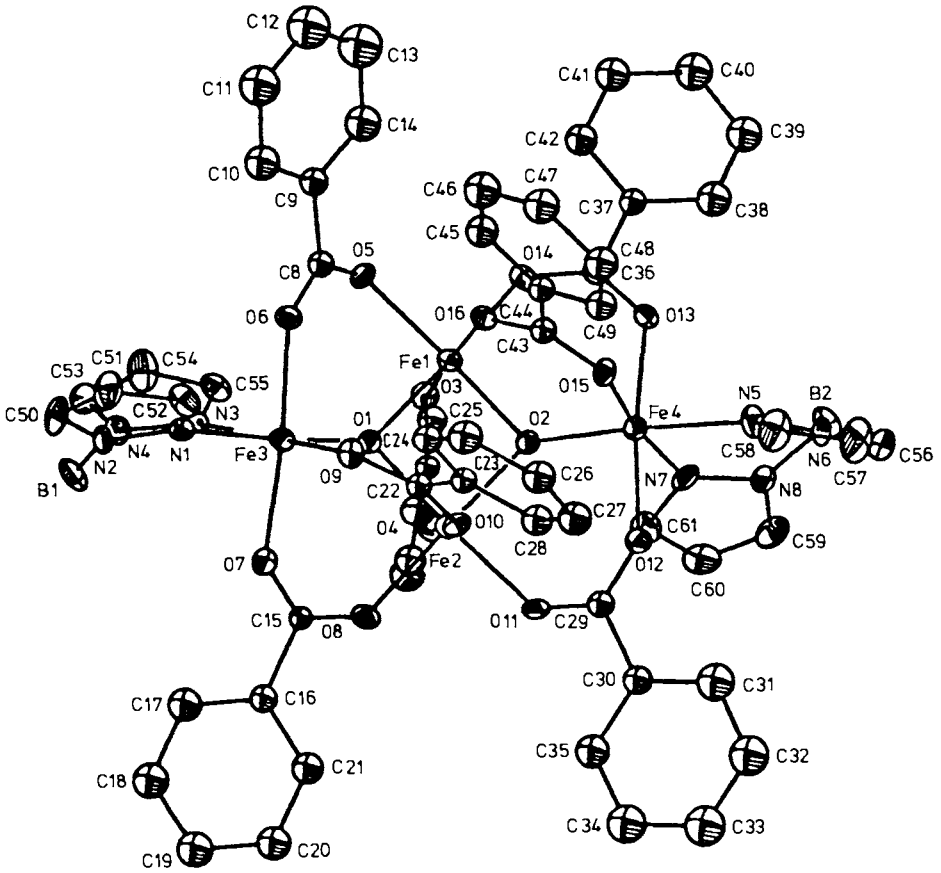

Fig. 15. Structure of **9**, R = Ph [122].

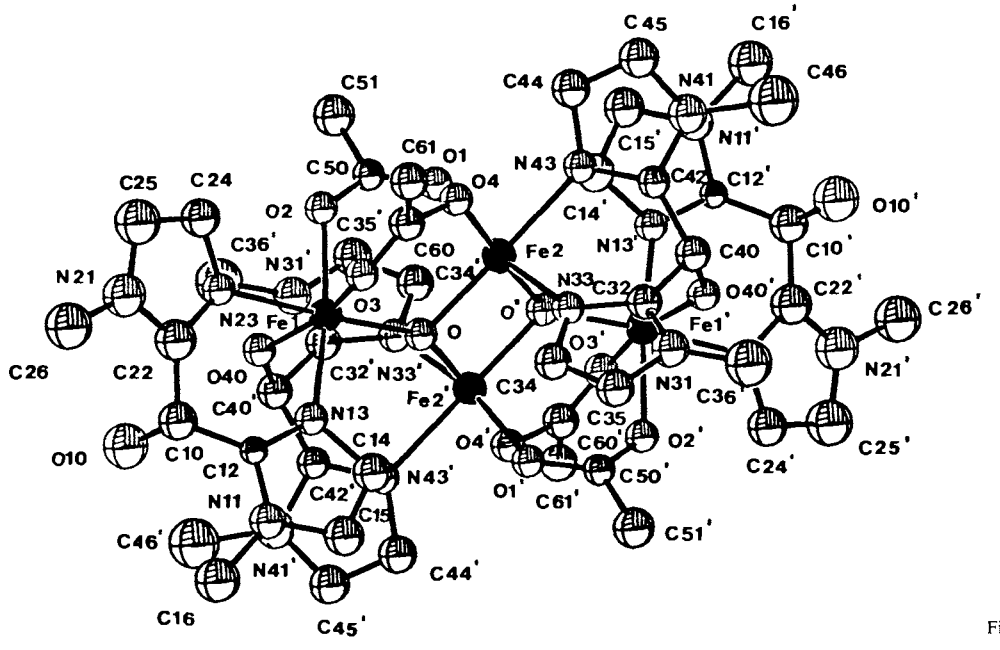

Fig. 16. Structure of **10** [124].

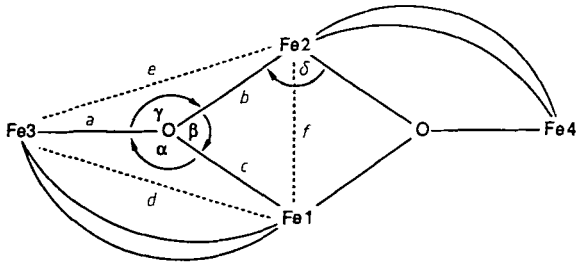
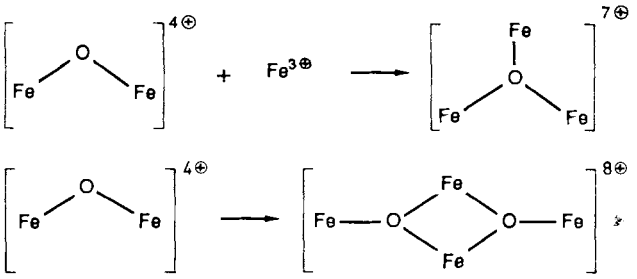


Scheme 1. Structure of the $[Fe_4O_2]^{8\oplus}$ core of **9** and **10**.



Scheme 2.

A related tetranuclear compound, **11**·$2H_2O$, has been synthesized by slow evaporation in air of solutions containing the trinuclear mixed-valence iron complex $[Fe_3O(O_2CCF_3)_6(H_2O)_3]\cdot 3.5H_2O$.[125] The structure of **11** is

$[Fe_4O_2(O_2CCF_3)_8(H_2O)_6]$ **11**

illustrated in Figure 17 and, schematically, in Scheme 3. Magnetic susceptibility and Mössbauer spectroscopic studies of all three of these novel $[Fe_4O_2]^{8\oplus}$-containing complexes reveal a diamagnetic (S = 0) ground state,[122, 124, 126] consistent with antiferromagnetic coupling

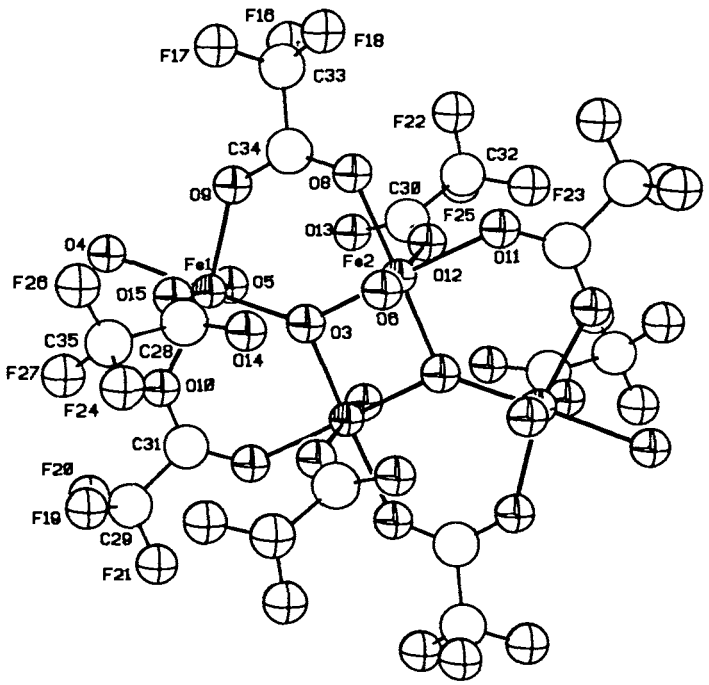


Fig. 17. Structure of **11** (drawn from the coordinates in Ref. [125]).

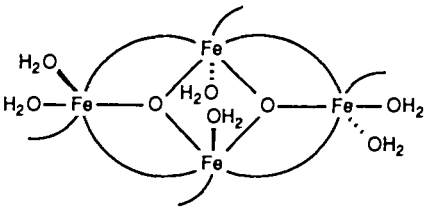


Scheme 3. Schematic structure of **11**.

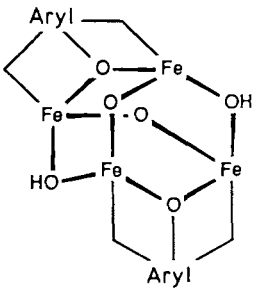
through the μ_3-oxo bridges. Geometric comparisons of the $[Fe_4O_2]^{8\oplus}$ cores in **10**,[125] **11**,[126] and the mineral amarantite, $[Fe_4O_2(SO_4)_4]$,[127] reveal the central $[Fe_2O_2]$ unit ("kernel") to be a structural invariant,[124] with parameters *b*, *c*, *f*, β, and δ (see Scheme 1) being in the respective ranges 1.96–1.97 Å, 1.93–1.94 Å, 2.90–2.93 Å, 95.7–96.8°, and 82.9–83.7°. The geometry of the $[Fe_4O_2]^{8\oplus}$ core in **9**, R = Ph,[122] is similar, with small but significant differences arising from its nonplanarity.

5.2. Other Tetranuclear Iron(III) Oxo Aggregates

Two other complexes of this class have been recently synthesized, in which the iron-oxo core geometries differ from those of the $[Fe_4O_2]^{8\oplus}$-containing molecules **9**–**11**. Addition of NaOH to an aqueous solution of $Fe(NO_3)_3$ and the protonated ligand 5-Me-hxta (Fig. 11) gives rise first to a red binuclear complex, $[Fe_2(5\text{-Me-hxta})(OH)(H_2O)_2]$, and eventually to the orange tetranuclear compound (pyrrH)$_4$·**12**·$2CH_3OH$, where

$[Fe_4O_2(OH)_2(5\text{-Me-hxta})_2]^{4\ominus}$ **12**

pyrrH is the pyrrolidinium cation, $C_4H_{10}N^{\oplus}$.[128] As shown in Figure 18, the complex is comprised of a tetrahedral array of iron atoms bridged on its six edges by oxygen atoms, two from oxo ligands, two from hydroxo ligands, and two from the 5-Me-hxta phenolate groups. The resulting $[Fe_4O_6]$ core has the adamantane structure (Scheme 4). The



Scheme 4. Adamantane structure of the $[Fe_4C_6]$ core of **12**.

$Fe-O_{\mu\text{-oxo}}$ bonds are short (1.791(3) Å) and the Fe–O–Fe bond angle is 151.23(19)°. Magnetic susceptibility studies reveal a singlet (S = 0) ground state.[129]

Another, topologically distinctive, tetranuclear iron oxo complex is $Na_6[Fe_4O_2(CO_3)_2L_2]$, where L is the pentaanionic form of 1,3-diamino-2-hydroxypropane-*N*,*N*,*N'*,*N'*-tetraacetic acid (Fig. 11).[130] The structure of this aggregate is illustrated in Figure 19. Iron centers Fe(1) and Fe(2′) are linked by μ-oxo bridges (Fe–O distances,

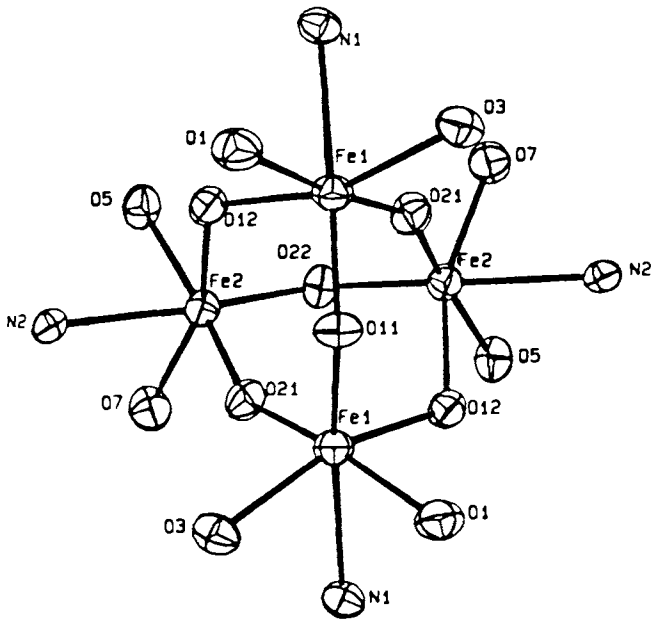


Fig. 18. Structure of the $[Fe_4O_x]$ core of **12** (reproduced by permission from Ref. [128]). The oxo and hydroxo groups are labeled O21 and O11/O22, respectively.

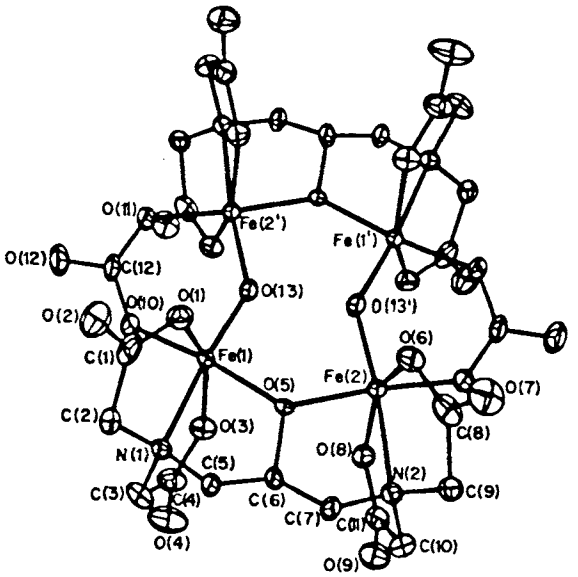

Fig. 19. Structure of $[Fe_4O_2(CO_3)_2L_2]^{6\ominus}$ (reproduced by permission from Ref. [130]).

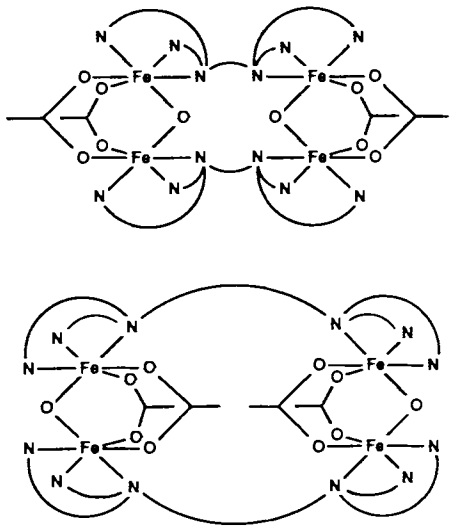
1.828(4) and 1.830(4) Å; Fe-O-Fe angle, 136.4(3)°) and carbonate bridges, previously unknown in iron(III) chemistry. The $Fe\text{-}O_{\mu\text{-oxo}}$ bridge bonds are among the longest of their kind, and a very short intramolecular nonbonded oxygen-oxygen contact of 2.408(9) Å occurs between O(13) and O(13'). Both of these results are suggestive of H-bonding between O(13) and O(13'), although the evidence seems to favor the bridges being purely oxo, rather than a mixture of oxo and hydroxo.[130] The temperature dependence of the magnetic susceptibility of this complex reveals a superexchange pathway through the oxo bridges, characterized by an antiferromagnetic exchange coupling constant J of $-63.4\ cm^{-1}$. The two alkoxide bridges mediate a weaker antiferromagnetic exchange interaction having $J = -11.2\ cm^{-1}$. The former value is nicely consistent with the correlation[118] between $Fe\text{-}O_{\mu\text{-oxo}}$ bond distances and the magnitude of J for multiply bridged diiron(III) complexes. The $[Fe_4O_2(CO_3)_2L_2]^{6\ominus}$ ion is the only structurally characterized tetrairon oxo aggregate studied thus far for which J values have been determined.



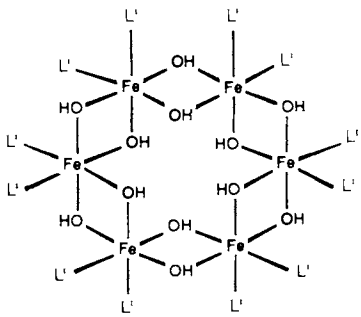
Scheme 5. Schematic structure of $[Fe_2O(O_2CCH_3)_2L'_2]^{2\oplus}_2$.

