The first thing which strikes one about the book reviewed here is its exorbitant price: a princely DM 156.—for a book which is presumably intended as an introduction. One might therefore ask why the book is so highly priced, and whether this could not have been avoided. One cause of this is a use of space which could scarcely be rivalled in its extravagance. With an approximate page format of $24\ cm \times 17\ cm = 408\ cm^2$, the print area is only about $21\ cm \times 9\ cm = 189\ cm^2$. Admittedly the extremely wide margin—about double the usual width—is partly used for figure legends, but these generally only contain information on the sources for the figures, e.g. the caption "Photograph by the authors", which is repeated about 40 times. The 421 literature references occupy three times as much space as they would in other books, owing to the very large gaps between individual references, allowing only 15 to a page. In addition the number of examples included is wastefully large, many of them scarcely adding anything to the understanding of the material. Or do you believe that the concept of antisymmetry will be made significantly clearer to a novice by having before him a picture showing a McDonald's adjacent to a more up-market restaurant? ("Photograph by the authors"). Likewise "*Eszter Hargittai* in front of a shop window (1980) ("Photograph by the authors") makes only a minimal contribution to the understanding of mirror symmetry. Altogether one gets the impression that the authors have tried, in their understandable enthusiasm for the subject, to include in this book every quotation related to symmetry which they have collected over the years. As a result there are long sections which are more like a family album of personal recollections than a guide through the subject written with the object of instructing the reader. Further, the information content is sometimes appallingly thinly spread. For example, seven pages are needed to explain what a matrix is and how two matrices are multiplied, and ten pages to discuss the symmetry properties of the HMOs in benzene. *Dietrich Stauffer*, in his excellent and wittily written book "Introduction to Percolation Theory", writes: "You may

complain that the square lattice in Figure 1(a) is not very large, but the publishers did not allow me to fill the remaining pages of this book with these squares, ...". One wishes that the authors of the present book had been given similarly valuable advice by the publishers, so that its length—and presumably its price—could have been reduced without difficulty by at least one third, with no sacrifice of information and with a rather more sensible layout.

When we ask the question for whom this book was written, we find that the potential reader must have a very strange, contradictory make-up. It is evidently assumed that he has no knowledge whatsoever of the most elementary matrix operations, nor has he heard of symmetry or crystallography, let alone of group theory, all of which are nowadays obligatory topics in the first semesters of a chemistry course. Is it then a book for the interested layman? By no means! The reader must not only have mastered the formal language of chemistry in all its subtleties, and have a thorough knowledge of much of stereochemistry, in order to understand the significance of the examples, many of which are quite advanced. In addition, this reader, who has just encountered matrices and the simplest types of symmetry considerations for the first time in his life a few pages earlier, must without any previous experience be able to understand and use the operator formalism of the Schrödinger equation, and—without any detailed explanation—be familiar with all relevant concepts of quantum mechanics and molecular orbital theory. In other words, the book is neither fish nor fowl. For the chemistry student who has not been asleep during the first semesters, and who has obtained his knowledge of physical chemistry from a modern book such as the best-selling "Physical Chemistry" by *P. W. Atkins*, some long sections of this work will seem trivial. For the non-chemist, on the other hand, it assumes far too much knowledge, and it is especially at fault in explaining quite simple points at great length, whereas those steps which present real difficulties for the layman are just glossed over. Admittedly, for the reader who already has the necessary previous knowledge, and is interested in the ramifications of symmetry considerations both within and outside chemistry, the book is a fascinating, if over-priced, mine of information, which deserved to be written in a more concise form. The virtually exhaustive bibliography, and the (over)generous selection of examples mentioned earlier, make the book a welcome and useful work of reference for everyone who is seriously involved in teaching the application of symmetry concepts and has so far neglected those aspects not directly related to chemistry. On the other hand, anyone who has already concerned himself with such ideas will get a definite "déjà vu" feeling throughout large sections of the book. Thus it seems worth mentioning that most of the illustrations from art, biology and other fields can be found, for example, at a cost of only DM 40.—, and partly in color, in the excellent, 466-page first volume of the exhibition catalog "Symmetry in Art, Nature and Science" of the Mathildenhöhe in Darmstadt. (Volumes 2 and 3 contain further examples).

However, the publishers, VCH Verlagsgesellschaft, take the view that this book has been written expressly for students. In fact, the same publishers' German translation ("Physikalische Chemie") of the excellent book by *P. W. Atkins* mentioned earlier contains an unexpected innovation: whereas in the original English version the references given for further reading following the chapter on symmetry are to classic works such as *Hermann Weyl*'s "Symmetrie" and the well-known books by *Jaffe, Orchin*, and by *Cotton*, we now find that all these have been deleted from the German edition and replaced by a full-page advertisement for the book reviewed here!

The following quotation is offered to the authors as consolation: "The writer has collected his material together most diligently, and no discovery of importance which became known during the preparation of the work has been omitted. Our only regret is that he tells us indiscriminately and in immense detail everything which he has learned, and thereby unnecessarily increases the cost of his book."—From the 1831 review of the German translation, still well known even today, of the textbook by *Louis Jacques Thénard* (*Neues Journal der Pharmacie 22* (1831) 276).

Lasers in Chemistry. Von *D. L. Andrews*. Springer, Berlin 1986. xii, 176 pp., broschiert, DM 68.00.—ISBN 3-540-16161-9

This book with its just 163 pages may be looked upon as a very compact text addressing both the scientist with general interest and the undergraduate student. It is, however, by no means useless to the more advanced reader. It even impresses the reader by the wealth of laser applications mentioned, ranging out to such specialized topics as ceramic powder formation or cancer therapy by lasers. Its general attitude is very positive with regard to the uses of lasers in chemistry and high hopes for the future are expressed. The diligence and the depth of treatment must be viewed differently for the different chapters.

In chapters 1 and 2 attempts are made to provide an introduction into the physics (18 pages) and into the technology (25 pages) of lasers. Doubts are justified if this is really helpful (e.g. one page on the free electron laser). Perhaps the chemist user would benefit more from a simple table of common commercial lasers and their typical performance data. Such a user-oriented survey is indeed provided on page 164, although in rather short form. The strength of the book in the opinion of the referee lies in chapters 3 (Laser Instrumentation in Chemistry) and 4 (Chemical Spectroscopy with Lasers). Especially chapter 4 gives a fair summary of most of the important laser analytic methods in a systematic way. The treatment ranges from specialized absorption techniques over fluorescence and Raman spectroscopies to multiphoton processes and laser mass spectrometry. In the last chapter (Laser Induced Chemistry), which in the preface is said to be most promising among the different laser applications, the following topics are considered: Infrared multiphoton excitation, isotope separation, unimolecular laser induced and bimolecular laser enhanced reactions and—on three pages—surface chemistry with lasers as well as—also very briefly—psec phenomena. This treatment cannot do justice to the laser or to the field of chemical dynamics as such. Lasers are very special energy sources with their combined properties of coherence, high radiation intensity, ultrashort pulses and extreme monochromaticity. Their potential in chemistry cannot easily be realized by traditional chemical thinking and in the language of preparative chemistry. Besides, it should be mentioned that the main success of laser chemistry at present is not so much in synthetic chemistry than in materials research and processing. This is not adequately cov-

ered in the very short paragraph "laser surface chemistry".

All in all this book presents a laser chemistry survey which can only be recommended to the reader with some reservation.

Photochemistry in Microheterogeneous Systems. By *K. Kalyanasundaram*. Academic Press, New York 1987. xii, 388 pp., bound, $ 49.95.—ISBN 0-12-394995-5

After the many review articles on photochemical processes in microheterogeneous systems which have appeared recently, but have mainly treated special aspects, a general survey of this extensive field can only be welcomed. Further, in *K. Kalyanasundaram* the publishers have engaged the services of an experienced and competent author for this monograph.

Studies on photoreactions in microheterogeneous systems have generally been motivated by a combination of two factors: firstly, photochemical studies provide a uniquely powerful probe for investigating the static and dynamic properties of microheterogeneous systems, and secondly experiments in an organized reaction medium yield especially valuable information about the mechanism of such photoreactions. These two aspects of the motivation for research in this field also determine the topics covered in the book reviewed here, whose main themes are micellar systems and microemulsions (4 chapters), lipids, vesicles and liposomes, monolayers, lipid membranes and liquid crystalline systems, polymers, polyelectrolytes and ion-exchange membranes, inclusion complexes, and surfaces (one chapter each).

A concise but quite adequate introduction serves to familiarize even non-specialists with the many different types of microheterogeneous systems, with the fundamentals of photochemistry, and with some of the most frequently studied photoreactions. Considerable space (about a third of the book) is devoted to photophysical processes and photoreactions in micelles. The author has himself made many contributions to research on this first topic, and is therefore well able to give a comprehensive and authoritative review. This includes separate chapters on singlet and triplet processes. The next chapter describes reactions of photochemically generated radical pairs, with the main emphasis on cage effects, isotope effects and magnetic field effects, together with fragmentation and cycloaddition reactions. Another chapter deals with photochemical processes and reactions in reverse micelles and microemulsions.

The following chapter describes the special properties of vesicles and liposomes. Here again the author deals in turn with singlet processes, the dynamics of exciplex and excimer formation, and energy and charge transfer phenomena. The subject of the next chapter is highly ordered systems such as monolayers, black lipid membranes and liquid crystals. Particular attention is given to energy and electron transfer processes, isomerizations, dimerizations and photochemical fragmentation processes, and photoreactions of metalloporphyrins. The next chapter deals with polymers in solution, polyelectrolytes and ion exchange membranes; these large topics can only be treated in a selective way here. Here too the main emphasis is on studies of the dynamic properties of the systems.

In contrast to micelles, inclusion compounds, for example, cyclodextrins, zeolites, crown ethers and cryptates have well-defined molecular dimensions. For this reason these systems have also become increasingly important in recent years in investigations of selective photochemical processes. Especially detailed studies have been made on cyclodextrins and zeolites, and these are therefore given most space in this chapter. The final chapter discusses photochemical processes and reactions involving molecules adsorbed on colloidal SiO_2, colloidal clays, silica gel, porous vypor glass, and aluminum oxide surfaces. The distribution and the degree of local organization of the adsorbed species greatly influence the reaction behavior, as does the limited diffusion which occurs in the surface layer. For reasons of space it has not been possible to include heterogeneous photocatalysis and colloidal semiconductor systems.

The book is written in a clear style. Each chapter concludes with a comprehensive bibliography, thus enabling the reader to study topics in greater depth. A further useful feature is that the appendix includes an updated bibliography for work published in 1985. The book can be recommended to anyone seeking a survey of the present situation in this area of research.

ADVANCED MATERIALS

Editorial Advisors: E. M. Engler (USA), D. Haarer (FRG), N. Ogata (Japan), G. Petzow (FRG), J. M. Thomas (UK), G. Wegner (FRG)

Editorial

Modern science and technology rely on specialists. Nevertheless, the complexity of many problems is all too often an obstacle to gaining a deeper understanding of physical and chemical phenomena. In particular, the development of advanced materials and new technologies requires the joint efforts of many specialists from a variety of disciplines. The nature of ceramics, polymers, composites and other new materials is such that successful processing must integrate the individual steps of molecular and microstructural design, engineering, testing and manufacturing. The once common distinction between the product, its function in a system, and the material from which it is made has lost its meaning in a context wherein new materials are created on demand to serve special requirements. This implies that a multidisciplinary team of experts is more likely to be successful in the development and application of advanced materials than are individual researchers working within the limits of their special field.

It is always surprising to see that despite the diversity of all the materials in use and under development, the concepts, phenomena and transformations involved in making and using ceramics, metals, polymers and composites are strikingly similar. Important features are phase equilibria, phase transformation mechanisms, defect structures, flow and fracture mechanisms, structures of crystals and glasses and their relationships, internal boundaries and their contribution to macroscopic behavior, the motion or confinement of charge carriers, the statistical mechanics of assemblies of subsystems; these features not only serve to characterize the individual materials in which they were first studied, but also determine the behavior and performance of other materials which at first sight are totally unrelated.

It is this intellectual relationship between the phenomena that are seen in different materials and between the seemingly distinct features that are found in the same material, which has given birth to *Materials Science* as a discipline in its own right. It is also a meeting place of constituent sciences. One of the most challenging tasks is to provide the link between the thinking of the chemist who considers materials mainly in terms of structure and dynamics on the atomic and molecular scale and the concepts of the physicist whose models are often based on the continuous nature of matter. Moreover, materials science integrates important aspects of engineering in so far as certain properties of materials arise solely from the process of manufacturing owing to the physical and chemical methods of handling. The latter is most obvious in modern polymer materials where the supermolecular structure of the constituent chain molecules is entirely determined by the processing methods.

Recent years have witnessed an unprecedented explosion of new structural materials. Today the pace of technological change due to the availability of more and more specialized high performance materials is rapid. We are only begining to realize the opportunities provided by the new materials. In addition to changing the engineering landscape, advanced structural materials have also altered

traditional policies regarding materials. Historically, national interests in materials have centered around the problem of shortages of supply of certain "critical" ores and minerals. The potential of the new materials such as high performance composites goes far beyond substitution. They provide performance and manufacturing advances which cannot be achieved with traditional metals and they are often the key for new technologies. Therefore, an active governmental role in accelerating the development and commercialization of such materials is seen in all major industrialized countries.

Advanced materials are now ranked together with microelectronics and biotechnology as the most promising "high-tech" industries of the future. With the rise of materials science as a recognizable discipline, many new journals covering different aspects of the field have been founded, all of them publishing either original papers or long, in-depth reviews. In addition, there exist book series, a plethora of monographs and even an encyclopedia for this new discipline. What the materials community is still lacking is a truly international journal that provides stimulating short reviews comprehensible to the many subgroups of the discipline, a journal that presents highlights from the recent original literature, conference reports, book reviews, information about funding programs and materials science institutes, as well as other important news, i.e., all those ingredients that make a journal enjoyable and timely. ADVANCED MATERIALS is intended to serve this purpose.

ADVANCED MATERIALS will appear again in July and regularly every month from September on as a distinct addition to both the German and English versions of ANGEWANDTE CHEMIE, the traditional chemistry journal that caters to all chemistry subdisciplines. This journal has, of course, published excellent materials related short communications and reviews in the past—take the molecular beam epitaxy article in this issue as an example—and this practice will not be changed.

ADVANCED MATERIALS will cover all aspects of materials science, but especially genuine new materials and methods for their preparation, modification and investigation; important theoretical concepts will also be discussed. The following list of topics gives examples only and is not intended to be complete:

Development of new materials such as

- organic low and high molecular weight materials with novel electrical, optical, and magnetic properties
- polymers with unconventional mechanical properties
- liquid crystals
- thin films
- colloids
- fibers
- composites as structural materials
- composites for dielectric and electrical/electronics applications
- inorganic materials with applicationally interesting properties
- amorphous metals
- high temperature ceramics
- superconducting ceramics
- intermetallics
- catalysts
- multicomponent alloys
- glasses
- biomedical materials
- sensor materials

Developments in new methods of preparation and characterization

- surface and interface characterization and engineering
- plasma assisted polymerization, etching etc.
- laser methods
- electrochemical methods
- spectroscopic techniques of characterization
- diffraction methods
- modern microscopy techniques
- modern casting and powder metallurgical techniques
- powder technology
- nondestructive testing techniques
- materials modeling

An interdisciplinary approach will be emphasized in all contributions. The key question is, what does the physicist want to know from the chemist and vice versa, and what do both have to communicate with the materials scientists? ADVANCED MATERIALS is planned to stimulate fruitful discussions and to promote cooperation between scientists from different disciplines.

E. M. Engler, D. Haarer,
N. Ogata, G. Petzow,
J. M. Thomas, G. Wegner

Six editorial advisors (see opposite page), together with Dr. Gölitz, the editor of ANGEWANDTE CHEMIE, and Ligia Dominguez, editorial assistant, will shape ADVANCED MATERIALS. We welcome contributions from all over the world, from academia and from industry, from chemists, physicists and materials scientists, provided they are in keeping with the program outlined in the editorial. Authors who are interested in writing short reviews (up to 15 pages of double-spaced manuscript together with an appropriate number of figures and/or formulas) should contact the editor. Please send all manuscripts and inquiries to:

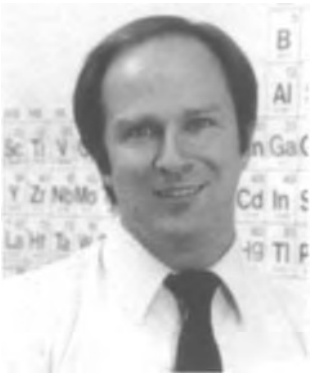
Editorial Advisors



Dr. *Edward M. Engler* is manager of Optical Science and Technology at the IBM Almaden Research Center (650 Harry Road, K32/803D, San Jose, CA 95120-6099, USA). A chemist by training, he received his B.Sc. from Providence College and his Ph.D. from Princeton University. His research has focused on unusual solid-state electronic materials, about which he has published extensively, particularly in the area of organic metals and high temperature superconductors.

Dr. *Naoya Ogata* is Professor of Chemistry at Sophia University, Tokyo (7-1 Kioicho, Chiyoda-ku, Tokyo, Japan). As a chemist he obtained his B.Sc. and his Ph.D. (1961) at Tokyo University. After several postdoctoral years in the USA he started his career at the department of chemistry at Sophia University in 1966. He has written several books and over 250 papers on Langmuir-Blodgett membrane techniques, conducting polymers, and polymeric adsorbents.

Dr. *John M. Thomas*, F.R.S., is Director of the Royal Institution of Great Britain (Davy Faraday Research Laboratory, Royal Institution of Great Britain, 21 Albemarle St., London W1X 4BS, UK). He obtained his Ph.D. in chemistry in 1958 at Queen Mary College in London. After some years as a reader at Bangor, North Wales, he became head of the chemistry department at the University College of Wales in Aberystwyth in 1969. From 1978–1986 he was head of the physical chemistry department at the University of Cambridge. He is author of several books and over 500 papers and his research focusses on the characterization of polycrystalline, quasicrystalline and amorphous solids.

Dr. *Dietrich Haarer* is Professor of Physics at the University of Bayreuth (Lehrstuhl für Experimentalphysik IV, Universitätsstrasse 30, D-8580 Bayreuth, FRG). A physicist by training, he received his Ph.D. in 1969 from the University of Stuttgart. With short interruptions he then worked until 1980 at the IBM research laboratory in San Jose, California, which he left as manager of the Organic Solids Department taking up his current position. His research activities include laser spectroscopy and laser chemistry.

Dr. *Günter Petzow* is Director at the Max Planck Institute for Metals Research in Stuttgart (Max-Planck-Institut für Metallforschung, Institut für Werkstoffwissenschaften, Pulvermetallurgisches Laboratorium, Heisenbergstrasse 5, D-7000 Stuttgart 80, FRG) and a professor at the universities of Stuttgart and Berlin. He studied chemistry and physical metallurgy at the University of Stuttgart and at the Max Planck Institute for Metals Research and received his Ph.D. in 1959. His current research interests are in physical metallurgy, powder metallurgy and ceramics. He has published more than 350 technical papers and four books, and he holds 23 patents.

Dr. *Gerhard Wegner* is Director at the Max Planck Institute for Polymer Research and chemistry professor at the University of Mainz (Max-Planck-Institut für Polymerforschung, Jakob-Welder-Weg 11, D-6500 Mainz, FRG). He obtained his Ph.D. (1965) in chemistry at the University of Mainz. After two postdoctoral years in the USA he started a university career in Mainz. In 1974 he joined the University of Freiburg as professor for polymer chemistry and became Director of the Institute for Macromolecular Chemistry. He has written numerous papers on polymers, especially conducting polymers, and on solid state organic chemistry.

Advanced Materials—a Critical View

By Claus Razim*

Competition in a free market makes ever more exacting demands on all kinds of manufacturers to offer products which are attractive in their performance and price. By using detailed knowledge and experience gained from theoretical and empirical studies, and by the increased application of computer technology in forms such as FEM (finite element methods), CAD (computer aided design), CAM (computer aided manufacturing), data banks, and computer networks, through to the currently much discussed "expert systems" and CIM (computer integrated manufacturing) systems, conventional methods and technologies can be pushed to the full limit of their potential. The urgency of taking advantage of opportunities such as these comes both from economic pressures and from policies on employment.

Further advances, which in many cases open up new markets, can result from increased use of microelectronics, and from putting into practice ideas for new products. Implementing such ideas in many cases gives rise to a desire, or an urgent need, for new materials, further developments of existing materials, or specially treated materials.

In view of this situation, one can understand why a number of countries have intensive research programs on materials science, and why this type of research is emphasized in the media. Although the media reports on modern materials technology are welcome, they are, unfortunately, too often associated with negative side effects. Thus one finds that the media are quite keen to cover aspects of materials technology, but the treatment is often superficial and distorted, owing to well-meaning attempts to present complex facts in a form which can be easily understood. The resulting neglect of scientific and factual consistency confuses the readers, listeners or viewers far more than if they were given a true factual account. In some circumstances this over-simplification can even lead people to draw false conclusions, which may have adverse effects on making special decisions related to work on materials.

For example, the need for progress in developing "revolutionary" materials—e.g., composites, ceramics, and superconductors—is very often emphasized in the media. Even in seriously regarded publications or broadcasts, euphoric reports announce "the end of the iron age", and promote "high tech" as the non-plus-ultra in materials technology. Such one-sided appraisal of unconventional materials developments carries the risk of neglecting the further development of cheap and already familiar conventional materials, which is absolutely essential on overall economic grounds.

The future for materials of very high performance is not restricted to "super-materials", which are certainly very important and which call for intensive efforts to make use of all their potential properties. Equally important is further work on conventional materials and their processing technology. This is made even more urgent by the fact that the relationships between materials properties and treatment processes, and between the properties of a material and the behavior of the components made from it, including their influence on the reliability of the overall assembly, are in many cases not sufficiently known, and have consequently not been formulated in engineering terms.

As an example, Figure 1 shows the remarkably large improvements in fatigue strength which can be obtained in steels through heat and surface treatments. The effects produced by such modifying treatments, and the details of the processes, depend on the type of alloy used, i.e., on its chemical composition, and from a metallurgical standpoint they arise from changes in the microstructure of the material. The ability to produce these changes is the basis for the extremely wide variations that are possible in manufacturing steels with macroscopic properties suited for different engineering uses.

Figure 2 shows the historical development of the different basic types of steels during the last 130 years. From the sigmoid shaped curve found here, which is typical in many different sorts of technological developments, it may be concluded that the development of fundamentally new types of steels is approaching an end! It can be seen that the basic types of steel now known were all developed within a period of about 60 years, and that from 1940 onwards, except for the microalloyed steels, no basically new types of iron alloy materials were "discovered". However, this by no means implies that development has come to a

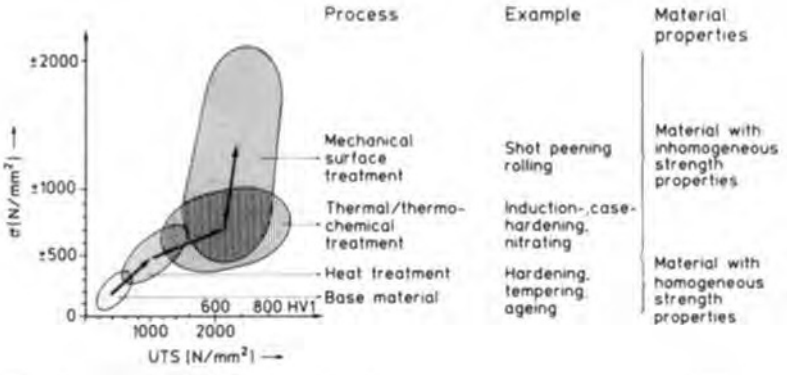


Fig. 1. Improvements in fatigue strength σ of steels by heat and surface treatments. UTS = ultimate tensile strength, HV1 = Vickers hardness.

[*] Prof. Dr.-Ing. C. Razim
Daimler-Benz AG

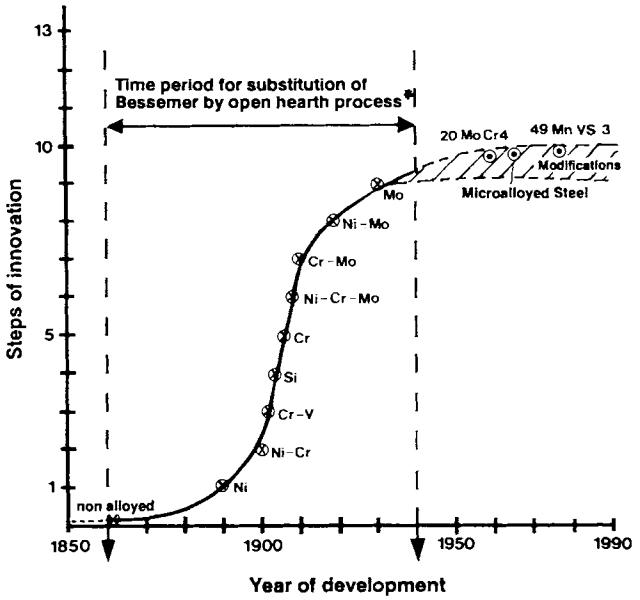

Fig. 2. Steps of development of basic types of steel (*G. H. Robinson*, General Motors Research Center 1980) and use in the automotive industry. *: *C. Marchetti, N. Nakicenovic*, Int. Inst. Appl. Systems Analysis, Laxenburg, Austria 1979.

stop; a wealth of modifications and variations of the known basic types have been developed, bringing about considerable improvements in the performance of these materials.

A remarkably similar development curve, though shifted in time by about 40 years, is found in the case of plastics. Here too, for about the past 15 years, in addition to an intensified use of blending technology, research has been dominated by modifications of already known basic types.

In the application of both the modified old and the new materials, an essential prerequisite is that suitable refined test methods must be developed and made available.

It is only through close interdisciplinary collaboration between chemists, physicists, materials scientists and engineers involved in design and production that new materials and the related treatment technologies for components with desired properties can be developed and successfully introduced into series production.

Irrespective of the choice of particular materials and appropriate treatment methods, the techno-economic aspects of industrial materials technology are of great importance. It is particularly essential to achieve a harmonic optimization of the key parameters of the cost of a material and its behavior during production and use.

Applying these criteria leads to the conclusion that steel and iron, due to their universal suitability, to the relative ease with which their mechanical, corrosion and tribological properties can be varied over a very wide range, and to their generally good processing behavior and ease of working, will continue in the foreseeable future to have great importance in the manufacture of vehicles, machines, and industrial plants. These favorable characteristics are further reinforced by relatively low material costs. An additional factor in favor of these materials, which should not be underestimated, is that of familiarity and long experience.

Depending on the type of application, on needs which are specific to particular business areas, and/or on cost considerations, it may be advantageous or essential to use other materials in place of steel. Those available include the broad palette of non-ferrous metals, ferrous and non-ferrous sintered materials, polymers and composite materials, ceramics, glass, and special materials such as memory metals, amorphous metals and superconductors. However, using materials such as these is not always free of problems, and would be unwise in some cases. For a material to possess just one outstanding property is not generally sufficient in engineering applications; the overall behavior with regard to a range of different properties is usually more important. Here again it may be possible to find solutions through interdisciplinary collaboration of the kind mentioned earlier.

In addition to considerations of function and cost, the choice of materials will become increasingly influenced by ecological factors, waste recycling and conservation of resources, not only for social reasons but equally importantly on economic grounds.

The complexity of the factors involved in finding the "optimal" materials to use in different applications, arising from the numerous aspects which must be considered, indicates a general increase in the importance of materials specialists.

Prof. Dr. Claus Razim, born on March 25, 1930, studied metallurgy at the Technische Universität Berlin and Rheinisch-Westfälische Technische Hochschule Aachen from 1950–1956. He received his Ph.D. from the University of Stuttgart in 1967. After a short employmnet at the Stahlwerke Südwestfalen (1956–1958) he started in 1958 to work for the Daimler-Benz AG in the Central Materials Testing Department. In 1977 he became Head of the Central Materials Department and in 1988 Senior Director of the Research Production Technology Unit. He has authored or co-authored more than 30 publications and received many awards including a Honorary Professorship from the Technische Universität Berlin (1978) and the VDI Gold Metal (1977). Since 1984 he has also been President of the Foundation Institute for Materials Technology in Bremen, FRG, and he is currently President of the International Society for Heat Treatment of Materials.

ADVANCED MATERIALS

Controlling the Microstructure of Monomolecular Layers**

Ultrathin Organic Films
Proteins in Thin Films
Fluorescence Microscopy
X-ray Scattering

By Helmuth Möhwald*

This review reports on the range of lateral structures which have been detected in ultrathin organic films using the newly-developed techniques of fluorescence microscopy and X-ray scattering, together with more conventional methods. A number of unusual low-dimensional ordering processes have been revealed. Hexagonal, lamellar or fractal domain structures are observed and shown to result from an interplay of electrostatic forces due to molecular alignment at interfaces, line energy between different phases and growth kinetics. On a molecular level the microstructure is distinguished by low coherence length of positional order but long coherence length concerning the orientation of crystallographic axes. It is demonstrated that the ideas presented are also relevant to adsorbate structures at interfaces and to the protein arrangement in monolayers.

1. Introduction

In designing a new organic material to perform a given function, it is typically necessary to link many atoms together in the desired spatial arrangement, using well-understood synthetic techniques. For some functions, however, these techniques are not sufficient, as it is also necessary to orient the resulting molecules. A number of different solutions to this problem are known, including crystallization, stretching or extrusion of a loaded polymer, dissolving the functional molecule in a liquid-crystalline matrix, and even the use of lithographically defined nm-sized holes. Here another technique is described, which achieves a very high degree of orientation of densely packed molecules. This technique, involving the principle of self-assembly and orientation of molecules at an interface, was first demonstrated by *Langmuir* and *Blodgett*.[1] It was extensively developed by the elegant work of *Kuhn* and coworkers who demonstrated the feasibility of building molecular machines.[2]

I will show that it is not only possible to design structures consisting of multilayers of ultrathin films with individual thickness of about 2 nm but that the lateral organization of molecules within these films can also be controlled. For this I will concentrate mainly on the monolayer at the air/water interface since the parameters in this system may be varied over a wide range, making it most suitable for understanding the underlying processes. These studies yield insight into new and interesting physics of two dimensions. This was possible by using the novel techniques of fluorescence microscopy and X-ray scattering together with established methods such as film balance and surface potential measurements as well as electron microscopy and spectroscopy. These techniques have become applicable to films as thin as 25 Å mainly due to the development of extremely sensitive TV cameras and of high intensity Synchrotron X-ray sources.

Experimental

Most of the experiments were performed with the phospholipids L-α-dimyristoylphosphatidic acid (DMPA) or L-α-dimyristoylphosphatidylethanolamine (DMPE) (Fluka). Both lipids are highly insoluble in water and form stable monolayers at the air/water interface when spread from solution (3 : 1 chloroform/methanol). The monolayer molecules are oriented, with the hydrophilic head groups pointing towards the water surface and the aliphatic chains towards the air. Varying the subphase ionic conditions by adding NaOH, NaCl (Fluka, p.a.), $CdCl_2$ (Merck), or other divalent ion salts or by binding divalent ions through addition of sodium ethylenediaminetetraacetate (EDTA, Sigma) affects the head group repulsion and thus also alters the microstructure.

As a more simple model compound arachidic acid $CH_3(CH_2)_{18}COOH$ (Fluka) was used. The charge-transfer salt *N*-docosylpyridinium-tetracyanoquinodimethane (Py-TCNQ) was obtained from *A. Barraud, J. Richard, A. Ruaudel-Teixier* and *M. Vandevyver* at Saclay, France; the diacetylenic lipid **1** ("Bronco") was a gift from *H. Ringsdorf*, Mainz. The positively charged surfactant dihexadecyldimethylammonium bromide used for studies of the adsorption of the water soluble disulfonated cyanine dye (Nippon, Kauko, Shikiso, NK 2012) was obtained from *M. Shimomura*, Tokyo, Japan. Concanavalin A (Con A) and dextran were obtained from Sigma. Water was Millipore filtered.

Fluorescence microscopy studies of the monolayer at the air/water interface were performed using a dedicated film balance with an integrated microscope. [3] Contrast is observed in the images leading to Figures 1 and 2 (section 2) since the dye probe NBD-PE **2** (dipalmitoyl-nitrobenzoxadiazolphosphatidylethanolamine) incorporated into the monolayer in a molar con-

2, R = $(CH_2)_{14}CH_3$

centration below 1% is less soluble in the more ordered phase than in the fluid one. Different solubility in different phases also yields good contrast if a fluorescently labeled protein is used (Fig. 6, section 5). In a third variant of the technique, a water-soluble dye was not incorporated into the main monolayer, but instead formed extensive two-dimensional crystalline layers, or J-aggregates—aggregates of strongly interacting dyes in a coplanar arrangement—adjacent to it and under its influence. These J-aggregates typically had a high fluorescence yield and are shown in Figure 5.

X-ray scattering experiments with monolayers at the air/water interface were performed at the Synchrotron source of HASYLAB, DESY, Hamburg, in collaboration with *K. Kjaer* and *J. Als-Nielsen*, Risø, Denmark. [4-7] For measurements of X-ray diffraction with in-plane wave-vector transfer $Q_{\parallel} = \frac{4\pi}{\lambda} \sin\theta$ ($\lambda = 1.3815$ Å being the wavelength and θ the diffraction angle) the beam enters the surface at glancing incidence. For studies of X-ray reflection (normal wave-vector transfer) as a function of incidence angle α the height of the film balance at the sample stage of the diffractometer is varied. In these experiments the film balance with a pressure measuring system of the *Wilhelmy* type is embedded in a gas-tight housing.

For the electron micrographs, microscope grids were sandwiched between a glass slide and a formvar film, which was coated by vacuum deposition of 100 Å carbon and 50 Å SiO_2. Subsequently, the monolayer was deposited by the Langmuir-Blodgett technique. The observed contrast was due to differential charging of the crystalline and amorphous domains in the Philips EM 400 microscope. [8]

2. Domain Structure at the µm Level

Figure 1 gives a variety of fluorescence microscopic images observed after compression of a monolayer at the air/water interface to achieve a lateral pressure above π_c. The latter is defined from a distinct change in the slope of the isotherm "surface pressure as a function of area per molecule". It corresponds to the onset of the main phase transition of a lipid from a fluid to a more ordered state.[9] The transition is of first order and involves a change in the two-dimensional molecular density by up to 50%. In the denser phase the aliphatic tails are nearly parallel and in the all-*trans* configuration. Thus, the solubility is low for any impurity (e.g., the dye) and the phase appears dark under the fluorescence microscope. It is possible to observe coexistence of phases and to follow domain formation as a function of environmental parameters and time. Until recently, the domain shapes and superstructures presented in Figure 1 were completely unexpected. I will show by qualitative arguments that the periodic structures in Figure 1a, b form due to long-range electrostatic forces, whereas the shapes in Figure 1c, d are kinetically determined.

Electrostatic forces are a peculiar feature of this interfacial system and consist of two contributions: 1. Lipids have dissociable head groups and therefore the monolayer can be charged. The surface charge is counterbalanced either by ions in the subphase (e.g., divalent ions) that strongly bind to the head groups or by ions in the diffuse double layer. Thus, considering long range forces, the monolayer may be viewed as a dipolar sheet. The corresponding dipole moment can be calculated rather satisfactorily on the basis of Gouy-Chapman-Stern theory and varied via pH and ionic milieu.[10-13] 2. A qualitatively similar contribution results from the dipolar nature of the surfactant molecules. As the component of the dipole moment normal to the surface is not compensated due to the partial molecular alignment at the interface a total surface dipole moment results. This contribution is very difficult to assess because a molecule like a phospholipid contains many polar groups and the projection of these groups on the surface normal has to be known. Furthermore, due to the screening by water, the position relative to the water surface is very important. E.g., comparing a polar group above and below the water surface and a change in the dielectric constant from $\varepsilon(\text{water}) \approx 80$ to $\varepsilon(\text{hydrocarbon}) \approx 2$ the contribution of the group under water is reduced by a factor of $\varepsilon^2 \approx 6000$.[13] Therefore this contribution very sensitively depends on the local surface structure.

Despite this difficulty in theoretically quantifying these contributions their sum can be measured rather easily and accurately by surface potential measurements. According

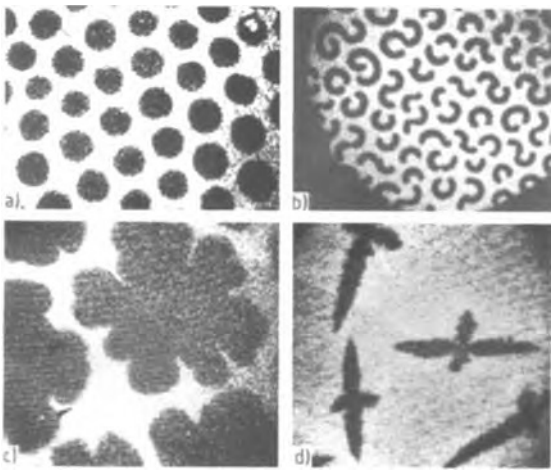

Fig. 1. Fluorescence micrographs of lipid monolayers containing about 1 mol% of the dye NBD-PE **2** in the phase coexistence region of a fluid (bright) and an ordered (dark) phase. The size of an image corresponds to 150 µm. a) DMPA, pH 11.3, 100 mM NaCl, 1 µM $CaCl_2$, $T = 10.5$°C; b) DMPA, 1 mol% cholesterol, pH 11.4, $T = 10$°C; c) DMPA, pH 5.5, $T = 20$°C; d) Bronco after a stepwise pressure increase, pH 5.5, $T = 20$°C.

to the Helmholtz equation the surface potential ΔV and the surface dipole moment are related by

$$\Delta V = \frac{\rho_D}{\varepsilon_0} \quad \text{(a)}$$

$\varepsilon_0 = 8.9 \times 10^{-12}$ C^2 m^{-2} N^{-1} and ρ_D is the dipole density normal to the surface. It is also possible to measure the differences in surface potential of fluid and ordered phases and then to calculate the differences in dipole density. These dipole density differences $\Delta\rho_D$, typically on the order of 100 mDebye nm^{-2} (and due to the difference in molecular density), enter into the calculation of long-range forces. To explain the hexagonal lattice of Figure 1a we have to answer two questions: 1. Why do individual domains repel one another over distances of several 10 μm? 2. Why do these domains exhibit uniform size?

Ad 1: As argued above the condensed phase domain can be considered as a dipolar disc of radius r with dipole moment P given by $P = \pi r^2 \Delta\rho_D$. The repulsive energy of two such discs at a center to center distance d can be estimated as[14]

$$W_{rep} = \frac{1}{4\pi\varepsilon\varepsilon_0 d^3} P^2 \quad \text{(b)}$$

Taking experimental numbers, it is easy to show that W_{rep} is much larger than kT (k = Boltzman const., T = absolute temperature), i.e., the repulsive energy is large enough to overcome any thermal motion.

Ad 2: Usually, for domain sizes above a critical radius r_c, the growth of larger domains is favored at the expense of smaller ones. This is due to the fact that the surface energy per molecule is smaller for a larger domain. The same holds also for a two-dimensional system where changes in surface energy may be ascribed to a line tension in the boundary between the ordered and fluid phases. Uniform domain size in an equilibrium situation therefore requires a force favoring small domains and thus counteracting line tension. Electrostatic forces, being of long range, yield such a contribution, because the energy density of a dipolar disc increases with size due to the dipolar repulsion of the individual molecules. Therefore one expects an equilibrium domain size. The quantitative calculation of the energy density, only logarithmically diverging with r, yields very poor agreement with experiment.[15] Furthermore, the domain dimensions can be varied via nucleation conditions indicating that they are nonequilibrium features.[16] On the other hand, these dimensions can be maintained over hours, and therefore the structure corresponds to a local minimum of free energy.

Hence the most plausible mechanism for formation of hexagonal superstructures is that a certain number of critical nuclei are formed during the initial stages of domain growth. These domains are of uniform size due to identical growth conditions, and they do not split into smaller pieces due to line tension, nor do they fuse due to electrostatic repulsion.

An interesting aspect left for further studies is to determine whether there is an interaction, probably inhibitory, between two growing domains. Electrostatic forces can also be considered to be responsible for formation of elongated domains. In the latter case electrostatic energy would be reduced since the mean distance between interacting molecular dipoles is increased. Elongation, however, requires additional line energy and therefore the balance between these forces determines an equilibrium shape. In the example shown in Figure 1b the electrostatic energy has been increased by increasing the pH (to 11) and reducing the temperature, and the line energy decreased by adding a small amount (1 mol%) of cholesterol.[17, 18] Varying these parameters, one can reversibly change the domain width, which is an apparent equilibrium feature, and induce abrupt changes from lamellar to circular shapes. To understand the spiral shapes one additionally has to take into account molecular chirality.

In many cases domain formation at the air/water interface leads to smooth but irregular shapes that do not become circular even after hours (Fig. 1c). These shapes develop from much more convoluted domains similar to those of Figure 2. The sharpest edges are annealed due to the action of line tension whereas other edges remain.[19] The latter may be due to the presence of impurities which may be enriched in the areas between two protrusions of one domain. This locally reduces line tension, the force responsible for reduction of the domain boundary length.

In special cases one may also observe a pronounced anisotropy of domain morphology which, like in the case of a three-dimensional crystal, reflects the underlying crystallographic lattice.[20] For the case of the diacetylenic lipid Bronco one can show that there is a nearly orthorhombic

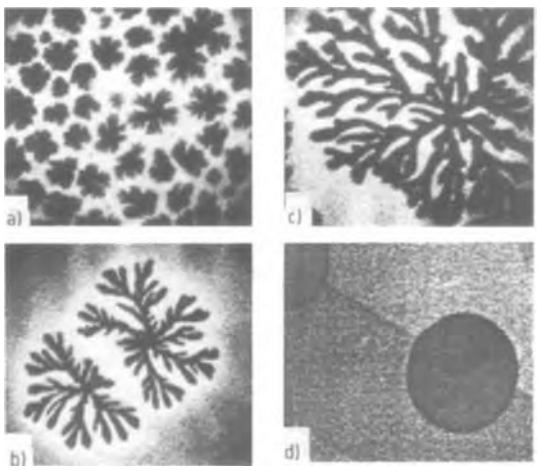

Fig. 2. Fluorescence micrographs of DMPE monolayers containing different concentrations c of a dye probe and at rather fast compression speed (1 Å^2 molecule^{-1} s^{-1}) a) $c = 6$ mol%, b) $c = 1.3$ mol%, c) $c = 0.3$ mol%. The shapes formed at high c do not anneal, whereas they become round at low c; see, e.g., Fig. 2d: $c = 0.7$ mol% after 20 min at constant pressure.

ADVANCED MATERIALS

lattice and that the two axes of preferred growth correspond to diagonals of the unit cell (see Fig. 1d).

These considerations show that the surface morphology strongly depends on growth kinetics, and useful structures may result. Thus it is very important to understand and to control the growth process. One way of doing this is to quickly vary the surface pressure and measure the development of domain size, domain shape, and pressure relaxation. Another possibility is to add impurities, of which the most convenient is the dye probe itself. Via analysis of the images, the impurity distribution can be measured.[19,21]

Typical images at different impurity (dye) concentrations are given in Figure 2. At very low dye concentrations highly convoluted structures are formed (Fig. 2b). These develop within times (<0.1 s) too short to be observed in our experiments. For intermediate dye concentrations (1 mol%) the structures are less intricate but their formation is slow enough to be followed (several seconds, Fig. 2c). For still higher dye concentrations many small domains result, again within very short times (Fig. 2a).

In the intermediate concentration range, where the development of the above mentioned parameters can be measured, the growth kinetics can be described within the framework of constitutional supercooling. During domain growth the impurities are less soluble in the ordered phase and are therefore enriched at the phase boundary.[19] There they reduce the melting temperature and thus inhibit the growth process. For further growth the process is controlled by impurity diffusion away from the interfacial area. The rate of diffusion to a protruding feature will be greater than that to an indentation leading to amplification of any initial roughness and ultimately to a highly folded boundary. Computer simulations on diffusion limited aggregation[22] reveal a self-similar structure with a fractal dimension of $f = 1.5$ in accordance with the value determined by analysis of the images obtained immediately after a pressure jump.[21] f is measured and defined from the equation $M = R^f$, where M is the area of a domain within a radius R about its center. The rounding off at later times (see Fig. 2d) is again due to the influence of line tension. Since the latter is decreased for high impurity concentrations, one understands that structures formed at high dye concentrations never anneal within experimental times. On the other hand, since impurities favor the formation of critical nuclei this could explain the increase in the number of domains with impurity concentrations.

3. Microstructure at the Molecular Level

The variety of domain morphologies presented in Figure 1 is expected to correspond to qualitatively different crystallographic lattice structures. This has indeed been demonstrated in electron diffraction experiments with monolayers on solid supports. The diffraction pattern for a typical phospholipid like DMPE shows a hexagonally symmetric arrangement of rather broad spots and no second order diffraction peak.[12,23] It displays a hexagonal lattice with d_{10} spacings between 4.2 and 4.3 Å typical for vertically oriented aliphatic chains. The local crystallographic axes are parallel within one domain.

In the other extreme when domains with very sharp edges were observed, many narrow diffraction spots with lower than threefold symmetry are encountered. Examples for this are monolayers of the polymerized lipid[24] studied in Figure 1d, of cyanine dyes,[25] and of the Py-TCNQ[26] salt presented in Figure 3. For the latter, electron microscopy shows domains with straight faces and sharp edges. Due to charging by the intense beam applied for diffraction studies, the circular area from which the diffracted intensity was taken could be visualized. The pattern in the insert of Figure 3 shows a variety of spots that are still under more detailed analysis. Apparently in this case the very rigid and well-ordered structure is determined by the extended planar head groups that exhibit no flexibility.

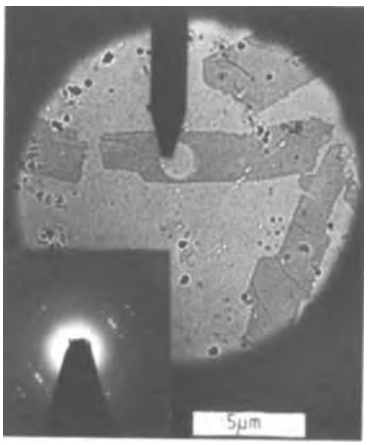

Fig. 3. Electron micrograph and electron diffraction pattern (insert) of a Py-TCNQ bilayer prepared by compression of a monolayer and transferred by the Langmuir-Blodgett technique.

To probe *in situ* the monolayer structure at the air/water interface X-ray diffraction[4,5,7] and reflexion studies[6,7] were performed with different monolayers at various surface pressures, densities, and subphase conditions. As an example, Figure 4 gives data for monolayers of the most frequently studied model compound arachidic acid. Figure 4a gives the intensity as a function of in plane scattering angle on increasing the surface pressure from bottom to top. Considering the variation of intensity and position with surface pressure one clearly observes three different regimes: I: For low surface pressures (high area per molecule, above A_t), the peak position is constant and the intensity increases with pressure. II: For intermediate areas per molecule, $A_s < A < A_t$, the intensity is constant but the position changes. III: Decreasing the area per molecule below A_s, the intensity abruptly increases whereas at higher pressures the line remains virtually unchanged.

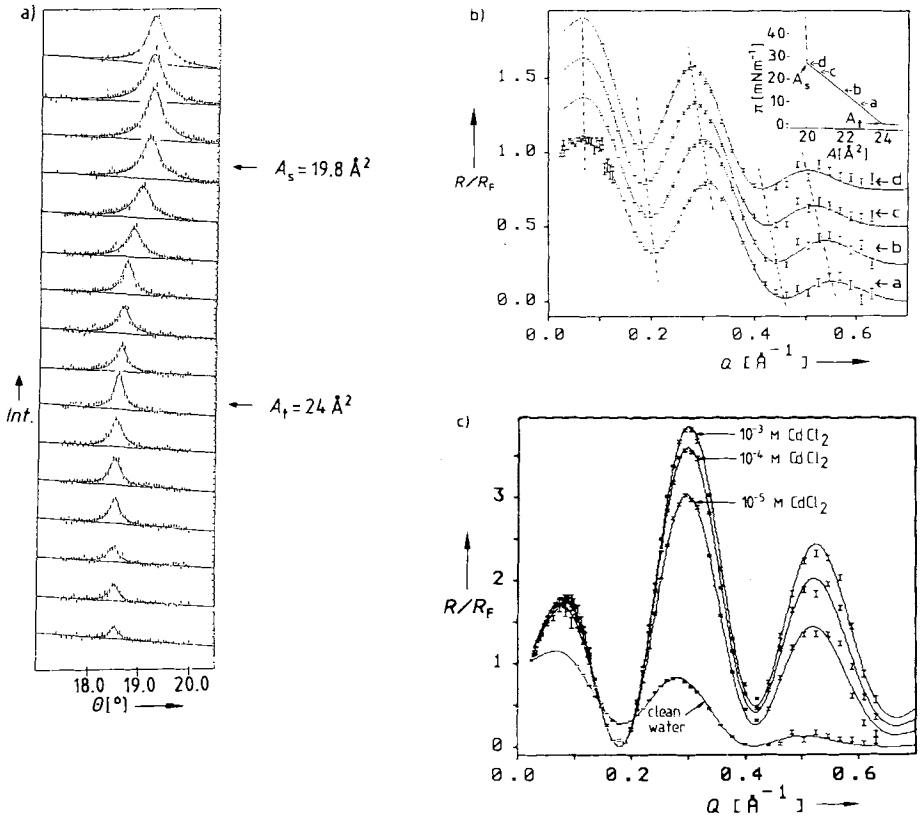

Fig. 4. X-ray scattering data of arachidic acid monolayers at the air/water interface. a) Diffracted intensity as a function of in plane diffraction angle θ for arachidic acid monolayers in the absence of ions and increasing the surface pressure from bottom to top. Indicated are also the areas per molecule A_s, A_t corresponding to breaks in the isotherm slope seen in the insert of b). b) X-ray reflectivity R normalized to the *Fresnel* reflectivity R_F as a function of vertical wave-vector transfer $Q = \frac{4\pi}{\lambda}\sin\alpha$, α being the reflection angle. The lines through the measurement points were obtained from a data fit using the referenced box model. No ions in the subphase, pH 5.5, $T = 20°C$. The measurements are displaced by 0.25 units along the ordinate and correspond to the points indicated on the isotherm in the insert. c) Reflectivity in the absence and presence (concentration indicated) of $CdCl_2$ in the subphase.

These regimes can be correlated with the pressure/area isotherm given in the insert in Figure 4b and interpreted as follows: I corresponds to the coexistence of an expanded disordered with a compressible ordered phase. One measures diffraction of the ordered phase with area fraction decreasing with pressure. Regime II is ascribed to an ordered phase where the structure varies continuously with surface pressure. III is a much less compressible phase normally called the solid phase.[1]

It is especially interesting to study the structural change in regime II in more detail, and this can be done by analysis of X-ray reflection. The reflection intensity R normalized to the value R_F expected for a stepwise density change R_F, as a function of incidence angle α $\left(Q = \frac{4\pi}{\lambda}\sin\alpha\right)$ is given in Figure 4b for various positions along the isotherm. The curves can be simulated using a box model[6,27] where the monolayer consists of two different slabs with defined density and thickness. On the water surface there is the slab containing the head groups (carboxy in this case); it is thus of higher electron density than water. A second slab above the first one contains the hydrocarbon tails and thus exhibits lower electron density. Obviously data have to be analyzed by a sensible combination of simulation and molecular modeling. For a more qualitative approach, however, one may use the fact that the first minimum in the reflectivity curve is due to a destructive interference of reflection at the air/hydrocarbon interface with that from the center of the head groups. The corresponding wave vector Q_{min} is therefore related to the lengths of head group and tail, l_H and l_T, respectively, according to

$$Q_{min} \cdot (l_T + l_{H/2}) = \frac{3}{2}\pi \qquad (c)$$

The shift of the minimum in Figure 4b with surface pressure can therefore be understood as an increase in film thickness. A more detailed analysis shows that within regime II the electron density in the tail region is constant and very high.[28] This demonstrates a uniform alignment of aliphatic tails in the all-*trans* configuration. Comparing the film thickness determined (l_T) with that expected for vertical tail orientation (l_T°) one may calculate the tilt angle φ with respect to the surface normal

$$\cos\varphi = \frac{l_T}{l_T^\circ} \qquad (d)$$

From the reflectivity data one then derives a continuous reduction of the tilt angle from about 30° to 0° in reducing the area per molecule from A_t to A_s. Compression of the monolayer therefore enforces a continuous change of the chain tilt and of the lattice constant.

ADVANCED MATERIALS

To demonstrate the high sensitivity of the X-ray technique to monitor the electron density near the interface Figure 4c compares the X-ray reflectivity measured in the absence and presence of different concentrations of $CdCl_2$ in the subphase for a monolayer in the highly condensed state. One realizes the dramatic influence of the counterion which is almost saturated at the lowest concentration used. This influence is basically due to the increase in electron density in the head group moiety by addition of $1/2\,Cd^{2+}$ per head group.

From a line shape analysis one may derive the positional coherence length. Assuming a grain-like structure one may calculate the grain size L/d from the measured line width Δ according to $L/d = 0.443/\Delta$.

In the example presented above one determines $L/d \approx 100$. This is in marked contrast to the coherence length of crystallographic axes (orientational order) which is larger than $10^5 d$, as determined from electron diffraction[23] and fluorescence polarization data.[29] Similar features were also observed for monolayers of phospholipids[4,5] where in addition a phase transition was found with a drastic change in positional coherence length. Phases with long range positional and short range orientational order are expected theoretically for two-dimensional systems.[30] These calculations also showed the strong influence of trapped impurities on the line shape in accordance with our findings.

4. Structure Formation During Adsorption

The ideas discussed in the preceding sections should not only be valid for surfactant monolayers but more generally for two-dimensional structures at interfaces. An example on this is presented in Figure 5. In a subphase containing a negatively charged dye, it is possible to concentrate the dye near the interface by spreading a positively charged monolayer. If the concentration exceeds the solubility limit the dye crystallizes and in the present example may form brightly fluorescing J-aggregates.[31] Varying the subphase and monolayer conditions various crystal morphologies can be prepared[32] and distinguished by polarization microscopy. On spreading and compressing a monolayer, circular patches of nonoriented aggregates are formed (Fig. 5a). These exhibit dimensions and superstructures similar to those of lipid domains. After some minutes recrystallization becomes observable at the boundary of these domains yielding much brighter linear aggregates (Fig. 5a). On expanding the film the domains disappear and on a second compression the linear aggregates dominate (Fig. c, d). These are of very homogeneous size, which is determined by growth conditions, and repel one another similar to the lamellae of Figure 1. Due to the very high order within these domains sharp electron diffraction spots can be observed.[33]

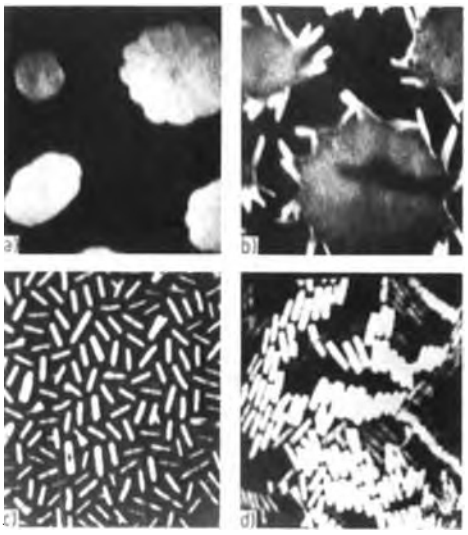

Fig. 5. Fluorescence micrographs of J-aggregates of a water-soluble cyanine dye electrostatically bound to a positively charged monolayer. a) Structure formed immediately after compression and b) about 10 min at a fixed area per molecule. c, d) Second compression with highest molecular density. Different brightnesses are due to the intrinsic polarization of the detection system pH 5.5, $T = 20\,^{\circ}C$, the image size corresponds to 150 μm.

5. Proteins in Thin Films

It has been shown that proteins can be arranged and distributed in a monolayer in a similar way as staining dyes.[34,35] They are generally less soluble in the more condensed phase and therefore concentrated in the fluid environment. This opens new possibilities for increasing local concentrations of reactants and thus to enhance reaction rates. One step further along this line may be to increase protein concentrations at boundaries.

As an example of the latter, Figure 6 presents fluorescence micrographs showing the distribution of fluores-

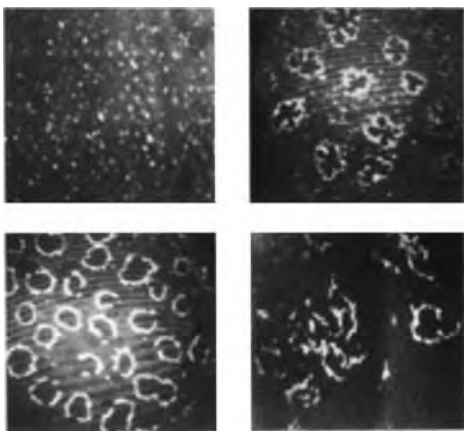

Fig. 6. Fluorescence micrograph of a DMPE monolayer containing aggregated fluorescently labeled Con A. Protein patches already present in the fluid monolayer phase (upper left) are attracted to the fluid/solid domain boundary when the monolayer is in the phase coexistence range (upper right and lower left). On reexpansion the solid (darkest) DMPE domains melt leaving strings of protein (lower right) $T = 20\,^{\circ}C$, pH 7, 100 μM $MnCl_2$, 100 μM $CaCl_2$, 100 mM NaCl.

cently labeled Concanavalin A (Con A) in a DMPE monolayer in the phase coexistence range. One clearly observes the condensed phase DMPE domains (dark) surrounded by a frame of protein patches in those images except in that on the top left where the complete monolayer is fluid. The arrangement of these patches can be understood as follows: According to surface potential data the protein has a normal dipole moment opposite to that of the lipid.[36] Its patches are therefore attracted by the condensed phase domains. Due to the dense packing of the latter, however, they are not incorporated in these domains and therefore remain near the boundary. The protein boundary is a rather loose structure and allows lipid penetration to the interface, since the DMPE domains continue to grow on further compression. On the other hand, on expansion of the monolayer the DMPE domains melt, but the protein patches remain connected to form strings.[37]

6. Concluding Remarks

It is now possible to produce ultrathin films with a periodic arrangement of functional molecules like dyes or proteins. Such control, on an almost molecular level, is a central requirement for any future device fabrication. New ways and physical principles to achieve this were described in this article. Our studies were performed with compounds similar to biological systems. The systems may be considered too artificial by a biologist and too biological by a materials scientist. Nevertheless I tried to demonstrate that part of the ideas presented may be applicable to seemingly different systems like adsorbates or to the fabrication of biosensors requiring oriented arrays of receptor proteins. Beyond that, there are many serious attempts to use this class of organic films for optical, optoelectronic, lubrication, lithographic and other applications, all requiring microstructure control. This report should primarily stimulate more elaborate experimental as well as theoretical studies.

Last minute information:

EUROPEAN SYMPOSIUM ON ADVANCED MATERIALS; THEIR ROLE IN NEW TECHNOLOGIES

MADRID, Congress Center
June 27–29, 1988

Main topics: Semiconductors, Opto-electronics, Ceramic and other Sensor Materials, Magnetic Materials, Superconductivity, Molecular Electronics, Artificially Structured Materials, Composite Materials, Surfaces and Interfaces, Micro Nondestructive Evaluation.
The symposium will be a joint discussion between industry and university researchers. It will be linked directly to the research program of the European Institute of Technology (EIT) in materials science. It is expected that the initial EIT grants under this program to universities and public laboratories will be announced during the symposium.
This symposium will be hosted by AT&T Microelectrónica de España.
The EIT is a major new industrial consortium for scientific and engineering research and education. Founding Members of EIT are: Montedison, Philips, IBM Europe, AT&T and ENICHEM.
For all further information, please contact:

EUROPEAN INSTITUTE OF TECHNOLOGY

ADVANCED MATERIALS

Perovskite-Type Oxides—the New Approach to High-T_c Superconductivity**

Nobel Lecture

By J. Georg Bednorz* and K. Alex Müller*

Part 1: The Early Work in Rüschlikon

In our lecture, we take the opportunity to describe the guiding ideas and our effort in the search for high-T_c superconductivity. They directed the way from the cubic niobium-containing alloys to layered copper-containing oxides of perovskite-type structure. We shall also throw some light onto the circumstances and the environment which made this breakthrough possible. In the second part, properties of the new superconductors are described.

The Background

At IBM's Zürich Research Laboratory, there had been a tradition of more than two decades of research efforts in insulating oxides. The key materials under investigation were perovskites like $SrTiO_3$ and $LaAlO_3$, used as model crystals to study structural and ferroelectric phase transitions. The pioneering ESR experiments by *Alex Müller (KAM)*[1.1] and *W. Berlinger* on transition-metal impurities in the perovskite host lattice brought substantial insight into the local symmetry of these crystals, i.e., the rotations of the TiO_6 octahedra, the characteristic building units of the lattice.

One of us *(KAM)* first became aware of the possibility of high-temperature superconductivity in the 100 K range from the calculations of *T. Schneider* and *E. Stoll* on metallic hydrogen.[1.2] Such a hydrogen state was estimated to be in the 2-3 Mbar range. Subsequent discussions with *T. Schneider* on the possibility of incorporating sufficient hydrogen into a high-dielectric-constant material like $SrTiO_3$ to induce a metallic state led, however, to the conclusion that the density required could not be reached.

While working on my Ph.D. thesis at the Solid State Physics Laboratory of the ETH Zurich, I *(JGB)* gained my first experience in low-temperature experiments by studying the structural and ferroelectric properties of perovskite solid-solution crystals. It was fascinating to learn about the large variety of properties of these materials and how one could change them by varying their compositions. The key material, pure $SrTiO_3$, could even be turned into a superconductor if it were reduced, i.e., if oxygen were partially removed from its lattice.[1.3] The transition temperature of 0.3 K, however, was too low to cause much excitement in the world of superconductivity research. Nevertheless, it was interesting that superconductivity occurred at all, because the carrier densities were so low compared to superconducting NbO, which has carrier densities like a normal metal.

My (*JGB*'s) personal interest in the fascinating phenomenon of superconductivity was triggered in 1978 by a telephone call from *Heinrich Rohrer*, the manager of a new arrival at IBM Rüschlikon, *Gerd Binnig*. With his background in superconductivity and tunneling, *Gerd* was interested in studying the superconductive properties of $SrTiO_3$, especially in the case when the carrier density in the system was increased. For me (*JGB*), this was the start of a short but stimulating collaboration, as within a few days I was able to provide the IBM group with Nb-doped single crystals which had an enhanced carrier density compared to the simply reduced material. The increase in T_c was exciting for us. In the Nb-doped samples ($n = 2 \times 10^{20}$ cm^{-3}) the plasma edge lies below the highest optical phonon, which is therefore unshielded.[1.4] The enhanced electron–phonon coupling led to a T_c of 0.7 K.[1.5] By further increasing the dopant concentration, the T_c even rose to 1.2 K, but this turned out to be the *limit*, because the plasma edge passes the highest phonon. *Gerd* then lost his interest in this project, and with deep disappointment I realized that he had started to develop what was called a scanning tunneling microscope (STM). However, for *Gerd* and *Heinrich Rohrer*, it turned out to be a good decision, as everyone realized by 1986 at the latest, when they were awarded the Nobel Prize in Physics. For my part, I concentrated on my thesis.

It was in 1978 that *Alex (KAM)*, my second supervisor, took an 18-month sabbatical at IBM's T. J. Watson Research Center in Yorktown Heights, NY, where he started working in the field of superconductivity. After his return in 1980, he also taught an introductory course at the University of Zürich. His special interest was the field of granular superconductivity, an example being aluminum,[1.6]

where small metallic grains are surrounded by oxide layers acting as Josephson junctions. In granular systems, the T_c's were higher, up to 2.8 K, as compared to pure Al with $T_c = 1.1$ K.

Involvement with the Problem

It was in the fall of 1983 that *Alex*, heading his IBM Fellow group, approached me and asked whether I would be interested in collaborating in the search for superconductivity in oxides. Without hesitation, I immediately agreed. *Alex* later told me he had been surprised that he had hardly needed to use any arguments to convince me; of course, it was the result of the short episode of my activities in connection with the superconducting $SrTiO_3$—he was knocking a door already open. And indeed, for somebody not directly involved in pushing T_c's to the limit and having a background in the physics of oxides, casual observation of the development of the increase of superconducting transition temperatures, shown in Figure 1.1, would naturally lead to the conviction that intermetallic compounds should not be pursued any further, as the highest T_c had remained since 1973 at 23.3 K.[1.7] But nevertheless, the fact that superconductivity had been observed in several complex oxides evoked our special interest.

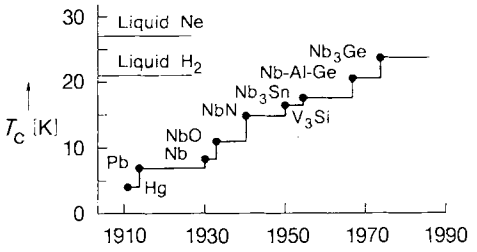

Fig. 1.1. Development of superconducting transition temperatures after the discovery of the phenomenon in 1911. The materials named are metals or intermetallic compounds and gave the highest T_c's at the time.

The second oxide after $SrTiO_3$ to exhibit surprisingly high T_c's of 13 K was discovered in the Li-Ti-O system by *Johnston* et al.[1.8] in 1973. Their multiphase samples contained a $Li_{1+x}Ti_{2-x}O_4$ spinel responsible for the high T_c. Owing to the presence of different phases and difficulties in preparation, the general interest remained low, especially as in 1975 *Sleight* et al.[1.9] discovered the $BaPb_{1-x}Bi_xO_3$ perovskite also exhibiting a T_c of 13 K. This compound could easily be prepared as a single phase and even thin films for device applications could be grown, a fact that triggered increased activities in the United States and Japan. According to the BCS theory[1.10] which gives

$$k \times T_c = 1.13 \hbar \omega_D e^{-1/(N(E_F)) \times V^*}$$

both mixed-valent oxides, having a low carrier density $n = 4 \times 10^{21}$ cm^{-3} and a comparatively low density of states per unit cell $N(E_F)$ at the Fermi level, should have a large electron-phonon coupling constant, leading to the high T_c's. Subsequently, attempts were made to raise the T_c in the perovskite by increasing $N(E_F)$ via changing the Pb : Bi ratio, but the compound underwent a metal-insulator transition with a different structure, and thus all attempts failed.

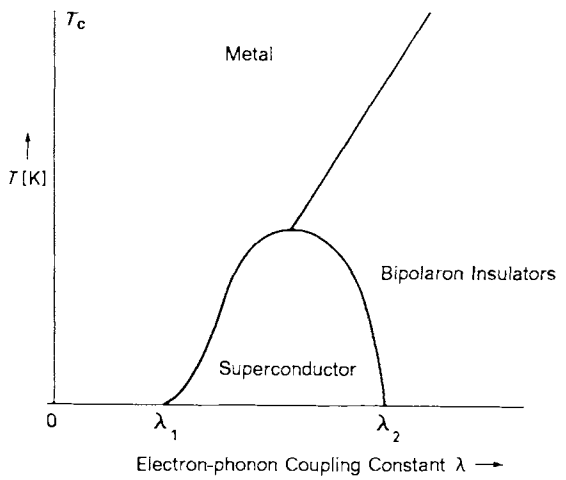

Fig. 1.2. Phase diagram as a function of electron-phonon coupling strength (adapted from [1.11]).

We in Rüschlikon took up this challenge, as we expected other metallic oxides to exist where even higher T_c's could be reached by increasing $N(E_F)$ and/or the electron-phonon coupling. Possibly we could enhance the latter by polaron formation as proposed theoretically by *Chakraverty*[1.11] or by the introduction of mixed valencies. The intuitive phase diagram of the coupling constant $\lambda = N(E_F) \times V^*$ versus T proposed by *Chakraverty* for polaronic contributions is shown in Figure 1.2. There are three phases, a metallic one for small λ and an insulating bipolaronic one for large λ, with a superconductive phase between them, i.e., a metal-insulator transition occurs for large λ. For intermediate λ, a high-T_c superconductor might be expected. The question was, in which systems to look for superconductive transitions.

The Concept

The guiding idea in developing the concept was influenced by the Jahn-Teller (JT) polaron model, as studied in a linear chain model for narrow-band intermetallic compounds by *Höck* et al.[1.12] The Jahn-Teller (JT) theorem is well known in the chemistry of complex states. A nonlinear molecule or a molecular complex exhibiting an electronic degeneracy will spontaneously distort to remove or reduce this degeneracy. Complexes containing specific transition metal (TM) central ions with special valency show this effect. In the linear chain model,[1.12] for small JT distortions with a stabilization energy E_{JT} smaller than the bandwidth of the metal, only a slight perturbation of the

ADVANCED MATERIALS

traveling electrons is present. With increasing E_{JT}, the tendency to localization is enhanced, and for the case where E_{JT} is comparable with the bandwidth, the formation of JT polarons was postulated.

These composites of an electron and a surrounding lattice distortion with a high effective mass can travel through the lattice as a whole, and a strong electron-phonon coupling exists. In our opinion, this model could fit the Chakraverty phase diagram perfectly. Based on the experience from studies of isolated JT ions in the perovskite insulators, our assumption was that the model would also apply to the oxides, our field of expertise, if they could be turned into conductors. We knew there were many of them. Oxides containing TM ions with partially filled e_g orbitals, like Ni^{3+}, Fe^{4+} or Cu^{2+} exhibit a strong JT effect (Fig. 1.3), and we considered these as possible candidates for new superconductors.

Copper Ions in the Oxide Octahedron

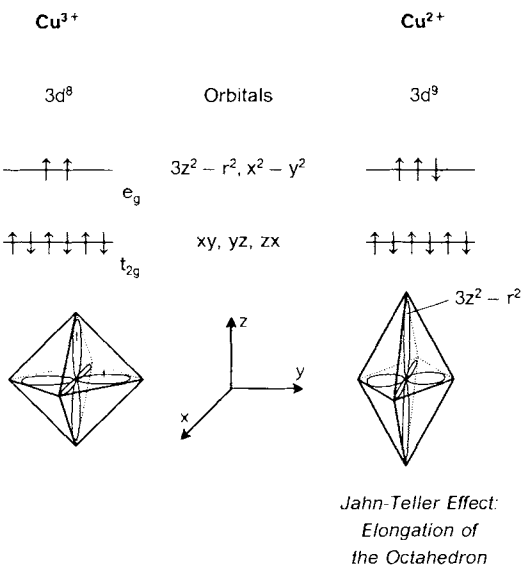

Fig. 1.3. Schematic representation of electron orbitals for octahedrally coordinated copper ions in oxides. For Cu^{3+} with $3d^8$ configuration, the orbitals transforming as base functions of the cubic e_g group are half-filled, thus a singlet ground state is formed. In the presence of Cu^{2+} with $3d^9$ configuration, the ground state is degenerate, and a spontaneous distortion of the octahedron occurs to remove this degeneracy. This is known as the Jahn-Teller effect.

The Search and Breakthrough

We started the search for high-T_c superconductivity in late summer 1983 with the La-Ni-O system. $LaNiO_3$ is a metallic conductor with the transfer energy of the JT-e_g electrons larger than the JT stabilization energy, and thus the JT distortion of the oxygen octahedra surrounding the Ni^{3+} is suppressed.[1,13] However, even the preparation of the pure compound brought some surprises, as the material obtained by our standard co-precipitation method[1,14] and subsequent solid-state reaction turned out to be sensitive not only to the chemicals involved[1,15] but also to the reaction temperatures. Having overcome all difficulties with the pure compound, we started to partially replace Ni^{3+} by Al^{3+} to reduce the metallic bandwidth of the Ni^{3+} ions and make it comparable to the Ni^{3+} Jahn-Teller stabilization energy. With increasing Al^{3+} concentration, the metallic characteristics (see Fig. 1.4) of the pure $LaNiO_3$ gradually changed, first to give a general increase in the resistivity and finally with high substitution leading to a semiconducting behavior with a transition to localization at low temperatures. The idea did not seem to work out the way we had thought, so we considered the introduction of some internal strain within the $LaNiO_3$ lattice to reduce the bandwidth. We achieved this through replacing the La^{3+} ion by the smaller Y^{3+} ion, keeping the Ni^{3+} site unaffected. The resistance behavior changed in a way we had already observed in the previous case, and at that point we started wondering whether the target at which we were aiming really did exist. Would the path we decided to embark upon finally lead into a blind alley?

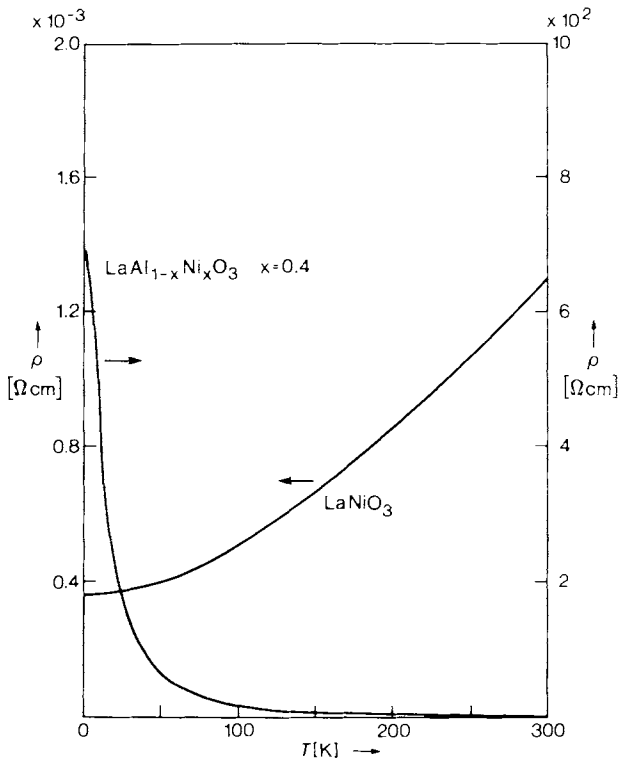

Fig. 1.4. Temperature dependence of the resistivity for metallic $LaNiO_3$ and $LaAl_{1-x}Ni_xO_3$, where substitution of Ni^{3+} by Al^{3+} leads to insulating behavior for $x = 0.4$.

It was in 1985 that the project entered this critical phase, and it probably only survived because the experimental situation, which had generally hampered our efforts, was improved. The period of sharing another group's

equipment for resistivity measurements came to an end as our colleague, *Pierre Guéret*, agreed to my established right to use a newly set up automatic system. Thus, the measuring time was transferred from late evening to normal working hours. *Toni Schneider*, at that time acting manager of the Physics department, supported the plans to improve the obsolete X-ray analytical equipment to simplify systematic phase analysis, and in addition we had some hopes in our new idea, involving another TM element encountered in our search, namely copper. In a new series of compounds, partial replacement of the JT Ni^{3+} by the non-JT Cu^{3+} increased the absolute value of the resistance, although the metallic character of the solid solutions was preserved down to 4 K.[1.13] But again, we found no evidence of superconductivity. The time to study the literature and reflect on the past had arrived.

It was in late 1985 that the turning point was reached. I became aware of an article by the French scientists *C. Michel, L. Er-Rakho* and *B. Raveau*, who had investigated a Ba-La-Cu oxide with perovskite structure exhibiting metallic conductivity between 300 and $-100\,^{\circ}C$.[1.16] That group studied the catalytic properties of oxygen-deficient compounds at elevated temperatures.[1.17] In the Ba-La-Cu oxide with a perovskite-type structure containing Cu in two different valencies, all our concept requirements seemed to be fulfilled.

I immediately went to the ground-floor laboratory and started preparations for a series of solid solutions, since by varying the Ba : La ratio one would have a sensitive tool to continuously tune the mixed valency of copper. Within one day the synthesis was complete, but the measurement had to be postponed, owing to the announcement of the visit of Dr. *Ralph Gomory*, our Director of Research. These visits always kept people occupied for a while, preparing their presentations.

Having lived through this important visit, and returning from an extended vacation in mid-January 1986, I recalled that when reading about the Ba-La-Cu oxide, it had intuitively attracted my attention. I decided to resume my measurements on the new compound. When performing the four-point resistivity measurement, the temperature dependence did not seem to be anything special when compared with the dozens of samples measured earlier. During cooling, however, a metallic-like decrease was first observed, followed by an increase at low temperatures, indicating a transition to localization. My inner tension, always increasing as the temperature approached the 30 K range, started to be released when a sudden resistivity drop of 50% occurred at 11 K. Was this the first indication of superconductivity?

Alex and I were really excited, as repeated measurements showed perfect reproducibility and an error could be ruled out. Compositions as well as the thermal treatment were varied, and within two weeks we were able to shift the onset of the resistivity drop to 35 K (Fig. 1.5). This was an incredibly high value compared to the highest T_c in the Nb_3Ge superconductor.

We knew that in the past there had been numerous reports on high-T_c superconductivity, which had turned out to be non-irreproducible;[1.7] therefore before to the publishing of our results, we asked ourselves critical questions about its origin. A metal-to-metal transition, for example, was unlikely, owing to the fact that with increasing measuring current the onset of the resistivity drop was shifted to

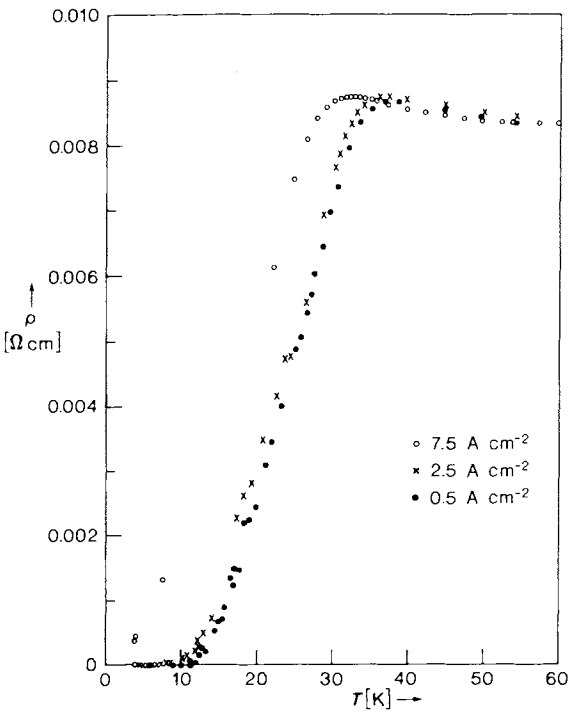

Fig. 1.5. Low-temperature resistivity of a sample with $x(Ba)=0.75$, recorded for different current densities (adapted from [1.19]).

ADVANCED MATERIALS

lower temperatures. On the other hand, this behavior supported our interpretation that the drop in $\rho(T)$ was related to the onset of superconductivity in granular materials. These are, for example, polycrystalline films of $BaPb_{1-x}Bi_xO_3$[1.18] exhibiting grain boundaries, or different crystallographic phases with interpenetrating grains as in the Li-Ti oxide.[1.7] Indeed, X-ray diffraction patterns of our samples revealed the presence of at least two different phases (see Fig. 1.6). Although we started the preparation process of the material with the same cation ratios as the French group, the wet-chemical process did not lead to the same result. This later turned out to be a stroke of luck, in the sense that the compound we wanted to form was not superconducting. The dominating phase could be identified as having a layered perovskite-like structure of K_2NiF_4-type as seen from Figure 1.7. The diffraction lines of the second phase resembled those of an oxygen-deficient perovskite with a three-dimensionally connected network of octahedra. In both structures, La was partially replaced by Ba, as we learned from an electron microprobe analysis which Dr. *Jürg Sommerauer* at the ETH Zürich performed for us as a favor. However, the question was "which is the compound where the mixed valency of the copper leads to the superconductive transition?"

We had difficulties in finding a conclusive answer at the time; however, we rated the importance of our discovery so high that we decided to publish our findings, despite the fact that we had not yet been able to perform magnetic measurements to show the presence of the Meissner-Ochsenfeld effect. Thus, our report was cautiously entitled "Possible High T_c Superconductivity in the Ba-La-Cu-O System".[1.19] We approached *Eric Courtens*, my manager at the time, who in late 1985 had already strongly supported our request to purchase a dc SQUID magnetometer, and who is on the editorial board of *Zeitschrift für Physik*. In this capacity, we solicited his help to receive and submit the paper, although, admittedly, it did involve some gentle persuasion on our part!

Alex and I then decided to ask Dr. *Masaaki Takashige* whether he would be interested in our project. Dr. *Takashige*, a visiting scientist from Japan, had joined our Laboratory in February 1986 for one year. He was attached to *Alex*'s Fellowship group, and I had given him some support in pursuing his activities in the field of amorphous oxides. As he was sharing my office, I was able to judge his reaction, and noted how his careful sceptical comments changed to supporting conviction while we were discussing the results. We had found our first ally.

Following this, while awaiting delivery of the magnetometer, we tried hard to identify the superconducting

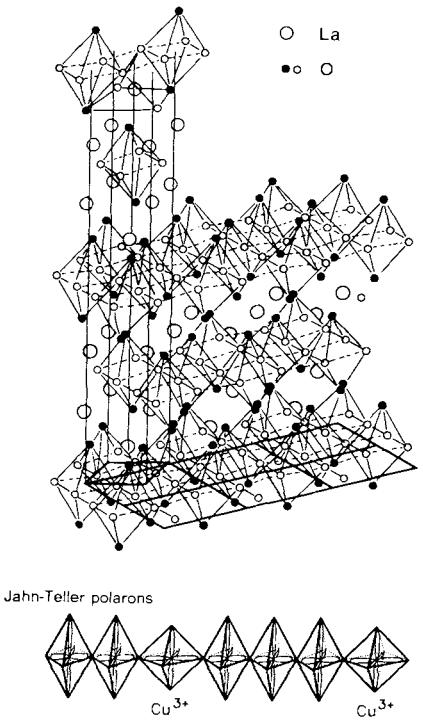

Fig. 1.7. Top: Structure of the orthorhombic La_2CuO_4. Large open circles represent the lanthanum ions, small open and filled circles the oxygen ions. The copper ions (not shown) are centered in the oxygen octahedra (from [1.29], © American Association for the Advancement of Science, 1987). Bottom: It is schematically shown how, in a linear chain, substitution of trivalent La by a divalent alkaline-earth element would lead to a symmetric change of the oxygen polyhedra in the presence of Cu^{3+}.

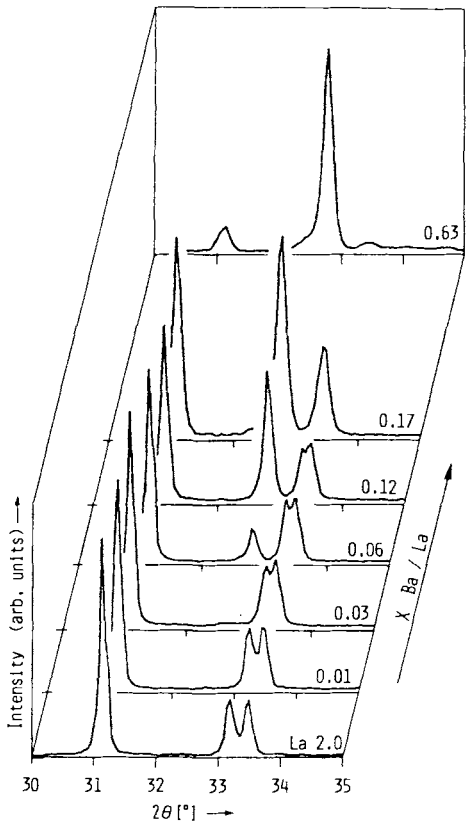

Fig. 1.8. Characteristic part of the X-ray diffraction pattern, showing the orthorhombic-to-tetragonal structural phase transition with increasing Ba : La ratio. Concentration axis not to scale (adapted from [1.20]).

phase by systematically changing the composition and measuring the lattice parameters and electrical properties. We found strong indications that the Ba-containing La_2CuO_4 was the phase responsible for the superconducting transition in our samples. Starting from the orthorhombically distorted host lattice, increasing the Ba substitution led to a continuous variation of the lattice towards a tetragonal unit cell[1.20] (see Fig. 1.8). The highest T_c's were obtained with a Ba concentration close to this transition (Fig. 1.9), whereas when the perovskite phase became dominant, the transition was suppressed and the samples showed only metallic characteristics.

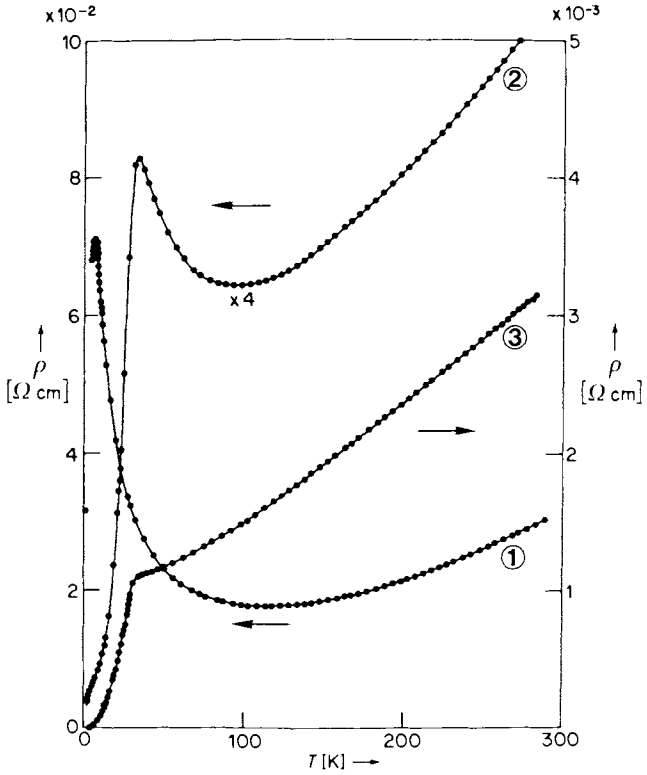

Fig. 1.9. Resistivity as a function of temperature for La_2CuO_{4-y} : Ba samples with three different Ba : La ratios. Curves ①, ②, and ③ correspond to ratios of 0.03, 0.06, and 0.07, respectively (adapted from [1.20]).

Finally, in September 1986, the susceptometer had been set up and we were all ready to run the magnetic measurements. To ensure that with the new magnetometer we did not measure any false results, *Masaaki* and I decided to gain experience on a known superconductor such as lead rather than starting on our samples. The Ba-La-Cu oxide we measured first had a low Ba content, where metallic behavior had been measured down to 100 K and a transition to localization occurred at lower temperatures. Accordingly, the magnetic susceptibility exhibited Pauli-like positive, temperature-independent and Curie-Weiss behavior at low temperatures, as illustrated by Figure 1.10. Most importantly, in samples showing a resistivity drop, a transition from para- to diamagnetism occurred at slightly lower temperatures (see Fig. 1.11) indicating that superconductivity-related shielding currents existed. The diamagnetic transition started below what is presumably the highest T_c in the samples as indicated by theories[1.21, 1.22] describing the behavior of percolative superconductors. In all our samples, the transition to the diamagnetic state was systematically related to the results of our resistivity measurements. The final proof of superconductivity, the presence of the Meissner-Ochsenfeld effect, had been demonstrated. Combining the X-ray analysis, resistivity and susceptibility measurements, it was now possible to clearly identify the Ba-doped La_2CuO_4 as the superconducting compound.

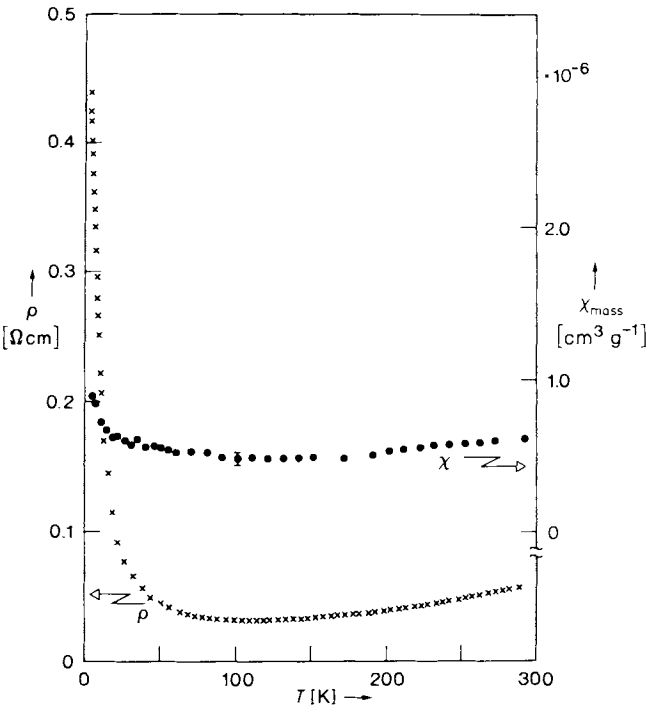

Fig. 1.10. Temperature dependence of resistivity (×) and mass susceptibility (●) of sample ① (adapted from [1.23]).

First Responses and Confirmations

The number of our troops was indeed growing. *Richard Greene* at our Research Center in Yorktown Heights had learned about our results and became excited. He had made substantial contributions in the field of organic superconductors and wanted to collaborate in measuring specific-heat data on our samples. We initiated an exchange of information, telefaxing the latest results of our research and sending samples. Realizing that our first paper had now appeared in the open literature, we rushed to get the results of our susceptibility data written up for publication.

ADVANCED MATERIALS

The day we made the final corrections to our report turned out to be one of the most remarkable days in the history of our Laboratory. *Alex, Masaaki* and I were sitting together, when the announcement was made over our P.A. system that the 1986 Nobel Prize for Physics had been awarded to our colleagues *Gerd Binnig* and *Heinrich Rohrer*. With everything prepared for the submission of our paper,[1.23] for one more day we could forget about our work, and together with the whole Laboratory celebrate the new laureates. One day later we were back to reality, and I started to prepare a set of samples for *Richard Greene. Praveen Chaudhari*, our director of Physical Science in Yorktown Heights, took them with him the same evening.

Later in November, we received the first response to our latest work from Professor *W. Buckel*, to whom *Alex* had send a preprint with the results of the magnetic measurements. His congratulations on our work were an encouragement, as we began to realize that we would probably have a difficult time getting our results accepted. Indeed, *Alex* and I had started giving talks about our discovery and, although the presence of the Meissner effect should have convinced people, at first we were met by a skeptical audience. However, this period turned out to be very short indeed.

We continued with the magnetic characterization of the superconducting samples and found interesting properties related to the behavior of a spin glass.[1.24] We then intensively studied the magnetic field and time dependences of the magnetization, before finally starting to realize an obvious idea, namely, to replace La also by other alkaline-earth elements like Sr and Ca. In particular Sr^{2+} had the same ionic radius as La^{3+}. We started experiments on the new materials, which indicated that for the Sr-substituted samples T_c was approaching 40 K and the diamagnetism was even higher (see Fig. 1.12).[1.25] It was just at that time that we learned from the Asahi-Shinbun International Satellite Edition [28 November 1986] that the group of Professor *Tanaka* at the University of Tokyo had repeated our experiments and could confirm our result.[1.26] We were relieved, and even more so when we received a letter from Professor *C. W. Chu* at the University of Houston, who was also convinced that within the Ba-La-Cu-O system superconductivity occurred at 35 K.[1.27] Colleagues who had not paid any attention to our work at all suddenly became

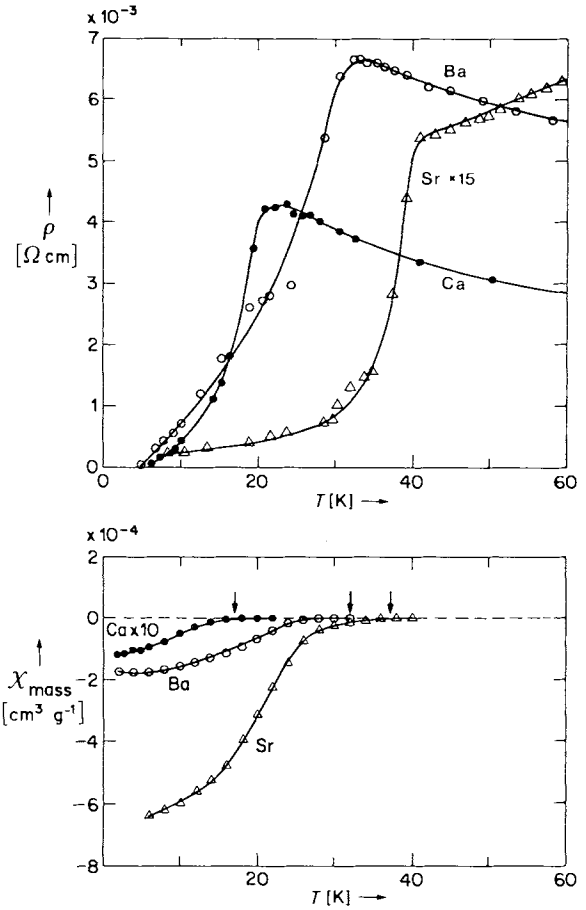

Fig. 1.12. Top: Resistivity as a function of temperature for Ca (●), Sr (△), and Ba (○) substitution with substituent to La ratios of 0.2/1.8, 0.2/1.8, 0.15/1.85, respectively. The Sr curve has been vertically expanded by a factor of 15. Bottom: Magnetic susceptibility of these samples. The substituents are Ca (●), Sr (△), and Ba (○), with total sample masses of 0.14, 0.21, and 0.13 g, respectively. The Ca curve has been expanded by a factor of 10. Arrows indicate onset temperatures (adapted from [1.25]).

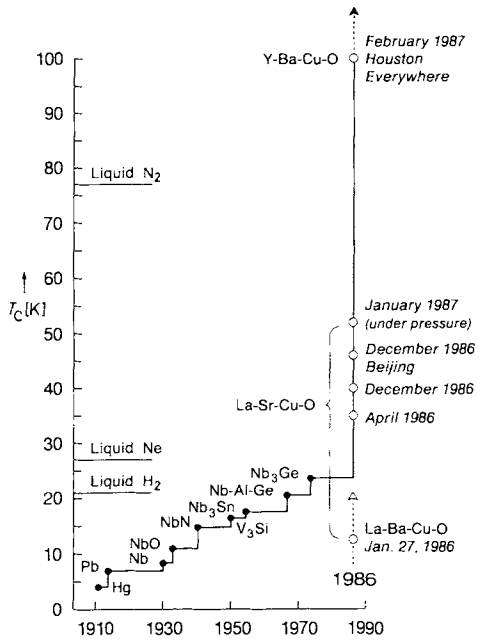

Fig. 1.13. Evolution of the superconductive transition temperature subsequent to the discovery of the phenomenon (adapted from [1.29]).

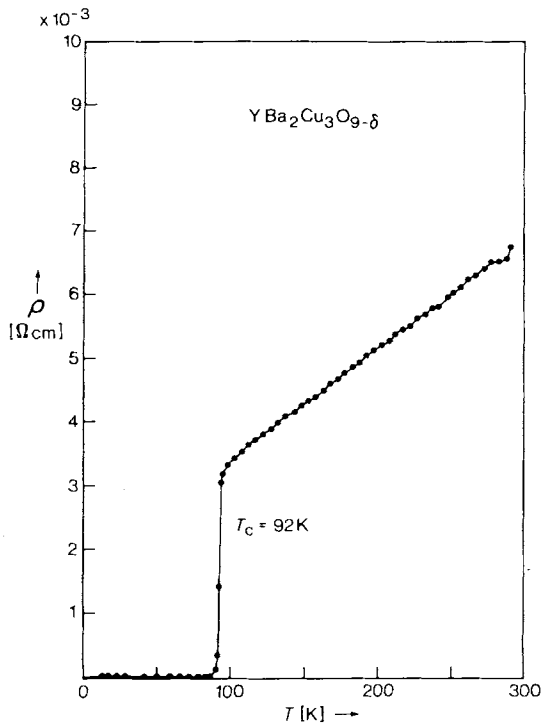

Fig. 1.14. Resistivity of a single-phase $YBa_2Cu_3O_7$ sample ("123 compound") as a function of temperature.

alert. By applying hydrostatic pressure to the samples, Professor *Chu* was able to shift the superconductive transition from 35 to almost 50 K.[1.27] Modification of the original oxides by introducing the smaller yttrium for the larger lanthanum ion resulted in a giant jump of T_c to 92 K in multiphase samples[1.28] (Fig. 1.13). At a breathtaking pace, dozens of groups now repeated these experiments and after an effort of only a few days the new superconducting compound could be isolated and identified. The resistive transition in the new $YBa_2Cu_3O_7$ compound was complete at 92 K (Fig. 1.14), and even more impressive was the fact that the Meissner effect could now be demonstrated without any experimental difficulties with liquid nitrogen as the coolant. Within several months, the field of superconductivity had experienced a tremendous revival, with an explosive development of T_c's such that nobody can predict where it will end.

An early account of the discovery appeared in the September 4 1987 issue of *Science*, which was dedicated to science in Europe.[1.29]

Part 2: Properties of the New Superconductors

In the second part, properties of the new layered oxygen superconductors are described. Since their discovery, summarized in the first part, a real avalanche of papers has appeared; thus it would be beyond the scope of this lecture to review all of them here. A forthcoming international conference in Interlaken, Switzerland, in late February 1988, is intended to fulfill this task and will be chaired by one of us *(KAM)*[*]. Therefore, only a selected number of experiments was discussed in Stockholm—those judged of importance at this time for the understanding of superconductivity in the layered copper oxides. In some of them, the laureates themselves were involved, in others not. Owing to the frantic activity in the field, it may be possible that equivalent work with priority existed unknown to us. Should this indeed be the case, we apologize and propose that the following be read for what it is, namely, a write-up of the lecture given, including the transparencies shown.

After the existence of the new high-T_c superconductors had been confirmed, one of the first questions was "What type of superconductivity is it?" Does one again have Cooper pairing[2.1] or not? This question could be answered in the affirmative. The earliest experiment to come to our knowledge was that of the Saclay-Orsay collaboration. *Estève* et al.[2.2] measured the I-V characteristics of sintered $La_{1.85}Sr_{0.15}CuO_4$ ceramics using nonsuperconducting Pt-Rh, Cu or Ag contacts. In doing so, they observed weak link characteristics internal to the superconductor, to which we shall return later. They then applied microwaves at $\nu = 9.4$ GHz and observed Shapiro steps[2.3] at $V_s = 19\ \mu V$ intervals. From the well-known Josephson formula[2.4]

$$V_s = h\nu/q, \tag{2.1}$$

they obtained $q = 2e$, i.e., Cooper pairs were present. Figure 2.1 illustrates these steps.

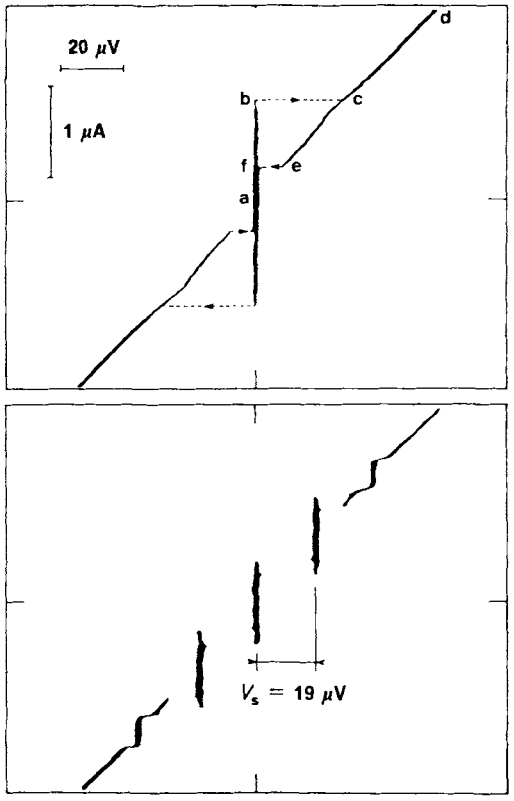

Fig. 2.1. Top: Oscilloscope trace of a current-voltage characteristic obtained at 4.2 K with an aluminum tip on a $La_{1.85}Sr_{0.15}CuO_4$ sample. Letters a through f indicate direction of trace. Dashed lines have been added to indicate the switching between the two branches. Bottom: Steps induced by microwave irradiation at frequency $\nu = 9.4$ GHz; all other experimental conditions identical (adapted from [2.2]).

From the fundamental London equations, the flux ϕ through a ring is quantized:[2.5]

$$\phi = n\phi_0$$
$$\phi_0 = hc/q \tag{2.2}$$

The clearest experiment, essentially following the classical experiments in 1961, was carried out in Birmingham, England, by *C. E. Gough* et al.[2.6] They detected the output of an r.f.-SQUID magnetometer showing small integral numbers of flux quanta ϕ_0 jumping in and out of the ring of $Y_{1.2}Ba_{0.8}CuO_4$ (see Fig. 2.2). The outcome clearly confirmed that $q = 2e$.

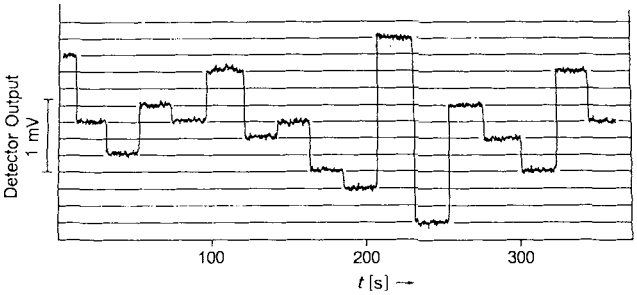

Fig. 2.2. Output of the r.f.-SQUID magnetometer showing small integral numbers of flux quanta jumping in and out of a ring (adapted from [2.6]).

[*] See conference report on page 749 of this issue.

To understand the mechanism, it was of relevance to know the nature of the charge carrier present. In La_2CuO_4 with very little doping, the early measurements[1,23] showed localization upon doping with divalent Ba^{2+} or Sr^{2+} and Ca^{2+}; it was most likely that these ions substituted for the trivalent La^{3+} ions. Thus, from charge-neutrality requirements, the compounds had to contain holes. Subsequent thermopower measurements confirmed this assumption.[2.7] The holes were thought to be localized on the Cu ions. Because the copper valence is two in the stoichiometric insulator La_2CuO_4, doping would create Cu^{3+} ions. Thus a mixed Cu^{2+}/Cu^{3+} state had to be present. By the same argument, this mixed-valence state ought also to occur in $YBa_2CuO_{7-\delta}$ ($\delta \approx 0.1$). Early photoelectron core-level spectra (XPS and UPS) by *Fujimori* et al.[2.8] and *Bianconi* et al.[2.9] in $(La_{1-x}Sr_x)_2CuO_{4-y}$ and $YBa_2La_3Cu_{6.7}$ did not reveal a $\underline{2p}\ 3d^8$ final state arising from a $Cu^{3+}\ 3d^8$ state (the underlining indicates a hole). However, the excitation

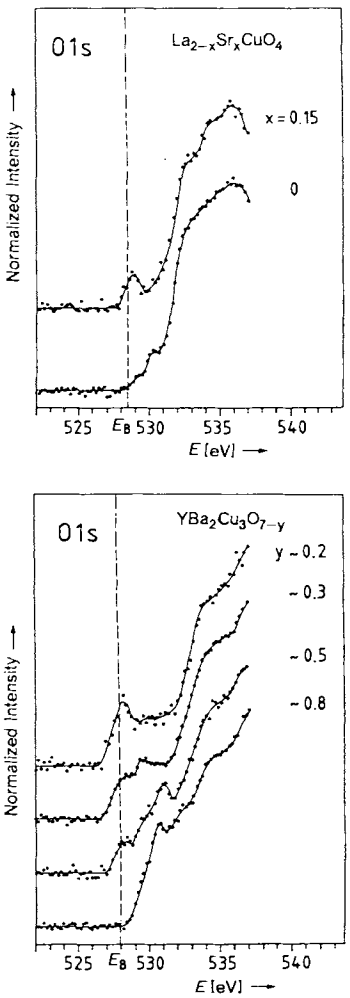

Fig. 2.3. Oxygen 1s absorption edges of $La_{2-x}Sr_xCuO_4$ (top) and $YBa_2Cu_3O_{7-y}$ (bottom) measured by energy-loss spectroscopy. The binding energy of the O 1s level, as determined by X-ray induced photoemission, is shown by the dashed line. In the framework of an interpretation of the spectra in terms of the density of unoccupied states, this line would correspond to the Fermi energy (adapted from [2.11]).

was consistent with the formation of holes $\underline{L}$ in the oxygen-derived band, i.e., a predominant $3d^9\ \underline{L}$ configuration for the formal Cu^{3+} state. Photo-X-ray absorption near the edge structure was also interpreted in the same manner by comparison with other known Cu compounds. Emission spectra by *Petroff*'s group[2.10] pointed in the same direction, since the excitation thresholds were compatible with the presence of holes in Cu–O hybrid bands. From their data, both groups concluded that strong correlation effects were present for the valence carriers. However, these results were challenged by other groups working in the field, partly because the spectra involved the interpretation of Cu-atom satellites. A beautifully direct confirmation of the presence of holes on the oxygen p-levels, like $\underline{L}$, was carried out by *Nücker* et al.[2.11] These authors investigated the core-level excitation of oxygen 1s electrons into empty 2p states of oxygen at 528 eV. This is an oxygen-specific experiment. If no holes are present on the p-level, no absorption will occur. Figure 2.3 summarizes their data on $La_{2-x}Sr_xCuO_4$ and $YBa_2Cu_3O_{7-\delta}$. It is shown that for $x=0$ and $\delta=0.5$, no oxygen p-holes are present and thus no absorption is observed, whereas upon increasing x or reducing δ, a $\underline{2p}$ hole density at the Fermi level is detected in both compounds.

Of considerable interest is the dependence of the transition temperature on the hole concentration. The electron deficiency is hereafter written in the form $[Cu\text{–}O]^+$ as a peroxide complex in which the probability of the hole is about 70% $3d^9\ \underline{2p}$, as discussed above, and 30% $3d^8$ as recently inferred from an XPS study.[2.12] Hall-effect data are difficult to analyze in the presence of two-band conduction, which is possible in these copper oxide compounds, owing to the well known compensation effects. Therefore, *M. W. Shafer, T. Penney,* and *B. L. Olson*[2.13] determined

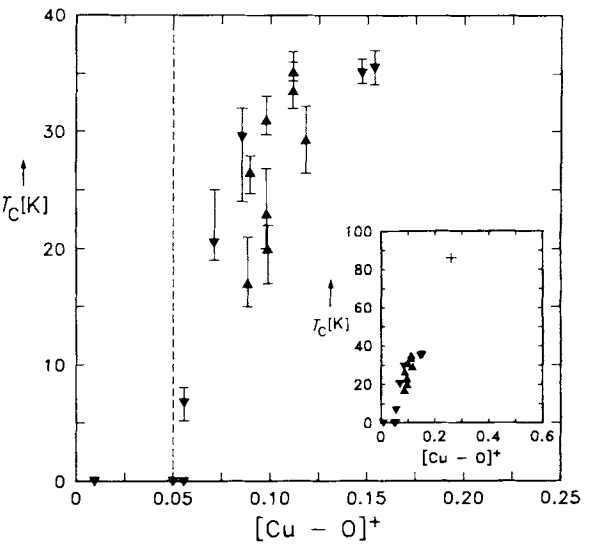

Fig. 2.4. T_c vs the hole concentration $[Cu\text{–}O]^+$, as a fraction of total copper. Down triangles are for compositions with $x<0.15$, up triangles for $x>0.15$. Insert shows same data plus points for a single $YBa_2CuO_{6.6}$ sample as discussed in the text (adapted from [2.13]).

ADVANCED MATERIALS

the concentration by wet chemistry according to the reaction $[Cu-O]^+ + Fe^{2+} \rightleftarrows Cu^{2+} + Fe^{3+} + O^{2-}$ in the $La_{2-x}Sr_xCuO_{4-\delta}$ compound. Figure 2.4 shows a plot of T_c vs $[Cu-O]^+$ concentration with a maximum of 35 K at 15% total copper present. There is also a clear threshold at about 5%. From the study, it is apparent that 15–16% $[Cu-O]^+$ is the maximum number of holes the La_2CuO_4 structure accepts. Beyond this concentration, oxygen vacancies are formed. The relationship between T_c and $[Cu-O]^+$ in $La_{2-x}Sr_xCuO_4$ was extended to $YBa_2Cu_3O_{7-\delta}$. The insert of Figure 2.4 illustrates the results under the assumption that two layers in the 123 compound are active for $\delta \approx 0.1$ and $\delta \approx 0.3$, i.e., T_c's of 92 K and 55 K.[2.14] The latter transition, first reported by *Tarascon* et al., was confirmed by near-room-temperature plasma oxidation of the oxygen-deficient Y-compound.[2.14]

The $La_{2-x}Sr_xCuO_{4-y}$ with its less complicated structure allows easier testing of models. Its magnetic properties below the hole threshold concentration, $x=0.05$, are of special interest. For $x=0$, the susceptibility $\chi(T)=M(T)/H$ exhibits a maximum at low fields of $H=0.05$ T below 300 K. This maximum increases in height and shifts to lower temperatures for higher magnetic fields up to 4.5 T[2.15] as seen in Figure 2.5a. Such behavior is indicative of spin density waves or antiferromagnetic fluctuations. Indeed, neutron diffraction experiments by *Vaknin* et al.[2.16] proved three-dimensional (3-D) antiferromagnetic ordering up to 240 K depending on oxygen stoichiometry (i.e., hole concentration). The structure is shown in Figure 2.5b. Subsequent neutron scattering experiments on a single crystal revealed a novel two-dimensional (2-D) antiferromagnetic correlation well above and also *below* the 3-D Néel temperature T_N as shown in Figure 2.6. This instantaneous (not time-averaged) ordering, seen even above room temperature, was termed a quantum spin fluid (Q.S.F.).[2.17] The existence of antiferromagnetism (A.F.) supports models in which holes lead either to localization or to pairing in the strong-coupling limit as proposed by *Emery*[2.18] and others.[2.19] The resonant valence-band state is also related to the A.F. state.[2.20]

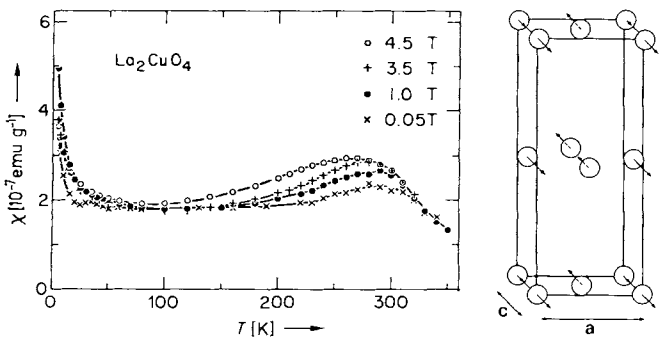

Fig. 2.5. Left: Temperature dependence of the magnetic susceptibility $\chi = M/H$ of La_2CuO_4 in different fields H (adapted from [2.15]). Right: Spin structure of antiferromagnetic La_2CuO_{4-y}. Only copper sites in the orthorhombic unit cell are shown for clarity (adapted from [2.16]).

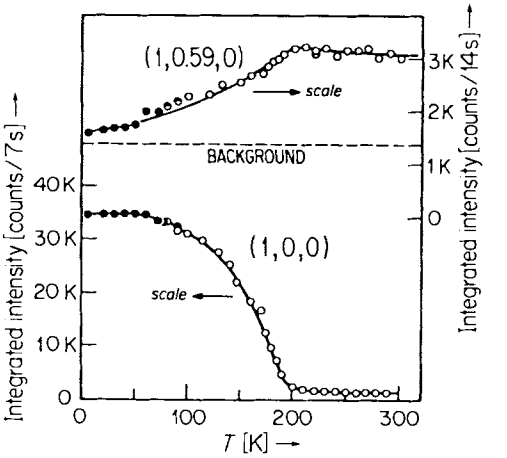

Fig. 2.6. Integrated intensities of the (100) 3-D antiferromagnetic Bragg peak and the (1,0.59,0) 2-D quantum spin fluid ridge. The open and filled circles represent separate experiments (adapted from [2.17]).

From the prevalence of magnetic interactions as a primary cause for the occurrence of high-T_c superconductivity, one would expect the isotope effect to be absent, since it occurs when the Cooper pairing is mediated by phonon interaction, as found in most of the metallic superconductors previously known. Indeed, substituting O^{16} by O^{18} in the $YBa_2Cu_3O_{7-\delta}$ compound at AT&T did not reveal a shift in T_c.[2.21] However, substitution experiments in $La_{2-x}Sr_xCuO_{4-y}$ oxide carried out shortly thereafter did reveal an isotope effect with $0.14 < \beta < 0.35$[2.22] as compared with the full effect of $\beta = 0.5$ deduced from the weak-coupling formula[1.10]

$$T_c = 1.13\,\Theta_D \exp -(1/N(E_F) \times V^*), \tag{2.3}$$

with the Debye temperature $\Theta_D \propto 1/M^{1/2}$, where M is the reduced mass. Thus in the lanthanum compound, oxygen motion is certainly present. As it is highly unlikely that the mechanism is substantially different in the 123 compound, oxygen motion should also be there. This is because absence of the isotope effect does not necessarily exclude a phonon mechanism, which has to be present if Jahn-Teller polarons participate. Indeed, a subsequent, more accurate experiment did show a weak isotope effect in $YBa_2Cu_3O_{7-\delta}$ with $\Delta T_c \approx 0.3$ to 0.5 K.[2.23] From these results, it appears likely that there is more than one interaction present which leads to the high transition temperatures, the low quasi-2D properties certainly being of relevance.

The X-ray and photoemission studies mentioned earlier had indicated strong correlation effects. Cooper pairing having been ascertained, it was therefore of considerable interest whether the new superconductors were of the strong- or the weak-coupling variety. In the latter case, the ratio of the gap 2Δ to kT_c is:[1.10]

$$\frac{2\Delta}{kT_c} = 3.52 \tag{2.4}$$

whereas in the former it is larger.

Tunneling experiments have been widely used to determine the gap in the classical superconductors. However, the very short coherence length yields too low values of 2Δ, as will be discussed later.[2.24] Infrared transmission and reflectivity measurements on powders were carried out at quite an early stage. With the availability of $YBa_2Cu_3O_7$ single crystals, powder infrared data are less relevant, but are quoted in the more recent work. A beautiful example is the reflectivity study by *Schlesinger* et al.[2.25] of superconducting $YBa_2Cu_3O_7$ and a Drude fit to the nonsuperconducting $YBa_2Cu_3O_{6.5}$ data. From the Mattis-Bardeen enhanced peak in the superconducting state, these authors obtained $2\Delta_{ab}/kT_c \approx 8$, i.e., strong coupling in the Cu-O planes (see Fig. 2.7). NMR relaxation experiments by *Mali* et al.,[2.26] although not yet completely analyzed, yield two gaps with ratios 4.3 and 9.3, respectively, the latter being in the range of the infrared data.

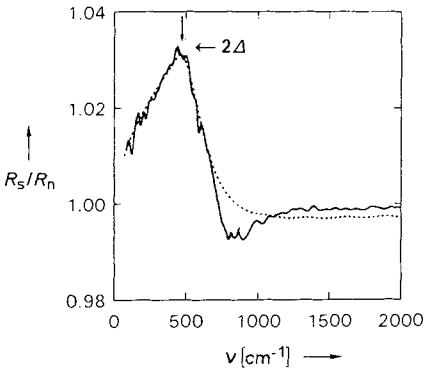

Fig. 2.7. Normalized infrared reflectivity of a single crystal of $YBa_2Cu_3O_7$ and fitted Mattis-Bardeen form of $\delta(\omega)$ (dotted line) in the superconducting state. The arrow shows the peak occurring at $2\Delta \approx 480$ cm^{-1}, hence $2\Delta \approx 8kT_c$ with $T_c = 92$ K (adapted from [2.25]).

NMR relaxation experiments were among the first at the time to prove the existence of a gap.[2.27] They also appear to be important for the new class of superconductors.

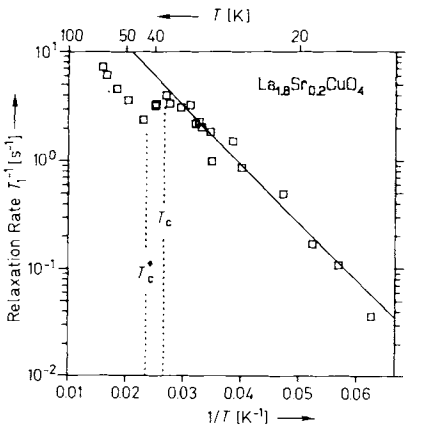

Fig. 2.8. Semilogarithmic plot of $1/T_1$ vs $1/T$. The straight line demonstrates the activated behavior $1/T_1 \sim \exp[-\Delta/kT]$ for $T \ll T_c^*$. An activation energy of $\Delta/k = 135$ K is obtained from this graph (adapted from [2.28]).

Zero-field nuclear spin lattice relaxation measurements on ^{139}La in $La_{1.8}Sr_{0.2}CuO_{4-\delta}$ below T_c follow the relationship $1/T_1 \propto \exp(-\Delta/kT)$ (see Fig. 2.8) with activation energy $\Delta = 1.1$ meV; at low temperatures $kT \ll 2\Delta$ due to a $T_c = 38$ K. A ratio of $2\Delta/kT_c = 7.1$ was obtained.[2.28] Therefore, strong coupling is also present in the La compound. The value of Δ probably has to be attributed to the gap parallel to the planes. In fact, it has been shown that infrared reflectivity data on powders measure the gap along the c-axis, and a ratio of $2\Delta_c/kT_c \approx 2.5$ was given.[2.29] Thus the coupling between the planes appears to be weak. Such a substantial anisotropic property was not previously found in other superconductors.

From the first measurements of resistivity as a function of magnetic field, the slopes dH_{c_2}/dT near T_c could be obtained, and from them very high critical fields at low temperatures were extrapolated. From the many papers published, we quote that of *Decroux* et al.,[2.30] also because this was the first paper to report a specific-heat plateau at T_c. The group at the University of Geneva found $dH_{c_2}/dT = -2.5\,\mathrm{T\,K^{-1}}$, yielding an extrapolated $H_{c_2}(T=0) = 64$ T.

From the well-known formula for the critical field in type-II superconductors

$$H_{c_2} = \frac{\phi_0}{2\pi\xi^2} \tag{2.5}$$

one calculates that the coherence length ζ is of the order of the lattice distances. Actually the coherence lengths evaluated have become smaller; recent results on single crystals by an IBM group in Yorktown Heights[2.31] and on epitaxial layers by the Stanford group [2.32] are of the order $\xi_c \approx 3$–4 Å for the coherence length parallel to c and $\xi_{ab} \approx 20$–30 Å perpendicular to c.

Such short coherence lengths could be expected when one considers the relationship between ξ, the gap and the Fermi energy E_F. *Weisskopf*[2.33] deduced

$$\xi \approx \frac{E_F}{\Delta} d \tag{2.6}$$

from the Heisenberg uncertainty principle. In equation (2.6), d is the screening length, which one can assume to be of the order of a unit cell distance. The ratio E_F/Δ is near unity owing to the large Δ and the small E_F, the latter resulting from the low carrier density and the sizeable electron mass. Therefore in oxides, ξ is considerably smaller than in metals. Because Δ is anisotropic, so is ξ. The comparable size of E_F and Δ indicates that most of the carriers participate in the superconductivity of the new oxides for temperatures $T < T_c$, in contrast to the classical superconductors, where $E_F \gg \Delta \approx 1.7\,kT_c$.

The short coherence lengths in the layered copper oxide superconductors are important theoretically, experimentally, and applicationwise: The short ξ's and carrier concentrations of the order of $n = 10^{21}$ cm^{-3} make one wonder

ADVANCED MATERIALS

whether boson-condensation approaches are not more appropriate, i.e., real-space Cooper pairing in contrast to the wave-vector space pairing of classical BCS theory,[1.10] which applies so well for metals with large ξ's and concentrations n. Actually, *Schafroth*[2.34] back in 1955 was the first to work out a superconducting theory with boson condensation. Referring to *Chakraverty*'s phase diagram in Figure 1.2,[1.11] one may regard the metal superconducting phase line as BCS with weak coupling, and the superconductor-insulator boundary for large coupling constants λ as the Schafroth line.

The short coherence lengths induce considerable weakening of the pair potential at surfaces and interfaces, as emphasized by *Deutscher* and *Müller*.[2.24] Using an expression for the "extrapolation length" b[2.35] for the boundary condition at the superconductor-insulator interface, the $\Delta(x)$ profile was deduced as shown in Figure 2.9 for $T \lesssim T_c$ and $T \ll T_c$.

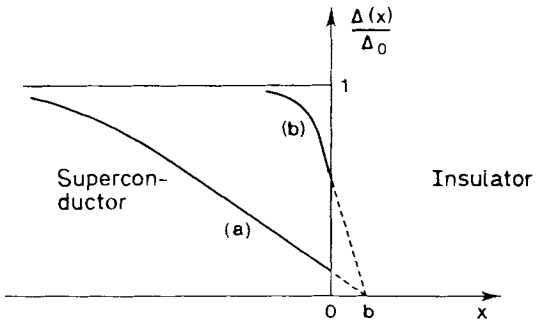

Fig. 2.9. Profile of the pair potential in a short-coherence-length superconductor near a superconductor-insulator boundary. Curve (a): $T \lesssim T_c$; curve (b): $T \ll T_c$ (adapted from [2.24]).

Analogous behavior of $\Delta(x)$ will also be present at superconducting-normal (SN) interfaces. Thus, the depressed order parameter involving experiments of SIS and SNS will result in tunneling characteristics[2.24] with a marked reduction in the observed value of Δ. In consequence, such experiments are less suitable than infrared and NMR studies to determine Δ, and actually lead to erroneous conclusions regarding gapless superconductivity also in point-contact spectroscopy.[2.36] $YBa_2Cu_3O_7$ undergoes a tetragonal-to-orthorhombic phase transition near 700°C. Thus upon cooling, (110) twin boundaries are formed, separating the orthorhombic domains and inducing *intragrain* Josephson or weak-link junctions. These junctions form a network dividing the crystallites into Josephson-coupled domains, with the possibility of fluxon trapping as well. Therefore even single crystals form a superconducting glass *in the presence* of a sizeable magnetic field.

The basic Hamiltonian regarding the phases is[1.22]

$$\beta \mathscr{H} = -\sum J_{ij} \cos(\phi_i - \phi_j - A_{ij}) \tag{2.7}$$

Here, J_{ij} is the Josephson coupling constant between domains. The phase factors $A_{ij} = K_{ij} \boldsymbol{H}$ introduce randomness for $\boldsymbol{H} \neq 0$ because K_{ij} is a random geometric factor. A review of the superconducting glass state has recently appeared.[2.37]

The first evidence indicating the presence of superconducting glassy behavior was deduced from field-cooled and zero-field-cooled magnetization data[1.24,2.38] in $La_{2-x}Ba_xCuO_4$ ceramics. In addition to the twin-boundary-induced *intragrain* junctions, such a material also has junctions resulting from the *intergrain* boundaries. The latter J_{ij}'s are much weaker and uncouple at lower magnetic fields and currents j_c. Consequently, the critical currents observed in the ceramics are more of the order of 10^3 to 10^4 A cm^{-2},[2.39] whereas those in epitaxial layers[2.40] and single crystals[2.1] are of the order of 10^6 to 10^7 A cm^{-2}.[2.41] The latter work, carried out by two IBM groups, is a major breakthrough in the field.

The decay lengths of the superconducting wave functions at SNS and SIS junctions are both of the order of $\xi(0)$. This entails an anomalous temperature dependence $J_c \propto (T - T_c)^2$. Such behavior is seen in the mid-temperature range for $J_c(T)$ in the $YBa_2Cu_3O_{7-\delta}$ epilayer on $SrTiO_3$ of Figure 2.10.[2.40] Such critical currents are acceptable for thin film applications at 77 K for low magnetic fields (Fig. 2.10), whereas in the ceramics the much lower J_c's indicate a need for further development work, or, perhaps better still, the discovery of a new type of high-T_c superconductor that should exist.

The geometrical critical magnetic field $H_{c_1}^*$ is of the order of[1.22]

$$H_{c_1}^* = \phi_0 / 2S \tag{2.8}$$

where S is the projected area of the superconducting loop with uniform phase. In single crystals, the S of domains is of the order of 100 μm^2, whereas that of grains in ceramics is 1–10 μm^2. In agreement with equation (2.8), $H_{c_1}^*$ is of the order of 0.5 G for the penetration of H into twinned crystals, and 5 to 100 G to disrupt intergranular nets in ceramics.

Since the publication on the existence of this new class of materials, the interest and work have far exceeded the expectations of the laureates, whose aim was primarily to show that oxides could "do better" in superconductivity than metals and alloys. Due to this frenzy, progress on the experimental side has been rapid and is expected to continue. This will also assist in finding new compounds, with T_c's reaching at least 130 K (Fig. 2.4). Quantitative theoretical models are expected in the not too distant future, first perhaps phenomenological ones. On this rapidly growing tree of research, separate branches are becoming strong, such as glass aspects, growth techniques for single crystals, epitaxial films, and preparation of ceramics, the latter two being of crucial importance for applications. The former will dominate the small-current microelectronics field, while the latter will have to be mastered in the large-current field. Here the hopes are for energy transport, and

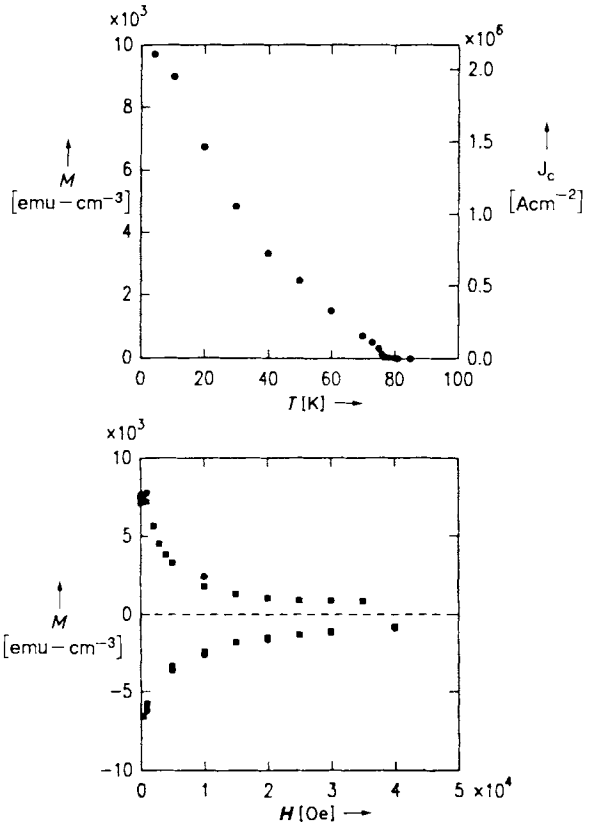

Fig. 2.10. Top: The volume magnetization M vs temperature for an epitaxial sample. The y-axis scale on the right was obtained with the use of the Bean formula $J_c = 30\ M/d$, with the mean radius of the sample $d = 0.14$ cm. Bottom: The volume magnetization M vs applied field H at 4.2 K for two samples (adapted from [2.40]).

later large magnetic field applications, for example in beam bending in accelerators and plasma containment in fusion.

Conference Reports

High-T_c Superconductors in Interlaken

With the discovery of superconductivity in a La-Ba-Cu-O compound just two years ago, the IBM researchers *J. G. Bednorz* and *K. A. Müller* triggered an unprecedented scientific race in laboratories around the world for new superconducting materials with yet higher critical temperatures.[1] The first paper by *Bednorz* and *Müller* received little attention until late 1986, when Japanese and American scientists confirmed the Zürich results at the Materials Research Society meeting in December 1986.[2–4] Early in 1987, the group of *C. W. "Paul" Chu* at the University of Houston announced the existence of superconductivity in a Y-Ba-Cu-O compound with a critical temperature as high as 92 K.[5] This was a dramatic breakthrough because for the first time it was possible to observe superconductivity above liquid nitrogen temperatures. *Paul Chu*'s results were confirmed almost simultaneously by research groups around the world[6,7] and soon the superconducting phase was identified as the black 123-compound $YBa_2Cu_3O_{7-x}$ having an oxygen deficient, perovskite-like structure.[8,9]

Special sessions on High-T_c Superconductivity were scheduled at all major conferences in materials science, physics and chemistry, and scientists from all over the world discussed their views on experimental and theoretical aspects of High-T_c Superconductivity. Since then a flood of publications and numerous conferences and symposia have demonstrated the worldwide impact of *Bednorz* and *Müller*'s discovery. Now, not quite a year after the legendary "Woodstock of the Physicists" at the American Physical Society March Meeting, IBM Rüschlikon, the ETH Zürich, the University of Geneva, the University of Neuchatel, the Swiss National Science Foundation, and the Swiss Academy of Science invited experts to the *International Conference on High-Tc Superconductors and Materials and Mechanisms of Superconductivity (HTSC-M²S)* from February 29 to March 4, 1988, in Interlaken, Switzerland. About 1150 scientists were welcomed by *Alex Müller* of IBM, Rüschlikon. The conference was designed to provide an overview on all current developments of superconductivity in experimental and theoretical physics, chemistry, and applications. About 95 invited lectures were scheduled, 10 of them given in plenary sessions and about 85 in symposia and panel discussions organized in two parallel sessions. Special panel discussions and short talks on very recent results were organized in the evenings. Around 800 contributed papers were presented as posters in three all day sessions, with two hours in the afternoon reserved for the poster discussions and no other scheduled program in parallel. All invited and contributed papers were refereed during the conference and will be published in a special issue of "Physica C—Superconductivity" approximately three months after the conference.

Highlights were certainly the Tuesday and Wednesday evening sessions on new oxide superconductors. Two new groups of superconducting materials with onset temperatures above 100 K, namely Bi-Sr-Ca-Cu-O and Tl-Ba-Ca-Cu-O, were discussed in invited lectures and additionally scheduled five-minute talks. Bi-Sr/Ca-Cu-O compounds were investigated as early as February 1987 by researchers from the Max Planck Institute for Solid State Research and the Hoechst AG.[10] Superconductivity in Bi-Sr-Cu-O compounds was first reported by *Bernard Raveau* of the University of Caen, France, late in 1987.[11] Many other research groups began experimenting with bismuth substitutions into the 123-compound; *Hirshi Maeda* at the National Research Institute for Metals in Tsukuba, Japan, first announced results on January 22, 1988:[12a] superconductivity at 105 K was claimed, however, the group did not succeed in preparing a single phase sample. In his talk during the Tuesday evening session, *Maeda* gave the nominal composition of his sample as $BiSrCaCu_2O_x$. He reported a steep drop in the resistance vs. temperature curve, starting at about 120 K and leveling off near 105 K; $R=0$ was finally reached at 80 K. This behavior was confirmed by other researchers and is considered to be due to a low-T_c phase ($T_c=80$ K) and a high-T_c phase (T_c near 105 K). Other groups, among them *Art Sleight*'s from DuPont and *Bob Cava*'s from Bell Labs, reported $Bi_2Sr_2Ca_1Cu_2O_{8+x}$ as the superconducting compound, again with indications of low- and high-T_c phases.[12b]

More controversial is the structure of the new Bi-compounds. Several groups made proposals for the structure which do not agree with each other on several points. Some more or less common structural features are: The unit cell is made up of two Bi-O layers followed by five perovskite layers (Sr-O, Cu-O, Ca). Most peaks in the X-ray diffraction spectra can be indexed on the basis of a pseudo-tetragonal unit cell with $a=5.40$ Å, $c=30.83$ Å. An incommensurate modulation along the b-axis is observed by some groups, but that could turn out to be a sample and preparation dependent effect. There do not appear to be Cu-O chains in the new Bi-compounds; consequently the Cu-O and Bi-O planar arrangements are considered important for the superconductivity, in the Bi-compounds as well as in the "old" 123-compound. Preparation of samples follows a "shake and bake" recipe similar to the 123-material, but at lower temperatures (between 800 and

850°C). A slow cooling to adjust the oxygen content of the samples does not seem to be necessary with the Bi-compounds.

Superconductivity in Tl-compounds, discovered by scientists of the University of Arkansas,[13] was discussed by *Paul Chu* from the University of Houston and *Paul Grant* from the IBM Almaden Research Center, San Jose, among others. The compounds were synthesized at 950°C and subsequently quenched in air and the composition was given as $Tl_2Ca_2Ba_1Cu_2O_x$. Both *Chu* and *Grant* pointed out that thallium is extremely toxic and great care must be taken in working with these substances. *Grant* presented resistivity curves and magnetometer data that showed complete superconductivity at $T = 118$ K; on Wednesday night he announced that he had obtained new data from his lab via telefax showing bulk superconductivity at $T = 125$ K in the Tl-compounds. Spontaneous applause—and once again a little "Woodstock" atmosphere could be felt. Minutes later, in the conference center lobby, *Paul Grant* was surrounded by reporters, a picture usually associated with politicians rather than scientists.

Even though much was said about the new Bi- and Tl-compounds, most of the invited and contributed papers covered aspects of superconductivity in the "old" 123-compound $YBa_2Cu_3O_{7-x}$. During the symposium on crystal chemistry and structure detailed studies of the interdependence of structure, oxygen content, and superconductivity were presented. A panel discussed oxygen vacancy ordering, oxygen deficiency, and twinning. The role of twinning in the mechanism of superconductivity is still controversial. Processing and preparation of high-T_c superconducting materials were covered by three symposia: growth and properties of single crystals, superconducting glass properties, and thin films. Many posters also addressed the preparation of large single crystals, films of various thicknesses and on a variety of substrates, and dense, polycrystalline samples. Two symposia were scheduled to discuss electronic properties, including panel discussions on thermal and optical properties. Substitutions for Y and Cu, antiferromagnetic ordering, and magnetic flux penetration were presented during the symposium on magnetic properties. An entire evening session was devoted to the discussion of resonance experiments. It became clear that the frequency assignment for the Cu sites in nuclear quadrupole resonance (NQR) experiments will remain controversial until it is possible to reliably calculate the electric field gradient (EFG) at the respective Cu sites. The point charge calculations currently employed were considered insufficient. Various potential uses of high-T_c superconductors were presented and discussed in the symposium on applications. It was pointed out that even for applications such as superconducting connections on circuit boards a critical current density of at least 10^5 A cm^{-2} is absolutely essential. Consequently, many lectures and posters discussed the improvement of the critical current density, the role of grain boundaries for the critical current density, etc. Models on mechanisms, resonant valence bond and related models, bosonic models, and new ideas on theory were presented and debated during two symposia and two evening sessions.

The HTSC-M^{2}S conference demonstrated that one year after the discovery of the 90 K superconductors the interest in these substances is still enormous. Our knowledge of these compounds has grown considerably. Some controversies, e.g., about the existence of a distinct 60 K superconductor with 6.6-6.7 oxygens per formula unit, have been resolved. Great efforts are currently being made to find ways to increase the critical current densities in polycrystalline samples or thin films, predominantly deposited on $SrTiO_3$ substrates, that already exhibit high critical current densities. Particularly interesting work is being conducted at the IBM laboratory in Yorktown Heights, NY, where researchers are working on micro-patterning to "write" superconducting structures in thin films, e.g., loops for use in SQUIDs. New high-T_c superconducting materials will, without doubt, continue to play a significant role in the development of the field. The trend points towards increasingly complex structures. As *Paul Chu* put it "... one layer gives a T_c of 30 K, two give 60 K, three layers give 90 K, and now we have four layers and 120 K". The importance of this lies not only in the higher T_c, but also in the fact that scientists now have different structures available for their studies and so will be able to pin-point the common features in the different substances. This will ultimately help the theorists in their search for the "right" mechanism. *Robert Schrieffer*, summarizing the leading theoretical approaches, talked about conventional phonon mechanisms and charge fluctuations, but also mentioned such exotic concepts as half-fermions and x-ons ("... that's anything you like!"). But after the recent 30% isotope effect found by *Keven Ott* from Los Alamos National Lab, a conventional phonon-mediated mechanism must be re-examined.

A final comment is that, as with other superconductor meetings to date, the HTSC-M^{2}S conference in Interlaken was dominated by physicists and chemists. Only a few materials scientists presented papers or gave talks. There is still a wide gap between basic research and applications, such as interconnects, power transmission lines, or Josephson devices. The future of these applications depends on the materials properties of these substances, and it will be up to the materials scientists to fill the wide gap between basic research and applications.

... and Bad Nauheim (FRG)

A symposium on the structure and microstructure of high-temperature superconductors was held on April 21–22, 1988, in Bad Nauheim, Federal Republic of Germany. The aim of this comprehensive two-day symposium, organized by the Deutsche Gesellschaft für Metallkunde and chaired by *H. C. Freyhardt*, Göttingen, was to assemble an interdisciplinary group of scientists (physicists, chemists, crystallographers and materials scientists) and provide a forum for discussions devoted to the structure, microstructure, preparation and shaping, and applications of ceramic high-temperature superconductors (HTSCs). Leading scientists from Europe, the United States and Japan were invited to summarize the achievements in the field and to provide an evaluation of recent progress and unresolved problems.

The following lectures were presented: Structural aspects of mixed valence copper oxides and their relationships with superconductivity (*Raveau*, France)/Oxygen stoichiometry in pure and 3d-metal-doped $YBa_2Cu_3O_{7\pm y}$ (*Greene*, USA)/Structural aspects of the new Bi and Tl based high-T_c superconductors (*Batlogg*, USA)/Physical properties of high-T_c superconductors (*Steglich*, FRG)/On the microstructure of high-T_c superconductors (*Heeger*, FRG)/High-resolution transmission electron microscopy; principles and results on $YBa_2Cu_3O_{7-x}$ (*Gruehn*, FRG)/Phase diagrams of non-stoichiometric superconducting oxides (*Hauck*, FRG)/Crystal growth of high-T_c superconductors (*Hosoya*, Japan)/Bulk materials, shaping and prospects for applications (*Krauth*, FRG)/Application of high-T_c thin films in microelectronics (*Rogalla*, Netherlands).

In addition to the ten review talks, the latest results were presented on about 50 posters which were discussed in two plenary sessions. While the structure and properties of HTSCs were at the center of numerous discussions during the first day, the interest on the second day focused on "the real problems", as *H. E. Hoenig* from Siemens put it, namely preparation, shaping and applications. Controversies concerning the structure of the Bi-based superconductors do still exist, as a very lively discussion at the end of the first day showed.

The key quantity for HTSC applications in energy technology and superconducting electronics is the critical current density J_C. Based on magnetization curves of sintered, polycrystalline ceramic superconductors, the critical current density within a single grain was estimated to be of the order of 10^6 Acm^{-2} at $T=4.2$ K. The reason for the much lower J_C in sintered samples—typically 100–1000 Acm^{-2}—is considered to be the *weak links* between the grains in these materials. Defects such as voids, cracks and micro-cracks, second phase, including grain-boundary segregations and oxygen deficiency were also listed as reasons for the degradations of the transport properties. While the critical current densities in sintered HTSC materials are presently too low for most applilcations, J_C values in thin films prepared by a variety of methods are much more promising. However, not only the current carrying capability but also the film morphology must be considered; applications in superconducting electronics require very flat film surfaces for multiple stacked layers. The surface of epitaxially grown films or films made by laser ablation is too rough for applications in superconducting electronics. A further problem associated with thin films of HTSCs is the substrate-film compatibility. Evidence for Mg–Cu interdiffusion of $YBa_2Cu_3O_7$ films on MgO substrates was shown, and the necessity for passivation layers, e.g. silicon nitride on silicon substrates, was suggested. Various methods for the structuring of films were discussed, mostly for the fabrication of Josephson junctions. Because of the small coherence lengths in the HTSC materials, these Josephson junctions are difficult to prepare. Thus superconducting chip-interconnects seem much more likely applications at present than on-chip application of Josephson switching elements.

At this symposium the necessity of an interdisciplinary approach to the problem of high-T_C superconductivity became clear once again. Exact determination of the physical properties of these materials requires samples of higher phase purity and, of course, larger single crystals. Thorough investigations of preparation and shaping of these interesting substances are an important prerequisite for technological applications.

Conducting Polymers, Polyelectrolytes and Ultrathin Polymer Films in Mainz (FRG)

At the beginning of 1987, two inter-Nordic projects covering the areas of "molecular electronics" and "conductive polymers" were created and found support by the Nordic Fund for Industrial and Technological Development under the guidance of the Royal Swedish Academy of Engineering Sciences. One of the projects relates to the development of ultrathin organic films for use in electronics and biotechnology while the other involves the production and application of processable conductive polymers. The considerable overlap of these research topics with the current activities at the Max-Planck-Institut für Polymerforschung in Mainz, FRG, stimulated the convening of a one-day symposium held on 21 February 1988 in Mainz.

The symposium served as a platform for the exchange of information between all groups of scientists involved in the projects, i.e. both from the four Nordic countries Denmark, Finland, Norway and Sweden and from the Max Planck Institute, on the state of the art of research in these novel polymer systems including aspects of application in microelectronics, sensor technology and design of devices.

In the opening lecture *J. Böler* (Stockholm) presented an overview of the projects, pointing out that research on conducting ultrathin polymer films is being carried out at the University of Copenhagen (Denmark), Norsk Hydro (Porsbrunn, Norway), Center for Industriforsikring (Oslo, Norway), KSV Chemicals (Helsingfors, Finland), and the Royal Institute of Technology (Stockholm, Sweden). Processable conducting polymers are being studied at Linköping Technical University (Linköping, Sweden), Neste (Kullo, Finland), the Technical Research Center (Helsingfors, Finland), and Chalmers University of Technology (Gothenburg, Sweden).

J. Rühe (Mainz) then discussed hopping conduction in poly(3,4-cycloalkylpyrrole) perchlorates and presented new results on poly(3-alkylpyrroles). *H. Stubb* (Helsinki) described investigations on high-energy ion implantation in polythiophene films and polymer composites containing poly(octylthiophene). The following two lectures dealt with model compounds for conducting polymers. *V. Enkelmann* (Mainz) discussed X-ray structural analysis data of radical cation salts of aromatic hydrocarbons, especially salts of oligophenylenes, which serve as models for poly(*p*-phenylene), while *H. Hjertberg* (Gothenburg) presented some results obtained in synthetic and NMR studies on aniline oligomers.

O. Wennerström (Gothenburg) lectured about NMR studies on conjugated macrocyclophanes and band structure calculations of linear conjugated polymers. *W. Meyer* (Mainz) reviewed the properties of solid polymer electrolytes which might find application in batteries. He concentrated on the properties of ionenes having a constant ion density. The dielectric properties of these polymers were described by *F. Kremer* (Mainz). From the relaxation behavior in an electric field, information is obtained about the transport of charge carriers in these materials. *T. A. Ezquerra* (Mainz) talked about the percolative behavior of spherical poly(pyrrole) particles with a monodisperse distribution in an poly(ethylene oxide) matrix as an example for an insulator-conductor composite. He explained the dc and ac conductivity in such composites in terms of a hopping theory using the random resistor network model of *Miller* and *Abrahams*. Substituted poly(thiophenes) were the subject of two other lectures. *J. Laako* (Kullo) focused on processable conducting polymer blends from poly(alkylthiophenes), which have potential application as shielding materials, and *G. Inganäs* (Linköping) discussed thermochromic effects in these polymers.

The session on ultrathin films began with a lecture by *C. Bubeck* (Mainz) who reviewed briefly the production of ultrathin layers of polymers by the Langmuir-Blodgett (LB) technique. He presented results on LB films consisting of relatively stiff macromolecules like poly(phthalocyaninatosiloxanes) and poly(glutamates). *J. Virtanen* (Helsingfors) and *K. J. Jens* (Oslo) presented results on LB multilayers of conducting compounds, and *J. Raabe* (Mainz) described the determination of structural parameters in ultrathin polymer films by tunneling electron microscopy. The symposium ended with a lecture by *B. Krische* (Stockholm) on oligothiophenes.

In their closing remarks *J. Böler* and *G. Wegner* emphasized the importance of joint research efforts and continuous exchange of information in these novel fields of research which have great future potential in device technology.

Polymer Liquid Crystals Forming Biaxial Nematic Phases

The field of polymer liquid crystals has experienced an enormous growth over the last years. It is now established that the different types of molecular ordering (nematic, smectic, cholesteric) can also be realized in polymer liquid crystals.[1] Recently it has been demonstrated by *Finkelmann* et al.[2] that polymer liquid crystals with mesogenic groups in the side chain can form biaxial nematic phases. This type of molecular ordering has not yet been observed in low molecular weight liquid crystals.

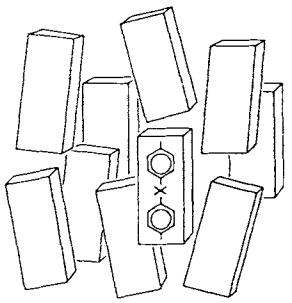

Fig. 1. Biaxial arrangement of lath-like particles [2b].

In a conventional nematic phase the rod-like mesogenic particles rotate around their long axis leading to an optically uniaxial system. For a system of lath-like particles (Fig. 1) orientational correlation may exist not only for their long axis but also for their short axes. The existence of such a biaxial nematic phase was predicted by *Freiser*[3] in 1970. Since then biaxial nematic phases have been the subject of numerous theoretical investigations (see [2b] for further references). A biaxial nematic phase in lyotropic liquid crystals was first observed by *Yu* and *Saupe*[4] in 1980. For thermotropic systems theory predicts[3] that the uniaxial phase should exhibit a second-order transition to the biaxial state upon lowering the temperature. However, this transition has never been observed experimentally for conventional low molecular weight liquid crystals and polymer liquid crystals with mesogenic groups in the side chain, since usually the onset of crystallization or the transition to a smectic phase or to the glassy state intervenes at lower temperatures. *Finkelmann* et al.[2] succeeded in showing that the stability of the biaxial state can be enhanced significantly if the rotation of lath-like mesogens is hindered by lateral attachment to a polymer main chain (Fig. 2, top).

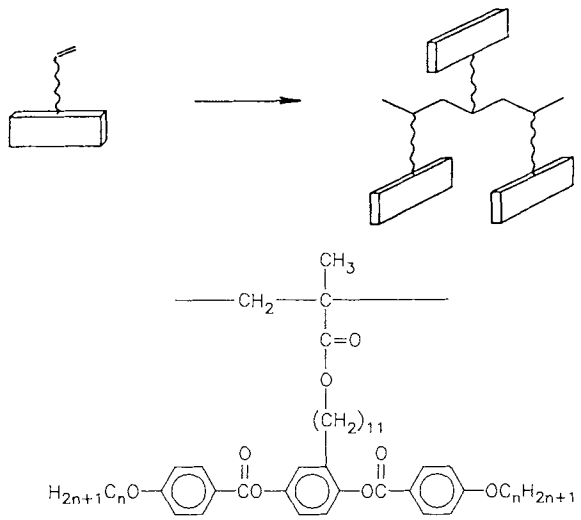

Fig. 2. Polymer liquid crystals with mesogenic groups attached laterally to the polymer backbone [2b]. Top: Schematic drawing; bottom: compounds that exhibit a biaxial nematic phase.

Thus, systems of the type shown in the lower part of Figure 2 exhibit a biaxial nematic phase which transforms into the isotropic state at the clearing temperature. The optical biaxiality was detected directly by conoscopic investigations of aligned samples. This exciting first observation of a thermotropic biaxial nematic phase demonstrates that by means of polymer liquid crystals new types of molecular ordering can be produced which could not be observed in low molecular weight systems. In this context it is important to note that *Ebert* et al.[5] have recently found direct conoscopic evidence for a biaxial nematic phase in a main chain liquid crystal polymer. Here again the stability of the biaxial arrangement was enhanced by long, laterally attached substituents which hinder the rotation around the long axis of the molecule.

Book Reviews

Materials Research—The Birth of a Science

Advancing Materials Research. Edited by *P. A. Psaras* and *H. D. Langford* (on behalf of the National Academy of Engineering and the National Academy of Sciences). National Academy Press, Washington, D.C., 1987. xvi, 391 pp., bound, $ 47.50.—ISBN 0-309-03697-6

The book is based on presentations and discussions from a symposium held in Washington, D.C., on 28–29 October 1985 under the same heading, celebrating the twenty-fifth anniversary of the "Materials Research Laboratories". These laboratories were and are active in selected areas of materials science and engineering—"polymers, ceramics, metals, catalysis, crystallography, mechanical and microstructural properties of materials, artificially structured materials, electronic and magnetic materials, materials chemistry and surface science, solid state physics, and materials processing", to quote the preface of *T. H. Geballe*, Center for Materials Research, Stanford University, and *D. White*, Laboratory for Research on the Structure of Matter, University of Pennsylvania.

The historical aspects of this very successful chapter of the US funding system can only be appreciated by a true insider of the system—to which the author of this review does not belong. The scientific impact of this funding program, however, and the perspectives which arise after 25 years are of more general importance and point to a competitive future, in which the United States, Japan, and Europe will seek to cover research fields which are considered vital for their economies. The US program was initiated by President *Eisenhower* in 1960, some time after the launch of Sputnik I, on 4 October 1957.

What started in 1960 in three "Interdisciplinary Laboratories" (IDLs, to quote one of the book's many, many abbreviations and acronyms) has grown into a funding scheme which now includes about 15 IDLs and MRLs (Materials Research Laboratories). The first three laboratories were at Cornell, Pennsylvania State, and Northwestern universities; eight laboratories followed in 1961 and six between 1962 and 1982. The funding of the different materials science subdisciplines has certainly changed over the years: Metallurgy, which had originally obtained 31% of the resources, is now funded on a 17% level; the so-called "Materials" showed an almost fivefold increase in funding during the same period (from 11% to 51%). This field of "Materials" will be the main subject of this essay.

Although the book contains a lot of basics in materials science, it does not follow the pattern of a textbook, but rather reflects views of the symposium participants on various basic aspects of materials science. The field is truly interdisciplinary; the book summarizes research projects, most of which were physics (35%) and chemistry related (25%) in 1970, until by 1985 materials science (35%) had caught up with physics (35%), and had left chemistry behind (17%), at least in numbers.

In a list of accomplishments we read on page 44:
- Organic Metals
- Ultralow Temperatures
- Lower-Dimensionality Materials
- Surfaces and Interfaces
- Phase Transitions and
- New Materials

No doubt there would be a different emphasis two years after the discovery of a high-temperature superconductor in a European Laboratory of a US company: Neither organic metals nor ultralow temperatures nor 1-dimensionality was the solution to the dream of high-T_c superconductors—to our surprise (speaking for most of us).

After the historical perspective of materials research has been dealt with in the three articles of part one of the book, a report on "Progress and Prospects in Metallurgical Research" opens the second part. This contribution shows that research in metals is more than a race to increase *Young*'s modulus by investigating sophisticated alloys and by freezing-in non-equilibrium systems, etc.; the article points out that metal alloys play a dominant role as silicides in MOS semiconductor devices, as metallic glasses in power transformers (extrapolated savings of $ 0.7 billion per year), and as magneto-optical layers for optical memories. The second article gives a review of the fundamentals of dislocation theory and of the understanding of the ductile properties of metals. The third article reflects mainly those aspects of metals which are appealing to physicists: Heavy electrons (up to 1000 m_e), quantized *Hall* effect and quantum interference effects in superconducting metals.

In crystallography the advent of quasi-periodic structures with 8-, 10-, and 22-fold diffraction rotation axes has given rise to new excitement in a world where the mathematical boundary conditions of space filling and infinite crystals have so long prevailed.

The short article on "New and Artificially Structured Electronic and Magnetic Materials" covers the field from superionic conductors to quantum well semiconductors, with only brief discussions of the organic 1-dimensional conductors and conducting polymers which have kept many theorists and experimentalists busy after *A. Heeger*'s work on TTF-TCNQ in 1973. I am sure that a similar book in 25 years would feature several articles with headings similar to the one of this chapter.

The article on catalysis is short and emphasizes the EXAFS method, leaving out many aspects of metal-substrate interactions and modern analytical surface characterization tools, e.g., electron spectroscopy and imaging.

The question of "The Role of Chemistry in Materials Science" is treated more like a survey over various topics (new polymers, interface-modifying agents, ..., self assembling systems). It is followed by a short review on "Advanced Ceramics"—too short considering the relevance of these materials. The article on "Organic Polymers" is also very didactically styled. Questions like: How does a very long 'snake-like' molecule diffuse? are treated in enough detail to be understandable.

The last article of the second part, "New Ways of Looking at Surfaces", is more a short presentation of methods and recent applications avoiding details, which would be valuable for the technically interested reader.

The last and shortest part of the book, "Current Topics in Materials Research", reports on facilities and instrumentation, and may therefore be important for people interested in funding practices and politics.

In spite of its inhomogeneous character, with detailed articles describing dislocation theories of metals or the reptation model of polymer diffusion on the one hand, and articles which only give keywords without further explanation on the other hand, the book serves its purpose: It gives a rather complete summary over the first funding period of a gigantic and successful program and it sketches important challenges. Maybe the international competitiveness of today's research in materials science is responsible for the fact that extremely topical research areas such as impact-resistant ceramics, quantum wells, and new aspects of semiconductor research, are only touched upon briefly.

There is no equivalent European or Japanese book on the same topic. The book reflects a good American tradition of formulating and reviewing national goals. I hope that some European programs are stimulating and powerful enough to be the basis for a rewarding book 25 years from now.

Biosensors

Biosensors International Workshop 1987 (GBF Monographs, Vol. 10). Edited by *R. D. Schmid*. VCH Verlagsgesellschaft, Weinheim 1987, XIV, 346 pp, paperback, DM 128.00, ISBN 3-527-26801-4

In June 1987 the "Gesellschaft für Biotechnologische Forschung (GBF)" invited a representative circle of speakers to a workshop on biosensors in Braunschweig (FRG). The conference proceedings, published late in 1987, offer a good survey of the great variety of lectures held at the GBF. These topical proceedings illustrate, with a well suited mixture of reviews and reports, the broad range of biosensor research as well as the innovative power and the state of the art of this technology.

One of the purposes of this workshop was to define the position of the West German biosensor research in comparison with international activities in the field. In the preface the editor comments on the current situation and describes the position of the FRG by way of analyzing statistical data about biosensor publications and patents. Based on data from 1985, the West German biosensor research has to be placed in the sixth rank, far behind the dominating Japan and even behind the GDR.

Brilliant examples of new biosensors that make use of all important transducer technologies (potentiometric, amperometric, fiber optic and piezoelectric) were presented and their enormous potential, especially in medicine, was illustrated with ion-, enzyme-, and immunosensors. In addition, possible applications of biosensors in process engineering and environmental protection were discussed.

The performance of biosensors is already impressive. Gas sensors for organophophorus compounds with ppb sensitivities and immunosensors with detection limits beyond the picomolar range were reported. The large number of lectures about glucose sensors gives an impression of the topicality and importance of this subject. The long-term goal is an implantable glucose sensor which, combined with an insulin pump, would improve the life of many diabetics. In general, most of the biosensors are developed as diagnostic tools. Because of their excellent performance and cost effectiveness they have already become serious competitors to established methods. Remarkable success in this field is reported from the GDR.

There are many different approaches to reach the long-term goals, i.e., the combination of smale size (mm scale), cheapness (less than 50 cents), high sensitivity (nM–μM) and selectivity (10^5 or better), longevity (years), and high reliability (margin of error less than 1%) in one biosensor. The capabilities of living systems serve as a model. The detection sensitivities of sea animals to minimal water contaminations (down to 10^{-13} M) that are used, for example, to control the quality of drinking-water are still unrivalled. Biosensors with natural receptors are the way to imitate nature in this respect.

The efficient interdisciplinary cooperation of different fields like biology, chemistry, electronics, physics, and medicine is an important key to success and characterizes the internationally leading groups. It should be mentioned that there were also a few interesting contributions from West German researchers, and they demonstrated that a variety of innovations in this field are awaiting a breakthrough. The question remains why biosensor research, which will be an important economic factor in the next decades, has been so long neglected in the FRG. It is estimated that the nineties will see the commercial breakthrough of biosensors. For the year 2000 a study predicts an American biosensor market of $ 200 million for medical applications alone. Biosensors are also important for biotechnology, environmental technology, and the food industry. However, the proceedings of this workshop leave no doubt that medical applications predominate. The current situation in biosensor research in West Germany bears some similarities to the status of microelectronics and gene technology research a few years ago; in both fields, the FRG is now having to undertake enormous efforts to reach international standards. Will biosensor research have a similar fate? Immediate strong support for this interdisciplinary field could help prevent this.

A final word on the workshop proceedings: The editor should have insisted on a better elaboration of some of the abstracts. In a few cases a half-page summary of a lecture is all that is provided. However, the book enables one to rapidly obtain a comprehensive overview of the state of the art in biosensor research. Also, the book gives an impression of the innovative power of this technology.

Conference Calendar

June 1988

26-2 **Synthetic Metals**
Los Alamos (USA)
Contact: M. Aldissi, ICSM '88, Los Alamos Natl. Lab., P.O. Box 1663, MS K764, Los Alamos, NM 87545, USA

26-8 **Superconductive Electronics,**
NATO Adv. Study Inst.
Il Ciocco (Italy)
Contact: H. Weinstock, AFOSR/NE Bolling AFB, Washington, DC 20332-6448, USA

29-30 **Organic Materials for Nonlinear Optics (OMNO '88)**
Oxford (United Kingdom)
Contact: Mrs. E. S. Wellingham, OMNO '88, 6 Craig-yr-Haul Drive, Castleton, Cardiff CF3 8SA, UK

July 1988

3-15 **Polymer Colloids III,**
NATO Adv. Study Inst.
Strasbourg (France)
Contact: R. H. Ottewill, Univ. of Bristol, Cantocks Close, Bristol BSB 1 TS, UK

5-8 **Modified Polymers,**
7th IUPAC Int. Conf.
Bratislava (Czechoslovakia)
Contact: A. Romanov, Polymer Inst. CCR, Slovak Acad., Bratislava, CSSR

10-24 **Surfaces and Grain Boundaries of Oxide Ceramics,**
NATO Adv. Study Inst.
Stuttgart (Fed. Rep. Germany)
Contact: Dr. J. Nowotny, Max-Planck-Institut für Festkörperforschung, Heisenbergstraße 1, Postfach 800065, D-7000 Stuttgart 80, FRG

12-15 **Joint Magnetism and Magnetic Materials (MMM)-Intermagn. Conf. (4M3I)**
Vancouver (Canada)
Contact: IEEE, Technical Activities Dept., 345 E 47th St., New York, NY 10017, USA

18-21 **Carbon Fibers and Composites**
Buffalo (USA)
Contact: D. D. L. Chung, Dept. of Mechanical & Aerospace Engineering, SUNY, Buffalo, NY 14260, USA

18-21 **Macromolecules,**
31st Microsymp.
Prague (Czechoslovakia)
Contact: P. M. M. Secretariat, Inst. of Macromol. Chem., 1888 Petriny, Prague 6, CSSR

25-27 **Laser Materials and Laser Spectroscopy**
Shanghai (People's Rep. China)
Contact: Prof. Wang Zhijiang, Chinese Optical Society, P.O. Box 8211, Shanghai, People's Rep. of China

August 1988

1-6 **Macromolecules,**
32nd IUPAC Int. Symp.
Kyoto (Japan)
Contact: Soc. of Polym. Sci. 5-12-8 Ginza, Chuo-ku, Tokyo 104, Japan

8-12 **Superlattices, Microstructure and Microdevices,**
4th Int. Conf.
Trieste (Italy)
Contact: Prof. G. H. Döhler, Univ. Erlangen-Nürnberg, Institut für Technische Physik, Erwin-Rommel-Str. 1, D-8520 Erlangen, FRG

14-19 **Optical and Optoelectronic Applied Sci. and Eng.,**
32nd Annu. Int. Tech. Symp.
San Francisco (USA)
Contact: SPIE, P.O. Box 10, Bellengham, WA 98225, USA

15-19 **Controlled Release of Bioactive Materials,**
15th Int. Symp.
Basel (Switzerland)
Contact: Administrative Office, Controlled Release Soc., 16 Nottingham Dr., Lincolnshire, ILL. 60015, USA

15-19 **Liquid Crystals,**
12th Int. Conf.
Freiburg (Fed. Rep. Germany)
Contact: Dr. G. Baur, Fraunhofer-Institut IAF, Eckerstr. 4, D-7800 Freiburg, FRG

22-25 **Nonlinear Optical Properties of Materials**
Troy (USA)
Contact: OSA, 1816 Jefferson Pl. NW, Washington, DC 20036, USA

22-26 **Ceramic Developments - Past, Present and Future,**
Int. Ceramic Conf. and Fair
Sydney (Australia)
Contact: G. Henness, New South Wales Inst. of Technology, Dept. of Materials Sci., P.O. Box 123, Broadway NSW 2007, Australia

28-1 **Molecular Beam Epitaxy (MBE-5)**
Sapporo (Japan)
Contact: Prof. M. Konagai, Tokyo Inst. Tech., Dept. of Electrical and Electronic Eng., 1-12-1 Okayama, Meguro-ku, Tokyo 152, Japan

28-10 **Structure-Property Relationships in Surface Modified Ceramics**
NATO Adv. Study Inst.
Pisa (Italy)
Contact: C. J. McHargue, Metals & Ceramics Division, Oak Ridge Natl. Lab. P.O. Box 10, Oak Ridge, TN 37831-6118, USA

29-1 **Applications of Polar Dielectrics and Ferroelectrics,**
Int. Symp.
Zürich (Switzerland)
Contact: H. Arend, Swiss Federal Inst. of Tech., Lab. of Solid State Physics, CH-8093 Zürich, Switzerland

29-10 **Ion Beam Analysis of Solids,**
Summerschool
Jena (German Dem. Rep.)
Contact: Prof. G. Götz, Friedrich-Schiller-Univ., Sektion Physik, Max-Wien-Platz 1, DDR-6900 Jena, DDR

September 1988

4-8 **Zeolites as Catalysts, Sorbents and Detergent Builders,**
Int. Symp.
Würzburg (Fed. Rep. Germany)
Contact: Dr. H. G. Karge, Fritz-Haber-Inst. der Max-Planck-Gesellsch., Faradayweg 4-6, D-1000 Berlin 33

4-9 **Metal-Hydrogen Systems, Fundamentals and Applications,**
Int. Symp.
Stuttgart (Fed. Rep. Germany)
Contact: Dr. E. Fromm, Max-Planck-Institut für Metallforschung, Inst. für Werkstoffwissenschaften, Seestraße 92, D-7000 Stuttgart 1, FRG

4-16 **Surfaces and Interfaces on Ceramic Materials,**
NATO Adv. Study Inst.
Oleron (France)
Contact: Dr. L. C. Dufour, Chemie des Materiaux IREQ, CP 1000, Varennes, Quebec JOL 2PO, Canada

4-16 **Plasma Surface Interactions and Processing of Materials,**
NATO Adv. Study Inst.
Alicante (Spain)
Contact: Prof. O. Auciello, NC State Univ., Dept. of Nuclear Eng., Raleigh, NC 27695-7909, USA

5-7 **Electrical, Optical and Acoustic Properties of Polymers**
Canterbury (United Kingdom)
Contact: The Plastics and Rubber Inst., 11 Hobart Pl., London SW1X OHL, UK

5-8 **Surface Science,**
Eur. Conf. (ECOSS-10)
Bologna (Italy)
Contact: Prof. O. Bisi, Univ. di Modena, Dipto. di Fisica, 213/a Via Campi, I-41100 Modena, Italy

10-17 **Electrochemistry of Conductive Polymers**
Sulejow (Poland)
Contact: Janusz Ptocharski, Inst. of Inorganic Technology, ul. Noakowskiego 3, 00664 Warszawa, Poland

12-14 **Materialforschung 1988,**
BMFT Symp.
Hamm (Fed. Rep. Germany)
Contact: Material- und Rohstofforsch., KFA Jülich GmbH, Postfach 1913, D-5170 Jülich, FRG

12-16 **Surface Modification of Metals by Ion Beams,**
6th Int. Conf. (SMMIB '6)
Riva del Garda (Italy)
Contact: Dr. L. Guzman, Technologica in Trento, Istituto per la Ricerca Scientifica, I-38050 Povo, Trento, Italy

12-16 **Properties and Applications of Dielectric Materials,**
2nd Int. Conf. (ICPADM-2)
Beijing (People's Rep. China)
Contact: Prof. Z. Renyu, Tsinghua University, Dept. of Electrical Eng., Beijing, People's Rep. of China

12-15 **Solid State Protonic Conductors IV**
Exeter (United Kingdom)
Contact: Dr. R. C. Slade, Univ. of Exeter, Dept. of Chem., Stocker Rd., Exeter EX4 4QD, UK

12-17 **Evaluation of Adv. Semiconductor Materials by Electron Microscopy,**
NATO Adv. Workshop.
Bristol (United Kingdom)
Contact: Dr. D. Cherns, HH Wills Phys. Lab. Univ. Tyndall Ave., Bristol BSB 1 TL, UK

13-15 **Speciality Polymers,**
3rd Int. Conf.
Cambridge (United Kingdom)
Contact: Monique Heald, Butterworth Scientific Ltd., P.O. Box 63, Westbury House, Bury St., Guilford, Surrey GU2 5BH, UK

13-16 **Structure and Reactivity of Solids**
Trieste (Italy)
Contact: Prof. C. Morterra, Ist. Chimica Fisica, C.so M D'Azeglio 48, I-10125 Torino, Italy

13-16 **Polymers, Laminations & Coatings**
Atlanta (USA)
Contact: Meet. Dept., TAPPI, Technology Park, Atlanta, GA 30348-5113, USA

20-23 **Polymer Surfaces and Interfaces,**
Workshop
Pacific Grove, CA (USA)
Contact: J. Rabolt, IBM, Almaden Research Ctr., 650 Harry Rd., San Jose, CA 95120-6099, USA

21-23 **Solid-State Circuits,**
14th Eur. Conf. (ESSCIRC-14)
Manchester (United Kingdom)
Contact: Dr. P. J. Hicks, UMIST, Dept. of Electrical Eng. and Electronics, P.O. Box 88, Manchester M60 IQD, UK

22-23 **Oxidation of High-Temperature Intermetallics,**
Workshop
Westlake, OH (USA)
Contact: T. Grobstein, NASA Lewis Research Center 2100 Brookpark Rd., M/S49-1 Cleveland, OH 44135-3191, USA

24-30 **World Materials Congress**
Chicago (USA)
Contact: World Materials Congress, Technical Department ASM International, Metals Park, OH 44073, USA

26-30 **Polymer Networks Group,**
9th Mtg.
Freiburg (Fed. Rep. Germany)
Contact: W. Burchard, Inst. für Makromolekulare Chemie, Univ. of Freiburg, Stefan-Meier-Strasse 31, D-7800 Freiburg, FRG

28-30 **Ungewöhnliche Valenzzustände in Festkörpern,**
5. Vortragstagung der Fachgruppe Festkörperchemie der Gesellsch. Dtsch. Chem.
Erlangen (Fed. Rep. Germany)
Contact: GDCh, Abtlg. Tagungen, Postfach 900440, D-6000 Frankfurt am Main 90, FRG

October 1988

3-6 **Farbensymposium,**
10. Int. Symp.
Trier (Fed. Rep. Germany)
Contact: Dr. E. Hahn, BASF AG, D-6700 Ludwigshafen, FRG

9-14 **Ultrafast Phenomena and Nonlinear Optics**
Chicago (USA)
Contact: R. R. Alfano, City College of New York, 138 St. and Convent Ave., New York, NY 10031, USA

12-14 **Ceramic Powder Processing Science,**
2nd Int. Conf.
Berchtesgaden (Fed. Rep. Germany)
Contact: Dtsch. Keram. Gesellsch., Postfach 1226, D-5340 Bad Honnef 1, FRG

18-20 **Deutsche Keramische Gesellschaft,**
Annu. Congr.
Munich (Fed. Rep. Germany)
Contact: Dtsch. Keram. Gesellsch., Postfach 1226, D-5340 Bad Honnef 1, FRG

18-22 **ceramitech '88,**
4th Int. Fair/3rd Int. Symp.
Munich (Fed. Rep. Germany)
Contact: Münchener Messe- und Ausstellungsgesellsch., Postfach 121009 D-8000 München 12, FRG

19-21 **Raw Materials for New Technologies,**
5th Int. Symp. on Mineral Resources
Hannover (Fed. Rep. Germany)
Contact: Dr. Arnt Müller, Bundesanstalt für Geowissenschaften und Rohstoffe, Postfach 510153, D-3000 Hannover 51, FRG

21-24 **Functional and Fine Polymers,**
XISFFP Xian Int. Symp.
Xian (People's Rep. China)
Contact: Prof. Hua Zhao, Xian Modern Chemistry Research Inst., P.O. Box 18, Xian, People's Rep. of China

23-26 **Combustion and Plasma Synthesis of High-Temperatur Materials,**
Int. Symp.
San Francisco (USA)
Contact: Dr. J. B. Holt, Lawrence Livermore Natl. Lab., P.O. Box 808, L-369, Livermore, CA 94550, USA

November 1988

8-10 **European MRS Fall Conference**
Strasbourg (France)
Contact: P. Siffert, Centre de Recherches Nucléaires, Lab. "PHASE", 23, Rue du Loess, F-67037 Strasbourg (France)

9-11 **Perspectives on the New Superconductivity**
Boston (USA)
Contact: D. Berger, Nature Publ. Co., 65 Bleecker St., New York, NY 10012, USA

10-11 **Microstructural and Microanalytic Characterisation of Ceramic Materials**
Bad Nauheim (Fed. Rep. Germany)
Contact: Deutsche Gesellschaft für Metallkunde eV., Adenauerallee 21, D-6370 Oberursel, FRG

19-23 **Multiphase Macromolecular Systems,**
14th Biennial Polymer Symp.
San Diego (USA)
Contact: B. Culbertson, Ashland Chemical Co., P.O. Box 2219, Columbus, OH 43216, USA

27-30 **Ceramic Materials and Components for Engines,**
3rd Int. Symp.
Las Vegas (USA)

If you want to have your conference, symposium, workshop or fair announced in this Calendar, please send all relevant material to

ADVANCED MATERIALS/ ANGEWANDTE CHEMIE
Postfach 1260/1280
D-6940 Weinheim
Federal Republic of Germany

ADVANCED MATERIALS will again appear in the July issue of this journal and from September onwards, monthly.

