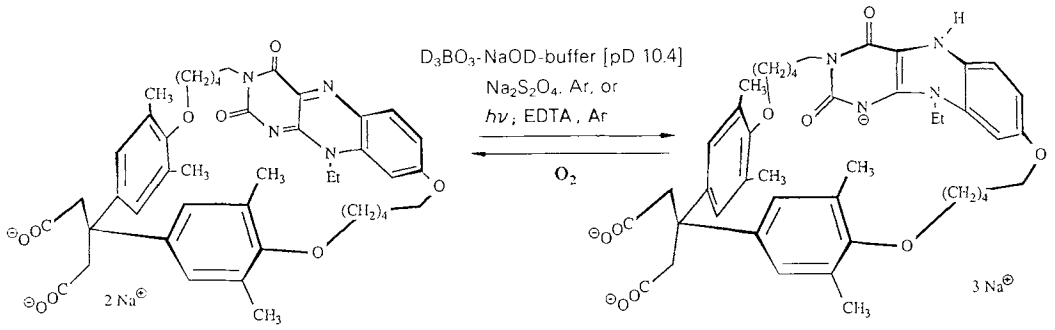
Soon after his first fundamental studies on molecular complexation by cyclodextrins, *Cramer* investigated the enzyme-like catalytic properties of these systems.[7,8] Following this, a large variety of stimulating and innovative studies on the catalytic properties of the cyclodextrins have been conducted by *Cramer* himself[8c] and by research workers in the laboratories of *Bender*,[9] *Breslow*,[10] and *Tabushi*.[11] These together with the pioneering work in the seventies in the laboratories of *Cram*,[50] *Lehn*,[49] *Murakami*,[53] and *Kellogg*[39] on catalysis in synthetic supramolecular complexes have generated a fascination for the rational development of efficient bioorganic catalysts. Since then, an increasing number of chemists became interested in this important new area of research. The scope of this article does not allow discussion of the original work of these researchers. It should, however, be noted that cyclophanes with binding sites for neutral molecules[11b,43,52c,53,144a,176,218b,225–228] have been designed and studied in an increasing number as bioorganic catalysts.[35,45a,103b,180c,229–237] The remaining part of this article will provide a short account of our first studies in the field of molecular catalysis.[74,238,239]

Current research objectives in our laboratories address the activation of coenzymes by the specific microenvironment of an apolar active site as well as the influence of coenzymes on the strength of substrate binding.[74] For these studies, we prepare water-soluble macrocycles with coenzyme models attached in a defined way to the periphery of the preorganized binding sites.[10,11e] A considerable influence of the coenzyme on the strength of substrate binding can be expected especially for flavoenzymes. The flavin coenzymes FMN (flavin mononucleotide) or FAD (flavin adenine dinucleotide) are known to be tightly bound or, in some cases, even covalently attached to the active sites of flavoenzymes.[240] To explore how the large isoalloxazine unit of these coenzymes affects the complexation ability of a molecular binding site, we prepared the flavin host **40a** with an isoalloxazine unit as cavity wall. In aqueous alkaline borate buffer (pH = 10) under argon, the flavin host **40a** could be readily and quantitatively reduced to the trianionic host **40b** with a dihydroisoalloxazine unit as the cavity wall. Upon introduction of oxygen into the solution of **40b**, the oxidized flavin host **40a** is regenerated quantitatively. The redox cycles **40a** ⇌ **40b** can be repeated numerous times without affecting the molecular structure of the host.

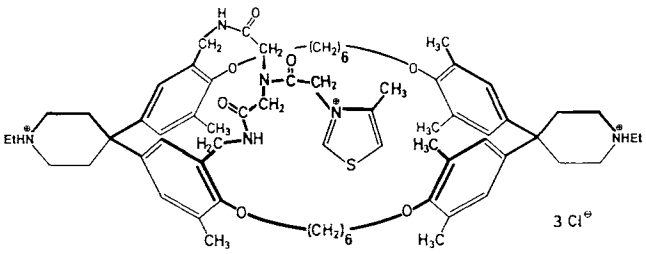


40a 40b

The geometry of the binding site of the host systems **40a/b** is highly dependent on the redox state of the flavin unit. The oxidized isoalloxazine unit in **40a** is planar while the $2e^{\ominus}$-reduced dihydroisoalloxazine unit in **40b** is butterfly shaped as shown in the formula. Values of 30° have been observed in X-ray crystal structures for the angle about the two nitrogens N-5 and N-10 of the central ring in the dihydroisoalloxazine unit.[240] The different geometry of the tricyclic system in the two redox states influences the binding properties of the macrocycles. Both **40a** and **40b** form complexes in aqueous solution with 2,6-disubstituted naphthalene derivatives ($K_a \approx 100$–500 L mol^{-1}). In the cavity of **40a**, the guests assume a near cofacial orientation to the isoalloxazine unit. In the cavity of **40b**, the guests take a similar position as in the complexes of the bis(diphenylmethane) hosts, e.g. **18**. Differences in the stability of the complexes of **40a** and **40b** can result from differences in the charge and geometry of the binding sites as well as from electron donor-acceptor interactions. EDA interactions are responsible for the strongly redox-dependent complexation of acceptor-acceptor substituted guests. Compounds like 2,6-naphthalenedicarbonitrile or 2,6-dinitronaphthalene only undergo complexation with the reduced host **40b** and not with the oxidized host **40a**. We explain this different complexing behavior by favorable electronic complementarity between the electron-rich host **40b** and the acceptor guests only. Electrostatic repulsion between the electron-accepting isoalloxazine unit of the oxidized host **40a** and these guests leads to a complete absence of binding. In addition to further quantitative binding studies involving biological substrates, we now focus on the catalysis of redox processes in the supramolecular complexes formed by the flavin host systems **40a/b**.[241,242]

A major advantage for the development of bioorganic catalysts is the easy and selective functionalization of our tetraoxa[n.1.n.1]paracyclophanes, especially at the aromatic rings.[238,239,243] We prepared the thiazolium derivative **41** in order to explore the influence of an apolar macrocyclic cavity binding site on the activity of thiazolium ions in the benzoin condensation.[244,245] In this macrobicyclic system, a thiazolium ring is attached in a favorable position to the binding site which provides space for the two benzaldehyde molecules to react to give benzoin. The entropically favorable proximity and orientation of the substrate and the coenzyme model were expected to effect catalysis.[66a]

The macrobicycle **41** represents a very complete model system for thiamine pyrophosphate-dependent ligases. In protic solvents, where complexation of benzaldehyde takes place, **41** is a better turnover catalyst ($k_{cat} = 1.1$ min^{-1} in

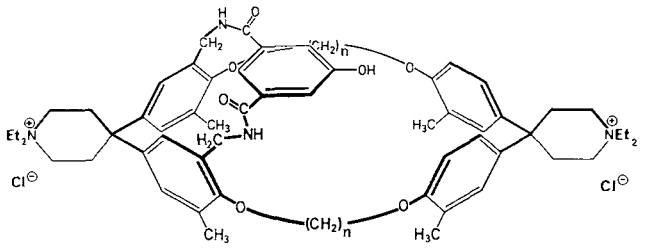


41

methanol, [Et_3N] = 160 mmol L^{-1}, [$Et_4N^{\oplus}Cl^{\ominus}$] = 100 mmol L^{-1}, $T = 35$°C) for the benzoin condensation than non-macrocyclic thiazolium derivatives. The observed saturation kinetics, describing a sigmoid curve, could be best evaluated by assuming the formation of a 1:2 Michaelis–Menten complex. In methanol, the equilibrium of the benzoin condensation is far on the benzoin side, and in reactions catalyzed by **41**, benzoin could be isolated in 93% yield. In Me_2SO, the equilibrium is far less on the side of benzoin, and by starting from pure benzoin, benzaldehyde could be isolated. In aqueous buffers, we could demonstrate a specific activation of the thiazolium ring by the binding site of **41** which is of lower polarity than the surrounding solution.[238,244] We observed a strong influence of the cavity of **41** on the H/D exchange,[246,247] which is considerably faster at C-2 of the thiazolium ring of **41** than at C-2 of thiazolium derivatives without a macrocyclic binding site. We explain this H/D exchange rate enhancement by a micropolarity effect of the cavity of **41** on the (kinetic) acidity of the proton 2-H of the thiazolium ring. Therefore, one of the catalytic advantages of **41** relative to non-macrocyclic thiazolium derivatives could be the formation of a larger amount of reactive ylide at a given pH.

Like many other researchers [8–11,49,50f,53,103b,226,228c,229–231,234–237] we also focus on the development of synthetic hydrolases.[239] At the active sites of proteases[66a], e.g. the well studied serine proteases, the thiol proteases, or the aspartyl proteases, highly efficient catalytic mechanisms are generated through a specific array of functional groups. The isolated forms of these functionalities demonstrate lit-

tle or no catalytic activity. Only by their cooperative action at the specific active site do catalytic mechanisms such as transition state binding and stabilization, acid-base catalysis, nucleophilic and electrophilic catalysis become effective.[66a, 248] It is not surprising that the possibility of generating such catalytic mechanisms in designed supramolecular complexes is a fascinating objective for many research groups.



42, n = 4
43, n = 6

On the way to synthetic hydrolases, we have prepared the macrobicycles **42** and **43**.[239] These systems possess phenolic hydroxyl groups as nucleophiles that are active at near physiological pH. The nucleophiles are positioned in a well defined way atop the macrocyclic binding sites. By comparing the esterase activity of **42** and **43**, we have obtained a fine example for the concept of *productive versus non-productive binding*, a mechanism believed to generate substrate specificity in enzymatic catalysis.[249] Both macrocycles form complexes of similar stability with naphthalene guests in aqueous solution. With 4-nitro-1-naphthylacetate as a substrate, we observed a large difference in the transacylation rates. In aqueous phosphate buffer at pH 8.0 ($T = 20°C$; [host] $= 5.0 \times 10^{-4}$ mol L^{-1}; [4-nitro-1-naphthylacetate] $= 2.0 \times 10^{-5}$ mol L^{-1}) the acylation of **42** by the naphthyl ester is only 14 times ($k_{obs} = 2.43 \times 10^{-4}$ s^{-1}) faster than the hydrolysis in pure buffer. Under these conditions, the acylation of **43** by the complexed ester is 178 times faster ($k_{obs} = 3.21 \times 10^{-3}$ s^{-1}) than the hydrolysis in pure buffer. For the acyl transfer in the presence of **43**, saturation kinetics is observed, whereas the reaction in the presence of **42** strictly follows second order kinetics. Only host **43** forms a productive complex with a favorable proximity between the phenolic hydroxyl group and the substrate carbonyl group. The smaller host **42** also forms a stable complex with the naphthyl ester. In this complex, however, the phenol ring completely blocks one side of the cavity. The ester residue of the guest extends in a non-productive manner out of the cavity on the side opposite to the nucleophile and undergoes an intermolecular reaction with the phenol group of another host molecule.

The phenolic OH group in **43** is not only a good nucleophile in the transacylation step but, with its estimated pK_a of ≈ 8.4, also represents a favorable leaving group in the deacylation step as indicated by a weak but significant catalytic turnover.[239, 250] With [**43**] $= 1.0 \times 10^{-5}$ mol L^{-1} and [4-nitro-1-naphthylacetate] $= 1.0 \times 10^{-4}$ mol L^{-1} under the above mentioned conditions, the covalently catalyzed ester hydrolysis is accelerated by a factor of 1.3 compared to the hydrolysis in pure buffer. Under these conditions, only $\approx 15\%$ of the total amount of host is complexed. Having discovered the optimum size of the binding site and the favorable role of the phenolic nucleophile in covalently catalyzed ester hydrolysis, we will now continue the further development of the host system **43** to a synthetic hydrolase to give high catalytic turnover in aqueous solution.[239a]

8. Perspectives

One of the more fascinating and gratifying aspects of research in the field of molecular complexation and catalysis is the multidisciplinary approach to generate interesting research objectives and to subsequently target them in experiments. Inspiration is provided by studying problems of interest and importance in biological sciences. Open fundamental questions are recognized which can be better answered with the methods of more exact, molecular-based chemical science. In addition, the intensive occupation with the extraordinary properties of biological systems such as enzymes and receptors stimulates a strong desire to generate similar properties in designed systems. The application of computer modeling to the design of molecular receptors and catalysts is becoming increasingly important. A large variety of state of the art synthetic, analytical, and physical-organic techniques are applied during the experimental research phase. This multidisciplinary approach breaks new frontiers in organic chemistry. In addition, it guarantees a future-oriented and flexibility-mediating education of chemists. This is of special importance at a time where many chemists enter professional careers where barriers between organic chemistry, biochemistry, and biotechnology can no longer be defined.

In this article, interesting open questions have been discussed which need to be answered for a better understanding of the principles of molecular recognition and catalysis. Some additional research objectives, to be targeted with cyclophane hosts, are added at the end of this article. Studies of complexation at binding sites of pronounced apolar character will contribute to a clearer definition, on a molecular basis, of the hydrophobic effect. The discovery of efficient complexation of neutral apolar molecules in a variety of organic solvents has made it possible to determine specific effects of the solvent in comparative binding studies in organic and aqueous solutions.

Efficient synthetic receptors are currently not available for many important classes of compounds, e.g. for sugars and, despite isolated progress, for neutral aliphatic and heteroaliphatic guests. Also, the preparation of hosts with spacious binding sites for large biological molecules, e.g. for double stranded DNA, can be expected in the near future.

Host systems with two or more neighboring binding sites in a well-defined spatial orientation should be subject to increasing research efforts. Multiple interactions in the complexes of these hosts allow for very high guest selectivity.[45b, 49e, 54f] It is unknown how the complexing ability of one binding site is influenced by a second, adjacent binding site and its solvation pattern. An improved understanding of multiple interactions in molecular complexes will

benefit the rational development of optically active hosts which discriminate effectively between racemic guests. The immobilization of optically active cyclophane hosts with apolar binding sites could lead to novel chiral phases of hydrophobic character.

The interaction between binding sites located at larger but still well-defined distances in molecular hosts deserves increasing attention for several reasons. These di- or polytopic host systems will mimic and contribute to the understanding of cooperative and allosteric effects in biological systems.[40a] Such systems will allow one to explore how the information of complexation can be selectively transferred from one binding site to a second binding site over larger distances in a molecule. Novel molecular sensors could be obtained by the conversion of binding information into an electrical signal. In materials science research, there is a need for novel crystalline host systems which, by specific orientation of complexed dipolar guests, could generate non-linear optical properties.[16]

In environmental science and technology, host-guest systems could be useful to sequester extremely toxic compounds from soils and waters even if these compounds are present in high dilution only. Polymer-bound cyclophane hosts could be very effective in removing carcinogenic polycyclic aromatic hydrocarbons and substituted dibenzofurans and dibenzodioxins from aqueous solution.

Research in the field of bioorganic catalysis will lead to compounds with specific advantages such as superior stability and broad applicability compared to organometallic catalysts, to enzymes and their mutants,[66a] or to other catalysts derived from biological materials, e.g. catalytic antibodies[251] and semi-synthetic enzymes.[252] These synthetic catalysts could recognize a large variety of substrates and accelerate many reactions for which no biological catalysts are available. The most worthwile objective of the current research efforts on the way to such catalysts is to learn how to generate the efficient principles and mechanisms of enzymatic catalysis in synthetic organic systems. The successful development of bioorganic catalysts could well represent an ultimate test for the depth of our understanding of enzymatic catalysis. The author of this article is convinced that we possess a true understanding of enzymatic catalytic mechanisms only if we are able to reproduce them with the same or even at enhanced efficiency in synthetic systems. In this sense, the development of bioorganic catalysts will help to define, from a chemical viewpoint, the degree of molecular understanding of enzymatic catalysis that has been achieved.

I warmly thank my coworkers who, by their skills, their engagement and their enthusiasm, contributed to the development of cyclophane molecules as efficient receptors and catalysts. I would like to express on this occasion my special thanks to Mr. Klaus Dick, now at BASF Ludwigshafen, who has made major experimental contributions to all the results obtained during my Habilitation time in Heidelberg. I warmly thank my coworkers Dr. Eileen Seward and Stephen B. Ferguson for assisting in the English translation of the original German manuscript. The work performed at the Department of Organic Chemistry at the Max-Planck-Institute for medical research in Heidelberg was generously supported by the Max-Planck-Society through funding provided by Prof. Dr. H. A. Staab and by the Deutsche Forschungsgemeinschaft. The work performed at the University of California at Los Angeles and the writing of this article was supported in a generous way by the Office of Naval Research and the National Science Foundation. We also thank BASF and Merck Sharp & Dohme for additional support of our work.

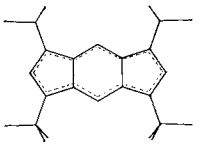
Equilibrium Structure, Stabilized Transition State, or Disorder in the Crystal? Studies of the Antiaromatic Systems Tetra-*tert*-butyl-*s*-indacene and Tetra-*tert*-butylcyclobutadiene by Low-Temperature Crystal Structure Analysis**

By *Jack D. Dunitz,* Carl Krüger, Hermann Irngartinger, Emily F. Maverick, Yu Wang,* and *Matthias Nixdorf*

The crystal structure of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene **1** as determined at room temperature[1] shows effective D_{2h} symmetry of the carbon skeleton. Similarly, the



1

presence of only four ^{13}C-NMR signals that show no perceptible line broadening down to -130 °C for the twelve C atoms of the perimeter is consistent either with a very low energy barrier between the valence isomers or with a completely delocalized twelve-electron π system. According to calculations[1] (MINDO/3 method), the energy barrier is only about 8 kJ mol^{-1} for the tetrasubstituted molecule **1**, although it is considerably larger for the parent hydrocarbon.[2]

We now report results of a new, more accurate low-temperature (100 K) X-ray analysis of **1**, which substantiate and extend these indications.[3,4] Although the (crystallographic) molecular site symmetry is only C_i ($\bar{1}$), the molecular geometry (Fig. 1) shows no significant deviations from D_{2h} symmetry.

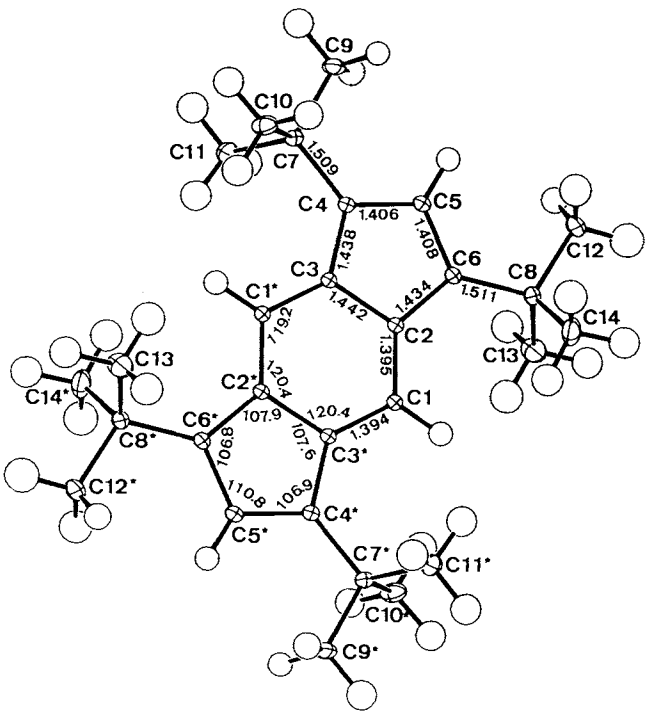


Fig. 1. ORTEP [27] drawing of **1** at 100 K; parameters from the HO refinement [3]. Bond lengths [10^2 pm] and angles [°] are indicated. Ellipsoids are scaled to enclose 50% probability.

Moreover, as described below, a detailed analysis of the anisotropic displacement parameters U^{ij} (ADPs)[5] of the carbon atoms gives no evidence for disorder between two sets of atomic positions for the skeletal atoms. We conclude that either the equilibrium structure of **1** has D_{2h} symmetry with a localized π system or we are observing not the ground-state molecular structure in the crystal but rather the transition state for the valence isomerization, which may be stabilized by crystal packing forces. The example of biphenyl, planar in its crystal structure, nonplanar as a free molecule, can serve as a precedent.[7]

Analysis of the ADPs with *Trueblood*'s THMA program[8] leads to the following indications:

(1) Calculation of mean-square displacement amplitudes (MSDAs)[9] along all interatomic vectors shows that the molecule does not behave as a rigid body in the crystal. The MSDAs between nonbonded pairs of atoms—and indeed the ellipsoids in Figure 1—reveal appreciable motions of the *tert*-butyl groups relative to the indacene skeleton. On the other hand, the rigid-bond criterion[10] is satisfied reasonably well, especially for the indacene skeleton, for which $\langle\Delta(\mathrm{MSDA})^2\rangle^{1/2} = 7$ pm^2.

(2) The translational (***T***) and librational (***L***) analysis,[11] including allowance for internal libration of the *tert*-butyl groups about the exocyclic bonds C4–C7 and C6–C8, leads to mean-square libration amplitudes, $\langle\phi^2\rangle$, of 9 and 20 (°)^2, respectively,[12] considerably larger than the eigenvalues of the **L** tensor (4.9, 0.9, 0.4 (°)^2, with the major eigenvalue approximately along the long axis of the molecule).[13]

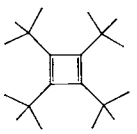
(3) Although the above model leads to reasonable agreement between observed and calculated U tensors ($\langle(\Delta U^{ij})^2\rangle^{1/2} = 15$ pm^2), the residual discrepancies show systematic features. In the direction perpendicular to the ring plane, U_{obsd} is significantly larger than U_{calcd} for the ring atoms C2, C3, and especially C5 ($\Delta U^{33} = 51$ pm^2); for C7 and C8, the reverse is true. Thus the model tends to ascribe too much motion to the quaternary C atoms C7 and C8, and too little to the ring atoms that are not attached to *tert*-butyl groups. This suggests that the ring atoms (especially C5) are moving in a direction perpendicular to the plane. Allowance for out-of-plane bending or buckling of the ring skeleton, as inferred in a variable-temperature study of naphthalene,[15] would reduce these discrepancies. Within the molecular plane there are no significant differences between U_{obsd} and U_{calcd} components for the ring atoms, whereas in an averaged structure involving superposition of two valence isomers with localized single and double bonds, we would expect $U_{obsd} > U_{calcd}$ to allow for the effect of disorder.[16] If the observed structure were such a superposition, the two sets of atomic positions could not differ from the averaged positions by more than about 3 pm.

The observed structure, if it is indeed the transition state for interconversion of the free molecules, may be stabilized relative to the structures with localized bonds by better packing of the *tert*-butyl groups. Model calculations suggest that the packing energy would be reduced by about 4 kJ mol^{-1} per *tert*-butyl group for the small in-plane displacements of these groups that would be associated with the reorganization of the indacene skeleton.

In contrast, a comparable analysis of the ADPs from a low-temperature study of tetra-*tert*-butylcyclobutadiene **2**[17] shows that in this crystal at 123 K there is still residual



2

disorder of the atoms of the central four-membered ring, corresponding to the coexistence of both valence isomers (although not in equal amounts).

The room-temperature X-ray analysis of **2** led to a structure in which the sides of the slightly nonplanar four-membered ring were almost equal (146.4 and 148.3 pm).[18] This result was in conflict with those obtained for other cyclobutadiene derivatives where much larger differences (14–26 pm) between the ring bonds were observed.[19] On the basis of quantum-mechanical model calculations, *Borden* and *Davidson*[20] suggested that the bulky *tert*-butyl groups could exert a considerable "quadratization effect," but this was countered by *Ermer* and *Heilbronner*,[21] who argued from photoelectron spectroscopic evidence and force-field calculations that **2** must have a rectangular structure with appreciably different ring bond lengths. They proposed that the nearly square arrangement of the ring atoms found in the room-temperature analysis did not correspond to the actual molecular structure but rather to averaged atomic positions resulting from disorder among two rectangular structures. Indeed, ring bond lengths found in the subsequent low-temperature crystal structure analysis at 123 K were different (144.1 and 152.7 pm),[17] but the question of whether residual disorder was still present at this temperature was left open. From a detailed analysis of the anisotropic displacement parameters U^{ij}[5] of the carbon atoms in the 123 K structure, we now conclude that residual disorder is indeed still present at this temperature. The results are compatible with an averaged superposition of two mutually perpendicular rectangular rings with sides approximately 160 and 134 pm,[22] and with one orientation several times more probable than the other.

ADPs from the 123 K structure determination were analyzed, as for the indacene derivative **1**, with THMA.[8] Standard deviations of U tensor components are of the order of 5 pm^2. Casual inspection of the probability ellipsoids (Fig. 2) shows that those of the methyl group carbon atoms are systematically larger than those of the other atoms. Calculation of MSDAs[9] along interatomic vectors shows that in contrast to the indacene derivative **1** the rigid-bond criterion[10] is not obeyed for **2**. For example, for the C1–C6 bond Δ(MSDA) is 19 pm^2. This in itself is an indication of possible disorder. However, MSDA differences between nonbonded pairs of atoms are much larger (up to 100 pm^2) and indicate appreciable motions of the *tert*-butyl groups relative to the inner ring.[24]

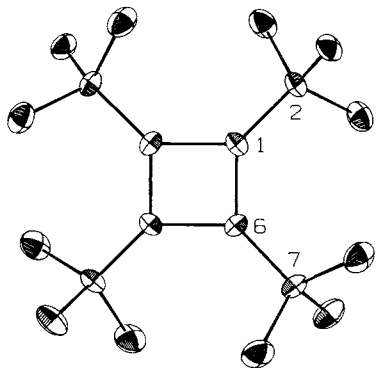


Fig. 2. ORTEP [26] drawing of **2** at 123 K. Ellipsoids are scaled to enclose 50% probability. Hydrogen atoms are omitted for clarity.

The T, L, and screw tensor (S) analysis, including internal libration of the two independent *tert*-butyl groups about the C1–C2 and C6–C7 bonds, leads to mean-square libration amplitudes $\langle\phi^2\rangle$ of 14 and 23 (°)^2 for the two internal motions, respectively.[12] These are several times larger than the eigenvalues of the L tensor (4.4, 2.4, 2.2 (°)^2, with the lowest value along the crystallographic twofold rotation axis; the molecule has effective D_2 symmetry but only one of the symmetry elements is imposed by the space group).[25]

The residual discrepancies between observed and calculated U tensors show systematic features. One of these is the striking excess of 51 and 31 pm^2 of the observed over the calculated tangential components of C1 and C6 (Table 1). This feature cannot be attributed to underestimation of the overall molecular libration (this would affect the outer atoms rather than the inner ones), but it is qualitatively in

Table 1. Calculated and observed mean-square displacement amplitudes [pm^2] for the ring atoms C1 and C6 in **2** along the tangential, radial, and ring-normal directions.

	Observed	Calculated
C1	221, 126, 170	170, 166, 154
C6	210, 126, 164	179, 157, 145

accord with the disorder model proposed by *Ermer* and *Heilbronner* (see Fig. 1 in Ref. [21]). In the crystal it is not necessary that the two perpendicular orientations of the rectangular ring have a common center (indeed, the above-mentioned Δ(MSDA) of 19 pm^2 between C1 and C6 suggests that they do not). However, if we wish to make a rough estimate of the proportions of major and minor orientation present, it simplifies the argument somewhat if we assume this condition to be satisfied and use the averaged tangential MSDA excess of 41 pm^2.

For equal occupancy of the two perpendicular orientations of a rectangular ring with sides of 134 and 160 pm[22] and a common center, we expect an excess MSDA of 84 pm^2 in the tangential direction (in agreement with *Ermer* and *Heilbronner*'s estimate of 80 pm^2[21]). For other occupancy factors p, the excess is then $336\,p(1-p)$ and hence $p \approx 0.86$ for the observed excess MSDA of 41 pm^2 at 123 K.[26]

These examples, 1,3,5,7-tetra-*tert*-butyl-*s*-indacene with indications of delocalization consistent with a stabilized transition state between two valence isomers, and tetra-*tert*-butylcyclobutadiene with evidence for disorder among the two isomers, show how ADPs derived from high-quality diffraction data can provide information about the nature and extent of mean displacements of atoms from their equilibrium positions and hence allow differentiation among alternative models compatible with these positions.

Measured reflections: $\pm h\ \pm k\ l$ $0<\theta<42°$, $\psi=0°$; $\pm h\ \pm k\ l$ $0<\theta<42°$, $\psi=15°$; $\pm h\ \pm k\ l$ $0<\theta<16°$, $\psi=-45/45°$. Normal data set 45 kV/32 mA; attenuated reflection set 50 kV/8 mA, 40 kV/8 mA. Further details of the crystal structure investigation may be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the number CSD-52900, the names of the authors, and the complete citation of the article.

[4] We thank Prof. *K. Hafner* for supplying samples and Prof. *H. J. Lindner* for sending the room-temperature crystal data and other information.

[5] U^{ij} are the components of the symmetric second-order tensor $\boldsymbol{U}$ which defines the matrix of second moments of the probability distribution function for each atom. They are obtained along with positional coordinates of the atoms by least-squares analysis of the experimental structure amplitudes from X-ray or neutron diffraction. The interpretation of ADPs is discussed in some detail in a recent review [6].

[8] K. N. Trueblood, *Acta Crystallogr. Sect. A 34* (1978) 950. Several versions of this program are in circulation, the latest being THMA 11.

[9] The mean-square displacement amplitude in the direction of a unit vector $\boldsymbol{n}$ is given by $\boldsymbol{n}^T\boldsymbol{U}\boldsymbol{n}$, where the components of $\boldsymbol{n}$ are referred to unit-length reciprocal basis vectors.

[10] F. L. Hirshfeld, *Acta Crystallogr. Sect. A 32* (1976) 239.

[11] For the analysis of **1** described here, the screw tensor $\boldsymbol{S}$ vanishes because of the molecular site symmetry. In the $\boldsymbol{T}$, $\boldsymbol{L}$ analysis we used the parameters from refinement of the full data set, but results obtained with parameters from the HO refinement [3] are practically the same.

[12] As discussed by *V. Schomaker* and *K. N. Trueblood, Acta Crystallogr. Sect. A 40* Suppl. (1984) C-339 (see also [6]), these values correspond strictly not to $\langle\phi^2\rangle$ but to $\langle\phi^2\rangle+\langle\phi\lambda^{II}\rangle$, where $\langle\phi\lambda^{II}\rangle$ is the parallel component of the overall molecular libration. However, since the overall libration is here small compared with the internal libration, their quadratic average must also be small.

[13] Values of mean-square libration amplitudes $\langle\phi^2\rangle$ were also estimated by numerical integration of

$$\int \phi^2 \exp(-V(\phi)/RT)\,d\phi \Big/ \int \exp(-V(\phi)/RT)\,d\phi$$

where $V(\phi)$ was obtained from calculated potential energy curves [14] for step-by-step rotation of the *tert*-butyl groups about the appropriate axes without relaxation of the surrounding crystal structure. The calculated values of $\langle\phi^2\rangle$ are about 50% too small, but larger for C6-C8 than for C4-C7, as found in the ADP analysis.

[25] Calculations [13] reproduce the difference in internal motion between these groups but the values of $\langle\phi^2\rangle$ are too small. However, since the intramolecular overcrowding among the *tert*-butyl groups is so severe, allowance for correlated motion will certainly need to be included in a more realistic model.

[26] From the observed bond lengths of 144.1 and 152.7 pm we would estimate $p \approx 0.7$, assuming the same rectangular ring. For a more thorough discussion of the disorder on Δ(MSDA) values see K. Chandrasekhar, H. B. Bürgi, *Acta Crystallogr. Sect. B 40* (1984) 387.)

Reaction of 1,3-Azaphosphinines with 2-*tert*-Butyl-1-phosphaethyne: 9-Aza-2,4,6-triphosphatetracyclo-[5.3.0.0^{2,4}.0^{3,6}]deca-8,10(1)-diene

By *Gottfried Märkl,* Stefan Dietl, Manfred L. Ziegler,* and *Bernd Nuber*

Recently, we reported the synthesis of 1,3-azaphosphinines **1** from 3-azapyrylium salts by O/P exchange with $(Me_3Si)_3P$.[1]

In contrast to phosphinines, which only undergo Diels-Alder reactions with highly reactive alkyne dienophiles (e.g., hexafluorobutyne) under drastic reaction conditions to give 1-phosphabarrelenes,[2] 1,3-azaphosphinines **1** react with all alkynes so far investigated even under mild condi-

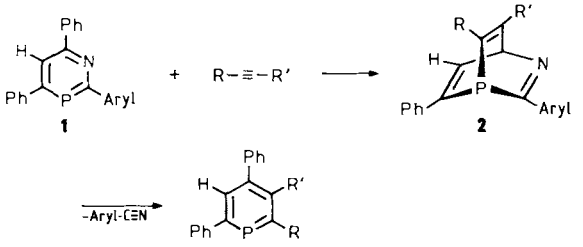
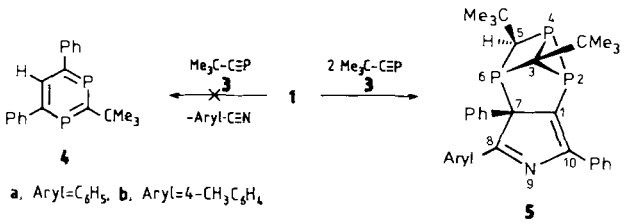
tions to give the [4+2] cycloadducts **2**. The initially formed heterobarrelenes **2** eliminate (substituted) benzonitrile, undergoing cycloreversion with aromatization to give the corresponding substituted phosphinines.[3]



As heteroalkyne, 2-*tert*-butyl-1-phosphaethyne **3**[4] reacts with the 2,4,6-triaryl-substituted 1,3-azaphosphinines **1** at about 100°C in toluene (reaction bomb)—as investigated so far—completely different. The mass spectrum and elementary analysis show that **1** and **3** react in a molar ratio of 1:2 without elimination of (substituted) benzonitrile. Thus, a secondary product of the possibly expected 1,3-diphosphinine **4** is not present.



The crystal structure analysis (Fig. 1) shows that the tetracyclic triphosphane **5a** is formed from **1a**. It contains a 3*H*-pyrrole, a 1,3-diphosphacyclopentane, a 1,3-diphosphacyclobutane, and a diphosphacyclopropane system[5] (numbering of **5** according to IUPAC nomenclature).

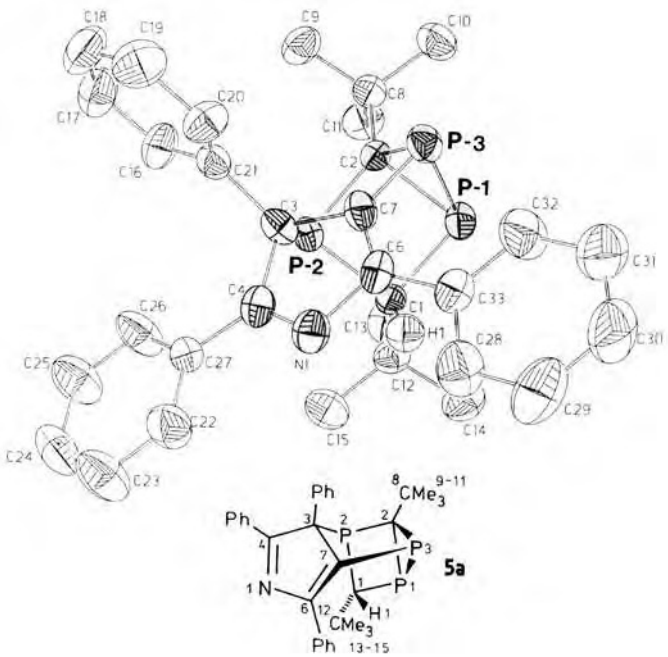


Fig. 1. Molecular structure of **5a** (arbitrary numbering) [5].

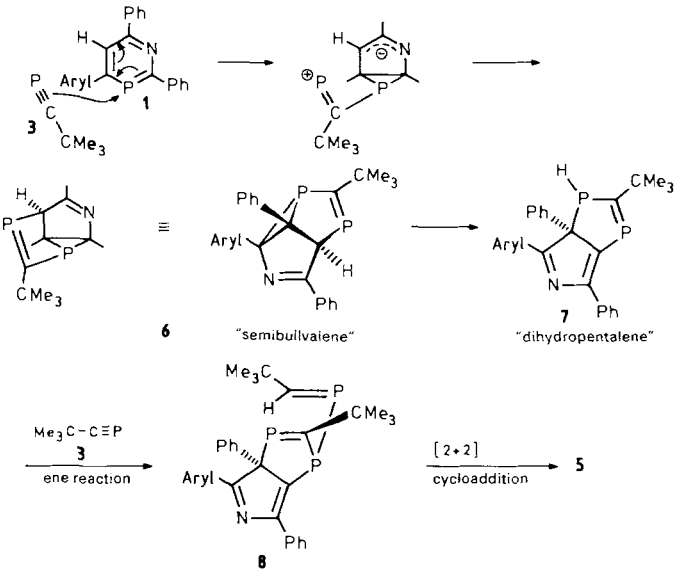
Thus, the six-membered 1,3-azaphosphinine system of **1** undergoes rearrangement and ring contraction to give a 3*H*-pyrrole system containing phosphorus in the *exo* position. The positions of the phenyl moieties and the nitrogen show that P-2 is derived from **1**.

The formation of **5** presumably begins with a cycloaddition of **3** at the 3,5 position of **1** to give the heterosemibullvalene **6**. This cycloaddition to give **6** may be initiated by a nucleophilic attack of the sp ethyne carbon atom in **3** on the $\lambda^3\sigma^2$ phosphorus of **1**; there exists a purely formal analogy to the cycloaddition of alkenes to benzene to give tetrahydrosemibullvalenes, which presumably occurs via the photochemically excited singlet state $^1B_{2u}$ ("prefulvene").[6]

Under the reaction conditions, **6** rearranges to give the secondary phosphane **7** having a dihydropentalene structure. The cycloaddition of the second molecule **3** begins with an ene reaction with the vinylphosphane structural element in **7** leading to the formation of **8**.[7] An intramolecular [2+2] cycloaddition of the two phosphaalkene units in **8** affords the 1,3-diphosphabutane and the diphosphapropane ring in **5**. It has not been possible so far to isolate intermediates, even by changing the stoichiometry or the reaction conditions.



The exceptional stability of **5** is indicated by the mass spectra,[8] in which, apart from the molecular-ion peaks, only a few low-intensity fragment peaks are observed.

In the ^{1}H-NMR spectra of **5a** and **5b**,[8] the signal for H-1 is observed at $\delta = -0.76$ owing to strong shielding; the assignment of the signals for the *t*Bu groups was accomplished by means of NOE difference spectra. The assignment of the $^{31}P\{^1H\}$-NMR signal of P-1 ($\delta = -158.8$, d ($J_{P\text{-}1/P\text{-}3} = 176.0$ Hz)) and of P-3 ($\delta = -56.8$, d) is based on observations made for other diphosphacyclopropanes.[7] The downfield shift of P-2 ($\delta = +77.4$ (s)) lies far beyond the values observed for tertiary phosphanes, but is in agreement with more recent observations made for phosphanes of similar structure; however, an interpretation is not yet possible.[9]

Experimental Procedure

1a (0.81 g, 2.5 mmol) and **3** (0.55 g, 5.5 mmol) in dry toluene (4 mL) were allowed to react in a reaction bomb at 145°C for 48 h. After removal of the solvent, the reaction products were chromatographed on silica 60 (dried by heating under vacuum): **5a** was eluted with benzene/petroleum ether (1:1).

Recrystallization from $CHCl_3$/EtOH afforded yellow needles, m.p. = 214–215°C. Yield: 15%. **5b** was synthesized analogously, m.p. = 192–196°C. Yield: 10%. In addition to **5** and a small amount of azaphosphinine **1**, only amorphous, nondefinable products were obtained.

The Fluoronium Ions $H_2F^{\oplus}$ and $H_3F_2^{\oplus}$: Characterization by Crystal Structure Analysis**

By *Dietrich Mootz** and *Klemens Bartmann*

In relation to their existence, structure, and hydrogen bonding in the solid state, mostly in hydrates of strong acids, oxonium ions, such as $H_3O^{\oplus}$ and $H_5O_2^{\oplus}$, but also species containing more water, have been thoroughly investigated by crystal structure analysis.[1] A corresponding characterization of fluoronium ions, in particular $H_2F^{\ominus}$ and $H_3F_2^{\oplus}$, has so far been completely missing. It has now been accomplished for the first time, viz. for crystalline compounds in the system hydrogen fluoride–antimony pentafluoride.

According to an IR-spectroscopic study, this system as the strongest known liquid superacid[2] contains the $H_3F_2^{\oplus}$ ion as the predominant cationic species for concentrations up to 40 mol% SbF_5, whereas at higher concentrations the $H_2F^{\oplus}$ ion is observed.[3] Concerning the formation of solid phases in this system, two investigations yield largely contradictory results.[4] In initial examinations of our own, we managed to grow single crystals of two phases at temperatures between −20 and −30°C, containing 40 and 50 mol% SbF_5 (molecular formulae $3HF \cdot 2SbF_5$ and $HF \cdot SbF_5$, respectively), and characterize them by X-ray structure analysis as the fluoronium salts **1** and **2**.[5]

$H_3F_2^{\oplus}Sb_2F_{11}^{\ominus}$ **1** $H_2F^{\oplus}Sb_2F_{11}^{\ominus}$ **2**

The $H_3F_2^{\oplus}$ ion of **1** (Fig. 1) is located on a symmetry center of the space group and thus has *trans* conformation. With an F···F distance of 2.30(1) Å its inner hydrogen bond is only slightly weaker than the strongest known hydrogen bonds (F···F down to 2.26 Å) in a series of hydrogen difluorides[6] and poly(hydrogen fluorides).[7] By longer hydrogen bonds of 2.41(1) Å the cations are linked with the anions in infinite chains. The dioctahedral $Sb_2F_{11}^{\ominus}$ ion is also centrosymmetric and thus its central fluorine bridge linear.

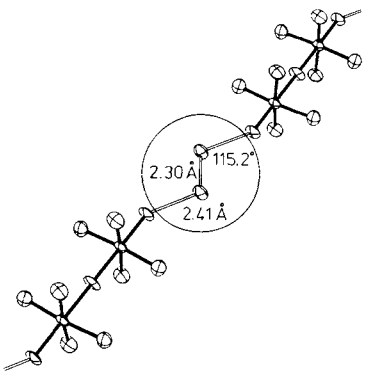

Fig. 1. Detail of the crystal structure of **1**. The fluoronium ion $H_3F_2^{\oplus}$ with its hydrogen bonds is shown in the circle (without the hydrogen atoms, which were not localized in the structure analysis). Thermal ellipsoids at the 50% probability level.

In the structure of **2** the ions occupy general positions. With much longer and less gradated F···F distances to the anions (six distances between 2.64 and 2.78 Å) the $H_2F^{\oplus}$ ion exhibits orientational disorder. The bridging angle of the anion amounts to 144.2(3)°.

The Crystal Structure of Hypofluorous Acid: Chain Formation by O–H···O Hydrogen Bonds**

By *Wolfgang Poll, Gottfried Pawelke, Dietrich Mootz,** and *Evan H. Appelman*

Hypofluorous acid, HOF, can be isolated only at very low temperature as an intermediate of the well-known reaction of fluorine with water to hydrogen fluoride and oxygen.[1] So far, it is the only hypohalogenous acid obtained pure in condensed phase. Initial IR- and Raman-spectroscopic examinations of the solid-state structure of HOF[2] led to the assumption that the molecules are linked in planar zigzag chains by O–H···F hydrogen bonds. However, according to a recent interpretation of the data, supported by the results of theoretical calculations, O–H···O type hydrogen bonds are more probable.[3] We have now carried out a single-crystal X-ray structure analysis which confirms the linking of the molecules by O–H···O hydrogen bonds to form infinite angular chains.

Due to the ready and often explosive decomposition of the substance even at low temperatures, the handling of samples was quite difficult. A tube made of Teflon-PFA, with its middle section drawn to a capillary ca. 60 cm long, was attached to a vacuum system at both ends, evacuated, and then dipped into liquid nitrogen. An amount of roughly one drop of the compound, prepared by means of a circulation method,[4] was condensed from a cold trap (-78 °C) into one of the narrowing ends of the tube. From there it was sucked as a liquid into a part of the capillary suitable for the X-ray measurements and at last resolidified. After sealing the capillary at both ends of the solid, it had a length of ca. 3 cm and was fixed mechanically in a Lindemann glass capillary which was then mounted on a four-circle diffractometer (Syntex $P2_1$) equipped with a low-temperature device.

The sample was again liquefied, apart from a tiny residue, and this nucleus was used to grow a single crystal by slowly lowering the temperature (6 K/h) from a starting point at -130 °C. After further cooling to -160 °C, the dimensions and symmetry of the lattice were determined and the reflection intensities of one hemisphere in the range of $3° \leq 2\theta \leq 70°$ were measured (ω scan). The determination and refinement of the structure were carried out with the common methods using the program SHELXTL (Nicolet) on an ECLIPSE S/140 (Data General) computer.[5]

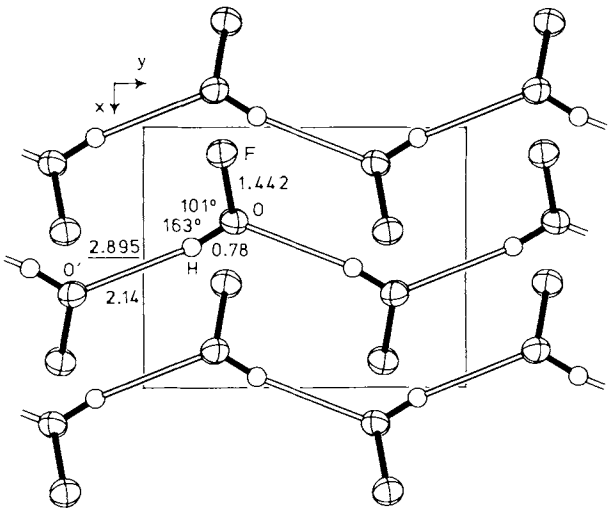

Fig. 1. Structure of HOF in the crystal with interatomic distances [Å] and angles [°] (O···O' distance of the hydrogen bond underlined). The standard deviations are 0.001 Å for the distances O-F and O···O', 0.02 Å for O-H and H···O, and 1° for the angles. The atom O' is generated from the atom O by the operation of a 2_1 screw axis parallel to the *b* axis (symmetry operation $1-x, -1/2+y, 1/2-z$). The chains appearing to be contiguous in the drawing are displaced in the *z* direction by half a lattice constant *c*. The thermal ellipsoids are drawn at the 50% probability level.

The geometry of the molecule obtained (Fig. 1) is in good agreement with that in the gaseous state;[6] only the O-H bond shows the usual systematic shortening, due to the X-ray method, as compared to the distance between the nuclei in question. The rather small bond angle may result from intramolecular Coulomb attraction of opposite charges of the hydrogen and the fluorine atom. Presumably in this connection the clearly dominating proton acceptor of the *intermolecular* hydrogen bonding is the oxygen atom. By almost linear O–H···O hydrogen bonds the molecules are linked to form angular chains (Fig. 1). The chains have the direction [010]; their polarity alternates along [100].

Cyclodextrins Increase Surface Tension and Critical Micelle Concentrations of Detergent Solutions

By *Wolfram Saenger** and *Anke Müller-Fahrnow*

The amphiphilic detergent molecules have a characteristic tendency to self-aggregate in aqueous solution such that their hydrophobic parts are removed from and their hydrophilic parts are exposed to the solvent. At low concentrations, the detergents form a variety of low-molecular-weight aggregates in solution, and monolayers are formed at the surface of the solvent which reduces the surface tension. Above the "critical micelle concentration" (*cmc*), micelles coexist in solution. It should in principle be possible to destroy the surface monolayers and the micelles, and to change the properties of the detergent solutions, by transferring the amphiphilic molecules to bulk solvent, i.e., by making them better soluble.

Based on this assumption, we have added cyclodextrins to detergent solutions, because these cyclically closed oligosaccharides with six, seven, or eight α-D-glucoses per macrocycle (α-, β-, γ-cyclodextrins) are able to form inclusion complexes[1,2] and have been used to enhance the solubility of organic molecules in water.[3,4]

The central cavity of the cyclodextrins is of hydrophobic character and has a diameter of 5 Å (α), 6–7 Å (β), and 7–8 Å (γ),[1,2] which is ideally suited to accommodate the hydrophobic, aliphatic part of the chosen detergent molecules with a diameter of about 5 Å (*n*-dodecylmaltoside (*n*-DM), *N*,*N*-dimethyl-*N*-lauryl-*N*-amine oxide (LDAO), decanoyl-*N*-methylglucamide (MEGA-10), β-octylglucoside (β-OG), Triton X-100). Moreover, the rims of the cyclodextrins are lined with OH groups, which should be able to form hydrogen bonds with the hydrophilic parts of the enclosed amphiphilic molecules and thus add to the stability of the formed complexes.

Experiments were carried out by the ring removal method with an interfacial tensiometer based on the concept of *Lecomte du Noüy*. The detergent solution (20 mL) was contained in a quartz beaker thermostated at 20 °C, in which a platinum ring was immersed. The ring was attached to a balance and by lowering the beaker, the surface tension (σ) could directly be measured in mN m^{-1} when the surface film broke. As calibration, pure water was used ($\sigma \approx 72$ mN m^{-1}).

Solutions of the detergents used were prepared with concentrations about 10 times the literature *cmc* values, and then diluted in series to afford solutions with concentration ratios of 1 : 1/2 : 1/4 : 1/8, etc. The surface tensions of these solutions were first measured and then a 10-, 100-, or 300-μL aliquot of a 10^{-1} M α-cyclodextrin solution was added to each of the 20-mL solutions and the surface tension again measured. The obtained values were plotted versus the logarithms of the detergent concentrations to derive the *cmc* (see the results for *n*-DM in Fig. 1a). For *n*-DM, we have also added β- and γ-cyclodextrin (Fig. 1b, c) and the permethylated tri-*O*-methyl-β-cyclodextrin (Fig. 2) to study the dependence of surface tension and *cmc* of the detergent solutions on ring size and hydrophilic character of the cyclodextrin.

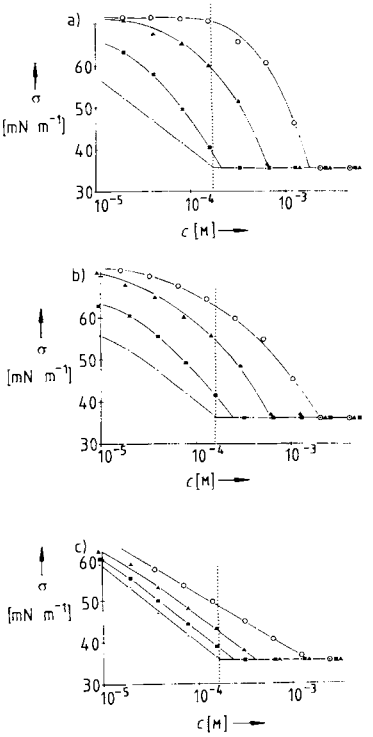

Fig. 1. Dependence of surface tension σ on the concentration c of the detergent *n*-DM without (•) and with added cyclodextrin. a) ■ 10^{-4} M, ▲ 6×10^{-4} M, ○ 21×10^{-4} M α-cyclodextrin. b) ■ 10^{-4} M, ▲ 5.7×10^{-4} M, ○ 17.4×10^{-4} M β-cyclodextrin. c) ■ 6×10^{-4} M, ▲ 20×10^{-4} M, ○ 66.3×10^{-4} M γ-cyclodextrin. The concentration at the vertical dotted line corresponds to the *cmc* of *n*-DM in water.

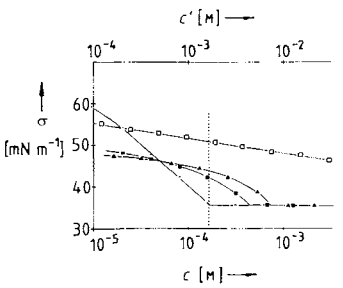

Fig. 2. Dependence of surface tension σ on the concentration c of the detergent *n*-DM without (•) cyclodextrin and in the presence of 5.66×10^{-4} M (■) and 17.44×10^{-4} M (▲) tri-*O*-methyl-β-cyclodextrin. Additional measurements were carried out without detergent (□) and with varying concentration c of tri-*O*-methyl-β-cyclodextrin (top abscissa). The dotted line corresponds to the *cmc* of *n*-DM in water.

[**] We are grateful to *Barbara Saenger* for carrying out the measurements, and to the Institut für Physikalische Chemie, Freie Universität Berlin, for providing the Interfacial Tensiometer. This work was supported in part by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 312, Teilprojekt D1) and by the Fonds der Chemischen Industrie.

For all the investigated detergents, the addition of α-cyclodextrin shifts the *cmc* to higher concentrations by up to one order of magnitude, depending on the detergent. A similar effect is observed with the surface tension, as indicated by the dotted line in Figure 1 and by the data in Table 1. For *n*-DM and LDAO, the addition of 2.1×10^{-3} and 6.5×10^{-3} M α-cyclodextrin, respectively, shifts the surface tension from that measured at the *cmc* (ca. 36 mN m^{-1}) to that of pure water.

The change of surface tension induced by 6.5×10^{-3} M α-cyclodextrin at *cmc* condition is medium for MEGA-10 (56 mN m^{-1}) but only modest for the other detergents used, Triton X-100 and β-OG (see Table 1).

Table 1. Dependence of *cmc* and surface tension of detergents on the concentration of added α-, β-, and γ-cyclodextrin (α-CD, β-CD, γ-CD).

Detergent and added cyclodextrin	*cmc* (M) (Literature values in parentheses)	σ at *cmc* of pure detergent [mN m^{-1}]
n-DM	1.7×10^{-4}	35.8
	(1.6×10^{-4})	
10^{-4} M α-CD	2×10^{-4}	38.5

For the larger analogues β- and γ-cyclodextrin and for the permethylated β-cyclodextrin, a systematic study was only performed with *n*-DM. The effects are smaller with β-cyclodextrin and even more reduced with γ-cyclodextrin (Table 1). As to the permethylated β-cyclodextrin, it gives rise to a large increase in *cmc*, which is, however, smaller compared to unmethylated β-cyclodextrin (cf. Figs. 1b and 2). The change in surface tension is much less with permethylated β-cyclodextrin and, in the range of measurement, does not exceed 50 mN m^{-1}. At a detergent concentration of 5×10^{-4} M the data points describing surface tension in the presence of the permethylated β-cyclodextrin even cross that found for pure detergent, suggesting that permethylated β-cyclodextrin itself reduces the surface tension. In order to test this finding, the surface tension of aqueous solutions of permethylated β-cyclodextrin was measured (see Fig. 2). It is in fact surface active, but the concentration dependence is low.

The effects of the cyclodextrins on the surface tension and on the *cmc* of the different detergents studied here can be explained with the formation of inclusion complexes. This interpretation is suggested by the complex-forming ability of the cyclodextrins for *n*-DM which decreases in the series α- > β- > γ-cyclodextrin, probably because the fit of the aliphatic part of the detergent is tightest with α-cyclodextrin with a cavity diameter of ca. 5 Å. We have tried to determine the equilibrium constants assuming a simple 1 : 1 complex formation. Since we did not obtain a consistent value from the measured data, we have to infer that the complex formation between the detergents and the cyclodextrins is of a more complicated nature.

The detergent molecules become more water soluble by inclusion complexation, and are transported from the micelles or from the surface of the solution into bulk aqueous solvent. This obviously interferes with the aggregation of the detergent molecules into micelles, thereby shifting the *cmc* to higher concentration, and, as is indicated by the large rise in surface tension, it also removes the amphiphilic molecules from the surface monolayer.

The addition of cyclodextrins to detergent solutions can be used to advantage in all cases where micelles have to be destroyed or where the surface tension should be increased, e.g., in order to avoid foaming. The detergents chosen in this study were taken from our work with membrane proteins, but we expect that the effects also apply to other detergents as long as they are able to form inclusion complexes with the cyclodextrins.

Methylrhenium Oxides: Synthesis from R_2O_7 and Catalytic Activity in Olefin Metathesis**

By *Wolfgang A. Herrmann,* Josef G. Kuchler, Josef K. Felixberger, Eberhardt Herdtweck,* and *Werner Wagner*

The system Re_2O_7/Al_2O_3 is an effective heterogeneous catalyst for carrying out olefin metatheses under mild conditions. Its activity can be further increased by the addition of alkyltin compounds SnR_4, and tin-containing cocatalysts are essential for the metathesis of *functionalized* olefins (e.g., unsaturated carboxylic esters and nitriles), which is of special industrial importance.[1] Since the first synthesis of hexamethylrhenium(VI) and several alkylrhenium oxides was reported by *Wilkinson* et al., the general accessibility of alkyl complexes of rhenium is no longer in question.[2] However, there has been little subsequent investiga-

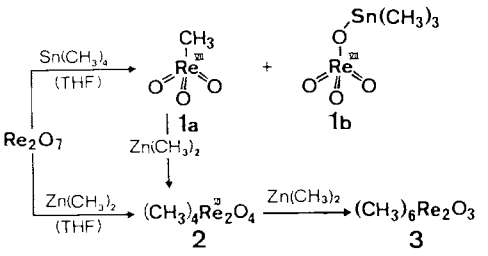
[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 50.—Part 49: W. A. Herrmann, R. A. Fischer, E. Herdtweck, *J. Organomet. Chem. 329* (1987) C 1.

tion of this class of substances and, therefore, virtually nothing is known about the chemistry of rhenium-containing metathesis catalysts.[1f] We have now found that simple methylation of dirhenium heptoxide provides a straightforward, extremely useful approach to these catalysts.

The components of the catalyst, dirhenium heptoxide and tetramethyltin, react rapidly and quantitatively in refluxing THF (Scheme 1) to give the mononuclear com-



Scheme 1.

pounds trioxomethylrhenium(VII) **1a** and trioxo(trimethylstannoxy)rhenium(VII) **1b** (Scheme 1). The organorhenium oxide **1a**, which is stable toward air and moisture, can—like its CD_3 derivative **1a'**—be isolated from the crude product by vacuum sublimation (50–70 °C/10^{-2} torr) and is obtained as colorless, strongly refractive needles (Table 1). By way of contrast, the perrhenium ester **1b** can be extracted with THF from the residue remaining after sublimation. The (redox-neutral) monomethylation stage is not surpassed even if an excess of tetramethyltin is used. Re_2O_7 also reacts with other alkyltin compounds. If their alkyl groups contain β hydrogen atoms, however, low-valent rhenium oxides are formed with alkane/alkene liberation (e.g., C_4H_{10}/*cis*- and *trans*-C_4H_8 in the case of tetra(*n*-butyl)tin); an analogous reaction had been observed in the reaction of $Sn(n\text{-}C_4H_9)_4$ with $[(\eta^5\text{-}C_5H_5)ReCl_4]$.[3] The corresponding alkylsilanes, e.g., $Si(CH_3)_4$, do not react with dirhenium heptoxide under comparable conditions.

Until now, **1a** has only been accessible by oxidation of paramagnetic $[(CH_3)_4ReO]$ with O_2, a long and laborious route, which was not always reproducible;[4a] owing to the poor accessibility of **1a**, nothing was known about its chemistry, in contrast to the case for the structurally analogous π-complex $[(\eta^5\text{-}C_5Me_5)ReO_3]$.[5] The perrhenium ester **1b**[4b] is also now available for the first time by a clearly defined route and in an analytically pure form.

The methylrhenium oxide **1a** effects the metathesis of acyclic olefins in the presence of $AlCl_3$ even at room temperature; an example is the conversion of 2-pentene to 2-butene and 3-hexene (*cis/trans* mixture). In addition, the system **1a**/$Sn(CH_3)_4$/$AlCl_3$ is also able to catalyze the ring-opening polymerization of cycloolefins to polyalkenamers having elastomeric properties. Likewise, the π-complex $[(\eta^5\text{-}C_5Me_5)ReO_3]$ and its derivatives catalyze metathetic ring opening, for instance by virtue of the systems

$[(\eta^5\text{-}C_5Me_5)ReOCl_2]/Sn(CH_3)_4/AlCl_3$,
$[(\eta^5\text{-}C_5Me_5)ReX_4]/Sn(CH_3)_4/AlCl_3$ (X = Cl, Br), and
$[(\eta^5\text{-}C_5Me_5)Re(CH_3)X_3]/Sn(CH_3)_4/AlCl_3$ (X = Cl, Br).

It is to be noted that both a Lewis acid (AlX_3) and a cocatalyst (SnR_4) are required to achieve metathesis.

Complex **1a** is further methylated only upon treatment with dimethylzinc (Scheme 1). In the temperature region −78 to 30 °C and for short reaction times, reduction and dimerization lead to the new, likewise sublimable, lemon-yellow methylrhenium oxide **2**. A single-crystal X-ray structure analysis[6] establishes the binuclear structure of this Re^{VI} compound, which, owing to a metal–metal single bond (259.3(< 1) pm) is spin-paired and therefore diamagnetic. In addition, the four methyl groups are *cis* with respect to the Re_2O_2 core structure, which is puckered along the Re–Re bond (Fig. 1); the same geometry was found for the complex $[R_4Re_2O_4]$ ($R = CH_2C(CH_3)_2C_6H_5$) obtained by a different, albeit poorly defined route.[7] Solid-state thermolysis of **2** ($T = 200$ °C) affords 90% methane and higher hydrocarbons up to C_4 (GC/MS analysis). In contrast, heating of **1a** even at 200 °C results in only trace amounts of methane and ethane, indicating the thermal robustness of the Re^{VII} title compound.

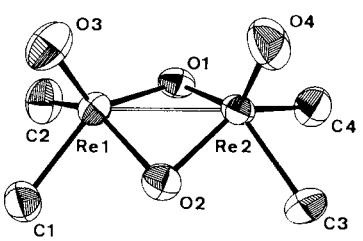


Fig. 1. Molecular structure of **2** (ORTEP, hydrogen atoms omitted, thermal ellipsoids at the 50% probability level). Selected bond lengths [pm] and angles [°]: Re1-Re2 259.3(< 1), Re1-C1 210.8(6), Re1-C2 210.2(6), Re2-C3 213.9(6), Re2-C4 210.3(7), Re1-O1 193.4(4), Re1-O2 197.5(4), Re1-O3 165.2(4), Re2-O1 193.0(4), Re2-O2 193.2(4), Re2-O4 165.9(5); Re1-O1-Re2 84.3(1), Re1-O2-Re2 83.1(2), between the planes Re1/O2/Re2 and Re1/O1/Re2 139.0. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52591, the names of the authors, and the journal citation.

The binuclear complex **2** also catalyzes the metathetic ring-opening polymerization of cyclopentene in the presence of $Sn(CH_3)_4/AlCl_3$. This particular compound represents the so far missing member of the series

$(CH_3)_6Re$ $(CH_3)_4ReO$ $[(CH_3)_2ReO_2]_2$ $[ReO_3]_\infty$,
A **B** **C** = 2 **D**

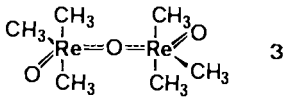
[a] Correct C, H, O, and Re analyses were obtained. Unless noted otherwise: NMR spectra recorded at 28 °C in $CDCl_3$, JEOL JNM GX-270 and JNM GX-400 (the NMR spectra do not change upon lowering the temperature (−80 °C)); mass spectra at 70 eV, T_Q = 30–70 °C, Finnigan MAT 311-A.

in which the degree of aggregation increases as a result of decreasing ligand/metal ratio (CN 5 or 6). With the exception of **2**, the Re^{VI} complexes of the series $R_{6-2n}ReO_n$ are either paramagnetic (**A** and **B**) or metallic conducting (**D**; perovskite-type structure).

Excess dimethylzinc effects even further methylation of **2** within 1 h at 30–60 °C (Scheme 1). The oxo ligand of **2** is thereby replaced by two methyl groups with retention of the binuclear structure and the bright red compound **3** is obtained (Table 1). This compound, which was obtainable earlier only via the siloxy derivative $[(Me_3SiO)ReO_3]$ in a two-step reaction,[8] is diamagnetic despite the d^1 configuration ("spin superexchange" in the linear ReORe framework). According to Scheme 1, **3** is now obtained quantita-



3

tively directly from dirhenium heptoxide and dimethylzinc in a molar ratio of 1:3 (in refluxing THF). Complex **3** catalyzes ring-opening polymerization (cyclopentene), even when the catalyst $Sn(CH_3)_4$ necessary in the case of **1a** and **2** is absent. Solid-state thermolysis of **3** at 200 °C gives mainly methane and isobutylene along with small amounts of other C_2–C_4 hydrocarbons.

Although the methylrhenium oxides **1a** and **3** are not new compounds, the reactions of Re_2O_7 with alkyltin and alkylzinc reagents described here offer a selective and high-yield route to these compounds. Important for future studies of catalysis is the observation that *one* methyl group in the rhenium-containing catalytic component is not necessary for the catalytic activity but is also not sufficient: **1b** also catalyzes olefin metathesis in the presence of $Sn(CH_3)_4/AlCl_3$, while **3** no longer needs the cocatalyst $Sn(CH_3)_4$ which provides the additional methyl groups.

On the basis of the findings presented here, there can no longer be any doubt that complexes **1a** and **1b** are the actual catalytic precursors in the system $Re_2O_7/Sn(CH_3)_4$. At present $AlCl_3$ is thought to be required for the generation of the catalyst because it opens up additional coordination sites for consecutive alkylations by the alkyltin cocatalysts.[1a–e, 9] We are currently investigating this question in terms of a preparative approach.

Structure solved by Patterson methods; numerical absorption correction, $\mu = 255.5$ cm^{-1}; correction for extinction, $\varepsilon = 0.3425 \times 10^{-6}$. The positions of the hydrogen atoms were calculated for an ideal geometry (d(C–H) = 95 pm) and used with collective isotropic temperature factors in the calculation of structural factors, but not refined. Anomalous dispersion was taken into consideration. Shift/error < 0.00 in the final refinement cycle; residual electron density, $+3.99\, e_0 \cdot$ Å^{-3} at 68 pm next to the heavy atom rhenium. Upon refinement of the enantiomorphic presentation, the R values did not change significantly.

$[Cp_2Co][Bi\{Co(CO)_4\}_4]$: A Paramagnetic, Ten-Electron, Tetrahedral Complex of Bismuth**

By *J. Scott Leigh* and *Kenton H. Whitmire**

It is well established that the incorporation of main-group heteroatoms into transition-metal clusters has a pronounced effect on cluster reactivity. Studies of mixed main-group/transition-metal clusters have led to the stabilization of intriguing metal-cluster geometries.[1] The extremely large element bismuth has shown surprising structural versatility in its compounds. For example, structures with EM_3 frameworks (E = main-group atom, M = transition metal) of the first-row transition metals have been isolated in which the Bi atom is surrounded by an open framework, as in $[BiCo_3(CO)_{12}]$,[2] $[BiMn_3(CO)_{15}]$,[3a] and $[BiFe_3(CO)_6Cp_3]$.[3b] Other open structures for mixed clusters in which a main-group atom is tetrahedrally surrounded by four ML_n units have been proposed for In and Tl,[4] as well as Sn and Pb,[5] and confirmed for $[Et_4N]_3[BiFe_4(CO)_{16}]$.[6] It was thought at one time that the large size of the Bi atom would prevent the formation of transition-metal–transition-metal bonds in these compounds, yet closed EM_3 structures for Bi have also been isolated, as in $[BiCo_3(CO)_9]$,[7] $[Bi_2Fe_3(CO)_9]$,[8] and $[BiFe_3(CO)_3Cp_3]$.[3b] More complicated structures with more than one Bi atom have been reported for $[Et_4N]_2[Bi_2Fe_4(CO)_{13}]$ and $[Et_4N][Bi_2Fe_2Co(CO)_{10}]$,[9] $[Et_4N]_2[Bi_4Fe_4(CO)_{13}]$,[10] and $[Bi_2W_3(CO)_{15}]$.[11] The latter three complexes are believed to have some degree of Bi–Bi bonding. Here we present the isolation and characterization of $[Cp_2Co][Bi\{Co(CO)_4\}_4]$, **1** ($Cp = C_5H_5$), a paramagnetic, ten-electron, tetrahedral complex of bismuth.

[**] This work was supported by the National Science Foundation (CHE-8421217) and the Alexander von Humboldt Foundation. Note added in proof: Another synthesis of the anion $[Bi\{Co(CO)_4\}_4]^{\ominus}$ was recently reported: S. Martinengo, G. Ciani, *J. Chem. Soc. Chem. Commun. 1987*, 1589.

Complex **1**[12] is synthesized by treating $[BiCo_3(CO)_{12}]$ with $[Cp_2Co][Co(CO)_4]$ generated in situ [Eq. (a)]. Isolated

$$[Cp_2Co][Co(CO)_4] + [BiCo_3(CO)_{12}] \rightleftharpoons \underset{\mathbf{1}}{[Cp_2Co][BiCo_4(CO)_{16}]} \quad (a)$$

yields of up to 86% have been obtained. Complex **1** is also formed from the direct reaction of $[BiCo_3(CO)_{12}]$ with $[Cp_2Co]$ in CH_2Cl_2. This process probably proceeds via the intermediate formation of $[Cp_2Co][Co(CO)_4]$, generated from the degradation of $[BiCo_3(CO)_{12}]$ by $[Cp_2Co]$. The $[Cp_2Co][Co(CO)_4]$ may then react with another $[BiCo_3(CO)_{12}]$ to form **1**.

X-ray quality reddish-brown crystals of **1**[13,14] were obtained from a concentrated CH_2Cl_2 solution cooled at $-20\,^{\circ}C$ for several days. The crystal structure of **1** (Fig. 1)

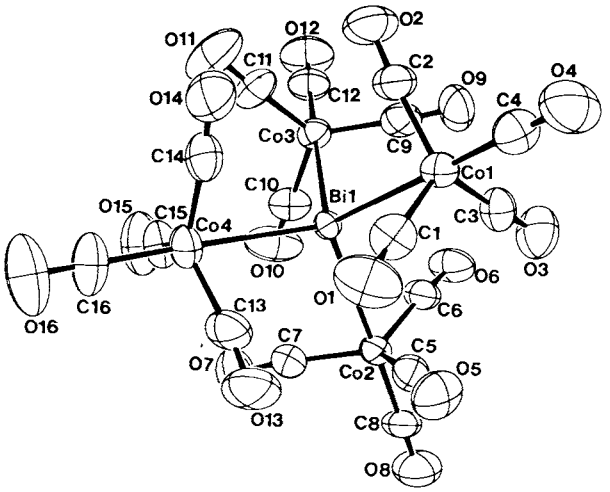

Fig. 1. ORTEP diagram of the $[Bi\{Co(CO)_4\}_4]^-$ anion showing 50% thermal probability ellipsoids and atom labeling. Important bond distances [Å] and angles [°]: Bi1-Co1 2.939(2), Bi1-Co2 2.898(2), Bi1-Co3 2.912(3), Bi1-Co4 2.876(2), Co-C(average) 1.79, C-O(average) 1.14; Co4-Bi1-Co2 109.76(6), Co4-Bi1-Co3 110.31(7), Co4-Bi1-Co1 108.74(7), Co2-Bi1-Co3 108.31(7), Co2-Bi1-Co1 108.96(6), Co3-Bi1-Co1 110.73(6).

consists of ordered $[Cp_2Co]^{\oplus}$ cations and $[BiCo_4(CO)_{16}]^{\ominus}$ anions in a 1:1 ratio. The Cp rings of the cation are staggered as in most standard $[Cp_2Co]^{\oplus}$ salts such as $[Cp_2Co][ClO_4]$[15] and $[CoCp(C_5H_4CO_2H)][PF_6]$.[16] The molecular structure of the anion, which approaches T_d point group symmetry, consists of a bismuth atom that is tetrahedrally surrounded by four $[Co(CO)_4]^{\ominus}$ units. The Bi–Co bonds are extremely long, ranging from 2.876 to 2.939 Å (average 2.906 Å). For comparison, the average Bi–Co bond distance in $[BiCo_3(CO)_{12}]$ is 2.766 Å,[2] and the Bi–Co distance in $[BiCo_3(CO)_9]$ is 2.613 Å.[7] The Co–Bi–Co bond angles range from 108.31 to 110.73° (average 109.47°).

The unusual feature of $[Cp_2Co][Bi\{Co(CO)_4\}_4]$ **1** that separates it from other open, tetrahedral $[E\{ML_4\}_4]$ complexes such as $[ECo_4(CO)_{16}]^{\ominus}$ (E = In, Tl),[4] $[ECo_4(CO)_{16}]$ (E = Sn, Pb),[5] and $[Et_4N][BiFe_4(CO)_{16}]$[6] is the electron count. The bismuth is a 10-electron center, having two electrons more than required to meet the EAN rule. Similar "hypervalency" has been observed in $[CpMoFe(CO)_5\{Te_2Br\}]$ and $[CpMoFe(CO)_5\{Te_2\text{-}(S_2CNEt_2)\}]$.[17] The two extra electrons, which are apparently stereochemically inactive, are unpaired, making **1** paramagnetic ($\mu_{eff} = 3.40\,\mu_B$ at room temperature).[18] Thus, the extremely long Bi–Co bonds may result from the extra electron density in the metal framework.

Experimental Procedure

1: Under nitrogen atmosphere, $[Co_2(CO)_8]$ (0.059 g, 0.17 mmol) and $[Cp_2Co]$ (0.066 g, 0.35 mmol) were mixed in a Schlenk flask with a magnetic stir bar. CH_2Cl_2 (30 mL) was added via syringe, and the solution was stirred a little over 1 h. The solution was then filtered onto solid $[BiCo_3(CO)_{12}]$ (0.250 g, 0.346 mmol), and the resulting solution was stirred a little over 1 h. The solution was filtered, and the solvent was removed under vacuum. The solid, **1**, was isolated in 86% yield (0.324 g, 0.299 mmol). The product is formed quite cleanly in this reaction if nearly exact stoichiometric amounts of reactants are used. Slight stoichiometric variations in the reactants cause the formation of small amounts of neutral byproducts, which can be removed easily by washing the solid with toluene.

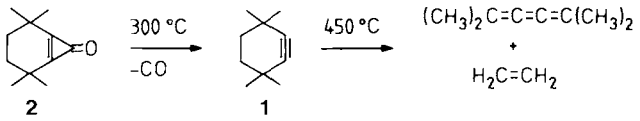
3,3,6,6-Tetramethylcyclohexyne**

By *Wolfram Sander* and *Orville L. Chapman**

Thermolysis and photolysis of cyclopropenones provide attractive routes to strained acetylenes.[1] We now describe 3,3,6,6-tetramethylcyclohexyne **1**, prepared from 2,2,5,5-tetramethylbicyclo[4.1.0]hept-1(6)-en-7-one **2**. *Suda* and *Masamune* showed **2** to be stable at 100°C in CH_2Cl_2 for 5 h.[2] In our hands, irradiation ($\lambda > 208$ nm) of **2** matrix-isolated in argon gave only a small amount of carbon monoxide.[3] Compound **2** thus shows remarkable thermal and photochemical stability for a cyclopropenone, and more vigorous methods were required.



Thermolysis of **2**[4] at 600°C (10^{-6} torr) and trapping the product in argon at 12 K gives carbon monoxide, ethylene, and tetramethylbutatriene[5] as the only products. The products were identified by comparison of the IR spectra with those of authentic samples.[6] Tetramethylbutatriene was further characterized by ^{1}H-NMR spectroscopy[7] after warming the matrix and isolation. At temperatures of 300–450°C a new product was trapped in addition to tetramethylbutatriene. This product is 3,3,6,6-tetramethylcyclohexyne **1** [IR (Ar, 12 K): $\tilde{\nu}$ = 2977 (s), 2939 (m), 1470 (w), 1455 (m), 1365 (m), 1305 (w), 1256 (m), 1215 (m), 894 (w), 838 (w), 815 (w), 798 (w), 700 (w), 563 (w), 445 (s), 405 (m) cm^{-1}] (see Fig. 1). The optimum yield of **1** is obtained at 370°C (10^{-6} torr) with argon trapping at 12 K.

Thermolysis (370°C) of **2** at slightly higher pressure followed by trapping at 12 K in argon gives **1** with a small amount of dimer **3**, ethylene, and tetramethylbutatriene (Fig. 2, top). When the matrix is warmed above 40 K, the argon vaporizes. Continued deposition at 45 K gives only dimer **3** and small amounts of ethylene and tetramethylbutatriene (Fig. 2, bottom). At the higher temperature (45 K) in the absence of argon, 3,3,6,6-tetramethylcyclohexyne **1** dimerizes to **3**. Thermolysis of **2** at 370°C (0.02 torr) and warming the product to room temperature gave dimer **3**, tetramethylbutatriene, and one minor, unidentified product. An authentic sample of dimer **3** was prepared from **4**.[8]

[**] This research was supported by the National Science Foundation (grant CHE-11196) and the IBM Corporation. The Humboldt Foundation provided a fellowship for *W. Sander*.

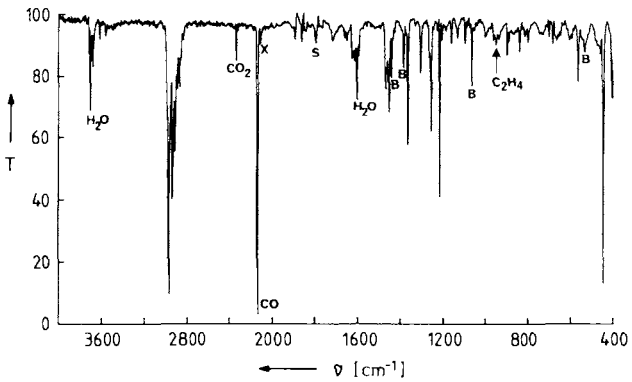

Fig. 1. IR spectrum of 3,3,6,6-tetramethylcyclohexyne **1** produced by pyrolysis of **2** at 350°C and trapping the products in argon at 12 K. The bands of the remaining cyclopropenone **2** were subtracted. S = cyclopropenone **2**, B = tetramethylbutatriene (T = transmission).

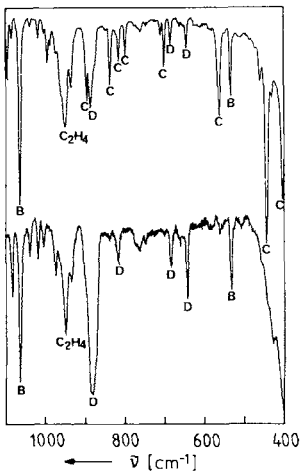

Fig. 2. Top: IR spectrum of 3,3,6,6-tetramethylcyclohexyne **1** from pyrolysis at 370°C with argon trapping at 12 K. Bottom: IR spectrum from same thermolysis with window at 45 K. B = tetramethylbutatriene, C = **1**, D = dimer **3**.

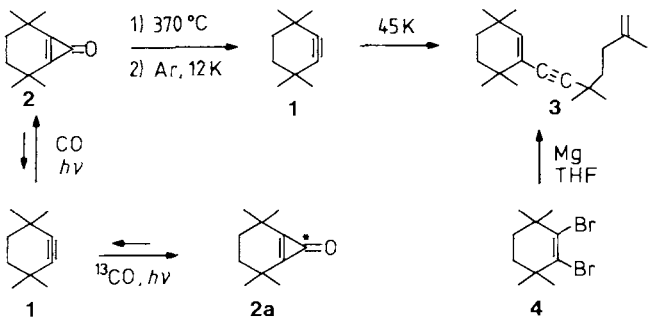
Irradiation ($\lambda > 208$ nm) of **1** generated by thermolysis of **2** and trapping in argon gave no tetramethylbutatriene but did give small amounts of **2**. This observation suggested that **1** photochemically adds carbon monoxide giving **2**.[9] If the photostationary state in the system favored **2**, the reason for failure in the photodecarbonylation of **2**



would be clear. Irradiation of **2** matrix-isolated in argon containing ^{13}C-carbon monoxide (95 atom% ^{13}C; 1.5% CO in Ar) gave ^{13}C-labeled **2a**. A similar experiment using thermally generated **1** in an argon matrix containing ^{13}C-carbon monoxide (95 atom% ^{13}C; 1.5% CO in Ar) gave **2a** on irradiation. The shifts in the IR bands in the spectrum of **2a** relative to **2** (Table 1) are in excellent agreement with the corresponding shifts in diphenylcyclopropenone.[10]

Table 1. IR bands of **2** and **2a** matrix-isolated in argon at 12 K.

$\tilde{\nu}$ [cm^{-1}]		$\Delta\tilde{\nu}$ [cm^{-1}]
2	**2a**	
1890 s	1856 s	34
1858 vs	1825 vs	33
1789 s	1775 s	14
1629 s	1619 s	10

The only disappointment in the IR spectrum of **1** (Fig. 1) is the absence of an identifiable triple-bond stretch. It is probably either hidden under the carbon monoxide bands (2139, 2149 cm^{-1}) or is very weak compared to other bands in **1** and thus not observed.[11] The other IR bands of **1** are due to vibrations very similar to those of the hydrocarbon portion of **2**. The most striking shifts are those of the bands at 684 and 643 cm^{-1} in **2** to 445 and 405 cm^{-1} in **1**.

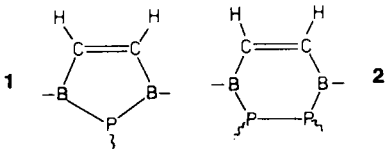
[11] Recently, the triple-bond stretching frequency for unsubstituted cyclohexyne was calculated to be 2003 cm^{-1}: S. Olivella, M. A. Pericàs, A. Riera, A. Solé, *J. Org. Chem. 52* (1987) 4160. The intensities of the bands were not calculated and therefore the comparison with the experimental values is difficult. The IR spectrum of **1** shows no IR band in the range 1900–2100 cm^{-1} (Fig. 1).

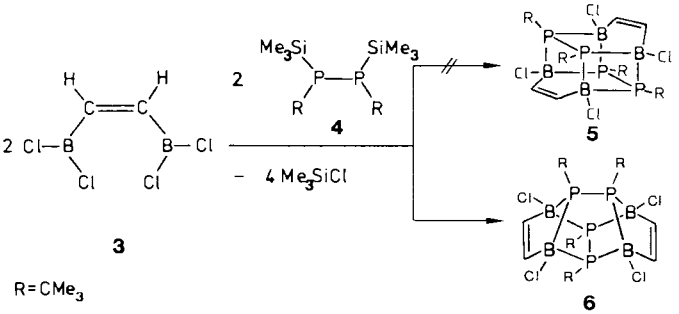
Novel Boron–Phosphorus Cages with $C_4B_4P_4$ and $C_2B_4P_4$ Frameworks**

By *Matthias Driess, Hans Pritzkow,* and *Walter Siebert**

In contrast to aminoboranes, phosphinoboranes exist mainly as cyclic dimers or trimers.[1,2] However, if electronic stabilization is achieved by amino substituents on the boron atom or if kinetic stabilization is achieved by bulky substituents on the boron and phosphorus atoms, then the corresponding phosphinoboranes are monomeric.[2b,3] Derivatives of the heterocycles 2,5-dihydro-1*H*-1,2,5-phosphadiborol **1**[4] and 1,2,3,6-tetrahydro-1,2,3,6-diphosphadiborin **2**[5] with amino substituents on boron are also monomeric. We have now synthesized a derivative of **2** that is dimeric.



Reaction of **3** with 1,2-di-*tert*-butyl-1,2-bis(trimethylsilyl)diphosphane **4** results in elimination of Me_3SiCl and formation of a dimeric product, which is not the cubane-like compound **5** but, surprisingly, the colorless, constitutionally isomeric compound **6**, having the cuneane cage as a structural element. Thus, its structure is analogous to that of S_4N_4 or Hittorf phosphorus. Compound **6** is stable toward oxygen and moisture up to ca. 100°C. In contrast to compounds of types **1** and **2**, compound **6** does not react with sulfur or selenium in refluxing toluene.



The $^1H\{^{31}P\}$-NMR spectrum of **6** exhibits two singlets for the *tert*-butyl protons and the $^{31}P\{^1H\}$-NMR spectrum exhibits two triplets at 220 K, which are broadened owing to ^{11}B–^{31}P coupling. The ^{11}B-NMR signal at $\delta = 4.2$ ($b_{1/2} = 170$ Hz) is in a region characteristic for tetracoordinated boron. These findings are not in agreement with structure **5** but rather with structure **6**. This conclusion is further corroborated by the result of X-ray structure analyses (Fig. 1),[6] according to which **6** is present in two modifications, one of which contains two independent molecules in the unit cell. The structures of the molecules, however, are not significantly different.

The formation of **6** within twelve hours (at 300 K) can be followed by ^1H-, ^{11}B-, and ^{31}P-NMR spectroscopy. The elimination of Me_3SiCl was thereby shown to proceed in two steps via an intermediate that has not yet been characterized. The intermediate, in turn, gives **6** quantitatively (^1H-NMR spectroscopy).

In order to determine what effect the kind of hydrocarbon bridge has on the cage formation, we incorporated the methylene group in place of the ethenylene group. The reaction of $CH_2(BCl_2)_2$ **7** with **4** does not result in formation of compound **8**, which is analogous to **6**, but rather in formation of the colorless, constitutionally isomeric compound **9**, which is moderately soluble in CH_2Cl_2 and

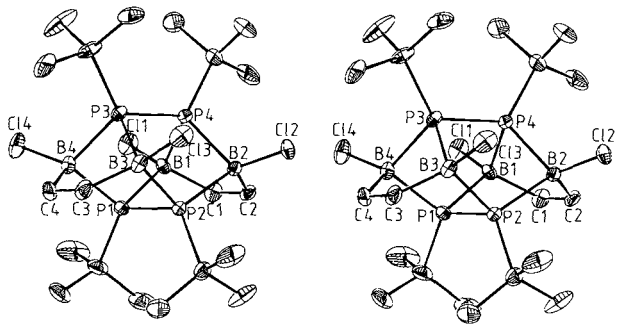

Fig. 1. Stereodrawing of the molecular structure of **6**. Important bond lengths [Å] and angles [°] (standard deviations for modification I: 0.003–0.015 Å, 0.2–0.8°; for modification II: 0.002–0.009 Å, 0.1–0.5°; averages for three molecules): P1-P2 2.273, P3-P4 2.254, P1(2)-B 2.02, P3(4)-B 2.000, B-C 1.573, C-C 1.330; B-P1(2)-B 110.3, B-P3(4)-B 86.7, P1(2)-P2(1)-B 96.7, P3(4)-P4(3)-B 104.9, P1(2)-B-C 110.2, P3(4)-B-C 100.8, P-B-P 95.0, C-C-B 116.7.

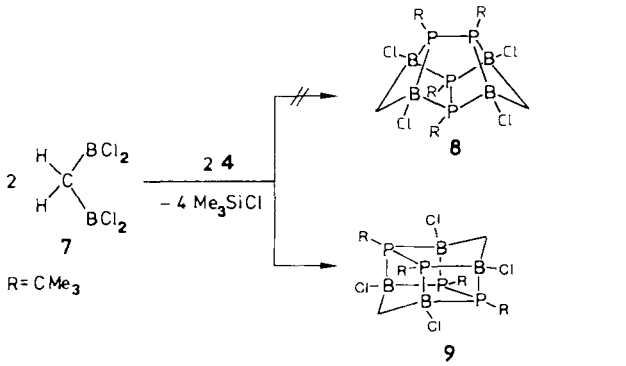
CH_3CN and whose stability toward oxygen and moisture is similar to that of **6**.



The $^1H\{^{31}P\}$- and $^{31}P\{^1H\}$-NMR spectra[7] of **9** indicate a highly symmetric arrangement of atoms in the molecule, which is confirmed by the results of an X-ray structure analysis (Fig. 2).[8] Compound **9** contains two CB_2P_2 five-membered rings joined by donor-acceptor bonds, whereas **8** displays two less favorable CB_2P four-membered rings.

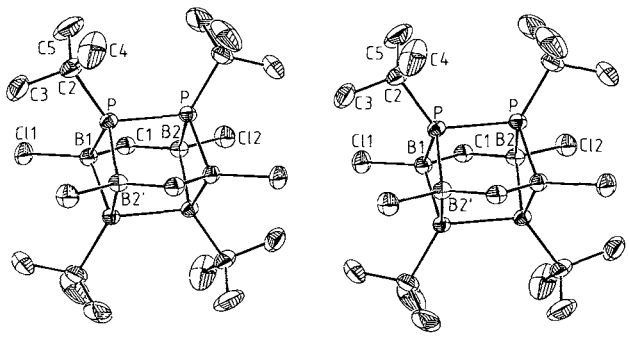


Fig. 2. Stereodrawing of the molecular structure of **9**. Important bond lengths [Å] and angles [°]: P-P 2.242(1), P-B 2.041, 2.036(2), B-C 1.584, 1.587(4); P-P-B 95.0(1), B1-P-B2' 93.9(1), C1-B-P 110.3, 110.0(1), B1-C1-B2 110.3(2).

Experimental Procedure

6 (2,3,8,9-tetra-*tert*-butyl-1,4,7,10-tetrachloro-2,3,8,9-tetraphosphonia-1,4,7,10-tetraboratapentacyclo[6.4.0.0^{2,10}.0^{3,7}.0^{4,9}]dodeca-5,11-diene): **3** (3.4 g, 17.8 mmol) was dissolved in CH_2Cl_2 (200 mL) at −20°C. **4** (5.73 g, 17.8 mmol) in CH_2Cl_2 (100 mL) was then added to this vigorously stirred solution. The clear orange-yellow solution was then allowed to warm to room temperature and stirred for an additional 12 h. After removal of all readily volatile components under vacuum, an orange powder remained, which was recrystallized from toluene (−30°C). Yield: 2.95 g (56%) **6**, m.p. = 308°C (dec.), correct C,H,P elemental analysis.—$^1H\{^{31}P\}$-NMR (300 MHz, CD_2Cl_2, 300 K): δ = 1.49 (s, 18H), 1.61 (s, 18H), 6.23 (br. s, 4H); $^{31}P\{^1H\}$-NMR (80.0 MHz, CD_2Cl_2, 220 K): δ = 19.92 (t, 2P, ^2J(PP) = 87.5 Hz), 14.70 (t, 2P); ^{13}C-NMR (50.3 MHz, CD_2Cl_2, 300 K): δ = 32.82 (m, 6C; CH_3), 33.38 (m, 6C; CCH_3), 43.18 (m, 2C; CCH_3), 43.26 (m, 2C; CCH_3), 145.08 (br. s, 4C; CB); MS (CI, CH_4): *m/z* 588 (4%, $M^{\oplus}$), 531 (6%, $[M-t\mathrm{Bu}]^{\oplus}$), 474 (4%, $[M-2t\mathrm{Bu}]^{\oplus}$), 57 (100%, $t\mathrm{Bu}^{\oplus}$).

9 (2,3,7,8-tetra-*tert*-butyl-1,4,6,9-tetrachloro-2,3,7,8-tetraphosphonia-1,4,6,9-tetraboratapentacyclo[5.3.0.0^{2,6}.0^{3,9}.0^{4,8}]decane): **4** (5.49 g, 17 mmol) in CH_2Cl_2 (100 mL) was added slowly at −40°C to **7** (3.03 g, 17 mmol) in CH_2Cl_2 (300 mL). After warming to room temperature, the clear orange reaction solution was concentrated to ca. 80 mL and allowed to stand for 24 h, resulting in the crystallization of **9**, which was further purified by washing with warm CCl_4. Yield: 2.02 g (42%) **9**, m.p. = 218°C (dec.). Correct C,H,P elemental analysis.—$^1H\{^{31}P\}$-NMR (300 MHz, $CDCl_3$, 300 K): δ = 1.78 (s, 36H), 1.45 (br. s, 4H); $^{31}P\{^1H\}$-NMR (121.5 MHz, $CDCl_3$, 210 K): δ = 2.03 (br. s); ^{11}B-NMR (29.8 MHz, $CDCl_3$, 300 K): δ = 8.6 (s, $b_{1/2}$ = 130 Hz); $^{13}C\{^1H\}$-NMR (50.3 MHz, $CDCl_3$, 300 K): δ = 33.45 (m, 12C; CCH_3), 43.41 (m, 4C, CCH_3), a signal for CB was not observed; MS (EI, 70 eV): *m/z* 564 (3%, $M^{\oplus}$), 507 (23%, $[M-t\mathrm{Bu}]^{\oplus}$), 451 (24%, $[M-t\mathrm{Bu}-C_4H_8]^{\oplus}$), 282 (4%, $[M/2]^{\oplus}$), 57 (100%, $t\mathrm{Bu}^{\oplus}$).

Synthesis and Properties of N^{α}-Di-*tert*-Butoxycarbonyl and N^{α}-Benzyloxycarbonyl *tert*-Butoxycarbonyl Amino Acids**

By *Kerstin Gunnarsson, Leif Grehn,* and *Ulf Ragnarsson**

Benzyloxycarbonyl[1] (Z) and *tert*-butoxycarbonyl[2,3] (Boc) amino acids are derivatives of fundamental importance in modern peptide synthesis.[4] The two groups

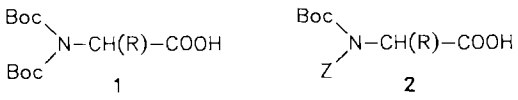
complement each other for protection purposes since both of them can be selectively removed under rather mild conditions.

We recently demonstrated that *N*-Boc_2 derivatives of simple model compounds could be prepared and that they were surprisingly stable.[5,6] Also mixed *N*-Boc(Z) derivatives were made.[6,7] This led us to try the synthesis of Boc_2-(**1**) and Boc(Z)-amino acids (**2**).



For the synthesis of compounds **1** three methods are used. In the first one (method A), a Boc-amino acid is converted into its benzyl ester,[8] which is then exhaustively *tert*-butoxycarbonylated[5] with Boc_2O and dimethylaminopyridine to give the Boc_2-amino acid benzyl ester. In the case of glycine, the corresponding derivative can be prepared from benzyl α-bromoacetate by a Gabriel reaction with di-*tert*-butyl iminodicarboxylate $HNBoc_2$.[9] The benzyl ester is then cleaved by catalytic hydrogenolysis over Pd/C or catalytic transfer hydrogenolysis to give the Boc_2-amino acid **1**.

If the Boc-amino acid contains a benzyl protecting group in its side chain, method A cannot be applied. Therefore, an alternative method, not requiring catalytic hydrogenolysis, was sought. First, we tried the base-labile 9-fluorenylmethyl esters[10] (method B). This approach also offered a possibility for the synthesis of mixed Boc(Z)-amino acids **2** and was applied to compounds **2a** and **2b**. However, although this procedure worked reasonably well for Boc- and Z-glycine and Z-alanine, in the case of Boc-Ser(Bzl) and Boc-Tyr(Bzl) difficulties were encountered already in the *tert*-butoxycarbonylation step, whereas for Boc(Z)-Phe the ester could not be subsequently cleaved with piperidine. From these experiments it was concluded that the 9-fluorenylmethyl esters were not the ideal solution to our problem, mainly due to their size and concomitant steric hindrance.

With the shortcomings of method B in mind, we directed our attention instead toward small protecting groups for the carboxyl function and we decided to try allyl esters[11] (method C). Their *tert*-butoxycarbonylation seemed much easier to accomplish and also their subsequent specific cleavage with tris(triphenylphosphane)rhodium(I) chloride at 70°C presented no particular problems. This procedure was tried in three cases, **1e**, **1f**, and **2a**, all with good results.

All Boc_2- and Boc(Z)-amino acids made so far are stable for several months at room temperature. The Boc_2 derivatives are resistant to moderately strong bases like piperidine, which was used for the final cleavage of the carboxyl protecting group in method B. With respect to their other properties, it can be mentioned that these *N*-protected amino acids form salts with dicyclohexylamine and active esters with *p*-nitrophenol and hydroxysuccinimide.

The new derivatives have been employed in the synthesis of a few dipeptides related to Leu-enkephalin: Boc_2-Gly-Phe-OBzl [via the *p*-nitrophenyl ester, 88% yield, m.p. = 74–75°C; $[\alpha]_D^{25}$ −1.2 (*c* = 1, DMF)], Boc_2-Gly-Phe-ONb [Nb = *p*-nitrobenzyl, via the *p*-nitrophenyl ester, 90% yield, m.p. = 165–166°C; $[\alpha]_D^{25}$ −9.7 (*c* = 1, DMF)], Boc_2-Phe-Leu-OBzl [via the *p*-nitrophenyl ester, 92% crude yield, 59% yield after chromatography, m.p. = 61.5–62°C; $[\alpha]_D^{25}$ −53.8 (*c* = 1, DMF); also made with dicyclohexylcarbodiimide (DCC) in 99% crude yield], Boc(Z)-Gly-Phe-ONb [with DCC, 88% yield, m.p. = 139–140°C; $[\alpha]_D^{25}$ −9.4 (*c* = 1, DMF)]. All peptides were chromatographically and spectroscopically pure and gave on amino acid analysis, after hydrolysis, the expected amino acid ratios.

Table 1. Yields and physical data of the new Boc_2- and Boc(Z)-amino acids **1** and **2**, respectively.

Tetranuclear Complexes as Intermediates in Transannular Oxidative-Addition Reactions. Structure of the First Tetrairidium Linear Cluster**

By *Miguel A. Ciriano, Santiago Sebastián, Luis A. Oro,* Antonio Tiripicchio, Marisa Tiripicchio Camellini,* and *Fernando J. Lahoz*

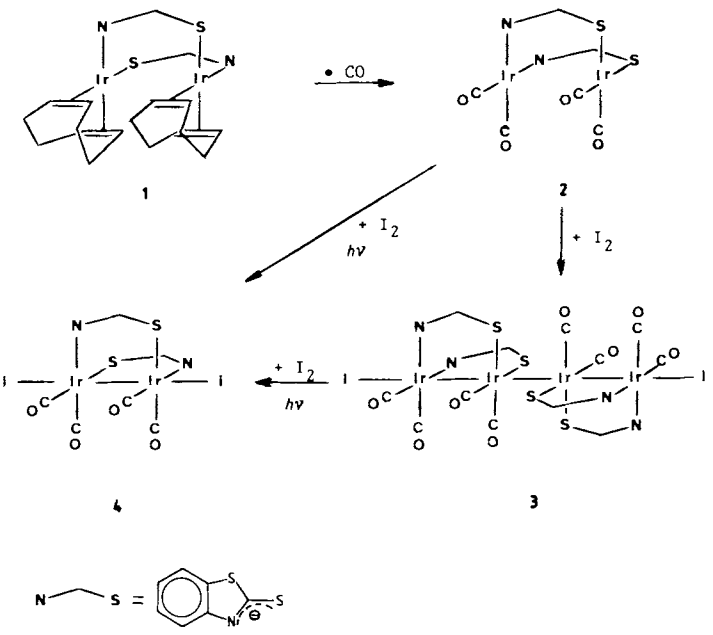
One of the emerging patterns of reactivity of bridged binuclear complexes significantly different from those of the mononuclear counterparts is the transannular oxidative-addition reaction discovered by *Schmidbaur* et al.[1a] [Eq. (a)]. This reaction[1b] results in a formal one-electron

$$X-Y + \overset{\frown}{M\quad M} \longrightarrow X-\overset{\frown}{M-M}-Y \qquad (a)$$

oxidation of each metal center and in creation of a metal-metal bond. Although a free-radical mechanism has been suggested for this type of reaction, e.g., the addition of iodine to the complexes $[\{Ir(\mu\text{-}StBu)(CO)(PR_3)\}_2]$,[2a] mechanistic studies are scarce,[2b] intermediates have not been isolated, and the role of the second metal center is not fully understood.

On the other hand, there is an increasing interest in binuclear complexes that are bridged through both hard and soft donor atoms. Our activity in this area began in 1984 when it was found that the binuclear complexes $[\{M(\mu\text{-}X)L_2\}_2]$ (X = 2-pyridinethiolate (C_5H_4NS) or benzothiazole-2-thiolate ($C_7H_4NS_2$); L_2 = diolefin or $(CO)_2$) may lead to: (1) the construction of homo- or hetero-trinuclear aggregates in which the metal atoms are in close proximity;[3] (2) the stabilization of otherwise reactive species such as the binuclear iodomethyldiiridium complex $[Ir_2(\mu\text{-}C_5H_4NS)_2(CH_2I)I(CO)_4]$.[4] Herein we describe the isolation and characterization of the unique linear Ir_4 cluster $[Ir_4(\mu\text{-}C_7H_4NS_2)_4(I)_2(CO)_8]$ **3** as intermediate in a transannular oxidative-addition reaction (see Scheme 1).

The red-orange binuclear complex $[\{Ir(\mu\text{-}C_7H_4NS_2)(cod)\}_2]$ **1** (cod = 1,5-cyclooctadiene) can be prepared in excellent yield as described for the analogous rhodium compound.[3b] Complex **1** is fluxional but its ^1H- and $^{13}C\{^1H\}$-NMR spectra[5] in the slow-exchange region are in accordance with the presence of a single species in solution, either the head-to-head (C_s) or the head-to-tail (C_2) isomer depicted in Scheme 1. Carbon monoxide immediately replaces the diolefin in **1** to yield a deep purple solution of the highly air-sensitive compound $[\{Ir(\mu\text{-}C_7H_4NS_2)(CO)_2\}_2]$ **2**.[6] Isomerization arising from the relative disposition of the bridging ligands occurs during this reaction and results in an equilibrium mixture of the head-to-tail and the head-to-head *cis*-tetracarbonyl isomers of **2** in 1:3 ratio in $[D_6]$benzene at 20°C. Iodine reacts with **2**, in dichloromethane upon exposure to sunlight, affording the red-orange transannular oxidative-addition product



Scheme 1.

$[\{Ir(\mu\text{-}C_7H_4NS_2)I(CO)_2\}_2]$ **4**. If the reaction is carried out in toluene, the tetranuclear cluster **3** crystallizes out rapidly as a dichroic golden-brown solid in 85% yield. Further reaction of **3** with iodine in dichloromethane rapidly gives complex **4**; in toluene, in which **3** is slightly soluble, this step requires intense irradiation with visible light.

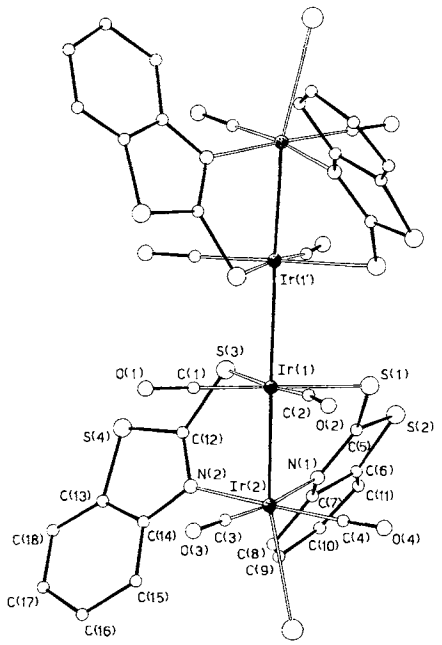


Fig. 1. View of the structure of $[Ir_4(\mu\text{-}C_7H_4NS_2)_4I_2(CO)_8]$ **3**. Selected bond lengths [Å] and angles [°]: Ir(1)-Ir(1') 2.828(2), Ir(1)-Ir(2) 2.731(2), Ir(2)-I 2.892(3), Ir(1)-S(1) 2.408(6), Ir(1)-S(3) 2.382(7), Ir(2)-N(1) 2.09(2), Ir(2)-N(2) 2.11(2); Ir(1)-Ir(2)-I 168.5(1), Ir(2)-Ir(1)-Ir(1') 170.2(1). The primed atoms are related to the nonprimed ones by a twofold axis.

The structures of complexes **3** (as toluene solvate) and **4**, determined by single-crystal X-ray diffraction studies, are depicted in Figures 1 and 2, respectively.[7] Complex **3**

shows a novel linear arrangement of the four metal atoms and can be considered to be made up of two binuclear halves related by a crystallographic twofold axis. Each half is formed by two iridium atoms separated by a distance of 2.731(2) Å, corresponding to a metal-metal bond, bridged by two benzothiazole-2-thiolate ligands through the N atom and the S atom exterior to the heterocycle, and bonded to two terminal carbonyl groups. The outer iridium atom, Ir(2), completes its octahedral coordination with a iodine atom, whereas the inner one, Ir(1), forms a nonbridged metal-metal bond, of 2.828(2) Å, with its symmetry-related atom. The almost linear chain of three metal-metal bonds makes **3** "EPR-silent." Noteworthy is the head-to-head coordination of the four ligands, which are bonded to the inner iridium atoms through the sulfur atoms and to the outer iridium atoms through the nitrogen atoms. As far as we know, a similar linear M_4 disposition has only been reported for $[Rh_4(1,3\text{-diisocyanopropane})_8Cl]^{5\oplus}$[8a] and in a small number of platinum-blue analogues.[8b]

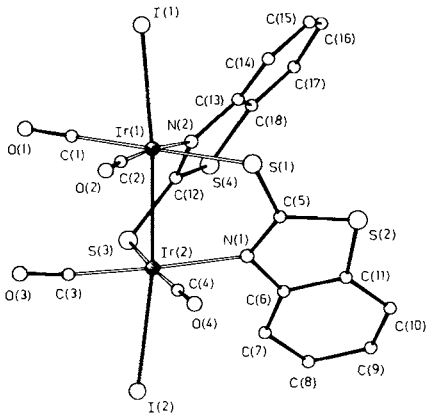

Fig. 2. View of the structure of $[\{Ir(\mu\text{-}C_7H_4NS_2)I(CO)_2\}_2]$ **4**. Selected bond lengths [Å] and angles [°]: Ir(1)-Ir(2) 2.676(2), Ir(1)-I(1) 2.797(2), Ir(2)-I(2) 2.788(2), Ir(1)-S(1) 2.386(5), Ir(2)-S(3) 2.395(6), Ir(1)-N(2) 2.10(2), Ir(2)-N(1) 2.13(1); Ir(2)-Ir(1)-I(1) 175.1(1), Ir(1)-Ir(2)-I(2) 173.5(1).

The final product of the oxidative addition, **4**, is a dimeric molecule with two iridium atoms separated by a typical metal-metal bond distance of 2.676(2) Å and bridged by two benzothiazole-2-thiolate ligands, which are coordinated in a head-to-tail manner. Both iridium atoms show analogous octahedral environments, each being additionally bonded to two carbonyls and to an iodine. All the features of this structure are reminiscent of those of the complex $[Ir_2(\mu\text{-}C_5H_4NS)_2(CH_2I)I(CO)_4]$ with the analogous N-C-S 2-pyridinethiolate ligand.[4]

The structure of **3** suggests that iodine attacks one of the metal centers in **2** to give presumably the radical complex $[Ir_2(\mu\text{-}C_7H_4NS_2)_2I(CO)_4]^{\odot}$ having a metal-metal bond,[9] which dimerizes rapidly. In this way, the second metal center, which is involved in the formation of the tetranuclear intermediate complex, can also provide "anchimeric assistance"[10] in cleaving the added molecule (in this case, I_2). The addition of iodine to the nonbridged metal-metal bond in **3** corresponds to the visible-light-assisted reaction. The change in the relative disposition of the bridging ligands on going from **3** to **4** is probably associated with their mobility since both compounds exhibit a fluxional behavior.

In conclusion, we have presented factual evidence of the so far unsuspected feature that tetranuclear complexes can be involved in oxidative-additions to binuclear complexes.

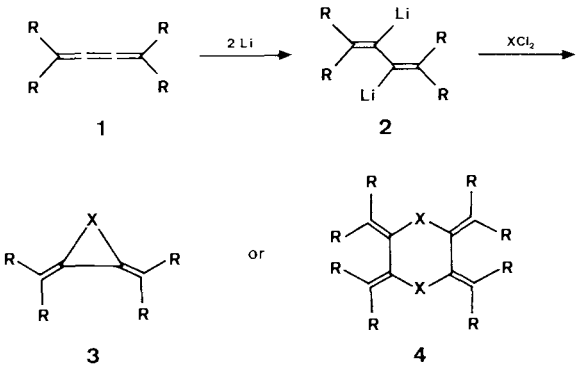
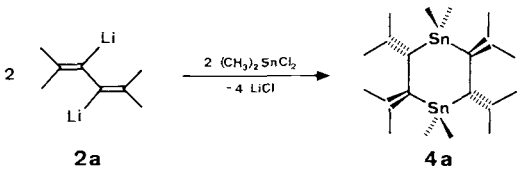
A Tetramethylene-1,4-distannacyclohexane from 3,4-Dilithio-2,5-dimethyl-2,4-hexadiene and Dichlorodimethylstannane: the First Dimetalla[6]radialene**

By *Adalbert Maercker,* Franz Brauers, Walter Brieden, Michael Jung,* and *Heinz Dieter Lutz*

2,3-Dilithio-1,3-butadiene derivatives are readily accessible by addition of lithium to the central double bond of aliphatic butatriene derivatives **1**[1,2] and are therefore of value for the synthesis of heterocyclic radialene derivatives. The formation of three-membered ring products **3** or six-membered ring products **4** is expected. So far, only one example of each of the compounds **3** and **4** (X = S, R = CH_3) is known; the yields of the multistep syntheses, however, are unsatisfactory.[3]



The reaction of 3,4-dilithio-2,5-dimethyl-2,4-hexadiene **2a**[1,2] with dichlorodimethylstannane in diethyl ether at 0°C does not result in formation of the three-membered ring compound **3** (X = $Sn(CH_3)_2$, R = CH_3), but rather of the formal dimer, the six-membered ring compound 1,1,4,4-tetramethyl-2,3,5,6-tetra-2-propylidene-1,4-distannacyclohexane **4a** (yield 45%, not optimized, the remainder being presumably polymer), a colorless, crystalline, air-stable substance.



The six-membered ring structure is indicated by the long-range SnH and SnC couplings in the ^{1}H- and ^{13}C-NMR spectrum, respectively, and by the mass spectrum (Table 1). Thus, the signals of the allyl protons of **4a** at $\delta = 1.59$ and 1.75, for example, exhibit not only a $^4J_{SnH}$ coupling to *one* tin atom but also an additional $^5J_{SnH}$ coupling to a second tin atom. The different SnC couplings to the two tin atoms make it possible to assign unequivocally the ^{13}C-NMR signals of the olefinic C atoms. Differences in the magnitudes of the coupling constants to the nuclei ^{117}Sn and ^{119}Sn are only observed for the Sn-bonded C atoms and for the protons of the Sn-bonded methyl groups.

Table 1. ^{1}H- and ^{13}C-NMR data and MS data for **4a**; J values in Hz for ^{119}Sn in each case.

^{1}H-NMR (80 MHz, $CDCl_3$): $\delta = 0.25$ (s, 12H, $2 \times Sn(CH_3)_2$, $^2J(SnH) = 52.2$), 1.59 (s, 12H, $4 \times CH_3$, $^4J(SnH) = 12.3$, $^5J(SnH) = 7.6$), 1.75 (s, 12H, $4 \times CH_3$, $^4J(SnH) = 16.7$, $^5J(SnH) = 10.6$)

^{13}C-NMR (20.1 MHz, $CDCl_3$): $\delta = -5.63$ ($Sn(CH_3)_2$, $^1J(SnC) = 302.7$), 21.03 (CH_3, $^3J(SnC) = 53.7$), 26.24 (CH_3, $^3J(SnC) = 45.2$), 135.71 (CMe_2, $^2J(SnC) = 28.1$, $^3J(SnC) = 41.5$), 142.25 (SnC, $^1J(SnC) = 468.8$, $^2J(SnC) = 28.1$)

MS: m/z 514 ($M^{\oplus}$, 14%), 499 ($M^{\oplus}$ – Me, 12%), 297 (66%), 135 (100%)

The Sn-bonded methyl groups gave rise to only a single, temperature-independent signal in the ^{1}H-NMR spectrum (even at −90°C) and in the ^{13}C-NMR spectrum. This is evidence in disfavor of a rigid chair conformation. On the other hand, a rapid ring inversion is not expected, since the bulky isopropylidene groups—as revealed by examination of models—can only move past one another with difficulty. In order to clarify unequivocally the conformation of **4a**, an X-ray structure analysis[4] was carried out; it shows that **4a** exists in a twist conformation (Fig. 1).

[**] Polylithium Organic Compounds, Part 8. This work was supported by the Fonds der Chemischen Industrie and the Stiftung Volkswagenwerk.—Part 7: A. Maercker, B. Grebe, *J. Organomet. Chem. 334* (1987) C21.

of **4a** by HPLC on chiral stationary phases have been unsuccessful so far,[5] indicating that the stationary phases were not suitable or that the barrier to inversion of **4a** is too low.

Noteworthy in the structure of **4a** are, on the one hand, the large dihedral angles within the two butadiene units—the angles C6-C5-C9-C10 and C14-C13-C17-C18 (Fig. 1) are 84 and 83°, respectively—and, on the other, the torsion angle of 48° between the two $C_{CH_3}SnC_{CH_3}$ planes; both indicate that the six-membered ring is strained. The central bonds of the butadiene units, which are not conjugated, have lengths of 1.522(10) (C13-C17) and 1.517(10) Å (C5-C9).

In contrast to the analogous disulfur compound **4** (X = S, R = CH_3),[3] **4a** does not undergo [4+2] cycloaddition with 4-phenyl-1,2,4-triazole-3,5-dione. Presumably, the coplanar arrangement of the isopropylidene groups is rendered even more difficult by the Sn methyl groups.

Experimental Procedure

4a: A 1.0 molar solution of **2a** (55 mL) in diethyl ether (450 mL) was added over 2 h to a stirred solution of dichlorodimethylstannane (11.0 g, 0.05 mol; Merck) in diethyl ether (50 mL) at 0°C. After aqueous workup, the residue was distilled (135–145°C/0.01 torr). After addition of *n*-hexane, **4a** crystallized at −25°C. It was then recrystallized from *n*-hexane. Yield according to GC: 45% (standard: *trans*-stilbene); yield of pure product, 2.3 g (18%); m.p. = 195–196°C; correct C,H analysis.

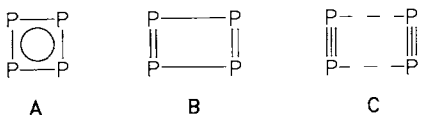
[(η⁵-C_5Me_4Et)Rh(μ,η²-P_2)]$_2$Rh(η⁵-C_5Me_4Et)], a Sandwich Complex with a P_4 Rectangle**

By *Otto J. Scherer,* Magdalena Swarowsky,* and *Gotthelf Wolmershäuser*

Triple-decker sandwich complexes containing a *cyclo*-P_x middle deck are known for *cyclo*-P_3,[1] *cyclo*-P_5,[2] and *cyclo*-P_6.[3] The question of what form planar P_4 (square **A**, rectangles **B** and **C**) would be stabilized in such complexes remains to be answered.[4a]



A partial answer is provided by the structural elucidation of the binuclear sandwich complex **2b**, which we obtained from **1b** and white phosphorus (P_4).

$$2[LRh(CO)_2] \xrightarrow[8\ h,\ 150°C]{P_4,\ xylene} [LRh(P_4)RhL]$$

1 **2**

a, L = (η⁵-C_5Me_5); **b**, L = (η⁵-C_5Me_4Et)

Complexes **2a,b** form orange crystals, which may be handled in the air and which are moderately soluble in *n*-pentane and readily soluble in dichloromethane and toluene. The ^{1}H- and ^{31}P{^{1}H}-NMR data[5] of **2a,b** show hardly any differences. Noteworthy in both cases is the small ^1J(RhP) coupling of ca. 27 Hz; values of this order of magnitude are also found for **3**[6] and **4a,b**, which contain 1,3-diphosphacyclobutadiene as ligand.[7] In the mass spectrum[5] of **2a,b**, the most intense peak is due to the molecular ion; P_4 and P_2 appear as P_x fragments.

[(η³-P_3)Rh{$MeC(CH_2PPh_2)_3$}] **3**[6]

[{η⁴-(*t*BuCP)$_2$}Rh(η⁵-C_5R_5)] **4a**, R = H; **4b**, R = Me[7]

The X-ray structure analysis[8] shows that the two five-membered rings and the P_4 structural unit of **2b** are planar and parallel to one another (Fig. 1). Whereas the P1–P2

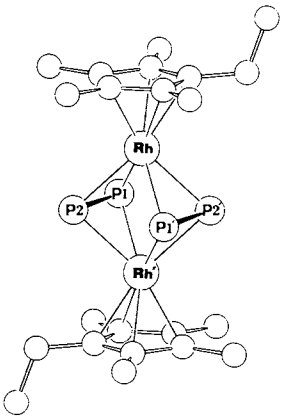


Fig. 1. Molecular structure of **2b**. Selected bond lengths [Å] and angles [°]: Rh···Rh' 3.324(1), Rh-P1 2.418(1), Rh-P2 2.413(1), Rh-P1' 2.416(1), Rh-P2' 2.418(1), Rh-C 2.198(4)–2.220(4), P1-P2 2.052(2), P1···P2' 2.845(2), $C_{(r)}$-$C_{(r)}$ 1.414(6)–1.438(6), $C_{(r)}$-$C_{(t)}$ 1.493(7)–1.513(6), Rh-$L_{(centr.)}$ 1.851, Rh-$P_{4(centr.)}$ 1.662; P1-P2-P1' 90.0(1), P2-P1-P2' 90.0(1), Rh-P1-Rh' 86.9(1), Rh-P2-Rh' 86.9(1), P1-Rh-P2 50.3(1), P1-P2-Rh 65.0(1), P2-P1-Rh 64.8(1). — (r) = ring, (t) = terminal, L = η⁵-C_5Me_4Et.

distance (2.052(2) Å) of the shorter side of the P_4 rectangle lies in the range expected for μ,η²-P_2 units,[4] the length of its long side (P1···P2' 2.845(2) Å) is nearly identical with that of the "short" P···P side (2.849(5) Å) of the P_4 trapezoid of **5**;[9] this value lies just in the range found for the "long" P–P distances (2.4–2.8 Å) of metal phosphides.[10] The RhP_4Rh framework of **2** may be regarded as the molecular pendant to the three-dimensionally linked NbP_4Nb fragment of the NbPS solid-state structure.[11] Whereas **2b**

[+] X-ray structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie.

should be regarded as a binuclear sandwich complex having two four-electron donor μ,η^2-P_2 ligands (i.e., 18 valence electrons (VE) per Rh atom), the bonding in the Co analogue **6** is more complicated. The X-ray structure analysis reveals two independent molecules per unit cell,[12] each of whose Co-Co distances is ca. 3.1 Å. In this case, the P_4

cis-$[(\eta^5\text{-}C_5Me_5)(CO)MoP_2\{Cr(CO)_5\}]_2$ **5**[9]

$[(\eta^5\text{-}C_5Me_4Et)Co(P_4)Co(\eta^5\text{-}C_5Me_4Et)]$ **6**[12]

$[Rh_2Cl_2\{(\eta^5\text{-}C_5H_5)Rh\{\eta^4\text{-}(t\text{BuCP})_2\}\}_4]$ **7**[14]

bridging ligand forms a "long" (similar to that of **2b**) and a "short" (32-VE triple-decker with *cyclo*-P_4?) rectangle, whose average P-P values correspond almost exactly to the distance of 2.38 Å in the cubic (metallic) modification[13] of black phosphorus ($\bar{d}$(P-P) = 2.45 Å for **2b**). The Rh-Rh' distance of **2b** (3.324(1) Å) is significantly longer than d(M-M) for triple-decker complexes (2.63–2.73 Å) containing a *cyclo*-$P_{5(6)}$ middle deck and exhibiting metal-metal interaction;[2,3] the average Rh-P value for **2b** (2.416 Å) is larger than that observed for 7 (2.335 Å).[14]

Experimental Procedure

2a,b: **1a** (650 mg, 2.2 mmol) [15a] [**1b** (600 mg, 1.95 mmol) [15b]] and P_4 (547 mg, 4.4 mmol) [483 mg, 3.9 mmol) were stirred in refluxing xylene (ca. 30 mL) for 8 h. The reaction solution (containing small amounts of insoluble components) was concentrated to 10 mL under oil-pump vacuum, treated with 3 g of Al_2O_3 (basic, activity II), and then dried under oil-pump vacuum to afford a freely flowing solid. Upon chromatography (column: 25 × 2.5 cm), excess P_4 was eluted as a yellow forerun with pentane. Elution with pentane/toluene (1 : 1) then afforded **2a,b** as a yellow-orange fraction. After removal of the solvent under oil-pump vacuum, **2a,b** were obtained as spectroscopically pure, orange powders. Recrystallization from pentane (ca. −18 °C) afforded **2a** as needle-shaped and **2b** as cube-shaped, orange crystals. Yield **2a**: 207 mg (31%) [**2b**: 190 mg (31%)].

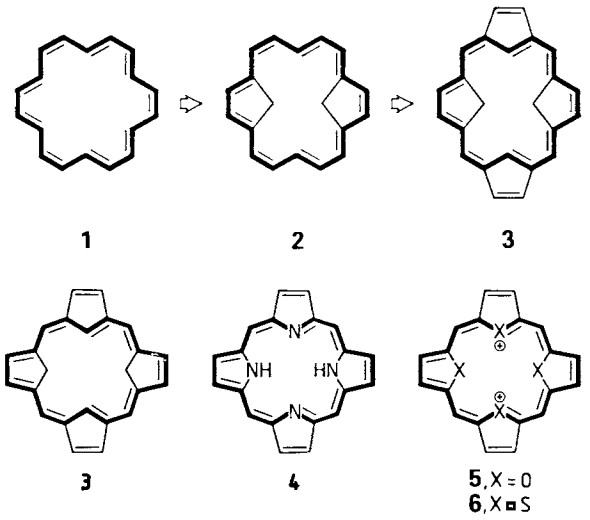
Tetraoxaporphyrin Dication**

By *Emanuel Vogel,* Wilhelm Haas, Bernd Knipp, Johann Lex,* and *Hans Schmickler*

Sondheimer's [18]annulene **1**,[1] the classic example of a simple benzene homologue that conforms to the Hückel rule, exhibits a striking dichotomy with respect to aromatic character: although the molecule fulfills the physical criteria for aromaticity, it displays a high reactivity similar to that of polyenes owing to its conformational flexibility. Comparison of the chemical behavior of **1** with that of bridged annulenes, such as 1,6-methano[10]annulene,[2] clearly highlights the fact that the rigidity of the ring skeleton is an essential prerequisite for the stability of a [4n + 2]annulene with n > 1.



Among the numerous possible ways of making the [18]annulene **1** rigid while maintaining planarity,[3] the incorporation, according to **2** and **3**, of two CH_2 and two CH=CH groups as inner and outer bridges, respectively, is a representative case. The resulting bridged [18]annulene **3**, which has not been reported so far, commands great scientific interest since it constitutes the hydrocarbon parent structure of the *porphyrins* (**4**: porphyrin[4]) — *the*

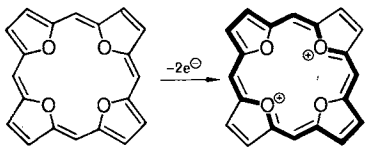
[**] Presented in a plenary lecture at the Autumn Meeting of the Royal Society of Chemistry, Nottingham (England), September 22–24, 1987.

bridged annulenes of nature. Like **3**, the no less intriguing oxygen and sulfur analogues of the porphyrins,[5,6] tetraoxaporphyrin and tetrathiaporphyrin, **5** and **6**, respectively, still await synthesis. In terms of 18π-electron systems, **5** and **6** are dications[7] describable by resonance structures with oxonium oxygen and sulfonium sulfur atoms, respectively (see structural formula), as well as by those with a dicationic C_{20} perimeter. Similar to square-planar metalloporphyrins, **5** most likely exhibits D_{4h} symmetry, whereas, in the case of **6**, the possibility must be considered that the molecule deviates from planarity owing to the large sulfur atoms. Despite the fact that porphyrins are now commonly regarded as NH-bridged diaza[18]annulenes, quite a number of questions remain unanswered regarding the π-electron structure of these chemically and biologically extremely important tetrapyrrolic macrocycles.[8] The prospect of arriving at a deeper understanding of the bonding in porphyrins by means of **3**, **5**, and **6** makes these three new ring systems attractive synthetic goals.

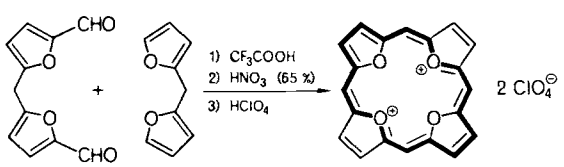
We report here on a route to the tetraoxaporphyrin dication **5** as its perchlorate **5a**. A possible synthetic approach to **5** suggesting itself is the two-electron oxidation of the oxygen-bridged [20]annulene **7**, which is likewise unknown. Since **5** is certain to exhibit considerable resonance stabilization, the readiness with which the annulene **7** undergoes electron transfer might be so pronounced that it could be regarded as a "pseudometal."[9] Such reasoning about **5**/**7** also provided the motivation for the synthesis of the tetraoxaporphycene dication **10** (as the perchlorate), which was realized in a parallel investigation.[10]



7 **5**

Synthetic approach

Compound **7**[11] should, in principle, be easy to synthesize by a MacDonald condensation[9, 12] of 5,5′-methylenedi-2-furaldehyde **8**[13] with 2,2′-difurylmethane **9**. Unlike the case in porphyrin syntheses, this condensation would not be followed by a dehydrogenation step. Reaction of **8** (1.02 g, 5 mmol) with **9** (0.74 g, 5 mmol) in dichloromethane (100 mL) in the presence of 40 mL of trifluoroacetic acid (2 h, room temperature) was not encouraging, however, since it resulted in the formation of a reaction mixture showing no spectroscopic evidence of **7**. A closer inspection of the literature on porphyrins made us speculate that **7** might be present in latent form and thus led us to oxidize the mixture (after removal of solvent) by direct addition of 30 mL of 65% nitric acid (48 h, room temperature) — as in the preparation of the tetraoxaporphycene dication **10**.[10] This unconventional experiment was indeed successful. A reddish-brown solution formed from which, upon slow addition of 10 mL of 70% perchloric acid, the desired tetraoxaporphyrin dication **5** separated as the perchlorate **5a** in the form of violet crystals (needles) [dec. above 310°C; yield 206 mg (8%)].



8 **9** **5a**

Compound **5a** is virtually insoluble in common organic solvents. In water, it undergoes decomposition in a surface reaction. Thus, strong mineral acids, preferably concentrated sulfuric acid (good solubility) are the primary solvents of choice.[14] The spectroscopic structural proof of **5a** was very easy owing to the high symmetry of the compound as well as to the fact that the tetraoxaporphycene dication **10** provided an ideal reference substance.[10]

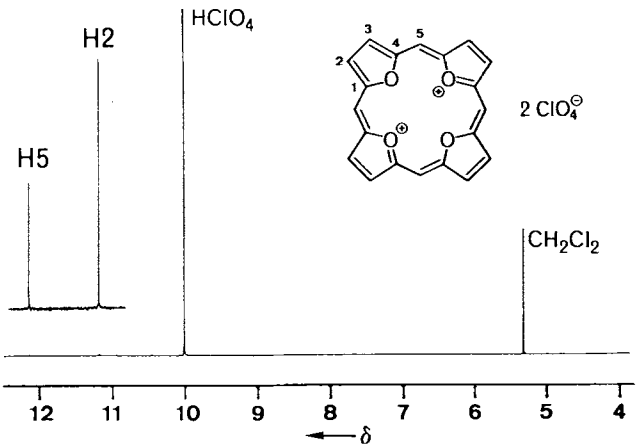


Fig. 1. ^{1}H NMR spectrum of **5a** (300 MHz, 68% $DClO_4$, CH_2Cl_2 int.).

The ^{1}H NMR spectrum (Table 1 and Fig. 1) shows only two signals ($\delta = 12.13$ and 11.17) in the region expected for an aromatic dication **5** describable by resonance structures involving oxonium oxygen atoms,[10, 15] while the ^{13}C NMR spectrum complements these results in displaying three signals, one for a quaternary and two for proton-bearing sp^2-hybridized carbon atoms. If any further argument were needed to demonstrate the close structural relationship between porphyrin and porphycene systems,[10, 16] it is provided by the striking agreement in the ^{1}H and ^{13}C NMR parameters between **5a** and **10**.

Table 1. ^{1}H NMR (300 MHz) and ^{13}C NMR data (75.5 MHz) of **5a** and **10** (68% $DClO_4$, CH_2Cl_2 int.). Chemical shifts δ_H and δ_C and coupling constants J [Hz].

	H2	H3	H5	C1	C2	C3	C4	C5
		$^3J(^1H\text{-}^1H)$				$^1J(^{13}C\text{-}^1H)$		
5a	11.17		12.13	157.03	139.61			104.87
	$J(2,3)=4.71$ [a]			—	188 [a]			168 [a]
10	10.93	11.46	11.30 [b]	159.25	140.52	135.91	148.12	118.84 [b]
	$J(2,3)=4.87$			—	188	189	—	166
	$J(9,10)=11.6$							

[a] The coupling constants were taken from the spectrum of **5a** in 68% DNO_3 (better solubility of **5a**); [b] δ_H of H9, δ_C of C9 (for numbering of **10** see [10]).

The UV/VIS spectrum of **5a** [in 96% H_2SO_4: $\lambda_{max} = 298$ nm ($\varepsilon = 7500$), 325 (7100), 341 (16700) sh, 351 (51000), 359 (79000), 370 (1020000), 470 (430) sh, 486 (1330) sh, 494 (1580) sh, 499 (1910), 524 (18600), 529 (14600) sh, 543 (3400) sh, 569 (1600)] has — like that of **10** — the shape characteristic of porphyrin spectra: a strong B band (Soret

band) in the near ultraviolet and weak Q bands in the visible region.[8b] As revealed in Figure 2, the change from **10**

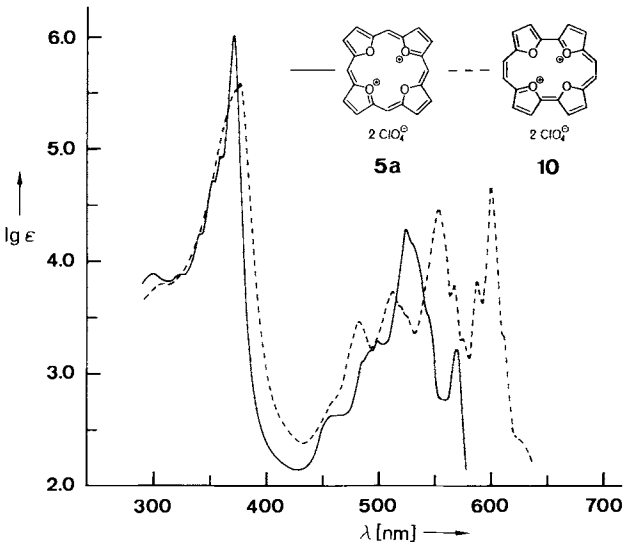

Fig. 2. UV/VIS spectra of **5a** (96% H_2SO_4) and **10** (70% $HClO_4$).

to **5a** is reflected in the spectrum primarily by a reduction in the splitting of both types of bands, especially the Q bands. It seems reasonable to interpret these differences in terms of a transformation from a D_{2h}- to a D_{4h}-type of spectrum (in analogy to porphyrin versus metalloporphyrin spectra).[17]

The IR spectrum of **5a** exhibits relatively few bands,[18] which is in agreement with the assumption that, in analogy to square-planar-coordinated metalloporphyrins,[19] **5** possesses D_{4h} symmetry (for **5**, this symmetry leads to the expectation of seventeen IR-active in-plane and five IR-active out-of-plane normal mode vibrations).

An insight into the molecular structure of **5a** is provided by an X-ray structure analysis[20] (Fig. 3). The dication **5** is very nearly planar (maximum deviation of the C and O atoms from the mean plane, ±0.03 Å; maximum torsional angle, 2.6°) and has virtually the postulated D_{4h} symmetry. The molecular shape of **5** (Fig. 3, top) is largely in agreement with that of porphyrin **4**,[21] but the replacement of nitrogen by oxygen atoms results in the C_α–C_β bond lengths in the heterocyclic five-membered rings being strikingly short [1.442 versus 1.406 Å (average values)], the C_β–C_β bond lengths remaining roughly constant. In parallel herewith, the internal bond angles at the *meso*-methine carbon atoms are expanded by ca. 3.7° [from 127.1 to 130.8° (average values)]. Interestingly, these structural changes, which amount to a contraction of the C_{20} molecular perimeter, do not have an effect on the dimensions of the inner cavity: The O···O distances (O···O′, 2.869 Å; O···O‴, 2.900 Å) are the same within the limits of error as the N···N distances in porphyrin (between 2.879 and 2.901 Å).[22] As shown in the side view of the molecule (Fig. 3, bottom), the dicationic tetraoxaporphyrin, in accordance with the stoichiometry, is associated with two perchlorate ions, which are situated above and below the ring framework.

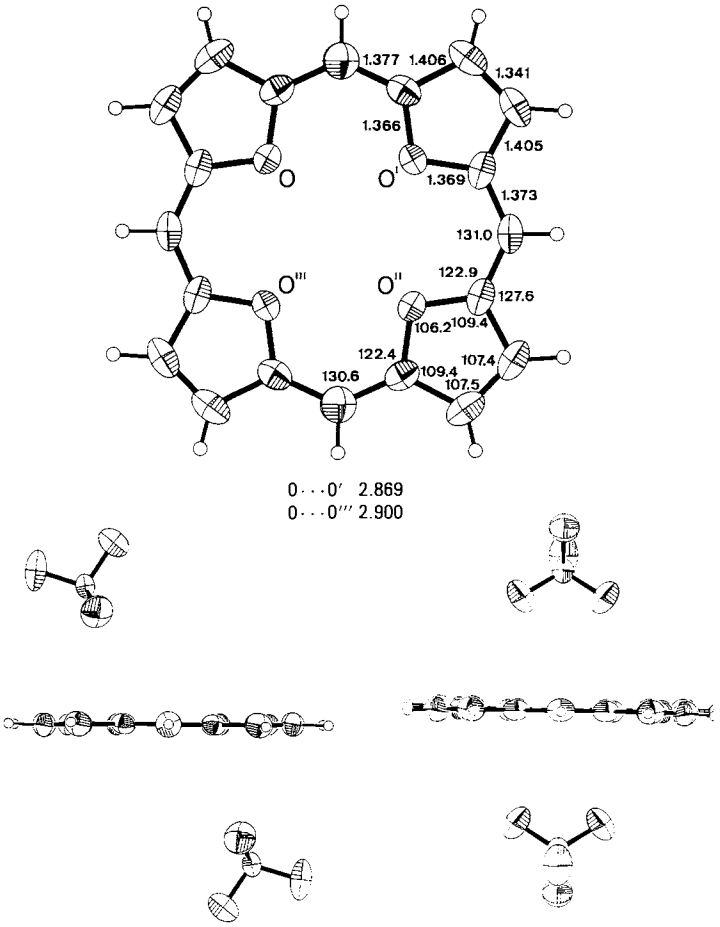

Fig. 3. Molecular structure of **5a**. Top: Viewed from above (tetraoxaporphyrin dication). Bottom: Two side views (rotated by 90°) of an isolated unit consisting of a tetraoxaporphyrin dication and two perchlorate ions. Selected bond lengths, nonbonded contacts [Å], and bond angles [°]; standard deviations ca. 0.003 Å and 0.2°. The thermal ellipsoids are drawn at the 40% probability level.

In view of the long history of porphyrin chemistry, it is amazing that the conceptually very simple tetraoxaporphyrin dication **5** remained unknown for so long. The synthesis of this compound occupies a position of central importance in our research, since it establishes a bridge between annulene and porphyrin chemistry, a connection we have sought since the first NH-bridged [4n+2]annulene, i.e., 1,6-imino[10]annulene,[23] was made in this laboratory more than two decades ago.

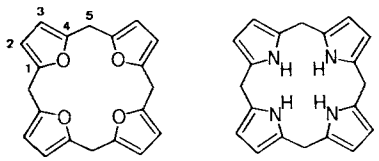
Tetraoxaporphyrinogen (Tetraoxaquaterene): Oxidation to the Tetraoxaporphyrin Dication

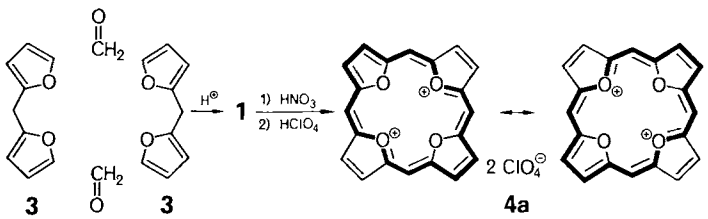
By *Wilhelm Haas, Bernd Knipp, Martin Sicken, Johann Lex,* and *Emanuel Vogel**

The porphyrinogens, colorless tetrapyrrolic macrocycles having the structure type **2**, play a central role in porphyrin chemistry, since they are the primary cyclic intermediates in the biosynthesis of hemins and chlorophylls[1] as well as in important laboratory syntheses of porphyrins.[2] The most pertinent chemical feature of these hexahydroporphyrins is the ease with which they undergo oxidation (even in the solid state) to the corresponding porphyrins upon exposure to oxygen or upon treatment with other oxidants. In order to isolate porphyrinogens, therefore, anaerobic conditions are usually required.



1 **2**

After we synthesized the tetraoxaporphyrin dication **4** as its perchlorate **4a**,[3] the question was raised whether tetraoxaporphyrinogen **1**—in analogy to the biologically significant porphyrinogen-porphyrin transformation—would be oxidizable to **4**. Surprisingly, the parent compound **1** was unknown,[4] although an extensive literature exists regarding the synthesis of tetraoxaporphyrinogens —the so-called tetraoxaquaterenes[5]—by cyclocondensation of furan with ketones and aldehydes.[6] Whereas the route to tetraoxaporphyrin dications is blocked by the geminal substituents in the case of tetraoxaporphyrinogens prepared from ketones, those made from aldehydes, such as 5,10,15,20-tetramethyltetraoxaporphyrinogen,[6c, g] constitute potential precursors of dications of the present kind. We have now succeeded in obtaining **1** and in extending the porphyrinogen-porphyrin transformation to the "tetraoxa series."



3 **3** **4a**

The acid-catalyzed condensation of furan with formaldehyde[7] affords a complex mixture of products, consisting mainly of polymers, which did not encourage us to search for tetraoxaporphyrinogen **1** that might possibly have been formed. The conjecture that it might be easier to detect **1** if the condensation component furan were replaced by the conceivable intermediate 2,2′-difurylme-

[*] Prof. Dr. E. Vogel, Dr. W. Haas, B. Knipp, M. Sicken, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)

thane **3** turned out to be correct. When **3** was allowed to react in methanol/water in the presence of lithium perchlorate and perchloric acid with a 30% aqueous solution of formaldehyde (room temperature, 3 d),[8] the desired **1** could be isolated in small amounts by conventional chromatographic workup of the reaction products on silica gel with toluene as eluent.[9] After sublimation and crystallization from ethanol,[10] **1** was obtained as colorless needles (m.p. = 158–159 °C, yield 0.5–1%).

The ^{1}H NMR spectrum (300 MHz, $CDCl_3$) of **1** exhibits two singlets at $\delta = 5.95$ (H2, $^3J_{2,3} = 2.87$ Hz) and 3.83 (H5), while the ^{13}C NMR spectrum (75.5 MHz, $CDCl_3$), in parallel herewith, shows three resonances at $\delta = 150.91$ (C1), 106.63 (C2, $^1J_{CH} = 172.8$ Hz), and 27.47 (C5, $^1J_{CH} = 128.5$ Hz). The presence of the tetraoxa compound, rather than of an oligomer, is indicated by the base peak at m/z 320 ($M^{\oplus}$) in the mass spectrum (EI, 75 eV). The UV spectrum [in cyclohexane: $\lambda_{max} = 222$ nm ($\varepsilon = 34\,400$)] is in fair agreement with that of 2,5-dimethylfuran[11] with respect to the position of the maximum, but displays an extinction coefficient that is more than four times higher. In the IR spectrum (KBr), strong to medium-strong bands are found at $\tilde{\nu} = 3104$, 2914, 1557, 1217, 1016, 955, 790, 770, and 758 cm^{-1}.

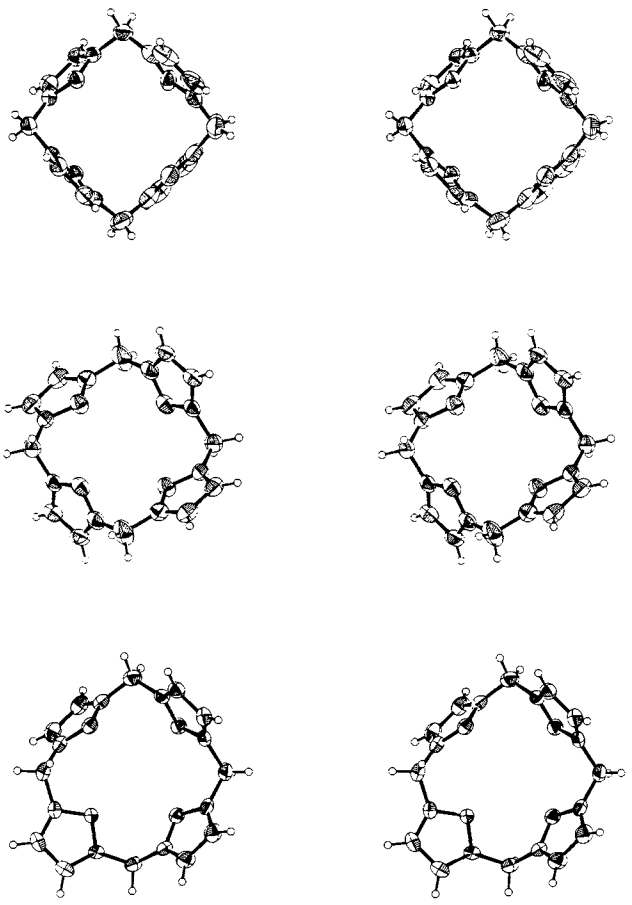


Fig. 1. Top: Stereoprojection of the molecular structure of **1** in the monoclinic crystal modification. Middle and bottom: Stereoprojections of the two independent molecules of **1** in the triclinic crystal modification. The thermal ellipsoids are drawn at the 40% probability level.

According to the X-ray structure analysis (Fig. 1), **1** crystallizes from ethanol in two modifications (form A, monoclinic;[12] form B, triclinic[13]). In form A, **1** exists in only one conformation, whereas two conformations are present in form B, both of which differ significantly from that in form A. The molecules in form A have approximately D_{2d} symmetry (Fig. 1, top). In the case of the two molecular structures in form B, two related conformations are involved (Fig. 1, middle and bottom), one of which (Fig. 1, middle) is characterized by a center of symmetry.[4] In all three conformations, the bond lengths and bond angles are normal.

In contrast to porphyrinogens, tetraoxaporphyrinogen **1** is stable toward oxygen, but it can be converted into **4** by employing nitric acid, the oxidizing agent used advantageously in the original synthesis of the tetraoxaporphyrin dication **4**.[3] Upon treatment of **1** at 0 °C with 65% nitric acid, a reddish-brown solution forms after a short time. Slow addition of perchloric acid to this solution results in the crystallization of the perchlorate **4a** (violet needles, yield 10%). The **4a** thus obtained is identical (^{1}H NMR, UV/VIS, and IR) with an authentic sample.[3]

The attempt to oxidize the known 5,10,15,20-tetramethyltetraoxaporphyrinogen[6c, g] with nitric acid to give the 5,10,15,20-tetramethyl derivative of **4** led, unexpectedly, to complete degradation of the molecule. If, on the other hand, the compound is treated with bromine in dichloromethane and the bromination product, after removal of the solvent, is dissolved in perchloric acid, the perchlorate of the 5,10,15,20-tetramethyltetraoxaporphyrin dication precipitates on standing. A more detailed investigation of this product is currently in progress.[14]

[7] W. H. Brown, H. Sawatsky, *Can. J. Chem. 34* (1956) 1147. 2,2'-Difurylmethane (yield 1.7%) was obtained as the only defined product in the reaction of furan and formaldehyde.
[8] The relative amounts of 2,2'-difurylmethane, formaldehyde, lithium perchlorate, and perchloric acid are the same as those reported by *Högberg* and *Weber* [6g] for the condensation of 1,1-di(2-furyl)ethane with acetaldehyde.
[9] In order to detect **1**, the HNO_3 oxidation to **4** proved useful: If the TLC plate was sprayed with concentrated HNO_3, **1** could be localized on the basis of the characteristic red fluorescence (upon excitation with light of 366-nm wavelength) of the dication **4**.
[10] The (preliminary) low yield of **1** serves to illustrate the importance of the *gem*-dialkyl effect involved in the tetraoxaquaterene syntheses with ketones as carbonyl components [N. L. Allinger, V. Zalkow, *J. Org. Chem. 25* (1960) 701]. The yield of **1** did not improve appreciably when **3** was condensed with the diol 5,5'-methylenedifurfuryl alcohol instead of with formaldehyde.

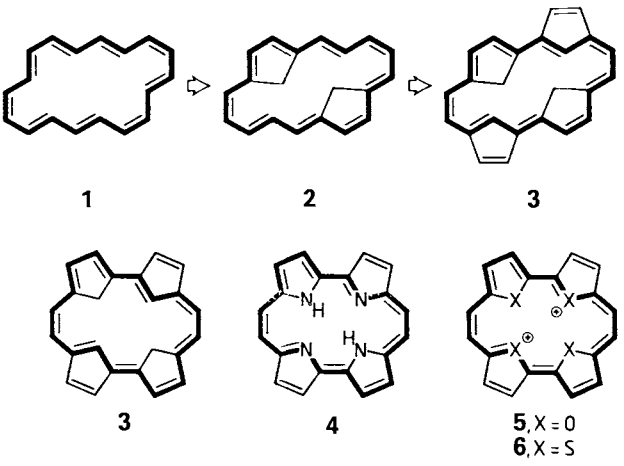
Tetraoxaporphycene Dication

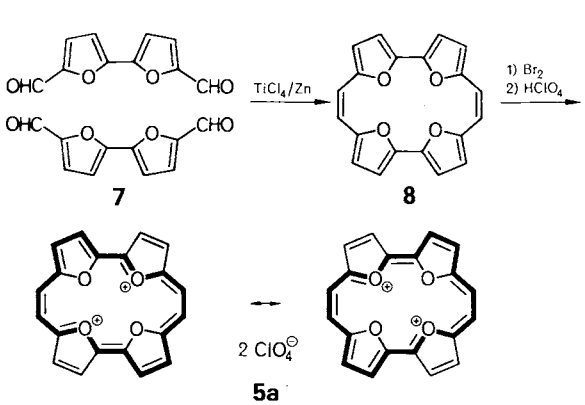
By *Emanuel Vogel,* Martin Sicken, Peter Röhrig, Hans Schmickler, Johann Lex,* and *Otto Ermer*

The conception and synthesis of the tetraoxaporphyrin dication[1] demonstrate the significance of [18]annulene, possessing D_{6h} symmetry,[2] as the underlying structure of important macrocyclic rings, in particular the porphyrins, which can be regarded as bridged [18]annulenes. Bridging of the hypothetical [18]annulene **1**, which exhibits C_{2h} symmetry and which presumably does not exist owing to conformational strain, should also lead to interesting ring systems. Surprisingly, however, such systems, although closely related structurally to the porphyrins, have not been investigated until very recently.

If, in analogy to the pattern described for the higher-symmetry [18]annulene,[1] two inner CH_2 and two outer CH=CH bridges are incorporated into **1**, the rigid [18]annulene **3** is obtained (via the still relatively flexible **2**). Compound **3**, which is expected to have a rectangular molecular framework, is the hydrocarbon parent structure of the recently synthesized porphycene **4**,[3] a planar and aromatic, tetrapyrrolic macrocycle resembling porphyrin in many ways. The H···H repulsions in the center of **3** need not necessarily result in a nonplanar ring framework; hence this hydrocarbon, although considerably strained, might also exhibit aromaticity. The oxygen analogue of **4**, the tetraoxaporphycene dication **5**, can be predicted with great confidence to exist as an 18π Hückel arene having D_{2h} symmetry. Obviously, not only the resonance structures with oxonium oxygen atoms shown here but also resonance structures having a dicationic C_{20} perimeter should contribute to the stabilization of **5**. A prognosis concerning the π-electron structure of the tetrathiaporphycene dication **6** is more problematical, since it is not certain whether the spatial demands of the sulfur atoms would still permit a planar conformation of the molecule.[4]



Having already prepared porphycene **4**, we have now succeeded in synthesizing the tetraoxaporphycene dication **5** as the perchlorate **5a** and the hydrogen dinitrate **5b** and have confirmed the porphyrinoid nature of the compound. As the method of choice for the synthesis of the dication **5**, the two-electron oxidation of the oxygen-bridged [20]annulene **8** corresponding to **5** suggested itself. Ready oxidizability of the [4n]annulene **8** appeared guaranteed in view of the observation that the nitrogen analogue of **8**, 22,24-dihydroporphycene, underwent dehydrogenation to **4** even under the reducing conditions of its formation.[3a]



The required [20]annulene **8** is formed as the main low-molecular-weight product[5] when 5,5'-bi-2,2'-furaldehyde[6] **7** is subjected to reductive coupling using low-valent titanium[7] according to the procedure reported for 5,5'-bi-2,2'-pyrrolecarbaldehyde.[3a] In contrast to 22,24-dihydroporphycene, **8** is a relatively stable [4n]annulene,

Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (FRG)

whose isolation requires no special protective measures [violet leaflets (from ether/hexane), m.p. = 270–271 °C; yield 16%].

The ^{1}H NMR spectrum of **8** (Table 1 and Fig. 1, top), which, as expected, consists of an AB system and a singlet, reveals a pronounced paramagnetic ring current; the ^{1}H resonances (center of gravity $\bar{\delta}_H = 4.68$) appear at relatively high field, similar to those of the corresponding vinylic protons in simple[8] and bridged[9] macrocyclic [4n]annulenes, especially in 1,6:9,14-dimethano[16]annulene ($\bar{\delta}_H = 4.96$).[9c-e] The assumption that **8** is present in the form of the thermodynamically more stable double-bond isomer having four furan units is supported by the magnitudes of the vicinal coupling constants.

An X-ray structure analysis[10] (Fig. 2a) reveals **8** as a crystallographically centrosymmetric molecule having a slightly puckered ring framework [maximum deviation of the C and O atoms from the mean plane, ±0.13 Å (C_β of the furan rings); maximum torsional angle, 8.2° (C7-C8-C9-C10)]. This slight nonplanarity may be due to O···O repulsions or to packing effects. The olefinic character of **8** is clearly evident from the alternation of the CC bond lengths, which is most pronounced in the ring segment C8-C9-C10-C11. Further noteworthy structural features of **8** are the nearly square configuration of the four oxygen atoms (O1···O2, 2.778 Å; O1···O2′, 2.729 Å) and the large increase in the CCC bond angles in the inner 16-membered ring to 134.6°.

The base peak in the mass spectrum is due to the doubly positively charged molecular ion. This finding provides further support for the expectation that the dication **5** is sufficiently stabilized as an 18 π arene to allow it to be isolated in the chemical two-electron oxidation of the [20]annulene **8**. Indeed, the transformation of **8** to **5** was achieved under conditions reminiscent of those involved in the formation of the tropylium ion from tropilidene.[11] When **8** is treated in dichloromethane with one equivalent of bromine, an apparently saltlike amorphous product separates spontaneously, which dissolves in 70% perchloric acid to give a reddish-violet solution (weak red fluorescence). Slow addition of water to this solution results in the formation of microcrystalline tetraoxaporphycene dication **5** as the perchlorate **5a** (95% crude product); recrystallization from 50% perchloric acid affords **5a** as violet needles [dec. above 300 °C; yield 90%].[12]

Table 1. ^{1}H NMR (300 MHz) and ^{13}C NMR data (75.5 MHz) of **8** (C_6D_6) and **5a** (68% $DClO_4$, CH_2Cl_2 int.). Chemical shifts δ_H and δ_C and coupling constants J [Hz].

	H2	H3	H9	C1	C2	C3	C4	C9
	$^3J(^1H,^1H)$			$^1J(^{13}C,^1H)$				
8	4.90	4.94	4.19	155.58	116.36	109.33	149.42	113.98
	$J(2,3) = 3.45$	$J(9,10) = 13.6$	—	175	176	—	157	
5a	10.93	11.46	11.30	159.25	140.52	135.91	148.12	118.84
	$J(2,3) = 4.87$	$J(9,10) = 11.6$	—	188	189	—	166	

The presence of the aromatic tetraoxaporphycene dication in the perchlorate **5a** is shown very convincingly in the ^{1}H NMR spectrum (Table 1 and Fig. 1, bottom) by the fact that the oxidation of **8** to the dication causes the center of gravity $\bar{\delta}_H$ of the ^{1}H chemical shift (with reversal of the relative positions of the signals of H2 and H9) to be moved downfield by no less than 6.6 ppm. The position of the ^{1}H resonances of the dication is in accordance with expectation, if dioxaporphyrins, which exist in diprotonated form,[13] are taken as reference compounds. That **5a**, in contrast to **8**, is delocalized is revealed not only by the chemical shifts, but also by a partial equalization of the vicinal coupling constants. In the ^{13}C NMR spectrum of **5a**, like in that of **8**, five resonance signals are observed.

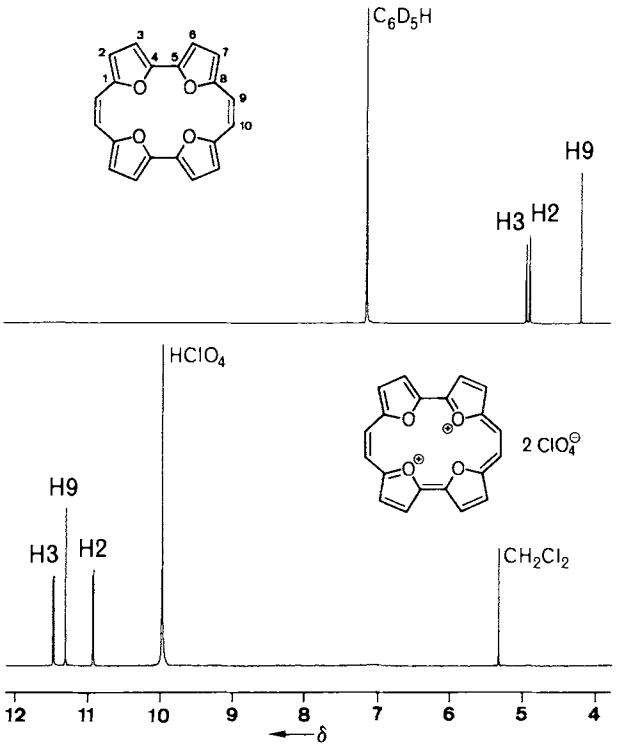

Fig. 1. ^{1}H NMR spectra of **8** (300 MHz, C_6D_6) and **5a** (300 MHz, 68% $DClO_4$, CH_2Cl_2 int.).

Significantly, on conversion of **8** into **5a** the center of gravity $\bar{\delta}_C$ of the ^{13}C chemical shifts migrates downfield by only 12 ppm ($\Delta\bar{\delta}_C$), while, according to the correlation between chemical shift and charge density (160 ppm/π electron) that holds for numerous (4n + 2)π-electron systems, a value of $\Delta\bar{\delta}_C = 16$ ppm[14] would have been expected for a system in which two positive charges are distributed over twenty C atoms. From the difference between the measured and estimated $\Delta\bar{\delta}_C$ values it is apparent that the oxygen atoms also bear charge. It seems justified, therefore, to describe **5** primarily by resonance structures in which the 18 π conjugation pathway includes two oxonium oxygen atoms as shown in the formula.

The UV/VIS spectrum of **5a** is similar to that of porphycene,[3a,e] apart from the larger number of bands in the long-wavelength region.

Although the X-ray analysis of **5a** supported the molecular structure derived from the spectra, a complete structure determination was prevented by partial disorder effects (two orientations of **5** mutually rotated in the molecular plane). Guided by the notion that a planar anion should allow better intermolecular contacts than the more spherical perchlorate ion, and thus should reduce the propensity toward disorder in the crystal, the prepara-

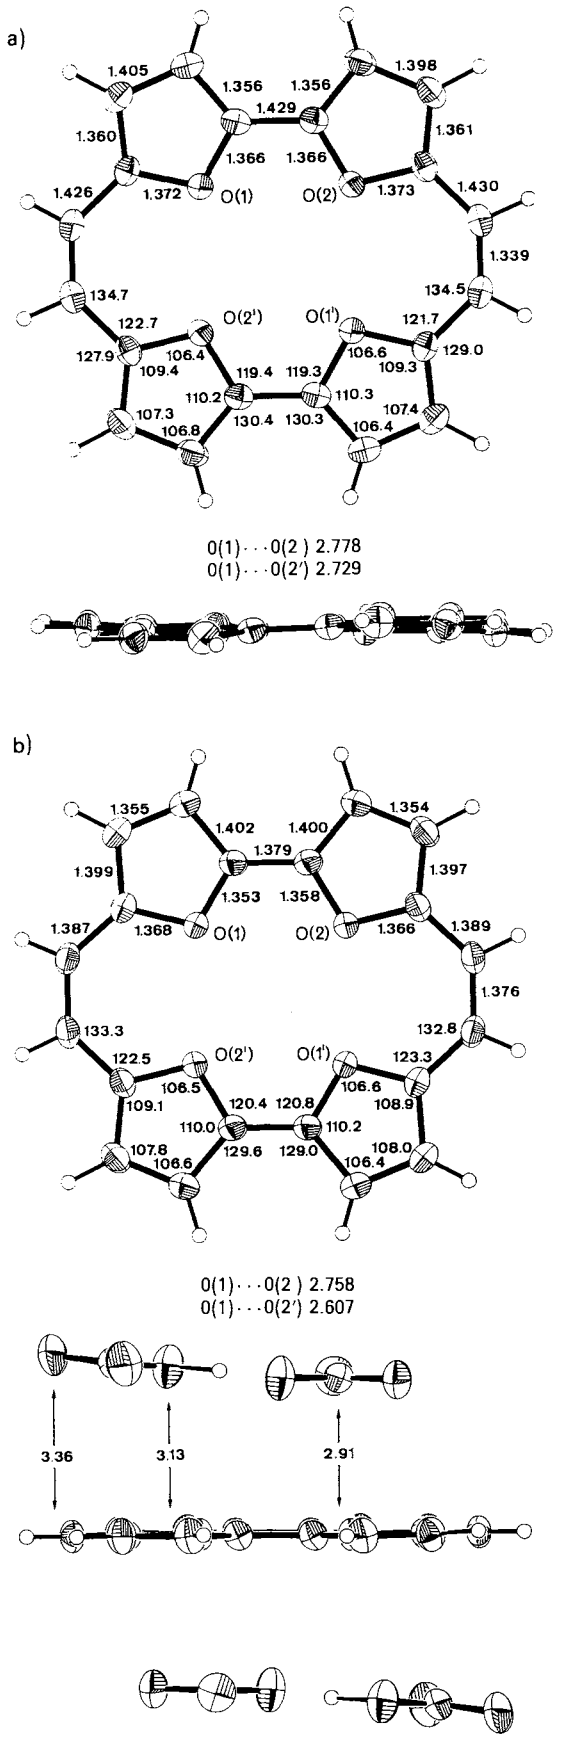

Fig. 2. a) Structure of **8**. Top: View perpendicular to the molecular plane. Bottom: Side view. b) Structure of **5b**. Top: View of dication. Bottom: Side view of a "sandwich" consisting of one tetraoxaporphycene dication and two hydrogen dinitrate ions situated above and below the dication. Selected bond lengths, nonbonded contacts [Å], and bond angles [°]; standard deviations ca. 0.002 Å and 0.1°. The thermal ellipsoids are shown at the 40% probability level.

tion of the nitrate of **5** was attempted. Whereas **8** did not give a well-defined crystalline product with silver nitrate (various media), upon treatment with 65% nitric acid (!) at room temperature it immediately afforded a salt, which, surprisingly, differed from the expected nitrate by containing two additional equivalents of HNO_3 (yield almost quantitative). Violet rhombs (dec. above 270°C upon rapid heating) were grown by slow crystallization from concentrated nitric acid. In fact, these crystals did not suffer from crystallographic disorder perturbations and turned out to consist of the hydrogen dinitrate **5b** $[(C_{20}H_{12}O_4)^{2\oplus}2(NO_3\cdot HNO_3)^{\ominus}]$[15] of the tetraoxaporphycene dication **5** (**5b** tends to decompose, presumably by loss of HNO_3).

The X-ray structure of **5b**[16] (Fig. 2b) confirms that, in contrast to its annulene precursor **8**, the dication features a "porphyrinoid ring system." The following structural changes on going from **8** to **5b** are evident (Fig. 2): (1) *Planarity:* While **8** is slightly puckered, the dication **5** is practically planar (maximum deviation of the C and O atoms from the mean plane, ±0.02 Å; maximum torsional angle, 1.4°). (2) *Bond lengths:* Bond alternation is no longer present in the ring segment C8-C9-C10-C11, whereas the length relation C_β-$C_\beta > C_\alpha$-C_β is reversed, similar to what is observed in porphyrins and porphycenes. (3) *Configuration of the four heteroatoms:* The almost square O_4 core in **8** adopts a more rectangular shape in the dication (O1···O2, 2.758 Å; O1···O2′, 2.607 Å), presumably due in part to attractive $O^{\ominus}\cdots O$ 1,6 interactions (similar to the N-H···N hydrogen bonds in porphycene). As expected, the decrease in the O1···O2′ separation is accompanied by a CCC angle contraction in the inner 16-membered ring (by about 2°).

Table 2. Selected physical data for **8** and **5a, b**.

1,4:5,8:11,14:15,18-tetraoxido[20]annulene **8**: for ^1H and ^{13}C NMR data see Table 1; MS (70 eV): m/z 316 ($M^{\oplus}$, 30%), 158 ($M^{2\oplus}$, 100); IR (KBr): $\tilde{\nu}$ = 3132, 2977, 1899, 1673, 1632, 1619, 1530, 1439, 1403, 1393, 1348, 1206, 1030, 971, 958, 953, 848, 781, 773, 756, 751, 627 cm^{-1}; UV/VIS (benzene): λ_{max} = 303 nm (ε = 107000), 307 (106000), 317 (159000), 354 (5600) sh, 380 (3900) sh, 400 (1550) sh, 517 (640)

5a: for ^1H and ^{13}C NMR data see Table 1; IR (Nujol): $\tilde{\nu}$ = 3103, 3054, 3040, 3010, 1582, 1523, 1511, 1438, 1402, 1259, 1194, 1090 ($ClO_4^{\ominus}$), 1050 ($ClO_4^{\ominus}$), 959, 934, 913, 861, 818, 654, 624 ($ClO_4^{\ominus}$) cm^{-1}; UV/VIS (70% $HClO_4$): λ_{max} = 307 nm (ε = 6500), 372 (340000) sh, 376 (383000), 457 (550) sh, 482 (2900), 512 (5300), 523 (3400) sh, 552 (27900), 567 (6100), 575 (2050), 587 (6550), 599 (45300), 610 (2200) sh, 623 (280) sh

5b: ^1H NMR (300 MHz, 68% DNO_3, CH_2Cl_2 int.): δ = 11.65 (d, H3), 11.47 (s, H9), 11.08 (d, H2); ^{13}C NMR (75.5 MHz, 68% DNO_3, CH_2Cl_2 int.): δ = 158.58, 147.44, 139.49, 134.92, 117.85; IR (Nujol): $\tilde{\nu}$ = 3111, 3088, 3062, 3049, 1579, 1518, 1437, 1357 ($NO_3\cdot HNO_3^{\ominus}$), 1303, 1294, 1201, 934, 910, 864 cm^{-1}. UV/VIS (65% HNO_3): The λ_{max} values are in agreement with those of **5a**, whereas the ε values exhibit a slight scatter, presumably owing to loss of HNO_3 from **5b**.

The structure of the hydrogen dinitrate ion serving as counterion in **5b** is noteworthy; it consists of two nearly coplanar nitrate groups connected by a short asymmetric hydrogen bond (O···O, 2.490 Å).[15] The two hydrogen dinitrate ions are arranged layerlike above and below the dication, the layer separation being slightly different for $NO_3^{\ominus}$ and HNO_3 (Fig. 2b, bottom). In the crystal, these "sandwich-type" triple layers are stacked in a laterally displaced pattern.

[15] The hydrogen dinitrate ion takes on two distinctly different configurations in the crystal. The configuration observed for **5b**, containing coplanar nitrate groups linked by a short hydrogen bond, has precedence in the structure of tetraphenylarsonium hydrogen dinitrate (B. D. Faithful, S. C. Wallwork, *Chem. Commun. 1967*, 1211), but this appears to be an exception. In most cases, a configuration is present in which four oxygen atoms of two nitrate groups form a distorted tetrahedron around the bridging hydrogen atom: J. Roziere, M.-T. Roziere-Bories, J. M. Williams, *Inorg. Chem. 15* (1976) 2490, and other examples listed there.

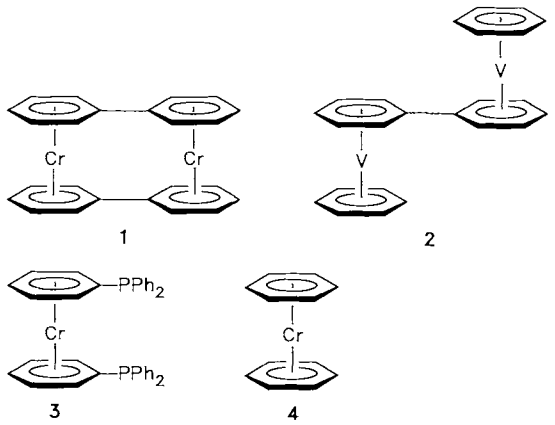
[17] Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52871, the names of the authors, and the journal citation.

Electron–Electron/Spin–Spin Long-Range Interaction as Studied in the Diradical Dication [Di{bis(dimethylphosphino-η^6-benzene)chromium(I)}-nickel(0)]$^{++}$ **

By *Christoph Elschenbroich,* Gottfried Heikenfeld, Martin Wünsch, Werner Massa,* and *Gerhard Baum*

Facile change in the oxidation state and favorable ESR properties make the $(\eta^6\text{-arene})_2M(d^5)$[2] unit a suitable probe for the study of mixed valence and intermediate valence states as well as of electron–electron/spin–spin interaction. After considering the cases of rigid parallel orientation (e.g., **1**[3]) and conformationally flexible orientation (e.g., **2**[4]), we focused our attention on oligonuclear sandwich compounds with orthogonally arranged moieties. A tetrahedrally coordinated Ni atom lends itself well as a spacer for the two orthogonal halves of the molecule.



In continuation of earlier work (**3**[5]), we have now synthesized the "organometallic diphos ligand" bis(dimethylphosphino-η^6-benzene)chromium **6** and allowed it to react with bis(1,5-cyclooctadiene)nickel to obtain the title compound **7** (Scheme 1).

The air-sensitive dimethylphosphino derivatives **5** and **6** are also labile towards hydrolysis; they are rapidly dephosphinylated in THF/5% H_2O, especially at the complex cation stage. The C–P bond in the bis(chelate) complex **7** as well as in the $Ni(CO)_2$ adduct **8**, synthesized for comparison, is more inert. Figure 1 shows the molecular structure of **7**.[7] Physical data are collected in Table 1.

The structural features of both the NiL_4 and $(\eta^6\text{-arene})_2Cr$ units are largely retained upon formation of **7**. The methyl groups of the PMe_2 bridges assume axial and equatorial positions with respect to the plane of the arene; overall, the "ligands" **6** coordinate to Ni to produce the *meso* form. The axes of the two sandwich moieties lie mutually perpendicular and the distance between their central atoms is 8.49 Å. The eclipsed arrangement of the benzene rings and the C–P–Ni bond angle, however, result in the three central atoms Cr, Ni, and Cr being non-colinear. In solution, **7** is conformationally flexible; only one ^{1}H-

and $v > 100$ mVs^{-1}. Comparison of the peak currents for samples of known concentration of **7** using **6** as standard indicates that $E^1_{1/2}$ is associated with the transfer of two electrons. Thus, the following assignment accrues (in DME, $(n\text{Bu})_4NClO_4$ (TBAP), at a glassy carbon electrode versus the saturated calomel electrode (SCE), v = 100 mVs^{-1}):

$$7 \equiv [(\mathbf{6})_2Ni] \xrightleftharpoons{-2e^{\ominus}} [(\mathbf{6}^{\odot\oplus})_2Ni]^{2\oplus} \xrightleftharpoons{-e^{\ominus}} [(\mathbf{6}^{\odot\oplus})_2Ni]^{3\oplus} \xrightarrow{-e^{\ominus}} [(\mathbf{6}^{\odot\oplus})_2Ni]^{4\oplus}$$

+20°C:	$E^1_{1/2} = -0.70$ V	$E^2_{1/2} = -0.52$ V	$E^3_{pa} = -0.12$ V (irrev.)
−25°C:	$E^1_{1/2} = -0.73$ V	$E^2_{1/2} = -0.55$ V	$E^3_{1/2} = -0.16$ V (rev.)

NMR signal is observed for the methyl groups in the range $-80°C < T < +40°C$.

The redox behavior of **7** was investigated by cyclic volt-ammetry (Fig. 2c). It is characterized by three electron-transfer steps, the first and second of which ($E^1_{1/2} = -0.70$ V, $E^2_{1/2} = -0.52$ V) are reversible in dimethoxyethane (DME) at room temperature. The third step ($E^3_{1/2} = -0.16$ V) becomes reversible only at $T < -25°C$

The potentials $E^2_{1/2}$ and $E^3_{1/2}$ are similar to those of the mononuclear complex bis(diphenylphosphinoethane)nickel;[8] $E^1_{1/2}$ is shifted cathodically in comparison to the value observed for the free ligand **6** ($E_{1/2} = -0.57$ V, reversible at 25°C). The shape of the signal and the peak current of the first wave indicate that no electrochemically measurable interaction exists between the two redox centers of the sandwich moieties; that is, electron transfer at

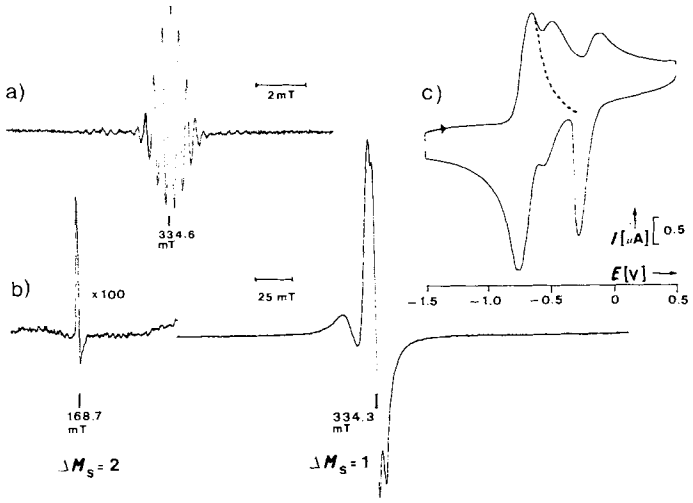

Fig. 2. a) ESR spectrum (2nd derivative) of $7(PF_6)_2$ in dimethylformamide (DMF)/chloroform (1:1), $T=25°C$. b) ESR spectrum of $7(PF_6)_2$ in glassy solution, DMF/$CHCl_3$ (1:1), $T=-160°C$; * not identified. c) Cyclic voltammogram of 7 in DME/TBAP (0.1 M), 20°C, at the glassy carbon electrode versus SCE, $v=50\ mVs^{-1}$.

the two centers occurs independently and in a purely statistical fashion.[9]

The first redox step $7 \rightarrow 7^{2\oplus}$ can also be realized on a preparative scale if the dication, once formed, is precipitated from solution as the hexafluorophosphate, thus preventing further attack by the oxidizing agent (see Scheme 1); O_2 or—preferentially—4-pyridinecarbaldehyde are suitable as oxidants.[6] From the ESR spectra of $7(PF_6)_2$ in fluid solution, hyperfine coupling constants $a(10\ ^1H_{arene})$ and $a(1\ ^{53}Cr)$ can be derived. The multiplicity and the magnitude of these hyperfine splittings, which largely correspond to those of the monoradical cation $8^{\odot\oplus}$, indicate that, for the diradical dication $7^{\ddagger\ddagger}$, the exchange interaction J is much smaller than the hyperfine interactions $a(^1H)$ and $a(^{53}Cr)$. Thus, in fluid solution, the ESR line width for $7^{\ddagger\ddagger}$ is only slightly increased compared with $8^{\odot\ominus}$. This behavior is in accord with the presence of two singly occupied, orthogonal, $Cr(3d_{z^2})$ orbitals centered at a distance of 8.49 Å. A sensitive means of detecting long-range electron-electron/spin-spin interaction is provided by the classical dipole-dipole coupling, which is manifested most clearly in the appearance of a "half-field signal" ($\Delta M_s=2$) in glassy solutions[10] (Fig. 2b). In accordance with the large separation of the two unpaired electrons in $7^{\ddagger\ddagger}$, the intensity of the half-field signal is only ca. 10^{-4} that of the main-field signal.[11] From the latter may be derived—and confirmed by spectral simulation[12]—the zero-field splitting parameters $D=2.7\times10^{-3}\ cm^{-1}$, $E=0.67\times10^{-3}\ cm^{-1}$, which, according to the equation $r=(0.650\ g^2/D)^{1/3}$ [Å],[10b] in turn, give an average interspin distance r and thus a Cr···Cr distance of 9.91 Å. In order to account for the only moderate agreement of this value with the results of the X-ray structure analysis, we are attempting to replace Ni in 7 by other bridging metal atoms.

[13] C atoms bonded to P in metal complexes containing *cis* phosphane ligands can give rise to five-line multiplets in the ^{13}C-NMR spectrum if $^2J(P,P')$ is small. (D. A. Redfield, L. W. Cary, J. H. Nelson, *Inorg. Chem. 14* (1975) 50).

The First Diphosphaallyl System Coordinated to Two Metal Centers**

By *Rolf Appel,* Winfried Schuhn,* and *Martin Nieger*

The complexation of transition-metal complex fragments to compounds in which phosphorus is involved in multiple bonding has been intensively investigated in recent years. Both terminal (η^1) coordination, as found for phosphanes, and side-on (η^2) coordination, as found for alkenes and alkynes, have been observed. Combination of both types of bonding has also been described.[1] The two modes of coordination of phosphaallyl compounds (η^3 and η^1) have so far only been realized with the 1-phosphaallyl system.[2]

We have now obtained the first diphosphaallyl complex in which, in addition to the η^3 coordination of the tricarbonyliron fragment via the lone pairs of the two phosphorus atoms, a further metal atom is bonded. Reaction of the sodium [(diphosphaallyl)ferrate] **1**[3] with nickelocene **2** in THF at room temperature results in cleavage of cyclopentadienylsodium and formation of a black-brown solution of **3**. Chromatographic workup of this solution afforded black crystals of **3**.

Elemental analysis, IR and NMR spectroscopic data (Table 1), and the mass spectrum are in agreement with the structure given. Particularly characteristic is the singlet for the two phosphorus atoms in the ^{31}P-NMR spectrum at high field.

[**] Low-Coordinate Phosphorus Compounds, Part 63.—Part 62: R. Appel, J. Kochta, V. Winkhaus, *Chem. Ber.*, in press.

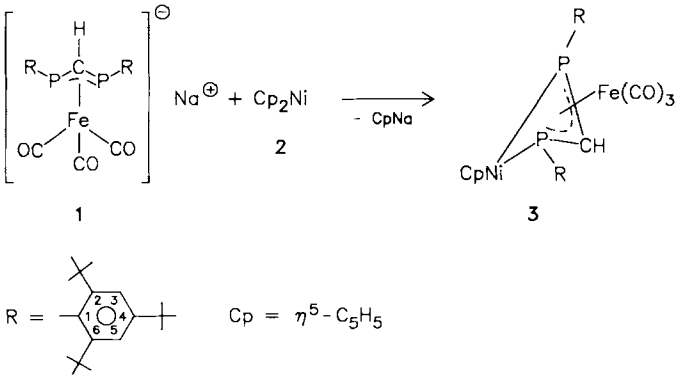

Table 1. Selected NMR and IR spectroscopic data for **3**.

^{31}P-NMR (32.2 MHz, H_3PO_4 ext., C_6D_6): $\delta = -125.8$ (s)

^{1}H-NMR (90 MHz, TMS int., C_6D_6): $\delta = 1.20$ (s, 18 H; 2× *p*-*t*Bu), 1.55 (s, 18 H; 2× *o*-*t*Bu), 1.95 (s, 18 H; 2× *o*-*t*Bu), 5.05 (s, 5 H; C_5H_5), 6.22 (s, 1 H; CH), 7.31 (s, 2 H; 3/5-H), 7.34 (s, 2 H; 3/5-H)

^{13}C{^{1}H}-NMR (50.288 Mhz, CD_2Cl_2): $\delta = 30.66$ (s, *p*-CCH_3), 33.59 (s, *o*-CCH_3), 34.89 (s, *o*-CCH_3), 34.43 (s, *p*-CCH_3), 39.81 (s, *o*-CCH_3), 40.39 (s, *o*-CCH_3), 63.27 (t, $J(CP) = 12.8$ Hz; CH), 91.45 (s; Cp), 122.97 (s, C3/5), 123.32 (t, C3/5), 125.38 (br. s, C1), 150.66 (s, C4), 154.87 (s, C2/6), 159.07 (t, C2/6), 195.0 (br., CO)

IR (KBr): $\tilde{\nu}$(CO) = 1930, 1945, 2010 cm^{-1}

According to an X-ray structure determination (Fig. 1),[4] the C^1 atoms of the aryl moieties and the PCHP framework form a plane, which is typical for phosphaallyl systems.[5] The η^3 coordination to the iron atom is confirmed by the short distance to the allyl C atom (202.5 pm). The lengths of the coordinative bonds to the nickel atom (220 pm) correspond to those in other (phosphane)nickel complexes.[6]

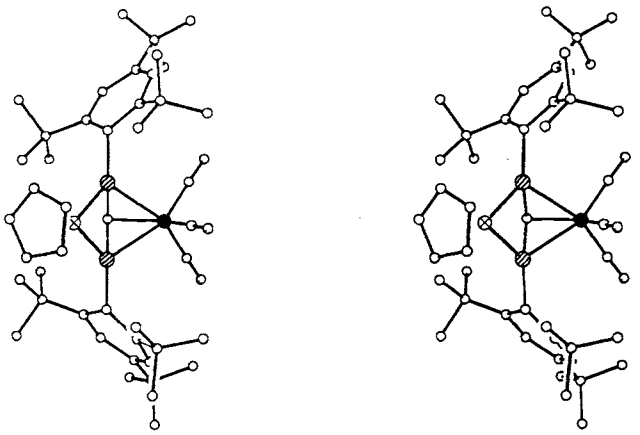

Fig. 1. Stereoprojection of the molecular structure of **3**: ● Fe, ⊗ Ni, ◎ P. Important distances [pm] and angles [°] (standard deviations in parentheses): Fe-P 231.0(2)/230.7(2), Fe-C(allyl) 202.5(7), P-C(allyl) 176.0(7)/176.8(7), Ni-P 219.4(2)/220.1(2); PCP 91.1(3), PFeP 66.1(1), PNiP 69.9(1); dihedral angle PCP/PNiP 35.1.

Experimental Procedure

A solution of **2** (0.40 g, 2.1 mmol) in THF (50 mL) was added to a solution of **1** (1.46 g, 2 mmol) in THF (50 mL) at room temperature over 15 min. The reaction mixture was allowed to stir for 6 h, then concentrated under vacuum and extracted with 150 mL of pentane. After separation of the precipitate, the filtrate was purified by column chromatography on Al_2O_3 (activity I, neutral, eluent toluene). Recrystallization from toluene/pentane (1:1) afforded 1.24 g (75%) of **3**; m.p. = 232 °C.

Weak Intramolecular Bonding Relationships: The Conformation-Determining Attractive Interaction between Gold(I) Centers**

By *Hubert Schmidbaur,* Wilhelm Graf*, and *Gerhard Müller*

Structural analyses[1, 2] and spectroscopic studies[3, 4] on mono- and polynuclear gold(I) compounds have provided a wealth of indirect evidence of an attractive interaction between the d^{10}-configurated gold atoms. This weak bonding relationship occurs perpendicular to the principle axis of the linearly two coordinated structural moieties and leads either to catenated or layered aggregation of the molecules via Au···Au contacts, some less than 3.0 Å in length, or to the intramolecular pairing of the gold atoms with similar equilibrium distances. The 5d^{10}–5d^{10} interaction concerned stems from a mixing of the 6s^2 states,[5] whose energy gap is reduced by relativistic effects.[6, 7] In the case of the neighboring element mercury these effects are already less pronounced, so the phenomenon rarely occurs.[8]

We have searched for convincing evidence for these interactions and for a possibility of measuring their strengths quantitatively. From the numerous structural data available[1] there emerged astonishingly many striking indications of such interactions,[9] yet proof thereof is so far still lacking, even after specially planned tests.[10] A new series of experiments have now furnished the positive results reported here.

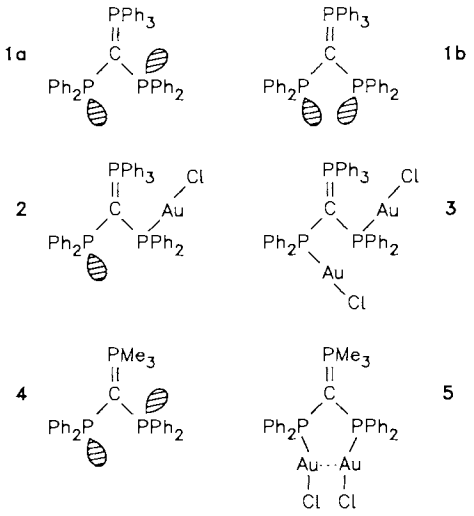
[+] X-ray structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz program), by the Fonds der Chemischen Industrie, and by Hoechst AG and Degussa AG. We thank Prof. Dr. *F. E. Wagner*, Physik-Department der Technischen Universität München, for the ^{197}Au-Mössbauer spectrum, and Herr *J. Riede* for supplying the crystallographic data sets.

Both in solution and in the crystalline state the doubly phosphino-substituted ylide **1** has the conformation given in the formula **1a** with *syn*- and *anti*-orientation, respectively, of the lone pairs.[11] A P-C rotation with establishment of the *syn/syn* conformation **1b** requires an activation energy of 11 kcalmol^{-1}. It was to be expected that after double complexation of **1** with AuCl—assuming sufficiently strong attraction of the gold atoms — the relative stability of these conformations should change in favor of the symmetrical form. Surprisingly, however, the unsymmetrical conformation is retained, both in the 1:1 adduct **2** as well as in the 1:2 adduct **3**.[10] Apparently the ground state conformation of **3** is still too strongly favored due to



the steric hindrance of the seven phenyl groups. Therefore, in order to make the Au···Au attraction recognizable, the steric hindrance had to be reduced. We first showed that the threefold methyl-substituted ylide **4** has the same *syn/anti* conformation as **1a**[12] (Fig. 1). Compound **4** was synthesized by methods, which, in principle, are known.[13-15] The ^{31}P-NMR spectroscopically determined activation energy of the P-C rotation, with $\Delta G^{\neq} = 9.5$ kcal mol^{-1}, is only slightly less than that of **1**.

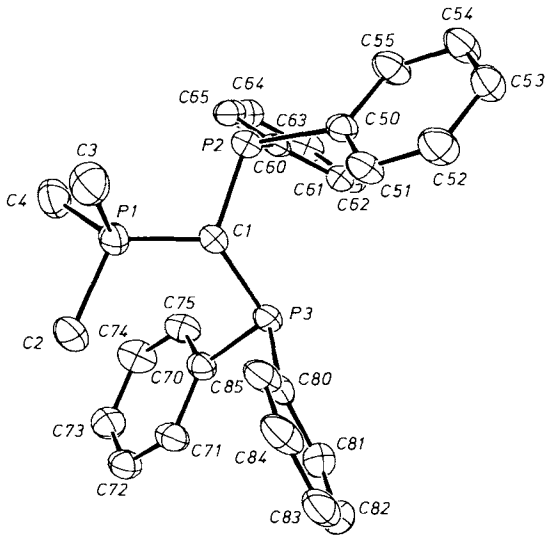


Fig. 1. Crystal structure of **4** (ORTEP, vibrational ellipsoids at the 50% probability level, H atoms omitted). Important bond lengths [Å] and angles [°]: P1-C1 1.725(2), P2-C1 1.792(2), P3-C1 1.777(3); P1-C1-P2 109.8(1), P1-C1-P3 126.4(1), P2-C1-P3 121.6(1).

Reaction of **4** with two equivalents of [(CO)AuCl] readily leads via elimination of CO to the 2:1 complex **5** in high yields. The ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra of **5** already showed that the two Ph_2PAuCl moieties in this molecule are equivalent in solution at low temperatures.[16] The X-ray crystallographic structure analysis[12] and the ^{197}Au-Mössbauer spectra subsequently also proved that the molecule has the hoped for *syn/syn* conformation (Fig. 2) in

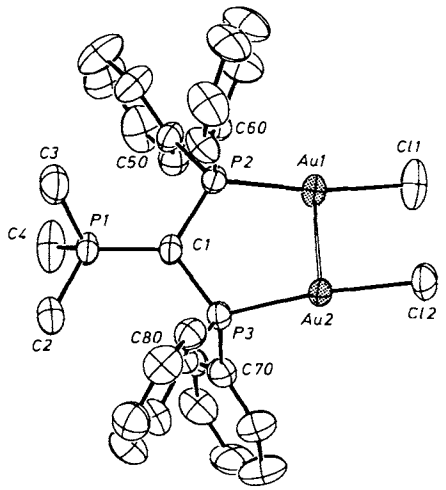

Fig. 2. Crystal structure of **5** (ORTEP, vibrational ellipsoids at the 50% probability level, H atoms omitted). Important bond lengths [Å] and angles [°]: P1-C1 1.742(6), P2-C1 1.772(6), P3-C1 1.777(6), P2-Au1 2.246(2), P3-Au2 2.247(2), Au1-Au2 3.000(1), Au1-Cl1 2.290(2), Au2-Cl2 2.290(2); P1-C1-P2 120.1(3), P1-C1-P3 125.2(4), P2-C1-P3 114.6(3), P2-Au1-Cl1 170.3(1), P3-Au2-Cl2 172.9(1).

the crystalline state, in which the two gold atoms are at a distance of only just over 3.000(1)Å from each other. With this interaction taken into account, the structure corresponds to a twist configurated five-membered ring. One of the two Ph_2P moieties rotates about the P-C bond during the transition from **4** to **5** such that the two gold centers are brought into contact. The mutual attraction of the metal atoms is also manifested in the marked decrease in the angle of the P-Au-Cl axes. Thus, through the reduction of the mutual hindrance of the organic groups on going from **1** to **4**, the Au···Au interaction can effectively function as a conformation-determining force. It should be pointed out that the P-C bond lengths in the free ylide **4** remain practically unchanged during complex formation. In contrast, the changes in the P-C-P angle very nicely reflects the repulsive interactions between organic groups and lone pairs in **4**, while the Au···Au attraction in **5** is manifested by virtue of a distinctly smaller P2-C1-P3 angle. That is, the attachment of the gold atoms to the phosphorus atoms does not lead to profound geometrical changes in the ligand with which the conformational change could be explained. The same agreement of bond distances was also observed in the case of **1a** and **3**,[10] in which no change in conformation occurs.

Interestingly, the ^{31}P-NMR spectrum of **5** is also temperature-dependent. The equivalence of the two PPh_2 groups is maintained over a wide temperature range, but the $J(P^{V}P^{III})$ coupling constant decreases with decreasing temperature. Below -35 °C (in CD_2Cl_2 as solvent) even a broadening of the P^{III} signal and disappearance of its multiplicity takes place. We attribute the decrease in the coupling constant to the different proportions of the possible

conformers according to the dihedral dependence of the spin-spin interaction. The signal-broadening may be due to a further hindering of P-C rotations. A similar situation is observed in the case of **3**.

From the above-mentioned energy barrier it can be estimated that the energy of the Au···Au interaction lies in the order of 7–8 kcal mol^{-1}. It is thus comparable with hydrogen bonding, wherein its conformation-determining influence finds a good parallel.

Experimental

$Me_3P{=}CH{-}PPh_2$: A solution of $Me_3P{=}CH_2$ [17] (4.15 g, 46 mmol) in toluene (50 ml) was treated at 0°C with a solution of Ph_2PCl (5.08 g, 4.23 mmol) in a little toluene. After 16 hours' stirring at 20°C the mixture was filtered and the filter-cake washed with toluene. Concentration of the combined filtrates by evaporation and careful addition of a layer of pentane led to crystallization of the desired product: yield 5.25 g (83%), m.p. 88–89°C; ^{31}P-NMR ([D$_8$]toluene, 25°C): $\delta = 4.4$, -21.3 (AX, $^2J(PP) = 163.3$ Hz).

4: A solution of $Me_3P{=}CH{-}PPh_2$ (820 mg, 2.99 mmol) in toluene (25 mL) was treated at 0°C with a solution of Ph_2PCl (330 mg, 1.49 mmol) in a small amount of the same solvent. Yield after analogous work-up as above: 590 mg (86%); m.p. 152–153°C; ^{31}P-NMR ([D$_8$]toluene, -80°C): $\delta = 16.6$ (dd, $^2J(PP) = 187.7$, 30.4 Hz), -1.9 (dd, $^2J(PP) = 187.7$, 10.5 Hz), -8.2 (dd, $^2J(PP) = 30.4$, 10.5 Hz); +50°C: $\delta = 14.1$ (t), 2.7 (d, $^2J(PP) = 77.1$ Hz); ^{1}H-NMR (C_6D_6, 25°C): $\delta = 0.90$ (d, $J(PH) = 11.4$ Hz, Me), 7.02–7.69 (m, Ph); ^{13}C-NMR ([D$_8$] toluene): $\delta = 17.2$ (dt, $J(PC) = 57.7$, 5.3 Hz, Me), 126.7, 127.9, 133.0 and 144.1 (Ph).

5: A solution of **4** (120 mg, 0.26 mmol) in toluene (25 mL) was treated with a solution of [(CO)AuCl] (136 mg, 0.52 mmol) in a small amount of toluene. Evolution of CO was observed. After 16 hours' stirring at 20°C any small amounts of pale violet precipitate of colloidal gold that separated out were removed by filtration, washed with toluene and the combined filtrates treated with nitrobenzene/pentane. The desired compound **5** crystallized out: yield 200 mg, (74%), m.p. 200–202°C (decomp), soluble in CH_3CN, CH_2Cl_2, nitrobenzene. ^{31}P-NMR (CD_2Cl_2, 0°C): $\delta = 20.9$(d), 6.9 (t, $J(PP) = 17.9$ Hz); -30°C: $\delta = 23.3$ (d), 6.8 (t, $J(PP) = 15.6$ Hz); -60°C: $\delta = 26$ (br.), 6.6 (t, $J(PP) = 12.1$ Hz); ^{13}C-NMR ($C_6D_5NO_2$, 25°C): $\delta = 18.1$ (d, $J(PC) = 58.7$ Hz, Me); ^{1}H-NMR (CD_2Cl_2, 25°C): $\delta = 1.50$ (d, $J(PH)$ 12.2 Hz, Me), 7.42–7.78 (m, Ph); ^{197}Au-Mössbauer spectrum (4 K): $I.S. = 2.6935$, $Q.S. = 6.9274$ mm s^{-1}.

Polyauriomethane Compounds**

By *Hubert Schmidbaur,* Franz Scherbaum, Brigitte Huber,* and *Gerhard Müller*

Polynuclear gold compounds are of great current interest, since, on the one hand, their structures and properties provide a fruitful framework on which to discuss the concepts of intermetallic interactions[1] and, on the other, they should open up improved routes to the thermal, chemical or photochemical deposition of metallic gold, e.g. in electronics and electron microscopy.

Not only gold clusters, in which the metal atoms are directly bonded to each other,[2] but also organogold compounds in which several metal atoms are bonded via a common carbon atom are of special importance. The close proximity of the gold atoms in such compounds should not only lead to clearly recognizable Au···Au bonding relationships but should also facilitate metal nucleation, which is important for the controlled deposition of gold. (The concomitant formation of a gold carbide is not to be expected.) The number of known polyaurioalkanes has increased significantly in recent years,[4–6] yet all attempts to prepare compounds in which more than two gold atoms are fixed to one carbon atom have thus far failed.[6, 7] In contrast, polymercuriomethanes including even tetramercuriomethanes have been relatively well documented.[8]

We were able to show already in 1976 that carbodiphosphoranes are suitable precursors for diauriomethane compounds, since the phosphonium centers facilitate polyauration.[4] In continuation of these studies we have now succeeded in synthesizing numerous further examples of this series of compounds. Not only hexamethylcarbodiphosphorane **1a** but also the dimethyltetraphenyl- and methylpentaphenyl-homologues proved to be exceptionally good donors for gold(I) centers. In contrast to **1a**, these phenylated double ylides only form 1:1 complexes with [MeAuPPh$_3$], namely **3a** and **3b**, respectively; but reaction of **1b** with [BrAuPPh$_3$] once again furnishes a cationic 1:2 complex (**4**).

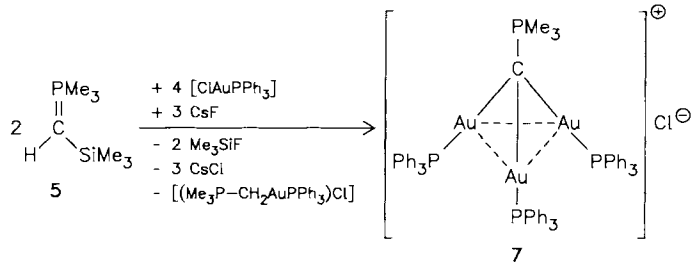
Attempts to synthesize non-ylidic diauriomethanes, on the other hand, have so far met without success. Neither reaction of boryl-substituted alkanes nor the treatment of halogenoalkylated gold complexes of the type $[ClCH_2AuPPh_3]$ with CsAu in the presence of PPh_3 led to satisfactory results.[9]

The desilylation of suitable silylphosphonium salts and their corresponding ylides,[10] however, proved to be favorable methods even for the synthesis of higher auriated products. For example, even a triply auriated cation such as **7** could be obtained by silyl cleavage with cesium fluoride in acetonitrile.[11]

Reaction of trimethylphosphonio(trimethylsilylmethanide) **5**[10] with $[ClAuPPh_3]$ affords, in quantitative yield, the adduct **6**, which corresponds to the homologue already mentioned previously.[12] Treatment of this precursor with CsF in the presence of further $[ClAuPPh_3]$, or the direct reaction of **5** with at least two equivalents of $[ClAuPPh_3]$, lead via several similar but not isolated intermediate stages to the [trimethyl(triauriomethyl)phosphonium] chloride **7**.



$[\{Me_3P{-}CH(SiMe_3)AuPPh_3\}\,Cl]$ **6**

The colorless salt **7** is stable towards air, light and water, and can be crystallized from aqueous acetonitrile as a, likewise, colorless and very stable hemihydrate **7a**. ^1H-, ^{13}C- and ^{31}P-NMR data for the solutions are consistent with the structural equivalence of the three Ph_3PAu moieties and the onium character of the Me_3P group on the common central C-atom. The ^{197}Au-Mössbauer spectrum, with a single, completely symmetrical quadrupole doublet of equal intensity also indicates, within the limits of accuracy, a comparable position of the gold centers in the crystal (Fig. 1). The FD-mass spectrum shows the mass of the cation at *m/z* 1465.

The X-ray structure analysis[13] confirms the proposed structure. The unit cell contains two crystallographically independent formula units, which merely differ in conformational details. The three gold atoms are about equidistant from the common carbon atom. Pairwise they form

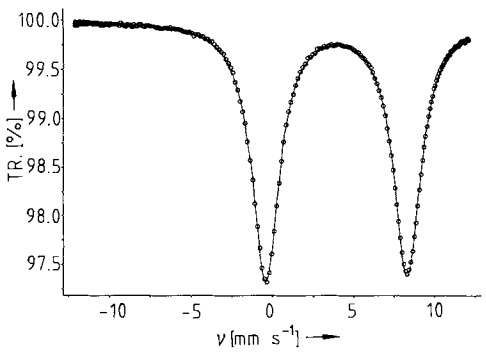


Fig. 1. ^{197}Au-Mössbauer spectrum of the triauriomethane compound **7** (at 4 K). TR = relative transmission, ν = relative rate.

angles with the ylidic C atom which are significantly less than the tetrahedral angle of 109° (Fig. 2); hence the P1–C1–Au angles are greater than 109°. The C1–Au–P axes deviate only slightly from linearity. The P1–C1 distance, with a mean value of 1.72 Å, compares very well with the values found for other metalated phosphonium salts and ylide complexes.[14] The P–Au and Au–C distances are also as would be expected. The chloride ion and the water of crystallization have no discrete contacts to the cations.

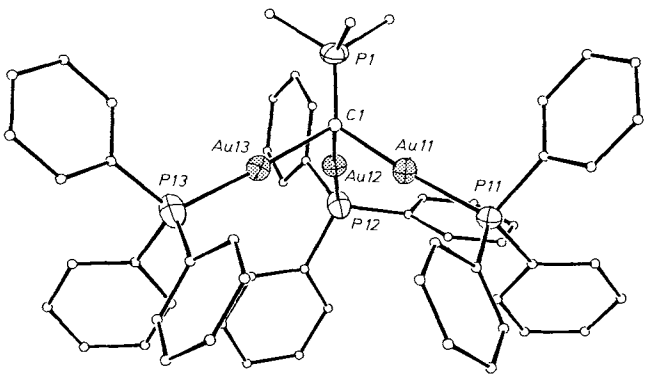

Fig. 2. Structure of one of the two crystallographically independent cations of **7a** ($7 \cdot \frac{1}{2}H_2O$; ORTEP, vibrational ellipsoids at the 50% probability level, C atoms with arbitrary radii). Important bond lengths [Å] and angles [°] for both cations: Au11–Au12 3.117(2)/3.138(2), Au11–Au13 3.233(2)/3.140(2), Au12–Au13 3.266(2)/3.166(2), Au11–C1 1.96(4)/1.95(3), Au12–C1 2.21(3)/2.05(3), Au13–C1 2.13(4)/2.04(4), Au11–P11 2.27(1)/2.29(1), Au12–P12 2.30(1)/2.27(1), Au13–P13 2.28(1)/2.29(1), P1–C1 1.62(4)/1.83(3); Au11–C1–Au12 96(1)/103(1), Au11–C1–Au13 104(2)/104(2), Au12–C1–Au13 97(1)/102(2), P1–C1–Au11 124(2)/116(2), P1–C1–Au12 115(2)/114(2), P1–C1–Au13 115(2)/117(2), C1–Au11–P11 173(1)/178(1), C1–Au12–P12 176(1)/176(1), C1–Au13–P13 175(1)/171(1).

The structure is in the first place remarkable in that all other previously known triaurioelement cations $[X(AuL)_3]^{\oplus}$ with X=O, S, Se oligomerize in such a way via Au···Au contacts that one Au_2-pair is bound other than the remaining third gold atom.[15] Particularly significant, however, is the clearly recognizable approach of the gold atoms in **7** to within an average 3.18 Å, which, despite the repulsion to be expected between the large PPh_3 ligands and the equidirectional formal charge on the metal atoms, leads to the above-mentioned narrowing of the Au–C1–Au angle. It confirms anew the concept of structure- and conformation-determining d^{10}-d^{10} interactions in the heavy late d-block elements.

Experimental

3b: A solution of [MeAuPPh$_3$] (0.92 g, 1.94 mmol) in diethyl ether (10 mL) was treated at −78 °C with a solution of **1c** (1.01 g, 2.10 mmol) in 35 mL of the same solvent and the stirred mixture allowed to warm within 2 h to room temperature. A yellow precipitate separated out, yield 1.15 g (86%), which decomposed on warming. ^{1}H-NMR (CD_2Cl_2, 25 °C): $\delta = -0.1$ (s, MeAu), 1.83 (d, J(PH) = 11.8 Hz, MeP), 7.1–8.1 (m, Ph); ^{31}P{^{1}H}-NMR (CD_2Cl_2, 25 °C): $\delta = 7.5$ and 9.7 (per d, J(PP) = 51.9); ^{13}C-NMR (CD_2Cl_2, 25 °C): $\delta = -3.65$ (s, MeAu), 21.5 (d, J(PC) = 74.2, MeP), two sets of resonances for PPh_2 and PPh_3.

4: A suspension of [BrAuPPh$_3$] (1.93 g, 3.6 mmol) in THF (40 mL) was treated at −78 °C with a solution of **1b** (0.74 g, 1.8 mmol) in 20 mL of THF. The stirred mixture was allowed to warm to room temperature within 3 h and treated with 50 mL of pentane; after filtration, the precipitate was dried under vacuum. Yield 2.6 g (98%), m.p. 180–182 °C (decomp.). ^{1}H-NMR (CD_3OD, 25 °C): $\delta = 2.60$ ($A_3XX'A'_3$, N = 12.6, Me), 7.1–8.6 (m, Ph), ^{31}P{^{1}H}-NMR (CD_3OD, 25 °C): $\delta = 21.19$ and 34.26 (s).

6: The colorless product obtained from equimolar amounts of **5** and [ClAuPPh$_3$] in THF was characterized by the following spectroscopic data: ^{1}H-NMR ($CDCl_3$, 25 °C): $\delta = 0.23$ (s, $SiMe_3$), 1.18 (dd, J(PH) = 18.8 and 8.8 Hz, CHP), 1.84 (d, J(PH) = 12.9, PMe_3), 7.3–7.6 (m, PPh_3); ^{31}P{^{1}H}-NMR ($CDCl_3$, 25 °C): $\delta = 26.68$ (d) and 41.93 (d, per J(PP) = 15.26 Hz); ^{29}Si-NMR ($CDCl_3$, −30 °C): $\delta = 1.72$ (dd, J(PSi) = 5.63 and 3.19); ^{13}C-NMR ($CDCl_3$, 25 °C): $\delta = 3.87$ (dd, J(PC) = 4.42 and 0.96, $SiMe_3$), 16.88 (dd, J(PC) = 57.22 and 1.96 Hz, PMe_3), 23.02 (dd, J(PC) = 68.23 and 36.44, CHP), 129.56 (J = 11.2), 132.09 (J = 2.45) and 133.82 (J = 13.7) for C2 to C4 in PPh_3 (C1 masked).

7/7a: A solution of [ClAuPPh$_3$] (1.16 g, 2.34 mmol) in THF (65 mL) was treated with a solution of **5** (0.19 g, 1.17 mmol) in 15 mL of THF and the mixture allowed to stand for 3.5 h at room temperature. The solvent was then removed and the residue treated with a solution of CsF (0.5 g, 3.3 mmol) in acetonitrile (70 mL); the mixture was then stirred for 23 h at 60–65 °C. After filtration under vacuum, the filtrate was evaporated to dryness and the residue extracted several times with benzene. On evaporation of the combined extracts to dryness a colorless product, **7**, precipitated which after washing with pentane could be crystallized from a mixture of acetonitrile and diethyl ether; yield 0.65 g (54%) **7a**, m.p. 190–192 °C. ^{1}H-NMR (CD_3CN, 25 °C): $\delta = 1.65$ (d, ^2J(PH) = 12.5 Hz, Me), 7.2–7.5 (m, Ph); ^{31}P{H}-NMR (CD_3CN, 25 °C): $\delta = 27.23$ (s, PMe_3), 37.95 (s, PPh_3); ^{13}C-NMR (CD_3CN, 25 °C): $\delta = 25.82$ (d, ^1J(PC) = 58.2 Hz, Me), 132.43 (d, J = 49.39), 134.88 (d, J = 14.18), 130.12 (d, J = 10.76), 132.34 (s) for C1 to C4 of C_6H_5; ^{197}Au-Mössbauer spectrum (4 K): $I.S.$ = 3.926(1) mm s^{-1}; $Q.S.$ = 8.705(2) mm s^{-1}.

Structure of Molecular PNO, Matrix Isolation and ab initio Calculations**

By *Reinhart Ahlrichs, Stephan Schunck,* and *Hansgeorg Schnöckel**

Dedicated to Professor Harald Schäfer on the occasion of his 75th birthday

We have already reported the synthesis and characterization of numerous molecules that are of theoretical interest regarding their bonding, e.g. SiO_2,[1] $SiOCl_2$,[2] and PO_2Cl[3] [Eq. (a)-(c)].

$$SiO + O \longrightarrow O{=}Si{=}O \quad (a)$$

$$SiO + Cl_2 \longrightarrow O{=}SiCl_2 \quad (b)$$

$$O{=}PCl + O \longrightarrow O_2P{-}Cl \quad (c)$$

PO_2Cl belongs to a type of compounds that has recently attracted increasing interest.[4] We now wanted to clarify whether P^V can also occur in compounds with coordination number two. By reaction of PN[5] and O_3 under matrix conditions it should be possible to prepare $N{\equiv}P^{\oplus}{-}O^{\ominus}$,[6] which is analogous to N_2O and isoelectronic with SiO_2. Figure 1 shows sections of the IR spectra which were recorded after cocondensation of PN and O_3[3] with an excess of Ar, and after subsequent photolysis.[7,8] After the photolysis, a series of low intensity absorptions is observed, together with a medium-strength band at 1755 cm^{-1} (1727 cm^{-1}).[9] This is not to be assigned to a PN vibration (e.g. in NPO),[10] but to an NO vibration. Numerous experiments carried out under different reaction conditions showed that only the band at 865 cm^{-1} (844 cm^{-1})[9] is changed simultaneously with that at 1755 cm^{-1}. On the basis of frequency calculations (GF method[13]) these

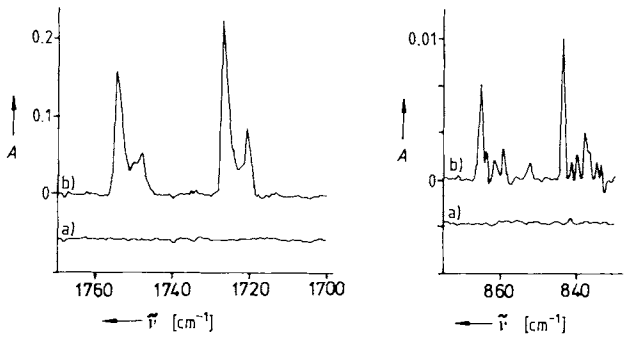

Fig. 1. Sections of the IR spectra of PN + $^{16}O_2/^{18}O_2$ (1:1) in an Ar matrix; a) before and b) after the photolysis (310 nm, 20 min). A = absorption.

Table 1. Measured and calculated frequencies of the PN and NO vibrations of PNO as wave numbers $\tilde{\nu}$ [cm^{-1}].

	$\tilde{\nu}$(PN) measured	$\tilde{\nu}$(NO) measured	$\tilde{\nu}$(PN) [12] calculated [11]	$\tilde{\nu}$(NO) calculated [11]
PN^{16}O	865.2	1754.7	865.2	1754.7
PN^{18}O	843.5	1727.2	842.5	1727.1

bands can only be assigned to a molecule P≡N$^{\oplus}$–O$^{\ominus}$ (Table 1). The force constants determined by these calculations are consistent with expectation (Scheme 1).

	P≡N$^{\oplus}$–O$^{\ominus}$		P≡N	N≡N$^{\oplus}$–O$^{\ominus}$		N≡N
f(XY)	7.95	11.5	9.9[11]	17.7	11.4[13]	22.4[11]
f(XY/YZ)	0.8			1.2		

Scheme 1. Stretching force constants f(X/Y) and interaction force constants f(XY/YZ) [mdyn Å^{-1}].

In connection with these experimental investigations we have carried out ab initio SCF calculations for some molecules XYZ (X,Y = P,N; Z = O,S).[14] Here also, the isomer PNO proved to be more stable than NPO (ΔE = 28 kJ mol^{-1}). The same trend is observed for the isomeric pair PNS/NPS. The most important results of these calculations are collected in Table 2. In addition, CI calculations by the CPF method using extended basis sets were carried out for the molecules PNO and NPO.[15] Once again PNO proved to be more stable than NPO (ΔE = 22 kJ mol^{-1}). Thus, all the quantum chemical calculations confirm the experimental result: in its highest oxidation state P avoids twofold coordination. The calculated structural data (bond lengths, charge and SEN,[16] Table 2) confirm the data obtained from force constants: in PNO the PN bond is weaker than in PN;[18] the NO bond is comparable to that in N_2O.

Summarizing, it can be said that the structure of PNO contradicts "chemical intuition," according to which the most electropositive atom should assume the central position in a triatomic molecule (e.g. O=N–F, N≡S–F),[19] since the molecule acquires an additional ionic stabilization in this way (cf. the charges q obtained from the population analysis in Table 2 for PNO and NPO).

Comprehensive quantum chemical calculations, on the other hand, are consistent with the experimental findings.[20] Apparently the absence of a possibility for ionic stabilization in PNO is overcompensated by other effects, e.g. the formation of an NO bond which is stronger than the PO bond in NPO.[21]

[6] This formulation is the same as the usual description for $NO_2^{\oplus}$ (N≡N$^{\oplus}$–O$^{\ominus}$) and was therefore chosen. The results described in this communication, however, show that the true bonding relationships are not reproduced with this formula or with the formula $^{\ominus}$P=N$^{\oplus}$=O.
[7] An isotopomeric mixture of O_3, formed from a 1:1 mixture of $^{16}O_2$ and $^{18}O_2$ in a high-frequency discharge, was used. For the photolysis of O_3 the mixture was irradiated with a high pressure Hg lamp for 20 min using a 310 nm filter (interfering thermal radiation was excluded by means of an H_2O filter).
[8] The spectra were recorded with an FT-IR spectrometer (Bruker IFS 113v).
[9] The frequency quoted in brackets refers to the isotopomer with ^{18}O.
[10] In the PN molecule $\tilde{\nu}_e$ = 1337 cm^{-1}. As model calculations show, in NPO the frequency should be shifted up to maximally 1500 cm^{-1} by coupling with the PO vibration.

[a] [14]; the following basis sets were used: P(11,7,1) [6,4,1], η(d) = 0.4; N(9,5) [5,3,1], η(d) = 0.8; O(9,5,1) [5,3,1], η(d) = 1.0. [b] [16] [c] The sequence in which the elements are described reflects the structure of the molecules. [d] [17]. [e] Calculated energy −395.121777 a.u.; d(PN) (calc.) = 146.2 pm; d(PN) (exp.) = 149 pm. [f] d(NN) = 109 pm.

[12] The calculated isotopic shift for the PN vibration is about 4% greater than the measured shift. We attribute this to an interaction between the fundamental of the stretching vibration and the overtone of the unobserved deformation vibration (Fermi resonance). Since the deformation vibration should absorb at 450 cm^{-1}, on the basis of a comparison of the corresponding frequencies of COS, CO_2 and N_2O (cf. [21]), an interaction of its overtone with the PN stretching vibration is conceivable. Such an effect is frequently observed (see, e.g., Refs. [2, 21]). For the PN vibration this would lead to an experimentally determined isotopic shift smaller than the calculated one. This is observed.

[14] The "Karlsruhe version" of the Columbus program systems was used: R. Ahlrichs, H. J. Böhm, C. Ehrhardt, P. Scharf, H. Schiffer, H. Lischka, M. Schindler, *J. Comput. Chem. 6* (1985) 200.

[15] R. Ahlrichs, P. Scharf, C. Ehrhardt, *J. Chem. Phys. 82* (1985) 890; with a larger basis set [P(11,7,2,1) [6,4,2,1], N, O (9,5,2,1) [5,3,2,1] and η(d,d,f) 0.7, 0.23, 0.5 (P); 1.78, 0.49, 1.085 (N); 2.47, 0.68, 1.5 (O)] the results listed in Table 3 were obtained. From these results the following frequencies were calculated for the XY and YZ vibrations: NPO 1604/1150 cm^{-1}; PNO 1922/945 cm^{-1}. The frequencies ca. 10% higher than the experimental values are consistent with expectation. They likewise confirm the greater stability of the isomer PNO.

Table 3. Results of CI calculations for NPO and PNO.

XYZ	d(XY) [pm]	d(YZ) [pm]	E(CPF) [a.u.]	f(XY) [mdyn Å^{-1}]	f(YZ) [mdyn Å^{-1}]	f(XY/YZ) [mdyn Å^{-1}]
NPO	149.8	147.3	−470.565219	12.1	11.1	0.2
PNO	152.3	119.4	−470.573433	10.4	13.7	1.2

[16] Here, the electronic structure is elucidated by a population analysis on the basis of occupation numbers: SEN (shared electron number) and charge on the relevant atom (q). For further detailed literature see, e.g., ref. [3]; for an introduction to this problem see R. Ahlrichs, C. Ehrhardt, *Chem. Unserer Zeit 19* (1985) 12. The SEN is regarded as a reliable measure of the strength of a covalent bond. To demonstrate this some typical values are: strong σ-bonds (CC, CH) 1.4; double bonds (CC) 2.2; triple bonds (CC, NN) ca. 3; lower SEN values are found for polar (NaF 0.3) and weak bonds (F_2 0.6).

[17] The experimentally determined structure is based on the calculations for N_2O: d(NN) = 112.6, d(NO) = 118.6 pm: A. E. Douglas, C. K. Moller, *J. Chem. Phys. 22* (1954) 275.

[18] a) The energy calculated for PN at the SCF level is −395.121777 a.u.; d(PN)(calc.) = 146.2, d(PN)(exp.) = 149 pm; b) the following PN distances are obtained for NPF_2 and $NPCl_2$ at the SCF level (singlet state, C_{2v} symmetry): in NPF_2 146.2, in $NPCl_2$ 147.6 pm: H. Plitt, S. Schunk, H. Schnöckel, unpublished.

[19] See, e.g., R. Ahlrichs, R. Becherer, M. Binnewies, H. Borrmann, M. Lakenbrink, S. Schunck, H. Schnöckel, *J. Am. Chem. Soc. 108* (1986) 7905.

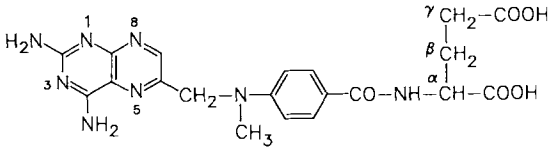
[20] On critical assessment of the methods of calculation available today, calculations which afforded comparable energies for PNO and NPO would also support our experimental findings.

[21] Similar unusual bonding situations are present in SNO, which could be prepared in an Ar matrix. M. Hawkins, A. J. Downs, *J. Phys. Chem. 88* (1984) 3042.

Evidence for a Folded Conformation of Methotrexate in Solution

By *Peter Faupel* and *Volker Buss**

Methotrexate (MTX) is a powerful antimetabolite: by complexing with dihydrofolate reductase (DHFR), it inhibits the reduction of dihydrofolate to tetrahydrofolate, an essential step in the biosynthesis of nucleotide bases. While the binding of this widely used chemotherapeutic agent to DHFR of *E. coli* has been investigated in detail using high resolution X-ray data,[1] the crystal structure of MTX itself was determined only recently:[2] the molecule is twisted through an angle of almost 90° at the CH_2 group between the rings.



MTX

The question as to what the conformation in solution might be has not yet been settled. We now present evidence, from low-temperature UV and CD spectroscopic studies in nonpolar solvents, to show that under these conditions the molecule adopts a folded conformation stabilized by intramolecular hydrogen-bonding.

The UV-spectrum of MTX in THF/CH_2Cl_2 (10:1) exhibits a pronounced temperature-dependence (Fig. 1, left): on cooling to −130°C, the main absorption band at 290 nm is red-shifted by about 13 nm while the bands at 265 and 380 nm disappear, making place for two new bands at 253 and 350 nm, respectively. These changes strikingly resemble the spectral changes observed for MTX in aqueous medium with decreasing pH-values, the low-temperature spectrum in THF/CH_2Cl_2 corresponding to the acidic form in water (Fig. 1, right).[3] There are several isosbestic points in the spectra, and we note a distinct hypochromic effect in going from −40 to −60°C.

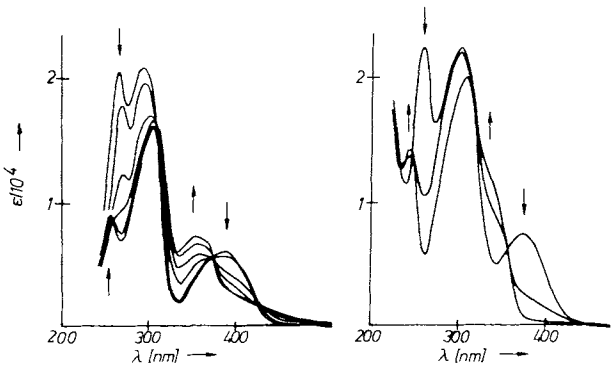


Fig. 1. Left: Temperature dependence of UV-spectra of MTX in THF/CH_2Cl_2 (10:1), $c = 7.7 \times 10^{-5}$ mol L^{-1}. Curves shown correspond to measurements at +10, −40, −60, −80, −110, and −130°C, respectively. Arrows indicate spectral changes with decreasing temperature; they are at 254, 265, 350, and 383 nm. Right: pH-dependence of UV-spectrum of MTX in water. Curves shown correspond to pH-values of, respectively, 1 and 5.6 ($c = 8.0 \times 10^{-5}$ mol L^{-1}) and > 10 ($c = 5.0 \times 10^{-5}$ mol L^{-1}). Arrows indicate spectral changes with increasing acidity; they are at 244, 259, 335, and 373 nm.