Two tetranuclear complexes of general formula $[Fe_2O(O_2CCH_3)_2L'_2]^{4\oplus}_2$, where L' is a hexadentate *N,N'*-tetrapicolinyl(xylylene)diamine or -(alkylene)diamine ligand, have been structurally characterized (Scheme 5).[96,131] Both of these molecules arose from unsuccessful attempts to link the two halves of a binuclear complex containing the (μ-oxo)bis(μ-carboxylato)diiron(III) core. Tetranuclear iron halo/methoxo and methoxo/alkanoato complexes have been postulated, but not structurally defined.[132-134]

6. Higher Nuclearity Iron(III) Oxo Complexes

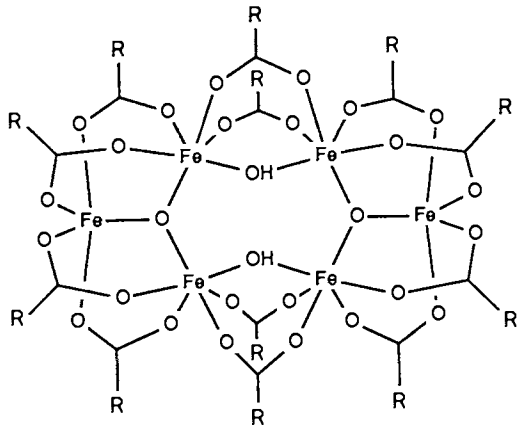
6.1. Hexairon(III) Species

Although there is good evidence for the existence of the cyclic hexanuclear complex $[Fe_6(OH)_{12}](OH)_6$ (Scheme 6) in solution,[91,92] the only hexairon(III) oxo/hydroxo com-



Scheme 6. Proposed structure of the complex $[Fe_6(OH)_{12}]^{6\oplus}$ in solution.

plex to be crystallographically characterized is $[Fe_6O_2(OH)_2(O_2CR)_{12}]$, where R is *tert*-butyl.[135] As shown in Scheme 7, two (μ-hydroxo)bis(μ-pivalato)diiron(III)



Scheme 7. Structure of $[Fe_6O_2(OH)_2(O_2CR)_{12}]$, R = *tert*-butyl.

units are linked to two trigonal-bipyramidally coordinated iron(III) centers by a triply bridging μ-oxo and two bridging pivalate ligands. This fascinating molecule was first detected in gas-phase mass spectroscopic studies of $[Fe_3O(O_2CR)_6(H_2O)_3]RCO_2 \cdot 2RCO_2H$ and subsequently generated from the latter, basic iron acetate type molecule by thermolysis in tetradecane at 200–220 °C for 15–20 min. The $Fe\text{-}O_{\mu\text{-oxo}}$ and $Fe\text{-}OH_{\mu\text{-hydroxo}}$ bond lengths are 1.946(6) Å and 1.962(9) Å, respectively, for the six-coordinate iron atoms; the equatorial Fe–O bond distance to the pentacoordinate iron atom is 1.848(5) Å.

6.2. An Octairon(III) Aggregate

Hydrolysis of $[Fe(tacn)Cl_3]$ at pH 9 in the presence of bromide ion over a 24-h period leads to brown crystals of the octairon(III) complex $[Fe_8O_2(OH)_{12}(tacn)_6]Br_8 \cdot 9H_2O$, where tacn is defined in Figure 11.[136] The structure of the cation is shown in Figure 20. At the center of the octairon(III) aggregate is an $[Fe_4O_2]^{8\oplus}$ core with geometric properties remarkably similar to those in the tetranuclear iron complexes described in Section 5.1.[124] Apart from its structure, there is little additional information available about this interesting cluster. The compound is reported to obey the Curie–Weiss law between 103 and 193 K with $\mu_{eff} = 3.72\mu_B$ and $\theta = 59.9$ K, but the ground state is unknown.[136]

6.3. Undecairon(III) Oxo-Hydroxo Complex

The largest discrete oxo-bridged polyiron compound known thus far is $[Fe_{11}O_6(OH)_6(O_2CPh)_{15}]$ **13**, synthesized by hydrolytic polymerization in nonaqueous solvents of simple mononuclear $[FeCl_4]^{\ominus}$ and binuclear $[Fe_2OCl_6]^{2\ominus}$ salts.[137] At least four different crystalline forms of this novel undecairon(III) aggregate exist,[129, 137–139] two of which, **13** · 6THF and **13** · (H_2O) · 8CH_3CN, have been described in detail.[138] The eleven iron atoms are arranged at the corners of a pentacapped twisted trigonal prism having a twist angle, α, of 17.4° (Fig. 21). Six triply bridging pla-

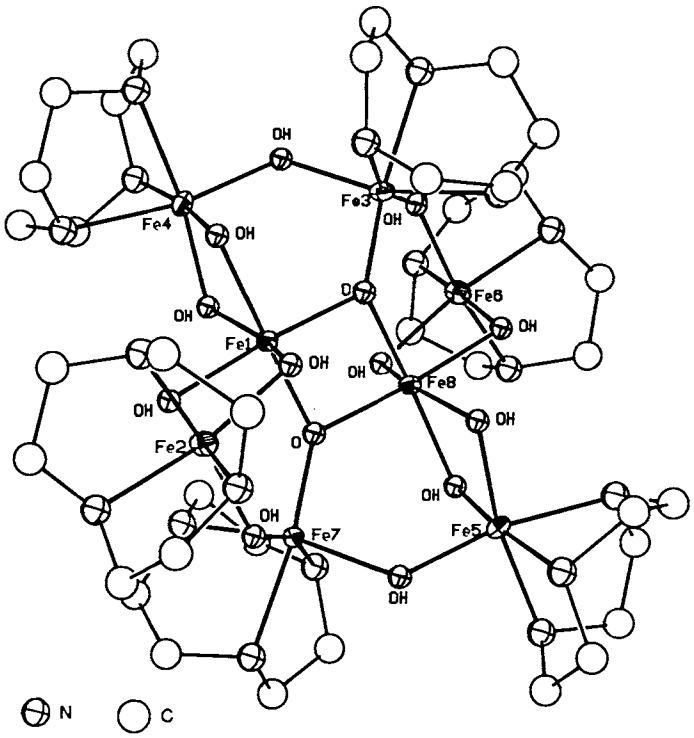


Fig. 20. Structure of $[Fe_8O_2(OH)_{12}(tacn)_6]^{8\ominus}$ (drawn from deposited coordinates, see Ref. [136]).

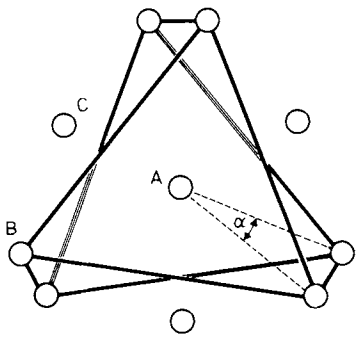

Fig. 21. Arrangement of iron atoms in **13**, showing the three types of iron atoms and twist angle α. The view is down the C_3 axis, which obscures one of the type-A iron atoms. For more discussion, see Ref. [138] (reproduced by permission from Ref. [138]).

nar μ-oxo and six triply bridging pyramidal μ-hydroxo ligands link the iron atoms together, while 30 oxygen atoms of bidentate bridging benzoate ligands fill the remaining, distorted octahedral coordination positions at each iron atom (Fig. 22). Hydrogen bonding of the hydroxyl group protons to THF, H_2O, or CH_3CN acceptor atoms of solvent in the lattice occurs in all structures (Fig. 23). The benzoate groups provide a hydrophobic sheath about the aggregate through which these hydrogen-bonding interactions can occur, and also serve further to knit together the structure.

Magnetic and Mössbauer studies of **13** reveal a ground state spin of $S_T = 1/2$ per aggregate and internal antiferro-

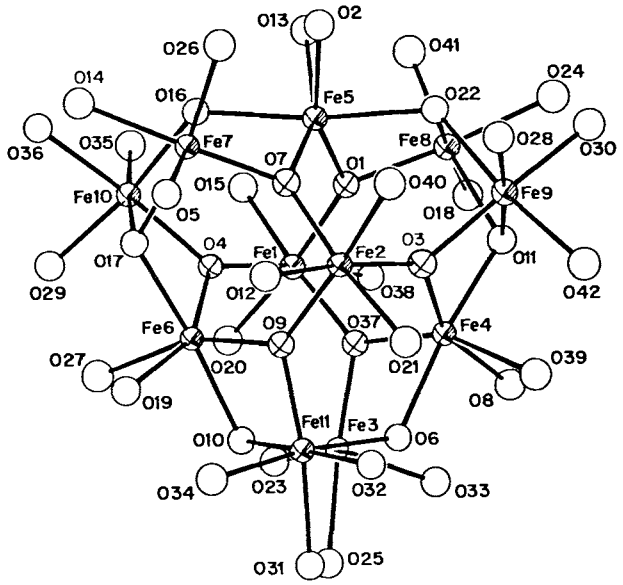

Fig. 22. Structure of **13**, omitting only the benzoate group carbon atoms (reproduced by permission from Ref. [138]).

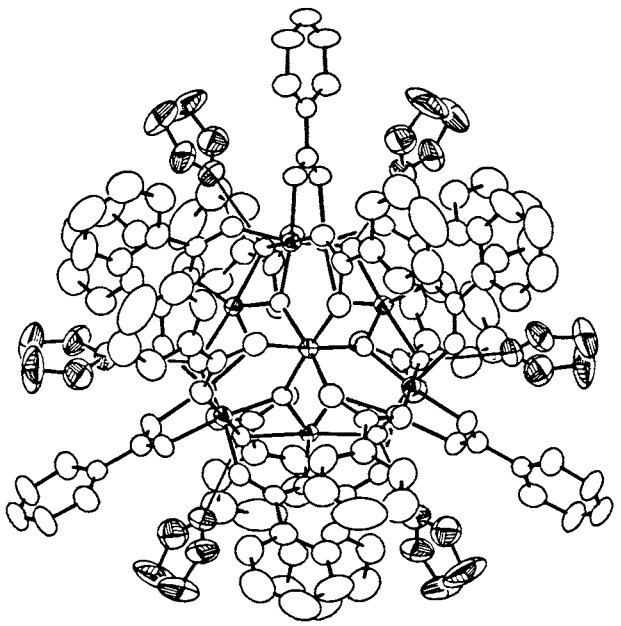

Fig. 23. Full structure of **13**·6THF. The THF solvent molecules, drawn using shaded ellipsoids, are hydrogen-bonded to the six hydroxyl groups (reproduced by permission from Ref. [138]).

magnetic spin exchange among the eleven bridged high-spin ferric centers.[138] A quasi-reversible reduction at $E_{1/2} = -0.31$ V vs. SCE has been observed by cyclic voltammetry and tentatively assigned to the formation of the $[Fe_{11}O_6(OH)_6(O_2CPh)_{15}]^{\ominus}$ anion. At more negative potentials, additional electrons may be added to the aggregate, but the waves are irreversible, possibly due to fragmentation of the undecairon unit. The mode of formation and ligands employed in the synthesis of **13** make it an attractive model for the polyiron core in ferritin, and detailed comparisons of the magnetic, spectroscopic, and structural properties of the two systems are available.[138]

6.4. Analogies to the Ferritin Core

The stability of **13** has led to speculations that in ferritin cores the iron atoms may be stored as discrete Fe_{11} units in which the bridging carboxylate groups are replaced by phosphate, oxo, or hydroxo ions.[138] A total of 409 ± 3 such Fe_{11} units have been shown to be sufficient to fill the entire core. Other synthetic iron polymers, including one of approximate composition $[Fe_4O_3(OH)_4(NO_3)_2] \cdot 1.5\,H_2O$[140,141] and a large ($\geq 250$) polynuclear iron cluster formed from a 4:1 ratio of Fe^{III} and ATP,[142] have been suggested as models for the polyiron core in ferritin. The synthesis, structural characterization, physical properties, redox behavior, and reactions, especially the stepwise release and addition of mononuclear or small polynuclear iron units, of these and related higher-order polyiron aggregates will continue to be of interest and importance in helping to define the true chemical nature of ferritin cores.

7. Conclusion

Attempts to model polynuclear iron oxo centers in biology have produced a fascinating array of novel aggregates scarcely imagined only a few years ago. Parallel work in manganese chemistry, some of it similarly motivated, has also resulted in a variety of di-, tri-, tetra-, nona-, and dodecanuclear oxo-bridged complexes.[99,100,115,123,143–145] These complexes have undoubtedly sharpened our insights into the structural and physical properties of polyiron oxo centers in biology. While such synthetic achievements can be admired for their intrinsic beauty, they are limited in their ability to elucidate chemical details underlying the biological functions of these units. Attention must now turn to systems with reaction chemistry that mimics that of the natural systems, including binuclear iron oxo centers that bind O_2 reversibly, oxygenate hydrocarbon substrates, reduce geminal diols, or hydrolyze phosphate esters. What features of the metal coordination chemistry of (μ-oxo)bis(μ-carboxylato)diiron(III) units, for example, dictate whether reversible oxygen binding or oxygen activation will occur? How much of this distinction arises from fine tuning of the electronic and steric properties of the bimetallic center and how much requires the protein chains? A precisely analogous question applies to binuclear copper centers that bind or activate O_2 in different proteins.[146]

Progress in studying the bioinorganic chemistry of rust is likely to have an impact in several related disciplines. New strategies for the synthesis of ceramic materials, catalysts for alkane oxidation, and corrosion inhibitors should arise from fundamental knowledge about the chemistry of polyiron oxo complexes. In the search for molecular systems that hydroxylate hydrocarbons, attention is already beginning to shift towards non-heme iron compounds, some of which are certain to be polynuclear. Applications to medicine may derive from a better understanding of the coordination chemistry of iron in aqueous media and of the principles that govern the loading and unloading of iron from ferritin cores. It will be interesting to follow these developing areas in the next several years.

Studies performed in the author's laboratory were supported by grant GM-32134 from the National Institute of General Medical Sciences, which is gratefully acknowledged. I also wish to thank my talented former MIT coworkers William H. Armstrong (currently at the University of California at Berkeley), Sergiu M. Gorun (Exxon), Alan Spool (IBM, San Jose), and Ian M. Williams (Oxford), as well as current MIT students and postdoctoral associates Robert H. Beer, James G. Bentsen, Judithann R. Hartman, R. Lynn Rardin, Mary E. Roth, and Petra N. Turowski for their hard work and stimulating ideas. Several excellent collaborators also contributed greatly to our progress, specifically Richard B. Frankel and Georgia Papaefthymiou of the Francis Bitter National Magnet Laboratory at MIT, Chuck Dismukes (Princeton), Britt Hedman and Keith Hodgson (Stanford), JoAnne Stubbe (Wisconsin, now at MIT), and Karl Wieghardt (Bochum). Dave Hendrickson, Don Kurtz, and Larry Que kindly sent preprints of their work prior to publication. Finally, I appreciate the assistance of Kazi Ahmed and Petra N. Turowski in preparing some figures and drawings for this article.

Complexation of Neutral Molecules by Cyclophane Hosts

By François Diederich*

In memoriam Iwao Tabushi

Since the discovery of the crown ethers by *Pedersen* twenty years ago, the chemistry of synthetic hosts for the selective complexation of organic and inorganic guests has seen an extraordinarily rapid development. This article discusses in particular the contributions provided by synthetic cyclophanes as hosts to the understanding of molecular complexation of neutral organic guest molecules in aqueous and organic solvents. In aqueous solution, cyclophanes form stoichiometric complexes with neutral aromatic guests which can approach enzyme-substrate complexes in their stability. Efficient molecular complexation is also observed in organic environments. Here, as a result of large solvation effects, the strength of complexation is strongly dependent on the nature of the organic solvent. Electron donor–acceptor interactions can contribute significantly to the stability of complexes formed between cyclophane hosts and aromatic guests. Force-field calculations together with computer graphics are powerful tools in the design of water-soluble, optically active hosts for chiral recognition of complexed racemic guests. Simple and selective functionalization of the cyclophane framework leads to stable, bioorganic catalysts. Like enzymes, these catalysts bind their substrates in a rapid equilibrium prior to the reaction steps. As a perspective, some fascinating research objectives in the field of molecular recognition and catalysis which can be targeted with designed cyclophane hosts are shown.