The July issue will contain short reviews on advanced powder metallurgy *(Petzow/Kaysser)* and polymer synthesis *(Reetz)* as well as contributions to the other sections of ADVANCED MATERIALS.

A number of free reprints of this ADVANCED MATERIALS part of the journal are available.

Please write to:

Tellurium-Rich Tellurides

By Peter Böttcher*

The tellurides represent a class of compounds which exhibit a wide range of physical and chemical properties. In addition to the salt-like compounds, some tellurides show metallic properties while others have strong covalent bonds. Like tellurium itself, many of these are semiconductors, e.g., the II–VI compounds CdTe and MnTe, and in this respect are of special interest. Other tellurides, e.g., $NbTe_4$ and $ZrTe_5$, have low-dimensional electronic transport properties. Some ternary transition metal–main group metal tellurides appear in an amorphous state with spin glass properties. The tellurium-rich tellurides are characterized without exception by directed Te–Te bonds. It turns out that general structural chemical relationships exist between them which allow these different compounds to be treated as a single comprehensive class of substances. They represent a link between the Zintl phases on the one hand, and molecular compounds on the other.

1. Introduction

In recent years the structures of a large number of tellurium-rich tellurides have been reported whose anionic networks are characterized by homonuclear Te–Te bonds. They do not usually follow the structural chemistry of the chalcogen-rich selenides and sulfides, which are found almost exclusively in helical zig-zag chains X_n^{2-} (X = S, Se; n = 4, 5, 6 ...), due to their prevalent two-coordinate covalency. On the other hand, the tellurides reflect the variety of structural possibilities of the element tellurium itself, since the anionic segment can frequently be derived from either known or hypothetical modifications of tellurium in which each atom is more than two-coordinate. The size of the fragment depends on the number of electrons transferred to tellurium, with the most electron-rich anionic components remaining as small, isolated, quasi-molecular fragments. This formal operation of transferring all valence electrons from the more electropositive to the more electronegative atoms is known as the Zintl–Klemm concept, which allows one to predict structural features for distinct classes of compounds.[1–5] In accordance with these ideas, some tellurides show infinite three-dimensional networks of tellurium, while others exhibit infinite two- or one-dimensional anionic building units, as well as those examples that contain only isolated anionic fragments.

2. Some Possible Arrangements of Tellurium

As a Group 6 element, tellurium can bind to a maximum of six neighbors. Several high-pressure experiments have been carried out with the aim of stabilizing a modification with six equivalent bond distances. The α- as well as the β-Po type would show suitable arrangements.[6,7] The close relationships between the α-Po type and the thermodynamically stable modification of Te have already been outlined. The six equivalent Te–Te distances are predicted to be 3.02 Å.[8] All experiments using pressures up to 10 GPa

have not produced the desired result, although Te undergoes two pressure-dependent phase transformations in this region (at 4.5 and 7 GPa[7, 9]). At 4 GPa one observes a structural change (two-bonded Te→four-bonded Te) together with a semiconductor-to-metal transition. At 7 GPa only a gliding change of the metric occurs (four-bonded $Te_{monoclinic}$→four-bonded $Te_{orthorhombic}$), without any fundamental rearrangement of the tellurium atoms. In addition, some changes in the physical properties are observed.[9] Two further pressure-induced phase transformations have been reported. One of them is said to occur around 3 GPa and results in the gray As structure type (two-bonded Te → three-bonded Te[10]). From this structure the observed modification of Te at 4.5 GPa, which shows four-bonded Te, could indeed arise. The second reported phase transformation was obtained at 7 GPa to give the β-Po structure type.[7] All observations present the following picture (b stands for "bonded"):

Te(2b, trigonal, thermodynamically stable modification) ⟶ [Te(3b, rhombohedral, As type, 3 GPa)] ⟶ Te(4b, monoclinic, 4.5 GPa) ⟶ [Te(6b, rhombohedral, β-Po type, 7 GPa)].

The increase in the bond number with increasing pressure is consistent with expectation.

Table 1 classifies both the existing modifications as well as some selected examples of hypothetical arrangements in a scheme that orders not only by the number of homonu-

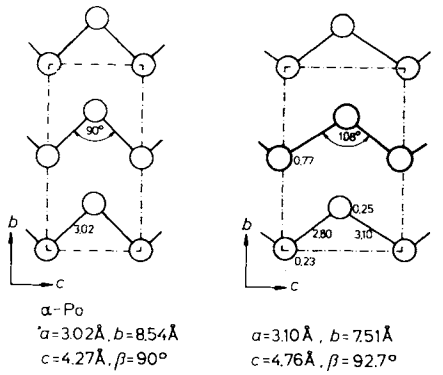
clear bonds but also by the localization or the delocalization of the nonbonding electrons that remain. Some of the possible structures are shown in Figure 1.

All modifications in which tellurium has an odd number of bonds should exhibit metallic properties on account of the extra unpaired electron (Fig. 1e: three-bonded Te, As type; Fig. 1i: five-bonded Te, 4^4 double nets). However, in some of the possible structures with an even number of bonds, all of the nonbonding electrons need not be localized into lone pairs. One can imagine four-coordinate Te with two delocalized electrons forming an infinite two-dimensional tetragonal plane (4^4 net). This represents a low-dimensional metal, just as in the two-dimensional double sheets containing five-coordinate Te shown in Figure 1i. Two-coordinate Te arises when four nonbonding electrons occur in two localized lone pairs (found as zig-zag chains—the thermodynamically stable modification). Planar zig-zag chains could arise from divalent tellurium which has one nonbonding pair and two delocalized electrons. Alternatively, divalent Te atoms having four delocalized electrons can produce linear chains. Some examples of such structural variations are realized in Zintl phases with suitable composition in which the electronegative element contains formally six valence electrons. The pressure-induced semiconductor-to-metal transition occurring at 4 GPa also leads to a structure that contains tellurium atoms with an even bond number (4b, cf. Fig. 1g and Fig. 2) in the metallic high-pressure state.

In this phase, which is stable above 4.5 GPa, the pleated 4^4 sheets are not stacked one on top of the other as in α-Po, but are shifted towards one another along the [010] direction by $a/2$ (Fig. 2), whereby the coordination number increases from six to eight (1+3+1+3, Table 1). The bond angle is 108°. Monoclinic behavior remains up to 6.6 GPa. As the pressure increases the monoclinic angle β shifts toward 90° and orthorhombic symmetry occurs. In addition, at 6.6 GPa some of the physical properties change.[9] The distances between the 4^4 nets are not affected with respect to the high pressure. As in the stable modification of Te at ambient pressure as well as in many tellurium-rich tellurides, it is around 3.5 Å.

The operation of bond breaking beginning with highly symmetric arrangements (cf. Fig. 1) has been occasionally discussed.[13–15] For example, it has been shown that 36



α-Po
a=3.02 Å, b=8.54 Å

possibilities exist for three-bonded atoms, if the primitive cubic array is used as a starting point. Among these 36 structures, that of gray As and black P have distinct energetic stability with respect to the majority of the alternatives.[13] This result is mirrored in the fact that pressure leads to the transformations P(black) → P(gray As) → P(α-Po) and Sb(As type) → Sb(α-Po).[16]

3. Structures of the Tellurides

According to the Zintl-Klemm concept the valence electrons are transferred from the cations to the more electronegative tellurium. As previously noted, the connectivity within the anionic segment becomes reduced as more electrons are transferred to it. The alkali metal tellurides are examples that clearly follow the expected trends (Table 2). Naturally, no severe correlations exist that would limit one and only one structural type for a given average tellurium oxidation number. Additional effects, such as increasing cation-anion or cation-cation interactions by the introduction of transition metal cations, can influence the structures of the anionic framework.

Table 2. Motifs of the alkali metal tellurides.

General formula	Average oxidation number	Motif of the anionic part	Ref.
MTe_4 (M = Cs)	−0.25	$^2_\infty[TeTe_3^-]$	[17]
MTe_3 (M = Li, Na)	−0.33	$^1_\infty[Te_{1/2}^{0}{}^-(Te_2)_3]$	[18, 19]
$MTe_{2.5}$ (M = Rb, Cs)	−0.40	$^1_\infty[TeTe_4^{2-}]$	[20, 21]
$MTe_{1.5}$ (M = K, Rb, Cs)	−0.67	isolated: Te_3^{2-}	[22, 23]
MTe (M = Na, K)	−1.00	isolated: Te_3^{4-}, Te_2^{2-}, Te^{2-}	[24, 25]
M_2Te (M = Li, Na, K, Rb, Cs)	−2.00	isolated: Te^{2-}	[26, 27]

3.1. Infinite Three-Dimensional Anionic Frameworks

Such frameworks are derived from the α-Po type structure (Fig. 3a) as one systematically removes atoms from its infinite three-dimensional network. Removal of every fourth Te atom results in one of the conceivable structures that contains exclusively four-coordinate Te in which both nonbonding electrons should be delocalized (Fig. 3e). The square planar fragment is marked, which is suitable to build up the network. This framework, which is also observed in the binary compound NbO (Fig. 3d[29]), occurs nearly undistorted in the structure of $AgTe_3$.[28] The bond angles at Te are 89.8° and 90.5° and the Te–Te distance is 3.05 Å. Since the Ag cations occupy the sites of the missing Te atoms (Ag–Te: 3.02 Å and 3.08 Å), the complete structure is essentially an undistorted 1:3 ordered variant of the α-Po type (Fig. 3c). Metallic properties have been confirmed by experiment. $LiTe_3$[18] and $NaTe_3$,[19] both of which are structurally related to $AgTe_3$, have a broken-up infinite three-dimensional anionic network. In these cases only infinite one-dimensional strands are found in which Te is either two- or three-coordinate. The change to the alkali metal cations causes, to some extent, an increased

localization of the nonbonding electrons, in which one recognizes ca. 20% increases in the volume of the anionic structural component over that for $AgTe_3$[26] (see Section 3.3 and Table 4).

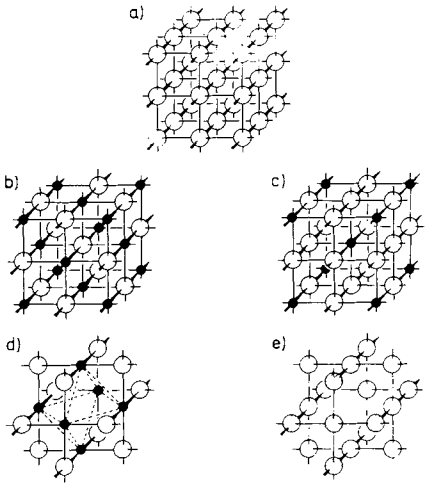

Fig. 3. Two derivatives of the primitive cubic arrangement: a)→b)→d): α-Po type, NaCl type, NbO; a)→c)→e): α-Po type, $AgTe_3$, $^3_\infty[Te_3^-]$.

The 1:3 ordered variant of the α-Po type (≙ $AgTe_3$, Fig. 3c) is compared with the corresponding 1:1 ordered type (≙ NaCl type, Fig. 3b). The same systematic removal of a fourth of all atoms in the case of the NaCl type leads to the NbO structure (Fig. 3d[29]), in the case of $AgTe_3$ there results the anionic structural component $^3_\infty[Te_3^-]$ (Fig. 3e).

3.2. Infinite Two-Dimensional Anionic Networks

The anionic structural component of $CsTe_4$[17] is related to the infinite two-dimensional framework containing five-coordinate Te atoms (Fig. 1i). It can be derived from this two-dimensional section of the α-Po structure through the systematic removal of every third Te atom. The remaining network contains only two and three-coordinate Te atoms, as in the case of the tritellurides $LiTe_3$ and $NaTe_3$. The relationship between the hypothetical double sheet with five-coordinate tellurium (Fig. 1i) and the observed Te network in $CsTe_4$ (Fig. 4) is similar to the relationship between the structure of black phosphorus (Fig. 1f) and pnictide nets in MX_3 materials (M = alkaline earth metal, X = pnicogen).[5,30] Because of the different constituents and oxidation numbers of the cations, puckered X_{14} rings occur within the pnictide nets, while puckered Te_{18} rings are found in $CsTe_4$. The three-coordinate pnicogen atoms in the polyanionic networks (X_3^{2-}) of the pnictides carry just a single nonbonding electron pair, whereas the three-coordinate Te^- ions in the polyanionic sheets of $CsTe_4$ have two nonbonding electron pairs, as does Br in the interhalogen compound BrF_3, due to their function as central atoms for their corresponding fragments. In fact, the interconnected Te_{18} rings can be broken down into 25e-fragments $TeTe_3^-$ (six valence electrons per Te plus one additional electron) analogous to the BrF_3 molecule (Fig. 4,

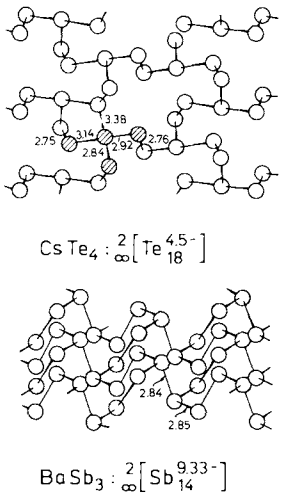

Fig. 4. Top: Anionic part of the $CsTe_4$ structure projected down [30$\bar{2}$]. Bottom: Anionic part of $BaSb_3$.

shaded fragment). On account of the deficiency of three valence electrons compared to BrF_3, the $TeTe_3^-$ units bridge together via the radical centers (the three terminal Te atoms of the T-shaped fragment, in a formal sense) to form 18-membered rings in the infinite two-dimensional sheets. The fragments are distorted: $Te_{central}$–Te_{apical}, 2.92 and 3.14 Å; $Te_{central}$–$Te_{equatorial}$, 2.84 Å; Te_{apical}–$Te_{central}$–$Te_{equatorial}$, 93.6° and 83.6°. As in pseudo trigonal bipyramidal molecules, the apical atoms on average (3.03 Å) lie farther from the central atom than the equatorial atoms. Adjacent fragments are connected via distances of 2.75 and 2.76 Å. When a Te···Te contact of 3.38 Å ($Te_{central}$···Te_{apical}) is included, the T-shaped fragment becomes a heavily distorted square planar structural group $TeTe_4$. In a more undistorted form this represents the preferred arrangement in many Te-rich tellurides.

The closed double sheet fragment of the α-Po structure with five-coordinate Te (Fig. 1i) remains completely maintained in the flat Te double sheets of the remarkable intercalation compound $(Te_2)_2I_2$ (Fig. 5).[31] Independent of whether the remaining nonbonding electrons are localized or delocalized, these nets are not known in any HP modification of Te or in the tellurides. In the compound $(Te_2)_2I_2$, the electronegativities argue against an electron transfer from iodine to tellurium and, therefore, against the formulation of the double nets as anions. Rather, one expects a partial electron loss from the double sheets of the hypothetical five-coordinate Te. Therefore, there are fewer than six electrons per tellurium in the flat double sheets. In a recently published work, both the topological and electronic relationships of this Te framework have been discussed with regard to the structure of β-SnS, which is related to the structure of black phosphorus through a "klassengleich" transformation (Fig. 5).

The bonding characteristics of $(Te_2)_2I_2$ can be qualitatively understood if one derives the band structure of the planar two-dimensional Te double sheets from the slightly puckered SnS double sheets. The differences in the electronic structure are primarily due to the energy difference between S and Sn centered orbitals, as opposed to no en-

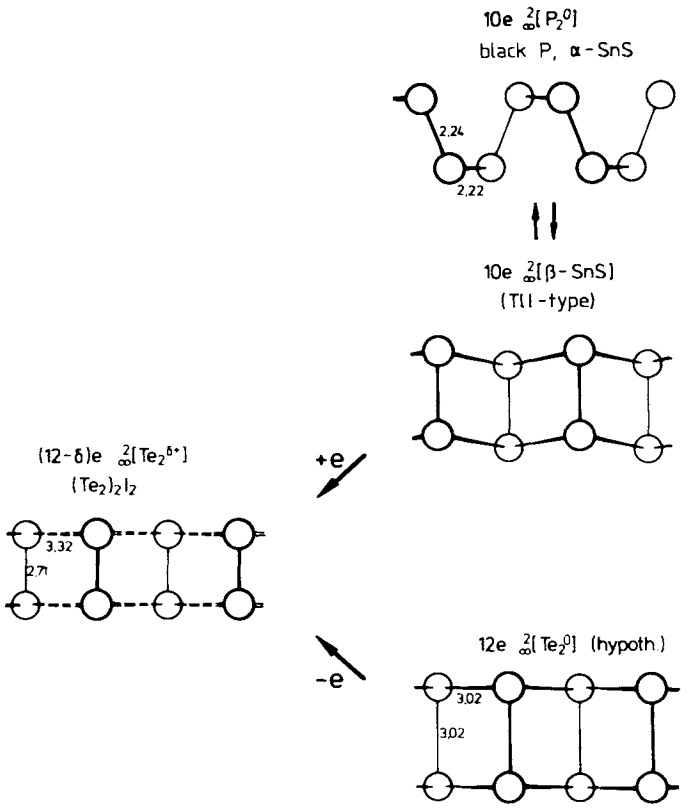

Fig. 5. Relationship between the structures of α- and β-SnS and the 4^4 double nets of $(Te_2)_2I_2$ as well as a double sheet of the hypothetical structure with five-coordinate tellurium.

ergy difference between atomic orbitals in the Te_2 unit, which reflects the relative atomic electronegativities in each material. Analysis of the band structure indicates strong Te–Te interactions perpendicular to the double sheets (Te_2 dimers: 2.71 Å) since the π^* orbitals of the diatomic unit are partially occupied. Parallel to the sheets (Te···Te: 3.32 Å) there is significant occupation of the antibonding region of both the π and π^* bands. Puckering of the Te double sheets is not predicted until significant oxidation of the Te partial structure occurs, which cannot be attained with intercalated halogens. The partial electron transfer expected to proceed from the Te double sheets to iodine leads to fractional occupation of the σ^* levels of I_2 and explains the observed expansion of the I–I distance.[32]

Two-dimensional sheets of Te atoms (4^4 nets cf. Fig. 1h) make up the structures of numerous lanthanoid and actinoid tellurides $LnTe_n$ ($n \geq 1.75$). Only the sesquitelluride $LnTe_{1.5}$ and the monotelluride LnTe are based upon other structural motifs and show no homonuclear Te–Te bonding. The simplest fundamental pattern is the *anti*-Cu_2Sb type,[33] which originates when two mixed lanthanoid/tellurium layers Ln/Te are inserted between every planar 4^4 Te net (stacking sequence: $\cdots 4^4$-(Ln/Te)-(Ln/Te)-$4^4\cdots$). Correspondingly, the ditellurides, $LnTe_2$, do crystallize in the *anti*-Cu_2Sb type. Both compounds of the known phases $LnTe_{2.5} = Ln_2Te_5$ and $LnTe_3$ (see Fig. 6) arise from similar stacking variations of these two types of layers. This has also been found for incompletely characterized compounds ($LnTe_{2.33} = Ln_3Te_7$, $LnTe_{2.75} = Ln_4Te_{11}, \ldots$; cf. Ref. [34]).

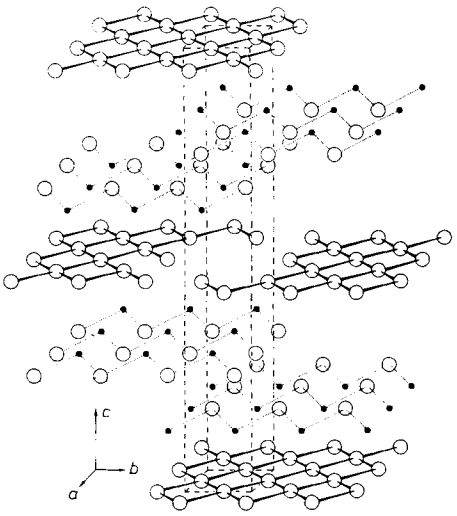

Fig. 6. Structure of $NdTe_3$. The 4^4 tellurium nets become separated from one another through intermediate puckered layers of Nd^{3+}/Te^{2-}

One of the first detailed structural determinations of the tritellurides was carried out for $NdTe_3$.[35] Its basic structure is shown in Figure 6. One recognizes the series of 4^4 tellurium nets, which are either adjacent to one another or are separated by two of the slightly puckered mixed lanthanoid/tellurium layers. The tellurium atoms in adjacent nets are separated by about 3.6 Å. The distances between the tellurium nets and the tellurium atoms in the puckered Ln/Te layers are 4 Å. From their local geometry the tellurium atoms not found in the 4^4 nets can be described as Te^{2-} ions. The compounds in Table 3 are described using an ionic formulation with the lanthanoids as trivalent cations. The examples with the smallest tellurium to metal ratio, $LnTe_2$, show the largest excess of delocalized electrons per 4^4 sheet. The Te–Te distance in the infinite two-dimensional 4^4 nets $^2_\infty[Te^{\delta-}]$ increases with increasing excess charge from 3.07 Å through 3.10 Å to 3.17 Å, which indicates an increasing occupation of antibonding states (Table 3). The *anti*-Cu_2Sb type frequently remains stable even if the 4^4 nets are incompletely occupied, e.g., $LnTe_{2-x}$ for $x \approx 0.25$. However, structures containing only isolated Te^{2-} ions begin with the sesquitellurides, $LnTe_{1.5}$. The 4^4 chalcogen nets of the disulfides and diselenides, LnX_2, are somewhat distorted due to their tendency to form X_2^{2-} dumbbells.[38,54–69] Therefore, they usually crystallize in low symmetry structures which can be derived from the *anti*-Cu_2Sb type (Fig. 7). Materials with incompletely occupied chalcogenide nets, LnX_{2-x}, have been described using the *anti*-Cu_2Sb type and show that a statistically averaged structure is necessary. This has been confirmed by the most recent results with $PrSe_{2-x}$ ($x \approx 0.2$).[69]

Table 3. Lanthanoid and actinoid tellurides $LnTe_n$ ($n \geq 1.75$).

General formula	Ionic description		Average Te-Te distance in the 4^4-nets	Ref.
$LnTe_{2\pm x}$	(Ln^{3+}/Te^{2-})	$^2_\infty[Te^{1/4}_{4/4}]$	3.17 Å	[36-44]
$LnTe_{2.5\pm x}$	(Ln^{3+}/Te^{2-})	$^2_\infty[Te^{0.67-}_{4/4}]_{1.5}$	3.10 Å	[37], [40], [45-48]
$LnTe_{3\pm x}$	(Ln^{3+}/Te^{2-})	$^2_\infty[Te^{0.5-}_{4/4}]_2$	3.07 Å	[35], [37], [40], [41], [49-53]

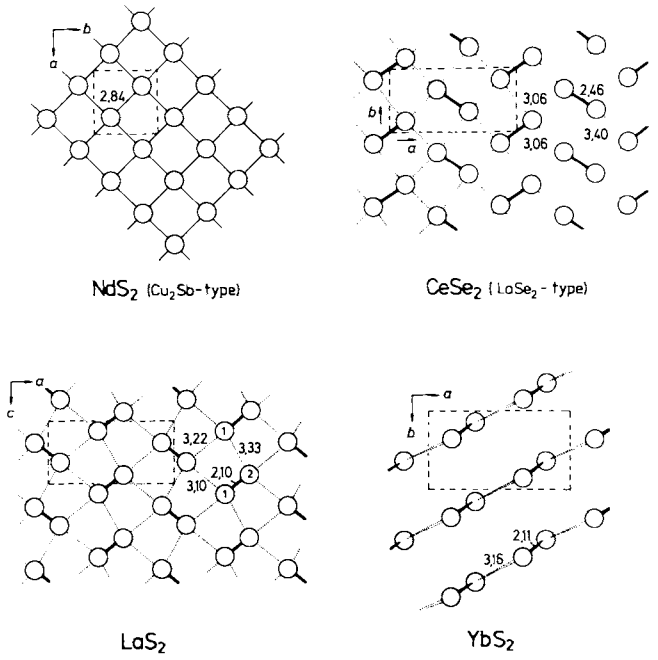

Fig. 7. Section from the anionic structural part of the lanthanoid dichalcogenides, LnX_2.

The electronic relationship between the $^2_\infty[Te_2^{\delta+}]$ double sheets of $(Te_2)_2I_2$ and the 10-electron structure of the β-SnS type has been discussed previously. Planar nets having a tetragonal arrangement of identical atoms occur, for example, in the structure of α-PbO or the $BaAl_4$ family and its ternary variants.[70-72] The oxygen atoms in α-PbO, the aluminum atoms in $BaAl_4$, and the pnicogen as well as the chalcogen atoms in the ternary variants are arranged in 4^4 nets. Over the center of each $M_{4/4}$ square there is an additional atom either of the same type ($AlAl_{4/4}$ of $BaAl_4$) or of a second type ($PbO_{4/4}$ of α-PbO). The band structure for the two-dimensional planar $Al_{4/4}$ net has been described previously. From the selected Al-Al distance of 3.2 Å, one can expect the qualitative results to be equally applicable to tellurium (Fig. 8). Simply, the dispersion of the bands

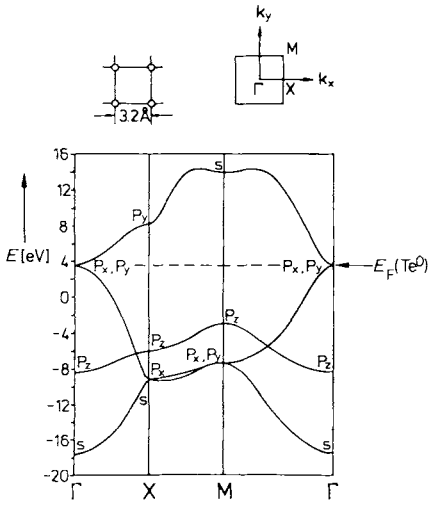

Fig. 8. Band structure for the two-dimensional 4^4 nets of the aluminum atoms in $BaAl_4$ (see [70-72]).

should increase due to the larger size of Te as compared to Al. For the tellurium net, the figure indicates the position of the Fermi level to be the energy of the $5p_x$ and $5p_y$ orbitals at Γ. An interesting consequence of this position of E_F for neutral Te is that an orthorhombic distortion of the square net will stabilize this structure. The band lying energetically higher than $E_F(Te^0)$ is Te-Te antibonding in nature. This agrees with the observation that by increasing the excess charge in the planar nets, the distances become larger (Table 3). In addition, one expects electrical conductivity for $(6+\delta)$ electrons ($\delta < 2$). Although comprehensive measurements are not known, the conductivity increases corresponding to the number of planar nets.[73]

Some further examples are known which suggest the occurrence of two-dimensional arrays of tellurium, if all Te-Te distances up to 3.3 Å are included (cf. $(Te_2)_2I_2$; Fig. 5).

The two tetratellurides $NbTe_4$ and $TaTe_4$ are examples whose structures are rather complicated in detail. The Peierl's distortion in the linear chains of d^1 M^{4+} transition metal cations is the most remarkable feature of the compounds, which leads to further distortions in the structure.[74-78] Theoretical predictions based upon band structure calculations are in agreement with experimental results.[79] Excluding all of the distortions, the structure is similar to that shown in Figure 9. The dimers of tellurium (Te-Te: 2.91 Å) are arranged in such a manner that infinite two-dimensional nets occur. The nets could be constructed from squares (Te-Te: 3.30 Å), which are stacked one on top of the other and twisted by 45° with respect to each other. The transition metals are found in the center of square antiprisms and form chains along [001]. The lower part of Figure 9 shows a 4^4 net from which every fifth atom is removed. It can be placed over the structure of MTe_4 (Fig. 9, top). Under constant unit cell dimensions, this 4^4 net fits best with the net of the tetratelluride structure if a distance of 2.91 Å is used. When the transition metal cations are inserted into the squares, the Te-Te distances increase to 3.30 Å. The Te-Te distances between the squares remain unchanged at 2.91 Å. The tetratellurides, MTe_4, are the first examples in which transition metal cations with incompletely filled d-shells occur. As a result, one may not neglect the cation-anion or the cation-cation interactions. The M^{4+} chains cause marked anisotropy in their electronic transport properties.[80]

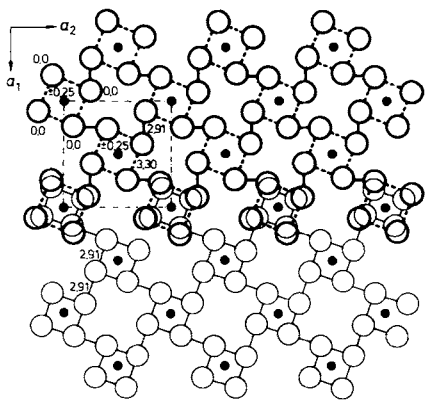

Fig. 9. Section from the structure of the tetratelluride, MTe_4 (M = Nb, Ta) from $z = -0.25$ to $z = 0.25$. In the lower part of the figure, the idealized hypothetical defect 4^4 net that underlies the structure is represented for comparison.

The two pentatellurides $ZrTe_5$ and $HfTe_5$[81] (Fig. 10) also belong to the class of compounds with low-dimensional transport properties. The pentatellurides, MTe_5, are expected to behave similarly to the trichalcogenides ($ZrSe_3$-type, $NbSe_3$-type, TaS_3-type[80]), whose structures are characterized by the description of stacked prisms, and which markedly show one-dimensional transport properties and anomalies. In the structure of the pentatellurides, the Te^{2-} ions (Te1) and the Te_2^{2-} dimers (Te2-Te2: 2.76 Å) assemble along [100] to form an infinite prismatic strand with common triangular faces that are centered by the metal cations (Fig. 10, bottom). The difference from the $ZrSe_3$ type (cf. Fig. 12) occurs only in the observation that the prisms along [001] do not lie directly next to each other, but are bonded to each other through inserted zig-zag chains $^1_\infty[Te_2^0]$: (Te3-Te3: 2.91 Å; Fig. 10). The tellurium atoms of the zig-zag chains (Te3) and the isolated Te1 atoms span a wavy, two-dimensional sheet, in which the average Te-Te distance is 3.17 Å (Fig. 10, top). One therefore expects two-dimensional rather than one-dimensional anisotropic properties. The marked cleavage parallel to the *ac*-plane as well as the missing anisotropy of the electrical resistivities in the *ac*-plane confirm this prediction.[81]

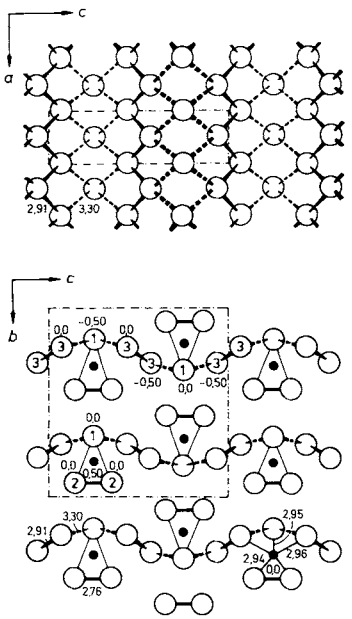

Fig. 10. Bottom: [100] projection of the structure of the pentatellurides MTe_5 (M = Zr, Hf). Top: Projection of the *ac*-plane of the puckered tellurium sheets made up of the Te1 and Te3 atoms.

Both pentatellurides are highly interesting because of the anomaly in their electrical resistivities, which show a maximum at 80 K ($HfTe_5$) and 140 K ($ZrTe_5$). According to the temperature dependence of the electrical resistivity both above and below the maximum, they behave as metals. In spite of many exact measurements, no clear evidence has been obtained for a phase transformation as an indication for the formation of spin or charge density waves.[83] The transport anomalies were also explained by a change in the charge carrier concentration and the fluctuation at the transition point. From the results of band structure calculations no charge density wave instability is expected.[84]

3.3. Infinite One-Dimensional Anionic Strings

The first examples to be considered are the structures of the alkali metal tritellurides, $LiTe_3$[18] and $NaTe_3$,[19] which are closely related to $AgTe_3$ (see Section 3.1). Through the tendency to localize the nonbonding electrons, the three-dimensional framework of the tellurium partial structure divides into one-dimensional strands that run along the [001] direction (Fig. 11, right). In the left part of Figure 11 the arrangement of atoms projected down the [001] direction is shown ($-0.13 < z < 0.13$). One can see the nearly undistorted cubes (shaded) which are in a densest packing arrangement. The corners of the cubes are occupied by six Te3 atoms (Te3-Te3: 3.16 Å) and two Na3 atoms (Na3-Te3: 3.19 Å). The strands along [001] are constructed using these cubes by connecting them via additional tellurium atoms (Te1, Te2). Together with the sodium atoms, Na1 and Na2, the Te1 and Te2 atoms also form cubes, albeit distorted (Te1-Te2: 2.77-3.59 Å; Na-Te: 3.07-3.31 Å). The mean value of the Te-Te distances in such a distorted cube always remains at 3.16 Å, as found in the undistorted ones. If all Te-Te distances are identical and only two different M-Te distances occur, Figure 11, in fact, shows the structure of $AgTe_3$. The resulting differences in the structures can be realized from a comparison of the lattice constants (Table 4). The increase (ca. 20%)[84] in the molar volumes of the tellurium partial structures has already been pointed out for the alkali metal tellurides in Section 3.1.

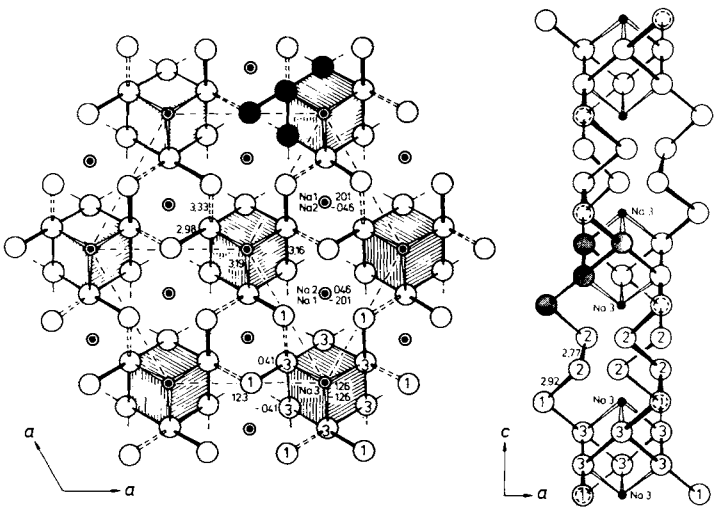

Fig. 11. Left: Section from the structure of the tritellurides MTe_3 (M = Li, Na) from $z = -0.13$ to $z = 0.13$. Right: Projection along [001] showing the tellurium strands.

a [Å]	8.465	8.714	9.032
c [Å]	5.272	21.35	21.93
V [cm^3 mol^{-1}]	66	70.5	78
V of the Te-anionic part [cm^3 mol^{-1}]	57	69	71

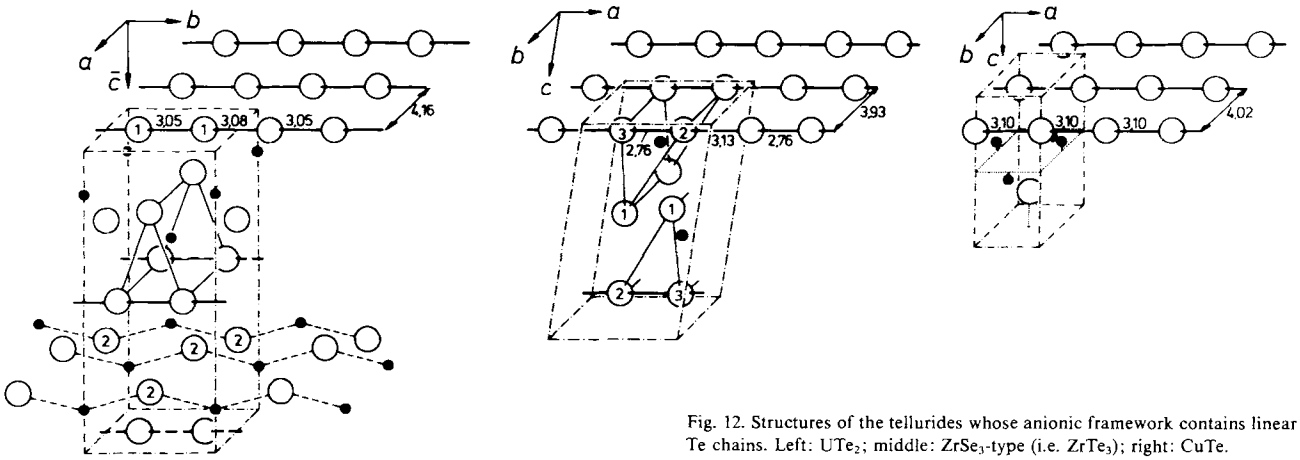

Fig. 12. Structures of the tellurides whose anionic framework contains linear Te chains. Left: UTe_2; middle: $ZrSe_3$-type (i.e. $ZrTe_3$); right: CuTe.

Three Te3 atoms and one Te1 atom form a T-shaped fragment (Fig. 11, shaded) and six of these fragments condense into the Te_{12} cluster ($Na_6^+Te_{12}^{6-}(Te_2^0)_3$). Therefore, the T-shaped fragment can be considered as isotypic to the BrF_3 type as in the case of $CsTe_4$. Furthermore, an additional contact exists (Te1···Te3: 3.33 Å) which produces a distorted square planar unit, $TeTe_4$, from the T-shaped fragment.

Infinite one-dimensional motifs determine the tellurium structural part in UTe_2,[85] in $ZrTe_3$, $HfTe_3$, and UTe_3,[86-88] which crystallize in the $ZrSe_3$-type, as well as in CuTe.[89] As shown in Figure 12, they contain linear tellurium chains with average Te–Te distances of 3.10 Å that are stacked directly above one another. The difference between the two intrachain Te–Te distances is largest for the trichalcogenides with the $ZrSe_3$ structure type (for example US_3 and USe_3). Perpendicular to these tellurium chains are characteristic stacks of trigonal prisms, which share common triangular faces and are centered by the metal cations. In UTe_2 these prismatic stacks actually consist of two metal-centered trigonal prisms which share a common rectangular face. Similarly, the difference in the distances between the directly stacked chalcogen atoms along [100] in the structures of US_3 and USe_3, for example, which crystallize in the $ZrSe_3$-type structure, become so large that they fall apart in a succession of X_2^{2-} dumbbells. Measurements of the magnetic susceptibilities of US_3, USe_3, UTe_3[87] revealed the difference between US_3 and USe_3 on the one hand and UTe_3 on the other.

The structures of both UTe_2 and UTe_3 certainly show a relationship to those of the lanthanoid di- and tritellurides. The linear chains lie approximately 4 Å away from one another and build sheets between which undulated U/Te layers are inserted. The ionic description in Table 5 uses tetravalent uranium (μ_B (spin only, U^{4+}) = 2.83; $\mu_{eff}(UTe_3) = 3.09$[87]). Comparison with the corresponding data for the lanthanoid tellurides in Table 3 suggests that the chains do not form genuine 4^4 nets, because too many excess electrons exist per net. This conclusion is supported by the fact that partial substitution of U^{4+} by Dy^{3+} can lead to the structure type containing 4^4 nets. The structural change only occurs when the excess charge becomes sufficiently reduced by the introduction of M^{3+} ions. Whereas $U_{0.5}Dy_{0.5}Te_2$ crystallizes in the UTe_2 type, $U_{0.5}Dy_{0.5}Te_3$ adopts the $NdTe_3$ type instead of $ZrSe_3$ (Table 5).

Table 5. Uranium tellurides UTe_n.

General formula	Structure type	Ionic description	Average distance in $^n_\infty[Te^{m-}]$	Ref.
UTe_2	UTe_2	$(M^{4+}/Te^{2-})\ ^1_\infty[Te^{2-}]$	3.06 Å	[85]
$U_{0.5}Dy_{0.5}Te_2$	UTe_2	$(M^{3.5+}/Te^{2-})\ ^1_\infty[Te^{1.5-}]$	3.05 Å	[90]
UTe_3	$ZrSe_3$	$(M^{4+}/Te^{2-})\ ^1_\infty[Te^{1-}]_2$	3.05 Å	[87, 88]
$U_{0.5}Dy_{0.5}Te_3$	$NdTe_3$	$(M^{3.5+}/Te^{2-})\ ^2_\infty[Te^{0.75-}_{2/4}]_2$	3.07 Å	[90]

Similar linear chains of two-bonded tellurium atoms are also found in the structure of TlTe[91] (Te3–Te3: 2.91 Å). Additionally, there are chains in the structure that contain two-bonded as well as four-bonded tellurium. These chains arise by crosswise stacking of linear triatomic moieties of tellurium and contain square planar Te_5 units (Te–Te: 3.04 Å and 3.09 Å, cf. Fig. 12).

Similar linear triatomic units as in TlTe are found in UTe_5 to create nonlinear chains[92] (Fig. 13; Te4–Te2: 3.14 Å). Beside the chains, it contains isolated Te_3^{2-} ions (Te3–Te1: 2.80 Å), which condense to form triangular faces (two Te1 and one Te2). As in the $ZrSe_3$ structure type, these triangles stack to produce a one-dimensional chain of face-sharing prisms centered by uranium atoms

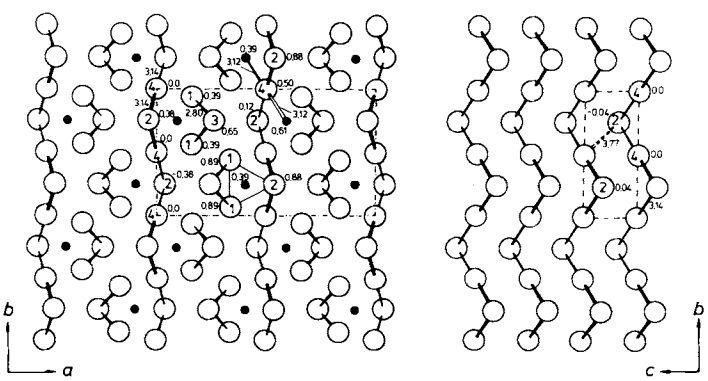

Fig. 13. Left: [001] projection of the structure of UTe_5. Right: The layered units in the *bc*-plane form from the bent chains of Te2 and Te4 atoms.

(Fig. 13 left). The chains are arranged such that a puckered sheet of tellurium atoms occurs (Fig. 13 right).

Finally, Rb_2Te_5 and Cs_2Te_5 belong to the group of infinite one-dimensional tellurium polyanions.[20,21] The partial anionic structure of Cs_2Te_5 arises from a systematic removal of every sixth tellurium atom from the hypothetical infinite two-dimensional double sheets with five-coordinate tellurium atoms. Analogously, another conceivable two-dimensional structural variant with five-coordinate Te is the basis for Rb_2Te_5. Both of the one-dimensional anionic structural motifs in Cs_2Te_5 and Rb_2Te_5 are related to each other just like the nets of black phosphorus and gray arsenic (Fig. 14; cf. also Fig. 1f and 1e).

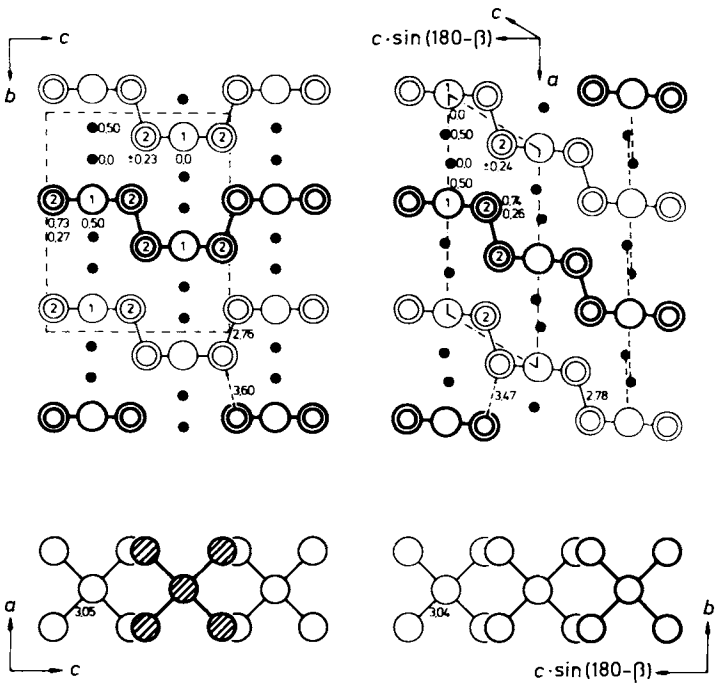

Fig. 14. Top: Projection of the structures of Cs_2Te_5 (left, along [100]) and Rb_2Te_5 (right, along [010]). The different heights of the $^1_\infty[Te_5^{2-}]$ strands above the projection plane are specified by differing line strength. The individual tellurium strands are shown in the lower part.

The quasi-molecular structural building block, $TeTe_4^{2-}$ (32e descendent of the 36e-XeF_4, see Fig. 14, shaded fragment), is fundamental to the structures of the pentatellurides of both Rb and Cs. The bonding distances from the central Te1 atom to the terminal Te2 atom of the fragment are 3.05 Å (Cs_2Te_5) and 3.04 Å (Rb_2Te_5). On account of the relative electron deficiency, the 32e-XeF analogues are connected to neighboring fragments via every terminal Te2 atom to form the infinite one-dimensional strands (Te2–Te2: 2.76 Å in Cs_2Te_5; Te2–Te2: 2.78 Å in Rb_2Te_5, Fig. 14). This corresponds exactly to the effect that has led to the structure of the infinite two-dimensional sheets in $CsTe_4$ from the 25e-$TeTe_3^-$ fragment. The shortest Te···Te contact between the two sheets in $CsTe_4$ (3.51 Å) also corresponds to the shortest Te···Te contact between the strands in Cs_2Te_5 (3.60 Å) and Rb_2Te_5 (3.47 Å).

The question still remains why Cs_2Te_5 and Rb_2Te_5 are not isotypic. When one deducts the volume occupied by the tellurium atoms from the total volume of the elementary cell, a much larger space remains for the cesium atoms in Cs_2Te_5 than for the rubidium atoms in Rb_2Te_5, as required by the larger space requirements of Cs. This occurs solely by the different folding of the strands—all distances and angles in both structures are nearly identical:

Volume	Cs_2Te_5 ($Z=4$)	Rb_2Te_5 ($Z=2$)
Elementary cell [$cm^3\ mol^{-1}$]	703	328
Volume increment of Te_5^{2-} [$cm^3\ mol^{-1}$]	4×120	2×120
Excess volume per M^+ [$cm^3\ mol^{-1}$]	28	22

The molar volume of the Te_5^{2-} ion has been calculated from the increments for four Te^0 atoms and one Te^{2-} ion as described by *Biltz*.[84] In spite of this crude assumption, values for the remaining excess volumes per cation are in good agreement with the values that are known from numerous structures: 26 $cm^3\ mol^{-1}$ and 20 $cm^3\ mol^{-1}$ for Cs^+ and Rb^+, respectively.

The topological similarity between the square planar $TeTe_4^{2-}$ fragments and molecules like XeF_4 is obvious. The same holds for the similarities between T-shaped fragments $TeTe_3$ of $CsTe_4$ and $NaTe_3$ (Section 3.2) with molecules like BrF_3 as well as between the linear fragments $TeTe_2$ of TlTe and UTe_5 with molecules like XeF_2. Only in the most simple cases can one assign an excess negative charge to the fragments, e.g. $TeTe_3^-$ in $CsTe_4$, $TeTe_4^{2-}$ in Rb_2Te_5 and Cs_2Te_5. Then, the deficit of valence electrons of these fragments with respect to the reference molecules (28e-BrF_3/25e-$TeTe_3^-$; 36e-XeF_4/32e-$TeTe_4^{2-}$) may be considered to be responsible for the infinite polyanions. The fragments make as many tellurium bridges to other fragments as the number of valence electrons lost.

It should also be mentioned that planar zig-zag chains with two-coordinate tellurium occur in the monoclinic modification of $AuTe_2$[93] (cf. Fig. 1d; Te–Te: 3.18 Å) and helical zig-zag chains with four- and two-coordinated tellurium in Te_3Cl_2 with partly very short Te–Te distances (2.67 Å).[94]

3.4. Isolated Anions

The previous discussion argues that one can always expect to find isolated, quasi-molecular structural motifs in tellurium-rich tellurides, if these fragments become isoelectronic to familiar reference molecules. This requires that the ionic situation in the sense of Zintl and Klemm holds true and that all other interactions can, in the first instance, be ignored.

3.4.1. XeF_4-Type Square Planar Fragments

The structure of Ga_2Te_5[95] represents an example in which one has the 36 electron $TeTe_4^{6-}$ anionic building block: $(Ga^{3+})_2Te_5^{6-}$ (Fig. 15). The bond distance is 3.03 Å (Te1–Te2) with the anions arranged so that each gallium atom becomes tetrahedrally coordinated. Cations and anions together form a three-dimensional network. The structures of both ternary tellurides, M_2SnTe_5 (M = K, Rb) are characterized by nearly identical 36e-$TeTe_4^{6-}$ ions:[96,97]

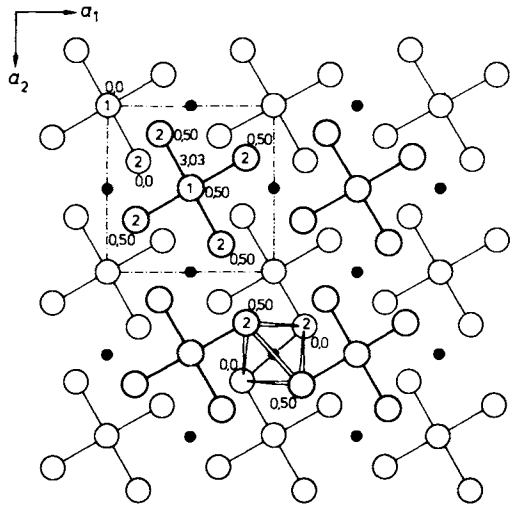

Fig. 15. Section from the structure of Ga_2Te_5. The tetrahedral coordination of the cation is shown.

$(M^+)_2Sn^{4+}Te_5^{6-}$ (Fig. 16). The tin atoms are tetrahedrally coordinated in a similar manner as the gallium atoms in Ga_2Te_5. In this case only infinite one-dimensional $^1_\infty[SnTe_5^{2-}]$ strings parallel to [001] are formed since the additional alkali metal cations must be accomodated. The Te–Te distances of 3.02 Å (Te1–Te3) and 3.05 Å (Te3–Te2)[96] are in good agreement with the analogous distances in Ga_2Te_5.

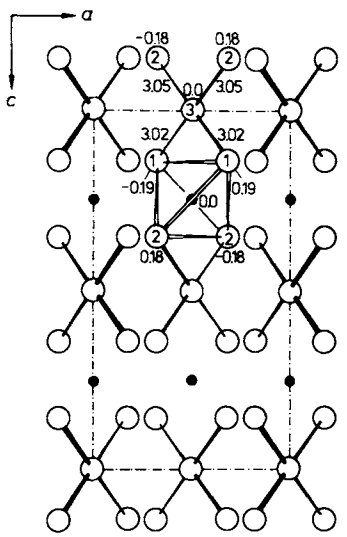

Fig. 16. Section from the structure of the ternary tellurides M_2SnTe_5 (M = K, Rb). The tetrahedral coordination of the tin atom is specified. The alkali metal atoms are not shown.

The third example containing the square planar $TeTe_4$ structural motif is Re_2Te_5.[98] The structure contains Re_6 octahedra whose first coordination sphere has eight tellurium atoms in a cubic arrangement so as to give a Re_6Te_8 cluster. Of the 42 electrons contributed by the six Re atoms, 24 are used to form twelve Re–Re bonds and another 16 are used for Te–Te bonding. The two remaining electrons are donated to the anionic fragment to give the formal structural composition as $Re_6Te_8^{2+}Te_7^{2-}$ ($\cong Re_2Te_5$). The $TeTe_4$ structural motif is the characteristic part of the anion, Te_7^{2-}, with Te–Te distances of 2.98 Å (Te1–Te8) and 3.02 Å (Te3–Te8). Two-coordinate Te2 atoms bridge two opposite pairs of terminal atoms in the $TeTe_4$ fragment to form the butterfly-like Te_7^{2-} ions (Fig. 17).

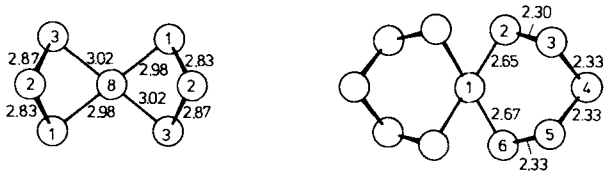

Fig. 17. The Te_7^{2-} anion in Re_2Te_5 (left) and the Se_{11}^{2-} anion in $(PPh_4)_2Se_{11}$ (right).

For comparison, the noteworthy Se_{11}^{2-} anion[99] is shown in Figure 17. It is an exceptional example, which, otherwise, only characterizes the structural chemistry of tellurium-rich tellurides. This anion also contains a central square planar 32e-$SeSe_4$ fragment with expanded distances of 2.65 Å and 2.67 Å. The two-coordinate bridging atoms have distances in the range appropriate for Se–Se covalent single bonds.

Two different structures have been proposed for Tl_5Te_3.[100,101] Assuming the structure proposed by *Man, Imamow* and *Pinsker*[100] to be correct, Tl_5Te_3 contains square planar $TeTe_4$ groups (Fig. 18). There are many more electrons available than required by the 36e-$TeTe_4^{6-}$ ions as well as the additional Te^{2-} ions (Te2). $Tl_{10}Te_6$ may be formally considered as $10\,Tl^+ + Te_5^{6-} + Te^{2-} + 2e$. The Te–Te distances within the $TeTe_4$ groups, which are usually around 3.1 Å, are expanded to a value of approximately 3.3 Å. Additional relatively short contacts form the tellurium sheets (Te1 $\cdots$ Te2 = 3.5 Å).

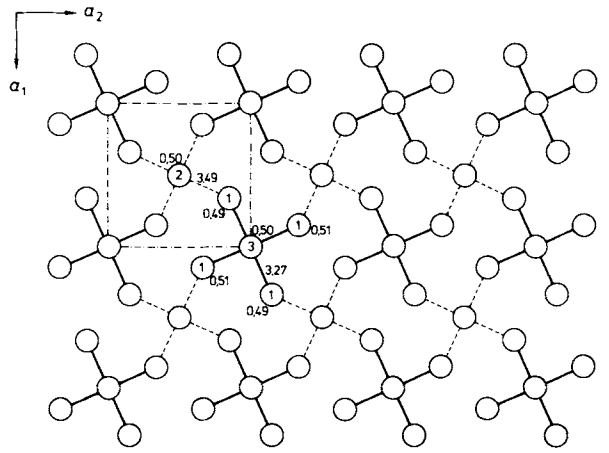

Fig. 18. Section of the structure of Tl_5Te_3 ($0.48 < z < 0.52$; Tl not shown) [100].

3.4.2. *BrF_3-Type T-Shaped Fragments*

Although T-shaped fragments have appeared in some of the previously illustrated structures (25e-$TeTe_3^-$ in $CsTe_4$, 78e-Te_{12}^{6-} fragment in $NaTe_3$), there is no example for the 28e-$TeTe_3^{4-}$ ion (isotypic to BrF_3). Suitable alkali metal tellurides must have a 1:1 composition (M_4Te_4). Since the

structures of NaTe (Section 3.4.3) and K_2Te_2 (Section 2.4.4) are constructed using different structural principles, the question regarding the preparation of simple substances like Rb_2Te_2, Cs_2Te_2, $CaTe_2$, $SrTe_2$, and $BaTe_2$ becomes interesting again.

3.4.3. Linear XeF_2-Type Fragments

There are no known examples in this group of compounds containing the 22e-$TeTe_2^{4-}$ ion isosteric with XeF_2. One expects such species to be preferred in the alkali metal-rich region. In the cesium/tellurium system there is an indication of the compounds, Cs_mTe_n $(m>n)$,[102] whose complete structure in the crystalline form is presently being studied.

NaTe contains isolated Te_5^{4-} ions.[24] A central linear triatomic unit and two additional singly bonded Te^- ions form the Z-shaped anion Te_5^{4-} (Fig. 19). The Te-Te distances behave as expected with distances in the linear part having a value of 3.08 Å, while the distances to each terminal atom are only 2.82 Å. The additional Te4 atoms are assigned as Te^{2-} ions to give the ionic formula, $(Na^+)_6Te_5^{4-}Te^{2-}$ ($\cong$ NaTe). Similar Te_5^{4-} polyanions are also found in Ba_2SnTe_5 $[(Ba^{2+})_6Te_5^{4-}(Sn_3Te_{10})^{8-}]$.[103] They are isoelectronic with the Z-shaped interhalogen cations, $I_3Cl_2^+$[104] and I_5^+.[105]

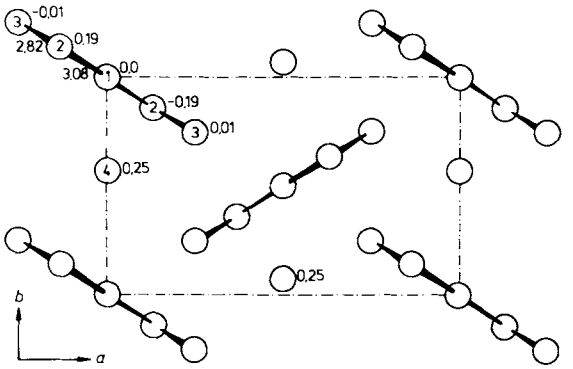

Fig. 19. Section of the structure of NaTe. The Te_5^{4-} ions are packed analogously as the I_2 dimers in elemental iodine.

3.4.4. Pseudotetrahedral Fragments in Te_n^{2-} Ion Chains

The anions of the polytellurides are derived from the infinite chain of the thermodynamically stable modification of the element. Their structural characteristics are analogous to the corresponding selenides and sulfides. Just as in the structures of the elements, the difference between the inter- and intra-chain distances are smaller in the tellurides than in the sulfides or selenides.

There are many known examples containing the dimers, Te_2^{2-}, which include the main group metal tellurides α- and β-K_2Te_2 (Na_2O_2 and Li_2O_2 type[25]), $MgTe_2$ (pyrite type[106]), and the transition metal tellurides $CoTe_2$ and $FeTe_2$ (marcasite type[107]). The Te-Te distances cover a relatively wide range of values (α-K_2Te_2: 2.86 Å; β-K_2Te_2: 2.79 Å; $MgTe_2$: 2.70 Å; $CoTe_2$: 2.91 Å; FeTe-2: 2.93 Å). The number of examples with longer Te_n^{2-} chains ($n=3$, 4, ...) is very small (Table 6). The Te-Te distances correspond exactly to the sum of the covalent radii only when the anions are completely separated by large cations.

Table 6. Zig-Zag chains Te_n^{2-} $(n>2)$.

	Te-Te distances [Å] within the chains	between the chains	Bond angles [°]	Ref.

4. Remarks about the Binding Situation in Some Alkali Metal Tellurides

Figure 20 illustrates once again that the square planar $TeTe_4$ moiety represents a prevalent fragment in tellurium-rich tellurides. The chemical bonding in substances with such AB_4 systems has been examined recently.[116, 118]

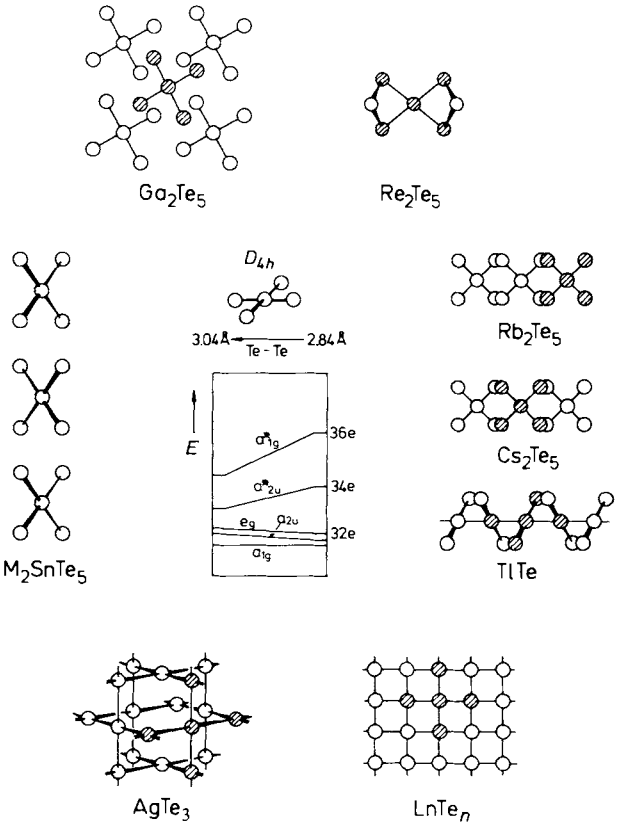

Fig. 20. Schematic trend of the highest occupied states in the $TeTe_4^{n-}$ fragment with D_{4h} symmetry for Te-Te distances ranging from 2.84 Å to 3.05 Å [116].

It is already known that an AB_4 system can possess D_{4h}, C_{4v}, C_{2v}, and T_d symmetry. To a first approximation, the actual observed structure depends upon the number of valence electrons.[117] The 36-electron AB_4 species prefers D_{4h} symmetry. A lengthening of the A–B distances generally leads to a stabilization because both of the highest occupied levels have A–B antibonding character. In cases for which the 36e-$TeTe_4^{6-}$ groups are formally possible (Ga_2Te_5, K_2SnTe_5, and Rb_2SnTe_5), $Te_{central}$–Te_{apical} distances of 3.05 Å ± 0.05 Å are found (the covalent radius of Te is 1.37 Å). For the experimental mean value of the $Te_{central}$–$Te_{terminal}$ distance, 3.04 Å, the a_{1g} and a_{2u} levels become lowered by about 3 eV and 0.5 eV, respectively, relative to the geometry using the distance in elemental tellurium, 2.84 Å. In contrast to ICl_4^- or XeF_4, there is high electron density on the terminal atoms for these two highest occupied antibonding levels due to no electronegativity difference between $Te_{central}$–$Te_{terminal}$. Therefore, in order to attain stability, the 36e-$TeTe_4^{6-}$ fragment will form covalent bonds to strongly electrophilic atoms via their terminal atoms, in order to reduce the electronic charge density at these sites. Such interactions are observed in the structures of Ga_2Te_5 and M_2SnTe_5 (M = K, Rb).

The most important question still remains: why do the 32e-$TeTe_4^{2-}$ species found in both Rb_2Te_5 and Cs_2Te_5 not exist as isolated tetrahedral tetratellurotellurate(VI) anions with T_d symmetry, but instead consist of $^1_\infty[TeTe_4^{2-}]$ fragments with local D_{4h} symmetry connected into chains? Numerous examples including the 32e-AB_4 system have, in particular, T_d symmetry as shown in Table 7. It is plausible that for the special case of the $TeTe_4^{2-}$ species, D_{4h} symmetry is favored for steric and not electronic reasons (the radius ratio r_A/r_B is 1.0). An analogous argument suggests steric in addition to electronic preferences to explain why C_{2v} symmetry is favored over C_{4v} symmetry for the 34e-AB_4 system, e.g., SF_4.[117]

Table 7. Selected examples of tetrahedrally coordinated 32e-AB_4 molecule anions.

[a] Electronegativity difference according to *Allred* and *Rochow* [120] and *Block* and *Schatteman* [121] (in brackets).

The band structures of Rb_2Te_5 and Cs_2Te_5 are very similar to each another until the Cs_2Te_5 bands are folded back as required on symmetry grounds. Both substances are predicted to be semiconductors with band gaps of the order of 1 eV.[116] The value agrees qualitatively with the results of the photoelectron spectrum of Rb_2Te_5, from which a distance of about 1 eV was found between the highest occupied level to the Fermi edge of the spectrometer.[134] This value is greater than the band gap for elemental tellurium (0.35 eV[135]) and indicates that the emphasis on the quasi-molecular nature of this fundamental structural fragment with nonbonding electrons in localized pairs is not unfounded.

The density of states distribution for K_2SnTe_5 shows the small contribution of the tin orbitals in the neighborhood of the Fermi edge and throughout all occupied bands. This results in the large positive charge calculated for tin,[116] and, therefore, supports the formulation of the tin atoms as Sn^{4+} in the ionic description.

Also, the photoelectron spectra for $NaTe_3$ and NaTe have revealed $NaTe_3$ as metallic (or as a semiconductor with very small band gap) and NaTe as semiconducting.[134] This result reflects the degree of connectivity in the partial anionic structure. It is further supported by observations that the solidified melt of $NaTe_3$ is silvery (the melt: gold color), while the crystals of Rb_2Te_5 and NaTe have dull black surfaces. It confirms again the close structural and electronic relationship of $NaTe_3$ to the metallic $AgTe_3$. The bonding energies of the core electrons have also been measured (Table 8). Succession to further different bonding situations of tellurium atoms (pseudo-noble gases, pseudo-halogens) in the fragments cannot be resolved via chemical shifts.

Table 8. Bond energies [eV] of some alkali metal tellurides.

The local symmetry of AB_3 systems depends on the number of valence electrons in a manner analogous to AB_4 systems. In general, 24e-species with D_{3h} symmetry (BX_3; X = halogen), 26e-species with C_{3v} symmetry (PCl_3), and 28e-species with C_{2v} symmetry (T-shaped, BrF_3) are stable. However, there exists a number of exceptions for the AB_3 system with structures that are not predicted by VSEPR theory (26e-NCl_3, pyramidal; 26e-$N(SiH_3)_3$, planar). For the explanation of this problem there must again be both electronic as well as steric arguments.[117] Also noteworthy is the D_{3h} symmetry of the 28e-$SiSi_3^{12-}$ fragments that are found in the solid state structure of $Li_{12}Si_7$.[136–138] In analogy to the electron-rich species containing the $TeTe_4^{m-}$ fragment (Ga_2Te_5, M_2SnTe_5) the destabilization of the highest occupied antibonding state of the $SiSi_3^{12-}$ fragment becomes neutralized through the Li–Si interactions. In this sense, the $^1_\infty[SnTe_5^{2-}]$ strands correspond to the polymeric $Li_{12}Si_4^0$ unit of $Li_{12}Si_7$.

The $TeTe_3^-$ fragments of the infinite two-dimensional sheets of $CsTe_4$ are 25e-AB_3 systems. They are isoelec-

tronic with CX_3^- radicals (X = H, Halogen) and BrO_3. Such species show either D_{3h} symmetry (CH_3) or C_{3v} symmetry (BrO_3). In comparison, the T-shaped geometry of the $TeTe_3^-$ fragments possesses nearly C_{2v} symmetry. Speculations are useless for these fragments, just as they are for the D_{4h}/C_{2v} alternatives for the AB_4 species, $TeTe_4^{m-}$. Again, a delicate balance exists between the obviously frequently occurring and energetically stable C_{3v} structure and the T-shaped structure, which is only observed in this case. The preference of the C_{2v} structure over the C_{3v} structure can be established by the radius ratio of 1.0 and no electronegativity difference between $Te_{central}$ and $Te_{terminal}$.

5. Closing Remarks

In the preceding sections the tellurium-rich tellurides have been discussed with special emphasis on the structural relationships between their tellurium structural components. Details concerning their physical properties have received far less discussion. Also little attention has been paid to factors characterizing structures in individual circumstances, like some cation-anion interactions, packing effects, and similar details. One must always realize, therefore, that with these considerations plus equally powerful generalized arguments (the Zintl-Klemm concept), only a partial understanding of the structural chemical relationships can be accomplished. These arguments cannot express the electronic situation of a compound, because only the number and not the state of the electrons transferred to the anionic part of the structure are considered. Moreover, structural chemical predictability warns against careless application. Substitution of electron donors with one another can lead to a variation in the anionic framework, as illustrated in the structural pairs $NaSbF_4/KSbF_4$[140] and M_4TeO_5 (M = Li, Na)/M'_4TeO_5 (M' = Li).[141,142]

It has been shown that the tellurium-rich tellurides can frequently be treated as a single group of compounds. They also illustrate a smooth transition between the Zintl phases and the molecular compounds of the nonmetals in their structural chemistry and in their physical properties. They are not only of theoretical interest. The transition metal compounds, MTe_4 (M = Nb, Ta), and MTe_5 (M = Zr, Hf), whose low dimensional transport properties have been described, as well as the compounds MTe (M = Pb, Cd, Hg ...) of the group II-VI semiconductors are important structural types. Ternary tellurides of the type M_2SnTe_4 (M = Cr, Mn, Fe, Co), whose representation has proceeded from main group metal tellurides like K_4SnTe_4, show spin-glass properties in amorphous form.[143-146] An extensive understanding of the structures of the tellurides, which can be of great help in the planned synthesis of new compounds, is therefore of importance.

My colleagues U. Kretschmann and R. Keller are gratefully thanked. Support by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft has been instrumental to the success of this work and is gratefully acknowledged. Lastly, my thanks go to Herrn K. Kruse for the preparation of the drawings, and also to Dr. G. Miller and Dr. D. Nagaki for their excellent translation of the article. I am also indebted to Dr. G. Miller for many helpful discussions.

Isoleucyl-tRNA Synthetase: An Enzyme with Several Catalytic Cycles Displaying Variation in Specificity and Energy Consumption

By Wolfgang Freist*

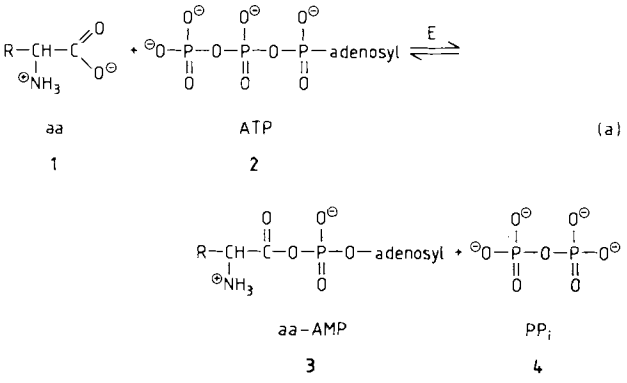
The translation of DNA via the genetic code into protein is a fundamental process carried out by all living systems. The extreme accuracy with which it is performed requires that the enzymes involved operate with extremely high specificity. It is for this reason that the structure and function of these proteins have been of special interest to molecular biologists and biochemists for the last twenty years. The discrimination between the different amino acids present in the cytosol and their esterification with the correct tRNA is the special task of the aminoacyl-tRNA synthetases. One of the most difficult discriminations that has to be performed is the specificity for isoleucine. There are many amino acids in the cell that have a structure similar to isoleucine, in particular valine. To solve this problem, the aminoacyl-tRNA synthetases have evolved unique proofreading mechanisms. The most detailed investigations of these mechanisms have been on the isoleucyl-tRNA synthetases from yeast and from *Escherichia coli*. Both enzymes are single-chain polypeptides with molecular weights of about 110000. Sequence homologies with other aminoacyl-tRNA synthetases seem to occur only within narrow regions, for example in the ATP binding site. The identification of the correct amino acid is achieved in a four-step process. In the first two steps the hydrophobic interaction of the amino acid side chain with the enzyme is utilized for discrimination. The two hydrolytic proofreading steps that follow make use of the steric hindrance associated with the amino acid side chain. The enzymes are characterized by the special property that slight variations in the reaction conditions cause conformational changes that affect the catalytic cycle. In this way the observed specificity of the enzymes can be changed to almost any value. In general, high specificity is associated with high energy cost, which is reflected in high ATP consumption. Under physiological conditions a medium level of specificity and energy consumption seems to be preferred.

1. Introduction

Since the mid-1950s, when the first aminoacyl-tRNA synthetases were discovered and found to be important enzymes of protein biosynthesis,[1-7] more than a hundred of these proteins have been isolated and characterized.[8-12] The quaternary structures and molecular weights of the various purified enzymes are very different. Most consist of a single polypeptide chain (α) or are dimers of two identical subunits (α_2). The molecular weights of the monomeric species range from 40000 to 140000, while the dimers are within the range of 65000 to 240000. A few enzymes have quaternary structures of the type $\alpha_2\beta_2$ ($M_r = 85000$–287000), $\alpha\beta$ ($M_r = 102000$–130000), or α_4 ($M_r = 116000$–380000).[8-12] Generally, these enzymes have one active site per subunit or, in the case of the $\alpha_2\beta_2$ types, one active site per $\alpha\beta$ pair.[9-11,13-21]

The reaction catalyzed by the aminoacyl-tRNA synthetases (E) involves a two-step process, where the amino acid is first activated, then transferred to the tRNA.[9,10] In the *activation step* (a) an aminoacyl adenylate **3** (and pyrophosphate **4**) is formed from the amino acid **1** and adenosine triphosphate (ATP) **2**. This intermediate remains bound to the enzyme and is protected from hydrolysis.

In the *transfer step* (b) the activated amino acid **3** is transferred to a hydroxyl group of the 3′ terminal ribose of the tRNA **5**, resulting in the formation of aminoacyl-tRNA **6** and adenosine monophosphate **7**.



For some synthetases it has been postulated by several workers that perhaps only a one-step mechanism is operating. In these cases a discrete aminoacyl-adenylate intermediate is presumably not formed.[8,22-25]

2. Structure and Reaction Mechanism

The isoleucyl-tRNA synthetases from yeast and *E. coli* are single polypeptide chains of type α. The molecular weight of the synthetase from *E. coli* B is 112000,[26] and

aa-AMP 3 tRNA 5 (b)

aa-tRNA 6 AMP 7

that of the enzyme from *E. coli* MRE600 is 102000.[27] For the synthetase from yeast, $M_r = 115000$.[28,29]

At present, the primary structure of only one isoleucyl-tRNA synthetase has been reported.[30] It was determined from the DNA sequence of the gene isolated from *E. coli* K12 and partly from peptide sequencing of the enzyme from *E. coli* MRE600. The enzyme consists of 939 amino acids and has a molecular weight of 105087. A small region of the sequence, corresponding to eleven amino acids, is homologous with three[31-33] of the seven[31-37] aminoacyl-tRNA sequences that have been determined.[*]

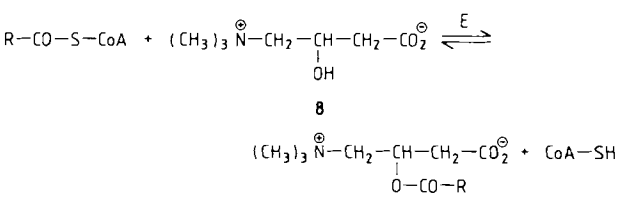
The stoichiometry of adenylate formation shows that isoleucyl-tRNA synthetase forms a 1:1 complex with isoleucyl adenylate **3**, R = *sec*-butyl.[14] This indicates that there is only one active center per peptide chain. The turnover number for aminoacylation of $tRNA^{Ile}$, under optimal reaction conditions, is $k_{cat} \approx 1\ s^{-1}$ for both the *E. coli* and yeast enzymes.[14,38] Compared with other aminoacyl-tRNA synthetases, which have k_{cat} values between 1 and $25\ s^{-1}$,[8,39-42] as well as with other important enzymes of metabolism (cf. Refs. [43-46]), the isoleucyl-tRNA synthetases are "slow" enzymes.

A formal analogy to aminoacylation of tRNA can be found in the activation of fatty acids for β oxidation. The acyl-CoA synthetases catalyze the formation of an enzyme-bound acyl-adenylate intermediate from which the acyl residue is transferred to the thiol group of coenzyme A.

$$R{-}CO_2^{\ominus} + ATP \xrightarrow{E} R{-}CO{-}AMP + PP_i$$

$$R{-}CO{-}AMP + CoA{-}SH \xrightarrow{E} R{-}CO{-}S{-}CoA + AMP$$

The acyl residue can then be easily transferred from the thiol group of CoA to an alcohol; for example, the enzyme carnitine acyltransferase catalyzes the transfer of the acyl group to carnitine **8**.[47,48]



8

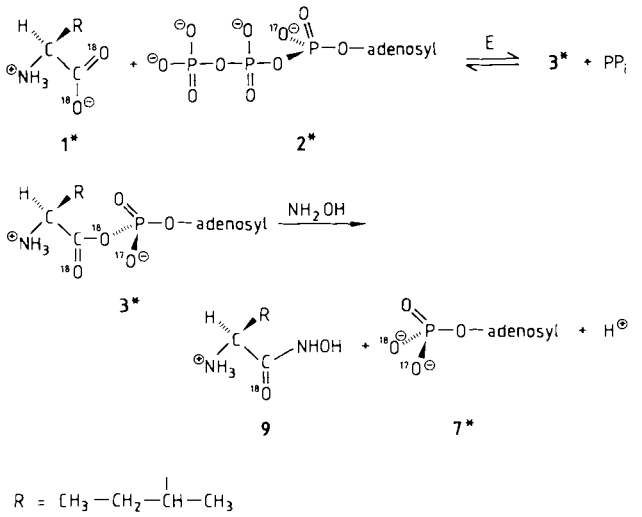
The gramicidin S-synthetases and related enzymes that are involved in the biosynthesis of peptide antibiotics also form an aminoacyl adenylate of type **3** from which the amino acid is transferred to a thiol group. The peptide bond is formed by reaction of the thioester.[49-51] It was reasonable to suspect that aminoacyl-tRNA synthetases might also synthesize thioesters of amino acids as intermediates; however, this has still not been unambiguously shown. Of the sixteen cysteine residues of *E. coli* isoleucyl-tRNA synthetase, eleven react with thio-labeling reagents[52] and one reacts very quickly.[52-54] Specific blocking of only this fast-reacting cysteine does not interfere with the activation reaction (a) but completely blocks the aminoacylation of tRNA.[52,54] This observation suggests that the amino acid is indeed transferred from the aminoacyl adenylate **3** to the tRNA via a thioester. However, other authors have found that even with one thiol group blocked there is still a low level of aminoacylation and have concluded that the fast-reacting cysteine may not be essential for catalysis.[55] When the primary structure was elucidated, the fast-reacting cysteine was assigned to position 431 of the peptide chain.[30] This position is 364 amino acid residues away from a group of 11 amino acids believed to make up the ATP binding site.[30] These 11 amino acids (positions 57-67) have direct sequence homology with other aminoacyl-tRNA synthetases. The location of these residues suggests that the active site is located in the *N*-terminal part of the enzyme.[30]

Whereas in the transfer step (b) the existence of a thioester intermediate is not quite clear, stereochemical investigations have shown that the presence of an intermediate in the activation step (a) is unlikely.[56] By using [$^{18}O_2$]isoleucine **1*** and adenosine 5′-[(*R*)-α-^{17}O]triphosphate **2*** as substrates and trapping the isoleucyl adenylate **3*** with hydroxylamine it was established that the reaction proceeds with inversion of configuration at the α-phosphorus atom of ATP, giving ^{17}O-labeled AMP **7***.

This indicates that a direct displacement of the pyrophosphate has occurred and excludes a reaction pathway with *one* intermediate, e.g., an adenylyl enzyme. However, the evidence does not exclude the rather unlikely possibility of *two* intermediates.

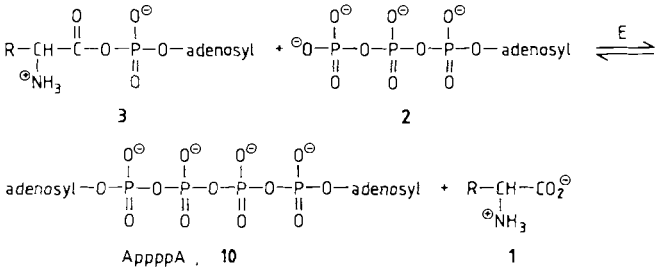
Aminoacyl adenylates (**3**) are mixed acid anhydrides and therefore contain both activated aminoacyl and adenylyl moieties. Thus, the aminoacyl-tRNA synthetases can also catalyze reactions in which the AMP residue is transferred to a phosphate moiety.[57-65] The simplest example is the reverse reaction of adenylate formation [reaction (a)]. This is easily followed by monitoring the incorporation of ^{32}P-labeled pyrophosphate into ATP. In another important reaction, the aminoacyl adenylate **3** formed by some aminoacyl-tRNA synthetases can react with ATP to form

[*] After completion of this article, some more primary structures of aminoacyl-tRNA synthetases were elucidated, among which is the amino acid sequence of isoleucyl-tRNA synthetase from yeast. This enzyme consists of 1073 amino acids ($M_r = 123040$) and shows 27% sequence homology with the enzyme from *E. coli*, especially in the supposed regions of the ATP and tRNA binding sites (U. Englisch, S. Englisch, P. Markmeyer, J. Schischkoff, H. Sternbach, H. Kratzin, F. Cramer, *Biol. Chem. Hoppe Seyler 368* (1987) 971).



R = $CH_3-CH_2-\underset{|}{CH}-CH_3$

diadenosine-5′,5‴-P^1,P^4-tetraphosphate (AppppA) **10**.[57,58,60–65] AppppA may have important functions in regulation of initiation of DNA replication, cell proliferation, and tRNA synthesis.[66–68] Whereas isoleucyl-tRNA synthetase from *E. coli* catalyzes the formation of AppppA, the enzyme from yeast does not. However, the yeast enzyme does form adenosine 5′-diphosphate (ppA) as a side product.[69] It is possible that this side product is produced by the splitting of AppppA formed in a preceding reaction step.[69]



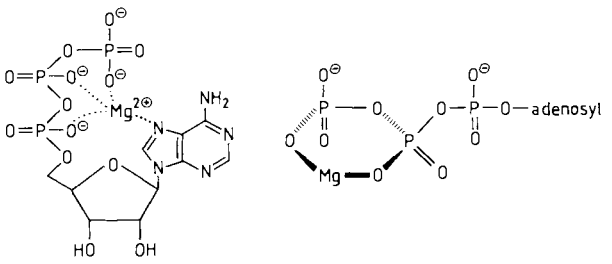
An open question for both enzymes is the possibility that the activity is regulated through phosphorylation by a kinase. Till now such a kinase has only been demonstrated for an isoleucyl-tRNA synthetase from rabbit reticulocytes.[70]

3. Substrate Specificity

3.1. ATP Analogues

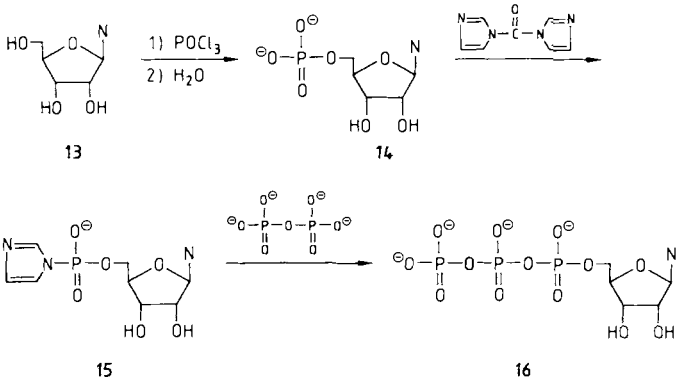
Since all aminoacyl-tRNA synthetases have ATP as a substrate, analogues of ATP can be used to investigate the differences in specificity between enzymes. By systematically testing various modified ATP molecules, the topology of the ATP binding site can be determined and the different enzymes arranged in groups showing similar specificities. For the isoleucyl-tRNA synthetases it was possible to elucidate tentative phylogenetic relationships with other aminoacyl-tRNA synthetases.

Difficulties in interpreting the results of these ATP-analogue studies arose from the fact that the real substrate for the synthetases is the ATP·$Mg^{2\oplus}$ complex and not free ATP.[8–11] The exact structure of this complex is still undetermined. Based on studies of the sodium salt of ATP[71] and NMR spectroscopic data,[72–74] a model for the ATP·$Mg^{2\oplus}$ complex, **11**, has been postulated in which the metal ion is coordinated with N-7 of the purine and one oxygen of the β, γ, and possibly also the α phosphate of the triphosphate moiety.[75] In another model, which is based on the affinity of hexokinase for the tetraamminecobalt(III)-ATP complex, the complex is formulated as a bidentate β,γ-complex **12**.[76] The possibility of coordination with the purine N-7 is not discussed in this model.[76]



The results obtained using ATP analogues indicate that the aminoacyl-tRNA synthetases use ATP·$Mg^{2\oplus}$ complexes of different structure. The data are consistent with both structural models cited above.

The ATP analogues employed were prepared starting from nucleoside derivatives for which syntheses have been described during the past thirty years[77,78] or from nucleoside antibiotics isolated from microorganisms.[79] In most cases the phosphorylation of the nucleosides **13** was carried out by simple methods such as reaction with $POCl_3$ to form the monophosphate **14** followed by conversion to the phosphate imidazolide **15** and finally reaction with pyrophosphate to give the triphosphate **16**.[80–83]



Of the 35 ATP analogues prepared a characteristic set of eight (**17a–h**) were tested as substrates or inhibitors of the aminoacylation reaction.[84–87] These compounds were used to determine the differences between the yeast and *E. coli* aminoacyl-tRNA synthetases.[88] Four of the analogues tested were modified at positions 2, 6, 7, and 8 of the purine ring. The other four were modified at the 2′ and 3′ positions of the ribose.

[a] In position 7, =N– is replaced by =CH–.

The results listed in Table 1 allow the aminoacyl-tRNA synthetases to be arranged in groups. Clearly, two main types of synthetases (I, II) are present in *E. coli* and yeast. However, minor types can also be distinguished. In *E. coli* there are three different groups which are represented by two enzymes each (III–V). Group V is also found in yeast. The histidyl-tRNA synthetases from both organisms are unique and must be regarded as a separate group (VI).

Almost all the enzymes require the amino group in the 6 position of the adenine ring for the binding of ATP (**17a**). Large substituents, such as a bromine atom at the 8 position, that hinder free rotation of the base around the glycosyl bond (see Appendix) and put the nucleotide into the *syn* conformation are not substrates for the aminoacyl-tRNA synthetases (**17c**). In the group I enzymes the nitrogen at position 7 of adenine is essential. This may indicate that these enzymes bind an ATP·$Mg^{2\oplus}$ complex of type **11** in which the $Mg^{2\oplus}$ ion is coordinated to N-7 (**17d**). The ribose hydroxyl groups are not essential for the binding by *E. coli* group I enzymes. In contrast, most of the group I yeast enzymes will not accept dATP or 3′dATP as substrates (**17e, f**). The enzymes from both organisms do not tolerate methoxy substituents at these positions (**17g, h**).

In group II the N-7 does not seem to be necessary for complexation of the $Mg^{2\oplus}$ ion. It is possible that the enzyme binds an ATP·$Mg^{2\oplus}$ complex of type **12** in which the $Mg^{2\oplus}$ ion is only coordinated to the phosphate oxygens (**17d**). The ribose 2′-OH group is not important at least for the *E. coli* enzymes (**17e, f**); *O*-methyl groups are not tolerated (**17g, h**).

The group III and most of the group V enzymes have no requirement for the N-7 of adenosine (**17d**). In the case of the group IV and VI enzymes no conclusions on the structure of the ATP·$Mg^{2\oplus}$ complex can be drawn. Remarkably, the enzymes of group V accept ATP analogues with methylated hydroxyl groups as substrates (**17g, h**).

Using ATP analogues other than the eight described above it is possible to probe more deeply the parts of the ATP molecule important for recognition by the synthetases.[87,89] From the "specificity raster" shown in Table 1, however, the isoleucyl-tRNA synthetase can be grouped with the leucine, valine, methionine, tyrosine, cysteine, glutamate, and glutamine enzymes. In this group, ATP binding sites of similar structure can be expected. Indeed, the amino acid sequence of isoleucyl-tRNA synthetase expected to be associated with ATP binding shows direct homology with the methionyl, tyrosyl, and glutaminyl enzymes.[30]

Table 1. Substrate specificity of 20 aminoacyl-tRNA synthetases from *E. coli* and 13 aminoacyl-tRNA synthetases from yeast with respect to ATP analogues **17a–h** (α_x characterizes the quaternary structure). sss means the compound has more than 50%, ss 10–50%, and s below 10% of the substrate activity of ATP. iii means the compound is active as an inhibitor and diminishes the substrate activity of ATP more than 50%, ii more than 20%, i more than 10% if ATP and inhibitor are present in the same concentration. – means the compound is neither a substrate nor an inhibitor.

3.2. Isoleucine Analogues

Precise translation of the genetic code requires high specificity with regard to the selection of the proper amino acid. That this is achieved is illustrated by the difficulty in detecting misacylation of $tRNA^{Ile}$ in the normal aminoacylation assay. In rabbit reticulocytes an error rate of 1:3000 has been determined for misincorporation of valine instead of isoleucine[90] into proteins. Because the misacylation reactions are extremely slow, they can only be measured under special experimental conditions (cf. Section 5).

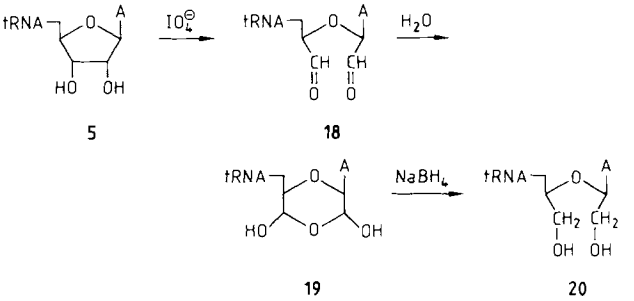
Higher error rates are found when the aminoacylation reaction is tested with unnatural amino acids. Presumably, the discrimination mechanism is poorer because it does not have the benefits of biological evolution to develop an efficient proofreading system. However, there is some species diversity in regard to misacylation of unnatural amino acids. For example, the yeast isoleucyl-tRNA synthetase accepts γ-hydroxyisoleucine and γ,δ-dehydroisoleucine as substrates but the corresponding *E. coli* enzyme does not.[91]

Detailed binding studies have been performed with the isoleucine derivatives 3-methylpentanoic acid, 2-methylbutylamine, and 2-amino-3-methyl-1-pentanol (isoleucinol). It was concluded that the carboxylate and protonated amino groups of isoleucine may function to open an ion pair on the enzyme surface.[92] A positive charge on the enzyme could act to diminish repulsion between the negatively charged triphosphate moiety of ATP and the carboxylate group.[93] The pH-dependence of the stability of the ATP-enzyme complex suggests that a histidyl or lysyl residue on the enzyme may be involved in binding ATP. Evidence exists as well that implicates a lysyl residue in the binding of isoleucine.[94] It has not been possible, however, to identify the specific histidyl or lysyl residue in the published enzyme sequence.[30]

3.3. tRNA Analogues

For most aminoacyl-tRNA synthetases several isoacceptor tRNAs exist.[95] Two tRNAs that are charged with isoleucine have been isolated from *E. coli*.[96] They consist of 77 and 76 nucleotides of which 27 are different. The *E. coli* $tRNA^{Phe}$ and $tRNA^{fMet}$ are also charged with isoleucine but at rates that are very low and just measureable.[97,98] These latter noncognate tRNAs have sequences that differ in 39 and 40 positions, respectively, when compared with $tRNA^{Ile}$.[96] Mischarging of $tRNA^{Val}$ by yeast isoleucyl-tRNA synthetase has been the subject of extensive kinetic investigations.[99] It is likely that the $tRNA^{Val}$ samples used in these studies contained a number of $tRNA^{Val}$ isoacceptors and the relative proportion of each species varied with each preparation. Despite a comparison of the various tRNA sequences, especially isoacceptors, and experiments with both chemically and enzymatically modified tRNAs, it has not been possible to elucidate the mechanism of tRNA recognition.[100]

Modified tRNAs have been useful in probing the mechanism of aminoacylation; especially important have been the tRNAs altered at the 3′-terminal nucleotide by enzymatic or chemical means.[101,102] The 3′-terminal ribose of the tRNA can be oxidized with periodate to yield the dialdehyde **18**, which in aqueous solution is in equilibrium with the hemiacetal hydrate **19**.[103,104] The generated $tRNA_{oxi}$ (**18**, **19**) can be reduced to the diol ($tRNA_{oxi\text{-}red}$) **20** by $NaBH_4$.[103]

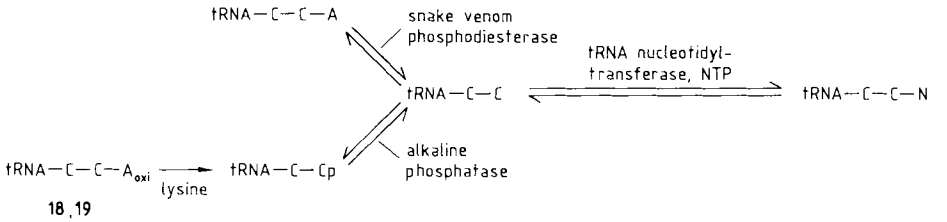


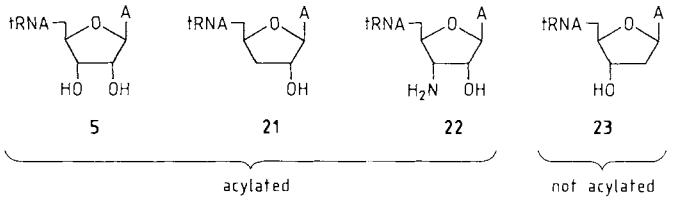
The $tRNA^{Ile}_{oxi\text{-}red}$ **20**, which is missing the bond between C2′ and C3′, is not a substrate for isoleucyl-tRNA synthetase. However, it is an inhibitor of the aminoacylation reaction. The $tRNA^{Ile}_{oxi}$ **19** is also an inhibitor but not a substrate for the enzyme.[29,105] Therefore, an intact terminal ribose is essential for enzymatic acylation of $tRNA^{Ile}$.

Other useful modifications of the C-C-A end of the tRNA can be carried out by enzymatic methods.[101,106-108] The terminal AMP nucleotide of the tRNA can be removed by controlled degradation with snake venom phosphodiesterase and AMP analogues can then be incorporated using tRNA nucleotidyltransferase. An alternative method starts with $tRNA_{oxi}$ **18**, which, when treated with lysine, eliminates the oxidized nucleoside. The terminal 3′ phosphate is removed using alkaline phosphatase and the modified nucleotide incorporated using tRNA nucleotidyltransferase.[109]

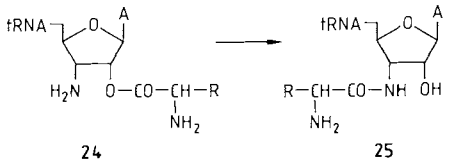
By incorporating in turn the 2′- and 3′-deoxyadenosine monophosphate nucleotides into tRNA it was determined which hydroxyl group is aminoacylated by the synthetase. Isoleucyl-tRNA synthetases from both yeast and *E. coli* acylate $tRNA^{Ile}$-C-C-3′dA **21** but not $tRNA^{Ile}$-C-C-2′dA **23**.[106,109,110]

From these results it was concluded that the natural $tRNA^{Ile}$-C-C-A **5** is acylated on the 2′-OH group by the





enzyme. However, the 2′-*O*-acyl-tRNA product will isomerize very quickly to a mixture of 2′- and 3′-isoleucyl-tRNA.[111-114] In analogous fashion, incorporation of 3′-deoxy-3′-aminoadenosine monophosphate yields $tRNA^{Ile}$-C-C-A(3′NH_2) **22**, which is also aminoacylated by both yeast and *E. coli* enzymes.[38,115-118] The 2′-*O*-acyl ester product **24** isomerizes by intramolecular aminolysis to the amino acid amide **25** at the 3′ position of the terminal ribose.[118]



This reaction is important because the product **25** is more stable against hydrolysis than the *O*-acyl ester **24**.[107] As will be described below, this property has made the $tRNA^{Ile}$-C-C-A(3′NH_2) **22** a valuable tool for the investigation of mechanisms which are responsible for the high specificity of the enzymes (see Section 5.1).

4. Substrate Binding and Catalysis

4.1. Determination of Substrate Binding Constants

4.1.1. Activation Reaction

The rate constants for the binding and dissociation of isoleucine and ATP have been determined using stopped flow techniques.[119] For the equilibrium (c)[*]

$$E + Ile \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E \cdot Ile \qquad (c)$$

the dissociation constant is

$$K_d^{Ile} = [Ile][E]/[E \cdot Ile] = k_{-1}/k_1 = 15\,s^{-1}/2.2 \times 10^6\,M^{-1}\,s^{-1} = 6.8 \times 10^{-6}\,M.$$

The rate constant for binding of isoleucine, k_1, is tenfold lower than the diffusion-controlled rate. At low temperatures a two-step process [Eq. (d)] for substrate binding can be detected. The first binding step is fast and is then followed by a slower enzyme isomerization to an active conformation. Perhaps this substrate-induced conformational change plays an important role in the recognition of the proper amino acid (see Section 5.2 for a discussion of the role of this effect in amino acid discrimination).

$$E + Ile \rightleftharpoons (E \cdot Ile)' \rightleftharpoons E \cdot Ile \qquad (d)$$

A standard free energy ($\Delta G°$) of -31.80 kJ mol^{-1} for the binding of isoleucine was determined from the temperature dependence of the dissociation constant.[119] This is now interpreted as being principally due to hydrophobic interactions between the amino acid and the enzyme surface[120] (see Section 5.1).

The dissociation constant for binding of ATP in the presence of $Mg^{2\oplus}$ is $K_d^{MgATP} = 1.75 \times 10^{-4}$ M.[119] Although the individual rate constants could not be determined exactly, it was apparent that ATP binds faster to the enzyme than does isoleucine.

Similar dissociation constants, $K_d^{Ile} = 4.0 \times 10^{-6}$ M and $K_d^{MgATP} = 1.5 \times 10^{-4}$ M, were calculated from kinetic measurements following the incorporation of ^{32}P-labeled pyrophosphate into ATP. This assay monitors the activation reaction (a) from the reverse direction and allows dissociation constants to be calculated by changing the substrate concentration.[121]

The reaction of enzyme-bound ATP and isoleucine to form the activated amino acid complex [Eq. (e)] has been

$$E \cdot Ile \cdot ATP \underset{k_b}{\overset{k_f}{\rightleftharpoons}} E \cdot Ile\text{-}AMP \cdot PP_i \qquad (e)$$

analyzed in detail. The forward rate, k_f, of 135 s^{-1} is slower than the back reaction rate, k_b, of 670 s^{-1}. Therefore, the equilibrium for this step ($K_E = k_f/k_b = 0.2$) favors the reactants Ile and ATP.[119]

The overall equilibrium constant for amino acid activation according to Equation (f)

$$ATP + Ile \rightleftharpoons Ile\text{-}AMP + PP_i \qquad (f)$$

has the low value of

$$K = [Ile\text{-}AMP][PP_i]/([Ile][ATP]) = 4.5 \times 10^{-4}.$$[119]

4.1.2. Aminoacylation Reaction

The dissociation constants K_d for binding of $tRNA^{Ile}$ or the charged Ile-$tRNA^{Ile}$ to the enzyme range from 10^{-6} to 10^{-8} M.[122,123] For the *E. coli* B enzyme the lowest dissociation constant obtained under optimal conditions is 3×10^{-7} M.[124] The equilibrium constant for the overall reaction

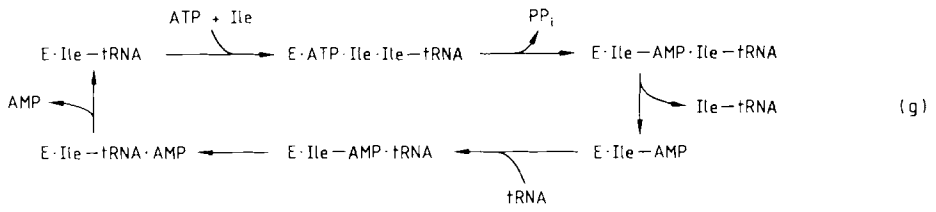
$$K_d = [E][tRNA]/[E \cdot tRNA]$$

$$K = [Ile\text{-}tRNA][AMP][PP_i]/([tRNA][ATP][Ile])$$

has a value close to unity.[125]

A comparison of the rate constants for the catalytic process in the *E. coli* B enzyme shows that the release of the acylated tRNA is the rate-determining step.[122] The

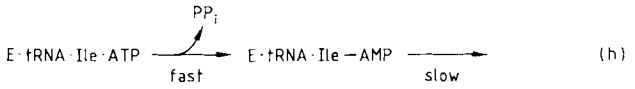
[*] In the following analysis a notation will be used that distinguishes between covalently and noncovalently bound complexes. A noncovalent interaction between two species such as the enzyme (E) and isoleucine (Ile) is indicated by a point: E · Ile. Covalent bonds are notated by a dash such as in aminoacyl adenylates: aa-AMP.



(g)

rate constant for adenylate formation is $<3.5\ s^{-1}$, for the acylation reaction $0.050\ s^{-1}$, and for dissociation of the E·Ile-tRNA complex $0.042\ s^{-1}$. For this enzyme the E·Ile-AMP·Ile-tRNA complex is the main species present in the assumed catalytic cycle (g).[122]

The enzyme from *E. coli* K12, as studied by pulsed quenched flow techniques, has a different rate-determining step.[14, 126] Transfer of the activated amino acid to the tRNA is very slow ($k = 1.47\ s^{-1}$) and follows fast isoleucyl adenylate formation ($k_{cat} = 62\ s^{-1}$ in the ATP/PP_i exchange reaction). The transfer-step rate determines the overall rate and turnover number of the aminoacylation reaction ($k_{cat} = 1.46\ s^{-1}$) [Eq. (h)].[14]



(h)

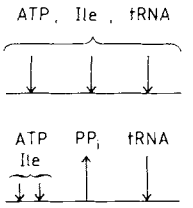
Thus, the release of the charged tRNA cannot be regarded a priori as rate determining. For the *E. coli* K12 enzyme the E·tRNA·Ile-AMP is the main species present in the catalytic cycle.

4.2. Order of Substrate Addition and Product Release

The order of substrate addition and product release has been determined by investigating the inhibition patterns of substrate analogues of type **17**. The methods for carrying out these initial rate kinetic measurements are well described in the literature and are summarized in the Appendix.[127–134] Analogues of ATP were found to be competitive, noncompetitive, and uncompetitive inhibitors. Modified tRNAs that cannot be charged (see Section 3.3) are competitive or noncompetitive inhibitors.

The first investigation on the order of substrate addition to isoleucyl-tRNA synthetases was performed on the *E. coli* B enzyme.[135] This experiment tested the influence of spermine on the aminoacylation reaction. Spermine, a polyamine, is found in all plant and animal cells.[136] Although not completely characterized, the reaction in the presence of spermine displays sequential substrate addition [see (i)]. In contrast, the reaction in the presence of $Mg^{2\oplus}$ has been postulated to display ping-pong kinetics [see (j)]. According to this mechanism, ATP and isoleucine are bound first and the isoleucyl adenylate is formed with the release of pyrophosphate before the tRNA is bound.

The results obtained from the spermine study have been used to argue that the aminoacyl adenylate is not a discrete intermediate in the reaction. Instead, the reaction mechanism is regarded as concerted and all substrates react in a



(i) (j)

simultaneous fashion.[8, 135] However, as will be shown below [cf. (l)] a mechanism with sequential addition of substrates can be formulated which includes an aminoacyl-adenylate intermediate. The effect of spermine may be not to affect the enzyme but to change the conformation of the tRNA and thereby make it a poorer substrate.[137]

In detailed investigations of yeast isoleucyl-tRNA synthetase, four reaction mechanisms were elucidated which depend on the assay conditions.[99, 138, 139] As shown in Table 2, the different reaction conditions can be regarded as approaching physiological conditions in a stepwise fashion.

Using an enzyme assay that is optimal for catalysis (pH 7.65, 0.1 M KCl, 15 mM $Mg^{2\oplus}$), the aminoacylation reaction can be shown to follow a sequential mechanism. ATP binds first followed by isoleucine and finally $tRNA^{Ile}$. The products are then released in the order pyrophosphate, Ile-$tRNA^{Ile}$, and AMP. The turnover number under these conditions is $0.83\ s^{-1}$. At pH 8.6 a similar reaction mechanism is observed but the turnover number is reduced to $0.52\ s^{-1}$. In contrast, when the pH is reduced to 6.5, a value also found in yeast cells,[140] the reaction mechanism changes such that the substrates are bound and products released in a random manner. At pH 6.5 the turnover number is $0.47\ s^{-1}$.

Pyrophosphatase (PPase) is present in relatively high amounts in *E. coli*[141] and yeast[142] cells. Addition of this enzyme to the aminoacylation reaction assay performed under optimum conditions changes the mechanism from a sequential to a ping-pong process. ATP and isoleucine bind to the enzyme in a random manner and pyrophosphate is released. Then $tRNA^{Ile}$ binds and the products, AMP and Ile-$tRNA^{Ile}$, are released in an unknown order. The turnover number under these conditions is increased to $1.4\ s^{-1}$. The influence of pyrophosphate on the catalytic pathway has not been investigated in detail; it is possible that this product is also involved in an allosteric interaction.[138]

When the elongation factor complex EF-Tu·GTP is added instead of pyrophosphatase, the reaction pathway remains sequential and the turnover number is reduced to $0.28\ s^{-1}$. It is well known that EF-Tu·GTP forms very specific complexes with acylated tRNAs[99, 143–147] and should thereby increase the turnover number by decreasing the

Table 2. Conditions of aminoacylation, order of substrate addition and product release for isoleucyl-tRNA synthetase from yeast (A = ATP, B = isoleucine, C = $tRNA^{Ile}$, P = pyrophosphate, Q = Ile-$tRNA^{Ile}$, R = AMP), and k_{cat} values; nomenclature of mechanisms according to *Cleland* [130, 134] (for abbreviations see text).

concentration of the free product formed in the reaction. However, up to now no good explanation for the reduced turnover number has been put forward.[148] Remarkably, when both pyrophosphatase and EF-Tu·GTP are present in the assay, turnover number and mechanism remain unchanged.

When spermine, pyrophosphatase, and EF-Tu·GTP are all added to the isoleucyl-tRNA synthetase reaction assay, an unusual ping-pong mechanism is encountered. Isoleucine is bound first and then ATP. Pyrophosphate is the first product released, followed by, remarkably, isoleucyl-tRNA. The kinetic quirk that explains how the product isoleucyl-tRNA can be formed before the $tRNA^{Ile}$ substrate is bound by the enzyme will be given later [cf. (k)]. To complete the catalytic sequence, $tRNA^{Ile}$ is bound next and finally AMP is released from the enzyme. The turnover number for this process (0.098 s^{-1}) is very low. Lowering the $Mg^{2\oplus}$ concentration from 15 mM, used in the "optimal" assay, to 1 mM, which is similar to that found under physiological conditions, increases the turnover number slightly to 0.135 s^{-1}.[149, 150] Even when the best conditions are used, however, the aminoacylation reaction remains about ten times slower than the "optimal" assay where the pyrophosphatase, EF-Tu·GTP, and spermine are omitted.

The *E. coli* MRE600 isoleucyl-tRNA synthetase has been found to display both a sequential and, under slightly different assay conditions, a ping-pong mechanism (Table 3).[151] Addition of the EF-Tu·GTP complex or spermine does not influence the turnover number. In the presence of spermine, however, different reaction mechanisms do occur but have not yet been studied in detail.[146] In total, this enzyme displays a series of reaction mechanisms as diverse as those found for the yeast enzyme and also performs some novel processes not observed in the enzymes from *E. coli* B or yeast.[135]

Table 3. Conditions of aminoacylation, order of substrate addition and product release for isoleucyl-tRNA synthetase from *E. coli* MRE600 (A = ATP, B = isoleucine, C = $tRNA^{Ile}$, P = pyrophosphate, Q = Ile-$tRNA^{Ile}$, R = AMP), and k_{cat} values; nomenclature of mechanisms according to *Cleland* [130, 134] (for abbreviations see text).

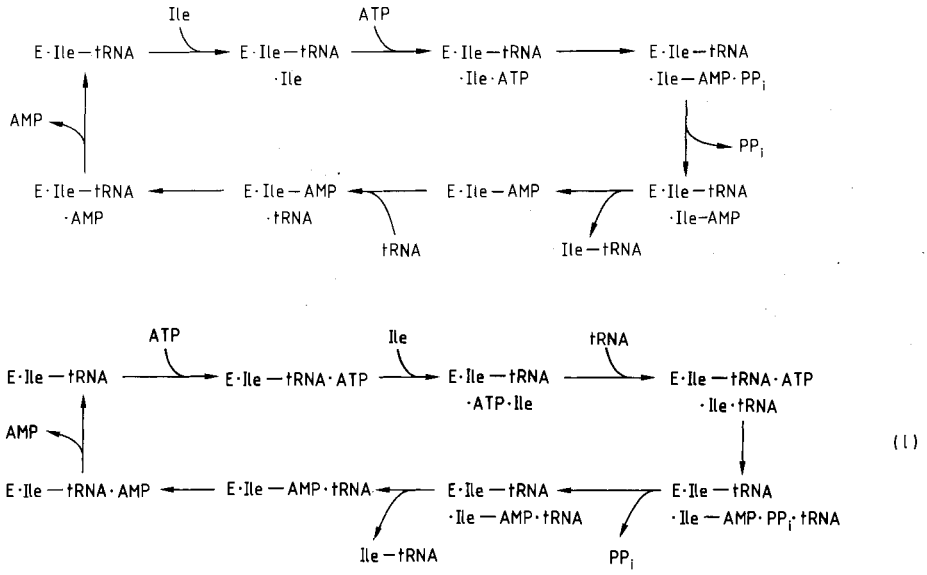
The analysis of "initial rate" kinetics yields information only on the sequence of substrate addition and product release. The type of enzyme–ligand complex associated with each step in a mechanism can only be inferred. It is possible that the enzyme designated as "E" in the schemes of Tables 2 and 3 and in the Appendix is not free enzyme but actually an enzyme–ligand complex formed earlier. Thus, in the special case noted above of the yeast enzyme assay with spermine added, isoleucine must be bound to an enzyme complex with Ile-$tRNA^{Ile}$. The catalytic cycle (k) is purely hypothetical.

Analogously, a sequential-ordered mechanism (l) can be postulated in which ATP and isoleucine are added to an E·Ile-tRNA·AMP complex. From (l) it will be noted



(l)

that ATP, Ile, and $tRNA^{Ile}$ are added in sequential order and an aminoacyl-adenylate intermediate (Ile-AMP) is formed. Similar schemes have been postulated for phenylalanyl-[152] and valyl-tRNA synthetases[153] from yeast; they also involve enzyme–substrate complexes in which two tRNA molecules are bound. Two tRNA binding sites have been suggested for the isoleucyl-tRNA synthetase based on the observation that some tRNA analogues act as noncompetitive inhibitors of the aminoacylation reaction.[29, 105] It is not clear, however, whether the two binding sites reside on a single peptide chain or result from a dimeric enzyme.[148]

The multiplicity of possible reaction pathways found for the isoleucyl-tRNA synthetases from yeast and *E. coli* indicates that the protein cannot be regarded as a rigid construction. Minimal alterations in the environment may cause a different conformation to form and result in a change in mechanism and corresponding change in reaction velocity. The physiological significance of this behavior, which was at first unclear, is apparently related to the specificity of the enzyme.

5. Error Rates in Aminoacylation

Enzyme specificity is characterized as the ratio of the velocities at which the cognate substrate and a noncognate substrate are converted into products. A discrimination factor D can be defined that allows the intrinsic enzyme specificity to be quantified independent of the relative concentrations of cognate and noncognate substrates. For example, the discrimination between isoleucine and valine is given by Equation (m):

$$v_{Ile}/v_{Val} = D \cdot ([Ile]/[Val]) \quad (m)$$

The factor D is related to the kinetic constants k_{cat} and K_m through Equation (n):

$$D = (k_{cat}/K_m)^{Ile}/(k_{cat}/K_m)^{Val} \quad (n)$$

Isoleucyl-tRNA synthetase displays very high specificity and it is therefore very difficult to measure the k_{cat} and K_m values for the noncognate substrates. The rates are very low and the level of radioactivity incorporated, via a radioactive amino acid, into tRNA is only slightly higher than the background radiation. Nevertheless, sufficiently accurate reaction rates can be estimated if the reactions are observed for relatively long periods, the measurements are repeated, and the data analyzed by statistical methods.[145] In this way the following D factor for discrimination of valine by yeast isoleucyl-tRNA synthetase was found:[139]

$$D = (0.83\ s^{-1}/0.02\ mM)/(0.0001\ s^{-1}/0.09\ mM) = 38000$$

The *E. coli* enzyme showed almost twofold higher discrimination:[154]

$$D = (0.82\ s^{-1}/0.006\ mM)/0.00019\ s^{-1}/0.1\ mM) = 71900$$

These values signify that at equal concentrations of the two amino acids only one noncognate valine is transferred to $tRNA^{Ile}$ while 38000 and 71900 isoleucines, respectively, would be incorporated. Both D values are much higher than expected for the difference between the side chains (isobutyl versus isopropyl) and cannot only result from hydrophobic interactions with the enzyme surface. *Pauling* has calculated that such an interaction can only achieve a specificity of 4.3 : 1 and he estimated that for the isoleucine/valine discrimination the upper limit was about 20 : 1.[155] To elucidate the processes that give this 4000-fold higher specificity, important insight was gained using modified tRNAs as tools, especially $tRNA^{Ile}$-C-C-A(3′NH_2) **22**.

5.1. Discrimination between Amino Acids during Aminoacylation of $tRNA^{Ile}$-C-C-A(3′NH_2)

In contrast to $tRNA^{Ile}$-C-C-A **5**, the modified $tRNA^{Ile}$-C-C-A(3′NH_2) **22** can be charged with noncognate amino acids at relatively high rates.[38, 115–118] This allowed the k_{cat}

Table 4. Discrimination factors D und D_2 ($\approx D_1$), stoichiometry of AMP formation in aminoacylation, and factors I_1, I_2, Π_1, Π_2 for discrimination between isoleucine and valine by isoleucyl-tRNA synthetase from yeast (for abbreviations see text).

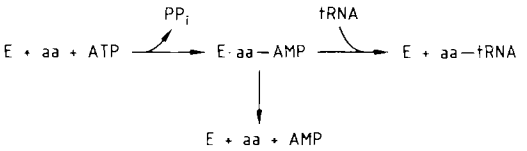
and K_m values for misacylation with the nineteen noncognate amino acids occurring in proteins to be determined and the corresponding discrimination factors (D_1) calculated.[120] These D_1 values are much lower than the discrimination factors D for acylation of $tRNA^{Ile}$-C-C-A **5** (cf. Table 4). The yeast enzyme, for example, discriminates against valine with a D value of 38000 but the D_1 value is only 167. However, the D_1 values are still higher than the theoretical results calculated by *Pauling* (e.g., 1 : 10 for valine).[155] The results with $tRNA^{Ile}$-C-C-A(3'NH_2) **22** show that the reaction steps that enhance specificity are considerably restricted during charging of the modified tRNA.

By measuring the stoichiometry of AMP formation [cf. Eq. (a) and (b)] it was found that more than one molecule of AMP was generated per molecule of tRNA acylated.[120] For example, the yeast enzyme hydrolyzes 111 molecules of ATP for each tRNA charged with valine; with the cognate amino acid, isoleucine, only 2.2 molecules of ATP are hydrolyzed. These high rates of AMP formation indicate that a hydrolytic proofreading step is operating. As early postulated,[156, 157] this step must be a "pretransfer proofreading" which acts to hydrolyze the noncognate aminoacyl adenylate. By using $tRNA^{Ile}$-C-C-A(3'NH_2) one can be sure that the measure of AMP formation represents *only* pretransfer proofreading. Although acylation does occur primarily at the 2'-OH group, transacylation to give the hydrolytically more stable 3'-acylamide **25** is much faster[116a, 120] than the rate for the enzymatic hydrolysis of aminoacyl esters.[28] Therefore, no posttransfer proofreading process can operate when using this $tRNA^{Ile}$ analogue. The pretransfer proofreading can be formulated as (o).



(o)

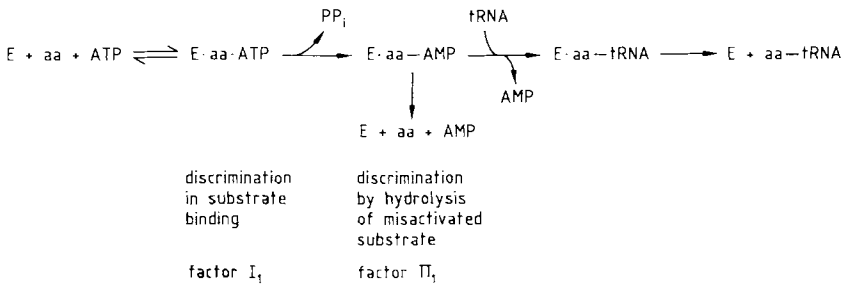
pretransfer proofreading

It is important to mention that this conclusion is only valid if transacylation of the amino acid from the 2'-OH to 3'-NH_2 (cf. **24**→**25**) is not hindered in the enzyme-tRNA complex. The ratio of the number of AMP molecules formed for each noncognate amino acid to the number formed for isoleucine shows how many more incorrect amino acids are rejected in the proofreading step than isoleucine. For valine this proofreading factor is $\Pi_1 = 111/2.2 = 50$ with the yeast enzyme.

The discrimination factor D_1, described above, is a function of the proofreading factor Π_1 and also of a factor I_1, which corresponds to the difference in Gibbs free energy of binding between cognate and noncognate substrates. Therefore, Equation (p) holds. The complete recognition

$$D_1 = I_1 \cdot \Pi_1 \qquad \text{(p)}$$

process for acylation of $tRNA^{Ile}$-C-C-A(3'NH_2) **22** is shown in (q).



(q)

The difference in Gibbs free energy for binding of a noncognate amino acid and isoleucine is given by Equation (r):[158]

$$\Delta\Delta G_{I_1} = RT\ln I_1 = RT\ln D_1/\Pi_1 \qquad (r)$$

For valine $\Delta\Delta G_{I_1}$ is 3.08 kJ mol^{-1},[139] which corresponds to a value of $I_1 = 3.3$. These values are very similar to those calculated theoretically by *Pauling* ("I" = 4.3, "$\Delta\Delta G$" = 3.77 kJ mol^{-1}).[155] The $\Delta\Delta G_{I_1}$ is consistent with the hydrophobic interaction energy of a methylene group with an enzyme. Values of the same order of magnitude can be estimated from a hydrophobicity scale derived for the transfer of an amino acid side chain from water to an organic solvent.[159]

From the analysis of protein structures it has been found that the accessible surface area of an amino acid is the main determinant in the magnitude of hydrophobic interactions.[160–162] The surface area is defined as the area covered by the center of a water molecule that is placed in van der Waals contact with the atoms of the amino acid without penetrating any of the atoms.[163] Each square angstrom of accessible surface area removed from contact with water contributes 105 J mol^{-1} in energy.[160–162]

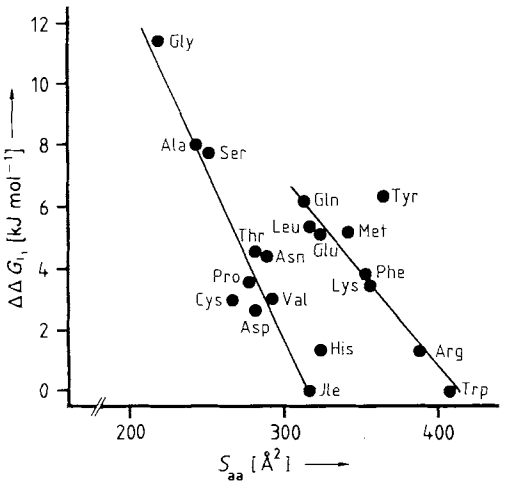


Fig. 1. Relation of differences in Gibbs free energy of binding ($\Delta\Delta G_{I_1}$) to accessible surface areas (S_{aa}) of amino acids.

As shown in Figure 1, a linear relationship exists between the $\Delta\Delta G_{I_1}$ values calculated from misacylation kinetics and the accessible surface of the amino acids (S_{aa}).[164] Strikingly, two groups of amino acids can be distinguished.[120] The first group includes all amino acids with a surface area or side-chain length smaller than isoleucine. The amino acids with side chains longer or with a larger surface area than isoleucine comprise the second group. The slopes of these relationships give the Gibbs free energy values and are 111 J mol^{-1} Å^{-2} and 61 J mol^{-1} Å^{-2}, respectively. Both values are consistent with a hydrophobic interaction. The intersection of the left line in Figure 1 with the ordinate gives the Gibbs free energy for the binding of isoleucine. The value of 34.93 kJ mol^{-1} is of the same order of magnitude as the value for the standard free energy of binding given in Section 4.1.1 ($\Delta G^\circ = -31.80$ kJ mol^{-1}).

A simple model of the amino acid binding site can be used to explain the subdivision of the amino acids into two groups (Fig. 2).[120] The binding cavity can be viewed as having a bulky group that restricts the binding of amino acids larger than isoleucine. The small amino acids are easily bound within the cavity, but for binding of the larger amino acids energy is required to push the bulky group aside. The amount of energy can be estimated from Figure 1 by extrapolating the line for the larger amino acids to the surface area for isoleucine. This yields a value of 6 kJ mol^{-1}.

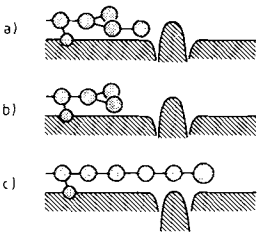

Fig. 2. Initial binding site with a) isoleucine (the binding cavity is completely filled by the isoleucine side chain), b) valine (the binding cavity is only partly filled, the Gibbs free energy of binding is diminished by a value corresponding to the difference in accessible surface area ($\Delta\Delta G_{I_1}$), c) lysine (the side chain of lysine must push aside the "stopper" group in the binding process). For the first group in Fig. 1, $\Delta\Delta G_{I\,1} = 111\ (S_{Ile} - S_{aa})$ [J mol^{-1}]; for the second group in Fig. 1. $\Delta\Delta G_{I\,1} = 61\ (S_{Ile} - S_{aa}) + 6000$ [J mol^{-1}] (S_{Ile} = accessible surface area of isoleucine, S_{aa} = accessible surface area of other amino acids).

A similar result is found for the *E. coli* enzyme[120] with the exception that leucine is included in the group of amino acids from glycine to isoleucine. The $\Delta\Delta G_{I_1}$ values are only slightly higher than those observed for the yeast enzyme (e.g., valine has a $\Delta\Delta G_{I_1}$ value for the *E. coli* enzyme of 3.87 kJ mol^{-1} but only 3.08 kJ mol^{-1} with yeast). This observation indicates that the binding sites of the enzymes from the two sources are similar.

If, in analogy to the $\Delta\Delta G_{I_1}$ values, the $\Delta\Delta G_{\Pi_1}$ values are plotted against the accessible surface area, no significant relation is observed. In general, for both enzymes, the scatter of the $\Delta\Delta G_{\Pi_1}$ values is about 10 kJ mol^{-1}. Therefore, in contrast to binding at the initial binding site, hydrophobic interactions do not seem to play an important role at the hydrolytic site. It remains unclear by which steric influences the cognate isoleucyl adenylate avoids hydrolysis.

5.2. Discrimination between Amino Acids during Aminoacylation of tRNA^{Ile}-C-C-A

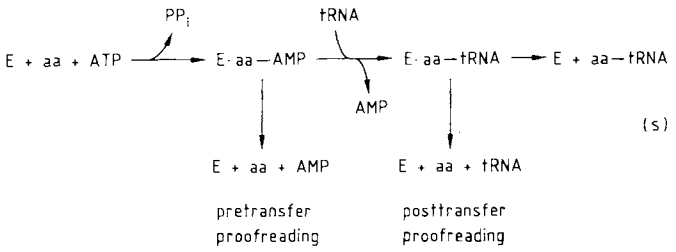
The D values calculated from k_{cat} and K_m are 200- to 300-fold higher than the corresponding D_1 values obtained in acylation of tRNA^{Ile}-C-C-A(3'NH$_2$) **22**.[165]

Unexpectedly low D values of 300 to 700 were found for cysteine, aspartic acid, asparagine, and tryptophan. Recently, low error rates have also been found in vivo (cysteine instead of arginine 1 : 1700,[166] lysine instead of arginine 1 : 500[167]). The highest discrimination factors were detected with the yeast enzyme for leucine, serine, methionine, glycine (10000–20000), and valine (38000). The D values for the remaining amino acids range between

2000 and 10000. The *E. coli* enzyme exhibits discrimination factors between 600 and 72000. The lowest values (600–3000) were calculated for cysteine, tryptophan, and arginine. The highest values (≈ 70000) were found for glycine, alanine, and valine. The D values for the other amino acids range from 20000 to 50000.[165]

It is surprising that both *E. coli* and yeast show the highest discrimination for those amino acids which are the most similar to isoleucine and a lower discrimination between the structurally more diverse amino acids cysteine, tryptophan, and arginine.

In parallel with the higher D values found for aminoacylation, higher rates of AMP formation are also observed in the presence of the natural tRNA (tRNA^{Ile}-C-C-A **5**) compared with tRNA^{Ile}-C-C-A(3′NH$_2$) **22** (cf. Table 4). The reason is most probably a second hydrolytic proofreading step which is carried out after transfer of the amino acid to the tRNA ("posttransfer proofreading"). The enzyme-bound aminoacyl-tRNA esters may be in many cases more rapidly hydrolyzed than isoleucyl-tRNA [cf. (s)].[28, 110, 168]



(s)

Proofreading factors for pretransfer (Π_1) and posttransfer proofreading (Π_2) multiply to give the overall proofreading factor Π'. Provided that in the aminoacylation of native tRNA^{Ile}-C-C-A **5** the pretransfer proofreading is of the same magnitude as that found for the acylation of tRNA^{Ile}-C-C-A(3′NH$_2$) **22**, factor Π_2 can be approximately determined as the quotient of Π' and Π_1.

The Π_2 factors calculated for the yeast enzyme are much lower than the Π_1 factors. Only in seven cases does the posttransfer proofreading enhance the discrimination factor D ($\Pi_2 \geqq 1$). Remarkably, the second hydrolytic step gives an improvement of only $\Pi_2 \approx 3$ between isoleucine and valine. For the other eleven amino acids $\Pi_2 \leqq 1$, so there is no discrimination against the proper amino acid.

It should be emphasized that Π_2 observed for valine ($\Pi_2 \approx 3$) corresponds to the Gibbs free energy of binding calculated by *Pauling* for a methylene group. The binding site at which the second hydrolytic proofreading step is carried out seems to serve mainly for discrimination between the isobutyl and isopropyl group. The other amino acids are hydrolyzed slightly faster or slower than isoleucine for steric reasons.

The $\Delta\Delta G_{\Pi_2}$ values, calculated analogously to $\Delta\Delta G_{\Pi_1}$, show no systematic relation to accessible surface areas or other structural properties of the amino acids.

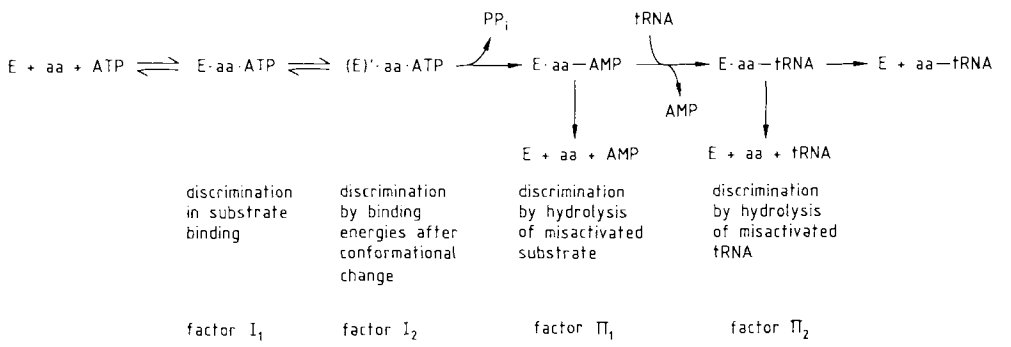
Similarly, as in the case of D_1, the discrimination factor D is the product of the Gibbs free energy for substrate binding (I') and the overall proofreading factor Π' [Eq. (t)].

$$D = I'\Pi' \qquad \text{(t)}$$

Factor I' is calculated from D and Π'. All I' values are higher than the corresponding I_1 values, so for valine a $\Delta\Delta G_{I'}$ value of 14.25 kJ mol^{-1} is found.[165] This value is about fourfold higher than that for the aminoacylation of tRNA^{Ile}-C-C-A(3′NH$_2$) **22**. Similar values were obtained from kinetic measurements of the activation reaction with isoleucine and valine.[157, 158] The reason for the deviation is still unknown. It may be that this phenomenon is related to the conformational change in the enzyme observed during binding of isoleucine (see Section 4.1.1). In the case of phenylalanyl-tRNA synthetase there are considerable differences in the kinetics of complex formation between enzyme·tRNA-C-C-A and enzyme with modified tRNAs.[169, 170] Possibly, in the aminoacylation of tRNA^{Ile}-C-C-A(3′NH$_2$) **22**, a conformational change does not occur which normally with a natural tRNA would be induced by binding of isoleucine and which would enhance hydrophobic interactions. A factor I_2 resulting from this process must multiply with I_1 to give I'. Therefore, the value D is given by Equation (u). Thus, the complete process of amino acid recognition is achieved (Scheme 5) following the scheme for aminoacylation of tRNA^{Ile}-C-C-A(3′NH$_2$) **22** [cf. (q) in Section 5.1].

$$D = I_1 \cdot I_2 \cdot \Pi_1 \cdot \Pi_2 \qquad \text{(u)}$$

$\Delta\Delta G_{I_2}$ calculated analogously to $\Delta\Delta G_{I_1}$ shows a linear relationship to the accessible surface areas of the amino acids. However, in this case the amino acids cannot be arranged into two groups. The most simple scheme requires three groups and is difficult to interpret.[165]



(v)

6. Modulation of Specificity and Energy Consumption

From the different catalytic pathways and reaction conditions listed in Table 2 the turnover numbers can be seen to vary in the range of 0.098 to 1.40 s^{-1}. Since these values determine directly the discrimination factor D it must be expected that isoleucyl-tRNA synthetase exhibits different substrate specificities under the different conditions. In fact, the discrimination factor varies in a range of 2000 to 38000 for the different reaction conditions (Table 4).[139] Consumption of ATP, or generation of AMP, has a stoichiometry of 3.0–6.9 in the synthesis of Ile-$tRNA^{Ile}$-C-C-A as catalyzed by the yeast enzyme and a value of 1.0–1.73 AMP molecules per Ile-$tRNA^{Ile}$-C-C-A for the enzyme from *E. coli*.[139, 165] Formation of the misacylation product Val-$tRNA^{Ile}$-C-C-A causes the release of between 118 and 1165 (*E. coli*) or 530 and 2700 (yeast enzyme) AMP molecules per aminoacyl-tRNA. In parallel with the D values, the discrimination factors D_2 determined for the acylation of $tRNA^{Ile}$-C-C-3′dA vary in a similar fashion (Table 4).[139] Only in the case of valine are these D_2 values practically identical with the D_1 factors observed in acylation of $tRNA^{Ile}$-C-C-A(3′NH_2). They can be used in place of D_1 values in further calculations. The values for AMP formation observed in acylation of $tRNA^{Ile}$-C-C-3′dA can also be used in place of values observed in acylation of $tRNA^{Ile}$-C-C-A(3′NH_2). Factors D_2 ($\approx D_1$) are in the range of 48 to 180, whereas the number of AMP molecules lies in the range of 1.1 to 3.12 for charging with isoleucine and 13 to 96 for charging with valine. The D_1 values determined for the enzyme from *E. coli* are in the range of 100 to 4400. In acylation with isoleucine 1.0–1.7 molecules of ATP are consumed and in acylation with valine 2.6–24.[120] If the single factors I_1, I_2, Π_1, and Π_2 are compared, it is found that, for the yeast enzyme in one case (pH 6.5, 0.1 M KCl, 15 mM $Mg^{2\oplus}$), the proofreading factor Π_2 is higher than Π_1. Under other reaction conditions, however, the reverse is observed. As listed in Table 2 the enzyme displays only at pH 6.5 a random mechanism in which the substrates are added and the products released in any order. This mechanism differs from others in that the enzyme uses a conformation that is more effective in the posttransfer proofreading than in the pretransfer step. A similar result has been found for the reaction pathways of the *E. coli* enzyme. At pH 7.6 this synthetase displays a random mechanism (Table 3) and the proofreading factor Π_2 is twice as high as factor Π_1. These observations confirm that the various pathways for catalysis, which differ in the order of substrate addition and product release, are connected with the overall specificity of the enzyme. The changes in specificity shown by the isoleucyl-tRNA synthetases result from two main causes. First, there may be a change in the catalytic cycle, each cycle being characterized by the different order of substrate addition and product release. Second, each cycle may have a different reaction velocity. Therefore, the specificity of the enzymes can be changed to any degree by changing the reaction conditions. In every case, however, a change in a specificity will be associated with a different energy consumption. Under the conditions which are the closest to the physiological one (pH 7.65, 0.1 M KCl, 1 mM $Mg^{2\oplus}$, EF-Tu·GTP, PPase, spermine) (Table 2), the enzymes work with a medium specificity and medium energy consumption (yeast enzyme: $D = 10500$, 3.4 AMP/isoleucyl-tRNA; *E. coli* enzyme: $D = 40600$, 1.04 AMP/isoleucyl-tRNA).

7. Summary and Outlook

Although in the past twenty years considerable progress has been made in the investigation of the aminoacyl-tRNA synthetases and hundreds of papers have been published, we are still far away from a complete understanding of functions and mechanisms of these enzymes. We do not have a concrete knowledge of the structure of the active site, the identity and reactivity of the functional groups involved in catalysis, or even the exact chemical transformations involved in amino acid activation and transfer to the tRNA.

Kinetic investigations show that the enzyme has many different active conformations and uses different catalytic cycles. No conclusions can be made as to the nature of these conformational differences at this time. Even if X-ray structure analysis could be done, it would be difficult to elucidate these processes, because in the crystals the molecules are in the "frozen" states favorable for crystal formation. Perhaps the conformational changes are connected with a "proteinquake" as postulated for myoglobin.[171]

The high specificity of these enzymes, which was mysterious at first glance, can only be achieved in the four-step process outlined here, because the differences in amino acid structures are insufficient. In the four steps, steric fitting and hydrophobic forces are important. Thus, the high specificity can be explained by simple well-known phenomena. The combination of these known phenomena in aminoacyl-tRNA synthetases results in a type of enzyme which can be adjusted to practically any degree of specificity. High specificity requires high energy consumption. However, in the cell a medium discrimination factor seems to be used (e.g., for valine in yeast, $D = 10000$; in *E. coli*, $D = 40000$) which is associated with medium energy consumption. In the case of the isoleucyl-tRNA synthetases the prokaryotic organism *Escherichia coli* possesses an enzyme which works with more precision than the enzyme from the eukaryotic yeast organism.

Appendix

Comments on Structure and Synthesis of ATP Analogues

N^6-Methyladenosine 5′-triphosphate (m^6ATP) **17a** can be synthesized starting from 6-chloropurine, which is first converted into 6-chloropurineriboside [172, 173]. The chlorine atom in position 6 is then substituted by methylamine [173, 174], and the product is phosphorylated via the monophosphate to the triphosphate.

2-Chloro- (cl^2ATP) and 8-bromoadenosine 5′-triphosphate (br^8ATP), **17b** and **17c**, respectively, exhibit different conformations about the glycosyl bond. cl^2ATP has an *anti* conformation which is also found in the natural substrate ATP in which the adenyl moiety is turned away from the ribose [75, 175, 176]. In the br^8ATP molecule the bromine atom is situated away from the ribose and the purine ring system is turned over the sugar plane [177, 178]; this conformation is called the *syn* conformation [175, 176]. 8-Bromoadenosine can be easily synthesized by bromination of adenosine [179, 180]; 2-chloroadenosine is made by conversion of 2,6-dichloropurine to the riboside and substitution of the chlorine atom in position 6 by ammonia [181].

7-Deazaadenosine, called tubercidine, is isolated from *Streptomyces tubercidicus* [77, 79, 182, 183]. In this molecule the nitrogen atom in position 7 is lacking; therefore, tubercidine 5′-triphosphate (TuTP) **17d** cannot form a $Mg^{2\oplus}$ complex with the $Mg^{2\oplus}$ ion coordinated to this atom. NMR measurements with tubercidine and tubercidine 5′-triphosphate show that the heterocyclic system can rotate around the glycosyl bond and prefers neither the *anti* nor the *syn* conformation [184].

2′- and 3′-deoxyadenosine are both isolated from natural sources; 2′-deoxyadenosine is a component of DNA, 3′-deoxyadenosine (also called cordycepine) a metabolic product of the microorganism *Cordyceps militaris* [77, 79, 185]. 2′- and 3′-methoxyadenosine can be easily prepared by methylation of adenosine with diazomethane [186, 187]. These four nucleoside analogues are also converted into the triphosphates.

Fundamental Principles of Initial Rate Kinetics

If the velocity of aminoacylation of tRNA is measured as a function of the concentration of one of the three substrates, classic linear Lineweaver-Burk plots [188] are obtained by plotting reciprocal velocities against reciprocal concentrations. The plots are related to the well-known Michaelis-Menten equation [189] which gives, by its intersection points with the coordinate axes, the constants K_m (Michaelis constant) and V (maximum velocity). Different inhibitor types are distinguished by the characteristic changes of Lineweaver-Burk plots (Fig. 3) observed when the inhibitor (I) is added to the reaction mixture.

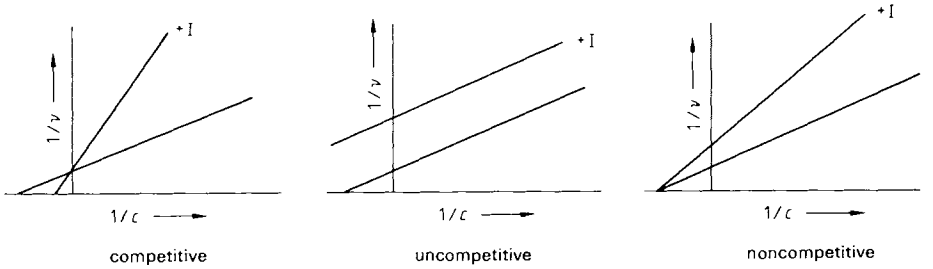


Fig. 3. Lineweaver-Burk plots for enzyme reactions with and without inhibitors. c = substrate concentration, v = reaction velocity (see text).

In the simplest enzymatic reaction [cf. (w)], in which only one substrate is converted, a competitive inhibitor would only change the slope of the plot.

$$E + S \rightleftharpoons E \cdot S \longrightarrow E + P \qquad (w)$$

This inhibitor would form with E an E·I complex which does not react further. If I does not react with E to E·I but with E·S to E·S·I, the slope of the plot is not changed but the intersection point with the $1/v$ axis does change; that means a parallel plot is observed. This inhibitor type is called uncompetitive. If I can react with E and with E·S, slope and intersection point are changed and the inhibitor is called noncompetitive [127, 129].

Whereas in the case of modified tRNAs the observation of noncompetitive inhibitors indicates the existence of a second binding site for this substrate, this conclusion cannot be made in the case of ATP analogues because, for this "small" substrate, binding at the hydrophobic pocket of the amino acid binding site [190] and nonspecific binding to aminoacyl-tRNA synthetases has been found [191].

In the aminoacylation reaction three substrates react instead of only one [cf. (x)]:

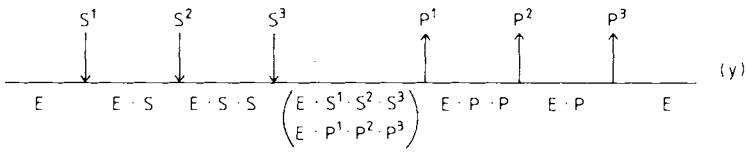
$$E + S^1 + S^2 + S^3 \longrightarrow E + P^1 + P^2 + P^3 \qquad (x)$$

Now the inhibitor type depends additionally on which one of the three substrates is chosen to be varied in the Lineweaver-Burk analysis. For example, an inhibitor may be competitive if the reciprocal reaction velocity is plotted against the reciprocal concentration of S^1, but noncompetitive if the velocity is measured at variable concentrations of S^2 or S^3. The way in which the inhibitor type is changed with the variable substrate depends on the reaction mechanism. Therefore, it depends on the order of substrate addition and product release. Inhibitor types that can be expected for nearly all possible mechanisms are listed in tables [127-129].

If three inhibitors are at disposal, each of which shows competitive inhibition with respect to one of the three substrates, characteristic inhibition patterns are observed when the other two substrates are also varied. These typical inhibition patterns allow one to identify the reaction mechanism (order of substrate addition and product release). In Table 5, inhibition patterns corresponding to two mechanisms are listed which have been found for the aminoacyl-tRNA synthetases (cf. Tables 2 and 3). In the first one, the substrates are added in the sequence S^1, S^2, and S^3; the chemical reaction then occurs, and products are released in the sequence P^1, P^2, and P^3. In the commonly used notation [130] it is written as shown in (y).

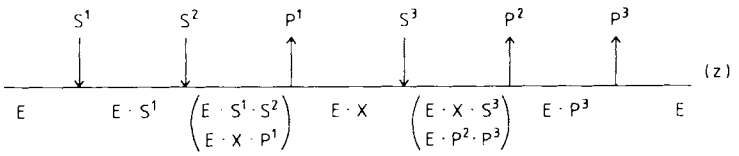
Table 5. Inhibition patterns of an ordered sequential and an ordered ping-pong mechanism (c = competive, u = uncompetitive, n = noncompetitive).

Sequential, ordered (y)				Ping-pong, ordered (z)			
Inhibitor	Variable substrate			Inhibitor	Variable substrate		
	S^1	S^2	S^3		S^1	S^2	S^3
I^1	c	n	n	I^1	c	n	u
I^2	u	c	n	I^2	u	c	u
I^3	u	u	c	I^3	u	u	c



In this scheme the reaction sequence is written from left to right, the enzyme is represented by a horizontal line, and the addition of substrates and release of products are indicated by perpendicular arrows. The numbers of substrates or products that are added or released in one direction are called "uni," "bi," and "tri." If all substrates are added before a product is released, the mechanism is called "sequential"; if one or more products dissociate from the enzyme before all substrates are added, the mechanism is called a "ping-pong" mechanism. If the sequence in which substrates are added or products are released is fixed, then the mechanism is "ordered"; if not, the mechanism is a "random" one. Consequently, mechanism (y) must be called "sequential ordered Ter-Ter."

In the second mechanism, an "ordered Bi-uni Uni-bi ping-pong" mechanism, the substrates S^1 and S^2 are first added, product P^1 is then released, substrate S^3 is added, and, finally, the products P^2 and P^3 dissociate from the enzyme [cf. (z); X = intermediate].



The inhibition patterns which belong to the two mechanisms are given in Table 5; they differ in two positions and thus allow unambiguous classifications of the mechanisms.

Photochemical Reactions of Ligands in Transition-Metal Complexes

By Anatoli L. Poznyak* and Valeri I. Pavlovski

Three types of photochemical reaction of coordination compounds are well-known and have often been discussed: redox reactions, substitutions, and isomerizations. Less well known is a fourth type of reaction, which occurs fairly frequently: reaction of the ligands themselves. It is the purpose of this article to fill the corresponding gap in the photochemical literature and to summarize our current knowledge of such reactions and of their mechanisms and possible applications.

1. Introduction**

1.1. The Scope of this Article

It can be seen from two monographs[1,2] and from numerous reviews (particular attention should be drawn to Refs. [3–5]) that the irradiation of solutions of transition-metal complexes with visible or ultraviolet light can lead to various types of reaction: (1) a change of oxidation state of the central metal atom, possibly associated with subsequent decomposition of the complex and release of the ligands or their oxidation products (redox reactions); (2) substitution of one of the coordinated ligands by another ligand present in solution or by a solvent molecule (photosubstitution); (3) various isomerization processes (photoisomerization). According to this classification, which is accepted by most photochemists, the photochemistry of coordination compounds should be concerned only with the three above-mentioned reaction types. Examples of photochemical reactions in which the structure or stoichiometry of the coordinated ligand underwent significant changes, but the complex was in all other respects preserved, were regarded as exceptions; they were generally observed in complexes with very complicated organic ligands and were assigned to the realm of organic photochemistry. For this reason, such reactions, although mentioned in articles on photochemistry of coordination compounds (e.g., Refs. [5–7]), have not been extensively discussed. However, the last two decades have seen numerous examples of photochemical reactions of relatively simple ligands in metal complexes and it may fairly be claimed that such reactions occur often enough to merit detailed investigation as a fourth type of photochemical reaction of metal complexes. This prompted us to summarize the current knowledge of this fourth reaction type.

[**] Abbreviations used in this article: baeg, *N,N*-bis(2-aminoethyl)glycinate; bpy, 2,2′-bipyridyl; chxn, *trans*-1,2-diaminocyclohexane; dtma, diethylenetriamine-1-monoacetate; dtmp, diethylenetriamine-1-monopropionate; diars, *o*-phenylenebis(dimethylarsane); eddp, ethylenediamine-*N,N*-dipropionate; edta, ethylenediaminetetraacetate; edtp, ethylenediaminetetrapropionate; edtra, ethylenediaminetriacetate; edtrp, ethylenediaminetripropionate; en, ethylenediamine; nta, nitrilotriacetate; gly, glycinate; phen, 1,10-phenanthroline; salen, 2,2′-ethylenebis(nitrilomethylidyne)diphenolate; trien, triethylenetetramine; M, transition metal; L, monodentate ligand (e.g., NH_3) or half a bidentate ligand (e.g., 1/2en); LMCT, ligand-to-metal electron transition; S, solvent molecule.

1.2. What are Photochemical Reactions of Coordinated Ligands?

In order to describe the photochemical reactions of coordinated ligands, it is advantageous first to consider the radical pair model proposed by *Adamson* et al. to explain the photochemical reactions of the complexes $[L_5Co^{III}X]^{2\oplus}$ (X = Cl, Br, I, NO_2, SCN, etc.; L = NH_3) on irradiation by light in the region of the LMCT (ligand-to-metal charge-transfer) bands.[8,9] According to this model, the absorption of the light quantum leads to the homolysis of the Co-X bond, forming a radical pair, $\{L_5Co^{2\oplus}, X^{\odot}\}$, surrounded by solvent [Eq. (1)]. Subsequent light-independent pro-

$$[L_5Co^{III}X]^{2\oplus} \xrightarrow[LMCT]{h\nu} \{L_5Co^{2\oplus}, \overset{\odot}{X}\} \quad (1)$$

cesses can be described by Equations (2)–(4) (among others), from which it can be seen how redox reactions [Eq. (2)], substitutions [Eq. (3)], or linkage isomerization of an ambidentate ligand [Eq. (4)] can occur.

$$\{L_5Co^{2\oplus}, \overset{\odot}{X}\} \xrightarrow{+Solv.} [L_5Co^{2\oplus}(Solv.), \overset{\odot}{X}] \longrightarrow Co^{2\oplus} + 5L + Solv. + \overset{\odot}{X} \quad (2)$$
(Redox reaction)

$$\{L_5Co^{2\oplus}, \overset{\odot}{X}\} \xrightarrow{Solv.} [L_5Co^{2\oplus}(Solv.), \overset{\odot}{X}] \longrightarrow [L_5CoSolv.^{3\oplus}] + X^{\ominus} \quad (3)$$
(Solvation)

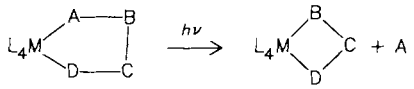
$$\{L_5Co^{2\oplus}, \overset{\odot}{X}\} \longrightarrow [L_5Co^{III}X]^{2\oplus} \quad (4)$$
(Recombination to re-form the starting complex or to form a complex in which the ligand X (e.g., NO_2, SCN) coordinates to the cobalt through a different donor atom.)

More details of this model can be found in Refs. [6, 10, 11]. Its extension to photochemical reactions of coordinated ligands is based on the assumption that the ligand X is composed of several atoms or groups of atoms (X = ABC) and that the ligand radical $ABC^{\odot}$ in the generated radical pair can either dissociate ($ABC^{\odot} \rightarrow A + BC^{\odot}$) or rearrange ($ABC^{\odot} \rightarrow BCA^{\odot}$). This extended radical pair model would then predict that LMCT excitation could also lead to the elimination of some ligand fragment A [Eq. (5)] or to the rearrangement of the ligand ABC [Eq. (6)].[12,13]

$$[L_5M(ABC)] \xrightarrow{h\nu} [L_5M(BC)] + A \quad (5)$$

$$[L_5M(ABC)] \xrightarrow{h\nu} [L_5M(BCA)] \quad (6)$$

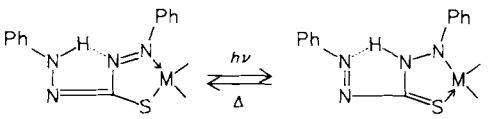
The contraction of a chelate ring (in complexes with polydentate ligands) may be regarded as a special case of elimination of a ligand fragment [Eq. (7)].



(7)

We may summarize these considerations in the statement that photochemical reactions of coordinated ligands should be understood as those photoinduced processes in which either some ligand fragment is eliminated, the remaining ligand moiety coordinating to the metal, or one of the coordinated ligands undergoes a substantial rearrangement (although retaining its overall stoichiometry) and possibly changes its coordination mode. The complex is, in the wider sense, preserved, although the oxidation state of the central metal atom may change.

The suggested model thus assumes that reactions of the type (5)–(7) occur via the excited LMCT state. It should however be mentioned that photochemical reactions of the ligands may occur in certain circumstances when the irradiation is in the region of the intraligand absorption bands. Well-known examples of such reactions are the photochromic isomerizations of 1,5-diphenylthiocarbazone complexes of a series of divalent metals [Eq. (8); the remaining ligands have been omitted for clarity].[1,4,5]



(8)

Equation (8) shows that the photolysis changes the structure of the ligand and thus, necessarily, its mode of coordination to the central metal atom, whereas the stoichiometry of the starting complex and the oxidation state of the central metal atom remain unchanged. Further examples of photochemical reactions of ligands are the *cis–trans* isomerization of dienes coordinated to tungsten(0) carbonyl complexes and the photoinduced rearrangements of ligands in some ferrocene derivatives.[5] However, the reactions proceeding from excited LMCT states according to Equations (5)–(7), in general describable as photoelimination of ligand fragments, are much more varied and interesting. Such reactions (among which photochemical transformations of many carboxylato, aminocarboxylato, ethylenediamine, and azido complexes may be numbered) will play a major role in the following discussion.[*] Analogously to the findings of *Chapman* concerning the photofragmentation of organic substances,[14] it would be expected that elimination of small fragments in the form of stable molecules with large heats of formation (e.g., N_2, CO_2, CO) should predominate. Here we shall discuss only well-studied photochemical reactions of coordinated ligands and shall offer new interpretations of some early work from a modern standpoint.

This article is organized according to the nature of the photolyzed ligand. Most of the examples presented are concerned with cobalt(III) complexes, because the charge-transfer photochemistry of cobalt(III) has been the subject of the most study.

2. Elimination of Molecular Nitrogen in the Photolysis of Azido Complexes

One of the first photoelimination reactions to be discovered was the so-called nitrene pathway in the photolysis of azido complexes.[15] According to Refs. [16–18], the primary step of the photolysis is the loss of a nitrogen molecule from the azido complex, whereupon other species present in solution can add to the nitrene intermediate to form stable end products [Eq. (9)–(11)].

$$[(NH_3)_5Ir^{III}(N_3)]^{2\oplus} \xrightarrow[+H^{\oplus},\,HCl]{h\nu} [(NH_3)_5Ir^{III}(NH_2Cl)]^{3\oplus} + N_2 \quad (9)$$

$$[(CO)_5W^0(N_3)]^{\ominus} \xrightarrow[+CO]{h\nu} [(CO)_5W^0(NCO)]^{\ominus} + N_2 \quad (10)$$

$$[(diars)_2ClRu^{II}(N_3)] \xrightarrow[+O_2]{h\nu} [(diars)_2ClRu^{II}(NO_2)] + N_2 \quad (11)$$

The nitrene pathway has also been demonstrated in the thermal decomposition of azido complexes.[15] It had even earlier been recognized that the thermal decomposition of azido complexes of metals with stable oxidation states $+n$ and $+(n+2)$ led to the formation of nitrido complexes [Eq. (12)]. It was later shown[20,21] that a similar process can

$$[M(N_3)]^{(n-1)\oplus} \xrightarrow{\Delta} [MN]^{(n-1)\oplus} + N_2 \quad (12)$$

be realized photochemically, e.g., with chromium(III) azido complexes of the type $[L_5Cr(N_3)]^{2\oplus}$ [Eq. (13)]. Reaction

$$[L_5Cr^{III}(N_3)]^{2\oplus} \xrightarrow{h\nu} [L_5Cr^{V}N]^{2\oplus} + N_2 \quad (13)$$

type (13) thus allowed the first preparation of a chromium(V) nitrido complex, $[CrN(salen)\cdot H_2O]$, which was obtained in crystalline form.[22] Other authors then used the photochemical method to prepare chromium(V) and manganese(V) nitrides, the structures of which were confirmed by X-ray structure analysis.[23,24] Reaction (13) may thus be considered as a "nitride pathway" for the photolysis of azido complexes (in contrast to the "nitrene pathway"), and the process may be generalized as Equation (14).

$$[L_5M^{n\oplus}(N_3^{\ominus})] \xrightarrow{h\nu} [L_5M^{(n+2)\oplus}(N^{3\ominus})] + N_2 \quad (14)$$

Reaction (14) also has the preparative advantage that it may be used to obtain nitrido complexes that are thermally unstable, because photolysis (unlike the other preparative methods) can be employed at low temperature if necessary.

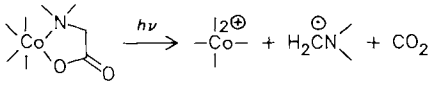
It has been claimed in several publications[25–28] that the photolysis of $[Cr(NH_3)_5N_3]^{2\oplus}$ with light of wavelength 313 nm leads to the formation of $Cr^{2\oplus}$ ions or coordinated nitrenes. The evidence presented in Ref. [22] shows convincingly, however, that such claims are based on incorrect

[*] Numerous photoelimination reactions are also known for organometallic complexes. This article deliberately omits discussion of the photochemical reactions of ligands in organometallic complexes, because this fascinating photochemical problem has already been reviewed in depth (see, e.g., G. L. Geofroy, M. S. Wrighton: *Organometallic Photochemistry*, Academic Press, New York 1979 or H. G. Alt, *Angew. Chem. 96* (1984) 752; *Angew. Chem. Int. Ed. Engl. 23* (1984) 877).

interpretation of the experimental results. There is no doubt that the photolysis of chromium(III) azides always leads to the formation of chromium(V) nitrido species, even if these are not isolable in the solid state.

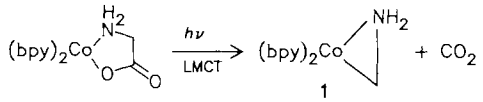
3. Photodecarboxylation and Chelate Ring Contraction of Aminocarboxylato Complexes

It is well known that some metal carboxylates can be thermally decarboxylated to form compounds containing σ M–C bonds.[29] Organomercury compounds can also be prepared by photochemical decarboxylation.[30] The photochemical synthesis of σ-organometallic complexes of transition metals, on the other hand, remained unknown for a long time because redox processes had generally been assumed for transition-metal carboxylates (despite the fact that the photolysis of some cobalt(III) oxalates involved organocobalt intermediates.[31] It was also accepted as a fact that cobalt(III) α-aminocarboxylates decomposed to $Co^{2\oplus}$ ions and ligand radicals (with loss of CO_2) in the primary photolytic step [Eq. (15)].[6]



(15)

Our understanding of the photochemical processes of aminocarboxylato complexes underwent a dramatic change when an organocobalt compound was obtained by photodecarboxylation of the corresponding aminocarboxylate.[32–35] The starting materials were cobalt(III) mixed-ligand complexes containing one bidentate glycinate ion and two molecules of bipyridyl or phenanthroline. The X-ray structure analysis of a single crystal of the photolysis product of $[Co(bpy)_2(gly)]^{2\oplus}$ revealed the presence of a three-membered Co–C–N ring.[35] It was thus shown that the primary process of the photolysis consisted of the elimination of carbon dioxide and the simultaneous contraction of the (originally five-membered) glycinate ring to a three-membered ring [Eq. (16)], whereas products corresponding to Equation (15) are formed via photoinduced or thermal decomposition of the primary photolysis product. It should be mentioned that the crystal structure analysis of **1** revealed only one of the presumably two hydrogen atoms at the nitrogen atom of the aminomethyl ligand;[36] however, additional spectroscopic evidence (e.g., ^{1}H-NMR) indicates that both hydrogens are present.[34]

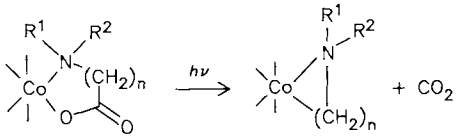


(16)

1

Similar organocobalt compounds, with a three-membered ring substituted at nitrogen, have recently been isolated as crystalline solids from the photodecarboxylation of complexes with ligands such as edta, dtma, and baeg.[37,38] The ^{1}H-NMR spectrum of the decarboxylation product of the baeg complex was easily interpreted and indicated that all the protons of the starting complex and also the mutual orientation of its chelate rings had been preserved.[38]

The photochemical contraction of aminocarboxylate chelate rings is also observed for rings of differing sizes; investigations of complexes with six- and seven-membered rings have demonstrated the validity of the generalized reaction shown in Equation (17), where n = 0, 1, 2 and



(17)

R^1, R^2 = hydrogen or other substituents. The extension of this principle to the case n = 3 has been prevented by the difficulty in preparing the starting complex with an eight-membered ring.

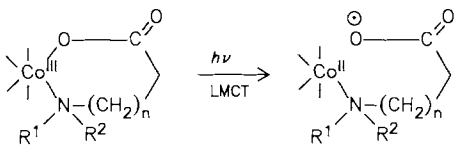
A comparison of the members of a homologous series of cobalt(III) complexes, each containing two ethylenediamine molecules and one bidentate anion of the amino acids glycine, β-alanine, and γ-aminobutyric acid, provides interesting information on the stability of the metallacyclic photolysis products as a function of chelate ring size. Consistent with Equation (17), the photodecarboxylation of these complexes leads to metallacycles with corresponding three-, four-, or five-membered chelate rings, namely, $[(en)_2\overline{CoCH_2NH_2}]^{2\oplus}$ **2**,[39] $[(en)_2\overline{CoCH_2CH_2NH_2}]^{2\oplus}$ **3**,[37] and $[(en)_2\overline{CoCH_2CH_2CH_2NH_2}]^{2\oplus}$ **4**.[40] In contrast to the photolysis product of $[Co(bpy)_2(gly)]^{2\oplus}$, these products do not contain π-acceptor ligands, which are known to "stabilize" M–C σ bonds,[41] so that their stability is mainly dependent on the chelate ring strain. The photolysis product from **2** contains a highly strained three-membered ring and is thermally not very stable in solution; it is impossible to isolate in the solid state.[39] The products **3** and **4**, on the other hand, possess less strained four- and five-membered rings and are correspondingly more stable; they can be isolated in crystalline form.[36,42] X-ray structure analysis confirms the presence of the four- and five-membered rings.

Stable organocobalt compounds with four-membered chelate rings were recently obtained by photodecarboxylation of a series of cobalt(III) complexes containing various aminopropionate ligands (edtp, eddp, and dtmp); their structures were also confirmed by X-ray analysis.[43–46]

It was once claimed that the metalation of nitrogen-containing donor ligands was impossible if the resulting chelate ring contained less than five atoms.[47] The above examples show that the exploitation of reactions of type (17), which in this case can be described as cyclometalating photodecarboxylations, can successfully lead to numerous cyclometalated complexes, including those with three- and four-membered chelate rings. Most known cyclometalated complexes contain an *ortho*-substituted phenyl group, so they are often termed *ortho*-metalated complexes.[47,48] A further advantage of the photochemical method is that it is also applicable with simple aminoalkyl ligands. Another point worth mentioning is that reactions of type (17) can be carried out in aqueous solution in the presence of air, in contrast to most previously known cyclometalation reac-

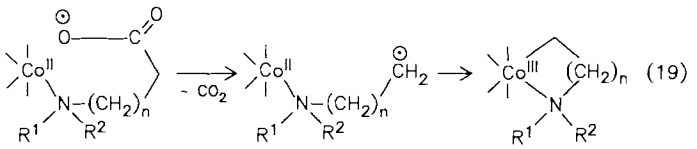
tions, which often had to be carried out using organolithium compounds.[49]

The photochemical cyclometalation reactions discussed here can be explained on the basis of the extended radical pair model (Section 1.2). We believe that the excitation of the LMCT state of the cobalt(III) aminocarboxylates leads directly to the formation of a radical pair, **5**, in which the cobalt(II) ion is bonded to the ligand radical via the nitrogen atom of the amino group [Eq. (18)]. Since alkanecarboxyl radicals are extremely unstable with respect to decomposition to carbon dioxide and the corresponding alkyl radical,[50] **5** loses carbon dioxide and is converted into a new radical pair; the subsequent reoxidation of the cobalt(II) ion by the aminoalkyl radical results in formation of the cyclometalated cobalt(III) compound [Eq. (19)].