The CD-spectra obtained under identical conditions reflect the spectral changes observed in the UV (Fig. 2, left). At room temperature, there are three broad unstructured bands of low intensities at 260, 290, and 350 nm. The low-temperature spectra show three intense bands developing, with alternating signs and maxima at 280, 307, and 345 nm.

Within the limits set by the solubility of MTX and experimental accuracy, these spectra are independent of concentration (Fig. 2, right). This suggests that the CD absorptions are not caused by intermolecular interactions such as dimerization or stacking processes, but result from a pre-

ferred molecular conformation evolving at low temperature.

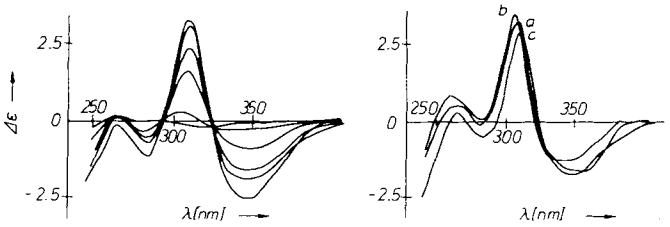

Fig. 2. CD-spectra of MTX in THF/CH_2Cl_2 (10:1), corrected for volume contraction. Left: Temperature dependence. Curves shown correspond to measurements at +10, −40, −60, −80, −100, and −115°C, $c = 8.0 \times 10^{-5}$ mol L^{-1}. Right: Concentration dependence; $c = 10 \times 10^{-5}$ (a), 8×10^{-5} (b), and 4.5×10^{-5} mol/L (c), $T = -120$°C.

Both the UV and CD data can be interpreted by assuming a folded MTX conformation characterized by close contact of the pteridine and benzene chromophores (Fig. 3). Evidence for electronic interaction between these two groups has led to the proposal of a similarly folded conformation of folic acid in water at high dilution.[4]

The folded MTX conformation is held together by a hydrogen-bond most probably involving the γ-carboxyl group of the glutamic acid and N1 of the pteridine moiety. Protonation of this site has been suggested[5] to account for the observed spectral shifts of 2,4-diaminopteridine in acid medium. In agreement with these observations, we calculate[6] for the protonated form a 30-nm blue-shift of the 380-nm absorption and a 20-nm red-shift of the 265-nm band. This latter band presumably appears in the low-temperature spectra as a shoulder of the strong 300-nm absorption, which is essentially an excitation of the *p*-aminobenzoic acid chromophore. Also, according to STO-3G calculations[7] N1 is favored relative to the other ring nitrogens with respect to protonation, though steric constraints could easily overcome any differences in basicity.

In addition to any chirality originating from non-planar conformations, MTX has a constitutional source of chirality in the asymmetric α-carbon atom of the glutamic acid moiety which obviously can differentiate between otherwise enantiomeric conformations. The reason why the absolute conformation depicted in Figure 3 should be preferred over the (distinguishable) inverted form is easily seen: with the hydrogen atom of the asymmetric center pointing towards the observer, the α-carboxyl group points down towards the C2-amino group, in perfect orientation to make a second hydrogen bond.

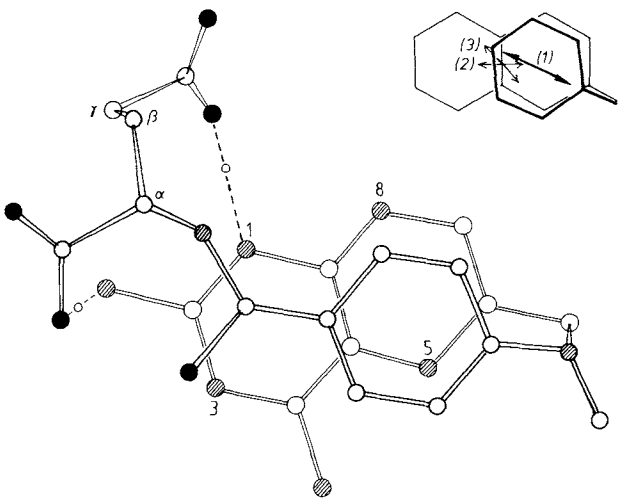

Fig. 3. Proposed structure of folded MTX conformation in solution. Open circles represent carbon atoms, hatched circles nitrogen atoms and black circles oxygen atoms. Small figure, top right: transition moments of the two chromophoric systems as obtained from CNDO/S calculations.

The signs of the three prominent CD bands can be rationalized on the basis of the proposed structure (Fig. 3, top right). According to our calculations, the direction of the 300-nm band transition moment (1) lies inside the acute angle formed by the transitions at 330 nm (2) and 280 nm (3). This results in positive rotational strengths for both the lower and higher energy absorptions from the interaction with the 300-nm band, while for the latter, negative rotational strengths are to be expected, in agreement with the experimental CD spectrum.—Quantitative calculations are in progress to test the viability of the proposed structure.

Preparation of 2,3,4-Tris(η^5-cyclopentadienyl)-1,5-diphenyl-1-phospha-2,3,4-tricobaltapentaborane(5); Phenyl Group Migration from Phosphorus to Boron**

By *Jiang Feilong, Thomas P. Fehlner,** and *Arnold L. Rheingold**

Only a few metal-rich metallaboranes (M/B > 1, direct metal boron interactions) are known[1]. We have shown that the reaction of [CpCoLL'] with $BH_3 \cdot THF$ is a source of metal-rich cobaltaboranes[2]. For low $BH_3 \cdot THF$/[CpCoLL'] ratios and $L = L' = PPh_3$, PPh_x (x = 1,2) fragments are incorporated into the clusters[3]. We have now demonstrated that C_6H_6 is a product of the preparative reaction and is formed, presumably, by the reaction of phenyl groups with hydrides[4, 5]. Here we report the formation of a metal-rich phosphacobaltaborane **1** which contains a BPh fragment in which the phenyl group on boron is also derived from the PPh_3 ligand of $[CpCo(PPh_3)_2]$. Hence, in addition to being eliminated as C_6H_6, the Ph group on PPh_3 can migrate from phosphorus to boron[6]. This behavior constitutes another manifesta-

tion of the "metallic" character of boron when found in a cluster environment.[7]

$[Cp_3CoPBPh_3]\cdot 0.5\,C_6H_6$ **1**

The new compound **1** was characterized by an X-ray structure analysis (Fig. 1)[8]. The structure exhibits a metal-

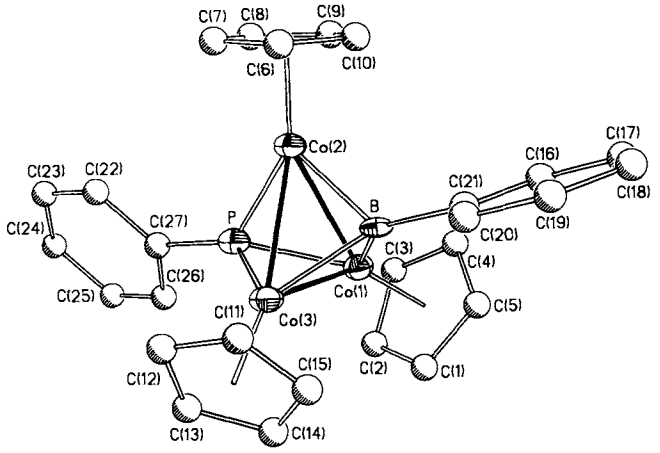

Fig. 1. The molecular structure of **1**. The solvent molecule and hydrogen atoms have been omitted for clarity. Important bond distances [Å] and angles [0]: Co(1)-Co(2) 2.553(1), Co(1)-Co(3) 2.473(2), Co(2)-Co(3) 2.561(1), P-Co(1) 2.089(8), P-Co(2) 2.082(2), P-Co(3) 2.100(2), B-Co(1) 2.065(8), B-Co(2) 2.018(8), B-Co(3) 2.031(9); Co(1)-Co(2)-Co(3) 57.81(7), Co(2)-Co(3)-Co(1) 60.87(7), Co(3)-Co(1)-Co(2) 61.21(8).

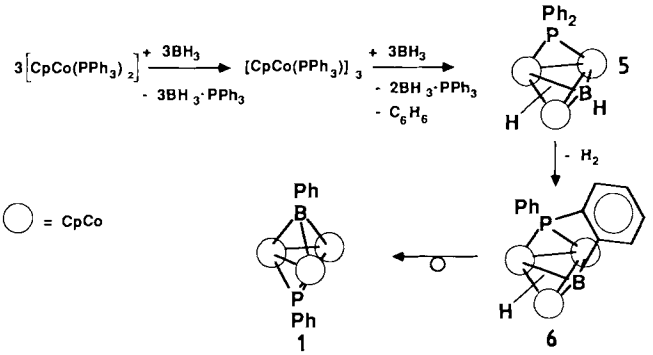
metal bonded, equilateral triangular array of Co atoms each bound to a η^5-C_5H_5 ligand and capped on one side by a μ_3-PPh fragment and on the other by a μ_3-BPh fragment. The metal-metal and metal-main group element distances lie within the ranges typical for clusters. However, note that the average CoB distance is only 0.05 Å shorter than the average CoP distance despite the fact that the difference in covalent radii is 0.24 Å. The three Co atoms, the P atom and the B atom of **1** form a trigonal bipyramidal cluster core which is isoelectronic with the cluster found in **2**[9], analogous to the cluster in **3**[10] and isolobal with the *closo* carbaborane **4**[11]. Comparison of the cobalt com-

$[Cp_3Co_3C_2R_2]$ **2** $[Cp_3Rh_3C_2R_2]$ **3** $C_2B_3H_5$ **4**

pounds **1** and **2** reveals a dependence of the structural parameters on the main group element. The average Co-Co distance in **1** is 0.15 Å longer than that in **2** and the difference in the average Co-B distance in **1** and the Co-C distance in **2** is larger than expected (0.13 Å). Thus, even though identical in terms of electron counting rules[12], these structural differences suggest significant differences in the bonding, perhaps associated with the fact that **1** has a polar character relative to **2** (i.e. BR, CR, and PR function as 2-, 3-, and 4-electron donors, respectively, in the cluster).

The NMR spectra of **1** in solution are consistent with the solid state structure[13]. Although main group elements capping transition metal triangles are very well known in general, there are only two well characterized examples involving boron without B-H-M bridge interactions[14]. Of particular note is the downfield chemical shift of the μ_3-boron atom in the ^{11}B-NMR spectrum. Extreme downfield shifts appear to be characteristic of BR fragments directly bound (no B-H-M bridges) to three or more transition metals.



Based on literature precedents, a reasonable mechanism for the production of **1** can be postulated. The trimerization of $[CpCo(CO)_2]$ is known[15]; in our system, $[CpCo(PPh_3))]_3$ is a likely intermediate in the formation of trinuclear clusters. Loss of PPh_3 (as $BH_3\cdot PPh_3$) and C_6H_6 from the Co_3 species and boronation lead to the critical intermediate **5**[16], which eliminates H_2 and yields a dehydrobenzene intermediate **6**[17] by orthocycloboronation. **6** affords directly the observed product. Orthocycloboronation is well documented[18]. But this is the first example of the complete transfer of a phenyl substituent from phosphorus to boron. We have no evidence for this mechanism but it serves to show that a chemically reasonable route to the unusual and unexpected product **1** exists.

Experimental Procedure

A solution of 2.8 mmol of $[CpCo(PPh_3)_2]$ in 20mL of toluene was treated with 5.5 mL (5.5 mmol) of 1 M BH_3·THF at −78°C. After warming to 25°C, the mixture was stirred for 24 h. According to the ^{11}B-NMR spectrum the major boron-containing product (besides $BH_3\cdot PPh_3$) is **1**. After concentration of the solution and partial precipitation of $BH_3\cdot PPh_3$, chromatography on silica gel (hexane/toluene) yielded a dark brown band ($R_f = 0.3$, hexane/toluene 1:1) which produced brown crystals in 7% yield (based on cobalt). The compound decomposes slowly in solution but is reasonably stable in the solid state. Mass spectrum: M^+ 568 (parent ion envelope for $C_{27}H_{25}BPCo_3$), *m/z* 567:568:569:570 = 0.15:0.63:0.19:0.03(obsd); 0.147: 0.639: 0.187: 0.027(calcd).

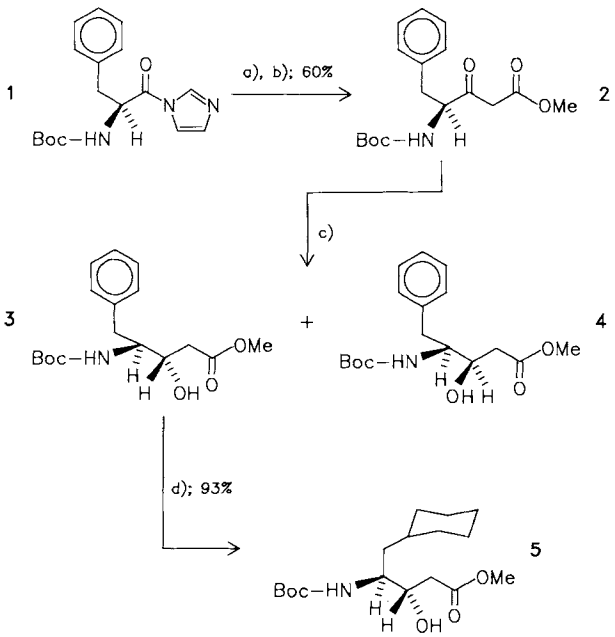
Reduction with Yeast Cells, the Key Step of an Efficient Synthesis of (3*S*, 4*S*)-4-Amino-3-hydroxypentanoic Acids**

By *Peter Raddatz, Hans-Eckart Radunz,* Günter Schneider,* and *Harry Schwartz**

Pepstatin,[1] a pentapeptide first isolated by *H. Umezawa,* contains the unusual γ-amino acid statine ((3*S*, 4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid). Statine and its analogues are central building blocks for many highly active, specific aspartyl protease inhibitors, including even renin inhibitors,[2] which are of interest as hypotensive drugs. Kinetic studies have shown that the hydroxy group in statines must be *S*-configurated, but the carbon chain at C-4 can be chemically modified.[3]

The current importance of such drugs warranted the search for a synthetic strategy enabling a flexible, diastereoselective synthesis of statine from readily accessible starting materials. At best, the methods of synthesis published so far[4] only partly fulfill these requirements, if at all.

In principle, in the case of the statine synthesis presented here any α-amino acid can be used as starting compound. This is allowed to react with a malonic acid building block, and the resulting γ-amino-β-ketoester can be diastereoselectively reduced to the β-hydroxy derivative with certain yeasts. The strategy will be described here for the synthesis of (3*S*, 4*S*)-*N*-Boc-4-amino-3-hydroxy-5-cyclohexylpentanoic acid methyl ester **5** (Scheme 1).



Scheme 1. Synthesis of **5**. a) $HO_2C-CH_2-CO_2Me$, *i*PrMgBr; b) 15% HCl; c) reduction with yeast; d) Rh/Al_2O_3. Boc = *tert*-butoxycarbonyl. For physical and spectroscopic data of **2**–**5** see Table 1.

The crucial step is the stereoselective reduction of **2**, which is formed from *N*-Boc-L-phenylalanine-imidazolide **1** and the magnesium enolate of the malonic acid monomethyl ester,[4b] to the alcohol **3** with *S* configuration at C-3. The catalytic hydrogenation of **2** with Raney nickel affords a 1:1 mixture of the diastereomeric alcohols **3** and **4**. Neither of the diastereomers is preferentially formed, even with complex, sterically bulky hydrides. In order to alter the conditions in favor of one of the diastereomers, reduction of the β-ketoester with bakers' yeast was attempted.[5] The attempts with commercially available yeast (*Saccharomyces cerevisiae*) merely resulted in incomplete reaction (30–50%), but nevertheless the desired 3*S*, 4*S*-diastereomer **3** was formed (*de* = 60%).

Table 1. Selected physical and spectroscopic data of the compounds **2**–**5** [a]. $[\alpha]_D^{20}$ values with $c = 0.68$ to 1.26 g/100 mL methanol. 500-MHz ^1H-NMR spectra ([D$_6$]DMSO, coupling constants *J* in Hz).

2: m.p. 91°C (petroleum ether/methyl *tert*-butyl ether): $[\alpha]_D^{20} = -64.8°$; ^1H-NMR: $\delta = 1.35$ (s, 9 H; $C(CH_3)_3$), 2.73 (dd, $J = 10.2$, 14, 1 H; CH_2Ph), 3.06 (dd, $J = 4.6$, 14, 1 H; CH_2Ph), 3.26 (br. s, 2 H; CH_2CO), 3.65 (s, 3 H; OCH_3), 4.25 (m, 1 H; CHN), 6.85 (br. m, 1 H, NH), 7.25 (m, 5 H; C_6H_5)

3: m.p. 99°C (diisopropyl ether); $[\alpha]_D^{20} = -35.4°$; ^1H-NMR: $\delta = 1.32$ (s, 9 H; $C(CH_3)_3$), 2.30 (dd, $J = 9.2$, 15, 1 H; CH_2CO), 2.5 (dd, $J = 4$, 15, 1 H; CH_2CO), 2.60 (dd, $J = 9.5$, 13, 1 H; CH_2Ph), 2.84 (dd, $J = 5.3$, 13, 1 H; CH_2Ph), 3.55 (s, 3 H; OCH_3), 3.68 (m, 1 H; CHN), 3.9 (m, 1 H; C*H*OH), 4.9 (br. d, $J = 7$, 1 H; OH), 6.48 (br. d, $J = 7.5$, 1 H; NH), 7.23 (m, 5 H; C_6H_5)

4: m.p. 139°C (methyl *tert*-butyl ether); $[\alpha]_D^{20} = -17.1°$; ^1H-NMR: $\delta = 1.25$ (s, 9 H; $C(CH_3)_3$), 2.30 (dd, $J = 9.3$, 15, 1 H; CH_2CO), 2.55 (m, 2 H; CH_2CO, CH_2Ph), 3.05 (dd, $J = 3.5$, 14, 1 H; CH_2Ph), 3.52 (m, 1 H; CHN), 3.6 (s, 3 H; OCH_3), 3.80 (m, 1 H; C*H*OH), 5.07 (br. d, $J = 7$, 1 H; OH), 6.61 (br. d, $J = 8$, 1 H; NH), 7.22 (m, 5 H; C_6H_5)

5: m.p. 69°C (petroleum ether); $[\alpha]_D^{20} = -36.5°$; ^1H-NMR: $\delta = 0.7$–1.3 (m, 8 H), 1.42 (s, 9 H; $C(CH_3)_3$), 1.5–1.85 (m, 5 H), 2.25 (dd, $J = 9.2$, 15, 1 H; CH_2CO), 2.45 (dd, $J = 4$, 15, 1 H; CH_2CO), 3.55 (m, 1 H; CHN), 3.60 (s, 3 H; OCH_3), 3.85 (m, 1 H; C*H*OH), 4.75 (br. d, $J = 7$, 1 H; OH), 6.25 (d, $J = 7.5$, 1 H; NH)

[a] All the compounds gave correct elemental analyses.

[**] We thank Dr. *M. Heinrich* for caryying out the fermentation and Herr *O. Kaser* for valuable assistance with the experiments.

Since baker's yeast behaves differently depending on its origin and strain we tried to improve the stereoselectivity by using pure cultures of selected yeast strains of the genera *Kloeckera*, *Hansenula*, *Candida*, and *Torulopsis*.[6] Only five of 74 yeast strains tested reduced the β-ketoester **2** completely. Four strains, including *Hansenula anomala*, formed the 3*S*, 4*S*-diastereomer **3** with *de* = 92%, whereas predominantly the 3*R*, 4*S*-diastereomer **4** was formed (90% *de*) by the yeast *Candida boidinii*. Further optimization attempts with resting cells of the yeast *Hansenula anomala* during fermentation of glucose revealed that reduction of the β-ketoester **2** proceeds almost quantitatively if the glucose concentration is 10%, the yeast concentration 1%, and the substrate concentration 0.1%; this holds true for sample volumes of 100 mL to 1000 L. Irrespective of whether intact cells, cells immobilized in polyacrylamide gel[7] or cell-free crude extracts of the strain *Hansenula anomala* were used, **2** was reduced almost completely (90–95% conversion) on a laboratory scale (100 mg to 1 g). The procedure optimized for small amounts was then extended to larger substrate amounts (50 g to 1000 g). On using 50 g of **2**, 96% was reduced after 48 hours' incubation; the ratio of the alcohols **3** and **4** was 23:1. After work-up and recrystallization from diisopropyl ether we obtained 35 g of **3** with 98% *de*. Subsequent recrystallization from cyclohexane increased the diastereomeric excess to >99%.

Experimental

For the production of cell masses, yeasts of the genus *Hansenula* were incubated under sterile conditions in 100-L fermenters with continuous aeration at 28 °C in a medium consisting of 2% glucose, 0.3% malt extract, 0.3% yeast extract and 0.5% peptone from casein. After reaching the stationary growth phase the cells were separated from the medium and washed with cold 0.9% NaCl solution. The reduction was carried out in a 100-L fermenter at 28 °C. 500 g of yeast (wet weight) was suspended in 50 L of a 10% glucose solution. After commencement of fermentation, a solution of 50 g of β-ketoester **2** in 500 mL of ethanol was added and the mixture incubated for 48 h with continuous stirring (200 rpm) and gentle aeration.

For the extraction, the yeast suspension was treated twice with dichloromethane (a total of 35 L) and stirred for one hour. The separated organic phase was filtered over diatomaceous earth and the filtrate dried over Na_2SO_4. After removal of solvent the residue was recrystallized from 500 mL of diisopropyl ether.

The enantiomeric purity was determined HPL chromatographically and NMR spectroscopically via the MTPA amides[8] of **3** (MTPA = α-methoxy-α-trifluoromethylphenylacetic acid) and gave >98% *ee*. Subsequent hydrogenation of the benzene ring of **3** with Rh on Al_2O_3 in methanol afforded **5** in 93% yield.[9]

Formation of Dioxirane from Carbonyl Oxide**

By *Dieter Cremer,* Thomas Schmidt, Jürgen Gauss,* and *T. P. Radhakrishnan*

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

Dioxirane **1** is an effective oxygen carrier for regio- and stereoselective epoxidations.[1] Spectroscopic investigations have provided evidence that **1** can be formed by thermal or photochemical isomerization of carbonyl oxide **2**, e.g. in the ozonolysis[2, 3] or the oxidation of carbenes.[4] According to ab initio calculations, the activation energy for the isomerization in the gas phase is 22.8 kcal mol^{-1}.[5] The transition state **3** (Fig. 1) of this reaction resembles **2** more closely than it does **1**, as is clear from the calculated geometries, in particular the large distance between C and the terminal O atom in **3** (Fig. 1).

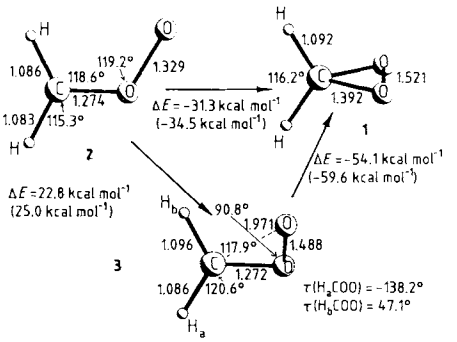

Fig. 1. Isomerization of carbonyl oxide **1** to dioxirane **2**. MP4(SDQ)/6-31G* energies and geometries for **1**, **2**, and **3**; distances in Å. The values in brackets are MP2/6-31G* results [5].

Further, the calculations show that the isomerization is not initiated by rotation about the CO bond but by pyramidalization at the central O atom. Negative charge is shifted from the C atom to the neighboring O atom, resulting in a weakening of the OO bonding due to enhanced charge repulsion (Fig. 1). The CO double-bond character, however, is essentially retained, since back-bonding between the orbital of a lone pair on the O atom and the depopulated 2pπ orbital on the C atom is possible (see **3a**).[6]

3a 3b

Accordingly, a substituent X with π-donor properties should stabilize the transition state (see **3b**), while π-acceptors should have a slight or noticeable destabilizing influence. These predictions are confirmed in the case of the monofluorocarbonyl oxides **4a** and **4b** (Fig. 2), whose isomerization to monofluorodioxirane **6** via **5a** and **5b** requires activation energies of 8 and 17 kcal mol^{-1}, respectively, according to ab initio calculations.[7] On the basis of these findings the formation of epoxides observed in the ozonolysis of fluoroalkenes[8] can be explained in terms of an enhanced formation of fluorodioxiranes, which epoxidize unchanged alkene.

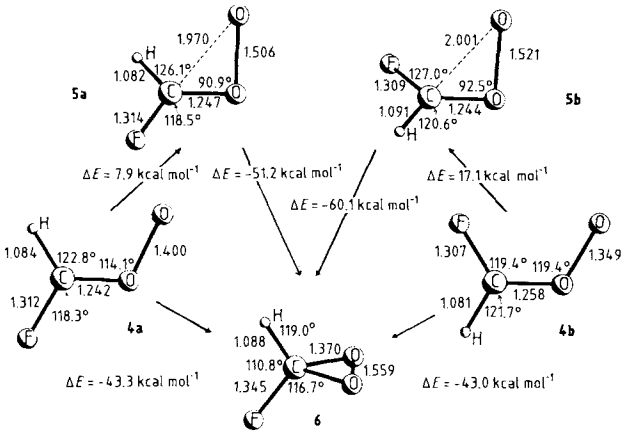

Fig. 2. Isomerization of monofluorocarbonyl oxide **4** to monofluorodioxirane **6**. MP2/6-31G* energies and geometries for **4**, **5**, and **6**; distances in Å. The dihedral angles τ(FCOO) and τ(HCOO) calculated for **5a** are −143.0 and 42.2°; for **5b** they are 53.6 and −137.3°, respectively.

Although **1** is 31.3 kcal mol^{-1} more stable than **2**, it cannot be detected under normal conditions.[2] Ring strain and the repulsion of lone pairs lead to a weak OO bond (R(OO) = 1.521 Å, Fig. 1), which is readily cleaved, either homolytically or, in the presence of Lewis acids, heterolytically.

The strain energy (SE) of **1** is estimated by ab initio calculations for the homodesmotic reaction (a) to be 24.7 kcal mol^{-1}.[9]

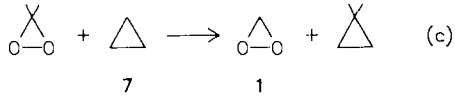
$$\mathbf{1} + H_2O_2 + 2CH_3OH \longrightarrow 2CH_3OOH + HOCH_2OH \qquad (a)$$

For the comproportionation of **1** and cyclopropane **7** leading to **8** [Eq. (b)], a reaction energy ΔE of −38.2 kcal

$$\mathbf{1} + \mathbf{7} \longrightarrow 2\,\mathbf{8} \qquad (b)$$

mol^{-1} is calculated.[9] If one assumes that ΔE(b) is determined by the difference in the SE values of the three-membered rings (SE(**1**) = 24.7, SE(**7**) = 27.5,[10] SE(**8**) = 26.9 kcal mol^{-1}[10]) and the bond energies (BE) of C–C (80 kcal mol^{-1}), C–O (78 kcal mol^{-1}[11]), and O–O bonds, then BE(O–O) is estimated at 36 kcal mol^{-1}, a value which is close to the calculated dissociation energy of 31 kcal mol^{-1}.[12] In the isomerization, **2** is formed with an excess energy of 54 kcal mol^{-1}, which, if not reduced by collision deactivation, leads to cleavage of the O–O bond and subsequent decomposition of the molecule.

A thermodynamic stabilization of **1** is achieved by geminal methyl groups. It can be estimated via the reaction energy ΔE(c) to be 21 kcal mol^{-1}.[13] Geminal methyl groups



7 1 (c)

also increase the kinetic stability of **1**; they fix the CCC bond angle at a value of 117° by steric interaction and thereby render difficult a rehybridization at the C atom during cleavage of the OO bond. This explains the relatively high stability of dimethyldioxirane, which was recently prepared by oxidation of acetone with $KHSO_5$.[14]

Fluorine as substituent also increases the thermodynamic stability of **1**, but at the same time it reduces its kinetic stability, as manifested in the relatively large O–O distance (1.56 Å) and the reduction in the exocyclic angle to 110.8°. Intermediary fluorodioxiranes are therefore probably stronger epoxidizing agents than dialkyl dioxiranes.

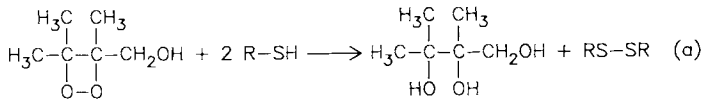
Facile Reduction of 1,2-Dioxetanes by Thiols as Potential Protective Measure against Photochemical Damage of Cellular DNA**

By *Waldemar Adam,* Bernd Epe, Dietmar Schiffmann, Franklin Vargas,* und *Dieter Wild*

In recent biological studies[1] it was demonstrated that 1,2-dioxetanes are genotoxic. Since these strained four-membered ring cyclic peroxides are known to be efficient chemical sources of n,π*-excited triplet carbonyl products,[2] we postulated that the observed DNA damage was of photochemical origin. However, in view of the quite moderate photo-genotoxicity displayed by the dioxetanes studied, we suspected that these labile peroxides were efficiently detoxified in the cell through chemical action. For example, the living cell guards itself against "oxidative stress"[3] by engaging glutathione, a tripeptide which deactivates reactive oxygen species including peroxides by reduction, itself being oxidized to its disulfide. We now report on the quantitative reduction of dioxetanes to the corresponding vicinal diols by glutathione [Eq. (a)], a reaction which also takes place with other thiols. The results are listed in Table 1.



1 2 (a)

Table 1. Reaction of **1** with thiols.

No.	Thiol [a] R-SH	Solvent	Reaction conditions T [°C]	t [h]	Product balance [%]	Product yields [mol] [b, c] Disulfide	**2**	Ketone [d]
1.	L-Glutathione	H_2O	5	0.16	97	0.97	0.96	–
2.	L-Cysteine	H_2O	20	0.16	95	0.98	0.92	–
3.	L-Penicillamine	H_2O	20	0.16	93	0.96	0.90	–
4.	*threo*-1,4-Dimercapto-2,3-butanediol	MeOH	10	1	99	0.99	0.99	–
5.	1,3-Propanedithiol	MeOh	−40	24	97	0.98	0.93	0.03

9.	Thiophenol	MeOH	−100	22	50	0.49	0.49	0.51

[a] Stoichiometry 2:1 except entries 4 and 5, for which it was 1:1. [b] 100% conversion; normalized to 1.00 mol; ±2% error limits. [c] Determined ^{1}H-NMR spectroscopically and/or isolated. [d] Acetone and hydroxyacetone formed in equal amounts.

On mixing aqueous solutions of the hydroxydioxetane **1** with glutathione at 5°C in a 1:2 stoichiometry, a fast reaction (100% conversion in 10 min, monitored by ^{1}H-NMR) ensued, leading essentially quantitatively to the glutathione dimer [m.p. 178–180°C (decomp.)[4], m.p.$_{obs.}$ 178–182°C (decomp.)] and the triol **2**. Both products were isolated and identified by comparison with authentic materials. Similar results were obtained for cysteine, penicillamine, and *threo*-1,4-dimercapto-2,3-butanediol (Entries 2–4 in Table 1), except that in the latter case the cyclic disulfide 1,2-dithiane was isolated and small amounts (ca. 3%) of the dioxetane cleavage products (acetone and hydroxyacetone) were detected by ^{1}H-NMR. Such cleavage products gain greater importance for the simple thiols (Entries 6–9, Table 1), although the reactions were conducted at subambient temperatures, at which thermal decomposition of the dioxetane is negligible. For example, with thiophenol (Entry 9 in Table 1) the extent of dioxetane cleavage was as much as 50%, even at −100°C, thus seriously competing with reduction to the triol **2**. Similar results were obtained for tetramethyl-1,2-dioxetane, undergoing quantitative reduction by glutathione to pinacol, but appreciable cleavage into acetone with thiophenol.

That glutathione is an efficient reagent for the reduction of peroxides is well established,[3] but that the labile dioxetanes can be so cleanly transformed into vicinal diols is somewhat astonishing, since in the few reported studies with divalent sulfur compounds, oxygen transfer prevails. Thus, the dioxetane is converted into an epoxide and/or a ketone, while the sulfide is oxidized to the sulfoxide.[5] Furthermore, dialkyl sulfoxylates $S(OR)_2$ are transformed via intermediary tetraalkylorthosulfites $S(OR)_4$ into dialkyl sulfites.[6] These oxygen transfer reactions have been mechanistically interpreted in terms of either a nucleophilic attack by the sulfide[5] on the peroxide linkage or a biphilic insertion by the dialkylsulfoxylate.[6] Consequently, we likewise expected oxygenated products rather than disulfides in the reaction with thiols. Indeed, when only equimolar amounts of glutathione and dioxetane **1** were used, the glutathione was converted quantitatively in a fast reaction into its dimer, and in a subsequent slow reaction (hours) the disulfide was oxidized to its *S*-monoxide, as anticipated for an oxygen transfer reaction. With L-methionine (in H_2O, 20°C, 20 min, 1:1 stoichiometry), **1** was quantitatively converted into the epoxide 2,3-dimethyl-2,3-epoxy-1-butanol, while the methionine itself was converted into the sulfoxide. In the case of dimethyl sulfide (in $CHCl_3$, −5°C, 3 h, 1:1 stoichiometry) oxygen transfer was the major reaction (ca. 85%), affording 60% sulfoxide and 12% sulfone as sulfide derived products, and 44% 2,3-dimethyl-2,3-epoxy-1-butanol and 41% of the rearranged, ketone 1-hydroxy-3,3-dimethyl-2-butanone as dioxetane derived products. Dioxetane cleavage into equal amounts of acetone and hydroxyacetone was observed as secondary reaction (ca. 15%). A control experiment showed that in a much slower reaction dimethyl sulfoxide was oxidized by dioxetane **1** to its sulfone. Clearly, the sulfides behave differently than the thiols in their reaction with dioxetanes.

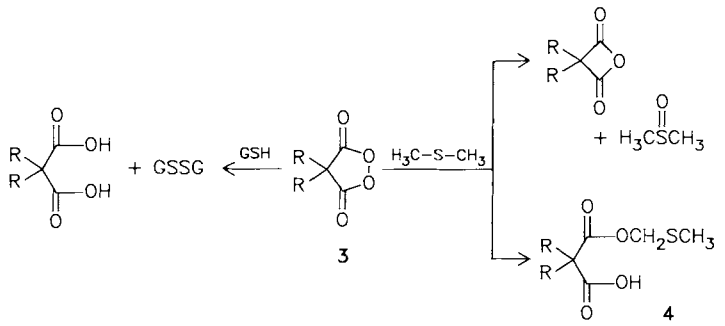
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich No. 172), the Fritz-Thyssen Stiftung, and the Fonds der Chemischen Industrie. *F. Vargas* thanks the DAAD for a doctoral fellowship.

In this context it was of interest to explore whether other cyclic peroxides, e.g. dimethylmalonyl peroxide **3**, would exhibit such differentiated chemical behavior towards thiols and sulfides. The results of the reactions of **3** with glutathione (GSH) and with dimethyl sulfide are shown in Scheme 1. The former gave quantitatively glutathione dimer (GSSG) and malonic acid, a reduction process identical to that of GSH with **1**. With dimethyl sulfide, on the other hand, the major reaction (ca. 62%) was oxygen transfer leading to malonic anhydride[7] and dimethyl sulfoxide.



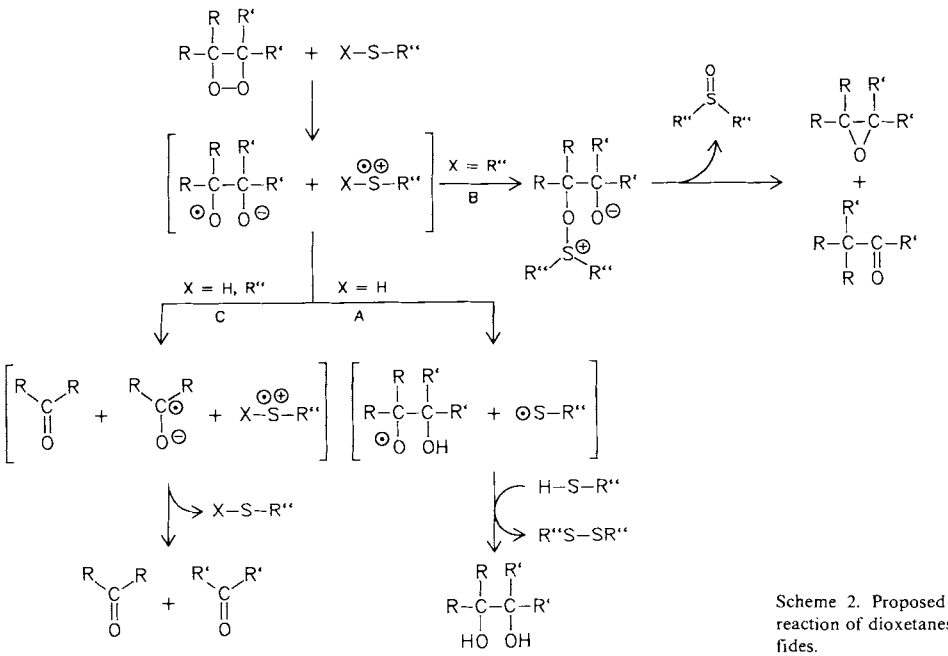
Scheme 1. R=CH_3

A mechanistically most revealing minor process (ca. 38%) gave rise to the insertion product **4**. The latter is indicative of electron transfer chemistry, as observed in the cytochrome P-450-catalyzed dealkylation of sulfides via α-hydroxylation of the intermediary sulfur-centered radical cation.[8] The fortunate happenstance of the present case, the first example of this type of electron transfer for a peroxide-sulfide reaction, is that the acetal moiety ($RO-CH_2-SR$) survives work-up. Preliminary experiments indicate that such an insertion product as structure **4** is formed also with dioxetane **1**, when allowed to react with thioanisole.

That product **4** is of free radical origin is immediately clear from preliminary CIDNP experiments, in that ^{1}H-NMR monitoring of the malonyl peroxide-sulfide reaction in $CDCl_3$ at $-30°C$ exhibited enhanced polarization of the methylene hydrogens of the acetal linkage. Moreover, it is of interest to mention that preliminary results with trimethylsilyl phenyl sulfide show that it behaves like a thiol in that reduction of the malonyl peroxide **3** takes place affording phenyl disulfide. The analogous reduction by trimethylsilyl phenyl sulfide obtains also for the dioxetane **1**.

In view of these findings, we propose that the reaction of dioxetanes with divalent sulfur compounds (thiols and sulfides) are induced by electron transfer, as outlined in Scheme 2. With the help of such electron transfer, one can rationalize in a unified manner all three reaction types observed for thiols and sulfides, i.e. reduction for thiols (X=H, route A), oxygen transfer for sulfides (X=R″, route B), and catalyzed cleavage for both (X=H, R″, route C).

Electron transfer involving dioxetanes constitutes the basis of the CIEEL mechanism[9] and also their dark catalytic decomposition by amines[10] is interpreted to proceed via radical ion pairs. In view of the relatively low oxidation potentials of divalent sulfur compounds,[11] such electron transfer with peroxide oxidants is likely. Although radical cations of sulfides[8] and thiols[12] are well documented, the novel feature in the present report is that such reactive intermediates can be generated in redox reactions with peroxides. Work is in progress employing polycyclic aromatic sulfur compounds as one-electron donors, whose radical cation chemistry is well established, e.g. chloropromazine.[13] Preliminary results with phenothiazine afford indeed its radical cation on treatment[14] with dioxetane **1** or malonyl peroxide **3**. Significant and relevant for our purposes is that it evidently also takes place on treatment of dioxetanes with thiols such as glutathione. That hydrogen abstraction from the thiol may be involved, generating thiyl radicals directly rather than via electron transfer (Scheme 2), seems to be unlikely, as substantiated by the finding that trimethylsilyl derivatives of thiols also reduce dioxetanes affording disulfides. We concede that mechanisms other than electron transfer (Scheme 2) can be proposed to rationalize the present observations and that



Scheme 2. Proposed mechanism for the reaction of dioxetanes with thiols and sulfides.

more work will be necessary to substantiate the novel redox process postulated here.

Irrespective of this mechanistic query, the fact that glutathione and other biological thiols such as cysteine and penicillamine (Table 1) quantitatively reduce dioxetanes to their vicinal diols provides an effective means for the detoxification of such genotoxic agents in the cell. Indeed, in this context it is important to mention that preliminary studies have revealed that addition of glutathione diminishes the mutagenic activity of dioxetane **1** in the Ames test. Furthermore, buthionine sulfoximine (an inhibitor of glutathione synthesis) increases the cytotoxicity of dioxetane **1** in studies with HL60 (promyelocytic leukemia) cells and SHE (Syrian hamster embryo) cells. Future studies plan using glutathione deficient bacterial strains and cell lines to enhance the photogenotoxity of 1,2-dioxetanes.

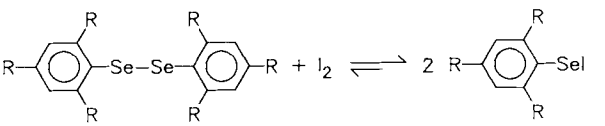
The Reagent Diphenyldiselane/Iodine: No Phenylselenenyl Iodide but a Charge Transfer Complex with Cyclic Moieties**

By *Silvia Kubiniok, Wolf-Walther du Mont,* Siegfried Pohl,** and *Wolfgang Saak*

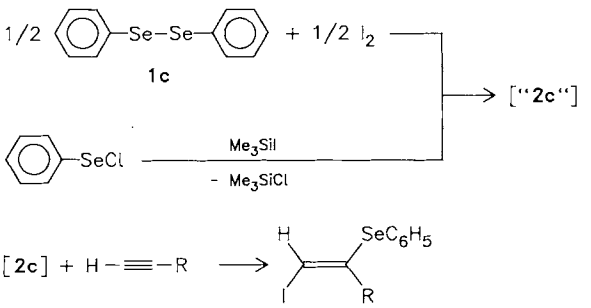
The elements sulfur and selenium do not react with elemental iodine to give stable molecular compounds containing chalcogen–iodine bonds. Only recently has it been possible to demonstrate, in special cases, that—by cleavage of selenium–selenium bonds with iodine—uncharged molecules with covalent selenium–iodine bonds can be generated and even isolated.[1] Thus, bis(2,4,6-tri-*tert*-butylphenyl)diselane **1a** and apparently also bis(2,4,6-trimethylphenyl)diselane **1b** give dismutation equilibria with iodine:[1] in solution the aryl(iodine) selenides **2a** and **2b**, respectively, as well as the starting diselanes **1a** and **1b** can be detected by ^{1}H- and ^{77}Se-NMR spectroscopy;[2] crystalline iodine(2,4,6-tri-*tert*-butylphenyl) selenide **2a** consists of monomeric molecules with selenium–iodine single bonding.[1]



1a, R = t-C_4H_9
1b, R = CH_3

2a, R = t-C_4H_9
2b, R = CH_3

The reagent diphenyldiselane **1c**/iodine,[3] which *Toshimitsu*, *Uemura*, and *Okano* recommend for specific CC coupling reactions, has been available commercially under the name "phenyl selenenyl iodide"[4] [alternative to iodine(phenyl) selenide] for some time. Indeed chemical reactions with the "Toshimitsu reagent" suggest the formation of a reactive species C_6H_5SeI **2c**;[5] thus, e.g., it was possible to carry out the iodoselenation of 1-hexyne with diphenyldiselane **1c**/iodine in the same way as with the product of the reaction of phenylselenenyl chloride with iodotrimethylsilane.[6]



^{13}C- and ^{77}Se-NMR spectra of the solution obtained upon reaction of **1c** with iodine, however, provided no reliable indication of the formation of molecular species **2c**.[7] On addition of half an equivalent of iodine to **1c** in chloroform, changes in the NMR shifts were observed but no separate signals could be resolved for the reaction product. When diselane **1c** is treated with an excess of iodine further shift changes occur compared to the ^{13}C-NMR values[6] quoted earlier for the Toshimitsu reagent.[7] These findings leave it undecided whether a dismutation equilibrium between **1c**/iodine and **2c** exists in solution which is rapidly established on the NMR time scale, or whether a (kinetically labile) charge transfer adduct is formed from the diselane **1c** with iodine.

The product of the reaction of **1c** with iodine can be prepared just as easily as the aryl(iodine) selenide **2a**. Mixing of the reactants in petroleum ether 40/60 and crystallization at −14 °C afford reddish-black shiny crystals, which after brief drying have the correct analytical composition.[8] If the product is left for a prolonged time (2–4 h) under reduced pressure, it gradually loses some iodine; this might explain why the compound was previously obtained only "almost pure" or "98%".[4–6]

[**] Properties of Chalcogen–Chalcogen Bonds, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 8: [1].

An X-ray structure analysis[9] of the compound obtained in crystalline form from petroleum ether revealed without doubt that *no* iodine(phenyl) selenide **2c** is present in the solid state but rather the diphenyldiselane–iodine charge transfer complex **3c** (Fig. 1). Two diphenyldiselane molecules are coupled with two I_2 molecules in such a way that a slightly puckered eight-membered ring containing two Se_2-groups and two I_2-groups is formed. Since the angles in this ring are alternately approximately 90° and 180°, almost a square geometry results. The Se–Se bonds (234.7 pm) and I–I bonds (277.5 pm)[9] are longer than those in **1c** (229 pm)[10] or elemental iodine (271.5 pm).[11] Diphenyldiselane coordinates a diiodine molecule, with one selenium atom acting as donor toward an iodine atom. In addition there are interactions between the other selenium atom and an iodine atom of the adjacent R_2Se_2–I_2 moiety; in this case the selenium atom plays the role of the acceptor. The mutual selenium/iodine donor/acceptor relationships can be analyzed on the basis of the characteristic coordination geometries of hypervalent (10-Se-3) acceptor selenium atoms (linear I-Se-Se arrangement) and (10-I-2) acceptor iodine atoms (linear Se-I-I moiety):[9] The donor atoms are located at the corners of the "square", the atoms with acceptor character at the midpoints of the edges (Fig. 1). Selenium–iodine contacts in **3c**, which result from Se(donor)–I(acceptor) interaction (299.2 pm), are about 50 pm longer than the Se–I single bond in the aryl(iodine) selenide **2a** (252.9 pm).[1, 12] The other selenium–iodine contacts in **3c**, which can be explained in terms of an I(donor)–Se(acceptor) interaction, already exceed the lengths of Se–I single bonds by about 100 pm. These internuclear distances are in the range of "secondary bonding"; they are comparable, e.g., with intermolecular contacts in the chain structure of the thermochromic tetramethyldistibane.[13] Contacts of this kind also exist in the solid between iodine molecules (350 pm) and between the chains of grey selenium (344 pm); the structure of **3c** is a remarkable heteronuclear variant thereof.[11] Iodine–iodine contacts (412.7 pm) between the corner iodine atoms (I2, I2a) lead to chain-like repeat linking of the square moieties in the crystal.

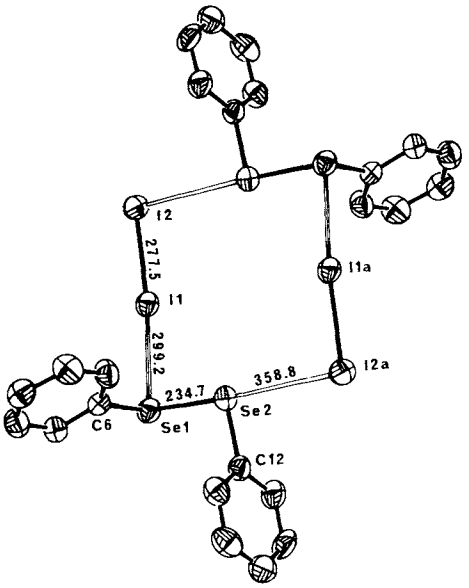

Fig. 1. Dimeric centrosymmetric moiety of $Ph_2Se_2 \cdot I_2$ **3c** in the crystal, without H atoms; vibration ellipsoids at the 50% probability level. Important bond lengths [pm] and angles [°] not quoted in the figure: Se1-C6 194.4(7), Se2-C12 192.8(6); Se2-Se1-I1 90.2(1), Se2-Se1-C6 104.3(2), I1-Se1-C6 94.7(2), Se1-Se2-I2a 176.5(1), Se1-Se2-C12 98.4(2), I2a-Se2-C12 84.0(2), Se1-I1-I2 174.2(1), I1a-I2a-Se2 88.4(1).

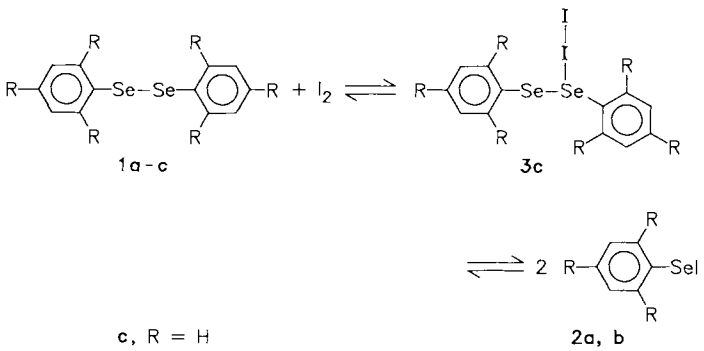
3c is labile in solution (NMR), and an association/dissociation equilibrium is established between the reactants **1c**/iodine (UV: weak absorption at 524 nm) and the charge transfer adduct **3c**. The well known chemical reactions with the reagent "C_6H_5SeI"[3,5,6] and the occurrence of the molecular peak of **2c** (C_6H_5SeI, m/z 284 with ^{80}Se) in the mass spectrum of **3c** suggest that scrambling reactions will take place between **1c**/iodine, **2c** and **3c**, which are favored by small differences in energy and low activation energies.



The formation of the cyclic diselane-diiodine charge transfer adduct **3c** with weakening of Se–Se and I–I bonds (compared to the educts **1c** and I_2) is already the primary step of a 2+2 dismutation of Se–Se bonds with I–I bonds. Sterically demanding substituents on selenium disfavor the tendency of formation of charge transfer complexes with iodine.[14] In the case of the diselanes **1a**, **b** the steric hindrance of the reactants favors the tendency to undergo dismutation with formation of molecules having covalent Se–I bonding (**2a**, **b**); the first example, **2a**, was recently confirmed by an X-ray structure analysis.[1] The ability of compounds **3** to exist alongside **2**, **1** and I_2 also provides an improved explanation of the catalytic action of iodine on the crystallization of elemental selenium.[15]

Enantioselective Synthesis of (*R*)-*N*-Boc-1-amino-2-arylcyclopropene-1-carboxylic Acid Methyl Ester**

By *Ulrich Schöllkopf,* Bernd Hupfeld, Stephan Küper, Ernst Egert,** and *Michael Dyrbusch*

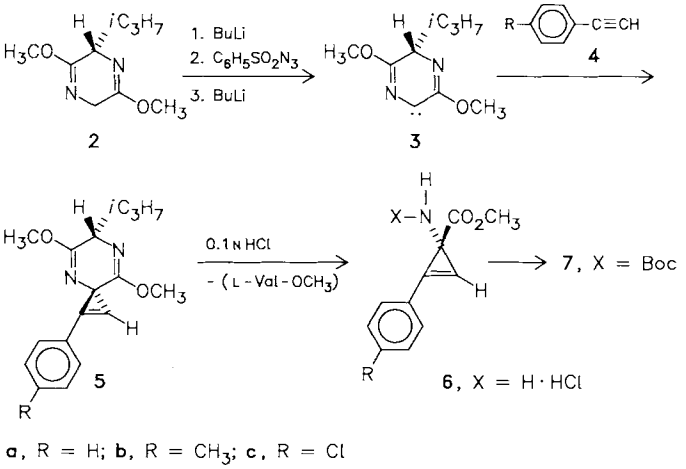
Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

β,γ-Unsaturated amino acids of the β-methylenephenylalanine type **1**[1] are of special interest as suicide-inhibitors[2] for pyridoxal phosphate-dependent enzymes. 1-Amino-2-aryl-cyclopropene-1-carboxylic acids (Type **7**)[3]—

1

structural variants of **1**—should be particularly effective inhibitors because of their extremely strained and thus highly reactive double bond. Since—as usual[4]—only one enantiomer may be biologically active, each enantiomer should be investigated separately. We describe here an enantioselective synthesis of *N*-Boc-1-amino-2-phenyl-, -(4-methylphenyl)-, and -(4-chlorophenyl)cyclopropene-1-carboxylic acid methyl esters **7a**, **b** and **c** utilizing the bislactim ether carbene **3**. The amino acid esters **7** are obtained in almost enantiomerically pure form (*ee* > 95%): with **3** the (*R*)-enantiomers and with *ent*-**3** the (*S*)-enantiomers.

The synthesis starts from **2**, the bislactim ether of cyclo(L-Val-Gly).[5] This is converted via the 2-lithium compound and the 2-diazo compound into the bislactim ether carbene **3**,[6] which is trapped with the arylethyne **4**. Within analytical accuracy only one diastereomer is formed, namely (*R*)-**5**. The configuration was confirmed by an X-ray structure analysis of **5a** (Fig. 1).[7]



a, R = H; **b**, R = CH_3; **c**, R = Cl

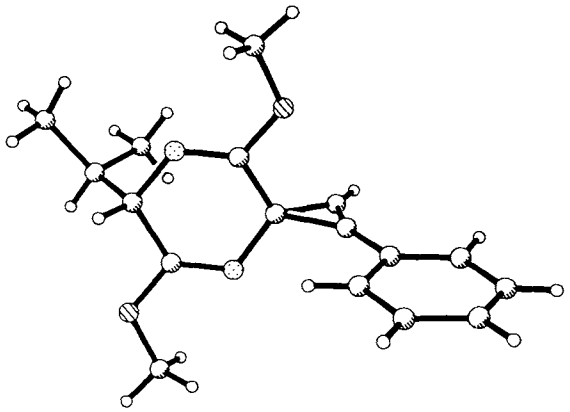


Fig. 1. Structure of the carbene adduct **5a** in the crystal [7]; ⊙ = N, ⊚ = O. Noteworthy is that the phenyl ring and the cyclopropene double bond are completely coplanar, thus indicating an effective conjugation of the two π-systems.

Hydrolysis of the carbene adducts **5** to **6**, the hydrochlorides of the amino acid esters, was achieved with two equivalents of 0.1 N HCl at room temperature. The salts **6** were transformed into the *N*-Boc derivatives **7**. After separation from Boc-L-Val-OMe these were reconverted into the compounds **6** by treatment with 0.5 N HCl in methanol (6 h, 60 °C).

Experimental

5: A solution of **2** (0.55 g, 3.0 mmol) in THF (7 mL) was treated dropwise at −78 °C with a solution of *n*BuLi (3.0 mmol) in hexane. After 15 min stirring, the resulting mixture was added via a Teflon tube (cooled with dry-ice) to a solution of 0.53 g (3.0 mmol) of benzenesulfonyl azide in 7 mL of THF. Stirring was continued for 2.5 h at −78 °C and then *n*-BuLi (3.0 mmol) was added to the mixture at such a rate that the temperature did not rise above −70 °C. After 10 min the mixture was added dropwise within 15 min through a Teflon tube (cooled with dry-ice) to 30 mL of **4**, which was warmed to 50–60 °C. After 30 min vigorous stirring, the mixture was allowed to cool to room temperature, treated with 150 mL of Et_2O, and washed with 3 × 30 mL of a 10% NaCl solution. The organic phase was dried over magnesium sulfate and the solvent removed in vacuo. Excess **4** was distilled off at 30–40 °C/0.01 torr and the residue chromatographed on silica gel (Kieselgel 60, 500 × 15 mm^2 column, petroleum ether/ether 15/1). — **5a**: 0.43 g (50%), m.p. 112–113 °C; **5b**: 0.45 g (50%), m.p. 70–71 °C; **5c**: 0.62 g (65%), m.p. 103–104 °C. Diastereomeric ratio > 49 : 1 [8].

Bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, a Novel 14π-Electron Heterocycle with High Electron Affinity

By *Yoshiro Yamashita,* Kenichi Saito, Takanori Suzuki, Chizuko Kabuto, Toshio Mukai,* and *Tsutomu Miyashi*

Cyclic thiazyl compounds have recently attracted considerable attention because of the interesting redox properties of the sulfur-nitrogen linkage.[1] We have already shown that the thiadiazole rings in 2,2′-(benzo[1,2-*c*;4,5-*c*′]-bis[1,2,5]thiadiazole-4,4,8,8-tetrayl)dimalononitrile, **1**, a new type of electron acceptor,[2] play an important role in decreasing Coulomb repulsion by delocalization of negative charge[3] and in forming two-dimensional networks by intermolecular interactions between the heteroatoms.[4] In this connection, bis([1,2,5]thiadiazolo)[3,4-*b*;3′,4′-*e*]pyrazine, **2**, is an interesting hypervalent sulfur-nitrogen heterocycle for which resonance structures such as **2a–c** come into consideration. We have succeeded in preparing **2** and found that it is a strong electron acceptor, in spite of its being a 14π-electron heterocycle.

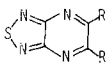
2c

5,6-Diamino[1,2,5]thiadiazolo[3,4-*b*]pyrazine **3a** was prepared by reaction of the dichloro compound **3b**[5] with potassium phthalimide followed by hydrolysis with hydrazine hydrate (yield 63%). Reaction of **3a** with thionyl chloride in the presence of pyridine in dichloromethane afforded, after sublimation, stable red crystals of **2** in 66% yield.[6]



3a, R=NH₂
3b, R=Cl

The half-wave reduction potentials ($E_1 = +0.10$, $E_2 = -0.82$ V vs. SCE) were measured by cyclic voltammetry.[7] The first reduction potential is more positive than that of **1** (−0.02 V),[2] i.e. **2** is a stronger electron acceptor than **1**, even though it does not contain any electron-withdrawing substituents. Moreover, the log K_{sem} value (15.86) is larger than that for **1** (8.10),[8] indicating that the radical anion of **2** is thermodynamically more stable than that of **1**. The high electron affinity of **2** can possibly be attributed to the generation of a new aromatic sextet in one thiadiazole ring by one-electron reduction to give the radical anion **4**. This assumption is supported by the fact that the reduction potential of **5**[9] ($E_1 = \doteq -0.46$ V vs. SCE) is less negative than that of the dichloro compound **3b** ($E_1 = -0.56$ V vs. SCE).

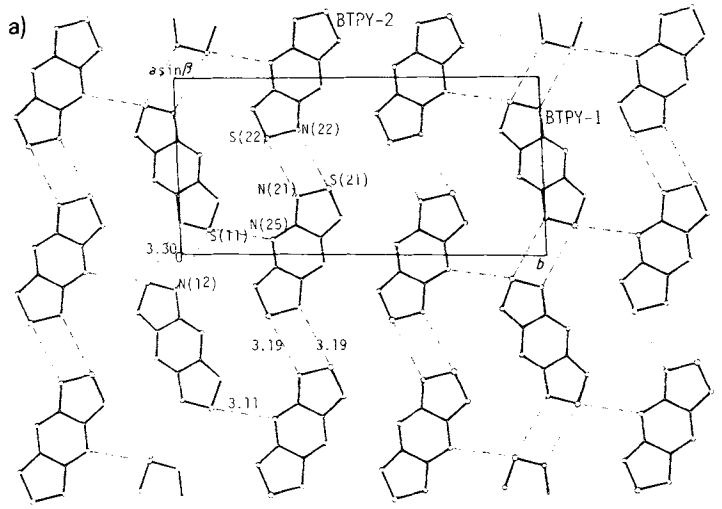
5

The single crystal required for an X-ray structure analysis[10] was obtained by sublimation.[11] Figure 1 shows two views of the crystal structure. In the crystal there exist two different kinds of **2** (abbreviated as BTPY-1 and BTPY-2); the molecular structures, however, are almost identical.[12] Figure 2 shows the molecular structure of BTPY-1, the center of which is related with the unit cell (Fig. 1a). The molecule is planar. The S–N bond lengths lie between those of an S–N single bond (1.73 Å)[13] and an S–N double bond in sulfur diimide (1.53 Å).[14] The C–N bonds and C–C bonds also have intermediate π-bond orders,[15, 16] although significant differences in the C–N bond lengths of the thiadiazole rings and a little bond alternation are observed. The calculated π-bond orders show a delocalization of the π-electrons.

From Figure 1 it is clear that the molecules form a three-dimensional network via S–N contacts. The BTPY-2 molecules are linked by strong S–N contacts between the thiadiazole rings (3.19 Å) to give a ribbon-like structure. The

[*] Dr. Y. Yamashita, K. Saito, T. Suzuki, Dr. C. Kabuto, Prof. Dr. T. Mukai, Prof. Dr. T. Miyashi
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980 (Japan)

ribbons are, in turn, bridged by BTPY-1 molecules, the S atoms of BTPY-1 and the N atoms of the pyrazine ring of BTPY-2 forming the contacts (3.11 Å). In addition, the BTPY-1 molecules form their own ribbons, although here the S-N contact distances are somewhat larger (3.30 Å) (Fig. 1a). The BTPY-2 ribbons interact with each other via



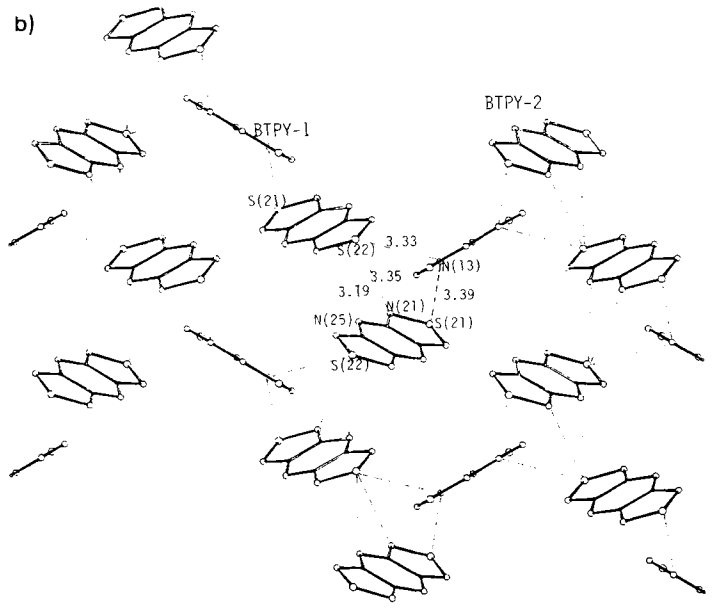


Fig. 1. Two views of the network structure of **2** in the crystal. Broken lines = S-N interactions. a) View of ribbon networks (*c* projection). S(11)-N(12) 3.30 Å, S(11)-N(25) 3.11 Å, S(21)-N(22) 3.19 Å, S(22)-N(21) 3.19 Å. b) Side view of the networks. S(21)-N(13) 3.39 Å, S(22)-N(13) 3.33 Å, S(22)-N(25) 3.19 Å, S(22)-N(21) 3.35 Å.

S-N contacts between the upper and lower sides along the [101] direction (Fig. 1b) but not in the *ab* plane including the ribbons. Such interactions lead to a dense packing in the crystal and thus to the calculated high density. The ribbon formation seems to be related to the bond alternation (Fig. 2), since the S-N contacts are via the longer S-N bonds (Fig. 1a). The observed participation of the N atoms of the pyrazine ring in the formation of a ribbon-like structure suggests that the resonance structure **2c** contributes considerably to the overall atructure of **2**.

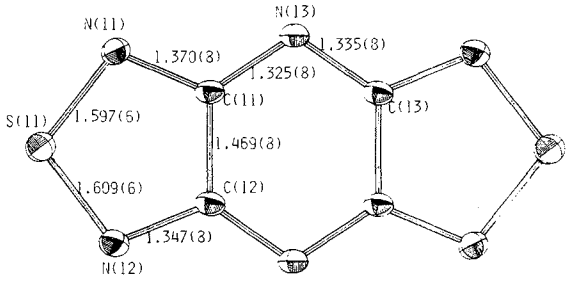

Fig. 2. Molecular structure of BTPY-1, with bond lengths [Å] (ORTEP).

On the basis of the results presented here, **2** should be suitable for the preparation of highly conductive compounds with multidimensionality. Studies on its charge transfer complexes with electron donors and its radical-ion salts are in progress.

2,4,6-$Ph_3C_6H_2M$ (M = Cu, Ag), Monomeric Cu^I- and Ag^I-Complexes with Coordination Number 1**

By *Regine Lingnau* and *Joachim Strähle**

Only few alkyl- and aryl-complexes of Ag^I and Au^I are known. *Floriani* et al.[1] synthesized tetrameric mesitylgold(I) in which the aryl moiety functions as bridging ligand between two metal centers and thereby has a coordination number 2 (multicenter bonding). In the case of univalent copper even some polymeric or oligomeric complexes $(RCu)_n$ have been obtained[1,2] in which aryl moieties function as bridging ligands. An interesting aspect of the complexes $(RM)_n$ is that the univalent metals form very short metal-metal bonds, despite their d^{10}-electron configuration. We report here on a novel complex, in which for the first time 2,4,6-$Ph_3C_6H_2$ ("2,4,6-triphenylphenyl"[***]) is bound as ligand to Cu^I and Ag^I. The bulkiness of the ligand precludes formation of a bridge, so monomeric complexes 2,4,6-$Ph_3C_6H_2M$ (M = Cu: 1; M = Ag: 2) in which the metal atom has coordination number 1 are formed.

For the synthesis of **1** and **2**, 2,4,6-$Ph_3C_6H_2MgBr$ is allowed to react with CuCl and AgCl, respectively, at −80 °C in THF. Colorless, air-stable crystals are formed which are readily soluble in organic solvents such as THF, acetone, or toluene. The compounds were characterized by elemental analyses, ^{1}H-NMR spectra, and crystal structure analyses. The ^{1}H-NMR spectra of **1** and **2** are almost identical and differ only slightly from the spectrum of the starting compound 2,4,6-$Ph_3C_6H_2Br$. No signals which would suggest the presence of a metal-bonded hydride could be observed.

Crystals of **1** and **2** were isolated from a concentrated $CHCl_3$ solution by careful addition of a layer of ethanol. **1** and **2** crystallize isotypically in the space group $P2_1/c$.[3] Figure 1 shows a unit cell of the crystal structures of **1** and **2**. The complexes are monomeric, and no further ligands are attached in the *trans* position to the aryl ligand. The nearest non-bonding neighbors of the metal atom are the atoms C21 and C61 of the phenyl substituents in the 2- and 6-positions, respectively, with distances of 3.185 Å and 3.158 Å as well as the atoms C21 to C26 of a neighboring complex at a distance of 3.613–3.962 Å and the respective H atoms H22 to H26 at distances of 3.96–4.64 Å. The Cu–C11 and Ag–C11 bond distances (1.890(6) and 1.902(5) Å, resp.) are very short because of the low coordination number. The values commonly observed for such covalent single bonds lie in the ranges 1.97–2.16 Å and 2.04–2.17 Å, respectively.[2c]

The unusual coordination number of 1 gave reason for investigating the reactivity of the complexes. So far such studies have mainly been carried out on **1** as example. Sterically demanding Lewis bases such as the solvent THF or pyridine and *tert*-butyl isocyanide are not coordinated. Small molecules such as CO and NO, on the other hand, are bonded. NO reacts with **1** in THF to give the adduct $[Ph_3C_6H_2Cu(NO)]$ **3**. Pale yellow crystals can be crystallized from the solution. The NO ligand gives rise to a characteristic NO stretching vibration at 1740 cm^{-1} in the IR spectrum. Reaction of **1** with CO in THF leads to formation of the adduct $[Ph_3C_6H_2Cu(CO)]$ **4**, which, however, decomposes with separation of elemental copper upon slow removal of solvent by passage of CO. The IR spectrum of the solution of **4** shows the $\nu_{(CO)}$ band at 1965 cm^{-1}.

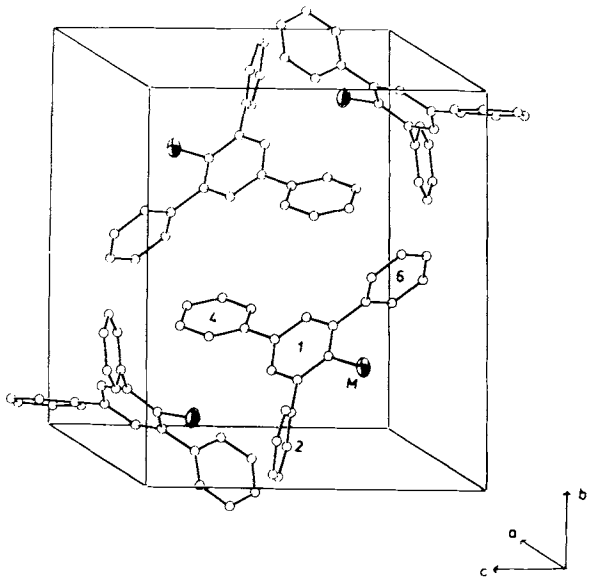

Fig. 1. Unit cell of the isotypic compounds **1** and **2** in the crystal (M = Cu and Ag, resp.). Important bond lengths [Å] and angles [°] of **1** [values for **2** in brackets]: M–C11 = 1.890(6) [1.902(5)], M–C21 = 3.185(5) [3.171(6)], M–C61 = 3.158(5) [3.214(5)]; interplanar angles: 2–1: 61.66 [61.1], 6–1: 73.73 [74.0], 4–1: 31.78 [32.4].

Experimental

1/2: The Grignard solution was treated with CuCl and AgCl respectively (2 equiv. in each case) at −80 °C in the complete absence of air and moisture.[4] The resulting white suspension was stirred for 24 h at −80 °C, slowly warmed to −10 °C, and then stirred for a further 12 h. After removal of insoluble material by filtration and evaporation of the filtrate to dryness the pale yellow crude product was dissolved in a little chloroform for crystal growing by addition of ethanol. After a few days at room temperature, colorless, transparent platelet-like crystals of **1** and **2**, respectively, were isolated (yields: 65%).

$[M(CO)_4\{CH_3C(CH_2PMe_2)_3\}]$, M = Ti, Zr, Hf, Complexes of Zerovalent Titanium, Zirconium, and Hafnium. First Structural Characterization of a Zr^0-Carbonyl Complex**

By *David W. Blackburn, Kai Ming Chi, Scott R. Frerichs, Mary L. Tinkham*, and *John E. Ellis**

So far, only three carbonylzirconium(0) complexes have been described: $[Zr(C_5H_5)(CO)_4]^{\ominus}$,[1] $[Zr(C_5Me_5)(CO)_4]^{\ominus}$[2] and the thermally unstable [Zr(butadiene)$_2$(dmpe)(CO)], dmpe = 1,2-bis(dimethylphosphino)ethane.[3] We have now found that the tripodal ligand, 1,1,1-tris(dimethylphosphinomethyl)ethane (trmpe), is unusually effective in stabilizing the unknown $Zr(CO)_7$ as well as the titanium and hafnium analogues and now present the first structural characterization of a Zr^0-carbonyl, $[Zr(CO)_4(trmpe)]$. The hafnium compound $[Hf(CO)_4(trmpe)]$ is of particular interest in that it is the first zerovalent hafnium species to have been prepared without the use of a metal atom vapor reactor. Only four Hf^0compounds have thus far been reported: $[Hf(C_6H_5R)_2(PMe_3)]$, R = H, CH_3,[4] $[Hf(1,3,5\text{-}tBu_3C_6H_3)_2]$ and its carbonyl adduct.[5] All were prepared with atomic hafnium.

The procedure [Eq. (1)] used for the synthesis of the complexes $[M(CO)_4(trmpe)]$, M = Ti **1**, M = Zr **2**, M = Hf **3**, is similar to that employed in the synthesis of the aforementioned $[Zr(C_5Me_5)(CO)_4]^{\ominus}$ (THF = tetrahydrofuran, DME = 1,2-dimethoxyethane, trmpe = $CH_3C(CH_2PMe_2)_3$, $C_{10}H_8$ = naphthalene).

$$MCl_4 \cdot 2THF + trmpe + 4KC_{10}H_8 + 4CO \xrightarrow[-60\text{ to }-70\,^{\circ}C]{THF\text{ or }DME} [M(CO)_4(trmpe)] + 4KCl + 4C_{10}H_8 + 2THF \quad (a)$$

1, M = Ti
2, M = Zr
3, M = Hf

Compounds **1**–**3** were isolated as air sensitive and thermally stable (20 °C) orange-red (**1**), deep violet (**2**), and red violet (**3**) microcrystalline materials of satisfactory purity.[6] Some spectroscopic data for these materials are shown in Table 1 and indicate that all three substances are likely to have the same basic molecular geometry. Also, comparison of the IR spectra in the ν(CO) region of **2** and $[Zr(C_5H_5)(CO)_4]^{\ominus}$ (1923 (m), 1781 cm^{-1} (s))[1] reveals strong similarities but indicates that $C_5H_5^{\ominus}$ is a somewhat better donor ligand than trmpe in these systems. Additional support for the composition of **1** was obtained from the proton-decoupled ^{13}C- and ^{31}P-NMR spectra of 99% ^{13}CO-enriched $[Ti(^{13}CO)_4(trmpe)]$. These temperature-independent spectra (down to −90 °C) show the expected splitting patterns for a fluxional seven coordinate molecule in which four equivalent carbonyls are coupled to three equivalent phosphane units.[7] Exceptionally zirconium-free $HfCl_4$[8] was used in the synthesis of compound **3** to minimize its contamination by **2**. Spectral data shown in Table 1 for these two materials are sufficiently different to leave no doubt that **3** is a genuine Hf^0-carbonyl complex.

Table 1. Selected spectroscopic properties of **1**–**3**.

Compound	M	IR [a] $\tilde{\nu}$(CO) [cm^{-1}]	$^{13}C\{^1H\}$-NMR [b] δ(CO)	$^{31}P\{^1H\}$-NMR [c] $\delta(^{31}P)$
1	Ti	1931 m, 1833 sh, 1810 s	278.9 quartet	−10.6 s
2	Zr	1938 m, 1820 s	284.4 br s	−25.1 s
3	Hf	1934 m, 1814 s	282.1 br s	−29.2 s

[a] Solvent: THF for **1**, DME for **2** and **3**. [b] 85.5 MHz, 23 °C, $[D_8]$THF, $J(^{13}C\text{-}^{31}P) = 9$ Hz for **1**. [c] 121.5 MHz, 23 °C, $[D_8]$THF; uncoordinated trmpe gives a ^{31}P-NMR signal at $\delta = -61$.

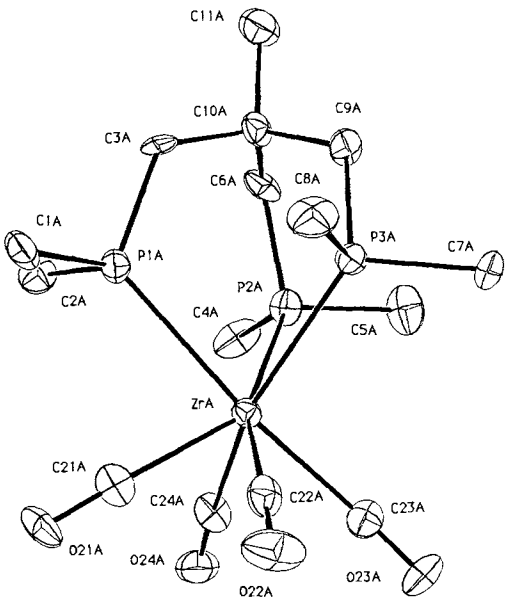

Fig. 1. ORTEP drawing of an independent molecule A of $[Zr(CO)_4(trmpe)]$ **2**. Thermal ellipsoids are drawn with 50% probability boundaries. Important interatomic distances [Å] and angles [°]: ZrA–P1A = 2.755(3); ZrA–P2A = 2.760(3); ZrA–P3A = 2.762(3); ZrA–C21A = 2.133(11), ZrA–C22A = 2.168(12); ZrA–C23A = 2.221(12); ZrA–C24A = 2.155(11); C21A–O21A = 1.182(13); C22A–O22A = 1.150(15); C23A–O23A = 1.120(14); C24A–O24A = 1.171(14); C–P (mean) = 1.83(2); C–C (mean) = 1.55(2); P1A–ZrA–P2A = 74.35(9); P1A–ZrA–P3A = 75.28(9); P2A–ZrA–P3A = 75.87(9); C21A–ZrA–C22A = 67.5(4); C21A–ZrA–C23A = 109.0(5); C21A–ZrA–C24A = 71.5(4); C22A–ZrA–C23A = 68.5(4); C22A–ZrA–C24A = 106.2(4); C23A–ZrA–C24A = 71.0(5); ZrA–C–O (mean) = 176(1).

The X-ray structural characterization of the complex $[Zr(CO)_4(trmpe)]$, **2**, revealed a unit cell containing two independent molecules of very similar structure.[9] One of these is shown in Figure 1 along with selected interatomic distances and angles. The structure may be described as a 4:3 piano stool structure,[10] and resembles that observed for $[Ti(C_5H_5)(CO)_4]^{\ominus}$,[1] where the cyclopentadienyl group is best considered a tridentate ligand. None of the interatomic distances are unusual; all are close to values obtained previously for zirconium carbonyls and phosphines. For example, in the independent molecules A and B, the respective mean Zr–C, C–O, and Zr–P distances are 2.17(4) and 2.17(3), 1.16(3) and 1.17(2), and 2.759(4) and 2.733(11), respectively. These values are similar to corresponding distances observed for $[Cp_2Zr(CO)_2]$ (mean value for Zr–C = 2.187(4) Å)[11] and $[\{(iPr_2PCH_2SiMe_2)_2N\}ZrCl_3]$ (mean

[**] Highly Reduced Organometallics, Part 24. This work was supported by the U. S. National Science Foundation and the Petroleum Research Fund administered by the American Chemical Society. *D. W. B.* thanks the NSF for a predoctoral fellowship (1986–1989).—Part 23: K. M. Chi, S. R. Frerichs, S. B. Philson, J. E. Ellis, *J. Am. Chem. Soc. 101* (1988) 303.—Note added in proof (February 17, 1988): A related complex, $[Ti(CO)_4\{tBuSi(CH_2PMe_2)_3\}]$, was reported after submission of this communication: T. G. Gardner, G. S. Girolami, *Organometallics 6* (1987) 2551.

value for Zr–P = 2.78(1) Å).[12] Somewhat shorter Zr–C and Zr–P distances have been found in $[Zr(C_5Me_5)_2(CO)_2]$ (mean value for Zr–C = 2.145(9) Å)[13] and $[Zr(C_5H_5)(PMe_3)(cyclohexyne)]$ (Zr–P = 2.689(3) Å).[14]

Since the tripodal ligand "trmpe" is readily obtained from Me_4P_2[15] and $[Zr(CO)_4(trmpe)]$ is thermally robust and available in reasonable yields (40–45%) from $ZrCl_4 \cdot 2THF$,[16] this new Zr^0-carbonyl compound and its Ti^0- and Hf^0-analogues should prove to be useful precursors for the investigation of zerovalent group 4 carbonyl metal compounds.

Experimental Procedure

$[Zr(CO)_4(trmpe)]$ **2**: 1.8 g (7.1 mmol) of trmpe was added to a cold (−30°C) solution of 2.69 g (7.14 mmol) of $ZrCl_4 \cdot 2THF$ in 100 mL of DME. A white precipitate of unknown composition formed immediately. The resulting slurry was stirred at ambient temperature for 0.5 h, cooled to −60°C, and then transferred by cannula to a mechanically stirred solution/slurry of 4.88 g (29.3 mmol) of $KC_{10}H_8$ and 3.75 g (29.3 mmol) of $C_{10}H_8$ in 150 mL DME under argon at −65°C. After 20 min, the solution had assumed a beautiful deep purple color and stirring was stopped. Argon was removed by evacuation, purified carbon monoxide was added to slightly above atmospheric pressure and stirring was resumed for 16 h at −65°C. After this time, the now deep red solution was warmed to −10°C over a 5 h period and filtered through Celite. Following removal of solvent under reduced pressure and thorough washing with pentane (2 × 200 mL; 2 × 50 mL) to remove naphthalene, 1.45 g (3.19 mmol, 45% yield) of microcrystalline dark violet **2** (decomp. at 150–153°C) was obtained which provided satisfactory analyses (C, H) without further purification. Crystals for the X-ray study were grown from pentane/CH_2Cl_2 over a six day period at −30°C. Similar syntheses starting from the corresponding $MCl_4 \cdot 2THF$ adducts provided $[Ti(CO)_4(trmpe)]$ **1** (decomp. at 163–166°C) and $[Hf(CO)_4(trmpe)]$ **3** (decomp. above 165°C, slow darkening) in 56 and about 2% yields, respectively, as thermally stable (20°C) materials which provided satisfactory elemental analyses (C, H). The yield of the hafnium compound **3** could be considerably improved (ca. 20%) by performing the low-temperature carbonylation step at about 5 atmospheres pressure of CO.

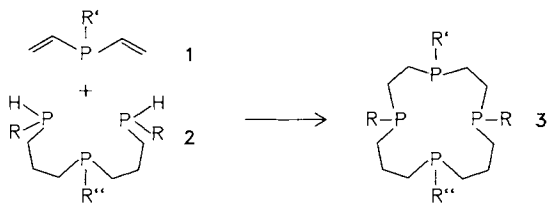
Template Synthesis of Macrocyclic Multiphosphane Ligands with Functional Groups**

By *David J. Brauer, Thomas Lebbe,* and *Othmar Stelzer**

Multidentate macrocyclic phosphane ligands—crown phosphanes—exhibit an unusual bonding behavior towards transition metals, which is determined by the sequence of the donor atoms.[1] Moreover, by suitable choice of substituents at the P atoms, such behavior can be controlled. These ligands, however, which are as potentially important as the known synthetic macrocyclic donor systems, have hitherto proven to be difficult to synthesize.

By exploiting the template effect[2] of Ni^{II} we have now been able to prepare a 14-membered crown phosphane with the donor sequence $P-C_2-P-C_2-P-C_3-P-C_3$ in almost quantitative yield by cyclization of a tertiary disecondary triphosphane **2** with a divinylphosphane **1**. In order to suppress formation of polymers in the reaction of **1** and **2**—which is favored even on using the dilution principle—the terminal PRH groups of **2** have to be fixed by coordination to a transition metal in a position which favors the cyclization reaction with **1** with formation of the macrocyclic ring system **3**.



The construction of a suitable template (**5**) for the ring closure reaction was possible starting from the Ni^{II}-complex $[NiBr_2(L)]$ **4** of the tertiary disecondary triphosphane $MeHP-(CH_2)_3-PPh-(CH_2)_3-PMeH$ (L) by extrusion of an anionic halide ligand $Br^{\ominus}$ with $Et_2N-P(CH=CH_2)_2$.[3] Complexes of the type $[MX_2(L)]$ (M = Ni, Pd; X = Cl, Br) are readily accessible from the phosphane ligand L and the M^{II}-halides ($NiBr_2 \cdot 3H_2O$, K_2PdCl_4, $PdCl_2$).[4]

The intermediary formation of the template complex **5** fixes the reaction partners in close proximity. Subsequent rapid addition of the two vinyl groups of the unsaturated phosphane ligand in **5** to the terminal PMeH moieties af-

fords **6a**, the complex of a 14-membered crown-phosphane with a functional group (NEt_2), as a mixture of four diastereomers, as shown by analysis of the $^{31}P\{^1H\}$-NMR spectrum of the crude product (Table 1). The phosphorus atoms of the diastereomers I–IV represent spin systems of the type A_2MX or ABMX (A, B = PMe, M = PPh, X = $PNEt_2$). A further isomer is formed in very small amounts. The isomer III ($^{31}P\{^1H\}$-NMR spin system A_2MX) can be precipitated and recovered in pure form from the CH_2Cl_2 solution of the crude product by addition of ether.

Table 1. $^{31}P\{^1H\}$-NMR data of the complexes **6a** and **6b** (δ(P) values relative to 85% H_3PO_4 ext.; labeling of the P-atoms as in formula **6a**).

IV	13.2	36.7	−24.1	180.0	−19	−34	223	113	−62	68

Treatment of **6a** in aqueous solution with an equimolar amount of KCN furnishes the monocyano cation **6b**, which can be precipitated as hexafluorophosphate with NH_4PF_6. The isomer IV ($^{31}P\{^1H\}$-NMR spin system ABMX) can be obtained in pure form by recrystallization from ethanol. According to an X-ray structure analysis this isomer of **6b**[5] contains a 14-membered ring system with the donor sequences P-C_2-P and P-C_3-P, which is folded along the P(2)-Ni-P(4) edge (Fig. 1). Ni is coordinated in a distorted trigonal-pyramidal fashion, with P(2) (=*P*NEt_2) and P(4) (=*P*Ph) in the axial positions. The $CN^\ominus$ ligand, P(1), and P(3) (= 2 × *P*Me) occupy the equatorial positions. Owing to steric interaction with the NEt_2 group on P(2), the $CN^\ominus$ ligand is not symmetrically arranged between P(1) and P(3). The P(3)–Ni–C(23) angle of 102.1(2)° is markedly smaller than the P(1)–Ni–C(23) angle (140.6(2)°); this is also constistent with the large Ni–P(3) distance (2.235(1) Å).

The $PNEt_2$ moiety in **6a** permits a variety of modifications of the macrocyclic ligand system. Thus, in **6a** (used as a mixture of the isomers II and III) the NEt_2 group

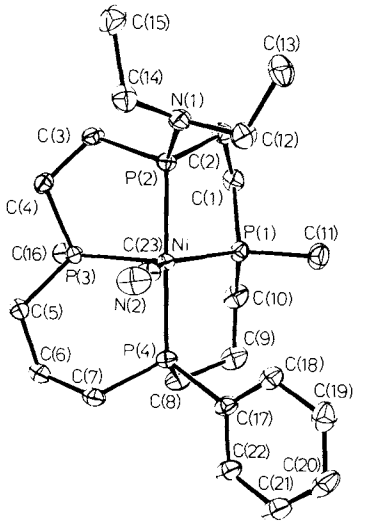

Fig. 1. Perspective view of the structure of the cation of **6b** in the crystal, without H atoms. Selected bond lengths [Å] and angles [°]: Ni-P(1) 2.173(2), Ni-P(2) 2.178(1), Ni-P(3) 2.235(1), Ni-P(4) 2.177(2), Ni-C(23) 1.910(5); P(2)-Ni-P(4) 178.87(6), P(1)-Ni-P(3) 117.17(6), P(1)-Ni-C(23) 140.6(2), P(3)-Ni-C(23) 102.1(2).

can be replaced by $Cl^\ominus$ by reaction with HCl, whereas with H_2S the NEt_2 group and the $Br^\ominus$ ligand are replaced by $HS^\ominus$. The macrocyclic phosphane ligand cannot be removed from **6a** with aqueous KCN in excess, even at elevated temperatures (80–100°C). By reaction with 10% H_2O_2, however, it is possible to convert **6a** via oxidative hydrolytic cleavage of the P–N bond into a phosphane oxide complex of the composition $Et_2NH_2[(C_{18}H_{31}P_4O_5)NiBr_2]\cdot 2H_2O$, from which the nickel can be extracted with ammonium sulfide or diacetyl dioxime.

Experimental

6a: [Bromo(4-diethylamino-1,7-dimethyl-11-phenyl-1,4,7,11-tetraphosphacyclotetradecane)nickel(II) bromide]: Solutions of $Et_2N-P(CH=CH_2)_2$ (3.53 g, 22.5 mmol) and **4** (11.36 g, 22.5 mmol) in CH_2Cl_2 (in each case 250 mL) were added dropwise at the same rate within 3h to 300 mL of CH_2Cl_2. The volume of the deep-red reaction mixture was reduced under vacuum (20°C, 0.2 mbar) to 20 mL and subsequently treated with 500 mL of ether. The brownish-yellow precipitate was filtered off and dried under vacuum (20°C, 0.02 mbar). Yield: 14.5 g (98%) of **6a** (correct elemental analyses).

Oriented Domains and Twins in the "Tetragonal" Superconductor $LaBa_2Cu_3O_{6.7}$

By *M. Hervieu,* B. Domengès, J. Provost, F. Deslandes, B. Raveau, B. Chevalier,* and *J. Etourneau*

A recent investigation of the system La-Ba-Cu-O allowed the oxide $LaBa_2Cu_3O_{6.7}$ to be isolated as superconductor with a critical temperature close to 70 K.[1] A preliminary X-ray diffraction study[2] has shown that the structure of this oxide is different from that of the superconductor $YBa_2Cu_3O_7$,[3–9] although closely related to it. Like $YBa_2Cu_3O_7$, $LaBa_2Cu_3O_{6.7}$ can be described as an ordered oxygen-deficient perovskite. Its structure differs from that of $YBa_2Cu_3O_7$ (Fig. 1) by its tetragonal symmetry

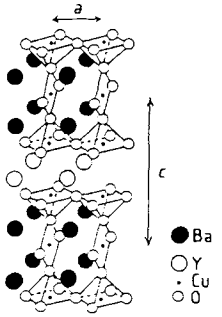

Fig. 1. Idealized representation of the structure of $YBa_2Cu_3O_7$.

involving at least a different ordering of the oxygen vacancies in the structure. Our recent high resolution electron microscopy studies[10, 13] showed that the orthorhombic superconductor $YBa_2Cu_3O_{7-x}$ is characterized by numerous twins and domains, closely related to the orthorhombic symmetry and to the orthorhombic-tetragonal phase transition. It was suggested that such domains could be correlated with the superconducting properties of this oxide. A different behavior should be expected for $LaBa_2Cu_3O_{6.7}$, owing to its tetragonal character. We report here on the results of a preliminary electron diffraction study of this oxide.

$LaBa_2Cu_3O_{6.7}$ was synthesized from $BaCO_3$, La_2O_3 and CuO as previously described.[1, 2] The sample is superconductive with midpoint resistive transition corresponding to $T_c = 70$ K. According to an X-ray structure analysis, the cell is tetragonal with $a = 3.895$ Å and $c = 11.727$ Å. The oxygen content was determined by microthermogravimetry (Setaram TAG24). The electron diffraction study was carried out with a Jeol 120 CX electron microscope fitted with a side entry eucentric goniometer ($\pm 60°$).

Most of the crystals show one or several boundaries which separate the crystals into very large domains (Fig. 2a). Most often, these domains are large enough to be characterized by selected area electron diffraction and medium resolution images, thus allowing the direction of the layer stacking ($\vec{c}$) to be displayed. The existence of two domains whose $\vec{c}$ axis are perpendicular are very often observed in the electron diffraction patterns (Fig. 2b). The weaker reflections are due to multiple diffraction phenom-

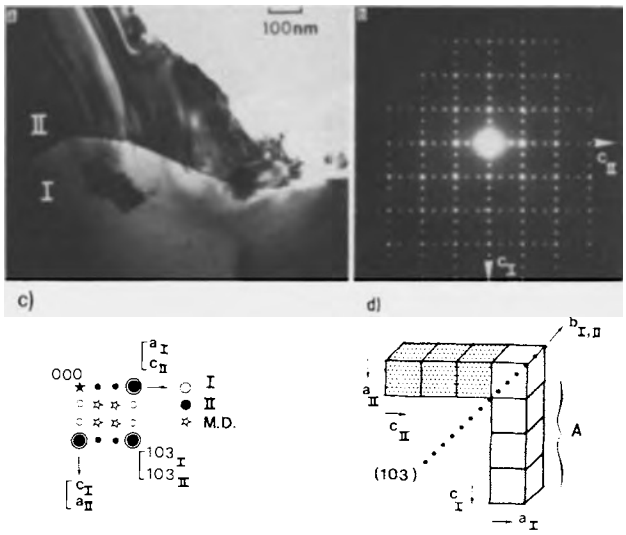

Fig. 2. a) Low-resolution electron micrographs of a crystal of $LaBa_2Cu_3O_{6.7}$; oriented domains are clearly visible. b) Electron diffraction pattern. c) Schematic representation of the electron diffraction patterns. M.D. = multiple diffraction. d) Relative orientations of the unit cells. A = Schematic cell built up from three perovskite units.

ena (Fig. 2c). Also, the [103]* direction deduced from the electron diffraction pattern is common to both domains. However, the corresponding low resolution image (Fig. 2a) shows that the boundary between the two domains does not correspond to a well-defined plane but wanders in the bulk. This type of oriented domains is labeled [103] owing to the role played by this family of planes (Fig. 2d). The same feature is illustrated in Figure 3, where a and b are the electron diffraction patterns of the domains I and II:

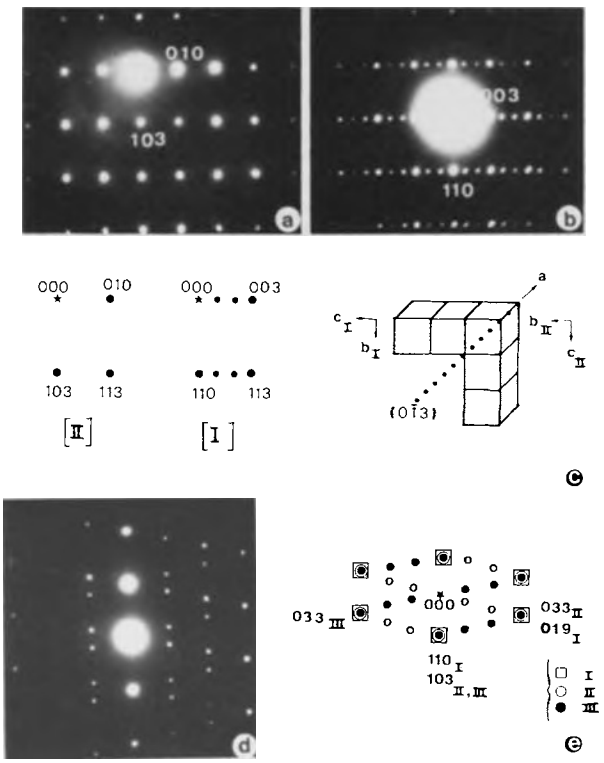

Fig. 3. a) and b) Electron diffraction patterns of domains II and I, respectively. c) Schematic drawings of the patterns (left) and the relative orientations of the unit cells (right). d) Intermediate electron diffraction pattern and e) schematic drawing.

$[1\bar{1}0]_I$ and $[30\bar{1}]_{II}$. The schematic representation (Fig. 3c) shows the equivalent roles played by $[(110)_I$ and $(103)_{II}]$ and $[(003)_I$ and $(010)_{II}]$; in this case, the plane $(0\bar{1}3)$ is common to both domains I and II. However, from the reconstruction of the reciprocal space, it appears that the phenomenon is more complex. Indeed, the intermediate electron diffraction pattern (Fig. 3d) and its schematic representation (Fig. 3e) show that three domains (I, II and III) coexist in the bulk, and it is clear that domains II and III share the (103) plane.

The relative orientations of the unit cells and common planes between the domains are drawn schematically in Figure 4b; the corresponding low resolution image (Fig. 4a) shows the three domains and their overlapping. For the

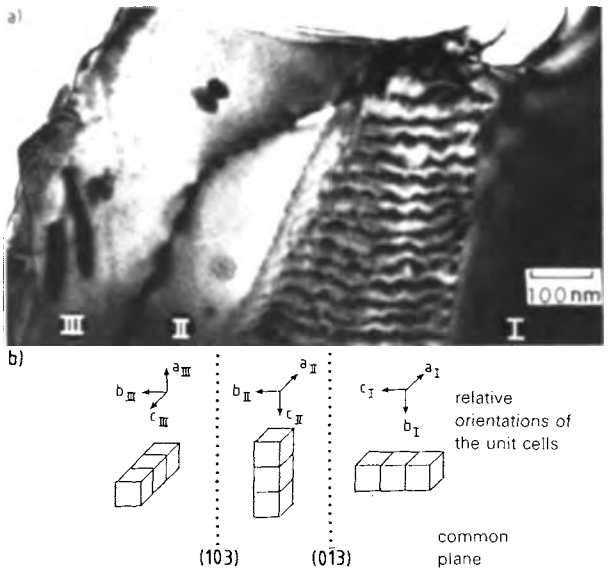

Fig. 4. a) Low-resolution electron micrograph of the crystal and b) relative orientation of the three unit cells.

particular orientation of the crystal providing the electron diffraction patterns in Figures 3a (i.e. $[30\bar{1}]_{II}$) and 3b (i.e. $[1\bar{1}0]_I$), the pattern corresponding to domain III is superimposed by the patterns of the other two domains. Such oriented domains can easily form, owing to the particular values of the parameter ratios $a/b(=1)$ and $c/3a$ (very close to 1). They correspond to the formation of a superstructure along the three perpendicular axes of the cubic perovskite subcell. This behavior is different from that observed for the superconductor $YBa_2Cu_3O_{7-x}$, for which the parameter ratios deviate significantly from 1.[3-9] However, such phenomena are often observed, especially in the oxygen-deficient perovskite[14-19] where they generally appear as localized domains.

A second group of domains has been encountered in a rather large number of crystals, which suggests that the corresponding crystals are, in fact, pseudo-tetragonal. These domains differ from those mentioned above in that they are distinctly smaller (a few 100 Å) and can thus be described as microdomains. Two types of behavior are observed: the microdomains are either stable or disappear upon slight heating by the electron beam. A large number of these domains are obviously microtwins, related to a distortion of the crystal cells; it is important to note that the amplitude of these distortions is variable and besides crystals exhibiting diffraction patterns with clearly visible splitting of the reflections (Fig. 5a) some show electron diffraction patterns and dark field images corresponding to very slight distortion of the unit cells (Fig. 5b, c). Some crystals are characterized by a more complex splitting of the reflections (Fig. 6a) in the electron diffraction patterns;

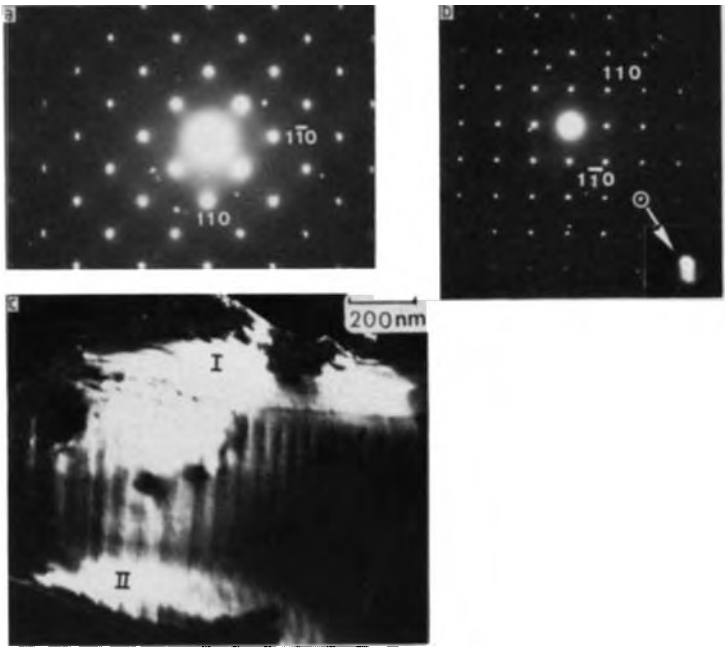

Fig. 5. a) Splitting of the reflections in the [001] pattern. b) Electron diffraction pattern along [001] and enlargement of the (220) reflection (bottom, right) of a slightly distorted crystal. c) Corresponding dark field image (domain I is not twinned).

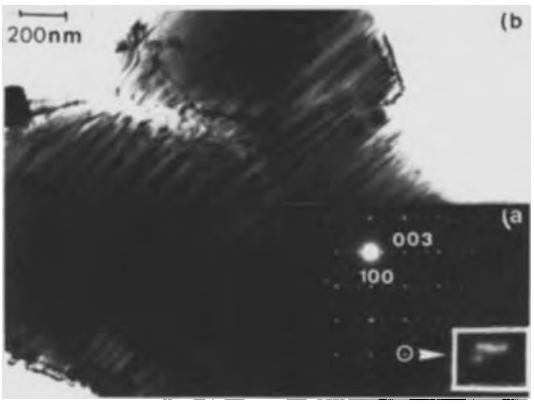

Fig. 6. a) Complex splitting of the reflections of a [010] pattern; the (303) reflection is enlarged. b) Low-resolution image.

the low resolution image (Fig. 6b) shows the corresponding microdomains and the slight misorientations observed between the different areas of the crystals; these "domains" vary upon slight heating by the electron beam. The nature of such domains is not quite clear; even if they remind one of the characteristic features of the superconductor $YBa_2Cu_3O_{7-x}$, it must be pointed out that they behave differently and that numerous distorted perovskites exhibit this type of twinning domains. Such distortions may indeed arise from local variations of the oxygen distribution (especially in the oxygen-deficient $BaO_{(1)}$ plane[2]) which

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0303-0441 $ 02.50/0

can lead to oriented domains and/or antiphase boundaries. High resolution electron microscopic investigations will help us elucidate these features.

Finally, numerous crystals exhibit both phenomena simultaneously (Fig. 5c); microtwins can then appear in only one of the crystal domains (domain II). Moreover, the microtwins are not observed anymore for the non-superconducting tetragonal phase $LaBa_2Cu_3O_{7-x}$, obtained from a different thermal treatment (quenched sample). This is to be compared with the absence of twinning domains for the tetragonal non-superconducting phase $YBa_2Cu_3O_{6.5}$[12, 20–23].

The preliminary electron microscopy investigations of the superconductor $LaBa_2Cu_3O_{6.7}$ thus show that this oxide is characterized, like $YBa_2Cu_3O_{7-x}$, by the presence of numerous domains, in spite of its apparent tetragonal symmetry deduced from X-ray observation. Indeed, it appears that two sorts of crystals exist in the bulk of the superconducting oxide $LaBa_2Cu_3O_{6.7}$: rigorous tetragonal crystals and distorted, presumably orthorhombic crystals which exhibit microtwins. This deviation from tetragonal symmetry observed for many crystals which could not be observed by X-ray powder diffraction is most informative: both phenomena—structural distortion and superconductivity—could be closely related.

Synthesis, Structure and Bonding of $[Cl_2Sn\{Rh(PMe_3)_3Cl\}_2]\cdot THF$, an Unusual Sn^{II}-Rh^{I} Adduct**

By *Dominic M. T. Chan** and *Todd B. Marder**

It has long been known that Group 8 transition metal complexes react with tin(II) halides to produce effective catalysts for hydrogenation, hydroformylation and isomerization.[1, 2] Although there has been intense interest in these systems, the exact nature of the active catalysts still remains uncertain. It is therefore of interest to examine possible geometries and bonding modes available to Sn^{II} adducts of group 8 metals.

Two recent studies of the reaction of $SnCl_2$ with *trans*-$[M(PR_3)_2(CO)Cl]$ complexes ($M=Ir$[3] and $M=Rh$[4]) in which unusual 1:1 (Ir:Sn) and 2:2 (Rh:Sn) adducts were obtained respectively and a study[5] of Ir^{I}_2–Pb^{II}- and I^{I}_2–Tl^{I}-adducts prompt us to report the syntheses and structural characterization of the first Lewis acid-base adducts involving one $SnCl_2$ and *two* L_3MCl units ($M=Rh$, Ir; $L=PMe_3$). In contrast to the previously reported Rh_2- and Ir_2-complexes[4, 5] in which the two Rh or Ir centers are constrained by a pair of bridging phosphane ligands, the adducts reported herein do not arise from any such constraints. We also discuss the bonding interactions between formal Sn^{II} and Rh^{I}, Ir^{II} centers in light of the observed structure of the Rh_2Sn adduct.

$SnCl_2$ reacts readily and cleanly with 2 equivalents of $[Rh(PMe_3)_3Cl]$, **1a**, at room temperature in THF to produce an intense purple solution. Evaporation of solvent results in an 89% yield of the diamagnetic complex $[Cl_2Sn\{Rh(PMe_3)_3Cl\}_2]$, **2a**,[6] as crystals which appear red by transmitted light and green by reflected light. Similarly, reaction of $SnCl_2$ with 2 equivalents of [Ir(cyclooctene)-$(PMe_3)_3Cl$][7], **1b**, gives a blue solution from which a 97% yield of $[Cl_2Sn\{Ir(PMe_3)_3Cl\}_2]$, **2b**,[6] was obtained [Eq. (a)].

$$2\,L_nMCl + SnCl_2 \longrightarrow [Cl_2Sn\{M(PMe_3)_3Cl\}_2] \qquad (a)$$

1a, $M=Rh$, $L_n=(PMe_3)_3$ **2a**, $M=Rh$
1b, $M=Ir$, $L_n=(C_8H_{14})(PMe_3)_3$ **2b**, $M=Ir$

A single-crystal X-ray diffraction study of the Sn–Rh adduct[8] confirms our structural assignment for **2a** (Fig. 1). The Rh_2SnCl_2 moiety adopts a highly distorted geometry, neither tetrahedral nor trigonal bipyramidal at tin, with essentially no interaction between the two rhodium atoms (d(Rh-Rh) = 5.1 Å). The P_3RhCl units are slightly pyramidalized with the Rh atom located 0.33 Å above the least square plane defined by the chlorine and phosphorus atoms.[9]

No adduct formation was observed between $SnCl_2$ and other complexes such as $[Rh(PPh_3)_3Cl]$[10] and

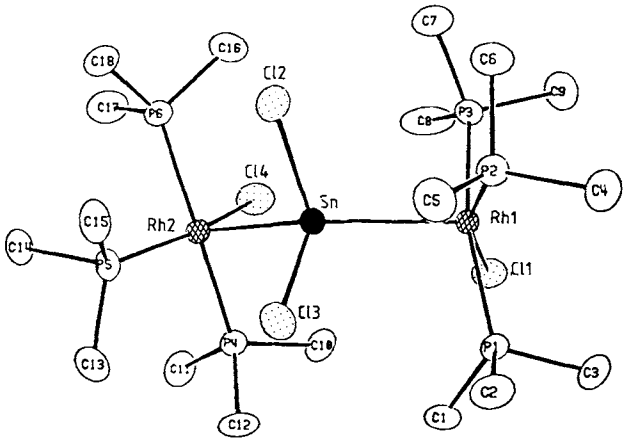

Fig. 1. Perspective drawing of the structure of $[Cl_2Sn\{Rh(PMe_3)_3Cl\}_2]$ in the crystal of **2a**. THF (thermal ellipsoids at the 30% probability level). The THF molecule and hydrogen atoms have been omitted for clarity. Selected distances [Å], Sn–Rh(1) = 2.712(1), Sn–Rh(2) = 2.721(1), Rh(1)–Cl(1) = 2.417(2), Rh(2)–Cl(4) = 2.420(2), Sn–Cl(2) = 2.557(2), Sn–Cl(3) = 2.543(2), and angles [°], Rh(1)–Sn–Rh(2) = 142.52(3), Cl(2)–Sn–Cl(3) = 92.28(9), P(1)–Rh(1)–Sn = 100.81(6), Cl(1)–Rh(1)–P(2) = 159.04(9).

$[Ir(PEt_3)_3Cl]$.[7] Reaction of Sn^{II}-halides with a ligated d^8 metal halide often result in the insertion of Sn^{II} into the metal-halide bond to produce a trihalogentin complex[4, 10] [Eq. (b)]. Formation of simple Rh_2–Sn and Ir_2–Sn adducts is apparently unique to the trimethylphosphane ligand system.[11] Thus, both high electron density and lack of steric hindrance around the metal center are essential for successful complexation.

$$L_nMX + SnX_2 \longrightarrow [L_nM{-}SnX_3] \qquad (b)$$
$M = Rh^{I}, Ir^{I}, Pt^{II}$; X = Cl, Br

The bonding between Rh and Sn in **2a** requires some comment. A valence bond approach yields two extreme models for the Rh–Sn interactions. Thus, the Rh^0 units each possess filled dz^2 orbitals capable of σ-donation to an empty p orbital on Sn^{II}. This would result in Sn having ten valence electrons; a TBP structure involving a linear Rh–Sn–Rh arrangement and an equatorial lone pair on Sn might be expected. However, the Cl–Sn–Cl and Rh–Sn–Rh angles (92.28° and 142.6° respectively) combined with the pyramidization at Rh are not consistent with this simple model. The other extreme would involve sp^3 hybridization at Sn producing two orbitals with a total of two electrons which could be used to form an electron deficient 2e,3c bonding arrangement with the symmetry adapted linear combinations of the two vacant Rh $5p_z$ orbitals. This would lead to a tetrahedral geometry at Sn with an Rh–Sn–Rh angle near 109°. Clearly, neither model suffices to explain the novel structure for **2a**. The bonding picture is most likely intermediate between the two extremes, i.e. some degree of participation of both filled Th $4d_{z^2}$ and empty Rh $5p_z$ orbitals. Preliminary results of molecular orbital calculations combined with a careful examination of the structural models outlined above suggest that the extreme cases may be precluded by severe steric interactions. The extreme oxygen sensitivity of **2a**, **b** indicates their electron-rich nature (i.e. high-lying HOMO) and the absorption spectra[6] indicate a low-lying allowed electronic transition. Further synthetic studies and molecular orbital calculations (extended Hückel and SCF-Xα) are underway to elucidate the bonding, spectra and reactivity of the novel complexes.

Organoselenium and Organotellurium Chemistry in an Up-Current

Organic compounds containing selenium and tellurium have been known since the middle of last century, but because they have been found to be mostly evil-smelling and toxic, and often obtainable in pure form only with difficulty, they have been relegated to the small print of the textbooks. Only during the last two decades have organoselenium compounds, like modern organometallic transition metal reagents, established themselves as important tools in organic synthesis. Modern organoselenium chemistry began around 1973/1974, at the same time as the publication of two basic monographs by *Klayman* and *Günther* (Wiley, 1973) and *Zingaro* and *Cooper* (Van Nostrand Reinhold, 1974), and also of the standard work on organotellurium chemistry by *Irgolic* (Gordon and Breach, 1974). The volumes reviewed here, namely

Selenium Reagents and Intermediates in Organic Synthesis. By *C. Paulmier*. Pergamon Press, Oxford 1986. xiii, 463 pp., paperback, $ 30.00.—ISBN 0-08-032485-1

The Chemistry of Organic Selenium and Tellurium Compounds, Vol. 1. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester 1986. xiv, 939 pp., bound, £ 150.00.—ISBN 0-471-90425-2

Organoselenium Chemistry. Edited by *D. Liotta*. Wiley, Chichester 1987. ix, 422 pp., bound, $ 62.25.—ISBN 0-471-88867-2

are evidence of the much increased interest in organoselenium and organotellurium reagents that has arisen during the past 15 years. The main reason for this is summarized by *Sir Derek Barton* in his preface to *Paulmier*'s book: although organoselenium reagents are in general more costly and more toxic than the corresponding sulfur compounds, they react under much milder conditions. For example, selenolate ions are better nucleophiles, and can be more easily introduced by substitution reactions; selenenyl chlorides are easier to handle and react more effectively with enolates. Mild reaction conditions are especially important in reactions of unsaturated molecules with various functional groups, e.g. in natural products chemistry. Some organoselenium reagents also fulfil the needs which arise nowadays with regard to chemo-, regio- and stereoselectivity.

The decrease in bonding strength in the series S—Se—Te leads to reduced stability in certain selenium and tellurium compounds, e.g. those with small rings, or molecules with C=Se or C=Te bonds. However, it is exactly this behavior which is often useful in organic synthesis, as shown, for example, by the ease of the RSe/Li exchange in selenoacetals, or in epoxide ring opening followed by spontaneous loss of selenium or tellurium.

The book by *Paulmier* is aimed at preparative organic chemists. The book, written in a fluent style, begins with a short outline describing classes of compounds, commercially available selenium reagents, and the *inorganic selenium reagents* of greatest importance for organic chemists. The preparation and reactions of organoselenium functional groups are described in Chapters II to VI. I especially like the treatment of their reactive properties, e.g. the sections on *syn* elimination (p. 132 onwards), and on the 2,3-sigmatropic rearrangements of allylic selenium oxides (p. 143 onwards). Equally useful are the systematically organized chapters on addition reactions (VII), addition reactions with cyclization (VIII), oxidation reactions (XII), and reduction reactions (XIII), the latter including special reactions using elemental selenium, alkali metal selenolates and COSe. The chemistry of selenium substituted carbocations is outlined briefly, and Chapter IX is devoted to carbanions; the main features of selenocarbonyl chemistry are also clearly presented.

As the title of the book indicates, *Paulmier* is mainly concerned with synthetic aspects, and limits the discussions about structure, bonding and spectroscopic data to what is essential. This leads to a pleasingly concise treatment, which after covering the serious business of the book still leaves room for a more relaxed chapter (XIV) on special structures, natural products and biologically active compounds. In this chapter *Paulmier* also describes examples of syntheses to illustrate the methodology of organoselenium chemistry.

Literature references, which are mainly to work published in the period 1974–1984, are included with each chapter, and there are useful author and key word indexes. Although the book has been prepared by photoreproduction of the original typescript, the text (supported by clear structural formula diagrams and reaction schemes) is easy to read—it is well worth buying!

Volume 1 of the two-volume work "The Chemistry of Organic Selenium and Tellurium Compounds", edited by *Patai* and *Rappoport*, is not in competition with *Paulmier*'s book, as it is totally different in concept. Following the general pattern of this series "The Chemistry of Functional Groups", the 18 chapters by recognized experts deal with the topics in greater depth. This has resulted in a comprehensive compilation of material in which some of the individual chapters are monographs in themselves. Following the guidelines laid down by the editors, most of the authors have concentrated on the latest developments rather than aiming at completeness. However, two particularly comprehensive articles are the one of nearly 100 pages on structural chemistry by *I. Hargittai* and *B. Rozsondai*, which may serve as a Se/Te sequel to *Hargittai*'s book on the structures of volatile sulfur compounds, and that of more than 170 pages on complexes with Se and Te ligands, by *H. J. Gysling*, which is superbly compiled, and is a mine of information for inorganic chemists. Other highlights are contributions on NMR and ESR spectroscopy, mass spectrometry, analysis, heterocycles, and directing and activating effects. The articles on functional groups with Se and Te in various oxidation states (*N. Sonada* and *A. Ogawa*) and on derivatives of Se and Te with valencies of four or more (*J. Bergmann, L. Engman*, and *J. Sidén*) include synthetic applications, but the complete treatment of synthetic methods and applications is not due to appear until the publication of Volume 2[*]. The two volumes together will certainly constitute an indispensable, but unfortunately

[*] Volume 2 appeared late in 1987:
The Chemistry of Organic Selenium and Tellurium Compounds. Vol. 2. Edited by *S. Patai*. Wiley, Chichester 1987. xiv, 864 pp., bound, £ 140.00.—ISBN 0-471-91020-1

very expensive, handbook on organoselenium and organotellurium chemistry. It is to be welcomed, since this subject has not been covered in "Comprehensive Organometallic Chemistry". It is an advantage to have selenium and tellurium chemistry treated together, with frequent comparisons of structure and reactivity in the S—Se—Te series. This helps the reader to understand the basic trends and relationships in Main Group VI, and contributes to the systematization of our knowledge.

Liotta's "Organoselenium Chemistry", which is likewise published by Wiley, consists of nine review articles, dealing with the electrophilic, nucleophilic and free radical reactions of organoselenium compounds, their oxidation reactions, and the chemistry of selenium-containing carbanions and organic conductors. These specialized aspects of selenium chemistry are very well described (e.g. in the article by *H. J. Reich* on selenoacetals, carbanions and sigmatropic rearrangements). However, the book as a whole is by no means an alternative to Volume I of the *Patai* series, especially as the excellent contributions by *T. G. Back* on electrophilic and free radical reactions, and by *F. S. Guziec* on selenocarbonyls, in the book edited by *Liotta*, are to be followed by articles from the same authors in Volume 2 of *Patai/Rappoport*[*].

Fachbereich Chemie
der Universität Oldenburg (FRG)

Tin in Organic Synthesis. By *M. Pereyre, J.-P. Quintard,* and *A. Rahm.* Butterworths, London 1986. 342 pp., bound, £ 50.00.—ISBN 0-408-01435-0

This book, containing 17 chapters, is divided into four parts: Part I is an introduction, containing two chapters. Part II concerns the reduction of various functional groups with tin hydrides, each of five chapters treating a different functional group. Part III covers the synthetic applications, including chapters on the cleavage of tin-carbon bonds by various reagents, transmetallation reactions (primarily for the synthesis of organolithium reagents) and the coupling reactions of organotin reagents in the formation of carbon-carbon bonds. Part IV covers syntheses involving tin-heteroatom bonds in seven chapters. The references are collected at the end of each part (rather than at the end of each chapter). There is an excellent compilation of references on organotin chemistry. Unfortunately the references cover only through 1984 (with a few 1985 references) so there is a two year gap between writing and publication at a time when the field was undergoing an explosive development. A few noteworthy books and references on the synthesis of tin compounds have not been listed in the references for Part I. With these exceptions, the references are quite inclusive.

All areas of tin reagents in organic synthesis have good coverage, with the possible exception of the synthesis of certain organostannanes in Part I. For example, the reaction of tin amides with monosubstituted acetylenes to yield tin acetylides and the mild, palladium catalyzed reaction of hexaalkylditins with vinyl and aryl halides to yield vinyl- and arylstannanes are omitted. Perhaps too much coverage was given to desulfurization reactions of xanthates with tin hydrides and on the benzylation, acylation and alkylation of sugars. The discussion of radical cyclization reactions in Chapter 3 could have been made more coherent and presented more clearly by utilizing the framework of Baldwin's rules.

In most of the book the chemistry is easy to follow. In some chapters, however, the material is not as logically organized as it could be, and this leads to a somewhat disjointed presentation. In some places the equations are not adequately explained and consequently are not readily understood. In many cases, results from the literature are given without comment or a critical evaluation of the results; occasionally the equation for an unusual reaction is presented without comment or speculation as to the mechanism. To include this kind of commentary, however, is a formidable task, so it is understandable that the authors chose not to do so. In other chapters, the chemistry becomes repetitive such that it possibly would have been better to include tables rather than going through example after example, each with an equation and verbal explanation.

There are relatively few mistakes and inconsistencies, most of which will be apparent to organic chemists.

Overall, I highly recommend this book both for those involved in organotin chemistry and in general organic chemistry. It not only serves as an excellent text for introducing organotin chemistry, but also is an excellent reference source. It is the only book of its kind available.

Fine Chemicals for the Electronics Industry. By *P. Bamfield.* The Royal Society of Chemistry, London 1986. v, 247 pp., bound, £ 27.50.—ISBN 0-85186-636-0

This book contains 14 papers presented at a specialist symposium in April 1986, and provides a good insight into the manufacture of chemicals for high-technology applications. Although each of the papers relates to a specialist topic, the combined effect provides an excellent and nearly up-to-date picture of this fascinating branch of materials science. In addition to the more conventional materials such as luminescent substances, the topics covered include newer ones such as optical fibers, ceramics and semiconductors, including materials used in solar energy conversion. It is pleasing that the materials discussed include not only inorganic, but also organometallic and organic substances. The interaction between manufacturing technology and the requirements to be met for different applications (including those concerning purity) comes out very clearly. It would have been helpful to have a little more information under the topic "Sampling and Analysis", including the techniques and their limitations, e.g. limits of detection. The chemistry involved in the applications is explained more effectively than the chemical manufacturing processes, owing to the more informative diagrams provided in the former case.

Nearly every contribution illustrates the complexity of the materials problems nowadays encountered in the area of advanced technology. In almost every case one is concerned with high value products which are used only in relatively small quantities. Some discussion of the international competitive situation, and of the availability of raw materials, would have been useful, but would have gone beyond the scope of the report.

A clear impression emerges that much of this high-technology business still relies to a very large extent on providing tailormade systems designed on an empirical basis for specific applications. Many such areas are still at a development stage, and one cannot yet predict the final out-

come. How quickly the state of knowledge can change in these areas is strikingly illustrated by the topic "Superconducting Materials", where already now, only a year and a half after the symposium, a new era has begun. It is also clearly evident that here, more than in most other areas of knowledge, there is a close interaction between materials science research, development and production, which calls for much interdisciplinary work. Just as the papers from this symposium deal with levels of purity which were inconceivable 20 years ago, so one might envisage that the next 20 years will see the development of a materials scene altered beyond recognition from that of today.

Organosilicon Chemistry. By *S. Pawlenko*. W. de Gruyter, Berlin 1986. xi, 186 pp., bound, DM 180.00.—ISBN 3-11-010329-X

According to the preface the aim of this monograph is to give an account of the organic chemistry of silicon for industrial and academic chemists. A brief glance through the list of contents reveals straight away that the book is not much concerned with the uses of organosilicon compounds for organic synthesis, as one might have assumed from its title. Instead there is a strong emphasis on systems containing a silicon-heteroatom bond, with the remaining silicon valences being usually occupied by alkyl or aryl groups, which, of course, can therefore be regarded as organic compounds. Nevertheless, the majority of the reactions described belong more to inorganic than to organic chemistry, even though organic chemists will find them of interest and may occasionally use them.

The first short chapter (12 pages) introduces the reader to the bonding properties of silicon. However, the discussion of the Si-C bond does not include the simple but useful rules as formulated by *Fleming*, which make it easier to understand the chemistry of organosilicon compounds. The industrial production of the basic chemicals concerned is touched upon only briefly, in Chapter 2. The main part of the book (Chapter 3, approx. 90 pages) deals with the preparation and properties of more specialized organosilicon compounds. A considerable amount of information is collected here on compounds of silicon with nearly all the other elements of the Periodic Table. It is, of course, very useful to have a review of the most important results in this field, but it is questionable whether boiling points (with pressures given both in Pa and in mm Hg), melting points, and in some cases details of the preparative procedure, should also be included in a comparatively slim book such as this.

Chapter 4 is devoted to the uses of organosilicon compounds in industry, organic synthesis, and medicine. The synthetic uses of silicon-containing precursors are dealt with in about 15 pages, with in addition a few of the most important reactions being described in the previous chapter. This compression of the topic made it especially important to choose representative examples carefully, so as to illustrate the principles, but such a choice has regrettably not been achieved. The activation (and deblocking) of organosilicon compounds by flouride ions receives practically no attention. The particular affinity of silicon towards fluorine is not mentioned, and in equation 4.29 the essential tetrabutylammonium fluoride is omitted. Again, the discussion of Lewis acid induced reactions fails to point out the general principles involved. The author classifies silyl enol ethers as *protected* carbonyl compounds, despite the importance of their activation for selective reactions with electrophilic reagents, which is in fact described in some of the examples. It is astonishing that none of *Mukaiyama*'s work is cited, and that other pioneers in this field (*Reetz, Fleming, Magnus, Paquette* ...) are ignored or barely mentioned. The index entry Peterson olefination does not appear at all.

The final chapter on analytical methods is again very informative, but on the whole the impression remains that it is scarcely possible in about 150 pages to effectively cover such a large field as organosilicon chemistry has now become. Anyone whose main need is for information on applications to organic synthesis will not get his money's worth from this book. For that purpose there are better and less expensive alternatives (the price of about DM 1.— per page is at a level seldom reached by other publishers).

Multiphoton-Ionization-Mass Spectrometry (MUPI-MS)**

New Analytical Methods (34)

By Jürgen Grotemeyer* and Edward W. Schlag

Mass spectrometry is one of the most important analytical tools in chemistry, biology, medicine and related areas. During the past 30 years, methods have been developed, both for the qualitative as well as the quantitative analysis of a wide variety of substances. The introduction of lasers into chemistry has also profited mass spectrometry, since its nonlinear properties and its tunability open up fundamentally new frontiers. Multiphoton ionization mass spectrometry combines UV-spectroscopy and mass spectrometry, thus providing a two-dimensional method that enables substance-specific and even state-specific analyses. This progress report presents the fundamentals and possibilities of MUPI mass spectrometry and discusses investigations on amino acids, peptides, chlorophylls and sugars. For each substance, multiphoton ionization can be tuned in such a way that only the molecular ion is formed. An increase of laser intensity induces substance-specific fragmentations of the molecule, thus contributing to a quick and easy identification of the substance.

1. Introduction

Analytical tasks, i.e., the identification of a substance and the elucidation of its structure, have always been the chief concern of mass spectrometry. On the one hand, a compound can be identified via its molecular ion, which leads to the exact determination of the molecular weight and thus to the elemental composition and the empirical formula of the molecule, while on the other, a fragmentation of the molecule giving a specific fragmentation pattern is also important for identification and structure elucidation.[1]

Informative mass spectra are only to be expected, however, if the four principal technical prerequisites of mass spectrometry are met with:

- The substance under investigation must either be evaporated as an intact neutral molecule and ionized later or must be vaporized and ionized in one step.
- Evaporation and ionization should be soft enough to ensure that the signal of the molecular ion is detectable with adequate intensity. However, the signals of substance-specific fragmentation should also be observable.
- The ions produced must be separated according to mass with the highest possible accuracy.
- Finally, these ions must be detected without any discrimination due to their absolute mass.

[**] A number of abbreviations exist for photon ionization. All terms like MPI, REMPI, R2PI or REMPI/F describe a two-photon excitation leading to ionization. For *multiphoton ionization* we prefer to use the generic term MUPI, because, as described in this paper, three-, four- or multiphoton ionizations via resonant intermediate states as well as nonresonant absorptions can lead to ionization.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0104-00447 $ 02.50/0

During the past decade, several techniques have been developed that can fulfill these demands, at least in part, and the mass range for routine investigations has been increased from some 100 Da to some 1000 Da. The driving force thereby has been the ever increasing need to analyze larger molecules, especially in biochemical investigations.

In this progress report it will be demonstrated that the use of a laser light source for "optical ionization" is a new, generally useful ionization method in mass spectrometry. Coupling mass spectrometry with the tunable laser ionization results in a two-dimensional analytical method that gives absorption spectroscopic as well as mass spectrometric data. This technique is somewhat equivalent to other well known two-dimensional methods such as the coupling of mass spectrometry with gas chromatography (GC/MS),[2] with liquid chromatography (LC/MS),[3] or even with mass spectrometry itself (MS/MS).[4]

2. Fundamentals

The methods that have been developed in the last few years for investigating involatile and large molecules[*] by mass spectrometric techniques are often only applicable to special problems. Of general use are the so-called *particle impact* methods that utilize atomic particles to desorb ions from a matrix into the gas phase: secondary ion mass spectrometry (SIMS),[5] fast atom bombardment (FAB),[6] ^{252}Cf-plasma desorption (^{252}Cf-PD),[7] and laser desorption (LD).[8] In addition, direct chemical ionization (DCI)[9] and field desorption (FD)[10] are employed for the investigation of large molecules.

Although these methods differ widely in their technical details they have one principal feature in common: The desorption and the ionization are coupled directly.[11] A steering of the ionization process, and thus of the degree of fragmentation, is therefore impossible. In general, the molecular ion is not detectable, but several adduct ions are found which stem from the addition of protons and/or alkali cations to the molecule. Often, there is also an ionization of the matrix molecules, which leads to a considerable amount of non-substance-specific ions and thereby to further complications in the interpretation of the mass spectrum. To achieve a tunable ionization, the evaporation and ionization must be carried out stepwise.

In a MUPI experiment the substance is first vaporized by some method (see Section 2.2), then the molecules are ionized in the gas phase with laser light and finally mass analyzed. Such a two-step process aims at much higher ion yields and is more flexible than one-step direct ionization.

2.1. Multiphoton Ionization

A molecule that undergoes multiphoton ionization becomes a radical cation. Radical cations also result from all conventional impact ionization methods such as electron impact ionization (EI), ionization via charge exchange (CE), and one-photon ionization (PI).[*] Hence, MUPI must be compared with these methods.

Tunable multiphoton ionization was first used by *Boesl* et al.[12] and *Zandee* et al.[13] in 1978, and since then has been discussed in several reviews.[14–17]

In the conventional ionization methods, an energy that is higher than the ionization energy is supplied to the molecule in *one* step, so that fragmentations occur as well as ionization, whereas in MUPI the energy of a single photon is lower than the ionization energy (Fig. 1). The wavelength of the photon is tuned to the energy difference between the ground state and an excited state of the neutral molecule. For ionization, a multiple absorption of photons in the molecule has to take place to accumulate the necessary energy.

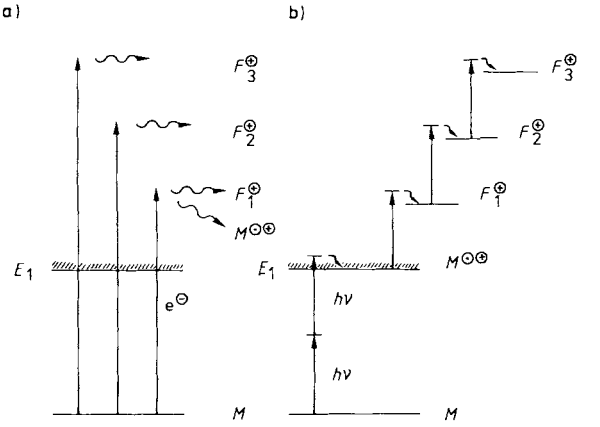

Fig. 1. The difference between a) electron impact ionization (EI) and b) multiphoton ionization (MUPI). E_1 = first ionization energy, $F_1^{\oplus}$, $F_2^{\oplus}$, $F_3^{\oplus}$ = fragmentation ions. Other than in EI, in MUPI the molecular ions are formed with a narrow energy distribution and little excess energy.

In general, the absorption of photons into a molecule is a process of low efficiency. If, however, the wavelength of the absorbed photons just corresponds to the energy difference between the molecular ground state and an excited molecular state, the efficiency of the absorption process is increased by several orders of magnitude (resonance enhancement),[18,19] particularly if the wavelength of the photon corresponds to a maximum in the electronic spectrum of the molecule.

In the most simple case, the absorption of two UV-photons leads to ionization of the molecule. But a three- or four-photon ionization is also possible (2b, c).[20,22] A multiphoton ionization with photons of different wavelength (Fig. 2d) can also be realized. Figure 2e shows the special case of a nonresonant two-photon ionization. This process needs much higher laser intensities than the resonance-enhanced excitation.

MUPI succeeds in state selective formation of molecular ions. As demonstrated by several molecules,[22] MUPI leads to molecular ions that populate a well defined vibrational level, predominantly the vibrational ground state.

[*] The classification of the molecules discussed in this report into small (<300 Da), middle sized (300–1000 Da), and large (>1000 Da) molecules is arbitrary.

[*] In general, SI-, FAB-, CI-, ^{252}PD- and LD-mass spectrometry produce adduct ions containing the molecule and a proton and/or an alkali cation.

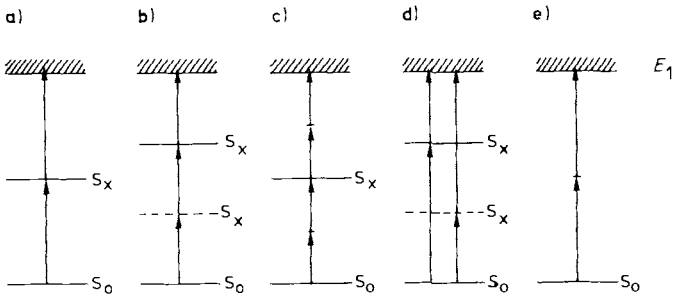

Fig. 2. Some features of multiphoton ionization (MUPI). S_x indicates "allowed" intermediate state, mostly the S_1 state. But the usage of higher states is also possible. a) "Normal" resonant two-photon ionization. b) Resonant three-photon ionization via two intermediate states. c) Four-photon ionization via one intermediate state. d) Resonant two-photon ionization with photons of different wavelength. e) Nonresonant two-photon ionization.

The excess of energy supplied in the ionization step is removed as kinetic energy by the electron leaving the molecule, so the molecular ions have equal or only slightly different energies (Fig. 1). In contrast, in the case of EI the excess energy remains in the ions; this leads to a wide energy distribution, reflecting the energy distribution of the impact electrons. With increasing laser intensity, absorption of photons by the molecular ions induces fragmentation reactions. Several mechanisms have been put forward[23-27] to explain these fragmentations. Generally accepted is the "ladder switching model", which is supported by experimental findings[28] and theoretical studies.[29] As shown in Figure 1, the neutral molecule absorbs two photons on its "absorption ladder" and is ionized. Here the internal energy is only slightly higher than the ionization energy. The molecular ion then absorbs one or several photons, thereby starting the first fragmentation reaction. The system then switches from the molecular absorption ladder to a fragment ion, which can absorb further photons on *its* absorption ladder, inducing further fragmentation reactions. This absorption-fragmentation mechanism may occur several times during typical laser pulses of 6-10 ns and, with sufficient laser densities, result in a total breakdown of the molecule into the atomic particles.

Because of the narrow energy distribution in the molecular ions in MUPI experiments, the absorption-fragmentation mechanism leads to an increased amount of metastable ions.[30, 75, 87] This aspect is of importance in energetic and dynamic investigations of elementary reactions in the gas phase (see Section 3).

2.1.1. *Soft Ionization*

The absorption yield is clearly dependent on the intensity of the laser light. By keeping the intensity low, e.g. 10^6 W/cm^2, the absorption of photons can be limited to form exclusively molecular ions. In Figure 3a, this is demonstrated with the example of *p*-xylene. Since an absorption of photons by the molecular ions is almost impossible at this low laser light intensity, no fragmentation takes place. This possibility of inducing fragmentations in a controlled way is unique in mass spectrometry. Even for large molecules the ionization can be tuned to form only molecular ions.

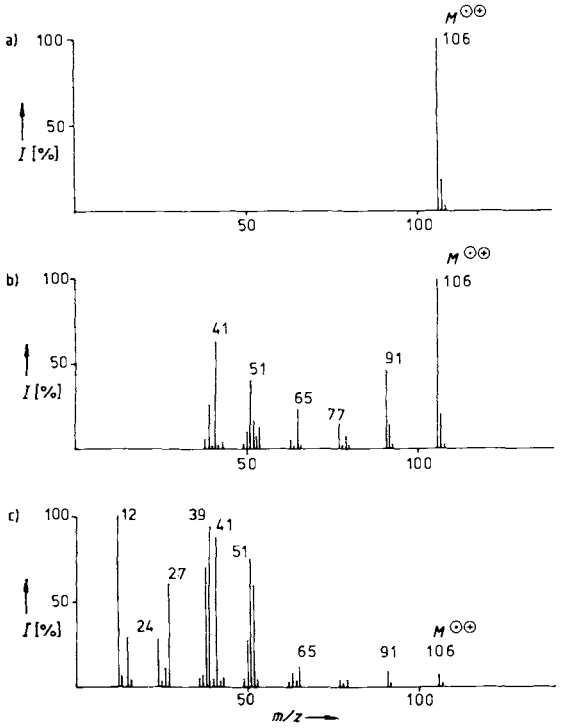

Fig. 3. MUPI-mass spectra of *p*-xylene. a) Soft ionization without fragmentation of the molecular ion, laser intensity about 10^6 W cm^{-2}. b) Partially hard ionization of *p*-xylene with little fragmentation, laser intensity about 10^7 W cm^{-2}. c) Very hard ionization with strong fragmentation, laser intensity about 10^9 W cm^{-2}. I = relative intensity. Excitation wavelength $\lambda = 272$ nm.

2.1.2. *Hard Ionization*

Increasing the laser intensity leads to an additional absorption of photons by the molecular ion, which then undergoes the energetically and kinetically most favored fragmentation. Such a moderate ionization/fragmentation is referred to as "partially hard ionization". For the mass spectrum in Figure 3b, the density of the photons was adjusted to a level that allowed observation of both the signals of the molecular ion as well as of those of the products of the first fragmentation, e.g. m/z 91.

Tuning to higher laser light intensities induces further fragmentations, and, depending on the photon density, the system can switch fragmentation ladders until a decomposition of the molecule into its atomic particles occurs. Figure 3c demonstrates this. Here the fragmentation has advanced to the formation of atomic carbon. This means that the *p*-xylene molecular ion must have absorbed about nine photons of wavelength 272 nm. No other mass spectrometric ionization method can accumulate such a high energy in a molecule. The advantages from the analytical viewpoint, of this possibility of controlling the amount of fragmentation by tuning the laser light intensity are demonstrated in Section 3.

2.1.3. *Wavelength Selectivity*

In multiphoton ionization, not only the intensity but also the wavelength of the light can be varied. The absorption maximum of a molecule and thus the position of the

resonant intermediate state are intrinsic properties of the molecule and therefore substance specific. This is of great importance for the investigation of mixtures, since the component that has an intermediate state in resonance with the wavelength used is preferably ionized; therefore it is possible to detect traces in a mixture with increased sensitivity. Thus, in blood serum, for example, several metals and organometallic compounds can be measured quantitatively in concentrations of about 1 ng per 1 mL serum.[31] Thereby, both the electronic spectrum, measured for one substance-specific mass, as well as the mass spectrum of the substance, measured at a fixed wavelength, can serve for the identification of the components. This method of analysis has been used very successfully,[32-37] both on mixtures of several substances as well as mixtures of structural isomers.[38]

One example of a selective excitation from a mixture is shown in Figure 4.[39] Here a sample of *p*-xylene with natural isotopic composition ($^{12}C_8H_{10}/^{13}C^{12}C_7H_{10}$: 100/8.8%) was investigated. Recording a mass selected optical absorption spectrum of *p*-xylene (*m/z* 106) and the ^{13}C-isotopomer (*m/z* 107) yields absorption lines of the resonant intermediate state shown on the left-hand side of Figure 4. It can be seen that the positions of the absorption maxima of the two molecules differ slightly.

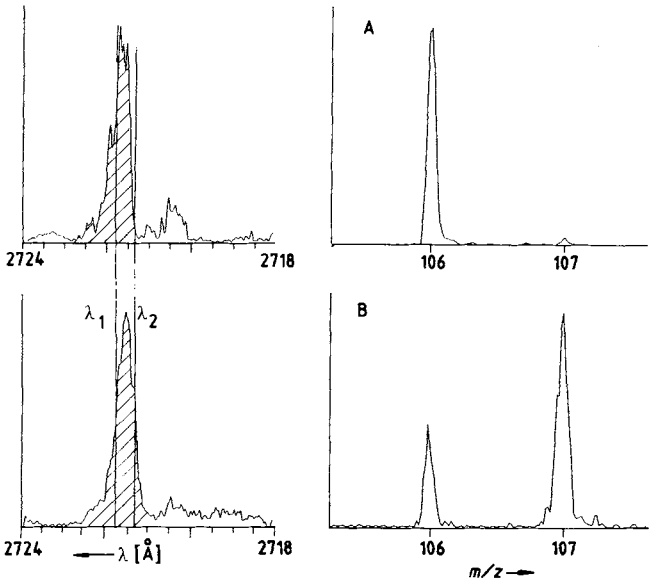

Fig. 4. Left-hand side: mass selective absorption spectrum of *p*-xylene; top: spectrum of the species *m/z* 106; bottom: spectrum of the species *m/z* 107. Normally, the intensity ratio in the mass spectrum of *p*-xylene is *m/z* 106 : *m/z* 107 = 100 : 8.8. As the mass spectra show (right), this ratio is drastically influenced (100 : 0.5 in A; 50 : 100 in B) by the choice of the excitation energy for the MUPI-experiment (λ_1 for A, λ_2 for B).

By choosing the appropriate wavelength from these absorption spectra, the signal of the mono-^{13}C-xylene molecular ion in the mass spectrum can be either amplified or suppressed (Fig. 4, right).

The improvement of the mass spectrum of a substance present in only trace amounts in a mixture is a possibility which only multiphoton ionization can offer.

2.2. Vaporization of Molecules

The gas-phase UV/VIS absorption spectra of polyatomic molecules at room temperature normally show broad and unstructured bands, since a large number of vibrational and rotational states are populated. To investigate molecules with MUPI-mass spectrometry, their thermal excitation should be as low as possible, so that the broad absorption bands become sharp peaks and a selective excitation is possible. Cooling can be achieved by isentropic expansion of a jet of noble gas into the vacuum. Small amounts of the sample under investigation, which must have a sufficiently high vapor pressure, are mixed into the gaseous stream.[40-42]

In typical "seeded supersonic beam expansion" experiments, a gaseous mixture of argon and the sample is allowed to lead from a reservoir through a nozzle of diameter 100–500 μm. The temperature obtainable thereby is about 2 K for the translational degrees of freedom, and 20 K and 50 K respectively for the rotational and vibrational degrees of freedom.[39] This method of injection resembles that of a GC/MS coupling. The reservoir can easily be replaced by a gas chromatograph or a HPLC instrument. Several authors have described a GC/MS coupling under the conditions of supersonic beam expansion and multiphoton ionization.[43-46] *Johnston* et al. have recently reported the coupling of liquid chromatography with MUPI-mass spectrometry.[47] But these methods, using MUPI, are still in the development stage.

Chromatography with supercritical gases, which has found increasing interest during the past few years, is especially suitable for use with MUPI, since highly pressurized gases are used as solvents. In the expansion step, the separation of these gases from the sample is very easy and no clustering with the sample molecules occurs, a problem that is often encountered in liquid chromatography experiments. Up to now, only molecules smaller than 250 Da have been investigated with this method.[50,51]

In an other approach, the thermospray method[52,53] was modified by *Levy* et al.[54] to vaporize involatile samples such as tryptophan as neutral molecules.

All these injection methods are well suited for the separation of mixtures and the evaporation of small, thermally stable molecules, but they cannot be used for the investigation of large, thermally labile molecules. The methods developed for such compounds aim to evaporate and ionize the molecules in one step. But in these methods more neutral molecules are desorbed than there are ions produced. Thus, investigations by *Cotter* et al.[55] have shown that in laser desorption with an IR-laser, the yield of neutral molecules is much larger than the ion yield, as has also been found to be the case by *Budzikiewicz* et al.[56] and *Campana* et al.[57] for the FAB-method. Typical values for the ratio of neutral molecules to ions is about $10^4 : 1$ in laser desorption experiments.[55] Theoretical studies have been undertaken in an attempt to clarify the processes of desorption,[11,58] but many details still remain unexplained.

To make use of the large ratio of neutral molecules to ions we have utilized since 1983 a tandem arrangement of *l*aser *e*vaporation of *i*ntact neutral *m*olecules (LEIM) into a supersonic beam followed by multiphoton ionization.[59,60]

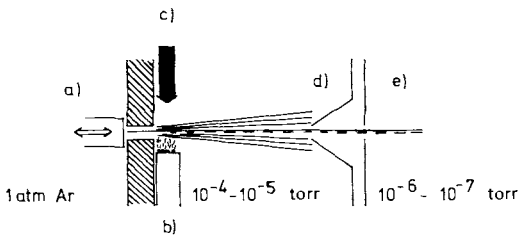

Fig. 5. Typical experimental set-up for the laser desorption into a supersonic beam. a) Pulsed valve with nozzle; b) probe tip mounted in the vacuum in front of the nozzle; c) beam of laser light (produced by a CO_2-IR-laser); d) skimmer; e) ion source.

In a typical LEIM-MUPI experiment (Fig. 5) the sample is dissolved in a suitable solvent, the solution placed on a probe tip, and the solvent evaporated. The probe tip is thus coated with hundreds to thousands of layers of molecules, and is now mounted in the vacuum close to the nozzle for the supersonic beam. The molecules are then desorbed from the surface by IR-photons into the expanding supersonic beam. As described above, the desorbed particles are cooled in their internal degrees of freedom and at the same time transported into the ion source. The pulsed system of this experiment consists of a pulsed valve for the production of the supersonic beam and a small CO_2-laser for the desorption of the neutral molecules.

2.3. Mass Spectrometric Detection

In principle, the ions produced by pulsed MUPI can be analyzed with any type of mass spectrometer. However, instruments that were developed for a continuous cyclic scanning of the mass range, such as magnetic sector instruments, are much less suitable for coupling with MUPI than quadrupole instruments, ICR-spectrometers,[*] and time-of-flight mass spectrometers.

2.3.1. *Quadrupole and ICR-Mass Spectrometry*

In the first studies[12,61,62] concerning the mass spectrometric investigation of ions produced by MUPI, quadrupole instruments were used for the mass separation. Quadrupole instruments are often chosen in GC/MS coupling, because they are easy to handle and have a rapid scanning cycle. However, due to their limited mass range, about 2000 Dalton, and their low mass resolving power,[**] their suitability for coupling with MUPI is somewhat limited. Also the ion transmission of quadrupole fields is not very high.

The coupling of ICR-mass spectrometry with MUPI has also been described.[63-65] It offers the advantage of high mass resolution,[66] but up to now the mass range is still limited to about 4000 Dalton. For technical reasons, the production of ions should be very low in ICR-experiments.[67] But MUPI produces, even with low laser intensities, considerable ion yields, so that the coupling of this ionization method with an ICR-instrument is still complicated. There might be some possibilities in the future, when ICR-mass spectrometry can be operated with high mass resolving power and *simultaneous* recording of the complete mass spectrum.

2.3.2. *Time-of-Flight Mass Spectrometry*

The mass spectrometric method that really takes advantage of the pulsed nature of ion production by MUPI, is the technique of *time-of-flight* (TOF) mass spectrometry.[68] TOF mass spectrometers are simple instruments with extremely high transmission. As opposed to all other mass spectrometers, in these systems a complete mass spectrum is recorded with every laser pulse. The fundamental parts of a TOF mass spectrometer are the ion source, the drift region (flight tube), and the detecting system. On coupling with an EI-ion source, a mass resolving power of only 200-400 could be achieved because of the broad kinetic energy distribution of the ions generated. This low resolution is the reason for TOF mass spectrometers having seldom been used, despite being known for more than 40 years.

Because of the development of pulsed ion sources like SIMS[69] or plasma desorption[70] (but also because of MUPI[39]), the interest in TOF mass spectrometers has grown during the last few years. By using a two-step acceleration field (*Wiley-McLaren*[71]) and multiphoton ionization, a mass resolving power of 400 was reached in a linear TOF mass spectrometer for the *simultaneous* detection of all masses.[72]

Several attempts[72] to increase the mass resolution in TOF instruments have been made, but with limited success. The most promising attempt was made by *Mamyrin* et al.[74] using an electrostatic field that reflects the ion beam at the end of the drift section. This reflecting field not only lengthens the flight distance, but is also able to compensate for most of the differences in the kinetic energy of ions of one nominal mass and thereby the differences in the flight time (Fig. 6). In our experiment, the ions produced by MUPI are accelerated by a constant field of about 800 V and then drift through a length of 80 cm. At the end of this field-free drift region, the mass separated ion packets are slowed down by a short deceleration field and reflected with only low energy in the following reflec-

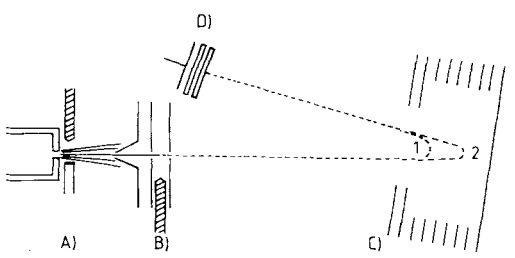

Fig. 6. Schematic representation of the time-of-flight mass spectrometer. 1) Flight path of ions with low kinetic energy; 2) flight path of ions with the same mass but higher kinetic energy. A) Evaporation chamber; B) beam of ionizing laser light; C) reflecting field; D) detector.

[*] ICR = Ion Cyclotron Resonance.

[**] Mass resolving power means the ability to distinguish between two neighboring masses. The signals of two masses are resolved when they are separated by a "valley"; two definitions are usual in mass spectrometry, "10% valley" and "50% valley". In this report the "50% valley" definition is always used. For example a mass resolving power of 1000 separates the masses 500.00 and 500.50.

tor field. After leaving the reflector and deceleration field, the ions fly through the drift region in the opposite direction till they impinge on the detector.

Ions with higher kinetic energy penetrate deeper into the reflector field and therefore have a somewhat longer flight path than ions with lower kinetic energy. As a consequence the differences in the flight time of ions of the same mass are compensated, simultaneously, for all masses. In 1982, *Boesl* et al.[75] succeeded in combining the multiphoton ion source with a reflection time-of-flight (RETOF) mass spectrometer. In these first experiments, a mass resolving power of 3800 could already be reached. *Lubman* et al.[76] and *El-Sayed* et al.[77] have also reported a coupling of MUPI with a reflection TOF instrument, but with different experimental results.

By optimizing the parameters, considerably higher mass resolutions are possible. In particular, it could be shown that the grids used in a classical RETOF-mass spectrometer to define the electrostatical fields lead to a dispersion of the ions and thereby affect the transmission and the mass resolving power. In contrast a gridless ion mirror allows a clean reflection of the ion beam and is autofocussing. *Boesl* et al. succeeded in increasing the mass resolving power to more than 10000[39,78-80] by incorporating a supersonic beam to cool the neutral molecules in their translational degrees of freedom, shortening the laser pulse from 5–8 ns down to 1.5 ns, and lowering the laser intensity. Even further enhancement seems to be possible. Theoretical values of 100000 up to 1000000 have been discussed for the mass resolving power in a RETOF-mass spectrometer.[80]

In the mean time, the reflecting electrostatical field method has also been used in combination with other ionization techniques (SIMS; 1985[81] and ^{252}Cf-PD; 1987[82]).

The advantages of time-of-flight mass spectrometers compared to other mass spectrometers are manifold: first, this technique offers an almost unlimited mass range; with every laser pulse a complete mass spectrum is detected. A registration of up to 100 mass spectra per second is possible; this number is limited only by the capacity of the computer. Today, the mass resolving power and transmission of RETOF instruments are already better than in the case of quadrupole or small magnetic sector instruments.[83] Moreover, time-of-flight mass spectrometry has one physical feature that is unique in comparison to other techniques: the mass resolving power increases with increasing mass. The detection of metastable ions[75] (especially important for MS/MS investigations) is also possible because of the incorporation of the reflecting field.

The location of the evaporation is confined to only a few μm, which is especially important for the investigation of surfaces. The time window of the sampling is limited by the laser pulse to a few ns. Due to the high repetition rate 10–100 spectra can be measured for a signal lasting one second, e.g. from a gas chromatograph.

3. Mass Spectra

MUPI-mass spectrometry was for a long time only used for kinetic investigations of the fragmentation processes of small molecules in the gas phase.[84] It is well suited for this purpose, not only because of the very sharply defined energy for the ionization and fragmentation of molecules, but also because reactions of metastable ions can be investigated.

Since 1983, however, MUPI has found increasing application as a general method of mass spectrometry for the investigation of organic and biochemical samples. A number of examples of such investigations will be outlined in the following sections.

3.1. Small Molecules

Small arenes, such as benzene,[85] alkylbenzenes,[86-88] halogen-substituted aromatic compounds,[89] aromatic amines,[90,91] phenol[92] and aromatic aldehydes,[93] as well as organometallic compounds and several di- and triatomic compounds have been investigated in detail with the help of MUPI. In the main, these experiments were aimed at elucidating the physical processes of ionization by multiphoton excitation or details of certain fragmentation reactions. Interesting reviews of such investigations are to be found in articles by *El-Sayed*[16] and *Neusser*.[84] All the measured samples were volatile and their introduction into the ion source was simple. In this report, we shall concern ourselves with some mass spectra of small, biochemically interesting substances that are either thermally labile or involatile. Amino acids, with their variety of polar, hydrophilic, and hydrophobic residues, are good models in this respect.

The EI mass spectra of free amino acids have been well documented.[94-97] In most cases, the signal for the molecular ion is either small or not detectable at all. Figure 7

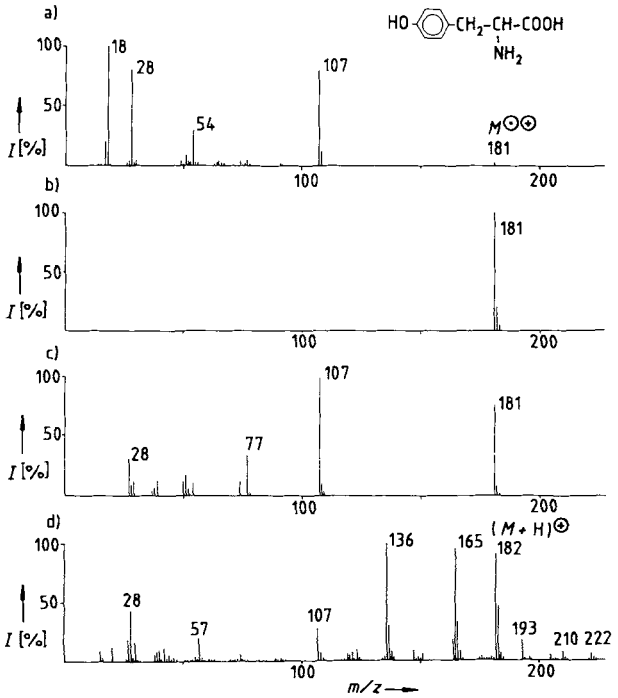

Fig. 7. Comparison of mass spectra of L-tyrosine. a) EI-mass spectrum; note the intensity of the molecular ion signal at m/z 181. b) Soft MUPI-mass spectrum; exclusively the molecular ion is formed. c) Mass spectrum after partially hard MUPI; ionization wavelength $\lambda = 272$ nm. d) CI-(methane)-mass spectrum, corrected for the methane background.

shows two MUPI mass spectra of the amino acid L-tyrosine obtained after laser evaporation, and, for comparison, an EI spectrum and a CI spectrum. The advantages of MUPI are obvious. In the spectrum obtained after soft MUPI (Fig. 7b), the molecular ion signal is the base peak, whereas in the EI spectrum (Fig. 7a), the relative intensity of this signal is only 5%. After background correction, the CI mass spectrum (Fig. 7d) affords the signal of the H-adduct molecular ion with relatively high intensity, but the identification of this ion is clearly complicated by the appearance of the signals of larger adduct ions. Increasing the intensity of the laser light (partially hard ionization) gives rise to the spectrum shown in Figure 7c. Despite pronounced fragmentation, the molecular ion signal is still remarkably intense. It has been shown[98] from the mass spectra of the amino acids that the fragmentation pathways remain virtually unchanged upon tuning the ionization wavelength by up to 40 nm, but the relative intensities of these fragmentations might change drastically. This behavior can be attributed to the different absorption cross sections of the fragmentations. Extreme changes in the relative intensities are observed, for example, in the case of tryptophan.[99]

In the case of aromatic amino acids, the wavelength used for the ionization normally corresponds to an absorption in the aromatic ring system. But the amino acid arginine has no chromophoric group absorbing above 250 nm. Therefore, in this case only a nonresonant absorption can occur (see also Section 2.1). Arginine is known to be particularly thermolabile and neither an EI-spectrum nor a CI-mass spectrum has been published up to now. Field desorption methods give a mass spectrum, but only the protonated molecular ion is detectable.[100] In the MUPI mass spectrum (Fig. 8), the signal of the molecular ion of arginine has been measured for the first time. This ion is of special interest, because arginine is extremely polar and is one of the strongest organic acids.

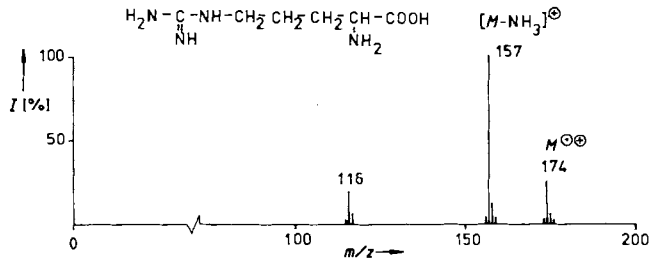

Fig. 8. Mass spectrum of L-arginine after nonresonant MUPI. Ionization wavelength $\lambda = 250$ nm.

Of the amino acid derivatives the phenylhydantoins[101] have already been investigated by MUPI-spectrometry.[98, 102] It was possible to detect less than subfemtogram amounts of these compounds in the gas phase.[102] Some phenylhydantoins, however, proved to be impossible to detect by way of the molecular ion. In contrast, we were able to show[98] that, by optimal tuning of the wavelength, the ionization can be achieved softly enough to obtain exclusively molecular ions.

Lubman et al.[103] also reported that the molecular ion was not always detectable in the investigation of dipeptides containing aromatic amino acids. As example, we shall discuss here phenylalanyl-tyrosine (Fig. 9). According to *Lubman* et al.,[103] the mass spectrum shows only a

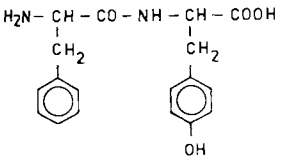

Fig. 9. The dipeptide phenylalanyl-tyrosine.

signal stemming from the loss of an hydroxy radical from the molecule. This fragmentation seems to be an artifact of the special experimental setup of the evaporation and ionization and can easily be avoided. Figure 10 shows the mass spectra of this compound obtained by soft and by partially hard MUPI under various experimental conditions.[104, 105] In the soft ionization spectrum, only the signal of the molecular ion is detected. With increasing laser light intensity, a number of fragmentations occur. The important fragments have *m/z* 236 and *m/z* 208. They correspond to the formation of an acylium ion (*m/z* 236) on rupture of the peptide bond and a further loss of CO from this ion (*m/z* 208). The cleavage of the peptide bond was found to be the favored fragmentation in more than 50 investigated dipeptides.[104–106]

Figure 11 shows a mass spectrum of saccharose that was obtained by nonresonant multiphoton ionization. Saccharose is a classical example for compounds that do not give molecular ions upon electron impact ionization. There

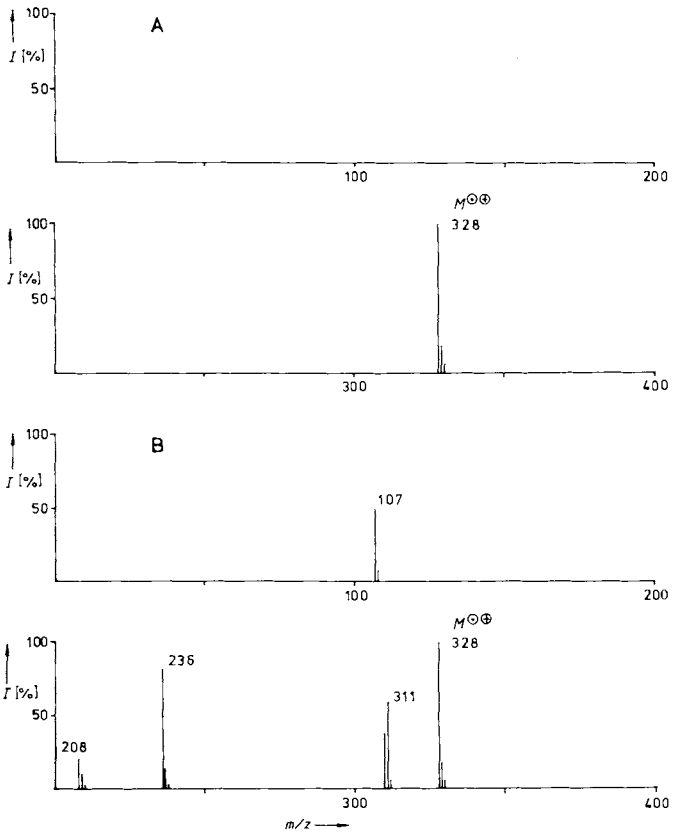

Fig. 10. Comparison of the mass spectra of phenylalanyl-tyrosine obtained by soft (A) and the partially hard (B) MUPI. Ionization wavelength $\lambda = 272$ nm. The signal in B at *m/z* 209 stems from the formation of the X[1] fragment (see Fig. 13).

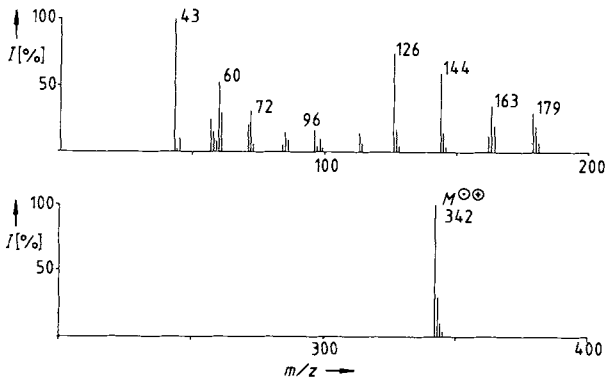

Fig. 11. Mass spectrum of saccharose after partially hard, nonresonant MUPI. Ionization wavelength $\lambda = 252$ nm. The signal at m/z 43 stems from an acylium ion.

have been controversial discussions in the literature[107] on whether molecular ions of sugars actually exist under EI or FD conditions. On the other hand, under MUPI conditions the molecular ion of saccharose is clearly detectable.[108]

The fragmentation reactions of saccharose (Fig. 12) are well known from pyrolysis-FI mass spectra.[109] The main fragmentation is the rupture of the glycosidic bond followed by the successive lost of water molecules.

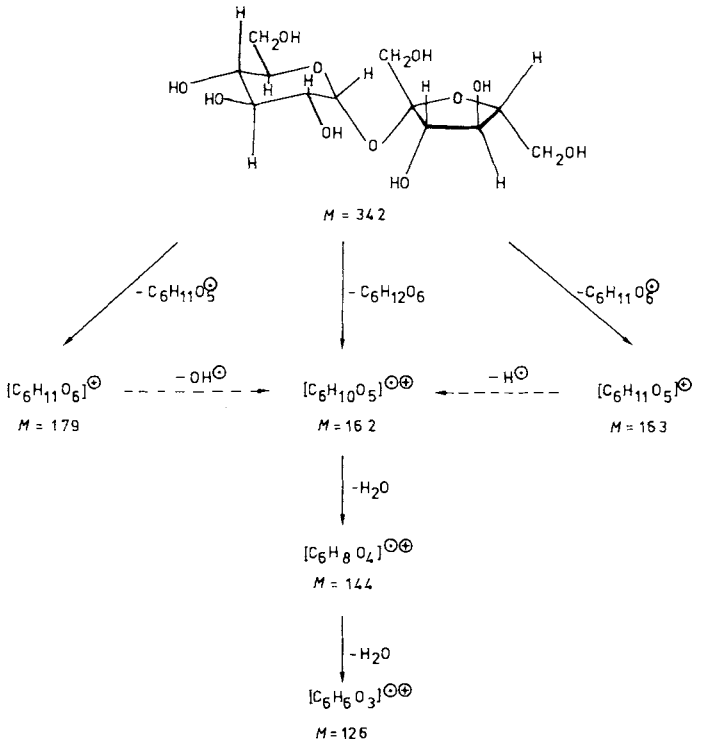

Fig. 12. Fragmentation scheme of saccharose. Some of the decomposition paths have been confirmed by the occurrence of metastable ions.

Further biochemically important small molecules whose MUPI-mass spectra have been obtained include steroids,[104, 107, 110] catecholamines,[111] neuroleptic drugs and vitamins,[112, 113] and purine bases.[114]

3.2. Middle Sized Molecules

The MUPI-mass spectra of several protected tripeptides have also been recorded[115] and compared with EI-spectra.[116] In the mass spectra obtained under partially hard ionization conditions the rupture of the peptide bond is again dominating. Complete series of the A and B fragments are detected (Fig. 13). The nomenclature of the

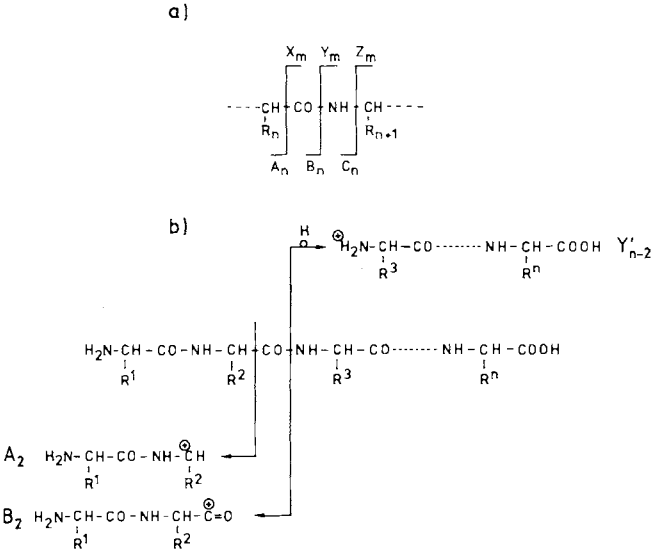

Fig. 13. a) Principal fragmentations of a peptide backbone and the nomenclature of the fragments (*Roepstorff* et al. [117]). The products of proton migrations are labeled, e.g., as A'_n, A''_n, or A'''_n indicating the number of protons isomerized prior to the fragmentation. b) Main fragmentations of peptides that have been observed in MUPI-mass spectra.

acylium ions (B) and the acyliminium ions (A) follows the concept of *Roepstorff* and *Fohlman*.[117] Besides the A and B fragments containing the *N*-terminal end of the peptide chain, also fragments of the Y′-series (Fig. 13) are detectable. These fragment ions contain the *C*-terminal end of the peptide.

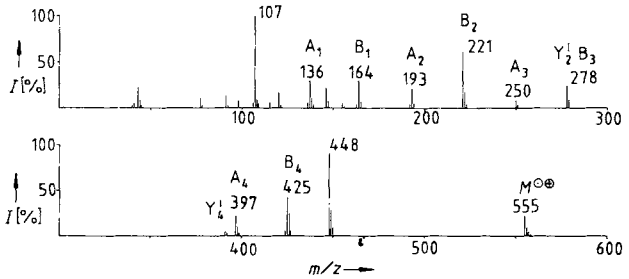

Fig. 14. Mass spectrum of Leu-enkephalin after partially hard MUPI. Ionization wavelength $\lambda = 272$ nm.

Figure 14 shows the mass spectrum of leucine-enkephalin, an unprotected pentapeptide,[118] after partially hard multiphoton ionization; the molecular ion is clearly recognizable. Other intense signals are those of the fragment ions originating from rupture of the peptide chain (Fig. 15). Signals indicating fragmentations in the side chains are only of minor intensity, as is characteristic for MUPI. Once again, besides the complete series of A and B frag-

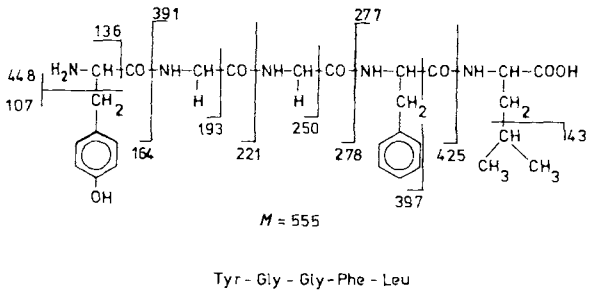

Fig. 15. Structure and fragmentations of Leu-enkephalin.

ments, the signals of some Y′ ions (Fig. 13) are also observed. It should be mentioned here that these complementary fragments are necessary in order to unequivocally prove the sequence of a peptide.

Various smaller peptides, such as pentagastrin,[119] the "sleep inducing peptide" (SLP)[106] and others,[120] have been successfully analyzed by MUPI-mass spectrometry. The favored fragmentation reaction in all cases is the cleavage of the peptide bond.

The spectra of other classes of compounds, for example of erythromycin, have also been recorded.[106] The molecular ions are always formed with high efficiency, and substance-specific ions can be detected without any protection of the molecule prior to the measurements. MUPI enabled the first successful mass spectrometric detection of porphyrins[121] and natural chlorophylls[122] without protecting groups. Natural chlorophyll and its derivatives could be detected in a biological sample containing about 30 different substances, including, inter alia, lipids and glycosides. Figure 16 shows the EI- and MUPI-mass spectra of this sample. It can clearly be seen that the wavelength selectivity of MUPI (Section 2.3.1) enables a separation of the

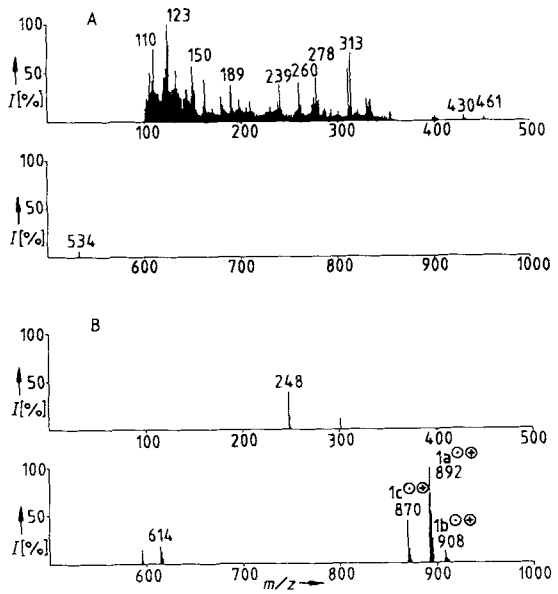

Fig. 16. Comparison of the EI- (A) and MUPI- (B) mass spectra of a biological sample from *Spirulina geitlerie*. In the EI-spectrum, ions of masses below *m/z* 100 are not shown. The ionization wavelength was $\lambda = 281$ nm in the MUPI-mass spectrum. Identifiable are the following molecular ions: *m/z* 870 = pheophytin a; *m/z* 892 = chlorophyll a; *m/z* 908 = 10-hydroxychlorophyll a.

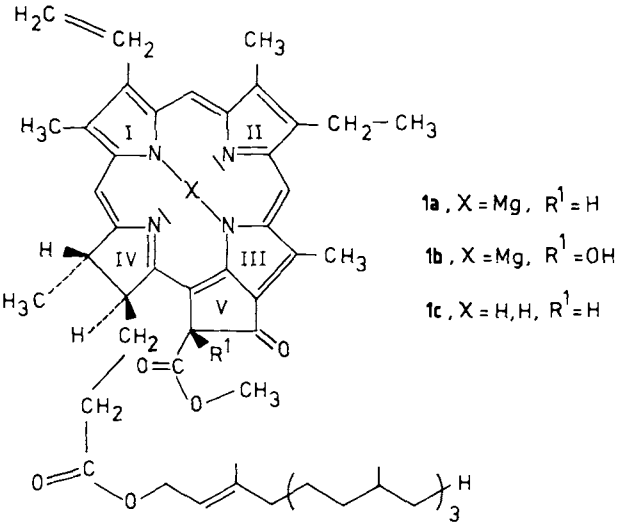

Fig. 17. Structures of the chlorophylls **1a-c** detected mass spectrometrically in a sample of *Spirulina geitlerie*.

substances, and three different chlorophyll derivatives (Fig. 17) can easily be identified. These are pheophytin a (**1c**) at mass *m/z* 870, 10-hydroxychlorophyll a (**1b**) at mass *m/z* 908, and chlorophyll a (**1a**) at mass *m/z* 892.

3.3. Large Molecules

Very informative mass spectra can also be obtained by MUPI combined with LEIM in the mass range above 1000 Da, which hitherto was reserved to SIMS, the FAB method, or plasma desorption. Thus, it could be shown that a soft ionization and controlled fragmentation of the unprotected decapeptide angiotensin I (Fig. 18) is possible by multiphoton excitation.[123] Figure 19 shows the mass spectrum of this compound obtained after partially hard ionization. Fragmentations close to the peptide bonds lead to intense signals; the complete series of A and B fragments are clearly recognizable, and once again the important signals of the Y′ ions containing the C-terminus are also detected. As was found in the smaller peptide chains, fragmentations in the amino acid side chains are only of minor importance.

Figure 21 enables a comparison of the results of peptide investigations with the FAB-MS/MS-method[4, 124] using collisional activation and MUPI-mass spectrometry. The FAB-MS/MS experiment on substance P (Fig. 20) was carried out with a triple sector instrument (*Biemann* et al.[125]). The protonated molecule was mass separated from the fragment ions in the first stage and then fragmentations were induced by collisional activation. By this method predominantly sequence ions of the A series are formed. The signals of the ions of the B series are only of minor intensity. Ions containing the C-terminus are not detectable. In addition, a large number of signals are observed that cannot be definitely assigned (Fig. 21a).

In contrast, the MUPI-mass spectrum (Fig. 21b) of this compound shows signals for all ions of the A series and B series with good intensities. Signals stemming from side-chain fragmentations are of minor significance. As in all of

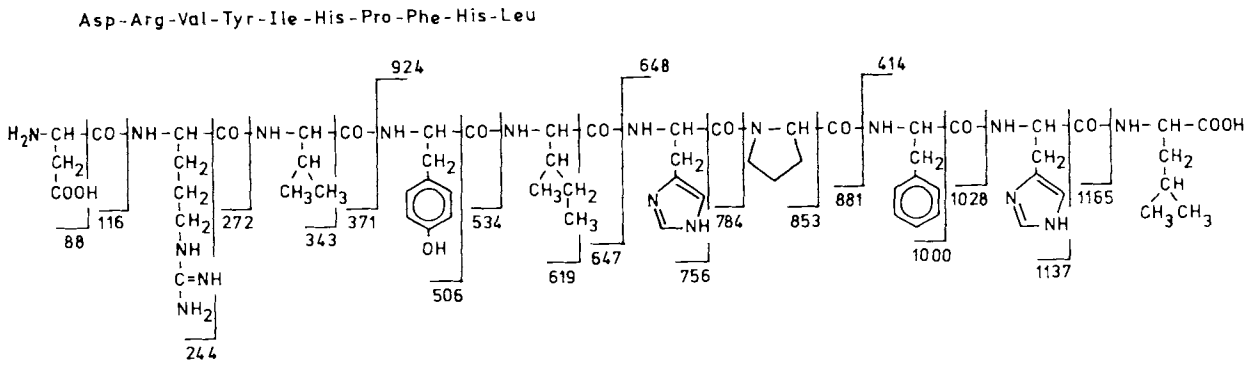

Fig. 18. Structure and fragmentations of angiotensin I (M = 1295).

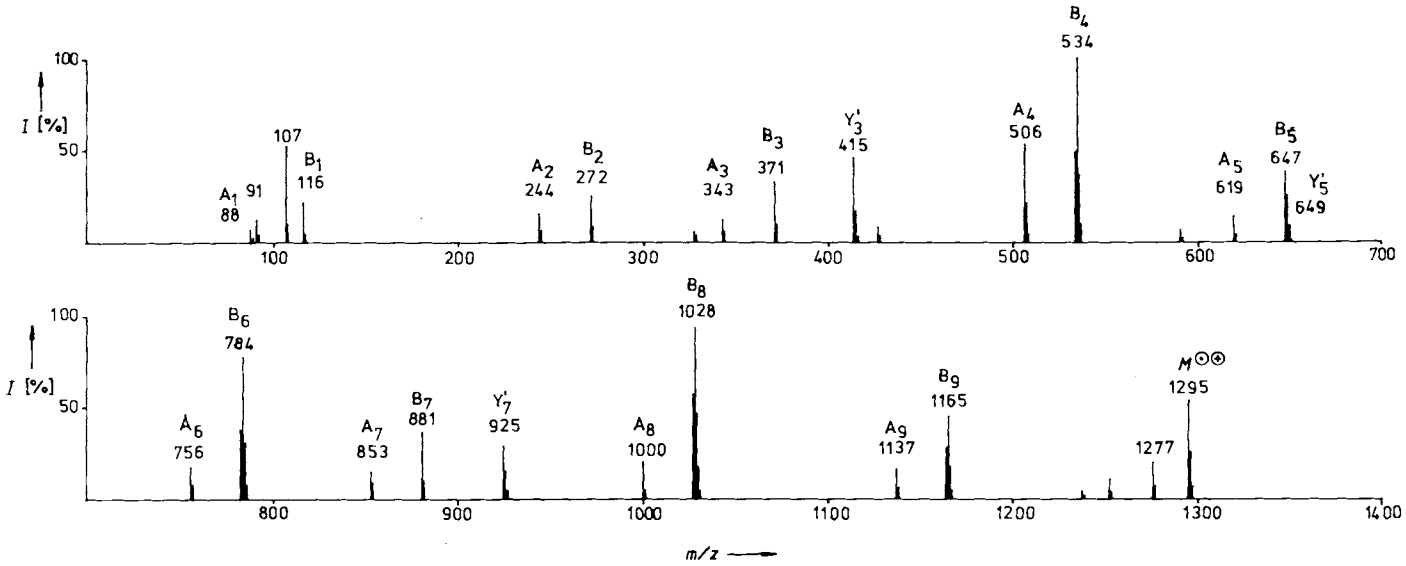

Fig. 19. Mass spectrum of angiotensin I after partially hard MUPI. Ionization wavelength $\lambda = 272$ nm.

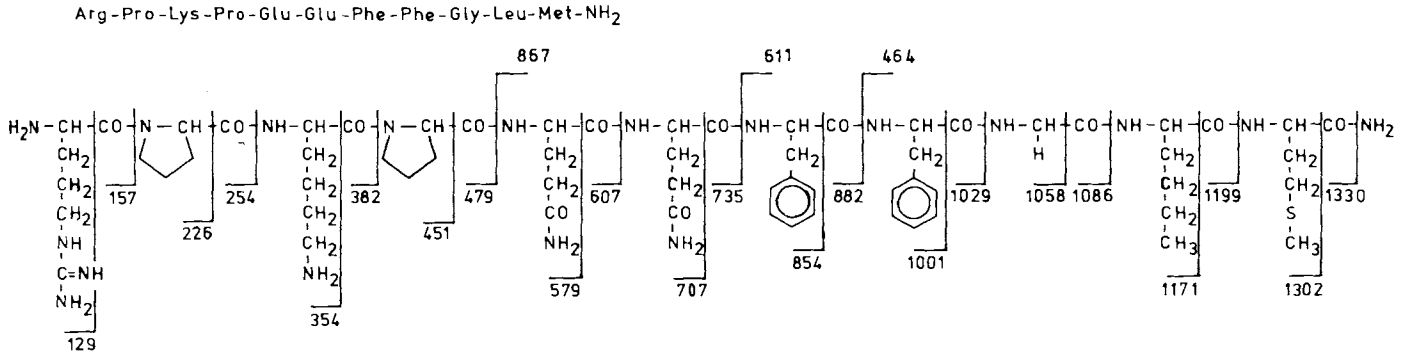

Fig. 20. Structure and fragmentations of substance P.

the above described MUPI-mass spectra of peptides, signals for fragments of the Y′ series are also detectable; hence, the peptide sequence can be unambiguously deduced from the spectrum.

Thus, both methods enable the sequencing of peptides in the gas phase, but the FAB-MS/MS experiment is much more expensive than the investigation by LEIM-MUPI-mass spectrometry.

In Figure 22, a FAB-mass spectrum and a MUPI-mass spectrum of an unknown sample are compared. The aim of the experiment was to investigate whether the compound shown in Figure 23, which should have been formed in a chemical reaction,[126] was present in the sample. MUPI leads to an intense signal corresponding to the molecular ion of the compound, while FAB produces only the signals of the fragmentation products. Thus, together with other

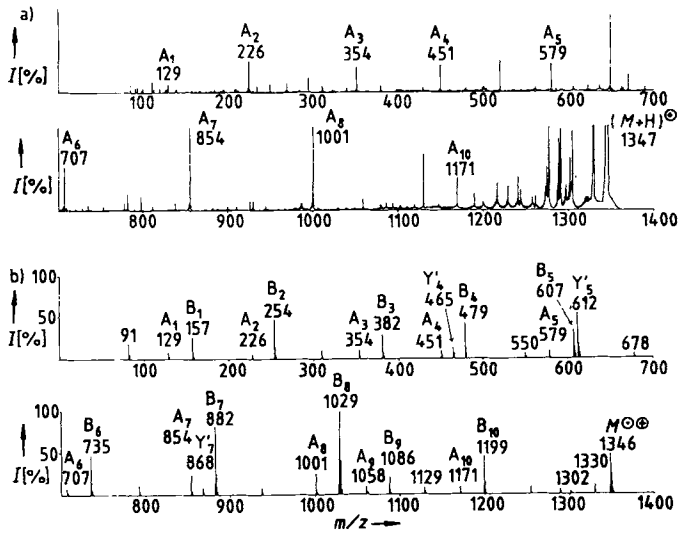

Fig. 21. Comparison of the mass spectra of substance P (a) from a FAB-MS/MS experiment and b) after MUPI.

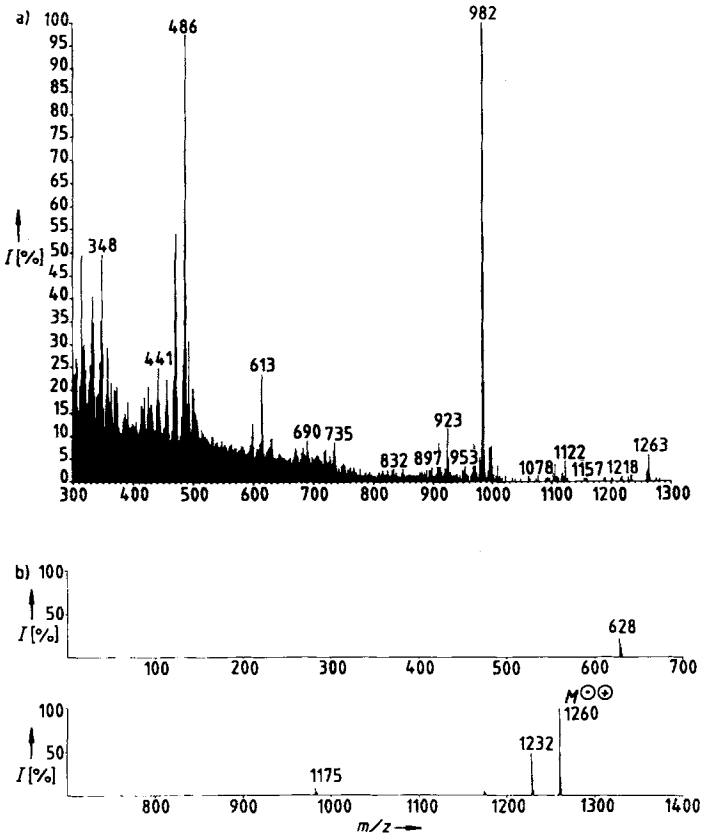

Fig. 22. Comparison of the FAB-mass spectrum (a) and the MUPI-mass spectrum (b) of the product shown in Figure 23.

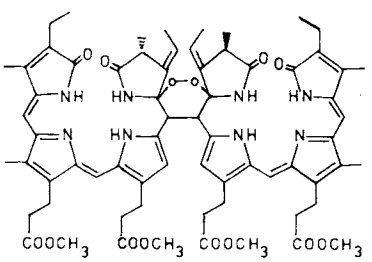

Fig. 23. Postulated structure of a compound in the sample used for the mass spectra in Figure 22.

analytical methods, MUPI-MS was able to give evidence for the existence of the compound.

As a final example of the potential of MUPI-mass spectrometry in the investigation of large molecules, Figure 24 displays the soft ionization spectrum of bovine insulin.[127]

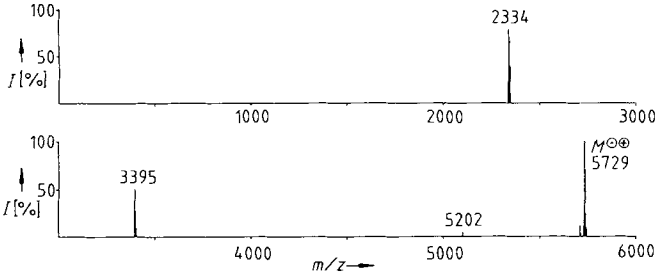

Fig. 24. MUPI-mass spectrum of bovine insulin. Ionization wavelength $\lambda = 272$ nm.

The most intense signal after multiphoton ionization is that of the molecular ion at *m/z* 5729, which is far less noticeable in the mass spectra recorded under FAB or PD-conditions. It should be mentioned again that, unlike in other methods, no background correction is necessary in the case of the MUPI-mass spectra. Figure 25 shows the experimental and calculated patterns of the isotopic distribution for the signal groups of the molecular ion and of the A and B chains.

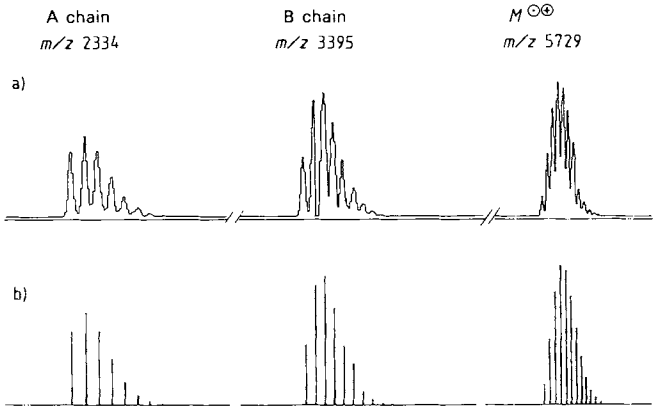

Fig. 25. Comparison of the experimental intensity ratios (a) for the molecular ion of bovine insulin and the fragment signals for the A and the B chains with the isotopic pattern (b) calculated from the elemental composition.

The superimposability of these two patterns for the signal group of the molecular ion proves that the insulin is desorbed into the gas phase as intact molecule without any addition of protons or alkali cations and is then ionized. The main fragmentations can easily be identified on the basis of the signal for the A chain at *m/z* 2334 and the signal for the B chain at *m/z* 3395. These results demonstrate that very large molecules can also be analyzed by MUPI-MS. In the meantime, numerous interesting molecules, like gramicidin and others[105] have also been investigated by this technique.

4. Conclusion and Outlook

The present review has outlined some of the advantages that are gained by combining the laser evaporation of intact neutral molecules with multiphoton ionization and mass spectrometry.

The MUPI-mass spectra of organic and biochemical compounds differ in some particular characteristics from the spectra obtained by other mass spectrometric methods. MUPI-mass spectra always show an intense signal for the molecular ion, thus allowing an easy identification. Since the occurrence of fragmentations can be controlled by appropriately tuning the excitation energy, MUPI-mass spectroscopy enables very detailed analyses.

Investigation of the possibilities opened up by this tunability, not only for mass spectrometric but also absorption spectroscopic analysis, has just begun.

One important aspect of the method described here is that it can be used for nonvolatile and labile compounds; this is possible because of the spatial and temporal separation of the evaporation step from the ionization step. Thus, the intrinsic difficulties caused by simultaneous vaporization and ionization in other mass spectrometric techniques can be avoided. This has a positive effect on the signal to noise ratio, so that, in contrast to other mass spectrometric methods, no background correction is necessary in MUPI-MS.

The very high sensitivity of multiphoton ionization is a further advantage of MUPI-mass spectrometry. Femtogram and subfemtogram amounts of substances can easily be detected by MUPI-MS, thus opening up new applications in trace analysis.

The generation of ions by the influence of light is still more expensive than their production by conventional methods,[128] but the advantages of this excitation method are evident. On the other hand, analysis of the ions in a time-of-flight instrument is very simple, and the overall costs are comparable with those for other types of mass spectrometers.

The range of potential applications of MUPI with respect to the identification of biological material is virtually limitless. The intrinsic features of MUPI, such as soft ionization and the ionization efficiency as a function of the wavelength, the different classes of compounds that can be ionized, and the absolute size of molecules that can be examined, all point to areas of future research and exploitation.

For the investigation of molecules with masses between 20000 and 50000 Da, the main limitation is detection: all commercially available systems have an upper mass limit in this range. Solutions to this problem have been discussed in the literature,[129] but further developments have to be made. Although MUPI-mass spectrometry is still a relatively young method, its future course of development is already forseeable. Parallel with improvements in mass resolving power and higher sensitivity MUPI-mass spectrometry will find increasing importance, in particular, for the elucidation of the structure of biomolecules of higher masses, but also for surface studies and material analyses. Furthermore, the ability of the system to rapidly and selectively (by wavelength changes) mass analyze a sample makes it well suited for the monitoring of technological processes, with the additional dimension of time-selected sampling.

The technique of producing ions with light is still in a state of rapid development, but it is already clear that it will find increasing application during the next few years, not only in mass spectrometric analysis, but also in the quality control of pharmaceutical products and in trace analysis, as well as in resolving diverse clinical and pharmacological problems.

The authors thank the "Deutsche Forschungsgemeinschaft", the "Fonds der Chemischen Industrie" and the "Bundesministerium für Forschung und Technologie" for financial support of this work and Dr. U. Boesl and K. Walter for their cooperation in the development of multiphoton ionization and the set-up of the time-of-flight mass spectrometer.

Pheromones in Nanogram Quantities: Structure Determination by Combined Microchemical and Gas Chromatographic Methods

New Analytical Methods (35)

By Athula B. Attygalle and E. David Morgan*

What can a chemist do with a few nanograms of valuable organic substance, pure or impure? The answer may be, a great deal. Its components may be quantified, separated, isolated, degraded, derivatized, extracted by solvent partition, as well as the more obvious recording of their mass spectra. Provided a substance is not contaminated by large quantities of solvent, manipulations are possible without much loss or dilution. Necessity is the mother of invention. The examples given in this review show what can be accomplished today in nanochemistry and should act as a stimulus to direct the scientist to discover other applications appropriate to his needs and his circumstances. The examples are largely taken from the field of insect chemistry, but their general applicability is emphasized. This review illustrates how gas chromatography and reaction gas chromatography, alone or combined with mass spectrometry are potent tools in the hands of the chemist to deduce the unique structure of volatile organic substances available only in nanogram quantities.

1. Introduction

From the birth of their subject, organic chemists have devoted a great deal of skill and ingenuity to the determination of the structure of organic molecules. The advances in spectroscopic methods of the past quarter century have made the use of classical methods of degradation and derivatization almost redundant. As a result of this spectroscopic revolution, the elucidation of the structure of natural products has become almost routine. Nuclear magnetic resonance (NMR) spectroscopy, makes the greatest contribution to the assignment of structure to most new natural products. But the chemist probing the secrets of nature often finds substances of interest in quantities far too small for study by NMR spectroscopy. For example, for the pheromone chemist it is difficult to obtain sufficient pure substance for an NMR spectrum. With the exception of mass spectrometry, the other spectral methods usually require microgram to milligram samples of pure substances to obtain useful spectra (Table 1). There are examples of NMR spectra taken on samples as small as 1 to 2 μg,[1,2] but for complex substances it is customary to have about 1 mg.

Fourier transform infrared (FT-IR) spectroscopy is reaching towards the nanogram level when linked to gas chromatography, but the amount of structural information IR spectroscopy can provide is limited.

For the identification of nanogram quantities of natural products a chromatographic separation must precede or accompany spectroscopy. The spectral technique above all others for nanochemistry is mass spectroscopy; and the marriage of gas chromatography and mass spectrometry (GC-MS) is a powerful method of separation, detection and analysis. Although mass spectrometry can provide structural information and may sometimes completely define a compound, usually it does not give enough information for a unique structure of a new natural product. The pheromone chemist, for example, is faced with the choice of the labor and expense of collecting large numbers of insects in order to use NMR spectrometry (perhaps a thousand times that required for a mass spectrum) or to devise some other means of obtaining structural information from the small amount available.

The chemist who sees gas chromatography (GC) only as a high resolution separation and quantitation technique fails to see its potential as a source of structural information. In the simplest way, use of the specific detectors for the elements nitrogen, phosphorus and sulfur (Table 1) can indicate presence of these elements. Noting the retention of the substance on polar and nonpolar stationary phases can indicate the molecular mass and some information about the polarity of a substance. With degradative reactions or by conversion of the compound into a derivative, GC begins to yield more information, and when these are combined with MS, the structural information is increased considerably.

The degradative or derivatizing reaction may be carried out in a separate step, but is more conveniently combined with gas chromatography, either by reaction in the injector, or in a pre-column or a post-column reactor. Such a combined method is called reaction gas chromatography.

2. Solid Injection Techniques

2.1. Disadvantages of Solvents

Generally a mixture is dispersed in a solvent for chromatography, but solvents are a curse to the nanochemist.

Table 1. Practical limits of detection of gas chromatographic and spectroscopic detectors [a].

Detector	Abbreviation	Selectivity	Detectable quantity Minimum	Customary	Remarks:
Gas chromatographic [3]					
Flame ionization	FID	non-selective to all organic compounds, however highly oxidized compounds such as HCHO, CS_2 show very low responses	100 pg for alkanes	10 ng	destructive
Electron capture	ECD	selective; responds to electron adsorbing compounds e.g. halogens, nitro compounds, conjugated carbonyls	0.1 pg for lindane	100 pg	non-destructive
Thermal conductivity	TCD	non-selective	100 ng	1 μg	non-destructive
Nitrogen-phosphorus	NPD	highly selective; detection of carbon can be varied	1 pg	1 ng	destructive
Flame photometric	FPD	selective for sulfur and phosphorus	100 pg	10 ng	destructive
Spectroscopic					
Nuclear magnetic Resonance	^{1}H-NMR	selective: protons only	75 μg [b] 1 μg [c]	1 mg	non-destructive
	^{13}C-NMR	selective; ^{13}C only	500 μg [d]	5 mg [e]	non-destructive
Infrared	IR	selective	1 ng [f]	1 mg	non-destructive
Ultraviolet	UV	highly selective for the chromophores present	highly variable depending on the substance		non-destructive
Mass spectrometry	MS	non-selective in general	200 pg	5–500 ng	destructive

[a] This table serves only as a rough comparative guide, the absolute values will depend on the particular substance examined, conditions and the make and model of a particular instrument. [b] Vitamin B_{12} (5.5×10^{-8} mol); accumulation time 10 min. [c] Cortisone-21-acetate; accumulation time 13.9 h. [d] Cholesterol (1.3×10^{-6} mol); accumulation time 10 h. [e] Cholesterol (1.3×10^{-5} mol); accumulation time 10 min. [f] Using Fourier Transform IR spectroscopy.

An injection of 99.9% purity solvent onto a capillary GC system at high sensitivity demonstrates the impurity of such solvents. Moreover, plasticizers, stabilizers and antioxidants are picked up from contact with plastic and rubber with the greatest ease. Very volatile components may be lost in the solvent peak, this can be especially serious when looking for small fragment molecules from a degradation reaction. The solvent chosen may be selective for certain compounds of the mixture, so the composition from these gas chromatograms may not represent the true composition, and, occasionally, the solvent may react with and alter the components. Hence, for sensitive work, solvents are best avoided.

2.2. Solvent-free Techniques

A number of solventless injection techniques have been described, the earliest in 1958.[4] Each method appears to have its own merits depending upon the conditions and type of sample analyzed. Generally they have been used with packed columns, but there is no fundamental difficulty in adapting a solventless injector to capillary columns.

Bridges and *Guinn*, studying bark beetle pheromones, placed a whole beetle in the injection port of a GC, using a wire basket.[5a] A similar method has been used to introduce beetle defensive secretions into the injection port, using a cold plunger with a tiny groove to hold the sample.[5b] In another case, the sample was placed in the open end of a capillary pushed through a hole in the injection septum. However this is reported to give irreproducible retention times.[5c]

Solid injection techniques have been used to study plant tissues containing essential oils.[5d,e] In the study of sex pheromones of Lepidoptera, *Weatherston* and *MacLean* have used a commercially available solid sampler (Perkin–Elmer MS-41) with packed columns.[5f] The insect material was sealed in an aluminum or gold capsule, heated in the injection port and the capsule pierced with a needle. *Descoin*'s group in France have used this method extensively in the study of female lepidopteran pheromones,[6] on packed columns. Although a modification of this system has been used with capillary columns,[7] no applications of its use for natural products have been reported.

Another solvent-less injection technique is the precolumn designed by *Ställberg-Stenhagen*.[8a] Volatile substances from insect or plant material are trapped in a precolumn filled with an adsorbant such as Tenax-GC. The precolumn is then connected to a capillary column and rapidly heated to desorb the collected volatiles.[8b,c]

2.3. A Solid Sampler for Natural Products

A solid injection technique has been in use in our laboratory for insect studies since 1970.[9] Its most obvious advantages are simplicity of operation, reduced chance of contamination, and no dilution. The whole sample available can be placed on the column with minimum manipulations. Even the most volatile substances, such as methanol or acetaldehyde can be recognized and quantified. Most important, the GC instrument can be operated at maximum sensitivity, and accurate quantifications can be made of even minor components without fear of selectivity in extraction.

The sample is sealed inside a glass capillary, and placed in the heated injector for a few minutes to allow the sample to volatilize, or for a biological sample to heat through (Fig. 1). The tube is then crushed with a plunger and the volatile material is swept directly onto the column by the carrier gas.[9,10]

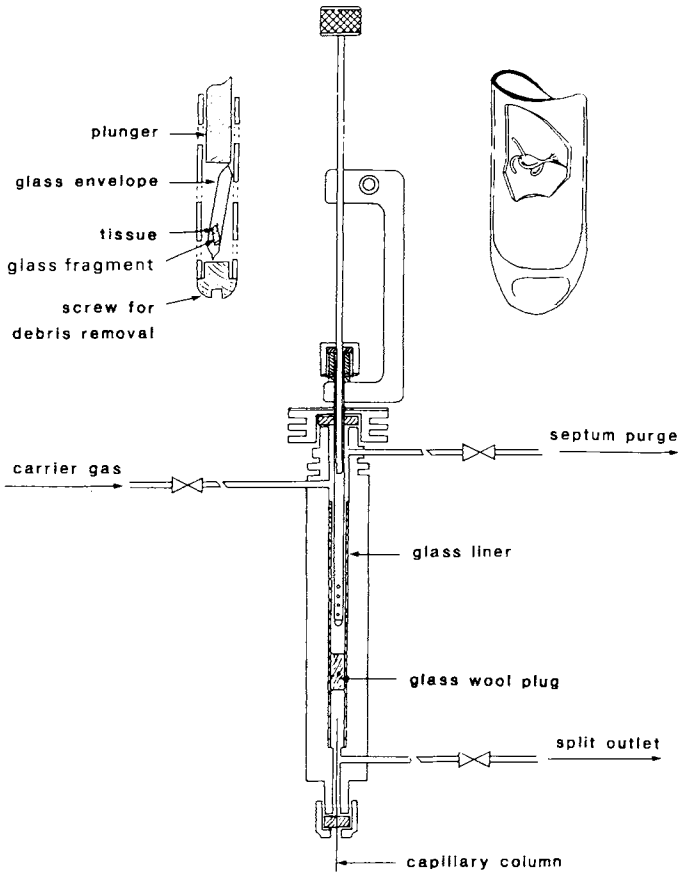

Fig. 1. The solid sample injector, for introducing samples into a gas chromatography column without the intervention of solvent. Illustrated as used with a capillary column. The arrangement is simpler for packed columns. The tip of the device (top left) and the biological tissue on a fragment of glass (top right) are shown enlarged.

2.3.1. *Use with Capillary Columns*

The system is adaptable to capillary columns, when mounted inside the glass insert of a splitless injection system. It is adapted to the Carlo Erba Fractovap splitless injector simply by drilling a larger hole in the metal cap that holds the injection septum. The narrow glass liners used in the injection ports of many other capillary instruments can be replaced by a 4 mm internal diameter glass tube.

The split vent is closed before the sample is crushed, then reopened about 30 seconds later. The oven temperature is initially low for a few min, then rapidly increased at the start of the program. The volatile substances are vaporized in the injector, condensed in the column and are then selectively vaporized with the increasing oven temperature. This yields a better focussing and narrower peaks. With very volatile components, it may be necessary to actively cool the first region of the column.

2.3.2. *Use in Sampling Biological Tissues*

Glandular reservoirs, such as the Dufour gland or poison vesicle of ants, are prepared for chromatography by dissecting under water, then the tissue is attached to a small fragment of glass, excess water is removed by touching with a fragment of paper tissue or filter paper, and the fragment of glass dropped into the glass capillary and the capillary sealed.[9, 11a, b] When a biological tissue is heated inside its sealed capillary and the capillary crushed, the cells are completely disrupted by the steam produced from the cellular fluid. Complete release of volatile material is thereby ensured. If it is necessary to show that the substances examined come from the glandular sac and not from droplets in the tissue, the gland can be pierced by a fine glass capillary of diameter smaller than the gland, the contents removed by capillarity and the fine glass capillary itself is sealed in a larger one and submitted to GC.[12]

Some aphids secrete alarm pheromones from a pair of tubular structures (cornicles) on the posterior abdomen, when disturbed. The cornicle droplets can be collected in capillaries in a similar manner, sealed in larger capillaries and chromatographed. Whole insects that are sufficiently small or pieces of tissue can be examined in this way. A gas chromatogram of the mandibular gland substances from the head of a *Myrmica* ant is shown in Figure 2.

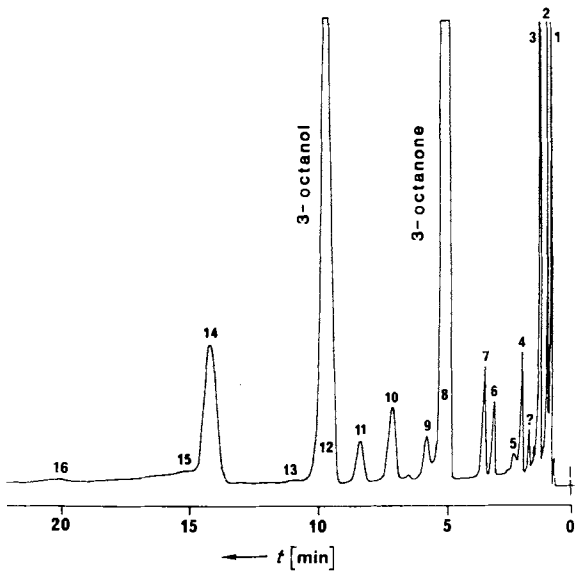

Fig. 2. Gas chromatogram of the mandibular gland contents of one worker of the ant *Myrmica albuferensis*, using the solid sampling technique with a packed column (2.75 m × 4 mm of 10% PEG 20M on Chromosorb W at 130°C). 1, ethanol; 2, acetone; 3, 2-methylpropanal; 4, 3-hexanone; 5, 3-pentanol; 6, 3-heptanone; 7, 3-hexanol; 8, 3-octanone; 9, 3-heptanol; 10, 6-methyl-3-octanone; 11, 3-nonanone; 12, 3-octanol; 13, 6-methyl-3-octanol; 14, 3-decanone; 15, 3-nonanol; 16, 3-undecanone.

The solid sampling method has been used extensively at Keele for the study of glandular substances of ants, generally with packed columns,[13] though with some early applications of capillary columns.[14] The advantages of capillary columns in this work was illustrated when re-examining the Dufour gland substances of the ant *Lasius niger*. Over 50 components were recognized with a capillary column[15a] where only 15 had been identified previously.[15b] A capillary chromatogram from a Dufour gland of *Lasius fuliginosus* is illustrated in Figure 3.

The solid sampling method with capillary columns has been used in analyzing intact sex pheromone glands excised from a number of female moths.[16] These pheromones are located in a small glandular area of the abdom-

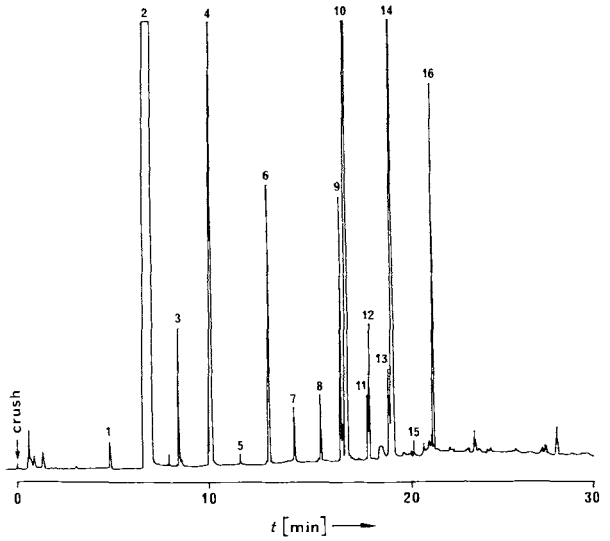

Fig. 3. Gas chromatogram of the Dufour gland contents of one worker of the ant *Lasius fuliginosus*, using the solid sampling technique with a capillary column. 1, decane; 2, undecane; 3, dodecane; 4, tridecane; 5, tetradecane; 6, pentadecane; 7, 2-tridecanone; 8, 2-tetradecanone; 10, 2-pentadecanone; 11, heptadecane; 12, 2-hexadecanone; 14, 2-heptadecanone; 15, 2-octadecanone; 16, 2-nonadecanone; 9 and 13 are two unidentified carbonyl compounds.

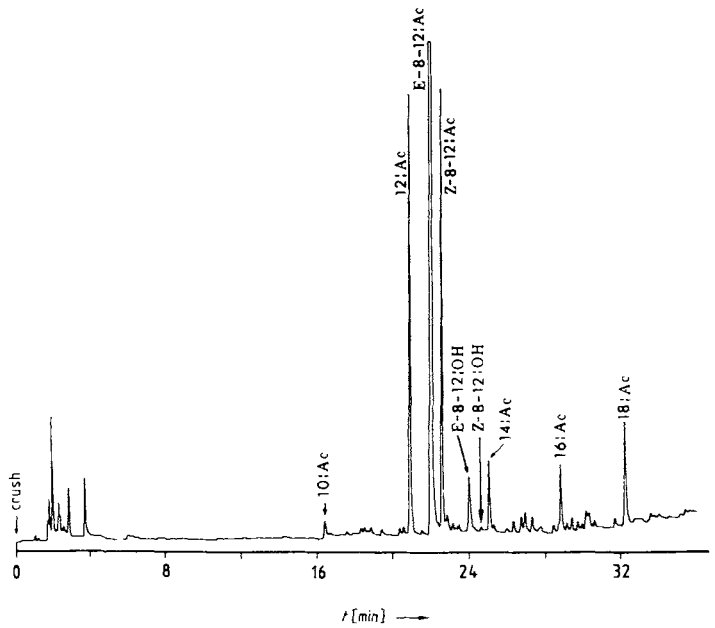

Fig. 4. A gas chromatogram obtained from a sex pheromone gland of an adult female *Cryptophlebia leucotreta*, by solid sampling on a 25 m × 0.22 mm fused silica capillary column, coated with SP-2340. The oven temperature was held at 60 °C for 2 min and programmed to 195 °C at 4 °C/min. 10:Ac, decyl acetate; 12:Ac, dodecyl acetate; 14:Ac, tetradecyl acetate; 16:Ac, hexadecyl acetate; 18:Ac, octadecyl acetate; E-8-12:Ac, (*E*)-8-dodecenyl acetate; Z-8-12:Ac, (*Z*)-8-dodecenyl acetate; E-8-12:OH, (*E*)-8-dodecenol; Z-8-12:OH, (*Z*)-8-dodecen-1-ol.

inal tip, and the females secrete the pheromone only in the period when they are "calling" the males. Hence, the sample must be prepared during this calling period. Figure 4 shows a gas chromatogram obtained from an individual female of the false codling moth *Cryptophlebia leucotreta*.[16c] The technique has been useful in biosynthetic studies, in determining the fate of a precursor after local application.[17]

3. Trapping and Rechromatography

The homogeneity of a peak suspected of being an unresolved mixture of substances can be checked by rechromatographing on a stationary phase of different polarity. But if the mixture is complex, new heterogeneous peaks may occur in the second chromatogram. The solution is to rechromatograph only one peak or a narrow region of the chromatogram. This principle, called multidimensional gas chromatography (MDGC), was first conceived by *Deans*,[18] but did not receive much attention until the appearance of capillary columns.[19] A commercial instrument (Siemens, Sichromat-2) is available with two ovens linked together. Any peak resolved on a nonpolar packed column in the first oven can be switched to a second column, preferably a capillary, for further resolution in the second oven.[20,21] Many other systems of column switching have been devised. MDGC should be useful in determining the optical isomeric composition of chiral pheromones. Columns coated with chiral chromatographic phases[22] have been used for such analyses. These chiral phases are very delicate, hence crude mixtures must be prepurified before chromatography. The use of a chiral column as the second column in MDFG simplifies the manipulation.[23] However, a two-oven chromatograph may be beyond the means or needs of most chromatographers. The same result can be achieved in a simple way by trapping a peak and rechromatographing it on a different phase.

3.1. Effluent Splitting

Trapping of individual peaks may also be required for biological testing, or pure material may be required to accumulate for an NMR or UV spectrum. Structural information may be obtained by chemical reaction on the trapped substance before or during rechromatography. With the nondestructive thermal conductivity detector, the whole of the sample can be collected after the detector, but the low sensitivity of the detector rules it out for many purposes. With the flame ionization detector (FID) a number of effluent splitters have been described, by which a small proportion of the carrier gas reaches the detector and most of it is diverted to a cooled receiver. All-glass splitters are preferred to the early metal ones,[24,25] to avoid catalytic transformations on the hot metal surface. An all-glass splitter for packed columns,[26] simple to make and operate, has been used in our laboratory for a number of years with success (Fig. 5).

No make-up gas is necessary with flow rates normally employed with packed columns (30 to 60 mL min^{-1}). The low flow rates used in capillary columns (0.5 to 2 mL min^{-1}) require a make-up gas if the effluent is split to collect peaks. A few elaborate systems have been described for preparative capillary gas chromatography[27] but a very simple system, such as that of *Williams* and *Vinson*[28] is all that is required.

3.2. Peak Trapping

Many systems of collection and design of traps have been described for gas chromatography.[29] For the collec-

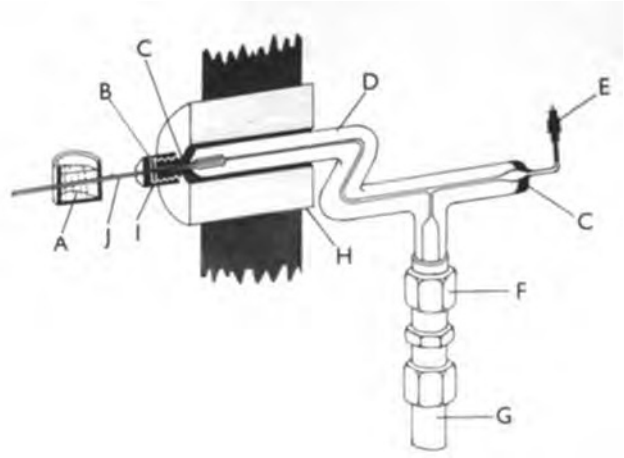

Fig. 5. The effluent splitter for packed columns with trapping capillary attached. A, liquid nitrogen coolant; B, silicone rubber septum; C, glass-to-metal seal; D, glass capillary; E, connection to detector with restrictor wire; F, Swagelok union; G, chromatography column; H, outlet heater; I, hexagonal nut; J, glass capillary.

tion of larger samples (up to μg) we have used steel capillary tubing bent into a U-shape. The U-tube is cooled in liquid nitrogen.[24] Some users prefer glass tubes because of their relative chemical inertness, or to place some column packing, quartz wool or cotton inside the capillary collector or to coat its inside walls. However, others have quoted up to 90% recovery can be achieved with empty glass capillaries, under optimum conditions,[25] and our experience bears this out. It is better to avoid coolant baths using a solvent, because of the chance of contamination, and to use either crushed dry ice[30,31] or liquid nitrogen.[32]

The factors governing trapping efficiency are not well understood, but boiling point, polarity and molecular shape of the compound as well as dimensions of the trapping capillary and gas flow rate all play a part. The temperature of the trap and temperature gradient[25] before the trap seem to affect efficiency. *Klimes* et al.[33] have studied the influence of some of these parameters upon trapping efficiency.

For trapping nanograms of pure compounds from either packed or capillary columns, we have found that a simple arrangement of a glass capillary pushed through two holes in a plastic cap from a specimen tube is convenient and efficient.[32] The internal diameter of the tubes seems critical. Aerosol formation can occur in larger-diameter tubes. One end of the capillary is pushed through a pin-hole in a silicone rubber disc held in the screw or female Luer fitting which fits the splitter of Figure 5. An example of myristic acid trapped in such a capillary is shown in Figure 6. The sharp temperature boundary on the inlet side is clearly seen.

3.3. Rechromatography without Solvent; Melting Point Determination

The glass trapping capillary can be sealed at both ends in a flame and used directly for rechromatography on a different phase or stored until needed. Figure 7 shows the results of a trapping and rechromatography experiment. A synthetic mixture of tetradecane and pentadecane was chromatographed. In a second run the pentadecane was trapped out. Only 5% of the sample went to the detector. The material collected in the glass capillary was sealed and directly rechromatographed; in this way, trapping efficiencies up to 85% have been obtained.[32]

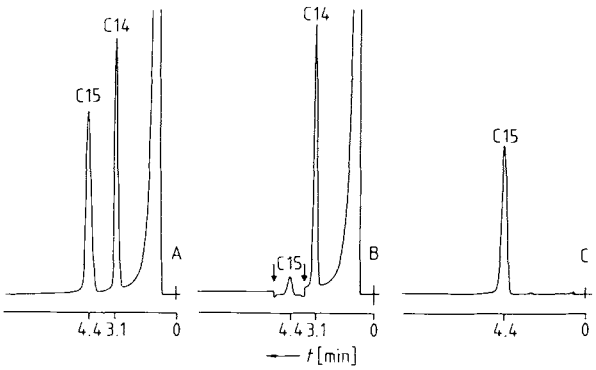

Fig. 7. Efficiency of trapping. A) Tetradecane and pentadecane (250 ng each) in 0.5 μL of hexane chromatographed on a 1.5 m × 4 mm column of 5% SE-30 at 145°C. B) The same amount injected, trapping the effluent between the times indicated by the arrows. C) The total trapped sample is reinjected by the solid injection technique.

When a Dufour gland of the ant *Myrmica rubra* was chromatographed on a polar stationary phase, two components of the secretion, heptadecadiene and (*Z,E*)-α-farnesene eluted together. This peak could be resolved into its components by trapping and rechromatographing on a non-polar SE-30 silicone phase.[32]

Many of the natural products subjected to gas chromatography are liquids at room temperature, but some, including some insect pheromones are solids. The melting points of solids, trapped from the vapor in glass capillaries, such as the myristic acid shown in Figure 6, can be determined with great accuracy using a hot stage microscope.[34] The amount required is chiefly limited by the magnifying power of the microscope. This method can also be used to examine chirality, if both enantiomers are available. Coinjection of each enantiomer in turn with the unknown, trapping the eluate and determining the melting points will reveal which is the racemate by its altered melting point.

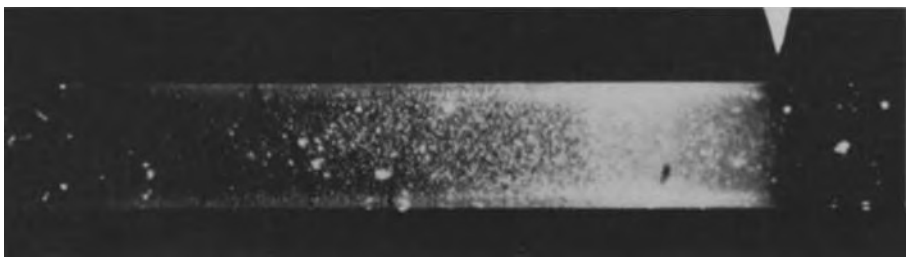

Fig. 6. A few micrograms of myristic acid were trapped in a glass capillary as shown in Fig. 7, from a 1 m × 4 mm 15% FFAP column. Gas flow from the right. The arrow marks the boundary of the cooled zone, and the deposition of crystalline myristic acid.

3.4. Rechromatography with Solvent

The substance trapped in the glass capillaries does not have to be rechromatographed with the solid sampler. If more convenient, 1 μL of a suitable solvent can be injected from a syringe with a fine needle, just inside the capillary end (Fig. 8). The only requirement is that the needle diam-

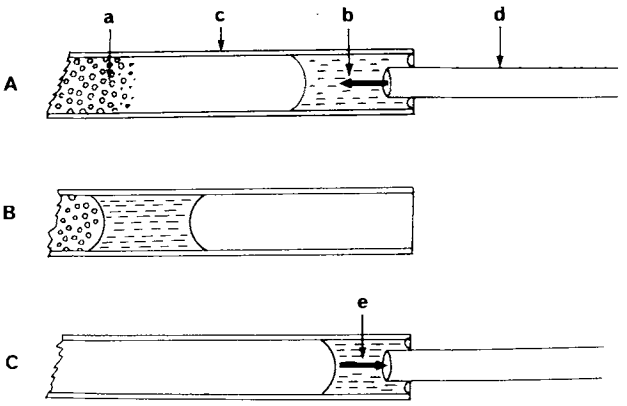

Fig. 8. Reaction in a glass capillary. A) The reagent solution b (1 μL), is added to the trapped material a, in a trapping capillary c, by inserting the tip of a fine syringe needle d (75 mm × 0.17 mm o.d.), just inside the glass capillary. B) The reagent solution is mixed with the trapped material by tilting the capillary. C, the reaction mixture e is tipped back to the end of the capillary and withdrawn with the syringe.