1. Introduction

The first descriptions of clathrate formation, the inclusion of organic and inorganic guests in the interstices of the crystal lattices of hosts such as hydroquinone, urea, and cholic acids, date back to the middle of the nineteenth century.[1–4] In contrast, the first evidence for the inclusion of a guest within the intramolecular cavity of a host was first reported in 1938. At that time, *Freudenberg* and *Meyer-Delius* proposed that the formation of an adduct between iodine and cyclodextrins was a result of a cavity formed by the cyclodextrin ring.[5] During his habilitation with *Freudenberg* at the end of the forties and at the beginning of the fifties, *Cramer* pioneered the research area which is now known as host-guest chemistry[6] or molecular recognition. At that time, he undertook the first systematic studies on the cavity inclusion complexation between cyclodextrins and organic guests in aqueous solution and in the solid state.[7] *Cramer* et al. also explored for the first time the acceleration and the stereoselectivity of reactions as a result of substrate binding in the cyclodextrin cavity.[8] This early work of *Cramer* et al. was well ahead of its time and it subsequently initiated numerous successful studies of natural and modified cyclodextrins as receptor and enzyme models. Without doubt, the development of fully synthetic hosts, especially of the water-soluble cyclophanes, has been stimulated by the past and the on-going creative research with cyclodextrins in the laboratories of *Bender*,[9] *Breslow*,[10] *Tabushi*[11], and others.[12–17]

Despite the successful studies of *Cramer* at the beginning of the fifties on molecular complexation and catalysis by the *natural* cyclodextrins, the progression to synthetic hosts for organic and inorganic guests did not occur until fifteen years later. Only *Stetter* and *Roos*[18] in 1955 published a paper in this direction. The long interval between the first studies on cyclodextrins and the development of synthetic hosts can certainly be explained in terms of insufficient understanding of the intermolecular interactions that hold together complexes formed by enzymes, biological receptors, and the natural cyclodextrins. The fundamental discovery of the *synthetic* crown ethers by *Pedersen* in 1967[19] was needed to trigger the development of efficient synthetic hosts. *Pedersen*'s discovery demonstrated that molecular complexation is not limited to natural systems but can also occur effectively with fully synthetic receptors. The scope of this article does not allow for a discussion of the wide variety of molecular hosts that have been prepared since 1967 for the selective complexation of anionic, cationic, and hydrogen-bonding neutral guests. The reader is referred to numerous monographs[20–29] and to some of the reviews that have appeared.[30–48] However, the inspiring work of *Lehn* et al.[49] and *Cram* et al.[6, 50] should be specifically mentioned here. These researchers quickly recognized the implications of *Pedersen*'s discovery. With their stimulating and innovative contributions to supramolecular complexation, chiral recognition and catalysis, they have established the constituency of the field of synthetic host-guest chemistry. With great joy the author of this article may now add to this introduction that *Pedersen*, *Cram*, and *Lehn* were awarded the 1987 Nobel Prize in Chemistry for their future-oriented work.

The above mentioned work of *Stetter* and *Roos*,[18] reported in 1955, has to be seen as the first approach towards

the synthesis of systems with binding sites for apolar molecules. They recognized the potential of cyclophanes for inclusion complexation and prepared the macrocycles **1–3** derived from benzidine. In their paper, they described the formation of stable crystalline 1:1 complexes with benzene and dioxane when the macrocycles **2** and **3** were recrystallized from these solvents. Until 1982, these complexes were thought to be of the cavity inclusion type. At that time, *Hilgenfeld* and *Saenger*[51] showed by X-ray crystallography that the largest macrocycle **3** and benzene do not form an intramolecular cavity inclusion complex but rather a clathrate in which benzene is accomodated between host molecules in the crystal lattice.

3, n = 4

In the seventies, the research groups of *Tabushi*,[11b,52] *Murakami*,[53] and *Koga*[54] in Japan and of *Whitlock*[55] in the United States started developing water-soluble, cyclophane-type macrocycles and analyzed their ability to act as hosts in aqueous solution. Among theses studies, the work of *Koga* et al. is considered a milestone contribution. In 1980, they reported the first stoichiometric inclusion of an apolar guest in the cavity of a synthetic cyclophane-host both in aqueous solution as well as in the solid state.[54a] By ^{1}H-NMR spectroscopy, they demonstrated the formation of a 1:1 complex ($K_a = 2.8 \times 10^3$ L mol^{-1}) between host **4** and 2,7-naphthalenediol in dilute hydrochloric acid at pH < 2. From acidic aqueous solution, they crystallized a 1:1 complex of **4** and durene and characterized it unambiguously by X-ray crystallography as a cavity inclusion complex. By variation of the bridges between the diphenylmethane units as well as of the aromatic spacers, *Koga* et al. subsequently prepared other tetraazaparacyclophanes and studied the complexation of aromatic guests, especially of those bearing anionic residues, in aqueous solution.[54b–e]

2. Concept for the Design of Water-Soluble Cyclophane Hosts with Pronounced Hydrophobic Cavity Binding Sites

Our original interest in the development of water-soluble hosts stems from a desire to study in detail the hydrophobic effect, i.e. the specific driving force for the association of apolar binding partners in aqueous solution.[56–65] All theories of the hydrophobic effect agree that this driving force for complexation originates from the specific interactions between the water molecules; these cohesive forces are larger than the forces between the water molecules and apolar solutes. In modern biochemistry texts, the hydrophobic effect is mainly attributed to a specific, highly positive entropic contribution.[66] As an example, water-molecules around the apolar surfaces at an enzyme active site and around an apolar guest arrange to form a highly structured hydrogen-bonding network. Upon complexation, these structured surface water molecules are released into the bulk solution, which results in a positive entropy change. Despite many experimental and theoretical studies, it is still unclear as to what extent the entropy change due to desolvation in an aqueous solution is more positive than the corresponding entropy change in an organic solvent.[65c]

A favorable (negative) enthalpic contribution to the complexation process in aqueous solution is explained by the lower polarizability of the OH-residues of water as compared to CH_2-units.[63,66a] Since the polarizability, in addition to the interatomic distance, predominantly defines the attractive potential of the London dispersion interactions, these interactions are stronger between associated hydrocarbons than between hydrocarbon solutes and water molecules. A negative heat capacity change (ΔC_p^0) is often measured upon association or complexation of apolar binding partners in aqueous solution and is considered another criterion for the hydrophobic effect.[62,67] The negative heat capacity change of the aqueous system can be explained by the high thermal lability of the layer of water molecules which are arranged in a structured way around the free binding partners and which are released into the bulk upon complexation. A large negative heat capacity change was measured for the complexation between 1-adamantanecarboxylic acid and cyclodextrins in aqueous solution.[68a]

A multitude of binding interactions are effective in complex biological systems and consequently the hydrophobic effect, isolated from other driving forces for complexation, is difficult to study. We therefore planned to undertake such a study using geometrically well-defined water-soluble cyclophane hosts. The host components described by *Koga* et al.[54] were not ideal for such studies since the hydrophobic character of their binding sites is perturbed by ionic, strongly hydrated ammonium centers in the periphery of the macrocyclic cavity. For the construction of water-soluble hosts with apolar cavity binding sites shaped by hydrocarbon residues, we proposed to locate water-solubility-providing ionic groups remote from the cavity.[69,70] To achieve this goal, quaternary ammonium centers providing water-solubility at neutral pH could either be introduced by bicyclic, propellane or spiro-type arrangements (Fig. 1).

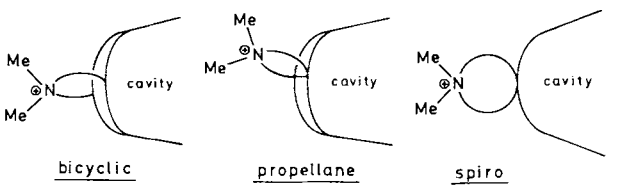

Fig. 1. Possible arrangements which locate water-solubility providing quaternary ammonium nitrogens remote from the cavity. Ammonium centers as shown here effect solubility of the host molecule at pH 7 in water.

We chose spiro piperidinium rings, since **5**–**7** provide building blocks which combine the spiro system with the diphenylmethane unit in a desired spatial arrangement. The building blocks **5**–**7**, introduced in our macrocycles, e.g. **11**–**18**,[71] can be readily prepared in one step in 90% yield from the corresponding phenol and *N*-acetylpiperidine. In other cyclophane hosts, e.g. **19**, we have introduced carboxylate residues to provide water-solubility. The specific fixation at the central carbon atom of the diphenylmethane spacer orients the carboxylate residues away from the binding site.[55e,72,73] The building blocks **8**–**10**, needed to prepare hosts such as **19**, can also be obtained in one step in very good yield starting with the corresponding phenol and diethyl acetonedicarboxylate.[74]

Other research groups have introduced bicyclic aromatic units, e.g. derivatives of *Tröger*'s base[75,76] or 9,10-bridged 9,10-dihydroanthracenes[77] into macrocyclic hosts. These units are spacers similar to **5**–**10** in their ability to shape cavity binding sites and direct water-solubility-providing groups outwards. Water-soluble hosts with propellane units have also been prepared.[78] In the latter systems, however, the ionic groups are aligned in the cavity periphery.

The diphenylmethane units of our macromonocyclic hosts are bridged by α,ω-dioxaalkane chains. Variation of the chain length leads to cavity binding sites of variable size (**11**–**14**).[69,71] The X-ray structure analyses and the computer modeling studies described below show that the lone pairs of the four ether oxygens in the cavity periphery are directed outwards. This enhances the hydrophobic character of the binding site. In the series **15**–**18**, two, four, six, and eight methyl groups are attached to the host. As a result, the cavity becomes successively deeper and more hydrophobic.[71]

To increase the molecular-dispersed water-solubility (see Section 4.1), we attached spiro piperidinium groups to the bridging chains in host **20** to locate two additional ionic centers away from the cavity binding site.[79,80] The two spiro units also help to enforce the binding site by limiting the number of conformations of the aliphatic bridges in the sense of a "*gem*-dimethyl effect". For a tighter encapsulation of the complexed guests, we prepared the macrobicyclic hosts **21** and **22** which are soluble in weakly acidic aqueous solution. These compounds are designed according to the cryptand-concept of *Lehn*[49a] and possess three diphenylmethane units bridged by chains stemming from two "cryptand" nitrogen atoms.[81,82]

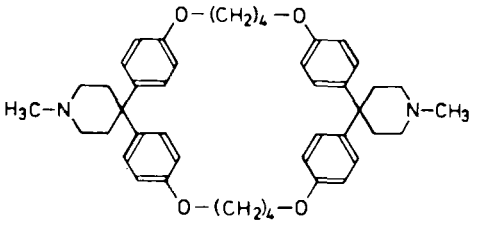
3. Crystal Structures of the Host Molecules

In the entire field of host-guest chemistry, two principles have been found to be of special importance for the successful design of strongly binding host molecules: (i) the principle of stereoelectronic complementarity between host and guest and (ii) the principle of preorganization of a binding site prior to complexation. The former essentially represents a modern formulation of the lock-and-key principle of *Emil Fischer*.[83] The latter principle has been defined by *Cram* et al.[50d] in a series of systematic and elegant studies. It states that the preorganization of a host prior to complexation is an essential factor controlling the association strength. If a host binding site is not completely organized, a reorganization must occur upon complexation of the guest. This reorganization can cost part of the free binding energy. In the most unfavorable case, the energy needed to reorganize the binding site is larger than the free complexation energy and no binding will occur. *Cram* et al. also showed that the guest selectivity increases with increasing preorganization of a binding site.[50d]

A comparison of the X-ray crystal structures of hosts and their complexes is often used to determine the degree of preorganization of a binding site.[50d,84,85] Solid state structures, of course, are only of limited value for making predictions about the conformations of hosts and complexes in solution. When **13a**, the bis(*N*-methylpiperidine) precursor of bisquaternary host **13**, was recrystallized from aromatic solvents, crystalline complexes suitable for an X-ray analysis were obtained (Fig. 2).[86,87] In the 1:1 host-guest complex obtained from toluene, the disordered toluene molecules are located in the interstitial spaces of the crystal lattice (Fig. 2A). From wet benzene, we obtained a crystalline 1:2:1 (host/benzene/water) complex. One of the two benzene rings is perfectly enclosed within the intramolecular cavity of the host (Fig. 2B). The second benzene ring and the water molecule are located in the interstitial spaces of the crystal lattice. A third crystalline 1:1 host-guest complex of **13a** was obtained from *p*-xylene. In



13a

this complex, which is not shown, the host molecules stack along a crystal axis. The guest molecules are enclosed in a sandwich-type array between host molecules in the stacks.[86] The methyl groups of the guest extend into the intramolecular cavities of the two surrounding host molecules.

The inclusion of benzene,[18,88-90] toluene,[91,92a,b] *p*-xylene,[93] durene,[54a] naphthalene,[54e] anisole,[92c] and *p*-nitrophenol[85] was demonstrated by X-ray analysis for crystalline complexes of a variety of cyclophane hosts with

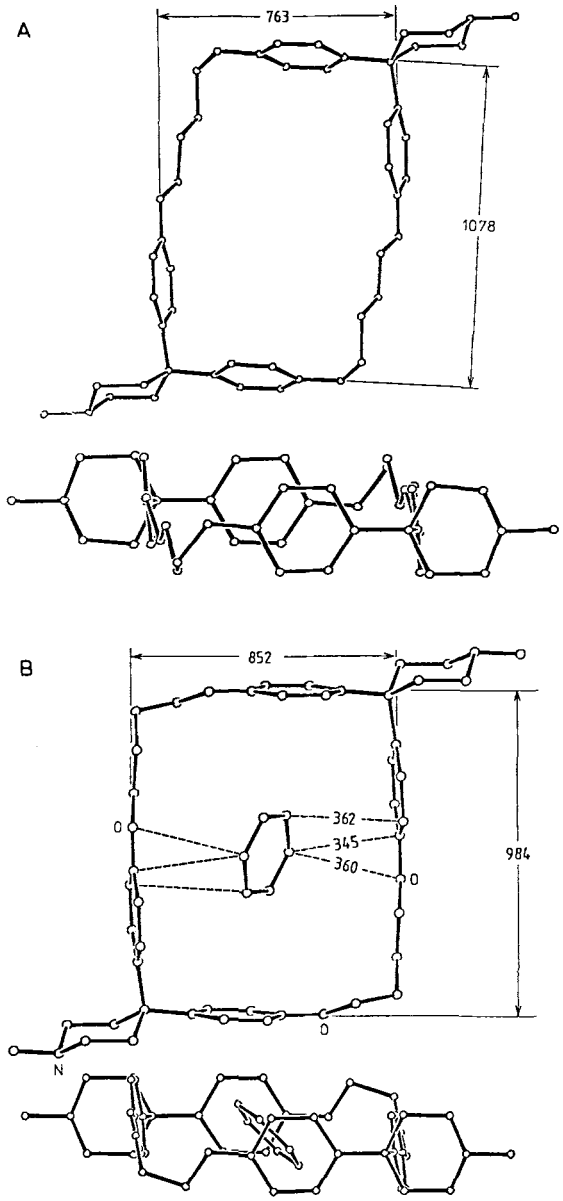


Fig. 2. View onto the least square plane of the host and view parallel to the least square plane of the host: A) in the **13a** · toluene (1:1) complex (only the host is shown and not the toluene molecules which are located in a disordered way in the crystal lattice); B) in the **13a** · benzene (1:2) monohydrate (only the host and the benzene ring in the intramolecular cavity are shown; an additional benzene ring and a water molecule are located in the crystal lattice).

apolar cavities, e.g. the calix[4]arenes.[91,92] In analogy to our results, the guests in these complexes are found both in the intramolecular cavity of the host[54a,e,85,88,91,92a] as well as in the crystal lattice.[18,89,90,92b,c,93] A crystal lattice inclusion of the guest is often observed even if the binding site of the host is sufficiently large and preorganized for intramolecular cavity inclusion. The large cyclophane hosts often crystallize with large interstitial spaces in the crystal lattice. If such interstices have geometric complementarity for the guests, the guests can encounter a large number of tight van der Waals contacts and crystal lattice inclusion can become very favorable. The formation of crystalline complexes between cyclophane hosts with apolar cavities and neutral molecules is not limited to aromatic guests. The inclusion of chloroform,[94-96] dichloromethane,[96,97]

1,2-dichloroethane,[85] carbon disulfide,[98] and acetonitrile[99] in the intramolecular cavities of cyclophane hosts, and of acetone[100] and 1,4-dioxane[93,101] in the crystal lattice between host molecules has been observed.

In the three crystalline complexes of **13a** with benzene, toluene, and *p*-xylene, the host adopts the face-to-face conformation.[52c] The four benzene rings are oriented more or less perpendicular to the mean molecular plane. The three crystal structures only differ in the sequence of the three antiperiplanar and the two synclinical torsion angles in the C_{aryl}-O-$(CH_2)_4$-O-C_{aryl}-bridges. Depending on the position of the two synclinal torsional angles, the cavity adopts a more rectangular (Fig. 2A) or a more square (Fig. 2B) shape. The structure of the host in the toluene clathrate (Fig. 2A) resembles the structure of the host in the benzene complex (Fig. 2B) and in the *p*-xylene complex which is not shown.[86] Hence, we conclude that, in the solid state, the hosts shaped by two diphenylmethane units possess highly preorganized binding sites.