(18)

5



(19)

5

A natural question arising at this point is whether the reaction scheme proposed here is the only deactivation route of the excited LMCT state or whether other processes (e.g., the primary redox process) occur parallel to it. It has been shown[51] that the photoinduced decomposition of $[Co(edta)]^{\ominus}$ involves organocobalt intermediates to the extent of at least 80%, and it might be assumed that this figure really lies nearer to 100%. The photochemistry of cobalt(III) aminocarboxylates is thus the chemistry of the organocobalt products of the primary decarboxylation process. For this reason, a knowledge of the properties of such products is of great importance.

In contrast to the starting materials, the decarboxylation products of cobalt(III) aminocarboxylates are generally stereochemically labile in solution at room temperature, and are thus subject to rapid isomerization or racemization. An interesting exception is furnished by the photodecarboxylation product of $[Co(baeg)(phen)]^{2\oplus}$, in which the geometric configuration of the starting complex is also preserved in solution.[38] The photodecarboxylation products decompose via a spontaneous redox process, apparently by formation of reduced cobalt(II) ions and ligand radicals (homolysis of the Co-C σ bond). In some cases the decarboxylation products show such a marked tendency to undergo redox decomposition that they can only be detected by electronic or CD spectra following photolysis of the solutions at low temperature. Sometimes the products can be chromatographically isolated.[13,39,51-59] It has also been shown that organocobalt products are involved in bimolecular redox reactions in which the starting complexes are reduced.[51,53] However, if the thermal decomposition of the primary decomposition products was restricted to redox processes, this would not alter the mechanism assumed in the literature for the photolysis of cobalt(III) aminocarboxylates.

The photodecarboxylation products of cobalt(III) aminocarboxylates are doubtless also subject to hydrolysis (solvolysis) involving no change of the oxidation state of the central metal atom. This possibility was investigated for photodecarboxylation products isolated in the solid state. For instance, the hydrolysis of the decarboxylation product of $[Co(CN)_2(edta)]^{3\ominus}$ leads to cobalt(III) complexes with edtra as ligand and differing cyanide content, whereas, for the photolysis product of $[Co(edtp)]^{\ominus}$ in solution, a neutral complex, $[Co(edtrp)(H_2O)]$, and a series of unidentified anionic cobalt(III) complexes were demonstrated. This shows that the formation of $[Co(edtrp)(H_2O)]$ by photolysis of $[Co(edtp)]^{\ominus}$, which had already been reported,[60,61] is also to be ascribed to hydrolysis of the primary photodecarboxylation product.

The role of hydrolytic decomposition of primary photodecarboxylation products is clear from the example above, the photolysis of $[Co(edta)]^{\ominus}$. It has been shown[62,63] that the photodecomposition of this complex in neutral aqueous solution at room temperature largely consists in deacetylation [Eq. (20)], whereas the redox decomposition accounts for at most 25% of the entire process. For cobalt(III) complexes with edta and mono- or bidentate ligands such as $Cl^{\ominus}$, $NO_2^{\ominus}$, $CN^{\ominus}$, NH_3, or en, a deacetylation was also observed (as well as the redox decomposition), which was accompanied by a labilization of the second ligand X [Eq. (21)].

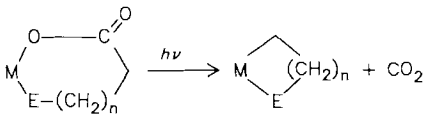
$$[Co^{III}(edta)]^{\ominus} \xrightarrow{h\nu} [Co^{III}(edtra)(H_2O)] + CO_2 + \text{other products} \quad (20)$$

$$[Co^{III}(edta)(X)] \xrightarrow{h\nu} [Co^{III}(edtra)(H_2O)] + X + \text{other products} \quad (21)$$

Photodeacetylation has also been observed for copper(II) complexes of nta[64] or edta.[65]

4. Photolysis of Oxalato Complexes

It is logical to assume that the photodecarboxylation reaction takes place not only for cobalt(III) complexes with nitrogen-containing chelate ligands, but also for complexes of other metals, for other heteroatoms in the chelate ring, and for rings with a second carboxyl group (oxalato or malonato complexes) [Eq. (22), where E represents a heteroatom (N, P, S, As, etc.) or a carboxyl group]. Postulations of such a process (based to varying extents on ex-

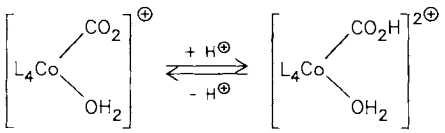


(22)

perimental results) have been published for photolysis of malonato complexes of cobalt(III),[66] manganese(III),[67] and copper(II);[68,69] iron(II) and manganese(III) complexes of ethylenediaminetetraacetate or 1,2-cyclohexanediaminetetraacetate;[70,71] copper(II) complexes with α-hydroxy acids and amino acids;[68,72,73] and a series of transition-metal oxalato complexes.[31,68,74-77]

Here we shall discuss only the photolysis of oxalato complexes, because this photochemical system has proved to be extremely interesting, yet difficult to investigate, and has fascinated photochemists for some decades. So many different, in some cases contradictory, theories as to the nature of the primary photolysis products have been put forward that there is no clear general understanding of the photolysis of such complexes. However, it is our view that the results in the literature (especially those of *Endicott*, *Hoffman*, and co-workers[31,74]) are sufficient to construct a uniform reaction scheme for the photolysis of oxalato complexes.

The so-called long-lived intermediate photolysis products of cobalt(III) complexes of the $[L_4Co(C_2O_4)]^{2\oplus}$ type, where L_4 represents two en or four NH_3 ligands, are almost certainly cobalt(III) complexes with monodentate ligands $CO_2^{2\ominus}$ or the corresponding protonated forms with $CO_2H^{\ominus}$, which are related by the acid-base equilibrium (23). A characteristic of the protonated intermediate



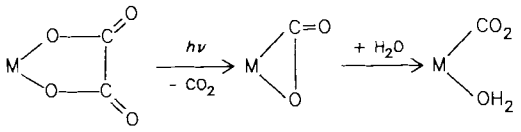
(23)

$[(en)_2Co(CO_2H)(H_2O)]^{\oplus}$ is the $^1A_{1g} \rightarrow {}^1T_{1g}$ band in the electronic spectrum, which is not split and which, in comparison with the corresponding band ($\lambda_{max} = 500$ nm) of the starting complex $[(en)_2Co(C_2O_4)]^{\oplus}$, is strongly shifted to shorter wavelength (421 nm). Similar intermediate photolysis products have been identified for many other cobalt(III) oxalato complexes.[75]

In this context it should be mentioned that a series of relatively stable transition-metal complexes involving the fragment $[M(CO_2)]^{n\ominus}$ have recently been prepared. They are generally regarded as complexes of carbon dioxide, although the formal oxidation state of the central metal atom has not been definitively assigned. X-ray structure analyses of such complexes have shown that the carbon dioxide can be monodentate (η^1-coordination) or bidentate (η^2-coordination).[78-82]

In the photolysis of manganese(III) and copper(II) oxalato complexes, intermediates were observed that presumably contain the fragments $[Mn^{III}(CO_2)]^{\oplus}$ and $[Cu^{II}(CO_2)]$.[68,76,77] We believe that the intermediates observed in the flash photolysis of solutions of $[Fe(C_2O_4)_3]^{3\ominus}$[6,83] and the continuous irradiation of frozen solutions of the same complex[84] may also be regarded as carbon dioxide complexes.

As regards the mechanism of formation of these intermediate photolysis products, it may be assumed that they are formed directly from the excited LMCT state by elimination of carbon dioxide [Eq. (24)], whereby the complex



(24)

initially formed (with bidentate carbon dioxide) is converted into a complex with monodentate carbon dioxide and simultaneously aquated. We do not consider it necessary to invoke an "excited ligand state L*"[74] to explain the formation of the intermediate $[M(CO_2)]^{n\oplus}$; such a state was proposed to cause an intramolecular sensitization of the coordinated oxalate ion and to be responsible for the heterolysis of the C-C bond.

For cobalt(III) complexes, the formation of the product $[L_4Co(\eta^2\text{-}CO_2)]^{\oplus}$ in the first photolysis step, and its conversion to $[L_4Co(\eta^1\text{-}CO_2)]^{\oplus}$, can be spectroscopically confirmed by the existence of two distinct forms of the photolysis product of $[Co(C_2O_4)_3]^{3\ominus}$. One of these forms[85] is only stable to 220 K and is characterized (like any low-spin cobalt(III) complex) by two d-d bands, the lower-energy band lying at 505 nm (cf. 600 nm for the starting complex). The other form can only be observed at lower temperatures (163 K); at ca. 200 K it is irreversibly converted into the first form. The electronic spectrum of the second form also shows the characteristics of low-spin cobalt(III) complexes, but the lower-energy band is split into two components at 510 and 633 nm. We believe that this second form corresponds to the complex with η^2-coordinated carbon dioxide, the d-d splitting being due to the low symmetry of this complex. The first, higher-temperature form is thus assignable as the complex with η^1-coordinated carbon dioxide. Finally, it should be noted that a further increase in temperature leads to the redox decomposition of these intermediates, with formation of the products typical of the room temperature photolysis.

5. Decarboxylation and Ligand Rearrangement in the Photolysis of Carboxylato Complexes

The work of *Endicott*, *Hoffman*, and co-workers[31,74] also showed that cobalt(III) complexes with monodentate oxalato ligands, e.g., $[(NH_3)_5Co(C_2O_4H)]^{2\ominus}$, underwent photodecarboxylation with formation of protonated carbon dioxide complexes [Eq. (25), $L_5 = (NH_3)_5$, $(en)_2(H_2O)$].

$$[L_5Co(O_2CCO_2H)]^{2\oplus} \xrightarrow{h\nu} [L_5Co(CO_2H)]^{2\oplus} + CO_2 \qquad (25)$$

It was therefore to be expected that other complexes with monodentate carboxylato ligands would be photolyzed to corresponding σ-organometallic complexes. The flash photolysis of solutions of acetato(pentaammine)cobalt(III) and related complexes, carried out by *Endicott*, *Hoffman*, and co-workers seemed to indicate a simple redox decomposition.[86,87] Our results, however, show that the photolysis of (pentammine)carboxylato complexes leads to organometallic complexes stable at low temperature, and thus

that Equation (26), where R indicates an alkyl or alkylaryl group, is valid for a series of complexes.[12,88]

$$[L_5Co(O_2CR)]^{2\oplus} \xrightarrow{h\nu} [L_5CoR]^{2\oplus} + CO_2 \quad (26)$$

A similar photochemical process has been assumed for copper(II) carboxylates in a series of publications [Eq. (27)].[68,89-91]

$$[Cu(O_2CR)]^{\oplus} \xrightarrow{h\nu} [CuR]^{\oplus} + CO_2 \quad (27)$$

Since the M–C bond in σ-organometallic complexes is thermally labile (especially in the absence of stabilizing π-acceptor ligands) it is understandable that the products in reactions (25) to (27) are unstable at room temperature, decomposing to reduced metal ions and alkyl radicals. It is nevertheless possible to utilize this reaction for the preparation of σ-organometallic complexes. *Roche* and *Endicott* photolyzed cobalt(III) carboxylates in the presence of cobalt(II) complexes of N_4 chelating ligands capable of stabilizing M–C σ bonds; they obtained a series of stable cobalt(III) alkyl complexes that had clearly arisen by oxidation of the cobalt(II) complexes by alkyl radicals formed from the homolysis of the Co–C bond.[92,93] An alternative mechanism would be a ligand exchange between the primary photolysis product $[L_5CoR]^{2\oplus}$ and the kinetically labile cobalt(II) complex.

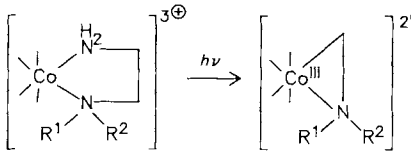
Cobalt(III) formato complexes, e.g., (pentaammine)formatocobalt(III) complexes, display interesting behavior on photolysis. *Hoffman* and co-workers[31,94] have discovered a reaction of such complexes that can be regarded as a photoinduced ligand rearrangement [Eq. (28)]. It is proba-

$$[L_5Co(OC(O)H)]^{2\oplus} \xrightarrow{h\nu} [L_5Co(C(O)OH)]^{2\oplus} \quad (28)$$

ble that a migration of the labile hydrogen atom in the radical $HC(O)\overset{\odot}{O}$ can take place during the lifetime of the radical pair $(HC(O)\overset{\odot}{O}\rightarrow\overset{\odot}{C}(O)OH)$, which would explain why the photoinduced ligand rearrangement occurs for formato complexes but not for other carboxylato complexes. Furthermore, it cannot be ruled out that a decarboxylation [Eq. (26)] takes place parallel to the ligand rearrangement in the photolysis of formato complexes, but the putative products, the hydrido complexes $[L_5CoH]^{2\oplus}$, have never been detected.

6. The Elimination of Ligand Fragments in the Photolysis of Ethylenediamine Complexes

An interesting case of photoelimination was discovered in the photolysis of cobalt(III) complexes of ethylenediamine.[39] Irradiation in the LMCT region induces a contraction of the five-membered chelate ring to a three-membered ring, with elimination of the $CH_2NH_2^{\oplus}$ ion [Eq. (29)]. The photolysis products should thus be identical with those of the photodecarboxylation of analogous α-aminocarboxylato complexes (i.e., those with the same number of carbon atoms in the chelate ring) [compare Eq. (16) with Eq. (29)]. This has indeed been observed for some



(29)

pairs of complexes, namely, $[Co(en)_3]^{3\oplus}$ and $[Co(en)_2(gly)]^{2\oplus}$,[39] $[Co(trien)(phen)]^{3\oplus}$ and $[Co(dtma)(phen)]^{2\oplus}$,[37] and $[Co(bpy)_2(en)]^{3\oplus}$ and $[Co(bpy)^2(gly)]^{2\oplus}$.[34] Flash photolysis of glycinato and ethylenediamine complexes of copper(II) occurs via the same intermediates, which have been identified as copper complexes with C-bonded methylamine.[72]

The intermediate photolysis product of the complex $[Co(en)_3]^{3\oplus}$, formed in an elimination reaction, is sufficiently stable to allow its chromatographic isolation in solution. It undergoes parallel redox and hydrolysis processes, the relative proportion of the reactions being pH-dependent. The chemically determinable concentration of $[Co(H_2O)_6]^{2\oplus}$ ions in the photolyzed solution of $[Co(en)_3]^{3\oplus}$ is of course dependent on the time elapsed since the onset of irradiation, if this is comparable with the half-life of the intermediate. This explains why the quantum yield of the photoreduction is pH-dependent and why different authors have obtained different quantum yields.[95] It is interesting to note that no such pH-dependence has been observed for the quantum yield of the photoreduction of the $[Co(chxn)_3]^{3\oplus}$ complex, in which a chelate ring contraction is rendered impossible by the nature of the diamine ligand.[96]

The photolysis of ethylenediamine complexes can be explained, analogously to that of aminocarboxylato complexes, using the extended radical pair model.[39] It is assumed that the primary radical pair generated by irradiation in the LMCT region, $[Co^{II}-NH_2CH_2CH_2\overset{\odot}{N}H_2]$, undergoes homolysis of the C–C bond, whereupon the secondary radical pair $[Co^{II}-NH_2\overset{\odot}{C}H_2]$ recombines to form a cobalt(III) complex with a Co–C–N three-membered ring. It is well known from radiochemistry, however, that γ-irradiation of amines leads to radical cations that lose a proton, thereby being converted into uncharged radicals [Eq. (30)]. We have observed a similar process in a hexacyano-

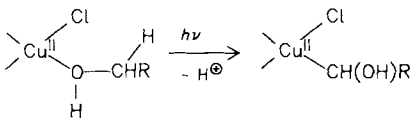
$$RNH_2 \xrightarrow[-e^{\ominus}]{\gamma \text{ or } h\nu} RNH_2^{\odot\oplus} \longrightarrow \overset{\odot}{R}NH + H^{\oplus} \quad (30)$$

ferrate(III)-sensitized oxidation of ethylenediamine.[97,98] The breaking of the C–C bond in the photolysis of ethylenediamine complexes can clearly be ascribed to the influence of the central metal atom on the reactivity of the ligand.

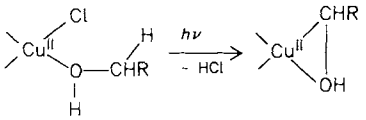
7. Further Elimination Reactions of Complexes

One further example of a photochemical reaction localized at a ligand can be found in the photochemistry of chlorocopper(II) complexes in organic solvents. The photolysis of such complexes occurs via intermediate products, which were first observed by us[99] and later investi-

gated in detail by *Bazhin* and co-workers.[100–104] These intermediates arise on excitation of chlorocopper(II) complexes in the region of the $Cl \rightarrow Cu^{II}$ CT bands; in alcohols they take the form of copper(II) α-hydroxyalkyl derivatives (*Bazhin* and co-workers described them as copper(I) complexes of α-hydroxyalkyl radicals). The intermediates can be assigned one of the two structures presented in Equations (31) and (32). Although it is not yet clear which route is in fact realized, the formation of these intermediates must be regarded as an elimination.



(31)



(32)

Another reaction that can be regarded as an elimination is the formation of a ruthenium(IV) *N,N*-dimethylthiocarboxamido complex in the benzophenone-sensitized photolysis of tris(*N,N*-dimethyldithiocarbamato)ruthenium(III) in chloroform [Eq. (33)].[105]

(33)

8. Conclusions and Prospects

In this article we have presented practically all known examples of photochemical reactions that take place from excited states of the LMCT type and that are localized at relatively simple ligands. Since such reactions are known for a number of complexes (M = Co, Fe, Cu, Cr, Mn, etc.; L = azide, carboxylate, aminocarboxylate, amine), this reaction type is presumably widespread in the photochemistry of coordination compounds. Our sketchy knowledge of the photochemical reactions of ligands is to be attributed to the fact that this area of photochemistry still represents practically "virgin territory." Such reactions—in contrast to other types of photoreaction—have been investigated only for a limited range of metals and ligands; in spite of this it is already possible to utilize them for certain preparative purposes. The photodecarboxylation of aminocarboxylato complexes, for example, allows the synthesis of metallacyclic compounds with simple chelating ligands that would not be attainable using conventional chemical methods. The photoelimination of molecular nitrogen from azido complexes is a simple method of preparing transition-metal nitrides. Particulary promising in this context are photochemical experiments with transition-metal complexes containing bi- or polydentate ligands with various combinations of donor atoms or groups (e.g., N-O, N-S, N-P, S-COO, P-COO, As-COO, S-S); it may be expected that the photolysis of such complexes will proceed via the elimination of various ligand fragments to yield novel metallacyclic complexes. Furthermore, it cannot be ruled out that some photoelimination or photorearrangement reactions might form unusual organic substances as ligands that could be isolated in pure form from their complexes. With a few exceptions (e.g., aliphatic hydrocarbons) almost all classes of organic compounds can be regarded as potential ligands; this would suggest that new kinds of photochemical reactions of coordinated ligands may be discovered in the future.

Cyclobutanones and Cyclobutenones in Nature and in Synthesis

New Synthetic Methods (71)

By Daniel Belluš* and Beat Ernst*

Dedicated to Professor Vladimir Prelog

The chemical reactivity of cyclobutanones and cyclobutenones is considerably different from that of cyclic ketones with larger rings; this is due to their ring strain of ca. 25 kcal/mol. Detailed knowledge regarding the influence of this ring strain on regio-, chemo- and stereoselective transformations of four-membered ring ketones is of particular importance. While several reactions, such as the Baeyer–Villiger reaction, the Beckmann and Favorskii rearrangements and *cine*-substitution often proceed in a manner specific to four-membered rings, other reactions such as the facile ring-opening by nucleophiles, the rearrangement to tropolones, the thermal [2+2]-cycloreversion, the isomerization to vinylketenes and the photochemical formation of oxacarbenes are rather specific to cyclobutanones and cyclobutenones. The remarkable selectivity and the excellent yields of such transformations, which are favored or caused by ring strain as the inherent driving force, offer the synthetic chemist fascinating possibilities for the development of new strategies for the synthesis of natural products and biologically active compounds.

1. Introduction

Four-membered ring compounds have definitely developed from academic curiosities to excellent tools in organic synthesis.[1] Cyclobutanones and cyclobutenones are among the most readily available derivatives of cyclobutane. This applies in particular to their substituted derivatives: though a number of syntheses have recently been developed, it is not yet possible to obtain the unsubstituted four-membered ring ketones[2] simply and cheaply in larger quantities.

While up until the mid-1970s interest was focussed on methods for the preparation of cyclobutanones[3,4] and cyclobutenones,[5] the last decade has seen a rapid development of their application as synthetic intermediates. This is certainly no coincidence, because they are in many ways remarkable compounds. Apart from the ready availability already mentioned, their large ring strain,[6] the high electrophilicity of the carbonyl carbon atom, the puckering of the cyclobutanone caused by the repulsion of substituents at C2 and C4,[7] and the high photochemical reactivity all offer interesting preparative and mechanistic aspects. The purpose of this review article is to provide a detailed survey of the synthetic transformations of cyclobutanones and cyclobutenones with particular respect to their regio-, chemo- and stereospecific peculiarities. The cited characteristic examples will take into account in particular the use of cyclobutanones and cyclobutenones as intermediates in the synthesis of naturally-occurring target molecules. Apart from a few important examples from the older literature, only publications which have appeared in the last twelve years will be considered.

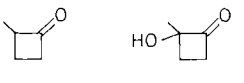
For reasons of space it is however not possible to exemplify the syntheses of cyclobutanones and cyclobutenones by formula schemes in all cases. They will be shown only if the method of preparation is new, i.e. it has not been mentioned in previous review articles (e.g. syntheses of **13**, **16**, **124**, **195**, **196**, **1** (from **269**), **274**, **279**, **305**, **321**, **357**, and **417**). It should be mentioned that in the articles cited here and in other papers an enormous amount of spectroscopic, chiroptical and physical data on four-membered ring ketones is published. It would be worthwhile collecting, summarizing, and evaluating these data, since no recent review of this type exists: however, this task would exceed the scope of the present review.

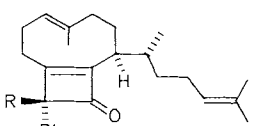
2. Naturally Occurring Cyclobutanones and Cyclobutenones

Numerous compounds with small rings, which occur in nature in an optically active form (e.g. chrysanthemate esters, penicillins, cephalosporins, pinenes) still provide an important (although no longer the exclusive) source for the syntheses of structurally related small ring derivatives. They are used in particular as the starting materials when a product with a certain absolute configuration is required. In contrast, the naturally-occurring four-membered ring ketones presently known (**1**–**4**, **7**, **11**, and **18**) are of no preparative importance, as only their constitution has been described.



1

2



3: R = OCOMe, R' = H
4: R = H, R' = OCOMe

Thus for example no optical rotation values for the simple cyclobutanones **1** and **2** (isolated from the low-molec-

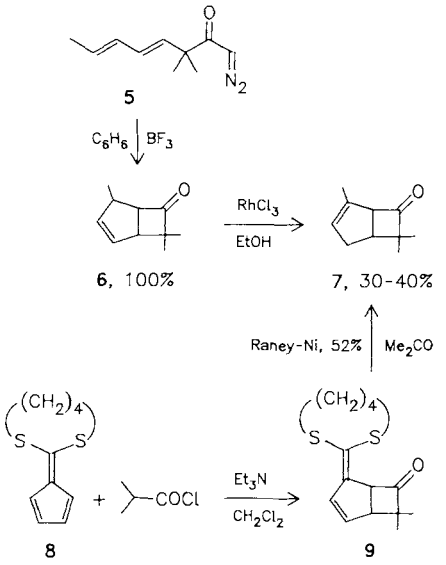
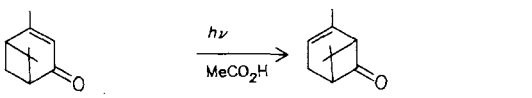
ular latex fraction of the rubber tree *Hevea brasiliensis*[8]), or for the diterpenes acetylcoriacenone **3** and isoacetylcoriacenone **4** (isolated from the brown sea-alga *Pachydictyon coriaceum*[9]) are known.



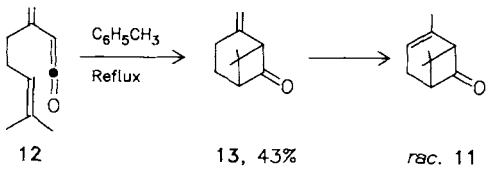
It is interesting that the monoterpene filifolone **7** occurs in nature in both enantiomeric forms. The (1*S*,5*S*)-isomer was isolated from *Artemisia filifolia* Torrey, a sand sage from Arizona, and the (1*R*,5*R*)-isomer from *Ziera smithii* Andrews from Australia.[10,11] **7** was prepared from geranic acid four years prior to its discovery as a natural product.[12] Syntheses from isomeric monoterpenes followed: by photolysis from verbenone **10**,[13] by acid-catalyzed rearrangement of chrysanthenone **11**[14] and by $AlCl_3$-catalyzed cyclization from ocimenone.[15] The (±)-filifolone **7** has recently been prepared by total synthesis starting either from the diazoketone **5**[16] or from 6,6-(tetramethylenedithio)fulvene **8**.[17]

The monoterpene chrysanthenone **11** was isolated in 1957 from the flowers of *Chrysanthemum sinese* Sabin.[18] Its absolute configuration appears to be still unknown, although both enantiomers have now been obtained photochemically from (+)- and (−)-verbenone **10** (though not with clearly defined optical purity).[13]

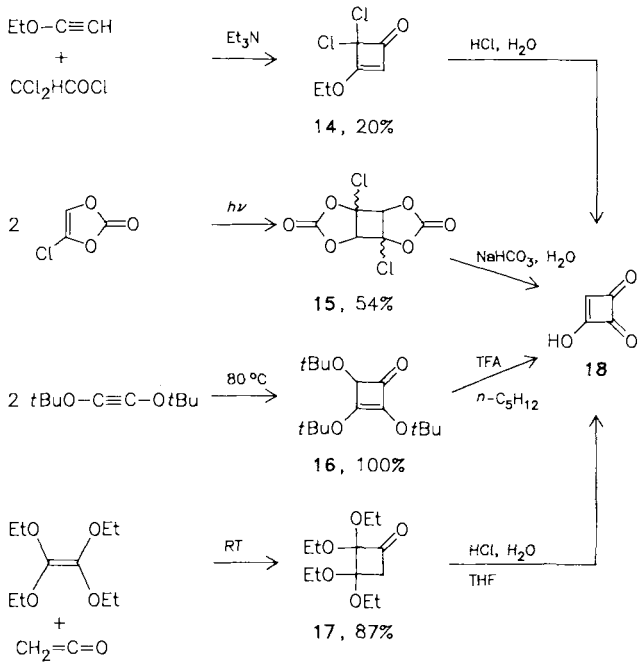


Kulkarni and *Snider*[19] have recently described a simple route to the racemic chrysanthenone **11** via an intramolecular [2+2]-cycloaddition of the vinylketene **12** (from geranyl chloride) to give **13**, followed by a double bond shift.

The mycotoxin moniliformine isolated in 1973 from the maize mold *Fusarium moniliforme*[20] and in 1974 from *Giberella fujikuroi*[21] has a structure which is remarkably simple and unusual for a natural product. It is the potassium salt of **18**. Moniliformine and particularly its esters show



growth-regulating effects on various types of plant. Several syntheses of the strong acid **18** ($pK_a = 0.0 \pm 0.05$[5e,23]) have been described; their common feature is the formation of a hydrolyzable four-membered ring precursor via a [2+2]-cycloaddition (e.g. **14**,[21] **15**,[24] **16**,[25] and **17**[23]).



The principle of the latter synthesis, i.e. a [2+2]-cycloaddition of a ketene to a tetraalkoxyethylene as the ring-forming step, can be used for the synthesis of a large series of moniliformine derivatives: thus 2-substituted moniliformines can be prepared from alkyl-, aryl- and vinylketenes;[26] the use of alkoxy-, acetoxy- and chloroketenes allows a very simple synthesis of the dermatologically active[27] squaric acid (2-hydroxy-**18**)[28] or [1-^{14}C]-squaric acid[29] in total yields of up to 90%.

The biosynthesis of moniliformine was recently studied:[30] sodium [2-^{14}C]-acetate was shown to be a precursor of **18**.

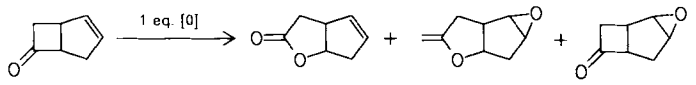
3. Ring Enlargements of Cyclobutanones and Cyclobutenones

3.1. γ-Butyrolactones

γ-Butyrolactones are used a great deal as intermediates in synthesis. The Baeyer-Villiger oxidation[31] of cyclobutanones represents an important synthetic route to γ-butyrolactones. A large number of oxidizing agents have already been used for this transformation: H_2O_2;[32] H_2O_2/AcOH;[33] H_2O_2/NaOH;[32,34] NaOBr;[34a] NaOCl/$RuCl_3$;[35] $Me_3SiOOSiMe_3/SnCl_4$[36] or Me_3SiOTf (Tf = tri-

fluoromethanesulfonate);[37] *t*BuOOH/NaOH;[38] *m*-chloroperbenzoic acid;[4b, 15a, 39] trifluoroperacetic acid;[40] alkoxyperformic acid.[39d] The use of $K_2Cr_2O_7/H_2SO_4$ is limited to the oxidation of cyclobutanones to γ-lactones:[41] for example, 2,2,5,5-tetramethylcyclopentanone is recovered quantitatively under these reaction conditions.[42]

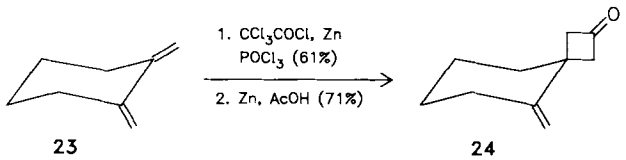
The *first central problem* is the chemoselectivity of the oxidizing reagents. A comparison of their reactivity in the oxidation of cyclobutanones, alkenes, and thioethers shows that the substrate specificity can differ from molecule to molecule. Thus the commercially available bicyclo[3.2.0]hept-2-en-6-one **19** (Merck-Schuchardt), which can be used in many ways for the synthesis of prostaglandins,[43] is oxidized mainly to the γ-lactone **20**.[39d]



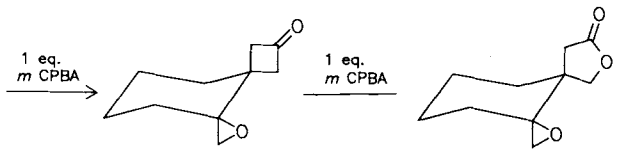
19 **20** **21** **22**

*m*CPBA	95	:	3	:	1
$EtOCO_3H$	69	:	21	:	9
$Cl_3CCH_2OCO_3H$	28	:	40	:	31

In contrast, the double bond and the cyclobutanone carbonyl group in **24** show a remarkable difference in reactivity.[44]

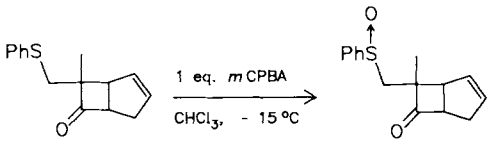


23 **24**



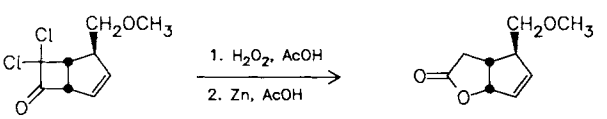
25, 71% **26**, 70%

In cyclobutanone thioethers, the thioether function is oxidized first; thus **27** is converted into **28**:[45]



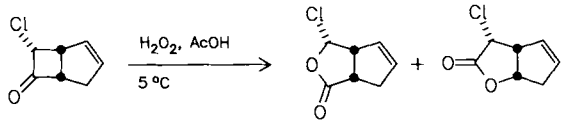
27 **28**, 98%

The *second central problem* is that of the regiospecificity. As in the case of the majority of ketones[31a, b] the oxygen insertion in cyclobutanones occurs between the carbonyl carbon and the more substituted α-carbon or the α-carbon which is not substituted by electronegative groups.[33a, c, 34b, c, 46] Thus, for stereoelectronic reasons the oxidation of **29**[47] gives only **30**.



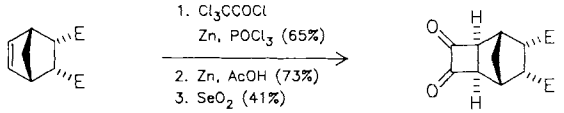
29 **30**, 62%

The Baeyer–Villiger oxidation of the α-chlorocyclobutanone **31** is less specific: the two regioisomeric lactones **32** and **33** are formed in the ratio 19 : 45.[4b]

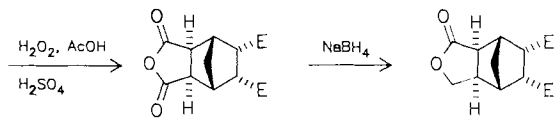


31 **32**, 19% **33**, 45%

In order to insert the oxygen solely on the less substituted side of the four-membered ring ketone, the cyclobutanedione **35** was transformed into the γ-lactone **37** in a two-step process via the anhydride **36**.[48] However, when in a transformation of the type **34** → **35** an unsymmetrical cyclobutane-1,2-dione is formed, this method loses its appeal, since then the regioselectivity problem would reappear at a later stage, i.e. during the reduction of the anhydride.

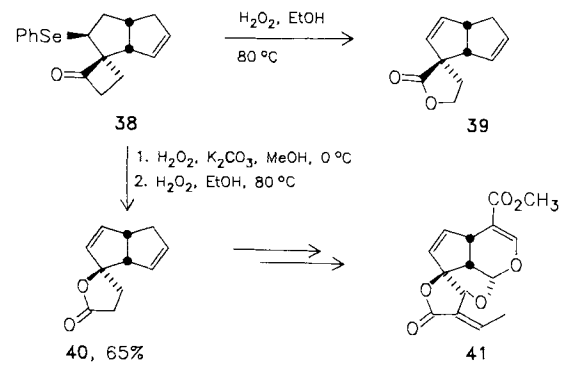


34, E = CO_2Me **35**



36, 64% **37**, 75%

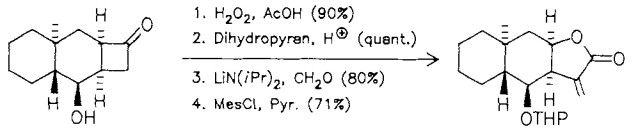
During his studies on spirolactonization in connection with the synthesis of the widely biologically active lactone plumericine **41**, *Trost* et al. found an unusual influence of selenium substituents on the Baeyer–Villiger oxidation of the cyclobutanone **38**:[32, 49] either **39** or **40** is formed regioselectively, depending on the reaction conditions.



38 **39**

40, 65% **41**

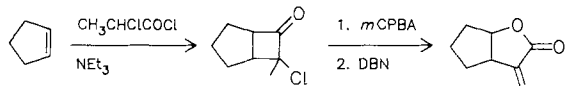
A number of naturally-occurring sesquiterpene-γ-lactones have been investigated with regard to their cytotoxicity.[50] It was shown that the structural element α-methylene-γ-butyrolactone is responsible for the cytotoxicity. This explains the great synthetic interest in this class of



42 43

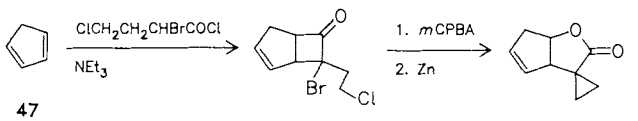
compounds.[33a,38,51] *Grieco* and *Hiroi*[51a] transformed the cyclobutanone **42** into the α-methylene-γ-lactone **43** by oxidation with H_2O_2/AcOH and subsequent condensation with formaldehyde (Pyr = pyridine, THP = tetrahydropyranyl).

Ali and *Roberts* have shown that the transformation of cyclobutanones into α-methylene-γ-lactones can be shortened to three steps if the methylene carbon is first introduced via chloromethylketene in the [2+2]-cycloaddition step (**44** → **45**)[33c,39a,52] (DBN = diazabicyclononene).



44 45, 77% 46, 80%

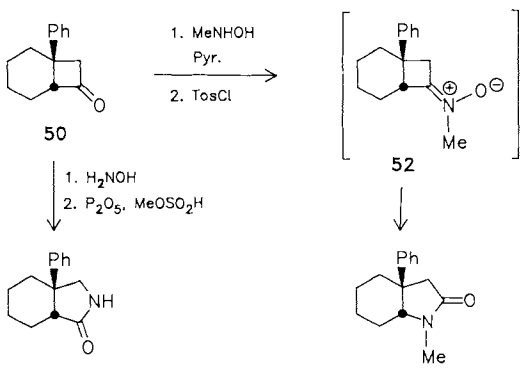
The cyclopropyl analogue **49** was prepared using an analogous reaction sequence.[53]



47 48, 70% 49, 65%

3.2. Pyrrolidones

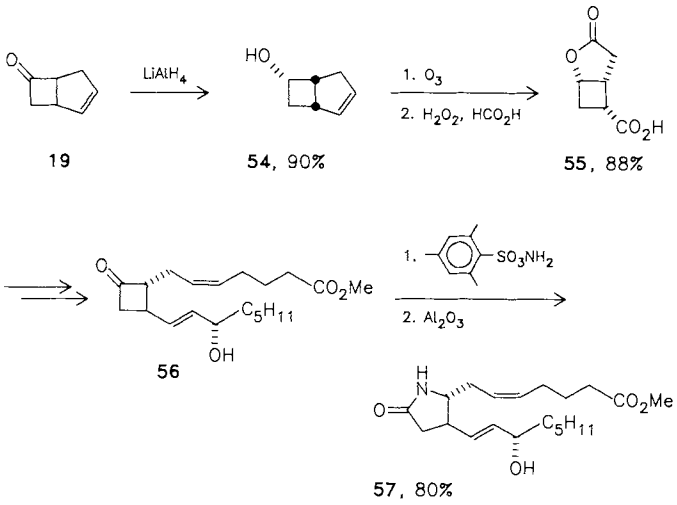
A large number of cyclization reactions are available for the classical synthesis of pyrrolidones.[54] The nitrogen insertion into cyclobutanones, which leads to the corresponding pyrrolidones, has been little used so far. Starting from the cyclobutanone **50**, *Jeffs* et al.[40] found a method for the preparation of the two regioisomeric γ-lactams **51** and **53**. Under the normal Beckmann rearrangement conditions the lactam **51** was formed from the oxime of **50**. The rearrangement of the *N*-methylnitrone **52**, however, afforded the *N*-methyl derivative of the isomeric lactam **53**, a precursor for the alkaloid mesembrine.



50 52

51, 40% 53, 32%

Greene et al.[55] used the Tamura reagent[56] for the preparation of the lactam-prostanoid **57** via the two cyclobutanones **19** and **56**.

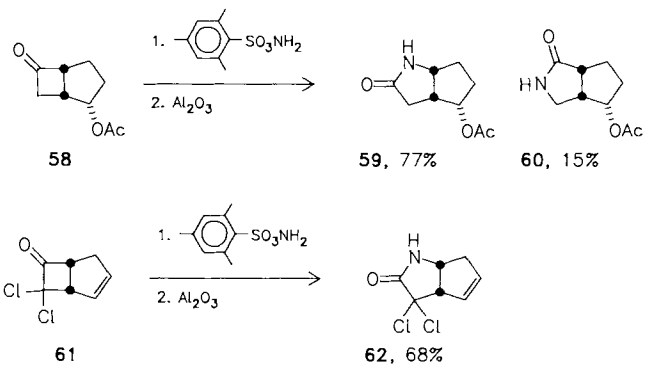


19 54, 90% 55, 88%

56

57, 80%

The Beckmann rearrangement also occurred regioselectively in this case, the nitrogen being inserted on the more substituted side of the four-membered ring ketone. Similar results were obtained by *Bartmann* et al.[57] in a synthesis of prostacyclin analogues. The contribution of *Luh* et al.[58] to the improvement of the regioselectivity of this rearrangement provides a valuable addition to the work cited above: **58** leads to a mixture of **59** and **60** (77 : 15), while **61**, which has electronegative substituents in the α-position, is transformed exclusively into the lactam **62**.



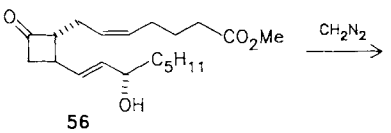
58 59, 77% 60, 15%

61 62, 68%

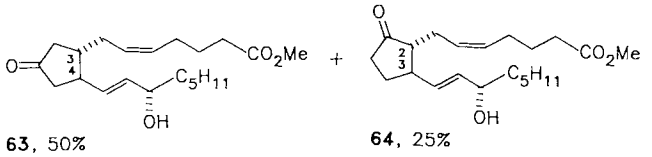
3.3. Cyclopentanones

Only a few synthetic methods are available for the regioselective annelation of a functionalized cyclopentane ring to an olefin.[59] One of them, the transformation of an olefin into a cyclobutanone derivative, followed by ring enlargement with a diazoalkane[60] to the corresponding cyclopentanone, is broadly applicable. The experiments with the 11-norprostaglandin derivative **56**[55b] clearly demonstrated, however, that in the case of alkyl-substituted cyclobutanones the ring enlargement with diazomethane occurs in a good chemical yield but with only poor regioselectivity.

There are however methods available which permit a regioselective preparation of the required cyclopentanone. *Greene* et al.[61] used an elegant approach for the synthesis

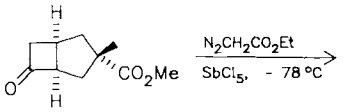


56

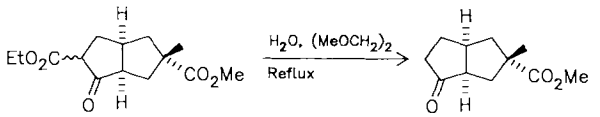


63, 50% 64, 25%

of a 2,3-disubstituted cyclopentanone of type **64**. When the optically active cyclobutanone (−)-**65** is treated with ethyl diazoacetate in the presence of $SbCl_5$, the 2,3-disubstituted cyclopentanone (−)-**67** is formed (via (−)-**66**) almost exclusively (98:2). Diazomethane, however, reacts unselectively, giving rise to both (−)-**67** and the isomeric 3,4-disubstituted cyclopentanone of type **63** in equal amounts.

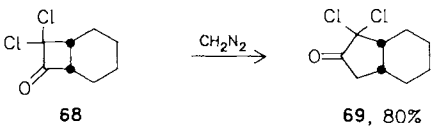


(−)-65



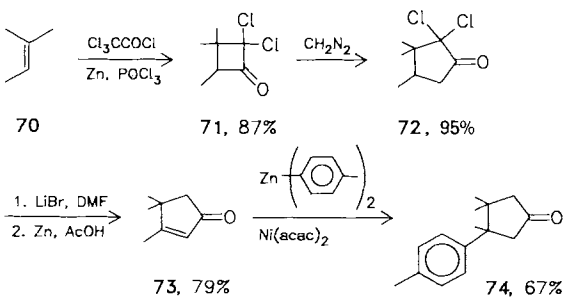
(−)-66 (−)-67, 63%

As can be expected from the electron-withdrawing effects of chlorine substituents, α-chloro- and α,α-dichlorocyclobutanones react faster and more regioselectively in the ring enlargement reaction using diazomethane:[62] no methylene insertion on the halogen-substituted side is observed. This effect can be exploited for the regioselective preparation of a 3,4-disubstituted cyclopentanone (**68** → **69**).[62b]



68 69, 80%

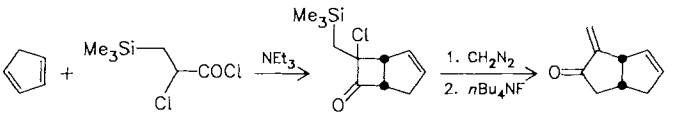
The synthetic potential of this regioselective method has already been widely applied in natural product syntheses.[61,63] Thus an elegant synthesis of racemic β-cuparenone **74** has recently been carried out.[64]



70 71, 87% 72, 95%

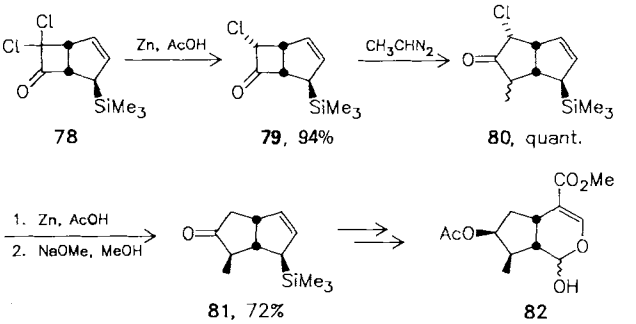
73, 79% 74, 67%

Suitably substituted cycloaddition products enable a very short synthesis of α-methylenecyclopentanones,[65] e.g. **77** from the cyclobutanone **76**:



47 75 76, 67% 77, 59%

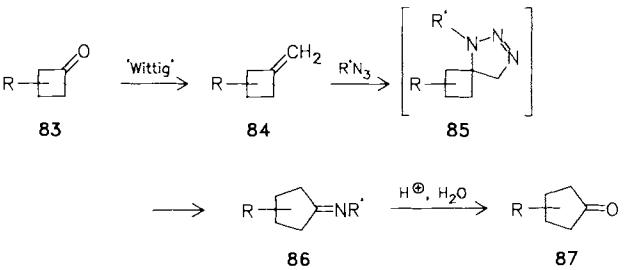
The racemic aglycon acetate of loganine **82**, a key compound in alkaloid biosynthesis, can be readily prepared by the diazoethane ring enlargement of the cyclobutanone **79**.[66] *Corey* et al.[62] have recently used the same method in their remarkable synthesis of racemic retrigeranic acid.



78 79, 94% 80, quant.

81, 72% 82

Fitjer et al.[68] have applied the three-step ring enlargement sequence **83** → **87** (R′ = *p*-$NO_2C_6H_4SO_2$−) in their recent synthesis of [3.3.3]propellanes (32% overall yield). No further preparative applications of this sequence have been reported to date.

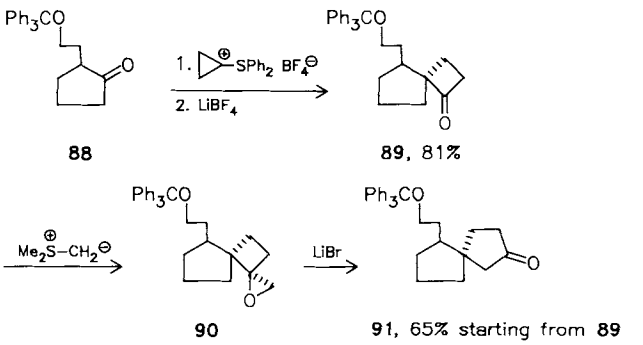


83 84 85

86 87

R′ = *p*-O_2N−C_6H_5−SO_2

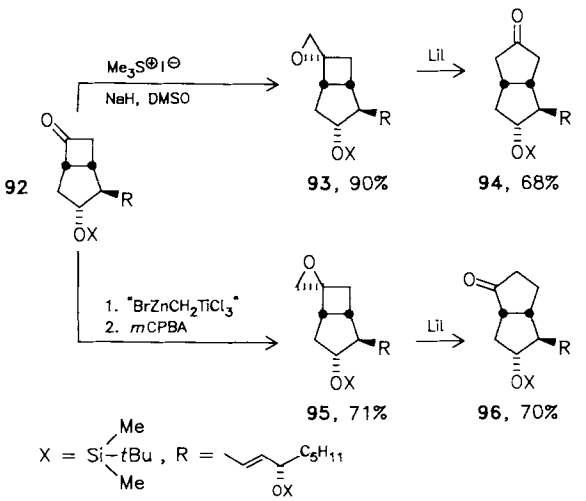
Another method for the ring enlargement of cyclobutanones by means of the rearrangement of spiroannelated oxiranes has been developed by *Trost* and *Latimer*.[69] For example, the spirocyclobutanone **89** can be used as the starting material for a synthesis of the gibberellin intermediate **91**.



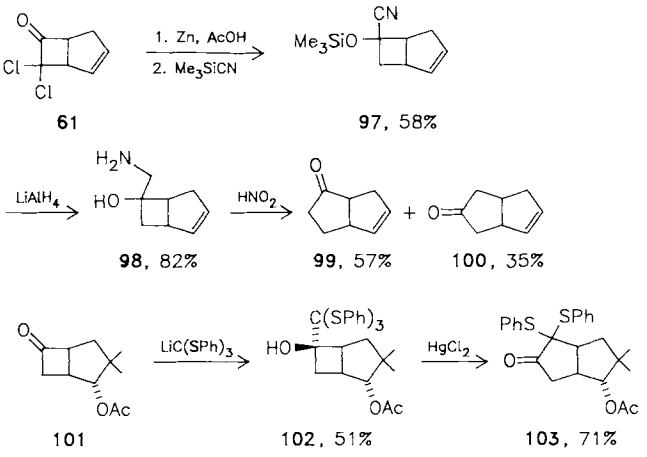
88 89, 81%

90 91, 65% starting from **89**

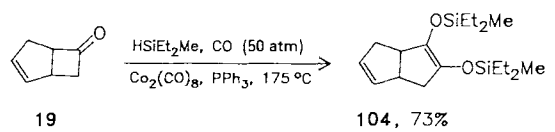
A similar reaction sequence was used for the synthesis of the sesquiterpene isocomene.[70] A regioselective synthesis of the two cyclopentanones **94** and **96** (carbaprostacyclin precursors) via the spirooxiranes **93** and **95** respectively demonstrate the feasibility of the spiroannelation methodology: both can be synthesized stereoselectively from **92**.[71]



Mechanistically similar ring enlargements of cyclobutanones have been applied in the synthesis of a number of cyclopentanone derivatives using chloride,[72] iodide,[73] ROS–,[70] RSe–,[74] or ROSe–[75] as leaving groups. In addition, the ring enlargement to cyclopentanones is also possible starting from either the readily available cyclobutanone cyanohydrins (e.g. **97**) via a Tiffeneau–Demjanov reaction[76] or starting from cyclobutanols of type **102**.[77] **103** is an intermediate in the synthesis of the cytostatic compound coriolin.

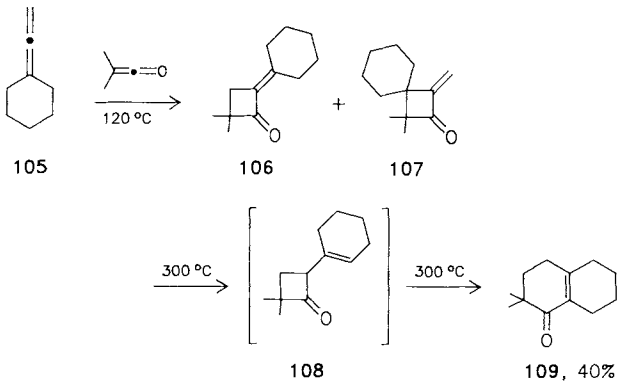


The otherwise unusual carbonylation of a carbon–oxygen double bond functions well with various cyclobutanones: the cobalt-catalyzed insertion of carbon monoxide affords the isolable disilyl ethers of 2-hydroxycyclopentanones in high yields (70–90%). As a specific example **19** affords the pentalene derivative **104**[78] in good yields.

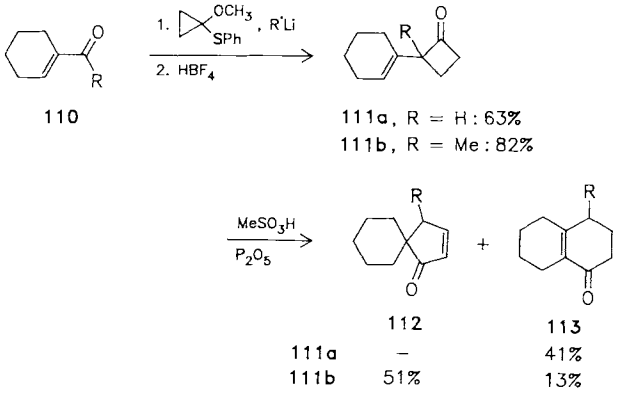


3.4. Cyclopentenones and Cyclohexenones

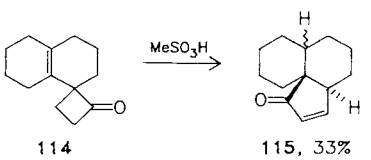
General methods for the preparation of 2-vinylcyclobutanones have only become available in recent years.[79] This explains why these potentially promising intermediates for the preparation of 5-, 6-, and 8-membered rings have not yet been studied more thoroughly. Thermolysis experiments using the readily available alkylidenecyclobutanones **106** and **107** afforded the first interesting results in this field.[80] The 1,3-rearrangement to **109** occurred at 300 °C via the 2-vinylcyclobutanone **108** as the common intermediate.[81]



Cohen and *Matz* demonstrated the possibilities of the 1,2- and 1,3-rearrangements under acid conditions.[79d,82] The formation of the cyclohexenone derivative **113** appears to dominate. When however the α-position carries a substituent which can stabilize the carbenium ion, the 1,2-rearrangement to **112** is favored[82] (R'Li = lithium 1-(dimethylamino)naphthalenide).

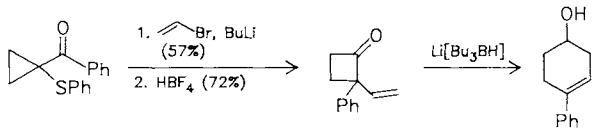


The 1,3-rearrangement can be completely suppressed in the ring enlargement of spirovinyl cyclobutanones.[83] Thus **114** affords solely **115** in a 1,2-rearrangement; a 1,3-rearrangement would in this case violate Bredt's rule.[82]



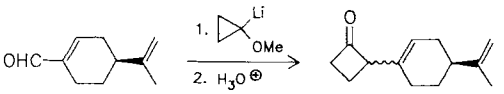
Further studies towards understanding the factors which favor the 1,3-rearrangement were carried out by *Dreiding* et al.[84,85]

The principle found by *Evans* and *Golob*,[86] according to which a correctly positioned alkoxide anion greatly accelerates 3,3-sigmatropic rearrangements, has also been applied to 1,3-rearrangements. While the 1,3-rearrangement of vinylcyclobutanone to cyclohexene requires temperatures of up to 550°,[87] the 1,3-rearrangement of the lithium or potassium salts of 2-vinylcyclobutanols occurs at temperatures as low as 20–70°C. For example, *Danheiser* et al. found that the cyclobutanolate anion of the reduced vinylcyclobutanone **117** rearranges to 4-phenylcyclohex-3-en-1-ol (**118**) merely on warming from −78°C to room temperature.[87]

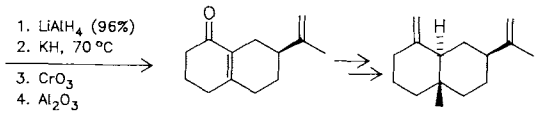


116 117 118, 65%

The potential of this method has also been used in the stereoselective synthesis of the sesquiterpene (−)-β-selinene **122** via the cyclobutanone **120**.[88]



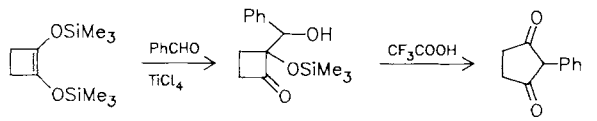
(−)-119 120, 67%



(−)-121, 64% (−)-122

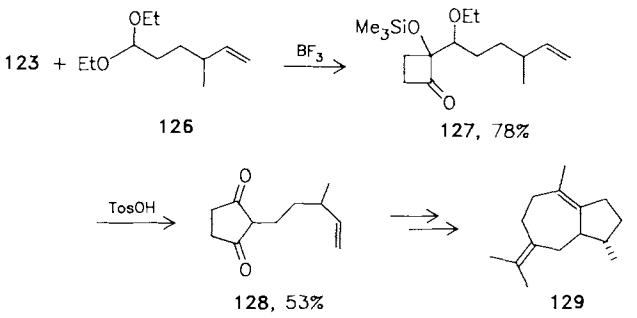
3.5. 1,3-Cyclopentanediones

The disilylated derivative of 2-hydroxycyclobutanone **123**, which can readily be obtained from succinic acid by an acyloin condensation,[89] has a large synthetic potential.[90] Examples in which a cyclobutanone intermediate is involved include the syntheses of cyclopentenones[91] and 1,3-cyclopentadiones.[92] Thus, the condensation of **123** with benzaldehyde affords the cyclobutanone pinacol **124**, which rearranges under acid catalysis to the 2-substituted 1,3-cyclopentanedione **125**.[92b] The release of strain in the four-membered ring is the obvious driving force of this type of rearrangement.



123 124, 78% 125, 97%

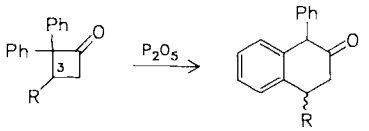
Similarly, *Oppolzer* and *Wylie* used **123** (via the cyclobutanone **127**) for the synthesis of the sesquiterpene β-bulnesene **129**.[92c]



126 127, 78% 128, 53% 129

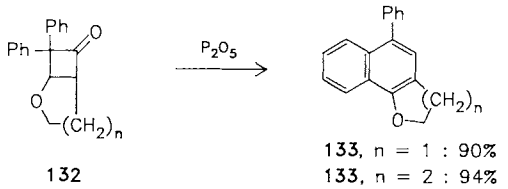
3.6. Tetralones

Starting from 2-arylcyclobutanones (such as **130**), *Lee-Ruff* et al.[93] found a new approach to tetralone derivatives. However, preparatively useful yields are only obtained when the positive charge which is generated during the reaction at the 3-position of the cyclobutanone can be stabilized by a suitable substituent R. The corresponding tetralone derivative **131** could not be isolated starting from **130**, R = H.

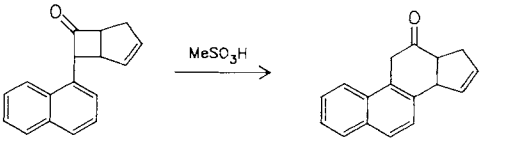


130 131, R = Ph : 85%
131, R = CH=CHCH3 : 85%

This simple method also permits the synthesis of polycyclic dihydrofurans and dihydropyrans, e.g. **133**,[94] as well as steroid-like tetracyclic compounds of type **135**.[95]



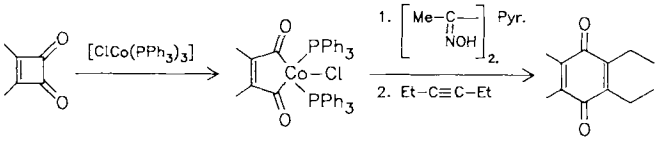
132 133, n = 1 : 90%
133, n = 2 : 94%



134

3.7. Quinones

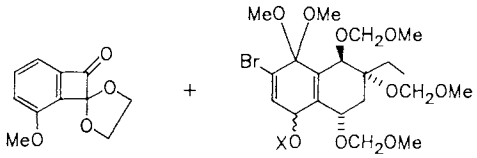
Quinones form an important class of compounds which show interesting biological activities.[96] A novel synthetic approach to a wide range of quinone derivatives, starting from cyclobutenediones, was recently reported by *Liebeskind* et al.[97] The key intermediate in his reaction sequence is a maleoylcobalt complex of type **137**:



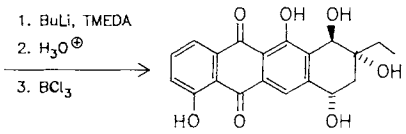
136 137, 90% 138, 65%

Using an intramolecular variant of his own procedure he was able[98] to realize an elegant synthesis of the pyranonaphthoquinone (±)-nanaomycin. Because of their potential antitumor properties, this class of compounds is presently attracting a great deal of attention among research groups engaged in the synthesis of biologically active compounds.

Swenton et al.[99] studied annelation reactions of cyclobutabenzenedione monoketals and found them to be useful for the synthesis of the anthracyclinone (±)-α-citromycinone **141**. The procedure involves reaction of the lithiated *p*-quinone derivative **140** with **139**, which is the equivalent of a 1,4-dipole.



139 **140**, X = $SiMe_2tBu$

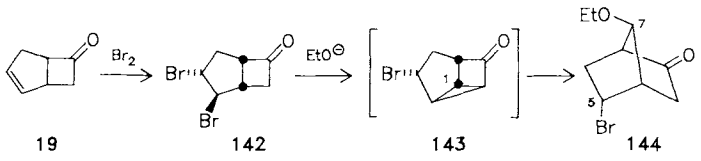


141, 48%

The specific examples mentioned above represent completely new synthetic routes to quinones. Due to the considerably improved accessibility of cyclobutenediones,[97a,100] they may gain broad synthetic acceptance. An additional new synthetic method for highly substituted quinones of type **317** via cyclobutenediones is described in Section 8.

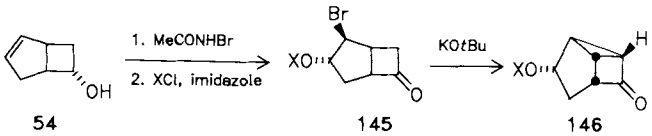
3.8. Bicyclo[2.2.1]heptanones for Prostaglandin Syntheses

It was realized as early as 1960[101] that the tricyclo[3.2.0.$0^{2,7}$]heptan-6-one **143**, which can be generated in situ from dibromobicyclo[3.2.0]heptanone **142** (and was later isolated[102]) constitutes a valuable intermediate for the synthesis of bicyclo[2.2.1]heptan-2-ones of the type **144**.

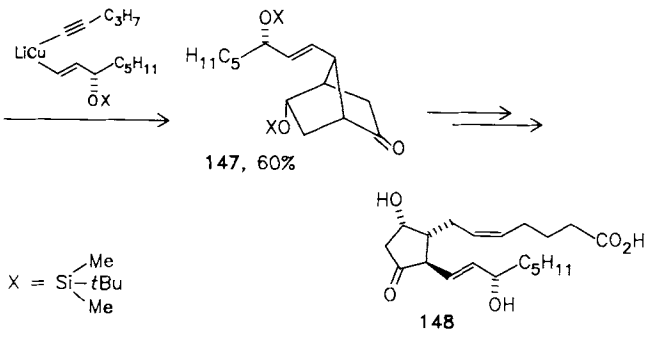


19 **142** **143** **144**

While the above reaction sequence is limited to a substitution of C-1 in **143** by the same nucleophile which is used for its in situ generation, *Roberts* et al.[103] were able to show clearly that the homoconjugated addition to isolated tricyclo[3.2.0.$0^{2,7}$]heptane-6-ones of the type **143** can be carried out with various nucleophiles (halogenide ions, cyanide ions, cuprates, alcoholates). 5-*endo*-7-*anti*-disubstituted bicyclo[2.2.1]heptan-2-ones of the type **144** are formed stereospecifically in all cases. This skeletal rearrangement has been found to be very useful in prostaglandin synthesis: thus the Glaxo synthesis of PGD_2 **148**,[43,104] which starts from the optically active cyclobutanol **54** obtained by a yeast reduction (see Section 7), uses this concept. The 13-azaprostacyclin synthesis of *Collington* et al.[105] represents a further application.



54 **145** **146**



147, 60%

148

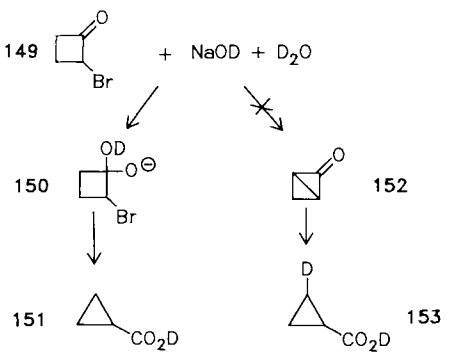
Other interesting ring enlargement reactions of cyclobutanones, which begin with the addition of an alkyl- or alkenylmetal compound to the carbonyl group, are described in Section 8 (**292**→**294**, **316**→**317**, **318**) and in Section 10 (**372**→**374**, **377**→**381**, **383**→**384**).

4. The Favorskii Rearrangement

Because of the numerous studies of its mechanism and stereochemistry,[4a-d,107] the rearrangement described by *Favorskii* in 1894[106] has become a reliable tool for the synthetic organic chemist. We know today that the Favorskii rearrangement of α-haloketones to carboxylic acids and their derivatives can proceed by two different mechanisms.

The cyclopropanone mechanism, which was established by *Loftfield* in 1951,[108] is observed for α-haloketones which carry a hydrogen in the α′-position. *Loftfield*'s remarkable experiments with ^{14}C-labeled 2-chlorocyclohexanone show clearly that a symmetrical cyclopropanone intermediate is formed.

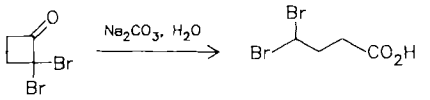
α-Haloketones bearing no hydrogen atoms in the α′-position have been suggested to react via a semibenzilic acid mechanism.[109] In experiments with 2-bromocyclobutanone **149**, *Conia* and *Salaun*[110] demonstrated that this



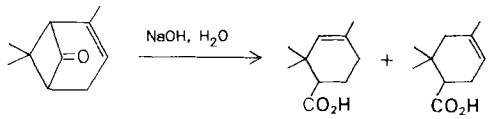
149 **150** **151** **152** **153**

mechanism is also valid for the Favorskii rearrangement of cyclobutanones. The bicyclo[1.1.0]butanone **152** which would be an intermediate in the Loftfield mechanism[108] is apparently avoided because of its very high strain energy content.

Ring opening, *cine*-substitution (see Section 5) and in the case of the [3.2.0]-bicyclic cyclobutanones the formation of tropolones (see Section 5) are all observed as competing reactions in Favorskii rearrangements of α-halocyclobutanones. The ring opening prevails when the α-position of the cyclobutanone is adequately substituted by anion-stabilizing groups, e.g. in **154**[111] and in **156**.[112]

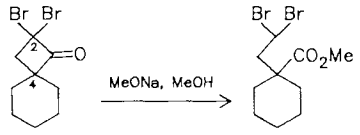


154 **155**, 43%

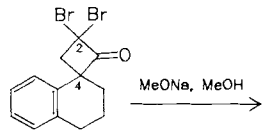


156 **157** 57% **158**
86 : 14

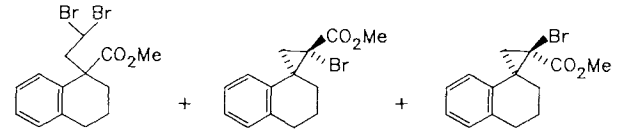
The cyclobutanones **159**[113] and **161**[114] demonstrate very clearly the competitive situation between ring-opening and ring contraction reactions. Since in **159** the negative charge can only be stabilized at C-2, which carries a bromine substituent, an exclusive ring opening to **160** is observed. In contrast, the negative charge generated in the reaction of **161** with an alkoxide anion is apparently better stabilized at the benzylic C-4; thus ring contraction to **163** and **164** occurs preferably.



159 **160**, 97%

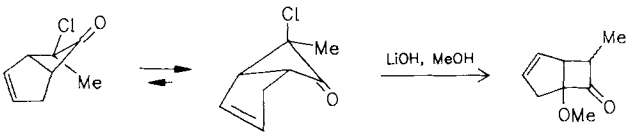


161



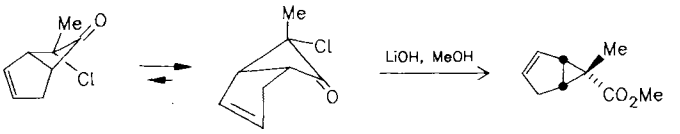
162, 12% **163**, 70% **164**, 18%

A necessary condition for the Favorskii rearrangement in bicyclic systems appears to be the pseudoequatorial position of the α-halogen atom. This was convincingly proven in the case of the two diastereomeric α-chlorocyclobutanones **165** and **167**.[115]



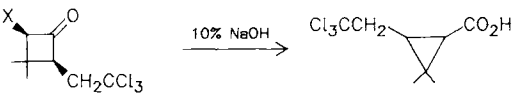
165-ae **165-ax** **166**, quant.

The steric interaction in **165** between the *endo*-methyl group and the five-membered ring forces the chlorine atom into a pseudoaxial position. On treatment with LiOH/MeOH, quantitative reaction to the isomer mixture **166** is observed even at room temperature. The mechanism of this *cine*-substitution is discussed in Section 5. When however a pseudoequatorial position for the chlorine atom is thermodynamically more favored (compare **167**), stereospecific ring contraction to the cyclopropanecarboxylic acid **168** occurs under the same reaction conditions. Many other illustrative examples have been described.[116]



167-ax **167-ae** **168**, 83%

The influence of the leaving group (X = mesyloxy, 4-bromo- or 4-methyl-phenylsulfonyloxy, chloride, bromide; see Table 1), solvent (H_2O, dioxane, toluene, ethanol) and reaction temperature (−10 to +70 °C) on the stereochemical outcome of the Favorskii rearrangement of cyclobutanone **169** has been systematically studied.[117]



169a-g **170**, 90–95%

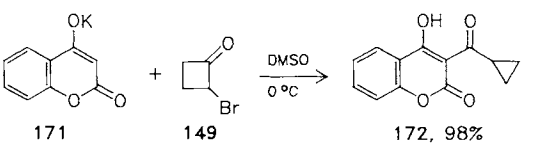
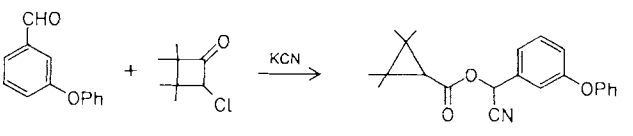
As far as the nature of the nucleophiles involved is concerned, the potassium enolate **171**[118] and the cyanohydrin anion of **173**[119] are worthy of mention.



171 **149** **172**, 98%



173 **174** **175**, 88%

In addition to the classical Favorskii rearrangement, some of its variations should also be mentioned. Thus the ring contractions of α-halocyclobutanols induced by dehydrohalogenation[120] (e.g. of type **177**[121]) provide a direct access to cyclopropanecarbaldehydes; the cyclobutanols are readily formed from α-halocyclobutanones by reduction with $NaBH_4$.

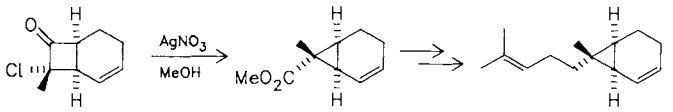
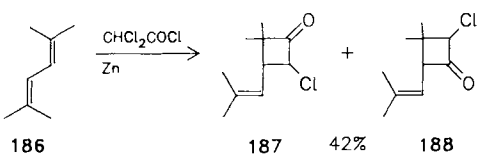
The silver-ion-assisted ring contraction of α-chlorocyclobutanone **183**[123] was used in the synthesis of the dimethylsesquicarene **185**.[123a]



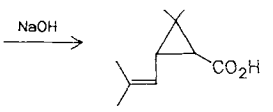
183 **184**, 68% **185**

The photochemical variant of the Favorskii reaction of α-halocyclobutanones, i.e. the photolytic ring contraction to cyclopropanecarboxylic acid derivatives, is also known.[124] A characteristic example, the ring contraction of **169**,[125] is shown in Section 9.

The industrial interest in the Favorskii reaction concentrates on the synthesis of the acid part of chrysanthemates and pyrethroids which show high insecticidal activity. Thus *Van den Brink* et al.[126] have developed an extremely simple synthesis for the racemic chrysanthemic acid **189** via the isomeric cyclobutanones **187** and **188**.



186 **187** 42% **188**



189, 88%

An analogous synthesis[127] starts with the cycloaddition of dichloroketene (generated from trichloroacetyl chloride) to 2,5-dimethyl-2,4-hexadiene **186**. The regioisomeric dichlorocyclobutanone derivatives so obtained are selectively reduced to a 3 : 1 mixture of **187** and **188**.

The dihalovinyl-substituted cyclopropanecarboxylates count among the most active pyrethroids.[128] A very simple entry to them has been developed in the Ciba-Geigy laboratories. Polyhalogenated butyryl chlorides (e.g. **190**) are prepared via Cu(I)-catalyzed addition reactions. These can then be transformed by bases or zinc into haloketenes, which in turn undergo a [2 + 2]-cycloaddition with terminal olefins to give α-halogenocyclobutanones (e.g. **191**). *Cine*-rearrangement (see Section 5) to stereochemically uniform 2,4-*cis*-isomers (e.g. **169e**), followed by Favorskii rearrangement, gives cyclopropanecarboxylic acids containing the required high content of the biologically more active *cis*-isomer. Dichlorovinyl- (**192**),[7d, 124c, 125, 129] dibromovinyl-,[130] and chloroalkylvinyl- or fluoroalkylvinyl-substituted[131] cyclopropanecarboxylic acids have become readily available using such a sequence.

A Favorskii rearrangement of the cyclobutanone **196**, which may readily be prepared starting from the chloroenamine **193**, also gives **192**.[132] However, in this case the main product is the undesired *trans*-isomer, since in contrast to **169e** the cyclobutanone **196** is formed in a sterically non-uniform manner. Spiroalkyl-,[131, 133] phenyl-,[134] and phenoxy-substituted[135] cyclopropanecarboxylic acids are also readily prepared from the corresponding cyclobutanones via Favorskii rearrangement.

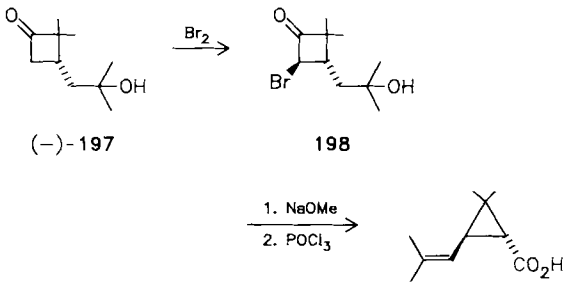
The esters of the two possible enantiomer pairs of the *cis*- and *trans*-cyclopropanecarboxylic acids **189** and **192**

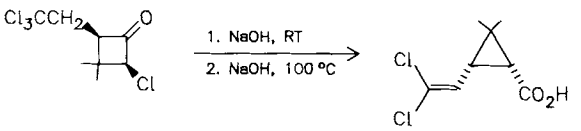
do not show the same biological activity. In order to keep the amount of active substance employed as small as possible, it is worthwhile using only the biologically most active isomers for the ester formation, namely (+)-*trans*-chrysanthemic acid ((+)-*trans*-**189**) and (1*R*,3*R*)-*cis*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylic acid ((+)-*cis*-**192**), respectively.

Enantiomerically pure (+)-*trans*-chrysanthemic acid ((+)-*trans*-**189**) has been synthesized starting from the optically active cyclobutanone **197** (see Section 7) via the unstable bromocyclobutanone **198** and subsequent ring contraction.[136] Since the ring contraction occurs stereospecifically (as expected for the semibenzilic acid mechanism[111]) and only the (+)-*trans*-isomer **189** can be isolated, one has to assume that the bromination to **198** also occurs stereospecifically in a *trans* manner.



(−)-**197** **198** (+)-*trans*-**189**, 23% starting from (−)-**197**

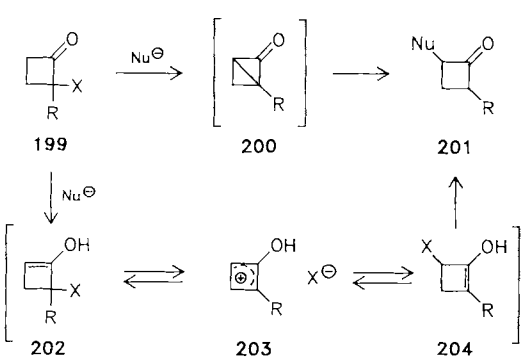
Enantiomerically pure (+)-*cis*-**192** can be obtained by a Favorskii rearrangement of the optically active cyclobutanone (+)-*cis*-**169e** (Section 7) followed by HCl-elimination.[137]



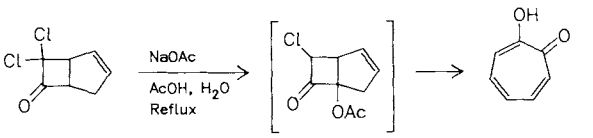
(+)-*cis*-**169e** (+)-*cis*-**192**, 72%

5. *cine*-Substitution, *cine*-Rearrangement

The term *cine*-substitution is used to describe nucleophilic substitution reactions of 2-halogenocyclobutanones of type **199** in which the new substituent enters at the 4-position (**201**). Two possible mechanisms are envisaged: either an enolate/bicyclobutanone mechanism involving intermediates like **200** or an enol/ion pair mechanism via such intermediates as **202**, **203**, and **204**.[7d]



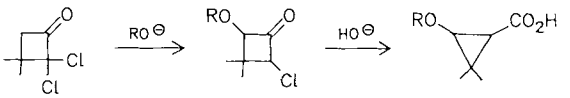
The best-known application of the *cine*-substitution reaction is the synthesis of tropolones, which are of considerable interest because of their antibacterial and fungicidal activity. A principal synthetic approach was described as early as 1965 by *Stevens*,[138] as exemplified by the preparation of the tropolone **206** starting from the dichlorocyclobutanone derivative **61**.



61 **205** **206**, 52%

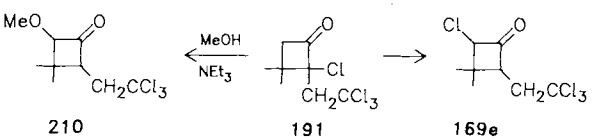
Bartlett and *Ando*[139] demonstrated by ^{14}C-labeling that the first step is a *cine*-substitution of **61** by acetate anion, which leads to the intermediate **205**. The Stevens tropolone synthesis was later used in the synthesis of α-dolabrine and β- and γ-thujaplicine.[140,141] The use of this type of reaction prior to 1981 has been documented in detail in review articles;[4a-d,i] it has recently been applied to the formation of annelated tropolones.[142]

The *cine*-substitution reaction has also been used as a key step in the syntheses of 3-alkoxy- and 3-aryloxy-2,2-dimethylcyclopropanecarboxylic acids **209** from the simple cyclobutanone **207** (the [2+2]-cycloadduct of dichloroketene and isobutylene).[133b] Several esters of **209** exhibit a strong insecticidal activity.[135]



207 **208** **209**

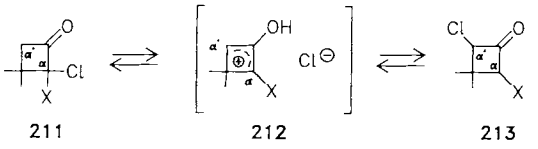
In the presence of a nucleophile, cyclobutanone **191** also undergoes a *cine*-substitution reaction, e.g. to **210**. If the reaction is carried out in the presence of catalytic amounts of a tertiary amine (e.g. Et_3N in toluene under reflux, 68% yield) or a tetraalkylammonium chloride (e.g. nBu_4NCl in the melt, 81% yield), but in absence of an external nucleophile, the *cine*-rearrangement product **169e** can be isolated.[7d]



210 **191** **169e**

The experimental results show that the outcome of the *cine*-rearrangement depends on the electronic as well as the steric character of the second α-substituent. The product distribution, which is obtained independent of whether the cyclobutanones **211** or **213** are subjected to a triethylamine-catalyzed *cine*-rearrangement[72,125] indicates a tran-

sition state with a considerable degree of ionic character, e.g., an ion pair of type **212** (Table 2).



211 **212** **213**

Table 2. Influence of the second α-substituents X on the product pattern in the *cine*-rearrangement of **211** or **213** in presence of triethylamine. **211a ≡ 191**; **213a ≡ 169e**.

	X	211	:	213
a	CH_2CCl_3	0	:	100
b	Cl	0	:	100
c	Me	57	:	43
d	$(CH_2)_2CHMe_2$	15	:	85

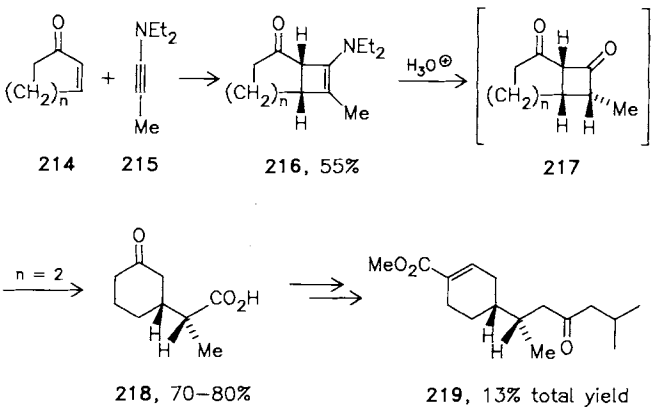
The electron-withdrawing groups, such as Cl or CH_2CCl_3, clearly destabilize the positive charge in the α-position of the allyl cation, thus directing the chloride ion completely towards the electronically *and* sterically favored α'-position. α-Alkyl groups, which are able to stabilize the positive charge on the α-carbon, however allow the chloride ion to reenter partially also in the sterically less favored α-position. In terms of stereoselectivity a thermodynamic control of product formation is observed: due to the puckered cyclobutanone ring, the main products of the *cine*-rearrangement, for example cyclobutanones **169** (**213a ≡ 169e**),[7d] exist in the thermodynamically more favorable *cis*-configuration, in which the substituents in α- and α'-position are mutually pseudoequatorial.

Because of the fact that Favorskii ring contractions of α-halocyclobutanones occur with a high stereoselectivity, the *cine*-rearrangement of cyclobutanones of type **191** proved to be an excellent entry to insecticidal *cis*-cyclopropanecarboxylates.[143] An example is the stereoselective synthesis of the *cis*-dichlorovinylcyclopropanecarboxylic acid **192** starting from **191** and proceeding via the *cine*-rearrangement product **169e**[125] (as discussed in Section 4).

6. Ring Opening Reactions of Cyclobutanones and Cyclobutenones

6.1. Monofunctionalization of Double Bonds

Although this synthetic principle has seldom been used so far, it can offer advantages in special cases in which an unambiguous regio- or stereocontrol is required. Thus, *Ficini* et al.[144,145] used the β-monofunctionalization of the α,β-unsaturated ketone **214** via an intermediate cyclobutanone **217** for the first stereospecific synthesis of (±)-juvabione **219**, a sesquiterpene with juvenile hormone activity. The cyclobutanone ring could be annelated to **214** via a [2+2]-cycloaddition of the ynamine **215** to the double bond of **214**. For n=1, the β-diketone **217** could be isolated. With n=2, however, **217** was cleaved directly to give the required diastereomerically pure oxo acid **218**.[145]

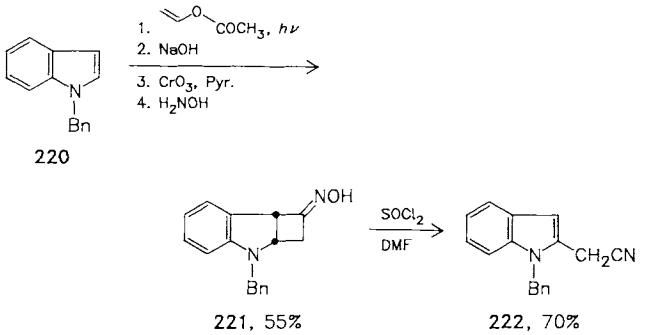


214 **215** **216, 55%** **217**

218, 70–80% **219, 13% total yield**

Other examples of β-monofunctionalization of α,β-unsaturated compounds according to this principle were described later.[146]

The introduction of a 2-cyanomethyl group into the indole **220** via the cyclobutanone oxime **221** under the conditions of a Beckmann rearrangement is also worthy of mention.[147]

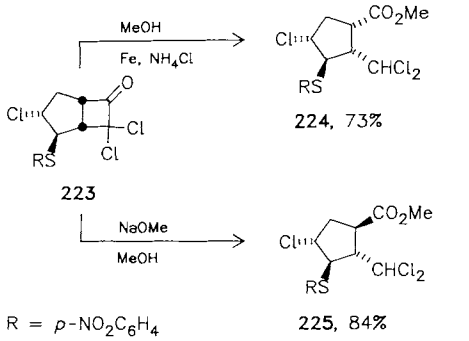


220

221, 55% **222, 70%**

6.2. Vicinal Difunctionalization of Double Bonds

Cyclobutanones are useful intermediates in the conversion of an olefin into the corresponding vicinally disubstituted saturated compound ('vicinal functionalization'). The first step generally involves the addition of a ketene to the double bond which is to be functionalized. Cleavage of the cyclobutanone thus formed by nucleophiles yields regio- and stereoselectively vicinally disubstituted products. Smooth cleavage can be expected if the cyclobutanone ring bears anion-stabilizing substituents in the α-position. Accordingly, it was possible to convert the dichlorocyclobutanone **223** into the cyclopentane derivatives **224** or **225** by correct choice of the reaction conditions.[148]



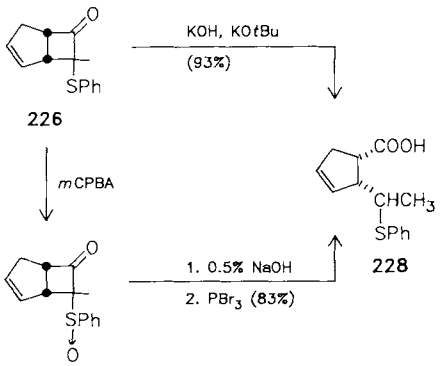
223

224, 73%

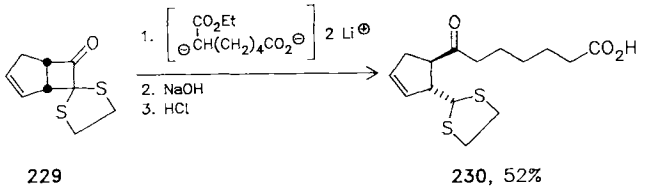
R = *p*-$NO_2C_6H_4$ **225, 84%**

Apart from α,α-dichloro-[148, 149] and α,α-dibromosubstituents,[149c, 150] the ring cleavage of cyclobutanones is also favored by other α-substituents with −I and −M effect. Thus a clean cleavage to the vicinally disubstituted product occurred if thioketal,[151] sulfoxide,[151b] ester[152] or aryl substituents[153] were present in the α-position.

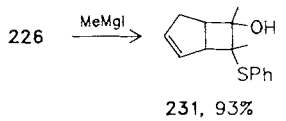
The decisive role of the anion-stabilizing substituent was clearly demonstrated by *Ghosez* et al. for the cyclobutanone derivatives **226** and **227**.[151b] Whereas ring opening of **226** takes place only when KOH/*t*BuOK is used, the better stabilization of the carbanion formed during the reaction permits the cyclobutanone ring in **227** to be opened even with 0.5% NaOH.



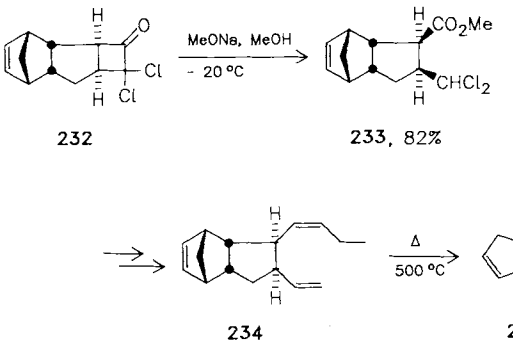
The cleavage of the cyclobutanone ring to give vicinally disubstituted products can also be carried out by C-nucleophiles. Thus the cyclopentene derivative **230** can be prepared from **229** using the dianion of the half-ester of pimelic acid.[151b]



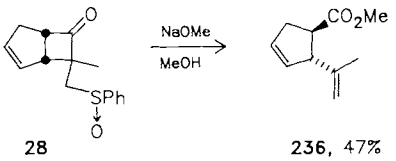
If however the anion-stabilization is not sufficient, the reaction with C-nucleophiles (MeMgI, *n*BuLi) only yields 1,2-addition products. Thus reaction of **226** with methylmagnesium iodide leads exclusively to the tertiary alcohol **231**.[151b] Further examples of such 1,2-additions which do not afford ring-opened products are described in Section 10.



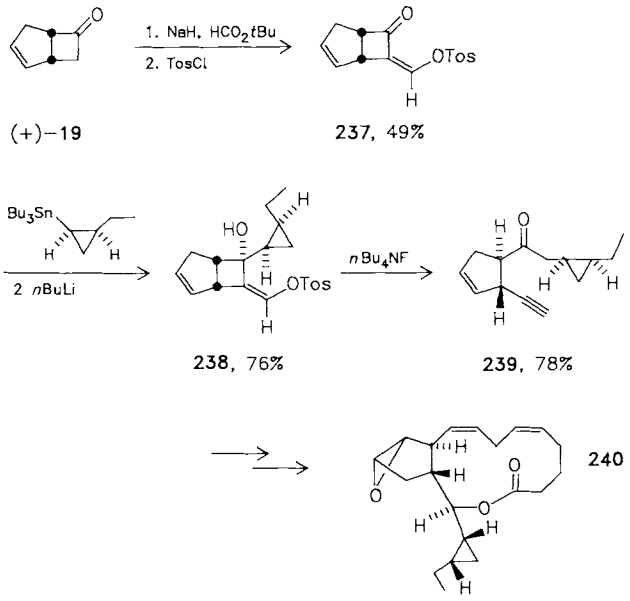
This method of stereoselective vicinal substitution was used for the synthesis of multifidene, a component of the Mediterranean brown alga *Culteria multifida*.[149c, 150a] Starting from the cyclobutanone **232** (one of the two regioisomeric products of cycloaddition of dichloroketene to dicyclopentadiene), the ring cleavage with NaOMe at −20 °C gave only the *cis* ring-opened product **233**. Wittig-olefination (to **234**) followed by pyrolytic elimination of cyclopentadiene (which served in this case as a double-bond protecting group) yielded multifidene (**235**). A more recent but less stereoselective synthesis of multifidene uses the same synthetic methodology, i.e. the vicinal functionalization via a cyclobutanone.[154]



Fragmentation reactions offer a further interesting possibility for vicinal functionalization of double bonds. In a typical example, sulfoxide **28** is smoothly converted into ester **236** by a fragmentation in which a double bond is simultaneously formed.[45]

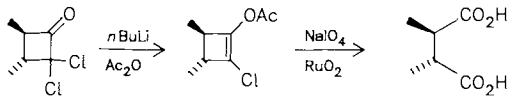


The fragmentation to the acetylene compound **239** is the key step in the synthesis of the macrocyclic lactone hybridalactone (**240**) isolated from the sea alga *Laurencia hybrida*.[155] The reaction of the condensation product **237** with the cyclopropyl nucleophile leads initially to the 1,2-addition product **238**. The cyclobutane ring-opening to the acetylene derivative **239** is carried out with nBu$_4$NF.



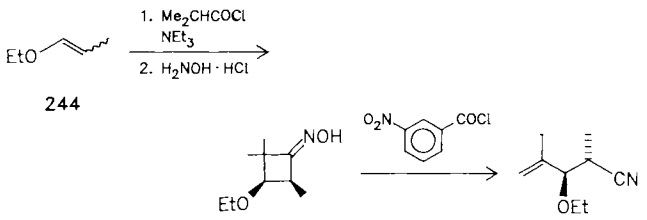
Greene et al.[156] recently reported a stereoselective transformation of olefins into vicinal dicarboxylic acids of type

243. The olefins were first converted into cyclobutanones of the type **241** by means of a [2+2]-cycloaddition with dichloroketene. Conversion into the α-chloroenol acetate **242**, followed by oxidative cleavage of the double bond, afforded the dicarboxylic acid **243** in good yield. This simple methodology was used by the same authors[157] in a short total synthesis of the sesquiterpene bakkenolide A.



241 242, quant. 243, 76%

A novel variant of vicinal difunctionalization was demonstrated by *Fráter* et al.:[158] the oxime **245** was stereoselectively converted into the bifunctionalized C_5-unit **246** (a macrolide intermediate) under the conditions of the Beckmann rearrangement.



244

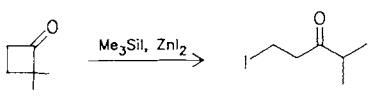
245, 74% 246, 61%

Moreover, the γ-lactones, which are readily available via oxidation of cyclobutanones (Section 3.1) or the γ-lactols formed by the reduction of such γ-lactones are de facto cyclic products of a vicinal difunctionalization of double bonds via cyclobutanones.[33a, 66b, 159]

6.3. Special Ring Opening Reactions

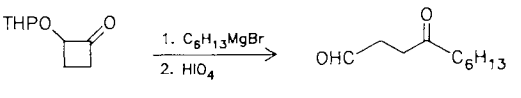
Examples of various thermal and photochemical ring opening reactions of cyclobutanones are discussed in Sections 8 and 9. Here we shall only mention two examples which hold promise of becoming preparatively useful reactions because of the simple experimental conditions.

The electrophilic trimethylsilyl iodide can bring about a regioselective ring-opening of the cyclobutanone **247** to the β-iodoketone **248** in the presence of ZnI_2 as a catalyst.[160]



247 248, 83%

It is possible to transform the cyclobutanone **249** in two simple steps (1,2-addition followed by an oxidative ring cleavage of the resulting 1,2-diol) into the γ-oxoaldehyde **250**, which serves as a precursor of dihydrojasmone.[161]



249 250, 45%

7. Optically Active Cyclobutanones: Formation and Applications

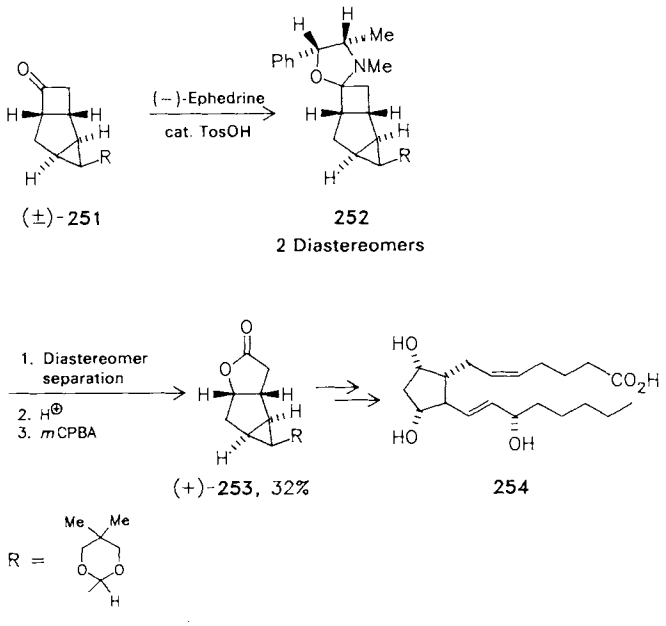
Cyclobutanones have proven to be useful starting materials for the synthesis of racemic prostaglandins and pyrethroids. Because of their interesting biological properties, the synthesis of optically active examples appeared worthy of consideration. In order to be able to apply the well established synthetic strategies in the subsequent steps it was first necessary to find methods for the preparation of optically active cyclobutanones.

Three possibilities will be discussed below: the separation of racemates, syntheses of optically active cyclobutanones starting from chiral building blocks, and asymmetric syntheses using chiral auxiliaries. Naturally-occurring cyclobutanones and cyclobutenones are discussed in Section 2.

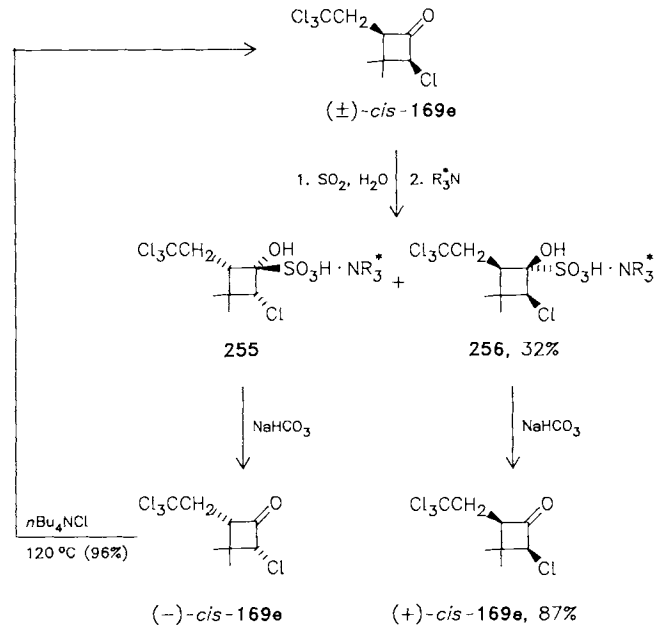
7.1. Optically Active Cyclobutanones via Separation of Racemates

When a racemic cyclobutanone is allowed to react with an optically active reagent, a new chiral center is generated at the prochiral carbonyl carbon. In principle, four diastereomers can be formed; this appears unattractive for an efficient racemate separation. If however the cyclobutanone to be separated reacts with an optically active reagent under reversible reaction conditions, only the two thermodynamically more stable diastereomeric cyclobutanes are generally formed; this can be explained by the known[162] preference of the two sterically most demanding substituents to occupy 1,3-pseudoequatorial positions in the puckered cyclobutane ring. The separation of diastereomers by recrystallization or chromatography, followed by regeneration of the cyclobutanones, permits the initial racemate to be separated. This method was used successfully by *Kelly* et al.,[163] who converted the racemic cyclobutanone (±)-**251** with either (+)- or (−)-ephedrine into the corresponding oxazolidines. As expected from the consideration of molecular models, steric hindrance led to formation of only two of the possible four diastereomers **252**. Diastereomer separation by recrystallization from methanol, acid hydrolysis and Baeyer-Villiger oxidation afforded the γ-butyrolactone (+)-**253**, which in turn was converted into **254**, prostaglandin $PGF_{2\alpha}$.

The cyclobutanone (+)-*cis*-**169e**, which is a starting material in the synthesis of (1*R*,3*R*)-*cis*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylic acid **192** (see Section 4), was also obtained by separation of the racemate.[137] (±)-*cis*-**169e** was first converted into the bisulfite adducts **255** and **256**. With chiral amines (e.g. (*S*)-1-phenylethylamine) only two of the four possible diastereomeric salts were formed. **255** and **256** could be readily separated by fractional crystallization. The optically active cyclobutanone (+)-*cis*-**169e** (2*S*,4*R*) could be obtained either by an acidic (6 N HCl, 60 °C) or a weakly basic ($NaHCO_3$, H_2O) hydrolysis. The enantiomer (−)-*cis*-**169e** (2*R*,4*S*) which cannot be used for the synthesis of the biologically interesting (1*R*,3*R*)-cyclopropanecarboxylic acid **192** racemizes readily with Bu_4NCl and can be utilized again in the sepa-

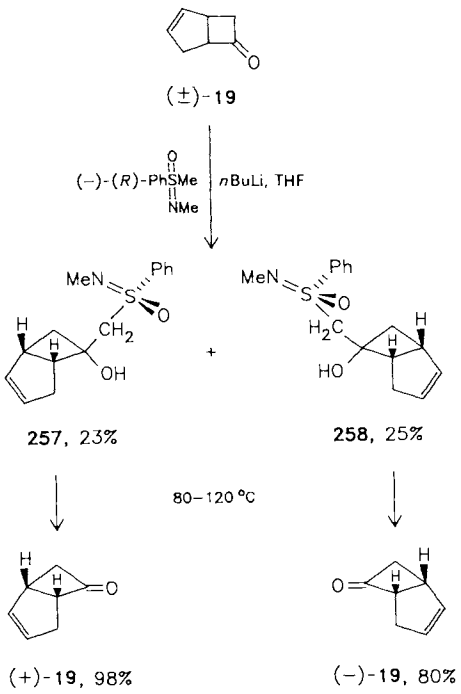


ration steps. Thus the whole procedure represents a chirally economic synthesis.

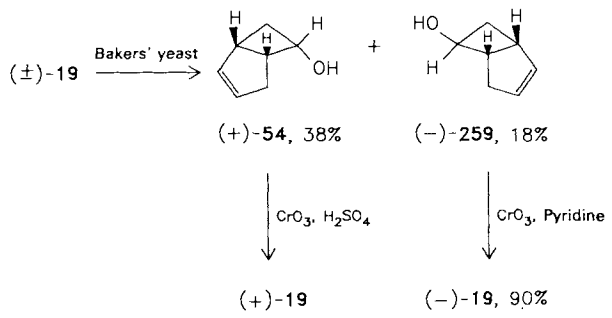


The same principle for obtaining optically active cyclobutanones was applied in the synthesis of prostaglandins E_2 and $F_{2\alpha}$ for the separation of racemic bicyclo[3.2.0]hept-2-en-6-one (±)-(**19**).[164] For the same cyclobutanone, another possibility for racemate separation was demonstrated:[165] because of the preferred *exo*-attack, the reaction of (±)-**19** with an optically active sulfoximine gave only two chromatographically separable α-hydroxysulfoximines (**257** and **258**). Regeneration of the cyclobutanones was carried out by the thermolysis of these adducts at temperatures up to 120 °C. The unusually facile cleavage of a C–C bond in both adducts is no doubt due to the stability of the ylide leaving group.

The enzyme-catalyzed reduction of prochiral cyclobutanones offers an attractive method for the separation of enantiomers. Thus it was possible[159a, 166] to reduce the racemic cyclobutanone (±)-**19** in good optical yield (84 and



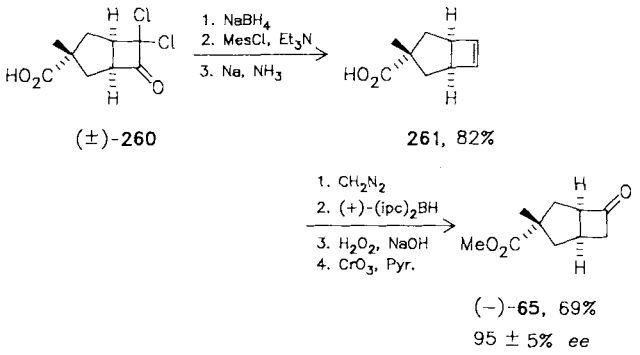
88% *ee* respectively) to the diastereomeric bicycloheptanols (+)-**54** and (−)-**259** using bakers' yeast. Both reduction products have *S*-configuration at the carbon bearing the OH-substituent; they are therefore diastereomers and can be separated by chromatographic methods.



Oxidation of the cyclobutanols (+)-**54** and (−)-**259** affords the enantiomeric cyclobutanones (+)-**19** and (−)-**19**, respectively. Both were used as starting materials in a synthesis of prostaglandin A_2.[167] The advantages of enzymatic separation are (a) the low cost of the chiral catalyst (the enzyme); (b) predictability of the stereochemical outcome of the reaction, since dehydrogenases generally furnish *S*-configurated secondary alcohols;[168] and (c) good separability of the diastereomers. The disadvantage of the low substrate-enantioselectivity was overcome by a broad screening of yeast and other fungus families. Thus starting from racemic (±)-**19**, only (+)-**19** is enantioselectively reduced to the alcohol (+)-**54** by, for example, *Curvularia falcata* or *Martierella ramanniana*. (−)-**19** is recovered unchanged.[166b] Very recently, the enantioselective enzymatic reduction of the 7,7-dimethyl derivative of **19** was reported.[169]

The only method which, in contrast to those described above, allows complete conversion of a racemic cyclobuta-

none into the desired enantiomer was described recently by *Greene* et al.[61] It is based on a conversion of the racemic α,α'-dichlorocyclobutanone (±)-**260** into the prochiral cyclobutene **261**; this in turn is transformed enantioselectively into a cyclobutanol via hydroboration with (+)-diisopinocamphenylborane, followed by Collins oxidation to the cyclobutanone (−)-**65**.



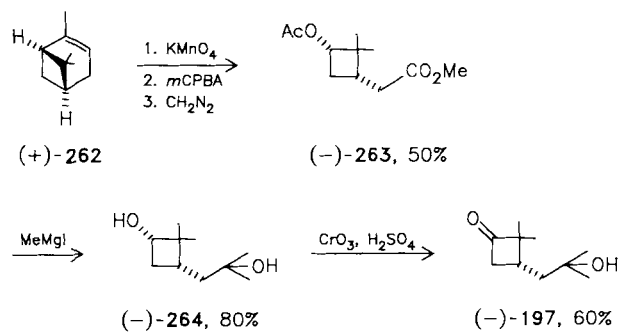
(±)-**260** → **261**, 82%

(−)-**65**, 69%
95 ± 5% *ee*

Since both (+)- and (−)-enantiomerically pure hydroboration reagents are now available,[170] this reaction sequence could develop into a widely applicable synthesis of optically active cyclobutanones.

7.2. Optically Active Cyclobutanones from Chiral Building Blocks

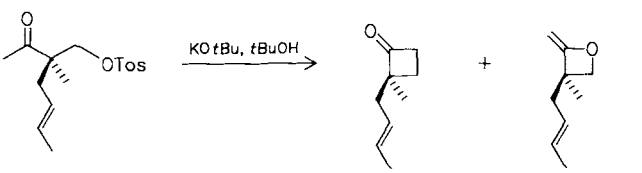
Only few syntheses of this type are mentioned in the literature. (+)-α-Pinene **262** was used as the starting material for the synthesis of the optically active cyclobutanone (−)-**197**;[136] this in turn was converted into (+)-*trans*-chrysanthemic acid **189** by ring contraction (see Section 4).



(+)-**262** → (−)-**263**, 50%

(−)-**264**, 80% → (−)-**197**, 60%

Fráter et al. have used the following procedure to obtain the optically active cyclobutanone (−)-**266**.[171] First, the ketone (+)-**265** was prepared from (*S*)-3-hydroxybutyric acid using classical methods. In the next step a base-catalyzed cyclization afforded a 3:4 mixture of the optically active cyclobutanone (−)-**266** and the oxetane (+)-**267**.

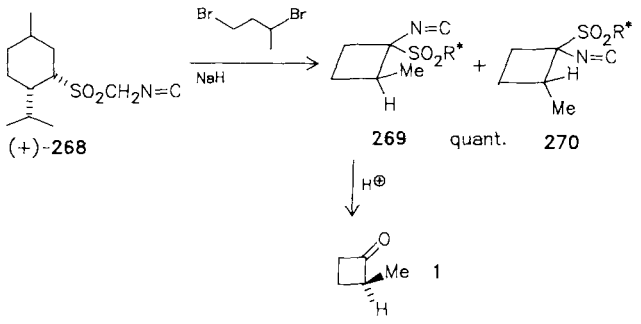


(+)-**265** → (−)-**266**, 34% + (+)-**267**, 43%

7.3. Asymmetric Synthesis of Cyclobutanones using Chiral Auxiliaries

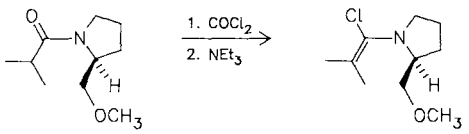
The typical feature of this type of synthesis is the use of a chiral starting material consisting of two parts which are linked by a labile bond. While the first (achiral) part is used for the construction of the cyclobutanone ring, the second (chiral) part induces the required optical activity. After the necessary synthetic steps have been performed, the chiral auxiliary part (terpene, amino acid, phosphane ligand) is removed and recovered.

In analogy to the cycloalkylation of tosylmethyl isocyanide with 1,3-dibromobutane,[2m] (+)-(neomenthylsulfonyl)methyl isocyanide ((+)-**268**) can be used to synthesize a 1:1 mixture of the two masked cyclobutanones **269** and **270**.[172] However, the hydrolysis of the enantiomerically pure **269** is accompanied by considerable racemization, especially on prolonged reaction: at 44% conversion of **269** into **1** the enantiomeric excess is 87%, while at 62% conversion it is only 43%.

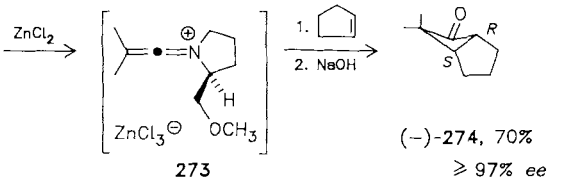


(+)-**268** → **269** quant. + **270** → **1**

Ghosez et al.[173] were the first to study asymmetric induction in [2+2]-cycloaddition reactions. The necessary optically active keteniminium salt **273** was prepared from (2*S*)-methoxymethylpyrrolidine **271** via the chloroenamine **272**. High asymmetric induction (*ee* > 97%) was achieved in the cycloaddition step with cyclopentene. Hydrolysis of the addition product gave the cyclobutanone (−)-**274**. *Greene* and *Charbonnier*[174] recently obtained [2+2]-cycloadducts with optical purities of up to 80% *ee* by reaction of dichloroketene with optically active vinyl ethers.



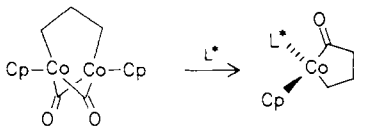
271 → **272**



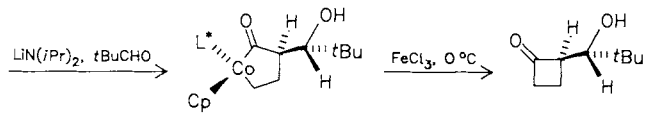
273 → (−)-**274**, 70%
≥ 97% *ee*

Acyl-transition metal complexes offer a further remarkable possibility for the synthesis of optically active cyclobu-

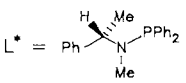
tanones. Thus the metallacycle **275** with the chiral phosphane ligand **276** was converted in 78% yield into a mixture of the acylcobalt complex (−)-**277** and its diastereomer with the opposite configuration at the cobalt atom.[175] Fractional crystallization led to pure (−)-**277**, which was converted by LDA into the lithium enolate, reaction of which with pivaldehyde proceeded with high asymmetric induction. The aldol product (−)-**278** was finally converted by $FeCl_3$ into the required optically pure cyclobutanone **279**.



275 **(−)-277**



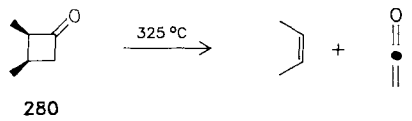
(−)-**278**, 98% **279**, 70%



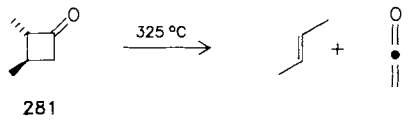
276

8. Thermal Conversions

Cyclobutanones decompose on heating to give ketenes and olefins.[176] These [2+2]-cycloreversions generally occur only at temperatures above 300°C and are therefore of little preparative interest. The concerted nature of the reaction has been demonstrated by *Carless* and *Lee*.[177] They determined stereospecificities of higher than 98% for the thermal cleavage of the stereoisomeric cyclobutanones **280** and **281**.



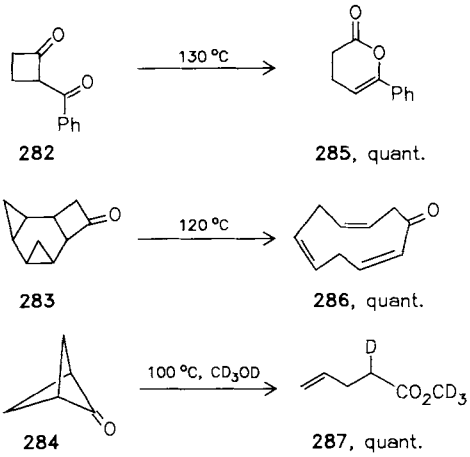
280



281

Some substituted cyclobutanones can however undergo thermal transformation at much lower temperatures. Thus the cyclobutanones **282**,[178] **283**,[179] and **284**[180] rearrange quantitatively on heating at comparatively low temperatures.

Thermal transformations of cyclobutanone derivatives which contain a 1,5-hexadiene structural element can be used in the synthesis of cyclooctane derivatives. Thus the synthesis of the cyclooctenone **291** is based on a [3,3]-sigmatropic rearrangement of the cyclobutanone **290**.[79e] **290** is readily available via a [2+2]-cycloaddition: the required vinylketene is formed either by electrocyclic ring opening

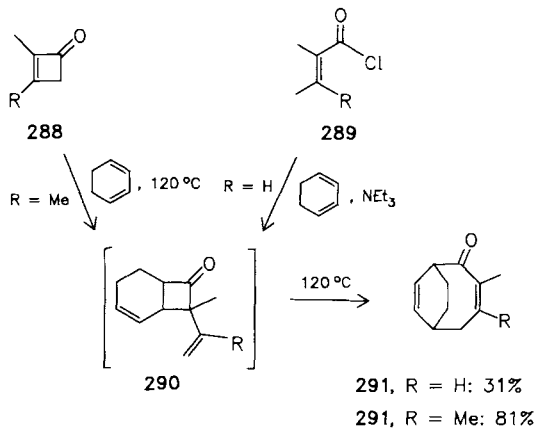


282 **285**, quant.

283 **286**, quant.

284 **287**, quant.

of the cyclobutenone **288** (R = CH_3) or by a 1,4-dehydrochlorination of the tiglic acid chloride **289** (R = H).



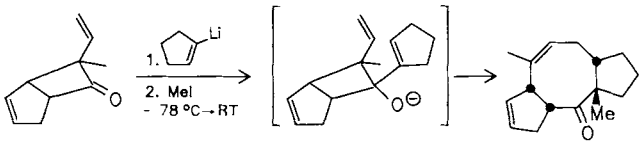
288 **289**

290

291, R = H: 31%

291, R = Me: 81%

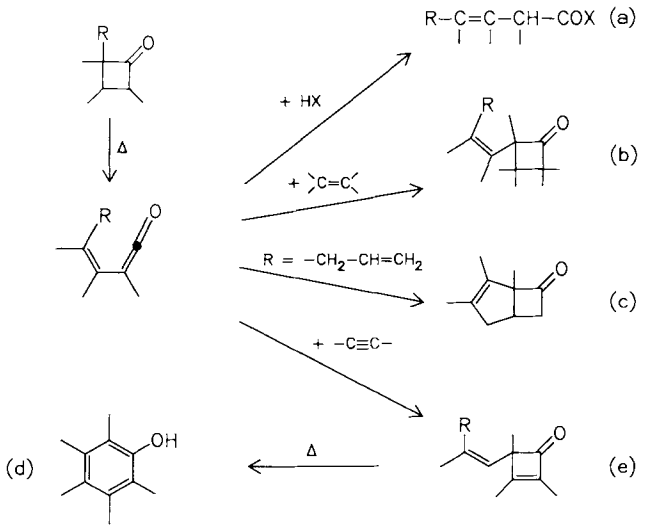
Another Cope rearrangement for the synthesis of cyclooctenones has been described by *Dreiding* et al.[84a,181] and *Trahanovsky* et al.[182] The anion-assisted oxy-Cope rearrangement of **292** to **294** via the carbanion adduct **293** can be carried out at much lower temperatures[183] than with **290**. The same strategy was used by *Gadwood* et al.[184] to synthesize the sesquiterpene diols poitediol and 4-epipoitediol and by *Still* et al. to obtain the cytotoxic eucannabinolide.[185]



292 **293** **294**, 96%

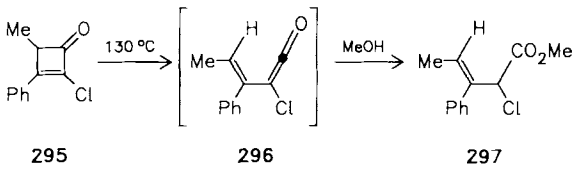
In contrast to the thermal reactions of cyclobutanones, which are of little preparative use, it has long been known that the thermally labile cyclobutenones can be converted into vinylketenes at temperatures of about 120°C. In this way, they may be used for various preparative purposes. The main reaction modes (a)-(e) are outlined in Scheme 1, and will now be illustrated by some examples.

(a) *Baldwin* and *McDaniel*[186] showed that the electrocyclic ring opening of cyclobutenones occurs stereoselec-

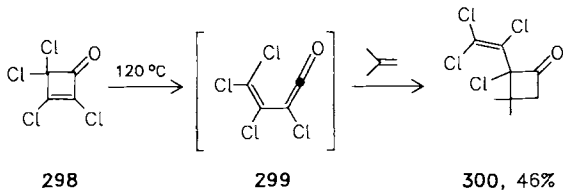


Scheme 1.

tively: thus starting from the cyclobutenone **295**, only the double bond isomer **297** was obtained via the vinylketene **296**.

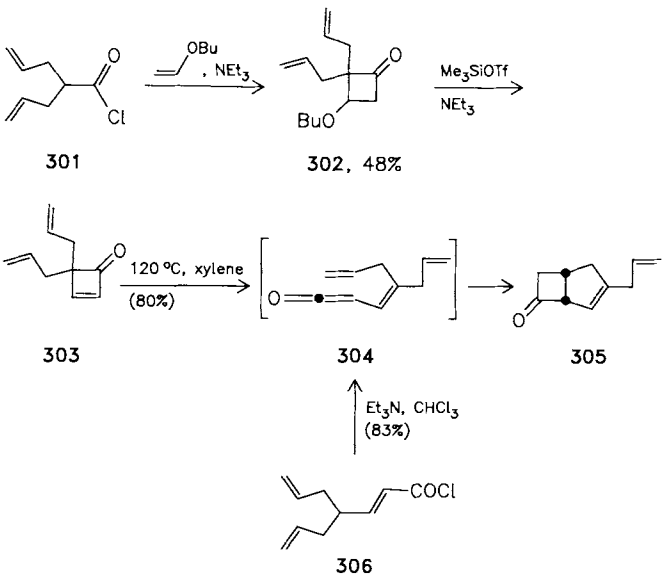


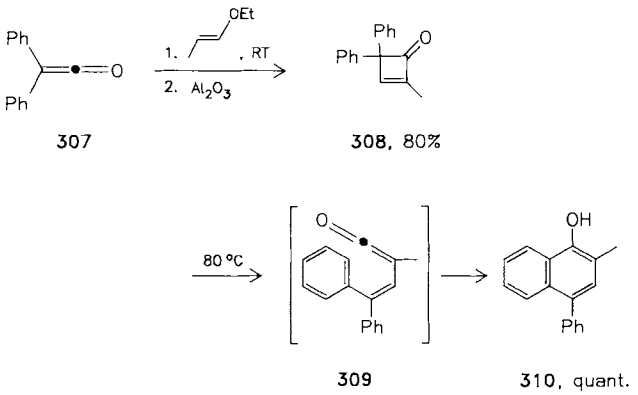
(b) The vinylketenes generated from cyclobutenones by electrocyclic ring opening can undergo an *inter*molecular [2+2]-cycloaddition with olefins. In this manner the trichlorovinyl-substituted cyclobutanone **300** could be obtained from the cyclobutenone **298** via the vinylketene **299**.[124c]



(c) After electrocyclic ring opening of the cyclobutenone **303** to the vinylketene **304**, one allyl side chain acts as ketenophile.[187] The *intra*molecular [2+2]-cycloaddition thus made possible gives the bicyclic cyclobutanone **305** in 80% yield. The elimination of *n*-butanol in **302** is carried out using Me_3SiOTf/NH_3; the conventional methods using Al_2O_3[188] or SiO_2/NEt_3[26b] led in the case of **302** only to complex product mixtures. The cycloadduct **305**, an example of a cyclobutane analog of a β-lactam (a type of compound which has recently been intensively studied[7g, 187, 189]) can also be accomplished in 83% yield from **306**[190] via the same vinylketene **304**.

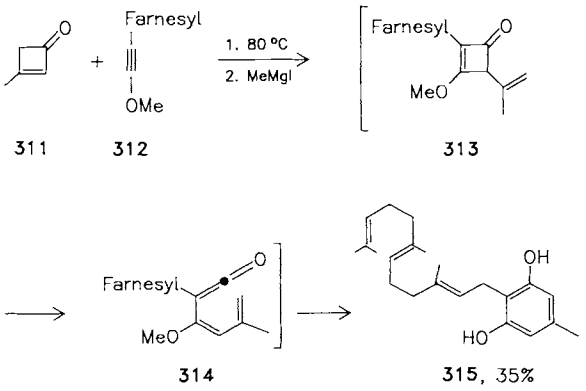
(d) *Mayr* and *Huisgen* showed in 1975 that geminally diphenyl-substituted cyclobutenones such as **308** can rearrange quantitatively to α-naphthols of type **310**[191]:**308** was converted by thermal ring opening into the arylvinylketene **309** (i.e. a 1,3,5-triene), which cyclized to the naphthol **310**.





(e) Highly substituted phenols are generally prepared from simple aromatic precursors via electrophilic substitution reactions and/or metalation–alkylation reactions.[192] However, it becomes more difficult to direct the regiochemical course of the substitution reactions as the number of substituents in the ring increases. Annelation strategies in which the aromatic ring is assembled in a single step with all substituents already in place are therefore favorable. This strategy was used by *Danheiser* and *Gee*[193] in a short synthesis of the antibiotic grifolin (**315**): the vinylketene generated thermally from **311** was allowed to react with the acetylene derivative **312** to give the vinyl-substituted cyclobutenone **313**. The latter was not isolated but under the same reaction conditions underwent a thermal ring opening to the butadienyl ketene **314** (i.e. a 1,3,5-triene). Electrocyclic ring closure of this butadienyl ketone, which was also not isolated, and subsequent aromatization led finally to the phenol derivative **315** (i.e. grifolin). The same strategy has recently been used for the synthesis of the antibiotically active mycophenolic acid[194] and cyanophenols.[195]

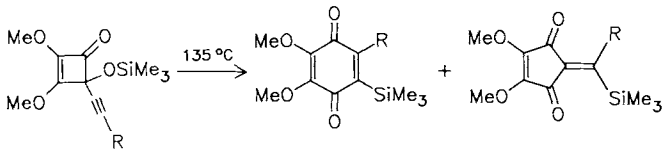
Moore et al.[196] studied the thermolysis of alkenyl- and alkynyl-substituted cyclobutenones (prepared from the dimethyl ester of squaric acid[197]) in boiling xylene. The vi-



311 312 313

314 315, 35%

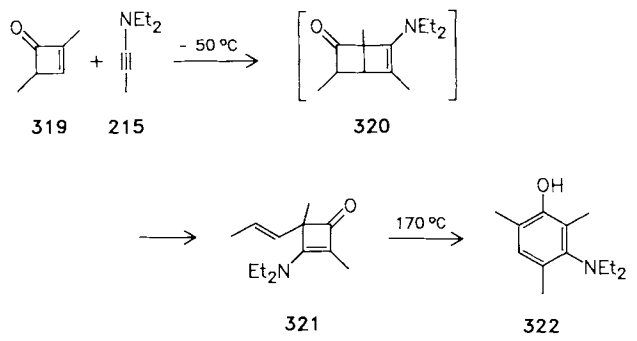
nylketene generated from **316** but not isolated, cyclized either to benzoquinones **317** or the cyclopentenediones **318**, depending on the electronic character of the substituent R.



316 317 318

R = CH_2OSiMe_3	80%	0%
R = Ph	13%	52%
R = CO_2Et	0%	43%

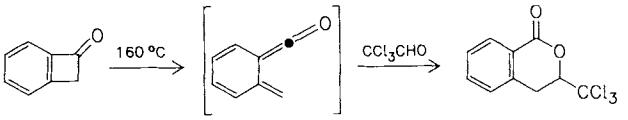
A similar approach to highly substituted phenol derivatives was described by *Ficini* et al.[144,198] as early as 1976. In contrast to the approach used by *Danheiser* et al.,[193,194] the electrophilic cyclobutenone **319** was not used as the source for the thermal formation of a vinylketene, but converted at $-50\,^{\circ}C$ in the presence of the heterosubstituted acetylene **215** into the vinyl-substituted cyclobutenone **321** (probably via the bicyclic [2+2]-cycloaddition product **320**). **321** was then thermally rearranged to the phenol **322** at 170°C.



319 215 320

321 322

The synthetic potential of *ortho*-quinoid vinylketenes of type **324**, which can easily be prepared in situ by valence isomerization[199] of readily available benzocyclobutenones[200] of type **323**, was recently indicated by *Schiess* et al.[199b] They found that **324** undergoes facile [4+2]-cycloaddition reactions with various dienophiles (e.g. with chloral to give **325**).

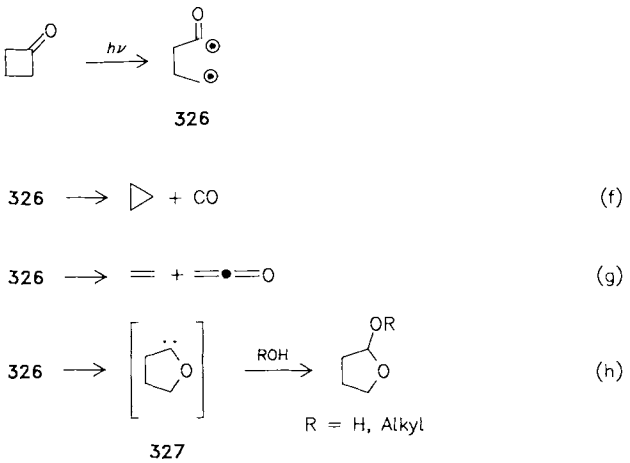


323 324 325, 92%

The great variety of accessible benzocyclobutenones and the simple thermal route to *ortho*-quinoid vinylketenes of type **324** makes it likely that the synthetic potential of this valence isomerization is by no means exhausted by the example **323** → **325**.

9. Photochemical Transformations

On irradiation in solution with UV-light, cyclobutanones can undergo three types of reactions (Scheme 2): *decarbonylation* (leading to cyclopropanes and carbon monoxide; Eq. (f)), [2+2]-cycloreversion (leading to olefins and ketenes; Eq. (g)), and ring enlargement (leading to 2-hydroxy- or 2-alkoxytetrahydrofurans; Eq. (h)). These three competing reactions are preceded by a common photochemical primary process, an α-cleavage to the 1,4-diradical **326**.

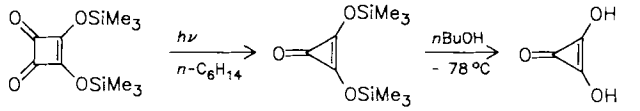


Scheme 2.

All three photoreactions generally occur together, though they are not necessarily of equal importance. Thus, though the photochemical behavior of variously substituted cyclobutanones has been studied in detail,[4k] the chemo-, regio- and stereochemical course of the photolysis of a particular cyclobutanone for preparative purposes is very difficult to predict. The best experimental conditions must be determined in each case, so that until now only a few product-oriented synthetic applications of the photochemistry of cyclobutanones are known.

Cyclic anions ($C_nO_n^{2-}$ are of theoretical interest, since they exhibit a large aromatic stabilization.[201] The first synthesis of the conjugate acid of the compound with n=3, the so-called "deltic acid" **330**, was carried out by *West* and *Eggerding*[202] by the photodecarbonylation of the bistrimethylsilyl ester of the squaric acid **328**. *Dehmlow* had

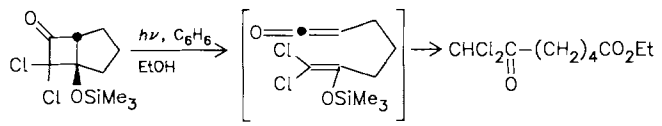
earlier obtained the diethyl ester of **330** in 10% yield by a similar procedure;[203] however, he did not succeed in hydrolyzing it to the free acid **330**.



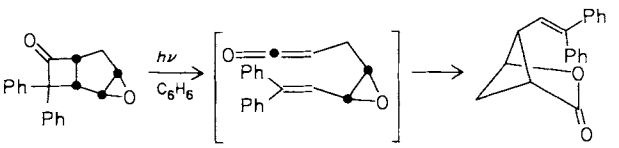
328 **329**, 15% **330**, quant.

Another theoretically interesting molecule, 1,3-dimethylenecyclobutadiene (a new benzene isomer with six π-electrons) was recently prepared by sensitized photodecarbonylation of the dimethylene derivative of **284** at 10°K.[204]

Only a few examples have been described for intramolecular [2+2]-cycloreversions of cyclobutanones annelated to a five-membered ring (e.g. **331** and **334**) which occur in preparatively useful yields.[205] Since cyclobutanones such as **331** and **334** are formed by [2+2]-cycloaddition of ketenes to cycloolefins, the formation of **332** and **335** represents de facto a two-step metathesis of two olefins.[205a]

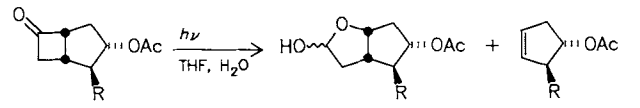


331 **332** **333**, 58%



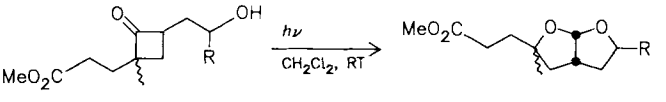
334 **335** **336**, 42%

Photochemical ring enlargement reactions of bicyclic cyclobutanones of type **337** have been used several times by *Roberts* et al. for the synthesis of racemic[206] and optically active[159a] prostaglandins, starting from the readily available adduct **61** of dichloroketene and cyclopentadiene. Apart from the regioselectively formed γ-lactols of type **338**, cyclopentenes of type **339** formed by ketene cleavage according to Eq. (g) were always isolated as by-products.[206c]



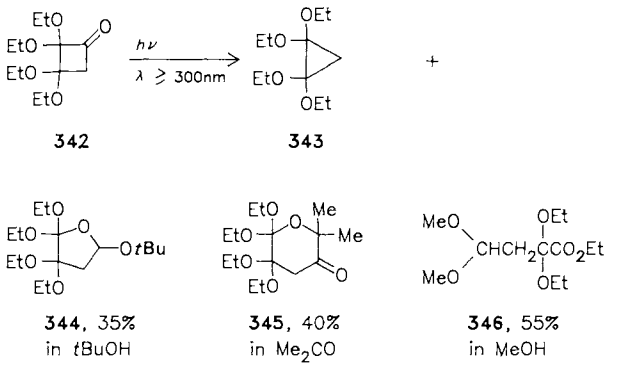
337 **338**, 50% **339**, 15%

In the conversion of **337** into **338** the intermediate oxacarbene of type **327** was trapped by water. Although the oxacarbene can also be trapped as its dimer, such a process[207] is very unusual and has not yet become preparatively important. Bicyclic acetals can be obtained by an intramolecular trapping reaction in the irradiation of cyclobutanones,[208] e.g. **341** from **340**. Such annelated tetrahydrofuran units form a part of the structure of the aflatoxins and caryoptins.



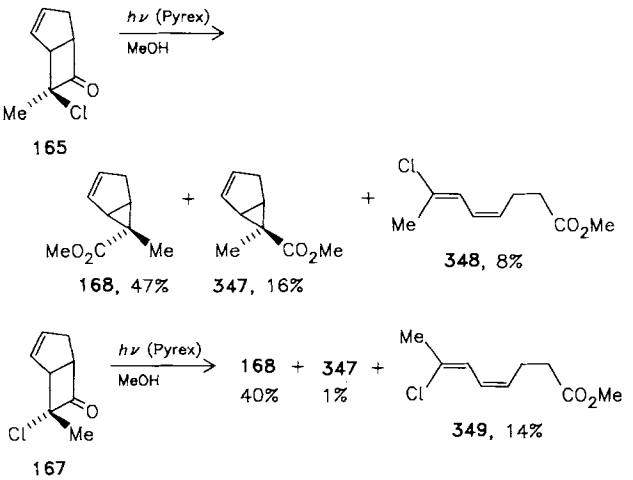
340 **341**, R = H: 70%
341, R = CN: 51%

The products of the direct photolysis of tetraethoxycyclobutanone **342** depend greatly on the solvent used.[209] In all cases 25–30% of the very pleasantly-smelling cyclopropane derivative **343** is isolated; in addition, in *tert*-butanol **344** is obtained (via an oxacarbene of type **327**), in acetone **345** (via cycloaddition of the 1,4-diradical of type **326** to the carbonyl group of acetone), and in methanol the unusual ester **346**. The formation of **346** (possibly also that of **345**) indicate a possible heterolytic α-cleavage of photoexcited **342**.



342 **343**
344, 35% in *t*BuOH **345**, 40% in Me_2CO **346**, 55% in MeOH

Depending on the substitution pattern, the irradiation of α-chlorocyclobutanones gives products of a [2+2]-cycloreversion [Scheme 2, Eq. (g)] in competition with the formation of derivatives of cyclopropanecarboxylic acids. The occurrence of a photo-Favorskii reaction was first observed by *Kaplan* and *Turner*[210] and later confirmed by *Jones* and *McDonnell*.[124a,b] The product distribution depends on the stereochemistry of the α-chlorocyclobutanones **165** and **167**.

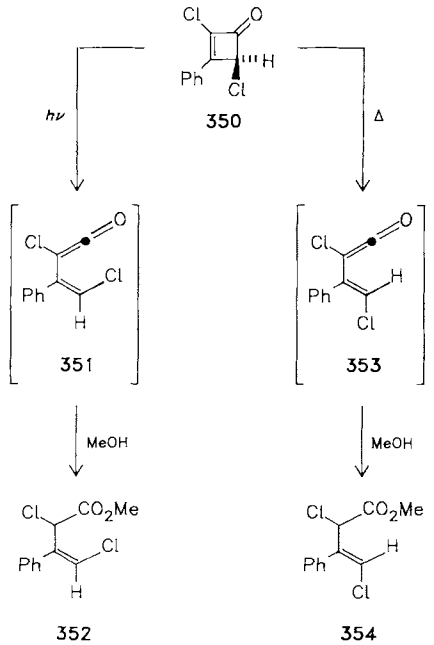


165
168, 47% **347**, 16% **348**, 8%
167
168 40% + **347** 1% + **349**, 14%

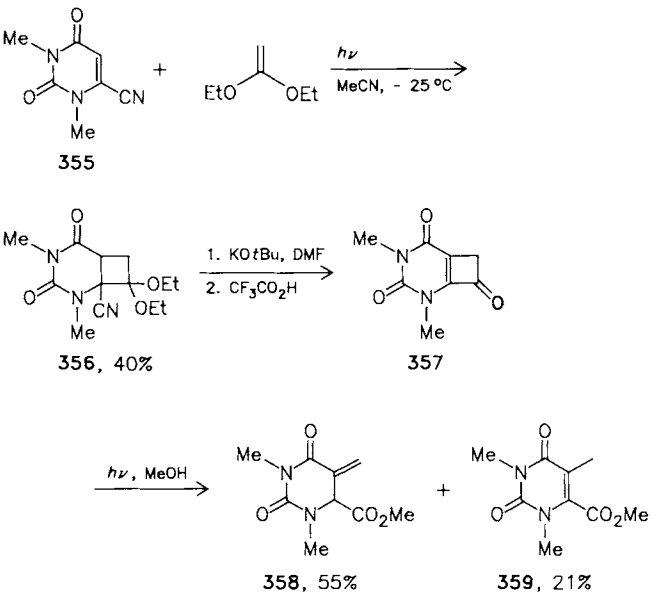
In contrast to **165** and **167**, the α-chlorocyclobutanone **169e** affords a complex mixture of products on irradiation in alcohol. However, its photolysis occurs very cleanly in a water/acetone solution (1 : 4).[125] The stereoisomeric cyclopropanecarboxylic acids *cis*-**170** and *trans*-**170** are formed in 97% total yield. While however the stereoselective Favorskii rearrangement of **160** under basic conditions gives an 8 : 2 mixture of *cis*- and *trans*-**170** (Section 4, Table 1), the biologically interesting[133a] *cis*-isomer **170** forms only one third of the product of the photo-Favorskii reaction.

This unfavorable outcome of the photo-Favorskii reaction of **169** can be explained by the mechanism suggested by *Jones* and *McDonnell*.[124a] They assume that the primary step is a heterolytic cleavage of the α-chlorine-carbon bond to provide a trigonal α-oxocyclobutyl cation; this largely rearranges, losing the stereochemical information, to the thermodynamically more stable[211] *trans*-cyclopropylacyl cation, which is then trapped with water to form *trans*-**170**.[125]

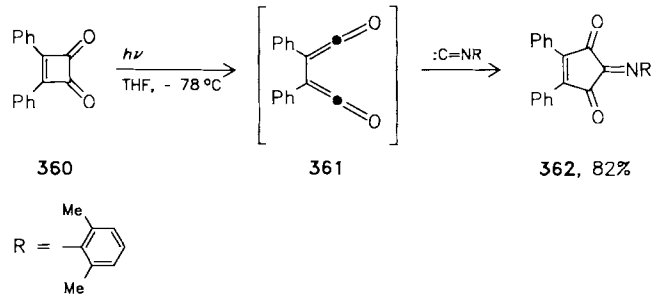
In a few cases, photolysis of cyclobutenones leads to products which formally correspond to the primary reactions (f)–(h) (Scheme 2), e.g. the formation of **329** by photodecarbonylation of **328**. The dominant photoreaction of the cyclobutenones is however their valence isomerization to vinylketenes.[212] The few comparative experiments reported indicate that the photochemical and thermal ring openings (Section 8) are stereochemically different (e.g. the reaction of **350** to give either the vinylketene **351** or **353**[186]).



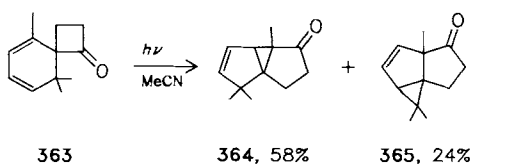
In contrast to the thermal ring opening of cyclobutenones, the photochemical method has until now rarely been used. However, UV-light was used twice in the preparation of the new pyrimidine bases **358** and **359**, first for the cyclobutenone formation **355**→**357** and then for the preparation of **358** via photolysis to the intermediate vinylketene, which was trapped with methanol (**359** is derived from **358**).[213]



While numerous studies of the photochemical behavior of cyclobutenones[199b,214] and cyclobutenediones[215] have not followed a clear synthetic goal, the efficient formation of **362**, a cyclopentene-1,2,3-trione derivative, could be of preparative interest:[216] the bisketene **361** generated photochemically from **360** was trapped in situ by 2,6-dimethylphenyl isocyanide.



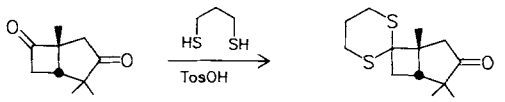
The photochemical behavior of bicyclic α-alkenyl- or α-dienylcyclobutanones (e.g. **363**) was studied by *Frei* et al.[217] Singlet excitation leads to products formed according to Equations (f) and (g) (Scheme 2); however, sensitized triplet excitation gives cyclopentanone derivatives (e.g. **364** and **365**) via a 1,2-acyl shift.



10. Reactions at the Carbonyl Group

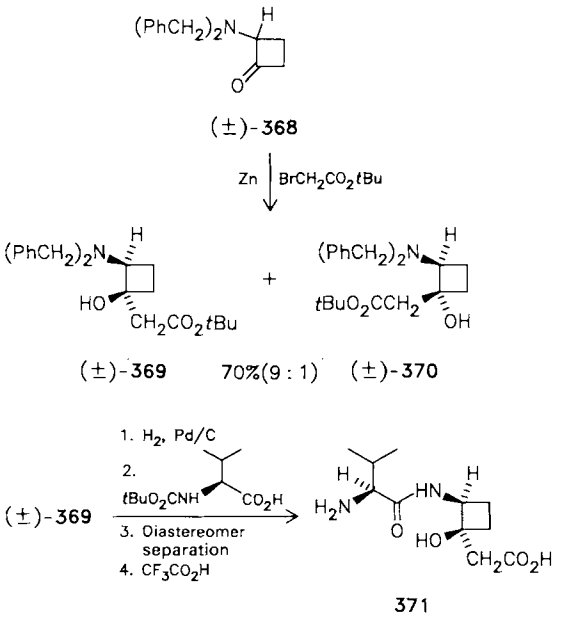
10.1. Reactions with Nucleophiles

The bond angle at the carbonyl carbon in cyclobutanone is compressed almost to 90°.[218] Reactions at the carbonyl group in which the sp^2 carbon is converted into an sp^3 carbon therefore lead to a reduction of the angle strain; this explains the unusual reactivity of the carbonyl group in cyclobutanones.[219] It is thus for example possible to convert **366** regioselectively into the thioketal **367**.[220]

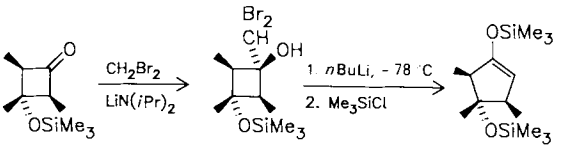


366 **367**, 60%

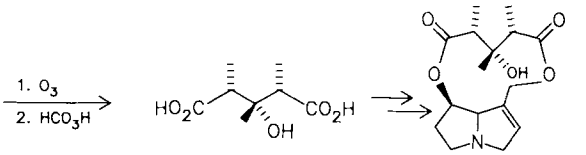
When the α-positions in a cyclobutanone are substituted with one or more anion-stabilizing groups, the attack of a nucleophile at the carbonyl group leads to ring cleavage (see Section 6). In the absence of anion-stabilizing groups in the α-position, tertiary alcohols are formed; these in turn can be used for the synthesis of interesting target molecules. Of the many examples known,[77,161,221] one in particular should be mentioned: the synthesis of the antibacterially active cyclobutanol derivative **371**. The cyclobutanone (±)-**368** was converted in a Reformatsky reaction into a mixture of the diastereomeric alcohols **369** and **370**. The main component (±)-**369** underwent reaction with Boc-(*S*)-valine to give the amino acid antimetabolite **371**, which had been isolated from *Streptomyces* X-1092.[222]



Vedejs and *Larsen*[223] allowed the cyclobutanone **372**, which is readily available from a [2 + 2]-cycloaddition reaction between methylketene and the corresponding silyl enol ether, to react with dibromomethyllithium; the reaction occurs stereoselectively to give the cyclobutanone **373**. Ring enlargement to **374** followed by ring opening afforded the γ-dicarboxylic acid **375**, which was used in the synthesis of fulvine **376**.

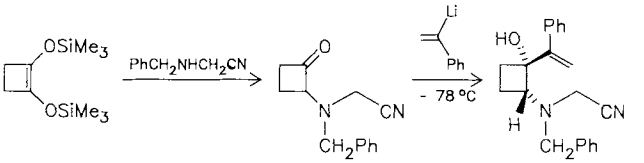


372 **373**, 84% **374**, 85%

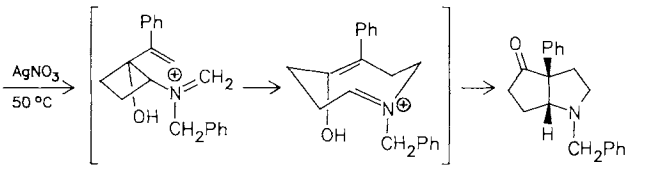


375, 79% **376**

The 1,2-adducts of vinylmetal compounds and cyclobutanones[183b,224] can undergo many useful transformations. When the cyclobutanone contains an additional vinyl substituent in the α-position, a thermal oxy-Cope rearrangement is possible (see Section 8). An example of a $Ag^{\oplus}$-induced aza-Cope rearrangement was reported by *Overman* et al.[224b] Their starting material was the disilylated 2-hydroxycyclobutanone **123**, which reacts with benzylaminoacetonitrile to give the cyclobutanone **377** in good yield.



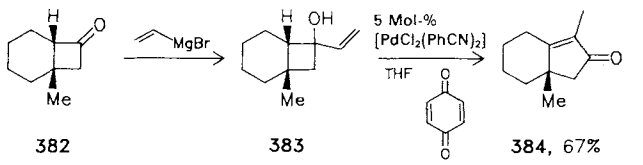
123 **377**, 75% **378**, 58%



379 **380** **381**, 93%

The attack of 1-phenylvinyllithium on the carbonyl group of **377** occurs exclusively *trans* to the dialkylamino group and leads to **378**. An $Ag^{\oplus}$-catalyzed aza-Cope rearrangement, followed by an intramolecular Mannich cyclization completes the synthesis of pyrrolidine **381**.

The Pd-catalyzed rearrangement of 1-vinyl-1-cyclobutanols (e.g. **383** → **384**) has been studied in some detail.[225] The addition of benzoquinone made it possible to carry out the rearrangement to the cyclopentanone **384** under catalytic conditions.



382 **383** **384**, 67%

Starting from cyclobutenones, alkylmetal compounds can be used for the selective synthesis of either 1,2- or 1,4-adducts. *Kraus*[226] showed that the resonance stabilization of the attacking carbanion is not the factor governing its mode of addition to dimethyl squarate (**385**). In fact, the main reason for the regioselectivity appears to be the nature of the metal cation: thus alkyl- and aryllithium compounds favor the 1,2-addition yielding **386** and **387**, while Grignard reagents prefer conjugate addition yielding **388** and **389** (see also Ref. [227]).

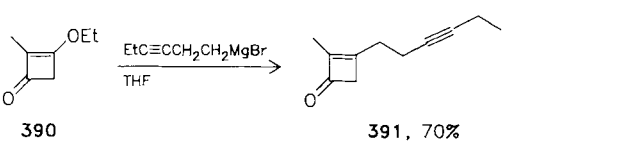
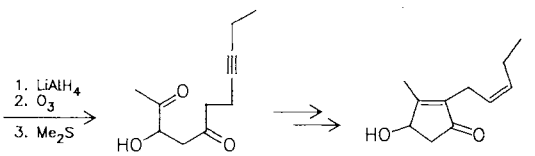
The 1,4-addition was applied to the synthesis of jasmolone **393**.[228] The cyclobutenone **390** was first converted via a 1,4-addition of hex-3-ynylmagnesium bromide into **391**. Reduction of the latter with $LiAlH_4$ (a 1,2-addition) and subsequent ozonolysis afforded the α-hydroxy-γ-diketone **392**, which underwent cyclization via an intramolecular Aldol condensation to give jasmolone **393**.

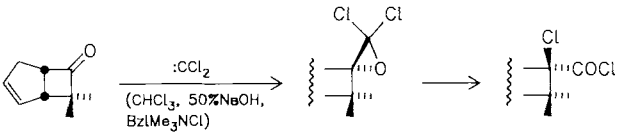


390 **391**, 70%



392, 72% **393**

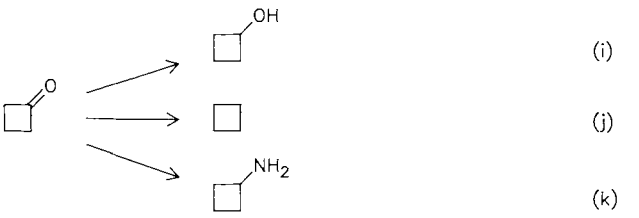
Olefinations of cyclobutanones using the methods of *Wittig* (e.g. [68,91,229]) or *Horner* (e.g. [230]) to give methylenecyclobutane derivatives occur as expected without difficulty.—It was the cyclobutanone **394** which allowed the first ever isolation of an adduct between dichlorocarbene and a carbonyl group: dichlorocarbene, generated under phase transfer conditions, reacts with **394** to give the isomerically pure dichlorooxirane **395**, which on heating rearranges stereospecifically to the *endo*-acid chloride **396**.[231]



394 **395**, 85% **396**, 97%

10.2. Reductions

The reduction of cyclobutanones to cyclobutanols (i) or cyclobutanes (j) and the reductive amination to cyclobutylamines (k) according to Scheme 3 are all processes which are well documented in the literature:



Scheme 3.

(i) Apart from enzymatic reduction[166a,b,232] (see also Section 7), various hydrides have been employed for the reduction of cyclobutanones to cyclobutanols: $LiAlH_4$,[55a,91,154,233] $NaBH_4$,[39b,145b,152,179,234] diisobutylaluminum hydride,[235] $Na[Al(OCH_2CH_2OMe)_2H_2]$,[236] $Li[Al(tBuO)_3H]$,[237] $(iPrO)_3Al/iPrOH$,[238] and $Li[(sBu)_3BH]$.[239] The reduction of cyclobutenones with either $LiAlH_4$[240] or with $NaBH_4$[234i] proceeds chemoselectively to afford the cyclobutenols, while with hydrogen and Ru/C as catalyst[241] only cyclobutanols are obtained.

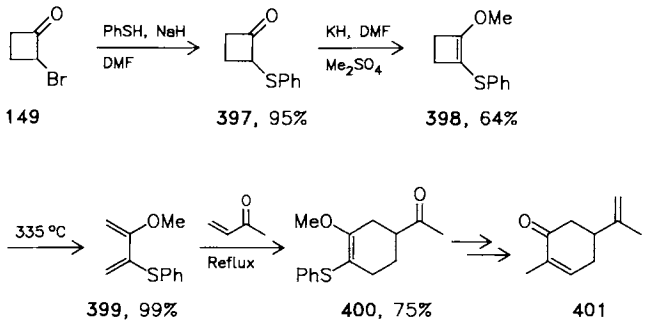
(j) The reduction of cyclobutanones to cyclobutanes can be accomplished by the usual methods such as Wolff-Kishner reduction,[42,73a,242] reduction of the corresponding tosylhydrazone with $NaBH_4$[2d] or reduction of the corresponding thioketal with Raney nickel.[220,234e]

(k) Several examples of straightforward reductive amination of cyclobutanes to cyclobutylamines via reduction of the corresponding cyclobutanone oximes with sodium in 2-propanol[243] or $LiAlH_4$[244] have been described.

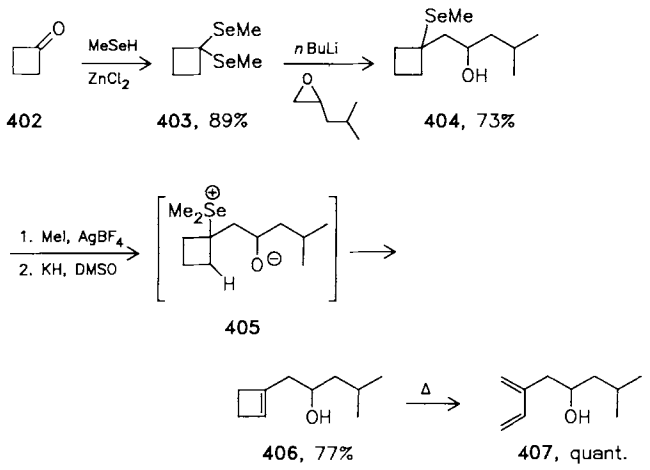
10.3. Syntheses of Cyclobutene Derivatives

Cyclobutene derivatives can be transformed into butadiene derivatives via an electrocyclic ring opening. This method of "in situ" preparation is particularly interesting for butadienes which cannot be isolated due to their high tendency to undergo polymerization. For this reason, the synthesis of the cyclobutenes which serve as starting materials often plays a key role. *Trost* et al. studied in detail the suitability of cyclobutanones for the preparation of 2,3-disubstituted butadienes of type **399**[245] and of 1,4-disubstituted butadienes[234b] via electrocyclic ring opening. The syntheses of carvone **401**[245a] and ipsenol **407**[246] illustrate the underlying synthetic principle: the cyclobutene deriva-

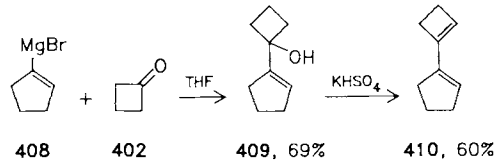
tive **398**, which is readily available from α-bromocyclobutanone **149**, can be transformed via a thermal electrocyclic ring opening into the butadiene **399**. The [4+2]-cycloaddition of **399** with methyl vinyl ketone gives the carvone precursor **400** with high regioselectivity.



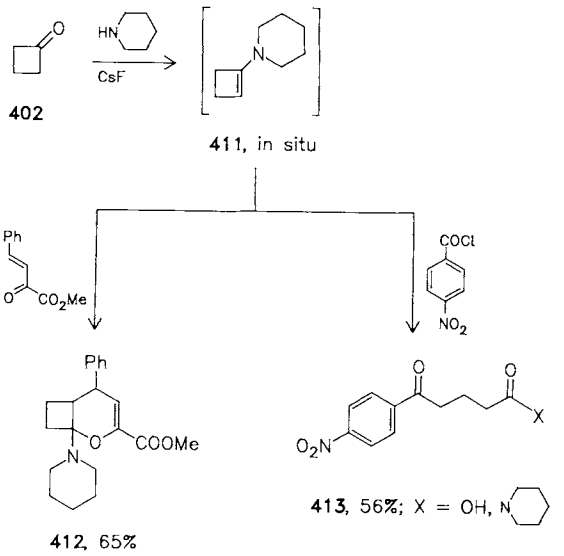
Krief and *Halazy* used the thermal electrocyclic ring opening of the cyclobutene derivative **406** in the synthesis of ipsenol **407**.[246] The former was prepared from cyclobutanone **402** via the 1,1-bis(methylseleno)cyclobutane **403** and the γ-(methylseleno)alcohol **404**.



A further method for the preparation of butadiene derivatives was described by *Thummel* et al.[247] During their studies on [4+2]-cycloadditions of 1-vinylcyclobutenes, they prepared the cyclobutene **410** via Grignard addition of **408** to the cyclobutanone **402**.



While the silyl enol ethers of cyclobutanones (precursors for synthetically useful electron-rich butadienes) can readily be obtained by a trimethylsilylation under basic conditions,[248] the first successful "in situ" preparation of the cyclobutanone enamine **411** by a modified Mannich–Davidson method has only recently been described.[249] **411** reacts both as a dienophile (→**412**) and as a typical enamine (→**413**).

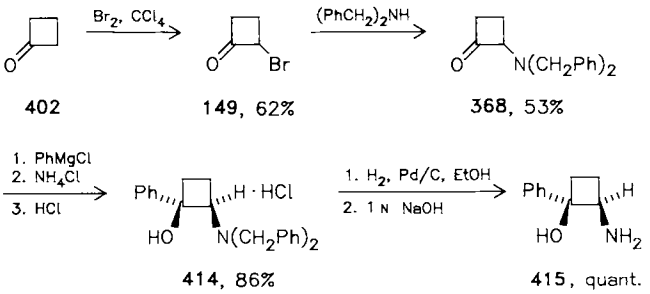


11. Substitution in the α-Position

The numerous methods of transforming α-substituted cyclobutanones which have been presented in the previous sections made it clear that the methods for α-functionalization are of particular synthetic importance. In general, they differ only little from the standard methods for α-functionalization of ketones; however, some reactions (e.g. the use of nucleophilic bases for generating α-anions) are of little use because of the tendency of cyclobutanones to undergo ring opening as well as self-condensation.

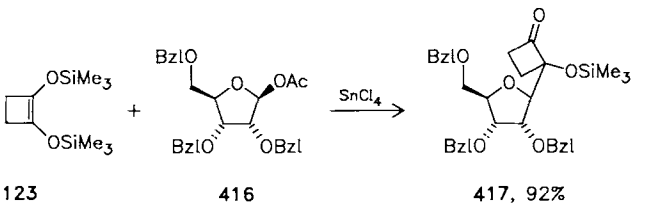
11.1. Mono- and Dibromination

Both monobromination in the α-position (e.g. **195**→**196**, see also Ref. [250]) as well as the α,α-dibromination[23,144] of cyclobutanones with bromine are readily carried out. The α-bromocyclobutanones are commonly subjected to the Favorskii ring contraction reactions (see Section 4). In addition, their use may be exemplified by the synthesis of the norephedrine analog **415**:[250b] the α-bromocyclobutanone **149** is allowed to react with dibenzylamine to give the α-aminocyclobutanone derivative **368**. Stereoselective *trans*-addition of phenylmagnesium chloride leads to the amino alcohol **414**, a precursor of **415**.

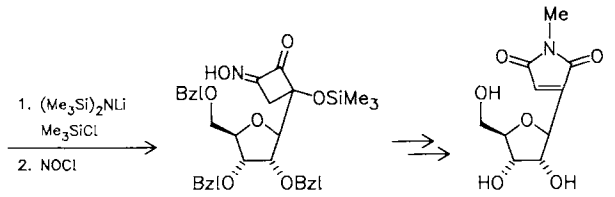


11.2. Oxidation

SeO_2-oxidation at the α-position of cyclobutanones converts them into cyclobutanedione derivatives (compare **34** → **35**). *Inoue* and *Kuwajima*[251] used the oxidation of the cyclobutanone derivative **417** to the 2-(hydroxyimino)cyclobutanone **418** with nitrosyl chloride in the remarkable synthesis of the nucleoside showdomycin **419**. The glycoside linkage to the α-position of the cyclobutanone **417** was formed by reaction of **123** with the β-D-ribose derivative **416** in the presence of $SnCl_4$.



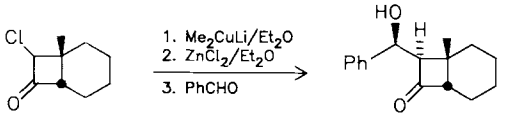
123 416 417, 92%



418, quant. 419

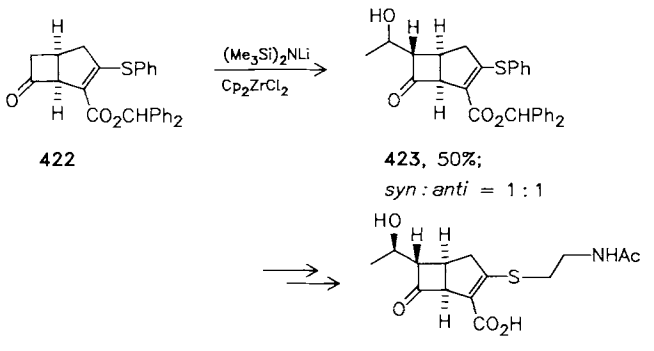
11.3. Condensation

The condensation of cyclobutanones with aldehydes via lithium enolates leads either to complex mixtures[252] or to the formation of products of self-condensation of the cyclobutanones.[253] However, *Clark* et al.[252] showed that the enolate prepared from α-chlorocyclobutanone **420** with Me_2CuLi can undergo reaction with a number of aldehydes to give aldol products in good yields.



420 421, 83%

A mild alternative is provided by zirconium enolates: thus the zirconium enolate of **422** was used in the synthesis of *N*-acetyl-1-deazathienamycin **424**, an example of a

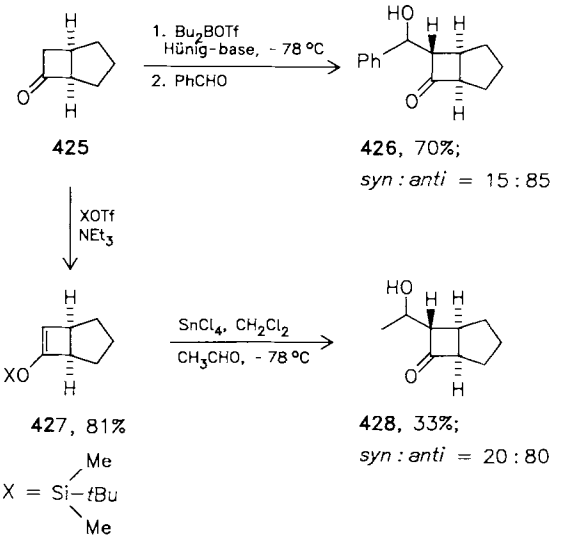


422 423, 50%; *syn* : *anti* = 1 : 1

424

cyclobutanone analogue of β-lactams[79,187,189] to introduce the hydroxyethyl side chain typical for thienamycin.[189d]

The condensation with aldehydes is also possible via boron enolates (e.g. **425** → **426**) or via the Lewis-acid-catalyzed reaction of silyl enol ethers (e.g. **427** → **428**).[253]



425 426, 70%; *syn* : *anti* = 15 : 85

427, 81% 428, 33%; *syn* : *anti* = 20 : 80

A further possibility for the functionalization of the α-position is provided by the condensation of cyclobutanones with *tert*-butyl formate (e.g. **19** → **237**) or with its equivalent $(Me_2N)_2CHOtBu$.[114,250a,254] In this manner *Greenlee*[254] succeeded in synthesizing the diterpene (±)-trihydroxydecipiadiene **432** starting from the cyclobutanone **429**. The tetracyclic compound **430** was prepared by spiroannelation of **429**[255] using the method of *Trost* et al.[79c,256] The synthesis involves a number of remarkable steps in which the construction and transformation of cyclobutanones play a key role (DMAP = 4-dimethylaminopyridine).

11.4. Dehalogenation in α-Position

The mono- and dihalogenocyclobutanones are very readily available via [2+2]-cycloaddition reactions of mono- and dihalogenoketenes[4a-d] to olefins. Thus, they are valuable polyfunctional precursors for a great variety of syntheses. However, since the target molecules are generally halogen-free, countless reductions of α-halogenocycloadducts to halogen-free cyclobutanones have been described. Besides the standard method with Zn/AcOH (e.g. **23**→**24** or **61**→**97**; see also Refs. [7g, 43, 44, 46c, 53, 66b, 76, 127, 189c, 206d, 233b, 234d, 239b]) and with $Zn/NH_4Cl/MeOH$,[33d,235d,254] the following reducing agents have also been employed: n-Bu_3SnH/azoisobutyronitrile (AIBN);[4a,39b,152,257] Ph_3SnH/AIBN[234a] and $CrCl_2$.[141,233c,258]

The selective reduction to monochloro derivatives is also possible: thus for example **61** is reduced selectively by Zn/AcOH[259] or Bu_3SnH/AIBN[257a] to the *endo*-monochloroisomer **31**. However, the exact experimental conditions for a monoreduction must be established in each particular case.

12. Summary and Outlook

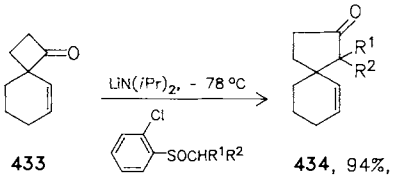
Since the first synthesis of a cyclobutane was accomplished by *Perkin* a hundred years ago,[260] the highly-strained four-membered ring compounds have demonstrated their unique usefulness in the interplay between theory and practice[261] as well as in the race to synthesize molecules with the maximum possible strain.[262] However, the inherent strain of the four-membered ring of ca. 25 kcal mol^{-1} was only definitively placed in the service of the preparative chemist in the past twenty years, when it became readily possible to obtain a large variety of substituted cyclobutanones. [2+2]-Cycloaddition reactions between ketenes and olefins and the Trost synthesis of cyclobutanones starting from aldehydes and ketones are broad in scope and now represent the most reliable routes to cyclobutanones and cyclobutenones. Several other methods which have only been mentioned briefly in this review, as well as the routes to optically active cyclobutanones described in Section 7, are certainly capable of considerable extension. They guarantee that the methods for transforming cyclobutanones and cyclobutenones summarized here will render new strategies in synthetic planning possible. One can expect that the complex and unique combination of strain, electrophilicity and puckering in the title compounds will frequently lead to many fascinating surprises. This review is intended to make a contribution towards overcoming the "trial and error" synthetic approach, so that a more precise and faster forecast of the required regio-, chemo-, and stereoselectivity of transformations of cyclobutanones and cyclobutenones can be achieved.

13. Addendum[*]

For the preparation of γ-butyrolactones (cf. Section 3.1) from cyclobutanones, *Matsumo* et al.[263] recommend the use of H_2O_2/2,2,2-trifluoroethanol.

[*] Received: May 6, 1988.

The ring enlargement of cyclobutanones of type **433** to cyclopentanones **434–436** (cf. Section 3.3) with α-lithioalkylaryl sulfoxides and selenoxides enables incorporation of both an unsubstituted as well as a mono- or disubstituted α-carbon atom in one step.[264]

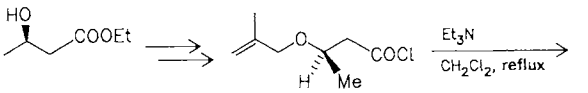


433

434, 94%, $R^1 = R^2 = H$
435, 63%, R^1 = Me, $R^2 = H$
436, 54%, $R^1 = R^2$ = Me

A ring enlargement to the cyclopentanone (cf. Section 3.3) can also be achieved by reaction of cyclobutanones with lithiated thioacetal.[265]

Starting from (*R*)-3-hydroxybutyrates **437**, *Mori* and *Miyake*[266] synthesized the ketene precursors **438**. An intramolecular ketene cycloaddition afforded the two diastereomeric cyclobutanones (+)-**439** and (−)-**440** in the ratio 7:2. The main product (+)-**439** was converted into (+)-grandisol **441**, the pheromone of the boll weevil (cf. Section 7.2).



437 **438**

Fráter et al.[267] showed that the [2+2]-cycloaddition of menthyloxymethylketene to (*Z*)-benzyl hexenyl ether **442** leads mainly to the kinetically controlled product **443**. Subsequent refluxing in triethylamine affords the cyclobutanone **445** as major product of a thermodynamically controlled reaction. Finally, (−)-blastamycinone **446** was obtained (cf. Section 7.3).

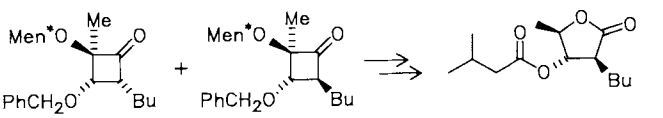
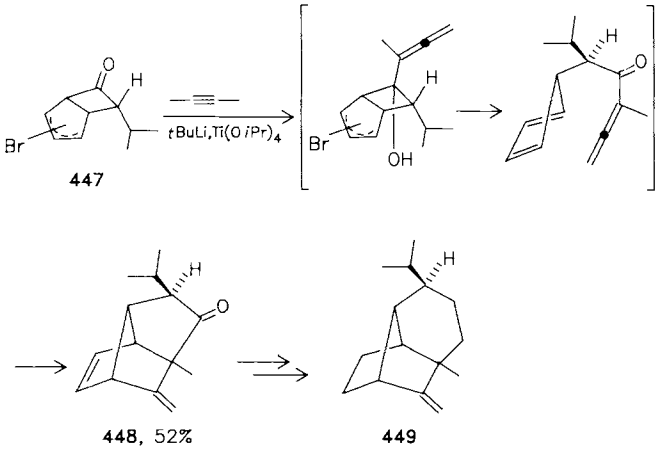
≡ Men*OCH(CH3)COCl



444 (1 : 9) **445** **446**, ≈ 70% *ee*

Pirrung and *Deamicis*[268] investigated many examples for the formation of α-O-, α-S- and α-N-substituted tetrahydrofurans by photolytic ring enlargement of cyclobutanones in the presence of O-, S- and N-nucleophiles (cf. Section 9).