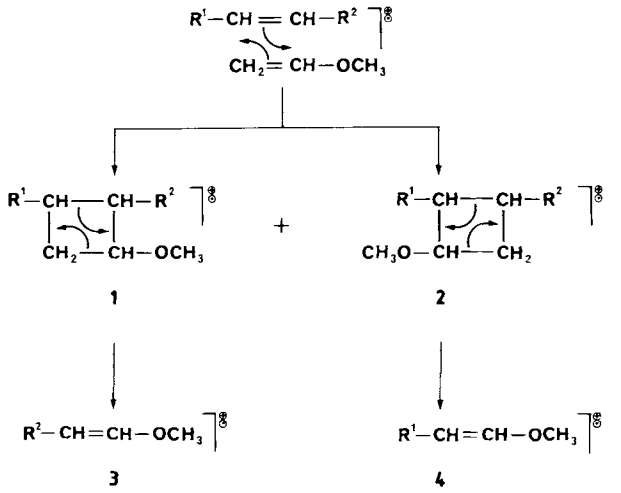
eter should fit easily inside the capillary. By tipping the capillary the column of solvent can be made to mix with the trapped material. The needle is reinserted and the solution is removed. Because of the fine needle used, the material must be rechromatographed through a septumless injector. Efficiencies of recovery of 80–90% have been experienced in our work.[34]

4. Location of Double Bond Positions

The location of the position of double bonds can be an important part of natural product structure determination. Electron impact mass spectrometry is not very helpful unless the spectra of the compound and all its double bond isomers are available. Frequently an indirect method has to be found when dealing with biologically important compounds[35] available only in nanogram quantities.

Even chemical ionization (CI) mass spectrometry with the usual reagent gases such as methane may not help, but methyl vinyl ether and a few other unsaturated gases have been successfully employed as the reagent gas to locate the double bond in mono-unsaturated compounds.[36] The alkene and methyl vinyl ether produce a pair of four-centered addition complexes **1**, **2**, which in turn fragment to produce two characteristic ions **3**, **4** (Scheme 1). The *m/z* values of the ions **3** and **4** can locate the position of the double bond. A mixture of methyl vinyl ether, nitrogen and carbon disulfide as reagent gas are said to give simpler spectra with identifiable molecular ions and characteristic ions to locate the double bond.[36b] However, others[37] report the method is not specific to alkene functions, since adduct ions are also observed with saturated compounds. Similar difficulties with methyl vinyl ether CI spectra have been observed by *Budzikiewicz* and *Busker*.[38] They found that the double bond could be located with isobutane as reagent gas in most cases, in difficult cases they recommend nitric oxide or methylamine. Isobutane CI-spectra have been used[39] for locating conjugated dienes in a range of compounds, including aldehydes, alcohols, formates, acetates, and hydrocarbons.



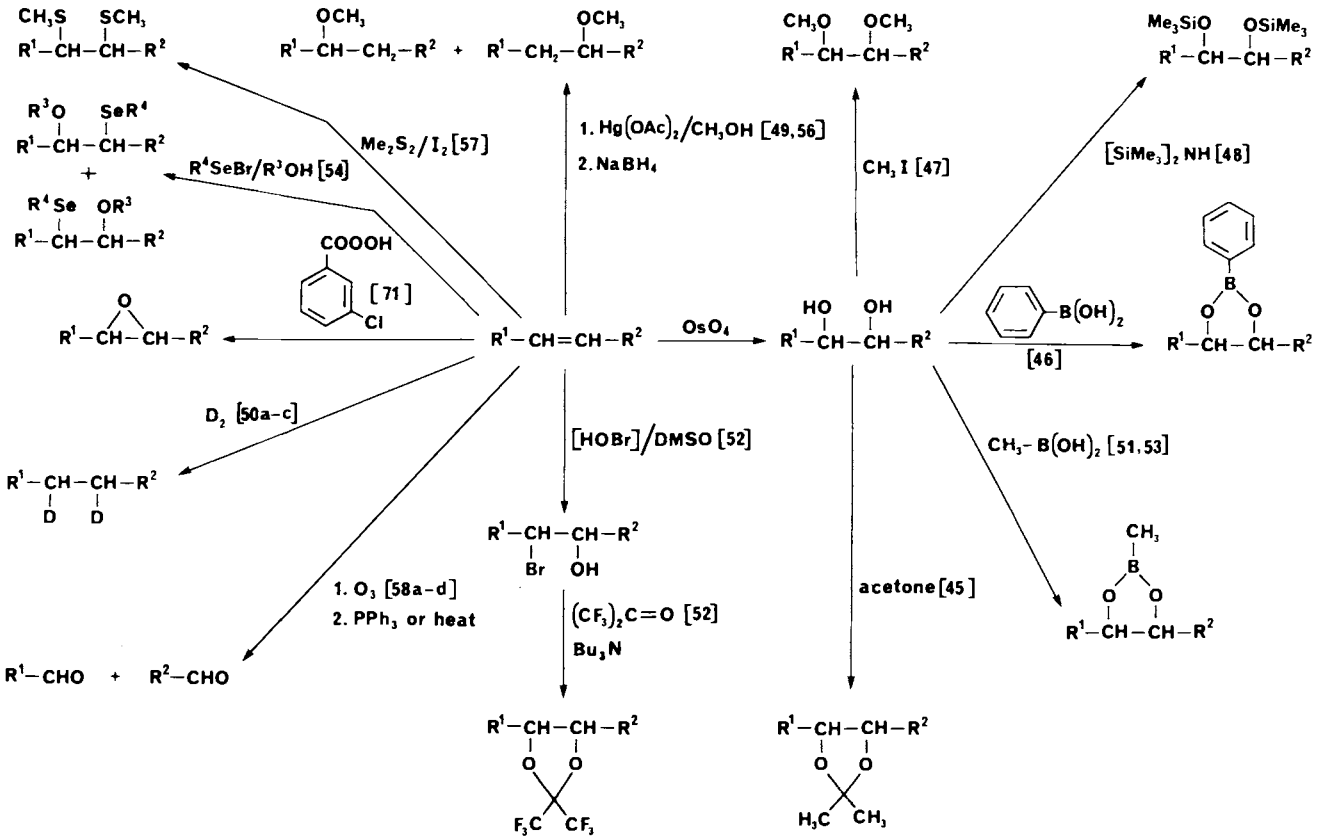
Scheme 1.

It is possible to locate the double bond of mono-unsaturated acetates and alcohols from the relative intensities of some ions of the electron impact spectrum, in spite of the ease of isomerization. *Horiike* et al.[40] first described this empirical approach to double bonds in tetradecenyl acetates. Two other groups have verified and refined the method for C_{12}, C_{14}, and C_{16} linear mono-unsaturated acetates.[41,42] The mass spectra of certain alkatrienes also show fragments characteristic of the double-bond positions.[43] To use this method, all the pure synthetic double-bond isomers are required, to compare with the unknown. Their synthesis alone can be tedious and if they are available, the same results can be achieved by comparing retention times of standards and unknown.

This does not exhaust the mass spectrometric methods that have been proposed, if advanced equipment is available. Negative ion MS/MS has been used to locate double bonds in unsaturated fatty acids. The acids are ionized by fast atom bombardment (FAB) and then collisional activated decomposition (CAD) spectra of the $[M-H]^{\ominus}$ ions are observed.[44]

Generally, the chemist has to resort to derivatization methods, as summarized in Scheme 2, to find the position of double bonds. In all these methods, the compound is converted into a derivative which in GC–MS gives characteristic cleavage ions at the point of attachment of the derivative groups.[45–57] Alternatively, the compound is cleaved at the double bond into smaller fragments that can be identified by GC retention times and possibly mass spectra.[58a–d]

All of these methods tax the skill and ingenuity of the chemist when dealing with nanogram samples.



Scheme 2.

5. Nanogram Reactions with Trapped Compounds

Valuable information can be obtained concerning the carbon skeleton or the functional groups of a molecule by performing derivatization or degradation reactions, before, during or after gas chromatography. When the reaction and chromatography are combined, by use of a pre- or post-column reactor, the technique is referred to as reaction gas chromatography.[59,60] Such a technique is particularly useful where only nanograms of sample are available, because of the convenience of handling; however, because of its ease of use and simplicity, the procedure is gaining popularity even when sample size is not a limitation. Some substances must be derivatized to impart better gas chromatographic characteristics to the molecule. Sometimes a crude reaction mixture can be directly injected into the GC. In other cases, the product must be first extracted into an organic solvent.

5.1. Reactions without a Solvent Extraction Step

5.1.1. Ozonolysis

Ozonolysis is a particularly simple and useful technique for the location of carbon-carbon double bonds and has been known for some time.[58a,b] However, its development as a microchemical technique owes much to the work of *Beroza* et al.[58c,d] A relatively inexpensive ozone microgenerator can be assembled from commercially available components, similarly to that described by *Beroza* and *Bierl*,[61] (Fig. 9). The sample is taken up in 5 μL of solvent and, after passage of ozone, is ready for gas chromatography by splitless injection. The customary addition of triphenylphosphane to reduce the ozonides is not essential,[30,32,62] since they are readily cleaved in the GC injection port to carbonyl compounds. Moreover, excess Ph_3P would be only slowly eluted from the column and thus interfere with subsequent analyses.

The main drawback of ozonolysis in a solvent is the difficulty of identifying the small molecular fragments formed because their GC signals are obscured by the solvent peak. *Beroza* and *Bierl*[58c,d] therefore suggested CS_2 as the most suitable solvent for molecules larger than pentanal. More recently, pentyl acetate and hexadecane[58e] have been proposed for molecules smaller than pentanal. The difficulty of solvent peak interference in detecting small molecules is best avoided by "dry" ozonolysis without a solvent.[16d,30-32]

In this technique the alkene is trapped in a glass capillary and ozonized oxygen is passed through a fused silica capillary onto the trapped alkene (Fig. 9). This can be sealed in a larger capillary and kept in the GC injector for three minutes before crushing the tube and releasing onto the column the carbonyl products formed by pyrolytic cleavage of the ozonides. Figure 10 shows the use of the technique in the ozonolysis of a mixture of heptadecane and (*Z*)-8-heptadecene. After ozonolysis, the (*Z*)-8-heptadecene peak disappears completely, octanal and nonanal

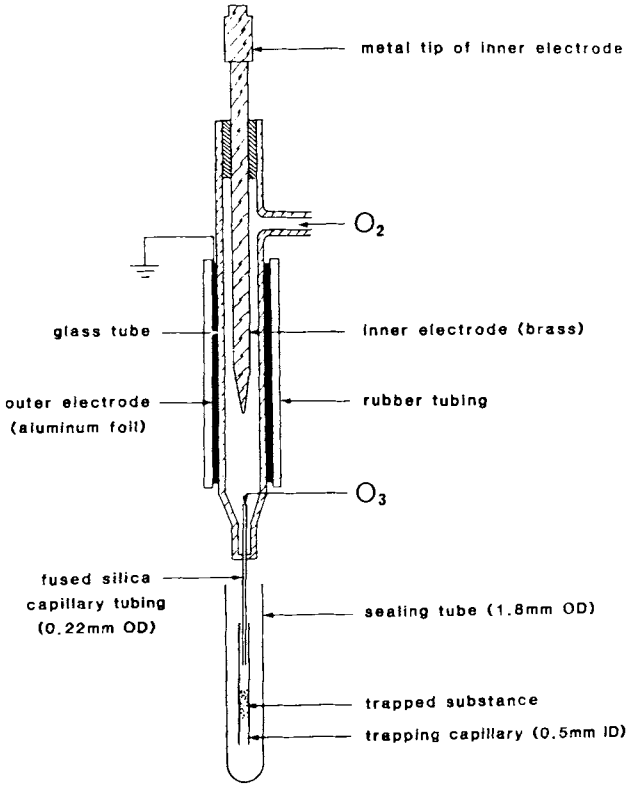


Fig. 9. Microgenerator for ozone. The ozonized air is fed directly to the trapped material through a short length of fused silica capillary tubing.

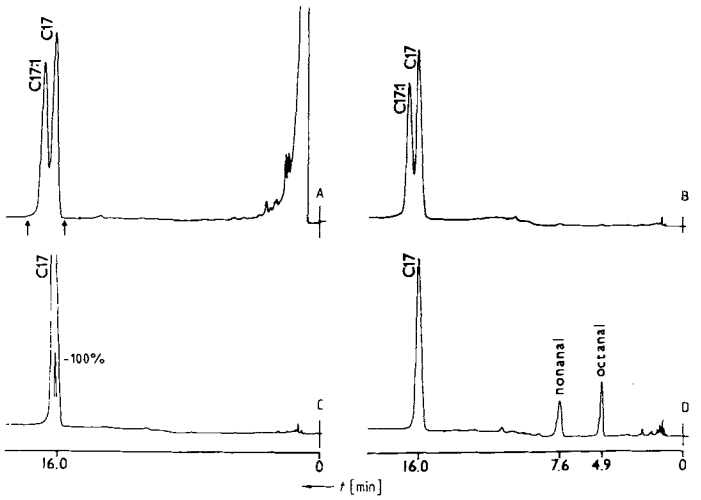

Fig. 10. Trapping, reaction and reinjection. A) Heptadecane and 8-heptadecene (350 ng of each) in 0.5 μL hexane chromatographed on a 10% PEGA column. B) The portion between the arrows in A was trapped and reinjected. C) The trapped portion was reinjected and hydrogenated on-column. D) The trapped portion was ozonized and reinjected. C17:1, (*Z*)-8-heptadecene.

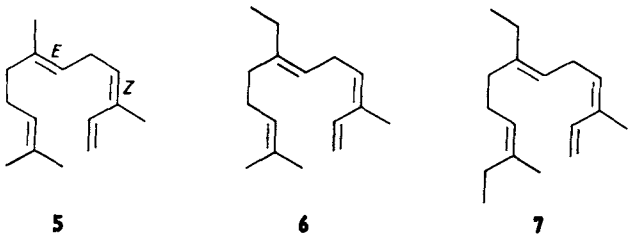
peaks appear, and heptadecane remains unaffected. This method was applied to the pentadecene isolated from the Dufour glands of the ant *Tetramorium caespitum*.[63] The mixture of pentadecane and pentadecene (total of 30 ng) from three Dufour glands was trapped and ozonolyzed. The production of hexanal, heptanal, octanal and nonanal indicated that the pentadecene peak was a mixture of 6- and 7-pentadecene.

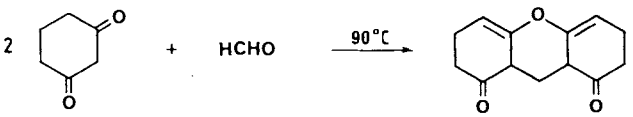
This method of "dry" ozonolysis is particularly useful for the determination of the carbon skeleton between the end of the chain and the first double bond. It has been used in the structure elucidation of farnesene **5** and its homologues **6** and **7** from the Dufour glands of *Myrmica* ants.[64] Microozonolysis demonstrated the presence of an



5 **6** **7**

isopropylidene group in farnesene **5** and homofarnesene **6**, through the production of acetone. The formation of butanone confirmed the presence of a 1-methylpropylidene group in bishomofarnesene **7**. About 50 ng of alkene is sufficient for an analysis. The products are introduced into the chromatograph as ozonides, rather than the more volatile carbonyl compounds, and losses are minimal. The use of ozonolysis to cleave alkynes and alkynoic esters has appeared recently.[65]

The detection of formaldehyde, arising from a terminal double bond, or small dialdehydes from the molecular fragment between two double bonds, presents difficulties. These compounds are not detected by FID. Several methods have been recommended for the detection of formaldehyde. In one, it is treated with 1,3-cyclohexanedione to produce the pyran derivative **8**, which is suitable for GC

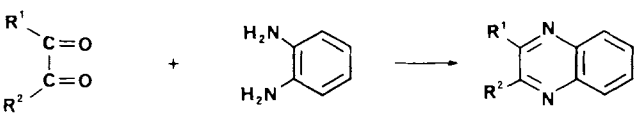


8

detection.[66] Other recommended methods are the formation of pentafluorophenylhydrazones,[67a] *O*-benzyloximes,[67b] *O*-(*p*-nitrobenzyl)oximes,[67b] and *O*-pentafluorobenzyloximes,[67c] all of which are detectable by GC.

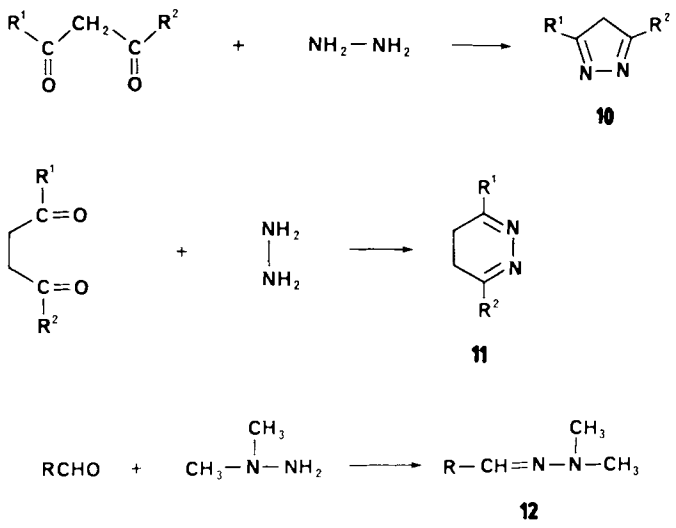
We have found two useful methods for determining nanogram quantities of formaldehyde and other low molecular mass carbonyl compounds. In the first, reaction with *O*-benzylhydroxylamine in a Keele microreactor (cf. Section 5.2) gives quantitative yields of benzyloximes, suitable for GC in the usual way.[68] In the second, the carbonyl compounds are reduced with $NaBH_4$ and the corresponding alcohols analyzed on a Porapak column.[69]

Polyfunctional carbonyl compounds have also been converted into derivatives suitable for gas chromatography. 1,2-Dicarbonyl compounds, as are formed, e.g., in the ozonolysis of conjugated double bonds, can be converted into quinoxalines **9** by reaction with *o*-phenylenediam-



9

ine.[66] Samples as small as 50 ng have been handled by this method.[30] Hydrazine hydrate can convert 1,3- and 1,4-dicarbonyl compounds into pyrazoles **10** and dihydropyridazines **11**, respectively.[66]



All these derivatives are also suitable for GC-MS analysis. Both quinoxalines and pyrazoles generally give the molecular ion as base peak, while dihydropyridazines give a large [M − 2] peak due to aromatization. Aldehydes as ozonolysis products or unsaturated aldehydes found in many pheromone mixtures tend to give featureless mass spectra. Both aldehydes and ketones can be converted into dimethylhydrazones **12**, which give suitable mass spectra with intense molecular ions (ca. 20–30% relative intensity).[70]

5.1.2. Epoxidation

The epoxides derived from alkenes and other unsaturated compounds can be prepared by reaction with *m*-chloroperbenzoic acid (MCPBA) (Scheme 2).[71] In the case of simple epoxides, electron impact (EI)-MS, and for more epoxides, chemical ionization (CI)-MS, can locate the position of the oxirane ring,[72] thus establishing position of the double bond in the parent compound. When more than one double bond is present in the molecule, epoxidation can still be used successfully.[1,72d] The reaction can be stopped at the monoepoxide stage and CI mass spectra of the two monoepoxides can indicate the positions of unsaturation in the parent compound.

This reaction is particularly useful in determining the (*E*)/(*Z*) ratios of geometrical isomeric mixtures. For many insect pheromones the characteristic (*E*)/(*Z*) ratio gives the maximum biological activity. Capillary columns coated with polar phases such as SP-2340 can yield base line separations of (*E*)- and (*Z*)-isomers of underivatized monoenes.[73a,b] However, the same result can also be achieved on nonpolar capillary columns or packed columns by converting the alkenes into the corresponding epoxides.

Nanogram quantities of alkenes trapped in glass capillaries can be epoxidized while keeping the total reaction volume to 1 μL. For example, a mixture of heptadecane and (*E*)- and (*Z*)-8-heptadecene was trapped and epoxidized by adding MCPBA in hexane, in a manner similar to that described in Section 3.4 (Fig. 11).[34] After the reaction, the 8-heptadecene peak in the chromatogram was completely replaced by the two corresponding epoxide signals, while the heptadecane peak remained unaffected. When the 8-heptadecene from the Dufour gland of the ant *Myrmica rubra* was epoxidized, only a single peak, co-chromatographing with the synthetic (*Z*)-8,9-epoxyheptadecane was obtained (Fig. 11c).

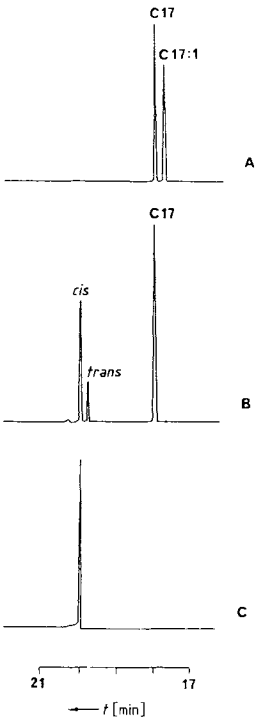


Fig. 11. Separation of (*E*)- and (*Z*)-8-heptadecenes by epoxidation. A) Mixture of heptadecane and heptadecene was chromatographed on an OV-1 capillary column. B) Both peaks from A were trapped in a single fraction, the mixture epoxidized with *m*-chloroperbenzoic acid and reinjected. C) (*Z*)-8-Heptadecene from the Dufour gland of *Myrmica rubra*, trapped, epoxidized and reinjected in the same way.

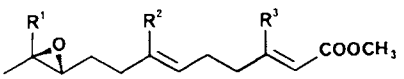
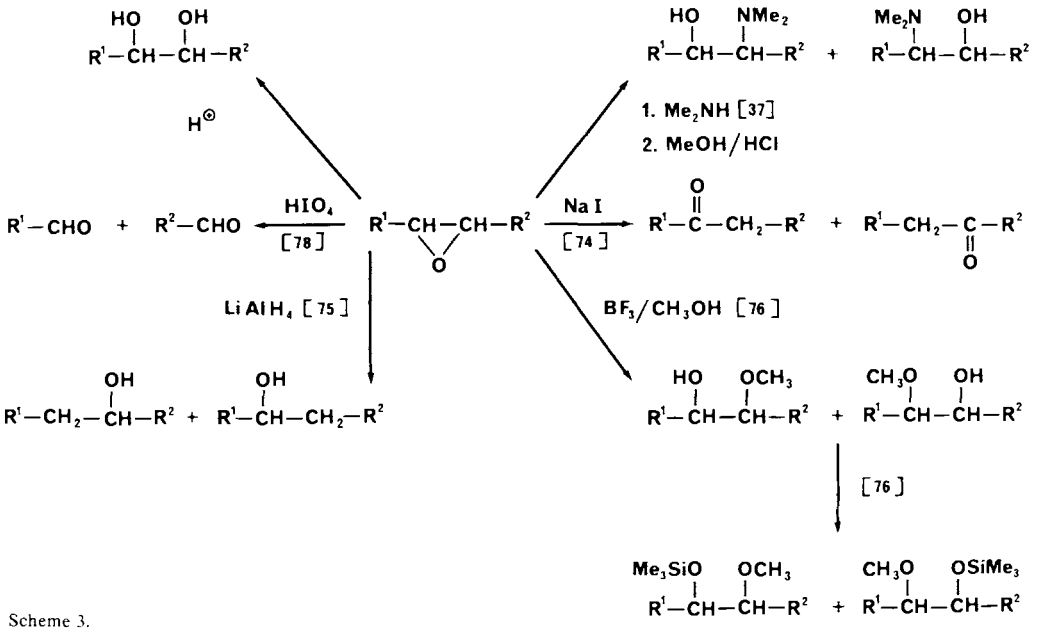
The epoxides can be converted into a number of secondary derivatives which possess better GC-MS characteristics (Scheme 3). *Minnikin*[77] has critically reviewed these methods. *N,N*-dimethylamino-alcohol derivatives[37] are particularly useful for CI-MS procedures.

5.1.3. Cleavage of Epoxides

Since epoxy groups are encountered in many natural products, e.g. the juvenile hormones **13** and some insect pheromones, microtechniques for locating the epoxide position are very important. Direct mass spectrometry usually



13 a, $R^1 = R^2 = R^3 = Et$ JHO
b, $R^1 = R^2 = Et$; $R^3 = Me$ JH I
c, $R^1 = Et$; $R^2 = R^3 = Me$ JH II
d, $R^1 = R^2 = R^3 = Me$ JH III



Scheme 3.

signals the presence of the epoxide. For confirmation, the epoxides can be converted into chemically or mass spectrometrically more easily recognizable entities (Scheme 3).

The epoxides can be cleaved with periodic acid to the corresponding carbonyl compounds, which can then be gas-chromatographed.[78] The geometrical configuration of the disubstituted epoxides can be examined by measuring the reaction time. The *trans*-epoxides are cleaved much more slowly than the *cis*-isomers.[78] Epoxide cleavage by reaction gas chromatography can be achieved simply by heating an epoxide collected in a glass capillary, with solid periodic acid in a sealed tube in the injection port of a gas chromatograph.[32] However, it is more convenient to have periodic acid in a precolumn.[79]

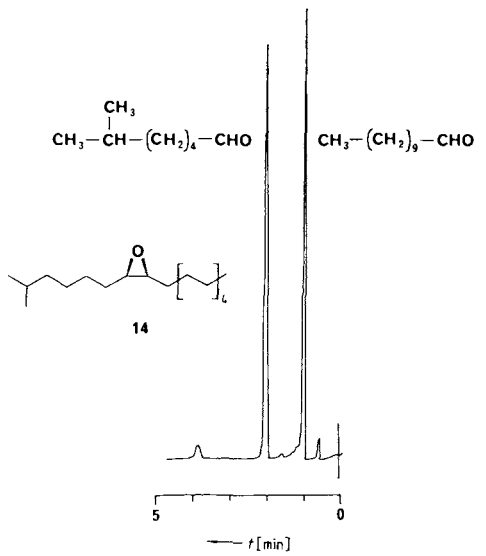


Fig. 12. Epoxide cleavage on a periodic acid precolumn. Disparlure (200 ng) was sealed in a glass capillary and introduced into the gas chromatograph by the solid sampling technique at 180°C. It passed through a periodic acid precolumn and then through a column of 10% PEG 20M.

Figure 12 illustrates the cleavage of the pheromone disparlure **14** by a periodic acid precolumn. Disparlure was trapped in a glass capillary and injected by the solid injection technique. The precolumn cleaved disparlure to 6-methylheptanal and undecanal. A periodic acid precolumn connected to the top of a Porapak Q column is useful for the study of low-mass epoxides. For example, 1,2-epoxypropane and 2,3-dimethyl-2,3-epoxybutane yield acetaldehyde and acetone respectively, whereas 2,3-epoxy-2-methylbutane is cleaved to both acetaldehyde and to acetone. Similarly, juvenile hormones I and II, (**13b**, **13c**) yield butanone as one product, thus indicating that the oxirane ring contains an ethyl group and a methyl group attached to the same carbon atom. In contrast, the juvenile hormone III (**13d**) furnishes acetone. Accordingly, in this case two methyl groups are attached to the same carbon of the epoxide ring.[79] The cleavage of epoxides is quantitative and only a few nanograms of sample are required for a determination.

5.1.4. Hydrogenation

The characterization of alkenes can be facilitated by hydrogenation to saturated analogues which often provide easily interpretable mass spectra. This is particularly useful for determining the carbon skeleton of an unsaturated terpenoid, and combined with mass spectrometry can help determine the number of rings and double bonds in the molecule. Reaction gas chromatographic hydrogenation of unsaturated compounds necessitates employment of a precolumn[32, 80a, b] or a postcolumn[80c] catalyst and hydrogen as the carrier gas. Reduction takes place almost instantaneously. Compounds with up to four C=C groups have been reduced completely using a precolumn catalyst of only a few cm in length.[64] The mass spectra can be obtained in the same step as the reduction when hydrogen is used as the carrier gas. Otherwise the hydrogenated substances can be trapped and re-introduced by the solid-sam-

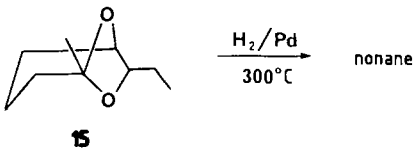
pling technique. The method is applicable to a few nanograms of unsaturated substance or can be used on a micropreparative scale. The reduction of (*Z*)-8-heptadecene (Fig. 10c) shows that the reaction can be quantitative.

A system of hydrogenation with capillary columns has been described for double-oven chromatography. It has been examined in detail for checking the suitability of the catalysts for the reduction of aromatic hydrocarbons and compounds containing polar functional groups.[81]

An alternative procedure is to trap the alkenes in a glass tube containing the catalyst,[30,31] fill the tube with hydrogen, seal, and heat in the injection port for a few minutes before crushing the tube and chromatographing the products.

5.1.5. *Hydrogenolysis*

The simplest derivative that can be prepared for the characterization of an organic compound is its parent alkane or cycloalkane. Complete hydrogenolysis to this parent, frequently called carbon skeleton chromatography, saturates multiple bonds and replaces functional groups containing halogen, oxygen, sulfur and nitrogen by hydrogen. The resulting products, usually the parent alkane or sometimes the next lower homologue or a mixture of the two can then be identified. The compound is allowed to react with hydrogen in a precolumn containing Pd or Pt catalysts at temperatures much higher than those normally used for hydrogenation.[82a-d] *Brownlee* and *Silverstein* have modified this procedure for use directly with trapped material without the intervention of a solvent.[25] When brevicomin **15**, a sex attractant of the Western pine beetle *Dendroctonus brevicomis*, was subjected to hydrogenolysis, they obtained *n*-nonane. A simpler, alternative procedure has been described by *Bierl-Leonhardt* and *DeVilbiss*.[83a] They heated neat or trapped substances, sealed in a tube, with platinum and $LiAlH_4$. The products were then taken up in hexane or hexadecane, depending upon the molecular mass of the expected products, and examined by GC or GC-MS.[83] $LiAlH_4$ apparently serves as a hydrogen source, since similar reaction with Pt alone yielded unsaturated products.



15

A method of structure determination for cyclic sulfur compounds has been devised which involves hydrodesulfurization in a microreactor connected between gas chromatograph and mass spectrometer.[84] Using both hydrogen and deuterium gas, structural information and ring size can be deduced.

5.1.6. *Reduction with $NaBH_4$*

The identification of aldehydes and ketones has been aided by their reduction to the corresponding alcohols with $NaBH_4$, followed by GC and GC-MS analysis.[85] The identification of aldehydes is particularly difficult because of their tendency to oxidize and because they give rather featureless mass spectra. Reduction products larger than hexanol have been identified by reduction with an ethanolic or aqueous solution of $NaBH_4$ in the barrel of a syringe.[86] Surprisingly, it is possible to carry out the reduction with solid $NaHB_4$ in a sealed glass tube, without hydrolysis or additional moisture, at least for a range of carbonyl compounds thus far tested.[14,32,87] An application of this procedure is illustrated in Figure 13. The mandibular gland of *Myrmia* ants contains a mixture of 3-alkanols and 3-alkanones (Figs. 2 and 13A). 3-Octanone, and the minor component 3-heptanol, which elutes as a shoulder on the 3-octanone peak, were trapped in a glass tube, and rechromatographed with finely powdered solid $NaBH_4$. The 3-octanone was quantitatively reduced to 3-octanol and the unchanged 3-heptanol became clearly visible (Fig.

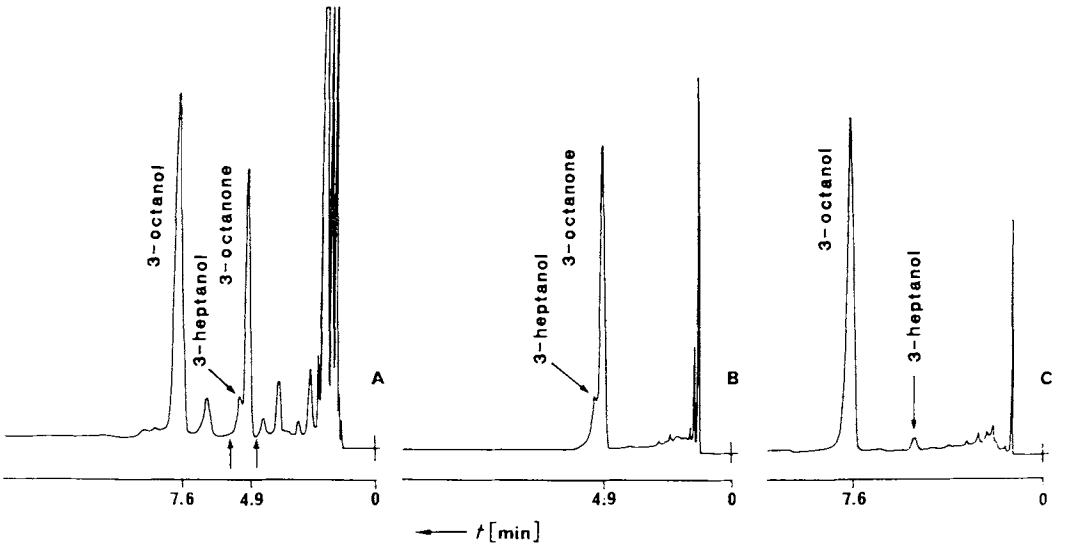


Fig. 13. Reduction of carbonyl compounds. A) The total contents of the mandibular glands of one *Myrmica ruginodis* worker chromatographed on a 10% PEGA column at 125 °C. B) The effluent between the arrows in (A) was trapped and reinjected; C) the effluent was trapped, treated with $NaBH_4$ and injected.

13C). Most probably the reduction takes place between the carbonyl vapors and solid $NaBH_4$ in the injection port.

Alternatively, the reduction can be carried out with $NaBH_4$ in a solvent (not water or ethanol) suitable for on-column injection, such as tetrahydrofuran (THF) or dimethoxyethane, although the solubility of $NaBH_4$ in THF is poor. In one application, saturated $NaBH_4$ in THF was injected into 3-octanone trapped in a glass capillary. The reduction was over 90% complete in 10 minutes[60] (cf. Section 3.4).

A method has been described which is the reverse of this carbonyl reduction. Using a pre-column of activated copper dust at 300–325 °C, primary and secondary alcohols can be dehydrogenated to the corresponding aldehydes and ketones prior to mass spectrometric investigation.[88] This enables a distinction to be made between primary, secondary and tertiary alcohols and dialkyl ethers.

5.1.7. Bromination

A method to differentiate between the peaks of saturated and unsaturated substances in a GC profile is extremely valuable to the microchemist. Bromination shifts all the peaks of the unsaturated compounds, leaving those of the saturated intact. The reaction is instantaneous and the brominated products elute much more slowly than the original alkanes, so that the bromo adducts with more than ten carbon atoms are rarely observed in the chromatogram. Bromination is a stereospecific *trans* addition. Hence the reaction can be used to monitor the geometry of low molecular weight alkenes.[89] Usually the adduct from the *trans*-alkene elutes before that of the corresponding *cis*-isomer. The use of an extremely dilute solution of bromine in a solvent such as hexane or carbon disulfide is recommended. Nanogram amounts of material trapped in glass capillaries can be brominated by the method described in Section 3.4. Figure 14 shows an example of the technique applied to a mixture of heptadecane, 8-heptadecene, nonadecane, and 9-nonadecene.[34] Microscale bromination of glandular components can be achieved by adding 1 μL of bromine solution onto a dissected gland, which can then be chromatographed by a solid injection technique.

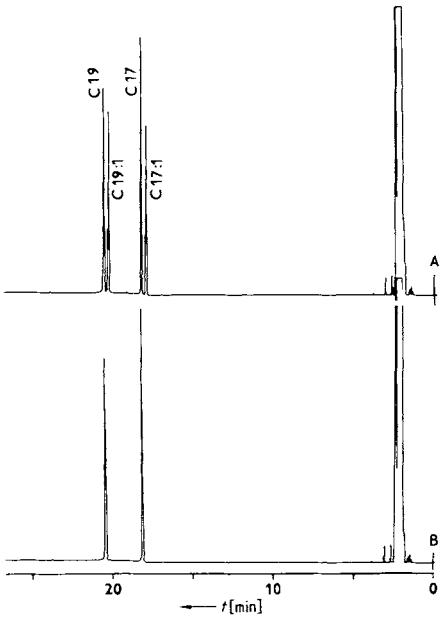

Fig. 14. Bromination of alkenes. A) A mixture of heptadecane, (*Z*)- and (*E*)-8-heptadecene, nonadecane and (*Z*)- and (*E*)-9-nonadecenes (100 ng each) were trapped in a glass capillary and reinjected. B) The same mixture treated with bromine before reinjection. Chromatographed on an OV-1 capillary column programmed from 40 to 300 °C at 10 °C/min.

5.1.8. Esterification with Diazomethane

The lower members of aliphatic monocarboxylic acids are sufficiently volatile to be separated directly by GC. However, adsorption of acids onto the chromatographic support often leads to tailing of the peaks. Esterification is frequently used to convert relatively nonvolatile and polar carboxylic acids into less polar methyl esters with better GC characteristics. The wide variety of techniques available for the esterification of fatty acids has been reviewed.[90a, b] Fatty acids can be trapped from the GC effluent in glass capillaries, and conveniently esterified using CH_2N_2 in THF.[34] The reaction mixture can be rechromatographed as described in Section 3.4. *Huwyler* et al. used a comparable method to esterify low-molecular weight fatty acids and identified the fatty acid components of the trail pheromone of the ant *Lasius fuliginosus*.[91] There is one example reported of a procedure in which octanoic acid was injected into the chromatograph shortly before an ethereal solution of CH_2N_2.[92] Other reaction GC methods available for the esterification of fatty acids have been reviewed by *Harris*.[93]

5.1.9. Acetylation of Alcohols

Acetylation is a useful reaction to check the identification of alcohols and then to distinguish between a primary and a secondary alcohols. Furthermore, if the substance has biological activity, a loss of activity upon acetylation and its return upon saponification may indicate that the active substance is an alcohol.

Primary and secondary alcohols can be acetylated on a microscale by a method similar to that described by *Huwyler*.[94] For primary alcohols trapped in a glass capillary, THF containing acetic anhydride and pyridine can be added, and the mixture examined by GC by on-column injection. Although the reaction is slow for secondary alcohols, it is quantitative. The same procedure can also be used for acetylating phenols, and the number of phenolic groups present can be estimated from the shift in retention time. The method is applicable to samples of a few nanograms.

5.1.10. Dehydration

Dehydration of alcohols to alkenes by reaction GC has been known for some time. Under favorably mild conditions, alcohols can be dehydrated in such a way that the new double bond is formed and remains at the original position of attachment of the hydroxy group. A number of dehydrating agents such as alumina,[87] $KHSO_4$,[87]

H_3PO_4,[95] and hexamethylphosphoric triamide[87] have been employed.

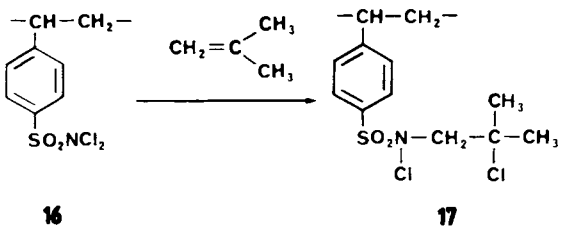
Drawert et al.[59,95] used a precolumn reactor containing phosphoric acid. *Stanley*[87] conducted the dehydration of trapped alcohols in sealed glass capillaries. Recently, *Kobold* et al. and *Bestmann* et al.[96] have used a few milligrams of Al_2O_3 in the insert liner of the injection block for the dehydration of terpene alcohols. *Stanley*[87] found that basic alumina gives fewer rearrangement products than acidic alumina: for example, 1-heptene was the major product of dehydration of 1-heptanol, whereas acidic alumina yielded all five isomeric heptenes.

5.1.11. Subtraction Techniques

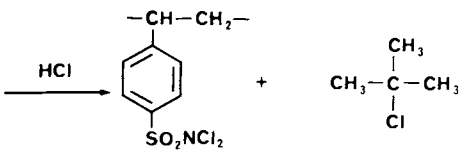
Information about functional groups present in a compound can be obtained by the subtraction-loop technique. An appropriate reagent deposited on a solid support, placed before or after the analytical column forms nonvolatile products and thereby abstracts the reacted compounds from a mixture.[82d]

Subtraction techniques for packed columns have been known for some time and many reviews of the subject are available.[97] Only recent advances in this area will be mentioned here. Benzidine has been used to remove carbonyl compounds; however, it is a potent carcinogen and its use is now forbidden. Non-mutagenic 3,3',5,5'-tetramethylbenzidine may be used instead.

Alieshoev et al.[98] have described a reagent for the subtraction of unsaturated aliphatic hydrocarbons. The compound, a styrene-divinylbenzene copolymer with *N,N*-



16 **17**



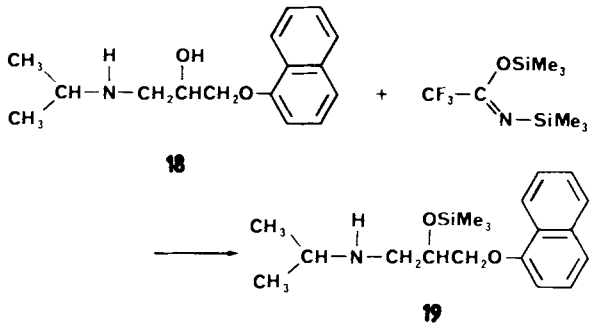
16

dichlorosulfonamide groups (**16**), removes alkenes and alkynes quantitatively, whereas alkanes and aromatic compounds remain unattacked. Furthermore, the used polymer (**17**) can be converted back into the active form **16** by a current of hydrogen chloride. *Kalo*[99] has described the use of subtraction techniques with capillary gas chromatography, where the subtracting agent is deposited on the wall of a glass capillary column.

5.1.12. Other Methods

There are many other reactions which could swell the armory of nanoscale chemistry. Alcohols have been oxidized in sealed glass capillaries[87] to carbonyl compounds by potassium dichromate crystals. A periodic acid precolumn can also convert alcohols into carbonyl compounds, although the yields are poor.[32] A number of microreactions can be performed by leaving the reactants in the syringe barrel for a few minutes[85,86] before chromatography.

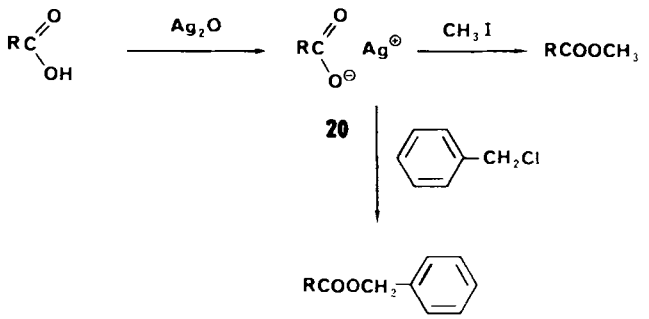
In many cases, compounds containing active hydrogen (e.g. **18**) display better gas chromatographic characteristics when silylated (**19**). Moreover, the mass spectra of silyl



18 **19**

ethers can yield more structural information, e.g. the position of the OH group in a secondary alcohol can often be located in this way.[58e] Many of the large number of silylating techniques available[100] may be adapted for use on a microscale.

Non-esterified, low molecular weight fatty acids have been trapped into tubes containing Ag_2O to give the silver salts **20**. After introducing either methyl iodide or benzyl chloride[101] to the trapped material, it can be rechromatographed in the form of the ester using a solid-injection technique.



20

A number of other microchemical derivatization methods are available[102] that might be adapted for use on a nanogram scale. It is evident from the examples given that a large number of chemical reactions long practiced on a macroscale are adaptable, with a little ingenuity, to very small quantities.

5.2. Reactions Requiring a Solvent Extraction

Many of the reactions of macroscale organic chemistry require considerable work-up to isolate the product: a compound may have to be released from a salt, excess reagent destroyed, or the product separated from an aqueous mixture of spent reagents. It may not be possible to adapt such reactions directly to the microscale and inject the crude reaction mixture into a gas chromatograph. The reagents and spent products may be corrosive or destructive to the stationary phase or interfere with the analysis. A review by *Poole* and *Schuette*[103] discusses the methods available for sample preparation before capillary GC, including extraction and concentration, and summarizes the problems associated therewith.

Separating funnel partitions require mL quantities of solvent while only a few μL are sufficient for chromatography. Either the small and valuable sample is going to be in very dilute solution, or the solvent must be removed, concentrating impurities in the residue and possibly losing valuable volatile components.

A recent method described by *Cais* and *Shimoni*[104] shows recoveries of more than 80% from extractions, but requires at least 2 mL of extracting solvent. Much lower solvent volumes, have been used by *Grob* et al.[105] for the extraction of organic substances from water samples. *Murray*[106] has improved this method to give better recoveries. A simple but efficient extraction method using a glass syringe has been described by *van Rensburg* and *Hassett*.[107] The sample is extracted in the syringe barrel, which is then turned upside down and the solvent is withdrawn from the tip by gently pushing the plunger.

None of the above methods and devices are suitable for derivatization before extraction, especially when the reaction requires heating. Therefore, we developed a technique that allows derivatization and extraction in the same container with the minimum of manipulation and transfers. The device, which we call the *Keele microreactor*[108] (Figs. 15 and 16), is available commercially.

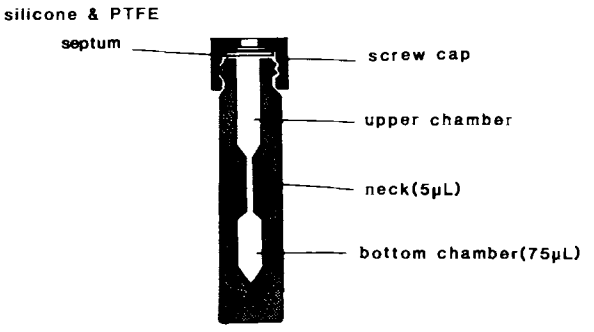


Fig. 15. A sectional view of the Keele microreactor. The microreactor is available from Wheaton Scientific, Millville, NJ 08332 (USA) and their distributors world-wide.

The Keele microreactor has essentially three features; a bottom chamber, a narrow capillary neck, and an upper chamber. When using the microreactor for reaction or extraction, the required liquid layer is drawn into the narrow capillary neck, from which it can be efficiently and almost completely removed for analysis. One of the main advantages of this procedure is that the substances can be extracted with solvents either lighter or heavier than water. The microreactor can be sealed with a teflon liner and screw cap and heated up to 200°C in an oven without any loss of material.

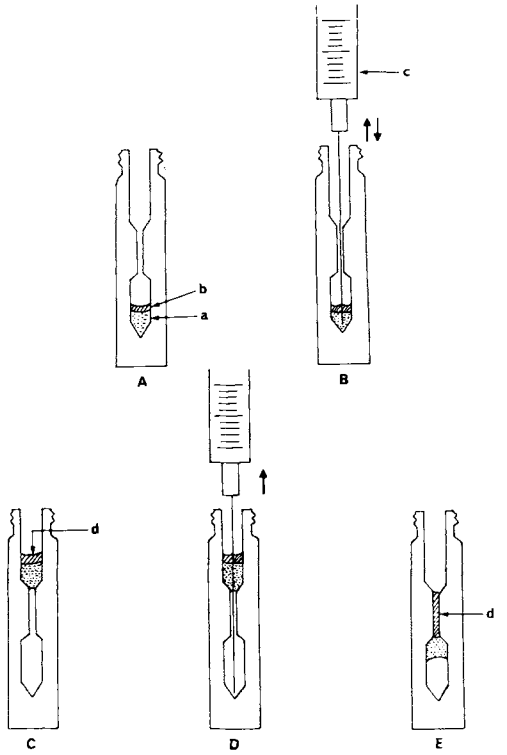

Fig. 16. Use of the Keele microreactor. A) After reaction in the lower chamber, an extraction solvent b is added to the reaction mixture a. B) The two phases are mixed by pumping through a syringe (100 μL). C) The two phases are placed in the upper chamber to separate. D) The spent reagents are drawn into the lower chamber by withdrawing air by a syringe. E) The product in solution is left in the middle chamber d, from which it can be withdrawn efficiently by a microliter syringe.

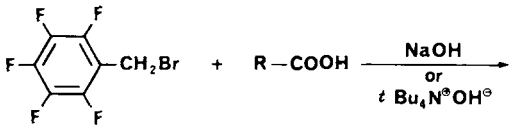
In a typical extraction procedure the aqueous solution (about 50 μL) is mixed with a solvent such as hexane (10 μL) by pumping the mixture in and out of a glass syringe (Fig. 16B). This process ensures the breakage of the liquid mass into tiny droplets causing an intimate mixing of the two phases. The liquid mixture is allowed to settle in the upper chamber. The surface tension of the liquid in the narrow neck and air in the bottom chamber prevents the liquids running into the lower chamber. A fine syringe needle (0.17 mm OD) is inserted into the lower chamber and air is withdrawn until the desired organic liquid layer enters the neck region (Fig. 16D). Then the organic layer can be withdrawn efficiently for GC or HPLC analysis. Typical recoveries were 40–65% for a single extraction step and nearly 90% for three consecutive extractions.[108]

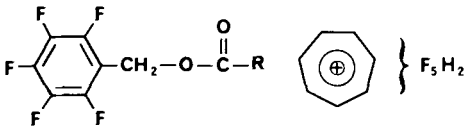
Some derivatization reactions requiring extraction demonstrate the usefulness of the reactor. Further examples can be devised to suit the chromatographer's problem.

5.2.1. *Pentafluorobenzylation of Carboxylic acids*

Pentafluorobenzyl bromide is a useful reagent for the derivatization of phenols, mercaptans, sulfonamides and carboxylic acids[109] prior to a GC analysis. In a typical derivatization, the acid and pentafluorobenzyl bromide **21**



21



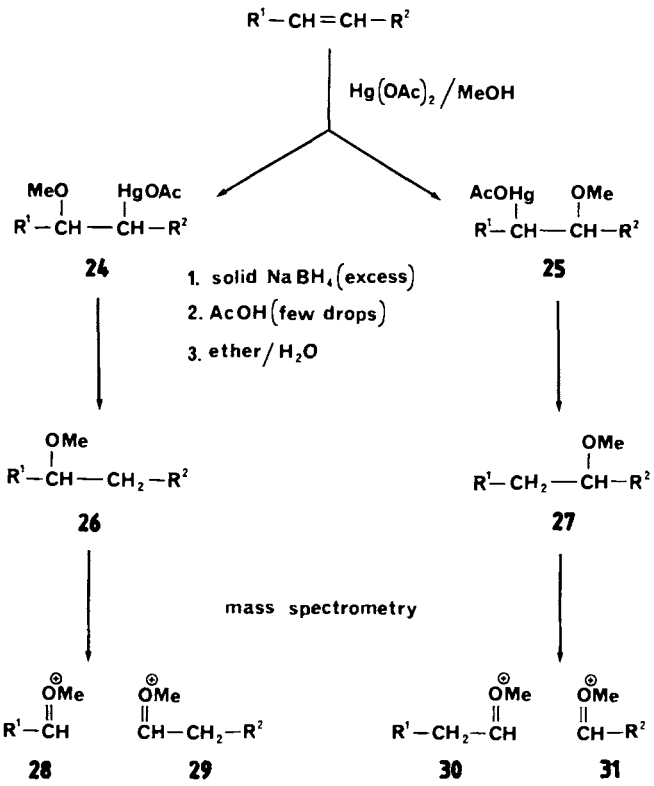
22 **23**

are placed in the bottom chamber of the microreactor. A strong base such as aqueous tetra-*tert*-butylammonium hydroxide is added to remove hydrogen bromide. The reactants are drawn up and down into a glass syringe several times to ensure thorough mixing. The reaction mixture is placed back in the bottom chamber, the vial is closed and shaken. After the reaction is complete 20 µL of water and 10 µL of hexane are added and the organic layer is removed for GC examination.[108] The reaction is fast and quantitative. The derivatives **22** can be identified easily by GC–MS, due to the presence of the pentafluorotropylium cation **23**. Only a few nanograms are required for flame ionization detection. The sensitivity can be increased to picogram level when an electron capture detector (ECD) is used.

5.2.2. *Methoxymercuration–Demercuration of Alkenes*

Methoxymercuration-demercuration has gained popularity as a method for locating the position of double bonds in alkyl chains. *Abley* et al.[49] first described the application of GC–MS to these methoxy derivatives (Scheme 4). The reaction produces two adducts, **24** and **25**, for a single mono-unsaturated compound. The two methoxy derivatives **26** and **27** usually co-elute in GC. The fragmentation of the derivatives in the mass spectrometer results in preferential cleavage on either side of the methoxy group to yield four intense and characteristic fragment ions **28**–**31**. From the masses of these ions, the original double bond position can be deduced.

Many applications of this technique have been reported.[56, 110] The methoxy derivatives **26** and **27** produced must be partitioned between water and ether or hexane before the non-aqueous layer is examined by GC. Such extraction usually requires 50 µL or more of the nonaqueous solvent to allow convenient withdrawal of the upper layer. By the use of the Keele microreactor, 200 ng of alkene samples were conveniently derivatized and the methoxy derivatives could be extracted into 5 µL of hexane.[108]



Scheme 4.

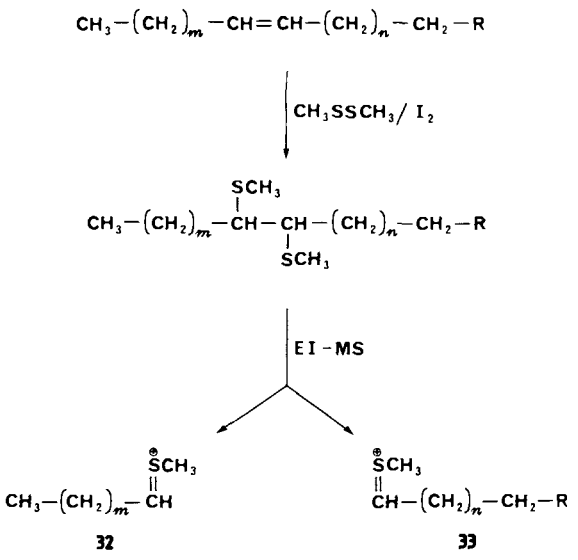
5.2.3. *Methylthiolation of Alkenes*

The addition of dimethyl disulfide (DMDS) to monounsaturated alkenes,[57] acetates,[111a] fatty acid esters, aldehydes and alcohols[111b,c] is a more recent method used to locate double bond positions. The addition is stereospecific for both (*E*)- and (*Z*)-isomers yielding a single adduct in each case. The adducts cleave in the mass spectrometer preferentially across the carbon–carbon bond between the CH_3S substituents, leading to two major fragment ions **32** and **33** (Scheme 5). These give intense peaks, one of them usually the base peak, which can be employed to locate the double bond in the parent molecule.

In the procedures described by *Buser* et al.[111a] and *Dunkelblum* et al.[111b] the adducts are finally extracted into 200 µL of hexane and concentrated before chromatographic examination. By employing the Keele microreactor the sensitivity of the method is improved manyfold.[108]

Methylthiolation has a number of advantages over the more widely used methoxymercuration-demercuration method.[63] In the latter the reaction mixture is heterogeneous and is difficult to handle once mercury has been displaced. The reaction is not quantitative, the yields being typically between 55 and 70%. In contrast, methylthiolation is a homogenous reaction, all the components are miscible, much smaller quantities of the unsaturated compound can be used, and the reaction is near quantitative. In methoxymercuration-demercuration a mixed mass spectrum is obtained of the two derivatives (Scheme 4) and each monounsaturated compound gives four characteristic peaks. Methylthiolation leads to only one product with two intense ions (Scheme 5), which are generally more in-

tense than those of methoxy derivatives. Further, the methoxy derivatives rarely show a molecular ion, so identification is less certain. While the underivatized alkenyl acetates, alcohols and aldehydes rarely show molecular ions, the DMDS derivatives examined have always shown a prominent molecular ion. The DMDS adducts of alkenyl acetates and methyl esters of fatty acids show significant fragment ions arising from a loss of acetic acid or methanol respectively from the ion **33**.[111a,b] Similarly, the spectra of unsaturated alcohols and aldehydes show a weak loss of water from the ion **33**.[111c] These ions help to establish the functionality of the compound when a mixture is being examined.



Scheme 5.

Finally, the methoxy-derivative method does not distinguish between (*E*)- and (*Z*)-isomers, whereas the methylthioether method proceeds with stereospecific *trans* addition. The (*E*)- and (*Z*)-isomers yield *erythro*- and *threo*-isomers respectively, which may give almost identical mass spectra, but they are resolved by capillary GC, with the *threo*-isomer usually eluting first. Hence the geometry of an unknown compound can be determined by comparing the retention time with those from a standard (*E*)- and (*Z*)-mixture.

Although methylthiolation has been frequently used only with monoenes, recent results[112] show that it is applicable to dienes also. However, the mass spectra of diene derivatives are not so simple as those of monoenes. Methylthiolation is certainly the preferred method for locating mono-unsaturation.

5.2.4. Esterification of Carboxylic Acids with Boron Trifluoride–Methanol

Esterification with BF_3-methanol is a convenient method for preparing methyl esters of carboxylic acids.[113] However, the crude reaction mixture cannot be injected onto the gas chromatograph because BF_3 is destructive to many stationary phases. The esters must be solvent extracted before injection and sensitivity of the method is substantially increased using the Keele microreactor.[108]

McDaniel and *Howard* have recently reported[70] that 1,1-dimethylhydrazine can also form methyl esters from fatty acids. The reaction is almost quantitative when the acid and 1,1-dimethylhydrazine are heated in a sealed microreactor. The mechanism of the reaction is unknown. The products are partitioned between hexane and dilute sulfuric acid.

6. Liquid Chromatography–Gas Chromatography

In the analysis of crude samples a liquid chromatographic fractionation (LC) is often performed before GC.

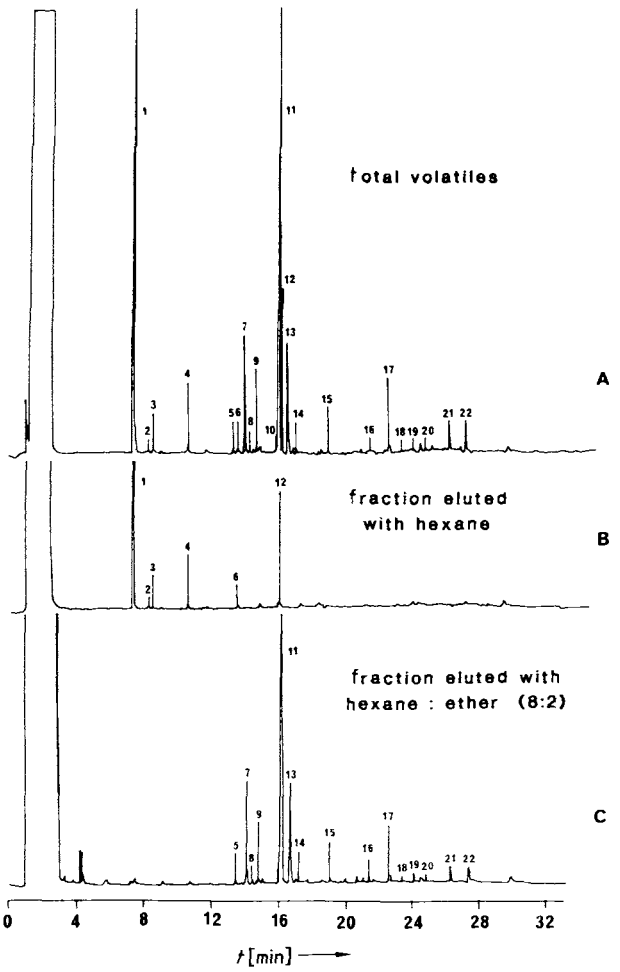


Fig. 17. Use of a microcolumn with gas chromatography to separate classes of compounds. A) An extract of Dufour gland substances of the ant *Lasius niger* in hexane was chromatographed on an OV-17 capillary column, at 60°C for 2 min then programmed at 10°C/min to 270°C. Splitless injection with the split vent kept closed for 30 s. B) A chromatogram of the hexane fraction eluted from a microcolumn directly onto the GC. All peaks are hydrocarbons. C) A chromatogram of the hexane–ether (8:2) eluent from the micro-column directly into the GC. All the peaks (except 9) are due to esters. 1, undecane; 2, 5-methylundecane; 3, 3-methylundecane; 4, tridecane; 5, decyl acetate; 6, pentadecane; 7, 5-methyldecyl acetate; 8, 3-methyldecyl acetate; 9, undecyl acetate + dodecanol; 10, dodecenyl acetate; 11, dodecyl acetate; 12, heptadecane; 13, a branched tridecyl acetate; 14, dodecyl propionate; 15, farnesyl acetate; 16, heptadecyl propionate; 17, octadecyl acetate; 18, octadecyl propionate; 19, dodecyl decanoate; 20, decyl tridecanoate; 21, dodecyl dodecanoate; 22, dodecyl tridecanoate.

However, this procedure is time consuming and wasteful if only a small amount of sample is available. *Sandra*[114] recently described an elegant method for accomplishing liquid chromatographic fractionation before GC in a simple but efficient way. An on-column syringe is used with a polyimide cartridge holding milligram amounts of silica gel or similar materials.

A "microcolumn" of fine silica gel can be made in a similar way in the barrel of a 100 μL syringe[115] and similar devices are now available commercially. An application of the technique for the analysis of a Dufour gland of the ant *Lasius niger* is illustrated in Figure 17. The gland contains over 50 compounds with several functionalities (Fig. 17A).[15a] An individual gland was placed on top of the microcolumn and eluted first with hexane directly into the gas chromatograph via a splitless injector. Only the hydrocarbon peaks were present in the chromatograms obtained from the first two hexane fractions (Fig. 17B). The third hexane fraction contained only the major hydrocarbons, whereas the fourth fraction showed no significant peaks. The microcolumn was then eluted with mixtures of hexane and ether. In the second hexane/ether fraction only the ester peaks were present (Fig. 17C). A subsequent elution of the microcolumn with pure ether gave the alcohols.

The LC-GC method has great potential in the microanalysis of organic functionalities. For example *Bestmann* et al.[115] employed this method for the identification of the sex pheromone of the moth *Cnepasia longana*. Dilute samples can be concentrated before elution into the GC column. When combined with subtraction reactions, this can produce further information about functionality. Further, crude reaction mixtures can be purified before the desired products are eluted into the gas chromatograph.

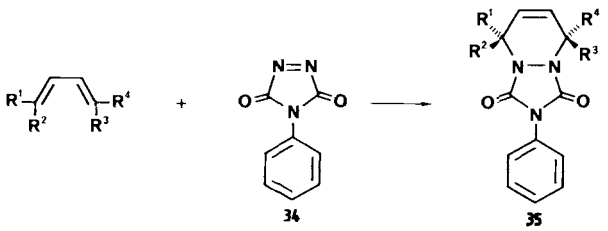
7. Summary and Outlook

The research worker or analyst may be surprised by what can be done with nanogram samples of organic materials, pure or impure. Provided one does not contaminate them with large quantities of solvents, they may be taken through many manipulations. It is not always necessary to rely on an existing library of mass spectra to deduce the structure of a new substance available only in minute quantities. Conventional chemical training can be called into play, along with a little ingenuity and skill to carry out reactions, degrade or derivatize the substance, even when accompanied by many others, to learn something of its carbon skeleton or its functional groups. Equally minute amounts of substance can be separated from mixtures for further testing. Though the authors' experience has been largely drawn from insect chemistry, the applications are clearly much wider. Examples may be found in forensic science, archaeology, environmental monitoring, pharmacology and drug metabolism.

8. Addendum[*]

Since preparing this manuscript, two reviews have been published on derivatization techniques applicable to microcromethods.[116a,b] Traps coated with a very thick film of stationary phase have been used for recovering material after capillary gas chromatography.[117] A reaction gas chromatographic method for the conversion of water into acetylene has been reported,[118] which could be useful for the determination of water in biological samples. GC-FTIR shows promise of being widely applied in the determination of the geometric configuration of double bonds in pheromones.[119a,b] Water vapor has been used as the carrier gas for the separation of geometric isomers by gas chromatography on a support impregnated with silver nitrate.[120]

Two comprehensive reviews on the location of double bonds in carbon chains have been published.[119a,121] The mass spectra of cycloadducts **35** formed by the addition of 4-phenyl-1,2,4-triazole-3,5-dione **34** to conjugated dienes



34 **35**

display characteristic ions, diagnostic of the diene position in the chain.[122] The addition of tetracyanoethylene can be used similarly.[123] The methylthiolation procedure for locating double bonds (cf. Section 5.3.2) has been extended to many diene compounds.[124] Recent advances in chemical-ionization mass spectrometry, using reagents such as Fe^{+}[125] and NO,[126] show potential for use in double-bond location, although the principles governing the reactions remain unclear.[127] Further examples of the use of tandem mass spectrometry for double-bond location have been published.[128a,b]

A convenient procedure for determining dialdehydes produced by the ozonolysis of polyenes has been described.[129] The aldehyde groups are converted into 1,3-dioxanes by reducing the ozonides in the presence of 1,3-propanedithiol.

A. B. A. thanks the British Council and the Nuffield Foundation for financial assistance, the Alexander-von-Humboldt Foundation for support, and Professor Dr. H. J. Bestmann for kind hospitality during the preparation of this manuscript. E. D. M. thanks the Royal Society for a grant for equipment, K. T. Alston for help in devising equipment and T. Bolam for many of the illustrations. We thank Dr. O. Vostrowsky for critically reading this manuscript.

One or Several Pioneers? The Discovery of Noble-Gas Compounds

By Pierre Laszlo* and Gary J. Schrobilgen*

For the general public, science history and restaurant menus share a labeling style. Like Melba peach, Soubise sauce, or tournedos Rossini, many a scientific discovery is credited to a single thinker or tinkerer. Such ultrasimplification rubs into oblivion other important contributors or codiscoverers. The discovery of noble-gas compounds conforms to such a stereotyped and mythic view: according to the standard account, *Neil S. Bartlett*, then at the University of British Columbia, made it a quarter of a century ago on March 23, 1962. We do not attempt here a full and definitive history; it would be premature and we do not have the space. Rather, we shall document the concept and the earlier attempts at synthesis—they antedated *Bartlett*'s success by three decades. The motivation for this note may be summarized in the following questions: (1) What sort of insight and input were those of *Linus Pauling*? (2) What were the likely causes for failure of the attempt by *Yost* and *Kaye* to synthesize noble-gas fluorides in the 1930s? (3) Were there other researchers who envisioned a noble-gas reactivity?

1. The Very Early Story

As always, there are scraps of a prehistory. After the discovery of argon in 1894 by *William Ramsay* and *Lord Rayleigh (J. W. Strutt)*,[1] *Ramsay* provided *Moissan* with about 100 mL of the gas so that he could react it with fluorine, which *Moissan* had isolated in 1886. *Moissan* attempted the reaction of the two gases at room temperature or under the action of an induction spark, but without success.[2] In the same year as *Moissan*'s report, *Marcelin Berthelot* announced that he had combined helium with benzene and with carbon disulfide using a silent electric discharge.[3] *R. J. Strutt* had already drawn attention to the intriguing occlusion of helium in beryl, in the absence of any radioactive source.[4] He repeated *Berthelot*'s experiments and was unable to reproduce his results.[5]

The next episode is epistolary rather than experimental. In 1902, *Giuseppe Oddo*, then a professor in Cagliari, wrote to *Sir William Ramsay* to suggest that, due to the general increase in valence down a row of the periodic table, krypton ought to show a certain tendency toward chemical combination, while xenon ought to have yet a more pronounced such tendency. *Ramsay* agreed that krypton and xenon ought to be more reactive than their lighter relatives. But he could not share the enthusiasm of his Italian correspondent, pointing out that it would be extremely difficult to isolate enough of these two gases to run the experiments. There the matter rested till *Oddo*, reading in 1932 a report of the preparation by *Antropoff* and his co-workers of krypton chloride, decided to publish his correspondence with *Sir William Ramsay* of 30 years back.[6] One should note also the report by *Boomer* of formation of a stable WHe_3 compound under intense electric discharge from a tungsten filament in low-pressure helium.[7] This brings us to the *Antropoff* 1932 "preparation" and to its antecedents.

2. The Early Story

The *Antropoff* part of the story is endearing. He strikes us as an opinionated visionary who knew that he was on the right track. *A. von Antropoff*, then in Karlsruhe, published a paper in the April 17, 1924 issue of *Zeitschrift für angewandte Chemie*.[8] *Antropoff* was building, in part, on the semitheoretical paper of the physicist *Kossel* who predicted, on the basis of ionization potentials, that it should be feasible to form compounds between the heavier noble gases and the most electronegative element. *Kossel* predicted the existence of a xenon fluoride and a krypton fluoride.[9] *Antropoff*'s article discusses the position of the noble gases in the periodic table. In an extremely lucid and well-argued manner, *Antropoff* suggests placing the rare gases in group VIIIb of the periodic system (with the present controversy about the best numbering of the rows in the periodic table, we need no reminder of the importance of such considerations). Accordingly, *Antropoff* pointed out, rare gases will thus be potentially reactive. Such a positioning will give them a maximum valence of eight, and, in *Antropoff*'s words, "one should not forget that as the valence number increases from one group to the next, the intensity of the valence forces decreases." His key sentence is: "*Die Stellung in der Gruppe VIIIb lässt aber die Möglichkeit der Bildung von Verbindungen mit negativen Elementen offen*" (placement in group VIIIb leaves them the possibility to form bonds with negative elements).[8]

This proposal did not go unnoticed. *H. Danneel* published soon afterwards a reply[10] with the all-too-usual

plea to leave things as they were till more conclusive evidence could be lined up. *Antropoff* jumped back to his desk and penned another article[11] in support of his idea, drawing upon evidence provided by *Danneel* himself and by *Paneth*.[12]

Not only did *Antropoff* stick to his guns, a number of years later he did experiments to form halogen compounds of the noble gases. Taken together with his conceptual considerations,[8,11] they make him a true pioneer in the discovery of noble-gas compounds. *Antropoff* and his coworkers attempted to react krypton with both chlorine and bromine under an intense electric discharge. Not only did reaction take place, as indicated by the drop in gas pressure resulting from combination; they could also isolate a solid, dark red substance.[13] With *Antropoff*'s permission, *Otto Ruff* and *Walter Menzel* in Breslau also conducted similar experiments, with argon-fluorine and krypton-fluorine mixtures, but without success.[15] *Antropoff* was undaunted by their failure, and pointed out that their reaction conditions differed enough from his to explain such lack of success.[14] However, he must have felt the inward challenge. In any case, he decided to reinvestigate his own work. Thus, he had to report in 1933 (he was now at Bonn) that the dark red compound formed in his apparatus was an already known compound of NO and HCl.[16]

This retraction article[16] makes for interesting reading. The authors point out that they still cannot account for certain losses in krypton pressure. Maybe they were still hopeful, and *Antropoff* was still sticking to his guns. One wonders whether he was wont to predict to his associates and students the confirmation of his ideas and the future preparation of noble-gas compounds; it would have been in character for him to do so.

3. *Linus Pauling* Steps In

In 1933, *Linus Pauling* published an article in the *Journal of the American Chemical Society*[17] which dealt ostensibly with the formula of antimonic acid. *Pauling* pointed out that the molecules of oxo acids can be seen as consisting of a central cation surrounded by as many oxygens as will fit around it. Simple consideration of ionic radii is then sufficient to predict reliably coordination numbers: for instance, "the coordination number three is indicated for B, C and N, whose acids should have the formulas H_3BO_3, H_2CO_3 and HNO_3 in agreement with observation."[17] Such simple arguments led *Pauling* to predict oxygen coordination numbers of four and six for krypton and xenon, respectively. He thus conjectured the formula H_4XeO_6 for xenic acid, and predicted quite naturally that it "should form salts such as Ag_4XeO_6 and AgH_3XeO_6."[17] At the end of his paper, *Pauling* moved on to consider fluorides. The same sphere-packing considerations gave him a series of structures in agreement with observation, and led him to the "predicted formulas KrF_6 and XeF_6, with XeF_8 as an unstable compound which might be capable of existence."[17]

Several of these predicted species were actually prepared in the early sixties at Argonne National Laboratory. *Pauling* told us that his conjectures on antimonic acid and noble-gas compounds (perxenic acid and its salts) were really largely directed by reasoning from analogy with other then-known hypervalent species such as $Te(OH)_6$ or $IO(OH)_6$. As for antimonic acid, *Pauling* gave its formula as $HSb(OH)_6$, but, as an ironical footnote to this work, he pointed out in a short note a few months later that, unknown to him, this formula had already been published by *Louis Hammett* a few years before.[18]

4. A Near-Miss, the *Yost* and *Kaye* Experiments

The next and arguably the most fascinating episode took place at Caltech (California Institute of Technology) in 1932 and 1933, with *Linus Pauling* as a most interested onlooker. The senior protagonist was Professor *Don M. L. Yost* (1893–1977), an extremely intent scientist who brought extreme honesty to his work. When *Albert L. Kaye*, who had obtained his B. S. and M. S. engineering degrees at MIT (Massachusetts Institute of Technology), entered the graduate school at Caltech in the fall of 1932, *Yost* recruited him. *Yost* had a very attractive personality, which drew *Kaye* to his work. *Yost* gave *Kaye* the project of forming noble-gas compounds. This was in line with *Yost*'s philosophy that everything could be proved with experiments. He also told *Kaye* of *Antropoff*'s work in 1924 and gave him the initial task of researching all the published attempts at reacting the noble gases.[19] He told *Kaye* to think also of alternative routes to their combination with other elements. *Kaye* must have struck *Yost* as an outstanding choice for such work, because of his earlier training as an electrochemist. *Walter Schumb* had been *Kaye*'s freshman chemistry teacher at MIT and *Schumb* had a strong interest in halogen chemistry. Thus the decision was taken to make an attempt at reacting the noble gases.

Some of the conditions were highly favorable. As *Yost* later wrote,[20] "there were no redundant administrators, safety officers, or editors to bother us or to suggest delicious sins that we might be tempted to commit." Other conditions were less desirable.

In those days the labs at Caltech were small. *Kaye* was eager to get going. He needed good ventilation for handling fluorine. *Yost* answered this request by suggesting that the experiments be run in his office, which doubled as a small laboratory, in the basement of the Gates Chemical Laboratory. The ventilation was inadequate. *Yost* and *Kaye* arranged for a fume hood to be installed. When this was done, in the late fall of 1932, work could start. *Yost* and *Kaye* were very optimistic. They were the brunt of some gentle kidding in the department, and were often told that "they were out to rape xenon."

But first the would-be rapists had to build their own fluorine generator, using the electrolysis of molten HF-KF. They had a cryogenic purification train for fluorine, which caused various difficulties. They blew their own glass[20] [sic; vide infra]. The actual vessel for containing the electric discharge (they used cast-off Ford induction coils as the high-potential source[20]) was machined from a solid bar of copper. *Kaye* himself designed the copper discharge vessel and window.

He now describes it as follows:

> The copper reaction vessel was machined from [an] approximately 4" round bar of solid copper about 12" long. This was bored eccentrically in from both ends and the bores thus met at the center of the bar length which was then enlarged at the center and for a short length toward either end. The enlarged center cavity was provided with a copper stop-cock to drain off any liquid which might accumulate in this area and provided with two holes at the top to accommodate the electrodes. The ends of the vessel were sealed with fitting copper caps with holes for the gas inlet tubes. The only reason the foregoing is clear in my mind is that I remember it taking me quite a while to sell the chemistry department's machine shop foreman on the idea of machining such a maverick contraption to which he contributed a minimum of enthusiasm toward tackling!

Figure 1 shows a (reduced) sketch of the apparatus, which Dr. *A. L. Kaye* drew from memory for this article.

As they were uncertain about the state of aggregation of the product(s), *Yost* and *Kaye* had made provision for observation if the material was solid or liquid. They had a drain on the vessel to allow for the former. *Kaye* had the machine shop make a copper sphere to insert in the copper reactor and to be rolled by gravity to ensure mixing of the xenon and fluorine gases. *Kaye* remembers that they had trouble getting the discharge apparatus leak-tight and had the most trouble with copper-to-glass seals, which they eventually solved by applying some cements. *Kaye* recalls that his relationship with *Yost* was, in his words, like the journeyman and apprentice. Unknown to *Kaye*, the xenon was supplied through *Pauling*; it came from Professor *Fredrick J. Allen* at Purdue. *Linus Pauling* wrote him on September 13, 1932: "I should like to do some work (with Professor Yost) in an attempt to prepare certain compounds of xenon suggested by theoretical arguments. No doubt your xenon is precious; if, however, you could lend us 10 cc. or so ... we would try to return it to you either as such or in some compound (I hope) and we would be properly grateful." The original letter is shown in Figure 2, top left. *Fred Allen* complied with this request and sent a sample (200 mL at less than one-half atmosphere pressure). *Linus Pauling* acknowledged receipt and wrote to *Fred Allen* on October 12, 1932: "We are going to try to make XeF_8 or XeF_6 at once. Some of the excitement is removed by the appearance since I wrote you of a note by von Antropoff et al.[13] in Die Naturw. saying that they have a chloride + bromide of Kr" (the original letter is shown in Fig. 2, rop right).

While *Kaye* was already involved in this project, he was asked to present one of the regular departmental seminars about it. Professor *Arthur A. Noyes* was then chairman. Every Thursday, the chemistry department ran a seminar, usually given by one of the graduate students. *Kaye* presented his seminar in the fall (November) of 1932. *Pauling* attended the seminar. From his remarks, he made it clear that he was already very familiar with *Kaye*'s subject. *Kaye* has a vivid recollection of one particular incident. He *(Kaye)* had prepared what he termed "a pony," i.e., a crib sheet as a guide, on which he had set *Antropoff*'s early predictions. However, in his enthusiasm to portray the experimental aspects, he failed to mention these predictions in his presentation. It was *Linus Pauling* who, in the discussion afterwards, told *Kaye* that he had left out a very important piece of work and brought up *Antropoff*'s 1924 contribution, displaying considerable familiarity with it. More generally, *Kaye* was very much impressed by *Pauling*'s "profound knowledge of the subject." Before he presented his seminar, *Kaye* had no inkling that *Pauling* also had been thinking about the possibility of noble-gas compounds. Obviously, *Yost* must have known of *Pauling*'s in-

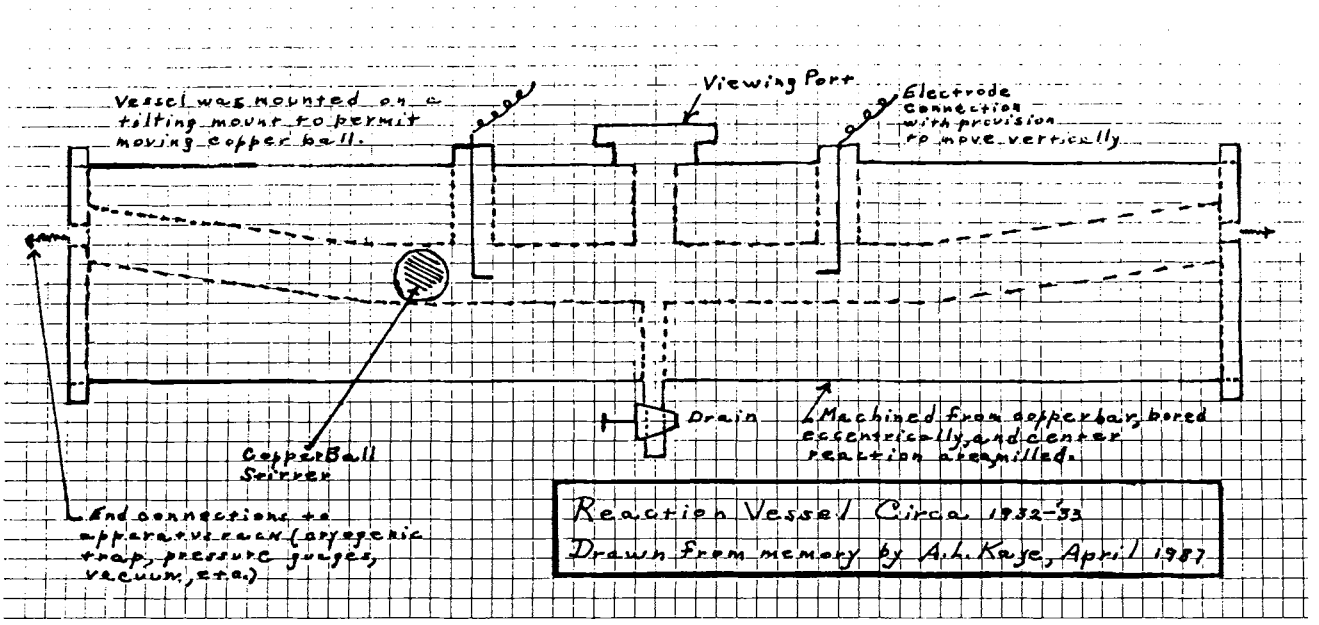

Fig. 1. The copper electrical discharge vessel used by *Yost* and *Kaye* for the reaction of xenon with fluorine (see text).

PASADENA

GATES CHEMICAL LABORATORY

September 13, 1932

Dear Fred:

I should like to do some work (with Professor Yost) in an attempt to prepare certain compounds of xenon suggested by theoretical arguments. No doubt your xenon is precious; if, however, you could lend us 10 cc. or so (of not necessarily pure stuff), we would try to return it to you either as such or in some compound (I hope), and we would be properly grateful. If this is asking too much, or if you can't lend it, could you give us advice as to where we might possibly obtain some?

We were pleased to get your letter & pictures some time ago, and hope our card also arrived. Next Christmas we'll need a larger card, with room for Linda, now 13 weeks old.

We hope you are getting along well.

Sincerely,
Linus Pauling

CALIFORNIA INSTITUTE OF TECHNOLOGY
PASADENA

October 12, 1932.

Dear Fred:

Thanks immensely for the xenon, which arrived safely. We are going to try to make XeF_8 or XeF_6 at once. Some of the excitement is removed by the appearance since I wrote you of a note by von Antropoff et al. in Die Naturw. saying that they have a chloride & bromide of Kr.

I'll let you know if we have any luck.

Yours sincerely,
Linus

This was later retracted but it got an AP front page item in Lafayette Journal Courier

GATES CHEMICAL LABORATORY

Nov. 16, 1933

Dear Fred:

The 70 mm of xenon was the pressure in mm of mercury, the volume of the system being 300 or 400 cc. Hence there was plenty of xenon present. Yost should have mentioned the volume. We still have the xenon, but Yost would like to make another try at preparing a compound, (unless you want the xenon returned soon). I still think XF_6 should be stable.

I wish to offer my congratulations and best wishes on the impending event. We are still satisfied with three little roughnecks.

My work is going on as usual. We are doing a good bit of electron diffraction work. If you prepare any new or unusual compounds, I hope you will remember that we are on the lookout for substances to study with x-rays or electrons.

I hope to be able to stops at Purdue sometime. At present I have no plans for a trip East, except possibly to the Nat. Acad. next April.

Sincerely,
Linus Pauling

July 12, 1933

Dr. F. J. Allen,
Chemistry Department,
Purdue University,
Lafayette, Ind.

Dear Fred:

At last I can send you some information regarding the xenon experiments, which Dr. Yost has been carrying on, inasmuch as he is thoroughly experienced in the chemistry of the halogens. He found that he could not prepare a compound of xenon with either chlorine or fluorine by any of the means that he tried, and he has now given up the investigation. He and his student, Kaye, have sent a note on the experiments to the Journal of the American Chemical Society, in which they thank you for providing the xenon. I am sorry that the experiments have turned out in this way since I felt confident that xenon would combine with fluorine, at any rate. Yost obtained some rod crystals, which he at one time thought contained xenon, but which he later decided were the pink form of hydrogen chloride.

My wife and I have just visited Oregon, where we saw Prof Fulton, Gilbert, and a lot of other people. We had such a good time that we are thinking of spending our vacation there next year.

With best wishes to you and Mrs. Allen, I am

Very sincerely yours,
Linus Pauling

LP:M

P.S. I want to thank you very much for providing the xenon. If there is anything that I can do for you, let me know and I shall try to do it.

Fig. 2. Four letters (reduced facsimiles) of *Linus Pauling* which he wrote to *Fred J. Allen* in connection with attempts to synthesize noble-gas compounds. The handwriting at the bottom of the letter at the top right is due to *F. J. Allen*. In the letter at the bottom right, the line "Gates Chemical Laboratory" at the top is not shown owing to lack of space.

terest and they probably discussed the matter a number of times, which led to the request of a xenon sample from *Fred Allen* at Purdue. This happened, in all likelihood, a few weeks before *Kaye* gave his seminar.

Kaye doesn't recall how they measured the potential. The *actual* value was probably of the order of one kV. *Yost* and *Kaye* repeated the electric discharge experiments 20 times for a week. They failed. *Yost* told *Kaye* that although their experiment had failed, he was going to report their efforts anyway in a letter to the *Journal of the American Chemical Society* to show that they had at least tried. *Linus Pauling* wrote to *Fred Allen*, at Purdue, on July 12, 1933 (the *Yost* and *Kaye* communication to the editor of *J. Am. Chem. Soc.*[21] was received on July 7), as follows:

> At last I can send you some information regarding the xenon experiments, which Dr. Yost has been carrying on, inasmuch as he is thoroughly experienced in the chemistry of the halogens. He found that he could not prepare a compound of xenon with either chlorine or fluorine by any of the means that he tried, and he has now given up the investigation. ... I am sorry that the experiments have turned out in this way since I felt confident that xenon would combine with fluorine, at any rate. Yost obtained some red crystals, which he at one time thought contained xenon, but which he later decided were the pink form of hydrogen chloride.

The original letter is shown in Figure 2, bottom right. The xenon sample was not returned immediately to Professor *Allen*.

The communication to the *Journal of the American Chemical Society*[21] noted that "the side tube was appreciably attacked after some time, and this might be due to the action of a reactive xenon fluoride ... It cannot be said that definitive evidence for compound formation was found. It does not follow, of course, that xenon fluoride is incapable of existing." *Yost* still felt that he had a chance of making such a compound. As *Linus Pauling* wrote to *Fred Allen* on November 16, 1933, "the 70 mm of xenon[21] was the *pressure* in mm of mercury, the volume of the system being 300 or 400 cc. Hence there was plenty of xenon present. Yost should have mentioned the volume. We still have the xenon, but Yost would like to make another try at preparing a compound (unless you want the xenon returned soon). I still think X(e)F_6 should be stable." The original letter is shown in Figure 2, bottom left. Ultimately, the xenon sample was returned to *Fred Allen*. One of us *(G. S.)* was shown it by Professor *Derek Davenport* when he visited Purdue in 1978. According to *Davenport*, the sample was analyzed several years ago by mass spectrometry, showing that *Yost* and *Kaye* had recovered a pure sample of xenon from their apparently failed experiments.

From hindsight, given the success of later attempts using similar reaction conditions, it is tempting to speculate about the most plausible reasons for the failure of the *Yost* and *Kaye* experiments. But first, did they drop the matter there? *Kaye* says now that their failure was as much his as it was *Yost*'s. He remembers them discussing another possible approach, trying various types of radiant energy, or even catalysis. This shows that they were not quitters. However, *Kaye* had decided in the meanwhile to return to MIT to complete his engineering studies. He does not know why *Yost* dropped the matter after his departure. Maybe he simply could not find someone with comparable skills to *Kaye*'s, and/or he lost faith.

5. Reasons for this Non-Happening?

The high initial pressure used in *Yost* and *Kaye*'s experiments (600 torr of fluorine and 30 torr of xenon) apparently precluded the use of lower potentials (a *nominal* potential of 30 kV was reported[21]) making it impossible to achieve a "silent discharge." The ensuing arcing with its accompanying high temperature may have prevented formation of xenon difluoride, particularly in the absence of a "cold finger" for product condensation.

There is also the possibility that the F_2/Xe ratio (20 : 1) used by *Yost* and *Kaye* ought to have led to XeF_6 formation. Once discharge had been initiated in such high-pressure mixtures, the potential would have plummeted, perhaps to a few kV. At these lower potentials, it is now known that xenon fluorides are formed. *Yost* and *Kaye* mention[21] the etching of a side arm used for condensing xenon and fluorine into the "all-quartz"[21] discharge apparatus. This side arm would have probably been the coolest region of the apparatus while a discharge was under way. This would afford the only cold point where a fluoride of relatively low volatility (such as XeF_6) might condense. In so doing, XeF_6 would slowly react with the quartz surface to form the more volatile $XeOF_4$. In such a scenario, the latter oxyfluoride could have reacted further with the quartz apparatus, producing a uniform and virtually imperceptible etch over its entire surface. Decomposition of thin deposits of the resulting thermally unstable XeO_2F_2—if it did not react further with the quartz surface—and XeO_3 presumably would also remain undetected by *Yost* and *Kaye*'s visual inspection.

It is also conceivable that $XeOF_4$ could be fluorinated under electric discharge to give XeF_6, O_2, and/or OF_2. Even a substantial buildup of oxygen difluoride, pale yellow as a liquid, would have been easily masked by the more intense yellow-green color of gaseous fluorine.

In any case, based on the experience in the field of one of us *(G. S.)*, it is probable that a compound was made, that it consisted mostly of xenon hexafluoride, that it reacted with the quartz surface as it formed, leaving only its telltale etch in the cooler (near-ambient) region of the reactor.

This reactor consisted of a quartz-and-copper apparatus. The communication in the *Journal of the American Chemical Society*[21] mentions an all-quartz apparatus but *Pauling* and *Kaye* both recall the use of metal. Borosilicate glass was rare at the time in North America; it was almost exclusive to the French. (Although borosilicate glass was developed in Germany prior to World War I by Schott, its patent was turned over to France as part of Germany's war reparations payment.) This is probably why quartz was used in the *Yost* and *Kaye* apparatus, and it speaks highly of the technical skill within *Yost*'s laboratory. *Pauling* re-

calls that the entire apparatus was metallic, *except* for the cold finger region projecting away from the discharge vessel and associated connections and storage bulbs. He maintains that the discharge region was made of metal (nickel?, copper?), and hence a product if it formed could have been missed because of the opacity.

What were the consequences of the failure of the *Yost* and *Kaye* attempt? As *Yost* wrote:[20] "Mr. Kaye and I will have to rest content with the fringe virtue of having said in print that we hadn't proved by our experiments that a xenon fluoride was incapable of existing." What about *Linus Pauling*, who had been instrumental in getting this experiment launched and who must have been very much interested in its outcome, given his prediction of the existence of several xenon fluorides?

6. *Pauling*'s Change of Heart in the Aftermath of the *Yost* and *Kaye* Experiments

It looks as if *Linus Pauling* back-tracked somewhat. "The Nature of the Chemical Bond"[22] makes no reference to noble-gas compound formation in the second (1940) or third (1960) edition. Nor could we find such a reference in other Pauling books: the second (1953) edition of "General Chemistry,"[23] "College Chemistry"[24] (1952), and "The Chemical Bond"[25] (1967). It appears that the 1933 paper in the *Journal of the American Chemical Society*[17] is the only place where his predictions appear. Interestingly, *Pauling* published an almost-retraction, when he wrote in his 1961 article on general anesthesia:[26] "Xenon is completely unreactive chemically. It has no ability whatever to form ordinary chemical compounds, involving covalent or ionic bonds. The only property it has is that of taking part in the formation of clathrate crystals."

Another indication is provided by the appearance of the periodic table in *Pauling*'s books: as *Antropoff* noted,[8] the position and the labeling of the noble gases had a direct connection with belief or disbelief in their potential reactivity. *Pauling* used a periodic table in all of the above book titles in which the noble gases were alloted to Group 0—even in his 1970 edition of "General Chemistry," long after noble-gas reactivity was discovered. This table also repeats the noble-gas column, placing it to the left of the alkali metals and to the right of the halogens (see Fig. 3). As *Pauling* told us, he prefers his version, based on a very early table (*Moseley*'s), because it makes no break between metals and nonmetals. In that same volume *Pauling* includes a section on his 1933 predictions[17] and a discussion of noble-gas compounds known at the time. In his pre-1962 general chemistry book, *Pauling* describes the noble gases as inert. For example, in the 1952 edition of "College Chemistry"[24a] he stated that these elements are "completely unreactive chemically; they do not form any chemical compounds" and "the failure of these inert elements to form chemical compounds is similarly due to the great stability of their electronic structures." Pauling, however, did make an ex post facto citation of his 1933 predictions in his 1964 edition of "College Chemistry,"[24b] two years after the discovery of noble-gas reactivity: "The possibility of synthesizing fluorides and oxygen compounds of xenon (XeF_6, XeF_8, KrF_6, H_4XeO_6, and others) was predicted long ago from structural arguments [Linus Pauling, *J. Am. Chem. Soc.* 55, 1895 (1933)]. An early effort to make xenon fluoride was unsuccessful [D. M. Yost and A. L. Kaye, *ibid.* 55, 3890 (1933)]."

As to why *Pauling* may not have pursued the matter further, he thinks it was because of his emerging interests in biological molecules in the early 1930s. Back in 1924, in a letter of October 25 when he was trying to fill *Fred Allen* in on the available research areas, were he to come to Caltech, *Pauling* wrote: "The only graduate work in chemistry is in physical, inorganic, and biochemistry. The last is in-

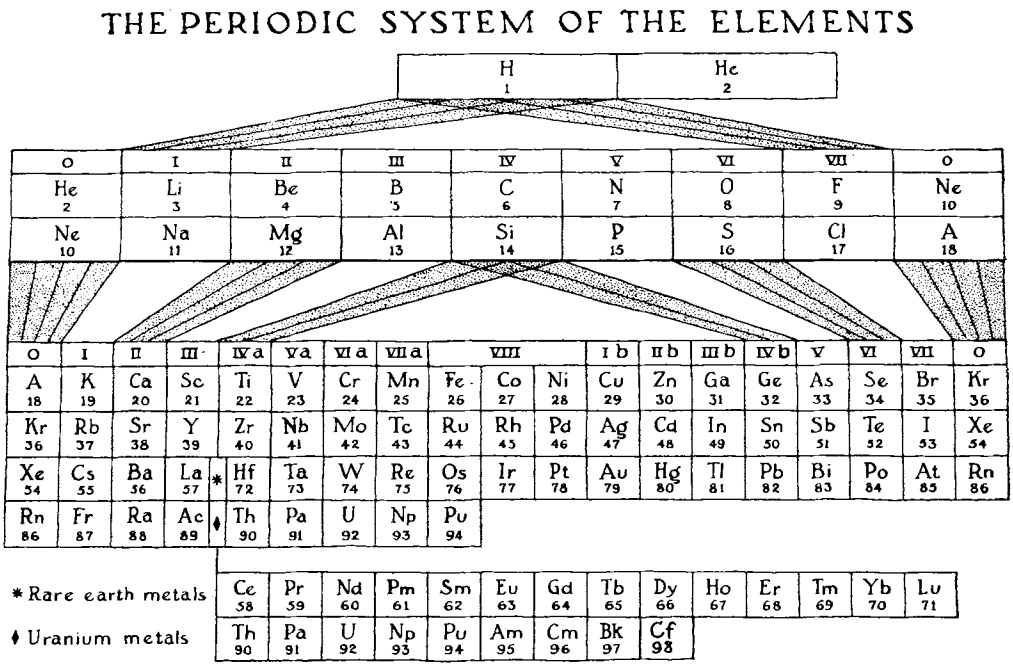

Fig. 3. The periodic table as used by *Pauling* in "General Chemistry" (1970) (cf. [23]).

teresting, but I wouldn't want to do it."[27] His present (1986) feelings are largely the same, he says; he still doesn't care much for biochemistry.

In any case, *Pauling*'s change of attitude about the lack of reactivity of the noble gases and his deep influence may explain the dead calm of the field from 1933 on.[19,28] That year was the turning-point; it saw the retraction of *Antropoff* et al.,[16] the *Pauling* predictions,[17] and the report of the failure of the *Yost* and *Kaye* experiments.[21]

7. Other Attempts

Grimm and *Herzfeld* based on a Born–Haber cycle an estimate of an enthalpy of formation of 246 kcal mol^{-1} for Ne^+Cl^- in 1923.[29] *Booth* and *Willson* carried out in the early 1930s experimental work contemporary with the *Pauling* predictions and the *Yost* and *Kaye* experiment. Their 1935 publication[30] has a footnote to the effect that, on the editor's advice, they withheld publication of a preliminary note submitted on July 17, 1932. *Booth* and *Willson* based their investigation on a sound and well-argued analogy: since boron trifluoride can accept electrons from a full octet in complexes such as dimethyl ether–boron trifluoride, it should be feasible to form likewise compounds between BF_3 and the noble gases. They did a thermal analysis of argon–boron trifluoride mixtures and concluded that formation of $Ar \cdot BF_3$, $Ar \cdot 2BF_3$, $Ar \cdot 3BF_3$, $Ar \cdot 6BF_3$, $Ar \cdot 8BF_3$, and $Ar \cdot 16BF_3$ could occur in the temperature range -127 to -133 °C.[30] *Wiberg* and *Karbe* showed these observations to be in error.[31]

In 1951, *George C. Pimentel* gave a nice MO description of bonding in the trihalides.[32] Overlap of the three atomic p orbitals leads to a bonding, a nonbonding, and an antibonding MO. Two electrons go into the bonding MO, and the other two into the nonbonding MO. This results in two one-electron bonds. *Pimentel* had the foresight to point out that a similar description would be applicable to molecules formed by rare gases with the halogens. He believed that both *Boomer*[7] and *Antropoff*[13] had earlier obtained such compounds. Obviously, he did not know of *Antropoff*'s retraction of 1933.[16] He cited only the *Antropoff, Weil,* and *Frauenhof* 1932 "success."[13] Neither did he refer to *Yost* and *Kaye*.[21] And he predicted confidently[32] formation of rare-gas compounds from mixtures of "helium–iodine, argon–chlorine, krypton–chlorine, and krypton–bromine."

8. The Story: The Multiple Discovery

The rest is history and is well-documented.[19,28] Hence, we shall content ourselves with a brief reminder of the main protagonists, adding only a few footnotes here and there.

Rudolf Hoppe joined the inorganic chemistry group of Professor *W. Klemm* at Münster in 1949. He proposed to his mentor preparation of XeF_4 by direct fluorination of xenon.[33] In 1951, determination of the heat of formation of IF_5 by *A. A. Woolf* served this visionary of noble-gas reactivity to extrapolate it to estimates for the bond energies in XeF_4 and XeF_2 of at least 20–40 kcal mol^{-1}. He provided an estimate by extrapolation for the boiling point of xenon tetrafluoride as 90 °C (1949), revised to 120 °C (1960–1961). *Hoppe* brought to a Gordon Conference in 1961 slides showing this boiling point together with values of the heats of formation predicted for xenon difluoride and xenon tetrafluoride. He showed these to Professor *R. D. Peacock* (now at Leicester University), who felt strongly that it was inadvisable to release such limited information. In August 1961, he decided (against the objections of *Klemm*) to attempt the synthesis. In 1962, the *Hoppe* group in Münster succeeded in preparing xenon difluoride by submitting a mixture of xenon and fluorine (1 : 2) to electric discharges in a sealed quartz vessel (cf. Fig. 4).[34] They missed beating *Bartlett* to the published discovery by just a few weeks. This is a little ironic as the compound made, XeF_2, was well and correctly characterized by *Hoppe*'s group.[33,35] *Bartlett*'s compound is still not definitively characterized after 25 years. Figure 5 shows the first XeF_2 single crystals obtained by *Hoppe* et al.

The other irony was *Hoppe*'s success using a very similar method to that which *Yost* and *Kaye* could not bring to work, which is another reason to believe that *Yost* and *Kaye* may have unknowingly prepared some amount of a xenon fluoride (see Section 4).

At Argonne, the late *Herbert H. Hyman* produced the fine organizational climate that permitted people like *Claassen, Malm, Selig, Chernick,* and others to accomplish so much in such a very short span. They had no prior knowledge of *Hoppe*'s ideas and work, nor of *Pauling*'s predictions.

The context was a wish, on the part of some, to disprove *Bartlett*'s experiment. (The reader is referred here to the cover of the May 1964 issue of *Scientific American*, with a dramatic illustration of the original *Bartlett* experiment as carried out in the hands of the Argonne group. The reaction vessel, containing red-brown PtF_6 vapor, was shown on the left. The same reaction vessel was shown again on the right, this time containing yellow $XePtF_6$ that had partially solidified from the red-brown vapor.) The first time the Argonne group heard of *Bartlett*'s work was when his paper was first published.[36] The general attitude in the Argonne group was lukewarm.

John Malm could bring a lot of expertise to such a test of the *Bartlett* result.[36] Together with *Bernard Weinstock* (died 1984), he had been heavily involved in the Manhattan Project, preparing uranium hexafluoride for isotopic separation. *Malm* and *Weinstock* used to study the periodic table with the view to prepare other hexafluorides (those of platinum, rhodium, and ruthenium). It never occurred to them to try xenon. This group could easily duplicate or refute *Bartlett*'s findings; they had been working with platinum hexafluoride (*Bartlett*'s oxidant) over the past five or six years.

The next day, *Malm* had a glass apparatus made, similar to that described by *Bartlett*,[36] got hold of some xenon (the most difficult part of the experiment), and within two days had repeated *Bartlett*'s experiment. Still, *Malm* was concerned about a possible impurity in xenon such as oxygen, which *Bartlett* had previously shown to be oxidized at ambient temperature by PtF_6 to yield $O_2^+PtF_6^-$. *Malm* neglected to hydrolyze the product. This would also have told him that xenon, not dioxygen, had combined by the

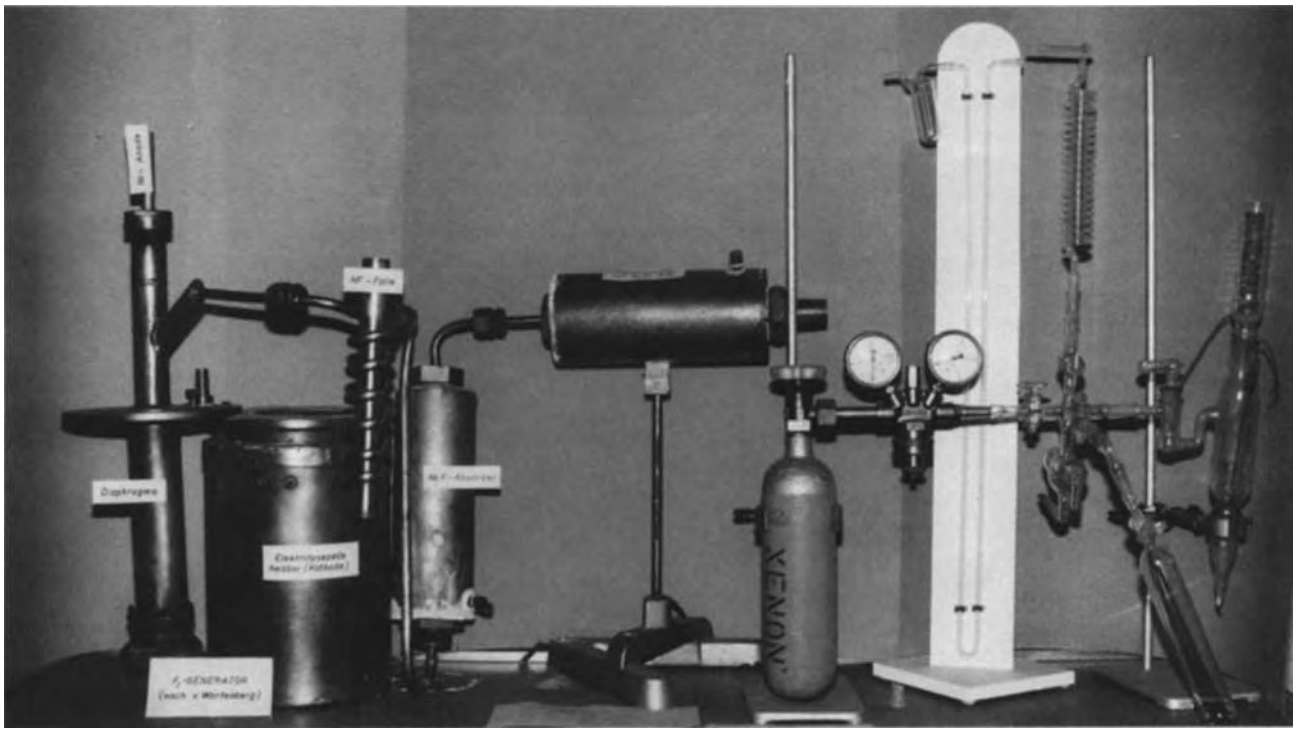

Fig. 4. Apparatus used by *Hoppe* et al. in 1962 to synthesize XeF_2 (cf. [34]). The apparatus is partly disassembled.

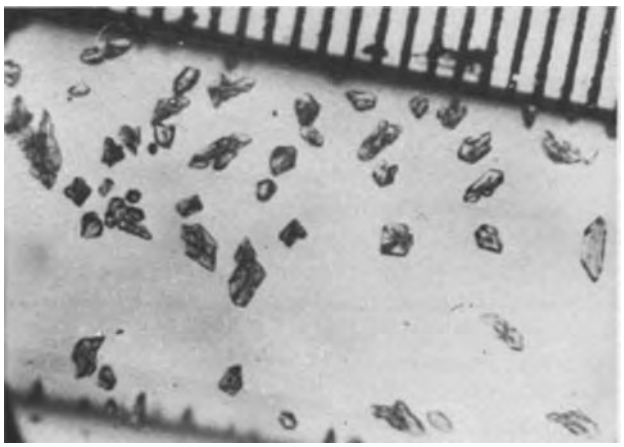

Fig. 5. XeF_2 single crystals (enlarged) prepared by *Hoppe* et al.

liquid-nitrogen-condensible xenon gas released. In the next week he and *Cedric Chernick* ran through all the metal hexafluorides they had on hand, but only platinum hexafluoride worked. They did not have ruthenium hexafluoride on hand at that time, which they later found would also oxidize xenon.

It was then that *Howard Claassen*, a physicist, suggested reacting directly fluorine with xenon to produce a xenon fluoride. This was proposed over coffee and was greeted with skepticism: in *John Malm*'s words, "as a physicist he didn't know any better." The xenon–fluorine reaction was tried by *Claassen* and *Malm*. This was easy since all the high-pressure gear, including a nickel reaction canister were available among *Malm* and *Weinstock*'s paraphernalia. They reacted xenon and fluorine at 400 °C, selecting accidentally the conditions which would give them 97% xenon tetrafluoride. The resulting compound had a very low vapor pressure. Because *Claassen* was a vibrational spectroscopist, his first reaction was to get it into an IR gas cell as quickly as possible. *Howard* knew immediately from the IR spectrum that the molecule was square planar, the only example of a volatile square-planar molecule.

At about this time, *Henry Selig* arrived. He and *Malm* took over the synthetic aspects in *Malm* and *Weinstock*'s laboratory. One of *John Malm*'s tasks was to obtain an analysis of the product. They could obtain the stoichiometry directly from the weights when they employed a small light-weight nickel reaction vessel. He tried hydrolysis. He could titrate fluorine and collect xenon, with a Toepler pump presumably. However, there was always a xenon deficit, later to be shown to arise from disproportionation to the water soluble xenate(VI) and xenon gas. He accomplished the analysis by hydrogen reduction and then titrated the liberated HF as well.

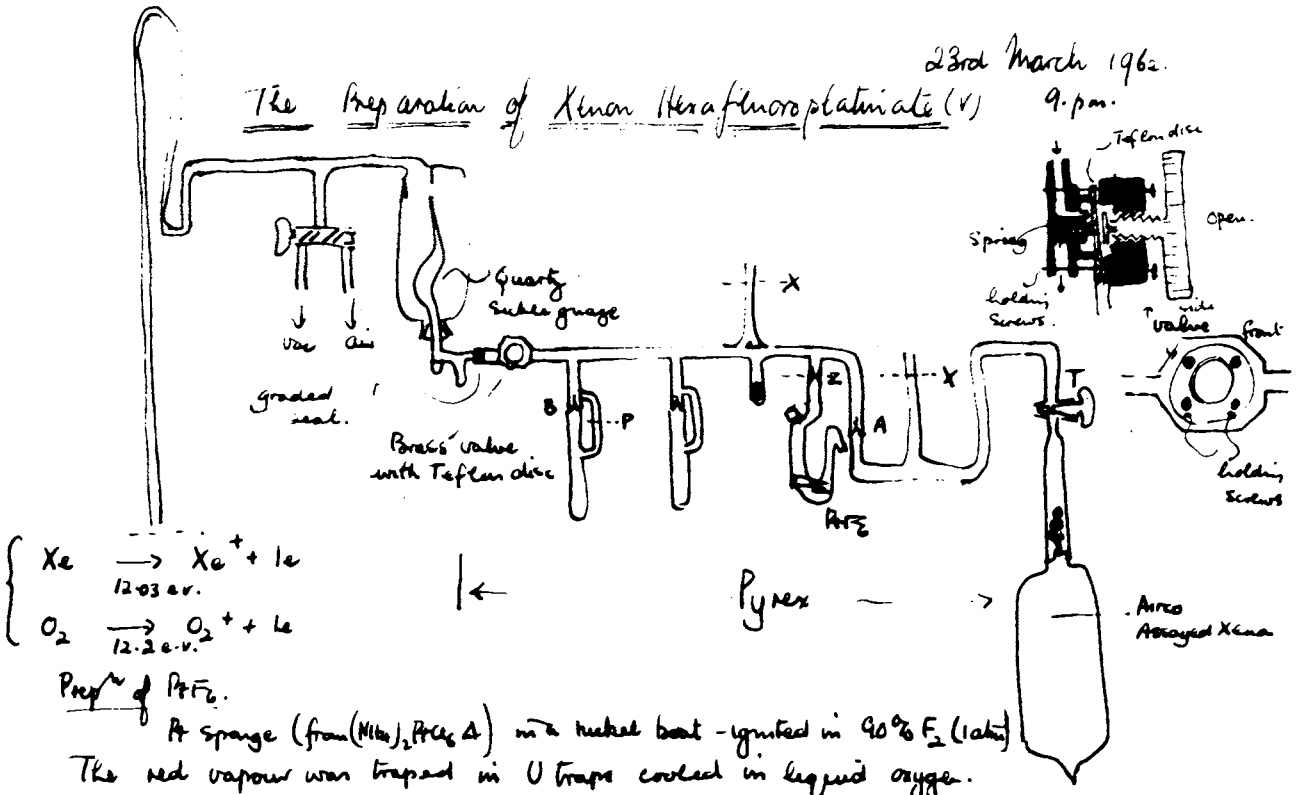
Only two weeks from the first evidence for xenon tetrafluoride, the *Journal of the American Chemical Society* had published their work in a September 1962 issue.[37] The Argonne group only became aware of *Pauling*'s early predictions on perxenate and other noble-gas species after their paper had been published.[17]

Linus Pauling reacted to the Argonne discovery of XeF_4 in a cryptic dictated reply, dated October 24, 1962, to a letter of Professor *F. J. Allen* on the subject: "I must say that I don't understand how Yost could have failed to have discovered xenon tetrafluoride—just bad luck, I guess."

Now, to *Bartlett*'s familiar story. He was the first to knowingly make a compound of a rare gas, beating the Münster and the Argonne groups to it by a few months.

23rd March 1962.

The Preparation of Xenon Hexafluoroplatinate (V) 9.p.m.



Prep^{n} of PtF_6.

Pt sponge (from $(NH_4)_2PtCl_6$ Δ) in a nickel boat - ignited in 90% F_2 (1 atm). The red vapour was trapped in U traps cooled in liquid oxygen. When the spontaneous platinum ignition stopped the preparation was terminated to reduce contamination by SiF_4 to a minimum.

Measurement of PtF_6

The sample of PtF_6 contained in its original trap (cooled at -183) was connected to a Pyrex - Silica system as shown. The entire system was evacuated and flamed then sealed under vacuum at X. The PtF_6 was transferred to the well of the Pirani gauge (cooled in liq O_2) and the brass valve closed. As the PtF_6 warmed up the pressure developed was balanced by admitting air to the surrounding chamber. A manometer recorded the pressure of the outer chamber. The vapour was deep red (only subdued lighting was used during the experiment to reduce photolysis).

Pressure of PtF_6 taken — 45 mm.
Pressure of Xe taken — 95 "
Residual pressure 40 mm.

The PtF_6 was condensed in the break seal bottle B which was subsequently sealed at P.

Meanwhile the Xenon system - isolated by the breakseal A had been evacuated under vacuum with the tap T open. This system was sealed at X, T closed and the break-seal on the Xenon bottle broken.

Measurement of Xenon.

A was broken and the brass valve opened. Tap T was cautiously opened and the pressure developed balanced by admitting air to the outer Pirani gauge chamber. T was closed when the pressure developed matched that of the PtF_6. The brass valve was closed and the tap T closed. The Xenon between T and the brass valve was pumped out via λ, the system again flamed

Fig. 6. A page from *Bartlett*'s laboratory notebook dated March 23, 1962 (slightly reduced facsimile).

We draw upon *Bartlett*'s recollections, as given to *C. B. Hunt*:[38]

> The crucial step occurred in late February, 1962 ... By chance, as I was flicking through (a textbook), the familiar plot of first ionisation energies of the elements caught my eye. In an instant the old thought, of the possibility of oxidising the noble gases, returned. A quick check confirmed my immediate suspicion that the heavier gases should be oxidisable by PtF_6 ... xenon looked good since its ionisation energy, 1170 $kJ \cdot mol^{-1}$, was marginally less than that of oxygen (1176 $kJ \cdot mol^{-1}$).

Thus, we come full circle to the pioneering insight of *Kossel* 46 years earlier.[9] *Bartlett* was also driven on by another consideration: just about this time he and his graduate student *D. H. Lohmann* had already observed the direct oxidation of oxygen gas by PtF_6 vapor at ambient temperature and they were about to publish these observations (they appeared in the March 1962 issue of the *Proceedings of the Chemical Society*[39]).

Bartlett made himself an apparatus in which he could introduce the deep red-brown PtF_6 vapor and xenon gas, separated by a break-seal. On March 23, 1962, everything was set up. *Bartlett* recalls that "I wasn't ready to break the glass capillary separating the xenon and PtF_6 until about 6.45 p.m. My students had left for supper (they never admitted to scepticism) and I was alone when the capillary was broken. Of course, I was overjoyed when there was an immediate interaction of the gases." Figure 6 shows a page from *Bartlett*'s laboratory notebook, written almost immediately after the successful experiment. On May 14, 1962, he mailed in his communication to the *Proceedings of the Chemical Society*.[36] This achievement is breathtaking and spectacular: single-handedly, *Bartlett* had made a crucial breakthrough, he had revived a whole *problématique*, and opened up a whole avenue of investigation.

9. Concluding Remarks: Rambling Thoughts on Some of the Underlying Patterns

We shall start with the most popular, and arguably least important aspect of the story: the myth of chemical inertness of the rare gases. What this story shows is that it was not in full force till relatively recently, when, for instance, *Neil Bartlett* feared ridicule from his colleagues in the department and from his students.[38] During the whole period 1895–1933, this myth was *not* all-powerful, as the numerous attempts at making compounds of the noble gases show.[19,28] Only after *Yost* and *Kaye*'s failure and the attendant loss of faith by *Linus Pauling* did this myth ascend into a dogma. No doubt, *Pauling*'s influence and his becoming interested in more biological quests had a lot to do with this. In other terms, the octet rule was not seen as a deterrent to the existence of noble-gas compounds till the mid-1930s. It is true that "The Atom and the Molecule" paper by *G. N. Lewis*, with the octet theory, dates back to 1916 and that *Irving Langmuir* published his concept of the atom as made of concentric electronic shells in 1919. However, the *Kossel* paper,[9] coincidentally published also in 1916, and arguing from the same standpoint of a stable configuration of eight electrons, could make the prediction of xenon and krypton fluorides. The 1930s saw the protracted and generalized acceptance by chemists of modern electronic theories of the atom as the basis for the periodic table. After 1933, when *Linus Pauling* himself started to assert the inertness of the noble gases, the octet rule became entrenched. His authority may have made it easier for the octet rule to rigidify into a stultifying dogma. We do not adjudge here between theory and experiment. Theory had the leading role in the earlier *Kossel–Antropoff* part of the story. Theory may have led experiment in the *Yost* and *Kaye* episode. Theory—or rather the watered-down version of theory that percolates into teaching—had the inverse role, it paralyzed experimentation during the whole period 1933–1962.

A tightly coupled reason for the protracted discovery—it *could* have been made at the turn of the century with existing technology and from the supply of xenon that could have been provided; it *should* have been made by *Yost* and *Kaye*, who were particularly unlucky (see below)—is the overwhelming importance of iconic representations: the presentation of the periodic table with the noble gases in the "zero" column. *Antropoff*'s lasting contribution was to explode the myth of chemical inertness and to propose that noble gases be assigned to the VIIIb column.[11]

Yost and *Kaye* also attempted photochemical generation. Their bad luck was that they tried a xenon–chlorine mixture, which did not react. Had they tried a xenon–fluorine mixture in a similar apparatus under their mercury arc lamp, they would have seen xenon difluoride crystals appear in a matter of hours if not sooner (they ran the xenon–chlorine mixture for 12 h). A number of experiments by the *Strengs*[40] show that the photochemical addition of fluorine to xenon readily takes place *Holloway*[41] has shown that XeF_2 can even be produced in a Pyrex glass bulb under the natural sunlight in Aberdeen, Scotland! Figure 7 shows a glass bulb containing photochemically prepared XeF_2.

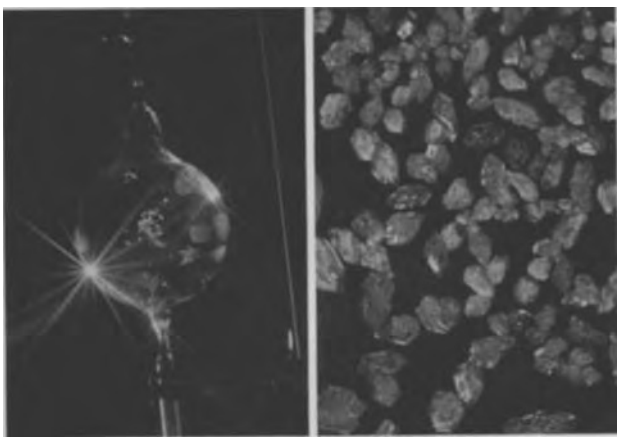


Fig. 7. Left: Glass bulb containing XeF_2 crystals formed by UV irradiation of a 1:1 mixture of Xe and F_2 at McMaster University (*G. S.*). Right: XeF_2 crystals (enlargement).

Alan F. Clifford and a student, *G. R. Zeilenga*, started to investigate the reactions of xenon and fluorine in 1961. Their conditions were similar to those of *Yost* and *Kaye*. They actually obtained white solids and also determined that they contained xenon! The finding was not finalized in time—there may have been a student problem—and it did not receive, like *Hoppe*, priority recognition. After the appearance of *Bartlett*'s work, they assigned the formula Xe_2SiF_6 to their product.[42]

Another interesting story is that of the Oak Ridge fused salt nuclear reactor. *Kirsilis*, *Blankenship*, and *Grimes* had studied molten fluoride fuels. The neutron irradiation was sufficient to cause fission of substantial fractions of the $^{235}UF_4$ present. They noticed that the gas above these melts, if it contained the expected amount of krypton as a fission product, had no xenon! *DeForest Smith*, who was then at Oak Ridge, read the first publication on xenon fluorides to come from Argonne: he remarked that the earlier observation at Oak Ridge, several years before *Bartlett*'s discovery, had been made by engineers rather than by scientists. It was only after they saw the Argonne publication on xenon tetrafluoride that they ascribed the observed absence of xenon above the solidified melts to xenon fluoride formation.[43]

Lastly, there are reasons for the multiple discovery at British Columbia, Münster, and Argonne (in that published order). One is the coming of age of inorganic chemistry, as signaled by *Nyholm*'s 1956 inaugural lecture for his chair at University College, London, entitled "The Renaissance of Inorganic Chemistry"[44] and by the appearance of *Cotton* and *Wilkinson*'s book[45] in the same year, 1962, coincidentally. Another reason was the big progress which World War II, especially the Manhattan Project (Argonne), had led to in the handling of fluorine, and the experience it gave in the chemical properties of hexafluorides.

Yet another factor was the mushrooming of new physical methods, both diffraction and spectroscopic, that became available in many laboratories in the early 1960s. This is apparent in perusal of the Proceedings of the first symposium on noble-gas compounds held at Argonne National Laboratory in 1963;[46] the 58 separate contributions representing the work of 105 researchers published in book form in 1963 are heavily laced with applications of physical methods to structure determinations in the new field of noble-gas chemistry.

The non-discovery of noble-gas compounds in the 1930s can be conjectured to have stifled research on topics such as what we now term hypervalent molecules, van der Waals molecules, strong oxidants, etc. Instead of a fertile area, a desert followed. *Bartlett*'s, *Hoppe*'s too, immense merit was to make it flower again.

We are very deeply indebted to Dr. Albert L. Kaye and John Malm and to Professors Neil Bartlett, Derek Davenport, Rudolf Hoppe, and Linus Pauling for their help. They have shared with us letters and laboratory notes from their archives, giving us permission to quote from them. Yet more importantly, they have entrusted us with their recollections in the course of several interviews, conducted on the phone or in person.

Two-Dimensional NMR Spectroscopy: Background and Overview of the Experiments

New Analytical Methods (36)

By Horst Kessler,* Matthias Gehrke, and Christian Griesinger

An exact knowledge of the structure, dynamics, and reactions of molecules provides the key to understand their functions and properties. NMR spectroscopy has developed, through the introduction of two-dimensional methods, into the most important method for the investigation of these questions in solution. A great variety of different techniques is available. However, for their successful application not only the appropriate equipment is required, but also the right choice of experiments and optimum measurement parameters, as well as a careful evaluation of the spectra. This contribution describes the necessary background for modern NMR spectroscopy. With the aid of the so-called product operator formalism it is possible to understand pulsed Fourier transform NMR spectroscopy both qualitatively and quantitatively. Very few, readily understandable assumptions are sufficient for confident application of these methods. This article attempts to introduce in a simple manner this formalism as well as phase cycles necessary for the understanding of pulse sequences, and to train the reader through the discussion of several 2D NMR techniques. An overview of the most important techniques is given in the second part of this article.

1. Introduction

NMR spectroscopy has undergone a revolution with the introduction of 2D techniques.[1-3] Although several reviews on this subject have been published,[2,4-23] we find it useful to provide a readily understandable introduction to and application of the product operator formalism (with Cartesian basis operators).[24-27] In this way the experiments can be understood both qualitatively and quantitatively, without recourse to the somewhat more cumbersome quantum mechanical treatment (keyword: spin density matrix). The product operator formalism makes it possible to describe the behavior of weakly coupled spin systems (i.e., systems in which the difference in chemical shifts of two nuclei is large relative to the J coupling between them) under the influence of pulse sequences by the application of a few simple rules. Thus even nonexperts may follow and apply the experiments.

Along with the description of product operators, some understanding of phase cycles in 2D NMR experiments is also necessary. Phase cycles suppress undesired signals in a multipulse experiment. This concept, as well as the associated "coherence order"[28-32] will be introduced and discussed in Section 2.2.3. Suffice it to mention, at this point, that by following the "coherence-transfer pathways" a simple and powerful tool is provided for the development of phase cycles. The reader will soon recognize that with the product operator formalism and coherence-transfer pathways a theory is now available which in terms of clarity, simplicity, and accuracy by far exceeds the widely used, yet quite cumbersome and insufficient, vector description.

Another reason for writing this article is the experience which has accumulated in applications of the various experiments and which has led to a realization of the advantages and disadvantages of each technique. Thus, for instance, J-resolved[2,33-35] and spin echo correlated spectroscopy,[36-38] which once played a major role in 2D NMR spectroscopy, are now employed only in a few special cases. We can of course only describe a selection of the different 2D NMR techniques. Some 500 pulse sequences for high-resolution NMR spectroscopy have been published. Only a small fraction of those found their way to general recognition and application, and the entire field is still in flux. Thus a whole new series of better experiments is now available, which *quantitatively* measure such parameters as NOE values and vicinal coupling constants, necessary for the determination of structure and dynamics. In addition, the NMR spectroscopy of insensitive nuclei has become more and more accessible, even in large molecules, through the application of inverse techniques.[39-54]

We have tried to write in such a way that the required prior knowledge of the reader be minimal. Therefore the text has been divided into two levels: for a first reading it should be sufficient to cover the normal print. For further discussion and insight the small-print sections should be followed.

2. Background

Nuclear magnetic resonance deals with the interaction between the magnetic moments of atomic nuclei and magnetic fields. The magnetic moment of the nucleus is associated with the nuclear spin S. Only those nuclei for which $S \neq 0$ have a magnetic moment. The high-resolution NMR spectroscopy described in this review is used predomi-

nantly to investigate nuclei with spin 1/2, which have no quadrupole moment and hence give rise to sharp spectral lines. The nuclei of greatest interest for organic chemistry and biochemistry, H, C, N, and P, all have isotopes with spin 1/2, though for C and N the natural abundance of these isotopes is very small. The proton, the most abundant nucleus in organic compounds, has (with the exception of tritium) the largest nuclear magnetic moment and hence is the simplest nucleus for investigation. However, the NMR spectroscopy of the more "exotic" nuclei, which are of greater significance in organometallic and inorganic chemistry, has also become increasingly important.

2.1. One-Dimensional NMR Spectroscopy

The method now generally used for recording 1D NMR spectra is the Fourier technique introduced by *Ernst* and *Anderson*.[55–57] Since the principles of this technique also underlie 2D NMR spectroscopy, we shall begin with its description.

Nuclei with spin 1/2 are aligned either in a parallel or an antiparallel orientation with respect to the applied $\boldsymbol{B}_0$ field. Only these two states exist, which are marked α and β, respectively. The parallel α state[*] is lower in energy than the antiparallel β state. Therefore, the population of the α state is greater than that of the β state (Boltzmann distribution), and a macroscopic magnetization along the $\boldsymbol{B}_0$ field ("longitudinal magnetization") exists due to this population difference. The macroscopic magnetization can be expressed in terms of the Bloch equations.[58] According to usual convention, the so-called rotating-frame coordinate system is used. The coordinate system rotates about the z axis, which is aligned with the $\boldsymbol{B}_0$ field, at the "carrier frequency" ω_0 of the radio frequency pulse.

Pulses are short-term high-frequency oscillating magnetic fields of the form $\boldsymbol{B}_1 \cos\omega_0 t$. Because the magnetization precesses about $\boldsymbol{B}_0$ during the pulse, a very complicated motion results. A simplified description is achieved in a coordinate system rotating at $\omega_0 = \gamma \boldsymbol{B}_0$ such that the magnetization appears to rotate about $\boldsymbol{B}_1$ alone.

The linearly polarized $\boldsymbol{B}_1$ field (e.g., only the x component) may be divided into two circularly polarized fields [Eq. (1)]. The two vectors rotate at equal frequencies but in opposite directions. In the rotating frame $(\boldsymbol{e}'_x, \boldsymbol{e}'_y)$ one obtains Equation (2).

$$\boldsymbol{B}_1(t) = \boldsymbol{B}_1^\circ \cos\omega_0 t \boldsymbol{e}_x = \tfrac{1}{2}\boldsymbol{B}_1^\circ(\cos\omega_0 t \boldsymbol{e}_x + \sin\omega_0 t \boldsymbol{e}_y) + \tfrac{1}{2}\boldsymbol{B}_1^\circ(\cos\omega_0 t \boldsymbol{e}_x - \sin\omega_0 t \boldsymbol{e}_y) \quad (1)$$

$$\boldsymbol{B}'_1(t) = \tfrac{1}{2}\boldsymbol{B}_1^\circ \boldsymbol{e}'_x + \tfrac{1}{2}\boldsymbol{B}_1^\circ(\cos 2\omega_0 t \boldsymbol{e}'_x - \sin 2\omega_0 t \boldsymbol{e}'_y) \quad (2)$$

The component in (2) rotating at twice the Larmor frequency does not meet the resonance condition and can therefore be neglected. Only the time-independent (!) component $\tfrac{1}{2}\boldsymbol{B}_1^\circ \boldsymbol{e}'_x$ is considered. Thus, the Bloch equation contains only time-independent fields and is readily solved. The static fields ($\boldsymbol{B}_0$ and $\boldsymbol{B}'_1$) cause rotations of the magnetization about the corresponding axes (x or z', respectively). The magnetization rotates by a certain angle, the so-called flip angle, depending on the duration of the $\boldsymbol{B}_1$ field (the pulse length). Therefore pulses are often characterized by their flip angle, rather than by their field strength and duration.

Pulses may be described as rotations by a certain angle (flip angle) about a certain axis in the x,y plane (phase). For example, application of a short radio frequency pulse generally labeled β_y will rotate the magnetization about the y axis by an angle β from the z axis [Eq. (3) and Fig. 1].[*]

$$M_z \xrightarrow{\beta_y} M_z \cos\beta + M_x \sin\beta \quad (3)$$

Equation (3) means that the M_z magnetization[**] transforms under the influence of a β_y pulse in part ($\sin\beta$) into M_x magnetization, the other part ($\cos\beta$) remaining along the z axis.

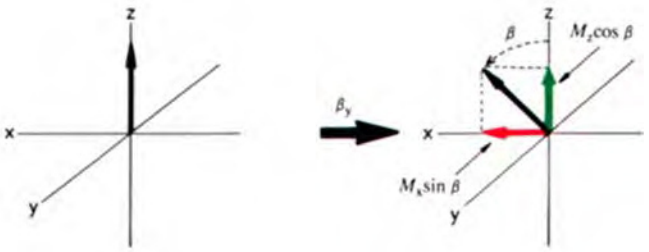

Fig. 1. The effect of an on-resonance radio frequency pulse in the y direction in the rotating frame and a flip angle β on longitudinal magnetization. We have rotated the coordinate system by 90° from the usual representation (x in front) for easier understanding.

After application of the pulse, the transverse magnetization M_x begins to precess about the z axis at a precession frequency $\omega = \gamma \boldsymbol{B}_{\text{eff}}$. The chemical shifts of the different nuclei are represented by $\boldsymbol{B}_{\text{eff}}$. Nuclei of the same isotope (e.g., protons) have equal γ and nearly the same $\boldsymbol{B}_{\text{eff}}$, so that their precession frequencies fall within a narrow range. For protons this frequency varies, depending on individual chemical shifts, within ca. $10^{-5}\,\omega_0$, or 10 ppm. In the rotating-frame the observer (i.e., detector) also rotates about the z axis at the carrier frequency ω_0. The detector "sees" now only difference frequencies $\omega - \omega_0$. Henceforth we shall term these difference frequencies *precession frequencies* or *chemical shifts*, Ω (Fig. 2). In the rotating frame we thus obtain Equation (4).

$$M_x \xrightarrow{\Omega t} M_x \cos\Omega t + M_y \sin\Omega t \quad (4)$$

The precession frequency Ω is the deviation of the Larmor frequency from the carrier frequency ω_0, which is reg-

[*] The assignment α and β for parallel and antiparallel, respectively, follows the notation in Ref. [3], and will be used here throughout. Sometimes the opposite assignment can be found in the literature.

[*] The direction of rotation of the magnetization under the influence of pulses follows Ref. [3], and is in accordance with the mathematical sense of rotation. Frequently, the opposite definition is found in the literature (in our example this would correspond to a rotation to $-x$).

[**] M_x, M_y, and M_z mean unit magnetizations given by the initial polarization along the corresponding axes.

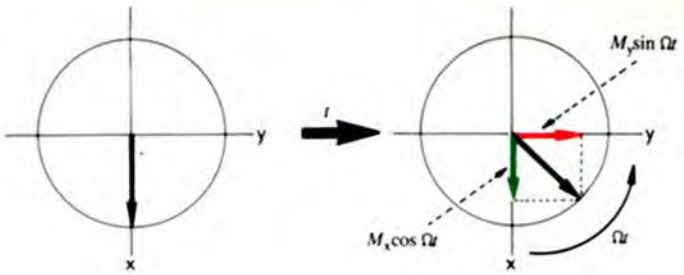

Fig. 2. Evolution of the chemical shift Ω during time t. A view onto the x,y plane in the rotating frame is shown.

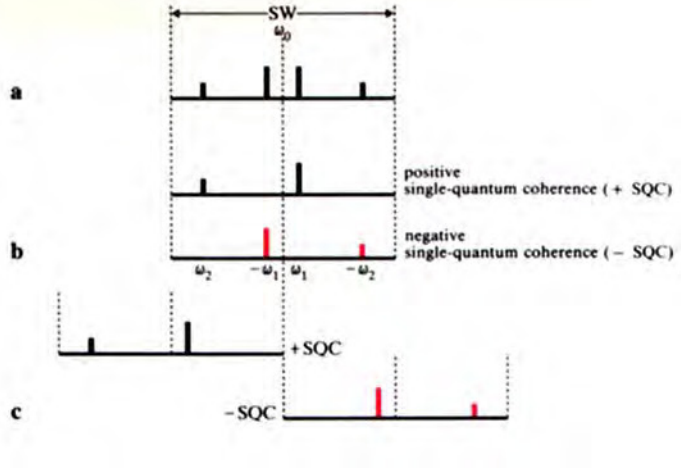

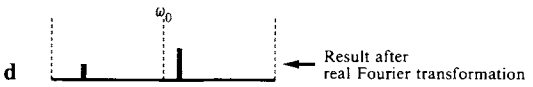

Fig. 3. Principle of the Redfield technique. A single-channel detection spectrum, obtained after complex Fourier transformation (a) contains signals at both positive and negative frequencies, which are shown separately in (b). This corresponds to positive and negative single-quantum coherences. The two spectral parts no longer overlap (c) when the receiver rotates at frequency SW/2 in the rotating frame. After folding about $\omega_t = 0$, , i.e., real Fourier transformation, a spectrum is obtained (d) which contains only the positive frequencies.

istered as a signal by the detector aligned, for example, with the x axis in the rotating frame. Thus a signal $S(t)$ oscillating at frequency Ω is obtained, the so-called *free induction decay* (FID). A Fourier transformation will convert this signal into a spectrum with a single signal ("peak") at frequency Ω (see also Fig. 4).

Fourier transformation is a mathematical procedure by which frequencies, which are detected in an oscillating function of time, are transformed into signals at the corresponding positions on a frequency scale.

The function $\cos\Omega t$ in Equation (4) contains the frequency $\omega = +\Omega$ as well as to $\omega = -\Omega$, and hence a distinction between these frequencies is impossible. It is however desirable to know the sign of a given frequency, for only then can the carrier frequency be placed in the center of the spectral range. Quadrature detection,[59,60] by which both x and y magnetizations in the rotating frame are detected, allows the sign discrimination of the detected frequency. A signal $\cos\Omega t$ is constructed in the x channel (K_x) from the x magnetization M_x in (4), and a signal $\sin\Omega t$ in the y channel (K_y) from the y magnetization M_y. When the two signals are combined, $K_x + iK_y$, the complex expression $e^{i\Omega t}$ is obtained, which after complex Fourier transformation produces a single line at frequency $+\Omega$ (and indeed not also at $-\Omega$). The disadvantage of this procedure is that it requires simultaneous collection of two signals.

A trick introduced by *Redfield* et al.[61,62] is utilized in some instruments, whereby, starting with the (+x) direction, signal detection is alternated among the (+x), (+y), (−x), and (−y) directions (Fig. 3). Hence the receiver rotates in the rotating frame with an additional frequency Ω_R. The recorded signal is then $\cos(\Omega + \Omega_R)t$. Ω_R is set to one-half the spectral width (SW/2) (Fig. 3b). After a complex Fourier transformation, a spectrum is obtained in which signals with positive and negative frequencies no longer overlap (Fig. 3c). Finally, the spectrum may be "folded" about $\Omega = 0$ (Fig. 3d), or, equally well, a real Fourier transformation may be performed.

We now wish to describe the same experiment in terms of the product operator formalism.[24] In contrast to the vector formalism discussed above, in which the macroscopic magnetization rotates under the influence of pulses and/or precesses under the influence of chemical shift, the entire state of the spins or spin system (only the observable magnetization) is described by means of the density matrix. The observable quantities must then be "read out" of the spin state. The following short discussion of the quantum mechanical formalism should be fully sufficient for the understanding of 2D NMR experiments (for detailed discussions of the physical background see Refs. [63–67]).

The ground state of the system in thermal equilibrium is described by a polarization along the z axis, I_z. This state is associated with a magnetization M_z. Under the influence of pulses from the y direction (henceforth termed in short "y pulses") I_z, as well as I_x and I_y, transform according to (5)–(7) (see also Fig. 1).

$$I_x \xrightarrow{\beta I_y} I_x \cos\beta - I_z \sin\beta \tag{5}$$

$$I_y \xrightarrow{\beta I_y} I_y \tag{6}$$

$$I_z \xrightarrow{\beta I_y} I_z \cos\beta + I_x \sin\beta \tag{7}$$

The Cartesian operators[*] (I_x, I_y, I_z) transform like magnetizations when a rotation is performed. The properties of a state I_x, I_y, or I_z can be read off directly in such simple product operators which consist of only *one* operator. I_x is associated with an x magnetization, I_y with a y magnetization, and I_z with a z magnetization.

We have yet to explain the notations used in Equations[**] (5) to (7), as well as in other expressions throughout the paper. The starting state of the spin system is on the left-hand side of the equation. On the right is the end

[*] We use throughout this article the symbols I (or S) for the operator as well as for the expectation value, and not the symbol $\hat{I}$ (or $\hat{S}$) for the operator.

[**] Strictly speaking one should use the term "transformations." However, in this article we use the term "equation" not in its strict mathematical definition.

state after the "propagation," i.e., the evolution under the influence of a particular operator responsible for a specific interaction (e.g., for pulses, chemical shift, coupling). The terms above the arrows are the parts of the Hamiltonian operator (which describes the interactions of the spins with external fields and with each other) under which the system evolves. Thus,

(a) $\beta I_{x,y}$ or in general βI_φ represents a pulse with a flip angle β about an axis in the x,y plane, which forms an angle φ with the x axis,
(b) $\Omega I_z t$ represents the evolution of chemical shift Ω of nucleus I during time t, and
(c) $2\pi J I_{1z} I_{2z} t$ stands for the evolution of coupling J between nuclei I^1 and I^2 during time t.

Equations (8)–(10) apply to the evolution of chemical shifts (see also Fig. 2). The operators behave here again like the magnetizations. For a single particle of spin 1/2 the description is equivalent to that of the vector formalism.

$$I_x \xrightarrow{\Omega t I_z} I_x \cos \Omega t + I_y \sin \Omega t \tag{8}$$

$$I_y \xrightarrow{\Omega t I_z} I_y \cos \Omega t - I_x \sin \Omega t \tag{9}$$

$$I_z \xrightarrow{\Omega t I_z} I_z \tag{10}$$

The detection of x magnetization means that the signal is built up (in Eq. (9), for instance) by the coefficient $-\sin\Omega t$ of I_x. Fourier transformation yields a single line at $\pm\Omega$. Quadrature detection, which is now available on all spectrometers, allows the selection of only one frequency, $+\Omega$ or $-\Omega$.

Quadrature detection means, as we have seen earlier, the addition of the measured x components of the magnetization to i times the corresponding y components ($K_x + i K_y$). This yields the complex signal $e^{i\Omega t}$. This corresponds to the detection of I^- according to the conventions and transformations (11)–(13).

$$I^+ = I_x + iI_y \tag{11}$$

$$I^- = I_x - iI_y \tag{12}$$

$$I_x \cos \Omega t + I_y \sin \Omega t = \tfrac{1}{2}(I^+ e^{-i\Omega t} + I^- e^{i\Omega t}) \tag{13}$$

Figure 4 summarizes again the principles of 1D NMR spectroscopy for a one-spin system. Application of a high-frequency pulse to the z magnetization (spin state I_z), initially at its Boltzmann equilibrium, produces transverse magnetization (state I_x). This state, the so-called *coherence* evolves, i.e., develops during the detection period t. This variation of the intensity with time can be observed by the detection of an induced signal in the receiver coil (I_x, I_y are associated with transverse magnetization). Thus, coherences produced by product operators are displayed in the spectrum at their characteristic frequencies.

The following discussion should serve to clarify the concept of coherence. In contrast to populations (occupation of states in the energy level scheme) the coherences describe transitions among different energy levels. These transitions are characterized by a change Δm_z in the quantum number m_z. This change, Δm_z, is the coherence order p, which is essential for describing phase cycles (see Section 2.2.3). Although in general many of the possible coherences occur under the influence of pulses in a pulse sequence, only a few are associated with observable magnetizations, namely those for which $\Delta m_z = \pm 1$ (the selection rule for NMR spectroscopy). Of these so-called single-quantum coherences only a few are detectable under weak coupling conditions, those in which the state of exactly one spin is changed, i.e., product operators with only *one* transverse operator.

Finally, a technical remark: The induced signal in 1D NMR experiments is not registered in a continuous manner. The signal picked up by the receiver coil is sampled in discrete time intervals Δt ("horizontal" time digitization) and then digitized "vertically" by an analog-to-digital converter. An FID is obtained consisting of N points, where $N \cdot \Delta t$ yields the acquisition time. The horizontal digitization is possible according to the sampling theorem [68–73]

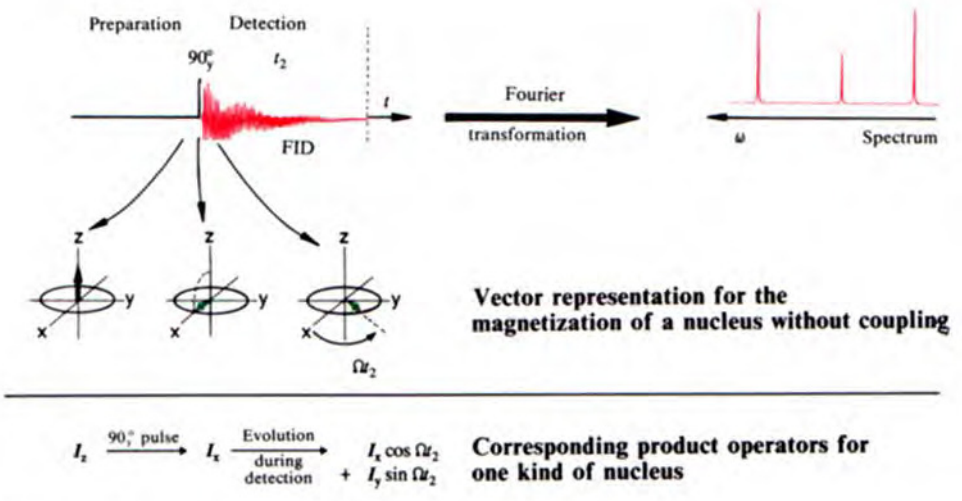

Fig. 4. Principle of 1D NMR spectroscopy. Evolution of magnetization is shown in the vector description and by product operators.

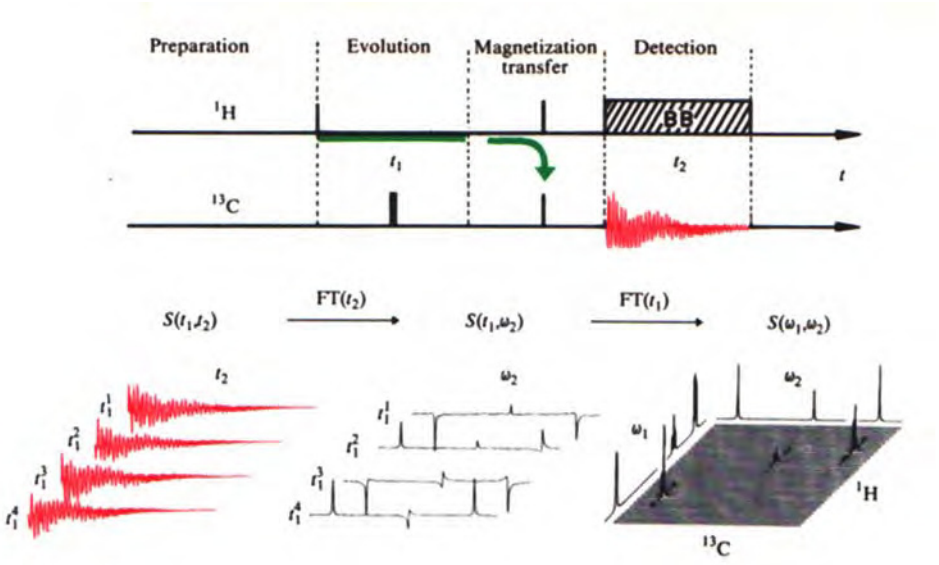

Fig. 5. Principle of 2D NMR spectroscopy, exemplified by H,C-COSY. Note the intensity variation of the carbon signals after the first Fourier transformation (lower center), which reflects the evolution of proton magnetization during t_1.

since the spectral width, i.e., the range of possible frequencies, is limited due to the nature of the sample and to analog filtering. Discrete sampling is essential for 2D NMR spectroscopy, since it enables the definition of a second time scale in digital form (see Section 2.2).

2.2. Two-Dimensional NMR Spectroscopy

The pulse sequence of a 2D NMR experiment may be divided in general into the following blocks:[2]

preparation-evolution(t_1)-mixing-detection(t_2).

The detection period corresponds exactly to the one for 1D NMR spectroscopy (Section 2.1). The time t_2 provides, after Fourier transformation, the ω_2 frequency axis of a 2D NMR spectrum. The trick of 2D NMR spectroscopy is that a second time variable, the evolution time t_1, is introduced. The evolution time t_1 is made stepwise longer, i.e., incremented, in analogy to the detection time t_2. For each t_1 increment a separate FID is detected in t_2. Thus a signal is obtained which is a function of two time variables, t_1 and t_2: $S(t_1,t_2)$. A series of ω_2 spectra is then obtained upon Fourier transformation of each of the FIDs. They differ from one another in the intensities and/or phases of the individual signals, according to the different t_1 increments. A second Fourier transformation over t_1, "perpendicular" to the ω_2 dimension, results in a spectrum as a function of two frequencies (ω_2 horizontal, ω_1 vertical).

The principles of 2D NMR spectroscopy are demonstrated in Figure 5 with an example of proton-carbon chemical shift correlation (H,C-COSY). First, a transverse proton magnetization (coherence) is generated, which is subsequently transferred to carbon during the mixing period by means of ^{1}H and ^{13}C 90° pulses. The exact mechanism of this transfer will be discussed in Section 2.2.1. Finally, the carbon magnetization is detected.

Let us consider this experiment again in greater detail using the pulse sequence of Figure 5 with product operators.[*] After the preparation, which in this case consists of a 90°_y pulse, transverse magnetization I_x (single-quantum coherence) is generated from the equilibrium magnetization. During the evolution time t_1, I_x evolves with its characteristic frequency [Eq. (14)]. Through the mixing sequence consisting of 90° pulses in ^{1}H and ^{13}C, the proton coherence is transferred to ^{13}C coherence (i.e., I_x transforms into S_x). The I_y term is not considered further, since, as we shall see in Section 2.2.1, it is not relevant for this experiment. The mechanism of the coherence transfer is likewise not discussed further at this point. S_x evolves during t_2 with its characteristic frequency [Eq. (15)]. The state of the spin system after a time t_2 is given by Equation (16).

$$I_x \xrightarrow{\Omega_I t_1 I_z} I_x \cos \Omega_I t_1 + I_y \sin \Omega_I t_1 \tag{14}$$

$$S_x \xrightarrow{\Omega_S t_2 S_z} S_x \cos \Omega_S t_2 + S_y \sin \Omega_S t_2 \tag{15}$$

$$\cos \Omega_I t_1 \, (S_x \cos \Omega_S t_2 + S_y \sin \Omega_S t_2) \tag{16}$$

Thus the coefficients of the S operator describing the time evolution in t_1 and t_2 contain not only its own characteristic frequencies Ω_S, but also the I-spin frequency Ω_I. This is sometimes referred to as "labeling." S_{xy} is labeled during t_1 with the I frequency. Quadrature detection converts the operator combination of Equation (16) into a complex signal [Eq. (17)]. Fourier transformation along t_1 and t_2 results in the frequencies, namely, $\pm\Omega_I$ in ω_1 and Ω_S in ω_2. A spectrum like the one shown schematically in Figure 6 is obtained. A line in position (Ω_I, Ω_S) in the 2D NMR spectrum will appear when the signal is modulated in t_1 by the frequency Ω_I and in t_2 by the frequency Ω_S.

$$\cos \Omega_I t_1 \, e^{i\Omega_S t_2} \tag{17}$$

The 2D NMR spectrum is thus a representation of the transfer processes of coherences, whereby peaks arise at the characteristic frequencies of the interconnected coherences. The intensity of the signals is determined by the ef-

[*] Originally I and S were identified with "insensitive" and "sensitive," respectively. Nevertheless we use here I for the proton, although it is magnetically the more sensitive nucleus, and S for the heterospin, to correspond to conventional use.

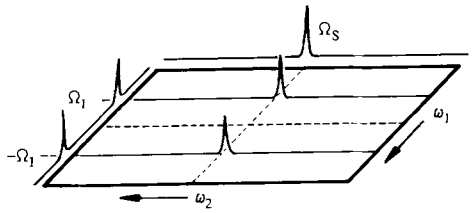

Fig. 6. Schematic cross signals of I and S nuclei in a hypothetical 2D NMR spectrum. The spectra on the margins represent projections along the axes. In ω_2 the Redfield technique (see Fig. 3) was used.

ficiency of the mixing process. The transferability of coherences depends, on the one hand, on the properties of the spin system: on structural, dynamic, and chemical molecular properties which reflect the behavior of the magnetically active nuclei. On the other hand, it is determined by the mixing sequence of the particular 2D NMR experiment. The multitude of 2D NMR experiments relates directly to these various transfer processes.

In high-resolution NMR spectroscopy there are essentially two spin-spin interactions which can be used to effect coherence transfer: one is the through-bond scalar spin-spin coupling (J coupling), well known in 1D NMR spectroscopy since it gives rise to the observed multiplet splitting. It is effective only between spins which are separated by few bonds in the molecule. Therefore it is particularly useful for the elucidation of connectivities, i.e., bonds, between atoms, and serves for the investigation of the *constitution* of organic compounds, as well as for spectral assignments. The magnitude of the scalar coupling is a sensitive measure of the torsion angle about single and double bonds, and hence provides important information about spatial structure *(conformation)*.[74-76]

The other interaction is the *dipolar* coupling of two spins, which operates through space. It is responsible for the dominating mechanism of relaxation in solution,[77-79] but is only indirectly apparent in the 1D NMR spectrum as line broadening. Dipolar coupling generates also the mutual relaxation between spatially neighboring nuclei, the so-called cross relaxation. The intramolecular cross relaxation gives rise to the nuclear Overhauser enhancement (NOE) effect, i.e., to a variation in the intensity of a signal as a result of a disturbance in the populations of another nucleus.[77-82] The NOE effect depends on the distance between the cross-relaxing nuclei, and hence allows the determination of intramolecular interatomic distances.[83-88] NOE values therefore provide the most important parameter for the determination of three-dimensional structures. The quantitative measurement of distances for larger molecules became only practicable[94-101] through 2D NMR spectroscopy.[89-93] NOE effects and J couplings are complementary to each other in their structural information content.

A third mechanism for coherence transfer is provided by exchange processes, such as chemical reactions.[102,103] In contrast to the other processes mentioned above, this coherence transfer does not involve multispin systems. The fact that a nucleus may have different chemical shifts when it is in molecule A or B is sufficient to observe so-called exchange spectra. This was applied very early in kinetic studies.[102-115] The introduction of 2D exchange NMR spectroscopy[89,116,117,371] brought advantages not only for the measurement of rate constants of reactions at equilibrium (such as in vivo reactions), but also for the determination of rates and mechanisms of site exchanges in fluxional molecules.

2.2.1. Scalar Coupling

Scalar coupling underlies most of the 2D NMR experiments. It also leads to the failure of the vector description of NMR experiments. Because of the fundamental role of scalar coupling in 2D NMR spectroscopy we shall discuss it first.

Scalar Coupling in the Product Operator Formalism

Scalar coupling is the interaction between two spins, which occurs predominantly through bonds (indirect coupling) and only occasionally "through space."[118] It leads to splitting of the resonances in the NMR spectrum (multiplet structure). In terms of the product operator formalism, spin-spin coupling between two nuclei 1 and 2 may be described according to (18)-(21). The resulting expressions

$$I_{1x} \xrightarrow{\pi J_{12} t\, 2I_{1z}I_{2z}} I_{1x}\cos \pi J_{12}t + 2I_{1y}I_{2z}\sin \pi J_{12}t \tag{18}$$

$$I_{1y} \xrightarrow{\pi J_{12} t\, 2I_{1z}I_{2z}} I_{1y}\cos \pi J_{12}t - 2I_{1x}I_{2z}\sin \pi J_{12}t \tag{19}$$

$$2I_{1x}I_{2z} \xrightarrow{\pi J_{12} t\, 2I_{1z}I_{2z}} 2I_{1x}I_{2z}\cos \pi J_{12}t + I_{1y}\sin \pi J_{12}t \tag{20}$$

$$2I_{1y}I_{2z} \xrightarrow{\pi J_{12} t\, 2I_{1z}I_{2z}} 2I_{1y}I_{2z}\cos \pi J_{12}t - I_{1x}\sin \pi J_{12}t \tag{21}$$

are quite similar to those obtained for the evolution of chemical shifts. However, here for the first time products of two operators are obtained, to which this formalism owes its name. We turn back for a moment to the vector description in order to clarify the above equations. Coupling between spin 1 and spin 2 is shown in the vector picture as two vectors for spin 1, precessing at different angular velocities corresponding to either the α state or the β state of spin 2 (Fig. 7). The x magnetization of spin 1 is

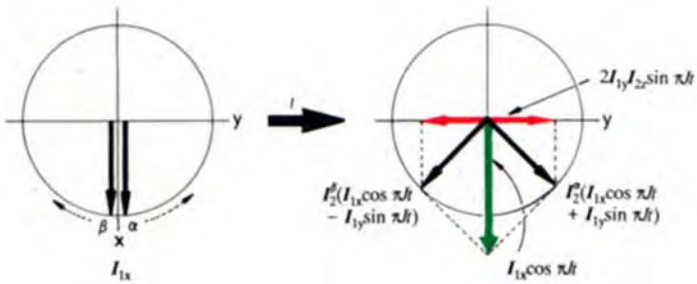

Fig. 7. Evolution of scalar coupling during time t, starting from x magnetization. The resulting anti-phase magnetization is shown in red, the remaining in-phase magnetization in green.

apparently modulated by $\cos \pi Jt$, as is also shown in the first part of Equation (18). In addition there is a magnetization along the y axis (red), which is described by $I_{1y}(I_2^\alpha - I_2^\beta)$ (the y magnetization of spin 1 points to +y for

spin 2 in the α state, and to $-y$ for spin 2 in the β state). This y magnetization is not observable; thus, in the macroscopic sense, it is not really a magnetization, since the positive and negative components cancel exactly. The difference in populations of the α and β levels ($I^{\alpha}-I^{\beta}$) is given by $2I_z$. Hence, $I_{1y}(I_2^{\alpha}-I_2^{\beta})$ is identical with $2I_{1y}I_{2z}$, which is obviously modulated by $\sin \pi Jt$ [cf. Eq. (18)].

In contrast to the evolution under chemical shift and/or pulses, the evolution of coupling "creates" or "annihilates" operators: $I_{1x} \rightarrow 2I_{1y}I_{2z}$ and $2I_{1x}I_{2z} \rightarrow I_{1y}$. Annihilation of operators occurs since a squared operator always equals the unit operator (in this case, $I_zI_z = 1/4$). Only coupling and not chemical shift can "bring other nuclei into the scene." This is the salient point for coherence transfer,[*] since polarization can only be transferred when a second spin is involved in the product operator.

Before we can proceed to use the product operator formalism, we need a number of rules which regulate operator transformations:

(a) A product operator evolves under the effect of chemical shift or pulses such that each operator in the product is transformed separately [Eq. (22)–(24)]. I_z does not evolve under chemical shift [see Eq. (10)].

$$2I_{1x}I_{2z} \xrightarrow{90^{\circ}_{y}} -2I_{1z}I_{2x} \tag{22}$$

$$2I_{1x}I_{2z} \xrightarrow{\Omega_1 tI_{1z}+\Omega_2 tI_{2z}} 2I_{1x}I_{2z}\cos\Omega_1 t + 2I_{1y}I_{2z}\sin\Omega_1 t \tag{23}$$

$$2I_{1x}I_{2y} \xrightarrow{\Omega_1 tI_{1z}+\Omega_2 tI_{2z}} 2(I_{1x}\cos\Omega_1 t + I_{1y}\sin\Omega_1 t)(I_{2y}\cos\Omega_2 t - I_{2x}\sin\Omega_2 t) \tag{24}$$

One must be careful when dealing with scalar coupling, since in this case also pairs of product operators of the mutually coupled nuclei must be treated together. For example, $2I_{1x}I_{2z}$ evolves under a 1,3 coupling according to (25)

$$2I_{1x}I_{2z} \xrightarrow{\pi J_{13}t\,2I_{1z}I_{3z}} 2I_{1x}I_{2z}\cos\pi J_{13}t + 4I_{1y}I_{2z}I_{3z}\sin\pi J_{13}t \tag{25}$$

(i.e., only the transverse operator I_{1x} evolves [cf. Eq. (18)]). Under 1,2 coupling, however, $2I_{1x}I_{2z}$ evolves according to Equation (26).

$$2I_{1x}I_{2z} \xrightarrow{\pi J_{12}t\,2I_{1z}I_{2z}} 2I_{1x}I_{2z}\cos\pi J_{12}t + I_{1y}\sin\pi J_{12}t \tag{26}$$

It is also important to note that product operators of two transverse operators [Eq. (27) and (28)], as well as product operators of two longitudinal operators, do not develop mutual coupling [Eq. (29)].

$$2I_{1x}I_{2x} \xrightarrow{\pi J_{12}t\,2I_{1z}I_{2z}} 2I_{1x}I_{2x} \quad \text{(two transverse operators)} \tag{27}$$

$$2I_{1x}I_{2y} \xrightarrow{\pi J_{12}t\,2I_{1z}I_{2z}} 2I_{1x}I_{2y} \quad \text{(two transverse operators)} \tag{28}$$

$$2I_{1z}I_{2z} \xrightarrow{\pi J_{12}t\,2I_{1z}I_{2z}} 2I_{1z}I_{2z} \quad \text{(two longitudinal operators)} \tag{29}$$

However, $2I_{1x}I_{2y}$ develops coupling to a *third* spin (I_{3z}) [Eq. (30)]. In this equation we have already made use of rule (b).

$$2I_{1x}I_{2y} \xrightarrow{\pi J_{13}t\,2I_{1z}I_{3z}} 2I_{1x}I_{2y}\cos\pi J_{13}t + 4I_{1y}I_{2y}I_{3z}\sin\pi J_{13}t \xrightarrow{\pi J_{23}t\,2I_{2z}I_{3z}}$$
$$2I_{1x}I_{2y}\cos\pi J_{13}t\cos\pi J_{23}t + 4I_{1y}I_{2y}I_{3z}\sin\pi J_{13}t\cos\pi J_{23}t \tag{30}$$
$$-4I_{1x}I_{2x}I_{3z}\cos\pi J_{13}t\sin\pi J_{23}t - 2I_{1y}I_{2x}\sin\pi J_{13}t\sin\pi J_{23}t$$

(b) Couplings and chemical shifts operate simultaneously; in the absence of strong coupling, however, the evolution under these interactions may formally be considered sequential. This is due to the commutation of the operators of chemical shift and weak coupling. This does *not* apply to pulses. Therefore pulses limit the periods of free precession.

The product operators only "come to life" when one realizes to which signals in the spectrum they give rise. The following is valid for weak coupling:

(a) Only product operators with *one* transverse operator (I_x or I_y) are observable. All other products cannot be observed.

(b) Product operators with one transverse operator (I_x, I_y) and any number of longitudinal operators (I_z) evolve into "observable" operators as long as the "transverse" spin is scalar-coupled to all the "longitudinal" ones.

(c) All other product operators are not observable, and do not evolve into observable operators.

We turn now to discuss product operators in a three-spin system, in which nucleus 1 is coupled to two other nuclei, 2 and 3 (Fig. 8). I_{1x} generates the well-known dou-

Fig. 8. Schematic in-phase double doublet (line spectrum).

ble doublet at chemical shift Ω_1. This results from Equation (31). We make use of the fact that only I_{1x} and I_{1y} are

$$I_{1x} \longrightarrow I_{1x}\cos\Omega_1 t\cos\pi J_{12}t\cos\pi J_{13}t + I_{1y}\sin\Omega_1 t\cos\pi J_{12}t\cos\pi J_{13}t + \ldots \tag{31}$$

observable, and neglect all other 6 unobservable terms. Before we can show how a spectrum is constructed from this time function we need to add a few comments on phases and Fourier transforms: The absolute phase of a signal cannot be defined in a significant manner. While the phase can change owing to the electronics, it may be corrected by

[*] Most often the expression "polarization transfer" is used instead of "coherence transfer." However, we think the latter is more precise.

the experimenter as desired through zero-order phase correction. However, the definition of relative phases, which remain invariant with respect to phase correction, is significant. The following rule may be formulated: the relative phase equals 90° multiplied by the number of sine factors counted in the coefficients of the x magnetizations. We can, for example, adjust the absolute phase such that an I_x term with only cosine factors as coefficients will be in absorption. The following will then hold for the phases of the other terms (see Fig. 9):

0, 4, ... sine factors: absorption
1, 5, ... sine factor: dispersion
2, 6, ... sine factors: negative absorption
3, 7, ... sine factors: negative dispersion

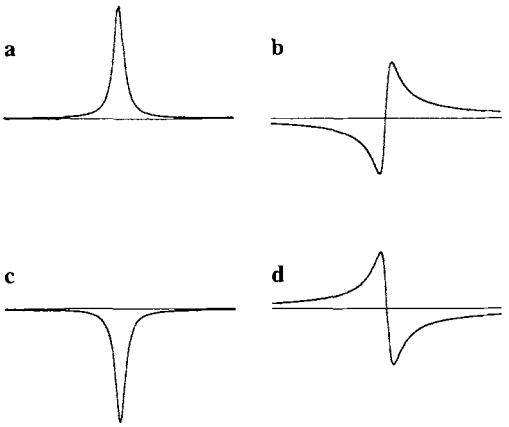

Fig. 9. Line shapes in NMR spectra: a) absorption signal, b) dispersion signal, c) negative absorption signal (emission), d) negative dispersion signal.

The modulation of the time signal by coupling occurs exclusively through amplitude factors of the form $\cos \pi Jt$ and $\sin \pi Jt$. Its Fourier transform is shown in Figure 10.

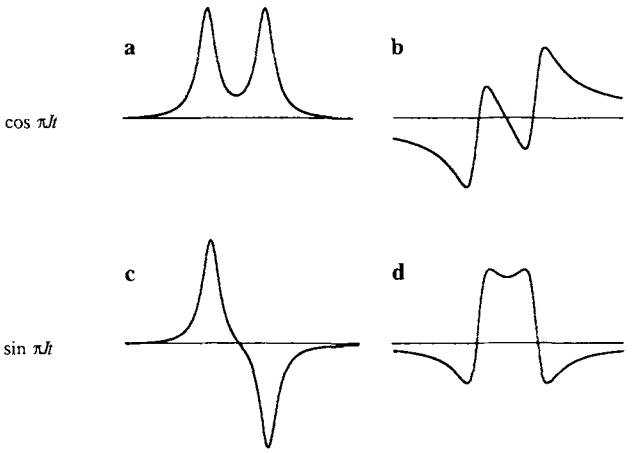

Fig. 10. Signal shapes for a doublet with in-phase structure (a and b), and antiphase structure (c and d). The spectra on the left (a, c) are in absorption, those on the right (b, d) in dispersion.

A starting point for the construction of a signal from a product of functions [see, for instance, Eq. (30)] is the folding principle: The Fourier transform of a product of functions can be constructed from the Fourier transforms of the individual functions by convolution. In our case, the product consists of the trigonometric functions, the Fourier transforms of which are well known. The preceding discussion, applied to the terms in Equation (31), leads to the signals shown in Figure 11.

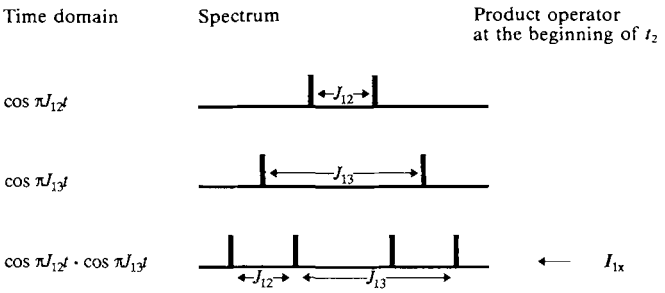

Fig. 11. Construction of an in-phase multiplet from the two in-phase doublets corresponding to J_{12} and J_{13} through convolution.

Antiphase operators behave as follows: $2I_{1x}I_{2z}$ is not directly detectable [rule (a)]; however, it develops observable magnetization according to Equation (32). If the J_{12} coupling equals 0, no observable magnetization evolves [rule (b)], as can also be seen directly in (32).

$$2I_{1z}I_{2z} \xrightarrow{\pi J_{12}t\ 2I_{1z}I_{2z}} I_{1y} \sin \pi J_{12}t \xrightarrow{\pi J_{13}t\ 2I_{1z}I_{3z}} I_{1y} \sin \pi J_{12}t \cos \pi J_{13}t \xrightarrow{\Omega t I_{1z}} I_{1y} \cos \Omega_1 t \sin \pi J_{12}t \cos \pi J_{13}t - I_{1x} \sin \Omega_1 t \sin \pi J_{12}t \cos \pi J_{13}t \quad (32)$$

We apply again the convolution principle and obtain the result shown in Figure 12. An in-phase doublet is obtained

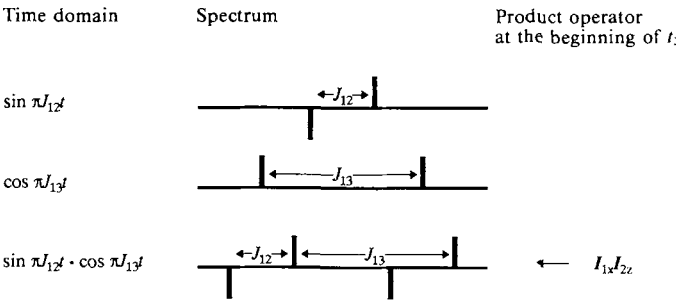

Fig. 12. Construction of a double doublet with antiphase structure with respect to J_{12} and in-phase structure with respect to J_{13}.

for J_{13} (cosine) and an antiphase doublet for J_{12} (sine). The x component contains two sine factors, so that finally a negative absorption signal is obtained, in-phase with respect to J_{13} and antiphase with respect to J_{12}. The spectra for the remaining product operators are likewise obtained using the same "recipe."

At this point we need no longer denote the time domain signal. According to the recipe stating that *every z operator generates an antiphase doublet and the others generate in-*

phase doublets, we can construct the missing spectra, which are shown in Figure 13.

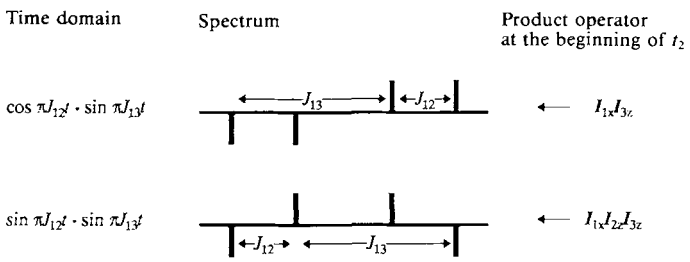

Fig. 13. Double doublets with different antiphase structures: upper part, antiphase with respect to J_{13}. Lower part, with respect to both J_{12} and J_{13}.

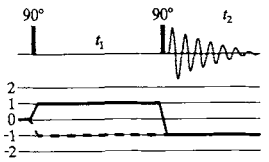
There are rules also for the phases of signals (absorption, dispersion): All the terms with an I_x operator (e.g., I_{1x}, $2I_{1x}I_{2z}$, $4I_{1x}I_{2z}I_{3z}$, etc.) are in absorption (an even number of sine factors). It is readily seen that product operators with an I_y operator are in dispersion. Absorption and dispersion can be exchanged by means of a phase correction. In a 2D NMR signal there is an independent phase for each of the frequency dimensions ω_1, ω_2. The phases can hence be either equal or different in both dimensions.

The following is a discussion of the H,H-COSY experiment[1,2] (pulse sequence PI) in greater detail. It has only two pulses and hence is one of the simplest 2D NMR pulse sequences.[*]



(PI)

Historically 2D COSY was the first 2D NMR experiment,[1] and it remains the most important one. It relates to the earlier mentioned coherence transfer. We have seen that coupling is associated with antiphase terms such as $2I_{1x}I_{2z}$, which can lead to observable magnetization. When a 90°_y pulse is applied to an operator $2I_{1x}I_{2z}$ the latter transforms into $-2I_{1z}I_{2x}$ [cf. also Eq. (22)]. That means that spin 1, which was transverse before the pulse, becomes longitudinal, and the longitudinal spin 2 becomes transverse. Thus the coherence of spin 1 ($2I_{1x}I_{2z}$ evolves with the chemical shift of nucleus 1) has been transferred into the coherence of spin 2. The COSY experiment is based on this coherence transfer.

Let us examine again a three-spin system with spins 1, 2, and 3. The first 90°_y pulse generates from the equilibrium magnetization a transverse magnetization $I_{1x}+I_{2x}+I_{3x}$. In the following discussions we shall not evaluate all the terms, but shall instead ignore the irrelevant ones, which do not lead to signals in the spectrum.

Only terms I_{1x}, I_{2x}, or I_{3x} are detected at the end of the detection period t_2. Let us focus on the I_{2x} term, since the transfer $I_{1x} \rightarrow I_{2x}$ gives rise to a cross signal at Ω_1 in ω_1 (vertical axis) and Ω_2 in ω_2 (horizontal axis). We noted earlier that only coupling can introduce an additional spin into the product operator. The evolution (33) must hence take

$$I_{1x} \longrightarrow 2I_{1x}I_{2z} \tag{33}$$

place during t_1. Only this product operator is converted by a 90°_y pulse completely into $-2I_{1z}I_{2x}$. The transfer diagram for the 1,2 cross signal in the COSY experiment is thus given by Equation 34. There is no other way to transfer magnetization from spin 1 to spin 2 in this pulse sequence. Exactly one z operator, which will subsequently transform into a transverse operator during t_2, is required before the mixing. Spin 1 must be present during t_1 with an x operator I_{1x}. More than one z operator in the product operator would transform into several transverse operators, which are undetectable. The coefficients of these operators are obtained as follows. During t_1, I_{1x} evolves under chemical shift and coupling as in (35). All the couplings to nuclei that are not responsible for the transfer enter as cosine factors. Here only one such coupling, to nucleus 3, was considered. The polarization transfer takes place through the 90°_y pulse, resulting in (36). This evolves into observable magnetization according to Equations (18) and (20). The overall amplitude of the signal, the so-called transfer function, is given by (37).

$$I_{1z} \xrightarrow{90^\circ_y} I_{1x} \xrightarrow{t_1} -2I_{1x}I_{2z} \xrightarrow{90^\circ_y} 2I_{1z}I_{2x} \xrightarrow{t_2} I_{2x} \tag{34}$$

$$-2I_{1x}I_{2z} \sin \Omega_1 t_1 \sin \pi J_{12} t_1 \cos \pi J_{13} t_1 \tag{35}$$

$$2I_{1z}I_{2x} \sin \Omega_1 t_1 \sin \pi J_{12} t_1 \cos \pi J_{13} t_1 \tag{36}$$

$$\sin \Omega_1 t_1 \sin \pi J_{12} t_1 \cos \pi J_{13} t_1 \sin \Omega_2 t_2 \sin \pi J_{12} t_2 \cos \pi J_{23} t_2 \tag{37}$$

Construction of 2D Multiplets

We have discussed the construction scheme for 1D NMR spectra from their time-domain signals, and now apply it to the construction of a 2D NMR spectrum. From the multiplets shown in Figure 14 in ω_1 and ω_2 the 2D NMR spectrum is constructed by placing peaks at the intersection points of the lines. The intensity is obtained from the product of the intensities of the crossing lines. The phases in ω_1 and ω_2 are identical with those of the corresponding "1D NMR spectra" discussed above.

So far we have only dealt with a single cross peak, that for spins 1 and 2. The others are obtained similarly, e.g.,

[*] The "staffs" given under the actual pulse sequences show the corresponding coherence-transfer pathway. They will be explained separately later in the text.

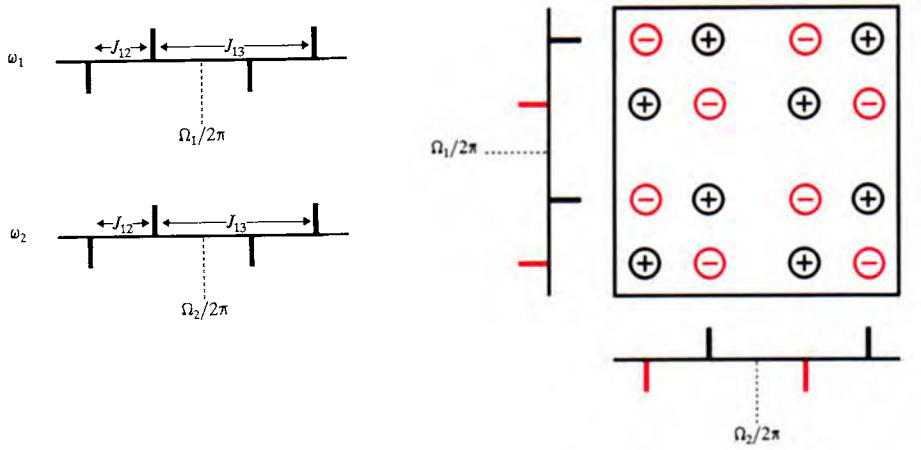


Fig. 14. Construction of a 2D multiplet from the corresponding 1D NMR spectra. The signals in the 2D NMR spectrum (right) arise at the crossing points of the 1D NMR spectra (left). Their intensities result from the product of the intensities of the 1D NMR spectra.

that between 2 and 3 by starting with I_{2x} after the 90° pulse and detecting I_{3x}.

We now summarize again the formation of cross signals. During t_1, coherences evolve under the chemical shift of spin 1; during t_2, under the chemical shift of spin 2. For a coherence transfer with a 90°_y pulse a term $2I_{1x}I_{2z}$ is required, which is converted into $-2I_{1z}I_{2x}$; i.e., antiphase magnetization exists before and after the coherence transfer, caused by the J_{12} coupling. The J_{12} coupling is referred to as *active coupling*. Couplings to other nuclei such as spin 3 appear in-phase and are termed *passive*. They do not participate in the transfer.

Diagonal signals (e.g., $\omega_1=\omega_2=\Omega_1$) are also formed in a COSY spectrum. For a 1,1 diagonal signal the product operator must have *one* transverse operator for spin 1 before the mixing, or else no chemical shift for that spin would evolve during t_1. Likewise the operator for spin 1 must remain transverse after the mixing, in order to appear as a signal at Ω_1 in ω_2. No terms with more than one I_z operator can exist before the mixing pulse, for they would transform into transverse operators by the 90° pulse, and thus generate unobservable terms with more than one transverse operator at the beginning of t_2. The transfer diagram for diagonal signals is given by (38) and the corresponding transfer amplitude by (39).

$$I_{1z} \xrightarrow{90^\circ_y} I_{1x} \xrightarrow{t_1} I_{1y} \xrightarrow{90^\circ_y} I_{1y} \xrightarrow{t_2} I_{1x} \tag{38}$$

$$\sin \Omega_1 t_1 \cos \pi J_{12} t_1 \cos \pi J_{13} t_1 \sin \Omega_1 t_2 \cos \pi J_{12} t_2 \cos \pi J_{13} t_2 \tag{39}$$

The analysis of the multiplet structure reveals dispersive (a single sine factor for both time dimensions) in-phase signals (cosine factors for the couplings) in both frequency dimensions. The diagonal signals in the COSY spectrum are dispersive in both dimensions (double dispersive), while the cross signals are absorptive in both dimensions (double absorptive). Absorption and dispersion can, of course, be exchanged also in 2D NMR spectra by a separate phase correction in each dimension. The diagonal signal is in-phase with respect to all couplings, since they appear as cosines.

So far we have analyzed only the useful transfers (cross and diagonal signals). The undesired signals were simply ignored. In the COSY experiment, so-called *axial peaks* occur as artifacts. They arise when an I_z term at the end of t_1 is converted by the 90° pulse into a transverse operator I_x observable in t_2. Since it is not modulated in t_1 it gives rise to a signal at $\Omega_1=0$ (axial peak). The spectroscopist has, nevertheless, a powerful tool to suppress artifacts: *phase cycling*. Before we elaborate further on this, we wish to describe the second important process for magnetization transfer between two spins, the dipolar coupling.

2.2.2. Dipolar Coupling

The dipolar coupling plays an entirely different role in high-resolution NMR spectroscopy compared to the scalar coupling. In 1D NMR spectroscopy it operates only as a relaxation phenomenon and gives rise to line broadening (T_2), and of course T_1 processes are responsible for the establishment of the Boltzmann state after a certain time. Scalar coupling, on the other hand, leads to oscillations of the FID and splitting of lines in the spectrum. As explained above, J coupling generates during evolution periods operators which cause coherence transfer under the influence of pulses. Thus the scalar coupling generates a state which can then (even without the effect of coupling during the mixing) be converted by pulses into the desired final state [Eq. (40)].

$$I_x \xrightarrow{J(t_1)} 2I_yS_z \xrightarrow{\text{Mixing}} 2I_zS_y \xrightarrow{J(t_2)} S_x \tag{40}$$

The situation is different for mixing through dipolar coupling. There the dipolar coupling must be effective during the mixing period, while it need not be effective in the evolution or detection times [Eq. (41)].

$$I_x \xrightarrow{t_1} I_z \xrightarrow{\text{NOE}} S_z \xrightarrow{t_2} S_x \tag{41}$$

Dipolar Relaxation

Dipolar coupling is the interaction of the magnetic moments of two spins through space.[65,77,78,119] The magnetic field B_D, which is generated by spin 2 at the site of spin 1, is orientation dependent [Eq. (42), where r_{12} is the

internuclear distance and Θ_{12} the angle between the interatomic vector and the B_0 field].

$$B_D^1 = \gamma_2(3\cos^2\Theta_{12} - 1)\, r_{12}^{-3} \tag{42}$$

The rapid reorientation of molecules in solution produces alternating magnetic fields at the sites of the nuclei (Fig. 15). These lead to exchange of spin polarization (z magnetization) and cause relaxation of a spin system, which deviates from the Boltzmann distribution, back to its equilibrium state.

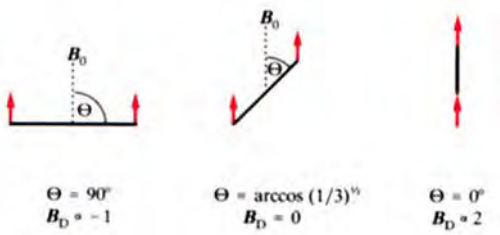

Fig. 15. Dipole-dipole interaction between two spins in the field B_0, and its dependence on the orientation angle Θ. The field reaches a maximum at $\Theta=0$, a minimum at $\Theta=90°$, and vanishes at the magic angle $\Theta=\arccos(1/3)^{1/2}$.

Because of the dipolar coupling, the two spins do not relax independently, but influence each other; i.e., each deviation of a spin state from equilibrium is transferred to the other spin state, which therefore also deviates from equilibrium. This effect is termed nuclear Overhauser enhancement (NOE). Figure 16 depicts the situation for two dipolar coupled spins, I and S:

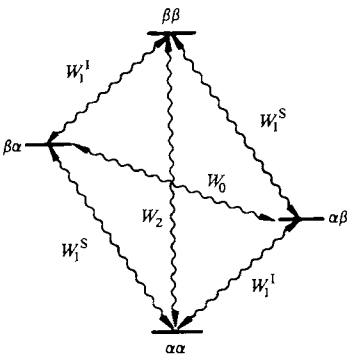

Fig. 16. Relaxation in a two-spin system. Zero-, single-, and double-quantum transitions are labeled W_0, W_1, and W_2, respectively.

Equations (43)–(45)[77] express the transition probabilities W ("rates") under isotropic reorientation of the interatomic vector.

$$W_1^I = \frac{3}{20} \cdot \frac{\gamma_I^2\gamma_S^2\hbar^2}{r^6} \cdot \frac{\tau_c}{1+\omega_I^2\tau_c^2} \tag{43}$$

$$W_0 = \frac{1}{10} \cdot \frac{\gamma_I^2\gamma_S^2\hbar^2}{r^6} \cdot \frac{\tau_c}{1+(\omega_I-\omega_S)^2\tau_c^2} \tag{44}$$

$$W_2 = \frac{3}{5} \cdot \frac{\gamma_I^2\gamma_S^2\hbar^2}{r^6} \cdot \frac{\tau_c}{1+(\omega_I+\omega_S)^2\tau_c^2} \tag{45}$$

To get a feeling for these transition probabilities, we now examine the relaxation generated by polarization of spin I (I_z). Only deviations from the Boltzmann equili-

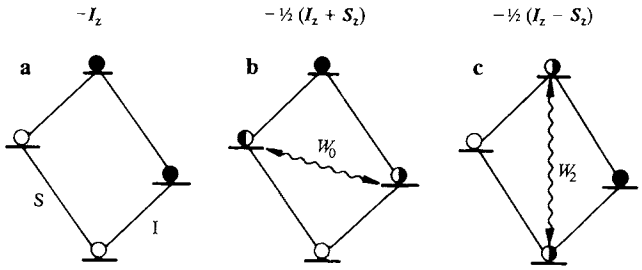

Fig. 17. Population changes due to dipolar relaxation. Note that only deviations from the Boltzmann distribution are shown schematically. a) Initial state I_z, b) after relaxation under the influence of W_0 alone, c) after relaxation under W_2 alone.

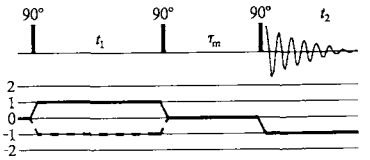
brium are shown in Figure 17. Hence, the state shown in Figure 17a corresponds to the Boltzmann equilibrium of spin S and saturation of spin I, resulting in a difference magnetization $-I_z$. We recognize that W_1^S does not affect and W_1^I equalizes the population difference for the I transition, and thus leads to a decay of $-I_z$ (relaxation). Since this applies equally to both I transitions, there is no change in the population difference for the S spin. If W_0 alone is effective, however, the populations of the two middle levels equalize, and the population distribution shown schematically in Figure 17b is obtained, corresponding to a change in population of the S spin at the same time. Thus W_0 relaxation converts an I_z operator in part into S_z, and hence enables magnetization transfer through dipolar coupling. The overall polarization remains unchanged in this process. If W_2 alone operates, the upper and lower levels equalize, resulting in the situation shown in Figure 17c. Magnetization is transferred again from spin I to spin S, however this time with a change in sign, since now the lower levels of S become more densely populated than the higher ones. Evidently the overall polarization is not preserved by this process.

The effectiveness of the relaxation processes W_0 and W_2 is determined by the rate of the molecular reorientation. When the molecular rotation in the external field is slow (corresponding to a long "correlation time," $\tau_c > \omega_0^{-1}$), cross-relaxation occurs mainly through the low-frequency transitions W_0 ($\triangleq \omega_I - \omega_S$) [see Eq. (44)]. Conversely, the relaxation through W_2 ($\triangleq \omega_I + \omega_S$) is only possible when the molecular reorientation is fast [Eq. (45)], corresponding to a short correlation time τ_c. Depending on whether W_0 or W_2 dominates, the cross-relaxation rate $W_2 - W_0$ may be either negative or positive and hence also the NOE effect. For $W_2 - W_0$, the cross relaxation rate vanishes. Conventionally, the positive cross-relaxation rate and the enhanced intensity of the S-spin signal correspond to a positive NOE; conversely, a negative rate and a decreased S-signal intensity correspond to a negative NOE.[78]

Just as COSY is for the coherence transfer, so is the NOESY experiment the fundamental and most important pulse sequence for the incoherent magnetization transfer. We have seen that the transfer of magnetization via NOE is achieved by creating a nonequilibrium situation and then waiting (pulse sequence P2).[89]



(P2)

The relevant product operators result from the following ideas: at the beginning and the end of τ_m, z magnetization is required. It is converted into transverse magnetization (detectable coherence), and is also generated from transverse magnetization. Hence the transformation (46) results. The transfer amplitude is given by (47), where $\prod_i \cos \pi J_{Ii} t_1$ is the product[*] of all $\cos \pi J_{Ii} t_1$ factors and J_{Ii} are the scalar couplings between spin I and other spins i; $\prod_i \cos \pi J_{Si} t_2$ is the equivalent expression for spin S.

$$I_z \xrightarrow{90°_x} -I_y \xrightarrow{t_1} -I_y \xrightarrow{90°_x} -I_z \xrightarrow{\text{NOE}} -S_z \xrightarrow{90°_x} S_y \xrightarrow{t_2} -S_x \quad (46)$$

$$\cos \Omega_I t_1 \prod_i \cos \pi J_{Ii} t_1 \sin \Omega_S t_2 \prod_i \cos \pi J_{Si} t_2 \quad (47)$$

As far as the relative signs of the diagonal and cross signals in the NOESY spectrum are concerned, when the NOE is positive ($W_2 - W_0 > 0$), I_z evolves into $-S_z$; i.e., the signs of the diagonal and cross signals are opposite. If the NOE is negative ($W_2 - W_0 < 0$), however, I_z evolves into S_z, and the signs of the diagonal and cross signals are the same.

The NOESY signal is in-phase with respect to all the couplings (only cosine factors), and can be corrected to pure absorption. We shall later discuss in greater detail the analysis of NOESY spectra and a few of its variants.

We now come to discuss phase cycles, which are an important means for the elimination of artifact (i.e., unwanted) signals from spectra. For example, it is evident from the NOESY sequence that also the transfer (48) be-

$$I_z \xrightarrow{90°_x} -I_y \xrightarrow{t_1} 2I_yS_z \xrightarrow{90°_x} -2I_zS_y \xrightarrow{\tau_m} S_x \xrightarrow{90°_x} S_x \xrightarrow{t_2} S_x \quad (48)$$

tween two coupled spins is possible. It leads to an undesired signal due to scalar coupling, which overlaps with the NOE signal. Phase cycling allows the suppression of such undesired signals.

2.2.3. Coherence Orders and Phase Cycles

In a phase cycle a pulse sequence is repeated, whereby the phases of the single pulses (transmitter) and the receiver phase are varied systematically ("cycled"), while all other parameters (delays, flip angles, etc.) remain constant. All the FIDs obtained in this way for one t_1 increment are added up. Phase cycles serve to select a desired transfer and simultaneously to suppress undesired magnetizations. They are only useful when the phase dependencies of the desired and undesired transfer processes are different.

A simple example follows. Cross signals arise in the COSY experiment due to the transfer (49). Nothing in the

$$2I_{1x}I_{2z} \xrightarrow{90°_y} -2I_{1z}I_{2x} \quad (49)$$

product operator changes upon rotation of the phase of the 90° mixing pulse by 180° [see (50)].

$$2I_{1x}I_{2z} \xrightarrow{90°_{\bar{y}}} -2I_{1z}I_{2x} \quad (50)$$

Common artifacts in almost all 2D NMR experiments are the so-called axial peaks, which arise from transfer of longitudinal magnetization by the mixing sequence into detectable transverse magnetization. This magnetization is not modulated during t_1, and hence resonates at $\omega_1 = 0$ (the term axial results from "on the $\omega_1 = 0$ axis"). Under $90°_y$ and $90°_{\pm y}$ pulses the axial signals transform according to (51) and (52). Thus, in contrast to the desired cross signals,

$$I_{1z} \xrightarrow{90°_y} I_{1x} \quad (51)$$

$$I_{1z} \xrightarrow{90°_{\bar{y}}} -I_{1x} \quad (52)$$

the axial signals are dependent on the phase of the second pulse in the COSY experiment.

Therefore, the axial signals can be suppressed and the desired signals preserved by adding up the two experiments: $90°_y$-t_1-$90°_y$-t_2 and $90°_y$-t_1-$90°_{\pm y}$-t_2. The axial signals are canceled, while the desired signals add up. We turn now to describe a systematic way which will lead to a recipe for the construction of phase cycles.

Coherence Order[29,30]

As we have seen, pulse phases are related to rotation about the z axis. Hence, let us consider now the behavior of the various operators under such rotation [Eq. (53)-(55), note the analogy with Eq. (8)-(10) with $\varphi = \Omega t$]. It is appar-

$$I_x \xrightarrow{\varphi_z} I_x \cos \varphi + I_y \sin \varphi \quad (53)$$

$$I_y \xrightarrow{\varphi_z} I_y \cos \varphi - I_x \sin \varphi \quad (54)$$

$$I_z \xrightarrow{\varphi_z} I_z \quad (55)$$

ent that the operators I_x and I_y do not transform independently under rotation about the z axis, but rather as a mixture; i.e., a pure I_x operator transforms into a mixture of I_x and I_y. The Cartesian basis is, for reasons beyond the scope of this article, rather unsuitable for describing phase cycles. However, there exists another basis in which operators do transform independently. It is the basis of the one-element operators[120-125] [Eq. (56) and (57)].

[*] Here and later in the text the index i (or j) in the product $\prod_i$ denotes the spins in the system which do not appear in the equation.

$$I^+ = I_x + iI_y \xrightarrow{\varphi_z} I^+ e^{+i\varphi} \quad (56)$$

$$I^- = I_x - iI_y \xrightarrow{\varphi_z} I^- e^{+i\varphi} \quad (57)$$

According to the rules for product operators (successive application of the transformations to each operator), we obtain, for instance, Equation (58) for $I_1^+ I_2^-$. Thus the operator remains invariant under rotation about the z axis. For $I_1^+ I_2^+$, on the other hand, we obtain Equation (59).

$$I_1^+ I_2^- \xrightarrow{\varphi_z} I_1^+ e^{-i\varphi} I_2^- e^{+i\varphi} = I_1^+ I_2^-, \quad (58)$$

$$I_1^+ I_2^+ \xrightarrow{\varphi_z} I_1^+ e^{-i\varphi} I_2^+ e^{-i\varphi} = I_1^+ I_2^+ e^{-2i\varphi} \quad (59)$$

We always find phase factors $e^{-ip\varphi}$ with the rotation about the z axis. p is the so-called *coherence order*. It is the number of I^+ operators minus the number of I^- operators in a product operator. Thus, for $I_1^+ I_2^-$, it follows that $p = 0$ and this coherence is called zero-quantum coherence, while $I_1^+ I_2^+$ is a double-quantum coherence ($p = +2$). $I_1^- I_2^-$ is likewise a double-quantum coherence ($p = -2$). Populations as well as operators that have only longitudinal operators behave like zero-quantum coherences. The significance of coherence order for the classification of coherences results from the fact that it is preserved during periods of free precession.

I^+ is the "raising" operator and I^- the "lowering" operator. "Raising" and "lowering" refer to changes in the quantum number m_z and not the energy. They describe processes in which a single quantum is either emitted ($\beta \rightarrow \alpha$ through I^+) or absorbed ($\alpha \rightarrow \beta$ through I^-), respectively. The number of absorbed quanta equals the number of I^- minus the number of I^+ in the product operator (Fig. 18).

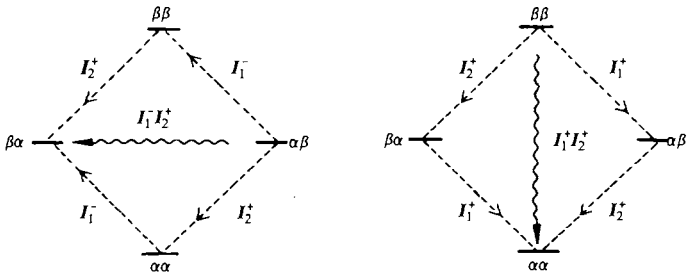


Fig. 18. A graphic representation of zero-quantum coherence (ZQC, left) and double-quantum coherence (DQC, right) in a two-spin energy level scheme. Only one of the two possible transitions is shown in each case, i.e., only absorption in the case of DQC. For further explanation see text.

The symmetry of the spin Hamiltonian for rotations about the z axis (axial symmetry), which is valid during free evolution, forms the basis for classification of coherences by coherence orders. A symmetry corresponds always to a conservation rule,[126] in this case the conservation of coherence order during pulse-free periods. The symmetry breaks down under the influence of pulses; i.e., pulses induce coherence order jumps.

The Cartesian product operators are always associated with a set of coherence orders. Thus I_{1x} and I_{1y} represent sums of positive and negative single-quantum coherences [Eq. (60) and (61), cf. the definitions for I^+ and I^- in Eq. (56) and (57)]. $2I_{1x}I_{2z}$ contains the same coherence orders [Eq. (62)].

$$I_{1x} = \tfrac{1}{2}(I_1^+ + I_1^-) \quad (60)$$

$$I_{1y} = -\tfrac{1}{2}i(I_1^+ - I_1^-) \quad (61)$$

$$2I_{1x}I_{2z} = (I_1^+ + I_1^-)I_{2z} \quad (62)$$

Finally we arrive at the following result: the number of transverse operators determines the highest ($p = +n$) and lowest ($p = -n$) coherence order present in a product operator. All the values from $p = -n$ to $p = +n$ in increments of 2 are valid coherence orders [see (63)–(65)].

$$2I_{1x}I_{2z} \quad : +1, -1 \quad (63)$$

$$4I_{1x}I_{2x}I_{3x} \quad : +3, +1, -1, -3 \quad (64)$$

$$4I_{1y}I_{2x}I_{3z} \quad : +2, 0, -2 \quad (65)$$

We can now see which coherence orders are present at any moment by following the product operators during a 2D NMR experiment. This is commonly represented in a pictorial form (Fig. 19), where lines are drawn (similar to those in musical notation) to indicate the coherence orders during given periods.[30] The straight horizontal lines represent the conservation of coherence orders during periods of free evolution. Figure 19 represents, for example, a positive single-quantum coherence during t_1 and a negative single-quantum coherence during t_2.

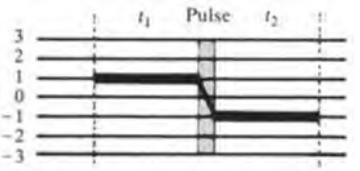

Fig. 19. Representation of various coherence orders in a "staff." In contrast to free evolution, pulses do not conserve the coherence order.

Selection of Coherence Order Jumps

Phase cycles select jumps in the coherence orders. These jumps are generated by pulses. A β_y pulse transforms, for instance, z magnetization into a mixture of x and z magnetizations (Fig. 20). The transfer amplitudes for the various coherence-order jumps are not represented in this diagram.

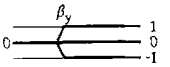

Fig. 20. Coherence orders resulting from longitudinal magnetization after a β pulse.

In general, pulses excite all the coherence orders between p = −n and p = +n, where n is the number of terms in the product operator [Eq. (66)]. This multitude of coher-

$$I_{1x}I_{2y}I_{3z} \xrightarrow{\beta_x} I_{1x}(I_{2y}\cos\beta + I_{2z}\sin\beta)(I_{3z}\cos\beta - I_{3y}\sin\beta) \quad (66)$$

ence-transfer processes (Fig. 21a) can be disentangled with phase cycling. Phase cycles act like masks, in that they only let certain coherence order jumps happen at a certain position. Such a mask may, for instance, act in the form shown schematically in Figure 21b. The form of the mask is determined by two parameters: the selectivity N of the phase cycle and the coherence order jump Δp. There is, however, not just one coherence order jump for a given phase cycle, but an infinite number incremented by N. The selectivity is the interval between successive "holes" in the mask (in the present example N = 3). A phase cycle allows all the coherence order jumps Δp ± k N (where k = 0, 1, 2, ...).

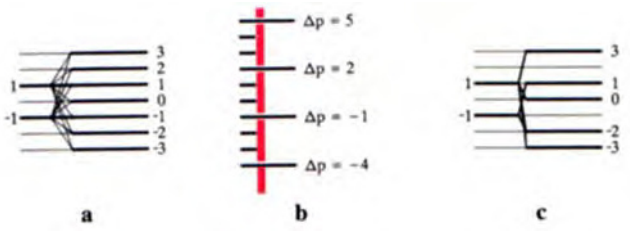

Fig. 21. a) Coherence orders of a three-spin system generated by a pulse from a single-quantum coherence (±SQC). Schematic representation of the phase cycle mask (b), by which certain coherence order jumps (c) can be selected. The mask selects all of the jumps of Δp ± k N (k = 0, 1, 2, ...), where the selectivity N in this example is 3 and Δp is −1. Thus, from ±SQC all of the generated coherence orders can pass the mask which correspond to a jump Δp of −4, −1, 2, or 5 (c).

If we now place this mask over the excitation scheme of Figure 21a, the number of possible coherence-transfer pathways is reduced dramatically (Fig. 21c). Only 5 of the 14 possible ways were selected.

Setting Up Phase Cycles

The selectivity N of a phase cycle for a pulse ($\phi^{(k)} = k\Delta\phi + \phi^{(0)}$ with k = 0, 1 ...) is related to the phase increment $\Delta\varphi$: $\Delta\varphi = 2\pi/N$. It follows that for the mask in Figure 21 with N = 3 the phase increment is $120° = 2\pi/3$. Δp determines the receiver phase φ_{det}: if the pulse phase is increased by $\Delta\varphi$, the receiver phase must also be increased by $-\Delta p \cdot \Delta\varphi$, hereby $-(-1)\cdot 120° = 120°$. It relates to the periodicity of the trigonometric functions that any selected Δp can be chosen. In this way the desired coherence pathway is followed exactly by the receiver. Other unwanted pathways are turned off. Finally, the general formula (67) is obtained for the calculation of phase cycles. Δp_i is the coherence-order jump which should be selected by the i-th pulse.

$$\varphi_{det} = -\sum_i \Delta p_i \cdot \Delta\varphi_i \quad (67)$$

Thus the mask shown in Figure 21 would be realized through the following phase cycle:

k	0	1	2		0	1	2
Pulse	0	120	240	or	3	123	243
Receiver	0	120	240		238	358	118

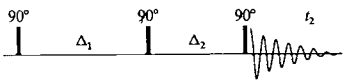
Only the phase *increments* are of importance. The reference phase $\phi^{(0)}$, to which the phase increments are added, is not determined. The reference phase does not play a role in the selection of coherence-transfer pathways; it is, nevertheless, often significant for the effectiveness by which the selected coherence transfers take place (e.g., even/odd selection of multiple-quantum coherence through 90°-τ-180°-τ-90°).

Before we go into the detailed arrangement of phase cycles, we wish to point out the following two essential facts:

(1) The detector conventionally selects negative single-quantum coherences [cf. the detection of I^-, Eq. (11)–(13)].

(2) The first pulse can only create a single-quantum coherence (positive and negative) from the thermal equilibrium state (p = 0).

Let us proceed one step further and consider now several three-pulse experiments (Table 1) with the pulse sequence (P3). We shall elaborate later on the individual



(P3)

Table 1. Various 2D NMR experiments with three 90° pulses [a].

Experiment	Δ_1	Δ_2	Comment	Section
COSY with MQF [b]	t_1	Δ	Δ is very small	3.1
Relayed COSY	t_1	Δ	Refocusing by a 180° pulse during the mixing time is advantageous	3.1.6
NOESY	t_1	τ	Transfer of dipolar coupling during τ	2.2.2
MQ spectroscopy	Δ	t_1	Refocusing in the middle of Δ by a 180° pulse is advantageous	3.1.8

[a] Because there is no generally accepted preference for the meaning of delays Δ and τ, we use in this article mainly Δ if the delay evolves coupling, and τ if other processes such as relaxation or exchange are of importance. [b] Multiple-quantum filter.

techniques. They differ essentially in the function of the second 90° pulse: In the Relayed COSY experiment it creates coherence transfer via single-quantum antiphase magnetization ($2I_{kx}I_{lz} \rightarrow 2I_{kz}I_{lx}$); in the NOESY experiment it generates longitudinal z magnetization ($I_x \rightarrow I_z$); while in DQF-COSY as well as in MQ experiments it produces multiple-quantum coherence ($2I_{kx}I_{lz} \rightarrow 2I_{kx}I_{ly}$). The desired effect is determined by the direction of the second 90° pulse relative to the first one in the selection of antiphase magnetization [see (68)].

$$2I_{kx}I_{ly} \xleftarrow{90°_x} 2I_{kx}I_{lz} \xrightarrow{90°_y} 2I_{kz}I_{lx} \quad (68)$$

The desired coherence order (in the example given above, zero-, single-, or multiple-quantum coherence), and hence the determination of the correct phases, can be achieved by considering the *coherence-transfer pathway*. The derivation of the phase cycle for an H,H-COSY experiment with double-quantum filtering (DQF-COSY) is shown below.

Double-quantum coherence should be selected by the second 90° pulse. The desired changes in coherence orders are presented in the coherence-transfer pathway in Figure 22, left.

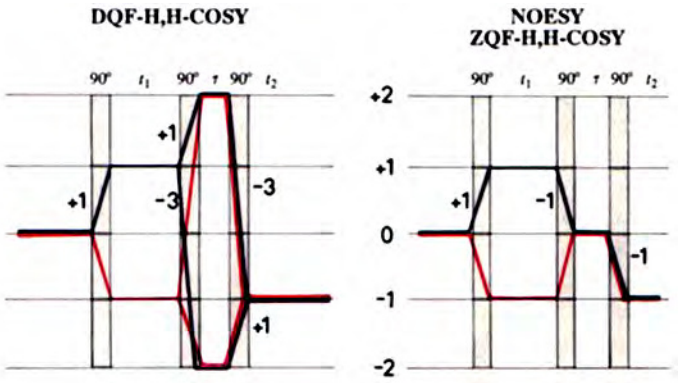


Fig. 22. Coherence-transfer pathways for a phase-sensitive DQF-COSY (left) and a NOESY experiment (right).

On the right-hand side of Figure 22 is shown, for comparison, the here unwanted pathway which would lead to a NOESY experiment (selection of longitudinal magnetization, which in the phase cycles behaves like a zero-quantum coherence). This pathway is successfully suppressed by phase cycling. Sequences with the same coherence-transfer pathway as in NOESY, but with mixing pulses smaller than 90°, are known as z-COSY (Section 3.1.4) and zz spectroscopy (Section 3.4.2).[127-130]

In the DQF-COSY example discussed above the Δp for the first pulse is $+1$ or -1, for the second pulse either $+1/-3$ or $+3/-1$, and in the third pulse $+1$ or -3. The complete phase cycle for an experiment with L pulses consists of $N_1 \times N_2 \times \cdots \times N_L$ variations, where each pulse i is varied independently of other pulses by $2\pi/N_i$ steps. We have seen that in addition to the desired pathways with Δp_i also pathways having $\Delta p_i + k N_i$ are selected. The greater N_i, the more selective is the phase cycle. However, with the increase of N_i also the number of necessary accumulations for each t_1 increment increases. Thus N_i is kept as small as possible; i.e., one must decide whether the undesired transfer pathways which pass the phase cycle really matter. Often this decision is made unnecessary by the availability of only a 90°-phase shifter; hence only $N_i = 2,4$ are available options. If we take $N_i = 4$ in our example, we obtain $4^3 = 64$ variations.

When phase-sensitive spectra are recorded (see Section 2.2.4) it must be noted that during t_1 both the positive and the negative coherence orders (in this case, $p = +1$ and $p = -1$) are necessary. Only in this way can a Fourier transformation over t_1 lead to signals of pure phase (i.e., either absorption or dispersion). It follows that the relative phase shifts of both pulses that limit the t_1 period (in this case, with phases φ_1 and φ_2) can only be 0 or π. Thus the number of variations in a phase-sensitive spectrum is reduced by one-half ($=32$ for our case).

At first the phase of the first pulse (φ_1) is shifted in steps of 90°. The phase variation (φ_2) of the second pulse follows from the rules for phase-sensitive detection. The phase φ_3 for the third pulse is kept constant at first. The receiver phase is calculated in accord with Equation (67). Thus the phases for the first four scans are obtained. The phase variation for the second pulse follows under consideration of the rule for phase-sensitive detection, so that all four directions are included. After these eight scans the phase of the third pulse can be varied. These variations are shown explicitly, whereby the shorthand notation is used ($0 = 0°$, $1 = 90°$, $2 = 180°$, and $3 = 270°$). The entire phase cycle for the above-mentioned spectrum is thus obtained as follows:

φ_1: 0 1 2 3 0 1 2 3 0 1 2 3 0 | 1 | 2 3 0 1 2 3 0 1 2 3 0 1 2 3 0 1 2 3
φ_2: 0 1 0 1 2 3 2 3 0 1 0 1 2 3 | 3 | 2 3 0 1 0 1 2 3 2 3 0 1 0 1 2 3 2 3
φ_3: 0 0 0 0 0 0 0 0 1 1 1 1 1 1 | 1 | 1 1 2 2 2 2 2 2 2 2 3 3 3 3 3 3 3 3
φ_{det}: 0 2 2 0 2 0 0 2 3 1 1 3 1 3 | 3 | 3 1 2 0 0 2 0 2 2 0 1 3 3 1 3 1 1 3

The determination of the receiver phase φ_{det} is demonstrated for the fourteenth scan, which is framed in the above scheme [Eq. (69)].

$$\varphi_{det} = -\{(+1)\cdot 1 + (+1)\cdot 3 + (-3)\cdot 1\} = -1 \qquad (69)$$

This result corresponds to a receiver phase shift of 3, due to the fourfold periodicity of phase shifting ($-1 \triangleq -90° = +270° \triangleq 3$). The alternative way through $p = -1$ during t_1 can similarly be formulated.

Thus a phase-sensitive DQF-COSY experiment requires a 32-scan phase cycle. This could lead to excessively long measuring times in cases where the desired resolution calls for many t_1 increments, or where sample concentrations are high enough to permit fewer scans. A reduction of the phase cycle can be obtained as follows:

(a) Out of the 32 phase constellations introduced above, 24 can be constructed from 8 basic phases, when at the same time all phases are rotated by 90°. This rotation of the phases by 90° serves to compensate for imperfect receiver phase shifts. The eight basic phases are obtained by leaving out the variation of the third pulse. This yields the first eight experiments shown in the scheme above.

(b) Additional reduction is obtained when one realizes that axial peaks, which are formed from z magnetization at the end of t_1, cannot be transformed by the second pulse into double quanta. The double-quantum filter thus suppresses also axial peaks. Therefore the explicit suppression of axial peaks with the second pulse may be left out. The remaining four phases are:

φ_1:	0	1	2	3
φ_2:	0	1	2	3
φ_3:	0	0	0	0
φ_{det}:	0	2	0	2

Experience shows, however, that pulse and phase imperfections are best averaged out when large phase cycles are used. In order to cancel out differences in receiver channels it is useful to apply the CYCLOPS sequence[131] in both 1D and 2D NMR spectroscopy; i.e. all the phases are shifted by 90° increments.

2.2.4. *Phase-Sensitive 2D NMR Spectra*

The expression "phase-sensitive" reception of 2D NMR spectra is somewhat unfortunate, since, in fact, every ac-

quisition is phase sensitive. It is the different method of processing of the data which leads to either phase-sensitive spectra or spectra which are displayed in absolute value mode. Phase-sensitive processing is done in those cases where some or all of the signals in a 2D NMR spectrum can be corrected to pure phases. The sign information thus obtained and the smaller line width relative to the absolute value mode are the main reasons for doing so.

We do not wish to elaborate extensively on the background for phase-sensitive 2D NMR spectroscopy. For a detailed discussion we recommend the article by *J. Keeler* and *D. Neuhaus*.[132] Suffice it to say that phase-sensitive spectra require an amplitude modulation of the signal in t_1. Practically all of the most often used experiments, like COSY, NOESY, Relayed, TOCSY, ROESY, and heteronuclear shift correlation, generate amplitude-modulated signals.

There are two methods for obtaining phase-sensitive spectra. The method of *States, Haberkorn,* and *Ruben*[133, 134] generates two data sets for each t_1 value. In one set the signal in t_1 is cosine-modulated, in the other sine-modulated (in analogy with the synchronous two-channel detection in t_2). If each data set is subjected separately to a complex Fourier transformation, the two spectra shown schematically on the left-hand side of Figure 23 are obtained. The addition of the two spectra results in the desired spectrum (Fig. 23, right).

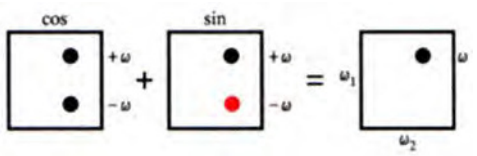

Fig. 23. The result of quadrature detection in t_1 according to *States, Haberkorn,* and *Ruben*. Signals modulated by $\cos\Omega t_1$ are accumulated separately from those modulated by $\sin\Omega t_1$ for each t_1 value, and then, again separately, complex Fourier transformed and added up.

The other method uses a real Fourier transformation and applies in t_1 the same Redfield method already described for quadrature detection in t_2. Detection is done at twice the rate (the t_1 increment is divided by two) and with a 90° phase shift after each t_1 increment. This phase shift in t_1 is a pulse phase, which leads to the name of the method: *T*ime *P*roportional *P*hase *I*ncrementation (TPPI).[135, 136]

The two methods are equivalent. They both require twice as many data points as needed for a non-phase-sensitive spectrum of the same resolution (and equal measuring time).

3. Survey of 2D NMR Techniques

The most important 2D NMR techniques in current use are listed in Tables 2–5. Groups are arranged according to the type of correlated nuclei (homo- or heteronuclear) and according to the type of correlation.[*]

In previous chapters we have explained the underlying principles required in order to understand the currently used techniques. In the following discussion of pulse sequences we shall encounter further methods which, like phase cycles, are designed to discriminate between coherences on the basis of their different properties, in order to either select or suppress them: multiple-quantum filter, z-filter, editing techniques, low-pass *J*-filter, X-filter, and BIRD pulses.

The time t_1, which in contrast to t_2 is not a "real" time, can also be manipulated. Thus particular interactions can be influenced or scaled during t_1. These include, among others, ω_1 decoupling, BIRD pulses during t_1, and selective decoupling.

Manipulation of the t_2 time is relatively difficult. The most common one is heteronuclear decoupling, which is applied in practically all heteronuclear experiments. The associated pulse sequences (see Section 3.2.10) are highly developed and have reached astounding efficiency.

We shall explain these methods in the discussion of pulse sequences and try to show their common features. First we shall describe the most important experiments associated with homonuclear coherence transfer.

3.1. Homonuclear Experiments

3.1.1. H,H-COSY and Variants

The cross signals in a COSY experiment are caused, as we have seen in Section 2.2.1, by two-operator terms like $2I_{1x}I_{2z}$ (with a y-mixing pulse). The cross signals are antiphase with respect to the active J_{12} coupling and in-phase with respect to all other couplings. The diagonal signals are formed from a transfer of the type $I_{1y} \rightarrow I_{1y}$. They are in-phase dispersion signals in both dimensions. Cross signals near the diagonal are often severely distorted and difficult to observe due to the dispersive extensions from the diagonal signals.

This problem can be solved with the application of multiple-quantum filters (pulse sequence (P3), delays as shown in Table 1, coherence-transfer pathways in Fig. 22):[138–141] the product operator responsible for the diagonal signals before the mixing pulse contains a single operator (I_y). In contrast, the one responsible for the cross signals contains two operators ($2I_{1x}I_{2z}$). Double-quantum coherence cannot be generated from a single operator by the mixing pulse; it can, however, be generated from a two-operator term. Thus a $90_x°$ pulse is applied to cause a double-quantum excitation of the two-spin operator term mentioned above, according to Equation (70) [cf. Eq. (60) and (61)].

$$2I_{1x}I_{2z} \xrightarrow{90°_x} -2I_{1x}I_{2y} = -\tfrac{1}{2}\,i(I_1^+I_2^+ - I_1^-I_2^-) - \tfrac{1}{2}\,i(I_1^-I_2^+ - I_1^+I_2^-) \qquad (70)$$

The first term on the right-hand side represents positive and negative double-quantum coherence and the second term zero-quantum coherence. The double-quantum coherence is selected by phase cycling as described in Section 2.3.3 and finally converted back, by a $90_y°$ pulse, into single-quantum magnetization. This leads to filtration of

[*] The explanations of the acronyms used in the text for pulse sequences are given in the Appendix.

Table 2. Homonuclear 2D NMR techniques through mixing by means of coherence transfers.

Symbol	Name	Application	Comment (A: advantage; D: disadvantage)	Reference	Pulse sequence
H–(–)$_n$H	H,H-COSY	Homonuclear shift correlation	Most important technique	[2, 137]	(P1)
	a) normal	Identification of spin systems, signal assignment	Fast routine technique		
	b) with delay	Detection of small couplings	D: No pure phases	[137]	
	c) DQF-COSY	Identification of spin systems, determination of J values	Best standard technique A: Low-intensity diagonal signals	[138–141]	
	d) "Constant time" COSY	Decoupling in t_1	D: Artifacts in case of strong coupling, no pure phases, strong dispersive contributions on the diagonal	[137, 142]	(P7)
	e) β-COSY	Relative sign of J	Alternatives: f, g, h	[2, 137, 143]	
	f) E.COSY	Accurate measurement of J	A: High resolution, good suppression of dispersion signals on the diagonal	[144–146]	
	g) P.E.COSY	Accurate measurement of J	A: Simpler method than E.COSY D: Not as accurate as E.COSY	[147]	
	h) z-COSY	E.COSY-like spectra	A: Absorptive diagonal D: Simultaneous formation of NOE cross signals especially for macromolecules	[130, 148, 149]	(P38)
	i) zz-COSY	Solvent-signal suppression, Determination of J	A: Absorptive diagonal	[127–129]	(P37)
	j) JR-COSY	Solvent-signal suppression	D: No quadrature detection in ω_1	[150]	
	k) X-Filter COSY	Simplification of proton spectra, spectroscopy of very large molecules	Only protons bound to a heteroatom give rise to cross signals	[151, 152]	(P32), (P33)
	l) X-Half-filter COSY	Same applications as k)	A: More flexible than k) since the filter operates only in one frequency domain	[153]	(P34), (P35)
	MQ spectroscopy	a) With emphasis on direct coupling - different representation (in case of overlapping signals in the COSY spectrum)	D: J dependence of excitation efficiency, no pure phases	[154–158]	
		- For measurements in water	A: Cross peaks to resonances under the water signal	[374]	
		b) With emphasis on remote coupling	Information similar to relayed spectrum	[159]	
	TOCSY (HOHAHA)	For macromolecules since cross peaks appear also in case of broad lines (in-phase multiplets)	Transfer across the total spin system possible. This may cause assignment problems	[160–163]	
X–X	INADEQUATE	C connectivity	D: Very insensitive, requires ^{13}C–^{13}C pairs	[50, 164–167]	(P11)
	INEPT-INADEQUATE	C connectivity	Slightly better sensitivity, alternative in some cases: C-relayed H,C-COSY (see Table 5)	[168]	
	Inverse variants			[169]	

the single-spin operator terms (dispersive diagonal signals) introduced above [Eq. (71)].

$$-\tfrac{1}{2}(I_1^+I_2^+ - I_1^-I_2^-) = \tfrac{1}{2}(2I_{1x}I_{2y} + 2I_{1y}I_{2x}) \xrightarrow{90°_y} -\tfrac{1}{2}(2I_{1z}I_{2y} + 2I_{1y}I_{2z}) \quad (71)$$

We thus obtain, through double-quantum coherences, among others the desired transfer from spin 1 to spin 2 [Eq. (72)].

$$2I_{1x}I_{2z} \longrightarrow \tfrac{1}{2}(2I_{1x}I_{2y}) \quad (72)$$

The transfer $2I_{1x}I_{2z} \rightarrow \tfrac{1}{2}(2I_{1y}I_{2z})$, which is effected at the same time, leads to the diagonal peaks in the DQF-COSY experiment. They are now antiphase and absorptive as desired (like the cross peaks). We realize also that, through the factor 0.5, the transfer is now only half as efficient as in a conventional COSY.