4. Complexation in Aqueous Solution

4.1. Aggregation Behavior of the Host Molecules in Aqueous Solution

A serious problem in previous studies of the complexation between apolar hosts and guests in aqueous solution involved the potential self-aggregation of the host and/or guest molecules leading to the formation of aggregates of higher molecular weight.[53b,102,103] The same hydrophobic interactions that act as a driving force for stoichiometric host-guest complexation can also lead to the segregated association of host and/or guest molecules and to the formation of mixed aggregates with poorly defined orientation of host and guest, similar to micellar systems. The formation of stoichiometric complexes should therefore be studied in a concentration range in which the complexation equilibrium is not perturbed by additional equilibria leading to aggregation. Hence, the aggregation behavior of both host and guest should be known. We suggest that a study of stoichiometric complexation with a new host, designed to provide significant thermodynamic and kinetic data, should always begin with the investigation of the aggregation behavior of the host component.

We found that the critical aggregation concentration (CAC) of cyclophane hosts, below which stoichiometric complexation is studied, can be determined in an easy way by ^{1}H-NMR spectroscopy.[69-71] This method has been applied to measure the critical micelle concentration (CMC) of micellar systems.[104-106] As an example, Figure 3 shows the chemical shifts of the protons of **20** plotted as a function of the concentration of this host in aqueous solution. In the curves, a well-defined discontinuity is observed at approximately the same concentration. This concentration can be considered as the ^{1}H-NMR CAC of this compound. Below this value, the host is present in a molecular-dispersed form and the chemical shifts are independent of concentration. Above the CAC, the chemical shifts become dependent on concentration, since the anisotropic regions of the aromatic rings influence the signal positions of the

Table 1. Critical aggregation concentrations (CAC's) of the hosts determined by ^{1}H-NMR spectroscopy and maximum water-solubilities (T = 303 K).

Host	CAC [mol L^{-1}]	Maximum water-solubility [mol L^{-1}]
11 [a]	2.5×10^{-3}	$\approx 2\times10^{-2}$
12 [a]	2.5×10^{-3}	$\approx 1\times10^{-1}$
13 [a]	1.6×10^{-4}	$\approx 1\times10^{-1}$
18 [a]	$\leq 2\times10^{-5}$	$\approx 6\times10^{-2}$
19 [b]	1.5×10^{-3}	$\approx 1\times10^{-2}$
20 [a]	7.5×10^{-3}	$\approx 1\times10^{-1}$
21 [c]	1.0×10^{-3}	$\approx 1\times10^{-2}$
22 [c]	5.0×10^{-3}	$\approx 1\times10^{-1}$

aggregating hosts. In addition, a strong line-broadening, increasing at higher concentrations, of the signals is observed for some but not for all hosts above the CAC. A good agreement was observed between the ^{1}H-NMR CAC of the host **13** and the CAC value determined by monitoring the light scattering at a 90° angle.[71] Table 1 includes the CAC values for some of our host systems.[70-72,82] The table clearly shows the large reduction in aggregation tendency which occurs upon introduction of the two additional spiro piperidinium units in host **20**. The CAC of **20** (7.5×10^{-3} mol L^{-1}) is more than two magnitudes higher than the CAC of the comparable host **18** with only two ionic centers ($\leq 2\times10^{-5}$ mol L^{-1}). Below the very low CAC of **18**, the application of ^{1}H-NMR spectroscopy to host-guest complexation analysis was not possible.

Figure 3 shows that the aggregation-induced shifts of the host signals above the CAC are quite significant.[71] These shifts can be of the same magnitude as the shifts resulting from the formation of a stoichiometric molecular complex. Therefore, it is not possible to decide whether shifts of the host resonances observed in solutions of host and guest above the CAC result from molecular complexation or from aggregation. Future investigations have to clarify

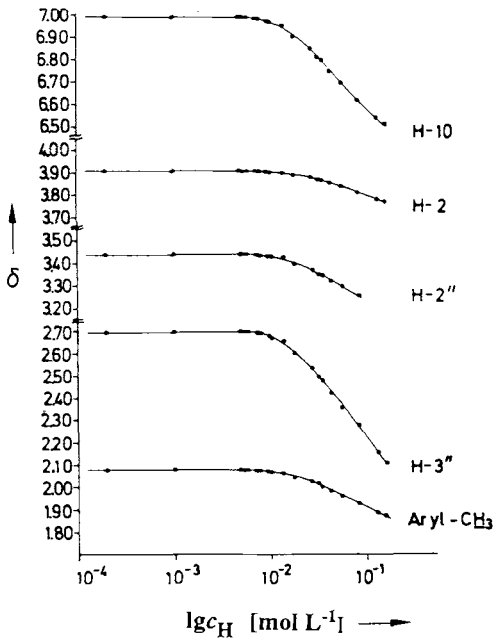

Fig. 3. Chemical shifts (δ values) of the protons of **20** as a function of the concentration (c_H) of **20** in D_2O [360 MHz, 303 K, ext. standard: sodium 2,2,3,3-tetradeuterio-3-(trimethylsilyl)propionate (TSP)].

how aggregation equilibria interfere with the equilibrium of stoichiometric, geometrically well defined molecular complexation. Studies must also address how the guest alters the aggregation behavior of the host. We have obtained preliminary evidence that the aggregation tendency of complexes can be considerably reduced if complexed guest components possess ionic groups extending out of the cavity.[107] These preliminary observations must be supported by additional quantitative studies.

In all binding studies described below, aqueous solutions with host concentrations below the CAC have been used.

4.2. Evidence for the Formation of Inclusion Complexes in Solution and Determination of the Association Constant K_a of Host-Guest Complexes

A large variety of analytical methods has been employed to provide conclusive evidence for inclusion complex formation by cyclodextrins in aqueous solution.[9, 12a, 13] To provide such evidence in studies with cyclophane hosts, ^{1}H-NMR spectroscopy is by far the method of choice.[33, 108–111] This method allows the thermodynamics and the kinetics of complexation equilibria to be analyzed quantitatively.[33, 82, 111–116] In addition, extensive information can be obtained about the structures of the cyclophane complexes as shown in Section 4.3.[117] Since the inclusion of a guest in the intramolecular cavity of a cyclophane can be demonstrated in the most convincing way by ^{1}H-NMR spectroscopy, this method should be applied in the first place to the analysis of the complexation behavior of a new cyclophane host in solution.

A versatile methodology has been developed for the determination of the stability constants of molecular charge-transfer complexes[118–122] and of cyclodextrin inclusion complexes.[9, 12, 13, 123] These methods have also been used for the quantitative analysis of the stability of synthetic host-guest complexes. For a comprehensive discussion of the methods available for measuring binding constants of molecular complexes, the reader is referred to a new excellent monograph by *Connors*.[124] The application of computers to the evaluation of experimental binding data and to the determination of complex stability constants has also been recently reviewed in a monograph.[125] Included are print-outs of computer programs which can be applied directly or, after modifications, to a given problem.

For the quantitative determination of the thermodynamic stability of the inclusion complexes formed by our hosts in aqueous and organic solutions, we have relied on various methodologies. For all host-guest interactions discussed in this review, we could demonstrate the exclusive formation of complexes with 1 : 1 host-guest stoichiometry in the concentration ranges used in the binding studies. In many cases, the association constant K_a (L mol^{-1}) of a given host-guest complex was determined by several independent methods,[70, 82] and we always found good agreement between such values. The following methods were employed:

1. *Solid-Liquid and Liquid-Liquid Extractions.* These procedures are indispensable for the preparation of aqueous solutions of complexes formed by guests that are extremely insoluble in water, e.g. perylene, pyrene, fluoranthene, naphthalene, or durene. For the preparation of aqueous solutions of complexes by solid-liquid extraction, an excess of finely powdered solid guest was extracted at constant temperature with an aqueous solution of the hosts **20** or **21**[70, 77, 82, 126] by vigorous stirring and shaking or ultrasonic radiation until establishment of the extraction equilibrium; the excess of solid guest was then removed by centrifugation and filtration. The complex stability constants K_a from solid-liquid extraction procedures were in good agreement with those obtained by other procedures. For accurate K_a values, it is important that residual microcrystals of the solid guest are completely removed by centrifugation and filtration from the aqueous complex solution obtained by the extraction. For the solutions of the complexes formed by perylene, pyrene, or fluoranthene, the absence of microcrystals could be elegantly demonstrated by the complete absence of the excimer fluorescence which is characteristic of the crystalline materials.[127]

Liquid-liquid extraction procedures are often the methods of choice to prepare organic solutions of polyethercation complexes and to determine the thermodynamic constants of the association, distribution, and extraction equilibria [Eq. (1)–(4)] which define the efficiency of the extraction.[128, 129] For the preparation of aqueous solutions of arenes that are extremely insoluble in water, we extracted at constant temperature solutions of the guests in *n*-hexane with aqueous solutions of the hosts **20** or **21**.[70, 82] Using Equations (1)–(4), the association constant K_a, the distribution constant K_d, and the extraction constant K_e could be determined in a very reproducible way.

$$[\text{host}_{H_2O}] + [\text{guest}_{H_2O}] \overset{K_a}{\rightleftharpoons} [\text{host-guest complex}_{H_2O}] \quad (1)$$

$$[\text{guest}_{\text{hexane}}] \overset{K_d}{\rightleftharpoons} [\text{guest}_{H_2O}] \quad (2)$$

$$[\text{guest}_{\text{hexane}}] + [\text{host}_{H_2O}] \overset{K_e}{\rightleftharpoons} [\text{host-guest complex}_{H_2O}] \quad (3)$$

2. *Determination of the Stoichiometry and Stability of the Complexes by ^{1}H-NMR Titration and Optical Titration.* In these titrations at constant guest concentration, the change of a guest property X is monitored as a function of increasing host concentration.[70, 71, 82] The property X can be the chemical shift of a guest proton or the intensity of an electronic absorption or fluorescence band of the guest. The titration curves are obtained by plotting the change of the guest property (ΔX) as a function of increasing host concentration. From these curves, the stoichiometry of the complexes and the K_a values are obtained using the following methods of analysis.

a) If a 1 : 1 complex is formed exclusively, the titration curves are described by a quadratic equation[124] with the change of the guest property ΔX_{sat} at saturation binding and the association constant K_a as the two unknowns. In some fluorescence and ^{1}H-NMR titrations, especially with host **20**, saturation binding could be reached[70, 82] and ΔX_{sat} could therefore be directly determined. In these experiments, K_a was the only unknown quantity and could be easily and directly evaluated from the titration curve.

b) If saturation binding was not observed, the association constant K_a as well as ΔX_{sat} could be determined from the straight lines in the double reciprocal plots obtained by evaluation of the titration data according to *Benesi* and *Hildebrand*.[130] To evaluate titration data according to *Benesi* and *Hildebrand* or by using the related semi-reciprocal treatments described by *Scott*[131] or *Scatchard*,[132] the concentration of free host must be considerably larger than the concentration of the host-guest complex over the entire titration range.[133-135] This boundary condition can be best obeyed by choosing over the entire titration range a total host concentration $[host]_0$ which is much larger (≥ 10 times) than the total guest concentration $[guest]_0$.[135]

c) Over the past two years, we have switched to a computer-assisted, non-linear curve-fitting evaluation of those titrations in which saturation binding was not reached.[136] Figure 4 shows the experimental data points of a ^{1}H-NMR titration to determine the association constant of the **18** · 2,6-naphthalenedicarbonitrile complex in [D$_4$]methanol and the non-linear least square curve fit to calculate the saturation shift $\Delta\delta_{sat}$ of the guest proton 1-H and the association constant K_a. The non-linear curve fitting has a

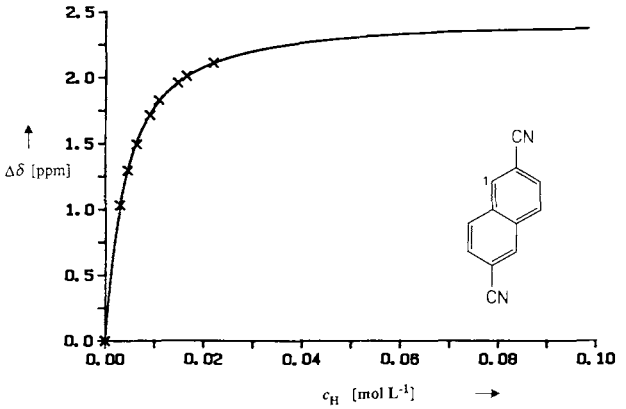

Fig. 4. Determination of the association constant (K_a) of the **18** · 2,6-naphthalenedicarbonitrile complex in [D$_4$]methanol (T=303 K) by computer-assisted non-linear curve fitting of the experimental data [x] of a ^{1}H-NMR titration (500 MHz, CH_3OD as internal standard, $[host]=2\times10^{-3}$–2×10^{-2} mol L^{-1}; $[guest]=5\times10^{-3}$ mol L^{-1}). The complexation-induced shifts $\Delta\delta$ observed for the guest proton 1-H are plotted against the host concentration c_H.

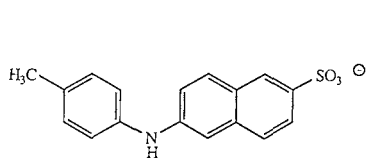
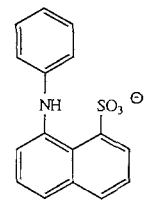
major advantage over the treatment of *Benesi* and *Hildebrand*, since no boundary condition with respect to the ratio of the concentrations of the two binding partners must be obeyed during the titration. Hence, this evaluation is of much broader applicability and, in view of the increasing use of computers, will presumably displace in the future the evaluations according to *Benesi* and *Hildebrand*, and to *Scott*, or *Scatchard*.[76,77,137-139a]

3. *Competitive Inhibition of the Complexation of a Fluorescing Guest by a Non-Fluorescing Inhibitor.* This method was applied in binding studies with the host **20**, when the complex stability constants could not be determined from extraction procedures or from the titration methods described above.[70] In a fluorescence titration with the boundary condition $[inhibitor]_0 \gg [host]_0 \gg [guest]_0$, the host concentration is continuously increased at constant inhibitor and guest concentration. Evaluation of the change in fluorescence intensity in a procedure analogous to the *Benesi* and *Hildebrand* treatment afforded the unknown association constant K_i of the inhibitor complex.[140] It is essential for the accuracy of this method that the association constant of the complex of the fluorescing guest, whose binding is competitively inhibited, can be determined exactly. As fluorescing guests in our studies, we used 6-(4-methylphenyl)amino-2-naphthalenesulfonate (TNS) **23** and 8-phenylamino-1-naphthalenesulfonate (ANS) **24**. These compounds form highly stable 1 : 1 complexes with the host **20** in aqueous solution and their stability constants could be very accurately determined from direct evaluations of the fluorescence titration curves.[70]



23



24

The two fluorescence probes TNS (**23**) and ANS (**24**) have been preferentially employed in the analysis of the complexation behavior of cyclophane hosts with apolar binding sites in aqueous solution.[52c,53d,54b,55c,69-71,78,123,141-147] In these studies, valuable information on the micropolarity of the binding sites is obtained from the fluorescence intensity as well as from the position of the emission maximum.[148-150]

4. *^{1}H-NMR Spectroscopic Estimation of the Association Constant of a Host-Guest Complex in a Series of Solvents.*[82] The degree of complexation and subsequently the stability constant in a given solvent is calculated from the complexation shifts $\Delta\delta_{obs}$ of host and guest protons observed in this solvent and the complexation shifts at saturation binding ($\Delta\delta_{sat}$) observed in another solvent. This method allowed the rapid determination of the complexing properties of host **22** in a larger series of solvents without resorting to the more exact but significantly more time-consuming NMR titrations.[82] Comparisons showed that the K_a-values calculated in this manner are in good agreement with the values determined from complete titrations. Significant binding constants are only obtained by this rapid method if, as demonstrated for the complexes of **22**, the geometry of the given host-guest complex is very similar in the two solvents. Only then can one expect similar complexation shifts at saturation binding ($\Delta\delta_{sat}$) in both solvents. This, however, is the prerequisite for using the $\Delta\delta_{sat}$ value from one solvent to determine the degree of complexation and the complex stability constant in a second one.

4.3. Stability and Structure of Complexes Formed by Polycyclic Aromatic Hydrocarbons in Aqueous Solution

With the host molecule **20**, by using solid-liquid and liquid-liquid extraction procedures, we were able to prepare for the first time a series of 1 : 1 complexes of polycyclic

aromatic hydrocarbons of variable size in aqueous solution.[70, 79] The amount of extremely insoluble hydrocarbon that can be solubilized in water is dramatically increased by host-guest complexation. As an example, the maximum solubility of pyrene in water is only 8×10^{-7} mol L^{-1}. With a 5.5×10^{-3} M aqueous solution of **20** in solid-liquid extractions, however, a complex solution can be prepared containing a total pyrene concentration of 2.8×10^{-3} mol L^{-1}. The association constants of the 1 : 1 complexes of arenes, determined from the two extraction procedures, are listed in Table 2.