Dreiding et al.[269] used an interesting conversion of the 1,2-adduct of the buta-1,2-dienyltitanium compound (from but-2-yne, *t*-BuLi and $Ti(OiPr)_4$) with the cyclobutanone **447** for the synthesis of (±)-sativene **499** (cf. Section 10.1).



Wakamatsu et al.[270] developed two methods for the 1,2-carbonyl transposition in cyclobutanones (cf. Section 11).

The selective monodehalogenation of 2,2-dichlorocyclobutanones can be carried out in moderate to good yields[271] with magnesium-anthracene (cf. Section 11.4).

Danheiser and *Savariar*[272] have shown that 4,4-dichlorocyclobutenones can be reduced in yields of 70–90% to the corresponding cyclobutenones with zinc/ethanol in the presence of 5 equivalents each of AcOH and TMEDA.

Our own work cited here would not have been possible without the dedicated efforts of many colleagues whose names appear in the literature references; to them we wish to express our heartfelt thanks.

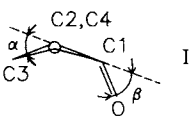
[7] Cyclobutanones are generally puckered in order to relieve strain. A survey of the X-ray structural analyses of 26 cyclobutanones showed that the dihedral angle α between the planes defined by the atoms C(1), C(2) and C(3) and C(1), C(2) and C(4) can reach a value of 41.6° [7a]. In addition, an unexpected deviation β of the carbonyl oxygen atom to the *endo*-side ("Concorde-nose") is demonstrated by the projection **I**. The angles α and β are interdependent: an increase in α is generally also linked with an increase in β: 5-*endo*-(*o*-hydroxyphenoxy)-1,2,5,6-tetramethyltricyclo[2.2.0.$0^{2,6}$]hexan-3-one, $\alpha = 38.2°$; $\beta = 11.3°$ [7b]; 4'-chloro-1',2',3',4'-tetrahydro-3'-oxocyclobuta[1',2':2,3]cholestan-3-yl acetate, $\alpha = 35.4°$; $\beta = 13.5°$ [7c]; 2-chloro-3,3-dimethyl-4-(2,2,2-trichloroethyl)cyclobutanone, $\alpha = 31.5°$; $\beta = 10.6°$ [7d]; 2,2-diphenyltricyclo[4.4.1.$0^{1,4}$]undecan-3-one, $\alpha = 26.2°$; $\beta = 6.3°$ [7e]; 2,2,4,4-tetramethyl-3-pyrrolidinocyclobutanone, $\alpha = 19.4°$; $\beta = 3.0°$ [7f]; 6,6-dichloro-7-



I

oxobicyclo[3.2.0]hept-3-ene-2-carboxylic acid, $\alpha = 16.9°$; $\beta = 1.0°$ [7g]. This O1-*endo*-deviation β allows the p-orbitals at C(1) and O(1) to take a position perpendicular to the C(1) tangential plane of the cyclobutanone "banana" bonds, thus enabling an optimal sp^2-hybridization at C(1) [7d]. – a) C. [218] The values found in the literature for the bond angle C(2)C(1)C(4) in monocyclic cyclobutanones, which are taken from X-ray structural determinations, vary between 90.4 [218a] and 93.5° [7f]. The corresponding angle in the unsubstituted cyclobutanone was determined by microwave spectroscopy to be 93.1±0.3° [218b]. – a) R. Hoge, J. Jager, K. Fischer, *Cryst. Struct. (Mesityl)$_2$Ge(fluorenylidene)—Stabilization of a Ge–C Double Bond by Charge Transfer into an Aromatic System**

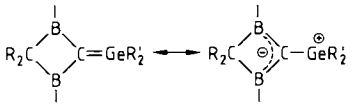
By *Mohamed Lazraq, Jean Escudié,* Claude Couret, Jacques Satgé, Martin Dräger,** and *Ralph Dammel**

Multiple bonds to elements of groups 14 and 15 have been the subject of broad interest in recent years.[1] This is especially true for investigations[2] on silaethenes **1** stabi-

$R_2C{=}SiR'_2$ (1) $R_2C{=}GeR'_2$ (2)

lized by bulky groups; the analogous germaethenes **2**, on the other hand, could only be detected until recently by trapping reactions.[3] Newly obtained pure germaethenes **3**



(3)

are stabilized by resonance with an ylide form,[4a] and, for the ether adduct **4b**, we have postulated resonance stabilization involving the fluorenylidene system.[4b] As evidence, we have sought to obtain donor-free **4b** (=**4c**) and to carry out crystal structure analyses of **4c** and of the dihydride **4d** for comparison.

Direct dehydrofluorination of **4a** in a nondonor solvent always gives a nonseparable mixture of **4a/4c/4d**, whereas, in ether, smooth reaction occurs to yield **4b**.[4b] Compound **4b** is very stable thermally; heating it for 15 h at 110°C converts it into **4c**,[5] and reductive hydrogenation of **4b** or **4c** provides **4d**.[4b]

The results of the X-ray structure analyses of **4d** and **4c** are shown in Figures 1 and 2, respectively.[6] The Ge–C1 bond in **4d** (201 pm) is one of the longest known Ge–C

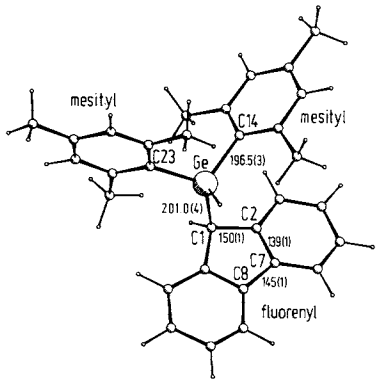

Fig. 1. Structure of **4d** [6] with mean distances [pm] around Ge and in the five-membered ring (with experimental esd's of the individual values Ge–C14 196.4, Ge–C23 196.5; angles around Ge 113.4(2), around C1 105.5(3)°). For a normal fluorenyl group, the mean distances [pm] in the five-membered ring (with standard deviations of the mean value) obtained from analysis of 45 structures [7] are C1–C2 151.9(12), C2–C7 139.5(9), C7–C8 146.3(11) (individual fluctuation C1–C2 148.9–154.1, C2–C7 137.3–142.2, C7–C8 144.0–149.1).

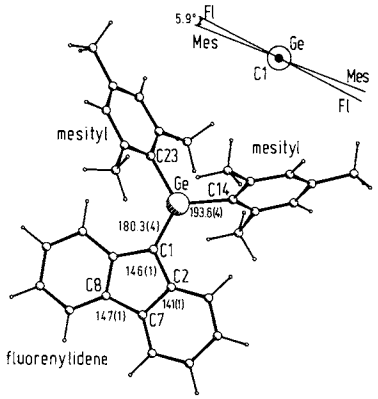

Fig. 2. Structure of **4c** [6] (two crystallographically independent molecules which hardly differ otherwise) with mean distances [pm] around Ge and in the five-membered ring (with experimental esd's of the individual values Ge=C1 180.1 and 180.6, Ge–C14/C23 193.1–194.4; sum of angles around Ge 360.0(2), around C1 360.0(3)°). Above right: Mean twisting around the Ge=C1 bond (variation of the eight torsional angles 4.8–8.6 and 171.0–180.0°). For a normal fluorenylidene group, the mean distances [pm] in the five-membered ring (with standard deviations of the mean values) obtained from analysis of 27 structures [7] are C1–C2 147.2(16), C2–C7 140.5(12), C7–C8 145.9(1) (individual fluctuation C1–C2 144.0–149.6, C2–C7 138.1–143.2, C7–C8 143.6–148.7).

single bonds and, as further evidence for the increased steric encumbrance, differs markedly in length from those of the bonds Ge-C14 and Ge-C23, which lie in the normal range. The Ge atom in **4c** exhibits trigonal-planar coordination (mean deviation ± 1.4 pm). The Ge-C1 distance is 21 pm shorter than in **4d**, and the bonds Ge-C14 and Ge-C23 are also shorter (3 pm) owing to the involvement of sp^2 Ge. In **3**, the length of the Ge=C bond is 183 pm.[4a] Since the mesityl groups in **4c** are twisted to the same extent, it is possible to view the Ge=C bond (= Ge-C1) as a twofold axis.

The fluorene moiety in both compounds corresponds well to the literature data for fluorenyl and fluorenylidene groups. In **4c**, the fluorenylidene moiety is planar (mean deviation ± 2.5 pm), and the planarity extends to the Ge-(C14)-C23 group as well (mean distance of these atoms above the fluorenylidene plane and mean angle made with the plane, +15.1 pm and 7.0°, respectively; mean twisting around Ge=C 6° compared with 36° in **3**). This finding, namely that sixteen atoms lie nearly in the same plane despite higher steric strain than in **4d**, supports our postulate of a stabilization of **4c** by electronic interactions between Ge=C and the fluorenylidene moiety. Similar stabilization of a P-C and of a B-C double bond by the fluorenylidene system is known;[8] for P-C double bonds, interactions with the fluorenylidene π electrons have been proposed.[8a]

Owing to its size, the system **4c** is still too large for the ab initio calculations routinely performed. To study theoretically the above hypothesis, we therefore employed semiempirical (MNDO) calculations, which could provide a satisfactory description of the Ge=C bonding (Table 1), as shown by a comparison of the results obtained for the parent compound $H_2Ge{=}CH_2$ using semiempirical and detailed SCF calculations.[9] The MNDO optimization of the geometric parameters[10a] gave values that, within the limits of error of the method, are in good agreement with the results of X-ray analysis.[10b] The Ge-C double bond is strongly polar; the bond order is significantly less than that of the parent compound (1.50 vs. 1.81). The dipole moment of **4c** is estimated to be 4 Debye. The great importance of a resonance structure $R'_2\overset{\oplus}{G}e{=}C\overset{\ominus}{R}_2$ for describing compounds of type **2** readily explains the better stabilization of **4c** compared with the compounds $R'_2Ge{=}C(Aryl)_2$. The delocalization of the excess negative charge into the fluorenylidene system is much better than in two aryl moieties.[11]

The Raman spectra of finely crystalline **4c** and **4d** hardly differ. To estimate the position of a Ge=C valence vibration, we employed once again ab initio SCF and MNDO calculations.[9, 10c] Such calculations have proved surprisingly reliable for a compound with a Ge-P double bond (Table 1).[12] For **4c**, the Raman- and IR-active valence vibrations of the Ge-C double bond are expected at about 1000 cm^{-1}. In this region, the totally symmetric arene vibrations of the powder sample of **4c** are more strongly structured than those of **4d**, but are not resolved. In order to resolve or decouple further, we recorded single-crystal Raman spectra for several orientations of the two compounds. The only significant difference is a marked emission at 988 cm^{-1} for **4c**, which we assign to the Ge=C valence vibration.

Table 1. Ab initio and MNDO calculated values and experimental values for the distances d(Ge=X) and valence vibrations of compounds containing Ge-X double bonds.

Compound	Calculated		Observed	
	d [pm]	$\tilde{\nu}$ [cm^{-1}]	d [pm]	$\tilde{\nu}$ [cm^{-1}]
$H_2Ge{=}PH$	216.9	481 [a]		
$Mes_2Ge{=}PAryl$ [c]			213.8	503
$H_2Ge{=}CH_2$	177.6	906 [a]		
	172	854 [b]		
4c [d]	177	1018 [b]	180.3	988

Distorted Triple-Diamond Structure of 3,3-Bis(carboxymethyl)glutaric Acid ("Methanetetraacetic Acid")**

By *Otto Ermer** and *Andreas Eling*

Tetrafunctional organic molecules with tetrahedrally directed substituents are endowed with the fascinating faculty of building novel diamond-like networks in the crystal

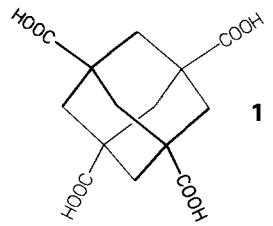
("diamondoid" crystal structures). A first and prototypal example is adamantane-1,3,5,7-tetracarboxylic acid **1**,[1]

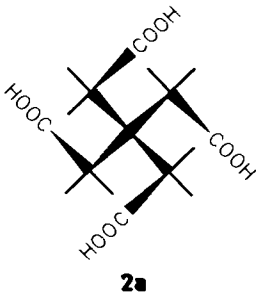


1

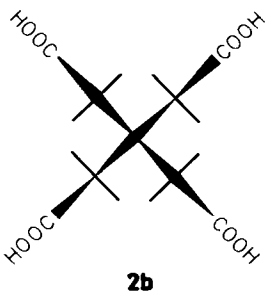
which contains tetrahedrally directed carboxyl groups to a good approximation and has a relatively rigid carbon skeleton. The carboxyl groups are interconnected by pairwise hydrogen bonds, such that a molecular architecture results which corresponds to an almost undistorted "super-diamond" structure. However, this highly symmetric, three-dimensional network has very large cavities since the distance between neighboring hydrogen-bonded molecules is appreciable (ca. 10.1 Å). These unfavorable interstices are filled in the crystal in a unique fashion through mutual interpenetration of altogether no less than five translationally equivalent diamondoid networks of **1** (fivefold-diamond structure). The concatenated diamondoid networks are otherwise unconnected; hydrogen bonds occur only within one and the same diamondoid network.[1]

The structure analysis of the adamantanetetracarboxylic acid **1** marked the beginning of a more comprehensive and systematic study of the crystal packing modes of tetrafunctional organic molecules with tetrahedrally directed substituents, especially those capable of forming intermolecular hydrogen bonds. We are particularly interested in the possible capability of such systems to serve as host structures in solid-state inclusion compounds, which may be anticipated in view of the open-meshed three-dimensional networks. Furthermore, diamondoid molecular architectures represent structural models for hypothetical "diamondoid polymers" potentially displaying isotropic high-performance properties.

For the four carboxyl groups of 3,3-bis(carboxymethyl)glutaric acid ("methanetetraacetic acid") **2**[2] tetrahedral directionality may also be envisaged. Accordingly, **2** may also in principle build up diamondoid molecular



2a



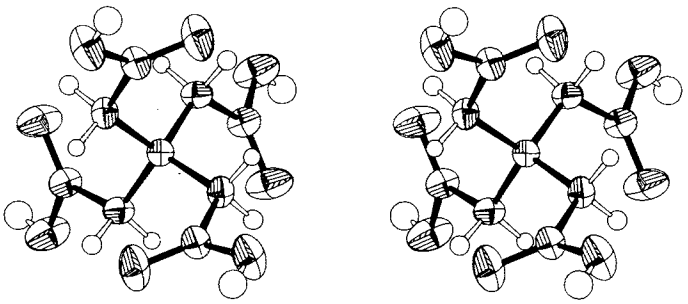
2b

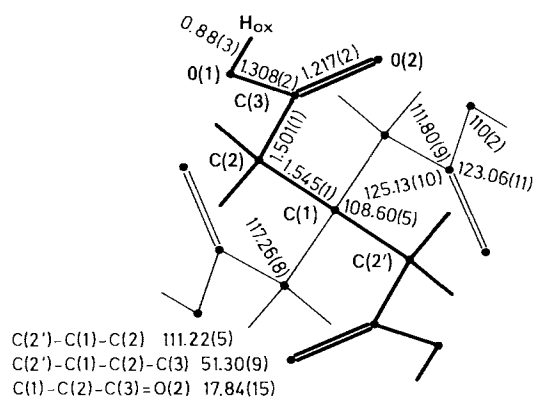
frameworks in the crystal. Model considerations show that diamondoid networks of **2** again involve large cavities (see Fig. 2), yet not as large as in **1**. If **2** indeed forms diamondoid networks, interpenetration of several such architectures thus appears inevitable once again, although the degree of interpenetration (= number of mutually interlocking networks) is expected to be smaller than for **1**. It should be borne in mind, however, that the prerequisites for building up diamondoid structures appear less favorable in the case of **2** than of **1**. On the one hand, the carbon skeleton of **2** is, in contrast to **1**, conformationally flexible, and an approximate tetrahedral orientation of the carboxyl groups is only possible if conformations of type **2a** or **2b** are taken up (highest possible symmetries, S_4 and D_{2d}, respectively).[3] On the other hand, strictly speaking the carboxyl functions in **2a** and **2b** are oriented tetrahedrally merely in a displaced fashion since these groups are not, as in **1**, directed towards a common point, viz. the molecular center. Conversely, however, the conformational flexibility of **2** could also lead to better compliance with diamondoid packing requirements.

These thoughts led us to perform an illuminating crystal structure analysis of **2**, which is reported here. The X-ray measurements show that the molecules of **2**, like those of **1**, do indeed join to build up mutually interlaced, hydrogen-bonded diamondoid networks.

The molecules of methanetetraacetic acid **2** exhibit S_4 symmetry in the tetragonal crystals and adopt the conformation **2a** (Fig. 1).[4] This structure is strained, as evidenced by the angles C(1)-C(2)-C(3), which are opened out to 117.26(8)°. These angle openings may be attributed to four pairs of short intramolecular O···H contacts (2.44 and 2.51 Å) involving the carbonyl oxygen atoms. If the hydroxyl oxygen atoms were involved instead, even stronger O···H repulsions would arise given the preferred bond lengths and angles in carboxyl groups. This reasoning also helps to explain why no orientational disorder of the carboxyl groups is observed, unlike quite frequently in other cases.

In the crystal, **2** forms tetragonally (along the crystallographic axis *c*) elongated diamondoid networks, which are





C(2')-C(1)-C(2) 111.22(5)
C(2')-C(1)-C(2)-C(3) 51.30(9)
C(1)-C(2)-C(3)=O(2) 17.84(15)
O(2)=C(3)-O(1)-H_{ox} -5(2)

Fig. 1. Above: Stereoview of **2** along the fourfold rotation-inversion axis S_4; thermal ellipsoids with 50% probability, temperature factors of hydrogen atoms divided by 3. Below: Selected bond lengths [Å], bond and torsion angles [°], and atomic numbering.

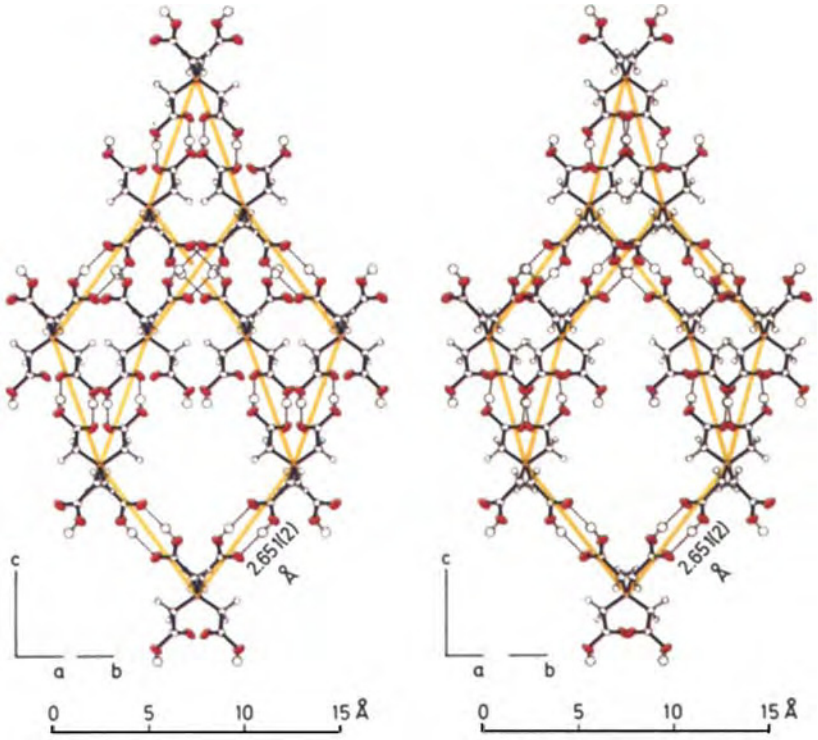


Fig. 2. Stereoview (perpendicular to c axis) of a hydrogen-bonded superadamantane unit of a diamondoid network of **2**. Note the tetragonal elongation along c and the large central cavity, which is filled in the crystal by two equivalent, interpenetrating diamondoid networks. The oxygen atoms are shown in red, and the superadamantane framework is highlighted by yellow lines interconnecting the molecular centers.

held together by pairwise hydrogen bonds between the carboxyl groups; the distance between bridged neighboring molecules is 8.761 Å. A "superadamantane" section of such a network is shown in Figure 2. The distance between opposite molecules along the c axis is $3c$ and that at right angles $\sqrt{2}\,a$, which results in an elongation factor of $3c/(\sqrt{2}\,a) = 1.6914$ (see also Figs. 3 and 4). The corresponding factor for the only slightly distorted diamondoid networks of the adamantanetetracarboxylic acid **1**, which also crystallizes tetragonally, is 0.9376.[1]

The diamondoid networks of **2** are hollow (Fig. 2), although less pronounced than in **1**. The cavities are filled in such a way that each network is interpenetrated by two further ones. Thus altogether three diamondoid networks mutually interpenetrate in **2** (degree of interpenetration = 3), as compared to five in the case of **1**. The distorted triple-diamond structure of **2** is without precedent; only a number of double-diamond structures are known (see Ref. [1]). The three interlaced diamondoid networks of **2** are translationally equivalent and may be merged into each other by shifting them along the c axis by the value of the cell edge $c = 8.962$ Å.[4] This both simple and beautiful mode of interpenetration is illustrated schematically in Figure 3. Three diamondoid networks are shown (black, red, yellow), each consisting of two connected superadamantane frameworks. Only the molecular centers are drawn (small spheres) and interconnected by rods symbolizing hydrogen bonding. The mode of interpenetration of the fivefold-diamond structure of **1** is different and not as simple, although both tetracarboxylic acids crystallize in space group $I4_1/a$.[1,4,6]

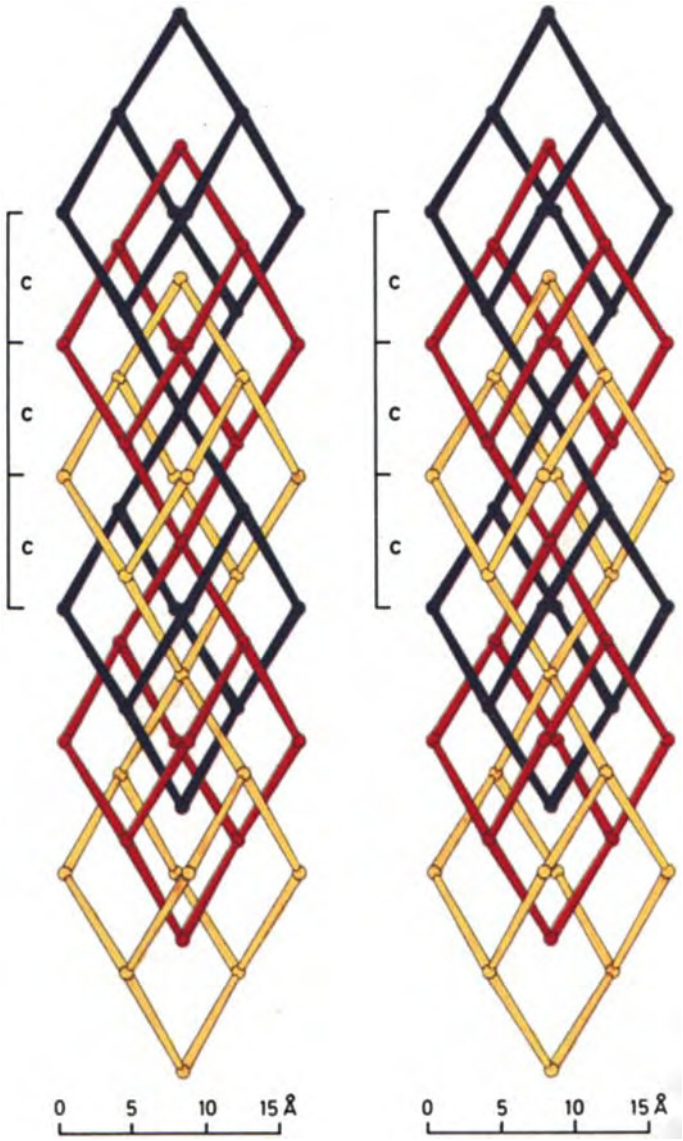

Fig. 3. Schematic stereoview (along the bisector between a and b axes) of the three interpenetrating, tetragonally elongated diamondoid networks of **2** (black, red, yellow), which are each represented by two connected superadamantane frameworks. The translational equivalence of the networks is clearly evident. Only the central carbon atoms of **2** are shown (S_4 axes); the interconnecting rods symbolize the methylene groups and the carboxyl functions tied together by pairwise hydrogen bonds (cf. Fig. 2).

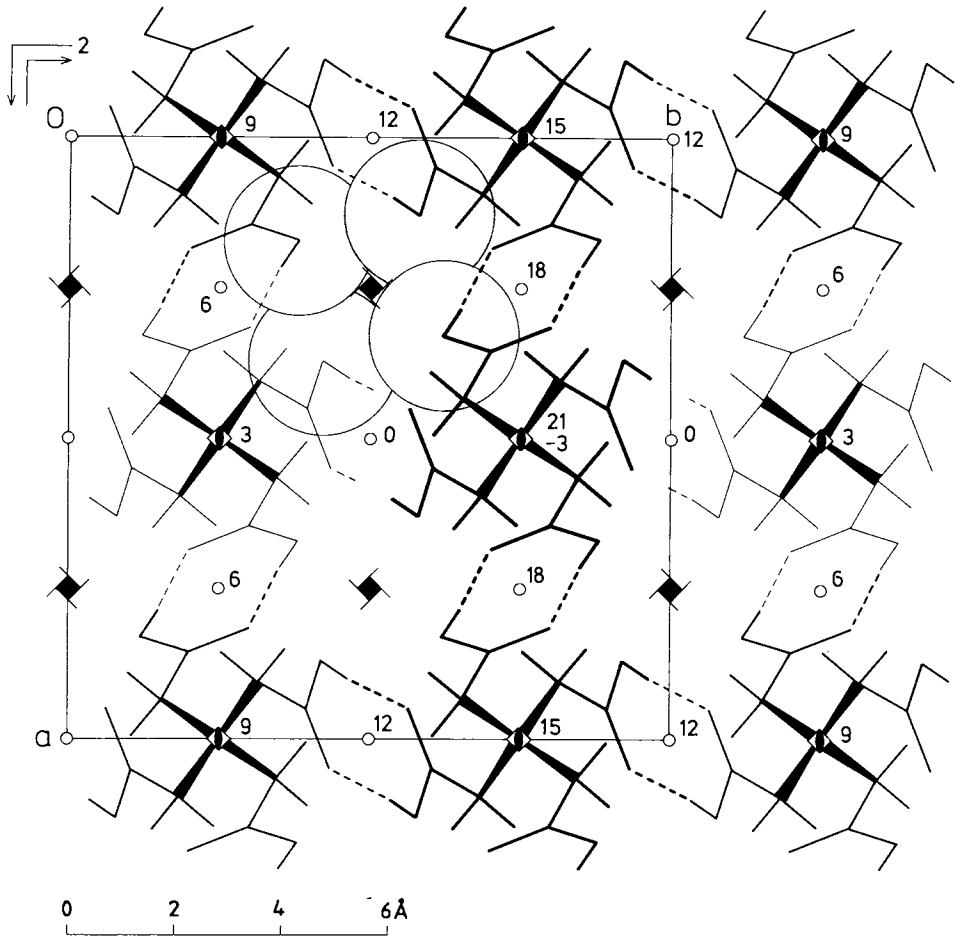

Fig. 4. Space group symmetry diagram of **2**, projected along the tetragonal *c* axis. The symmetry elements of the space group $I4_1/a$ are given, as are the heights of the molecular centers (S_4 axes) in units of $c/8$. Ten molecules of **2** are shown, which build up an elongated superadamantane framework (see Fig. 2). The space required by four hydroxyl oxygen atoms about a fourfold screw axis is indicated by circles with van der Waals radius 1.4 Å, in order to point out that no open channels exist along these symmetry elements (see text). Two molecules in the middle of the diagram are superimposed in this projection.

In the diagram of Figure 4 showing the packing and symmetry of the crystals of **2**, channels are perceptible along the fourfold screw axes, i.e., in the direction of translation of the interlocking diamondoid networks. These channels are not empty, however, but appear adequately filled by the carboxyl groups, such that the formation of solid-state inclusion compounds may hardly be visualized within the triple-diamond structure of **2**. This view is supported by the observation that no uptake of water into the crystals occurs, despite crystallization from aqueous medium.[4] On the other hand, a lower degree of interpenetration, say within a double- or even single-diamond structure, may render feasible the formation of inclusion compounds of **2**.

An interesting structural analogy between methanetetraacetic acid **2** and potassium dihydrogen phosphate KH_2PO_4[7] may be drawn. Above 123 K, KH_2PO_4 crystallizes tetragonally (space group $I\bar{4}2d$), and the $H_2PO_4^{\ominus}$ ions form, like **2**, a diamondoid network held together by hydrogen bonds. Unlike in **2**, however, the $H_2PO_4^{\ominus}$ ions are, for stoichiometric reasons, tied together by single rather than pairwise hydrogen bonds. Averaged over space and/or time, the single O-H···O hydrogen bonds are symmetric (disordered), and, owing to the negative charge, shortened (O···O distance, 2.487(5) Å[7c]). Furthermore, the diamondoid network of the $H_2PO_4^{\ominus}$ ions exhibits a severe tetragonal compression (by a factor of 0.6606) and is less hollow, so that only a single distorted diamondoid anionic architecture is built. Nonetheless, holes are still present, and are occupied by the $K^{\oplus}$ ions in such a way that one $K^{\oplus}$ ion lies in the center of each compressed superadamantane subunit. KH_2PO_4 may thus be considered as a tetragonally compressed diamondoid structure with two interpenetrating networks, one formed by the hydrogen-bonded $H_2PO_4^{\ominus}$ ions and one by the $K^{\oplus}$ ions (distorted "mixed" double-diamond structure).[8]

At 123 K, KH_2PO_4 undergoes a phase change and is polar orthorhombic below this temperature (space group *Fdd*2) with ordered asymmetric O-H···O hydrogen bonds.[7] This ordering process is accompanied by the onset of ferroelectric and piezoelectric properties, which can be utilized technologically. Thus, by straightforward analogy, the appealing possibility emerges that dihydrogen tetracarboxylates with tetrahedral molecular cores of general composition $T(COOH)_2(COO^{\ominus})_2$ may form (interpenetrating) diamondoid networks tied together by single, yet short, charged O-H···O hydrogen bonds. (In the current examples **1** and **2**, T stands for the central adamantane and tetramethylmethane skeletons, respectively.) Singly or multiply charged metal ions could play the role of counter-

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0606-0832 $ 02.50/0

ions, which may be accommodated in the cavities of the interlocked diamondoid anionic networks. Like KH_2PO_4, diamondoid dihydrogen tetracarboxylates could exhibit interesting ferroelectric and piezoelectric properties, provided the short hydrogen bonds are also asymmetric (double-minimum potential).

[5] More than 60 years ago, *Knaggs* reported an axial ratio $a:c=1.786$ for **2** from measurements of dihedral angles between crystal faces (I. E. Knaggs, *J. Chem. Soc. 1923*, 71). This ratio agrees closely with $\sqrt{2}$ times our X-ray value (=1.774), and follows from rotating the axis system about the tetragonal c axis by 45°. Furthermore, *Knaggs* measured a density of 1.460 g cm^{-3}, and the refraction indices $n_e(\parallel c)=1.518$, $n_o(\perp c)=1.487$. The crystal class she gave as holohedral (D_{4h}), whereas it is actually C_{4h}, as evidenced by our measurements. Presumably, this discrepancy is due to the fact that her crystals had no general faces developed. On the whole, there appears to be little doubt that the crystals *Knaggs* examined and ours are the same.
[6] A referee has kindly drawn our attention to theoretical structural studies of *W. Fischer* on interpenetrating tetragonal sphere packings of low density, in particular three- and fivefold interpenetration patterns in space group $I4_1/a$: W. Fischer, *Habilitationsschrift*, Universität Marburg 1970, pp. 40f, 138ff; compare also: W. Fischer, *Acta Crystallogr., Sect. A 25* (1969) S4; *Z. Kristallogr., Kristallgeom., Kristallphys., Kristallchem. 133* (1971) 18; W. Fischer, E. Koch, *Acta Crystallogr., Sect. A 32* (1976) 225. *Fischer* describes the threefold sphere interpenetration in $I4_1/a$ as a system of three coaxial, eight-storeyed screws, and the fivefold interpenetration as five interlocking eight-storeyed screws that do not wind about a common axis. This characterization may readily be carried over to our threefold and fivefold diamondoid interpenetrations, if one bears in mind that the diamond structure may be considered as a framework of interlinked four-storeyed helices winding about the fourfold screw axes. We are grateful to Prof. *Fischer* for providing us with excerpts of his Habilitationsschrift and reprints.

[8] Related are also the structure types of scheelite $CaWO_4$ (space group, $I4_1/a$, like **2**), and zircon $ZrSiO_4$ (space group, $I4_1/amd$), which may again be described as tetragonally distorted double-diamond structures; see Landolt-Börnstein: *Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik und Technik, Band I, Teil 4*, Springer, Berlin 1955, pp. 59, 73 (types HO_4 and $S1_1$, respectively). A particularly striking example as compared to **2** is ammonium perrhenate, NH_4ReO_4 (scheelite type; G. J. Kruger, E. C. Reynhardt, *Acta Crystallogr., Sect. B 34* (1978) 259), which adopts a tetragonally elongated double-diamond structure, in which both equivalent diamondoid networks are held together by hydrogen bonds.

Mono- and Dinuclear Nickel(0) Complexes of Butadiyne**

By *Werner Bonrath, Klaus R. Pörschke,* Günther Wilke, Klaus Angermund,* and *Carl Krüger*

Dedicated to Professor Klaus Hafner on the occasion of his 60th birthday

In connection with our investigations on nickel(0) complexes containing ethyne and 1-alkynes[1,2] as ligands, we were interested in whether butadiyne could also form complexes with nickel(0). Coordination compounds formed between butadiyne and transition metals have not been described in detail so far.[3] Butadiyne, which is formed in large amounts as a byproduct in the industrial production of acetylene by the electric arc process, readily polymerizes and is potentially explosive in the presence of oxygen. It has therefore not been of commercial value so far. The investigations of the complexation chemistry of butadiyne described here possibly provide a foundation for its catalytic transformations.

Complexes of the type $[L_2M(cod)]$ (M = Ni, Pd, Pt; $L=PR_3$ or $L_2=R_2P(CH_2)_nPR_2$ (n = 2, 3), bpy; cod = 1,5-cyclooctadiene) react with butadiyne with the liberation of cod and the formation of mono- or dinuclear compounds $[(L_2M)_m(HC{\equiv}CC{\equiv}CH)]$, m = 1, 2.[4] Thus, the reactions of **1a** and **1b**,[4] which are prepared from $[Ni(cod)_2]$[5] and $iPr_2PC_2H_4P$-iPr_2 or $iPr_2PC_3H_6P$-iPr_2, respectively, with one or one-half equivalent of butadiyne in pentane at −30°C result in the formation of intensely red solutions, from which the mononuclear complexes **2a** (fine yellow needles) and **2b** (long yellow needles), respectively, or the dinuclear complexes **3a** (long yellow needles) and **3b** (dark yellow needles),[4] respectively, separate in over 90% yield. Complexes **2** are converted into the dinuclear complexes **3** by reaction with the cod complexes **1**. Complexes

3, in turn, can be converted back into the mononuclear complexes **2** by reaction with butadiyne.

Compounds **1**–**3** are crystalline, stable under inert gas at room temperature, and soluble in pentane. Their spectroscopic data are summarized in Table 1. Reaction with $P(OPh)_3$ results in displacement of all ligands from the nickel(0) center; the butadiyne thereby liberated from **2** and **3** can be identified by gas chromatography (85% of the theoretically expected amount). Reaction of **3b** with four equivalents of CO (pentane, 20°C) results in polymerization of the butadiyne released from the nickel center and the formation of two equivalents of $[(i\mathrm{Pr}_2\mathrm{PC}_3\mathrm{H}_6\mathrm{P}\text{-}i\mathrm{Pr}_2)\mathrm{Ni(CO)}_2]$ (^{31}P-NMR: $\delta = 36.3$). It has not been possible so far to add the butadiyne bound in **2** and **3** to free butadiyne, ethyne, butadiene, or CO_2; coupling with C_2F_4 is under investigation at present.

Table 1. Spectroscopic data for the compounds **1a**, **2a**, **2b**, and **3a** (MS, 70 eV; IR, KBr; ^{1}H-NMR: 200 MHz, [D$_8$]THF, relative to TMS; ^{13}C-NMR, 75.5 MHz, [D$_8$]THF, relative to TMS; ^{31}P-NMR, 32.4 MHz, [D$_8$]THF, relative to 85% aqueous H_3PO_4).

3a: MS (130°C): *m/z* 690 ($M^{\oplus}$, 30% rel. int.), 320 ($(i\mathrm{Pr}_2\mathrm{PC}_2\mathrm{H}_4\mathrm{P}\text{-}i\mathrm{Pr}_2)\mathrm{Ni}^{\oplus}$,20); IR: $\tilde{\nu}$ [cm^{-1}] = 3085 (≡C–H), 1757, 1601 (C≡C); ^{1}H-NMR (38°C): $\delta = 6.85$ (m, 2H; ≡CH), 2.05 ("octet," 4H; PCH), 2.01 ("octet," 4H; P'CH), 1.57 (m, 4H; PCH_2), 1.50 (m, 4H; P'CH_2), 1.16, 1.12, 1.05, 1.04 (each: m, 12H; CH_3); ^{13}C-NMR (38°C): $\delta = 132.1$ (m, 2C; –C≡), 116.3 (m, 2C, ^1J(CH) = 202 Hz; ≡CH), 26.12 (m, 4C; PCH), 26.07 (m, 4C; P'CH), 23.0 (m, 2C; PCH_2), 22.95 (m, 2C; P'CH_2), 20.6, 20.15, 19.5, 19.5 (each: m, 4C; CH_3); ^{31}P-NMR (38°C): $\delta = 80.3$, 75.9 (AA'BB', $J(P_AP_B) = 51.4$, $J(P_AP_{A'}) = 7.8$, $J(P_AP_{B'}) = 0$, $J(P_BP_{B'}) = 0.3$ Hz)

The mass spectra of **1**–**3** display peaks for the molecular ions; the mononuclear complexes **2** fragment with elimination of the butadiyne ligand. The IR spectra of **2** exhibit two intense bands at ca. 2060 and ca. 1670 cm^{-1}, which may be assigned to the C≡C stretching vibrations of the free and the coordinated triple bond, respectively. On the other hand, **3**, which contain bridging butadiyne ligands, afford spectra with bands at ca. 1760 and ca. 1600 cm^{-1}, which may be assigned to the coordinated triple bonds. In the Raman spectrum of **3a** we found a C≡C band at 1760 cm^{-1}.

In the ^{1}H- and ^{13}C-NMR spectra of **2**, the signals of the H and C atoms, respectively, of the complexed triple bond (**2b**: $\delta_{H1} = 7.24$, $\delta_{C1} = 129.2$, $^1J_{CH} = 201$ Hz; $\delta_{C2} = 120.8$) are strongly shifted downfield compared with those of the free triple bond ($\delta_{H4} = 4.50$, $\delta_{C4} = 91.1$, $^1J_{CH} = 249$ Hz; $\delta_{C3} = 81.1$). In the dinuclear complexes **3**, the protons and terminal C atoms of the butadiyne ligand are less deshielded and the middle C atoms are more deshielded (**3a**: $\delta_{H2} = 6.85$, $\delta_{C2} = 116.3$, $^1J_{CH} = 202$ Hz; $\delta_{C1} = 132.1$) than in the mononuclear complexes. The coupling constants J_{CH} correspond to those found for bis(phosphane)(ethyne)nickel(0) complexes.[1,2] The NMR spectra of **2** and **3** reveal no evidence for rotation of the complex-bound C≡C groups around the bond axis to the nickel atom at the measurement temperatures (up to 38°C).

The essential results of the crystal structure analyses of **2b**[6] and **3a**[7] are shown in Figures 1 and 2, respectively. As expected, the nickel atoms in the two complexes are coordinated in a trigonal-planar fashion by the two phosphorus atoms and a C≡C group, with the C≡C bond in the P_2Ni plane. The angle P1-Ni-P2 in the PC_3PNi six-membered ring of **2b** is 102.7(1)° and in the PC_2PNi five-membered ring of **3a** it is 92.0(1)°. The complex-bound C≡C bonds in **2b** and **3a** (1.279(9) Å and 1.272(4) Å, respectively) are equally lengthened (uncomplexed C≡C bond of **2b**: 1.19(1) Å). The angles formed upon binding to nickel(0) (**2b**: C1-C2-C3 146.2(6)°; **3a**: C2*-C1*-C1 149.4(3)°) are in accordance with expectations for alkynenickel(0) complexes[1a,b,d] and may be ascribed to partial hybridization change of the C atoms. Particularly noteworthy is the fact that the length of the uncomplexed triple bond in the mononuclear complex **2b** corresponds exactly to the C≡C bond length of free butadiyne.[8] The structure of the dinuclear complex **3a** is characterized by a twofold axis (perpendicular to C1-C1*) determined by the space group. Owing to the torsional angle of 94° (C2-C1-C1*-C2°), the triple-bond π orbitals used for complexation of one part of the butadiyne ligand and those of the neighboring triple bond not used are nearly parallel.

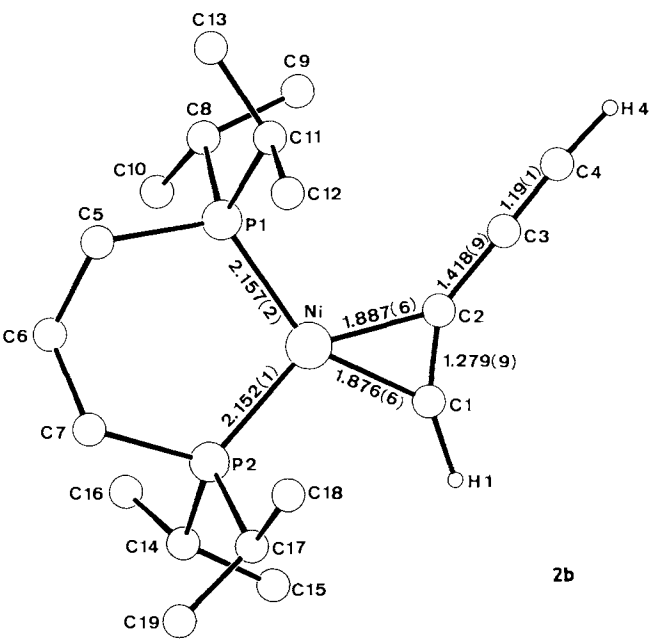

Fig. 1. Molecular structure of **2b** [6]. Bond lengths in Å. Angles [°]: P1-Ni-P2 102.7(1), C1-Ni-C2 39.7(3), C1-C2-C3 146.2(6), C2-C3-C4 177.9(7).

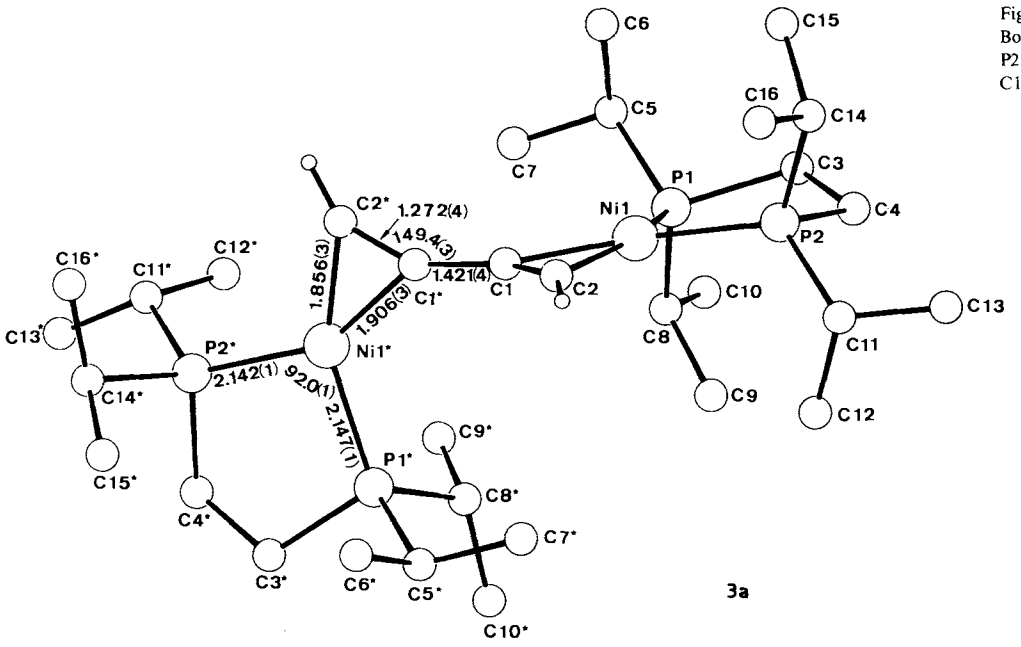

Fig. 2. Molecular structure of **3a** [7]. Bond lengths in Å. Angles [°]: P1-Ni1-P2 92.0(1), C1-Ni1-C2 39.5(1), C2*-C1*-C1 149.4(3).

Experimental Procedure

1a: A suspension of $[Ni(cod)_2]$ (2.75 g, 10.0 mmol) in ether (40 mL) was allowed to react at −20°C with bis(diisopropylphosphino)ethane (2.62 g, 10.0 mmol) in ether (10 mL). Slow warming (16 h) to 20°C resulted in the formation of a clear yellow reaction solution, from which a finely crystalline solid precipitated at −78°C. After removal of the mother liquor with a capillary siphon, the precipitate was washed twice with cold ether and dried under oil-pump vacuum. Yield: 4.0 g (93%); correct elemental analysis: m.p. = 121°C.

2a: A yellow solution of **1a** (1.288 g, 3.0 mmol) in pentane (50 mL) was allowed to react at −78°C with a solution of butadiyne (0.2 mL, 3 mmol) in pentane (10 mL). Upon warming to −30°C, the reaction mixture turned red and, at −78°C, fine yellow needles crystallized and were freed from the mother liquor with a capillary siphon. The crystalline product was washed twice with cold pentane and dried at −30°C under oil-pump vacuum. Yield: 1.02 g (92%); correct elemental analysis.

2b: A solution of **1b** (2.22 g, 5.0 mmol) in pentane (50 mL) was allowed to react at −78°C with butadiyne (0.34 mL, 5.0 mmol) in pentane (10 mL). At −30°C, the initially yellow reaction solution turned burgundy red and long yellow needles slowly crystallized. The crystalline product was isolated as described for **1a** and dried at −30°C. Yield: 1.77 g (92%); correct elemental analysis; m.p. ≈ 45°C (dec.).

3a: a) A clear yellow solution of **1a** (858.5 mg, 2.0 mmol) in pentane (40 mL) was siphoned at −30°C into a yellow solution of **2a** (742.3 mg, 2.0 mmol). The reaction solution was warmed slowly to 20°C; the color turned orange-red (1 h). At −30°C, long yellow needles crystallized. The crystalline product was freed of mother liquor with a capillary siphon, washed twice with cold pentane, and dried under oil-pump vacuum. Yield: 1.27 g (92%). b) A clear yellow solution of **1a** (2.146 g, 5.0 mmol) in pentane (40 mL) was allowed to react at −78°C with butadiyne (0.17 mL, 2.5 mmol) in pentane (10 mL) and the reaction solution was then warmed slowly to −10°C. Yellow needles crystallized from the deep red reaction solution and were isolated as described above. Yield: 1.56 g (90%); correct elemental analysis; m.p. = 112°C.

Synthesis and Crystal Structure of a Chiral C_3-Symmetric Monophosphane**

By *Carsten Bolm, William M. Davis, Ronald L. Halterman,* and *K. Barry Sharpless**

Mono- and bidentate phosphanes play an important role in transition metal chemistry.[1] Steric and electronic properties of the ligands markedly affect the stability and reactivity of the complexes.[2] Optically active phosphanes have been extensively used in transition-metal-catalyzed asymmetric syntheses.[3] We now report the preparation of the first C_3-symmetric monophosphane that does not contain a chiral carbon atom.[4]

Compound **2** was synthesized in a one-pot procedure by treatment of the corresponding 2-bromophenol **1** with two

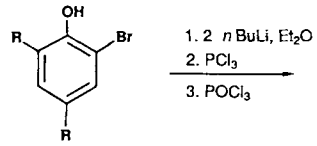
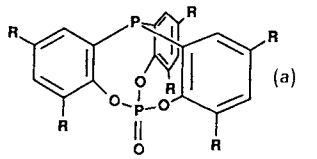
equivalents of *n*-butyllithium[5] followed by successive quenching of the lithium *o*-lithiophenolate with phosphorus trichloride and phosphoryl trichloride (in high dilution) [Eq. (a)].[6] Using analogous reaction conditions the desired [4.4.4]bicyclic product starting from 2-bromobenzyl alcohol could not be obtained.



1



2

a, R = H ; **b**, R = *t*Bu

As determined by X-ray crystallography,[7] compound **2a** is a chiral molecule with a threefold axis of symmetry (Fig. 1).

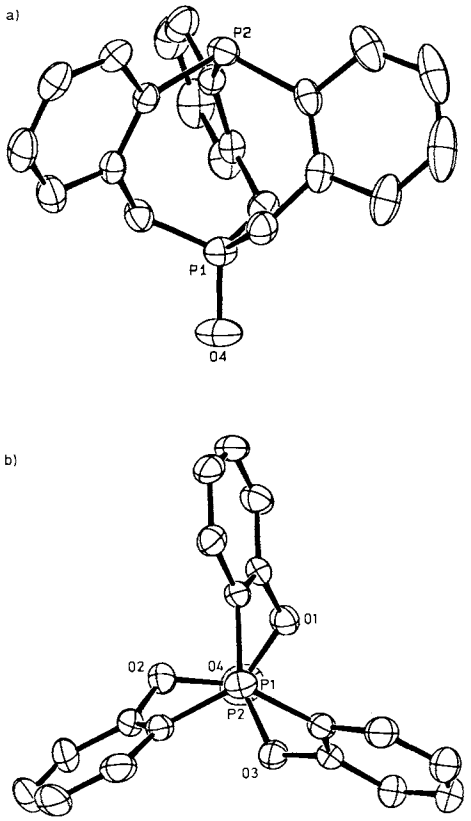


Fig. 1. Structure of **2a** in the crystal (two views, H atoms omitted) [7]. a) Side view. b) Top view, along the P2-P1-O4 axis.

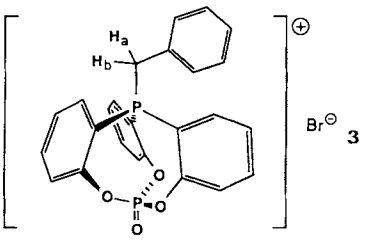
The phosphane–phosphate axis is tilted by about 27° with respect to the planes of the aromatic rings. Both enantiomers are present in the unit cell.

To estimate the energy required for interconversion of the enantiomers (enantiotopomerization), **2a** was converted into the benzylphosphonium bromide **3** (heating of **2a** in pure benzyl bromide, 150°C, 2 h). Via the diastereo-



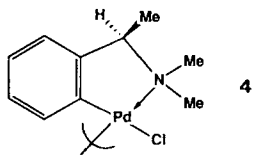
3

topic protons H_a and H_b of the benzyl group in **3**, a mutarotational energy of 11.8 kcal mol^{-1} was determined by variable-temperature NMR experiments. The phosphonium salt of **2b** could not be obtained under the reaction conditions described for the generation of **3**.

Doubly or triply charged ions are commonly found in the mass spectrum of phosphatriptycenes or compounds that contain heteroatoms, on which the positive charge may be localized.[8] No multiply charged ions were observed for **2a** (FD- and EI-MS).

The chemical shift in the ^{31}P-NMR spectrum for the "phosphane" phosphorus in **2a** (P2: $\delta = -33.2$[9]) indicates increased s-character for the lone pair orbital on phosphorus.[10] The "phosphate" phosphorus (P1: $\delta = -15.9$[9]) shows a chemical shift that lies close to the values reported for analogous bicyclic compounds.[11] In the phosphonium salt **3** a strong downfield shift for P2 is observed (^{31}P{^{1}H}-NMR data (CD_3OD, 85% H_3PO_4 ext.): $\delta = -8.1$ (P1), +21 (P2); compare triphenylphosphane, $\delta(^{31}P) = -5.5$, benzyltriphenylphosphonium bromide, $\delta(^{31}P) = +21.4$[12]).

In order to determine the ability of **2** to coordinate to transition metals, **2a** and **2b** were examined by NMR spectroscopy in the presence of $[PdCl_2 \cdot (C_6H_5CN)_2]$ (excess). Complexation was indicated in the ^{31}P-NMR spectrum by the characteristic downfield shift of P2[13] (^{31}P{^{1}H}-NMR data:[9] **2a**/$[PdCl_2 \cdot (C_6H_5CN)_2]$: $\delta = -18.4$ (P1), +15.1 (P2); **2b**/$[PdCl_2 \cdot (C_6H_5CN)_2]$: $\delta = -21.7$ (P1), +23.7 (P2)). Upon complexation the aromatic protons also resonated at lower field.



4

2

The optically active palladium complex **4** has been used for the resolution of racemic tertiary phosphanes.[14] In its reaction with **2a** and **2b** no diastereomeric complexes could be distinguished by NMR spectroscopy (^{31}P{^{1}H}-NMR data:[9] **2a/4**: $\delta = -17.3$ (P1), +29.3 (P2); **2b/4**: $\delta = -21.1$ (P1), +37.2 (P2)). Fractional crystallization did not result in a detectable enrichment of one diastereomer.

The concept of C_3-symmetric phosphane ligands is being pursued by the synthesis of compounds which are

structurally related to those described here, but which will hopefully have much greater configurational stability. Optically active C_3-phosphanes might be expected to serve as useful ligands in transition-metal-catalyzed asymmetric processes.

Experimental Procedure

Under argon at -15 °C a solution of **1a** (1.73 g, 10 mmol) in 40 mL of anhydrous ether was treated with 8 mL of a 2.5 M hexane solution of *n*-butyllithium (20 mmol). After 1 h at 0 °C a solution of phosphorus trichloride (457 mg, 3.33 mmol) in 8 mL of ether was added dropwise, forming a white precipitate. The mixture was stirred for 1 h at 0 °C and refluxed for 1 h followed by the addition of 200 mL of anhydrous ether. At 0 °C under vigorous stirring a solution of phosphoryl trichloride (537 mg, 3.5 mmol) in 60 mL of ether was added dropwise (over 4 h). After stirring at room temperature overnight, the mixture was poured into 75 mL of water. The organic layer (including the precipitate) was separated and the aqueous layer extracted twice with 100-mL portions of ether. The precipitate was removed by filtration, and the combined organic layers were dried over $MgSO_4$. After removal of the solvent by evaporation, the residue (0.36 g) was chromatographed (15 g silica gel, petroleum ether : 2-propanol = 20 : 1); yield: 130 mg (11%) of pure **2a**; white crystals, which can be recrystallized using benzene/petroleum ether [6]. The precipitate described above was dissolved in dichloromethane and the solution dried over $MgSO_4$. After evaporation of the solvent another 20 mg (1.7%) of **2a** could be obtained by chromatography.

The same sequence using **1b** (29.2 mmol [15]) yields, after chromatography, 2.49 g (37%) of the analogous product **2b** [6]. No precipitate was formed during the workup.

Formation of the Diphosphatricyclo[2.1.0.0^{2,5}]pentane Ring System via Phosphaalkyne Dimerization and Carbon Monoxide Incorporation**

By *Andrew R. Barron, Alan H. Cowley,* Stephen W. Hall,* and *Christine M. Nunn*

In principle, the oligomerization of phosphaalkynes represents an excellent synthetic route to a fascinating array of new heterocycles. Indeed, recent research has demonstrated that it is possible to dimerize[1] or trimerize[2] phosphaalkynes within a coordination sphere. However, in each case, the oligomer has remained bound to the transition metal. We report the first instance of the production of an uncoordinated heterocycle starting with a phosphaalkyne and using a transition-metal substrate. Furthermore, the product of this reaction, **1**, constitutes the first example of a new class of phosphorus compound.

The reaction of $[(\eta^5\text{-}C_5H_5)_2Ti(CO)_2]$[3] with *t*BuC≡P[4] in refluxing hexane affords a colorless solid, **1**, with a composition corresponding to $(t\text{BuCP})_2\text{CO}$. The medium-resolution mass spectrum (70 eV) of **1** exhibits a parent peak at *m/z* 228. A fragmentation peak at *m/z* 200 corresponds to the loss of CO, and this is followed by peaks at *m/z* 185, 170, 155, and 143 corresponding to the sequential loss of three methyl groups and one *tert*-butyl group, respectively. The ^{31}P{^{1}H}-NMR spectrum of **1** (121.5 MHz, C_6D_6, 85% H_3PO_4 ext.) exhibits a singlet at $\delta = -346.6$. Such a low-frequency ^{31}P chemical shift is strongly indicative of a tetrahedrane-type phosphorus environment and may be compared with those for P_4 ($\delta = -460$)[5] and **2** ($\delta = -247$).[1c]

The ^{1}H-NMR spectrum of **1** (300 MHz, C_6D_6, TMS ext.) consists of a singlet at $\delta = 0.82$. The ^{13}C{^{1}H}-NMR spec-

Department of Chemistry, The University of Texas at Austin
Austin, TX 78712 (USA)

[**] This work was supported by the National Science Foundation (USA) and Robert A. Welch Foundation.

trum of **1** (75.5 MHz, C_6D_6, TMS ext.) shows three resonances assignable as follows: $\delta = 29.35$ (s, $(CH_3)_3C$), 77.56 (t, $^2J_{PC} = 37.7$ Hz, Me_3C), and 178.52 (t, $^1J_{PC} = 15.1$ Hz, C_a). Ring carbon C_b is not detectable by $^{13}C\{H\}$-NMR; nevertheless, the presence of a C=O group is evident from the observation of an IR stretching frequency at 1717 cm^{-1}. The above structure was confirmed by X-ray analysis (Fig. 1).[6] Interestingly, the P-P distance (2.118(3) Å) is 0.09 Å shorter than that of a P-P single bond, thus suggesting a slight multiple-bond character. The complex **2** also features a short P-P bond distance (2.146(1) Å).[1c]

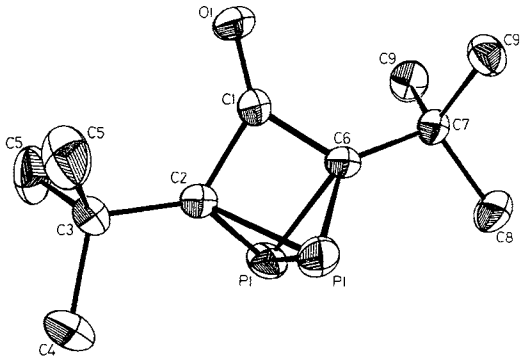

Fig. 1. Structure of **1** in the crystal. Selected bond lengths [Å]: P1-P1 2.118(3), P1-C2 1.897(8), P1-C6 1.895(7), C1-C6 1.514(13), C1-C2 1.511(12), C1-O1 1.200(11). Each molecule of **1** resides on a plane of symmetry perpendicular to the P-P bond.

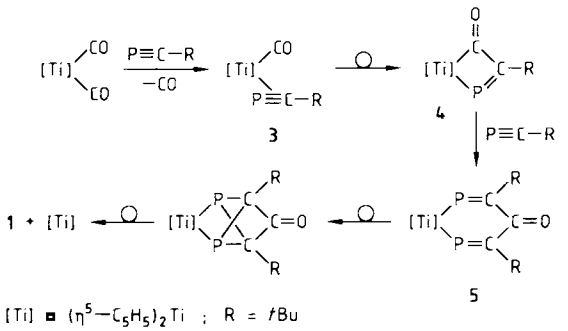
At present we do not have any direct evidence bearing on the mechanism of formation of **1**. However, it is possible that the sequence of reactions shown in Scheme 1 is involved.



Scheme 1.

The attack of CO on the C atom of coordinated *t*BuC≡P (**3**→**4**) finds precedent in the work of *Nixon* et al.[7] Moreover, the same group has isolated a Rh complex of the P=CR–C(O)–CR=P (R = adamantyl) unit (cf. **5**).

Experimental Procedure

The reaction of $[(\eta^5-C_5H_5)_2Ti(CO)_2]$ [3] (1.0 g, 4.3 mmol) with *t*BuC≡P [4] (1.0 g, 10.0 mmol) in hexane at 25°C results initially in the formation of a bright yellow solid. Upon refluxing for a few hours, the color of the reaction mixture darkens to orange. Filtration results in an orange solid that contains no phosphorus. Evaporation of the filtrate, followed by sublimation of the resulting residue (35°C, 10^{-3} torr) affords colorless, solid **1** in 63.7% yield (0.625 g, 2.74 mmol).

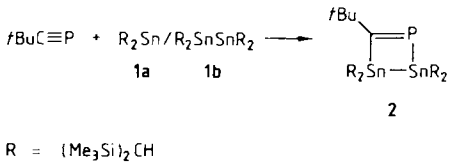
Addition of a Distannene to a Phosphaalkyne. Formation of a Phosphadistannacyclobutene**

By *Alan H. Cowley,* Stephen W. Hall, Christine M. Nunn,* and *John M. Power*

Recently it has been demonstrated that carbenes[1] and silylenes[2] will add to phosphaalkynes, RC≡P, to afford three-membered rings containing phosphorus-carbon double bonds. We have found that the corresponding tin chemistry proceeds in a different fashion.

The stannylidene $[(Me_3Si)_2CH]_2Sn$ exists as a dimer **1b** in the solid state.[3] In solution, however, recent evidence indicates that there is a dynamic equilibrium between the monomer **1a** and dimer **1b**.[4] We find that *t*BuC≡P[5] reacts with this monomer/dimer mixture to afford the first example of a phosphadistannacyclobutene, **2**.



The ^{31}P-NMR chemical shift of **2**[6] falls in the region anticipated for a P=C moiety.[7] Moreover, the presence of two Sn atoms is indicated both by two separate sets of $^{117}Sn/^{119}Sn$ satellites in the $^{31}P\{^1H\}$-NMR spectra and by the observation of two distinct ^{119}Sn resonances. The large Sn/Sn coupling constant of 892.2 Hz is consistent with the presence of a tin-tin bond. The observation of four Me_3Si

[*] Prof. Dr. A. H. Cowley, S. W. Hall, Dr. C. M. Nunn, Dr. J. M. Power
Department of Chemistry, The University of Texas at Austin
Austin, TX 78712 (USA)

[**] This work was supported by the National Science Foundation (USA) and Robert A. Welch Foundation.

resonances in the ^{1}H- and ^{13}C{^{1}H}-NMR spectra is ascribable to the presence of two nonequivalent Sn atoms and to the fact that each $(Me_3Si)_2CH$ group is diastereotopic.

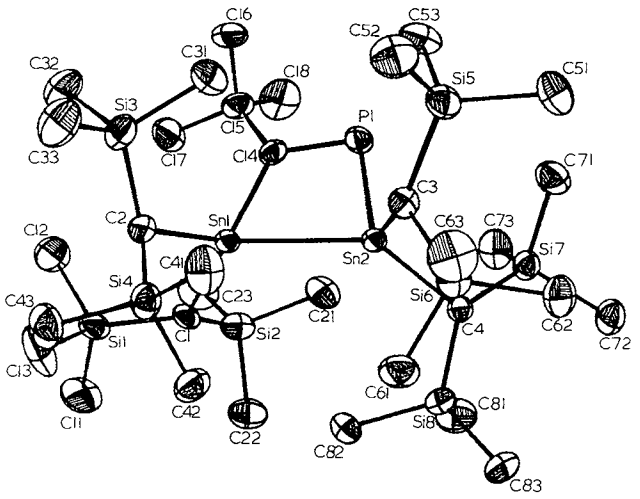


Fig. 1. Structure of **2** in the crystal showing the atom numbering scheme for molecule I. Selected bond lengths [Å] and bond angles [°] for molecule I: Sn1-Sn2 2.878(1), Sn1-C14 2.203(13), Sn2-P1 2.544(4), P1-C14 1.712(15); Sn2-Sn1-C14 76.1(4), Sn1-Sn2-P1 74.78(9), Sn2-P1-C14 94.5(4), Sn1-C14-P1 114.5(6).

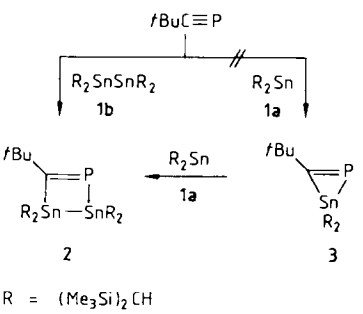
The above structure assignment is confirmed by X-ray analysis (Fig. 1).[8] Note that there are two independent molecules per asymmetric unit. Within experimental error, the Sn_2PC ring is planar and the sum of angles at the ring carbon average 359.5°. In contrast to the free distannene **1b**, which adopts a *trans* structure,[3] the conformation of the R_2SnSnR_2 moiety in **2** is *cis*. As expected, the Sn–Sn bond distance in **2** (average 2.886(1) Å) is somewhat longer than that in **1b** (2.768(1) Å) but comparable to that in the distannane, $R_2(Cl)SnSn(Cl)R_2$ (2.844(1) Å).[9] The phosphorus–carbon distance (average 1.697(15) Å) is consistent with a bond order of approximately two.[7]

In principle, the phosphadistannacyclobutene **2** could be formed either by [2+2] cycloaddition of the distannene **1b** to *t*BuC≡P or via the insertion of a second R_2Sn unit into an initially formed phosphastannirene, **3**. However,



we have found no spectroscopic evidence for the existence of **3** even when an excess of the phosphaalkyne is employed. Moreover, the isoelectronic $[(Me_3Si)_2N]_2Sn$, which exists exclusively as a monomer,[10] fails to react with *t*BuC≡P. This suggests that **2** arises via a distannene/phosphaalkyne reaction.

Experimental Procedure

A magenta solution of $[(Me_3Si)_2CH]_2Sn$ (0.66 g, 0.76 mmol) in *n*-hexane (30 mL) at 25°C was treated via syringe with a dimethoxyethane solution of *t*BuC≡P (1.85 mL of a 0.42 M solution, 0.76 mmol). After 6 h the resulting orange solution was concentrated and microcrystalline **2** was obtained at −20°C. Recrystallization from dichloromethane afforded pure **2** as red-orange crystals. Yield: 0.18 g (24%), m.p. = 136–138°C (dec.).

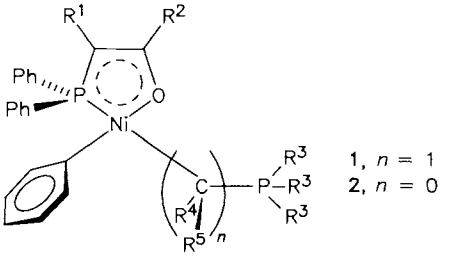
Acetylene Polymerization with Ylide–Nickel Catalysts

By *K. Alexander Ostoja Starzewski** and *Josef Witte*

In solution bis(ylide)nickel catalyst systems Ni^0/$Ph_3PCR^1CR^2O$/$R^3_3PCR^4R^5$ (R^1 to R^5 can, for example, be alkyl and aryl groups or heteroatom substituents) preferentially form square-planar phenylnickel complexes containing a phosphinoenolate ligand and a structurally intact coordinated ylide ligand, **1**.[1] These compounds are highly efficient catalysts for ethylene oligomerization and poly-



[*] Dr. K. A. Ostoja Starzewski, Dr. J. Witte

Wissenschaftliches Hauptlaboratorium
D-5090 Leverkusen 1 (FRG)

merization[1-3] as well as for the copolymerization of ethylene with α-olefins.[4] Their reactivity exceeds that of the related phosphane complexes **2**.[5]

We have now discovered that complexes **1** and **2** also catalyze acetylene polymerization. Although the *stoichiometric insertion* of diphenylacetylene into the Ni–C_{phenyl} bond of a phosphane complex related to **2** was recently described,[6] no catalytic reactions were reported. The reaction does not proceed beyond the conceivable initial step of the catalytic cycle.

Noteworthy is the catalytic activity of the bis(ylide)nickel catalysts **1** for the polymerization of acetylene in a wide variety of solvents (Table 1). In contrast to the behavior of the phosphane derivatives **2**, the turnover numbers of **1** increase markedly with solvent polarity. The polymerization catalyzed by the complex [NiPh($Ph_2PCHCPhO$)(Me_3PCH_2)] **1a** in dimethyl sulfoxide at 60°C under normal pressure for 1 h results in the conversion of ca. 500 moles of acetylene per mole of nickel·bar.

Table 1. Acetylene polymerization activity of the ylide-nickel catalyst **1a** in various solvents at ca. 60°C and 1 bar acetylene.

Solvent	Activity [a]
Cyclohexane	22
Acetone [b]	31
Acetonitrile	169
Dimethylformamide (DMF)	223
Dimethyl sulfoxide (DMSO)	492

[a] Moles of converted acetylene per mole of nickel. [b] Reflux.

The reaction in DMSO is rapid. After admitting acetylene for 5 min into a solution containing 1 mmol of the catalyst **1a** (single-pulse procedure), 5 g of polyacetylene can be isolated; this corresponds to a conversion of ca. 200 moles of acetylene per mole of nickel. The polymerization is strongly exothermic, and the internal temperature, without cooling, increases from 60 to 110°C.[7] The yield of polyacetylene depends markedly on the reaction temperature. Optimal activity is attained at 60°C, but even at 100°C approximately 300 moles of acetylene per mole of nickel are converted in 1 h.

The normalized activity (mol C_2H_2/mol Ni·bar·h) of the bis(ylide)nickel system thus exceeds, to the best of our knowledge, that of all known acetylene polymerization catalysts based on nickel.[8,9]

The isolable one-component catalysts are especially well suited to study specific ligand effects. With respect to structure/activity relations there are interesting parallels between the polymerization of acetylene and that of ethylene. In both cases, complexes containing intact ylide ligands such as **1** are catalytically more active than related phosphane derivatives **2**.[10] In the case of the acetyl catalysts [NiPh($Ph_2PCHCMeO$)(ylide intact)], benzylidene(triisopropyl)phosphorane effects an especially pronounced increase in activity (Table 2). As observed for ethylene polymerization, the activity increases in the series formyl (R^2 = H) < acetyl (R^2 = Me) < benzoyl (R^2 = Ph), while keeping trimethyl(methylene)phosphorane as structurally intact coordinated ylide ligand.

Table 2. Acetylene polymerization activity of various ylide-nickel catalysts **1**, **2**.

Catalyst [a]	Procedure [b]	Activity [c]
[NiPh($Ph_2PCHCMeO$)(Ph_3P)] **2a**	A	35
[NiPh($Ph_2PCHCMeO$)($NiPr_3PCH_2$)] **1b**	A	215
[NiPh($Ph_2PCHCMeO$)($NiPr_3PCHPh$)] **1c**	A	319
[NiPh($Ph_2PCHCHO$)(Me_3PCH_2)] **1d**	B	73
[NiPh($Ph_2PCHCMeO$)(Me_3PCH_2)] **1e**	B	258
[NiPh($Ph_2PCHCPhO$)(Me_3PCH_2)] **1a**	B	492

[a] 1 mmol in 20 mL of toluene, polymerization in 80 mL of DMSO, polymerization temperature 60°C, polymerization time 1 h. [b] A = single-pulse procedure, B = multi-pulse procedure. [c] Moles of converted acetylene per mole of nickel.

Experimental Procedure

1a (529 mg, 1 mmol) [1] in toluene (20 mL) was added to 80 mL of DMSO at 60°C to which acetylene was being admitted. All operations were carried out with strict exclusion of air and moisture and the catalyst addition was performed at such a rate that, without external heating, the internal temperature was maintained at 60°C. After 1 h at 60°C, black polyacetylene powder was isolated by Schlenk filtration, washed sequentially with ethanol, acetone, and ether, and dried under vacuum. Yield: 12.8 g (93% *trans*, 7% *cis* double bonds, FT-IR).

[7] In order to avoid undesired peaks in temperature in the single-pulse procedure, the polymerization can also be performed according to the multi-pulse method, the desolved catalyst being added parallel to the consumption of acetylene. The temperature of the reaction solution can then be controlled by means of the heat of polymerization.

Synthesis and Properties of a Bridged *syn*-Tricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene: Formation of Propella[3$_4$]prismane**

By *Rolf Gleiter* and *Michael Karcher*

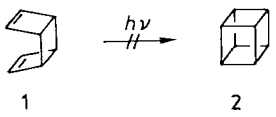
In memoriam David Ginsburg

syn-Tricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene **1** does not isomerize to cubane **2** upon irradiation; the same holds for

[*] Prof. Dr. R. Gleiter, Dr. M. Karcher
Institut für Organische Chemie der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

[**] This work was supported by the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie, and the BASF Aktiengesellschaft. We thank Dr. *P. Kunzelmann* and Dr. *G. Schilling* for recording the NMR spectra.

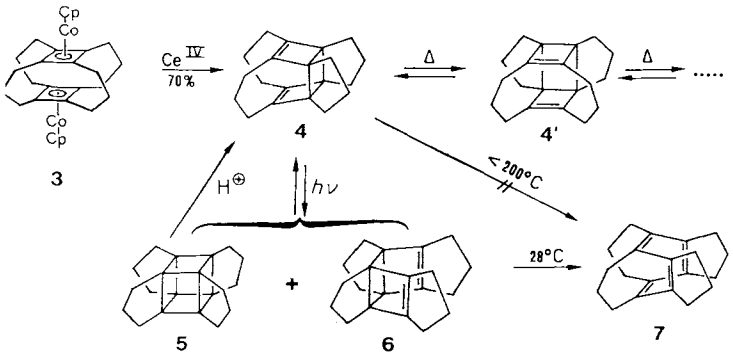
alkyl derivatives of **1**.[1,2] Essentially three reasons have been given to explain this finding: (1) the large difference in strain energy between educt and product;[3] (2) the relatively large separation (3.05 Å) between the two olefinic moieties in **1**;[3] (3) owing to the dominance of through-bond interaction in **1**, π_+ lies above π_- for both sets of π MOs (i.e., reaction (a) is symmetry-forbidden).[4]



1 2 (a)

Bridging of the two olefinic moieties should favor the photochemical ring closure shown in reaction (a), since, for a sufficiently short bridge, the strain energy of the educt should increase more than that of the product and the separation between the olefinic moieties of the educt should become smaller. With two C_3 bridges, the situation should be especially favorable, since the through-bond effect of two C_3 bridges should nearly compensate that of the C_2 bridges (C1–C2 and C5–C6) in **1**.[5]

Starting from the readily accessible superphane **3**,[6] it was possible to synthesize a tricyclo[4.2.0.0^{2,5}]octadiene bridged by C_3 units (Scheme 1). Oxidation of **3** with Ce^{IV} in aqueous ethanol at 0°C leads smoothly to heptacyclo[10.8.0.0^{2,6}.0^{2,11}.0^{6,17}.0^{7,11}.0^{7,16}]icosa-1(12),16-diene **4**.



Scheme 1. Synthesis and reactions of **4**.

The reduced separation (ca. 2.6 Å[7]) of the two olefinic moieties in **4**, caused by the bridges, is revealed, for example, by a single signal for the π bands ($I_{v,1}$ = 7.6 eV) in the photoelectron spectrum and by a degenerate Cope rearrangement upon warming. The free energy of activation for the Cope rearrangement can be estimated as 71–76 kJ mol^{-1} from the coalescence temperature (ca. 90°C) for the signals of the CH_2 carbons in the ^{13}C-NMR spectrum.[8] In contrast, **1** undergoes rearrangement at 90–120°C to give cyclooctatetraene,[9] whereas an irreversible valence isomerization at 135°C has been reported for brominated derivatives of **1**.[10]

Irradiation of **4** in degassed *n*-pentane at room temperature with a 500-W high-pressure mercury lamp results in the formation of an equilibrating mixture of **4** and two new products (**5** and **6**) (Scheme 1). At room temperature, the ratio **4** : **5** : **6** is 10 : 1 : 4.

Compounds **5** + **6** can be separated from **4** by chromatography (Al_2O_3/*n*-pentane). Separation of **5** and **6** has only been achieved so far after rearrangement of **6** to **7** at 28°C (Scheme 1) by means of chromatography on Al_2O_3 using *n*-pentane as eluent. The cubane derivative **5** rearranges to **4** in the presence of traces of acid.[11] Irradiation of **5** + **6** affords once again a mixture of **4**, **5**, and **6**. The bridged cyclooctatetraene **7** could not be obtained by thermolysis (< 200°C) of **4**.

Table 1. Spectroscopic data for **4**–**7**.

4: IR (KBr): $\tilde{\nu}$ = 1630 cm^{-1}; UV (*n*-pentane): λ = 225 nm (sh); ^{1}H-NMR (300 MHz, $CDCl_3$): δ = 2.22–2.32 (m, 4H), 2.04–2.09 (m, 4H), 1.56–1.89 (m, 16H); ^{13}C-NMR (75.46 MHz, $CDCl_3$): δ = 144.13 (s), 58.16 (s), 27.36 (t), 25.95 (t), 25.26 (t), 24.48 (t); MS (70 eV): *m/z* 264 (62%, $M^{\oplus}$)

5: ^{1}H-NMR (200 MHz, $CDCl_3$): δ = 1.46–1.70 (m); ^{13}C-NMR (50.32 MHz, $CDCl_3$): δ = 56.72 (s), 31.45 (t), 25.49 (t); high-resolution MS: *m/z* ($M^{\oplus}$) calcd 264.1878, found 264.1851

6: ^{13}C-NMR (50.32 MHz, $CDCl_3$): δ = 153.04 (s), 52.30 (s), 33.64 (t), 29.38 (t), 26.72 (t), 24.13 (t); high-resolution MS: *m/z* ($M^{\oplus}$) calcd 264.1878, found 264.1862

7: IR (KBr): $\tilde{\nu}$ = 1620 cm^{-1}; ^{1}H-NMR (200 MHz, $CDCl_3$): δ = 2.15–2.57 (m), 1.82–2.07 (m), 1.46–1.63 (m); ^{13}C-NMR (50.32 MHz, $CDCl_3$): δ = 142.25 (s), 136.91 (s), 32.57 (t), 25.47 (t), 24.89 (t), 23.70 (t); high-resolution MS: *m/z* ($M^{\oplus}$) calcd 264.1878, found 264.1903

The proposed structures of **5**–**7** are based on analytical data (Table 1), in particular the ^{13}C-NMR spectra. The number of lines in the ^{13}C-NMR spectrum, their multiplicity (DEPT experiment), and their chemical shifts[12] lead to an unambiguous assignment. The cubane derivative **4** can be regarded either as a member of the propella[n$_m$]prismane series (n = 3, m = 4) (point group D_{mh}) having the general formula **8**[13] or as a tetrameric cyclopentyne.[14]

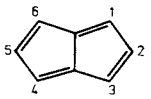
1,3,4,6-Tetraamino-2,5-diazapentalenes: Delocalized Antiaromatic Compounds**

By *Fritz Closs, Rudolf Gompper,* Heinrich Nöth,* and *Hans-Ulrich Wagner*

As we have shown through several examples, combinations of donor and acceptor substituents stabilize cyclopolyenes containing (4n) π electrons. They may even take on the properties of arenes (e.g., positive resonance energies).[1] The question of double-bond delocalization in such systems could only be approached so far for diethyl 2,4-bis(diethylamino)cyclobutadiene-1,3-dicarboxylate;[2-4] in contrast to tetra-*tert*-butylcyclobutadiene,[5,6] it exhibits a "benzene-like" double-bond delocalization ("λ_{max}" = 1.24; see below). In continuation of our studies on 2,5-diazapentalenes,[7] we posed the question whether it might also be possible to achieve a delocalization of the double bonds in pentalene by the incorporation of suitable donor–acceptor substituents.

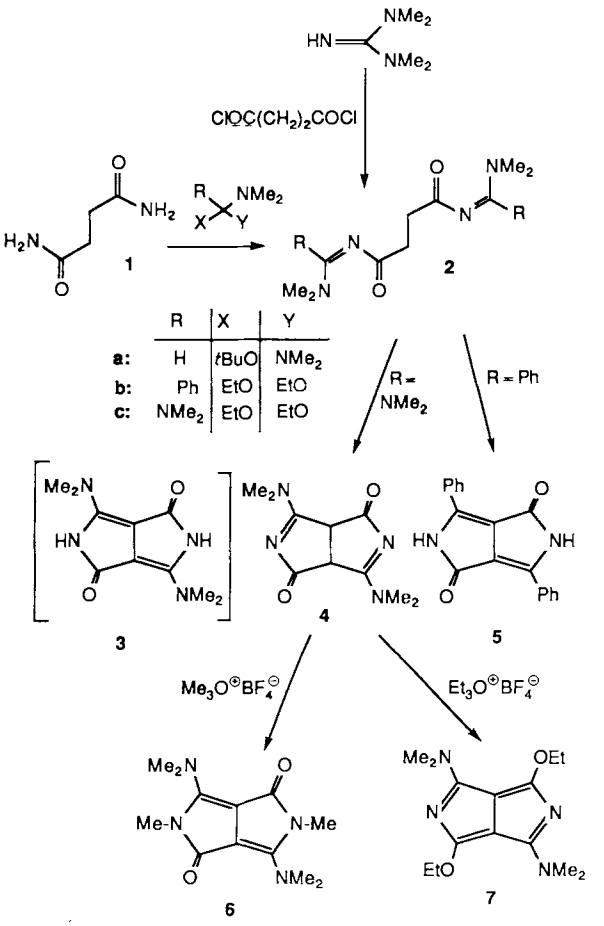
By way of 1,3,5-tri-*tert*-butylpentalene as example it has been shown[8-10] that alkylated pentalenes display bond alternation and that a rapid valence isomerization occurs. These findings are in agreement with the double-bond localization parameter "λ_{max}" (see Table 1) calculated according to *Binsch* and *Heilbronner* et al.;[11,12] its value is significantly higher than the critical value. The "λ_{max}" values of the compounds 1,3,4,6-tetraamino-, 2,5-diaza-, and, above all, 1,3,4,6-tetraamino-2,5-diazapentalene are less than the critical value. This finding and the larger HOMO–LUMO gap lead to the expectation that 1,3,4,6-tetradonor-2,5-diacceptor-substituted pentalenes should exhibit aromatic stabilization and a delocalized π-bonding system (cf. also Ref. [13]).

Table 1. The effect of substituents on the double-bond localization in pentalenes ($\lambda_{crit} \approx 1.7$) [$\alpha_X = \alpha_C + h_X\beta_{CC}$; $h_{NR2} = 1.5$, $h_N = 0.5$]). The ring nitrogen atoms are also regarded here as substituents.



Substituents	$\Delta E_{HOMO-LUMO}$ [β]	"λ_{max}" neutral	radical cation	dication
none (6H)	0.471	2.357	1.358	1.312
1,3,4,6-tetraamino (+2H)	0.918	1.153	6.517	12.393
2,5-diaza (+4H)	0.738	1.677	1.505	2.539
1,3,4,6-tetraamino-2,5-diaza	0.942	0.967	1.094	1.614

In addition to the reaction of succinate esters with aromatic nitriles,[14] the reaction of succinamide **1** with amide acetals[7] offers a simple method for the preparation of pyrrolo[3,4-*c*]pyrrole-1,4(2*H*,5*H*)-diones (e.g., **5**). As amide acetals, we have so far employed a dimethylformamide derivative (cf. **a**) and dimethylbenzamide acetal (cf. **b**).



Heating **1** with tetramethylurea diethyl acetal (cf. **c**) affords a high yield of a colorless crystalline compound. The product is not the dione **3**, expected in analogy to the red compound **5**, but rather 3,6-bis(dimethylamino)pyrrolo[3,4-*c*]pyrrole-1,4(3a*H*,6a*H*)-dione **4** (for selected data for all new compounds, see Table 3). The permethylated succinylguanidine **2c**, identified as an intermediate, can also be prepared from tetramethylguanidine and succinyl dichloride and then converted into **4** by treatment with sodium hydride in dimethylformamide. (We are currently investigating the generality of this procedure.)

The readily accessible **4** makes possible the synthesis of numerous 2,5-diazapentalene derivatives. *N*-Methylation with trimethyloxonium tetrafluoroborate yields yellow 3,6-bis(dimethylamino)-2,5-dimethylpyrrolo[3,4-*c*]pyrrole-

antimonate) has been reported,[16] its structure could not be confirmed. Dications of dibenzopentalene(indenoindenes) have been generated in solution and characterized by NMR spectroscopy,[17] and the radical cation of 1,3,5-tri-*tert*-butylpentalene, which is stable to −77°C, has also been obtained in solution.[18, 19] The tetradonor-substituted diazapentalenes now make possible the simple preparation of a whole series of stable, crystalline dication salts. The double-bond localization parameter "λ_{max}" (Table 1) for **17** is larger than for **11** and **14**. It remains an open question whether **17** is better represented by the structure given or by the delocalized structure **17'** (the Wiberg bond index[20] for C3a–C6a for **17/17'** is 1.852, which almost corresponds to a CC double bond in accordance with **17**). Structure **17** would be analogous to that of the salt **20**.[1] Oxidation of 1,3,5,7-tetrakis(dimethylamino)-2,6-diaza-*s*-indacene[1] to **20** proceeds much more smoothly than that of **14** to **17**, presumably owing to the better spatial separation of the charges in **20** than in **17**.

Tetradonor-substituted 2,5-diazapentalenes are relatively strong bases (pK_a [in 50% EtOH]: **11** = 8.63, 4.28; **14** = 10.35, 6.40; 1,8-bis(dimethylamino)naphthaline = 10.40 [in H_2O = 12.34[21]]; 1,3-bis(dimethylamino)-2-azapentalene[22] = 6.82). It is remarkable that **14** is as basic as "proton sponge,"[21] whereas 1,3-bis(dimethylamino)-2-azapentalene is significantly weaker as a base. This compound also undergoes electrochemical oxidation at 0.62 V to the radical cation; interestingly, the reduction to the radical anion at −1.92 V occurs at practically the same potential as that of **14**. Protonation of **11** and **14** does not occur at the dialkylamino groups, however, as in the case of "proton sponge," but rather at the ring N atoms. Treatment of **11** with tetrafluoroboric acid–ether in dichloromethane leads to the yellow NH salt **18**, which, in the region of its melting point (at ca. 200°C) or in acetonitrile at room temperature, is transformed into the colorless CH salt **19**. Compounds **19**, **20**, and **17** form a series of dications in which two 2-azaallyl moieties are linked increasingly more closely by a CC single bond, a benzene ring, and a CC double bond, respectively.

Table 3. Selected data for the compounds **2c**, **4**, and **6**–**19** (^{1}H-NMR, 80 MHz; ^{13}C-NMR, 20 MHz).

2c: Colorless needles, m.p. = 106°C

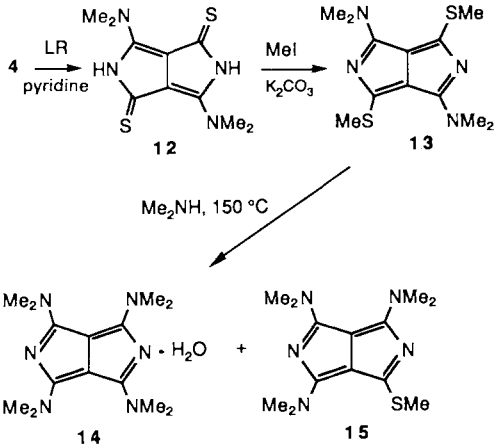
1,4(2*H*,5*H*)-dione **6**. Treatment with triethyloxonium tetrafluoroborate, on the other hand, affords the likewise yellow 1,4-diethoxy-3,6-bis(dimethylamino)-2,5-diazapentalene **7**, the first tetradonor–diacceptor pentalene.

Reaction of **4** with phosphorus oxychloride in the presence of diethylaniline gives 1,4-dichloro-3,6-bis(dimethylamino)-2,5-diazapentalene **8**. When pyridine is used as base, this reaction yields the betaine **9**, which is of interest owing, among other things, to its strong solvatochromism. Although **8** should be regarded as an electron-rich compound, it reacts with numerous nucleophiles. Reaction with phenylmagnesium bromide in THF, for example, affords 1,4-bis(dimethylamino)-3,6-diphenyl-2,5-diazapentalene **10**. With respect to the question of bond delocalization discussed at the beginning, the most interesting reaction is that of **8** with morpholine to give 1,3,4,6-tetramorpholino-2,5-diazapentalene **11**.



Sulfurization of **4** with Lawesson reagent (LR) yields 3,6-bis(dimethylamino)pyrrolo[3,4-*c*]pyrrole-1,4(2*H*,5*H*)-dithione **12**, which, in contrast to **4**, exists in the enamine form. Methylation of **12** leads to 1,4-bis(dimethylamino)-3,6-bis(methylthio)-2,5-diazapentalene **13**, which, upon heating with dimethylamine in an autoclave, gives **15** and 1,3,4,6-tetrakis(dimethylamino)-2,5-diazapentalene **14**. Compounds **14** and **15** can be separated by fractional crystallization. Compound **14** has C_{2h} symmetry in the localized and D_{2h} symmetry in the delocalized structure.

The X-ray structure analysis of **14** (Fig. 1) shows the double-bond delocalization predicted by theory. It is not possible to rule out completely a rapidly established equilibrium between two localized structures. However, the fact that, in the case of 1,3,5-tri-*tert*-butylpentalene,[8–10] the X-ray structure analysis reveals the theoretically predicted double-bond localization, despite the very rapid valence isomerization, makes it very probable that the double bonds in **14** are delocalized. Accordingly, the compound can be referred to as an "aromatic (4n) π system," since it exhibits the characteristics of an aromatic compound.

Compounds **6**, **7**, **10**, **11**, and **13**–**15** all undergo multistep redox reactions (cf. Table 2). Compound **17a**, X = BF_4, is obtained on a preparative scale as reddish violet crystals by reaction of **11** with trityl tetrafluoroborate in dichloromethane; blue-violet **16a** is obtained by combining **11** with **17a**, X = BF_4, in acetonitrile.

The salts **17** are the first dicationic pentalene derivatives to be isolated and characterized. Although the preparation of a hexachlorodihydropentalenedi(ylium) bis(hexachloro-

Formation of Difluoroethyne as a Ligand by Coupling of Two Fluoromethylidyne Ligands**

By *Dieter Lentz** and *Heike Michael*

Difluoroethyne F–C≡C–F is an extremely unstable molecule,[1] so that its use in the synthesis of difluoroethyne complexes has not been possible so far. We have now succeeded in forming a difluoroethyne ligand by C–C bond formation between the two fluoromethylidyne ligands of **1**[2] in the cluster expansion reaction with **2** [Cp* = $C_5(CH_3)_5$].

$$\underset{\mathbf{1}}{[Fe_3(CO)_9(\mu_3\text{-}CF)_2]} + \underset{\mathbf{2}}{[Cp^*Co(CO)_2]} \xrightarrow[\text{pentane}]{h\nu} \underset{\mathbf{3}}{[Cp^*CoFe_3(CO)_9(\mu_4\text{-}\eta^2\text{-}FC{\equiv}CF)]} + 2\,CO \qquad \text{(a)}$$

The *closo* cluster **1** reacts with **2** in a straightforward fashion with cleavage of two carbonyl ligands to give **3** [reaction (a)].[3] According to the Wade rules,[4] the Cp*Co fragment contributes two framework electrons, so that its incorporation into cluster **1** should yield once again a *closo* structure. The Wade rules provide no information, however, on which of the possible *closo* structures (Fig. 1) is present.

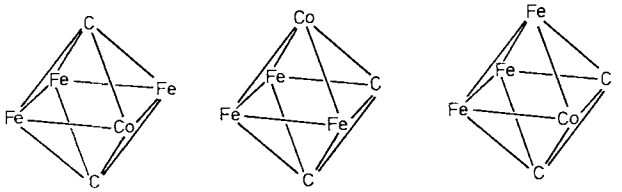

Fig. 1. Schematic drawing of the possible structural isomers of **3**.

The crystal structure investigation (Fig. 2)[5] revealed the presence of two crystallographically independent molecules in the unit cell, which, apart from orientation, display only minor differences. The metal atoms and the difluoroethyne carbon atoms form a severely distorted octahedron. The metal–metal distances lie between 244.5(2) and 265.1(2) pm. The short Co1–Fe1 distance is due to the fact that a carbonyl ligand on Fe1 is directed toward Co1, thus serving as a semi-bridging ligand. The two metal triangles Co1, Fe1, Fe2 and Fe1, Fe2, Fe3 form an angle of 112° (butterfly structure). The distances of the carbon atoms of the difluoroethyne ligands from Fe1 and Fe2 (192(1) pm) are markedly shorter than those to the remaining metal atoms Co1 and Fe3 (196(2) to 208(2) pm). Obviously, the C–C bond of the difluoroethyne ligand is significantly stretched by coordination to the four metal atoms, and the C–C–F structural unit is bent; i.e., the coordinated difluoroethyne has lost its identity and should be viewed as a component of the *closo* cluster.

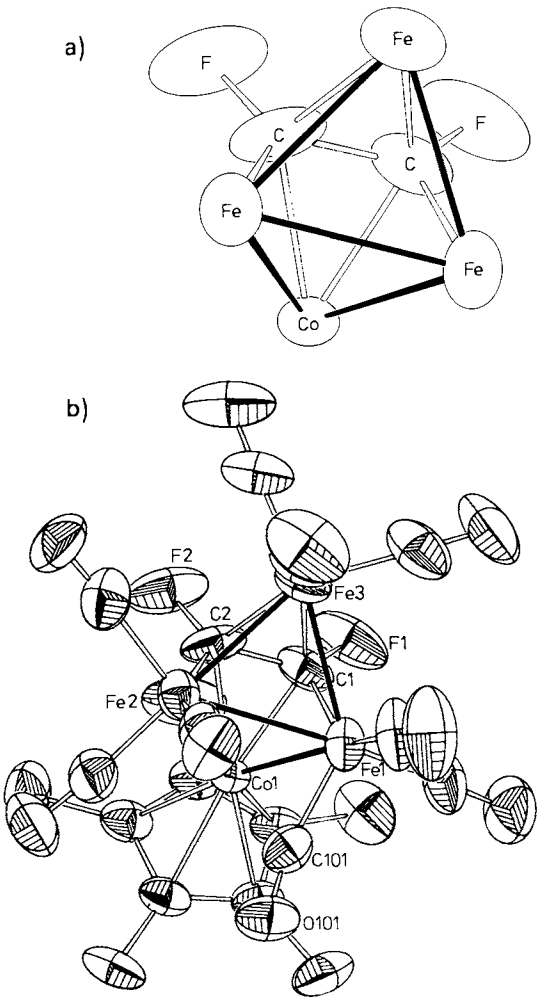

Fig. 2. a) Structure of **3** with ligand spheres omitted. b) Molecular structure of **3** (molecule I). Important bond lengths [pm] and angles [°]. Molecule I/II: Co1-Fe1 244.5(2)/245.7(2), Co1-Fe2 259.1(2)/257.9(2), Fe1-Fe2 263.3(2)/265.1(2), Fe1-Fe3 249.7(3)/251.1(2), Fe2-Fe3 254.2(3)/252.8(2), Co1-C1 196(2)/198.0(8), Co1-C2 202.5(9)/199.4(8), Fe1-C1 192.4(9)/195.0(8), Fe2-C2 192(1)/193.4(9), Fe3-C1 202.1(9)/202.6(9), Fe3-C2 208(2)/207.1(8), Fe1-C101 182(2)/177(1), Co1-C101 243.7(9)/252(1), C1-C2 145(2)/143(2); Co1-Fe1-Fe3 92.1(1)/91.0(1), Co1-Fe2-Fe3 87.8(1)/87.9(1), Fe2-Fe1-C1 72.1(4)/72.2(3), Fe1-Fe2-C2 71.9(4)/71.2(3), Fe1-C1-C2 107.6(7)/106.7(6), Fe1-C1-F1 131.1(8)/132.1(6), Co1-C1-Fe3 126.6(6)/124.5(5), Fe2-C2-C1 108.4(7)/109.8(6), Fe2-C2-F2 131.4(9)/129.2(7), Co1-C2-Fe3 120.2(6)/121.4(4), Co1-C101-O101 124.9(8)/122.4(7), Fe1-C101-O101 165.7(9)/170.3(9).

Although butterfly structures containing alkyne ligands are known for osmium ($[Os_4(CO)_{12}(\mu_4\text{-}\eta^2\text{-}C_2R_2)]$[6]) and ruthenium ($[Ru_4(CO)_{12}(\mu_4\text{-}\eta^2\text{-}C_2R_2)]$[7]), they are formed in a completely different way and no unstable alkynes are stabilized. A similar cluster expansion reaction of $[Fe_3(CO)_9(RC{\equiv}CR)]$ with $[CpRh(CO)_2]$ to give

[**] This work was supported by the Fonds der Chemischen Industrie and by BASF AG (donation of pentacarbonyliron). We thank Prof. Dr. *J. Fuchs*, Berlin, for his help in the crystal structure investigation.

$[CpRhFe_3(CO)_9(RC{\equiv}CR)]$ has been reported by *Vahrenkamp* et al.;[8] in that case, however, the formation of an alkyne ligand by C–C bond formation did not occur.

The cleavage and formation of alkynes coordinated to a cluster has been of great recent interest.[9]

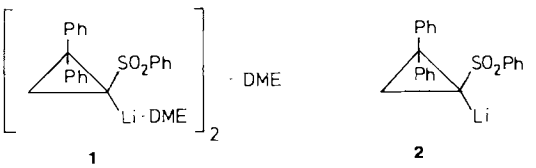
X-Ray Structure Investigation of 2,2-Diphenyl-1-(phenylsulfonyl)cyclopropyllithium–Dimethoxyethane (2/3): A Sulfonyl "Carbanion" Having an α-C Atom with a Tetrahedral Configuration**

By *Werner Hollstein, Klaus Harms, Michael Marsch,* and *Gernot Boche**

Does the anionic C atom in α-sulfonyl "carbanions" have to display a planar configuration or is a tetrahedral configuration also appropriate for stabilization by an RSO_2 group? The X-ray structure investigations of α-sulfonyl carbanions reported so far do not provide a conclusive answer to this question. In these examples, the environment of the α-C atom is either planar[1a] or does not deviate to a sufficiently large extent from planarity.[1b,c,2] If the "cyclopropyl effect"[3] is taken into consideration in answering this question, one even arrives at contradictory conclusions. Whereas *Zimmerman* et al.[4] and *Cram* et al.[5] found roughly the same equilibrium acidities for cyclopropyl- and isopropylsulfonyl compounds and *DeBoer* et al.[6] and *Kirmse* et al.[7] reported higher kinetic acidities for cyclopropylsulfonyl compounds, *Bordwell* et al.[8] found higher acidities for the isopropyl compounds. *Bordwell* concluded from his results that overlap of the carbon p orbital with a sulfur d orbital was necessary for stabilization of the "anion"; accordingly, α-sulfonyl "carbanions" should be planar like enolate and nitronate ions.[8b] The ^{13}C-NMR investigations of *Marquet* et al.,[9] on the other hand, revealed a hybridization of "between sp^2 and sp^3" for the α-C atom of t-$BuSO_2CH_2Li$. Finally, detailed calculations performed by *Streitwieser* et al.[10] on the stabilization of a negative charge by an RSO_2 group indicated that a p_π–d_π interaction is not important. Thus, the energy difference (3-21G(*)+) between planar $CH_3SO_2CH_2^{\ominus}$ and a $CH_3SO_2CH_2^{\ominus}$ structure in which the H atoms at C_α are bent from planarity by 20° is only +0.57 kcal mol^{-1}. The X-ray crystal structure investigation of (1-phenylsulfonyl)-2,2-diphenylcyclopropyllithium **2**, crystallized as 2,2-diphenyl-1-(phenylsulfonyl)cyclopropyllithium–dimethoxyethane(2/3) **1**, which we describe here, supports those findings



1 **2**

indicating that α-sulfonyl "carbanions" are also stabilized when the α-C atom has a tetrahedral configuration.[20]

Compound **1**[14] is present as a dimer in the crystal (Fig. 1); the lithium atoms are bonded to the O atoms of the sulfonyl groups and to two of the three dimethoxyethane molecules. This results in the formation of the (S-O-Li-O-S-O-Li-O) eight-membered ring characteristic of lithiosulfones.[1,2] The third molecule of dimethoxyethane cocrystallizes. Of special importance is the finding that the $PhSO_2$ group is bent out of the plane of the cyclopropane ring by 61.7(5)° (S1 lies 131.5(3) pm above the plane of the three-membered ring), so that the α-C atom deviates considerably from a planar configuration.[15] The C1–S1 distance (167.6(7) pm) and the S1–O1 distance (148.0(5) pm) are 3.5 and 1.5 pm larger, respectively, than in [α-(phenylsulfonyl)benzyllithium(tmeda)]$_2$.[1a] A salient feature of lithiosulfones is also the additional coordination of the Li atom to the α-C atom (C1–Li1A 244.0(14) pm); this is presumably due to the high charge density in the exocyclic orbital containing the negative charge. The bond axis C1–Li1A is bent by 24.9(6)° out of the plane of the three-membered ring (Li1A lies 103(1) pm below the plane of the three-membered ring). Thus, p_π–d_π interaction indeed plays no role in the stabilization of these (and other) α-sulfonyl "carbanions." Instead, an n–σ* interaction is im-

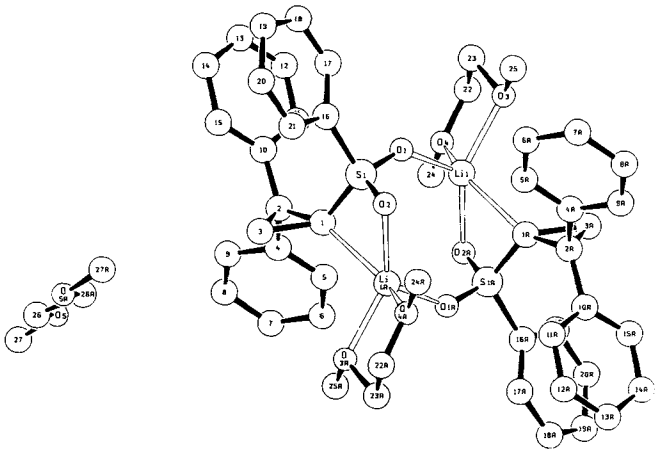

Fig. 1. Crystal structure of **1** [11]. Both the "dimer" and the cocrystallizing molecule of dimethoxyethane have a crystallographic center of symmetry. Symmetry-generated atoms are marked with "A." Crystal structure data of **1**: space group $P\bar{1}$, $a = 1014.7(3)$, $b = 1069.3(2)$, $c = 1191.9(3)$ pm, $\alpha = 86.94(2)$, $\beta = 88.69(2)$, $\gamma = 85.89(2)°$, $Z = 2$ (based on the monomer). Four-circle diffractometer CAD4 (Enraf-Nonius), $Cu_{K\alpha}$ radiation, graphite monochromator, 4059 measured reflections in the range $\theta = 2$–$50°$, 180 K. Solution by direct methods [12], refinement [13] to $R = 0.049$ for 1923 unique reflections with $F > 3\sigma(F)$, all non-hydrogen atoms anisotropic, H atoms, except for those on the three-membered ring, "riding" with a common isotropic temperature factor. Important bond lengths [pm]: C1-C2 152.6(9); C2-C3 154.3(10); C1-C3 152.5(10); C1-S1 167.6(7); S1-O1 148.0(5); S1-O2 147.1(4); C1-Li1A 244.0(14); S1-C16 175.8(8). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52892, the names of the authors, and the journal citation.

portant, as found by means of calculations.[10] Figure 2 shows the configuration at C1 and S1 as well as the conformation around C1-S1.

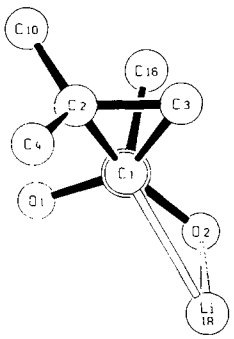

Fig. 2. Configuration at C1 and S1 (not visible) as well as conformation around C1-S1 of **1**. Important bond angles [°]: C2-C1-S1 123.9(5); C3-C1-S1 120.5(5); O1-S1-O2 115.2(3); C10-C2-C4 115.0(6); C2-C1-C3 60.8(5); C1-C2-C3 59.6(5); C1-C3-C2 59.7(5); torsion angles [°]: O1-S1-C1-C2 −72.0(6); O2-S1-C1-C3 90.8(6).

Compound **1** thus differs significantly from cyclopropyl "anions," whose negative charge is stabilized by delocalization, as in ester enolates or nitronates. Accordingly, enolate esters of cyclopropanecarboxylic acids are even highly reactive at −78 °C owing to the additional strain caused by the exocyclic double bond,[16] and cyclopropylnitronate can neither be trapped with an electrophile nor spectroscopically studied.[17] In contrast, 2,2-dimethyl-1-(phenylsulfonyl)cyclopropyllithium—fully in accordance with the above finding—is even stable at 80 °C in THF/DMSO.[5, 18, 19]

[1] a) [(PhCHSO$_2$Ph)Li(tmeda)]$_2$: G. Boche, M. Marsch, K. Harms, G. M. Sheldrick, *Angew. Chem. 97* (1985) 577; *Angew. Chem. Int. Ed. Engl. 24* (1985) 573; b) [(CH$_2$SO$_2$Ph)Li(tmeda)]$_2$: H.-J. Gais, H. J. Lindner, J. Vollhardt, *ibid. 97* (1985) 865 and *24* (1985) 859; c) [(CH$_2$=CHCHSO$_2$Ph)Li(diglyme)]$_2$: *ibid. 98* (1986) 916 and *25* (1986) 939; the deviations from planarity are most striking in this case: the H atom is bent out of the plane by 12°, the C atom by 14° [20].

[2] The structure of [(Me$_3$SiCHSO$_2$Ph)Li(tmeda)]$_2$ corresponds in essential respects to the structure of the compounds mentioned in [1a–c]: G. Boche, W. Hollstein, M. Marsch, K. Harms, unpublished results.

[3] Cyclopropyl effect: If an acceptor substituent X stabilizes a neighboring negative charge mainly by delocalization involving formation of a π bond, then the cyclopropyl compound C_3H_5–X is less acidic than the corresponding isopropyl compound C_3H_7–X, even though cyclopropane is more acidic than propane. Cause: The exocyclic π bond in the three-membered ring "anion" causes an additional strain of ca. 13 kcal mol^{-1}. For a different kind of stabilization, the cyclopropyl compound is more acidic [6].

[20] Note added in proof (May 5, 1988): A remarkably pyramidalized α-C atom has been found in the case of [(phenylsulfonyl)isopropyllithium·diglyme]$_2$, the two methyl groups being bent out of planarity (away from the O atoms of the $C_6H_5SO_2$ group) by 23.6 and 27.1° (H.-J. Gais, J. Vollhardt, G. Hellmann, H. Paulus, H. J. Lindner, *Tetrahedron Lett. 29* (1988) 1259).

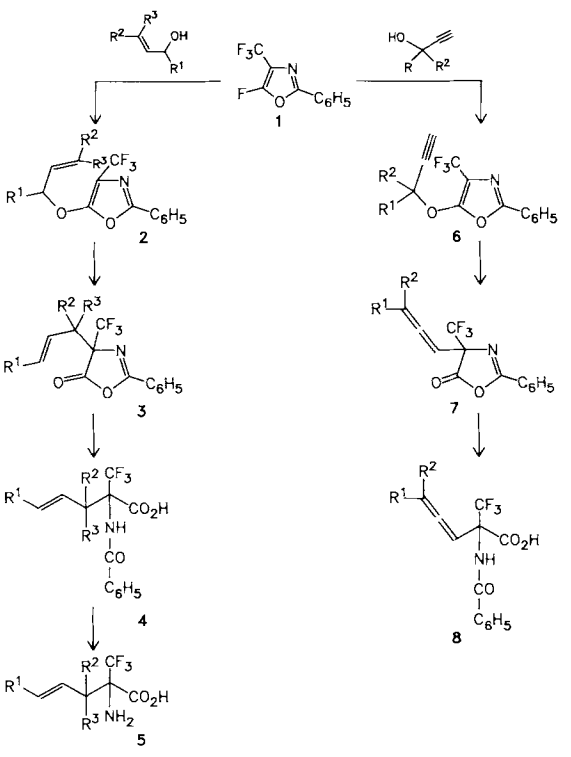
A Simple Access to 2-Substituted 3,3,3-Trifluoroalanine Derivatives**

By *Klaus Burger,* Klaus Geith,* and *Karl Gaa*

Of the partially fluorinated amino acids,[2,3,4b] trifluoroalanine[1] and its α-substituted derivatives[5] are of special interest because of the highly increased acidity of the carboxyl function and the greatly reduced basicity of the amino function.[6,7] The lesser known 2-substituted 3,3,3-trifluoroalanine derivatives have been found to be highly specific, irreversible enzyme inhibitors.[4b,8] The incorporation of the fluoro- and/or trifluoromethyl-substituted amino acids into proteins enables further structural studies on proteins by ^{19}F-NMR spectroscopy.[8]

We recently reported on a new method for the synthesis of trifluoroalanine[1] using the readily accessible 5-fluoro-2-phenyl-4-trifluoromethyloxazole **1**[9] as starting material. We have now found that **1** can also be used for the synthesis of 2-substituted 3,3,3-trifluoroalanine derivatives (Scheme 1).

5-Fluoro-4-trifluoromethyl-1,3-azoles[9] readily undergo nucleophilic displacement reactions at the 5-position of the ring.[10] When (allylic) alkenyl alcohols are used as nucleophiles in the presence of KOH as base, a spontaneous exothermic reaction is observed. The products **2** actually expected undergo a hetero-Cope rearrangement under the reaction conditions, yielding the 4-alkenyl-5(4*H*)-oxazalones **3**. The trifluoromethyl group present at position 4 of the ring impedes any further migration of the alkenyl moiety to the 2-position—as *Steglich* et al. have already observed for structurally similar 4-alkyl- and 4-aryl-substituted systems.[11]



Scheme 1. Substituents R^1–R^3 other than H atoms: **4b**, $R^1=CH_3$; **4c**, $R^1=C_2H_5$; **4d**, $R^1=n\text{-}C_3H_7$; **4e**, $R^1=C_2H_3$; **4f**, $R^2=CH_3$; **4g**, $R^2=n\text{-}C_3H_7$; **4h**, $R^2=R^3=CH_3$; **8b**, $R^1=C_2H_5$; **8c**, $R^1=CH_3$, $R^2=C_2H_5$.

For the synthesis of the 2-substituted 3,3,3-trifluoroalanine derivatives **4**, the isolation of the 5(4*H*)-oxazolones **3** is unnecessary. The ring-opening **3**→**4** is achieved by addition of water to the reaction mixture. The amino function is deblocked by boiling with concentrated HCl. The 5(4*H*)-oxazolones **3**, are amino acid derivatives with protected amino groups and activated carboxyl groups and are suitable for direct use in peptide syntheses.[12]

The substitution pattern (R^1–R^3) of the alkenyl alcohol can be varied within a wide range; even highly substituted alcohols $R^5R^4C{=}CR^3CR^2R^1{-}OH$ have been employed. The CC double bond as well as the CC single bond of the alcohol can be part of a ring system. This opens up an entry to trifluoroalanine derivatives bearing heteroarenes, arenes, heterocycles, and carbocycles as substituents.[13]

Moreover, the double bond introduced by the reaction sequence **1**→**2**→**3**→**4** can be functionalized manyfold, so that polyfunctional trifluoromethyl-substituted amino acids are also accessible by this strategy.[13] When $R^2 \neq R^3$, diastereomeric pairs are formed which can be separated by crystallization.

If alkynyl alcohols are used instead of alkenyl alcohols in the above sequence, the reaction leads via **6** and **7** to 3,3,3-trifluoroalanine derivatives containing an α,β-diene function in the 2-position. When $R^1 \neq R^2$, diastereomeric pairs are formed once again. The ring-opening **7**→**8** presents no problems, whereas all attempts to cleave the *N*-benzoyl protective group have always led to a transformation of the α,β-diene function. To our knowledge, amino acids of type **8** were hitherto unknown; their C=C=C moiety should be useful for syntheses of a broad spectrum of novel trifluoroalanine derivatives. The new compounds were characterized by their melting points, IR, ^{1}H-NMR, ^{13}C-NMR and ^{19}F-NMR spectral data (Table 1), and by mass spectra, and elemental analyses.

Table 1. Data of the compounds **4a** and **8a** (all R = H) [a].

4a: Yield 78%; m.p. 141 °C; IR (KBr): $\tilde{\nu}$ = 3380, 1740, 1730, 1631, 1518 cm^{-1}; ^{19}F-NMR: δ = 4.9 (s); ^{1}H-NMR: δ = 3.07 (1H, dd, $^2J_{gem}$ = 14.2, $^3J_{vic}$ = 7.4 Hz; $-CH_2-$), 3.38 (1H, dd, $^2J_{gem}$ = 14.2, $^3J_{vic}$ = 7.1 Hz; $-CH_2-$), 5.18 (1H, dd, $^2J_{gem}$ = 1.8, $^3J_{cis}$ = 11.0 Hz; $H_2C{=}CH-$), 5.28 (1H, dd, $^2J_{gem}$ = 1.8, $^3J_{trans}$ = 17.1 Hz; $H_2C{=}CH-$), 5.84 (1H, dddd, $^3J_{vic}$(HC−CH$_2$) = 7.1, $^3J_{vic}$(HC−CH$_2$) = 7.4, $^3J_{cis}$ = 11.0, $^3J_{trans}$ = 17.1 Hz; $H_2C{=}CH-$), 7.46-7.59 (3H, m; phenyl-H), 7.86-7.88 (2H, m; phenyl-H) NH and OH not observable; ^{13}C-NMR: δ = 29.81 ($-CH_2-$), 65.67 ($C{-}CF_3$; q, J = 27.7 Hz), 120.63 ($H_2C{=}CH-$), 125.37 (CF_3; q, J = 286.3 Hz), 128.04 (phenyl-C), 129.27 (phenyl-C), 131.20 ($H_2C{=}CH-$), 132.61 (phenyl-C), 134.83 (phenyl-C), 167.01, 167.21 (Ph−CO−, $-CO_2H$)

8a: Yield 64%; m.p. 113-116 °C; IR (KBr): $\tilde{\nu}$ = 3290, 1982, 1762, 1650, 1533 cm^{-1}; ^{19}F-NMR: δ = 4.4 (s); ^{1}H-NMR: δ = 5.18 (2H, dd, $^2J_{gem}$ = 3.3, ^4J = 6.7 Hz; $H_2C{=}C{=}CH-$), 5.84 (1H, t, ^4J = 6.7 Hz; $H_2C{=}C{=}CH-$), 7.44-7.57 (3H, m; phenyl-H), 7.88-7.90 (2H, m; phenyl-H), 8.19 (1H, broad; NH), OH not observable; ^{13}C-NMR: δ = 64.52 ($C{-}CF_3$; q, J = 27.9 Hz), 81.21 ($H_2C{=}C{=}CH-$), 87.91 ($H_2C{=}C{=}CH-$), 124.85 (CF_3; q, J = 285.9 Hz), 128.40 (phenyl-C), 129.18 (phenyl-C), 132.67 (phenyl-C), 134.47 (phenyl-C), 165.89, 167.16 (Ph−CO−, $-CO_2H$), 209.15 ($H_2C{=}C{=}CH-$)

[a] ^{19}F-NMR: 56 MHz, [D$_6$]acetone, trifluoroacetic acid (ext); ^{1}H-NMR: 360.134 MHz, [D$_6$]acetone, TMS (int); ^{13}C-NMR: 90.556 MHz, [D$_6$]acetone, TMS (int), proton broad-band decoupled.

Further possible applications of 5-fluoro-4-trifluoromethyl-1,3-azoles for the synthesis of 3,3,3-trifluoroalanine derivatives and for the synthesis of trifluoromethyl-substituted, medium-sized heterocyclic ring systems will be reported elsewhere.

[**] Synthesis of Naturally Occurring and Synthetic Amino Acids, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 2: [1a].

Experimental

A solution of **1** (2.31 g, 10 mmol) in anhydrous dioxane (30 mL) was treated with 10 mmol of the corresponding alkenyl or alkynyl alcohol and 1.12 g (20 mmol) of solid KOH. After a brief induction period, an exothermic reaction occurs. As soon as the ^{19}F-NMR analysis indicated complete conversion, the reaction mixture was treated with 10 mL of water, and, after complete ring-opening of **3** or **7**, respectively (^{19}F-NMR analysis), evaporated to dryness. The residue was taken up in water/ether (1/1) and the ether phase extracted twice with water. The combined aqueous phases were acidified with half-concentrated HCl (pH 1-2) and extracted twice with ether. The ether extracts were dried over sodium sulfate. After removal of the solvent under reduced pressure, the residue was recrystallized from ether/pentane.

Equipotential Surfaces in Periodic Charge Distributions

By *Alan Lindsay Mackay**

Von Schnering and *Nesper*[1] have produced very beautiful pictures of the zero potential surfaces in various crystal structures by exploiting the capabilities of modern computer graphics. They have thus made it easy to visualize the electrostatics implicit in *Pauling*'s rules for ionic structures and in the electrostatics now recognized as important in proteins (for example by *Sternberg* et al.[2]).

Their method involves the calculation of the potential of an exploratory charge at a test point (x,y,z). This requires the use of the full Ewald-Bertaut algorithm, where part of the calculation is carried out in real space and part in reciprocal space to ensure convergence. As explained most clearly by *Ashcroft* and *Mermin*[3] this slow convergence "is not just a mathematical nuisance. It reflects the physical fact that Coulomb interactions are of such long range that the energy of a collection of charged particles can depend crucially on the configuration of a negligibly small fraction of them on the surface". Computers now make it possible to calculate the energy of small finite clusters of atoms which may comprise real materials.

We have used a microcomputer (Commodore Amiga 1000) to draw some of the same surfaces using a different but related algorithm, which is less exact yet one that gives a good approximation. (We have hitherto used[4] a "finite element analysis" type of algorithm for minimal surfaces, while *Liden* and *Hyde*[5] have recently given another algorithm based on the projection of the normals of a minimal surface onto a sphere to give the Gaussian image.)

Our method was suggested by the standard expressions for the Fermi surfaces of cubic metals which are given (*Kittel*[6]; k = reciprocal lattice vector, a = real lattice vector) as

$$\text{simple cubic: const.} = \cos(\mathbf{k}_x\mathbf{a}) + \cos(\mathbf{k}_y\mathbf{a}) + \cos(\mathbf{k}_z\mathbf{a}) \quad (a)$$

$$\text{body-centred cubic: const.} = \cos(\mathbf{k}_x\mathbf{a}) \times \cos(\mathbf{k}_y\mathbf{a}) \times \cos(\mathbf{k}_z\mathbf{a}) \quad (b)$$

$$\text{face-centred cubic: const.} = \cos(0.5\,\mathbf{k}_x\mathbf{a}) \times \cos(0.5\,\mathbf{k}_y\mathbf{a}) + \cos(0.5\,\mathbf{k}_y\mathbf{a}) \times \cos(0.5\,\mathbf{k}_z\mathbf{a}) + \cos(0.5\,\mathbf{k}_z\mathbf{a}) \times \cos(0.5\,\mathbf{k}_x\mathbf{a}). \quad (c)$$

and are readily seen to be the sum of the Fourier terms:

$$\text{simple cubic: } 100,\ 010,\ 001 \quad (d)$$

$$\text{body-centred cubic: } 111,\ 11\bar{1},\ 1\bar{1}1,\ \bar{1}11 \quad (e)$$

$$\text{face-centred cubic: } 011,\ 01\bar{1},\ 101,\ 10\bar{1},\ 1\bar{1}0,\ 110 \quad (f)$$

If we calculate structure factors for a CsCl structure with a charge of +1 at 000 and a charge of −1 at ½, ½, ½, then the first factors are $F(000)=0$, $F(100)=2$, $F(200)=0$ and, in general, $F(hkl)=1-\cos(2\pi(h+k+l)/2)$. Thus, of the reflections with $N=h^2+k^2+l^2\leq 3$ only those with $hkl=100$, 010, and 001 are non-zero; they are identical with those found for the simple cubic Fermi surface [see (d)].

Similarly, for the NaCl structure with a positive charge at 000 and a negative charge at ½, 0, 0, of the expected first few terms 111, 200, 220, 311, 222 (noting that the reciprocal lattice of a real face-centered cubic lattice is body-centered cubic) only 111 and 311 are non-zero. Thus, of all reflections with $N<11$, only those with $hkl=111$; $11\bar{1}$; $1\bar{1}1$; $1\bar{1}\bar{1}$ are non-zero, as in the body-centered cubic Fermi surface.

For the body-centered cubic structure with a charge of +2 at 000 and ½, ½, ½ and six (doubly) negative charges at ½, 0, 0 plus eight (singly) positive charges at ¼, ¼, ¼ (as suggested by *von Schnering* and *Nesper*) the structure factors (the reciprocal lattice being f.c.c.) are: $F(110)=8$, $F(200)=-8$, $F(211)=8$, $F(220)=0$.

If we transform only the reflections 110, as in the calculation of the Fermi surface for a face-centered cubic metal (which has a body-centered cubic reciprocal lattice), then we obtain a surface very similar to that with eight tunnels (*Schoen*'s $I-WP$ surface) described by *von Schnering* and *Nesper*.

Taking the simple cubic surface [cf. Eq. (a)] we see, on taking the second derivatives, that Laplace's equation is satisfied if the constant is zero. Thus, the curve obtained is a solution of Laplace's equation and a zero equipotential.

Our procedure then is to carry out the normal Fourier summation for the electron density, but using only the first very few Fourier terms and concentrating only on plotting the zero potential contour (although other equipotentials can readily be plotted instead). We note that the scattering of electrons in electron microscopy and electron diffraction structure analysis is by the potential and the resultant plot is of that potential (not the electron density as in X-ray structure analysis). If we were calculating structure factors for this purpose from an array of electrons and positrons we would use the form factors which would show the very slow fall off in potential (according to $1/r$). The transform in reciprocal space would thus fall off even more sharply than the Gaussian factor entering into the Ewald-Bertaut method.

If we concentrate on plotting the zero potential this is equivalent to taking more terms, since the partition of space into two regions (positive and negative) by a single sinusoidal wave leads to a square wave which would otherwise be generated by adding up an infinite series of harmonics.

The equipotential surfaces for crystal structures can now be drawn using the tables of charge positions which *von Schnering* and *Nesper* have very usefully collected. First, the structure factors are calculated ($F(000)$ is always zero since there are equal numbers of positive and negative charges). Then the Fourier synthesis is calculated using the first one or two terms only, and finally the zero potential surface is plotted. In simple cases we have plotted contours of this surface directly, by finding, for each pair of y and z coordinates on a grid, the values for x at which the potential is zero. For the simplest cases there is a direct solution but usually the zero of a function of x has been found numerically. Calculations need be made only for the fundamental region which is repeated by the space group to fill space, although a more satisfactory grid is obtained if the whole unit cell is calculated.

For example, to plot the Neovius surface, which corresponds to the NaCl and CsCl charge distributions superimposed in the ratio 1 to 4, we obtain the surface shown (Fig. 1) by adding the Fourier terms of the type 110 and 111. The equipotential surfaces around protein molecules or other ionic structures, can be plotted similarly.

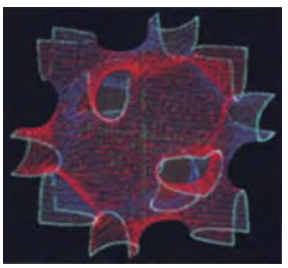

Fig. 1. The cubic unit cell of the zero equipotential surface in the Neovius surface [1].

Thus, the exploration of equipotential surfaces, which *von Schnering* and *Nesper* (as well as *Hyde* and *Andersson*[7]) have shown to be of great importance in understanding chemical properties, is within the compass of comparatively small microcomputers.

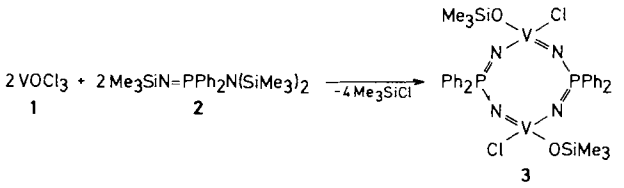
Synthesis and Structure of $[ClV(OSiMe_3)N_2PPh_2]_2$, the First Cyclodimetallaphosphazene—an Eight-Membered Planar Unsaturated Heterocycle**

By *Michael Witt*,* *Herbert W. Roesky*, *Mathias Noltemeyer*, and *George M. Sheldrick*

Dedicated to Professor Ulrich Wannagat on the occasion of his 65th birthday

We recently reported on the synthesis of six-membered cyclometallaphosphazenes containing a 6π-electron framework.[1] Eight-membered cyclophosphazenes in which one or two phosphorus atoms are replaced by a transition metal were hitherto unknown. Herein we describe the first synthesis of such a cyclodimetallaphosphazene.

Vanadyl chloride **1** reacts with $Me_3SiN{=}PPh_2N(SiMe_3)_2$ **2** in dichloromethane or acetonitrile with cleavage of Me_3SiCl to give $[ClV(OSiMe_3)N_2PPh_2]_2$ **3**,[2] a brick-red



substance that is extremely sensitive to moisture. Crystals of **3** suitable for an X-ray structure analysis were obtained by recrystallization from CH_2Cl_2/CH_3CN at $-30\,^{\circ}C$.

Within the limits of error the single crystal X-ray structure analysis[5] confirms the presence of a planar eight-membered ring. In contrast to the two other cyclic systems containing a N-V-N moiety in the ring, $[S_2N_3VCl_2]_n$[6] and $[(Ph_2P)_2N_3VCl_2]\cdot 2CH_3CN$,[1] which exhibit octahedral coordination at the metal atom, the vanadium atom in **3** shows only tetrahedral coordination, as observed in most open-chain nitrenevanadium compounds.[7] The V-N

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

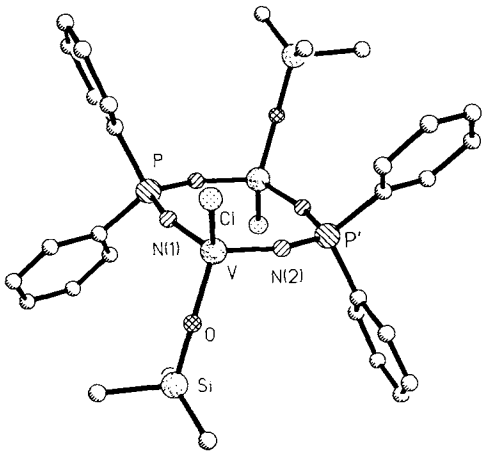

Fig. 1. Crystal structure of **3** (hydrogen atoms omitted). Important bond lengths [pm]: V-N(1) 167.9(5), V-N(2) 166.0(5), V-O 173.5(5), V-Cl 221.4(2), P-N(1) 161.8(5), P'-N(2) 162.1(5), O-Si 162.5(5). Bond angles [°] in the central eight-membered ring at V 110.8(3), N 158.4(3), P 116.9(3). The molecule possesses a crystallographic inversion center.

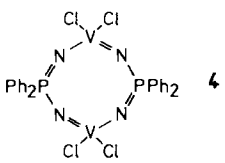
bonds are ca. 5–15 pm shorter than those in $[S_2N_3VCl_2]_n$,[6] but closely resemble those in open-chain systems.[7]

The P–N bond lengths, on the other hand, lie in the same range as those of similar cyclophosphazene systems.[1,8] The angles at the nitrogen atoms are about 10° greater than those in $P_4N_4F_8$, the only planar eight-membered phosphazene ring thus far reported in the literature.[9]

In mass spectroscopic investigations of **3**, the molecular ion could not be observed. The ^{1}H-decoupled NMR spectra show singlets in the expected regions with extremely large half-widths, which change very little even on lowering the temperature and which cannot be attributed to paramagnetism.[10]



4

Similar effects are observed in the case of **4**, which is accessible from $[Cl_3VNSiMe_3]$[11] and $Me_3SiN{=}PPh_2Cl$. **4** cannot be obtained by reaction of **3** with $SOCl_2$ or PCl_5.[12]

The First "Adamantoid" Alkaline Earth Metal Chelate Complex: Synthesis, Structure, and Reactivity**

By *Rolf W. Saalfrank,* Armin Stark, Karl Peters,* and *Hans Georg von Schnering**

n,n-Dilithioalkanes are of special interest both from the theoretical point of view and because of their remarkable synthetic potential.[1] The same holds true for 1,1-dilithioallyl phenyl sulfone,[2] dilithio(phenylsulfonyl)(trimethylsilyl)methane,[3] and dilithio(tosyl)methyl isocyanide.[4] To our knowledge dilithiomalonate esters have so far never been the subject of a concrete study. The C,C-dialkylation or C,O-diacylation of malonic esters proceeds in two steps via the malonic ester monoanion.[5]

The synthon strategy has proven to be best for the development of new synthetic methods.[6] In this connection we have paid special attention to tetradonor-substituted allenes **1**, which formally react like 1,1-/1,3-dianions **2** of malonic ester ($R^1 = R^2 = OEt$) or malonic amides ($R^1 = R^2 = NR_2$).[7] In extension of the concept developed for the allenes **1** we have also used silyl enol ethers **3** of 1,3-dicarbonyl compounds as 1,3-dianion equivalents **2** (R^1, R^2 = OEt, aryl).[8]

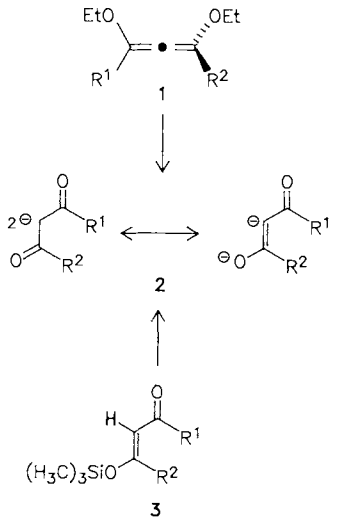
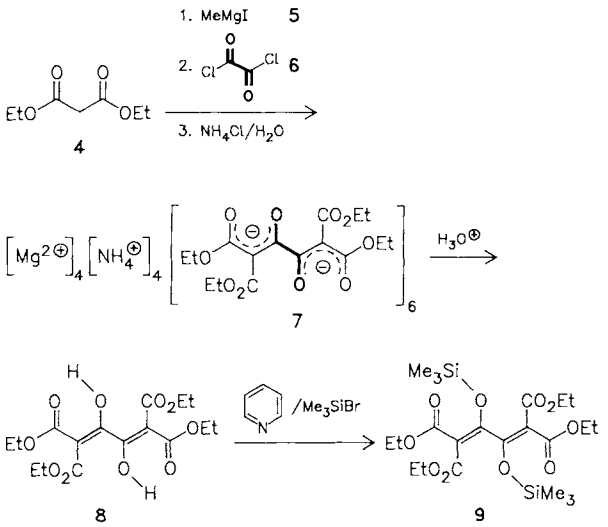
[**] "Adamantoid" Chelate Complexes, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



The direct use of doubly metalated 1,3-dicarbonyl compounds $2 \cdot 2\,M^{\oplus}$ could make the circuitous route via tetradonor-substituted allenes **1** or silyl enol ethers **3** superfluous. The malonic ester dianion serves as model species thereby, since it can be regarded as a tetradonor-substituted allene **1** ($R^1 = R^2 = O^{\ominus}$, OM).[9]

Metalation of malonic ester **4** in the presence of two equivalents of methylmagnesium iodide **5** in tetrahydrofuran (THF) at −78 °C followed by addition of a half equivalent of oxalyl chloride **6** and subsequent work-up with aqueous ammonium chloride solution furnished tetraammonium hexakis[tetraethyl-2,3-dioxobutane-1,1,4,4-tetracarboxylato(2−)-$O^{1'},O^2:O^3,O^{4'}$]tetramagnesate(4−) **7** as colorless crystals in ca. 40% yield. If, however, **4**, **5**, and **6** are allowed to react in the molecular ratio 1 : 1 : 0.25, the yield of **7** is increased to 85%. Careful hydrolysis of **7**



(pH ≈ 5, 20 °C, 2 minutes' ultrasonication) affords tetraethyl 2,3-dihydroxy-1,3-butadiene-1,1,4,4-tetracarboxylate **8** (keto-enol equilibrium). Compounds of type **8** were hitherto unknown. So far **8** could not be obtained in analytically pure form since it readily undergoes an acid cleavage to give two equivalents of malonic ester and one equivalent of oxalic acid. It can be reconverted into **7** by reaction with sodium hydride, magnesium bromide and aqueous ammonium chloride solution. If zinc bromide is used instead of magnesium bromide it is possible to prepare the zinc complex analogue of **7** from **8**. Compound **8** reacts with bromotrimethylsilane/pyridine to give tetraethyl 2,3-bis(trimethylsilyloxy)-1,3-butadiene-1,1,4,4-tetracarboxylate **9**.

When the ratio of the reactants **4** : **5** : **6** = 1 : 1 : 0.25, **7** is formed in a two-step mechanism via the malonic ester monoanion. Evidence against formation of the "dianion **1**" ($R^1 = R^2 = OMgI$) as intermediate is provided by the finding that only one volume equivalent of methane is formed upon reaction of **4** and **5** in the molar ratio 1 : 2 at −78 °C. Liberation of the second volume equivalent of methane (based on the yield of **7**) is first observed upon dropwise addition of **6**. This is consistent with participation of the system monoanion/methyl-Grignard reagent in the formation of **7**.

The ^{1}H- and ^{13}C-NMR spectra of **7** are impressively simple [empirical formula of **7**: $C_{96}H_{120}O_{60}Mg_4(NH_4)_4$; T_d symmetry, eight (!) ^{13}C-NMR signals] and thus provide no detailed information whatsoever about its structure. We therefore carried out an X-ray structure analysis of **7**; this revealed that **7** is present in the crystal in the form of a tetraammonium salt of the first known adamantoid tetramagnesium chelate complex. [Graphical representation of

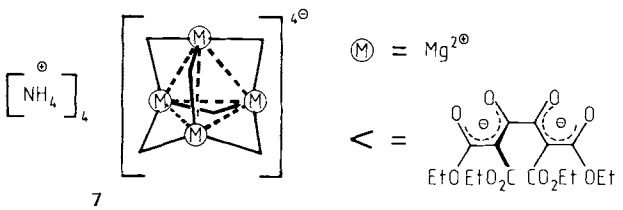


Fig. 1. Graphical representation (schematic) of **7**.

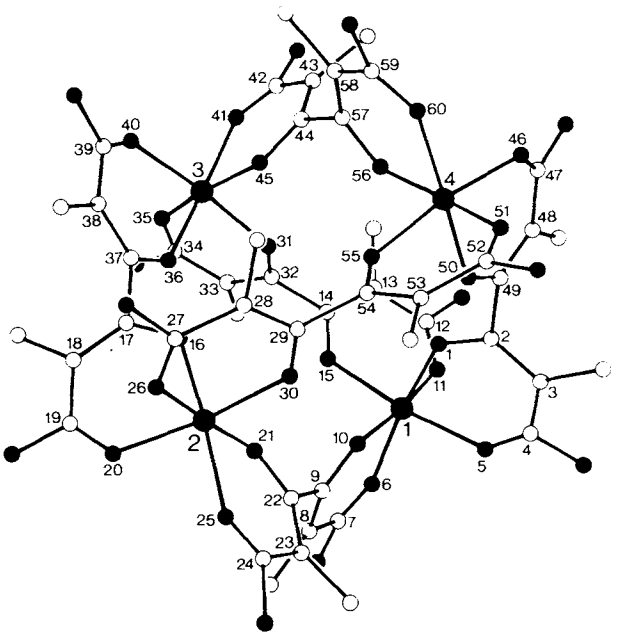

Fig. 2. Stereographic projection of the chelate complex anion of **7** with crystallographic labeling of the skeletal atoms. Large and small black dots indicate Mg and O atoms respectively, circles C atoms. Unlabeled C and O symbols stand for CO_2Et and OEt respectively. The atomic positions of the terminal groups are very inaccurate and were only isotropically refined. The compound crystallizes with one equivalent of 2,3-dihydroxy-2,3-dimethylbutane [14] in the triclinic system, $P\bar{1}$, $a = 1875.6(12)$, $b = 2007.2(7)$, $c = 1777.1(9)$ pm, $\alpha = 103.93(3)$, $\beta = 93.50(5)$, $\gamma = 90.45(4)°$, $Z = 2$, $\rho_{calcd} = 1.169$ g cm^{-3}, 8508 *hkl* with $F > 3\sigma(F)$, $R = 0.144$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-52856, the names of the authors, and the journal citation.

the chelate complex (schematic) in Fig. 1; stereographic projection of the chelate complex in Fig. 2].[10] The core of the chelate complex anion of **7** forms a tetrahedron of four magnesium ions; these are coupled via each of the six edges of the tetrahedron by a tetradentate tetraethyl-2,3-dioxobutane-1,1,4,4-tetracarboxylato(2−) bracket such that each of the four magnesium ions is octahedrally surrounded by six oxygen atoms.

The spectroscopic data of the zinc chelate complex differ only slightly from those measured for the corresponding magnesium chelate complex **7**.

Experimental

7: A suspension of **5** (60 mmol) in anhydrous THF (150 mL) was treated (under N_2, −78 °C) within 30 min with a solution of **4** (9.6 g, 60 mmol) in THF (50 mL) and the resulting mixture stirred for 2 h at −78 °C. It was then treated dropwise within 1 h with a solution of oxalyl chloride (1.9 g, 15 mmol) in THF (50 mL), heated to 20 °C within 18 h, and worked-up with aqueous ammonium chloride solution. Yield: 5.1 g (85%), decomp. 180 °C (from acetone).—IR (KBr): $\tilde{\nu}$ = 1690 (C=O), 1635 cm^{-1} (C=C).—^{1}H-NMR (400 MHz, CD_3OD): δ = 1.19 and 1.28 (each t, 72 H; 24 CH_3), 3.95, 4.06, 4.17, and 4.27 (each mc, 48 H; 24 CH_2), 4.84 (s, 16 H; 4 $NH_4^{\oplus}$).—^{13}C-NMR (100.5 MHz, CD_3OD): δ = 14.56 and 14.60 (24 CH_3), 61.22 and 61.71 (24 OCH_2), 96.10 (12 =C), 169.57, 172.01, and 186.31 (24 C=O, 12 C=O).

9: A suspension of **7** (1.2 g, 0.5 mmol) in water (100 mL) was treated with a solution of aluminum sulfate (15 g) in water (50 mL) and the mixture ultrasonicated for 2 min. The aqueous phase was extracted twice with 100 mL of dichloromethane and the combined extracts dried over sodium sulfate. After removal of solvent the remaining enol **8** (reddish oil) was dissolved in 20 mL of diethyl ether (under N_2) and treated with 0.5 g (6 mmol) of pyridine and 4.6 g (30 mmol) of bromotrimethylsilane. The mixture was then stirred for 1 h at 20 °C and filtered. After removal of solvent, the remaining silyl enol ether **9** (orange colored oil) was freed of all volatile impurities at 20 °C under vacuum. Yield: 1.5 g (95%). Decomp. ≈ 55 °C.—IR (film): $\tilde{\nu}$ = 1725 (C=O), 1630 cm^{-1} (C=C).—^{1}H-NMR (400 MHz, $CDCl_3$): δ = 0.20 (s, 18 H; 2 $Si(CH_3)_3$), 1.17 (t, 6 H; 2 CH_3), 1.23 (t, 6 H; 2 CH_3), 4.09 (q, 4 H; 2 OCH_2), 4.18 (q, 4 H; 2 OCH_2).—^{13}C-NMR (100.5 MHz, $CDCl_3$): δ = 0.35 (2 $Si(CH_3)_3$), 13.75 (2 CH_3), 14.01 (2 CH_3), 60.79 (2 OCH_2), 60.97 (2 OCH_2), 113.25 (2 =C), 156.46, 163.59, and 164.11 (O−C=O and =C−O).—MS (70 eV): *m/z* 518 ($M^{\oplus}$).

Preparative UV-Laser Photochemistry: A Biscarbene Intermediate in the Synthesis of a 5,6-Dihydrodibenzo[*a,e*]cyclooctene Containing a *trans*-Double Bond**

By *Klaus Hannemann** and *Jakob Wirz*

The extremely high light intensities of laser light sources enable multiphoton processes to be achieved which cannot be initiated with conventional lamps. These multiphoton processes were hitherto primarily investigated spectroscopically;[1] in some cases new products have been isolated.[2] Depending upon the time interval between the absorption processes, multiphoton processes range from quasi-simultaneous multiphoton absorption to secondary excitation of singlet and triplet states[2a–f] to photochemical reactions of reactive intermediates.[2g–j] A further interesting case is the photolysis of dichromophores.[4] If both chromophores of a dichromophoric molecule are excited with high-intensity light, a difunctionally reactive intermediate can be formed which may lead to new products. As an example of a dichromophoric system we chose the bis(diazomethane) **1**, and describe here the preparative laser photolysis of **1** as compared to its conventional photolysis.

The bis(diazo) compound **1**[5] was prepared from the bishydrazone of *o,o'*-dibenzoyl(bibenzyl)[2j] by oxidation with activated manganese(IV) oxide. As shown in Scheme 1 conventional irradiation of the starting compound **1** leads to the hydrocarbons **7**–**9**[6] and to small yields of the novel cyclic azine **10**, which is formed via an intramolecular carbene addition to the remaining diazo group of **2**. The formation of the hydrocarbons **7**–**9** can be readily

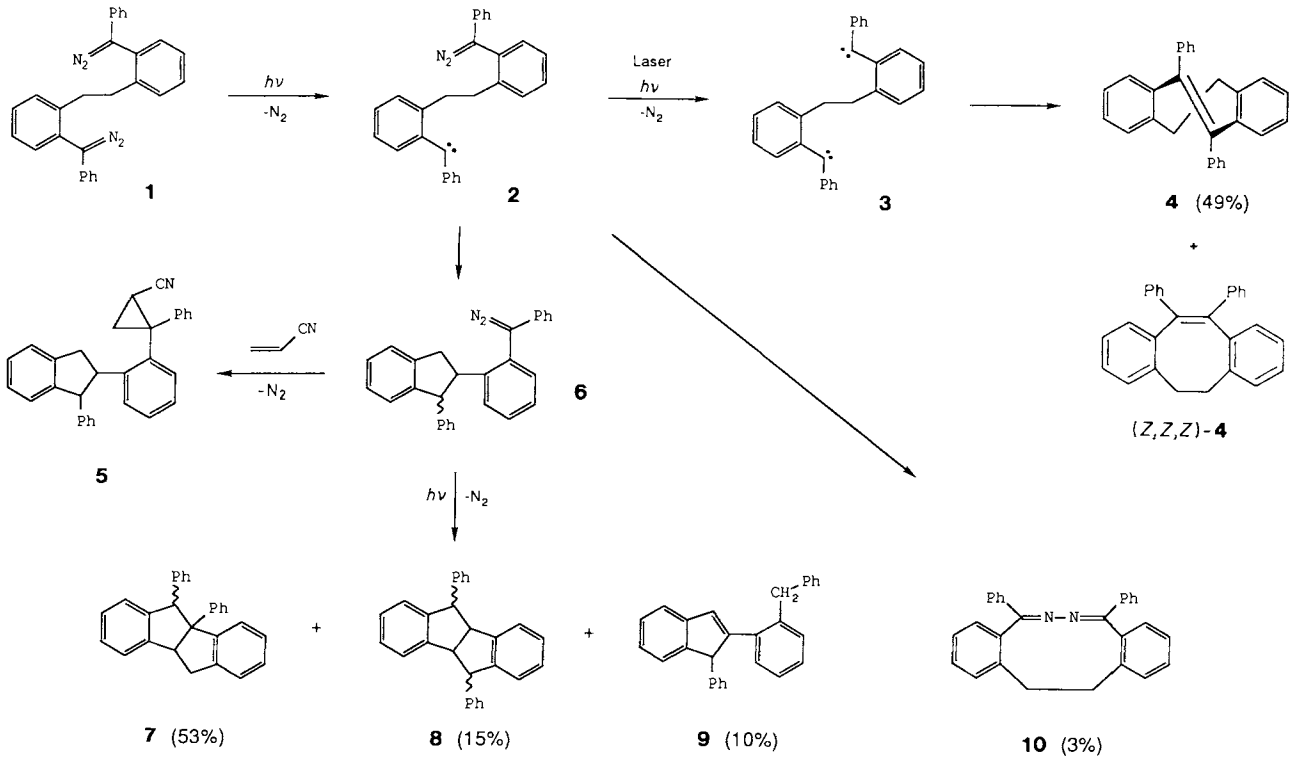

Scheme 1.

explained in terms of sequential cleavage of the diazo groups: elimination of one molecule of nitrogen leads to formation of the diazocarbene **2**, which reacts by way of an intramolecular 1,5-H abstraction[7] via a 1,5-diradical and ring closure to give the diazomethane **6**. The carbene formed from **6** by photochemical elimination of nitrogen cyclizes after a further 1,5-H abstraction to give the hydrocarbons **7** and **8**; disproportionation of **6** furnishes the indene derivative **9**. The existence of the intermediary diazomethane **6** could be demonstrated by trapping with acrylonitrile to give the cyclopropane derivative **5**.

Irradiation of the bis(diazomethane) **1** with a pulsed excimer laser at 248 nm[8] leads to formation of a new compound which is not detectable in a conventional irradiation (254 nm) experiment. The compound could be isolated in 49% yield by chromatography on silica gel and was identified as (*Z,E,Z*)-5,6-dihydro-11,12-diphenyldibenzo[*a,e*]cyclooctene **4**.[9] Control experiments showed that the cyclooctatriene **4** is not formed on laser photolysis of the photoproducts **7**–**10**. Compound **4** is already clearly detectable in the reaction mixture after a single laser pulse on the basis of its strong absorption at 365 nm; its concentration increases linearly with the number of laser pulses. The product-determining reaction steps for the formation of **4** must therefore take place within the laser pulse of 20 ns.

On the basis of the known dimerization of carbenes to olefins[10] it may be assumed that the dicarbene **3** is the precursor of the main product **4**. As could be demonstrated by time-resolved spectroscopy,[11] diphenylcarbene is formed from diphenyldiazomethane within a nanosecond. There is thus sufficient time to excite the diazocarbene **2** formed from **1** once more within the same laser pulse and thereby eliminate the second nitrogen. A thermal denitrogenation of **2** can be ruled out, since conventional photolysis furnishes no **4**. It is noteworthy that intramolecular carbene-dimerization of **3** yields primarily the isomer **4** with a *trans* double bond. (*Z,Z,Z*)-**4**[12] could be detected to the extent of 7% in the photolysis mixture by NMR spectroscopy; the possibility that **4** is formed by photochemical *cis/trans* isomerization of (*Z,Z,Z*)-**4** within a laser pulse, can, however, be ruled out, since the laser photolysis of pure (*Z,Z,Z*)-**4** furnishes far less of the (*Z,E,Z*)-compound **4** than does photolysis of the bis(diazomethane) **1** under the same conditions. As other photochemical studies have already shown,[13] the conformation of an intermediate can decisively influence the further course of the reaction. The biscarbene **3** could exist in a conformation which strongly favors the reaction leading to the (*Z,E,Z*)-olefin **4**. Moreover, it can be assumed that the dimerization of two triplet carbenes does not lead directly to the ground state of the olefin, but mainly proceeds via its triplet state. From molecular models it can be deduced that a hypothetical triplet state twisted by 90° is geometrically more similar to the (*Z,E,Z*)-olefin in the ground state than to the (*Z,Z,Z*)-olefin. We presume, therefore, that a deactivation of the triplet state preferably leads to the (*Z,E,Z*)-isomer **4**.

As we have shown here, the high light intensity of the laser light fundamentally changes the photochemical behavior of the dichromophoric bis(diazomethane) **1**. The main product **4**, the first (*Z,E,Z*)-cyclooctatriene derivative, is preparatively accessible in good yields by laser photolysis.

Reduction of Epoxides, α,β-Unsaturated Aldehydes, and Vicinal Diketones with "Reactive Titanocene"

By *Rainer Schobert**

When titanocene dichloride **1** is reduced with one equivalent of magnesium in tetrahydrofuran under argon, deep-green solutions are formed which according to *Brintzinger* et al.[1] and *van Tamelen* et al.[2] contain THF adducts of "reactive titanocene" $[Cp_2Ti]_{1-2}$. These solutions, which decompose within a few hours to brown titanocene alkoxide complexes, have been intensively investigated with regard to their suitability as nitrogen and hydrogen activators[4,5] in the same way as the hydrido species obtainable from **1** with other reducing agents and solvents.[3] *Rausch* and *Herberhold* et al.[6] recently developed a convenient method for the in situ synthesis of stable titanocene derivatives using **1**, magnesium, and an excess of ligand.

As can be seen in Table 1 it has now been found that such solutions of "reactive titanocene" in tetrahydrofuran deoxygenate equivalent amounts of epoxides **2** smoothly and in high yields to the alkenes **3**. *trans*-Epoxides lead exclusively to *trans*-alkenes, *cis*-epoxides furnish predominantly *cis*-alkenes. Even sensitive epoxides such as 2-methyl-2-phenyloxirane **2e**, which form only little olefin with other reducing agents,[7] react here in satisfactory yields.

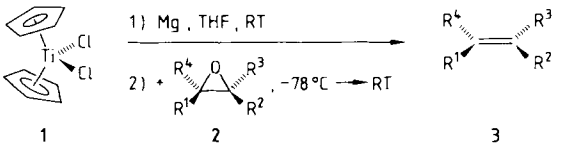

Table 1. Alkenes **3** by reduction of epoxides **2** with "reactive titanocene".

	R^1	R^2	R^3	R^4	Yield [%] [a]	*E/Z* [b]

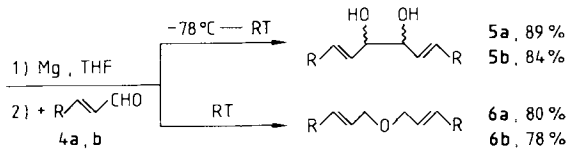
[a] Based on purified, isolated product. [b] Gas chromatographically determined isomeric ratio. [c] 20% 2-phenylpropanal as by-product when reduced at −78°C; 24% cumol as by-product when reduced at 20°C.

Many methods described hitherto for the synthesis of alkenes by reduction of epoxides use either non-stereoselective reducing agents such as titanium(III) chloride/$LiAlH_4$,[7] zinc/copper couple,[8] sodium amalgam/transition-metal complex,[9] magnesium amalgam,[10] or are evidenced by only a single example, such as the reduction with dibenzenetitanium[11] or triphenylphosphane selenide.[12] Zinc bromide/phosphorus oxide chloride,[13] tungsten(VI) chloride/alkyllithium,[14] alkali metal (dicarbonylcyclopentadienyl)ferrate,[15] iron(III) chloride/butyllithium,[16] lithium diphenylphosphane,[17] and chromium(II) perchlorate/ethylenediamine[18] have proven to be good stereoselective reducing agents.

Under the conditions described here, both simple carbonyl functions, esters, olefins as well as ethers and acetals are inert. Saturated aldehydes are reduced to the alcohols only after 24 h at room temperature without coupling products being formed. α,β-Unsaturated aldehydes **4**, however, react rapidly at −78°C to give the corresponding vicinal bis(allyl alcohols) **5**, which are formed as a diastereomeric mixture with a diastereomeric excess of 30% in favor of the *threo*-racemates.[19] At room temperature, **4** is

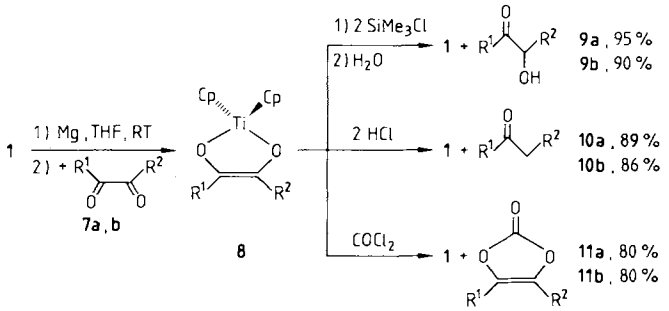
[*] Dr. R. Schobert
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (FRG)

reduced to the bis(allyl) ethers **6**. Presumably the initially formed radical allyloxytitanium species is so stable at low temperatures that it can dimerize with formation of pinacol, whereas at room temperature the rapid reaction with free aldehyde with CO-bond formation and deoxygenation is preferred (Scheme 1).



Scheme 1. **a**: $R=CH_3$; **b**: $R=n\text{-}C_3H_7$. Compound **6b** is new; b.p. 50 °C/0.1 torr. Structure proven on the basis of ^{1}H-NMR and GC/MS spectra; correct elemental analyses were obtained.

Vicinal diketones **7** react rapidly with "reactive titanocene" in tetrahydrofuran at room temperature to give deep-green chelate complexes **8**,[20] which, as shown in Scheme 2, furnish: acyloins **9** on work-up with trimethylchlorosilane/water; surprisingly and so far unexplainably saturated monoketones **10** upon treatment with anhydrous hydrogen chloride; and vinylene carbonates **11** on treatment with phosgene. In all cases **1** can be re-formed quantitatively.



Scheme 2. **a**: $R^1=R^2=C_6H_5$; **b**: $R^1=C_6H_5$, $R^2=C_6H_5CH_2$. Compound **11b** is new, b.p. 111 °C/0.04 torr. Confirmation of structure based on ^{1}H-NMR and GC/MS spectra; correct elemental analyses were obtained.

Further investigations with difunctional carbonyl compounds are presently under way.

Experimental

3: A suspension of **1** (2.49 g, 10 mmol) and magnesium (0.24 g, 10 mmol) in 50 mL of anhydrous tetrahydrofuran was stirred at room temperature until a clear deep-green solution was formed. This was cooled to −78 °C and treated dropwise with a solution of 10 mmol of **2** in 20 mL of tetrahydrofuran. After allowing to stand for 12 h at room temperature and evaporation of the solvent, the residue was filtered through 20 g of silica gel with 200 mL of hexane/ether (1/1) and the filtrate purified by distillation or recrystallization.

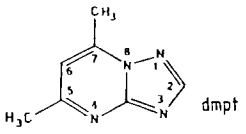
A Novel Tetranuclear Copper(I) Cluster with Alternate Bridging Halide and Triazolopyrimidine Ligands**

By *Jaap G. Haasnoot,* T. Loek F. Favre, Winfried Hinrichs,* and *Jan Reedijk*

The ligand 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (dmtp) has three potential donor atoms. Coordination through the sterically least hindered N3 nitrogen is normally observed,[1] and it appears that the two methyl groups prevent coordination through the other two nitrogens. Only recently has a coordination through N1 been observed[2] in derivative ligands without the methyl substituent at C7. In this communication coordination through the sterically unfavorable N4 is reported.



In principle, one could expect coordination through both N3 and N4, in a way similar to the coordination found in dimeric copper(II) species like **1**[3] and in the well-known copper(II)-adenine compounds like **2**.[4] Nevertheless, various attempts with several copper(II) salts yielded only compounds with N3 coordination.[5]

$[Cu_2(1,8\text{-naphthyridine})_2Cl_4]$ **1**

$[Cu_2(ade)_4Cl_2]Cl_2\cdot 6H_2O$ **2**

$[Cu_4(dtmp)_4Cl_2]^{2\oplus}[Cu_2Cl_4]^{2\ominus}$ **3**

[**] The authors are indebted to Dr. *R. Prins* and Mr. *M. J. Suijker* for valuable contributions to this work.

However, when copper(II) chloride was used and allowed to react with dmtp at elevated temperature in ethanol a product **3** of composition $[Cu(dmtp)_{2/3}Cl]$ was obtained.[6] The same product could be obtained directly, starting from CuCl. According to an X-ray structure analysis,[7] **3** consists of a unique tetranuclear cation and the rare anion di(μ-chloro)dichlorodicuprate(I) (Fig. 1). In the

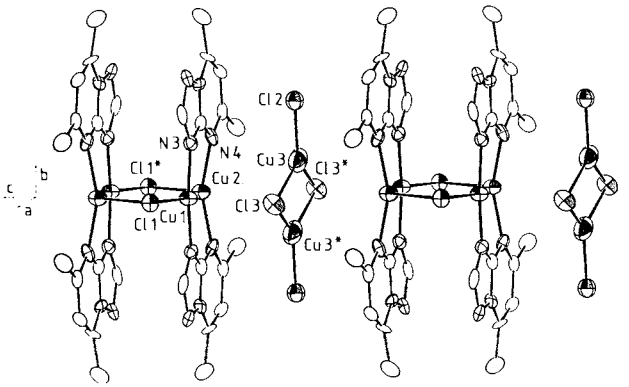

Fig. 1. Structure of $[Cu_4(dmtp)_4Cl_2]^{2\oplus}[Cu_2Cl_4]^{2\ominus}$ **3** in the crystal (ORTEP plot, view on the *bc*-plane). * denotes symmetry-related atoms [7].

cation two $Cu_2(dmtp)_2$ units are bridged by two chloro ligands. The distance between the N-C-N-bridged Cu atoms in the $Cu_2(dmtp)$ units (290.9 pm) is significantly larger than the Cu···Cu distance in other oligonuclear Cu(I) compounds with comparable bridges. For instance, in $[Cu_4(6\text{-methylpyridin-2-olate})_4]$, N-C-O bridge 266–271 pm;[8] in $[Cu_4(MeN_3Me)_4]$, N-N-N bridge 264–268 pm.[9] This enlargement can be attributed to the geometrical demands of the annelated triazole ring, by which its coordinating electron pair is directed away from the pair of the pyrimidine ring. The same effect is found on comparing the $Cu^{II}\cdots Cu^{II}$ distances in acetate bridges (258–262 pm[10]) or in the N-C-N bridge of **1** (266 pm[3]) with those in adenine bridges (cf. **2**, ca. 300 pm[4]).

The distance between the chloride-bridged Cu atoms of the cation, which with 310.7 pm lies in the usual range for Cu^{I}-Cl-Cu^{I} bridges, may be influenced by intraionic stacking interactions of the dmtp ligands.

The Cu···Cu distance in the anionic Cu-Cl-Cu bridge is only 243.3 pm, which is extremely short and only comparable with the bridges in polymeric copper iodides like $[NMe_4][Cu_2I_3]$.[11] All Cu-Cl bonding distances match those of an earlier observation,[12] a difference occurring only in the Cl-Cu-Cl endocyclic angle (118.2° in the present case and 96.8° in the reported one). It is possible that packing effects on the exocyclic chloride distort the ring angle and thus indirectly influence the anionic Cu···Cu distance (Fig. 1). All metal-to-ligand distances lie in the range expected for copper(I) compounds.[13]

The dmtp ligands are arranged in pairs of parallel planes. The distance between these planes within a pair corresponds to the distance between the almost parallel ligands in the cations (320 pm). This means that stacking effects of the rings contribute to the stability of the structure. The packing between the pairs of ligand planes is through contacts via layers of anions; the exocyclic chlorides are thereby "sandwiched" between dmtp ligands (the distance between the anion plane and dmtp plane is 337 pm). No other close contacts have been found.

The dianion $[Cu_2Cl_4]^{2\ominus}$, a member of a series of polynuclear copper(I) chloride anions,[14] has hitherto only been prepared[2] as the anion of the likewise very large cation $[VO(salen)(H_2O)]^{\oplus}$; it is the chloride analogue of $[Cu_2Br_4]^{2\ominus}$[15] and $[Cu_2I_4]^{2\ominus}$.[16]

The cation could also be crystallized with other anions. Under slightly different experimental conditions, yellow needles of the composition $[Cu(dmtp)_{1/2}Cl]$ (Cu, Cl, C, H, N analysis) were obtained. As the IR spectrum of this product is nearly identical to that of **3**, the composition **4** (or **4** with $\{[Cu_2Cl_3]^{\ominus}\}_2$ as anion) is proposed for this product.

$[Cu_4(dmtp)_4Cl_2]^{2\oplus}[Cu_4Cl_6]^{2\ominus}$ **4**

$[Cu_4(dmtp)_4Cl_2]^{2\oplus}[PtCl_4]^{2\ominus}$ **5**

Addition of $K_2[PtCl_4]$ in water to a solution of **3** gave an orange precipitate whose elemental analysis (Cu, C, H, N, Cl, and Pt) is consistent with the composition **5**. The IR spectrum of **5** is likewise identical to that of **3**, apart from in the FIR region where the absorption of the $[PtCl_4]^{2\ominus}$ ion is obvious.

The compounds **3**, **4**, and **5** appear to be quite stable on exposure to air; no change in crystal habit is observed upon storage in open vessels for several months. Oxidation to copper(II) compounds is observed, however, after several days in water/ethanol solutions. Addition of L-ascorbic acid stabilizes the copper(I) state.

Starting from CuBr or CuI and dmtp, substances of the composition $[Cu(dmtp)_{1/2}X]$ (X = Br, I) could be obtained, the IR spectra of which are almost identical to those of the analogous chloride; we therefore suppose that it likewise has tetranuclear cations.

The compounds described here add to the great variety of structural types for copper(I) clusters and illustrate once more the extensive coordinating properties of (de)azapurines, the study of which is of major importance to bioinorganic chemistry.

Synthesis of Peptides Containing (*S*)-α-Methylserine**

By *Eva Altmann, Karl-Heinz Altmann*, and *Manfred Mutter**

A large number of chiral α-alkyl-α-amino acids have become accessible by asymmetric synthesis during the last years;[1a,b] however, only a few attempts have been made to incorporate such potential helix-inducing residues into peptides.[2–4]

Our ongoing studies on the design and synthesis of artificial proteins[5a,b] made it highly desirable to have access to a *hydrophilic* helix-inducing amino acid; consequently, we have directed our interest to the chemistry of α-methylserine. Herein we report on the solution synthesis of (*S*)-α-methylserine(α-MeSer)-containing peptides without side chain protection, and on the synthesis of H-α-MeSer(O*t*Bu)-OH as a key intermediate in the future synthesis of larger α-MeSer-peptides.

H-α-MeSer **1** was synthesized according to the procedure of *Seebach* et al.;[1a,6,7] for its use in peptide synthesis, **1** was converted into the methyl ester hydrochloride HCl·H-α-MeSer-OMe **2**.

Table 1. Yields and melting points of α-MeSer-containing peptides [a].

Peptide	Yield [%]	M.p. [°C]
Boc-Ala-α-MeSer-OMe **3**	56	113.7–114.2
Boc-Val-α-MeSer-OMe **4**	55	104.0–107.0
Z-Ala-α-MeSer-OMe **5**	58	oil
Boc-Ala-α-MeSer-OH **6** [b]	90	162.3–163.8
Z-Ala-α-MeSer-OH **7** [b]	92	136.2–137.9

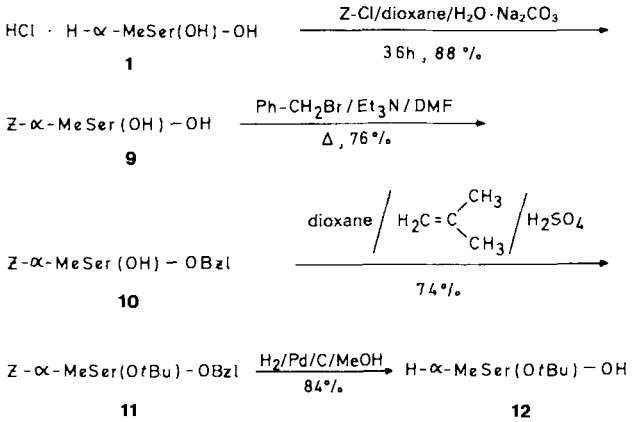
[a] Typical reaction conditions for the preparation of methyl esters **3**–**5**: 2.5 mmol of N_α-protected amino acid; 2.4 mmol of **2**; 2.6 mmol BOP; 5 mmol DIPEA, 35 mL DMF, RT, 15 h. [b] **6** and **7** were obtained by alkaline saponification of **3** and **5**, respectively.

The dipeptide methyl esters **3**–**5** (Table 1) were obtained by BOP (benzotriazol-1-yloxytris(dimethylamino)hexafluorophosphate)[8] mediated couplings of N_α-Boc (*tert*-butyloxycarbonyl) or Z (benzyloxycarbonyl) protected Val or Ala with **2** in DMF with DIPEA (diisopropylethylamine) as neutralizing base. The yields varied between 55% and 58% after chromatographic purification and subsequent crystallization (except for **5**, which could not be crystallized). In contrast, preactivation of Boc-Ala-OH with DCC/HOBt (*N,N'*-dicyclohexylcarbodiimide/1-hydroxybenzotriazole)[9] (1 h at 0°C, 1 h at RT) provided **3** in only 37% yield.

Alkaline saponification (2.5 h, RT) of **3** and **5** with 2 equivalents of NaOH in MeOH provided the corresponding acids **6** and **7** in excellent yields and crystalline form. Boc-cleavage (1.2 N HCl/AcOH, 0.5 h, RT) from **3** and reaction with Boc-Ala-Ala-OH (DCC/HOBt activation) afforded the tetrapeptide Boc-Ala-Ala-Ala-α-MeSer-OMe **8** in 37% yield after chromatographic purification and crystallization from acetone/ether (m.p. 164–165.1°C).