The concept of multiple-quantum filtration can also be formulated in a general form: a coherence of the type $I_{1y}I_{2z}\cdots I_{nz}$ can give rise maximally to an n-quantum coherence. An m-quantum filter with $m>n$ would hence suppress such a product operator. Certain spin topologies may then be selected: A spin I^1, which is coupled to $n-1$ other nuclei ($J_{1i}\neq 0$ for $i=2, 3, \ldots, n$), evolves, e.g., after $90°_x$-t_1, product operators with a maximum of n operators. This means that all the peaks that originate from I^1 are suppressed in a spectrum with an m-quantum filter ($m>n$).[138]

The cross signals in an n-quantum-filtered (nQF)-COSY are obtained through the transfer (73). For the generation of the relevant coherence before mixing, I^1 must be coupled to $n-1$ spins; for the

Table 3. Heteronuclear 2D NMR techniques through mixing by means of coherence transfers.

Symbol	Name	Application	Comment (A: advantage; D: disadvantage)	Reference	Pulse sequence
H–X	H,X-COSY (HETCOR)	Heteronuclear shift correlation		[170, 171]	(P14)
	a) normal	Routine method at present		[170–173]	
	b) DEPT-COSY	Permits editing	A: Phase-sensitive representation	[174–177]	(P15), (P16)
	c) H,X-COSY with ω_1 decoupling			[178–180]	(P25)
	d) Modified DEPT-COSY		No advantage over b)	[181]	
	e) COLOC for $^1J_{CH}$	Short measuring time		[182]	
	f) Modified COLOC for $^1J_{CH}$	Short measuring time	A: Not as strongly J dependent as e)	[181]	
	X,H-COSY (inverse heteronuclear correlation)	For small substance quantities, most sensitive method	D: Requires special spectrometer hardware	[39–54, 183, 184]	(P27)
H–$(H)_n$–X	Hetero-TOCSY	Transfer from proton magnetization via TOCSY followed by INEPT transfer	D: Intensity loss through distribution of polarization over many protons	[185, 186]	
H–$(-)_n$X	H,X-COSY for long-range coupling		COLOC should be preferred	[187, 188]	
	COLOC	Assignment of quaternary C, indirect detection of C connectivity, recognition of proton spin systems, qualitative evaluation of $^nJ_{CH}$		[189–193]	(P12)
	modified COLOC (XCORFE)	For discrimination of $^2J_{CH}$ and $^3J_{CH}$ couplings to proton-bearing carbons		[194]	
	"*Freeman* experiment"	Determination of $^nJ_{CH}$	D: Lack of resolution and intensity	[195]	
	X,H correlation through long-range coupling		A: Very sensitive	[50, 54, 196]	
	Hetero E.COSY, β-COSY	Exact determination of $^nJ_{CH}$	D: Relatively insensitive	[143, 197]	

Table 4. 2D NMR techniques with mixing through NOE and/or exchange.

Symbol	Name	Application	Comment (A: advantage; D: disadvantage)	Reference	Pulse sequence
H···H	Homonuclear nuclear Overhauser and exchange spectroscopy				
	NOESY	Distance information, three-dimensional structure of molecules, exchange spectroscopy	Besides COSY most important technique	[17, 89]	(P2)
	zz-NOESY	Solvent-peak suppression, separation of chemical exchange and NOE.		[127, 128]	(P36)
	ROESY (CAMELSPIN)	Separation of chemical exchange and NOE in medium-sized molecules without NOE effects	Suppression of J cross peaks necessary	[198–202]	(P39)
H···X	Heteronuclear nuclear Overhauser and exchange spectroscopy				
	H,X-NOESY, HOESY		D: Low sensitivity	[203–207, 368]	(P20)

$$I_{1x} \longrightarrow 2^{n-1}I_{1x}I_{2z}I_{3z}\ldots I_{nz} \xrightarrow{90^\circ_x} 2^{n-1}I_{1x}I_{2y}I_{3y}\ldots I_{ny} \xrightarrow{nQF} I_{1y}I_{2z}I_{3y}\ldots I_{ny}$$
$$\xrightarrow{90^\circ_x} I_{1x}I_{2x}I_{3z}\ldots I_{nz} \longrightarrow 2^{1-n}I_{2x} \qquad (73)$$

conversion of the resulting coherence into observable magnetization, I^2 must be coupled to the same spins ($J_{i2} \neq 0$ for $i = 1, 3, 4, \ldots, n$).[138]

Cross signals are generated between two coupled spins in an n-quantum-filtered COSY spectrum when they have in common additional $n-2$ coupled nuclei. The multiplet structure of this cross signal shows in both dimensions $n-1$ couplings in antiphase. Multiple-quantum filters with $n > 2$ are not very common. This is due to the reduction of intensity by the factor 2^{n-1}. Another reason is the fact that the higher the order of the multiple-quantum filter the fewer moieties in a molecule "pass it," so that one gets information only on some parts of the structure. Triple-quantum-filtered COSY spectra are used in the analysis of proteins when, for instance, the identification of glycine units is sought; these units are the only amino acids which give rise to cross signals in the TQF-COSY spectrum between the NH protons and both of the α protons.[259]

The net intensity obtained upon integration of the diagonal peak in a multiple-quantum-filtered COSY spectrum ($I_{1x} \rightarrow I_{1x}$, $I_{1y} \rightarrow I_{1y}$) is zero. Thus the problem of the intense diagonal peaks is solved through double-quantum filtration; no dispersion signals are obtained. This is, however, achieved at the cost of a cross-peak intensity reduced by a factor of one-half. The advantage of the strongly reduced diagonal peaks has nevertheless made the DQF-COSY experiment the most widely used technique. An example is shown in Figure 24.[260]

Table 5. Additional 2D NMR methods.

Symbol	Name	Application	Comment (A: advantage; D: disadvantage)	Reference	Pulse sequence
Methods with more than one mixing step					
a) Two consecutive *J* mixings					
H–H–H	H-Relayed H,H-COSY (RCT spectroscopy) or H-Relayed H,H-DQF-COSY	Assignment in crowded spectral regions	A: Stepwise elucidation of connectivities D: Less sensitive than TOCSY For special problems 1D variants [210] are applicable	[208, 209] [211, 212]	(P8)
H–H–X	H-Relayed H,X-COSY	In overcrowded ^{1}H-NMR signals	Mostly well replaceable by COLOC	[213–218]	(P17), (P18)
	Inverse variants			[53, 219]	(P28)
H–X–H	X-Relayed H,H-COSY			[220, 221]	(P29)
H–X–X	X-Relayed H,X-COSY	C connectivity in H-C-C fragments	Also used in a 1D variant A: Relatively insensitive, but more sensitive than INADEQUATE	[222–225]	(P19)
X–H–H	H-Relayed X,H-COSY		D: Useful only for heteronuclei with large γ (e.g. ^{31}P, ^{19}F)	[226, 227]	
b) Mixing through scalar and dipolar coupling					
H–H···H H···H–H	Relayed NOESY	In crowded regions, peptide sequential assignment	D: Useful only when large NOE effects are observed		
	a) normal			[228]	
	b) with DQF	For spectral assignment near the diagonal		[229]	(P40)
	c) with antisymmetrization			[230, 231]	
H–(H)$_n$···H	TORO TOCSY-NOESY	Peptide sequencing	A: No need for α-proton resolution	[232] [233]	(P41)
H···H–(H)$_n$	ROTO			[232]	
H···H–X	Hetero-relayed NOESY		D: Low sensitivity	[234, 368]	
Separation of chemical shift and coupling					
J_H,δ_H	Homonuclear 2D *J* spectroscopy	Determination of *J* and δ	Replaced by DISCO and E.COSY	[5, 235–240]	(P4)
J_{HC},δ_C	Heteronuclear 2D *J* spectroscopy	Determination of multiplicity, determination of *J* Determination of $^nJ_{CH}$	Generally replaceable by DEPT	[241–246] [247, 248]	
	Heteronuclear 2D *J* spectroscopy with selective H pulse	Determination of $^nJ_{CH}$	D: separated H signal required, for coupling to each H one 2D NMR experiment necessary	[249]	
One-dimensional equivalents of 2D NMR experiments					
		Excitation with Gaussian pulses	Traces from 2D NMR spectra obtained A: Time and disc-space saving in case of few well-aimed questions	[210, 250]	
2D NMR spectroscopy with selective excitation					
			Possible with all pulse sequences A: Sometimes sensitivity gained vs. 2D NMR methods with nonselective pulses	[251, 373]	
3D NMR experiments					
	3D J,δ			[252]	
	COSY-COSY			[253–255]	
	NOESY-COSY, and other combinations				
Various					
	CIDNP-COSY	Connection of photochemical excitation with 2D NMR spectroscopy	Part of the molecule must be photochemically active (e.g. arenes)	[256]	
	CIDNP-NOESY			[257]	
	COCONOSY	Simultaneous COSY and NOESY experiment	D: Low resolution in the COSY spectrum	[258]	

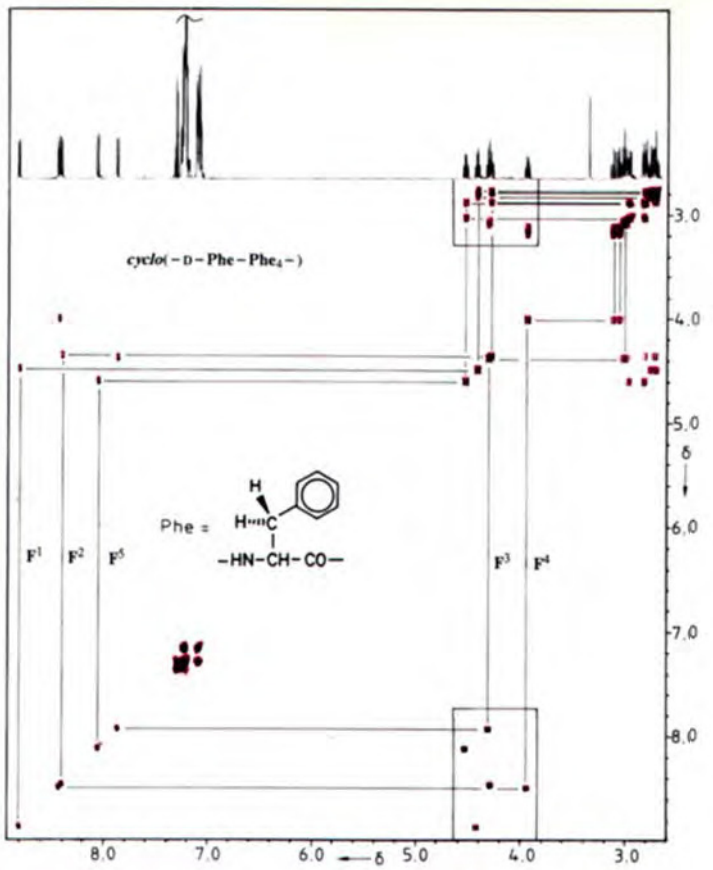

Fig. 24. DQF-H,H-COSY NMR spectrum of *cyclo*(-D-Phe-Phe$_4$-) in [D$_6$]DMSO, 500 MHz. The connectivities within the phenylalanines (F^1 to F^5) are indicated with lines. The signals in the boxes are expanded in Figure 25. The assignment of the amino acids to the peptide sequence does not follow from such a spectrum.

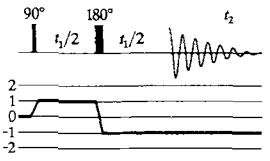
The multiplet structure in COSY spectra contains valuable information about coupling constants. The fine structure of the cross signals in Figure 24 is readily apparent from the enlarged section of the spectrum shown in Figure 25.

The coupling constants over three bonds depend on dihedral angles according to the Karplus relationship.[74,75] The magnitude of the coupling constants is thus related to the spatial structure of the corresponding molecule.

In 1D NMR spectra of complex systems the coupling constants can no longer be read out directly. Therefore 2D NMR methods suitable for the analysis of not-too-strongly coupled systems (see Section 3.1.2) were developed.

3.1.2. 2D *J* Spectroscopy

The first 2D NMR experiment suggested for the analysis of spin systems was the 2D *J*-resolved spectrum.[5] The pulse sequence (P4) for this experiment is the only one, in addition to that in the COSY experiment, with only two pulses and is hence likewise easy to analyze.



(P4)

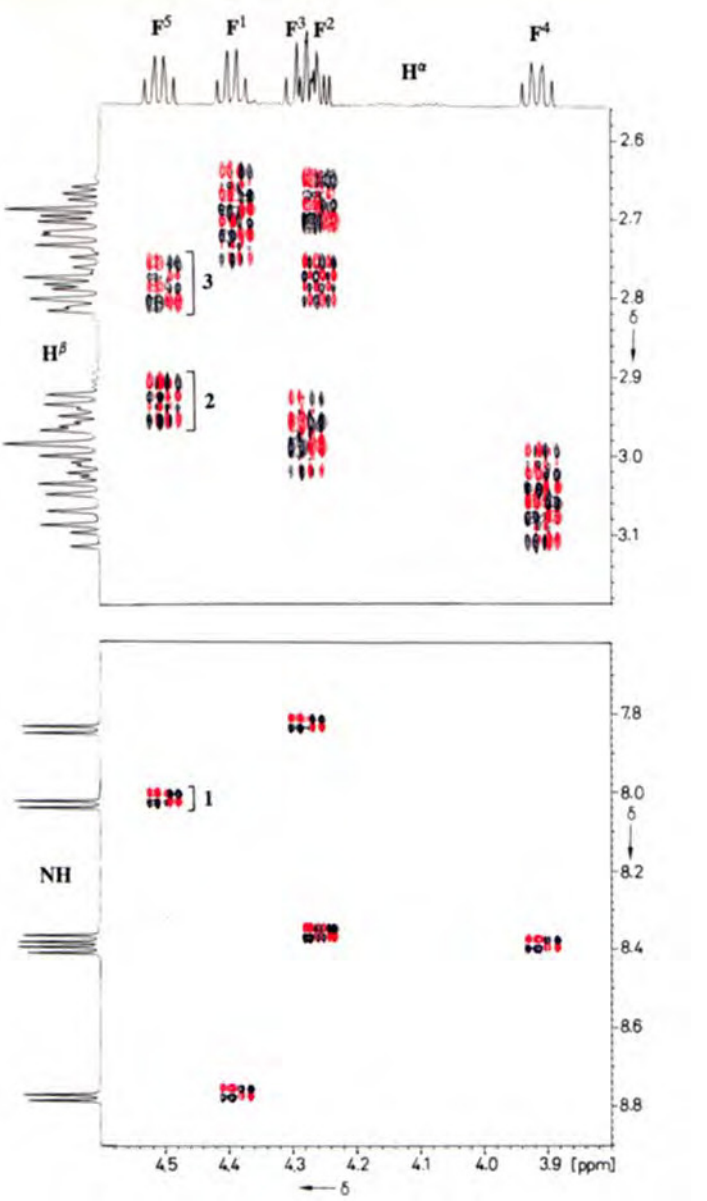


Fig. 25. Expansions from the spectrum in Figure 24: the NH-H$_\alpha$ region (bottom) and H$_\alpha$-H$_\beta$ region (top). The signals labeled 1, 2, and 3 were used for the DISCO procedure (see Fig. 28).

The Effect of 180° Pulses

180° pulses are often used to improve pulse sequences. They have different effects on chemical shift and coupling, and can therefore be utilized to manipulate interactions. We show now that the evolution of coupling is not affected by a 180° pulse [Eq. (74) and (75)]. The *relative* signs of the

$$I_{1x}\cos\pi Jt + 2I_{1y}I_{2z}\sin\pi Jt \xrightarrow{180°_{x,y}} \pm(I_{1x}\cos\pi Jt + 2I_{1y}I_{2z}\sin\pi Jt) \quad (74)$$

$$I_{1y}\cos\pi Jt - 2I_{1x}I_{2z}\sin\pi Jt \xrightarrow{180°_{x,y}} \mp(I_{1y}\cos\pi Jt - 2I_{1x}I_{2z}\sin\pi Jt) \quad (75)$$

two operators remain unchanged; i.e., the evolution of coupling, apart from a possible overall exchange of sign, remains unaffected by the 180° pulse. The chemical shift,

in contrast, reacts differently [Eq. (76)]. The right-hand term in Equation (76) is identical with (77). After the 180° pulse the system is, with respect to chemical shift, in a state

$$I_x \cos \Omega t + I_y \sin \Omega t \xrightarrow{180°_{x,y}} \pm (I_x \cos \Omega t - I_y \sin \Omega t) \quad (76)$$

$$\pm (I_x \cos \Omega(-t) + I_y \sin \Omega(-t)) \quad (77)$$

as if it had evolved in the first period t backward (t has to be replaced by $-t$, time reversal). In other words, further evolution after the 180° pulse will lead after a second period t to the starting situation, i.e., to refocusing of the chemical shift [Eq. (78)].

$$I_x \xrightarrow{t} I_x \cos \Omega t + I_y \sin \Omega t \xrightarrow{180°_x} I_x \cos \Omega t - I_y \sin \Omega t \xrightarrow{t} I_x \quad (78)$$

Thus chemical shift evolves in the 2D J sequence only during t_2, while coupling evolves during both t_1 and t_2. The resulting signal amplitude for spin 1 is given by (79), where

$$\prod_i \cos \pi J_{1i}(t_1 + t_2) \cos \Omega_1 t_2 = \prod_i \cos (\pi J_{1i} t_1 + \pi J_{1i} t_2) \cos \Omega_1 t_2 \quad (79)$$

$\prod_i \cos \pi J_{1i}$ is the product over all couplings of spin 1. Complex Fourier transformation of this expression and absolute value representation yield the multiplets shown schematically in Figure 26a. Projection of such 2D multiplets on the ω_1 or ω_2 axis affords directly the coupling constants. After tilting according to $\omega_1' = \omega_1$, $\omega_2' = \omega_2 - \omega_1$,[34] the spectrum shown in Figure 26b is obtained, in which now ω_2 represents only chemical shifts, and ω_1 only coupling constants. 2D J-resolved NMR spectra are phase-modulated in t_1 ($\pi J_{11} t_1$ is a phase) and hence cannot be corrected to pure phase. The mixed phases lead to false line positions and make the determination of coupling constants unreliable. Furthermore, the resolution achieved through the reduction of multiplets to singlets along ω_2 in tilted 2D J NMR spectra is often insufficient in complex spin systems,[261,262] and artifacts may appear in the presence of strong coupling.

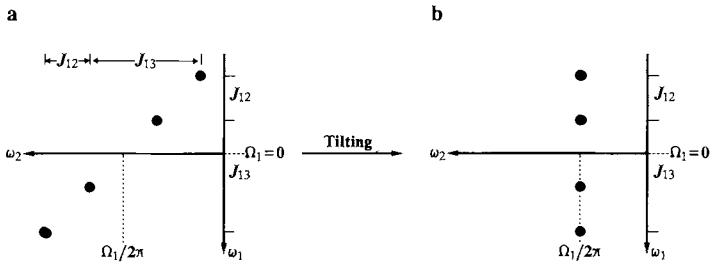

Fig. 26. a) Schematic peak in a homonuclear 2D J-resolved NMR spectrum of a three-spin system; b) separation of chemical shifts (projection on the ω_2 axis) and coupling constants (projection on the ω_1 axis) after tilting.

3.1.3. *Determination of Coupling Constants from COSY Spectra*

Direct Extraction of Coupling Constants from COSY

For very simple multiplets, coupling constants can be measured directly from 2D NMR spectra.[136] However, this is not possible for complex spin systems.

DISCO[263–265]

The disadvantages of 2D J-resolved spectroscopy mentioned in Section 3.1.2 (impure phases, insufficient resolution) are not found in DQF-COSY. The cross signals in DQF-COSY show a rather well resolved multiplet structure, with the active couplings antiphase and all the others in-phase. Consider a three-spin system, in which $J_{13} = 0$. We focus on the two cross signals, the 1,2 and the 2,3 signals. The multiplet structure for the 1,2 cross signal in ω_2 is described by (80) and for the 2,3 cross signal by (81). Summation of the two signals yields a signal in the time domain described by (82); i.e., the active coupling in this "hybrid trace" is $J_{12} + J_{23}$. The number of lines in this signal has been reduced by one-half. Through the reduction in the number of lines, multiplet structures become easier to analyze. The active coupling appears in DISCO spectra as the sum of two couplings and is hence effectively increased, so that cancellation of lines from antiphase signals is less likely (Fig. 27).

$$\sin \pi J_{12} t_2 \cos \pi J_{23} t_2 \prod_i \cos \pi J_{2i} t_2 \quad (80)$$

$$\sin \pi J_{23} t_2 \cos \pi J_{12} t_2 \prod_i \cos \pi J_{2i} t_2 \quad (81)$$

$$\sin \pi (J_{12} + J_{23}) t_2 \prod_i \cos \pi J_{2i} t_2 \quad (82)$$

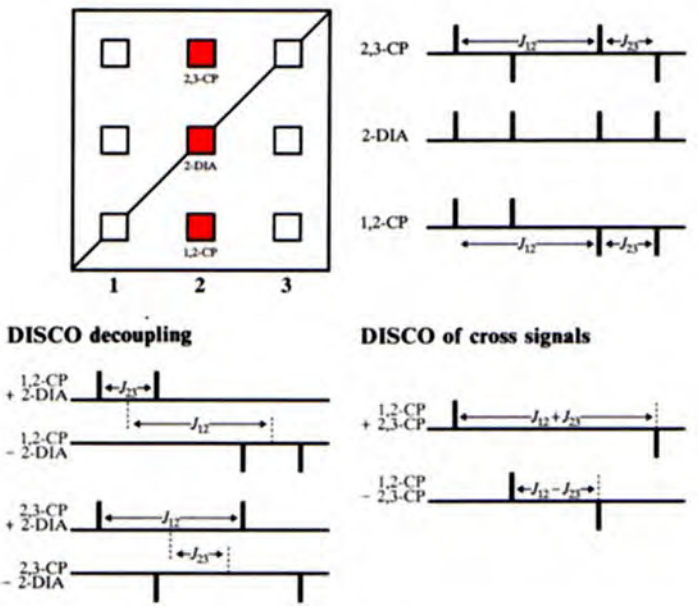

Fig. 27. DISCO with the cross signals of spin 2 of a three-spin system. Note that the diagonal signal is 90° phase-shifted (dispersive). In order to use this signal (2-DIA) for "DISCO-decoupling," the COSY spectrum for the diagonal signals must be calculated with an additional 90° phase correction in both dimensions. Upper left: schematic COSY spectrum. Upper right: cross-sections of 1,2 and 2,3 cross signals (1,2-CP, 2,3-CP) and the diagonal signal (2-DIA) for spin 2 in ω_2. Lower left: DISCO decoupling through addition and subtraction of cross signal and diagonal signal. Lower right: DISCO through addition and subtraction of the cross signals.

If the diagonal signals in a COSY spectrum are free, the DISCO procedure can be applied to these diagonal signals in combination with the corresponding cross signals with equal chemical shifts in ω_2. Since the cross signals are in-phase, Equation (83) is obtained, i.e., a multiplet without

$$\cos \pi J_{12}t_2 \cos \pi J_{23}t_2 \prod_i \cos \pi J_{2i}t_2 \pm i \sin \pi J_{12}t_2 \cos \pi J_{23}t_2 \prod_i \cos \pi J_{2i}t_2$$
$$= e^{\pm i\pi J_{12}t_2} \cos \pi J_{23}t_2 \prod_i \cos \pi J_{2i}t_2 \quad (83)$$

the active coupling (decoupled multiplet), in a position shifted by either $+\pi J_{12}$ or $-\pi J_{12}$. Comparison of the two spectra obtained by addition or subtraction yields the active coupling constant.

A practical example is shown in Figure 28, with a DISCO evaluation of the cross signals due to the α protons of the amino acid Phe[5] in the spectrum of the cyclic pentapeptide from Figure 25.

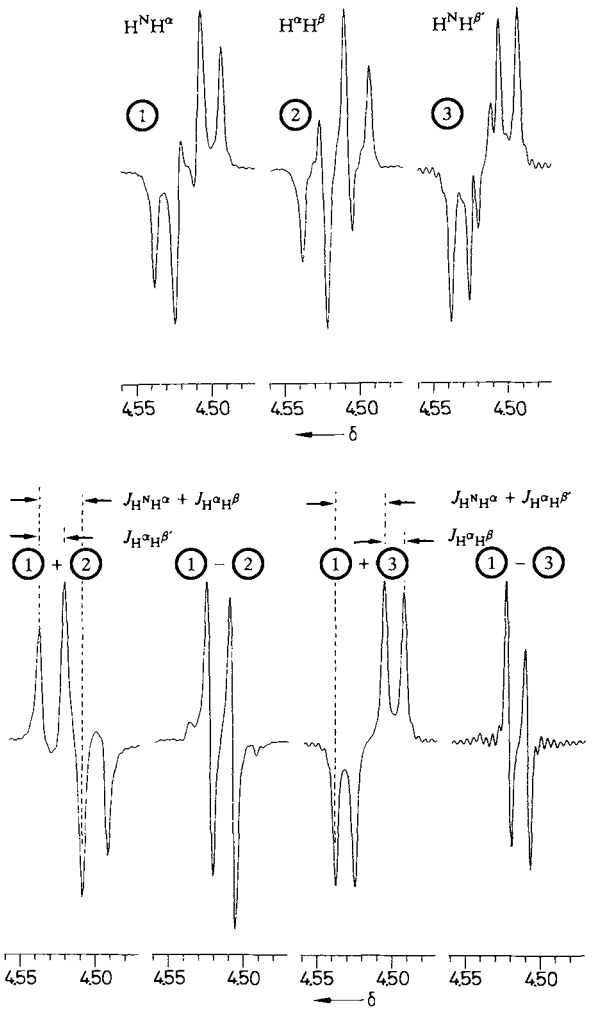

Fig. 28. DISCO spectra from the spectrum of Figure 25. The signals labeled there with 1, 2, and 3 were used. Pseudo 1D spectra (top), obtained by coaddition of the traces, were added up or subtracted (bottom). The simplification of multiplets is clearly evident, particularly after addition, in that the signals are well resolved.

To improve the signal-to-noise ratio, coaddition[*] is performed over the entire cross signal, and the resulting pseudo 1D NMR spectra are summed together.[265] The digital resolution can be improved by a reverse Fourier transformation, zero filling (to 64 K, for example) followed by retransformation. The true scaling factor for the combination of two spectra is unknown and poses some difficulty in the DISCO evaluation. It must be determined from the result of the combination. This makes the application of DISCO in complex or strongly coupled spin systems difficult.

3.1.4. E. COSY

A second procedure (E. COSY[144-146]) simplifies the cross-signal pattern, as shown schematically in Figure 29.

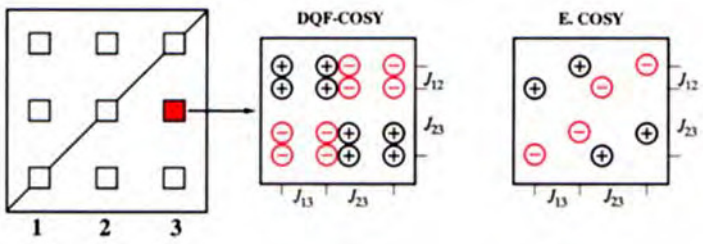

Fig. 29. Multiplet fine structure of a cross signal in a DQF-COSY spectrum (center) and in an E. COSY spectrum (right).

In order to understand this technique we turn back to the multiple-quantum-filtered COSY spectra. We saw that in the DQF-COSY spectrum only two-operator terms contributed. This determines the multiplet structure in COSY and DQF-COSY spectra. Higher-quantum filters (e.g., a triple-quantum filter, TQF) can be used instead of the double-quantum filter. The pulse sequence remains the same (P3, COSY with MQF); only the phase cycle changes. In the TQF-COSY experiment the phases ϕ_1 and ϕ_2 go through the values 0°, 60°, 120°, 180°, 240°, 300°, and during t_2 alternating signals are added and subtracted. The multiplet structure is shown schematically in Figure 30. The cross signals are generated only by the transfer $I_{1x}I_{2z}I_{3z} \rightarrow I_{1z}I_{2x}I_{3z}$. A factor 4 in intensity is lost in such a spectrum, relative to the unfiltered COSY spectrum (a factor 2 in the DQF-COSY spectrum). The multiplet structure is antiphase in both dimensions: with respect to J_{12} and J_{13} in ω_1 and with respect to J_{12} and J_{23} in ω_2.

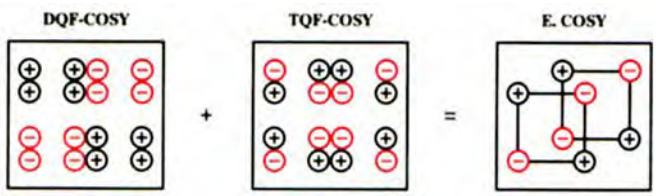

Fig. 30. Fine structure of an E. COSY cross signal from a DQF-COSY and a TQF-COSY spectrum. The E. COSY spectrum is obtained, theoretically, from weighted addition of these two spectra. When additional passive couplings render the spectrum more complex, correspondingly more multiple-quantum spectra must be added.

[*] Coaddition is a special way of addition where each trace is multiplied with the sign of a reference point in that trace in order to avoid cancellation when summing up over antiphase multiplets.

Examination of the multiplet structure in DQF- and TQF-COSY spectra reveals that summation of the two (see Fig. 30) greatly simplifies the multiplet pattern.

A general treatment for more than three spins can be found in the original literature.[144-146] An example of the extraction of coupling constants from an E. COSY spectrum is shown in Figure 31.

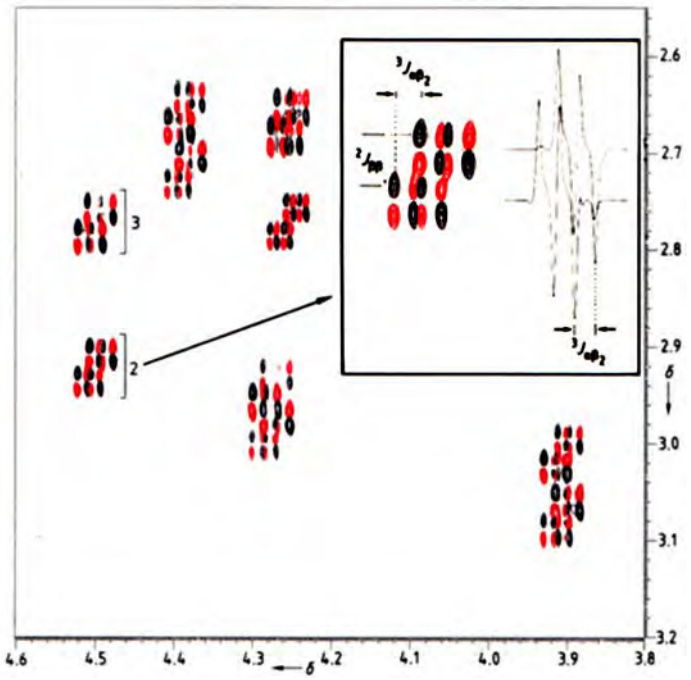

Fig. 31. E. COSY spectrum of *cyclo*(-D-Phe-Phe$_4$-) in [D$_6$]DMSO, the same region as in Figure 25. The expansion of signal 2 is shown in the upper right along with the associated co-added traces. The passive coupling constant $^3J_{\alpha\beta_2}$ can be measured very accurately from the distance between two peaks.

The appearance of a cross signal in an E. COSY spectrum resembles that in a COSY spectrum, in which a mixing pulse with a small flip angle is used (β-COSY).[137] However, there are large dispersive parts in the diagonal peaks, which make the interpretation of cross signals near the diagonal very difficult. This disadvantage is overcome by a technique introduced in Ref. [45] and called later P. E. COSY.[141, 144, 145, 147] Another possibility is the introduction of a z-filter[266] ("z-COSY").[148] However, both methods fail to quantitatively suppress nonconnected transfers. For the last method cross relaxation during the z-filter delay may occur in large molecules.

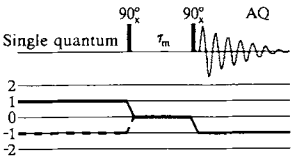
z-Filter

The z-filter is an additional method to select certain coherences (or in this case populations) which cannot be separated by phase cycles. We saw the multiple-quantum filter as a "high-pass filter" for the number of operators in a product operator, in so far as all the products with fewer operators than the multiple-quantum order were suppressed. In contrast, the z-filter (P5) selects populations and suppresses coherences.

(P5)

With the phase cycle of the β pulses zero-quantum coherences and populations are selected. The zero-quantum coherences are then suppressed by variation of τ_m, which is based on the fact that they are modulated with the difference of the chemical shifts of the two involved spins. Populations, on the other hand, are invariant under variation of τ_m (disregarding relaxation). Therefore, if τ_m is varied and the resulting spectra added, the zero-quantum coherences average out, and ideally only the populations are left.

The z-filter can be used, for instance, to select pure in-phase magnetization just before the detection (P6). Of all



(P6)

the detectable single-quantum coherences only I_y is transformed by the first 90$_x^\circ$ pulse into a population and then regenerated by the second pulse. All the antiphase terms are suppressed, in the ideal case.

This principle is used in the 1D z-filtered COSY technique, where the antiphase terms are refocused after the COSY transfer and undesired contributions with other phases are suppressed by the z-filter. A pure in-phase multiplet for spin 2, which is coupled to spin 1, is obtained through excitation of the latter. This multiplet can then be further simplified through the DISCO procedure.[210]

The z-filter function is more complicated in the z-COSY experiment, for here the z-filter is flanked by pulses with small flip angles. Essentially, transformation (84) should be selected. This then provides substantially simplified cross signals of the E. COSY type.

$$I_{1y}I_{2z}I_{3z}...I_{nz} \xrightarrow{\beta_x} I_{1z}I_{2z}I_{3z}...I_{nz} \xrightarrow{\beta_x} I_{1y}I_{2y}I_{3z}...I_{nz} \qquad (84)$$

3.1.5. *Additional COSY Variants*

Two older COSY variants are described in this section, which were introduced only for signal assignment, i.e., for qualitative NMR spectroscopy. They have lost some of their significance, but are discussed here since they clarify some important principles.

Delay COSY

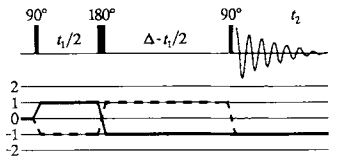
The signals in a COSY spectrum are antiphase with respect to the active coupling in both frequency domains (see Section 3.1.1). Taking into account the line width, this multiplet structure is not optimal because broad lines in antiphase are likely to cancel partially. Another point is that the resolution determined by t_1^{max} is often not sufficient to resolve small couplings. However, if a delay is introduced before and after the 90° pulse[137] (if necessary, with 180° pulses in the middle of the delays to refocus chemical shifts and compensate for field inhomogeneities: SUPERCOSY[267-269]), in-phase portions are also obtained [Eq. (85)], which do not cancel, irrespective of the ratio of

$$\sin \pi J(t_1+\Delta_1) \sin \pi J(t_2+\Delta_2) = (\sin \pi J t_1 \cos \pi J\Delta_1 + \cos \pi J t_1 \sin \pi J\Delta_1)$$
$$(\sin \pi J t_2 \cos \pi J\Delta_2 + \cos \pi J t_2 \sin \pi J\Delta_2) \qquad (85)$$
$$= \sin \pi J\Delta_1 \sin \pi J\Delta_2 \cos \pi J t_1 \cos \pi J t_2 + ...$$

line width to coupling constant. This type of spectrum[270] therefore produces cross signals with mixed phases, which is the reason why it is now seldom used. In contrast, refocusing and defocusing are widely applied in heteronuclear NMR spectroscopy.

ω_1-Decoupled COSY

ω_1-Decoupling can be achieved almost universally through "constant time" variants of pulse sequences. ω_1-Decoupling causes complete disappearance of the multiplet structure in ω_1, which means a gain in resolution.[137,271] The simplest sequence of this type is the ω_1-decoupled COSY[137] (P7), in which chemical shift evolution is generated by a "wandering" 180° pulse.



(P7)

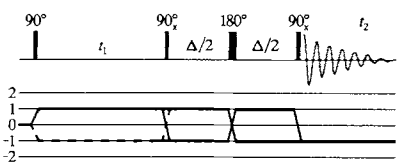
In the 2D *J* NMR experiment (Section 3.1.2) 180° pulses do not affect the evolution of coupling, but they reverse the evolution of chemical shifts. As a result the homonuclear coupling in the pulse sequence (P7) evolves during the entire delay Δ between the 90° pulses, whereas chemical shift evolves during $-t_1/2+(\Delta-t_1/2)=\Delta-t_1$. The transfer amplitude for a 1,2 cross signal between two nuclei in constant time COSY is given by (86). The multiplet

$$\sin \pi J_{12}\Delta \prod_i \cos \pi J^{\mathrm{R}}_{1i}\Delta \cos \Omega_1(\Delta-t_1) \sin \pi J_{12}t_2 \prod_i \cos \pi J^{\mathrm{R}}_{2i}t_2 \cos \Omega_2 t_2 \quad (86)$$

structure in ω_1 is lost completely, since the signal is modulated in t_1 only by the chemical shift ($\cos\Omega_1(\Delta-t_1)$). However, the size of the coupling constant enters through the intensity of the cross signal (transfer amplitude). ω_1-Decoupled spectra can, with some difficulty, be corrected to pure phase.

3.1.6. Relayed Spectroscopy

There is only one coherence transfer step in the COSY experiment. Hence magnetization is transferred from one nucleus to another one which is coupled to it: $2I_{1x}I_{2z} \rightarrow 2I_{1z}I_{2x}$. Relayed spectroscopy introduces one or more additional steps of this type. The Relayed COSY pulse sequence is (P8).[208,209]



(P8)

We consider again only those terms which are relevant for a relayed signal. Coherence transfer is accomplished by 90° pulses; therefore only two-operator terms are of interest [Eq. (87)]. After preparation (90° pulse) and labeling

$$I_{1z} \xrightarrow{90°_y} I_{1x} \xrightarrow{t_1} 2I_{1y}I_{2z} \xrightarrow{90°_x} -2I_{1z}I_{2y} \xrightarrow{\Delta/2-180°-\Delta/2} 2I_{2y}I_{3z} \xrightarrow{90°_x} 2I_{2z}I_{3y} \xrightarrow{t_2} I_{3x} \quad (87)$$

(evolution of chemical shifts and coupling during t_1) ($2I_{1y}I_{2z}$) the first mixing pulse follows. Antiphase magnetization of spin 2 is obtained ($-2I_{1z}I_{2y}$), labeled with the chemical shift of spin 1. In the following period $\Delta/2$-180°-$\Delta/2$ only coupling evolves, since chemical shifts are refocused. The J_{12} coupling refocuses ($-2I_{1z}I_{2y} \rightarrow I_{2x}$) and antiphase magnetization with respect to spin 3 evolves ($I_{2x} \rightarrow 2I_{2y}I_{3z}$). Spin 3 becomes transverse through the second mixing pulse ($-2I_{2z}I_{3y}$), and, after refocusing of the coupling to spin 2 during t_2, magnetization of spin 3 can be detected. Since the coherence-transfer pathways in Relayed COSY correspond to those in COSY, relayed *as well as* direct COSY signals can always be found in the spectrum. Phase-sensitive processing is possible like in COSY. However, only the phases of the relayed peaks are pure, whereas those of the COSY-type peaks are mixed and depend on Δ. The relayed peaks have no simple multiplet structure when more than one intermediate spin contributes to a cross peak. The transfer amplitude is given by (88).

$$\sin \pi J_{12}t_1 \prod_i \cos \pi J^{\mathrm{R}}_{1i}t_1 \sin \pi J_{12}\Delta \sin \pi J_{23}\Delta \prod_i \cos \pi J^{\mathrm{R}}_{2i}\Delta \sin \pi J_{23}t_2 \prod_i \cos \pi J^{\mathrm{R}}_{3i}t_2 \quad (88)$$

The delay Δ must be optimized with respect to the magnitude of the coupling constants. It must be short enough with respect to the largest coupling, such that $\cos \pi J\Delta \not\approx 0$, for otherwise this passive coupling leads to disappearance of the relayed signals. Long delays should also be avoided in order to keep intensity losses due to relaxation at a minimum.

Relayed spectroscopy enables transfer of magnetization from spin 1 through a relay spin to a third spin not directly coupled with spin 1. This procedure is very useful for spectral assignments. If, for example, in an AMX and a BNY spin system the spins M and N overlap, but spins A and B as well as X and Y do not, assignment of A to X and B to Y can be made with the aid of this technique. An example is shown in Figure 32.

Experiments with several relayed-transfer steps were successfully applied in the spectral assignment of peptides[272] and in the analysis of sugars.[273] When the coupling constants are known the transfer amplitudes can be optimized by the right choice of the delays.[209] Relayed cross signals are often formed through more than one transfer. If there is more than one possible relay spin, the relayed signals consist of the sum of different multiplet structures. This problem of overlapping multiplet patterns in relayed spectra can be solved with the 1D-relayed sequence through selective transfer of magnetization.[210] Such a 1D relayed spectrum is shown in Figure 33.

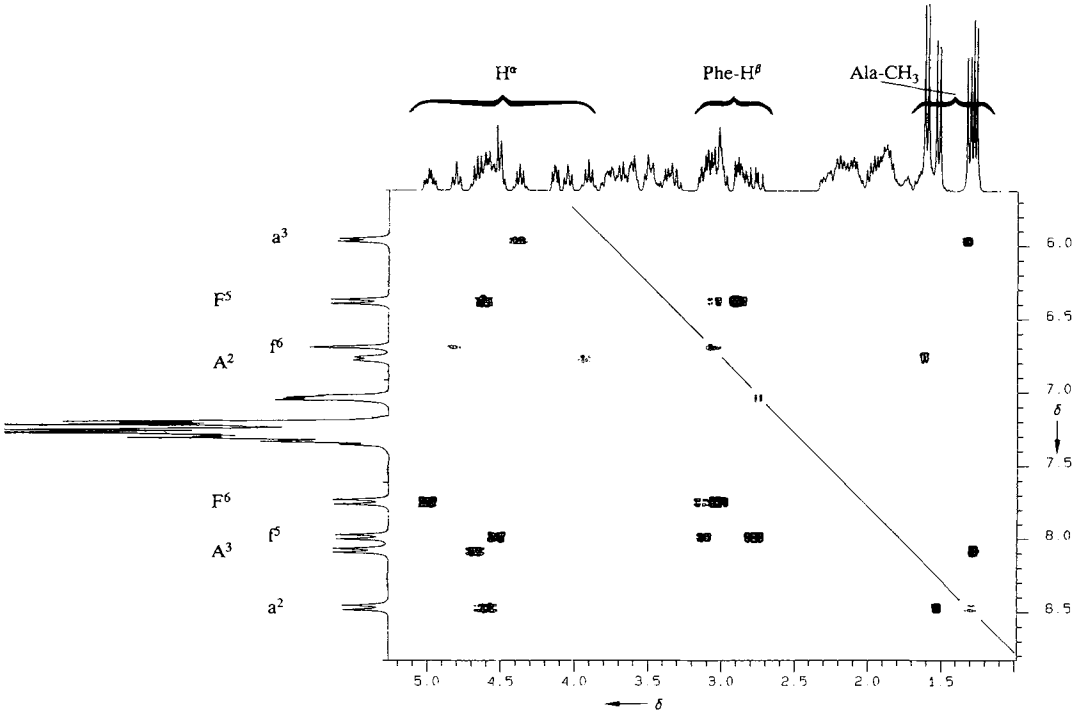


Fig. 32. H-Relayed H,H-COSY of *cyclo*(-Pro^1-Ala^2-Ala^3-D-Pro^4-Phe^5-Phe^6-) in $CDCl_3$ (270 MHz). The NH region in ω_1 is shown and the corresponding cross signals with α and β protons (ω_2). Note that two conformations exist in slow exchange in this solvent (two signal sets labeled with upper- and lower-case letters). The alanine (A and a) and phenylalanine (F, f) spin systems are readily identified through the relayed peaks to the β protons in the right part of the spectrum. This type of spectrum does not lead to assignment of the signals to the peptide sequence. Signals on the counterdiagonal are due to instrument-specific artifacts.

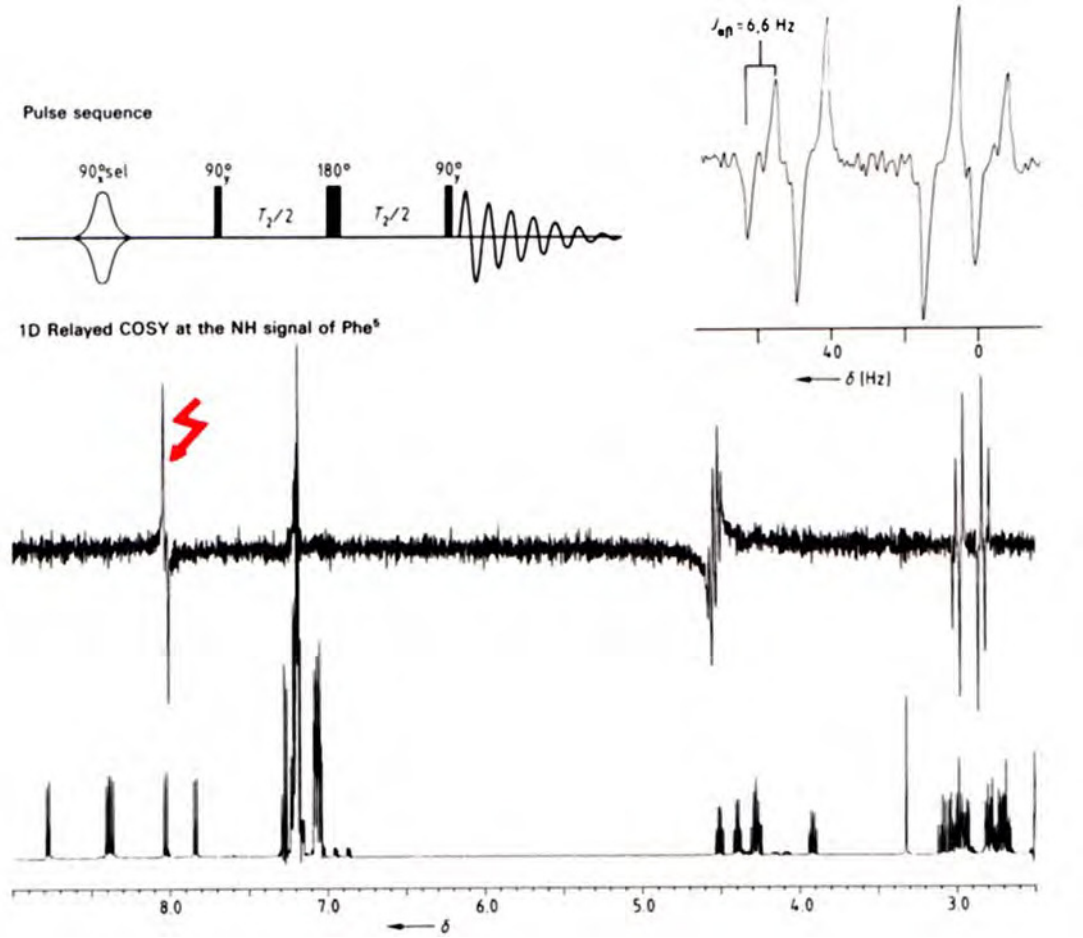

Fig. 33. 1D Relayed spectrum of *cyclo*(-D-Phe-Phe$_4$-). The NH signal of Phe^5 was selectively irradiated. With the right choice of the first delay the corresponding α signal appears dispersive in-phase, while the relayed signals show the multiplet of both β protons in absorptive antiphase. As the expanded region in the upper right corner shows, coupling constants can easily be determined from this multiplet.

3.1.7. TOCSY

A fundamentally different method for the transfer of coupling information is utilized in the TOCSY experiment.[160] In contrast to the COSY experiment, in-phase signals are obtained, i.e., the following transfer takes place: $I_{1x} \rightarrow I_{2x}$ (similar to the NOESY experiment). Mixing is achieved while a spin-lock field is applied, and ideally the effect of chemical shift is completely removed. All the spins are temporarily equivalent (AMX becomes AA'A''). The spin-lock sequences are termed according to *Chandrakumar* et al. as isotropic mixing (no effective field) or as Hartmann-Hahn mixing (with effective field: HOHAHA experiment).[161] Theoretical investigations are described in several publications.[193, 274–280]

The isotropic Hamiltonian includes only the scalar coupling, which is insensitive towards rotation (isotropic). If, however, a residual field remains which is equal for all the chemical shifts, the isotropy of the Hamiltonian is lost and only axial symmetry remains. This condition is termed in analogy to solid-state NMR experiments "Hartmann-Hahn Match." The spins remain strongly coupled, which is essential for the transfer.

Isotropic mixing leads to spectra with mixed phases (phase modulation), whereas in the Hartmann-Hahn mixing pure phases are obtained.[160, 281] The multiplets, even when generated over different mixing times, give rise to combinations of different mirror-symmetric multiplet patterns.[197] Ideally cross signals are formed between all the nuclei in a spin system.

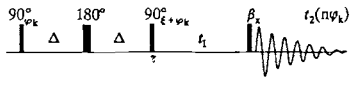
Several pulse sequences have been proposed for the mixing in the TOCSY experiment. The most successful is MLEV-17,[283–285] introduced by *Bax* et al.,[282] which is also used with heteronuclear decoupling (see Section 3.2.10). A further technical realization is found in Ref. [365], theory in Refs. [366, 367].

TOCSY is particularly useful in the analysis of peptides in which the line widths are of the order of couplings, in which case COSY becomes insensitive due to the antiphase structure of the cross signals. The number of nuclei to which magnetization is distributed is controlled through the duration of the spin-lock periods. Short mixing times produce cross signals practically only between directly coupled nuclei, whereas longer mixing times give rise also to relayed and multiple-relayed peaks.

3.1.8. Multiple-Quantum Spectroscopy

We saw in the discussion of the multiple-quantum-filtered COSY technique (Section 3.1.1) that single-quantum coherences were mutually connected through intermediate multiple-quantum coherences. In multiple-quantum spectra,[157, 158, 286–291] however, multiple-quantum coherences are correlated with single-quantum coherences.

Despite the fact that multiple-quantum coherences are not detectable, they can be observed with the aid of 2D NMR spectroscopy. The pulse sequence for an n-quantum



(P9)

spectrum is (P9), where $\xi = (n \bmod 2)90°$ and $\phi_k = k(\pi/n)$ with $k = 0, 1, \ldots, 2n-1$.

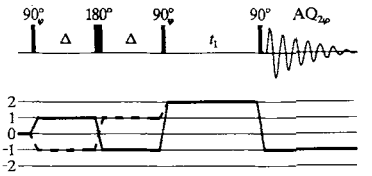
We first treat multiple-quantum spectra with two-spin systems. Indeed, double-quantum spectroscopy is used mainly for the correlation of ^{13}C nuclei (INADEQUATE[164]). Due to the small natural abundance of this nucleus (ca. 1%) only signals from two-spin systems are detected.

Double-quantum coherence evolves under chemical shift according to (89) and (90), i.e., the sums of the frequencies evolve. In contrast, J_{12} coupling between the spins participating in the double-quantum coherence does not evolve.

$$2(I_{1x}I_{2y} + I_{1y}I_{2x}) \xrightarrow{(\Omega_1 I_{1z} + \Omega_2 I_{2z})t} 2(I_{1x}I_{2y} + I_{1y}I_{2x})\cos(\Omega_1+\Omega_2)t + 2(I_{1y}I_{2y} - I_{1x}I_{2x})\sin(\Omega_1+\Omega_2)t \quad (89)$$

$$2(I_{1y}I_{2y} - I_{1x}I_{2x}) \xrightarrow{(\Omega_1 I_{1z} + \Omega_2 I_{2z})t} 2(I_{1y}I_{2y} - I_{1x}I_{2x})\cos(\Omega_1+\Omega_2)t - 2(I_{1x}I_{2y} + I_{1y}I_{2x})\sin(\Omega_1+\Omega_2)t \quad (90)$$

The INADEQUATE sequence is (P10), whereby the phase φ changes through 0°, 90°, 180°, and 270°. The first "sandwich" ($90°_{\varphi}$-Δ-180°-Δ-$90°_{\varphi}$) generates double-quantum coherences. For $\varphi = 90°$, for example, (91) is obtained:



(P10)

$$I_{1x} + I_{2x} \xrightarrow{2\Delta} 2I_{1y}I_{2z} + 2I_{1z}I_{2y} \xrightarrow{90°_x} 2I_{1y}I_{2x} + 2I_{1x}I_{2y} \quad (91)$$

Zero- and single-quantum coherences are suppressed by the appropriate phase cycles. With the correctly tuned delays only molecules with two adjacent ^{13}C nuclei give rise to signals in INADEQUATE spectra.

Chemical shift of the double-quantum coherence, which, as shown in Equation (89), corresponds to the sum of the frequences of the single-quantum coherences of the two spins, evolves during t_1. The 90° pulse that follows converts the double-quantum coherence into antiphase single-quantum coherence, which is evenly distributed between both spins [Eq. (92)]. The resulting spectrum is shown schematically in Figure 34.

$$2(I_{1x}I_{2y} + I_{1y}I_{2x}) \xrightarrow{90°_x} 2(I_{1x}I_{2z} + I_{1z}I_{2x}) \quad (92)$$

There is no multiplet structure in ω_1. Each pair of cross signals at equal ω_1 frequency represents a C-C connectivity. There is hence a direct correlation between constitution

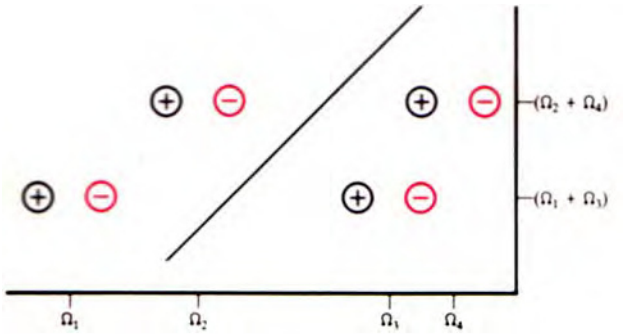


Fig. 34. A schematic INADEQUATE spectrum for an isolated two-spin system, as it appears for "dilute" nuclei. Pairs of antiphase doublets are obtained, symmetrical with respect to the skew diagonal at $\omega_1 = 2\omega_2$.

and spectrum. For a detailed discussion see *J. Buddrus* and *H. Bauer*.[292] The INADEQUATE technique offers maximum sensitivity for the correlation of nuclei of low natural abundance. However, indirect excitation and detection of the heteronuclei by protons as discussed later as "inverse spectroscopy" (Section 3.2.11) leads to an additional increase of intensity.

INADEQUATE spectra with pure phases, as well as quadrature detection in ω_1, are achieved by 45° phase incrementation. Other variants achieve quadrature detection in ω_1 without such phase incrementation, using pulse angles other than 90°. Details of the method can be found in the above-mentioned review[292] or in the original literature.

Double-quantum spectra of larger spin systems (e.g., protons) are substantially more complicated.[157] First we note the coupling to other nuclei. We find (93) and (94). Thus the sum of the coupling constants of the active spins with the passive spins evolves.

$$2(I_{1x}I_{2y} + I_{1y}I_{2x}) \xrightarrow{(\pi J_{13}\, 2I_{1z}I_{3z} + \pi J_{23}\, 2I_{2z}I_{3z})t} 2(I_{1x}I_{2y} + I_{1y}I_{2x})\cos \pi(J_{12}+J_{23})t - 4(I_{1x}I_{2x} + I_{1y}I_{2y})I_{3z} \sin \pi(J_{12}+J_{23})t \quad (93)$$

$$2(I_{1x}I_{2x} + I_{1y}I_{2y}) \xrightarrow{(\pi J_{13}\, 2I_{1z}I_{3z} + \pi J_{23}\, 2I_{2z}I_{3z})t} 2(I_{1x}I_{2x} + I_{1y}I_{2y})\cos \pi(J_{12}+J_{23})t - 4(I_{1x}I_{2y} + I_{1y}I_{2x})I_{3z} \sin \pi(J_{12}+J_{23})t \quad (94)$$

Direct connectivities are found in the double-quantum spectrum according to (95), which leads to the cross-signal pair in ω_1 at the sum of the chemical shifts $(\Omega_1+\Omega_2,\Omega_1)$ and $(\Omega_1+\Omega_2,\Omega_2)$, symmetrical about the diagonal $\omega_1 = 2\omega_2$.

$$2I_{1x}I_{2z} \xrightarrow{90^\circ_x} 2I_{1x}I_{2y} \xrightarrow{t_1} 2I_{1x}I_{2y} + 2I_{1y}I_{2x} \xrightarrow{90^\circ_x} 2I_{1x}I_{2z} + 2I_{1z}I_{2x} \quad (95)$$

In linear spin systems of the type I^1-I^2-I^3 additional "remote" peaks are found according to Equation (96). They appear in ω_2 at the frequency of spin 2, but in ω_1 at the sum of the frequencies for spin 1 and 3 $(\Omega_1+\Omega_3,\Omega_2)$. In contrast to the direct signals, they have no symmetry reflection about the diagonal; they contain, however, the relayed information.

$$4I_{1z}I_{2y}I_{3z} \xrightarrow{90^\circ_x} 4I_{1y}I_{2z}I_{3y} \xrightarrow{t_1} 4I_{1y}I_{2z}I_{3y} \xrightarrow{90^\circ_x} 4I_{1z}I_{2y}I_{3z} \quad (96)$$

For three spins which are all mutually coupled, both types of signals, "direct" as well as "remote" peaks, are found in the spectrum. These signals have mixed phases. For example, the cross peak with the coordinates $(\Omega_1+\Omega_2,\Omega_1)$ arises from (97). This direct signal is in absorption in both frequency dimensions and in-phase with respect to the J_{13} and J_{23} coupling in ω_1. Another pathway is (98). The resulting cross peak is dispersive in ω_1, absorptive in ω_2, and antiphase with respect to both couplings in ω_1. Both transfers give rise to a cross peak at $(\Omega_1+\Omega_2,\Omega_1)$.

$$2I_{1x}I_{2z} \xrightarrow{90^\circ_x} 2I_{1x}I_{2y} \xrightarrow{t_1} 2I_{1x}I_{2y} \xrightarrow{90^\circ_x} 2I_{1x}I_{2z} \quad (97)$$

$$4I_{1z}I_{2z}I_{3y} \xrightarrow{90^\circ_x} 4I_{1y}I_{2y}I_{3z} \xrightarrow{t_1} 2I_{1x}I_{2y} \xrightarrow{90^\circ_x} 2I_{1x}I_{2z} \quad (98)$$

Similarly, for the "remote" peak at coordinates $(\Omega_2+\Omega_3,\Omega_1)$ one obtains (99). The resulting signal is in absorption in both dimensions and in-phase with respect to both couplings in ω_1. Still another transfer route is conceivable [Eq. (100)]. Now dispersion is found in ω_1, absorption in ω_2, and antiphase with respect to both couplings. Again, the cross peak is a mixture of multiplets with different phases and fine structure.

$$4I_{1y}I_{2z}I_{3z} \xrightarrow{90^\circ_x} 4I_{1z}I_{2y}I_{3y} \xrightarrow{t_1} 4I_{1z}I_{2y}I_{3y} \xrightarrow{90^\circ_x} 4I_{1y}I_{2z}I_{3z} \quad (99)$$

$$2I_{2x}I_{3z} \xrightarrow{90^\circ_x} 2I_{2x}I_{3y} \xrightarrow{t_1} 4I_{1z}I_{2y}I_{3y} \xrightarrow{90^\circ_x} 4I_{1y}I_{2z}I_{3z} \quad (100)$$

Because of the different mapping of connectivities in the spectrum, double-quantum spectroscopy is sometimes used to simplify assignments in complex spectra. The use of multiple-quantum spectroscopy is however not widespread, mainly because of the complex multiplet structures of the cross peaks, the dependence of the cross signal intensities upon the length of the delays in the preparation sandwich, the need for phase increments smaller than 90°, and the inconveniency in connection with the evaluation of the ω_1 chemical shift. The use of a z-filter offers some improvement with respect to the phases of the cross peaks.[293]

3.2. Heteronuclear Experiments

Almost all the heteronuclear 1D and 2D NMR techniques are also associated with coherence transfer. Optimal sensitivity of the measurement of heteroatoms is of particular importance, for they practically all (except tritium) have smaller gyromagnetic ratios γ than the proton, and their natural abundance is often very small.

We first comment on the sensitivity of heteronuclear NMR experiments in general. The "global" sensitivity factor of any NMR experiment is $\gamma^{5/2} B_0^{3/2}$. It contains a factor γ, which stems from the polarization at thermal equilibrium. For experiments which start with heteronuclear excitation, the polarization at thermal equilibrium is given by $\gamma_X S_z$, where S stands for the heteronuclear magnetization.

If, however, the experiment starts with proton magnetization, then the corresponding polarization is $\gamma_H I_z$ (I for proton magnetization). Thus the gain in sensitivity in experiments that start with proton rather than heteronuclear magnetization is γ_H/γ_X. The remaining factor $\gamma^{3/2}$ in the global sensitivity is due to detection; when multiplied by the gyromagnetic ratio of the excited nucleus it is proportional to the signal-to-noise ratio (S/N). In conventional heteronuclear experiments the heteronucleus is detected and the factor is $\gamma_X^{3/2}$. In "inverse" spectroscopy protons are detected, and the factor is $\gamma_H^{3/2}$. Thus an additional gain in sensitivity of $\gamma_H^{3/2}/\gamma_X^{3/2}$ is obtained in indirectly detected versus conventionally detected spectra[46] (see Section 3.2.1).

Practically all the homonuclear experiments discussed so far have heteronuclear analogues. A proton pulse of angle β in the homonuclear experiment is analogous to simultaneous pulses of angle β on *both* protons and heteronuclei in the heteronuclear experiment. It follows that every homonuclear 2D NMR experiment can readily be transferred to a heteronuclear system. However, often these direct transfers do not represent the optimum in terms of sensitivity. A nonselective pulse in homonuclear experiments operates equally (neglecting off-resonance effects) on all the nuclei. In contrast, in heteronuclear experiments the two different nuclei can be operated on separately. This leads in certain cases to an enormous gain in sensitivity.

The heteronuclear analogue of the homonuclear COSY experiment (90°(^{1}H)-t_1-90°(^{1}H,^{13}C)-t_2) would only yield, for an HC fragment, one-fourth of the intensity obtained by the conventional H,C shift correlation technique.

A second property of heteronuclear systems, which is significant for the arrangement of pulse sequences, is the large difference in magnitude between direct couplings over one bond, $^1J_{HX}$, and what is termed in heterosystems "long-range coupling" over n bonds ($n \geq 2$), $^nJ_{HX}$. Therefore, to a first approximation, H_nX units can be treated as isolated systems. In addition, the variation in $^1J_{HX}$ is limited, in favorable cases, within a narrow range (the $^1J_{HP}$ coupling is an exception).

3.2.1. The Role of 180° Pulses

Let us first treat the role of 180° pulses in heteronuclear pulse sequences. The effect of a 180°$_I$ pulse on the evolution of chemical shift of spin I after time t (the chemical shift of the heterospin S is obviously unaffected) is shown in (101). Thus a time reversal of period t before the 180° pulse takes place [cf. Eq. (76) and (77)].

$$I_x \cos \Omega t + I_y \sin \Omega t \xrightarrow{180°_{x,y}} \pm (I_x \cos \Omega(-t) + I_y \sin \Omega(-t)) \quad (101)$$

The homonuclear I coupling remains, as we saw earlier, unaffected. The same is true also for homonuclear S coupling. The heteronuclear coupling, however, behaves differently [Eq. (102)]. The corresponding expression for the 180° (S) pulse is (103). Thus, in contrast to homonuclear coupling, after time t and a 180° pulse on one of the heteronuclear species the heteronuclear coupling has evolved backwards, just like chemical shift. It can hence be refocused by a sequence Δ-180°(I)-Δ or Δ-180°(S)-Δ.

$$I_x \cos \pi Jt + 2I_yS_z \sin \pi Jt \xrightarrow{180°_{x,y}(I)} \pm (I_x \cos \pi Jt + 2I_yS_z \sin \pi Jt) = \pm (I_x \cos \pi J(-t) + 2I_yS_z \sin \pi J(-t)) \quad (102)$$

$$S_x \cos \pi Jt + 2S_yI_z \sin \pi Jt \xrightarrow{180°_{x,y}(S)} \pm (S_x \cos \pi Jt + 2S_yI_z \sin \pi Jt) = \pm (S_x \cos \pi J(-t) + 2S_yI_z \sin \pi J(-t)) \quad (103)$$

Two simultaneous 180° pulses on both spins have the same effect as one 180° pulse in a homonuclear system: refocusing of chemical shift, no effect on homo- or heteronuclear coupling.

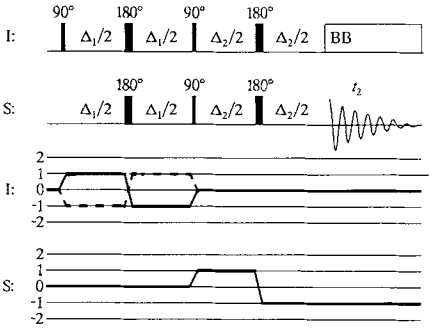
A final comment: The rules for phase cycling can readily be transferred to heterosystems. It is recommended to use two "staffs" in heteronuclear systems, since the different nuclei are separately excited by pulses.

There are essentially two 1D NMR techniques which perform heteronuclear coherence transfer: INEPT and DEPT.

3.2.2. INEPT

Coherence Transfer in Heteronuclear Spin Systems through $^1J_{CH}$ Couplings

The pulse sequence for INEPT[294] is (P11). It corresponds to COSY: a 90° excitation pulse and a 90° pulse on each of the two nuclei for the coherence transfer. The 180° pulses serve merely for the refocusing of the chemical shift evolution.



(P11)

We now analyze the INEPT experiment in terms of the product operator formalism. The starting magnetization at thermal equilibrium is $\gamma_I I_z + \gamma_S S_z$. The 90°$_y$ I pulse generates transverse I-spin magnetization: $\gamma_I I_x$. The S-spin magnetization remains longitudinal and can be suppressed by phase cycling (x, −x for the first pulse). During the following period $\Delta_1/2$-180°(I,S)-$\Delta_1/2$, heteronuclear coupling $^1J_{IS}$ as well as homonuclear coupling $^nJ_{II}$ evolve, while chemical shifts for both nuclei are refocused. If the direct heteronuclear coupling $^1J_{IS}$ is large relative to the heteronuclear long-range coupling $^nJ_{IS}$ and the homonuclear coupling J_{II}, one obtains Equation (104). As usual only the antiphase term is effective in the polarization transfer [Eq.

(105)]. The phase of the second 90° pulse must be shifted by 90° relative to the first one.

$$I_x \longrightarrow I_x \cos \pi^1 J_{IS}\Delta_1 + 2I_yS_z \sin \pi^1 J_{IS}\Delta_1 \quad (104)$$

$$2I_yS_z \xrightarrow{90°_x(I,S)} -2I_zS_y \quad (105)$$

The sequence that follows $\Delta_2/2$-180°(I,S)-$\Delta_2/2$ results in refocusing of the heteronuclear coupling into detectable in-phase magnetization of spin S [Eq. (106)].

$$-2I_zS_y \longrightarrow -2I_yS_z \cos \pi J_{IS}\Delta_2 + S_x \sin \pi J_{IS}\Delta_2 \quad (106)$$

The broadband decoupling at the beginning of the acquisition time destroys all the I-spin magnetization. This means that all the product operators that contain I-spin operators are destroyed, and hence can be left out.

The delays Δ_1 and Δ_2 can be set to $\Delta_1 = \Delta_2 = (2J)^{-1}$ so that all the transfer factors equal 1 ($\sin \pi J\Delta = 1$, $\cos \pi J\Delta = 0$); the full factor γ_I/γ_S is gained in sensitivity relative to a broadband decoupled spectrum (without NOE), because of the initial excitation of the I spin. A factor 4 is obtained for $^1H/^{13}C$, and a factor 10 for $^1H/^{15}N$.

When several I nuclei are bound to one S nucleus, care must be taken that the passive I spins contribute a $\cos \pi J\Delta_2$ term during the delay Δ_2. Hence we find for an SI_n group (only relevant operators are observed) Equation (107).

$$n\gamma_I I_z \xrightarrow{90°_x(I)} -n\gamma_I I_y \xrightarrow{\Delta_1} n\gamma_I 2I_xS_z \sin \pi^1 J_{IS}\Delta_1 \xrightarrow{90°(I,S)}$$
$$n\gamma_I 2I_zS_y \sin \pi^1 J_{IS}\Delta_1 \xrightarrow{\Delta_2} -n\gamma_I S_x \sin \pi^1 J_{IS}\Delta_1 \sin \pi^1 J_{IS}\Delta_2 \cos^{n-1} \pi^1 J_{IS}\Delta_2 \quad (107)$$

This transfer function is the key to editing methods, which enable sorting of signals according to the number of I nuclei connected to S. We note the analogy to multiple-quantum filters. Here, however, we are no longer dealing with a high-pass filter, but with a band-pass filter, which selects product operators with *exactly* n operators. With $\pi^1 J_{IS}\Delta_2 = \Theta$ and neglecting the factor $\gamma_I \sin \pi^1 J_{IS}\Delta_1$, which is anyhow always the same, we obtain the factor $n \sin \Theta \cos^{n-1} \Theta$ for the signal intensity.

The cosine factor is negative for $\Theta > 90°$. It follows that $\cos^{n-1} \Theta$ responds to the multiplicity of the S nucleus, i.e., to the number of I nuclei connected to S. Negative signals are obtained for even n, and positive ones for odd n. A selection according to multiplicity is achieved through the combination of spectra with different Θ values. This is done by adding three successive experiments with different Θ values (for the sake of simplicity we use here degrees rather than radians):

$$\Theta_1 = +\Theta;\ \Theta_2 = 90°;\ \Theta_3 = 180° - \Theta$$

If $\Theta = 345°$ is chosen, the coefficients shown in Table 6 are obtained. From the Table we see that the spectrum for SI_3 groups is obtained according to (108), while for SI groups

Table 6. Relative signal intensities for the INEPT experiment as a function of $\Theta = \pi J_{HC}\Delta_2$.

	n	Θ 45°	Θ 90°	Θ 135°
CH	1	$1/\sqrt{2}$	1	$1/\sqrt{2}$
CH_2	2	1	0	−1
CH_3	3	$3/(2\sqrt{2})$	0	$3/(2\sqrt{2})$

it is spectrum(90°). The spectrum for SI_2 groups is always obtained by subtraction of the spectrum for Θ_1 from the one for Θ_3.

$$\text{spectrum}(45°) + \text{spectrum}(135°) - \text{spectrum}(90°) \cdot \sqrt{2} \quad (108)$$

It should further be noted that the quality of the editing by INEPT depends on the assumption of equal coupling constants. A 10% variation in coupling constants changes the angles $\Theta = 45°$, 90°, and 135° to ca. $\Theta \approx 40°$, 80°, and 120°, respectively. The corresponding signal intensities are shown in Table 7. Clearly, the signal suppression under these conditions is no longer complete.

Table 7. Relative signal intensities with editing using the INEPT sequence assuming a 10% deviation of the coupling from the ideal value.

	Intensity of CH	CH_2	CH_3
CH subspectrum	0.99	0.3	0.07
CH_2 subspectrum	−0.2	1.88	0.43
CH_3 subspectrum	0.1	−0.34	1.72

Transfer through Long-Range Couplings

Magnetization can obviously also be transferred in the INEPT experiment from the I spin to the S spin through long-range couplings $^nJ_{IS}$.[188] The delays must be changed for this purpose. In contrast with transfer through direct couplings, homonuclear I,I couplings must also be taken into account, for they are in general of the same order of magnitude as the heteronuclear long-range couplings.

The amplitude for a transfer from I_k to S_i in the INEPT experiment is given by (109). The optimal setting of the delays depends on the actual coupling constants. When these are known approximately, the delays can be optimized, whereby due to relaxation short delays should be preferred.

$$\sin \pi J_{I_kS_i}\Delta_1 \prod_i \cos \pi J_{I_kI_i}\Delta_1 \sin \pi J_{I_kS_i}\Delta_2 \prod_i \cos \pi J_{I_iS_i}\Delta_2 \quad (109)$$

The excitation pathway is not evident from the INEPT experiment; i.e., it is not known from which I spin the measured magnetization was transferred to the S spin. If, however, clarification of this pathway is desired for the elucidation of connectivities, either a selective INEPT or a 2D NMR experiment must be performed.

Selective INEPT

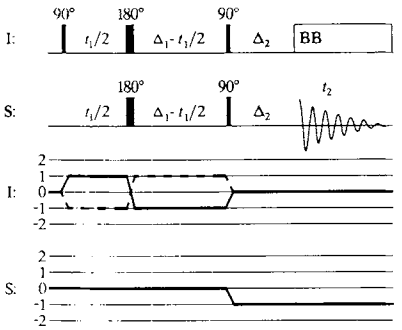
In this method all the I pulses are replaced by selective pulses on I_k.[295,296] In this way all the passive I spins relate to the S spin as well as to the I_k spin as heterospins. The transfer amplitude is thus simplified to (110); i.e., the in-

$$\sin \pi J_{I_kS_i}\Delta_1 \sin \pi J_{I_kS_i}\Delta_2 \quad (110)$$

tensity in this spectrum is substantially higher than in INEPT with nonselective, "hard" pulses. In addition, due to the choice of a particular proton signal for the selective excitation, the transfer pathway is unequivocal. A prerequisite is, of course, a sufficiently resolved proton spectrum.

3.2.3. 2D Variants of INEPT: COLOC

The second possibility to separate the transfer pathways is the constant time 2D variant of INEPT, the COLOC experiment.[189] In the constant time 2D NMR experiment the total evolution time is constant. Evolution of chemical shift is achieved by a 180° pulse, which is shifted within the delay (see Section 3.1.5). In the heteronuclear experiment, after the initial INEPT excitation, two 180° pulses are simultaneously shifted, one for protons and the other for the heteronucleus. Hence the COLOC pulse sequence (P12) is obtained.



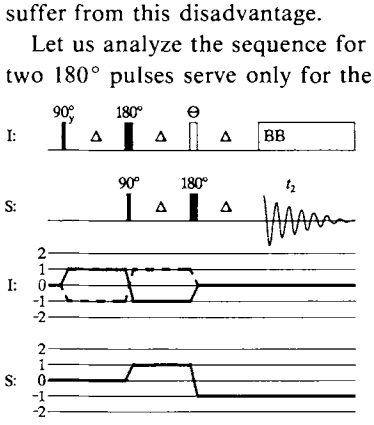
(P12)

There is a direct analogy with the ω_1-decoupled homonuclear COSY experiment (Section 3.1.5): here, too, the cross signals in ω_1 are decoupled (no homonuclear I coupling). The transfer amplitude is, except for the term for chemical shift evolution, the same as for the INEPT experiment. All the signals appear in one spectrum, which makes up for the lower intensity relative to the selective INEPT experiment. However, the selective INEPT experiment is more sensitive if one is only interested in a few correlations, ignoring the greater effort in setting up the experiment.

3.2.4. DEPT

We saw in Section 3.2.2 that the quality of spectral editing in INEPT depends strongly on variations in the coupling constants. The DEPT sequence[297–299] (P13) does not suffer from this disadvantage.

Let us analyze the sequence for an SI_n group. Since the two 180° pulses serve only for the refocusing of chemical



(P13)

shift, we will ignore them in the following discussion, as well as the evolution of chemical shift. The delay should be $\Delta=(2\,{}^1J_{IS})^{-1}$. Equation (111) is obtained. The cosine

$$n\gamma_I I_z \xrightarrow{90°_y(I)} n\gamma_I I_x \xrightarrow{\Delta} n\gamma_I 2I_y S_z \xrightarrow{90°_y(S)} n\gamma_I 2I_y S_x \xrightarrow{\Delta}$$
$$n\gamma_I 2^n I_y S_{x,y}(I_z)^{n-1} \xrightarrow{\Theta_x} 2^n S_{x,y}(I_z)^n n\gamma_I \sin\Theta\cos^{n-1}\Theta \xrightarrow{\Delta} S_x n\gamma_I \sin\Theta\cos^{n-1}\Theta \quad (111)$$

term results from the coupling of protons that do not participate in the generation of heteronuclear antiphase terms $2I_yS_z$, which is effective in the second half of the pulse sequence in transverse $S_{x,y}$ coherence. The transfer function is, like in the INEPT experiment, $\sin\Theta\cos^{n-1}\Theta$; however, here Θ is a tuneable pulse angle, *independent* of J.

So far we have not discussed the J dependence in the transfer amplitude. J was set equal to $(2\Delta)^{-1}$. We repeat the analysis and focus now on terms which originate from SI_n groups, but appear in the edited spectrum as an SI_m group. Such a "cross talk" is possible in an n-spin system when a product operator $S_yI_y(I_z)^{m-1}$ appears before the Θ pulse. It follows immediately that $n \geq m$. This operator behaves in the editing process like an SI_m group. It is built up as shown in (112). When we again assume the values 45°, 90°, and 180°[300] for Θ and a 10% deviation of the coupling constants from the ideal ${}^1J_{IS}=(2\Delta)^{-1}$ is considered, we obtain the

$$n\gamma_I I_z \xrightarrow{90°_y(I)} n\gamma_I I_x \xrightarrow{\Delta} n\gamma_I 2I_y S_z \sin\pi J\Delta \xrightarrow{90°_y(S)} n\gamma_I 2I_y S_x \sin\pi J\Delta$$
$$\xrightarrow{\Delta} n\,\gamma_I\binom{m-1}{n-1}(\sin\pi J\Delta)^m(\cos\pi J\Delta)^{n-m}\,2^m I_y S_x(I_z)^{m-1}$$
$$\xrightarrow{\Theta(I)} n\,\gamma_I\binom{m-1}{n-1}(\sin\pi J\Delta)^m(\cos\pi J\Delta)^{n-m}\,2^m S_x(I_z)^m \sin\Theta\cos^{m-1}\Theta \quad (112)$$
$$\xrightarrow{\Delta} n\,\gamma_I\binom{m-1}{n-1}(\sin\pi J\Delta)^{2m}(\cos\pi J\Delta)^{2(n-m)} S_x \sin\Theta\cos^{m-1}\Theta$$

editing results summarized in Table 8. This result is significantly better in comparison with the INEPT experiment (see Table 7). Further improvement is achieved through DEPT-GL.[301]

Table 8. Relative signal intensities with editing using the DEPT sequence assuming a 10% deviation of the coupling from the ideal value.

	Intensity of		
	CH	CH_2	CH_3

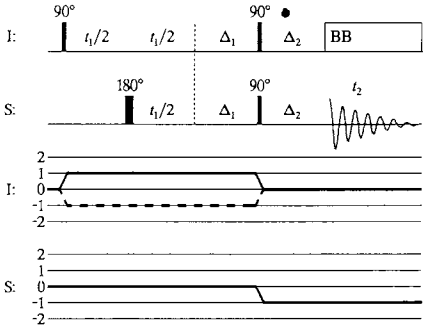
CH_2 subspectrum	0.0	1.9	0.14
CH_3 subspectrum	0.0	0.0	2.89

3.2.5. Heteronuclear Shift Correlation

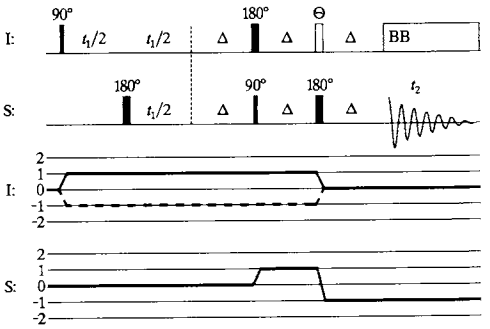
Both INEPT and DEPT serve as the one-dimensional precursor of heteronuclear shift correlation via ${}^1J_{IS}$ coupling. A 2D NMR experiment is formed by the introduction of a variable evolution period (t_1) after the 90° preparation pulse. Decoupling of the heteronuclear coupling in ω_1 is achieved by a 180° pulse on the heteronuclei in the middle of t_1. The spectra that are obtained show no heteronuclear coupling in ω_1. Starting from the INEPT sequence we obtain the pulse sequence for the H,X-COSY experiment[162, 172, 1737][*] (P14), and starting from the DEPT

[*] We use here the term COSY (*C*orrelated *S*pectroscop*y*) also for heteronuclear experiments. Often this term is used only for homonuclear experiments. For H,X-COSY one often finds other expressions in use, such as HETCOR or simply shift correlation.

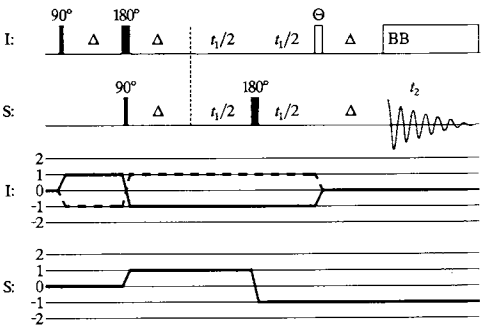


(P14)

sequence that for the DEPT-COSY experiment is obtained,[174-177] (P15) and (P16). The same spectrum is obtained from pulse sequences (P15) and (P16), although (P16) has one pulse less. The evolution of proton chemical shifts takes place in (P15) before the generation of transverse heteronuclear magnetization; in (P16) the two blocks are exchanged.



(P15)



(P16)

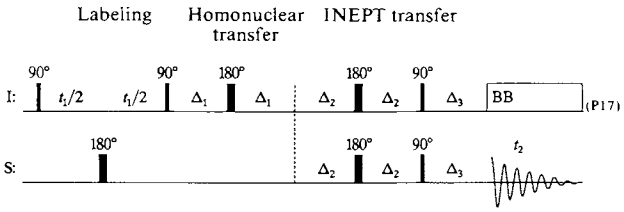
The DEPT-COSY sequence is fully refocused; i.e., for $t_1 = t_2 = 0$ no chemical shift evolves. This is an advantage for the phase correction, since only small frequency-dependent phase correction values are obtained. Spectrum editing is equally possible as in the 1D variant.[302] In contrast, the INEPT sequence is less suitable for pure phase 2D spectra, since for $t_1 = t_2 = 0$ proton chemical shift evolves in Δ_1 as well as heteronuclear chemical shift in Δ_2. This introduces a large first-order phase correction in ω_1 and ω_2.[171, 172]

The COLOC sequence and its variant with a BIRD pulse (see Section 3.2.8) can also be used for heteronuclear shift correlation via one bond,[180] if the requirement for resolution in t_1 (protons) is sufficiently small. We only see an advantage in the constant time variants of INEPT and DEPT transfers if the $^1J_{IS}$ dependence of the transfer amplitude is eliminated through the application of a pair of time-shifted "wandering" 180° pulses.[181]

3.2.6. *Heteronuclear Relayed Experiments*

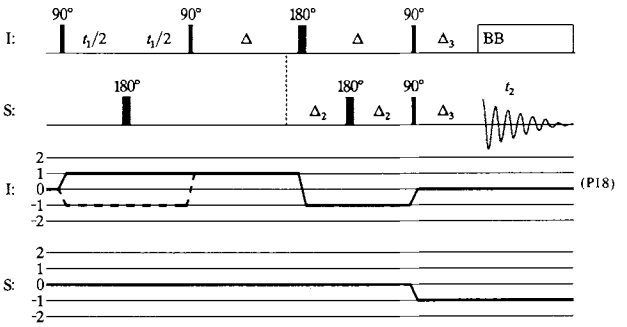
H-Relayed H,X-COSY

Other heteronuclear experiments can be designed through combinations of pulse sequences. Thus by inserting an additional H,H polarization transfer in the H,X-COSY sequence we arrive at the H-Relayed H,X-COSY sequence[213, 214] (P17). After evolution with heterodecou-



(P17)

pling, polarization is transferred from spin I^1 to other I spins coupled to I^1. The evolution of I-spin chemical shift is refocused in this relay transfer by the first 180° (I) pulse. It is advantageous to refocus the I-spin chemical shift also in the INEPT transfer which follows.[216, 217] The two 180° I-refocusing pulses can be replaced by a single 180° pulse in the middle of the delays ($2\Delta_1$ and $2\Delta_2$), without changing the net effect. Since any addition of pulses to a sequence is a further possible source of artifacts, sequences with fewer pulses are generally preferred. Thus the sequence (P18) is obtained for the heteronuclear H-Relayed H,X-COSY experiment, with $\Delta = \Delta_1 + \Delta_2$.[215, 216] An example of an H-Relayed H,X-COSY is shown in Figure 35b.



(P18)

We find that in comparison with the H,C-COSY spectrum (Fig. 35a) additional signals, so-called relayed peaks, appear, which are marked by arrows. They are formed by H^1-H^2-C^2 fragments and hence provide indirect information on carbon connectivity.[215] For example, all proton signals and carbon signals of the tetrabenzylglucose ring were assigned as shown in Figure 35. However, the signals due to direct H^2,C^2 coupling are also seen in the spectrum. This is due to the fact that relayed transfer uses single-quantum coherence, like the magnetization remaining on H^1, and thus selection through phase cycling is impossible (see homonuclear relayed experiment). If necessary, the H,X-COSY parts can be filtered with a low-pass *J*-filter, taking advantage of the different magnitudes of the coupling constants (e.g., $^1J_{HC}$ and $^nJ_{HC}$) (see Section 3.2.8).

X-Relayed H,X-COSY

A further variant of the heteronuclear relayed spectroscopy is the X-Relayed H,X-COSY experiment.[222, 223] The pulse sequence is (P19). This experiment, like the INADE-

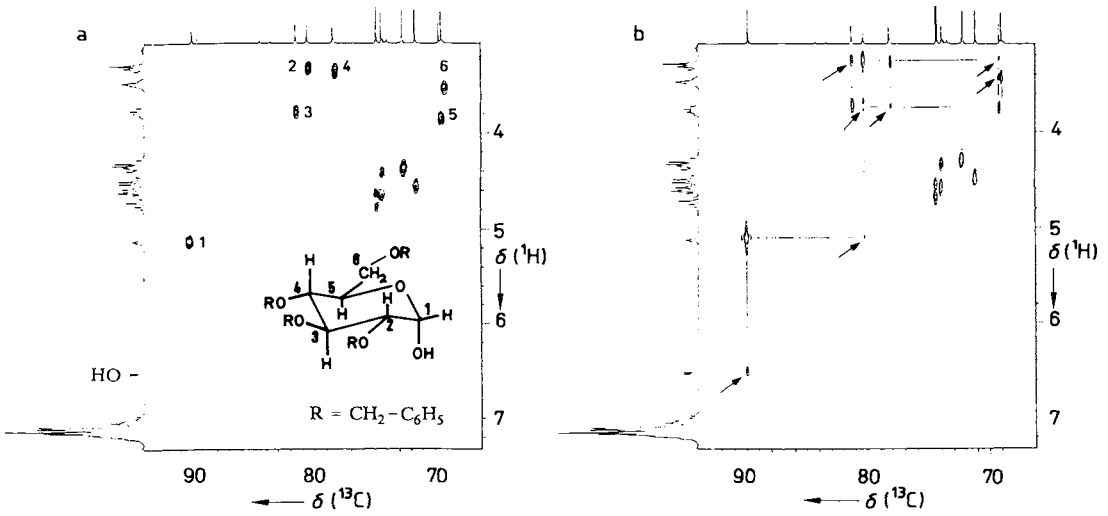


Fig. 35. a) H,C-COSY and b) H-Relayed H,C-COSY of tetrabenzylglucose in [D$_6$]DMSO. The CH cross-signal assignment of the sugar is given in (a). It follows directly from the relayed spectrum (b) without additional assumptions, when the proton signal intensities are consulted (signal 6 is due to two protons attached to one carbon and can hence serve as a starting point for the sequential assignment).

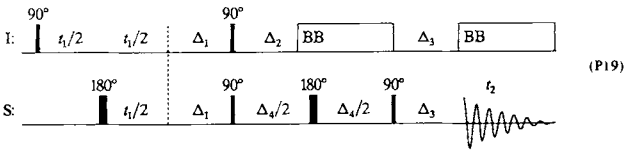
QUATE experiment, serves to resolve connections in which quaternary carbons participate. It also enables extraction of $^1J_{CC}$ coupling constants.



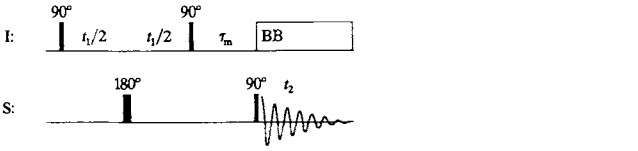
(P19)

3.2.7. Heteronuclear NOESY

The heteronuclear NOESY experiment (P20)[203–207,368] is almost a direct conversion from the homonuclear experiment (P2). Heteronuclear NOEs are often too small to produce useful signals in spectra of larger molecules.

3.2.8. Filters and Their Applications

The low-pass J-filter[303] and BIRD pulses[304] serve to modify the heteronuclear pulse sequences discussed so far. In cases of large differences between $^1J_{IS}$ and $^nJ_{IS}$ and extreme dilution of the S spin, it is possible to selectively manipulate those I spins which have a $^1J_{IS}$ coupling with an S spin. In the isotopomer (**A**) in Figure 36 it is possible to discriminate H^1 and H^2 from H^3, since the first two have a $^1J_{CH}$ coupling, whereas H^3 does not. The opposite is true for the isotopomer **B**.



(P20)

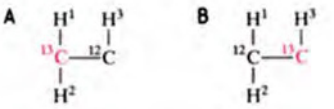


Fig. 36. Different isotopomers of a CH_2CH fragment. The different signals in a ^{13}C-NMR spectrum arise from different isotopomers of the compound investigated.

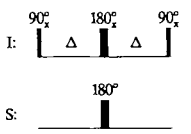
BIRD

Let us consider the "pulse sandwich"[304] (P21) with $\Delta=(2\,^1J_{IS})^{-1}$. This $BIRD_x$ pulse is essentially a 360° pulse



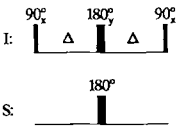
(P21)

for I spins which are not directly connected to an S spin (due to the short delays, long-range and homonuclear couplings can be neglected to a good approximation). For an I spin which is connected to an S spin through $^1J_{IS}$, however, we obtain (for $\Delta=(2J)^{-1}$) Equations (113) and (114). Thus the $BIRD_x$ pulse acts as a 180°_y pulse for I spins which are coupled with S, while for I spins which are not coupled with S it acts as a 0° pulse.

$$I_x \xrightarrow{90^\circ_x} I_x \xrightarrow{\Delta} 2I_yS_z \xrightarrow{180^\circ_x(I,S)} 2I_yS_z \xrightarrow{\Delta} -I_x \xrightarrow{90^\circ_x} -I_x \quad (113)$$

$$I_y \xrightarrow{90^\circ_x} I_z \xrightarrow{\Delta} I_z \xrightarrow{180^\circ_x(I,S)} -I_z \xrightarrow{\Delta} -I_z \xrightarrow{90^\circ_x} I_y \quad (114)$$

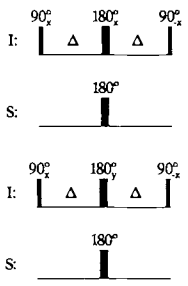
If the phase of the 180° pulse is changed to y ($BIRD_y$, P22), the effect of the BIRD sequence is reversed. Now I



(P22)

spins with $^1J_{IS}$ remain unaffected, and those without $^1J_{IS}$ undergo inversion. (P23) is yet another representation of $BIRD_y$ and (P24) of $BIRD_x$. Applications of BIRD pulses

are presented in the following sections, dealing with proton-carbon correlations.



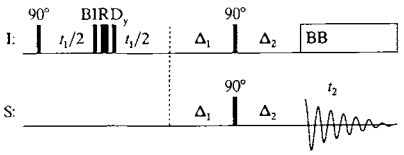
(P23)

(P24)

ω_1-Decoupled Shift Correlation

In H,C shift correlation the spectra of different isotopomers overlap to yield the final spectrum. A line in the ^{13}C-NMR spectrum means that only that carbon in the molecule is a ^{13}C isotope. Only those protons which are directly bound to the ^{13}C atom can be called "carbon bearing," in our way of speech; all the others are not.

ω_1-Decoupling in shift correlation[178] (P25) is achieved by a selective inversion of the passive protons after $t_1/2$, while the active protons are left unaffected.[178-180] This is done with the BIRD$_y$ sandwich. The necessary 180°(S) pulse gives with the 180°(S) decoupling pulse a 360° pulse, and hence can be left out. Homonuclear coupling between geminal protons is not refocused, since geminal protons are always both carbon-bearing. The same concept can be applied in the DEPT-COSY experiment.[305]



(P25)

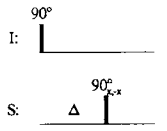
COLOC with Protonated Carbons

During the refocusing period Δ_2 in the COLOC experiment also the rapidly oscillating $^1J_{CH}$ couplings evolve with the amplitude $\cos\pi\,^1J_{CH}\Delta_2$. Even a small scatter in $^1J_{CH}$ will therefore have a strong effect on the transfer amplitude. The problem can be solved with a BIRD$_x$ pulse,[195] which inverts protons bound to ^{13}C. In this way the $^1J_{CH}$ couplings are selectively refocused in Δ_2,[194, 195, 306-308] while the long-range couplings remain unaffected.

The BIRD$_y$ pulse in t_1 of the COLOC experiment serves also to discriminate between $^2J_{CH}$ and $^3J_{CH}$ couplings in long-range correlations to proton-bearing ^{13}C nuclei (XCORFE[194]). The pair of wandering 180° pulses in the COLOC sequence is replaced by a BIRD$_y$ pulse. The latter has no effect on protons directly bound to ^{13}C (H^1 in the fragment ^{13}CH^1-^{12}CH^2-^{12}CH^3), as opposed to the other protons. Now protons H^2, which are coupled to H^1 and inverted by the BIRD$_y$ pulse, evolve $^3J_{H^1H^2}$ coupling. If this coupling is large enough, then splitting of the CH^2 cross signal is observed (doublet for ^{13}CH-^{12}CH^2, double doublet for ^{13}CH$_2$-^{12}CH^2, etc.). However, protons that are coupled to that carbon through $^3J_{CH}$ (e.g., in the fragment H^{12}C-^{12}C-^{13}CH$_n^1$) transmit to the corresponding proton H^1 only a negligibly small $^4J_{HH}$ coupling, which does not lead to measurable splitting.[194] In this way the coupling via two bonds can be discriminated from that via three bonds.

Low-Pass J-Filter

It is sometimes desirable, in correlation experiments involving long-range couplings as well as in relayed spectroscopy, to suppress direct I,S correlations, for they generally lead to strong cross signals and thus may interfere with weaker signals. $^1J_{IS}$ cross signals can be suppressed with the low-pass *J*-filter[303] (P26). For $\Delta=(2\,^1J_{IS})^{-1}$, pro-



(P26)

tons directly bound to ^{13}C appear after the 90° S pulse as I_xS_y or as $-I_xS_y$, depending on the pulse phase. Thus the magnetization of the I spin directly bound to the S spin is totally destroyed through addition. However, the magnetization of I spins that are coupled to S spins with long-range couplings is only slightly attenuated, by the factor $\cos^n\pi J_{IS}\Delta$.

Low-pass *J*-filters are easy to install in ^{1}H,^{13}C correlation experiments, since the $^1J_{CH}$ and $^nJ_{CH}$ coupling constants lie within narrow ranges. Details about the optimization of these filters can be found in Ref. [303]. They are used in heteronuclear relayed[303] and in COLOC spectroscopy.[197]

3.2.9. Composite Pulses

So far we have worked only with ideal pulses; for example, a 90° pulse should be exactly 90° for all of the nuclei of one type, should have no phase distortions, and should be of zero length. In real pulses there are complications due to off-resonance effects and B_1 inhomogeneity. Off-resonance effects arise because the chemical shift is not "turned off" during the pulse. As a result the magnetization rotates about a tilted field and by a greater angle than the nominal pulse angle. Inhomogeneities in B_1 arise from imperfect coils, which do not generate a constant field within a given volume, and outside this volume generate no field at all.

Composite pulses serve to remove these imperfections. The literature is quite extensive.[333] Yet, with the exception of decoupling and TOCSY sequences, composite pulses have rarely been used. We therefore limit the discussion to a few examples.

180° Pulse

The most common pulse is 90°_x-180°_y-90°_x.[309-327] It achieves an inversion of z magnetization over a large chemical-shift range, and is moderately sensitive to B_1 inhomogeneities. It is applied, for instance, in T_1 measurements of ^{13}C resonances and in shift correlations in the middle of t_1.

90° Pulse

The 90° pulse is substantially self-compensating against offset effects. Similar compensation against B_1 inhomogeneities is achieved through the sequence 90°_x-90°_y.[309,310] Note that this pulse is exactly one-half of the composite inversion pulse.

One must be careful in the construction of pulse sequences with composite pulses, since straightforward substitution of simple pulses by composite pulses does not lead to the goal. The reason is that these pulses introduce additional phases. An example of the construction of a pulse sequence with composite pulses can be found in Ref. [320]. Composite pulses with essentially no phase distortions, as well as pulses that compensate for both offset effects and B_1 inhomogeneities, are discussed in Refs. [312, 323, 326].

3.2.10. Heteronuclear Decoupling

Most of the heteronuclear experiments work with heteronuclear broadband decoupling during detection. The removal of the heteronuclear coupling leads to an increase in intensity, since the multiplet structure due to heteronuclear coupling collapses. The difficulty in broadband heteronuclear decoupling arises from the sometimes huge chemical shift range of the decoupled nucleus. Thus at 300 MHz, for instance, the proton shift range is ca. 3 kHz, whereas for ^{13}C it is 15 kHz and for ^{19}F approximately 60 kHz. On the other hand, the decoupler cannot operate at excessively high power levels because of heating of the sample. The main goal here is to find decoupling sequences which are, as much as possible, offset independent.

This goal is, to state it in a simple way, to keep the decoupled spin rotating in such a way that its α and β states are equally populated. The exchange between α and β states must be faster than the spin-spin interaction, since the multiplet structure (e.g., of a ^{13}C multiplet) depends on the fact that the α and β states of the coupled nucleus are well defined.

The first method introduced for heteronuclear broadband decoupling through stochastic modulation of the decoupler field[328] yielded good results. The decoupled spins are stochastically led around the unit sphere such that all of the orientations of the magnetization are equally probable.

Soon better methods were developed, utilizing composite-pulse decoupling sequences. The first of these sequences, MLEV with 16 composite pulses, uses the composite 180° pulse $(90^\circ_x\text{-}180^\circ_y\text{-}90^\circ_x)$[309,315] to achieve an inversion of the spins to be decoupled with as little as possible offset dependence. A sophisticated expansion[283,284] leads to compensation for imperfections of ever higher order. The band width of MLEV-16 is about $\pm\gamma B_2$, which is the strength of the decoupler field.

Another method, which is now generally used for decoupling of ^{13}C-NMR spectra, is WALTZ-16. Here, in contrast to the MLEV sequences, 90° pulses are permuted. The basic inversion pulse is $90^\circ_x\text{-}180^\circ_x\text{-}270^\circ_x$. WALTZ, like MLEV, has an offset range of $\pm\gamma B_2$. However, the scaling of the coupling is by far better. Precision measurements showed ^{13}C-NMR line broadening of only ca. 10 mHz.[329-321]. WALTZ is also significantly less sensitive to phase errors than MLEV.[333]

The GARP sequence[332] is particularly suitable for very large spectral ranges. It decouples over a range of $\pm 2.5\gamma B_2$, and can hence be applied, for example, for ^{13}C decoupling in proton-detected C,H experiments.

Ref. [333] provides a very good review of decoupling sequences.

3.2.11. Inverse Spectroscopy

All of the heteronuclear spectroscopic methods discussed so far involve the excitation of proton magnetization and the observation of heteronuclear magnetization. When one estimates the sensitivity of a given pulse sequence, there is a factor $\gamma_H(\gamma_X)^{3/2}$ in addition to the specific transfer function of the sequence. Inverse spectroscopy starts likewise with proton magnetization, but also detects proton magnetization, whereby $(\gamma_H)^{5/2}$ is obtained for the sequence-independent sensitivity factor. The factor is thus eight times greater in proton-detected C,H correlation than in conventional spectroscopy. It is, of course, even greater for heteronuclei with smaller γ, e.g., ^{15}N. This substantial gain in sensitivity makes inverse spectroscopy (sometimes called reverse spectroscopy) very attractive. In samples with small natural abundance, however, the suppression of proton signals from molecules without NMR-active heteroatoms is problematic. Thus for ^{13}C the suppression must be 1 to 200, and in ^{15}N 1 to 600. This places a severe stability requirement on the NMR spectrometer, which, when not met, leads to strong t_1 noise (see Appendix). We shall later show methods to suppress t_1 noise by the modification of the NMR experiment. Often, however, the problem can be solved by enrichment of the NMR-active heteronucleus.

Table 9 compares the relative sensitivities of the various detection methods. The first column gives the general signal-to-noise ratio (S/N), the second shows the resulting amplification factor. The last two columns show, for ^{13}C and ^{15}N measurements, respectively, the theoretical gain in intensity for inverse detection.

The most frequently used sequence (P27) is also the simplest one.

Table 9. Comparison of sensitivities of the various heteronuclear NMR experiments as a function of different excitations and detections.

Experiment	S/N	Amplification factor	^{13}C	^{15}N
a) Direct observation	$\gamma_X(\gamma_X)^{3/2}$		1.0	1.0
b) INEPT	$\gamma_H(\gamma_X)^{3/2}$			
compared with a)		(γ_H/γ_X)	4.0	9.9
c) Inverse INEPT	$\gamma_X(\gamma_H)^{3/2}$			
compared with a)		$(\gamma_H/\gamma_X)^{3/2}$	7.9	31.0

(P27)

We examine only the relevant operators for an $I_k S_i$ cross signal: the transverse proton magnetization following the first 90° pulse evolves homonuclear coupling during $(\Delta + t_1 + t_2$; chemical shift, however, is evolved only during $\Delta + t_2$. The proton network leads therefore to the transfer amplitude (115). This includes all the passive protons. So far the heteronuclear coupling was disregarded, although it is responsible for the cross peak. The active heteronuclear I_h, S_i coupling (J_{ih}) evolves during Δ and contributes a factor $\sin \pi J_{ih} \Delta$ to the transfer amplitude. During t_1 the 180° (I) pulse prevents evolution of heteronuclear coupling. Finally, during t_2 the J_{ih} coupling is refocused and contributes a factor $\sin \pi J_{ih} \Delta t_2$. Combination with Equation (116) leads to the final transfer amplitude (117). The multiplet pattern is like that in a 2D J spectrum

$$\prod_i \cos\{\pi J_{I_k I_i}(t_1 + \Delta + t_2)\} \cos\{\Omega_{I_k}(\Delta + t_2)\} \tag{115}$$

$$\begin{aligned} &I_{kz} \xrightarrow{90°_y} I_{kx} \xrightarrow{\Delta} 2I_{ky}S_{iz} \xrightarrow{90°_y(S)} 2I_{ky}S_{ix} \xrightarrow{t_1} 2I_{ky}S_{ix}\cos\Omega_{S_i}t_1 \\ &\xrightarrow{90°_y(S)} -2I_{ky}S_{iz}\cos\Omega_{S_i}t_1 \xrightarrow{t_2} +I_{kx}\cos\Omega_{S_i}t_1 \sin \pi J_{I_kS_i}t_2 \end{aligned} \tag{116}$$

$$\prod_i \cos\{\pi J_{I_k I_i}(t_1 + \Delta + t_2)\} \cos\Omega_{S_i}t_1 \cos\{\Omega_{I_k}(\Delta + t_2)\} \sin \pi J_{I_kS_i}t_2 \tag{117}$$

(phase-modulated in t_1). It is therefore impossible to obtain pure phases. In the ideal case, in which all of the coupling constants are sufficiently different from each other and greater than the line width, the pattern shown in Figure 37, left, is obtained for a CH^1-CH^2H^3 spin system. Figure 37, right, shows the corresponding pattern which would be obtained in a conventional spectrum.

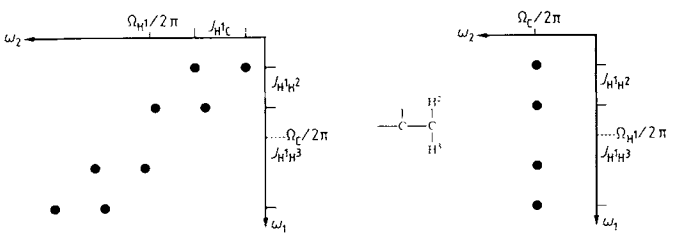

Fig. 37. Schematic representation of the multiplet splitting in the H^1-^{13}C cross signal of a CH^1-CH^2H^3 fragment in an inverse spectrum (left) compared with that in a conventional H,C-COSY spectrum (right).

A factor 4 in sensitivity is gained in the inverse C,H shift correlation; the factor 8 is not gained because the spectrum splits into twice as many lines, as can be seen in Figure 37 (eight lines instead of the four obtained in the usual H,C shift correlation). A factor 16 is obtained for the measuring time, since the sensitivity corresponds to the square root of the measuring time. Such factors in pulse sequences must always be taken into account when an exact comparison of sensitivities is attempted. Thus in the above example only the ^{13}C multiplicity of the protons (in this case 2) is of interest for the comparison of inverse/conventional shift correlation spectroscopy.

A further gain in sensitivity can be reached through the insertion of a refocusing delay after the second 90° S pulse, followed by heterospin decoupling. In this way the $^1J_{IS}$ coupling in ω_2 is removed and, in addition, a factor of 2 in sensitivity is gained. Thus the inverse heteronuclear shift correlation with a refocusing delay should be eight times more sensitive than the conventional shift correlation. This makes even proteins accessible to heteronuclear measurements.[53]

Presaturation of Protons Not Bound to NMR-Active Heteronuclei

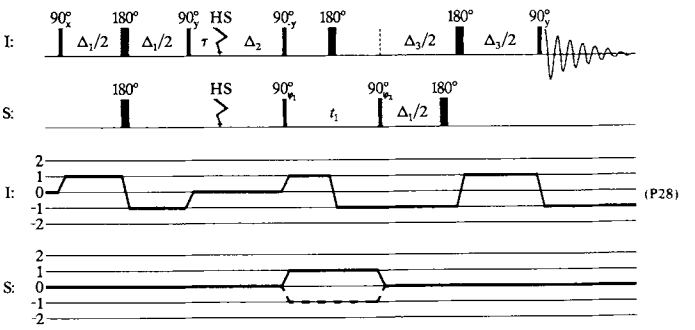
A BIRD pulse, which we described earlier in connection with conventional heteronuclear spectroscopy, finds an important use in inverse spectroscopy for reasons mentioned above. By installing a $BIRD_y$ pulse it is possible to eliminate the protons which are not bound to an NMR-active heteroatom. The $BIRD_y$ pulse inverts these protons, and after a delay period of $T_1^H \cdot \ln 2$ the signal due to these protons is minimal (passes through zero). If now the sequence for the inverse shift correlation is started, only coherences due to the protons bound to active heteronuclei are generated. Undesired signals are hence suppressed more effectively.[51] This procedure is only applicable for correlations through direct coupling.

Inverse Correlation through Long-Range Couplings

An increase of the delay Δ enables inverse correlations through heteronuclear long-range couplings. Obviously the common variants, like the low-pass J-filter, can be applied here as well.[196] Long-range couplings contain not only valuable information about constitution, but also about the molecular conformation.[334] Quantitative extraction of heteronuclear long-range coupling constants is possible for the first time with good sensitivity through the use of inverse spectroscopy.[335]

Inverse Relayed Spectroscopy

Relayed spectroscopy has also been successfully carried out in the inverse mode.[53] The suppression of signals due to protons that are not carbon-bearing happens as follows: after the excitation sequence $90°_y(I)$-$\Delta_1/2$-$180°(I,S)$-$\Delta_1/2$ the resulting antiphase magnetization $2I_xS_z$ is transformed by a $90°_y(I)$ pulse into longitudinal two-spin order $(-2I_zS_z)$. The remaining transverse proton magnetization is then destroyed by a homospoil pulse (HS, see Appendix), which results in extensive suppression of signals from protons which are not heteroatom-bearing. The overall pulse sequence is then (P28).



After a recovery period Δ_2 the sequence described in Equation (116) begins: the 90° pulses on both nuclei give rise to heteronuclear double-quantum coherence $(-2I_{1x}S_x)$, which is then labeled during t_1 with the chemical shift of the heteronucleus. This is transformed by the

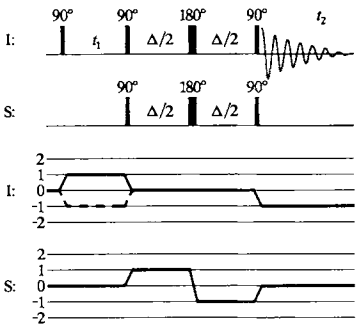
90°(S) pulse into antiphase magnetization ($2I_{1x}S_z$), which is refocused during Δ_1 to I_{1y}. During $t_1+\Delta_3+\Delta_1$ antiphase magnetization to another proton can evolve ($2I_{1x}I_{2z}$), whereby the last 90°_y(I) pulse generates a coherence transfer to the I^2 spin. With this pulse sequence a successful ^{13}C-NMR spectral assignment of a small protein was achieved.[53] This pulse sequence can be improved if the 90_{-y}(I) pulse is not set directly after Δ_2 but, instead, before the begin of the Δ_3 delay. Then the modulation of the signals by homonuclear coupling in t_1 disappears.

3.3. Homonuclear Correlations through Heterospins

The NMR experiments described in the following sections do not involve proton and heteroatom correlations, but correlations between protons which are, either singly or together, coupled to a heterospin. The experiments that fall in this category are essentially the X-Relayed H,H-COSY, as well as sequences like COSY, NOESY, and TOCSY combined with X-filter or X-half-filter.

3.3.1. X-Relayed H,H-COSY

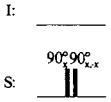
The oldest of these experiments is the X-Relayed H,H-COSY[220,221] (P29). It correlates protons in a fragment H-X-H. The magnetization is stepwise transferred from H to X and back to H. I-spin magnetization that evolved during t_1 is transferred to S magnetization by the two 90° pulses. The second I spin is activated through the heteronuclear coupling and finally the S magnetization is transferred to the I spin. Consequently the sequence detects a linear H-X-H coupling network. Application of this technique to ^{31}P-NMR spectra has been described in the literature.[220,221]



(P29)

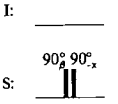
3.3.2. X-Filter and X-Half-Filter

Recently, the so-called X-filter and X-half-filter[151-153,336] (P30) have been introduced. They are building blocks which can be incorporated into any homonuclear pulse sequence. The purpose of the filter is to test at a given point in a pulse sequence whether or not a heterospin is involved in the product operator, and depending on the result either to suppress or to select cross signals. Note the similarity with the low-pass *J*-filter. Coherences with an S_z operator remain unchanged under 90°_x-90°_{-x}, but change sign under 90°_x-90°_x. Coherences without an S_z operator remain totally unaffected. Subtraction of two such sequences suppresses all of the coherences which do not contain S_z.



(P30)

The sequence (P31) is a generalized form. Product operators with nS_z operators are influenced as shown in (118).



(P31)

$$S_z^n \longrightarrow S_z^n \cos^n\beta \; + \text{ transverse terms} \qquad (118)$$

The spectra can be edited to produce subspectra which result from any desired number of S_z operators. Depending on the pulse phase β one obtains for different n values the different coefficients shown in Table 10, by which the corresponding transfer functions must be multiplied.

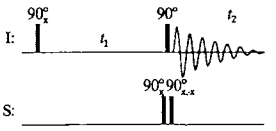
Table 10. Coefficients for different numbers n of S_z operators as a function of the phase β in the X-filter.

n	$\beta=0$	60	120	180
0	1	−8	8	1
1	1	−4	−4	1
2	1	−1	−1	1
3	1	−2	2	−1

In the following section we shall examine a series of useful sequences, in which the X-filter has been installed.

X-Filter COSY

In the sequence (P32) only protons that are coupled to a common heterospin should give rise to cross signals. The necessary coupling network is $\overset{\frown}{I^1\text{-}S\text{-}I^2}$. The X-filter is thus applied together with the mixing pulse. Heteronuclear antiphase terms evolve and refocus, respectively, during the evolution and detection periods. The transfer is similar to that of a conventional COSY experiment, except that heteronuclear coupling must be taken into account [Eq. (119)]. A 90°_x-90°_x (S) pulse during the mixing pulse inverts all the terms which contain an S_z operator.



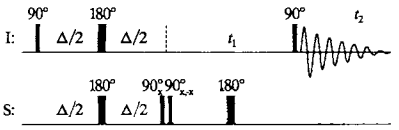
(P32)

$$I_{1z} \xrightarrow{90^\circ_x} I_{1y} \xrightarrow{t_1} -2I_{1x}I_{2x} - 4I_{1x}I_{2z}S_z \xrightarrow{90^\circ_y} 2I_{1x}I_{2x} + 4I_{1z}I_{2z}S_z \qquad (119)$$

If the subspectra for 90°_x-90°_x or for 90°_x-90°_{-x} are added, cross signals resulting from operators without heterospin are formed (i.e., the cross signals are in-phase with respect to the heteronuclear coupling). If, however, the subspectra are subtracted, only cross signals due to I spins that are coupled to a common S spin are obtained, since the terms without an S_z operator are eliminated. The heteronuclear coupling appears in antiphase. The spectrum is substantially simplified compared with the conventional spectrum, since now only a part of the total number of cross signals appears.

The X-filter can obviously be applied not only with a 90° mixing pulse, but with more complicated mixing sequences (MQF-COSY, E.COSY). The heteronuclear coupling is then present as antiphase splitting in the spectrum.

The pulse sequence (P33) selects the same type of coupling network. Here a fixed delay $\Delta=(2^1J_{IS})^{-1}$ serves to build up heteronuclear antiphase terms.[152] These are selected, such that at the beginning of t_1 only coherences of

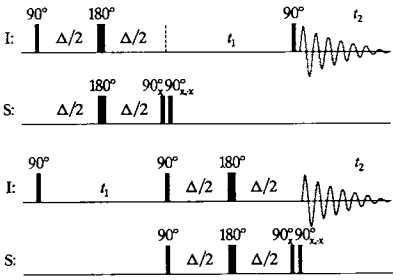


(P33)

S-bound I spins are present. Due to the 180° pulse in the middle of t_1, no heteronuclear coupling evolves, so that coherence of the type $2I_{1x}I_{2z}S_z$ is transformed by the 90° proton mixing pulse into $2I_{1z}I_{2x}S_z$. This coherence refocuses during t_2. The structural requirement is therefore again an $\overset{\frown}{I^1\text{-}S\text{-}I^2}$ system, with $J_{12}\neq 0$. The advantage of this realization of the X-filter is that during t_1 no multiplet structure develops due to the heteronuclear coupling, which would lead to a decrease in the signal-to-noise ratio.

X-Half-Filter COSY

If in the sequence (P33)[153,336] the 180° refocusing pulse in the middle of t_1 is left out, the heteronuclear antiphase magnetization can already refocus in t_1. This enables also spin systems of type $S\text{-}I^1\text{-}I^2$ to pass, and the X-half-filter is



(P34)

(P35)

obtained. The sequence for the (ω_1)-half-filter COSY is thus (P34). This filter can also be introduced at the beginning of t_2 instead of at the beginning of t_1, whereby the (ω_2)-half-filter COSY (P35) is obtained. The simultaneous 90° (S) pulse and 90° (I) mixing pulse serve to select, at the beginning of t_2, only product operators which do not contain heterospin components.

The X-filter and X-half-filter techniques find more and more use, mainly with very large proteins,[337] in which the resolution in conventional 2D NMR spectra is no longer sufficient. The better resolved heterospin resonances are used, or else the NMR-active isotope of the heteronucleus is selectively enriched, so that subspectra of the conventional spectrum are obtained, corresponding to certain subunits of the protein near the isotopic labels. We may expect further success in this area in the future, with the development of ever simpler genetic-engineering methods for the preparation of selectively enriched proteins.

3.4. Experiments Utilizing the Dipolar Coupling

3.4.1. NOESY

Dipolar relaxation and the NOESY experiment have already been discussed briefly. We return to them now in greater detail.

Quantitative Evaluation of NOE Information

Cross signals in a NOESY spectrum rely on the cross relaxation of longitudinal magnetization during the mixing period. The intensity of the signals (the integral) contains valuable information about internuclear distances.[338-344] The exact analysis shows that the cross relaxation rate σ, which determines the efficiency of the NOE transfer, is given (for an isolated two-spin system IS) by Equation (120). Thus the distance information (r) is built into the cross relaxation rate.

$$\sigma = W_2 - W_0 = \frac{\gamma_I^2\gamma_S^2\hbar^2\tau_c}{10r^6}\left(\frac{6}{1+(\omega_I+\omega_S)^2\tau_c^2}-\frac{1}{1+(\omega_I-\omega_S)^2\tau_c^2}\right) \qquad (120)$$

In order to determine the cross relaxation rate from the NOESY spectrum, one either studies the slope of the buildup of the NOE rates for $\tau_m=0$, the so-called "initial buildup rate" (by measuring NOE spectra for various mixing times), or one makes use of the linear approximation. In the second case it is assumed that during the selected mixing time τ_m the system is still linear, i.e., the intensity of the cross signals depends only on the cross relaxation rate. Recently attempts have been made to extract NOE values from a *single* spectrum without the initial rate approximation. These approaches consider multistep transfers, or even solve the entire relaxation matrix.[345-346]

With the aid of one known distance r_{kl} in a molecule (e.g., two protons in a CH_2 group) and the corresponding cross signal rate σ_{kl}, an unknown distance r_{mn} can be calculated from a measured rate σ_{mn} (where I_{kl} and I_{mn} are the intensities of the corresponding cross signals) [Eq. (121)], whereby it is assumed that the correlation times for

$$\sqrt[6]{\frac{I_{kl}}{I_{mn}}} = \frac{r_{mn}}{r_{kl}} \qquad (121)$$

reorientation, τ_c, for the various distance vectors are equal. This can be verified experimentally through ^{13}C relaxation times or steady-state values of the heteronuclear NOEs. A different way is the simultaneous evaluation of NOESY and ROESY, which permits the determination of τ_c and σ.[370]

Artifacts

The phase cycling in a NOESY experiment is set such that during the mixing time τ_m nonzero quantum coherences are filtered out. Zero-quantum coherences are not affected and thus are present in the NOESY spectrum just like the desired NOE cross signals. Let us examine their

$$I_xS_z \xrightarrow{90°_x} \tfrac{1}{2}(I_xS_y+I_yS_x) \xrightarrow{\tau_m} \tfrac{1}{2}(I_xS_y+I_yS_x)\cos(\Omega_I-\Omega_S)\tau_m \xrightarrow{90°_x} \tfrac{1}{2}(I_xS_z+I_zS_x)\cos(\Omega_I-\Omega_S)\tau_m \qquad (122)$$

fine structure as represented by the product operator description [Eq. (122)]. Zero-quantum coherences precess in τ_m and finally lead to dispersion signals with double antiphase structure in the spectrum. Although their integral is zero, they can nevertheless interfere with the integration of cross signals.

Suppression is most successful when a 180° pulse is applied in the mixing period. This pulse is shifted within the constant mixing

time. τ_m thus becomes $\{\Delta/2\text{-}180°\text{-}(\tau_m\text{-}\Delta/2)\}$. The pulse refocuses zero-quantum coherences, so that they evolve with $\cos(\Omega_I-\Omega_S)(\tau_m-\Delta)$. Random[347] or also systematic[93] variation of Δ suppresses the zero-quantum coherences, because the argument of the cosine assumes positive or negative values, depending on Δ, and thus the terms average out. Since in this experiment the mixing time remains constant, no additional t_1 noise is introduced, in contrast with the random variation of τ_m.

Another possibility is to shift the zero-quantum coherence or to split it. If τ_m is incremented synchronously with the evolution time by κt_1, then the zero-quantum coherences give a signal which is modulated by $\cos(\Omega_I-\Omega_S)\kappa t_1$. These signals are placed at $\Omega_I \pm (\Omega_I-\Omega_S)\kappa$ in ω_1, rather than at Ω_I, and are thus shifted out of the region of interest through this procedure.[348]

3.4.2. *Longitudinal Multiple-Spin Orders*

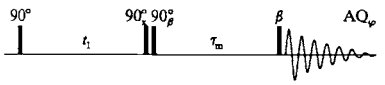
Through the use of 90° mixing pulses in the NOESY experiment, exclusively z magnetization is generated. Operators with more than one z operator cannot be formed from transverse magnetization by 90° pulses. The situation is different when pulses with small flip angles are used. In this case also $2I_{1z}I_{2z}$ operators can be generated from $2I_{1x}I_{2z}$ by a y pulse. This so-called longitudinal multiple-spin order is the cornerstone for several pulse sequences.

zz Spectroscopy

Longitudinal two-spin order can be used to distinguish between certain exchange and cross relaxation signals, as well as between inter- and intramolecular NOEs.[127, 128] Through phase cycling only those cross signals are selected which correspond to the conversion of the operator $2I_{1z}I_{2z}$ to $2I_{3z}I_{4z}$. The spins I^3 and I^4 must likewise be coupled with scalar coupling, like, for instance, for cross signals generated by chemical exchange.

The selection of zz operators (product operators with an even number of z operators) can be achieved by the application of a 180° pulse in every second scan. The resulting signals are added together. Operators with an odd number of z operators are inverted, whereas zz operators are not.

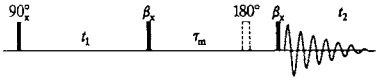
Another possibility for the selection of zz operators is the use of a particular phase cycle with the pulse sequence (P36). Here β equals $45°+n90°$ and the receiver phase is 2β.



(P36)

zz-COSY

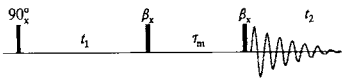
The pulse sequence is the same as in zz spectroscopy. However, in zz-COSY one is only interested in the "COSY"-type cross signals which are formed in zz spectroscopy; hence τ_m is set correspondingly short. zz Operators are selected as above. The transfer efficiency is $\frac{1}{4}\sin^2 2\beta$; i.e., $\beta=45°$ corresponds to the maximum intensity, which is, however, only one-quarter of that of a conventional COSY experiment. The sequence is nevertheless useful, for it offers an effective method for suppression of water signals.[129] By applying a homospoil pulse the undesired transverse magnetization of water is destroyed. The remaining longitudinal magnetization is suppressed, since it cannot evolve into longitudinal multiple-spin order. The pulse sequence is (P37).



(P37)

z-COSY

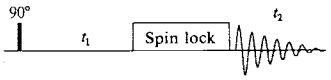
We mentioned this sequence earlier (Section 3.1.4) in connection with the E. COSY technique. By using β pulses as flanking pulses for a z-filter one obtains cross signals with E. COSY-like multiplet structure. If the z-filter (P38) is made long enough to permit cross relaxation, it is possible, in ideal cases of coupled spin systems, to separately observe the W_0, W_1, and W_2 rates between two spins.[130]



(P38)

3.4.3. *ROESY*

We mentioned earlier (Section 2.2.2) that unfavorable correlation times may lead to $W_2-W_1=0$, and hence to a situation in which there is no cross relaxation. The solution for these cases is provided by the CAMELSPIN experiment,[198] introduced by *Bothner-By* et al., which we shall term ROESY after a suggestion by *Bax*.[199] The mixing in the ROESY experiment (P39) is done in a spin-lock period.



(P39)

NOESY relates to the mutual cross relaxation of z magnetization. In ROESY, transverse components cross-relax, which are prevented by the spin-lock field from precessing about the z axis. For magnetization which is locked along the x axis, for instance, one finds the relaxation rates (123)–(125) for a two-spin system.[77, 198, 202] In contrast to

$$W_1 = \frac{3}{40}\frac{\gamma_I^2\gamma_S^2\hbar^2\tau_c}{r^6}\left(\frac{1}{1+\omega^2\tau_c^2}+\frac{1}{1+4\omega^2\tau_c^2}\right) \quad (123)$$

$$W_0 = \frac{3}{40}\frac{\gamma_I^2\gamma_S^2\hbar^2\tau_c}{r^6}\left(\frac{1}{3}+\frac{1}{1+4\omega^2\tau_c^2}\right) \quad (124)$$

$$W_2 = \frac{3}{40}\frac{\gamma_I^2\gamma_S^2\hbar^2\tau_c}{r^6}\left(3+\frac{4}{1+\omega^2\tau_c^2}+\frac{1}{1+4\omega^2\tau_c^2}\right) \quad (125)$$

$$W_2 - W_0 = \frac{\gamma_I^2\gamma_S^2\hbar^2\tau_c}{10\,r^6}\left(2+\frac{3}{1+\omega^2\tau_c^2}\right) \quad (126)$$

NOE, the ROE is always positive (negative cross signals with respect to the diagonals). This is shown in Figure 38, which gives a graphic representation of the maximum NOE and ROE as a function of the correlation time τ_c in a two-spin system.

In addition, the ROE build-up rates are always (except for $\tau_c=0$) greater than the NOE rates, as shown in Figure 39. However, the time for which the linear approximation is valid is also shorter than in NOESY.

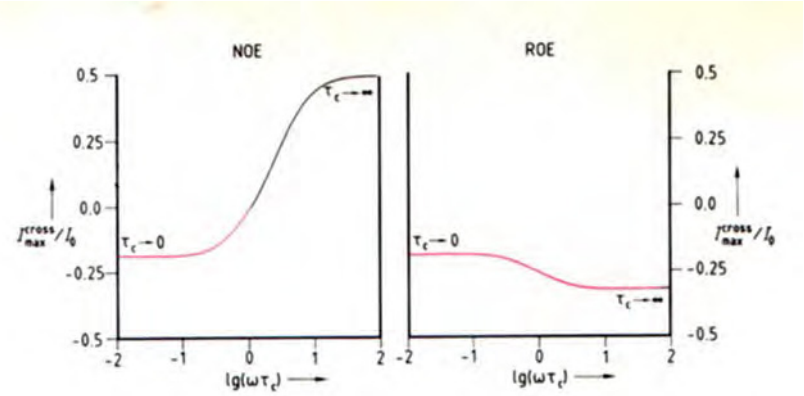


Fig. 38. Maximum intensity I_{max}^{cross} of a cross signal in 2D NOESY and 2D ROESY spectra for a two-spin system, normalized for I_0, the intensity of a diagonal signal with a mixing time $\tau_m = 0$. In the NOESY spectrum the intensity of the cross signal at $\tau_c \to 0$ is ca. 20% of that of a diagonal signal, it vanishes at $\omega_0 \tau_c = 1$, and reaches 50% of the diagonal signal intensity for $\tau_c \to \infty$. In the ROESY spectrum, in contrast, the maximum intensity is about 20% for $\tau_c \to 0$, and ca. 34% for $\tau_c \to \infty$.

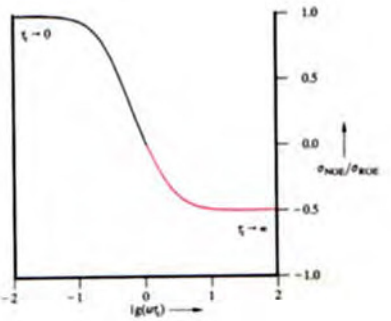

Fig. 39. The relation of the cross relaxation rates σ in a 2D NOESY and a 2D ROESY spectrum. For $\tau_c \to 0$ the rates are equal. Otherwise σ_{ROE} is always greater than σ_{NOE}.

The quantitative evaluation of ROESY spectra[349] is similar to that of NOESY spectra. When the correlation times are near the value $\tau_c \approx (5/4)^{1/2}/\omega_0$, the intensities of NOESY signals are small and can therefore be determined only inaccurately. In addition, cross-peak intensities are very sensitive to different individual correlation times within the same molecule. This can easily lead to errors in the interpretation of molecular distances. In the ROESY experiment, in comparison, this effect is less significant, due to the smaller τ_c dependence of the intensity of the cross signals. The lock field must be weak in order to avoid contributions to the spectrum from transfer through scalar coupling. These contributions are stronger near the diagonal and near the counterdiagonal. A reasonable recommended value is a lock field of the order of one-half of the spectral width [Eq. (127)]. For a quantitative evaluation

$$\gamma B_1 \approx \frac{SW}{2} \qquad (127)$$

one must take into account the ROE dependence on the distance of the resonance from the lock frequency (offset effect).[202]

The spin lock can equally well be generated by a CW irradiation with low power or by a series of pulses $(\beta\tau)_n$. β should be set as small as possible[201] and τ is calculated from Equation (128), where β is given in radians and τ_β is the β pulse length in seconds.

$$\frac{2\pi\beta}{(\tau+\tau_\beta)} = \gamma B_1 \qquad (128)$$

In an improved version with higher sensitivity, 90° pulses are applied before and after the spin-lock period.[202]

3.4.4. *Relayed NOESY*

The combination of NOESY and relayed-pulse sequences is of some significance.[228] Like in the other relayed experiments, one often achieves through the relayed transfer an unequivocal assignment of NOE cross signals in overcrowded spectral regions. The introduction of a double-quantum filter (P40) after the relayed transfer can be useful in order to filter out the (now dispersive) diagonal signals.[229]

(P40)

A second possibility with slightly different spectra is offered by the antisymmetrized pulse sequence.[230,231] The pulse sequence shown above is identical with the NOESY sequence up to the third 90° pulse, which precedes the relayed transfer period. It thus generates in ω_1 absorptive in-phase signals, modulated by the chemical shift of the first spin. After t_1, however, the magnetization is transferred through dipolar coupling to a second spin (NOE transfer), and then transferred again through scalar coupling to a third spin (relayed transfer). Antiphase magnetization of the third spin is thus detected in t_2. Therefore the signal in ω_2 is antiphase. It should be further noted that the spectrum is also asymmetric with respect to the position of the cross signals.[231]

The combination of TOCSY and ROESY (P41) has become particularly useful for medium-sized molecules. It is easily achieved through variation of the mixing se-

(P41)

quence[232] (e.g., 30 ms TOCSY with MLEV-17, followed by 170 ms of a series of pulses with small flip angles). The short TOCSY transfer provides COSY-type in-phase correlations (the transfer goes preferentially via one coupling), which can be used directly for the ROE transfer. The asymmetry of the spectrum directly provides, for example in the NH region of peptides, both the sequence and its direction even when the α-proton region is not resolved. For larger molecules the TOCSY-NOESY combination can be applied.[233]

3.5. Exchange Spectroscopy

A different possibility for the transfer of magnetization from one spin to another is offered by chemical exchange. Two isomers or topomers[102, 103, 350] must exchange moderately rapidly in a chemical equilibrium. Depending on the rate of exchange, either separate sets of signals (slow exchange) or one set of average signals (fast exchange) may be observed in the NMR spectrum. The variation in line shapes in the intermediate region serves to determine the exchange kinetics.[107, 108, 111, 113, 114, 351] In the slow exchange range polarization can be transferred from one site to the other (e.g., saturation transfer[352]). The NOESY and ROESY sequences[353, 354] can be used to determine such exchange processes. The advantage of the 2D NMR technique is straightforward: mutual assignments can be compared,[355, 371] exchange mechanisms are immediately visible,[356–358] and quantitative evaluations are possible.[359, 360] Cross signals due to chemical exchange, as well as those due to negative NOE effects (large molecules, viscous solvent, low temperature, high field), have the same sign as the diagonal signals in spectra with pure phases. In NOESY spectra of small molecules in low-viscosity solvents (positive NOE effects), and in *all* ROESY spectra, exchange signals[361–362] as well as NOEs[201, 363] over several nuclei are readily distinguished from direct NOE cross signals due to the different signs.

An example is shown in Figure 40. This proline-containing cyclic hexapeptide exchanges between two conformations, in which the proline amide bond is either in the *trans* or *cis* configuration. The exchanging NH signals of the two conformations are correlated by positive (black) cross signals (with respect to positive diagonals), while the negative (red) signals represent NOE in the rotating frame (ROE).

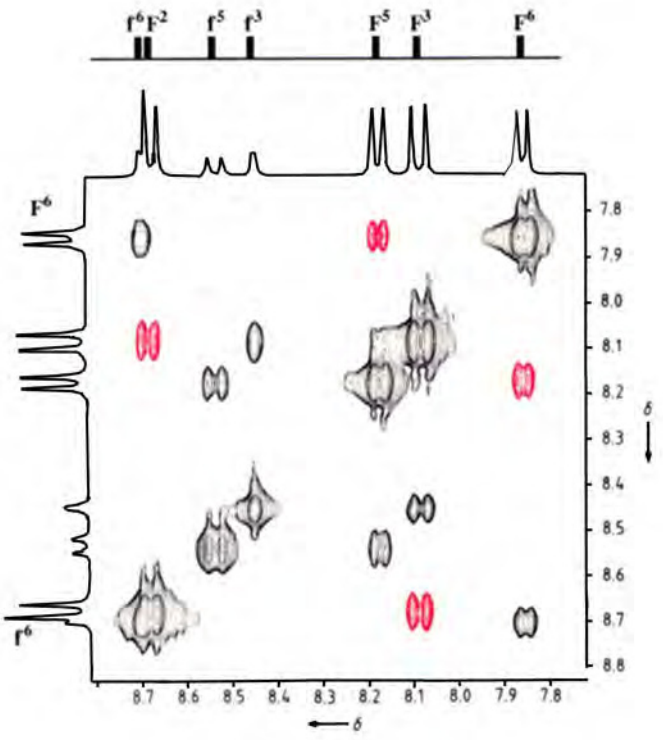

Fig. 40. Section from a 300-MHz ROESY spectrum of *cyclo*(-D-Pro^1-Phe^2-Phe^3-Pro^4-Phe^5-Phe^6-) in [D_6]DMSO, 320 K, β pulse angle 24°, mixing time 200 ms. The molecule is present in two conformations. The exchange between them is evident from the positive cross signals (black). NOE effects between NH signals give rise to negative (red) cross signals (F^2–F^3 and F^5–F^6). Phenylalanine = F, f (the major isomer is labeled with capital letters).

3.6. Further 2D NMR Experiments

A number of additional 2D NMR experiments are obtained by combinations of the techniques discussed above. Variants of these can be created by the introduction of filters,[364] pulse sandwiches, various decoupling schemes, and similar means, and are frequently found in the literature. Conversions of homonuclear techniques into heteronuclear experiments have also been realized (e.g., hetero-TOCSY[185, 186]). Furthermore, photochemical excitation has also been successfully associated with nuclear magnetic resonance (photo-CIDNP).[256, 257]

Recently, a series of 1D variants of 2D NMR techniques have been introduced[210] through the use of semiselective pulses with programmed line shapes, which, for simple problems, open novel aspects. The introduction of semiselective pulses into 2D[251, 335, 372] and 3D NMR spectra[253–255] opens yet another branch for methodological research. A more detailed description of these newest developments would, however, range beyond the scope of this article.

4. Conclusion

In this article we have laid the theoretical foundations for the most important 2D NMR experiments. Thus we now have at our disposal the tool which should enable useful application of these techniques, even though not all of the possible variants could be fully treated. The goal of this article has been to review today's most widely used techniques and to provide experimentalists with the necessary understanding of the theory, so that they can be in a position to:

- select the right experiment for their problem,
- select and set the optimal delays and phase cycles which are most suitable for their particular problem, and
- recognize artifacts in the spectrum and possibly avoid or minimize them.

Thanks to many discussions with various colleagues and the co-workers of our group the manuscript has been considerably improved. However, we especially acknowledge Prof. Dr. D. Kost, Beer Sheva, Israel, for his stimulating discussions and his contributions during the translation into English. Some of the figures were kindly provided from our coworkers U. Anders (Fig. 32), Dr. H. Kogler (Fig. 35), K. Wagner (Fig. 40), and M. Will (Figs. 24, 25, 31, 33). Financial support for the scientific results of our laboratory was provided by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. C. G. thanks Prof. Dr. R. R. Ernst, Zürich, for support.

Appendix 1

Important concepts and abbreviations used in the text:

ω_1	The first frequency domain in a 2D NMR spectrum, obtained by Fourier transformation in t_1
ω_2	Second frequency domain
1D	One dimensional
2D	Two dimensional
Acquisition, AQ	Reception of the NMR signal; in 2D NMR experiments it takes place during the time t_2
Antiphase	Multiplet structure with opposite phases; the multiplet lines change signs
$\boldsymbol{B}_0$	Static magnetic field, oriented along the z axis according to convention
$\boldsymbol{B}_1$	Generally an additional transverse magnetic field, used for instance for pulses
$\boldsymbol{B}_2$	Another magnetic field, used for decoupling sequences, spin lock, etc.
"Band-pass filter"	Filter for the selection of a specified coherence order p
BB	Broadband decoupling of a spin type. Used in heteronuclear experiments to destroy the magnetization of one of the spin types, and generally employed during acquisition time. Nowadays commonly achieved through highly developed composite pulse sequences
$\boldsymbol{B}_{\text{eff}}$	Effective magnetic field, caused by the electronic environment around the nucleus (chemical shift). Often also: the residual field in the rotating frame, generated in cases of incomplete decoupling
Carrier frequency	ω_0, Transmitter frequency of the high-frequency pulses
Chemical shift	The difference in precession frequencies between a nucleus and the carrier frequency. It is often referred to a standard and divided by the carrier frequency (in ppm)
Coherence	Corresponds to a transition between two eigenstates and is an extension of the expression "transverse magnetization," which relates only to allowed transitions. From a quantum mechanical point of view a coherence corresponds to an off-diagonal element in the spin density matrix
Coherence order p	The difference in magnetic quantum numbers Δm_z of two energy levels which participate in the same coherence (e.g., zero-quantum coherence, single-quantum coherence)
Coherence transfer	Transfer of coherence from one nucleus type to another
Coherence-transfer pathway	Progress of a coherence order in a pulse sequence
Composite pulse	A pulse composed of a number of pulses. It is employed in order to compensate for phase errors, $\boldsymbol{B}_1$ field inhomogeneities or offset effects
Constant time	In constant-time variants of NMR experiments, the total duration of each t_1 experiment is constant, since t_1 is limited by pulses within a fixed delay
Convolution	A mathematical operation $F*G=\int_{-\infty}^{+\infty} F(x-y)G(y)\,dy$ Its significance for NMR spectroscopy results from the following relation: $F*G=\mathcal{F}(f\cdot g)$, whereby $\mathcal{F}(f)$ is the Fourier transform of f. That is, the Fourier transform of a product of two functions equals the convolution of the Fourier transforms of the functions
Correlation time	The correlation time τ_c is the mean time required for a rotation of a molecule. It is responsible for relaxation
Cross relaxation	Describes the mutual relaxation (inter- or intramolecular) of magnetically active nuclei, for instance through dipolar relaxation
Density matrix	Describes the state of a quantum mechanical object
Dipolar coupling	A through-space interaction between two spins. It is orientation dependent, and averages out in solution due to rapid reorientation of the molecule. Responsible for relaxation and NOE
DQF	Double-quantum filter
Editing	By setting a few parameters in a pulse sequence (e.g., pulses, delays), a set of subspectra is obtained, which deliver different information, for instance about multiplicities of signals (like subspectra for ^{13}CH, $^{13}CH_2$, and $^{13}CH_3$)
FID	*F*ree *I*nduction *D*ecay of the NMR signal
Flip angle	The angle by which the magnetization vector is rotated
Folding	Used in connection with Fourier transformation. Folding about $\omega_1=0$ means $S_f(\omega_1,\omega_2)=S(\omega_1,\omega_2)+S(-\omega_1,\omega_2)$

Fourier transformation	A mathematical method which determines the frequencies contained in a time-dependent function. The Fourier transform $F(\omega)$ in a complex Fourier transformation is given by $F(\omega) = \int_{-\infty}^{+\infty} e^{-i\omega t} f(t)\,dt$ and in a real Fourier transformation by $F(\omega) = \int_{-\infty}^{+\infty} f(t)\cos(\omega t + \varphi)\,dt$
"High-pass filter"	Filter for the selection of coherence orders $\geq p$
Homospoil pulse, HS	A pulse which generates short-time field inhomogeneities. Serves to eliminate undesired coherences (transverse magnetizations)
In-phase	Multiplet structure with equal phase, multiplet lines do not change signs
Inverse techniques	Heteronuclear experiments which detect the heteronucleus indirectly through proton magnetization. Also called "reversed techniques"
Longitudinal magnetization	Magnetization along the $\boldsymbol{B}_0$ field, i.e., along the z axis
Long-range coupling	Scalar coupling over several bonds
"Low-pass filter"	Filter for the selection of coherence orders $\leq p$
Multiplicity	The splitting of NMR signals by scalar coupling into doublets, triplets, etc.; in ^{13}C-NMR spectra it is also used synonymously to describe the large splitting through direct coupling in order to distinguish quaternary ^{13}C nuclei, CH, CH_2, and CH_3 groups
NOE	*N*uclear *O*verhauser *E*nhancement. An intensity change of an NMR signal induced by another nucleus in a nonequilibrium state. It is caused by dipolar coupling
Peak	Signal in an NMR spectrum; also used for a part of a multiplet
Phase cycle	Pulse sequences used for NMR spectra are mostly combinations of sequences which differ from one another only in the phases of the individual pulses. Systematic variation of the phases constitutes the phase cycle which suppresses unwanted coherences and artifacts
Polarization	It is based on the population difference of energy levels. A polarization must not always be connected with magnetization
Polarization transfer	Transfer of polarization from one nucleus type to another: it is often used synonymously with coherence transfer, even if coherences are transferred
Precession frequency	Larmor frequency ω of the nucleas precessing about the z axis. In the rotating frame it describes only the difference frequency Ω_i from an individual Larmor frequency of the nuclei $\omega_i = \gamma \boldsymbol{B}_{eff}$ and the carrier frequency $\omega_0 = \gamma \boldsymbol{B}_0$
Product operator	Set of orthogonal operators which can be connected to each other by a product
Product operator formalism	Formalism to describe NMR experiments (see extensive explanation in the text)
Pulse	Application of an additional high-frequency magnetic field with a carrier frequency ω_0 for a short time interval
Pulse sequence	Carefully designed series of radio frequency pulses and times of free evolution (delays) with subsequent detection of the produced transverse magnetization
Quadrature detection	A procedure for the detection of NMR signals which allows discrimination of signs of frequencies (in contrast: one-channel detection)
ROE	*R*otating frame N*OE*. NOE caused by relaxation in the rotating frame $T_{1\rho}$
Rotating frame	Frame rotating at frequency ω_0; simplifies the description of pulses and periods of free precession
Scan	A single running of an NMR experiment
Scalar coupling	Mutual interaction between two spins, which is transmitted through chemical bonds. Also called *J* coupling. It is scalar, i.e., independent of the orientation, and yields the multiplet splittings of the NMR signals
t_1	Evolution time. Incremented time in a 2D NMR experiment. Yields after Fourier transformation the first frequency domain
t_2	Detection time, generates after Fourier transformation the second frequency domain
t_1 noise	Noise which appears in 2D NMR spectra parallel to the ω_1 axis, and is particularly visible where there are intense signals in the spectrum. It is mostly due to technical factors associated with the instrument such as random variations of phases, pulses, temperature, $\boldsymbol{B}_0$ inhomogeneity
Thermal equilibrium	A state in which the energy levels are populated according to the Boltzmann distribution: $p(E_i) = e^{-E_i/kT} / \sum_i e^{-E_i/kT}$
Tilting	Transformation of a spectrum by $\omega_1' = \omega$, $\omega_2' = \omega_2 + k \cdot \omega_1$
TQF	Triple-quantum filter

Transverse magnetization	Magnetization in the x,y plane
Transverse operator	Designates I_x or I_y
Weak coupling	J coupling constant for the coupling between two spins is small compared with the difference of their chemical shifts; it causes first-order spectra
Zero-filling	Addition of zeros to the FID in order to improve the digital resolution

The Cyclopropyl Group in Studies of Enzyme Mechanism and Inhibition

By Colin J. Suckling*

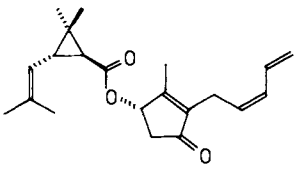
The cyclopropyl group—particularly in compounds such as cyclopropylmethanol, phenylcyclopropylamine, and cyclopropanone hydrate—has proved to be very useful in the study of enzyme reactions. Whether the cyclopropane ring is opened to form a radical or remains intact can provide much information about reactions occurring at the active site.

1. Introduction

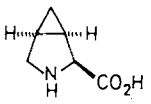
One of the most significant developments in the field of bioorganic chemistry in the last ten years has been the symbiosis of studies of the mechanisms of action of enzymes and the design of specific enzyme inhibitors.[1,2] Increasing pressures for specific drugs have encouraged rational approaches to drug design based upon mechanistic arguments and one of the most attractive of these approaches is the design of enzyme-activated inhibitors. Highly specific action at the site of the target enzyme is in principle assured if one can design a drug that is inactive until it encounters the target enzyme, which activates it, thus causing inhibition. One route to designing such biologically active compounds lies in selecting a small, inert functional group that can be modified into a reactive species either by undergoing a transformation itself or through the effect of an altered neighboring group. For example, haloethenyl substituents have been introduced into phenylethylamines to generate inhibitors of amine oxidases and some compounds have great promise as drugs for the treatment of Parkinson's disease.[2a] Similarly, halomethyl groups can lead to potent and selective enzyme inhibitors with potential as antibacterial agents.[2b] This review concerns a further group with this potential, the cyclopropyl group. The intrinsic chemistry of cyclopropane-containing compounds has been of great general interest for many years, but it is only relatively recently that the bioorganic chemistry of cyclopropanes has been extensively explored. The following discussion surveys firstly the scope of cyclopropanes and related small rings in natural product and enzyme chemistry followed by the chemical properties of cyclopropanes relevant to inhibition and mechanistic studies. The third part of the review deals with the interactions of enzymes and cyclopropanes.

1.1. Cyclopropanes in Natural Products

The inherent strain in the cyclopropane ring has not prevented the widespread occurrence of cyclopropane-containing natural products. In many cases, such rings are stable entities and are substructures of molecules at the ends of biosynthetic pathways. For example, many fatty acids, terpenes, and steroids are alkyl cyclopropanes. An especially significant example is pyrethrin **1**, which is the basis of an important series of insecticides.[3] There are equally significant examples, however, in which the reactivity of the cyclopropane is essential for a particular biosynthetic transformation. The conversion of farnesyl pyrophosphate into squalene via presqualene can be understood in terms of a rearrangement reaction of a cyclopropylalkyl cation.[4] A number of cyclopropyl amino acids are known and several have toxic properties;[5] the toxicity of such compounds can often be related to enzyme inhibition (see Section 4). In contrast, 1-aminocyclopropanecarboxylic acid is well known to be the biosynthetic precursor of ethylene, a hormone involved in the ripening of fruit, and has been



1

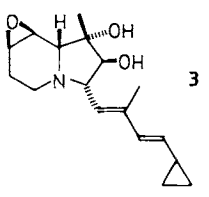


2

isolated from many organisms. The stereochemical details of many of its biosynthetic transformations have been elucidated[6] and there is evidence to implicate the ring opening of cyclopropylammonium radical cations in the biosynthesis.[7a] An ingenious application of the ring opening of cyclopropylalkyl radicals has been shown by *Pirrung* et al. to lead to inhibition of ethylene biosynthesis (see Section 4).[7b] The bicyclic amino acid methanoproline **2** is an inhibitor of proline biosynthesis in plants and can promote sterility in pollen, a feature which has application in the maintenance of true breeding strains of F1 hybrids.[8]

1.2. Unreactive Cyclopropanes

There are several cases of nonnatural cyclopropane-containing compounds in which the small ring is inert but provides a convenient molecular framework to ensure a good match of the compound to its receptor. For example, in



3

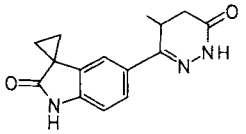
pyrethroids there is no evidence to suggest that a chemical reaction of the cyclopropane ring is important in insecticidal activity.[3] Fatty alcohol esters of cyclopropanecarboxylic acid have shown to be miticidal agents,[9] again without apparent reactivity in the ring. The active feature of the antibiotic cyclizidine **3** is thought to reside in the indolizidine ring system and not the cyclopropane.[10] *O'Leary* et al. found that 1-hydroxycyclopropanecarboxylic acid phosphate is a reversible inhibitor of enzymes that act upon pyruvate enol phosphate.[11] Presumably in this case, the inhibitor presents the enzymes with a very close geometric match when compared with the substrate. The importance of small groups such as cyclopropanes in providing conformational control of molecules can also be illustrated by its use in investigations of the conformational requirements of the highly flexible neurotransmitter GABA (γ-aminobutyric acid).[12] Such studies are obviously relevant to the design of selective drugs and many compounds containing cyclopropanes have been shown to have biological activity. In some cases, the small ring appears to serve the function of providing favorable binding interactions as a small, rigid alkyl group[13–15] and this may also be the case for a number of compounds with reported central nervous system (CNS) activity.[16] These compounds contain cyclopropyl pyridines and cyclopropyl ketones, structures which would be expected to have reactivity at enzyme sites (see Section 5). The same can be said about several other drugs[17,18] including antimineralocorticoids[19] and antiandrogens.[20]

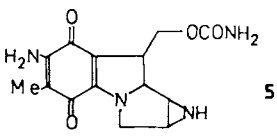
Cyclopropane-containing compounds with potent biological activities continue to appear. For example, **4** is an inotropic agent that is a competitive inhibitor of cAMP phosphodiesterase.[133]



4

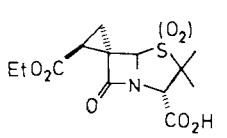
1.3. Cyclopropanes and Other Small Rings

The context in which cyclopropane reactivity can be best discussed in terms of biological activity is completed by comparison with small heterocycles. In these compounds, the ring strain is supplemented by the polarization of bonds caused by the heteroatom, leading in many cases to extremely high reactivity and toxicity. For example, aziridines are formed in reactions of β-haloamines, which are components of many drugs (the so-called nitrogen mustards) used in cancer chemotherapy.[21] The naturally occurring antitumor drug mitomycin **5** contains an aziridine

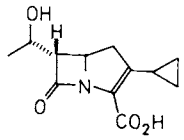


5

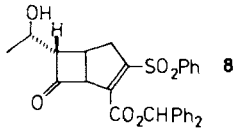
that has been implicated in its cytotoxicity.[22] Aziridine-containing amino acids are also known but no enzyme-inhibiting activity of their peptides has been described.[23] Similarly, thiiranes ("epithio derivatives") have high biological activities, exhibited originally in mustard gas[24] and more recently suggested to be responsible for the mutagenicity of 1,2-dihaloethanes through conjugation with glutathione.[25] Epoxides, too, can be used in cancer chemotherapy and they are commonly encountered in enzyme inhibitors.[26,27] Biological activity is not exclusive to three-membered heterocycles. β-Propiolactone was once regarded as a disinfectant but its mutagenicity has limited its use. The most extensively researched area of biologically active small heterocycles, of course, is that of the β-lactam antibiotics. Although it was once thought that the strain in the ring was an important contributor to biological activity, it is now generally accepted that the ability of a β-lactam to acylate its target enzyme is principally a function of the properties of the leaving amino group;[28] in other words, electron-withdrawing groups in the five-membered ring promote activity. Interestingly, a few β-lactams containing cyclopropyl substituents have been reported (e.g., **6** and **7**), but no biological activity attributable to the cyclopropane ring has been described.[29] A number of attempts have been made to prepare antibacterial compounds similar to β-lactams but containing cyclobutanones as the reactive group.[30] The comparison with cyclopropanones is interesting (see Sections 2.2 and 4). However, only in one case (**8**) in which analogues of thienamycin were prepared has antibacterial activity been reported.[30e]



6



7



8

2. The Chemical Reactivity of Cyclopropanes

2.1. The Cyclopropane Ring

The acute angles of the three-membered ring in cyclopropanes are obvious sources of ring strain and, in addition, all of the carbon–hydrogen bonds are eclipsed. Together, these factors contribute to a strain energy of 117.6 kJ mol^{-1}.[31,32] The thermodynamic driving force for ring opening is thus great and many of the common reactions of cyclopropanes are addition reactions that parallel those of alkenes: for example, addition of halogen to yield 1,3-dihalides and catalytic hydrogenation to afford alkanes.[32] In common with most vinyl and aryl C–H bonds, the C–H bonds of cyclopropane are strong, which accounts for the lack of radical reactions occurring through hydrogen abstraction pathways. In parallel with reactions of electrophiles, radical reactions tend to lead to net addition to the cyclopropane ring.

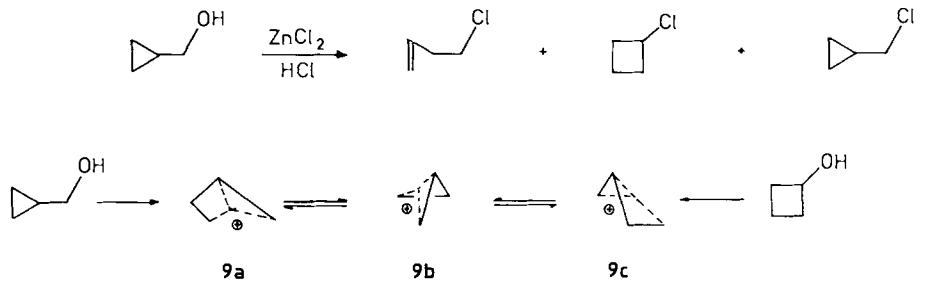


Fig. 1. Cationic rearrangements of cyclopropylmethyl derivatives via cations **9a–c**.

The description of cyclopropanes as homo-alkenes parallels that of epoxides as homo-carbonyl groups and has led to many descriptions of the bonding in cyclopropane. For example, the valence bond treatment generates a bonding picture that includes so-called bent or banana bonds which, because of the nature of the overlap of the component orbitals, have some π character.[33] Alternatively in a description due to *Walsh*,[34] the π character arises from the overlap of centrally pointing p orbitals.

2.2. Cyclopropanones

As will be discussed in Sections 4 and 5.1, cyclopropanones and their imino derivatives have figured greatly in studies of enzyme inhibition. The basic chemical reactivity that accounts for this is the high stability of cyclopropanone hydrate compared with most other ketone hydrates.[35] It has been argued that the cyclopropanone ring is even more strained internally than the cyclopropane ring itself because the preferred bond angle of the carbonyl group (120°) is further away from the enforced bond angle (≈60°) than the tetrahedral bond angle (109°28′).[36] However, a mobile equilibrium between the hydrate and the ketone does exist because ligand exchange occurs readily; this reaction is thought to be the basis for the inhibition of dehydrogenases and some oxidases by cyclopropanones and their equivalents.

2.3. Cyclopropanes Activated by an Electron-Withdrawing Substituent

Into this class of cyclopropane derivatives, two systems can be placed, namely, cyclopropyl aldehydes, ketones, and esters and their relatives, and cyclopropylmethyl halides or cyclopropylmethanols and their esters. The characteristic reaction of this class of compound is nucleophilic attack on the cyclopropane ring leading to ring opening. For cyclopropylcarbonyl derivatives, the stability of the ring to addition by protonic acids is enhanced, a fact that considerably facilitates the synthesis of complex molecules containing cyclopropanes.

The biosynthesis of squalene from presqualene has been reationalized on the basis of the reactivity of a cyclopropylmethyl ester[4] and, in particular, its propensity to rearrange. The prototype rearrangement has been known for many years[37] as the "cyclopropylcarbinyl" rearrangement (Fig. 1). The solvolysis of cyclopropylmethyl halides and toluenesulfonates has been shown to lead to a mixture of products in which the ring is retained, broken, or enlarged, depending upon the reactants and reaction conditions.[38] When experiments with isotopic labels were carried out,[39] it was shown that the connectivity of the labeled carbon atoms was altered even in the products that retained the three-membered ring. Clearly, the intermediate cation has a great many reaction paths of similar energy open to it. Perhaps the best indication of its structure came from experiments in superacid media by *Olah* et al.[40] He interpreted ^{13}C-NMR spectra of the cation in terms of an equilibrium between three species, **9a–c** (Fig. 1), and the same equilibrium was reached with either cyclopropylmethanol or cyclobutanol as the starting material. The point of relevance with regard to squalene biosynthesis is that such reactions allow an apical carbon of the ring to bond to the carbon of the substituent that bears the leaving group. In both this biosynthetic reaction and in transformations of carbocyclic systems, it is believed that the methylene group of the cyclopropane to which the new bond is formed undergoes inversion of configuration.[41] A feature of potential significance of the structure of such rearranging cations with regard to enzyme inhibition is the great opportunity that they give for attack by a nucleophile at the enzyme's active site. Despite this potential, no inhibition reactions have so far been reported to occur through such a mechanism. This is possibly because such solvolysis reactions are relatively slow, with rate constants typically on the order of $10^{-3}\,s^{-1}$ at 30–40°C.[42] Nevertheless, the cyclopropane ring has a strong electron-donating effect that is manifested not only in solvolysis reactions but also in electrophilic aromatic substitution.[32]

Some of the reactions mentioned above (e.g., **10**→**11**) lead to ring-opened products and, in several cases, there is good stereochemical control of the alkene generated. *Julia* et al.[43a] were the first to report such a reaction (Fig. 2) and their work was extended by *Johnson* et al.[43b] The stereochemical course of these reactions has been rationalized by considering the conformation of the cyclopropane ring with respect to the leaving group as illustrated in **12a** and **12b**. The stereoelectronic requirement is for overlap of a cyclopropane bond with the bond to the leaving group. Conformation **12a** minimizes torsional interactions and leads to the observed products with *E* configuration. There is a parallel between these reactions and the inhibition of some dehydrogenases to be described later (see Sections 6.1 and 6.2).

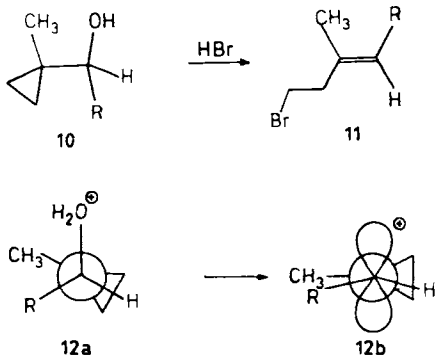

Fig. 2. Formation of alkene **11** from cyclopropylmethanols **10** via cations **12a** and **12b**.

Cyclopropylcarbonyl compounds can be considered as close analogues of the above cationic systems in which the polarized carbonyl group provides the partial positive charge. In many reactions with nucleophiles, addition to a single carbonyl substituent group takes place without cleavage of the small ring. Thus cyclopropyl methyl ketones can be reduced to secondary alcohols with $NaBH_4$ in methanol and esters of cyclopropanecarboxylic acid react with $LiAlH_4$ to yield the corresponding primary alcohols.[44] However, if the carbonyl group's polarization is enhanced by coordination with a Lewis acid, ring opening can take place (e.g., **13** → **14** in Fig. 3); this reaction is a useful synthetic route to homoallylic halides.[45] As will be seen in Section 6, coordination of cyclopropylcarbonyl groups to metal ions is important in the inhibition of metalloenzymes. Under severe conditions, nucleophilic ring

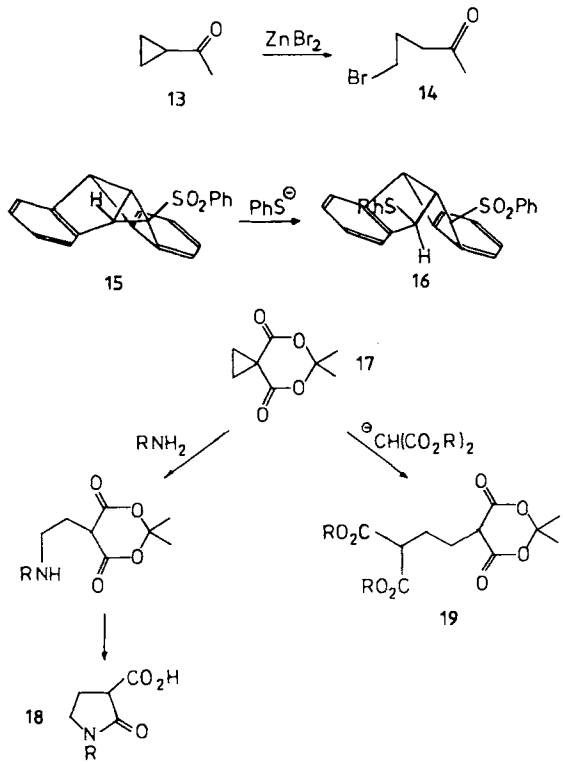

Fig. 3. Nucleophilic substitution with ring opening at cyclopropanes **13**, **15**, and **17** bearing electron-withdrawing substituents.

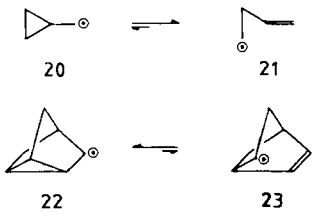
opening of substituted cyclopropanes is possible without acid catalysis either by a metal ion or a proton. In a particularly interesting example, *Cristol* et al.[46] showed that inversion of configuration occurred when thiophenolate attacked the cyclopropane of the fused ring system (**15** → **16**, Fig. 3). Where the stereochemical course has been determined, nucleophilic ring-opening reactions of activated cyclopropanes have been shown to occur with inversion of configuration at the attacked carbon.

The presence of two electron-withdrawing groups renders the ring susceptible to nucleophilic cleavage without special activation. For example, quite weak nucleophiles can add to the spirocyclic cyclopropane **17**, giving the products **18** and **19** (Fig. 3); the presence of the ester substituents in **18** and **19** opens up further reaction paths that can be useful in synthesis. The ease of this reaction is enhanced by the restricted conformation of the cyclopropane ring which places the scissile C–C bond in a favorable orientation with regard to the electron-accepting carbonyl group.[47] Enzyme inhibitors containing doubly activated cyclopropane rings may therefore be unselective.

2.4. Cyclopropylalkyl Radicals

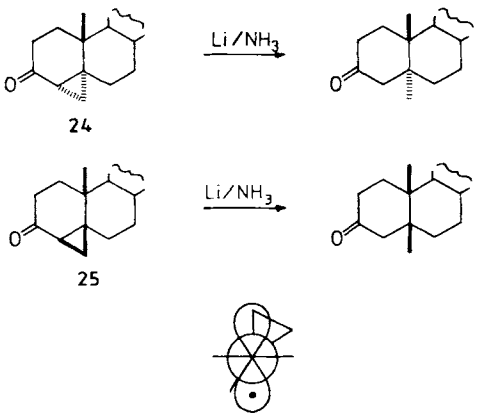
The cyclopropylmethyl radical (**20**) has held a distinguished place in the chemistry of cyclopropanes and in their bioorganic chemistry since *Ingold* et al. reported that the rate of its ring opening to form the homoallyl radical **21** was $10^8\ s^{-1}$ at 25 °C.[48] It was quickly realized that this



fast reaction could have a useful role in detecting the intermediacy of radicals. There have been many applications of the same general reaction in attempts to elucidate the mechanisms of enzyme-catalyzed reactions and to generate inhibitors. *Ingold* et al. also reported that the ring-opening rate of alkylcyclopropylaminyl radicals, which is very relevant to many inhibition reactions, was too fast to measure by kinetic ESR spectroscopy and was independent of the alkyl substituent.[49a] Very recently, the ring opening of cyclopropylamine radical cation has been shown to proceed via a γ-iminium radical cation[49b] in a manner agreeing with many mechanisms proposed for enzyme inhibition.

The success or otherwise of the enzymic experiments employing cyclopropanes, however, depends critically upon a good understanding of the chemistry of this ring-opening reaction. Several factors must be considered. Firstly, it has been demonstrated that the reaction is an equilibrium;[50] for a monocyclic compound, the equilibrium constant has been determined to be 10^{-5} at 25 °C in favor of the ring-opened radical (cf. **21**). But the position of this equilibrium is decisively influenced by the carbon skeleton into which the cyclopropane is built. The nortri-

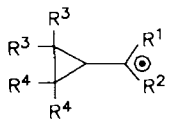
cyclyl radical **22** having a cyclopropane ring, for example, is stable at room temperature.[51] Secondly, few enzyme substrates or inhibitors are simple cycloalkanes and so the effect of substituents on the rate of ring-opening reactions must be considered. That cyclopropylalkoxyl radicals readily undergo ring opening has been known for nearly twenty years through the work of *Dauben* et al.[52] who showed that the 3-oxo steroid derivatives **24** and **25** un-



derwent cyclopropane ring opening on treatment with lithium in ammonia. The reaction is quite general[53] and, interestingly, drew attention to a stereoelectronic requirement for ring opening. *Dauben*'s results showed that the cyclopropane C–C bond that better overlaps with the singly occupied orbital of the radical will be broken.[52] None of these results, however, provided a measure of the rate of ring opening of cyclopropylalkoxyl radicals.

Since knowledge of such rates was of critical importance in our work, we have taken some trouble to obtain relevant values (Table 1).[44,54] Using ESR spectroscopic techniques principally with silyl ethers as substrates, we found that the rate of ring opening of a simple cyclopropylalkyl radical was reduced by about a factor of 10 by oxygen substitution. In contrast, the inclusion of alkyl groups, which presumably increase the strain in the cyclopropane ring, accelerates ring opening by a similar factor. A most remarkable result was obtained with disubstituted radicals in which a donor alkoxy group is paired with an acceptor carbonyl or cyano group. In neither case was it possible to observe the ring-opened radical under accessible conditions. The result has been interpreted in terms of the so-called capto-dative stabilization of radicals[55] and is one of the most extreme examples known. Together, all of these observations show that for the ring opening to be rapid and useful as a mechanistic probe for the intermediacy of radicals, several criteria must be satisfied: (1) there must be no substantial stabilization of the radical site itself by delocalization, (2) there must be a conformation available in which a C–C bond of the ring overlaps with the singly occupied orbital, and (3) the structure of the compound must not be so compressed that ring closure is entropically favored. How these factors work out in enzyme-catalyzed reactions will be seen in Section 6.

Table 1. Stability of substituted cyclopropylmethyl radicals and/or alkenyl radicals assessed by variable-temperature ESR spectroscopy.



R^1	R^2	R^3	R^4	k [s^{-1}]
H	H	H	H	2.2×10^8
Me	$OSiMe_3$	H	H	2.4×10^7
H	$OSiMe_3$	Me	H	only ring-opened radical observed down to −153 °C
H	$OSiMe_3$	Me	Me	only ring-opened radical observed down to −173 °C
H	CO_2Me	H	H	ring opening not detected up to 7 °C
$OSiMe_3$	CO_2Me	H	H	ring opening not detected up to 110 °C
$OSiMe_3$	CN	H	H	ring opening not detected up to 110 °C

The rates of ring opening of substituted cyclopropylalkyl radicals were studied by photochemical generation of radicals at low temperature.[44,45,54] The temperature dependence of the rate of ring opening in the range 30–89 °C has now been examined using the thermal decomposition of diazo compounds to produce cyclopropylmethyl radicals. It was found that the activation parameters in this temperature range differed significantly from those determined for the range from −120 to −145 °C.[134]

2.5. Cyclopropylalkyl Anions and Their Relatives

Although the π-bonding characteristics of cyclopropanes would suggest that they should stabilize adjacent carbanions, experiments have shown that cyclopropanes are very poor acceptors. Rates of exchange of hydrogen for deuterium in benzyl-substituted cyclopropanes indicate very little stabilization of the anion by the cyclopropyl group[56] in agreement with studies of gas-phase acidities.[57] Nevertheless, cyclopropyl anions have an extensive synthetic chemistry.[58] Interestingly, the cyclopropoxide anion has been found to undergo slow ring opening[59] and the rate of reaction is increased substantially if the carbanion resulting from ring cleavage is delocalized. It can thus be seen that cyclopropylmethyl anions, cations, and radicals can all undergo ring opening, the radical being distinctly the fastest.

3. The Enzyme Chemistry of Cyclopropane and Unactivated Alkylcyclopropanes

Although the majority of cyclopropane derivatives studied in enzyme chemistry contain potentially reactive substituents, some simple alkyl cyclopropanes have been used to characterize the reactivity of oxidizing enzymes. The first example of such experiments using a purified enzyme preparation was reported by *Golding, Dalton* et al.[60] who showed that the monooxygenase enzyme from *Methylococcus capsulatus* was capable of oxidizing cyclopropane to cyclopropanol and methylcyclopropane to cyclopropylmethanol. Interestingly, but-3-en-1-ol, a product of oxidation with ring opening of a cyclopropylmethyl radical, was not observed. Together with other observations, this result suggested to the authors that the oxidase from *M. capsulatus*

functioned through a metal-bound oxygen species that is capable of insertion into a C–H bond and that no radical or cationic intermediates were involved.

Simple cyclopropane derivatives are sometimes cleaved by enzymes. Cyclopropane itself has been oxidized to propanal by *Mycobacterium spp.*[61] Haloperoxidase treats cyclopropane as a typical alkene and adds to afford 3-bromopropanol;[61,62] the orientation of similar reactions using alkenes as substrates suggests that a cationic intermediate is involved in this case. Haloperoxidase is a heme-containing enzyme that is thought to operate through a mechanism different from that of cytochrome P-450. For the latter, model reactions have been very helpful in providing clues as to the reaction mechanism[63] and cyclopropanes have been used as substrates. *Groves* et al.[64] found that bicyclo[4.1.0]heptane was oxidized by manganese(III) tetraphenylporphyrin in the presence of iodosylbenzene to a mixture of products of which 32% were homoallylic alcohols or halides resulting from ring opening. A larger proportion of the products (42%) retained the cyclopropane ring. The results were consistent with a radical mechanism which has become known as the "oxygen rebound" mechanism and has served as a framework for mechanistic discussions relating to cytochromes P-450 (Fig. 4).[63] The proportion of ring-opened products observed in a reaction using an alkylcyclopropane as a mechanistic probe will clearly depend upon the relative rates of ring opening and capture of the intermediate radical. In *Grove*'s case[64] the two rates are comparable.

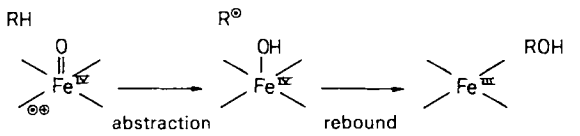


Fig. 4. Hydroxylation of alkanes by cytochromes P450—the oxygen rebound mechanism.

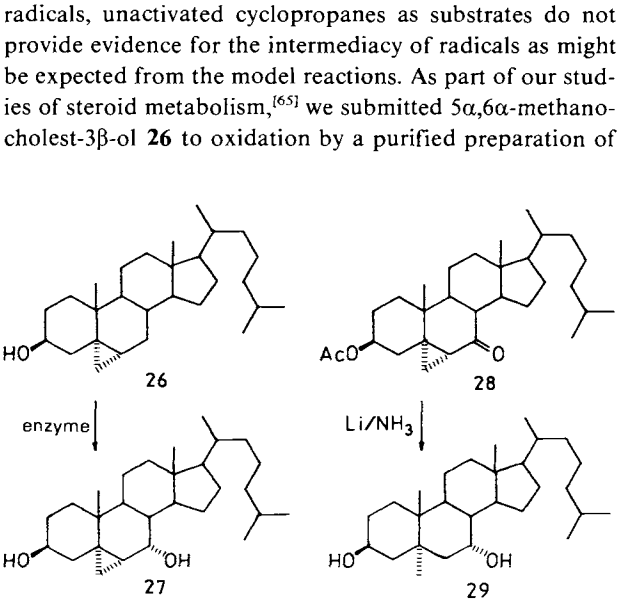
Although many enzymic experiments have been rationalized with the aid of the oxygen rebound mechanism (see Section 5), especially with regard to the intermediacy of radicals, unactivated cyclopropanes as substrates do not provide evidence for the intermediacy of radicals as might be expected from the model reactions. As part of our studies of steroid metabolism,[65] we submitted 5α,6α-methanocholest-3β-ol **26** to oxidation by a purified preparation of cholesterol 7α-hydroxylase. The cyclopropyl steroid **26** proved to be a competitive substrate with respect to cholesterol and was oxidized to the corresponding 7-hydroxy derivative **27** without any evidence of ring opening. We showed that there was no chemical impediment to ring opening of a 7-radical by reducing the 7-oxo-5α,6α-methano steroid **28** with lithium in ether/liquid ammonia following *Dauben* et al.;[52] the product was the ring-opened diol **29**. It seems improbable that cholesterol 7α-hydroxylase, which is otherwise a typical cytochrome P-450 enzyme, should function by a totally different oxidation mechanism from its relatives. However, it is known that the enzyme is especially selective with regard to its substrate; even the loss of one side-chain methyl group causes an appreciable loss of reactivity towards oxidation.[66] If the enzyme is capable of binding the substrate tightly, a radical mechanism can still be accommodated if the oxygen rebound step is faster than the ring-opening step, but an alternative mechanism cannot be ruled out on the basis of this experiment. The cytochrome P-450 responsible for the side-chain cleavage of cholesterol during steroid hormone biosynthesis has also been shown to oxidize a cyclopropane-containing analogue of the substrate without cleaving the three-membered ring.[67] Recently, *Ortiz de Montellano* et al. have provided a rounded background to these results, showing that whereas methylcyclopropane does not undergo ring opening on oxidation by cytochrome P-450, the strained bicyclo[2.1.0]pentane undergoes partial ring opening. These results imply that the radical pair in the rebound mechanism collapses at a rate greater than $10^9\ s^{-1}$.



4. Enzyme Inhibition by Amino Acids Containing Cyclopropyl Groups and by Cyclopropanone Derivatives

Two of the first cyclopropane-containing enzyme inhibitors to be described were toxic amino acid derivatives, namely, coprine **30**[69] and hypoglycine A **31** (Fig. 5).[70] Although coprine is clearly a cyclopropanone adduct of glutamine, it is not immediately obvious what biological activity hypoglycine has. *Abeles*[71a] has suggested that deamination and decarboxylation takes place to yield a vinylogous cyclopropanone system as its thiol ester **32**; this compound is suggested to be a substrate of a general acyl-CoA-dependent dehydrogenase which is inactivated by nucleophilic addition. In contrast, *Ghisla*[71b,c] believes that deamination and decarboxylation leads to **33**, the saturated analogue of **32**; the readily formed carbanion from this molecule then adds to the flavin cofactor in a manner similar to alkynes that inhibit lactate oxidase.[72] The inhibition of glutaryl-CoA dehydrogenase has been reported to occur with methylenecyclopropaneacetic acid and its coenzyme A ester,[73] but the detailed mechanism has not been established for either case.

Methylenecyclopropanecarboxylate CoA ester has recently been synthesized and shown to inhibit a general acyl-CoA dehydrogenase from pig kidney.[135]

Coprine, a product of *Coprinus atramentarius*, the common ink cap mushroom, provided the stimulus for the development of a number of enzyme inhibitors. It was

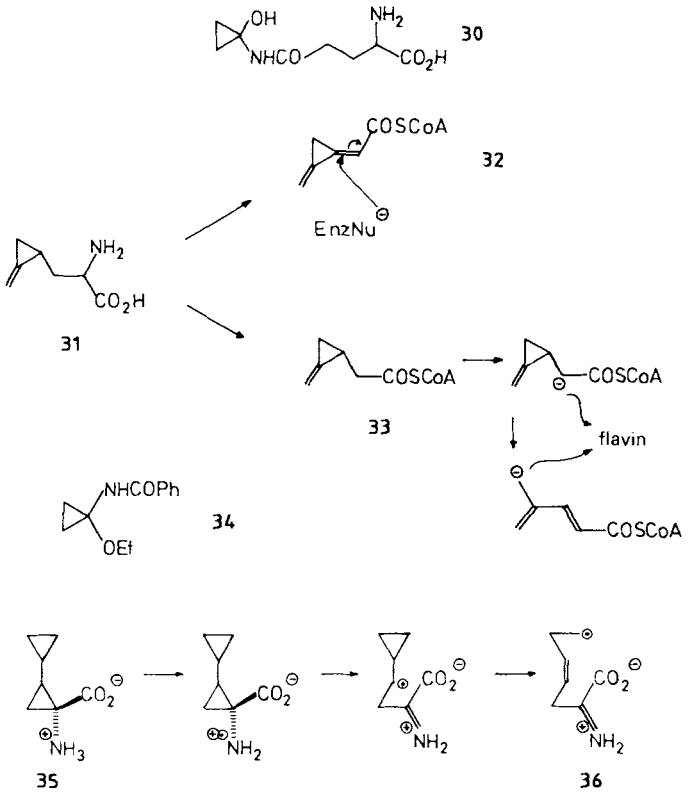


Fig. 5. Enzyme inhibition by cyclopropane-containing amino acids. $EnzNu^{\ominus}$ stands for a nucleophilic group of the enzyme.

shown[74] that coprine is a proinhibitor for aldehyde dehydrogenase, and its ability to inhibit the liver enzyme suggested a use in the treatment of alcoholism. However, neither coprine itself, **30**, nor simple synthetic analogues such as **34**[74] proved suitable for clinical use because of their toxicity. During his studies on ethylene biosynthesis, *Pirrung* et al.[7] reasoned that the cyclopropyl-substituted 1-aminocyclopropanecarboxylic acid **35** should be an inhibitor of the enzyme through the ring-opening reaction **35** → **36**. It was possible to demonstrate time-dependent inhibition of ethylene formation in mungbean hypocotyl segments and substrate protection was observed. The bicyclopropane derivative **35** is an unusual example of a mechanism-based inhibitor of plant enzymes and emphasizes the importance of ring opening of cyclopropylaminium radical cations in ethylene biosynthesis.

The possibility of using cyclopropanones more widely was pursued by many groups. *Abeles* et al. firstly demonstrated that cyclopropanone hydrate was an inhibitor of yeast aldehyde dehydrogenase apparently through addition of a thiol to replace one of the hydroxyl groups.[75] At about the same time, *Singer* et al.[76] and *Silverman* et al.[77] independently described studies of the inhibition of mitochondrial monoamine oxidases (flavoenzymes) by cyclopropylamines. Both groups initially interpreted their results in terms of cyclopropanone chemistry.

trans-2-Phenylcyclopropylamine (tranylcypromine) **37** was the first cyclopropyl enzyme inhibitor to be studied and the first to be shown to follow time-dependent kinetics.[78] *Singer*'s later study showed that inhibition occurred without irreversibly altering the flavin chromophore.[76] He

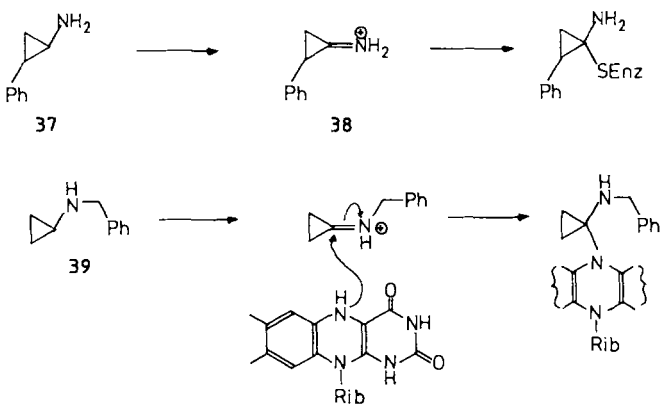

Fig. 6. Proposed mechanisms for the inhibition of monoamine oxidase by cyclopropylamines via cyclopropanone equivalents.

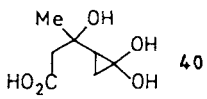
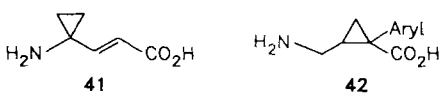
therefore suggested that addition of an enzymic thiol group to the cyclopropyliminium ion **38**, which is the primary oxidation product, again led to inhibition (Fig. 6); this hypothesis was supported by the fact that 2-phenylcyclopropanone had an equivalent inhibitory effect. *Silverman* et al.[77] studied *N*-alkylcyclopropylamines, for example *N*-benzylcyclopropylamine **39**, which were also inhibitors. They found, however, that the flavin chromophore was altered during inhibition and postulated that N-5 of the flavin might also be a suitable nucleophile to add to **38** (Fig. 6). The possibility that electron transfer reactions and multiple pathways might be involved was raised later[79] (see Section 5).

The small cyclopropane ring is attractive for inclusion into many enzyme substrates in order to transform them into inhibitors (see Section 1). *Abeles* et al. have shown that the strategy is successful for hydroxymethylglutaryl-CoA reductase.[80] They synthesized two diastereoisomers of cyclomevalonic acid **40** and showed it to be an inhibitor. It is



worth noting in passing that addition of nucleophiles to carbonyl groups to form adducts has been successful with electrophilic aldehydes,[81] as well as with trifluoromethyl ketones and peptides.[82, 138]

Further amino acid derivatives of cyclopropanes with biological activity have been described. Although GABA-transaminase was inhibited irreversibly by aminofluoropentenoic acid, the cyclopropane amino acid **41** was a noncompetitive inhibitor. It was suggested that the geometrical structure of this compound made binding at the active site unfavorable.[136]



A new series of potential antidepressants, **42**, has been described.[137] Interestingly, these compounds appear to have a different pharmacological profile from tricyclic antidepressants and tranylcypromine **37**; they can also be viewed as GABA analogues.

5. Inhibitors Based Upon Heteroatom-Substituted Cyclopropanes and Their Ring-Opened Derivatives

5.1. Hemoproteins and Monoamine Oxidases

The early experiments with cyclopropylamines seem to have neglected the possibility that radical reactions might lead to inhibition through ring opening prior to radical capture. The first indications that such a mechanism might be reasonable came from studies of the inhibition of cytochromes P-450 by cyclopropylamines. Using *N*-benzylcyclopropylamine **39**, *Hanzlik* et al.[83] showed that cytochrome P-450 from rat liver microsomes was irreversibly inhibited. This result could be accounted for by an addition mechanism (see Section 4), but when it was found that *N*-benzyl-1-methylcyclopropylamine **43** was also an irreversible inhibitor, the possibility of an alternative mechanism became strong, because this inhibitor clearly cannot form a cyclopropanone equivalent. The radical cation **44** was implicated and two modes of reaction were postulated (Fig. 7); firstly, the ring-opening reaction of a cyclopropylalkyl radical equivalent leading to **45**; secondly, ring expansion to an azetidinium radical cation **46**. Chemical analogies existed for each type of reaction[35,84] but the latter was preferred because of the observed tight binding of labeled inhibitors to microsomal protein.

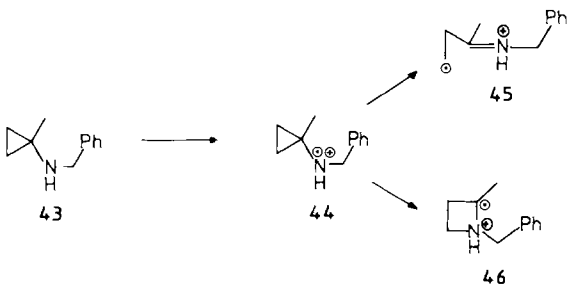


Fig. 7. Formation of radicals in the inhibition of monoamine oxidase by *N*-benzyl-1-methylcyclopropylamine **43**.

Concurrently with this report, *MacDonald, Guengerich* et al.[85] described a further alternative whereby a ring-opened radical such as **45** attacks the porphyrin ring, causing enzyme inactivation. Both *N*-benzylcyclopropylamine **39** and its 1-methyl analogue **43** were studied and it was clearly demonstrated that both benzphetamine and aminopyrine *N*-deethylase activities were inhibited by these compounds, although some activity was recoverable on dialysis.

Naturally, these results have relevance to the mechanism of inhibition of monoamine oxidase[79] and *Silverman* et al. undertook further investigations. When the radical mechanism is applied to 2-phenylcyclopropylamine **37** as an inhibitor, ring opening of the cyclopropane would lead to a benzylic radical, **47** (Fig. 8). By isolation of derivatives of hydrolysis products from the inhibited enzyme it was shown that monoamine oxidase is inhibited not by a cyclopropanone equivalent, but by a cinnamaldehyde equivalent, **49**.[86] Interestingly, further evidence in support of a radical mechanism for monoamine oxidase has been found from experiments with 1-amino-1-phenylcyclobutane.[87]

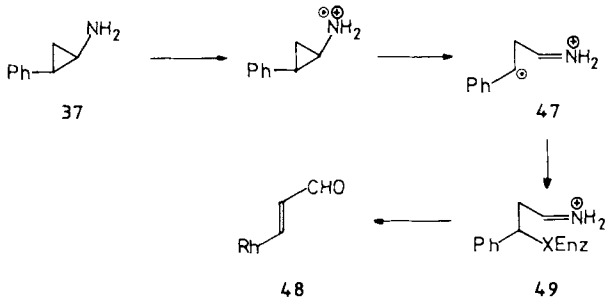

Fig. 8. Possible course of inhibition of monoamine oxidase by 2-phenylcyclopropylamine **37**. Cinnamaldehyde **48** has been detected.

To establish which fragments of cyclopropyl inhibitors were attached to monoamine oxidase, *Silverman* et al. studied labeled *N*-benzyl-1-methylcyclopropylamine **43** and found that only the methyl and cyclopropyl carbon atoms remained attached.[88] The results were interpreted in terms of the mechanism which postulates that a flavin radical couples with the ring-opened radical **45**;[49] hydrolysis of the imine would then liberate benzylamine and leave the inhibitor attached to the flavin as a 3-oxobutyl substituent. In a similar way, the behavior of 1-phenylcyclopropylamine has been rationalized through the observation of phenyl ketones and iminium salts as products.[89] The importance of the cyclopropane in this reaction was shown by the fact that dimethylbenzylamine fails to inactivate the enzyme. The most recent addition to understanding of these reactions has come from the identification of a cysteine residue that forms a transient intermediate with 1-phenylcyclopropylamine during inhibition of mitochondrial monoamine oxidase.[90]

When electron transfer reactions were first considered to be responsible for inhibition of monoamine oxidase, it was felt that related cyclopropanols would not react in this way because of the greater difficulty of removal of an electron from oxygen compared with nitrogen.[83] However, it appears that such reactions can occur if the enzyme possesses a sufficiently powerful oxidizing agent. For example, *Wiseman* et al.[91] found that horse radish peroxidase, a hemoprotein, was inhibited by cyclopropane hydrate **50**. The

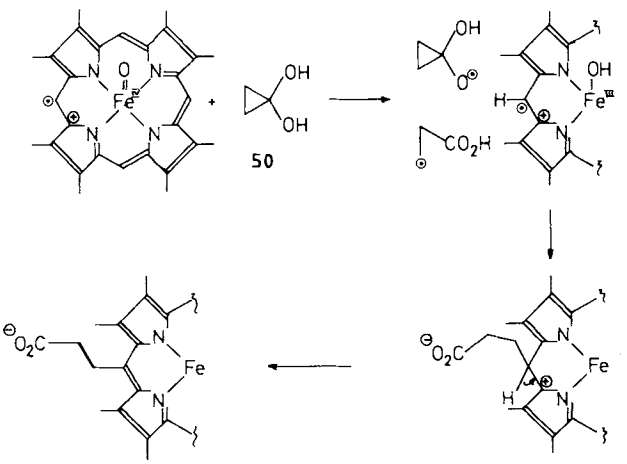

Fig. 9. Mechanism proposed to account for the inhibition of horse radish peroxidase by cyclopropanone hydrate **50**.

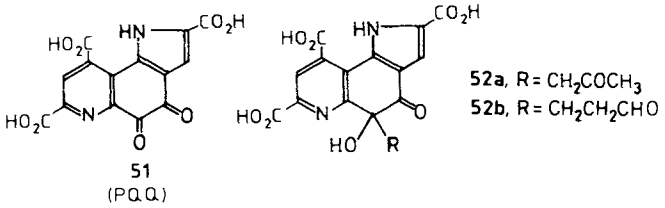
visible spectra of the inhibited enzyme were interpreted in terms of alkylation of the porphyrin ring (Fig. 9) in a manner related to the inhibition of cytochrome P-450.

5.2. Methanol Oxidizing Enzymes

Recently there has been a great deal of interest in a newly discovered coenzyme that is responsible for the oxidation of methanol.[92] This cofactor is a pyrroloquinoline quinone (PQQ, **51**) and has also been called methoxatin.[93]



During the course of isolation and structure determination of PQQ, an acetone adduct, **52**, was formed and this compound has influenced thoughts on the mechanism of oxidation of alcohols by PQQ-dependent enzymes.[94,95] The detailed mechanism of action of PQQ is not yet established. Experiments from *Duine*'s laboratory are strongly indicative of a radical pathway, at least for some substrates,[95] although different views have been expressed.[96] Isolated methanol dehydrogenase appears to contain PQQ in a semiquinone form that undergoes one-electron oxidation to the quinone form, which appears to be catalytically active. One of the complications in elucidating the mechanism of action of methanol oxidation is that there are several types of enzyme, some monomeric and some dimeric. One part of the mechanistic problem relates to clarifying the enzymological relationships between the enzymes and the other part relates to the chemical mechanism of oxidation.

Abeles et al.[96] found that cyclopropanol inactivates the enzyme from *M. methanica* in the presence of phenazine methyl sulfate without a measurable primary deuterium or tritium isotope effect.[96b] A base-labile adduct of PQQ and the inhibitor was isolated and assigned the structure **52b**. However, there was no suggestion as to how **52b** might arise except through the radical semiquinone form of the cofactor. *Duine* et al. also have found that cyclopropanol is an inhibitor of dimeric methanol dehydrogenase and also of a monomeric enzyme from *Pseudomonas* BB1[97a] but that cyclopropylmethanol, cyclobutanol, and cyclohexanol are all substrates. In his experiments, enzymes containing PQQ in the semiquinone form were not inactivated. Further it was found that PQQ-dependent dehydrogenases that are capable of oxidizing secondary alcohols (the *Pseudomonas* enzyme) are inhibited by cyclopropanone hydrate **50** and cyclopropanone ethyl hemiketal. The modified PQQs from cyclopropanol and the cyclopropanone derivatives were found to be different, suggesting that a mechanism involving oxidation of cyclopropanol to cyclopropanone is not operative. The structure of the adduct has now been characterized as **52b**[97b] and, with this result in mind, the inhibition of the enzymes was rationalized (Fig. 10) through one-electron oxidation of the alcohol to

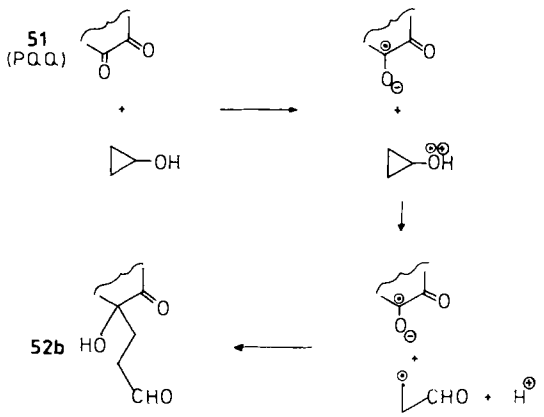


Fig. 10. Suggested mechanism of inhibition of *Pseudomonas* PQQ-dependent methanol dehydrogenase by cyclopropanol.

afford a PQQ radical anion and a cyclopropyloxonium radical. Rapid ring opening of the oxonium radical and combination with the PQQ radical then leads to a molecule with a structure identical to that proposed by *Abeles*, **52b**.

A further class of methanol oxidizing enzyme is known, namely, a flavoprotein oxidase which has also been studied by *Abeles* et al. using cyclopropanol as a probe.[98] The enzyme is inhibited by cyclopropanol through the formation of an *N*-5 flavin adduct as has commonly been suggested. Two possible mechanisms were considered, one in which a cyclopropoxy radical undergoes ring opening before combining with the flavin and the other in which the cyclopropoxide ion undergoes ring opening prior to adding to the oxidized flavin. In view of the very slow rate of the latter ring opening (see Section 2.5),[59] *Abeles* favored the radical mechanism. He also found that cyclopropylmethanol was a substrate for the enzyme and not an inhibitor. This result is consistent with a radical mechanism in which electron transfer from the oxygen atom occurs; the product of this oxidation has a methylene group between the cyclopropane ring and the oxygen radical and would therefore not be expected to undergo rapid ring opening. In contrast, a mechanism involving abstraction of a hydrogen atom from the methylene group might conceivably yield a ring-opened product if the radical formed had a sufficiently long lifetime. Such arguments were raised by *Abeles* in commenting upon our results concerning nicotinamide-dependent dehydrogenases which will be discussed in the following section. He is right to point out, as had been realized earlier, that the lack of ring opening of a cyclopropylalkyl radical is not conclusive evidence against radical intermediates. Indeed, our experience with cytochromes P-450 confirms this.[65,67,68] However we have taken some trouble to establish the limits to which conclusions concerning the intermediacy of radicals can be drawn in the case of nicotinamide-dependent alcohol dehydrogenase[44,45] and these arguments will now be reviewed.

6. Cyclopropylmethanols and Their Derivatives

We have studied the enzyme chemistry of cyclopropylmethanols, and their alkylated and oxidized derivatives

both as inhibitors of enzymes and as mechanistic probes for the intermediacy of radicals in enzyme-catalyzed reactions involving NAD$^{\oplus}$/NADH. It has proved possible to dissect both functions and both will be discussed.

6.1. The Mechanism of Hydrogen Transfer by Nicotinamide Coenzymes

The possibility that hydrogen transfer reactions by nicotinamide coenzymes might involve radical intermediates was strongly raised in 1971 by *Hamilton*[99a] and a great deal of work was stimulated chiefly using model compounds.[99b] We felt, however, that it was important to obtain the best possible information about the reaction occurring at an enzyme's active site. The way to approach this challenge was through the rapid ring opening of cyclopropylalkyl radicals. Since the rates of hydrogen transfer by horse liver alcohol dehydrogenase had been shown to be between 30 and 100 s^{-1},[100] it was possible that a radical intermediate formed during the redox reaction would have ample time to open and hence the products of the reaction would reveal the intermediacy or otherwise of radicals. Our first experiments used horse liver alcohol dehydrogenase with bicyclo[4.1.0]heptane-7-methanol **53** and the corresponding aldehyde.[101] Under preparative conditions with recycling of NAD$^{\oplus}$ or NADH as appropriate, we isolated products and starting material with intact cyclopropane rings. These experiments thus provided no evidence for radical intermediates.

We then extended the investigation to lactate dehydrogenase using cyclopropaneglycolic and cyclopropaneglyoxylic acids. Just as with alcohol dehydrogenase, no ring-opened products were detected in either oxidative or reductive reactions. To correlate these results with those of model studies in which radical intermediates had been postulated,[102] we examined the reduction of methyl cyclopropaneglyoxylate with *N*-benzyl-1,4-dihydronicotinamide in the presence of $Mg^{2\oplus}$ ions. Once again, no ring opening was detected.[103] A parallel study was carried out by *Pandit* et al.[104] who found that *N*-cyclopropylmethylenephenylamines were reduced by Hantzsch ester (dimethyl 1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate) without ring opening. All of the results from these experiments fail to support radical intermediates but it is important to ensure that the stringent conditions for applicability of the cyclopropylalkyl radical as a mechanistic probe mentioned in the introduction have been fulfilled.

At its simplest, it must be shown that radical reagents acting at the site of the redox reaction afford ring-opened products. This condition was satisfied for both cyclopropaneglyoxylate ester[103] and the above-mentioned Schiff base[104] by treatment with tin hydride reagents and an initiator. The important conclusion from these simple experiments is that radical intermediates in the traditional model reactions are most improbable since there are no conformational constraints upon the probe molecules that might militate against ring opening. Similar results were obtained with the bicyclic substrates (cf. **53**)[101] in agreement with previous work.[105] However, in order to evaluate the enzyme-catalyzed reactions, more precise information was needed to establish the effect of substitution upon the rate of ring opening of cyclopropylalkyl radicals (cf. Table 1 in Section 2.4). Thus the introduction of a single oxygen substituent caused a decrease in the rate of ring opening by only a factor of 10 and hence for alcohol dehydrogenase, the mechanistic probe passed this test.[44,45,101] In contrast, the rate of ring opening of cyclopropylalkyl radicals doubly substituted with a donor and an acceptor group was not measurable by ESR spectroscopy under accessible conditions. In this case, therefore, the lack of ring opening in the reactions catalyzed by lactate dehydrogenase is inconclusive. The model reactions are nevertheless indicative of the essential chemical character of the system.[103]

Table 2. Kinetic parameters for the interaction of substituted cyclopropylmethanol and its derivatives with horse liver alcohol dehydrogenase. K_m = Michaelis constant for substrate behavior, k_{ox} = rate constant for oxidation, k_{in} = rate constant for inhibition.

		K_m [$M \times 10^5$]	k_{ox} [s^{-1}]	k_{in} [$s^{-1} \times 10^3$]	$\frac{k_{ox}}{k_{in}}$
53		1.92	1.70	13.5	126
54		6.38	4.72	5.13	920
55		6.89	4.24	4.33	980
56		6.3	5.64	1.33	4240
57		15.9	19.2	0.4	48000

Included in this series of experiments were di- and tetraalkyl cyclopropylmethanols (Table 2) and the rate of ring opening of radicals derived from silyl ethers of these compounds was too rapid to measure by the ESR technique used.[54] This information provided an excellent opportunity to reinforce the conclusions from the first experiments by carrying out preparative reactions with alcohol dehydrogenase. Not only are the methyl-substituted probes intrinsically more reactive with respect to ring opening of the derived radicals, but the alkyl substitution severely reduces their effectiveness as enzyme inhibitors by hindering nucleophilic attack at the cyclopropane ring (see below); experiments with these probes thus concentrate upon the hydrogen-transfer event. As before, no ring-opened products were detectable.[54] It remained then to check that the enzyme presented no impediments to ring opening such as the prevention of attainment of the conformation required for ring opening of a radical intermediate[52,53] or coercion to remain in a ring-closed form. The force of the latter factor is emphasized by the equilibrium position of the nortricyclyl radical **22**[51] which makes its use as a probe for radical intermediates inappropriate.[68,106] The importance of these factors for alcohol dehydrogenase was assessed with the aid of computer graphics techniques.[107] Using a model of the active site of alcohol dehydrogenase constructed from the X-ray crystallographic study of the 4-bromobenzyl alcohol complex,[108] we were able to show that for tetramethylcyclopropaneme-

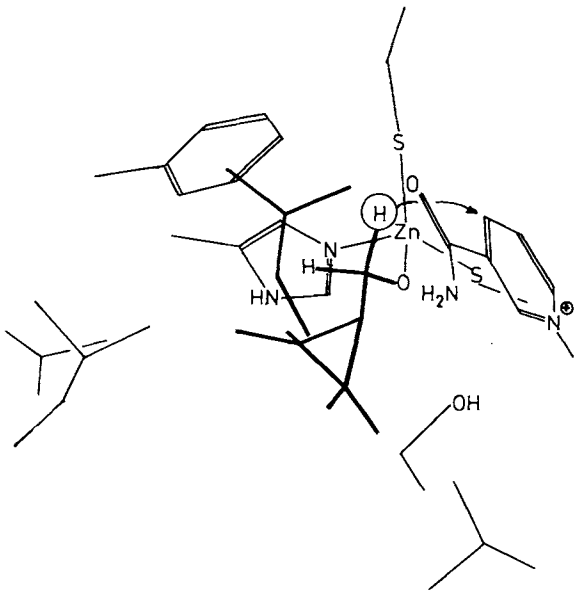

Fig. 11. Active site complex of horse liver alcohol dehydrogenase and tetramethylcyclopropylmethanol in the conformation required for H-transfer and ring opening (deduced from molecular graphics). The probe molecule is shown in bold lines.

thanol **57**, the required conformation for ring opening was accessible (Fig. 11) and that no severe pressure against ring opening existed. These results thus define the limits of confidence within which an interpretation of the lack of ring opening of cyclopropylalkyl substrates can be made. For alcohol dehydrogenase, all of the criteria required of a cyclopropyl probe have been satisfied. Although arguments have been presented for transient intermediates in the oxidation of alcohols by alcohol dehydrogenase and $NAD^{\oplus}$,[109] there is no evidence to support radical intermediates in reactions of simple alkyl aldehydes and ketones with $NAD^{\oplus}$/NADH and alcohol dehydrogenase. It has been argued from other experiments that in any case, single electron transfer mechanisms would only be expected for dihydropyridines reacting with obligate one-electron oxidants such as iron(III) and its complexes.[110]

6.2. Enzyme Inhibition by Alkylcyclopropylmethanol Derivatives

When our work on the inhibition of dehydrogenases began, activation of latent inhibitors by oxidation had not been described. We[111] and others[112] showed that unsaturated alcohols such as but-3-yn-1-ol and 3-ethylthioprop-2-en-1-ol inhibited horse liver alcohol dehydrogenase in a time-dependent manner. However, in the latter case,[111] inhibition proved to be reversible, malondialdehyde and ethanethiol being detected as reaction products. The probable origin of these products was a reverse Michael reaction in which the inhibited enzyme was reactivated; in order to avoid this net hydrolysis, the cyclopropanes were introduced. In this case, reversal of inhibition by ring closure would be improbable. The first series of compounds to be examined was based upon bicyclo[4.1.0]heptane-7-methanol **53**, the compound used initially to probe the mechanism of hydrogen transfer. All the alcohols studied proved to be inhibitors (Table 2), the bicyclic primary alcohols being the most effective, causing inhibition approximately once every 100 catalytic events.

Just as the di- and tetramethylcyclopropylmethanols, **56** and **57** respectively, gave further information on the question of the mechanism of hydrogen transfer, so they also assisted in clarifying the course of the inhibition reactions. A priori there are two sites in the cyclopropylmethanol inhibitors that are capable of reacting with nucleophiles, namely, the carbon bearing the oxygen atom and the remote apices of the cyclopropane ring. If inhibition by the alcohols occurred by nucleophilic attack at the cyclopropane ring, it would be expected that substitution at this site by methyl groups would decrease the rate of inhibition. Tetramethylcyclopropylmethanol **57**, which has the same number of carbon atoms as the prototype inhibitor **53**, was found to bind to the enzyme with comparable affinity.[54] However, it was a poorer inhibitor by 380-fold (Table 2), the dimethyl analogue **56** also being a poorer inhibitor than **53**. Both experiments suggest strongly that the methyl groups interfere with inhibition and implicate the apices of the cyclopropane ring as the target for the enzyme's nucleophile.

From the data in Table 2 and the known affinities of typical substrates for horse liver alcohol dehydrogenase, with the aid of computer graphics it is possible to suggest what the nucleophile responsible for inhibition might be.[107, 108] The inhibitors can bind in two possible orientations at the active site but only in one (Fig. 12) can the *pro-R* hydrogen, the one usually removed by this enzyme,

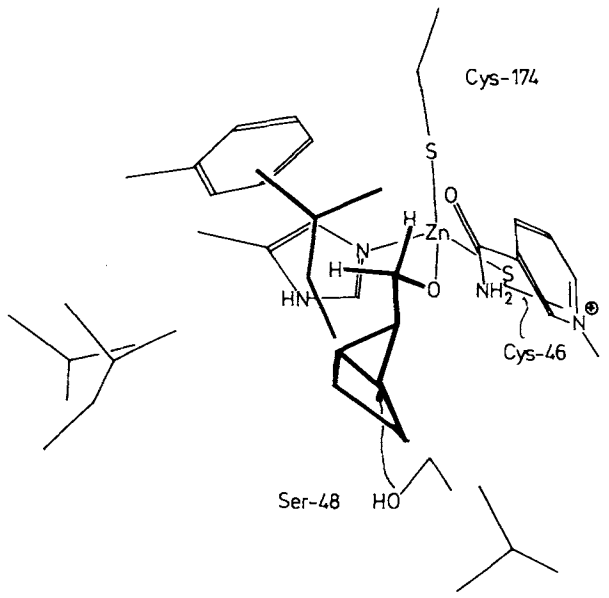

Fig. 12. Mechanism of inhibition of horse liver alcohol dehydrogenase by cyclopropylmethanols as suggested by molecular graphics. The inhibitor is shown in bold lines.

be transferred to $NAD^{\oplus}$ at the same time placing a nucleophile within bonding distance of the apex of the cyclopropane ring. That nucleophile is the hydroxyl group of Ser-48. A comparable situation was found to obtain for lactate dehydrogenase; in this case, the likely nucleophile is the hydroxyl group of threonine-246. Both results are consis-

tent with the stereochemical course of nucleophilic ring opening of cyclopropanes (see Section 2) and with predictions of frontier orbital theory.[107]

6.3. Inhibition of Chemotherapeutically Significant Enzymes by Cyclopropane Derivatives

The examples of alcohol and lactate dehydrogenases show that the cyclopropane derivatives can be effective inhibitors at active sites that involve either metal ions as Lewis acids or proton-transferring groups. It was therefore of interest to extend the concept to other enzymes that possessed similar possibilities for activation, especially enzymes that have relevance in chemotherapy. A most interesting case is dihydrofolate reductase (DHFR), the mechanism of which has been discussed in detail on the basis of both X-ray crystallography[113] and NMR studies.[114] It has been established that diaminopyrimidine inhibitors are protonated by an aspartic acid at the active site of DHFR and this residue has also been implicated in protonating N-5 of the dihydrofolate at some stage in the catalytic mechanism. Bearing in mind the success with lactate dehydrogenase, we wondered whether such protonation could activate a cyclopropane-containing analogue of either diaminopyrimidines or dihydrofolate to generate a reactive inhibitor (Fig. 13). Accordingly we synthesized the pteridine **59** and the pyrimidine **60**.[115] Assay of the inhibition properties of the two compounds showed that the pyrimidine **60** was a competitive inhibitor only, whereas the pteridine **59** behaved as a classic time-dependent irreversible inhibitor. The reason for the difference is being sought in synthetic and modeling studies.

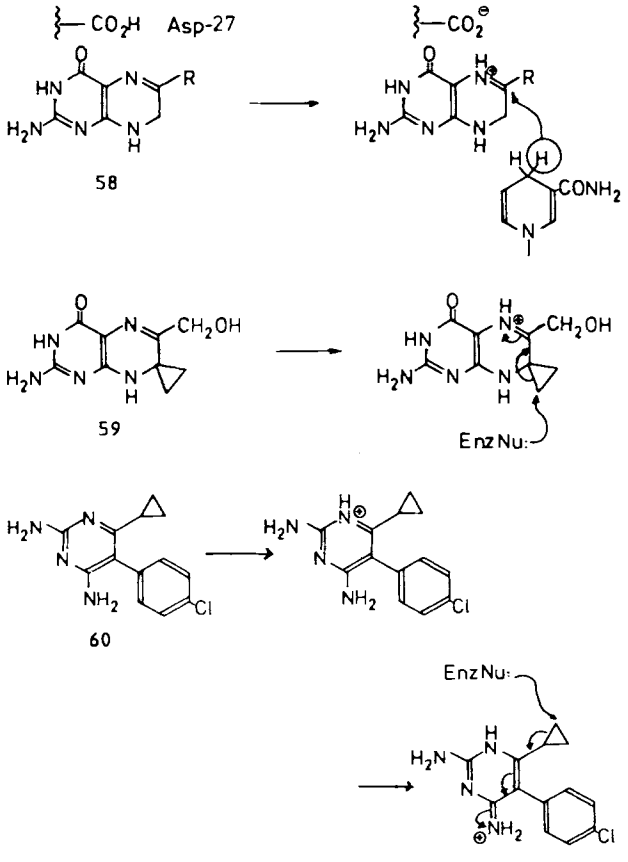

Fig. 13. Mechanism-based design of inhibitors of dihydrofolate reductase.

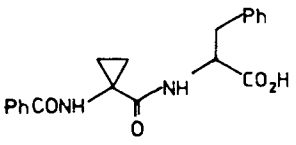
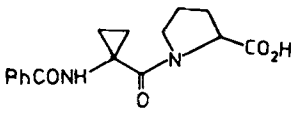
A further enzyme of interest as a prototype for chemotherapeutic agents is carboxypeptidase A; many important endopeptidases such as angiotensin-converting enzyme are related to carboxypeptidase A.[116] These enzymes are metalloenzymes containing a zinc cation that functions as a Lewis acid at the active site. It was therefore interesting to see whether a cyclopropyl amino acid could be activated in the same way as a cyclopropyl alcohol in alcohol dehydrogenase. We therefore prepared a series of peptides and acyl amino acids based upon 1-aminocyclopropanecarboxylic acid and also using cyclopropanecarbonyl as a simple acyl group. Both types of compounds have been reported as components of peptide inhibitors of enzymes,[117,118] but no evidence for a time-dependent reaction has been presented. We found that the phenylalanyl peptide **61** was a modest inhibitor of carboxypeptidase A and also a poor substrate. In contrast, the prolyl analogue **62** was purely a time-dependent inhibitor with no substrate properties.[119] We have suggested that the close juxtaposition of the proline and cyclopropane rings effectively blocks nucleophilic attack on the scissile carbonyl group.[117,119]



61



62

The potential of cyclopropane-containing peptides and peptide analogues as inhibitors of peptidases has recently been extended by the demonstration that *N*-cyclopropylamides and the corresponding secondary alcohols are inhibitors of carboxypeptidase A. Further, evidence has been obtained to show that serine and cysteine peptidases can be inhibited by cyclopropane-containing peptides.[139]

The last enzyme that we have so far been able to inhibit by this type of cyclopropane is dihydroorotate dehydrogenase. This enzyme is a key enzyme in the biosynthesis of pyrimidines[120] and after the serendipitous discovery of some hydantoin inhibitors of this enzyme,[121] we found that the spirocyclic compound 5,5-ethylenebarbituric acid was a time-dependent irreversible inhibitor. We have no information regarding the mechanism of this reaction. It is noteworthy, however, that the enzyme is a flavoprotein, and that the inhibitor is intrinsically reactive since it contains a cyclopropane ring substituted by two carbonyl groups. Direct nucleophilic attack or radical pathways are all possible.[122]

7. Aryl- and Benzylcyclopropanes and Hydroxylating Enzymes

Our initial interest in cytochrome P-450 and cyclopropane-containing substrates was to investigate the mechanism of aromatic hydroxylation. We found, however, that reaction took place at the three-membered ring rather than

on the aromatic ring. The first substrate to be examined was cyclopropylbenzene;[123] this compound was competitive for ethoxycoumarin in the enzyme from rabbit liver.[124] Unlike alkenes, which are often inhibitors of cytochrome P-450, no time-dependent inhibition was observed and the surprising major product of the reaction was benzoic acid. We initially interpreted this product as arising from the addition of radicals formed by homolysis of a peroxy intermediate at the active site. The possibility of a peracid or its equivalent was considered,[68] but in view of the recent X-ray analysis of the structure of cytochrome P-450cam, such an intermediate is less likely.[125] However, the essential feature of the mechanism leading to benzoic acid is that a diol would be formed at the active site; such an intermediate can arise via homolytic mechanisms, with or without single electron transfer, or via heterolytic mechanisms. The subsequent oxidative cleavage to benzoic acid was envisaged as occurring in a manner similar to the 19-demethylation of steroids[126] and would afford acetaldehyde as the coproduct. This labile molecule was not detected. However, using 1,2-diphenylcyclopropane as substrate, we were able to characterize benzoic acid and phenylacetaldehyde as products of enzymatic oxidation, a result that supports the general outline of the mechanism proposed for the formation of benzoic acid (Fig. 14). Further research into the chemistry of this intriguing oxidation and its potential biological applications is in progress.

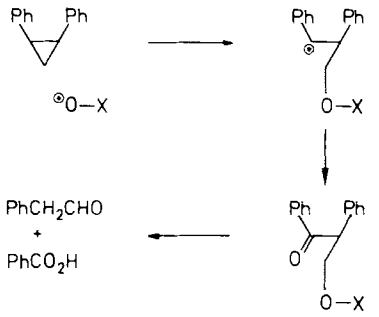


Fig. 14. A possible pathway for the oxidative cleavage of diphenylcyclopropane by cytochrome P-450. $^{\odot}$OX represents an enzyme-bound radical.

The lack of inhibition of cytochrome P-450 by aryl cyclopropanes does not imply that hydroxylating enzymes cannot be inhibited by substituted cyclopropanes. *Fitzpatrick, Villafranca* et al.[127] have shown that dopamine β-hydroxylase, a copper-containing enzyme, is inhibited by alkenes, alkynes, and cyclopropane-containing substrate analogues. The presumed mechanism of action is shown in Figure 15; once again, inhibition was attributed to ring opening of the cyclopropylalkyl radical. Unlike the inhibition of monoamine oxidase by ring-opening reactions, no ring-opened byproducts were detectable in this reaction.

8. Cyclopropanes as Probes of the Mechanism of Coenzyme B_{12}-Mediated Rearrangements

The mechanism by which coenzyme B_{12} directs an intriguing group of molecular rearrangements has been a topic of continuous interest in bioorganic chemistry for

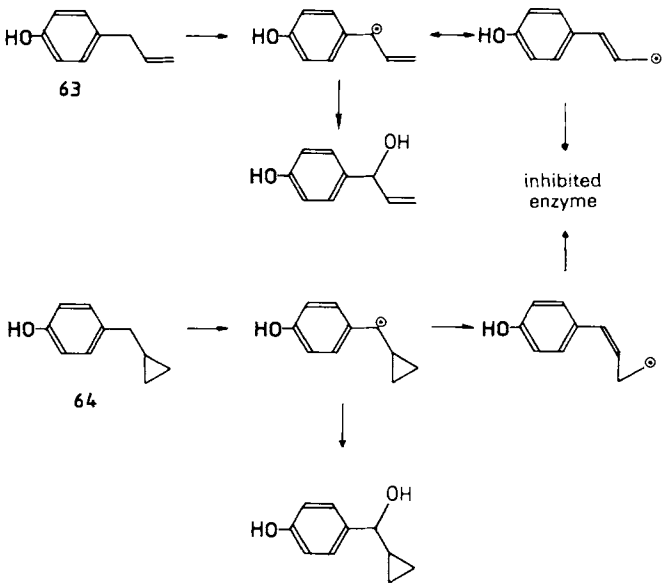

Fig. 15. Inhibition of dopamine β-hydroxylase by alkenyl- and cyclopropyl-substituted phenols as exemplified by *p*-allyl- and *p*-cyclopropylmethylphenol, **63** and **64**, respectively.

more than 20 years.[128] In the early studies, interest was heightened because of the lack of chemical precedent for the 1,2 shifts of both hydrogen and a heavy atom that occur in these reactions (Fig. 16A). The lability of the cobalt–carbon bond of the coenzyme was clearly an important factor; it was known, for example, that homolytic cleavage to give a cobalt(II) complex and an organic radical was possible and such dissociation had been observed in enzyme–substrate complexes. The connection between radical chemistry and the mechanism of action of B_{12} was strengthened when it was found that the reaction of hy-

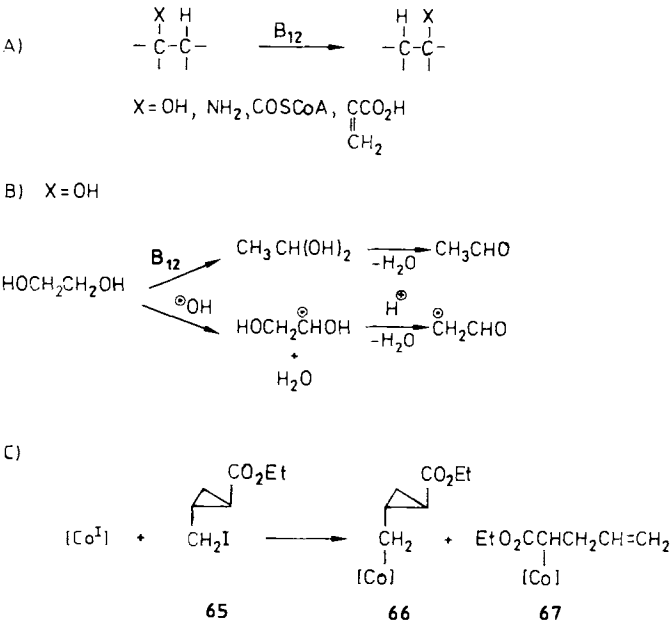

Fig. 16. A) Type of rearrangement catalyzed by coenzyme B_{12}. B) Coenzyme B_{12}-catalyzed rearrangement of ethylene glycol (top) in the presence of $^{\odot}$OH radicals (bottom). C) Model reactions (see text); [Co] stands for bis(dimethylglyoximato)pyridine cobalt.

droxyl radicals with ethylene glycol led to the formation of acetaldehyde radicals (Fig. 16B).[129] There were thus several possible mechanisms for consideration for the rearrangement process once a substrate radical had been formed. Two mechanisms involved electron transfer, but the chief contenders were a radical rearrangement or a mechanism involving a new organocobalt bond formed by combination of the substrate-derived radical with the cobalt; π complexes were also considered. The closest approach to a resolution of this problem has come through studies by *Golding* et al.[130] of model systems that relate to rearrangements in which carbon atoms undergo migration.