Table 2. Association constants (K_a) and free enthalpies of complexation ($-\Delta G$)[a] for the 1 : 1 complexes of the hosts **20** and **21** with aromatic hydrocarbons in aqueous solution (T = 293-295 K).

Guest	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
a) Complexes of host **20** *in water:*		
Perylene	1.6×10^7	9.6
Fluoranthene	1.8×10^6	8.4
Pyrene	1.8×10^6	8.4
Biphenyl	2.2×10^4	5.8
Azulene	2.1×10^4	5.8
Naphthalene	1.2×10^4	5.5
Durene	1.9×10^3	4.4
b) Complexes of host **21** *in 0.5 M* KH_2PO_4, *pH* = 4.7:		
Pyrene	3.1×10^6	8.7
Naphthalene	1.6×10^4	5.6

[a] Free enthalpies are also known as Gibbs free energies of systems at constant T,p.

Table 2 shows that host **20** can form complexes with apolar guests in aqueous solution which are comparable in stability to enzyme-substrate complexes. The most stable complex is formed with perylene, the guest with the highest complementarity to the binding site and with the largest surface for hydrophobic and van der Waals interactions. The geometric complementarity between **20** and smaller arenes is less favorable and, expectedly, the complex stability decreases. Perylene binds better than pyrene and fluoranthene and a strong decrease in complex stability is observed with the smaller guests biphenyl, azulene, and naphthalene.[151] Durene is similar in size and shape to naphthalene and azulene. However, the association constant of the durene complex is about one magnitude smaller than those of the naphthalene and azulene complexes. This demonstrates the importance of van der Waals interactions for the stability of the complexes. These interactions are more effective in the complexes of the more polarizable guests naphthalene and azulene than in the durene complex. Hydrophobic interactions, however, represent the single most important driving force for complexation, as shown by the solvent dependency of the binding strength. Strong complexation is only observed in aqueous solution. In methanol, the free binding enthalpy of the **20** · pyrene complex ($K_a \approx 75$ L mol^{-1}) is 5.9 kcal mol^{-1} smaller than in water and, in dimethyl sulfoxide, almost no complexation at all is observed. In concentration ranges below 10^{-2} mol L^{-1}, we could not detect any molecular complexation of arenes in water by comparison compounds lacking the macrocyclic binding site.

The comparison of the two hosts **21** and **22** in weakly acidic aqueous solution underscores in an impressive way the importance of locating ionic groups remote from the binding site if strong hydrophobic complexation is to occur. In host **21**, only the three piperidine nitrogen atoms directed outwards are protonated. Hence, this macrocycle is a very good host for neutral arenes (Table 2). In addition to the three piperidine nitrogens, host **22** possesses two tertiary cryptand nitrogen atoms in the periphery of the cavity which are also protonated and favorably solvated. Hence, the hydrophobic character of the binding site is reduced and the complexation of arenes is much weaker. By solid-liquid extraction, the association constant of the **22** · pyrene complex in 0.5 M KH_2PO_4 was estimated as $K_a \approx 10^4$ L mol^{-1}. The complexation of pyrene in 0.5 M KH_2PO_4 by host **22** is therefore about 3.5 kcal mol^{-1} less favorable than the complexation of this guest by host **21** (Table 2).

Similar stability constants were measured for the arene complexes of the hosts **20** and **21** (Table 2).[82] The **21** · pyrene complex is only slightly more stable than the pyrene complex of **20**, and naphthalene even forms complexes of very similar stability with the two ligands. This high similarity in the complexing properties of two geometrically very different hosts was quite surprising at first. We had expected a considerably better binding by the more spherical host **21** as consequence of a much better encapsulation of the enclosed guest. The small difference in complexing ability between hosts **20** and **21** in aqueous solution indicates that the macromonocyclic host **20** already envelops and encapsulates efficiently arenes of complementary size. In addition, favorable solvation of the two amide groups in the periphery of the binding site of **21** interferes with hydrophobic complexation.

Detailed information about the spatial relationship between the two binding partners in the complexes of hosts **20**-**22** could be obtained by ^{1}H-NMR spectroscopy.[82, 111] In the complexes, the diatropic ring currents of both host and guest mutually influence the positions of their proton resonances and selective complexation shifts are observed. The extent of these complexation shifts depends on the distance and orientation of the two binding partners in the complex. Extensive ^{1}H-NMR studies showed that all aromatic guests prefer a location in a specific plane in the cavity of the host **20**.[111] This plane, which we have named the arene-guest plane of **20**, passes through the two spiro carbon atoms of the two diphenylmethane units and perpendicular to the mean molecular plane of the host. An incorporation of an aromatic guest in this plane is easily recognized in the ^{1}H-NMR spectrum by a characteristic pattern of upfield and downfield shifts of the host signals as well as by specific upfield shifts of the guest signals. Table 3 shows the complexation-induced shifts of the host and guest resonances in an aqueous solution of the **20** · pyrene complex. These characteristic signal shifts support the preferred orientation of pyrene in the arene-guest plane of **20** shown in Figure 5A. As depicted schematically in Figure 5A, the piperidinium rings attached to the aliphatic bridges approach and further envelop the enclosed guest. This

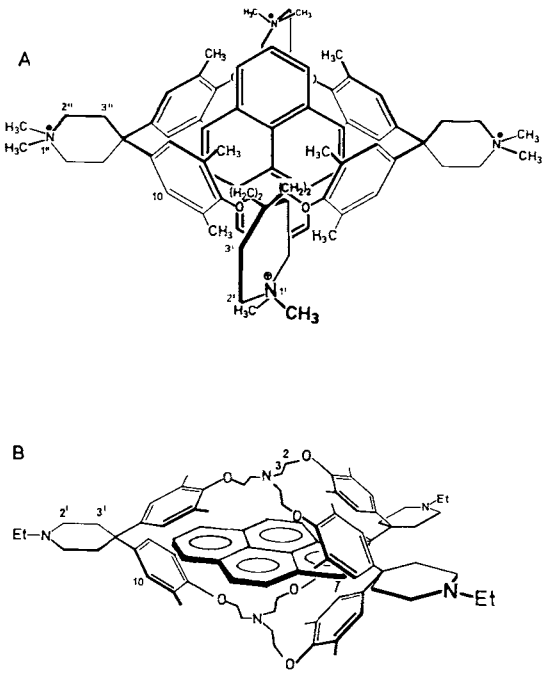


Fig. 5. Schematic drawing of the geometry of the complex which, according to ^{1}H-NMR, is highly favored for A) the **20** · pyrene complex in aqueous solution (the piperidinium rings of the bridges can also be oriented to the same cavity side), and for B) the **22** · pyrene complex in methanol (for the **21** · pyrene complex in aqueous solution, a very similar geometry is supported by ^{1}H-NMR spectroscopy).

leads to additional favorable shielding of the complexed apolar guest from the solvent.

In the complexes of **21** and **22** in aqueous as well as in organic solutions, the arene guests are exclusively located in the plane of the cavity passing through the three spiro centers of the host (Fig. 5B). Table 3 includes the complexation-induced shifts of the host and guest resonances for methanol solutions of the **22** · pyrene complex. These signal shifts clearly support the inclusion complex geometry shown in Figure 5B.

Table 3. Complexation-induced shifts ($\Delta\delta$ values, + = upfield shift) of host and guest proton resonances in the 360-MHz ^{1}H-NMR spectra of solutions of the **20** · pyrene complex in D_2O and of the **22** · pyrene complex in [D_4]methanol (see Fig. 5).

*a) **20** · pyrene complex in D_2O* [a]:

Host **20**	$\Delta\delta$ [ppm]	Pyrene	$\Delta\delta$ [ppm]
2-H	+0.81	1-H	+1.02
2′-H	+0.49	2-H	+0.44
2″-H	−0.07	4-H	+1.25
3-H	+0.52		
3′-H	+0.77	N(1′)-CH_3	+0.20

10-H	−0.31		
ArylCH_3	−0.02		

*b) **22** · pyrene complex in [D_4]methanol* [b]:

Host **22**	$\Delta\delta$ [ppm]	Pyrene	$\Delta\delta$ [ppm]
2-H	+2.14	1-H	+1.79
2′-H	−0.16	2-H	+1.21
3-H	+0.85	4-H	+1.98
3′-H	−0.43		
10-H	−0.60	N−CH_2−CH_3	−0.04
Aryl-CH_3	+0.08	N−CH_2−CH_3	−0.04

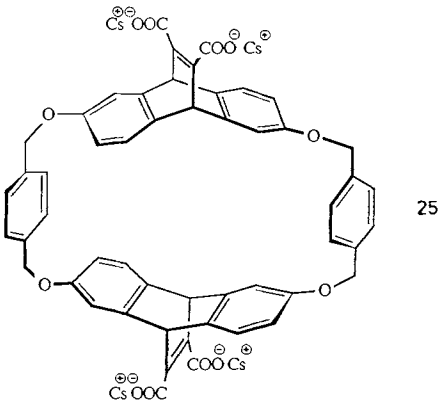
[a] This complex solution, obtained by solid-liquid extraction, contains [**20**] = 5.5×10^{-3} mol L^{-1} and [pyrene] = 2.8×10^{-3} mol L^{-1}. 2 H and 3 H, see formula **20** in Section 2. [b] Pyrene signals in a solution with [**22**] = 2.0×10^{-2} mol L^{-1} and [pyrene] = 2.0×10^{-3} mol L^{-1} and host signals in a solution with [pyrene] = 2.0×10^{-2} mol L^{-1} and [**22**] = 2.0×10^{-3} mol L^{-1}.

The ^{1}H-NMR studies have provided preliminary information on the kinetics of complex formation between our hosts and arenes in aqueous solution.[152] On the ^{1}H-NMR time scale (360 MHz), the dissociation of the **20** · pyrene and the **20** · fluoranthene complexes is slow at 273 K, while the dissociation of the **21** · pyrene complex is slow at 303 K. For the dissociation of the **20** · pyrene complex, the first order decomplexation rate constant was determined at the coalescence temperature as $k_{-1} = 495\ s^{-1}$ ($T = 273$ K). With an association constant $K_a = k_1/k_{-1}$ of 1.8×10^6 L mol^{-1} ($T = 293$ K), the second order complexation rate constant can be estimated as approximately $k_1 \approx 9 \times 10^8$ s^{-1} L mol^{-1}. Hence, the formation of the highly stable complexes of pyrene and fluoranthene in aqueous solution is not much slower than diffusion controlled. This fast complexation rate is not unexpected in view of the easy steric accessibility of the binding sites of our hosts. In addition, the desolvation of apolar binding sites and of the apolar arenes during the complexation step apparently requires only a small activation energy. The dissociation of the complexes formed by the smaller and weaker binding arenes, e.g. naphthalene and azulene, is fast on the NMR time scale.

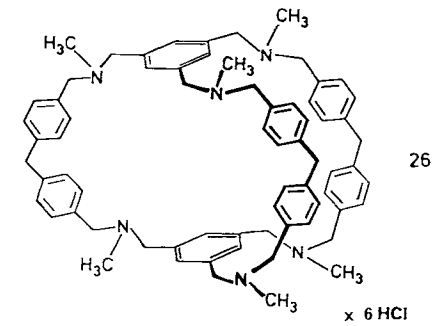
Different kinetics are observed if the aromatic guests possess polar neutral substituents capable of forming strong hydrogen bonds to the solvent (−$CONH_2$, −NH_2, −COOH, −OH). In the ^{1}H-NMR spectra of aqueous or methanolic solutions of complexes formed between the hosts **18** or **20** and 2,6-disubstituted naphthalenes as guests with these substituents, extreme signal broadening is observed at room temperature.[152] This broadening indicates decomplexation rates on the ^{1}H-NMR time scale. From the association constants measured in aqueous solution ($K_a = 10^4$ L mol^{-1}) and in methanol in particular ($K_a \approx 30$–350 L mol^{-1}), which are considerably smaller than in the case of the **20** · pyrene complex in water, it follows that the complexation steps must be significantly slower than diffusion controlled for the dissociation of the complexes to be observed on the NMR time scale. We explain the slower complexation step by the higher activation energy needed to desolvate the polar, hydrogen-bonding substituent upon penetration of the guest into the cavity binding site. The application of faster relaxation methods, e.g. ultrasonic relaxation, for studying the kinetics of the complexation of cyclophane hosts and organic molecules seems very desirable.[42a, 153] From such studies, interesting information on the energies needed to desolvate neutral polar substituents could be obtained.

In the meantime, other efficient hosts for the complexation of larger arenes in aqueous solutions have been described. *Dougherty* et al.[77] reported on the inclusion of anthracene as well as of pyrene ($K_a = 2 \times 10^6$ L mol^{-1}) by the macrocyclic ligand **25**. *Vögtle* et al.[126] obtained in a very short synthetic sequence the macrobicyclic host **26** which is soluble in dilute hydrochloric acid. Following the extraction procedures described above, solutions of complexes with large arenes, including benzo[*g,h,i*]perylene,

benzo[*a*]pyrene and triphenylene, could be prepared. The host **26** forms a very stable complex with phenanthrene but binds anthracene only weakly. This binding selectivity could be exploited for the separation of phenanthrene from anthracene by solid-liquid extraction. Furthermore, it was possible through complex formation with host **26** to separate partially hydrogenated arenes from the parent arenes, e.g. hexahydropyrene from pyrene and dodecahydrotriphenylene from triphenylene. In liquid-liquid extractions, only the strongly binding arenes are transferred from a *n*-hexane phase into the aqueous solution, whereas the poorly binding partially hydrogenated compounds are not extracted.



25



26 x 6 HCl

4.4. Acceleration of the Transport of Arenes through Aqueous Solutions

With the host **20**, we observed for the first time the molecular carrier-mediated acceleration of the transport of lipophilic arenes through an aqueous phase along a concentration gradient.[70, 154] Such a transport represents the inverted form of the molecular transport of cations through lipophilic membranes mediated by natural or synthetic ionophores.[155–159] The U-type cell shown in Figure 6 was used in our transport experiments. We measured the relative rate of transport of arenes from one hexane phase into a second hexane phase through an aqueous phase in the presence of and absence of host **20** in the aqueous phase. When the aqueous phase contained the host, the transport, especially of the larger arenes, was considerably accelerated. Competitive inhibition experiments demonstrated that the acceleration is a consequence of host-guest complexation in the aqueous phase. High guest selectivity in the transport acceleration was observed. Table 4 shows

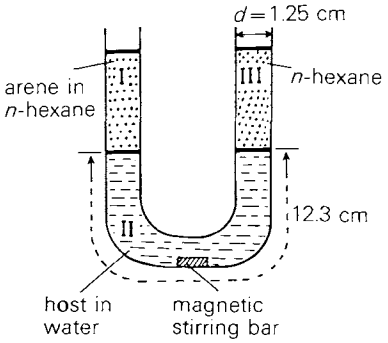


Fig. 6. U-type cell for studying the transport of arenes through an aqueous phase mediated by **20** as molecular carrier. The transport data of Table 4 were obtained with this cell.

that the highest acceleration is measured for the arenes with the lowest distribution constant K_d [Eq. (2)] and the highest association constant K_a of the complex formed with **20** in the aqueous phase.

Table 4. Acceleration of the transport of arenes through a 5×10^{-4} M solution of **20** as aqueous phase II against the transport through pure water ($T = 293$–295 K). The experiments were run in the U-type cell shown in Fig. 6. The initial concentration of the arenes in the *n*-hexane phase I was 10^{-2} mol L^{-1}. The association and distribution constants included in the table were obtained by liquid-liquid extractions.

Arene	Acceleration factor	K_a[L mol^{-1}]	K_d
Pyrene	430	1.8×10^6	8.3×10^{-6}
Fluoranthene	395	1.8×10^6	1.1×10^{-5}
Naphthalene	3.7	1.2×10^4	3.8×10^{-4}
Azulene	3.6	2.1×10^4	6.0×10^{-4}
Durene	1.8	1.9×10^3	3.8×10^{-5}

The molecular carrier-mediated transport of lipophilic molecules through aqueous solutions has also been studied by other research groups.[126, 160, 161] *Vögtle* et al.[126] described the separation of naphthalene from phenanthrene in transport experiments using U-type cells and the macrobicycle **26** as molecular carrier. Only phenanthrene forms a very stable carrier complex and, hence, only the transport of this arene is accelerated.