In contrast to the synthesis of peptides in solution, side chain protection of α-MeSer becomes mandatory for its use in polymer supported peptide synthesis.[10] We have therefore explored the synthesis of the side chain protected derivative H-α-MeSer(O*t*Bu)-OH **12**, which is of particular importance in the stepwise synthesis of peptides according to the Fmoc/*t*Bu strategy.[11] **12** represents the key intermediate for the synthesis of Fmoc-α-MeSer(O*t*Bu)-OH and of protected dipeptides of the type Fmoc-Xxx-α-MeSer(O*t*Bu)-OH (Xxx, any amino acid).[12] The synthesis of **12** was accomplished in four steps (starting from **1**) in an overall yield of 42% (Scheme 1), similarly to the synthetic scheme developed by *Wünsch* and *Jentsch* for the synthesis of *tert*-butyl ethers of common hydroxy α-amino acids.[14]

Studies on the conformational properties of α-MeSer containing peptides[15] synthesized by the techniques outlined here indicate that this residue exerts a helix inducing effect, thus representing a valuable building block in the design of new proteins.[5]



Scheme 1. Synthesis of **12** from **1**.

Experimental

Reaction of (*S*)-α-MeSer with benzyl chloroformate afforded the N_α-Z-protected derivative **9** (88%, oil, $[\alpha]_D^{25} = +8.4°$, $c = 2$ in $CHCl_3$), esterification of which with benzyl bromide in DMF furnished the benzyl ester **10** (76%, oil, $[\alpha]_D^{25} = +13.6°$, $c = 2$ in $CHCl_3$). This was converted into the fully protected derivative **11** by reaction with isobutene/H_2SO_4 in CH_2Cl_2 (74%, m.p. 50.0–51.7°C ($CHCl_3$/pentane), $[\alpha]_D^{25} = +10.0°$, $c = 0.2$ in $CHCl_3$). Simultaneous removal of the Z and benzyl ester moieties from **11** by catalytic hydrogenation over 10% Pd/C in MeOH provided the desired compound **12** as hemihydrate in 84% yield (m.p. 230°C (decomposition) (MeOH/Et_2O), $[\alpha]_D^{25} = +2.7$, $c = 0.4$ in MeOH, $[\alpha]_D^{25} = +1.7$, $c = 0.41$ in H_2O).

[12] According to our experience peptide chain elongation with α,α-dialkyl amino acids on a polymeric support should be performed by coupling protected dipeptides containing the α,α-dialkyl amino acids as the *C*-terminal residue rather than the N_α-protected α,α-dialkyl amino acid itself. This excludes any difficulties connected with couplings to the hindered *N*-terminus of this type of amino acid [13]. However, attempts to synthesize Fmoc-Ala-(*S*)-α-MeSer(O*t*Bu)-OH by *tert*-butylation of **5**, saponification of the methyl ester, removal of the Z-group by hydrogenation and reprotection with the Fmoc-group gave an overall yield of only 13% (referred to **5**), mainly due to a yield of only 20% in the *tert*-butylation step. Furthermore this strategy would require a new multistep synthesis for each individual dipeptide Fmoc-Xxx-α-MeSer-OH.

Oxidative Coupling of Racemic and of Optically Active 3,6-Di-*tert*-butylocta-1,4,7-triyne-3,6-diol

By *Fumio Toda,* Jyōji Okada,* and *Koji Mori**

The differences in behavior of racemic and optically active monomers in oligomerization and polymerization have been the subject of very few reports. One of the few exceptions has reported that the ring-size of macrolides formed by oligomerization after cationic ring-opening of 6,8-dioxabicycli[3.2.1]octan-7-one depends on whether the monomer is racemic or optically active.[1] We have now found very drastic differences in the reaction behavior of racemic and optically active 3,6-di-*tert*-butylocta-1,4,7-triyne-3,6-diol **1** upon oxidative coupling.

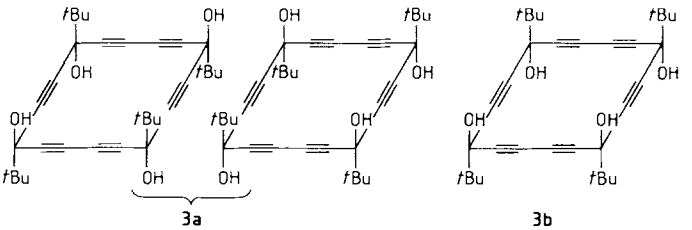
1 **2**

Scheme 1. **a**, racemic; **b**, (−)-form; **c**, (+)-form.

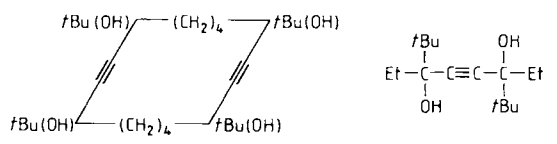
Racemic **1** (= **1a**) was prepared by reaction of methyl pivalate and sodium acetylide in liquid NH_3 using a method which did not furnish any *meso*-isomer.[2] Optical resolution of **1a** was carried out by a complexation method with brucine:[3,4] When a solution of **1a** (7.8 g, 32 mmol) and brucine (12.5 g, 32 mmol) in acetone (190 mL) was kept at room temperature for 12 h, a 1:1 complex of (−)-**1** (= **1b**) and brucine was formed as colorless needles (15.1 g, m.p. 183–184 °C). Decomposition of the complex with dilute HCl afforded **1b** with 94% *ee*, which on recrystallization from ether/petroleum ether furnished **1b** with 100% *ee* [1.8 g, 46%, m.p. 112–113 °C, $[\alpha]_D$ −16.0 (c = 0.3, THF)]. The optical purity of **1b** was determined by measuring the ^{1}H-NMR spectrum of its diacetate (**2b**) (Scheme 1) [m.p. 105–107 °C, $[\alpha]_D$ −7.2 (c = 0.5, THF)] in $CDCl_3$ using $Eu(hfc)_3$ as chiral shift reagent.

Oxidative coupling of **1** was carried out according to the method of *Eglinton* et al.:[5] A solution of **1a** (1 g, 4.1 mmol) and $Cu(OAc)_2 \cdot H_2O$ (12.2 g, 61 mmol) in pyridine (170 mL) was stirred at 55 °C for 4 h and at room temperature for 12 h. The reaction mixture was worked up in the usual way[5] to give a mixture of crude products, which upon treatment with acetone furnished a 1:4 complex of optically inactive cyclic dimer **3** and acetone as colorless prisms (0.31 g, 21%, m.p. > 300 °C), and upon subsequent heating in vacuo gave **3**. The cyclic structure of **3** followed



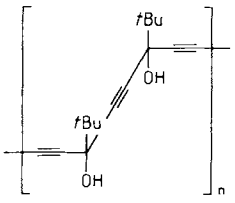
3a **3b**

from its IR spectrum, which does not show any C≡C–H stretching vibrations. The dimeric nature of **3** was ascertained indirectly from a mass spectrum of its hexadecahydrogenation product **4** (**3** is thermally too labile to measure the spectrum). On Pd/C, only the diyne units of **3** are hydrogenated—probably due to steric factors; under the same conditions **1** is hydrogenated to **5**. **3** not only forms 1:4 inclusion complexes with acetone but also with ethanol, 2-propanol, 1-butanol, dimethylformamide, and pyridine. After separation of **3** from the product mixture there remained an oily residue.



4 **5**

At present, there is no direct evidence of whether **3** is present as racemate (**3a**) or as *meso*-isomer (**3b**). Support for the *meso*-isomer is provided by the fact that optically active **1** does not give any cyclic dimer; the selective formation of **3b** shows that **1b** "recognizes" the enantiomer **1c** precisely, but does not couple with another molecule of **1b**. In contrast, the sole isolable product of the oxidative coupling of **1b** is the optically active polymer **6** [white



6

powder, yield 75%, m.p. >300°C, $[\alpha]_D$ −191 (c=0.2, THF)]; this polymer (M_n=16700, M_w=35300, M_z=62400, M_w/M_n=2.12, M_z/M_n=3.74) consists of about a hundred monomer units. It is not completely clear whether the high $[\alpha]_D$ value of **6** can be attributed to its asymmetric carbons or its helical structure; high $[\alpha]_D$ values of optically active polymers such as induced asymmetric polymethacrylate have been attributed to helicity.[6,7]

That polymers with a regular structure (e.g. helix) are formed only from an optically active monomer, but not from a racemic one is interesting with respect to the formation of helical polypeptides from optically active amino acids.

BOOK REVIEWS

Electrochemistry: Theoretical Foundations, Quantum and Statistical Mechanics, Thermodynamics, the Solid State. By *J. Goodisman*. Wiley, Chichester 1987. ix, 374 pp., bound, £ 50.45.—ISBN 0-471-82850-5

Electrochemistry is predominantly an experimental science; there are only few professional theoreticians in this field, and even fewer books on theoretical electrochemistry. So the appearance of this work—written, significantly, by a quantum chemist—is highly welcome. *J. Goodisman*, well known as the author of a successful introduction to contemporary quantum chemistry, presents his view of the foundations of theoretical electrochemistry in ten chapters, which contain: a general introduction to electrochemistry, the thermodynamics of surfaces, and statistical mechanics (Chapters 1-3); a more detailed discussion of surfaces and interfaces (Chapters 4-6); electrode kinetics from both a classical and a quantum mechanical point of view (Chapters 8-10).

Chapter 7 on diffusion does not really fit into the otherwise well organized presentation. Each chapter is subdivided into smaller, often self-contained units, so that the material may be digested a bit at a time.

While a wide range of topics is covered, certain of these might well have been left to specialist works: the introduction to statistical mechanics, and the derivation of the Gamow tunnelling formula, for example. In many cases the presentation of the material is so condensed that an electrochemist with an average theoretical background will have difficulty in following it. Also, for some of the theoretical results presented, no examples of applications are given. In a revised edition, it would be advisable to shorten the general theoretical material, and devote more space to specific electrochemical problems; this would also give the opportunity to fill in certain gaps: proton transfer reactions, and the foundations of modern spectroscopic methods, for example, are not covered.

Only a few diagrams illustrate the text, and these are badly chosen. Most figures are schematic; only two experimental curves are shown, both for double layer properties. By the end of the second chapter, if not sooner, the reader will notice with regret the absence of a glossary of symbols, a surprising omission in a work of which some 40% consists of formulas. That we find the term "electromotive force" outmoded may be attributed to our personal prejudices, but the sign conventions employed defy both electrochemical tradition and common sense: cathodic currents are taken as positive, but cathodic overpotentials as negative.

In summary: a book on a subject of eminent importance, well conceived, with many good ideas, and a number of weaknesses, which should be remedied in a second, revised edition. In its present form most experimental electrochemists will understand large parts of it only after further consultation of the literature.

Solid-State Chemistry: Techniques. Edited by *A. K. Cheetham* and *P. Day*. Clarendon Press, Oxford 1987. xiv, 393 pp., bound, £ 35.00.—ISBN 0-19-855165-7

The first volume ("Techniques") of a two-volume account of solid state chemistry has now appeared (the second volume is to be subtitled "Compounds"). The work, which is edited by two Oxford experts, is intended to fill a gap. According to the editors it is aimed at final-year undergraduates and first-year post-graduates who are studying solid state chemistry for the first time. Considering this in relation to the requirement for a basic training in solid state chemistry in the German Federal Republic situation, the work is suitable for use by advanced students about to take their final examinations, and by diploma students who wish to prepare themselves for their chosen special area of study. In addition it would be a valuable resource for preparing lectures, and it is also suitable for use by chemists whose specialization is outside the solid state area and who seek information and an extension of their knowledge. In brief: it should be in every library.

This first volume provides a survey of the experimental methods of solid state chemistry. It begins with a chapter on "Synthesis of Solid State Materials" (author: *J. D. Corbett*), which occupies 38 of the 393 pages (a mere 10%!). This is excellent, and shows that, 15 years after *H. Schäfer*'s plea in this journal for more attention to be given to the preparative aspects of solid state chemistry,[*] the learning process then begun is now also bearing fruit in book form. It is clear from this chapter that solid state chemists involved in preparative work (a description which is almost a pleonasm!) are much better than is suggested by their reputation as bakers using powder mixtures.

This is followed by the (one might almost say, unavoidable) chapters on *physical* techniques which the solid state chemist must use to characterize his materials: Diffraction methods *(A. K. Cheetham)*, X-ray photoelectron spectroscopy and related methods *(G. K. Wertheim)*, Magnetic measurements *(W. E. Hatfield)*, Optical techniques *(R. G. Denning)*, High-resolution solid-state MAS NMR investigations of inorganic systems *(C. A. Fyfe* and *R. E. Wasylishen)*, Computational techniques and simulation of crystal structures *(C. R. A. Catlow)*, Transport measurements *(A. Hamnett)* and Vibrational spectroscopy *(D. M. Adams)*. The book concludes with a chapter by *A. Navrotsky* on "Thermodynamic aspects of inorganic solid-state chemistry."

The index, consisting of only four pages, is rather scanty, but since the book is by no means intended to be an encyclopedia but rather is a textbook, this shortcoming can be excused. The fact that all the authors are from the English-speaking world has no doubt made the editorial work easier, but this should not be taken as an indication that solid state chemistry work going on elsewhere is not of the highest standard.

To summarize, this is an indispensable book. This reviewer looks forward with keen anticipation to reading the second volume, which will be of greater interest to him in view of the declared intention to cover "Compounds".

Institut für Anorganische und Analytische Chemie
der Universität Giessen (FRG)

[*] *H. Schäfer:* Zur Situation der präparativen Feststoffchemie—The Present Situation in Preparative Solid-State Chemistry (*Angew. Chem. 83* (1971) 35; *Angew. Chem. Int. Ed. Engl. 10* (1971) 43).

Radiation Chemistry. Principles and Applications. Edited by *Farhataziz* and *M. A. J. Rodgers*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1987. 641 pp., bound, DM 208.00.—ISBN 3-527-26197-4/0-89573-127-4

Radiation chemistry is concerned with chemical reactions which are triggered by ionizing radiations. Its importance extends very much further than is often supposed. For example, ionizing radiation makes it possible for the chemist to create free radicals independently of the temperature, color and state of aggregation of the medium, which is not usually possible with other methods, and pulsed radiolysis allows one to investigate the kinetics of free-radical reactions (and also of some non-radical reactions) in a way which is almost unique. Radiation chemistry also provides the basis for a better understanding of the primary chemical processes involved in radiation biology and radiation medicine (the killing of cells by radiation, radiation-induced mutagenesis, tumor therapy etc.). Radiation-chemical techniques have now also become well established in industry.

Various monographs on radiation chemistry have appeared over the years. That most familiar to German readers is the excellent book by *Henglein, Wendenburg,* and *Schnabel* (Einführung in die Strahlenchemie, Verlag Chemie, Weinheim 1967), which is not outdated in its essentials even today. The book reviewed here differs from most of its predecessors in what it sets out to do. It is not so much a textbook as a collection of review articles. It contains contributions from more than twenty authors, although, surprisingly, neither of the two editors has written an article themselves. The fact that it is a multi-author work gives it both its strengths and its weaknesses. The editors have tried to indicate the broadness of the range of areas where radiation chemistry makes an important contribution. Since the number of such areas is too great to be adequately covered, even in more than 600 pages, the editors have had to be highly selective in what has been included. In accordance with their own bias of interest, they have mainly included authors who are active in work on primary radiation-chemical processes. For example, there are detailed discussions of energy absorption and theoretical aspects of radiation chemistry *(A. Chatterjee, J. L. Magee,* and *N. V. Klassen)*, the properties of the electron *(R. A. Holroyd* and *N. R. Kestner)*, reaction kinetics *(A. Hummel)*, and evidence for short-lived transient species, in which the various different pulse radiolysis techniques *(L. K. Patterson)* will be of great interest to many readers. Other topics covered are the special features of the radiation chemistry of gases *(D. A. Armstrong)*, aqueous solutions *(G. V. Buxton)*, organic liquids *(A. J. Swallow)* and solids *(J. E. Willard)*, colloidal aggregates *(J. K. Thomas)*, alkali halides *(V. J. Robinson* and *M. R. Chandratillake)*, and polymers *(A. Charlesby)*.

These chapters, which are mainly oriented towards physical chemistry and theory, make up almost 80% of the book. In contrast the chapter on biopolymers *(L. M. Mee)* is short and consequently unsatisfying, dealing in 22 pages with the radiation chemistry of nucleic acids, chromatin, proteins, lipids and polysaccharides. The excellent chapter by *P. Wardman* on some applications of radiation chemistry in biochemistry and radiation biology gives some indication of the great potential of radiation chemistry beyond its usual domain. It would have been desirable to give non-radiation chemists a wider picture of the many possibilities offered by radiation chemistry techniques for elucidating

free radical, and also non-radical, reactions in organic and inorganic chemistry. Instead of this the editors have included two chapters on the radiation biology of microorganisms *(D. Ewing)* and of mammalian cells *(J. E. Biaglow)*, both of which are very specialized and fail to give any more detailed information about, for example, radiation risks and radiation-induced mutagenesis. The book ends with a chapter by *M. Takehisa* and *S. Machi* on the engineering applications of radiation chemistry (with emphasis on the situation in Japan).

The book will be of interest to readers oriented towards physical chemistry. Because of the articles of a fundamental nature which it contains, it should be included in the library of every academic chemistry department or research institute.

Clemens von Sonntag [NB 867 IE]
Max-Planck-Institut für Strahlenchemie,
Mülheim/Ruhr (FRG)

Ab-initio Molecular Orbital Theory. By *W. J. Hehre, L. Radom, P. von R. Schleyer,* and *J. A. Pople.* Wiley, Chichester 1986. xviii, 548 pp., bound, £ 81.80.—ISBN 0-471-81241-2

After a very brief introduction to the quantum-mechanical basis of ab-initio MO theory, the program packages available under the name "GAUSSIAN-*n*" (where *n* is one of the years 70, 76, 80, 82, or 85) are described. Several of the authors played a considerable part in the development of these programs, which are introduced in a rather pragmatic manner. Most of the book is devoted to applications of the GAUSSIAN-*n* programs, though calculations using other systems are also considered, especially when no GAUSSIAN-*n* calculations are available for the purpose in hand.

This compilation of numerical results is extremely valuable. It spares the reader a tiresome search through the original literature, and since all the calculations carried out with the GAUSSIAN program satisfy certain standardizing criteria, results from various groups can be compared. The wealth of material itself makes the book exceedingly useful. The things that can be done today with ab-initio MO calculations are most impressive—from determination of equilibrium molecular structures, calculation of vibrational spectra, rotation and inversion barriers, bond and reaction energies and intermolecular interactions, to the elucidation of reaction mechanisms. The results concerning carbocations and carbodications deserve special mention, as do those on lithium-carbon compounds. Reading this book should convince any organic chemist that the study of his subject is no longer conceivable without ab-initio MO theory. For anyone who is interested in this type of calculation, an indispensable reference work is now available, including also a good introduction to the use of the GAUSSIAN programs. The book is not, and does not claim to be, an account of the current state of ab-initio quantum-chemical methodology (in this sense the title of the book is misleading). Although it is oriented too much towards GAUSSIAN-*n*, and does not explore fundamental questions sufficiently (for example electron-correlation, and non-adiabatic or relativistic effects), the majority of readers will hardly see this as a disadvantage.

Fakultät für Chemie
der Universität Bochum (FRG)

Dynamics of Proteins and Nucleic Acids. By *J. A. McCammon* and *S. C. Harvey.* Cambridge University Press, Cambridge 1987. 234 pp., hard cover, £ 25.00.—ISBN 0-521-30750-3

The aim of this book is to provide the reader with a self-contained introduction to the theoretical aspects of proteins and nucleic acid dynamics. It is intended for graduate students as well as for research workers in the fields of physical biochemistry and molecular biotechnology. The principal goal of the authors is threefold: (1) to outline theoretical methods and their capabilities, (2) to provide an insight into the nature and biological significance of biomolecular dynamics, mainly by summarizing of and reference to theoretical studies, and (3) to indicate prospects and directions of future work in this area.

The books definitely meets these goals. It is organized as follows: The first three chapters (34 pages) contain a brief introduction to the function, structure and dynamics of proteins and nucleic acids. Chapter 4 (44 pages) discusses the theoretical methods that have been used to describe and model the dynamics of these molecules. On this basis the next four chapters (88 pages) deal with dynamical behavior by reviewing the literature of the last decade. Ordered according to the time scale and spatial scale of the different types of motions, the following are discussed: short time dynamics, local structural transitions, global structural changes, and the dynamics of molecular association. The last chapter (16 pages) stands a bit apart from the rest of the book. It mentions a number of new developments in the field of computer simulation of biomolecules. The book is completed by three appendices (21 pages) discussing some technical details of computer simulation, a list of references, and a subject index.

The authors have done a good job. They have reached the goals they set out. Starting from basic data the book summarizes the literature on theoretical studies of protein and nucleic acid dynamics. The referencing is done very carefully, many numerical examples are given and also the influence of solvent surroundings on the structure and dynamics of biomolecules is not neglected. It may be best characterized as an overview of the theoretical work in the field of biomolecular dynamics up till 1986. Perhaps due to its descriptive style the book is not very critical of the various studies, and space spent on the description of applications is not allotted according to the scientific value of the methods used, but more according to the number of published applications. An example is the relatively exhaustive attention given to normal mode calculations of proteins, which are—as the authors admit (p. 91)—of rather limited value because of the very anharmonic character of protein motion. The most promising practical applications of simulation techniques are only mentioned in the last chapter; the use of molecular dynamics simulation in the refinement of the spatial structures of proteins based on nuclear magnetic resonance atom-atom distance data or on crystallographic X-ray intensities; the thermodynamic cycle integration technique to obtain relative binding constants is briefly but not critically discussed.

The book does not provide sufficient information for the chemist who wishes to use theoretical methods in the study of biomolecular structure and dynamics. It lacks a critical evaluation of the various force fields in use for biomolecules. When discussing the limitations of simulation methods (p. 66) the yet insufficient accuracy of force fields is not even mentioned, whereas a critical discussion of factors contributing to accuracy is essential for a proper as-

sessment of the value of simulation techniques to a specific application. From a critical and detailed comparison with experimental data one would obtain an impression of the predictive power of the methods that are used.

Although chapter 4 and the three appendices contain some more detailed technical information on simulation methods, the level of detail is not sufficient to guide newcomers in the field. Metric tensor corrections which arise from transformations from cartesian to internal coordinates, are not mentioned. The Beeman algorithm for integrating equations of motion is said to be more efficient than the Verlet one (p. 175), whereas it has been proven in the literature that both algorithms generate *exactly* identical atomic trajectories.

However, to be fair to the authors, they did not intend to write a users guide to simulation techniques, nor a critical assessment of the various techniques and applications. They have written a book that nicely summarizes the various studies of the past. It definitely is an enrichment for a library, since new developments in certain areas tend to be rather scattered over a variety of journals. I would strongly recommend this book to any non-specialist who wishes to know more about the application of theoretical methods to the description of the dynamics of proteins and nucleic acids.

A Pictorial Approach to Molecular Bonding. By *J. G. Verkade*. Springer, Berlin 1986. xiii, 282 pp., bound, DM 125.00.—ISBN 3-540-96271-9

We have here an old set of lecture notes from the early seventies, which has just come into print and is available at the price given above. It is well known, however, that not all wines improve with the years. The pictorial treatment of chemical bonding which is given here is not only free from all considerations of energy, but also completely ignores the different sizes of atoms and atomic orbitals.

Starting from these assumptions, there has been no problem in arranging the contents of the book in a clear and orderly way. The part which deals with general principles is short, and is concerned with hydrogen orbitals and with the formal representation of the idea of hybridization. Since the author, as has already been made clear above, regards only the directional properties of the hydrogen orbitals as important, all radial-dependent factors are neglected from the start. It is true that there are some belated short comments regarding the sizes and energies of the hydrogen orbitals, but no use is made of these subsequently when discussing chemical bonding. Before one has learned anything at all about atoms other than hydrogen, the discussion of chemical bonding begins. This is systematically illustrated using familiar examples. It starts off with diatomic molecules, followed by triatomic molecules. The molecules are classified according to their geometrical shapes. Thus, the chapters which follow deal in turn with tetrahedral molecules, ring molecules, octahedral molecules, bipyramidal molecules and prismatic molecules. The aim in each case is to give the topological shape of the molecular orbitals and qualitative MO correlation diagrams. Those who wish to follow the author in this must familiarize themselves with unusual methods of depicting orbitals and with new abbreviations. Atomic orbitals are represented not by contour lines but by arrows, with the phase having positive sign at the tip of the arrow and negative sign at the tail. Accordingly also molecular orbitals are represented not as LCAOs but as LCVOs (linear combination of vector orbitals). All molecular orbitals are made up of GOs (generator orbitals), which are fictional atomic orbitals in the centers of the molecules. The VOs on central atoms are SOs (symmetry orbitals).

A further aspect of the viewpoint adopted deserves special mention. Wherever possible, in addition to the canonical, delocalized molecular orbitals, localized orbitals are also given. These too are made up from a special set of GOs. This idea is useful and successful, provided that the molecules have sufficient symmetry.

The slightly dated origins of the book, mentioned at the start, occasionally show up rather drastically, as when cyclobutadiene is mentioned as having been discovered only recently and having a triplet ground state, or when prismane is described as a still unknown molecule. A set of exercises is given at the end of each chapter. Some readers may pick up useful ideas from this book regarding the construction of molecular orbitals.

Spectroscopy with Polarized Light. Solute Alignment by Photoselection, in Liquid Crystals, Polymers, and Membranes. By *J. Michl* and *E. W. Thulstrup*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1986. xvi, 573 pp., bound, DM 265.00.—ISBN 3-527-26516-3/0-89573-346-3

In recent years sophisticated NMR techniques have sometimes led to the impression that other spectroscopic methods of structure determination are obsolete. The book reviewed here, dealing in great detail mainly with the UV and IR spectroscopy of (partially) oriented molecular ensembles, demonstrates that such a view is far from correct.

The book begins with a concise and mathematically rigorous account of the theoretical basis of optical spectroscopy (the nature of light, stationary and time-dependent wave functions, the interaction between light and molecules, and the effects of externally applied fields on absorption). Formulas are derived for the circular dichroism (CD) of (partially) oriented molecules in field-free space and in magnetic or electric fields, including a detailed description of the rotatory strength tensor. The reasons for the appearance of fine structure in CD spectra, and the associated difficulties in determining the rotatory strength, are also thoroughly discussed.

The second chapter is devoted to a detailed treatment of transition moments, dealing with electric dipole and quadrupole transitions and magnetic dipole transitions, and to the description of (symmetry and multiplicity) allowed and forbidden transitions in both absorption and emission. The theoretical concepts are put to the test using partially oriented pyrene as a practical example; the conclusions which can be derived from spectra of this kind are worked through in detail, and reference is made to situations where approximations break down.

A separate chapter is devoted to the practical aspects of recording spectra, especially the stretching of films which are used as sample supporting media. Since it is not possi-

ble by this means to obtain perfect orientation as, for example, in single crystals, it is still essential to average over many orientations. The quantitative description of the degree of this averaging is covered in the next chapter, which also discusses alternative orientation techniques. For this description one uses an "orientation triangle", in which molecules of different shapes (cylindrical shapes, flat disks, rectangular prisms of small height, etc.) are characterized according to different positions.

The fifth chapter discusses absorption and emission processes which arise solely as a result of changes in the electric transition moment. These are described by tensors of rank 2, but in general there are not enough equations available to determine the independent tensor components. They can be determined only in three special cases, namely for disk-shaped or rod-shaped molecules, or for those in which the component of the electric transition moment in one particular direction is practically zero, as is the case in most aromatic molecules for example. However, the molecules must have either at least two C_2 axes or two mutually perpendicular planes of symmetry. This TEM model (an acronym for *Thulstrup/Eggers/Michl*, a fact not mentioned anywhere in this book by the authors *Michl* and *Thulstrup*!), which is limited to uniaxial molecules, is compared with the other three frequently used approximations of *Fraser* and *Beer*, of *Tanizaki*, and of *Popov*, and it is shown that these latter three may all give incorrect results in cases whose occurrence is not always predictable.

The next (very brief) chapter deals with phenomena which can be analyzed by reducing to tensors of rank 2, such as magnetic dipole allowed transitions and the circular dichroism (of optically active compounds, or induced by a magnetic field). The last of the theoretical chapters is devoted to processes which can only be described by tensors of rank 4, such as electric quadrupole absorption and emission, and two-photon processes, e.g. photoluminescence and photodichroism. Here one can only obtain unambiguous information in cases of high molecular symmetry; for less symmetrical molecules the discussion is limited to spectra in which the individual bands do not overlap.

The final, very long, chapter gives many examples which illustrate the application of the methods described. Whilst most of the examples are of aromatic and heteroaromatic systems, some inorganic complexes, free radicals and biopolymers are also included. The use of such measurements to determine molecular conformations is exemplified by results on some steroids, aniline derivatives, peptides and DNA, and reference is also made to a few molecular complexes of biochemical importance. Finally there is a short account of the possibility of storing information in permanent or erasable form using birefringent polymers.

The book is completed by three appendices which give a very compact summary of the fundamentals of group theory and its applications to spectroscopy, Cartesian tensors, and the Mueller-Stokes formalism for describing the interaction between polarized light and anisotropic materials.

This is the first complete monograph on the subject to be published. It is very clearly presented in a good style of language, despite the difficulties of the mathematical formalism which will often be unfamiliar to the experimentalist. Also all the important formulas are thoroughly explained, allowing one to use them correctly even when one has had to gloss over their derivation. Constant warnings are given against over-interpretation of data, and the limitations of the methods are frequently pointed out; these aspects are often overlooked by epigones. The authors have also taken great care to give the units for all important quantities. The coverage of published work extends to quite recent papers. Occasionally when quoting from work by other authors their less exact language is also carried over. The reviewer noticed only a few printing errors (to substantiate this two are noted here: in Equation 1.43 the symbol $\hat{p}$ is missing, and in Equation 5.5, which can be deciphered only with difficulty owing to its very small print, h appears instead of $\hbar$). On page 213 the definition of pseudorotation is different from that generally accepted in stereochemistry, and in redrawing Fig. 8.37 some methyl groups have been overlooked.

This monograph can be warmly recommended to anyone who wishes to gain a greater knowledge of one or more of the topics mentioned. The authors have applied a considerable amount of self-criticism in writing the book. Its very high price will regrettably discourage the wide readership which it deserves.

"Proton Sponges" and the Geometry of Hydrogen Bonds: Aromatic Nitrogen Bases with Exceptional Basicities**

By Heinz A. Staab* and Thomas Saupe

Certain aromatic diamines (the "proton sponges") are found to have exceptionally high basicity constants: this is due to spatial interaction of the basic centers, which are in close proximity. The two factors which are most important in causing this effect are, on the one hand, the extreme steric strain in these systems and the destabilizing effect of the overlap of the nitrogen lone pairs of the neutral diamines and, on the other, the strong N···H···N hydrogen bonds which are formed on *mono*protonation and which lead to a considerable relaxation of the steric strain. By the systematic variation of the structures of such aromatic diamines we have been able to study these effects as a function of steric factors, in particular of the geometry and the bond length of the N···H···N hydrogen bonds, by means of X-ray structural analysis. The hydrophobic shielding of the basic centers and the N···H···N hydrogen bonds, which was characteristic of the "proton sponge" compounds studied previously, is indeed responsible for the extremely low rate of protonation and deprotonation of these compounds; however, it apparently has no influence on their high thermodynamic basicity. The recent synthesis and basicity determination of a new type of "proton sponge" with no hydrophobic shielding whatever show that not only very strong but also kinetically active bases are accessible using the "proton sponge" concept. Their unusual properties, which are discussed here as the result of steric interactions between two basic centers, provide examples of the fact that cooperative steric interactions of reactive structural elements can lead to properties which cannot be derived from an isolated consideration of the various functional groups. Such "proximity effects" are certainly of general importance in chemistry and biochemistry; the study of their structure-function relationships is worthy of closer consideration.

1. Introduction

Acidity and basicity are two of the properties of chemical compounds which have been a source of particular interest since chemistry became a real science. The amount of quantitative information on the dissociation constants of organic acids and bases which has been available for many years has in the last decades played a deciding role in the theoretical understanding of bonding in organic compounds. Our knowledge of the dependence of acidity and basicity on structural and electronic factors such as inductive and mesomeric effects thus appeared to rest on such a secure basis[2] that surprising new results could hardly be expected in this area. The report by *Alder* et al.[3] in 1968 on the unusually high basicity of a relatively simple organic compound was therefore the subject of con-

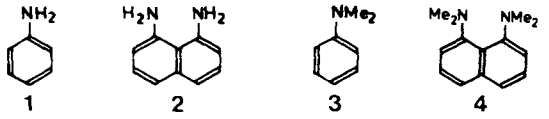
siderable attention: whereas aniline **1** and 1,8-diaminonaphthalene **2** have similar basicities typical of aromatic amines ($pK_a \approx 4.6$), 1,8-bis(dimethylamino)naphthalene **4** ($pK_a = 12.1$[4]) has a basicity ten million times higher than that of *N,N*-dimethylaniline **3** ($pK_a \approx 5.1$).



1 **2** **3** **4**

Detailed investigations were carried out in the following years in order to determine the reasons for the high basicity of **4**, particularly by the groups of *Alder*[5-7] and *Hibbert*.[4,5] However, they remained essentially limited to compounds which, like **4**, belong to the class of the *peri*-disubstituted naphthalenes. During the past five years we ourselves have synthesized "proton sponges" with other, more varied basic aromatic structures and carried out basicity and structure determinations for these compounds; we have been able to show that unusually high basicities are also observed for other aromatic diamines with closely neighboring nitrogen atoms. In this way we were able to study this effect on a wider basis as a function of the distance between and the spatial orientation of the basic centers.

Our interest in the title compounds started from the assumption that the high basicity of **4** and its analogues is determined mainly by the formation of a particularly stable N···H···N hydrogen bond in the *mono*protonated bases (see Section 2). The great general importance of hydrogen bonds in chemistry and biochemistry is clearly recognized today; for example, it is well known that hydrogen bonds determine the secondary structures of proteins and are responsible for the base pairing in nucleic acids. It is hence even more surprising that the experimentally available information on the dependence of the bond strength of hydrogen bonds on geometric factors is still so sparse. The questions as to how the bond energy of a hydrogen bond X–H···Y depends on the distance X···Y and whether a linear X–H···Y geometry and an orientation in the direction of the lone pair of the hydrogen bond acceptor Y are energetically particularly favorable have often been discussed in the literature;[8] however, completely convincing experimental answers to these questions could not be given until now.[9] This is due to the fact that in such investigations the crystal structures of compounds with *inter*molecular hydrogen bonds have been used: however, these do not of necessity correspond to optimal hydrogen bond geometries but represent a compromise between the sum of all the lattice forces. In contrast, the *mono*protonated forms of the "proton sponges" have *intra*molecular hydrogen bonds which in turn influence a molecular property which can be measured independently, i.e. the basicity. By systematically varying the geometrical arrangement of the two basic centers it should therefore be possible in principle to obtain information on the dependence of the strength of the hydrogen bonds on geometric factors via the basicity constants. This corresponds to the concept of the simulation of *inter*molecular interactions by structurally clearly defined *intra*molecular bonding systems, a concept which we have used, for example, to determine the structure dependence of charge transfer and excimer interactions.[10,11]

The present review will first deal with the situation of research on "proton sponges" at the beginning of the 1980's. It will continue with an account dealing mainly with our own contributions to this area during the last five years; these are by no means completed, so that quite a number of questions, particularly with respect to the goals formulated above, still remain unanswered.

2. "Proton Sponge" Compounds with Naphthalene Structure

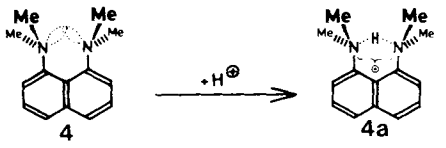
Table 1 shows the pK_a values for some substituted 1,8-diaminonaphthalenes. While increasing *N*-methylation of **3** results in the case of the bis(methylamino) compound **5** and even in the *N,N,N'*-trimethyl derivative **6** in only a small increase in basicity (this being mainly the result of inductive effects), the introduction of the fourth *N*-methyl group to give **4** causes a sudden increase in basicity by nearly six powers of ten.

Table 1. Basicities of some substituted 1,8-diaminonaphthalenes [5]. For further basicity values see Table 3 in Section 6.

	R^1	R^2	R^3	pK_a	Ref.
2	NH_2	NH_2	H	4.61	[3]
5	NHMe	NHMe	H	5.61	[3]
6	NMe_2	NHMe	H	6.43	[3]
4	NMe_2	NMe_2	H	12.1	[3, 4]
7	NEt_2	NEt_2	H	12.7	[3, 4]
8	NMe_2	NMe_2	OMe	16.1	[5]
9	NEt_2	NEt_2	OMe	16.3	[5]

The way in which the basicity increases with increasing *N*-methylation of **2** suggests that steric effects play a very important role. This assumption is supported by the observation that the replacement of dimethylamino by diethylamino groups (compound **7**) leads to a further increase in basicity. Introduction of methoxy groups in positions 2 and 7 is particularly effective in increasing the basicity (compounds **8** and **9** in Table 1): these groups are suggested to exert "buttressing" steric effects.[5,6]

The increase in basicity on increasing the steric hindrance around the two amino groups in the *peri*-positions is considered to be due to two factors which work in the same direction: firstly the dialkylamino groups are increasingly forced into an arrangement in which the repulsion between the nitrogen lone pairs has a destabilizing effect on the free bases, and secondly protonation yields a monocation in which a particularly stable intramolecular hydrogen bond is formed because of the structurally fixed short N···N distance. The latter removes the destabilizing "lone pair" interaction and thus causes a considerable decrease in the steric strain.



The stability of the monocation (e.g. **4a**) is responsible for the fact that "proton sponges" such as **4** undergo only *mono*protonation even in the presence of an excess of such strong acids as perchloric and tetrafluoroboric acid; under such conditions **2** is doubly protonated. The basicity difference between the first and second protonation steps has been estimated to be at least 20 pK_a units for "proton sponges" of type **4**,[7] although for diamino compounds this difference normally lies between 1 and 5 pK_a units, depending on their structure.

The high basicity of the "proton sponges" is accompanied by an extremely low rate of proton transfer, the latter decreasing in the series **4** > **7** > **8** > **9** as the basicity increases. While the deprotonation of ammonium ions by hydroxide ion is generally diffusion-controlled ($k \approx 10^{10}$ L mol^{-1} s^{-1}),[12] the rate constants for the proton transfer reaction are several orders of ten lower for "proton sponges". Table 2 shows this for the deprotonation of **4a** and some analogues by the hydroxide ion.

Table 2. Rate constants for the reaction of protonated "proton sponges" with the hydroxide ion (DMSO = dimethyl sulfoxide) [13].

	R	X	Solvent [v/v]	k [L·mol^{-1}·s^{-1}]
4a	Me	H	water	$1.9 \pm 0.4 \times 10^5$
			30% DMSO/water	$6.1 \pm 0.5 \times 10^5$
7a	Et	H	30% DMSO/water	$1.6 \pm 0.2 \times 10^4$
8a	Me	OMe	60% DMSO/water	$4.4 \pm 0.5 \times 10^2$
9a	Et	OMe	60% DMSO/water	3.3 ± 0.4

The main reasons for the low rates of proton transfer are the stable intramolecular hydrogen bonds and their shielding by hydrophobic groups. This would apply for both a one-step deprotonation mechanism via direct attack by the base at the bridge proton and a two-step process in which the hydrogen bond is first broken and the "open form" subsequently deprotonated. It is difficult to decide unambiguously which of these mechanisms is correct, though various observations point to the latter two-step mechanism.[13, 14]

The high thermodynamic basicity of the 1,8-bis(dialkylamino)naphthalenes combined with their kinetic inactivity has led to the name "proton sponges", as their behavior has been compared with that of a sponge with regard to water: "Sponges are not kinetically active in seeking water, they merely mop it up when it is presented to them".[6] The kinetic inactivity of the "proton sponges" described above has the consequence that in spite of their high basicity and their extremely low nucleophilicity these compounds have so far found hardly any use as auxiliary bases in organic syntheses.[15]

Because of the paramount importance of steric effects in determining the properties of the "proton sponges", exact information on the molecular structures of both the free base and the *mono*protonated salts is of particular interest. In the series of 1,8-bis(dialkylamino)naphthalenes, X-ray structural determinations have been made for **4** and **4a**. The structure of **4**[16] makes it clear that the steric strain induced by the two dimethylamino groups in *peri*-position leads to a clear deviation of the naphthalene skeleton from planarity. The central C4a–C8a bond is twisted so that the dimethylamino groups are on different sides of the naphthalene plane: their nitrogen atoms then lie 40 pm above and below this plane. The angle C1–C8a–C8 is widened to 125.8°, so that the C1···C8 distance is increased to 256 pm (naphthalene: 245 pm): this results in a further increase of the distance between the dimethylamino groups, the N···N distance of 279 pm being much larger than the fictitious distance of 245 pm which would result for a planar naphthalene system with parallel C_{aryl}–N bonds. Via rotation about the C_{aryl}–N bonds the dimethylamino groups assume a conformation such that one methyl group of each lies almost in the plane of the ring and the lone pairs on nitrogen avoid the destabilizing overlap as far as possible.

The relief of the steric strain which occurs on protonation of **4** is immediately evident from the structure of the *mono*protonated cation **4a**. Although the results of structure determinations for **4a** (one for copper(II) and magnesium tris(hexafluoroacetylacetonates),[17] the other for a bromide dihydrate[18]) conflict to some extent, the two structures do agree in one respect: the deviation of the naphthalene system from planarity is much less in **4a** than in **4**. The N···N distance in **4a** (260 and 265 pm[17] or 255.4 pm[18]) is correspondingly considerably shorter than in **4**. Because of the formation of a stable intramolecular hydrogen bond and the resulting elimination of the lone pair repulsion the dimethylamino groups are twisted towards one another about the C_{aryl}–N bond. However, the hydrogen bonds cannot lie in a straight line because of the spatial arrangement of the molecule: the N···H···N angles are 141°[17] and 153°.[18] The positions of the atoms of **4a** other than hydrogen are symmetrical within the limits of error with respect to the hydrogen bridge: however, the X-ray structural analyses do not allow us to decide whether the bridge itself is symmetric (see Section 3).

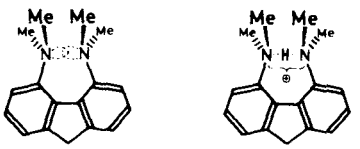
The ^{1}H-NMR spectrum of **4a** shows the proton of the N···H···N group as a broad singlet with an unusual low-field shift: $\delta = 18.31$ (in dimethyl sulfoxide) and $\delta = 19.5$ (in trifluoroacetic acid).[3] Coupling with this proton causes the twelve protons of the two dimethylamino groups to be split into a doublet: thus the methyl protons in **4a** are magnetically equivalent, just as are the naphthalene protons in corresponding positions. However, this information is also not sufficient to establish a structural equivalence in the sense of a symmetric N···H···N hydrogen bridge:[19] the expected rapid exchange of the bridging proton between the two positions of an unsymmetrical hydrogen bridge would also explain the observed magnetic equivalence.

However, the ^{2}H isotope effect on the chemical shift of the bridging hydrogen in **4a** ($\Delta\delta(^1H,^2H) = +0.6$ ppm)[20] and the theoretical arguments offered by *S. Forsén* et al.[21]

are in favor of a very strong but unsymmetrical hydrogen bridge. ESCA studies on **4a**-tetrafluoroborate also support the presence of two non-equivalent nitrogen atoms in **4a**, thus pointing to the presence of an unsymmetrical N···H···N hydrogen bridge.[22]

3. "Proton Sponge" Compounds with Fluorene Structure

It is remarkable that after the discovery of the unusual basicity of the 1,8-bis(dimethylamino)naphthalene **4**[3] the search for new, more basic "proton sponges" was limited for a considerable time to the modification of the 1,8-diaminonaphthalene system by introducing various substituents. This is particularly surprising since for structural reasons the two effects responsible for the "proton sponge" properties cannot function in these systems in an optimum manner: firstly the repulsive interaction between the lone pairs, which destabilizes the free bases, whould be smaller for amino groups in *peri*-positions of naphthalene than in systems in which these lone pairs are more strongly directed towards each other along the line joining the nitrogens; and secondly, as is shown by the X-ray structure of **4a**, it is not possible in the case of protonated "proton sponges" of the naphthalene type to form N···H···N bridges with the linear geometry generally considered to be optimal[8]. The consideration of simple molecular models shows that these factors should both be more favorable in the case of fluorenes with dialkylamino groups in 4- and 5-positions: the N···N distance would be smaller (on the basis of the fluorene structure it would be 231 pm in a fictitious planar molecule compared to 245 pm in *peri*-substituted naphthalenes), and in particular it was to be expected that in a 4,5-bis(dialkylamino)fluorene, in contrast to **4**, the lone pairs would be directed nearly along the N···N line, so that an almost linear N···H···N bridge would be formed on monoprotonation.



10 **10a**

On the basis of these considerations we synthesized the 4,5-bis(dimethylamino)fluorene **10**.[23] In this synthesis it was remarkable that 4,5-diaminofluorene easily underwent fourfold *N*-methylation on treatment with dimethyl sulfate in the presence of sodium hydride[24] (in tetrahydrofuran, 3 h at reflux); in spite of the considerable steric strain built up during this procedure, the yield was 90%.

10 exhibits typical "proton sponge" behavior in that it is not doubly protonated by excess perchloric acid: only the *mono*protonated **10a**-perchlorate is formed. In the ^{1}H-NMR spectrum of the latter the bridging proton absorbs at very low field ($\delta = 18.25$ in [D$_6$]DMSO, 360 MHz) as a broad singlet. The four methyl groups give one single signal at $\delta = 3.19$ ppm, split into a doublet by coupling with the bridging proton; the coupling constant of $J = 2.03$ Hz is significantly larger than for the perchlorate of **4a** ($J = 1.92$ Hz).

The greater basicity of **10** in comparison with **4** is shown by simple transprotonation experiments: when **4a**-perchlorate was added to a solution of **10** in [D$_6$]DMSO in a molar ratio of 1 : 1, integration of the Me$_2$N signals in the ^{1}H-NMR spectrum (**4**: $\delta = 2.73$; **10**: $\delta = 2.62$; **4a**: $\delta = 3.11$; **10a**: $\delta = 3.19$; 360 MHz) showed that **4a** had undergone almost complete deprotonation by **10**. The determination of the pK_a value of **10** on the basis of the UV/VIS spectroscopic measurement of the ratio of **10** to **10a** in 35% (v/v) dimethyl sulfoxide/water (I = 0.1 mol L^{-1}, 25 °C) gave a value of 12.8 ± 0.1,[32] compared with that of 12.1 ± 0.1 obtained for **4** under analogous conditions.[25,32]

It follows from the X-ray structural analysis of the perchlorate of **10a**[23] that the **10a** moiety of the molecule has C_2-symmetry with a C_2 axis through C9 and the midpoint of the central C–C bond of the five-membered ring (Fig. 1); the C_2 axis lies in the direction of the crystallographic *b* axis. The atoms C4 and C4i (≡C5) are displaced 10 pm in opposite directions out of the median plane formed by the remaining carbon atoms of the fluorene skeleton; this is a result of the steric interactions between the two dimethylamino groups, the nitrogen atoms of which lie 23 pm above and below the median molecular plane, respectively. The deviations from planarity as a result of the steric strain in **10a** are similar to those of the naphthalene system in **4a**. However, in contrast to **4a** the

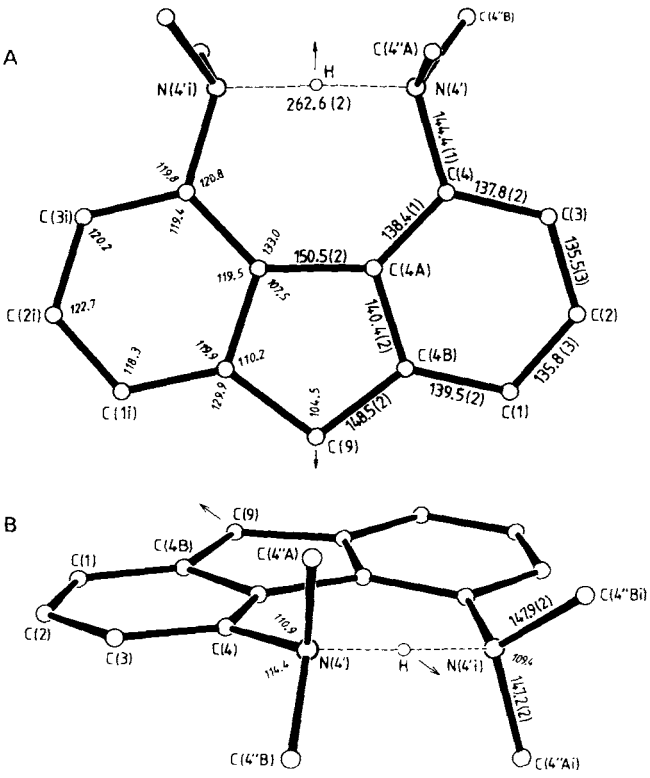


Fig. 1. Molecular structure of the **10a** part of **10a**-perchlorate (A) looking directly down on the fluorene plane, (B) looking sideways on from a position just above the fluorene plane (bond angles in degrees, distances in pm; standard deviations in brackets) [23].

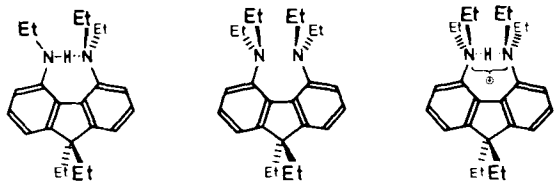
N···H···N hydrogen bridge is nearly linear (N···H···N angle: 178°). When the hydrogen bridge is included, the bond angles at the nitrogen atoms correspond very closely to a tetrahedral arrangement, as was expected from the models referred to above. The N···N distance is unusually short for a linear N···H···N hydrogen bridge: the value is 262.6(2) pm compared with normal N···N distances in N···H—N bridges of 290–320 pm[8] (which, however, don't carry a positive charge on nitrogen).

The C_2-symmetry of **10a** could correspond to a symmetrical hydrogen bridge with a single potential minimum; however, the X-ray structural analysis does not allow us to conclude that this is in fact the case, since such an analysis cannot distinguish between a symmetrical hydrogen bridge and a short unsymmetrical bridge with very close double potential minima. A 1 : 1 disorder effect could also give an apparent C_2-symmetry. The deuterium isotope effect for **10a**-perchlorate ($\Delta\delta(^1H,^2H)$ is $+0.50\pm0.03$ ppm ([D$_6$]-DMSO, 360 MHz, 33 °C) and thus according to *Forsén* et al.[21] suggests a very strong but still unsymmetrical hydrogen bridge.

The considerations which formed the basis for the synthesis of **10** as an effective "proton sponge" are also confirmed by its He(I) photoelectron spectrum.[26] The assignment of this spectrum, which is supported by those for model substances and corresponding MO calculations, shows a splitting of $\Delta E = 2.2$ eV between the two lone pair orbitals n_+ and n_- of the dimethylamino groups. This splitting, which is a measure of the through-space interaction between the lone pairs of the nitrogen atoms, is significantly larger than for **4** ($\Delta E = 2.0$ eV[27]). This suggests that the destabilizing interaction between the two dimethylamino groups in the free base **10**, which in addition to the hydrogen bridge in the *mono*protonated salt is considered to lead to the "proton sponge" properties, differs from that in **4** in the sense of an increase in basicity.

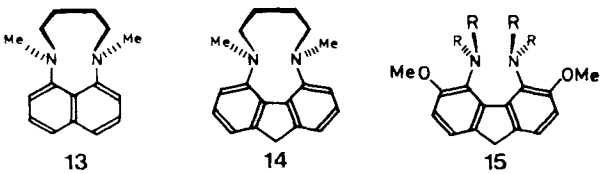
In contrast to the ready synthesis of the bis(dimethylamino) compound **10**, the sterically more demanding fourfold *N*-ethylation of 4,5-diaminofluorene did not occur as originally hoped. Even under conditions where only a threefold ethylation at nitrogen took place (ethyl iodide, sodium hydride, 3 h in refluxing tetrahydrofuran) the 9-position of fluorene was completely ethylated: the product obtained in 70% yield was 4-diethylamino-5-ethylamino-9,9-diethylfluorene **11**.[28] Both the extreme downfield shift of the amino proton ($\delta = 9.5$ rather than the usual range of $\delta = 3.0$–3.5 for aryl NH protons) and the infrared spectrum show that in this compound there is a strong intramolecular N···H···N hydrogen bridge. It can be assumed that the introduction of the fourth *N*-ethyl group is hindered by this hydrogen bridge, particularly since the attack of the auxiliary base sodium hydride at this proton and the subsequent reaction with ethyl iodide are made more difficult by the efficient shielding by the three space-filling ethyl groups. Attempts to introduce the fourth *N*-ethyl group into **11** using excess sodium hydride and ethyl iodide to give **12** failed: even after 15 h in refluxing THF, **11** remained unchanged. However, **12** was obtained in 74% yield by the reaction of 4,5-diaminofluorene with excess diethyl sulfate in the presence of sodium hydride (4 d in refluxing THF).[29]



11 **12** **12a**

As expected, **12** formed the corresponding **12a**-monoperchlorate with perchloric acid, even when the latter was in excess. ^{1}H-NMR transprotonation experiments between **4** and **12** indicated the latter to be more basic than **10**. The determination of the pK_a-value in the solvent mixture used previously (35% (v/v) dimethyl sulfoxide/water) was not possible, since the six ethyl groups in **12** make the molecule so hydrophobic that a sufficient solubility requires the mixture to contain 60% DMSO. The UV-spectroscopic determination of the **12/12a** equilibrium via extrapolation with respect to compound **9**, which was also studied in such a solvent mixture (see Table 1)[5] gave a pK_a-value of 13.6 ($\pm$0.2).[28] Thus the increase in basicity with respect to **10** (p$K_a = 12.8\pm0.1$) corresponds within the limits of error to that determined in the naphthalene series when the bis(diethylamino) compound **7** and the bis(dimethylamino) compound **4** were compared.

A comparison between **13** (p$K_a = 13.6$)[30] and **14** (p$K_a = 14.1\pm0.1$)[29] also shows that with corresponding substituents the "proton sponges" of the fluorene series are stronger bases than those of the naphthalene series. In this connection we are interested in 3,6-dimethoxy-4,5-bis(dialkylamino)fluorenes **15** and have commenced work on their synthesis:[31] they are expected to be the most basic "proton sponges" in the naphthalene and fluorene series.

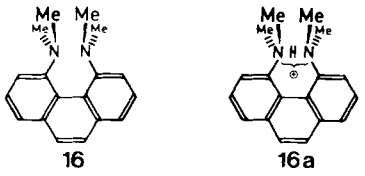


13 **14** **15**

4. "Proton Sponge" Compounds with Phenanthrene Structure

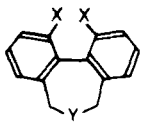
The results obtained in the fluorene series suggested that 4,5-bis(dialkylamino) derivatives of phenanthrene would be suitable candidates for the role of even more potent "proton sponges": molecular models such as those which had led to the choice of the fluorene system indicated the N···N distance to be even shorter in 4,5-bis(dimethylamino)phenanthrene **16** than in the fluorene compound **10**, so that an even greater steric hindrance of the dimethylamino groups with unfavorable overlap of the nitrogen lone pairs would be expected. In addition, the monocation **16a** should form an approximately linear N···H···N hydrogen bridge with an N···N distance shorter than in **10a**.

The synthesis of this molecule was extremely difficult because of its extreme steric strain. Among the various



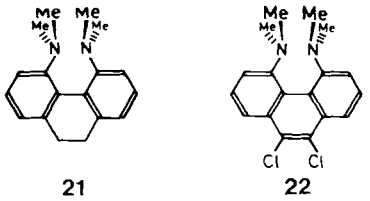
16 16a

routes tried[28] we will mention only the following: starting from 2,2'-bis(bromomethyl)-6,6'-dinitrobiphenyl one can obtain the dibenzo[*c*,*e*]thiepin **17** using sodium sulfide. Reduction of **17** with zinc dust and acetic acid gave the diamino compound **18**, which underwent methylation to the bis(dimethylamino) compound **19** on treatment with dimethyl sulfate and sodium hydride in THF. Oxidation with peroxytrifluoroacetic acid led to the cyclic sulfone **20**; gas phase vacuum pyrolysis of which gave 4,5-bis(dimethylamino)-9,10-dihydrophenanthrene **21** in satisfactory yield.[32] We shall discuss the "proton sponge" properties of **21** in Section 6 in connection with its non-planar structure.



17, X = NO_2, Y = S
18, X = NH_2, Y = S
19, X = NMe_2, Y = S
20, X = NMe_2, Y = SO_2

None of the various dehydrogenation methods applied was successful in converting the 9,10-dihydrophenanthrene compound **21** into **16**, apparently because of the necessary introduction of an extremely large steric strain. However, the synthesis of **16** was possible starting from **20** using a Ramberg-Bäcklund rearrangement as modified by *Meyers* et al.:[33] in spite of its high steric requirements, this procedure gave the 4,5-bis(dimethylamino)-9,10-dichlorophenanthrene **22** in the surprisingly high yield of 53%. Halogen-metal exchange (lithium, THF, 1.5 h, −55 °C to −35 °C) followed by treatment with methanol led to **16** in 55% yield.[32]



21 22

As expected, **16** gives only a *mono*protonated derivative, even with an excess of acid: thus perchloric acid gives the perchlorate of **16a**, in the proton NMR spectrum of which ([D_6]dimethyl sulfoxide, 360 MHz) the proton forming the N···H···N bridge absorbs at $\delta = 18.37$. The large positive isotope effect observed for this proton [$\Delta\delta(^1H,^2H) = +0.47 \pm 0.03$ ppm] suggests that the hydrogen bridge is in this case also very strong but still unsymmetrical. The variation in the coupling between the bridging proton and the *N*-methyl protons also indicates the presence of a particularly strong hydrogen bridge (**4a**: $J = 1.92$; **10a**: 2.03; **16a**: 2.17 Hz).

While the deviations of the aromatic skeleton from planarity were not very marked in the *mono*protonated systems **4a** and **10a**, the considerable increase in the steric interaction in **16a** (Fig. 2) leads to a drastic deformation of the aromatic system (because of the two-atom bridge, **16a** is of course much more readily able to undergo deformation than are **4a** or **10a**). The structure of **16a** is characterized by a large helical twist (23°) of the phenanthrene system along the C12–C13 axis (Fig. 2). This causes C4 and C5 to lie 30 and 29 pm, and N4' and N5' to lie 75 and 72 pm above or below the plane of the phenanthrene ring. The increase of the bond angles at C12 and C13 to 128° decreases the interaction between the two dimethylamino groups still further: even so, the N···N distance of 254.4 pm in **16a** is significantly shorter than that in **10a** (262.6 pm), and is one of the shortest distances for an approximately linear N···H···N bridge which has yet been found. The small deviation of the hydrogen bridge from

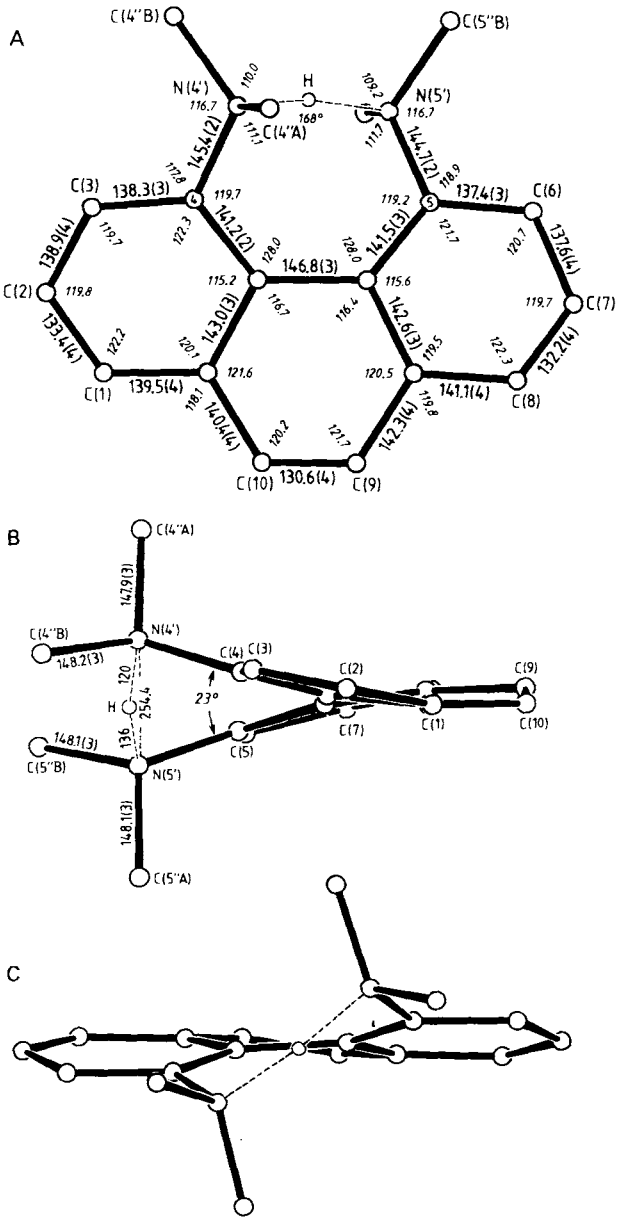


Fig. 2. Molecular structure of the **16a** part of **16a**-perchlorate looking down on the phenanthrene system (A), from the side along the C2–C7 axis (B), and looking along the (approximate) C_2-axis (C) (bond angles in degrees, distances in pm; standard deviations in brackets) [32].

linearity (the angle N···H···N is 168°) is in agreement with the retention of a nearly tetrahedral geometry at the two nitrogen atoms.

The X-ray structural analysis of **16a**-perchlorate and the ^{1}H-NMR results allow us to assume the existence of a strong N···H···N hydrogen bridge. In addition the free base **16** was expected to have a shorter N···N distance than that in **4** or **10**, leading in turn to a more strongly destabilising interaction between the nitrogen lone pairs; this is in agreement with preliminary PE-spectroscopic results ($\Delta E = 2.6$ eV for the n_+/n_- splitting).[34] Both effects led us to expect the basicity of **16** to be considerably higher than that of **10**; experimentally we do find **16** to have the high basicity typical of a "proton sponge", but the exact determination of its pK_a-value under the conditions used for **10** (see above) shows it to have a basicity which is not higher but in fact *lower* than that of **10** ($pK_a = 11.5 \pm 0.1$)[32] (see Table 3 in Section 6).

Various structural factors could be responsible for the observed variation in basicity in the series **4** ($pK_a = 12.1$), **10** (12.8), **16** (11.5). A possible explanation for the reduced basicity of **16** compared to **10** could be that the N···H···N hydrogen bridge in **16a** is, as a result of the particularly large steric strain in this system, compressed beyond the energetically optimal N···N distance of such a hydrogen bridge. Also a plausible assumption, however, would be that the steric strain in **16** is so much stronger than in **4** and **10** that the protonation can not bring steric relief corresponding to that shown by a comparison of the molecular structures **4/4a** and the systems **24/24a** and **25/25a** (Figs. 4 and 5) described later. The strong deformation of **16a** compared to **4a** and **10a**, which follows from the X-ray structure analysis, would appear to support this thesis. The recent successful structure analysis of **16**[35] (Fig. 3) shows that the torsion of the "biphenyl unit" about the central CC bond of the phenanthrene in this compound is 36° and that the C4–N4′ and C5–N5′ bonds form an angle of 44° (Fig. 3B). Besides the twisting about the central CC bond, there is a noticeable bending of the peripheral six-membered rings of the phenanthrene moiety towards each other, whereby the atoms C2, C12, C13, and C7 no longer lie on an axis (Fig. 3C). This, in addition to the widening of the C5–C13–C12 and C4–C12–C13 angles, leads to a mean deviation of C4 and C5 of about 53 pm and for N4′ and N5′ of about 104 pm in opposite directions from the mean plane of the atoms of the central six-membered ring. The result of these deformations is an N···N distance of 278.3 pm for the dimethylamino groups, which—as the structure of **16a** shows (Fig. 2)—is reduced to 254.4 ppm by the *mono*protonation of **16**. Hence the protonation of **16** obviously leads to a reduction in the steric repulsion of the dimethyl groups. However, the ensuing stronger planarization of the phenanthrene system is accompanied by steric deformations at other sites, as shown for example by the additional widening of the external angles at C12 and C13. A quantitative estimation of the net relief of steric strain is therefore hardly possible.

In connection with this result we should finally note the following structural difference between **4a** and **10a** on the one hand and **16a** on the other: because of the small deviation from planarity of the aromatic skeletons in **4a** and **10a** the dimethylamino groups are so arranged that they hydrophobically shield the N···H···N bridge considerably from all sides (see Fig. 1 and Refs. [17, 18]). However, in **16a** the extreme steric strain displaces the dimethylamino groups so far in opposite directions from the median phenanthrene plane and twists them so far about the C_{aryl}–N bonds to obtain a linear N···H···N bridge that this bridge is no longer hydrophobically shielded in all directions as it is in **4a** and **10a** (see Figs. 1B and 2C). If it is indeed the case that the strength of the hydrogen bridge (and thus the basicity of the "proton sponges") is determined not only by the N···N distance and the geometric arrangement (linear or non-linear) of the N···H···N hydrogen bridge but also by the hydrophobic shielding of the

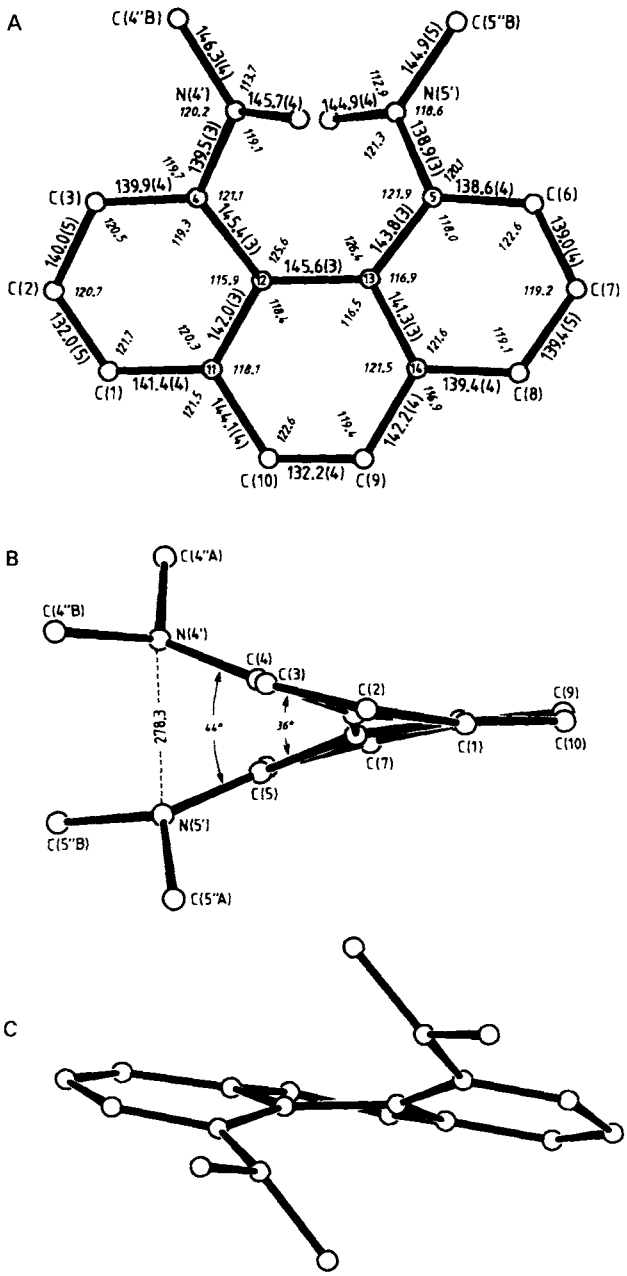

Fig. 3. Molecular structure of **16**, (A) looking down on the phenanthrene plane, (B) side view, (C) view along the (approximate) C_2 axis (bond angles in degrees, bond distances in pm; standard deviations in brackets) [35].

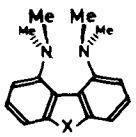
latter, then the observed basicity difference between **16a** and **10a** (or **4a**) could find an explanation on this basis (for a further discussion of this point see Section 8).

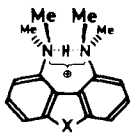
These attempts at explaining the variations in basicity in the series **4/10/16** show that several different factors must be taken into account, even within this series of very similar and relatively simple compounds. Our goal of being able to differentiate better between these factors led us to the syntheses of the systems described in Sections 5 and 6.

The 9,10-dichloro compound **22** also forms a monoperchlorate, as expected: in the proton NMR spectrum the N···H···N proton absorbs at $\delta = 17.7$ ([D$_6$]DMSO, 360 MHz); the coupling between this proton and the neighboring *N*-methyl protons is ca. 1.5 Hz. The NMR spectroscopic determination of the transprotonation equilibrium with **4** gave a pK_a-value for **22** of ca. 10.4: the reduction compared to the pK_a-value of **16** (11.5) is probably due to the inductive effect of the chlorine substituents in positions 9 and 10.—The basicity of the 4,5-bis(dimethylamino)-9,10-dihydrophenanthrene **21** will be discussed in Section 6 together with that of related biphenyl systems.

5. "Proton Sponge" Compounds with Dibenzofuran, Dibenzothiophene and Dibenzoselenophene Structures

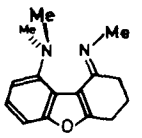
The preceding comparison of the basicities of the "proton sponges" with naphthalene, fluorene and phenanthrene structures (**4/10/16**) showed that in this series a maximum was observed for the fluorene system **10**. Attempts to prepare and determine the basicities of the fluorene analogues **23**–**26** in which the heteroatom in the central five-membered ring is varied from oxygen via sulfur and selenium to tellurium were therefore of interest: in this series we can expect a stepwise change in the interaction between the dimethylamino groups in positions 1 and 9. On the basis of the X-ray structural analyses for dibenzofuran, dibenzothiophene, dibenzoselenophene and dibenzotellurophene and with the fictitious assumption that the bis(dimethylamino) compounds are planar we can expect the N···N distance to decrease on going from **23** via **24** and **25** to **26**: the fluorene derivative **10** should lie between **24** and **25**, while the phenanthrene derivative **16** has the shortest N···N distance and thus should follow **26**. This order did not change when this crude model based on the assumption of planar structures was replaced by force field calculations;[36] these take into account the deformation of the molecule resulting from the interactions between the dimethylamino groups and thus provide a more realistic basis for the interpretation of the protonation equilibria.



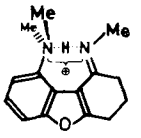


23, X = O ; **24**, X = S; **25**, X = Se; **26**, X = Te **23a**, X = O ; **24a**, X = S; **25a**, X = Se; **26a**, X = Te

The synthesis of the 1,9-bis(dimethylamino)benzofuran **23** has not as yet been completed. However, attempts to synthesize it afforded compound **27**;[36] in contrast to those of the "proton sponges" discussed previously, the basic centers of this compound are unsymmetric, but their arrangement in space corresponds roughly to that in **23**. With tetrafluoroboric acid **27** forms a tetrafluoroborate **27a** · BF_4, the proton NMR spectrum of which ([D$_6$]-DMSO, 500 MHz) shows a resonance at 13.34 ppm characteristic of a strong N···H···N hydrogen bridge. ^{1}H-NMR-spectroscopic determination of the transprotonation equilibrium with **4a** gives an unexpectedly high pK_a-value for **27a** of 12.3 ± 0.1. This result leads us to expect particularly marked "proton sponge" properties for the symmetrical fourfold *N*-methylated 1,9-dibenzofuran **23**.

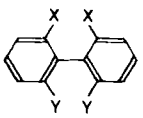


27



27a

The following route was used in the synthesis of the 1,9-bis(dimethylamino)dibenzothiophene **24**:[37] 2,2′-dibromo-6,6′-dinitrobiphenyl **28** (from 1,2-dibromo-3-nitrobenzene via an Ullmann reaction) was reduced by iron(III) chloride and hydrazine to afford 2,2′-diamino-6,6′-dibromodiphenyl **29**. Fourfold methylation (dimethyl sulfate, sodium hydride, tetrahydrofuran) to give the bis(dimethylamino) compound **30** was followed by treatment with *n*-butyllithium (tetrahydrofuran, −78 °C) to yield the dilithio compound **31**; this gave the desired dibenzothiophene **24** when treated with bis(phenylsulfonyl) sulfide.



28, X = Br, Y = NO_2
29, X = Br, Y = NH_2
30, X = Br, Y = NMe_2
31, X = Li, Y = NMe_2

With excess tetrafluoroboric acid **24** forms the *mono*protonated **24a**-tetrafluoroborate, the bridging proton of which absorbs at extremely low field ($\delta = 19.06$ ppm, [D$_6$]-DMSO, 500 MHz). The transprotonation equilibrium with **4a** was studied by comparing the intensities of the *N*-methyl signals in the proton spectra: a pK_a-value for **24a** of 11.9 was obtained. Thus the basicity of the dibenzothiophene compound lies between those of the fluorene and phenanthrene "proton sponges" **10** and **16** (see Table 3 in Section 6).

X-ray structure analyses have been carried out for both **24** and **24a** (Fig. 4).[37] The extreme steric strain caused by the interactions between the dimethylamino groups is shown by a very definite deviation from planarity: this is demonstrated particularly by the torsion around the central C9a–C9b bond (21.3°), which causes C1 and C9 to be displaced in opposite directions by 33.1 and 30.3 pm respectively from the median plane of the five-membered ring. N1′ and N9′ are thus displaced 74.8 and 65.6 pm above and below this plane, so that the N···N distance is 286.1 pm.

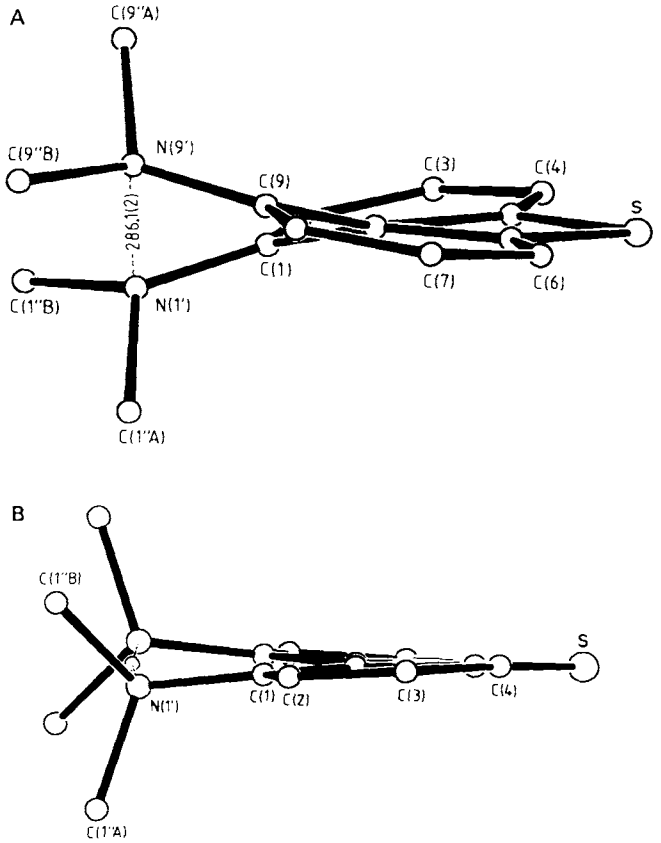


Fig. 4. Structures of **24** (A) and the **24a** part of **24a**-tetrafluoroborate (B) seen from the side along the C3···C7 axis [37].

A comparison of the molecular structures of **24** and **24a**-tetrafluoroborate (Fig. 4) from the side, looking along the C3···C7 axis) shows directly how much the protonation of **24** and the concomitant introduction of a strong N···H···N hydrogen bridge leads to a relief of the steric strain: in **24a** the torsion angle about the central CC bond referred to above is only 7.7° (instead of 21.3° in **24**); C1 and N1′ are displaced only by 9.9 and 24.9 pm respectively out of the plane of the five-membered ring, so that the N···N distance is reduced by 27.4 to 258.7 pm. The N···H···N bridge is almost linear, the angle being 175°.

The 1,9-bis(dimethylamino)dibenzoselenophene **25** was obtained by treating **31** with selenium powder. **25** also gives a monotetrafluoroborate **25a** · BF_4, the N···H···N proton of which absorbs at 19.28 ppm ([D_6]DMSO, 500 MHz). The structures of **25** and **25a**[37] correspond very closely to those of the analogous sulfur compounds **24** and **24a**. The comparison between **25** and the *mono*protonated cation **25a** (Fig. 5) makes clear the reduction in the steric strain which results on protonation, just as in the case of **24/24a**. The N···N distance is reduced from 282.3 to 257.3 pm, and the N···H···N bridge is here again almost linear (175°).

In view of the extremely similar structures of **24** and **25** and their monocations **24a** and **25a** it is not surprising that the basicities of the sulfur and selenium compounds are very similar: estimation of the pK_a of **25**, carried out as for **24** by NMR-spectroscopic determination of the transprotonation equilibrium with **4a** ([D_6]DMSO, 500 MHz), gave a value of 11.8 (within the limits of experimental error the same as that for **24** (11.9)).

Treatment of **31** with elemental tellurium gave the corresponding dibenzotellurophene **26**, from which a tetrafluoroborate was obtained on treatment with tetrafluoroboric acid. Both compounds have been clearly characterised by their mass and proton NMR spectra; however, they have not until now been obtained in sufficient quantities to permit basicity and structural studies.

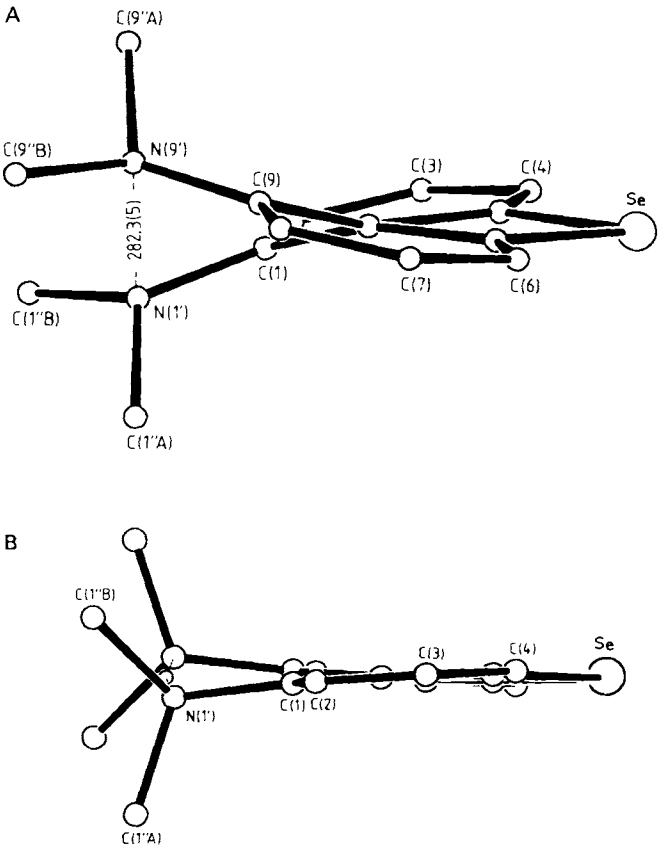

Fig. 5. Structures of **25** (A) and the **25a** part of **25a**-tetrafluoroborate (B) seen from the side along the C3-C7 axis [37].

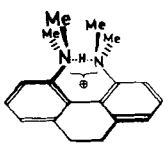
6. "Proton Sponge" Compounds with Biphenyl Structure; *ortho*-Bis(dimethylamino)benzenes

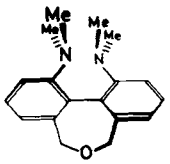
The bis(dimethylamino)arenes discussed previously are inflexible systems with a large degree of steric strain; they are derivatives of arenes with planar parent structures. The compounds to be described below are however conformationally flexible and sterically less strained, and are derived from non-polar parent structures. Thus one of the two factors discussed above which are responsible for the high basicity of the "proton sponges", the destabilizing interaction of the lone pairs of the dimethylamino groups, should have little or no influence because the latter can more readily move apart; however, the preconditions for forming stable, nearly linear hydrogen bridges are still present. Thus a comparison of these two types of compound was of interest for the purpose of differentiating between and estimating the relative importance of these two factors.

A compound which with respect to its steric situation lies between the actual biphenyl derivatives and the systems derived from planar parent structures is 4,5-bis(dimethylamino)-9,10-dihydrophenanthrene **21**, the synthesis of which has been mentioned in Section 4. As in biphenyls the two aromatic rings in 9,10-dihydrophenanthrene are twisted away from one another around the central C_{aryl}–C_{aryl} bond. The dimethylamino groups in positions 4 and 5 enforce a further deviation from planarity, but the steric strain in **21** should be considerably lower than that in the corresponding phenanthrene derivative **16**.

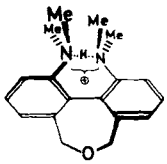
However, **21** still has the typical properties of a "proton sponge", though these are less pronounced than in the corresponding phenanthrene derivative **16**: with perchloric acid, **21** forms **21a**-*mono*perchlorate, the N···H···N proton of which absorbs at 16.50 ppm ([D6]DMSO, 360 MHz). The pK_a-value was estimated from transprotonation experiments with **4a** to be ca. 10.9.[32]



21a



32



32a

Structural analyses of **21** and its monoprotonation product **21a** have not yet been carried out; however, information on the steric interactions in **21** and **21a**[38] can be obtained from the proton NMR spectra of **21** and **21a**-perchlorate and in particular from a comparison of the temperature-dependence of these spectra. At room temperature (360 MHz, [D2]dichloromethane) the protons of the *N*-methyl groups of **21** give a singlet at $\delta = 2.50$, while the methylene protons at C9 and C10 give an AA'BB'-multiplet with $\delta_A = 2.54$, $\delta_B = 2.77$ and J_{AB} ca. 9.7 Hz. On lowering the temperature the *N*-methyl signal is continually broadened until the coalescence temperature $T_C = 243$ K is reached; at 163 K these protons give two sharp singlets (1:1 intensity ratio) at $\delta = 2.01$ and 2.99. The dynamic process leading to an equivalence of the two pairs of *N*-methyl groups is apparently a nitrogen inversion with concomitant rotation about the C_{aryl}–N bond; $\Delta G^{\ddagger}_{T_c} = 45.7$ kJ mol^{-1}. A "flip" of the twisted ring system by means of a rotation about the central "biphenyl" bond, which would also lead to magnetic equivalence of the *N*-methyl protons, can be excluded because the absorption of the methylene protons at C9 and C10 remains unchanged over the above range of temperature: this multiplet undergoes broadening only above 400 K, though coalescence is still not observed at 423 K (in [D6]DMSO).

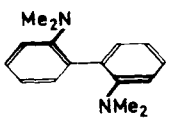
In contrast, the temperature-dependence of the proton spectrum of **21a**-perchlorate ([D3]acetonitrile, 360 MHz) shows a completely different dynamic behavior. At 243 K the two singlets for the two pairs of *N*-methyl protons ($\delta = 2.50$ and 3.23) and the splitting of the methylene protons (AA'BB' with $\delta_A = 2.64$, $\delta_B = 2.95$ and J_{AB} ca. 9.2 Hz) show that the two possible motional processes are "frozen" with regard to the NMR time scale, while on raising the temperature coalescence is observed for the methylene protons at 273 K and for the *N*-methyl protons at 283 K; at 353 K both the methylene and the *N*-methyl protons give a singlet ($\delta = 2.79$ and 2.88, respectively). The barriers to rotation for both groups of signals are in agreement ($\Delta G^{\ddagger}_{T_c} = 54.5 \pm 0.4$ and 54.3 ± 0.4 kJ/mol), indicating that the magnetic equivalence is caused by the same process, the flip of the 9,10-dihydrophenanthrene system. Thus this process occurs much more readily for the monocation **21a** than for **21**, due to its closer approach to planarity and the reduction of the steric hindrance of the dimethylamino groups by the N···H···N hydrogen bridge. On the other hand the nitrogen inversion in **21a** is not so facile as in the unprotonated diamine **21**; this again can be plausibly explained as a result of the formation of the strong N···H···N hydrogen bridge.

The 1,11-bis(dimethylamino)-5,7-dihydrodibenzo[*c*,*e*]oxepin **32** is a compound which has an even more twisted biphenyl unit than does **21**, so that the steric interactions between the two dimethylamino groups should be even further reduced. **32** was prepared starting from 2,2'-bis(hydroxymethyl)-6,6'-dinitrobiphenyl via 1,11-dinitro-5,7-dihydrodibenzo[*c*,*e*]oxepin: the diamino compound obtained from the latter by catalytic hydrogenation gave **32** on fourfold *N*-methylation.[38] **32** also shows "proton sponge" properties, even though these are considerably reduced: with excess perchloric acid in acetonitrile or chloroform one obtains **32a**-*mono*perchlorate, the N···H···N proton of which is much less low-field shifted than those of the "proton sponge" compounds discussed previously ($\delta = 11.76$; [D6]DMSO, 360 MHz). NMR-spectroscopic determination of the transprotonation equilibrium between **32a** and **4** gave a pK_a-value of ca. 9.4: this is still surprisingly high, but considerably lower than those of typical "proton sponges" and also lower than that of **21** (10.9).

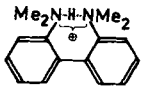
As in the case of **21** and **21a**, the temperature dependence of the proton NMR spectra provides information on the steric situation in **32** and the monocation **32a** derived therefrom.[38] The spectrum of **32** is unchanged between 163 and 303 K; the twelve dimethylamino protons give a singlet at 2.46 ppm, while the benzylic protons of the dihydrooxepin ring form an AB-system with $\delta_A = 4.45$, $\delta_B = 4.17$ and $J_{AB} = 11.2$ Hz (CD_2Cl_2, 360 MHz). This indicates that the inversion-rotation process undergone by the dimethylamino groups in **32** occurs more readily here than in **21** because of the reduced steric interaction. However, the temperature-invariant AB-spectrum of the benzylic protons shows that the rotation about the central bond of the "biphenyl unit" is also strongly hindered in **32**, as in **21**. In spite of the reduction of the interaction of the dimethylamino groups caused by protonation, this flip of the dibenzooxepin skeleton in **32a** is in contrast to **21a** so slow that no change is observed for the AB-system formed by the benzylic protons of the dibenzooxepin ring between 273 and 353 K ($\delta = 3.81$ and 4.59 (each 2H), $J_{AB} = 11.4$ Hz; [D6]DMSO, 360 MHz). Apparently the seven-membered ring raises the barrier to the approach of the molecule to planarity, the necessary precondition for the flip process. On the other hand, in contrast to **21a**, the inversion/rotation of the dimethylamino groups can be observed in isolation in **32a**: the latter give two signals of equal intensity at 273 K ($\delta = 2.50$ and 3.19 ppm; [D3]acetonitrile, 360 MHz),

which coalesce at 338 K and give a single sharp line ($\delta = 2.82$ ppm) in [D$_6$]DMSO at 363 K. The barrier for the inversion-rotation process undergone by the dimethylamino groups in **32a** is $\Delta G_{T_c}^{\ddagger} = 65.4 \pm 0.4$ kJ mol^{-1}.

Compounds **21** and **32**, which differ from the "proton sponges" with a rigid arene structure and fixed dialkylamino groups by their greater conformational flexibility, lead over to systems in which no steric strain whatever due to interactions between the dialkylamino groups is to be expected. A simple example of such a compound is the 2,2′-bis(dimethylamino)biphenyl **33**: a steric interaction between the two *ortho*-substituents can be avoided by rotation of the aryl rings about the central C–C bond, while on the other hand these substituents are arranged in such a manner that they can be brought together by monoprotonation (to **33a**) to give an N···H···N hydrogen bridge of the type found in the "proton sponges".



33



33a

33 had already been described in the literature;[39] we have obtained it in good yield from 2,2′-diaminobiphenyl using the methylation procedure[24] used successfully in the "proton sponges" (sodium hydride/dimethyl sulfate, tetrahydrofuran).[40] The molecular structure of **33** is shown in Figure 6A looking in the direction of the longitudinal axis of the molecule. The aryl rings are twisted by 57° around the central C–C bond and the dimethylamino groups in the two *ortho*-positions are arranged in an "*anti*-conformation" (i.e. far away from each other). The N···N distance is 473.8 pm, so that in contrast to all other bis(dimethylamino)arenes discussed previously there is obviously no steric interaction between the two dimethylamino groups. However, **33** also gives a *mono*hydrobromide with hydrogen bromide in *n*-hexane; the structure of this cation **33a** as determined by an X-ray analysis is shown in Figure 6B. The intramolecular N···H···N bridge formed on protonation brings the dimethylamino groups together so that the N···N distance is 265.0 pm; the hydrogen bridge is almost linear (175°).

NMR-spectroscopic determination of the transprotonation equilibrium with 1,8-dimorpholinonaphthalene[6] gave a pK_a-value of 7.9 ± 0.1 for **33**.[40] The observed increase of the basicity constant by almost three orders of ten compared with *N,N*-dimethylaniline must in this case be due solely to the formation of an N···H···N hydrogen bridge with a favorable geometry, since the destabilization of the free base by steric interactions between the dimethylamino groups discussed above as an additional effect for the actual "proton sponges" cannot exist for the reasons stated. It appears justified to regard the basicity increase for **33** as the *minimum* contribution made by the hydrogen bridge to the basicity increase in the actual "proton sponges". However, this value cannot be used in a quantitative classification of the energetic factors which lead to the unusual basicities of these compounds, since in "proton sponges" such as **4**, **10**, **16**, **24**, or **25** the formation of the hydrogen

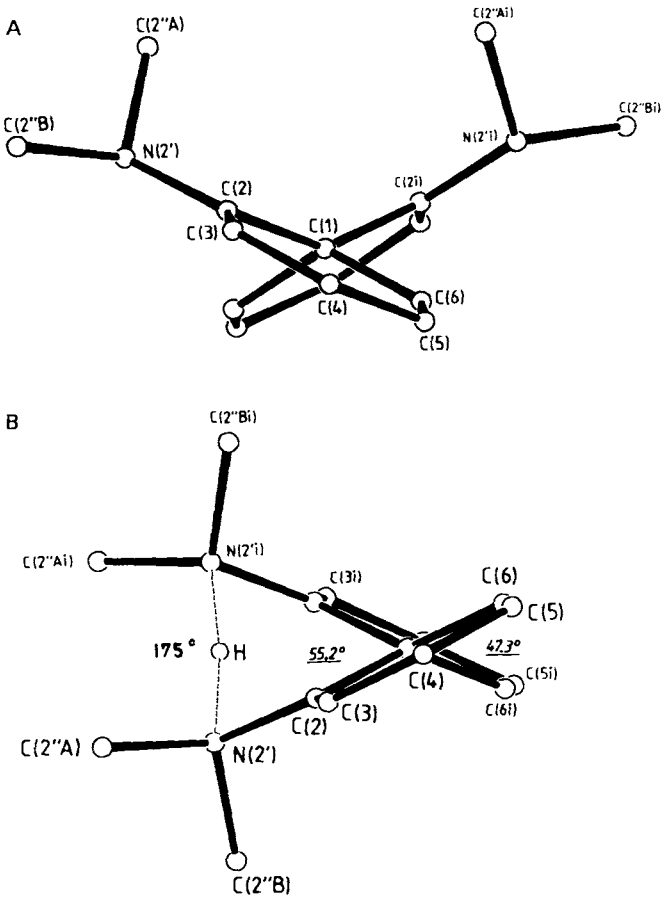


Fig. 6. Molecular structures of **33** (A) and the **33a**-part of **33**- monohydrobromide (B), looking in each case along the longitudinal axis of the biphenyl system [40].

bridge is inseparably connected with the decrease in steric strain resulting from the planarization of the aromatic rings and a normalization of bond lengths and angles. Some data for "proton sponges" are collected in Table 3.

The examples of bis(dimethylamino)arenes with conformational flexibility show that there is a gradual transition from the typical "proton sponges" with rigid structures and strong interactions between the dimethylamino groups

Table 3. Basicities of some "proton sponges"; N···N-distances and angles NHN in the corresponding monocations. For individual details see text.

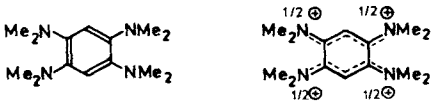
[a] Additional coordination to water molecules (forked hydrogen bonds).

to compounds in which this steric strain is increasingly reduced until it disappears completely. Part of the "proton sponge" behavior will be retained as long as the geometrical preconditions for the formation of a strong N···H···N bridge are fulfilled. The last example in this series will show that on the other hand rigid arene systems with dimethylamino groups situated very close together do *not* show this unusual behavior when the steric preconditions for both a destabilizing interaction between the lone pairs of the free base and a stable N···H···N hydrogen bridge in the *mono*protonated system are unfavorable. For other reasons, in this case because of its unusual properties as an extremely strong *two*-electron donor, we recently synthesized 1,2,4,5-tetrakis(dimethylamino)benzene **34**, which contains two pairs of dimethylamino groups in positions *ortho* to one another. The steric interaction between the dimethylamino groups in **34** is shown by the fact that the unusually easy release of two electrons ($E_{ox}^{1,2} = -0.266$ V) is connected with the transition of the planar aromatic system into a dication **34a** with two polymethine units, which according to the X-ray structural analysis are tilted away from one another by 49°, thus causing a *twist* arrangement of the six-membered ring.[41]



34 **34a**

Although **34** has two pairs of dimethylamino groups in *ortho* positions to one another, the preconditions for "proton sponge" properties are not favorable; because of the diverging C_{aryl}–N bonds the dimethylamino groups must have a larger N···N distance than in the "proton sponges" discussed above. For the same reason the lone pairs cannot be directed towards each other, and of course linear N···H···N hydrogen bridges cannot be formed along the preferred directions of the nitrogen lone pairs.

A **34**-dihydrobromide dihydrate is, however, in fact obtained when a 48% aqueous solution of hydrogen bromide is added to a concentrated solution of **34** in ether; thus each pair of dimethylamino groups undergoes only a monoprotonation. The structure of the dication of **34** is shown in Figure 7A looking down on the benzene ring, and in Figure 7B from the side.[42] The four nitrogens of the dimethylamino group are almost coplanar with the aromatic ring, and the N···N distance of 271.6 pm is so short that relatively strong hydrogen bonds could in fact have been formed if a linear arrangement were possible. However, this is hindered by the preferred directions of the N1-H bonds and the lone pairs on the neighboring nitrogens, so that two very unsymmetrical N–H···N bridges with an angle of 119° are formed. These hydrogen bridges appear to be so labile that their stabilization requires the additional coordination to water molecules in a bifurcated hydrogen bridge, as shown in Figure 7A. Thus, **34** does *not* exhibit the typical properties of "proton sponge" compounds in spite of the close approach of the dimethylamino groups within each pair.

7. Mass Spectra of "Proton Sponge" Compounds

The small distance between the dialkylamino groups, which is so important in determining the "proton sponge" properties of the compounds discussed here, also causes these compounds to exhibit a characteristic behavior under mass spectrometric conditions. Table 4 gives the relative intensities of the most important ions observed in the mass spectra of a series of bis(dimethylamino)arenes on electron impact (EI) ionization. The most prominent fragment ion, which forms the base peak in all these spectra, is formed from the molecular ion by the cleavage of a fragment of

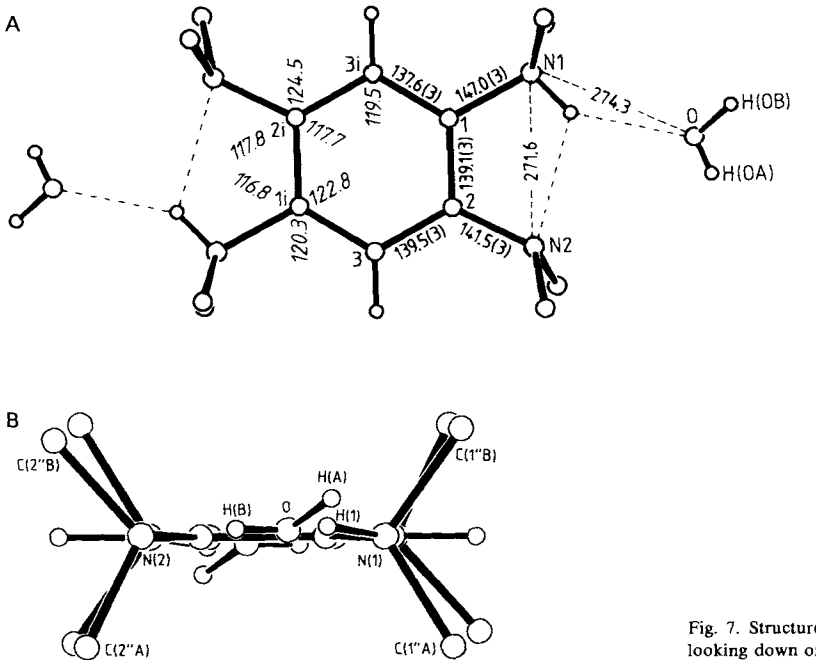


Fig. 7. Structure of the **34**-dication part of **34**-dihydrobromide dihydrate looking down on the benzene plane (A) and from the side (B) [42].

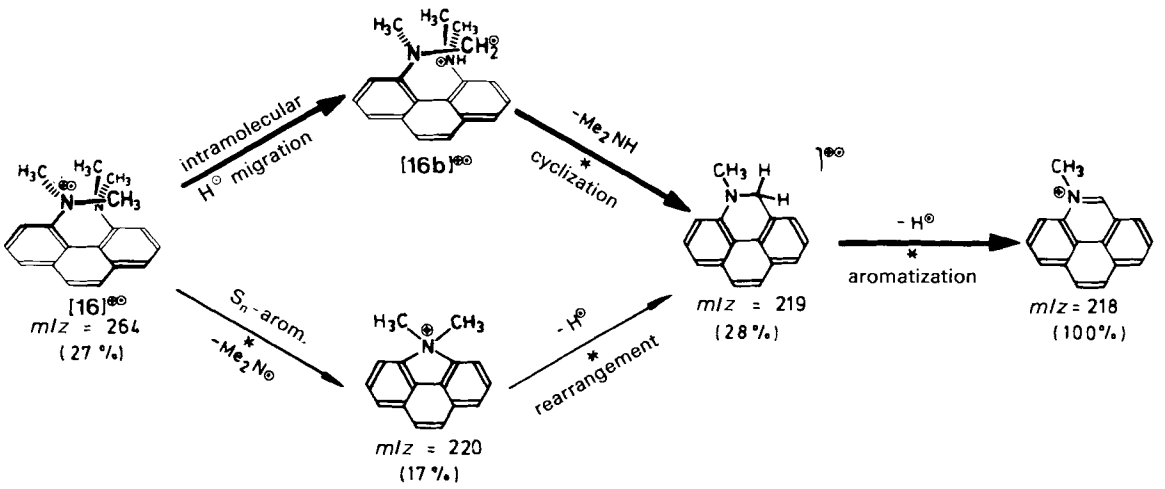

Scheme 1. Main fragmentation routes for 4,5-bis(dimethylamino)phenanthrene **16** under the conditions of EI mass spectrometry [43].

mass 46, which is formally equivalent to dimethylamine plus one hydrogen. Detailed mass-spectrometric studies showed that this fragmentation behavior is the result of rearrangement, cleavage and cyclization processes which are all due to the short distance between the two dimethylamino groups.[43,44]

The driving force in this process is the formation of stable ions with aromatic bonding systems. This is shown in Scheme 1 for the fragmentation of the phenanthrene "proton sponge" **16**.

Similar fragmentation processes have been documented for the other compounds in Table 4,[43,44] and analogous mass-spectrometric decomposition mechanisms have also been found to apply for 1,8-bis(dimethylamino)naphthalene **4** and 4,5-bis(dimethylamino)fluorene **10**.[45]

Table 4. Relative intensities of the most important ions in the EI mass spectra of several "proton sponge" compounds (corrected for their ^{13}C and ^{37}Cl content) [43, 44].

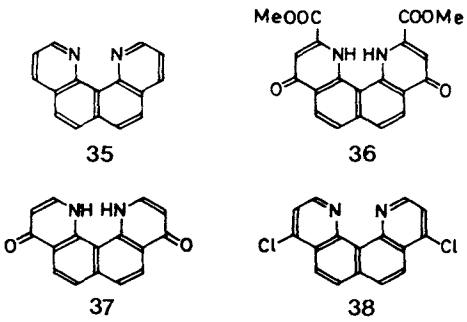
8. Quino[7,8*h*]quinoline, a "Proton Sponge" of a New Type

All the "proton sponge" compounds discussed so far are bis(dialkylamino)arenes in which the basic centers, and thus the N···H···N hydrogen bridges of the monoprotonated species, are hydrophobically shielded. It is not yet clear how the bond strength of hydrogen bridges is influenced by such hydrophobic surroundings, but it is certainly the case that the very low rates of proton transfer found for presently known "proton sponges" are connected with this hydrophobic shielding (see Table 2).

In this context a compound which was of interest to us was quino[7,8*h*]quinoline **35**, a compound in which such a hydrophobic shielding is not present but in which two nitrogen atoms are arranged in a manner similar to that in 1,8-bis(dimethylamino)naphthalene **4**, the prototype of a "proton sponge".

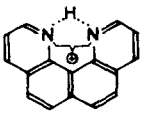


Several reports on the preparation and properties of **35** have appeared in the last four decades:[46,47] however, these reports have in all cases been later shown to be incorrect. In one case the compound reported as **35** was a structural isomer[48] and in a second a Skraup synthesis which should yield **35**[47] actually gave 2-methyl-1,3-diazapyrene.[49] Thus quino[7,8-*h*]quinoline was hitherto unknown.

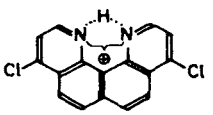
In our recently reported synthesis of **35**[1] we treated **3** with dimethyl acetylenedicarboxylate to give 2,2'-(1,8-naphthylenediimino)di(methylfumarate),[50] which was thermally cyclized to **36**. Alkaline hydrolysis and thermal decarboxylation (335–370 °C/10^{-5} torr) led to **37**, which was treated with phosphoryl chloride to give 4,9-dichloro[7,8*h*]quinoline **38**. Catalytic hydrogenation (Pd/C, glacial acetic acid, sodium acetate) yielded **35**, the structure of which was determined analytically and spectroscopically, and confirmed by a recent X-ray structure analysis.[51]

Like other "proton sponge" compounds, **35** forms only a *mono*perchlorate with excess perchloric acid; its struc-

ture **35a** follows from the proton NMR spectrum, which shows an absorption at $\delta = 19.38$ (in DMSO), the most strongly downfield-shifted signal yet observed for an N···H···N hydrogen bridge. **37** similarly forms **37a**-perchlorate, for which the absorption of the hydrogen bridge proton is observed at $\delta = 19.34$ (in DMSO).

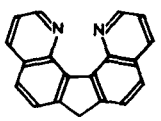


35a

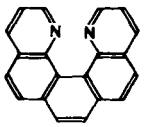


38a

On the basis of transprotonation experiments of **35** with **4a** and of **35a** with **4** the pK_a-value of **35** was estimated by proton NMR spectroscopy (500 MHz, [D$_6$]DMSO) to be ca. 12.8. Thus the basicity of **35** is increased by nearly eight powers of ten compared to that of quinoline ($pK_a = 4.91$), slightly exceeding the increase in basicity of **4** compared with *N,N*-dimethylaniline (cf. Section 1). Thus, the hydrophobic shielding of the N···H···N hydrogen bridge apparently plays no part in determining the high thermodynamic basicity of the "proton sponge" compounds. It does, however, have a great influence on the kinetics of proton transfer: ^{1}H-NMR spectra of mixtures of **35** and **35a** in [D$_6$]DMSO at room temperature already show coalesced signals for the different groups of protons at mean values corresponding to the ratio **35/35a**, so that in contrast to the other types of "proton sponge" discussed above the proton exchange between **35** and **35a** is apparently fast. These results show that according to the "proton sponge" concept not only strong but also kinetically active bases are available when the hydrophobic shielding of the basic centers and the N···H···N hydrogen bridge are avoided. Compounds such as **39** and **40**, the syntheses of which are at present in progress,[52] are of interest since the basicity of **39** at least is expected to be greater than that of **35**.



39



40

9. Future Prospects

The present report on "proton sponge" compounds should make it clear that we are dealing here with a fascinating group of compounds which is of interest not only because of the unusual basicity of its members: it is in fact the combination of the basic properties with steric structural factors and the question of the optimum geometry of hydrogen bridges which makes this area of chemistry so intriguing for us.

In this report we have concentrated on work which has been done in our own group in Heidelberg and have drawn thematic boundaries by restricting ourselves to *aromatic* diamines. Although we are also working in the interesting area of the *mono-* and *bi*cyclic *aliphatic* diamines[29] we have excluded these from the present report, since reviews on this area already exist, even if they are somewhat dated.[53]

Peculiar properties, such as those discussed above which result from steric interactions between basic centers, are certainly also of importance outside the narrow area of the compounds discussed here.[54] We consider them to be examples of cooperative spatial interactions between reactive structural elements which can lead to unusual and gradually varying properties which could not be expected from an isolated treatment of the various functional groups. Such "proximity effects" are indeed of greater importance in chemistry and biochemistry than is reflected by the amount of work so far put into their systematic study.

We thank Dr. Marina Rentzea, Claus Krieger, Dr. Matthias Höne, Dr. Wolfgang Brox, Dipl.-Chem. Michael A. Zirnstein and Dipl.-Chem. Klaus Oberdorf for their engaged and very successful cooperation in dealing with the problems discussed here.

Atomic Motions in Molecular Crystals from Diffraction Measurements

By Jack D. Dunitz,* Emily F. Maverick,* and Kenneth N. Trueblood*

The information provided by modern crystal structure analyses is not limited to the atomic arrangement. It also includes, for each atom, a set of quantities known as anisotropic Gaussian displacement parameters (ADP's), which provide information about averaged displacements of atoms from their mean positions. From analysis of these quantities, conclusions can be drawn about the rigid-body motion of molecules, about large-amplitude internal molecular motions, and about the identification of any disorder present in the crystals as being mainly dynamic or mainly static in nature. For some crystals, such analyses yield energy barriers to rotation of rigid molecules or molecular fragments that are in good agreement with values obtained by other physical methods.

1. What this Article Is About

The atoms in a crystal are not stationary; they move appreciably about their mean positions. From diffraction studies one obtains information not only about the mean atomic positions but also about the probability density functions of the individual atoms, a measure of their time-averaged displacements from their mean positions, averaged again over all the repeating units in the crystal. Both kinds of information are expressed in the innumerable pictures in the chemical and crystallographic literature where atoms are conventionally represented by "vibration ellipsoids".[1] From such pictures it is not difficult to recognize qualitative features of the atomic motions; in Figure 1, for example, it is apparent that the atoms vibrate preferentially in definite directions and by different amounts. Analysis of the numerical parameters on which such pictures are based often makes it possible to obtain quantitative information about the rigidity of molecules in crystals, about the nature and degree of rigid-body molecular motions, and even about internal motions of supposedly rigid fragments in nonrigid molecules. With the aid of a few rather simple additional assumptions, it is then in principle possible to derive quantities such as force constants or rotation barriers that are normally associated with the realm of spectroscopic methods. The purpose of this article is to describe to chemists and other scientists what can be learned about atomic motions in crystals from the interpretation of diffraction data.

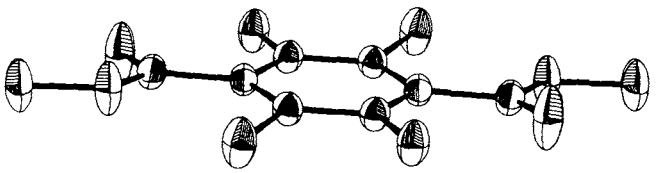

Fig. 1. Vibration ellipsoids for all atoms except hydrogens in the molecule of dimethyl 3,6-dichloro-2,5-dihydroxyterephthalate (see formula **3** in Section 6).

2. Preliminaries

In most modern X-ray or neutron crystallographic studies of small-molecule structures, it is assumed that the probability density function (pdf) of each individual atom can be represented by a Gaussian. In one dimension, this would be Equation (1), where u^2 is the second moment

$$D(x)=(2\pi u^2)^{-1/2}\exp(-x^2/2u^2) \quad (1)$$

(sometimes known as the variance or dispersion) of the pdf. In three dimensions, the corresponding equation looks more complicated, but it is exactly analogous [Eq. (2)]. Here $\boldsymbol{x}$ is now a vector with three components

$$D(\boldsymbol{x})=(2\pi)^{-3/2}(\det \boldsymbol{U}^{-1})^{1/2}\exp(-\boldsymbol{x}^{\mathrm{T}}\boldsymbol{U}^{-1}\boldsymbol{x}/2) \quad (2)$$

(x_1, x_2, x_3), and $\boldsymbol{U}^{-1}$ is the inverse of the symmetric second-moment matrix $\boldsymbol{U}$. The equiprobability surfaces of this pdf are ellipsoids, and its second moment in an arbitrary direction defined by a unit vector $\boldsymbol{n}(n_1, n_2, n_3)$ is $u^2=\boldsymbol{n}^{\mathrm{T}}\boldsymbol{U}\boldsymbol{n}$, corresponding to the mean-square displacement amplitude (MSDA) in that direction.[2] It must be emphasized that these pdf's are *not* the functions that describe the electron density of the stationary atoms; rather, they approximate the ways in which these electron densities are further spread out (Fig. 2) by the diffuseness in the nuclear positions resulting from lack of perfect periodicity in the crystal. In the real crystal, the atoms are vibrating about their equilibrium positions (dynamic disorder), and they may also be distributed at random over different sets of equilibrium positions from one unit cell to another (static disorder). The pdf's approximate the distributions obtained by averaging the instantaneous atomic positions over time and over all unit cells in the crystal.

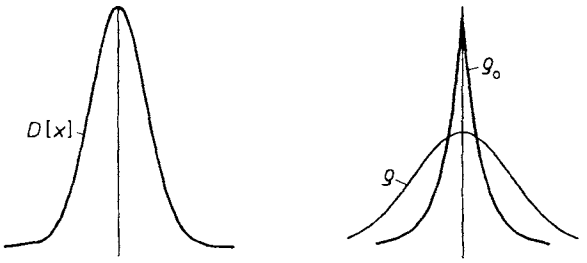

Fig. 2. The one-dimensional electron-density distribution $\rho(x)$ is the convolution of the static density $\rho_0(x)$ with the probability distribution function $D(x)$. The second moment of $D(x)$ (u^2) corresponds to the MSDA of the atom from its average position.

The scattering power (or form factor) of a stationary atom is given by the Fourier transform of its electron density distribution. For a vibrating atom, this form factor has to be multiplied by the Fourier transform of the corresponding pdf. One advantage of the Gaussian description is that the Fourier transform of a Gaussian is also a Gaussian. In three dimensions, this is given by Equation (3),

$$T(\boldsymbol{h}) = \exp(-2\pi^2 \boldsymbol{h}^T \boldsymbol{U} \boldsymbol{h}) \tag{3}$$

where $\boldsymbol{h}(h_1, h_2, h_3)$ is the scattering vector (of length $2\sin\theta/\lambda$) and $\boldsymbol{U}$ is the second-moment matrix mentioned. The quantity $T(\boldsymbol{h})$ is traditionally known as the "temperature factor", here the *anisotropic* temperature factor since it has different values in different directions. It may, or it may not, however, have anything to do with the temperature; it will, if the pdf associated with $\boldsymbol{U}$ is due mainly to dynamic disorder. On the other hand, if the pdf is due mainly to static disorder, some components of $\boldsymbol{U}$ will show little or no temperature dependence.

The components of $\boldsymbol{U}$ (in general, six for each atom) are usually included as parameters, together with the atomic positional parameters, in the least-squares refinement stages of a crystal structure analysis. They have sometimes been called "vibration parameters" and sometimes "thermal parameters", but we prefer a description that is more neutral concerning the possible physical significance of these quantities; we shall therefore refer to them simply as anisotropic displacement parameters (ADP's). Isotropic, one-parameter pdf's are usually assumed in X-ray analysis for hydrogen atoms, and sometimes also for other light atoms in the presence of heavy ones. This is not because the corresponding motions are thought to be really isotropic, but rather because the weak relative scattering power of these atoms calls for extreme economy in the number of parameters involved in the description of their pdf's.

For organic crystals at room temperature, typical MSDA's are around 500 to 1000 pm^2, corresponding to root-mean-square (rms) displacement amplitudes in the range 25 to 30 pm. At 100 K the MSDA's would be reduced to about a third of their room-temperature values. Nominal standard deviations in atomic positions obtained from carefully measured diffraction data are often 1 pm or less. Thus the breadth of an atomic pdf (the rms displacement) is many times larger than the uncertainty in the position of its centroid and is an appreciable fraction of a typical interatomic distance.

A Gaussian atomic pdf would correspond to motion of the atoms in a quadratic potential. In principle, the additional terms (higher cumulants) required for the description of non-Gaussian pdf's could also be determined by including appropriate parameters in the least-squares analysis. In addition to the six parameters describing the second moments, one might include ten cubic terms, fifteen quartic ones, and so on. The main problem is that these higher terms are only likely to be important when the second moments are large. However, the larger the second moments, the more rapidly the scattering from the atom in question falls off with scattering angle. Thus, it is just when the higher terms become important that they become virtually impossible to measure.

The "vibration ellipsoids" that adorn so many crystallographic publications are surfaces given by Equation (4)

$$\boldsymbol{x}^T \boldsymbol{U}^{-1} \boldsymbol{x} = \text{constant} \tag{4}$$

that enclose some specified probability (usually 50%). Although one can obtain a vivid impression of the directions and relative magnitudes of the atomic motions from the ellipsoids, a more quantitative interpretation requires a detailed analysis of the numbers from which they are obtained, the ADP's themselves.

3. Problems in the Interpretation of ADP's

Before we discuss the potentialities of ADP's for the study of atomic motion in crystals, we have to mention some difficulties. First, there is the problem that the ADP's associated with a given atomic center in a crystal structure refer to the motion of an *averaged* atom and not to the motion of any individual one. Thus, although a Gaussian pdf for an individual atom could be regarded as evidence for a harmonic potential for its motion, it is by no means obvious how far this would apply to the motion of the averaged one, where the averaging has been made over all the unit cells in the crystal. (There is a sense in which we can say that this averaged atom does not exist, any more than the average family with 1.743 children exists.) In the second place, the displacements of the individual atoms are highly correlated, and the ADP's provide no information whatsoever about the nature of these correlations; an important part of the information necessary to describe the atomic motions has therefore been lost. The assumption that particular groupings of atoms, e.g., molecules or molecular fragments, are rigid can be very helpful here. It is equivalent to assuming certain types of correlations involving amplitude and phase relationships among the atomic displacements, and we shall make considerable use of it. But even with this assumption, we still have to ignore all forms of correlation between the displacements of atoms belonging to neighboring molecules or between rigid groupings within the same molecule.

We can circumvent these problems to some extent by adopting what can be described as a mean-field model. We assume that the motion of a given atom (or molecule) in the crystal is governed by the effective potential imposed by its averaged environment. If a suitable force field is

available, this potential can be calculated by summing all relevant interatomic interactions, assuming one atom (or molecule) to be displaced while all neighboring atoms (or molecules) remain fixed in their average positions.[3] Although this model is vastly oversimplified, it nevertheless helps us to visualize important aspects of the real, more complex situation, and, as we shall see later, it often even leads to conclusions that agree remarkably well with the experimental observations.

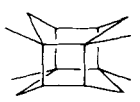
4. The Rigid-Body Model

Most interpretations of ADP's are based on the assumption that the crystal contains more-or-less rigid groupings of atoms. Except for certain kinds of constrained refinement, the U^{ij} parameters, the components of the atomic $\boldsymbol{U}$ matrices, are treated as independent variables. However, it is clear that for a perfectly rigid molecule of known geometry, the values of these U^{ij} parameters would be completely determined by the molecular translational and librational oscillations—under the given conditions, they are the only types of motion possible. Even if the molecule is not perfectly rigid, the amplitudes of the individual atomic motions resulting from its internal vibrations can generally be expected to be much smaller than those from its overall translational and rotational motions. It is therefore often reasonable to use the rigid-body model, at least as a first approximation, and attempt to fit the parameters that describe its translational and rotational motions to the observed U^{ij} values. To describe the translational motion we need six numbers, the components $\langle t^i t^j \rangle$ of a symmetric matrix $\boldsymbol{T}$, analogous to $\boldsymbol{U}$ but now referring to the molecule as a whole. The translational contribution to the ADP's is necessarily the same for all the atoms in the rigid body. The librational motion is more complicated, but it can also be described by the components $\langle \lambda^i \lambda^j \rangle$ of a symmetric matrix $\boldsymbol{L}$. The fitting of the components of $\boldsymbol{T}$ and $\boldsymbol{L}$ to the observed atomic U^{ij} values can be accomplished by a straightforward linear least-squares procedure.

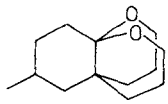
The pioneering work in this direction was done more than thirty years ago by *Cruickshank*[4] who showed how the room-temperature ADP's of the individual carbon atoms in anthracene[5] and naphthalene[6] could be analyzed in terms of the overall molecular translational and librational oscillations. Within rather large experimental uncertainty (the data were decidedly poor by present-day standards), the principal axes of the motion were found to coincide with the principal inertial axes of the molecule. Both the largest translational vibration (mean-square amplitude $\langle t^2 \rangle$ ca. 380 pm^2) and the major librational axis ($\langle \lambda^2 \rangle$ ca. 15(°)^2) were found to be roughly parallel to the long axis of the molecule, as seems reasonable.

Cruickshank assumed that the librational axes intersect at a point (for anthracene and naphthalene, the molecular center of symmetry). However, unless such a molecular center is imposed by the space-group symmetry, there is no reason to suppose that the molecular libration axes intersect at all. The more general case, analyzed in detail by *Schomaker* and *Trueblood*,[7] requires additional parameters to allow for the quadratic correlation between the pure translational and pure librational motions—the most general motion of a rigid body is rotation about an axis, coupled with a translation parallel to this axis, a screw rotation. The additional parameters, nine in number, are of the type $\langle \lambda^i t^j \rangle$ and form the elements of a new matrix $\boldsymbol{S}$, which is unsymmetrical, since $\langle \lambda^i t^j \rangle$ is different from $\langle \lambda^j t^i \rangle$. In the general case, the elements of $\boldsymbol{T}$, $\boldsymbol{L}$, and $\boldsymbol{S}$ can be found by a linear least-squares fit to the observed ADP's, except that the diagonal elements of $\boldsymbol{S}$ cannot be determined completely in this way; only their differences can be obtained. In the computer program THMA[8] (several versions abroad, the latest available being THMA11[9]), the sum of the diagonal elements is arbitrarily set to zero. Except for very small molecules, the minimum of 20 independent U^{ij} values required to fix the 20 determinable elements of $\boldsymbol{T}$, $\boldsymbol{L}$, and $\boldsymbol{S}$, is usually comfortably exceeded. However, there are a few special cases where the least-squares equations may be ill-conditioned because of the particular geometrical arrangement of the atoms.

During the last thirty years, the rigid-body model has been applied, often rather indiscriminately, to the analysis of ADP's from thousands of crystal structures. Where the assumption of reasonable molecular rigidity seems justified, e.g., carbon skeletons of polycyclic molecules, the model usually gives a very good account of itself. For example, applied to the centrosymmetric isomer of tetramethyltetraasterane **1**[10] or to the tricyclic ketal **2** at 96 K,[11] the rigid-body analysis yields calculated ADP's in almost perfect agreement with the observed values.



1



2

Another way of assessing the physical significance of the quantities derived from the rigid-body analysis is to compare them with results of a calculation. In principle, given the equilibrium positions of the atoms in a crystal, together with a suitable set of atom–atom potentials, the elements of the $\boldsymbol{T}$, $\boldsymbol{L}$, and $\boldsymbol{S}$ matrices for the oscillatory motions of rigid molecules can be obtained from lattice-dynamical calculations. These are basically similar to the type of calculation employed to obtain the vibrational frequencies and normal vibrations of free molecules, but involve infinite, periodic arrays of molecules. For crystals of several aromatic hydrocarbons (e.g., benzene, naphthalene, anthracene, pyrene)[12] the matrices calculated by lattice dynamics are in at least fair agreement with those obtained by analysis of the experimental ADP's, even when the latter were not of the highest quality. This serves to show that, whatever uncertainties there may be in the interpretation of these quantities, they cannot be entirely devoid of physical significance.

5. The Rigid-Molecule and Rigid-Bond Tests

For a perfectly rigid molecule, the interatomic distances do not change by definition, no matter how the individual atoms may move when the molecule is translated or rotated. Furthermore, because the individual atoms necessar-

ily move in phase, the mean-square displacement amplitudes (MSDA's) for every pair of atoms A, B must be equal along the interatomic direction [Eq. (5)], where $\boldsymbol{n}$ is the unit

$$\Delta_{A,B} = u_A^2 - u_B^2 = \boldsymbol{n}^T \boldsymbol{U}_A \boldsymbol{n} - \boldsymbol{n}^T \boldsymbol{U}_B \boldsymbol{n} = 0 \quad (5)$$

vector in the A,B direction. Note that the converse does not necessarily hold; for example, $\Delta_{A,B}$ will not differ appreciably from zero for planar or linear molecules with modest vibrations perpendicular to the molecular plane or line. Nevertheless, Equation (5) provides a simple method of testing whether the ADP's obtained for a given molecule are compatible with the rigid-body model.[13] It is also often useful as a test of the overall quality of the ADP's. Bond-stretching vibrations are generally of much smaller amplitude than other kinds of internal motion; for pairs of bonded atoms, therefore, the Δ's should be small, according to *Hirshfeld*,[14] not greater than 10 pm^2 for typical bonds in organic molecules, such as C–C, C–N, and C–O, but excluding bonds involving hydrogen atoms. Thus, if the Δ's for the bonds in an organic molecule are appreciably larger than 10 pm^2, there is ground for suspicion that the ADP's are not of the highest quality.

Mere inspection of the matrix of $\Delta_{A,B}$ values can often reveal relative motion of more or less rigid subgroups in a nonrigid molecule. Within the subgroups, the Δ values should not differ significantly from zero, while relative motion of the subgroups will be manifested by much larger deviations of some of the intergroup Δ's. Table 1 shows Δ values obtained by X-ray analysis for the triphenylphosphine oxide[*] molecule in its orthorhombic crystal modification at 100 K.[15] The triangles labeled A, B, and C contain Δ values for the three phenyl rings (Fig. 3); the three rectangular blocks AB, AC, and BC contain Δ values for pairs of atoms belonging to different rings. The estimated standard deviation (esd) of these Δ values is about 7 pm^2, and the root-mean-square (rms) Δ values for the three individual rings are 11, 6, and 8 pm^2, respectively. Thus, each ring is essentially rigid (ignoring any out-of-plane deformations, which would not be revealed by this test). On the other hand, there is clear evidence of significant motion of the rings *relative* to one another, especially of ring A relative to rings B and C; the rms Δ values for blocks AB and AC are four to five times as large as those within the rings. A calculation of the torsional librational amplitude of each ring about its P–C bond (see Section 6) is consistent with these qualitative conclusions; ring A shows a mean-square libration amplitude of 42(°)^2, almost an order of magnitude larger than those of rings B and C. With data taken at 150 K for the same crystal, the picture is qualitatively similar, the Δ values and mean-square libration amplitudes

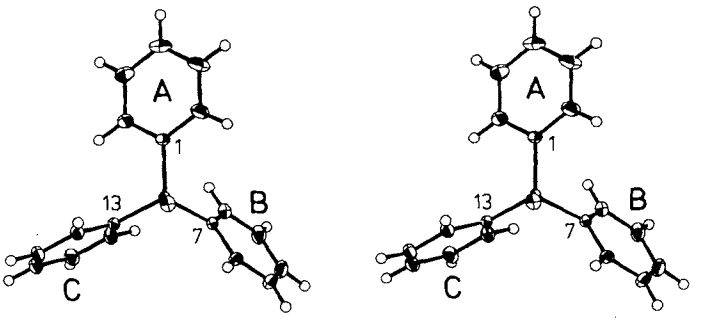


Fig. 3. Stereoview of triphenylphosphine oxide molecule. The rings A, B, and C, attached to the phosphorus at atoms 1, 7, and 13 respectively, correspond to the triangular blocks in Table 1.

[*] Note added by the editorial staff: Since the *systematic* name of PH_3 is phosphane according to IUPAC rule 2.3 (inorganic nomenclature) and IUPAC rule D-5.11 + footnote (organic nomenclature), the editorial staff prefers the use of the -ane nomenclature but has allowed the use of the name triphenylphosphine oxide for Ph_3PO at the authors' request. Indeed, rule 2.3 permits the use of phosphine as an alternative while rule D-5.11 retains only this trivial name.

Table 1. Matrix of Δ values [pm^2] for triphenylphosphine oxide at 100 K. For atom numbering see Figure 3. Positive Δ's mean that the MSDA along the interatomic vector $\overrightarrow{A_1A_2}$ is larger for A_2 than for A_1; negative Δ's mean the reverse.

being about 50% larger, as expected for the higher temperature.

Our second example involves an internal motion that can be identified as incipient inversion of the pyramidal amino nitrogen atom in the [3.1.1]propellane derivative shown in Figure 4. The Δ values obtained from an X-ray analysis at 95 K[16] are shown in Table 2 and have esd's of about 7 pm^2 for all bonded pairs and only 6 pm^2 for *all* $15 \times 14/2$ atom pairs of the hexacyclic skeleton (the atoms C1–C14 and N in Figure 4), an indication of how remarkably rigid most of this molecule is. Inspection of Table 2 shows that all Δ values larger than 18 pm^2 involve the *N*-methyl carbon atom (C17); the four largest (25–39 pm^2) are for the vectors between this atom and the phenyl carbons C11–C14. The signs of these four largest Δ's in the column headed C17 are all positive, indicating that this atom has a perceptible motion relative to the others. The pattern of Δ's indicates that the excess motion of C17 is almost normal to the N–C17 bond and in the molecular mirror plane, that is, along the path that would ultimately lead to inversion at the nitrogen atom. (This direction of motion is indeed suggested by the ellipsoid of C17 in Figure 4, but the effect is shown more convincingly by the Δ's in Table 1[17]).

Because of the ever-present internal molecular vibrations, the rigid-body model can be expected to apply tolerably well only for groupings composed of atoms of comparable mass. In organic molecules, the hydrogen atoms are expected to have quite substantial motions relative to the carbon skeleton; consequently, they have to be excluded from the scope of a rigid-body model calculation, or else their ADP's have to be corrected for the effect of the internal vibrations. The best way of making such corrections would be on the basis of a complete normal-mode calculation for the molecule in question, but this is seldom possible.

The Δ matrix calculated from the ADP's taken from a very recent, highly accurate neutron-diffraction study of perdeuterobenzene at 15 K[18] clearly shows the relative motion of the deuterium atoms in the molecular plane (Table 3a). At this temperature we are seeing mainly the zero-point motion. Fortunately, a complete normal-mode calculation has been made for benzene.[19] When the calculated zero-point vibration amplitudes for the molecule are subtracted from the observed U^{ij} values (expressed in an appropriate molecular coordinate system), the corrected Δ matrix (Table 3b) is essentially that expected for a rigid body.

The zero-point vibration amplitude of an atom depends on its mass and should therefore be sensitive to isotopic substitution.[20] The mass effect is largest for the isotopes of hydrogen. From *Johnson*'s values for the internal vibration amplitudes of the atoms in the benzene molecule,[21] the difference between the MSDA's of protium and deuterium can be estimated to be about 16, 36, and 60 pm^2 in the radial, tangential, and perpendicular directions, respectively. The difference in the spherically averaged MSDA's is thus about 37 pm^2.

Although the X-ray scattering powers of different isotopes are identical, we can consider the possibility of distinguishing between protium and deuterium by X-ray analysis on the basis of the difference in their MSDA's. (This distinction is no problem for neutron diffraction, where the scattering power depends on the nuclear structure and is very different for different isotopes.) An attempt in this direction has been carried out for isotopically labeled (2*S*)-malic acid obtained by enzymatic addition of D_2O to fumaric acid. From parallel X-ray analyses of the monoammonium salts of the unlabeled and labeled acids at 93 K,[22] the isotropic MSDA of one of the two methylene hydrogen atoms was found to decrease by about 40 pm^2 (as expected for the switch from protium to deuterium), while the other hardly changed. The configuration of the malate was thereby indicated as (2*S*,3*R*). Since the esd's of the hydrogen MSDA's in this experiment were about 20 pm^2, the statistical significance of the result is certainly not overwhelming. Nevertheless, it was encouraging that the relative configuration indicated by the X-ray experiment was in agreement with that established by other methods (including neutron diffraction of the corresponding phenylethylammonium salt[23]). At any rate, the experiment shows that the use of X-ray diffraction for distinguishing between deuterium and protium should not be dismissed, especially in cases where a neutron-diffraction analysis seems impracticable.

In coordination complexes where the ligand atoms may have an appreciably smaller mass than the metal atom to which they are bonded, the Hirshfeld rigid-bond postulate is again to be interpreted in a somewhat relaxed form; for such ligand–metal bonds, Δ values of the order of 30 pm^2 are to be expected (the MSDA of the lighter atom being the larger). Gross violations of this less stringent test have been exploited to detect spin crossover in crystalline $[Fe^{III}(S_2CNR_2)_3]$ complexes[24] and to estimate the magnitude of dynamic Jahn–Teller distortions in crystals of Cu^{II} and Mn^{III} complexes.[25] For example, for five octahedral $[Cu^{II}L_6]$ complexes expected to show dynamic distortion the average Δ along the Cu–L direction was 210 pm^2, whereas for analogous $[Ni^{II}L_6]$ complexes the average was 25 pm^2. The larger value in the Cu complexes is satisfactorily explained in terms of a statistical distribution of distorted octahedra, each having four short Cu–L bonds of 205 pm and two long ones of 233 pm.

The spin-crossover analysis[24] contains an interesting correlation of Δ values against bond distance. The Fe–S distance is about 230 pm^2 in low-spin $[Fe^{III}(S_2CNR_2)_3]$ complexes and about 245 pm^2 in high-spin ones. For a sample of more than 30 crystal structure analyses, it was noticed that complexes with Fe–S distances close to these extreme values had relatively small Δ(Fe–S) values (ca. 20–30 pm^2), whereas intermediate Fe–S distances were associated with Δ(Fe–S) values of up to 100 pm^2. Indeed, the Δ(Fe–S) versus d(Fe–S) plot was an approximately parabolic curve with its maximum Δ at an Fe–S distance of about 238 pm. These observations can be explained by assuming that for the intermediate range of Fe–S distances, the crystals contain disordered arrangements of molecules in both spin states. For fraction p of the molecules in the low-spin state, and fraction $(1-p)$ in the high-spin one, the apparent Fe–S distance (in pm) would be approximately $230p+245(1-p)$ and it would be associated with a Δ value (in pm^2) of approximately $(15)^2p(1-p)$ over and above the "normal" Δ(Fe–S) value. This is roughly what was found.

6. Internal Molecular Motion in Crystals

Breakdown of the rigid-body model for molecules in crystals may be evident from a casual glance at the displacement ellipsoids (Fig. 1) or from inspection of the matrix of Δ values (Tables 1–3). In general, for free molecules, vibrations involving mainly torsional motions have lower frequencies (and larger amplitudes) than those involving changes in bond distances and angles. For molecules in a crystal, internal and external modes of motion will be strongly coupled, so that no rigorous separation is possible. Nevertheless, as we saw in Section 5, internal motions estimated for free perdeuterobenzene, subtracted from the raw ADP's, were quite adequate to correct for the effect of internal motions in the crystal.

For more flexible molecules with reasonably large-amplitude torsional motions of semirigid groups (e.g., triphenylphosphine oxide, Fig. 3, Table 1), the magnitudes of such motions can be estimated by a slight modification of the usual ***T***, ***L***, ***S*** analysis. In the simplest version, due to *Dunitz* and *White*,[26] an additional parameter, $\langle\phi^2\rangle$, a mean-square torsional amplitude, is added for each group suspected of undergoing appreciable torsional motion. In this approach, the torsional axis needs to be specified in advance, the group undergoing the torsional motion is assumed to be rigid, and all correlations between the internal motion and the overall motion are neglected.

In spite of its simplicity, the Dunitz–White model has been shown to yield essentially the same $\langle\phi^2\rangle$ values as those derived from more elaborate models for the internal molecular motion.[8] Nevertheless, there are problems that cannot be ignored.

First, there is the problem of specifying the correct kind of internal motion to be included in the model. There is no rigorous way to do this, as all information about the relative motions of the different atoms has been lost. Chemical experience and intuition may be valuable guides here, but they can also occasionally lead us astray. A poor guess about the nature of the internal motion is sometimes detectable in that it leads to a $\langle\phi^2\rangle$ value not significantly different from zero, or to a physically unreasonable result, for example, a negative value of $\langle\phi^2\rangle$. Moreover, the impossibility of distinguishing between types of internal molecular motion that differ only with respect to the relative phases of the atomic displacements leads to unavoidable ambigui-

ties. The torsional and out-of-plane bending motions of a nitro group provide us with an example (Fig. 5). In the torsional motion of such a group about the ONO bisector, the two oxygen atoms move by equal amounts in opposite directions. In the corresponding out-of-plane bending distortion (which may be simulated by torsion about an axis perpendicular to the ONO bisector and in the plane of the group), the two oxygen atoms move by equal amounts but in the same direction. From the ADP's alone, we cannot distinguish between these two types of motion.

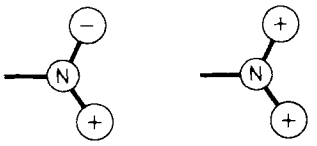

Fig. 5. Rotation (left) and out-of-plane bending (right) of the nitro group differ only in the relative signs (or phases) associated with the displacements of the oxygen atoms (see text).

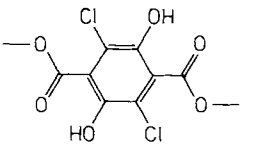
A second problem concerns the total disregard in the Dunitz–White model of the correlations among the different types of motion. Just as, in the rigid-body model, the components of the S matrix were needed to allow for the quadratic correlation between the pure translational and pure librational motions, so similar terms are called for to allow for the analogous correlations among different types of internal motion and between them and the overall translations and rotations. It is not always easy to decide in advance whether these correlation terms are important or not; in the computer program THMA11,[8,27] they can be included if the nature of the problem seems to make this desirable. Correlations between motions of groups that have no atom in common cannot be determined from the U^{ij}'s.

Even when the extra correlation terms are included in the least-squares fitting, an unavoidable indeterminacy remains concerning the value of $\langle\phi\lambda^{\parallel}\rangle$, where $\lambda^{\parallel}$ denotes the overall libration about an axis parallel to the internal torsion axis. A mathematical analysis, not given here,[27] shows that only $\langle(\lambda^{\parallel})^2\rangle$ and the sum $\langle\phi^2\rangle+2\langle\phi\lambda^{\parallel}\rangle$ can be determined from the U^{ij}'s. This means that when $\langle\phi^2\rangle$ is determined by the Dunitz–White method, the value is only meaningful when it is very large compared with the parallel component of L. Since, usually, we are interested in the internal molecular motions only when they do have fairly large amplitudes, this restriction is often fairly innocuous. Similarly, when the quantity $\langle\phi^2\rangle+2\langle\phi\lambda^{\parallel}\rangle$, as obtained in the model including correlation, is large compared with the parallel component of L, it may be regarded as a good approximation to $\langle\phi^2\rangle$ itself.

Correlations between internal and overall molecular motions can sometimes be important. In one of the three known crystal modifications of dimethyl 3,6-dichloro-2,5-dihydroxyterephthalate **3**, the torsional motion of the carboxyl groups about the exocyclic C–C bonds is extremely large ($\langle\phi^2\rangle\approx 150(^\circ)^2$ at room temperature), corresponding to rms displacements of the carboxyl oxygen atoms of about 25 pm from the mean molecular plane.[28] (This is the molecule illustrated in Figure 1 with its vibration ellipsoids). The molecular libration axes in the molecular plane also produce displacements of these oxygen atoms perpendicular to this plane (Fig. 6). As mentioned above, correlation of the torsion with the parallel libration axis is indeterminate, but correlation with the perpendicular libration axis adds to the out-of-plane displacement of one of the two oxygen atoms and subtracts from the other, leading to unequal rms displacements, as observed in the crystal structure analysis. The introduction of these correlation terms into the internal motion analysis gave a dramatic improvement in the agreement between observed and calculated U^{ij}'s, the R factor[29] decreasing by a factor of 4, from 0.126 to 0.032.



3

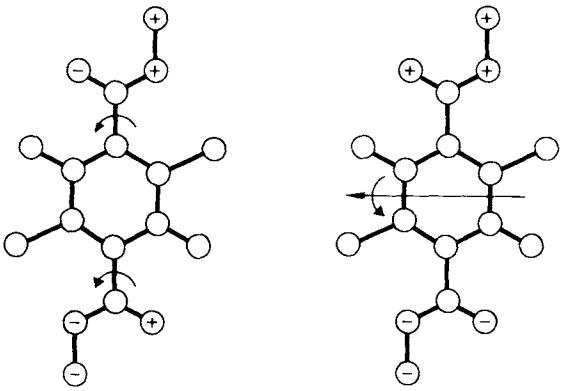


Fig. 6. Torsional rotation of the carboxyl group about the exocyclic C–C bond (left) and libration of the entire molecule about the horizontal axis (right) lead to different relative out-of-plane displacements of the carboxyl oxygen atoms.

7. Relations between Mean-Square Amplitudes and Potential Energy

For a particle in a one-dimensional quadratic potential, $V(x)=fx^2/2$, the classical Boltzmann distribution of displacements from equilibrium is given by Equation (6),

$$p(x)=(2\pi kT/f)^{-1/2}\exp(-fx^2/2kT) \tag{6}$$

which can be recognized as a Gaussian with second moment $\langle x^2\rangle$ given by Equation (7). For many crystals, the sec-

$$\langle x^2\rangle = kT/f \tag{7}$$

ond moments of the atomic pdf's are indeed approximately proportional to the absolute temperature over a considerable range. At sufficiently low and sufficiently high temperatures, however, deviations from this linear dependence are to be expected. At 0 K, it would lead to a zero value of $\langle x^2\rangle$, i.e., to an infinitely sharp pdf, in contradiction to the uncertainty principle. The classical Boltzmann averaging is clearly invalid here. When the averaging is made over the energy levels of a quantized harmonic os-

cillator, the expression for the second moment of the distribution is given by Equation (8), where ν is the frequency

$$\langle x^2 \rangle = (h/8\pi^2\mu\nu)\coth(h\nu/2kT) \quad (8)$$

and μ the reduced mass (or, for a rotational oscillation, the moment of inertia, I). For $h\nu \gg 2kT$, the coth factor is unity, and the expression reduces to Equation (9), corresponding to the zero-point motion. On the other hand, for $h\nu \ll 2kT$, the coth factor becomes $2kT/h\nu$, leading back to the same linear dependence of $\langle x^2 \rangle$ on T as was obtained with the classical Boltzmann averaging (with f set equal to $4\pi^2\mu\nu^2$). The temperature dependence of $\langle x^2 \rangle$, as given by Equations (7) and (8), is shown in Figure 7.

$$\langle x^2 \rangle = h/8\pi^2\mu\nu \quad (9)$$

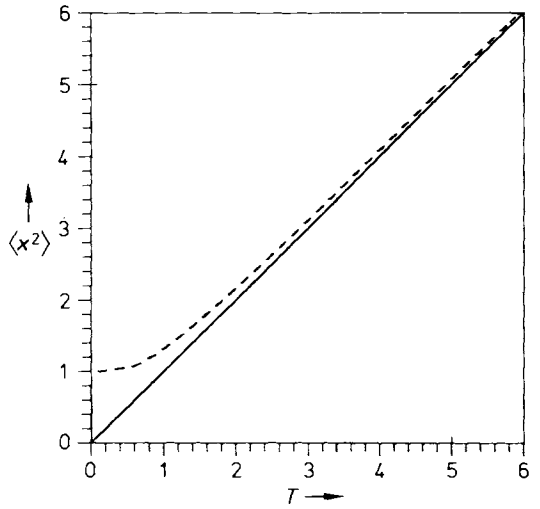

Fig. 7. Variation of MSDA $\langle x^2 \rangle$ (in units of $h/8\pi^2\mu\nu$) with temperature (in units of $h\nu/2k$) for a one-dimensional harmonic oscillator. The linear dependence depicted by the full line is based on the assumption of a classical Boltzmann distribution, while the dashed curve corresponds to a quantized distribution.

For many crystals, the effective mean-field potential in which the atoms move seems to be reasonably quadratic, as judged by the observed temperature dependence of the ADP's or of quantities derived from them, such as $\boldsymbol{T}$ and $\boldsymbol{L}$ components. A fairly thorough study has been made for naphthalene.[30] The main deviation from the behavior expected for a quadratic potential is that experimental ADP's tend to increase with temperature rather more steeply than implied by the linear dependence. This can be explained as a consequence of the general softening of the effective potential as the crystal expands on warming. In a more realistic model—the quasi-harmonic model[31]—the effective force constant of Equation (7) is *not* constant but decreases with increasing temperature. For a diverse set of inorganic solids, the ADP's are found to be approximately proportional to $T^{1.5}$,[32] and a similar relationship has been shown to hold for lithium hydrogen phthalate monohydrate,[33] with ADP's estimated by neutron diffraction at 15, 100, and 298 K.

As mentioned earlier in Section 3, the experimental ADP's refer to the motion of an averaged atom or molecule. From experimental values of $\langle x^2 \rangle$ and a knowledge of the temperatures at which they were measured, Equations (7) or (8) provide estimates of effective quadratic force constants (or frequencies) for the mean-field motions in question. The mean-field potential associated with a given type of motion can be obtained, at least conceptually, by following the potential energy variation when one atom (or molecule) is gradually displaced from its equilibrium position or orientation, all neighboring atoms (or molecules) being held in their equilibrium positions. This is an oversimplified picture. A more realistic model should contain some means of allowing for the ways in which the instantaneous displacements of different atoms (or molecules) are correlated. This is achievable from a complete lattice-dynamical treatment, but only at the cost of considerable additional mathematical complexity and loss of conceptual simplicity. In lattice dynamics,[34] a suitable force field is used to solve the equations of motion for the whole periodic ensemble of molecules that constitute the crystal structure. The calculation yields the frequencies of all the normal modes of vibration of the crystal. The MSDA's of the atoms (or molecules) are then obtained by summing contributions from these normal modes. For each type of motion, say, a molecular libration about a particular axis, characterized by a single frequency in the mean-field model, we now have a range of frequencies, a so-called branch of the frequency spectrum. However, the calculations show that the frequency dispersion within a given branch is usually not very large.

Thus, although the precise physical significance of the effective mean-field force constants and frequencies derived from Equations (7) and (8) may be open to question, the numerical values should generally not differ too much from analogous quantities that appear in more complete dynamical models. In fact, as shown in Table 4, experimental ADP's for a variety of librating rigid groups (such as methyl and *tert*-butyl) yield quadratic force constants and corresponding cosine-function rotation barriers (see Section 8) that are at least in the same range as those derived by other physical methods.[35]

Table 4. Some cosine-function torsional barriers derived from ADP's.

Group	Attached atom	Range of barriers [kJ mol^{-1}] From ADP's	Other methods [a]
CH_3	C, N (trigonally coordinated)	1.5–9.6	(s) 1.2–8.5
	C, N, P (tetrahedrally coordinated)	4–26	(g) 12–22
	O	1–9	CH_3OH (g) 4.5 other (s) 15–19
$NH_3^{\oplus}$	C	14–62 (well correlated with H-bonding)	
CF_3	C (trigonally coordinated)	4–10	(g) 4–7
	C (tetrahedrally coordinated)	9–66	(g) 13–25
$C(CH_3)_3$	C, N, P	7–112	(g) 2–27

[a] s = solid; g = gas.

8. Rotation Barriers in Crystals from ADP's

Consider an individual molecule in crystalline benzene. The molecule, assumed rigid for the moment, will oscillate about its mean orientation, and, as shown by NMR methods, will also from time to time carry out 60° rotational jumps that turn it from one orientation to an equivalent one. The energy barrier hindering such a rotation must have sixfold periodicity in the angular coordinate and, to a first approximation, it can be represented by Equation (10), where B is the barrier height per mole and $n=6$. For

$$V(\phi)=B(1-\cos n\phi)/2 \tag{10}$$

small excursions from the equilibrium orientation at $\phi=0°$, we have $\cos n\phi=1-n^2\phi^2/2$, and hence Equation (11). In this approximation, the potential energy is a quadratic function of ϕ. With the help of Equation (7), derived on the basis of a classical Boltzmann distribution, relationship (11) is converted into Equation (12), where ϕ^2 is replaced by its mean value. Thus, the barrier may be estimated from a knowledge of $\langle\phi^2\rangle$, which is obtainable from analysis of the ADP's. This is the approximation used by *Trueblood* and *Dunitz*[35] in the study leading to the results shown in Table 4; it is valid only when $\langle n^2\phi^2\rangle$ is much smaller than unity, i.e., when the barrier B is at least several times larger than RT.

$$V(\phi)=Bn^2\phi^2/4 \tag{11}$$

$$B=2RT/n^2\phi^2 \tag{12}$$

When this condition is not satisfied, $V(\phi)$ can no longer be approximated as a quadratic function and the probability distribution for ϕ is no longer Gaussian. By analogy with Equation (6), however, the dependence of this probability distribution on B/RT can be obtained from (13),

$$p(\phi)=N\exp\{-B(1-\cos n\phi)/2RT\} \tag{13}$$

where N is a normalization factor. This function is shown in Figure 8, where the gradual change from nearly Gaussian for $RT\ll B$ to nearly flat distribution for $RT>B$ is clearly seen.

A more accurate relationship giving $\langle\phi^2\rangle$ as a function of B and RT [Eq. (14)] is obtained by integrating the classical Boltzmann expression (13). Numerical integration of Equation (14) for various values of RT/B leads to the solutions shown graphically (for $n=5$) in Figure 9, where the linear dependence expected for the quadratic potential described by Equation (11) is also shown. At very low values of RT/B, the classical averaging leading to Figure 9 cannot be expected to hold. The value of $\langle\phi^2\rangle$ must then be estimated from an expression analogous to Equation (8), based on quantum mechanical averaging.

$$\langle\phi^2\rangle=\frac{\int\phi^2\exp\{-B(1-\cos n\phi)/2RT\}\,d\phi}{\int\exp\{-B(1-\cos n\phi)/2RT\}\,d\phi} \tag{14}$$

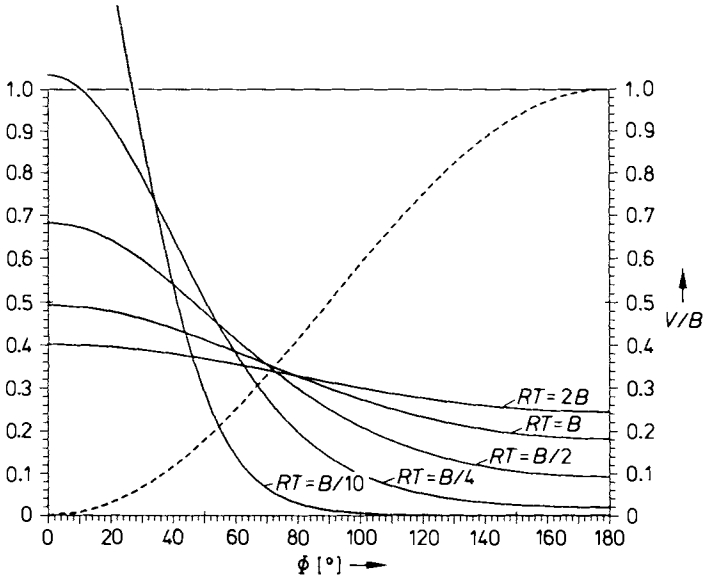

Fig. 8. One-dimensional probability distribution functions [Eq. (13)] for a sinusoidal potential (dashed curve) with barrier height B at various temperatures.

The estimation of a rotation barrier with the help of Figure 9 is quite simple. From an observed value of $\langle\phi^2\rangle$ for a given librating group in a crystal, one reads off the corresponding value of RT/B. A knowledge of the temperature T at which the measurement was carried out then leads directly to the barrier B.

The method has been applied[36] to a series of crystalline metallocenes, for which extensive diffraction data are available over a wide temperature range, and for which barriers for rotation of the cyclopentadienyl rings have also been estimated by NMR spectroscopy (mainly from ^1H spin-lattice relaxation times), by incoherent quasi-elastic neutron scattering (IQENS), and by Raman and IR

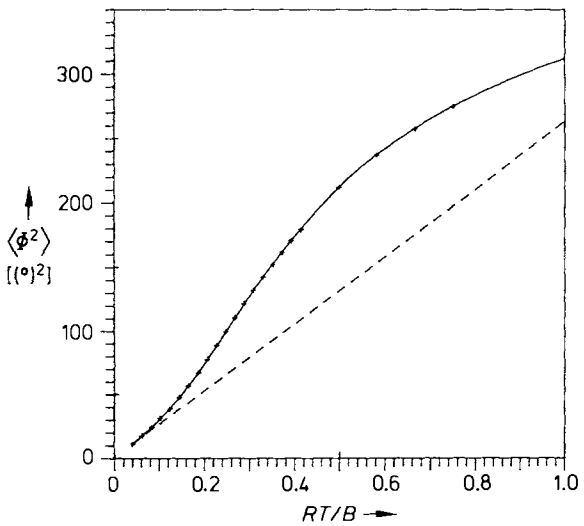

Fig. 9. Full curve: Variation of mean-square libration amplitude $\langle\phi^2\rangle$ with RT/B for a fivefold periodic sinusoidal restricting potential with barrier height B. Dashed curve: $\langle\phi^2\rangle$ for harmonic oscillator potential with the same quadratic force constant. At very low temperatures, both curves should run parallel to the horizontal axis at the nonzero value of $\langle\phi^2\rangle$ corresponding to the zero-point motion, as indicated in Figure 7.

spectroscopy. A comparison of the results obtained by the different methods is given in Table 5.

Table 5. Apparent barriers to ring rotation [kJ mol^{-1}] (esd's in parentheses) in crystalline metallocenes by various methods. (Diffraction results yield individual barriers for symmetry-independent rings at the measurement temperature.)

Compound	Diffraction			Other methods: NMR unless mentioned (see [36] for detailed references)
Ferrocene (triclinic)	101 K	123 K	148 K	
	7.6(7)	6.4(4)	5.9(5)	7.5(8); 10.3(5), 11(2); 8.3;
	12(2)	10.2(5)	10(2)	≈9 (IQENS)
	8.4(6)	6.8(7)	7.0(6)	
	9(2)	8.5(8)	8(1)	
Ferrocene (orthorhombic)		98 K		
		23(20)		24.8(1.0)
		33(16)		
Ferrocene (monoclinic)	173 K	293 K		
	2.7(5)	4.7(8)		5.4(5); 4.4(5) (IQENS)
Nickelocene (monoclinic)	101 K	293 K		
	6.5(6)	5.2(5)		5.0 (Raman); 6.3 (IQENS)
Ruthenocene (orthorhombic)	101 K	293 K		
	25(10)	24(7)		9.6(8); 18.9
	>50	38(13)		

The most extensive diffraction results[37] are for triclinic ferrocene, stable or at least metastable below 164 K. There are four symmetry-independent cyclopentadienyl rings, and the crystal structure was determined at three temperatures (101, 123, 148 K). Table 6 shows that the $\langle\phi^2\rangle$ values increase with temperature and also vary from ring to ring.

Table 6. Mean-square libration amplitudes $\langle\phi^2\rangle$ [(°)^2] (with esd's in parentheses) in crystalline metallocenes at various temperatures.

Compound	Triclinic			Orthorhombic			Monoclinic	
Ferrocene	101 K	123 K	148 K		98 K		173 K	293 K
ring 1A	35(4)	55(5)	78(8)	ring 1	9(7)		231(27)	220(30)
1B	20(4)	30(3)	37(5)	2	7(3)			
2A	31(3)	47(6)	63(6)					
2B	26(3)	38(5)	47(9)					
Nickelocene							101 K	293 K
							45(4)	199(18)
Ruthenocene					101 K	293 K		
				ring 1	9(3)	32(9)		
				2	2(2)	17(5)		

The first trend may be explained by the thermal expansion of the crystal, which will increase intermolecular distances and thus lower the intermolecular contribution to the barrier. The variation from ring to ring is also probably genuine, arising from differences in packing of the individual rings. This is supported by packing energy calculations,[38] using atom-atom potentials, which reproduce the general pattern.[39] From Table 5 it is seen that for triclinic ferrocene, the barrier heights derived from $\langle\phi^2\rangle$ values agree as well as can be expected with those from NMR and IQENS, considering that the latter values refer to averages over a considerable temperature range and that differences among the individual rings are not resolved by the spectroscopic methods.

In monoclinic ferrocene,[40] there is only one symmetry-independent cyclopentadienyl ring. Although the room-temperature result appears to agree well with the spectroscopic values, this is almost certainly fortuitous. From Table 6, it is seen that $\langle\phi^2\rangle$ for the monoclinic modification is virtually constant between 173 and 293 K, a strong indication of static disorder in the ring orientations. Indeed, both X-ray[42] and neutron diffraction[41] analyses have shown that the centrosymmetric, staggered arrangement of the cyclopentadienyl rings, which appears to be demanded by the space-group symmetry of monoclinic ferrocene,[42] is actually a result of static disorder. Since Figure 9 is based on the assumption that the $\langle\phi^2\rangle$ value in question is due to genuine librational motion and not to static disorder, little confidence can be placed in the barriers derived by this method for monoclinic ferrocene. Although a rotation barrier can be obtained from a $\langle\phi^2\rangle$ value at a single temperature, this example illustrates the advisability of multiple-temperature measurements, if only to detect the presence of disorder masquerading as vibration. For nickelocene, too, the good agreement indicated in Table 5 between the different methods should perhaps also be regarded with a certain reserve, as there are indications that an order-disorder phase change may possibly occur in this crystal at some intermediate temperature.

For orthorhombic ferrocene and ruthenocene, the low-temperature values of $\langle\phi^2\rangle$ are so small that they may be due mainly to zero-point motion, in which case the use of Figure 9 (based on classical averaging) to estimate the barriers may lead to inaccuracies. Besides, the low relative precision of $\langle\phi^2\rangle$ leads to further uncertainties in the derived values of the barriers. In view of these difficulties, the agreement (Table 5) between the barriers obtained from $\langle\phi^2\rangle$ and from spectroscopic methods seems eminently satisfactory.

The solid-state barriers are considerably larger than those found for the free molecules. In the gas phase, ferrocene is eclipsed, with a barrier to rotation of the cyclopentadienyl rings of about 3.8 kJ mol^{-1};[43] the barrier in nickelocene is probably still lower.[44] For free ruthenocene, no experimental value is available, but a theoretical study[45] suggests that the barrier is about 2 kJ mol^{-1} higher than that in ferrocene. The increase in the barriers in the solid state is due to intermolecular packing effects and is reproduced nicely by force-field calculations.[38]

The recent highly accurate neutron-diffraction study of crystalline perdeuterated benzene C_6D_6[18] offers another opportunity to test the $\langle\phi^2\rangle$ method of obtaining rotation barriers. Here the crystallographically imposed molecular symmetry is a center of inversion. For the libration of the molecule in its own plane, $\langle\phi^2\rangle$ is estimated to be 2.6(°)^2 at 15 K and 11.0(°)^2 at 123 K. The latter value corresponds to a sixfold rotation barrier of 17 kJ mol^{-1}, well within the range (16.5–18.4 kJ mol^{-1}) obtained by solid-state NMR measurements.[46] The barrier obtained from the 15 K analysis is only 8 kJ mol^{-1}, but here again the use of Figure 9

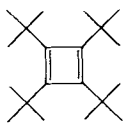
(adapted for $n=6$) is probably impermissible because of quantum effects at this low temperature; the 17 kJ mol^{-1} barrier would actually correspond to a zero-point libration of about $4(°)^2$, not too different from the observed $\langle\phi^2\rangle$ at 15 K.

It seems quite remarkable that barrier heights obtained from $\langle\phi^2\rangle$ values agree so well on the whole with those estimated by spectroscopic methods. After all, the underlying assumptions behind the two kinds of analysis are so very different. Spectroscopy provides frequencies, relaxation times, and correlation or residence times, which, in turn, can be used to yield rotation barriers by assuming an Arrhenius type of dependence of rate or time on temperature. Starting from $\langle\phi^2\rangle$, on the other hand, we use classical Boltzmann averaging for a cosine type potential (which can be, at best, the leading term in the Fourier expansion of the periodic potential) to estimate the barrier height at a given temperature. In a sense, one can say that spectroscopy sees the rate at which molecules cross the barrier, while diffraction sees the bottom of the potential well; we derive roughly the same barrier height as long as the potential is approximately sinusoidal. The two methods are thus nicely complementary for studies of molecular motion in the solid state.

9. Vibration or Static Disorder?

Among crystallographers, disorder is usually regarded as a nuisance, occasionally as an opportunity to test some potential improvement in refinement techniques, but only seldom as a phenomenon interesting in its own right. Yet disorder is ubiquitous, even in the "ordered" crystalline state, and the physical properties of solids usually depend just as much on the nature and number of the defects from the idealized, perfectly ordered, periodic structure, as on the structure itself. It also has to be admitted that, although diffraction methods are highly successful in establishing the averaged structure of the crystal unit cell, they have much less to say about the nature of the fluctuations from this averaged structure. This is because the influence of all types of disorder on the main Bragg reflections is summed up in the atomic pdf's. However, as we have seen, it is possible from temperature-dependence studies to distinguish disorder that is mainly dynamic (vibrational) from that which is mainly static in origin. Beyond that, the most we can do is to enquire whether a given set of atomic pdf's is compatible with a proposed disorder model or not. Such enquiries sometimes lead to interesting answers.

The room-temperature X-ray analysis of tetra-*tert*-butylcyclobutadiene **4**[47] led to a structure in which the sides of



4

the slightly nonplanar four-membered ring were almost equal (146.4 and 148.3 pm), in contrast to results for other cyclobutadiene derivatives where much larger differences (up to 26 pm) between the ring bonds were observed. *Ermer* and *Heilbronner*[48] proposed that the nearly square ring found at room temperature did not correspond to the actual molecular structure but to averaged atomic positions resulting from disorder among two rectangular structures. This was confirmed by a subsequent low-temperature analysis at 123 K,[49] where the ring bond lengths were found to differ significantly (144.1 and 152.7 pm), but still not as much as might have been expected. This raises the question whether residual disorder may not still be present at the lower temperature. To answer this, we can postulate a model, calculate a set of ADP's for it, and examine the pattern of discrepancies between the observed ADP's and those calculated for the model.

The crystallographically imposed molecular symmetry is here a C_2 axis (although the effective molecular symmetry in the crystal is D_2). An analysis of the ADP's in terms of the ***T,L,S*** model with allowance for internal libration of the two independent *tert*-butyl groups about the exocyclic C–C bonds[50] leads to $\langle\phi^2\rangle$ values of 14 and 23 $(°)^2$ for the two internal motions, several times larger than the overall molecular librations. Among the discrepancies between observed U^{ij} components and those calculated for this model, the excess apparent motion of the ring atoms in the tangential directions (by 51 and 31 pm^2 for the two symmetry-independent atoms) is striking and is in qualitative agreement with the disorder model proposed by *Ermer* and *Heilbronner*[48] (Fig. 10). In the crystal it is not necessary that the two perpendicular orientations of the rectangular ring have a common center, as shown in Figure 10, and,

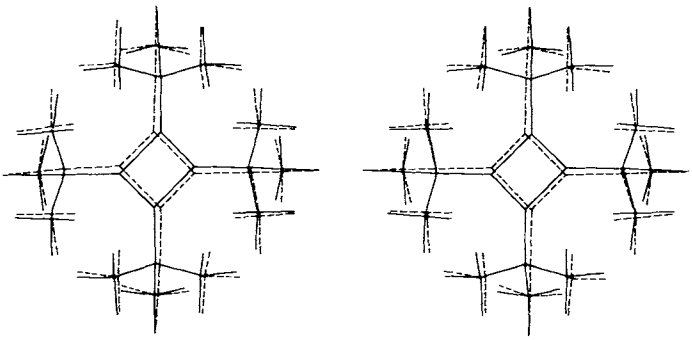


Fig. 10. Disorder model for **4** as proposed by *Ermer* and *Heilbronner* [48] and confirmed by analysis of experimental ADP's from the 123 K crystal structure analysis [50]. In the crystal, one orientation is about four to five times more frequent than the other.

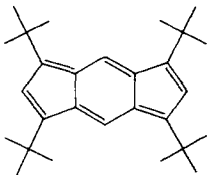
indeed, there are indications that their centers do not quite coincide. The observed excess apparent motion indicated by this analysis is compatible with the presence of two perpendicular orientations of a rectangular ring with sides 134 and 160 pm, with one orientation about four to five times more frequent than the other.

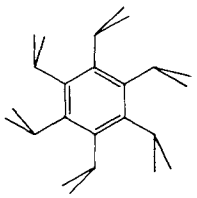
On the other hand, a quite different result is obtained from a comparable analysis of the ADP's from the low-temperature (100 K) crystal structure analysis of 1,3,5,7-tetra-*tert*-butyl-*s*-indacene **5**.[50] In solution, the twelve C atoms of the ring system give only four ^{13}C-NMR signals that show no perceptible line broadening down to -130 °C;[51] this is consistent either with a very low energy



5

barrier between the two valence isomers or with a completely delocalized 12-electron π system. In agreement with this, the X-ray analysis at 100 K (and at room temperature) shows effective D_{2h} symmetry of the carbon skeleton, even though the crystallographically imposed molecular symmetry is only C_i. Here again the ***T,L,S*** analysis with allowance for torsional motion of the *tert*-butyl groups leads to a systematic pattern of discrepancies between calculated and observed U^{ij} components, but the indications are now such that any additional motion required to improve the agreement must be perpendicular to the molecular plane, as would be produced by an out-of-plane bending or buckling of the ring skeleton. There is no indication of disorder between two sets of atomic positions for the skeletal atoms in the molecular plane, as found in **4**. Either the equilibrium structure of **5** has D_{2h} symmetry with a delocalized π-eletron system, or, possibly, the set of atomic positions found in this crystal does not correspond to the ground-state molecular structure but rather to the transition state for the valence isomerization. In the crystal, such a transition state could be stabilized relative to the ground state by packing forces. As a precedent, in a somewhat analogous conformational isomerization, we are reminded of the example of biphenyl, planar in its crystal structure, nonplanar as a free molecule.[52]

The low-temperature (99 K) X-ray analysis of crystalline hexaisopropylbenzene **6**[53] provides another carefully



6

studied example of a disordered structure resulting from the presence of two molecular orientations at crystallographically equivalent sites. In the final structural model (Fig. 11), based on a combination of X-ray evidence and force-field calculations, the two orientations are present in about 2 : 1 ratio, and distances between positions of corresponding atoms are 35.7, 76.9, and 11.5 pm for the aromatic, methine, and methyl carbon atoms, respectively. In the standard least-squares refinement, only the two methine carbons were assigned individual positions and ADP's, the aromatic and methyl atom pairs being treated as single scatterers. The "vibration ellipsoids" for the aromatic carbon atoms, based on this model, clearly show the additional motion in the tangential direction, corresponding to the unresolved disorder between the two atomic sites. Since the homomerization energy of **6** is calculated to be about 150 kJ mol^{-1}, the disorder in this crystal is to be classed as static, in contrast to the previous examples.

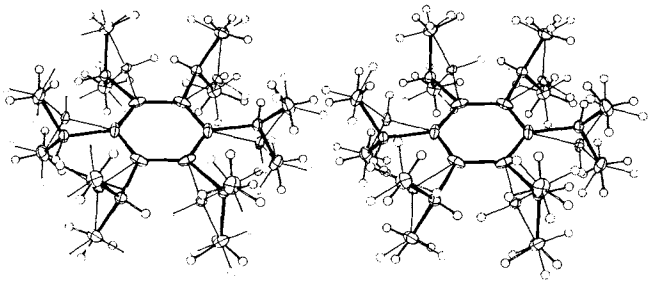


Fig. 11. Disorder model (stereoview) for **6** as deduced from the crystal structure analysis at 99 K and from force-field calculations [53]. The major and minor orientations (thick and thin lines) are present in a ratio of approximately 2 : 1.

10. Corrections to Interatomic Distances

The rigid-body model has been applied in the analysis of ADP's from thousands of crystal structures.[54] Usually, the main objective has been to obtain libration corrections to interatomic distances. As first noted by *Cruickshank*,[55] rotational oscillations of molecules cause the apparent atomic positions to be slightly displaced from the true positions towards the rotation axes. For a mean-square libration $\langle\phi^2\rangle$, the radial displacement $\overline{PB}$ is given approximately by $r\phi^2/2$, where r is the distance of the atom from the axis (Fig. 12). Errors from librational motions about orthogonal axes are additive.

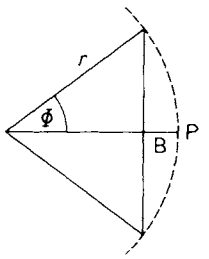

Fig. 12. The displacement $\overline{PB}=r-r\cos\phi\approx r\phi^2/2$, caused by libration.