Cyclopropane chemistry can be used to study the rearrangement catalyzed by α-methyleneglutarate mutase and *Golding* et al.,[130] using the model compounds **65** and **66** (Fig. 16C), set out to investigate whether the cobalt remained attached to the organic substrate during rearrangement (2-methyleneglutarate→2-methyl-3-methylenesuccinate) or whether a radical free from cobalt was involved. The appropriate probe for a model reaction is a cyclopropyl cobaloxime such as **66**: this was prepared from the corresponding iodide **65** and cobaloxime(I) with partial ring opening to **67**, indicative of a radical substitution pathway. The more hindered *cis* isomer of **66** led exclusively to the ring-opened product **67**, a result that is in keeping with our experience in the ring opening of substituted cyclopropylalkyl radicals.[44] Both isomers of the iodide **65** underwent ring opening upon radiolysis at 77 K thus confirming the sensitivity of the chosen probe to the formation of a radical. In contrast to this reaction, the cyclopropane-substituted cobaloxime **66** did not undergo rearrangement and ring opening. This important result indicates that the cobalt-carbon bond must break for rearrangement to occur and hence that the cobalt is not a direct partner in the rearrangement process. It has, in *Golding*'s words,[130] a "spectator" and not a "conductor" role. The model result thus suggests that in the enzyme-catalyzed reaction, an alkyl cobalamin would be too stable to undergo rearrangement and assigns a role to the deoxyadenosine formed in the reaction, namely to prevent recombination of the rearranging organic substrate radical to afford a stable organocobalt species. In the case of α-methyleneglutarate mutase, it was inferred that the rearrangement takes place via a cyclopropylalkyl radical.[130]

9. Conclusions

The value of the cyclopropyl group in many fields of chemistry is its versatile reactivity. Nowhere is this more true than in the field of enzyme chemistry as the above examples have shown. The interpretations of the likely courses of enzyme-mediated reactions are based upon sound chemical precedent but in many cases, lack of structural information concerning the enzymes makes the interpretations more tentative than one would like. Further examples of the use of cyclopropanes as mechanistic probes in enzyme chemistry nevertheless continue to appear, most recently in a study of the bacterial degradation of phosphonate esters related to nerve gases.[131] The use of cyclopropanol as a tool in the exploration of bacterial alcohol oxidation has been advocated by *Duine* et al.[132] In this application, advantage is taken of the ability of this compound to inhibit only PQQ-dependent enzymes and not NAD-dependent dehydrogenases.

There is a natural scientific progression from basic mechanistic enzymology through metabolic probes to the invention of new drugs. For cyclopropanes, the first two stages have been investigated. It is to be hoped that the third stage will follow. However, the future development of the use of cyclopropanes as mechanistic probes or in inhibitors would benefit from more detailed studies of the intimate interactions of these versatile compounds with the enzymes themselves.

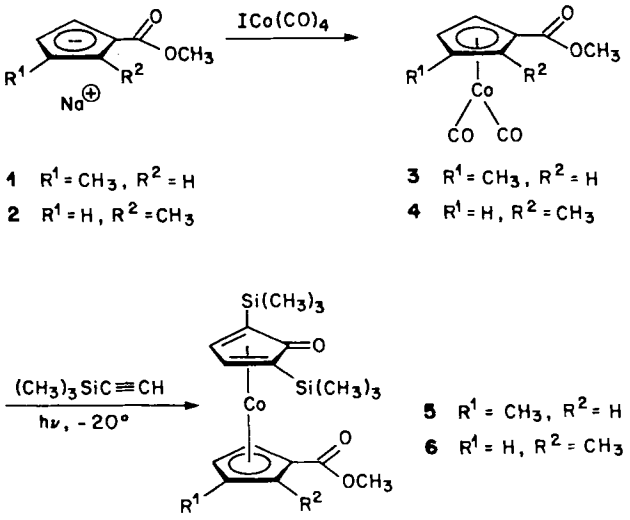
First Case of Interannular, Possibly Electronically Transmitted, Asymmetric Induction in an Organometallic Compound**

By *Roland Boese, Dieter Bläser, Ronald L. Halterman,* and *K. Peter C. Vollhardt**

The topic of enantio- and diastereoface control in organic reactions is one of intense current interest.[1] Electronic effects have been invoked in those cases in which steric considerations were insufficient or inappropriate to explain the observed results.[1,2] Although theoretical and experimental analyses have led to the postulation of a variety of phenomena and rules to rationalize both steric and electronic influences,[3] a clear differentiation between these effects has been difficult, in particular because of the lack of systems in which the approaching *reagent and the reacting center* are distant from the chiral auxiliary. Among the more intriguing organometallic examples are $[(\eta^5\text{-}C_5H_5)Re(NO)\{P(C_6H_5)_3\}(C{\equiv}CR)]$[4] and $[(\eta^5\text{-}C_5H_5)Mo(NO)(CO)(allyl)]^{\oplus}$,[5] both of which undergo seemingly remote stereoselective electro- and nucleophilic addition, respectively, controlled by the metal-based stereocenter.[6] We report here the first case of interannular transfer of asymmetry (possibly electronic in nature) in an organometallic system and an unprecedented example of carbon–carbon bond formation to a π-bound ligand in which diastereoselectivity is induced by a chiral unit whose asymmetry originates by complexation of a heterodisubstituted cyclopentadienyl ring to a metal that is thus rendered stereogenic.[7]

Acylation of methylcyclopentadienylsodium produced a nearly equimolar mixture of the salts **1** and **2**[8] which were converted into the dicarbonylcobalt complexes **3** and **4** (17.2%)[8] by treatment with tetracarbonyl(iodo)cobalt.[9] The mixture of **3** and **4** (0.03 M in THF) was photolyzed (450-W Hanovia Hg-vapor lamp, −20°C, 10 h)[10] in the presence of trimethylsilylethyne to give the chiral cyclopentadienone complexes **5** and **6** (73% separated on silica).[8] The chirality in these compounds is due to the presence of the unsymmetrically substituted ligand, from now on referred to as the "bottom" ring. The substitution pattern of the bottom ring in **6** was ascertained using the FUCOUP NMR technique.[11,12] In both isomers the diastereotopic hydrogens attached to the top ring have quite different chemical shifts,[8] boding well for potential differences in reactivity at these two sites.



To probe for the origin of this finding and to corroborate the structural assignments, an X-ray structural analysis of **5** was executed (Fig. 1).[13]

There are two rotamers **5a** and **5b** with respect to the orientation of the ester group in the unit cell. Interestingly, while rotamer **5a** contains the relevant carbons C3 and C4

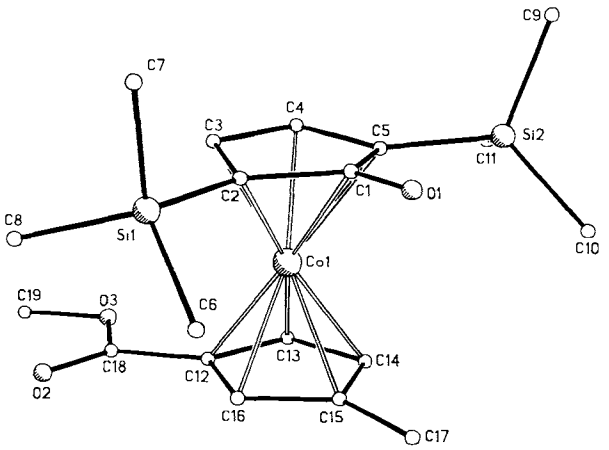


Fig. 1. Crystal structure of **5**. Important bond lengths and nonbonding distances [Å]: **5a**: Co1-C1 2.212(6), Co1-C2 2.057(6), Co1-C3 2.004(7), Co1-C4 2.010(7), Co1-C5 2.069(6), Si1-C2 1.875(6), Si2-C5 1.876(6), C1-O1 1.272(8), C1-C2 1.459(9), C1-C5 1.451(8), C2-C3 1.419(9), C3-C4 1.419(9), C4-C5 1.424(9), C1-C15 3.375, O1-C17 3.452, C2-C16 3.261, C3-C12 3.357, C4-C13 3.375, C5-C14 3.295, C6-O2 5.184, C6-C12 4.943, C6-C16 3.837, C8-O2 3.505, C8-C18 4.133, C8-O2 3.505; **5b**: Co2-C21 2.237(6), Co2-C22 2.059(6), Co2-C23 2.000(7), Co2-C24 2.005(6), Co2-C25 2.066(6), Si4-C22 1.864(6), Si3-C25 1.886(6), C21-O21 1.266(8), C21-C22 1.470(8), C21-C25 1.461(9), C22-C23 1.436(9), C23-C24 1.409(9), C24-C25 1.406(9), C21-C35 3.441, O21-C37 3.518, C22-C36 3.269, C23-C32 3.368, C24-C33 3.380, C25-C34 3.289, C26-O21 3.437, C28-O23 3.511, C28-C39 3.956, C28-C38 4.220.

7 $R^1 = CH_3$, $R^2 = H$
8 $R^1 = H$, $R^2 = CH_3$

9a-c $R^1 = CH_3$, $R^2 = H$
10a-c $R^1 = H$, $R^2 = CH_3$

in an (within the error limits) equal environment, **5b** does not, although the differences are subtle. However, it can be seen clearly that the substituents on the bottom ring induce measurable structural changes in its top counterpart compared to [η^4-2,5-bis(trimethylsilyl)cyclopentadienone](η^5-cyclopentadienyl)cobalt,[14] including coplanarity of the respective ring carbons and the enforcement of an eclipsed configuration, *despite the absence of recognizable steric interactions*.[15]

Methylation of **5** or **6** with dimethyl sulfate yielded the (not isolated) cobaltocenium salts **7** and **8**, the substrates required to test for the feasibility of diastereoselective attack. Nucleophilic addition to such structures is known to take place *exo* with respect to the metal, thus clearly avoiding any steric interference by the other ligand.[16,17] Nevertheless, when **7** was exposed to nucleophiles **11**–**13** (chosen to maximize top ring addition),[16] modest but *pronounced and reproducible diastereoselectivity in the formation of* **9**[8] *was observed* (Table 1). The yields of addition (including 20% to the bottom ring) were high, thus ruling out any complications associated with potentially (if unlikely) differing stabilities of the products. The similarity of the ^{1}H-NMR spectral data for the respective sets of isomers suggests that preferential reaction occurred at the same diastereotopic carbon in each instance. The addition to **8** (→**10**) not only gave more bottom ring addition (60%), but also negligible stereoselectivity. To detect any possible involvement of solvent in these transformations, **7** was treated with **11** in THF/hexamethylphosphoramide without any change in the product distribution. Similarly, no change in selectivity was observed over the temperature range −78°C to 20°C.

Table 1. Diastereoselectivities in the additions of nucleophiles **11**–**13** to **7** and **8** [a].

Nucleophile	Stereoselectivity [b] (yield [%] [c])	
	9	**10**
$(CH_3)_3SiC{\equiv}CLi$ **11**	70 : 30 (73.0)	54 : 46 (87.4)
n-$C_6H_{13}C{\equiv}CLi$ **12**	67 : 33 (91.3)	52 : 48 (94.6)
$C_2H_5OC{\equiv}CLi$ **13**	75 : 25 (90.7)	50 : 50 (90.6)

[a] The stereoselectivities were measured by ^{1}H-NMR integration of several characteristic peaks [e.g., those for the cyclopentadienyl and $(CH_3)_3Si$ groups]. [b] Ratio of major to minor isomer. [c] Total yield for the reaction, including bottom ring addition.

It is difficult to find a clear rationale for the observed selectivities. A possible explanation is the operation of a hitherto unobserved interannular electronic transmission of asymmetry. Inter-ring electronic effects in ordinary metallocenes are known and may be related in origin to our observations.[18] Although we cannot completely rule out a subtle steric differentiation between the two transition-state structures when formulated in the form of an extreme conformation that places the methyl ester hydrogens in closest proximity to the reacting top ring carbons, such an effect appears unlikely to be important in view of the fact that the product emerges bearing the resulting complexed cyclopentadiene ring in an envelope configuration in which the sp^3 carbon is *even further* removed from the bottom ring, the potentially interfering hydrogen being located in a pseudo-equatorial position.[17] Regardless of the mechanism by which this preference for nucleophilic attack on **7** and **8** comes about, the present work demonstrates for the first time the feasibility of chiral differentiation in such systems, a phenomenon that, when optimized and properly understood, may be of utility in synthesis.

Experimental Procedure

9a: To a solution of **5** (0.029 g, 0.07 mmol) in diethyl ether (0.5 mL) at room temperature under nitrogen was added dimethyl sulfate (0.030 g, 0.24 mmol) via syringe. This red solution was stirred 40 h until it became clear pale yellow. The solvent was removed by a stream of nitrogen, leaving a yellow oil of the cobaltocenium salt **7**. THF (5 mL) was added and the solution was cooled to −78°C. A solution of **11** in THF, prepared by adding methyllithium (1.0 mL, 1.4 M in diethyl ether/hexane, 1.4 mmol) to trimethylsilylethyne (0.147 g, 1.5 mmol) in THF (5 mL) at −78°C and warming to 0°C over 20 min, was introduced dropwise at −78°C. The reaction mixture turned immediately dark red. After stirring for 1 h at −78°C, water (1 mL) was added and the mixture allowed to warm to room temperature. The deep red solution was extracted with diethyl ether (3 × 5 mL), the combined organic portions were washed with water (1 × 1 mL) and dried over $MgSO_4$, and the volatiles were removed by rotary evaporation. Filtration of the resulting red oil through alumina (2 g, activity 3) with diethyl ether and subsequent reverse-phase HPLC (two 10-mm × 25-cm ODS columns, CH_3CN, 2.8 mL min^{-1}, solvent front 10 min) provided a fraction after 35 min of **9a** [8].

Real-Time Atomic-Resolution Imaging of Polymorphic Changes in Ruthenium Clusters**

By *Jan-Olle Malm, Jan-Olov Bovin,* Amanda Petford-Long, David J. Smith, Günter Schmid,* and *N. Klein*

A knowledge of the microstructure including free surfaces and defects of small particles, and of any variations of these properties with time, is of great importance for an understanding of the mechanisms involved in heterogeneous catalysis, and in surface reactions such as corrosion. The activity and selectivity of small metal crystal catalysts depend on the surfaces involved in the reaction. It has been shown, for example, that the (111) surface of iron is about four hundred times more active than the (110) surface during ammonia synthesis.[1] The abundance and extent of a specific surface is a direct function of the crystal structure, shape and size, as well as of any structural rearrangements with time. This means that catalytic reactions involve not only the dynamics of any surface atoms of the metal but also the dynamics of the total structure. Consequently, it is desirable to study the behavior of different metals at temperatures relevant for catalytic reactions.

It has recently been shown[2,3] that the atomic structure of small metal particles (≈ 1–10 nm) can be imaged directly by means of modern high-resolution electron microscopes (HREM). Dynamic in situ HREM observations at TV rate, using low-light-level, silicon-intensified target cameras, have revealed structural rearrangements,[4] crystal growth,[5] and surface structures[6] associated with small metal crystals of gold,[7] platinum, rhodium, ruthenium, and zinc.[5] We demonstrate here that video recordings made at atomic resolution with an HREM can yield important information on the morphology and atomic structure of small ruthenium particles.

Novel preparation methods[8] have made it possible to obtain ruthenium metal clusters $[Ru_{55}(PtBu_3)_{12}Cl_{20}]$, with constant size and reasonable stability for transportation into the electron microscope.

The Ru cluster compound is easily oxidized in air and is dispersed in methanol and transferred onto a holey carbon support film in an inert gas (N_2) atmosphere. The sample is then loaded into the microscope while still wet with methanol, and the high vacuum ($\approx 5 \times 10^{-7}$ torr) inside the microscope column is used to evaporate the solvent. The organic ligands and chlorine atoms that cover the 55-atom metal core are removed when the electron beam (typical current density of 20–40 A cm^{-2}) irradiates the area of observation, leaving bare metal particles exposed on the substrate of amorphous carbon. Electron microscopy was performed with a JEM-4000 EX, which was operated at an electron accelerating voltage of 400 kV and could achieve

[**] This work was supported by the Swedish National Science Research Council (K-KU3914-120), the National Swedish Board for Technical Development (81-5366), the Swedish National Energy Administration (276332-1), and the American Office for Naval Research, and made use of facilities within the National Facility for High Resolution Electron Microscopy at Arizona State University, funded by the U. S. National Science Foundation (grant DMR-8306501).

a structural resolution of better than 0.17 nm. The typical electron-optical magnification used was 800000×. A fiber-optically coupled TV system, equipped with an yttrium-aluminum-garnet (YAG) detector and an intensifier, was used for video recordings. The recorded images were treated with a Quantex DS-30 digital video processor for noise reduction using a resolution of 512×512×256. It was possible to freeze individual frames (1/30 s recording time) at any time with the processor in order to take photographs of the images visible on the TV monitor.

X-ray diffraction studies[9] of ruthenium metal from room temperature to 1300°C suggest that its crystal structure is hexagonal close-packed (hcp) over the whole range, with a unit cell described by $a = 0.2713$ nm and $c = 0.4303$ nm at 500°C. The existence of only one phase in this temperature range does not agree with earlier specific heat measurements[10] between 0°C and 1600°C which showed two different phases up to 1200°C and an additional two at higher temperatures. The structures of these phases have not been determined. The precise structural arrangements of the 55 ruthenium atoms in the center of the clusters studied here is not known, although we have observed one very small crystal containing approximately 50–60 atoms (Fig. 1), which displays structural characteristics similar to a hexagonal close-packed structure when compared with a computer-simulated image projected along ⟨100⟩ (see Fig. 5a). (The main problem with recording genuine crystal structure images of small crystals[7] is the occurrence of structural rearrangements which are faster than the frame rate of 1/30 s per frame.)

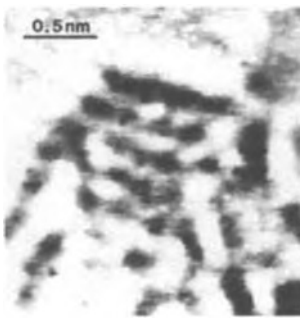

Fig. 1. Ruthenium crystal, containing approximately 50–60 atoms, which originates from the cluster molecule $[Ru_{55}(PtBu_3)_{12}Cl_{20}]$ and which could be regarded as the metal core of the molecules. Comparison with image simulations confirms that the crystal has roughly hcp characteristics (cf. Fig. 5a).

The Ru crystals were found to be randomly oriented and dispersed over the substrate. Those located along the edges of holes in the carbon film were chosen for observation to avoid their images being obscured by contrast from the underlying amorphous carbon support film. Similar to the clusters of gold, platinum and rhodium studied previously,[7] the 55-atom clusters of Ru start to grow under the influence of temperature increases generated by the electron beam as it irradiates the substrate. This growth results in crystals with typical sizes in the range of 2–5 nm. Crystals of this approximate size change their structure rather slowly, with the rate of change also dependent on the size of the contact area with the support. With better contact, the rearrangements usually become slower.

Video recordings of these Ru crystals reveal that their structure is not solely restricted to the known bulk hcp structure. The cubic close-packed (ccp) structure was often seen and a crystal was occasionally observed made up of half ccp and half hcp structures (Fig. 2). It has been known for a long time[11, 12] that the hcp structure could be described as ccp with regular twinning along the ⟨111⟩ direction. The crystal structure image shown in Figure 2 reveals that the lower right part of the crystal is ccp for five atomic planes, viewed here along $\langle 110\rangle_{ccp}$, and the upper half of the crystal contains regularly twinned planes (ten in all) along $\langle 111\rangle_{ccp}$. This results in the normal hcp structure being obtained, viewed here along $\langle 100\rangle_{hcp}$.

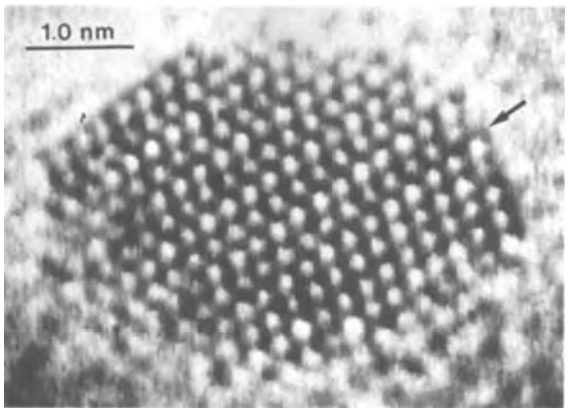

Fig. 2. Structure image confirming the coexistence of hexagonal close-packing and cubic close-packing in the same ruthenium crystal. At the upper left of the image is the characteristic hcp structure, viewed along $\langle 100\rangle_{hcp}$. The five ⟨111⟩ planes at lower right are clearly ordered ccp. The ⟨111⟩ plane that separates the hexagonal structure from the cubic is marked with an arrow.

The calculated structural energy difference between ccp and hcp has been reported to be higher for Ru than for any other 4d element.[13] Experimental enthalpy differences derived from phase diagrams give values which are smaller by about a factor of 10.[14] Moreover, since the same crystal of Ru contains both ccp and hcp structures at the same time, it might be concluded that the energy levels for ccp and hcp stacking are very close to each other. If the atomic volume is considered to be the same for the two types of atomic stacking in ruthenium, as in cobalt metal,[15] the cubic lattice parameter can be calculated to be $a = 0.379$ nm. The projected interatomic distances of Ru viewed along $\langle 110\rangle_{ccp}$ would be 0.232 nm, almost identical to the corresponding distances (0.235 nm) known from images (cf. Fig. 2) recorded of hcp crystals. The image in Figure 2 is the first experimental micrograph that verifies the coexistence of ccp and hcp structures in the same Ru crystal, with both interatomic distances approximately 0.27 nm.

The rearrangements of the small ruthenium crystals not only involved hcp and ccp structures. The video recordings revealed that body-centered cubic (bcc) and icosahedral packing existed for short periods, ranging from 1/30 s (lower limit of recording for one TV frame) to several seconds. The crystal shown in Figure 3 was observed continuously for more than 30 min while it was constantly changing its structure without noticeably growing. Irregular twinning of the ccp structure gives rise to a disordered hcp structure, as reported earlier for hcp cobalt,[16] and such defect twinning also occurs for ruthenium (see Fig. 3b). The stacking sequence of close-packed (111) atom planes from left to right can be represented as

B C A C A B A B A B A

if the white dots are counted as atomic columns, starting from the plane marked with an arrow. This same crystal

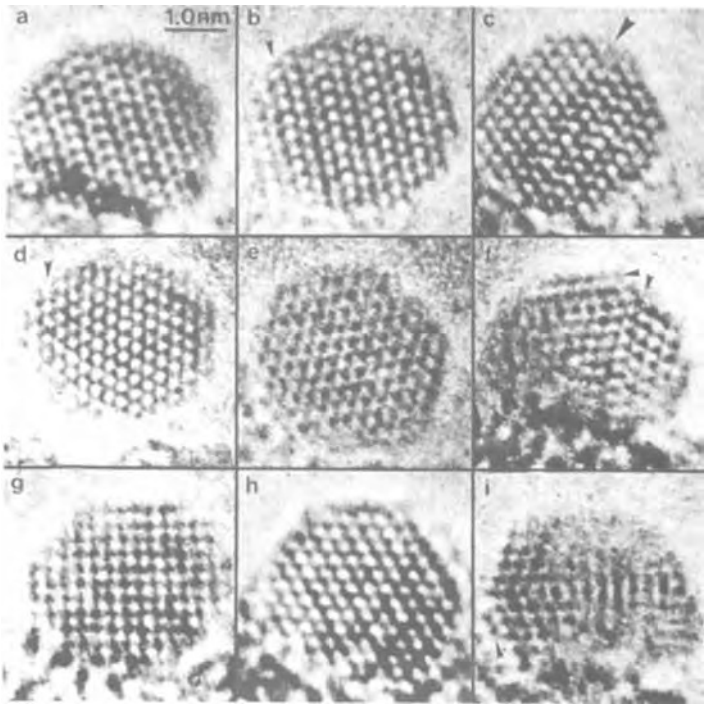

Fig. 3. Images of the same 3-nm ruthenium crystal, recorded during a 30-min period, which show rearrangements in the crystal structure and the occurrence of four basic structure types. a) The hcp structure viewed along ⟨100⟩. b) Disordered hcp structure which can be derived from irregularly twinned ccp. See text for details of stacking sequence of ⟨111⟩ planes. c) Half hcp and half ccp structure: the ⟨111⟩ plane separating the two structure types is marked with an arrow. d) Mostly ccp, except for three/four planes (at left) which show hcp stacking. See text for details of stacking sequence. e) Entire structure is ccp. f) Defects and twinning (marked with an arrow) are common in the ccp state. g) The bcc structure, viewed along ⟨100⟩. h) The bcc structure, viewed along ⟨111⟩. i) The multiply twinned isosahedral stacking. The two outer atomic columns (marked with an arrow) are not located in the expected positions compared with the bulk structure.

also had a structural state of half ccp and half hcp (Fig. 3c), and states having only a minor hcp region were also recorded (see Fig. 3d). The stacking sequence of the (111) atomic planes from left to right in this case is

A C B A B C A B C A B C
hcp ccp

under the same conditions as above. The cubeoctahedral crystal shape in the ccp structure was just as frequently seen as hcp, and one example is shown in Figure 3e. Twinning and antiphase boundaries were very common, as reported earlier for Au.[4] A typical defect in the ccp crystal packing is shown in Figure 3f: two defect planes are visible.

The third basic structural type for metals, namely body-centered cubic (bcc) packing, was imaged several times along different crystallographic axes (Fig. 3g, h). Energy calculations for different structures,[13] as well as experimental enthalpy measurements,[14] indicate that bcc packing should be unlikely for ruthenium. However, theoretical calculations do not predict the existence of the experimentally well-established bcc structure for the corresponding 3d element iron. The very early specific heat experiments for Ru and Fe[10] indicated the close resemblance between the curves of the two elements. Like iron, molybdenum is also reported as adopting both ccp and bcc structures.[17] The atomic radius for iron is 0.130 nm for ccp and 0.126 nm for bcc structures, which is a difference of about 3%. The corresponding difference for molybdenum is about 8% ($r_{ccp} = 0.147$ nm and $r_{bcc} = 0.136$ nm). If the corresponding difference for ruthenium is assumed to be about 5%, then the bcc radius is calculated as 0.130 nm for the unit-cell parameter $a = 0.300$ nm. The projected distances between atomic columns of small bcc Ru crystals, when imaged in the ⟨100⟩ direction, should then be 0.212 nm (in a square net), which is in agreement with the distances measured in the image in Figure 3g. When the same crystal is viewed along the ⟨111⟩ direction (Fig. 3h), a hexagonal net of atomic columns should be seen with a separation of 0.245 nm between the black dots. Note that a hexagonal contrast pattern would appear for an hcp crystal viewed along the c axis, but the shortest distance between the atom columns would be 0.117 nm, which is beyond the structural resolution of the particular microscope used in this study. Computer simulations indicate that the unit cell repeat of 0.271 nm should be visible in the image, and that it should be easily differentiated from the 0.245-nm distance occurring along ⟨111⟩ for bcc Ru.

Icosahedral packing of atoms is expected to be favorable for very small metal clusters ($N \leq 14$ atoms) when the energy of configuration is taken into account.[18] When a third layer of atoms is added, the proper coordination number and bond distances can no longer be obtained. Surface and internal defects are thus introduced as the crystal grows. Defects of this type have been observed previously by HREM for larger silver crystals (≈ 10 nm).[19] Small gold crystals (≈ 3.5 nm) can sometimes attain an icosahedral structure during rearrangements:[5,6] the image in Figure 3 shows that this structural type also occurs for Ru. This structure is, however, not very common—only a couple of cases were observed during the entire recording period. (Note that the two outermost columns of atoms at one surface (arrow) are not located in the expected positions relative to the bulk structure.)

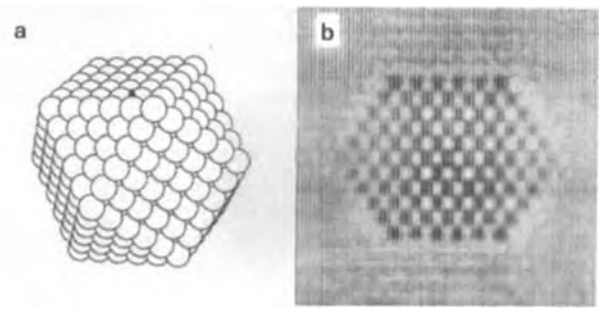

Fig. 4. a) Model for an ideal cubeoctahedron, containing 561 atoms, of the same approximate size as the crystal shown in Fig. 3a. b) Corresponding image simulation, viewed along ⟨110⟩, using the electron-optical parameters of the JEM-4000 EX.

Image simulations, taking into account the microscope imaging conditions, were used to confirm the appearances expected for the various structural types adopted by the Ru clusters. A model for a ccp cubeoctahedron containing 561 atoms, viewed along ⟨110⟩, is shown in Figure 4a, with the corresponding image simulation shown in Figure 4b. This computer simulation can be compared with the experimental micrograph (Fig. 3e). The hcp state of the same crystal (Fig. 3a) can be compared with the image simulation shown in Figure 5a. In this case, the computation was

done for a much smaller (54-atom) crystal of the same shape in order to minimize computation time. Figure 5b shows the computation for an ideal cubeoctahedron containing 55 atoms as viewed along ⟨110⟩. Finally, Figures 5c and 5d show the image simulations for the bcc structure as viewed along ⟨100⟩ and ⟨111⟩, respectively, which should be compared with the experimental images shown in Figures 3g and 3h, respectively.

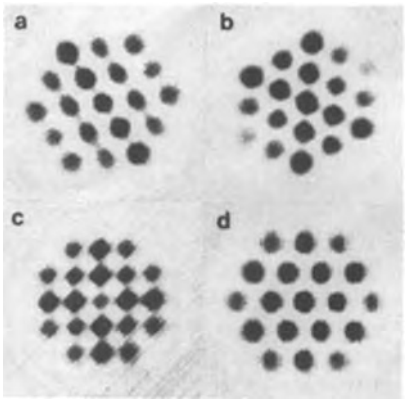

Fig. 5. Computer simulations of various structural types for comparison with the experimental micrographs: a) hcp along ⟨100⟩ containing 54 atoms; b) ccp along ⟨110⟩ containing 55 atoms (ideal cubeoctahedron); c) bcc along ⟨100⟩ containing 59 atoms; d) bcc along ⟨111⟩ containing 59 atoms.

These observations of the important catalyst ruthenium show that its overall crystal structure, and hence its surface structure, change very rapidly under the influence of the electron beam. Earlier studies of small gold crystals[4] indicated that the local temperature in the vicinity of the illuminated area was probably above 500 °C. This constantly changing nature of the metal clusters could well be a quasi-liquid state previously not shown to exist because of the difficulties involved in observing or recording it. Recent results from time-resolved NMR spectroscopy[20] could be interpreted to mean that the small metal clusters with ligands surrounding them altered their structure in solution even at room temperature. These results are of crucial importance for future research on the mechanisms involved in catalytic reactions on metal surfaces.

Unsaturated Hydrindanone Derivatives from Arenes by Hetero-Claisen Rearrangement**

By *Annegrit Bosum* and *Siegfried Blechert**

The Claisen rearrangement of aromatic compounds proceeds via olefinic intermediates and thus releases the latent functionalities of the arene. The preparative use of these functionalities is usually not possible, however, owing to spontaneous rearomatization, e.g., in the case of *ortho*-substituted arenes, by a second [3,3]-sigmatropic rearrangement to give *para*-substituted products.[1] For carbanion-accelerated hetero-Claisen rearrangement of *N*-aryl-*O*-vinyl systems, very mild reaction conditions may be employed,[2] thereby excluding a subsequent hetero-Cope rearrangement, since the essential driving force for the hetero-Claisen rearrangement—a weak N–O bond and the formation of a C=O bond—is no longer present. Thus, imines may be generated by rearrangement of *ortho*-substituted *N*-phenylhydroxylamine derivatives. These imines, in turn, may be trapped intramolecularly by nucleophiles, leading to the formation of novel five-membered rings.[3]

We have used this strategy to synthesize unsaturated hydrindanone derivatives or other cyclic olefins directly from arenes. In order to avoid regioselectivity problems in the hetero-Claisen rearrangement, we initially employed symmetrically substituted compounds. Reaction of the lithium salt **1**[4] with the readily accessible, acceptor-substituted allenes **2**[5] in tetrahydrofuran at room temperature resulted in Michael addition, rearrangement, and cyclization, leading to formation of the hydrindanone derivatives **5**,[6] in preparatively useful yields, which could be purified by chromatography (for spectroscopic data of the compounds **5a**, **6**, and **7**, see Table 1). The intramolecular trapping reaction is highly stereoselective for the *N*-acylated imine **4**.[7] Intermediates could not be detected.

Because of its position (tertiary allylic), the *N*-acyl group of **5** proved to be a sufficiently good leaving group, so that, by retro-Michael addition, an unsaturated five-membered ring ketone could readily form, which, in turn, leads to material losses upon chromatographic purification of **5**. It is best, therefore, to use unpurified **5** (one-pot reaction) in subsequent reactions. Thus, for studies of the synthesis of terpenes, **5** was hydrogenated with H_2 in the presence of Pd on $BaSO_4$, whereby only the less substituted double bond was attacked. Filtration over neutral Al_2O_3 resulted in amide cleavage. Thus, **7**[6] was obtained from **5a** in 65% overall yield (based on **1**) in a one-pot reaction.

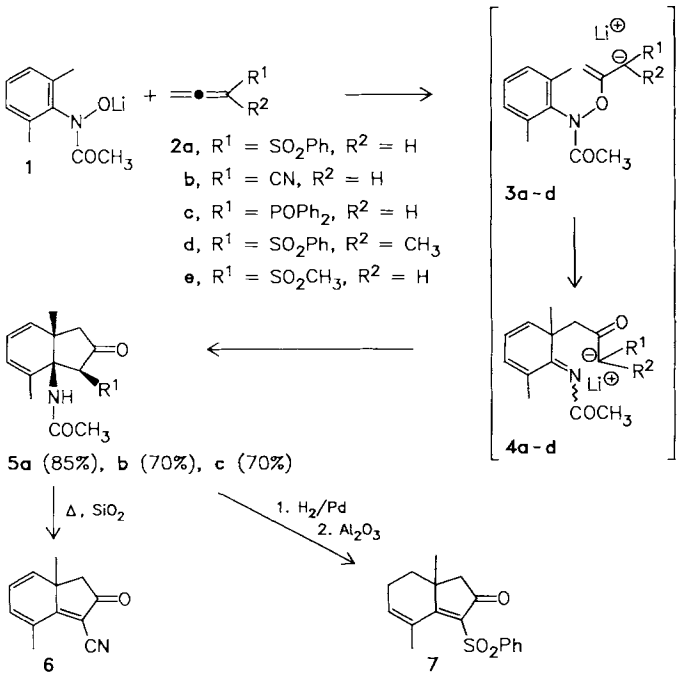
[**] Hetero-Cope Rearrangement, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 6: J. Wilkens, A. Kühling, S. Blechert, *Tetrahedron 43* (1987) 3237.



When unpurified **5b** was transferred to a silica surface and heated at 100°C for 5–10 min, **6**,[6,7] as retro-Michael product, was obtained in nearly quantitative yield upon elution with diethyl ether. Compound **6** should be of interest as a readily accessible derivative of the unstable 3a-methyl-3a*H*-indene.[8] Although retro-Michael additions of **5** can also be accomplished by heating in a solvent, indene derivatives of type **6** undergo rapid dimerization and can be handled in solution even at room temperature for only a few minutes.

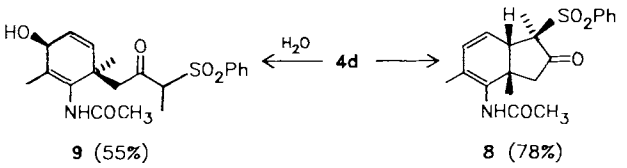
Table 1. Selected spectroscopic data for the compounds **5a**, **6**, and **7**. 200-MHz ^{1}H-NMR in $CDCl_3$, *J* in Hz.

5a: IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 3380, 1750, 1700. — ^{1}H-NMR: δ = 7.9 (dd, *J* = 7.5, 2.0, 2H), 7.4–7.7 (m, 3H), 7.39 (br. s, 1H), 5.9 (m, 2H), 5.35 (dd, *J* = 7.5, 2.0, 1H), 4.2 (s, 1H), 3.0 (d, *J* = 16.5, 1H), 2.8 (d, *J* = 16.5, 1H), 2.19 (s, 3H), 2.15 (s, 3H), 1.2 (s, 3H)

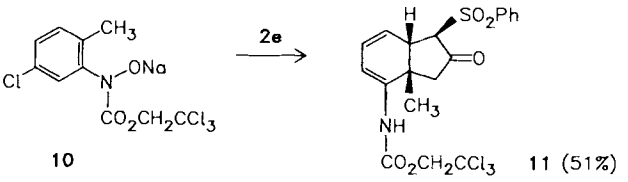
6: UV (CH_3OH): λ_{max} = 354 nm. — IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 1725, 1635, 1600. — ^{1}H-NMR: δ = 6.43 (dd, *J* = 9.0, 1.5, 1H), 6.35 (dd, *J* = 6.0, 1.5, 1H), 6.11 (dd, *J* = 9.0, 6.0, 1H), 2.58 (s, 2H), 2.35 (s, 3H), 1.36 (s, 3H)

7: IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 1720, 1620. — ^{1}H-NMR: δ = 8.05 (dd, *J* = 8.0, 1.5, 2H), 7.55 (m, 3H), 6.25 (br. s, 1H), 2.44 (d, *J* = 8.0, 1H), 2.43 (d, *J* = 8.0, 1H), 2.35 (s, 3H), 2.34 (dt, *J* = 8.0, 4.0, 2H), 1.80 (t, *J* = 8, 2H), 1.18 (s, 3H)

The conjugated *N*-acylated imines **4**, formed by hetero-Claisen rearrangement, can also be trapped by vinylogous attack, leading to hydrindanone derivatives having a different pattern of substitution. This goal is easy to attain with sterically demanding carbanions such as **4d**. Instead of direct cyclization with the imine moiety, which would lead to the formation of three neighboring quaternary centers, stereochemically uniform formation of **8**[6,7] is observed (78% yield after chromatographic purification on silica gel). Because of the low nucleophilicity of the carbanionic center of **4d**, water as a competing nucleophile can attack the imine group vinylogously. When **1** is allowed to react with **2d** at 40°C in the presence of a small amount of water, the main product obtained (55% yield) is the diastereomerically pure allyl alcohol **9**,[6] which is unstable and undergoes ready transformation to **8**.



Hetero-Claisen rearrangements of mono-*ortho*-substituted arenes can lead to cyclic olefins or to arenes. We investigated possibilities to control the regioselectivity of the rearrangement in order to selectively synthesize hydrindanone derivatives.[9] The studies of regioselectivity revealed, among other things, a pronounced steric effect of substituents on the arenes as well as on the nitrogen atom. In some cases, this can be used to control the regioselectivity of the rearrangement and of the subsequent cyclization. The hetero-Claisen system generated by reaction of **10** and **2e** rearranges preferentially with involvement of the methyl-substituted position; the formation of the apparently sterically unfavored tetrasubstituted arene is thereby avoided. The vinylogous trapping reaction of the imine is stereochemically unambiguous and affords, after chromatography on silica gel, the functionalized unsaturated hydrindanone derivative **11**.[6,7]



Experimental Procedure

5, **8**, **11**: Hydroxamic acid (2 mmol) was deprotonated in 10 mL of dry tetrahydrofuran with 2 mmol of NaH as a 50% suspension in mineral oil. Water-free lithium fluoroacetate (2.5 mmol) and allene **2** (2.2 mmol) were then added. After the reaction had ended (20 min, monitored by TLC), the mixture was neutralized with formic acid, poured into 60 mL of water, and extracted with 60 mL of dichloromethane. After distillation of the solvent, the crude product was worked up further or—for characterization—purified by flash chromatography.

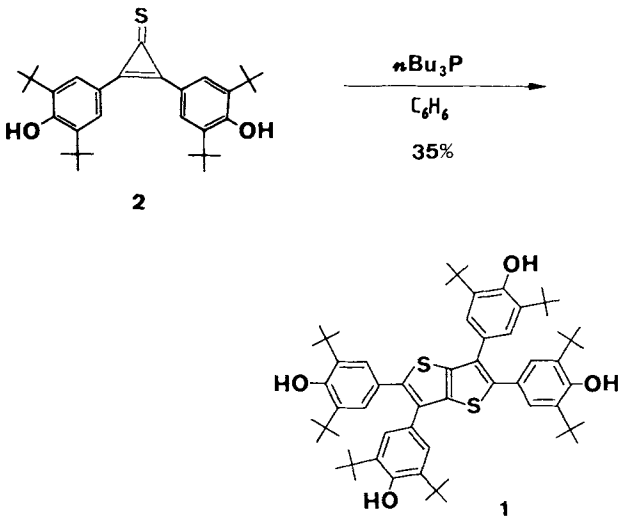
Redox-Active Thieno[3,2-*b*]thiophene as a Novel, Three-Color Electrochromic System

By *Toyonari Sugimoto, Toshio Nagatomi, Hiroshi Ando,* and *Zen-ichi Yoshida**

Organic materials exhibiting electrochromism, a phenomenon of reversible coloration change induced by electrochemical redox reactions,[1] are of current interest in the development of organic electrochromic display devices, the main advantages of which are low-voltage (0.5–5 V) operation, wide-angle vision, and vivid multicoloration. However, except for viologens,[2] such electrochromic systems are limited to metal complexes such as rare-earth metal phthalocyanines[3] and tris(bipyridyl)ruthenium(II) complexes.[4] We have now prepared a metal-free organic electrochromic system displaying three colors and exhibiting high durability, which is composed of 2,3,5,6-tetrakis (3,5-di-*tert*-butyl-4-hydroxyphenyl)thieno[3,2-*b*]thiophene **1** and its two- and four-electron oxidized partners.

A benzene solution of bis(3,5-di-*tert*-butyl-4-hydroxyphenyl)cyclopropenethione **2**[5] and 1.1 equivalents of tri-*n*-butylphosphane was refluxed for 4 h under argon atmosphere. After evaporation of the solvent, the residue was chromatographed on silica gel with CH_2Cl_2/hexane (1 : 4), followed by recrystallization from benzene/hexane, to afford **1** as pale yellow crystals (m.p. >300 °C) in 35% yield.[6] This is the first case of thieno[3,2-*b*]thiophene formation by thermal dimerization of cyclopropenethiones,



although its photochemical counterpart is already known.[7] When other trivalent phosphorus compounds, such as triphenylphosphane, trimethylphosphite, and hexamethylphosphorous triamide were used, **1** was not formed at all.[8] The structure of **1** was determined from the ^{1}H- and ^{13}C-NMR spectral data (see Table 1).[9] The ^{1}H-NMR spectrum showed the presence of two magnetically different aryl groups. In the ^{13}C-NMR spectrum 15 signals appeared, of which those at $\delta = 138.41$, 137.85, and 131.12 are assigned to the thieno[3,2-*b*]thiophene skeletal carbons.[10]

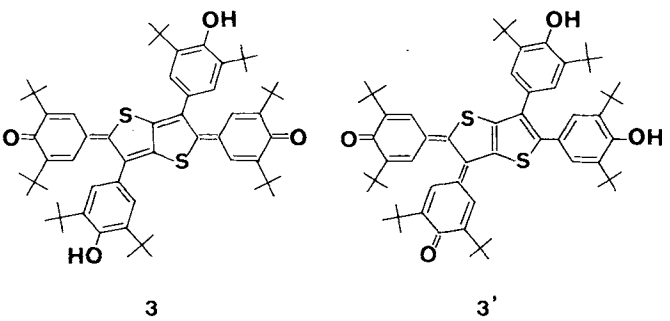
Table 1. Characteristic spectroscopic data for **1**, **3**, and **4**.

Compd	λ_{max}[nm](lgε) (CH_2Cl_2)	IR (KBr) $\tilde{\nu}$ [cm^{-1}]	^{1}H-NMR ($CDCl_3$) δ value
1 [a]	263 (4.41), 303 (4.31), 348 (4.42)	3620, 2940, 2900, 2850, 1425, 1360, 1310, 1230, 1150, 1110, 895	7.24 (s, 4H), 7.13 (s, 4H), 5.17 (s, 2H), 5.16 (s, 2H), 1.35 (s, 36H), 1.33 (s, 36H)
3	279 (3.78), 304 (3.52), 395 (3.47), 634 (4.71)	3620, 2950, 2910, 2850, 1740, 1580, 1450, 1360, 1340, 1130	7.25 (d, J = 2.7 Hz, 2H), 7.24 (s, 4H), 7.01 (d, J = 2.7 Hz, 2H), 5.52 (s, 2H), 1.47 (s, 36H), 1.29 (s, 18H), 0.94 (s, 18H)
4	266 (4.54), 398 (4.78), 516 (4.77), 620 (4.28), 782 (4.54)	2980, 2940, 2900, 2850, 1590, 1570, 1480, 1450, 1390, 1360, 1250, 1120, 1090, 1030	7.29 (br. s, 8H), 1.33 (br. s, 36H), 1.28 (br. s, 36H)

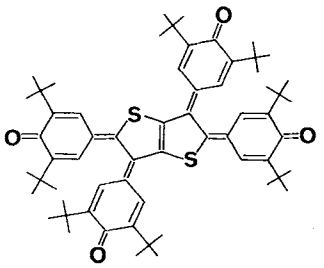
[a] δ(^{13}C) = 153.29, 152.92, 138.41, 137.85, 135.99, 135.92, 131.12, 126.64, 126.56, 126.48, 125.91, 34.38, 34.25, 30.35, 30.21.

By choosing appropriate oxidizing agents, **1** was separately converted into two oxidized products, which were successfully isolated and characterized. Thus, treatment of **1** with iodine, copper(II) chloride, or silver oxide in CH_2Cl_2 containing triethylamine gave almost quantitatively the thieno[3,2-*b*]thiophene **3** (m.p. >300 °C), which contains two quinonoid groups, as dark green crystals after recrystallization from ether. For **3** another structure (**3'**) is



conceivable, but can be excluded by the ^{1}H-NMR spectral data (Table 1). The aryl protons appear as only one singlet,[11] and the two protons on each 4-oxocyclohexadienylidene group are observed as two doublets at $\delta = 7.25$ and 7.01, the former doublet being shifted to lower field than the latter by the anisotropic effect of the neighboring phenyl group. Conversely, this effect causes the high-field shift of the protons of the *tert*-butyl group neighboring the phenyl group. On the other hand, after oxidation of **1** in benzene or CH_2Cl_2 with excess $K_3Fe(CN)_6$ in aqueous 0.1 N NaOH, we isolated a 2,3,5,6-tetrakis(3,5-di-*tert*-butyl-4-oxocyclohexadienylidene)thieno[3,2-*b*]thiophene **4** as a dark brown solid (m.p. ≈260 °C (dec.)) in almost quantitative yield. The redox behavior of **4** was investigated by using cyclic voltammetry.[12] Two pairs of quasi-reversible waves appeared at +0.42 and +0.95 V vs. Ag/AgCl,[13] both of which involve simultaneous transfer of two electrons.[14] Furthermore, **4** could also be reconverted into **3**

and **3** into **1** in quantitative yield by chemical reduction, e.g., with *p*-hydroquinone in benzonitrile.



4

The electronic spectra of **1**, **3**, and **4** were measured in CH_2Cl_2 (Table 1). In agreement with the positions of the absorption maxima, the solution of **1** is very pale yellow and that of **3** is very vivid blue. However, **4** exhibits faint brownish-red coloration because of stronger absorption at 516 nm. Most noteworthy is the fact that **1**, **3**, and **4** show very distinct and different coloration. Accordingly, this stable and reversible redox system might provide the basis for developing a new type of three-color electrochromic device.

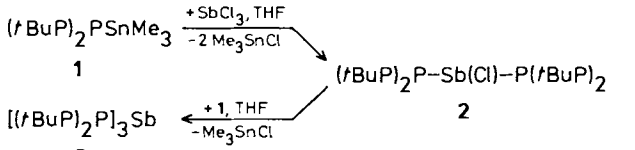
[4] C. M. Elliott, *J. Chem. Soc. Chem. Commun. 1980*, 261; C. M. Elliott, J. G. Redepenning, *J. Electroanal. Chem. 197* (1986) 219.
[5] The corresponding cyclopropenone was prepared according to the method of *West* et al. (R. West, D. C. Zecher, K. Koster, D. Eggerding, *J. Org. Chem. 40* (1975) 2295). Compound **2** was obtained as pale yellow crystals (m.p. = 221–222 °C) in 80% yield by the reaction of the cyclopropenone with phosphorus(V) pentasulfide in refluxing benzene. IR (KBr): $\tilde{\nu}$ = 3620, 2950, 1595, 1340, 1255, 1240, 1120, 1025, 890 cm^{-1}. ^{1}H-NMR (60 MHz, $CDCl_3$): δ = 1.53 (s, 36H, $C(CH_3)_3$), 5.92 (s, 2H, OH), 8.03 (s, 4H, H_{aryl}).
[6] The present result makes a marked contrast with a recent report on the exclusive formation of another isomeric thieno[3,4-*c*]thiophene by the reaction of bis(*tert*-butylthio)cyclopropenethione with tri-*n*-butyl- or triphenylphosphane: S. Yoneda, K. Ozaki, T. Inoue, A. Sugimoto, K. Yanagi, M. Minobe, *J. Am. Chem. Soc. 107* (1985) 5801.
[7] A. Schönberg, M. Mamluk, *Tetrahedron Lett. 1971*, 4993; S. Singh, M. M. Bhadbhade, K. Venkatesan, *J. Org. Chem. 47* (1982) 3550.
[8] When triphenylphosphane was used, no reaction occurred, and uncharacterized tarry materials were only obtained in the reaction with trimethylphosphite. The reaction of **2** with hexamethylphosphorous triamide afforded a fairly unstable blue material, whose structure is now being characterized.
[9] The mass spectrum and elemental analysis gave satisfactory results.
[10] For the ^{13}C-NMR spectral data of thieno[3,2-*b*]thiophene and its derivatives see S. Gronowitz, I. Johnson, A. Bugge, *Acta Chem. Scand. B 30* (1976) 417.
[11] Assuming the structure **3'**, the *ortho* protons should give rise to six signals in the ^{1}H-NMR spectrum.
[12] The measurement was carried out at 20 °C in benzonitrile containing 0.1 M $(n\text{Bu})_4\text{NClO}_4$ as supporting electrolyte by using platinum working and counter electrodes and a standard Ag/AgCl reference electrode (scan rate: 100 mV s^{-1}).
[13] Both two-electron redox potentials of **4** are comparatively high. Thus, the lower redox potential is almost the same as the first one-electron reduction potential (+0.47 V vs. Ag/AgCl) of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, a commonly used electron acceptor (M. E. Peover, *J. Chem. Soc. 1962*, 4540). On the other hand, the higher redox potential is comparable to the first one-electron reduction potentials of a *p*-benzoquinodimethane bearing eight cyano substituents (+1.19 V vs. SCE) (L. Bucsis, K. Friedrich, *Chem. Ber. 109* (1976) 2469), a [3]radialene bearing six cyano substituents (+1.13 V vs. SCE) (T. Fukunaga, *J. Am. Chem. Soc. 98* (1976) 610; T. Fukunaga, M. D. Gordon, P. J. Krusic, *J. Am. Chem. Soc. 98* (1976) 611), and tetracyano-*p*-benzoquinone (+1.00 V vs. SCE) (K. Wallenfels, G. Bachmann, *Angew. Chem. 73* (1961) 142). Consequently, **4** (and also **3**) can be used as potent oxidizing agents.
[14] The number of transferred electrons in each pair of waves was determined from the dependence of the peak currents on sample concentrations.

Tris(2,3-di-*tert*-butylcyclotriphosphanyl)stibane—A Compound Containing Three P_3 Rings Linked by an Antimony Atom**

By *Marianne Baudler** and *Loert de Riese-Meyer*

Functionalized cyclotriphosphanes of the type $(PR)_2PX$ (X = functional group) are suitable building blocks for the synthesis of novel compounds containing P_3 rings. For instance, reaction of 1,2-di-*tert*-butyl-3-trimethylstannylcyclotriphosphane **1**[1] with $(t\text{BuP})_2\text{PCl}$ (1:1) and with MePCl_2 (2:1) gave the 1,1'-bicyclotriphosphane $(t\text{BuP})_2\text{P}-\text{P}(t\text{BuP})_2$[2] and the bis(cyclotriphosphanyl)methylphosphane $(t\text{BuP})_2\text{P}-\text{P(Me)}-\text{P}(t\text{BuP})_2$,[3] respectively. However, reaction of **1** with PCl_3 (3:1) leads to partial ring rearrangement and the formation of a 1,2-bis(cyclotriphosphanyl)cyclotetraphosphane $[(t\text{BuP})_2\text{P}]_2t\text{Bu}_2\text{P}_4$.[4] In order to link three P_3 rings through *one* atom, a central atom larger than phosphorus is apparently necessary. We report here on the condensation reaction of **1** with antimony(III) chloride, which leads to the new phosphorus-antimony compounds bis(2,3-di-*tert*-butylcyclotriphosphanyl)chlorostibane **2** and tris(2,3-di-*tert*-butylcyclotriphosphanyl)stibane **3**.



Compound **1** reacts with $SbCl_3$ even in a molar ratio of 1:1 (−78 °C) to give almost exclusively **2** as a mixture of the two configurational isomers **2a** and **2b** (Table 1). No evidence was found for the intermediate $(t\text{BuP})_2\text{P}-\text{SbCl}_2$, which is thus appreciably more reactive than $SbCl_3$.

Increasing the reactant ratio to 3:1 results in the almost exclusive formation of **3** as the two configurational isomers **3a** and **3b** (approx. 1:1). Whereas the symmetric isomer **3a** precipitates from the reaction mixture and can be isolated in analytically pure form at low temperature,[5] the asymmetric isomer **3b** has only been characterized in solution by ^{31}P-NMR spectroscopy. Evidence was not observed for an interconversion between the two diastereomers under conditions where **3** is stable.

Compound **3a** is a yellow solid, which is stable below −30 °C in the absence of air and light. At higher tempera-

[a] Determined from the center of gravity of the signal groups in the 1D NMR spectrum of **3a** and in the 2D NMR spectrum of **3b**.

Proof of the constitutions of **3a, b** is provided by the ^{31}P-NMR data (Table 2); in addition, a 2D $^{31}P\{^1H\}$-NMR spectrum (COSY 45)[6] was recorded for **3b**. The chemical shifts of all P atoms lie in the high-field region characteristic of phosphorus three-membered ring compounds,[7] the atoms bonded to antimony exhibiting the largest upfield shift in both isomers. The relative arrangement of the *trans*-oriented tert-butyl groups at the three rings is revealed by the spin systems and by the relative magnitudes of the chemical shifts of the respective P atoms. Thus, in **3a**, the downfield position of $\delta(^{31}P_A)$ with respect to $\delta(^{31}P_B)$ indicates that the substituents on P_A, $P_{A'}$, and $P_{A''}$ are in *cis* positions with respect to the exocyclic phosphorus–antimony bond. The analogous facts for **3b** show that the *tert*-butyl groups on P_A, P_B, and P_C are in the corresponding *cis* positions. According to all the NMR spectroscopic findings,[5] **3a** has C_3 symmetry, whereas **3b** has no symmetry element. The two isomers are present as pairs of enantiomers.

The conformations of **3a, b** may be derived from the large P,P long-range couplings, which indicate that the lone pairs on the respective P atoms are directed toward each other.[8] Thus, in the case of **3a**, the absence of fine structure in the upfield group at $\delta = -188$ has to be ascribed to large ^2J couplings between the nuclei P_C, $P_{C'}$, and $P_{C''}$. For **3b**, significant ^2J couplings between P_G and P_H as well as between P_H and P_I are revealed by corresponding cross peaks in the 2D NMR spectrum. The $^3J(P_GP_D)$ coupling constant, which can additionally be observed by variation of the filter function, confirms, in agreement with model considerations, that the three-membered ring $P_BP_FP_G$ is twisted around the exocyclic bond owing to steric interactions between the *t*Bu groups on P_B and P_C.

The first tris(cyclotriphosphanyl) compound, **3**, owes its existence to the relatively large covalent radius of antimony (1.41 Å[9]). Because of its "open" structure, **3** exhibits a high reactivity, which tends to result in a preferred elimination of the central atom.

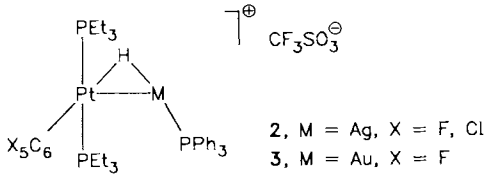
A Pt_2AgH_2 Complex**

By *Alberto Albinati, Francesco Demartin, Luigi M. Venanzi,* and Martin K. Wolfer*

Recent studies have shown that the monocations of the Group 11 metals easily form heterometallic hydrido-bridged complexes.[1-3] Remarkable among them are those formed by Ag^I where a variety of coordination geometries at silver are observed. One frequently occurring type contains a single M-H-Ag bridge arising from the coordination of a mononuclear hydrido complex such as *trans*-$[PtH(C_6X_5)(PEt_3)_2]$ **1** to a $Ag^{\oplus}$ ion, the coordination at silver being completed by a phosphane ligand. In compounds of this type (e.g., **2**), one can describe the bonding in the Pt-H-Ag moiety in terms of a three-center, two-electron interaction of "closed" type.[4]



2, M = Ag, X = F, Cl
3, M = Au, X = F

We now find that the phosphane ligand in complexes of type **2** can be replaced by a molecule of **1** resulting in the formation of compounds such as **4**.[5] Related compounds

$[(PEt_3)_2(C_6Cl_5)Pt(\mu\text{-}H)Ag(\mu\text{-}H)Pt(C_6Cl_5)(PEt_3)_2][CF_3SO_3]$ **4**

(e.g., where C_6Cl_5 has been replaced by C_6F_5 and PEt_3 by PMe_3) have also been obtained.[6] Figure 1 shows the metal and donor atom arrangement in the cation of **4** which consists of two square-planar *trans*-$[PtH(C_6Cl_5)(PEt_3)_2]$ units joined by a $Ag^{\oplus}$ ion, the dihedral angle between the two planes being 83.5°.[7]

Both Pt-H-Ag units are similar to the Pt-H-Au unit found in the cation of **3**.[1] Thus relatively short Pt-M distances and small Pt-H-M angles are observed [**4**: Pt-Ag = 2.791(1) Å; Pt-H-Ag = 107(2)°; **3**: Pt-Au = 2.714(1) Å; Pt-H-Au = 103(4)° (average values)]. The other distances and angles, including Pt-H and Ag-H, fall in the expected range for compounds of this type.[1]

The coordination polyhedron around silver can be visualized in different ways depending on the bonding scheme used to describe the Pt-H-Ag interaction. Thus, using a three-center, two-electron model of closed type,[4] i.e., one including a significant, direct Pt-Ag interaction, the coordination at silver can be considered as pseudo-tetrahedral with a spirane-like arrangement of Ag, H, and Pt atoms. On the other hand, if one describes the Ag/Pt-H interaction as arising from the donation to silver of the Pt-H σ-bonding electrons, the coordination at silver can be visualized as being digonal. These two models are qualitatively equivalent to those used to describe $M(H_2)$ interactions given the isolobality of H_2 and the Pt-H fragment.[8] Both models are in agreement with the known coordination chemistry of Ag^I where digonal and tetrahedral geometries are of frequent occurrence.

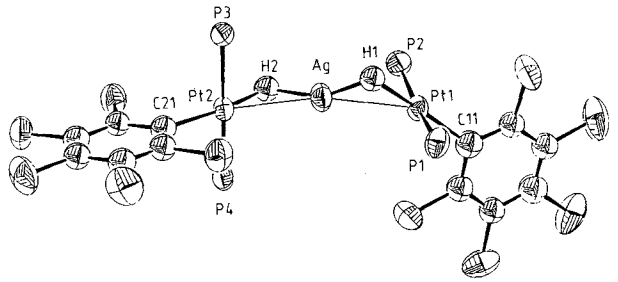


Fig. 1. ORTEP drawing of the cation of **4** with the alkyl groups of the phosphane ligands omitted for clarity. Selected bond lengths [Å] and angles [°] are: Ag-Pt(1) 2.791(1), Ag-Pt(2) 2.790(2), Pt-H 1.75(9), Ag-H 1.70(12) (average values), Pt(1)-P(1) 2.311(5), Pt(1)-P(2) 2.330(5), Pt(2)-P(3) 2.334(6), Pt(2)-P(4) 2.306(6), Pt(1)-C(11) 2.07(1), Pt(2)-C(21) 2.06(2); Pt(1)-Ag-Pt(2) 166.05(4), Ag-H(1)-Pt(1) 106(4), Ag-H(2)-Pt(2) 109(5), H(1)-Ag-H(2) 152(2), P(1)-Pt(1)-P(2) 171.95(6), P(3)-Pt(2)-P(4) 171.91(7), Ag-Pt(1)-C(11) 149.7(1), Ag-Pt(2)-C(21) 147.3(2).

It is noteworthy that small amounts of cations of the type $[(PR_3)_2(C_6X_5)Pt(\mu\text{-}H)Ag(\mu\text{-}H)Pt(C_6X_5)(PR_3)_2]^{\oplus}$ (R = Me, Et; X = Cl, F) together with equivalent amounts of the cations $[Ag(PR'_3)_2]^{\oplus}$ are in equilibrium with a bimetallic species of the type $[(PR_3)_2(C_6X_5)Pt(\mu\text{-}H)Ag(PR'_3)]^{\oplus}$ when solid samples containing the latter cations are dissolved in solvents such as dichloromethane.[1,6]

NOESY-TOCSY, an Advantageous 2D NMR Technique for the Analysis of Peptide Sequences**

By *Horst Kessler,** *Gerd Gemmecker,* and *Stefan Steuernagel*

With the introduction of two-dimensional NMR techniques, the problems in the interpretation of spectra resulting from overlapping lines have been greatly reduced. Nonetheless, difficulties are still encountered with increasing molecular size, especially for molecules of biological interest. Here we describe a new variant of the Relayed-NOESY experiment that is particularly suitable for solving these problems in the case of biopolymers.

If a second coherence-transfer step through scalar J coupling is included in a two-dimensional NMR experiment, it is possible to transfer the cross peaks between two nuclei to the resonance frequencies of other nuclei in less crowded regions of the spectrum. In the H-Relayed H,H-COSY experiment[1] two equivalent coherence-transfer steps in which nuclei are correlated by J coupling are combined. *G. Wagner* showed that even the combination of an incoherent transfer step (i.e., one caused by NOE effects) with a coherent transfer step leads to useful information (Relayed-NOESY experiment[2]). Difficulties in phase correction to pure absorption, which is especially advantageous for signals near the diagonal, can be overcome by the introduction of a double-quantum filter (DQF).[3]

We recently showed that in such pulse sequences the two different successive transfer steps can also be replaced by spin-lock periods in the rotating frame;[4] hence this technique, in contrast to Relayed NOESY, is now also applicable to medium-sized molecules with vanishing NOEs (owing to $\omega_0 \tau_c \approx 1$) because the NOE transfer is replaced by an ROE (rotating frame NOE) transfer,[5] which is relatively insensitive to molecular tumbling rates.

All the latter techniques having two different transfer steps afford unsymmetric spectra, since the mixing sequences are not symmetric (i.e., not invariant with respect to time and phase reversal[6]). This important feature is best exemplified by the analysis of peptide and protein sequences, a particularly interesting application of these techniques (Fig. 1). The non-symmetry results from the fact that, across the peptide bond, NOE but no scalar coupling of protons is observed. Thus, the peptide sequence can be "read" directly from the spectrum by means of the unsymmetric cross peaks.[3,4]

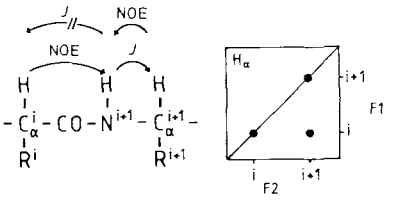

Fig. 1. The formation of cross peaks between the α protons of neighboring amino acids in peptides and proteins via two transfer steps: First step via NOE, second step via J coupling (NOESY-TOCSY). It can be seen that in this experiment a transfer from H_α^i (in the F1 dimension, vertical) to H_α^{i+1} (in the F2 dimension, horizontal) is possible. Since the reverse pathway is blocked due to the absence of J coupling through the peptide bond, the two-dimensional spectrum is unsymmetric. If the sequence of transfer steps is reversed (TOCSY-NOESY), the cross peak appears on the other side of the diagonal.

We now describe two new variants of these unsymmetric pulse sequences and their application to the analysis of a nonadecapeptide which shows strongly negative NOEs. The new pulse sequences (Fig. 2) combine the NOESY experiment with an additional J-coupling transfer step consisting of an MLEV-17 spin-lock period,[7] like that used for TOCSY spectra.[8] The mixing time for the TOCSY transfer is kept so short (ca. 20 ms) that coherences are only transferred to the next nucleus (the transfer pathways thereby remain unambiguous). In analogy to the Relayed-NOESY experiment, we call this technique TOCSY-NOESY or NOESY-TOCSY, depending on the sequence of the two transfer steps.

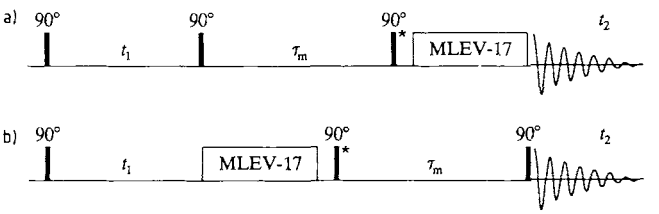

Fig. 2. Pulse sequence for NOESY-TOCSY (a) and TOCSY-NOESY (b). The phase difference between the marked 90° pulse (asterisk) and the spin-lock field must be ±90°. The rest of the phase cycle is fully analogous to that of the NOESY experiment [12].

In many respects, these new techniques are superior to those already described:[2,3,4] Large molecules (like most biopolymers) show strongly negative NOEs. Because the signals in ROESY spectra always contain ROE *and* NOE components with differing signs, which can partially cancel each other, the analysis of pure NOE effects is preferred for such molecules.[9] However, since the signals of these molecules are relatively broad owing to short T_2 times, antiphase structure in the cross peaks leads to their partial cancellation. Hence, some interesting cross peaks in conventional Relayed-NOESY and DQF-Relayed-NOESY spectra can be completely lost. Recording a Relayed-NOESY spectrum with the NOE transfer as the second step would be of little advantage, on the other hand, since, due to the low resolution in F1, increased cancellation of the antiphase signals in this dimension would occur. Replacement of the Relayed step by a TOCSY transfer solves this problem, since the cross peaks then contain only in-phase components. Furthermore, it is now possible to employ an NOE transfer after a TOCSY transfer (in the TOCSY-NOESY version), since only signals with in-phase components are present.

As an example, we show in Figure 3 part of the NOESY-TOCSY spectrum of the polycyclic peptide RO 09-0198.[3] Compared to the DQF-Relayed-NOESY spectrum (Fig. 8a in Ref. [3]), a significantly improved signal-to-noise ratio is attained under identical measurement conditions (same sample, same instrument, same recording time), as shown by the cross sections of the two spectra in Figure 4.

Since pure NOESY signals as well as pure TOCSY signals cannot be suppressed in spectra with combined NOE and J transfer,[2] it is desirable to process the spectra further so that the true "relayed" signals are easier to recognize.

Two methods for reducing the number of cross peaks in these unsymmetric spectra were recently described.[4,6] An *asymmetrization*[4] removes all symmetric contributions from a two-dimensional spectrum and can be easily ob-

Niederurseler Hang, D-6000 Frankfurt am Main 50 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

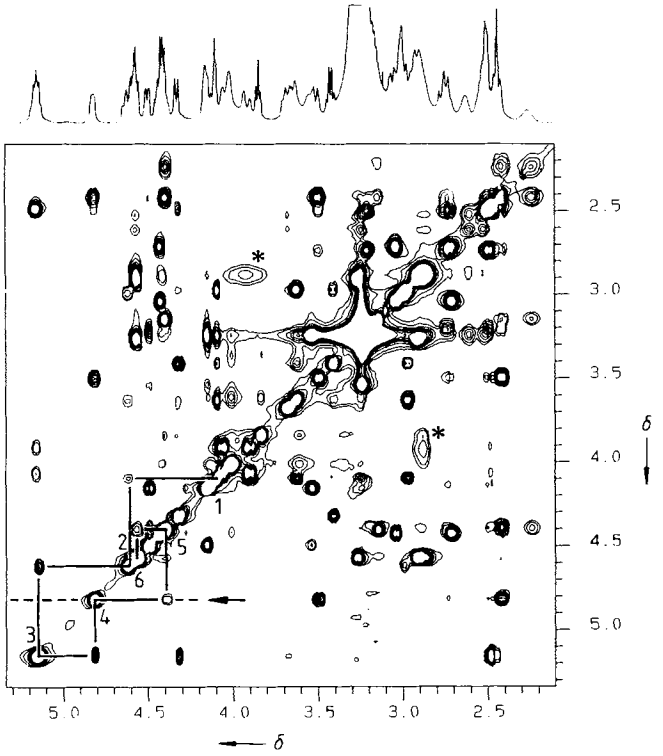

Fig. 3. Part of the 500-MHz NOESY-TOCSY spectrum of RO 09-0198 [3]. Relaxation delay, 2.5 s; 90° pulse, 19 μs; spin-lock field, 5 kHz over 20 ms; NOE mixing time, 300 ms (±20 ms for suppression of zero quanta [13]); sample concentration, 50 mmol. The H_α region is shown; the sequence analysis for the fragment H-Lan^1-Arg^2-Gln^3-Lan^4-Lan^5-Xaa^6 (Lan = one-half of a lanthionine, Xaa = alanine part of lysinoalanine) via H_α-H_α cross peaks is shown (the numbers correspond to the positions of the α protons in the peptide sequence). Peaks appearing symmetrically with respect to the diagonal are caused by pure NOESY or pure TOCSY transfer (e.g., the TOCSY peak marked with an asterisk between H_α and H_β of Phe^{10}). The cross section along the dashed line (arrow) is shown in Figure 4.

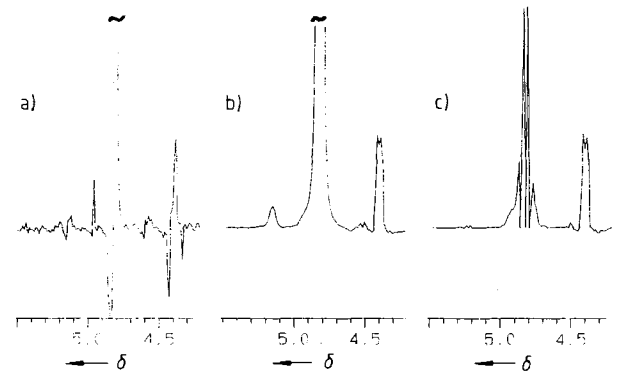

Fig. 4. Cross sections from the 2D NMR spectra of Figure 8a in [3] and from Figures 3 and 6; the part chosen is also marked there. a) DQF Relayed-NOESY [3]. b) NOESY-TOCSY. This spectrum shows the improved signal-to-noise ratio obtained under the same conditions of measurement as for (a). The signal at $\delta = 5.15$ is due to a nonsuppressed pure NOESY transfer. c) NOESY-TOCSY after asymmetrization. The NOESY signal at $\delta = 5.15$ is fully suppressed by this way of data processing.

tained by subtraction of a symmetrized copy of the original data matrix (Fig. 5a). This procedure is very easy to employ, since the symmetrization with commercially available NMR program packages can be carried out very quickly on an array processor.[10] However, this procedure requires

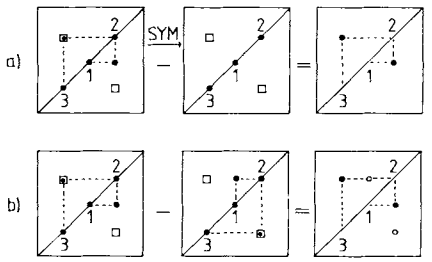

Fig. 5. Schematic drawing of the asymmetrization (a) and anti-symmetrization (b) of a NOESY-TOCSY spectrum in order to eliminate the symmetric components (see text). The square symbolizes a pure NOESY cross peak (symmetric with respect to the diagonal) which overlaps with the unsymmetric NOESY-TOCSY peak (filled circle). SYM = symmetrization [10].

the same line shapes and the same resolution in the two dimensions. Since, in general, the resolution in F2 feasible from the raw data is significantly greater than that in F1, the resolution in F1 is the limiting factor. If the resolution of the recorded FIDs is not reduced to that in F1, then the asymmetrization leads to residual signals having a characteristic "fine structure." This is clearly seen in the asymmetric version of the NOESY-TOCSY spectrum of Figure 3 (Fig. 6).

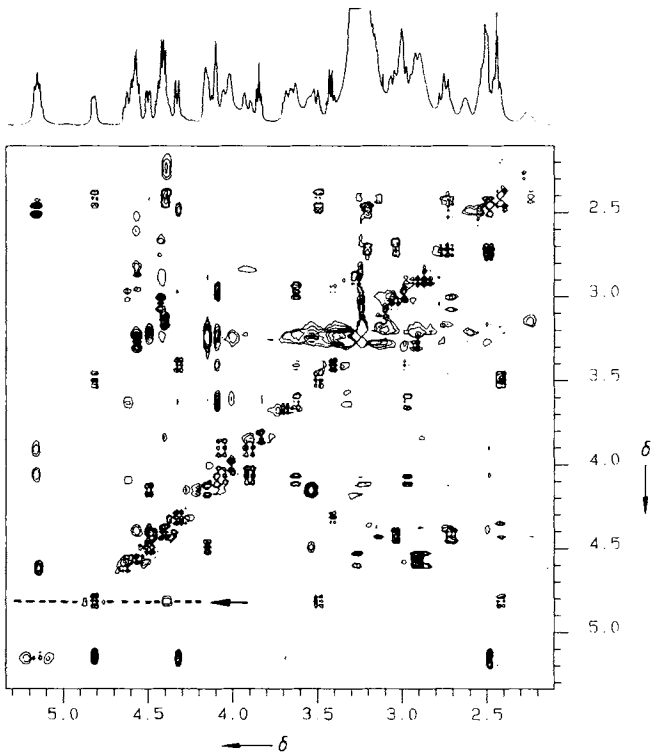

Fig. 6. NOESY-TOCSY spectrum of Figure 3 (same part) after asymmetrization. The cross section along the dashed line (arrow) is shown in Figure 4.

Another possibility of spectral simplification is *anti-symmetrization*,[6] which also removes all symmetric signals from the 2D matrix. However, *both* spectra (namely, TOCSY-NOESY and NOESY-TOCSY) are required, and they must be recorded under identical conditions and processed with the same parameters (apodization, zero-filling, scaling), in order to ensure the same line shapes and intensities in the two spectra. On the other hand, the same resolution in F1 and F2 is no longer necessary, since the

two spectra are substracted row by row. One obtains a "spectrum" with the originally unsymmetric components of the cross peaks on *both* sides of the diagonal but having *different* signs (Fig. 5b). Figure 7 shows the results of this anti-symmetrization carried out for the spectrum of the nonadecapeptide RO 09-0198.[11]

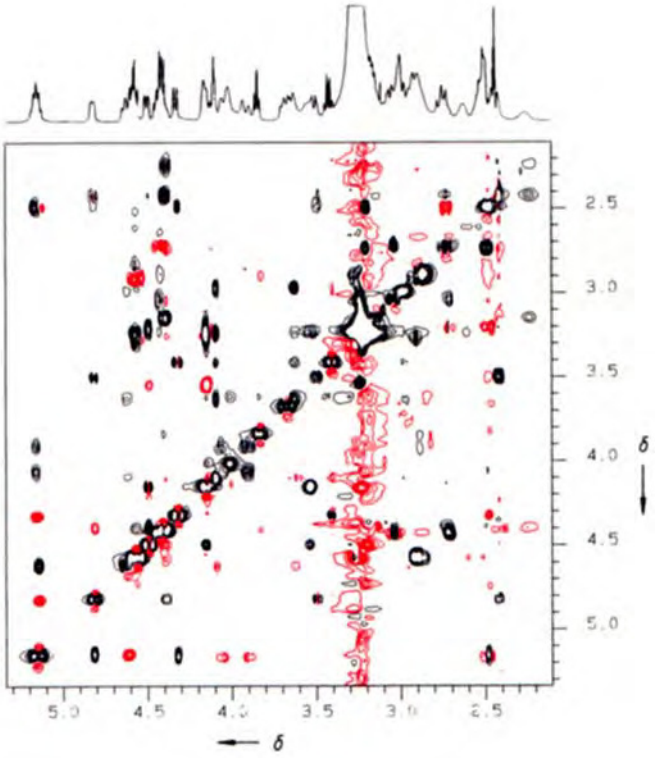

Fig. 7. NOESY-TOCSY spectrum of Figure 3 after antisymmetrization by combination with a TOCSY-NOESY spectrum (same section as in Fig. 3) recorded under the same conditions. Negative signals are shown in red.

The advantages of the NOESY-TOCSY and TOCSY-NOESY techniques presented here are, above all, an improved signal-to-noise ratio, especially in the case of broad signals, and the possibility of reversing the sequence of transfer steps without loss of sensitivity. The methods of data processing described here facilitate the interpretation of these spectra. The NOESY-TOCSY experiment is primarily attractive for larger molecules, which give rise to strongly negative NOEs and broad lines, owing to short relaxation times.

[10] The algorithm used ("SYMA" routine in the DISNMR programs of BRUKER GmbH) reintroduces into the 2D matrix on both sides of the diagonal the smaller value of the two points lying symmetrically with respect to the diagonal with the sign of the smaller value. In the subsequent difference formation with the unprocessed 2D matrix, one therefore always obtains zero for the smaller contribution and the difference of the two original values for the point on the other side of the diagonal. The spectrum so obtained is called the *asymmetrized* spectrum and contains only that component of the magnetization that has passed the desired NOESY-TOCSY transfer. Difficulties in the interpretation of the asymmetrized spectrum can arise when the symmetric and asymmetric components in the original 2D NMR spectrum have different signs, since in that case (dependent on the relative magnitudes of the two components) a signal can appear on the opposite side of the diagonal in the asymmetrized spectrum, albeit with opposite sign. The TOCSY transfer, however, retains the sign, and the pure NOESY signals therefore have the same sign as the NOESY-TOCSY signals, so that the problem can be ignored in this case, particularly, since pure TOCSY signals cannot appear between different amino acid residues (moreover, in the case of large molecules with always negative NOEs ($\omega_0 r_c \gg 1$), they exhibit the same sign as that of the NOESY components).
[11] A single NOESY-TOCSY spectrum can also be decomposed into a symmetric and an antisymmetric component if the symmetrization routine is so modified that every value in the 2D matrix is replaced by the difference between it and the mean value of the two values lying symmetrically with respect to the diagonal. However, this procedure is just as sensitive as an *asymmetrization* toward different line shapes in F1 and F2. Furthermore, this decomposition into a symmetric and an antisymmetric spectrum has no physical meaning, since none of the possible transfer pathways in the NOESY-TOCSY experiment leads to an antisymmetric contribution. The information content of the antisymmetric component, however, would be the same as that of the asymmetrized spectrum.

C_5O_2 (1,2,3,4-Pentatetraene-1,5-dione), a New Oxide of Carbon

By *Günther Maier,* Hans Peter Reisenauer, Ulrich Schäfer,* and *Heinz Balli*

The amazing fact that cyclopropenylidene[1] is one of the most common interstellar molecules[2] inspired us to search for further compounds that might be found to exist as "molecules between the stars." Based on the experience gathered so far,[3] possibilities include systems with polycumulated double bonds. Our first investigations in this direction have led to the isolation of the surprisingly stable carbon oxide C_5O_2, the longest such molecule known.

The tris(diazo) ketone **1**,[4] which may be prepared easily by diazo group transfer from phloroglucinol, affords the carbon oxide **2** as sole product upon irradiation (254 nm) in an argon matrix at 12 K. Compound **2** exhibits the IR absorptions shown in Table 1. The same species is obtained when **1** is subjected to pyrolysis in the gas phase (700 °C) and the fragments (in addition to the major component **2**, carbon suboxide is also formed) are condensed along with argon on a window at 12 K.

In agreement with the prognosis[5] that carbon oxides C_nO_2 having an odd number of C atoms should be more stable than those having an even number, it is also possible to prepare **2** on a preparative scale. If **2**, prepared at 10^{-3} torr and 600 °C, is condensed with a low-melting solvent on a cold finger cooled with liquid nitrogen, a solution of **2** may be obtained after thawing in which the compound

$\tilde{\nu}$ [cm^{-1}] (rel. int.)	Assignment
3717.7 (0.030)	combination mode
3418.3 (0.018)	combination mode
3327.7 (0.003)	combination mode
2759.7 (0.042)	combination mode
2213.0 (1.000)	asymmetric stretching mode
2058.7 (0.340)	asymmetric stretching mode
1144.1 (0.026)	asymmetric stretching mode [a]
1049.6 (0.011)	combination mode [a]
539.0 (0.029)	asymmetric deformation mode
470.0 (0.007)	asymmetric deformation mode

[a] Indefinite assignment.

remains unchanged even after several days at room temperature. Pure **2**, on the other hand, is only stable to about -90 °C (yellow solid). At this temperature, it polymerizes to give a black solid having the composition C_5O_2.

Proof of the structure of **2** was based, on the one hand, on the observation that the yellow solution lost its color immediately upon addition of methanol and the known dimethyl allenedicarboxylate **4**[6] was formed, as shown by comparison of its spectra with those of authentic material. On the other hand, the spectroscopic data establish unequivocally the presence of **2**: In the ^{13}C-NMR spectrum [CH_2Cl_2, -60 °C, Cr(acac)$_3$] three signals are observed at $\delta = 119.0$ (C1/5), 101.2 (C3), and 15.2 (C2/4) in a ratio of 2:1:2.[7] The UV spectrum (cyclohexane) displays an extremely strong absorption at 231 nm ($\log\varepsilon = 5.38$) and a second, weaker band ($\log\varepsilon = 2.18$) at 435 nm. In the mass spectrum, the "correct" molecular ion peak is found at $m/z = 91.9899$ (calcd 91.9898). Finally, the IR spectrum (Table 1 and Fig. 1, top) is in qualitative agreement with the spectrum calculated by the MNDO method[8] [bands at 2493 ($I_{rel.} = 1.00$), 2358 (0.50), 1285 (<0.01), 719 (0.03), 537 (<0.01), and 99 (<0.01) cm^{-1}]. At least, this comparison shows that—as experimentally found[9]—two predominant absorptions in an intensity ratio of about 2:1 should appear in the ketene region.[10]

When matrix-isolated **2** is irradiated with 230-nm light (irradiation at the wavelength of the intense UV band), CO is cleaved off and a new species with IR absorptions at 2221.7 (1.00), 1922.7 (0.65), 1431.5 (0.04), 774.8 (0.01), and 484.0 (0.06) cm^{-1} is formed (Fig. 1, bottom). This spectrum is clearly that of 1,2,3-butatrien-1-one. The calculated IR spectrum[8] for **3** requires—as found—the presence of two strong bands, one in the ketene region [2549 (0.88)] and one in the allene region [2208 cm^{-1} (1.00)].[11]

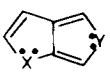
[7] Carbon suboxide C_3O_2 exhibits ^{13}C-NMR signals at $\delta = 129.7$ (C1/3) and -14.6 (C2): E. A. Williams, J. D. Cargioli, A. Ewo, *J. Chem. Soc. Chem. Commun. 1975*, 366.
[8] QCPE program No. 506 (AMPAC). The spectrum is calculated on the basis of a linear structure for **2**. Ab initio (SCF/4-31G) calculations indicate as minimum a nonlinear molecule with IR bands at 2506 (0.00), 2396 (1.00), 2232 (0.50), 1827 (0.00), 1216 (0.02), 781 (0.02), 726 (0.01), 615 (0.00), 605 (0.00), 586 (0.01), 568 (0.01), 181 (0.00), 61 (0.00) cm^{-1} (B. A. Hess, Jr., L. J. Schaad (Nashville, TN, USA), personal communication).
[9] Preliminary results of *F. Holland* and *M. Winnewisser*, Giessen, have established that the molecule possesses inversion symmetry, since the separation of the rotational lines is $4B$ (B = rotational constant). A decision as to the linearity or quasi-linearity of the molecule can only be made after a detailed analysis of the rotational-vibrational spectrum has been carried out.
[10] Only one ketene band would have been expected for the originally expected compound C_6O_3 (three-membered ring with a ketene unit at each corner), which would have been formed by three Wolff rearrangements.
[11] Note added on February 17, 1988: According to an ESR spectroscopic analysis, C_4O is also formed by photoaddition of CO to matrix-isolated graphite vapor: R. J. Van Zee, G. R. Smith, W. Weltner, Jr., *J. Am. Chem. Soc. 110* (1988) 609. We have repeated the irradiation of **2** under our conditions and have observed the same ESR signal for our product **3**.

A Simple Route to Furo[3,4-*b*]furans, Compounds with a New Diheteropentalene System**

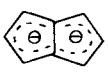
By *Wolfgang Eberbach,* Hans Fritz,* and *Norbert Laber*

Dedicated to Professor Edward Taylor on the occasion of his 65th birthday

Diheteropentalenes **1** are isoelectronic with the pentalene dianion **2**.[1] According to calculations, the resonance stabilization of this 10π-electron system is slightly smaller than that of its analogues with the heteroatoms in 1,4 and 1,6 position;[2a-c] experimental evidence for its expected higher reactivity is available for derivatives with X, Y = S, S or S, N.[2b-d]

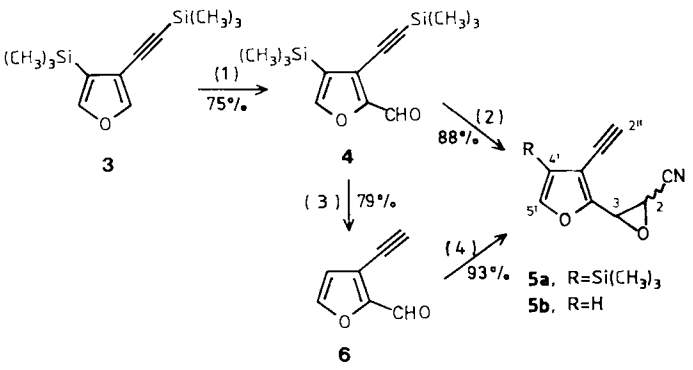


1



2

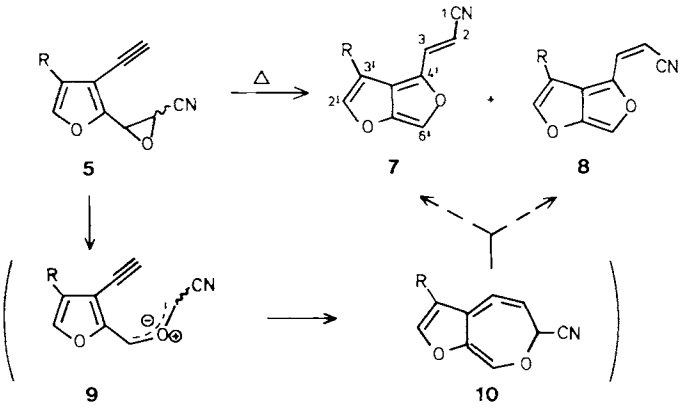
Although much work has been done with the structurally related 3,4-benzoannelated pyrroles,[3] thiophenes,[4] and furans[5]—also with respect to preparative applications—relatively few investigations with derivatives of **1** have been described.[6] The series of known diheteropentalenes was recently extended by thieno[3,4-*b*]furan (**1**, X = O, Y = S)[7] and by a thieno[2,3-*c*]furan derivative (**1**, X = S, Y = O).[8] We now report on the preparation of two furo[3,4-*b*]furan (**1**, X = Y = O) derivatives. For the synthesis, we took advantage of the observation that the thermal isomerization of (*Z*)-1,2-epoxy-3-hexen-5-ynes affords 2-vinylfurans, usually in high yields.[9] As starting compounds, the two (alkynylfuryl)oxiranes **5a** and **5b** were used, which are accessible from **3**[10] via the intermediate **4** (and **6**) in 66 and 55% yield, respectively.



3 **4** **6**

Scheme 1. Synthesis of **5a** and **5b**. (1) a) *n*BuLi, THF; b) *N*-formylmorpholine. (2) Chloroacetonitrile, NaOH, triethylbenzylammonium chloride, acetonitrile. (3) a) Ethylene glycol, *p*-TosOH, benzene; b) NaOH, triethylbenzylammonium chloride, acetonitrile; c) Bu_4NF, THF; d) acetone/H_2O, *p*-TosOH. (4) Chloroacetonitrile, KO*t*Bu, *t*BuOH/ether.

When **5a** or **5b** are heated under short-time or flash vacuum thermolysis conditions (STT: 350°C, ca. 10 s; FVT: 450°C, ca. 10^{-6} torr), a crude reaction mixture is formed containing 60–70% of the two *E*/*Z*-isomeric furofurylacrylnitriles **7** and **8** as the only monomeric reaction products [yields after chromatographic separation: 26% **7a**, 23% **8a** and 31% **7b**, 21% **8b** (average values)]. The *E* isomers, **7a** and **7b**, which were isolated as stable yellow crystals, exhibit intense, relatively long-wavelength UV absorption maxima at 347 ($\varepsilon = 30\,100$) and 345 nm (27 800), respectively (for other data see Table 1).[11]



The reaction pathway leading to **7** and **8** presumably proceeds via the carbonyl ylide **9** and its 1,7-dipolar cyclization to the cycloallene derivative **10**, which is subsequently transformed into the furo[3,4-*b*]furan via a pathway involving diradical and/or carbene intermediates.[9]

[a] ^{1}H-NMR spectra: 250 and 400 MHz, $CDCl_3$; ^{13}C-NMR spectra: 100 MHz, $CDCl_3$.

As expected, the isoannelated furans **7** and **8** display a high Diels–Alder reactivity: **7a** reacts with *N*-phenylmaleimide (NPMI) or dimethyl acetylenedicarboxylate (DMAD) already at 20°C. In both cases—even when using an excess of dienophile—only the 1:2 addition compounds **12** and **13**, respectively, are formed via the corresponding 1:1 adducts (**11** in the case of NPMI); the two stereoisomers *exo*-**12** and *endo*-**12** are obtained in a 7:3 ratio[12] (77% yield; the configuration of **12** was established by detailed NMR experiments). The DMAD addition product **13** is not stable under the reaction conditions and undergoes a Diels–Alder reversion providing the furyldihydrofuran derivative **14** (yield 70%).[14]

The route to furo[3,4-*b*]furans described here should be applicable to the preparation of other isoannelated heteroarenes.

[14] In the case of the reaction of DMAD with **7b**, the corresponding diadduct **13** (R = H) is stable and can be detected by NMR spectroscopy together with **14** (R = H) as a 4:1 mixture. However, the overall reaction is less clean.

Coupling Metal Centers with Linearly Bridging, Delocalized, π-Bonded Ligands: *p*-Phenylenediimido Dimolybdenum Complexes**

By *Eric A. Maatta** and *David D. Devore*

Transition-metal complexes in which the metal atoms are linked by a bridging group containing a delocalized π system have been the subjects of intense research activity in recent years, perhaps most notably in studies of intervalent electron transfer in dimeric systems and in the construction of polymeric materials of low dimensionality.[1] In the majority of such applications, the bridging ligands employed have been difunctional σ donors, as exemplified by pyrazine in the archetypal Creutz–Taube ion[2] and in various bridged polymers containing metal phthalocyanine[3] or metal porphyrin[4] subunits. While the use of pyrazine and related bridging groups has led to a variety of interesting and important developments, the use of conjugated difunctional σ-donor ligands as bridging groups imposes certain limitations on the kinds of metal fragments that can be interconnected. In particular, it is often observed that coordination of a metal complex to one end of

[*] Prof. Dr. E. A. Maatta, D. D. Devore

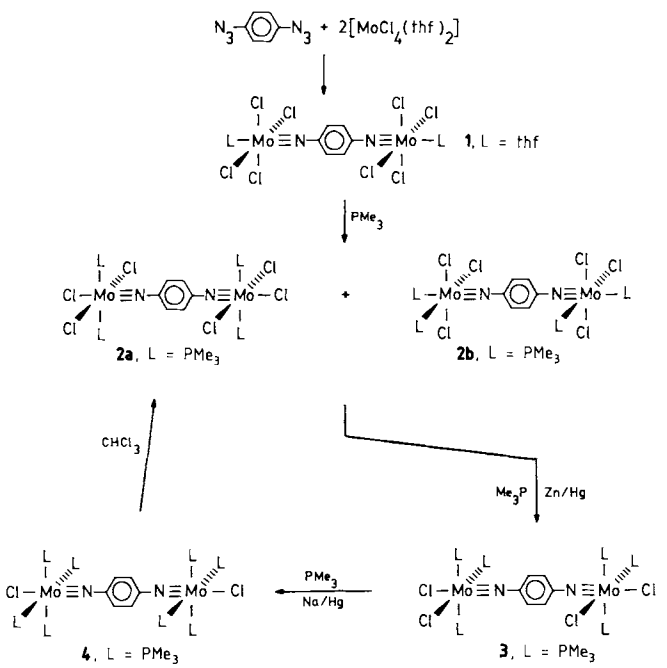
Manhattan, KS 66506 (USA)

[**] This work was supported by the National Science Foundation (USA).

the difunctional σ-donor bridge results in a diminished binding constant for coordination of the remaining donor site; thus, dissociation into mononuclear species is often observed in solution.[5] Second, since metal-to-ligand π backbonding is an integral feature of the ligand–metal interactions in these systems, the majority of studies have focused on rather low-valent metal systems with high d-electron counts.

We wish to report our preliminary studies involving the use of *p*-phenylenediimido ligands as bridging units. In these systems, the ligand binds to the metal via formal M≡N triple bonds, thus obviating any dissociation behavior. Furthermore, since imido-type ligands prefer to bind to high-valent metal fragments, studies of high-oxidation-state systems can be accommodated.



Scheme 1.

The Mo_2^{VI} *p*-phenylenediimido complex **1**[6] is obtained as shown in Scheme 1. The structure indicated is consistent with the observation of a singlet at $\delta = 6.95$ in the 400-MHz ^{1}H-NMR spectrum and is analogous to that determined crystallographically for the related *p*-tolylimido complex $[Mo(NC_6H_4CH_3)Cl_4(thf)]$.[7]

In the presence of PMe_3 in toluene solution, **1** undergoes reduction to yield the 17-electron d^1–d^1 Mo^V dimer **2**.[8] ESR evidence indicates that **2** is formed as a mixture of two geometric isomers: isomer **2a** (major) displays a *trans*-phosphane, *mer*-trichloride configuration at each Mo site and isomer **2b** displays a *cis*-phosphane, *mer*-trichloride configuration at each Mo site of the dimer. Taking the *z* axis as being coincident with the Mo–N bond vectors, the unpaired electron on each Mo^V center will reside in a formally nonbonding d_{xy} orbital. Species **2** undergoes reduction by Zn amalgam in the presence of PMe_3 to form the 18-electron d^2–d^2 Mo^{IV} dimer **3**.[9] The ^{1}H-NMR spectrum of **3** is similar to that of the structurally characterized *p*-tolylimido analogue *cis, mer*-$[Mo(NC_6H_4CH_3)Cl_2(PMe_3)_3]$[10] and supports the assignment of a *cis, mer* geometry for **3**; although **3** is drawn with overall C_{2v} symmetry in Scheme 1, a C_{2h} configuration is also possible.

Treatment of **3** (or **2**) with Na amalgam in toluene in the presence of PMe_3 induces further reduction to yield a lustrous green solid, tentatively identified as the d^3–d^3 Mo^{III} dimer **4**.[11] Complex **4** is paramagnetic, thermally unstable, and extremely air-sensitive. Its formulation as a symmetrical *p*-phenylenediimido-bridged species is supported by its ready reaction with chloroform to afford the Mo^V dimer **2a**.

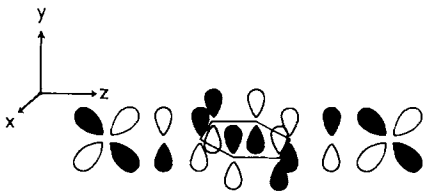


Fig. 1. HOMO for complex **4** as obtained from extended Hückel calculations.

The nature of the bridge bonding in **4** has been investigated by extended Hückel techniques and the nature of the HOMO is as shown in Figure 1. Significantly, it is seen that this orbital consists of a continuously conjugated π system comprising the d_{yz} orbitals on each Mo center and the p_y orbitals of nitrogen and carbon in the *p*-phenylenediimido ligand. This result suggests that the incorporation of d^3–d^3 dimetallo(*p*-phenylenediimido) units into an appropriate polymer network could result in novel types of conducting materials.

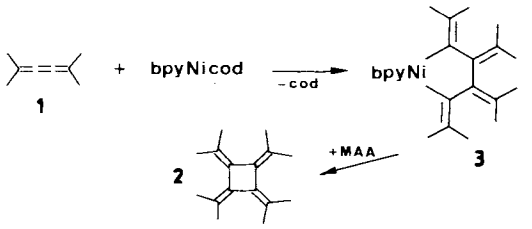
The intensely blue-green solution was filtered, and the filtrate was taken to dryness to yield the lustrous green solid product. ESR (C_6H_6, 25°C): broad singlet ($g = 1.980$).

Cobalt-Catalyzed Reactions of Octamethyl-[4]-radialene and 2,5-Dimethyl-2,3,4-hexatriene with Ethene

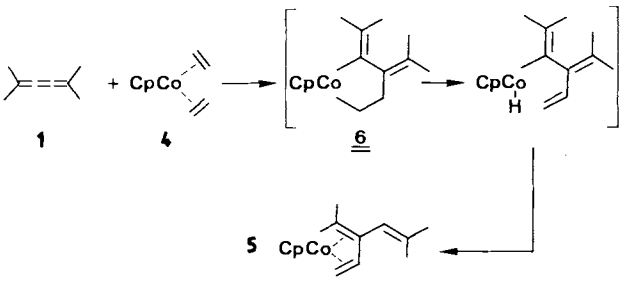
By *Ludwig Stehling* and *Günther Wilke**

Dedicated to Professor Emanuel Vogel on the occasion of his 60th birthday

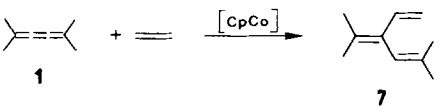
We recently reported[1] the cyclodimerization of 2,5-dimethyl-2,3,4-hexatriene **1** to octamethyl-[4]-radialene **2** on nickel(0). The intermediate **3** with a nickelacyclopentane structure could be isolated and was characterized by a crystal structure analysis. **2** is the result of a reductive elimination with ring closure from **3** (cod = 1,5-cyclooctadiene, MAA = maleic acid anhydride).



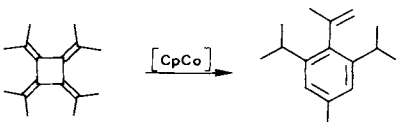
It is already known from the cobalt-catalyzed synthesis of pyridine from acetylene and nitriles[2] that cobaltacyclopentanes are formed as intermediates. This suggested investigating whether the reaction of **1** with $[CpCo(C_2H_4)_2]$ **4** would afford a complex similar to **3**. The components react at room temperature in the ratio 1:1 to give, in almost quantitative yield, the complex **5**, whose structure has been determined X-ray crystallographically.[3] Apparently, **1** and an ethene ligand of **4** initially react at the CpCo moiety to give a cobaltacyclopentane **6**, which after β-H elimination and hydrogen transfer is converted into **5**.



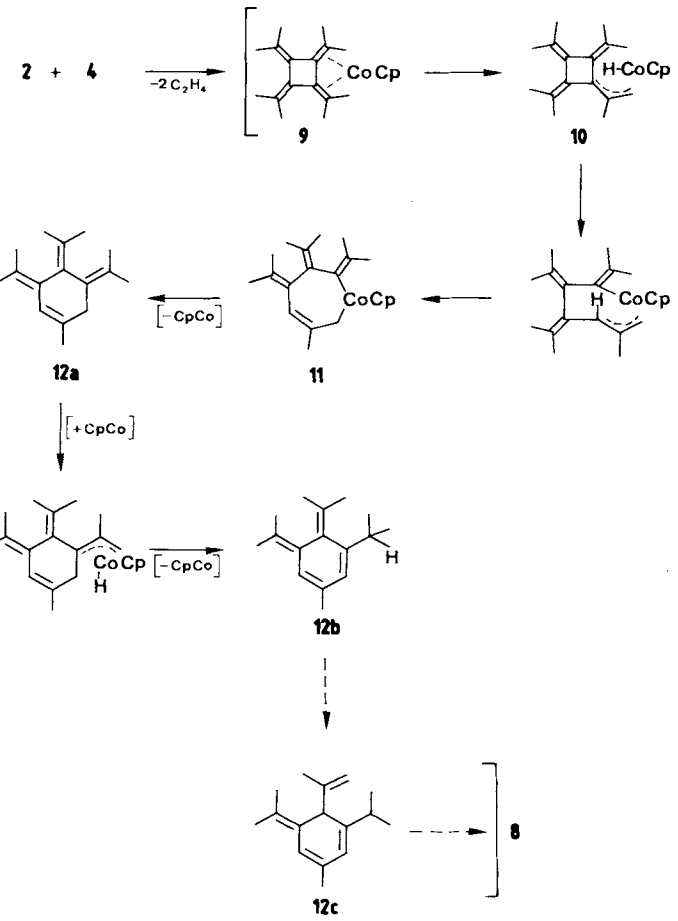
Under ethene pressure at 50°C a catalytic codimerization of **1** with ethene takes place, and the 2,5-dimethyl-3-vinyl-2,4-hexadiene **7**, which is bonded as a 1,3-diene in **5**, is obtained; i.e. **1** and ethene facilitate extrusion of **7** from **5**, with the CpCo moiety functioning as catalytically active species.



2 cannot be prepared using **4** as the catalyst. Surprisingly, however, in attempts to convert **2** (a bis-1,3-diene) with **4** into a complex with loss of ethene, a catalytic rearrangement of **2** to 2-isopropenyl-1,3-diisopropyl-5-methylbenzene **8** was observed. **8**, which was previously unknown, was unequivocally characterized on the basis of ^{1}H- and ^{13}C-NMR spectra and a crystal structure analysis.[3]



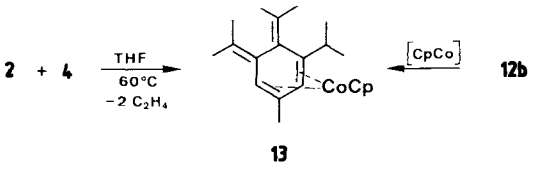
The catalytic rearrangement is presumably initiated by the initial tendency of **2** to undergo complexation with formation of **9**. The crystal structure of **2**[3] suggests that the H atoms of a CH_3 group of **9** lie in close proximity to the Co atom and sterically favor the formation of an alkylcobalt hydride **10**. This, however, adds to the neighboring



[*] Prof. Dr. G. Wilke, L. Stehling
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

C-C bond of the four-membered ring to give a seven-membered cobaltacycle **11**. If a reductive elimination now follows, then a six-membered ring derivative **12** is formed which is converted by several cobalt-induced 1,3-hydrogen shifts into the arene **8**.

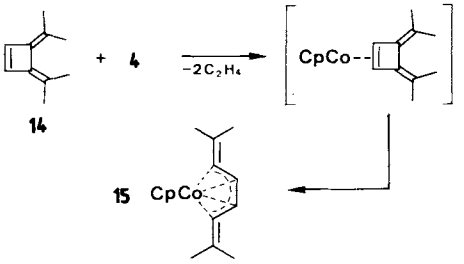
This catalytic rearrangement occurs in toluene at 60 °C. Under these conditions no intermediates could be isolated; the reaction course shown can only be regarded as tentative. In THF at 60 °C, however, an isolable complex which may be regarded as an intermediate, namely **13**, is formed.[4]



13

Surprisingly, dodecamethyl-[6]-radialene, which can be obtained catalytically from **1** with nickel(0), does not react with **4** under analogous conditions. The crystal structure of dodecamethyl-[6]-radialene[3] shows that the six-membered ring which contains six sp^2-hybridized C-atoms adopts a chair conformation, since neighboring isopropylidene groups strongly hinder each other sterically, thereby blocking the C=C bonds and making them inaccessible for a catalyst.

In this connection the behavior of a diisopropylidenecyclobutene **14**[4] towards **4** is also interesting. Even at room temperature a 1:1 adduct **15**,[5] which was characterized on the basis of ^{1}H- and ^{13}C-NMR spectra and a crystal structure analysis, is formed.[3] After displacement of the ethene molecules and possible complexation of the ring double bond, an oxidative addition to the bond on the opposite side of the ring takes place. In the resulting product **15**, the delocalized π-system is η^4-bonded to the CpCo moiety.



Thus, **15** is in a sense related to **3**, although only two of the four ring C-atoms in **3** are bonded to the Ni atom.

Experimental

5: A solution of **1** (1.31 g, 7.29 mmol) in THF (60 mL) was treated under argon at −78 °C with a solution of **4** (0.799 g, 7.29 mmol) in THF (20 mL). The mixture was warmed slowly to room temperature and, after 12 h, the THF was removed. Yield 1.84 g (7.07 mmol, 96.8%) of pure **5**. Recrystallization from ether furnished 1.4 g (5.38 mmol, 74%) of **5**. ^{1}H-NMR (200 MHz, [D$_6$]benzene): δ = 6.38 (s, 1 H), 4.94 (dd, 1 H), 4.50 (s, 5 H), 1.76 (dd, 1 H), 1.74 (s, 3 H), 1.61 (s, 3 H), 1.20 (s, 3 H), 1.00 (dd, 1 H), 0.60 (s, 3 H). ^{13}C-NMR (75.5 MHz, [D$_6$]benzene): δ = 134.97, 127.61, 96.78, 81.86, 81.14, 53.18, 32.35, 30.92, 25.77, 23.06, 19.65. MS: *m/z* 260 ($M^{\oplus}$, 100%). The structure of **5** was determined X-ray crystallographically.

7: A solution of **1** (30 g, 277 mmol) and **4** (0.46 g, 2.53 mmol) in THF (270 mL) was heated in an autoclave at 50 °C for 24 h under 60 bar ethene. The THF was then removed at 0.1 bar and 50 °C. According to a GC analysis the residue contained 7.82 g (57.8 mmol) of **7** together with unchanged **1** and 5.49 g (33.48 mmol) of C_{12}-hydrocarbons. The conversion of **1** was 33%; 33 cycles. **7** was characterized by combined GC/MS, hydrogenation, and MS (*m/z* 136, $M^{\oplus}$, 45%).

8: A solution of **2** (1.06 g, 5.84 mmol) in toluene (50 mL) was treated under argon with a solution of **4** (1.26 g, 5.84 mmol) in toluene (20 mL) and the mixture heated in a sealed ampoule at 60 °C for 48 h. After removal of the toluene, the residue was taken up in hexane and chromatographed on silica gel. Sublimation of the eluate after removal of hexane furnished 0.76 g (3.51 mmol, 60%) of **8**, which was recrystallized (m.p. 61 °C) from pentane. ^{1}H-NMR (200 MHz, [D$_6$]benzene): δ = 1.20 (d, 6 H), 1.22 (d, 6 H), 1.92 (s, 3 H), 2.22 (s, 3 H), 3.14 (sep. 2 H), 4.84 (dq, 1 H), 5.21 (dq, 1 H), 6.98 (s, 2 H). ^{13}C-NMR (75.5 MHz, CD_2Cl_2): δ = 20.6, 21.7, 24.4, 25.6, 26.4, 115.7, 123.9, 136.9, 138.5, 145.2, 146.1. MS: *m/z* 216 ($M^{\oplus}$, 56%). The C,H analysis agrees with the calculated values. The structure of **8** was unequivocally confirmed by an X-ray crystallographic analysis.

15: 171.7 mg (1.28 mmol) of **14** and 231.7 mg (1.28 mmol) of **4** were dissolved in benzene (50 mL) under argon and the reaction vessel partially evacuated several times over a period of 4 h at room temperature. After removal of the benzene there remained 270 mg of a reddish-brown product, which on recrystallization from ether at −78 °C furnished golden brown crystals. Yield 110 mg (0.42 mmol, 33%) of **15**. ^{1}H-NMR (80 MHz, [D$_6$]benzene): δ = 1.81 (s, 6 H), 1.95 (s, 6 H), 4.36 (d, 2 H), 4.85 (s, 5 H). ^{13}C-NMR (75.5 MHz, [D$_6$]benzene): δ = 23.6, 26.5, 63.4, 82.5, 117.8, 153.1. The NMR spectra of the crude product and the crystals are identical. The structure of **15** was determined X-ray crystallographically.

4-Oxo-2,5-Cyclohexadienylidene — a Carbene with a Stable Triplet and Metastable Singlet State?**

By *Wolfram Sander,** *Wolfgang Müller,* and *Reiner Sustmann*

Of crucial importance in carbene chemistry is the rate of singlet-triplet interconversion (k_{ST}), which, in many cases, might determine the product distribution. A study of diphenylmethylene has shown an ultrafast interconversion rate ($k_{ST} = 3.2 \times 10^9\ s^{-1}$) and equilibration between carbene spin states in a time that is short compared to most reactions.[1]

In this paper we report the generation and matrix isolation of 4-oxo-2,5-cyclohexadienylidene **1**. This carbene can be converted by visible light irradiation in a completely reversible manner from the stable triplet state **1** into a metastable singlet species. The slow thermal conversion of this metastable compound back to **1** at low temperatures (9–60 K) shows a pronounced external heavy-atom effect.

Carbene **1** was generated in solid argon at 9 K by irradiation of 4-diazo-2,5-cyclohexadienone **3**[2] with visible light

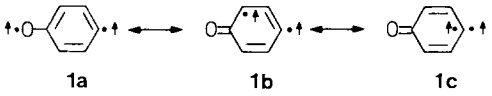
[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. *R. Gleiter* for supporting this work and for helpful discussions.

($\lambda > 495$ nm, 30 min). The IR-, UV-, and ESR-spectra of **1** are in accordance with an electronic structure described by resonance structures **1a**–**1c**.[3]



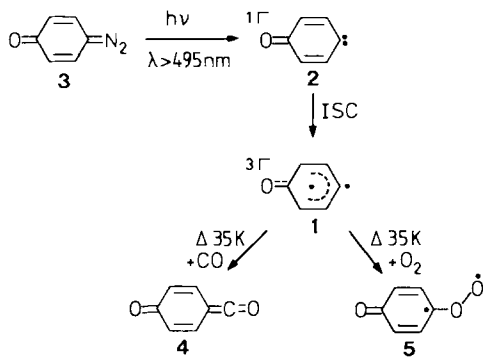
1a **1b** **1c**

In the IR spectrum of **1** the ν(CO) mode is found at 1496 cm^{-1} (Table 1), which indicates a bond order of the C–O bond considerably less than 2. The UV/VIS spectrum[3] shows a long wavelength band [UV (Ar, 10 K): $\lambda = 508$, 521, 535, 551, 566 nm] of medium intensity typical for triplet carbenes.[4] The ESR spectrum of **1**, measured in argon at 23 K, is in good agreement with the reported spectrum of a powder sample at 4 K.[5]

Table 1. IR spectroscopic data of **1**, [D_4]-**1**, **2**, and [D_4]-**2**, matrix isolated in argon at 9 K.

1	[D_4]-1	2	[D_4]-2
1496 s	1487	1720 s	1718
1375 m	1298	1713 vs	1709
1362 w		1679 w	1652
1260 m		1663 w	
1076 m		1520 w	
937 w	929	1305 w	1157
819 s	706	1005 m	
		896 w	876
		892 w	826
		843 m	816
		799 m	766
		741 m	
		583 s	493

Carbene **1** shows the low-temperature chemistry of a triplet carbene. Warming a matrix containing both **1** and carbon monoxide (1% in Ar) to 35 K (softening point of the argon matrix) generates a keto-ketene which is tentatively assigned the structure **4** [IR (Ar, 10 K): $\tilde{\nu} = 2110$ s, 1635 s, 1158 m, 851 m, 707 m cm^{-1}]. If the argon matrix is doped with 1% O_2, *p*-benzoquinone *O*-oxide (**5**) is formed under the same conditions.[3]



3 **2** **1** **4** **5**

Irradiation (543 ± 10-nm interference filter, 500W mercury high pressure arc lamp) into the long wavelength transition of **1** readily produces a new species **2** (Table 1, Fig. 1) (UV: $\lambda = 440$ (br), 337 nm). After several hours irradiation the conversion of **1** into **2** is >90%; other products are not observed IR spectroscopically.[6]

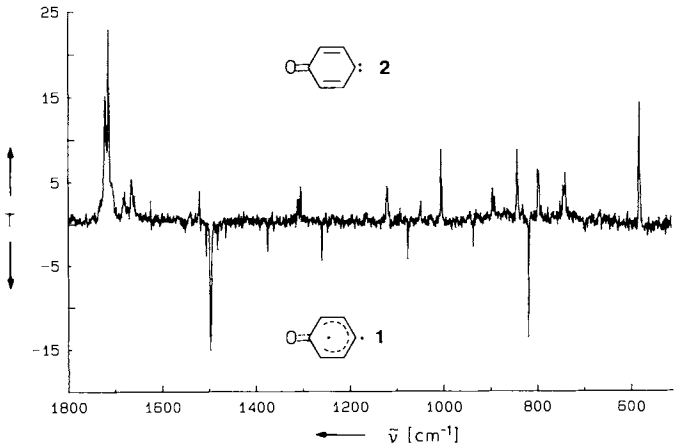


Fig. 1. Difference IR spectrum of the photochemistry of **1**. Bottom: bands assigned to **1**, vanishing on irradiation ($\lambda = 543 \pm 10$ nm). Top: bands assigned to **2**, appearing on irradiation.

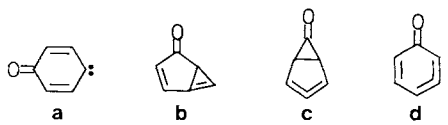
Compound **2** is very labile and rearranges back to **1** (>99%) under the following conditions:

- Broad band irradiation ($\lambda > 495$-nm cut-off filter, several min).
- Infrared irradiation (Nernst glower, visible light blocked by using a germanium filter). The disappearance of **2** and appearance of **1** obeys first order kinetics if a constant IR source (IR spectrometer) is used. In Ar, Kr, and Xe matrices the relative rates are 1 : 2.7 : 5.8.
- Standing in the dark. In Ar at 9 K, $t_{1/2} = 165 \pm 30$ h; in Xe at 9 K, $t_{1/2} = 10 \pm 2$ h.[7]

When **1** was irradiated ($\lambda = 543 \pm 10$ nm, Ar, 23 K) in the cavity of the ESR spectrometer, the signal intensity decreased by about 60% within 70 min. No other signal appeared. On standing in the dark the signal intensity increased again slowly, in agreement with the results from the IR experiments. This process was faster in Xe than in Ar matrix. On broad band irradiation ($\lambda > 475$ nm, 1 min), 92% of the original ESR intensity was restored.

The pronounced external heavy atom effect observed both for the IR induced and the thermal rearrangement is evidence for a spin-forbidden intersystem crossing (ISC) step determining the rate constants.[8]

Compound **2** is a carbonyl compound with a singlet ground state energetically lying above the triplet ground state of **1**. The most likely structures for **2** are a singlet carbene **a**, bicyclo[3.1.0]hexa-3,5-dien-2-one **b**, bicyclo-[3.1.0]hexa-2,3-dien-6-one **c**, and cyclohexa-2,3,5-trien-1-one **d**. Although structures **b**–**d** cannot be rigorously excluded, the IR spectrum of **2** (Table 1, Fig. 1) differs from what would be expected for these compounds.



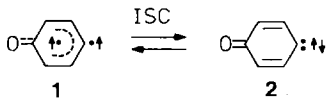
a **b** **c** **d**

Cyclopropene **b** should show a ring vibration in the region 1700–1800 cm^{-1}, exhibiting a characteristic 45 cm^{-1} shift on deuteration of the olefinic position,[9] which is not observed (Table 1). For cyclopropanone **c**, a ν(C=O)

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0404-0573 $ 02.50/0

mode $\approx 1820\ cm^{-1}$ is expected,[10] and allene **d** should show an allene band (1800–1900 cm^{-1}). There are no IR bands in the range 1750–2500 cm^{-1}, and thus structures **c** and **d** are unlikely. In addition, the rearrangement of **b**, **c**, or **d** to **1** requires the rupture of C–C or C–H bonds, and it is not reasonable to assume that these processes occur with such a low activation barrier (kT at 10 K is only 20 cal/mol).

The extremely slow intersystem crossing rate for the conversion of **2** into **1** might be explained in terms of the different structures of **1** and **2**. Whereas **1** is best described as a diradical with a phenyl type σ-system and a phenoxyl type π-system (partially "aromatic" ring system), **2** has a more localized cyclohexadienone structure.



1 **2**

The intersystem crossing thus requires a large geometric change of the molecule, although no covalent bands are rearranged. This new kind of isomerism was first predicted by *Dewar* and *Narayanaswami*[11] and recently postulated in the case of cycloheptatrienylidene.[12] Clearly, more experimental and theoretical studies are necessary to elucidate the factors determining the intersystem crossing rates in carbene reactions.

[6] UV irradiation ($\lambda > 345$ nm) of **1** rapidly produces a ring-opened compound containing both a ketene and a terminal acetylene functional group [IR (Ar, 10 K): $\tilde{\nu}$ = 3316 m, 2134 s, 1755 m, 1594 m, 1423 m, 1383 w, 1067 w, 819 w, 648 m, 592 w, 580 w cm^{-1}]. The acetylenes **6a** and **6b** are possible structures; however, an assignment has not been possible so far.

6a **6b**

[7] Rate constants were measured by IR spectroscopy. Both the disappearance of **2** and the appearance of **1** were observed with several bands. To measure the thermal interconversion, the IR beam was turned on for only a short period of time. Due to IR photolysis there is still a systematic error in the rate constants.

The Crystal Structures of the Superconducting Oxides $Bi_2(Sr_{1-x}Ca_x)_2CuO_{8-\delta}$ and $Bi_2(Sr_{1-y}Ca_y)_3Cu_2O_{10-\delta}$ with $0 \le x \le 0.3$ and $0.16 \le y \le 0.33$**

By *H. G. von Schnering,* L. Walz, M. Schwarz, W. Becker, M. Hartweg, T. Popp, B. Hettich, P. Müller,* and *G. Kämpf*

The enthusiasm awakened by the epoch-making discovery of *Bednorz* and *Müller*[1] did not pass our laboratories without leaving its trace. Based on earlier experiences with ternary oxides and with the considerable number of variants of the perovskite structure,[2] having in mind especially the $BiO^{\oplus}$ derivatives as investigated by *Aurivillius*[3] and *Sillén*,[4] we started in February 1987 to deal with complex oxides of the type $(Bi_2O_2)M'_{m-1}M_mO_{3m+1}$ with $m = 1, 2, \ldots$ In principle, all metal atoms are eligible to be the cation M′ or the central atom M if the condition $d(M'\text{-}O)/d(M\text{-}O) \simeq \sqrt{2}$, $d(M\text{-}O) = 185\text{–}205$ pm is approximately fulfilled. We assumed—admittedly without further scientific foundation—that the expected strong electron-phonon coupling is due to a 'virtual valence instability' of M, associated with a 'virtual change of the coordination' (cf. Ref. [5]). M should have an odd number of electrons and there should be a strong antiferromagnetic spin coupling. From chemical experience $Cu^{2\oplus}$ was considered most promising for a quick success.

Already in April 1987 we obtained a superconducting phase, and a single crystal X-ray analysis yielded the principal arrangement of the positions of the metal atoms. However, the positions of the oxygen atoms remained unclear. The exact identification as

$Bi_2(Sr_{1-x}Ca_x)_2CuO_{8-\delta}$ **1**

and its reproducible synthesis failed until October 1987.[6] The complications were due to strong absorption effects and to the existence of additional phases, at least to that of

$Bi_2(Sr_{1-y}Ca_y)_3Cu_2O_{10-\delta}$ **2**

Recently *Maeda* et al.[7] and *Chu* et al.[8] reported on the results of investigations of **2**. We are sure that the compound "$Bi_2Sr_2Cu_2O_{7-\delta}$" described by *Michel* et al.[9] is identical to $Bi_2(Sr_{1-x}Ca_x)_2CuO_{8-\delta}$ **1**.

Compounds **1** and **2** can be obtained by reaction of the metal oxides or carbonates at $1070\ K \le T \le 1225\ K$ in air (corundum crucibles). Homogeneous powder samples are obtained by sintering at 1070–1100 K for a few hours. At

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *Dachs*, Berlin, for the possibility to carry out the neutron diffraction measurements at the TAS1, Risø National Laboratories, Denmark.—These results were presented at the International Conference on High T_c Superconductors and Materials and Mechanisms of Superconductivity (HTSC-M^{2}S) that was held in Interlaken (Switzerland) on February 29.

about 1150 K the reaction mixtures begin to melt, and after a few minutes, crystals can be drawn from the molten phases. **1** and **2** form black glossy plate-like crystals with well-developed faces. They grow up to 5 mm in length along [010]. The ratio of **1** to **2** is influenced less by the stoichiometry of the reactants than by the thermal treatment. Reactions at $T \geq 1070$ K, followed by slow cooling or annealing at 970 K, lead to **1**, whereas **2** is preferably formed if the molten reaction mixture is quenched. It would seem that an excess of CuO is necessary for a successful synthesis of **2**. We assume that an excess of CuO prevents the formation of by-products. The reaction product near the side of the crucible is colorless and chemical analyses show distinct presence of Al, while the clearly separated superconducting material is free of Al.

An important observation is the change in color (black→dark brown) of samples of **1** as a function of the thermal treatment and of the O_2 partial pressure. The structure remains unchanged, although the oxidation activity varies (formation of Cl_2 from HCl). This is related to the number of defects δ within the $(Bi_2O_{4-\delta})^{2\oplus}$ partial structure, and is in agreement with the results obtained from neutron scattering experiments.

The crystal structures of **1** and **2** were determined by X-ray single crystal methods and by powder neutron diffraction measurements. The compounds crystallize orthorhombically in the space group *Amaa* (No. 66), with four formula units per unit cell (Table 1). In both cases reflections of the type $h+k$, $h+l=2n+1$ are very weak, but it must be emphasized that they are essential for the orthorhombic symmetry and the resulting atomic arrangement, and that the fast weakening of the intensities with increasing order of h is of great importance. These effects are due to: a) An unusual anisotropy of the bismuth atoms parallel to [100] that can be described with $U_{11}=0.18$ Å^2 or split positions $x=\pm 0.06 \neq 0$ for **1**, and 0.11 Å^2 or $x=\pm 0.04 \neq 0$ for **2**, respectively. b) A distinct displacement of the bismuth atoms parallel to [010] with $x=0.275 \neq 1/4$. If one neglects these facts, the impression arises that **1** and **2** crystallize tetragonally in the space group $F4/mmm$ ($\triangleq I4/mmm$ with $a'=b'=a/\sqrt{2} \simeq 385$ pm). Indeed, we have also found crystals for which the reflections mentioned above are diffuse. Furthermore, we obtained crystals which exhibit a five-fold, incommensurate superstructure along [100], which is coupled to a twofold one along [001]. It is likely that these superstructures are due to a longitudinal modulation of the parameter x (Bi) along [100]. An exact determination of the oxygen atoms based on X-ray data presents great difficulties, as also indicated in a recent study of **2** by *Subramanian* et al.[10] Only the oxygen atoms within the CuO_2 layers (see Fig. 1) can be localized, while the re-

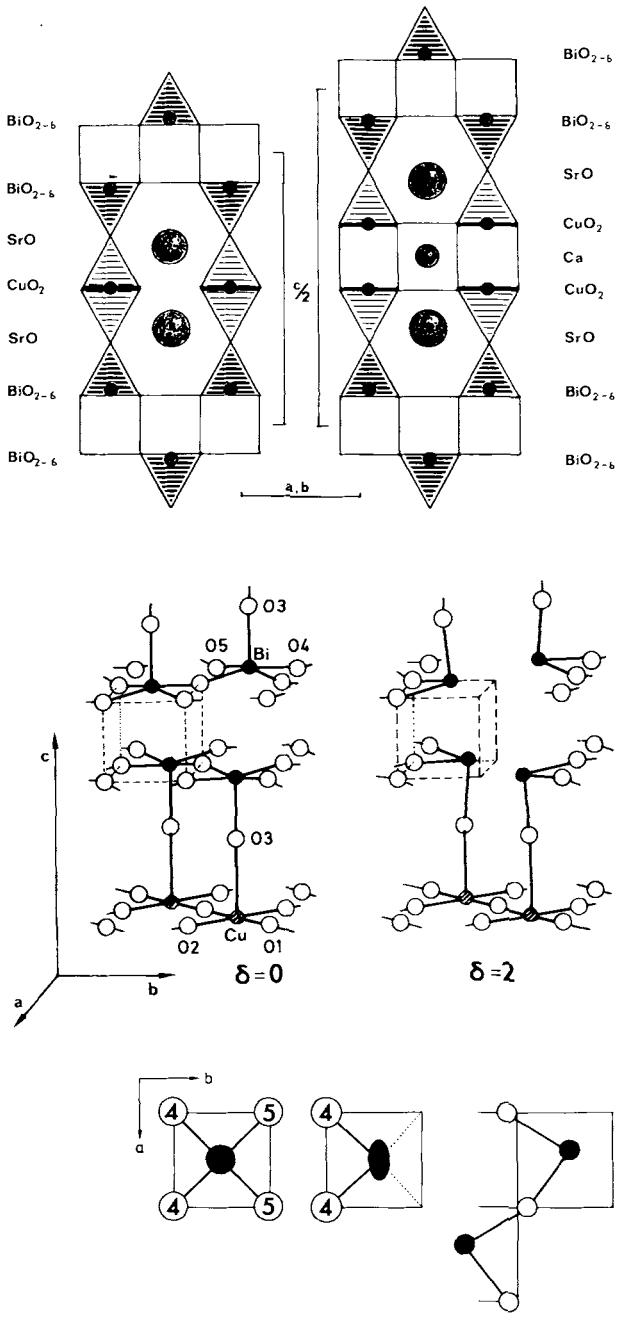

Fig. 1. Top: Schematic and idealized representation of the structures **1** and **2** ($a/2$ in projection). The O atoms occupy all crossing points of the polygons. The small, but significant displacements of the Bi atoms are marked by an arrow. Center: Perspective view showing the Bi-O-Cu-O connection; left part: $\delta=0$, right part: $\delta=2$. Bottom: Section of the $(Bi_2O_{4-\delta})$ plane with $\delta=0$, $x(\mathrm{Bi})=0$, and $y(\mathrm{Bi})=1/4$ (left); $\delta=2$, $y(\mathrm{Bi})=0.275$, and $U_{11}=0.18$ Å^2 (center) and an ordering model (right) with a structure modulated along [100] ($\delta=2$, $x(\mathrm{Bi})=0.05$, $y=0.275$). The size of the atoms (Bi = black) is in agreement with the thermal parameters.

maining ones, especially those in the $Bi_2O_{4-\delta}$ region are considerably displaced together with the Bi atoms. However, the neutron scattering experiments allow an exact determination (cf. Table 1).

The results are given in Figure 1. The structures of **1** and **2** are the first members of the homologous series $Bi_2M'_2M''_nM_{n+1}O_{8+2n-\delta}$ ($n=0, 1$) with $d(M'\text{-}O) \geq d(M''\text{-}O)$ and $d(M'\text{-}O)/d(M\text{-}O) \simeq \sqrt{2}$. The structure of **1** exists with M = Cu and $M' = Sr_{1-x}Ca_x$ ($0 \leq x \leq 0.3$). On varying x, the lattice constants are changed only very little. The single crystal investigated contained only Sr. The structure of **2** exists with M = Cu, M' = Sr, and $M'' = Sr_{1-x}Ca_x$ ($0.5 \leq x \leq 1$; corresponding to $0.16 \leq y \leq 0.33$). The single crystal used for the X-ray determination contained $x = 0.5$ Ca. In **1** and **2** the Bi_2O_4 layers frame different sized fragments of the perovskite structure (Fig. 1, top). The adaptation of the two partial structures is rather unusual. It differs essentially from the known $(Bi_2O_2)^{2\oplus}$ derivatives[3] because of direct Bi-O-Cu sequences along [001] (Fig. 1, center). The lowering of the 12-fold coordination of M' and M'' to a square antiprismatic or cubic 8-fold coordination arises, on the one hand, from the (Bi-O-Cu) packing and, on the other, from the absence of Cu-O-Cu bridges along [001] within **2**. In particular, the copper atoms in **1** are linked to 4+2 oxygen atoms with $d(Cu\text{-}O) = 191$ pm (4×) and 231 pm (2×), leading to a typically elongated $^2_\infty[CuO_{4/2}O_2]$ partial structure. The copper atoms in **2**, however, have a 4+1 coordination with $d(Cu\text{-}O) = 191$ pm (4×) and 225 pm (1×). Distorted tetragonal CuO_{4+1} prisms arranged *trans* to each other are connected by $M''O_8$ cubes (Fig. 1). The coordination of the cations, $Sr^{2\oplus}$ and $Ca^{2\oplus}$, are as expected ($d(Sr\text{-}O) \simeq 260$ pm). In contrast, a completely unusual coordination is found for the bismuth atoms. If the positions of O4 and O5 are completely occupied ($\delta = 0$), then bismuth is present as Bi^V and it is likely that four short Bi-O distances (Bi-O4 2×, Bi-O5 2×) of about 192 pm will be obtained assuming $y(Bi) = 1/4$, together with Bi-O3 = 221 pm and 217 pm, respectively. However, Bi^{III} is present if the position of O5 is completely unoccupied ($\delta = 2$). With $y(Bi) = 0.275$, three convenient Bi-O distances result, and an orientation of the lone pair nearly parallel to (001) occurs, an orientation never observed in such structures.

Indeed, the results of the neutron scattering experiments prove that the defects δ occur only on the position of O5 if $y(Bi) \geq 1/4$. The remarkable feature of these structures is that adaptation of all oxidation states $Bi^{q\oplus}$ ($3 \leq q \leq 5$) within the $(Bi_2O_{4-\delta})$ partial structure is possible. It can be expected that formal charge transfer processes of the kind $Bi^V\text{-}O\text{-}Cu^{II} \rightleftharpoons Bi^{IV}\text{-}O\text{-}Cu^{III}$ as well as $Bi^{IV}\text{-}O\text{-}Cu^{II} \rightleftharpoons Bi^{III}\text{-}O\text{-}Cu^{III}$ and $Bi^{IV}\text{-}O\text{-}Bi^{IV} \rightleftharpoons Bi^{III}\text{-}O\text{-}Bi^V$ play an important role concerning the superconducting properties of these materials. In this connection, we mention the superstructure of **1**, which indicates a periodic modulation of the Bi_2O_4 layers (see Fig. 1, bottom). Changes in the Bi-O coordination are qualitatively in agreement with the process $2\,Bi^{IV} \rightleftharpoons Bi^{III} + Bi^V$. There is good reason to believe that this modulation is related to the number of defects δ. For the crystals investigated δ is about 1.5, i.e., formally Bi^{IV} and Bi^{III} are present, but slight variations of the lattice constants for different powder samples confirm a distinct variability of δ. For instance, deep-black samples of **1** yield slightly smaller values for a and b (535.0 pm). In the case of **2**, a comparison of the values given for the length of the c-axis shows that it can also vary over a greater range (3086 pm,[7] 3078 pm,[8] 3090.4 pm,[10] 3062.8 pm [this work]). This may be due to a different Ca content.

Measurements of the resistivity (four-probe technique) and of the Meissner effect (SQUID) carried out on small rods show critical temperatures of 70–85 K (for some samples only 40 K) with broad transition regions and variable parts of superconducting material (5–50%). A knowledge of the thermal behavior and of the structures allows us to explain this by an oxygen content that hitherto has not been completely optimized. Obviously the range of δ (oxygen defects within the Bi_2O_4 partial structure), in which superconductivity occurs, is smaller for **1** than for **2**. In the case of a sample with the approximate composition $Bi_2Sr_2CuO_x$ and only marginal amounts of Ca, we observed on one occasion a sharp decrease in the resistivity at 140 K ($\Delta T \leq 2$ K) down to a very small resistance, which vanished at 80 K. Attempts to reproduce this experiment have thus far failed.

Dinuclear Vanadium(II)- and Vanadium(III)-guaiacolato Complexes Related to Vanadium-based Systems for the Reduction of Nitrogen**

By *Carlo Floriani,* Marinella Mazzanti, Angiola Chiesi-Villa,* and *Carlo Guastini*

Vanadium(II) is a powerful reducing agent for a variety of substrates,[1,2] including dinitrogen.[2] In the latter case the reduction is promoted by the heterogeneous $V(OH)_2/Mg(OH)_2$ system[2a,c] or by the homogeneous vanadium(II)-

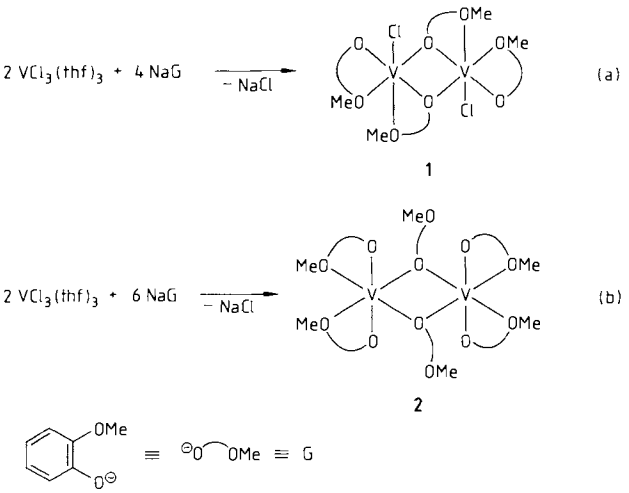
pyrocatechol system.[2b,c] These findings suggest that vanadium(II) in a coordination sphere provided by oxygen donor atoms, and with an undefined molecular complexity may be the required active species.[2c] Any hypothesis at the molecular level, however, is prevented by the paucity of our knowledge concerning the coordination chemistry of vanadium(II) in environments like those mentioned above,[3] information being available only on organometallic derivatives containing a very different class of ligands.[4] So far only a few and very diversified vanadium(II) coordination compounds have been studied.[5]

In the search for unconventional model compounds for dinitrogen activation, we focused our attention on vanadium(II)-vanadium(III) complexes containing only oxygen donor atoms, and with a ligand which can, somehow, modulate the redox potential of the metal. We report here our findings on guaiacolatovanadium(II)/vanadium(III) systems.

Upon reaction of a solution of sodium guaiacolate (NaG) with $VCl_3(thf)_3$ in THF we obtained, depending on the ligand/metal ratio, the complexes **1** or **2**. Reaction (a) was carried out at $-60°C$. After warming the suspension to room temperature, the volatile components were removed by evaporation. The residue dissolved in toluene gave, after removal of NaCl and addition of *n*-hexane, red-brown crystals of **1** (ca. 65%). Reaction (b) was carried out at room temperature. The complex **2** crystallized as violet crystals from the THF solution (ca. 57%).



Complexes **1** and **2** are air-sensitive. They have magnetic moments of 2.73 BM and 2.53 BM respectively at 292 K, corresponding to a d^2 high-spin configuration. The magnetic moment of **2**, thus lying lower than the spin-only value, would seem to suggest some coupling between the two vanadium(III) centers. The structures of **1** and **2**[6] have been elucidated by X-ray analyses, but details will be given only for **1** (Fig. 1), which crystallizes with two molecules of toluene.[7]

1 is a centrosymmetric dimer, in which each vanadium exhibits a pseudooctahedral coordination involving a chlorine atom and the oxygen atoms from two guaiacolato anions behaving as chelating ligands. One of the two guaiacolato ions bridges an adjacent centrosymmetric vanadium through the O11 oxygen atom. The distortion of the octa-

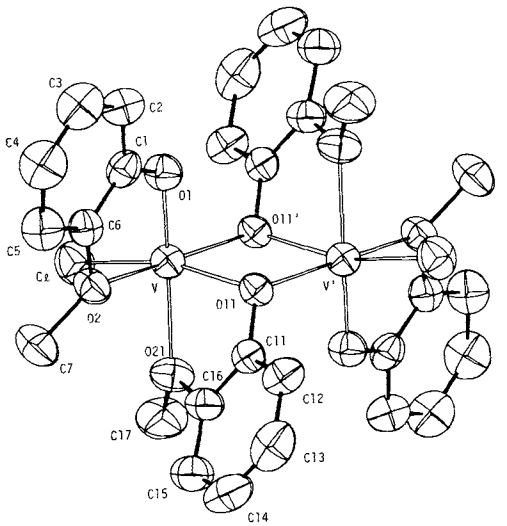


Fig. 1. Crystal structure of the complex **1** (without toluene) (ORTEP). Important bond distances [Å] and angles [°]: V-Cl 2.347(2), V-O1 1.884(5), V-O2 2.133(5), V-O11 2.027(4), V-O11' 2.078(5), V-O21 2.195(6); O1-V-O2 81.5(2), O11-V-O21 75.9(2), O11-V-O11' 77.6(2), O2-V-O11' 169.4(2), O2-V-O11 93.8(2), O1-V-O21 163.4(2), O1-V-O11 94.8(2), Cl-V-O11' 97.7(1), Cl-V-O11 161.0(2), Cl-V-O2 92.5(2), V-O11-V' 102.4(2). Prime indicates a transformation of $-x, -y, -z$.

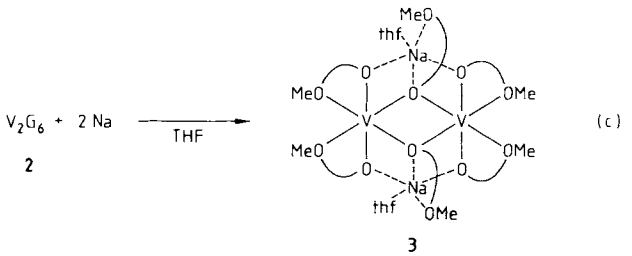
hedron is mainly due to the bite of the organic ligand [O1-V-O2 81.5(2); O11-V-O21 75.9(2)°] as well as to the bridging mode [O11-V-O11' 77.6(2)°]. The V-O distances range from 1.884(5) to 2.195(6) Å, probably as a consequence of intraligand steric interactions. They are significantly different from those observed in the analogous vanadium(III) complex $[K_3\{V(cat)_3\}]$ [cat ≡ catecholato dianion] ranging from 1.984(1) to 2.036(1) Å.[6] An additional remarkable difference is that **1** is dimeric and $[K_3\{V(cat)_3\}]$ is monomeric. The V-Cl bond length is unexceptional.[8] The two organic ligands are essentially planar, in spite of some distortions in the case of the bridging ligand. However, the five-membered metal-chelate rings assume an envelope conformation, vanadium lying at 0.176(1) and 0.823(2) Å from the planes through O1, C1, C6, O2 and O11, C11, C16, O21, respectively. The V···V separation [3.200(2) Å] rules out any metal-metal interaction. Complex **1** is especially worthy of attention, because of the presence of two potentially reducible and functionalizable vanadium(III) centers.

Compounds **1** and **2** behave in the same way upon reaction with sodium sand, giving the dinuclear vanadium(II) complex **3**. Reduction of **2** was carried out in THF at room temperature, and complex **3** was obtained, after re-



crystallization, as green crystals (ca. 51%). Reduction of **1** leads to formation of a second vanadium complex which has not yet been identified.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0404-0577 $ 02.50/0

The complex **3** has a magnetic moment significantly lower than expected for a d^3-high spin complex [$\mu = 3.11$ BM at 292 K]; the two bridging oxygens lead to an antiferromagnetic coupling between the two vanadium atoms. The structure of **3** was determined by an X-ray analysis.[9] Figure 2 shows the coordination sphere of the metal ions.

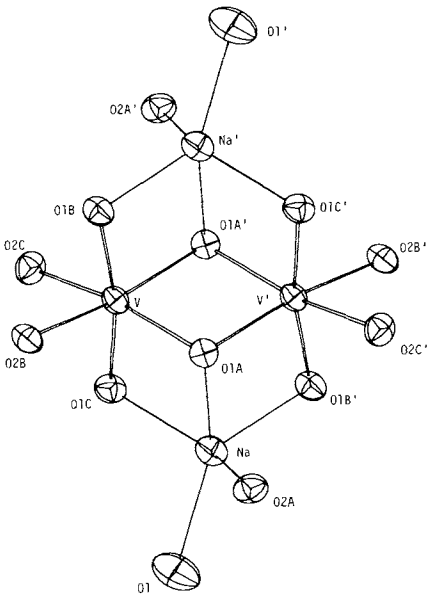


Fig. 2. An ORTEP drawing of the coordination sphere of the metal ions of complex **3**. O1A and O2A, O1B and O2B, and O1C and O2C belong to the guaiacolato ligands A, B and C. Oxygen bearing the methyl group in the guaiacolato ligand is labeled as O2; O1 is the oxygen atom from THF. Important bond distances [Å] and angles [°]: V-O1A 2.104(3), V-O1A' 2.149(4), V-O1B 2.094(5), V-O2B 2.170(5), V-O1C 2.083(4), V-O2C 2.201(4), Na-O1A 2.412(5), Na-O2A 2.393(5), Na-O1B' 2.243(5), Na-O1C 2.251(5), Na-O1 2.371(5); O1B-V-O2B 76.9(2), O1C-V-O2C 76.1(2), O1B-V-O1C 168.9(2), V-O1A-V' 98.2(1). Prime indicates a transformation of $-x, -y, 1-z$.

3 is a centrosymmetric dimer; each vanadium atom is surrounded by three guaiacolato anions (A, B, C) in a pseudo-octahedral environment. The ions B and C act as chelating ligands toward vanadium, while the ion A forms a chelate complex with a sodium atom and, at the same time, bridges the two vanadium atoms through O1A. A very close relationship exists between the structures of **2** and **3**; the reduction in the oxidation state of vanadium and the coordination of $Na^{\oplus}$ affect the parameters of the coordination sphere of vanadium only. The coordination polyhedron around vanadium in **3** is distorted mainly as a consequence of the ligand bite. The V-O distances, ranging from 2.083(4) to 2.201(4) Å, are longer than those found in complexes **1** and **2**[6] as a result of stronger intraligand steric interactions. The Na-O distances vary from 2.243(5) to 2.412(5) Å and have the usual values. The guaiacolate ions B and C are essentially planar, while the anion A, which is greatly influenced by the coordination, shows more significant distortions from planarity, O1 and O2 being at $-0.095(5)$ and 0.043(5) Å from the plane of the aromatic ring. The five-membered chelating rings, like in complex **1**, assume an envelope conformation, the vanadium atoms lying at 0.161(1) and 0.279(2) Å from the planes through the other four atoms for B and C respectively. The sodium atom is displaced 0.239(3) Å from the O1A, C1A, C2A, O2A plane. The V···V separation [3.215(2) Å], like in complex **1**, rules out any metal-metal interaction.

Many characteristics of **3** are worthy of mentioning. It is quite a rare dinuclear vanadium(II) complex having oxygen as unique type of donor atoms. The structure contains both transition metal ions in a low oxidation state as well as a Lewis acid ($Na^{\oplus}$). Such a dianionic structure is a potential ligand for building polynuclear structures.—Studies on the redox properties of complexes **1**-**3** will certainly contribute to an understanding of dinitrogen activation by very similar V^{III}-V^{II} compounds.

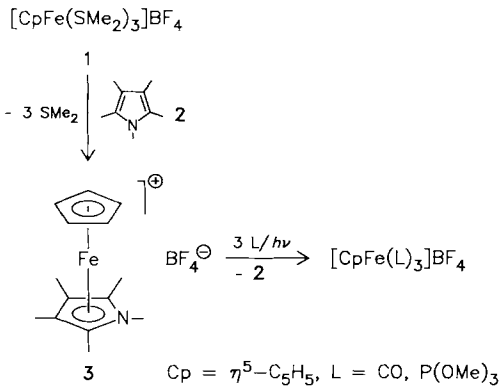
Stable Sandwich Complexes with Pentamethylpyrrole Ligands**

By *Norbert Kuhn,* Eva-Maria Horn, Edgar Zauder, Dieter Bläser,* and *Roland Boese*

Very few transition metal complexes of pyrrole are known,[1] and of these, owing to the poor stability of the pyrrole-metal bond, only $[(C_4H_4NMe)Cr(CO)_3]$ has been adequately characterized.[1c,d] The replacement of hydrogen atoms by methyl groups, a strategy which has proven useful for the stabilization of cyclopentadienylmetal complexes,[2] has also been found to be effective in the case of pyrrole coordination. In contrast to the less adequately characterized analogous complex of *N*-methylpyrrole,[1a,b] the complex **3**[5] obtainable by reaction of the sulfane complex **1**[3] with pentamethylpyrrole **2**[4] is stable both in solution and in the solid state up to 80°C.



The structure of the cation of **3** in the crystalline state (Fig. 1) reveals its metallocene character;[6] the angle between the "mean" planes of the ring ligands is 3.4°. The pyrrole ring is folded about the C1-N3 axis (angle of fold 12.3°), the cyclopentadienyl ring about the C13-C15 axis (angle of fold 14.5°). The carbon atom C2 is oriented toward the iron atom, while the carbon atom C14 diagonally opposite to C2 is oriented away from the iron atom. The perpendicular from the coordination center to the mean plane of the pyrrole ring forms an angle of only 1.1° with a line joining the iron atom and the geometrical midpoint of the pyrrole ring; i.e. no significant ligand shift is observed. The methyl group bound to the nitrogen atom is located at a distance of 0.31 Å from the ring plane in the direction away from the coordination center. The distances between the centers of the ring ligands and the central metal of 1.65 Å (Fe-C_5H_5) and 1.62 Å (Fe-C_4H_4NMe) are not exceptional.

The cation of **3** not only resembles the ferrocenes, but is also related to arene(cyclopentadienyl)iron cations.[7] The ^{13}C-chemical shift of the C_5H_5 ligand of **3** ($\delta = 76.01$) lies in the usual range (e.g. $\delta = 77.35$ for $[(C_5H_5)Fe(C_6Me_6)]^{\oplus}$[8]). The possible substitution of the pyrrole ligand in **3** by other neutral ligands (e.g. CO, $P(OMe)_3$) by photochemical excitation also correlates with the reaction behavior of the arene complexes.[9]

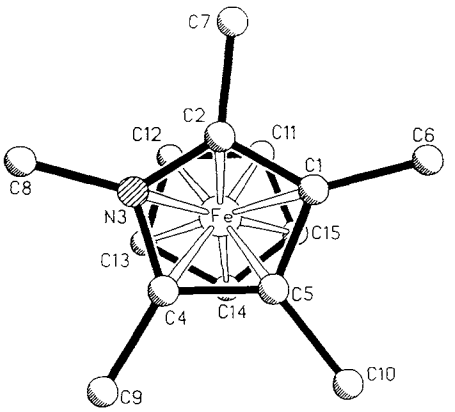


Fig. 1. Crystal structure of **3** (hydrogen atoms omitted). Selected bond lengths [Å] and angles [°]: C1-C2 1.40(1), C1-C5 1.41(3), C2-N3 1.34(2), N3-C4 1.36(3), C4-C5 1.42(3), Fe-C1 2.09(1), Fe-C2 1.88(2), Fe-N3 2.04(2), Fe-C4 2.03(1), Fe-C5 1.96(2), Fe-C11 2.07(1), Fe-C12 2.01(1), Fe-C13 1.94(3), Fe-C14 2.09(1), Fe-C15 2.04(4), Fe-Cp center 1.65, Fe-C_4N center 1.62, $\bar{d}$(C-C(Cp)) 1.40; Cp-center-Fe-C_4N-center 179; the mean torsion angle C(n)-C_4N-center-Cp-center-C(n+10) is 39°.

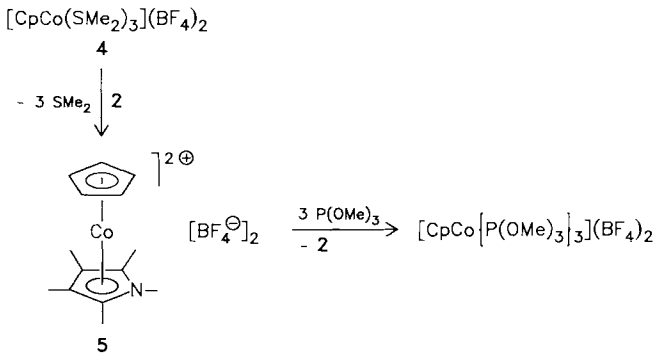

The cobalt complex **5** isoelectronic with **3** is obtained analogously from the sulfane complex **4**.[10,11] **5** is storable for several weeks in nitromethane, but reacts rapidly with trimethyl phosphite with cleavage of the pyrrole ligand to give the $[C_5H_5Co\{P(OMe)_3\}_3]^{2\oplus}$ ion; here also the relationship with the corresponding arene complexes is clearly recognizable on comparing the ^{13}C-NMR data ($\delta(C_5H_5) = 93.27$ (**5**) and 96.8 $[(C_5H_5)Co(C_6Me_6)]^{2\oplus}$[12]).

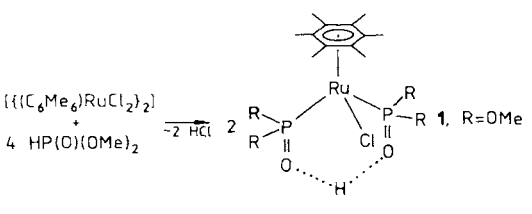
Cu^{II} and Cu^{I} Coordination Chemistry of a Novel *O,O,Cl*-Chelate Ligand. Formation of a Stable Carbonylcopper Complex**

By *Wolfgang Kläui** and *Elke Buchholz*

We have already reported in detail on the coordination chemistry of the anionic tridentate ligand $[CpCo\{P(O)(OEt)_2\}_3]^\ominus$.[1a] The complex anion $[(C_6Me_6)RuCl\{P(O)(OMe)_2\}_2]^\ominus$ $[1\text{-}H]^\ominus$, which is accessible via a Michaelis-Arbuzov-type reaction of the trimethyl phosphite complex $[(C_6Me_6)RuCl\{P(OMe)_3\}_2]^\oplus$ with iodide leading to cleavage of iodomethane, also behaves as a chelate ligand toward metal ions.[1b] However, in contrast to the tripodal ligands it can react as a bidentate *O,O*- or tridentate *O,O,Cl*-ligand, depending on the steric and electronic requirements. Noteworthy is its tendency to react with alkali metal salts to give adducts which are readily soluble in apolar solvents. This property, which it shares with other *O,O,X*-chelate ligands of analogous structure, frequently makes its synthesis in pure form difficult.[2] We therefore searched for an alternative synthetic route and have now found a facile entry to $[(C_6Me_6)RuCl\{P(O)(OMe)_2\}\{P(OH)(OMe)_2\}]$ **1**, the protonated form of this *O,O,Cl*-ligand.

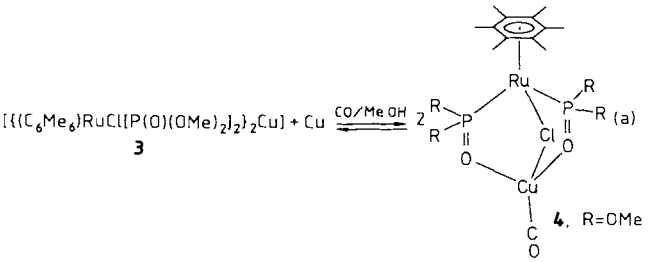


For the reaction of $[\{(C_6Me_6)RuCl_2\}_2]$ with dimethyl phosphite to give **1** it is decisively important to provide an additional driving force in the form of chloride-ion solvation by a good solvating solvent such as methanol. In chloroform, the reaction stops at the stage of $[(C_6Me_6)RuCl_2\{P(OH)(OMe)_2\}]$.

1 is stable toward air and is readily soluble in chlorinated hydrocarbons and THF but only sparingly soluble in diethyl ether, pentane, and water. For use as chelate ligand, **1** can be converted directly into bis(ligand)metal complexes, e.g. with aqueous solutions of metal(II) acetates. For reactions with organometallic compounds that are sensitive to hydrolysis, **1** can be first converted into **2**. This is achieved by reaction with solid potassium hydride in dichloromethane, which leads to evolution of hydrogen.

$K[(C_6Me_6)RuCl\{P(O)(OMe)_2\}_2]$ **2**[3]

2 is readily soluble in dichloromethane. In investigations of the coordination chemistry of copper(I) compounds we have surprisingly found that the bis(ligand)copper(II) complex **3** reacts with copper powder in methanol to give the carbonylcopper complex **4** on introduction of CO.



The comproportionation equilibrium (a) is established within a few hours at room temperature, and at 1 atm CO it lies completely on the right-hand side. It is astonishing how rapidly the carbonyl complex **4** is formed, for the copper(II) complex **3** is almost completely insoluble in methanol. The comproportionation takes place significantly more slowly, however, even in dichloromethane. The carbonyl complex **4** is remarkably stable compared to [Cu(CO)Cl] or $[Cu(CO)Cl(H_2O)_2]$.[4] No loss of CO was observed after 1 hours' drying under high vacuum at room temperature.

However, on exposure to air, **4** decomposes with formation of a green compound whose composition is still unknown. **4** reacts immediately with PMe_3 and PPh_3 with extrusion of the CO-ligand. The products that are formed are also sensitive to oxidation. The ν(CO) frequency in the IR spectrum of **4** (2089 cm^{-1} in methanol) is as low as that of the solvent complexes of [Cu(CO)Cl] in methanol and THF.[5] Apparently, the *O,O,Cl*-ligand $[(C_6Me_6)RuCl\{P(O)(OMe)_2\}_2]^\ominus$ $[1\text{-}H]^\ominus$ creates an electronic environment which resembles that in the above mentioned solvent complexes. The high thermal stability of **4**, which is attributed to the chelate effect, is surprising when one considers that the methanol and THF solvent complexes lose CO on isolation, even under a CO atmosphere at 0 °C.[5] The readiness with which the carbonylcopper complex **4** is formed, and its stability, suggest an interesting synthetic potential for this ligand in organometallic chemistry.

Institut für Anorganische Chemie der Technischen Hochschule Templergraben 55, D-5100 Aachen (FRG)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen (FRG), by the Fonds der Chemischen Industrie, and by Heraeus (gifts of chemicals). We thank Mr. *P. Dharmawan* for valuable assistance with the experiments.

Experimental

1: A mixture of $[\{(C_6Me_6)RuCl_2\}_2]$ (6.60 g, 9.87 mmol) and dimethyl phosphite (40 mL) in methanol (500 mL) was heated under reflux with stirring for 4 d until the initially red solution had turned yellow in color. On subsequent evaporation of the solution under high vacuum a yellow precipitate separated out, which after addition of 100 mL of dichloromethane went into solution again. The solution thus obtained was extracted with 6 × 15 mL of water to remove hydrochloric acid and any unchanged dimethyl phosphite. On removal of the solvent the product precipitated out as a yellow powder. Yield 9.75 g (95%). Recrystallization from dichloromethane/hexane afforded fine yellow crystals. ^{1}H-NMR (80 MHz, $CDCl_3$): $\delta = 2.1$ (t, $^4J(PRuCCH) = 0.9$ Hz, 18 H; CCH_3), 3.59 (virt. t, $^3J(POCH) = 11.1$ Hz, 6 H; OCH_3), 3.72 (virt. t, $^3J(POCH) = 10.3$ Hz, 6 H; OCH_3), 12.7 (br. s, 1 H; PO–H).

3: A suspension of 1.50 g (2.9 mmol) of **1** in 20 mL of water was treated with 570 mg (2.9 mmol) of $Cu(OAc)_2 \cdot H_2O$ and the resulting mixture stirred for 4 h. The product was centrifuged off, washed twice with a small amount of water and dried under high vacuum. Yield 1.49 g (94%). After recrystallization from dichloromethane/pentane, analytically pure yellow crystals were obtained.

4: A mixture of **3** (150 mg, 0.14 mmol) and copper powder (200 mg, 3.15 mmol) in 15 mL of methanol was stirred under a CO-atmosphere until the copper(II) complex had completely dissolved (ca. 3 h). The yellow solution was separated from the excess metal under a CO atmosphere and then evaporated to dryness. The yellow solid product was dried for 1 h under high vacuum. Yield 135 mg (81%). IR (CH_3OH): 2089 cm^{-1} (s, ν(CO)). **4** is readily soluble in methanol and dichloromethane and insoluble in saturated hydrocarbons. It decomposes on exposure to air, rapidly in methanol, but more slowly in dichloromethane and in the solid state.

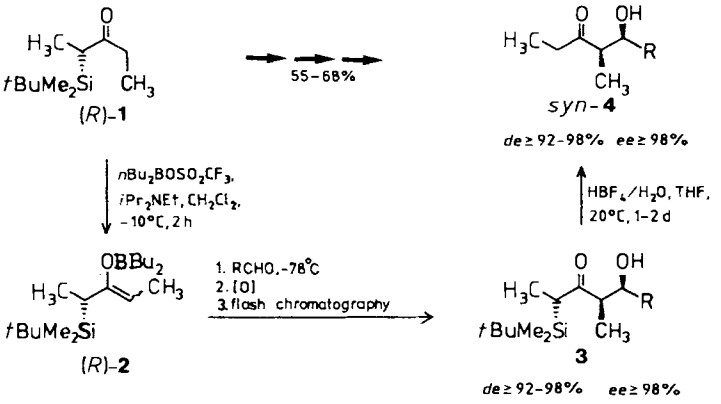
Diastereo- and Enantioselective Aldol Reactions via α-Silyl Ketones, Asymmetric Synthesis of the Aggregation Pheromone Sitophilure**

By *Dieter Enders** and *Braj Bhushan Lohray*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

Diastereo- and enantioselective aldol reactions have been the subject of intensive study in recent years.[1] Whereas excellent diastereo- and enantioselectivities have been achieved with aldol-like processes that lead to hydroxycarboxylic acids and their derivatives,[2] direct aldol syntheses of β-hydroxyketones are less widely developed and, in part still unsatisfactory with regard to enantiomeric excesses.[3] We recently reported on a facile entry to highly enantiomerically pure α-trialkylsilyl ketones and α-trialkylsilylaldehydes.[4] We have now found that α-silyl ketones of type **1** can be employed as chiral methylene compounds in aldol reactions and enable the stereoselective synthesis of *syn*-configurated β-hydroxyketones **4** in high diastereomeric and enantiomeric excesses.



For example, (*R*)-2-(*tert*-butyldimethylsilyl)pentan-3-one, (*R*)-**1**, was converted by reaction with di-*n*-butylboryl triflate in dichloromethane in the presence of Hünig base into the boron enolate (*R*)-**2** and then allowed to react with aldehydes at −78 °C. Subsequent oxidative work-up[5] and flash chromatography furnished the *syn*-aldol adducts **3**, which could be desilylated with 60% aqueous tetrafluoroboric acid in THF to the *syn*-aldol products **4** with high diastereomeric (*de*: 92 to ≥98%) and enantiomeric purity (*ee* ≥ 98%) (Table 1).

Table 1. β-Hydroxy ketones *syn*-**4** prepared by diastereo- and enantioselective aldol reaction with (*R*)- or (*S*)-**1**.

4d	$C_6H_5(CH_2)_2$	55	−37.6 (1.0, ether)	92	≥98	(4*R*,5*S*)
4e	C_6H_5	68	−16.0 (1.3, benzene)	≥98	≥98	(4*S*,5*S*) [h]

[a] Determined ^{13}C- and ^{19}F-NMR spectroscopically via the corresponding (*S*)-MTPA ester [7] (MTPA = Ph–C(OCH_3)(CF_3)–CO_2H). [b] Determined as in [a] and also ^{1}H-NMR spectroscopically with Eu(hfc)$_3$ as well as polarimetrically by comparison with literature data [9, 10, 3 h]. [c] Assignment based on a comparison with data in the literature [9, 10, 3 h]. [d] In [9]: $[\alpha]_D^{21} = -30.2$ (c = 1.43, ether). [e] Contaminated with 2% anti-isomer (4*S*,5*S*)-**4b**; in [10]: $[\alpha]_D^{20} = -26.7$ (*c* = 1.52, ether). [f] (*S*)-**1** was used as chiral methylene component. [g] −2.14 (*c* = 1.0, ether); (4*S*,5*R*)-**4c** [3 h]: $[\alpha]_D^{20} = -23.2$ (*c* = 1.8, $CHCl_3$) corresponding to 66% *ee*; the change in sense of rotation on changing the solvent from ether to chloroform is typical for the aldol adducts *syn*-**4**; we thank Dr. *I. Paterson*, Cambridge, for helpful discussions. [h] Confirmed by X-ray structure analysis of the corresponding SAMP-hydrazone [3d, 11].

The simple diastereoselectivity of the aldol C–C coupling can be determined ^{1}H- and ^{13}C-NMR spectroscopically at the stage of the crude adducts **3**. The *syn* : *anti* ratio is ca. 9 : 1, irrespective of the aldehyde employed. From this and from the ^{13}C-NMR spectroscopic and gas-chro-

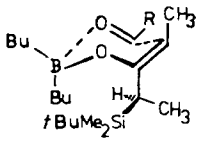
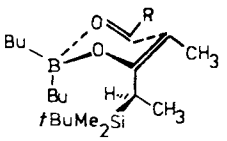
matographic monitoring of (*R*)-**2** after conversion into the corresponding trimethylsilyl enol ether[5,6] we derive a *Z*:*E* ratio of ca. 9:1 in the case of (*R*)-**2**. The high enantiomeric purity ($ee \geq 98\%$) of the *syn* adducts **3** and **4** was determined NMR spectroscopically via the corresponding (*S*)-MTPA ester[7] (^{13}C,^{19}F) and by shift experiments [with Eu(hfc)$_3$], as well as polarimetrically (**4**). The agreement in the *de* and *ee* values provides proof of an epimerization-free and racemization-free desilylation. The absolute configurations of the β-hydroxy ketones **4** quoted in Table 1 are based on a comparison of the polarimetric data with data in the literature. As expected, the use of the (*S*)-configurated methylene components (*S*)-**1** leads to the other *syn*-enantiomer (**4b**, Table 1).[8]

The stereochemistry of the diastereo- and enantioselective C–C coupling is consistent with a six-membered transition state in the sense of the Zimmermann-Traxler model.[12] In the case of **4a** and **4b**, the chromatographically separated *anti*-isomers that are formed in small amounts could each be assigned the (4*S*,5*S*)-configuration ($ee \geq 98\%$) on the basis of the ^{13}C-NMR spectra.[11] Accordingly, in the case of aliphatic aldehydes the transition state T_Z leads to the *syn* isomers with (4*R*,5*S*)-configuration, and T_E to the *anti* isomers with (4*S*,5*S*)-configuration.[13] An exception is the benzaldehyde adduct **4e**, which according to an X-ray structure analysis[3d,11] of the corresponding SAMP-hydrazone has the enantiomeric (4*S*,5*S*)-configuration based on T_Z/T_E.[14] The correlation between the *Z*/*E* ratio of the boron enolate and the *syn*/*anti* ratio of **4** (in each case 9:1) indicates a *virtually complete asymmetric induction*.

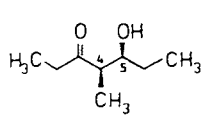


T_Z ⟶ (4*R*,5*S*)-**4** (*syn*)



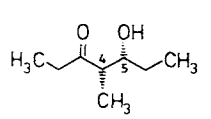
T_E ⟶ (4*S*,5*S*)-**4** (*anti*)

Rice weevils (*Sitophilus oryzae L.*) and maize weevils (*S. zeamis Motsch*) cause some hundreds of millions of dollars worth of damage per annum in the storage of grain. The aggregation-promoting pheromone of these insects was recently identified as *syn*-5-hydroxy-4-methylheptan-3-one (**4b**) (sitophilure) and has been synthesized; its absolute configuration is still unknown.[15,10] Starting from (*R*)-**1** and (*S*)-**1**, we have prepared both enantiomers of sitophilure, (4*R*,5*S*)-**4b** and (4*S*,5*R*)-**4b**, in total yields of 58–62% and high diastereomeric and enantiomeric purity, respectively, thus demonstrating the preparative value of this new variant of the aldol reaction.



(4*R*,5*S*)-**4b**

$de \geq 96\%$, $ee \geq 98\%$



(4*S*,5*R*)-**4b**

$de \geq 98\%$, $ee \geq 98\%$

[*] Note added in proof: Another synthesis of this enantiomer has been reported recently: G. Fuganti, H. E. Höberg, G. Pedrocchi-Fantoni, S. Servi, *Chem. Lett. 1988*, 385.

Experimental

A stirred solution of 12 mmol of ethyl diisopropylamine in 25 mL of dichloromethane was treated under an argon atmosphere at −10°C with 11 mmol of di-*n*-butylboryl triflate **2b**, and then dropwise with a solution of 10 mmol of (*R*)-**1** in 10 mL of dichloromethane. After two hours' stirring at −10°C the reaction mixture, which now contained the boron enolate (*R*)-**2**, was cooled to −78°C and treated with 10 mmol of aldehyde (in the case of enolizable aldehydes: 12–15 mmol dissolved in 20–30 mL of dichloromethane). The mixture was stirred for a further 0.5 h at −78°C and 1 h at 0°C and then subjected as follows to oxidative work-up in analogy to the method used by *Evans* et al.[5], in the case of aromatic aldehydes with 30% H_2O_2 (without sodium hydrogencarbonate solution), in the case of enolizable aldehydes with MoO_5·pyridine·HMPA (MoOPH) [17]: the resulting di-*n*-butylalkoxyborane that was formed was oxidized by addition of 15 mmol of MoOPH at 0°C. The yellow reaction mixture was stirred for 0.5 h at 0°C and 1 h at room temperature and then treated with 100 mL of pH7-buffer solution. After 15 minutes' stirring, the organic phase was separated off and the aqueous phase extracted twice with dichloromethane. The combined organic phases were washed twice with 100 mL of ice-cold 0.5 N HCl and once with saturated NaCl solution, and dried over magnesium sulfate. Removal of the solvent afforded the crude aldol adducts **3** as a *syn*/*anti* mixture (ca. 9:1) which was separated by flash chromatography (silica gel, ether/*n*-pentane 1/4, $R_f(syn) > R_f(anti)$). A stirred solution of 10 mmol of pure *syn*-adduct **3** in 50 mL of THF was treated at room temperature with 10 mL of 60% tetrafluoroboric acid. After 1–2 days stirring the THF was removed and the residue extracted with 3 × 100 mL of ether. The combined ether phases were washed with 5% sodium hydrogencarbonate solution and dried over magnesium sulfate. Removal of the solvent and chromatographic purification (silica gel, ether/*n*-pentane 1/4) furnished *syn*-**4**.

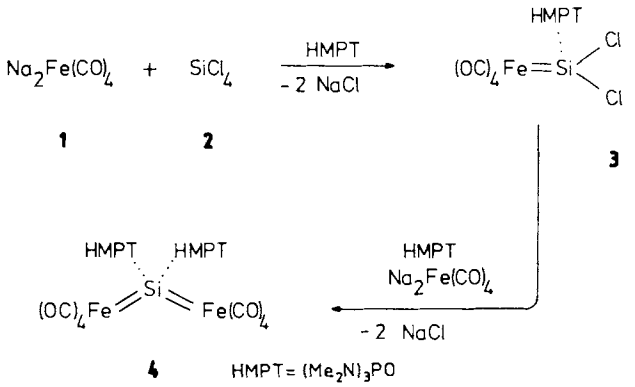
Synthesis and Structure of $[(OC)_4Fe{=}Si{=}Fe(CO)_4 \cdot 2(Me_2N)_3PO]$— a Complex of Formally Zerovalent Silicon**

By *Christian Zybill,* Dallas L. Wilkinson,* and *Gerhard Müller*

Recently, it has been demonstrated that silanediyl(silylene)-transition metal complexes (**A**) are stable as weak donor adducts.[1] In contrast, μ-Si complexes (**B**) with formally zerovalent silicon and allene-like structure have hitherto defied isolation. Analogous compounds of the higher homologues germanium and lead, on the other hand, are already known.[2] We now present the diiron complex **4** as first example of a donor-stabilized silicon(0) complex of type **B**.

The synthesis of compound **4** was accomplished by reaction of disodiumtetracarbonyl ferrate **1** with silicon tetrachloride **2** in an appropriate donor solvent.[3] The reaction presumably proceeds via the silanediyl complex **3** as intermediate.[1]

After chromatographic separation and crystallization from THF, **4** is obtained as colorless, moderately air- and moisture-sensitive crystals. The silicon complex of type **B** primarily differs from the well-known analogous coordination compounds of germanium and lead[2] with "naked" elements of group 14 by the increase in coordination number of the silicon from 2 to 4 and by the almost tetrahedral



geometry. An indication of the unusual bonding of the silicon is already provided by the increased coupling constant $^3J(^{31}P^1H) = 23.3$ Hz.[4] The vibration spectra show the typical bands for terminal trigonal-pyramidally (tbp) coordinated $Fe(CO)_4$ moieties.[4] Two bands of equal intensity are observed both for the ν_{PO}- as well as for the $\nu_{CO_{ax}}$-vibrations; this is fully consistent with the C_2 symmetry of the complex.[5] The X-ray structure analysis[6] confirms the proposed structure (Fig. 1). The molecule has approxi-

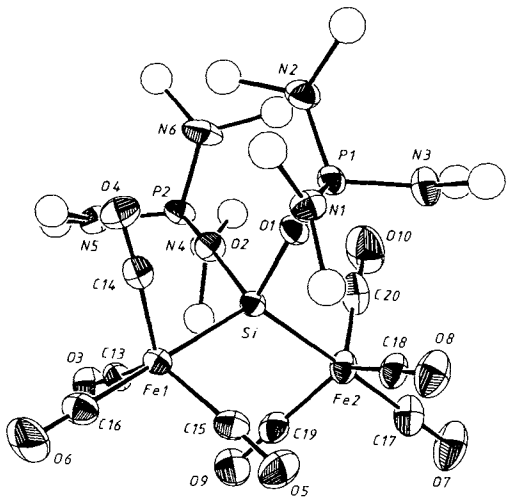


Fig. 1. Crystal structure of **4**·THF (ORTEP, displacement ellipsoids at the 50% probability level, methyl groups with arbitrary radii, without H-atoms and THF). Important bond lengths [Å] and angles [°]: Si-Fe1 2.339(1), Si-Fe2 2.341(1), Si-O1 1.745(2), Si-O2 1.748(3), P1-O1 1.530(2), P2-O2 1.526(3), Fe1-C13 1.769(3), Fe1-C14 1.760(3), Fe1-C15 1.783(4), Fe1-C16 1.788(5), Fe2-C17 1.782(4), Fe2-C18 1.762(4), Fe2-C19 1.787(4), Fe2-C20 1.753(6); Fe1-Si-Fe2 122.6(1), O1-Si-O2 92.1(1), Fe1-Si-O1 110.6(1), Fe1-Si-O2 107.6(1), Fe2-Si-O1 109.2(1), Fe2-Si-O2 110.4(1), Si-O1-P1 160.7(2), Si-O2-P2 167.1(1).

mately C_2 symmetry; the silicon atom is bound to two $Fe(CO)_4$ fragments and occupies an axial position of the tbp-configurated iron atoms. Long donor contacts to the oxygen atoms of the two HMPT molecules complete a distorted tetrahedral coordination of the silicon atom. A striking feature of the structure is that the Fe1-Si-Fe2 angle (122.6(1)°) is significantly widened at the expense of the O1-Si-O2 angle (92.1(1)°), whereas the remaining angles deviate only slightly from the normal tetrahedral angle. The two Fe–Si bonds are almost equal in length (Si-Fe1 2.339(1), Si-Fe2 2.341(1) Å) and somewhat longer than the Si–Fe "double bond" in $[(OC)_4Fe{=}Si(O\,t\mathrm{Bu})_2 \cdot \mathrm{HMPT}]$

Synthesis and Structure of [{Na(tmeda)}$_3$][LiPh$_4$], an Organometallic Complex Containing Two Different Alkali Metals**

By *Uwe Schümann* and *Erwin Weiss**

As long ago as 1958 *G. Wittig* et al. reported on sodium diphenyllithiate ("diphenyllithium-sodium"), which they formulated as Na[$C_6H_5LiC_6H_5$] **1**.[2] They found that etheral solutions of **1** are capable of stabilizing phenylsodium in any desirable excess, whereas phenylsodium alone is rapidly decomposed by ether. On the other hand, **1** proved to be a more aggressive metalating agent than phenyllithium. So far, however, it has never been fully characterized. In continuation of our systematic investigation of organo(alkali metal) compounds we have now succeeded for the first time in isolating a crystalline ate complex containing two different alkali metals as a tmeda adduct (tmeda = *N,N,N',N'*-tetramethylethylenediamine).

Whereas phenyllithium suspended in hexane can be brought into solution as [{PhLi(tmeda)}$_2$] **2**[3] by addition of an equimolar amount of tmeda, in the case of phenylsodium this is only possible by addition of tmeda in large excess. We have now found that hexane solutions of **1** dissolve suspended phenylsodium at room temperature up to a PhNa/PhLi ratio of about 2.2/1 with a deepening in color of the solution. After filtration the title compound [{Na(tmeda)}$_3$][LiPh$_4$] **3** crystallizes from the 2.2/1 solution at −30 °C in the form of yellow, pyrophoric crystals. Attempts to crystallize a PhLi-PhNa 1/1-complex always gave the Li compound **2** only. ^{7}Li-NMR investigations, however, show that several PhLi/PhNa species are present which undergo partly rapid, partly slow exchange in solution.

The result of an X-ray structure analysis of **3** (Fig. 1)[8] is surprising. The Li atom, which is located in the center of the anion of this ate complex, is pseudo-tetrahedrally coordinated by four phenyl groups and lies approximately at the center of an almost equilateral triangle of tmeda-coordinated Na atoms. Thus, of the two alkali-metal ions, the smaller Li ion is the stronger complexing species. Further, since the coordination number 4 is preferred, there is one lithiate ion to three [Na(tmeda)]$^\oplus$ ions. It thus corresponds to the tetraphenyl- and tetramethylmagnesate ions $[MgPh_4]^{2\ominus}$[4] and $[MgMe_4]^{2\ominus}$[5] which we have previously been able to detect in Li/Mg complexes.

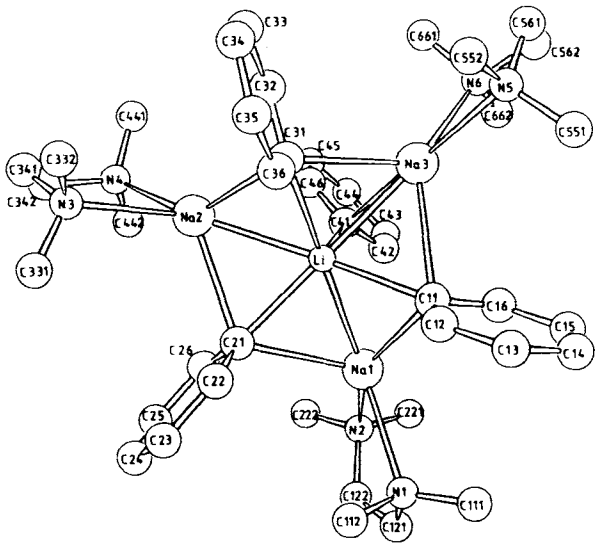

Fig. 1. Crystal structure of **3** with atomic numbering [8]. Important bond lengths [pm] and angles [°]: Li-C11 224(2), Li-C21 225(2), Li-C31 223(2), Li-C41 243(2), Li-Na1 260(2), Li-Na2 261(2), Li-Na3 253(2), Na1-C11 265.8(8), Na1-C21 264.5(8), Na2-C21 256.6(8), Na2-C31 262.7(8), Na3-C11 268.1(8), Na3-C31 271.6(8), Na3-C41 275.6(9), Na1-C41 311(1), Na2-C41 338(1); C11-Li-C21 114.8(7), C11-Li-C31 111.6(6), C11-Li-C41 102.8(6), C21-Li-C31 114.2(6), C21-Li-C41 105.2(6), C31-Li-C41 107.1(6), C11-Na1-C21 91.0(3), C21-Na2-C31 92.7(3), C11-Na3-C31 86.4(2), C12-C11-C16 111.7(7), C22-C21-C26 112.8(8), C32-C31-C36 111.4(7), C42-C41-C46 111.4(10).

[**] Alkyl- und Arylmetal Compounds, Part 36. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 35: [1].

Hitherto, only the structure of $[Li(thf)_4][Li\{C(SiMe_3)_3\}_2]$ **4**,[6] an organolithiate complex with twofold linearly coordinated Li ion, was known. Ate complexes are formally formulated with negative charges, but nevertheless they contain positively charged central atoms, as has been shown by MO calculations; the negative charge is delocalized in the organic ligands. In accord with the formula there is also a close relationship between the title compound **3** and the mixed alkali metal-tetramethylguanidino complex $[LiNa_3\{O=P(NMe_2)_3\}_3\{N=C(NMe_2)_2\}_4]$,[7] though a different coordination is found in the latter: the alkali metal atoms and nitrogen atoms of the guanidino ligands are located at the corners of a cube ($LiNa_3N_4$-cubane). Thus, the Li atom is no special coordination center as in **3**.

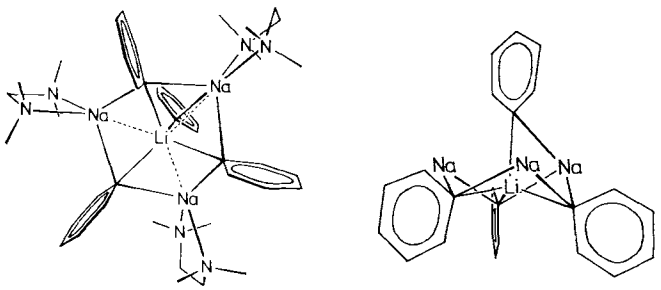

Fig. 2. Line formulas of **3**; right: without tmeda ligands.

The following details about the structure should be mentioned: The Na atoms form an almost equilateral triangle with the Li atom located centrally below the Na_3 plane at a distance of 63 pm. They bridge three of the four phenyl groups and have their shortest contacts to the C atoms bound to the Li atom. These Na-C distances are normal, but vary between 257 and 272 nm. The cause of the remaining deviations of the $LiNa_3Ph_4$-framework from ideal symmetry (C_{3v}) is to be sought in the fourth phenyl group, which bridges Li and Na3. We assume that the metal-carbon interactions are essentially ionic; but a small amount of covalent bonding (multicenter bonds) may be present. The C atoms of the phenyl groups form markedly deformed six-membered rings, as has previously been observed in all phenyl(alkali metal) compounds. The C-C-C angles at the bridging C-atoms are 111 to 113° and thus are clearly smaller than the ideal value of 120°.

Experimental

3: 0.3 g (3.6 mmol) of phenyllithium was dissolved together with 0.6 mL (4.0 mmol) of dry tmeda, in 30 mL of hexane. The stirred solution was then treated dropwise with a suspension of 0.8 g (8.0 mmol) of phenylsodium (prepared from phenyllithium and *t*BuONa[10]) in 30 mL of hexane and 1 mL (6.7 mmol) of tmeda). A considerable part of the phenylsodium immediately goes into solution, which deepens in color from light yellowish-brown to dark brown. The filtered solution was stored for two weeks at −30°C for growing single crystals. Yellow, pyrophoric rectangular parallelepipeds. Yield 63 mg (3%) $C_{42}H_{68}N_6LiNa_3$ (733.0 g mol^{-1}). Elemental analysis: calc. Li 0.95, Na 9.41, C 68.83, H 9.35, N 11.47%; gef. Li 0.92, Na 10.56, C 70.93, H 10.69, N 13.56%.

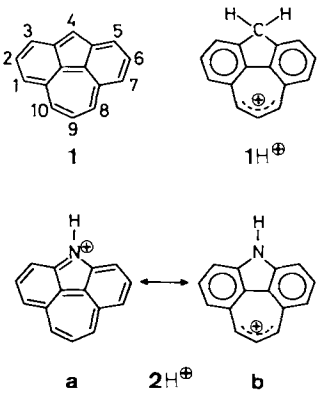
The Cyclohepta[*def*]carbazolium Ion**

By *Beat Freiermuth* and *Jakob Wirz**
Dedicated to Professor Edgar Heilbronner

Cyclohepta[*def*]fluorene (**1**) is the last unknown representative of seven nonalternant pyrene isomers. While the conjugate acid $\mathbf{1H}^{\oplus}$ has been isolated as a salt, all attempts to form **1** by deprotonation of $\mathbf{1H}^{\oplus}$ have failed.[1-3] In 1965, *Heilbronner* et al. drew attention to the biradicaloid nature of the electronic structure of **1** and predicted an unusually low-lying triplet state for this molecule and a strong polarization of charge in the singlet state.[4] This has led us to the expectation that the system should be stabilized by the substitution of an inductive acceptor in the negatively charged position 4. We now report the synthesis of the cyclohepta[*def*]carbazolium ion $\mathbf{2H}^{\oplus}$, the first compound exhibiting the π-topology of **1**.



Starting from 2,2′-bis(bromomethyl)-6-nitrobiphenyl (**3**)[5] we have obtained 8,10-dihydrocyclohepta[*def*]carbazol-9(4*H*)-one (**4**) in 14% yield by Thorpe-Ziegler condensation, hydrolysis, and reductive cyclization. After the reduction of the ketone **4**, the dehydration of the resulting alcohol to the somewhat unstable 4,8-dihydrocyclohep-

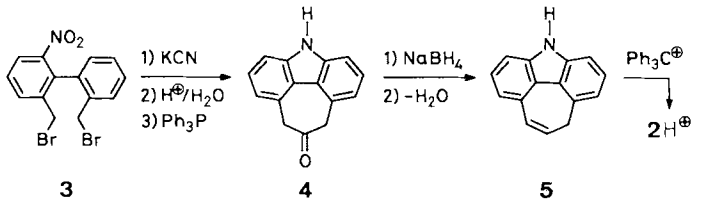
ta[*def*]carbazole **5** was achieved in moderate yield (ca. 20%) by pyrolysis on alumina. Hydride abstraction finally gave the $BF_4^{\ominus}$ salt of $2H^{\oplus}$ in quantitative yield as a dark



3 **4** **5**

blue solid which decayed within a few days even at $-20°C$ and in the absence of air. Dilute solutions of $2H^{\oplus}$ in 70% perchloric acid were stable for several months. In 1 M aqueous perchloric acid, however, the absorption of $2H^{\oplus}$ disappeared within a few hours, nearly as fast as that of $1H^{\oplus}$ under the same conditions. According to *Munday* and *Sutherland*[1b] the decomposition of $1H^{\oplus}$ in aqueous solution proceeds by hydration of the carbocation at position 8 or 10. We conclude that the high reactivity of $1H^{\oplus}$ towards nucleophilic reagents is hardly reduced in $2H^{\oplus}$ and it is not surprising that our attempts to form the neutral cyclohepta[*def*]carbazole **2** have failed, as with **1**.

A comparison of the ^{1}H-NMR spectra of $1H^{\oplus}$[6] and $2H^{\oplus}$ (see Experimental) confirms that replacement of the CH_2 group ($1H^{\oplus}$) by an NH group contributing two π electrons ($2H^{\oplus}$) does not give rise to a noticeable increase in the charge density at the electrophilic centers C8 and C10; the chemical shifts and coupling constants in the seven-membered ring are very nearly the same in both compounds. The chemical shifts of the ^{1}H-NMR signals may be taken as a reliable measure of the charge distribution,[7] since ring current effects are negligible in $2H^{\oplus}$, as can be seen from a comparison of the chemical shifts of fluorene and $1H^{\oplus}$, and carbazole and $2H^{\oplus}$, respectively.

The above observations correspond precisely to the predictions of an HMO calculation for **1**: the atom-atom polarizabilities $\pi_{4,8}=\pi_{4,10}=-0.0002$ are very small, i.e. the charge distributions q at the atoms 8 and 10 are practically independent of the electronegativity of atom 4 and have the same value of $q_8=q_{10}=0.768$ for all of the compounds **1**, $1H^{\oplus}$, **2**, and $2H^{\oplus}$! Therefore $2H^{\oplus}$ in the electronic ground state is best described by the resonance structure **b**. This is remarkable inasmuch as the resonance structure **a** has one additional π bond; apparently, the latter fact is overruled by the presence of two aromatic sextets in structure b.

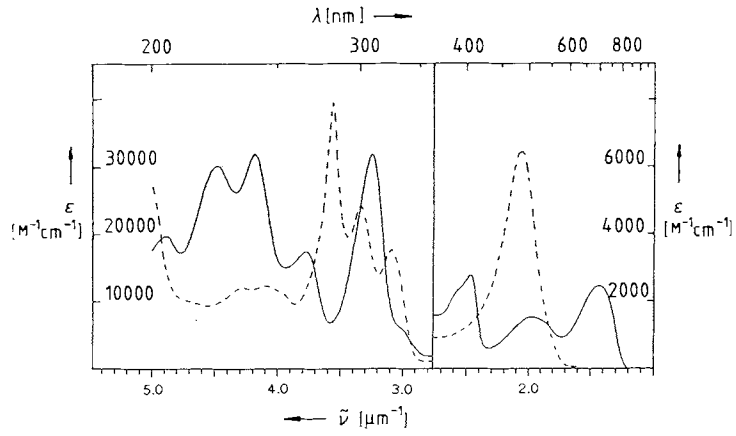


Fig. 1. Absorption spectra of $1H^{\oplus}$ (----) and $2H^{\oplus}$ (——) in 60% $HClO_4$.

In sharp contrast to the ^{1}H-NMR spectra, the UV/VIS absorption spectra of $1H^{\oplus}$ and $2H^{\oplus}$ are entirely different (Fig. 1). As expected, the absorption spectrum of $1H^{\oplus}$ is quite similar to that of the dibenzo[*a*,*c*]tropylium ion.[8] On the other hand, the additional conjugation through the extra lone pair of the nitrogen atom obviously becomes important in the excited states of $2H^{\oplus}$. The predictions of the electronic absorption spectra of $1H^{\oplus}$ and $2H^{\oplus}$ obtained by PPP-SCF-SCI calculations are in satisfactory agreement with experiment.[9] No doubt the first absorption band of singlet **1** lies far in the infrared, as anticipated long ago by *Heilbronner* et al.[4]

Experimental

4: A solution of 28 g (73 mmol) of **3** [5] and 20 g (ca. 300 mmol) of KCN in 2.3 L of MeOH was stirred for 48 h at room temperature and then refluxed for 6 h. Neutralization with dilute HCl, evaporation of the solvent, extraction with ethyl acetate, and chromatography on silica gel (CH_2Cl_2/ether) gave an amorphous yellow solid [6-amino-x-nitro-5*H*-dibenzo[*a*,*c*]cycloheptene-7-carbonitrile, x = 1 or 11, 8.1 g, 40%, m.p. after crystallization from ethyl acetate/hexane 193–197°C; MS (70 eV): *m/z* 277 (100%, $M^{\oplus}$); IR (KBr): $\tilde{\nu}$ = 2184, 1642, 1585, 1524 cm^{-1}], which was dissolved in a mixture of 130 mL ethyl acetate, 35 mL water, and 13.5 mL H_2SO_4 and heated to 150°C for 50 min in an autoclave. Extraction with ether, washing with a bicarbonate solution, and chromatography with CH_2Cl_2 on silica gel furnished 5,7-dihydro-1-nitro-dibenzo[*a*,*c*]cyclohepten-6-one [3.4 g (46%), m.p. 154–155°C (acetate/hexane); MS (70 eV): *m/z* 253 (31%, $M^{\oplus}$), 205 (100%); IR (KBr): $\tilde{\nu}$ = 1710 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ = 3.5 (s, 2H), 3.6 (m, 2H), 7.2–7.9 (m, 7H)]. Heating the nitro compound with triphenylphosphane following the general procedure of *Ames* et al. [10] (6 d, 160°C) and chromatography with CH_2Cl_2 on silica gel gave 2.2 g (74%) of yellow crystals of **4**, m.p. 229–233°C, correct elementary analysis (C, H, N); IR (KBr): $\tilde{\nu}$ = 3363, 1696, 770, 721 cm^{-1}; UV (EtOH, λ_{max}[nm] (logε) = 246 (4.64), 292 (4.01), 325 (3.59), 340 (3.63); ^{1}H-NMR ($CDCl_3$): δ = 4.4 (s, 4H), 6.9–7.6 (m, 6H), 8.1 (br. s, 1H).

$2H^{\oplus}$: The ketone **4** (200 mg, 0.91 mmol) was reduced with 35 mg (0.93 mmol) of $NaBH_4$ in 6.5 mL of ethanol (30 min, 25°C). Work-up by extraction and sublimation (100°C, 1 Pa) gave 4,8,9,10-tetrahydrocyclohepta[*def*]carbazol-9-ol [197 mg (98%), m.p. 146–148°C; ^{1}H-NMR ($CDCl_3$): δ = 3.4–3.8 (m, 5H), 4.6–4.8 (m, 1H), 6.9–7.4 (m, 6H), 8.1 (br. s, 1H)]. The alcohol (70 mg) was dissolved in CH_2Cl_2 and adsorbed on activated alumina (3 g, Fluka Type 504C, acidic). After evaporation of the solvent, the residue was heated in vacuo (1 Pa), first for 1 h to 200°C and subsequently for 3 h to 250°C. In order to facilitate the evaporation of the product, the alumina, which gradually turned green, was constantly agitated. The sublimate (30 mg) was collected at $-10°C$ on a cold finger and, according to ^{1}H-NMR analysis, contained ca. 80% of **5** and ca. 20% of 4,8,9,10-tetrahydrocyclohepta[*def*]carbazole. The mixture had to be kept in solution (CH_2Cl_2), since **5** polymerizes within a few days when kept as a solid. The above mixture was added dropwise to a stirred solution of 23 mg (0.07 mmol) of tritylium tetrafluoroborate in 1 mL CH_2Cl_2 until the yellow color had disappeared (ca. 14 mg of **5**). The resulting suspension of a dark solid was separated three times by centrifugation and washed with benzene. Upon drying there remained 16.5 mg of dark blue flakes of the $BF_4^{\ominus}$-salt of $2H^{\oplus}$: IR (KBr): $\tilde{\nu}$ = 3375, 3223, 1576, 1477, 1084, 728 cm^{-1}; ^{1}H-NMR (CD_3NO_2, 400 MHz): δ = 8.77 (t, 1H, $J(8,9)$ = 10.3 Hz, H9), 8.80 (dd, 2H, $J(1,2) \cong J(2,3) \cong 7.5$ Hz, H2 and H6), 8.85 (d, 2H, $J(1,2) \cong 7.5$ Hz; H1 and H7 (or H3 and H5)), 8.95 (d, 2H, $J(2,3) \cong 7.5$ Hz, H3 and H5 (or H1 and H7)), 9.95 (d, 2H, $J(8,9)$ = 10.3 Hz, H8 and H10), 11.08 (br. s, 1H, NH).

Synthesis and Structure of a Resonance Stabilized (Trimethylphosphonio)metallapropenide**

By *Dimitrios Lappas, David M. Hoffman,* Kirsten Folting,* and *John C. Huffman*

Phosphorus ylides have attracted much research attention due to their frequent application as reagents in organic and organometallic synthesis and a desire to understand the P-C_{ylide} bonding.[1-3] Numerous so-called stabilized ylides have been studied in which the negative charge is resonance delocalized over an organic framework.[3b,4] We describe here the synthesis and structure of a propenide analog, wherein resonance stabilization involves an organometallic moiety (**1**). There is precedent for phos-

$[ReO(\eta^1\text{-}CHCH(PMe_3))(CH_2SiMe_3)_3]$ **1**

phoniopropenide analogs,[5] but all others have a stabilizing substituent at the M-C_α position (e.g., $OSiMe_3$ and $C(=O)OR$[5a]), and **1** is the first structurally characterized example in which the organometallic fragment is in a high oxidation state.[5f] Furthermore, the reaction that yields **1** is unusual because it does not involve a preformed ylide as a reactant.[5e]

The synthesis of **1** is accomplished by reaction of **2** in toluene with an excess of ethyne [Eq. (a)].[6] The reaction

$$\underset{\mathbf{2}}{[ReO(PMe_3)(CH_2SiMe_3)_3]} + C_2H_2 \longrightarrow \underset{\mathbf{1}}{[ReO(\eta^1\text{-}CHCH(PMe_3))(CH_2SiMe_3)_3]} \quad (a)$$

produces a mixture of compounds from which red cubic crystals of **1** can be isolated in 46% first-crop yield. The crystals are analytically pure, but ^{1}H-NMR spectra recorded for the crystals often reveal a trace of another compound.[7]

[**] This work was supported in part by the Donors of the Petroleum Research fund, administered by the American Chemical Society.

Figure 1 shows the crystal structure of **1**.[8] The complex is square pyramidal with the oxo ligand in the apical position. Re(1) is displaced by 73 pm from the basal plane in the direction of the oxo ligand. The CHCH(PMe_3) ligand

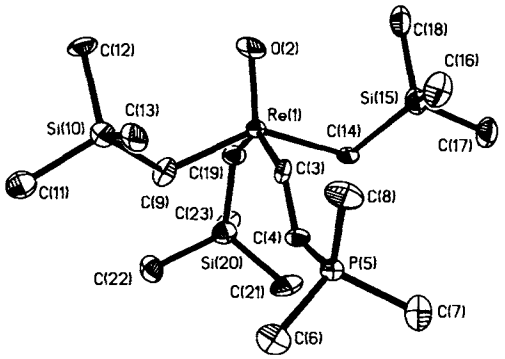

Fig. 1. ORTEP drawing of **1** showing 50% probability ellipsoids and atom-numbering scheme.

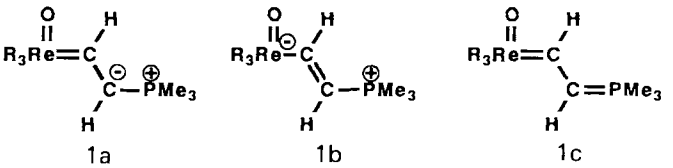
is attached to the rhenium via one carbon atom, C(3), such that there is an (*E*)-ReCH=CH(PMe_3) arrangement. The Re-C(3) bond distance of 199.6(9) pm is approximately 13 pm shorter than the alkyl-ligand Re-CH_2 distances, which indicates that the Re-C(3) bond has some multiple bond character. On the other hand, the Re-C(3) bond is not a normal Re-alkylidene bond, because the bond length is 13 pm longer than the Re=C distance in the alkylidene complex **3**.[9]

$[Re(C\mathit{t}Bu)(CH\mathit{t}Bu)I_2(py)_2]$ **3**

The C(3)-C(4) distance, 135.5(13) pm, is typical of an olefin, as is the P(5)-C(4)-C(3) angle of 124.4(8)°. The P-C_{ylide} bond distance, $d(P(5)\text{-}C(4)) = 173.7(10)$ pm, is within 3σ of the average P-Me distance, 178.8(17) pm, and is much longer than the P-C_{ylide} bond distance of 166.1(8) pm reported for the unstabilized ylide Ph_3PCH_2.[10] The P(5)-C(4) distance is comparable to the P-C_{ylide} distances reported for the resonance stabilized ylides (triphenylphosphonio)cyclopentadienide (171.8(2) pm)[4c] and (triphenylphosphonio)dicyanomethanide (175.3(8) pm).[4f]

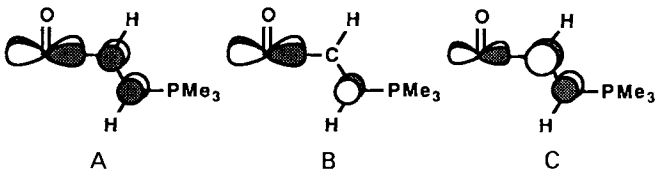
The structural data for the ReCHCH(PMe_3) fragment suggests that the resonance composite [**1a** ↔ **1b**] best describes the bonding in **1**.[5] Structure **1b** is more important than **1a** since the $P^{\oplus}$-$C^{\ominus}$ interaction in **1a** would be inconsistent with the long P(5)-C(4) bond. Resonance structure **1c** is excluded only on the basis of previously published results that favor a 1,2-zwitterionic description for P-C_{ylide} bonding.[2a,b,3a] In addition, because the Re=O bond distance (170.0(6) pm) and IR stretching frequency (982 cm^{-1}) are normal, resonance structures in which the



Re=O bond is involved in the delocalization can be excluded.[11] The valence bond description [**1a** ↔ **1b**] represents a resonance stabilized phosphoniometallapropenide.

Further support for the structure and [**1a** ↔ **1b**] bonding description comes from NMR studies of **1**. The chemical shift of the ylide carbon atom ($\delta(C4)=85$) is near the value reported for C_{ylide} in resonance stabilized (triphenylphosphonio)cyclopentadienide ($\delta=78$).[4a] Both shifts are downfield relative to those reported for unstabilized ylides (e.g., $\delta(Me_3P{=}CH_2)=-2.4$).[3b, 4b, 12] The $^{13}C_{ylide}$–H coupling constant, 163 Hz, is similar to the values reported for other ylides,[4b, 12] and the coupling constant across the C=C bond, $^3J_{HH}=17$ Hz, indicates that the (*E*)-ReCH=CH(PMe_3) configuration observed in the solid state is retained in solution. In ReCHCH(PMe_3), the chemical shifts for Re–*C* and Re–C*H* are $\delta=228$ and 12.3, respectively, and $^1J_{CH}=122$ Hz. These values are similar to those reported for Schrock-type rhenium alkylidenes and are further evidence of the Re–C multiple bond character.[9] Overall, the structure and spectroscopic data for **1** are similar to those reported for other phosphoniopropenide analogs.[5]

The molecular orbitals involved in the anion stabilization, excluding any d-orbital contribution from the phosphorus, are **A**–**C**.[3b] The orbitals **A** and **B** are filled, and the HOMO for **1** should be **B**. The orbital **C** is empty and lies just above the empty Re–O π-antibonding MOs in energy. The allyl-like orbitals **A**–**C** are consistent with the



valence bond formulation (**1a**, **1b**). They also explain why the Re=O bond in **1** is not involved in the resonance stabilization: The Re-based orbital involved in the resonance stabilization of the ylides is of the wrong symmetry to interact with the oxo ligand. If the assignment of the HOMO is correct, frontier orbital and steric considerations would suggest that electrophilic attack will occur at the ylide carbon, C(4).[5a, c] Also, the presence of the low-lying MO **C** implies that nucleophilic attack on the CHCH(PMe_3) ligand will occur at C(3), the carbon attached to the Re.

There are three conceivable routes for the formation of **1**: 1. The (*E*)-ReCH=CH(PMe_3) configuration found in **1** suggests that the molecule is formed via attack of external PMe_3 on the coordinated ethyne in a [$ReO(C_2H_2)(CH_2SiMe_3)_3$] intermediate.[5e, 14] 2. It could be formed by insertion of ethyne into the Re–P bond of **2** to yield (*Z*)-ReCH=CH(PMe_3) followed by isomerization.[5a, 14] 3. A dipolar intermediate [$Me_3\overset{\oplus}{P}CH=\overset{\ominus}{C}H$], formed from free PMe_3 and ethyne,[15] could have reacted with **2** or [$ReO(CH_2SiMe_3)_3$]. Further studies concerning the generality of reaction (a) and the reactivity of **1** are in progress.

Experimental

1: In a Schlenk reaction flask, [$ReO(PMe_3)(CH_2SiMe_3)_3$] (0.140 g, 0.26 mmol) was dissolved in toluene (30 mL).[6] The greenish-brown solution was frozen and excess C_2H_2 (2 mmol) was condensed into the flask via a calibrated vacuum manifold. After the mixture was allowed to warm to room temperature, it was stirred for 48 h. The volatiles were then removed under reduced pressure, and the residue was extracted with CH_3CN (5 × 5 mL). The extracts were filtered and the solution was reduced in volume. Upon slowly cooling the solution to −30 °C, red cubic crystals separated out. The crystals were isolated by removing the supernatant liquid via a cannula (yield: 0.068 g, 46%).[13]

[7] The other compound has been tentatively identified as [$ReO(\eta^1\text{-}CHCH(PMe_3))(\eta^1\text{-}CHCH(CH_2SiMe_3))(CH_2SiMe_3)_2$].

[8] Crystal data for **1** at −151 °C: $a=1409.7(6)$ pm, $b=1324.2(5)$ pm, $c=1380.7(6)$ pm, $Z=4$, $\rho_{calcd}=1.459$ g cm^{-3}, $V=2577.26\times10^6$ pm^3, $\mu=49.802$ cm^{-1} and space group $P2_12_12_1$. A total of 6032 reflections were collected ($Mo_{K\alpha}$, $6°<2\theta<45°$) of which 3322 were unique and 2905 with $F_o>3.0\sigma(F_o)$ were used in the structure refinement. The structure was solved by a combination of direct methods (MULTAN 78) and Fourier techniques, and refined by full-matrix least squares (383 parameters). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined isotropically. Several of the hydrogen atoms behaved poorly during the refinement, but because the positions were qualitatively correct, their positions were not fixed. No absorption correction was deemed necessary. Final residuals were $R(F)=0.0434$ and $R_w(F)=0.0436$ with a final goodness of fit of 0.874. Further details of the crystal structure investigation are available from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53039, the names of the authors, and the full citation of the journal.

Errata

Dinuclear Complexes of Gold(I) Containing Bridging Cyclometalated Arylphosphane or Arylarsane Ligands

By *Martin A. Bennett,* Suresh K. Bhargava, K. David Griffiths, Glen B. Robertson, Wasantha A. Wickramasinghe,* and *Anthony C. Willis*

Following a suggestion by Professor *P. G. Jones*[1] we have reexamined the crystal structure of [Au$_2$(*o*-C$_6$H$_4$PEt$_2$)$_2$][2] and find the space group to be $P\bar{1}$ with two independent centrosymmetric molecules per unit cell (at 0,0,0 and $\frac{1}{2},\frac{1}{2},0$) rather than $P1$ with two independent acentric molecules per cell. For $P\bar{1}$, $R = 0.034$ and $R_w = 0.041$ (cf. 0.032 and 0.038 for $P1$) but refinement is better conditioned and standard error estimates are substantially decreased. The remarked absolute configuration determination in $P1$ (R-factor ratio = 1.022)[3] is apparently an artifact of the overparameterized scattering model. Revised atom coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre. Revised Au–Au distances [2.8623(5), 2.8493(5) Å] do not differ significantly from the previously quoted values.

Hypercarbon Chemistry. By *G. A. Olah, G. K. Surya Prakash, R. E. Williams, L. D. Field,* and *K. Wade.* John Wiley, New York 1987. 311 pp., bound, $ 69.95.—ISBN 0-471-06473-4

Despite the wide occurrence of multicentered two-electron bonds in compounds of elements which lie to the left of carbon in the Periodic System, hypercoordinated carbon (hypercarbon) is often regarded only as an extreme special case. The topic is usually completely ignored in organic chemistry textbooks. What organic textbook is there which even deals with carbaboranes? This monograph gives, for the first time, a coherent account of the many different aspects of the chemistry of compounds containing hypercoordinated carbon atoms.

The first chapter (37 pp., 78 references) introduces the definitions which are essential to the topic, and discusses some typical structures containing hypercoordinated carbon. The different types of localized and delocalized multicentered bonds are described in terms of MO energy diagrams and the isolobal concept. The chapters which follow introduce different types of compounds with hypercoordinated carbon, covering a remarkably wide range. The first to be discussed are a representative selection of bridged and associated alkyl compounds of main group and subgroup metals, which generally involve five- and six-coordinated carbon atoms (32 pp., 96 references).

The next two chapters discuss the importance of hypercoordinated carbon in the extensive area of cluster chemistry. The chapter on carbaboranes and metallacarbaboranes (29 pp., 52 references) includes, in addition to a discussion of structure and bonding, a short account of methods of synthesizing carbaboranes and of their reactions. The following chapter (22 pp., 104 references) reviews the possible types of bonding and coordination of hypercoordinated carbon in mixed metal-carbon cluster compounds and metal carbides. In addition to being of special value to readers who are not very familiar with these more "inorganic" topics, these two chapters form a useful combination with the following chapter on hypercoordinated carbocations (42 pp., 160 references).

Methods for identifying carbocations with hypercoordinated carbon, and experimental results concerning their structures, are summarized here in a similar form to that in the book "Superacids" by *Olah* et al., which appeared from the same publishers in 1985, with some updating of the material. However, in the context of "Hypercarbon Chemistry" this chapter has a different significance. It is made clear to the reader that such carbocations are only one aspect, though an important one, of the broader chemistry of compounds with hypercoordinated carbon atoms. The 2-norbornyl cation, which unfortunately is too often discussed only as an isolated case, is here considered logically along with other hypercoordinated carbocations such as bicyclobutonium ions, bicyclo[2.1.1]hexyl cations, trishomocyclopropenium cations, the Coates cation and the Hogeveen dication. The latest revival of the old controversy about the "nonclassical", i.e. hypercoordinated, structure of the 2-norbornyl cation will be seen as an anachronism after reading this book. The next chapter (20 pp., 45 references) expands on the above topic by dealing with structural analogies and correlations between ^{13}C and ^{11}B NMR chemical shifts, and again brings out very clearly the common features of hypercoordinated carbocations and polyboranes.

The last and longest chapter (64 pp., 192 references) is devoted to short-lived intermediates and transition states involving hypercoordinated carbon atoms. Protolytic reactions of hydrocarbons in superacid media, and reactions between other electrophiles, metal compounds with coordinative unsaturation, carbenes etc. and C–H and C–C σ-bonds are discussed as examples; these provide a contribution to basic understanding of the mechanisms of many organic reactions. This chapter clearly shows that traditional organic chemistry textbooks, in which the chemistry does not begin until after describing the saturated hydrocarbons, are outdated.

There are some problems, which quickly become apparent to the reader, with regard to the different ways of representing bonds to hypercoordinated atoms in structural formulas, using either solid lines or broken lines. For example, one finds two formulas for the μ-hydridoosmium cluster compound $[Os_3H(CO)_{10}CH_3]$, both of which differ from that in the original paper by *Shapley* et al. The method introduced by *Olah* in 1972 of representing a three-centered two-electron bond by broken lines in the middle of a triangle formed by the three coordinated atoms is not always clear, and can easily lead to misunderstanding, as there is no atom at the intersection of the broken lines. The structural formula for the 2-bicyclo[2.2.1]heptyl cation (2-norbornyl cation) on p. 167 is only marginally different from that for the 2-bicyclo[2.1.1]hexyl cation (p. 170). The different ways of writing the same structure are not always formally equivalent. The μ-hydrido bridged cycloalkyl cation $[1,6\text{-}Me_2C_{10}H_{17}]^{\oplus}$ is represented in the introduction with hyper- (two-) coordinated hydrogen and hyper- (five-) coordinated carbon. According to this the cation should have a structure with a closed three-center bond, giving significant transannular C–C interaction. At a later point the formula for the same cation is written with only the μ-hydrogen hypercoordinated. This corresponds to an open three-center bond, a form which was in fact preferred in the original paper by *Sorensen* et al.

The layout and execution of the formulas are not generally up to the normal standard. The diagrams are in some cases too large and in others too small. Some formulas are incorrect. Many of the entries in the subject index (22 pp.) are of little use. For example, how many readers are likely to look up phrases such as "*A*cute Mn-C-Mn bond angles", "*M*athematical explanation", or "*H*ighly stereoregular"?

The book brings together under a unified point of view many items of knowledge from different areas. It not only deals with an aspect of organic chemistry which has hitherto been seriously neglected, but also cuts across the traditional boundaries between inorganic and organic chemistry. It is these qualities which give the monograph its particular value, despite the criticisms of detail mentioned above. In their treatment of hypercarbon chemistry the authors have succeeded in reawakening the reader, who often may have all too easily become a specialist in a narrow field, to the fundamental unity of the many different areas of chemistry.

Phosphorus-31 NMR Spectroscopy in Stereochemical Analysis. Edited by *J. G. Verkade* and *L. D. Quin*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, Deerfield Beach 1987. xvi, 717 pp., hard cover, DM 258.00.—ISBN 3-527-26465-5/0-89573-149-5

In "P-31 NMR Spectroscopy in Stereochemical Analysis," *John Verkade* and *Louis Quin* have provided a thorough coverage of the field involving organophosphorus compounds and phosphorus-metal complexes. The 20 chapters and over 700 pages written by experts in the field cover nearly all aspects of ^{31}P-NMR spectroscopy. A discussion of ^{31}P chemical shifts and their interpretation is presented in the first two chapters. A useful "nuts and bolts" approach to obtaining ^{31}P NMR spectra is provided by *J. C. Tebby* in Chapter 1. A short compilation of representative ^{31}P chemical shifts is also provided. *E. Fluck* and *G. Heckmann* discuss empirical methods for interpreting ^{31}P chemical shifts, largely of compounds with P-heteroatom multiple bonds. These compounds have not often been included in recent reviews of ^{31}P chemical shifts. Chapters 3–6 discuss more detailed theoretical and experimental aspects, including one- and two-dimensional multiple pulse experiments. ^{31}P NMR of oriented phases and theoretical analysis of ^{31}P chemical shifts and coupling constants complete the first section. Both the chapter by *C. B. Chesnut* on ^{31}P chemical shifts and that by *D. J. Jameson* on coupling constants spend considerable time on basic theory. In fact in the later, most of the discussion is directed towards a generalized analysis of coupling between first- and second-row elements, with a minor emphasis on phosphorus.

Chapters 7–10 provide specific applications of the use of ^{31}P chemical shifts in solving structural, conformational, and mechanistic aspects of phosphorus chemistry. The importance of the stereospecificity of ^{31}P coupling constants to all the NMR-active elements is described in Chapters 11–13. The remainder of the book is devoted to stereochemical aspects of metal–phosphorus compounds.

Considering that two other ^{31}P NMR books have recently appeared (D. G. Gorenstein (ed.): *P-31 NMR: Principles and Applications*, Academic Press, New York 1984; C. Tyler Burt: *Phosphorus NMR in Biology*, CRC Press, Boca Raton, FL, USA 1987) and that the *Verkade* and *Quin* book costs \$125, is another book on ^{31}P NMR needed? The answer is a definite yes. The authors have done a really commendable job in minimizing the overlap between the three recent ^{31}P NMR books. The 1984 and 1987 (Tyler) books largely have emphasized theory and applications to biological phosphorus studies and the book by *Verkade* and *Quin* has emphasized organophosphorus and phosphorus–metal complexes. They have provided a highly readable book that researchers in the field will find very useful. It was once possible to largely cover the field of phosphorus NMR in the single volume by *John Van Wazer*. All of the more recent books are needed to adequately cover this enormous field and still have been highly selective in the material they could cover.

There are a few minor typos (*McFarlane*'s equation for line width at half height and a missing third 90° pulse in the NOESY sequence, for example) and a few minor questionable statements (*Gallagher*'s comment about the concentration effect (?) on O-18 isotope shifts on p. 322), but otherwise the book is very well written. The one unfortunate consequence of putting together such a massive undertaking is the time it must have taken for the book to be published. Many of the chapters have references only to 1984 and some even earlier. These are only minor concerns, however, and overall *John Verkade* and *Louis Quin* and the publisher should be commended for putting together a fine volume.

Diazo Compounds. Properties and Synthesis. By *M. Regitz* and *G. Maas*. Academic Press, New York 1986. xvi, 596 pp., bound, \$ 125.00.—ISBN 0-12-585840-X

In addition to their importance as a starting point for preparing carbenes (*G. Maas*, Transition-metal Catalyzed Decomposition of Aliphatic Diazo Compounds—New Results and Application in Organic Synthesis, *Top. Curr. Chem. 137* (1987) 75), diazoalkanes are useful building blocks for cycloadditions (*M. Regitz* and *H. Heydt:* "Diazoalkanes" in *S. Patai* (Ed.): *1,3-Dipolar Cycloaddition Chemistry, Vol. 1*, p. 393, Wiley, New York 1984). Since diazo compounds are so useful in synthesis, everyone who works with them must have felt the lack of an updated account of developments in this area. The comprehensive treatment in the book reviewed here now satisfies this long-standing need. The authors, who have many years of practical experience in this field, intend the treatment to be suitable for final year degree students and preparative chemists in universities and industry.

The book consists of two parts. Part I, "Properties of Aliphatic Diazo Compounds", contains four chapters (structure and spectroscopic properties, thermal properties, reactivity towards acids, and photochemistry). Part II, "Syntheses of Aliphatic Diazo Compounds", has twelve chapters, covering methods which include the diazotization of amines, the Forster reaction, the dehydrogenation of hydrazones, the Bamford-Stevens reaction, the cleavage of *N*-alkyl-*N*-nitroso compounds, the transfer of diazo groups, and substitution reactions of diazoalkanes and isotopically labeled diazo compounds. The reader benefits greatly from the orderly arrangement of the material, and from the carefully prepared formula schemes which can be taken in at a glance, and are in many cases supported by comprehensive tables and bibliography.

The tightly-knit, factual style is pleasing. However, the treatment of the Forster reaction in Chapter 6 is too brief, and on pages 221, 222, and 226 we find three different mechanistic versions of this reaction directly adjacent to each other without any additional discussion. Similarly, virtually no mechanistic interpretation is given for the introduction of diazo groups using the nitroso reaction (Chapter 7).

The book is a mine of information for the specialist, not least because of the literature references, of which there are more than 1800, covering the period up to the end of 1982. The incomprehensibly long delay in the appearance of the book—for which the publishers are no doubt chiefly responsible—has been bridged by the authors' inclusion of an addendum, which is, however, very condensed (it contains no structural formulas!), and therefore makes difficult reading. It contains 184 literature references, for the period up to and including January 1986.

The layout of the monograph is attractive. The text contains scarcely any printing errors. The same is not quite so true of the structural formulas and tables, but this hardly detracts from the excellent overall impression left by this first edition of the work.

In summary, the book is a skilfully written teaching resource, which gives an excellent detailed survey of diazo chemistry, and well represents the present situation in this field of research. In view of the flood of original papers, widely scattered through the various journals, this monograph is a good example of the up-to-date and effective presentation of specialist information. It is certainly well up to the standard required for inclusion in every science library.

Catalyst Design. Progress and Perspectives. Edited by *L. L. Hegedus*. Wiley, New York 1987. xi, 288 pp., bound, £ 43.60.—ISBN 0-471-85138-8

Catalysis is a very complex field that has hitherto largely defied all efforts towards a systematic approach to the design of new catalysts—a fact which constantly troubles those engaged in it, especially in industry. It is therefore a welcome initiative when scientists from academic research and industry come together to discuss the possibilities and problems of rational planning for new catalyst development on the basis of the present situation in research. This book contains eight articles by well-known US authors, each discussing the general theme of catalyst design from a different point of view. The topics covered are mainly restricted to heterogeneous catalyst systems; homogeneous catalysis is only touched on briefly in some of the articles, and the area of enzymic catalysis has been omitted.

In the introductory chapter *L. L. Hegedus* (W. R. Grace) briefly discusses the economic importance of catalysis, the technological and scientific progress made in the last 10 to 15 years, and some basic problems in understanding and predicting the effectiveness of catalysts. The article by *G. K. Somorjai* (University of California, Berkeley) deals with the effects of surface morphology and composition on catalyst performance; the various possible ways of controlling the reaction, e.g. by coadsorption or by incorporating structure or bonding modifiers, are clearly described, taking the most recent research results as examples. The starting point for the contribution by *B. C. Gates* (University of Delaware) is organometallic chemistry. The chapter addresses the opportunities in catalyst design by anchoring organometallic complexes to solid surfaces and the stability problems that need to be solved. *A. T. Bell* (University of California, Berkeley) discusses the function of the support and the influence of the method of preparation on the interaction between metal and support, and considers how these effects can be used to increase the performance of metal catalysts. In a more theoretical chapter *M. Boudart* (Stanford University) examines the importance of reaction kinetics in designing new catalysts; for example, he discusses the question of how the selectivity of catalysts can be manipulated in a chosen direction by interfering with the appropriate elementary surface reaction steps which take place sequentially or in parallel in the course of a surface-catalyzed reaction. The article by *R. Aris* (University of Minnesota) discusses quantitative mathematical models of chemical reactivity and transport processes as an aid to optimizing the performance of porous catalysts. Two contributions more closely related to industrial practice are those by *W. O. Haag* and *N. Y. Chen* (Mobil Research and Development) on zeolite catalysts and by *J. Wei* (Massachusetts Institute of Technology) on the design of specific large-scale catalysts for removing metallic impurities from distillation residues in oil refineries.

According to the preface, the book is intended both for academic scientists and for those engaged in industrial catalyst development. The latter will perhaps regret that the book does not give a comprehensive survey of the literature related to more practical aspects of catalyst design or selection. The numerous semiempirical rules for catalyst selection contained in the literature have not been covered here. One might also regret that reaction types and catalyst systems of industrial importance, such as selective oxidation reactions using complex metal oxide catalysts, have not been discussed. When it is stated in the introduction that, in view of the finite number of elements in the Periodic System, future developments in heterogeneous catalysis will lead to multicomponent catalyst systems with complex structures, this is merely describing a trend which has already been evident for a long time in commercial oxidation catalysis. However, apart from these reservations the book gives, on the whole, a realistic survey on the one hand of the advances which have been achieved using modern techniques of investigation and on the other hand of the many different problems which must still be overcome before the eminent empirical work that is required for the development of commercial catalysts can be shortened by a design strategy on a rational basis.