The molecular understanding of the carrier-mediated transport through aqueous solutions is still poorly developed. In particular, the relationship between the rate of transport and the stability constant of the carrier-complex needs to be determined. For the cation transport through lipophilic membranes, *Kirch* and *Lehn*[162, 163] as well as *Izatt*, *Christensen* et al.[159] have shown that the rate of transport initially increases with the cation-carrier complex stability to reach a plateau at K_a-values around 10^4–10^5 L mol^{-1}. Finally, at still higher K_a-values, the transport rate starts to decrease. It would be interesting to explore within a series of hosts, whether a similar dependency exists between the rates of transport in aqueous solution and the association constants of the arene-carrier complexes.

The transport monitored in our U-type cell is a "passive transport" along a concentration gradient. After approximately 10–15% of the total quantity of arene initially present in the source phase has been transported into the receiving phase, back transport becomes significant. The occurrence of back transport limits the utilization of the high

transport selectivity for efficient material separations. To take advantage of the high transport selectivity[70, 126] and to obtain higher separation yields, the transport has to occur in one defined direction. For the transport and separation of cations through lipophilic membranes, a variety of carrier-ligands which allow for "active transport" in one defined direction have been described.[43b, 164] As a characteristic feature, the complexing properties of these ligands can be rapidly and reversibly altered. The driving force for the unidirectional "active transport" can be provided by the electron flow in a redox process,[163, 165] by the light energy in a photochemical process,[43b, 164, 166] or by the proton flux in a pH-gradient.[164]

The complexing properties of the flavin-host **40** can be controlled by a redox process (Section 7). This system represents the first stage in the development of carriers for the separation of neutral molecules by "active transport" through aqueous solutions.[74]

4.5. Structure and Stability of Complexes of the Host 20 with Naphthalene Derivatives in Aqueous Solution

To explore the influence of guest substituents on the stability and structure of complexes in aqueous solution, we carried out extensive studies on the binding between the host **20** and a variety of naphthalene derivatives.[70]

Table 5. K_a and $-\Delta G$ of the 1 : 1 complexes of the host **20** und naphthalene derivatives in aqueous solution ($T = 293$ K). For comparison: naphthalene: $K_a = 1.2 \times 10^4$ L mol^{-1}; $-\Delta G = 5.5$ kcal mol^{-1} ($T = 293$–295 K); see Table 2.

Guest	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
a) Naphthalene derivatives with neutral substituents:		
1,5-Dimethylnaphthalene	3.3×10^4	6.0
2,6-Dimethylnaphthalene	2.6×10^4	5.9
2,7-Naphthalenediol	1.9×10^4	5.7
1,3-Naphthalenediol	9.8×10^3	5.4
1,5-Bis(dimethylamino)naphthalene [a]	9.7×10^3	5.4
1-(Dimethylamino)naphthalene	9.3×10^3	5.3
b) Naphthalene derivatives with ionic substituents:		
TNS **23**	5.0×10^6	9.0

2-Naphthalenesulfonate	4.0×10^5	7.5
1-Naphthalenesulfonate	3.5×10^5	7.4
5-Dimethylamino-1-naphthalenesulfonate	1.4×10^5	6.9
1-(Trimethylammonium)naphthalene-fluorosulfonate	1.7×10^3	4.3
1,5-Bis(dimethylammonium)naphthalenebis(deuterium chloride) [b]	$\approx < 10$	$\approx < 1.3$

[a] 1.5×10^{-2} M K_2CO_3, pH ≈ 11. [b] D_2O/DCl/KCl; pD = 1.2, ionic strength $I = 0.27$ mol L^{-1}.

Table 5a shows that naphthalene itself and derivatives with non-ionic substituents form complexes of similar stability ($K_a \approx 10^4$ L mol^{-1}, $\Delta G \approx -5.4$ kcal mol^{-1}). Our initial study included only naphthalene derivatives with donor substituents; such guests have unfavorable electronic complementarity to the electron-rich host **20**. At that time, the importance of electron donor-acceptor interactions in molecular complexes of our hosts had not yet been recognized. More recent studies (Section 5.2)[136] have demonstrated that a higher stability can be expected for complexes of **20** and naphthalene derivatives with acceptor substituents ($-CN$, $-NO_2$) than for the complexes of the non-ionic derivatives included in Table 5a.

^{1}H-NMR studies[111] have shown that substituents of the complexed guests extend out of the cavity into the aqueous solution; this occurs both for steric reasons and for reasons of favorable solvation of polar and ionic groups. The spectra indicated that, depending on the position of the substituents, the guests, especially the disubstituted naphthalenes, take a highly preferred orientation in the arene-guest plane of the cavity of **20** (Fig. 7). Naphthalene itself does not seem to prefer a specific orientation; Figure 7 shows its equatorial inclusion. Both 1,3- and 2,3-naphthalenediol prefer an axial, 2,6- and 2,7-disubstituted derivatives a pseudo-axial, and 1,5-disubstituted naphthalenes a pseudo-equatorial position in the arene-guest plane. These structural assignments are based on characteristic upfield shift patterns of the guest resonances in the ^{1}H-NMR spectra. It is apparent from Figure 7 that protons 1,4,5,8-H of an axially enclosed guest should encounter a specifically large upfield complexation shift. Similarly, a large upfield shift can be expected for the resonances of 4,8-H in a preferred pseudo-axial inclusion and for the resonances of 3,7-H in a preferred pseudo-equatorial inclusion. Experimentally, these complexation shifts are observed in the NMR spectra. The preferred pseudo-axial inclusion of disubstituted naphthalenes could be further supported by docking experiments in computer modeling studies. For the complexes formed by **4** or other tetraaza[n.1.n.1]paracyclophanes and naphthalene derivatives, *Koga* et al. had derived similar structures to those shown in Figure 7 from ^{1}H-NMR experiments.[54e, 110] They also proposed the nomenclature which we use to describe the different orientations of the guests in the cavity.

Additional ion-pairing can lead to extraordinary binding selectivity in a series of guests which fit well into the binding site (Table 5b). The host **20** forms complexes with naphthalene mono- and disulfonates that are considerably more stable than those of the neutral naphthalene derivatives in Table 5a. Thus, for example, host **20** forms the most stable complexes known with the anionic fluorescence probes ANS and TNS.[54b, 70, 144d, e] In the complexes of the naphthalenesulfonates, both apolar interactions in the cavity and ion-pairing interactions at the cavity periphery are operative. Efficient ion-pairing results from the electrostatic attraction between the anionic residues of the guests and the quaternary nitrogen atoms of the piperidinium rings attached to the aliphatic bridges of the host. This is shown in Figure 8 for the **20** · 2,6-naphthalenedisulfonate complex, a highly structured complex according to ^{1}H-NMR analysis. The importance of ionic interactions is demonstrated in an impressive way by the weaker binding of 1-(trimethylammonium)naphthalene fluorosulfonate and especially by the almost complete absence of complexation of 1,5-bis(dimethylammonium)naphthalene dihydrochloride (Table 5b).[80] This strongly reduced complexation is explained by the electrostatic repulsion between the cationic centers of both binding partners. Table 5b shows, that favorable versus unfavorable ionic interactions in

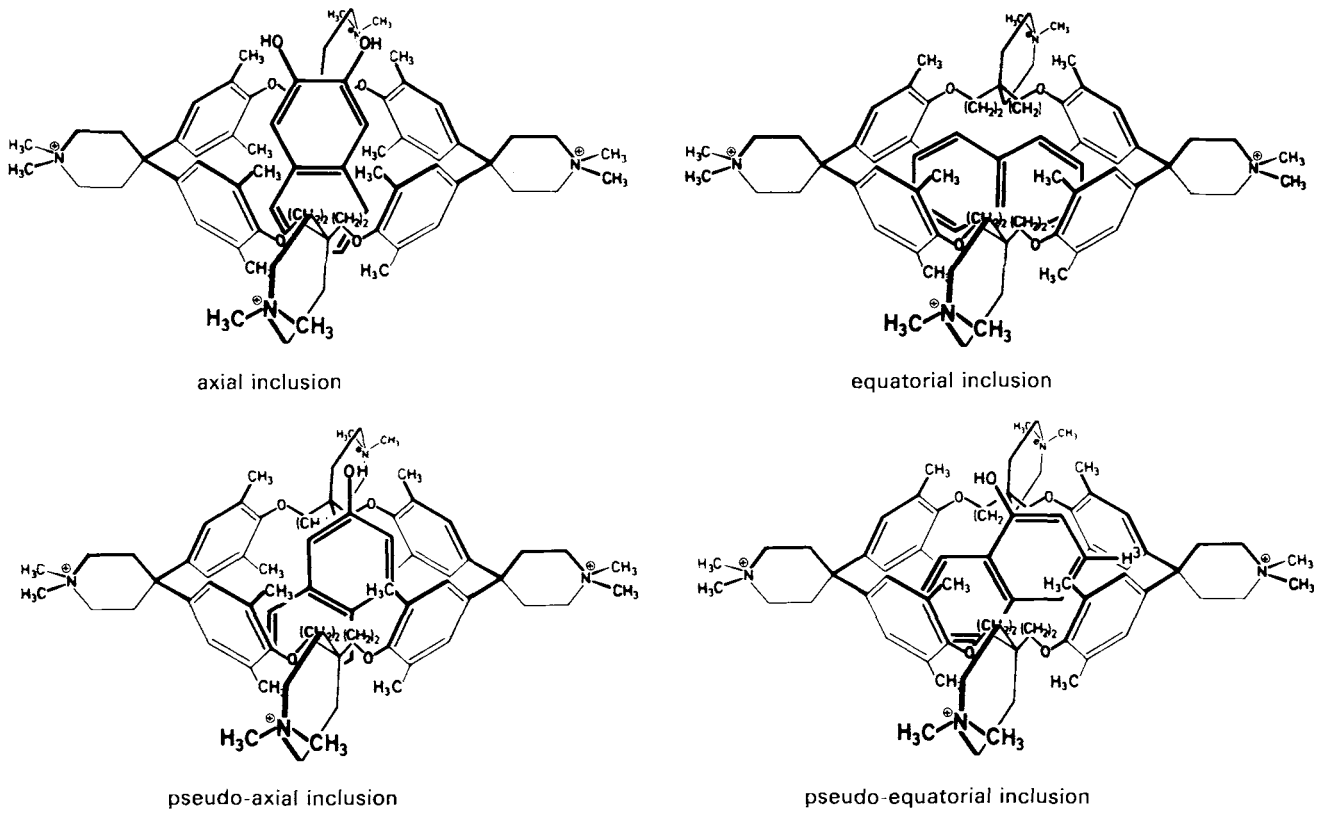

Fig. 7. Different possible positions of naphthalene and of substituted naphthalene derivatives in the cavity of **20**. The position of the spiro piperidinium rings fixed in the aliphatic chains of **20** is arbitrarily chosen. The inclusion of the following guests is shown: 2,3-naphthalenediol (axial), naphthalene (equatorial), 2,6-naphthalenediol (pseudo-axial), 1,5-naphthalenediol (pseudo-equatorial).

complexes of **20** with substrates of similar geometry [2,6-naphthalenedisulfonate and 1,5-bis(dimethylammonium)-naphthalene dihydrochloride] can lead to differences in the free enthalpy of complexation (ΔG) of more than 6.5 kcal mol^{-1}! Hence, multiple interactions in the complexes of cyclophanes lead to excellent, enzyme-like selectivity in the binding of a variety of guests which all fit well in the binding site. The efficient complexation of *p*-toluenesulfonate (Table 6) in the cavity of **20**, which is too spacious for a good fit of benzene guests, represents another example of hydrophobic interactions combined with ion-pairing acting as the driving force for complexation. This combination of binding modes is also at the origin of the strong complexation between the cationic hosts described by *Koga* et al., e.g. **4**, and arenesulfonates.[54b, 167]

Table 6. K_a and $-\Delta G$ of the 1:1 complexes of the hosts **20** and **12** with benzene derivatives and alicyclic compounds in aqueous solution ($T = 293$ K).

Host	Guest	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
a) Benzene derivatives:			
20	*p*-Toluenesulfonate	7.6×10^3	5.2
	Durene	1.9×10^3	4.4
12	TNS (**24**) [a]	1.5×10^3	4.3
	p-Benzenedicarbonitrile	1.5×10^3	4.3
	p-Dinitrobenzene	1.3×10^3	4.2
	p-Nitrotoluene	6.2×10^2	3.7
	Ethyl anthranilate	2.0×10^2	3.1
	p-Dimethoxybenzene	78	2.5
	p-Xylene	< 10	< 1.3
b) Alicyclic guests:			
20	Cyclohexyl acetate	7.4×10^2	3.8
	trans-1,4-Cyclohexanedimethanol	5.0×10^2	3.6
	1-Adamantanol	1.6×10^2	2.9

[a] Only the toluidine residue fits into the cavity.

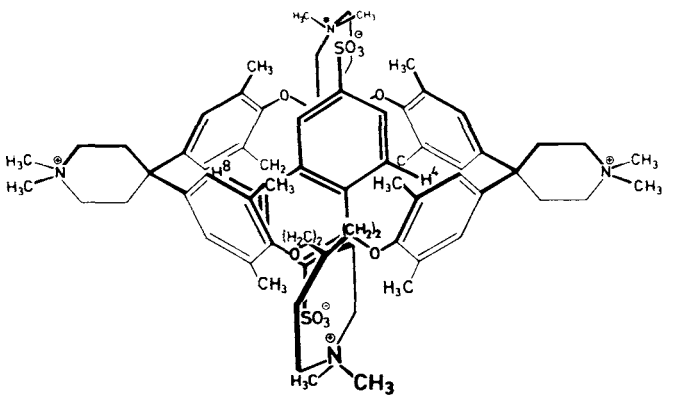

Fig. 8. Schematic drawing of the geometry of the **20** · 2,6-naphthalenedisulfonate complex, which, according to the ^{1}H-NMR spectrum is highly favored in aqueous solution. Observed complexation shifts of the guest resonances in an aqueous solution with [host] = [guest] = 4×10^{-3} mol L^{-1}: $\Delta\delta$ [in ppm] = 1.36 (1-H), 0.94 (3-H), and 3.09 (4-H).

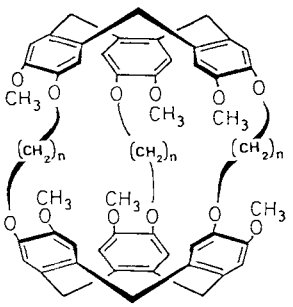
Dissociation of the highly stable **20** · 2,6-naphthalenedisulfonate complex is slow on the ^{1}H-NMR time scale at room temperature. This is also observed for the less stable complexes formed in methanol between host **18** and 2,6-disubstituted naphthalene derivatives with ionic substituents ($-SO_3^{\ominus}$, $-COO^{\ominus}$, $-SMe_2^{\oplus}$, $-NR_3^{\oplus}$). This again indi-

cates that the complexation rate is much slower than diffusion controlled. The slow complexation rates can be easily explained by the energetically unfavorable desolvation of one of the two ionic substituents required for the penetration of the guest into the cavity.

4.6. Complexation of Benzene Derivatives in Aqueous Solution

With the spherands, *Cram* et al. have designed the most efficient systems for the strong complexation of inorganic cations. CPK (*C*orey-*P*auling-*K*oltun) molecular models of the spherand complexes indicate an extremely tight encapsulation of these ions.[50d, 168, 169] In the design of hosts with specificity for benzene or naphthalene derivatives, however, we found that efficient complexation did not occur if CPK model examinations predicted the formation of such a tight complex. The modeling suggested the formation of a very stable complex between benzene derivatives and host **11** with the $(CH_2)_2$-bridges and between axially enclosed naphthalene guests and host **12** with the $(CH_2)_3$-bridges. In both cases, we did not observe any significant inclusion complexation.[71] Inclusion complexation only occurs with hosts that are larger: benzene derivatives form stable complexes with **12** and naphthalene derivatives take axial positions in the cavity of host **13** with the $(CH_2)_4$-bridges.



27a, n = 2
27b, n = 3

A similar discrepancy between CPK molecular model predictions and experimentally observed binding was also reported by *Collet* et al. who studied the binding of halogenated methanes by the bis(cyclotriveratrylenyl) hosts **27a,b** in 1,1,2,2-tetrachloroethane.[170] The host **27a** was designed to specifically bind chloroform; experimentally, however, the complexation of the smaller guest dichloromethane was preferred. Similarly, host **27b** was designed for carbon tetrachloride, but the complex formed with chloroform was two magnitudes more stable. We conclude from studies in *Collet*'s and in our laboratories that a host designed to complex a neutral organic molecule must incorporate a larger cavity than that suggested by CPK model examinations.[71]

The cavity of the host **12** with three methylene units in each bridge possesses optimum complementarity for benzene derivatives.[71] By ^{1}H-NMR spectroscopy, we observed the axial inclusion of more than ten *p*-disubstituted benzene derivatives in aqueous solution. This study revealed that the guest components with the most pronounced hydrophobic character, e.g. *p*-xylene, do not form the most stable complexes with **12** in aqueous solution. The complex stability is highest, as shown in Table 6, when host and guest possess optimum electronic complementarity in terms of electron donor-acceptor interactions (Section 5.2).[171]

A better complexation of benzene derivatives[144c] can be expected when the aromatic rings of a host similar to **12** are substituted with eight methyl groups in *ortho* positions to the ether oxygen atoms. An incremental increase in binding ability was observed upon stepwise introduction of two, four, six, and eight methyl groups in hosts **15**–**18**.[71] The methyl groups deepen the cavity and increase the hydrophobic character of the binding site. In addition, force-field calculations and computer graphics show[172, 173] that the methyl groups favorably influence the torsional angles in the dioxaalkane chains and enforce conformations of the host having a preorganized binding site.