More generally, X-ray and neutron diffraction analyses locate the centroids of pdf's, and separations computed from these centroids cannot be interpreted directly as average interatomic distances[56] (Fig. 13). To determine the corrections required to convert such separations into interatomic distances, we need information about the correlations between the instantaneous atomic displacements, and this information is usually unavailable. Any estimate of the corrections must then depend on assumptions about the

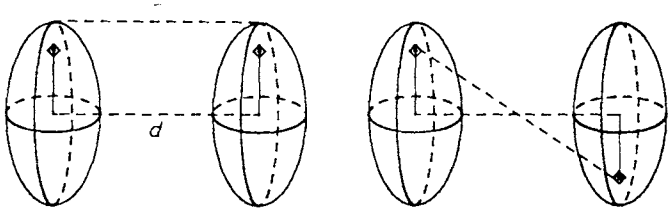

Fig. 13. The distance d between the atomic pdf centroids equals the interatomic distance for in-phase motion of the two atoms. For out-of-phase motion the mean interatomic distance is larger than d.

relative phases of the motions of different atoms.[57] In the rigid-body model, molecular libration corresponds to a correlated motion that makes the molecule appear to shrink slightly.

In room-temperature structures, errors in interatomic distances derived from centroids of atomic pdf's without corrections may amount to more than 5 pm, considerably greater than all the other errors put together. Bond distances derived from such structures should be regarded as highly unreliable, because even when corrections are made they are often based on assumptions whose validity is by no means assured. In particular, estimates of libration amplitudes obtained with the ***T,L,S*** analysis may be wildly in error when the implicit assumption of molecular rigidity is not warranted. In the *riding model*, it is assumed that one atom, the "riding" atom, has all the motion of the atom to which it is bonded, plus an additional uncorrelated motion. This model is particularly appropriate for hydrogen atoms (in cases where the ADP's are available from neutron diffraction studies), and X-H bond distance corrections from this source alone can amount to 5 pm.[58]

Uncorrected bond distances tend to become shorter with increasing temperature. In reasonably accurately determined structures, however, the motional corrections lead to fairly constant values. For example, the mean apparent (uncorrected) C–C distance in triclinic ferrocene[37] decreases from 142.6(1) to 141.5(1) pm as the temperature increases from 101 to 148 K, but the motional corrections lead to much more nearly equal values, 143.3 and 143.0 pm, respectively. Similarly, for naphthalene at five temperatures between 92 and 239 K, the trend towards shorter C–C bonds virtually disappears when corrections are made for the effects of rigid-body librational motion.[30]

Nevertheless, when bond distances are to be determined with the highest possible accuracy, it is best to reduce libration corrections by performing the crystal structure analysis at as low a temperature as possible. This also has the advantage that all the other types of atomic motions, where motional corrections are more difficult to apply, are reduced as well. But even bond distances obtained by low-temperature X-ray analysis and corrected for residual libration may be in error if the centroids of the atomic pdf's are displaced from the nuclear positions by contamination with the nonspherical bonding electron density. This depends on the resolving power of the experiment and brings us to the discussion of the experimental problems involved in the measurement of pdf's, a topic that we have avoided so far.

11. Experimental and Computational Aspects

The quality of the ADP's obtained in a crystal structure analysis obviously depends in the first place on the quality and range of the experimental observations—how accurately the intensities of the Bragg reflections were measured, and how many observations were made. This, in turn, depends on many factors, the quality of the crystals, their chemical and physical stability under the measurement conditions, the temperature at which the measurements were made, the wavelength of the radiation, the mechanical and electronic stability of the diffractometer, the appropriateness of the measurement protocol to the particular problem at hand, and many other factors besides. Important aspects of these problems, particularly in the context of X-ray analysis, have been recently examined by *Seiler*,[59] who has discussed strategies for reducing the errors in the measurement of Bragg reflections. The ADP's obtained in an analysis are also quite sensitive to the way in which the numerical data are treated, especially to details of the least-squares procedures used in the refinement of the structure. Since this article is aimed at the chemist, not at the practicing crystallographer, we mention only a few points that seem particularly relevant.

We are often interested in the precision and accuracy of the ADP's as well as in their particular values. The nominal standard deviations associated with the ADP's depend on the extent as well as on the quality of the experimental data.[60] With a given set of diffraction data, the ADP's of atoms of stronger scattering power will be the more precisely determined; for atoms of the same type, esd's of diagonal U^{ii} components appear to be roughly proportional to the U^{ii} values themselves.[22] An independent estimate of the precision of the ADP's can sometimes be made by examining the Δ values [Eq. (5)] for parts of molecules, such as carbon skeletons of benzene rings, that can reasonably be assumed to behave as rigid bodies; the rms Δ for a supposedly rigid body should be roughly $\sqrt{2}$ times the average esd of the atomic U components. At the lower end of the quality spectrum, a minimal criterion for the physical significance of the ADP's is that the U matrices must be positive definite; i.e., the constant probability surfaces of Equation (4) must correspond to ellipsoids and not to other quadratic surfaces, such as hyperboloids.

Apart from the random errors of measurement, most kinds of experimental error affect the ADP's in a systematic way; i.e., they tend to make the ADP's of *all* the atoms too large, or too small, or too large in one direction and too small in another. In the rigid-body model, these systematic errors affect mainly the description of the translational motion; the librational motion, and also the $\Delta_{A,B}$ values [Eq. (5)], are relatively unaffected. This means that estimates of rigid-body librational motion or of internal torsional motion may still be reasonable, even when the experimental data are seriously flawed.[61]

In X-ray analysis (not in neutron diffraction), one of the main problems in obtaining accurate ADP's (and atomic positions as well) is the fact that the electron-density distribution in the crystal differs slightly from the superposition of the electron densities of the isolated, spherically averaged atoms. This difference, known as the deformation density or bonding density, is of interest in the study of chemical bonding and is a subject for itself.[62] The standard, spherically symmetrical, atomic scattering factors used in the analysis of X-ray diffraction data from crystals take no account of these deformations. This neglect leads to a bias in the atomic positions (and also in the ADP's), the amount of which depends in a complicated way on the nature of the atom, its environment, and the extent of the data set. For example, carbonyl oxygen centroids tend to be drawn towards the lone-pair region, away from the car-

bon atom to which they are bonded, and C=O bond lengths tend therefore to be slightly (about 1 pm) too long. Similarly, the pdf's of carbon atoms in benzene rings tend to be slightly too large in the direction perpendicular to the plane of the ring, because the atomic vibration in this direction is not resolved from the π-electron density.

One way to reduce the free-atom bias is to use exclusively high-order reflections in the least-squares refinement[63] or to assign artificially large weights to these reflections.[64] This is because the valence electrons lie mainly in the outer part of the charge distribution around an atom, so that their contribution to the X-ray scattering falls off more rapidly with increasing scattering angle than that of the inner, core electrons. In fact, not inconsiderable errors in the positional parameters (up to 1–2 pm) and ADP's (up to 50 pm^2) may be introduced by refining only with low-order reflections (say, within the limit of $Cu_{K\alpha}$ radiation) or even with more extensive data sets that include low-order reflections.[65]

Probably the best way of reducing such errors is to model the deformation density by a suitable set of multipole terms centered at each atom. The free-atom scattering factors are augmented by the Fourier transforms of the multipole deformation terms,[66] and the coefficients of these additional terms are then obtained, together with the positional parameters and ADP's, in a special kind of least-squares refinement. However, the additional computational effort can be quite formidable and is only justified when the experimental data are of the very highest quality.

In spite of all the above-mentioned difficulties, reasonably accurate ADP's have been measured for thousands of crystal structures. The main problem today is that much of the information has disappeared, some of it, we fear, irretrievably. For some time now, nearly all published numerical data describing crystal structures have been restricted to a list of atomic positional coordinates with "isotropic" or "equivalent" displacement parameters; the information expressed by the six components of U has been compressed into a single scalar quantity. The ADP's have been relegated to supplementary information, which is sometimes deposited in libraries or other institutions and sometimes not. Deposited ADP's can in principle be retrieved (but often only at the cost of considerable delay, inconvenience, and expense). Numerical data that are not printed are rarely checked. As a result, deposited ADP's, when they can be found at all, are riddled with errors that are difficult to detect and sometimes impossible to correct. Some journals lack a deposition scheme altogether, so that data supplementary to papers published in them are simply lost. One can sympathize with the reluctance of editors of scientific journals to publish long lists of numbers (six per atom for the usual Gaussian ADP's), but at the same time steps have to be taken to secure the information and make it more easily accessible. Data bases probably offer the best solution to the problem. At present, the Inorganic Crystal Structure Data Base (ICSD)[67] contains ADP's for about half of its 25 000 entries. The Cambridge Structural Data Base (CSD),[68] dealing with organic crystal structures, has yet to include them,[69] but we are assured that this omission will be remedied very soon.

12. Macromolecules

The ideas and applications outlined in this article should be particularly relevant to the study of biological macromolecules, proteins, and nucleic acids. Experimental evidence and theoretical arguments agree that these are fluctuating systems that exist in a very large number of conformational substates.[70] In the "equilibrium structure" of such biological macromolecules, some atoms should have very diffuse, anisotropic pdf's, while others should be fairly well localized. For an understanding of the detailed mechanisms of biomolecular recognition processes and enzymatic reactions, a knowledge of the relative flexibility and rigidity of different parts of these molecules will certainly be needed, and it is this information that can be provided, in principle at least, by analysis of the ADP's.

Unfortunately, however, when it comes to the measurement and interpretation of ADP's from crystalline proteins and oligonucleotides, the problems mentioned in the earlier sections become vastly more severe. In the first place, the experimental resolution attainable for most macromolecular crystals is so limited that refinement of ADP's is usually out of the question. There are simply not enough experimental data. In most analyses of crystalline proteins, only isotropic atomic U's have been determined, leading in some cases to deductions about the general rigidity or looseness of different parts of the structures. The second main problem concerns the interpretation, which is even less straightforward than for small-molecule structures. In protein crystals, the atomic MSDA's are compounded of displacements arising from several sources: the multiplicity of conformational substates, diffusion (as in fluid-like regions of the structure), lattice disorder, and genuine vibration. These will all have different kinds of temperature dependence, and it is almost impossible to separate their contributions to the total mean-square displacements.

In a few cases, the temperature dependence of the isotropic U's has been followed; myoglobin is probably the best studied example.[71] In macromolecules, where the excursions of the atoms from their mean positions are much larger than in small-molecule structures, the potential energy associated with such displacements will not necessarily be quadratic, and the temperature dependence of U expressed in Equation (7) cannot be expected to hold. In myoglobin, different types of temperature dependence were observed for atoms in different regions of the molecule, and attempts were made to interpret these results in terms of the functionality.

More recently, ADP's have been obtained by refinement of more extensive diffraction data for several small proteins, including carp muscle calcium binding protein,[72] rubredoxin (for atoms in 30 of its 54 amino acids),[73] and avian pancreatic polypeptide (for atoms in all 36 of its amino acids.[74] No very striking conclusions have been drawn, but many of the results could be interpreted in terms of models involving concerted motions of groups of atoms in distinct regions of each molecule.

A model in which biomolecules are regarded as being built from semirigid groups of atoms, each of which moves more or less independently of the others, is the basis for what has been termed[75] the "segmented rigid-body model

of thermal motion".[76] With this model, in the refinement of the overall structure, the 20 components of T, L, and S are determined for each of a number of assumedly rigid subgroups in the macromolecule, as if each were an independent unit. Refinement of a dodecanucleotide with this model helped to improve the agreement between calculated and observed diffraction intensities and thus reduced the noise level of the difference Fourier map, allowing additional low-occupancy water molecules to be identified. In the analysis of bovine pancreatic ribonuclease A, a model of this kind was applied to the 13 aromatic side-groups (histidine, tyrosine, phenylalanine).[77] The resulting L components were small and inconclusive, the greater part of the group motions being derived from translation. The pattern of results again suggested collective motions of atoms in regions larger than single residues.

Advances in measurement techniques (synchroton radiation, area detectors) and in constrained refinement procedures will undoubtedly soon lead to ratios of data to adjustable parameters large enough to permit a determination of anisotropy for at least some of the atoms in many other macromolecules. Together with the kind of information about structure and dynamics that is becoming available from high-resolution two-dimensional NMR studies,[78] these advances should eventually lead to a better understanding of structure-function relationships in biological macromolecules.

Much of this article was written while E. F. M. and K. N. T. were on sabbatical leave in Zürich. The work described here has been supported over the years by the Swiss National Science Foundation.

[57] In principle, information about correlations among the atomic motions is available from the generalized mean-square displacement matrix computed in a complete lattice-dynamical calculation. See, for example, C. Scheringer, *Acta Crystallogr. Sect. A 28* (1972) 512, 616. Corrections to interatomic distances have sometimes been made in this way: for example, C. M. Gramaccioli, G. Filippini, *ibid. A 41* (1985) 356 and [52a].
[58] A correction due to anharmonicity in the X-H stretching vibration may amount to half of this, in the opposite direction, and so may cancel out much of the riding correction. See a) J. A. Ibers, *Acta Crystallogr. 12* (1959) 251; b) G. A. Jeffrey, J. R. Ruble, *Trans. Am. Crystallogr. Assoc. 20* (1984) 129; c) B. M. Craven, S. Swaminathan, *ibid. 20* (1984) 133.

[60] When ADP's are transformed from one coordinate system to another, the variances of the transformed coordinates depend not only on the variances in the initial system but also on the covariances. This information is routinely calculated in most least-squares programs but it is usually ignored.
[61] For example, *Cruickshank*'s 1956 estimates of rigid-body librational amplitudes in anthracene [5] were based on data that are very poor by present standards although exemplary for the time (visually estimated three-dimensional set of reflection intensities from Weissenberg photographs obtained several years earlier by A. McL. Mathieson, J. M. Robertson, V. C. Sinclair, *Acta Crystallogr. 3* (1950) 245).

[69] As electronic transfer of numerical information becomes more common, direct submission of parameter files containing atomic coordinates and ADP's to databases, such as the ICSD [67] or the CSD [68], should become standard practice. This will avoid the present tedious and error-prone stages of copying from printed records.

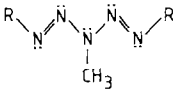
The Pentazadienide Ion as a Ligand in Metal Complexes

By Johannes Beck* and Joachim Strähle

The pentazadienide ion is a surprisingly versatile ligand. The planar, zigzag N_5 chain can utilize its atoms N1, N3, and N5 to complex one, two, or three metal atoms in a monodentate or bidentate fashion. Of particular interest is the ligand's ability to promote short metal-metal contacts in complexes with d^{10} metal ions.

1. Introduction

Nitrogen can form chains of from two to eight atoms. The only stable nitrogen-hydrogen compounds at room temperature are hydrazine, H_2N-NH_2, and hydrazoic acid, HN_3. 2-Tetrazene, $H_2N-N=N-NH_2$, decomposes at $T<0°C$. Organic substituents are necessary to stabilize longer chains; 1,5-diphenyl-3-methyl-1,4-pentazadiene **1a** does not decompose until 112°C. However, the 3-unsubstituted analogue, 1,5-diphenyl-1,4-pentazadiene explodes on



1a, R = phenyl
b, R = tolyl

gentle warming. It may be stabilized by using tolyl rather than phenyl substituents. 1,5-Diaryl-1,4-pentazadienes were first obtained by *P. Griess*[1] in 1866 by the reaction of aryldiazonium salts with amines; the constitution of these compounds was not deduced correctly until 1894 by *H. von Pechmann* and *L. Frobenius*.[2]

Whereas hydrazido, diimido, azido, and triazenido complexes have been known for some time and in considerable variety, 1,4-tetrazadiene complexes have only recently been synthesized and structurally investigated.[3-5] Prior to our investigations, no complexes of pentazadiene or the pentazadienide ion had been reported.

We first attempted to use the more stable **1a** as a ligand, but obtained no metal complexes, because the N_5 chain was always cleaved; for example, the reaction with $MoCl_5$ gives phenyldiazonium hexachloromolybdate(v) as the main product.[6,7]

The 3-unsubstituted 1,5-ditolyl-1,4-pentazadiene **2** has acid character; we have succeeded in synthesizing a large number of novel complexes with the corresponding anion **3**, which displays an astonishing versatility in its role as a ligand.

2. The Ligand 1,5-Ditolyl-1,4-pentazadienide 3

2.1. Synthesis and Properties

The intense yellow pentazadiene **2** can be synthesized in aqueous solution from tolyldiazonium chloride and NH_3.[2] In pure form it is extremely explosive and must therefore be handled with the greatest care, preferably while still moist. In alkaline solution **2** functions as an acid and is converted into its anion **3**, which crystallizes from aqueous ammonia, with $Cs^{\oplus}$ as counterion, as Cs(tolN_5tol) **4**.

2.2. Structure of the Pentazadienide Ion 3

The anions **3** are essentially uncoordinated in the cesium salt **4**. The structure analysis[8] reveals a planar, all-*trans* N_5 zigzag chain with symmetry C_2 (Fig. 1). The all-*trans* configuration is also found in all metal complexes of **3**. The tolyl substituents are twisted away from the N_5 plane in **3** and also in most of the metal complexes; the interplane angle in **4** is 25.5°. The N-N bond lengths in **4** indicate slightly lengthened double bonds N1-N2 (127.8 pm) and appreciably shortened single bonds N2-N3 (136.9 pm). The $Cs^{\oplus}$ ions are each surrounded by four N_5 chains, leading to a distorted square antiprismatic coordination with Cs-N contacts between 314.4 and 365.8 pm.

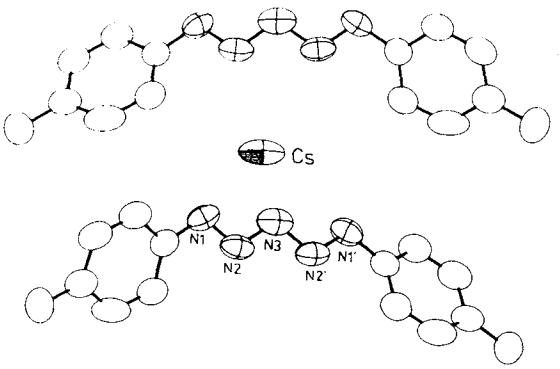

Fig. 1. Molecular structure of **4** projected parallel to [010]. The $Cs^{\oplus}$ ion and the N3 atom of the anion occupy special positions on twofold axes at $y=0.25$ (Cs) and $y=-0.25$ and 0.75 (N3).

[Tl(tolN_5tol)] **13** is a compound with a strongly polar metal-nitrogen bond (Fig. 10 in Section 3.3.6). The partial saltlike character of **13** is evident from the long Tl-N bonds (271.5-279.5 pm) and the lack of coplanarity between the Tl-N bonds and the N_5 plane. Compound **13** is

the only example so far in which all N–N bond lengths are approximately equal (129.6–131.7 pm; Table 1). The extended conjugation indicated by these bond lengths is probably associated with the partial saltlike character of **13**. The observation that the N–N bonds in the cesium salt **4** are of differing lengths (Table 1, N4 = N2′, N5 = N1′) can be explained in terms of a polarization of the anion **3** by the $Cs^{\oplus}$ ion; whereas the distances Tl-N1, Tl-N3, and Tl-N5 are roughly equal, the $Cs^{\oplus}$ ion in **4** is involved in a short contact to the central atom N3 (314.4 pm) but in longer contacts to the outer atoms N1 and N5 (349.6, 410.1 pm). This leads to a concentration of negative charge at N3 and thus to the observed differences in bond length.

Table 1. N-N bond lengths [pm] in **3** (see Scheme 1 in Section 3.2 for details of the compounds).

	N1-N2	N2-N3	N3-N4	N4-N5
uncoordinated **3** in				
4	127.8	136.9	136.9	127.8
symmetrically coordinated **3** in				
1b	126.7	136.2	136.2	126.7
5	122.8	132.7	140.0	119.8
8	129.1	134.9	135.4	128.2
9	127.0	134.2	133.1	128.2
unsymmetrically coordinated **3** in				
6	126.1	128.8	137.2	126.2
7	128.5	132.7	137.1	124.8
10	131.0	132.6	136.0	126.6
(N1,N3)-η^2-, (N5)-η^1-coordinated **3** in				
11	128.2	134.5	135.5	127.9
12	129.0	132.9	136.3	127.5
13	131.7	129.6	130.3	131.6
14	127.9	134.7	133.1	128.6

The unperturbed free anion **3** in solution presumably possesses N–N bonds of differing lengths. However, the difference in energy between the two forms would appear to be small.[8]

3. Metal Complexes of 3

3.1. Synthesis and Properties

The metal complexes of the pentazadienide **3** are synthesized most simply from **2** and soluble metal ammine complexes in aqueous ammonia [Eq. (a)]. In this way we

$$[M(NH_3)_x]^{n\oplus} + n\,\mathbf{3} \longrightarrow [M(tolN_5tol)_n] + x\,NH_3 \qquad (a)$$

obtained the complexes $[Ag(tolN_5tol)]_2$ **8**,[9] $[M^{II}(tolN_5tol)_2]$ (M = Cu (**6**),[10b] Ni (**11**),[7] Co,[11] Zn,[6] Cd,[6] and Pd[6]), and $[Co(tolN_5tol)_3]$,[13] which are precipitated as sparingly soluble complexes. $[Pt(NH_3)_4]^{2\oplus}$, $[Rh(NH_3)_5Cl]^{2\oplus}$, and $[Ru(NH_3)_5Cl]^{2\oplus}$ do not react with **3** in this manner.

[Tl(tolN$_5$tol)] **13** can be prepared in alkaline aqueous solution from TlOH and **2**.[12] AuI, which is insoluble in aqueous NH_3, reacts with **2** in liquid NH_3 to give $[Au(tolN_5tol)]$.[6] $[Mo(\eta^5\text{-}C_5H_5)(CO)_2(tolN_5tol)]$ **10** is formed from $[Mo(\eta^5\text{-}C_5H_5)(CO)_3Br]$ and **2** in ethanol in the presence of NaOH.[10a] $[(Ph_3PAu)]ClO_4$ reacts with **13** in toluene to give $[Au(PPh_3)(tolN_5tol)]$ **5** and $TlClO_4$.[10b]

A further method of synthesizing metal complexes of **3** is to react **8** with halogen–metal compounds in organic solvents [Eq. (b)]. $[Ru(CO)_4I_2]$ reacts under the same con-

$$[Fe(CO)_4I_2] + 2\,\mathbf{8} \longrightarrow [Fe(tolN_5tol)_2] + 2\,AgI + 4\,CO \qquad (b)$$

14

ditions to give $[Ru(CO)_3(tolN_5tol)]_2$ **7**,[13] the ruthenium being reduced. The reducing properties of **3** also result in the formation of $[Cu(tolN_5tol)]_3$ **9** when a solution of **6** is refluxed in organic solvents.[7]

Alcohols replace one pentazadienido ligand in $[Co(tolN_5tol)_2]_2$ to form the hexameric $[Co(OR)(tolN_5tol)]_6$ [Eq. (c)].[11]

$$\mathbf{6}\,[Co(tolN_5tol)_2] + 6\,CH_3OH \longrightarrow [Co(OCH_3)(tolN_5tol)]_6 + 6\,Tol_2N_5H \qquad (c)$$

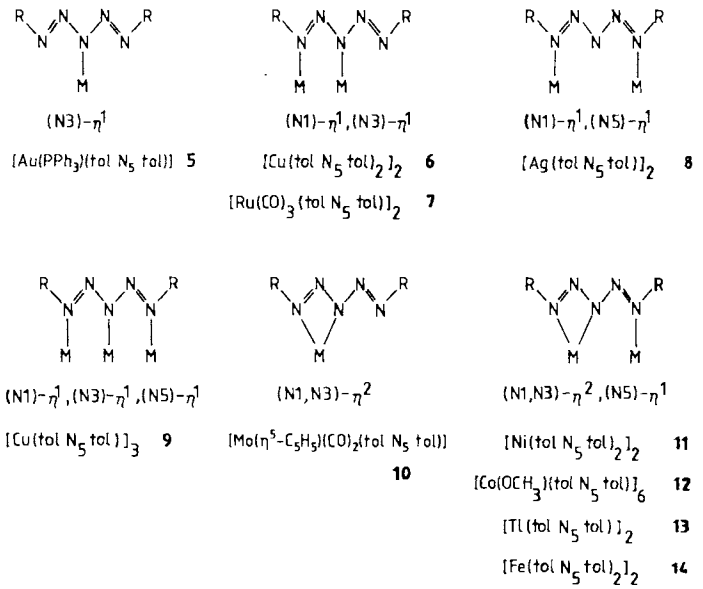
12

The pentazadienido complexes are all more intensely colored than **3**, **2**, or **1**, which are orange or yellow. The intense color can presumably be attributed to charge-transfer transitions from the metal to the ligand. The molar extinction coefficient of **11**, for example, is 5.6×10^7 cm^2 mol^{-1} at $\lambda = 415$ nm.[6] The absorption maxima lie in at 252 and 415 nm.

The metal complexes generally deflagrate at higher temperatures. They are however not as explosive as the pentazadiene **2**.

3.2. The Coordination Patterns of the Ligand 3

Scheme 1 presents a summary of the six modes of coordination that we have found for the ligand **3**. The atoms N1, N3, and N5 can function as donors.



Scheme 1. Observed modes of coordination of **3**.

3.3. Structures of Metal Complexes of 3

3.3.1. 3 as an (N3)-η^1 Ligand: [Au(PPh$_3$)(tolN$_5$tol)]$_5$ 5

In the pentazadienes **1** and **2**, a methyl group or a hydrogen atom is bonded to the atom N3 in the N_5 chain. It is therefore not surprising that the $(Ph_3P)Au$ group, which is isolobal to both the methyl group and the hydrogen atom, also binds to N3. The structure of **5** is shown in Figure 2a,[10b] and corresponds to the structure of **1b** (Fig. 2b).[10b] Another reason for preferential bonding through N3 is that it possesses the highest basicity, the negative charge of **3** being largely localized at N3.

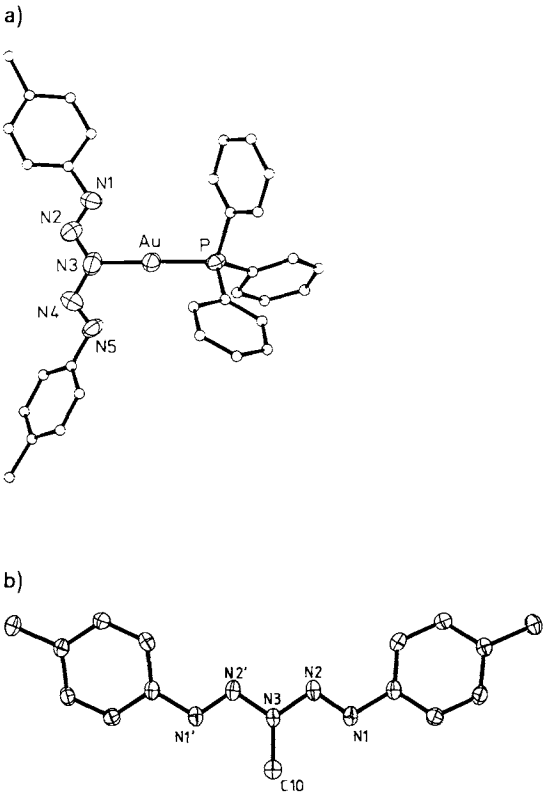


Fig. 2. Molecular structure of a) **5** and b) **1b**.

The Au–N bond length (208.2 pm) corresponds to a single covalent bond. The N–N bond lengths are 121.3 pm (average) for N1-N2 and N4-N5 and 136.4 pm (average) for N2-N3 and N3-N4 (Table 1).

The analogy between **1** and **5** can also be seen in the N–N bond lengths of **1b**, which are 126.7 pm for N1-N2 and 136.2 pm for N2-N3 (Table 1).

3.3.2. 3 as an (N1)-η^1,(N3)-η^1 Ligand: [Cu(tolN$_5$tol)$_2$]$_2$ 6 and [Ru(CO)$_3$(tolN$_5$tol)]$_2$ 7

The anion **3** can behave like the triazenido ligand $RN_3R^{\ominus}$ and bridge two metal atoms. This leads to short metal–metal contacts, since the N1–N3 bite is only ca. 223 pm. Complexes containing **3** as an (N1)-η^1,(N3)-η^1 ligand are therefore preferentially formed by metals that tend to display metal–metal interactions.

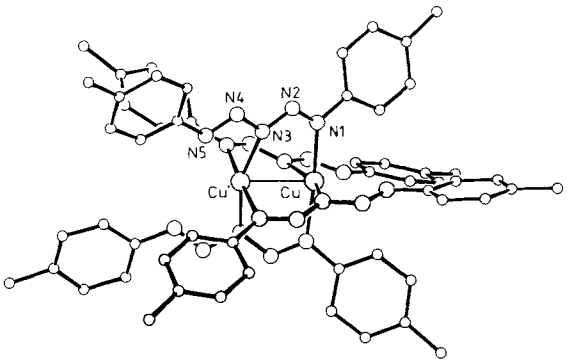

Fig. 3. Molecular structure of **6**. The complex has D_2 symmetry.

In the Cu^{II} complex **6** (Fig. 3),[10b] a structure similar to those of $[Cu(PhN_3Ph)_2]_2$[14] and carboxylato complexes[15] is attained. The crystal structure analysis shows that the complex **6** possesses crystallographic symmetry 222 (D_2), which is a point symmetry seldom observed. The Cu–Cu distance is 253.0 pm, comparable to those in $[Cu(PhN_3Ph)_2]_2$ (245 pm) and the Cu^{II} carboxylato complexes. The Cu–N bond lengths (202 pm) correspond to single bonds. The N–N bond lengths differ from those in **3** because of the unsymmetrical coordination; those in the Cu_2N_3 ring are approximately equal (N1-N2 126.1, N2-N3 128.8 pm), whereas those in the noncoordinating part of the N_5 chain differ appreciably (N3-N4 137.2, N4-N5 126.2 pm; Table 1).

Just as the complex **6** is related to Cu^{II} carboxylato complexes, so the complex **7**[13] is analogous to the Ru^{I} benzoato and acetato complexes $[Ru(CO)_3(O_2CR)]_2$ ($R = CH_3$, Ph).[16] The structure of **7** is shown in Figure 4. In contrast to the eclipsed conformation of the equatorial ligand atoms in the carboxylato complexes, the RuC_2N_2 equatorial planes in **7** are rotated with respect to each other, resulting in a staggered geometry. The Ru–Ru bond length (267.5 pm) is essentially equal to those in $[Ru(CO)_3(O_2R)]_2$ ($R = CH_3$, 268.9 pm; R = Ph, 270.4 pm),

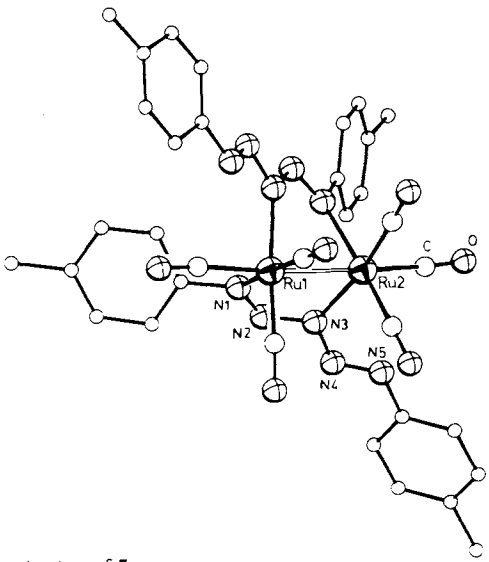

Fig. 4. Molecular structure of **7**.

and is consistent with the assumption of a single bond. The average Ru–N bond length is 212.5 pm. The unsymmetrical coordination has the same effect on the N–N bond lengths as in **6** and **10** (Table 1): N1-N2 128.5, N2-N3 132.7, N3-N4 137.1, N4-N5 124.8 pm.

3.3.3. 3 as an (N1)-η^1,(N5)-η^1 Ligand: [Ag(tolN$_5$tol)]$_2$ 8

In **8** the two silver atoms are coordinated approximately linearly by the outermost N atoms of two pentazadienide ions arranged with their long axes parallel (Fig. 5).[9] A planar Ag_2N_{10} ring results; the tolyl substituents also lie approximately in this plane, so that the overall symmetry is close to D_{2h}. The Ag–N bond lengths of 217 pm lie in the expected range for single bonds. As in **4**, **5**, and **9**, the N–N bond lengths differ appreciably; N1-N2 and N4-N5 (average) 128.7 pm, N2-N3 and N3-N4 (average) 135.2 pm (Table 1).

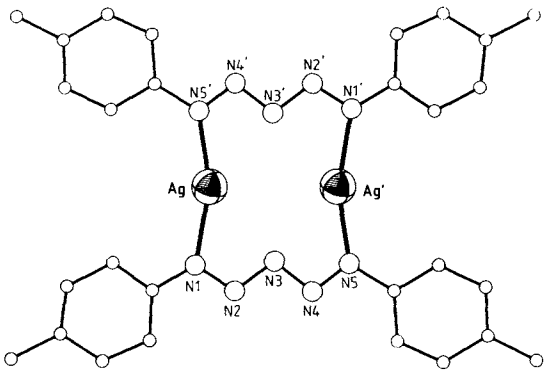

Fig. 5. Molecular structure of **8**.

3.3.4. 3 as an (N1)-η^1,(N3)-η^1,(N5)-η^1 Ligand: [Cu(tolN$_5$tol)]$_3$ 9

The (N1)-η^1,(N3)-η^1,(N5)-η^1 coordination of **3** in **9** gives rise to a linear $Cu_3^{3\oplus}$ chain with extremely short Cu–Cu contacts of 235.2 pm (Fig. 6). This value is lower than that in the Cu^{II} complex **6** (253 pm); it corresponds to twice the covalent radius of copper (234 pm[17]) and can thus be attributed to bonding interactions, although none would be formally expected for the closed d^{10} shells. Hückel MO calculations for d^{10} systems suggest a purely antibonding interaction if only the nd orbitals are considered, but the interaction becomes bonding if the empty

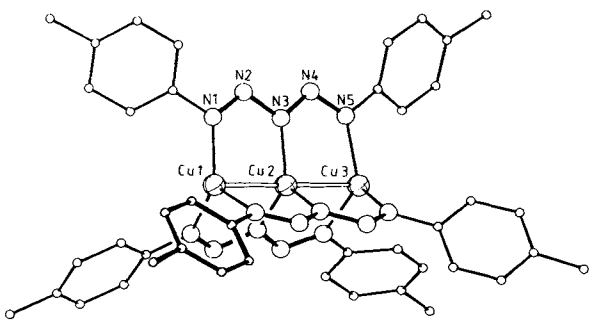

Fig. 6. Molecular structure of **9**.

(n+1)s and (n+1)p orbitals are mixed in.[18–20] The same result has been reached by *K. M. Merz, Jr.* and *R. Hoffmann* for **9**.[21]

Short metal–metal contacts are also observed in [Ag(PhN$_3$Ph)]$_2$[9] and [Au(PhN$_3$Ph)]$_4$,[22] complexes of the related triazenido ligand; we therefore assume that both the triazenido and the pentazadienido ions are capable of promoting d^{10}–d^{10} interactions.

The average Cu–N bond lengths in **9** correspond to those in **6**. The bond to the more strongly basic central N3 atom is somewhat shorter (194.5 pm) than those to the outermost atoms N1 and N5 (203.6 pm). The N–N bond lengths in **9**, like those in **4**, **5**, and **8**, fall into two groups; two shorter bonds of ca. 127.6 pm and two longer ones of ca. 133.7 pm.

3.3.5. 3 as an (N1,N3)-η^2 Ligand: [Mo(η^5-C$_5$H$_5$)(CO)$_2$(tolN$_5$tol)] 10

The structure of the Mo^{II} complex **10** is shown in Figure 7.[10a] The pentazadienide ion coordinates through the atoms N1 and N3 and functions as a chelating bidentate ligand. The N–N bond lengths in the chelate ring are similar (131.0 and 132.6 pm); in the noncoordinating part of the chain, however, they differ appreciably (as in complexes **6** and **7** with (N1)-η^1,(N3)-η^1 coordination: N3-N4 136.0, N4-N5 126.6 pm; Table 1), corresponding to a shortened single bond and a largely localized double bond. The Mo–N bond lengths (Mo-N1 214.9, Mo-N3 211.3 pm) again demonstrate clearly the higher basicity of the atom N3.

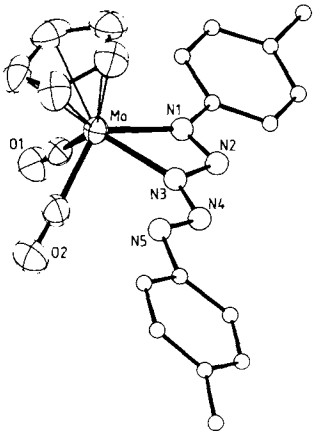

Fig. 7. Molecular structure of **10**.

The Co^{II} complex [Co(tolN$_5$tol)$_2$] is monomeric in solution; (N1,N3)-η^2 coordination by both ligands may be assumed, the $Co^{2\oplus}$ ion thus being tetrahedrally coordinated.[11]

3.3.6. 3 as an (N1,N3)-η^2,(N5)-η^1 Ligand

(N1,N3)-η^2,(N5)-η^1 coordination by the ligand **3** is the most frequently observed. It may also be assumed in the complexes [Zn(tolN$_5$tol)$_2$] and [Cd(tolN$_5$tol)$_2$], the structures of which have not been determined, but which should be analogous to those of the Ni complex **11** and the Fe complex **14**. Three crystalline modifications of **11**

have been studied; a monoclinic, solvated form **11** · THF[7] and two unsolvated forms, one triclinic and one tetragonal. The crystal structures of the monoclinic and tetragonal modifications have been determined. Figure 8 shows the

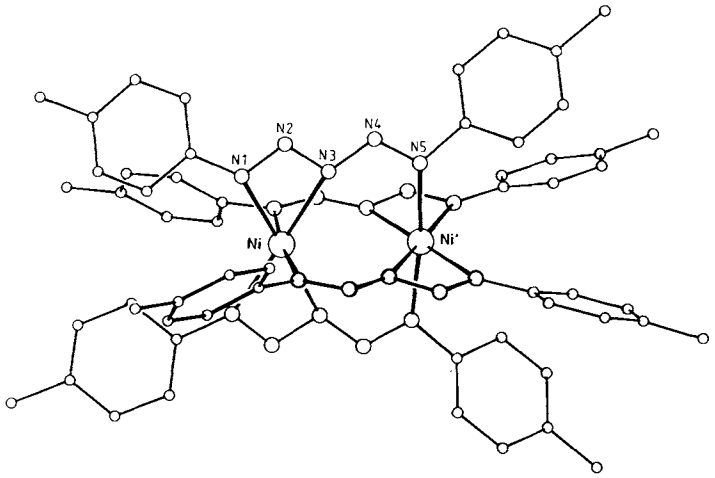

Fig. 8. Molecular structure of **11**. The complex has S_4 symmetry.

structure of tetragonal **11**;[23] the complex possesses crystallographic point symmetry $\bar{4}$ (S_4). In monoclinic **11** · THF this symmetry is only approximately fulfilled because of a rotation of the tolyl groups. The same structure is observed for **14**.[13] In **11** and **14** four parallel zigzag N_5 chains coordinate two $M^{2\oplus}$ ions in a distorted octahedral fashion; the equatorial planes of the octahedra are defined by two chelating N_3 fragments. The Ni–N bond lengths in these planes are 213.5 pm, whereas those to the apices of the octahedra are 206.4 pm. They correspond to single coordinate bonds. The N–N bond lengths in **11** are analogous to those associated with symmetric coordination; the outer, shorter N–N bonds are ca. 128 pm (Table 1); the inner, longer ones are ca. 135 pm. Similar values are observed in **14**; Fe-N 224.7, 215.8, N-N 128.3, 133.9 pm.

The central structural unit of the hexanuclear Co complex **12**[11] is a twelve-membered ring of six $Co^{2\oplus}$ ions and six methoxy O atoms (Fig. 9). The $Co^{2\oplus}$ ions lie in a plane, with the O atoms alternately above and below the plane, giving the ring the approximate symmetry D_{3d}. The pentazadienide ions each bridge two Co atoms, one being chelated and the other singly coordinated. In this way, half the cobalt atoms acquire tetrahedral coordination geometry from two monodentate N atoms (of two pentazadienide ligands) and two methoxy groups; the other half are coordinated octahedrally by two chelating pentazadienides and two methoxy groups. The Co–N bond lengths in the octahedra are longer than in the tetrahedra (221.4, 206.3 pm). The N–N bond lengths (Table 1) suggest the presence of double (128.2 pm) and shortened single (134.6 pm) bonds.

The structure of the Tl^{I} compound **13** is shown in Figure 10.[12] If **13** is regarded as a coordination compound, the coordination mode (N1,N3)-η^2,(N5)-η^1 applies. However, we have already indicated (Section 2.2) that **13** displays a partial saltlike character with markedly polar Tl–N bonds.

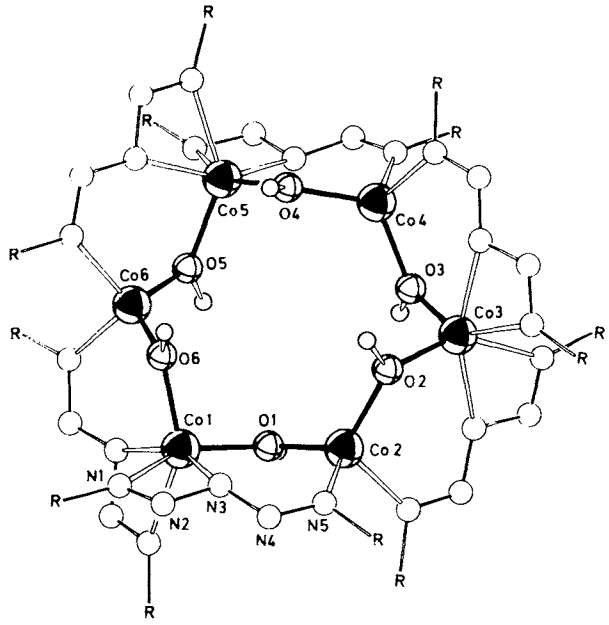

Fig. 9. Molecular structure of **12**.

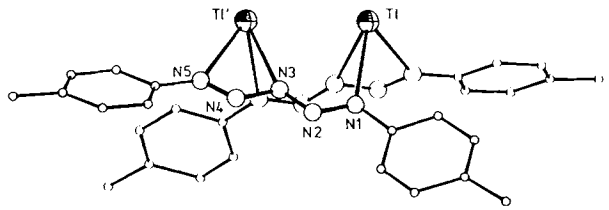

Fig. 10. Molecular structure of **13**.

4. Summary and Prospects

We have presented here several examples of recent structure determinations of metal complexes of the pentazadienide anion and have thus demonstrated its surprising versatility as a ligand. It is probable that we have not yet exhausted all possibilities, because our studies have mostly centered on metals in oxidation states +1 and +2; future investigations with transition metals in oxidation states 0 or higher than +2 would seem worthwhile. Furthermore, initial studies have shown that substituents on the organic groups of **3** can alter the electronic properties of the ligand and thus, for example, permit the control of its influence on d^{10}–d^{10} interactions. The chemistry of derivatives of **3** not involving metals is also clearly an interesting field.

We wish to thank Dipl.-Chem. R. Schmid for his enthusiastic assistance in these studies. The work was financially assisted by generous grants from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Surfactants, Micelles and Fascinating Phenomena

By Heinz Hoffmann* and Gerlinde Ebert

In this article we shall describe processes and phenomena which may appear startling and unusual for someone who is familiar with the behavior of solutions of low molecular weight solutes. Some of these phenomena might even be surprising for someone who works with surfactants. The authors still remember their astonishment when they first became aware of a viscoelastic surfactant solution. This was many years after our group had started investigations on surfactants. But all of the solutions we had encountered until that time had behaved normally. Some of the phenomena which will be discussed are also encountered in solutions of polymers. Due to their high molecular weight one expects to find properties which are different from the properties of low molecular weight solutions and does not find them so surprising. Surfactant solutions, however, are aqueous solutions of small molecules with typical molecular weights of 200 to 400. For some of our experiments even dilute solutions were used which contained only up to one percent of surfactant.

1. Introduction

Most of the phenomena described here arise from the ability of the surfactant molecules to form large aggregates of different shapes. In a thermodynamic sense these aggregates—even though they consist of many molecules—can be treated as *single* particles or large molecules that exert forces on each other. For this reason, micelles can be considered as a van-der-Waals-gas, and like real gases, they are capable of condensation or can convert into the crystalline—(in this case the liquid crystalline) state.

The forces of interaction between the particles are determined by the size and the number of charges on the particles. One of the fascinating aspects of these systems is the fact that slight changes in the system on a microscopic level can lead to dramatic changes in the macroscopic properties of the system. Surfactant molecules have in many ways similar properties as membrane-forming lipids. They exist as single chain and double chain molecules. It is therefore likely that nature uses some of the processes which are described here with simple surfactant molecules in the functioning and control of life processes.

One of our goals is to bring these fascinating control mechanisms to the attention of a larger audience which is not directly involved with research in surfactant chemistry. All the experiments mentioned in the text can easily be carried out without the need for elaborate equipment. The chemicals required for such experiments are commercially available and can be purchased at low cost. In principle the phenomena described here are well suited for high-school experiments. We might also mention that some of the described effects are of considerable interest and practical importance from the technological point of view.

Inspite of how startling and unexpected the phenomena may seem, they are nevertheless based on a few rather simple principles; they are always reproducible and can be described quantitatively.

2. Viscoelastic Surfactant Solutions

Many surfactants, in particular commercially produced detergents, dissolve readily in water and form Newtonian solutions up to high concentrations. In these solutions the surfactant molecules aggregate into globular micelles and the solutions are optically isotropic and of low viscosity. Micelles can however grow into rodlike or disklike aggregates, and these structures can be so large that they can form entanglements. The shape of the micelles is controlled by the packing parameters of the surfactant molecule in the micellar assembly. The situation is shown schematically in Figure 1.

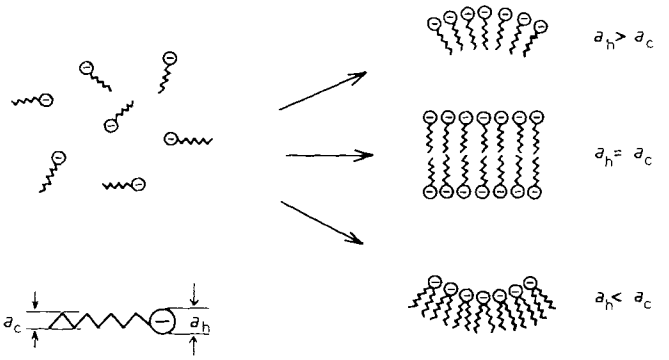

Fig. 1. Schematic illustration of the importance of the natural radius of curvature for micellar structures. The radius of curvature is controlled by the ratio of the required headgroup area a_h of a surfactant molecule at the interface and the cross section of the chain a_c.

If the hydrophobic head at the micellar interface requires an area a_h which is larger than the cross section a_c of the chain in its average surrounding, the system will form aggregates with a convex curvature. If both areas are of the same size, planar structures are favored and if $a_c > a_h$ the system prefers to form inverse structures if this is possible by other constraints.[1]

Surfactant solutions with rodlike micelles can be highly viscoelastic,[2] i.e. exhibit both viscous as well as elastic behavior. Such systems can be prepared by mixing two nor-

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0707-0902 $ 02.50/0

mal micellar solutions or a micellar solution and a salt solution which contains a particular counter-ion that strongly binds to the surfactant-ion. The starting solutions are optically clear and have a viscosity which is close to the viscosity of water. Upon mixing two such solutions one obtains almost instantaneously—with perhaps a few seconds delay after the mixing process— a highly viscoelastic system. The new solution, which in its properties is reminiscent of a gel, is optically clear and has single phase character. Its consistency reminds one of gelatine or fruit jelly. Bubbles which are trapped in the starting solutions during the mixing and shaking process recoil when rotation of the flask or test-tube in which the solution is held is abruptly stopped. The elasticity of the system can be so high that the bubbles do not only show a single recoil but oscillate a few times. Test-tubes with a cross section of 2–3 cm are particularly well suited for demonstrating this phenomena. When we try to empty the test-tube it can be turned almost upside down before the liquid starts flowing; and even then it does not flow smoothly. The solution can even be pulled back into the glass tube after it has already crossed the rim of the glass by abruptly turning the tube again with the open-end pointing upward.

This phenomena is best demonstrated by mixing two equal volumes of a 50 mM cetyltrimethylammonium bromide solution (CTAB) with a 30 mM sodium salicylate solution (NaSal), both of which are Newtonian solutions. The effect can also be observed at other surfactant/salt ratios and other concentrations but is optimized at this surfactant/salt ratio.[3]

The same behavior can be observed on mixing other surfactants. Table 1 lists some surfactants which are suitable for preparing viscoelastic solutions.

Table 1. Surfactants which form viscoelastic solutions.

N-$C_{16}H_{33}$–pyridinium + salicylate
$C_{16}H_{33}-\overset{\oplus}{N}(CH_3)_3$ + salicylate
$C_{16}H_{33}-\overset{\oplus}{N}(CH_3)_3$ + trichloroacetate
$C_{16}H_{33}-\overset{\oplus}{N}(CH_3)_3$ + $SCN^{\ominus}$
$C_{16}H_{33}-\overset{\oplus}{N}(CH_3)_3$ + *p*-chlorobenzoate
$C_{16}H_{33}-\overset{\oplus}{N}(CH_3)_3$ + perfluorobutyrate
$C_{14}H_{29}-\overset{\oplus}{N}(CH_3)_2-O^{\ominus}$ + $C_{12}H_{25}SO_4Na$
$C_{14}H_{29}-\overset{\oplus}{N}(CH_3)_2-O^{\ominus}$ + $C_7F_{15}CO_2Na$
$C_{14}H_{29}-\overset{\oplus}{N}(CH_3)_2-(CH_2)_3CO_2^{\ominus}$ + $C_{12}H_{25}SO_4Na$
$N(C_2H_5)_4^{\oplus}C_8F_{17}SO_3^{\ominus}$
$N(CH_3)_4^{\oplus}C_9F_{19}CO_2^{\ominus}$

What happens in these experiments? In surfactant solutions exhibiting normal behavior, globular micelles are present; these are charged and are surrounded by an electric double layer. The mean distance between neighboring micelles is much greater than their size and the solutions are in this sense dilute and behave like a dilute dispersion. The counterions which are added with the salt bind more strongly to the micellar interface than the original counterions and displace the latter from the micellar interface. As a consequence of this the surfactant headgroups can pack more tightly and form rodlike micelles. The rods grow rapidly in size until their lengths are greater than the intermicellar distance and the system can now be called semidilute. In this situation the rods can—like polymer chains—form entanglements, or they actually may even form a three-dimensional network because the system strives to achieve a state in which global micelles and thus also end caps of the rods are no longer present (Fig. 2).

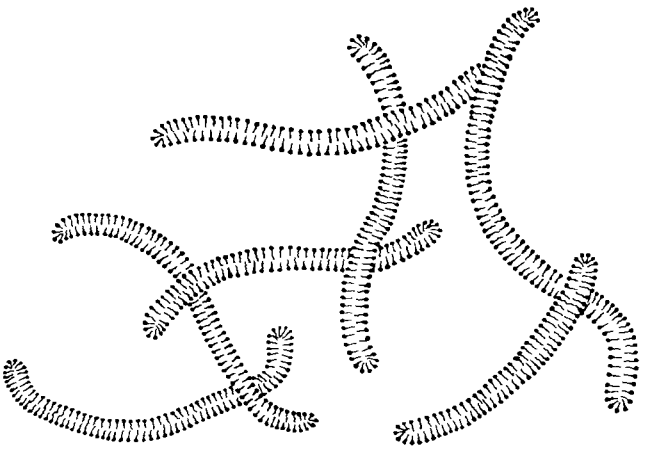

Fig. 2. Schematic drawing of a network of rodlike micelles in a viscoelastic surfactant solution.

Very recently *Hirata* et al. successfully obtained some electron micrographs of networks in viscoelastic surfactants.[3c] These pictures show that the micellar rods can be rather stiff. Depending on the systems and conditions their mean radius of curvature can be more than 1000 Å. Networks possess an entropy of elasticity when they are deformed. The deformation leads to a preferential orientation of the branches of the network and hence to an increase of order and a concomitant decrease of the entropy in the system. Elasticity occurs because of the tendency to increase the entropy of the system. Any deformation is coupled with a strong birefringence.[4] The surfactant network, however, is not a permanent one like the network in a rubber, which is formed by cross-linking of polymers; rather, the situation in the case of surfactant networks is similar to that in entanglement networks.[5]

Any shear stress which has been built up by a deformation of the network relaxes again with a characteristic time constant. In entanglement networks this time constant is determined by diffusional processes. In the case of surfactant networks, the stress can also relax through breakage of the long rods. The network is a temporary one which is continuously broken and reformed by Brownian motion. The dynamic properties of such a network are characterized by the structural relaxation time τ_s. In systems in which the viscoelastic behavior is obvious, the structural relaxation time can be as long as 10 s, sometimes even longer. It is noteworthy however that this time constant can be shortened for the same system by many orders of magnitude by other additives without the network properties being lost. This will be discussed separately in Section 3.1).

For experiments in which a strain is effective for a duration $t < \tau_s$ the system has mainly elastic properties and for experiments in which $t > \tau_s$ the viscous properties dominate. Viscoelastic surfactant solutions do not have a yield point. This can easily be observed with trapped bubbles, which always move slowly upward when the solution is at

rest. In water they need only a few seconds to rise several centimeters, whereas in viscoelastic systems they can need many hours for the same distance. It should be noted however that surfactant systems with yield points do indeed exist. In such systems the bubbles do not rise at all. Such systems are of practical interest for the preparation of stable emulsions and dispersions because these systems rule out any sedimentation.

As in the case of rubbers the elastic properties of a surfactant network can be characterized by an elasticity modulus or a shear modulus G_0. This is defined as the force which acts on a face of a cubic volume element when the volume element is deformed. It has therefore the dimension of a pressure and is normally given in the SI unit Pascal. The value of this modulus is mainly determined by the volume fraction of surfactant in the solution. On the other hand, it is essentially independent of parameters like excess salt concentration, temperature, and type and even chain length of the surfactant.[6] As long as the system remains in the viscoelastic region these parameters have little influence on G_0. They do however strongly influence the characteristic time constant τ_s. The zero-shear viscosity of viscoelastic systems is given by the product of G_0 and τ_s and therefore also depends on both of these parameters. As far as the value of the modulus for the surfactant networks is concerned the situation is analogous to that in the case of polymer networks, where the modulus is independent of the molecular weight of the macromolecules when the coils of the molecules overlap and the solution is in a semidilute state.[7] Furthermore, the modulus is dependent upon the number of entanglements in the system, but independent of the number of free ends in the network. A 100 mM viscoelastic surfactant solution has a typical shear modulus of 10^4 mPa. Polymer solutions containing the same volume fraction of polymers have similar shear moduli. Since the shear stress is given by the modulus of the system and the deformation, it is clear that the restoring forces in sheared viscoelastic solutions can be quite large. This is even more so in the case of normal stress differences which are proportional to the square of the shear rate. The shear modulus is related to the volume fraction ϕ as given in Eq. (a).

$$G_0 \approx \phi^{2.3} \tag{a}$$

From network theories G_0 is directly proportional to the number density c of entanglements [Eq. (b), k = Boltzmann constant].[8]

$$G_0 \approx ckT \tag{b}$$

Viscoelastic networks can even be formed at extremely small surfactant concentrations; they have been observed at volume concentrations of less than 0.1% of surfactant. These systems represent cases in which both the hydrocarbon chains of the surfactants and the water form continuous phases. They are therefore examples of bicontinuous phases with an extremely low hydrocarbon/water-ratio. The networks can be swollen to some extent by further hydrocarbon molecules, and the charge density of the rodlike micelles can be varied without destroying the network structure.

3. Breakdown of Elasticity by Solubilization

3.1. Solubilization of Alcohols

While a viscoelastic surfactant system can be built up by mixing an additive to a micellar solution it is likewise possible to destroy the viscoelastic properties again by the addition of a third component.[9] When 0.5 mL of pentanol is added to 100 mL of the viscoelastic system described in Section 2, the viscoelasticity of the system disappears as soon as the two solutions are mixed. Although the elasticity of the system seems to have completely disappeared—the solution flows again like water or a normal surfactant solution—the situation is actually more complicated than it appears. Detailed scattering experiments on such solutions revealed that the surfactant network is still present and has actually suffered little change upon addition of the alcohol. That is, the alcohol influences the structural relaxation time without having any great effect on the structure of the network. Actually, most of the alcohol is not adsorbed at the network but is in a molecularly dispersed form in the bulk state.[10] Only a fraction of it is adsorbed at the micellar interface. The alcohol molecules act as local lubricants and accelerate the breaking and reforming process of the networks; this shortens the structural relaxation time of the network by three to four orders of magnitude.[11] The dynamics of the system is now so rapid that in the normal handling of the solution the network is not deformed and the elasticity is therefore not observed. However, when such solutions are exposed to high shear rates, deforming forces become apparent again and it is possible under such conditions to orient the network and to observe flow birefringence in the system. Some of the amphiphilic alcohol molecules adsorb at the micellar interface. Their hydrophobic nature is small and for this reason they can quickly adsorb and desorb whenever a new hydrophobic interface is formed. This is the reason why they can be so efficient in accelerating dynamic processes in micellar solutions.

3.2. Solubilization of Hydrocarbons

In Section 3.1 it has been shown how it is possible to apparently destroy the elastic properties; in reality, however, the elastic effect is only diminished. Nevertheless it is indeed also possible to destroy the networks. In a way this is even more spectacular because it can occur with fewer added molecules per surfactant molecule than in the previous situation where the pentanol/surfactant ratio was approximately 8/1.

Surfactant solutions have a general tendency to solubilize a certain amount of hydrocarbon. Surfactant systems with rodlike micelles can actually solubilize rather large amounts of hydrocarbons.[9] For hydrocarbons which have a somewhat shorter chain length than the surfactant, the hydrocarbon/surfactant ratio in a saturated solution has a value of about one. For systems with globular micelles this number is typically at least one order of magnitude smaller.

When the network is monitored while more and more hydrocarbon is solubilized we find that it is transformed

into globular aggregates long before the solution is saturated with the hydrocarbon. The situation is shown schematically in Figure 3.

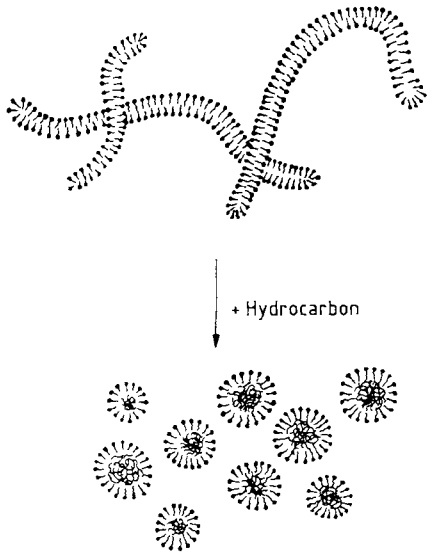

Fig. 3. Illustration of the transformation of rodlike micelles into globular structures by the solubilization of hydrocarbon in the surfactant solution.

The transition from the network to globular aggregates can easily be monitored by light-scattering measurements. Typical results are shown in Figure 4. For the same amount of dissolved surfactant the scattering intensity of light is proportional to the volume of the scattering particles. The scattering intensity R_θ of rodlike particles is very high. While the solutions are still completely transparent to the naked eye their scattering intensity is actually typically 1000 times larger than the scattering intensity of water. The volume of the globular micelles which form in the transformation process is much smaller—in extreme cases the volume ratio of rods and globules can be between

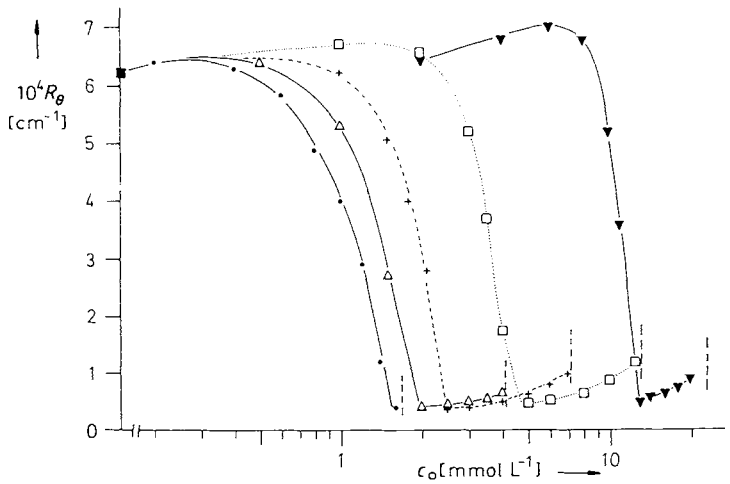

Fig. 4. Plot of the light scattering intensity R_θ of a mixture of a 10 mM solution of trimethyltetradecylammonium salicylate and a 10 mM NaBr solution against the concentration c_0 of solubilized hydrocarbon. The broken perpendicular lines indicate the phase boundaries (maximum solubilization capacity is reached). Note that the breakdown concentration of the rods shifts with decreasing chain length of the hydrocarbon to higher hydrocarbon concentrations. The following hydrocarbons were used (T=25°C): ● tetradecane; △ dodecane; + decane; □ octane; ▼ hexane.

10:1 and 100:1. The transformation therefore leads to a large drop in the scattering intensity. The curve plotted in Figure 4 shows that the transition is rather sharp and that the transformation can already be complete at a hydrocarbon/surfactant ratio of 0.1/1.

With the breakdown of the network the viscoelastic properties disappear and the solution behaves like a normal Newtonian liquid with a shear-independent viscosity and a viscosity like that of water. The solubilization of hydrocarbons in a surfactant solution does not proceed instantaneously but requires time because of their very low solubility in water. Depending on the chain length of the hydrocarbon, several hours' stirring may be necessary in order to achieve solubilization. This makes it difficult to demonstrate the breakdown of the viscosity; it is therefore advisable to prepare the solutions in advance for demonstration purposes. This experiment shows quite dramatically that the aggregation behavior of surfactants which leads to different micellar shapes is dominated by severe packing constraints by the surfactant and the hydrocarbon.

The observed transformation can be explained as follows: The hydrocarbon molecule with no polar headgroup is solubilized in the interior of the rodlike micelles (Fig. 5); the transformation of the rods can only be understood in terms of a simple geometrical model. In the rods the surfactant headgroups are rather tightly packed with a packing parameter of p=2 ($p=a_h l/v$, where l=chain length of the surfactant, v=volume of the hydrocarbon chain). With the solubilization of the hydrocarbon the cross section of the rods begins to increase. As soon as the inner core reaches a size which allows the packing parameter to be the same as in globular particles, the system undergoes transformation because the higher number of globular particles which can be formed from a single long rod are entropy favored.

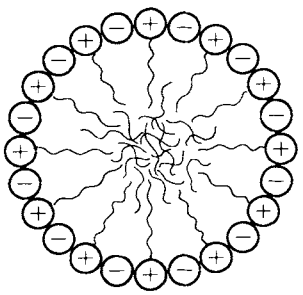

Fig. 5. Schematic view of a microemulsion droplet. The greater part of the solubilized hydrocarbon is located in the interior of the micelle. The interface is covered by the surfactant molecules. There is probably some penetration of the hydrocarbon into the micellar interface.

Figure 4 also shows that the transformation of the network into globular micelles by shorter hydrocarbons is first realized at higher concentrations. The reason for this is that smaller hydrocarbons can better penetrate the palisade layer of the surfactants and are therefore not restricted to the interior of the micelles. We can therefore find situations in which the saturation concentration is reached before the transition concentration. Under these conditions the network is not destroyed by the solubilization but is swollen by the hydrocarbon and typical bicontinuous

phases result.[12] Such systems exhibit very remarkable phenomena and fully unexpected properties.

From Figure 4 it is also clear that saturation of the micellar solution with hydrocarbon is in no way achieved when the transformation is complete, but that the small globules formed now increase in size until saturation is finally reached. Under optimized conditions for the solubilization, the diameters of the globules can become as large as 1000 Å. Extremely high values have been reported by *Strey* et al.[12b] A schematic drawing of micellar globules is shown in Figure 5. By varying the external conditions, the radii of these globules can be continuously changed from 20 to 500 Å. For the very large droplets it becomes increasingly difficult to differentiate between microemulsion droplets which are thermodynamically stable and emulsion droplets which are not stable.

4. From Turbid to Clear Solutions by Solubilization of Hydrocarbons

4.1. From a Condensed Network to Swollen Globular Micelles

If more hydrocarbon than can be solubilized is added to a surfactant solution, then a turbid emulsion is formed which on prolonged standing separates into two distinct macroscopic phases. This is common experience. But with a network system the situation may be more complicated. Such solutions very often separate into two macroscopic phases when excess salt is added or the charge of the rods is neutralized by hydrophobic counterions. The separation into two phases corresponds in the thermodynamic sense to a condensation of the network. We obtain a dilute phase and a more dense phase, as shown schematically in Figure 6.

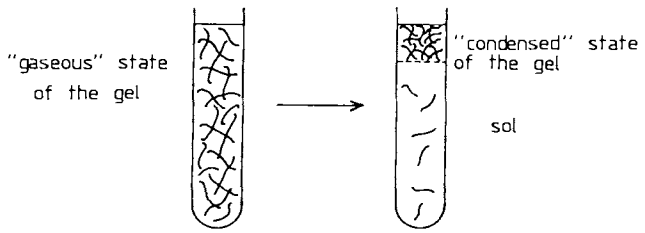

Fig. 6. Schematic representation of the transformation of a viscoelastic network in the "gaseous state" into a condensed state and a sol.

In the literature such phase separations are referred to as coacervation.[13] They are brought about by increased attractive forces between the branches of the network. Increased attraction is also brought about by the solubilization of the hydrocarbons. Coacervation is therefore sometimes observed upon solubilization of a hydrocarbon. Such an example is shown in Figure 7.

Upon addition of ethylbenzene to the starting solution the solution becomes turbid; two phases are formed. When addition of ethylbenzene is continued, however, the turbidity disappears and the system becomes transparent again and now has a much lower scattering intensity than the starting solution. The explanation: The condensed network has undergone a rod-sphere transition and the attractive forces between the smaller globules are not large enough to induce a phase separation.

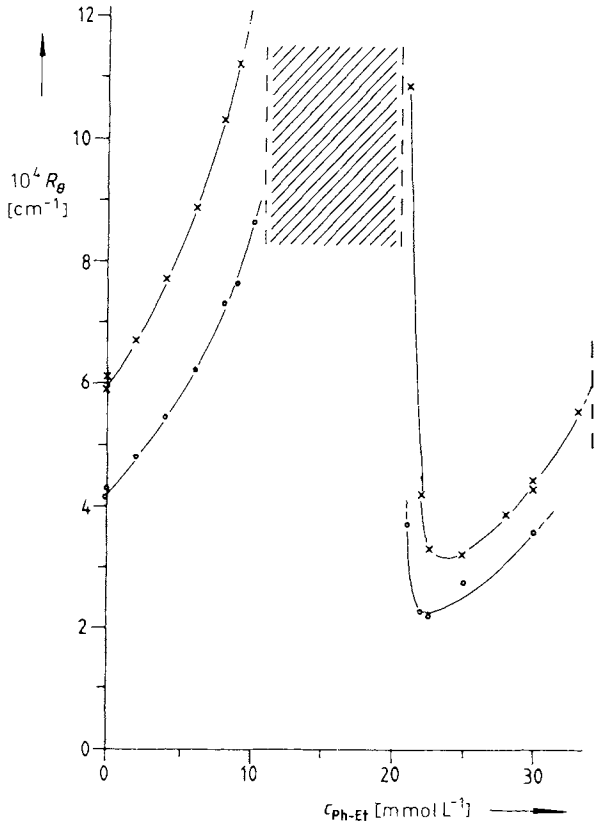

Fig. 7. Light scattering data during the solubilization of ethylbenzene in a solution of 10 mM TAB and 10 mM NaSal (T=25 °C). The hatched area is a turbid two-phase region. Symbols used: × R_δ^{45-7}; ○ R_θ^{180}; the broken lines are ⋮ phase boundaries.

4.2. From Lamellar Phases to Microemulsions

In this Section we present an example of other biphasic systems which are converted into single phase systems by solubilization. We have seen (Section 3.2) that systems with rodlike micelles have a relatively large capacity for the solubilization of hydrocarbons. Rodlike micelles can be formed by adding intermediate chain length alcohols like decanol to nonionic or ionic surfactants containing globular micelles. At a certain alcohol/surfactant ratio characteristic for the surfactant a situation is reached when rods are formed. When the alcohol/surfactant ratio is increased further, phase separation is observed. This may be due to a coacervation, as described in Section 4.1.

The more concentrated phase can also be a lamellar liquid crystalline phase.[14] In this case we have again a turbid two-phase system. Such systems can be again converted back into single phase isotropic systems by solubilization of hydrocarbon. Results for a particular case are shown in Figure 8. Here, the saturation concentration of the hydrocarbon increases continuously with the alcohol/surfactant ratio until appearance of the liquid crystalline phase region. This example also demonstrates that whenever it is of interest to use systems with a high hydrocarbon/surfactant ratio it is of advantage to start from surfactant systems which form lamellar phases in the dilute bi-

nary system. Hydrocarbon/surfactant ratios may easily reach values of over 10/1 in such systems.

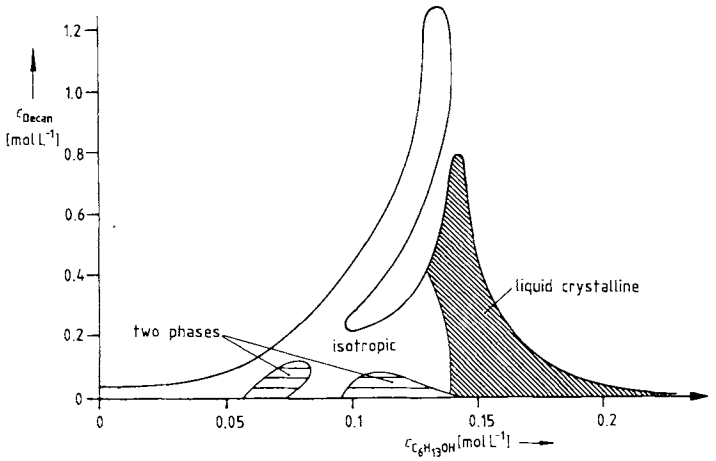

Fig. 8. Dependence of the solubilization capacity of a 0.1 M surfactant solution of (tetradecyl)dimethylamine oxide for decane as a function of the concentration of hexanol (T=20°C). Note that the region of the binary system in which a liquid crystalline phase is in equilibrium with a micellar solution has a much larger solubilization capacity than the isotropic solution. The liquid crystalline phase is however transformed into an isotropic phase by the solubilization.

One of the decisive parameters for the solubilization of the hydrocarbon in surfactant solutions is the mean curvature of the interfaces in the micellar assembly.[15] As seen from the hydrocarbon the mean radius of curvature increases on going from the globular micelle to the rodlike micelle to the lamellar phase. The solubilization capacity also increases, and reaches a maximum when the mean radius of curvature approaches infinity.

5. Inverse Systems: Breakdown of the Conductivity with Increasing Water Content in the System

In the previously mentioned examples the surfactant was always dissolved in the solvent water. Some surfactants, in particular double-chain systems, also have a high solubility in organic solvents like octane, especially in the presence of small amounts of water. It is therefore conceivable that we can expect to find phenomena in these system which are related to networks and structure transformations. This is indeed the case.

F. Evans et al. have shown that didodecyldimethylammonium bromide is soluble in organic solvents.[16] In the presence of less than 10% water such solutions have a high electric conductivity. When the water content in these systems is increased to about 40%—which is possible only with particular solvents—the conductivity decreases by several orders of magnitude (Fig. 9).

This is a very surprising effect, since we are going from a hydrocarbon solvent with a very low dielectric constant to a solvent which should be more water-like. Recent studies on the system have shown that this situation is analogous to the situation in Section 2: it is merely reversed in as much as the organic phase is now the bulk phase and the water and the surfactant form continuous channels which enable the transport of electric current. In a viscoelastic

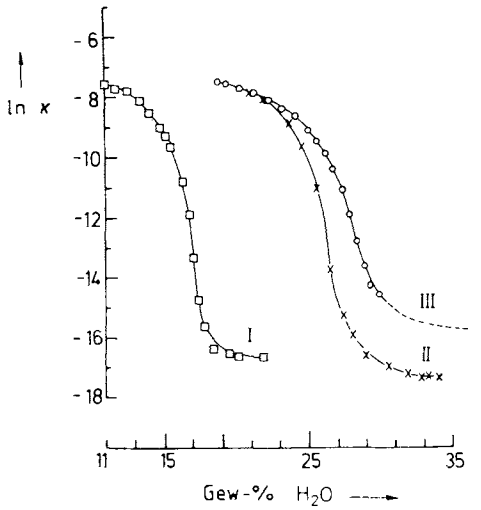

Fig. 9. Breakdown of the electric conductivity k of a microemulsion of didodecyldimethylammonium bromide and water in hydrocarbons with increasing water content [16]. Hydrocarbons used: I=octane; II=decane; III=dodecane.

system with water as solvent the network was destroyed by the solubilization of a hydrocarbon, whereas now the network in the organic phase breaks down by addition of water. With the transformation of the aqueous channels into globular water droplets the conducting channels disappear and the conductivity breaks down. The reason for the transformation of networks into isolated globules is the same in the normal as well as in the inverse case.

6. Large pH-Changes by the Mixing of Two Neutral Surfactants

When two neutral surfactant solutions are mixed we usually do not expect the solution to turn acidic or basic. This behavior, however, has actually been observed and such an example will be described below.

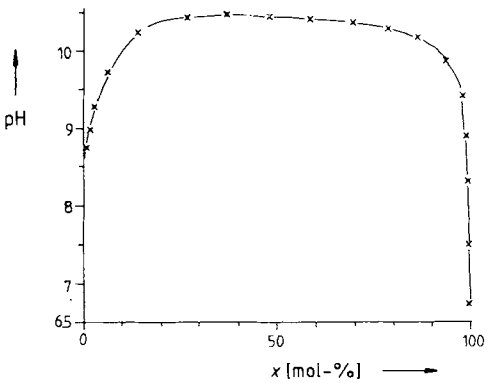

Fig. 10. Plot of the pH of surfactant solutions against the mixing ratio of the two surfactants $C_{14}H_{29}N(CH_3)_2O$ and $C_8F_{17}COON(CH_3)_4$. x=mole fraction of the perfluorononoate. The total concentration is 25 mM.

In Figure 10 the pH of a mixture of 100 mM solutions of perfluorononanoate and dimethyltetradecylamine oxide is plotted against the molar fraction of the perfluorononoate. The solution of the perfluoro compound is neutral, while that of the amine oxide is weakly basic due to the basicity

of the oxygen atom. In the mixture the pH is several orders of magnitude higher.

A similar effect is also observed for other combinations.[17] The perfluorononanoate can be replaced by other anionic surfactants including normal hydrocarbon surfactants, and the amine oxide can be replaced by other amines or by alkylethoxyamines. The effect always occurs when an anionic surfactant is combined with a weakly basic surfactant. It is caused by the change in basicity of the amine oxide group due to neighboring negative charges. The two surfactants form mixed micelles in which the amine oxide is surrounded by negative charges. The combined electric fields of these charges increase the basicity of the N–O groups, which become protonated by water, and OH-ions are released.

This effect of negative charges is also responsible for the fact that pK_{a1} and pK_{a2} of a dibasic acid differ considerably.

This effect, which has already been described in the literature by *Rosen* et al.,[18] can be resorted to for the determination of electric fields in electric double layers of micellar aggregates by incorporating dye indicators into the micelles.[19] The conclusion which we have to draw is that charged micellar interfaces can shift the pK-values of incorporated molecules by several orders of magnitude. The effect is also responsible for an astonishing phenomenon in perfluorocarboxylic acids: Perfluorocarboxylic acids are strong acids and are thus completely dissociated in the monomeric state; the micellar assemblies of these surfactants are however practically completely associated.[20] This is not true however in the case of the perfluoroalkylsulfonic acids. The protonation of the carboxyl groups in the micellar state is probably due to an increase of the acidity constants by the formation of micellar aggregates. The pK_a of the acids in the assemblies is shifted to a value around the pH of the solution, and this is sufficient to bring about protonation of the micellar carboxylates.

7. Gelification of Hydrocarbons by Surfactants

Hydrocarbons like pentane or hexane are highly volatile liquids with low viscosity. By addition of small amounts of surfactants they can be transformed into transparent isotropic gels with viscoelastic properties whose yield points are large enough to prevent flow under gravitational forces. Such a system is shown in Figure 11. A glass vessel containing the hydrocarbon gel was turned in the upside down position. The system can be kept in this position for many hours without any significant motion of the gel being observable. Such systems can contain up to 99.5% of the hydrocarbon, the rest being surfactant and water. The trick in obtaining such systems lies in their preparation. They do not automatically form when we try to dissolve or emulsify a small amount of an aqueous surfactant solution in a relatively large amount of a hydrocarbon phase. They are not even formed spontaneously on using high speed emulsifiers. Rather, such highly mechanical procedures may actually lead to the breakdown of gel systems that may be realizable otherwise. Such systems were first described in the literature by *K. J. Lissant*.[22] *G. Platz* and *G. Ebert* have recently carried out intensive investigations on these systems.[22] They have determined the amounts of different hydrocarbons which can be gelified by this procedure by various surfactants, and have also investigated the viscoelastic properties of the systems as a function of the composition. These investigations have shown that such gel systems consist of polyhedra of surfactant layers filled with the hydrocarbon; the water is contained in the spaces between the polyhedra. They have the same structure as the polyhedral structure of foams. The continuous phase-type character of the small amount of water is expressed in the relatively high conductivities of the systems.

Fig. 11. Transparent hydrocarbon gels; glass vessel in the up-side down position to demonstrate the gel properties. The gel consists of 99% of pentane. SDS (sodium dodecyl sulfate) was used as surfactant.

The polyhedra have typical dimensions of around 5 μm. They can be made visible under the microscope if the gel is swollen by dilution with a small amount of water. To increase the visibility of the phase boundaries, the water layers can be colored by addition of water soluble dye molecules. A typical micrograph with the visible structures is shown in Figure 12.

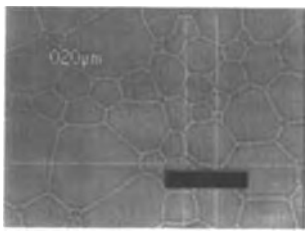

Fig. 12. Micrograph of the structure of a hydrocarbon gel. Note that the angles where two layers meet are always about 120°. The figure 0.20 μm refers to the distance between the two vertical lines.

The gels are of particular high transparency when the amount of water in the system is very small and the refractive index of the surfactant/water mixture is matched to that of the hydrocarbon. For the formation of the gel systems it is necessary to start with a concentrated aqueous surfactant solution. Particularly well suited for this purpose are surfactant solutions whose compositions lie between those of the liquid crystalline hexagonal phase and those of the lamellar phase. Small amounts of the hydro-

carbon can be added to equally small amounts of the surfactant solution; the concentrated gel thus obtained can then be diluted by continuous addition of more hydrocarbon. While these systems in their final form are probably still two-phase systems in the thermodynamic sense it is interesting to note that there is an upper limit for the solubility of the hydrocarbons in the system. If too much hydrocarbon is added an excess phase of the hydrocarbon separates which is in equilibrium with the highly viscous system. It is also noteworthy that the transparent viscous system in this state is flowable and does not exhibit a yield point if it is not shaken too vigorously during its preparation. When such a purely viscous system is given a vigorous jerk, however, it gelifies immediately and remains gelified for a long time. On the other hand, the gel can be completely broken by ultrasonic treatment. Upon sonication, the system separates into two liquid phases. Both cationic and anionic surfactants may be used for the preparation of the gels. If a gel prepared from a cationic surfactant is brought into contact with a gel prepared from an anionic surfactant, the gel structure is destroyed—due to mutual neutralization of the oppositely charged surfactant molecules. Hydrocarbon separates from both systems.

The elastic properties of the gels can be described by equations which were originally developed by *Princen* for the elasticity of foams.[23] The essential parameters are the interfacial tension and the size of the polyhedra. Under a shear deformation the interfacial area of the lamella is increased; this leads to a restoring force. For the shear modulus, *Princen* derived the following equation (σ = interfacial tension, R_{32} = mean drop radius).

$$G_0 = 1.769\sigma\phi^{1/3}(\phi - 0.712)/R_{32} \qquad (c)$$

On the basis of the polyhedra model it is also possible to explain the term 'yield point'. The system starts to flow when the deformation is large enough to allow two neighboring volume elements to pass each other. The situation is shown schematically in Figure 13.

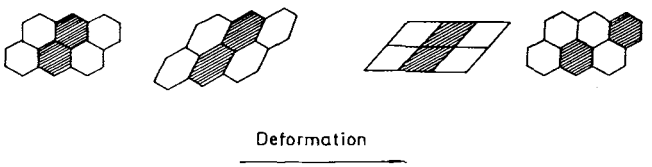

Fig. 13. Schematic representation of the yield value in hydrocarbon gels. The polyhedra are deformed under strain until two neighboring structures can slide past each other. The yield value is therefore determined by the shear modulus and a critical strain.

Platz, *Ebert*, and *Rehage* have shown that the experimentally determined elastic constants and yield values are in good agreement with the theoretically predicted values using this simple model.[24] One of the most remarkable features of these hydrocarbon gels is the fact that the hydrocarbon does not form a continuous phase even though the system consists of 99% of hydrocarbon. All the hydrocarbon is compartmented into small volume elements which are separated by thin aqueous layers and which are stabilized by the surfactant.

This poses the question of the possible existence of inverse gels, i.e. systems which consist of 99% of water, a small amount of surfactant, and possibly some hydrocarbon. The water would be compartmented in polyhedric cells, and the hydrocarbon would form the continuous phase. The walls of the cells would be formed by the surfactant. It is likely that such systems can indeed be formed. There are indications that the L_3-phase in the phase diagram of alkyl polyglycol ethers may indeed represent such a system. *B. Lindman* et al. have shown that the surfactants in these systems form a continuous phase even when the amount of surfactant is very small.[25] The aggregates in the L_3-phase are disklike and they could conceivably form a three-dimensional network. In the presence of salt such systems should have a low conductivity.

8. Microemulsion Gels (Ringing Gels)

We have learned so far that even small amounts of surfactants can, under certain conditions, gelify both water as well as hydrocarbons. It is therefore not surprising to find that gels are indeed formed at higher surfactant concentrations. There is however a particular kind of gel that is formed which exhibits very remarkable properties, and it is therefore only fitting to include such a system in our summary on fascinating phenomena in surfactant systems. Such a gel occurs, e.g., at high concentrations of surfactant in the systems surfactant-water-hydrocarbon. Usually the volume fraction of water is around 50–60% and the sum of the volume fraction of surfactant plus hydrocarbon makes up the remaining part. The volume fraction of hydrocarbon can vary between 0 and 30%. The systems are optically isotropic, transparent, and have a "pudding-like" consistency. Their yield value is high enough to suspend even large, high density particles (Fig. 14). Their most fascinating property, however, is their ability to give off a ringing sound when the vessel in which they are contained is tapped with a soft object like a piece of rubber. For a vessel with a cross section of a few centimeters the sound is in the audible frequency range of around 1000 Hz and decreases with a time constant of about 1 s. All the other gels which

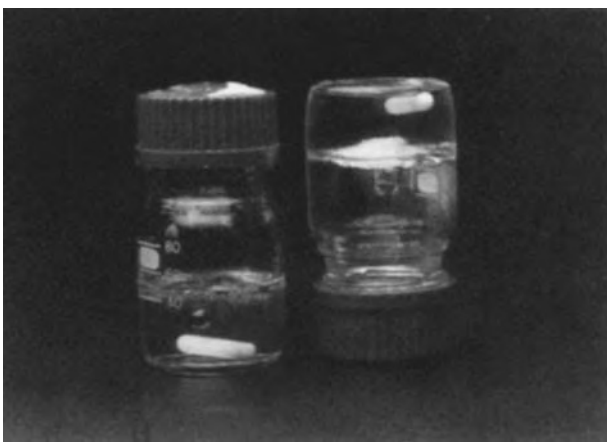

Fig. 14. View of a microemulsion or ringing gel with suspended steel ball bearings.

have been mentioned so far behave very differently in this respect, despite the fact that any gel can be deformed and therefore excited to the point of oscillation. However, the elastic energy is transformed into heat after only a few oscillations, because the elasticity of such gel systems is an entropy elasticity. The network is deformed and the entropy is thereby reduced. When the force which has stretched or deformed the network is released, the network relaxes back to its original state. The system may overshoot its equilibrium position a few times before reaching its final state. During this relaxation the branches of the network slide past solvent molecules; this leads to friction, and hence to dissipation of energy. It is for this reason that the stored energy is rapidly converted into heat. The slowly decreasing sound in the ringing gels indicates that the situation in these systems must be different. The elasticity cannot be caused by entropy but must have the same origin as the vibrations in solids like crystals or glasses. Both situations actually seem to occur in surfactant systems.

The ringing gels were first discovered in ternary systems of alkyl polyglycol ethers, paraffin-oil, and water. The phases with these peculiar properties were called microemulsion gels. It was assumed that hydrogen bonds between the ethoxy groups and water play a key role in the properties. *Führer* et al. and *Nürnberg* et al. carried out intensive investigations on both the microscopic structures in these samples and their elastic properties.[26] Electronmicrographs revealed the presence of globular aggregates with dimensions of up to about 300 Å. The dimensions were also in agreement with SAXS (small angle X-ray structure) data. According to these data the systems must consist of closely packed globular aggregates; the globules are filled with the hydrocarbon, and water forms the continuous phase.[26c]

The SAXS data for some of these systems show a strong correlation peak but no indication of long range order. The situation therefore corresponds to a microemulsion phase, formed from globular particles which are so densely packed that translational motion of the particles is no longer possible. The system seems to be rigidified to a glassy state. A similar conclusion was very recently reached by *A. Junginger* and *Joosten* et al. on the basis of SAXS data.[26c] The diffraction pattern obtained for the gel phases provided little information about the structure.

Systems with similar properties were recently observed by *H. Hoffmann* and *G. Oetter*.[27] In these systems an alkyldimethylamine oxide was used as surfactant. This means that the hydrogen bonds of the ethoxy groups cannot be the main reason for the elastic properties of the aforementioned systems. The phenomenon seems therefore to be a general one in surfactant chemistry and ringing gels can presumably be prepared from many different surfactants. It seems, however, that a few conditions must be fulfilled if they are to be formed. One such condition is that the surfactant in the isotropic binary surfactant solution is capable of forming rodlike micelles. When these rods undergo a rod-sphere transition with increasing solubilization of a hydrocarbon, the resulting little droplets behave like hard core globules in diffraction experiments and can form ringing gels, when the surfactant/hydrocarbon ratio which is necessary for the rod-sphere transformation is kept constant and the total amount of the mixture is increased.

In systems where the surfactant is saturated with hydrocarbons before the transition the microemulsion gels are not formed. It seems therefore that globular aggregates in the dilute solution are a prerequisite for the formation of microemulsion gels. Equally important is the interaction of globular aggregates. This means, moreover, that the surfactant layers and the hydrocarbon core of the globules are not connected to a continuous phase but that the alkyl chains are compartmentalized in small cells.

Densely packed globular particles can however also form cubic phases if all the globules have the same size. Such phases have recently been observed by *Fontell* et al. in the system didodecyldimethylammonium bromide/water/decane.[28] This binary surfactant/water system forms a lamellar phase. After solubilization of a hydrocarbon in the liquid crystalline phase, which contains between 30–40% surfactant, a cubic phase is formed. Obviously the hydrocarbon enforces the transformation of the surfactant layers into globular aggregates. The cubic phase for this system has been characterized by SAXS experiments. Its macroscopic properties are very similar to those of the previously described microemulsion gels. It seems therefore that ringing gels can occur both in the glassy state as well as in the more ordered liquid crystalline state with cubic symmetry.

9. Increase of Viscosity with Increasing Temperature

From experience with normal solutions, a decrease of the viscosity will usually be observed with increasing temperature. This is also the situation with many surfactant solutions, in particular with ionic surfactants. In some of the surfactant systems which are mentioned at the beginning of this article the viscosity decreases many orders of magnitude between 20°C and 80°C. However, the situation can also be the other way around. In solutions of nonionic surfactants like ethoxyalkanes the viscosity increases with increasing temperature.[29] The effects are usually not very large, but can however be dramatic in systems containing alkyl polyether sulfonates (Fig. 15).

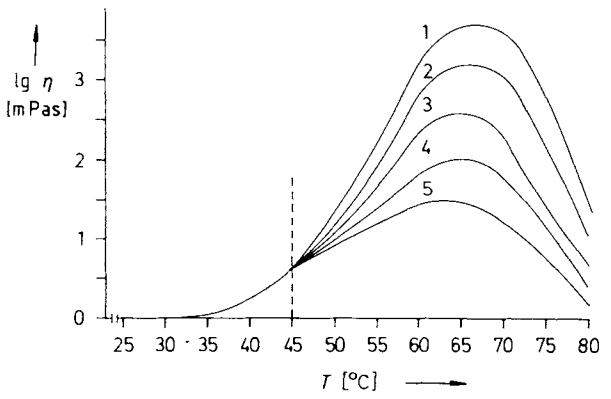

Fig. 15. Increase of the viscosity η with temperature for a surfactant solution of 0.01 M $C_{18}-C_6H_4-P_5-E_{11}-SO_3Na$ in the presence of 3.5% NaCl solution. The curves were recorded at different shear rates [s^{-1}]: 0.10 (1), 0.47 (2), 2.24 (3), 10.60 (4), 50.00 (5).

Recently, data on such a system have been published by *M. J. Greenhill-Hooper* et al.[30] A 2% solution of $C_{18}H_{37}-C_6H_4-(CH(CH_3)-CH_2-O)_5(CH_2-CH_2-O)_{11}SO_3Na$ ($=C_{18}-C_6H_4-P_5-E_{11}-SO_3Na$) in the presence of 3.5% NaCl solution has the same viscosity as water at room temperature. With increasing temperature, the viscosity increases by four orders of magnitude and reaches a maximum at 60°C. At higher temperatures it decreases again.

This effect is due to the transformation of globular micelles into rodlike micelles and finally into networks with increasing temperature. At low temperatures the ethoxy groups are strongly solvated and thus hydrophilic. They occupy a large interfacial area at the micellar interface; this forces the micelles into the globular state. With increasing temperature, the solvation is reduced and the ethoxy groups become more hydrophobic and require less space at the interface. The micelles can grow to rods and the viscosity begins to rise. Other nonionic systems like alkyldimethylamine oxide or phosphine oxide show a similar behavior. These examples show that it is possible to design systems in which the viscosity can increase or decrease with temperature. By exploiting the underlying principle of this effect it is possible to design systems with a very high viscosity over a large temperature range.

10. Phenomena under Shear or during Flow

The emphasis has so far been on phenomena occurring in surfactant systems at rest. For the most part the transient nature of the structures in these systems has not been considered. We have, however, to keep in mind that all these structures are permanently broken and reformed by thermal energy. The micellar structures are in a kind of stationary state. All network systems formed from rodlike or disklike micelles require a certain time to recover when the equilibrium distribution is perturbed by external forces which can be of mechanical, electric or magnetic origin. The systems can also form new equilibrium structures in the presence of these force fields and we can therefore expect to observe unusual phenomena when these parameters are varied.

One variable which plays an important role in surfactant chemistry is the shear rate which acts on flowing systems. All solutions flowing through pipes or which are stirred or pumped are under the influence of shear gradients which may or may not be constant in the whole phase. The shear gradients can have the same effect as a thermodynamic variable like temperature or pressure and contribute to a shift of phase boundaries. In addition, shear may affect systems differently than the temperature since shear is connected with a directional force while temperature is not. Orientational effects can therefore play an important role in surfactant systems under shear.

Many of these effects have not yet been studied in detail. We shall for this reason only mention them briefly in the following description of one particular phenomenon which has been studied extensively because of its industrial importance, namely the "drag reduction" phenomenon.[31] Some dilute surfactant systems suppress flow resistance in the region of turbulent flow. The effect can therefore be used to save energy in the transport of large quantities of water. Detailed studies on effective systems have shown that only those surfactant solutions are effective in which small rodlike micelles are present. Above a critical threshold shear rate these small rods form strings of rods and the strings then align in the direction of flow[32] (Fig. 16). As a consequence of this, small eddies which are present in turbulent flow are, to some extent, suppressed and the flow is laminarized; this leads to a reduction of friction.

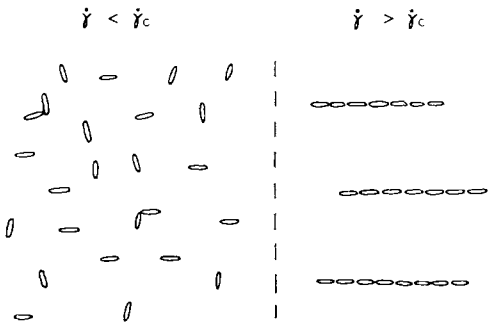

Fig. 16. Schematic view of the build up of large micellar structures under shear above a critical shear rate $\dot{\gamma}_c$. Note that the shear-induced structures are completely aligned, while for $\dot{\gamma} < \dot{\gamma}_c$ the solution is optically isotropic [32].

Viscoelastic surfactant solutions in the semidilute concentration range can also become turbid under flow.[33] It has been shown by flow birefringence measurements that the turbidity develops when the shear rate is high enough to align the large rodlike micelles. It is conceivable that the orientation of the rods reduces the mutual repulsion between them and that the attractive forces between the rods can become dominant, thus resulting in phase separation.

On the other hand, situations are possible in which two phase systems are transformed into an isotropic single phase solution by shear. If, e.g., a solution of 20 mM $C_{16}H_{33}(O-CH_2-CH_2)_3OSO_3Na$ is mixed with a solution of 20 mM $C_{14}H_{29}-NMe_3Br$ in the ratio 4:6, the solution becomes turbid and separates into two distinct macroscopic phases. If this system is vigorously shaken, a clear viscoelastic system is formed which separates into phases again upon standing.[34]

This phenomena is also observed in the case of ternary systems, e.g. the system 2-butanol/water/SDS/hexane.[35] This system separates into two clear phases which are transformable into a single phase by shaking or stirring. In systems of this kind, it would seem that the size of the structures is reduced by the shearing forces and as a consequence the attractive forces between the structures become smaller. The system is thereby transformed from a "condensed two phase equilibrium state" into the "gaseous" state.

11. Summary

The phenomena which have been described in this article are related to the formation or breakdown of surfactant networks. The network can be formed both in the aqueous phase and in a hydrocarbon phase if small quantities of water are present. In water, the networks are formed from entangled, long rodlike micelles, whereas the networks in

hydrocarbons consist of connected channels of water which form the interior of inverse rodlike micelles. Both types of systems can be considered as examples of bicontinuous phases. Under suitably optimized conditions such systems can contain as little as 0.1% of surfactant. In binary systems the diameter of the rods is determined by the chain length of a fully stretched surfactant molecule. In the aqueous phase the micelles can be swollen by solubilization of a hydrocarbon in the network, while in the hydrocarbon phase a swelling of the structure is possible by solubilization of water.

If too much hydrocarbon or water is solubilized the network of long cylindrical aggregates is transformed into globular structures. The network character thereby disappears, as does also the elastic properties and various phenomena associated with network formation. Under certain conditions the network can be saturated with hydrocarbon before the transformation into globular aggregates takes place. Surfactant networks are generally formed by modifying the chemistry of the surfactant, but they can also be formed by increasing the temperature. In systems in which they are formed by increasing temperature, a marked increase of the viscosity with increasing temperature is observed. Under very specific conditions, networks can even be formed under shear. These effects can be used to control the flow behavior of solutions. As a rule, viscoelastic surfactant solutions do not exhibit a yield point. The networks are of a temporary nature. Systems with high yield values are observed in microemulsion gels. These systems consist of densely packed globular structures and have yield values that can be so high that large metal particles can be suspended in them.

Networks do not however always consist of one-dimensional, more or less flexible rods; they can also be formed from two-dimensional planar structures. In such cases the solvent is compartmented in closed cells which are surrounded by sheets of surfactants. The buildup of such structures can lead to a complete gelification of the solvent. In contrast to networks of one-dimensional structures those made up of two-dimensional layered aggregates seem to be thermodynamically unstable; once they are mechanically destroyed, they cannot be reformed. A system in the gel state, however, can be stored for many weeks without fear of its special properties being lost.

Catalytic Activity of Enzymes Altered at Their Active Sites**

By Emil Thomas Kaiser*

Protein engineering has as its goals the design and construction of new peptides and proteins with novel binding and catalytic properties. In one approach to protein engineering, new active sites have been introduced into naturally occurring proteins either by site-directed mutagenesis or by chemical modification. Providing that important changes in the tertiary structures do not result from such alterations, at least a portion of the binding site of the original protein should be available for the formation of complexes between the altered enzyme and its substrates. Many examples of active-site mutations have been described, including the generation by us of a cysteine mutant of alkaline phosphatase. A fundamental limitation of the site-directed mutagenesis methodology is that replacements of residues are restricted to the twenty naturally occurring amino acids. The alternative, chemical modification, is difficult to carry out for the specific replacement of one amino acid by another. However, we have shown that through such modification coenzyme analogues can be introduced covalently into appropriate positions in proteins, allowing us to produce semisynthetic enzymes with catalytic activities radically altered from those of their precursor proteins. In another approach to protein engineering efforts have focused on the construction of systems where, as a first approximation, folding can be neglected and the preparation of secondary structural units is the target. Examples of the successful design of biologically active peptides and proteins along such lines, taken from our own work, include molecules mimicking apolipoproteins, toxins, and many hormones. In recent studies we have progressed to the stage where we are starting to combine the two general approaches to protein engineering we have described and are able to construct small enzymes like ribonuclease T_1 and its structural analogues.

1. Introduction

An important goal of our research in the field of protein engineering is the design of new enzymatic catalysts starting from the constituent amino acids. This is a daunting challenge, particularly since there are, at the present time, no reliable procedures for predicting tertiary or folded structures from primary amino acid sequences. Accordingly, a number of years ago when we began our protein engineering efforts we decided to proceed along two different routes. In one route, we elected to start with naturally occurring folded structures and to introduce new active sites by either chemical modification[1-3] or site-directed mutagenesis.[4] As long as major changes in the tertiary structure do not result from such alterations, this route should allow us to utilize at least part of the binding site of the original protein for the formation of complexes between the modified enzymes and substrates.

Our second approach to the construction of new proteins focuses on the design of structural regions, holding active sites constant where they occur. In contrast to tertiary structures, it appears quite feasible to predict amino acid sequences which form well-defined secondary structures, particularly in cases where peptides or proteins bind at biological interfaces. Thus, for surface-active peptides and proteins ranging in their biological activity from apolipoproteins through chemotactic agents and peptide toxins to peptide hormones, we believe that amphiphilic secondary structures (that is, secondary structures which are hydrophilic on one face and hydrophobic on the other) are readily induced when binding occurs to amphiphilic surfaces such as those found at biological interfaces.[5-7] We have developed design principles permitting the construction of model peptides and polypeptides which simulate the biological and physical properties of the naturally occurring amphiphilic systems. For example, careful examination of a space-filling model of salmon calcitonin, a peptide hormone with high hypocalcemic activity, led us to propose that the biologically active structure of this hormone consists of three parts[8,9] (Fig. 1A). First, there is the "active site" comprising residues 1-7 which are contained in a disulfide loop. The second structural region consists of residues 8-22 which have the potential to form an amphiphilic α-helix (Fig. 1B). When one examines this helix, it is striking that only one residue, the glutamic acid at position 15, violates the hydrophobic-hydrophilic segregation. The final region consists of residues 23-32, a region which serves as a kind of hydrophilic spacer. The proline amide residue at the C-terminus is crucial for the biological activity of the hormone, and perhaps it should be considered to be part of the active site of the hormone in addition to the N-terminal region (residues 1-7). In our model building, we have focused our attention on testing the importance of

SCT-I MCT-II MCT-III

Fig. 1. A) Sequences of salmon calcitonin I (SCT-I) and model calcitonins MCT-II and MCT-III. MCT-II differs from MCT-III in having a leucine residue at position 15 and has hypocalcemic activity roughly comparable to that of SCT-I, while MCT-III is somewhat more active. B) α-Helical projections of the 8-22 sequences of SCT-I, MCT-II, and MCT-III. The amino acid residues in the shaded areas are hydrophobic and the unshaded residues are hydrophilic. The segregation of the faces of the helices into hydrophobic and hydrophilic regions can be clearly seen.

the amphiphilic secondary structure (residues 8–22) through the construction of analogues. The N-terminal active-site region has been maintained constant, but the putative helical region has been replaced by sequences which have an accentuated potential for forming amphiphilic α-helical structures but differ very significantly from the natural sequence in the region 8–22. The hydrophobic face of salmon calcitonin's helical region consists of a considerable number of leucine residues which are very good aliphatic α-helix formers. In designing our replacement helices, we have found that the most active analogue structures preserve, in large part, the sequence and distribution of residues on the hydrophobic face of the salmon calcitonin helix but have a radically different sequence with increased α-helical potential on the hydrophilic face (Fig. 1B). Our most recent analogue, MCT-III, has a hydrophilic face quite different from that of natural salmon calcitonin but preserves, except for a very minor change, the residues present in the natural hormone's hydrophobic face (Fig. 1). This latest analogue shows about 2½ to 3 times the hypocalcemic activity of the naturally occurring hormone.[10] Studies in which we have designed and constructed models along similar lines have shown that for many hormones, like β-endorphin, corticotropin-releasing hormone, glucagon, growth hormone releasing factor, neuropeptide Y, and vasoactive intestinal peptide, amphiphilic secondary structures play an important role in the biological and physical properties of the hormone.[11]

In this article we are going to concentrate on the approach in which new active sites are introduced into existing tertiary structures. However, as will be seen later, we are now proceeding from the design of secondary structural systems in molecules like calcitonin, where, to a first approximation, tertiary structure has been neglected, to cases in which tertiary structure is crucial. As we learn an increasing amount about the redesign of secondary structural regions in molecules where tertiary structure is all important, we are moving closer to the time when it will be possible to put together what we have learned about building molecules in regions outside the active site with the work which we have done on the active sites so that we can consider the construction of whole enzymatic systems with new structural features and catalytic functions.

2. Choice of Protein Templates for Introduction of New Catalytic Functionalities

In choosing protein structures in which to introduce new catalytic sites, we have felt that it was important to start with systems where the tertiary structure was well defined through X-ray crystallographic studies. Another important consideration is that the proteins being altered be readily available and easily purified. Since we wanted to make the conceptual development of the design of active sites the focal point of our work, we have tried to avoid working on systems where technical difficulties in obtaining purified and well-characterized modified enzymes will occur. The four main proteins whose active sites we have altered are *E. coli* alkaline phosphatase,[12] glyceraldehyde-3-phosphate dehydrogenase (rabbit skeletal muscle[13] and *Bacillus thermophilus*[14]), hemoglobin,[15] and papain.[16–22] In the case of alkaline phosphatase, the active site has been altered by site-specific mutagenesis and for the other three enzymes alterations have been made by chemical modification to produce what we have termed "semisynthetic" enzymes. For each of the proteins where we have redesigned the active site through model building and the use of computer graphics based on the X-ray coordinates, we have examined whether the active-site modifications we have proposed will permit the productive binding of potential substrates. We have found that such model building has been enormously useful in helping us to predict what sorts of substrates we might employ for the study of the mutated enzymes.

3. Choice of Residues for Modification

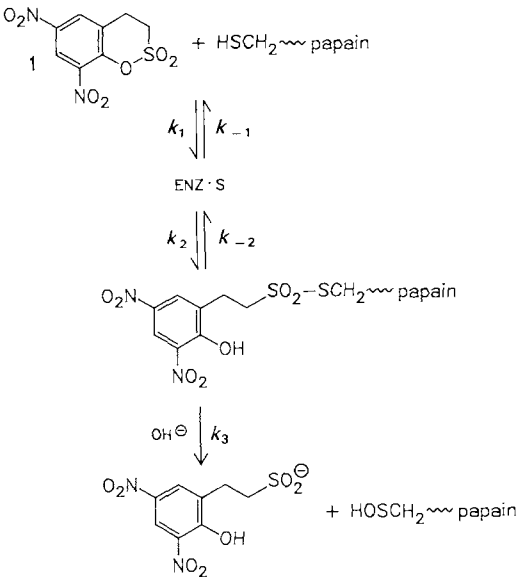
When site-specific mutagenesis is used as the technique for altering an enzyme's active site, there is a great deal of flexibility in picking a residue to be altered. Although steric and electrostatic considerations are important, there is no restriction on which residues might be altered except for problems which can be encountered in the expression of the mutant gene. In altering enzyme active sites by chemical modification, on the other hand, nucleophilic groups in the enzyme are usually the most convenient targets since most of the reagents with which stoichiometric modifications can be performed contain electrophilic centers. Thus, in our generation of semisynthetic enzymes by the chemical modification of glyceraldehyde-3-phosphate dehydrogenase, hemoglobin, and papain, we have utilized uniquely reactive sulfhydryl groups in these proteins for modification by coenzyme analogues.[13-22] Of course, an important factor in our choice of residues for modification is the apparent accessibility of the modified active site to the binding of appropriate substrates, as judged from model building.

4. Approaches to the Introduction of New Active Site Groups in Proteins

4.1. Chemical Methodology

The first example of the conversion of one active-site nucleophilic residue to another was studied independently by *Bender*[23] and *Koshland*[24] and their co-workers. They found that the treatment of subtilisin with α-toluenesulfonyl fluoride, followed by displacement of the resulting sulfonate group using thiolacetate and subsequent hydrolysis of the acetyl group, gave rise to thiolsubtilisin, a mutated enzyme containing cysteine in place of serine at its active site. Because thiolsubtilisin contains a histidine residue in close proximity to the new cysteine, it seemed possible that the enzyme would show proteolytic activity in much the same way as the naturally occurring thiol enzyme papain does. It was found, however, that thiolsubtilisin was an extremely poor endopeptidase, although it retained the ability to undergo acylation at the active-site thiol group by activated derivatives such as active esters and acyl imidazoles. Subsequent to the thiolsubtilisin work, we explored the consequences of introducing new potential nucleophilic groups into enzyme active sites through modification with highly reactive cyclic esters.[25-28] We were able to show, for example, that the phenolic hydroxyl group introduced into papain by modification of the enzyme's active-site sulfhydryl group (Cys-25) with the sultone 1 could act as an effective intramolecular nucleophile, resulting in the desulfonylation of the enzyme accompanied by re-formation of the cyclic sulfonate (k_{-2} of Scheme 1). Of course, this reaction did not involve generation of a new catalytic nucleophile, but it did show that a nucleophilic group different from that originally in the enzyme active site could be introduced and could function effectively in the enzyme template.

Active-site nucleophiles have been altered in a number of enzymes involved in acyl transfer reactions.[4,29-31] In



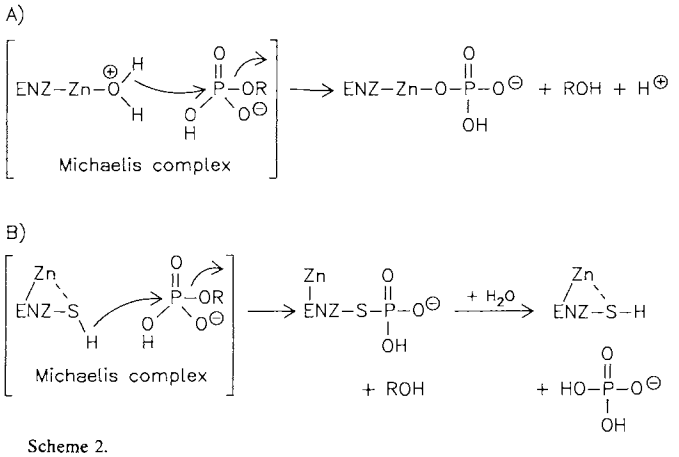
Scheme 1.

general, the mutations result in enzymes possessing low activity towards all but the more highly activated substrates, just as had been observed with thiolsubtilisin. The catalytic pathway for most acyl transfer reactions involves the formation and decomposition of tetrahedral intermediates (except possibly in those cases where very good leaving groups are involved) and requires a series of rapid proton transfers. The replacement of a nucleophilic residue at the active site of a proteolytic enzyme by a new nucleophile may result in the retardation of some proton transfer steps causing a bottleneck in the overall catalytic process. If this hypothesis is correct, then it is possible that to obtain effective new active-site nucleophiles in acyl transfer enzymes there may have to be accompanying alterations of the active-site environment through additional mutations.

4.2. Site-Directed Mutagenesis

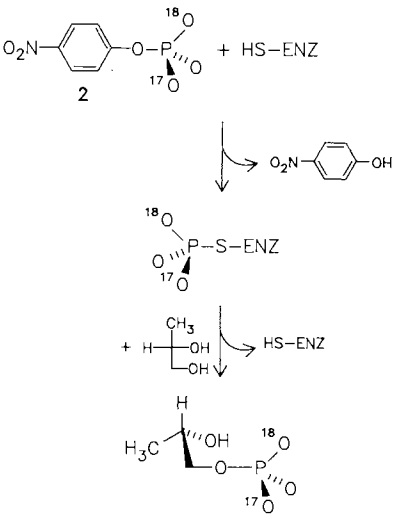
The possibility that alteration of active-site nucleophiles may have less deleterious effects in enzymes catalyzing other types of group transfer reactions where proton transfers may not be a requirement for effective catalysis has led us to studies on *E. coli* alkaline phosphatase.[12,31] Conversion of the active-site serine to cysteine by site-directed mutagenesis in alkaline phosphatase results in a mutated enzyme which shows high catalytic activity towards substrates such as 4-nitrophenyl phosphate and 2,4-dinitrophenyl phosphate. Unlike the wild-type enzyme, which shows for many substrates an invariant k_{cat} with changes in the leaving-group tendency, the "thiol alkaline phosphatase" exhibits a marked dependence of its k_{cat} values on the leaving-group tendency. Furthermore, when experiments were done using Tris as a trapping nucleophile, in the case of the wild-type enzyme the amount of trapping of the phosphoryl group by the nucleophile did not, in general, depend upon the nature of the leaving group in the phosphate monoester used. However, for the thiol enzyme there was a strong dependence of the trapping reaction upon the nature of the leaving group. Attempts to titrate

the active-site thiol group in thiol alkaline phosphatase with sulfhydryl reagents such as 5,5'-dithiobis(2-nitrobenzoic acid), DTNB, were unsuccessful. The lack of success could conceivably be due either to steric problems in binding the DTNB in the active site or, alternatively, to the binding of the thiol group by the active-site zinc ion in the mutant enzyme. Only when the active-site metal ion had been removed by treatment of the enzyme at low pH could the sulfhydryl group be titrated. An attempt to detect the formation of a phosphoryl enzyme in the action of the thiol alkaline phosphatase by the use of stopped-flow spectrophotometry employing 2,4-dinitrophenyl phosphate under conditions where a "burst" could be observed in a similar experiment with the wild-type enzyme[32] revealed no such burst for the mutant species.[33] The interpretation of these various results was ambiguous. In particular, one possible explanation seemed to be that coordination of the thiol group of thiol alkaline phosphatase to the active-site zinc resulted in a mutant enzyme which reacted by a new pathway, namely a carbonic anhydrase mechanism, involving the attack by either water or hydroxide ion coordinated to zinc on the phosphate monoester substrates (Scheme 2A). Alternatively, it seemed quite possible that no change



Scheme 2.

in mechanism had occurred but that only a change in the rate-limiting step of the reaction to give rate-limiting phosphorylation of the mutant enzyme had happened (Scheme 2B). To differentiate between these possibilities we performed an experiment with 4-nitrophenyl phosphate chirally labeled with different isotopes of oxygen in the phosphoryl group (**2**). If the mechanism had changed to a zinc-hydroxide or a zinc-water type (Scheme 2A), then we would expect that the reaction would involve a single displacement and, if we transferred the phosphoryl group to a suitable acceptor, we would expect to see stereochemical inversion by such a route. On the other hand, if the thiol group was acting by the usual mechanistic pathway involving the transient formation of a phosphoryl enzyme (Scheme 2B), the stereochemical outcome should be one of retention, due to the expected inversion in the phosphoryl enzyme-forming step and another inversion in the decomposition of the phosphoryl enzyme.[34,35] We found that retention occurred when we followed the course of reaction with the thiol enzyme using (*S*)-propane-1,2-diol as the



phosphoryl group acceptor.[33] Thus, it appears that the mechanism of attack of the thiol alkaline phosphatase on phosphate monoester substrates involves a normal pathway (Scheme 2B) with a change, however, in what is the rate-limiting step. For the thiol enzyme under the conditions we have employed, it appears that rate-limiting phosphorylation occurs in contrast to the situation for the wild-type species where, depending upon the pH, dephosphorylation or release of product inorganic phosphate is rate-controlling.

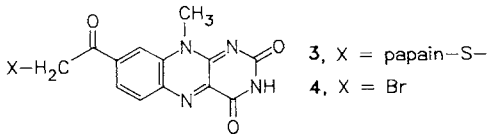
4.3. Semisynthetic Enzymes Obtained by Covalent Modification of Active Sites Using Coenzyme Analogues

In view of the results on proteolytic enzymes showing that the replacement of nucleophiles at the active site was not a strategy which readily produced highly active mutated enzymes, a number of years ago we decided to focus on the construction of modified enzymes which we termed semisynthetic enzymes where effective catalysis should not require a series of rapid proton transfer steps.[1,3,13-22] In our approach, we produced semisynthetic enzymes by chemical modification of an amino acid residue of an appropriate protein template with a reactive coenzyme analogue. We postulated that, if properly designed, the hybrid species could exhibit a combination of the general binding properties of the original protein template and the catalytic activity of the covalently bound coenzyme. Flavin cofactors have proved to be particularly good prosthetic groups in our work, although many other cofactors remain to be examined. Such isoalloxazine derivatives are readily synthesized, act as good model compounds for the biological cofactors FAD and FMN and catalyze in solution many of the same reactions promoted by naturally occurring flavoenzymes, although with lower rates and selectivities. To date, we have successfully used a series of isoalloxazine derivatives to modify three templates: papain, glyceraldehyde-3-phosphate dehydrogenase, and hemoglobin. These systems, all of which can function as efficient flavin-dependent oxidoreductases, will be discussed in turn.

4.3.1. *Flavopapain*

Among the most successful targets for our approach to the preparation of semisynthetic enzymes has been the hydrolytic enzyme papain. On the basis of both X-ray crystallographic investigations[36,37] and solution studies, it is known that there is an extended groove approximately 25 Å long in the vicinity of the active-site residue Cys-25. Furthermore, this residue is highly reactive to modification with reagents containing electrophilic centers, and the course of modification can be readily monitored by a variety of techniques including sulfhydryl titration and the loss of the enzyme's proteolytic activity. Using the X-ray structural data it is possible to show with appropriate models that modification of the Cys-25 sulfhydryl group with various flavin coenzyme analogues should permit the extended binding groove near the Cys residue to remain accessible to potential substrates which might interact with the flavin moiety. Our choice of the flavins as the coenzyme analogues for the modification experiments was motivated by the knowledge that these compounds are fairly effective even in the absence of enzyme in catalyzing various oxidation–reduction reactions.[38] Therefore, we felt that it might be sufficient to bind a potential substrate in a geometrically favorable fashion in the vicinity of the enzyme-bound flavin in order to achieve a rapid rate of reaction. In other words, unlike hydrolysis reactions where it seems likely that amino acid functional groups from the protein have to be placed correctly to enhance proton transfer reactions, for the enzyme-bound-flavin reactions to occur it might be sufficient to utilize the binding cavity of the enzyme without requiring specific participation of any enzyme-bound functional groups.[1,13,16–20,36,37] Because our earlier work on flavopapain has been reviewed rather extensively,[1,39] only the more recent studies will be described here.

The most effective flavopapain prepared, **3**, was obtained by alkylation with 8-bromoacetyl-10-methylisoalloxazine **4**. This modified enzyme reacts rapidly with a variety of hydrophobic *N*-alkyl-1,4-dihydronicotinamides. The k_{cat}/K_m value measured for the oxidation of the best of the substrates examined, *N*-hexyl-1,4-dihydronicotinamide, is in the vicinity of $10^6\ M^{-1}\ s^{-1}$ in air-saturated buffer at pH 7.5 and 25 °C.[20,21] Comparison of this rate parameter to the second-order rate constant for the corresponding oxidation reaction catalyzed by the simple model compound 8-acetyl-10-methylisoalloxazine shows that there is more than a 10^3-fold rate acceleration for the enzymatic system. Using anaerobic conditions and the stopped-flow technique, we have investigated the individual steps in the oxidation of *N*-alkyl-1,4-dihydronicotinamides catalyzed by 8-acetylflavopapain **3**. The kinetic results obtained are consistent with Scheme 3.



3, X = papain–S–
4, X = Br

$$E_{ox} + NRNH \underset{K_s}{\rightleftharpoons} E_{ox} \cdot NRNH \xrightarrow{k_2} EH_2 + NRN$$

Scheme 3. E_{ox} = the oxidized form of flavopapain **3**, EH_2 = the reduced form of flavopapain **3**, $E_{ox} \cdot NRNH$ = the Michaelis complex, NRNH = *N*-alkyl-1,4-dihydronicotinamide, NRN = *N*-alkylnicotinamide.

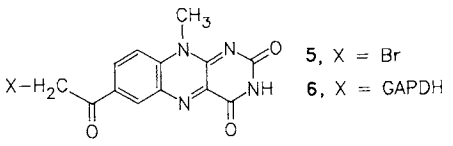
For three dihydronicotinamides, *N*-hexyl-, *N*-benzyl-, and *N*-propyl-1,4-dihydronicotinamide, very high values of k_2, the rate constant for the conversion of the Michaelis complex to the reduced dihydroflavopapain species, were obtained ($370 \pm 70\ s^{-1}$, $29 \pm 5.5\ s^{-1}$, and $31 \pm 11\ s^{-1}$, respectively). Indeed, for the *N*-hexyl compound the k_2 value ($\approx 400\ s^{-1}$) was sufficiently large that even using a very efficient stopped-flow instrument only an estimate of this rate constant could be calculated.

Because oxygen is a relatively poor oxidant for the dihydro form of flavopapain **3**, under the turnover conditions used for the aerobic reactions of the dihydronicotinamides, the reaction with dihydroflavopapain was found to be largely rate-limiting over the substrate concentration range employed.[21] Therefore, to achieve turnover conditions where the reduction step rather than the oxidation of the dihydroflavopapain is rate-limiting, it is necessary to employ an acceptor that reacts more rapidly than oxygen. We found that 3-(4,5-dimethylthiazol-2-yl)-2,4-diphenyltetrazolium bromide (MTT), was an especially effective acceptor for achieving high turnover rates in the action of flavopapain **3**. With MTT at about 400 μM, we obtained k_{cat} values for the oxidation of *N*-benzyl- and *N*-propyl-1,4-dihydronicotinamides ($31.5 \pm 1.0\ s^{-1}$ and $62.5 \pm 9.5\ s^{-1}$, respectively) which corresponded reasonably well to the rate constants k_2 (Scheme 3) obtained under anaerobic conditions for the reduction of 8-acetylflavopapain **3** by these substrates. This work demonstrates that a flavoenzyme exhibiting high catalytic efficiency both in terms of k_{cat}/K_m and of the value of the turnover number can be constructed by utilizing the active and binding sites of the hydrolytic enzyme papain. The naturally occurring coenzyme NADH is a relatively poor substrate for flavopapain **3**; this is understandable since the structure of papain indicates that the binding region of the enzyme is quite hydrophobic and should, therefore, interact much better with the *N*-alkyl-1,4-dihydronicotinamides than with NADH.

We have also shown that flavopapains can mediate the oxidation of thiols to disulfides.[22,40] Once again, 8-acetylflavopapain **3** was found to be an effective catalyst for such reactions. Under anaerobic conditions the k_2/K_s values (cf. Scheme 3) for the reduction of the flavopapain by DL-dihydrolipoamide and DL-dihydrolipoic acid were 4400 and $3400\ M^{-1}\ s^{-1}$, respectively. These rate parameters were 126 and 200 times larger than the second-order rate constants for the corresponding reactions of DL-dihydrolipoamide and DL-dihydrolipoic acid with the model compound 8-acetyl-10-methylisoalloxazine. With the dye MTT as an electron acceptor we obtained k_{cat} and K_m values for the oxidation of dihydrolipoamide by flavopapain **3**, under turnover conditions, which were in approximate agreement with the k_2 and K_s values measured under anaerobic conditions, demonstrating that the rate-limiting step of the catalytic cycle is substrate oxidation rather than oxidation of dihydroflavin.[22]

4.3.2. Studies with Flavo-Glyceraldehyde-3-phosphate Dehydrogenase (Flavo-GAPDH)

Recently, we have worked extensively with a new enzyme template, GAPDH, a readily available tetrameric enzyme for which both the primary and tertiary structures are available.[41] The active site contains a binding site for $NAD^{\oplus}$/NADH adjacent to Cys-149 and the catalytic region where glyceraldehyde-3-phosphate binds. Alkylation, even by sterically demanding groups, of this sulfhydryl group, which is essential for catalysis, does not prevent nicotinamide binding.[42,43] Computer graphics modeling (Evans and Sutherland PS-300) using the X-ray coordinates for the thermophilic enzyme from *Bacillus stearothermophilus*[44] suggested that GAPDH might be a good template for the rational design of flavin-dependent oxidoreductases selective for NADH rather than for the hydrophobic *N*-alkyl-1,4-dihydronicotinamides which are oxidized preferentially by flavopapain **3**. At first, we employed GAPDH from rabbit muscle tissue[13] but most of our more recent work has been done on the thermophilic enzyme from *Bacillus stearothermophilus*[14] which is much more stable than the muscle protein. Modification of apo-GAPDH from the respective species with 7-bromoacetyl-10-methylisoalloxazine **5** resulted in incorporation of only one flavin molecule per subunit of these tetrameric enzymes.



5, X = Br
6, X = GAPDH

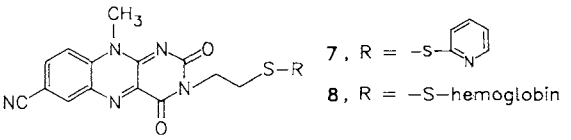
Our HPLC and gel filtration data indicate that the initially formed 7-acetylflavo-GAPDH **6** is tetrameric. However, in a process that is apparently irreversible the bacterial semisynthetic enzyme subsequently undergoes dissociation (approximately 1 day at 4 °C) into dimers. For the thermophilic enzyme we have principally studied the dimer. The rabbit muscle flavoenzyme is far less robust, losing 40–60% of its activity within about 12 h.[13] Therefore, in the latter case, only the tetramer was studied. In examining the reactivity of the dihydronicotinamides with the flavo-GAPDH species, we found that, as expected, NADH is the optimal substrate for both proteins. The data obtained with the tetrameric rabbit muscle enzyme are readily fit by standard Michaelis-Menten kinetics. However, pronounced negative cooperativity is observed with the bacterial dimer. We cannot conclusively rule out trivial explanations for the apparent cooperativity (a population of heterogeneous active sites, for instance) at this time. Still, since half-of-the-sites reactivity is well documented for GAPDH itself, cooperative catalysis by bacterial **6** may not be an unreasonable possibility.

The second-order rate constant, k_2, for the oxidation of NADH by 7-acetyl-10-methylisoalloxazine at 25 °C in air-saturated buffer is only 12.9 $M^{-1} s^{-1}$. Under these conditions, the rate enhancement observed in the case of the rabbit muscle enzyme as judged from the rate constant k_{cat}/K_m is 83-fold[13] and for the bacterial flavoprotein it is nearly 6000-fold (under circumstances where negative cooperativity is minimal).[14] Clearly, the magnitude of k_{cat}/K_m for bacterial 7-acetylflavo-GAPDH **6** at low substrate concentrations is in the range of k_{cat}/K_m values observed for naturally occurring flavoenzymes that oxidize NADH. As we have seen for 8-acetylflavopapain **3**, turnover of 7-acetylflavo-GAPDH **6** under aerobic conditions is limited by the rate of reoxidation of the dihydroflavin generated during each catalytic cycle. For this reason, the value of k_{cat} measured depends explicitly on the oxygen concentration and does not reflect the true efficiency of the hydride transfer step. Therefore, we used rapid mixing techniques under anaerobic conditions to determine the rates of reduction of the flavin in the enzyme-substrate complex. In contrast to the situation with rabbit muscle 7-acetylflavo-GAPDH **6**, which is too fragile for stopped-flow experiments, the bleaching of the enzyme-bound flavin cofactor in the bacterial **6**, which followed biphasic kinetics in the presence of excess NADH, could be readily observed by stopped-flow methodology. Approximately half of the isoalloxazines are reduced in a very rapid step and the remainder at a much slower rate, behavior typical of negatively cooperative enzymes that exhibit half-of-the-sites activity.[45] Saturation kinetics are observed for the rate data in the fast phase step of the reduction of bacterial **6**. A rate constant of $k_1 = 1.14\ s^{-1}$ for the reduction of the rapidly reacting subunit proceeding from the corresponding Michaelis complex and an apparent dissociation constant for the Michaelis complex of 12.4 μM were obtained from kinetic measurements on the fast phase. Thus, the apparent second-order rate constant for the reduction of the rapidly reacting subunit of the enzyme is 91900 $M^{-1} s^{-1}$, a value only slightly larger than the steady-state value of k_{cat}/K_m (75600 $M^{-1} s^{-1}$) determined for NADH with this enzyme and comparing very favorably with k_{cat}/K_m obtained for naturally occurring flavoenzymes that oxidize NADH. If a suitable electron acceptor reacting much more rapidly than oxygen to reoxidize dihydroflavo-GAPDH could be found, the turnover number for this bacterial flavoenzyme could approach $1\ s^{-1}$, a value comparable to numbers seen for several natural systems. The work that we have done to date amply demonstrates that GAPDH is an excellent choice as a template for the construction of artificial enzymes.

4.3.3. Studies on Flavohemoglobin

Recently, we have generated a new type of semisynthetic enzyme, flavohemoglobin, in which the heme group is maintained in the protein but a flavin molecule is added by covalent modification.[15] Heme proteins like cytochrome P-450, which carry out redox reactions, function typically by means of single electron transfers in each step.[46] When they operate with the usual biological electron donors like NADPH, which act by two electron transfers, there is a requirement for an electron-transport system. In a typical P-450-like electron-transport system consisting of NADPH, O_2, and NADPH-cytochrome P-450 reductase, a major flavoprotein in the microsomal electron-transport system,[47] hemoglobin has been found to catalyze a wide variety of monooxygenase reactions.[48–52] We sought to de-

termine whether hemoglobin could be modified in a fashion such that it might react directly with two electron donors without the intervention of the full electron transport system. Accordingly, we attached an isoalloxazine residue covalently to hemoglobin in the vicinity of the heme with the hope that the flavin moiety could mediate electron transfer, obviating the need for the P-450 reductase (EC 1.6.2.4). We have found that the flavohemoglobin species did indeed serve as a hydroxylase for aniline in the absence of the reductase protein.[15] The chemical modification was carried out by reaction of a derivative of 7-cyanoisoalloxazine **7**, containing a reactive disulfide group attached through a tether to the N-3 position, with the thiol group of cysteine β-93 in carbon monoxide-hemoglobin ($COHb^{2\oplus}$). Subsequently, ferric flavohemoglobin (Fl-$Hb^{3\oplus}$) **8** was prepared by the oxidation of the covalently modified species Fl-$COHb^{2\oplus}$ with potassium ferricyanide.



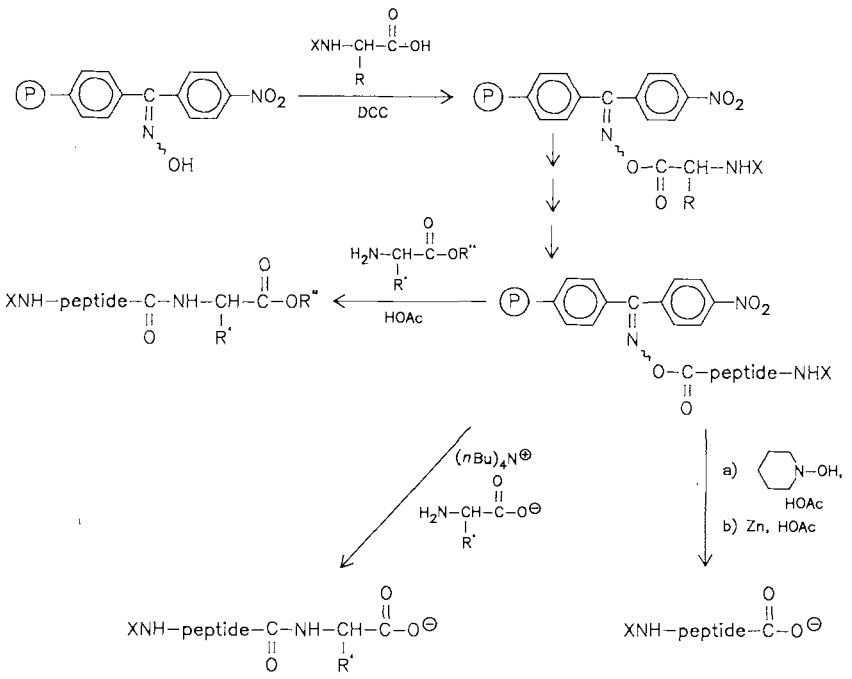
Kinetic measurements on the aniline hydroxylase activity of Fl-$Hb^{3\oplus}$ at pH 7.5 showed that the apparent K_m values for aniline observed were essentially the same as those for ferric hemoglobin, $Hb^{3\oplus}$, assayed in the presence and absence of NADPH-cytochrome P-450 reductase. The apparent k_{cat} for $Hb^{3\oplus}$ was increased considerably when we reconstituted that system with P-450 reductase.[48-52] Still, the apparent k_{cat} for $Hb^{3\oplus}$ in the reconstituted system was smaller than that seen for Fl-$Hb^{3\oplus}$ by itself. Thus, it is clear that the flavin covalently bound to hemoglobin in Fl-$Hb^{3\oplus}$ is able to substitute effectively for the reductase. Electron transfer between the neighboring prosthetic groups in Fl-$Hb^{3\oplus}$ proceeds even more efficiently than that in the combined $Hb^{3\oplus}$–reductase system.

Since a free model flavin does not catalyze the *p*-hydroxylation of aniline in the absence of hemoglobin, it is clear that the heme group is directly involved in the reaction of flavohemoglobin with aniline. The predominance of *p*-hydroxylation over *o*-hydroxylation ($p/o > 4/1$) suggests also that the active oxygen species is likely to be bound to heme and is probably not freely diffusible as in the case of aniline hydroxylation mediated by Fenton's reagent where *o*-aminophenol is the major product. It thus may be that flavohemoglobin acts in a fashion analogous to the cytochrome P-450 system (microsomal mixed-function oxidase). However, there are ambiguities in the detailed mechanism for oxygen activation by flavohemoglobin that need to be resolved, and this is a problem to which we are currently addressing ourselves.

5. Synthetic Applications of Enzymes Altered at Their Active Sites

Recently, we initiated studies on the first practical application of a semisynthetic enzyme to synthesis.[53] In work which will be described briefly here, we have been engaged in the total synthesis of small proteins such as ribonuclease T_1 and its structural analogues. In principle, we could have approached the synthesis of this enzyme through genetic engineering utilizing either the naturally occurring gene or a synthetic gene,[54] and we could consider making the various structural mutants that we would like to design through either site-directed mutagenesis on the natural gene or through alterations in the synthesis of the gene itself. We have chosen, however, to carry out the preparation of the enzyme by a peptide segment synthesis-condensation approach.[55] There are several reasons why we have done this rather than using the genetic methodology. First, of course, we can avoid the problem of expression when we make mutant structures. It is already known that in making some mutants of ribonuclease T_1 the expression has been rather poor because the mutants have had a deleterious effect on the bacteria in which they are being produced.[54] Another point where the synthetic methodology has an advantage is that we can introduce labeled or unnatural amino acids at specific locations where we wish to incorporate them. This ability to introduce labels specifically has great advantages in terms of possible use in fluorescence and NMR studies. Further, we can not only introduce unnatural amino acids at various points in the protein structure by synthesis, but also we have the possibility even of introducing nonpeptidic linkages. This means that we may be able to engineer modified proteins containing structural regions where the use of nonpeptidic segments might prevent degradation by proteolysis, which might normally occur in a biological milieu. A case in point where we have already achieved such a replacement is in our work on models for the peptide hormone β-endorphin[56] where we have replaced the part of the sequence from residue 6 to 13, which we believe to function as a hydrophilic linker region, with a repeating unit of four γ-hydroxymethyl-γ-aminobutyric acid residues hooked together through amide linkages. While this redesigned region still contains amide bonds, the linkages are not the usual peptide linkages, and yet we have found that the β-endorphin model so generated is still very effective, for example, as an analgesic agent.

In carrying out the segment synthesis-condensation methodology, for the preparation of small proteins, the first problem that we had to solve was to develop an efficient synthesis of peptide segments with the protecting groups intact so that the segments could be readily coupled further after purification. The method that we have used for the peptide segment synthesis is based on our development of an oxime polymer[57-59] and is illustrated in Scheme 4. Briefly, the generation of the polymer involves treatment of a polystyrene–1% divinylbenzene copolymer with *p*-nitrobenzoyl chloride. The resultant ketone species is treated with hydroxylamine to generate the corresponding oxime. Subsequently, the first amino acid is attached to the resin using dicyclohexylcarbodiimide as the coupling agent and employing protection such as the Boc group on the α-amino function and appropriate groups on potentially reactive side chains. Once the first amino acid has been attached, a series of deprotection and coupling reactions is performed leading to the formation of a protected peptide derivative attached to the polymer through the ox-



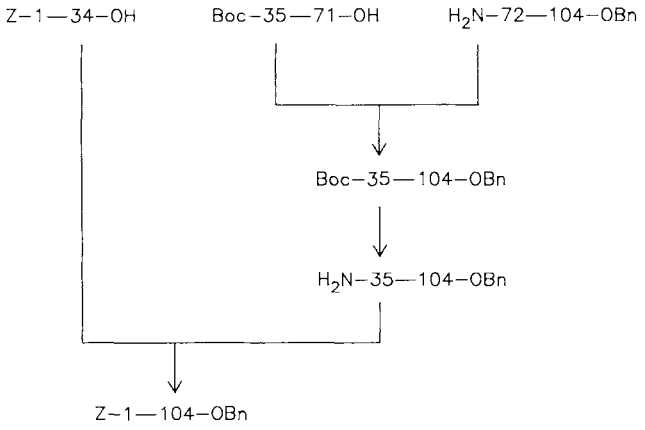
Scheme 4. The three downward pointing arrows represent repetitive deprotection and coupling. X = protecting group.

ime ester linkage. Because the linkage is more labile than the usual linkages such as the benzyl group used in the stepwise Merrifield synthesis, peptides substantially longer than ten amino acid residues are not usually prepared on the oxime resin since losses from the resin start to mount with increases in the length of the peptide. A great advantage of the oxime polymer is, however, that the growing peptide chain can be removed in a variety of ways which can afford a protected peptide segment containing either a free C-terminal carboxyl group or a free C-terminal ester function. An exhaustive list of the methods for removing the peptide from the polymer will not be given here. However, it should suffice to indicate that the peptide chain can be removed by treatment with *N*-hydroxypiperidine, an α-nucleophile, resulting in the formation of the protected peptide ester of *N*-hydroxypiperidine. This peptide ester can be then converted into the protected peptide with a free carboxyl group by the use of zinc and acetic acid, a treatment which is quite general, except for peptides containing sulfur functions, as in the case of methionine. Alternatively, the protected peptide can be removed from the resin by the use of the tetra-*n*-butylammonium salt[60] of the amino acid or by treatment of the resin-bound peptide with an amino acid ester having a free amino group, several equivalents of acetic acid being employed to catalyze the reaction. These procedures result in the insertion at the C-terminus of either the amino acid or the amino acid ester used for the displacement reaction.

In our synthesis of ribonuclease T_1[55] we have used a strategy in which the molecule has been divided into three major fragments chosen both for their synthetic accessibility and because they contain structural features of the enzyme on which we want to focus. For example, from the known X-ray structure of the enzyme the segment corresponding to residues 1–34 can be seen to contain a helical region from residue 12 to 29 which has amphiphilic character.[61] One of the objectives of our current work is to synthesize a helix replacement preserving the amphiphilic characteristics of the natural system but utilizing a significantly different sequence of amino acids. The objective of this work is to establish whether or not incorporation of such a redesigned helix into the ribonuclease T_1 structure will still allow the enzyme to fold properly and function effectively in catalysis.

We have utilized segments prepared by the oxime polymer method to assemble each of the three major segments of ribonuclease T_1. This assembly has been achieved by taking the smaller segments, which have been purified and fully characterized by standard chemical methodology including NMR, mass spectroscopy, and amino acid analysis, and coupling the segments sequentially on a polymeric support. The coupling has typically been carried out using dicyclohexylcarbodiimide and *N*-hydroxybenzotriazole to suppress racemization. We have tried as much as possible to avoid segment couplings where racemization is likely to be an important problem, but the possibility of racemization is one which cannot be totally avoided by our procedures. Of course, after we have assembled the segments we have taken the major segments off the resin and purified them extensively. The final coupling of the three major segments (Scheme 5) has been carried out in solution.

While the synthesis of small proteins such as ribonuclease T_1 is now accessible through fragment synthesis–coupling, it is clear that this approach suffers by comparison with DNA synthesis in an important way. While our syntheses of protected peptide segments by the oxime ester approach are quite convenient, there are still many difficulties in the subsequent condensation of the segments. Yields are not always high, one must be on guard against the possibility of racemization, and sometimes, because protected peptides are used, solubility problems can be en-



Scheme 5. Synthesis of ribonuclease T_1.

countered. A major difference between the synthesis of small proteins by the methodology outlined here and the synthesis of genes by DNA methodology is that in the case of the DNA synthesis ligases are available which can connect DNA segments. It is true that, in many instances, peptides have been coupled utilizing enzymatic catalysis.[62-69] However, these reactions, which generally involve the use of endopeptidases or exopeptidases, necessitate finding conditions where the equilibrium between peptide-bond synthesis and peptide-bond hydrolysis favors the former process. Sometimes, reactions can be driven by the decreased solubility of the product obtained from coupling. In other cases, solvent conditions, including solvent composition and pH, can be varied to favor peptide-bond synthesis. The difficulty is that each case of a peptide-bond synthesis by the use of a proteolytic enzyme involves determining the optimal conditions for the coupling process. In other words, peptide-bond synthesis using enzymes usually requires finding a new set of conditions for each reaction which is run. Ideally, one would be able to find peptide ligases where a general set of conditions could be developed for coupling peptide segments. One can ask the question, at this point, whether or not it is realistic to consider that such ligases can be found or developed. In work with the semisynthetic enzyme, thiolsubtilisin, we have obtained data which suggest that we have found a beginning to the solution of the problem of developing peptide ligases. As mentioned near the beginning of this article, when *Bender*[23] and *Koshland*[24] described thiolsubtilisin they found that the endopeptidase activity of the enzyme was poor but that the nucleophilic SH group at the active site still did accept acyl groups from activated derivatives such as active esters and acyl imidazoles. We have recognized that just these properties are suitable for the use of an enzyme as a peptide ligase. Specifically, thiolsubtilisin can be acylated at its active site thiol group by an *N*-protected peptide segment containing a C-terminal active ester group, the *p*-chlorophenyl ester function. Since the acyl derivative formed is a thiol ester, it is very susceptible to aminolysis by appropriate amino components. Thus, thiolsubtilisin should be able to catalyze an amide-bond-forming reaction between an *N*-protected peptide active ester and a free N-terminal amino group of another peptide segment. The driving force for the peptide-bond-forming step is the reaction of an active ester with an amino component, and once the peptide bond is formed, we do not have to concern ourselves with rapid hydrolysis because thiolsubtilisin is a damaged endopeptidase. We have carried out numerous peptide syntheses using this approach, and the syntheses of [Leu]^5-enkephalin amide (Scheme 6A) and the segment of ribonuclease T_1 corresponding to residues 12–23 (Scheme 6B) by the enzyme-catalyzed procedure have been accomplished.

R = C_6H_4Cl-*p*

Scheme 6. A) Synthesis of (Leu)^5-enkephalin amide. Conditions: pH 8.0, 0.1 M phosphate buffer/DMF (50/50, v/v), room temperature, 5 h. B) Synthesis of segment 12–23 of ribonuclease T_1. Conditions: pH 7.0, 0.01 M phosphate buffer/DMF (50/50, v/v) room temperature, 30 min. Thiolsubtilisin was used as catalyst in A and B.

Of course, thiolsubtilisin will be useful in coupling peptide segments which have specificities appropriate to the binding pocket of the enzyme. To broaden the scope of the enzyme-catalyzed ligation, it will be necessary to utilize other enzymes with different specificities in a related fashion. Furthermore, although the cysteine mutants of other serine proteases seem appropriate targets for further work on peptide ligases, the possibility that other types of mutants will be found exhibiting reactivity with active esters and lack of reactivity with peptides must be considered. Also, it seems likely that solvent conditions can be utilized where unmutated endopeptidases show reactivity to peptide esters but do not catalyze at rapid rates the hydrolysis of peptide bonds.

6. Future Prospects

At the beginning of this article we saw that the properties of the first semisynthetic enzyme, thiolsubtilisin, did not appear to augur well for the development of the field. However, the low activity of this mutated enzyme may reflect the importance of achieving rapid proton transfer in several steps involved in the overall catalysis process, steps which could be affected by the difference in the acidity of the original nucleophile, the hydroxyl group in the native enzyme, from that of the sulfhydryl group in the mutated species. Through attachment of flavin analogues to suitable locations in several proteins, we have shown that we can obtain highly efficient semisynthetic enzymes which can perform reactions such as oxidation-reduction and hydroxylation. In these reactions it seems unlikely that the precise positioning of enzyme-bound functional groups, which would be involved in proton transfer reactions, is required. Rather, the effectiveness of our semisynthetic en-

zymes is likely to be due to the ability of these species to bind substrates in close proximity to the reactive coenzyme functions. In future studies it will be important to increase the range of the coenzymatic species utilized. Also, the catalytic versatilities of semisynthetic enzymes such as flavohemoglobin have not been explored fully, and this is an important pursuit of our laboratory at the present time. To increase the flexibility of the chemical modification approach, we contemplate in the future to combine it with site-specific mutagenesis. In particular, we are initiating research in which we will place, by site-directed mutagenesis, appropriate "handles" in locations where chemical modification with the coenzyme analogue is likely to result in a species with desirable binding properties for substrates. The semisynthetic enzyme approach will be far more powerful if we will rely not only on the presence of suitable sites for chemical modification which are available in the natural protein systems but also if we can utilize sites which we can introduce by genetic engineering. In closing, it should be noted that very interesting activities have been obtained through the generation of catalytic antibodies[70-72] and that a promising route for the application of the semisynthetic concept will be to apply reactions to the modification of the antibodies similar to those which we have employed with the semisynthetic enzymes.

The experimental efforts and conceptual contributions of my co-workers whose names are given in the various articles cited here are gratefully acknowledged. This research was supported in part by the National Science Foundation (CHE-8418878).

Catalytic Fixation of Nitrogen by the Photocatalytic $CdS/Pt/RuO_2$ Particulate System in the Presence of Aqueous $[Ru(Hedta)N_2]^{\ominus}$ Complex

By *Mirza M. Taqui Khan,* Ramesh C. Bhardwaj,* and *C. Bhardwaj*

The reduction of coordinated dinitrogen to ammonia under ambient conditions has been the subject of active research in recent years.[1-3] In every case, the reduction of dinitrogen to NH_3 or N_2H_4 was achieved either in a stoichiometric manner or at the expense of large quantities of reducing agents such as sodium dihydronaphthylide,[4] metallic Al,[5] $Ti(OH)_2$, V^{II}, Mo^{III}, Nb^{III}, and Ta^{III}[6,7] or was carried out electrolytically.[8] Recently, small quantities of ammonia and hydrazine were obtained[9,10] by a protonation/electrolysis cycle involving the complex $[W(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2]$. Catalytic fixation of nitrogen to NH_3 by ruthenium on active carbon with 32 wt% metallic potassium at ambient conditions has also been reported.[11] The amount of NH_3 obtained was 0.011 mmol per gram of catalyst per day.[11] Photoreduction of nitrogen to NH_3 has been achieved using TiO_2 or iron-doped TiO_2[12] or a gallium phosphide[13] photocathode and an oxidizable anode. In all these photoreductions, N_2 was reduced to NH_3 through a complicated, poorly understood mechanism with the expenditure of large quantities of the anode materials.

A truly catalytic fixation of dinitrogen at room temperature and atmospheric pressure, however, has not been realized so far. An obvious obstacle has been the nonavailability of redox electrons at the desired potential for the reduction of coordinated dinitrogen. These electrons have only been obtained at the expense of large inputs of energy (electrolytic) or costly reducing agents.[2] A possible solution of the problem seems to be the selection of a proper photocatalytic system which could generate photoelectrons for the reduction of coordinated dinitrogen.

Herein we report the photochemical fixation of N_2 to NH_3 in aqueous solution under ambient conditions (30°C and 1 atm of N_2) in the presence of a semiconductor particulate system, $CdS/Pt/RuO_2$, excited by visible light ($\lambda = 505$ nm) and catalyzed by the Ru(II) dinitrogen complex **1**. The yield of ammonia was 6.8 moles of NH_3 per mole of catalyst per hour. In the absence of **1**, the particulate system $CdS/Pt/RuO_2$ brings about the photodecomposition of water.[14] In the absence of $CdS/Pt/RuO_2$, there was no reduction of dinitrogen to NH_3. The catalyst **1** was recovered unchanged from the reaction cell after 24 hours. This was confirmed by the elemental analysis, the electronic and vibrational spectra of the complex, and the cyclic voltammograms before and after the nitrogen fixation experiments.

$[Ru(Hedta)N_2]^{\ominus}$ **1**
Hedta = trianion of ethylenediaminetetraacetic acid

The experiments on the photocatalytic reduction of N_2 to NH_3 were conducted in a water-jacketed glass cell in aqueous solution at 30°C. About 100 mg of $CdS/Pt/RuO_2$ powder was suspended in 25 mL of an aqueous solution of **1** in a glass cell of 100-mL capacity and the system was irradiated at 505 nm, which corresponds to the band gap of 2.2 eV for the particulate system, with a 250-W xenon lamp equipped with a 505-nm filter. Nitrogen gas freed from carbon dioxide was bubbled through the system at a constant rate of 150 mL min^{-1}, fast enough to ensure complete saturation of the solution with respect to dissolved nitrogen at any instant. During the reaction N_2 was dispersed uniformly through the solution by stirring. Most of the ammonia produced was dissolved before escaping into HCl traps. The total amount of ammonia produced was calculated both from the traps and the cell by *Nessler*'s spectrophotometric method. The rate of ammonia production versus time for different concentrations of dinitrogen complex **1** is shown in Figure 1. The yield of ammonia

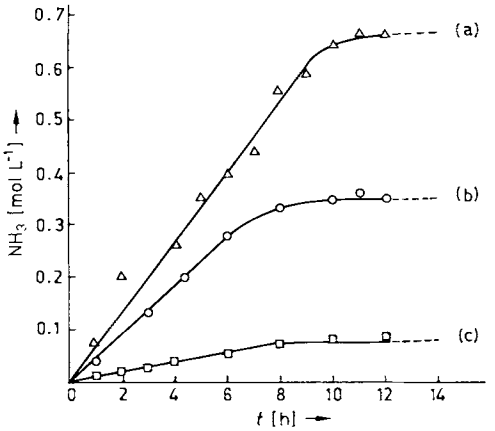

Fig. 1. Amount of NH_3 produced vs. time for different concentrations of $[Ru(Hedta)N_2]^{\ominus}$ **1**: (a) 7.82×10^{-3} mol L^{-1}, (b) 3.91×10^{-3} mol L^{-1}, and (c) 1.96×10^{-3} mol L^{-1}. For conditions see text.

attains a maximum after 12 hours and the reaction continues with only slight change up to 24 hours. After the absorption of NH_3 in the traps the gases contain a mixture of O_2 and excess N_2. The gases were allowed to collect in a column for an hour at the peak of NH_3 production (8th hour). The amount of oxygen in the mixture was determined by absorption in a known volume of alkaline pyrogallol. The amount of O_2 absorbed was about 0.7 mole per mole of NH_3 produced, confirming the stoichiometry of the reaction:

[*] Prof. Dr. M. M. Taqui Khan, R. C. Bhardwaj, C. Bhardwaj
Coordination Chemistry and Catalysis Group
Central Salt & Marine Chemicals Research Institute
Bhavnagar-364002 (India)

$$N_2 + 3H_2O \xrightarrow[cat.]{h\nu} 2NH_3 + 3/2\,O_2$$

The rate of ammonia production for different concentrations of the dinitrogen complex **1** is shown in Figure 2. One observes a first-order dependence of the rate of NH_3 production on the catalyst concentration at lower concentration of the catalyst. The pseudo-first-order rate constant of $2.8 \times 10^{-3}\ s^{-1}$ was calculated from the slope of the plot in Figure 2.

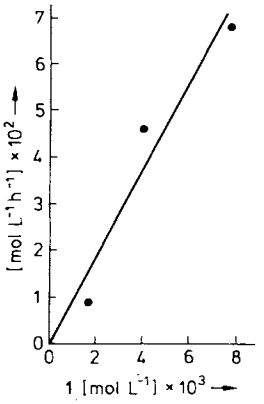

Fig. 2. Amount of NH_3 produced per hour vs. concentration of $[Ru(Hedta)N_2]^{\ominus}$ **1**. For conditions see text.

In order to confirm the source of NH_3 isotopic studies were conducted with $^{15}N_2$ (25% enrichment) as the source of N_2. The NH_3 obtained was absorbed in HNO_3 and the NH_4NO_3 was carefully dried and subjected to mass spectrometric analysis. Peaks were obtained at m/z 44 and 45 in the ratio of 3:1 corresponding to the formation of $^{14}N_2O$ and $^{14}N^{15}NO$, respectively. The reaction did not show any isotopic effect in D_2O.

Based on the kinetics of the reaction, a first-order dependence on the concentration of **1**, the following mechanism is proposed for the photocatalytic reduction of N_2 to NH_3 (the photolysis of water is not shown):

$$\underset{\mathbf{2}}{[Ru(L)H_2O]^{\ominus}} + N_2 \overset{K_1}{\rightleftharpoons} \underset{\mathbf{1}}{[Ru(L)N_2]^{\ominus}} + H_2O$$

$$CdS \xrightarrow{h\nu} h^{\oplus} + e^{\ominus} + \cdots$$

$$\underset{\mathbf{1}}{[Ru(L)N_2]^{\ominus}} + e^{\ominus} \xrightarrow[slow]{k} \underset{\mathbf{3}}{[Ru(L)N_2]^{2\ominus}}$$

$$\underset{\mathbf{3}}{[Ru(L)N_2]^{2\ominus}} + 6H^{\oplus} + 5e^{\ominus} + H_2O \xrightarrow{fast} 2NH_3 + \underset{\mathbf{2}}{[RuL(H_2O)]^{\ominus}}$$

L = Hedta

The irradiation of $CdS/Pt/RuO_2$ in aqueous solution excites an electron from the valence band to the conduction band and a hole is created in the valence band. The holes trap the electrons released in the RuO_2-catalyzed photooxidation of water to $2H^{\oplus}$ and $1/2\,O_2$. The RuO_2 in this system thus acts as a hole scavanger. There is a competition between $H^{\oplus}$ and the dinitrogen complex **1** for electrons in the conduction band. Because of the negative potential of the Ru^{II}/Ru^{I} couple (-0.46 V), the complex is a stronger oxidizing agent than the protons and competes successfully with the latter for the electron.

The electron is transferred in a rate-determining step to **1** to form an intermediate species **3**, where the extra electron can be accommodated on either the metal ion or the dinitrogen ligand. Fast protonation and successive electron transfer to **3** produces NH_3 as the end product and species **2**, which reacts with dinitrogen in the preequilibrium step to form **1** and continue the catalytic cycle. The lack of a deuterium isotope effect rules out a coupled proton transfer in the rate-determining step.

Electrochemical reduction of **1** in the presence of N_2 in the pH range 4–7 at the controlled potential of -0.20 to -0.40 V, corresponding to the redox potential of the Ru^{II}/Ru^{I} couple, gave 5×10^{-4} moles of NH_3 in three hours. The yield then droped rapidly.[15] This confirms the role of the metal ion in the electron transfer to N_2.

A blank experiment in the absence of **1** (see above) produced only hydrogen by the photodecomposition of water.[14] This indicates the role of **1** in the activation of N_2 and its reduction to NH_3. The same experiment conducted in the presence of H_4edta again results in the photodecomposition of water. This rules out the possibility of formation of NH_3 from the decomposition of H_4edta. This is further confirmed by the isotopic studies with $^{15}N_2$; the products contain the label in the same ratio as the dinitrogen employed. The composition of the dinitrogen complex **1** did not change even after 12 hours of experiment, as confirmed by elemental analysis and spectrophotometry. The experiments conducted in the presence of **1** and nitrogen but in the absence of the particulate system also failed to produce NH_3 even after 48 hours. These experiments indicate that the redox electron from the photoexcitation of the particulate system is essential for the reaction. The photocatalytic cycle is shown in Figure 3.

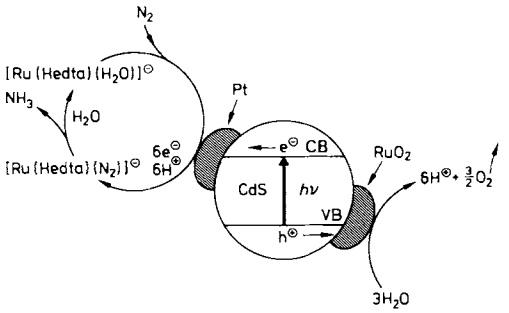

Fig. 3. Mechanism of photocatalytic ammonia production. CB = conduction band, VB = valence band.

The decrease in the yield of NH_3 after 12 hours can be attributed to the photocorrosion of the semiconductor:

$$CdS \xrightarrow{h\nu} CdS(h^{\oplus}_{VB} + e^{\ominus}_{CB})$$

$$2h^{\oplus}_{VB} + CdS \longrightarrow S + Cd^{2\oplus}$$

Thus the photocorrosion takes place only when the rate of the electron transfer is inadequate for the number of holes generated in the system. This may be partly due to the inefficient scavanging of the holes by RuO_2 particles loaded on the semiconductor. The main cause, however, is presumably the poisoning of the CdS by O_2 which is generated in the system.[16]

In conclusion, we feel that efficient reduction of N_2 to NH_3 at ambient conditions is possible if a proper photocatalyst is used and dinitrogen is activated by coordinating to a suitable metal center.

Experimental Procedure

1: $[Ru^{III}(Hedta)Cl]^{\ominus}$ was reduced to $[Ru^{II}(Hedta)(H_2O)]^{\ominus}$ **2** using hydrogen over platinum black under an atmosphere of hydrogen.[17] The photocatalyst $CdS/Pt/RuO_2$ was prepared by the published procedure [18]. Complex **2** exhibits LMCT peaks at 283, 332, and 296 nm. On passing N_2 through dilute solutions of **2** ($\approx 10^{-4}$ M), the peaks corresponding to **2** decrease with the appearance of a new peak at 221 nm, which was taken as a marker peak for the calculation of the stability constant of **1**. The equilibrium constant for the formation of **1** is given by the following expression:

$$\underset{\mathbf{2}}{[Ru(Hedta)(H_2O)]^{\ominus}} + N_2 \overset{K_1}{\rightleftharpoons} \underset{\mathbf{1}}{[Ru(Hedta)(N_2)]^{\ominus}} + H_2O$$

From the solubility of N_2 in water at 25° (7.81×10^{-4} mol L^{-1}) the equilibrium constant for the formation of **1** at 25° was calculated as $\log K_1 = 2.90 \pm 0.02$.

Complex **1** exhibits the $\nu(M-N_2)$ band at 2040 cm^{-1}. Differential pulse polarography (DPP) of **1** gives a single peak at −0.48 V corresponding to the redox couple Ru^{II}/Ru^{I}. The cyclic voltammogram of **1** gives reversible peaks at −0.24 and −1.0 V for the Ru^{III}/Ru^{II} and $H^{\oplus}/H$ potentials, respectively. The peak corresponding to Ru^{II}/Ru^{I} cannot be observed because of the crossover of the cathodic-potential and anodic-potential curves in this region.

The First *closo*-Diphosphahexaborane $P_2B_4Cl_4$**

By *Wolfgang Haubold,* Willi Keller,* and *Gisela Sawitzki*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Higher boranes have often been prepared by pyrolysis of smaller boranes. If appropriate mixtures of boranes and hydrocarbons are used, carboranes are obtained.[1] Both synthetic principles can be extended to haloboranes.

Tetrahalodiborane(4) molecules B_2X_4 are transformed upon heating into trihaloboranes and short-lived BX species[2] or into stable cage molecules B_nX_n (X = Cl, Br; n = 8–12).[3] Copyrolysis of halogenated hydrocarbons and B_2X_4 results in the formation of perhalogenated carboranes;[4] little is known about the reaction course. The investigation described here was motivated by the question whether other heteroatoms could be incorporated into halogen-substituted boron clusters.

Pyrolysis of a mixture of B_2Cl_4 and PCl_3 at 330 °C resulted in the formation of *closo*-3,4,5,6-tetrachloro-1,2-diphosphahexaborane(4) **1** as a hygroscopic, colorless, crystalline solid, in addition to small amounts of side products. B_2Cl_4 is apparently not only the source of "BCl" units but acts at the same time as a reducing agent. The idealized formulation of the reaction is given in Equation (a). In the mass spectrum of the crude product, additional signals are observed which have to be assigned to a molecule having the composition $P_2B_5Cl_5$.

$$7\,B_2Cl_4 + 2\,PCl_3 \longrightarrow \underset{\mathbf{1}}{P_2B_4Cl_4} + 10\,BCl_3 \qquad (a)$$

The composition and structure of the phosphaborane **1** are derived from the spectroscopic data (Table 1). Since the two phosphorus atoms can each contribute three electrons to the framework bonds, a *closo*-hexaborane is to be expected according to the Wade rules. Its structure should be derivable from an octahedron. The structure of the cluster is derived from the values for the chemical shift of the boron atoms, and the *cis* arrangement of the phosphorus atoms from the fact that two ^{11}B-NMR signals (1:1 ratio) are observed. The X-ray structure analysis confirms the interpretation of the spectra (Fig. 1).[5]

Table 1. Spectroscopic data for **1**.

^{11}B-NMR (relative to $BF_3 \cdot OEt_2$, 25.67 MHz, C_6D_6, room temperature (RT)): $\delta_1 = 2.5$, $\delta_2 = 22.1$ (intensity ratio 1:1, halfwidth 128 Hz).—^{31}P-NMR (relative to 85% H_3PO_4, 32.2 MHz, C_6D_6, RT): $\delta = -187$.—MS (70 eV); calculated and measured pattern of $^{35}Cl/^{37}Cl/^{11}B/^{10}B$ isotope distribution are in agreement): $M^{\oplus}$ (rel. intensity 84%), $B_4Cl_3^{\oplus}$ (7), $B_3Cl_3^{\oplus}$ (7), $[M-BCl_3]^{\oplus}$ (100), $P_4^{\oplus}$ (30), $PB_2Cl_2^{\oplus}$ (27), $P_2B_2Cl^{\oplus}$ (12), $B_2Cl_2^{\oplus}$ (8), $BCl_2^{\oplus}$ (17)

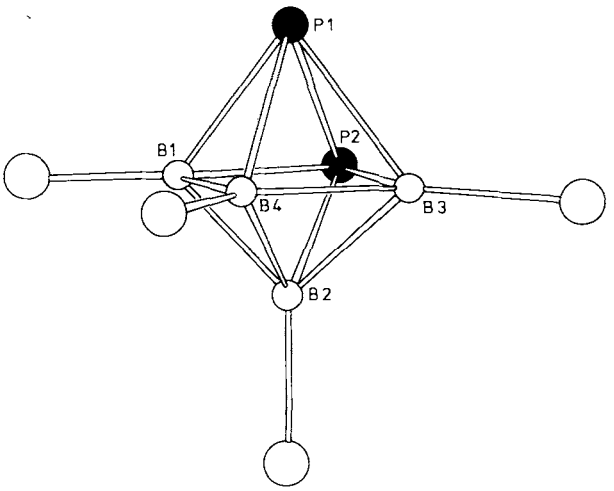

Fig. 1. Molecular structure of **1**. Selected distances [pm] and angles [°]: P1-P2 222.2(3), B2-B4 167.8(12), other B-B(average) 173, B-P(average) 200, B-Cl(average) 176; B1-P1-B3 76.8(4), B1-P2-B3 77.6(4), P1-P2-B2 81.9(3), P2-P1-B4 82.3(3), P2-B2-B4 98.2(5), B1-B2-B3 94.0(6), P1-B4-B2 97.6(5), B1-B4-B3 92.3(6).

The distances and angles reveal the distortion of the octahedron caused by the large phosphorus atoms. The angles at the phosphorus atoms are reduced by displacement of these atoms from the ideal octahedral positions. Those at the boron atoms B2 and B4, in *trans* positions, are increased. The P–P distance corresponds to that of a single bond. The B2–B4 bond on the opposite side (168 pm) is shorter than usual for B–B bonds in clusters. The B–P and the remaining B–B bonds are, as expected for **1**, longer than corresponding two-center bonds. In phosphane–boranes $R_3P{-}BR'_3$, the B–P bonds, with one exception, are shorter than 190 pm; in the diphosphaborirane three-membered ring of $(t\mathrm{BuP})_2\mathrm{BNEt}_2$, the B–P distance is 189.3 pm,[6] and in one of the few known clusters containing phosphorus atoms in the framework, the phosphacarborane $CHPB_{10}H_8Cl_2$, it is 202 pm.[7]

Experimental Procedure

B_2Cl_4 (1.5 g, 9.2 mmol) and PCl_3 (1.0 g, 7.2 mmol) were condensed into a 250-mL thick-walled flask equipped with a break seal. After melting and thawing, the mixture was heated to 330 °C for 1 h and then cooled over ca. 12 h to room temperature. The volatiles were removed at 0 °C and the ocher-colored residue remaining was extracted several times with ca. 5 mL of BCl_3. The solvent was removed and the colorless solid was sublimed by gentle warming onto the cooled neck of the flask and then washed with a small amount of BCl_3 into another pyrolysis flask. Boron trichloride was removed under vacuum. After heating for a short time at 240 °C and slowly cooling, 50 to 100 mg of **1** separated out as colorless, moisture-sensitive needles. In a sealed, evacuated tube, the compound melts at 74–75 °C. Yield: 15–25% [reaction according to Eq. (a)].

Synthesis and Structure of a 1,2,5,6-Tetrahydro-1,2,5,6-tetraborocine**

By *Albrecht Krämer, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Dehalogenation of (*Z*)-1,2-diborylethenes **1** with Na/K alloy furnishes 1,2- and 1,3-dihydrodiboretes (**1a** → **2**;[1a] **1b** → 1,3 isomer[1b]) or carbaboranes (**1c** → $(CEt)_4(BCl)_4$[1c]), but no eight-membered ring derivatives.[2] Attempted dimerization of planar **2** to give the diene **3** was also unsuccessful; instead, an intramolecular rearrangement occurred, giving the puckered 1,3 isomer of **2**.[1a] A metal-dependent ring formation reaction is observed upon dehalogenation of [2-(bromomethyl)phenyl]chloro(diisopropylamino)borane;[3] reaction with lithium leads to the formation of 1-(diisopropylamino)dihydrobenzoborete (30%) and reaction with Na/K alloy to 5,11-bis(diisopropylamino)tetrahydrodibenzo[*b,f*][1,5]diborocine (9%).

3

Herein we report the synthesis of the 1,2,5,6-tetrahydro-1,2,5,6-tetraborocine derivative **3** from **2** in the presence of hydrogen and Lindlar catalyst. In addition to **3** (27%) and the starting material **2**, **1d** could be isolated in low yield.

In the dimerization of **2**, hydrogen (via PdH_2?) serves an activating function, since no **3** is formed in the presence of Lindlar catalyst alone. Our initial assumption that **1d**, formed by hydrogenation of **2**, might be the intermediate involved in the formation of **3** was not confirmed when we treated **1d** with the catalyst. The mechanism of formation of **3** is still unclear.

The constitution of **3** was established by the NMR and mass spectra. In the ^{11}B-NMR spectrum a signal at $\delta = 51.4$, which is characteristic of diborane(4) derivatives with alkenyl and dialkylamino substituents, was found.[4] Owing to the BN π bond, the two *i*Pr groups on each of the N atoms are nonequivalent [$\delta(^1\mathrm{H})$ of **3** = 1.09 (d, $J = 7.0$ Hz, 24 H), 1.25 (d, 24 H), 3.35 (m, 8 H), 6.65 (br. s, 4 H)]. In the mass spectrum, the molecular ion peak, with an isotope distribution characteristic of four boron atoms, appears at *m/z* 496 (14.9%).