Microscopical Structuring of Solids by Molecular Beam Epitaxy—Spatially Resolved Materials Synthesis

By Klaus Ploog*

Dedicated to Professor A. Rabenau on the occasion of his 65th birthday

Interfaces and heterojunctions which are incorporated into a crystal in well-defined geometrical and spatial arrangements can lead to a structuring or engineering of (semiconducting) solids down to atomic dimensions. The electrical and optical properties are then defined locally, and phenomena related to extremely small dimensions ("quantum size effects") become more important than the actual chemical properties of the materials used. The technique of molecular beam epitaxy allows an atomic layer-by-layer deposition in a two-dimensional growth process, and crystalline materials in alternating layers of arbitrary composition and only a few atomic layers thickness are formed. The synthesis of microscopically structured solids by molecular beam epitaxy affords access to a new class of materials with accurately tailored electrical, optical, magnetic, dielectric, mechanical etc. properties. The semiconductor and metal superlattices described in this article, which are made of alternating thin layers of two different materials, symbolize just the beginning of a new area of materials engineering on a molecular (or atomic) scale. This periodic modulation of the chemical composition normal to the surface imposes an artificial periodicity on the semiconductor or metal crystal, a periodicity of one or two orders of magnitude larger than its natural lattice spacing. The synthesis of other materials combinations, including semiconductor/metal, semiconductor/insulator, metal/insulator, polymers, and magnetic materials, with entirely different properties and for completely different applications will certainly follow. Finally, a large variety of desired combinations of elements can be selected, and even metastable compounds with novel exciting properties can be synthesized by molecular beam epitaxy.

1. Introduction

In modern materials science and materials technology the accurately defined structuring of known solids down to microscopically controlled dimensions is now becoming more important than the continual search for new chemical compounds. Statistically affected preparation techniques, involving e.g. alloying and diffusion, are being replaced more and more by chemically and physically well defined methods, as e.g. epitaxy.[1] This trend is most obvious in the domain of semiconductor research and development, but it also applies to other materials, e.g. ceramics

and composites, and in a more general sense even to the most recent developments in the field of high-temperature superconductors.[2] Semiconductor materials required for use in devices must be of extreme purity and their crystal perfection should be as high as possible. Interfaces and accurately defined impurities ("dopants") have to be incorporated into the crystal intentionally and with high spatial resolution, in order to define locally the electrical properties and to adjust the desired potential differences. The important consequence of an accurate structuring of solids in increasingly smaller dimensions is that phenomena related to these restricted small dimensions ("quantum size effects") become more important than the chemical properties of the materials used. A striking example for this postulate is the quantum Hall effect.[3] The numerical value of the Hall resistance depends only on fundamental constants, while the compositions and the dimensions of the crystals become unimportant.

The microscopical structuring of semiconducting solids down to nanometer dimensions is achieved by heterojunctions (i.e. interfaces between two lattice-matched materials of different composition) and by p/n doping interfaces (homojunctions) which are intentionally incorporated into the crystal with high spatial resolution. This process leads to the concept of "band-gap engineering"[4,5] (Fig. 1), the origin of which is already to be found in the patent application for the transitor by *Shockley*[6] and in the later theoretical studies on heterojunctions by *Krömer*.[7] The first experimental confirmation of this concept was accomplished by the successful fabrication of GaAs/$Al_xGa_{1-x}As$ heterojunction lasers[8] which could be operated continuously at room temperature. The real breakthrough for band gap engineering came with the revitalized development of molecular beam epitaxy of III-V compound semiconductors at the Bell Laboratories[9] and with the stimulated efforts to realize artificial semiconductor superlattices in the IBM Thomas J. Watson Laboratories[10] at the beginning of the seventies.

The concept of semiconductor superlattices[10] infers that, by periodic modulation of the chemical composition (e.g. GaAs/$Al_xGa_{1-x}As$) in the direction of growth, an artificial one-dimensional periodicity is imposed on the semiconductor crystal (Fig. 1b). This additional periodicity is one or two orders of magnitude larger than the natural spacing of the lattice planes, but it is smaller than the de Broglie wavelength of electrons, which is about 25 nm in GaAs. The artificial periodicity, which is superimposed on the crystal potential, gives rise to the formation of mini- or sub-bands for electrons and for holes and thus leads to novel electrical and optical properties of the layered material. For many familiar materials the new structures result in unusual electronic properties which open up new technical applications.

The technique of molecular beam epitaxy[9,11] made feasible the first reproducible preparation of multilayer heterostructures with atomically abrupt material transitions at the interfaces and with accurately controlled profiles of composition and doping over regions only a few nanometers wide. Of particular importance is that the single crystalline pattern of the lattice unit in successive layers continues without disruption or distortion across the interfaces between the layers, if lattice matched material systems, such as e.g. GaAs/AlAs, are used.[*]

Table 1. Band gap E_g and lattice constant a of binary III-V compound semiconductors and of the group IV element semiconductors Si and Ge at room temperature. The band-structure type is indicated by d (≙direct) and i (≙indirect). The wavelength λ is calculated according to $\lambda = 1.24/E_g$.

Semiconductor	E_g [eV]	λ [μm]	a [nm]
GaAs	1.425 (d)	0.87	0.5653
AlAs	2.16 (i)	0.57	0.5661
InP	1.35 (d)	0.92	0.5869
InAs	0.36 (d)	3.44	0.6057
GaP	2.26 (i)	0.55	0.5451
GaSb	0.73 (d)	1.70	0.6095
InSb	0.17 (d)	7.29	0.6479
AlSb	1.65 (i)	0.75	0.6135
Si	1.12 (i)	1.10	0.5431
Ge	0.66 (i)	1.88	0.5658

The theoretical concept of semiconductor superlattices and the unique capability of molecular beam epitaxy provided the basis for the successful fabrication of quantum wells, which represent a section out a of a superlattice and thereby form a key element of band-gap engineering (Fig. 1c). The quantum wells are formed by embedding a thin layer of a semiconductor with smaller band gap (e.g. GaAs) between two semiconductor layers with larger band

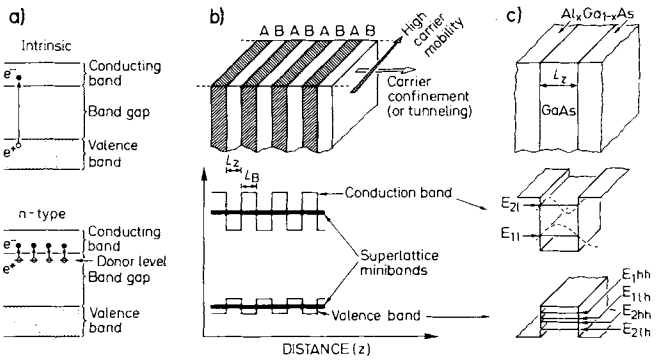

Fig. 1. Schematic illustration of the concept of band-gap engineering in semiconductor superlattices and quantum wells. a) Scheme of conduction and valence band edge in an undoped and in an n-doped semiconductor having a band gap (energy gap) of E_g. b) Periodic modulation of conduction and valence band edge in a superlattice, made of two semiconducting materials with different band gap, and formation of sub-bands for electrons and for holes. c) GaAs quantum well embedded by two $Al_xGa_{1-x}As$ barriers and formation of sub-bands for electrons (E_{1e}) as well as for heavy (E_{1hh}) and light holes (E_{1lh}).

[*] The III-V compound semiconductors are particularly suitable for the fabrication of heterostructures with nearly perfect interfaces because most of them, including GaAs and AlAs, crystallize in the "zinc blende" structure. Within the same group of the periodic table of elements the different constituent elements can be mixed over a wide range, e.g. the Group III elements Al, Ga, In. In this way we can form ternary, quaternary etc. alloy semiconductors without changing the structure type [12]. The lattice constants and the electronic properties of these semiconductors can thus be modified arbitrarily over a wide range simply by the choice of the alloy composition (Table 1). The band gap of the ternary alloy $Al_xGa_{1-x}As$, e.g., increases from 1.42 eV for GaAs (at 300 K) to 1.91 eV for the mole fraction $x = 0.4$. At higher Al content ($x \geq 0.4$) the $Al_xGa_{1-x}As$ alloy transforms from a direct into an indirect-gap semiconductor, where the indirect X-minimum (valley) of the conduction band drops below the direct Γ-minimum [12]. Therefore, for most applications of GaAs/$Al_xGa_{1-x}As$ heterostructures the ternary alloy $Al_xGa_{1-x}As$ of mole fraction $x < 0.4$ is preferred to the binary compound AlAs.

gap (e.g. $Al_{0.3}Ga_{0.7}As$). When the thickness of the embedded GaAs layer is comparable to or smaller than the de Broglie wavelength for electrons, distinct sub-bands for the electrons and holes confined in this potential well are formed. The energy position and the spacing of these subbands depend only on the thickness (width) and on the depth of the quantum well.[13] The depth in turn is given by the energy difference between the conduction band edges (or valence band edges in the case of holes) of the two semiconductors. These energy differences are also called band discontinuities. The wavelength or energy, respectively, of the light emitted or absorbed by the III-V semiconductors in these quantum wells is thus mainly determined by the well width, which is simply a geometric parameter. Similarly to the quantum Hall effect the local chemical composition of the material becomes less important in these layered structures and quantum size effects determine the important features. The preparation and investigation of quantum wells made of III-V semiconductors was crucial for the development of quantum well lasers,[14] which show dramatically improved characteristics as compared to conventional heterostructure lasers, and for the development of novel photodetectors.[15] These two types of devices are decisive for the new technology of photonics, which is based on the optical processing of signals. The application of molecular beam epitaxy for the synthesis of materials with a spatial resolution on an atomic scale has led to a variety of artificially layered semiconductors where the motion of electrons and holes is quantized *in* the layer plane. An important challenge for microstructure materials science lies in the fabrication of quantum wires and quantum dots in which an additional confinement of the carriers in one or two more dimensions *within* the layer plane is required.

In the present review paper we start in Section 2 with an outline of the basic principles of molecular beam epitaxy applied to the growth of III-V semiconductors and discuss the characteristic features of this technique which allow the spatially resolved synthesis of materials. In Section 3, four distinct methods for characterizing artificially layered solids with atomic layer resolution are presented: transmission electron microscopy (TEM), double-crystal X-ray diffraction, luminescence and absorption spectroscopy, and Hall effect measurements. It is shown that improved methods of materials characterization can have a strong impact on the future development of the spatially resolved synthesis of materials. In Section 4 we present some selected examples for the microscopical structuring of solids normal to the crystal surface, and we discuss the exciting electronic properties of the following artificially layered materials: superlattices and quantum well structures made of III-V semiconductors, spatial separation of electrons from their ionized parent impurities in selectively doped III-V heterostructures, $(GaAs)_1(AlAs)_1$ monolayer alloys as example for an ordered alloy of composition $Al_{0.5}Ga_{0.5}As$, monolayer doping in GaAs, combination of a chemical with a structural periodic modulation in Si/Ge superlattices, and finally metal superlattices. In the closing Section 5 a brief outlook on the future developments of spatially resolved materials synthesis and microstructure materials science is given.

2. Fundamentals of Molecular Beam Epitaxy

The controlled fabrication of semiconductor thin films of high crystal perfection requires the application of epitaxial growth techniques, i.e. oriented layer growth on the well ordered surface of a host crystal ("substrate"). The arrangement of the lattice units in the growing layers is predetermined primarily by the structure of the host crystal. Epitaxial growth techniques have been refined dramatically in the past ten years, especially for the III-V semiconductor layers which are now used in the fabrication of optoelectronic (photonic) and high-frequency electron devices. Depending on the scientific and technological requirements, one of the three complementary methods of vapor phase epitaxy, liquid phase epitaxy, or molecular beam epitaxy is used.[16]

Molecular beam epitaxy (MBE) is a method for the fabrication of extremely thin crystalline films of semiconductors and metals as well as artificially layered structures by means of atomic or molecular beams.[11, 17] The specific advantages of this sophisticated technique are that artificially layered solids can be accurately tailored to within atomic dimensions. Distinct atomic layers of a material can be manipulated one by one. Figure 2 shows schematically the basic principle of molecular beam epitaxy for the III-V semiconductors GaAs, $Al_xGa_{1-x}As$, $Ga_xIn_{1-x}As$, and $Al_xIn_{1-x}As$. The growth process is based on the reaction of thermal, non-ionized molecular beams of the constituent elements with a (001) oriented GaAs or InP substrate surface heated to 500–600 °C. At this substrate temperature the impinging species of the molecular beams can react with each other and the atoms can migrate sufficiently fast to their lattice sites so that no defects are formed. The molecular beams are generated by evaporation of the elements Ga, Al, In, and As in small cylindrical effusion cells having a capacity of about 10–100 cm^3. The doping impurities Be for p-type and Si for n-type doping, which are important for adjusting the electrical properties of III-V semiconductors, are incorporated from separate molecular beams into the growing films. Mechanical shutters are

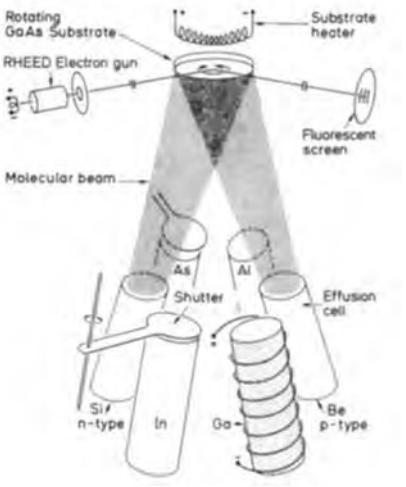

Fig. 2. Schematic illustration of evaporation and deposition process during molecular beam epitaxy of III-V compounds. RHEED = *R*eflection *H*igh-*E*nergy *E*lectron *D*iffraction (see also Fig. 6).

mounted in front of the orifices of the effusion cells. They allow the molecular beams that are directed onto the substrate to be switched on or off within fractions of a second. In this way highly refined layered structures with the composition and/or doping changing over a range of just a few (or even one) atomic layers can be deposited without any deleterious distortion of the crystal growth. The macroscopic electrical and optical properties of the layered structures can be accurately tailored as desired simply by choosing the correct composition and thickness of the constituent layers. In principle, molecular beam epitaxy is a rather elementary synthetic process, since no foreign atoms are present at the gas-solid interface and by-products are not formed.

The basic concepts of the MBE growth process were first developed in the mid-fifties at the Siemens Research Laboratories in Erlangen. Using his so-called "Three-Temperature Method", *Günther*[19] was able to prepare the first stoichiometric thin films of the III-V semiconductors InAs, InSb, and GaAs on glass substrates. The specific difficulty for achieving stoichiometry was that the constituent elements of III-V compounds (i.e. compounds formed from elements of the third and fifth main groups of the periodic table) have largely differing vapor pressures so that these compounds exhibit considerable decomposition at their evaporation temperature (incongruent evaporation). *Günther* used the Group V-element source oven, kept at a low temperature T_1 (e.g. 300°C for As), to maintain a constant vapor pressure in the reaction chamber. The source oven for the Group III element was kept at a much higher temperature T_3 (e.g. 950°C for Ga), thus providing a flux of atoms incident on the substrate that determined the condensation rate of the III-V compounds. The choice of the substrate temperature T_2 was most crucial. This intermediate temperature had to be kept below the incongruent evaporation point, so that a condensation of the III-V compounds could occur, but it had to be increased to a value that ensured re-evaporation of the excess Group V component, which had not reacted, from the substrate surface. The early films prepared by *Günther* were polycrystalline, since they were deposited on amorphous substrates. Furthermore, the vacuum conditions of 10^{-5} torr in the reaction chamber available 30 years ago in the laboratory were not adequate enough for ensuring a reasonable purity of the films. The molecular beam epitaxy of crystalline semiconductor films followed some ten years later in the mid-sixties, when *Arthur*[20] and *Cho*[9] at the Bell Laboratories studied the fundamental aspects of the interaction of Ga atoms and As_2 molecules with crystalline GaAs surfaces under ultrahigh vacuum (UHV) conditions (base pressure 10^{-11} torr). In the author's laboratory, molecular beam epitaxy has been pursued since 1974.

The most characteristic feature of molecular beam epitaxy is its low growth rate of about one lattice plane or monolayer [i.e. one complete layer of Ga plus one complete layer of As on the (001) surface] per second (≙0.3 nm/s). The important consequence of this is that the monocrystalline thin film can be built up atom by atom in a highly controlled manner, and atomically flat growth surfaces are formed. Thus, a high crystal perfection is also achieved for extremely thin films. Owing to the stringent

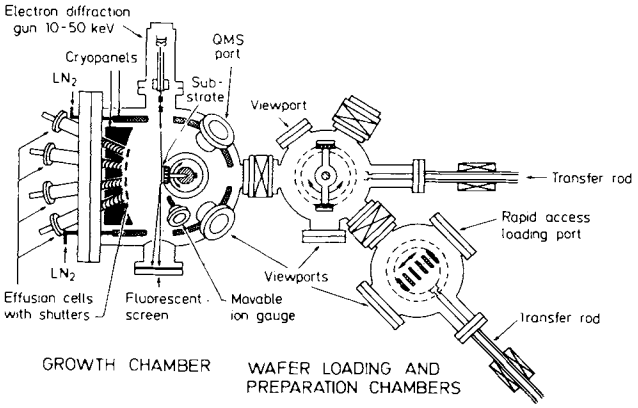

Fig. 3. Schematic cross-section of UHV system used for molecular beam epitaxy of III-V compounds, including reaction chamber, preparation chamber, and load-lock chamber. From the preparation chamber the samples can also be transferred to other processing units or to detailed surface analytical investigations.

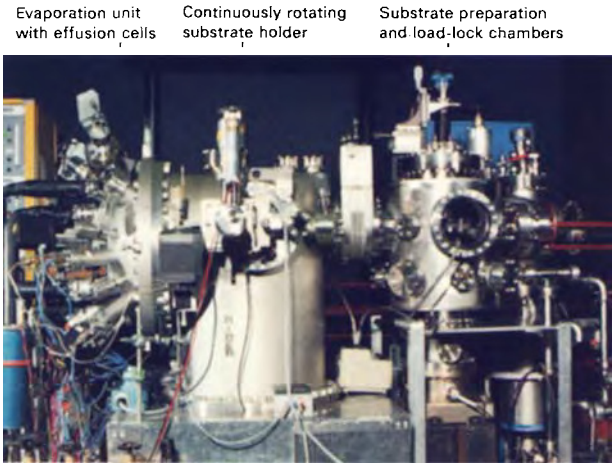

Fig. 4. Side view of a system for molecular beam epitaxy of III-V compounds constructed in the author's laboratory.

purity requirements for semiconductors, the film growth has to be carried out in bakeable UHV systems made of stainless steel and having a base pressure of 10^{-11} torr (this tolerable residual gas pressure is five orders of magnitude lower than in the regions of space traversed by the spacelab). Figure 3 shows a schematic cross-section and Figure 4 a side-view of a three-chamber UHV system for molecular beam epitaxy installed in the author's laboratory. The system consists of the following basic components:

- UHV reaction chamber of 45 cm (≙18 inch) diameter, internally lined with a liquid-nitrogen (LN_2) cooled cryopanel
- evaporator unit with six to ten effusion cells which are thermally isolated from each other by an additional cryopanel
- substrate manipulator for positioning and heating large-area (up to 75-mm diameter) substrate wafers
- load-lock and preparation chamber to introduce and exchange the substrate
- measurement system to control the purity of the system, the molecular beam fluxes, the substrate temperature, and the crystal growth.

Reaction chamber, preparation chamber and load-lock chamber are isolated from each other by large-diameter all-metal gate valves and they are pumped independently of each other. The load-lock chamber is pumped by a closed-loop He cryopump for rapid pump-down cycles, and the two other chambers are each pumped by a combination of ion getter pump and Ti sublimation pump. It is important to make sure that the amount of undesirable hydrocarbons and oxygen-containing compounds in the residual gas of the reaction chamber is kept as low as possible. The substrate wafers mounted on Mo support devices are transferred by magnetically coupled transfer rods from one chamber to the other and they are fixed to the respective heater blocks by a bajonet joint. The material fluxes emerging from the effusion cells are determined by the temperature of each of the cells and monitored by a movable Bayard–Alpert ion gauge which can be moved into the position of the substrate (the central portion of the constituent flux distributions should intersect at this position). The flux measurements by the ion gauge are sufficiently accurate; however, they are not element-specific. To determine accurately the composition of the residual gas and to measure the fluxes specific to the constituent elements, a quadrupole mass spectrometer (QMS) of high sensitivity can be used. For quantitative flux measurements the ionization chamber of the QMS placed in the beam path has to be surrounded by a LN_2 cryopanel, and, owing to material deposits, the spectrometer must be readjusted continuously. The crystal growth on the substrate surface is monitored by electron diffraction under grazing incidence [reflection high-energy electron diffraction (RHEED)]. Details of this important technique for in-situ growth control during MBE will be discussed later (see Fig. 6).

The design of high-quality molecular beam sources fabricated from nonreactive refractory materials is the most important requirement for successful MBE growth. The evaporation sources have to provide stable high-purity molecular beams of the desired intensity and uniformity, and they must withstand operating temperatures up to 1400 °C without themselves contributing to the molecular beams. Precise temperature stability ($\pm 0.1°$ at 1000 °C operating temperature) and reproducibility are essential. For accurate kinetic studies relevant to the growth process, Knudsen (equilibrium) effusion cells with small orifices have been used in the past (Fig. 5a) to produce collision-free thermal energy beams of the constituent elements. The analytical formulas used to calculate the angular intensity distribution of molecular beams emerging from Knudsen cells have been compiled by *Herman*.[21] Unfortunately, only very limited experimental data are available to check the validity of the theoretical approaches. For practical MBE growth, non-equilibrium (Langmuir-type) effusion cells with large orifices are used nowadays (Fig. 5b). In addition to the vapor pressure of the starting materials, the intensity of the molecular beams is also determined by the evaporation geometry. The crucibles made of pyrolytic boron nitride (PBN) are of either cylindrical or conical (tapered) shape, and have a length of about 5 to 10 times greater than their orifice diameter. The crucible capacity of 10 to 100 cm^3 for the different starting materials should be large enough to achieve continuous operating times of several months before recharging is required. The helical Ta wire to heat the crucible is wound in such a way to avoid magnetic stray fields deleterious for the operation of the electron diffraction during growth. Several sheets of thin crimped Ta foil provide a good thermal isolation to keep the heating loss as low as possible. The adjustment and regulation of the temperature is accomplished by continuously operating high-precision regulators having *p*roportional, *i*ntegral and *d*ifferential adjustment (PID regulator). The temperature is measured by a W/Re thermocouple fixed close to the outside bottom of the cylindrical crucible (the W/Re thermocouples do not react with the molecular beams). It is not important to measure the absolute temperature of the melt in the crucible but to detect the temperature at a fixed location of the thermocouple in a reproducible manner. This relative temperature is then related to the molecular beam flux arriving at the substrate surface which is independently determined by the movable ion gauge or by the thickness of the deposited material. *Saito* and *Shibatomi*[22] have recently performed a systematic investigation of the dependence of the uniformity of the molecular beams across the substrate on the geometrical relationship between the Langmuir-type effusion cells and the substrate. Over a substrate diameter of 75 mm they reduced the variation of the composition of $Al_xGa_{1-x}As$ layers to less than $\pm 1\%$ by optimizing the following three geometrical parameters: distance between substrate and effusion cells, taper φ_0 of the conical crucible wall, and diameter of the cell aperture.

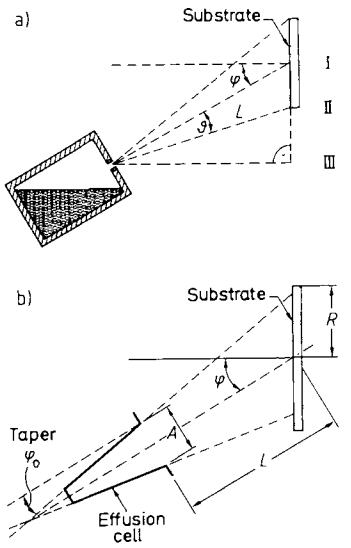

Fig. 5. Schematic illustration of (a) Knudsen (equilibrium) effusion cell and (b) non-equilibrium (Langmuir-type) effusion cell used for molecular beam epitaxy. ϑ = distribution angle of the molecular beam, L = distance between cell orifice and substrate, A = diameter of cell orifice, R = substrate radius, φ = angle of impinging molecular beam with respect to substrate normal, φ_0 = taper of effusion cell wall.

Evaporation of the Group III elements of the periodic table under UHV conditions produces atomic species, i.e. atomic beams emerge from the respective effusion cells. Evaporation of the Group V elements, on the other hand, produces almost exclusively tetrahedrally shaped tetrameric molecules (P_4, As_4, Sb_4) by sublimation. For the preparation of phosphides (GaP, InP, etc.) and for some other special applications dimeric molecules (P_2, As_2, Sb_2) are

required which can be produced by three different methods. First, incongruent evaporation of the binary III-V compounds yields dimeric molecules.[23] Second, the dimeric species are obtained by thermal decomposition of gaseous PH_3 or AsH_3,[24] which, however, also produces a large amount of hydrogen in the UHV system. Third, dimers can be generated from the elements by using a two-zone effusion cell ("cracker cell").[25] A flux of tetramers is first formed in a conventional effusion cell and then passed through an optically baffled high-temperature stage where complete conversion to P_2, As_2, or Sb_2 occurs above 900°C.

The growth of III-V semiconductors during molecular beam epitaxy is essentially determined by the sticking coefficient of the atoms and molecules impinging onto the substrate surface.[23] The substrate temperature is in general chosen to be below the incongruent evaporation temperature of the growing compound. The sticking coefficient of the Group III elements Al, Ga, and In is unity on (001)-oriented GaAs, InP, or GaSb substrates, i.e. each impinging atom sticks. On the other hand, the sticking coefficient of the Group V elements on clean (001) substrate surfaces is zero at the growth temperature. Their condensation occurs only when Al, Ga, or In adatoms have already been deposited on the substrate surface. The growth rate of the films is thus exclusively determined by the arrival rate of the Group III elements. The stoichiometry of most III-V semiconductors during MBE growth is self-regulating as long as excess Group V element molecules are impinging on the growing surface. In practice a two- to tenfold excess is used. The excess species of the Group V elements do not stick on the heated growth surface. As a result, the crystal is built layer-by-layer in the [001] direction, i.e. first a monolayer of GaAs (or InP, AlAs, etc.) is nearly completed before growth of the next monolayer starts. The detailed growth mechanism of III-V semiconductors was first established by *Foxon* and *Joyce*,[26] who studied the surface chemical processes by modulated molecular beam spectroscopy, and it has now been confirmed by investigations of the periodic intensity oscillations of the diffraction features in the RHEED pattern (see Fig. 7).

A good control of the composition of the ternary III-III-V alloys $Al_xGa_{1-x}As$, $Ga_xIn_{1-x}As$, etc. can be achieved by supplying excess Group V species and adjusting the flux intensities of the impinging Group III element beams, as long as the substrate temperature is kept below the congruent evaporation limit of the less stable of the constituent binary III-V compounds (e.g. GaAs in the case of $Al_xGa_{1-x}As$ or InAs in the case of $Ga_xIn_{1-x}As$).[27] At higher growth temperatures, however, preferential desorption of the more volatile Group III element (i.e. Ga from $Al_xGa_{1-x}As$) occurs, so that the final film composition is not only determined by the added flux intensities but also by the differences in the desorption rates. To a first approximation we can estimate the rate of loss of the Group III elements from their vapor pressure data. This assumption is reasonable because the vapor pressure of the element over the compound, e.g. Ga over GaAs, is similar to the vapor pressure of this element over its melt.[28] In Table 2 the rates of loss of Al, Ga, and In are compiled for different substrate temperatures. The surface of alloys grown at high temperatures will thus be enriched by the least volatile Group III element. As a consequence, we expect a significant loss of In in $Ga_xIn_{1-x}As$ films grown above 550°C and a loss of Ga in $Al_xGa_{1-x}As$ films grown above 650°C. For accurate adjustments of the effusion cell temperatures an intermittant calibration based on independently measured film composition, e.g. by X-ray diffraction or photoluminescence measurements (see Section 3), is therefore required. The lower limit of the substrate temperature during MBE growth was in most cases given by the deterioration of the crystal quality owing to the strong increase of the defect density, which occurs, e.g., for GaAs below 450°C. However, *Horikoshi* et al.[29] have recently shown that high quality GaAs and AlAs can be grown at a substrate temperature as low as 300°C, if Ga (or Al) and As_4 are alternately supplied to the growing surface. In an arsenic-free environment, which exists for a short period, the surface migration of Ga and Al is obviously strongly enhanced.

Table 2. Approximate rate of loss of Group III elements (in monolayers per second) from the surface of ternary III-III-V semiconductors estimated from vapor pressure data.

T [°C]	Al	Ga	In
550	—	—	0.03
600	—	—	0.3
650	—	0.06	1.4
700	—	0.4	8
750	0.05	2	30

The growth of ternary III-V-V alloy films such as, e.g., GaP_yAs_{1-y} by MBE is more complicated, since, in particular in phosphorus-containing compounds, the relative amounts of the Group V element incorporated in the growing film are not simply proportional to their relative arrival rates, even at moderate substrate temperatures.[30] In addition, the flux intensity of the Group III element arriving at the growing surface affects the incorporation of the Group V elements. At present the various factors controlling this incorporation behavior are not well understood, and it is difficult to obtain a reproducible composition control of ternary III-V-V alloys during MBE growth. For ternary III-III-V alloys, on the other hand, the simplicity of the MBE process allows composition control from $x=0$ to $x=1$ in $Al_xGa_{1-x}As$, $Ga_xIn_{1-x}As$, etc. with a precision of ± 0.001 and doping control, both n- and p-type, from the 10^{14} to the 10^{19} atoms cm^{-3} range with a precision of a few percent. The accuracy is largely determined by the care with which the growth rate and doping level was previously calibrated in test layers.

In general MBE growth of III-V semiconductors is accomplished on (001) oriented substrate slices of GaAs, InP, or GaSb having thicknesses of 300–500 μm. Before introduction into the growth chamber the substrate surface should be free of crystallographic defects and clean on an atomic scale, so that the crystal film can indeed be built in a two-dimensional growth process. Impurities and defects form nucleation centers for three-dimensional (3D) growth. The substrate preparation always involves treatment with organic solvents and with oxidizing solutions, and the final step consists of chemical etching to produce a

relatively stable oxide on the substrate surface.[11,17] This surface oxide protects the substrate against contamination. After insertion of the substrate into the MBE system the surface oxide is removed by heating to a temperature just below the limit of congruent evaporation, and clean crystallographically well ordered substrate surfaces are obtained. Smaller substrate slices are soldered with liquid In to the circular Mo mounting plate (In becomes liquid at 160°C and it has a high surface tension), and the whole device is then transferred and heated. Larger substrate wafers having a constant diameter of 50 or 75 mm (2 or 3 inches) are fixed without In to a special Mo holder designed for direct-radiation substrate heating. After insertion of one of these Mo holders with the chemically etched substrate into the load-lock chamber and evacuation to a pressure below 10^{-8} torr the substrate is preheated to remove physisorbed gaseous impurities, e.g. H_2O and CO. Then the substrate is transferred to the preparation chamber where the intentionally produced surface oxide is removed by controlled heating. The removal of the surface oxide can also be accomplished in the reaction chamber, in order to observe this process by RHEED. The transfer between the chambers is made by trolleys and magnetically coupled transfer mechanisms. In the growth chamber the Mo mounting plate holding the substrate wafer is fixed by a bayonet joint to the Mo heater block which is originally attached to a special manipulator. This manipulator positions correctly the substrate wafer relative to the evaporation sources, heats it to the required temperature, and continuously rotates it azimuthally for optimum film uniformity.

On using high-purity starting materials (>99.9999%), the purity of the semiconductor films depends crucially on the residual background impurities in the reaction chamber. Recently, unintentionally doped GaAs with an extremely low residual acceptor concentration of 2×10^{13} atoms cm^{-3} was obtained.[31] The residual acceptor is probably due to carbon impurities from the residual gas of the reaction chamber. The application of MBE grown films for fundamental studies as well as in device structures requires the control of the electrical and optical material properties by the deliberate incorporation of small amounts of impurity (dopant) elements from additional effusion cells. The most common dopants used during MBE growth of III-V semiconductors are Be for p-type and Si for n-type doping. Over a large range of growth conditions both elements have a sticking coefficient of unity. Abrupt doping profiles normal to the growth surface can be obtained simply by actuating the shutters in front of the effusion cells. Be substitutes for Ga atoms in the GaAs sublattice and forms a nearly ideal shallow acceptor.[32] For doping concentrations up to 2×10^{19} atoms cm^{-3} each incident Be atom produces one ionized impurity species. By lowering the substrate temperature to 500°C even extremely high acceptor concentrations up to 2×10^{20} cm^{-3} are feasible in Be-doped GaAs with perfect surface morphology. For (001)-oriented substrates, also Si primarily substitutes for Ga atoms in the GaAs sublattice and forms a shallow donor.[33] The electrically measured doping concentration is up to $n=1\times10^{19}$ cm^{-3} directly proportional to the dopant arrival rate, provided care is taken to minimize the background H_2O and CO level during growth. At present, the origin of the upper limit of 1×10^{19} cm^{-3} for the electron concentration in Si-doped GaAs is not exactly clear. Three mechanisms are discussed, (i) autocompensation by incorporation of Si on As sites or on interstitials,[34] (ii) additional impurities evolving from the Si effusion cell heated to above 1300°C,[35] or (iii) formation of Si-vacancy complexes acting as acceptors which lead to a compensation in heavily n-doped GaAs.[36] The possibility of Si migration or diffusion during MBE growth of $Al_xGa_{1-x}As$ films at high substrate temperatures and/or with high donor concentration has been the subject of controversial discussion,[37] because of its deleterious effects on the properties of selectively doped n-$Al_xGa_{1-x}As$/GaAs heterostructures which require abrupt doping profiles. There is some evidence that a migration of Si in $Al_xGa_{1-x}As$ can only occur at high doping concentration ($>2\times10^{18}$ atoms cm^{-3}) as the result of a concentration-dependent diffusion process, which is enhanced at high substrate temperatures. It is finally important to note that the incorporation of Si atoms on either Ga or As sites depends significantly on the orientation of the GaAs substrate.[38] In GaAs grown on (001), (111)B, (211)B, (311)B, (511)A, (511)B, and higher-index orientations, Si atoms predominantly occupy Ga sites and act as donors, while they occupy As sites and act as acceptors on (111)A, (211)A, and (311)A orientations. This different incorporation behavior of Si is now utilized, e.g., to produce a series of lateral p/n junctions in GaAs on graded steps of the (001) substrate surface.[39] Based on this method of spatially resolved synthesis during MBE, semiconductors with a few nanometers wide lateral regions of totally different electrical properties are produced.

Reflection electron diffraction under grazing incidence (RHEED) is the most important technique for in-situ monitoring of the crystal growth during molecular beam epitaxy.[11] The forward scattering geometry with a grazing incidence angle of 1 to 3° schematically shown in Figure 6a implies that also at a primary-beam energy of 10–30 keV the information (penetration) depth is restricted to the out-

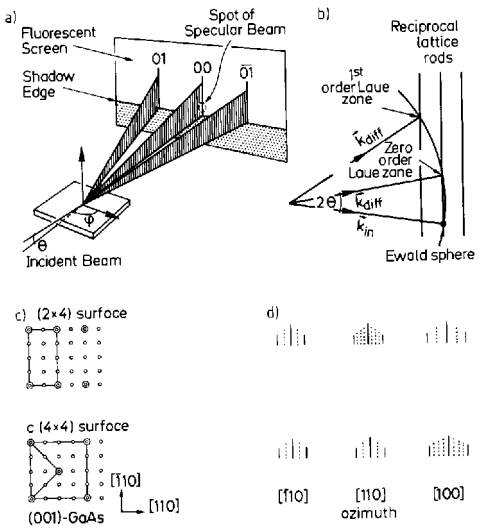

Fig. 6. Geometric arrangement of electron diffraction with grazing-angle incidence (RHEED) used as in-situ analytical tool during molecular beam epitaxy; (b) Ewald construction to interpret the diffraction conditions; (c) and (d) surface unit cell ("mesh") and diffraction patterns of two important reconstructions during molecular beam epitaxy (not to scale).

ermost atomic layers of the growing crystal. This geometry makes RHEED fully compatible with the MBE growth process, and the diffraction pattern can be observed directly on the fluorescent screen ("in-situ"). The diffraction spots are elongated to characteristic streaks normal to the shadow edge. The appearance of streaks instead of spots cannot fully be explained by means of the Ewald construction (Fig. 6b), where in reciprocal space the lattice rods intersect the Ewald sphere tangentially when the diffraction condition is fulfilled. In addition, we have to assume a specific disorder in certain directions of the growing crystal surface.[40] The existence of surface reconstructions characteristic for MBE growth (Fig. 6c) leads to additional features in the RHEED pattern (Fig. 6d) at fractional intervals between the bulk (zinc blende-type) diffraction streaks.[11] The re-ordering of the surface atoms during reconstruction gives rise to a lowering of the symmetry at the surface. In most cases the surface unit cell ("mesh") has a larger periodicity. This rearrangement at the surface results from the rehybridization of binding orbitals in order to minimize the free energy of the surface. The (001) surface of III-V semiconductors exhibits a number of different reconstructions during MBE growth which are directly related to the surface stoichiometry. The surface composition, on the other hand, depends crucially on the growth conditions (substrate temperature, ratio of molecular beam fluxes, etc.).[41] Figure 6d shows (schematically) the diffraction patterns of the two most important surface reconstructions during MBE growth of GaAs, i.e. the arsenic-stable (2×4)- and the (4×4)-reconstruction, taken at different azimuths. From the occurrence of specific surface reconstructions, identified from the diffraction pattern, we can in turn derive the actual reaction conditions, and if necessary we can modify them. The monitoring of the RHEED pattern is of particular importance at the beginning of the epitaxial growth on the chemically etched and thermally heated substrate wafer as well as during the preparation of abrupt material interfaces.

Another characteristic feature of this type of electron diffraction under grazing incidence is the existence of pronounced periodic intensity oscillations of the specularly reflected and of the diffracted beams during MBE growth (Fig. 7, top). The period of these oscillations corresponds exactly to the time required to deposit a monolayer of GaAs (or AlAs, $Al_xGa_{1-x}As$, etc.) on the (001) surface.[42] To explain these features we can to a first approximation assume (Fig. 7, bottom) that the amplitude of the intensity oscillation reaches its maximum when the monolayer is just completed (maximum reflectivity). The formation of the following lattice plane starts with statistically distributed 2D islands having the height of one GaAs monolayer. The intensity of the diffracted (or reflected) electron beam decreases with increasing size of the island. The minimum reflectivity occurs at half-layer coverage ($\theta=0.5$). When the coverage is further increased the islands coalesce more and more, and the reflectivity finally reaches a maximum again at $\theta=1$. The observed damping of the intensity amplitude is probably due to the fact that the individual surface domains probed by the electron beam are not in phase. The damping of the RHEED oscillations can be eliminated when the surface migration of the Group III

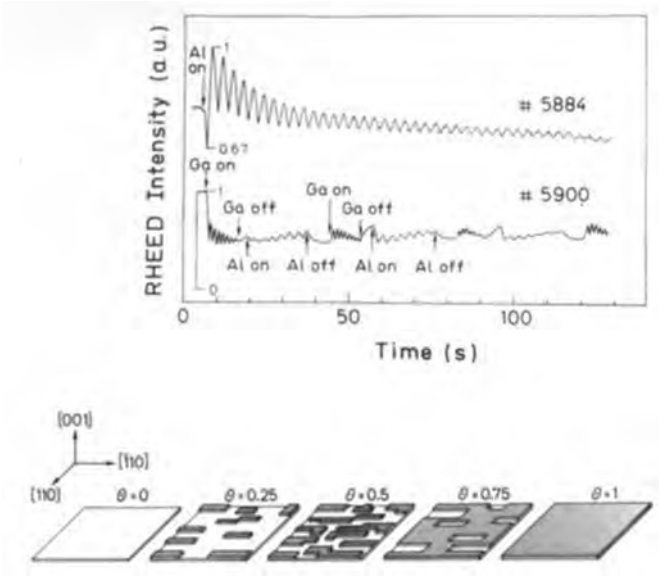

Fig. 7. Top: Periodic intensity oscillation of the specularly reflected electron beam in the RHEED pattern as a function of time during molecular beam epitaxy of GaAs/AlAs layers. Bottom: Formation of 2D growth islands of monolayer height but different lateral size to illustrate the varying reflectivity of the incident electron beam from the growing surface (not to scale).

elements is greatly enhanced by short synchronized cessations of the arsenic flux.[43] In this case only a few large domains are formed on the growing surface. The existence of periodic intensity oscillations in the RHEED pattern is a conclusive confirmation of the assumption that crystals are indeed formed in a 2D layer-by-layer growth mode during molecular beam epitaxy. The RHEED intensity oscillations are now widely used to calibrate and to monitor absolute growth rates in real time and with monolayer resolution and to provide direct real-time evidence of the formation of interfaces on an atomic scale during abrupt deliberate change of the composition.[44] As in the case of the widely used $GaAs/Al_xGa_{1-x}As$ heterointerface, e.g., the sequence of layer growth ternary-to-binary exhibits considerably different properties (structural and electronic) than the sequence binary-to-ternary, since the Ga and Al atoms have a strongly different surface migration rate at normal MBE growth conditions. These differences in the heterointerfaces can be compensated to a certain extent by the interruption of growth at each interface for a short time (10^1–10^2 s, the value depends on the actual growth conditions).

3. Characterization of Microscopically Structured Solids

The characterization of solids which are microscopically structured down to atomic dimensions requires analytical techniques having a high spatial resolution and a high sensitivity and accuracy. The necessity of a detailed characterization stems directly from the historical development of the semiconductor superlattices. In this field, a sound theory made it first possible to predict the intriguing properties of these microscopically structured semiconducting materials. Sophisticated measurement systems were then used to assess the degree to which the predictions have

been fulfilled. It is important to note that the interface perfection experimentally achievable by MBE is now so high that conventional methods of depth profiling analysis, which involve sputtering to section the material combined with some means of composition determination (such as Auger electron spectroscopy or secondary ion mass spectroscopy) are no longer adequate for the required resolution. Therefore, the continuous development of already existing and of new analytical and measurement techniques is an unquestionable requirement. Improved techniques for characterizing materials can in turn also have a strong impact on the development of spatially resolved materials synthesis.

In this paper we briefly introduce four methods for characterizing materials which are routinely used today to assess the specific properties of microscopically structured solids, in particular semiconductors: transmission electron microscopy, double-crystal X-ray diffraction, luminescence and absorption spectroscopy, and Hall effect measurements. In many cases a combination of two or more methods is necessary.

3.1. Transmission Electron Microscopy

The method of cross-section transmission electron microscopy (TEM) with dark-field and lattice imaging was first used by *Petroff*[45] to analyze the periodicity, the degree of order at the interfaces, and the composition in GaAs/AlAs superlattices. This imaging mode requires that the incident electron beam is nearly parallel to the layers of the superlattice, i.e. parallel to the (001) plane in the [110] direction (see Fig. 8, top). To prepare the thin TEM specimen, the (001)-oriented substrate with the epitaxial layer is first cleaved parallel to the (110) plane, and the cleaved fragments are then thinned by chemical etching and ion beam etching down to a thickness of 10–20 nm.[46] The regular layer sequence A, B, A, B, ... in the epitaxial film leads to a periodic array of interfaces which in turn generates a periodic variation of the crystal potential acting as a phase grating for the incident electron beam (provided the coherence length of the electron beam is larger than the grating periodicity). Thus, in addition to the diffraction spots arising from the diffracting lattice planes of the layers A and B, we observe characteristic superlattice spots in the transmission electron diffraction pattern, which represent a Fourier transform of the phase grating. Lattice images are formed either in the bright- or dark-field mode by selecting the transmitted or diffracted beam and one or more of the superlattice diffraction spots with the objective aperture (Fig. 8, top). The intensity distribution in the resulting lattice image shows a periodicity. However, this periodicity represents the true distribution of interfaces in the sample as well as order or disorder at the interfaces only under very crucial imaging conditions. The specimen thickness and the defocussing of the objective lens, for example, strongly affect the periodicity observed in the image.

In Figure 8 (middle and bottom) we show examples for a cross-sectional dark-field TEM image of a 10-nm GaAs/10-nm AlAs superlattice and for a high-resolution lattice image of a 2.8-nm GaAs/2.3-nm AlAs superlattice, respectively. Inspection of the lattice image clearly reveals that the perfect ordering of the lattice units continues without distortion also across the interfaces. The two binary components GaAs and AlAs provide the highest contrast at the interfaces of these superlattices. *Suzuki* and *Okamoto*[47] have recently demonstrated that a high contrast in the lattice plane images can also be obtained for the technologically important $GaAs/Al_xGa_{1-x}As$ superlattices with $x = 0.3$, if the TEM specimens are cut out of the epitaxial layer in (001) orientation so that the electron beam is incident in the [100] direction. However, the specimen preparation for this orientation is rather elaborate because a (100) cleavage plane does not exist for the III-V semiconductors. When the periodicity of the superlattice is larger than several lattice planes it becomes difficult for a microscope of lower resolution to form a dark field image from the superlattice spots, as these spots are then located too

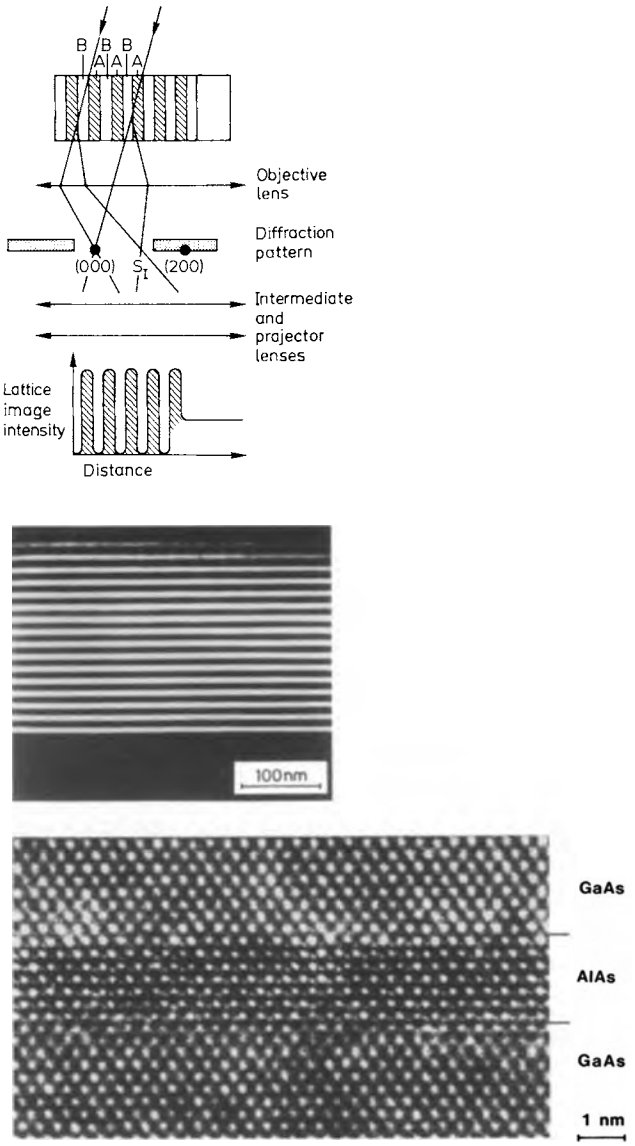

Fig. 8. Top: Geometric arrangement of incident electron beam and constituent layers of a superlattice as well as generation of the imaging conditions for high-resolution transmission electron microscopy (TEM). Middle and bottom: Cross-sectional dark-field TEM image and high-resolution lattice image of GaAs/AlAs superlattices. The TEM micrographs were kindly taken by Dr. *H. Oppolzer*, Siemens AG, Munich.

close to the main lattice reflections. But since the Ga and Al atoms have significantly different scattering factors, the periodic layer sequence can still be imaged as shown in Figure 8 (bottom). In this micrograph the dark bands are GaAs and the light bands are AlAs. It is evident, however, that the resolution is not adequate enough to define the interfaces on an atomic scale.

3.2. Double-Crystal X-Ray Diffraction

Transmission electron microscopy is a destructive analytical method for the wafer, and it calls for an elaborate preparation of suitable specimens. Double-crystal X-ray diffraction, on the other hand, is a non-destructive method and it requires far less experimental effort. X-ray diffraction was already used in the early seventies for the characterization of semiconductor superlattices[48] but it soon lost importance because of its analytical limitations at that time. For about three years the method has experienced a renewed widely spread application, which was initiated by the significantly improved theoretical analysis of the experimentally determined diffraction curves.[49] In a semiconductor superlattice the lattice parameter as well as the scattering power are subject to a one-dimensional periodic modulation in the direction of the layer sequence. As a consequence, the diffraction pattern consists of a series of satellite reflections located symmetrically around the respective Bragg reflection. Figure 9 shows schematically the diffraction geometry of an epitaxial layer grown on a crystalline substrate and the basic principle of a double-crystal X-ray diffractometer operating in a non-dispersive anti-parallel Bragg arrangement. A dislocation-free Ge crystal is used as monochromator and collimator to produce a collimated monochromatic X-ray beam. The appropriate choice of the asymmetry factor of the collimator crystal minimizes the angular divergence of the beam incident on the specimen. In our case the divergence is about 2.35 seconds of arc, and we obtain a very high resolution with such an instrument.[49]

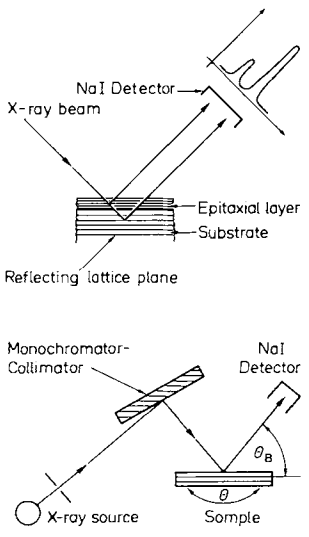

Fig. 9. Schematic illustration of X-ray diffraction from a crystalline epitaxial layer deposited on a crystalline substrate (top) and basic principle of a double-crystal X-ray diffractometer in non-dispersive anti-parallel Bragg arrangement (bottom).

The small difference in the lattice constants between the $Al_xGa_{1-x}As$ epitaxial layer and the GaAs substrate crystal gives rise to a slight distortion of the unit cell of the epitaxy crystal. This distortion of the unit cell can be determined by measuring two reflection curves, one from the lattice planes parallel to the (001) crystal surface and one from lattice planes inclined to the crystal surface. Our measurements have conclusively shown that for this materials system a change of the lattice constant *parallel* to the (001) surface does not exist, while the change of the lattice constant perpendicular to the epitaxial layer surface, i.e. in the [001] direction, depends linearly on the chemical composition of the $Al_xGa_{1-x}As$ layer, i.e. on x. The relative change of the GaAs and AlAs lattice constants perpendicular to the crystal surface amount to $\Delta a = 1.583 \times 10^{-3}$ nm and for a relaxed lattice to $(\Delta a)_{relax} = 0.72 \times 10^{-3}$ nm. After conversion of Δa to $(\Delta a)_{relax}$ using the elastic stiffness constants we can thus determine the composition of the epitaxial $Al_xGa_{1-x}As$ layer very accurately. The thickness of the epitaxial layer can be deduced from the angular spacing of pendellösung fringes,[*] if its total thickness is less than 2 μm (≙ X-ray extinction length).

When very thin layers (thickness < 100 nm) or when layered structures are studied, the diffraction maxima of the epitaxial layer and of the substrate crystal are in general not exactly distinguished, and an unambiguous assessment of lattice distortion and crystal thickness can no longer be made. In this case it is necessary to perform a theoretical treatment of the reflection behavior of the whole crystal (epitaxial layer). We have used a semi-kinematical approach of the dynamical theory of X-ray diffraction for distorted crystals.[49] The theoretical fit of the experimental diffraction curves yields detailed information on the strain profile (lattice distortion), the chemical composition, and the thickness of heterostructures. In Figure 10 we show the comparison between measured and calculated diffraction curves for a ten-period GaAs/AlAs superlattice recorded in the vicinity of the symmetric (004) $Cu_{K\alpha 1}$ reflection. The average Al concentration of the entire superlattice is determined from the angular spacing between the substrate peak and the main epitaxial-layer peak (zeroth-order peak). The angular distance $(\Delta\theta)_{\pm 1}$ between the zeroth-order ("0") peak and the satellite peak "+1" (or "−1") yields the superlattice periodicity T according to the relation

$$T = \frac{\lambda}{(\Delta\theta)_{\pm 1} \sin(2\theta_B)} \tag{1}$$

where λ is the X-ray wavelength and θ_B is the diffraction angle of the zeroth-order peak. Also the thickness of the constituent GaAs and AlAs layers can be determined accurately from these data. The position, the intensity, the half-width, and the number of the satellite peaks are crucial criteria for the layer thickness, the composition, periodicity fluctuations, the inhomogeneity of composition and the in-

[*] Pendellösung fringes = oscillations of the X-ray diffraction curve due to interferences of waves scattered at different depths of the epitaxial layer.

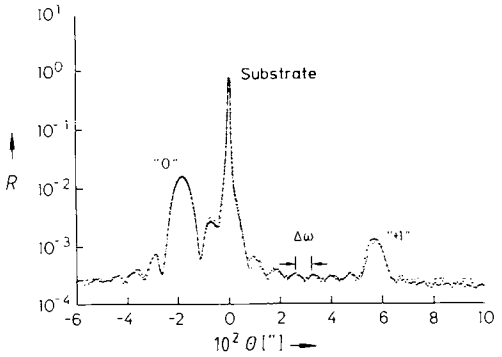

Fig. 10. Experimental (dashed line) and theoretical (solid line) X-ray diffraction curves of a $(GaAs)_{46}(AlAs)_{44}$ superlattice taken in the vicinity of the (004) reflection with $Cu_{K\alpha 1}$ radiation.

terface quality. Figure 11 shows an example for the investigation of interface homogeneity and broadening in GaAs/AlAs superlattices. The diffraction curves were recorded in the vicinity of the quasi-forbidden (002) reflection, because in this geometry the satellite peaks are more pronounced and therefore more sensitive to interface effects. For the (002) reflection the structure factor of AlAs is ten times larger than that of GaAs. The existence of interface disorder (broadening) manifests itself in an increase of the halfwidth and in a decrease of the intensity of the satellite peaks. The two GaAs/AlAs superlattices whose results are depicted in Figure 11 were grown under the same growth conditions and their periodicity is exactly the same, i.e. the maxima of the satellite peaks have the same angular spacing from the zeroth-order peak. The differences between the two superlattices are the following: During growth of sample A the growth was stopped for 10 s at each GaAs/AlAs and AlAs/GaAs interface, while sample B was grown continuously by sequentional opening and closing of the Ga and Al shutters. A detailed quantitative analysis of the diffraction curves in Figure 11 reveals that during continuous growth 2D islands with a

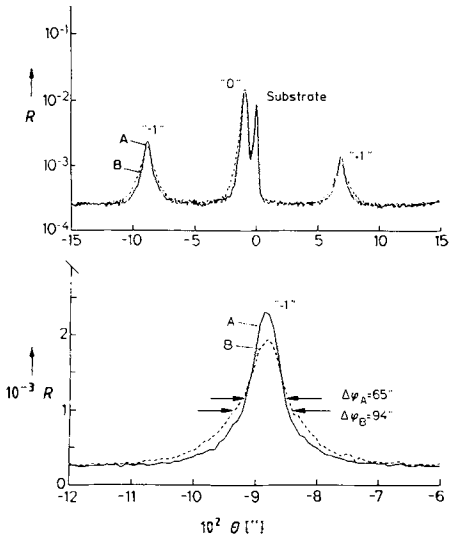

Fig. 11. X-ray diffraction curves of two $(GaAs)_{34}(AlAs)_{42}$ superlattices taken in the vicinity of the quasi-forbidden (002) reflection with $Cu_{K\alpha 1}$ radiation. Sample A was prepared with and sample B without growth interruption at the heterointerfaces.

height of one monolayer (≙lattice plane) are formed which lead to a disorder and thus broadening of the interfaces in the order of a lattice constant (≙0.56 nm). The growth interruption of 10 s is sufficient to smooth the growth surface and to produce abrupt material transitions and extremely sharp interfaces. This result is in accordance with the investigations of the RHEED intensity oscillations.[43,44]

The quantitative analysis of the interface quality by X-ray diffraction becomes even more important when the lattice parameters of the epitaxial layers have to be matched to those of the substrate by appropriate choice of the layer composition, as for $Ga_xIn_{1-x}As$ with $x=0.47$ and $Al_xIn_{1-x}As$ with $x=0.48$ on InP substrates. Therefore, in $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$ superlattices also the chemical composition of the constituent layers has to be evaluated accurately. Deviations of more than one percent from the ideal value cause strain effects which give rise to significant changes in the electronic properties of the material. In some cases the semi-kinematic approach of the dynamical diffraction theory is not sufficient to analyze the measured diffraction curves quantitatively, and the more elaborate dynamical theory must be applied.[50] In Figure 12 (top) we show a comparison between the measured and the calculated diffraction curve of a $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$ superlattice. The capability of both the epitaxial growth method and of the characterization method follows directly from a comparison of data compiled in Table 3 for four superlattices of this type. Finally, it should be pointed out that in an ideally lattice-matched $Ga_{0.468}In_{0.532}As/Al_{0.477}In_{0.523}As$ superlattice on InP substrate the satellite peaks have almost disappeared, as shown in Figure 12 (bottom). The low residual intensity and the pendellösung fringes are caused only by the periodicity of the structure factors in the superlattice. A high intensity of the satellite peaks thus indicates a periodic variation of the strain in

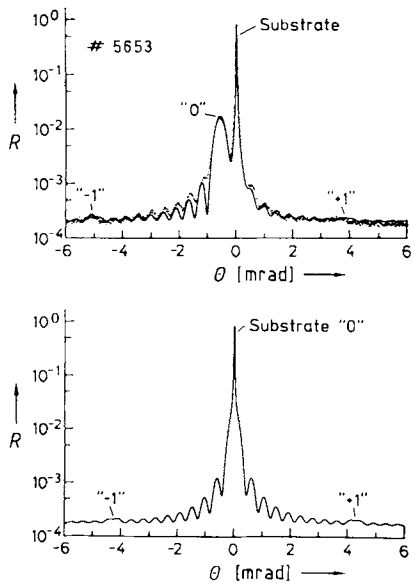

Fig. 12. X-ray diffraction curves of $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$ superlattices on InP substrate taken in the vicinity of the (004) reflection with $Cu_{K\alpha 1}$ radiation. strained-layer superlattices. However, when the lattice strain of the constituent $Ga_xIn_{1-x}As$ and $Al_xIn_{1-x}As$ layers are of the same magnitude, the satellite peaks also exhibit a weak intensity (see Fig. 12 (top) and Table 3).

3.3. Luminescence and Absorption Spectroscopy

For many III-V semiconductors the specific optical properties[12] play an important role for their application in optoelectronic devices. Methods to evaluate these optical properties are thus ideally also employed for a detailed characterization of microscopically structured solids composed of these materials. The measurement of the luminescence energy of bound excitons (electron-hole pair) $E_0(x)$ in the ternary $Al_xGa_{1-x}As$ alloy at 4 K, which shifts to higher energy with increasing x according to

$$E_0(x) = 1.515\ \text{eV} + x(1.247\ \text{eV}) \quad [\text{for } 0 < x < 0.45] \tag{2}$$

has for long been used to determine the Al content (in GaAs, i.e. $x = 0$, the temperature dependent band gap decreases from 1.515 eV at 4 K to 1.424 eV at 300 K). In the introduction we have already pointed out that the confinement of electrons and holes in the GaAs quantum wells gives rise to the existence of distinct energy levels (sub- or mini-bands) in the conduction and valence bands. The energy spacing between the sub-bands in the conduction and valence bands determines the spectral (energy) position of the light emission (photo- and electroluminescence) and the optical absorption characteristics.[13] In Figure 13a we show schematically the process to create electron-hole pairs by the absorption of photons and the recombination mechanism of electrons and holes, which results in light emission (luminescence). The energy position of the sub-bands depends primarily on the width (thickness) L_z and to a lesser extent on the depth V_0 of the quantum well. The energy for the confinement of electrons, i.e. the spacing between the bottom of the conduction band and the n-th sub-band, assuming infinitely deep wells is to a first approximation given by[13]

$$E_n = (n^2 \pi \hbar^2)/(2 m_e^* L_z^2) \tag{3}$$

with m_e^* = effective mass of conducting electrons[*] and $\hbar$ = Planck's constant divided by 2π. (For more accurate calculations the finite depth of the quantum well has to be taken into account. The allowed sub-bands for the electrons and holes are then given by solutions of the Schrödinger equation normalized by the boundary condition that the wave functions and their derivatives are continuous at the $GaAs/Al_xGa_{1-x}As$ interface.) From Equation (3) it follows that the energy spacing between the allowed sub-band and the band edge is directly proportional to $1/L_z^2$. Consequently, the "optical" band gap which is relevant for luminescence depends primarily on the width of the GaAs quantum well; it becomes larger when the quantum well becomes narrower. This expectation is confirmed

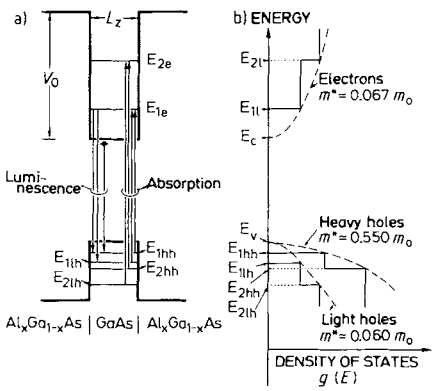

Fig. 13. Schematic illustration of (a) radiative electron-hole transitions during emission or absorption of light in a GaAs quantum well and (b) energy dependence of the density of states $g(E)$ in a homogeneous semiconductor (dotted line) and in a quantum well (solid line).

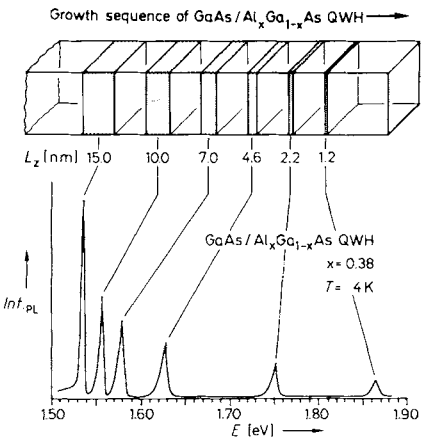

Fig. 14. Photoluminescence spectra of GaAs quantum wells of different well widths L_z. With decreasing well width a strong blue-shift (i.e. to higher energy) of the luminescence is observed. Int. = intensity in arbitrary units.

[*] In semiconductors m_e^* is used instead of the electron mass m_e to account for the influence of the crystal lattice on the conduction electrons ("effective mass approach").

by the photoluminescence measurements on GaAs quantum wells of different widths, the results of which are shown in Figure 14. The luminescence energy $(\hbar\omega)_{PL}$ is given by the energy of the transition between the n=1 electron sub-band E_{1e} and the n=1 heavy-hole sub-band E_{1hh} minus the exciton binding energy E_{ex},[51] according to

$$(\hbar\omega)_{PL} = E_g + E_{1e} + E_{1hh} - E_{ex} \quad (4)$$

(E_g = band-gap energy of GaAs). When the photoluminescence measurements are performed at low temperatures (4 K), also the phenomena arising from defects and impurities and the influence of the interface "roughness" can be studied in detail. The origin of the interface roughness are the 2D growth islands with a height of one monolayer ($a_0/2 = 0.283$ nm) discussed before, which have different lateral extensions. As shown schematically in Figure 15, these islands give rise to different widths of the quantum wells and consequently to different luminescence ener-

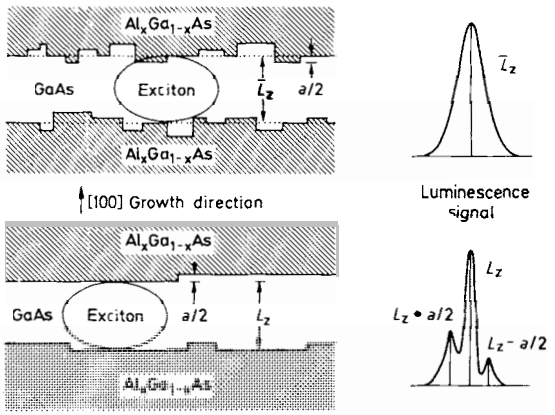

Fig. 15. Influence of the different lateral size of the 2D growth islands at the GaAs/$Al_xGa_{1-x}As$ interface on the effective width L_z of the quantum well and on the localization of excitons.

gies.[52] When the lateral extension W of the growth islands is larger than twice the Bohr radius of the exciton a_B, i.e. $2a_B$ larger than 30 nm (see also Section 4.2), then several peaks appear in the photoluminescence spectrum at different energies corresponding to the distinct islands. However, when W becomes less than $2a_B$ for smaller growth islands, then the exciton "senses" different widths of the quantum well and a spectral broadening $\Delta(\hbar\omega)_{PL}$ of the luminescence occurs,[53] given by

$$\Delta(\hbar\omega)_{PL} = (\hbar^2/m_e^*)(\Delta L_z/L_z^3) \quad (5)$$

In the experiments an increase of the linewidth with decreasing width of the GaAs quantum well was observed, because the relative influence of growth islands of constant height ($a_0/2 = 0.283$ nm) becomes larger. This undesired roughness caused by the small islands ($W < 2a_B$) can be reduced quite markedly by the interruption of growth at the interfaces.[52] Also an enhancement of the surface migration of the Group III elements results in an expansion of the larger islands at the expense of the smaller ones. This discussion emphasizes the importance of actuating the shutters of the effusion cells always at the maximum of the RHEED intensity oscillations.

In the photoluminescence spectra one generally observes electron-hole transitions only between the lowest sub-bands E_{1e} and E_{1hh} (or E_{1lh}, resp.), because the injected carriers relax extremely fast to these levels. Higher sub-band transitions, on the other hand, can be best observed by optical absorption measurements (see Fig. 13a). The absorption spectra of a $Ga_{0.47}In_{0.53}As/Al_{0.48}In_{0.52}As$ superlattice taken at 4 K and at 300 K are shown in Figure 16.[54] The steplike behavior of the absorption coefficient

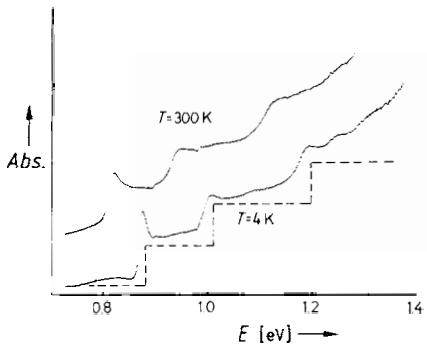

Fig. 16. Absorption spectra of a $Ga_{0.47}In_{0.53}As/Al_{0.48}In_{0.52}As$ superlattice taken at 4 K and 300 K. The dotted line indicates the steplike behavior of the two-dimensional density of states $g(E)$. Abs. = absorption in arbitrary units (logarithmic scale).

as a function of energy is clearly seen. It is caused by the modified density of states in quasi-2D systems. In addition, the absorption edge is shifted by a few meV to lower energies, and distinct excitonic absorption peaks appear (see also Section 4.1.2). For the radiative electron-hole transitions between the higher sub-band levels the selection rule $\Delta n = 0$ holds, i.e. the quantum number n does not change.

The quantization of the wave functions for electrons and for holes in one direction (i.e. in the quantum well) also results in a distinct modification of the energy dependence of the density of states $g(E)$, i.e. the number of the allowed states per energy interval, which now assumes a steplike (staircase) form (Fig. 13b).[13] In bulk semiconductors where the minimum of the characteristic lengths is much larger than the mean free path of an electron, the $g(E)$ curve always exhibits a parabolic shape and it is equal to zero at the minimum energy, i.e. at the band edge. In the case of semiconductor crystals consisting of different elements only the curvature of the parabolic $g(E)$ curve changes. In contrast to bulk material, the steplike $g(E)$ curve of quasi-2D systems has a finite non-zero value of the density of states even at the minimum energy. In addition, the distinct shape of the steplike curve can be adjusted ("tailored") by appropriate choice of the well width L_z and the potential barrier V_0. The artificial arrangement of the constituent atoms leads to a completely different shape of the $g(E)$ curve even for materials made of the most familiar semiconductor crystals, like GaAs and AlAs. To the concept of band-gap engineering mentioned in the introduction we can now add the concept of density-of-states modification. Inspection of Figure 13b further re-

veals that the size quantization also lifts the degeneracy of the light and the heavy holes in GaAs, i.e. two bound states E_{nhh} and E_{nlh} with different energies exist in quantum wells.[13]

For the measurements of the optical absorption of epitaxial layers the substrate must either be a transparent substrate, as is the case for InP in $Ga_{0.47}In_{0.53}As/Al_{0.48}In_{0.52}As$ superlattices,[54] or it must be removed by selective etching, as in the case of the GaAs substrate used to deposit $GaAs/Al_xGa_{1-x}As$ superlattices.[13] The selective removal of the substrate is difficult, and during this treatment strain can be induced in the epitaxial layers. Therefore, instead of absorption measurements, photoluminescence excitation measurements are now frequently used to acquire information on the excitonic resonances and on the energy dependence of the density of states. In this technique the luminescence intensity is measured at a fixed energy (wavelength) while the exciting laser energy is varied across the energy range of interest. Figure 17 shows such a photoluminescence excitation spectrum of a GaAs double quantum well structure. The transitions to higher subbands, which are also observable in the absorption spectrum, are clearly seen.

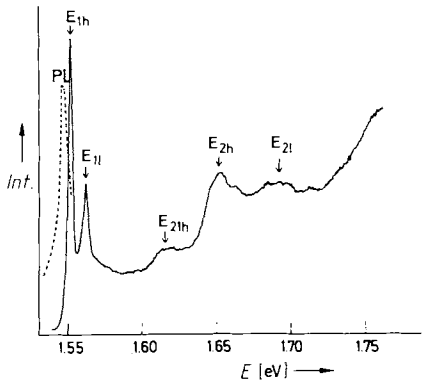

Fig. 17. Photoluminescence excitation spectrum of a 9-nm wide GaAs quantum well taken at 4 K. The dotted curve indicates the position of the photoluminescence line. Int. = luminescence intensity in arbitrary units.

3.4. Hall Effect Measurements

The feasibility of doping semiconductors intentionally with donors (to create free electrons) and with acceptors (to create free holes) and thus to form p/n junctions (or diodes) within a crystal is one of the most important basic requirements for the technical applications of these materials. The measurement of the conductivity (or resistivity, respectively) and of the Hall effect are the most important methods for determining the concentration, the mobility, and the carrier type (electrons or holes) in a semiconductor thin film. When free carriers passing through a crystal are subject to a transverse magnetic field,a phenomenon called the Hall effect appears.[55] Under these conditions an electric field is produced whose direction is perpendicular to the current direction and to the magnetic field vector. The transverse or "Hall" voltage V_H induced by the electric field is proportional to the current I and the magnetic field $\boldsymbol{B}$ and inversely proportional to the thickness of the sample d, as given in equation (6).

$$V_H = R_H \frac{I \cdot \boldsymbol{B}}{d} \tag{6}$$

The proportionality factor R_H, denoted Hall constant or Hall coefficient, is given by

$$R_H = \frac{1}{ne} \tag{7}$$

where e is the electronic charge (negative sign) and n is the electron (carrier) concentration per cm^3. An analogous relation holds for the holes.

Measurement of the Hall coefficient R_H enables determination of the carrier concentration n, which represents a characteristic quantity of semiconducting materials. When electrons as well as holes contribute to the carrier transport in the sample, the Hall coefficient depends also on the respective mobilities. The mobility μ is the proportionality factor in the relation between the drift velocity v of electrons (or holes) in a semiconducting crystal and an applied external electric field $\boldsymbol{E}$. As long as the average drift velocity is small compared to the thermal velocity, the simple relation

$$|\vec{v}| = \mu |\vec{E}| \tag{8}$$

is valid.

The Hall coefficient and the conductivity (or resistivity, respectively) of semiconducting thin films are measured by a method developed by *van der Pauw*.[56] The reciprocal of the mobility determined in this way is a direct measure of the retardation of the free-carrier drift by the influence of the crystal lattice. At low temperatures the scattering of electrons (holes) by ionized donors (acceptors) and by lattice imperfections, such as dislocations, grain boundaries, interstitials, etc., dominates. At higher temperatures, e.g. at room temperature, numerous lattice vibrations are excited so that a strong scattering by lattice vibrations ("phonons") is added to this. The various scattering mechanisms exhibit a different temperature dependence.[57] Further-

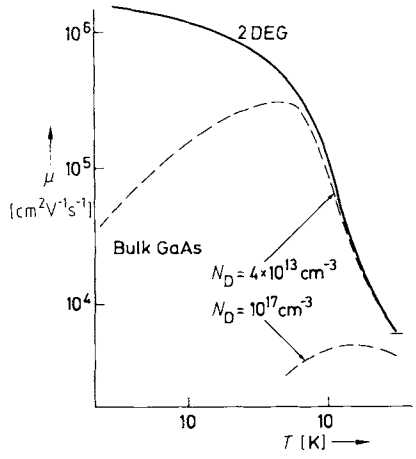

Fig. 18. Dependence of electron mobility on temperature for three different sample configurations determined by Hall effect measurements. The distinct behaviour of each curve indicates a different influence of the various scattering mechanisms in the samples. 2DEG = two-dimensional electron gas. N_D = concentration of dopant atoms.

more, electrons and holes behave differently in the various scattering processes. As a consequence, we often observe a complicated relationship between mobility and sample temperature. Figure 18 shows the dependence of the electron mobility on temperature for three different sample configurations. The highest mobility at low temperatures is obtained from a microscopically structured selectively doped GaAs/$Al_xGa_{1-x}As$ heterostructure. The layer sequence and the properties of this artificially layered structure are described in detail in Section 4.2.

4. Selected Examples for Microscopical Structuring Normal to the Crystal Surface

In the original concept of semiconductor superlattices[10] *Esaki* and *Tsu* in particular elaborated the theoretical possibilities of a carrier transport *perpendicular* to the constituent layers. They proposed the existence of extremely fast so-called Bloch oscillations due to Bragg reflections at the boundaries of the mini Brillouin zone and predicted a negative dynamic conductivity associated with the transfer of electrons into regions of negative mass of the mini Brillouin zone. As yet, however, the Bloch oscillations have never been observed experimentally and today it is anticipated that at the high electric fields required intersubband transitions of the electrons rather than Bragg reflections will occur.[58] A negative differential resistance in the current-voltage characteristics perpendicular to the layers can also be obtained from semiconductor superlattices with thicker barriers owing to "resonant" tunneling phenomena of electrons between adjacent quantum wells. This process requires matching of the energies of the ground state (first sub-band) and of the excited state (second sub-band) in the next well at a certain value of the applied external electric field, i.e. the sub-band levels are in "resonance" (see Fig. 19a for illustration). The first experiments related to this phenomenon, performed in the early seventies,[59] were not unequivocal, because at that time the material quality of the artificially layered structures did not meet the requirements. In particular, the fluctuations of the layer thickness within each quantum well, which are due to the growth islands of monolayer height discussed in Section 3.3 (see also Fig. 15), resulted in fluctuations of the sub-band energy levels of the quantum wells as well as in a destruction of the coherence between the interfering electron waves reflected at the two interfaces. Therefore, fifteen years ago other intriguing properties of the periodically layered semiconductor structures came into the forefront which had not been discussed in the original concept, i.e. the optical (excitonic) properties and the carrier transport parallel to the constituent layers (quasi-2D electron and hole systems). The microscopically structured semiconductors used for the investigation and device application of these phenomena are in general comprised of one or more quantum wells which are isolated from each other by rather thick (>5 nm) barriers. Theoretical calculations have shown that to a good approximation these multiquantum well heterostructures can be treated as if each constituent layer contributes its characteristic electronic properties to the entire system.[60]

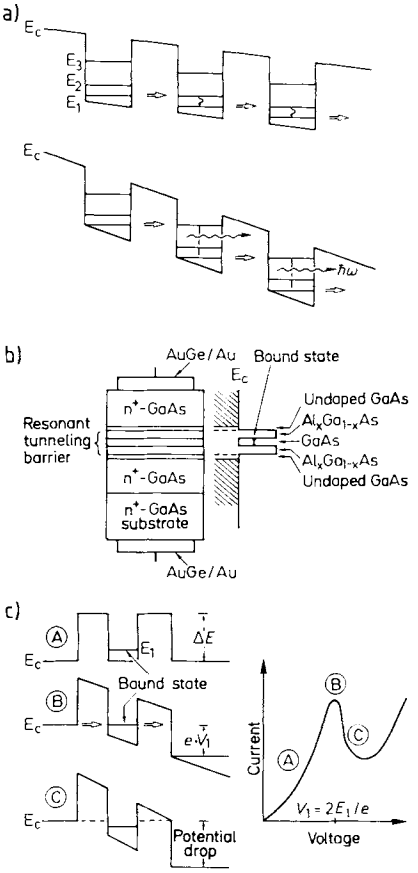

Fig. 19. Schematic illustration of resonant tunneling (i.e. vertical transport perpendicular to the layers) of electrons in GaAs/$Al_xGa_{1-x}As$ superlattices and quantum wells. a) Sequential resonant tunneling in a superlattice occurring when the potential drop across a superlattice period is equal to the energy spacing between a first excited state and ground state or between second excited state and ground state. b) Schematic layer sequence of GaAs/$Al_xGa_{1-x}As$ double-barrier diode for investigating resonant tunneling. c) Process of resonant tunneling in the double-barrier diode and plot of the measured current-voltage characteristics (not to scale).

Before some selected examples for the exciting optical and electrical properties of quasi-2D electron systems will be presented, ist should be pointed out that in the last five years the improvement of the crucial interface quality has inspired a revival of investigations related to resonant tunneling phenomena in microscopically structures semiconductors.[61] The double-barrier structures schematically depicted in Figure 19b are particularly promising for application of the resonant tunneling effect in microwave devices with extremely high switching frequencies. The operating principle of these resonant-tunneling diodes follows directly from the illustrations of Figure 19c. Electrons can tunnel through the double barrier only when the potential (Fermi) energy of the injecting (left) side coincides (is in resonance) with the sub-band energy E_{1e} in the quantum well between the two $Al_xGa_{1-x}As$ barriers by applying an external voltage. The resonant transmission of electrons gives rise to a current maximum in the I/V characteristics at an external voltage of $V = 2E_1e^{-1}$ (the applied voltage is split into two equal voltage drops at each barrier). When the applied voltage is further increased, the current drops steeply ("negative differential resistance"), since the extremely sharp resonance condition is detuned. The potential successful operation of microwave diodes based on the

resonant tunneling effect even at room temperature, imposes stringent requirements, upon the interface quality which can be met only by the application of RHEED intensity oscillation features combined with growth interruption during the spatially resolved synthesis of materials by molecular beam epitaxy.[62] This procedure makes feasible the fabrication of amplifiers and oscillators operating in the submillimeter range with a response time of less than 10^{-13} s. The frequency limit of these diodes is given by the electron tunneling time of $\tau \approx 10^{-13}$ s, which in turn derives from the ultimate limit of the uncertainty relation according to $\tau \leq \hbar/\Delta E$ (ΔE = energy broadening of the tunneling state).

4.1. Optical (Excitonic) Properties of Quasi-2D Electron and Hole Systems

4.1.1. Quantum Well Heterostructure Lasers

In conventional $GaAs/Al_xGa_{1-x}As$ double-heterostructure lasers having a 0.1–0.2 μm thick active layer the energy of the emitted laser light is primarily determined by the band gap of the material forming the active layer ($\simeq 1.42$ eV for GaAs at 300 K).[12] In addition, impurities (or dopants, respectively) of the GaAs layer significantly affect the light emission. The emission energy is always slightly reduced as compared to the band-gap energy, because this "extrinsic" luminescence dominates in doped material. The radiative electron-hole transitions responsible for luminescence change their nature drastically when the thickness of the active GaAs layer is reduced to below 30 nm. At these dimensions the formation of quantum wells with sub-bands for electrons and for holes commences (see Fig. 13). The electrons and holes can still move freely along the layers (i.e. in x- and y-direction), while perpendicular to the layers the impulse, the energy, and the wave function are quantized. It has already been shown in Section 3.3 that under normal excitation conditions the luminescence in these quasi-2D systems is given by the radiative recombination of electrons populating the lowest conduction sub-band E_{1e} with heavy holes populating the uppermost valence sub-band E_{1hh} (transitions from higher populated sub-bands retaining the quantum number selection rules of $\Delta n = 0$ are observable only under high excitation conditions). As a consequence, this "intrinsic" luminescence dominates in (undoped) quantum wells. Since the energy of the sub-bands for electrons and for holes depends primarily on L_z [see Eq. (3)], we have the possibility of adjusting the energy of the emitted light arbitrarily between 1.42 eV (for GaAs) and approximately the band-gap energy of the $Al_xGa_{1-x}As$ barriers (or cladding layers) by matching the appropriate choice of the well width during MBE growth, which is a simple geometric parameter (see Fig. 14).

In addition to the adjustable (or tunable) wavelength of the emitted light, the strongly modified density of states $g(E)$ of these quasi-2D systems was the other important motivation for the development of quantum well laser structures whose layer sequence is schematically shown in Figure 20a. Depending on the requirements for the performance of the laser diode, different configurations of the

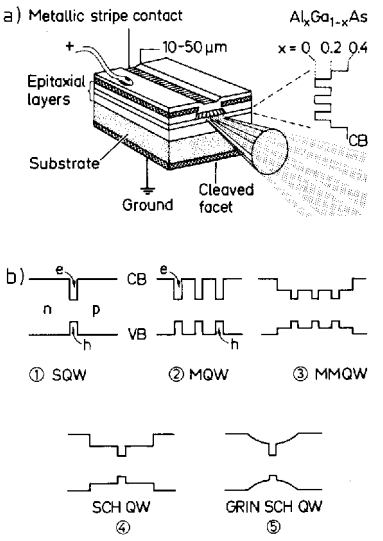

Fig. 20. Schematic layer sequence of quantum well heterostructure laser. a) Layer sequence of a modified multi quantum well (MMQW) laser and real-space energy band diagram. b) Various configurations (layer sequences) of the active region of quantum well lasers illustrated by means of the distinct real-space energy band diagrams (QW = quantum well, MQW = multi QW, SCH QW = separate confinement heterostructure QW, GRIN SCH QW = graded index separate confinement heterostructure QW).

active region are chosen (see Fig. 20b), which result in a modification of the electrical and optical confinement of the injected carriers and of the light, respectively. The simultaneous electrical and optical confinement is only possible because of the reciprocal behavior of direct band gap and refractive index in these semiconductors. However, single quantum wells often do not provide sufficient optical confinement for operation of the laser. Therefore, in the so-called separate confinement heterostructures (SCH), a separate electrical (in the quantum well) and optical confinement (in the superimposed double heterostructure) is accomplished (see Fig. 20b).

The general advantages of quantum well heterostructure lasers can be summarized as follows:[63]

1. The steplike energy dependence of the density of states $g(E)$ in quasi-2D systems gives rise to a narrow bandwidth of the optical gain and a high peak value as compared to the parabolic $g(E)$ behavior in conventional 3D systems. The population inversion required for laser operation is thus achieved at a much lower driving current, and threshold current densities can be obtained which are three to five times lower than in conventional lasers.[14]
2. The characteristic temperature T_0, which is a criterion for the temperature sensitivity of the threshold current I, has a much higher value.[64] The temperature dependence of the threshold current for semiconductor lasers is given by the empirical relation

$$I = I_0 \exp(T/T_0) \tag{9}$$

The steplike function of the density of states $g(E)$ leads to a reduced sensitivity of the energy distribution of the carriers. The resulting decreased temperature sensitivity of the emission wavelength is of particular importance

for $Ga_xIn_{1-x}P_yAs_{1-y}/InP$ and $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$ lasers which operate in the long-wavelength range of 1.3–1.65 μm.

3. The quantum well lasers oscillate more easily in a single longitudinal mode (single wavelength oscillation). The device can thus be operated under direct current modulation up to a very high frequency limit, i.e. at very high bit rates.[65]
4. Quantum well lasers are especially well suited for monolithic integration with other active and passive components on a common substrate,[66] since the absorption coefficient of the non-excited part of the quantum well structure is three to five times lower at the wavelength of the emitted laser light than in conventional laser structures.

At present the best characteristics for GaAs laser diodes are achieved with the parabolic shape of the band edges depicted in Figure 20b ⑤. The parabolic shape is obtained by an appropriate grading of the Al concentration in the $Al_xGa_{1-x}As$ barriers. These so-called GRIN SCH (derived from "*Gr*aded *In*dex *S*eparate *C*onfinement *H*eterostructure) lasers can be operated with threshold current densities as low as 150 A/cm^2.[67] The accurately controlled variation of the composition and of the doping as a function of layer thickness to obtain the symmetric parabolic shape of conduction and valence band edges in these GRIN SCH structures imposes stringent requirements on the spatially resolved materials synthesis.

The wavelength range of minimum optical loss in glass fibers has been shifted from previously 0.85 μm via 1.3 μm to 1.55 μm today. Therefore laser diodes made of $Ga_xIn_{1-x}P_yAs_{1-y}/InP$ and $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$ lattice-matched to InP substrate as well as $GaSb/Al_xGa_{1-x}Sb$ are now used for optical communication systems designed for long distances. The composition of the ternary and quaternary materials and the widths of the quantum wells have to be adjusted accurately such that the lasers emit in the desired wavelength range. The field of application of GaAs quantum well laser diodes is shifting more and more to optical data storage and processing as well as to information transmission and processing in local networks (including computer networks).

4.1.2. *Excitonic Phenomena*

An important consequence of the confinement of electrons and holes is that the excitonic effects have a distinct impact on the optical properties of these microscopically structured semiconductors.[51,68] Excitons are bound electron-hole pairs with a small binding energy, e.g. 4 meV in GaAs; they are created during the absorption of photons. In most homogeneous materials the "fragile" excitons are therefore observable only at low temperatures. The confinement of excitons in quantum wells prevents any dissociation induced by thermal energy, so that excitonic phenomena become observable even at and above room temperature.[69] These effects are now exploited in novel optoelectronic and photonic devices. The enhancement of the binding energy associated with the confinement of the excitons can be understood from the illustrations depicted in Figure 21. The 3D exciton in GaAs has a Bohr radius of about 14 nm. In a quantum well with a width of less than 28 nm the exciton has to shrink and it is squeezed into an elliptic form to fit to the well. The increased interaction between electron and hole induced by the confinement results in an increase of the exciton binding energy by a factor of four in a 5-nm wide GaAs quantum well.[70] In narrower quantum wells and in short-period superlattices the exciton wave function partly penetrates the barriers. The volume of the elliptic exciton thus increases and its binding energy decreases again.

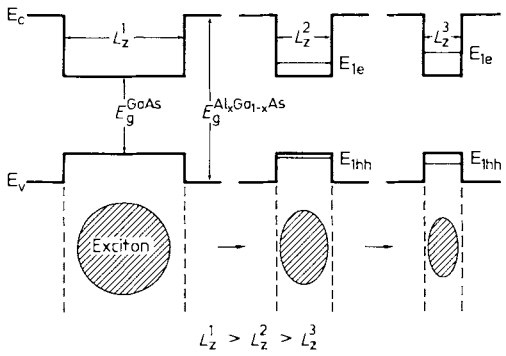

Fig. 21. Schematic illustration of the confinement of excitons in quantum wells of different widths L_z.

As a consequence of the stability of the exciton up to room temperature and higher temperatures, the semiconductor quantum wells and superlattices exhibit pronounced nonlinearities for the absorption coefficient as well as for the refractive index.[71] A saturation of the excitonic absorption is already observed at a very low intensity of the incident radiation because of the screening of the excitons by free carriers. A small increase in the incident light intensity can result in an instantaneous strong increase of the re-emitted intensity.[72] These very pronounced nonlinear optical properties make feasible the application of microscopically structured semiconductors as active elements in photonic circuits used in all-optical computers.[73]

The confinement in quantum wells makes excitons also stable against ionization in an electric field. However, when the electric field is applied perpendicular to the layers, a strong red shift (i.e. shift to lower energy) and a slight decrease in intensity of the excitonic resonances in the absorption and emission spectra is observed.[74] As shown in Figure 22, this electric field in the order of 10 mV per 10 nm (corresponding to several 10^4 V/cm) gives rise to a strong polarization of the electron and hole wave functions in opposite directions towards the interfaces. The electric field pulls the electron-hole pair apart, while the potential barriers hold the two sufficiently close together to remain bound and thus prevent ionization. The ionization can only occur when the electric field is large enough to surmount the confinement energy and the particles can tunnel out of the well.[75] It is, therefore, possible to apply fields about 50 times larger than the classical ionization field and still observe excitonic resonances. In this

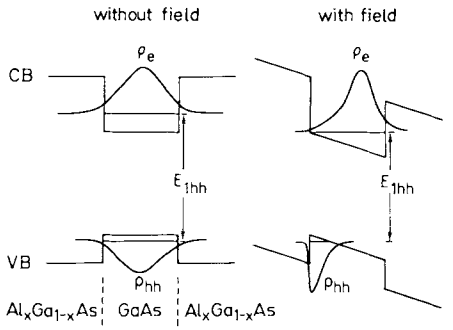

Fig. 22. Opposite polarization of electron and hole wave functions in a GaAs quantum well subject to an external electric field perpendicular to the layers. CB = conduction band edge, VB = valence band edge, ϱ_e and ϱ_{hh} = wave functions for electrons and heavy holes, respectively.

way a red shift of the absorption peak in these structures corresponding to 2.5 times the exciton binding energy is obtained even at room temperature. The pronounced optical nonlinearities and the distinct red shift of the excitonic absorption have provided a basis for the development of extremely fast (131 ps) optical modulators[76] and of self-regulating electro-optical devices (SEED, derived from *S*elf-*E*lectrooptic *E*ffect *D*evice).[77] The latter are promising for application as optical gates requiring a very low switching power, as self-linearized modulators, and as optical switching register.

The red shift of the excitonic features in microscopically structured semiconductors upon application of an electric field is observed not only in absorption but also in emission. The field-induced shift of the excitonic emission energy is particularly pronounced at low temperatures. According to the theory developed by *Brum* and *Bastard*,[78] the low-energy shift ΔE_{1e} of the lowest conduction sub-band in a perpendicular electric field of strength $\boldsymbol{E}$ is given by

$$\Delta E_{1e} \simeq \text{const}\, \boldsymbol{E}^2 L_z^4 \qquad (10)$$

i.e. it is most pronounced in wide GaAs quantum wells. This assumption is fully confirmed by the experimental results shown in Figure 23. Therefore a compromise must be found between the desired large energy shift in the electric field and the necessary confinement when choosing the width of the quantum well. An accurate analysis of the shift of the *absorption* spectra in a perpendicular electric field provides detailed information on the energy structure of the valence sub-bands. This structure is extremely complicated and at present not well understood because of the L_z-dependent partial mixing of sub-bands of heavy and light holes. The method of photocurrent spectroscopy has turned out to be extremely successful, as shown by the data in Figure 24. The observed variation of the photocurrent as a function of energy of the incident light at different electric fields yields a direct replica of the real optical absorption spectrum.[79] The change in the photocurrent can be measured with higher accuracy than the change in the absorption coefficient. The results in Figure 24 demonstrate that the quantum-number selection rules for the radiative electron-hole transitions are no longer

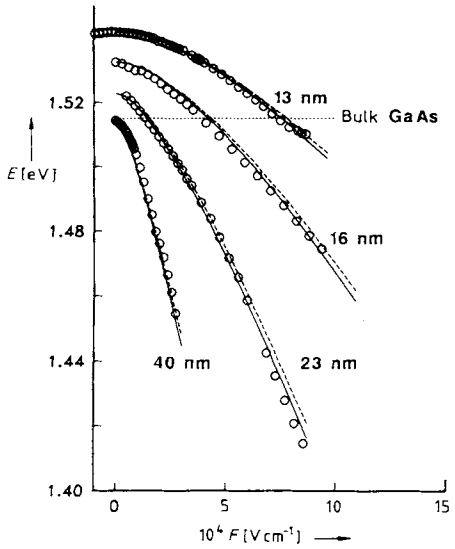

Fig. 23. Shift of the photoluminescence to lower energy (red shift) observed in GaAs quantum wells of different widths L_z subject to a perpendicular electric field. The red shift is most pronounced for the larger L_z values.

valid because of the deformation of the wave function in the electric field, and thus parity-forbidden transitions with $\Delta n \neq 0$ also become possible. These forbidden transitions, in particular, provide the unique possibility of gaining a deeper insight into the energy structure of sub-bands in quantum wells and superlattices. At the close of this section it should be pointed out that the described field-induced effect is comparable to the well-known Stark effect which is observed for atoms in an electric field. Therefore, this effect is now called the quantum confined Stark effect (QCSE).

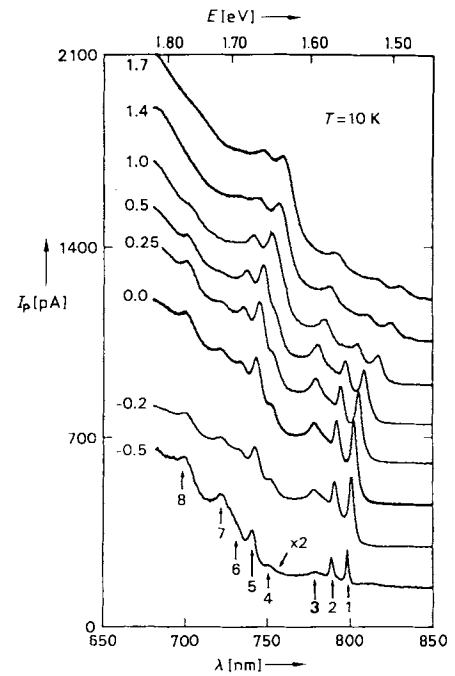

Fig. 24. Photocurrent spectra of a $GaAs/Al_{0.3}Ga_{0.7}As$ superlattice with $L_z = 8.5$ nm subject to different electric fields perpendicular to the layers. For clarity each spectrum is shifted by 150 pA on the vertical axis. At the left-hand side the individual numerical voltage values are indicated.

4.2. Spatial Separation of Free Carriers and Ionized Impurities in Selectively Doped Heterostructures

The unusual electrical properties of quasi-2D electron and hole systems were exploited in an impressive manner in the investigation of the quantum Hall effect and in the development of high electron mobility transistors, both made from selectively doped GaAs/$Al_xGa_{1-x}As$ heterostructures. The fabrication of these microscopically structured semiconductors requires that the abrupt change in composition is synchronized with the abrupt change in doping. The spatially resolved material synthesis during molecular beam epitaxy ensures that only the material with the larger band gap (here: $Al_xGa_{1-x}As$) is selectively doped with Si donors (or acceptors) in an accurately defined region and with a well defined concentration, while the material having the smaller band gap (here: GaAs) is left undoped and is of extreme purity.[80] In Figure 25 we

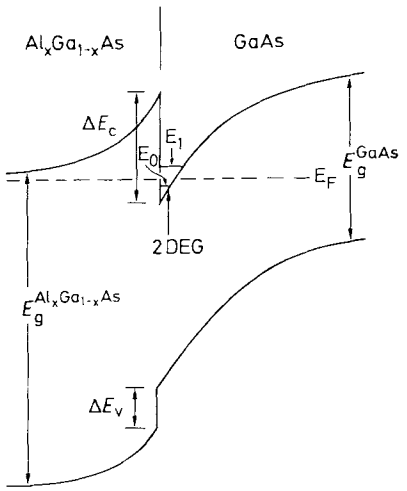

Fig. 25. Schematic plot of conduction and valence band edge in a selectively n-doped GaAs/$Al_xGa_{1-x}As$ heterostructure where only the $Al_xGa_{1-x}As$ is intentionally doped with Si donors. At the interface a quasi two-dimensional accumulation channel for electrons is formed in the GaAs.

show that in this case the free electrons arising from the shallow Si donors are transferred to the energetically more favorable conduction sub-band E_1 in the adjacent GaAs (in an analogous way the holes coming from the shallow Be acceptors would be transferred to the uppermost valence band). The n-$Al_xGa_{1-x}As$ is thus depleted at the interface, while in the GaAs close to the interface a quasi-2D accumulation channel for electrons is formed (a strong band bending towards the interface also exists of course in the GaAs). The band edge discontinuity existing at the GaAs/Al_xGa_{1-x} interface has thus led to a spatial separation of the free carriers from their parent ionized impurities confined to the n- (or p-) $Al_xGa_{1-x}As$. As a result, the ionized impurity scattering for the free carriers confined to the 2D channel in the GaAs is strongly reduced, and extremely high mobilities are observed as compared to homogeneously doped GaAs having an equivalent 3D carrier concentration of about 2×10^{17} cm^{-3}, particularly at low temperatures (see Figs. 18 and 26). But even at room temperature, where thermal phonon scattering is the dominant scattering process, selectively n-doped heterostructures exhibit an electron mobility enhanced by a factor of two.[57]

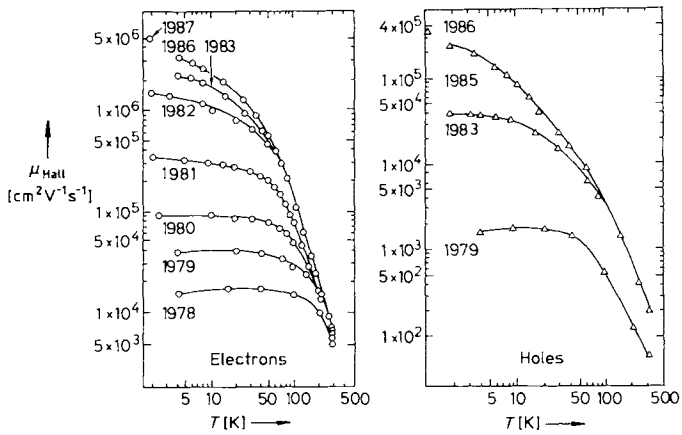

Fig. 26. Improvement of the Hall mobility of electrons (left) and of holes (right) as a function of temperature T in selectively doped GaAs/$Al_xGa_{1-x}As$ heterostructures since 1978.

In Figures 18 and 26 we demonstrate the characteristic feature of the Hall mobility μ of the 2D electron gas (2 DEG) as a function of temperature for different samples. With decreasing temperature, a very steep increase in the mobility is observed down to 77 K and then a less pronounced increase further down to liquid-He temperature (4.2 K). The sheet carrier concentrations of the 2 DEG are typically in the range $n_s=(2\text{ to }6)\times10^{11}$ cm^{-2} at 4.2 K, so that only the lowest sub-band in the triangular potential well at the interface is populated (see Fig. 25). Also the continuous increase in the carrier mobility down to very low temperatures is a characteristic feature of selectively doped heterostructures (GaAs/$Al_xGa_{1-x}As$, $Ga_xIn_{1-x}As$/InP, $Ga_xIn_{1-x}As/Al_xIn_{1-x}As$, etc.) with 2 DEG, and it is a direct consequence of the absence (or strong reduction) of scattering at ionized impurities which represents the dominant scattering process in homogeneously doped material at low temperatures. Ever since the first application of selective (or modulation) doping in heterostructures and superlattices by *Dingle* et al.[81] in 1978, every year has seen new records of electron and hole mobilities being reported (Figure 26). This continuous improvement of the carrier mobility has been achieved through taking the following measures during sample preparation:

1. The originally employed superlattice,[81] in which only the $Al_xGa_{1-x}As$ barriers were doped, was replaced by a simple heterostructure having just one heterojunction, as shown in Figure 25.
2. A thin (10–30 nm) undoped $Al_xGa_{1-x}As$ layer ("spacer") was interspersed between the interface and the doped $Al_xGa_{1-x}As$ region,[82] in order to increase the spatial separation between the free carriers in the 2D accumulation channel and their parent ionized impurities.
3. The growth conditions during molecular beam epitaxy were refined such that the residual impurity concentration of the GaAs with the 2 DEG is now in the low 10^{13} cm^{-3} range and that the GaAs/$Al_xGa_{1-x}As$ interface

is, as far as possible, free of defects.[83] When selecting the design parameters of the heterostructure (layer thicknesses, Al composition, and doping concentration) care must be taken that the $Al_xGa_{1-x}As$ layer is totally depleted and all free carriers are confined to the 2 DEG.

Inspection of Figure 26 reveals that the highest mobility achieved at present for electrons is in the order of 5×10^6 $cm^2 V^{-1} s^{-1}$. The mobilities of holes are about one order of magnitude lower because of their larger effective mass.

The selectively doped $GaAs/Al_xGa_{1-x}As$ heterostructures described above are now used worldwide in many research and development laboratories in order to fabricate electron devices having extremely high switching speeds and low power consumption (HEMT, GaAs IC)[84] and to investigate the quantum Hall effect.[3,85] The minimized devices of integrated circuits (ICs) are often based on the field-effect transistor (FET) principle, the arrangement of which is schematically shown in Figure 27. At present, there is a strong demand for shorter and shorter switching times, i.e. for higher frequency limits. The realization of short switching times requires short gate lengths ($L_G < 1$ μm) and high electron mobilities in the active channel, which exist in particular in selectively doped heterostructures. Switching speeds per gate as low as 10 ps at 300 K and 5 ps at 77 K have been obtained from test circuits (ring oscillators) equipped with two series of high electron mobility transistors (HEMTs).[86] These values are comparable to switching speeds previously only reached by the fastest switching Josephson elements which, however, had to be operated at much lower temperatures (4.2 K). The evolution of heterostructures with high-mobility holes and electrons makes feasible the application of a complementary transistor logic based on GaAs. At present the primary applications of transistors and circuits fabricated from selectively doped heterostructures are extremely fast processor units for supercomputers, extremely fast operating digital-analog and analog-digital converters, as well as low-noise analog amplifiers for microwave technology.[84] The latter ones are now commercially available from various manufacturers.

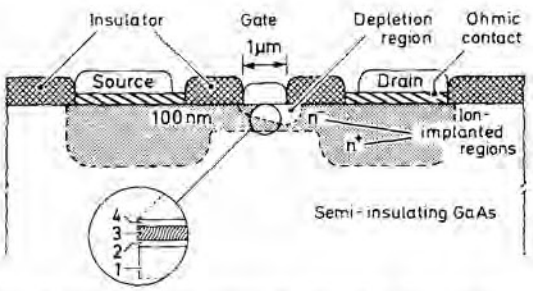

Fig. 27. Schematic configuration of a field-effect transistor ("HEMT") with the active region composed of a selectively doped $GaAs/Al_xGa_{1-x}As$ heterostructure.

The quantization of the Hall resistance in quasi-2D electron and hole systems is of great importance not only for metrology (determination of the unit of the electrical resistance and of Sommerfeld's fine structure constant, α, respectively[87]) but also for fundamental areas of experimental and theoretical solid state physics (localization, Wigner lattice, electron-electron correlation, many body effects, etc.).[3,85] A strong magnetic field ($5 < \boldsymbol{B} < 20$ T) is applied perpendicular to the 2 DEG plane at low temperatures ($T < 4.2$ K) in order to measure these macroscopic quantum phenomena. Under these conditions the electron system is completely quantized. In addition to the electrical quantization of the motion perpendicular to the interface, the magnetic quantization of the motion parallel to the interface is imposed on the carriers; this leads to the formation of the familiar Landau levels, whose energy is characterized by the Landau quantum numbers. Each Landau level can accommodate only a limited number of electrons, and this number depends only on e/h and $\boldsymbol{B}$. Macroscopic quantum phenomena, as e.g. the relative extrema in the electrical resistance of the sample, always occur under the condition that the Fermi level E_F crosses a Landau level. In selectively doped heterostructures having a constant carrier density such quantum oscillations can thus be observed when the transverse magnetic flux density (induction) $\boldsymbol{B}$ is varied continuously from 0 to 20 T. With increasing flux density the Landau levels move across the Fermi level, which on average remains constant, and we observe oscillations in the magnetoresistance (i.e. the longitudinal resistance) R_{xx} (see Fig. 28), which are known as Shubnikov-de Haas oscillations.[57] The measured Hall voltage U_H of the 2 DEG is given by $U_H = R_H I \boldsymbol{B}$ [see also Eq. (6)], where the Hall constant R_H of the 2D carrier system depends only on the (constant) carrier density and on the (constant) elementary charge. When we now introduce the Hall resistance as $R_{H,i} = M_{H,i}/I$ and measure this quantity under the condition that only a certain number i of Landau levels is completely filled, i.e. at certain $\boldsymbol{B}$ values, this gives rise to a quantization of the Hall resistance in rational fractions of (h/e^2).

Figure 28 shows characteristic plots of the magnetoresistance R_{xx} and of the Hall resistance $R_{H,i}$ measured on a selectively doped $GaAs/Al_xGa_{1-x}As$ heterostructure at a

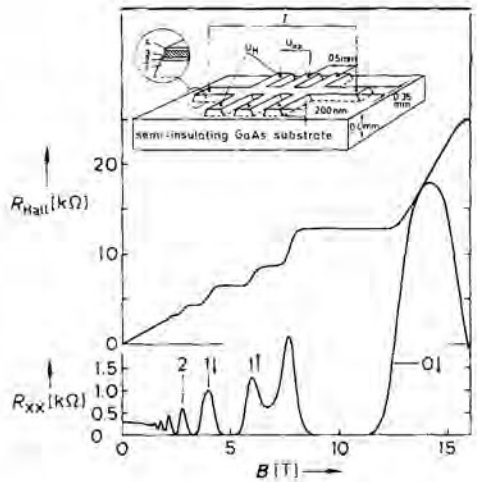

Fig. 28. Hall resistance R_H and magneto- ("longitudinal") resistance R_{xx} of a selectively doped $GaAs/Al_xGa_{1-x}As$ heterostructure as a function of the magnetic flux density $\boldsymbol{B}$. The configuration of the Hall-bar is schematically shown in the upper inset.

temperature of 1.3 K.[3] The curve of the magnetoresistance clearly displays the well-known Shubnikov-de Haas oscillations. Always when a certain number i of Landau levels is completely filled at a well defined magnetic flux density, the Fermi level E_F is just located in the range of the energy gap between two Landau levels and the conductivity σ_{xx} goes to zero with decreasing temperature (since free states in the vicinity of E_F do not exist, a scattering cannot occur). The individual Landau levels are labeled in Figure 28 by the corresponding quantum numbers n. The additional structure for $n \leq 2$ is caused by the additional spin splitting. For magnetic fluxes of $B \geq 3\,T$ the minima of the magnetoresistance are considerably broadened, and in the $R_{H,i}$ curve we observe pronounced regions (plateaus) of constant resistance. These resistance plateaus always appear at values of h/ie^2 and they are totally independent of the specific geometry of the Hall bar and on the design parameters of the heterostructure.[85] The Hall plateaus are extremely flat, and they can therefore be measured with high accuracy. The values of the rational fractions of the quantized Hall resistance are not only independent of the sample employed, but also appear at exactly the same values for many other materials. Thus, the chemical properties of the materials play only a minor role in the existence of these macroscopic quantum phenomena. The explanation for the occurrence of these plateaus is based on the assumption that localized states between the discrete Landau levels exist which are generated by defects or residual impurities in the samples.[3] As a consequence, in samples with higher electron mobility ($\mu > 2 \times 10^5$ cm^2 V^{-1} s^{-1}) the Hall plateaus are observed at lower magnetic flux densities; however, the width of the plateaus decreases drastically in these samples having a lower residual impurity concentration. For fundamental investigations of the quantum Hall effect we have recently incorporated a certain amount of impurities into the 2 DEG region of selectively doped heterostructures with a high spatial resolution.[88]

Based on the results described previously, the Physikalisch-Technische Bundesanstalt (PTB) in Braunschweig has performed precision measurements of the quantized Hall resistance.[89] An accuracy and reproducibility has been obtained for different samples which had never been reached before. The Hall resistance at the step $i = 2$ was determined as $R_{H,2} = 12906.403\ (1 \pm 2.7 \times 10^{-7})$ Ohm, from which a value of $\alpha^{-1} = 137.035992\ (1 \pm 2.7 \times 10^{-7})$ follows for the fine structure constant. During a longer measuring period a standard deviation as low as $s = 4.6 \times 10^{-8}$ was obtained for the ratio of the Hall resistance at the step $i = 2$ to a conventional reference (standard) resistor having nearly the same numerical resistance value. This extremely high precision makes feasible the application of the quantized Hall resistance as a reference resistor for the maintenance of the Ohm preserved in the various national standard laboratories.

4.3. GaAs/AlAs Monolayer Alloys

The control of spatially resolved materials synthesis by molecular beam epitaxy has now reached a standard that makes feasible the reproducible fabrication of periodically layered structures composed of III-V compound semiconductors or of group-IV-elements whose periodicities are equal to or less than the lattice constant of the components of the superlattice.[90] Figure 29 shows schematically the

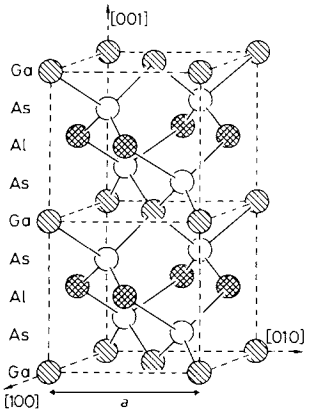

Fig. 29. Schematic arrangement of constituent atoms in a $(GaAs)_1(AlAs)_1$ superlattice ("monolayer alloy") which represents an ordered ternary alloy of composition $Al_{0.5}Ga_{0.5}As$.

arrangement of the atoms in the $(GaAs)_1(AlAs)_1$ superlattice, which is composed of alternating (001) GaAs and (001) AlAs monolayers. The $(GaAs)_1(AlAs)_1$ superlattice is therefore also called monolayer solid solution or monolayer alloy. It has the same composition as the ternary alloy $Al_{0.5}Ga_{0.5}As$ and can thus be considered as an ordered alloy.[91] The motivation for the fabrication of these $(GaAs)_m(AlAs)_n$ superlattices with $(m,n) < 5$ were careful considerations to substitute the ternary $Al_xGa_{1-x}As$ alloy, where the Al and Ga atoms are statistically distributed on the lattice sites of the Group III elements and which exhibits some detrimental structural, electrical, and optical properties. First, the $Al_{0.5}Ga_{0.5}As$ is an indirect-gap semiconductor[12] and the radiative electron-hole recombination requires the assistance of a phonon. Second, the electrical properties of n-type $Al_xGa_{1-x}As$ for $x > 0.2$ are controlled by a deep donor ("DX center") in addition to the hydrogen-like shallow donor due to the peculiar band structure of the alloy.[92] The concentration of the deep donor increases with x and it is the origin of the persistent photoconductivity effect. Third, the interface roughness for growth of binary GaAs or AlAs on the ternary alloy due to the differences in the Ga and Al surface migration yields inferior excitonic and transport properties.[43,44]

During growth of $(GaAs)_m(AlAs)_n$ superlattices with $(m,n) < 5$ by molecular beam epitaxy the growth rate and the interface formation were accurately controlled by monitoring the RHEED intensity oscillations.[90] The growth temperature was lowered to 500 °C to prevent the interdiffusion of Ga and Al across the interfaces, and the growth rate was reduced to one monolayer per 5 s to facilitate the build-up of the crystal atom by atom.[91] At each interface the growth was interrupted for 5 s to produce an atomically flat growth surface before the next monolayer was deposited. Excellent UHV conditions in the MBE system were the most crucial requirements in order to accomplish these growth parameters. The well-ordered periodic layer-by-layer arrangement of Ga and Al atoms on the ap-

propriate lattice sites in the [001] direction in the $(GaAs)_m(AlAs)_n$ superlattices with $m=n$ and $m=1$, 2, 3 manifests itself in the appearance of distinct satellite peaks around the Bragg reflections of the X-ray diffraction patterns shown in Figure 30.[91] As expected, these short-period superlattices exhibit a slight tetragonal distortion in

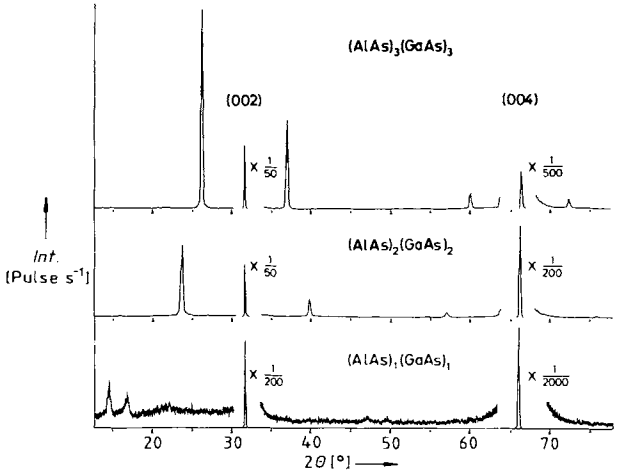

Fig. 30. X-ray diffraction patterns of three short-period $(GaAs)_m(AlAs)_m$ superlattices with $m=1$, 2, 3 taken with $Cu_{K\alpha}$ radiation.

the z-direction. The important structural parameters of the $(GaAs)_m(AlAs)_m$ superlattices compiled in Table 4 were obtained from the position of the satellite peaks and from the angular spacing $\Delta\theta_{0,S}$ between the Bragg reflection of the epitaxial layer and the substrate (not shown in Fig. 30) in a similar manner as described in Section 3.2. The results of Table 4 indicate that the periodicity of the $m=1$ superlattice is about 8% larger than the ideal value of 0.566 nm. However, this deviation does not have any influence on the unique optical properties of this sample.

Table 4. Structural properties of ultrathin-layer $(GaAs)_m(AlAs)_m$ superlattices obtained from X-ray diffraction measurements using $Cu_{K\alpha}$ radiation.

Superlattice configuration	$\Delta\theta_{0,S}$ $\times 10^{-4}$ rad (004)	Average Al content x	Satellite peak position [°] (002)		(004)		Period T [nm]	T/a
$(AlAs)_1(GaAs)_1$	−9.27	0.51	8.43	23.49	24.8		0.6117	1.08
$(AlAs)_2(GaAs)_2$	−9.27	0.51	11.83	19.87	28.45	37.88	1.135	2.01
$(AlAs)_3(GaAs)_3$	−8.81	0.49	13.73	18.55	30.25	36.73	1.714	3.03

This naturally poses the question of the actual differences in the electronic properties between these short-period $(GaAs)_m(AlAs)_n$ superlattices and the ternary $Al_{0.5}Ga_{0.5}As$ alloy having the same composition. To answer this question we have compared the photoluminescence spectra obtained from these samples; the results are compiled in Figure 31 and in Table 5.[91] The luminescence spectrum of the $Al_{0.5}Ga_{0.5}As$ alloy (indirect-gap semiconductor) consists of three bands having approximately the same intensity (the two lower energy lines arise from phonon-assisted transitions), while the $(GaAs)_m(AlAs)_m$ superlattices with $1<m<4$ exhibit only one broad line which strongly shifts in energy as a function of periodicity. It is important to note that the luminescence energy is highest at $m=3$ but then decreases significantly for $m<3$ and $m>3$. According to calculations of the bound states in quantum wells and superlattices, the low-energy shift for $m>3$ is expected, whereas the observed red shift of the luminescence from $m=3$ via $m=2$ to $m=1$ is in contrast to this simple approximation. We can no longer describe the electronic properties of these short-period superlattices with $m=1$, 2, and 3 by the simple assumption that each constituent layer contributes its characteristic properties to the whole system. The shift of the luminescence from the $(GaAs)_1(AlAs)_1$ monolayer alloy by 146 meV to lower energy as compared to the $Al_{0.52}Ga_{0.48}As$ ternary alloy clearly indicates the existence of a new artificial synthetic material. Calculations of the energy band structure of short-period superlattices thus require the treatment of the superlattice crystal as a whole. Recent theoretical calculations performed on this basis are in good agreement with our experimental luminescence results obtained from $(GaAs)_m(AlAs)_m$ superlattices with $m=1$, 2, 3, 4.[93] Also the electrical properties of the $(GaAs)_1(AlAs)_1$ monolayer alloy are possibly of special interest. A pronounced reduction in the alloy scattering is anticipated in doped samples.[94] This additional scattering mechanism results in a significant reduction of the carrier mobilities in random ternary and quaternary alloys.

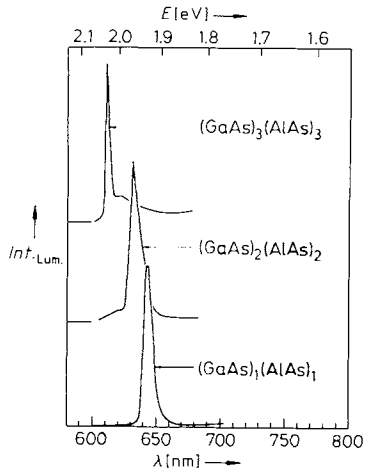

Fig. 31. Low-temperature photoluminescence spectra taken from the short-period $(GaAs)_m(AlAs)_m$ superlattices with $m=1$, 2, 3. Int.$_{Lum.}$ = luminescence intensity in arbitrary units (linear scale).

Table 5. Variation of photoluminescence peak energy as a function of period length observed in ultrathin-layer $(AlAs)_m$-$(GaAs)_m$ superlattices kept at 2 K. For comparison, the energy of the bound-exiton luminescence detected in the ternary $Al_xGa_{1-x}As$ alloy is also listed.

Superlattice configuration	Average Al content x	Luminescence peak energy [eV]
$(AlAs)_1(GaAs)_1$	0.51	1.931
$(AlAs)_2(GaAs)_2$	0.51	1.968
$(AlAs)_3(GaAs)_3$	0.49	2.033
$(AlAs)_4(GaAs)_4$	0.49	1.964
$Al_xGa_{1-x}As$ alloy	0.52	2.077

The short-period superlattices with periodicities down to monolayer alloys have been fabricated not only from lattice-matched components such as GaAs/AlAs, but also from components which exhibit considerable differences in the lattice constants, e.g. GaAs/InAs (7% lattice mismatch)[95] and Si/Ge (4% lattice mismatch).[96] In all cases, successful fabrication was accomplished by spatially resolved synthesis during molecular beam epitaxy.

4.4. Monolayer Doping in GaAs

The concept of monolayer doping, also called delta (δ) or atomic-plane doping and schematically shown in Figure 32, was originally proposed to improve the doping profiles

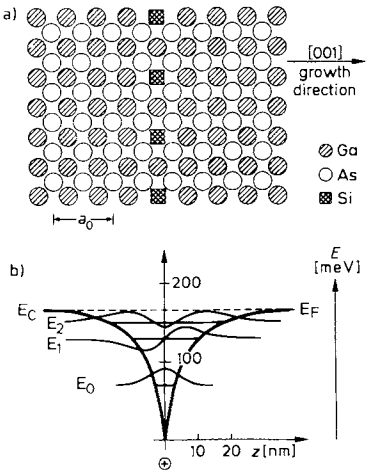

Fig. 32. a) Illustration of the concept of monolayer (delta) doping in GaAs. b) Formation of a V-shaped potential well for electrons by Si monolayer doping (not to scale).

of Ge-doped n-type GaAs layers.[97] We have employed the implementation of monolayer doping profiles with Si donors and Be acceptors in GaAs to generate symmetric, V-shaped potential wells with a quasi-2D carrier gas and to create a new sawtooth doping superlattice having a significantly reduced effective energy gap.[98] The dopant atoms are located in an atomic monolayer parallel to the surface of the (001)-oriented GaAs host material, and the ionized Si donors (or Be acceptors) provide a continuous sheet of positive (or negative) charge. The fractional occupation of the available Ga sites in the (001) plane by dopant atoms can reach several percent. The impurity charge distribution N_D can mathematically be described by the Dirac-delta function according to $N_D = N_D^{2D}\delta(z)$, where N_D^{2D} is the 2D donor concentration. The positive sheet of charge creates a V-shaped potential well. Due to the electrostatic attraction, the electrons remain close to their parent ionized donors and form a quasi-2D electron gas with quantized energy levels (sub-bands) in the narrow potential well. Direct evidence for the existence of a quasi-2D electron system was provided by magnetotransport measurements.[99]

The monolayer doping profiles were obtained during molecular beam epitaxy by interrupting the growth of the GaAs host crystal at the desired position by closing the shutter in front of the Ga effusion cell and leaving the arsenic shutter open. The shutter of the respective dopant effusion cell is opened for a certain time interval (depending on the required doping level up to several minutes). After the intended doping level has been reached, the effusion cell shutter is closed, and the crystal can continue to grow without distortion by opening of the shutter of the Ga source. When the growth temperature is kept below 550°C the distribution of the dopant atoms is indeed restricted to one (001) monolayer. In this way high doping densities of more than 1×10^{13} cm^{-2} in GaAs can easily be achieved with Si as well as with Be dopants. These high densities locally exceed the solubility limit of the respective impurities in GaAs. But nevertheless almost all donors (or acceptors) are ionized and the measured free-carrier concentrations give a realistic picture of the intentionally incorporated impurity atoms.[98] Due to the close proximity of the ionized impurities, the mobilities of the electrons (holes) confined to the V-shaped potential well are comparable to homogeneously doped material, and they are thus much lower than in the selectively doped heterostructures described in Section 4.2.

The concept of monolayer doping during molecular beam epitaxy makes feasible the spatially resolved incorporation of a sheet of electrons and/or holes confined to one lattice plane into a semiconductor crystal. For the reader it is important to note that even at a doping density of 5×10^{12} cm^{-2} not more than one out of one hundred Ga atoms on the (001) plane is replaced by an impurity atom. This explains the crucial purity requirements during growth of the epitaxial layer. We present here two examples for the application of a high-density sheet of electrons in GaAs confined to one (001) monolayer: (i) non-alloyed ohmic contacts having a low contact resistance[98] and (ii) field effect transistors (FETs) having a high transconductance.[100] When the lattice plane doped by an amount of 1×10^{13} cm^{-2} impurity atoms is located just 3 nm beneath the (001) crystal surface, the electrons (or holes) can virtually tunnel without any potential barrier between a metal electrode deposited on the surface and the quasi-2D carrier system. This arrangement thus represents an ohmic contact between the deposited metal and the underlying semiconductor, which exhibits a low specific contact resistance of less than 10^{-6} Ω cm^{-2} without the necessity of alloying (i.e. heating for a short time to 400°C in a stream of hydrogen gas). A (001) GaAs lattice plane having $N_D^{2D} = 4\text{–}6 \times 10^{12}$ cm^{-2} carriers and positioned 25 nm beneath the crystal surface can be employed as current-conducting sheet in a field-effect transistor. Detailed investigations of the HEMTs described in Section 4.2 have demonstrated that, in addition to the enhanced electron mobility, primarily the confinement of the electrons to a quasi-2D channel is responsible for the highly improved characteristics of this device. In the monolayer-doped FET (δ-FET) the electrons are confined to the V-shaped potential well and, thus, during pinch-off below the gate they cannot escape to the undoped semiconductor region. In this way, high transconductances can be achieved in this transistor. In addition, electron densities as high as 6×10^{12} cm^{-2} can be realized in the δ-FET, which are larger by a factor of three than in the HEMT. This higher electron density more than compensates for the lower electron mobility, and the δ-FET exhibits excellent device characteristics.

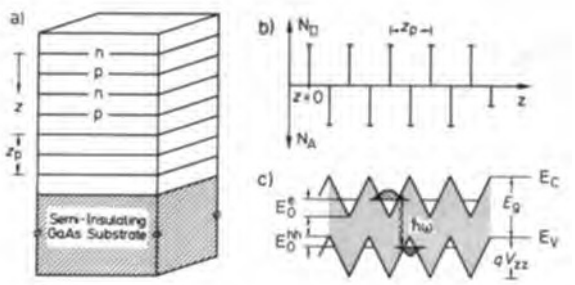

Fig. 33. a) Schematic configuration of a GaAs sawtooth doping superlattice which is composed of a periodic sequence of alternating n- and p-doped monolayers interspersed by undoped GaAs. b) Periodic variation of the doping profile in the direction of layer sequence. c) Sawtooth-shaped modulation of conduction and valence band edge. Also indicated is the radiative electron-hole recombination between the lowest electron and hole subbands.

The layer sequence of GaAs sawtooth doping superlattices is schematically shown in Figure 33a. The structure consists of a periodic sequence of alternating n- and p-type monolayers equally spaced by 5–20 nm undoped GaAs regions.[101] The doping profile (Fig. 33b) can be described by a periodic train of δ-functions. The periodic variation of the positive and negative space charge in the z-direction gives rise to a sawtooth-shaped modulation of conduction and valence band edges (Fig. 33c). In this superlattice the electron-hole recombination important for the emission of light occurs between the lowest electron and hole subbands, E_{1e} and E_{1hh}, in adjacent potential wells. The "optical" band gap given by

$$E_g^{SL} = E_g^0 - qV_z + E_{1e} + E_{1hh} \tag{11}$$

is thus *smaller* than the band gap E_g^0 of the homogeneous material. In Equation (11), q denotes the elementary charge and $V_z = \frac{1}{4}(q/\varepsilon)N^{2D}z_p$ the amplitude of the band-edge modulation (z_p = periodicity of the superlattice and ε = permittivity of the semiconductor). The effective band gap of GaAs sawtooth doping superlattices can thus be shifted by several hundred meV to lower energies by appropriate choice of the monolayer doping density and of the periodicity. We have used this effect to fabricate light emitting diodes and lasers operating in the wavelength range $\lambda > 900$ nm. As a result, we have produced a new material with accurately tailored optical properties by the spatially resolved incorporation of donor- and acceptor-rich lattice planes into a GaAs crystal.

4.5. Strained Si/Ge Superlattices

In the lattice-matched semiconductor superlattices described previously, the lattice constants of the components differ by less than 0.5%. The ordering of the energy band edges at the interfaces is therefore mainly affected by the discontinuity in electron affinity across the heterojunction. However, the strain of the constituent layers in GaSb/AlSb superlattices having a lattice mismatch of only 0.7% can already affect the ordering of the electronic bands.[12] For larger lattice mismatches the strain increases, and it can produce a complete new ordering of the energy band edges. During their investigations of superlattices made of the GaP/GaAs materials system, *Mathews* and *Blakeslee*[103] had recognized already at the beginning of the seventies that semiconductor superlattices almost free of dislocations at the interfaces can be fabricated also from components with a large lattice mismatch, if the constituent layer thicknesses do not exceed a certain critical value of, e.g. 10 nm. Under these conditions the lattice mismatch is totally accommodated by coherent elastic strain and no misfit dislocations are formed at the interfaces. The procedure to build up strained-layer superlattices is schematically shown in Figure 34. The early studies on this subject, which were almost ignored at that time, were revived again at the beginning of the eighties, and today strained-layer superlattices have become the subject of intensive investigations. As a characteristic example of strained-layer superlattices for this review paper we have selected the Si/Ge system, because it is of particular importance for device application.[104]

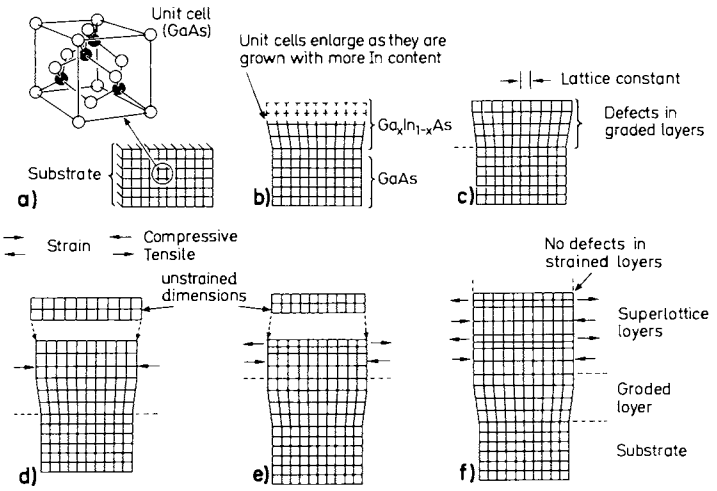

Fig. 34. Schematic illustration of the formation of strained layer superlattices, e.g. GaAs/$Ga_xIn_{1-x}As$ with $x \simeq 0.3$.

According to Vegard's law the lattice mismatch η_0 between Si and Si_xGe_{1-x} is given by $\eta_0 = (a_{SiGe} - a_{Si})/a_{Si} = 0.042x$, where a_{Si} and a_{SiGe} are the respective lattice constants. The successful fabrication of Si/Si_xGe_{1-x} superlattices over the whole composition range was accomplished only after the substrate temperature was reduced during MBE growth to below 600°C (the Si source material is evaporated by electron beam evaporation owing to the high crucible temperature required). In these experiments it has been shown that the upper critical layer thicknesses, at which the formation of misfit dislocation begins, are considerably larger than predicted by the theoretical model of *van der Merwe*.[104]

The aspect of particular importance in strained-layer superlattices is the possibility of modifying the distribution of the strain of the whole epitaxial film on the constituent layers arbitrarily by appropriate choice of the substrate or of the buffer layer (see Fig. 35 for illustration). In this manner the ordering of the conduction and valence band edges across the heterojunctions can be deliberately adjusted.[105] The tetragonal strain existing in the Si/Ge system induces a splitting of the sixfold degenerate conduc-

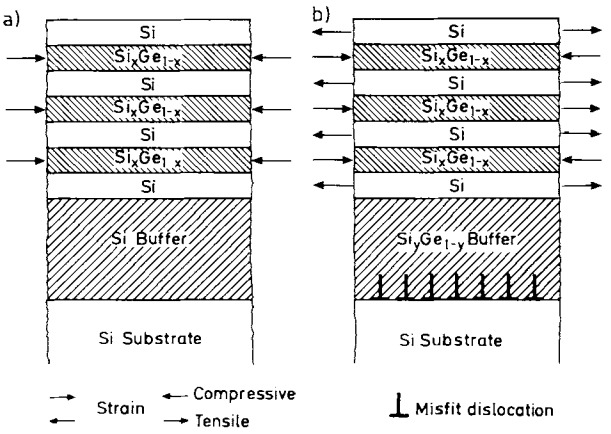

Fig. 35. Schematic illustration of the distribution of the strain of the entire epitaxial film on the constituent superlattice layers by appropriate choice of the buffer layer or of the substrate (for details see text).

tion band into twofold and fourfold degenerate valleys. When the $Si/Si_{0.5}Ge_{0.5}$ superlattice is grown on a Si substrate or buffer layer, as shown in Figure 35a, the constituent Si layers of the superlattice are not strained, whereas the constituent $Si_{0.5}Ge_{0.5}$ layers have to accommodate the total (compressive) strain. This strain, however, can be distributed symmetrically on the two constituent layers when the superlattice is grown on a thick $Si_{0.75}Ge_{0.25}$ buffer layer whose lattice constant is between that of Si and that of $Si_{0.5}Ge_{0.5}$ (see Fig. 35b). In this case the two constituent layers are strained by the same smaller amount, but in opposite directions (i.e. tensile strain in Si and compressive strain in $Si_{0.5}Ge_{0.5}$). These two possibilities of strain distribution result in a completely different position of the energy band edges relative to each other, as schematically shown in Figure 36.

It is important to note that the conduction band edge of the wider-gap material Si can be *lower* in energy than that of $Si_{0.5}Ge_{0.5}$ when a $Si_{0.75}Ge_{0.25}$ buffer layer is employed.[105] As a consequence we can obtain a quasi-2D electron gas with considerably enhanced mobility in the Si layers by selective doping of the constituent $Si_{0.5}Ge_{0.5}$

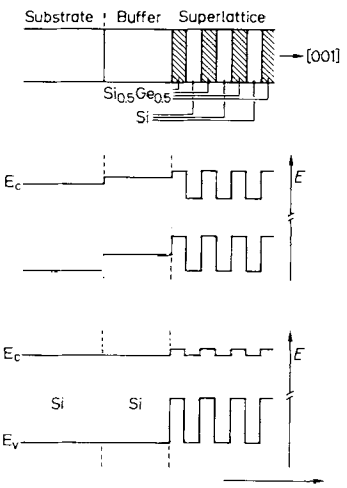

Fig. 36. Variation of the energy position of the band edges in $Si/Si_{0.5}Ge_{0.5}$ superlattices with respect to each other as a function of the distinct distribution of the total strain on the constituent layers by the selection of two different buffer layers.

layers with Sb donor impurities (Fig. 37). A selective n-type doping of the Si layers of the superlattice does not yield a mobility enhancement. On the other hand, also a quasi-2D hole gas of enhanced mobility in the Si layers can be formed by selective doping of the constituent $Si_{0.5}Ge_{0.5}$ layers with Ga acceptor impurites.[106] The significantly enhanced carrier mobilities in these selectively doped Si/Si_xGe_{1-x} superlattices are of great current interest for application in high-speed transistors which operate according to the same principle as the HEMT described in Section 4.2.

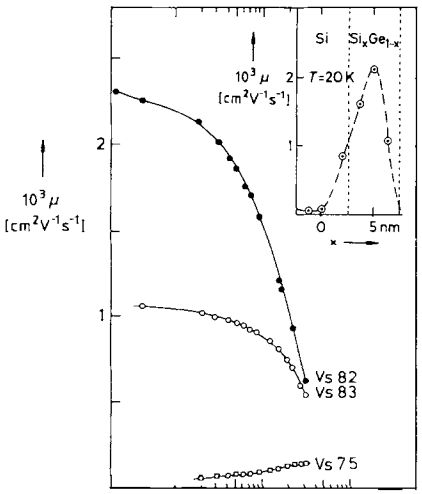

Fig. 37. Temperature dependence of the Hall mobility μ in selectively n-doped strained $Si/Si_{0.5}Ge_{0.5}$ superlattices deposited on $Si_{0.75}Ge_{0.25}$ buffer layers for three samples with different positions of the Sb dopant atoms (Vs 75: center of the Si layer, Vs 82: center of the $Si_{0.5}Ge_{0.5}$ layer, Vs 83: edge of the $Si_{0.5}Ge_{0.5}$ layer). In the upper inset the observed variation of the Hall mobility μ at 20 K as a function of the position of the Sb dopant atoms x is depicted.

In the strained-layer superlattices a structural periodic modulation exists in addition to the chemical modulation in the direction of the layer sequence. This coexistence provides a new degree of freedom to adjust the intriguing custom-tailored electronic properties of these materials. In this field we have just arrived at the very beginning of an exciting stage of development, because the possibilities of combining different materials are far more abundant than in the case of the lattice-matched materials systems.

In metallic materials systems, there are no rigid, directed covalent bonds as in semiconductors. Therefore, the constituent elements for the formation of artificial superlattices always have to be chosen very carefully such that the expected periodic modulation of the chemical composition in the growth direction remains stable at the required growth temperature. Research activities in the field of metal superlattices were very few until 1980, when *Schuller*[107] successfully fabricated a Nb/Cu superlattice. The constituent elements of this superlattice exhibit totally different crystal structures, and they show large differences in their lattice constants. The cubic body-centered Nb grows in the

[110] direction in this superlattice. Since that time the metal superlattices can roughly be devided into two groups: In group 1 superlattices, the two constituent elements have the same crystal structure and they form a continuous series of solid solutions. The periodic modulation of the composition, which is produced during growth, is intrinsically unstable. Examples include the combinations Cu/Ni, Ag/Pd, Nb/Ta, and Gd/Y. In group 2 superlattices, the two constituent elements have a different crystal structure, and their miscibility is rather limited. Therefore, the periodic modulation of the composition in the direction of layer growth exhibits a higher stability. Examples include Nb/Cu, Nb/Al, and Mo/Ni. To a first approximation, geometrical considerations can be taken into account in order to select the two constituent elements suitable for a group 2 superlattice and their orientation with respect to each other.[108] The most common situation for their orientation is that lattice planes of such orientation preferably grow one on top of the other where the packing density of atoms in the plane (atoms per nm^2) is maximized *and* similar for both elements.

Metal superlattices of group 1 have in general been fabricated by molecular beam epitaxy. Carefully synthesized monocrystalline samples, e.g. Nb/Ta superlattices[109] and Gd/Y superlattices,[110] exhibit a coherence length of several hundred nanometer in the periodic modulation, and the broadening at their interfaces amounts to only a few atomic layers. The periodicity of $(Gd)_m(Y)_n$ superlattices could be reduced to 10 atomic layers, i.e. (m, n) is equal to 5. The superlattices of group 2, on the other hand, have as yet been mainly prepared by sputtering techniques,[111] where rather high residual gas concentrations are present in the reaction chamber. It is well established that many metals are excellent getter materials for a number of residual gas constituents. However, at present, any systematic investigations on the influence of impurities on the properties of these artificial multilayer structures do not exist. It is thus most probable that in many cases incoherent periodic multilayer structures were actually obtained or that at least the coherence length was extremely small. In the field of metal superlattices further efforts with respect to preparative aspects are necessary in order to provide a more realistic basis for the numerous investigations of the structural and elastic properties as well as of the electrical and magnetic properties and their correlation to each other.

5. Final Remarks and Future Prospects

Interfaces or heterojunctions, respectively, are incorporated spatially resolved into the crystal. This leads to a microscopical structuring of semiconducting solids. The resulting local discontinuities of conduction and valence band edges provide a basis for the concept of band-gap (or wave-function, or band-structure, respectively) engineering in semiconductors. The electrical and optical properties are locally defined, and phenomena in extremely small dimensions (quantum size effects) become more important than the chemical properties of the employed materials. The microscopical structuring yields novel electronic properties in otherwise familiar semiconducting materials.

The technique of molecular beam epitaxy makes it feasible to build up crystals atom-by-atom to an extremely perfect arrangement. Based on the 2D growth mode the crystal is stacked lattice plane by lattice plane, and atomically flat surfaces are produced. The low growth rate of approximately one monolayer per second allows the accurately controlled regulation of the layer thickness down to one monolayer and the deposition of crystalline materials of arbitrary composition in alternating sheets of only a few atomic layers thick. The comparatively low growth temperature of several hundred °C prevents the interdiffusion of the constituent materials, and extremely abrupt and clean interfaces are formed. The specific advantages of this sophisticated crystal growth technique lie in the unique possibilities to structure solids arbitrarily down to atomic dimensions. In this way superlattices are created by exactly defined periodic modulation of the chemical composition perpendicular to the growth surface. An artificial periodicity in the direction of growth is superimposed on the crystal potential, which is by one or two orders larger than the natural lattice spacing.

The synthesis of periodically modulated structures by molecular beam epitaxy has opened up access to a new class of solids with accurately custom-tailored electrical, optical, magnetic, dielectric, etc. properties. The semiconductor and metal superlattices described in Section 4 constitute just the beginning. The materials combinations semiconductor/metal, semiconductor/insulator, metal/insulator, and magnetic materials having totally different properties and with as yet unpredictable potential applications will certainly follow. It is important to note, however, that in future the materials scientists (chemists) will become engaged more and more in the most profound questions of solid state physics and quantum theory. For example, for the effective prediction of the electronic properties of periodically modulated semiconductor structures, it is not sufficient to be merely aware of the bulk properties of the constituent layers; the electronic phenomena arising from the interfaces must also be understood and explicitly taken into account.

The concept of band-gap engineering is currently seeing significant extension, as evidenced, inter alia, by the first reported efforts to make the locally defined discontinuities of the energy bands adjustable or even tunable by external action. An example for the adjustability of the conduction and valence band discontinuities has already been mentioned with the strained Si/Si_xGe_{1-x} superlattices described in Section 4.5. In this case the various possibilities to distribute the total strain on the constituent layers in a locally well defined manner leads to completely different energy positions of the band edges with respect to each other. A further possibility of adjusting or tuning the band discontinuities locally arises when a fraction of or a monolayer of impurity material is epitaxially incorporated in the vicinity of or directly at the interface. This intermediate layer leads locally to a significant modification of the band discontinuities.[112] Finally, in the case of the third possibility, ultrathin ionized donor and acceptor sheets are incorporated by monolayer doping within a few nanometers of both sides of the heterojunction interface. The electrostatic potential of this double layer of ionized donors and ac-

ceptors ("dipole layer") is either added to or substracted from the potential of the band discontinuity depending on the polarity.[113] When the distance between the sheets of positive and negative charge is in the order of the de Broglie wavelength, the electrons crossing the heterointerface "experience" a new band discontinuity $\Delta E_c \pm e\Delta(\phi)$, where $\Delta\phi$ is the potential of the double layer. These new possibilities of spatially resolved band-gap engineering add a powerful degree of freedom to the investigation and separate tuning of the properties of electrons and holes in accurately defined microscopical regions. These features will certainly establish new electronic functions for electronic and photonic devices which are based on electrical and optical signal processing, respectively.

The application of molecular beam epitaxy to spatially resolved materials synthesis now makes feasible the routine fabrication of a large variety of microscopically structured solids exhibiting a (periodic) modulation in chemical composition perpendicular to the crystal surface down to atomic dimensions. In such artificially layered quasi-2D semiconductors the motion of free charge carriers is quantized within the layer plane. Theoretical considerations have indicated that quantum size effects in low-dimensional semiconductors are significantly enhanced when the dimensionality of the system is further reduced. In order to study the electronic properties of quasi-one-dimensional (1D) and zero-dimensional (OD) systems experimentally, the motion of electrons and holes has to be confined (quantized) not only to *within* the plane but also *perpendicular* to the plane, i.e. the carriers must be confined to a quantum wire or to a quantum box whose relevant dimensions are smaller than one of the characteristic lengths of the carriers. Depending on the properties to be investigated the characteristic lengths can be the de Broglie wavelength of the electron, the elastic scattering length, or the inelastic diffusion length. Although selectively doped $GaAs/Al_xGa_{1-x}As$ heterostructures with electron mobilities of 10^5–10^6 $cm^2\ V^{-1}\ s^{-1}$ at 4 K exhibit comparatively large values of 5 μm for the inelastic diffusion length and of 500 nm for the elastic scattering length, little progress was hitherto made in the fabrication of quantum wires and quantum boxes. Starting from artificially layered quasi-2D semiconductors the following two methods are now preferentially used for lateral patterning in the nanometer range:

a) Optical holography or electron beam lithography combined with reactive ion beam or plasma etching for the distinct local removal of appropriate materials.[114]
b) Selected-area (laterally defined to within a few tens of nanometers) enhanced interdiffusion in $GaAs/Al_xGa_{1-x}As$ quantum wells induced by finely focussed (<50 nm) Ga ion implantation and subsequent rapid thermal annealing.[115]

In addition, attempts are being made to achieve the supplementary confinement of carriers by application of appropriately structured substrates or arbitrarily off-axis oriented substrates during MBE growth.

With respect to the electrical properties, strongly enhanced electron mobilities have been predicted in the case of quantum wires,[116] whereas the quantum boxes should be insulating. The optical properties should also be fundamentally affected, both by the new quantum confinement of excitons and by the modified density of states [in a quantum box, $g(E)$ becomes a periodic sequence of δ-functions].[117] The energy of the sub-bands for electrons and holes, the relaxation of excited carriers, and the interaction of carriers should change drastically. The lower dimensional structures will significantly modify the formation of excitons, the localization of carriers, possible crystallization effects of the electrons, and the saturation of optical absorption. Recently, *Hirayama* et al.[115] were able to confirm the modification of the density of states and the additional quantization, respectively, by the observation of several additional lines in the photoluminescence spectra of $GaAs/Al_xGa_{1-x}As$ quantum wires.

The reproducible fabrication of microscopically structured (semiconducting) solids having quasi-1D and quasi-0D electronic properties remains one of the major challenges in spatially resolved materials synthesis and, moreover, in the entire field of microstructure materials science. Methods must be developed which will enable the removal of materials atom-by-atom or lattice plane-by-lattice plane, respectively, in well-defined spatial and geometrical arrangements without causing any damage to the crystal surface. The etching techniques developed so far are not suitable for this purpose. The necessity for the development of methods and techniques to manipulate the atoms in a crystal one-by-one (growth, removal, displacement)[118] can be justified by a few simple considerations directed far into the future. In today's most advanced commercially available semiconductor memory, the 4 Mbit DRAM (*D*ynamic *R*andom *A*ccess *M*emory), about 10^{13} Si atoms are used for a 1 bit memory cell. In the 1 Gbit DRAM, planned for the end of the nineties, about 10^{11} to 10^{12} Si atoms will be needed for the 1 bit memory. On the other hand, the recently proposed concept of molecular electronics assumes that the molecular or "bio" memory requires only about 10^3 atoms per 1 bit memory. When in the future we also have to try to adopt some important biological principles in (inorganic) semiconductor design in order to further miniaturize the information-processing circuits, the mere diminution of the physical size of materials (or linewidths) will no longer suffice. Totally different operating principles must be realized for transistors and information processing and storage by exploiting "exotic" effects. The imprinting of multifunctional atomic structures onto the (semiconducting) crystal should make it feasible to accomplish the processing of information with a definite selectivity, imitating to a certain degree the unique stereoselectivity of the large biomolecules. Microstructure materials science techniques must be developed for the fabrication and processing of these (inorganic) materials, whose "active" region is shrinking in physical size from micron to subnanometer dimensions.

In conclusion, it is must be emphasized that the aforementioned activities in the field of microstructure materials science represent important contributions to a major branch of *chemistry*. This field of research should also have its established position in the universities, and should not be left almost exclusively to the engineering and physics departments—as was often the case in the past. This

fascinating field of materials science pursues the addition or removal of appropriate materials in accurately defined geometrical and spatial arrangements; it is concerned with the microscopic mechanisms of growth or removal of atoms, ions or molecules, which is essential for developing new materials and new (alternate) processing technologies; it is concerned with the properties of metals, semiconductors, dielectrics (insulators), magnetic materials, ceramics, polymers, and their composites in restricted dimensions; and finally, it is concerned with the interfaces between these materials. With the ever decreasing physical sizes being dealt with, down to subnanometer dimensions, there should ultimately emerge an answer to the fundamental question at which size an agglomeration of a few atoms ("cluster") begins to develop the characteristic properties of crystalline solids.[119]

The author would like to thank his colleagues who were very actively committed to the development of the technique of molecular beam epitaxy and the specific field of microstructure materials science described here, including A. Fischer, H. Fronius, Dr. K. Fujiwara, M. Hauser, Dr. Y. Horikoshi, Dr. T. Isu, Dr. H. Jung, J. Knecht, Dr. H. Künzel, Dr. J. Nagle, Dr. E. F. Schubert, Dr. L. Tapfer, Dr. S. Tarucha, and Mrs. H. Willerscheid. The continuous support of the present research by Prof. Dr. A. Rabenau, Prof. Dr. H. J. Queisser, and Prof. Dr. K. von Klitzing is gratefully acknowledged. The author appreciates the preparation of the line drawings for the figures by Mrs. E. Klasmeier, the typing of the manuscript by Mrs. I. Zane, and the critical reading of the manuscript by Dr. J. Maier. Finally, the financial support of the Bundesministerium für Forschung und Technologie (BMFT) and of the Stiftung Volkswagenwerk is acknowledged. It is through their grants that the author has been able to develop his research in this area.

Microbial and Enzymatic Processes for the Production of Biologically and Chemically Useful Compounds

New Synthetic Methods (69)

By Hideaki Yamada* and Sakayu Shimizu*

In recent years, the most significant development in the field of synthetic organic chemistry has been the application of biological systems to chemical reactions. Reactions catalyzed by enzymes and enzyme systems display far greater specificities than more conventional organic reactions. Biological and/or enzymatic syntheses and transformations, that is, "microbial transformations," have great potential. Some of these reactions have already been shown to have useful applications in the fields of synthetic organic chemistry and biotechnology. This article reviews the current status of the rapidly developing field of microbial transformation, the methodology, available technological procedures, and fields of application being described especially in relation to conventional organic synthesis methods.

1. Introduction

During the last ten years, the biochemical reactions performed by microorganisms or catalyzed by enzymes have been extensively evaluated from the viewpoint of synthetic organic chemistry, and as a consequence they have been shown to have a high potential for both theoretical and practical applications to synthetic chemistry. Many attempts to utilize biological reactions for practical synthetic processes have been made; for example, for the preparation of pharmaceuticals, fine chemicals, food additives, and commodity chemicals. Such synthetic technology is called microbial transformation, or, alternatively, "microbial conversion," "biotransformation," "bioconversion," or "enzymation." It is somewhat different from so-called fermentation, another major synthetic technology based on biological reactions, and is a rapidly developing field of synthetic chemistry overlapping both organic chemistry and biochemistry.

A microbial transformation is the conversion of one substance (substrate) to another (product) by a microorganism. It is a chemical reaction catalyzed by a particular cellular enzyme or by an enzyme originally produced within cells. Most such enzymes are necessary for the normal functioning of the life processes of cellular metabolism and reproduction. In microbial transformations, however, these enzymes simply act as catalysts (biocatalysts) for chemical reactions. In addition to their natural substrates, many of these enzymes can utilize other structurally related compounds as substrates and therefore occasionally catalyze unnatural reactions upon addition of foreign substrates to the reaction medium. Thus, microbial transformation constitutes a specific category of chemical synthesis.

Numerous reviews on this topic have been published by both biotechnologists[1-8] and organic chemists.[9-15] In this review, we attempt to evaluate several important aspects of this field and to describe the most recent developments.

2. Characteristics of Enzyme Reactions Used in Microbial Transformations

As mentioned in Sections 2.1 and 2.2, microbial transformation is a technique for the synthesis or production of useful compounds which is based fundamentally on both chemical synthesis and fermentation. Therefore, the characteristics of microbial transformation somewhat overlap those of either chemical synthesis or fermentation.

2.1. Microbial Transformation versus Chemical Synthesis

Chemical reactions performed by microorganisms or catalyzed by enzymes are essentially the same as those carried out in conventional inorganic or organic chemistry. The differences in the outcome of a reaction depend on the catalyst used (see Table 1). Enzymes (or biocatalysts) used for microbial transformations increase the reaction rate by lowering the activation energy as normal catalysts do. The most striking differences between enzymes and chemical catalysts, however, lie in their substrate specificities. They catalyze specific reactions involving one or only a few structurally related compounds, distinguishing almost absolutely between stereoisomers or regioisomers. Therefore, only a very specific change in a functional group or bond of a compound is accelerated by the enzyme. As a result, a single product can be expected as long as only one enzyme is involved in a conversion.

High catalytic efficiency is another characteristic property of enzymes. For example, the rate of hydrolysis of an amide by chymotrypsin is about 4000 times higher than that for the corresponding base catalysis.[16] Enzymes increase the catalytic turnover number (moles of product per mole of enzyme per unit time) without a large energy requirement; that is, only a small amount of enzyme is needed to catalyze the conversion of a large amount of substrate. As a result, enzymes exhibit their activity under mild reaction conditions under which normal chemical catalysts hardly function at all, such as atmospheric pressure, temperatures around 20 to 40°C, and pH values near neutrality. These unique properties of enzymes are extremely useful when unstable molecules are to be converted without undesired side reactions.

Table 1. General characteristics of enzymatic and chemical reactions.

	Enzymatic reaction	Chemical reaction
Reaction conditions		
Temperature	physiological	high
Pressure	physiological	high
Source of the reaction energy	change in enzyme conformation (making and breaking of van der Waals bonds, hydrogen bonds, etc.)	thermal
Solvent	water	water, organic solvents
Specificity		
Substrate specificity	high	low
Stereospecificity	high	low
Regiospecificity	high	low
Concentration of substrate and/or product	low	high

On the other hand, these unique features occasionally make enzymes hard to use as convenient catalysts. For example, the high catalytic activity of enzymes under mild reaction conditions does not mean that they are active under drastic conditions. Indeed, under drastic reaction conditions enzymes are quite inert, whereas normal chemical catalysts often exhibit good activity. Enzymes presumably exhibit their activity *only* under mild reaction conditions because of their delicate protein structures which are maintained, for example, by van der Waals forces and a network of hydrogen bonds. The high selectivity of enzyme catalysis, which is one of the most important characteristics that make enzymes promising as catalysts in synthetic chemistry, may also be a disadvantage, because the selectivity implies limitations. For example, platinum is far superior to a reductase in its ability to reduce a wide variety of compounds.

The International Union of Biochemistry lists more than 2000 enzymes.[17] They are classified according to the reactions they catalyze. Almost all types of chemical reactions also catalyzed by normal chemical catalysts can be found. More than 800 kinds of cell-free enzymes are commercially available.[18] In some cases, therefore, one may easily find an enzyme suitable for a desired conversion.

2.2. Microbial Transformation versus Fermentation

There are two ways of using microorganisms in the production of useful compounds; microbial transformation and fermentation. Fermentation has been performed since ancient times, a good example being alcohol fermentation[19] and it is still a powerful technique for the production of such compounds as organic acids,[20] solvents,[21] antibiotics,[22] amino acids,[23] and nucleic acid-related compounds.[24] In contrast to microbial transformation, fermentation is considered to be a rather biological method, because it is a result of the actual life process of a microorganism. In other words, the product is the result of the complex metabolism of the microorganism involving inexpensive carbon and nitrogen sources. Therefore, living or growing cells are required for fermentation, and the fermentation products are always natural products.

In microbial transformations, on the other hand, it is not so important whether the cells are alive or not. The life process of a microorganism is required only for the production of enzymes and the microorganism itself is simply used as a bag of enzymes or catalysts.

Microbial transformation requires a substrate instead of the carbon and nitrogen sources required for fermentation. A simple and specific change in a substrate molecule occurs under the catalysis of an enzyme. The substrates need not necessarily be natural; unnatural substrates can also undergo a change as long as it is catalyzed by the enzyme. Therefore, not only natural products but also unnatural ones can be produced through microbial transformation.

Table 2. General characteristics of microbial transformation and fermentation.

	Microbial transformation	Fermentation
Microorganism	growing, resting, or treated cells	growing cells
Reaction	simple catalytic reaction (one or several steps)	life process (multistep reaction)
Reaction time	short	long
Starting materials	expensive substrates	inexpensive carbon and nitrogen sources
Product	natural or unnatural	natural
Product concentration	high	low
Product isolation	easy	tedious

The advantages and disadvantages of these two microbial processes are briefly summarized in Table 2. Figure 1 may be useful for imagining the essential differences between microbial transformation and fermentation. However, it is not always possible to draw a clear line between the two categories.

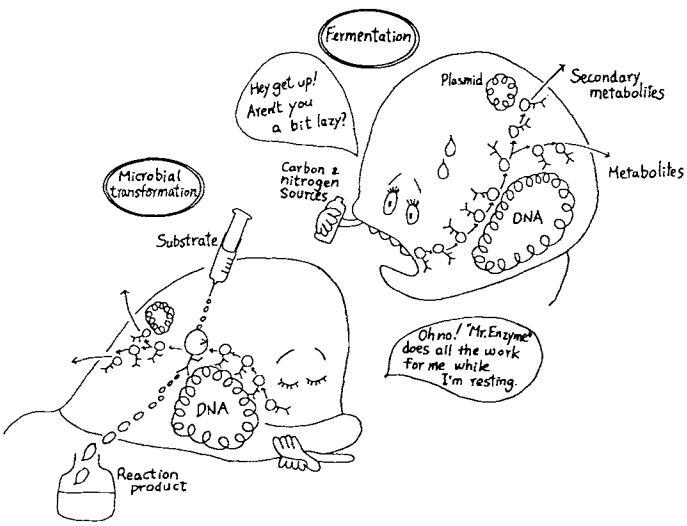

Fig. 1. Illustration of the essential differences between two microbial processes, "microbial transformation" and "fermentation."

3. Historical Background and Present Status of Microbial Transformation

Microbial transformation is an ancient art. The oldest and best known prototype is vinegar production, which has been performed since the dawn of recorded history. The process has been further developed along traditional lines of fermentation without knowledge of the underlying biochemistry. Today, the characteristic oxidation of ethanol to acetic acid by acetic acid bacteria is well understood to proceed by means of two successive dehydrogenations that depend on the cytochrome system for the transfer of electrons to atmospheric oxygen as the ultimate hydrogen acceptor:

$$C_2H_5OH + 1/2O_2 \longrightarrow CH_3CHO + H_2O$$

$$CH_3CHO + 1/2O_2 \longrightarrow CH_3COOH$$

In 1921, a microbial reaction for the stereospecific preparation of D-(−)-ephedrine was described.[25] Yeast cells, actively fermenting glucose to acetaldehyde, were found to condense added benzaldehyde with the acetaldehyde to form optically active L-1-hydroxy-1-phenyl-2-propanone. This product was in turn converted chemically into D-(−)-ephedrine. This was the first example of the successful combination of chemical and enzymatic reactions.

It was only much later, through the discovery of the specific modification of steroids by microorganisms, that microbial transformation obtained the significance it has today.[26,27] Various kinds of steroid modifications, such as hydroxylation, epoxidation, dehydrogenation, isomerization, and hydrolysis, are performed by a wide variety of microorganisms. Many of these reactions cannot be achieved by means of conventional chemical synthesis. Through these microbial reactions, many novel intermediates for the chemical synthesis of new steroid pharmaceuticals became available. In addition to their considerable practical value, the amazing versatility of microorganisms in the transformation of steroids provided an important theoretical background for the application of microbial enzymes to chemical synthesis.[28]

Thousands of microbial transformations involving different types of reactions with organic compounds and natural products are now known; some of them have proved to be very useful for synthetic organic chemistry. It should be noted that remarkable developments in the fields of biochemistry, enzymology, genetics, molecular biology, and microbial cultivation technology also have contributed significantly to the rapid development in this field.

The current technological importance of microbial transformations or enzymatic processes is well recognized in many fields of biotechnology (see Fig. 2). Modification of biologically derived complex molecules (e.g., proteins, polypeptides, lipoproteins, glycoproteins, polysaccharides, and polynucleotides) has high potential for the preparation of pharmaceuticals. For example, various kinds of peptide hormones can be prepared with proteases or peptidases[29] (see also Section 5.2). Conversion of porcine insulin to human insulin has already been commercialized[30–32] (cf. Fig. 9). Enzymatic manipulation is also indispensable for the preparation of DNA and RNA, which are used for genetic engineering.[33]

Enzymes are the best practical catalysts for the preparation of special or fine chemicals. There are many commercial processes for the production of such biological molecules as amino acids, nucleic acid-related compounds, sugars, and lipids. For example, L-alanine (aspartate β-decarboxylase),[34] L-aspartic acid (aspartase),[35] high-fructose corn syrup (glucose isomerase),[36] and 6-aminopenicillanic acid for semisynthetic penicillins (penicillin acylase)[37,38] are produced almost solely through enzymatic processes. A wide variety of chemicals used for analysis and research in clinical chemistry, biochemistry, metabolism, and pharmacology are also produced using enzymes.

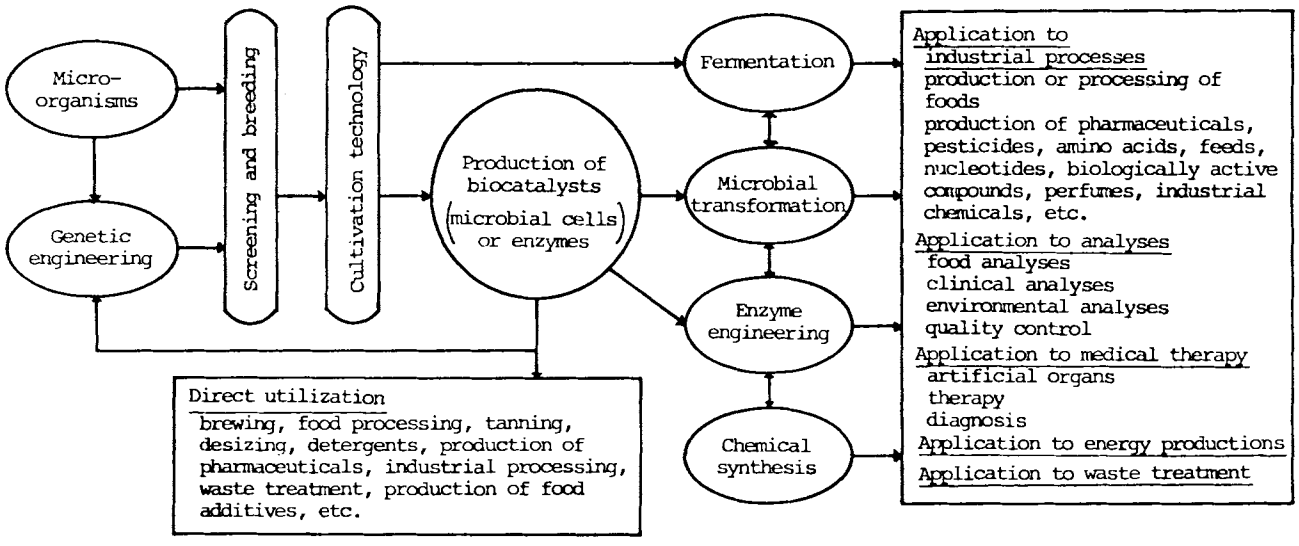

Fig. 2. Area of application of microbial enzymes, microbial transformations, and enzymatic processes in the field of biotechnology.

The production of commodity chemicals is currently one of the fast developing fields of microbial transformation. The use of enzyme reactions in practical processes has been extensively evaluated from the following viewpoints: preparation of high-purity products, energy saving, and environmental acceptability. Acrylamide is now produced commercially from acrylonitrile using nitrile hydratase[39] (see Section 5.6). Oxygenase (or haloperoxidase and halohydrin epoxidase), methanol oxidase, secondary alcohol dehydrogenase, and gallic acid decarboxylase are, respectively, suggested to be useful catalysts for the production of alkene oxides,[40] formaldehyde,[41] ketones,[42] and pyrogallol.[43]

The preparation of chiral synthons using enzyme catalysts is an area of current intense activity in organic and pharmaceutical chemistry. The practical importance of this area has been shown, for example, in the preparation of mevalonolactone,[44] carbapenem antibiotics,[45] nucleoside antibiotics,[46] insect hormones,[47] α-tocopherol,[48] and muscone.[49]

4. Process Designing in Microbial Transformation

In designing a microbial transformation process, many important aspects require careful consideration. They are summarized in Table 3. The selection of the target compound to be synthesized and a survey of available substrates and routes or reactions are especially important.

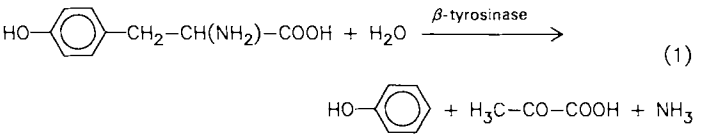
4.1. Evaluation of Enzyme Potential

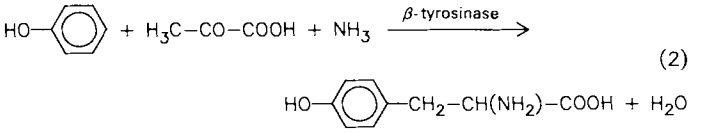
Occasionally the discovery of a new enzyme or new reaction provides a clue for the designing of a new microbial transformation process. In such a case, the first task is to determine what are the potential characteristics of the new enzyme for practical purposes. The synthetic scheme involving the enzyme or the reaction should be determined through a careful survey of the properties of the enzyme. A typical example is the application of *Achromobacter* protease I; this enzyme specifically hydrolyzes the amide bond at the carboxyl end of L-lysine residues in polypeptides.[50] Therefore, the enzyme can be used to convert porcine insulin into human insulin[31] (cf. Fig. 9).

Another interesting example is the production of L-tyrosine and L-Dopa with bacterial β-tyrosinase.[51] This enzyme had long been believed to be a simple hydrolytic enzyme that catalyzed the α,β-elimination of L-tyrosine to phenol, pyruvate, and ammonia [Eq. (1)].

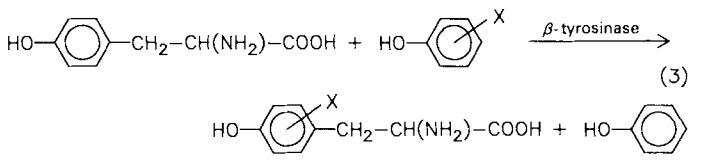


(1)

The enzyme was then found, however, to catalyze the reverse of this α,β-elimination reaction [Eq. (2)], and also the β-replacement reaction of L-tyrosine with phenol derivatives [Eq. (3)].



(2)



(3)

The application of these reactions to the synthesis of L-tyrosine and L-Dopa did not take long. Subsequently, similar reactions were found to take place under catalysis by various kinds of pyridoxal phosphate-dependent enzymes, and they were successfully applied to the synthesis of optically active aromatic and sulfur-containing amino acids[51-55] (see Section 5.1.2).

These successful examples demonstrate the importance of reassessing the capabilities of well-known enzymes or reactions.

4.2. Searching for New or Suitable Enzymes

Occasionally a synthetic scheme is outlined but the appropriate enzyme(s) or reaction(s) remain unknown. In such a case, it is necessary to search for suitable microbial strains or enzymes. The production of L-lysine from DL-α-amino-ε-caprolactam is a typical example.[56] This process was designed to utilize cyclohexene, a major by-product of nylon production. In this process (Fig. 3), the microorganism or enzyme is required to hydrolyze only the L isomer of α-amino-ε-caprolactam to yield L-lysine. Through a survey of microorganisms capable of catalyzing such a conversion, two microorganisms were found; one of

them hydrolyzes the L isomer of the substrate and the other racemizes the remaining D isomer. As a result, the racemic substrate can be stoichiometrically converted into L-lysine without any optical resolution step.

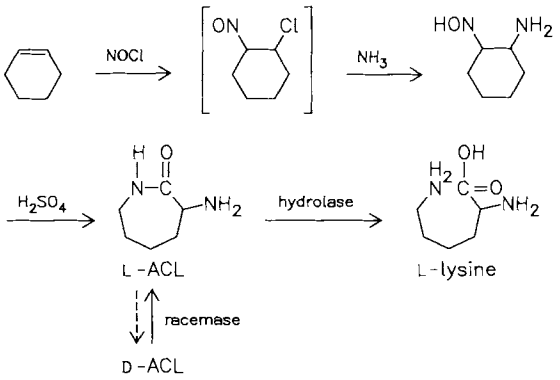


Fig. 3. Chemical and enzymatic process for L-lysine production involving stereoselective hydrolysis of α-amino-ε-caprolactam (ACL) (see text).

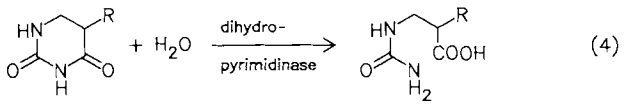
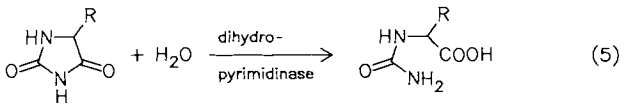
The ring-opening hydrolysis of DL 5-substituted hydantoins to yield *N*-carbamoyl-D-amino acids by dihydropyrimidinase is also an interesting example.[53,57,58] This scheme (see Fig. 6) was originally designed for the synthesis of L-methionine from the corresponding DL 5-monosubstituted hydantoin. The scheme itself is very similar to the conventional chemical process of *Bucherer* and *Steiner*[59] for the synthesis of racemic amino acids. In this case, the microorganism is again required for asymmetric hydrolysis of the racemic substrate. Surprisingly, the hydrolysis was found to occur only with the D isomers of various hydantoin compounds. The enzyme catalyzing this hydrolysis was soon revealed to be a known enzyme, dihydropyrimidinase (EC 5.3.2.2), which catalyzes the hydrolytic ring-opening of dihydropyrimidines to *N*-carbamoyl-β-amino acids. These two ring-opening hydrolyses are essentially the same, except for the size of the rings, as shown by Equations (4) and (5).



(4)



(5)

This finding was a turning point for the strategy. The target product was switched to D-*p*-hydroxyphenylglycine, which is an important intermediate in the synthesis of semisynthetic penicillins and cephalosporins. A new and efficient synthetic route was established to obtain the starting substrate, DL-5-(*p*-hydroxyphenyl)hydantoin. The final results surpassed by far the initial expectations (see Section 5.1.1 for details).

On the conversion of unnatural substrates, it is occasionally uncertain whether the desired reaction takes place or not. The usual way of testing this is by addition of the substrate to be converted to the growth or reaction medium, followed by assaying for the desired reaction products.[60,61] Such a test should be carried out for a wide variety of microorganisms for the following reasons: (1) Enzymes catalyze a variety of chemical reactions as well as chemical catalysts do. We already know of more than 2000 reactions catalyzed by enzymes;[17] some of these enzymes showed better catalysis than chemical catalysts, as seen in the examples described above. (2) There is no limitation as to the number of microorganisms to be tested in nature and they are quite different from one another. They modify or degrade a great variety of complex organic compounds, so at least one of them can be expected to catalyze the desired reaction. Figure 4 shows the diversity of microbial ability as to the reduction of ketopantoyl lactone to pantoyl lactone.[61]

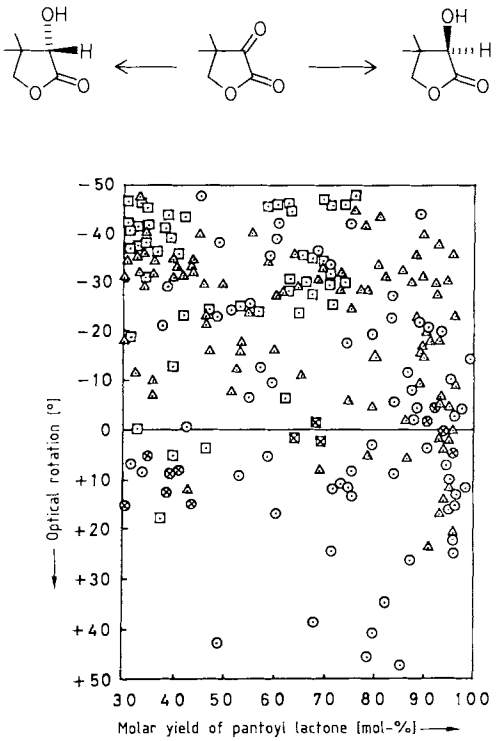


Fig. 4. Diversity of microbial reduction of ketopantoyl lactone to pantoyl lactone (see [61] for details). △, yeasts; ⊙, molds; □, bacteria; ⊗, actinomycetes; ⊠, basidiomycetes.

Many of the tested strains of bacteria, actinomycetes, yeasts, molds, and basidiomycetes exhibit this activity in very different ways; they usually produce mixtures of the D-(−) and L-(+) isomers, but their enantioselectivities vary. Some of them produce predominantly the D-(−) isomer in high yields. On the other hand, there are some strains which produce almost only the L-(+) isomer. Through this test, *Candida parapsilosis* was found to convert 100 g L^{-1} of the added ketopantoyl lactone into D-(−)-pantoyl lactone in a molar yield of nearly 100%[53] (see Section 5.5 for details). Such a test, also called screening, may be one of the most important steps for a successful microbial conversion.[62]

4.3. Substrates

Theoretically any substrate can be used for a microbial transformation, provided the substrate molecules come into contact with the enzyme. Even gases such as methane are effective substrates when bubbled into the reaction medium.[40,63] A substrate should be soluble in the medium and also be able to pass through the cell membrane, unless cell-free enzymes are being used as catalysts. The substrate is usually added to the reaction medium neat or as a concentrated solution.

Only a dissolved substrate is converted. Therefore, slightly soluble substrates must first be dissolved and, after conversion, the products may crystallize from the solution:

substrate (solid) $\rightleftharpoons$ substrate (solution) $\rightleftharpoons$ product (solution) $\rightleftharpoons$ product (solid)

For example, powdered cortisol, at concentrations of up to 500 g L^{-1}, is converted almost stoichiometrically into crystalline prednisolone by *Arthrobacter simplex*.[64] Substrates may also be dissolved in water-miscible organic solvents. The lower alcohols, acetone, dimethylformamide, and dimethyl sulfoxide are suitable solvents. Surfactants can also be used to disperse a substrate. The combination of a water-miscible solvent and a surfactant may have some advantage. In some cases, chemical modification of the substrate may improve its solubility.

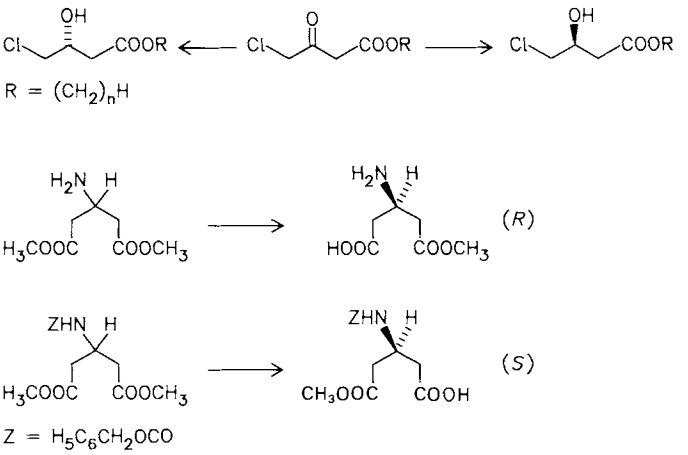
When a substrate does not pass through the cell membrane, it is necessary to treat the cells in order to improve the permeability. Grinding with glass beads, air-drying, acetone-drying, lyophilization, autolysis, lysozyme digestion, surfactant treatment, osmotic shock, freezing and thawing, and sonication are usually performed. The use of cell-free enzyme preparations or purified enzymes is also favorable for eliminating the permeability barrier.

If a substrate does not suit the desired conversion, chemical modification of the substrate should be considered. Addition, variation, or removal of a protecting group or modification of a functional group in the substrate molecule sometimes makes it interact with the enzyme more efficiently. In addition, these modifications may protect the substrate from an undesired side reaction or degradation. The systematic assaying for a suitable chloroacetoacetate ester for enantioselective reduction to yield L-4-chloro-3-hydroxybutanoate ester, a promising precursor for the chemical synthesis of L-carnitine, by baker's yeast is an example.[65] A change in the stereoselectivity of a single enzyme, pig liver esterase, on substrate modification was also reported.[45]

In such cases, the potential ability of a microorganism or enzyme is found by screening for the most suitable substrate, instead of screening for the best-suited microorganism or enzyme.

4.4. Types of Catalysts and Reaction Systems

Conventional vegetative cell cultures are most commonly performed. Several alternative systems have been evaluated extensively with regard to, for example, increased yields, control of side reactions, simplification of processes, and improved economy. Advantages and disadvantages of these systems are briefly summarized in Table 4.



Various types of biocatalysts are useful for microbial transformations. They include whole or treated cells, organelles, cell-free multienzyme systems, and single cell-free enzymes.

Table 4. Types of biocatalysts and reaction systems used in microbial transformations.

Transformation with growing cultures:
The substrate is added to the growth medium during either inoculation or an appropriate phase of growth. The preparation and inoculation of the medium, addition of substrate, and incubation are successively carried out in one flask until the reaction is completed. Because of its extreme simplicity, this procedure is frequently used not only for screening, but also in large-scale production. If high cell densities are required for the transformation, this procedure is not recommended.

Transformation with previously grown cells:
The microorganism is grown under suitable conditions and then cells are collected by centrifugation or filtration. They are resuspended in a simple reaction medium (e.g., a buffer solution or water containing the substrate and appropriate additives if necessary). The reaction is then carried out directly or after suitable treatment of the cells (e.g., washing, improvement of permeability, drying). Growth and reaction steps are controlled independently for optimization.

Transformation with spores [66]:
Many fungal spores have as many useful enzymes as vegetative or grown cells. The spores separated from mycelium can be used as catalysts in a similar way as described above. Usually spores can be stored stably for long periods.

Transformation with immobilized cells [7, 8, 66–72]:
Immobilized cells are cells that have either been fixed or bound to a surface or entrapped in gel matrix. All of the above-mentioned cells can be immobilized. In successful cases, the immobilized calls retain their activities over several months and show a higher operational stability than unsupported cells. Additional advantages are: (1) easy removal of the cells from the reaction mixture, (2) repeated use of the cells, (3) continuous operation of the reaction, (4) cell regeneration by immersion into an appropriate nutrient medium, and (5) easy product isolation. On the other hand, disadvantages must also be considered: (1) The catalytic activity of cells usually decreases during the immobilization procedure. (2) The immobilization itself requires special equipment. The transformation step, especially operated continuously, also requires a special engineering design.

Transformations with cell-free enzymes or purified enzymes [73–75]:
In general, the use of cell-free enzymes or purified enzymes is expensive, because purification of enzymes is often tedious and time-consuming. However, there are several cases in which they are advantageous over systems using cells. Such cases are: (1) poor substrate or product permeability through the cell wall, (2) problems caused by undesired side reactions, (3) availability of the desired enzyme at an acceptable cost. If an extracellular enzyme is used, cells are not involved at all. Cell-free enzymes can also be used as immobilized catalysts.

Multistep reactions with different catalysts are also possible. Any combination of catalysts may be used simultaneously or sequentially for more than two sequential reactions. At present, however, only combinations of catalysts of the same type can be successfully used. Such applications have so far included the continuous production of L-alanine from ammonium fumarate via L-aspartic acid as the intermediate with immobilized *Escherichia coli* (aspartase) and *Pseudomonas dacunhae* (aspartate β-decarboxylase) cells,[76] the complete condensation of racemic homocysteine and adenosine with *Alcaligenes faecalis* (*S*-adenosylhomocysteine hydrolase) and *Pseudomonas putida* (racemase) cells,[77] the production of L-tryptophan from DL-serine and indole (tryptophan synthase and amino acid racemase),[78] complete hydrolysis of racemic α-amino-ε-caprolactam (see Fig. 3),[56] the continuous reduction of benzoylformate to *R*-(−)-mandelic acid by two kinds of cell-free enzymes,[75] and the continuous or batchwise amination of α-keto acids to yield L-amino acids with two kinds of cell-free enzymes.[74,79,80] Current recombinant DNA technology is allowing the combination of such separated enzyme catalysts in a single microorganism.[81]

On the other hand, the synthesis of coenzyme A from pantothenic acid, L-cysteine, and ATP (or AMP), involving five sequential steps, is being commercially performed solely with *Brevibacterium ammoniagenes* cells—a possibility suggested by screening[82] (see Section 5.4.2 for details).

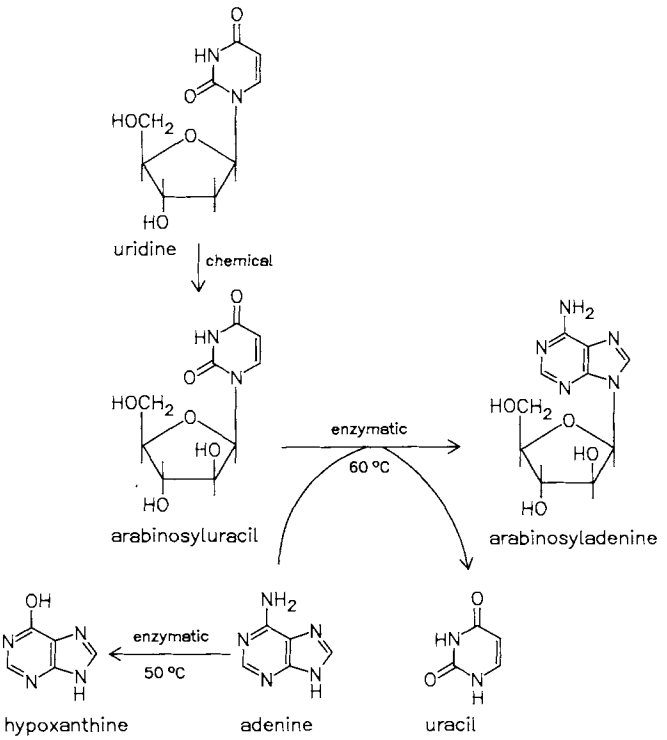


Fig. 5. Chemical and enzymatic process for the synthesis of arabinosyladenine through *trans-N*-arabinosylation by nucleoside pyrophosphorylases at 60°C.

Table 5. Elimination of side reactions by physical or chemical treatment.

Desired reaction	Side reaction	Treatment	Ref.
Ammonium fumarate → L-aspartic acid (*Escherichia coli* aspartase)	Fumaric acid → L-malic acid	Incubation of culture broth at pH 5 and 45°C for 1 h	[76]
Fumaric acid → L-malic acid (*Brevibacterium ammoniagenes* fumarase)	Fumaric acid → succinic acid	Treatment of immobilized cells with 0.6% bile extract	[84]
L-Aspartic acid → L-alanine (*Pseudomonas dacunhae* aspartate β-decarboxylase)	L-Alanine → D-alanine	Incubation of culture broth at pH 4.75 and 30°C for 1 h	[76]
Cholesterol → 1,4-androstadiene-3,17-dione (*Arthrobacter simplex* multistep conversion)	Further decomposition of the steroid ring	Addition of α,α'-bipyridyl (1 mM) to the culture broth for the conversion	[85]
β-Sitosterol → 17-oxosteroids (*Nocardia* sp. multistep conversion)	Further decomposition of the steroid ring	Addition of α,α'-bipyridyl (0.3 mM) to the conversion mixture	[86]
DL-2-Amino-4,5-dihydrothiazole-4-carboxylate → L-cysteine (*Pseudomonas thiazolinophilum* multistep conversion)	Further degradation of L-cysteine	Addition of hydroxylamine or semicarbazide to the reaction mixture	[87]

4.5. Side Reactions

High selectivity is one of the most important characteristics of enzyme catalysts. It means that undesired side reactions are not involved as long as a single purified enzyme is used. The use of purified enzymes, however, is often troublesome owing to their limited availability and instability and for economic reasons. Therefore, usual catalysts (e.g., cells and cell-free enzymes) comprise mixed enzymes or complex enzyme systems, some of which may cause undesired side reactions. Physical or chemical treatment, such as heating, pH changes, and the addition of detergents, organic solvents, or specific inhibitors of a catalyst may lead to specific inactivation of the undesired enzymes. For example, the *trans-N*-arabinosylation of adenine with synthetic arabinosyluracil yielding arabinosyladenine, an antiviral agent, by *Enterobacter aerogenes* cells takes place only at temperatures above 60°C. The reaction does not proceed below 50°C because hypoxanthine is formed by adenine deaminase before the *trans-N*-arabinosylation by the two kinds of nucleoside phosphorylases takes place. Fortunately, these phosphorylases are still active at 60°C, whereas the deaminase is completely inactivated at this temperature (Fig. 5).[83] Other examples are summarized in Table 5.

In some senses, screening for suitable microorganisms and structural modification of a substrate (see Section 4.4) can also be a means of preventing side reactions.

Improvement of the selected microorganism can also successfully overcome such undesired problems. The standard methods of strain improvement include the isolation of single colonies, optionally after mutagenesis, followed by screening for the best-suited isolates. Such conventional genetic manipulation techniques have been de-

veloped during the last 35 to 40 years for the improvement of useful strains. Today, recombinant DNA technology is providing new prospects of strain improvement (see Section 4.6).

4.6. Application of New Biotechnology

At present, several new techniques are rapidly being developed in connection with new biotechnology. One of them is recombinant DNA technology. Plasmids or phage vectors can transfer DNA fragments of microbial, plant, animal, or even synthetic origin into a suitable recipient microorganism. This technology has great potential especially for the construction of new microorganisms,[81] increases in enzyme activity,[88,89] and the improvement of enzyme properties such as stability and substrate specificity. However, it should also be noted that this technology is not so useful for finding new enzymes (e.g., new genes) or new reactions. At present, only in the case of a few microorganisms, such as *Escherichia coli, Bacillus subtilis,* and *Saccharomyces cerevisiae,* for which the genetic background and the appropriate host-vector systems are well-known, has recombinant DNA technology been beneficial. The practical application of this technology to microbial transformations is rare.[81] However, it will undoubtedly provide one of the most important keys for the future development of microbial transformations.

Since their discovery, enzymes have been thought to be inert catalysts in organic solvents. This is basically true, but recent technological advances have made available enzymes that are catalytically active in water-miscible organic solvents. For example, chemically modified peroxidase exhibits its activity well in benzene and *n*-hexane.[90] Polyphenol oxidase converts phenol nearly quantitatively into catechol when the reaction is carried out in chloroform containing only 1–2% water.[91] Such liquid-liquid multiphase systems with low water contents can also be used to shift the hydrolytic equilibrium toward water elimination. The synthesis of esters, amides, and peptides by this method shows great practical potential.[92] The conversion of lipophilic compounds with this system has also been extensively studied.[93]

Microorganisms are undoubtedly the most superior enzyme sources among living organisms. They show high adaptability to new environments and high growth rates. These characteristics are especially useful for easy handling and large-scale cultivation without a high cost. However, there are also many characteristic enzymes and reactions in animals and plants. Use of these organisms has also become more promising with current cell-culture technology.[94,95] Furthermore, protein engineering and cell technology, such as cell fusion, will become useful techniques for microbial transformations in the near future.

5. Specific Applications

A large number of biologically and chemically useful compounds are prepared through microbial transformations. They are briefly summarized in Table 6 together with key references. A brief review of some practical applications follows.

Table 6. Recent advances in microbial transformations.

Transformation of steroids and sterols [28, 96]: Hydroxylation (oxygenases), dehydrogenation (dehydrogenases), side-chain degradation (oxygenases), hydrolysis (hydrolases), peroxidation, reduction (dehydrogenases), isomerization (isomerases), conjugation etc.
Transformation of terpenoids [97]
Transformation of alkaloids [98]
Synthesis of semisynthetic antibiotics [99] (see also Section 5.3): Synthesis of semisynthetic penicillins and cephalosporins (acylases) [100, 101], hydrolysis of penicillins to 6-aminopenicillanic acid (penicillin acylase) [102], modification of carbapenem side chain (acylases) [103]
Synthesis of organic acids (see also Section 5.5): Hydration of fumaric acid (fumarase) [104], α,ω-oxidation of alkenes (oxygenase) [105], asymmetric hydrolysis of epoxysuccinic acid (hydrolase) [106], stereoselective oxidation of isobutyric acid (dehydrogenase) [107], stereoselective reduction of ketopantoyl lactone (reductase) [53, 108], stereoselective reduction of 3-chloroacetoacetic acid ester (reductase) [65], aminolysis of L-histidine (L-histidine amonia-lyase) [109]
Transformation of sugars [110]: Isomerization of glucose (glucose isomerase), hydrolysis of starch (amylases), hydrolysis of cellulose (cellulase), hydrolysis of sucrose (invertase)
Synthesis of peptides and proteins [29, 111, 112] (see also Section 5.2 and Table 8): Synthesis of plastin (proteases) [113], semisynthesis of human insulin (proteases) [30, 31, 114], synthesis of aspartame (protease) [115]
Synthesis of amino acids [23, 116–118] (see Section 5.1 and Table 7)
Synthesis of nucleic acid-related compounds [24, 119] (see also Section 5.4 und Table 9): *trans-N*-Ribosylation and *trans-N*-arabinosylation (phosphorylase) [83], phosphorylation of nucleosides (phosphotransferases) [120], pyrophosphorylation of nucleotides (pyrophosphorylase) [121], synthesis of sugar nucleotides (pyrophosphorylases) [122], nucleosidylation of L-methionine (*S*-adenosylmethionine synthetase) [77], nucleosidylation of L-homocysteine (*S*-adenosylhomocysteine hydrolase) [77], synthesis of coenzymes [119]
Synthesis of amines: Decarboxylation of amino acids (amino acid decarboxylases)
Synthesis of commodity chemicals (see also Section 5.6): Synthesis of alkene oxides (oxygenases) [40], synthesis of ketones (secondary alcohol dehydrogenases) [42], synthesis of aldehydes (alcohol oxidases) [41], synthesis of pyrogallol (decarboxylase) [43], synthesis of amides (nitrile hydratase) [39]

5.1. Optically Active Amino Acids

Numerous useful enzyme reactions are known for the preparation of enantiomerically pure amino acids (Table 7). They can be grouped into four fundamental types; (1) enantioselective hydrolysis of synthetically available racemic precursors (e.g., DL-amino acid esters, *N*-acyl-DL-amino acids, 5-substituted DL-hydantoins), (2) stereospecific condensation of achiral compounds (e.g., ammonia addition to fumaric acid, reverse of α,β-elimination), (3) modification of chiral precursors (e.g., β-replacement), and (4) reductive amination or transamination of α-keto acids).

5.1.1. Use of Hydrolytic Enzymes

The usual enzymatic resolution processes are based on the stereospecific hydrolysis of racemic amino acid derivatives to one enantiomer of an amino acid followed by reracemization of the remaining isomer. Aminoacylase is widely used for this purpose.[139] Esterase, amidase, and ni-

Table 7. Amino acid production by microbial transformations [a].

Amino acid	Reaction	Microorganism und enzyme	Ref.
L-Amino acid	*N*-acyl-L-amino acid + H_2O → L-amino acid + acetic acid	aminoacylase	[123]
S-Adenosylhomocysteine (AdoHcy)	L-Hcy + adenosine → AdoHcy + H_2O	*Alcaligenes faecalis* (*S*-adenosylhomocysteine hydrolase)	[77]
L-Alanine	L-Asp + H_2O → L-Ala + CO_2	*Pseudomonas dacunhae* (Asp β-decarboxylase)	[76]
L-Aspartic acid	fumaric acid + NH_3 → L-Asp	*Escherichia coli* (aspartase)	[60, 76]
	maleic acid + NH_3 → L-Asp	*A. faecalis* (maleate isomerase and aspartase)	[124]
L-Citrulline	L-Arg + H_2O → L-Cit + NH_3	*P. putida* (Arg deiminase)	[125]
L-Cysteine	DL-ATC + $2H_2O$ → L-Cys + NH_3 + CO_2	*P. thiazolinophilum* (ATC racemase, ATC hydrolase, and *S*-carbamoyl-L-cysteine hydrolase)	[87]
	3-chloro-L-Ala + H_2S → L-Cys + HCl	*Enterobacter cloacae* (Cys desulfhydrase) or *Bacillus sphaericus* (Cys synthase)	[52, 55]
L-Cystathionine	L-Cys + *O*-succinyl-L-homoserine → L-cystathionine + succinic acid	cystathionine γ-lyase or cystathionine γ-synthase	[127, 128]
L-Dopa	pyrocatechol + pyruvate + NH_3 → L-Dopa + H_2O	*Erwinia herbicola* (β-tyrosinase)	[51, 52]
	pyrocatechol + DL-Ser → L-Dopa + H_2O		
	L-Tyr + O_2 → L-Dopa + H_2O	*Aspergillus oryzae* (Tyr hydroxylase)	[128]
L-Glutamic acid	DL-5-carboxymethylhydantoin + $2H_2O$ → L-Glu + NH_3 + CO_2	*B. brevis* (hydantoinase and *N*-carbamoyl-L-Glu hydrolase)	[129]
5-Hydroxy-L-tryptophan	5-hydroxyindole + pyruvate + NH_3 → 5-hydroxy-L-Trp	*Proteus rettgeri* (tryptophanase)	[52]
L-Lysine	DL-ACL + H_2O → L-Lys	*Achromobacter obae* and *Cryptococcus laurentii* (ACL racemase and ACL hydrolase)	[56]
L-Phenylalanine	DL-5-benzylhydantoin + $2H_2O$ → L-Phe + NH_3 + CO_2	*Flavobacterium aminogenes* (hydantoinase and *N*-carbamoyl-L-Phe hydrolase)	[130]
	trans-cinnamic acid + NH_3 → L-Phe	*Rhodtorula glutinis* (Phe ammonia-lyase)	[131]
	cinnamate acetamide + amine donor → L-Phe + keto acid	*A. faecalis* (acylase and transaminase)	[132]
	phenylpyruvate + L-Asp → L-Phe + oxaloacetic acid	*E. coli* (Phe transaminase)	[133]
	phenylpyruvate + NH_3 + NADH → L-Phe + NAD	Phe dehydrogenase	[79, 80]
S- or *Se*-substituted L-homocysteine	L-Met + RSH (or RSeH) → *S*- or *Se*-substituted L-Hcy + MeSH	Met γ-lyase	[134]
L-Serine	Gly + HCHO → L-Ser	*Pseudomonas* 3ab, *Sarcina albida*, *Hyphomicrobium methylovorum*, etc. (Ser hydroxymethyltransferase)	[135]
	DL-OOC + H_2O → L-Ser + CO_2	*P. testosteroni* and *B. subtillis* (L-OOC hydrolase and OOC racemase)	[136]
L-Tryptophan	indole + pyruvate + NH_3 → L-Trp + H_2O	*Proteus rettgeri* (tryptophanase)	[52]
	indole + L-Ser → L-Trp	*E. coli* (Trp synthase)	[78, 137]
	DL-IMH + $2H_2O$ → L-Trp + NH_3 + CO_2	*F. amminogenes* (hydantoinase, *N*-carbamoyl-L-Trp hydrolase)	[138]
L-Tyrosine	phenol + pyruvate + NH_3 → L-Tyr + H_2O	*Erwinia herbicola* (β-tyrosinase)	[51, 52]
D-Amino acids	DL-5-substituted hydantoin + H_2O → *N*-carbamoyl-D-amino acid	*P. putida* (dihydropyrimidinase)	[57, 58]
D-Cysteine	3-chloro-D-Ala + NaHS → D-Cys + NaCl	*P. putida* (3-chloro-D-Ala dehydrochlorinase)	[55]
D-*p*-Hydroxyphenylglycine	DL-5-(*p*-hydroxyphenyl)hydantoin + H_2O → *N*-carbamoyl-D-*p*-hydroxyphenylglycine + NH_3 + CO_2	*P. putida* (dihydropyrimidinase)	[57, 58]
D-Phenylglycine	DL-5-phenylhydantoin + H_2O → *N*-carbamoyl-D-phenylglycine	*P. putida* (dihydropyrimidinase)	[57, 58]
D-Valine	DL-5-isopropylhydantoin + H_2O → *N*-carbamoyl-D-Val + NH_3 + CO_2	*P. putida* (dihydropyrimidinase)	[57, 58]

[a] Abbreviations: ATC, 2-amino-4,5-dihydrothiazole-4-carboxylic acid; Dopa, 3,4-dihydroxyphenylalanine; ACL, α-amino-ε-caprolactam; OOC, 2-oxooxazolidine-4-carboxylic acid; IMH, 5-indolylmethylhydantoin.

trilase can also be used. Several other hydrolytic enzymes with more specific substrate specificities are used for the preparation of L-lysine (L-α-amino-ε-caprolactam hydrolase, see Fig. 3),[56] L-cysteine (L-2-amino-4,5-dihydrothiazole-4-carboxylate hydrolase),[87] L-tryptophan and L-phenylalanine (hydantoinase),[130,138] and D-*p*-hydroxyphenylglycine (dihydropyrimidinase/hydantoinase, see Fig. 6).[53,57,58] In contrast to the acylase method, asymmetric hydrolysis is accompanied by reracemization by a specific racemase or under base catalysis in one step in these processes.

D-*p*-Hydroxyphenylglycine[57,58] and its derivatives are important as side-chain precursors for semisynthetic penicillins and caphalosporins. We found that these amino acids can be efficiently prepared from the corresponding 5-substituted hydantoins using bacterial dihydropyrimidi-

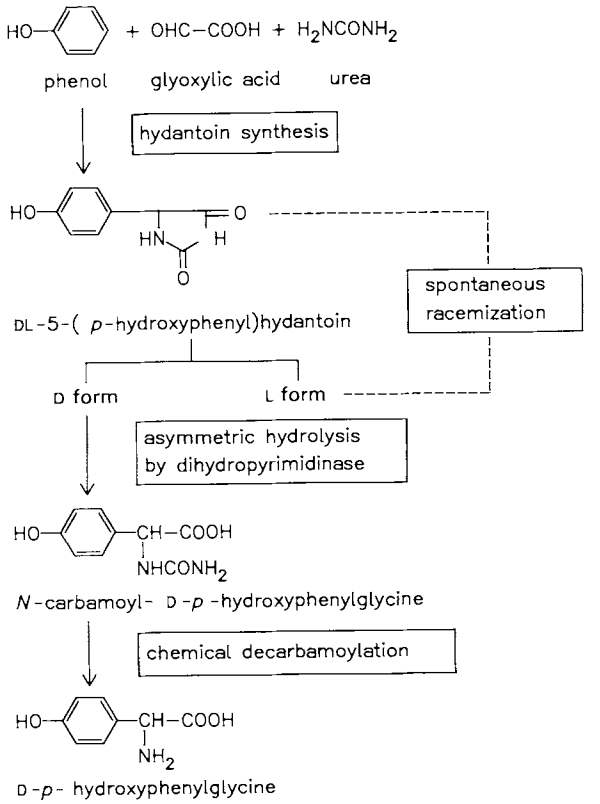

Fig. 6. Chemical and enzymatic process for the production of D-*p*-hydroxyphenylglycine involving stereoselective hydrolysis of DL-5-(*p*-hydroxyphenyl)hydantoin.

nase. High activity of this enzyme is found in a wide variety of bacteria, especially, in *Aerobacter*, *Corynebacterium*, *Agrobacterium*, *Pseudomonas*, *Bacillus*, and *Streptomyces*.[140] The bacterial enzyme has been isolated as crystals from cells of *Pseudomonas putida*. The enzyme shows the highest activity and affinity toward dihydrouracil, but also attacks a variety of aliphatic and aromatic 5-monosubstituted D-hydantoins, yielding the corresponding D-form *N*-carbamoyl-α-amino acids.[141] Thus, the enzyme can be used as a catalyst for the preparation of D-amino acids. The synthetic process involves two chemical steps and one enzymatic step.[142] The substrate hydantoins are generally synthesized by the method of *Bucherer* and *Steiner*[59] with aldehydes as the starting materials. Then, the D-hydantoins are hydrolyzed enzymatically to *N*-carbamoyl-D-amino acids. In practice, bacterial cells exhibiting high enzyme activity can be used directly as the catalyst. Preparation of these cells is carried out by culturing the selected bacterium in a medium supplemented with hydantoin or uracil as the inducer. Under the conditions used for the enzymatic reaction at pH 8 to 10, the L isomers of the remaining hydantoins are racemized rapidly and spontaneously through base catalysis. Therefore, the racemic hydantoins can be converted quantitatively into *N*-carbamoyl-D-amino acids through this step. Decarbamoylation to D-amino acids is performed by treating the *N*-carbamoyl-D-amino acids with equimolar nitrite under acidic conditions.[143] The configuration is completely retained throughout this step, with a nearly quantitative molar yield. Based on these results, a new commercial process for the production of D-*p*-hydroxyphenylglycine has been developed. To avoid the use of expensive *p*-hydroxybenzaldehyde for preparation of the substrate, DL-5-(*p*-hydroxyphenyl)hydantoin, a new and efficient chemical method involving the amidoalkylation reaction of phenol with glyoxylic acid and urea under acidic conditions was developed.[144] Figure 6 shows the overall process for the production of D-*p*-hydroxyphenylglycine. This may be one of the most economical processes for the larger-scale production of this amino acid. In a similar manner, D-phenylglycine and D-valine, which are important intermediates for the synthesis of semisynthetic penicillins and pesticides, respectively, have been commercially produced.

The decarbamoylation step can also be carried out enzymatically.[145] For example, *Pseudomonas* sp. was reported to produce decarbamoylase together with hydantoinase. Therefore, a sequence of two enzyme-catalyzed reactions, the stereospecific hydrolysis of DL-5-(*p*-hydroxyphenyl)hydantoin and subsequent hydrolysis of the D-carbamoyl derivative to D-*p*-hydroxyphenylglycine, is possible.[146] At present, however, enhancement of the activity of the latter enzyme is necessary for practical purposes. Recently, one such decarbamoylase was characterized in detail.[147]

5.1.2. *Use of Pyridoxal Phosphate-Dependent Enzymes*

Most pyridoxal 5′-phosphate-dependent enzymes are involved in the metabolism of amino acids. These enzymes catalyze a variety of reactions, including transamination, racemization, elimination, replacement, decarboxylation, and aldol-type condensation and retrocondensation reactions. Thus, these enzymes are occasionally used for the preparation of a variety of amino acids. Aspartate β-decarboxylase,[76] β-tyrosinase,[51,52] and phenylalanine transaminase[133] are used for the commercial preparation of L-alanine, L-tyrosine, and L-phenylalanine, respectively.

Aromatic Amino Acids and Sulfur-Containing Amino Acids:[51,52,55] β-Tyrosinase (EC 4.1.99.2) and tryptophanase (EC 4.1.99.1) are enzymes which catalyze the degradation of L-tyrosine to phenol, pyruvate, and ammonia, and L-tryptophan to indole, pyruvate, and ammonia, respectively. The properties of the crystalline enzymes prepared from *Citrobacter intermedius* and *Proteus rettgeri*, respectively, were established in some detail.[51,52,148] They catalyze a variety of reactions, e.g., α,β-elimination [Eq. (6)], β-replacement [Eq. (7)], and the reverse of α,β-elimination [Eq. (8)].

$$RCH_2{-}CH(NH_2){-}COOH + H_2O \longrightarrow RH + CH_3{-}CO{-}COOH + NH_3 \quad (6)$$

$$RCH_2{-}CH(NH_2){-}COOH + R'H \longrightarrow R'CH_2{-}CH(NH_2){-}COOH + RH \quad (7)$$

$$R'H + CH_3{-}CO{-}COOH + NH_3 \longrightarrow R'CH_2{-}CH(NH_2){-}COOH + H_2O \quad (8)$$

For β-tyrosinase, R = hydroxyphenyl, OH, SH, Cl, R′ = hydroxyphenyl; for tryptophanase, R = indolyl, OH, Cl, R′ = indolyl.

In the α,β-elimination [Eq. (7)] and β-replacement [Eq. (7)] reactions of β-tyrosinase, L-tyrosine, L-serine, *S*-methyl-L-cysteine, and 3-chloro-L-alanine are substrates. In

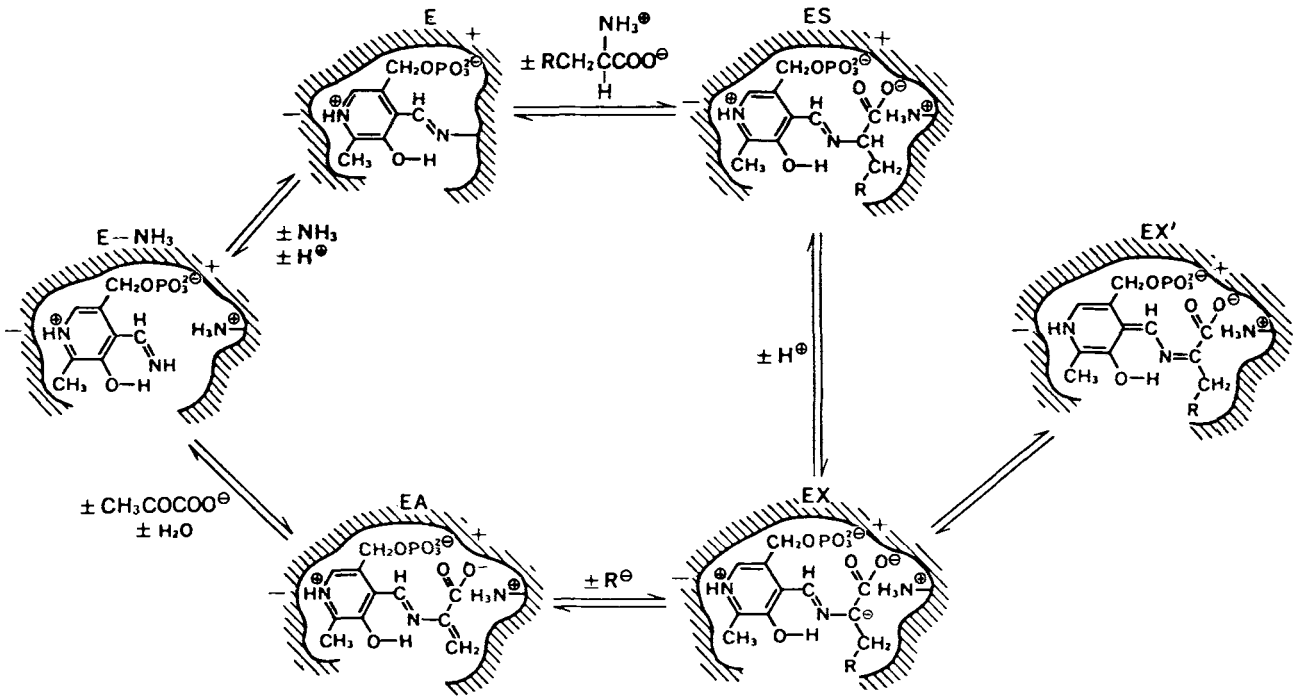

Fig. 7. The mechanism for reactions catalyzed by β-tyrosinase. E, enzyme; S, substrate; ES, EX, EX', and EA, enzyme-substrate complexes; EA, enzyme-α-aminoacrylate complex; E-NH_3, enzyme-ammonia complex.

the β-replacement reaction, phenol is the second substrate for the synthesis of L-tyrosine. When either pyrocatechol, resorcinol, pyrogallol, or hydroxyhydroquinone is the second substrate, instead of phenol, L-Dopa, 2-hydroxy-L-tyrosine, 2,3-dihydroxy-L-tyrosine, and 2,5-dihydroxy-L-tyrosine are synthesized, respectively. L-Tyrosine is also synthesized through the reverse of the α,β-elimination reaction [Eq. (8)] from phenol, pyruvate, and ammonia. As substrates, pyrocatechol, resorcinol, and various kinds of *o*- and *m*-halogenated phenols and alkylated phenols are as good as phenol in the reverse reaction.[51,52,149] These tyrosine derivatives readily crystallize out under the reaction conditions used, thus driving the reaction forward to completion. The mechanism of the tyrosinase-catalyzed reactions can be understood on the basis of the general mechanism for pyridoxal 5'-phosphate-dependent reactions, shown in Figure 7, in which the enzyme-α-aminoacrylate complex (EA in Fig. 7) is the key intermediate for all three reactions.[51]

As in the case of the β-tyrosinase reaction, L-tryptophan and some of its derivatives, such as 5-hydroxy-, 5-amino- and 5-methyl-L-tryptophan, can be synthesized efficiently when tryptophanase is the catalyst.[150]

Based on the results with the crystalline enzymes, simple and efficient enzymatic processes for the production of these aromatic L-amino acids have been developed. In these processes, bacterial cells exhibiting high enzyme activity are directly used as the catalysts. L-Tyrosine, L-Dopa, L-tryptophan, and 5-hydroxy-L-tryptophan can be synthesized in excellent yields.[51,52,151]

Cysteine desulfhydrase (EC 4.1.1.1), *O*-acetylserine sulfhydrolase (EC 4.2.99.8), and 3-chloro-D-alanine dehydrochlorinase (EC 4.5.1.2) catalyze similar reactions. The usefulness of these enzymes for the preparation of L- and D-cysteine and their derivatives has been shown.[52,55,152] Furthermore, γ-replacement reactions catalyzed by cystathionine γ-lyase (EC 4.4.1.1) and cystathionine γ-synthase (EC 4.2.99.9), as well as one catalyzed by methionine γ-lyase (EC 4.4.1.11), have been suggested for the synthesis of L-cystathionine[126,127] and *S*- or *Se*-substituted L-homocysteines.[134]

L-Phenylalanine is an important building block for the low-calorie sweetner aspartame. Various routes to this amino acid have been reported (see Table 7). A recently developed large-scale process involves alkaline hydrolysis of benzylidenehydantoin to phenylpyruvic acid, which in turn is aminated enzymatically (Fig. 8). The enzymatic conversion of phenylpyruvic acid is carried out with L-aspartic acid as the amine donor and L-phenylalanine transaminase as the catalyst.[133,153] When *Escherichia coli* cells immobilized with polyazetidine are used as the catalyst, 30 g L^{-1} of L-phenylalanine can be produced in a molar yield of 98%. The activity of the immobilized cells is quite stable; the half-life has been estimated to be more than

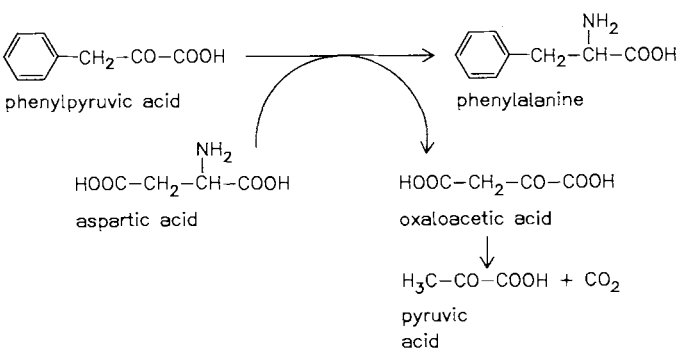

Fig. 8. Chemical and enzymatic process for the production of L-phenylalanine involving enzymatic transamination.

eight months. Although the equilibrium constant for this reaction is approximately one, the reaction is driven to completion by removal of one of the reaction products, oxaloacetic acid, through rapid decarboxylation to pyruvic acid.[133]

5.1.3. *Use of Amino Acid Dehydrogenase*

A recently developed route to L-amino acids of high optical purity is the reductive amination of a series of α-keto acids with amino acid dehydrogenases. The enzymes catalyzing this reaction require NAD(P)H as a cofactor. To avoid an equimolar consumption of the expensive cofactor, a continuous cofactor regeneration system has been suggested. The most successful example is the continuous L-leucine production with leucine dehydrogenase (EC 1.4.1.9) entrapped in a membrane reactor together with formate dehydrogenase and polymer-bound NAD.[74] L-Alanine dehydrogenase (EC 1.4.1.1) and phenylalanine dehydrogenase have been shown to be useful for the production of L-alanine[74] and L-phenylalanine,[79,80] respectively. Such a type of reaction is generally applicable to amino acid production, if suitable dehydrogenases and α-keto acids are available.

5.2. Peptides

The high practical potential of proteolytic enzymes for peptide transformations was recognized in pioneering studies in the 1970s: e.g., the modification of soybean trypsin inhibitor,[154,155] nutritional enrichment of proteins,[113] and synthesis of some biologically active small peptides.[156] The successful semisynthesis of insulin[30–32,114] further emphasized their value as effective catalysts. Since then, various biologically active small peptides including hormones and neuropeptides have been prepared using proteolytic enzymes (Table 8). The application of proteolytic enzymes has recently expanded to include the preparation or modification of large-molecular-weight peptides (e.g., enzymes, antibodies, protein hormones). Other useful enzymes for peptide preparation are nucleoside triphosphate-dependent synthetases. The synthesis of gramicidin S,[166] glutathione and related peptides,[167] and kyotorphin[164] has also been reported.

Human Insulin: Porcine insulin and human insulin differ only in the *C*-terminal amino acid of the B chain. As shown in Figure 9, the selective hydrolysis of the B-chain *C*-terminal alanine residue of porcine insulin and subsequent condensation of the des(AlaB30) insulin with a threonine ester derivative are efficiently catalyzed by a serine protease, *Achromobacter* protease I. The enzyme specifically cleaves the carboxyl side of lysine residues. Although the process involves reactions at pH 8.3 (hydrolysis) and pH 6.5 (condensation) with intermediate isolation and lyophilization of the des(AlaB30) insulin, overall yields of 52% for porcine insulin and 58% for bovine insulin were reported.[31] The unreacted des(AlaB30) insulin can be reused. At present, human insulin is commercially prepared from porcine insulin through such enzymatic transformation and through direct fermentation with an *Escherichia coli* mutant constructed by means of recombinant DNA technology.

Table 8. Enzymatic transformations of biologically important peptides.

Peptide	Enzymes	Ref.
Aspartame	Thermolysin	[115]
(Val^5)-Angiotensin II (1-8)	Papain	[155]
Substance P-related peptide (1-6)-NH_2	Pepsin	[156]
Enkephalin	Papain and chymotrypsin or carboxypeptidase Y	[157] [158]
Caerulein	Chymotrypsin, papain, subtilisin, metalloprotease, and aspartic protease	[159]
Eledoisin-related peptide (1-6)-NH_2	Pepsin	[156]
Salmon calcitonin I (1-32)	Trypsin	[160]
Human insulin	*Achromobacter* protease I or trypsin	[31] [30]
Dynorphin (1-8)	Chymotrypsin, papain, and trypsin	[161]
(Lys^{63})- and (Trp^{63})-soybean-trypsin inhibitors	Chymotrypsin and carboxypeptidase A	[162]
(Arg^{15})- and (Trp^{15})-bovine trypsin-kallikrein inhibitors	Trypsin and carboxypeptidase A, and Chymotrypsin and carboxypeptidase A, respectively	[163]
Kyotorphin	Leucyl-tRNA synthetase or chymotrypsin	[164] [165]

5.3. Antibiotics

A large number of antibiotics have been modified with the use of microorganisms or enzymes. Many of these modifications were based on simple and chemically defined reactions (e.g., hydrolysis, acylation and deacylation,

nucleotidylation, phosphorylation, glycosidation, methylation and demethylation, amination and deamination, oxidation and reduction, isomerization, hydration, halogenation). Some of these reactions have considerable practical significance for the preparation of new semisynthetic antibiotics.

β-Lactam antibiotics have been extensively studied. The deacylation of penicillins and the acylation of 6-aminopenicillanic acid (6-APA), 7-aminocephalosporanic acid, and 7-amino-3-deacetoxycephalosporanic acid are especially important for practical purposes. In general, a single enzyme, penicillin acylase (EC 3.5.1.11), catalyzes the penicillin acylation and deacylation reactions, the directional equilibrium being controlled by pH. Thus, the enzyme can be used for the preparation of either 6-APA or semisynthetic penicillins. The industrial processes for the preparation of 6-APA from penicillin G involve immobilized penicillin acylase[172,173] or immobilized *Escherichia coli* cells containing it.[102] The 6-APA, in turn, serves as a substrate for the preparation of novel semisynthetic penicillins with improved therapeutic properties. Although chemical acylation is usually carried out for this purpose, effective enzymatic acylation reactions are known for the preparation of ampicillin and amoxycillin from 6-APA and, respectively, D-phenylglycine methyl ester and D-*p*-hydroxyphenylglycine ethyl ester.[173] An effective two-step enzymatic process involving the deacylation of benzylpenicillin by *Kluyvera citrophila* at pH 7.5, yielding 6-APA, followed by acylation of the latter with DL-phenylglycine methyl ester at pH 5.5 by *Pseudomonas melagogenum*, yielding ampicillin, has been reported.[174] In this case, the *Pseudomonas* acylase does not attack the benzylpenicillin, which remains unaffected during the acylation step.

5.4. Coenzymes

Some coenzymes are produced on an industrial scale and are used as pharmaceuticals for various diseases. Many methods of preparation, including microbial transformation, fermentation, and chemical synthesis, are known. In addition to their importance as pharmaceuticals, coenzymes are important as cofactors in many enzyme reactions which are useful for microbial transformations. To avoid the stoichiometric consumption of the expensive coenzymes, several systems for their generation or regeneration, especially for ATP and NAD(P)H, have been developed.

5.4.1. Regeneration Systems for Coenzymes and Their Application

ATP: Because ATP is used not only as an energy source but also as a substrate in various enzyme reactions, both regeneration (recycling) and generation (production) must be considered. The generally applicable methods for ATP generation or regeneration are as follows:

(1) Yeast glycolysis system: Ground or dried cells of baker's or brewer's yeast efficiently phosphorylate the added adenosine (or AMP) to ADP and ATP on incubation with high concentrations of glucose and inorganic phosphate.[175] Under suitable conditions using brewer's yeast, 190 μmol mL^{-1} of ATP was produced in a molar yield of 63%.[176] Other yeasts and bacteria are also used for this purpose. In particular, the use of *Saccharomyces cerevisiae* cells, in which hexokinase or glucokinase was enriched by gene technology, led to almost stoichiometric conversion of adenosine (130 mM) to ATP.[177] The mechanism involved in the ATP production is thought to be the substrate-level phosphorylation of AMP or adenosine via ADP using the energy provided by glycolysis, as shown in Figure 10a. An advantage of this method is that readily available baker's yeast can be used as the catalyst.

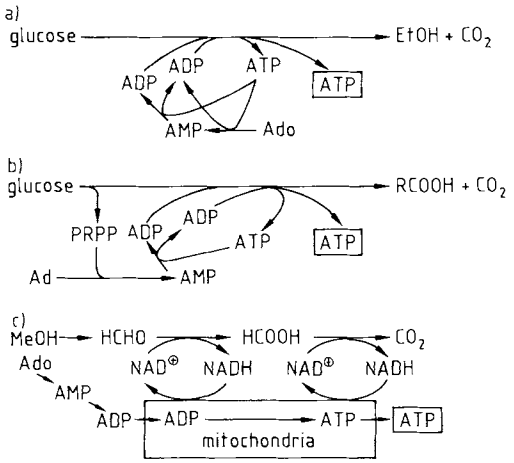

Fig. 10. Schematic representations of the reaction systems for ATP generation through a) yeast fermentation, b) ribotidation of adenine, and c) mitochondrial oxidative phosphorylation. Ad, adenine; Ado, adenosine; PRPP, 5-phosphoribosyl-1-pyrophosphate.