The ^{1}H-NMR spectra recorded on solutions of complexes formed between **12** and benzene derivatives show only weak complexation shifts of the host resonances. There appears to be no preferred orientation of benzene in the cavity of **12**. Figure 9A includes a space-filling computer graphics representation of the complex formed between *p*-benzodicarbonitrile and the bis(*N*-methylpiperidine) precursor of **12**. The graphics suggest that π-π-interactions ("stacking interactions") between the almost cofacially oriented aromatic rings of host and guest as well as aryl-H_{guest}-aryl$_{host}$ interactions can contribute significantly to the stability of the complex. Similar stabilizing interactions are also apparent from the crystal structure of the **13a** · benzene complex shown in Figure 2B. The complex formed between the bis(*N*-methylpiperidine) precursor of

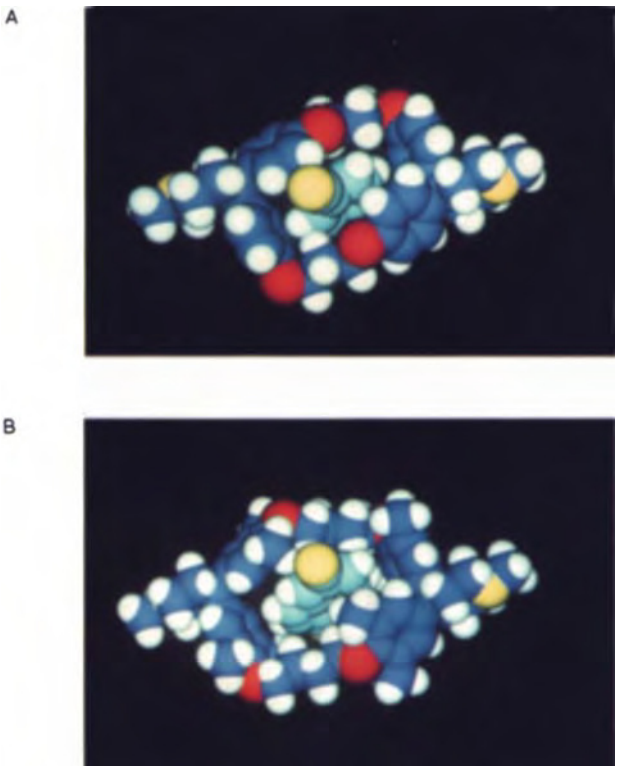


Fig. 9. Optimized space-filling structures generated on a Silicon Graphics IRIS 3130 workstation by the Hydra color graphics software A) for the complex formed between the bis(*N*-methylpiperidine) precursor of **12** and *p*-benzenedicarbonitrile and B) for the complex formed between the bis(*N*-methylpiperidine) precursor of **18** and 2,6-naphthalenedicarbonitrile.

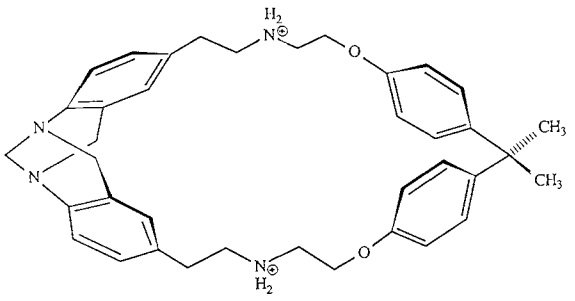
18 and 2,6-naphthalene dicarbonitrile is reproduced in Figure 9B. The color graphics of Figure 9 were generated by docking the guests into low energy conformations of the host that have been calculated by using a modified MM2 force-field.[173-175] The docking procedure involves the minimization of van der Waals energy during complex formation.[174]

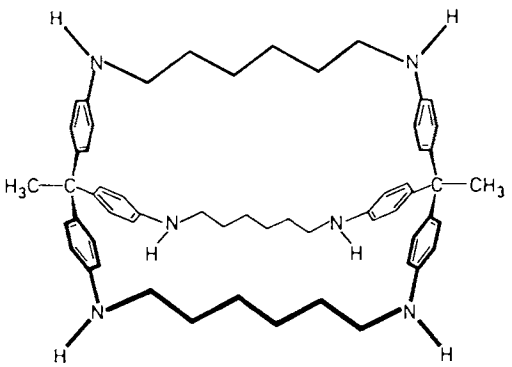
Wilcox et al. recently described the formation of stable complexes between host **28** and benzene derivatives in acidic aqueous solution.[144c] The binding site of **28** is shaped by a diphenylmethane unit and a derivative of *Tröger*'s base.[76]



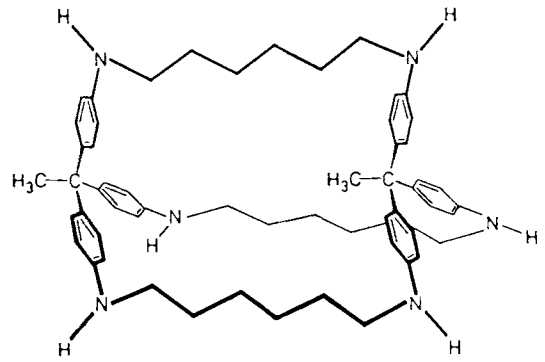
28

4.7. The Complexation of Neutral Non-Aromatic Molecules in Aqueous Solutions

The host **20** is also capable of complexing alicyclic derivatives[176] in aqueous solution (Table 6).[80] Since the cavity of **20** is quite narrow between the aliphatic chains, only flat alicyclic compounds possess complementary size to the binding site. Hence, **20** forms more stable complexes with cyclohexane than with the more spherical adamantane derivatives.



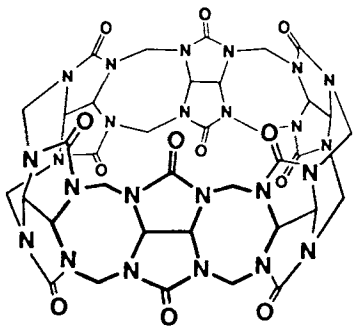
29a



29b

Water-soluble hosts with larger binding sites for the inclusion of adamantane derivatives and of steroids have been reported by *Vögtle* et al.,[144a] by *Koga* et al.,[54d] and by *Dougherty* et al.[77b] The interesting hosts **29a** and **29b**, which show very different complexation ability have been prepared by *Vögtle* et al.[144a] With its two triphenylethane methyl groups turned outwards, host **29a** possesses a spacious cavity and incorporates adamantane as well as derivatives with neutral substituents in acidic aqueous solution. In host **29b**, one of the two triphenylethane methyl groups is turned into the cavity, which drastically reduces the space available to a guest. Hence, **29b** does not complex molecules as large as adamantane. With $K_a = 1.2 \times 10^5$ L mol^{-1}, host **25** forms a very stable complex with 1-adamantyltrimethylammonium iodide. It would be of interest to determine the contribution of ion-pairing interactions to this strong binding.[77b]

By condensation of four acetaldehyde and four resorcinol molecules, *Schneider* et al.[177,178] prepared a host which, in basic aqueous solution, is soluble as a tetraanion and which shows a high binding affinity for quaternary ammonium ions.[139] Thus, for example, choline and the tetraanionic macrocycle form a 1:1 complex with a free enthalpy of formation of $\Delta G = -6.4$ kcal mol^{-1}. *Lehn* et al. have also reported a host for the specific complexation of quaternary aliphatic ammonium ions in aqueous solution.[179] The binding site of this host is shaped by two diphenylmethane units bridged by two tartrate residues. Complexation of neutral molecules was not described for these anionic host systems; ion-pairing rather than apolar interactions can be assumed as the major binding force in the complexes. Apolar host-guest interactions represent a major driving force for the inclusion complexation between cucurbituril (**30**) and aliphatic or aromatic primary



30

and secondary ammonium salts in aqueous formic acid.[114,180] In systematic binding studies, *Mock* et al. determined stability constants of $K_a = 10^3$–10^7 L mol^{-1} for the complexes of these ionic guests. In addition, they obtained ^{1}H-NMR spectroscopic evidence for the inclusion of cyclopentane, tetrahydrofuran (THF), and tetrahydrothiophene in the cavity of **30**. The binding of these neutral guests is, however, weaker than the binding of the ammonium compounds. The complexes of the latter guests are stabilized by ionic hydrogen bonding between the guest ammonium hydrogens and the host urea carbonyls in addition to the hydrophobic interactions.

Busch et al.[181] described relaxation time measurements and ^{13}C-NMR titrations to demonstrate the interactions in

aqueous solutions between aliphatic alcohols or phenols and the molecular cavities of transition metal complexes. Interesting ternary complexes are formed when the organic guests, e.g. *n*-butanol, are incorporated in the molecular cavity binding sites of these macrocyclic cobalt(II) and iron(II) complexes and when, in addition, oxygen binds reversibly to the transition metal ion.

By replacing the six methoxy groups in **27a** by OCH_2COOH residues, *Collet* et al.[182] prepared a water-soluble cyclophane host. The stability of the complexes formed by this host and dichloromethane or chloroform in aqueous solution is much higher than the stability of the complexes of host **27a** with these guests in 1,1,2,2-tetrachloroethane. The driving force for chloroform complexation by the modified host in water is $\Delta G = -5.3$ kcal mol^{-1} ($T = 300$ K); in the organic solvent the **27a** · chloroform complex is stabilized by only $\Delta G = -3.3$ kcal mol^{-1}.

Despite isolated progress, our understanding of the principles of molecular recognition of aliphatic guests by synthetic ligands and by cyclodextrins[68] in aqueous solution still leaves much to be desired compared to our understanding of the principles of molecular recognition of aromatic molecules.

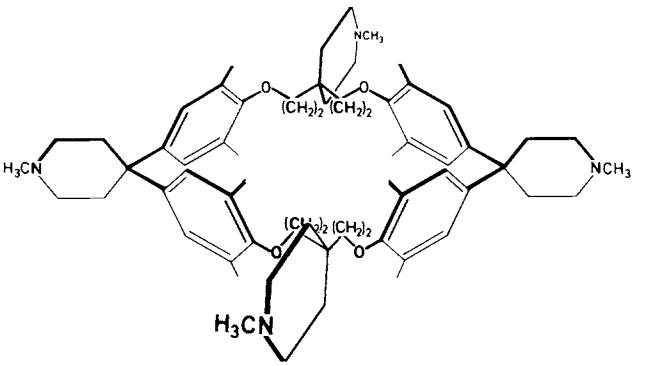
5. Complexation of Neutral Molecules by Cyclophane Hosts in Organic Solution

When we extended our studies with cyclophanes to non-aqueous solutions,[81,82] few examples of the molecular complexation of neutral molecules by macrocycles in organic solvents had been reported. In 1974, *Cram* et al.[183] described the formation of a crystalline complex between [18]crown-6 and acetonitrile. In the following years, the structures of many solid-state complexes of crown ethers with neutral small molecules possessing C–H, N–H, and O–H acidic functionalities were determined by X-ray crystallography.[184,185] However, first thermodynamic studies of the interactions between crown ethers and these neutral polar compounds in solution were only described in recent years.[138,186] An article in 1975 by *Siegel* and *Breslow*[187] first reported on the complexation of neutral, apolar molecules in organic solvents. In this paper, the authors described the inclusion complexation of arenes, e.g. toluene and anisole, as well as of ferrocence by cyclodextrins in dimethyl sulfoxide (Me_2SO) and in dimethylformamide (DMF). Other studies with cyclodextrins in organic solvents[188,189] include the interesting observation of complexation of nitrophenols and indoles by a peralkylated cyclodextrin in heptane by *Menger* et al.[190] Furthermore, it was observed that cyclophane hosts form complexes in organic solvents with carbon disulfide or methylacetylene[98a] and dichloromethane.[97c]

5.1. Complexation of Polycyclic Arenes

For our complexation studies in non-aqueous environments, we chose the neutral host molecules **21** and **22**, since these macrobicycles are readily soluble in almost the entire range of organic solvents. We investigated the complexation of the arenes perylene, pyrene, fluoranthene, naphthalene, and durene and were initially surprised by the magnitude of complexation observed in many organic solvents, specially for the larger guests. The ^{1}H-NMR spectra showed that all arene guests are encapsulated in the cavities of **21** and **22** as shown schematically for pyrene in Figure 5B. The geometry of a given complex, e.g. of the **22** · pyrene complex, is very similar in all solvents. Following the methodology described in Section 4.2, we determined the stability constants of the 1 : 1 complexes over a wide solvent polarity range.

To our surprise, host **22** with its two tertiary cryptand nitrogen atoms is a much better binder in organic solvents than host **21** with the two amide groups in the periphery of the cavity. The association constants of the perylene complexes formed by hosts **21**, **22**, and **31** in methanol ($T = 303$ K) are listed in Table 7. The free enthalpy of formation (ΔG) of the **22** · perylene complex is -7.0 kcal mol^{-1}, whereas the complexation of perylene by **21** is less favorable by 3.2 kcal mol^{-1} and thus similar only in strength to the complexation of this guest by the macromonocyclic host **31**. CPK model examinations do not support an explanation based on geometrical factors for the large difference in binding ability between the two spherical hosts **21** and **22**. We explain this difference, which is observed in all solvents, by complexation-induced unfavorable changes in the solvation of the two amide groups in the periphery of the cavity of **21**. We have accumulated additional experimental evidence both in aqueous and organic solutions of the impact of complexation-induced changes in the solvation of functional groups, especially of amide groups, on the binding strength.[192] If the energetically favorable solvation of a polar functional group of one of the binding partners is reduced in the complex compared to the free component and if no new binding interactions in the complex compensate for this loss in solvation energy, a considerably lower complexation strength will be observed.



31

Table 7. K_a and $-\Delta G$ of the 1 : 1 complexes of the hosts **21**, **22** and **31** with perylene in methanol ($T = 303$ K).

Host	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
22	1.1×10^5	7.0
21	5.6×10^2	3.8
31	8.4×10^2	4.0

Similar to aqueous solutions, the complementarity between host and guest in organic solvents is crucial in determining the strength of complexation. The sequence of the stability of the arene complexes shown in Table 8 for methanol is also observed in all other solvents. The same sequence was observed for the complexes of host **20** in aqueous solution (Table 2). The driving force for complexation in organic solvents is predominantly enthalpic in nature. For the **22** · perylene complex in ethanol, the enthalpic and the entropic contributions to ΔG were determined as $\Delta H = -10.7$ kcal mol^{-1} and $\Delta S_{303\,K} = -13.4$ cal mol^{-1} K^{-1}.

Table 8. K_a and $-\Delta G$ for the 1:1 complexes formed between the host **22** and arenes in methanol ($T = 303$ K).

Guest	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
Perylene	1.1×10^5	7.0
Fluoranthene	7.2×10^4	6.7
Pyrene	4.4×10^4	6.4
Naphthalene	1.2×10^2	2.9
Durene	27	2.0

Complexation of arenes occurs in a large variety of solvents. In each case, however, the binding is considerably weaker than in aqueous solution. An impressive dependency of the complexation strength on the nature of the solvent was observed. This dependency is shown in Table 9 for the **22** · pyrene complex. The driving force for complexation decreases from $\Delta G = -6.4$ kcal mol^{-1} in methanol to $\Delta G = -1.3$ kcal mol^{-1} in carbon disulfide. The strongest binding is observed in alcohols. Weaker but still considerable complexation occurs in dipolar-aprotic solvents, e.g. acetone, Me_2SO, DMF, and THF. The binding is weakest in chloroform, benzene, and carbon disulfide. Nevertheless, it is remarkable that arenes such as perylene, pyrene, and fluoranthene can be complexed in an aromatic solvent like benzene. For all complexes of hosts **21**, **22**, and **31** and the guests of Table 8, the same solvent dependency of the complexation strength as shown in Table 9 for the **22** · pyrene complex was observed.

Table 9. K_a and $-\Delta G$ of the **22** · pyrene complex in various organic solvents ($T = 303$ K).