The X-ray structure analysis shows that **3** is present in the crystal as a nonplanar eight-membered ring (Fig. 1).[5] The molecule displays a crystallographically determined twofold axis. Four ring atoms (B1, C1, C2′, B2′, and B2, C2, C1′, B1′) are located in a plane (±0.03 Å). The two planes form an angle of 42° and the bonds B1B2 and B1′B2′ are nearly perpendicular to each other (82°). The distances in **3** differ slightly, but significantly, from those in **2**:[1a] the B–B distance is shorter (1.718 vs. 1.749 Å); the B–N distances (1.412 vs. 1.377 Å) and C=C distances (1.346 vs. 1.312 Å) are longer. Better agreement is found upon comparison with the distances in the 1,2,4,5-tetraborinane ring.[6]

Compound **3** is the first organoborane belonging to the $(CR^1)_4(BR^2)_4$ class; three further compounds having this general formula ($R^1/R^2 = CH_3/H$,[7] C_2H_5/CH_3,[8] C_2H_5/Cl[1c]) exist as carbaboranes owing to their electron deficiency at the boron atoms. In **3**, the diisopropylamino groups satisfy the electron demand of the boron atoms and

so stabilize the organoborane skeleton relative to the carbaborane skeleton.

The relative stabilities of *cyclo*-organoborane/carbaborane compounds (*nido* and *closo*) have been studied in detail for $(CR^1)_4(BR^2)_2$, $(CR^1)_2(BR^2)_3$, and $(CR^1)_2(BR^2)_4$ using PRDDO calculations.[9]

Experimental Procedure

2 (520 mg, 2.1 mmol) was dissolved under nitrogen in 30 mL of pentane, and Lindlar catalyst (130 mg, 5% Pd) and H_2 (47 mL, 2.1 mmol) were then added. After stirring for 6 d, the reaction mixture was filtered at 20°C and the concentrated filtrate (10 mL) was allowed to stand at −20°C, resulting in the crystallization of colorless **3** [(134 mg, 27.0%, m.p. = 196°C (dec.)]. From the mother liquor, 46 mg of **1d** [8.6%, m.p. = 132°C (benzene)] along with the starting material **2** were isolated.

Spectroscopic data for **1d**: ^{1}H-NMR (C_6D_6): δ = 1.10 (d, 12H, ^3J(HH) = 7.6 Hz), 1.18 (d, 12H), 3.29 (sept, 2H), 3.98 (sept, 2H), 6.78 (br. s, 2H), BH signals not identifiable; ^{11}B-NMR ($CDCl_3$): δ = 35.3 (d, ^1J(BH) = 120 Hz); EI-MS: *m/z* 250 ($M^{\oplus}$, 9.7%), 235 (($M^{\oplus} - CH_3$, 15.2%), 207 ($M^{\oplus} - i$Pr, 83.8%), 43 (*i*Pr, 100%).

Silica-Supported Fe-Pd Bimetallic Particles: Formation from Mixed-Metal Clusters and Catalytic Activity**

By *Pierre Braunstein,* Robert Devenish, Pierre Gallezot, Brian T. Heaton,* Colin J. Humphreys, Jacques Kervennal,* Suzanne Mulley,* and *Michel Ries*

Improved selectivity and stability are found for bi- and multimetallic heterogeneous catalysts when compared with their monometallic counterparts,[1,2] but there is still much to be done in order to understand why these improvements occur.

Previous work has shown that nitrobenzene may be catalytically converted into phenyl isocyanate (240°C/200 atm CO) using the heterogeneous catalyst resulting from impregnation and thermal decomposition and activation of complex **1** on γ-Al_2O_3.[3] This reaction has been extended to the reductive carbonylation of *o*-nitrophenol **3** to benzoxazol-2(3*H*)-one, using **2** on silica as catalyst precursor.[4]

We report now that complex **4**[4b,5] also leads to a heterogeneous catalyst having significantly improved properties over those of a conventional catalyst prepared by coimpregnation of iron oxalate and palladium acetate (Table 1, No. 1). Using analytical electron microscopy (AEM) to investigate the catalysts prepared from **2** and **4**, we have shown (1) that bimetallic particles are present at the start of the reaction, (2) that their composition closely parallels that of the metal core in **2** and **4**, and (3) that metal segregation occurs during this reaction. This appears to be the first report addressing, in a combined manner, the formation, catalytic activity, and fate of bimetallic, cluster-derived particles.

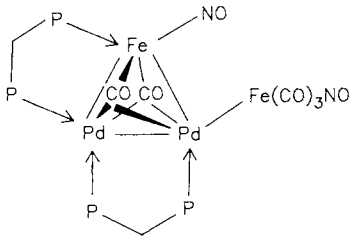
[a] The impregnation was carried out by the spray method [3]. Catalysts for Nos. 1 and 2: see [4]. For No. 3, **4** (1.38 g) in THF (40 mL) was used to impregnate 9.7 g of SiO_2 (Shell), which was then dried at 450°C for 16 h. [b] Determined by analysis. [c] Ratio of benzoxazol-2(3*H*)-one produced to **3** reacted.



4

The catalytic experiments suggest that a more intimate interaction between Fe and Pd results from the use of a mixed-metal cluster precursor and is, at least in part, responsible for the improved properties of the catalytic system. Indeed, the individual metal particles resulting from **2** have been analyzed by energy-dispersive X-ray analysis (EDX) with a field-emission-gun scanning transmission microscope (FEG-STEM) giving a 1-nm spatial resolution of analysis (0.5-nm spot size). Before catalysis, the particles have a diameter of ca. 20–50 Å (Fig. 1) and are all bimetallic. No Fe or Pd signal is observed outside these particles. The atomic composition of these particles (29.6–38.7 atom% Fe, 70.4–61.3 atom% Pd) is in very good agreement with the theoretical stoichiometry (33.3 atom% Fe and 66.6 atom% Pd).

Particles resulting from **4** have been analyzed with a conventional transmission electron microscope (TEM) and, because of the larger electron probe size (500 nm), EDX analysis encompasses many particles. Before catalysis, the particles are very uniformly distributed on the support. EDX data on 10 different areas were obtained (53.8 ± 2.7 atom% Pd, 45.9 ± 5.3 atom% Fe, 0.2 ± 0.25 atom% Ni), and apart from the presence of Ni, which is probably there as a contaminant from the reactor vessel, these values are very close to that required for **4**.

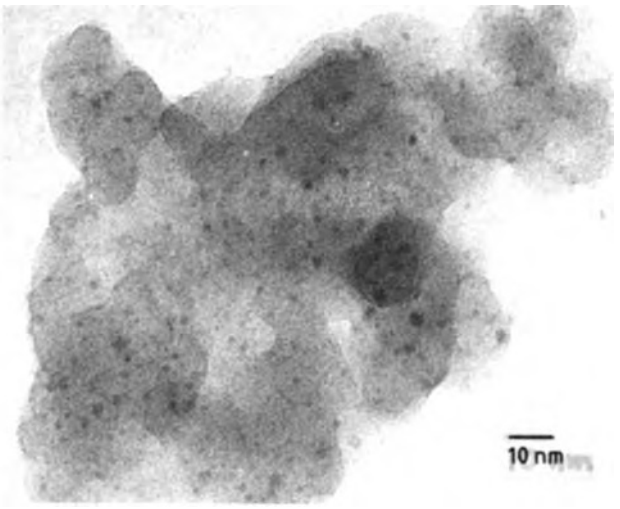


Fig. 1. Transmission electron microscope (TEM) view of the catalyst derived from **2** before catalytic reaction (Fe–Pd clusters).

In contrast, no small bimetallic particles are detected in the conventional, coimpregnated catalyst. Large, micron-size agglomerated particles are observed, whose composition analyzed with the FEG-STEM is variable from one to the other and which appear to be iron-rich in the center. Small particles (30–40 Å) containing only Pd are also observed.

After 4 h of reaction with the catalyst derived from **2**, small bimetallic particles similar to those observed before catalysis were still present. However, large 100–300-Å particles of palladium were formed (Fig. 2). In the case of **4**, we find that 200–500-Å particles are now present on the silica and these particles are either pure Pd or pure Fe. Therefore, there are only slight differences in the fate of the two cluster-derived catalysts after reaction.

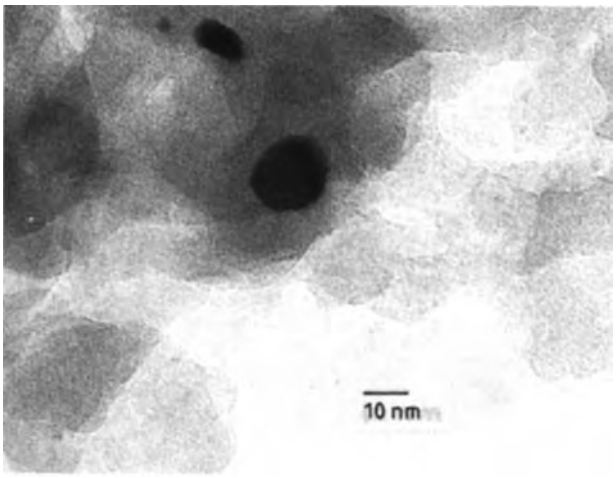

Fig. 2. TEM view of the catalyst derived from **2** after catalytic reaction (Pd particles issued from segregation and sintering of Fe–Pd clusters).

Although Fe and Pd have different crystal structures (bcc and fcc, respectively), up to ca. 75 atom% Pd is found in FePd phases below 600°C[6] and this appears to be the first report of metal segregation occurring during catalysis with a heteropolynuclear carbonyl-cluster-derived heterogeneous[7] catalyst. It is probably induced by the redox character of the reaction studied, the reductive carbonylation of **3**, and/or by the presence of CO, since it is already known from surface science studies that CO adsorption onto bimetallic alloy films causes surface enrichment of one metal, which in some cases is reversible upon desorbing the CO.[10] Interestingly, it has been reported recently that deposition of the mixed-metal clusters **5**, **6**, or **7** onto a partially hydroxylated magnesia support, followed by H_2

treatment at 400°C, gives very small bimetallic particles that have the same bulk metal composition as that of the cluster precursor.[11] Information about their fate under catalytic conditions is not yet available.

Synthesis of TiNF and Structure Determination by Powder Diffraction using Synchrotron Radiation**

By *Claus Wüstefeld, Thomas Vogt, Ulrich Löchner, Joachim Strähle,* and *Hartmut Fuess**

Owing to its high intensity and low divergence, synchrotron radiation allows powder diagrams to be recorded with high resolution. Herein we report on the synthesis and structure analysis of TiNF, which, according to *Andersson*,[1] is a pseudooxide because of $N^{3\ominus}$ and $F^{\ominus}$ formally replacing two $O^{2\ominus}$. X-ray diffraction using synchrotron radiation suggested itself as a method of structure determination since only a small amount of the substance was available and since very small deviations of the lattice symmetry from that of a high-symmetry oxide structure were possible. Furthermore, the excellent signal-to-noise ratio was expected to permit the observation of weak superstructure reflections in case of an ordering of N and F ions in the anion lattice. Moreover, the mathematical description of Bragg reflections allows structure refinement from powder data by the Rietveld method.[4]

TiNF was synthesized by ammonolysis of activated $(NH_4)_2TiF_6$.[2] To activate the fluorometalate, two reaction steps are necessary. First, $(NH_4)_2TiF_6$ is heated to 400°C with an equimolar amount of NH_4Cl in a sealed system (welded Pt crucible, inert gas) for ca. 12 h to form $(NH_4)_2TiF_6 \cdot NH_4Cl$. The NH_4Cl adduct is then thermally decomposed at 280°C under inert gas. Thus activated, $(NH_4)_2TiF_6$, by subsequent ammonolysis in a dry and oxygen-free stream of NH_3, yields TiNF. Without activation, TiN is the main product.[3] TiNF is a light green to olive green substance and, like TiO_2, thermally stable and largely chemically inert.

The compound could be indexed in analogy to anatase ($a = 3.785$ Å, $c = 9.514$ Å)[5] on a body-centered tetragonal cell with $a = 3.7891(4)$ Å and $c = 9.4863(9)$ Å.[6] Line-shape analysis of the Bragg reflections showed that the line shape did not correspond to a pure Gaussian curve but contained appreciable Lorentz components. Use of the pseudo-Voigt function[7] gave 53% Gaussian line shape. This is due to the method of sample preparation which leads to a small average particle size. The Rietveld refinement[8] led to the atomic parameters Ti(0; 3/4; 1/8), $B = 0.58(6)$ Å^2; N/F(0; 1/4; 0.0833(4)), $B = 0.04(11)$ Å^2.

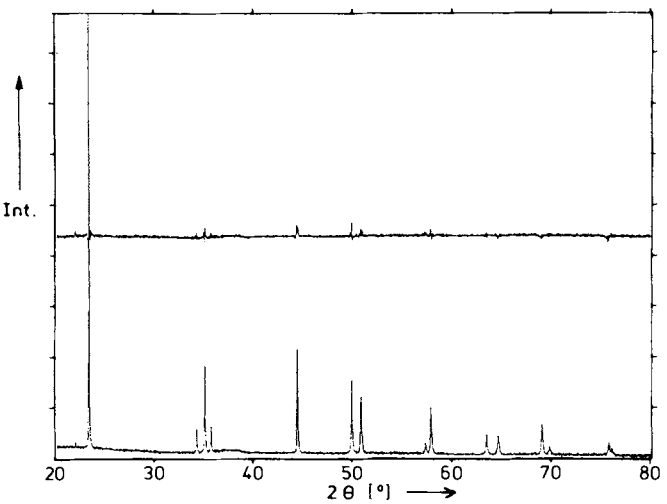

Fig. 1. Measured diffraction pattern (below) and difference between measured and calculated [8] diffraction pattern (above) of TiNF.

Figure 1 shows the measured intensities (below) and the difference between measured and calculated diffraction patterns (above). The refinement was carried out in space group $I4_1/amd$. Refinements in isomorphic subgroups did not lead to better residual figures-of-merit. Since high-resolution electron diffraction and electron microscopic analysis showed no superstructure either,[9] only neutron diffraction powder spectra, where the scattering contributions of F and N are different, can answer the question of a possible order in the anion lattice.

Experimental Procedure

The powder pattern was recorded at the beamline F1 of Hasylab at the Deutsches Elektronen Synchrotron (DESY) in Hamburg. An oil smear of TiNF on a Si(711) plate was fitted into a swinging sample holder, the assembly corresponding to the Cox diffraction geometry [10, 11]. Conditions: Ge(111) monochromator and analyzer, NaI(Tl) scintillation counter, wavelength 1.4358 Å, 2θ steps of 0.01, average measuring time per step 5.2 s. The

A Topologically Chiral [2]Catenand**

By *Dennis K. Mitchell* and *Jean-Pierre Sauvage**

Chemical interest in nonplanar molecular graphs has increased dramatically with the advent of synthetic strategies allowing easy access to entwined and interlocked molecules. The first topologically nonplanar molecule to be synthesized was reported in 1981.[1,6] It corresponds to *Kuratowski*'s $\mathbf{K_5}$ figure[1,2] (complete graph on five vertices). Another example of a molecule whose graph is nonplanar was recently described by *Walba* et al.[7] It consists of a Moebius strip with three rungs and is isomorphic to $\mathbf{K_{3,3}}$ (complete bipartite graph on two sets of three vertices).

Molecular graphs of interlocked rings (catenanes) and knots[3–5] are nonplanar when embedded in three-dimensional space. Nonplanar graphs can be labeled so as to retain their chirality over all presentations. The term "topological chirality" was coined for this property and has been applied to molecules as well as molecular graphs.[8,10]

Topological chirality requires that mirror image presentations be topologically distinct.[8] As a consequence, it is necessary (but not sufficient) that the molecular graph be nonplanar in three-dimensional space. Although chemical chirality of the K_5 and $K_{3,3}$ nonplanar molecules mentioned above was proven previously,[1,7] it is only recently that their topological chirality was demonstrated.[9]

Oriented linked rings are the prototypical topologically chiral objects. We now report the synthesis of the first isolated topologically chiral catenane,[10] containing *two interlocked directed* rings (Fig. 1).

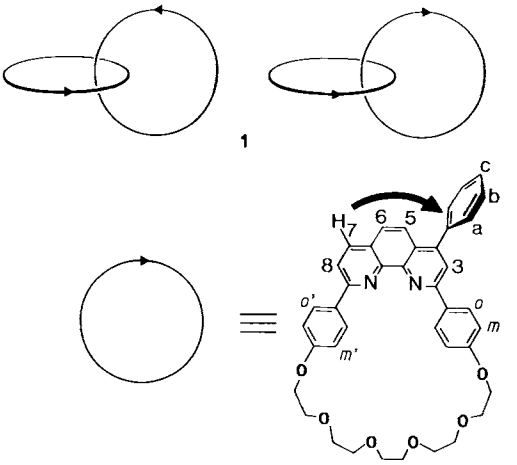

Fig. 1. Principle of construction of topologically chiral [2]catenands **1** and structure of the individual rings showing their directed nature.

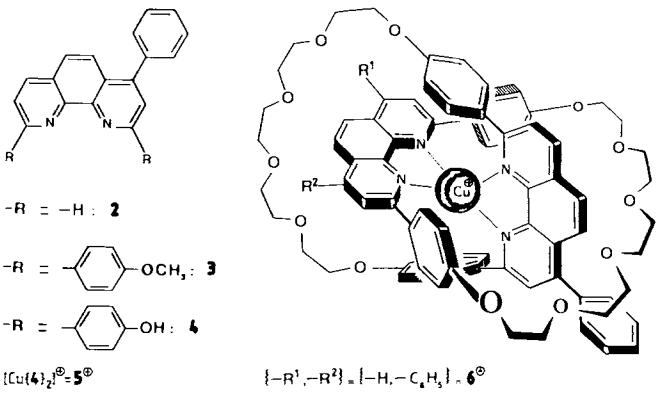
We have taken advantage of the previously developed templated synthesis of catenates and catenands.[11] Compound **1** was prepared in five steps from 4-phenyl-1,10-phenanthroline **2**.[12] Compound **2** was reacted with 4-lithioanisole as previously described for 1,10-phenanthroline,[11] leading to **3** in 35% yield. Demethylation of **3** (pyridine, HCl, 210°C) gave a 90% yield of **4**, which, in the presence of 0.5 equivalent of $[Cu(CH_3CN)_4^{\oplus}][BF_4^{\ominus}]$, furnished quantitatively the complex $\mathbf{5}^{\oplus}$, consisting of two ligands **4** entwined around a copper(I) center. Cyclization of $\mathbf{5}^{\oplus}$ to $\mathbf{6}^{\oplus}$ was performed under high-dilution conditions (DMF, 70°C), with a stoichiometric amount of the diiodo derivative of pentaethylene glycol, $ICH_2(CH_2OCH_2)_4CH_2I$, in the presence of a large excess of Cs_2CO_3. Racemic $[\mathbf{6}^{\oplus}][BF_4^{\ominus}]$ was obtained from methanol as a deep red crystalline solid (m.p. 176–183°C), in 12% yield.[13]



The chirality of $\mathbf{6}^{\oplus}$ was supported by ^{1}H-NMR spectroscopy in the presence of *Pirkle*'s chiral reagent **7** (Fig. 2). Contrary to what was observed with another chiral catenate differing from $\mathbf{6}^{\oplus}$ in its graph-theoretical description,[14] the *entire spectrum* of $\mathbf{6}^{\oplus}$ was split, with the exception of the peaks corresponding to H-3, H-5, and H-6.

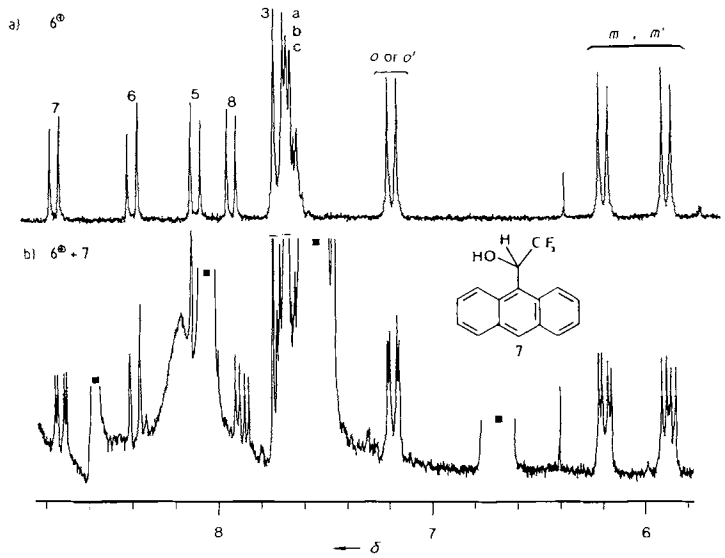


Fig. 2. Part of the ^{1}H-NMR spectra (200 MHz, CD_2Cl_2) of a) $6^{\oplus}$ and b) $6^{\oplus}$ plus ten equivalents of *Pirkle*'s reagent (*S*)-(+)-**7**. Peaks indicated by 7,8, *o* or *o'*, *m*, or *m'* in spectrum (a) (labeling given in Fig. 1) are split in spectrum (b). The signals corresponding to the chiral reagent are marked by a black square.

Those protons might be hidden by the 4-phenyl group and the pentaoxyethylene link so that their chemical shift is not sensitive to the particular environment induced by *Pirkle*'s reagent.

Spectrum 2b indicates that the topological chirality of $6^{\oplus}$ is accompanied by easy recognition of its enantiomers by a chiral reagent. This observation might be related to the high rigidity of the molecule. Demetalation of $6^{\oplus}$ (KCN in H_2O/CH_2Cl_2, 78% yield) leads to an extremely flexible system **1**, whose two rings can easily glide within one another. The catenane nature of **1** was supported by its mass spectrum (*m/z* 1284 (*M*) and 642 (*M*/2)). Its *topological chirality* is obvious from the directed nature of the starting compound **2** and the synthetic route followed. In contrast to $6^{\oplus}$, no clear enantioselective interaction with *Pirkle*'s reagent could be observed in the NMR spectra of **1**.

The present templated synthesis of chiral catenands indicates that separation of their enantiomers will be easiest at the stage of their intermediate rigid copper(I) catenates. These enantiomerically pure complexes are expected to show enantioselectivity in both photoinduced electron transfer and interaction with DNA helices.[15]

Conjugated and Nonconjugated Cyclopentenones by a Reaction Cascade from Methyl 6-Oxo-5-phenyl-1,3,4-oxadiazine-2-carboxylate and 1,3-Butadienes**

By *Joachim Hegmann, Manfred Christl,* Karl Peters, Eva-Maria Peters,* and *Hans Georg von Schnering*

Five-membered carbocycles are structural components of numerous natural products and therefore attractive synthetic goals.[1] Since synthetic procedures with a broad scope of application are still unknown, new methods are of interest. Herein we report on reactions of the title heterocyclic compound **1** with 1,3-butadienes **2**; these reactions, although multistep processes, afford conjugated and nonconjugated cyclopentenones in a one-pot procedure and also allow the annelation of these five-membered rings.

h	$(CH_2)_5$		H	CH_2Cl_2		48 (20)			**4h**	41	61–62

[a] Reaction times in h; t_1 refers to the complete conversion of **1** and t_2 to that of the corresponding γ-oxoketene, e.g., **5** in Scheme 1. [b] The products were isolated by flash chromatography (SiO_2, petroleum ether/ethyl acetate 4 : 1) or by crystallization (**3f**, **4g**, **4h**). Their structures are in agreement with the elemental analyses and the spectroscopic data (for several examples see Table 2). [c] Along with 38% of **7**, which was separated by crystallization and chromatography. [d] Dimethylbutadiene **2d** (200% excess) was used as a 3 : 1 mixture with its (*Z*) isomer, which reacts appreciably more slowly.

Thus, treatment of **1** with 1,3-butadiene **2a** in tetrachloromethane at 40°C, followed by heating at reflux, gave a 3 : 1 mixture of the conjugated cyclopentenone derivative **3a** and the nonconjugated isomer **4a** in a yield of ca. 20%. Products analogous to **3a** were formed from (*E*)-2-methyl-1,3-pentadiene **2e**, 1-vinylcyclopentene **2f**, 2,3-dimethyl-1,3-butadiene **2c** (at 20°C), and, in part, from isoprene **2b**. On the other hand, the reactions of **1** with (*E*)-3-methyl-1,3-pentadiene **2d**, 1-vinylcyclohexene **2g**, 1-vinylcycloheptene **2h**, 2,3-dimethyl-1,3-butadiene **2c** (at 80°C), and, in part, with isoprene **2b** afforded nonconjugated cyclopentenone derivatives **4**. The results are summarized in Table 1 and selected spectroscopic data are collected in Table 2. The relative configurations of C-1 and C-5 indicated in the formula were confirmed for **3f** by NOE experiments and are therefore plausible for the other compounds **3** as well. From those and from mechanistic considerations (see below) the relative configurations of C-1 and C-4 of compounds **4** were derived.

The reaction cascades presumably begin with the cycloaddition of a CC double bond of **2** to the diazabutadiene system of **1**. In the case of the nonsymmetric butadienes **2**, the unsubstituted vinyl group is expected to be the more reactive and the orientation should correspond to that observed in the addition of styrene to **1**.[2] As found for normal reactions of olefins with **1**,[2] the Diels–Alder adducts could not be observed. However, the products

formed from them, γ-oxoketenes such as **5**, could be detected in every case owing to an IR band of the reaction mixture at ca. 2100 cm^{-1}.

In the case of 2,3-dimethylbutadiene **2c**, we were able to identify a second intermediate in addition to the γ-oxoketene **5** (Scheme 1). This intermediate could be isolated (67% yield, m.p. = 133–136°C) when the reaction was carried out in dichloromethane at 20°C (1 d). According to the X-ray structure analysis, it is the tricyclic compound **7**. The bonds C1-C2 and C2-C7 (159.8 and 160.5 pm) in the four-membered ring are significantly lengthened, whereas the lengths of all other endocyclic CC bonds lie between 151.2 and 154.1 pm.[3] Heating of **7** in tetrachloromethane at 80°C resulted in the formation of **4c**, with **3c** being observed as an intermediate.

The zwitterion **6** appears to be a logical intermediate for the conversion of **5** into **3c** and **7**. Intramolecular addition of the enolate group to the carbenium-oxonium moiety would lead to **7**. This reaction is apparently reversible at elevated temperatures, so that **6** can undergo a retrograde Michael addition generating the more stable **3c**. Claisen rearrangement of **3c** then gives rise to **4c**.

Whether the reactions at 80°C lead to the pyruvic ester enol ethers **3** or to the pyruvic esters **4** presumably de-

pends on their relative thermodynamic stability. We draw this conclusion from the finding that alkyl substituents R^2 favor the formation of **4** in each case, at least at 80 °C. The exception, **3f**, might be due to the fact that it has a lower strain energy than **4f**, since the latter contains a CC double bond to a bridgehead.

The reaction **5**→**6** is an electrophilic attack of the ketene functionality at the α-vinyl group with participation of the γ-oxo oxygen atom. Out of a number of conceivable alternatives, the reaction times t_2 (Scheme 1, Table 1) lead us to prefer a two-step process involving a zwitterionic intermediate whose five-membered ring contains a carbocationic center in addition to the enolate moiety. In the second step, the oxo group acts as a nucleophile toward the cationic center. The slow conversion of the ketene intermediate for R^2 = H (compare t_2 in Table 1 for **2a**, **b**, **e**) and its rapid disappearance for R^2 = alkyl (compare t_2 for **2c**, **d**, **f**–**h**) indicate that secondary and tertiary carbocationic centers, respectively, are generated.

μ-Hydroxo- and μ-Oxobis(μ-acetato)diruthenium Complexes with Weak Intramolecular Ru···Ru Interactions**

By *Peter Neubold, Karl Wieghardt,* Bernhard Nuber,* and *Johannes Weiss*

The electron-spectroscopic, magnetic, and electrochemical properties of binuclear transition-metal complexes containing the structural unit $[M_2^{III}(\mu\text{-O})(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ are the subject of intensive investigation, in particular because the complexes of iron and manganese are model complexes for metalloproteins in which the metal centers are held together by μ-oxo and μ-hydroxobis(μ-carboxylato) bridges.[1,2] We recently showed that, in the case of the analogous molybdenum(III) complexes, a Mo≡Mo bond ($\sigma^2\pi^4$) is formed when a μ-hydroxo-bridged complex is deprotonated, giving $[Mo_2(\mu\text{-O})(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$.[3] The mixed-valence Mo^{III}–Mo^{IV} complex, which we also prepared, contains a weaker Mo–Mo bond with a bond order of 2.5 ($\sigma^2\pi^3$).[3b] It was therefore of interest to investigate the corresponding chemistry of ruthenium, since, in this case, only a Ru^{III}–Ru^{III} single bond ($\sigma^2\pi^4\pi^{*4}$) is expected and oxidation to the Ru^{III}–Ru^{IV} complex should result in an *increase* in the bond order to 1.5 ($\sigma^2\pi^4\pi^{*3}$).

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Degussa, Hanau, for a generous donation of $RuCl_3 \cdot H_2O$.

Hydrolysis of $LRuCl_3 \cdot H_2O$ (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) in aqueous NaOAc solution results in the formation of a deep violet solution, which, after addition of $NaPF_6$, affords violet crystals of **1** in 85% yield. Complex **1** undergoes protonation in 2 M hydrochloric acid, yielding dark green microcrystals of **2**. Dissolution of **2** in H_2O results in deprotonation and quantitative re-formation of **1**. The dissociation constant of **1** at 20 °C ($pK_a = 1.9$) was determined spectrophotometrically.

1 $[L_2Ru_2^{III}(\mu\text{-O})(\mu\text{-}CH_3CO_2)_2][PF_6]_2 \cdot 0.5\,H_2O$

2 $[L_2Ru_2^{III}(\mu\text{-OH})(\mu\text{-}CH_3CO_2)_2][PF_6]_3$

3 $[L_2Ru^{III}Ru^{IV}(\mu\text{-O})(\mu\text{-}CH_3CO_2)_2][PF_6]_3$

Complex **1** was oxidized in aqueous solution with $Na_2S_2O_8$ to the mixed-valence $Ru^{III}Ru^{IV}$ dimer **3**, which was isolated as the orange-brown $PF_6^\ominus$ salt. The electronic spectra of the new complexes are shown in Figure 1.

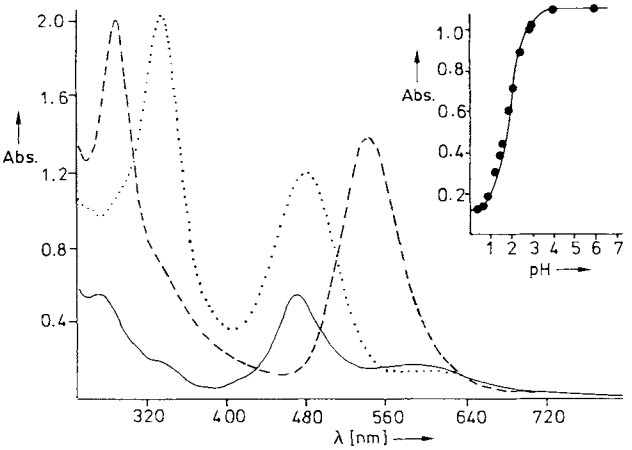

Fig. 1. Electronic spectra of **1** (H_2O), **2** (5 M HCl) and **3** (H_2O). ([1] = 2.15×10^{-4} M (----); [2] = 2.15×10^{-4} M (——); [3] = 2.15×10^{-4} M (·····); 1-cm cuvette); the inset shows the absorption of **1** at 540 nm as a function of pH.

The cyclovoltammogram of **1** in CH_3CN (0.1 M nBu_4NPF_6; Pt electrode) shows a reversible electron transfer at $E_{1/2} = +0.59$ V versus the normal hydrogen electrode (NHE)[4] as well as an irreversible reduction at −0.88 V versus NHE. Coulometry gave 1.0 ± 0.1 electron/dimer for the reversible transition.

Measurement of the molar magnetic susceptibility between 100 and 293 K using the Faraday method showed that **1** is diamagnetic, whereas **2** has a temperature-dependent magnetic moment per dimer of $\mu_{eff} = 0.68\,\mu_B$ (98 K) and $1.82\,\mu_B$ (293 K). Complex **2** exhibits intramolecular, antiferromagnetic coupling of the two low-spin Ru^{III} centers ($H = -2JS_1S_2$, $S_1 = S_2 = 1/2$, $J = -218$ cm^{-1}, $g = 2.4(1)$). For **3**, a weak temperature-dependent moment of $\mu_{eff} = 1.85\,\mu_B$/dimer (98 K) and $2.04\,\mu_B$ (293 K) was found, as expected for a $Ru^{III}Ru^{IV}$ complex containing one unpaired electron per dimer.

Figures 2 and 3 show the structures of the complex cations in **1** and **3** as determined by X-ray crystal structure analysis.[5] Important structural parameters of complexes containing $[M_2(\mu\text{-OH})(\mu\text{-}CH_3CO_2)_2]^{n\oplus}$ and $[M_2(\mu\text{-O})(\mu\text{-}CH_3CO_2)_2]^{m\oplus}$ frameworks are collected in Table 1. The structures of the cations in **1** and **3** are similar. Two Ru

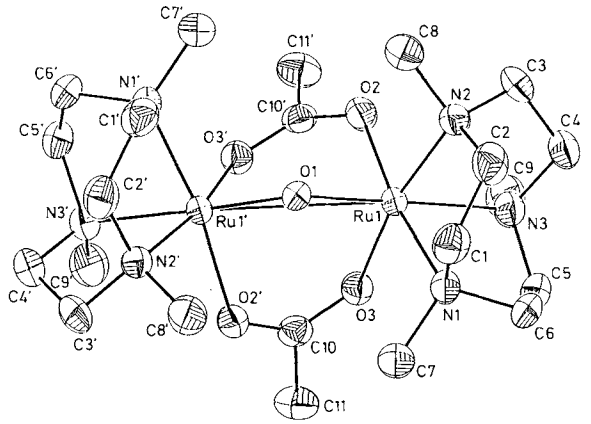

Fig. 2. Molecular structure of the cation of **1**. Selected distances [Å]: Ru1-N1 2.112(4); Ru1-N2 2.109(4); Ru1-N3 2.168(4); Ru1-O1 1.884(2); Ru1-O2 2.072(3); Ru1-O3 2.091(3); Ru1-Ru1'A 3.258(1).

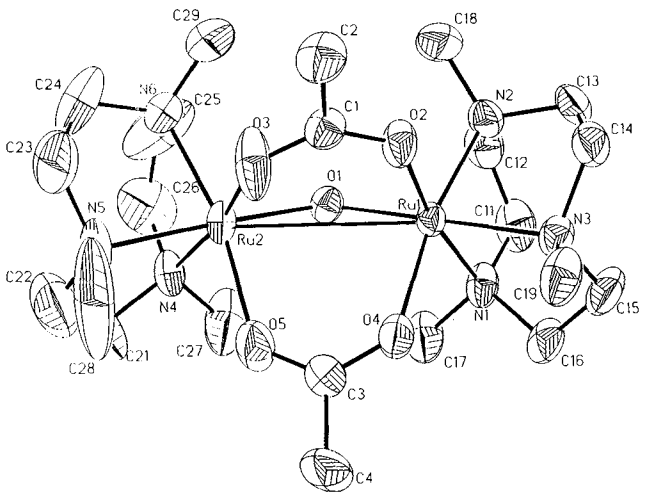

Fig. 3. Molecular structure of the cation of **3**. Selected distances [Å]: Ru1-N1 2.098(5); Ru1-N2 2.086(7); Ru1-N3 2.137(7); Ru2-N4 2.089(6); Ru2-N5 2.143(8); Ru2-N6 2.105(7); Ru1-O1 1.837(5); Ru1-O2 2.059(4); Ru1-O4 2.070(6); Ru2-O1 1.849(5), Ru2-O3 2.039(5); Ru2-O5 2.051(5); Ru1-Ru2 3.342(1).

centers are linked by one oxo and two acetato bridges (face-sharing octahedra having idealized C_{2v} symmetry of the $[N_6Ru_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]$ skeleton), and all Ru centers are coordinated facially to an amine ligand. The corresponding Ru–N and Ru–O distances in **3** are identical within the limits of experimental error for both of the Ru centers. This is not due to crystallographic symmetry; it points to a delocalization of the valences in **3**.[14] The one-electron oxidation of **1** to **3** leads to a small but significant shortening of all Ru–O and Ru–N distances (0.041 and 0.022 Å, respectively); *however, the Ru–Ru distance increases by 0.084 Å*. This is remarkable and is not in accordance with expectations based on a simple model of bonding (see above). The same effect was observed in the molybdenum complexes **5** and **6** (Δ(Mo···Mo) = 0.084 Å) (Table 1). In these cases, however, the presence of a Mo–Mo bond is unambiguously supported by the metal–metal distance, which is 0.37 Å shorter in each case than those in the Ru complexes **1** and **3**.

According to the bonding analyses of *McCarley* et al.,[6] *Hoffmann* et al.,[7] and *Cotton* et al.,[8] overlapping of the t_{2g} metal orbitals in face-sharing octahedra leads to the formation of one σ and two π bonds (*non* degenerate in C_{2v})

between the two metal centers. In the molybdenum complexes **5** and **6** (see Table 1), Mo–Mo bonds of bond order 3 ($\sigma^2\pi^4$) and 2.5 ($\sigma^2\pi^3$), respectively, are present. Complex **1** has a Ru–Ru single bond ($\sigma^2\pi^4\pi^{*4}$); **3** should have a bond order of 1.5 ($\sigma^2\pi^4\pi^{*3}$). On going from **1** to **3**, a shortening of the Ru–Ru bond should therefore be observed. On going from **4** to **5**, a lengthening of the Mo–Mo distance was found, as expected.

The Ru···Ru interactions in **1** and **3** are weak. The diamagnetism of **1** is unusual and may be regarded as an indication for a Ru···Ru bond ($\sigma^2\pi^4\pi^{*4}$), since the known Ru^{III}–O–Ru^{III} complexes show antiferromagnetic coupling.[9] Complexes **1** and **3** are borderline cases for direct metal–metal bonds. It is not easy to explain why the Ru–Ru distance in **3** is greater than in **1**.[10]

In the protonated form **2**, the Ru-$O_{hydroxo}$ bonds are probably longer than the Ru-O_{oxo} bonds in **1**. In the analogous hydroxo/oxo complexes of Mo^{III}, **4** and **5**, as well as of Fe^{III}, **7** and **8**, a lengthening of the M–O bonds by 0.145 and 0.156 Å, respectively, is observed (Table 1). Lengthening of the Ru–O bond in **2** leads to a greater Ru–Ru distance in **2** than in **1** and the weak Ru–Ru bond in **1** is broken upon protonation to give **2**. Accordingly, an intramolecular antiferromagnetic coupling of the two Ru^{III} centers is observed in **2**.

Interestingly, the Os···Os distance in *Walton*'s diamagnetic complex cation $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{4\oplus}$ is 3.440 Å;[13] it is thus 0.098 Å longer than the Ru–Ru bond in **3**. Therefore, an Os–Os double bond ($\sigma^2\pi^4\pi^{*2}$) is ruled out.

Experimental Procedure

$LRuCl_3 \cdot H_2O$: *N,N',N''*-Trimethyl-1,4,7-triazacyclononane(L) (0.8 g, 8 mmol) was added to a suspension of $[Ru^{II}Cl_2(dmso)_4]$ in 25 mL of absolute ethanol. The reaction solution was stirred at 60°C for 30 min and then heated at reflux for 2 h. After removal of the solvent, the red-orange residue was dissolved in 20 mL of concentrated hydrochloric acid and heated at reflux for 30 min, resulting in the formation of orange microcrystals of the product. After combination of the filtrates, additional product was obtained (yield: ca. 60%).—UV/VIS (CH_3CN): $\lambda = 397$ nm ($\varepsilon = 2260\ M^{-1}\ cm^{-1}$), 340 (sh), 300 (1300). Magnetic moment: $\mu_{eff}(293\ K) = 2.35\,\mu_B$.

1: A suspension of $LRuCl_3 \cdot H_2O$ (0.25 g, 0.6 mmol) in 15 mL of an aqueous solution containing 1 g of NaOAc was heated at reflux for 30 min. $NaPF_6$ (0.75 g) in 20 mL of H_2O was then added to the violet, hot solution. At 0°C, violet crystals of **1** formed. Recrystallization from H_2O (yield: 85%).

2: **1** (0.10 g, 0.1 mmol) was dissolved in 5 mL of 2 M HCl at 20°C, whereby the reaction solution turned from violet to green. After addition of $NaPF_6$ (0.15 g) in 5 mL of 2 M HCl, green **2** precipitated at 0°C (yield: 95%).

3: $Na_2S_2O_8$ (0.10 g) in 2 mL of H_2O was added to a solution of **1** (0.15 g, 0.15 mmol) in 10 mL of H_2O, whereby the reaction solution turned from violet to brown. After addition of $NaPF_6$ (0.20 g) in 3 mL of H_2O, brown **3** precipitated (yield: 94%). Single crystals of $[L_2Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2][ClO_4]_2[PF_6]$ suitable for crystal structure analysis were grown from aqueous solutions of **3** following addition of $NaClO_4 \cdot H_2O$.

All complexes gave correct elemental analyses (C, H, N, Ru).

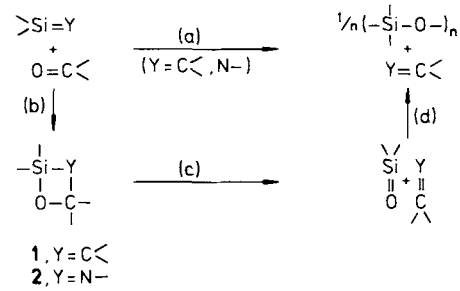
[14] A statistical disorder of the cations in **3** is also possible. This would lead to apparent equivalence of the delocalized Ru^{III}/Ru^{IV} valences. In the electronic spectrum of **3** an intervalence absorption is observed at 1590 nm ($\varepsilon = 276$ L mol^{-1} cm^{-1}). Therefore, a delocalized description with two Ru centers in the oxidation state +3.5 is preferable.

"Wittig Reactions" of Unsaturated Silicon Compounds >Si=Y: Isolation and Structure of Possible Intermediates**

By *Nils Wiberg,** *Klaus Schurz, Gerhard Müller,** and *Jürgen Riede*

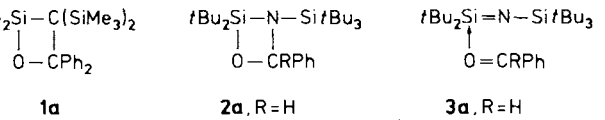
Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

When unsaturated silicon compounds >Si=Y of the type >Si=C< (silaethenes) or >Si=N– (silanimines) are generated in the presence of nonenolizable aldehydes or ketones, mutual exchange of Y and O occurs to give polysiloxanes and ethenes >C=C< or imines >C=N–, respectively (Scheme 1), the reaction possibly proceeding via a pseudo-Wittig mechanism involving **1** or **2**, respectively, and >Si=O (silanones).[2–4]



Scheme 1.

Attempts to prove the existence of the postulated intermediates **1** and **2** (oxasila- and oxaazasilacyclobutanes) were initially unsuccessful.[5,6] Several years ago, however, we obtained, for the first time, an oxasilacyclobutane as the [2+2] cycloadduct of benzophenone with the unstable silaethene $Me_2Si{=}C(SiMe_3)_2$.[7] By reaction of the sterically congested and therefore metastable silanimine $tBu_2Si{=}N{-}SitBu_3$[11] with benzaldehyde in pentane at –125°C, we have now also succeeded in preparing an oxaazasilacyclobutane, **2a**.[12]



1a | **2a**, R = H; **2b**, R = Ph | **3a**, R = H; **3b**, R = Ph

The question then arose as to the mechanism of formation of **1** and **2** (Eq. (b) in Scheme 1).[13] The [2+2] cycloaddition reaction of carbonyl compounds with >Si=Y compounds can occur in one or two steps,[2,3] the initial step in the latter case being possibly the formation of a bond between Si and O or between Y and C. We obtained evidence supporting the two-step mechanism with initial formation

[**] Unsaturated Silicon Compounds, Part 29, and Compounds of Silicon and Its Group Homologues, Part 81.—Parts 28 and 80: [1].

of a Si–O bond when we allowed tBu$_2$Si=N–SitBu$_3$[11] to react with benzophenone in diethyl ether. A potential precursor of **2** having constitution **3b**, according to the X-ray structure analysis (see below), was thereby isolated.

Adduct **3b** forms dark red, hydrolytically labile crystals from pentane at -78 °C;[14] it is readily soluble in diethyl ether and moderately soluble in pentane and benzene, but dissolves in tetrahydrofuran (THF) only with replacement of Ph$_2$C=O by THF. There are obvious steric reasons why **3b** is stable toward transformation to the [2+2] cycloadduct at room temperature, whereas other addition compounds such as Me$_2$Si=C(SiMe$_3$)$_2$·Ph$_2$C=O and **3a**[15] undergo spontaneous transformation to the corresponding [2+2] cycloadducts even at very low temperatures.

Gentle warming (60–80 °C) of a dark red benzene solution of **3b** results in dissociation of **3b** to form a lighter solution of the educts tBu$_2$Si=N–SitBu$_3$ (pale yellow) and Ph$_2$C=O. Thus, **3b** does not rearrange to the [2+2] cycloadduct **2b**. Cooling of the solution results once again in the formation of **3b**. When benzophenone is used as solvent, the thermal dissociation is suppressed so that such solutions remain initially dark red even at 90 °C. Since, under these conditions, **3b** is transformed slowly into uncharacterized products, however, solutions of **3b** in benzophenone also turn lighter within a few hours. In this case, cooling does not result in reappearance of the dark red color.

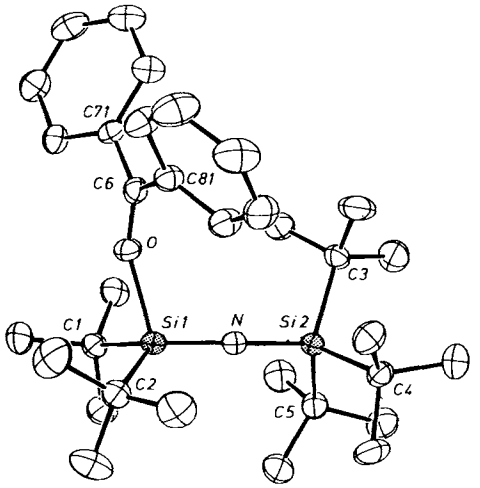

Fig. 1. Molecular structure of **3b** (ORTEP, displacement ellipsoids 50%, without H atoms). The silyl group Si2 is slightly displaced backwards out of the plane of the figure (Si1-N-Si2 169.3(2)°). Important distances [Å] and angles [°]: Si1-N 1.601(2), Si2-N 1.678(2), Si1-O 1.927(2), Si1-C1 1.930(3), Si1-C2 1.923(3), Si2-C3 1.950(3), Si2-C4 1.961(3), Si2-C5 1.961(3), O-C6 1.254(3); O-Si1-N 106.9(1), O-Si1-C1 91.3(1), O-Si1-C2 102.5(1), N-Si1-C1 120.4(1), N-Si1-C2 117.5(1), C1-Si1-C2 112.4(1), Si1-O-C6 153.7(2).

The X-ray structure analysis[16] reveals that **3b** may be regarded as a loose benzophenone adduct at the unsaturated Si atom of the silanimine tBu$_2$Si=N–SitBu$_3$ (Fig. 1). This is shown especially by the unusually long Si–O bond (1.927(2) Å, compared with a normal value of 1.55–1.75 Å[17]), the comparably short C–O distance (1.254(3) Å, compared with 1.231 Å in Ph$_2$C=O[18]), and the incompletely attained tetrahedral geometry of the unsaturated Si atom Si1 (trigonal-planar geometry in free silanimine[11]). The addition is associated with a slight lengthening of the N=Si1 bond (from 1.568(3) Å to 1.601(2) Å); on the other hand, the N–Si2 bond becomes somewhat shorter and the valence angle at the N atom decreases from 177.8(2)° to 169.3(2)°.

Diisocyanogen**

By *Thomas van der Does* and *Friedrich Bickelhaupt**

The cyano radical CN$^\odot$ could combine with other radicals R$^\odot$ by bond formation at C or N, resulting in either nitriles RCN or isonitriles RNC.[1,2] It dimerizes only

[*] Prof. Dr. F. Bickelhaupt, Drs. T. van der Does

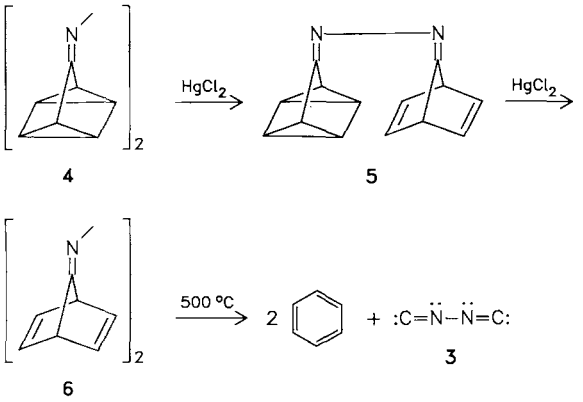
De Boelelaan 1083, NL-1081 HV Amsterdam (The Netherlands)

[**] We thank *R. F. Schmitz*, Amsterdam, for carrying out the difficult recording of the mass spectrum.

through carbon, however, to give cyanogen **1**, which has been known since 1815;[3] to the best of our knowledge, the isomeric cyanoisocyanide NCNC **2** and diisocyanogen CNNC **3** have been prepared neither by $CN^{\ominus}$ dimerization nor via other routes. Theoretical calculations[4] may provide an explanation for these observations; **2** and **3** are about 17 and 65 kcal mol^{-1}, respectively, less stable than **1**. Our research on phosphaalkenes,[5a] in particular 7-norbornadienylidenephosphane,[5b] prompted us to investigate the corresponding nitrogen analogues. This work led to the first synthesis of **3**, the least stable by far of the three isomers, namely by cheletropic elimination from the azine **6**.



Cheletropic eliminations proceed extremely smoothly for norbornadienes if, in addition to benzene, a second stable fragment is formed.[6] In the case of norbornadienones, the second species is the extremely stable carbon monoxide and the fragmentation occurs even below −70°C. In contrast, aryl isocyanides are eliminated from *N*-arylnorbornadien-7-ylidenamines at 20–80°C[5b,6d] and from benzonorbornadiene derivatives at ca. 120°C.[7] This approach can be used to synthesize **3** from **6** as starting material. We obtained **6** in 65% yield by catalytic isomerization of **4**;[6d,8] the catalyst employed, sublimate, was reported by *Rood* and *Klumpp* to be particularly well-suited for the rearrangement of quadricyclanes to norbornadienes.[9] As expected, the isomerization of **4** to **6** proceeds stepwise via **5**, which could be detected in the reaction mixture by ^{1}H-NMR spectroscopy.

In solution ([D_8]toluene) **6** decomposes above 80°C with polymerization; neither benzene nor other soluble products are formed. Therefore, **6** was subjected to flash vacuum pyrolysis and the products were collected in a trap cooled with liquid nitrogen. At 300–450°C a nearly quantitative mixture of **6**, benzene, and **3** was obtained. The monofragmentation product *N*-isocyanonorbornadien-7-ylidenamine was not found. Above 500°C the reaction of **6** was complete. Since **3** decomposes above −30°C with formation of a brown polymer,[10] the volatile products were condensed at low temperature along with [D_8]toluene in an NMR tube cooled with liquid nitrogen. At −65°C, only the resonance of benzene ($\delta = 7.07$) was observed in the ^{1}H-NMR spectrum; in the ^{13}C-NMR spectrum the resonance of benzene ($\delta = 128.5$) was observed along with a resonance at $\delta = 172$, which vanished at −30°C. We assign this signal to the C atoms of **3**, since it lies in the region characteristic of isocyanides.[13] The ^{13}C-NMR resonance of **1**, which, to the best of our knowledge, has not been previously measured, was found at $\delta = 93$. The ^{13}C-NMR signal of **3** is sharp ($\Delta\nu_{1/2} = 1.2$ Hz) and does not exhibit the ^{14}N coupling usually observed for isocyanides.[14] In the ^{14}N-NMR spectrum,[14] **3** ($\delta = -239$, external standard $MeNO_2$ ($\delta = 0$)) also differs in a characteristic fashion from **1** ($\delta = -118$);[15] here, too, the signal of **3** vanishes above −30°C. The identity of **3** was corroborated by mass spectroscopy (see Experimental Procedure). The molecular ion $C_2N_2^{\odot\oplus}$ is the base peak and the intensities of the fragment ions differ significantly from those observed for $\mathbf{1}^{\odot\oplus}$.[16]

Owing to its high volatility, its ready decomposition in solution, and its spectral data, the new compound can be unambiguously identified as diisocyanogen **3**. The reactivity of this new species is currently being investigated. Noteworthy, however, is the high thermal stability of **3** in the gas phase. Normally, isonitriles undergo rearrangement at temperatures above 200°C to the corresponding nitriles;[17] in contrast, **3** affords no **1**, even at 500°C. This surprising stability of the N–N bond of **3** can be explained by its theoretically predicted double-bond character.[4]

Experimental Procedure

6: A solution of **4** (340 mg, 1.63 mmol) [6d, 8] and $HgCl_2$ (200 mg, 0.74 mmol) in 25 mL of chloroform was stirred for 24 h. After removal of the solvent under vacuum, the residue was extracted with toluene and the filtrate was evaporated. The residue was sublimed (50–60°C, 10^{-5} mbar) and afforded 222 mg (1.07 mmol, 65%) of **6** as colorless crystals (m.p. = 140–142°C (dec)).—MS (70 eV): *m/z* 208 (5%; high resolution, found 208.1005, calcd 208.1000), 130 (8%), 104 (30%), 78 (100%), 77 (32%).—^{1}H-NMR ($CDCl_3$, 250 MHz): $\delta = 6.88$ (m, 4H), 6.79 (m, 4H), 4.47 (m, 2H), 4.01 (m, 2H).—^{13}C-NMR ($CDCl_3$, 62.89 MHz): $\delta = 180.1$ (s), 139.7 (d, $^1J(CH) = 178.5$ Hz), 138.5 (d, $^1J(CH) = 178.5$ Hz), 51.6 (d, $^1J(CH) = 153$ Hz), 47.6 (d, $^1J(CH) = 156$ Hz). ^{1}H–^{13}C double resonance experiments confirmed the expected couplings.—Correct C,H,N analyses.—If the reaction mixture is evaporated after about 3 h, and the residue dissolved in $CDCl_3$, then, in addition to the signals of **4** and **6**, those of **5** are observed in the ^{1}H-NMR spectrum: **5**: $\delta = 6.95$ (m, 2H), 6.89 (m, 2H), 4.76 (m, 1H), 4.09 (m, 1H), 2.05 (br. s, 5H), 1.57 (m, 1H).

3: **6** (100 mg, 0.48 mmol) was heated at 50–60°C and 10^{-5} mbar in a flash vacuum pyrolysis apparatus [18] and underwent sublimation over ca. 30 h through a hot tube (aluminum oxide, 25-cm length, 1.5-cm diameter, 500°C). The products were collected in a cold trap (liquid nitrogen). The cold trap was then removed from the cooling bath and the volatile products (**3**, benzene) were distilled into a second trap cooled with liquid nitrogen. *n*-Pentane was distilled into the trap and the mixture was slowly heated. At −30°C brown flakes began to separate out; this process was complete after several hours at 0°C. After removal under vacuum of pentane and benzene, 14 mg of a brown powder (assumed to be $(CN)_x$ [10], 60% yield) was obtained. In order to record the NMR spectra, the volatile products were collected (as described above) in an NMR tube sealed to the apparatus, followed by distillation of [D_8]toluene into the tube, which was then sealed.—In order to carry out the mass spectral studies, the pyrolysate was distilled into a tube (see above) cooled with liquid nitrogen and connected via a capillary with the direct inlet of a Varian MAT CH-5-DF mass spectrometer, followed by warming of the pyrolysate using a cryostat. Above −140°C the signals of **3** (without benzene signals) were recorded; above −100°C the signals of benzene were also observed. MS (70 eV): *m/z* 52 (100%; high-resolution; found 52.0059, calcd 52.0061), 53 (2.7%), 38 (2.7%), 26 (14%), 24 (23%).

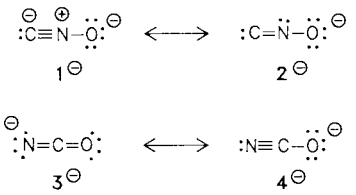
Carboxime (Isofulminic Acid)**

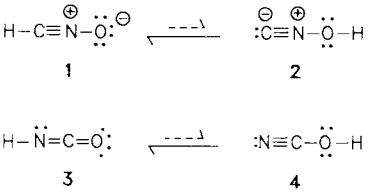
By *Günther Maier,* Joaquim Henrique Teles, B. Andes Hess, Jr.,* and *Lawrence J. Schaad*

When, after some controversy (1823–1826),[1] it became clear that silver fulminate (*Liebig*) and silver cyanate (*Wöhler*) have the same composition but different chemical properties, the theoretical interpretation followed inevitably: the phenomenon of isomerism had been observed (*Berzelius*, 1830[1]). The order of the C and N atoms in the two salts is interchanged.[2]

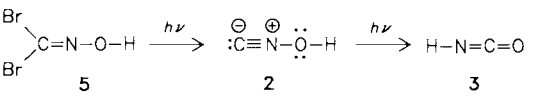


The discussion concerning the free acids **1**–**4** related to the fulminates ($\mathbf{1}^{\ominus} \leftrightarrow \mathbf{2}^{\ominus}$) and cyanates ($\mathbf{3}^{\ominus} \leftrightarrow \mathbf{4}^{\ominus}$) has continued until today: For fulminic acid only dimeric structures were considered initially.[3] *Nef*,[4] in 1894, was the first to recognize the monomeric constitution and ascribed to it the carboxime formula **2**. Seventy more years were to pass until fulminic acid was unequivocally characterized, on the basis of its spectroscopic data (IR[5a,b] and microwave spectrum[5c]), as formonitrile oxide **1** (instead of **2**).

Upon acidification the fulminates furnish exclusively formonitrile oxide **1**, whereas the cyanates give only isocyanic acid **3** (Raman[6a] and IR[6b] spectrum). In agreement with these observations the structural data indicate that resonance structure $\mathbf{1}^{\ominus}$ is the most important one in the case of silver fulminate and that the canonical form $\mathbf{3}^{\ominus}$ is the main contributor in the case of silver cyanate.



Only with the help of the matrix isolation technique has it been possible to demonstrate the existence of cyanic acid **4** directly.[7] Herein, we report that the last and only missing isomer, namely the real carboxime **2** (isofulminic acid)[8]—altogether there are four "chemically reasonable" linear arrangements (cf. formulas **1**–**4**) for a compound of the formula CHNO—is detectable by the same technique.



Irradiation of dibromoformoxime **5**[9] in argon at 12 K with a low-pressure mercury lamp leads to disappearance of all IR bands of **5** within 20 minutes, and one obtains the IR spectrum shown in Figure 1, which we assign to the carboxime **2**. Our arguments in support of this assignment are: 1. The new species shows a spectrum different from that of fulminic acid, and even more different from that of isocyanic acid or cyanic acid. 2. The asymmetric stretching vibration of the ONC unit in **2** appears at 2190 cm^{-1}. This

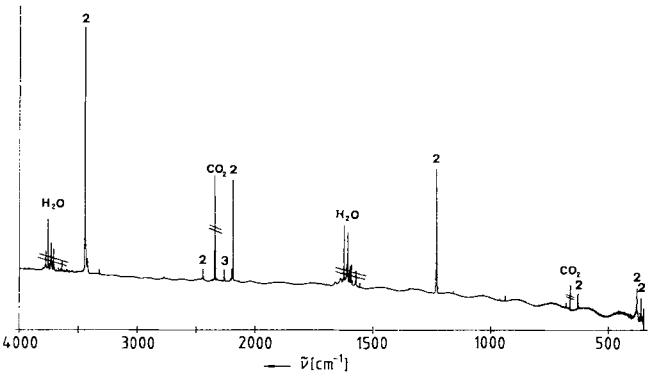


Fig. 1. IR spectrum of isofulminic acid in an Ar matrix at 12 K.

position almost coincides with the position of the corresponding band of fulminic acid **1** (2193 cm^{-1}), but is located at much lower wavelength than the corresponding absorption of isocyanic acid **3** (2260 cm^{-1}) or cyanic acid **4** (2286 cm^{-1}). Calculations also predict that carboxime **2** should show the smallest wave number for this vibration. 3. The difference of 96 cm^{-1} between the wavelengths at

which these absorptions of **4** and **2** appear has also been observed in the spectra of the corresponding esters; the *O*-alkyl derivatives of **2** prepared by *Wentrup* et al.[10] absorb at 2108–2160 cm^{-1}, the cyanates at about 2250 cm^{-1}. 4. The experimental and calculated IR spectra of **2** and its isotopomer [*D*]**2** (Table 1) are in satisfactory agreement, even though the difference is greater than in other cases.[12] 5. On prolonged irradiation (254 nm), the photoproduct of **5** is converted into isocyanic acid.

Table 1. Comparison of the experimental (Ar matrices, 12 K; relative integrated intensities) and calculated IR spectra of **2** and [D]**2**; ν- and δ-absorptions in cm^{-1}.

Assignment	Symmetry	**2**, exp.	**2**, calcd	[D]**2**, exp.	[D]**2**, calcd
$\nu_{OH(OD)}$	A′	3444(1.00)	3803(1.00)	2545(1.00)	2770(1.00)
ν^{as}_{ONC}	A′	2190(0.15)	2139(0.03)	2190(0.13)	2135(0.03)
$\delta_{HON(DON)}$	A′	1232(0.30)	1416(0.69)	903(0.22)	1059(0.88)

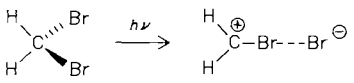
δ_{ONC}	A′	361(0.03)[a]	274(0.06)	362(0.09)[a]	267(0.10)
$2\times\delta_{HON(DON)}$	A′	2444(0.04)[b]	—	1794(0.03)[b]	—

[a] Assignment may have to be changed. [b] Assignment based on the matrix splitting.

A conceivable alternative is that **5** loses only one halogen atom upon irradiation, resulting in formation of the isomer **6**. This type of reaction has recently been described by us for iodine-containing dihalomethanes.[13a] Dibromomethane **7** could analogously be isomerized to **8**.[13b] This photoisomer shows a strong characteristic UV band at 360 nm. In contrast, no absorption is observed between 250 and 800 nm in the photolysis of **5**. In other words: irradiation of **5** does not lead to **6** but to carboxime **2**.

6



7 **8**

It is no wonder that compound **2** has hitherto evaded direct detection, since it has the highest energy of the four isomers **1**–**4**.

Stepwise Synthesis and Crystal Structure of Tricarbonyl[pentakis(methylthio)cyclopentadienyl]-manganese $[\{C_5(SMe)_5\}Mn(CO)_3]$**

By *Karlheinz Sünkel** and *Doris Motz*

Complexes containing cyclopentadienyl ligands substituted with functional groups are an interesting class of compounds.[2] Owing to both their electronic effect and their ability to coordinate further metal fragments, the functional groups can be of great importance for the reactivity, in particular the catalytic activity, of the complex.[3,4] Whereas a large number of metal complexes containing *one* functional group on the cyclopentadienyl ring are known, relatively few examples containing five such substituents R (R = Cl,[5] Br,[6] CO_2Me[7]) have been reported. Although the anions $[C_5(CN)_5]^{\ominus}$[8] and $[C_5(SMe)_5]^{\ominus}$[9] have been known for some time, it has not been possible so far to incorporate them into π complexes. In view of the increased interest in mono- and dichalcogen-substituted ferrocenes,[10] we have developed a stepwise synthesis of the complexes **5** starting from **1**, which is obtainable from $[(C_5Cl_4Br)Mn(CO)_3]$.[1]

By successive halogen–metal exchange and reactions with dimethyldisulfane, it is possible to prepare each member of the series $[\{\eta^5\text{-}C_5Cl_{5-x}(SMe)_x\}Mn(CO)_3]$ with x = 1–5.

The reaction of **1** with BuLi/Me_2S_2 can afford in principle two stereoisomers of **2**. An X-ray crystal structure analysis showed that the 1,3-disubstituted isomer was formed.[11]

5	SMe	SMe	SMe	SMe

The crystal structure of compound **5**, containing five methylthio substituents, could also be solved (Fig. 1).[12] Whereas in the free ligand (in the form of its $AsPh_4$ salt[9]), four methyl groups are situated on one side of the ring plane, in the complex three SMe groups (but four S atoms) are located on the side of the ring facing away from manganese. The deviations of the atoms in the five-membered ring from planarity (maximally +0.31 pm for C13 and −0.37 pm for C14) are small. The sulfur atoms whose methyl groups point toward manganese (S12 and S15) are significantly displaced from the ring plane away from the metal (by about 19.8 and 18.1 pm, respectively) and also exhibit the largest angle C_{ring}-S-C_{methyl} (104.2(4) and 104.4(4)°, respectively). The average distances Mn-C_{ring} and C-C are 214.7(9)±1.8 pm and 142.7(12) pm (142±2 pm in the free ligand[9]); only the short distance C11-C12 (140.4(12) pm) is notable.

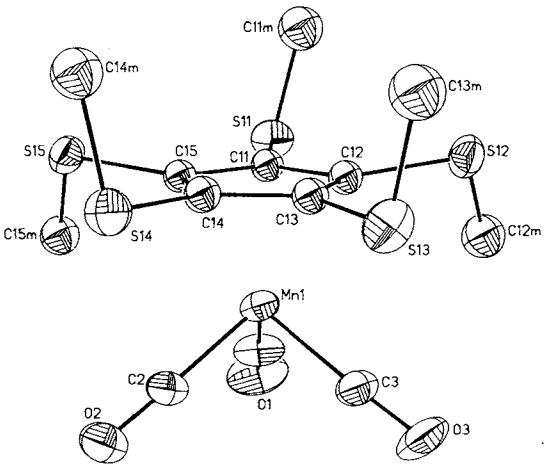

Fig. 1. Molecular structure of **5** (thermal ellipsoids at 20% probability) without H atoms. Selected bond lengths [pm] and bond angles [°]: Mn1-C11 216.5(9), Mn1-C12 215.3(8), Mn1-C13 213.5(9), Mn1-C14 213.1(9), Mn1-C15 215.0(8), C11-C12 140.4(12), C11-C15 143.4(12), C12-C13 143.7(12), C13-C14 142.6(12), C14-C15 143.5(12); C12-C11-C15 109.0(7), C11-C12-C13 108.3(7), C12-C13-C14 107.4(7), C13-C14-C15 108.5(7), C11-C15-C14 106.8(7), C11-S11-C11m 101.3(5), C12-S12-C12m 104.2(4), C13-S13-C13m 101.1(5), C14-S14-C14m 99.9(5), C15-S15-C15m 104.4(4).

The structures of **2** and **5** reveal that the sulfur substituents in **3** are probably in positions 1, 3, and 4 with the methyl groups directed away from manganese,[11b] whereas one methyl group in **4** points toward manganese. The spectroscopic data for **1**–**5** show that the electron density at sulfur decreases and that at the metal increases with increasing number of methylthio substituents: the methyl signals are shifted downfield in the ^{1}H-NMR spectrum and the ν(CO) frequencies are shifted to lower wave numbers. Interestingly, the methyl groups (except for those of **4**) always give only one signal in the 90-MHz ^{1}H-NMR spectrum. Even if a rapid inversion at sulfur at room temperature can be assumed, leading to averaging of the signals for the "*cis*" or "*trans*" methyl groups, it still remains unclear why the different nature of the neighboring groups leads to two absorptions in the case of **4** but not in that of **3**.

The compounds were also examined with respect to their ability to serve as complex ligands for other metals. The preliminary results reveal that they engage in reactions typical of thioethers. For instance, **3** reacts with $[Pd(PhCN)_2Cl_2]$ to form a compound in which the two neighboring methylthio groups are coordinated in a chelate fashion to a $PdCl_2$ moiety. In the ^{1}H-NMR spectrum, two singlets in a ratio of 2:1 appear; the first singlet is significantly shifted downfield in comparison with that of **3**.

Experimental Procedure

All operations were carried out under dry N_2. Correct C,H,S analyses were obtained for **2** to **5**.

2: $[(C_5Cl_4Br)Mn(CO)_3]$ (1.45 g, 3.47 mmol) was dissolved in 20 mL of Et_2O and the solution was cooled to −60°C. The solution was then treated successively with a 1.6 M BuLi solution in hexane (2.17 mL, 3.47 mmol), Me_2S_2 (0.3 mL, 3.47 mmol), BuLi solution (2.17 mL), and Me_2S_2 (0.3 mL). The temperature was allowed to rise to −30°C over 3 h and the solvent was then removed under vacuum. The residue was extracted twice with 20 mL of hexane. The extracts were then concentrated to about 1 mL and cooled to −78°C, resulting in the precipitation of yellow, crystalline **2**. Yield 1.02 g (74%), m.p. = 65–67°C. IR: ν(CO) (hexane): 2044, 2040, 1978, 1969 cm^{-1}. 90-MHz ^{1}H-NMR (C_6D_6): δ = 1.84 (SCH_3). ^{13}C-NMR (C_6D_6): δ = 111.5, 104.0, 89.8 (C_5R_5); 20.3 (SCH_3).

3: Yellow crystals of **3** were obtained from **2** (930 mg, 2.14 mmol), BuLi solution (1.34 mL, 2.14 mmol) and Me_2S_2 (0.19 mL, 2.14 mmol) in 10 mL of Et_2O as described for the synthesis of **2**. Yield 630 mg (66%), m.p. = 70–71°C. IR: ν(CO) (hexane): 2038, 2033, 1975, 1967 cm^{-1}. 90-MHz ^{1}H-NMR (C_6D_6): δ = 1.92 (SCH_3). ^{13}C-NMR (C_6D_6): δ = 112.0, 97.8, 91.6 (C_5R_5), 20.3 (SCH_3).

Likewise, **4** was obtained from **3** and **5** from **4**.

4: Yield 57%, m.p. = 59–60°C. IR: ν(CO) (hexane): 2037, 2033, 1965 cm^{-1}. 90-MHz ^{1}H-NMR (C_6D_6): δ = 2.06, 2.04 (SCH_3). ^{13}C-NMR (C_6D_6): δ = 113.2, 105.2, 99.2 (C_5R_5), 20.8, 20.1 (SCH_3).

5: Yield 32%, m.p. = 93–94°C. IR: ν(CO) (hexane): 2030, 2026, 1958 cm^{-1}. 90-MHz ^{1}H-NMR (C_6D_6): δ = 2.15 (SCH_3). ^{13}C-NMR (C_6D_6): δ = 106.6 (C_5R_5), 20.4 (SCH_3).

Stabilization of 1,2,4,5-Tetradehydrobenzene by Complexation at Two Nickel(0) Centers

By *Martin A. Bennett,* James S. Drage, K. David Griffiths, Nicholas K. Roberts, Glen B. Robertson,* and *Wasantha A. Wickramasinghe*

1,2-Didehydrobenzene, (C_6H_4) **1**, is a short-lived compound that can be observed only by spectroscopic methods in an argon matrix at 8 K or at low pressures in the gas phase;[1] however, it forms stable η^2-transition metal complexes.[2-4] A recent theoretical study[5] predicts that retrocyclization of 1,2,4,5-tetradehydrobenzene **2** and 1,2,3,4-tetradehydrobenzene **3** to HC≡C–C≡C–C≡CH is much more favored energetically than the corresponding ring-opening of 1,2-didehydrobenzene to HC≡CH and HC≡C–C≡CH. We show here that **2** can be stabilized as a dinickel(0) complex **4**.[6] During the preparation of this manuscript, *Buchwald* et al.[7] reported the synthesis and structural characterization of a related zirconium complex **5**.

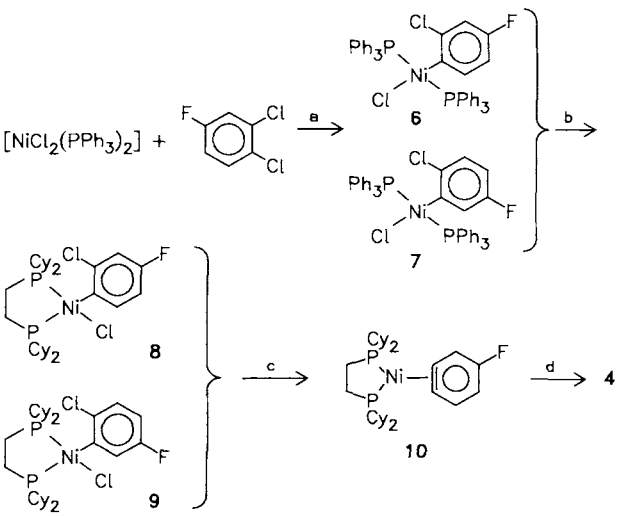
Treatment of a mixture of $[NiCl_2(PPh_3)_2]$, 1,2-dichloro-4-fluorobenzene, and a trace of 2,2′-azobis(2-methylpropionitrile) (AIBN) in THF at 45 °C with ultrasound-activated zinc powder affords a 10:1 mixture of the isomeric 2-chloro-4-fluoro- and 2-chloro-5-fluorophenylnickel(II) complexes **6** and **7**[8,9] (Scheme 1). Displacement of the PPh_3 ligands in **6** and **7** by $Cy_2PCH_2CH_2PCy_2$ (Cy = cyclohexyl) in boiling toluene gives a mixture of isomeric (chlorofluorophenyl)nickel(II) complexes **8** and **9**[10] which are reduced to the 4-fluoro-1,2-didehydrobenzene-nickel(0) complex **10** by treatment with two equivalents of potassium graphite (KC_8).[11-13]



Scheme 1. a) Zn powder, AIBN, ultrasound, 45 °C; b) $Cy_2PCH_2CH_2PCy_2$, toluene, 110 °C; c) KC_8 (2 equiv.), THF; d) $[Ni(C_2H_4)(Cy_2PCH_2CH_2PCy_2)]$, LiTMP, THF.

The last step required to form **4** relies on the fact that 1,2-didehydrobenzene generated by treatment of chlorobenzene with the strongly basic but weakly nucleophilic compound lithium 2,2,6,6-tetramethylpiperidide (LiTMP) can be intercepted by added nucleophiles such as PhSLi[14] [Eq. (a)] or by Diels–Alder reagents such as 1,3-diphenylisobenzofuran[15] [Eq. (b)], or even the nickel(0) complex **11**.[4,16] Thus, treatment of an equimolar mixture of fluorobenzene and **11** in THF at 20 °C with an excess of LiTMP gives **12** in 15–20% yield, together with other unidentified

products [Eq. (c)]. Similarly, addition of an excess of LiTMP to an equimolar mixture of **10** and **11** in THF gives the required tetradehydrobenzene complex **4** in surprisingly good yield and with few byproducts (Scheme 1).[17, 18]

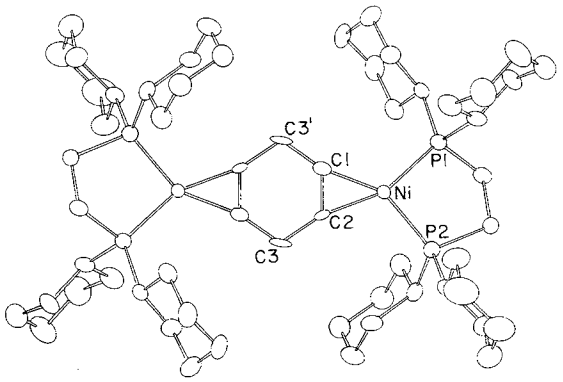

Fig. 1. Molecular structure of **4** (ORTEP [21]). 30% ellipsoids, hydrogen atoms omitted for clarity.

The structure of **4** has been determined by single-crystal X-ray diffraction analysis[19] (Fig. 1). The $(C_6H_2)Ni_2$ moiety is planar to within experimental error [Δ_{max} = 0.003(10) Å] but the nickel atoms are displaced 0.08(2) Å from their (PPCC) coordination planes. Bond lengths and bond angles in the six-membered ring indicate substantial π-electron localization at the ligating carbon atoms.[19] Surprisingly, the very substantial angle deformations in the C_6H_2-ring [e.g. C2-C3-C1′ = 112.2(8)°] are not observed in the analogous zirconium compound **5**.[7]

[7] S. L. Buchwald, E. A. Lucas, J. C. Dewan, *J. Am. Chem. Soc. 109* (1987) 4396.

[8] *Procedure* for **6** and **7**: A three-neck, round-bottom flask fitted with a nitrogen inlet, mechanical stirrer and solids addition tube was charged under nitrogen with zinc powder (2.7 g) and THF (30 mL) and partially immersed in an ultrasound water bath at 45 °C. After 40 min the vigorously stirred and ultrasonicated mixture was treated successively with 1,2-dichloro-4-fluorobenzene (3.8 mL, ca. 34.5 mmol), $[NiCl_2(PPh_3)_2]$ (18 g, 27.5 mmol) and AIBN (0.36 g). Within 1-2 min the color of the mixture changed from deep blue-green to orange. After 10 min the mixture was filtered through Kieselguhr and the product was washed through with dichloromethane. Concentration under reduced pressure and addition of methanol gave yellow crystals of **6**/**7** (14.1 g, 69%), m.p. 162-165 °C (dec.).

[9] **6**/**7**: ^{1}H-NMR (CD_2Cl_2): δ = 9.70 (12H), 7.40 (18H), 6.59 (1H), 6.00 (1H), 5.93 (1H) (each m; aromatic). $^{31}P\{^1H\}$-NMR (CD_2Cl_2, external standard 85% H_3PO_4): δ = 21.70 (d, J(PF) = 1.95 Hz, major isomer), 21.15 (d, J(PF) = 3.42 Hz, minor isomer) (10:1 ratio).

[10] **8**/**9**: ^{1}H-NMR (CD_2Cl_2): δ = 6.91 (2H), 6.46 (1H) (each m; aromatic), 2.5-1.0 (m, 48H, CH_2 and CH). $^{31}P\{^1H\}$-NMR (CH_2Cl_2): δ = 66.45 (apparent s). Satisfactory C,H-elemental analysis.

[11] Preparation and applications of potassium graphite and of other metals dispersed in graphite: D. Savoia, C. Trombini, A. Umani-Ronchi, *Pure Appl. Chem. 57* (1985) 1887. Naphthalenesodium or 1-methylnaphthalene sodium can also be used for this reduction but it is difficult to remove the aromatic hydrocarbon completely during work-up. Sodium amalgam (1%) does not work well in contrast to its use in the preparation of **12**.

[12] *Procedure* for **10**: A suspension of **8**/**9** (4.0 g, 70 mmol) and KC_8 (1.67 g, 8.1 mmol) in THF (100 mL) was stirred under argon for 30 min. Solids were removed by centrifugation and the solution was concentrated in vacuo to an oil. Trituration with hexane (10 mL) gave a yellow powder which was washed with hexane (3 × 10 mL) and dried in vacuo overnight. The product was spectroscopically but not analytically pure, and was used directly in the next step of the synthesis.

[13] **10**: IR (KBr): ν = 1592 cm^{-1} (s, C=C). ^{1}H-NMR (C_6D_6): δ = 7.87 (1H), 7.76 (1H), 7.18 (1H) (each m; aromatic), 1.95-1.70 (m, 48H, CH_2 and CH). $^{31}P\{^1H\}$-NMR (THF): δ = 79.60 (dd, J(PP′) = 21.97 Hz, J(PF) = 8.90 Hz), 79.00 (dd, J(PP′) = 21.97 Hz, J(PF) = 1.75 Hz). $^{13}C\{^1H\}$-NMR (CH_2Cl_2; aromatic region only): δ = 163.90 (dd, J/CF) = 147.08 Hz, J(CP) = 10.26 Hz; CF), 148.04, 137.92 (each m; dehydrobenzene C), 124.39, 114.33, 110.35 (all m; CH).

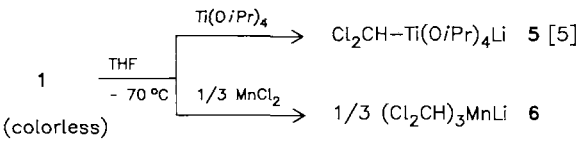
Higher Thermostability and Selectivity of Köbrich Reagents by Transmetalation**

By *Thomas Kauffmann,* Rolf Fobker,* and *Michael Wensing*

Can the stability of extremely thermolabile organolithium compounds be increased by complexation to transition metals without drastically decreasing the nucleophilicity? We have now checked this using the Köbrich reagents **1** (decomp. $-65\,^{\circ}C$)[2] and **2**–**4** (decomp. $-100\,^{\circ}C$ and below)[2,3] as examples and indeed have found, in some cases, considerable increases in stability. The more closely investigated transmetalation products **5**–**7** proved to be good dichloromethylating reagents exhibiting high chemoselectivity.[4]

Cl_2CHLi	Br_2CHLi	I_2CHLi	Cl_3CLi
1	**2**	**3**	**4**

Transmetalations: It was found that the decomposition temperature of the transmetalation products obtained from **1**–**4** according to or analogously to Scheme 1 can be determined optically: the solutions remain clear and intensely colored until decomposition sets in; at the limiting temperature of stability they become turbid and simultaneously



Scheme 1.

turn deep-brown to black in color. The reactions of the transmetalation products with aldehydes and ketones, which proceed in good yields only at temperatures ca. $10\,^{\circ}C$ below the so determined decomposition temperature, demonstrated that this change is a reliable stability criterium.

Table 1. Color in solution and decomposition temperature of the transmetalation products prepared in situ according to Scheme 1 (structures hypothetical).

	Color	Decomp. temp. [°C]		Color	Decomp. temp. [°C]
5 [5]	yellow-green	+10	$Cl_2CHTa(OEt)_5Li$	yellow-green	−30
$I_2CHTi(OiPr)_4Li$	yellow-green	−10	$Cl_2CHNb(OEt)_5Li$	red-brown	−30
$Cl_2CHTi(OnPr)_4Li$	yellow	−15	$Cl_2CHTi(OEt)_4Li$	green	−40

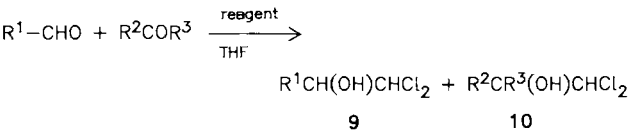
[**] Transition Metal-Activated Organic Compounds, Part 26. This work was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Fonds der Chemischen Industrie.—Part 25: [1].

As a rule, the transmetalations carried out in situ yielded more stable reagents (Table 1). On the other hand, the reactions of **1** with $Ti(OiPr)_3Cl$, and especially with CuCl, led to marked destabilization. The most noticeable increase in the decomposition temperature was achieved by complexation with $Ti(OiPr)_4$: For the reagents Hal_2CHLi the increase in the order Hal = Cl, Br, I was about 75, 80, and 90 K, respectively. The ate complexes are, in each case, more stable than the corresponding neutral complexes along the series Hal = Cl, Br, I.

Aldehyde vs. ketone selectivity: As shown in Table 2, in the 1:1:1 competition experiment (Scheme 2) **1** reacts



Scheme 2.

Table 2. Reactions according to Scheme 2 with a molar ratio of 1:1:1; after dropwise addition of the THF-solution of the carbonyl compound to the organometallic reagent at the given starting temperature the reaction mixture was warmed within ca. 12 h to room temperature [6].

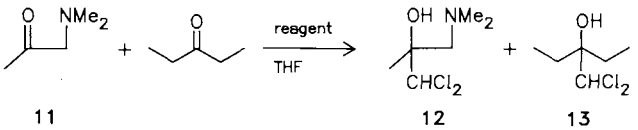
with the substrate pair benzaldehyde/acetophenone quite unselectively at $-90\,^{\circ}C$ to give the dichloromethylation products **9** and **10**. In contrast, the transmetalation products **5**–**7** investigated for the same substrate pair proved to be largely aldehyde-selective. High aldehyde-selectivity



Scheme 3.

Table 3. Reactions according to Scheme 3 with a molar ratio of 1:1:1; conditions as in the reactions according to Scheme 2 (Table 2) [6].

Reagent	Starting temp. [°C]	Yield [%] **12**	**13**
5	−30	71	trace
6	−40	66	trace
7	−90	71	trace
1	−80	33	34

was also achieved in competition reactions of **5**–**7** with the substrate pair heptanal/3-pentanone. In non-competition experiments acetophenone could be dichloromethylated in good yields with **5**–**7**; but only at 0 °C however in the case of **5** (enolate formation at −78 °C).

Grouping selectivity:[7] The reagents **5**–**7** dichloromethylate the α-dimethylaminoketone **11** completely grouping selectively in the presence of 3-pentanones (Scheme 3, Table 3), whereas the lithium compound reacts unselectively.

In contrast to **13** and the products of type **9** and **10** obtained according to Scheme 2, **12** has, to our knowledge, thus far never been described. Spectroscopic data for this oily, readily decomposable substance, which could not be obtained in analytically pure form, are listed in Table 4.

Table 4. Spectroscopic data of **12**.

^{1}H-NMR (300 MHz, $CDCl_3$, TMS): $\delta = 1.65$ (s, 3H; CCH_3), 2.34 (s, 6H; NCH_3), 2.38 (d, 1H; C*H*H), 2.75 (d, 1H; CH*H*), 5.70 (s, 1H; $CHCl_2$); OH signal not observed

^{13}C{^{1}H}-NMR (75 MHz, $CDCl_3$): $\delta = 21.3$ (CCH_3), 47.7 (NCH_3), 64.1 (CH_2), 75.0 (COH), 79.1 ($CHCl_2$)

[2] G. Köbrich, *Angew. Chem. 79* (1967) 15; *Angew. Chem. Int. Ed. Engl. 6* (1967) 41.
[3] According to *J. Villieras* et al. (J. Villieras, R. Tarhouni, B. Kirschleger, M. Rambaud, *Bull. Soc. Chim. Fr. 1985*, 825; *ibid. 1986*, 470) the addition of lithium salts to Köbrich carbenoids leads to a reasonable increase in thermal stability; consequently, better yields are achieved in additions to carbonyl compounds.
[4] These results are mainly taken from the Dissertation by *M. Wensing* (Universität Münster 1987).
[5] At −10 °C, the ^{1}H-NMR spectrum (300 MHz) of the hypothetical ate complex **5** dissolved in [D_8]THF shows a singlet at $\delta = 5.31$, which disappears at +10 °C and is therefore assigned to the proton of the Cl_2CH group. In the ^{13}C-NMR spectrum (75 MHz; THF; [D_6]benzene as internal standard) a singlet appears at $\delta = 91.2$ at −30 °C; this disappears on warming to +10 °C and is therefore likewise assigned to the Cl_2CH group. A band at 495 cm^{-1} in the IR spectrum (THF, −10 °C), which disappears at +10 °C, is assigned to a Ti–C vibration, since Ti–C vibrations have already been observed in the range 427–530 cm^{-1} for Ti-methyl complexes (G. L. Karapinka, J. J. Smith, W. L. Carrick, *J. Polym. Sci. 50* (1961) 143; G. W. A. Fowles, D. A. Rice, J. D. Wilkins, *J. Chem. Soc. A 1971*, 1920).
[6] Up to 85–95% of the unchanged carbonyl compounds was recovered.
[7] "Grouping" = combination of functional groups; see T. Kauffmann, T. Möller, H. Rennefeld, S. Welke, R. Wieschollek, *Angew. Chem. 97* (1985) 351; *Angew. Chem. Int. Ed. Engl. 24* (1985) 348.

In-Situ Blocking of an Aldehyde Function by Formation of (α-Triphenylphosphoniumalkoxy)-titanium or -niobium Complexes**

By *Thomas Kauffmann,* Thomas Abel,* and *Martin Schreer*

Investigations of the influence of electron donor compounds on the nucleophilicity of [$MeTiCl_3$] **1** toward aldehydes and ketones revealed that the nucleophilicity decreases as shown in Scheme 1,[2,3] i.e. the circumstances are the reverse to those observed in the case of lithium com-

[$MeTiCl_3(PPh_3)_2$] **2c**

Scheme 1. [4].

pounds. In these investigations it was found[3] that, in reactions with aldehyde/ketone pairs, the triphenylphosphane complexes **2b** and **2c** preferably methylate the ketone, that is in complete contrast to the tmeda-complex **2a**, which methylates aldehydes in CH_2Cl_2 and is almost inert toward ketones (Table 1).

Table 1. Reactions of phosphane complexes of the compound **1** as pure substances with substrate pairs in $CHCl_2$ at −25 °C (6 h).

Substrates A/B	Ligand	Molar ratio Ligand : **1** : A : B	Methylation product [%] of A	of B	Recovery [%] A	B

	dppe	1 : 1 : 1 : 1	17	61	81	39

[a] Reaction at 0 °C instead of at −25 °C (6 h).

An analogous ketone selectivity was found, albeit somewhat less pronounced, in the case of the complex formed from *P,P′*-ethylenebis(diphenylphosphane) (dppe) and **1** (Table 1).

The ketone selectivity of the complex **2b** can be attributed (and the same holds true for **2c**) to the fact that a

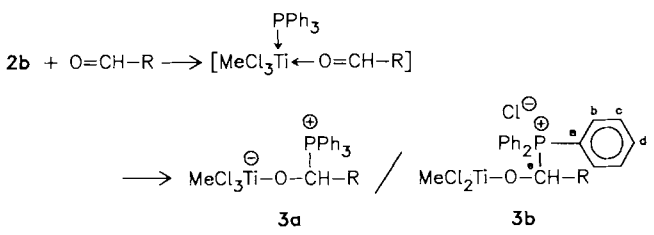
[**] Transition Metal-Activated Organic Compounds, Part 27. This work was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, and the Fonds der Chemischen Industrie.—Part 26: [1].



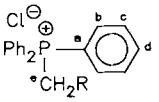
Scheme 2. R = *n*-hexyl.

phosphoniumalkoxy complex of type **3a** or **3b** is formed in reactions with aldehydes according to Scheme 2, whereby the aldehyde function is blocked. In the case of ketones, on the other hand, it is not the phosphane ligand but the methyl group that is transferred. Since 2-hexanone is still methylated to the extent of 28% in the reaction of **2b** with heptanal/2-hexanone in the molar ratio 1:1:1 (instead of 2:1:1) it can be assumed that not only **2b** but also the phosphoniumalkoxy complexes **3a** or **3b** formed therefrom are effective methylating agents.

The assumption of phosphoniumalkoxy compounds such as **3a** or **3b** as intermediates is supported by the following findings:

a) In the IR spectrum of the complex prepared from **2b** and heptanal in CH_2Cl_2 the carbonyl band expected to appear at ca. 1720 cm^{-1} is absent, but several strong bands are observed at ca. 1120 cm^{-1} that can be assigned to C–O vibrations, since transition metal alkoxides strongly absorb in the 1000–1200 cm^{-1} region.

b) The ^{31}P-NMR signal of the complex formed from **2b** and heptanal in $CDCl_3$ is shifted markedly downfield ($\delta = 20.0$) compared to that of PPh_3 ($\delta = -6.0$) and **2b** ($\delta = 10.0$), clearly indicating a triphenylphosphonium group (for comparison: **4b**: $\delta = 17.6$).



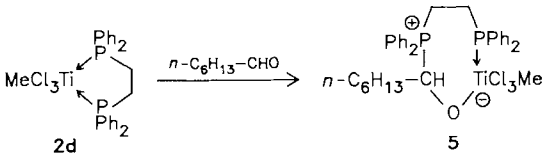
4a, R = Alkyl
b, R = OMe
c, R = Cl

c) In the ^{13}C-NMR spectrum of the complex formed from **2b** and heptanal in $CDCl_3$ the δ values for the phenyl C-atoms are very similar to those for the phosphonium salt **4**.[5] The same holds true for the coupling constants $^1J_{^{31}P^{13}C}$ (Table 2).

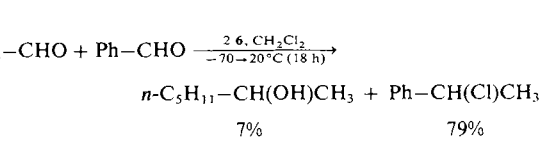
Table 2. $\delta(^{13}C)$ and coupling constants $^1J(^{31}P,^{13}C)$ [Hz] (in brackets) of the complex **3** formed from **2b** and heptanal in $CDCl_3$ (20 °C) and of the compounds **4** [5].

Compound	Indexing according to **3b** and **4**				
	[a]C	[b]C	[c]C	[d]C	[e]C
Complex **3a/3b**	116.9 (80.0)	134.0 (9.0)	130.0 (12.0)	135.0 —	85 (56)
4a	117–119 (80–89)	134 (9–11)	131 (12–13)	135 (3)	11–35
4b	117.0 (85.9)	136.6 (10.0)	131.1 (12.8)	135.9 (3.1)	66.2 (69.4)
4c	116.5 (88.3)	134.6 (10.2)	130.9 (13.0)	136.0 (3.0)	33.8 (56.8)

Table 1 shows that on using **1** + dppe (the known complex **2d**[6] may be formed thereby) aldehyde groups are less effectively blocked. This is understandable since **2d** contains a five-membered ring, whereas the complex **5** analogous to **3a** contains a seven-membered ring.

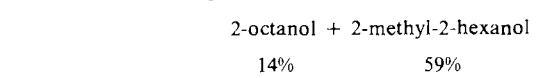


Complexes analogous to **3a/3b** have also been detected spectroscopically in reactions of $[MeNbCl_4(PPh_3)]$ **6**, $[TiCl_4(PPh_3)]$ **7**, and $[NbCl_5(PPh_3)]$ with aldehydes. The niobium complex **6** blocks the aldehyde group of heptanal, but (in contrast to **2b**) not that of benzaldehyde. This enabled the selective methylation of benzaldehyde according to Scheme 3. The complexes analogous to **6** with NPh_3 or $AsPh_3$ instead of PPh_3 did not block the aldehyde group of heptanal.



Scheme 3. [7].

Methylation according to Scheme 4 could be achieved with the complex **7**. The scope of application of this particularly convenient ketoselective alkylation method is presently under investigation.



Scheme 4 [3]. Reaction temperature 0 °C (6 h).

Reetz et al.[8] reported comparable possibilities of the reversal of selectivity by in-situ blocking of aldehyde groups: The reagent $[(allyl)Ti(NMe_2)_4MgCl]$ can be used for the selective allylation of a keto function in presence of an aldehyde function (one step method), whereas in the corresponding alkylations the aldehyde function must be chemoselectively blocked by addition of $[Ti(NEt_2)_4]$ and the keto function must be alkylated with moderately nucleophilic reagents (two-step method). The reversal of selectivity by use of phosphane complexes described here could be preparatively attractive because of the very easy access of the reagents.

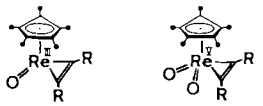
Alkyne Coordination to Organorhenium Oxides with Rhenium in High Oxidation States**

By *Josef K. Felixberger, Josef G. Kuchler, Eberhardt Herdtweck, Rocco A. Paciello,* and *Wolfgang A. Herrmann**

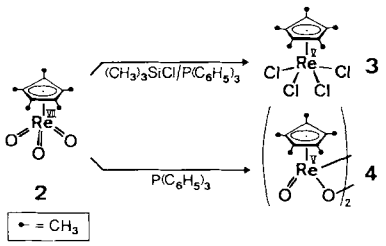
Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

It was hitherto uncertain whether very electron-deficient transition metals in organometal oxides are capable of complexing alkynes, especially as more recent MO theoretical results rather suggested the contrary.[1] Consistent with these theoretical results, it has proved impossible to oxidize the isolable Re^{III} complexes **1a** (R = alkyl, aryl) to the still unknown oxygen-rich Re^{V} derivatives **1b**.[2] And in all the alkynerhenium complexes known to date, the maximum oxidation state exhibited by the metal atom is +3.[3] However, since alkynes can be oxidatively coupled with organorhenium oxides to give furan derivatives,[4] we have directed our attention to the synthesis of suitable model compounds, and now report on a new, simple class of compounds of pentavalent rhenium.



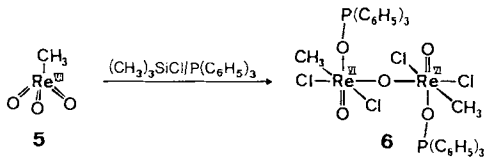
1a **1b**

Triphenylphosphane has proven to be a mild, selective deoxidizing reagent for trioxo(η^5-pentamethylcyclopentadienyl)rhenium(VII) **2** in the directed synthesis of functionalized Re^{V} derivatives.[5] Thus, the tetrachloro complex **3** is accessible according to Scheme 1 with triphenylphosphane/trimethylchlorosilane, whereas the dinuclear oxide **4** is formed on reaction of **2** with the phosphane alone.[5]



Scheme 1.

It now emerges that none of the mentioned reactions can be extended to the methylrhenium(VII) oxide **5**.[6] In the presence of Lewis base ligands, this compound, in contrast to the π-complex **2**, is prone to an increase in coordination number, because the methyl group is much less sterically demanding than the π-ligand with its additional nine C atoms. Thus, reaction of triphenylphosphane/trimethylchlorosilane with **5** according to Scheme 2 leads to formation of only the dinuclear rhenium(VI) complex **6** in 70% yield, which according to a single-crystal X-ray structure analysis (Fig. 1) has a centrosymmetric molecular structure.[7] As a result, the two slightly distorted octahedra are joined linearly via an oxygen bridge (O2). Electronic d^1-d^1 "superexchange" in the Re,O2,Re′ structural moiety with its shortened metal-oxygen bonds (184.7(< 1) pm) explains the diamagnetism of this Re_2^{VI} compound.



Scheme 2.

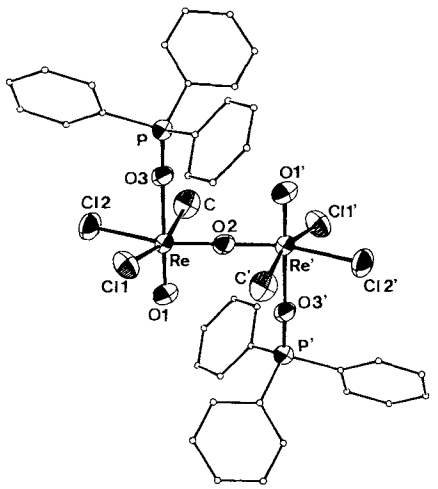


Fig. 1. Molecular structure (ORTEP) of **6**, which crystallizes from methylene chloride/*n*-pentane (1 : 1) at −25°C in the monoclinic space group $P2_1/c$. Selected bond lengths [pm] and angles [°]: Re-Cl1 242.9(2), Re-Cl2 234.2(2), Re-C 213.0(6), Re-O1 165.5(4), Re-O2 184.7(< 1), Re-O3 211.5(4), P-O3 152.4(4); ReO2Re′ 180.0(0), O2ReCl1 95.03(5), O2ReCl2 168.74(5), CReCl1 161.7(2), ReO3P 171.7(3) [12].

Unlike **2**, the complex **5** forms adducts with simple nitrogen bases; thus, on reaction with 1-azabicyclo[2.2.2]octane (quinuclidine) it forms a complex of the composition $CH_3ReO_3 \cdot NC_7H_{13}$.[8]

The complexation of the reducing agent triphenylphosphane, which is disadvantageous for the further use of complexes of type **6**, also hindered attempts to deoxygenate **5** in the presence of other ligands. This problem could be overcome, however, by the use of polymer-bound triphenylphosphane Ⓟ; the polymeric phosphane oxide formed during the reduction is insoluble and is removed from the reaction system, thus allowing for the synthesis of the new compounds **7** according to Scheme 3. Independent of the substituents of the alkynes the reaction is complete at room temperature within hours. The products can be recovered in pure form from the filtered reaction solutions by simple crystallization.

An X-ray structure analysis was carried out on the tolan complex **7h** (Fig. 2).[7] This revealed that the compounds **7** are derived from the educt **5** by reductive substitution of

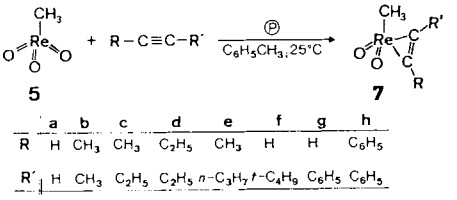

Scheme 3.

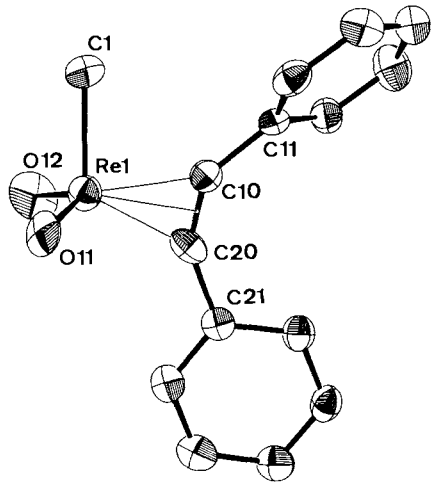

Fig. 2. Molecular structure (ORTEP) of the tolan complex **7h** in the crystal at −80 °C. The compound crystallizes from *n*-hexane at −25 °C in the monoclinic space group $P2_1/c$. The unit cell contains two crystallographically independent molecules A and B which differ only slightly in structure. Selected bond lengths [pm] and angles [°] for molecule A: Re-C1 209.2(7), Re-O11 171.0(4), Re-O12 174.0(4), Re-C10 205.7(7), Re-C20 201.2(7), C10-C20 128.0(9), C10-C11 146.8(9), C20-C21 148.8(9); C1ReO11 102.0(3), C1ReO12 102.2(3), O11ReO12 119.5(2), C11C10C20 141.8(7), C10C20C21 146.9(7) [12].

an oxo-group by the corresponding alkyne ligand without an alkyne/oxygen coupling taking place. The acetylene moiety, the rhenium atom, and the carbon atom of the methyl group lie in a plane that bisects the angle between the two oxo groups. The distances between the metal atom and the methyl group determined for molecule A (209.2(7) pm) and molecule B (203.4(6) pm) correspond to that of a single bond, whereas the Re–O bonds (171.0(4) and 174.0(4) pm for A; 166.8(5) and 172.3(5) pm for B) are typical double bonds. The C–C bond length of the alkyne (128.0(9) pm) for A, 130.1(9) pm for B) corresponds to that of a double bond; the distance between the metal and the center of the acetylene-ligand bond is 193.1 pm in A and 193.6 pm in B.

The observation of two independent molecules in the solid state can be attributed exclusively to packing effects. Molecule A and molecule B differ significantly only in the torsional angles of the acetylene moiety.

According to the ^{13}C-NMR data (Table 1), the alkynes in the d^2-Re^V complexes **7** function as 2e ligands.[9] A rapid rotation of the alkyne ligands around the bonding axis to the metal is not detectable by NMR spectroscopy, not even in the sterically undemanding parent compound **7a**. According to the ^{1}H- and ^{13}C-NMR spectra, **7a** has a rigid framework: the methyl group attached to rhenium couples with only *one* proton of the C_2H_2 ligand ($^4J_{H,H} = 1.8$ Hz), which in turn exhibits a ^3J-coupling of 0.25 Hz with the other CH unit. NOE experiments show that the methyl group attached to the metal couples with that half of the acetylene turned away from it (cf. Fig. 2). A similar NOE difference is observed for the alkyne methyl groups in **7b**. Two non-interconvertable isomers are formed in each of the cases **7c** (2-pentyne) and **7e** (2-hexyne). They can be distinguished by means of their NMR data (Table 1), and their existence is due to the opposite orientation of the alkyne ligands relative to the pyramidal, C_{2v}-symmetric CH_3ReO_2 fragment (see Scheme 3).

With further polymer-bound triphenylphosphane in boiling toluene (2 d), the Re^V complex **7b** can be reduced to the dinuclear Re^{IV} derivative **8**.[10] Alkyne complexes of tetravalent rhenium were hitherto unknown.

These results show that the methylrhenium(VII) compound **5** can be reduced stepwise by polymer-bound triphenylphosphane with retention of the methylrhenium partial structure to derivatives of hexa-, penta-, and tetravalent rhenium. That alkyne complexes of type **7** are stable substances, whereas the analogous C_5Me_5-complexes **1b** do not exist, could be attributed to the missing π-donor effect of the methyl as compared to the pentamethylcyclopentadienyl ligand or to a steric effect.

Experimental

7a: A solution of 500 mg (2.01 mmol) of **5** in 20 mL of toluene saturated with acetylene was treated with 700 mg (2.14 mmol) of polymer-bound $P(C_6H_5)_3$ [11] and the mixture stirred for 16 h in a C_2H_2 atmosphere. The mixture was then filtered over celite and the filtrate evaporated to dryness under vacuum. Recrystallization of the residue from *n*-hexane at -30°C furnished 130 mg (25%) of yellow crystals. M.p. 79°C.

7b–h: The procedure was the same as for the synthesis of **7a**, except that a twofold excess of the corresponding alkyne (referred to **5**) was used. Yields 60–95%. All compounds gave correct elemental analyses.

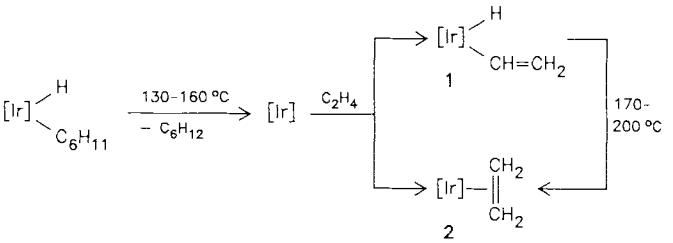
Synthesis of Octahedral Hydrido(vinyl)iridium(III) Complexes by C–H Activation: An Example of a Thermodynamically Favored Rearrangement [M(CHR=CHX)]→[M(H)(CR=CHX)]**

By *Helmut Werner,* Thomas Dirnberger,* and *Michael Schulz*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

During the course of intensive investigations into C–H activation,[1] *Stoutland* and *Bergman* reported in a much referenced paper in 1985 that not only aliphatic and aromatic hydrocarbons but also olefins such as ethylene react with a coordinatively unsaturated metal center by oxidative addition.[2] They concluded on the basis of the results summarized in Scheme 1, which have later been supported by MO calculations,[3] that in the thermal reaction of $[C_5Me_5(PMe_3)IrH(C_6H_{11})]$ with C_2H_4 the ethylene metal complex **2** is the thermodynamically favored product and thus is *not* an intermediate in the formation of **1**. Shortly thereafter, *Perutz* et al. demonstrated spectroscopically that photolysis of $[C_5H_5Ir(C_2H_4)_2]$ in an argon matrix leads to formation of the hydrido(vinyl)iridium compound $[C_5H_5(C_2H_4)IrH(C_2H_3)]$, which isomerizes at 0°C to regenerate the starting material $[C_5H_5Ir(C_2H_4)_2]$.[4]



Scheme 1. [Ir] = $[C_5Me_5(PMe_3)Ir]$.

In the present work, we report that the order of thermodynamic stability found by *Bergman* et al. and *Perutz* et al., [Ir](H)(CH=CHR) < [Ir](η^2-CH_2=CHR), is reversed if the coordination geometry at the iridium center is changed and if the hydrido(vinyl)metal moiety is stabilized by an additional linkage to the metal atom.

[**] This work has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and by Degussa AG.

Complex **4**, which is formed *in situ* from **3** and $PiPr_3$, reacts with H_2 and benzene to give the five-coordinated iridium(III) compounds **5** and **6**.[5] The osmium complex $[OsHCl(CO)(PiPr_3)_2]$, which is related in structure to **5** and **6**, reacts with olefins such as **7a** and **7b** (see Scheme 2) at room temperature to afford the corresponding adducts $[OsHCl(CO)(CH_2{=}CHX)(PiPr_3)_2]$ (X = CO_2Me, COMe);[6] by contrast, under the same conditions the iridium compounds **5** and **6** are inert toward the olefins **7a–c**. At higher temperature (C_6H_6, 80°C), a slow reaction occurs which leads to the formation of the hydrido(vinyl)metal complexes **9a–c** in excellent yield. The octahedral structure proposed for these compounds with *trans* phosphane ligands, metal-bound hydride and coordination of the C=O group is strongly supported by the NMR and IR data.[7] Participation of a carbene-type resonance form $[\overline{Ir}{=}C(R^1){-}C(R^2){=}C(R^3){-}\overline{O}$ ([Ir] = $IrHClL_2$) is ruled out primarily on the basis of the chemical shift of the α-C atom of the vinyl ligand in the ^{13}C-NMR spectrum of **9b**.[8]

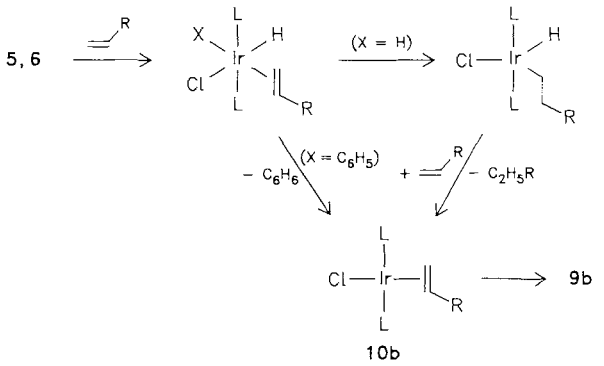
	R^1	R^2	R^3
a	H	H	OMe
b	H	H	Me
c	H	Me	OMe
d	CO_2Me	H	OMe

7a, $CH_2{=}CHCO_2Me$
7b, $CH_2{=}CHCOMe$
7c, $CH_2{=}C(CH_3)CO_2Me$
7d, (E)-$CH(CO_2Me){=}CH(CO_2Me)$

Scheme 2. L = $PiPr_3$.

In contrast to **7a–c**, dimethyl acetylenedicarboxylate reacts with **5** even at room temperature. The coordinatively unsaturated compound **8** is almost quantitatively formed by insertion of the alkyne into one of the Ir–H bonds. It is remarkably stable in the solid state and in solution, but rearranges on photolysis in benzene to give the hydrido(vinyl) complex **9d**. We assume that in presence of UV light a π-π* transition takes place which leads to a weakening of the C=C double bond of the vinyl ligand and, after rotation through 180°, to ring closure.

In the reactions of **5** and **6** with the olefin **7b**, the only other products besides **9b** which can be detected by GC/MS are 2-butanone and benzene. This finding supports the reaction mechanism shown in Scheme 3, which includes the olefin iridium complex **10b**, an isomer of **9b**, as an important intermediate. An attempt to prepare **10b** from **4** and **7b** in benzene at room temperature, however, led quantitatively to the formation of **9b**. By contrast, the olefins **7a** and **7d** react with **4** (C_6H_6, 25°C) to give the olefin–iridium compounds **10a** and **10d** (Scheme 2). The spectroscopic data of **10d**[7] provide no indication of whether the substituents at the C=C double bond are *cis* or *trans* oriented.



Scheme 3. L = $PiPr_3$; R = COMe.

On irradiation in benzene, the complexes **10a** and **10d** rearrange quantitatively to give the isomers **9a** and **9d**. The solvent is not involved in this process, as in C_6D_6 the deuterium-free products are also formed. The rearrangement can be easily followed visually as the olefin compounds are red whereas the hydrido(vinyl) compounds are colorless (**9a**) or yellow (**9d**), respectively.

Complex **9a** is also obtained by heating a solution of **4** and **7a** in refluxing benzene. Under similar conditions, treatment of **4** with **7c** gives the corresponding hydrido(vinyl) compound **9c**. We assume that, also in these reactions, an olefin complex (**10a** or **10c**) is most probably formed as an intermediate, which, however, reacts very rapidly at 80°C by intramolecular oxidative addition to afford **9a,c**.

A regeneration of **10a,d** from **9a,d** does not occur, either on heating or on photolysis. The stabilization of the hydrido(vinyl)iridium moiety caused by the chelate formation also manifests itself in the compounds **9a–d** being inert towards CO. Under a CO atmosphere, no opening of the chelate ring by breaking of the Ir–O bond takes place. On the contrary, the hydrido(vinyl) complex **8**, which is an isomer of **9d**, smoothly reacts with CO to give **11**, consistent with the behavior of other five-coordinated hydridoiridium(III) compounds.[5b,9]

The present results do not, of course, answer the question as to whether substituted olefins $CH_2{=}CHX$ or $CH_2{=}C(R)X$ (X = COMe, CO_2Me) *in general* react with coordinatively unsaturated transition-metal compounds to form hydrido(vinyl)metal complexes. It has already been shown in recent investigations by *Yamamoto* et al.[10] that the reaction of $[H_2Ru(PPh_3)_4]$ with methacrylic acid esters $CH_2{=}C(CH_3)CO_2R$ (R = Me, Et, *i*Pr, *n*Bu) leads to the formation of metallacyclic compounds of the type $[H(PPh_3)_3Ru{-}\overline{CH{=}C(CH_3){-}C(OMe){=}O}]$ by elimination of PPh_3 and H_2. Therefore, it is *not* new that a hydrido(vinyl) compound is formed from a reactive intermediate such as **4** and an olefin but it is now *evident* that this process occurs via an olefin-metal complex as an intermediate. The high energy barrier which had previously been observed for most of the reactions involving a C–H activation

of a coordinated olefin[2,3] is obviously reduced if the C=C double bond bears an electron-withdrawing substituent and if a chelate linkage of the generated vinyl group is possible. Various examples illustrating the highly facile formation and thermodynamic stability of five-membered rings of the general type $\overline{M-C(R)=C(R')-C(R'')=O}$ are already known.[11] The isolation of the complexes **10a,d** and their rearrangement to give **9a,d** supports the assumption that the C-H activation of benzene[5b] and other arenes[9b] with **4**, functioning as an electron-rich ligand-metal fragment, takes place via adduct formation, i.e., via a primary $[Ir(\eta^2\text{-}C_6H_{6-n}R_n)]$ intermediate.

Experimental

8: A solution of **5** (100 mg, 0.18 mmol) in benzene (7 mL) was treated with $C_2(CO_2Me)_2$ (26 mg, 0.18 mmol) with stirring at room temperature. Stirring was continued for 5 min, and the solution then concentrated to ca. 2 mL in vacuo, and chromatographed on Al_2O_3 (neutral, activity grade V) with hexane/benzene (4:1). After removal of the solvent the residue was washed with cold pentane to give an orange-red, moderately air-stable crystalline powder; m.p. 118°C (decomp.); yield 90%; correct elemental analysis.

9a-c: a) A suspension of **3** (120 mg, 0.13 mmol) in benzene (10 mL) was treated successively with $PiPr_3$ (86 mg, 0.54 mmol) and **7a-c** (0.26 mmol). The suspension was stirred 1) for 3 h under reflux (**7a**), 2) for 20 min at 25°C (**7b**), and 3) for 6 h under reflux (**7c**). After removal of the solvent in vacuo the oily residue was dissolved in hexane/benzene (2:1), and the solution was chromatographed on Al_2O_3 (neutral, activity grade V). Further work-up as for **8**; yield 80-90%.—b) A solution of **5** or **6** (0.18 mmol) in benzene (5 mL) was treated with **7a-c** (0.40 mmol) and heated under reflux for 12 h (**7a, b**) or 4 days (**7c**), respectively. Work-up as for **8**; yield 75-85%. White (**9a, c**) or light yellow (**9b**), moderately air-stable crystals; m.p. (decomp.) 167°C (**9a, b**), 192°C (**9c**); correct elemental analyses.

9d: A solution of **8** (80 mg, 0.12 mmol) in benzene (5 mL) was irradiated for 12 h (Hanovia 450 W). Work-up as for **9a-c**; yield 80%; yellow air-stable crystals, m.p. 175°C (decomp.); correct elemental analysis.

10a,d: A suspension of **3** (110 mg, 0.12 mmol) in benzene (10 mL) was treated successively with $PiPr_3$ (79 mg, 0.49 mmol) and **7a,d** (0.24 mmol) and stirred for 10 min at room temperature. After removal of the solvent the residue was recrystallized from pentane (25°C→−78°C); yield 70-80%. Red, moderately air-stable crystals; m.p. (decomp.) 110°C (**10a**), 121°C (**10d**); correct elemental analyses.—On irradiation in benzene (**10a**: 3 h; **10d**: 12 h) a rearrangement to **9a,d** occurs; yield 80%.

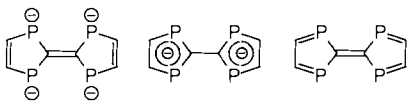
Tetraphosphafulvalenes

By *Nicole Maigrot, Louis Ricard, Claude Charrier,* and *François Mathey**

The search for new synthetic metals and superconductors is currently a very active field of research.[1] The polymeric backbones of most of these superconducting materials are based upon the tetrathiafulvalene (TTF)[2] or the tetraselenafulvalene structure.[3] Recently, tetratellurafulvalene was prepared,[4] and now extends the range of available building blocks for the construction of such materials. A further extension can be envisaged if phosphorus is used as a substitute for sulfur. Using the tetraphosphafulvalene moiety, it is indeed possible to build three structures which are isoelectronic to TTF and its cations (**A-C**). Of course, the redox and coordinating properties of these species could be different from those of their TTF counterparts.



As starting compound for the synthesis of the previously unknown tetraphosphafulvalene moiety we chose the 1,2-dihydro-1,2-diphosphete system **1**, which is now available with a wide range of substituents.[5] The cleavage of the P-P bond of this ring system by lithium in THF has already been described.[6] The dianions **2** thus obtained react with tetrachloroethylene to give the desired tetraphosphafulvalenes **3** (≙ type **A**) in modest but acceptable yields [Eq. (a)].

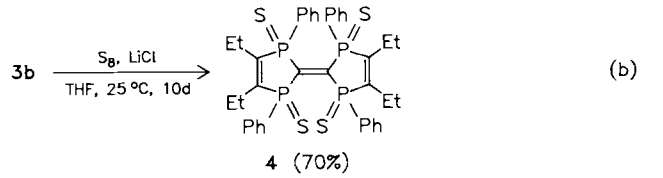
Table 1 shows the spectroscopic data of **3a-c**. In order to characterize this new structure more completely, we also carried out an X-ray crystal structure analysis of the tetra-



sulfide **4** (Fig. 1),[7] which is obtained as depicted in equation (b). The carbon–carbon double bonds are completely localized. The two five-membered rings are almost perfectly planar but are slightly tilted (interplanar angle 4.22(7)°). The torsion of the central C=C bond is, no doubt, due to steric congestion. The "all-*trans*" disposition of the sulfur atoms is also noteworthy.

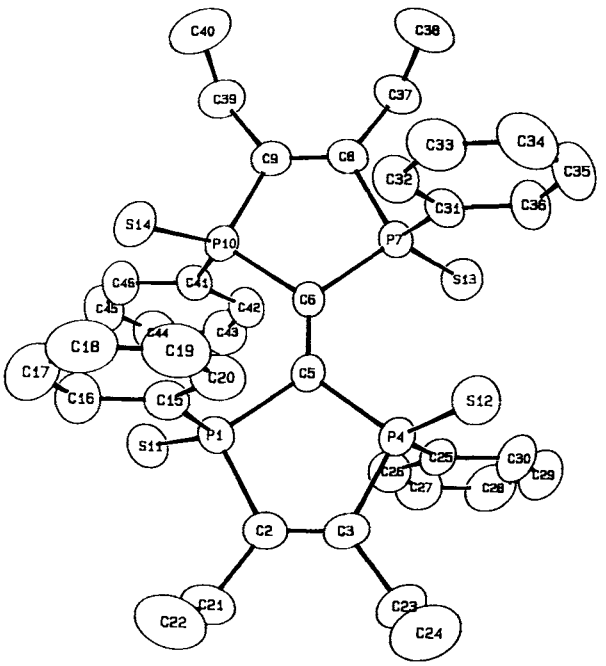


Fig. 1. Structure of 4 in the crystal [7]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Experimental

All reactions were carried out under argon in Schlenk tubes.

3a-c: A mixture of **1** (8 mmol) and lithium (17 mmol) in THF was stirred at room temperature for 3 h. The lithium was completely dissolved. The mixture was heated to 50 °C and treated dropwise with 0.41 mL (4 mmol) of C_2Cl_4. The reaction is almost instantaneous. After evaporation of the THF, the residue was chromatographed on silica gel with a degassed hexane/toluene mixture (80/20).

4: A mixture of **3b** (0.5 g, 0.8 mmol), S_8 (0.15 g), and LiCl (0.1 g) in 15 mL of THF was stirred for 10 days at 25 °C. After evaporation of the solvent, the residue was chromatographed on silica gel with toluene. Yield 0.4 g (70%). The crystallization can be carried out in dichloromethane.

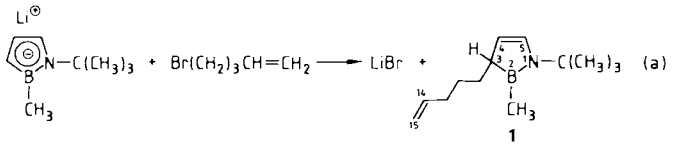
[7] Suitable single crystals of **4** were grown by slow evaporation of CH_2Cl_2 solutions at room temperature. Space group $P\bar{1}$ with $a = 9.635(2)$, $b = 11.391(2)$, $c = 20.917(3)$ Å, $\alpha = 79.58(1)$, $\beta = 87.61(1)$, $\gamma = 65.48°$, $V = 2052.78(85)$ Å^3, $Z = 2$, $\rho_{calc} = 1.372$ g/cm^3, $\mu = 5.4$ cm^{-1}, $F_{000} = 884$. Data were collected at room temperature (18 ± 1 °C) using graphite monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) and an Enraf-Nonius CAD4 diffractometer. The crystal structure was solved by direct methods using the Enraf-Nonius SDP program package. An ill-defined CH_2Cl_2 molecule co-crystallizes with the product. Hydrogen atoms were refined with fixed isotropic temperature factors equal to 1.3 times that of the attached carbon atom. 5641 unique reflections, $R = 0.050$, $R_w = 0.075$, GOF = 1.52. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-53 125, the names of the authors, and the journal citation.

Reversible Coupling and Opening of a Boron–Carbon Bond

By *Günter Schmid,* Wolfgang Meyer-Zaika, Roland Boese,* and *Norbert Augart*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Lithium salts of 2,5-dihydro-1*H*-1,2-azaboroles[1] serve in a variety of ways as starting compounds for the synthesis of transition metal complexes and main group metal complexes.[2–4] As a rule, groups such as $E(CH_3)_3$ (E = Si, Ge, Sn, Pb) are σ-bonded to the C3 atom of the anion, thus leading to formation of 2,3-dihydroazaboroles.[5] Reaction (a), in which the 1-*tert*-butyl-2,3-dihydro-2-methyl-3-(4-pentenyl)-1*H*-1,2-azaborole **1** is formed as a colorless liquid ($b.p._{20\,torr}$ = 126–127 °C; 65% yield), proceeds in the same way.[6]



(a)

1

1 can easily be characterized ^1H-, ^{11}B- and ^{13}C-NMR spectroscopically.[6] It is readily isolable by distillation, but, surprisingly, slowly rearranges on cooling below about 80 °C to give the tricyclic crystalline compound **3**,[8a] in which the original olefinic carbon atoms C14 and C15 of the pentenyl group are coupled to the ring atoms C4 and B2, respectively. The process is reversible; i.e. **3** rearranges to the pentenyl compound **1** again at temperatures above 80 °C, and rapidly so upon distillation. **1** vitrifies upon rapid cooling, but does not crystallize.

Scheme 1 outlines our interpretation of the rearrangement process; **1a**–**1c** are merely model representations of the possible changes of conformation of the pentenyl residue on going from **1** to **3**. We visualize the rearrangement as arising from a donor–acceptor interaction between the π-electron pair of the pentenyl group and the electrophilic boron atom, which finally leads to the formation of the B2–C15 σ-bond. The coupling of the B2–C15 and C4–C14 bonds is associated with rehybridizations of the B2 and C4 atoms from sp^2 to sp^3. This results in the five-membered heterocycle no longer being planar. The B2–C15 interaction renders the C14 atom strongly electrophilic, so that this can now interact with the π-electron pair of the C4=C5 double bond of the heterocycle. These unusual bonding situations are verified in **2** (see below). Formation of the C5=N1 double bond takes place concomitantly with that of the B2–C15 and C4–C14 bonds.

Although **2** is not the most thermodynamically stable product, it is a crystallographically independent structure. During the transition from **2** to **3** the disorders in the crystal disappear, since in **3** there are "normal" bonds between C4 and C14 and B2 and C15, and puckering of the heterocycle is terminated.

Dihydroazaboroles themselves neither tend to undergo dimerization nor to react, e.g., with alkenes. The processes depicted in Scheme 1 are not observed even with analogues of **1** which bear a butenyl or hexenyl group on the C3 atom. The unusual behavior of **1** can therefore be attributed to the fact that the reaction **1** ⇄ **3** with the pentenyl group as substituent group can proceed essentially free of strain.

The transition from **1** to **3** and vice versa can be readily monitored by ^{11}B-NMR spectroscopy. For example, when a solution of **3** in toluene is heated to 80 °C the signal of **3** at $\delta = 4.6$ decreases with time and that of **1** at $\delta = 50.2$ increases. After 1 h the intensity ratio of the signals is about 1 : 1 and after 3 h the conversion is quantitative. **2** is only crystallographically detectable, but not in solution. The in-

Scheme 1. Possible course of the reversible reaction 1⇄3. The inset shows, a "stroboscopic recording" of the postulated reaction.

teraction of a ring boron atom with an olefinic C–C bond was first presumed in 1964 on the basis of IR data.[7]

Crystals of **3**[8b,c] (triclinic, $P\bar{1}$) were obtained on allowing the liquid compound to stand for several days in a refrigerator. Data collections at 303 K for two crystals, one of which had been annealed just below the melting point (308 K) for two weeks, furnished comparable structural data, as did also further measurements at 260 K, 180 K and 100 K. The vibration amplitudes of the anisotropically refined atomic parameters increase almost linearly from 100 to 303 K. Thus, in the case of **3**, disorders can be ruled out even just below the melting point. There were also no indications of a phase transition in the crystal in the polymorphic structure of **2**[9] (monoclinic, $P2_1/n$), cylindrical crystals of which were drawn from the melt between 301 K and 317 K in a Lindemann capillary (diameter 0.3 mm) using the Bridgeman technique.[10] Also several crystals of **2** prepared in this way gave comparable structural data. Data collections and refinements at 298 K, 288 K and 248 K gave, especially for the atoms C11, C12, C13, C4 and C5, anisotropic vibration amplitudes with highly disordered structures at the measurement temperatures. The direction of the disorders follows from the illustration of **2** in Scheme 1. As to whether dynamic or static disorders are involved cannot be decided, but the electronic patterns in **2** are consistent with dynamic effects. The disorders were not resolvable, as also indicated, inter alia, by electron density maps. Consequently the atomic positions could not be determined accurately, and the R values and standard deviations are correspondingly high. Determination of the structure of **2** at $T<248$ K was not possible because of broadening of the reflections.

Enzymes and Curvature

By *Zoltan Blum,* Sven Lidin,* and *Sten Andersson*

Numerous proteins and enzyme structures consist of two building units—the α-helix and the β-sheet. Many of these structures seem to belong to two spatial arrangements of the β-sheets—the barrel and the twisted sheet arrangement. Recently *Louie* and *Somorjai*[1] have shown that the barrel, i.e., its inside, is catenoid-like and the twisted sheet is helicoid-like, and that such surfaces are adjoint, which means one can be transformed into the other isometrically (Bonnet transformation, Fig. 1). Figure 2 schematically shows a

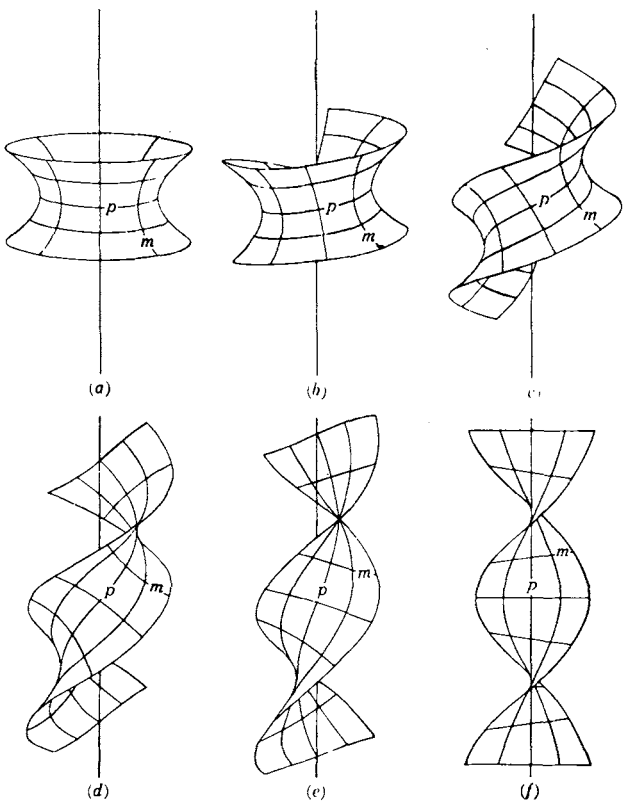

Fig. 1. The Bonnet transformation.

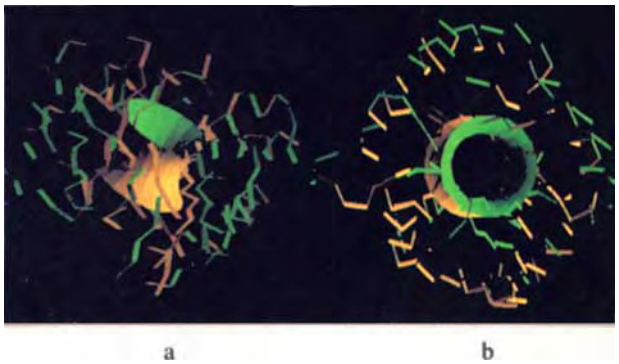

Fig. 2. α-Carbon representation of triose phosphate isomerase fitted to a catenoid; a) side view; b) view down the central "hole."

barrel protein with the catenoid fitted to the structure. The complete topology of the molecule can be approximated by a torus which has negative Gaussian curvature on the inside and positive on the outside. *Louie* and *Somorjai* also showed that the Bonnet transformation can be used to explain leading features of the much debated protein folding problem. They further propose that the Stieltjes integral, $\int F\mathrm{d}A$, describes the enzyme-substrate interaction. A is given by the equation $A = I + \mathrm{i}II$, where I and II are the first and second fundamental forms of equations of surfaces describing the enzyme structure, and F is a function describing the shape of the substrate. The Stieltjes integral is complex; therefore, projections onto the real plane are needed and they claim this is a way to understand catalysis, recognition, etc.

We find the propositions of *Louie* and *Somorjai* of extreme interest. Our approach, however, is different (see below) and also of direct use. It is allied in some ways to the DTE (*d*ynamic *t*ransduction of *e*nergy) theory[2] and, in fact, it seems to unify the static geometrical theory of *Louie* and *Somorjai* with the dynamic DTE theory.

In a number of articles we have demonstrated the use of differential geometry and especially minimal surfaces in chemistry.[3–7] It has also been shown that solids have periodic equi- or zero-potential surfaces, which are identical, or nearly so, with periodic minimal surfaces.[8] In two recent articles we have explained the adsorption properties of two different zeolites in terms of their integral curvature.[9, 10] The peculiar shape of the curves of differential heat versus initial adsorbed amount was explained by assuming a quasi-liquid state of molecules moving in the electrostatic field of the zeolite structure.[10] The initial heat developed at very low charge is often extremely high (Fig. 3).

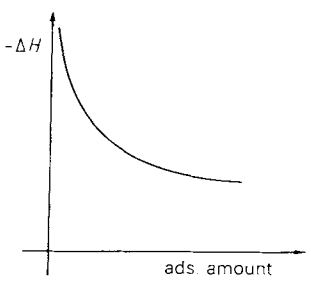

Fig. 3. Schematic representation of heat of adsorption versus loading on a zeolite.

We have explained the adsorptive properties of zeolites in terms of curvature [Eq. (1)]:

$$\Delta H = \mathrm{const}_1 K_{av} N \qquad (1)$$

K_{av} is the integral Gaussian curvature per surface area, ΔH the heat of adsorption, and N an interaction parameter. The first few molecules feel strong force fields focussed (van der Waals lens) via saddle rings of high intrinsic curvature, and high intrinsic heat is developed. This is obviously one of the reasons why zeolites are catalysts; molecules transform or crack even at room temperature owing to the intrinsic heat developed during their interaction with the zeolite surface structure of high curvature.

A unifying description of protein and enzyme structures, giving them negative Gaussian curvature, provides a simple explanation of their role in biosystems. We have estimated their negative average integral curvature to be 0.01–0.03 Å^{-2}. Therefore, according to Equation (1), intrinsic heats of adsorption high enough to start various reactions are easily developed.

The following description of protein action thus emerges; the substrate, conveniently viewed as a freely moving entity, reaches the vicinity of the protein. The latter can be either freely moving or bonded to some kind of biological matrix or "contrivance," e.g., a membrane. At a certain distance the substrate is influenced by attractive forces originating from the highly curved domain of the protein. The α-helices distending the β-sheets can be envisaged as providing discrimination, allowing access for substrates of proper size and/or configuration only. The substrate, so accepted, then enters the space close to the surface set up by the β-sheets. Each van der Waals active structural unit of the β-sheets contributes to a force field, which, owing to the curvature, is focussed, thereby enabling relatively remote units to act upon the substrate. A barrel protein can thus be conceived as a van der Waals lens. As the substrate is intercepted by the protein, kinetic energy is transformed into potential energy; i.e., the deceleration furnishes thermal excitation. Thus, intramolecular electron movement is substantially increased and bonding integrity may be regarded as partially lost. Explicit manipulations on the substrate can then be undertaken.

The model of van der Waals focussing is also valid in twisted sheet proteins because the surface set up by the twisted sheet, the helicoid, is isometric (curvature intact) to the inside of a barrel, the catenoid. Thus, when the substrate is located close to the highly curved surface of the protein it feels strong attractive forces from the entire protein.

Moreover, the relatively high flexibility of proteins permits a dynamic interaction with substrate molecules, thereby tuning the curvature; i.e., the energy "release" is partly governed by the entering substrate.

Other points of utmost importance in enzymatic reactions are concentration and extension. A serious shortcoming of the ordinary lock and key model is its failure to allow fully for the exceedingly low physiological concentrations of many enzyme substrates. Furthermore, a keyhole can only be arrived at by means of highly precise docking procedures; i.e., the reach of a keyhole into "space" is essentially nil. In view of the extraordinarily high turnover numbers often encountered in enzymatic processes it seems highly inexpedient to have a feeding mechanism that requires a low-concentration substrate to interact with the enzyme under conditions of extreme spatial ordering.

A saddle surface, i.e., a catenoid or a helicoid, on the other hand, has none of the keyhole restrictions. It could be regarded as infinite in terms of interactive impact. Any point on a saddle surface is the bull's-eye; the substrate would be intercepted and guided to the region of maximum curvature even though the preliminary encounter was of a random nature.

These ideas can be illustrated by a few examples; only enzymes describable as barrels or twisted sheets have been selected.[11] We have concentrated on enzymes displaying nonsophisticated chemical transformations and where a minimum of atom or group transfer is involved. Nevertheless, we believe that enzymes partaking in complex chemical transformations can be accounted for analogously; i.e., the major energy component is provided by the enzyme–substrate interaction.

Carboxypeptidase: a typical enzyme with the helicoid arrangement. It is a catabolic enzyme, degrading proteins by detaching amino acids starting from the carboxylic end. If we analyze the reaction in a strictly chemical sense, it is obviously a hydrolysis of an amide bond. Normally (i.e., in vitro) we accomplish this by heating an amide in water, adding a basic catalyst. The heat serves to energize the amide bond, i.e., to propagate the transient presence of high-energy entities and to confer additional thrust to the entering nucleophile (water). The catalyst simply transforms water into a more reactive form (hydroxide ion). If we assume that, by means of efficiently focussed van der Waals forces, carboxypeptidase imparts substantial thermal stress to the entering peptide, the free carboxylic end of which serves as an electron-rich target for nonbonding interactions, the transient existence of vibrationally excited entities coupled with heating of surrounding water molecules should provide the impetus necessary to bring about hydrolysis.

Triose phosphate isomerase; an archetypal catenoid enzyme. The reaction catalyzed by this enzyme is the transformation of dihydroxyacetone phosphate to glyceraldehyde-3-phosphate. Chemically this could be viewed either as a redox reaction, i.e., oxidation of an alcohol to an aldehyde and reduction of a ketone to an alcohol, or a re-enolization. Obviously there is no sophisticated chemistry involved and simple thermal excitation furnished by the van der Waals lens (triose phosphate isomerase) could be envisaged to propel the reaction. By analogy to the carboxylate in the example above the phosphate group could serve as an electron-rich target. In fact, one could seriously speculate that the presence of phosphate in biological systems, apart from buffering capacity, is explained by the need for a nontoxic, reasonably electron-rich van der Waals acceptor. Consequently, the role of phosphate esters as biochemical energy-carriers could be due to van der Waals targeting and the ease of hydrolysis of phosphate esters.

Pyruvate kinase; a catenoid enzyme. This enzyme catalyzes the detachment of phosphate from phosphoenolpyruvate yielding pyruvate. The phosphate group is concomitantly transferred to ADP. Chemically, the reaction is once again rather simple; hydrolysis of a phosphate ester followed by re-enolization. Again one can expect that thermal excitation in the presence of water and ADP is the major factor necessary for reaction.

Lactate dehydrogenase; a helicoid enzyme with the redox cofactor NADH. The reaction is a reduction of pyruvate to lactate. NADH is bound to the protein close to the curved arrangement of the β-sheets. Thermal excitation assists the entering hydride supplied by NADH.

Albumin; a carrier protein that cannot be described as either catenoid or helicoid. We have only been able to find clear representatives of the structure of prealbumin. Assuming that the curved nature of prealbumin is essentially preserved during its transformation to albumin, some interesting conclusions can be drawn. The structure can be characterized as an arbitrary part of a minimal surface. The curvature of the β-sheet arrangement appears to be lower than in the aforementioned proteins. Considering the function of albumin as a carrier of fatty acids, the relatively low curvature seems most reasonable. According to Equation (1), the impact of a curved surface on an entering molecule is dependent on the curvature of the surface. Obviously a carrier protein should have a curvature high enough to retain the molecules that are carried but not so high that damage is inflicted on the protein or that release of the molecules is too energy consuming. It is interesting to note that longer-chain fatty acids bind more readily to albumin than shorter-chain fatty acids. Furthermore, unsaturated fatty acids bind with higher affinity than saturated ones. If van der Waals interception is at work, one would indeed expect such behavior.

In this context it is tempting to propose that the extreme toxicity of 2,3,7,8-tetrachlorodibenzo[1,4]dioxin (TCD) might be a result of its interactions with highly curved proteins. If the interacting molecule is electron-rich and stable (both characteristics of TCD), the heat developed owing to the interaction could be sufficient to seriously damage the protein. The resulting collapse of structural integrity would release the TCD, undamaged and free to move to the next protein—the function of the dioxin becomes that of a more or less eternal projectile. Other chlorinated dioxins differ in toxicity, with TCD being the most toxic; owing to the arrangement of chlorine atoms, the slim, symmetrical TCD molecule should provide the best general fit to an arbitrary protein.

Extension of the latter proposal suggests an unprecedented approach to antiviral agents. It has been recently shown that the protein coat of polio viruses is compiled of four discrete proteins. Three of these are barrels. It is our opinion that these barrels are employed by the virus when a host cell is attacked. After binding to the surface of the cell, cell membrane components are attracted into the barrel thereby creating a hole in the cell membrane. Through this passage the virus can then inject the genetic material, the action of which finally proves fatal for the cell.

If this model of virus action is valid, it should be possible to exploit it advantageously in the treatment of viral diseases. By careful molecular design, it may be possible to prepare substances with the ability to interfere with the protein coat of viruses. These substances might irreversibly block the holes in the barrels, or, analogously to the proposed activity of dioxin, they might cause total destruction of the discrete proteins in the coat.

We feel that the recognition of highly curved protein structures represents a totally novel appreciation of protein function. Curvature-induced focussing of nonbonded interactions could also help to account for the energetics of many other biochemical events, such as transport across membranes, antigen-antibody interactions, splicing of mRNA precursors, action of tRNA in protein synthesis, and oxygen interception by hemoglobin.

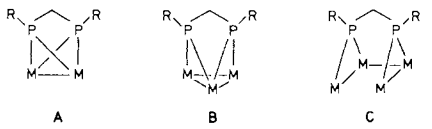
$[Cu_8(iPrPCH_2PiPr)_2Cl_4(py)_5]$, a Novel Cu^I Cluster Containing Pentacoordinated Phosphorus in μ_3-PRR′ Bridges (R = *i*Pr, R′ = CH_2PiPr)**

By *Franjo Gol, Peter C. Knüppel, Othmar Stelzer,** and *William S. Sheldrick**

Dedicated to Professor Ulrich Wannagat on the occasion of his 65th birthday

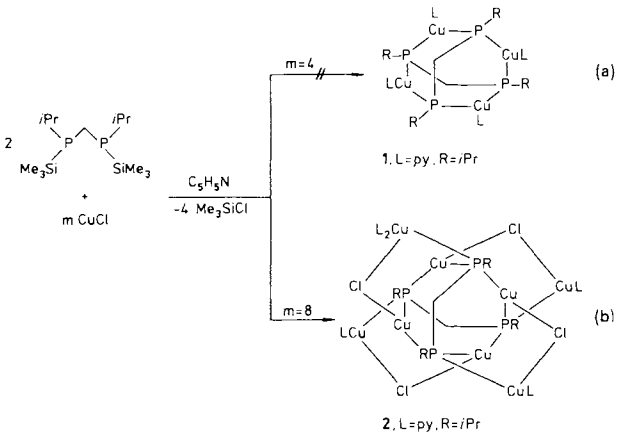
Methylenebisphosphanes $HRPCH_2PRH$[1] can be transformed by oxidative addition[2] into difunctional phosphido-bridges $RPCH_2PR$, bonding up to four transition-metal atoms (**A**–**C**).



A B C

Attempts to synthesize tetranuclear complexes of monovalent copper by reaction of copper chloride in the presence of pyridine with dianionic PCP ligands formed by cleavage of the P–Si bonds in $(Me_3Si)iPrPCH_2PiPr(SiMe_3)$[3] [reaction (a)] resulted in the formation of a product mixture. When excess CuCl (CuCl: phosphane ligand 4:1) was used, however, a smooth reaction occurred which afforded $[Cu_8(iPrPCH_2PiPr)_2Cl_4(py)_5]$ [reaction (b)].

The diamagnetic Cu_8 complex **2** is a nonelectrolyte in CH_2Cl_2 solution and exhibits a singlet at $\delta = -61.1$ in the $^{31}P\{^1H\}$-NMR spectrum (CH_2Cl_2, 25 °C), which is broad (half-width ca. 50 Hz) owing to the quadrupole effect of $^{63}Cu/^{65}Cu$. Molecular weight determinations (osmometric in CH_2Cl_2) gave lower values (ca. 850) than that expected for **2** (1369.95). These findings indicate that one of the five pyridine ligands (see below the discussion of the X-ray structure) dissociates from the complex [equilibrium reaction (c)].



1, L = py, R = *i*Pr

2, L = py, R = *i*Pr

$$2 \rightleftharpoons [Cu_8(iPrPCH_2PiPr)_2Cl_4(py)_4] + py \qquad (c)$$

According to the results of the X-ray structure analysis,[4] the structure of **2** is based on a central $[Cu_4(iPrPCH_2PiPr)_2]$ unit, to which four $CuCl(py)_x$ units ($x = 1, 2$) are joined through Cu–Cl–Cu and Cu–P–Cu bridges (Fig. 1). The Cu atoms Cu1, Cu3, Cu5, and Cu7 and the P atoms P2, P4, P6, and P8 form an eight-membered ring having a distorted boat conformation. P2 and P4 as well as P6 and P8 are linked in a strain-free fashion by CH_2 bridges (P2-C11-P4 105.1(4)°, P6-C72-P8 105.3(4)°, P2-C11 188.7(8), P4-C11 187.7(8), P6-C72 187.5(8), P8-C72 188.2(8) pm). With the exception of Cu6, the arrangement of ligands around the copper atoms is distorted trigonal-planar (sum of the bond angles 358.3 to 359.8°). Of the two pyridine ligands on Cu6, one (N51) is more loosely bound, as shown by a comparison of the bond lengths Cu6-N51 (214.8(8) pm) and Cu6-N61 (205.2(8)). It is presumably this pyridine ligand which dissociates from **2** in solution [cf. equilibrium (c)].

[**] Linear Oligophosphaalkanes, Part 22. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 21: [5].

A novel structural feature of **2** is provided by the $[Cu_3PRR']$ units (R = *i*Pr, R' = CH_2), which display a distorted trigonal-bipyramidal arrangement of the ligands around the P atoms. Two C atoms and a Cu atom together with the P atom form thereby a coordination plane. The two "axial" P–Cu bonds are bent toward each other in the direction of the "equatorial" P–Cu bond (Fig. 2). The μ_3 coordination of secondary phosphido ligands PRR' observed in **2** has only been reported so far in the complexes **3** recently described by us.[5]

$[Cu_4\{iPrPCH_2P(iPr)_2\}Cl_3(py)_2]$ **3**

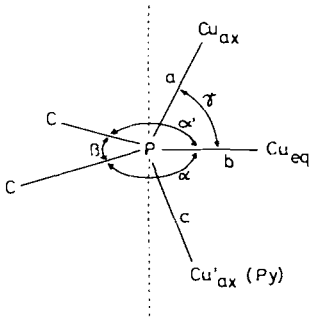

Fig. 2. μ_3-PRR' unit: average value $\bar{a}$ = 233.1 pm, $\bar{b}$ = 232.9 pm, $\bar{c}$ = 226.0 pm; $\bar{\alpha}$ = 128.3°, $\bar{\alpha}'$ = 128.5°, $\bar{\beta}$ = 103.1°, $\bar{\gamma}$ = 67.0°.

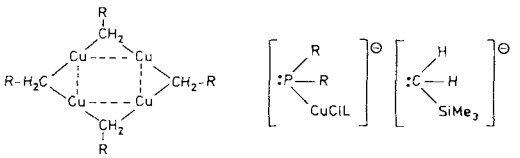
Only two electron pairs are available for bonding of the three Cu^I ions in the $[Cu_3PRR']$ units. If, in each case, one pair is used for coordination of the exocyclic $CuCl(py)_x$ groups ($x = 1, 2$), one pair remains for bonding of the four Cu^I ions in the central eight-membered ring. Analogous bonding is found in the electron-deficient system of organocopper(I) compounds of type **D**,[6] in which, instead of the $[PRR'CuClL]^{\ominus}$ units **E**, the isoelectronic bridging ligands $[CH_2SiMe_3]^{\ominus}$ **F** are present.



D, R = Me_3Si E, L = py F

In accordance with this formal description of the Cu–P bond in the $[Cu_4(PCH_2P)_2]$ core of **2** as an electron-deficient bond, the endocyclic Cu–P distances ($\bar{a}$, $\bar{b}$, Fig. 2) are up to 10 pm longer than the exocyclic distances (Cu(n)–P(n); n = 2, 4, 6, 8; $\bar{c}$, Fig. 2).

The two orthogonal PCP bridges in **2** hold the Cu^I ions close together and thereby create a favorable situation for interaction of the $3d^{10}$ systems.[6] The separations of the PRR'-bridged Cu atoms (265.0(2)–247.1(2) pm) are correspondingly short and are similar to those in copper (255.6 pm).[7] The μ_2-PPh_2 bridges in the complex $[Cu_2(PPh_2)_2(Ph_2PCH_2CH_2PPh_2)_2]$ **4**, on the other hand, result in considerably larger separations of the Cu atoms (333.0(1) pm).[8]

Complexes **2** and **3**, which exhibit novel bonding at the PRR' bridges, complement the small number of characterized phosphido complexes of the coinage metals. Complex **2** is the first cluster compound of a transition metal to be made up of M_3PRR' units.

Experimental Procedure

$(Me_3Si)iPrPCH_2PiPr(SiMe_3)$ (3.08 g, 10 mmol) was added over 10 min to a solution of CuCl (3.96 g, 40 mmol) and pyridine (6.32 g, 80 mmol) in 10 mL of acetonitrile at 0°C. The reaction mixture was then warmed to room temperature and allowed to stir for 16 h. The yellow crystals of **2** that formed were collected on a suction filter and washed with 2 mL of cold (0°C) acetonitrile. Yield 3.71 g (54%). Additional **2** could be isolated from the reaction solution.

The First Triphosphabicyclobutane—Evidence for a 1,2,3-Triphosphabutadiene**

By *Rolf Appel,** *Bärbel Niemann,* and *Martin Nieger*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Compounds derived from butadiene by replacement of one or two C atoms by twofold coordinated P atoms were first reported only a few years ago.[1] They are good complexing agents and—like the pure carbon compounds—are suitable for cycloadditions.[2]

Following the successful synthesis of a 1,2,4-triphosphabuta-1,3-diene,[3] we now attempted the preparation of a 1,2,3-triphosphabuta-1,3-diene. We found however that reaction of the dichlorophosphane **1**[4] with the bis(trimethylsilyl)phosphino-substituted phosphaalkene **2**[5] does not lead to the open-chain triphosphabutadiene **5** but to the triphosphabicyclobutane **6**. The condensation according to (b) likewise furnishes **6**. We explain the formation

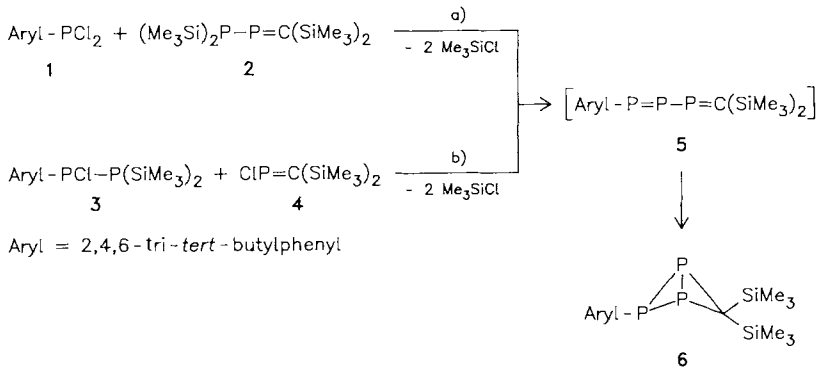
[**] Lower Coordinated Phosphorus Compounds, Part 67.—Part 66: R. Appel, J. Hünerbein, M. Nieger, *J. Organomet. Chem.*, in press.

[***] A triphosphabicyclobutane system, $(Me_3Si)_2N-N(SiMe_3)_2$ instead of aryl in **6**, can be obtained on reaction of $R^2NN(R)-P=P-R$ with $Cl-P=CR_2$ (R = $SiMe_3$): E. Niecke, O. Altmeyer, M. Nieger, *Chem. Commun.*, in press.



of the bicycle in terms of an intramolecular [2+2]-cycloaddition of **5**.[***]

The ^{31}P-NMR spectrum of **6** shows an AX_2 system with $\delta_A = -65.8$ and an X-part shifted strongly upfield for the bridgehead P atoms ($\delta_X = -244.3$). Similar shifts are quoted for tetraphosphabicyclobutane derivatives.[6] The empirical formula of **6** is confirmed by the ^{31}P- and ^{1}H-NMR spectroscopic data and by the high resolution mass spectrum as well as by a correct elemental analysis.[7] The structure was confirmed by an X-ray diffraction analysis[8] (Fig. 1).

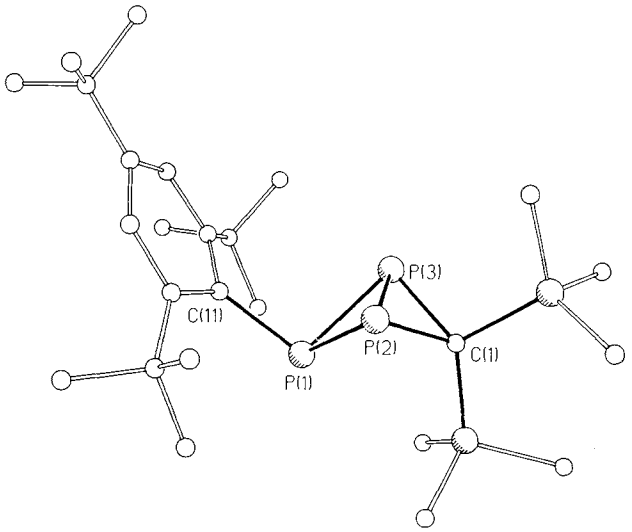


Fig. 1. Crystal structure of **6**. Important bond lengths [Å]: P(1)-P(2) 2.231(2), P(1)-P(3) 2.223(2), P(2)-P(3) 2.136(1), P(2)-C(1) 1.881(4), P(3)-C(1) 1.883(4).

The bond between the bridgehead P atoms in the bicycle is exceptionally short (2.136(1) Å), whereas the P-C bonds are longer than the P-P and P-C bonds in acyclic compounds. The angle between the P(1)-P(2)-P(3) and P(2)-P(3)-C(1) planes is 105°.

Experimental

6: a) A solution of **1** (1.8 g, 5 mmol) in toluene (10 mL) was treated with 1.7 g (5 mmol) of **2** and the mixture stirred for 24 h at room temperature. After removal of volatile components under vacuum the residue was crystallized several times from pentane. M.p. 152°C; yield 0.5 g (20%). b) A solution of **1** (1.7 g, 5 mmol) in ether (20 mL) was treated dropwise at −80°C with a solution of $LiP(SiMe_3)_2 \cdot 2\,THF$ (1.6 g, 5 mmol) in ether. The mixture was allowed to warm to room temperature, the solvent removed under vacuum, and the residue taken up in pentane. The resulting solution was filtered free of LiCl and the filtrate treated dropwise with 0.12 g (5 mmol) of **4**. The mixture was stirred for several hours and then worked up as in (a).

Synthesis and Structure of $[Cp_2NbH(tBuB{\equiv}NtBu)]$, a Compound with Side-on Coordinated Iminoborane**

By *Ece Bulak, Gerhard E. Herberich, Ian Manners, Horst Mayer,* and *Peter Paetzold**

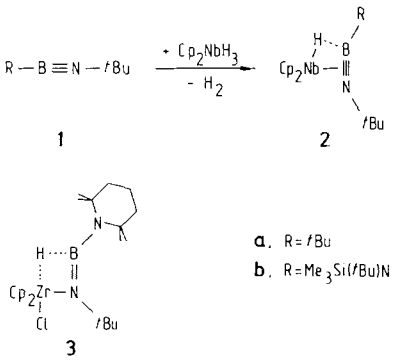
Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Iminoboranes RB≡NR′ are isoelectronic with acetylenes; in their structure and reactivity they especially resemble

[*] Prof. Dr. P. Paetzold, E. Bulak, Prof. Dr. G. Herberich, Dr. I. Manners, Dr. H. Mayer
Institut für Anorganische Chemie der Technischen Hochschule Templergraben 55, D-5100 Aachen (FRG)

[**] This work was supported by the government of Nordrhein-Westfalen. *I. M.* thanks the Royal Society (England) for a fellowship grant.

polar acetylenes (e.g. RC≡CF).[1] In the coordination sphere of transition-metal atoms, iminoboranes can dimerize to tetrahapto-bonded BNBN four-membered ring compounds analogous to cyclobutadiene, or they can bridge two metal atoms in the orthogonal position to the metal–metal bond.[1] A third structural type known for acetylenes, namely that with side-on bonding to transition metal atoms, has hitherto not been reported for iminoboranes. We therefore attempted, in analogy to a known reaction of acetylenes,[2] to couple the iminoboranes **1a,b**[3] side-on to niobium; by treatment with Cp_2NbH_3 we obtained the air-sensitive, brown, crystalline products **2a,b**.



The constitution of **2a,b**, as 1:1 adduct of **1a,b** and Cp_2NbH, follows from the NMR and mass spectra.[4] We assign the broad weak IR bands at 1680 (**2a**) and 1650 cm^{-1} (**2b**) (in hexane) to the Nb–H stretching vibration; its long wavelength position compared to that of $[Cp_2NbH(C_2Pr_2)]$ (1720 cm^{-1})[2a] could be due to an interaction with the B atom. An X-ray structure analysis of **2a** confirmed the side-on bonding between **1** and the niobium atom (cf. Fig. 1).[5]

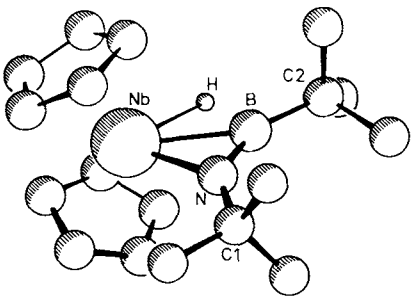


Fig. 1. Molecular structure of **2a** in the crystal (without C-bonded hydrogen atoms). Selected bond lengths and angles ([Å] and [°], resp.; standard deviations in parentheses): Nb-B 2.399(3), Nb-N 2.159(3), B-N 1.294(5), Nb-H 1.80(3), B-H 1.37(3), Nb-C_x 2.058(1), Nb-C_y 2.050(1), N-C1 149.6(5), B-C2 155.9(6), average C-C values of 2Cp 135.4, 136.8; B-Nb-N 32.5(1), Nb-N-B 84.0(2), Nb-B-N 63.5(2), Nb-H-B 98(2), Nb-N-C1 138.7(3), B-N-C1 137.3(4), Nb-B-C2 151.7(3), N-B-C2 144.8(4), C_x-Nb-C_y 133.9, (C_x, C_y: projections of Nb onto the Cp planes).

2a is a bent metallocene (133.9°). The central moiety of **2a** comprises the Nb-N-B triangle and the neighboring coplanar arrangement of the atoms H, C1 and C2. Compared to the typical NbC distances of 2.18–2.25 Å in niobocene-acetylene derivatives,[6] distances of 2.159(3) (NbN) and 2.399(4) Å (NbB) suggest strong bonding between the niobocene and the iminoborane **1a**. In **3**, the corresponding distances are 2.211(2) (ZrN) and 2.627(2) Å (ZrB) and indicate at most a weak ZrB interaction.[7] The BN distance of **1a** (1.258(4) Å) is only slightly expanded on coordination to the niobium; in **3**: 1.360(3) Å). The CBN and BNC angles in linear **1a** are only moderately narrowed (namely to 155.9(6) and 149.6(5)° respectively; in **3**: 140.3(3) and 130.5(2)°), whereas the corresponding CCC angles in niobocene-acetylene derivatives are found between 140 and 146°.[6] Thus, the back-bonding in the iminoborane complex **2a** is weaker than in the comparable acetylene complexes. Compared to the usual range of BH bond lengths of 1.10–1.35 Å,[8] the BH distance of 1.37(3) Å in **2a** suggests at most a very weak BH interaction; the NbH bond is not significantly lengthened (1.80(3) Å; cf. Cp_2NbH_3: 1.69 Å (average)[9]). Whereas **3** can be regarded as an *N*-metalated aminoborane, **2a,b** are side-on coordinated transition-metal complexes of iminoboranes.

Experimental

2a (η^2-[*tert*-Butyl(*tert*-butylimino)borane]bis(η^5-cyclopentadienyl)hydridoniobium): A solution of 0.22 g of **1a** and 0.23 g of Cp_2NbH_3 in 5 mL of toluene was heated to 85 °C for 90 min. Toluene was then removed by distillation under vacuum at room temperature and the residue taken up in pentane containing a trace of toluene. On cooling the solution to −80 °C, **2a** crystallized out (0.25 g, 68%); **2b** was prepared analogously (yield 73%).

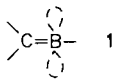
Lewis-Base Adducts of Methyleneboranes**

By *Heidi Lukasch, Günter Schmidt-Lukasch, Uwe Lippold,* and *Armin Berndt**

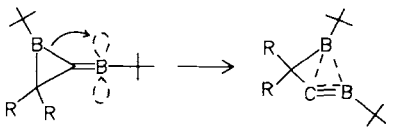
Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Jutzi pointed out already in 1975 that the dicoordinated boron atom of methyleneboranes **1** exhibits pronounced Lewis acid character.[1] In the stable[2] methyleneboranes



1

2–**4**[3–6] described in the meantime the vacant p-orbital at the boron atom is filled up *intra*molecularly, in **2**[3] non-classically by a neighboring borirane ring, in **3**[5] and **4**[6] classically by an electron pair from the nitrogen substituents on the boron atom.

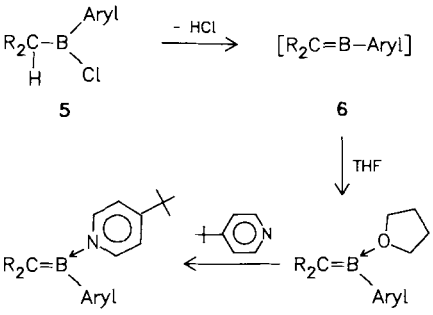


2, R = $Si(CH_3)_3$

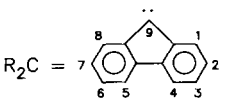
3, R_2C = fluorenylidene, HNR'_2 = 2,2,6,6-tetramethylpiperidine

4, R = $Si(CH_3)_3$, R' = *i*Pr

We have now prepared methyleneboranes in which the vacant p-orbital at the boron atom is occupied *inter*molecularly by Lewis bases (tetrahydrofuran, pyridine derivatives).



5 **6** **8** **7**

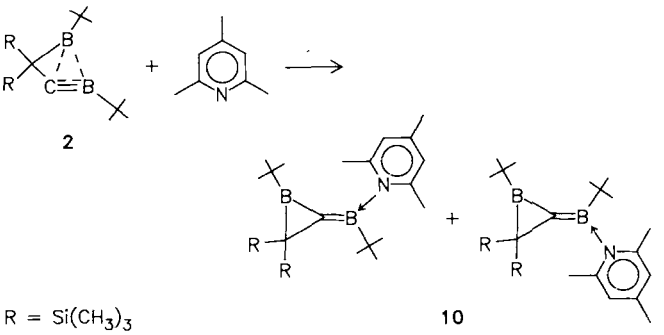


a, Aryl = 2,4,6-triisopropylphenyl;

b, Aryl = 2,3,5,6-tetramethylphenyl;

c, Aryl = 2,4,6-trimethylphenyl

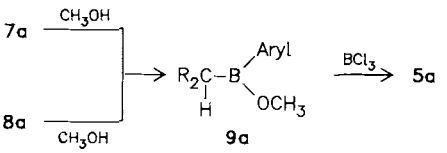
The arylchlorofluorenylboranes **5a** and **5b** can be prepared analogously to chlorofluorenylmesitylborane **5c**[7] from fluorenylsodium and the corresponding aryldichloroboranes in pentane. Reaction of **5a** and **5b** with *tert*-butyllithium in THF at −78°C furnishes the methyleneborane-tetrahydrofuran adducts **7a** and **7b**, respectively (**7a** crystallizes out). **7c** is obtained by reaction of **5c** with 2,4,6-tri-*tert*-butylphenyllithium as base. The coordinated THF in **7a**–**7c** can be easily replaced by 4-*tert*-butylpyridine to give deep-blue[8] **8a** and red[8] **8b** and **8c**, respectively. The non-classically stabilized **2** is inert toward THF, but reacts with 2,4,6-trimethylpyridine[9] to give the red adduct **10**. The formation of deep-colored adducts with pyridine derivatives can thus be used as a reaction for the detection of methyleneboranes.



2

R = $Si(CH_3)_3$ **10**

7a and **8a** add methanol with formation of the methoxyborane **9a**, while **7b**, **7c**, and **8b** are cleaved by methanol into fluorene and the corresponding aryldimethoxyboranes. **9a** can be reconverted into **5a** by reaction with BCl_3. The reactions of **7a** and **8a** with HCl lead to product mixtures which do not contain **5a**.



9a

The structures of the compounds **5** and **7**–**10** follow from the ^1H-, ^{13}C- and ^{11}B-NMR spectra[10] and from the described reaction cycle. The double-bond character of the C–B bond in **7** and **8** manifests itself in the different chemical shifts of the atoms C1–C4 and C8–C5 as well as C4a, C9a and C4b, C8a of the fluorene framework, which reflect the unsymmetric substitution at the boron atom. In **10**, both ends of the partial C–B double bond are unsymmetrically substituted, so that *Z,E*-isomers are to be expected; they are recognizable by a doubling of the number of signals in the ^{13}C-NMR spectrum. At room temperature, the second isomer is just recognizable; on cooling a saturated solution in CD_2Cl_2 to −40°C the isomer present in higher concentration partially crystallizes out, in solution both isomers are then present in comparable amounts. The chemical shifts of the C9 atoms of **7** and **8** ($\delta = 108$–110)[12] and that of the C atom doubly bonded to boron in **10** ($\delta = 92.8$) indicate an excess of electrons corresponding to resonance formula **B**.[12]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Delocalization of this charge leads to a shielding of the quasi *ortho* and *para* C atoms 1, 3, 6, 8, 4a, and 4b of the fluorene skeleton in **7** and **8** and of the boron atom in the three-membered ring of **10** ($\delta(^{11}B)=37$ compared to 80 in boriranes).

All attempts to convert **7a–c** into the Lewis base-free methyleneboranes **6a–c** led to decomposition of the compounds.

Experimental

7a: A stirred solution of **5a** (13.1 g, 31.5 mmol) in THF (130 mL) was treated dropwise and very slowly (ca. 1.5 h) at −78 °C with 75.0 mL of a 0.42 molar solution (31.5 mmol) of *tert*-butyllithium in pentane. The orange colored reaction mixture was slowly warmed to −10 to 0 °C, whereupon the precipitated product went completely into solution. At −40 °C, **7a** crystallized out quantitatively and in spectroscopically pure form.

8a: A suspension of 1.36 g (2.45 mmol) of **7a** in 20 mL of pentane was treated dropwise at −20 °C with 0.41 g (3.03 mmol) of 4-*tert*-butylpyridine. After slowly warming the mixture to room temperature it was stirred for 3 h, the solvent was removed by pipette, and the deep-blue precipitate was washed with 2 × 10 mL of pentane and dried in an oil-pump vacuum. **8a** is sparingly soluble in hydrocarbons and ethers, and decomposes rapidly in $CDCl_3$ and slowly in CD_2Cl_2.