(2) Bacterial ribotidation of adenine. Based on the finding that several coryneform bacteria ribotidate added bases with satisfactory yields,[178] a practical production method for ATP has been developed. Adenine (2 mg mL^{-1}) added to a three-day culture of *Brevibacterium ammoniagenes* was converted into ATP (1.57 mg mL^{-1}), ADP (1.59 mg mL^{-1}), and AMP (2.16 mg mL^{-1}) on further incubation for 24 h.[179] Washed cells of the same bacterium also produced more than 10 mg mL^{-1} of ATP in a molar yield of 83%.[180] Because adenine is one of the cheapest starting substrates, this system is widely applied for the practical preparation of many useful compounds. The formation of phosphoribosyl pyrophosphate from glucose followed by condensation with the added adenine, yielding AMP, and phosphorylation of the AMP to ATP by adenylate kinase are suggested to be key reactions involved in this system (Fig. 10b).

(3) Oxidative phosphorylation: Cells of a methylotrophic yeast, *Kloeckera* sp., which had been treated with a lytic enzyme, zymolyase, or by the addition of sorbitol to the reaction mixture, catalyzed the phosphorylation of adenosine in the presence of methanol as the energy source.[181] Sequential reactions, including the mitochondrial oxidative phosphorylation coupled with the oxidation of methanol to CO_2 and the phosphorylation of adenosine by adenosine kinase and of AMP by adenylate ki-

[a] The general principle of the reaction is illustrated in Fig. 9a. [b] This process involves direct ribotidation of bases or its modification. The general principle of the reaction is shown in Fig. 9b. [c] Guanosine 3',5'-bis(diphosphate). [d] Guanosine 3'-diphosphate-5'-triphosphate. [e] Diadenosine tetraphosphate.

nase, have been proposed as the reaction mechanism (Fig. 10c).[181] The efficient utilization of the energy derived from methanol, a cheap raw material, in this system suggests a general advantage for application to many transformation reactions.

(4) Photophosphorylation: Chromatophores isolated from photosynthetic bacteria grown in the light have been shown to phosphorylate ADP to ATP.[182] ATP generation using isolated thylakoids[183] or chloroplasts[184] has also been reported. These systems are presently of academic interest.

(5) Use of cell-free enzymes: Phosphotransferases (kinases) are enzymes which catalyze the transfer of a phosphate of ATP to their substrates, the ATP being converted into ADP. Some of these enzymes also catalyze the reverse reaction, and are useful for the generation of ATP. Pyruvate kinase (EC 2.7.1.40), carbamoyl kinase (EC 2.7.2.2), creatine kinase (EC 2.7.3.2), phosphoglycerate kinase (EC 2.7.2.3), and aspartokinase (EC 2.7.2.4) are such enzymes. The former three and especially acetate kinase (EC 2.7.2.1) are widely used for this purpose.[185] If the transformation of interest requires a cell-free enzyme, coupling of these enzyme systems is highly recommended.

Applications of the above systems are listed in Table 9. The advantages and disadvantages of (1), (2), and (5) were discussed by *Langer* et al.[206]

NADH and NADPH: Various regeneration systems for NAD(P)H are involved in the complex and regulated metabolism of living cells. For example, the pathway for glucose oxidation via glucose-6-phosphate involves two important reactions yielding NADPH, namely, the oxidation of glucose 6-phosphate by glucose-6-phosphate dehydrogenase followed by the oxidation of 6-phosphogluconate by 6-phosphogluconate dehydrogenase. By means of this system, endogenous NADPH or a catalytic amount of added NADPH can be efficiently regenerated by the simple mixing of microbial cells with glucose in an appropriate reaction mixture. The reductions of various carbonyl compounds by yeast cells occasionally performed in synthetic organic chemistry[15,61,65] are mainly based on this system. Similarly, the reactions involved in the oxidation of methanol to CO_2 by methylotrophic microorganisms are considered to be a very useful system for NADH regeneration (see Fig. 10c).

When cell-free enzymes requiring reduced nicotinamide cofactors are to be used, the construction of a suitable regenerating system is an additional requirement. The generally applicable systems were described by *Whitesides* and *Wong*.[14] Among them, the formate/formate dehydrogenase,[74] glucose/glucose dehydrogenase, and glucose 6-phosphate/glucose 6-phosphate dehydrogenase systems are most widely used, because of the availability of these hydrogen donor substrates and enzymes. In particular, the formate/formate dehydrogenase system is advantageous, because the reaction product from formate, CO_2, causes no problems for the isolation of the desired products. The application of this system has been extensively studied by the group of *Kula* and *Wandley*.[74,79]

5.4.2. *Production of Coenzymes*

Only three coenzymes, for which we developed large-scale production processes, will be described here (for others, see Ref. [119]).

Coenzyme A:[207] The biosynthesis of coenzyme A (CoA) from pantothenic acid, L-cysteine, and ATP is performed through five sequential enzymatic reactions as shown in Figure 11.[208] We found that *Brevibacterium ammoniagenes*

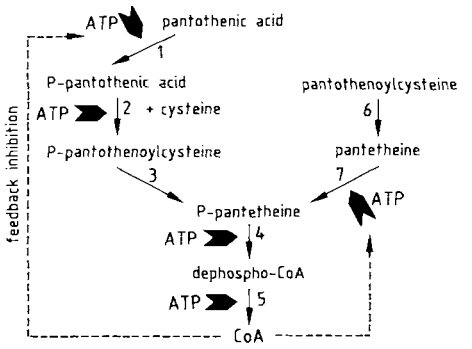

Fig. 11. The pathway for the biosynthesis of coenzyme A (see text).

cells contain all five enzymes necessary for the synthesis of CoA (Fig. 11, route 1-2-3-4-5 or route 7-4-5), all with high activities.[82, 196, 209] Using cells of this bacterium as the catalyst, CoA (2–5 g L^{-1}) can be synthesized from the above substrates efficiently.[82, 196, 207, 210] The CoA biosynthesis from these three substrates or from pantetheine and ATP in this bacterium is mainly regulated by feedback inhibition of pantothenate kinase (EC 2.7.1.33), which catalyzes the phosphorylation of pantothenate or pantetheine, by the end product, CoA. It was therefore difficult to improve the CoA yield, because the overproduced CoA inhibited the CoA synthesis. In order to avoid this feedback inhibition, the enzymatic phosphorylation of pantothenic acid was replaced with a chemical phosphorylation. Under suitable conditions, 1.65 g of CoA was synthesized in 50 mL of a reaction mixture containing *p*-pantothenic acid, L-cysteine, and ATP (molar yield based on ATP, 64.5%).[211] In a similar manner, 115 g L^{-1} of CoA was synthesized from *p*-pantetheine and ATP (quantitative yield).[211]

Another way to improve the CoA yield is to use mutants derepressed as to the feedback inhibition or ones showing elevated pantothenate kinase activity. A mutant strain of *B. ammoniagenes* resistant to oxypantetheine, an oxygen analogue of pantetheine, in which pantothenate kinase activity is threefold higher than in the parent strain, produces 9.3 g L^{-1} of CoA from pantothenic acid (3.6 g L^{-1}), L-cysteine (1.8 g L^{-1}), and AMP (6 g L^{-1}) or 11.5 g L^{-1} of CoA from pantetheine (5 g L^{-1}) and AMP (6 g L^{-1}) with the ATP generation system shown in Figure 10b (molar yield based on AMP, 70–100%).[212] These values are about threefold higher than those in the case of the parent strain.

The reaction conditions for the selective synthesis of *p*-pantothenic acid, *p*-pantetheine, or 3′-dephospho-CoA have also been established.[207, 213]

S-Adenosylmethionine (AdoMet), S-adenosylhomocysteine (AdoHcy)[77, 214] and related nucleosides have recently attracted great interest as key regulator compounds for many biological transmethylation reactions (Fig. 12). Although the great possibilities of these nucleosides in the pharmaceutical and chemotherapeutic fields have been suggested,[215] no process for the practical production of these nucleosides had been established before our current work.

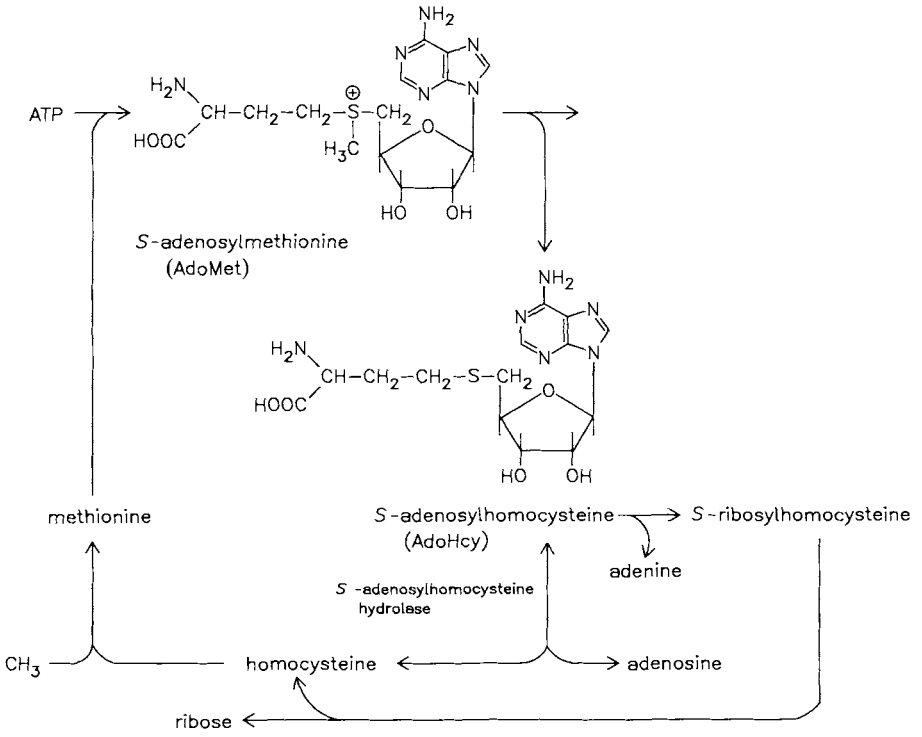

Fig. 12. The activated methyl cycle (*S*-adenosylmethionine).

We have tested a variety of microorganisms as to their ability to accumulate AdoMet derived from L-methionine and found that a group of sake yeasts (*Saccharomyces sake* strains) specifically accumulate the added methionine as AdoMet.[198] *S. sake* Kyokai No. 6, which was selected as the most promising producer, converts about 25% of the added L-methionine (10 g L^{-1}) into AdoMet, when grown with sucrose and urea as the main carbon and nitrogen sources, respectively. Under suitable conditions, 11 g L^{-1} of AdoMet is accumulated in vacuoles in the cells. This amounts to more than 25% of the total dry cell mass, comparing favorably with the commercially available AdoMet-rich yeast which contains only about 20 mg g^{-1} solids. Such abnormal production of AdoMet has been suggested to be mainly due to the significantly high methionine adenosyltransferase (EC 2.5.1.6) activity in this yeast.

AdoHcy is the product of biological transmethylation reactions that utilize AdoMet as the methyl donor. Before our work, two characteristic reactions, the cleavage of the glycosyl linkage of AdoHcy, yielding adenine and *S*-ribosylhomocysteine, followed by the hydrolysis of the *S*-ribosylhomocysteine to L-homocysteine and ribose, had long been believed to be the only reactions for the metabolism of AdoHcy in prokaryotic cells, whereas AdoHcy is directly hydrolyzed to L-homocysteine and adenosine by AdoHcy hydrolase in eukaryotic cells (see Fig. 12 and Ref. [215]). Our screening study for suitable enzymes for the synthesis of AdoHcy revealed that many prokaryotic cells contain AdoHcy hydrolase in considerably high amounts.[216] Prokaryotic AdoHcy hydrolase can easily be purified and crystallized from cells of *Alcaligenes faecalis*, in which the cellular content of this enzyme comprises about 2.5% of the total extractable protein.[216] This value is about 100 times higher than in the case of eukaryotic sources.

Since the synthetic direction is greatly favored for the in vitro hydrolysis of AdoHcy by AdoHcy hydrolase and the enzyme is considered to be a useful catalyst for the synthesis of AdoHcy from L-homocysteine and adenosine, the synthesis of AdoHcy is carried out by incubating adenosine and L-homocysteine with cells of *A. faecalis* (yield, 70–80 g L^{-1}).[217] A problem with this synthetic method was that the D isomer of homocysteine is not recognized by the enzyme. To overcome this, microbial strains capable of synthesizing AdoHcy from D-homocysteine were screened for. *Pseudomonas putida* was found to be such a strain. Although the *P. putida* hydrolase, like the *A. faecalis* enzyme, will only utilize L-homocysteine, the bacterium also produces a racemase which catalyzes the interconversion of the D- and L-homocysteine isomers. On mixing adenosine and DL-homocysteine with a mixture of *A. faecalis* cells (36 g L^{-1}) and *P. putida* cells (4 g L^{-1}) in potassium phosphate buffer, more than 70 g L^{-1} of AdoHcy was obtained in an essentially quantitative yield.[218]

In a similar manner, a number of other novel *S*-nucleosidylhomocysteines can be efficiently synthesized from the corresponding adenosine analogues, e.g., formycin A, neburalin, and adenosine N^1-oxide.[219] These may be promising in the pharmaceutical and chemotherapeutic fields.[215]

5.5. Organic Acids

Optically active α- and β-hydroxycarboxylic acids and their derivatives are important chiral building blocks. Various routes to them have been studied, especially in synthetic organic chemistry. Recently, several useful microorganisms, as described below, were found in screening studies. Other microbial transformations of practical importance yielding organic acids are listed in Table 6.

D-(−)-β-Hydroxyisobutyric acid: Optically active β-hydroxyisobutyric acid has been used as a versatile chiral building block. The L-(+) enantiomer has been used for the synthesis of α-tocopherol,[48] muscone,[49] lasalocid A,[220] calcimycin,[221] and other compounds, while the D-(−) enantiomer is useful for the synthesis of an angiotensin converting enzyme inhibitor, captopril.[222] Several routes to optically active β-hydroxyisobutyric acid have been reported; β-hydroxylation of isobutyric acid,[107,222] hydration of methacrylic acid,[107] enantioselective oxidation of prochiral 2-methyl-1,3-propanediol,[223] and stereoselective reduction of ethyl α-formylpropionate.[224] β-Hydroxylation of isobutyric acid by *Pseudomonas putida* and most other microorganisms yields the L-(+) enantiomer.[107,222] Only a few microorganisms, including *Candida rugosa*, specifically produce the D-(−) enantiomer.[107] A mutant strain derived from *C. rugosa* that lacks β-hydroxyisobutyrate dehydrogenase and is therefore unable to catalyze further oxidation of β-hydroxyisobutyric acid to isobutyraldehyde has been reported to produce 36.6 g L^{-1} of D-(−)-β-hydroxyisobutyric acid in a nearly quantitative yield.[225] This conversion has been applied to the commercial production of captopril (Fig. 13).[222]

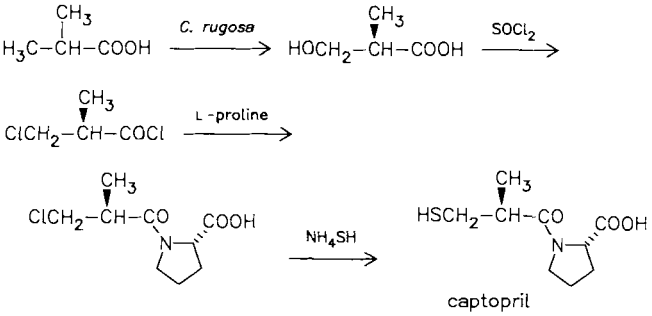

Fig. 13. Synthesis of captopril involving enzymatic oxidation of isobutyric acid.

D-(−)-Pantoyl lactone, the γ-lactone of D-(−)-pantoic acid, is an important starting chiral material for the synthesis of a vitamin, D-(+)-pantothenic acid. The conventional synthesis involves the tedious chemical resolution of racemic pantoyl lactone. We have recently reported two efficient microbial processes that overcome this problem. *Rhodococcus erythropolis* was found to convert only the L-(+) enantiomer in a racemic mixture of pantoyl lactone into the D-(−) enantiomer without any modification of the coexisting D-(−) enantiomer. Under suitable reaction conditions with washed cells as the catalyst, D-(−)-pantoyl lactone in the reaction mixture reached 18.2 g L^{-1} with an optical yield of 94.4% *e.e.* (chemical molar yield, 90.5%).[226] This unique conversion proceeds through the

successive reactions shown in Figure 14: (1) the enzymatic oxidation of L-(+)-pantoyl lactone to ketopantoyl lactone; (2) the rapid and spontaneous hydrolysis of the ketopantoyl lactone to ketopantoic acid; (3) the enzymatic reduction of the ketopantoic acid to D-(−)-pantoic acid. The process is simple and requires no reracemization step, which is necessary for the conventional chemical resolution.

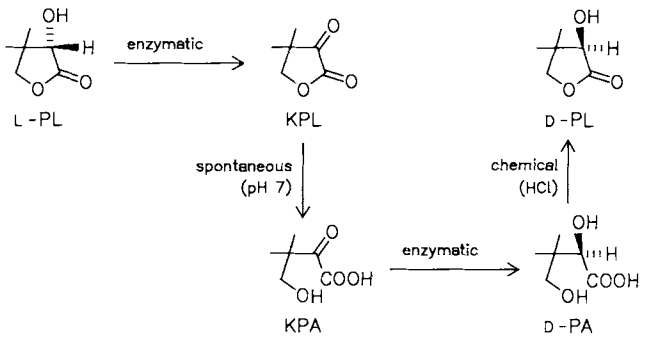

Fig. 14. Stereoselective oxidation and reduction system for the conversion of L-(+)-pantoyl lactone to the D-(−) enantiomer by *Rhodococcus erythropolis* cells. D-PL, D-(−)-pantoyl lactone; L-PL, L-(+)-pantoyl lactone; D-PA, D-(−)-pantoic acid; KPL, ketopantoyl lactone; KPA, ketopantic acid.

Another approach is the enantioselective reduction of ketopantoyl lactone to D-(−)-pantoyl lactone.[53,61,108,227] When *Candida parapsilosis* or *Rhodotorula minuta* cells are incubated with ketopantoyl lactone and glucose, about 100 or 50 g L^{-1}, respectively, of D-(−)-pantoyl lactone is produced in excellent chemical (95–100%) and optical (90–95% *e.e.*) yields.[53,108,227] In this reaction, the asymmetric reduction is catalyzed by a newly found carbonyl reductase specific to conjugated polyketones which requires NADPH as a cofactor.[53] Glucose is thought to be the energy source for the regeneration of NADPH.

5.6. Commodity Chemicals

Microbial transformations in the industrial production of commodity chemicals are rapidly gaining practical significance from several viewpoints (see Section 3). The first successful example, the production of acrylamide by bacterial nitrile hydratase, is described here. Other possible transformations of nitrile compounds are also discussed.

Acrylamide is widely used as a flocculant agent and as a component of synthetic fibers. The conventional synthetic process involves hydration of the nitrile with sulfuric acid or the use of copper salts or palladium complexes as catalysts. From the results obtained in extensive studies on the microbial degradation of nitrile compounds, we have established a new process involving a microbial enzyme, nitrile hydratase, as a catalyst for the hydration of the nitrile.[228]

A novel enzyme, aliphatic nitrile hydratase, which hydrates acetonitrile to acetamide, was highly purified from cells of an acetonitrile-utilizing *Arthrobacter* sp. and characterized in some detail.[229] The enzyme is quite different from nitrilase (EC 3.5.5.1), which catalyzes the formation of acids through hydrolytic elimination of the nitrogen atom to give the ammonium salt [Eq. (9)], in yielding amides through a simple hydration [Eq. (10)].

$$RCN + 2H_2O \longrightarrow RCOOH + NH_3 \quad (9)$$

$$RCN + H_2O \longrightarrow RCONH_2 \quad (10)$$

The proposed reaction mechanisms for nitrilase and nitrile hydratase are shown in Figure 15. A nucleophilic attack by a reactive thiol group of the respective enzyme on the nitrile carbon leads to the formation of an enzyme-bound imine, which is then hydrated to a tetrahedral intermediate (Fig. 15a). This process is the same for both enzymes. In the case of nitrilase catalysis, ammonia is then removed from the intermediate and an acyl-enzyme is formed. The acyl-enzyme is then hydrolyzed to a carboxylic acid (Fig. 15b). On the other hand, the enzyme itself is a leaving group in the case of nitrile hydratase. Thus, an amide is produced (Fig. 15c). The hydratase catalyzes the hydration of a variety of aliphatic nitriles including acrylonitrile and methacrylonitrile. However, when cells of *Arthrobacter* sp. were directly used as the catalyst for amide production, the substrate nitrile compounds were almost completely converted into the corresponding acids. This was due to the simultaneous inducible formation of an amidase (EC 3.5.1.4) showing high activity in the cells.[39] Therefore, screening for microorganisms with high nitrile hydratase and low amidase activities was carried out using various nitrile compounds as growth substrates. *Pseudomonas chlororaphis* B23 was found to be such a strain when grown with isobutyronitrile as the major nitrogen source. Although this bacterium inducibly produces an amidase (which shows some activity toward isobutyronitrile) together with the hydratase during growth, this amidase is, fortunately, almost completely inactive toward acrylamide.[39] This suggests that, theoretically, the stoichiometric conversion of acrylonitrile to acrylamide is possible even when the hydratase preparation is contaminated by amidase.

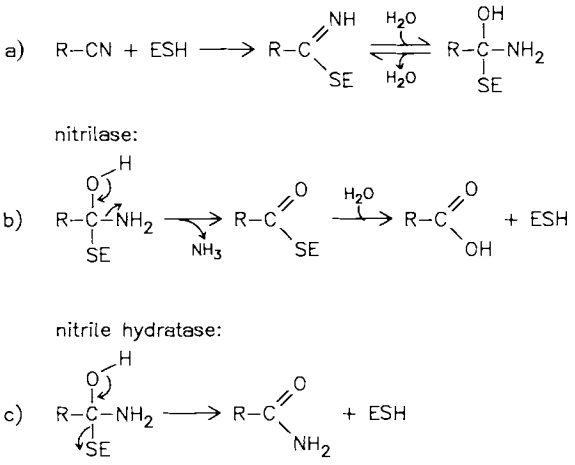

Fig. 15. The proposed reaction mechanism for nitrilase and nitrile hydratase. ESH, enzyme with thiol group (see text).

In practice, the reaction is carried out by incubating acrylonitrile with the *Pseudomonas* cells at low temperature (usually 5 to 10°C). Since acrylonitrile is a specific

modifier of general protein thiol groups, the active site of the nitrile hydratase may be masked by this nitrile at higher temperatures. Under suitable reaction conditions, more than 400 g L^{-1} of acrylamide can be produced in a nearly quantitative yield. In a similar manner, methacrylamide (200 g L^{-1}), acetamide (150 g L^{-1}), propionamide (560 g L^{-1}), *n*-butyramide (160 g L^{-1}), crotonamide (200 g L^{-1}), and isobutyramide (100 g L^{-1}) can be produced.[39]

After optimization of the culture conditions for *Pseudomonas* nitrile hydratase production, the enzyme activity in the culture broth was 900 times higher than that previously reported.[230] The *Pseudomonas* nitrile hydratase has recently been characterized in detail.[231] This process is simple, clean, and rapid, requires no special equipment to provide a source of energy and yields a highly pure product. *P. chlororaphis* B23 was used for the commercial production of acrylamide in 1987.

As suggested by the above example, nitrile converting enzymes such as nitrile hydratase, amidase, and nitrilase constitute a group of enzymes which are expected to have great potential as catalysts in organic chemical processing. In particular, hydratases and amidases are widely distributed in microorganisms. They are usually produced by a single microorganism and show broad substrate specificities. Therefore, these enzymes may be utilized not only for the preparation of amides but also for wide-ranging and more flexible purposes: for example, for the synthesis of optically pure amino acids and hydroxy acids from the corresponding amino nitriles or cyanohydrins, respectively. The enzymatic hydrolysis of a dinitrile, for example, may give rise to five different products, i.e., monoamide mononitrile, monoacid mononitrile, diamide, monoamide monoacid, and diacids, whereas acid- or base-catalyzed hydrolysis gives only diamide and diacid. Furthermore, many other useful compounds may be derived from a nitrile in connection with other chemical or enzymatic reactions (see Fig. 16).[232]

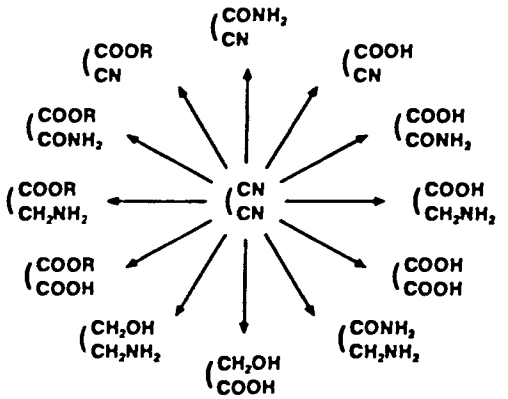

Fig. 16. Possible microbial transformations of dinitriles.

5.7. Lipids

The preparation of oleochemical intermediates such as fatty acids, fatty acid esters, and fatty alcohols involves steps which can also be carried out enzymatically. Lipases are key enzymes in such transformations.[233] They can be used for selective or partial fat splitting, hydrolysis of wax esters to yield fatty alcohols, and ester synthesis and transesterification.

Specific lipases yield valuable triacylglycerol mixtures, depending on their regioselectivity, which cannot be obtained by conventional chemical esterification processes. The transesterification of palm oil with fatty acid methyl esters leading to the cocoa butter equivalent and the hardening of plant oils through interesterification with higher-melting triacylglycerols are interesting examples in this field.[234]

Other examples are the terminal oxidation of fatty acids or *n*-alkanes to dicarboxylic acids,[105] the preparation of prostaglandin synthons, and the modification of prostaglandins.[235]

6. Concluding Remarks

Theoretically, it is possible to perform multistep reactions using microbial transformations, as shown for the synthesis of CoA. Microbial transformations are, however, mostly used in single-step reactions, where their highest potential lies.

Microbial transformation requires a substrate whose structure is closely related to the product, as is the case for conventional chemical synthesis. This is a drawback, because processes such as chemical synthesis and fermentation are required to supply the substrate.

In the production of useful compounds, microbial transformations, fermentative processes, and chemical syntheses seem to compete with each other. However, the best results are obtained with combinations of these methods, as the previous examples have shown.

Microorganisms show great ability to adapt to a wide variety of environments in comparison to higher cells. Therefore, they have a great potential for inducing new or novel enzyme systems capable of converting foreign substrates. It is possible to obtain and cultivate microorganisms that can survive or grow in extraordinary environments, e.g., psychrophilic, thermophilic, acidophilic, and alkalophilic ones. These microorganisms are capable of producing unique enzymes stable toward heat, alkali, and acid. In addition, techniques for cultivation and enzyme purification, as well as gene and enzyme technology, have made great advances. Taking all of these facts into consideration, there must be far more ways than one can imagine of using microorganisms for the production of useful compounds.

Electron-Transfer Chain Catalysis in Organotransition Metal Chemistry**

By Didier Astruc*

Dedicated to Professor Jean Tirouflet

Parallel to organic electrocatalysis, the field of organotransition metal electrocatalysis has developed explosively since 1980. The theoretical and experimental foundations established by *Feldberg* in 1971 (ECE mechanism) have been applied, using fast electrochemical techniques, to various organometallic reactions such as isomerization, ligand exchange, chelation, decomplexation, and CO insertion and extrusion. Most of the work performed to date concerns ligand exchange reactions of N-donors and P-donors in mononuclear compounds, initiated by oxidants (or anodes) and of carbonyls and P-donors in clusters, initiated by reducing agents (or cathodes). The preparative aspects of electrocatalysis have already been impressively developed in cluster chemistry and indicate that the technique is extremely useful. This review first delineates the principles and characteristics of electrocatalysis applied in organotransition metal chemistry, and then, after outlining the choice of efficient initiating reagents, goes on to describe the systems up to August 1986.

1. Introduction

"Electron-transfer (ET) catalysis" is an exceedingly large branch of chemistry which has its origin in the chlorine exchange reactions carried out in inorganic systems by *Taube* et al.,[1] as well as *Basolo*, and *Pearson* et al. (1954–1960).[2–5] In organic chemistry, its origin traces back to the discovery of catalytic nucleophilic substitution by *Kornblum*, the well documented $S_{RN}1$ mechanism so named and explored by *Bunnett*[8] and by *Russel* et al.[9, 10] The first applications in electrochemistry were reported by *Savéant* and *Amatore* et al.[11–15] Reviews by all these authors are available,[5, 7, 8, 10, 13] and recently critical views on the multiple aspects of ET catalysis have been reported by *Chanon* et al.[16–19] The scope of the present review is restricted to the electrocatalysis of organotransition metal reactions since these have indeed attracted a great deal of interest recently.[20–35] The technique has proven successful for ligand exchange reactions, decomplexations, chelations, isomerizations, insertions and extrusions. As we shall see, the success of all these reactions is due to the extremely fast interconversion of paramagnetic transition metal centers between 17- and 19-valence electron configurations[36–49] and to the ability of transition metal compounds to effect redox processes.[20] Some types of "electron-transfer catalysis" will not be considered here: (i) electrogeneration of transition metal catalysts, which subsequently behave according to pairwise pathways;[50–51] (ii) hydrogen-transfer and alkyl-transfer chain reactions;[21–23] (iii) electron-transfer reactions (as alternatives to electrophilic[40] or nucleophilic attacks[52]) occurring without an external catalytic source of electrons or electron holes.[16–20] Since there is considerable confusion in the literature concerning the nomenclature of redox catalysis and electron-transfer chain (ETC) catalysis (electrocatalysis), we shall start with their definition.

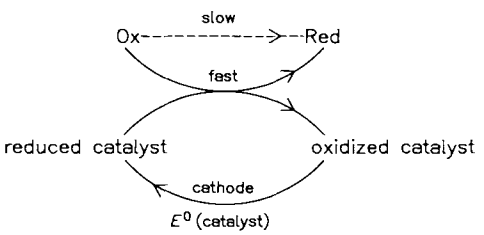
2. Distinction between ETC Catalysis (Electrocatalysis) and Redox Catalysis (Mediated Electrochemistry)

It is essential to distinguish between these two types of ET-catalyzed reactions.[53]

ETC catalysis concerns the catalysis of a reaction by an "electron" or by an "electron hole", which, overall, does not result in a redox change (a typical one is ligand exchange), whereas redox catalysis[54] consists in lowering the kinetic barrier of a reduction or of an oxidation which otherwise requires an overpotential (surtension) at the electrode (Scheme 1). For instance, an appropriate redox



Scheme 1. Principle of redox catalysis.

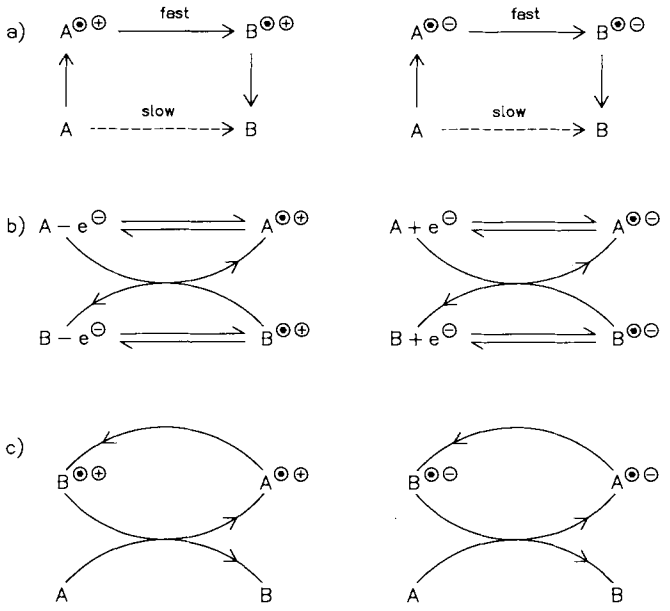
mediator can lower the potential of reduction of protons at a mercury cathode, or, in other words, diminish the surtension and bring the potential values as close as possible to the thermodynamic potential. In spectacular cases, the redox mediator may effect the reduction of a substrate which is not electroactive under normal working conditions, i.e. given the surtension of reduction of the substrate on the

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0505-0643 $ 02.50/0

cathode in this medium, the solvent or electrolyte would be reduced at a lower potential than the substrate. The redox mediator merely helps to convey the electrons in solution. This task, however, is a major one in saving energy, as is the case in the fuel cell for the photosplitting of water,[54-56] in the reduction of oxygen,[57] and in biological processes.[58]

3. The Principle of Electrocatalysis (ETC Catalysis)

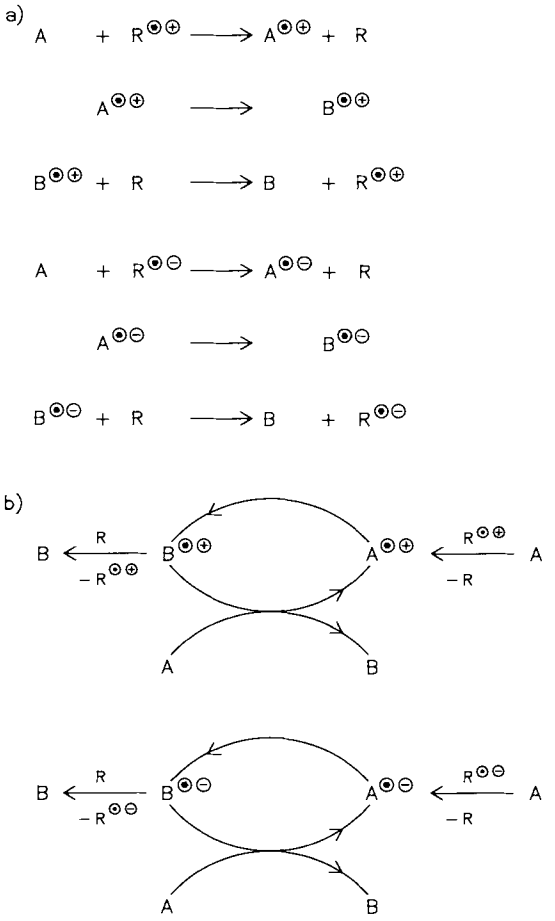
Catalytic amounts of an oxidizing or reducing agent can considerably increase the rate of a reaction. For instance, the substrate A, if neutral, is activated in the form of its radical cation or radical anion and reacts rapidly in this state to give the radical cation or the radical anion of the product. The latter reacts rapidly with the starting material in a "cross redox reaction" to give the product B, which closes the electrocatalytic cycle (Scheme 2).



Scheme 2. Schematic representations of the electrocatalysis of reaction A→B. Left: via radical cations. Right: via radical anions. Notation: a) as square; c) cyclic; b) mixture of (a) and (c).

In order to activate the substrate A, one can use a catalytic amount of a redox reagent or an electrode at an appropriate potential. In the case of a soluble redox reagent the ET is homogeneous, whereas in the case of an electrode it is heterogeneous. In both cases, the ET step closing the electrocatalytic cycle (formation of B) can proceed directly, or via the redox reagent or via the electrode, depending on their respective potentials. In the latter case, the redox reagent or the electrode plays a double role: that of initiator and that of electron transfer agent (Scheme 3).

Let us consider the slow reaction of a closed shell, 18-electron transition metal center A to give a product B, of the same 18-electron configuration. The use of a small amount of a suitable oxidant will provide a reactive paramagnetic 17-electron cation $A^{\oplus}$, to give the desired reaction $A^{\oplus} \rightarrow B^{\oplus}$. One may design the system such that the 17-electron complex $B^{\oplus}$ is a better oxidant than $A^{\ominus}$ and A will react with $B^{\oplus}$ in a cross redox reaction to close the electrocatalytic cycle:



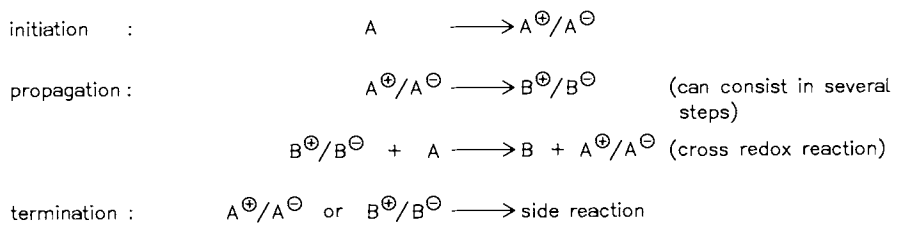
Scheme 3. In the case of an electrode, the redox forms of the electrocatalyst R are replaced by $\vec{E}$ and $\dot{E}$ at this electrode at the appropriate potential. a) Chain mechanism for electrocatalytic cycle where the back ET is mediated by the electrocatalyst R (or electrode). b) Cyclic representation for electrocatalysis where the back ET proceeds either directly by cross redox reaction or via mediation of the redox reagent R (or electrode). In each case reaction via radical cations above, reaction via radical anions below.

$$B^{\oplus}(17e^{\ominus}) + A(18e^{\ominus}) \longrightarrow B(18e^{\ominus}) + A^{\oplus}(17e^{\ominus})$$

This condition becomes indispensible if the reaction $A^{\ominus} \rightleftharpoons B^{\oplus}$ is reversible or shifted to the left; the cross redox reaction is the driving force. Similarly, if one designs a reaction catalyzed cathodically or by a reducing agent, the generation of $A^{\ominus}$, a paramagnetic 19-electron center, induces the reaction $A^{\ominus} \rightarrow B^{\ominus}$. The complex $B^{\ominus}$ is likewise a paramagnetic 19-electron species, which in order to enable the cross redox reaction $B^{\ominus} + A \rightarrow B + A^{\ominus}$ to complete the cycle, must be a better reducing agent than $A^{\ominus}$.

In this way, one is dealing with a catalytic chain process for the overall reaction A→B (Scheme 4). In a way, one may view the electron itself as the catalyst.

Both propagation steps must be very fast in order to limit the competition of side reactions of radical ions and of other intermediates eventually involved in the course of the reaction. If $B^{\oplus}$ is not a better oxidant than $A^{\oplus}$ (or if $B^{\ominus}$ is not a better reducing agent than $A^{\ominus}$), i.e. if the cross



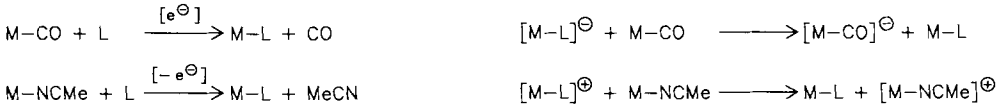
Scheme 4. Chain propagation step of an ETC reaction. The abbreviation $A^{\oplus}/A^{\ominus}$ embraces both oxidatively as well as reductively initiated reactions (cf. Scheme 2).

redox reaction is approximately isoergonic, the only remaining possibility of a driving force for the reactions A→B is the irreversibility of the first chain propagation step.

Electrochemists, who initiate such processes with electrodes, refer to electrocatalysis as an ÊCĒ mechanism (Ê: initiation by ET; C: chemical reaction, the first propagation step; Ē is a "back ET", the second propagation step which can occur in the solution or at the electrode). The ECE (electrocatalytic cycle) was first recognized as such and carefully studied by *Feldberg*[59] in 1972[60] using an organochromium system.[63]

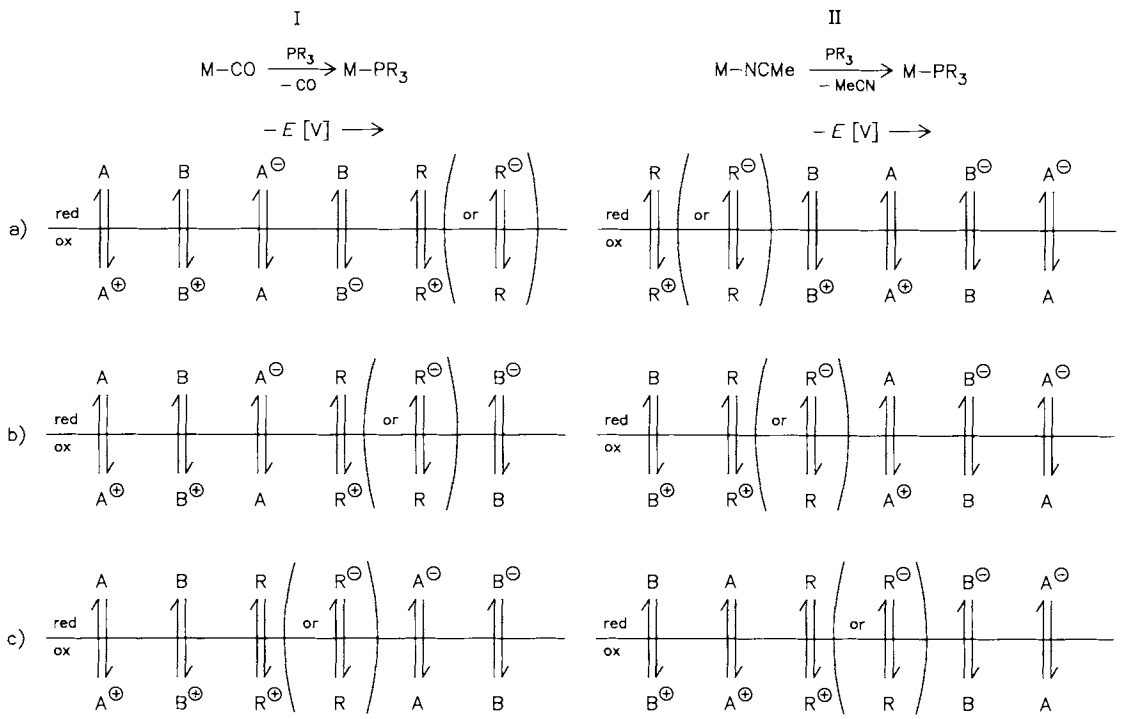
4. How to Initiate a Reaction?

Suppose that one needs to effect a reaction A→B, that the reaction is too slow, and that one wishes to achieve it using electrocatalysis. One may do this either with an electrode or with a redox reagent. The first questions which have to be answered are: (i) Will the reaction be initiated by an oxidizing or a reducing agent? (ii) What is the oxidizing or reducing power needed for the reaction? We have seen in Section 3 (Scheme 4) that there are two propagation steps and that the driving force will be provided by one of these steps. If one does not know "a priori" about the reversibility of the step $A^{\oplus}/A^{\ominus} \rightarrow B^{\oplus}/B^{\ominus}$, which is generally the case, one can envisage gaining the driving force from the ET propagation step $B^{\oplus}/B^{\ominus} + A \rightarrow B + A^{\oplus}/A^{\ominus}$. This means that, if B is more difficult to reduce than A, one can get a driving force in the ET propagation by choosing reduction. Note, however, that the driving force has nothing to do with the strength of the reducing agent which initiates the reaction. On the other hand, if B is more difficult to oxidize than A, one can gain the driving force in the ET propagation step by choosing oxidation. One may be required to guess the relative potentials of reduction and oxidation of A and B, especially if B is not yet a known compound. If oxidation and reduction do not involve the same orbitals (HOMO≠LUMO), it may be that both oxidation and reduction (or neither) provide a driving force. However, since A and B are often closely related compounds, the most frequent case is that only oxidation *or* reduction is suitable for initiation and a choice between the two is essential. If B and an electrochemical setup are available, one may easily check this by recording the cyclic voltammogram (CV) of A and B (if possible in the solvent chosen for the reaction) in order to determine the relative values of their oxidation and reduction potentials. For instance, when one wishes to replace CO by another neutral two-electron ligand, the product B will be more electron-rich than A because CO is one of the most electron withdrawing neutral ligands. One must choose reduction because the expected reaction product B is more difficult to reduce than A. On the other hand, if one wishes to replace MeCN in A by another ligand L, one must choose oxidation because B will be more difficult to oxidize than A (MeCN being one of the most electron releasing ligands; Scheme 5).



Scheme 5. Initiation of ligand exchange reactions (left) by $[e^{\ominus}]$ or $[-e^{\ominus}]$ to gain a driving force ($\Delta G < 0$) from the cross redox propagation step (right). π-Acidity [62]. CO > L > NCMe; E^0_{ox}: M-CO > M-L > M-NCMe$_3$; E^0_{red}: M-CO < M-L < MNCMe.

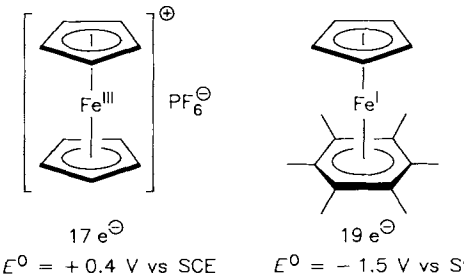
One must then choose the nature and strength of the redox reagent (R, $R^{\oplus}$ or $R^{\ominus}$) able to initiate the reaction. For this purpose, one is guided by a simple comparison of the oxidation or reduction potentials of A and of the initiator R. If one initiates the process by reduction, one must choose the reagent R or $R^{\ominus}$ so that its oxidation potential is at least close to (or more negative than) that of A. Conversely, if the initiator R or $R^{\oplus}$ is an oxidant, its reduction potential should be close to (or more positive than) that of A. The ET initiation need not be fast in order to obtain an efficient electrocatalytic cycle. This step can be reversible: $A + R \rightleftharpoons A^{\oplus} + R^{\ominus}$. Thus, there is considerable flexibility in this choice, provided the above condition is fulfilled. When the catalytic efficiency is low because of side reactions, selection of a redox reagent (or of an electrode) with a potential as close as possible to that of A improves the reaction yield since the redox reagent (or the electrode) can then serve as mediator for the "back" ET of $B^{\oplus}/B^{\ominus}$. If the rate of the "back" ET $B^{\oplus}/B^{\ominus} \rightarrow B$ is faster with the redox reagent (or the electrode) than with A (direct cross re-



Scheme 6. The redox initiator R is chosen as a function of the relative "electron-richness" of A and B and of the catalytic efficiency. I: B electron-rich, i.e. not as easily reduced as A; reductive initiation with R or $R^{\ominus}$. II: B electron-deficient, i.e. not as easily oxidized as A; oxidative initiation with R or $R^{\oplus}$. The potential of R relative to that of A and of B (a–c) is relatively unimportant in the case of efficient systems, but c > b > a is a good choice in the case of poorly efficient systems. The situation Ic/IIc can be realized best with an electrode as R, but redox reagents could work also.

dox reaction), this efficient process competes better with the side reactions of $B^{\oplus}/B^{\ominus}$ (Scheme 6).

Electrocatalysis has been efficiently practiced using either an electrode or a redox reagent as initiator (electrocatalyst). It is thus extremely useful to have at hand a library of redox reagents and a knowledge of their redox potentials. Table 1 provides a list of the most convenient and commonly used electrocatalytic initiators.[64] Stable, paramagnetic sandwich compounds of iron are very easy to prepare on a large scale: ferrocenium (17-$e^{\ominus}$)[65] is probably the most useful of all the one-electron oxidants and [$Fe^{I}CpC_6Me_6$] (19-$e^{\ominus}$)[47] one of the most useful reducing agents (Scheme 7).



Scheme 7. These two iron sandwiches are perfectly stable redox systems: Fe^{I}/Fe^{II} and Fe^{III}/Fe^{II}. They should be able to electrocatalyze most organometallic reactions dealt with in this review. The Fe^{I} compound has the advantage, over the reagents Na/Ph_2CO and $Na/C_{10}H_8$, in that its corresponding cation is large, so that large organometallic anions are stabilized, thus preventing their undergoing side reactions (cf. clusters).

In summary, one can most simply initiate an electrocatalytic reaction using a redox reagent; a more sophisticated means is the use of an electrode in a preparative electrolytic cell (application of a small current); an occasional means is photochemistry (photoelectrocatalysis), where the initiation is provided by ET between the photoexcited state and a quencher, which then liberates the redox reagent.

5. Coulombic Efficiency

In all cases where electrocatalysis has been used, the desired organometallic reaction was very slow or inefficient in the absence of an electrocatalyst. Low yields were eventually obtainable at high temperatures, typically 100 to 150 °C, but interest in this thermal process is limited, since the selectivity is often a problem and the substrate and products often decompose. In contrast, with an electrocatalyst the same reactions were found to proceed rapidly (typically a few minutes) and in very high yields (90–100%) at room temperature. Even the selectivity problem, when it arose, was easily overcome; for instance in cluster chemistry, the number of ligand exchange reactions can be well controlled. The catalytic chains were often very long. This impressive efficiency of the technique is no doubt due to the combination of two properties of transition metal complexes: their ability to change oxidation state very rapidly[5] (the ET propagation step is very fast) and the high rate of ligand exchange between a 17-electron and a 19-electron valence shell configuration ($17\,e^{\ominus} + L \rightleftharpoons 19\,e^{\ominus}$).[36–46] In spite of their high reactivity, these paramagnetic states turn out to be not too unstable (in many cases, they could be characterized quite well by spectroscopic techniques). Thus, side reactions were rather slower than the

Table 1. Redox reagents [64], candidates for electrocatalysis. Note, the redox potential of sandwich complexes can be finely tuned by modification of the number of ring substituents (only approximate values are given for the redox potentials). DMF = dimethylformamide.

desired propagation steps ($A^{\oplus}/A^{\ominus} \rightarrow B^{\oplus}/B^{\ominus}$). The catalytic efficiency (chain length) can be measured by determining the number of molecules B formed per electron transferred by the initiator R (redox reagent or electrode). It is also called the "coulombic efficiency." If 2% of one-electron transfer reagent is necessary to obtain an 80% yield, the coulombic efficiency is 40 molecules per electron, a number actually often surpassed. *Kochi* et al. obtained coulombic efficiencies of more than 1000 for ligand exchange reactions in Mn^I complexes initiated by oxidants.[66] Electrochemistry permitted coulometric experiments to be performed at constant intensity, with monitoring of the potential. The end of the reaction is then indicated by a sudden change of potential as in classical potentiometric titrations. If a redox reagent is used, its amount can be varied so as to determine the quantity needed to obtain an optimum yield. These experiments also give an idea of the rate of the reactions.

6. Simple Evidence for Electrocatalysis by Cyclic Voltammetry (CV)

Suppose one wishes to check the electrocatalytic reaction A → B, say a ligand exchange reaction. The CV gives a wave for A which may be reversible or not (at least a certain degree of reversibility should be observable on lowering the temperature and speeding up the scan). In the presence of the entering ligand L^1, the CV of A will show the appearance of a new wave due to the reaction product $B(A \xrightarrow[-L^2]{L^1} B)$. If the wave of A is a cathodic one ($A \rightarrow A^{\ominus}$), setting the potential at or sweeping through this wave generates $A^{\ominus}$ in the vicinity of the cathode. Thus, this initiation having occurred, the electrocatalytic reaction rapidly gives B in the vicinity of the cathode. This explains the observation of a CV wave for B. Meanwhile the CV wave of A is profoundly affected: since $A^{\ominus}$ reacts rapidly with L^1 to give B, its concentration in the neighborhood of the cathode is strongly diminished and can reach zero (depending on the relative rates of the sweep and of the propagation reaction of $A^{\ominus}$ with L^1). Thus, the return anodic wave of A ($A^{\ominus} \rightarrow A$) is much less intense in the presence of L^1. A is also consumed by the cross redox reaction ($A + B^{\ominus} \rightarrow A^{\ominus} + B$); hence, its intensity is also diminished. In this case the wave of B is located at a more negative potential than that of A (Fig. 1). If A can be both oxidized and reduced, one may compare the possibilities of cathodic and anodic electrocatalysis by examining both parts of the voltammogram.

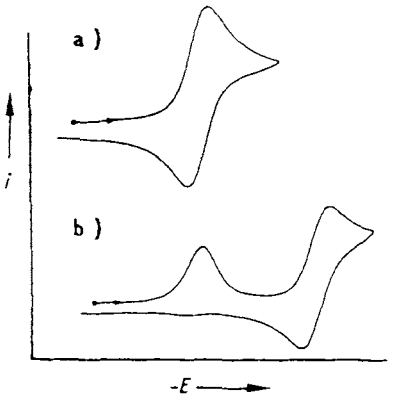

Fig. 1. CV wave of A: a) in the absence of Ligand L^1; b) in the presence of L^1 (appearance of the wave of B at a more negative potential). Electrocatalysis initiated by a cathodic current: $A \xrightarrow[(e^{\ominus})]{L^1} B$.

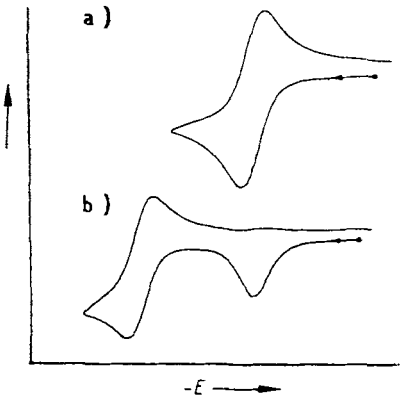

Fig. 2. CV wave of A: a) in the absence of L^1; b) in the presence of L^1 (appearance of the wave of B at a more positive potential). Electrocatalysis initiated by an anodic current $A \xrightarrow[(-e^{\ominus})]{L^1} B$. In the extreme case (fast ETC), the wave of A totally disappears in Figures 1 and 2.

On the other hand, if a ligand exchange reaction is electrocatalyzed by a small anodic current, the CV wave normally observed in the absence of the ligand is modified in the presence of this ligand and a new wave due to the reaction product appears at a more positive potential (Fig. 2).[67]

This behavior is characteristic of electrocatalysis and gives an idea of the rate of both propagation steps.

7. Reaction Mechanism

7.1. Observable Intermediates

On varying the scan rates, CV shows the disappearance of A, $A^{\oplus}/A^{\ominus}$, and $B^{\oplus}/B^{\ominus}$. These experiments can however be performed at room temperature in order to observe the overall electrocatalytic cycle at a reasonable scan rate. Lowering the temperature allows the observation of intermediates by freezing the reaction or effecting each step sequentially. Spectroscopy, especially ESR, enables a structural investigation of the intermediates, in particular the paramagnetic ones $A^{\oplus}/A^{\ominus}$ and $B^{\oplus}/B^{\ominus}$, since the diamagnetic, ESR-silent compounds A and B, although present in solution, are not observed. This type of experiment provides highly valuable information when the reaction studied is not exceedingly simple, i.e. it is important for checking whether other intermediates X and Y are observable besides and between $A^{\oplus}/A^{\ominus}$ and $B^{\oplus}/B^{\ominus}$ [Eq. (a)].

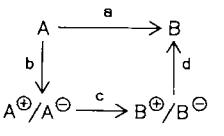
$$A^{\oplus}/A^{\ominus} \xrightarrow{a} X \xrightarrow{b} Y \xrightarrow{c} B^{\oplus}/B^{\ominus} \qquad \text{(a)}$$

7.2. Kinetics

After these important qualitative characterizations, one may proceed to a quantitative treatment of the electrochemical kinetics in order to determine the rate constant of the rate-limiting step. Usually, the ET propagation step is fast and the rate-limiting step concerns the other propagation step $A^{\oplus}/A^{\ominus} \rightarrow B^{\oplus}/B^{\ominus}$, or if there are other intermediates, as assumed in Equation (a), it can be step a, b or c. The rate constants can be determined by theoretical methods, but these will not be dealt with in detail here (construction of theoretical CV,[68-70] computer simulation of the CV by the method of finite differences,[69] a-dimensional analysis).[70] The determination of this rate constant at various temperatures will eventually provide an Arrhenius plot allowing the determination of ΔH and ΔS; additional mechanistic factors can be gleaned therefrom (e.g. a negative activation entropy is consistent with an associative mechanism).[66]

7.3. Thermodynamics

The two chain propagation steps of the catalytic cycle (Scheme 4) can each provide a driving force for the reaction, and the algebraic sum of the two gives the overall free energy ΔG of the reaction A→B (Scheme 8). Overall, ΔG must be negative.



$$\Delta G_{A\rightarrow B} = a = \Delta G_{ET} + \Delta G_{A^{\oplus}/A^{\ominus}\rightarrow B^{\oplus}/B^{\ominus}}$$
$$\Delta G_{ET} = b + d$$
$$\Delta G_{A^{\oplus}/A^{\ominus}\rightarrow B^{\oplus}/B^{\ominus}} = c$$
$$\longrightarrow c = a - (b + d)$$

Scheme 8. Gibbs energy distribution $\Delta G_{A\rightarrow B}$ of the reaction A→B.

The easiest determination is that of ΔG_{ET}, directly provided by the CV of A and of B.

Weller's equation [Eq. (b)][71] holds true when the

$$\Delta G_{ET}[\text{kcal/mol}] = 23(E^{\circ}_{B} - E^{\circ}_{A} + e^2/(\varepsilon_0 r^2)) \qquad \text{(b)}$$

thermodynamic potentials E° are expressed in volts. If the waves are at least partially reversible, then $E^{\circ} \approx 1/2(E^{a}_{p} - E^{c}_{p})$, E^{a}_{p} and E^{c}_{p} being the potential value at the peak for the anodic part and the cathodic part of the wave, respectively.[72] The coulombic term $e^2/(\varepsilon_0 r^2)$ in Equation (b) can be neglected. In the case of total irreversibility of the wave of A or B, ΔG cannot be determined.

The determination of $\Delta G_{A^{\oplus}/A\rightarrow B^{\oplus}/B^{\ominus}}$ is generally impossible, but, if the reaction $A \overset{K_{eq}}{\rightleftharpoons} B$ is somewhat equilibrated, i.e. a small fraction of A is spectroscopically measurable at equilibrium, one may determine the equilibrium constant K_{eq} and thus $\Delta G_{A\rightarrow B}$. Such a case applies only if ΔG is sufficiently small to allow the estimation of the concentration of A. If $\Delta G_{A\rightarrow B}$ and of ΔG_{ET} are known, then $\Delta G_{A^{\oplus}/A^{\ominus}\rightarrow B^{\oplus}/B^{\ominus}}$ can be determined by simple algebraic difference[73] (Scheme 8).

In most cases, in order to ensure a driving force for the reaction one is interested in a large ΔG_{ET} value. In this case the reaction A→B is no longer equilibrated and it is not possible to apply the above technique.

8. Examples of Electrocatalyzed Organometallic Reactions

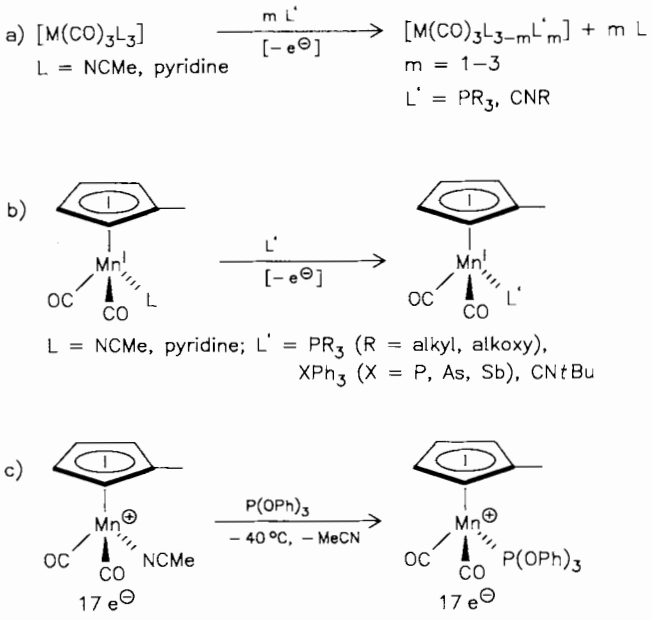
Feldberg et al. established the theoretical and experimental basis for the electrocatalytic ĒCĒ mechanism[60,61,69] using CV, chronoamperometry and chronocoulometry of the hydrolysis of the chromium–cyano bond in a Cr^{II} complex via the labile Cr^{II} intermediate[60] (Scheme 9).

Almost all of the electrocatalyzed processes studied up to now are similar ligand exchange reactions in mono- and polynuclear complexes, decomplexation and chelation being special examples of this kind. Very few reports have been published concerning other reactions such as isomerization, carbonyl insertion, and extrusion.

8.1. Exchange of a Two-Electron Ligand in Mononuclear Complexes (Oxidation)

The simple exchange of a CO ligand in a mononuclear complex has rarely been reported. The only example in

this sector is an intramolecular chelation[74,75] [see Eq. (e)]. On attempting to replace CO by phosphanes or phosphites in $[Fe(CO)_5]$ *Rieger* et al.[76] observed only a 10% reduction in the current of the first reduction wave and a wave of low intensity corresponding to $[Fe(CO)_4(PP_3)]$. This disappointing result is undoubtedly due to the great tendency of the 17-$e^{\ominus}$ radical anion $[Fe(CO)_4]^{\ominus\ominus}$ to effect side reactions.[24a] In contrast, *Kochi* et al. have shown that mixed complexes, bearing both N-donors (MeCN, pyridine) and carbonyls, exchange the N-donor ligand(s) for other two-electron ligands when a small anodic current is applied, with coulombic efficiencies sometimes reaching 1000 in complexes of the type $[Mn(\eta^5\text{-}C_5H_4Me)(CO)_2L]$[73] and more than 100 in the complexes $[M(CO)_3L_3]$ (n = 3, M = Cr, Mo, W).[77] N-Donors are not π-acids and therefore do not allow much flexibility regarding the oxidation state of the metal. These ligands are poor electron sinks and the strength of the M–N bond must be drastically diminished upon oxidation. However, the Mn^I compounds are reversibly oxidized, giving stable cations at −40 °C, which allows demonstration of their reactivity towards $P(OPh)_3$ at this temperature.[66] This compromise allows high coulombic efficiencies to be obtained (Scheme 10).



Scheme 10. a) Electrocatalytic exchange of one, two or three N-donor ligands by P- or C- donors, induced anodically in Cr^0-, Mo^0-, W^0-complexes; b) electrocatalytic exchange of a N-donor ligand with a P-, As-, Sb- or C-donor in Mn^I complexes, induced anodically with very high coulombic efficiencies; c) stoichiometric ligand exchange in a 17-electron Mn^{II}-complex.

overall reaction:

$$[Cr^{III}(CN)_6]^{3\ominus} + H_2O \longrightarrow [Cr^{III}(CN)_5(H_2O)]^{2\ominus} + CN^{\ominus}$$

mechanism:

$$[Cr^{III}(CN)_6]^{3\ominus} \xrightarrow[\text{initiation electrode}]{e^{\ominus}} [Cr^{II}(CN)_6]^{4\ominus}$$

$$[Cr^{II}(CN)_6]^{4\ominus} \xrightarrow[-\,CN^{\ominus}]{H_2O} [Cr^{II}(CN)_5(H_2O)]^{3\ominus}$$

$k = 11\ s^{-1}$ at 25 °C

$$[Cr^{II}(CN)_5(H_2O)]^{3\ominus} + [Cr^{III}(CN)_6]^{3\ominus} \longrightarrow [Cr^{III}(CN)_5(H_2O)]^{2\ominus} + [Cr^{II}(CN)_6]^{4\ominus}$$

$$[Cr^{II}(CN)_5(H_2O)]^{3\ominus} \xrightarrow[\text{back ET electrode}]{-\,e^{\ominus}} [Cr^{III}(CN)_5(H_2O)]^{2\ominus}$$

$k = 10^{-4}\ mol^{-1}s^{-1}$

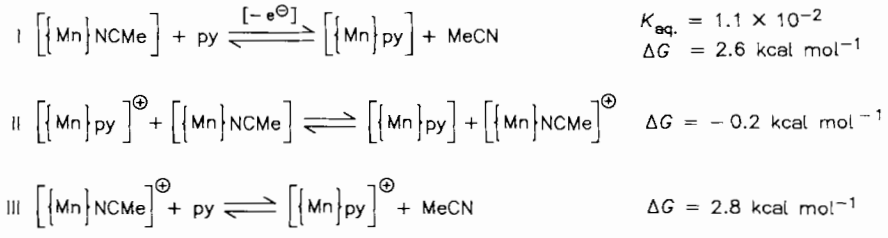
Scheme 9. ÉCÈ mechanism according to *Feldberg* et al. for the substitution of $CN^{\ominus}$ by H_2O in a Cr^{III} complex.

The use of *Savéant*'s a-dimensional analysis[76] allowed *Kochi*'s group to obtain kinetic data ($\Delta S = -25$ u.e. for Scheme 10b, $L' = PPh_3$) which, taken together with the reaction of Scheme 10c, suggest an essentially associative mechanism (S_N2 substitution) for the ligand exchange in the propagation step.[66]

The rate constant k for this step could be related to the Brønsted base strength of the leaving and entering ligands and to the conic angle θ of the entering ligand [Eq. (c)].[78]

$$\lg k_1 = 17 - 0.15\,pK_a^L + 0.28\,pK_a^{L'} - 12\theta \qquad (c)$$

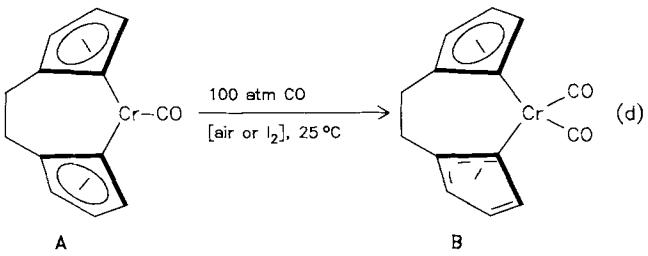
This equation reflects both the electronic and steric factors in the 19-electron intermediates. Thermodynamic data were also obtained in the case of the exchange of MeCN by pyridine, for which the ET propagation step is almost isoergonic ($\Delta E^\circ = 0.01$ V; $\Delta G_{ET} = 0.2$ kcal mol^{-1}). The driving force for the ligand exchange in the cation is thus 2.8 kcal mol^{-1} (Scheme 11).[73]



Scheme 11. Thermodynamics of the ligand exchange in Mn^I-complexes according to *Kochi*. {Mn} = $[Mn(\eta^5\text{-}C_5H_4Me)(CO)_2]$, py = pyridine. See Scheme 10 for the structure of the Mn^I-complex (piano-stool) and Scheme 8 for the square representation of the reaction course. ΔG for I from the IR spectra, for II from ΔE°.

In the series $[M(CO)_3L_3]$, it was not possible to find out whether the ligand exchange step is associative (S_N2 via 19-e$^{\circ}$) or dissociative (S_N1 via 15-e$^{\ominus}$, the one-electron oxidation is sometimes irreversible). However, the lack of reactivity of the large entering ligand $P(OPh)_3$ again suggests an associative mechanism.[77]

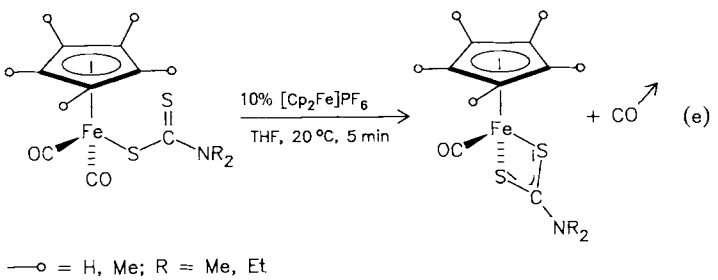
Brintzinger[79] has recently developed the electrocatalytic carbonylation of a Cr^{II} complex using catalytic amounts of air or of I_2 [Eq. (d)]. One Cp ligand is partly decoordinated, the hapticity shifting from *pentahapto* to *trihapto*. Since the displacement of a hydrocarbon ligand by CO decreases the electron density on the metal (lowers the HOMO), B is less easily oxidized than A and the oxidative initiation thus brings about an exergonic cross redox ET step.



(d)

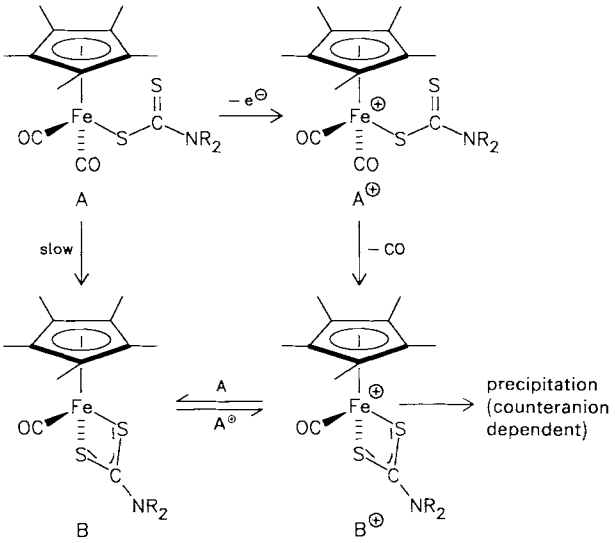
8.2. Chelation of the Dithiocarbamate (dtc) Ligands in $[Fe(\eta^5\text{-}C_5R_5)(CO)_2(\eta^1\text{-dtc})]$ (Oxidation)

Whereas, the dtc ligand usually prefers the chelating, *dihapto* mode of coordination in mononuclear complexes,[80a] several classical routes lead to the synthesis of the monodentate complexes $[Fp(\eta^1\text{-dtc})]$ ($Fp=[FeCp(CO)_2]$) and $[Fp^*(\eta^1\text{-dtc})]$ ($Fp^*=[FeCp^*(CO)_2]$). We attempted the syntheses of the corresponding chelate complexes, but, for instance, with [Fp(dtc)], only a 5% yield of the desired chelate complex was obtained at 100 °C after several hours, and extensive decomposition was observed.[80b] However, we found that if 10% of $[Cp_2Fe]PF_6$ is added to [Fp(dtc)] or [Fp*(dtc)], 50% yields of chelates are obtained at 20 °C in a few minutes [Eq. (e)].[74]



(e)

The mono- and bidentate complexes have oxidation potentials of $E=+1.25$ and $+0.5$ V vs SCE, respectively. Thus, no driving force is obtained from the ET propagation step. However, a driving force is clearly provided here by the irreversibility of the chelation step. In addition, the oxidation of the monodentate dtc complexes is irreversible. Both this and the endoergonicity of the cross redox step take into account the precipitation of the 17-electron chelates limiting the yields of the reactions (Scheme 12).

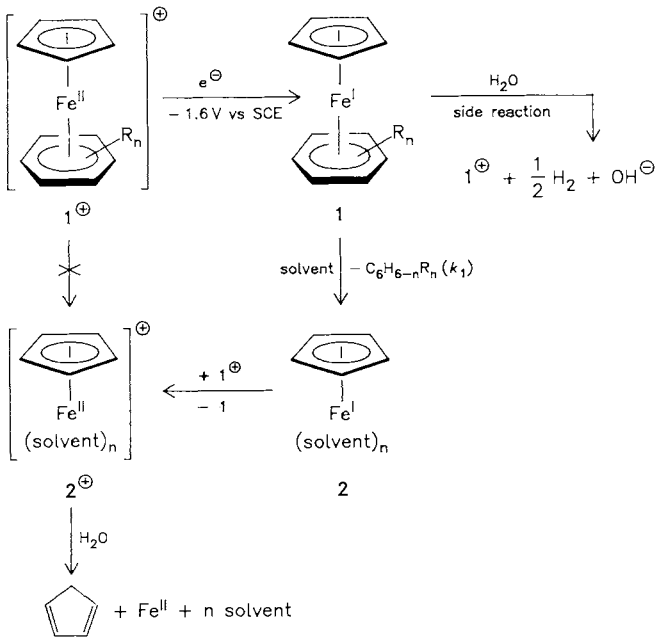


Scheme 12. Square electrocatalytic scheme for the chelation of [Fp(dtc)] with $[Cp_2Fe]PF_6$ as initiator. The endoergonicity of the cross ET and the precipitation of $B^{\oplus}$ limit the yield.

8.3. Decomplexation of Arenes (Reduction)

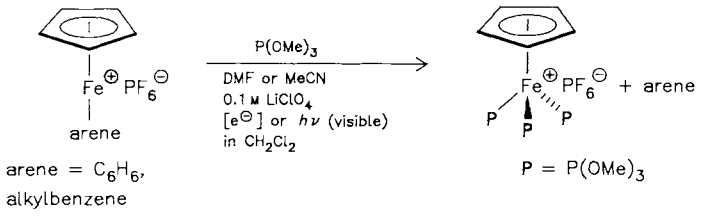
In the course of extensive studies on the stability and reactivity of 19-electron Fe^I complexes, we found[81] that soluble Fe^I complexes promote an electrocatalytic decomplexation of the otherwise robust[82] 18-electron complexes $[Fe^{II}Cp(arene)]^{\oplus}$ if the arene ligand in these complexes bears less than three methyls group. Thus, the cathodic reduction of $[Fe^{II}Cp(C_6H_6)]PF_6$ in 95% ethanol (Hg pool, 0.1 M LiOH) consumes only 0.3 Faraday to provide quantitatively $Fe^{2\oplus}$, cyclopentadiene and benzene (all species were characterized). In 1981, we proposed an electrocatalytic cycle taking into account this reaction (Scheme 13).[81] The exchange of the arene ligand for solvent molecules in the Fe^I complex **1** provides another Fe^I species, **2**, which reduces the cationic Fe^{II} starting complex and liberates its other ligands.

The stability of the Fe^I complex **1** increases with the number of methyl groups on the arene (k_1), and, when its lifetime is long enough, **1** reduces the medium ($H_2O \rightarrow H_2$). Thus, the unstable redox system **1/1**$^{\oplus}$ with several methyl groups on the arene ligand is also a redox mediator for the electroreduction of water (see Section 2). The cathodic reduction of **1**$^{\oplus}$ as such consumes a large amount of electricity—a trend exactly opposite to that expected from electrocatalysis. Thus, it is not surprising to observe that 0.3 Faraday is necessary to decompose **1**$^{\oplus}$, the apparent coulombic efficiency being 3.3. Similar complexes bearing a small number ($n<3$) of methyl groups can be decomposed in



Scheme 13. Electrocatalytic decomplexation of an arene ligand initiated by a Hg cathode. Coulombic efficiency = 3.3 for the quantitative decomplexation of benzene (n = 0) [81]. The side reaction is the reduction of H_2O by the Fe^I-complexes **1** and **2** (redox catalysis). This side reaction dominates when the arene bears more than 3 methyl groups (coulombic efficiency $\ll 1$). Driving forces are provided by both exoergonic propagation steps. R = CH_3; n = 0–6.

this way, but the catalytic efficiency is lower. The durene complex (n = 4) is only half decomplexed after a day (coulombic efficiency $\ll 1$), and the hexamethylbenzene complex (n = 6) is very stable. In this case, the cathodic current in the cell only serves to reduce the medium, a process for which the redox system Fe^{II}/Fe^I is a stable redox mediator.[81] The redox catalysis can be suppressed if no reducible substrate is present in solution. Recently, the electrocatalytic decomplexation of complexes of the type $\mathbf{1}^{\oplus}$ in the presence of $P(OMe)_3$ in DMF or CH_3CN (Scheme 14) has been the subject of a report by other authors. The

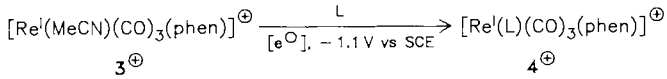


Scheme 14. Exchange of an arene ligand for three phosphite ligands by electrocatalysis or by visible light. (Neither technique works for arene = C_6Me_6.)

coulombic efficiencies were between 0.03 and 0.52, depending on the arene ligand.[83] In fact, it is possible that the variation in the observed coulombic efficiency arises from the differences in purity of the solvents. The latter work opens up a new entry to the compound $[Fe^{II}Cp\{P(OMe)_3\}_3]PF_6$, which can also be obtained in equally good yield from $\mathbf{1}^{\oplus}$ (n = 0) by using visible light.[84] (It is not certain that both methods are unrelated, though this point has not been mentioned yet, see Section 8.4.)

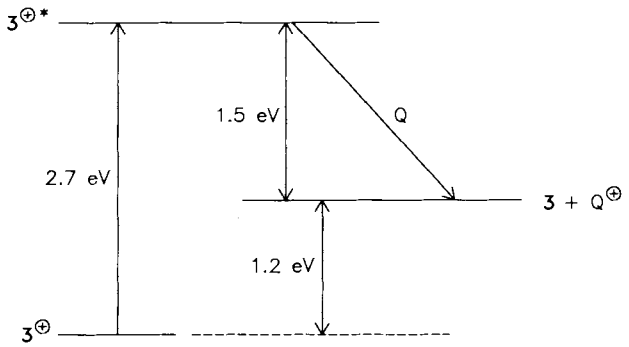
8.4. Initiation of Electrocatalysis by Light: Photoelectrocatalysis (Reduction)

Wrighton et al.[85] found that ligand exchange between MeCN and PPh_3 in $[Re^I(MeCN)(CO)_3(phen)]^{\oplus}$, $\mathbf{3}^{\oplus}$, can be initiated analogously to the reactions described in Section 8.1 by a cathodic current at -1.1 V vs SCE (Scheme 15). The potential for the reduction of $\mathbf{3}^{\oplus}$ is -1.2 V vs SCE (quasi-reversible). The coulombic efficiency is between 6.4 and 45 for quantitative spectroscopic yields.



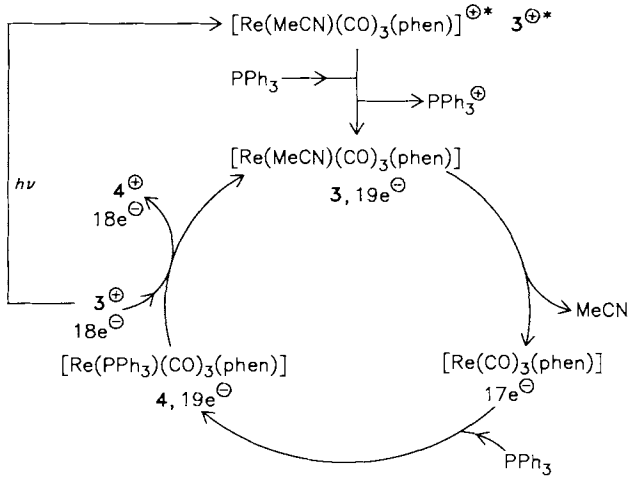
Scheme 15. Electrocatalytic ligand exchange in $\mathbf{3}^{\oplus}$. Catholyte: MeCN, 0.1 M nBu_4NClO_4; L = PPh_3, pyridine; phen = 1,10-phenanthroline.

More interestingly, *Wrighton* et al. showed that the cathode could be replaced by 436-nm irradiation (ca. 2×10^5 einstein), the same result being obtained with quantum yields (number of molecules $\mathbf{4}^{\oplus}$ found per 436-nm photon adsorbed). In order to work, the system needs a quencher, i.e. an oxidizable compound in the medium able to trap the excited state $\mathbf{3}^{\oplus}*$ of $\mathbf{3}^{\oplus}$. The reduction potential of $\mathbf{3}^{\oplus}*$ was estimated to be $+1.5$ V vs SCE. The quencher was *N,N'*-dimethyl-*p*-toluidine or PPh_3 itself. Thus, in the ligand exchange with PPh_3, both the starting complex as well as the entering ligand play a double role (Scheme 16).



Scheme 16. Energy diagram for the photoreduction of $\mathbf{3}^{\oplus}$ ($\lambda = 436$ nm) in the presence of a quencher Q. Note the redox potential of 1.5 V (vs SCE) of the redox couple $\mathbf{3}^{\oplus}*/\mathbf{3}$.

It is reasonable to assume that the 19-electron species **3** is substitutionally labile and loses MeCN in a dissociative process before combination with PPh_3, which furnishes a strongly reducing 19-electron species **4** (Scheme 17).

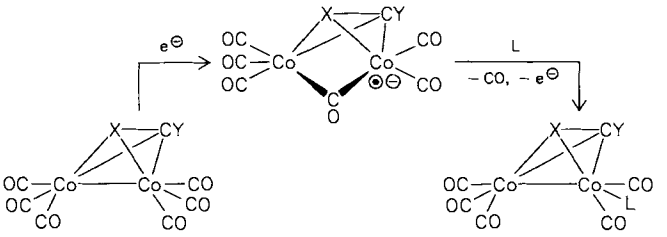


Scheme 17. Photoelectrocatalytic cycle for the exchange of MeCN by PPh_3 in the 18-electron complex $3^{\oplus}$.
Photo-initiation: $3^{\oplus} \xrightarrow{h\nu} 3^{\oplus *} \xrightarrow[-Q^{\oplus}]{Q} 3$;
Chain propagation: $3 \xrightarrow[-MeCN]{} [Re(CO)_3(phen)] \xrightarrow{PPh_3} 4 \xrightarrow[-3]{3^{\oplus}} 4^{\oplus}$

Although *Wrighton* et al. thus had a successfully functioning two-component system, self-activated by visible light, one may also envisage a broader use of photoelectrocatalysis by not restricting it to photoactive complexes. Since the photoprocess is catalytic, one could use an external photocatalyst for the electrocatalysis of reactions of photostable complexes.[86]

8.5. Selective Exchange of Carbonyl Ligands in Bimetallic Complexes and Clusters (Reduction)

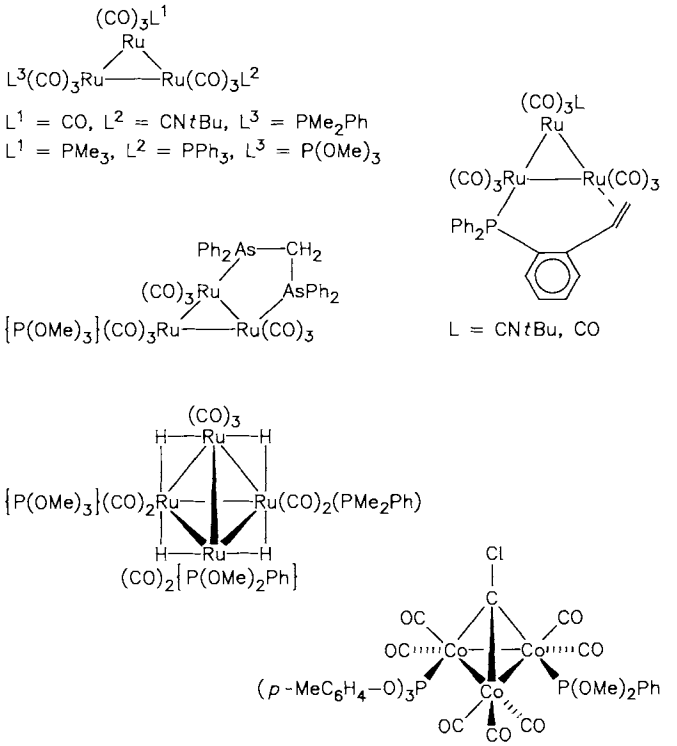
Rieger et al. stimulated interest in this area[76] when they showed that CO ligands can be readily replaced by phosphite or phosphane ligands in clusters of the type $[YCCo_3(CO)_9]$ (Y = Ph, Cl) on using a cathodic current. DC polarographic and cyclovoltammetric studies indicated that the current of the first reduction wave drops almost to zero in the presence of the P-ligand while the expected wave appears for the substitution product. A similar behavior[76] was found with the binuclear compound $[(PhCCPh)Co_2(CO)_6]$. *Rieger* et al. judiciously proposed[76] that radical anions of the bi- and trinuclear cobalt complexes have their extra electron in metal-metal antibonding orbitals, which leads to Co–Co bond cleavage. The terminal carbonyl of one of these two Co centers becomes bridging so that one Co center has 18 valence electrons again, while the other Co, bearing the negative charge, has only 17 valence electrons. This latter center is the active one, providing a rapid $17e^{\ominus} \rightleftharpoons 19e^{\ominus}$ interconversion in the same way as mononuclear complexes, so that the P-donor comes in and one of the CO's moves out (Scheme 18). Consistent with this prediction *Rieger* and *Robinson* et al.[87] observed that the ratio i_p^a/i_p^c (anodic/cathodic CV peak) for the primary electrode process, i.e. the lifetime of the primary radical anion, is not affected by the presence of Lewis bases or of CO. Thus, the rate-limiting step involves a reaction of this primary cluster radical anion with a species which reacts rapidly with the Lewis base, but does not involve the Lewis base itself.



Scheme 18. Mechanism proposed by *Rieger* et al. for the ligand exchange of CO by PR_3 in paramagnetic di- [X = CY; Y = Ph; L = PPh_3, PBu_3, $P(OMe)_3$] and trinuclear Co complexes [X = $Co(CO)_3$; Y = Ph, Cl; L = phosphane, phosphite].

Finally, this system allows the sequential replacement of CO's by one, two and three $P(OMe)_3$ ligands or by one and two PPh_3 ligands in the alkynedicobalt complexes. Good yields were obtained with hexafluorobutyne as alkyne ligand (for example monosubstitution products were obtained for L = MeCN, $P(OMe)_3$, $P(OPh)_3$, PPh_3, $P(C_6H_{11})_3$) and, with other alkyne ligands, the yields were variable, but correlated with the lifetime of the alkyne dicobalt complex radical anions.[88]

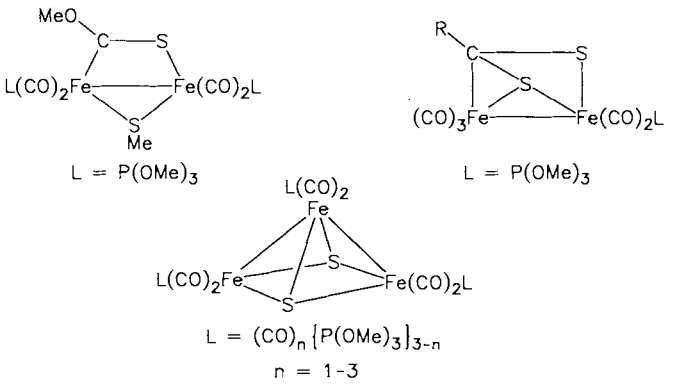
A series of papers have recently been published by *Downard, Robinson,* and *Simpson*[88b] in which the ETC-catalyzed replacement of CO by polydentate ligands (dppm, dppe, ttas and tpme) is studied in clusters of the type $[RCCo_3(CO)_9]$ (R = Ph, Me). This is a rare case where the authors find no net advantage in the ETC catalysis over traditional thermal methods. The catalytic efficiency of the first two-electron ligand exchange is independent of the latter but the rate of reaction is solvent-dependent. Subsequent chelation of the dangling ligands in [RC-



Scheme 19. Clusters obtained by sequential CO-L exchange (selected examples).

$Co_3(CO)_8(L\text{-}L)$] is much slower and of reduced catalytic efficiency. *Bruce* et al. have published[89,90] similar electrocatalytic syntheses of more than 40 clusters (Fe_3, Ru_3, Ru_4, Co_6, and Rh_6) in two reports. Several CO ligands were sequentially replaced by P, As, and C donor ligands. The reactions, initiated by $Na[Ph_2CO]$, were rapid at or just above room temperature. This impressive work demonstrated the efficiency and versatility of the electrocatalytic technique. Since the ligands are so easily and cleanly introduced, the authors[90] effected interesting combinations by sequential introduction of various ligands (Scheme 19). In this way, the first three mixed R_3As/R_3P-substituted Ru-clusters and the first olefin-Ru clusters were synthesized from $[Ru_3(CO)_{12}]$. Unusual olefin-isocyanide-PR_3 clusters of ruthenium were also prepared. Since chiral clusters were also accessible in this study, *Bruce* et al. pointed out[90] that the electrocatalytic route should prove an ideal one for future syntheses of new types of optically active clusters in which the chirality results from a combination of ligands in homometallic clusters, complementary to the known strategy which consisted in designing chiral clusters with different metals[91a] or optically active ligands.[91b]

In several papers,[92-96] *Patin* and *Darchen* et al. have reported the electrocatalytic syntheses of several bi- and trimetallic iron complexes using a cathodic current. These compounds were also obtained by the sequential exchange of CO ligands by $P(OMe)_3$ ligands (Scheme 20). Using this technique or a thermal route, the complex [(RO-C(S)SMe)$Fe_2(CO)_6$] is shown[95] to undergo rearrangement to [(μ_2-RO-CS)(μ_2-SMe)Fe_2CO_6] (R = CH_2-adamantyl).

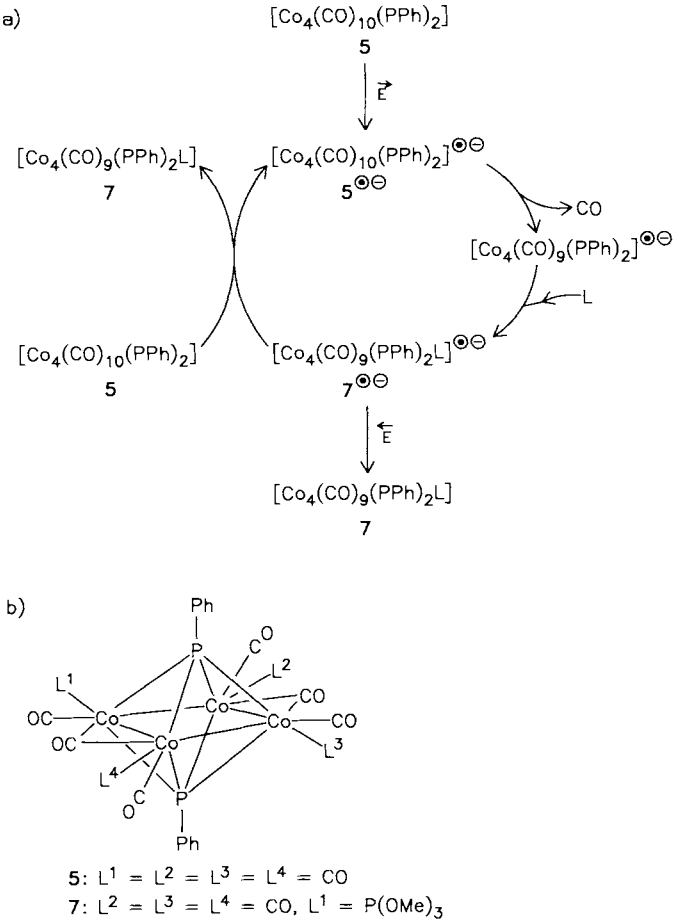


Scheme 20. Examples of electrocatalytically prepared Fe-complexes.

Kochi et al. have recently examined[97,98] the sequential replacement of CO ligands in the phosphanediyl capped clusters **5** and **6** by P donor ligands essentially using a

$[Co_4(CO)_{10}(\mu_4\text{-}PPh)_2]$ **5** $[Fe_3(CO)_9(\mu_3\text{-}PPh)_2]$ **6**

cathodic current.[97] Coulombic efficiencies were found to be low, between 4 and 11, because radical anionic intermediates tend to decompose at competitive rates, as in the alkynedicobalt systems (Scheme 18).[76,87,88] The lifetimes of the primary radical anions are independent of the P donor concentrations, indicating that the rate-limiting step does not involve the nucleophilic attack on the primary radical anion, but the formation of another intermediate which reacts with the P donor molecule. This behavior thus seems general in cluster chemistry; precedents for metal-metal bond breaking prior to substitution were found to exist in closed shell systems by *Vahrenkamp*.[99] However, whether a Co-Co bond or a Co-P bond breaks is not known in the case of **5**. The singly, doubly, and triply $P(OMe)_3$-substituted Co_4 clusters were selectively synthesized by application of a cathodic current at a potential slightly less negative than the E° of **5**; in such short chains, this choice of potential facilitates the formation of the neutral substitution product by heterogeneous ET at the electrode ($\mathbf{ML}^{\odot\ominus} \rightarrow \mathbf{ML}$, Scheme 21: **M** = $Co_4(CO)_9(PPh)_2$; cf. also Scheme 6).

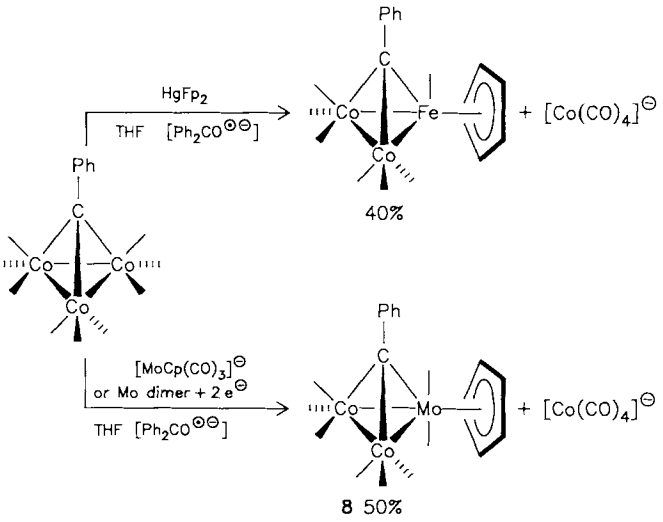


Scheme 21. Electrocatalytic exchange of CO by $P(OMe)_3$ ligands in the bicapped Co_4-cluster **5** [97]. a) Mechanism of electrocatalysis by a cathodic current with low coulombic efficiency (monosubstitution to give **7**); the structures and number of secondary radical anion intermediates is unknown (Co-Co or Co-P bond cleavage?). b) The following holds for the regioselectivity in the case of polysubstitution: disubstitution, $L^1 = L^3 = P(OMe_3)$, $L^2 = L^4 = CO$; trisubstitution, $L^1 = L^2 = L^3 = P(OMe)_3$, $L^4 = CO$. The tetrasubstituted cluster ($L^1 = L^2 = L^3 = L^4 = P(OMe_3)$) is not accessible electrocatalytically but prepared via an alternative route.

In a similar way, the cluster **6** can also exchange one, two or three CO ligands for $P(OMe)_3$ ligands sequentially with coulombic efficiencies of 10 to 20 by applying a cathodic potential.[100-102] Depending on the applied potential, the number of ligand substitutions desired can be achieved as in **5**. This general trend for cluster chemistry is characteristic of short catalytic chains. Note that, if no side

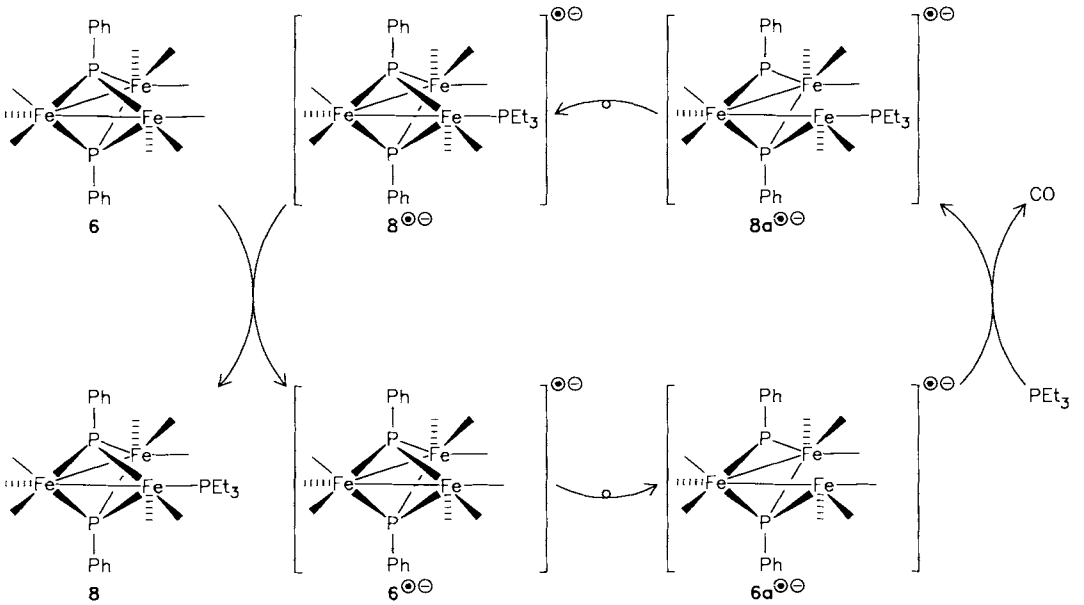
reactions of the paramagnetic intermediates were to occur, i.e. if the electrocatalytic chains were to be as long as are found in the mononuclear Mn^{I} series of Section 8.1, then the stoichiometry of CO substitution would only depend on the relative rates of successive CO substitution and, eventually on the stoichiometry of the P donor introduced in the solution. Thus, in the case of excess phosphane, no selectivity would be obtained with respect to the number of CO substitutions. To our knowledge, this point has thus far never been discussed as origin of the nice selectivity, which all authors have observed in electrocatalytic cluster synthesis. Sometimes the coulombic efficiencies may presumably become very poor when the yields are optimized. In most cases nothing is known concerning the radical anionic intermediates of the electrocatalytic cycles. Whereas oxidative electrocatalysis directly provides the "active 17-electron center", reduction does not, and, by contrast, considerable structural rearrangements, such as those reasonably proposed, are necessary. At each step of these pathways, side reactions may occur and shorten the chain. Fortunately, the recent investigations of *Kochi* and *Ohst*[100-102] on the electrocatalyses of **6** were successful in demonstrating the nature of these paramagnetic intermediates. ^{31}P-coupling provided both by the phosphanediyl caps and the incoming P donor allowed monitoring of the following by EPR: the opening of a Fe-P bond = ($\mu_3 \rightarrow \mu_2$ phosphanediyl slippage), the reaction of PEt_3 on the temporary open cluster anion, and the closure of the phosphane-substituted open cluster anion to the substituted closed one ($\mu_2 \rightarrow \mu_3$ back slippage) (Scheme 22). This unique demonstration,[100] while confirming the need of generating a reactive "17-electron center" by cleavage of one cluster edge, indicates that Fe-P cleavage is preferred over Fe-Fe cleavage and highlights the crucial role of the phosphanediyl cap (Scheme 21), also striking in non-electrocatalyzed paths.[98]

Heteronuclear clusters have been synthesized by *Robinson, Simpson* et al.[103] using the electrocatalytic technique with transition metal anions as nucleophiles (instead of the P donors above). The cluster substrates were $[RCCo_3(CO)_9]$ (R = Me, Ph, H) and the anionic nucleophiles were $[MCp(CO)_3]^{\ominus}$ (Cr, Mo, W) or $Fp^{\ominus}$ (it is likely that the latter reduces the Co_3 cluster; $[HgFp_2]$ gave good results, $Fp^{\ominus}$ did not, Scheme 23). The radical anion $Ph_2CO^{\odot\ominus}$ was the initiator.



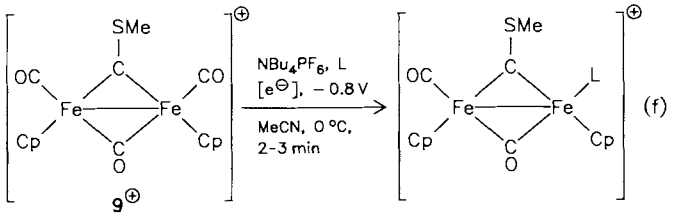
Scheme 23. Electrocatalytic syntheses of heteronuclear clusters using a anionic transition metal species as nucleophilic agent.

The Co_2Mo cluster **8** had already been synthesized by *Vahrenkampf* et al.,[104] but its non-electrocatalytic synthesis necessitates three-days' refluxing in benzene. Thus, both homo- and heteronuclear chiral clusters are now best accessible using electrocatalysis.



Scheme 22. Electrocatalytic exchange of CO by a P-donor in the bicapped cluster **6**: the four radical anions $\mathbf{6}^{\odot\ominus}$, $\mathbf{6a}^{\odot\ominus}$, $\mathbf{8a}^{\odot\ominus}$, and $\mathbf{8}^{\odot\ominus}$ participating in the propagation cycle have been characterized by EPR (coupling with P ligand(s) in a stepwise sequence at low temperature).

Recently, *Angelici* et al.[104c] reported that the relatively stable bridging thiocarbyne radical, $\mathbf{9}^{\ominus}$, produced by one-electron reduction of cationic precursor $\mathbf{9}^{\oplus}$, catalyzes CO exchange by P-donor ligands in the latter complex [Eq. (f)]. The results of CV studies support the electrocatalytic mechanism, and coulombic efficiencies between 32 and 46 are reported (only in the case of PPh_3 were they poorer: 2.4).



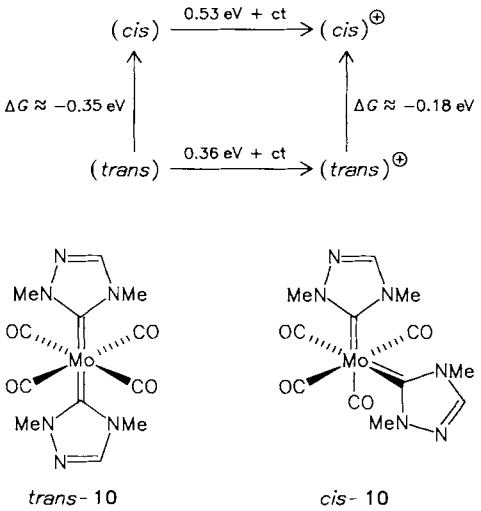
$9^{\oplus}$

L = PEt_3, PMe_2Ph, $PMePh_2$, $CNtBu$

Since the simple and efficient exchange of CO- by a P-donor ligand is not known to proceed electrocatalytically in mononuclear complexes, it is possible that the exchange mechanism in such a bridged dinuclear compound proceeds as in clusters, i.e. involves disruption of the Fe–Fe bond (compare Co–Co cleavage, Scheme 18) or of a Fe–C (carbyne) bond (cf. Fe–P cleavage, Scheme 22).

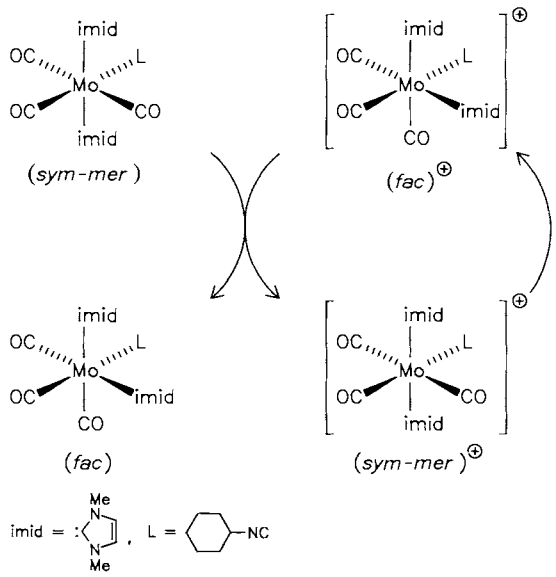
8.6. Isomerization (Oxidation or Reduction)

The reports by *Rieke, Öfele* et al.[105, 106] of the isomerization of the complexes [M(carbene)$_2$(CO)$_4$] [M = Mo, W, carbene = 2,4-dimethyl-2,4-dihydro-1,2,4-triazol-3-ylidene, 1,3-dimethyl-1,3-dihydroimidazol-2-ylidene (imid) or 1,3-dimethyldihydrobenzimidazol-2-ylidene] are of considerable importance in the electrocatalytic field because they appeared ten years ago, well before the explosion of the 1980's; these pioneering reports include electrochemical as well as preparative aspects and detail the kinetics and thermodynamics of the isomerization processes. The anode catalyzed *trans*→*cis* isomerizations[105] (coulombic efficiencies > 10) were found to occur according to the energy diagram of Scheme 24.



Scheme 24. Energy diagram of the electrocatalytic *trans*→*cis* isomerization of **10**. ct = constant.

Similar carbene complexes of the composition [Mo(imid)$_2$(CO)$_3$L] where L is a C, N, or P donor (cyclohexylisocyanide, triethyl- or triphenylphosphane, pyridine) can exist under the symmetric (*sym*), mericlinal (*mer*), facial (*fac*), or asymmetric (*asym*) *mer* forms. The *sym-mer* complex is electrolyzed in a few minutes with a coulombic efficiency > 10 to give the *fac* complex (Scheme 25); the latter is converted into the cation of the *asym-mer* isomer.[106] The redox process and isomerization were shown to be strongly dependent on the nature of the ligand L.



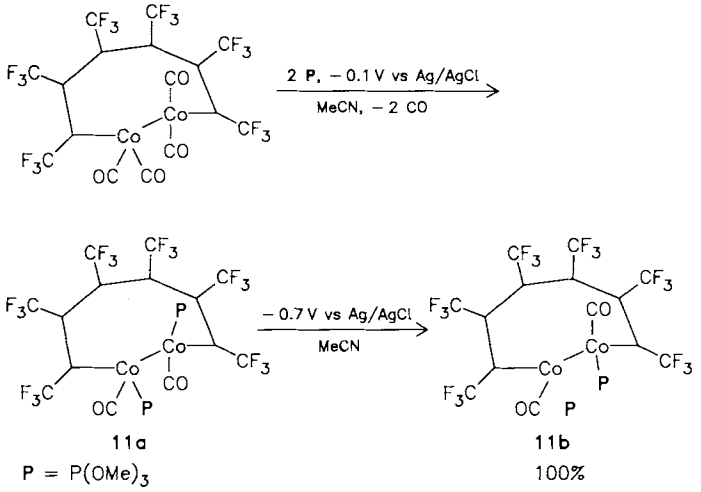
Scheme 25. Electrocatalytic cycle for the anodically initiated isomerization *sym-mer*→*fac* of the biscarbene complexes [Mo(1mid)$_2$(CO)$_3$L] ($k = 0.4\ s^{-1}$ at −20 °C in CH_2Cl_2 for L = cyclohexyl isocyanide).

Robinson, Simpson et al. reported[107] the isomerization of the "flyover" complex **11**. (This complex, as the mono-

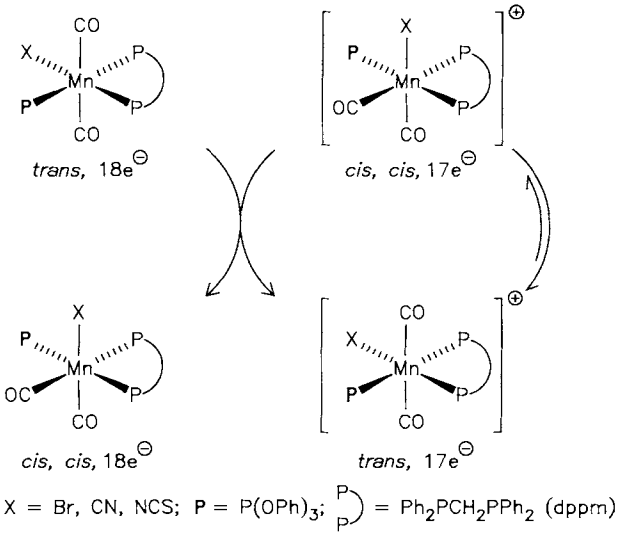
[Co_2({(CF$_3$)C}$_6$)(CO)$_2$[P(OMe)$_3$]$_2$] **11**

phosphite analogue, is synthesized by selective electrocatalytic reduction (−0.1 V vs Ag/AgCl) of the parent tetracarbonyl complex; Scheme 26.) The blue bis-phosphite complex isomerizes quantitatively to a purple complex upon application of a cathodic current at −0.7 V (vs Ag/AgCl). The authors explain this process by the cleavage of the Co–Co bond of the primary radical anion while a carbonyl ligand bridges these two metals. Thus, starting from the parent tetracarbonyl complex, either isomer can be synthesized selectively, depending on the applied potential: −0.1 V or −0.7 V vs Ag/AgCl in MeCN or CH_2Cl_2 with Bu_4NClO_4 (Scheme 26).

Connelly et al. have shown[108] that octahedral Mn^I complexes can effect electrocatalytic *trans*→*cis* isomerization quantitatively using a catalytic amount of anodic current (+0.5 V vs SCE) in CH_2Cl_2 (Scheme 27). Interestingly, the



Scheme 26. Electrocatalytic synthesis and isomerization of the "flyover" complex **11** (reductive initiation). For the isomerization **11a** → **11b**, catalytic amounts of reducing agent are required.



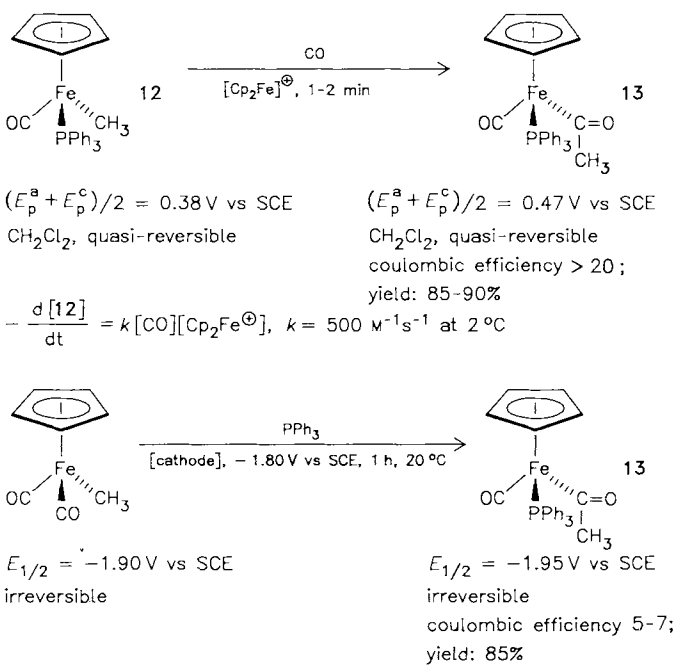
Scheme 27. Electrocatalytic cycle for the anodically induced *trans*→*cis* isomerization of *trans*-[Mn^{I}X(CO)$_2$\{P(OPh)$_3$\}(dppm)]. (Note that the *trans*-configurated complex cation is more stable than the *cis*-configurated.)

trans cation is more stable than its *cis* isomer; indeed, stoichiometric oxidation of the neutral *cis* form leads to the *trans* cation. In the electrocatalytic system, a strong driving force is provided by the favorable difference in the redox potential. Previously, *Bond* had noted[109] that the CV wave shapes of such complexes can only be explained by taking into account the cross redox reaction, as in Scheme 27. Other ETC-catalyzed structural transformations are noted in Section 8.5.[95]

8.7. CO Migratory Insertion (Oxidation or Reduction) and Extrusion (Reduction)

8.7.1. CO Insertion: Oxidative versus Reductive Initiation

The acetyl complex **13** is accessible both by oxidation as well as by reduction (Scheme 28). The subtle difference lies in the nature of one ligand in the educt (PPh_3 in **12**, CO in [$FpCH_3$]). The changeover from PPh_3 to CO is sufficient to invert the relative electron densities on the iron center in the educt and in the product, so that the ET-propagation step is exergonic in both cases. The two studies were published within a span of only a few months by *Vlček* et al. (reductive initiation)[110] and by *Magnuson, Giering* et al. (oxidative initiation).[111]



Scheme 28. Electrocatalytic migratory insertion of CO into the iron–methyl bond in **12** and [$FpCH_3$]. By suitable choice of the external ligand and the initiator (oxidizing or reducing), the same product **13** is obtained.

The oxidative process is extremely efficient, one driving force being the cross redox reaction ($\Delta G \simeq 2$ kcal mol^{-1}). The reductive process is less efficient because of side reactions of the radical anions [$FpCH_3$]$^{\odot\ominus}$ and **13**$^{\odot\ominus}$ (neither the reduction of [$FpCH_3$] nor that of **13** being reversible). The driving force provided by the cross redox reaction, although favorable, is also presumably less than that obtained in the oxidation process ($\Delta E_{1/2} = 0.05$ V, but the thermodynamic potentials are unknown).

This duality is of interest because it sheds light on the comparison between oxidative and reductive electrocatalysis. If one hesitates between the two possibilities in the case of an isoergonic cross redox reaction, one should consider the relative reversibilities of the oxidation and reduction CV waves. It is highly probable that the oxidation route is preferable because the catalytic cycle is very short as compared to that of the reduction route. Consistent with this hypothesis, coulombic efficiencies are higher in the oxidation route (see Scheme 28).

8.7.2. CO Extrusion: From Formyl to Hydride (Reduction)

It is well known that formyl complexes are unstable relative to the corresponding hydrides (CO insertion into an M–H bond is unfavorable), but CO extrusion may be slow

$$ArylX \xrightarrow{[e^{\ominus}]} ArylX^{\bullet\ominus} \longrightarrow Aryl^{\bullet} \xrightarrow{Nu^{\ominus}} ArylNu^{\bullet\ominus} \xrightarrow{ArylX} ArylNu$$

$$[M(CO)_n] \xrightarrow{[e^{\ominus}]} [M(CO)_n]^{\bullet\ominus} \longrightarrow [M(CO)_{n-1}]^{\bullet\ominus} \xrightarrow{P} [M(CO)_{n-1}P]^{\bullet\ominus} \xrightarrow{[M(CO)_n]} [M(CO)_{n-1}P]$$

Scheme 30. Close analogy between an $S_{RN}1$ reaction and reductively initiated CO substitution in clusters. $X^{\ominus} = Cl^{\ominus}$, $Nu^{\ominus} = NH_2^{\ominus}$, **P** = PR_3. Both processes suffer from side reactions due to a long catalytic cycle.

and therefore several stable formyl complexes have been isolated.[112] Thus, it is not surprising that electrocatalysis can efficiently facilitate CO extrusion from formyl complexes. Since a hydride ligand is more electron releasing than a formyl ligand, the reductive route should provide the second driving force of an electrocatalytic CO extrusion.

Kochi et al. have shown[113] that the stable anionic formyl complex **14** can be converted into the hydride by ap-

$[cis\text{-}(CO)_5ReRe(CO)_4CHO]^{\ominus}$ **14**

plying a potential of -2.1 V, at which an irreversible reduction is observed (Scheme 29). The process consumes only 0.035 F per mole of formyl complex (coulombic ef-

$$[(CO)_5ReRe(CO)_4(CHO)]^{\ominus} \xrightarrow[\text{yield: 100\%}]{\vec{E}} [(CO)_5ReRe(CO)_4H]^{\ominus} + CO$$

14

$E_{1/2} = -2.1$ V vs SCE (irrev.) $\qquad$ $E_{1/2} = -2.6$ V vs SCE (irrev.)

Scheme 29. Formation of a hydrido ligand from a formyl ligand by extrusion of CO. Both chain propagation steps are strongly exergonic and the electrocatalytic process is efficient.

ficiency = 30). The resulting hydride shows a reduction CV wave at -2.6 V which can be observed in the CV of the formyl complex, as expected for the electrocatalytic extrusion. Anthracenesodium (5 mol%) in THF also gives a 75% yield in 10 min at 25°C. Radical initiators are even more efficient.

9. Concluding Remarks

The field of organometallic electrocatalysis originates from *Feldberg*'s recognition and investigation of the ECE mechanism fifteen years ago using rapid electrochemical techniques. It parallels the electrocatalyzed nucleophilic substitution, $S_{RN}1$ mechanism, discovered by *Kornblum*, researched in aromatic chemistry by *Bennet* and for which *Savéant* and *Amatore* have established the useful a-dimensional analytic technique of kinetic investigation. The kinetic barriers of most classical organometallic reactions can be overcome by the use of this technique. The studies have demonstrated the exceptional reactivities of 17- and 19-electron transition metal centers in mono- and polymetallic compounds and have contributed considerably to the improvement of the syntheses of many known complexes. Some sophisticated chiral cluster syntheses have also already been achieved, the selectivity of which dramatically contrasts with mixtures obtained by tedious classical routes. The limitation of the coulombic efficiency is at the origin of this selectivity, the resulting ET chain being caused by the side reactions of the various radical anionic intermediates in these reductive electrocatalyses. In contrast, oxidative electrocatalysis, to which *Kochi* has made a comprehensive contribution, is most often used for mononuclear compounds; it enables high coulombic efficiencies to be achieved because the catalytic cycle is small (associative mechanisms involving $17e^{\ominus} \rightleftharpoons 19e^{\ominus}$ species). Finally, note that reductive electrocatalytic cluster synthesis curiously resembles aromatic substitution.[114] Both are nucleophilic substitutions encountering the same problem of side reactions of the radical intermediates (Scheme 30). Clearly, the extensive and related organic area developed in the 1970's has been most useful for the advancement of electrocatalytic organometallic chemistry.

It is likely that this field will expand further in the near future, and that this review will be complemented by a large number of reports on investigations of as yet unexplored electrocatalytic mechanisms and catalytic transformations of organic ligands.

I am grateful to Dr. Françoise Moulines and Dr. Marc Lacoste for helpful discussions and assistance, and to the University of Konstanz where this manuscript was prepared during the summer of 1986. Thanks are also due to Professor Hans H. Brintzinger for enjoyable discussions on this topic, and to Professor Gottfried Huttner and his group for enthusiastic scientific collaboration.

German version: *Angew. Chem. 100* (1988) 662

Addendum (November 19, 1987)

Since submission of this review, several important papers relevant to this subject have appeared.

J. E. Guerchais et al.[115] have reported electrocatalytic exchange of CO for MeCN (reduction) in a dinuclear Mo complex [Eq. (g)].

$$[Mo_2Cp_2(\mu\text{-}SMe)_2(CO)_4]^{2\oplus} \xrightarrow[-CO]{[e^{\ominus}]\ MeCN} [Mo_2Cp_2(\mu\text{-}SMe)_2(CO)_3(Me_3CN)]^{2\oplus} \quad (g)$$

Lahuerta and *Latorre* et al. have replaced CO by $P(OMe)_3$ in **15** [reduction; Eq. (h), N-N = 2,3-diazanor-

$$[Fe(N{-}N)(CO)_3] \xrightarrow[-CO]{[e^{\ominus}]\ P(OMe)_3} [Fe(N{-}N)(CO)_2\{P(OMe)_3\}] \quad (h)$$

15

bornene]—a rare case of CO exchange in a mononuclear complex.[116a] This study follows the more classical multiple CO exchange by $P(OMe)_3$ in the related trinuclear iron complex $[(N\text{-}N)Fe_3(CO)_9]$[116b] [reduction; Eq. (k), $L = P(OMe)_3$].

$$[(N-N)Fe_3(CO)_9] \xrightarrow{[e^-]} [(N-N)Fe_3(CO)_8L] \xrightarrow{[e^-]} [(N-N)Fe_3(CO)_7L_2] \quad (k)$$

The electrocatalytic exchange of CO by PMe_2Ph or $PMePh_2$ in the cluster $[Co_4(CO)_9(tripod)]$ has been induced cathodically by *Lemoine* et al.[117a] If one Co is replaced by Fe or Ru, ligand exchange of CO by PR_3 (R = Me, Ph) or DMF can be similarly induced in the monoanionic clusters.[117b] *Kotz* and *Garcia* have shown[117c] that electrocatalytic replacement of iodide by a solvent molecule in $[MoCp_2I_2]$ can be induced by the oxidant $[Ru(bipy)_3]^{3\oplus}$.

Photogenerated 19-electron species have been reported by *Tyler* et al.[118] to initiate CO exchange by PMe_2Ph in $[Ru_3(CO)_{12}]$ [Eq. (l)] and by $PnBu_3$ in $[FeCp(CO)_2PnBu_3]^{\oplus}$

$$[Ru_3CO_{12}] + PMe_2Ph \xrightarrow[h\nu]{[Mo_2Cp_2(CO)_6]} [Ru_3(CO)_{11}(PMe_2Ph)] + CO \quad (l)$$

$$[FeCp(CO)_2L]^{\ominus} + L \xrightarrow[h\nu]{[Fe_2Cp_2(CO)_4]} [FeCp(CO)L_2]^{\oplus} + CO \quad (m)$$

[Eq. (m), $L = PnBu_3$]. The reaction (m) substantiates the proposition that electron-rich species are generated by photolysis of $[Fe_2Cp_2(CO)_4]$ in the presence of a P donor.[117, 118]

The disproportionation of the dimeric compounds $[Fe_2Cp_2(CO)_4]$, $[Mo_2Cp_2(CO)_6]$ and $[M_2(CO)_{10}]$ (M = Mn, Re) in the presence of various ligands according to Equation (n) can be induced by a catalytic amount of photons

$$L_nM - ML_n \xrightarrow{P} [ML_nP]^{\oplus} + [L_nM]^{\ominus} \quad (n)$$

(quantum yields $\gg 1$) or of electrons (reduction).[119] This important series of reactions are electrocatalytic in the sense adopted here when initiation is effected by reduction (ET by an initiator and in the propagation); when the initiator is a photon, the first ET transfer intervenes only in the third step but the reaction can still be called electrocatalytic in a broader sense. It is also distinct from the other electrocatalytic reactions reviewed here in that a net overall redox change is involved in the stoichiometry of the reaction.

$$[L_nM - ML_n] \xrightarrow{h\nu} [2\,ML_n]^{\odot}$$

$$[ML_n]^{\odot} + P \longrightarrow [ML_nP]^{\odot}$$

$$[ML_nP]^{\odot} + [L_nM - ML_n] \longrightarrow [ML_nP]^{\oplus} + [L_nM - ML_n]^{\odot\ominus}$$

$$[L_nM - ML_n]^{\odot\ominus} \longrightarrow [L_nM]^{\odot} + [ML_n]^{\ominus}$$

Chanon has published another review on ETC catalysis where organic, inorganic and organometallic exemples are compared; note that the Table of organometallic reactions therein lists electrocatalytic cases having cross ET transfer propagation steps as well as others which have a free radical chain consisting of atom or radical transfers. It is possible to distinguish these two categories of chain mechanism (the latter is not reviewed here).

For instance, CO exchange by a phosphane can proceed easily according to a free-radical chain mechanism when the complex bears a hydride ligand which can be abstracted as a H atom by a radical initiator. Examples are the reactions (o)–(q),[121] for which the radical chain mechanism (r)–(t) holds.

$$cis\text{-}[Os(H)(CH_3)(CO)_4] \xrightarrow[-CO]{PPh_3} [Os(H)(CH_3)(PPh_3)(CO)_3] \quad (o)$$

$$cis\text{-}[Os(H)_2(CO)_4] \xrightarrow[-CO]{PEt_3} [Os(H)_2(CO)_2(PEt_3)_2] \quad (p)$$

$$[Re(CO)_5(H)] \xrightarrow[-CO]{PR_3} [Re(CO)_4H(PR_3)] \quad (q)$$

$$[M(L_n)(H)] \xrightarrow{R^{\odot}} RH + [ML_n]^{\odot} \quad (r)$$

$$[ML_n]^{\odot} \xrightarrow[-L]{PR_3} [M(L)_{n-1}(PR_3)]^{\odot} \quad (s)$$

$$[M(L)_{n-1}(PR_3)]^{\odot} + [M(L)_n(H)] \longrightarrow [M(L)_{n-1}(PR_3)(H)] + [ML_n]^{\odot} \quad (t)$$

Outer-sphere ET proceeds neither in the initiation nor in the propagation (it has been argued that atom or radical transfer is a form of inner sphere ET). Organotransition metal reactions proceeding by such a free-radical chain mechanism were pioneered by *Osborn*'s discovery of oxidative addition to low valent Pt complexes.[122] Recently *Halpern* has found insertion and oxidative addition on Rh porphyrin complexes;[123] photoinduced oxidative addition have also been shown to proceed in this way.[124]

However, metal hydride complexes such as $[VCp(CO)_3H]^{\ominus}$, which are very electron rich, can also initiate ETC ligand exchange in a complex $[ML_n]$ by ET in the initiation step.[125]

Note added in proof: For the coupling of ETC catalysis with organometallic catalysis see Ref. [126].

Carbon Dioxide as an Alternative C_1 Synthetic Unit: Activation by Transition-Metal Complexes

By Arno Behr*

The carbon dioxide molecule has been of limited importance as a synthetic unit in organic chemistry. When it is coordinated to transition metals, however, completely new possibilities arise; CO_2 can bond to metal complexes in a variety of ways and can enter into insertion and coupling reactions, or become catalytically attached to other substrates. The formation of C–C bonds between carbon dioxide and unsaturated hydrocarbons under conditions of homogeneous catalysis makes available new synthetic routes to industrially interesting organic compounds.

1. Introduction

Carbon dioxide, whether in free or chemically combined form, is a considerable natural source of carbon. At present it forms 0.034% of the air by volume.[1] The total quantity of carbon present as carbon dioxide, carbonate, and hydrogen carbonate in the atmosphere, hydrosphere, and lithosphere has been estimated as 10^{16} t.[2] Part of the carbon dioxide is subject to natural circulation processes that are influenced to some extent by man. Carbon dioxide and water are converted into carbohydrates and oxygen in plant chloroplasts; this photosynthetic process forms organic compounds from low-energy carbon dioxide by utilizing sunlight [Eq. (1)].[3] A rough estimate has indicated that ca. 200 billion tons of biomass are produced in this way per year. In terms of chemical throughput, therefore, photosynthesis is by far the most important synthetic process.

$$n\,CO_2 + n\,H_2O \rightleftharpoons (CH_2O)_n + n\,O_2 \qquad (1)$$

The respiration of man and animals and the decomposition of organic substances return carbon dioxide to the atmosphere in comparable quantities, and an equilibrium is thus set up. This equilibrium has however been considerably shifted in recent years by the activities of man.[4,5] The increasing demand for energy since the industrial revolution has led to the increased combustion of fossil fuels (coal, oil, gas), forming carbon dioxide; no one can be sure to what extent this increased CO_2 emission will affect our environment. There are many indications that the higher CO_2 concentration in the atmosphere can alter the earth's radiation balance and thus the world climate.[6–12]

A reduction of these negative effects could be achieved by a change in energy policy (a reduction of CO_2 emission by exploiting alternative energy sources). A certain contribution could also be made by chemically converting carbon dioxide into useful products in those places where it is formed in large concentrations, rather than merely allowing it to escape to the atmosphere.

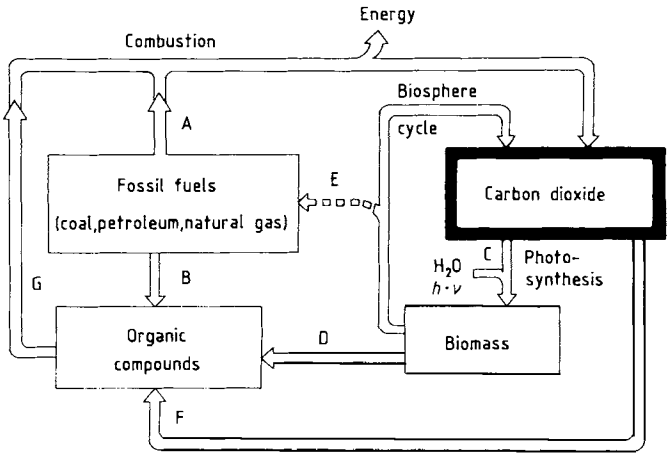

Fig. 1. Carbon dioxide cycle.

Figure 1 depicts the position of carbon dioxide in natural circulation and in processes influenced by man. Until now fossil raw materials (coal, oil, gas) have been used to generate energy (route A) and to synthesize chemicals (route B). The burning of fossil fuels to generate energy forms carbon dioxide, which is converted by photosynthesis (route C) into biomass; this biomass finds little use in chemical synthesis, except for a few special applications (route D). The greater part of the biomass is involved in natural circulation; most plants die and are reconverted into carbon dioxide and water by microorganisms in the soil, but some are eaten by man and animals and converted into CO_2 by respiration. Route E shows the formation of fossil fuels from organic sediments in the course of the earth's history.

Particularly important for industrial organic chemistry is route F, the direct transformation of carbon dioxide into carbon-containing chemicals, which can then be reconverted into CO_2 after use (route G). There are only four important large-scale industrial processes in which carbon dioxide is used for organic syntheses:[13] the synthesis of urea, of cyclic carbonates, of salicylic acid (the Kolbe–Schmitt process), and of methanol (Fig. 2).

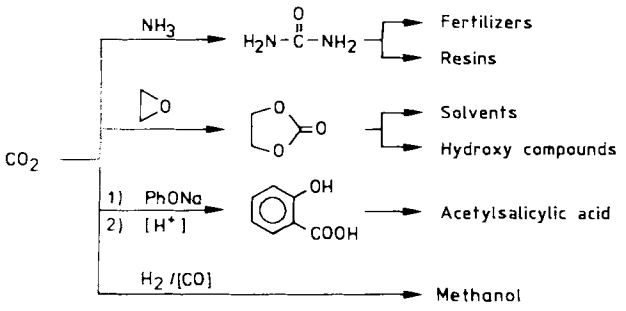

Fig. 2. Industrial organic syntheses with carbon dioxide.

Increased use of carbon dioxide will only be possible if the relatively inert carbon dioxide molecule can be activated. This goal can be achieved with the aid of transition-metal catalysts that lower the activation energy of CO_2 reactions and thus considerably increase the reaction rate. Figure 3 shows (purely schematically) how such a metal catalyst M can influence the bonding of CO_2 to an arbitrary substrate Su. For instance, step I might be the coordination of the substrate to the metal, forming a reactive complex; this could react with the carbon dioxide (step II), followed by elimination of the required molecule Su-[CO_2] (step III) and reformation of the starting complex (step IV). An alternative mechanism is the prior bonding of carbon dioxide to the metal catalyst (step V) and subsequent reaction with the substrate (step VI). Equally possible is the simultaneous coordination of CO_2 and substrate to the metal (step VII).

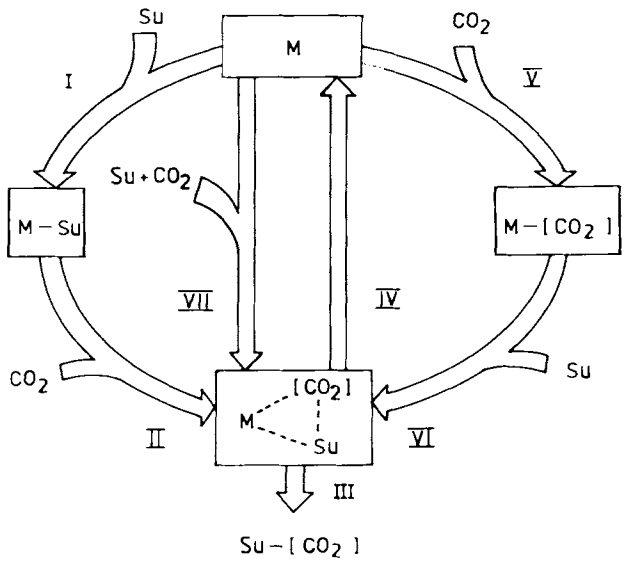

Fig. 3. Possible steps in the reaction of CO_2 with a substrate Su at a transition metal M.

This article will discuss the most important of these reaction steps in more detail:

- the coordination of CO_2 to the transition-metal complex (step V)
- the simultaneous coordination of CO_2 and substrate to the transition-metal complex (step VII)
- the insertion of CO_2 into the M-Su bond (step II)
- the catalytic combination of CO_2 with the substrate (steps III, IV)

2. Coordination of Carbon Dioxide to Transition-Metal Complexes

Carbon dioxide is a molecule with several potential reactive sites: the carbon is a Lewis acid center and the oxygens are weak Lewis bases. The carbon can thus be described as an electrophilic center and the oxygen atoms as nucleophilic centers. In addition, the molecule in its ground state possesses two equivalent C-O π bonds that could also play a role in bonding to a transition-metal center. This polyfunctionality of CO_2 leads to a wide variety of *potential* transition-metal CO_2 complexes (Table 1).

If a metal center reacts with one molecule of carbon dioxide, adducts **1** to **5** can be formed. Type **1**, with a metal-carbon bond, is sometimes termed a metallacarboxylate; electron-rich metal centers should be particularly suitable for forming this sort of bond. Structures **2** and **3** (side-on bonding) are very similar to each other, since the spatial arrangement of the atoms is comparable and only the bonding type (three-membered metallacycle or π complex) varies. Adducts **4** (end-on) seem less probable, because the coordination would be solely through the lone pair of an oxygen atom.

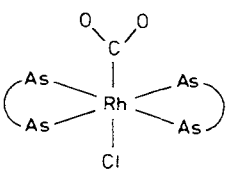
Since carbon dioxide displays up to three potential bonding modes, it is possible that more than one transition-metal center (perhaps different elements) could coordinate to one CO_2 molecule. Table 1 shows some examples (structures **6** to **11**) where two metal centers form adducts with one CO_2 molecule. Conversely, two molecules of CO_2 could in principle bind to one metal center (structures **12** to **19**). A further possibility is that two CO_2 ligands in the coordination sphere of the metal could bond to each other. Structures **20** to **24** are examples where metals and CO_2 combine to form rings or chains.

Many transition-metal CO_2 complexes have been described in the literature. It should however be noted that, especially in the older work, the identification of the complexes was solely on the basis of their IR spectra, which in some cases led to errors. An unambiguous classification of isolated CO_2 complexes according to the structural categories **1** to **24** is usually only possible if an X-ray structure analysis is carried out. Some CO_2 complexes for which this is indeed the case will now be described.

The first example of type **1** was the rhodium complex **25**, isolated by *Herskovitz* and his co-workers.[14,15] It is

[Rh(η^1-CO_2)Cl(diars)$_2$] **25**

likely that the η^1 bonding of CO_2 is stabilized by additional C-H···O interactions with the ligand 1,2-bis(dime-



25

Table 1. Potential coordinations of carbon dioxide to transition-metal centers M.

Ratio metal: CO_2	Electron transfer metal → C	Electron transfer metal → C and O → metal	Formation of a π complex	Electron transfer O → metal
1 : 1	 1	 2	 3	 4 5
2 : 1	 6	 7 8	 9	 10	 11

n : m	 20	 21	 22	 23 24

thylarsino)benzene (diars). In the iridium complex $[Ir(CO)_2Cl(dmpe)_2]$ (dmpe = 1,2-bis(dimethylphosphino)ethane) CO_2 is probably also η^1-coordinated.[16,17] Since the oxygen atoms remain accessible in this type of complex, reactions of the coordinated carbon dioxide are possible, e.g., the addition of a methyl cation [Eq. (2)]. This reaction is an example of step VI shown in Figure 3 with the methyl cation as "substrate."

$$[Ir(CO_2)Cl(dmpe)_2] + FSO_3Me \longrightarrow [Ir(CO_2Me)Cl(dmpe)_2]FSO_3 \quad (2)$$

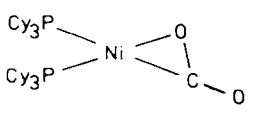
In 1975 *Aresta* and his co-workers assigned the structure type **2/3** to the nickel complex **26** (Cy = cyclohexyl).[18,19]

$[Ni(CO_2)(PCy_3)_2]$ **26**

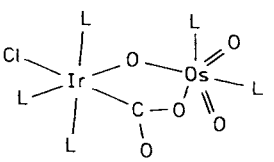
The niobium complex $[Nb(CO_2)(C_5H_4Me)_2(CH_2SiMe_3)]$ and the molybdenum complex $[Mo(CO_2)Cp_2]$ (Cp = cyclopentadienyl) also belong to this structure type.[20,21] They are examples of the ability of the earlier "oxophilic" transition metals to form stable CO_2 complexes.

Many structural variants are possible if two transition-metal centers are available for bonding. The structure **7** has been suggested for the iridium-osmium complex **27** (L = pyridine), prepared from Vaska's complex $[IrCl(CO)(PPh_3)_2]$ and osmium tetroxide in the presence of pyridine.[22] In this binuclear complex the bridging CO_2 ligand is formed from CO and oxygen. An X-ray structure analysis is available for the complex obtained by methylation of the exocyclic oxygen of the bridging CO_2 in **27** with methyl trifluoromethanesulfonate.

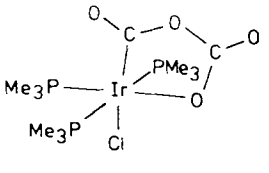
Fewer cases are known in which two CO_2 molecules are bound to the same transition-metal center. One example is the iridium complex **28** isolated by *Herskovitz* and his coworkers; the carbon of one CO_2 molecule is bonded to the oxygen of the second (structure **15**).[23,24] This type of CO_2 dimerization in the coordination sphere of the transition-metal center is known as "head-to-tail bonding." The authors assume that the uptake of CO_2 occurs stepwise and that the first CO_2 molecule binds to iridium through carbon.



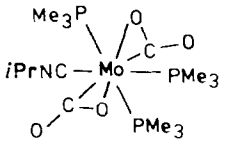
26



27



28

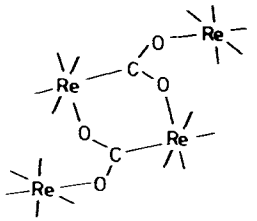


29

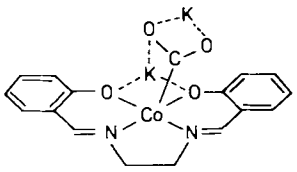
A further example is the molybdenum complex **29**, as described by *Carmona* et al.[25,26] Both CO_2 molecules are bonded "side-on" and are *trans* to each other. This structural type can, in simplified form, be represented by formulas **16/17**.

With a view to the use of carbon dioxide in syntheses it is interesting to look for complexes in which two carbon dioxide molecules are bonded "head-to-head" through their carbon atoms. This linkage leads to oxalato complexes and could represent a first step in a catalytic conversion of carbon dioxide to oxalic acid. *Fröhlich* et al. succeeded in 1983 in preparing the binuclear titanium oxalato complex $[Cp_2Ti(C_2O_4)TiCp_2]$ (structure type **24**) via such a dimerization of CO_2.[27] The synthesis of mononuclear oxalato complexes (corresponding to structure **19**) from carbon dioxide has not been reported.

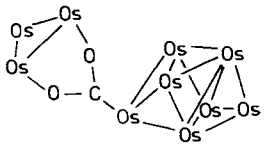
It remains to describe those structural types in which several metal centers combine with carbon dioxide to form ring structures. A μ_3-CO_2 bridge of the type **21** was demonstrated in the rhenium complex **30**.[28] This complex is not formed directly from CO_2, however, but from several "$Re(CO)_5OH$" units by elimination of water. Structure type **22** also contains a μ_3-CO_2 bridge. To this group belongs the cobalt complex **31**, synthesized by *Floriani* and his co-workers, in which the carbon atom is bonded to the transition-metal center and each oxygen enters into interactions with at least one potassium ion.[29-33] This structure is an interesting example of "bifunctional" CO_2 activation by a combination of basic and acid metal centers. It is notable that complex **31** functions as a reversible CO_2 carrier and that the Co-C bond is easily broken. Finally, complex **32** is presented as an example of structure type **22**, in which the metal atom assembly is homonuclear.[34,35]



30



31



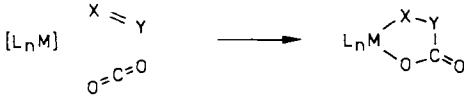
32

By far the most important synthetic reactions of CO_2 complexes are substitution and addition reactions, which also play a decisive role in homogeneous transition-metal catalysis. It is also striking that the synthetic reactions generally occur under mild conditions, nearly always at room temperature and normal pressure. Homogeneous, transition-metal-catalyzed reactions also generally take place at low pressures and temperatures.[36-43] These observations suggest that the use of carbon dioxide in homogeneously catalyzed processes is likely to be successful.

In catalytic reactions of carbon dioxide, the CO_2 molecule bonds to a substrate Su in the coordination sphere of a transition metal (cf. Fig. 3). This can occur by simultaneous oxidative coupling of CO_2 and substrate as they add to the metal (step VII in Fig. 3). It is equally possible that CO_2 inserts into a previously formed M-Su bond (step II in Fig. 3). More detailed investigations of these important potential catalytic steps are presented in Sections 3 and 4.

3. Oxidative Coupling with Carbon Dioxide

Oxidative coupling is an important basic reaction in stoichiometric carbon dioxide chemistry; it leads to products that have been postulated as intermediates in catalytic processes. In the following discussion oxidative coupling is understood to be a reaction of carbon dioxide in which a metal center M, an unsaturated compound X = Y, and CO_2 react together to form a metallacycle [Eq. (3)].

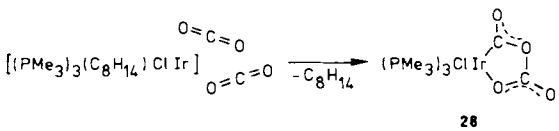


(3)

In all known examples of this type of compound, the oxygen of the CO_2 molecule binds to the metal center, not the carbon. The principle of oxidative coupling has been known for a long time; *Wilkinson* and his co-workers described the reaction of platinum phosphane complexes with oxygen and carbon dioxide in 1967. They obtained a peroxycarbonato complex [Eq. (4)] as well as a carbonato complex[44-48]. Similar reactions have been described for rhodium.[49,50]

(4)

A reaction that has already been presented in Section 2 is the joining of two CO_2 molecules at an electron-rich iridium center, forming the complex **28**.[23,24] This also can be regarded as an oxidative coupling [Eq. (5)].

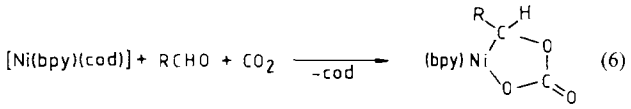


(5)

28

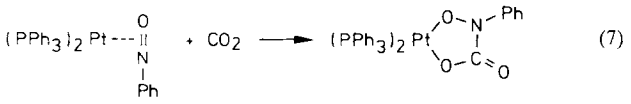
A more detailed investigation of oxidative coupling with CO_2 has been in progress since the beginning of the 1980s. It has been shown that, besides the O-CO_2 bond formation discussed above, N-CO_2 and C-CO_2 bonds can also be formed. The predominant transition-metal compounds were electron-rich Ni^0 complexes.

The reaction of carbon dioxide with aliphatic aldehydes in the presence of (2,2'-bipyridine)(1,5-cyclooctadiene)nickel(0), [Ni(bpy)(cod)], proceeds at room temperature and normal pressure to form an NiC_2O_2 ring [Eq. (6)].[51,52]



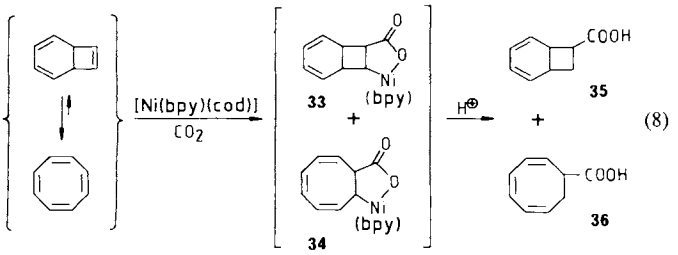
(6)

Analogous reactions, but this time with C–N bond formation, occur with azaolefins RCH=NR'.[53–56] The use of carbodiimides[57] or azadienes[58] also leads to N–C bond formation. *Cenini* and his co-workers observed an oxidative coupling of CO_2 with an η^2-bonded nitrosobenzene ligand [Eq. (7)].[59,60]



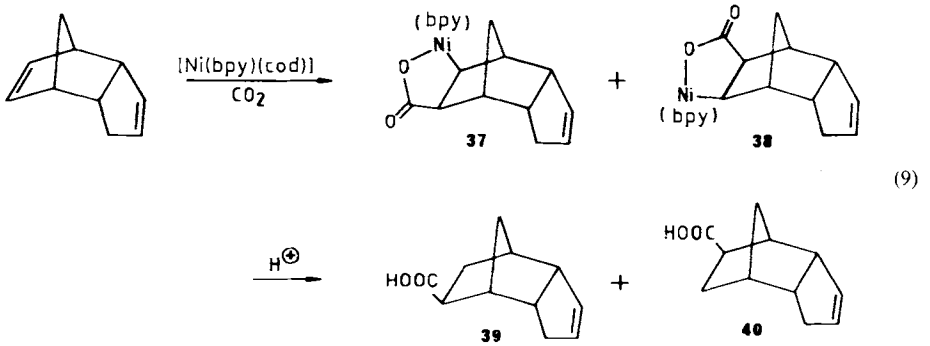
(7)

A C–C bond is formed when alkynes (e.g., acetylene, 2-butyne, or tolane) are allowed to react with carbon dioxide and nickel complexes;[61–63] oxanickelacyclopentene derivatives are formed in yields of between 40 and 90%. Olefins can be used instead of alkynes. Open-chain and cyclic olefins both lead to oxanickelacyclopentanes, which can either be isolated as complexes or identified on the basis of the products obtained by acidic decomposition.[63–67] The oxidative coupling with olefins is exemplified by the following reactions with cycloalkenes.[68] The reaction of the four-membered ring bicyclo[4.2.0]octatriene, which is in equilibrium with cyclooctatetraene, leads to an oxidative coupling of both isomers with CO_2 [Eq. (8)]. A mixture of the nickel complexes **33** and **34** is formed; these are de-



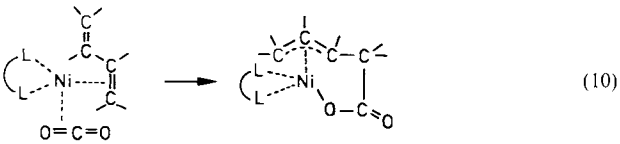
(8)

composed by hydrochloric acid, giving the carboxylic acids **35** and **36**. Dicyclopentadiene was employed as a "five-membered ring molecule"; it possesses two rings with greatly differing reactivities. Equation 9 shows that the norbornene double bond undergoes an oxidative coupling with CO_2 and nickel to form complexes **37** and **38**, which yield the diastereomeric carboxylic acids **39** and **40**



(9)

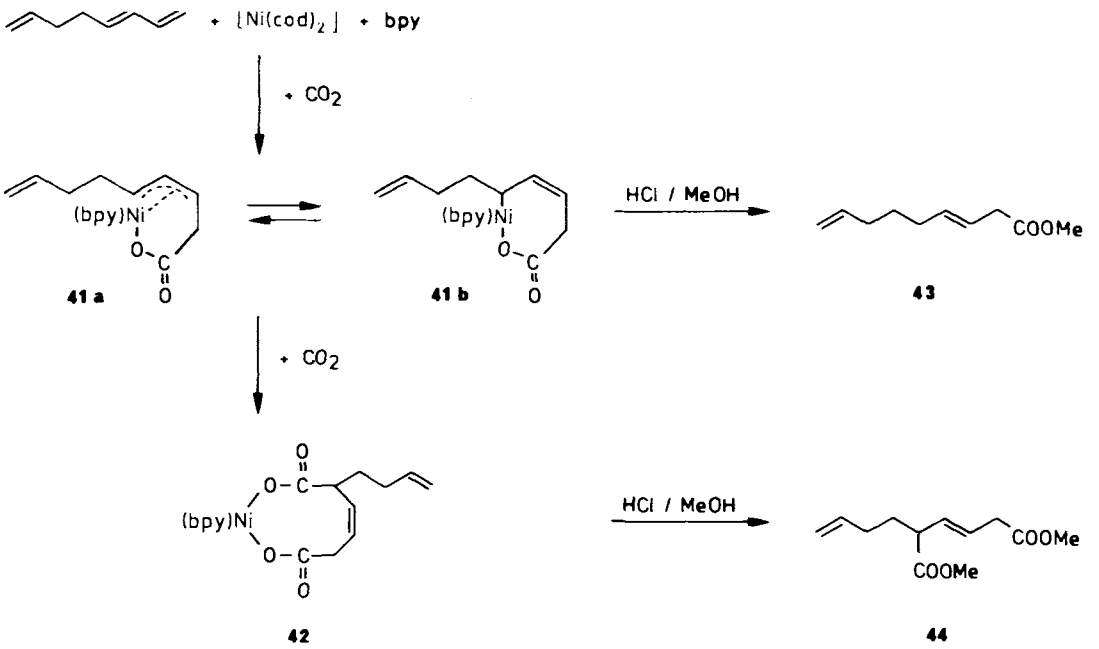
on treatment with hydrochloric acid. *Walther, Dinjus,* and their co-workers were able to show that conjugated dienes also react with carbon dioxide at nickel(0) complexes.[69–73] In contrast to the five-membered metallacycles described above, complexes with a dianionic ligand are formed, which contain an η^3-coordinated allyl group and a carboxylate group [Eq. (10)]. This C–C bond formation can be explained in terms of an initial η^2 coordination of the 1,3-diene. With L^L = tetramethylethylenediamine and with 2,3-dimethylbutadiene as diene a crystalline complex was obtained; a crystal structure analysis showed[71] that the monodentate carboxylate group, the allyl C atoms, and a nitrogen atom of the chelating ligand coordinate the nickel in a plane, whereas the second nitrogen atom interacts only weakly with the metal.



(10)

The hydrolysis of the complexes obtained according to Equation (10) with dilute mineral acids leads to 3-pentenecarboxylic acids. The idea of obtaining carboxylic acids from oxidative coupling of 1,3-dienes and carbon dioxide has formed the basis for intensive study. 1,3-Pentadiene can be converted into sorbic acid[74] (after workup with maleic anhydride) and butadiene into 2,4-pentadienecarboxylic acid.[75] In the presence of pyridine, reaction with a further CO_2 molecule yields an α,ω-dicarboxylic acid.[76]

Since both alkenes and 1,3-dienes can react with carbon dioxide at nickel(0) complexes, it is interesting to consider how a molecule with both functional groups would react. The reaction of 1,3,7-octatriene with (bipyridine)(cyclooctadiene)nickel and carbon dioxide leads to the nickel carboxylato complexes **41** and **42** (Scheme 1).[77] The decomposition of these complexes with HCl in methanol produces the monomethyl ester **43** and the dimethyl diester **44**. The nature of the products is evidence that the reaction takes place at the diene function of the starting material. The carboxylato complex **41a** containing an η^3-allyl group is formed by oxidative coupling of the diene analogously to Equation 10; **41a** is in equilibrium with **41b**, in which a Ni–C η^1 bond is present. A further molecule of CO_2 can insert into this bond, forming the dicarboxylato complex **42**. This reaction is an interesting example of an oxidative coupling and a CO_2 insertion occurring at the same nickel center.

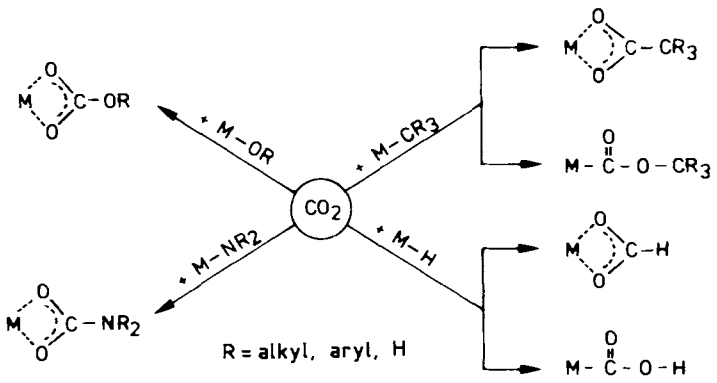


Scheme 1. Coupling of a molecule containing mono- and diene functions with CO_2.

4. Insertion Reactions of Carbon Dioxide

In the last two decades, many insertion reactions of carbon dioxide into M–C, M–H, M–O, and M–N bonds have been described in the literature. Scheme 2 provides a survey of some of the products.

The insertion of CO_2 into the M–C bond generally leads to a carboxylato complex via the formation of a new C–C bond. Insertions in the opposite sense, forming a new C–O bond and thus a 1-metalated formate ester, have only been observed in a few special cases. Similarly, the insertion into M–H bonds can lead to either formato complexes or 1-metalated formic acids. Insertion into M–O bonds preferentially forms alkyl or aryl carbonato complexes; insertion into M–N bonds forms carbaminato complexes.

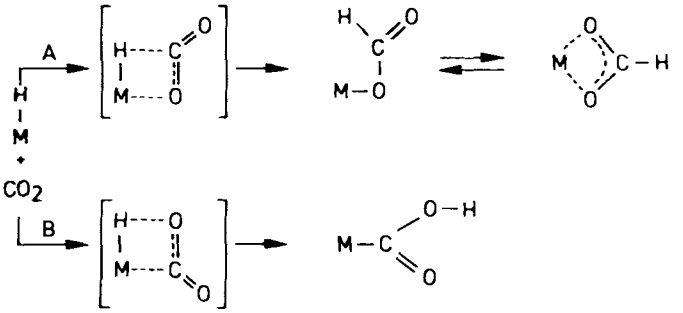


Scheme 2. Adducts formed by insertion of CO_2 into M–X bonds (X = H, O, N, C).

Several review articles covering these insertion reactions have been published.[78–85] Here we shall discuss CO_2 insertion in terms of some typical examples, showing the wide range of applications of this reaction type.

4.1. CO_2 Insertion into the M–H Bond

In insertion reactions the first step is the coordination of CO_2 to the M–X fragment (X = H, O, N, C). In the case of metal hydrido complexes, hydridometal–CO_2 intermediates can be formed (Scheme 3), which then rearrange by hydrogen migration to formato complexes (path A) or 1-metalated formic acids (path B).



Scheme 3. Insertion of CO_2 into the M–H bond.

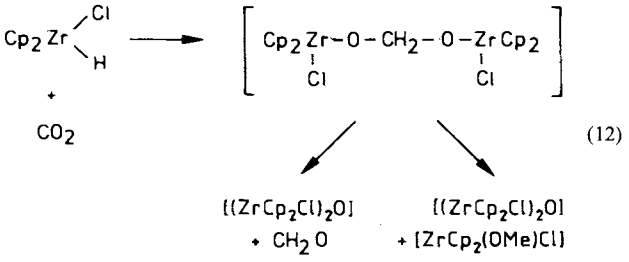
Most transition-metal hydrido complexes react with CO_2 to give formato complexes. Important examples are the hydridometal carbonyls $[MH(CO)_5]^{\ominus}$ (M = Cr, Mo, W)[86–88] as well as hydrido complexes of rhenium,[89,90] iron,[91] ruthenium,[92–94] and copper.[95,96] There is only one piece of indirect evidence for the existence of a 1-metalated formic acid: *Kolomnikov, Volpin,* and their co-workers found such a species in a yield of 17% from the reaction of a nitrogencobalt complex with CO_2.[78,97] As seen from Equation 11, the identification was based on the product

$$[Co(N_2)H(PPh_3)_3] + CO_2 \xrightarrow[-N_2]{} [Co(COOH)(PPh_3)_3] \xrightarrow{MeI} \xrightarrow[BF_3]{MeOH} Me-COOMe \quad (11)$$

of subsequent reaction with methyl iodide and methanol/BF_3. However, the reactions of hydridocobalt complexes with CO_2 generally lead to formato complexes.[98,99]

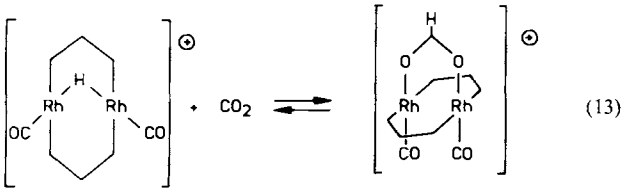
Transition-metal hydrido complexes are not limited to the formation of $M(O_2CH)$ or M-COOH complexes on reaction with CO_2, as demonstrated by the following examples.

The hydridozirconium complex $[ZrCp_2ClH]$ reacts with excess CO_2 to form $[(ZrCp_2Cl)_2O]$ and formaldehyde.[100-102] A reduction of the hydrido complex to the zirconium methanolato complex can be achieved by using the hydrido complex in excess. The different reaction products may be formed via a binuclear intermediate with an $O-CH_2-O$ bridge [Eq. (12)].



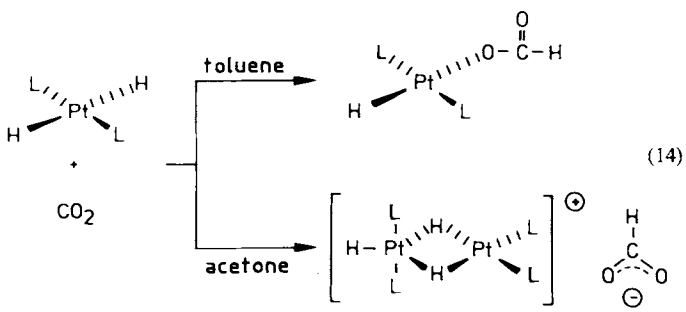
(12)

Another unusual reaction was studied by *Eisenberg* et al.; a hydrido-bridged dirhodium complex reacts with CO_2 to form a dirhodium complex with a formato bridge [Eq. (13)].[103]



(13)

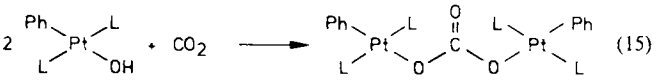
The reaction of CO_2 with hydridoplatinum complexes allowed an interesting observation; starting from the complexes $[PtH_2L_2]$ in benzene or toluene, a monoformato complex is obtained,[104] whereas in acetone or acetonitrile a binuclear cationic complex with a free formate counterion is formed [Eq. (14), $L = PEt_3$].[105]



(14)

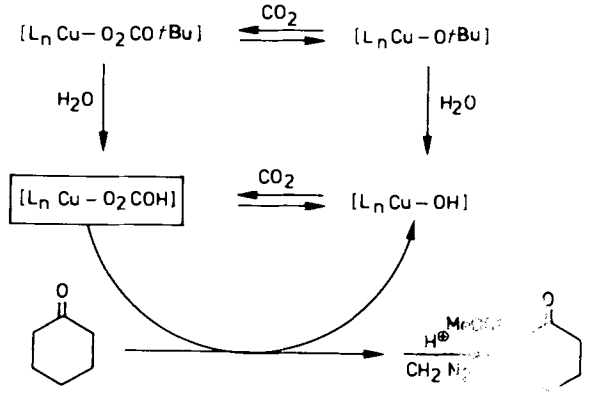
4.2. CO_2 Insertion into the M-O Bond

A variety of transition-metal complexes with M-OR groups undergo insertion reactions with CO_2. If R is an organic moiety, alkyl or aryl carbonato complexes are formed (cf. Scheme 2); if R is hydrogen, hydrogen carbonato species are obtained. Examples of alkyl carbonato complexes thus obtained are known for zirconium,[106] vanadium,[107] tantalum,[108] molybdenum,[109] and tungsten,[110] and also for the lanthanoids.[111] Alkyl carbonato complexes can be synthesized "in situ" from a suitable precursor complex, an alcohol, and carbon dioxide.[104,112-114] Hydrogen carbonato complexes have been established for (in particular) rhodium and iridium.[115,116] In some cases the formation of metal carbonato complexes was also observed.[117,118] An interesting dimeric carbonato complex, in which the CO_3 ligand functions as an η^1,η^1-bridging group, is obtained from the reaction of the hydroxoplatinum complex $[PtPhL_2(OH)]$ with CO_2 [Eq. (15), $L = P(CH_2Ph)_3$].[119]



(15)

The insertion of CO_2 into copper alkoxo complexes is worthy of particular attention in this respect. It leads not only to the expected alkyl carbonato complexes,[120,121] but also, by various routes, to a copper hydrogen carbonato complex[122,123] that decarboxylates in water or organic solvents and transfers the released CO_2 to an organic substrate. Scheme 4 shows the reaction with cyclohexanone as an example of such a transcarboxylation. The copper hydrogen carbonato complex functions here as a reversible CO_2 carrier, which could win importance in catalytic reactions.



Scheme 4. Insertion of CO_2 into copper alkoxo complexes. L = [illegible]

4.3. CO_2 Insertion into the M-N Bond

Many examples of insertion of CO_2 into M-N bonds are known for the early transition metals (as was also [illegible] to be the case for insertion into M-O bonds). Metal carbaminato complexes are formed in nearly all such reactions (cf. Scheme 2). *Chisholm* and *Extine* investigated CO_2 insertion into dimethylamine complexes of titanium and zirconium and observed a rapid exchange of ^{13}C-labeled carbon dioxide [Eq. (16)].[124,125] The carbon dioxide is obviously only loosely bound; the carbaminato complexes, like the copper hydrogen carbonato species shown in Scheme 4, may be considered to be "CO_2 carriers."

$$[Ti(NMe_2)_4] \xrightarrow{^{13}CO_2} [Ti(O_2{}^{13}C\text{-}NMe_2)_4] \qquad (16)$$
$$\xrightarrow{^{12}CO_2} [Ti(O_2{}^{12}C\text{-}NMe_2)_4]$$

CO_2 insertion into the M–N bond has been investigated not only for metals of the titanium group,[126–128] but also for metals of the vanadium[129] and chromium groups.[130–134] Mechanistic studies show that small amounts of free amine accelerate the reactions markedly. It may thus be assumed that amine and CO_2 form a carbamic acid, which then, in a second step, reacts with the metal amine complex [Eq. (17)]. This would imply that the reaction should strictly be classified as a ligand exchange rather than a CO_2 insertion.

$$Me_2NH + CO_2 \rightleftharpoons Me_2NCOOH \qquad (17)$$
$$\xrightarrow{+[M\text{-}NMe_2]} [M\text{-}O_2CNMe_2] + Me_2NH$$

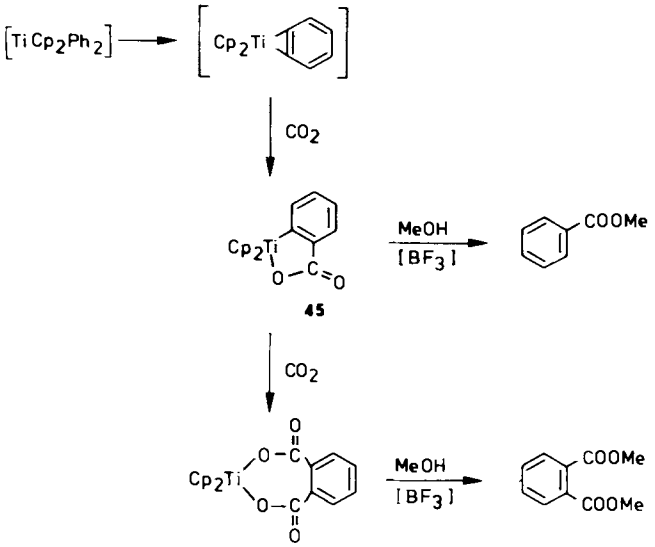
Reactions of CO_2 with amine complexes are also known for the metals uranium,[135] rhenium,[136] zinc,[113,137] and copper,[121,138–140] but not for the metals of the iron, cobalt, and nickel groups. The carbaminato complexes of the noble metals are however accessible by an indirect synthetic route, namely the reaction of metal complexes with amines and CO_2; the ruthenium hydrido complex $[RuH(PR_3)_5]PF_6$ reacts with dimethylamine and carbon dioxide to form the carbaminato complex $[Ru(O_2CNMe_2)(PR_3)_4]PF_6$ (R = Me, Ph), and the dimethylpalladium complexes $[PdMe_2L_2]$ react similarly to give $[PdMe(O_2CNMe_2)L_2]$ (L = PR_3).[141,142]

4.4. CO_2 Insertion into the M–C Bond

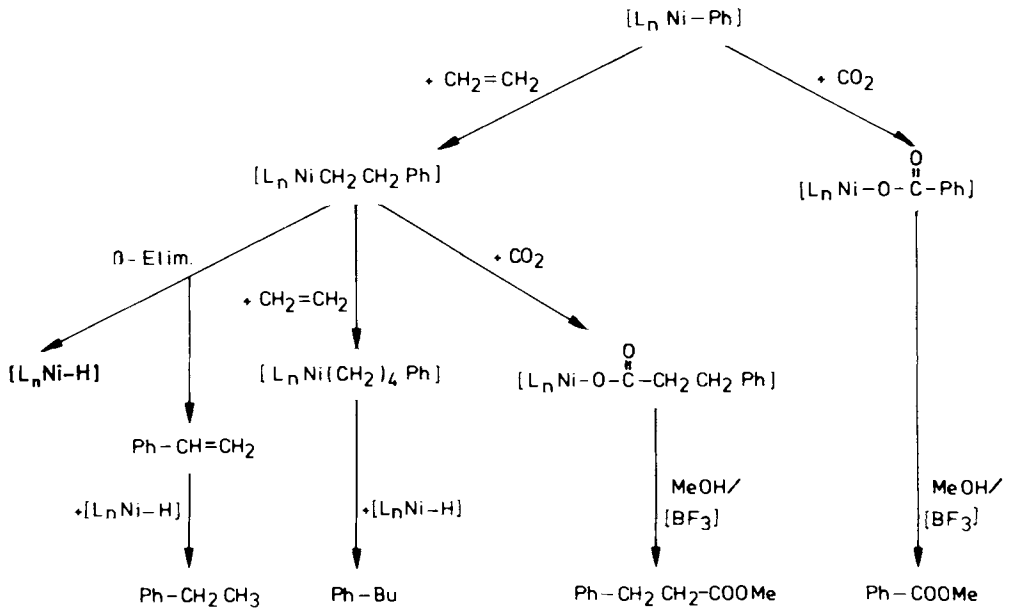
As shown in Scheme 2, there are two modes of CO_2 insertion into complexes with an M–C bond (as already noted for the M–H bond); the "normal" insertion to form a carboxylato complex and the "inverse" insertion to form a 1-metalated formate ester. However, this is a somewhat oversimplified description; CO_2 insertion into the M–C bond will be considered here in more detail.

4.4.1. Insertion into Metal–Aryl and Metal–Alkyl Bonds

The insertion of CO_2 into aryltitanium complexes was investigated in the 1970s.[143–145] *Kolomnikov* et al. observed the formation of the metallacycle **45** (Scheme 5) by the reaction of diphenyltitanocene with CO_2; the product was identified by X-ray structure determination. An arynetitanium complex was assumed to be an intermediate. Treatment of the crude product with methanol/BF_3 leads not only to the expected methyl benzoate but also to small quantities of dimethyl phthalate, the product of a double insertion.



Scheme 5. Insertion of CO_2 into diphenyltitanocene.



Scheme 6. Reactions with phenylnickel complexes. For L see [146].

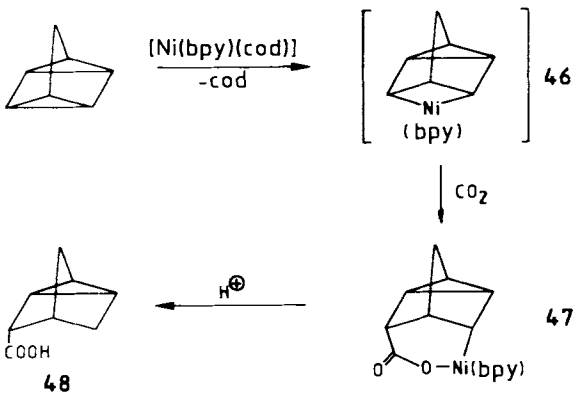
Phenylnickel complexes can also undergo CO_2 insertion to form nickel benzoato complexes, which are then esterified to release methyl benzoate (Scheme 6). It is also known that ethene can insert into the nickel–phenyl bond. A (2-phenylethyl)nickel complex is formed, which undergoes β-elimination of styrene. Double insertion leads to a (4-phenylbutyl)nickel complex; the subsequent elimination product, *n*-butylbenzene, was also identified.

Particular attention should be drawn to the first example of a combined insertion of ethene and carbon dioxide.[146] The initial product may be the (2-phenylethyl)nickel complex, into whose Ni–C bond the CO_2 then inserts. The subsequent treatment with methanol/BF_3 releases methyl β-phenylpropionate (Scheme 6).

4.4.2. *Insertion into Metallacycloalkanes*

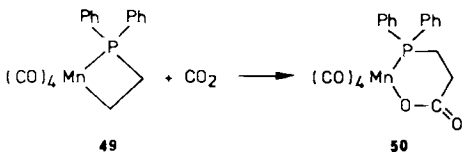
Insertion reactions of CO_2 into metallacycloalkanes are important because metallacycles are often postulated as intermediates in numerous transition-metal-catalyzed reactions forming C–C bonds, e.g., the dimerization of cyclopropene derivatives and methylenecyclopropane,[147] the oligomerization of allene,[148] and the dimerization of ethene.[149]

The nickelacyclobutane **46** is presented as an example of a metallacycle that undergoes insertion reactions; it is generated "in situ" from (bipyridine)(cyclooctadiene)nickel(0) and quadricyclane (Scheme 7). Its reaction with CO_2 at room temperature forms the nickel carboxylato complex **47** in 92% yield.[68] The decomposition of **47** with acid releases the *endo*-nortricyclane-3-carboxylic acid **48**.



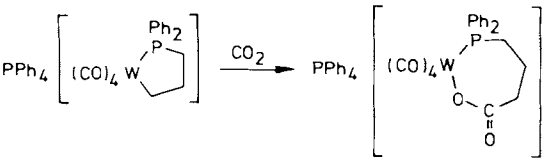
Scheme 7. Insertion of CO_2 into a nickelacycle.

The manganaphosphacyclobutane **49** reacts with CO_2 to form the insertion product **50** in yields of up to 40% [Eq. (18)].[150]



(18)

Whereas the manganacyclobutane forms a six-membered ring on CO_2 insertion, an analogous insertion into the manganaphosphacyclopentane (to form a seven-membered ring) does not occur. However, complexes of other transition metals—e.g., anionic complexes of tungsten [Eq. (19)]—form seven-membered rings of sufficient stability.[151]

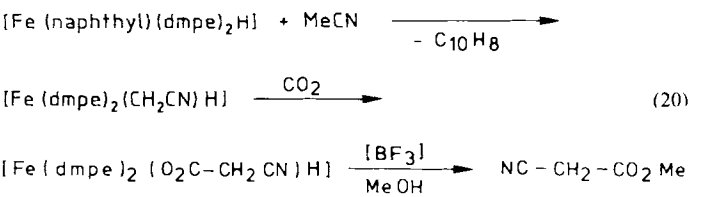


(19)

4.4.3. *Insertion into M–C Bonds Generated in situ*

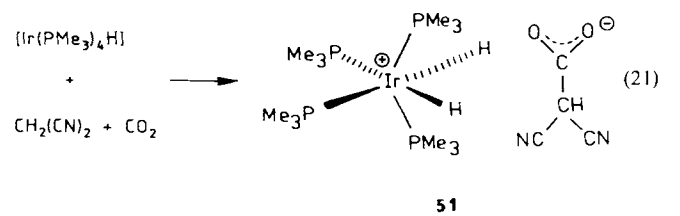
In Sections 4.4.1 and 4.4.2 carbon dioxide insertion reactions into η^1 transition-metal–carbon bonds of well-defined complexes were described. The possibility of generating the M–C bonds in situ, by oxidative addition of cycloalkanes to transition-metal complexes, was also mentioned (see Scheme 7). Here a further "in situ" method is presented; oxidative addition of compounds with acidic C–H functions can lead to intermediate alkylmetal complexes that then undergo CO_2 insertion.

Ittel, Tolman et al.[152] studied a hydrido-naphthyl complex of iron, to which $^{\ominus}H_2CCN$ (from MeCN) could be added oxidatively, naphthalene being eliminated. The insertion of CO_2 into the resulting Fe–C bond led to a carboxylato complex, which was identified spectroscopically and which reacted with methanol/BF_3 to give methyl cyanoacetate [Eq. (20)]. An analogous reaction in iridium chemistry was described by *English* and *Herskovitz*.[153] These reactions demonstrated the feasibility of forming C–C bonds between acidic hydrocarbons and carbon dioxide in the presence of transition-metal complexes.



(20)

In order to understand this reaction type better, further experiments were carried out using iridium and rhodium complexes and the strongly C–H-acidic malonodinitrile.[154] The complex **51** can be isolated from the reaction between hydridotetrakis(trimethylphosphane)iridium and equimolar amounts of malonodinitrile and carbon dioxide [Eq. (21)].



(21)

The distorted tetrahedral arrangement of the phosphane ligands inferred from spectroscopic data was confirmed by an X-ray structure analysis (Fig. 4); this also showed that the dicyanoacetate is dimeric. The central carbon atom,

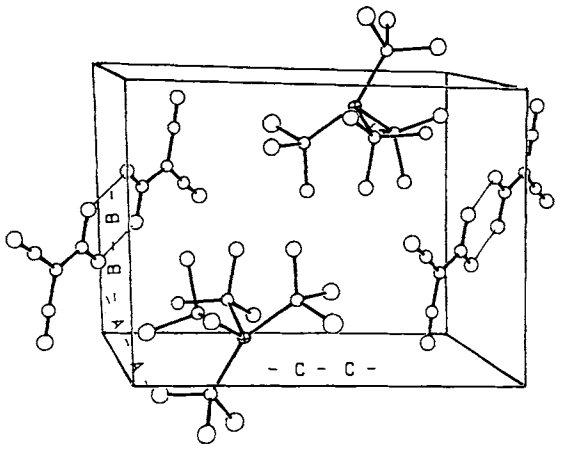


Fig. 4. Unit cell and molecular structure of complex **51**.

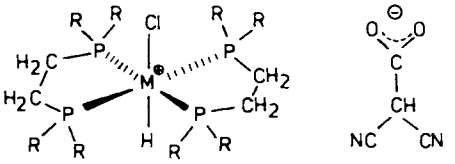
which bears the cyano and carboxylate groups, is sp^2-hybridized [see also Eq. (23)], and the distance of 258 pm between oxygen atoms in neighboring monomeric units is typical of carboxylic acid hydrogen bonding.

The formation of C–C bonds between malonodinitrile and CO_2 takes place not only with metal hydrido complexes but also with metal chloro complexes, e.g., $[Ir(depe)_2Cl]$ (depe = bis-1,2(diethylphosphino)ethane). In this case, however, octahedral complexes are formed in which the chloro ligand and the newly added hydrogen atom are mutually *trans* [Eq. (22)].

$$\left.\begin{matrix}[Ir(depe)_2]Cl \\ [Rh(dmpe)_2]Cl\end{matrix}\right\} \xrightarrow[CO_2]{CH_2(CN)_2} \quad (22)$$



52 : M = Ir, R = Et

53 : M = Rh, R = Me

The generalized Equation (23) summarizes the reactions of the iridium and rhodium complexes with malonodinitrile and carbon dioxide. The first step is the formation of a positively charged metal hydrido complex, stabilized in solution by a dicyanoacetate counterion. Malonodinitrile and CO_2 then undergo the expected C–C bond-forming reaction; however, they do not, as previously assumed, remain bonded to the transition metal as a ligand, but form a free anion in solution. On crystallization, a further remarkable feature is observed; the methine proton of the dicyanoacetate migrates to a carboxylate oxygen and forms a C-deprotonated acid that dimerizes by hydrogen bond formation.

$$[L_nM] + CH_2(CN)_2 + CO_2 \longrightarrow \left[[L_nM\text{-}H]^{\oplus}[(CN)_2CHCOO]^{\ominus}\right] \quad \text{in solution} \quad (23)$$

$$\left[[L_nM\text{-}H]^{\oplus}[(CN)_2CCOOH]^{\ominus}\right]_2 \quad \text{in the crystal}$$

M = Ir, Rh
L = PMe_3, dmpe, depe
n = 2, 4

The question arises as to how the reaction that forms the C–C bond actually proceeds. One possibility (path A in Fig. 5) involves the oxidative addition of the C–H-acidic

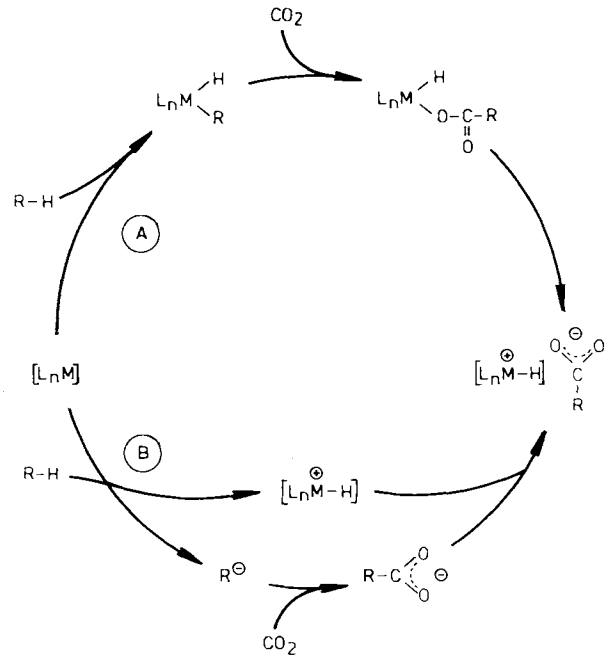


Fig. 5. Possible mechanisms in the reaction of C–H-acidic substrates with CO_2 in the presence of electron-rich transition-metal complexes.

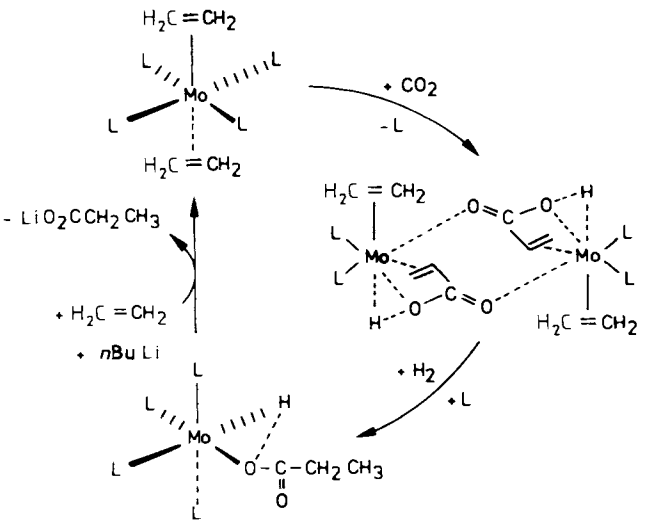
compound R–H to the transition-metal complex L_nM, forming an alkyl-hydrido complex. The insertion of CO_2 into the metal–carbon bond then leads to a carboxylato-hydrido intermediate, which rearranges to the ionic species $[L_nMH]^{\oplus}[RCOO]^{\ominus}$ because of the electron-withdrawing effect of the R group. The second possible reaction path (B in Fig. 5) involves a proton transfer from R–H to the transition-metal complex L_nM, leaving a carbanion $R^{\ominus}$, which then reacts with the electrophilic CO_2 to form the anion $R\text{-}COO^{\ominus}$. Path B, which may be described as a "transition-metal-initiated" C–C bond formation, cannot be considered as a CO_2 insertion; it is however a feasible alternative explanation for the formation of the complexes $[L_nM]^{\oplus}[RCOO]^{\ominus}$.

4.4.4. Insertion into Metal–Olefin Bonds

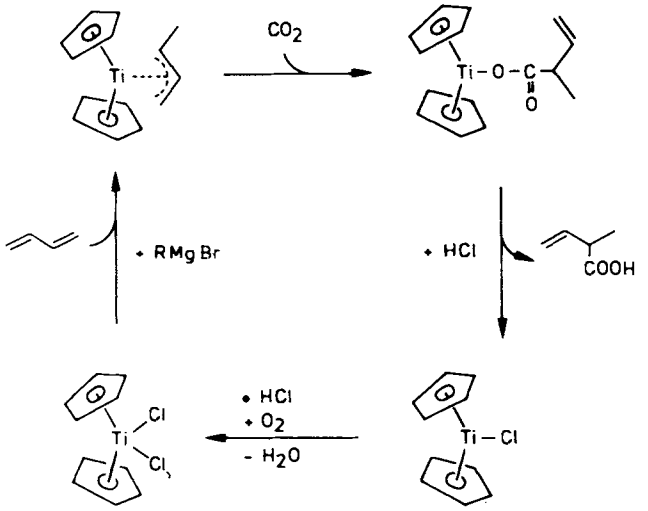
CO_2 reacts with the bis(ethene)molybdenum complex $[Mo(C_2H_4)_2(PMe_3)_4]$ in a remarkable way.[155] This complex possesses an electron-rich metal center surrounded by labile trimethylphosphane ligands. Carbon dioxide reacts with the coordinated ethene, forming a new C–C bond, and the product is a binuclear molybdenum complex with two bridging acrylic acid ligands (Scheme 8). Hydrogenation leads to a hydrido-propionato complex, which on treatment with *n*-butyllithium and ethene releases lithium propionate and re-forms the starting complex. This reaction sequence is of particular interest because it outlines a possible future catalytic synthesis of industrially important acrylic acid from ethene and carbon dioxide.



Scheme 8. Insertion of CO_2 into a Mo-ethene bond. L = PMe_3.

4.4.5. *Insertion into Metal–Allyl Bonds*

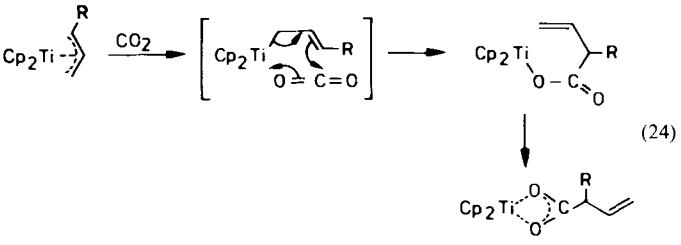
The insertion of CO_2 into η^3-allyl complexes of titanium has been studied in detail.[156–159] *Sato* et al. prepared the crotyltitanocene complex from $[TiCp_2Cl_2]$, butadiene, and a Grignard reagent (Scheme 9) and allowed it to react with CO_2 yielding a crotonato complex. Subsequent hydrolysis leads to 2-methyl-3-butenoic acid and $[TiCp_2Cl]$, which can be reconverted into $[TiCp_2Cl_2]$. This stoichiometric reaction sequence corresponds to a catalytic synthesis of



Scheme 9. Insertion of CO_2 into a titanium-allyl bond.

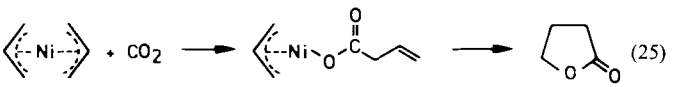
methylbutenoic acid from butadiene and CO_2, although HCl and Grignard reagent are consumed. Particularly notable is the fact that chiral cyclopentadienyl ligands cause an asymmetric insertion of CO_2; by use of a crotyltitanocene complex with a menthyl-substituted cyclopentadienyl ligand, the (*S*)-2-methyl-3-butenoic acid was formed with an optical yield of 18.9%.

Teuben et al. suggest an alternative electrocyclic mechanism, coupled with an allyl migration, for the reaction of the allyltitanium complexes with CO_2 [Eq. (24), R = H, CH_3].



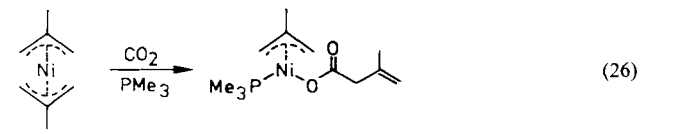
(24)

Bis(η^3-allyl)nickel reacts with CO_2 at room temperature, forming η^3-allyl(vinylacetato)nickel, which releases γ-butyrolactone on heating to 140°C [Eq. (25)].[160]



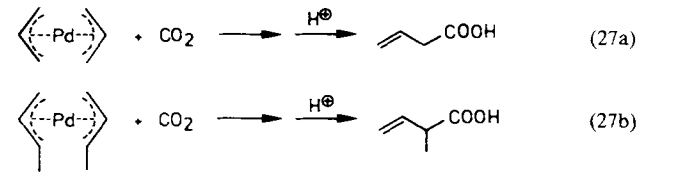
(25)

Jolly, Wilke et al. were able to show that bis(η^3-2-methylallyl)nickel reacts quantitatively with carbon dioxide at −30°C in the presence of basic phosphanes to form a carboxylato complex [Eq. (26)].[161]



(26)

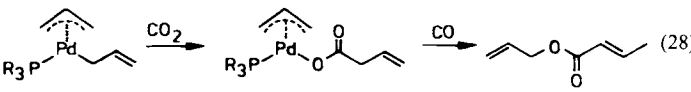
Allylpalladium complexes have also been treated with CO_2. *Ito* et al. carried out the reaction of bis(η^3-allyl)palladium and bis(η^3-crotyl)palladium with CO_2 and obtained the corresponding carboxylic acids after treatment with mineral acid [Eq. (27a), (27b)].[162]



(27a)

(27b)

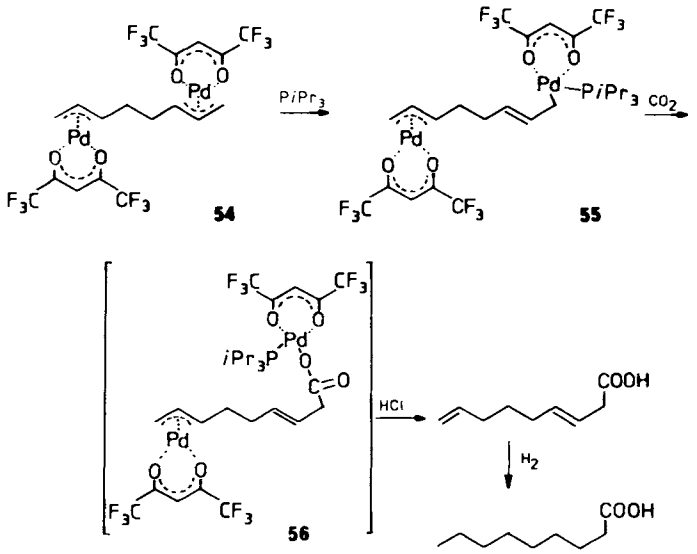
Jolly, Wilke et al. were able to trap the intermediates in this reaction by adding basic phosphanes.[163] With trimethyl- or tricyclohexylphosphane, complexes were formed that contained both an η^1 and an η^3 allyl ligand. The insertion of CO_2 into the Pd–C σ bond led to an allyl-carboxylato complex, the ligands of which could be displaced by carbon monoxide [Eq. (28), R = Me, Cy].



(28)

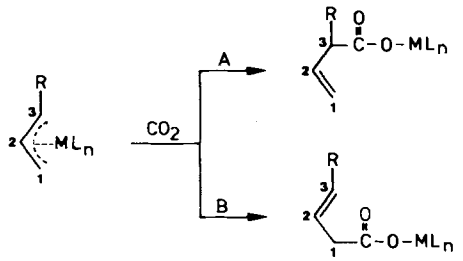
The binuclear octadienediylpalladium complex **54** displays some remarkable reactions (Scheme 10).[164,165] The addition of one equivalent of triisopropylphosphane leads selectively to complex **55**, in which only one palladium center has acquired a phosphane ligand. Complex **55** reacts with CO_2 to give **56**, which reacts with hydrochloric

acid, releasing 3,8-nonadiene-1-carboxylic acid. The catalytic hydrogenation of this acid yields pelargonic acid.



Scheme 10. Insertion of CO_2 into a complex containing two allyl ligands.

The insertion of CO_2 into a Pd–allyl bond, as described in Scheme 10, is unusual. Other insertion reactions into transition-metal allyl complexes with asymmetric allyl ligands always took place at the secondary carbon atom C3 [Eq. (29), path A] (see Scheme 9 for titanium complexes, Eq. (27) for palladium complexes). This necessarily led to branched-chain products. The insertion into complex **55**, however, takes place at the terminal carbon atom C1 [Eq. (29), path B] and the workup leads to a straight-chain product.



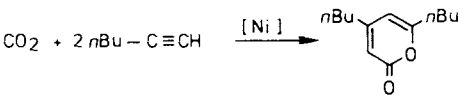
(29)

5. Homogeneously Catalyzed Reactions of Carbon Dioxide with Hydrocarbons[191]

The reaction between carbon dioxide and one or more hydrocarbon molecules can be described as a carboxylation. The well-known carboxylation of aromatic species (the Kolbe–Schmitt synthesis) does not require a transition-metal catalyst.[13] Analogous reactions can be carried out with saturated but C–H-acidic hydrocarbons.[166] Reactions of CO_2 with unsaturated hydrocarbons such as alkynes and mono- and dienes are however generally carried out using homogeneous transition-metal catalysts.

5.1. Reactions with Alkynes

The reaction of alkynes with carbon dioxide was first reported in 1977 by *Inoue* et al.[167] The reaction between 1-hexyne and CO_2 led to 4,6-dibutyl-2-pyrone in 50% yield [Eq. (30)]. Analogous reactions were observed with alkynes bearing nonterminal triple bonds (e.g., 3-hexyne, 4-octyne).[168] Nickel complexes with bidentate phosphane ligands were suitable catalysts.



(30)

The mechanism of this reaction type was intensively studied, and two possible reaction paths (A and B in Fig. 6) were discussed. In path A, the first step is the oxidative coupling of two alkyne molecules, forming a nickelacyclopentadiene species. The insertion of CO_2 into a Ni–C bond would then form a cyclic carboxylato complex, which would release the pyrone by reductive elimination. This catalytic cycle could however not be confirmed by comparative stoichiometric studies with nickelacyclopentadiene complexes. Path B involves the reaction of an alkyne and a CO_2 molecule to form an oxanickelacyclopentene complex, which then reacts with a further alkyne, expanding to a seven-membered ring. The use of a stabilizing ligand (e.g., the bidentate, basic *N,N,N',N'*-tetramethylethylenediamine ligand) made possible the isolation of both catalytic intermediates. This is reliable evidence that path B is the actual mechanism of nickel catalysis.

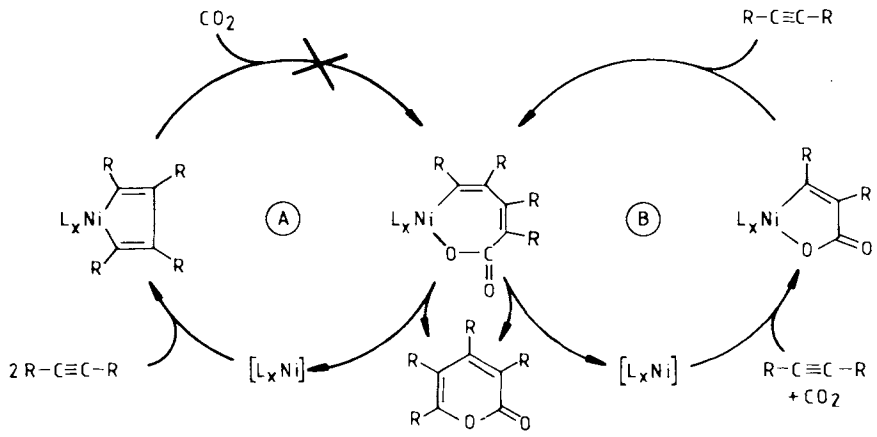


Fig. 6. Suggested mechanisms for the nickel-catalyzed reaction of alkynes with CO_2.

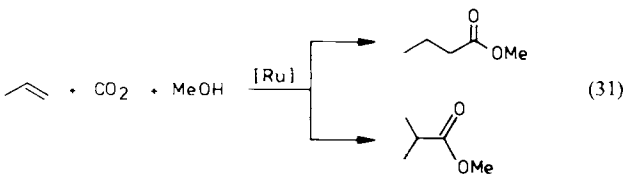
Aresta and *Albano*[169] studied the reaction of CO_2 and propyne with the catalyst [Rh(dppe)(η-BPh_4)] (dppe = 1,2-bis(diphenylphosphino)ethane). They observed the formation of 4,6-dimethyl-2-pyrone in yields of up to 3%. A mechanism was suggested in which the active intermediates were not metallacycles but rhodium complexes with noncyclic substituents.

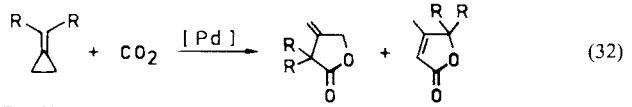
5.2. Reactions with Monoenes

Transition-metal-catalyzed reactions of carbon dioxide with monoenes are appreciably more difficult than those with alkynes. *Lapidus* et al.[170] reported in 1978 a rhodium-catalyzed reaction of CO_2 and ethene, forming propionic acid and ethyl propionate. Pressures of 700 bar and a catalytic system consisting of Wilkinson's complex and a hydrogen halide were necessary to achieve yields of up to 38%. *Besecke* and *Schröder*[171] patented in 1981 a method of synthesizing esters from propene and carbon dioxide in the presence of ruthenium catalysts and alcohols [Eq. (31)]. Mechanistic studies with ^{13}C-labeled methanol, however, showed that the carbon of the carboxyl group came not from the carbon dioxide but from the alcohol.[172]



(31)

Methylenecyclopropanes are more reactive than linear olefins. *Inoue* et al. succeeded in 1979 in converting substituted methylenecyclopropanes and carbon dioxide into γ-lactones by using palladium catalysts [Eq. (32)].[173]



(32)

R = Me
R, R = $-(CH_2)_5-$

In the presence of palladium complexes containing monodentate phosphane ligands, the β-methylene lactone is preferentially formed, whereas the use of [Pd(dppe)$_2$] leads to the α,β-unsaturated lactone as the main product.

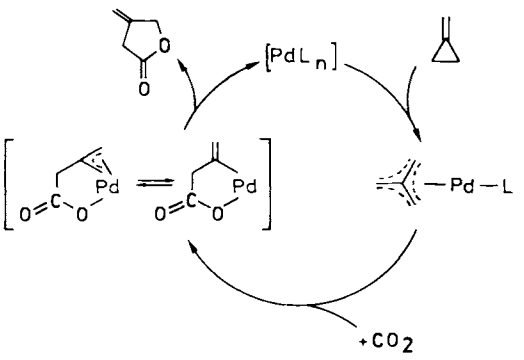


Fig. 7. Suggested mechanism for the reaction of methylenecyclopropane with CO_2.

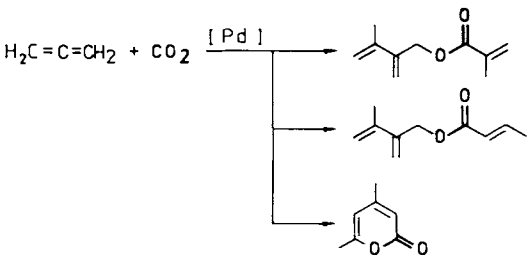
The suggested mechanism (Fig. 7) involves a trimethylenemethane-palladium intermediate. The CO_2 insertion forms a cyclic carboxylato species from which the lactone is released.

Binger et al.[174] have carried out extensive investigations on the reaction of carbon dioxide with the unsubstituted methylenecyclopropane. Optimum reaction conditions allow the formation of 3-methyl-2-butene-4-olide in 80% yield. In addition to this "co-dimer," however, the further reaction of the lactone with the starting material leads to co-trimers, co-tetramers, and co-pentamers.

5.3. Reactions with Dienes

Both cumulated and conjugated dienes can undergo reactions with CO_2. The palladium-catalyzed reaction of CO_2 with allene leads to the synthesis of two esters and a pyrone [Eq. (33)]. Since pyrones are also formed from al-



(33)

kynes and CO_2, it was assumed that the allene first isomerized to propyne. Experiments with propyne instead of allene showed, however, that the alkyne does not react with carbon dioxide under comparable reaction conditions.[175]

The optimum catalyst for the allene-CO_2 reaction is a combination of 1,2-bis(η^3-allyl)palladium and bis(cyclohexylphosphino)ethane. The synthesis presumably occurs via metallacyclic intermediates. Cyclic nickel carboxylato complexes were indeed isolated from stoichiometric reactions between allenes and carbon dioxide.[176]

The first studies of the catalytic reactions of 1,3-dienes with CO_2 were carried out by the research groups of *Inoue*[177,178] and *Musco*[179,180] at the end of the 1970s. They succeeded in synthesizing lactones and esters in small quantities from dienes and CO_2, and isolated the products using preparative gas chromatography or column chromatography. Since these first results, preparative methods have been developed that allow the synthesis of a variety of products from dienes and carbon dioxide on an industrial scale.[181-188]

The reaction of butadiene with CO_2 leads to various products, depending on the catalyst. Figure 8 shows that several connected catalytic cycles can be postulated, starting from the transition-metal complex ML_x. Cycle A applies to palladium, ruthenium, or nickel catalysts. The dimerization and addition of two butadiene molecules leads to the bis(η^3-allyl) complex **57**. Carbon dioxide inserts into one allyl bond, forming the allylcarboxylato complex **58**, from which the products **59** to **63** are released, regenerating the catalyst ML_x. Ring closure leads to the δ-lactone 2-ethylidene-6-hepten-5-olide **59** and the γ-lactones **60** and **61**; the esters **62** and **63** are obtained by addition of two further butadiene molecules.

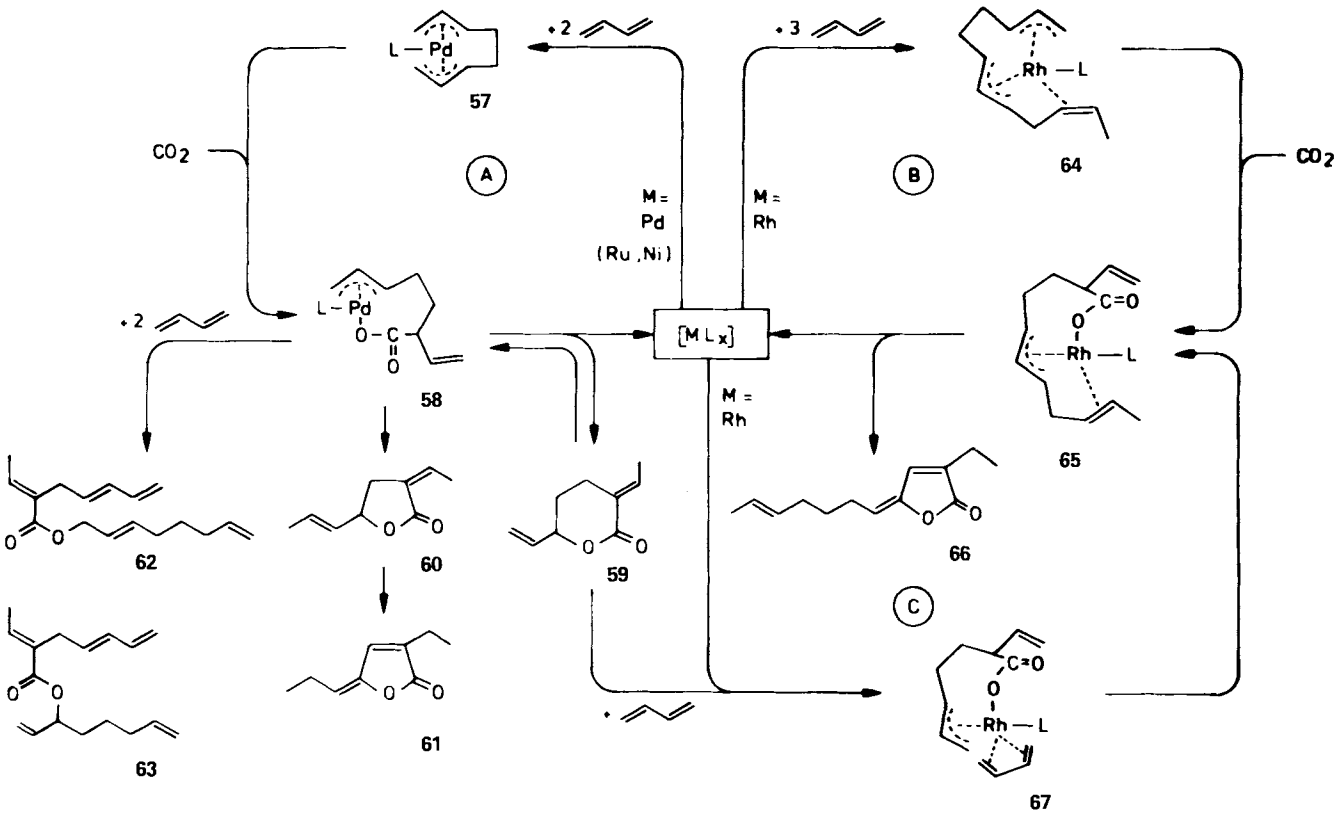


Fig. 8. Catalytic reaction between butadiene and carbon dioxide; products and postulated mechanism with intermediates. L = PR_3.

Cycle B is observed with rhodium catalysts. Three molecules of butadiene coordinate to the metal and form complex **64**; this reacts with carbon dioxide to give the intermediate **65**, from which the γ-lactone **66** is formed.

Cycle C describes a variant of the reaction catalyzed by rhodium. Rhodium compounds can bind the δ-lactone **59**, opening the ring, and simultaneously coordinate a further molecule of butadiene, leading to the intermediate complex **67**; C–C bond formation converts this into another intermediate **65**, the precursor of the γ-lactone **66**.

The crucial intermediates in the reaction of butadiene with CO_2 are carboxylato complexes. To support the proposed mechanisms (Fig. 8), the isolation of such a carboxylato species in a comparable stoichiometric experiment was attempted. The reaction of bis(acetylacetonato)palladium with triisopropylphosphane and the δ-lactone **59** allowed the isolation of the complex bis(2-ethylidene-4,6-heptadienoate)bis(triisopropylphosphane) **68**. The X-ray structure analysis of this complex (Fig. 9) shows that both phosphane ligands and both carboxylato ligands are *trans* at the square-planar-coordinated palladium atom and that the carboxylato ligands are monodentate.

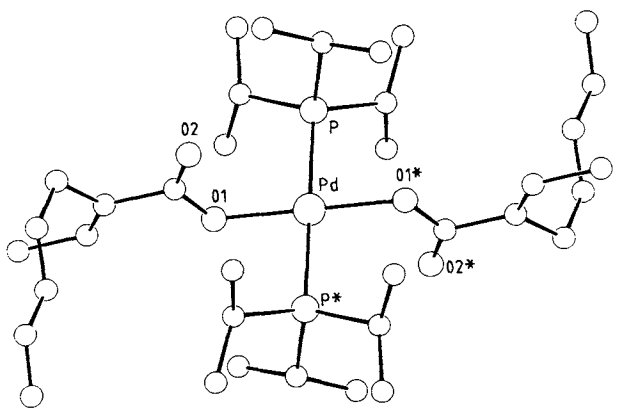

Fig. 9. Molecular structure of complex **68**.

Neither isoprene nor 1,3-pentadiene (piperylene) reacts with CO_2 in the presence of those catalysts that promote good yields (> 50%) with the butadiene-CO_2 reaction. However, it proved possible to react either isoprene or piperylene with butadiene and carbon dioxide; these composite syntheses lead to the lactones **69**, **71**, and **73** (Fig. 10) although the yields from such "three-component systems" are poor (maximum 5%).

The palladium-catalyzed reaction of isoprene with butadiene forms products that result from the linkage of butadiene with either end of the isoprene molecule. The corresponding intermediates should therefore be formulated as bis(η^3-allyl)palladium complexes with the additional methyl group in either the 3- or 2-position. The subsequent insertion of carbon dioxide occurs exclusively in the allyl group generated from butadiene.

The reaction between piperylene, butadiene, and carbon dioxide forms only the "tail-coupling" products **73**. The alternative "head-coupling," to produce the lactones **75** and **76**, is not observed. The CO_2 insertion, in exact analogy to the isoprene reaction, also occurs exclusively at the nonsubstituted allyl group.

Further three-component syntheses have been carried out with dienes, carbon dioxide, and epoxides. These reac-

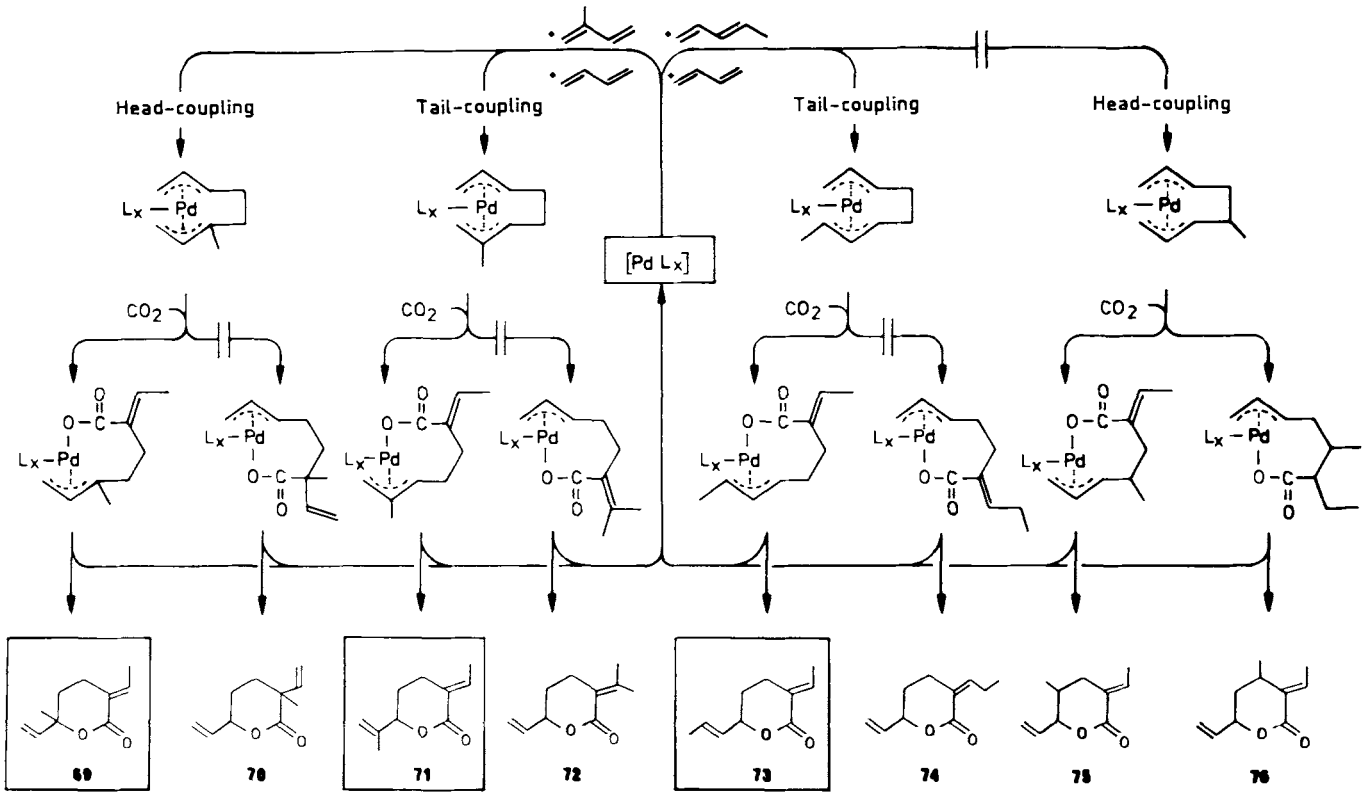

Fig. 10. Reaction combining isoprene or piperylene with butadiene and carbon dioxide. L = PR_3.

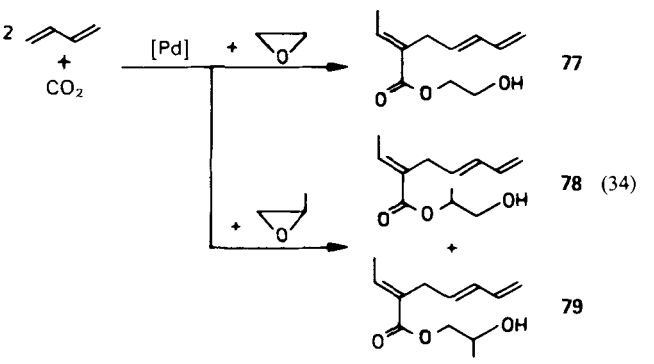
tions represent the attempt to extend the catalytic principles formulated in Figure 3 to reactions of carbon dioxide with two entirely different substrates Su.

Butadiene, carbon dioxide, and ethylene oxide react in the presence of palladium catalysts, forming **77**, the glycol ester of 2-ethylidene-4,6-heptadienoic acid [Eq. (34)].[189] The corresponding reaction with propylene oxide is analogous, but produces two isomeric esters **78** and **79** with different positions of the additional methyl group.



(34)

It is remarkable that the octadienyl esters **62** and **63** and the glycol esters **77** to **79** are derivatives of the same carboxylic acid. It is probable that the mechanisms of their formation are similar (Fig. 11). The first steps in the latter

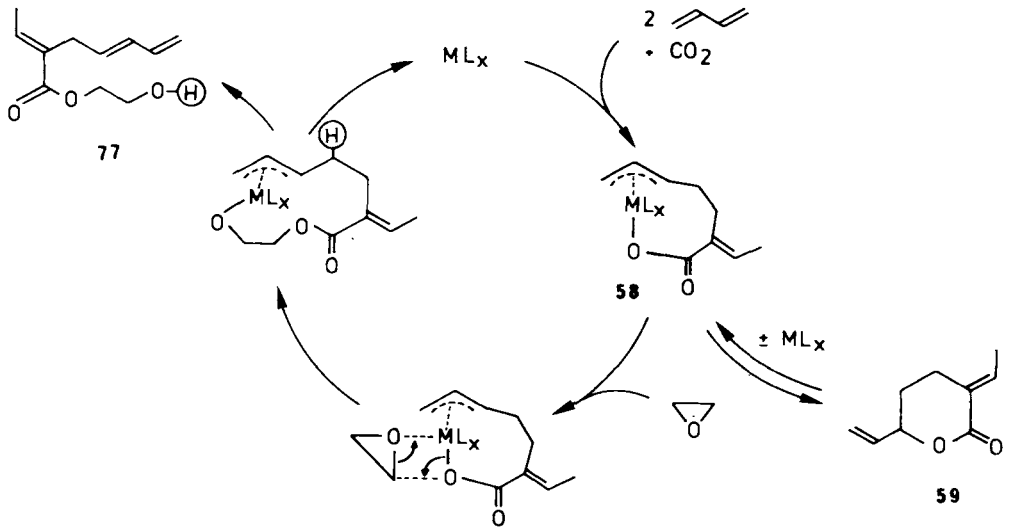


Fig. 11. Suggested mechanism for ester synthesis from butadiene, ethylene oxide, and carbon dioxide. M = Pd, Rh; L = PR_3.

reaction are the oxidative coupling of two butadiene molecules and the insertion of the CO_2, forming the palladium carboxylato complex **58**. The epoxide coordinates to this intermediate product, undergoes ring-opening, and inserts into the Pd-O bond. The catalyst is regenerated by elimination of the glycol ester.

6. Concluding Remarks

How will the chemistry of carbon dioxide develop? A wide variety of different possibilities were recognizable at the "NATO Summer School on Carbon Dioxide," which took place in June 1986 in Pugnochiuso (Italy).[190]

The electrochemical exploitation of CO_2 has become the object of great efforts. The electrochemical reduction of carbon dioxide to carbon monoxide, formic acid, or oxalic acid, and the electrocarboxylation of olefins, aromatic species, and carbonyl and halogen compounds are both being intensively studied. The photochemistry of CO_2 has also made great strides in the last few years, although an industrial application cannot yet be foreseen. A further possibility is that bacteria could be used to convert carbon dioxide into organic products.

Carbon dioxide undergoes a series of industrially important catalytic reactions. The activity and selectivity of heterogeneously catalyzed CO_2 reactions are often higher than those of corresponding reactions with carbon monoxide. The coordination chemistry of CO_2 and the related homogeneous catalysis by transition metals still seem particularly promising areas. "Tailor-made" metal-complex catalysts are able to control the reactions of CO_2 and allow high selectivity in the synthesis of organic chemicals. This interesting research area still has many novelties to be discovered.

Reduction and Hydrogenation with the System Hydrocarbon/Carbon

New Synthetic Methods (70)

By Toni Dockner*

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

For the synthesis of organic compounds, reduction is an indispensible reaction type which is also widely used on an industrial scale. In industrial processes hydrogen is usually used as reducing agent, since strong reducing agents like alkali metals and hydrides can only be used to a limited extent for safety and economic reasons. Very economical reducing agents that are convenient to handle and have high potential application are hydrocarbons in presence of carbon. Hydrocarbon/carbon systems can be readily used instead of molecular hydrogen and expensive metal catalysts for the hydrogenation of compounds containing, for example, CC-, CO-, or NO-double bonds. Furthermore, these systems can be used for carrying out reductions which hitherto required strong reducing agents such as zinc, tin, alkali metals and hydrides. Especially suitable as economic sources of hydrogen are refinery products such as vacuum gas oil, fuel oil S or vacuum residue oil. Hydrocarbons are dehydrogenated to unsaturated systems and finally to carbon.

1. Introduction

Alkanes[**] are considered as inert under the reaction conditions normally used in organic chemistry. C-C and C-H bonds can be cleaved only at temperatures above 400°C—and even then usually only unselectively. This is the case in the petrochemical industry in processes such as, e.g., steam cracking, re-forming, or hydrocracking.

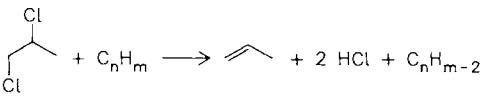
Recently, there have been numerous studies concerned with "CH activation". Thus, it has been demonstrated, e.g., that hydrocarbons can be incorporated into energy-rich metal-complexes via cleavage of the CH bond.[1]

In 1978, *Laily Bin Din* et al.[2] reported on the reduction of aromatic nitro compounds to anilines with liquid paraffin at 360-390°C, and, already in 1966, *Okamoto* et al.[3] found that predominantly ethylene instead of the expected vinyl chloride is formed in the pyrolysis of 1,2-dichloroethane at 300-400°C in the presence of toluene, benzene or *n*-hexane, and activated carbon as catalyst. Surprisingly, these two publications failed to stimulate further intensive studies on the potential of hydrocarbons as reducing agents. Consequently, the scope of application of the reduction system hydrocarbon/carbon remained unrecognized.

In the following sections a novel, general utilization of hydrocarbons for reduction and hydrogenation in organic chemistry will be outlined.

2. Reduction of Halogeno Compounds

On attempting to cleave 1,2-dichloropropane to allyl chloride and HCl in high-boiling vacuum residue oil at 350°C, we surprisingly found that propene and hydrogen chloride were formed in high yields according to Equation (a)[4] [cf. also Eq. (m)].



(a)

	Carbon black [%]	Conversion [%]	Selectivity [%]
Vacuum residue oil	23	78	90
Technical white oil	0	<3	—
Techn. white oil-activated carbon	25	78	90

On using other mineral oils such as technical white oil[***] we could not establish any reaction. When activated carbon was added to the white oil, however, the same results as with vacuum residue oil, which contains 23% carbon black, were obtained. Vacuum residue oil, consisting of paraffinic, aromatic and naphthenic hydrocarbons, serves as source of hydrogen. Carbon is formed from the hydrocarbons.

The homologues of 1,2-dichloropropane and also the bromo derivatives are cleaved in good yields, comparable with those obtained in the case of dichloropropane (Table 1). From 1,1,2-trichloroethane, vinyl chloride was obtained in 70% yield with almost quantitative conversion. Allyl chloride, like dichloropropane, is converted into propene. Table 1 permits a further conclusion to be drawn: the higher the degree of halogenation the higher the rate of reaction. Chloro compounds react more rapidly than bromo compounds; i.e. the electron withdrawing effect influences the rate of reaction.

Higher chlorinated hydrocarbons can be cleaved stepwise to yield the halogen-free compounds. Hexachlorocy-

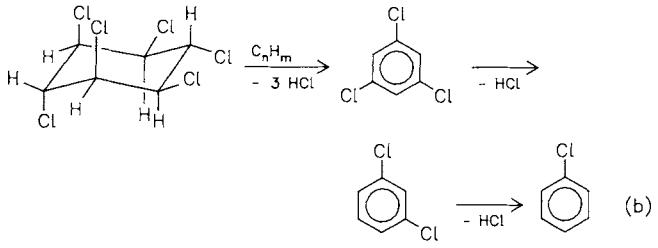
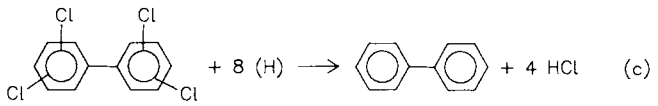
Table 1. Reductive dehalogenation with vacuum residual oil at 350°C.

Halogeno compound	Product	Conversion [%]	Selectivity [%]
1,2-Dichloropropane	Propene	78	90
1,2-Dibromopropane	Propene	60	60
1,2-Dichlorobutane	1-Butene	90	80
1,2-Dibromobutane	1-Butene	85	50
1,1,2-Trichloroethane	Vinyl chloride	98	70
Allyl chloride	Propene	50	75

clohexane (lindane) already reacts at 200°C with vigorous cleavage of HCl and is reductively dechlorinated at 250°C to monochlorobenzene [Eq. (b)]. The latter can be converted into benzene at 350°C. Perchlorinated biphenyls (PCB) are converted into biphenyl according to reaction (c); in both cases vacuum residue oil serves as reducing system.



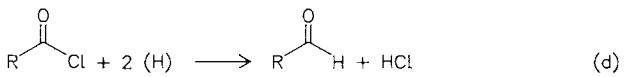
(b)



(c)

Aromatic acid chlorides are reduced according to Equation (d) at 350°C in the system technical white oil/activated carbon. As can be seen from Table 2, aldehydes or lactones are formed. Remarkable in this context is the fact that a COCl group of terephthaloyl chloride is even reduced to the methyl group.

Table 2. Reduction of acid chlorides with technical white oil and activated carbon at 350°C.



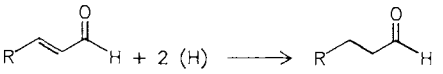
(d)

Acid chloride	Product	Conversion [%]	Selectivity [%]
		80	50
		70	80
		70	40

3. Hydrogenation of CC Double Bonds

The CC double bond of α,β-unsaturated aldehydes can be selectively hydrogenated, in some cases in very good yields[5] [Eq. (e)]. Table 3 lists some examples.