Solvent	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
Methanol	4.4×10^4	6.4
Ethanol	2.5×10^4	6.1
Acetone	1.2×10^3	4.3
Dimethyl sulfoxide	6.9×10^2	3.9
Dimethylformamide	1.2×10^2	2.9
Tetrahydrofuran	84	2.7
Chloroform	43	2.3
Benzene	12	1.5
Carbon disulfide	9	1.3

According to the ^{1}H-NMR spectrum the geometry of the **22** · pyrene complex is very similar in all solvents (Fig. 5B). The large decrease in binding strength upon changing the solvent from methanol to carbon disulfide therefore cannot result from differences in attractive van der Waals interactions between host and guest in the complexes formed in these solvents. Rather, solvation phenomena must be responsible for the observed differences in complexation strength. In agreement with this hypothesis, the solvent-dependent free enthalpies of formation of the **22** · pyrene complex shown in Table 9 can be nicely correlated with empirical solvent parameters, e.g. with the Dimroth-Reichardt parameter E_T as shown in Figure 10.[193]

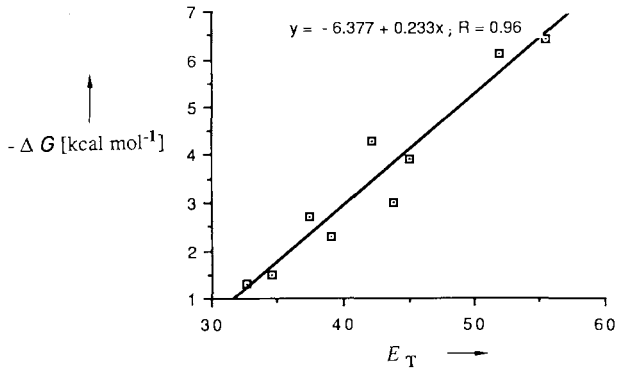


Fig. 10. Free enthalpies of complexation $-\Delta G$ (kcal mol^{-1}) of the **22** · pyrene complex in various organic solvents (see Table 9) plotted against the empirical solvent polarity parameters E_T [193] of these solvents.

For an explanation on a molecular basis of the observed differences in complexation strength, several parameters like the cohesive interactions of the solvent and the solvation of host, guest, and host-guest complex have to be considered. Differences in the external solvation of the complex as compared to the free host should not be of great importance since the encapsulated guest has no solvation-sensitive functional groups that extend out of the binding site. The observed sequence (Table 9) cannot be explained by the loss of heat of solvation upon desolvation of the guest during the inclusion process. There exists no significant correlation between heats of solvation[194] measured for benzene in the various solvents and the ΔG values of Table 9.

A larger part of the observed gradual change in binding strength could result from differences in the desolvation entropy gained upon inclusion of the solvated guest into the highly preorganized, solvated cavity of the host. In protic organic solvents, a favorable solvation-desolvation process similar to the hydrophobic effect in water could assist complexation, although such an effect will certainly be weaker here.

The weakest binding is observed in chloroform, benzene, and carbon disulfide. These solvents can compete with the guest for the binding site. As solvent molecules, these compounds are present in very large excess and, hence, their affinity for the cavity does not need to be very strong. Experimental evidence for favorable interactions between these molecules and the binding site of **22** are available. The affinity of carbon disulfide for apolar binding sites had been observed independently by *Cram* et al.[98a] Specific aromatic solvent induced shifts (ASIS)[55a,b] in the ^{1}H-NMR spectra of **22** in benzene indicate interactions of the benzene molecules with the cavity.[82] A chloro-

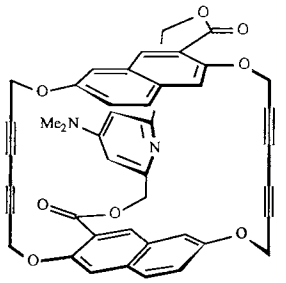
form molecule enclosed in the cavity can form a N···H-CCl_3 hydrogen bond to the cryptand nitrogen atoms of **22**.

The extent to which a solvent molecule can act as an efficient competitor of the guest for the cavity binding site is largely determined by the cohesive interactions in the solvent. These forces determine the energy needed to disrupt the interactions of a solvent molecule with the surrounding solvent molecules in the bulk and to transfer it for solvation into the host cavity. The molar heat of vaporization, ΔH_{vap} [kcal mol^{-1}] or, alternatively, the internal pressure, can be considered as a measure for the cohesive interactions in a given solvent.[195] We found a significant correlation, analogous to the one shown in Figure 10, between the ΔG values of the **22** · pyrene and the **22** · perylene complexes and the molar heats of vaporization ΔH_{vap} of the solvents. The decrease in free binding energy upon changing from protic solvents to dipolar aprotic solvents and to benzene and carbon disulfide is parallel to the decrease of the cohesive forces, expressed by the molar heats of vaporization. At smaller ΔH_{vap} values, it becomes increasingly favorable to transfer a solvent molecule for solvation from the bulk into the cavity. In this sequence, therefore, a solvent molecule becomes a more and more efficient competitor of the substrate for the host cavity.

Our studies clearly show that predictions of the stability of host-guest complexes based on computer-modeling can only be successful if specific solvation free energies are taken into account.

As mentioned in Section 4.6, *Collet* et al.[97,170] studied the complexation in organic solvents between hosts such as **27a** or **27b** and halogenated methanes. Recently, they described the molecular complexation of isobutane in 1,1,2,2-tetrachloroethane, and this represents the first report of alkane binding in an organic solvent.[191] Despite *Collet*'s and our work, the complexation of neutral molecules at apolar binding sites in organic solvents still remains relatively unexplored. Progress in this area is of special interest in the development of bioorganic, enzyme-like catalysts that complex their substrates prior to the actual reaction steps. Although enzymes are water-soluble and take their substrates mostly from aqueous environment, the catalytic processes occur in non-aqueous media at their active sites. Evidence is accumulating of the importance of desolvation for the large rate enhancements in enzymatic reactions. These reactions occur at active sites, dipolar-aprotic in nature, rather than in aqueous environment where solvation processes often lead to much higher reaction transition states.[196-198] The complete shielding from the solvent of the reactive sites of bioorganic, enzyme-like catalysts that are active in water could require the construction of very complex molecules. An easier alternative could well be the design and synthesis of hosts that bind and catalyze in dipolar-aprotic solvents.

Rebek et al.[40b,199] have described the stoichiometric complexation of heterocyclic arenes, e.g. pyrazine, phenoxaline, phenazine, pyridine, purine, and 9-ethyladenine[199b] by non-macrocyclic, cleft-type receptors. These complexes are held together mainly by hydrogen-bonding interactions. Hydrogen-bonding can also lead to selective complexation by cyclophane hosts as was shown by *Whitlock* et al.[85,200] In 1,2-dichloroethane solution and in the solid state, they observed the preferred inclusion of *p*-nitrophenol ($K_a = 3 \times 10^3$ L mol^{-1}) as well as of *p*-hydroxybenzonitrile ($K_a = 1.1 \times 10^3$ L mol^{-1}) in the completely preorganized cavity of **32**. At the desolvated binding site, a firm hydrogen bond forms between the pyridine nitrogen of the host and the phenolic hydroxyl group of the guest. *Whitlock* et al. found that geometrically comparable guests without a hydrogen-bond donor center did not undergo complexation with **32**. Interestingly, a large binding selectivity is also observed among guests which possess both geometric complementarity and a hydrogen-bond donor center. This selectivity is explained by the need for a special favorable relationship between the pK_a values of host and guest.

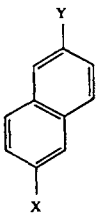


32

5.2. Electron Donor-Acceptor Interactions in Host-Guest Complexes

Over the past decades, the important role of electron donor-acceptor (EDA) interactions[201-205] for selective molecular complexation in biological systems[206-207] and also in synthetic host-guest complexes[50c,208,209] has been recognized. These interactions are also of key importance in chromatographic optical resolution processes on chiral phases and especially on Pirkle phases.[210] Major components of the interaction in EDA complexes are defined as electrostatic interaction, polarization interaction, and charge-transfer interaction as well as dispersion energy.[201,202] To explore the contribution of these interactions to the stability of the complexes formed by our cyclophane hosts, we studied the binding between host **18** and a series of 2,6-disubstituted naphthalene derivatives, e.g. **33a-i**, in methanol (Table 10).[136] These guests adopt a pseudo-axial position in the cavity of **18**, which allows for efficient π-π-interactions in the complexes. This can be seen in Figure 9B which shows in a space-filling computer graphics representation the energetically favorable location of 2,6-naphthalenedicarbonitrile (**33i**) in the cavity of the bis(*N*-methylpiperidine) precursor of **18** (Fig. 9B).

Our complexation studies revealed that the electron-deficient guests **33g-i** with two acceptor substituents form more stable complexes than the electron-rich guests **33a-c**, while the complexes of guests having one donor and one acceptor substituent (**33d-f**) demonstrate an intermediate stability (Table 10). The differences in free enthalpy, ΔG, determined from ^{1}H-NMR titrations (Fig. 4),[136] are as large as 1.48 kcal mol^{-1} at 303 K and result from a major contribution of intermolecular EDA interac-



33a-i

Table 10. K_a and $-\Delta G$ for the 1:1 complexes formed between the host **18** and the naphthalene derivatives **33a-i** in [D_4]methanol ($T = 303$ K).

Guest	X	Y	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]
a) Donor-donor guests:				
33a	OH	OH	24	1.91
33b	NH_2	NH_2	33	2.11
33c	OCH_3	OCH_3	47	2.32
b) Donor-acceptor guests:				
33d	NH_2	NO_2	102	2.78
33e	OCH_3	NO_2	109	2.82
33f	OCH_3	CN	117	2.87
c) Acceptor-acceptor guests:				
33g	$COOCH_3$	$COOCH_3$	188	3.15
33h	NO_2	NO_2	213	3.23
33i	CN	CN	277	3.39

tions in the complexes. With its four trialkylsubstituted anisole units, compound **18** can be considered as a donor host. As expected for EDA interactions, the most stable complexes are formed with the acceptor guests **33g-i**. The importance of attractive interactions in the complexes of the acceptor guests is reflected in the enthalpic and entropic contributions to the free enthalpy of complexation ΔG. For the **18-33i** complex in methanol, these contributions were determined as $\Delta H = -7.6$ kcal mol^{-1} and $\Delta S_{303\,K} = -14.1$ cal mol^{-1} K^{-1}.

In the meanwhile, our studies have shown that EDA interactions are of general importance in the complexes of our hosts with aromatic guests. This extra stabilization of complexes formed between donor hosts like **11-20** and acceptor guests has been observed in a large variety of solvents, e.g. in water, methanol, Me_2SO, and cyclohexane,[211] and results mainly from electrostatic and polarization interactions. Even the complexes with very good acceptor guests, e.g. *p*-benzoquinone, *p*-benzodicarbonitrile, *p*-dinitrobenzene, do not give a charge transfer band in the electronic absorption spectra,[204] since the ionization potential of the trialkylsubstituted anisole units of our hosts presumably is too high.

6. Chiral Recognition in Diastereomeric Host-Guest Complexes in Aqueous Solution

With increased understanding of molecular complexation in aqueous solution, we next addressed the development of optically active hosts for chiral recognition in water-soluble diastereomeric complexes. Free or polymer bound macrocycles with asymmetric binding sites could have great potential for the resolution of racemic guests in chromatographic, transport, or extraction processes. Asymmetric synthesis and catalysis in supramolecular complexes represents another fascinating perspective of this research.

The first reports on the synthesis of chiral macrocyclic polyethers by *Wudl* and *Gaeta*[212] and *Cram* et al.[213] appeared about fifteen years ago. Since then, a large variety of optically active macrocyclic polyethers have been prepared for the resolution of racemic cationic guests through complexation in organic solutions.[30,31,33a,47b,214,215] Chiral recognition of non-cationic racemic guests in diastereomeric complexes of macrocyclic hosts has until recently almost exclusively been limited to free or polymer-bound cyclodextrins.[9a,216,217] Only a few reports have appeared in recent years describing the formation of diastereomeric complexes between fully synthetic, optically active ligands and non-cationic guests in aqueous and organic solutions.[218-220] *Koga* et al. replaced the alkyl bridges in the host **4** by bridges derived from L-tartaric acid [$-CH_2-CH(OCH_3)-CH(OCH_3)-CH_2-$] and observed the formation of diastereomeric complexes in acidic aqueous solution with racemic guests like mandelic acid and atrolactic acid.[218] *Collet* et al. described the formation of diastereomeric inclusion complexes in chloroform between an optically active host resembling compound **27a** and (*R,S*)-bromofluoroiodomethane.[219]

In our first approach to the development of chiral hosts, we chose the biphenyl-macrocycle **35** as the target molecule.[221] This host, in optically active form, was designed to differentiate via complexation between the enantiomers of aromatic α-amino acids and arylpropionic acids, e.g. naproxen (**36**), an inhibitor of the enzyme cyclooxygenase responsible for prostaglandin biosynthesis. Differences in apolar interactions and ion-pairing as well as in steric interactions were expected to lead to the formation of diastereomeric complexes of different stability. Binding studies with **34** in acidic aqueous solution, however, clearly revealed that this biphenyl macrocycle did not act as a host. Contrary to expections based on CPK model examinations, compound **34** does not possess an efficient binding site for aromatic guests. Force-field calculations in combination with computer graphics provided an explanation for this absence of binding. According to the calculations, the biphenyl unit in **34** is not a suitable spacer group. With an O···O distance of 8.91 Å (in free form), the diphenylmethane unit incorporated in **34** and in our other hosts, e.g. **11-18**, favorably shapes and widens binding sites for arenes and flat cycloalkanes. At an O···O distance of only 4.10 Å (in free form), the biphenyl unit of **34** does not sufficiently widen the macrocyclic cavity binding site. In ad-

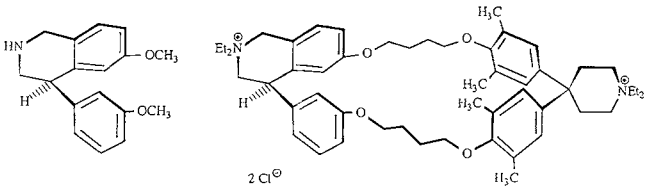
36, R = H
37, R = CH_3

dition, the computer graphics of the MM2 optimized[175] structure of **34** revealed that this macrocycle prefers an extensively twisted helical geometry. This helical twist further reduces the size of a possible binding site and was not expected from CPK model examinations.[172] The helical conformation seems to be imposed on the macrocycle by the tendency of the bridging alkane chains, which connect two spacers of very different O···O distances, to maximize the number of antiperiplanar torsional angles.

Force-field calculations indicated that the critical O···O distance in the 4-phenyl-1,2,3,4-tetrahydroisoquinoline derivative **38** would be considerably larger than in the biphenyl unit of **34**, and that **38** would consequently be a more favorable chiral spacer.[172] Starting from (−)-**38**, we prepared the optically active host (+)-**39**[222,223] and found its binding properties consistent with the force-field predictions. In water/methanol (60:40), (+)-**39** preferentially binds 2,6-disubstituted naphthalenes which take a pseudo-axial position in the cavity. By ^{1}H-NMR spectroscopy, we could clearly demonstrate the formation of diastereomeric complexes between (+)-**39** and (*R,S*) naproxen (**36**) or its methyl ester (*R,S*)-**37**. In the host conformation which is the most preorganized for complexation, but not however the most energetically favorable, the O···O distance at the chiral spacer is 7.58 Å.[172]



(−)-38 (+)-39

Besides providing clear evidence for the formation of diastereomeric complexes by host **39** in aqueous solution, our research efforts in the area of chiral recognition so far have shown ways to a more rational design of host systems.[55c,172] The ability of aromatic building blocks, especially of those with several energetically favorable conformations, to act as spacers in macrocyclic hosts can be tested prior to synthesis by force-field calculations. According to these calculations, a correct O···O distance in the aromatic spacers is crucial for the complexation properties of our macrocycles. For design purposes, diphenylmethane units like **5**–**7** with their favorable cavity opening O···O distance can be taken as a reference for new spacer building blocks suitable for the construction of binding sites for flat alicyclic and aromatic guests.[54c,224] We predict, that efficient hosts for these guests are formed when an achiral or chiral aromatic spacer unit with an O···O distance of ≥6.5 Å and a diphenylmethane unit like **5**–**10** are bridged by suitably sized aliphatic chains.

The computer modeling not only provided aesthetic visualizations of our macrocycles (e.g. in Fig. 9), it also advanced our knowledge on the principles of molecular recognition.[172] The experimentally observed binding properties of our macrocycles could be reproduced in the docking experiments. Further support could be provided for complex geometries, e.g. for the preferred pseudo-axial inclusion of 2,5-disubstituted naphthalenes (Fig. 9B), which had been previously deduced experimentally from extensive ^{1}H-NMR binding studies. The influence of the aliphatic bridge conformations on the spatial structure of our macrocycles has been recognized more clearly through the modeling studies. Affordable computers and sophisticated graphics programs are available to chemists, and it is safe to predict that computer assisted design will play a very important role in the future development of synthetic chiral and achiral receptors and catalysts.