Table 3. Selective hydrogenation of α,β-unsaturated aldehydes with technical white oil and activated carbon at 350°C.



(e)

Aldehyde	Product	Conversion [%]	Selectivity [%]
		88	50
		30	90
		56	85
		52	20

By increasing the pressure, and thus the solubility or residence time, it is possible to hydrogenate ethene, propene, and even arenes. In the case of the stable hydrocarbons the yields are very high at conversion rates which are partially not optimized. An example is reaction (f) in Table 4.

Table 4. Hydrogenation of olefins and arenes with technical white oil and activated carbon (Carboraffin P®) at 350–400°C and 5–35 bar.

Olefin or arene	Product	Conversion [%]	Selectivity [%]
$H_2C{=}CH_2$	$\longrightarrow H_3C{-}CH_3$ (f)	43	95
$H_2C{=}CH{-}CH_3$	$\longrightarrow H_3C{-}CH_2{-}CH_3$	37	90
		6	90
		50	20

In the case of hydrogen transfer in the presence of carbon a redox reaction is involved whose equilibrium is dependent on the reduction potential of the H donor and on the oxidation potential of the H acceptor. Thus, for example, naphthalene can be hydrogenated to tetralin with the hydrocarbon mixture technical white oil/activated carbon. Tetralin, however, can be used as source of hydrogen for the reduction of dichloropropane to propene; naphthalene is formed thereby.

The high reduction potential of the system hydrocarbon/carbon manifests itself in the reactions that are collected in Sections 4 to 7.

4. Reduction of Carbonyl Compounds

C=O-functions are reduced to methylene groups. This remarkable reaction takes place at 350°C under normal pressure [see Reaction (g)]. Table 5 contains two examples.

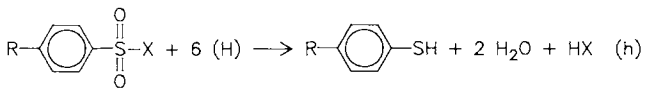
Table 5. Reduction of carbonyl compounds with technical white oil and 10% activated carbon at 350°C.

Carbonyl-compound	Product	Conversion [%]	Selectivity [%]
		5	>95
	(g)	26	>88

5. Reduction of Sulfur Compounds

The following reaction (h)—the reduction of sulfonic acids or sulfonic acid derivatives to thiols or thiophenols—possibly has some practical importance, especially with regard to aromatic compounds (Table 6). Aromatic sulfonic acid derivatives are known to be readily accessible by sulfonation reactions.

Table 6. Reduction of sulfonic acids and derivatives with technical white oil and activated carbon at 350°C. The yields are based on starting amount of acid or derivative (cf. Table 8).



(h)

R	X	Yield [%]	R	X	Yield [%]
H	–OH	78	CH_3	$–OCH_3$	48
H	–Cl	64	CH_3	–Cl	80

These reactions can be easily carried out on an industrial scale in good to very good yields with the system hydrocarbon/carbon without the trouble of ecologically unacceptable salt- or sulfur-containing effluents being formed. Also remarkable is the fact that not only the activated derivatives of the sulfonic acids but also the sulfonic acids themselves are reduced.

Thiols and thiophenols can also be obtained from the disulfides if the latter are treated with technical white oil and activated carbon at 350°C and residence times in the order of seconds [Reaction (i)]. Sulfides can be obtained analogously from sulfoxides according to reaction (k). If R = phenyl the yields are 99 and 66%, respectively.

$$R–S–S–R + 2(H) \longrightarrow 2\,R–S–H \quad (i)$$

$$R–SO–R + 2(H) \longrightarrow R–S–R + H_2O \quad (k)$$

6. Reduction of Phosphorus Compounds

Phosphane oxides, sulfides and dihalides can also be converted into phosphanes with technical white oil and activated carbon[6] [Eq. (l)]. Thus, triphenylphosphane oxide can be reduced to triphenylphosphane with a selectivity of 68%, while triphenylphosphane dichloride is reduced almost quantitatively to triphenylphosphane.

$$R_3PX_2 + C_nH_m \xrightarrow{[C]} R_3P + C_nH_{m-2} + 2\,HX \quad (l)$$

X = halogen; X,X = O,S

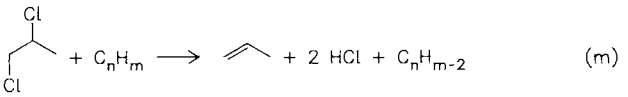
The formation of carbon from the saturated hydrocarbon proceeds, as indicated in Equation (l), via mono- or polyunsaturated hydrocarbons.

7. Reduction in the Gas Phase

The reduction reactions presented here, and others, can in principle also be carried out in the gas phase. The substrates are fed with volatile hydrocarbons such as propane, propene, cyclohexane, light petroleum over an activated carbon bed at 300–400°C.

As shown in Table 7, 1,2-dichloropropane was reduced with various saturated hydrocarbons at 400°C on Contarbon BA® according to Equation (m) [cf. also Eq. (a)].

Table 7. Reduction of 1,2-dichlorpropane according to Equation (m) (see text).



(m)

C_nH_m	Conversion [%]	Selectivity [%]
Methane	98	56
Ethane	98	74
Isobutane	98	88
Cyclohexane	98	91

8. Typical Procedures

Example 1: Reduction of 1,2-Dichloropropane according to Equation (a)

The apparatus employed is shown in Figure 1. 40 mL of 1,2-dichloropropane (1) and 8 L of nitrogen (2) were passed per hour through the 2-L agitator (3) containing 1.2 kg of vacuum residue oil at 350°C. In order to maintain the reaction temperature, unchanged dichloropropane together with volatiles were removed from the reaction mixture by condensation in the flask (4) at 90°C. 12.75 g of condensate (5) together with 80 wt-% dichloropropane were removed per hour, from which a conversion of 78% was calculated. The gaseous reaction products were passed through a washing column (6) for removal of hydrochloric acid. 15 L of exit gas (7) with 43 vol-% propene were collected per hour. This corresponds to a yield of 90% based on the conversion. 217 g of aqueous hydrochloric acid containing 10.5 wt-% HCl were collected in the washing column per hour. This corresponds to 76% of the chlorine contained in the dichloropropane feed.

Example 2: Conversion of Benzaldehyde into Toluene according to Reaction (g)

A mixture of 225 g of technical white oil and 25 g of activated carbon was heated to 350°C in a four-necked flask fitted with stirrer, thermometer, inlet tube and distillation arm. 10.5 g of benzaldehyde and ca. 5 L of nitrogen were then fed into the flask per hour. After 3 h, 33.7 g of condensate was collected, which according to gas chromatographic analysis of the distillate contained 18.6% toluene and 69.3% benzaldehyde. The conversion was thus 25.8%, tbe selectivity 88.6%. Under the same conditions, but without addition of activated carbon, no reaction took place.

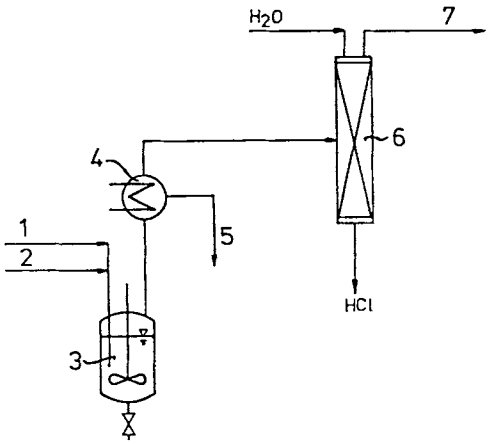


Fig. 1. Apparatus for the reduction of 1,2-dichloropropane according to Equation (a). 1 to 7, see text.

Example 3: Reduction of Aromatic Sulfonic Acids, Sulfonic Acid Derivatives, and Diphenylsulfane according to Reactions (h) and (i)

A mixture of white oil (450 g) and activated carbon (Carboraffin P®) (50 g) was heated to 350 °C and treated with 0.3 mol of the starting material quoted in Table 8 and 30 L of nitrogen per hour: The starting material was added dropwise to the stirred white oil/activated carbon mixture; the vapors leaving the reaction flask were condensed. Solid starting materials were melted at 90 or 140 °C before addition to the mixture. The amounts and yields of the products collected in the condensate after 4 h are listed in Table 8. In the case of *p*-toluenesulfonic acid chloride as starting material (Entry No. 1), the condensate was treated with 20% aqueous caustic soda, and the aqueous phase acidified and extracted with dichloromethane.

Table 8. Reduction of sulfonic acid derivatives and diphenyl disulfide (see text). R′ = *p*-tolyl, R = phenyl (cf. Table 6).

No.	Starting material	Amount [g h^{-1}]	Product	Amount [g] [a]	Yield [%] [b]
1	R′-SO_2Cl	57	R′-SH	131.4	88.3
2	R′-$SO_3H \cdot H_2O$	57	R′-SH	124.0	83.3
3	R′-SO_3CH_3	56	R′-SH	91.4	61.2
4	R-SO_2Cl	53	R-SH	106.8	80.8
5	R-SO_3H	48	R-SH	117.1	87.6
6	R-S-S-R	66	R-SH	263.2	98.8

[a] In examples 2 to 6 the amount of product collected in 4 h was determined by gas chromatographic analysis. [b] Based on amount of starting material.

Example 4: Reduction of Triphenylphosphane Oxide according to Equation (l)

A mixture of technical white oil (250 g) and pulverized activated carbon (25 g) was heated to 350 °C with stirring in a flask and treated with 27.18 g of triphenylphosphane oxide with concomitant passage of nitrogen (5 L per hour). The water formed in the ensuing reaction was continuously distilled off. The reaction was complete after 6 h, and 0.8 g of H_2O had collected in the condenser trap. The reaction mixture was cooled to room temperature and extracted with 5 × 100 mL of glacial acetic acid. After removal of the acetic acid by evaporation, the crystalline residue contained 13.3 g of unchanged triphenylphosphane oxide, 9.2 g of triphenylphosphane, and 6.2 g of acetic acid. The conversion was 52% with a selectivity of 68%.

Example 5: Reduction of 1,2-Dichloropropane in the Gas Phase according to Equation (m)

Figure 2 shows the apparatus employed. The fixed-bed furnace (4) (length 500 mm, diameter 25 mm) was filled with 70 g of activated carbon (Contarbon BA®, special, particle size 4 mm). 15 mL of 1,2-dichloropropane (1) and 15 L of isobutane, preheated to 350 °C via the evaporator (3), were passed at 400 °C over the fixed bed of the furnace per hour. The gases leaving the reactor were fed into the washing column (5) for removal of HCl. 410 g of aqueous hydrochloric acid containing 2.66 wt% HCl were collected per hour. This corresponds to a conversion of 98%. 17.6 L of exit gas containing 16.85 vol-% propene and 0.1 vol-% propane together with smaller amounts of methane, ethane, ethene, and butene were collected per hour. This corresponds to a yield of 88.2% propene based on the conversion.

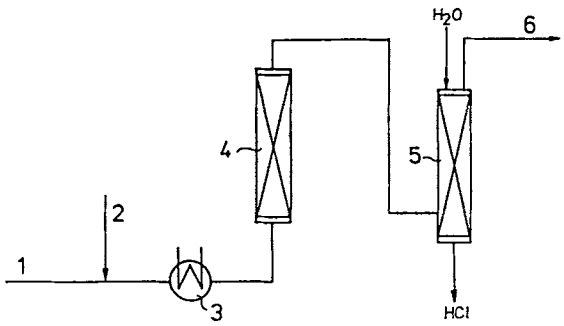

Fig. 2. Apparatus for the reduction of 1,2-dichloropropane in the gas phase according to Equation (m). 1 to 6, see text.

9. Outlook

The current basic raw materials for the chemical industry are petroleum and natural gas, which mainly consist of saturated hydrocarbons. For the synthesis of compounds, the petroleum fractions must be broken down by cracking into alkenes and alkynes or by re-forming into carbon monoxide and hydrogen. The direct functionalization of unsaturated hydrocarbons is still a priority in current research programs. In this context the scission of the C-H bond by incorporation of energy-rich metal-complexes is the correct strategy, yet this method can only be resorted to in industry if the metals are used in catalytic amounts or can be completely and easily recyclized.

The activation by carbon and the use of hydrocarbons as strong reducing agents not only opens up new preparative possibilities, in which the hydrogen from fossil sources can be used directly, but also interesting perspectives regarding radical reactions.

And last but not least, the concept of whether carbon-catalyzed reduction with CH species also plays a role in the formation of petroleum—with removal of oxygen, nitrogen and sulfur—warrants further discussion.

In view of this new potential application of hydrocarbons one is reminded of that intuitive recognition from the years of the oil crisis: "The C-H bond is too good for burning."

Rhodium-Catalyzed Reductive Carbonylation of Methyl Formate to Acetaldehyde**

By *Didier Vanhoye, Serge Melloul, Yves Castanet, André Mortreux,* and *Francis Petit**

The reductive carbonylation of methanol by syngas (CO/H_2) to yield acetaldehyde has been extensively studied.[1] This reaction is catalyzed, at least to some extent, by most Group VIII metals in conjunction with a halogen promoter, the most active system being cobalt salts with an iodide promoter.[2] However, the overall selectivity varies in most cases between 50 and 80% according to the experimental conditions. The main by-products are ethanol, methyl acetate, acetic acid, and 1,1-dimethoxyethane.

In the same way, methyl acetate carbonylation to acetic anhydride[3] (Rh catalysis) or acetaldehyde and acetic acid[4] (Co catalysis) is well known. On the other hand, these systems have been observed to isomerize methyl formate to acetic acid[5] and, upon ruthenium-catalyzed hydrocarbonylation of methyl formate, the nonselective production of acetaldehyde, together with methanol and ethanol, has been reported in the patent literature.[6]

We report here a selective route to acetaldehyde via the reaction of methyl formate with carbon monoxide catalyzed by rhodium complexes.

In a typical reaction, a solution of methyl formate in *N*-methylpyrrolidone (NMP) reacts in an autoclave with CO at 180°C and 80 bar in the presence of $RhCl_3 \cdot 3H_2O$ and LiI to give acetaldehyde and CO_2 in accordance with Equation (1).

$$HCOOCH_3 + CO \xrightarrow[NMP]{RhCl_3 \cdot 3H_2O/LiI} CH_3CHO + CO_2 \qquad (1)$$

Table 1, which lists some typical results obtained under various conditions, shows that different rhodium salts or complexes can be used as catalyst precursor without appreciable change of activity and selectivity for acetaldehyde formation (up to 80% in each case). On the other hand, the presence of an iodide salt $A^{\oplus}I^{\ominus}$ ($A^{\oplus}$ = alkali-metal ion or $[CH_3PPh_3]^{\oplus}$[7]) is absolutely necessary, since in the absence of iodide or in the presence of either I_2 (run 5) or CH_3I (run 6), the activity is very low. In these cases, the addition of triphenylphosphane (runs 4 and 7), which is able to generate a phosphonium iodide salt, results in rate enhancement to give activities which are comparable with those observed in the LiI systems. The addition of PPh_3 also enhances the rates of reactions carried out in the presence of HI. The production of the iodide salt from I_2 is explained according to Equation (3) via CH_3I formation [Eq. (2)], a process which has been already described elsewhere.[8]

Table 1. Acetaldehyde production from methyl formate on rhodium catalysts.

No.	Catalyst [a]	*t* [h]	Conversion [mol-%]	Product selectivity [b] [mol-%] MeCHO	MeOH	$MeCO_2Me$	[c]
1	$RhCl_3 \cdot 3H_2O$	1	29.3	72.9	20.0	—	7.1
	LiI (1.86 mmol)	3	60.5	81.3	11.1	—	7.6
2	$[Rh(CO)Cl(PPh_3)_2]$	1	33.4	82.6	15.6	—	1.8
	LiI (1.86 mmol)	3	58.8	77.0	12.2	—	10.8
3	$[RhCl(CO)_2]_2$	1	33.5	82.7	14.0	—	3.3
	LiI (1.86 mmol)	3	61.5	81.6	8.8	—	9.6
4	$[Rh(CO)Cl(PPh_3)_2]$ I_2 (0.25 mmol) PPh_3 (0.6 mmol)	2	37.9	84.4	1.6	—	14.0
5	$[Rh(CO)Cl(PPh_3)_2]$ I_2 (0.25 mmol)	15	26.0	15.4	76.9	—	7.7
6	$[Rh(CO)Cl(PPh_3)_2]$ CH_3I (0.3 mmol)	15	19.6	17.3	63.8	11.2	7.7
7	$[Rh(CO)Cl(PPh_3)_2]$ CH_3I (0.5 mmol) PPh_3 (0.6 mmol)	1	16.5	66.1	24.8	—	9.1
		3	37.1	81.4	10.2	—	8.4
8	$[Rh(CO)Cl(PPh_3)_2]$ I_2 (0.25 mmol) PPh_3 (0.6 mmol) toluene (50 mL)	15	40	21	3	75	1
9	$[Rh(CO)Cl(PPh_3)_2]$ LiI (1.86 mmol) pyrrolidone (50 mL)	2	75	—	100	—	—
10	$RhCl_3 \cdot 3H_2O$ LiI (1.86 mmol) H_2O (85 mmol)	2	49.6	49.6	48.6	—	1.8

[a] All reactions were conducted with 5 mL (81.2 mmol) of methyl formate in *N*-methylpyrrolidone (50 mL) unless otherwise specified (runs 8 and 9) in the presence of 0.125 mmol of rhodium; $p_{CO} = 80$ bar, $T = 180$°C. [b] In liquid phase. The gas phase contains CO, CO_2, and CH_4; typical $CH_4 : CO_2$ ratios were in the range 1 : 10 to 1 : 5. [c] Formic acid, methyl iodide, acetone, ethanol, butyraldehyde.

$$CH_3I + PPh_3 \longrightarrow [CH_3PPh_3]^{\oplus} + I^{\ominus} \qquad (3)$$

The activity increases with the iodide concentration, in which case however the selectivity for acetaldehyde formation tends to decrease.

The nature of the solvent is also very important, since the use of either pyrrolidone or toluene, instead of *N*-methylpyrrolidone, affects both the reaction rate (which is very low) and again the acetaldehyde selectivity (runs 8 and 9).

A mechanism similar to that envisaged for acetic acid synthesis from methanol and CO might be postulated for this reaction as most probable; the initial step is the cleav-

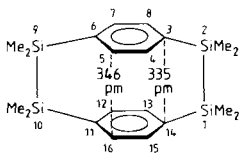
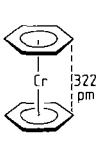
(Octamethyltetrasila-η^{12}-[2.2]paracyclophane)-chromium—Synthesis, Structure, and Characteristics**

By *Christoph Elschenbroich,* James Hurley, Werner Massa,* and *Gerhard Baum*

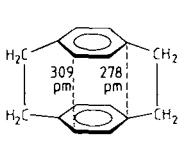
The recent synthesis in 1986 of 1,1,2,2,9,9,10,10-octamethyl-1,2,9,10-tetrasila[2.2]paracyclophane **1** provided the first example of a [2.2]paracyclophane containing heteroatoms only in the bridging units.[2] Whereas in [2.2]paracyclophane **3** the inter-ring distances are markedly shorter than in bis(η^6-benzene)chromium **2**, in **1** they are longer as compared to **2**. Since it is possible to introduce a chromium atom into the cavity of **3** by means of cocondensation techniques, we were intrigued by the prospect of *endo* coordination of a transition metal into **1** (complex **5**). The limited availability of **1**, however, suggested that the generation of **5** in a template reaction might be a more promising avenue of approach. In particular, the formation of two Si–Si bonds in a bis(disilyl-η^6-arene)metal precursor should be subject to less compression strain than that encountered in the free arenes [in bis(η^6-arene)metal complexes, the inter-ring distance falls short of the distance governed by the van der Waals radii of free arenes].



1



2



3

We have now found that compound **4**, a precursor to **5**, as well as **6**, which is a precursor to the singly tetramethyldisilano-bridged complex **7**, are accessible by means of metal-atom ligand-vapor cocondensation in relatively good yield. Dechlorinative coupling with lithium/naphthalene in dimethoxyethane (DME) leads to the complexes (1,1,2,2,9,9,10,10-octamethyl-1,2,9,10-tetrasila-η^{12}-[2.2]paracyclophane)chromium **5** and (1,1,2,2-tetramethyldi-1,2-η^6-phenyldisilane)-chromium **7**, respectively. Physical data of the new compounds **4**–**7** are collected in Table 1.

The complexes **5** (red rhombi) and **7** (brown needles) display high thermal stability: **5** melts without decomposition at 310–314 °C and in the EI mass spectrum no peaks, besides those of the molecular ion (100%) and ^{52}Cr (12%), occur with $I > 10\%$. The redox potentials of the couples

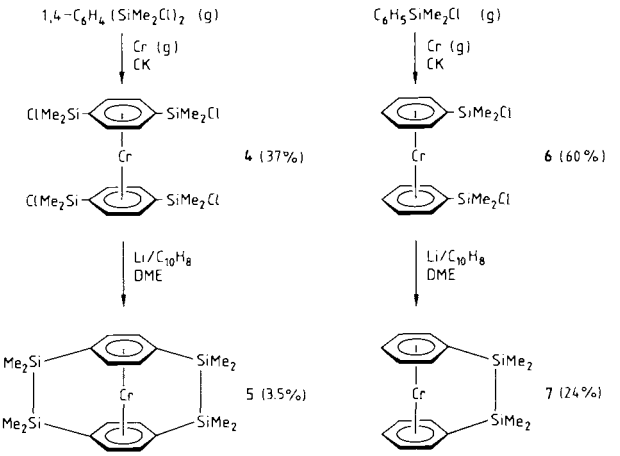


Table 1. Selected physical data for the new compounds **4**–**7**. ^1H-NMR: 300 MHz; ^{13}C-NMR: 75.5 MHz; ESR: X-band; MS: 70 eV; cyclic voltammetry (CV) versus the saturated calomel electrode.

[**] Metal π-Complexes of Benzene Derivatives, Part 32. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. *J. H.* gratefully acknowledges the award of a scholarship by the Deutscher Akademischer Austauschdienst (DAAD). We thank Dipl.-Chem. *M. Wünsch* for cyclovoltammetric measurements.—Part 31: [1].

neutral complex/radical cation are shifted only marginally relative to bis(benzene)chromium ($E_{1/2} = 0.675$ V). The decreased ESR coupling constants $a(^{53}Cr)$ for the bridged species $\mathbf{5}^{\oplus\ominus}$ and $\mathbf{7}^{\oplus\oplus}$, compared to the corresponding unbridged derivatives bis(trimethylsilyl-η^6-benzene)chromium$^{\oplus}$ [$a(^{53}Cr) = 1.82$ mT] and bis[1,4-bis(trimethylsilyl)-η^6-benzene]chromium$^{\oplus}$ [$a(^{53}Cr) = 1.85$ mT][5] point to a larger degree of metal→ligand spin delocalization in the metallocyclophanes. The high thermal stability of the complexes **5** and **7** contrasts with the solvolytic lability of the radical cations $\mathbf{5}^{\oplus\ominus}$ and $\mathbf{7}^{\oplus\oplus}$: the radical cation $\mathbf{5}^{\oplus\ominus}$, generated through oxidation by 4-pyridinecarbaldehyde, is stable in anhydrous THF for weeks; addition of water (5%) induces quantitative desilylation within a few minutes, however.

Figure 1 presents the structure of **5** in the crystal,[6] which presumably is isotypical to the recently characterized structure of the free ligand **1**.[2] Compound **5**, as well as **1**, possesses a center of inversion; the lattice constants of the metal complex **5** are somewhat decreased, however.[7] The distance between the "best ring planes" in **5** approaches the value for bis(benzene)chromium **2** (324 pm). As compared with the free ligand **1**, the mean C–C bond distances in the coordinated arenes (142.1 pm) are longer by about 3 pm. The boat deformation of the rings is strongly reduced in **5**: the inter-ring distance C1-C4′ [319.8(6) pm] is only slightly shorter than the inter-ring distances C2-C5′ [326.2(6) pm] and C3-C6′ [325.2(6) pm]. Therefore, within a benzene ring and referred to the axes C2···C6 and C3···C5, interplanar angles of only 2.5° and 2.0°, respectively, arise. The Si–Si bond distance in **5** [236.1(4)] is only insignificantly shorter than in **1** [237.6(4)]. The Si–Si–C bond angles are smaller in **5** by about 2.2°. Twisting along the Si–Si axes is not observed: the torsional angle C1-Si1-Si2-C4′ amounts to 0.18(33)°. The bonds C1-Si1 and C4-Si2′, with regard to the planes C1,C2,C6 and C3,C4,C5, form angles of 10.1 and 10.9°, respectively.

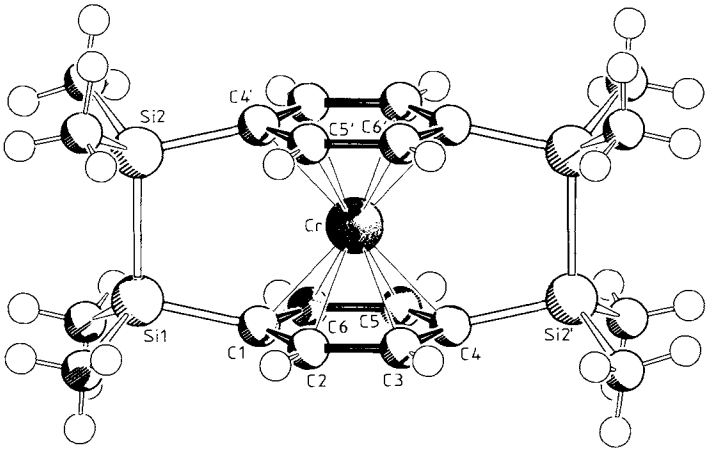

Fig. 1. SCHAKAL plot of a molecule of **5** in the crystal. Important interatomic distances [pm] and angles [°]: Cr-C1 216.3(4), Cr-C2 215.1(4), Cr-C3 214.6(5), Cr-C4 216.5(4), Cr-C5 214.9(5), Cr-C6 214.7(5) (mean Cr-C 215.4), C1-C2 141.7(7), C2-C3 141.3(6), C3-C4 142.0(7), C4-C5 142.8(7), C5-C6 140.9(6), C6-C1 143.6(7) (mean C-C 142.1), Si1-Si2 236.1(4), Si1-C1 188.9(5), Si2′-C4 189.6(5); C2-C1-C6 116.2(5), C1-C2-C3 122.0(5), C2-C3-C4 122.0(5), C3-C4-C5 116.3(5), C4-C5-C6 121.9(5), C5-C6-C1 121.6(5) (mean C-C-C 120.0), C1-Si1-Si2 102.7(3), Si1-Si2-C4′ 102.9(2).

Other chlorobis(organo)silyl derivatives of bis(arene)metal complexes accessible through cocondensation techniques should provide a route to higher-bridged silametallocyclophanes. This technique does not lend itself to the synthesis of carbocyclic metallocyclophanes, however, in that benzyl halides do not yield (η^6-arene)metal complexes under these conditions. Presumably metal insertion into the benzyl–halogen bond interferes.

Experimental Procedure

4: 1,4-bis(chlorodimethylsilyl)benzene (15 g, 26 mmol; internal vaporization) was cocondensed with chromium (0.52 g, 10 mmol) during 2 h at −196 °C/10^{-4} mbar. Extraction with toluene at room temperature, followed by removal of solvent and excess ligand under reduced pressure (70 °C, 10^{-3} mbar), yielded 2.16 g (37%) of **4** as a red-black, sublimable solid.

5: **4** (2.3 g, 4.0 mmol), dissolved in DME (250 mL) was added at −78 °C during 3 h to a solution of $Li^{\oplus}C_{10}H_8^{\ominus}$ (18.4 mmol) in DME (150 mL). After 2 h at −78 °C and warming to RT (12 h), solvent and naphthalene were removed at 50 °C/10^{-2} mbar. Extraction of the residue with toluene (350 mL, 50 °C), filtration through silylated silica gel, and concentration at reduced pressure yielded 60 mg (3.5%) of **5** as red, rhombic crystals.

6: Analogous to **4** by means of external vaporization of (chlorodimethylsilyl)benzene; 2.35 g (60%) of **6** as golden brown, sublimable solid.

7: Analogous to **5** from **6** (1.7 g, 4.3 mmol) in DME (100 mL) and $Li^{\oplus}C_{10}H_8^{\ominus}$ (9.1 mmol) in DME (150 mL). Extraction with petroleum ether (400 mL) and crystallization after concentration yielded 330 mg (24%) of **7** as brown needles.

[6] Space group $P2_1/n$, $Z = 2$, $a = 664.9(6)$, $b = 1327.2(4)$, $c = 1270.2(2)$ pm, $\beta = 98.49(4)°$; $\rho_{calcd} = 1.309$ g cm^{-3}; 1648 independent reflections, 1251 with $F_0 > 5\sigma(F_0)$, were collected on a four-circle diffractometer (CAD4, Enraf-Nonius) with $Cu_{K\alpha}$ radiation at 183 K; no absorption correction ($\mu = 61.8$ cm^{-1}), positions of H atoms refined using isotropic temperature factors. 180 parameters, $R = R_w = 0.042$ ($w = 1/\sigma^2(F_0)$). Further details of the crystal structure determination are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-52923, the names of the authors, and the journal citation.
[7] The identity of the value of b to that of c, given in [2], is obviously in error; from the density we calculate $b \approx 1330$ pm.

Base-Induced Intramolecular Formation of a Mo–Mo Bond in $[L_2Mo_2^{III}(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2]^{3\oplus}$ (L = *N,N′,N″*-Trimethyl-1,4,7-triazacyclononane)**

By *Ademir Neves, Ursula Bossek, Karl Wieghardt,* Bernd Nuber,* and *Johannes Weiss*

Little is known about the mechanism by which complexes containing metal–metal multiple bonds are formed from monomeric complexes in solution.[1] For instance, the monomeric, paramagnetic $[Mo^{III}(OH_2)_6]^{3\oplus}$ is well-

[**] This work was supported by the Fonds der Chemischen Industrie. *A. N.* (University of Florianopolis, Brazil) thanks the C.N.Pq. for a fellowship. We thank Dr. *G. Backes-Dahmann* (Oregon Research Center, USA) for preliminary preparative work.

studied,[2] whereas its binuclear, diamagnetic analogue $[Mo_2^{III}(\mu\text{-}OH)_2(OH_2)_8]^{4\oplus}$, containing a Mo–Mo bond, is little investigated.[3] It is surprising that the monomeric aqua ion does not dimerize in aqueous solution and that the reverse process, the formation of the monomer from the dimer, has not been described.

We have now found that the hydrolysis of yellow $[LMo^{III}Br_3]$[4] (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) in aqueous solution containing sodium acetate with strict exclusion of oxygen leads to formation of the binuclear cation **1**, which was obtained as a red PF_6 salt.

$[LMo^{III}(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2Mo^{III}L]^{3\oplus}$ **1**

Single crystals of $\mathbf{1}(ClO_4)_3 \cdot H_2O$[5] suitable for X-ray structure analysis were obtained from an aqueous solution of $\mathbf{1}(PF_6)_3$ by addition of $NaClO_4$ (*Warning*: $\mathbf{1}(ClO_4)_3 \cdot H_2O$ is very explosive). The structure of **1** is shown in Figure 1. Two Mo^{III} centers coordinated in a distorted octahedral fashion (*fac*-N_3O_3 donor set) are connected by two symmetrical acetate bridges and an OH bridge. The Mo···Mo distance of 3.555(1) Å rules out a direct metal–metal bond—the complex is a classical coordination compound of the Werner type. The two Mo–OH bonds are quite long (average 2.102(7) Å); they correspond to those in $[Mo(OH_2)_6]^{3\oplus}$[6] and in other μ-OH bridged complexes of Mo^{III}.[7] The electronic spectrum of **1** (Fig. 2) is in agreement with these findings; it shows two d–d transitions of low intensity in the visible region, which are characteristic of octahedral Mo^{III} complexes with d^3 configurations, and—interestingly—two spin-forbidden transitions (λ_{max} = 1029, 950 nm). Measurements of the temperature-dependent molar magnetic susceptibility (4–298 K) of solid $\mathbf{1}(ClO_4)_3 \cdot H_2O$ revealed a strong antiferromagnetic spin-spin coupling ($H = -2JS_1S_2$; $S_1 = S_2 = 3/2$; $J = -96$ cm^{-1}); in the analogous Cr_2^{III} dimer, it is significantly weaker ($J = -14$ cm^{-1}[8]).

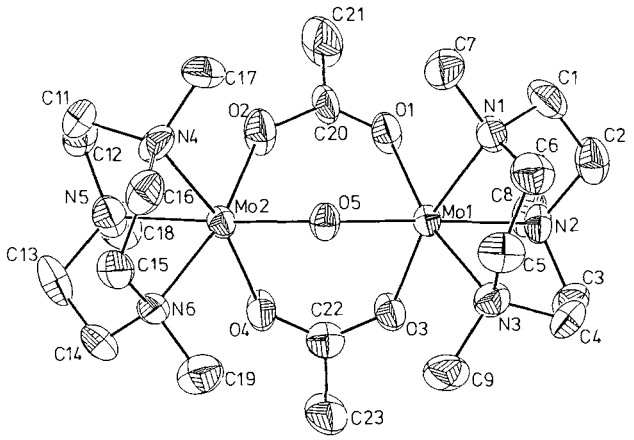

Fig. 1. The molecular structure of **1** in $\mathbf{1}(ClO_4)_3 \cdot H_2O$. Selected distances [Å] and angles [°]: Mo1-N1 2.20(1), Mo1-N2 2.20(1), Mo1-N3 2.19, Mo1-O1 2.100(7), Mo1-O3 2.082(7), Mo1-O5 2.098(7), Mo2-N4 2.18(1), Mo2-N5 2.19(1), Mo2-N6 2.21(1), Mo2-O2 2.092(7), Mo2-O4 2.075(7), Mo2-O5 2.107(7), Mo1-Mo2 3.555(1); Mo1-O5-Mo2 115.4(3).

The cation **1** is a weak acid. Aqueous solutions of **1** containing a small amount of triethylamine afforded brown **2** as crystalline $PF_6^{\ominus}$, $BF_4^{\ominus}$, and $ClO_4^{\ominus}$ salts. After addition of $NaClO_4$, alkaline aqueous solutions of $\mathbf{2}(BF_4)_2$ afforded single crystals of $\mathbf{2}(ClO_4)(BF_4) \cdot H_2O$. Complex **2** is the deprotonated form of **1**, the OH bridge being transformed into an oxo bridge. The pK_a value [Eq. (a)] was determined spectrophotometrically at 25 °C to be 6.8.

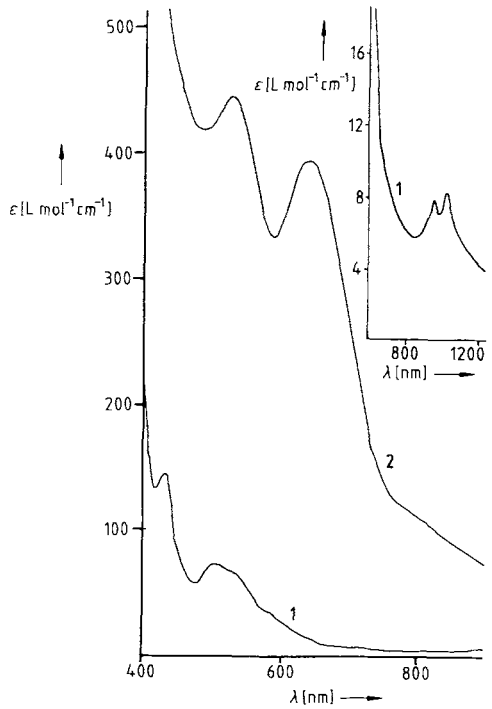

Fig. 2. Electronic spectra of $\mathbf{1}(PF_6)_3$ (insert: spectrum of $\mathbf{1}(PF_6)_3$ in the region 700–1200 nm) and $\mathbf{2}(PF_6)_2$ in acetonitrile (25 °C).

$[LMo^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mo^{III}L]^{2\oplus}$ **2**

$$\mathbf{1} \overset{K_a}{\rightleftharpoons} \mathbf{2} + H^{\ominus} \qquad \text{(a)}$$

The deprotonation of the OH bridge in **1** leads to a dramatic change in the structure (Fig. 3).[9] Not only is the expected shortening of the Mo–O bond (by 0.156 Å) observed, but, in addition, the distance between the two Mo^{III} centers is reduced by 0.67 Å (!), so that the Mo–Mo distance in **2** is only 2.885(1) Å. The comparable Mo–N and $Mo\text{–}O_{acetate}$ bonds in **1** and **2**, in contrast, are of the same length within the limits of error.

The electronic spectrum (Fig. 2) and the magnetic properties of **2** are significantly different from those of **1**:[10] **2** exhibits two strong intensity absorptions in the visible

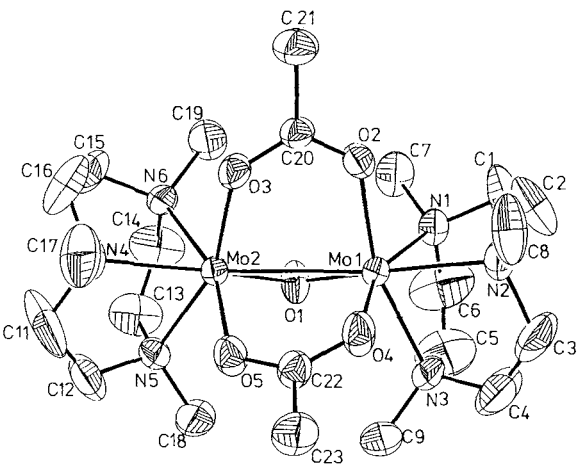

Fig. 3. The molecular structure of **2** in $\mathbf{2}(ClO_4)(BF_4) \cdot H_2O$. Selected distances [Å] and angles [°]: Mo1-O1 1.945(4), Mo1-O2 2.102(4), Mo1-O4 2.097(4), Mo1-N1 2.260(4), Mo1-N2 2.291(5), Mo1-N3 2.243(7), Mo1-Mo2 2.885(1), Mo2-O1 1.946(4), Mo2-O3 2.100(4), Mo2-O5 2.085(4), Mo2-N4 2.298(6), Mo2-N5 2.252(4), Mo2-N6 2.257(5); Mo1-O1-Mo2 95.7(2).

region (Fig. 2) and both $\mathbf{2}(PF_6)_2$ and $\mathbf{2}(ClO_4)_2 \cdot H_2O$ are diamagnetic. These findings point to the existence of a Mo–Mo bond in **2**.

The metal–metal bonding in **2** can be discussed in analogy to that in complexes of the general formula $[X_3M(\mu\text{-}X)_3MX_3]^{2\ominus/3\ominus}$, which have local D_{3h} symmetry,[11] taking into consideration the fact that the formal replacement of two μ-X bridges by two μ-acetate bridges causes a lowering of the symmetry to C_{2v}. The three d orbitals on the two Mo atoms that are available for Mo–Mo bonding are the d_{xy}, d_{yz}, and d_{xz} orbitals, assuming that the $d_{x^2-y^2}$ and d_{z^2} orbitals are mainly required for the Mo–ligand bonds. For D_{3h} symmetry, overlap of the above orbitals leads to one $\sigma(a_1')$ and two degenerate $\pi(e'')$ bonding MOs and to one $\sigma^*(a_1')$ and two degenerate $\pi^*(e'')$ antibonding MOs. For C_{2v} symmetry, the π orbitals are no longer degenerate; three bonding MOs are formed $[\sigma(a_1), \pi_1(a_1), \pi_2(b_1)]$ along with the corresponding antibonding MOs $[\sigma^*(a_1), \pi_1^*(a_2), \pi_2^*(b_2)]$. The Mo–Mo bond in **1** is thus a triple bond ($[\sigma(a_1)]^2[\pi(b_1)]^2[\pi(a_1)]^2$), and the two allowed transitions $\pi(a_1) \rightarrow \pi^*(a_2)$ and $\pi(a_1) \rightarrow \pi^*(b_2)$ are observed in the electronic excitation spectrum (Fig. 2).

The base-induced deprotonation of **1** thus leads to the intramolecular formation of a Mo–Mo bond. This process is completely reversible: protonation of **2** in aqueous solution (0.1 M $HClO_4$) affords **1** quantitatively.

Experimental Procedure

$\mathbf{1}(PF_6)_3$: $[LMoBr_3]$ [4] (0.35 g, 0.7 mmol) was added to an aqueous solution (40 mL) of $NH_4[CH_3CO_2]$ (1.2 g, 16 mmol) through which Ar was being bubbled. After heating for 4 h at reflux under Ar, the resulting reddish-brown solution was treated with $NaPF_6$ (0.2 g, 1.2 mmol) and allowed to stand for 24 h at 0°C. A reddish-brown microcrystalline powder formed which afforded red crystals of $\mathbf{1}(PF_6)_3$ upon recrystallization from H_2O (yield: 0.4 g).—IR (KBr): ν(OH) 3530, ν_{as}(C–O) 1540, ν_s(C–O) 1440, 1455 cm^{-1}; UV/VIS (CH_3CN): λ_{max}(ε per dimer) = 1029(8.6), 950(8.3), 501(66), 431(120) nm.

$\mathbf{2}(PF_6)_2 \cdot 3H_2O$: Triethylamine (1 mL) was added to an aqueous solution (30 mL) of $\mathbf{1}(PF_6)_3$ (0.10 g, 0.09 mmol) through which Ar was being bubbled. The solution turned dark brown. Addition of $NaPF_6$ (0.5 g, 3 mmol) resulted in the precipitation of brown $\mathbf{2}(PF_6)_2 \cdot 3H_2O$ (yield: 0.07 g).—IR (KBr): ν_{as}(C–O) 1510, ν_s(C–O) 1460, 1425 cm^{-1}; UV/VIS (CH_3CN): λ_{max}(ε per dimer) = 644(327), 527(433) nm.

Compounds **1** and **2** are unstable toward oxygen both in solution and in the solid state. The similarly prepared ClO_4 salts are explosive. All salts gave correct elemental analyses (C,H,N).

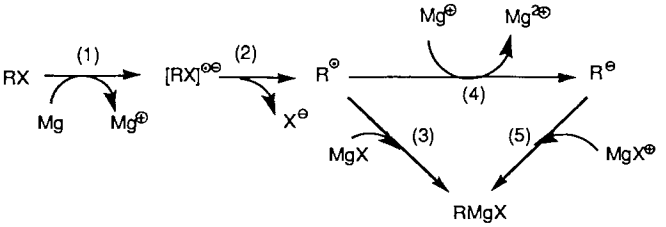
Carbanions as Intermediates in the Synthesis of Grignard Reagents

By *Henricus J. R. de Boer, Otto S. Akkerman,* and *Friedrich Bickelhaupt**

The mechanism of formation of Grignard compounds from organic halides and magnesium has been intensively investigated.[1–5] A broad consensus exists concerning most of the phases and intermediates shown in Scheme 1. This is especially true for steps (1) and (2); still unclear, among other things, is whether the radical $R^\odot$ formed in step (2) combines directly with the "magnesium subhalide" MgX to form the Grignard reagent $RMgX$[2,5] (3), or whether the reaction occurs initially by reduction of the radical to the carbanion $R^\ominus$ (4), which then reacts with $MgX^\oplus$ to form the Grignard reagent[1] (5). Since step (4) takes place, if at all, after the rate-limiting step,[5b] it cannot be detected at all kinetically and is otherwise difficult to detect. Herein we report a novel rearrangement reaction which provides convincing evidence for a carbanion intermediate $R^\odot$.



Scheme 1. Proposed mechanism for the formation of Grignard reagents RMgX.

In diethyl ether, *o*-bromobenzyltrimethylstannane **1** does not react with threefold sublimated magnesium. In tetrahydrofuran, on the other hand, rapid reaction occurs, the solution turning yellow (Scheme 2); a white precipitate slowly forms and, after 22 h, **1** is completely consumed. After hydrolysis, titration of the base (with HCl) and of the magnesium (with EDTA) gave values in agreement with a quantitative conversion of **1** to the corresponding Grignard compound **2**. Surprisingly, however, **2** is formed in only 15% yield, as shown by derivatization with chlorotrimethylgermane. Besides the expected **6** (15%), weighing and ^{1}H-NMR analysis showed the presence of **7** (29%), **4** (28%),

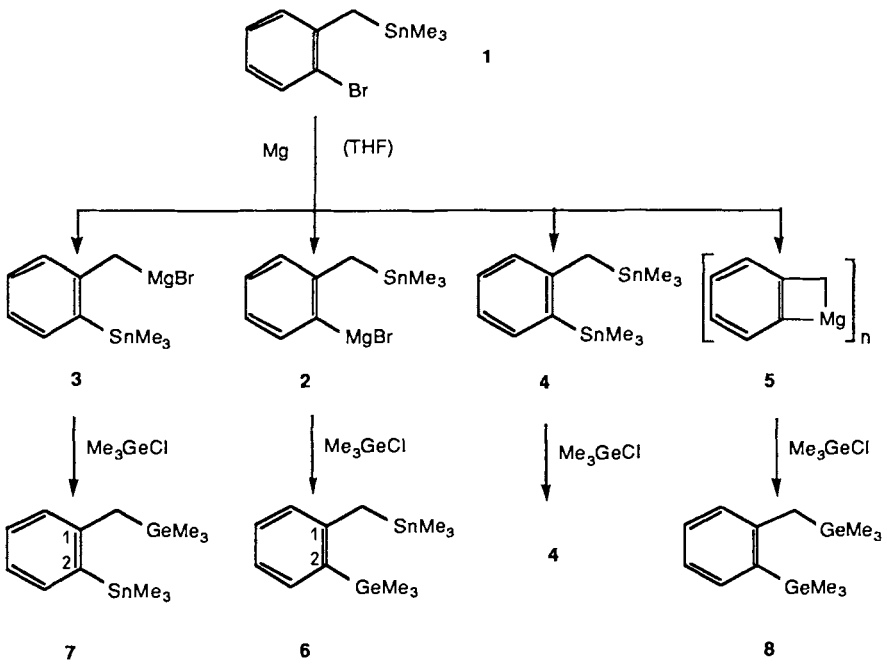


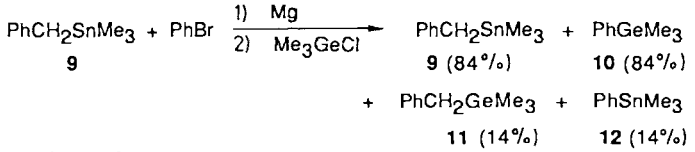
Scheme 2. Products of the reaction of **1** with Mg in THF.

and **8** (28%).[6] Deuterolysis of the reaction mixture afforded, in addition to **4**, the deuterium compounds (D instead of $GeMe_3$) corresponding to **6**–**8**. These findings indicate that, apart from **2**, the isomeric Grignard compound **3**, the distannyl compound **4**, and the (polymeric) magnesacyclobutane **5** are formed. Compound **5** is poorly soluble in THF,[7] which explains the formation of a precipitate. The completely reacted reaction mixture shows no further changes even after 108 h; thus, the unexpected products are only formed during the reaction of the halide with magnesium.

Noteworthy is the migration of the stannyl group from the benzylic position into the aryl position and the reverse migration of the magnesium substituent; this is *formally* (!) a metal-metal exchange reaction, which occurs both intramolecularly (**2** → **3**) and intermolecularly (**2** + **2** → **4** + **5**).

Such exchange reactions are unknown for organomagnesium compounds (except for their reaction with the very reactive stannacyclobutanes[8]), but have been observed for the more strongly carbanionoid organolithium compounds.[9] It is therefore plausible in our case as well to ascribe the extremely rapid and efficient exchange reaction to the carbanion $R^{\ominus}$ formed from **1** (in analogy to Scheme 1). Unequivocal evidence for the existence of this carbanion has not been obtained so far owing presumably to the fact that its lifetime is very short and its stationary concentration very small.

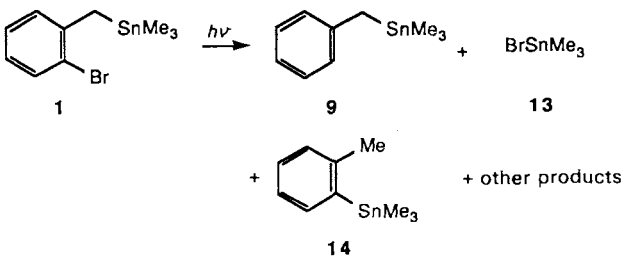
Intermolecular stannyl migrations also occur in other systems. As shown in Scheme 3, reaction of bromobenzene with magnesium in THF in the presence of an equivalent amount of benzyltrimethylstannane **9**, followed by reaction with chlorotrimethylgermane in excess, afforded **11** and **12**, in addition to **9** and **10**, in pairwise equal amounts. A control reaction showed that phenylmagnesium bromide did not react with **9**.



Scheme 3.

In principle, it cannot be ruled out that, instead of $R^{\ominus}$, the radical $R^{\odot}$ in Scheme 1, is responsible for the stannyl migration, since the latter species has been shown to be a true intermediate (!). Homolytic substitutions at stannanes are known, although usually heteroatom-centered radicals (and only in a few cases carbon-centered radicals) have been reported to be the reaction partner.[10] In order to exclude this pathway of reaction for the stannyl migration, it is necessary to investigate how aryl radicals, synthesized independently by a clearly defined route, behave toward benzylstannanes; however, this is not easy under our reaction conditions.[11] The experiments described below indicate, nonetheless, that the reaction of aryl radicals with **1** and **9** is completely different from that of the reactive intermediate involved in the formation of Grignard reagents.

Irradiation of **1** in *n*-pentane (Scheme 4) results not only in the desired cleavage of the carbon-bromine bond[12] but also in that of the carbon-tin bond.[13] At 254 nm, **1** (83%), **9** (4%), and bromotrimethylstannane **13** (13%) were obtained, but not the product of stannyl migration, *o*-trimethylstannyltoluene **14**. Longer irradiation in pentane with a medium-pressure mercury lamp resulted in partial polymerization along with the formation of up to 9% of **14**;[14] however, there are several possible mechanisms for the formation of **14**.[15] If one makes the simplified assumption



Scheme 4. Photochemical transformation of **1**.

that **14** is formed exclusively by stannyl migration from $R^{\odot}$, then the two alternative reaction modes of $R^{\odot}$, hydrogen abstraction and stannyl migration (i.e., formation of **9** and **14**, respectively), occur in a ratio of 3:1 (15 min[14]). If this product ratio is transferred to the $R^{\odot}$ that occurs with certainty in the formation of Grignard reagents, then it becomes immediately apparent that, in that case, a stannyl migration starting from $R^{\odot}$ can be completely neglected, since even the product of hydrogen abstraction (i.e., **9**) is totally absent (< 1%). In other words, **4** in Scheme 2 must be formed via an intermediate behaving just the opposite of $R^{\odot}$, since this intermediate reacts more quickly with the stannyl group than it is trapped by $MgX^{\oplus}$ (ratio (**3** + **4**) : **2** = 3.8 : 1).

Since a dramatically increased reactivity is not expected for the organotin function in **1**, only the carbanion $R^{\ominus}$, which is otherwise difficult to detect, comes into mind as the factor responsible for the stannyl migration, especially in view of the fact that organolithium compounds exhibit striking parallels in reaction behavior. The radical anion $[RX]^{\odot\ominus}$ can hardly be considered as an alternative, because its lifetime is so short that it is often discussed as a transition state rather than as an intermediate. Moreover, there is the mechanistic problem of how one is to formulate the transfer of the tetracoordinated tin to the radical anion of an organic halide. In further analogy to the reactions of the organolithium compounds, it may be assumed that the rearrangement occurs via stannate complexes.[6,8,16] These also presumably serve as a stabilizing reservoir of carbanions,[17] which would rationalize the surprisingly high proportion of *inter*molecular stannyl transfer.

This stage of the investigation does not permit more detailed statements concerning the identity of the postulated carbanion intermediate. In any case, its reactivity is significantly higher than that of the organolithium compounds: whereas the stannyl transfer requires several hours in the case of organolithium compounds,[9] $R^{\ominus}$ reacts "immediately" despite the presence of its extremely small stationary concentration. This indicates that $R^{\ominus}$ exists in a very reactive form, i.e., presumably as a rather free carbanion. Completely independent evidence for such a species was recently provided by side products obtained in the formation of several crown ether-Grignard compounds.[18]

Elementary Reactions at Metal-Sulfur Centers: Base-Induced Substitution of PPh_3 in $[Ru(PPh_3)_2(bmae)]$**

By *Dieter Sellmann** and *Olaf Käppler*

The transition-metal atoms in the active sites of numerous oxidoreductases, from sulfite oxidase to nitrogenase, are surrounded mainly by sulfur ligands and, in some cases, by oxo or amine ligands as well.[1] For practically all these enzymes, however, the molecular course of the elementary reactions is still unknown. This is also true for the mechanism of binding or release of a substrate Y according to

$$M + Y \rightleftharpoons M{-}Y$$

It is commonly assumed that, in the resting state, the metal centers bear protecting ligands L, which must be split

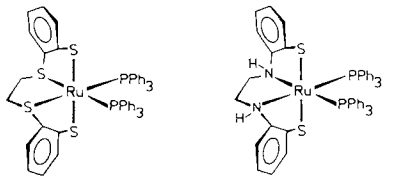
[**] Transition-Metal Complexes with Sulfur Ligands, Part 35. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 34: D. Sellmann, P. Franck, F. Knoch, *J. Organomet. Chem. 339* (1988) 1298. $bmae^{2\ominus}$ = 2,2′-ethylenediiminobis(thiophenolate).

off in precursor reactions in order to generate vacant coordination sites for the binding of Y. A question of fundamental chemical importance concerns the role played by sulfur ligands in such reactions as well as the effect of their replacement, e.g., by amine ligands. We have now found that, in coordinatively saturated thioether dithiolato complexes such as **1** ($dttd^{2\ominus}$ = 2,2′-ethylenedithiobis(thiophenolate)), the π-donor properties of the S atoms are sufficient for the generation of vacant coordination sites (that is, for the release of L), whereas in amino dithiolato complexes such as **2** ($bmae^{2\ominus}$ = 2,2′-ethylenediiminobis(thiophenolate)) the release of L can only be induced by an indirect attack (from the backside) of a base on the NH group of the $bmae^{2\ominus}$ ligand.



$[Ru(PPh_3)_2(dttd)]$ **1** $[Ru(PPh_3)_2(bmae)]$ **2**

Complexes **1**[2a] and **2**[2b] are isoelectronic and isostructural, but behave completely differently. Complex **1** reacts rapidly already at room temperature and 1 bar CO according to Equation (1); **2**, however, is fully inert under the same or considerably more energetic conditions.

$$\mathbf{1} + CO \xrightarrow[-PPh_3]{THF/RT/1\ bar/10\ min} [Ru(CO)(PPh_3)dttd] \qquad (1)$$

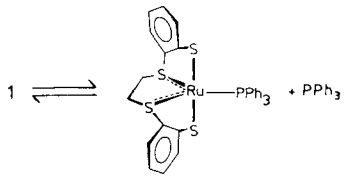
$$\mathbf{2} + CO \xrightarrow{THF/RT/1\ bar} \text{no reaction}$$

$$\mathbf{2} + CO \xrightarrow[-PPh_3]{THF/100\,^{\circ}C/80\ bar} [Ru(CO)(PPh_3)(bmae)] + [Ru(CO)_2(bmae)]$$

3 **4**

Only above 100°C and at 80 bar does complex **2** also undergo reaction with CO, resulting in the simultaneous formation of **3** and **4**.[3]

A comparison of **1** and **2** shows that the high reactivity of **1** is not due to steric factors such as the bulky PPh_3 ligands, but rather due to electronic factors. In the coordinatively unsaturated intermediate **1a** [Eq. (2)], the five-



1a

coordinate 16-electron ruthenium center is presumably stabilized by p electrons of the thioether S atoms or by $p_{\pi,S} \rightarrow d_{\pi,Ru}$ bonds.[4]

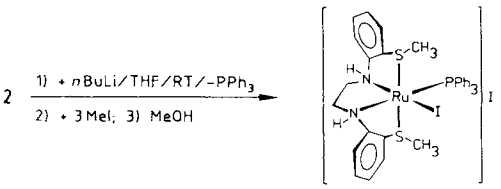
In order to support this interpretation, we attempted to deprotonate σ-donor amine functions of the unreactive **2**.[5] The resulting σ-π-donor amido centers, like the thioether S atoms in **1**, should stabilize coordinatively unsaturated intermediates (cf. **1a**).

Indeed, in the presence of strong bases such as *n*BuLi or $Na[N(SiMe_3)_2]$, **2** reacts rapidly with CO (room temperature, 1 bar CO). The yellow THF solution of **2** turns deep red on addition of *n*BuLi; stirring for 10 min under CO followed by hydrolysis with MeOH results in the formation of both **3** and **4**.[6]

$$\mathbf{2} + 2\,n\text{BuLi} \xrightarrow[2)\ +MeOH]{1)\ +1\ bar\ CO/THF/RT/10\ min/-PPh_3} \mathbf{3} + \mathbf{4}$$

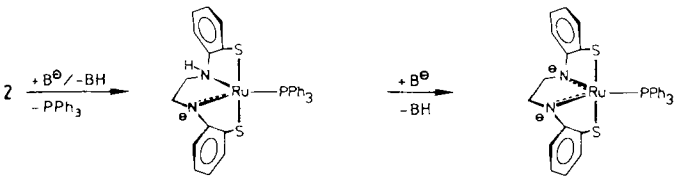
The deprotonation of the amine functions is shown by IR spectroscopy (absence of the ν_{NH} band of **2** at 3230 cm^{-1}), by $H^{\oplus}/D^{\oplus}$ exchange, which only occurs after addition of *n*BuLi,[7] and by the alkylation behavior of **2**. Whereas **2** reacts with excess MeI to give only the derivative **5**, alkylated on one thiolate S atom,[8] addition of *n*BuLi results in alkylation of both thiolate S atoms, accompanied by simultaneous replacement of PPh_3 by iodide.[9]

$[Ru(PPh_3)_2(bmae(CH_3)_2)]I$ **5**



6

The formation of **5** and **6** also shows how the number of alkylation steps is determined by the NH deprotonation. All results indicate the primary formation of the coordinatively unsaturated intermediates **7a** and **7b**, in which the



7a **7b**

Ru centers are stabilized by the p electrons of the amido groups.

The introduction of amine ligands into the sulfur coordination sphere of the metal atoms in oxidoreductases can thus lead to pH-dependent substitution, i.e., coordination/decoordination reactions.

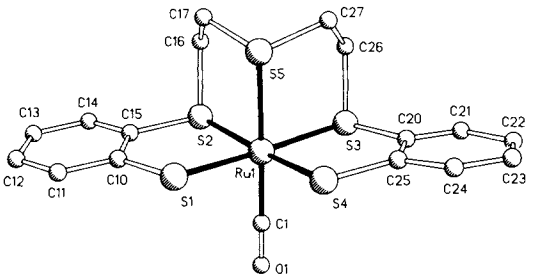
Transformation of Open-Chain Thioether-Dithiolato to Cyclic Thioether Ligands by C-S Bond Cleavage and Bond Formation at Ruthenium Centers: Synthesis of the Trithiobenzo[9]crown-3 Complex [Ru(Bzo-9S3)(CO)Br$_2$]**

By *Dieter Sellmann,* Falk Knoch,* and *Christina Wronna*

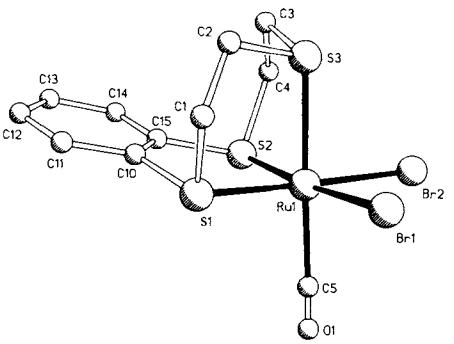
Sulfur-coordinated transition metals, as the active sites of numerous oxidoreductases, are directly involved in many life processes.[1] A basic understanding of these processes at the molecular level requires a knowledge of the specific properties of the metal centers that are due to the sulfur ligands. These include unusual structures,[2] the coordination, activation, and stabilization of stable or unstable species such as CO, NO, and N_2H_2,[3] and the stabilization of coordinatively and electronically unsaturated metal centers,[4] as well as the ability of many sulfur ligands to make accessible unusual oxidation states of metals.[5] Of equal importance are the reactions of the sulfur ligand framework and the question how the reactivity, for example of coordinated thiolates, is influenced by the metals, their oxidation states, and the coligands. We have now observed specific reaction control by metals for the homologous [M(CO)(dpttd)] complexes of iron and ruthenium (dpttd$^{2\ominus}$ = 2,2′-[thiobis(ethylenethio)]bis(thiophenolate)).[6] Whereas the dpttd$^{2\ominus}$ ligand in [Fe(CO)(dpttd)] undergoes alkylation by bis(2-bromoethyl) sulfide in refluxing THF to give the macrocycle hexathiodibenzo[18]crown-6 (Bzo_2-18S6),[7] [Ru(CO)(dpttd)] **1** only reacts above 120°C (in DMF). However, the reaction proceeds completely differently, leading to a complex containing the new ligand trithiobenzo[9]crown-3 (Bzo-9S3).

Complex **1** is obtained by alkylation of *cis*-[Ru(CO)$_2$(S$_2$C$_6$H$_4$)$_2$]$^{2\ominus}$,via [Ru(CO)$_2$(dpttd)].[8] Complex **1** is thermally so stable that it survives even 5 h of heating at 140°C. Single crystals of **1** · DMF are obtained from these solutions and were shown by X-ray crystallography to have the *meso* form.[9, 10]



meso-**1**

+ $S(C_2H_4Br)_2$/DMF/140°C
or
1,2-$C_2H_4Br_2$/≈ 6h



2 + ...

The attempt to alkylate the dpttd ligand in *meso*-**1** with bis(2-bromoethyl) sulfide to give Bzo_2-18S6 yielded a new CO species; however, it was not the expected [Ru(CO)(Bzo_2-18S6)]Br$_2$, but instead the complex [Ru(Bzo-9S3)(CO)Br$_2$] **2**, formed by cleavage of an *o*-benzenedithiolate group. Complex **2** was also characterized by X-ray crystallography.[11]

Although more facile alkylation of the dpttd ligand was expected for **1** as opposed to the Fe analogue, because the [Ru(CO)] fragment is more electron-rich that the [Fe(CO)] fragment, **1** underwent reaction only under considerably more energetic conditions and afforded a different type of product.

In order to interpret the unexpected reaction and the remarkable differences in reactivity between the homologous Fe and Ru complexes, the following findings are important:

(1) The CO ligand of **1**, in contrast to that of [Fe(CO)(dpttd)] is kinetically inert. Therefore, alkylation of **1** with bis(2-bromoethyl) sulfide does not result in release

[**] Transition-Metal Complexes with Sulfur Ligands, Part 36. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *M. Moll* for recording the NMR spectra.—Part 35: D. Sellmann, O. Käppler, *Angew. Chem. 100* (1988) 706; *Angew. Chem. Int. Ed. Engl. 27* (1988) 689.

of CO and formation of an intermediate having a vacant coordination site which would favor the formation of new $[MS_2C_2]$ five-membered rings, as is the case for the Fe complex.

(2) Complex **2** is also formed when **1** is allowed to react with 1,2-dibromoethane. Breaking of the C–S bond in the dpttd ligand is therefore probably initiated by attack of the alkylating agent; it still remains an open question whether this reaction occurs by an electrophilic mechanism or by a radical one.

Structurally noteworthy in **1**[10] are the Ru–S distances in the Ru(S1–S4) plane, which have nearly the same values. They lie between 235.9(2) and 237.7(2) and thus in the normal region for Ru^{II} complexes of this type. The Ru–S distance *trans* to the CO ligand, however, is significantly larger (242.4(2) pm). That this is indeed due to the *trans* effect of CO is shown by the corresponding Ru–S distance in the related complex $[Ru(PPh_3)L]$ of only 235.7(2) pm.[8] Here L is a dpttd ligand bearing four *t*Bu groups on the benzene rings. A similar effect is observed for **2**.[11] The two Ru–S distances *trans* to the Br ligands are 230.3(4) pm (average); the Ru–S distance *trans* to the CO ligand is considerably larger, however (242.6(4) pm).

The mirror symmetry of **1** and **2**, which was indicated by X-ray crystallography, is revealed by the ^{13}C-NMR spectra of the two complexes. They show only eight and five signals, respectively, for the sulfur ligands.

Trithiobenzo[9]crown-3 (Bzo-9S3) is the first benzoannelated derivative of trithio[9]crown-3 (or 1,4,7-trithiacyclononane). This ligand has been the object of considerable interest recently, since, owing to its favored rigid *endo* configuration (even in the free state),[13] it exhibits excellent complexation properties;[5b,c] this rigidity of the nine-membered ring should be increased by the presence of the benzene ring. The synthesis of **2** from **1** shows how the formation of such sterically encumbered ring systems can become the main reaction at certain metal centers.

Experimental Procedure

All reactions were carried out in dry solvents under N_2.

a) Single crystals of *meso*-**1** · DMF: A saturated solution of **1** in DMF at 140°C was allowed to cool over 12 h to 20°C. The crystals were filtered, washed with Et_2O, and dried for 3 h under high vacuum. ν_{CO} (IR) [cm^{-1}]: 1960 (in DMF), 1950 (in KBr). $^{13}C\{^1H\}$-NMR (270 MHz, 293 K, in $[D_7]$DMF or CD_2Cl_2): $\delta = 198.1$ (CO); 156.5, 132.7, 130.5, 130.2, 129.5, 122.9 (C_6H_4); 49.7, 35.9 (C_2H_4). MS: *m/z* 498 [$M^{\oplus}$]

b) **2** from **1** and $S(C_2H_4Br)_2$: A solution of **1** · DMF (1.5 g, 2.6 mmol) and $S(C_2H_4Br)_2$ (694 mg, 2.8 mmol) in DMF (50 mL) was heated at 130–140°C until the ν_{CO} absorption of **2** at 1980 cm^{-1} appeared as the most intense band in the IR spectrum of the solution. After complete evaporation of the solvent, the viscous residue was digested with 5 × 10 mL of CH_2Cl_2; the remaining powdery **2** (604 mg, 45%) afforded single crystals of **2** · CH_2Cl_2 (correct elemental analysis) upon recrystallization from CH_2Cl_2 (35→ −20°C). ν_{CO} (IR) [cm^{-1}]: 1985 (in DMF), 2000 (in CH_2Cl_2), 1975 (in KBr). $^{13}C\{^1H\}$-NMR (270 MHz, 293 K, in $[D_6]$DMSO): $\delta = 195.9$ (CO); 137.8, 132.3, 131.9 (C_6H_4); 46.3, 33.8 (C_2H_4). MS: *m/z* 517 [$M^{\oplus}$].

c) **2** from **1** and $C_2H_4Br_2$; **1** · DMF (920 mg, 1.63 mmol) and 1,2-$C_2H_4Br_2$ (0.16 mL, 1.80 mmol) were heated in DMF (60 mL) at 140°C, the reaction being followed by IR spectroscopy. The solvent was evaporated and the viscous residue was extracted with 2 × 20 mL of CH_2Cl_2; the powdery residue was recrystallized from 5 mL of DMF (20→0°C). Dark orange crystals of **2** (180 mg, 22%, not optimized, correct elemental analysis) were obtained.

ing in the field of photochemistry where supramolecular photochemistry[3] has, as its ambitious aim, the design of photochemical molecular devices capable of performing light-induced functions of practical utility. In the field of transition-metal complexes, one way to obtain supramolecular species is via second-sphere coordination, i.e., wrapping up the complex in an appropriate molecular host.[4] So far, however, only a few investigations have been published on the second-sphere photochemistry and photophysics of coordination compounds.[5] Here, we wish to report on the luminescent properties of the 1:1 adduct obtained when $[Pt(bpy)(NH_3)_2]^{2\oplus}$ is encapsulated by dibenzo[30]crown-10 (Fig. 1).[4,6]

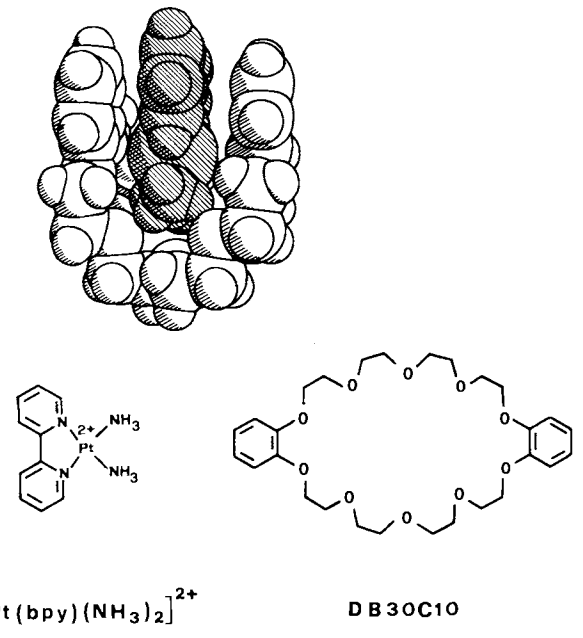

Fig. 1. The supramolecular structure of the $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 (DB30C10) adduct in the solid state. bpy = 2,2'-bipyridine (cf. [6a]).

$[Pt(bpy)(NH_3)_2]^{2\oplus}$ was prepared as its $PF_6^{\ominus}$ salt and dibenzo[30]crown-10 was synthesized as described previously.[6a] In acetonitrile solution at room temperature, $[Pt(bpy)(NH_3)_2]^{2\oplus}$ exhibits a structured luminescence with $\lambda_{max} = 488$ nm (Fig. 2). This luminescence can be attributed to a triplet ligand-centered excited state on the basis of the close similarity to the phosphorescence spectrum of bipyridine and the value of the radiative rate constant at 77 K ($k = 2 \times 10^4$ s^{-1}, obtained from the experimental lifetime, 25 μs, and the luminescence quantum yield of ca. 0.5 at 77 K). $[Pt(bpy)(NH_3)_2][PF_6]_2$ is not soluble in CH_2Cl_2, but it can be solubilized by the addition of dibenzo[18]crown-6, yielding a solution that exhibits a luminescence spectrum which is essentially the same as that of $[Pt(bpy)(NH_3)_2]^{2\oplus}$ in acetonitrile.

In CH_3CN or CH_2Cl_2 solution, dibenzo[30]crown-10 shows an emission band at 308 nm ($\tau < 20$ ns) that can be assigned as the fluorescence emission of its *ortho*-dimethoxybenzene-like units.

The $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 adduct was obtained as pale yellow crystals following a previously reported procedure[6a] or it was prepared in situ by addition of an equimolar amount of dibenzo[30]crown-10 to a CH_2Cl_2 suspension of $[Pt(bpy)(NH_3)_2][PF_6]_2$. In both cases,

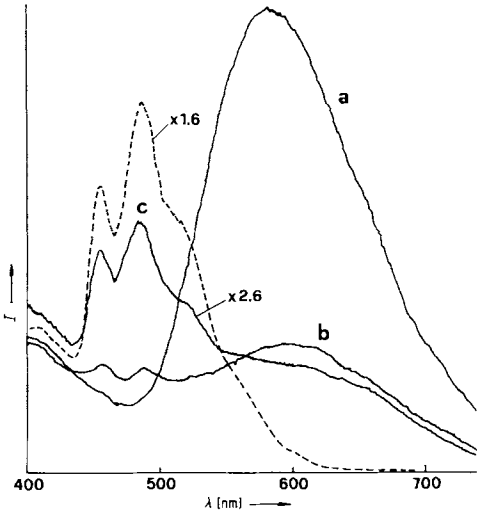

Fig. 2. Dashed line: Emission spectrum of $[Pt(bpy)(NH_3)_2]^{2\oplus}$ in CH_3CN. Full lines: Emission spectra of the $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 adduct in a) CH_2Cl_2, b) CH_2Cl_2-CH_3CN (1:1, v/v), and c) CH_3CN. Intensity I in arbitrary units.

the same properties have been observed. As previously noted,[6] the absorption spectrum of the adduct in CH_3CN or CH_2Cl_2 solution is similar but not identical to the sum of the spectra of the two components. In particular, the intensities of the $\pi \rightarrow \pi^*$ absorptions of the bpy ligand at 306 and 318 nm are reduced significantly while the intensity above 325 nm increases, indicating that a new broad band with maximum at ca. 350 nm is present.

In CH_2Cl_2 solution the adduct exhibits a new broad, relatively weak luminescence band with $\lambda_{max} = 580$ nm (Fig. 2, curve a), while the luminescence intensity in the 308- and 488-nm regions is at least 90% lower than that exhibited by the dibenzo[30]crown-10 and $[Pt(bpy)(NH_3)_2]^{2\oplus}$ components. A comparison among the corrected emission intensities at 580 nm after exciting the adduct at 275 nm (dibenzo[30]crown-10 band), 318 nm ($[Pt(bpy)(NH_3)_2]^{2\oplus}$ band), and 350 nm (adduct band) shows that the level responsible for the emission is populated with the same efficiency in all cases (experimental error ± 15%).

In CH_3CN solution the emission spectrum of the adduct (Fig. 2, curve c) shows a weak band in the 580-nm region and much stronger bands at 308 and 488 nm, indicating that the adduct stability is less in CH_3CN solution than in CH_2Cl_2 solution. This observation is in agreement with a conclusion previously reached on the basis of absorption measurements.[6] In CH_3CN/CH_2Cl_2 (1:1, v/v) mixtures, the 488- and 580-nm bands have comparable intensities (Fig. 2, curve b).

The results obtained show that the $[Pt(bpy)(NH_3)_2]^{2\oplus}$-dibenzo[30]crown-10 supermolecule exhibits absorption properties similar to those of the two components and completely new luminescence properties that arise from the presence of a low-energy "supramolecular" level. The broadness of the emission band suggests that such an energy level can be assigned to a charge-transfer transition, most likely from the π-electron-rich dialkoxybenzene units of dibenzo[30]crown-10 to the empty π* orbitals of bipyridine, i.e., the luminescent level is the triplet counterpart of the singlet charge-transfer excited state responsible for the broad absorption of the adduct in the 350-nm region. In principle, it should be possible to tune the energies of

these levels, and hence the absorption and emission properties of the adduct, by appropriate substitutions on the benzene or pyridine rings.

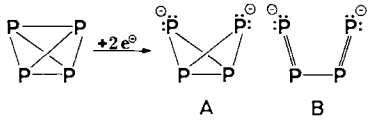
$P_4^{2\ominus}$ Isomers as Complex Ligands**

By *Otto J. Scherer,* Magdalena Swarowsky, Herbert Swarowsky,* and *Gotthelf Wolmershäuser*

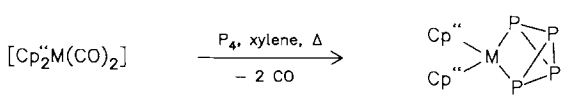
Dedicated to Professor Adolf Steinhofer on the occasion of his 80th birthday

Two-electron reduction of white phosphorus (P_4) should result in opening of one edge of the P_4 tetrahedron and formation of the polyphosphide ion $P_4^{2\ominus}$ **A**,[1] which is the dianion of tetraphosphabicyclobutane and has a butterfly-like structure. Opening of two further edges of **A** could result in isomerization to **B**, the dianion of tetraphosphabutadiene.[2] Herein we report that both dianions can be stabilized in the coordination sphere of transition metals.



Oxidative addition of white phosphorus to fragments of complexes **1** affords in quantitative yield the "metalated" tetraphosphabicyclobutane derivatives **2**, complexes exhibiting a new type of coordination[3] of the P_4 molecule. In this redox reaction, P_4^0 molecules are formally reduced to polyphosphide ions $P_4^{2\ominus}$ **A** and $M^{2\oplus}$ centers are formally oxidized to $M^{4\oplus}$ centers (M = Zr, Hf).

The air-stable complexes **2** are readily soluble in benzene, toluene, and dichloromethane and moderately soluble in pentane. In contrast to **2a,b**, the Cp* analogue $[Cp_2^*Zr(P_4)]$ **2c**, Cp* = η^5-C_5Me_5, is only stable in solution (^{31}P-NMR[4]). Attempted isolation of **2c** resulted in partial reductive elimination with formation of white phosphorus and "Cp_2^*Zr"[5] ($t_{1/2}$ at 140 °C in xylene: ca. 70 min). The $^{31}P\{^1H\}$-NMR spectra of **2** each show two triplets (A_2X_2 spin system[4]). The X-ray structure analyses[11b] of the isostructural P_4 complexes **2a,b** (disorder problems in the region of the Cp″ ligands prevent a satisfactory structural refinement) confirm the presence of a P_4 butterfly framework with a $Cp_2''M$ bridge. The distances and angles in the P_4 moiety are comparable to those in the tetraphosphabicyclobutane derivatives $P_2(PR)_2$ (R = $N(SiMe_3)_2$,[6a] 2,4,6-$tBu_3C_6H_2$[6b]). The M–P bond lengths are in the expected range.[7]



Cp″ = η^5-1,3-$C_5H_3(tBu)_2$; **a**, M = Zr; **b**, M = Hf

If, instead of the "early" transition metals (Zr, Hf), the "late" transition metal rhodium is employed, P_4 can be incorporated into a metallatetraphosphacyclopentadiene,[8] which, in turn, functions as an η^4 ligand in the sandwich complex **4**. Complex **4** forms red crystals, which are stable for only a short time upon exposure to air and are readily soluble in pentane and toluene. Its $^{31}P\{^1H\}$-NMR spectrum displays a complex pattern of signals.[10] The X-ray structure analysis[11a] shows that the planar P_4 fragment and the flat five-membered ring at the Rh1 atom in **4** are nearly parallel (deviation 3.5°) and are mutually oriented in an eclipsed fashion (Fig. 1). The nearly identical P–P distances (average value 2.154 Å) are somewhat shorter than those in the Co complex $[Co(Ph_2PCH_2PPh_2\text{-}P_4\text{-}PPh_2CH_2PPh_2)]BF_4$[12a] containing a zigzag-shaped η^4-phosphabutadiene moiety in the middle of the ligand; however, they are significantly longer than the short P–P distance (2.052(2) Å) in the P_4 rectangle of the sandwich complex **5**.[9] The nearly identically long Rh1–P bonds (average value 2.385 Å) are slightly longer than the Rh2–P bonds (both 2.347(2) Å). The atoms Rh1, P1, Rh2, and P4 form a nearly perfect rhombus (sum of angles in the four-membered ring = 359.4°). The Rh2 atom is displaced by about 55.7° from the plane of a planar five-membered ring. In terms of formal charges, an alternative to $P_4^{2\ominus}$ and d^8,d^6 Rh is $P_4^{4\ominus}$ and d^6,d^6 Rh. Complex **4** could also have been formed from $[(\eta^4\text{-}P_4)RhCp^*]$, a sandwich com-

Experimental Procedure

2a [**2b**]: A solution of **1a** (505 mg, 1.01 mmol) [13] [**1b** (520 mg, 0.88 mmol) [13]] in xylene (20 mL) was added within 10 min to a refluxing solution of P_4 (166 mg, 1.34 mmol) [152 mg (1.23 mmol)] in xylene (25 mL). The resulting reaction mixture was stirred under reflux for 5 min [25 min] and the solvent was then removed under oil-pump vacuum. The excess phosphorus was removed at 80°C/0.1 mbar. Yield 574 mg **2a** (100%) [577 mg **2b** (100%)]. Both complexes could be recrystallized from hexane.

4: **3** (1000 mg, 3.24 mmol) [13] and P_4 (663 mg, 5.13 mmol) were allowed to stir in ca. 30 mL of xylene in a Schlenk pressure tube at an oil-bath temperature of 200°C. IR spectroscopic control revealed the emergence of the new band of **4** at 2000 cm^{-1} (maximum after ca. 30 min). The red reaction solution containing small amounts of insoluble matter) was evaporated to ca. 10 mL under oil-pump vacuum, then treated with 3 g of Al_2O_3 (basic, activity II) and dried under oil-pump vacuum until freely flowing. In the chromatographic workup (column 25 × 2.5 cm), excess P_4 was eluted with pentane and unreacted **3** (100 mg, 10%) was eluted as a yellow forerun. Pentane/toluene (1:1) afforded **5** [9] (180 mg, 20%) as a yellowish orange fraction; a 1:2 mixture eluted **4** as a red fraction (an intermediary fraction contains both products). After removal of the solvent (oil-pump vacuum), 22 mg (2.3% based on reacted **4**) of pure **5** remained, which—after recrystallization from pentane—afforded red, cube-shaped crystals.

4,6,6-Trimethyl-4-cyclohexene-1,2,3-trione, a Contribution to the Biogenesis of Norcarotinoids**

By *Jürgen Detering* and *Hans-Dieter Martin**

Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The red pigment (3*S*,3′*S*)-actinioerythrin **1**, the ester of actinioerythrol **2** (2,2′-bisnorastaxanthin), is present in the see anemone *Actinia equina*.[1] The benzilic acid rearrangement of a highly oxidized derivative of astaxanthin **3** was suggested as the route of biogenesis.[2,3] This route (Scheme 1) should involve the *vic*-triketone **4** as a reactive intermediate, which could undergo ring contraction to **5**, induced by nucleophilic attack. Subsequent decarboxyla-

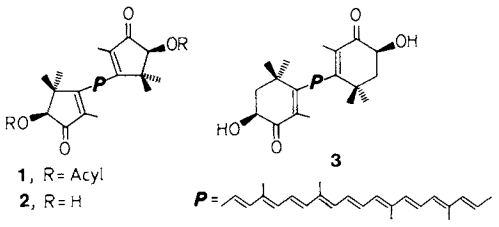
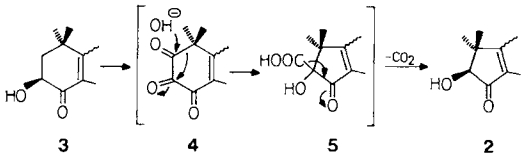
[**] Small and Medium-Sized Rings, Part 68. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. Part 67: K. Hassenrück, H.-D. Martin, B. Mayer, *Chem. Ber. 121* (1988) 373.



tion could then lead to **2**. In later work, the attack of the nucleophile was indicated to occur at C-2 of **4**.[4]



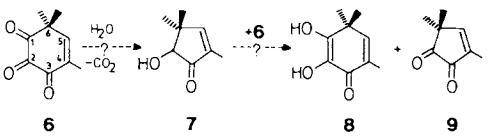
Scheme 1. Proposed route for the biogenesis of **2** from **3**.

This mechanistic proposal gives rise to the following considerations and questions:

(1) The chirality of astaxanthin **3** cannot be transferred to the actinioerythrol **2** according to this mechanism. Since the triketone **4** has not been observed so far, the question arises whether astaxanthin might perhaps remain bound to the same enzyme complex during the entire process.[4]

(2) If the hypothetical triketone **4** is indeed a discrete intermediate, then, in principle, each of the three carbonyl groups could undergo nucleophilic attack, since a priori it should be difficult to decide which of the four electrophilic positions in **4** (the three carbonyl carbon atoms, one Michael-like β position) would be the most reactive, depending on the reaction conditions. In short, what acceptor properties characterize the cyclohexenetrione structure **4**, which, to the best of our knowledge, is still unknown?

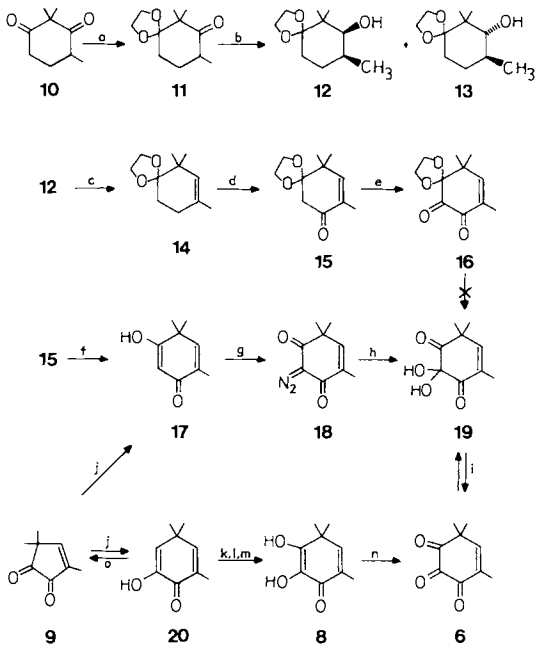
(3) As a *vic*-triketone, **4** could in principle undergo redox disproportionation.[5] As applied to the model compound **6**, this means first a benzilic acid rearrangement and then the decarboxylation to give the acyloin **7**, followed by a redox reaction with the excess **6** still present to give the *aci*-reductone **8** and the diketone **9**. The carotinoid terminal group of **2** could thus be formed via a compound of type **9** by enantioselective reduction. This would represent an alternative to formation from **5**.



Scheme 2. Possible course of redox disproportionation of the triketone **6**.

Herein we report the first synthesis of a *vic*-cyclohexenetrione, **6**, and describe some of its properties.

The synthesis of **6** started from the diketone **10**,[6a] since this starting compound should also allow the later incorporation of a polyene chain. The steps of the synthesis are shown in Scheme 3: Compound **10** was subjected to acetal formation at position 1 to give **11** (75%), which was then reduced with lithium aluminum hydride in THF. The isomeric mixture **12/13** (3.3 : 1) was formed in 85% yield. The isomer **13** separated out as a crystalline solid and could be isolated. Alcohol **12** can be dehydrated to give **14** (50%) with phosphorus oxychloride. Oxidation of **14** to **15** was achieved with Collins' reagent (40%). Treatment of **15** with SeO_2 affords the acetal-protected triketone **16** in 30% yield. Transformation of **16** to the hydrate **19** has not been accomplished so far. Attempts to remove the acetal group of **16** with mineral acid–THF mixtures resulted in the isolation of up to 80% unchanged acetal. Removal of the acetal group of **15** led to the enolized 1,3-diketone **17**[6b] (85%), which, in chloroform, exists in tautomeric equilibrium between a diketo form and two enol structures. Diazo group transfer afforded the diazoketone **18** (50%). Treatment with *tert*-butylhypochlorite in acetonitrile/water (11 : 1) resulted in formation of the triketone hydrate **19**. Dehydration of **19** by sublimation can be accomplished at 50°C/0.001 torr; triketone **6** was obtained as sticky, deep red crystals (40–50%), which undergo immediate decomposition upon exposure to air to form the hydrate **19**. The structure of **19** was established from the ^{13}C-NMR spectrum and shows that the attack of the nucleophile occurred at the middle carbonyl carbon atom of **6**.



Scheme 3. Synthesis of **6**. Reagents, reaction conditions, and yields: a) 1.5 equiv. ethylene glycol, 1.2 equiv. $HC(OEt)_3$, *p*-TosOH (catalyst), 20°C, 45 min, 75%. b) 0.5 equiv. $LiAlH_4$, THF, 20°C, 4 h, 85%. c) 1.6 equiv. $POCl_3$, pyridine, 20°C, 4 h, 50%. d) 20 equiv. $CrO_3 \cdot 2$pyridine, CH_2Cl_2, 20°C, 50 h, 40%. e) 1.0 equiv. SeO_2, glacial acetic acid, reflux, 3 h, 30%. f) 15% H_2SO_4, 20°C, 4 h, 85%. g) 1.0 equiv. *p*-$TosN_3$, 1.0 equiv. Et_3N, Et_2O/EtOH (1/1), 20°C, 5 h, 50%. h) 1.0 equiv. *t*BuOCl, CH_3CN/H_2O (11/1), 0°C, 20 min, 90%. i) 50°C, 0.001 torr, 40–50%. j) Diazomethane in ether (2 equiv. CH_2N_2)/4% KOH (1.4/1), **9** was added in portions, 20°C, 45 min, 75%. k) 1.3 equiv. Me_3SiCl, 1.0 equiv. pyridine, benzene, 20°C, 3.5 h. l) 1.6 equiv. *m*-chloroperbenzoic acid, *n*-hexane, 20°C, 4 h. m) MeOH, HCl (catalyst), 20°C, 4 h, 45% based on **20**. n) 1.0 equiv. DDQ, benzene, 20°C, 3.5 h. o) 2.0 equiv. SeO_2, glacial acetic acid, reflux, 3.5 h, 20%.

Compound **6** can also be prepared in two ways from the known cyclopentenedione **9**.[7] One of the routes converges with the route described above at **17**, the other utilizes the second ring-expansion product **20**. Compound **9** reacts with diazomethane[8] to afford a mixture of **17** and **20**[9] (2 : 1) in 75% yield. Separation of the two isomers is possible owing to their differing acidities: extraction of the so-

lution of **17/20** in ether with Na_2CO_3 removes **17**. Silylation, epoxidation, and ring opening of **20** gives the *aci*-reductone **8** (45%). Treatment of **8** with dichlorodicyano-*p*-benzoquinone (DDQ) results in formation of slightly impure **6**,[10] which, however, is suitable for further reactions (e.g., for quinoxaline syntheses[11]).

Triketone hydrate **19** does not show the reaction behavior expected for ring contraction accompanied by redox processes[5] as shown in Scheme 2. Compounds **8** and **9** are formed neither thermally nor in alkaline or acidic medium from **19**; only unidentified decomposition products are obtained. On the other hand, ring contraction of **20** to give **9** (20%) is observed upon heating **20** with selenium dioxide in acetic acid. Presumably, **20** undergoes initial oxidation to **6**, which, after ring contraction to **7**, is finally dehydrogenated by selenium dioxide to give **9**. These observations lead to the conclusion that the spontaneous redox disproportionation (i.e., ring contraction and redox behavior according to Scheme 2) plays no or at most only a minor role in the reaction behavior of triketones of structure type **6**. Because of the lability and ready decomposition of **6**, it is unlikely that species **4** exists for any great length of time as a free, achiral intermediate. The suggestion of actinioerythrol formation proposed in Ref. [4] and mentioned at the beginning is a plausible alternative to the route of formation via the free triketone. Besides an attack of the nucleophile as shown in Scheme 1, the attack at the middle carbonyl carbon atom should be considered, in analogy to the hydrate formation (**19**).

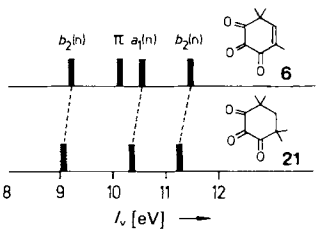


Fig. 1. Comparison of the vertical *n*-ionization energies I_v (He(Iα) PE spectrum) of **6** and **21**. The symmetry notation refers to the C_{2v} symmetry of the $(CO)_3$ structural unit.

In addition to the excitation energies and chemical shifts (Table 1), the ionization energies of **6** are also of interest. They allow conclusions to be drawn concerning the lone-pair splitting (Fig. 1). For saturated six-membered-ring *vic*-triketones, the third lone-pair ionization is often not clearly distinguishable from σ-orbital ionizations, which lie in the same energy region. This is the case for the saturated triketone **21**:[21] A decision as to whether the third n-ionization should be assigned to the band at 11.35 or to that at 12.12 eV in the photoelectron spectrum has not been possible so far. A comparison with the He(Iα) PE spectrum of **6** removes this uncertainty, since, owing to the π bond in **6**, its σ-orbital ionizations lie at higher energies than those of **21**. Only the ionization of **21** at 11.35 eV can be correlated with one of the three lone-pair ionizations of **6**. In this assignment, all three n bands of **21** are thus observed as expected at 0.1–0.2 eV lower ionization energies than those of the corresponding bands of **6**. This is due to the inductive effect of the double bond.[13]

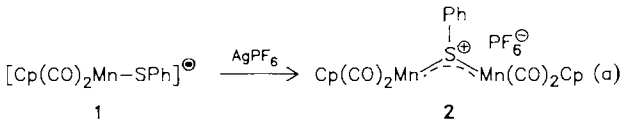
$[\{Cp(CO)_2Mn\}_2SPh]^{\oplus}$, the First Sulfur Analogue of a Phosphanediyl ("Phosphinidene") Complex**

By *Horst Braunwarth, Gottfried Huttner,** and *Laszlo Zsolnai*

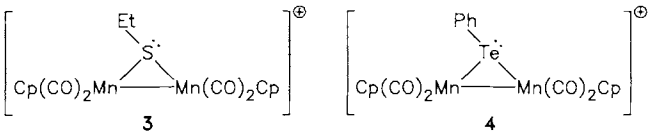
Dedicated to Professor Helmut Dörfel on the occasion of his 60th birthday

The chemistry of phosphanediyl complexes[***] $[(L_nM)_2PR]$ (L_n = 16-electron complex fragment, R = monovalent group) has developed into a broad area of research since the synthesis of the first such complex $[\{Cp(CO)_2Mn\}_2PPh]$ **5**.[1] The trigonal-planar coordination of the main-group element P by the two L_nM fragments and the monovalent group, which is characteristic of phosphanediyl complexes, has also been realized for the compounds $[(L_nM)_2XR]$ (X = As, Sb, Bi) involving the heavier elements homologous to phosphorus.[2] However, transfer of this characteristic bonding principle to the $RS^{\oplus}$ fragment as ligand, which is isoelectronic to RP, has not been accomplished so far. Herein we report on the synthesis of $[\{Cp(CO)_2Mn\}_2SPh]PF_6$ **2**, whose complex cation corresponds to that of the isoelectronic phosphanediyl complex **5** in structure and properties.



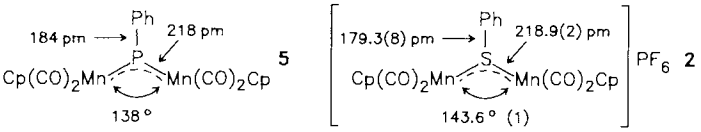
1 2

The mononuclear radical complex **1**[3] can be reversibly oxidized and reduced electrochemically.[4] Its oxidation with $AgPF_6$, however, results in formation of the binuclear compound **2** [Eq. (a)]. Whereas complex **3**, an analogue of



3 4

2 reported by *R. J. Haines* et al.,[5] and the tellurium analogue of **2**,[6] complex **4**, have an Mn–Mn bond and thus display pyramidal coordination around S and Te, respectively, the sulfur atom in **2** is coordinated in a trigonal-planar fashion.[7] The bonding in **2** thus corresponds in all respects to that in the isoelectronic **5**[1,2] (Scheme 1).



Scheme 1. Comparison of the structures of **2** and **5**.

Accordingly, **2** shows the UV/VIS spectrum characteristic of "diyl" complexes like **5**,[1,2,8] which features an intense long-wavelength absorption at 17860 cm^{-1} (Fig. 1).

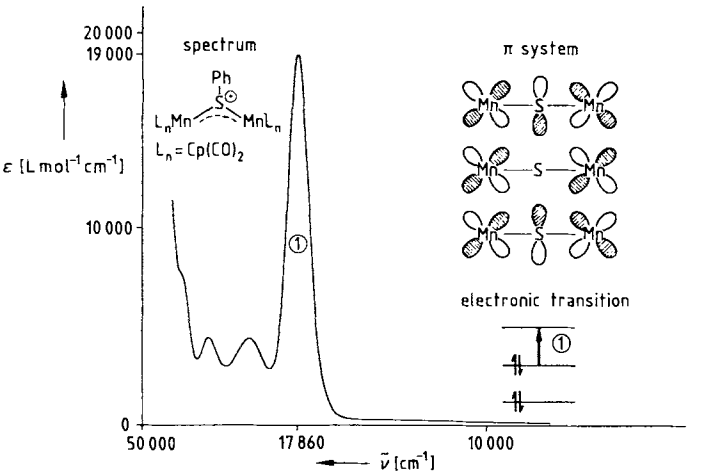


Fig. 1. UV/VIS spectrum of **2** (20 °C, CH_2Cl_2). The intense band at 17860 cm^{-1} is due to a transition in the three-center 4π-electron system Mn=S=Mn.

The fact that compound **2** crystallizes in the open form (Mn=S=Mn), whereas **3** crystallizes in the valence-isomeric closed form (Mn–S–Mn), although the two compounds differ only in the substituents R and S and in the counterion ($ClO_4^{\ominus}$ for **3**), shows that only a small difference in energy exists between the two forms. The valence isomerism between the allyl anion-analogous open form[2,8] and the cyclopropyl anion-analogous closed form in the fifth main group,[2,10] as inferred from trapping reactions for stibanediyl complexes, $[(L_nM)_2SbR]$[2,9] was only demonstrated there in one case.[11] The existence of **2** and **3** leads to the expectation that for the complexes $[(L_nM)_2YR]^{\oplus}$, Y = S, Se, Te, the position of the valence-isomeric equilibrium should be easier to control.

Experimental Procedure

2: **1** (100 mg, 0.35 mmol) (prepared analogously to the procedure described in [3]) was dissolved in toluene (10 mL) under N_2 and the stirred solution was treated with $AgPF_6$ (88 mg, 0.35 mmol). The color turned immediately from blue to violet. After 20 min of stirring, the toluene was removed under high vacuum; the residue was dissolved in 20 mL of CH_2Cl_2 and the resulting solution was filtered under N_2 through 2 cm of silanated silica gel. Crystallization at −30 °C afforded analytically pure **2**. Yield: 27 mg (25% based on Mn).—IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2051 s, 2015 s, 1986 s, 1935 w; ^{1}H-NMR (293 K, CD_2Cl_2): δ = 5.29 (s, 10H), 6.95–7.55 (m, 5H).

[7] X-ray structure analysis of **2**: $a=678.0(2)$, $b=1316.9(6)$, $c=1303.4(6)$ pm, $\beta=95.16(3)°$, space group $P2_1/m$, $Z=2$. In the space group $P2_1/m$, the $PF_6^\ominus$ ion and the Cp rings are disordered over two rotational positions. In the subgroup $P2_1$, the disorder of the $PF_6^\ominus$ ion remains. The refinement in the space group $P2_1/m$ [EXTL or SHELXTL program system, Sheldrick (Göttingen), 1984] led to the best result ($R=0.074$, $R_w=0.044$). The phenyl ring lies in the crystallographic mirror plane, which makes both $Cp(CO)_2Mn$ fragments symmetry equivalent; i.e., as for phosphanediyl complexes, it is rotated out of the plane of the M=X=M three-center 4π-electron system. Synthesis and Structure of (ET)[Ni{SC(CN)=C(CN)S}$_2$], a Radical Cation Salt of Bis(ethylenedithio)tetrathiafulvalene**

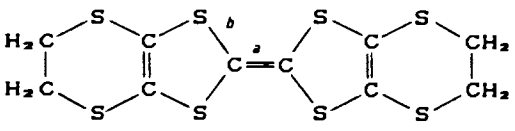
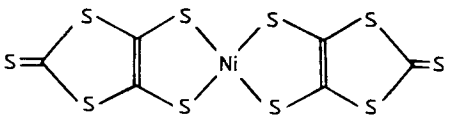
By *Walter Reith,* Kurt Polborn,* and *Eberhard Amberger*

The development of inorganic materials having dramatically higher transition temperatures T_c[1] has reawakened hope in increasing the transition temperatures of organic metals as well. Since the discovery of the first organic superconductor $(TMTSF)_2(PF_6)$[2] (TMTSF = tetramethyltetraselenafulvalene) in 1980, numerous radical cation salts of tetrathiafulvalene (TTF) derivatives have been synthesized.[3] The most promising donor at present is bis(ethylenedithio)tetrathiafulvalene (ET), also referred to as BEDT-TTF, whose salts are often superconducting under normal pressure. These salts include the organic superconductor having the highest transition temperature so far reported,[***] $(ET)_2(I_3)$ with $T_c=8$ K.[4,5] The compounds $(ET)_y(X)_z$ are interesting owing to their broad range of structures and their differing ET charge states.[6] Not only can the y/z ratio vary for the same X—for $X=[ReO_4]^\ominus$, $y=1, 2, 3$ and $z=1, 2$;[6] for $X=[TlCl_4]^\ominus$, $y=1, 2$ and $z=1$[7]—but, in addition, different structures occur for the same y/z ratio: α, β, γ, δ, t, z phases of $(ET)_2(I_3)$.[5,8]

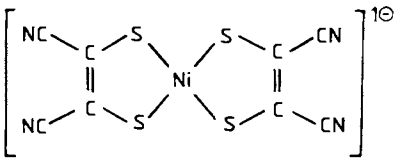


ET

These findings may be explained by several factors. Because of the ethylene moieties, which do not lie in the plane of the molecule, the ET molecules do not stack in a "face over face" fashion, as has been observed for other organic metals containing planar donors and/or acceptors. The "side to side" arrangement typical of ET molecules leads to the formation of two-dimensional layers separated by anions. The resulting sulfur–sulfur contacts are important for the conductivity. So far, ET salts containing small, symmetric inorganic anions have been prepared almost exclusively. A stronger involvement of the anions in the mechanism of conductivity would be desirable and might lead to an increase in the dimensionality. A very promising approach leading to the synthesis of new metals and superconductors is the use of metal complexes as anions. The compound $(TTF)[Ni(dmit)_2]_2$, for example, becomes superconducting at 1.7 kbar and 1.62 K.[9]



$[Ni(dmit)_2]$



$[Ni(mnt)_2]$

Herein we describe the synthesis and structure of $(ET)[Ni(mnt)_2]$ (mnt = malodinitriledithiolate). Black platelets of $(ET)[Ni(mnt)_2]$ having a metallic luster were obtained from a solution of ET and $(n-Bu_4N)[Ni(mnt)_2]$ in 1,1,2-trichloroethane by galvanostatic oxidation. The structure was determined by X-ray analysis (Fig. 1). Refinement of the structure with incorporation of the hydrogen atoms gave an R value of 0.024.[18]

The angle between the molecular plane of $ET^{\odot\oplus}$ and $[Ni(mnt)_2]^\ominus$ is 49.77(3)°. Four sulfur–sulfur contacts exist between each two Et radical cations; these S–S distances are significantly smaller than the sum of the van der Waals radii (3.70 Å) and the distances from the sulfur atom in the six-membered ring to that in the five-membered ring (3.524 Å) and to that in the six-membered ring (3.528 Å) are nearly identical (see Fig. 1).

The S–S distances between each two, nearly planar $[Ni(mnt)_2]^\ominus$ ions (3.700 Å) correspond exactly to the sum of the van der Waals radii. There are no sulfur–sulfur contacts between the donor and acceptor molecules. A comparison of ET ions in different oxidation states shows that

[**] We thank *Ralf Sieburger*, Sektion Physik der Universität München, for the investigations of superconductivity.

[***] Note added in proof by the editorial staff: A transition temperature of 10.4 K for $(ET)_2Cu(NCS)_2$ was reported in January: H. Urayama, H. Yamochi, G. Saito, K. Nozawa, T. Sugano, M. Kinoshita, S. Sato, K. Oshima, A. Kawamoto, J. Tanaka, *Chem. Lett. 1988*, 55; see also H. Urayama, H. Yamochi, G. Saito, S. Sato, A. Kawamoto, J. Tanaka, T. Mori, Y. Maruyama, H. Inokuchi, *ibid. 1988*, 463, and K. D. Carson, U. Geiser, A. M. Kini, H. H. Wang, L. K. Montgomery, W. K. Kwok, M. A. Beno, J. M. Williams, C. S. Cariss, G. W. Crabtree, M.-H. Whangbo, M. Evain, *Inorg. Chem. 27* (1988) 965.

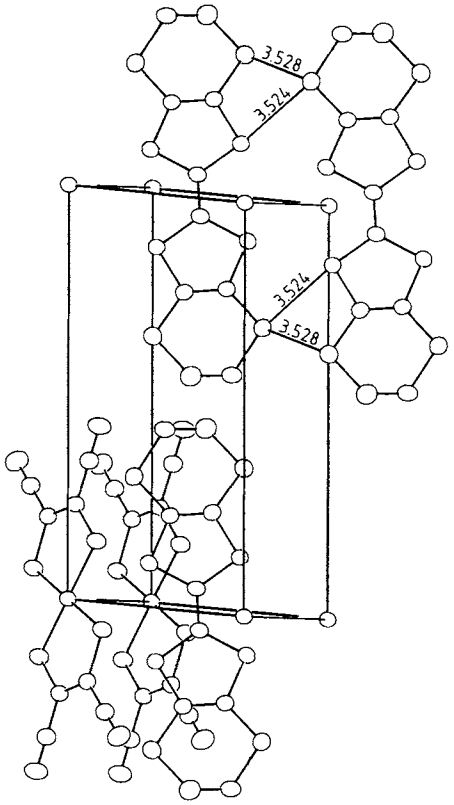

Fig. 1. *A-C* view (rotated by 70° around *B*) of (ET)[Ni(mnt)$_2$]. For the sake of clarity, some of the molecules were omitted. Both the cations and the anions are located on centers of symmetry.

the central C=C bond *a* becomes increasingly longer and bond *b* between these C atoms and the S atoms of the five-membered ring increasingly shorter with increasing oxidation. The ratio *b/a* is plotted against the charge of the cation for several ET compounds in Figure 2. In neutral ET,

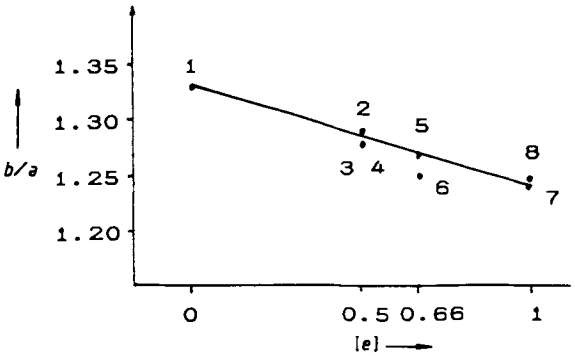

Fig. 2. Ratio of the bond lengths *b* and *a* as a function of the charge |*e*| of ET. For *b*, the mean values of the respective bonds were used. The numbers correspond to the following compounds: 1 = ET [12], 2 = (ET)$_2$[IAuBr] [13], 3 = (ET)$_2$(BrICl) [14], 4 = (ET)$_2$(IBr$_2$) [15], 5 = (ET)$_3$(NO$_3$)$_2$ [16], 6 = α-[(ET)$_3$(ReO$_4$)$_2$] [17], 7 = (ET)[TlCl$_4$] [7], 8 = (ET)[Ni(mnt)$_2$].

bond *a* is 1.32 Å long; in ET with the charges +0.5, +0.66, and +1, it is ca. 1.36, 1.37, and 1.38 Å, respectively. The corresponding values for the four C-S bonds are 1.76, 1.74, 1.73, and 1.72 Å, respectively (averages). With increasing oxidation of the donor ET, the electron density in the central C=C bond decreases.

Experimental Procedure

ET [10] and (*n*Bu$_4$N)[Ni(mnt)$_2$] [11] were prepared as described. Electrocrystallization: Neutral ET (2.34 mmol L^{-1}) and (*n*Bu$_4$N)[Ni(mnt)$_2$] (0.56 mmol L^{-1}) were oxidized galvanostatically in various solvents using a current density of 1 μA cm^{-2}. Black, rhomboid-shaped crystals, whose surfaces have a metallic luster (max. 2 × 1 × 0.5 mm^3), were obtained at a platinum electrode within several days from trichloroethane, acetonitrile, tetrahydrofuran, and dichloromethane. The crystals from trichloroethane were of the best quality. Potentiostatic oxidation ($U \approx 1$–1.5 V) in the same solvent afforded only black, microcrystalline coatings on the electrodes. (ET)[Ni(mnt)$_2$] crystallizes in the triclinic space group *P*-1 with $a = 6.273(1)$, $b = 7.833(1)$, $c = 13.127(2)$ Å, $\alpha = 96.170(15)$, $\beta = 92.591(18)$, $\gamma = 96.218(16)°$, $V = 636.4$ Å^3. Superconductivity was determined by measurement of alternating field susceptibility.

[18] Single crystal ca. 0.3 × 0.15 × 0.2 mm^3. Four-circle diffractometer CAD4, Enraf-Nonius, 28°C, Mo$_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), graphite monochromator. Data collection: $4° < 2\theta < 50°$, $\pm h$, $\pm k$, $+l$, $\omega - 2\theta$ scan, scan width: $0.90° + 0.35 \tan\theta$. Maximum measuring time: 30 s. 2133 measured reflections, 1942 of which were unique and 1815 with $I > 3\sigma(I)$, $R = 0.025$, $R_w = 0.024$, $w = 1/\sigma(F)^2$, 164 parameters. Three intensity control reflections were measured every 3600 s, empirical absorption correction with ψ scans of six reflections ($\mu = 17.32$ cm^{-1}). Solution by Patterson methods. Full-matrix refinement, hydrogen atoms "riding," all non-hydrogen atoms refined anisotropically. Residual peaks: +0.45 and −0.40 *e*/Å. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-52771, the names of the authors, and the journal citation.

Multidecker Metallocenophanes**

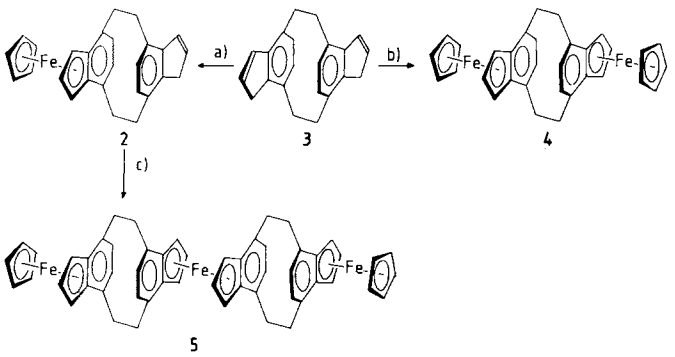
By *Henning Hopf** and *Jörg Dannheim*

Ferrocene and [2.2]paracyclophane are the most thoroughly investigated double-layer molecules in organometallic[2] and organic chemistry.[3] We suggested earlier[1] that these two prototypes might be linked with each other so as to form multilayer systems having the general structure **1**, in which inorganic and organic structural elements alternate.

–[2.2]phane–ferrocene–[2.2]phane–ferrocene–[2.2]phane– **1**

Oligomers and polymers of this type should have interesting structural, spectroscopic, and chemical properties; their electrochemical behavior is of particular interest. In the meantime, several authors have pointed out that multinuclear complexes derived from ferrocene may function as "electron reservoirs," thereby storing or transferring electrons either stoichiometrically or catalytically.[4]

We consider the carbanions derived from *anti*-[2.2]indenophane **3** to be particularly well-suited as organic structural components for the systems **1**. On the one hand, the benzene rings are separated from each other by only 300 pm, thus guaranteeing the transmission of electronic effects.[3,5] On the other, the *anti* arrangement of the complex-forming cyclopentadienyl rings assures that they do not engage in intramolecular complexation, which would prevent chain formation as shown in **1**.



Scheme 1. Synthesis of **2**, **4**, and **5**. a) 1 equiv. CH_3Li, C_5H_5Li, $FeCl_2 \cdot 2THF$. b) 2 equiv. CH_3Li, C_5H_5Li, $FeCl_2 \cdot 2THF$. c) 1 equiv. CH_3Li, $FeCl_2 \cdot 2THF$.

Herein we describe the first complexation experiments involving the carbanions **3**, the synthesis of which was recently reported.[5]

When the monoanion prepared by treatment of **3** with one equivalent of methyllithium in tetrahydrofuran was allowed to react at $-30°C$ with lithium cyclopentadienide in excess and iron(II) chloride·tetrahydrofuran, the monoiron complex **2** was obtained in yields of up to 85% (Scheme 1). Crystallization from petroleum ether afforded **2** as reddish violet needles (m.p. = 215 °C). Pure **2** is indefinitely stable, but, in solution, it is sensitive toward oxidation. Its reactivity toward oxygen increases with increasing solvent polarity. Treatment of **3** with two equivalents of methyllithium (tetrahydrofuran, $-78°C$) transforms it into the dianion,[5] which may be trapped as the diiron complex **4** (63%, reddish violet needles from benzene, dec. above 160 °C) by reaction at $-20°C$ with lithium cyclopentadienide and iron(II) chloride·tetrahydrofuran. Finally, the triferrocenophane **5**—the first "oligomeric section" of the general structure **1**—is obtained when the stable anion, prepared by reaction of **2** with methyllithium in tetrahydrofuran, is dimerized by reaction at $-20°C$ with iron(II) chloride·tetrahydrofuran (60%). The complex affords brownish red rhombic crystals (dec. above 160 °C) from benzene. In crystalline form the complex is stable, but it undergoes oxidation within a few hours in solution upon exposure to air.

The proposed structures for the three new complexes are based on the spectroscopic data. The ^1H-NMR signals of the coordinated cyclopentadienyl rings are particularly revealing (400 MHz, $CDCl_3$, int. TMS; **2**: $\delta = 3.38$ (s, 5H), 3.97 (t, 1H, $J = 2.5$ Hz), 4.35 (d, 2H); **4**: $\delta = 3.33$ (s, 10H), 3.90 (t, 2H, $J = 2.5$ Hz), 4.35 (d, 4H); **5**: $\delta = 3.23$ (s, 10H), 3.53 (ps-s, 6H; "inner" ferrocene moiety), 3.82 (t, 2H, $J = 2.5$ Hz), 4.24 (d, 4H). The structural assignments were unequivocally confirmed for **4** and **5** by X-ray structure analyses,[6] which will be reported together with further metal complexes of **3** and its isomers in a full article.

[1,2,4]Triazolo[1,2-*a*][1,2,4]triazole-1,3,5,7(2*H*,6*H*)-tetrone (Urazourazole), Synthesis and Structure**

By *Edgar Nachbaur,** *Gottfried Faleschini, Ferdinand Belaj,* and *Rudolf Janoschek*

Both the parent compound of the 1,2,4-triazolidine-3,5-diones, urazole **1**, as well as that of the 1,2,4-triazole-3,5(4*H*)-diones,[1] compound **2**, have been known for quite a long time. So far, however, no evidence has been reported for the existence of [1,2,4]triazolo]1,2-*a*][1,2,4]triazole-1,3,5,7(2*H*,6*H*)-tetrone **3** ("urazourazole") as a further parent compound, although the first member of this

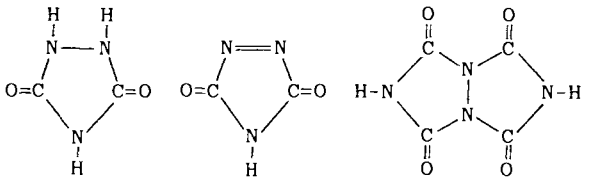
class of compounds, namely the 2,6-diphenyl derivative, was prepared already in 1912.[2]



1 2 3

2,6-Dialkyl- or diarylurazourazoles are obtained in good yield by thermolysis of the corresponding 4-substituted 1,2,4-triazole-3,5(4*H*)-diones with loss of N_2.[3] This method fails, however, in the case of the unsubstituted compound **2**, which is stable only in dilute solution at low temperatures.[1b] Otherwise, depending on the conditions, **2** decomposes more or less rapidly to yield N_2, CO, and HNCO,[1a] thus preventing its isolation in pure form.

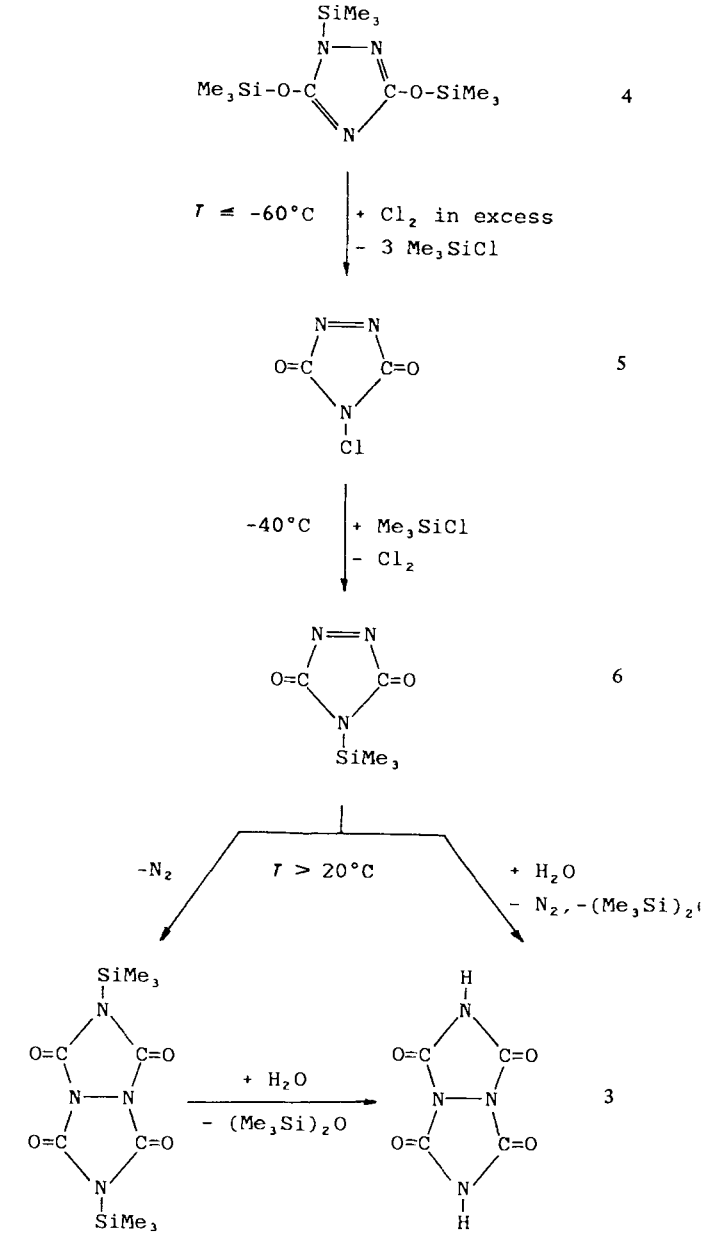
We have now succeeded in synthesizing **3** starting from persilylated urazole **4**, the structure of which we have been able to elucidate quite recently[4] (Scheme 1).

In the first reaction step all three trimethylsilyl groups are removed from **4** by low-temperature chlorination, and 4-chloro-1,2,4-triazole-3,5(4*H*)-dione **5** is formed. Owing to its lability, **5** could not be isolated, but its formation as an intermediate is supported by the following observation: if the excess of Cl_2 and a part of the solvent is removed at -40 °C by suction under vacuum, dark-red crystals separate, which on further heating react with Me_3SiCl present in the reaction mixture with evolution of Cl_2 to form red 4-trimethylsilyl-1,2,4-triazole-3,5(4*H*)-dione **6**. With the exclusion of water and light **6** is stable at temperatures around 0 °C pure and in solution and could be characterized spectroscopically; the UV/VIS and IR spectroscopic results are consistent with the proposed structure.

The formation of the colorless dideaza dimer **7** in the third reaction step is strongly exothermic and is accelerated still further by addition of donor solvents (dimethylformamide (DMF), pyridine) or by light. This finding is consistent with observations in the thermolysis of the 4-phenyl derivative of **2**.[3a] The hydrolysis of **7** to **3** on standing in a moist atmosphere is quantitative. The highest yield (67%) of **3** is achieved when **7** is not isolated but **6** allowed to stand for at least 48 hours at room temperature in a moist atmosphere.

3 is a colorless substance, crystallizing from water as long, fine needles, and decomposes at 340 °C, without any signs of melting, to yield N_2, CO, and HNCO. The alkalimetrically determined ionization constants of the dibasic acid **3**, $K_1 = 4.0 \times 10^{-4}$ and $K_2 = 1.0 \times 10^{-6}$ are unexpectedly high and indicate the compound as being a much stronger acid than urazole ($K_1 = 5.6 \times 10^{-7}$)[5] and cyanuric acid ($K_1 = 3.1 \times 10^{-7}$).[6]

The X-ray structure of **3** (Fig. 1)[7] shows that the two five-membered rings are significantly non-planar—the deviations of the ring atoms from the best plane being up to 0.043(5) Å—and in contrast to the planar 1,5-diazabicyclo[3.3.0]octane-2,4,6,8-tetrone[8] **8** (2 CH_2 groups instead of the NH groups of **3**) form an angle of 156.0(1)°. In comparison to the derivatives of urazole, the N–N bond is contracted and the N–C–N′ angles are diminished, while the C–N′–C angles are enlarged.[9] Each molecule has two donor and two acceptor hydrogen bonds to neighboring molecules. Since only two facing C=O groups form hydrogen



bridges, the C_{2v} symmetry of the molecule is lowered to C_2. Remarkable are the three intermolecular O···C=O contacts with short O···C distances in the range from 2.790(2) to 2.920(2) Å.[10] These, together with the low hydrogen content, contribute to the high density.

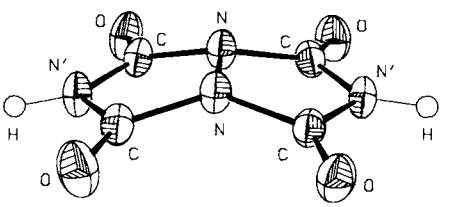


Fig. 1. Crystal structure of **3** (ORTEP), thermal ellipsoids at the 50% probability level (H atoms with arbitrary radii). Important bond lengths [Å] and angles [°] (standard deviations <0.002 Å and <0.1°, resp.): N-N 1.402, N-C 1.395–1.407, C-N′ 1.368–1.387, C-O 1.192–1.204; C-N-C 132.4–134.7, C-N-N 108.4–109.3, N-C-N′ 103.4–104.1, C-N′-C 114.2–114.3, N-C-O 126.0–127.5, N′-C-O 129.1–129.8.

Quantum chemical ab-initio calculations (SCF, 3-21G-basis set, experimental geometry), were carried out for **3** and the monoanion **3a**, as well as for **1** and its monoanion **1a**, in order to ascertain the reason for the markedly different acidities of the compounds **1** and **3**. The deprotonation energy of **1** was calculated to be 1573 kJ mol^{-1}, and that of **3** to be only 1452 kJ mol^{-1}. This result is understandable on the basis of population analyses according to *Mulliken*, which show a stronger delocalization of the additional electron in the bicyclic **3a** than in **1a**.

The question whether measured structural data (aplanarity of the bicyclic compound) are to be interpreted as molecular properties or must be attributed to packing effects in the crystal, could also be settled by quantum chemical calculations for **3**, the dianion **3b**,[11] and **8**. Comparison of a pyramidal and a planar environment for the nitrogen atom shows that planarity of the central R_2N–NR_2 fragment is more favorable for the molecules **3**, **3b**, and **8**: the relative stabilities for a planar R_2N–NR_2 fragment are +25.3 for **8** (folding angle as in **3**), +15.5 for **3**, and +5.9 kJ mol^{-1} for **3b**. Therefore the folding angles observed in **3** and **3b** in the crystalline state can be attributed to intermolecular interactions and to neighboring cations, respectively.

Experimental

6: A solution of **4** (30 g, 94.4 mmol) in CH_2Cl_2 (50 mL) was cooled to −60°C in the absence of moisture in a three-necked flask fitted with a cooled dropping funnel. 11 g (155.1 mmol) of chlorine (ca. 7 mL at −60°C) were condensed into the dropping funnel and added dropwise within 1 h to the solution of **4**, which turned deep red in color. All volatile components were then removed under vacuum and the temperature slowly raised to 0°C (great care must be taken here: vigorous evolution of Cl_2 takes place spontaneously at ca. −40°C); **6** separated out thereby in the form of red crystals. Yield: 14.4 g (89%). UV/VIS ($CHCl_3$): λ_{max} [nm] = 522 (s), 542 (s), 564 (s); IR (CCl_4): $\tilde{\nu}$(C–H) = 2960 (w), 2925 (w) cm^{-1}, $\tilde{\nu}$(C=O) = 1765 (vs) cm^{-1}, $\tilde{\nu}$(Me_3Si) = 1262 (vs), 850 (vs), 725 (m), 688 (m) cm^{-1}.

7: A solution of **6** (14.4 g, 84.1 mmol) in CH_2Cl_2 (50 mL) was treated with 5 mL of DMF and the mixture heated under reflux for 48 h. After removal of volatile components under vacuum, the pale yellow residue was sublimed at 150°C and 0.01 torr; pure **7** was obtained in the form of colorless needle-shaped crystals. M.p. 168°C: 4.6 g (34%). Correct elemental analysis.—IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2960 (w), 2910 (vw), 1780 (vs), 1430 (w), 1300 (vs), 1250 (s), 1160 (s), 1060 (s), 850 (vs), 780 (s), 765 (m); ^{29}Si-NMR ($CDCl_3$): δ = 7.69; ^{13}C-NMR ($CDCl_3$): δ = 147.5, −1.10.

3: 14.4 g (84.1 mmol) of **6** was allowed to stand for 48 h at room temperature in the presence of atmospheric moisture and then 24 h at 80°C in a dry box; the color of the substance changed from red to colorless. For purification, the crude product was recrystallized from 50 mL of water, whereby decomposition of **3** by hydrolysis could be essentially reduced by heating to not more than 80°C and rapidly cooling the filtrate to 0°C. Yield: 5.6 g (67%). Decomp. at 340°C. Correct elemental analysis.—IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3240 (vs), 2750 (sh), 1780 (vs), 1740 (s), 1480 (w), 1430 (s), 1360 (vs), 1180 (s), 1168 (s), 1133 (s), 945 (w), 745 (s); ^{13}C-NMR ([D_6]Me_2SO): δ = 159.79.

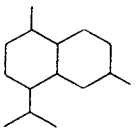
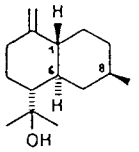
Stereoselective Synthesis of *trans*-Decalins via Intramolecular Ene Reactions; Synthesis of the Enantiomerically Pure Cadinane-Sesquiterpene Veticadinol**

By *Lutz F. Tietze,* Uwe Beifuss, Jochen Antel,* and *George M. Sheldrick*

The sesquiterpenes of the cadinane or cadalane series are widely distributed as plant constituents. They are found, inter alia, in vetiver oil, an important olfactory. The cadinanes contain 2,8-dimethyl-5-isopropyldecalin **1** as basic structural unit (numbering as in **2**). They are classified into four groups according to the type of annulation and the position of the isopropyl group: the true cadinanes (cadinane) and the bulgaranes with *trans*-fused rings, and the muurolanes and amorphanes with *cis*-fused rings.[1]



1



2

Few methods are as yet known for the stereoselective synthesis of both the *cis*- and the *trans*-fused ring systems of the cadinanes.[2] In our studies on the synthesis of terpenoid natural products we developed a novel stereoselective entry to the *trans*-coupled decalin system of the cadinanes which enabled us to synthesize the sesquiterpene veticadinol **2**.[3] From the retrosynthetic analysis it followed that it should be possible to synthesize the decalin system of **2** by two intramolecular cyclizations. The first cyclization is the intramolecular ene reaction of the alkylidenemalonate **5**,[5] which proceeds with high non-induced and induced diastereoselectivity,[4] and the second is the cyclization of **11** (Scheme 1). **5** already cyclizes in 92% yield at −78°C in

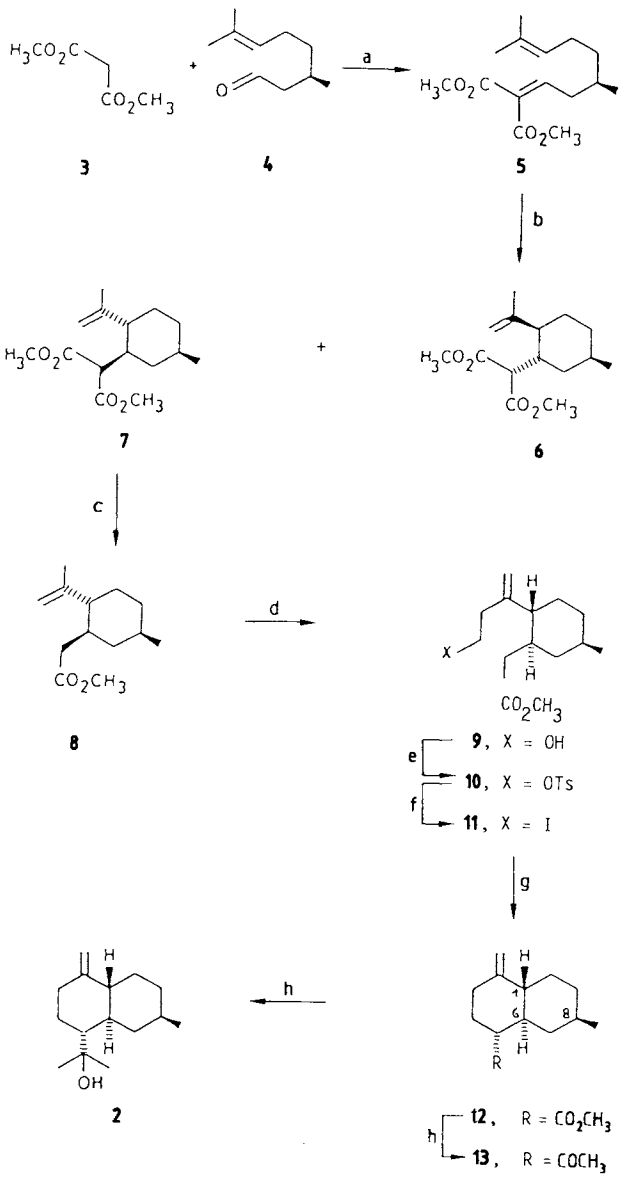
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *E. J. Brunke* and Dr. *K. G. Fahlbusch*, Dragoco Holzminden, for kindly supplying us with samples of citronellal and vetiver oil, and Dr. *B. Mauerer*, Firmenich, Geneva (Switzerland) for a gift of vetiver oil.

the presence of $FeCl_3$ on basic aluminum oxide[6] to give the *trans*-substituted cyclohexanes **7** and **6** in the ratio 98.8 : 1.2 (GC; *i-de* 97.6%, *ni-de* > 99%). The $FeCl_3/Al_2O_3$ catalyst newly introduced by us for the ene reaction has great advantages over other Lewis acids in that it is easy to handle, can be used in catalytic amounts and affords very good selectivities and high yields. The absence of almost any side products in the reaction with $FeCl_3/Al_2O_3$ is presumably due in part to the fact that this catalyst acts as a proton scavanger, similarly to alkylaluminum halides.[7]



Scheme 1. a) Piperidinium acetate, CH_2Cl_2, 20°C/1 h, 82%. b) $FeCl_3/Al_2O_3$, −78°C/2 h, 20°C/2 h, 92%. c) H_2O, NaCl, Me_2SO, 150°C/4 h, 92%. d) $(CH_2O)_n$, $(CH_3)_2AlCl$, CH_2Cl_2, 0°C, 20°C/4 h, 81%. e) TosCl, pyridine, 0°C/1 h, 5°C/12 h, 93%. f) NaI, acetone, 20°C/12 h, 95%. g) LDA, THF, −78°C, 20°C/2 h, 92%. h) CH_3MgI, Et_2O, 20°C/12 h, 37.5°C/12 h, 12% **13**, 77% **2**, chromatography on silica gel with ethyl acetate/hexane = 1/1. R_f(**13**) = 0.44, R_f(**2**) = 0.10.

The alkylidenemalonate **5** needed for the ene reaction is accessible in 82% yield by condensation of (*R*)-citronellal **4** with **3**.[5] The demethoxycarbonylation[8] of **7** which follows the intramolecular ene reaction furnishes the monoester **8** in 92% yield, which undergoes a Prinz reaction[7] with paraformaldehyde to give the alcohol **9** (81%). For the intramolecular alkylating cyclization,[9] **9** is converted via the tosylate **10** into the iodide **11**, which reacts with lithium diisopropylamide (LDA) in tetrahydrofuran at −78°C via an intermediary ester enolate to give the decalin derivative **12** in 92% yield. The assignment of the structure of **12** follows from the characteristic resonance at $\delta = 0.87$ for an equatorially arranged methyl group, and from the large coupling constants $^3J_{6\text{-H},7\text{-H}} = {}^3J_{7\text{-H},8\text{-H}} = 12$ Hz, indicating *trans* coupling of the rings. The equatorial position of the methoxycarbonyl group is confirmed by the coupling pattern of the signals for 5-H_{ax} at $\delta = 2.24$ with coupling constants $J = 12.3$, 11, and 3.5 Hz.[10] Reaction of **12** with methylmagnesium iodide affords the desired enantiomerically pure veticadinol **2** in 77% yield. In addition, the methyl ketone **13** is obtained in 12% yield in an incomplete reaction, despite the use of a large excess of methylmagnesium iodide. Since the citronellal used for the synthesis is obtainable in both the *R*- as well as *S*-configuration, the enantiomer of **2** can also be prepared in the same way. An X-ray structure analysis was carried out in order to establish unequivocally the relative configuration of **2**.[11]

The synthetic sequence presented here not only enabled the stereoselective preparation of the interesting olfactory veticadinol **2** for the first time,[12] but also provides a general entry to sesquiterpenoid compounds of the decalin type. Moreover, by variation of the aldehyde employed for the Knoevenagel condensation in (a) and of the Grignard reagent in (h), a large variety of compounds of interest for the perfumery industry can be prepared.

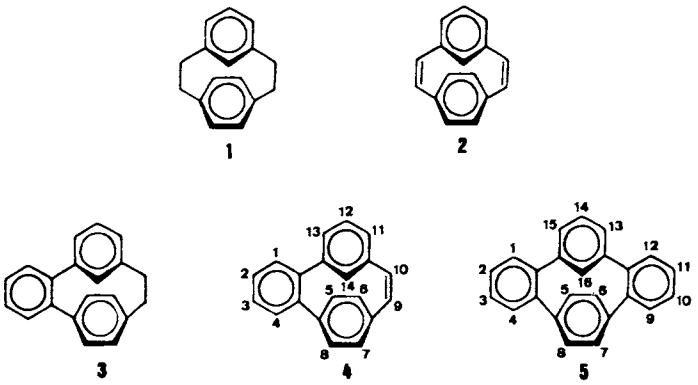
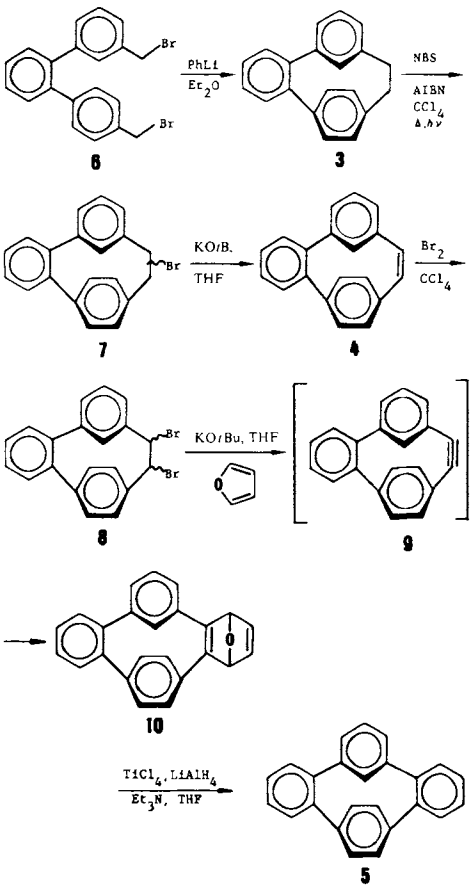
Synthesis and Conformational Behavior of Dibenzo[2.2]metaparacyclophanediene**

By *Timothy Wong, Siu Shing Cheung,* and *Henry N. C. Wong**

The preparation of [2.2]metaparacyclophane **1** was reported more than two decades ago by *Cram* et al.[2,3] Variable temperature NMR studies on **1**[4] showed that, due to conformational flipping of the molecule, the signals of the *p*-phenylene protons of **1** coalesced at 146 °C; this corresponds to a $\Delta G_c^{\neq}$ of 87 kJ/mol.[4] On the other hand, [2.2]metaparacyclophane-1,9-diene **2** showed a coalescence temperature $T_c = -96$ °C, thus resulting in $\Delta G_c^{\neq} = 35$ kJ/mol.[5] It was of interest to investigate the conformational behavior[6] of compounds **3**, **4**, and **5**, which are benzoannelated derivatives of **1** and **2**. We report here on the synthesis of **4** and **5** and on the results of variable temperature NMR studies on these compounds.



Benzo[2.2]metaparacyclophane **3** was first synthesized by *Vögtle* et al. via several steps starting from 3,4''-bis(bromomethyl)-1,1':2',1''-terphenyl **6**.[7] In the case of **3** $T_c = 116$ °C and $\Delta G_c^{\neq} = 75$ kJ/mol.[7] We were able to prepare compound **3** in one step: phenyllithium-induced coupling of **6**[7,8] resulted in the isolation of **3** in 44% yield. The physical and spectroscopic data of **3** were in accord with the literature data.[7] Bromination[8] of **3** with *N*-bromosuccinimide (NBS) in CCl_4 in the presence of azoisobutyronitrile (AIBN) furnished the monobromide **7** in 43% yield as a mixture of several isomers (m.p. 119–123 °C). The unpurified isomeric mixture was dehydrobrominated with KO*t*Bu, giving benzo[2.2]metaparacyclophan-9-ene **4** in 86% yield as the only isolable product.[8] Compound **4** forms colorless crystals (from hexane), which melt at 90–91 °C.[9]



Treatment of **4** with bromine afforded an isomeric mixture of dibromides **8** in 90% yield [MS: *m/z* 412 ($M^{\oplus}$), 414 ($M^{\oplus}+2$), 416 ($M^{\oplus}+4$)]. The dibromides **8** were not separated, but allowed to undergo direct KO*t*Bu dehydrobromination in the presence of furan. The reaction leading to the isomeric epoxides **10** (isolated in 53% yield) presumably proceeds via the species **9**[1,10,11] containing a CC triple bond. The mixture of isomers **10** [m.p. > 300 °C, MS: *m/z* 320 ($M^{\oplus}$)] was not separated, but directly deoxygenated with $TiCl_4$–$LiAlH_4$–Et_3N in THF,[12] to give the title compound dibenzo[2.2]metaparacyclophanediene **5** in 67% yield. Compound **5** forms colorless crystals (from hexane) which decompose at ca. 250 °C. The structure of **5** was established ^{1}H-NMR spectroscopically.[9] In [D_6]acetone at 24 °C, the protons H-5, H-6, H-7, and H-8 gave rise to only a single extremely broad peak at $\delta = 6.95$, which was diffi-

cult to detect. This interesting finding clearly indicates that the signals of the four *p*-phenylene protons of **5** coalesce due to flipping of the *p*-phenylene ring.[5,6] In order to prove this, we carried out a series of variable temperature NMR studies on **5** and **4**. Upon heating a $CDBr_3$-solution of **5** from 24°C to 96°C, the broad peak became narrower and narrower until a singlet resulted at $\delta = 6.95$ for H-5, H-6, H-7, and H-8. On cooling a [D_6]acetone-solution of **5** from 24°C to −21°C, however, two singlets appeared at $\delta = 6.51$ and $\delta = 7.50$ for H-5, H-6 and H-7, H-8 respectively. The signal at $\delta = 7.50$ was obscured by that of the *o*-phenylene protons. This situation corresponds to a $\Delta G_c^{\neq}$ of 57 kJ/mol.[13] Similar treatment of **4** (in [D_6]acetone) revealed a $\Delta G_c^{\neq}$ of 44 kJ/mol at $T_c = -41$°C.

In conclusion, the free energy of activation for the flipping process ($\Delta G_c^{\neq}$) and the coalescence temperature (T_c) seem to bear intrinsic relation with the bond distances of the bridges of [2.2]metaparacyclophanes, as can be seen from the aforementioned experimental results. It is thus apparent that the longer the bridge, the larger the values of $\Delta G_c^{\neq}$ and T_c. *Boekelheide* et al.[5] and *Mitchell*[6] have attributed this to the fact that opening of the bridge angle from 109.5° (sp^3) in **1** to 120° (sp^2) in **2** more than compensates for the shorter carbon-carbon double bond length on going from **1** to **2**, making the exchange process much more feasible. Since the length of the CC bonds of benzene lies between that of a single bond and that of a double bond, it is understandable that, in the case of the benzoannelated **5**, $\Delta G_c^{\neq}$ and T_c assume values between those of **3** and **4**: $\Delta G_c^{\neq}$ is 75 (**3**), 57 (**5**), and 44 kJ mol^{-1} (**4**); T_c is 116 (**3**), 24 (**5**), and −41°C (**4**). The values of **5** lie between those of **1** and **2**.

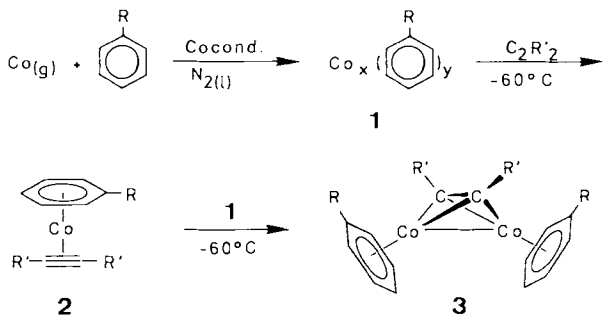
Alkyne(arene)cobalt, μ-Alkynebis(arenecobalt), and μ-Benzylidynetris(arenecobalt) from Arene/Cobalt Cocondensates**

By *Luis Vasquez, Hans Pritzkow,* and *Ulrich Zenneck**

Arene/cobalt cocondensates have already been used with success for the preparation of bis(2,2'-bipyridyl)cobalt,[2a] reactive organometallic slurries[2b] and catalytically active solutions,[3] but to our knowledge, all attempts have thus far failed to fix the arenes used for reaction with the cobalt as π-ligands in complexes.

We report here on the synthesis of mono-, di-, and trinuclear alkyne(arene)cobalt complexes from the product of the cocondensation of cobalt atoms and arenes.

Reactions of the cocondensates **1** (R = H, CH_3) at −100 to −20°C with alkynes [2-butyne, bis(trimethylsilyl)acetylene] lead, depending on the choice and concentrations of the reactants, to formation of both types of complexes **2** (green) and **3** (red) in varying amounts.



a, R = H, R' = CH_3; **b**, R = R' = CH_3; **c**, R = CH_3, R' = $Si(CH_3)_3$

Scheme 1. Synthesis of alkyne(arene)cobalt complexes via arene/cobalt cocondensation.

When butyne is allowed to react with **1**, R = H, the complex of type **2** is formed [**2a**: 5.6%, m.p. 73°C (decomp.)]. In the system toluene/butyne the type **3** complex is strongly preferred (**3b**: 15.2%, m.p. 90°C), but the amount of **2b** increases (0.4-1.2%, m.p. 55°C) with excess butyne; therefore, the reaction course depicted in Scheme 1 is assumed. With R' = $Si(CH_3)_3$ instead of CH_3 the type **2** complex is again preferred (**2c**: 22%, m.p. 45°C; **3c**: 0.4%, m.p. > 300°C). Thus far, losses have had to be expected in the work-up of the reaction products by fractional vacuum sublimation.

A dimetallatetrahedrane structure analogous to that of the [$Co_2(CO)_6$(μ-alkyne)] clusters[4] can be derived from the analytical data and the NMR spectra of the complexes **3** (Table 1), whereas the molecular structure of complexes of type **2** is without example, as unequivocally demonstrated by the crystal structure analysis of **2a**[5] (Fig. 1).

The butyne methyl groups are bent outwards from the metal center at angles of 35° and 32°, respectively. The plane through C7 to C10 and that through the planar ben-

Table 1. Spectroscopic data of the compounds **2a–c**, **3b,c**, and **4**.

a) X-band ESR data in toluene.

	g_1 [a]	g_2, g_3 [a, b]	$\langle g \rangle$ [c]	^{59}Co-Hyperfine structure [mT] a_1 [a]	a_2, a_3 [a, b]	$\langle a \rangle$ [c]
2a	2.187	2.00	2.089	12.00	3.5	6.12
2b	2.188	2.00	2.086	12.25	3.5	6.23
2c	2.250	2.00	2.106	11.50	4.5	6.31

b) ^{1}H-NMR data in C_6D_6 [d].

3b: $\delta = 2.04$ (s, 6H), 2.27 (s, 6H), 5.19 (m, 4H), 5.34 (m, 4H), 5.38 (m, 2H)
3c: $\delta = 0.3$ (s, 18H), 2.02 (s, 6H), 5.07 (m, 4H), 5.20 (m, 4H), 5.33 (m, 2H)
4: $\delta = 1.97$ (s, 9H), 5.07 (m, 6H), 5.15 (m, 6H), 5.56 (m, 3H), 7.29 (m, 1H), 7.43 (m, 2H), 7.95 (m, 2H)

[a] Measurement temperature $T = -160$°C. [b] Not accurately estimable, $\Delta g_{2,3} \approx \pm 0.05$, $\Delta a_{2,3} \approx \pm 0.5$ mT. [c] Measurement temperature $T = -60$°C. [d] 200 MHz, relative to TMS.

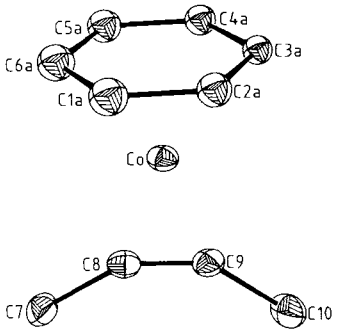

Fig. 1. Molecular structure of **2a**. Some selected bond distances [Å]: C8-C9 1.254(7), Co-C(benzene) 2.08(1)–2.16(1), Co-C8 1.885(4), Co-C9 1.901(5).

zene are almost perpendicular to each other (87°). The benzene ligand is disordered, with the C3a-C6a axis of one of the rotamers (occupation density 0.7) parallel to C8-C9 and that of the second rotamer rotated through ca. 30° to C8-C9. The Co-C8 and Co-C9 distances in particular suggest that all four π-electrons of butyne participate in the bonding to the metal center.[6] The same interpretation results from the ESR spectra (Fig. 2). The ESR data of the complexes **2** (Table 1) are in good agreement with those of anionic 19-valence electron (VE) cobalt complexes of the type [cyclopentadienyl(π^4-ligand)cobalt]$^{\ominus}$.[7,8] The data for the neutral 17-VE complex bis(pentafluorophenyl)(η^6-toluene)cobalt[9] or other 17-VE complexes of cobalt deviate significantly therefrom. Thus, we assume for **2** a HOMO(b_2) which is predominantly localized at the metal center analogous to that for the 19-VE complex anions.[7a] Attempts to oxidize **2a** and **2c** to **2a**$^{\oplus}$ and **2c**$^{\oplus}$ chemically or electrochemically have thus far met without success. The lifetimes of the presumed 18-VE complex cations **2**$^{\oplus}$ are very short. Even at −60°C, purely irreversible oxidations are observed.

In the thermal decomposition of the complexes **2a** and **2b**, small amounts of **3a** and **3b** are formed aside from hexamethylbenzene. At higher temperatures, these also afford the cyclotrimer of 2-butyne.

If the alkyne is replaced by acetonitrile in the reaction with the cocondensate **1**, R = CH_3, the dark-red trimetallatetrahedrane μ_3-benzylidinetris(toluenecobalt) **4** is formed in 0.9% yield together with large amounts of metallic cobalt. Complex **4** could not be observed on thermal decomposition of **1**, R = CH_3.

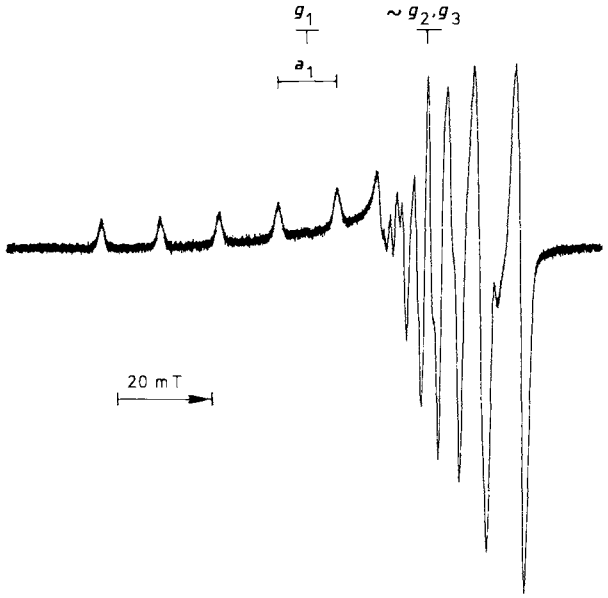

Fig. 2. ESR spectrum (recorded in the X-band of the microwave region) of **2a** in glassy frozen toluene at $T = -160$°C.

The crystal structure analysis[10] affords proof of the molecular structure derivable from the spectra. **4** is closely related to **3** and is formed by formal replacement of an RC fragment by an isolobal arenecobalt moiety (Fig. 3).

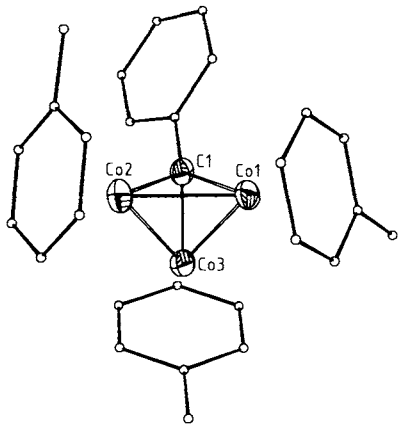

Fig. 3. Molecular structure of **4**.

The unit cell of the crystal contains two crystallographically independent and essentially identical molecules. The three cobalt atoms form an almost equilateral triangle with distances of 2.405(2) to 2.431(2) Å and are symmetrically bridged by the benzylidyne group [C1-Co distances between 1.84(1) and 1.87(1) Å]. The distances of the cobalt atoms from the ring carbon atoms of the toluene ligands are 2.07(2) to 2.18(2) Å. All the structural data thus lie in the expected range of values.[11]

Synthesis and Structure of $[(C_5Me_5)_2Rh_2S_8]$, a Dirhodium Complex with Unusual Polysulfide Bridge

By *Henri Brunner, Norbert Janietz, Walter Meier, Bernd Nuber, Joachim Wachter,** and *Manfred L. Ziegler*

Chalcogen-rich transition-metal complexes of the type $L_2M_2X_n$ (L = any substituted cyclopentadienyl ligand; X = S, Se; $n \geq 4$) are currently attracting interest because of their structural variability and versatile chemistry, both of which are strongly influenced by the nature of the metal.[1,2] The reaction of chalcogens with dimeric cyclopentadienylmetal complexes containing metal-metal multiple bonds has proven useful as a general synthetic route for such compounds. The chalcogen chains and rings undergo degradation thereby to mono- or diatomic moieties. Complexes with polysulfide ligands have been postulated as intermediates,[3] but only seldom has it been possible to detect them.[4] We now report on the synthesis and structure of the rhodium dinuclear complex $[Cp^*_2Rh_2S_8]$ **1** ($Cp^* = \eta^5$-C_5Me_5), which contains two unusually coordinated S_4 bridges.

The diamagnetic, red-brown complex **1** is obtainable in ca. 62% yield from $[Cp^*_2Rh_2(CO)_2]$ and sulfur (Rh : S 1 : 4, tetrahydrofuran, room temperature). Its composition is confirmed by elemental analysis; the field desorption mass spectrum, however, contains only the molecular ion less one sulfur atom. Contrary to expectation the ^{1}H-NMR spectrum[5] indicates a non-symmetrical structure for the compound. An X-ray structure analysis[6] on a single crystal of **1** (from toluene or CH_2Cl_2) confirms the non-equivalence of the Cp* rings (Fig. 1). The structure is characterized by two RhS_4 chelate rings, which are coupled to each other in such a way that they give the puckered Rh_2S_3 core (envelope conformation) of the molecule. Each S_4 ligand functions as 4e donor. As a consequence of this behavior the length of the S-S bonds varies from 2.032(3) to 2.106(3) Å. The bond angles fall in three ranges: The S-Rh-S angles lie between 78.2(1) and 94.0(1)°, while the other angles in the chelate ring, with exception of Rh1-S1-Rh2 (114.5(1)°) range from 100.1(1) to 109.2(1)°. The "real" chelate angles S1-Rh-S6 and S3-Rh2-S7 are both 94.0(1)°. Both RhS_4 rings have a slightly distorted envelope conformation. Their tips S3 and S4 are 3.539 Å from each other; this could possibly make them suitable for the

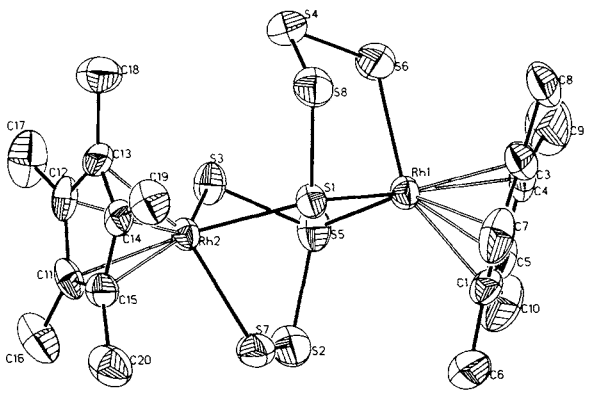

Fig. 1. Crystal structure of **1** (ORTEP). Selected bond lengths [Å] and angles [°]: Rh1-S1 2.384(2), Rh1-S5 2.327(2), Rh1-S6 2.384(2), Rh1-C(Cp^*1)$_{mean}$ 2.197(9), Rh2-S1 2.373(2), Rh2-S3 2.324(2), Rh2-S7 2.407(2), Rh2-C(Cp^*2)$_{mean}$ 2.196(9), S1-S8 2.103(3), S2-S5 2.106(3), S2-S7 2.043(3), S3-S5 2.032(3), S4-S6 2.057(3), S4-S8 2.040(3), Rh1···Rh2 3.999, S1···S5 3.372, S3···S4 3.539; S1-Rh1-S5 91.4(1), S1-Rh1-S6 94.0(1), S5-Rh1-S6 88.3(1), S1-Rh2-S3 91.3(1), S1-Rh2-S7 78.2(1), S3-Rh2-S7 94.0(1), Rh1-S1-Rh2 114.5(1), Rh1-S1-S8 100.1(1), S5-S2-S7 101.5(1), S6-S4-S8 101.7(1), Rh1-S5-S2 108.8(1), Rh1-S5-S3 109.2(1), S2-S5-S3 100.2(1), Rh1-S6-S4 107.4(1), S1-S8-S4 100.7(1).

bidentate coordination of unsaturated complex fragments. To our knowledge the only other bridge-forming S_4 ligands are found in copper(I) polysulfide clusters, in which two copper centers are each bridged by a terminal member of the S_4 chain.[3]

The formation of **1** proceeds via several intermediates. When the dark blue solution of $[Cp_2^*Rh_2(CO)_2]$ in THF is allowed to react with $1/8\,S_8$ at room temperature, the color changes to brown within 15 minutes, and the red-violet **2** can be isolated in 46% yield by column chromatography (Al_2O_3, toluene).[5] The Rh_2S three-membered ring in **2** can be expanded to a four-membered ring by addition of a further S atom. However, there is only IR spectroscopic proof available (ν_{CO} frequency at 2015 cm^{-1}) for the existence of the resulting complex **3**. The Se complex analogous to **3**, on the other hand, can be isolated.[7]

When, however, the reaction of $[Cp_2^*Rh_2(CO)_2]$ with sulfur is carried out at $-25\,^\circ C$ instead of at room temperature, about equal amounts of **1** and **4** can be isolated. The symmetrical compound[5] **4** may contain two RhS_4 chelate rings linked together by a Rh–Rh bond and a μ-CO group.[8] **4** slowly transforms into **1** in solution. The structural changes on going from **3** to **4** are indicated by weak ν_{CO} frequencies temporarily occurring at 1785 and 1980 cm^{-1}, which were observed between -80 and $-60\,^\circ C$. Unfortunately, these absorptions disappear in favor of those of **1** and **4** at higher temperatures, so that they cannot be assigned to specific structures. However, it cannot be ruled out that the monosulfide bridges in **2** and **3** are substitution-labile towards larger sulfur units, e.g. $S_4^{2\ominus}$. An indication in this direction is that the Se analogues of **2** and **3** can be converted into **1** with S_8.[7]

Although rhodium sulfides are of interest as hydrodesulfurization catalysts,[9] **1** is only the third structurally characterized rhodium polychalcogenide complex, after $[Cp_2^*Rh_2Se_5]$[10] and $[Rh(S_5)_3]^{3\ominus}$.[11] From the relatively high number of S–S bonds, a considerable reaction potential can be expected for **1**. Consistent with this prediction three irreversible oxidation waves were found at $E_{1/2} = +0.53$, $+1.38$ and 1.60 V in a cyclovoltammetric experiment (CH_2Cl_2, standard calomel electrode).

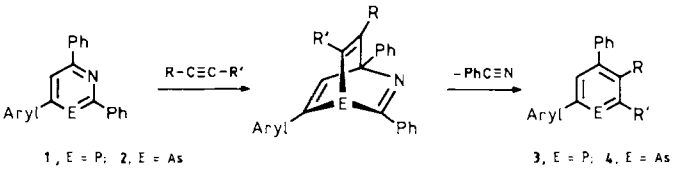
Reaction of 1,3-Azaarsinines with 2-*tert*-Butyl-1-phosphaethyne—2,9,10-Tri-*tert*-butyl-4,6-diphenyl-1,3,8-triphospha-7-arsatetracyclo[4.4.0.0^{2,8}.0^{3,7}]deca-4,9-diene

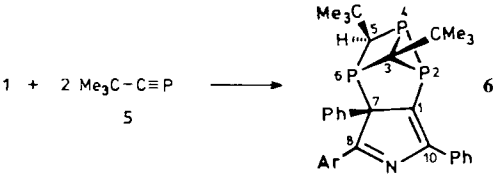
By *Gottfried Märkl,* Stefan Dietl, Manfred L. Ziegler,* and *Bernd Nuber*

The 1,3-azaphosphinines **1**[1] and 1,3-azaarsinines **2**[2] recently described by us undergo Diels–Alder reactions with a large variety of alkyne-dienophiles;[1,3,4] the bicycles initially formed rearomatize with elimination of benzonitrile to give the corresponding—in particular also functionally substituted—phosphinines **3**[1,3] and arsinines **4**.[4]



1, E = P; 2, E = As 3, E = P; 4, E = As

We have already reported on the fully unexpected reaction of the azaphosphinines **1** with the heteroalkyne *tert*-butyl-1-phosphaethyne **5** in the molar ratio 1:2; the tetracycles **6** are formed.[5]



6

We have now been able to show that the 1,3-azaarsinines **2** behave differently again toward **5**. Reaction with **5** in toluene at 120 °C in a Carius tube (48 h) furnishes (after treatment of the residue with ethyl acetate) a colorless, crystalline compound **7a**, m.p. 204–207 °C (from ethyl acetate), which according to an elemental analysis and its mass spectrum is a product formed from **2a** and **5** (in the molar ratio 1:3) with elimination of benzonitrile (Table 1). According to analytical and spectroscopic findings, **2b** reacts analogously to give **7b** (Table 1).

Both the ^{1}H-NMR spectrum, which shows three *tert*-butyl signals, and the ^{31}P-NMR spectrum, with three signals, are consistent with the unsymmetric structure of **7a**. The X-ray structure analysis shows that **7a** has a tetracyclic skeletal framework other than that in **6** and that all P

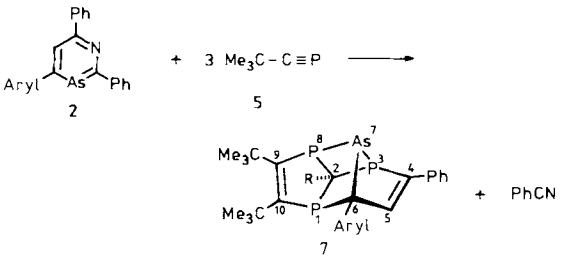
atoms and the As atom of **7a** are located in bridgehead positions.



a, Aryl = C_6H_5; b, Aryl = 4-CH_3-C_6H_4

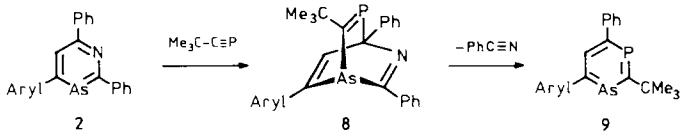
Table 1. Physical and spectroscopic data of **7a** and **7b**.

7a, yield 70%, m.p. 204–207°C (colorless crystals from ethyl acetate).—MS (70 eV): *m/z* 566 ($M^{\oplus\ominus}$, rel. int. 24%), 269 (4,5-di-*tert*-butyl-1,3-diphosphacyclopentadiene fragment, 100%).—^{1}H-NMR (250 MHz, $CDCl_3$): δ = 0.85 (d, J = 2.9 Hz, *t*Bu), 1.13 (s, *t*Bu), 1.45 (s, *t*Bu), 7.17–7.66 (m, Ph), 8.36 (dq, J = 9.2 Hz, 0.9 Hz, CH).—^{31}P{^{1}H}-NMR: we assign the signals as follows: δ = +77.11 (dd, J(P-3/P-8) = 13.5 Hz, J(P-3/P-1) = 6.6 Hz, P-3), +40.96 (dd, J(P-8/P-1) = 99.1 Hz, P-8), −54.87 (dd, J(P-8/P-1) = 99.1 Hz, J(P-3/P-1) = 6.6 Hz, P-1).—UV (CH_3CN): λ_{max} = 330 (sh, 4750), 255 (sh, 20700), 215 (30400) nm

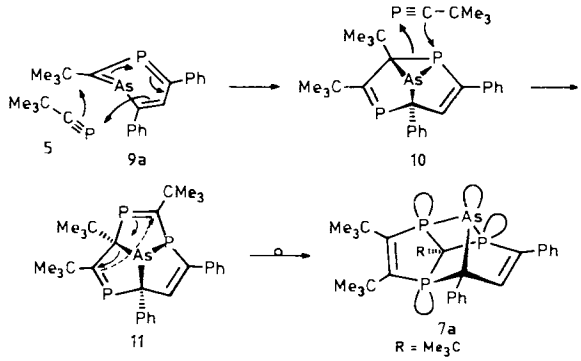
7b, yield 40%, m.p. 234–238°C (colorless crystals from ethyl acetate).—MS (70 eV): *m/z* 580 ($M^{\oplus\ominus}$, 19%), 534 ([$M-C_4H_8$]$^{\oplus\ominus}$, 2%), 269 (4,5-di-*tert*-butyl-1,3-diphosphacyclopentadiene fragment, 100%).—^{1}H-NMR: δ = 0.86 (d, J = 2.9 Hz, *t*Bu), 1.12 (s, *t*Bu), 1.45 (s, *t*Bu), 2.30 (s, CH_3–C_6H_4), 7.09–7.65 (m, Ph), 8.35 (dq, J = 8.9 Hz, 0.8 Hz, CH).—^{31}P{^{1}H}-NMR ($CDCl_3$): δ = +78.95 (dd, J(P-3/P-8) = 13.1 Hz, J(P-3/P-1) = 5.6 Hz, P-3), +43.99 (dd, J(P-3/P-8) = 13.1 Hz, J(P-8/P-1) = 99.0 Hz, P-1), −51.48 (dd, J(P-8/P-1) = 99.1 Hz, J(P-3/P-1) = 5.6 Hz, P-1).—UV (CH_3CN): λ_{max} = 330 (sh, 5100), 257 (sh, 23200), 215 (35900) nm

The chemical shift for P-1 is normal for a P atom in an unstrained tertiary phosphane; P-3 and P-8 in the diphosphaarsacyclobutane ring show downfield shifts of the ^{31}P-resonance signals characteristic for this ring system; the δ(^{31}P) value for P-3, as in similar systems,[6,7] could experience additional downfield shifts due to the proximity of P-3 to the CC double bond. The coupling constant J(P-8/P-1) ≈ 99 Hz lies in exactly the same range as in systems containing the *cis*-≻P–CR=CR′–P≺ structural unit, for which J values of ca. 30–150 Hz are observed.[8,9]

Thus, the azaarsinines **2**, as the higher homologues of **1**, behave quite differently. We interpret this finding in terms of the electrophilicity of the $\lambda^3\sigma^2$-arsenic in **2** being less than that of the $\lambda^3\sigma^2$-phosphorus in **1**, so that a Diels–Alder reaction to give **8** can first take place in the case of **2**. The bicyclic primary adduct **8** decomposes with elimination of benzonitrile to the 1,3-phosphaarsinine **9**.



The cycloaddition behavior of **9** toward further phosphaethyne **5** is completely different from that of the 1,3-azaphosphinine **2**. **9a** should furnish the semibullvalene



derivative **10** as intermediate, which reacts with further **5** with opening of the three-membered ring to give the "triquinazene derivative" **11**. The driving force for the rearrangement of **11** to **7a** is the conversion of two $\lambda^3\sigma^2$ P-atoms into two $\lambda^3\sigma^3$ P-atoms.

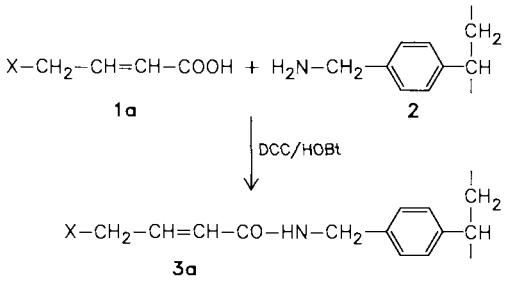
Solid Phase Synthesis of Peptides and Glycopeptides on Polymeric Supports with Allylic Anchor Groups**

By *Horst Kunz** and *Berthold Dombo*

Merrifield's concept of carrying out the synthesis of peptides on polymeric supports constitutes one of the milestones in modern chemistry.[1] Both in the original[2] as well as in the present day form of this solid-phase peptide synthesis[3] the *C*-terminal amino acid is anchored as substituted benzyl ester to the polymeric support (resin) either via a coupling group ("handle", spacer) or directly. Strong acids are used for detachment of the synthesized peptide from the resin. The *N*-terminal protecting groups and most of the side-chain protecting groups are removed at the same time. Alkoxybenzyl esters[4,5] as anchor groups enable removal of the peptide with trifluoroacetic acid. With dialkoxybenzyl esters as anchor groups,[6,7] even dilute trifluoroacetic acid can be used for removal of the peptide. Then, the fluorenylmethoxycarbonyl (Fmoc) group[8] has to be used as N_α-protecting group, since acid conditions must be carefully avoided during synthesis of the chain with such an acid-labile anchorage.

With the aim of constructing the acid-sensitive and in part also base-sensitive glycopeptides[9] in solid-phase syntheses, we have used the successful strategy of palladium(0)-catalyzed deblocking of peptide- and glycopeptide allyl esters[10] as well as allyloxycarbonyl(Aloc)-peptides and glycopeptides[11] for the development of a polymeric support with allylic anchor groups.[12] Thereby we were able to achieve both an acid- as well as base-stable anchorage of the peptide and glycopeptide chains to be synthesized on a resin, from which, however, they can be detached at room temperature under neutral, weakly acid or weakly basic conditions.[10,11] Suitable for the production of the polymers containing allylic anchor groups such as **3** is the reaction of resins containing aminomethyl groups, e.g. of aminomethylpolystyrene[13] **2** with haloalkenoic acids such as **1a**,[14] which have an allyl halide partial structure. **2** contains 0.8–3.3 mequiv. H_2N-CH_2 per gram resin. This reaction is particularly easy to carry out: **1** and **2** are condensed with dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBt)[15] in CH_2Cl_2 to give **3a**.



a, X = Br; b, X = OH

A cross-linking alkylation (formation of bromide ions) is not observed in this reaction. Among the possible anchor groups, the polar crotonyl group in **3** has the advantage of being highly acid-stable; therefore the model syntheses of peptides and glycopeptides on the resin **3a** are shown here. The corresponding alcohol **3b** can also be used, but there is the danger of racemization during the esterification with the *C*-terminal amino acids.

Reaction of the allyl halide-resin **3a** with the cesium salts[16] of *N*-protected amino acids **4** (molar ratio 1:1.5) furnishes the [4-(aminoacyloxy)crotonyl]aminomethyl resins **5**. The yields (determined by elemental analysis) of the hitherto unoptimized reactions are 70–82% (Table 1).

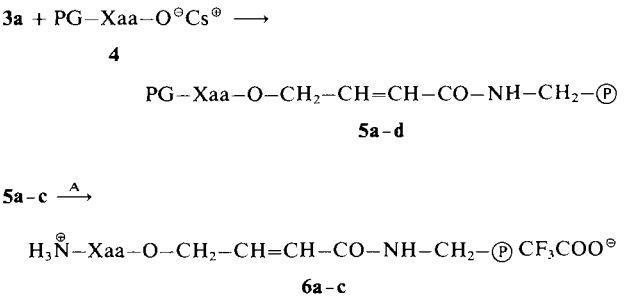


Table 1. Coupling of the amino acid salts **4** with the resin **3a** to protected aminoacyl-Hycram resins **5** and cleavage of the protecting group PG (Step A) with 50% CF_3COOH/CH_2Cl_2 (1 h) to give aminoacyl-hycram resins **6**.

5	PG-Xaa	Yield [%]	6	Xaa
a	Boc-Ala	82	**a**	Ala
b	Boc-Ile	70	**b**	Ile
c	Boc-Leu	73	**c**	Leu
d	Z-Ala	80		

Owing to the high acid-stability of the allylic ester bond, the N_α-Boc group in the protected aminoacyl-Hycram resins **5a–c** is selectively cleavable with trifluoroacetic acid/dichloromethane (step A). The polymer-bound salts **6** thus

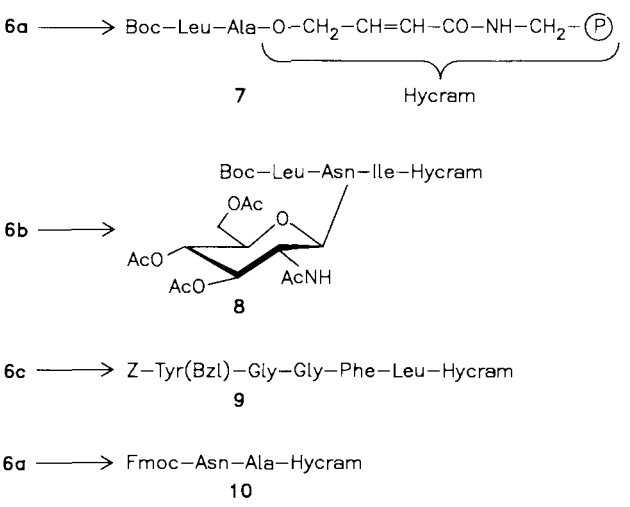

Table 2. Stepwise synthesis of the polymer-bound peptides and glycopeptides **7** to **10**. Normal conditions for step B, see text.

obtained are subjected to the synthesis cycle typical for solid-phase peptide syntheses.[1] In the coupling step B ethyldiisopropylamine, *N*-protected amino acid (PG-Xaa-OH), DCC and HOBt (5:5:6:6) are allowed to react with 1 mequiv. of aminoacyl-Hycram resin **6** with shaking in ca. 50 mL of dichloromethane or dichloromethane/DMF. The same solvent is used for the rewashing. The polymer-bound peptides and glycopeptides **7** to **10** are thus synthesized by stepwise chain lengthening (Table 2).

The coupling with Fmoc-Asn-OH (step B7) is carried out with a small excess of reagent (2:2:2:2) so as to avoid nitrile formation. It is obviously incomplete, since free alanine is found during later cleavage of the resin.

For a better assessment of the cleavage reaction we have synthesized the low molecular counterpart **11** of **7** from the *N*-benzylamide of 4-bromocrotonic acid.[14]

The Pd^0-catalyzed cleavage of **11** proceeds selectively and quantitatively[17,18] in less than 30 min in the way previously described by us.[10,11]

The polymer-bound peptide **7** reacts in a completely analogous way. Almost quantitative cleavage from the resin is achieved within 2 h (step C). Even the glycotripeptide **14** and the Leu-enkephalin **15** protected on the tyrosine are smoothly removed from the Hycram polymer in this way (Table 3).

Because of the incomplete coupling to **10**, the yield of Fmoc-dipeptide **16** is low. But no dipeptide with complete loss of Fmoc is found. Any alanine (formed from unchanged **6a**) and dimedone are separated off chromatographically on a short silica gel column (methanol/dichloromethane). The total yields of glycopeptide **14** and pentapeptide **15** are substantial, considering that no repeated coupling was applied in any of the reactions. It can be concluded therefore that the Pd^0-catalyzed cleavage reaction proceeds very effectively even in the case of the more complex resin-bound products **8** and **9**. The products **15** purified chromatographically with chloroform/methanol or reprecipitated from methanol/chloroform entrain some methanol. Their identity is confirmed by monitoring the 400-MHz ^{1}H-NMR spectra.[20,21]

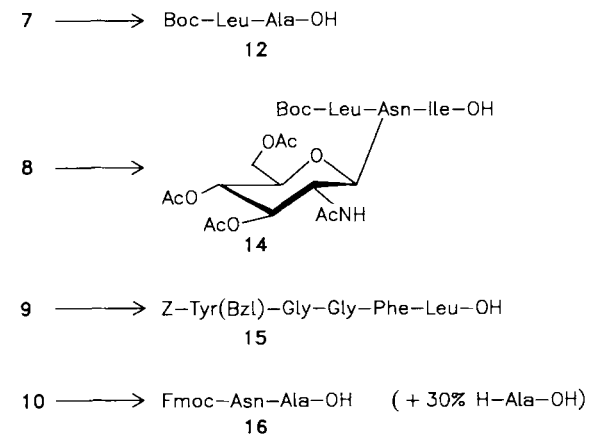

Table 3. Detachment of the peptides and glycopeptides **12** and **14** to **16** from the resin. Normal conditions for step C: 90 mg $(Ph_3P)_4Pd$ per mequiv. peptide or glycopeptide in 50 mL THF and 5 mL morpholine.

Reaction	Step(s)	Reagents etc.	Yield [%]

			80 (based on **3a**)
8 → **14** [20]	C1	see above, 10 h	76 (based on **5b**)
9 → **15** [21]	C1	see above, 12 h	63 (based on **5c**)
10 → **16** [22]	C2	see above, but in 30 mL THF and 1 g dimedone, 2 h; from washing **16** with methanol	48 (based on **5a**)

In summary, the polymeric supports such as **3a** with allylic anchor groups have the following advantages:

1. The solid-phase synthesis of peptides and glycopeptides on these supports can be carried out both with acid- as well as base-labile protecting groups.
2. The detachment of the synthesized product from the support can be carried out very effectively under almost neutral conditions.
3. Acid- (Boc) and base-labile (Fmoc or OAc in **14**) protective groups as well as the sensitive glycoside bonds remain intact during the cleavage.

Annelation of Carbene Ligands by λ^3-Phosphaalkynes, an Entry to Functionalized Phosphaarenes**

By *Karl Heinz Dötz,* Athanassios Tiriliomis, Klaus Harms, Manfred Regitz,* and *Ulrich Annen*

Following the synthesis of the first stable λ^3-phosphaalkyne[2] under normal conditions, a systematic investigation of this class of compounds became possible. [3+2] and [4+2] cycloadditions[3] as well as metal-induced oligomerizations[4] reveal close parallels with the reaction behavior of alkynes. We were interested in the question of whether phosphaalkynes can also be used for the annelation of carbene ligands. This type of reaction has proven useful for a direct entry to highly substituted hydroquinones[5] and for syntheses in the natural products series.[5,6]

The pentacarbonyl[alkoxy(1-naphthyl)carbene]chromium complex **1** reacts with 2,2-dimethylpropylidynephosphane-**2**, and by coupling of the phosphaalkyne, the carbene and a carbonyl ligand gives the phosphaphenanthrenehydroquinone complexes **3**. The $Cr(CO)_3$ fragment is coordinated to the newly constructed phosphaaromatic ring, whose ^{31}P-NMR signal is characteristically shifted upfield with $\delta=-26.50$ (**3a**) and -24.77 (**3b**), as in the case of the only previously known tricarbonyl(phosphaarene)-chromium complex tricarbonyl(2,4,6-triphenylphosphinine)chromium **5**.[7] Within the limits of NMR detection the incorporation of the P≡C moiety is regiospecific; the coupling constants of $^3J_{P,C}=34.3$ (**3a**) and 35.3 Hz (**3b**), respectively, observed in the ^{13}C-NMR spectrum for the OCH_3- and OCH_2-groups suggest the 3-phosphaphenanthrene structure. As in the carbene annelation with alkynes,[8] the regioselectivity is apparently sterically controlled. By ligand-exchange under CO pressure,[9] the phosphaarene **4** can be liberated almost quantitatively from **3b**; the $Cr(CO)_6$ formed in the reaction can be further used for the synthesis of the carbene complex **1**. As expected, in the ^{13}C- and ^{31}P-NMR spectra of **4** the signals for the ring atoms of the heterocycle are shifted downfield ($\Delta\delta(^{13}C)\approx 30$–40 ppm; $\Delta\delta(^{31}P)\approx 150$ ppm) compared to those of the coordinated phosphaarene **3b**.

In contrast to tricarbonyl(phenanthrene)chromium, in which the metal is coordinated unsymmetrically to the terminal ring,[10] in the phosphaphenanthrene complex **3a** the tricarbonylchromium group is bound centrally to the phosphinine ring (Fig. 1).[11] The metal is in a pseudo-octahe-

[**] Reactions of Complex Ligands, Part 33. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 32: [1].

slightly shorter than in **5**. Two carbonyl ligands are staggered with respect to the ring atoms; the third carbonyl group assumes ân almost eclipsed position relative to the phosphorus atom. This conformation apparently corresponds to that with the least steric interactions between the ring substituents and the carbonyl ligands, and rather resembles that in tricarbonyl(2-ethyl-4-methoxy-3-methyl-1-naphthol)chromium,[13] which has a comparable substitution pattern. In the N-, P- and S-heterocyclic complexes investigated so far,[12, 14] however, an approximate *trans*-arrangement of the ring heteroatoms to a carbonyl group was observed.

In contrast to both **5** as well as to uncoordinated phosphinines[15] the heterocycle in **3a** is slightly puckered (largest torsion angles: C13-P1-C1-C2 5.2(2)°, P1-C1-C2-C3 −5.8(4)°, for numbering see Fig. 1); this puckering is still found in the neighboring ring, whereas the third ring, with a maximum torsion angle of 2° at the coupling to the central ring, is almost planar. The C1-P1-C13 angle (101.73(6)°) in **3a** is about 2° larger than that found in **5**, and thus approaches that in uncoordinated phosphinines (ca. 103°). The C-C bond lengths in the heterocycle are significantly different; they also alternate in the neighbouring ring.

Bearing in mind the numerous possible structural variants of carbonyl(carbene) complexes, carbene annelation with phosphaalkynes can be expected to afford direct access to a broad spectrum of functionalized mononuclear and condensed phosphaarenes.[16]

Experimental

3a, **b**: A solution of 7.5 mmol of the carbene complex (2.72 g, **1a**; 2.82 g **1b**) and 0.75 g (7.50 mmol) of **2** in 20 mL of *tert*-butyl methyl ether was heated under an argon pressure of 5 bar for 2 h at 50°C. After removal of the solvent the residue was chromatographed at −25°C with CH_2Cl_2/pentane (1/3 to 1/1) on silica gel. Recrystallization from CH_2Cl_2/pentane (1/1) afforded dark red crystals. Yields: 2.59 g **3a** (82%), 2.41 g **3b** (82%).—**3a**: IR (hexane): $\tilde{\nu}$(C≡O) = 1965 (s), 1885 (s, br) cm^{-1}; ^{1}H-NMR (400 MHz, CD_3COCD_3): δ = 9.35 (dd, 1H; 5-H), 8.55 (s, 1H; OH), 8.32 (d, 1H; 10-H), 7.89 (dd, 1H; 8-H), 7.85 (d, 1H; 9-H), 7.65 (m, 2H; 6,7-H), 4.00 (d, 3H; OCH_3), 1.57 (d, 9H; $C(CH_3)_3$); ^{13}C-NMR (100.4 MHz, CD_3COCD_3): δ = 233.49 ($Cr(CO)_3$), 154.72 (C-2, ^1J(P,C) = 68.0 Hz), 133.04, 133.65, 131.12, 131.04, 130.07, 129.39, 129.19, 128.71, 123.27, 96.97 (C-4a-C-10a), 114.73 (C-4, ^1J(P,C) = 60.1 Hz), 101.06 (C-1, ^2J(P,C) = 7.7 Hz), 58.93 (OCH_3, ^3J(P,C) = 34.3 Hz), 38.01 ($C(CH_3)_3$, ^2J(P,C) = 19.6 Hz), 31.62 ($C(CH_3)_3$, ^3J(P,C) = 14.2 Hz); ^{31}P-NMR (121.4 MHz, CD_3COCD_3): δ = −26.50; MS: *m/z* 434 ($M^{\oplus}$).—**3b**: IR (hexane): $\tilde{\nu}$(C≡O) = 1957 (s), 1887 (s, br) cm^{-1}; ^{1}H-NMR (CD_3COCD_3): δ = 9.50 (d, 1H; 5-H), 7.91, 7.89 (each d, each 2H; 8,9,10-H, OH), 7.66 (m, 2H; 6,7-H), 4.30 (dq, 1H; OCH), 4.09 (dq, 1H; OCH), 1.58 (t, 3H; CH_3CH_2O), 1.57 (d, 9H; $C(CH_3)_3$); ^{13}C-NMR (CD_3COCD_3): δ = 233.67 ($Cr(CO)_3$), 153.72 (C-2, ^1J(P,C) = 68.2 Hz), 115.12 (C-4, ^1J(P,C) = 60.4 Hz), 133.90, 133.70, 131.11, 131.09, 130.17, 129.41, 129.17, 128.60, 123.34, 100.89, 97.04 (C-1, C-4a-C-10a), 70.15 (OCH_2, ^3J(P,C) = 35.3 Hz), 38.03 ($C(CH_3)_3$, ^2J(P,C) = 19.4 Hz), 31.46 ($C(CH_3)_3$, ^3J(P,C) = 14.3 Hz), 15.20 (CH_3CH_2O, ^4J(P,C) = 4.0 Hz); ^{31}P-NMR (CD_3COCD_3): δ = −24.77; MS: *m/z* 448 ($M^{\oplus}$).

4: A solution of **3b** (2 mmol) in ether (40 mL) was heated under a pressure of 30 bar CO for 14 h at 70°C. The solvent was then removed and the almost quantitatively recovered hexacarbonylchromium sublimed under Hg vacuum at 20°C. Column chromatographic purification of the residue on silica gel (10°C, ether/pentane as eluent) and recrystallization (pentane/CH_2Cl_2) afforded yellow crystals. Yield: 95%.—^{1}H-NMR (CD_3COCD_3): δ = 9.80 (d, 1H; 5-H), 8.39 (d, 1H; 10-H), 7.88 (m, 3H; 8,9-H, OH), 7.61 (m, 2H; 6,7-H), 4.48 (q, 2H; OCH_2), 1.71 (t, 3H; CH_3CH_2O), 1.68 (d (^4J(P,H)), 9H; $C(CH_3)_3$); ^{13}C-NMR (CD_3COCD_3): δ = 188.74 (C-2, ^1J(P,C) = 46.6 Hz), 153.97 (C-4, ^1J(P,C) = 47.5 Hz), 149.71, 133.70, 130.57, 129.43, 129.23, 129.16, 128.43, 127.46, 127.29, 122.99, 122.92 (C-1, C-4a-C-10a), 68.61 (OCH_2, ^3J(P,C) = 39.3 Hz), 38.94 ($C(CH_3)_3$, ^2J(P,C) = 23.7 Hz), 31.64 ($C(CH_3)_3$, ^3J(P,C) = 15.4 Hz), 15.39 (CH_3CH_2O), ^4J(P,C) = 4.1 Hz); ^{31}P-NMR (CD_3COCD_3): δ = 125.80; MS: *m/z* 312 ($M^{\oplus}$).

Inductivity and Bridging in Ammonium and Carbenium Ions

By *Cyril A. Grob,* Alfred Dratva, Martin Gründel,* and *Guangyi Wang*

The reactivities of the cationic centers in ammonium and carbenium ions are fundamentally different. Thus, in the first case the N atom is tetracoordinate and, hence, inert to nucleophiles. In the second case the C-atom is tricoordinate and so electrophilic that it reacts even with weak nucleophiles.

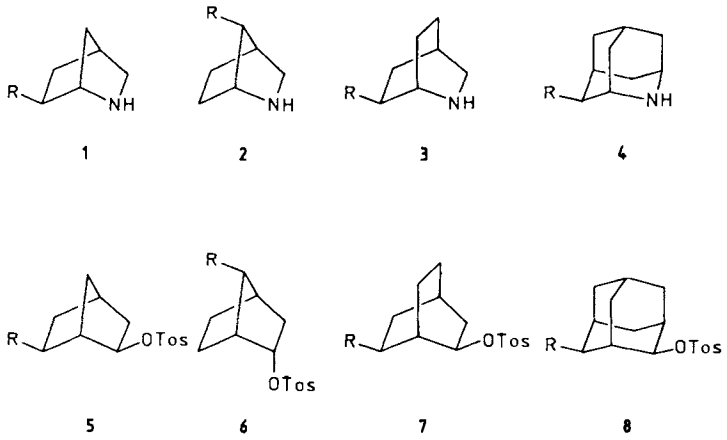
Institut für Organische Chemie der Universität
St.-Johanns-Ring 19, CH-4056 Basel (Switzerland)

The differences are also reflected in the way the inductive (I) effect of substituents control the formation of these cations. This is demonstrated by application of the *Hammett* equation $\lg(K/K_0)=\rho_I\cdot\sigma_I^q$ to the protonation of the bi- and tricyclic amines **1**–**4**, and to the solvolysis rates of the corresponding *p*-toluenesulfonates **5**–**8**. K and K_0 are



1 **2** **3** **4**

5 **6** **7** **8**

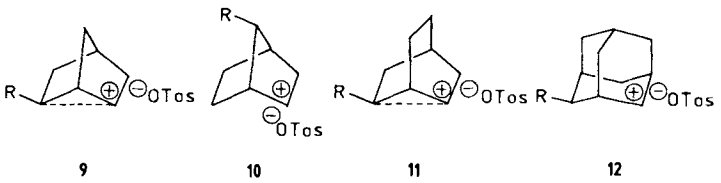
equilibrium or rate constants for the substituted[1] and unsubstituted compounds, respectively; σ_I^q are inductive substituent constants.[2] The reaction constants ρ_I are of primary importance because they serve as a measure of the *inductivity*,[3] i.e. of the intensity with which the I effect of the substituents is transmitted to the reaction center.

The pK_a values of the hydroperchlorates of the amines **1**–**4**[4] as well as the logarithms of the rate constants for the solvolysis of the toluenesulfonates **5**–**8** in 80% ethanol[5] correlate linearly with the corresponding σ_I^q values. Therefore, the protonation of the amines, as well as the ionization of the toluenesulfonates, are determined primarily by the I effect of the substituents. The ρ_I values, as calculated from the slopes of the plots of $\lg K$ vs. σ_I^q, are listed in Table 1. In the case of the amines **1**–**4** they are 1.03 (± 0.02); i.e. the ρ_I values, like the distances between the N atoms and the substituents, are practically the same. Therefore, inductivity is not dependent on the structure of the molecules.

Table 1. Inductivities ρ_I of the amines **1**–**4** and of the toluenesulfonates **5**–**8** (correlation coefficients in brackets). R = general substituent [1] (see formulas).

Compounds	ρ_I
6-*exo*-R-2-azanorbornanes **1**	1.05 (0.994)
7-*anti*-R-2-azanorbornanes **2**	1.01 (0.984)
6-*exo*-R-2-azabicyclo[2.2.2]octane **3**	1.04 (0.994)
4*e*-R-2-azaadamantanes **4**	1.00 (0.999)
6-*exo*-R-2-*exo*-norbornyltoluenesulfonates **5**	−2.00
7-*anti*-R-2-*endo*-norbornyltoluenesulfonates **6**	−0.72
6-*exo*-R-2-*exo*-bicyclo[2.2.2]octyltoluenesulfonates **7**	−1.50
4*e*-R-2*e*-adamantyltoluenesulfonates **8**	−0.80

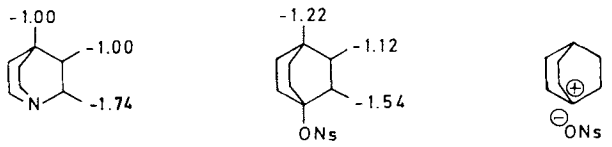
In contrast, the ρ_I values for the dissociation of the toluenesulfonates **5**–**8** to the ion pairs **9**–**12** differ markedly, although the distances and the partial structures are again practically the same. In these cases then, inductivity depends on the structure of the *whole* molecule. The large variations of ρ_I have been attributed to the varying tendency for dorsal and temporarily pentacoordinate C-atoms to bridge the electrophilic centers in the cations **9**–**12**,[3,5]



9 **10** **11** **12**

for bridging contributes substancially to the transmission of the I effect. As a directional bonding interaction, bridging generates strain which varies according to the structure of the molecule. Bridging strain is small in the cations **9** and **11**, but considerably larger in **10** and **12**.[6]

As shown by the ρ_I values for protonation of the 2-, 3-, and 4-substituted quinuclidines **13**[7] and for the solvolysis of the corresponding bicyclo[2.2.2]octyl *p*-nitrobenzenesulfonates **14**,[8] inductivity is considerably higher at C2 than at the more remote C atoms in both cases. Furthermore, ρ_I is distinctly higher at C2 in **13** than in **14**. This difference could be due to the presence of the anion in the contact ion pair **15** which partially shields the positive charge at C1 and thereby diminishes the I effect of neighboring substituents. On the other hand, the ρ_I values at C3 and C4 in **14** are slightly larger than at these positions in **13**, an indication that these carbons are weakly bridged.



13 **14** **15**

From these results it can be concluded that the transmission of inductive substituent effects in ammonium and carbenium ions differs in that in the first case it involves only structure-*in*dependent polarization, whereas in carbenium ions transmission also involves structure-dependent, short-range bridging. It should be noted, however, that the concept of graded bridging is derived from observed inductivities[3] and differs from the concept of "classical" and "nonclassical" ions, as employed by *Winstein* et al.[9a] and other authors.[9b,c]

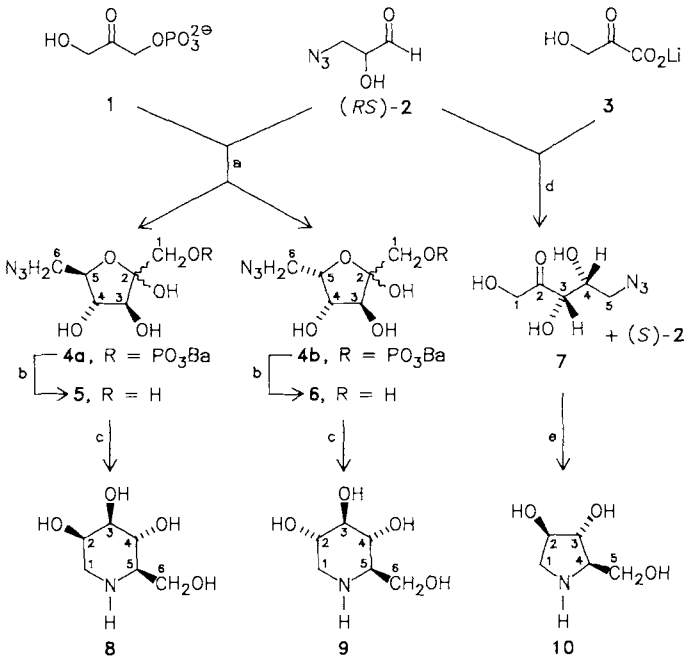
Enzyme-Catalyzed Synthesis of 1-Deoxymannojirimycin, 1-Deoxynojirimycin, and 1,4-Dideoxy-1,4-imino-D-arabinitol**

By *Thomas Ziegler, Alexander Straub,* and *Franz Effenberger**

1-Deoxymannojirimycin (1,5-dideoxy-1,5-imino-D-mannitol) **8**, 1-deoxynojirimycin (1,5-dideoxy-1,5-imino-D-glucitol) **9**, and 1,4-dideoxy-1,4-imino-D-arabinitol **10** are very effective glycosidase inhibitors.[1,2] The piperidine derivatives **8** and **9** have been known for some time,[1] whereas the pyrrolidine derivative **10** was first discovered in 1985 in two types of leguminoses, from which it was isolated.[3]

Because of their great importance as active agents a considerable number of methods have been developed for the synthesis of **8** and **9**, almost all of them starting from naturally occurring carbohydrates so as to introduce as many chirality centers from the very beginning.[4] Recently a synthesis of **9** from L-(+)-tartaric acid was described.[5] In the case of **10**, only one synthesis has been published so far;[6]



Scheme 1. a) **1** + (*R,S*)-**2**/pH 6/aldolase (EC 4.1.2.13)/12 h/25°C; pH 7/$BaCl_2 \cdot 2H_2O \rightarrow$ **4** (≡ **4a** + **4b**) (70%). b) **4**/phosphatase/pH 4.5/48 h/38°C/chromatography on Dowex 1×8 $HCO_3^{\ominus}$ with $H_2O \rightarrow$ **5** and **6** (each 80%). **5**: $[\alpha]_D^{20} = +52.49°$ ($c = 2.1$, H_2O), **6**: $[\alpha]_D^{20} = -53.78°$ ($c = 2.9$, H_2O). c) **5** or **6**/K_2CO_3/H_2O/Pd/C/80 bar H_2/4 h/50°C/HCl → **8** · HCl and **9** · HCl (each 65%). d) (*RS*)-**2** + **3**/$MgCl_2$/thiamine pyrophosphate/pH 8/transketolase (EC 2.2.1.1)/15 h/30°C/chromatography on Dowex 50 WX8 $Ca^{2\oplus}$ with $H_2O \rightarrow$ (*S*)-**2** (62%) and **7** (71%). (*S*)-**2**: $[\alpha]_D^{20} = -19°$ ($c = 0.4$, D_2O), **7**: $[\alpha]_D^{20} = -13.9°$ ($c = 0.4$, D_2O). e) **7**/K_2CO_3/H_2O/Pd/C/80 bar H_2/12 h/25°C → **10** · HCl and (4*S*)-**10** · HCl (11:1), after recrystallization from methanol/ether **10** · HCl (63%). $[\alpha]_D^{20} = +35.6°$ ($c = 0.4$, H_2O), m.p. 113°C (113–115°C [6]), ^{1}H-NMR-, ^{13}C-NMR-spectra identical with those given in [6].

it starts from D-xylose. Common to all these methods is the involvement of an extensive protecting group technique, which consequently requires a large number of reaction steps and thus leads to low overall yields.

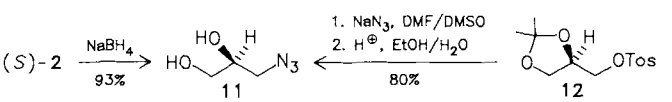
We recently reported on a simple synthesis of dihydroxyacetone phosphate (DHAP) **1** and its use in aldolase-catalyzed aldol additions.[7] We have now used this stereochemically unambiguous CC coupling as key reaction for the synthesis of the compounds **8** and **9** from a chiral precursor (Scheme 1).

In the reaction of **1** with (*R,S*)-3-azido-2-hydroxypropanal **2** catalyzed by rabbit-muscle aldolase we have isolated a diastereomeric mixture **4** of the barium sugar phosphates **4a** and **4b** in 70% yield. The enzymatically determined conversion was >99%. By acid or enzymatic cleavage of phosphate we obtained a diastereomeric mixture which could be readily resolved chromatographically on Dowex 1×8 into the D-fructo- and L-sorbo-compounds **5** and **6**, respectively (each in 80% yield). The purity and composition of the diastereomers **5** and **6** were confirmed by GC-MS analysis of the persilylated compounds (29% α-**5**, 71% β-**5**; 88% α-**6**, 12% β-**6**).

The anomers **5** and **6** were hydrogenated analogously to the method used for the preparation of hydroxypiperidines from 6-aminohexuloses.[4a-c] Thereby we obtained exclusively deoxymannojirimycin **8** from **5** and exclusively deoxynojirimycin **9** from **6**. The diastereomeric purity of **8** and **9** was confirmed by GC-MS analysis of the persilylated compounds; the ^{1}H-NMR, ^{13}C-NMR and MS data are consistent with the published data for **8** and **9**.[4f-h]

For the analogous synthesis of the pyrrolidine derivative **10**, azidoacetaldehyde, which, however, has so far proved impossible to prepare in pure form, had to be used in place of (*R,S*)-**2**. We have now succeeded, however, in preparing the 5-azido-5-deoxy-D-xylulose **7** in good yields from lithium hydroxypyruvate **3** and (*R,S*)-**2** via a transketolase-catalyzed CC coupling (Scheme 1). Upon hydrogenation, the azido sugar **7** furnishes the pyrrolidine derivative **10** in high yields (76%), containing less than 10% of the undesired (4*S*)-diastereomer. The latter byproduct can be removed by simple recrystallization of the hydrochloride from methanol/ether.

Transketolases have thus far found little preparative use.[8] This example demonstrates, not only their utility in the synthesis of sugars, but can also serve for the separation of racemic aldehydes, e.g. (*R,S*)-**2**. The configuration of the aldehyde (*S*)-**2** isolated besides **7** was confirmed



by reduction to the (*S*)-3-azido-1,2-propanediol **11** ($[\alpha]_D^{20} = -15°$). **11** ($[\alpha]_D^{20} = -15.8°$) was prepared via an independent route from the commercially available (*R*)-isopropylideneglycerol tosylate **12**.

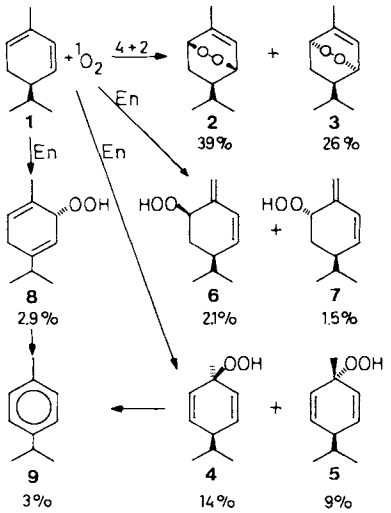
Competition of Endoperoxide and Hydroperoxide Formation in the Reaction of Singlet Oxygen with Cyclic, Conjugated Dienes**

By *Rudolf Matusch,** and *Gerhard Schmidt*

Singlet oxygen ($^1O_2$) usually reacts with cyclic, conjugated dienes in the sense of a [4+2] cycloaddition to give endoperoxides, whereas non-conjugated olefins with allylic hydrogen atoms undergo a double-bond shift with formation of hydroperoxides. In the following we show that both reactions can occur, and that a common intermediate can be formulated in the case of cyclic, conjugated dienes.

In the search for biologically active plant constituents we isolated the two endoperoxides **2** and **3** as active components which are accessible synthetically by reaction of $^1O_2$ with (*R*)-(−)-α-phellandrene **1**[1] and were previously considered to be the sole products of this reaction. To our surprise, however, not only the peroxides **2** and **3** are formed but also all theoretically possible hydroperoxides **4**, **5**, **6**, **7**, and **8**, together with the aromatization product *p*-cymol **9**.[2] Scheme 1 shows the distribution of all products after a preparative HPLC separation (data in wt-%).



Scheme 1.

Two facts emerge therefrom: First, hydroperooxides are formed to a considerable extent; that is, [4+2] cycloaddition and ene reaction compete. Second, the *cis-trans* ratio (based on the position of the peroxide function to the isopropyl group) is constant for both the endoperoxides as well as the diastereomeric hydroperoxides; it is 3:2.

The latter finding suggests the existence of a common intermediate for endo- and hydroperoxides. *Monroe*[3] has postulated this for the reaction of $^1O_2$ with acyclic dienes; for cyclic dienes, however, he proposed a concerted [4+2] cycloaddition exclusively, since only endoperoxide formation was observed.

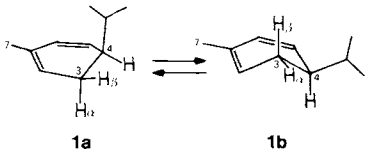


Fig. 1. Conformations **1a** and **1b** of (*R*)-(−)-α-phellandrene **1**.

Dreiding models show that α-phellandrene **1** can assume two conformations (Fig. 1). At room temperature a considerable amount of **1** is present in the conformation **1a**.[4] In a concerted [4+2] cycloaddition with attack of $^1O_2$ from above, steric interactions of the isopropyl group with the dienophile should be considerable for **1a** and negligible for **1b**. On the other hand, both conformers are equally likely to react with $^1O_2$ from below. In summary, therefore, more *trans*-endoperoxide **3** should result. The observed higher proportion of the *cis*-endoperoxide **2** thus contradicts an endoperoxide formation by concerted [4+2] cycloaddition.

Especially interesting concerning the hydroperoxides is the preferred *cis*-conformation of **6** compared to **7**. Since the abstracted H atom here comes from a methyl group, a *cis-trans* ratio of 1:1 would be expected, irrespective of the conformation,[5] if the $^1O_2$ does not preferably approach from above.

How then does this *cis*-directing effect come about? The point is that $^1O_2$ preferably abstracts axial allylic H atoms in an ene reaction, whereas equatorial allylic H-atoms remain undisturbed.[6]

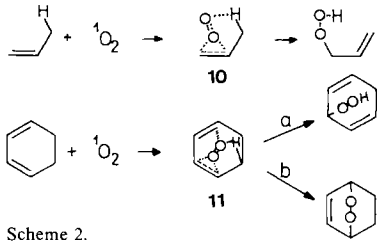
Regarding the *cis* sides of **1a** and **1b** in respect to the formation of **4** and **5**, H-3β being the only proton that could react in an ene reaction has the unreactive equatorial position in the case of **1a** and, additionally, the isopropyl group disfavors abstraction because of unfavorable steric interactions. In contrast this H-3β is axial in the conformer **1b**. Exactly the opposite holds true on the *trans* side for H-3α: in **1a** it is axial, and in **1b** it is equatorial. We therefore presumed that the *cis* products are mainly formed from the conformer **1b** and the *trans* products mainly from the conformer **1a**. To substantiate our assumption we carried out the reaction at −50°C. Since conformer **1a** is the energetically less favorable,[4c] the amount of *trans* products should decrease further. As expected the *cis-trans* ratio increases from 3:2 to 4:2, both in the case of the endo- as well as the hydroperoxides.

According to the above observations the mechanism of the ene reaction must first be considered. In the recent literature[7] a loose complex **10** is proposed in which $^1O_2$ interacts with the olefinic C atoms and with the allylic H atoms to be abstracted. If, as in the present case, both endo- as well as hydroperoxides are formed from a diene,

[*] Prof. Dr. R. Matusch, Dr. G. Schmidt
Institut für Pharmazeutische Chemie der Universität
Marbacher Weg 6, D-3550 Marburg (FRG)

[**] Lecture at the Annual Conference of the Deutsche Pharmazeutische Gesellschaft in Münster, September 10, 1987.

the interactions of the second O atom with the allylic H atom and with the second double bond must compete with each other, as indicated in **11**.



Scheme 2.

The relative strengths of these interactions and thus the electronic and steric factors now decide whether route a (ene reaction) or route b ([4+2]-cycloaddition) will dominate (Scheme 2). If **11** is used as a model for the two conformers **1a** and **1b**, then not only are interactions of the second O-atom with the axial H-3 and with the second double bond possible but also interactions with an H atom of the methyl group (Fig. 2; **1c** and **1d**).

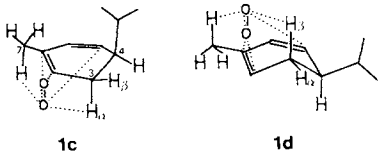


Fig. 2. Postulated intermediates **1c** and **1d** for the interactions of **1a** and **1b**, respectively, with singlet oxygen.

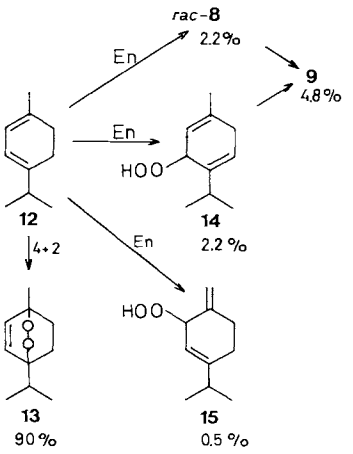
This, however, provides an explanation for the *cis-trans* ratio of the hydroperoxides **6** and **7**. Since a complex in which the second oxygen atom can undergo three interactions is obviously more favorable than a complex with a lower number of interactions, the respective axial H-3 and thus the conformer equilibrium **1a** $\rightleftarrows$ **1b** also directs the formation of **6** and **7**. Finally, enantiomerically pure **8** is formed by $^1O_2$-attack at the other double bond and abstraction of H-4.



Scheme 3.

The competition between cycloaddition and ene reaction in the case of cyclic, conjugated dienes can also be observed in the reaction of $^1O_2$ with α-terpinene **12**. Here too the endoperoxide, namely ascaridol **13**, was thought to be the only reaction product.[8] And, once again, on closer examination we found the racemic hydroperoxides (**8**, **14**, **15**) depicted quantitatively in Scheme 3.

[2] For the generation of singlet oxygen we used a sodium vapor lamp as light source, Bengal rose as sensitizer, and methanol as solvent. The reaction time at room temperature was 40 min. To rule out a radical reaction, the radical inhibitor 2,6-*tert*-butyl-*p*-cresol was added. The same product pattern was obtained when using other sensitizers (tetraphenylporphyrin, methylene blue) and other solvents (dichloromethane, isopropyl alcohol). Also no oxidative changes were observed after 40 minutes' treatment with $^3O_2$. Separation of the reaction mixture was accomplished by preparative HPLC (25 × 250 mm column; Li-Chrosorb Si 60, 5 μm, *n*-pentane/diethyl ether 9:1). The amounts of the products (wt-%) in Schemes 1 and 3 are based on the total amount of fractions eluted; the remaining 2.5% (Scheme 1) and 0.3% (Scheme 3) lie in the interstitial fractions. All the products gave correct analytical data.

Synthesis of Optically Active Phosphanes via Sharpless Epoxidation**

By *Henri Brunner** and *Adolf Sicheneder*

Optically active phosphanes are the most useful ligands in enantioselective catalysis with transition metal complexes.[2,3] Methods for preparing such phosphanes involve either a resolution step or the transformation of a chiral precursor from the chiral pool.[3] In the present paper we describe a new synthesis of optically active phosphanes making use of the high optical inductions accessible in the Sharpless epoxidation of allyl alcohols.[4-6] Using this methodology, achiral allyl alcohols can be converted in a few steps, via epoxy alcohols and their proper derivatization (Scheme 1), into optically active diphosphanes capable of forming five-membered and six-membered chelate rings.

The allyl alcohols **1a** and **1b** were transformed into the epoxy alcohols **2a** (yield 55%; 93% *ee*) and **2b** (yield 75%; >95% *ee*) as described by *Sharpless* et al.[7,8] The primary alcohol groups of **2a** and **2b** were easily tosylated without affecting the epoxide ring to give **3a** and **3b**. Subsequent reaction with $LiPPh_2$ introduced two PPh_2 substituents, one by tosylate replacement and the other by epoxide ring-opening.

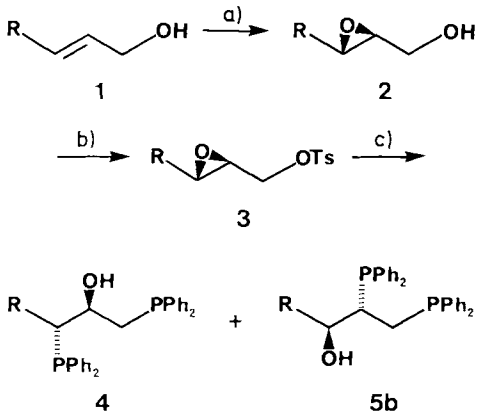
[**] Enantioselective Catalysis, Part 42. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen.—Part 41: [1].



Scheme 1. **a**, R = Ph; **b**, R = *n*Pr. a) Ti(O*i*Pr)$_4$, *t*BuOOH, diethyl tartrate, CH_2Cl_2, −20°C, 3 h. b) *p*-tosylCl, pyridine, −10°C, 20 h. c) $LiPPh_2$, THF, 20°C, 20 h.

The ring-opening of epoxides with strong bases occurs stereospecifically with inversion. However, it may take place at carbon atoms C-2 and C-3, respectively, resulting in a mixture of products. The site of nucleophilic attack can be controlled by steric and electronic effects.[9, 10] We found, that the reaction of **3a** with $LiPPh_2$ is regiospecific, giving exclusively **4a**. In the reaction of **3b** with $LiPPh_2$, however, we isolated a 2.5 : 1 mixture of **4b** and **5b**. All efforts, to separate **4b** and **5b** were unsuccessful.

The tosylates **3a** and **3b** were recrystallized three times. Therefore, we assume that **4a** and the components of **4b/5b** are optically pure. At present, most of the optically active diphosphanes are only accessible in multi-step procedures.[3] The new synthesis presented in this communication is short, operationally simple, and easily employed on a large scale and with a variety of substitution patterns. Moreover, the hydroxy group in **4** and **5** formed upon epoxide ring-opening is suitable for further derivatization.

4a and **4b/5b** served as chiral ligands in the $[Rh(cod)Cl]_2$-catalyzed enantioselective hydrogenation of (*Z*)-α-acetamidocinnamic acid with 1.1 bar H_2 in methanol solution at room temperature. With Rh/ligand ratios between 1 : 1.05 and 1 : 1.10 and Rh/substrate ratios of 1 : 50 the hydrogenation is quantitative within 3 hours. **4a** and **4b/5b** gave (*R*)-(−)-*N*-acetylphenylalanine in 54 and 83% *ee*, respectively, in the usual work-up.[11, 12]. We attribute the high optical induction obtained with the mixture of **4b/5b**, to the component **5b**, which represents a functionalized PROPHOS.[13]

Experimental

3a: The epoxidation of cinnamyl alcohol **1a** was carried out as described [7] to give **2a** in 55% yield, 93% *ee*, containing 15% unreacted **1a**. The pale amber, oily **2a** (6.1 g, 40.6 mmol) was tosylated with *p*-toluenesulfonylchloride (7.75 g, 40.7 mmol) in 40 mL of pyridine at −10°C. After 20 h the mixture was filtered, the filtrate concentrated, treated with 50 mL of 1 M H_3PO_4 and extracted three times with 50 mL CH_2Cl_2. Crystallization of the yellow oil from ether/hexane gave **3a** as colorless crystals: yield 8.6 g (70%). M.p. 68–69°C. $[\alpha]_D = -45°$ ($c = 2.5$, $CHCl_3$). ^{1}H-NMR (250 MHz, $CDCl_3$): $\delta = 7.34$–7.82 (m, 4H, AA'BB'), 7.27 (s, 5), 4.10–4.36 (m, 2), 3.70 (d, 1H, $J = 2$ Hz), 3.10–3.30 (m, 1H), 2.45 (s, 3H).

4a: 8.4 g (27.6 mmol) of **3a** were dissolved in 100 mL of THF and added to a solution of $LiPPh_2$ in 50 mL of THF, prepared by reaction of 10.5 g (56.4 mmol) $HPPh_2$ and 34.5 mL of a solution of BuLi in hexane (1.64 M). After 20 h stirring at room temperature, the mixture was hydrolyzed by addition of 100 mL of acetate buffer (pH 5.1). The aqueous phase was extracted with three 50 mL portions of ether. The combined organic layers were dried over Na_2SO_4, filtered and concentrated to give a pale yellow oil, which crystallized on trituration with cold methanol. Recrystallization from toluene/hexane gave pure **4a** as a colorless powder: yield 9.0 g (65%). M.p. 142–143°C. $[\alpha]_D = -74°$ ($c = 1.0$, $CHCl_3$). CI-MS (isobutane): m/z 505 ($MH^{\oplus}$). ^{1}H-NMR (250 MHz, $CDCl_3$): $\delta = 7.03$–7.57 (m, 25H), 3.85–3.93 (m, 2H), 2.01–2.17 (m, 3H). ^{31}P-NMR (101.257 MHz, $CDCl_3$): $\delta = -5.8$ (d, 1P, $J = 2$ Hz), −20.0 (d, 1P, $J = 2$ Hz). ^{13}C-NMR (22.64 MHz, $CDCl_3$): $\delta = 127.0$–138.0 (m), 68.9 (dd, 1C), 51.3 (dd, 1C), 35.9 (dd, 1C).

BOOK REVIEWS

The Electronic Structure and Chemistry of Solids. By *P. A Cox*. Oxford University Press, Oxford 1987. 259 pp., paperback, £ 12.50.—ISBN 0-19-855204-1

Solid state research is in vogue. New high temperature superconductors, conducting organic polymers, "heavy fermions", charge and spin density waves—interdisciplinary groups have achieved these and many other advances and discoveries in this field in very recent years. Surface science—a field with close links to both chemistry and physics—has also experienced an explosive growth during the past decade. One result of these developments is the necessity for communication in interdisciplinary fields, since many of the electronic properties of solids are now of interest not merely to a small circle of specialists but also to synthetic chemists. Although there are excellent textbooks available on solid state physics, such as *Kittel*'s "Introduction to Solid State Physics" and "Solid State Physics" by *Ashcroft* and *Mermin*, these standard works, written by physicists for physics students, are not very attractive to chemists for two reasons: first, the presentation of the material is often too mathematically advanced, and

second, the examples chosen are kept very simple and are therefore not of much interest to the chemist who is more concerned with complex substances and structures.

There is quite obviously a gap here, which the present book, derived from a series of lectures to advanced students at the University of Oxford, sets out to fill. In its conception it follows in the steps of the now rather dated "Seven Solid States" by *W. J. Moore*, which in its time familiarized chemists with basic solid state physics, using suitably chosen compounds as examples.

In the first three chapters of the book, basic concepts such as bonding situations in crystals, the free electron gas and optical processes are treated qualitatively and without giving mathematical derivations, illustrated by appropriate examples. Some spectroscopic techniques are outlined as well, with particular emphasis on photoelectron spectroscopy.

The remaining four chapters deal with special topics. An entire chapter is devoted to a "formal" introduction to energy band theory. The concepts needed for the analysis of band structures are worked through with the help of diagrams, without giving involved mathematical derivations, and are tested on simple examples such as graphite and ReO_3. This is followed by a short account of the experimental determination of band structures using angularly resolved photoemission spectroscopy. Two further chapters deal with electron repulsion effects in terms of the Hubbard model, and with lattice distortions and mixed valency compounds. The final chapter is concerned with semiconductors and their uses in photovoltaic cells, transistors etc.

Altogether the conception of the book and the way in which it has been put together make it a useful addition to the literature. The material is arranged in a clear manner, and the individual sections are lucidly written and illustrated by many well chosen examples. Some of the topics are discussed only briefly, but one cannot expect a book of 250 pages to cover every topic of current research in detail. The material included has been well chosen. The references to more detailed review articles and original papers which are included, with comments, at the end of each chapter give the interested reader easy access to further reading, and a short formula index included at the end of the book helps in locating compounds cited as examples.

In summary, the author *P. A. Cox* has brought considerable skill to the task of familiarizing chemists with the electronic structure of solids. At the very attractive price of £ 12.50 in its paperback edition, the book is certainly a worthwhile and useful aid to advanced students and to synthetic chemists.

Symmetry through the Eyes of a Chemist. By *I. Hargittai* and *M. Hargittai*. VCH Verlagsgesellschaft, Weinheim 1986. xii, 458 pp., bound, DM 156.00.—ISBN 3-527-26409-4

I spent the years 1950–51 in *Linus Pauling*'s group at the California Institute of Technology, which was then one of a mere handful of Meccas for theoretical chemists. Together with *Sidney Weinbaum* of $H_2^{\oplus}$ fame (he was—to my knowledge—the first to use an extended basis in a MO-calculation), I was assigned the task of calculating carbon clusters C_n by the then popular valence bond method. We met our Waterloo as soon as we reached the cubical C_8 cluster, not knowing how to factorize the general eigenvalue problem of order 14 into manageable parts. (Those were still the days of the B.C. era, i.e. before computers, even at Caltech.) There was nothing to be ashamed of, since we were in the best of company in our lack of knowledge. Indeed, even in most books on quantum chemistry written for "real" chemists, group theory was conspicuous by its absence. Even in *Streitwieser*'s classic on MO theory written in 1961, symmetry considerations play at best only a Cinderella role.

The situation has changed dramatically since those days. The enormous growth in the use of physical methods, especially spectroscopy, the wide application of quantum mechanics and of a new chemical language derived from it, and the discussion of reaction mechanisms and stereochemical problems in terms of symmetry, have led to a rapid increase of interest in symmetry and group theory. Chemists changed their outlook and began to collect Escher prints, and publishers started to outbid each other in producing introductions to these new fields. One consequence of this is that there is now scarcely a single library which owns a more than half complete collection of all books relating to this area, ranging from advanced mathematical works to those of a popular scientific type. Every newly published book on this theme must therefore be judged against this background of an overabundance of related literature which already exists.