10: A solution of **2** (1.68 g, 5.5 mmol) in pentane (20 mL) was treated dropwise at −40 °C with 0.73 mL (5.5 mmol) of 2,4,6-trimethylpyridine. The mixture was warmed to room temperature, stirred for 30 min, and treated with sufficient ether until the precipitated product **10** was redissolved (ca. 30 mL); **10** crystallized out on cooling the solution to −30 °C.

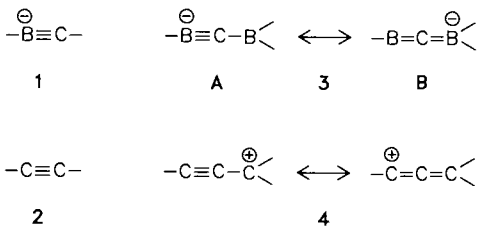
Compounds with Partial Boron–Carbon Triple Bonds**

By *Ralf Hunold, Jürgen Allwohn, Gerhard Baum, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Compounds containing a boron–carbon triple bond, i.e. borataalkyne ions[1] **1**, which are isoelectronic with alkynes **2**, have so far not been reported in the literature.[2] Herein

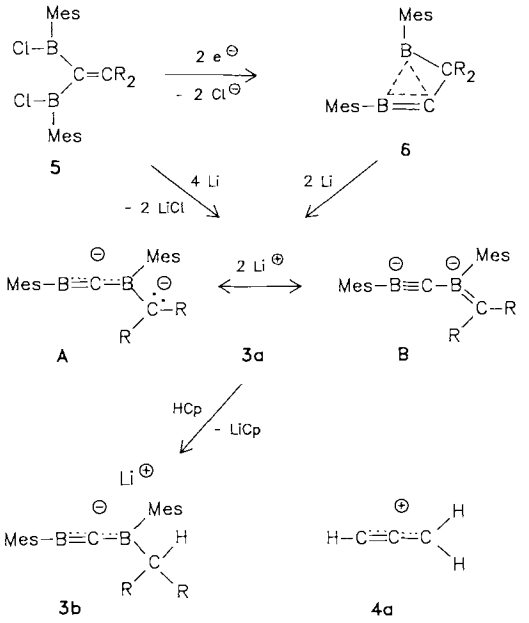


[*] Prof. Dr. A. Berndt, Dr. R. Hunold, J. Allwohn, G. Baum, Priv.-Doz. Dr. W. Massa
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

we present the first examples of compounds containing a partial boron-carbon triple bond, namely the diboro compounds **3**, which are isoelectronic with propargyl/allenyl cations **4**.[1,3]

The dianion **3a**[4] lithiated in the boryl residue is formed upon reaction of the 1,1-bis(boryl)ethene **5**,[5] or the compound **6** accessible therefrom with K/Na alloy in pentane, with an excess of lithium in diethyl ether. The crucial step in the conversion of **6** into **3a** is the reductive cleavage of the C-C bond of the C_2B_2 framework.



Mes = 2,4,6-trimethylphenyl; R = $Si(CH_3)_3$

Monoprotonation of **3a** with cyclopentadiene HCp leads to the lithium salt of the borylborataalkyne ion **3b**,[4] which crystallizes from pentane with one equivalent of diethyl ether. The result of an X-ray structure analysis[7] of **3b** is shown in Figure 1.

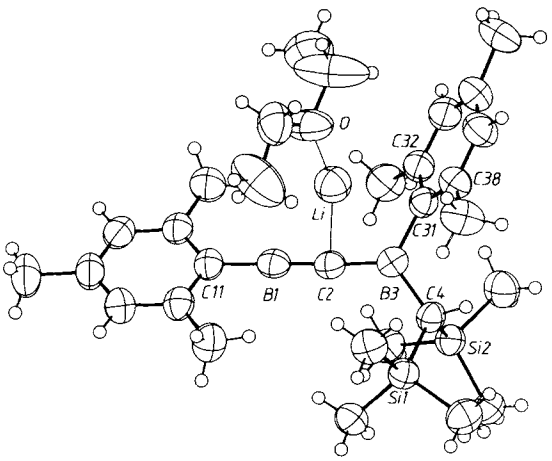


Fig. 1. Crystal structure of **3b** (ORTEP). The thermal ellipsoids are drawn at the 50% probability level. Projection approximately onto the C2-C4-C31 plane. Important distances [pm] and angles [°]: B1-C2 133.9(6), C2-B3 149.2(6), B1-C11 154.3(6), B3-C4 159.9(6), B3-C31 161.2(6), B1-Li 249.3(9), C2-Li 209.4(9), B3-Li 249.0(9), C31-Li 234.5(9); B1-C2-B3 176.5(5), C2-B1-C11 178.0(5), C2-B3-C4 122.6(4), C2-B3-C31 118.9(4), C4-B3-C31 118.4(4), B1-C2-Li 90.4(4), B3-C2-Li 86.3(4), C2-Li-O 155.9(5); Li-C2-B3-C31 −23.3(5), B3-C2-Li-O −143.7(12), C2-B3-C4-Si1 −39.3(6), C2-B3-C4-Si2 92.7(5), C2-B3-C31-C32 −65.7(6), C2-B3-C31-C38 112.9(5).

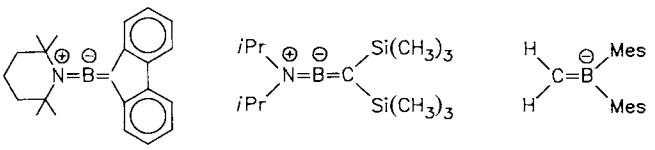
The BCB moiety is almost linear (BCB bond angle 176.5°, boron atoms bent toward Li). Values of 176.4° and 179.6°, respectively, have been determined for the NBC bond angles in **7**[8] and **8**.[9]



The plane of the mesityl ring attached to the sp-hybridized B1 forms an angle of 41° with the plane through the bonding partners of the sp^2-hybridized B3; B3 itself does not deviate significantly from this plane (0.5(5) pm), and the mesityl ring attached to B3 is twisted through about 66°.

The lithium ion coordinated through the O-atom of a diethyl ether molecule has additional short contacts: to the central carbon atom C2 (209.4(9) pm) bound to the two boron atoms, to C31, the *ipso*-C-atom of the mesityl ring attached to B3 (234.5(9) pm), and to both boron atoms (each about 249 pm). The C2-Li connecting line is not perpendicular to, but almost in the B3-C2-C4-C31 plane.[10]

At B3, the B-C bond lengths to the substituents are 161.2(6) and 159.9(6) pm, i.e. in the range typical for B-C single bonds (158-162 pm);[11] B1-C11 (154.3(6) pm) is markedly shorter. This may be due to the absence of steric hindrance and the increased s-character of the bond to B1. The B3-C2 distance (149.2(6) pm) is distinctly shorter than that of a B-C single bond, even if the sp hybridization of the carbon atom is taken into account;[12] however, in spite of the sp-hybridized C atom, it is noticeably longer than the B_{sp^2}–C_{sp^2} double bond in **9** (144 pm).[11] This indicates partial double-bond character of the C2-B3 bond in **3b** corresponding to resonance formula **3B**. The B1-C2 distance of 133.9(6) pm is the shortest so far measured for a B-C bond. It is markedly shorter than that of the B_{sp}–C_{sp^2} double bond in **7** (142 pm)[8] and **8** (139 pm).[9] About 2 pm of the difference of 5-8 pm can be attributed to sp hybridization of C2, as a comparison of the C=C distances in ethene (133.2 pm) and allene (131.2 pm) shows. The remaining difference of 3-6 pm indicates partial triple-bond character of the B1-C2 bond in **3b** corresponding to resonance formula **3A**.

Both C2-B bonds in **3b** are longer by the same amount (13 pm) than the corresponding C-C bonds in the propargyl cation **4a**, thus verifying the electronic similarity of **3** and **4**.

Since **3a** and **3b** show similar IR bands in the heteroallene region[8] (**3a**: $\tilde{\nu}$ = 1765 and 1810 cm^{-1}; **3b**: $\tilde{\nu}$ = 1765, 1790 and 1830 cm^{-1}), we conclude that the electronic structure of **3a** resembles that of **3b**, despite the additional negative charge. The chemical shift of the quaternary C atom of the $LiC(Si(CH_3)_3)_2$ group (δ = 58.3) shows that the negative charge is essentially localized on this C atom (resonance formula **3a A**). Also consistent with such a localization is the low rotation barrier about the Si_2C=B bond (resonance formula **3a B**) of 13.5 kcal mol^{-1}, which can be determined from the temperature dependence of the ^{13}C-NMR signals of the $Si(CH_3)_3$ groups. A barrier of 57 kcal mol^{-1} has been calculated for $H_2C{=}\overset{\ominus}{B}H_2$.[13]

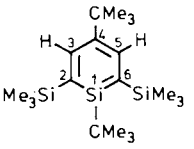
1,4-Di-*tert*-butyl-2,6-bis(trimethylsilyl)silabenzene, the First Silabenzene Stable in Solution at −100°C

By *Gottfried Märkl** and *Werner Schlosser*

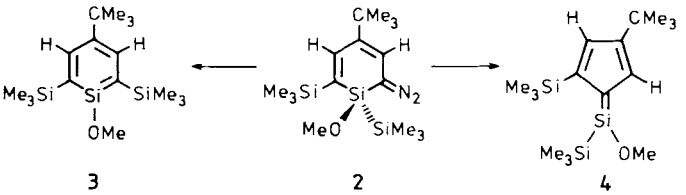
In the past few years *A. G. Brook* et al.[1] and *N. Wiberg* et al.[2] have reported the synthesis of a number of kinetically stabilized silaethenes which, under inert gas, are stable even at room temperature. In contrast, no comparable stable silabenzene derivatives have been described as yet. Silabenzene and 1-methylsilabenzene[3–5] have been identified IR-, UV- and PE-spectroscopically in an argon matrix at 10 K, 1-methylsilabenzene[6] and 1,4-di-*tert*-butylsilabenzene have been detected by trapping reactions with hexafluorobutyne[6] or 1,3-dienes and by dimer formation.[7]

We report here on 1,4-di-*tert*-butyl-2,6-bis(trimethylsilyl)silabenzene (**1**), which is stable up to ca. −100°C.



1

Recently, we described the photochemical and thermal elimination of N_2 from 6-diazo-1-methoxy-1,2-bis(trimethylsilyl)-4-*tert*-butyl-1-sila-2,4-cyclohexadiene **2**.[8a] On the basis of the product pattern we postulated that the initially formed carbene is transformed via a 1,2-silyl shift into the silabenzene **3** and via rearrangement of the skeletal framework into the silafulvene **4**, both of which can be trapped as reactive intermediates, e.g. with methanol and 2,3-dimethylbutadiene, respectively.



3 **2** **4**

We have now investigated the photochemical behavior of the diazo compound **6**, which is accessible in 5–10% yield from 1,4-di-*tert*-butyl-1,2-bis(trimethylsilyl)-1-sila-2,4-cyclohexadiene **5**[8b] via the lithium compound. Irradiation (3 h) of **6** in anhydrous methanol/THF (1/1) with a halogen lamp ($\lambda>410$ nm) at room temperature leads to elimination of N_2 and formation of the 1-*tert*-butyl-1-methoxysilacyclohexadiene **8**, which can be isolated in 45% yield by chromatographic work-up on silica gel 60 with petroleum ether/benzene (6:1). The formation of **8** can only be interpreted in terms of the carbene **7**, formed as intermediate from **6**, rearranging via a 1,2-Me_3Si-shift to the silabenzene **1**, which then adds methanol to give the stable *syn*-adduct **8**. The physical and spectroscopic properties of **5**, **6** and **8** are listed in Table 1.

Whereas the carbene generated from 4-diazo-1,1-dimethyl-1-sila-2,5-cyclohexadiene by thermolysis at 400°C does not rearrange—via 1,4-methyl-shift—into 1,4-dimethylsilabenzene but dimerizes to the ethene derivative,[9] the strong tendency of the silyl residue in **7** to migrate effects rearrangement to the silabenzene **1**.

After three hours' irradiation of **6** in a Trapp mixture (THF/ether/petroleum ether 4/1/1) at −110°C to −120°C, the reaction solution affords the methanol adduct **8** in 35–40% yield on addition of methanol, even 30 or 60 mins after completion of N_2-elimination. Since **8** is still formed in almost the same yield even after 4–5 h irradiation, a subsequent fast photochemical secondary reaction of **1** under these conditions can be ruled out. And since **8**

is formed only in 45% yield from **6**, even in the presence of methanol, it must be assumed that further products, which so far could not be isolated, are formed upon irradiation of **6**. No clearly identifiable products are formed upon irradiation of **6** in THF in the absence of trapping rearrangements at 25°C, 0°C, −30°C and −60°C; subsequent addition of methanol to these irradiated solutions no longer leads to the adduct **8**.

The assumption that the silabenzene **1** is stable up to ca. −100°C is further substantiated by low-temperature spectroscopy. The ^{29}Si-NMR spectrum of the diazo compound **6** in the Trapp mixture at −100°C shows three signals, at δ = −2.6 and −15.3 (Me_3Si) and at δ = −24.8 (ring Si). On irradiation of **6** in a Trapp mixture ($c \approx 60$ mg/mL) under pure nitrogen in a sealed NMR tube at −110°C to −120°C, the ^{29}Si-NMR signals of **6** disappear within 3 h; a new signal at δ = −17.8 is assigned to the $SiMe_3$-substituents in the 2,6 position, one at δ = +26.8 to the sp^2 ring-Si atom of the silabenzene **1**. On warming the solution to −70°C, these signals disappear. On addition of methanol to the NMR sample solution at $T \leq -110$°C, the methanol adduct is again obtained in 40% yield. The δ(^{29}Si) values for acyclic silaalkenes[11] in C_6D_6 lie between δ = +40 and δ = +144; it appears, however, that THF as donor ligand at the sp^2 silicon leads to a high-field shift of this signal. Thus, e.g., the ^{29}Si-NMR signal for the silanediyl complex $[(CO)_4Fe{=}Si(OtBu)_2 \cdot Do]$ appears at δ = 7.1 (Do = HMPT) and δ = −9.4 (Do = THF).[12]

The signals of the educt also almost completely disappear in the ^{13}C-NMR spectrum recorded at ca. −105°C three hours after irradiation of the solution of **6** ($c \approx 70$ mg/mL); new signals appear for C-2 to C-5 which we assign on the basis of off-resonance measurements to the ring C-atoms of **1** as follows ([D_8]THF/Et_2O/petroleum ether): δ = 166.8 (C-3, C-5), 126.0 (139.5) (C-2, C-6), 139.5 (126.0) (C-4).[13, 14] On briefly warming the solution to −10°C, these signals disappear.[15]

The C=N_2 vibration at 2050 cm^{-1} in the IR spectrum of **6** (Trapp mixture, c = 3 mg/mL, layer thickness 0.2 mm) at −120°C has almost completely disappeared after 6 min. In the UV spectrum (HBO 200, monochromator) after this time under the same conditions the absorption band of **6** at 380 nm has disappeared; the absorption band of **1**, which is to be expected in the same region, cannot be observed.[16] This observation is consistent with the results of *G. Meier* et al.[4] according to which the absorption bands of the silabenzene disappear upon brief irradiation, even in an argon matrix at 10 K.

At concentrations of **6** of ca. 100-fold less than that required for the ^{29}Si- and ^{13}C-NMR measurements, possible photochemical secondary steps or reactions with traces of moisture or oxygen (during irradiation times of 6 min) can lead to complete degradation of **1**. Upon irradiation of **6** in the 1-cm cuvette, the absorption band at 375–390 nm disappears much more slowly at −120°C than at room temperature. Thawing of the solutions of **6** after irradiation at −120°C for 5 min shows that the decreasing extinction accompanying the degradation of **6** is compensated by the synthesis of **1**: the extinction of the band decreases rapidly with increasing temperature. This finding is best explained in terms of the broad band observed at 375–390 nm for the solutions of **6** after irradiation for 5 min being caused by the concomitant presence of **1** and **6**.

From our findings we can conclude that the silabenzene **1** obtainable photochemically from **6** is stable up to about −100°C. Above this temperature, well-defined secondary products of **1** can no longer be isolated in the absence of trapping reagents. The formation of dimers, such as takes place in the case of the short-lived 1,4-di-*tert*-butylsilabenzene,[7] is not observed with **1** — obviously for steric reasons.

Some time ago, the possibility of a photochemical valence isomerization of silabenzene to the Dewar-silabenzene was discussed on the basis of MO calculations.[17]

The assumption made therefrom that silabenzene and silatoluene generated in the matrix already isomerize to Dewar-benzenes upon brief irradiation (rapid disappearance of the bands in the UV spectra) cannot be excluded by our results; the secondary reactions occurring under our conditions, however, must be so slow that unequivocal detection of **1** is possible in the concentration range required for NMR measurements at −100°C. δ(^{29}Si) values of −50 to −100 would be expected for a Dewar-isomer of **1**, in analogy to the values already known for silacyclobutenes and silacyclopropenes.[18] It is surprising that even silabenzene derivatives which should be kinetically highly stabilized, are not stable at room temperature.

Reaction of [NiCp(PPh$_3$)Cl] with E(SiMe$_3$)$_2$; the Structures of [Ni$_4$Se$_2$Cp$_4$] and [Ni$_4$E$_2$Cp$_4$(PPh$_3$)$_2$] (E = Se, Te)**

By *Dieter Fenske,* Achim Hollnagel,* and *Kurt Merzweiler*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

Transition-metal halides react with E(SiMe$_3$)$_2$ (E = S, Se, Te) in the presence of phosphane ligands to give metal-rich clusters.[1] Frequently, mixtures of substances are obtained and the structures of the clusters are dependent on the properties of the solvent. But the properties of the phosphane ligands may possibly also have an influence on the cluster size. For example, we also found that multinuclear complexes containing maximally six metal atoms are formed upon reaction of the cyclopentadienyl-transition-metal halides [TiCp$_2$Cl$_2$], [TiCpCl$_3$], [TaCpCl$_4$], [FeCp(CO)$_2$Br] and [VCp$_2$Cl$_2$] with E(SiMe$_3$)$_2$.[2,3]

When, however, [NiCp(PPh$_3$)Cl] is allowed to react with E(SiMe$_3$)$_2$ in THF as solvent a rapid change in color of the solution from violet to dark brown is observed, and a fine crystalline, black precipitate of **1** separates, which is readily soluble in THF. On covering this solution with heptane, **1** is obtained in the form of black platelets, and upon addition of hexane to the filtrate black needles of **2** can be isolated. **2a** and **2b** can also be obtained by reaction of **1a** and **1b**, respectively, with PPh$_3$.

$$[NiCp(PPh_3)Cl] \xrightarrow{E(SiMe_3)_2} \underset{\mathbf{1}}{[Ni_4E_2Cp_4]} + \underset{\mathbf{2}}{[Ni_4E_2Cp_4(PPh_3)_2]}$$

a, E = Se; **b**, E = Te

The molecular structures of **1a**, **2a** and **2b** were confirmed by crystal structure analyses.[4] **1a** (Fig. 1) contains a square planar Ni$_4$ cluster ($\bar{1}$ symmetry) in which each Ni atom is bound to an η^5-C$_5$H$_5$(Cp) ring and to two μ_4-Se ligands. If one assumes that Se$^{2\ominus}$ and Cp$^{\ominus}$ ligands are present in **1a**, then the Ni has the formal oxidation number +2. The Ni-Ni bond lengths resemble those in other Ni clusters containing Ni-Ni bonds.[1-5] Assuming that four Ni-Ni single bonds exist in the 68e cluster **1a**, it must contain four electrons more than would be expected according to the 18-electron rule.

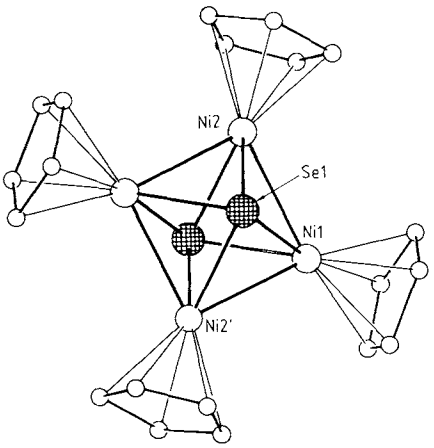

Fig. 1. Structure of **1a** in the crystal. Important bond lengths [pm] and angles [°]: Ni1-Ni2 257.0(1), Ni1-Ni2' 258.1(1), Ni-Se 237.2-238.4(1), Ni-C(Cp) 212.4-217.2(6), C(Cp)-C(Cp) 135.0-141.8(8); Ni-Ni-Ni 89.85-90.15(10), Ni-Se-Ni 65.4-80.0(1), Ni-Ni-Se 57.1-57.5(1), C(Cp)-C(Cp)-C(Cp) 106.0-110.2(4).

The distance between the two μ_4-bridging Se-ligands (305.3(1) pm) is significantly less than the van-der-Waals distance that has been found in Se and $Se_8^{2\oplus}$.[6] This could be due to a weak interaction between the Se ligands. However, it must be taken into account that there is a direct relationship between the Ni-Ni bond lengths and the Se-Se distance for a given Ni-Se distance. A similar situation has already been observed in $[Ni_3Se_2(PEt_3)_6]^{2\ominus}$ and $[Co_4(CO)_8(\mu_2\text{-}CO)_2(\mu_4\text{-}E)_2]$ (E = S, Te, PPh).[7,8]

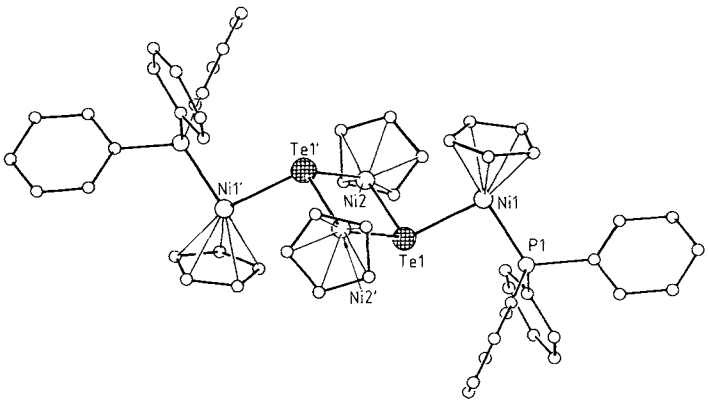

Fig. 2. Structure of **2b** in the crystal (without THF molecules). Important bond lengths [pm] and angles [°]: Ni1-Te1 251.9(1), Ni2-Te1 245.7(1), Ni1-P1 214.5(2), Te1···Te1' 327.7(1), P1-C 183.7-184.2(4), Ni-C(Cp) 208.3-216.3(5), C(Cp)-C(Cp) 138.0-142.0(9); P1-Ni1-Te1 93.1(1), Te1-Ni2-Te1' 83.7(1), Ni2-Te1-Ni1 107.5(1), Ni2-Te1-Ni2' 95.7(1), Ni1-Te1-Ni2' 106.6(1).

Figure 2 shows the molecular structure of **2b**.[4] **2b** ($\bar{1}$ symmetry) contains four NiCp units which are bridged by μ_3-Te ligands; two Ni atoms (Ni1, Ni1') are also bound to PPh_3, and the Ni–Te bonds are different in length. Diamagnetic **2b** contains 72 valence electrons and obeys the 18-electron rule. Accordingly, there are no bonding interactions between the Ni atoms (Ni···Ni2 398, Ni2···Ni2' 362 pm).

Similarly as in **1a**, the distances between the bridging E-ligands in **2b** (Te···Te 327.7(1) pm) and in the isostructural **2a** (Se···Se 311.7(1) pm) point to bonding interactions. The formation of **2** in the reaction of PPh_3 with the Ni_4 cluster of **1** is consistent with a cluster opening, for which further examples have already been found in other multinuclear complexes.[9] Thus, $[Ru_4(CO)_{11}(PPh_2)]$ reacts with CO with opening of a Ru–Ru bond to give $[Ru_4(CO)_{13}(PPh_2)]$.[10]

Experimental

1a/2a: A solution of $[NiCp(PPh_3)Cl]$ (1.5 g, 3.5 mmol) in THF (40 mL) was treated dropwise with a solution of $Se(SiMe_3)_2$ (0.38 mL, 1.75 mmol) in THF (10 mL). The solution turned dark brown in color within a few minutes. After 24 h the reaction mixture was filtered, yielding 0.4 g of **1a** (68% yield). Treatment of the residue with 30 mL of THF and covering of the mixture with heptane led to separation of crystalline **1a**. The filtered reaction solution was covered with a layer of hexane. This led to crystallization of 0.30 g of **2a** (29% yield).

1b and **2b** were obtained analogously by reaction of 2.8 g (6.6 mmol) of $NiCp(PPh_3)Cl$ with 0.91 g (3.3 mmol) of $Te(SiMe_3)_2$ in 40 mL of THF.

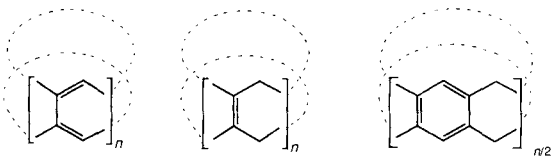
Towards the Making of [12]Collarene**

By *Peter R. Ashton, Neil S. Isaacs, Franz H. Kohnke, Alexandra M. Z. Slawin, Catriona M. Spencer, J. Fraser Stoddart,** and *David J. Williams*

[12]Cyclacene **1** ($n = 12$), a constitutional isomer of kekulene,[1] is a challenging and intriguing target on account of the mystery surrounding[2,3] its molecular and supramolecular properties. While unsaturated hydrocarbons, such as **1** ($n = 12$), are of considerable theoretical interest,[4] their extended conjugated π-systems could confer upon them high reactivities,[5] thus rendering them possibly less easy to prepare and handle than the partially-hydrogenated analogues, [12]beltene **2** ($n = 12$)[3] and [12]collarene **3**



1 **2** **3**

($n = 12$).[6] In this communication, we report the synthesis of the hydrocarbon **7**, which is a common and immediate precursor of [12]cyclacene **1** ($n = 12$) and [12]beltene **2** ($n = 12$) as well as of [12]collarene **3** ($n = 12$): in so doing, we describe how the octahydro[12]cyclacene derivative **7** can be prepared in two steps (Scheme 1) from **4**[7] via a dideoxy derivative **5**: also, we discuss the X-ray structure of the water complex formed by **5** in the solid state.

Deoxygenation[8] (Scheme 1) of **4** at the 3 and 9 o'clock positions[9] afforded[10] **5** in 43% yield. The X-ray crystal structure[11] of **5** (Fig. 1) reveals that, as expected, the four oxygen atoms at 1, 5, 7, and 11 o'clock in **5** lie on the outside of the macropolycycle whilst the four pairs of methine hydrogen atoms at 1:30, 4:30, 7:30, and 10:30[9] are directed into the center of the rigid molecular cavity. The most striking feature of this structure is the Celtic cross-like cavity within which the water molecule is trapped. The cavity has an approximately square cross-section with distances between the mean planes of the parallelly-disposed aromatic rings of 8.9 Å (3 to 9 o'clock) and 9.6 Å (6 to 12 o'clock). This geometry contrasts with the oval-like cavity present[7] in **4** in its solid state where the equivalent 6 to 12 o'clock distance is 7.9 Å. The water molecule which resides on the crystallographic center of symmetry at the center of the macropolycyclic ring in **5** does not enter into any hy-

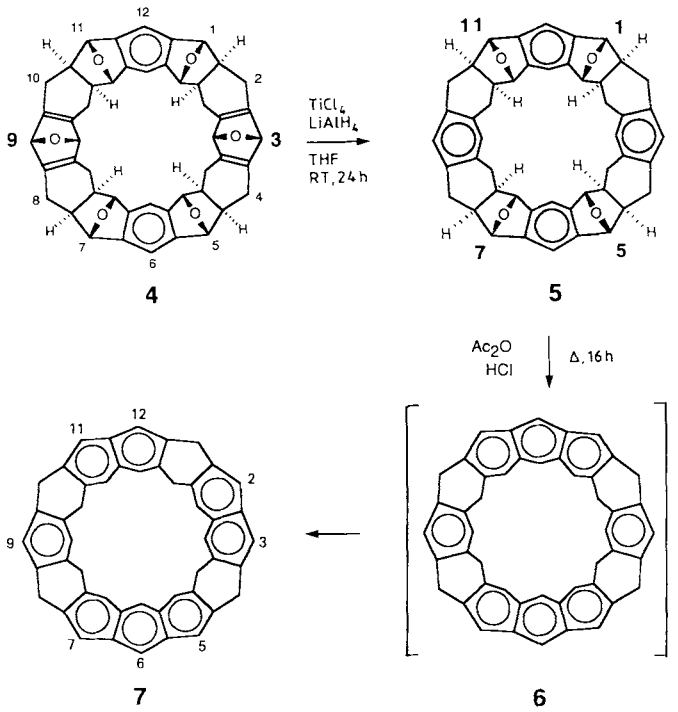

Scheme 1. Synthesis of **7** from **4** via **5** and (possibly) **6**.

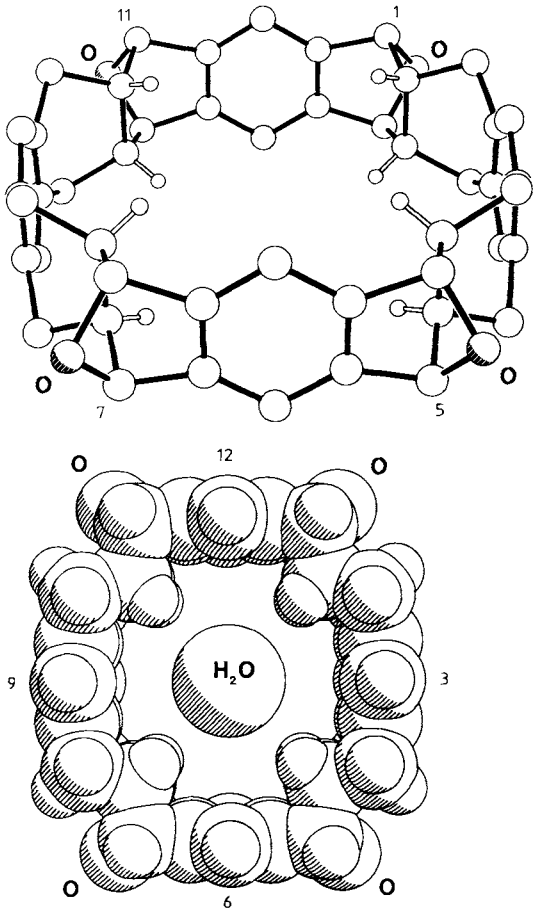

Fig. 1. Top: Structure of **5** in the crystal. Crystal data: orthorhombic, $a=12.026(10)$, $b=12.511(10)$, $c=23.890(15)$ Å, $V=3594$ Å^3, space group *Pbca*, $Z=4$ (the structure has a center of symmetry), $\rho=1.29$ g cm^{-3}, $\mu(Cu_{K\alpha})=6$ cm^{-1}, 1043 independent observed reflections [$|F_o| \geq 3\sigma(|F_o|)$], $\theta \leq 50°$], $R=0.128$. A disordered water molecule sits on the center of symmetry about which **5** is disposed. Bottom: Space-filling representation of the structure of **5**. In view of the disorder in the positions of the hydrogen atoms, the water molecule has been represented as a sphere with radius equivalent to the envelope of a water molecule.

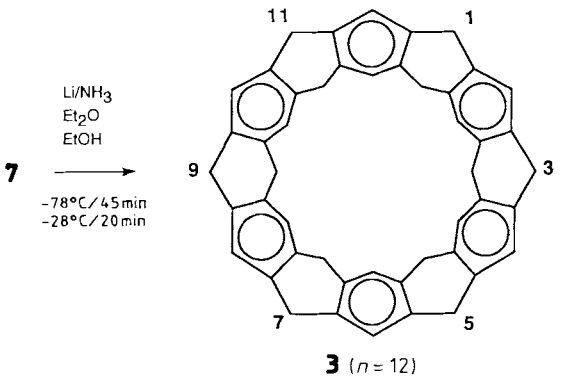
drogen bonding, the water hydrogen atoms being >2.7 Å away from any potential interactive sites within the cavity.[12]

Dehydration[13] of **5** at 1, 5, 7, and 11 o'clock (Scheme 1)[9] gave a mixture of isomeric hydrocarbons (all displaying molecular ions with *m/z* 608 in their EIMS) from which **7** was isolated as the major component after chromatography on much silica gel using a lot[14] of benzene as eluant! The constitution of **7**, which comprises *one benzene, one anthracene,* and *two naphthalene* units was confirmed by (*i*) the identification of *four anisochromous AB systems* in the ^{1}H-NMR spectrum (400 MHz) recorded in $C_6D_5CD_3$ ($\delta_{A1}=3.94$, $\delta_{B1}=3.49$; $\delta_{A2}=3.73$, $\delta_{B2}=3.37$; $\delta_{A3}=3.68$, $\delta_{B3}=3.31$; $\delta_{A4}=3.63$, $\delta_{B4}=3.35$)[15] arising from the *four constitutionally-heterotopic 1,4-cyclohexadiene units* uniquely present[16] in **7** and (*ii*) the ^{1}H-NMR chemical shifts in CD_2Cl_2 (400 MHz) at $\delta=6.91$ and 7.77 respectively for the protons on the benzene ring at 9 o'clock and for the protons[17] associated with the central aromatic ring of the anthracene unit located between 5 and 7 o'clock in **7**.

Hydrocarbon **6**, which is very likely the initial product of the dehydration of **5**, undergoes acid-catalyzed isomerization[18] to octahydro[12]cyclacene **7**. This hydrocarbon, which is expected to be thermodynamically more stable[18] than **6** on account of (*i*) the ability of **7** to attain[16] a higher resonance energy than **6** and (*ii*) the lower macroring strain energy present in **7** compared with **6**. The low solubility[14] and high thermal stability (m.p. >600 °C)[13] are reminiscent of the properties of kekulene.[1] The EIMS of **7** shows intense $M^{\oplus}$ and $M^{2\oplus}$ ions at *m/z* 608 and 304 respectively with the characteristic pattern for loss of hydrogen observed in the EIMS of compounds such as 1,2-dihydronaphthalene and 9,10-dihydrophenanthrene. This observation augurs well for the preparation of [12]cyclacene **1** ($n=12$).



Scheme 2. The conversion of **7** into the [12]collarene **3** ($n=6$) using Birch reduction conditions.

Preliminary investigations of the Birch reduction of **7** (Scheme 2), with [12]beltene **2** ($n=12$) as the synthetic objective, have revealed the presence in the desorption electron impact mass spectrum (with *m/z* 612) of a dodecahydro[12]cyclacene which probably has the constitution **3** ($n=12$). In view of the maximization of the resonance energy achieved[16] by the six alternating benzene rings in **3** ($n=12$), [12]collarene most likely occupies a global energy minimum along the reaction pathway between **7** and [12]beltene **2** ($n=12$).

Experimental

5: A suspension of **4** (315 mg, 0.44 mmol) in THF (15 mL) was added at 0°C to the reagent system previously prepared by refluxing THF (110 mL) containing $TiCl_4$ (1.9 mL, 17.3 mmol) and $LiAlH_4$ (350 mg, 9.21 mmol) for 5 min. The reaction mixture was stirred at room temperature for 18 h and then worked up by adding Et_3N then 20% aqueous K_2CO_3 solution before extracting the crude product with CH_2Cl_2 to yield, after chromatography (SiO_2/$CHCl_3$-MeOH), **5** [128 mg, 43%, crystallized from $CHCl_3$, m.p. > 250°C, *m/z* (positive ion FABMS) 680 for $M^{\oplus}$: ^{1}H-NMR ($CDCl_3$): $\delta = 1.11$ (m, 8H), 2.62 (m, 8H), 2.64 (m, 8H), 5.09 (s, 8H), 6.69 (s, 4H), 6.84 (s, 4H); ^{13}C-NMR ($CDCl_3$): $\delta = 31.8$, 47.0, 83.5, 110.6, 125.6, 138.1, 146.2]. Single crystals, suitable for X-ray crystallography, were grown by the vapor diffusion method ($CHCl_3$/MeOH).

7: **5** (100 mg, 0.147 mmol) was suspended (ultrasonication) in 5:1 Ac_2O:conc. HCl (30 mL) and heated under reflux (Ar) for 16 h. Work-up involved neutralization ($NaHCO_3$–H_2O/5 mL), liquid-liquid extraction (ultrasonication with boiling C_6H_6/80 mL), and chromatography (SiO_2) using hot C_6H_6 as eluant! Yield of **7**, 50.4 mg, 56%, sublimed at 450°C/10^{-3} torr, m.p. > 600°C, *m/z* (EIMS) 608.2501 for $M^{\oplus}$: ^{1}H-NMR (CD_2Cl_2): $\delta = 3.57$–4.23 (4AB, 16H), 6.91 (m, 2H), 7.25 (m, 8H), 7.40 (m, 4H), 7.77 (m, 2H).

3 ($n = 12$): A suspension of **7** (5 mg) in Et_2O (3 mL) was added to Li (150 mg) in NH_3 (50 mL) and EtOH (5–6 drops). The reaction mixture was stirred at −78°C for 45 min before allowing it to warm up so that the NH_3 evaporated. Excess of Li was destroyed (EtOH) and the product was partitioned between C_6H_6 and H_2O. The organic layer yielded a product which exhibited a λ_{max} at 235 nm in CH_2Cl_2 and gave *m/z* (positive ion FABMS) 613 for $(M+H)^{\oplus}$; desorption electron impact mass spectrometry carried out over the temperature range 400–900°C at 50°C/s indicated a mixture of compounds with the most intense peak emerging at *m/z* 612: this conclusion was confirmed by the ^{1}H-NMR (CD_2Cl_2) spectrum which revealed a prominent AB system ($\delta_A = 3.67$, $\delta_B = 3.48$ with $J_{AB} = 15$ Hz) and a prominent singlet ($\delta = 6.92$).

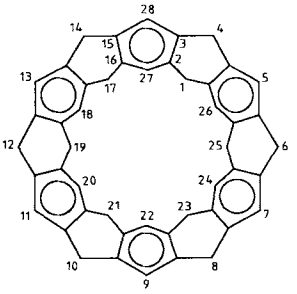
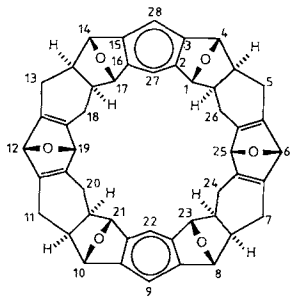
2 ($n = 12$)



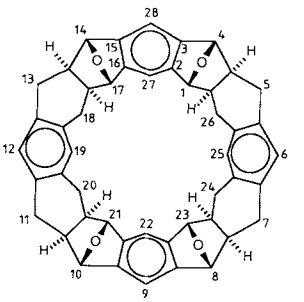
3 ($n = 12$)

which are comprised of alternating fused benzo and fused cyclohexa-1,4-diene as [*n*]collarenes. Thus, [12]collarene is represented by the full structural formula **3** ($n = 12$) shown in Scheme 2 and has the systematic name, 1,4,6,8,10,12,14,17,19,21,23,25-dodecahydro-2,16:3,15-dimethanoundecacene.

[7] The real advances in synthetic chemistry occur at the laboratory bench and not on the office desk. In personal recognition of the talent and tenacity shown by Dr. *Kohnke* in the synthesis (F. H. Kohnke, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem. 99* (1987) 941; *Angew. Chem. Int. Ed. Engl. 26* (1987) 892) of **4**, the senior author of this communication proposes (J. F. Stoddart, *J. Incl. Phenom.*, in press) to call **4**–the first macropolycyclic compound of its kind to be isolated and characterized—*kohnkene*. The systematic name for kohnkene **4** is *rel*-(1*R*,4*S*,4a*S*,7a*R*,8*R*,10*S*,10a*S*,13a*R*,14*R*,17*S*,17a*S*,20a*R*,21*R*,23*S*,23a*S*,26a*R*)-1,4:6,25:8,23:10,21:12,19:14,17-hexaepoxy-1,4,4a,5,6,7,7a,8,10,10a,11,12,13,13a,14,17,17a,18,19,20,20a,21,23,23a,24,25,26,26a-octacosahydro-2,16:3,15-dimethanoundecacene; we thank Dr. *A. D. McNaught* (The Royal Society of Chemistry, London) for his assistance in deriving systematic names for **2**–**4**.



4



5

[8] Deoxygenation of **4** to give **5** is *not* a trivial reaction. Before successfully employing the conditions reported in Scheme 1, we had established that PPh_3, PI_3, and P_2I_4 were unsuitable. These findings accord with those of others (H. Hart, G. Nwokogu, *J. Org. Chem. 46* (1981) 1251; Y. D. Xing, N. Z. Huang, *ibid. 47* (1982) 140) who have investigated the deoxygenation of 1,4-epoxyarenes. Using $TiCl_4$–$LiAlH_4$, *Xing* and *Huang* have prepared tetraphenylene from 1,4:9,12-diepoxy-1,4,9,12-tetrahydrotetraphenylene in 50% yield. Thus, the 43% yield obtained under identical conditions for the conversion (Scheme 1) of **4** into **5** compares favorably with results reported in the literature for less exotic compounds.

[9] We find the clock numbering system particularly useful when discussing the molecular structures, chemical modifications, and physical properties of derivatives of [12]cyclacene **1** ($n = 12$). While rings can be identified as occurring on the hour at 1, 2, 3, ... o'clock, the ring junctions correspond to half-past the hour and so can be identified at 1:30, 2:30, 3:30, ... etc. After this article was submitted for publication, a communication appeared in the literature (C. B. Knobler, F. C. A. Gaeta, D. J. Cram, *J. Chem. Soc. Chem. Commun. 1988*, 330) where a clock numbering system has been employed in discussing the solid state structure of a 1:1 complex between phenylglycine and a chiral crown ether.

[10] While **4**, when dissolved in CH_2Cl_2 or $CHCl_3$ solutions, undergoes a certain amount of decomposition on standing, possibly as a result of retro Diels–Alder reactions, this problem did not arise even when **5** was allowed to stand in CH_2Cl_2 or $CHCl_3$ solutions for many months.

[11] Nicolet R3m diffractometer, *w* scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically: the high value for *R* is a result of the limited and poor quality data obtained for a very small partially-twinned crystal. Further details of these structural investigations can be obtained from the Director of the Cambridge Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[12] Although disordered about the crystallographic center of symmetry, the positions of the individual hydrogen atoms in the water molecule have been determined and are directed principally towards the pairs of methine protons at 1:30 and 7:30. The water oxygen atom is > 3.5 Å removed from any of the four pairs of inward pointing methine hydrogen atoms.

[13] See, for example, H. Hart, N. Raja, M. A. Meador, D. L. Ward, *J. Org. Chem. 48* (1983) 4357.

[14] Whilst **4** and **5** are moderately soluble in both CH_2Cl_2 and $CHCl_3$, as expected, the hydrocarbon **7** is much less soluble in these solvents but is sparingly soluble in both C_6H_6 and $C_6H_5CH_3$, which do not dissolve **4** or **5**.

[2] F. Vögtle, *Top. Curr. Chem. 115* (1983) 157.

[3] R. W. Alder, R. B. Sessions, *J. Chem. Soc. Perkin Trans. 2 1985*, 1849. Compounds of the type **2** have been referred to in this paper as [*n*]beltenes. For more background to this trivial nomenclature system, see A. Nickon, E. F. Silversmith: *Organic Chemistry: The Name Game*. Pergamon Press, New York 1987, p. 110. Since this communication was submitted, a paper has been published in which the beltenes are referred to as columnenes: R. O. Angus, Jr., R. P. Johnson, *J. Org. Chem. 53* (1988) 314.

[4] S. Kivelson, O. L. Chapman, *Phys. Rev. B 28* (1983) 7236.

[5] Linear acenes from naphthalene to heptacene have been synthesized. See, for example, E. Clar, *Polycyclic Hydrocarbons, Vol. 1*, Academic Press, New York 1964, Ch. 10 and W. J. Bailey, Chien-Wei Liao, *J. Am. Chem. Soc. 77* (1955) 992. Higher homologues ($n > 7$) in the $(C_4H_2)_n$ series have proved to be too reactive to isolate using ordinary laboratory techniques.

[6] The systematic name for [12]beltene **2** ($n = 12$) is 1,4,5,6,7,8,9,10,11,12,13,14,17,18,19,20,21,22,23,24,25,26-docosahydro-2,16:3,15-dimethanoundecacene. We propose to refer to compounds of the general type **3**,

[15] The separate AB systems (J_{AB} = 12.5–13.5 Hz) were identified by a series of double irradiation experiments.

[16] If it is assumed that there are no more than *three* contiguous aromatic rings (i.e. there is no more than *one* fused cyclohexa-1,4-diene unit insulating the four aromatic residues) in the hydrocarbon resulting from complete dehydration of **5**, then **7** is the only constitution which can give rise to the observed ^{1}H-NMR spectroscopic data. If A ≡ anthracene, B ≡ benzene, N ≡ naphthalene and, if, to a first approximation, resonance energies (RE) of 84, 36, and 61 kcal mol^{-1} are assumed for A, B, and N respectively, then a constitution, e.g. the octahydro[12]cyclacene **7**, of [A + B + 2 N] units has a RE of 242 kcal mol^{-1}, which is more stable than a constitution, e.g. octahydro[12]cyclacene **6**, of [2 A + 2 B] units with 240 kcal mol^{-1} RE, but it is less stable than a constitution of [4 N] units with a RE of 244 kcal mol^{-1}. Thus, **7** may be an intermediate en route to the octahydro[12]cyclacene containing *four* naphthalene units. Following on this argument, it is recognized that **7** may not be the most thermodynamically-stable isomer: the acid-catalyzed dehydration of **5** merits detailed investigation to establish (a) if **6** can be isolated and (b) if **7** can be equilibrated to any other isomer, e.g. the octahydro[12]cyclacene containing *four* naphthalene units. Also, on the assumption that there are no more than three contiguous aromatic rings, the RE (kcal mol^{-1}) for the dodecahydro[12]cyclacenes containing different combinations of aromatic residues are [2 A] (168); [1 A + 1 B + 1 N] (181); [3 N] (183); [1 A + 3 B] (192); [2 B + 2 N] (194); [4 B + 1 N] (205); [6 B] (216). It follows that [12]collarene **3** (n = 12) has the highest possible RE of all the possible constitutional isomers that contain *six* aromatic and six insulating fused cyclohexa-1,4-diene rings.

[17] Note that the chemical shift for these central protons resonate ca. 0.63 ppm upfield from those in anthracene.

[18] Isomerizations of this type have been observed previously (E. Clar: *Polycyclic Hydrocarbons, Vol. I*, Academic Press, New York 1964, p. 65) in partially hydrogenated polyacenes. If a reshuffle of the aromatic rings can lead to a higher RE for the molecule, this will occur even under very mild conditions, e.g. the recently reported isomerization of I → II during the attempted crystallization of I: J. Luo, H. Hart, *J. Org. Chem. 52* (1987) 4833.

Extremely Short Non-Bonding Oxygen–Oxygen Distances: The Crystal Structures of $NbBO_4$, $NaNb_3O_8$, and $NaTa_3O_8$**

By *Klaus-Jürgen Range*,* *Manfred Wildenauer*, and *Anton M. Heyns*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

The distances between oxygen atoms not directly bound to each other in oxidic compounds can vary over a wide range.[1] Apart from some small anions in which very short O–O distances follow directly from very short central atom-oxygen distances,[2] only two examples have thus far been reported for O–O distances < 2.30 Å (Stishovite (high-pressure SiO_2): O–O 2.29 Å;[3] andalusite (Al_2SiO_5): O–O 2.25 Å[4]). We have now found unusually short oxygen-oxygen distances of around 2.20 Å in the compounds $NbBO_4$, $NaNb_3O_8$ and $NaTa_3O_8$ synthesized under high pressures in our laboratory.

$NbBO_4$ was first observed as a by-product in the high-pressure reaction of K_2CO_3 and Nb_2O_5 in a BN crucible.[5] It is a colorless substance and can be prepared in pure form by reaction of a stoichiometric mixture of H_3BO_3 and Nb_2O_5 at $p > 25$ kbar and $T > 800$ °C followed by quenching to ambient conditions.[6] $NbBO_4$ is metastable under normal pressure, and, on tempering (1 bar, 700 °C, 12 h), transforms into a mixture of γ'-Nb_2O_5 and amorphous B_2O_3.

$NbBO_4$ is the first structurally well characterized orthoborate of the type MBO_4[7] and concomitantly the only compound so far in the Nb_2O_5–B_2O_5 system with a definite composition.[8] Cations and anions occupy the respective positions of the zircon($ZrSiO_4$) structure,[9] although all coordination polyhedra are more strongly distorted than in $ZrSiO_4$.[10] Boron is coordinated tetrahedrally by oxygen (distances: B–O 1.469(2) Å (4×); O–O 2.222(3) Å (2×), 2.484(3) Å (4×), while niobium is surrounded by eight oxygen atoms in the form of a dodecahedron (distances: Nb–O 2.095(2) Å (4×), 2.037(2) Å (4×); O–O distances, see Table 1). The structure is determined by chains of edge-shared BO_4 tetrahedra and NbO_8 dodecahedra parallel to [001], which in turn are linked together by edge-shared dodecahedra. The common edges of tetrahedra and dodecahedra are markedly shortened (2.222 Å; Fig. 1 and Table 1). This drastic shortening cannot be explained electrostatically.

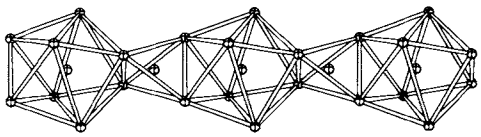

Fig. 1. Edge-shared NbO_8 dodecahedra and BO_4 tetrahedra in the crystal structure of $NbNO_4$. The O–O distance in the sharing edges is 2.222 Å.

The NbO_8 dodecahedra in $NbBO_4$ (Fig. 2) show characteristic distortions compared to the "most favorable dodecahedron" described by *Hoard* and *Silverton*[11] (Table 1). That these distortions cannot be attributed to the edge-sharing with BO_4-tetrahedra follows from the fact that NbO_8 dodecahedra with almost the same dimensions likewise occur in a high-pressure phase of $NaNb_3O_8$.

The synthesis of HD-$NaNb_3O_8$ was accomplished by high-pressure reaction of a mixture of $NaNbO_3$ and Nb_2O_5 in a modified Belt apparatus[6b] (pyrophyllite pressure capsule,[12] 30 kbar, 1100 °C, 30 min) followed by quenching to ambient conditions. The colorless compound is metastable at atmospheric pressure; after tempering (1 bar, 800 °C,

[e] Edge sharing between two dodecahedra. [f] Owing to the different point symmetries of the NbO_8 dodecahedra ($\bar{4}2m$ in $NbBO_4$ and 222 in $NaNb_3O_8$), splitting of the bonds takes place. [g] Edge sharing between dodecahedra and pentagonal bipyramids.

12 h), a Guinier photograph shows the reflections of the normal-pressure modification of $NaNb_3O_8$.[13,14] So far it has been impossible to clarify unequivocally whether the normal-pressure phase formed by reconversion has the ideal composition (Na : Nb = 1 : 3) or the deviating composition (Na : Nb = 1 : 2.7) postulated by *Craig* et al.[15]

HD-$NaNb_3O_8$[16] crystallizes in a novel tunnel structure. The structure[17] comprises two crystallographically independent niobium atoms, Nb(1) and Nb(2), which form different coordination polyhedra, namely dodecahedra $Nb(1)O_8$ (Nb-O distances: 4 × 2.070(1) Å, 4 × 2.081(1) Å) and distorted pentagonal bipyramids $Nb(2)O_7$ (Nb-O distances: 1.834(3) Å, 1.947(2) Å, 1.948(2) Å, 1.959(2) Å, 2.212(3) Å, 2 × 2.367(2) Å). Structurally decisive are chains of edge-shared $Nb(1)O_8$ dodecahedra (Fig. 3) and edge-

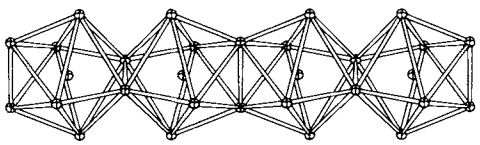

Fig. 3. Edge-shared $Nb(1)O_8$ dodecahedra in the structure of $NaNb_3O_8$. The O-O distance in the sharing edges is 2.218 Å.

shared pentagonal $Nb(2)O_7$ bipyramids parallel to [001]; the chains are connected to each other via common edges and corners. The special arrangement of the chains leads to the formation of channels having an elongated hexagonal cross-section, running along the *c* axis (Fig. 4), in which the $Na^{\oplus}$ ions are accomodated. Although the temperature factors indicate a relatively high mobility of the $Na^{\oplus}$ ions in these channels, we have thus far been unable to exchange the $Na^{\oplus}$ ions for other cations. Once again a

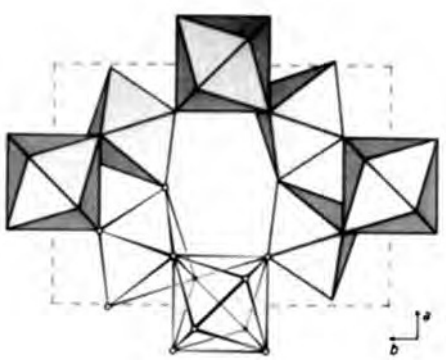

Fig. 4. $NaNb_3O_8$: projection of the crystal structure on the *a,b* plane.

remarkable structural feature is the drastic shortening of every opposite pair of dodecahedron edges, resulting in an oxygen–oxygen distance of 2.218 Å. To the best of our knowledge these are the shortest non-bonding oxygen–oxygen distances found so far in transition metal–oxygen polyhedra.

As shown in Table 1, the dimensions of the NbO_8 dodecahedra in $NbBO_4$ and HD-$NaNb_3O_8$, that is two compounds adopting completely different crystal structures, are almost identical. We are therefore convinced that MO_8 polyhedra, specifically MO_8 dodecahedra (M = Nb, but maybe also Ta, Mo, W), can be structure-determining to a much greater extent than has hitherto been assumed.[18]

$NaTa_3O_8$, which can be synthesized at 35 kbar and 1100 °C from $NaTaO_3$ and Ta_2O_5, is isotypic with $NaNb_3O_8$.[19] Because of the very similar ionic radii of $Nb^{5\oplus}$ and $Ta^{5\oplus}$, the lattice dimensions and bond lengths for $NaNb_3O_8$ and $NaTa_3O_8$ hardly differ from each other (shortest O-O distance in the $Ta(1)O_8$ dodecahedra: 2.225 Å).

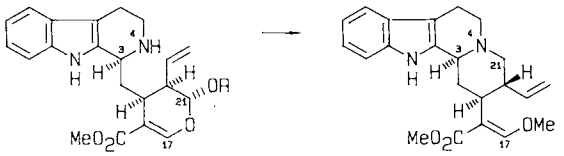
Synthesis of Strictosidine Analogues by Hetero-Diels–Alder Reaction and Their Biomimetic Transformation to Indole Alkaloids**

By *Lutz-F. Tietze,* Jürgen Bachmann,* and *Wolfgang Schul*

The glucoside strictosidine **1a**, which is formed in plants from secologanin[1] and tryptamine in a reaction catalyzed by strictosidine synthase,[2] is the first nitrogen-containing precursor of the over one thousand monoterpenoid indole alkaloids[3] as well as of the cinchona and pyrroloquinoline alkaloids. Many of these compounds exhibit pronounced biological activity[4] and are used as pharmaceuticals, for example the dimeric indole alkaloid vincristine.[5]

Enzymatic glycolysis[6] of strictosidine **1a** leads to the highly reactive aglycone **1b**, which can react in vivo via the dialdehyde form **1c** by reductive amination to give a large variety of products such as corynantheine **2**. A direct extension of this principle to the in vitro synthesis of indole alkaloids, however, encounters considerable difficulties owing to the small difference in reactivity of the aldehyde groups in **1c**; furthermore, the formation of **1b** from **1a** is limited to enzymatic cleavage in an aqueous system.[7] Accordingly, an efficient biomimetic synthesis of indole alkaloids[8] requires a simple route to strictosidine analogues that, instead of a glucosyl group as in **1a**, contain a readily removable protecting group and exhibit different reactivities at C-17 and C-21 in the aglycone. Moreover, the in vitro transformation of such strictosidine analogues should afford new insights into the so far only partially understood biosynthetic transformation of **1a** to indole alkaloids.



1a: R = β-D-glucose
1b: R = H
1c: dialdehyde form of **1b**

2

The synthesis of the strictosidine analogues **8** was achieved in a simple fashion in 92% yield by tandem Knoevenagel/hetero-Diels–Alder reaction[9] of the aldehyde **3a**, which is obtainable from tryptamine and a mixed malondialdehyde acetal,[10,11] *N,N*-dimethylbarbituric acid **4** and (*E*)-benzyl 1-butenyl ether **6**[12] (Scheme 1). The initially formed 2-alkylidene-1,3-dicarbonyl compound **5** reacts with **6** even at 20°C, since the heterodiene moiety in **5** has a low-lying LUMO[9] owing to the electron-accepting substituent in the α position. The stereoselectivity is less pronounced than for the intramolecular reactions, whose *i-de* and *ni-de* values[13] are greater than 90%. Compounds **8a**, **8b**, **8c**, and **8d** are thereby obtained in a ratio of 3 : 3.6 : 1 : 1.2 (HPLC); separation could be carried out by chromatography on silica gel. The diastereoselectivity induced by the stereogenic center C-3 is relatively high for a 1,3-induction in an acyclic system (**8a** + **8b** : **8c** + **8d** = 3 : 1); on the other hand, the *endo/exo* selectivity is low (**8b** : **8a** = 1.2 : 1; **8d** : **8c** = 1.2 : 1).

A discussion of the transition structures leading to the diastereomers is extremely difficult; thus, **8a** — and, similarly, **8b**–**d** — can be formed either via an *exo-E-syn* geometry[14] with attack occurring from above (*Re*)[15] or via an *endo-Z-syn* arrangement with attack occurring from below (*Si*), since two heterodiene systems (*E* and *Z*) are present in **5**. (*Z*) Heterodienes are generally less reactive.[16] We therefore propose the following transition-state structures: *Re-exo-E-syn* for **8a**, *Re-endo-E-anti* for **8b**, *Si-exo-E-syn* for **8c**, and *Si-endo-E-anti* for **8d**. The preferred attack from the *Re* side in **5** can be explained by steric shielding of the *Si* side of the (*E*)-heterodiene system by the substituent on nitrogen.

The subsequent cleavage of the protecting groups on C-21 and N-4 in **8** and the reductive amination proceed as a cascade reaction by hydrogenation with Pd/C as catalyst. The initially formed aglycone **9**, which was not isolated, undergoes transformation to the iminium salt **10** after initial opening to **7**; under the reaction conditions, **10** is immediately hydrogenated to **11**. Thus **8a**, which at all stereogenic centers has the same relative configuration as strictosidine **1a**, reacts to give **11a** in 86% yield.[17] Under the same conditions, **8b** affords a 1 : 1 mixture of **11a** and **11b** in 76% yield, whereas **8c** and **8d** each selectively lead in 72% yield to **11c**. The isomeric mixture of **8** can also be

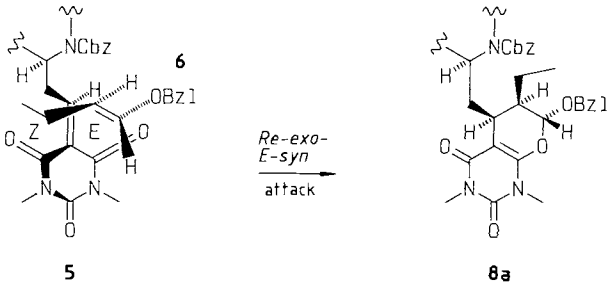
R_f(**8a**) = 0.60; R_f(**8b**) = 0.36; R_f(**8c**) = 0.77; R_f(**8d**) = 0.66.—b: H_2/Pd/C (10%), EtOH, 20°C/8 h. **8a** → **11a**: 86%; **8b** → **11a** + **11b** (ca. 1:1): 76%; **11b** can be obtained in pure form by recrystallization from MeOH; **8c** → **11c**: 72%; **8d** → **11c**: 72%.

employed directly in the hydrogenation to give **11a** in 45% yield. The reaction of **8b** to **11a** and of **8d** to **11c** is associated with an isomerization at C-20 demanding the intermediate formation of an enamine. It has not been possible so far to determine whether the hydrogenation occurs via the enamine or via the iminium salt structure; however, both reaction pathways should lead to the same distribution of products.[18] Also, the formation of an enamine is not necessary for the course of the reaction: use of benzyl 2-methyl-1-propenyl ether, instead of **6**, in the reaction sequence resulted in an 85% yield of the indole alkaloid derivatives **12a** and **12c** (2.7:1).



Compounds **11a** and **11b** are present as *trans*-quinolizidines (3-H(**11a**): $\delta = 3.90$), whereas **11c** displays a *cis*-quinolizidine structure (3-H: $\delta = 4.70$). The X-ray data reveals that the dimethylbarbituric acid group in **11b** is arranged axially and forms an intramolecular salt structure with N-4.[19]

The investigations have shown that the tandem Knoevenagel/hetero-Diels–Alder/hydrogenation sequence opens up a simple and general approach to the synthesis of indole alkaloids of the corynanthé type. By variation of the 1,3-dicarbonyl compound **4** and the enol ether **6**, it should be possible to obtain a wide range of products. The experiments described here were carried out with *rac*-**3b**; the reaction sequence can also be used, however, for the synthesis of enantiomerically pure indole alkaloids, since the acetal **3b** can be prepared in >95% *ee* from tryptophan.[20]

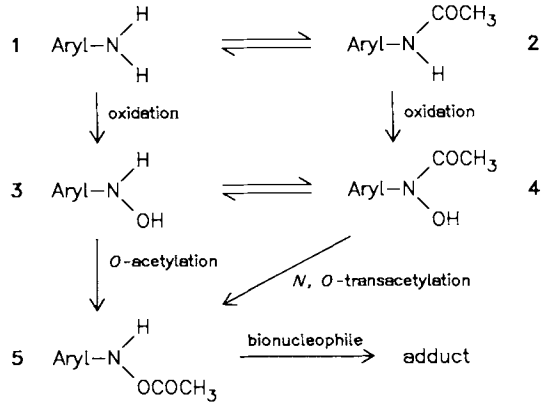
N-Aryl-*O*-acylhydroxylamines: Preparation by *O*-Acylation or *N*→*O* Transacylation and Reaction with Amines; Model Reactions for Key Steps Connected with the Carcinogenicity of Aromatic Amines**

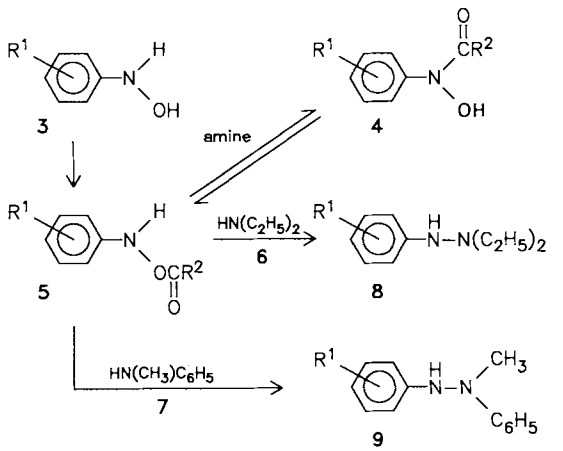
By *Gernot Boche,* Ferdinand Bosold,* and *Stefan Schröder*

The following reaction steps are considered to be important for the transformation of an aromatic amine into the active metabolite (ultimate carcinogen) and its decisive further reaction with bionucleophiles:[1]

After oxidation of the amine **1** to the hydroxylamine **3** or of the acetamide **2** to the hydroxamic acid **4**, *O*-acetylation of **3** or *N*→*O* transacetylation of **4**[2] should lead to the *N*-aryl-*O*-acetylhydroxylamine **5**, an active metabolite. It is assumed that such compounds react in the next step as electrophilic aminating reagents with bionucleophiles like DNA to give "adducts".[1] Herein we report on the in-vitro preparation of *o*-acyl derivatives of type **5** from **3** or from acylhydroxyamic acids such as **4**, and on the reaction of **5** with nucleophiles.



First of all we prepared the *O*-acylhydroxylamines **5aα**, **5aβ**, **5bα**, and **5bβ** by *O*-acylation of the corresponding hydroxylamines **3**[3–5] and investigated their reactivity towards the amines **6** and **7**. The hydrazines[4,6] **8** and **9**, respectively, are formed. The results are summarized in Table 1.[7]



a: R^1 = *m*-Br α: R^2 = CH_3
b: R^1 = H β: R^2 = $C(CH_3)_3$

Table 1. Reactions of the *O*-acyl compounds **5** with the amines **6** (**5**: 1.0 M in **6**) or **7** (**5**: 0.93 M in **7**) to give the hydrazines **8** and **9**, respectively.

No.	5	R^1	R^2	Amine	Hydrazine [%]	*T* [°C]	*t* [h]	Byproduct **A** [%] [a]
1	**5aα**	*m*-Br	CH_3	**6**	**8**, 40	55	0.5 [b]	55
2	**5aα**	*m*-Br	CH_3	**6**	**8**, 16	20	20	77
3	**5aα**	*m*-Br	CH_3	**7**	**9**, 88	80	1 [c]	—
4	**5aβ**	*m*-Br	$C(CH_3)_3$	**6**	**8**, 67	55	1 [c]	14
5	**5aβ**	*m*-Br	$C(CH_3)_3$	**7**	**9**, 85	20	72	—
6	**5bα**	H	CH_3	**6**	**8**, 27	20	5	73
7	**5bα**	H	CH_3	**7**	**9**, 90	20	5	—
8	**5bβ**	H	$C(CH_3)_3$	**6**	**8**, 20	20	16	72
9	**5bβ**	H	$C(CH_3)_3$	**7**	**9**, 50	20	16	45

[a] **A** = azoxy compound $R^1–C_6H_4–N{=}N^{\oplus}(O^{\ominus})–C_6H_4–R^1$ [5b, 9]. [b] **5aα** was added in **6**, which had been heated to 55°C. [c] The reaction partners were heated together.

The amination of *N*-nucleophiles by *O*-acylhydroxylamines **5**, especially by the *O-acetyl* compounds **5aα** and **5bα**, thus affords an in-vitro proof for the in-vivo reaction of this class of compounds with bionucleophiles.[1,10]

In addition, we were able to simulate in vitro the enzymatic *N*→*O*-transacetylation **4α**→**5α**[2] by amine catalysis.

[*] Prof. Dr. G. Boche, F. Bosold, Dipl.-Chem. S. Schröder
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, by the Deutsche Forschungsgemeinschaft, and by BASF AG.

To this end hydroxamic acids **4** were allowed to react with *diethylamine* **6** ($pK_a = 18.75$[11]) and the intermediary *O*-acylhydroxylamines **5** were trapped by the same amine to give the hydrazines **8**. In a second series of experiments the hydrazines **9** could likewise be obtained from the corresponding hydroxamic acid **4** by reaction with the less basic *N*-methylaniline **7** (pK_a ca. 11[11]), but only after *triethylamine* ($pK_a = 18.46$[11]) had been introduced for the catalysis of the $N \rightarrow O$-transacylation (see Table 2).

Table 2. Reactions of hydroxamic acids **4** with the amines **6** (**4**: 1.0 M in **6**) or **7** (**4**: 0.83 M in a 1:1 mixture of **7** and triethylamine) to give the hydrazines **8** and **9**, respectively.

No.	4	R^1	R^2	Amine	Product [%]	T [°C]	t [h]	Byproduct E [%] [a]
1	**4aα**	*m*-Br	CH_3	**6**	**8**, 84	55	40	—
2	**4aα**	*m*-Br	CH_3	**7**	**9**, 85	80	68	15
3	**4aβ**	*m*-Br	$C(CH_3)_3$	**6**	**8**, 92	55	8	—
4	**4aβ**	*m*-Br	$C(CH_3)_3$	**7**	**9**, 94	80	2	—
5	**4bα**	H	CH_3	**6**	**8**, 49	55	30	50
6	**4bα**	H	CH_3	**7**	**9**, 62	80	30	35
7	**4bβ**	H	$C(CH_3)_3$	**6**	**8**, 80	55	20	15
8	**4bβ**	H	$C(CH_3)_3$	**7**	**9**, 95	80	2	—

[a] E = Educt.

If the rate of formation of the *O*-acylhydroxylamine **5** is rapid, i.e. compared to its back reaction to the hydroxamic acid **4** and to any further reaction, it can be isolated. Thus, on treatment of the hydroxamic acid **4aβ** with triethylamine at 80°C for 1 h the *O*-pivaloylhydroxylamine **5aβ** is obtained in 95% yield.[5c] The higher stability of the *O-pivaloyl* derivative compared to the *N-pivaloyl* derivative was confirmed by MNDO calculations: according to the enthalpies of formation ΔH_f^0, **5bβ** (-25.2 kcal mol^{-1}) is preferred over **4bβ** (-20.1 kcal mol^{-1}) by $\Delta\Delta H_f^0 = 5.1$ kcal mol^{-1}.

Contrary to this finding, in the case of the *acetyl* compounds occurring in vivo the *hydroxamic acid* isomers are more stable. This was demonstrated by the reaction of **5aα** with two molar equivalents of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), the most effective amine catalyst ($pK_a = 24.32$[11]),[12] in triethylamine, which led after 10 min at 20°C to **4aα** in 98% yield. This experiment also proves the presence of an equilibrium, at least between **5aα** and **4aα**. The preferred formation of the acetylhydroxamic acid compared to the *O*-acetyl compound was again confirmed by the MNDO enthalpies of formation: **4bα** ($\Delta H_f^0 = -21.0$ kcal mol^{-1}) is 5.7 kcal mol^{-1} stabler than **5bα** ($\Delta H_f^0 = -15.3$ kcal mol^{-1}). It is therefore not surprising that all attempts to convert **4aα** and **4bα** with DBU (in triethylamine) into **5aα** and **5bα** respectively, were in vain.[13] In view of the in-vivo finding mentioned at the outset, however, it is decisive that acetylhydroxamic acids such as **4aα** and **4bα** can react via small equilibrium concentrations of the active metabolites **5aα** and **5bα** respectively with nucleophiles to give adducts.[14]

Summary: The *N*-aryl-*O*-acylhydroxylamines **5** described here can be prepared in vitro by *O*-acylation of the corresponding hydroxylamines **3** and by $N \rightarrow O$-transacylation from the corresponding hydroxamic acids **4**; they react with amines to give hydrazines such as **8** and **9**. Hence, reactions which are of fundamental importance for the carcinogenicity of aromatic amines could be simulated in vitro.

[3] Details on the preparation of **5aα**, **5aβ**, **5bα**, and **5bβ** as well as other *N*-aryl-*O*-acylhydroxylamines by acylation of hydroxylamines **3** with acetyl or pivaloyl cyanide will be given in a full paper.

[4] All the new compounds were characterized analytically (C,H,N), mass spectroscopically and IR spectroscopically or by their 400-MHz ^{1}H-NMR spectra.

[5] Numerous attempts have been made to synthesize *N*-aryl-*O*-acylhydroxylamines because of their importance in connection with the carcinogenicity of aromatic amines, but very few have been successful: a) *N*-acetoxy-2,4-dinitrophenylamine: W. Borsche, *Chem. Ber. 56* (1923) 1494; A. C. Huggett, J. L. Cone, S. S. Thorgeirsson, P. P. Roller, *J. Org. Chem. 52* (1987) 4933; b) the *O*-acylation of the arylhydroxylamines **3** with arylcarbonyl or acetyl cyanides has so far been the favored general method: S. Prabhakar, A. M. Lobo, M. M. Marques, *Tetrahedron Lett. 23* (1982) 1391; A. M. Lobo, M. M. Marques, S. Prabhakar, H. S. Rzepa, *J. Chem. Soc. Chem. Commun. 1985*, 1113; *J. Org. Chem. 52* (1987) 2925; c) *N*-(3-bromophenyl)-*O*-pivaloylhydroxylamine **5aβ**: M. Novak, L. H. Rovin, M. Pelecanou, J. J. Mulero, R. K. Lagerman, *ibid. 52* (1987) 2002; see also: d) T. R. Juneja, H. Dannenberg, *Tetrahedron 31* (1975) 701; e) E. S. Hand, W. W. Paudler, *J. Heterocycl. Chem. 12* (1975) 1063; f) Y. Kawazoe, O. Ogama, G.-F. Hung, *Tetrahedron 36* (1980) 2933; g) L. Christensen, P. E. Iversen, *Acta Chem. Scand. B33* (1979) 352; h) Y. Hashimoto, K. Shudo, T. Okamoto, *J. Am. Chem. Soc. 104* (1982) 7636; i) T. R. Juneja, A. Ojha, R. L. Gupta, *Indian J. Chem. 23B* (1984) 60; j) M. Demeunynck, M.-F. Lhomme, J. Lhomme, *J. Org. Chem. 48* (1983) 1171; k) M. Demeunynck, N. Tohme, M.-F. Lhomme, J. M. Mellor, J. Lhomme, *J. Am. Chem. Soc. 108* (1986) 3539.

[6] a) Hydrazines have also been observed in reactions of *N*-aryl-*O*-(diphenylphosphinoyl)hydroxylamines with amines: see G. Boche, R. H. Sommerlade, F. Bosold, *Angew. Chem. 98* (1986) 563; *Angew. Chem. Int. Ed. Engl. 25* (1986) 562; b) see also [5h].

[7] *Ortho* rearrangement products such as frequently occur in the case of *N*-aryl-*O*-acylhydroxylamines, or products in which the amine is in the phenyl ring [8], were not observed under the above reaction conditions.

[8] See [5b, c], and references cited therein.

[9] The formation of the azoxy compounds **A** in reactions of arylhydroxylamine derivatives is sufficiently well known; see also P. A. Smith: *Open Chain Nitrogen Compounds, Vol. 2*, W. A. Benjamin, Menlo Park 1966, p. 4.

Chirality Solely Due to the Presence of an Excited State**

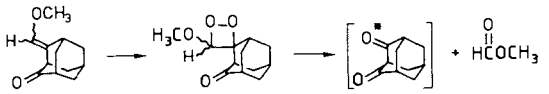
By *E. W. Meijer** and *Hans Wynberg*

One of the most fascinating challenges in the study of optical activity is the synthesis of a compound in which the optical activity is solely due to the presence of an excited state. This property is available in *meso* compounds with two identical chromophores, in which one of the chromophores is selectively excited. In the case of diketones with a plane of symmetry in the ground state, the chirality in the excited state is due to the out-of-plane geometry of one of the two carbonyl groups. We have focused our attention on 2,4-adamantanedione **1**, whose chiral excited state is **1***.

1 **1***

The only way to obtain **1*** in a high enantiomeric excess is by selective excitation of one of the two carbonyl groups of **1** by chemical conversion. The enantiomeric excess via a photochemical process is expected to be low, since the difference in absorption of right (or left) circular polarized light by the two carbonyls is governed by the dissymmetry factor in absorption. Obviously, resolution of an excited-state diketone belongs in the realm of fantasy.

Chemiexcitation of ketones is well known to occur via the decomposition of 1,2-dioxetanes.[1-3] A high yield of singlet-excited-state adamantanone is obtained from the 1,2-dioxetane of 2-(methoxymethylene)adamantane.[4] The chemical route towards optically active **1*** via the optically active 1,2-dioxetane **3** is based on our previous work.[5-8]



2 **3** **1***

The optically active precursor of **3** is enol ether **2**. The latter is prepared in several steps from adamantanone via the resolution of *endo*-bicyclo[3.3.1]non-6-ene-3-carboxylic acid.[8] A photooxygenation with $^1O_2$ at -50 °C, followed by rapid low-temperature column chromatography, afforded a solution of 1,2-dioxetane **3** in dichloromethane.

The ketodioxetane **3** was not stable enough to allow a structure determination. However, dilute solutions of **3** in *n*-heptane yielded chemiluminescence, ($\lambda_{max} = 420$ nm, characteristic of ketone fluorescence) when heated. The product, which could be isolated in almost quantitative yield proved to be 2,4-adamantanedione **1**. It is reasonable to assume that the chemiluminescence is obtained from the decomposition of **3**, which generates **1** in the excited state (**1***). The enantiomeric excess of **3** is assumed to be identical to that of the resolved starting material, to wit $ee = 69\%$. Therefore it is expected that in the formation of **1*** one of the two carbonyls is excited in favor over the other in an enantiomeric excess of 69%.

This synthesis of chiral **1*** is, to the best of our knowledge, the first example of a chemical route to a chiral compound (with high *ee*) whose chirality is solely due to the presence of an excited state.

The synthesis of **1*** is one challenge, the detection of optical activity in this short-lived molecule is another. It seemed obvious to measure the circular polarization of chemiluminescence (CPCL) in the thermal activation of **3**.[9] However, the CPCL measurements of **3** (10^{-3}-10^{-6} mol L^{-1} in *n*-heptane) showed complete lack of optical activity at the moment of emission ($g_{chemlum} = 0 \pm 3 \times 10^{-3}$).

This is probably caused by a fast racemization in the singlet-excited state. This racemization occurs by an energy transfer between the two carbonyls in the rigid conformation of **1***. This fast energy transfer in **1*** is reasonable due to the close proximity of the two carbonyls. The UV spectrum of **1** and the CD spectrum of its mono-^{18}O analogue even indicate some π overlap of these chromophores.[7] The intramolecular n,π^* energy transfer is fast relative to the lifetime of a singlet-excited-state ketone, pointing to a rate of energy transfer of $k_{ET} = 1 \times 10^{10}\ s^{-1}$. Energy transfer between carbonyl n,π^* excited states is a very intriguing phenomenon and several systems have been investigated,[10-13] showing both efficient and slow processes. Recently, the circular polarization in fluorescence was studied after excitation of *meso* diketones with circular polarized light,[13] indicating a very efficient energy transfer for carbonyl groups in close proximity to each other. Although triplet-triplet annihilation can be regarded as another source of racemization in the excited state, it is assumed to be of minor importance. This is based on both the reaction conditions used and the fact that up to now the occurrence of this phenomenon in 1,2-dioxetane chemiluminescence has not been reported.

From the preliminary results presented here we can conclude that a synthesis of a compound that is chiral solely in its excited state can be performed by chemiexcitation of a *meso* diketone via an optically active 1,2-dioxetane. In order to obtain stability with respect to racemization it is necessary to increase the distance between the two chromophores. This type of compound would enable us to investigate the rate of intramolecular energy transfer.

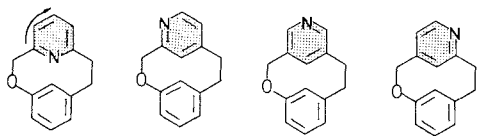
Influence of Chromophore Orientation on the Circular Dichroism of Isomeric Helical Molecules**

By *Klaus Jürgen Przybilla, Fritz Vögtle,* Martin Nieger,* and *Sybille Franken*

How does the circular dichroism of the helical[1] pyridinophane **1** change when the nitrogen atom in the six-membered ring successively moves further away from the O-atom (as in **2**-**4**)? The "rotation" of the pyridine chromophore in the plane of the six-membered ring systematically generates structural isomers—with retention of the rigid helical chiral molecular framework. The pyridinophanes **1**-**4** synthesized for the first time in connection



1 **2** **3** **4**

with our studies of this phenomenon differ only in the orientation[2] of the transition dipole moments of the two arene moieties with otherwise formally the same chromophores (e.g. **2** and **4**). In the pyridine-chromophores **1** and **3** the permanent dipole moments are in opposite directions.

Figure 1 shows the circular dichroism curves of the isomeric molecules after enantiomeric separation or enrichment on poly(diphenyl-2-pyridylmethylmethacrylate).[3] The isomers **1**-**4** show comparable curves: on going from right to left, i.e. from larger to smaller wavelengths, a strong negative Cotton effect is followed by a positive one and then a negative one again. All Cotton effects of **2**-**4** are shifted bathochromically, in the sequence $\mathbf{2} < \mathbf{4} < \mathbf{3}$, compared to those of **1**, and the distance between first and second maximum becomes progressively smaller in the same sequence.

The transition from pyridinophane to pyridiniophane by merely changing the measurement conditions (0.1 N aqueous HCl) leads to a significant bathochromic shift and broadening of the longest wavelength negative Cotton effect (Fig. 1b) and to a loss in structure of the curves. Thus, e.g., the weak maximum of **1** ($\Delta\varepsilon = +1.4$) at 293 nm disappears. In the short wavelength region, the CD curves are changed to such a significant extent that they cannot be correlated with those of the corresponding unprotonated molecules.[4] A comparison of the chiroptical properties of the pyridinophanes **1**-**4** with those of the likewise helical 1-oxa[2.2]metacyclophane **5** (see Scheme 2)[5] (Fig. 1a), whose resolution has now been successfully accomplished on cellulose-tris(3,5-dimethylphenyl)carbamate[6] in our laboratories, shows that, despite the simplicity of the molecular structures, a detailed analysis according to the exciton-chirality method[7] or the MO model[8] is necessary for the structure-chiroptic correlation.

The oxa[2.2]metacyclophane **5**,[5] with such a short C-O bond, is the narrowest-bracketed [2.2]metacyclophane

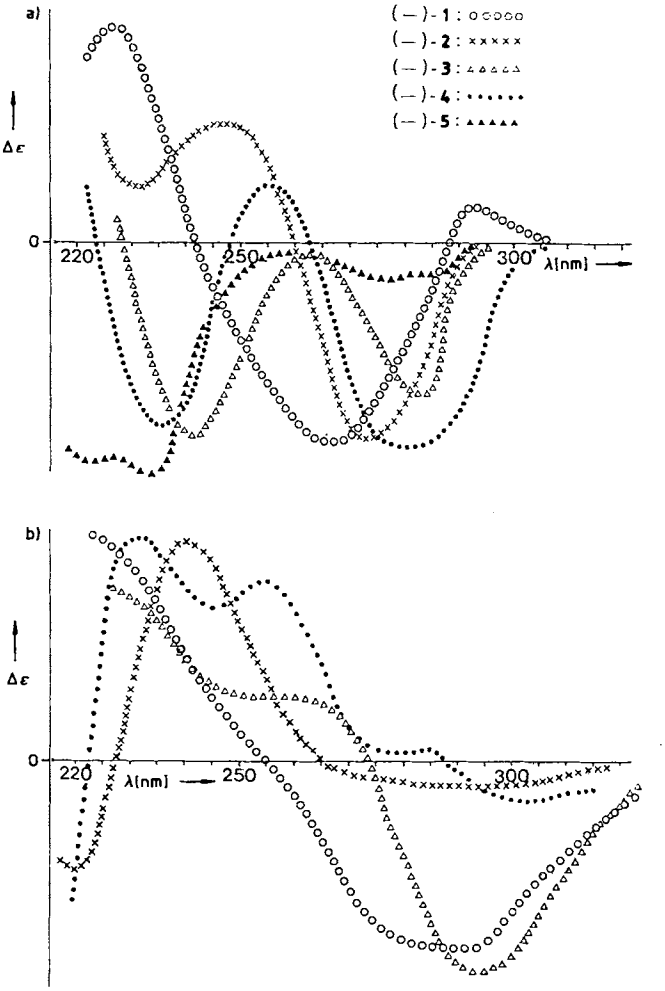


Fig. 1. Circular dichroism curves of the (enriched) (−)-enantiomers of **1**-**5**. a) In methanol, b) in 0.1 N HCl (**1** and **5** enantiomerically pure). **1**: $\Delta\varepsilon_{293} = +1.4$, $\Delta\varepsilon_{267} = -10.8$, $\Delta\varepsilon_{226} = +11.4$; **5**: $\Delta\varepsilon_{285} = -2.2$, $\Delta\varepsilon_{277} = -2.3$, $\Delta\varepsilon_{234} = -14.6$. (The CD curves of **2**-**4** are adjusted to the curve for **1**.)

known so far, as evidenced by the extreme, hitherto highest upfield shift found for an internal aromatic proton ($\delta(H_{i(a)}) = 3.86$) and the high racemization barrier of 131 kJ mol^{-1}. Figure 2 shows the result of the first X-ray crystal structure analysis of an oxa[2.2]phane. The C(3)-O(2) bond length is 138.5 pm, and is thus 11.6 pm shorter than the opposite C(7)-C(9) bond (150.1 pm). The CH_2-O bridge is likewise shorter (by 7.3 pm) than the CH_2-CH_2 bridge. As a result of these two short distances the planes of the arene rings are tilted at an angle of 3.6° to each other. The special case of the oxa[2.2]metacyclophanes also follows from

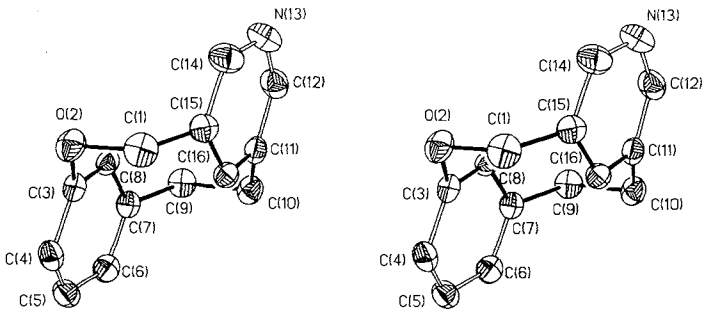

Fig. 2. Crystal structure of **3** (stereoview) ($\alpha = 2.00$, $\beta = 4.50$, $\gamma = 3.20$, $\delta = 3.60°$; for the definition of the "helicity angle" see [1]).

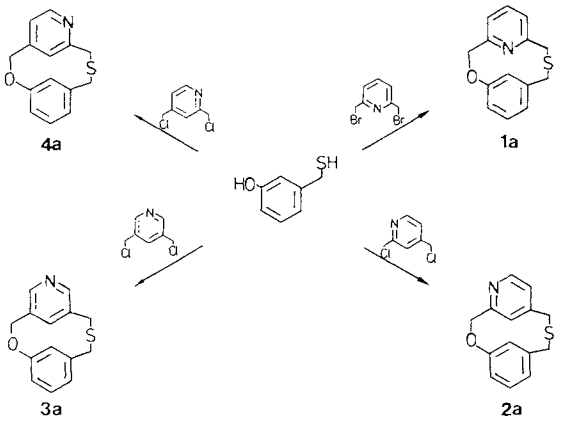
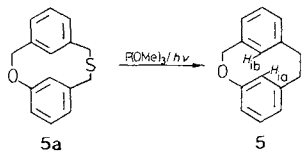
the fact that the shortest intramolecular distance known so far [C(8)–C(6) 257.9 pm] is observed in **3** (for comparison: 268.9 pm in [2.2]metacyclophane).

The synthesis of **5** has already been reported, but the method used involved several steps and the yields were low (only milligram amounts were isolated).[5] To obtain the pyridinophanes **1**–**4** in the required gram amounts we have developed a new, generally applicable two-step synthesis for heteroarenes: a bis(halogenomethyl)-substituted arene or heteroarene is cyclized with 3-(mercaptomethyl)phenol under dilution conditions[9] and in the presence of cesium carbonate[1] in ethanol to a [3.2]phane as precursor in good yields (up to 45%) (Scheme 1). Subsequent desulfurization[10] in a thiophilic solvent [$P(OMe)_3$ or $P(OEt)_3$] (Scheme 2) leads to the narrow-bracketed product in remarkably good yields (up to 40%), considering the hitherto narrowest [2.2]phane ring.



Scheme 1.



Scheme 2.

For the determination of the ring-inversion barriers of the [3.2]phanes **1a**–**5a** we have used the coalescence of the ^{1}H-NMR signals of the CH_2–O group: the free enthalpy of activation for **3a** is 95 kJ mol^{-1}. **1a** shows no coalescence up to −55 °C (90 MHz) because of the small steric demands of the lone pair of the nitrogen atom;[11] the corresponding barriers for **2a**, **4a** and **5a** all lie at 88 kJ mol^{-1}.

To gain a better insight into the influence of chromophore orientation on the circular dichroism we are currently studying further helical molecules with formal clockwise rotation of the chromophore in the molecule.

Experimental

Cyclization: The solutions of bis(halogenomethyl)arene [e.g. 1,3-bis(bromomethyl)benzene] (10.0 mmol) in ethanol (250 mL) and of 3-(mercaptomethyl)phenol (10.0 mmol) and potassium *tert*-butoxide (11.0 mmol) in 85% ethanol (250 mL) were added dropwise within 10 h to 1 L of boiling ethanol (dilution principle apparatus [12]). The cyclization was noticeably favored by addition of a spatula-tip of Cs_2CO_3. After a further 3 hours' boiling the reaction mixture was worked up column chromatographically [silica gel, dichloromethane/acetone mixture (20/1 to 10/1)].

Desulfurization: the [3.2]phane (3.00 mmol) was dissolved in $P(OMe)_3$ (freshly distilled over sodium) and irradiated in a quartz flask with a high-pressure mercury lamp (HQ 600; 15 h, argon, 30 °C). $P(OMe)_3$ was removed under vacuum and the residue chromatographed on silica gel [dichloromethane/acetone mixture (20/1 to 10/1)] [14].

Crystal structure analysis of **3** [14]: colorless crystals; crystal dimensions: $0.15 \times 0.25 \times 0.5$ mm^3; $M_r = 211.2$, space group $P2_12_12_1$, $a = 589.1(4)$, $b = 784.0(3)$, $c = 2336.8(13)$ pm. $V = 1.079$ nm^3, $Z = 4$, $\rho_{calcd} = 1.30$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.08$ mm^{-1}; 1886 symmetry independent reflections ($2\theta_{max} = 50°$); 1617 reflections with $|F| > 3\sigma(F)$ were used for the structure solution (direct methods) and refinement (145 parameters); non-hydrogen atoms anisotropically, H atoms (located by difference electron density determination) refined with a riding model; $R = 0.055$ [$R_w = 0.053$, $w^{-1} = \sigma^2(F) + 0.005F^2$]. The absolute configuration could not be determined.

Blocking of the Retro-Diels–Alder Reaction by Complex Formation: [(η^5-Cyclopentadienyl)(η^5-dicyclopentadienyl)iron]**

By *Janet Blümel, Frank H. Köhler,* Gerhard Müller,* and *Dallas L. Wilkinson*

The retro-Diels–Alder reaction is part of the standard repertoire[1,2] of the preparative chemist; nonetheless, a great deal of work is being invested towards the improvement of this reaction—for example, to circumvent the usually dras-

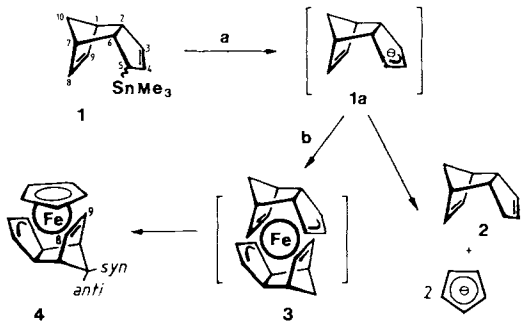
[**] This work was supported by the Fonds der Chemischen Industrie.

tic conditions required by pyrolysis. Recent chemical approaches have included the acceleration of the reaction by the incorporation of silyl groups,[2a] by acid catalysis in the aza variant,[2b] and by reducing the molecular strain[2c] or the basicity[2d-k] on going from the educt to the products. With regard to the latter variant, we recently found that the retro-Diels–Alder reaction can even proceed so rapidly that the actual starting compound cannot be observed.[3] For instance, the reaction of the stannylated dicyclopentadiene **1** with methyllithium leads to dicyclopentadiene **2** and cyclopentadienyllithium even at −78 °C. We have not yet been able to detect the proposed intermediate **1a**.



Scheme 1. a) MeLi/Et_2O, THF, −78 °C; b) $Fe_2Cl_4(THF)_3$, −78→25 °C; the counterions are $Li^{\oplus}$.

We have now found that **1a** may be trapped with solvated iron(II) chloride; the title compound η^5-cyclopentadienyl-(η^5-dicyclopentadienyl)iron,[4] **4**, the only isolable iron compound, is thereby formed in a yield of 20% (not optimized, based on **1**; Scheme 1). The identity of **4** ("DicpFeCp") follows from the correct elemental analysis and the spectroscopic data.[5] Important features include the following: The number of NMR signals corresponds to C_s symmetry in solution. The $\delta(^1H)$ and $\delta(^{13}C)$ data indicate the formation of an allylic system; the bonding of C8/9 to the iron is not supported by δ(H8/9), since a signal shift of only ca. −0.4 ppm is observed on going from **2** or **1**[3] to **4**. For the same transformations, however, the signal for C8/9 is shifted by ca. −60 ppm, which does reflect coordination of C8/9 to iron. ^1J(C8-H8) [^1J(C9-H9)][5,6] thereby decreases by only ca. 3 Hz; the rehybridization and a conceivable charge transfer from the allylic moiety to C8/9 thus have little effect. Noteworthy are the coupling constants ^1J(CH)[5,6] of **4**, which are 5–8 Hz smaller for C1/7 and C2/6 than those of **2**; this indicates a reduction in the angles at the corresponding carbon atoms owing to the binding to iron (compare below). Comparison of **4** with ferrocene reveals that the position of the ^{13}C-NMR signal of C_5H_5 at $\delta \approx 80$ is unusual; we ascribe this to a transannular effect of the Dicp ligand on Cp, which is much larger than that observed for ferrocenes.[7,8]

The X-ray structure analysis[9] of **4** (cf. Fig. 1) confirms the findings outlined above. A ferrocene analogue is present in which a Cp ligand is replaced by Dicp, with the Dicp forming a basketlike ligand. Both the olefinic and allylic moieties of the Dicp coordinate to the Fe atom. As a result, the double bond C8-C9 (1.420(4) Å) is characteristically lengthened[10] and the allyl plane (C3, C4, C5) is bent away from iron by 27.0° with respect to the plane A (C2, C3, C5, C6). The interplanar angle A/D (cf. caption to Figure 1) is 117.0°, and B/D is only 108.8°, so that the distances of the olefinic C atoms (C8/9) from the termini of the allylic moiety (C5/3) are only 2.69 and 2.67 Å, respectively. The Fe-C distances for Dicp and Cp are thus similar (except for Fe-C4, 2.017(2) Å). The Fe-C bond lengths lead to a distance of only 1.21 Å between the best plane E through C3, C4, C5, C8, and C9 and the iron, whereas the Fe-Cp(center) distance is 1.73 Å. The two planes form an angle of 3.6° and are thus ca. 0.4 Å closer in **4** than the corresponding planes in ferrocene;[11] this is revealed as a transannular effect in the ^{13}C-NMR data. These results and the absence of ferrocene (cf. Scheme 1) make the following route for the formation of **4** plausible: **3** is initially formed; the mutual steric hindrance of Dicp ligands in **3** is so large, however, that one of the two ligands cleaves off cyclopentadiene. The retro-Diels–Alder reaction is therefore only partially blocked. Thus, a general route[12] is now possible to complexes of the (Cp-metal) type, which are strongly perturbed owing to formal separation of the olefinic and allylic moieties.

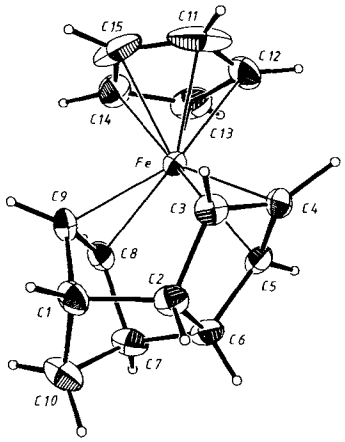


Fig. 1. Molecular structure of DicpFeCp **4** (ORTEP, displacement ellipsoids 50%, H atoms with arbitrary radii). Selected distances [Å]: Fe-C3 2.091(2), Fe-C4 2.017(2), Fe-C5 2.092(2), Fe-C8 2.077(2), Fe-C9 2.081(2), Fe-C11 2.109(3), Fe-C12 2.106(3), Fe-C13 2.101(3), Fe-C14 2.084(2), Fe-C15 2.111(3), C3-C4 1.413(4), C4-C5 1.421(4), C8-C9 1.420(4), C2-C6 1.573(3); interplanar angles [°]: A/D 117.0, B/D 108.8, B/C 127.2, C/D 124.1 with A = C2, C3, C5, C6, B = C1, C7, C8, C9, C = C1, C7, C10, D = C1, C2, C6, C7.

The redox behavior of **4** is similar to that of ferrocene. Cyclovoltammetry[13] shows a reversible ($I_{pa}/I_{pc} = 0.94$) oxidation, the half-wave potential of which is cathodically shifted by 260 mV relative to internal ferrocene. This finding is apparently typical[14] of the perturbation of ferrocenes, either by alkylation or by interruption of the cyclic conjugation in the ligands.

Modified Cyclodextrins— Novel, Highly Enantioselective Stationary Phases for Gas Chromatography**

By *Wilfried A. König,* Sabine Lutz,* and *Gerhard Wenz*

Capillary gas chromatography on chiral stationary phases[1] is being employed increasingly for the determination of the configuration of natural products, for investigating the enantiomeric purity of chiral pharmaceuticals, and for determinating enantiomeric excesses of asymmetric syntheses or enzymatic transformations, ever since suitable columns with thermostable phases have become commercially available[2] and new methods of derivatization[3] have enabled the separation of a large number of substances.

In most cases "chiral recognition" can be attributed to diastereomeric associates formed by hydrogen bonding between chiral substrate and stationary phase.[4] Hence, with few exceptions, only derivatives capable of such interactions (amides, carbamates, oximes, some alcohols) are separable in this way.

In the case of cyclodextrins, which are employed in liquid chromatography as chiral supports,[5] it is known that inclusion effects play an important role in the separation of enantiomers. A separation is achieved when the enantiomers differ in their ability to be accomodated in the cavity of the macrocyclic cyclodextrin molecule. *Sybilska* et al.[6] recently showed that this type of intermolecular interaction is also suitable for gas chromatographic enantiomeric separations. Due to their high melting points, however, the free cyclodextrins are suitable only as stationary phases for gas-solid chromatography. It was therefore thought worthwhile attempting to lower the melting point and increase the thermal stability by introducing hydrophobic moieties. This was achieved both by complete alkylation as well as by partial alkylation and acylation of the hydroxy functions of the cyclodextrins.[7]

It emerged that, e.g., per-*n*-pentylated α-cyclodextrin (Phase I) as well as the β-cyclodextrin pentylated at the hydroxy groups in position 2 and 6 and acetylated in position 3 (Phase II) exhibit a marked selectivity toward enantiomers. Especially high separation factors are obtained in the case of the enantiomers of trifluoroacetylated carbohydrates, methylglycosides, and the 1,5-anhydroalditols[9] as obtained on reductive degradation of polysaccharides.[8] Moreover, derivatives of many other chiral molecules are separated, including building blocks for natural product syntheses, e.g. hydroxy acids (Fig. 1), polyols, triols, vicinal diols, alcohols (Fig. 2), amino alcohols, amines and amino acids. The separation factors for trifluoroacetylated α-chi-

Phenylalanine	1.028	D	I	130

[a] 40-m glass capillary for Phase I; 11-m glass capillary for Phase II.

Since, in all cases, the highly volatile and readily accessible *O*- or *N*-trifluoroacetylated derivatives can be used, most of the separations are possible with short retention times and at low temperatures, i.e. in the region of particularly high separation efficiency of the gas chromatographic column.

A broader application of the permethylated β-cyclodextrin described as stationary phase for gas chromatographic enantiomer separation[10, 11] failed because of the high melting point of this derivative (> 155°C). By mixing with polysiloxanes it was possible, however, to use permethylated β-cyclodextrin at temperatures below 100°C for enantiomer separation.[12]

Particularly interesting in the case of the cyclodextrins are their different ring sizes and the numerous functional groups, which should enable the preparation of stationary phases that are tailor-made for specific separation problems.

[7] α-Cyclodextrin was allowed to react with a threefold excess of *n*-pentyl bromide and NaOH in dimethyl sulfoxide (as described by I. Ciucanci, F. Kerek, *Carbohydr. Res. 131* (1984) 209). The cyclodextrins pentylated in position 2 and 6 of the glucose building block are obtained in almost quantitative yield. The pentylation of the 3-positions could be achieved in THF with NaH/*n*-$C_5H_{11}Br$ by boiling under reflux for four days. The cyclodextrins acetylated in position 3 were prepared from the 2,6-dipentylated derivatives, acetic anhydride/triethylamine (3 molar equivalents each) and 5 mol-% 4-dimethylaminopyridine by 24 hours' boiling under reflux.

Accurate Determination of the Redox State in High-T_c Superconductor Oxides

By *J. Maier, P. Murugaraj*, C. Lange,* and *A. Rabenau*

Although little is absolutely clear as to the mechanism of conduction in the high temperature superconductors, it can be said with certainty that the redox state of the elements, at a given molar ratio of metal to oxygen content per formula unit, plays a significant role.[1] In this communication two methods will be described for the determination of the oxygen excess (δ) and experimental results will be presented for the prototypic superconductor $YBa_2Cu_3O_{6.5+\delta}$.[2] Here, $\delta = 0$ corresponds to the reference

[*] Dr. J. Maier, Dr. P. Murugaraj, C. Lange,

composition of the "normal compound" as determined from the oxidation states of the ions $Cu^{2\oplus}$, $Ba^{2\oplus}$, $Y^{3\oplus}$, $O^{2\ominus}$. Alternately, these average values may be compensated for by corresponding fractions of oxidation states (e.g. $Cu^{1\oplus}$, $Cu^{3\oplus}$ and/or $O^{2\oplus}$). Moreover, the real degree of covalency and delocalization does not enter into the theme presented here.[3]

For the sake of simplicity and without limiting the general validity of the method, we shall describe the redox process purely in terms of valence changes of the copper. The molar ratios of the metals are assumed to be established by spectroscopic or wet chemical analysis. In the case of $YBa_2Cu_3O_x$, ICP analysis (plasma excited atomic emission spectrometry) accomplishes this, e.g., with relative inaccuracies of $\leq 3\%$. Determination of the oxygen content merely from the difference in the mass balance is not accurate enough. Typically two methods have been used to determine the oxygen content: 1. Reduction of the compound at high temperatures (e.g. 1000 °C in the case of $YBa_2Cu_3O_x$) with CO or H_2, whereby Y_2O_3, BaO and metallic copper are formed, and determination of the change in mass by thermogravimetry.[1,6] With CO as reductant, the CO_2 that is formed can be advantageously detected by IR spectroscopy. (Commercially available O-analysis apparatus for the determination of the O-content of oxides are based on this method; temperatures up to 3000 K.) 2. Determination by redox titration with iodide/thiosulfate.[7]

In the first method the main sources of error inherently stem from the working technique used at high temperatures (temperature gradients, possible crucible reactions etc.). If one does not work at extremely high temperatures a further difficulty is encountered—in the subsequent (generally room temperature) phase analysis. Since not only the "excess oxygen" (i.e. the δ value) is determined, non-stoichiometric oxide in the compound and in the products as well as general instrumental errors also contribute significantly (see below).

The primary disadvantage of the second method arises from the fact that the redox potential of the $I^{\ominus}/I_2$ equilibrium lies not only below that of $Cu^{3\oplus}/Cu^{2\oplus}$, but also below that of $Cu^{2\oplus}/Cu^{\oplus}$ (see Table 1). Thus two measurements are necessary (before and after annihilation of the higher oxidized states), and δ is obtained as the difference of two comparably large numbers.

We report here on two very accurate methods from which δ is determined directly: A) determination of the shift of the $Fe^{2\oplus}/Fe^{3\oplus}$ concentration ratio (redox potential) and B) measurement of the O_2-pressure after reaction with H_2O.

In method A the superconducter is dissolved in a sulfuric acid solution of $[Fe(NH_4)_2(SO_4)_2(H_2O)_6]$ or $FeSO_4$ (previously stored over Fe) and transferred to a gas-tight quartz vessel. The final state ($BaSO_4$ + solution) must correspond to the oxidation states of the ions $Y^{3\oplus}$, $Ba^{2\oplus}$, $Cu^{2\oplus}$, and $O^{2\ominus}$. Under these conditions no evolution of oxygen is observed.[9] The $Fe^{3\oplus}$ that is formed is detected photometrically at 520 nm using salicyclic acid (buffering with $(NH_4)_2SO_4$/HOAc; pH 3).[10] At higher concentrations the natural color of the $Cu^{2\oplus}$-complex interferes somewhat but this can be compensated for in the calibration. $Fe^{2\oplus}$ does not interfere. Owing to the position of the redox potential (see Table 1). $Cu^{3\oplus}$ (representing the higher oxidation state) is reduced in this method, but not $Cu^{2\oplus}$. Anions such as $SCN^{\ominus}$, $I^{\ominus}$ (or even $OH^{\ominus}$) shift the redox potential above that of the introduced redox pair, because of the formation of sparingly soluble Cu^{I} compounds (see Table 1).

Table 1. Standard potentials referred to pH 3 [a] for some relevant redox equilibria.

Redox equilibria	E^0 [mV] [a]
$Cu^{2\oplus} + BaSO_4 \rightleftharpoons (Cu^{3\oplus} + Ba^{2\oplus}) + SO_4^{2\ominus} + e^{\ominus}$ [b]	> 1640
$Cu^{2\oplus} \rightleftharpoons (Cu^{3\oplus}) + e^{\ominus}$ [c]	> 1050 [d]
$H_2O \rightleftharpoons 1/2\,O_2 + 2e^{\ominus} + 2H^{\oplus}$	1050
$CuI \rightleftharpoons Cu^{2\oplus} + e^{\ominus} + I^{\ominus}$	840
$CuSCN \rightleftharpoons Cu^{2\oplus} + e^{\ominus} + SCN^{\ominus}$	800
$Fe^{2\oplus} \rightleftharpoons Fe^{3\oplus} + e^{\ominus}$	770
$Fe^{2\oplus} + 3\,SCN^{\ominus} \rightleftharpoons Fe(SCN)_3 + e^{\ominus}$	560
$I^{\ominus} \rightleftharpoons 1/2\,I_2 + e^{\ominus}$	540
$Cu^{\oplus} \rightleftharpoons Cu^{2\oplus} + e^{\ominus}$	170
$1/2\,H_2 \rightleftharpoons H^{\oplus} + e^{\ominus}$	− 180

[a] pH 3; other ionic activities in the redox equilibria normalized to 1. [b] Symbolic notation (see text); referred to the dissolution in H_2SO_4. [c] Symbolic notation (see text); verified by dissolution in HOAc. [d] *Rosamilia* et al. [8] quote a potential for $YBa_2Cu_3O_7$ in 1 M NaCl which lies ca. 100 mV above that of H_2O/O_2.

This precludes, for example, the use of the thiocyanate method for the determination of $Fe^{3\oplus}$ and of $I^{\ominus}$ as reducing agent.

The value of δ is obtained from equation (a) (M^* = molecular mass of the normal compound, $M_0 = 16$ g mol^{-1}; m_s = mass of sample).

$$\delta = \frac{M^* \Delta n}{2m_s - \Delta n M_0} \simeq \frac{M^*}{2m_s} \Delta n \qquad \text{(a)}$$

$\Delta n = n^{\infty}_{Fe^{3\oplus}} - n^{0}_{Fe^{3\oplus}}$, $n^{\infty}_{Fe^{3\oplus}}$ is the final number of gram molecules in solution, $n^{0}_{Fe^{3\oplus}}$ the $Fe^{3\oplus}$ content at the beginning of the measurement. Normally ($\delta \geq 0$), $n^{0}_{Fe^{3\oplus}}$ is simply the blank value, which is determined more accurately in a parallel blank experiment. A definite amount of ($n^{0}_{Fe^{3\oplus}}$) can be used at the beginning also, so as to oxidize any $Cu^{\oplus}$ that is present. Thus, a negative Δn corresponds to a negative δ value. As a rule, the absolute accuracy of detection is limited by the blank value.

In equation (a) it is seen that when $M_0\delta \ll M^*$ (typical error 0.5%) the expression for δ reduces to a proportionality.

In method B the compound is dissolved in H_2SO_4 (10 vol-%) in a gas-tight vessel, i.e. H_2O/O_2 acts as the redox pair. The oxygen evolved by $Cu^{3\oplus}$-reduction is detected by the increase in pressure in a sealed Hg manometer. There is no reduction of $Cu^{2\oplus}$, and any $Cu^{\oplus}$ present will be oxidized by O_2, so that negative δ values can also be determined. Since the dissolution kinetics are not known it is essential not to remove the evolved oxygen. Any CO_2 present can be removed by use of an appropriate filter.

A similar volumetric method[11] and mass spectrometric method[12] for the determination of the evolved oxygen have been described, however without any analytical details.

Correspondingly, we find (neglecting the change of volume compared to the total volume V, error typically 0.5%; Δp: pressure increase):

$$\delta = \frac{\Delta p V M^*}{RTm_s/2 - \Delta p V M_0} \approx \frac{2\Delta p V M^*}{RTm_s} \quad \text{(b)}$$

In this approximation, as in equation (a), a proportionality is found between δ and the measuring effect. This is important for the accuracy of both methods, since the relative errors are simply additive.

Assuming that by X-ray analysis a second phase ($\leq 5\%$) with "normal" valencies ($Cu^{2\oplus}$, $Ba^{2\oplus}$, $Y^{3\oplus}$) will be overlooked, then an error of up to 5% in δ can occur. In the case of $YBa_2Cu_3O_x$ a typical value for δ is ca. 0.2, i.e. $\Delta\delta = 0.01$, being negligible in all cases. Similarly, this will also hold true for "active" second phases. If the total oxygen as in the CO/H_2 method (typical value for x: 6.7) or the oxygen content beyond that of Y_2O_3 and BaO (typically 3.2) is measured, then the error increases by more than an order of magnitude; this argument also applies in the case of the determination of oxygen by difference in mass balance. Since, on the one hand, very small $Fe^{3\oplus}$-contents (> 0.1 ppm) can be measured by the salicylate method and blanks can be kept very small, and, on the other hand, pressure increases of ca. 1 torr are easy to measure, we estimate the accuracy for δ to be ca. 2% from method A and ca. 4% from method B. This corresponds to an accuracy of the δ value to the third decimal place, which is more than satisfactory in practice, where the accuracy is already influenced considerably by the uncertainty in the determination of the ratios of the metals (e.g. $\Delta M^*/M^* = 1\%$ for 3% accuracy in the Ba-content).

Table 2. Determination of the oxygen content δ in $YBa_{2-y}CuO_{6.5-y+\delta}$ by the methods A and B described in the text.

Ceramic	Remarks	δ		
		Method A	Method B	
			[b]	[c]
$YBa_2Cu_3O_{6.5+\delta}$	unannealed	0.18	0.17	0.18
$YBa_2Cu_3O_{6.5+\delta}$	annealed [a]	0.22	0.20	0.21

$YBa_{1.8}Cu_3O_{6.3+\delta}$	unannealed	0.15	0.14	0.15
$YBa_{1.8}Cu_3O_{6.3+\delta}$	annealed [a]	0.22	0.20	0.21

[a] 600°C, 10 h, $p(O_2) = 1$ atm. [b] Uncorrected. [c] Increased solubility of gas taken into account on increasing the pressure (the pressure coefficient of pure H_2O was used.

Table 2 shows the excellent agreement between the two values obtained for conventional $YBa_2Cu_3O_{6.5+\delta}$-ceramics and for the BaO-substoichiometric ceramics prepared by us,[13] of which $YBa_{2-y}Cu_{6.5-y}$ is the "normal compound." An obviously slight systematic deviation is partially eliminated (cf. Table 2) if, in the O_2-method, the pressure dependence of the gas absorption[14] is taken into account ($\Delta\delta = 0.012$ if, for lack of data, the pressure coefficient in water is used).[15]

An additional advantage of method B is the possibility of being able to easily determine the overall dissolution kinetics. We have always observed the existence of a maximum Δp; whether this can be attributed to intermediate formation of a $Cu^{\oplus}$ compound[16] which is then reoxidized or whether this simply reflects a slow O_2 absorption as a result of the increased pressure, is still unclear. Consistent with the latter mentioned effect is the fact that the subsequent small decrease in pressure corresponds exactly to the deviation in the uncorrected results between the two methods.

[15] A remark on the use of other methods is warranted: Isothermal degradation of oxygen has been attempted, but from the kinetics appears problematic. An electrochemical determination, by coulometric titration, can in principle be very accurate but requires a detailed knowledge of a series of parameters which are not available at present.

[16] A different rate of reaction of $Cu^{3\oplus}$ and $Cu^{\oplus}$ in the superconductor structure as a possible explanation appears unlikely in view of the reaction times.

***Ab Initio* Methods in Quantum Chemistry, Part I and Part II (Series: Advances in Chemical Physics, Vols. 67 and 69).** Series editors: *I. Prigogine* and *S. A. Rice*; volume editor: *K. P. Lawley*. Wiley, Chichester 1987. Part I: 556 pp., bound, £ 65.00.—ISBN 0-471-90900-9; Part II: 588 pp., bound, £ 59.95.—ISBN 0-471-90901-7

To the series "Advances in Chemical Physics", well known for its high quality, two extensive new volumes devoted to *ab initio* quantum chemistry have now been added, increasing the number of volumes in the series to 69. The aim of the editors of this series is to bring together in a single work review articles on specialist topics by internationally known experts, so as make new ideas in chemical physics accessible to a wide readership. The authors are encouraged to bring to task their own individual evaluations and viewpoints. Here once more those aims have been fulfilled very successfully. The books contain a wealth of new and highly interesting information and ideas, not only for theoreticians but also for experimentalists who need theory to help in guiding their work.

The first contribution in Part I (by *Bruna* and *Peyerimhoff*) is on electronic excited states, and comes from the Bonn group which is very active in this field; it contains a detailed survey of calculated properties, mainly of diatomic and triatomic molecules. It is clearly presented, and the schematic layout contributes to rapid assimilation of the ideas. This article will be greatly welcomed not only by quantum chemists but also by all who have an interest in the spectroscopic properties of small molecules. The article by *Amos* deals with the calculation of functions describing molecular properties, with special emphasis on methods for directly calculating dipolar properties and polarizabilities. The power of the theory is illustrated by numerous examples of calculations of IR and Raman intensities. In another contribution *Bernardi* and *Robb* have undertaken the important task of giving a critical summary of theoretical knowledge on mechanisms of typical reactions, mainly organic. Such studies would not be possible without using numerical methods to locate the extrema on multidimensional potential energy surfaces. The algorithms used for this purpose are described in a clear and comprehensible fashion in the article by *Schlegel*. *Balasubramanian* and *Pitzer* give details of the methods now available for calculations of relativistic effects, and describe various applications of relativistic quantum chemistry, mainly to spectroscopic problems. *Durand* and *Malrieu* have undertaken a detailed study of effective Hamiltonian operators and their physical significance. *Jones* describes methods and results based on the formalism of density functions. *Wilson* deals with the question of choosing between different basis sets and applying them. Lastly, *Ahlrichs* and *Scharf* give a concise description of methods based on coupled pairs approximations. In this important and interesting contribution, the various methods are critically compared and their advantages and disadvantages are discussed with the help of examples.

It seems impossible now to escape the increasing flood of new abbreviations to describe ever more detailed aspects of solutions of the Schrödinger equation for the motions of electrons and nuclei. Not only will most scientists working in the field be unaware, for example, that CEPA is also a botanical abbreviation defining the edible onion family, they are also likely to have difficulty with creations which they are often assumed to be familiar with such as WNR (wavefunction Hessian matrix Newton-Raphson), APT (atomic polar tensors), or SAC (symmetry adapted cluster approach). In view of the large number of new abbreviations, it would have been sensible to include in both volumes a glossary of these terms with explanations, and perhaps also literature references. In contrast, the index of cited authors contained in the book does not seem particularly useful, as each article has its own separate bibliography. In my opinion neither book is really suitable as an introduction to *ab initio* methods in quantum chemistry, which was the declared intention of the editors.

Taken as a whole, the first volume can be recommended to all readers who have some knowledge of or interest in *ab initio* methods in quantum chemistry. They will find much new material here, and in addition to its other merits the book is an extremely useful up-to-date work of reference on specialized aspects of theoretical chemistry. These are qualities which the "Advances in Chemical Physics" series has now been providing in an outstanding way for nearly thirty years, covering many fields of research.

The second volume is mainly concerned with modern algorithms of quantum chemistry. Five of the nine contributions deal with multi-configurational methods and their applications. Advanced *ab initio* methods of this kind are indispensable in, for example, exact calculations of dissociation energies, for calculations on near-degenerate electronic states, for dealing with regions in which a crossover of potentials is just avoided, and for spin coupling effects. The last few years have seen the introduction of new numerical methods, largely based on group theory considerations, which allow efficient handling of multi-reference problems. The application of these methods has been greatly helped by progress in computer technology, with the advent of large capacity vector-processing computers and super-minicomputers. These methods make it possible to solve problems formulated in more and more general terms. The appearance of this book is very much to be welcomed, since it deals with the latest developments and will undoubtedly have a stimulating effect.

The book begins with an article by *Werner* on direct methods for the solution of multi-reference problems involving configurational interaction. The author begins by describing his recent work on MCSCF methods which give fast and certain convergence, and on direct methods for the solution of the MCSCF-CI problem. All the algorithms described are especially suitable for vector computers. The article is very well written from a teaching standpoint, contains many new ideas, and can be warmly recommended to all who are interested in modern MCSCF methods. *Shepard*, in a very detailed contribution (134 pages!), reviews the development of MCSCF methods and discusses the different ways in which they can be formulated. *Roos* deals with the special case of the MCSCF method in which one considers all configurations for a given number of molecular orbitals. Valence bond methods, although they are based on a different theoretical model, are used for the same purposes as MCSCF methods. The present state of knowledge on these methods is reviewed by *Cooper*, *Gerratt*, and *Raimondi*. The theoretical treatment of transition metal compounds usually requires multi-reference methods. *Salahub* gives an excellent overview of methods ap-

plied to transition metal atoms and their dimers. This contribution can be recommended as a source of information for readers interested in the theory of chemical bonding involving metals. The calculation of potential energy surfaces for weakly bonded systems continues to present a great challenge for *ab initio* quantum chemical methods, as discussed in the contribution by *van Lenthe, van Diujneveldt,* and *van de Rijdt,* with particular attention to the basis superposition effect. A very competent article on analytical derivation methods in quantum chemistry is provided by *Pulay*, one of the pioneers in this highly topical area of research. As well as reviewing these methods, the author gives a critical appraisal and indicates possibilities for further developments. This contribution too is very valuable from a teaching standpoint. *Oddershede* deals with the propagator methods, which are especially useful for electronic excited states and applications such as calculation of dynamic polarizabilities. Everyone interested in previous work based on this formalism will find here a useful review and commentary on the methods. Finally, *Dunlop* discusses symmetry and degeneracy in the theory of $X\alpha$ functions and density functions.

This second volume, containing articles which are more oriented towards methodology, is aimed at the specialist to an even greater extent than is the first volume. The individual articles are of excellent quality, and they deal with topical research themes which are still rapidly developing. Consequently, the book will not only be indispensable for libraries, but will also provide theoreticians with a starting point for further developments in their armory of techniques.

Principles and Applications of Organotransition Metal Chemistry. By *J. P. Collman, L. G. Hegedus, J. R. Norton,* and *R. G. Finke.* Oxford University Press, Oxford 1987. xii, 989 pp., bound, £ 40.00.—ISBN 0-935702-51-2

When the first edition of *Collman* and *Hegedus* appeared on the market seven years ago it did not seem very impressive. It was made by direct reproduction of a typescript, with a result which was not altogether attractive to the eye, and it also contained many errors, especially in structural formulas and equations. However, even then a closer study of the book revealed its merits: for the first time it attempted, in a skilful and instructive way, to bridge the gulf between fundamental knowledge of organotransition metal chemistry and its importance for catalytic process technology, and also to show how this knowledge could be applied in organic synthesis. The success of the textbook was therefore already assured, despite the unsatisfactory manner of its production.

The second edition is now available; it has, naturally, turned out to be somewhat larger, and the involvement as co-authors of a further two organometallic chemists, *J. R. Norton* and *R. G. Finke*, who have a more inorganic bias, has remedied some weak points of the first edition. The text is divided into three parts: I. Basic Principles, II. Catalytic Processes and III. Applications to Organic Synthesis; their respective lengths of 500, 140 and 270 pages seem appropriate to the subject matter.

The longest, Part I, begins by discussing structure and bonding, then continues with a survey of the various types of organotransition metal complexes, arranged according to the nature of the ligands. This is followed by a very thorough treatment of the most important types of reactions which the previously listed complexes are known to undergo, discussed under the headings of ligand exchange processes, oxidative additions and reductive eliminations, intramolecular insertion reactions, and lastly nucleophilic and electrophilic attack of ligands. The majority of the examples are well chosen, and the sections on individual topics include details even of very recent and highly topical results, e.g. on electron transfer catalysis in substitution reactions, the oxidative addition of Si–H and C–H bonds to transition metals, carbene insertions, MHC three-centre bonding, and complexes containing SO, SO_2, CO_2, NS or diazoalkanes as ligands. Part I is concluded by a chapter on metallacycles, including discussions of olefin metathesis and other important reactions which involve metallacyclobutanes.

In Part II the discussion of catalytic processes begins with homogeneous catalytic hydrogenation, hydrosilylation and hydrocyanation, then continues with the metal-catalyzed polymerizations of olefins and acetylenes, and concludes with a concise survey of catalytic reactions involving carbon monoxide. In this chapter the Roelen oxo synthesis (hydroformylation), the Monsanto acetic acid process, and, of course, the Fischer-Tropsch synthesis are discussed. Commendable features of the treatment are that modern variations of well-known processes are also described in detail (e.g. the manufacture of ethylene glycol by the Fischer-Tropsch process), and that up-to-date figures relating to industrial production are given.

Part III, covering applications in organic synthesis, has without doubt undergone the greatest changes since the first edition, thereby reflecting one of the most important current trends affecting organometallic chemistry in recent years. Several monographs on the theme of organometallic compounds for organic synthesis have recently appeared in rapid succession, and it is also no accident that since 1981 a series of conferences on this topic has been set up. Here the authors have arranged the material according to the types of organometallic compounds used, i.e. metal hydride complexes, compounds with M–C σ-bonds, carbonyl and carbene complexes, metallacycles, olefin, diolefin, and dienyl compounds, alkyne and allyl complexes, and finally sandwich complexes formed by arene ligands. One can fairly confidently predict that in the next edition of the book Part III will again grow in size.

What are the good and bad features of "Collman, Hegedus, Norton and Finke"? The overall concept of the book is undoubtedly good, as is the balance between the different types of compounds and reactions, the way in which the chemistry is related to applications, and the topicality of content. The presentation, the reproduction of structural formulas and the typography are better than in the first edition. Regrettably many printing errors have again crept in (despite proof-reading by four authors). These appear as early as the first page of the contents list ("Formal-Metal Bonds" instead of Formal Metal-Metal Bonds, "Isolabal" instead of Isolobal), and continues through the tables (Historical Landmarks: "Reppe describes the catalytic cyclotrimerization of acetylene to cyclooctatetraene") to the individual chapters. Especially displeasing are incorrect formulas, as uninitiated readers at least will be confused by these; examples: p. 78, bottom left: this should read five-coordinate osmium(*0*)-complex, p. 106 bottom left: positive charge missing, p. 153: $PtCl_2(COD)$—not $PtCl_2(COD)_2$, p. 160: $Ru\text{-}PPh_3$—not $Ru\text{-}PPh_2$, p. 171: **154**

has not been synthesized by this method, p. 294, line 5: $(CO)_2$, p. 298, Eq. 5.31: the product is $[CpIrHL_2]^{\oplus}$, p. 317, middle left: negative charge missing, p. 321, Eq. 5.67: should be C_5Me_5, p. 380: C_6Me_6Ru—not Cp*Ru, and p. 890, Eq. 19.19: $MoO_2(acac)_2$ instead of $Mo(O_2)(acac)_2$. Also it is regrettable (and a little disappointing) to find that the historical milestones are in some cases viewed through "USA-tinted" spectacles. For example, in the chapter on "Historical Perspectives" there is no mention of *Walter Hieber* and his pioneering work on metal carbonyl complexes, and no reference is made reflecting the very important publications by *Dewar, Chatt,* and *Duncanson* on bonding in olefin–metal complexes. Again, the false impression is given that the structure of ferrocene was correctly proposed only by *Wilkinson, Rosenblum* and *Woodward,* whereas it also came simultaneously from *Fischer* and *Pfab*. Other omissions: when mention is made of the Monsanto process, why not also of the Wacker process, which is equal in technological importance? When, in connection with the discovery of the intermolecular oxidative addition of saturated hydrocarbons to transition metals, mention is correctly made of *Bergman*, why not also of *Graham* in the same breath? An opportunity has been missed here to present an objective picture (acceptable throughout the world) of the historical development of the subject; this is especially regrettable when one considers that students also need to be educated in the history of science.

However, taken as a whole the positive impressions given earlier outweigh these criticisms, and the textbook can be strongly recommended for reading by advanced students. Fortunately the price is also reasonable, something which is nowadays much appreciated.

Helmut Werner [NB 885 IE]
Institut für Anorganische Chemie
der Universität Würzburg (FRG)

Nitroazoles. The *C*-Nitro Derivatives of Five-Membered *N*- and *N,O*-Heterocycles. By *J. H. Boyer*. VCH Publishers, Deerfield Beach 1986. xv, 368 pp., bound, DM 185.00.—ISBN 0-89573-138-7

In the fifties and sixties, nitro compounds interested chemists primarily as propellants and explosives. Since then, however, this most easily introduced of functions, the nitro group, has been recognized to have an activating effect on numerous organic reactions, and to be easily convertible into other useful nitrogen functional groups. This is emphasized by the commencement of a new series, "Organic Nitro Chemistry", of which Volume 1, "Nitroazoles", has now appeared.

The 368-page work is divided into sections on nitration, chemical, physical (spectroscopic) and biological properties, reactions, and references. Inside this framework, nitropyrroles, nitroimidazoles, nitropyrazoles, nitrotriazoles and nitrotetrazoles are described, as are the nitro derivatives of isoxazoles, oxazoles, oxadiazoles and the heterocyclic systems derived from these by annelation of further rings. The table of contents, though very detailed, could have been more clearly laid out.

The bibliography contains 1501 original citations, and an extensive list of references is also appended to each chapter (the names of German, Austrian and Swiss workers are unfortunately often misquoted). While many classic heterocycle monographs, series, reviews, and articles are cited, one seeks in vain for the newest standard work, "Comprehensive Heterocyclic Chemistry" (published 1984). The author earns special praise for having analyzed and evaluated the overwhelming number of Soviet publications on the subject of nitroazoles. In doing so, he has made an area that has been intensively studied in the Soviet Union available in the West for the first time.

The first five chapters deal extensively with the most favorable reagents and methods for nitration of the various heterocycles. Where direct nitration is difficult, ring closure or ring transformation reactions often give the desired result. The sections on chemical reactivity include alkylation, acylation and arylation at both nitrogen and carbon, halogenation, reduction (including electrochemical methods), oxidation, decarboxylation, rearrangements, exchange of the nitro group for side-chains, nucleophilic and electrophilic substitution and addition, metallation, ring cleavage, free radical reactions, thermo- and photochemistry (degradation) and glycosylation. For important key reactions the yields are always reported, and stereochemical aspects are taken into account. Biotechnological conversions of amino- into nitroheterocycles are also described (p. 95). The sections on physical properties offer much information, and the biological properties of the nitroazoles and their derivatives are described in separate sections.

While the computer-drawn structural formulas are clear and informative in every respect, for a book in this price range they display numerous flaws and deficiencies. Bond lengths are too short or too long, heteroatoms are superimposed on bonds, substituents are cramped, rings are set out crookedly (e.g. pp. 190, 191, 227), carbonyl groups are distorted (p. 331), and substituents are twisted (p. 131). Many less expensive textbooks are able to offer more than this! The consistent numbering of formulas with the chapter number as prefix is very practical.

All in all, this monograph is a valuable addition to the chemical literature, and is highly recommended for anyone who comes in contact with the topic of azoles.

Heinrich Wamhoff [NB 888 IE]
Institut für Organische Chemie und Biochemie
der Universität Bonn (FRG)

Biohalogenation. Principles, Basic Roles, and Applications. By *S. L. Neidleman* and *J. Geigert*. Ellis Horwood, Chichester 1986. 203 pp., bound, £ 25.00.—ISBN 0-85312-984-3

Halogens and halogen compounds play an important role in many areas of chemistry. It therefore seems at first surprising that not very much is known about halogenation in biochemistry. Certainly many halogen compounds occur in nature, but there is no precise knowledge about their formation and importance. It has only recently become possible to detect and characterize halogenating enzymes in prokaryotic organisms, whereas they had already been recognized long before this in eukaryotic organisms (molds and algae). These enzymes were given the name "haloperoxidases", since in addition to halide ions they also need hydrogen peroxide in order to halogenate an organic compound.

The present state of knowledge on biohalogenation is reviewed for the first time in the book by *Neidleman* and *Geigert*. The nine chapters deal with some of the halogen compounds which occur in nature, the organisms producing them, the halogenating enzymes that have so far been isolated, and their importance to the organisms concerned.

A list of the halogen compounds produced by a wide range of different organisms gives impressive evidence of the large number of such compounds formed in nature. The chapters on halogenating enzymes include, in addition to a rather too detailed compilation of schemes for the purification of those haloperoxidases which have so far been isolated, a summary of the reactions catalyzed by these enzymes. The section on the mechanism of enzymatic halogenation deals with the various theories currently being considered, from which it is evident that it has not yet been possible to unambiguously clarify the mechanism. The importance of halogenating enzymes and of naturally occurring halogen compounds is discussed in terms of their enhanced biological activity compared with the corresponding non-halogenated compounds, with reference to a number of examples. One chapter deals with the relationship between halogenating enzymes and defence mechanisms in mammals. For example, hypochlorite can act as an antiseptic. Chapter 8 discusses biological dehalogenation, which is not simply a reversal of the halogenation process. This environmentally important topic is, however, not treated fully.

This book is indispensable for scientists involved in work on biological halogenation, and for others it undoubtedly makes interesting reading.

Franz Lingens, Karl-Heinz van Pée [NB 894 IE]
Institut für Mikrobiologie
der Universität Hohenheim (FRG)

Nonlinear Optical Properties of Organic Molecules and Crystals. Edited by *D. S. Chemla* and *J. Zyss*. Academic Press, Orlando, FL (USA) 1987. xiii, 482 pp., bound, $ 67.50.—ISBN 0-12-170611-7

Optical techniques are becoming increasingly important in the storage, transfer and processing of information. The demands for miniaturization and faster processing of data are forcing the adoption of technologies which make use of the unique properties of organic molecules. This book begins with a short introduction by *R. Silbey* ("The Structure and Properties of the Organic Solid State", 18 pp.), which gives a survey of the physics and chemistry of solid organic compounds in relation to their optical properties and electrical conductivity.

In the article "Quadratic Nonlinear Optics and Optimization of the Second-Order Nonlinear Optical Response of Molecular Crystals" (169 pp.) *J. Zyss* and *D. S. Chemla* deal with the physical and mathematical aspects of quadratic nonlinear optics in molecules and molecular crystals. *D. Pugh* and *J. O. Morley*, in the chapter "Molecular Hyperpolarizabilities of Organic Materials" (33 pp.), show how quantum theoretical models can be used to calculate polarizabilities and hyperpolarizabilities. The chapter "Design and Synthesis of Organic Molecular Compounds for Efficient Second-Harmonic Generation" (70 pp.) by *J. F. Nicoud* and *R. J. Twieg* continues the theme of the second chapter by treating the chemical and physicochemical aspects of "optical materials", with numerous examples and literature references. The contribution "Growth and Characterization of Molecular Crystals" (60 pp.) by *J. Badan, R. Hierle, A. Perigaud,* and *P. Vidakovic* deals with these important techniques as applied to organic crystals and waveguide structures. *A. Barraud* and *M. Vandemeyer*, in the chapter "Growth and Characterization of Organic Thin Films (Langmuir-Blodgett Films)" (27 pp.), discuss the preparative aspects and characterization of such films. "Properties and Applications of Urea" (20 pp.) by *J.-M. Halbout* and *C. L. Tang* is a well researched contribution dealing with the nonlinear optical properties of crystalline urea. Next, in the chapter "Nonlinear Optical Properties of Guest-Host Polymer Structures" (31 pp.), *D. J. Williams* discusses the physical properties of structures of this kind with organic molecule "guests", in which the host materials may be thermoplastic polymers, thermoplastic liquid crystal polymers, or polar polymer chains in an isotropic medium. The final chapter "Electro-Optic Organic Materials" (32 pp.) by *K. D. Singer, S. L. Lalama, J. E. Sohn,* and *R. D. Small* deals with electro-optical processes in organic materials; applications to optical integrated circuits are described with a number of examples.

Each chapter is followed by a detailed bibliography extending up to 1986. A comprehensive subject index enables one to find information on specialized topics. Certain equations and facts are frequently repeated in different chapters; cross-referencing here could have saved a few pages. The editors come out firmly against making a distinction between linear and nonlinear optics, pointing out that optics is in essence nonlinear. One can only agree with this statement and commend it to all authors who adopt too narrow a definition of nonlinear processes. The book can be recommended unreservedly to physicists, chemists and advanced students who are concerned with the optical properties of organic compounds.

Liquid Crystals—State of the Art

By Heino Finkelmann*

A century ago, in 1888, the liquid crystalline state of matter was discovered. One might suppose from this that liquid crystals have begun to grow old. Actually the reverse holds: liquid crystals have increased our possibilities for producing advanced materials par excellence. The realization of super-molecular organization in the liquid crystalline state offers additional dimensions for tuning the physical properties of organic or organometallic materials including macromolecular systems. Therefore the molecular design of liquid crystals to create materials with exceptional properties is a challenging task for chemists in cooperation with physicists, materials scientists and engineers.

What are the main aspects of liquid crystalline materials currently under investigation? Although the different basic molecular geometries and constitutions causing the formation of the liquid crystalline state are known, so far only systems built up by rigid rod-like molecules have proven to be suitable for new applications. This holds for low molar mass as well as for polymeric liquid crystals.

Low molar mass liquid crystals in the nematic phase, in which the rigid rod-like molecules are ordered with respect to their long molecular axis, have been intensively studied both experimentally and theoretically during the last few decades. This was mainly due to their potential applications in optoelectronics, especially for low energy consuming displays: by applying an electric field the preferred orientation of the molecules can be altered (due to the liquid state), which causes a change in the (anisotropic) optical properties. Although this process had already been developed early in the seventies, remarkable progress in the layout of the display cell and in thin film transistor (TFT) technology calls for new designs of liquid crystals. Their chemical constitution has to be optimized with respect to the anisotropic phase properties such as viscosity, dielectric and elastic constants. Several new classes of nematics have been designed, which give a increased output in display technology: super-twisted-nematic (STN) displays are available having high resolution (e.g. for computers) and TFT displays give excellent picture quality for pocket color TV sets or for projection of TV pictures.

Liquid crystals research currently focuses not only on nematics but also on the ferroelectric chiral smectic phases, especially the chiral smectic-C phase. In this phase the rod-like molecules also have long range positional order within layers, with the long molecular axis tilted relative to the layer normal. These ferroelectric liquid crystals allow the production of very fast switching displays, which compete with TFT displays for TV screens. Only a few years ago little was known about these smectics, especially with regard to the relationship between the chemical constitution of the molecules and the temperature regime of the smectic-C phase. Since then intensive research by chemists and physicists has allowed the systematic synthesis and blending of smectics, which can serve technological demands, especially of the optoelectronics industry.

Polymeric liquid crystals have attracted much attention during the last few years. The combination of polymer-specific properties with the anisotropic physical properties of the liquid crystalline state offers wide-ranging possibilities for the design of new materials. Two different types of polymers—both based on rigid rod-like monomer units, yet completely different in application—have been examined: the "LC-main-chain polymers", where the rod like monomer units are within the polymer backbone, and the "LC-side-chain polymers", where the rod like moieties are attached as side groups to the backbone.

LC-main-chain polymers exhibit an orientational long range order of the polymer main chains in the nematic state. A shear gradient—e.g. during a spinning process—causes a macroscopic alignment of the preferred orientation of the macromolecules. Fibers can be easily obtained, where the polymer main chains are highly ordered in the direction of the fiber axis. This yields outstanding mechanical properties. Due to the orientation of flow the (anisotropic) viscosity was also observed to be lower than the viscosity of amorphous melts, which makes the processing of these materials easier. Furthermore, injection molded samples have very small thermal expansion coefficients in the solid (partially crystalline) state and, as a result, can be used as construction elements, since they hardly change their dimensions with temperature.

For LC-side-chain polymers the most remarkable property is the vitrification process of the liquid crystalline polymer melt. Liquid crystalline polymers—smectic or nematic—do not change their structure when frozen in the glassy state and consequently become *anisotropic glasses*. This means that the liquid crystalline polymer melt can be macroscopically or locally aligned by external electric or magnetic fields and vitrified to the ordered, anisotropic glass, giving solid materials with anisotropic physical properties. The vitrification of ordered ferroelectric chiral smectic-C polymers, for example, might give a completely new class of materials. Furthermore their non-centrosymmetric phase structure makes them suitable for applications in nonlinear optics. Research in this field is, however, still in its infancy.

The enormous potential of LC-side-chain polymers, especially for optical applications, is demonstrated by an example recently developed in our laboratory. The chemical crosslinking of the linear LC-side-chain polymers yields liquid crystalline elastomers ("rubbers"). Mechanical deformation of these elastomers by stretching or compressing causes a macroscopic orientation of the liquid crystalline molecules similar to the electric field orientation of low molar mass liquid crystals. Elastomer films can be prepared, whose macroscopic optical properties are similar to the optical properties of an anisotropic single crystal having the same dimensions. There is, however, an additional feature to these elastomers: a local deformation of the macroscopically aligned film causes a local change of the optical properties. This is schematically shown in Figure 1. If the plane surface of the film is brought into contact with a

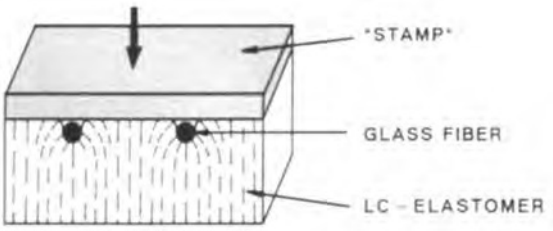

Fig. 1. Schematic drawing of the local deformation of the optical axis of an LC-elastomer by a "stamp" for application as planar light conductor for integrated optics. In this example a smooth stamp presses a glass fiber (10 μm diameter) into the elastomer surface. The arrow indicates the viewing direction parallel to the optical axis (of the undisturbed elastomer) as shown in Figure 2.

"stamp", which has a defined pattern of micron dimensions, the pattern deforms the elastomer surface and consequently the local direction of the optical axis. This can be directly observed in a polarizing microscope with crossed polarizers as shown in Figure 2. It is obvious that this offers a relatively simple technique for producing elements for the integrated optics. Light conducting pathways can be mechanically pressed into the liquid crystalline elastomer film (similar to the production of a record) and durably stored in the glassy state.

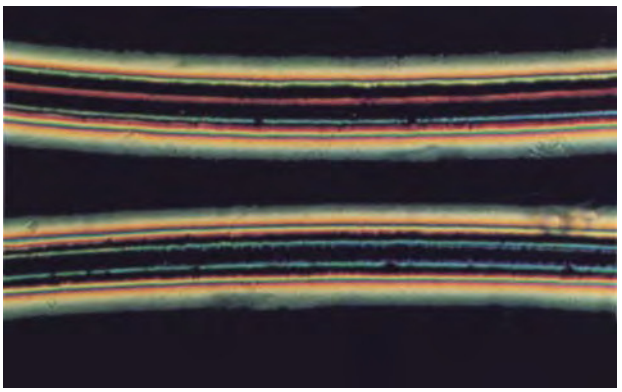

Fig. 2. Polarizing photomicrograph (crossed polarizers) of a locally deformed LC-elastomer. The local change of the birefringence is indicated by the interference pattern. The black area denotes regions where the optical axis of the elastomer is parallel to the viewing direction.

Although the liquid crystalline state of matter was discovered one hundred years ago, it was for many decades regarded only as a laboratory curiosity. The developments in the last twenty years impressively demonstrate the outstanding potential of liquid crystals as technologically relevant advanced materials.

Prof. Dr. Heino Finkelmann is Professor of Polymer Chemistry at the University of Freiburg, FRG. Born in 1945 in Gronau/Alfeld, he first became an engineer. Starting in 1969, he then studied chemistry at the Technical University of Berlin (Diplom in 1972) and at the University of Paderborn, where he earned his PhD under the supervision of H. Stegemeyer. He spent three postdoctoral years with H. Ringsdorf at the University of Mainz, and moved to the Technical University of Clausthal in 1978. Immediately after the Habilitation in 1984 in Clausthal he was offered his current position. He has been awarded the Carl-Duisberg-Gedächtnispreis of the Gesellschaft Deutscher Chemiker and the "Dozentenstipendium" of the Fonds der Chemischen Industrie. Professor Finkelmann is a member of the Scientific Committee of the 12th International Liquid Crystals Conference to be held in Freiburg from 15–19 August 1988.

Advanced Materials by Powder Metallurgy

Ceramics/Intermetallics
Hot Isostatic Pressing
Dispersion Hardening
Rapid Solidification

By Wolfgang A. Kaysser* and Günter Petzow

1. Introduction

One of the techniques which have an inherent potential to produce some of the future's tailored, high-tech materials is powder metallurgy (PM). The efficient use of powder metallurgy depends both on a scientific understanding of the complex physical and chemical problems of powder production, handling, forming and consolidation and on highly developed complex engineering capabilities. The interaction between materials science and engineering is a characteristic feature of the new powder metallurgy.

From the ancient powder forged pillar of Delhi to the present, powder metallurgy has shown itself to be a potent method for forming special, artificial materials when no other techniques are available due to high melting points or bad machinability of the materials or microstructures not obtainable by other techniques. PM high-tech materials must be fine grained and completely free of pores. Mechanisms of powder densification and simultaneous microstructural changes are therefore of major technical and scientific interest.

The basic steps of conventional powder metallurgy are powder preparation, handling, shaping, and consolidation.[1] Powders may be produced by chemical reactions from precursors or by disintegrating solid or liquid bulks. The powders are shaped in dies under uniaxial load or put into thin-walled capsules and isostatically pressed. The shaped compacts contain pores between the individual particles which amount to porosities between 60 and 10 vol-%. One of the purposes of the subsequent sintering, a heat treatment below the melting temperature of the major constituents, is to eliminate the pores; the process is driven by a reduction in solid–vapor interface area. Porosity reduction requires an increasing fraction of solid material in each unit volume cell by rearrangement or by shape change of the particles (Fig. 1 top).

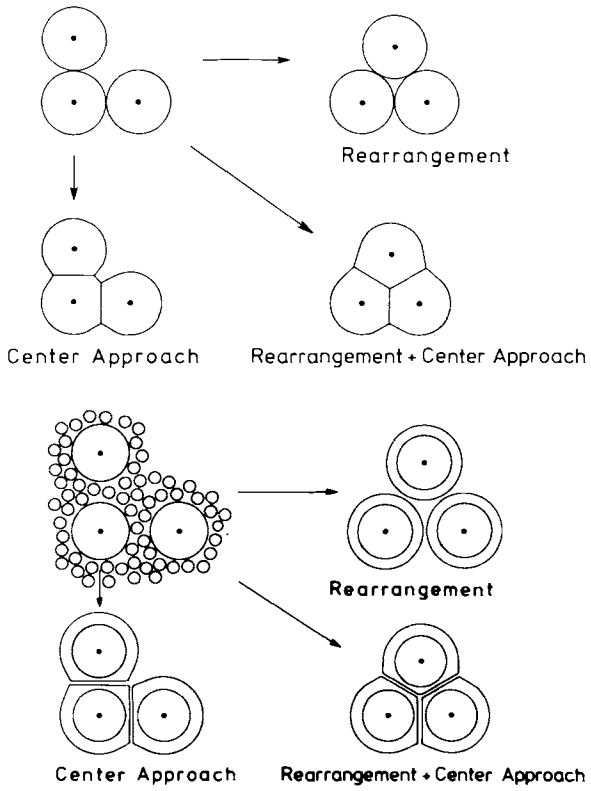

Fig. 1. Shrinkage by rearrangement and center approach (shape change) during sintering. Top: Monosized grains without coarsening. Bottom: Grains with broad size distribution and coarsening.

2. Advanced PM Materials by Pressureless Sintering

Shape change or center to center approach during solid state sintering occurs in a quantified way when vacancies diffuse from pores into the grain boundaries where they are subsequently eliminated. Unfortunately, the transport of vacancies to the grain boundary sinks by bulk diffusion or by grain boundary diffusion does not provide complete densification in metal powders of sizes between 1 and 100 μm. In the final stage of sintering, when the porosity is below 6%, the continuous pore channels transform into isolated pores which lie at grain boundaries. If the pores are too small to hold the grain boundaries, but too large, and therefore too immobile, to move along with the grain boundaries, grain boundaries and pores separate during regular grain growth (Fig. 2). Pores that are trapped inside the grains shrink at much lower rates than pores at grain boundaries, and they are therefore deleterious for densification. Powders can be sintered to full density if the diffusion mechanism controlling the vacancy transport from the

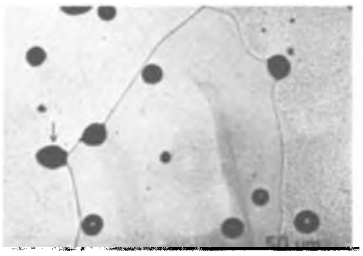

Fig. 2. Microstructure showing pore drag (asterisk) and pore/grain boundary separation (arrow) after final stage sintering of W – 0.15 wt.-% Ni at 1400°C for 3 h.

pores to the grain boundaries is enhanced and if the grain boundary mobility is decreased by additives. These basic principles were successfully applied to obtain translucent ceramic materials for sodium vapor pressure lamps. The dense alumina (Lucalox) can be produced by pressureless sintering when the bulk diffusivity is enhanced and the grain boundary mobility is reduced by doping the powder with less than 1000 ppm magnesia.[2]

The bulk diffusivity of metals, which controls a major transport path for vacancies from the pore to the grain boundary via diffusion through the bulk, can only be moderately increased by doping with small amounts of an alloying metal additive. The enhancement of the grain boundary self-diffusion, which controls a second major transport path for vacancies, as in W doped with Ni,[3] however, also increases the grain growth rate leading to increased pore/grain boundary separation.

The metallic materials produced by pressureless sintering, such as hard metals, heavy metal alloys and permanent magnets, are all sintered in the presence of a liquid phase, which reflects the problems of sintering to a pore-free material in the solid state, but also indicates the ability to obtain dense materials by liquid phase sintering. The microstructural development and the shrinkage during sintering in the presence of a liquid phase are governed by a number of basic principles.[4] At sintering temperatures in all materials one or more phases are solid and at least one phase is liquid. After processing the microstructure consists often of two solid (sometimes interpenetrating) networks. Densification during liquid phase sintering is also based on rearrangement and shape change of the solid constituent particles (Fig. 1 bottom). The driving force for both phenomena results from a decrease in energy caused by changes in the areas of the liquid/vapor, liquid/solid and solid/vapor interfaces during rearrangement and/or shape change. Melt may originate from low melting point particles or areas which have built low melting point compositions by diffusion during heating. With good wetting, the liquid phase is pulled by capillary forces into particle necks and small pores. As a reaction to the capillary forces, particles are rearranged if their mobility allows it. This rearrangement of the solid particles is a necessary prerequisite for effective densification throughout the sintering process even during later sintering stages, when, for example, the rates of particle shape change also limit the rearrangement rate. Shrinkage due to the shape change of the solid constituents always involves solution-reprecipitation processes, e.g., when during coarsening by diffusion controlled Ostwald ripening the grains accommodate their shape to a changing environment.[5] This is shown in Figure 3 for liquid phase sintering of Mo-Ni by internal etching boundaries. A major part of the shrinkage results from rearrangement when small particles are dissolved making way for the movement of larger particles (see also Fig. 1 bottom).

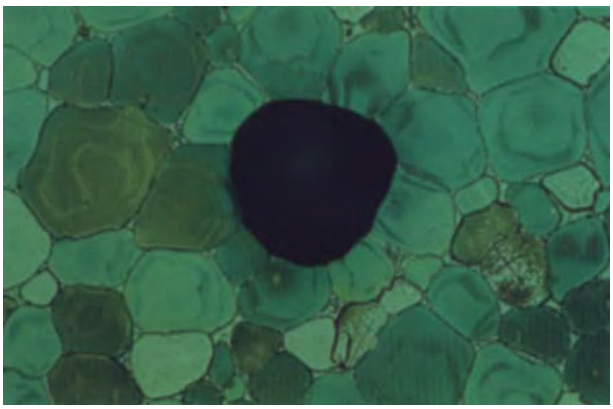

Fig. 3. Microstructure of Mo-4wt.-% Ni after cyclic liquid phase sintering between 1300 and 1460°C (Held at 1460°C for 30 min in each cycle). Etched with *Murakami*'s solution. [5] The bulk material is densely packed; the center is a pore. Scale: 24 mm equal 10 μm.

Due to the effective shrinkage mechanisms liquid phase sintering yields dense PM materials. As shown above, densification requires grain growth and rearrangement. Complete elimination of pores is thus limited to systems where either powders are fine initially or where large amounts of a suitable liquid phase are available. Typical examples of liquid phase sintered high performance materials are hard metals (e.g. WC-Co cutting tools) or hard magnets (e.g. Fe-Nd-B shown in Figure 4[6]).

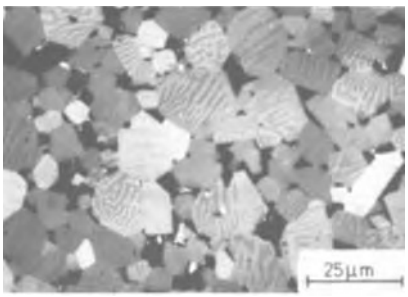

Fig. 4. Pore free microstructure of liquid phase sintered Fe-18.5Nd-6.5B. The magnetic grains are indicated by line patterns (Kerr effect). The black areas are solidified eutectic melt.

3. Advanced PM Materials by Pressure Assisted Consolidation

For most of the complex alloy systems fine powders and suitable melt phases are not available. The powder metal

lurgical production of these advanced materials of great commercial interest only became possible when, mainly in the early eighties, modern engineering provided production facilities for powder consolidation where heat (as during sintering) and pressure (as during compaction) could be applied simultaneously. The simultaneous application of pressure and heat allows the use of comparatively coarse, prealloyed powders with complex microstructures and high yield strength. Densification is readily attained without solid state sintering additives and without the presence of a liquid phase. The processes most frequently used are hot isostatic pressing and hot extrusion.

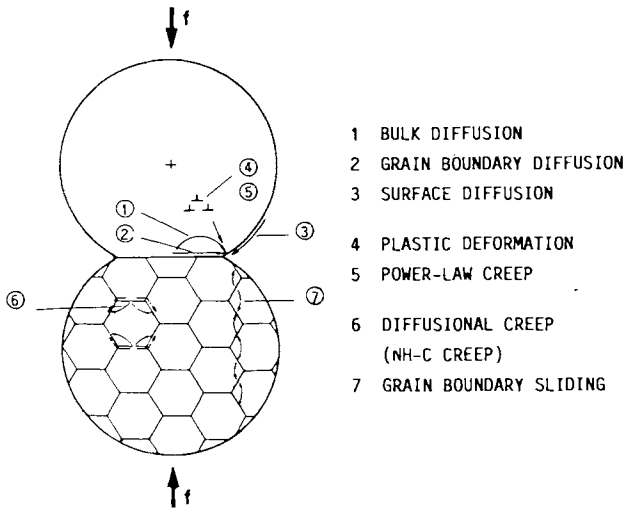

Fig. 5. Transport mechanisms during hot isostatic pressing. f = force.

During *hot isostatic pressing* (HIPing) plastic flow and a number of creep mechanisms contribute to densification (Fig. 5).[7,8] Which one of these mechanisms dominates shrinkage and neck growth rate depends on a number of powder parameters (size, grain size, current geometry, bulk material properties, interface properties) and processing parameters (pressure, temperature, time). The neck growth and center approach rates are described by analytical equations but can also be predicted from the deformation of single powder particles under a well controlled load in a dilatometer.[8] These experiments indicate power-law creep as the dominant densification mechanism for most metal alloys.

During normal HIPing the powders must be encapsulated in closed thin-walled preforms, a tedious and costly operation. In 1985 a new method, sinter-HIPing, started to come into use.[9] The development became possible through the construction of improved HIP equipment with pressure vessels which allow dewaxing of binders, often added to the initial powder mixtures for superior handling, vacuum sintering and subsequent HIPing in one cycle. The vacuum sintering is performed to closed porosity (porosity below 6%), i.e. to a state where all pores are separated from each other and completely enclosed in a dense material matrix. The sources for the closed pores are not limited to the usual porosity remaining from the starting porosity in dense randomly packed powder arrangements, but may also stem from undestroyed initial powder agglomerates, inhomogeneous flow of powder particles during mould filling or inhomogeneous drying in slip cast greens. The elimination of these larger pores, which constitute critical defects in the final material, during HIPing or sinter-HIPing makes the PM materials often superior to cast materials which frequently contain casting porosity. Figure 6 shows the collapse of a large pore during HIPing of presintered Al_2O_3-anorthite by a combined flow of Al_2O_3 grains and the anorthite glass.[9]

Fig. 6. Closing artificial pore in presintered Al_2O_3-10 vol-% anorthite after HIPing at 10 MPa for 30 min. The arrows indicate the formation of special boundaries by coalescence of the Al_2O_3 grains.

As mentioned above, the use of HIPing or hot extrusion provides dense materials also from unsinterable particulate combinations, such as short-fiber reinforced composites and oxide dispersion strengthened high-temperature alloys. Mixtures of fibers of high strength and high stiffness with fine powders are consolidated at temperatures low enough to avoid fiber decomposition by chemical reactions with the matrix, but sufficient to allow adequate bonding of the fibers to the matrix. Whereas reinforcement of metals and ceramics with long fibers was found economically unviable, *short-fiber reinforcement*, particularly with SiC whiskers, is seen to offer a more favorable cost property-improvement ratio.[10] At present the most frequently investigated systems are SiC-whisker reinforced Al_2O_3, Si_3N_4, and Al alloys.[10] A number of technical and economic problems are, however, still unsolved. The SiC whiskers are too expensive. The distribution of the whiskers in the fine powder matrix and sintering to closed porosity as well as chemical reactions between the whiskers and the matrix require further research.

Oxide dispersion hardened Al alloys or superalloys are produced by reaction milling in an attritor. During milling, surface oxides on the powder are destroyed and finely distributed in the interior of the powders together with other intentionally added fine oxide powders due to a continuing fracture and rejoining sequence.[11] A modification of this method is the reaction milling of a mixture of Al and graphite powder which provides an extremely homogeneous distribution of fine graphite inclusions in the Al matrix.[12] During tempering of the hot extruded milled blends, fine Al_4C dispersoids form at the sites of the fine graphite inclusions (Fig. 7). The tensile strength of this material at 400 °C is 50% of the room temperature tensile strength.

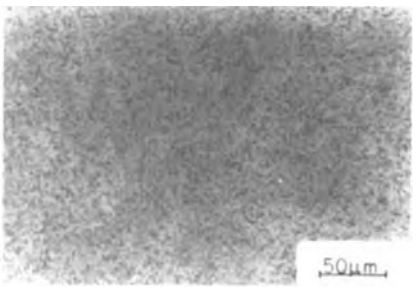

Fig. 7. Microstructure of a dispersion hardened Al alloy (DISPAL 1 Si 12 transv.).

HIPing and other new consolidation methods such as hot extrusion also allow fast densification and defect healing of coarse, unsinterable powders with unusual microstructures. Such powders are produced by *rapid solidification*; high cooling rates and high undercooling result in refined microstructures, decreased segregation, metastable and new phases, as well as in increased solid-solubility ranges. Gas or water atomization are valuable methods for producing rapidly solidified powders for high-performance materials in large quantities. With these methods a thin falling stream of the molten alloy is disintegrated into fine droplets by the impact of high pressure gas or water jets.[1]

An important aspect of the *microstructural refinement* is the cooling rate of the droplets which determines the velocity of the solidification front. The cooling rate is governed by the convective heat transfer from the droplet to the surrounding flowing gas. The cooling rates range from 10^4 to 10^7 K s^{-1} for droplets of 50 µm (argon) to 5 µm (helium) in diameter, respectively. For a special group of advanced PM materials fine microstructures are not sufficient, but *segregation-free microstructures* are required. They allow the formation of highly supersaturated solid solutions yielding a large amount of extremely fine precipitates during ageing. These are often stable against further coarsening due to a low equilibrium solid solubility of the alloying elements in the solvent at service temperatures. Segregation-free solidification is only possible if the growth velocity of the solidification front is larger than the diffusion speed of the solute atoms.[13] In Cu-7wt.-%Sn a solidification-front velocity of about 4 m s^{-1} is required for segregation-free solidification, which is high compared to the velocity of 0.02 m s^{-1} obtained during cooling of an atomized 5 µm droplet. To attain a sufficiently fast solidification-front movement in fine melt droplets, considerable undercooling of the liquid is necessary. Undercooling is possible if potent heterogeneous nuclei are absent. The probability of a potent heterogeneous nucleus being present in a droplet decreases rapidly with decreasing droplet volume. The percentage of powder particles which have solidified after considerable undercooling increases rapidly with decreasing particle size. Due to extensive engineering efforts and the application of advanced principles of fluid mechanics, facilities are now available for producing the required fine powders in large quantities.

From the abundance of recent developments of materials from rapidly solidified powders, three examples are presented. The first example, the aluminides, illustrates the beneficial use of high cooling rates to obtain finer microstructures. The other two examples, a dispersion strengthened Cu-Sn alloy and a Cu-Ti-B alloy, are indicative of the advantages of high undercooling.

Iron aluminide and nickel aluminide *intermetallics* have recently been the object of considerable interest as potential structural materials for high temperature applications. The cubic DO_3 (Fe_3Al), $L1_2$ (Ni_3Al), and B2 (FeAl, NiAl) lattice structures yield special properties such as a low density (compared to the superalloys), high strength and high elastic moduli which make them interesting for lightweight applications in the aerospace industry. Excellent corrosion resistance up to 800 °C with high yield strength at elevated temperatures open a wide field in coatings, especially in oxygen-rich hot gases, with an optimum relation of price to performance. A major problem of coarse-grained intermetallics is their extreme brittleness, whereas single crystals and polycrystals with grain sizes smaller than 20 µm display considerable ductility at room temperature.[14] The reasons for the failure of coarse-grained materials are the weak grain boundary structures and the sensitivity of grain boundaries to segregation of impurity atoms. Several remedies exist to improve the unfavorable properties, the most promising one being the use of rapid solidification to obtain fine-grained materials. Figure 8 top shows Ni_3Al powder with an average grain size below 15 µm which was obtained by Ar atomization.[15]

A homogeneous distribution of fine oxides, giving a *dispersion strengthened material*, can be obtained directly from rapidly solidified melts. The Ar-atomized Cu-7Sn particle shown in Figure 8 bottom has an area where segregation-free solidification occurred. Undercooling was increased by minimizing the number of potent nuclei. With the addition of Al, the metal oxides which were the initial potent nuclei of the melt were transformed into fine, dispersed Al_2O_3 particles of low potency. A homogeneous distribution of Al_2O_3 particles was obtained in areas which

ADVANCED MATERIALS

solidified segregation-free[16] (small bright spots in Fig. 8 bottom).

Cu-Ti alloys are mainly used as electric conductors and contact materials with increased microhardness and only slightly reduced electrical conductivity compared to unalloyed Cu.[17] The mechanical and electrical properties of Cu-Ti can be further improved by the addition of boron resulting in *dispersion hardened copper alloys* for welding machines, where a high microhardness is obtained by additional dispersion strengthening. If suitable amounts of B and Ti are added to Cu, extremely stable TiB_2 precipitates form during ageing with a negligible amount of Ti and B remaining in the solid solution, providing an increased hardness at high electrical conductivity. However, during cooling of ternary Cu-Ti-B melts at rates below 10^4 K s^{-1} the primary solidification of TiB_2 yields precipitates, which are too coarse for effective precipitation hardening. In atomized powders the primary precipitation of TiB_2 during solidification is suppressed due to undercooling and a high cooling rate. Ti and B remain in a supersaturated Cu solid solution, which provides a hardness of more than 500 $HV_{0.1}$ after ageing the powders at moderate temperatures.[18]

4. Outlook

Powder metallurgy (PM) is now recognized by most of the governments of the industrial nations to be key technology in the development of advanced materials. For example, in 1987, the Bundesministerium für Forschung und Technologie invested no less than 60 million DM in support of the German PM research and development program. Faith in the potential of powder metallurgy rests on two factors:

- PM can satisfy the demands of specific material requirements. The inherent flexibility of PM materials, as compared to cast materials, results from an almost unlimited number of workable phase combinations, which include ceramics, polymers and metals. PM is one of the most promising techniques for the production of complex composites.
- PM enables the production of refined, homogeneous and highly supersaturated materials. New classes of materials can be used, which require small grain sizes, such as the intermetallic phases.

Powders are increasingly being used for the production of thin layers and layered structures. The plasma spraying of powders has already established itself as one of the most important methods for the production of high quality surface coatings. The spray deposition of atomized liquid droplets onto substrates is increasingly serving the same purpose. Fine droplets form a rapidly solidifying thin liquid layer on a substrate. The latter method smoothly bridges the gap between PM and casting technology.

ADVANCED MATERIALS

New Methods for the Anionic Polymerization of α-Activated Olefins

Group Transfer Polymerization
Metal-free Polymerization
Living Polymers

By Manfred T. Reetz*

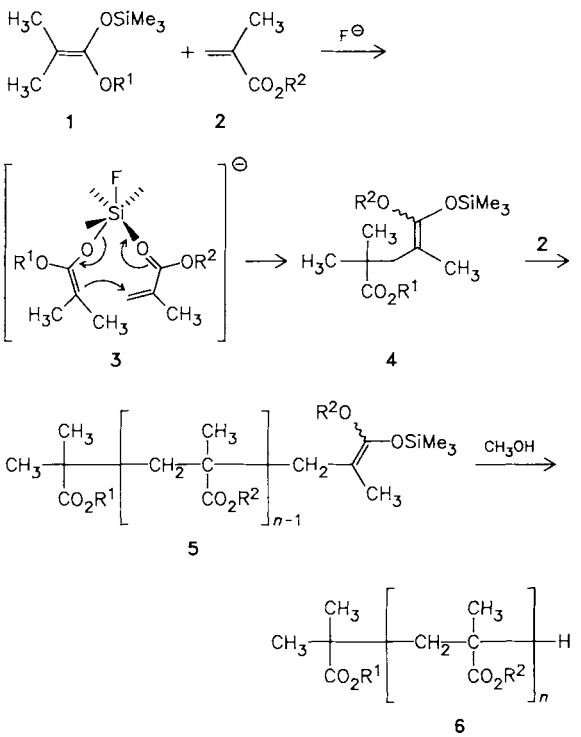
1. Introduction

One of the exciting developments in current polymer research concerns the controlled polymerization of monomers with formation of macromolecules having a defined molecular weight and a narrow molecular weight distribution. If a given process has the additional feature of yielding living polymers, such interesting reactions as functionalizations of the chain end and/or block and graft polymerizations are possible. The costs of these polymerizations may be higher than those of traditional processes lacking such characteristics. However, in certain applications this may be offset by the favorable properties of the polymers.

In recent years several different types of polymerizations have been developed with the aim of fulfilling some or all of the above mentioned requirements. These include cationic polymerizations of isobutylene and other electron rich olefins,[1] polymerization of cyclic olefins using olefin metathesis,[2] and anionic polymerizations of α-activated olefins such as acrylic and methacrylic acid esters.[3-12] This report deals with the latter area, with emphasis on the author's own research.

2. Group Transfer Polymerization

In 1983 *Webster* and co-workers at Du Pont startled the scientific community by introducing the so-called group transfer polymerization (GTP) of methacrylic acid esters **2** and other α-activated olefins.[3] Accordingly, the *O*-silyl ketene ketal **1** functions as the initiator in combination with a nucleophilic or electrophilic catalyst, e.g., fluorides or Lewis acids, respectively. It turned out that the former are better suited. Such fluorides as HF_2K, $FNnBu_4$ or $[Me_3SiF_2][S(NMe_2)_3]$ induce the quantitative polymerization of **2** at *room temperature* with formation of polymers having a narrow molecular weight distribution, i.e., *D* values of <1.3 ($D = M_w/M_n$; ratio of the weight average molecular weight to the number average molecular weight). Such results are significant because the classical anionic polymerization of methacrylates using hindered alkyllithium initiators requires low temperatures (-20 to -70 °C),[4] which is uneconomical.



R^1 = CH_3, *n*-alkyl, $CH_2CH_2OSiMe_3$
R^2 = CH_3, *n*-alkyl, allyl

The mechanism of GTP involves activation of the initiator by fluorides to form a pentavalent silicon species which then undergoes Michael addition to the monomer via the hexacoordinated intermediate **3**. Although the details of this step are still being studied,[5] it became clear that the silyl group migrates to the oxygen atom of the monomer, forming a new *O*-silyl ketene ketal **4** which in turn undergoes another Michael addition. Labeling experiments

ADVANCED MATERIALS

show that the silyl groups remain attached to the growing chain, i.e., they do not jump to other chains.[6]

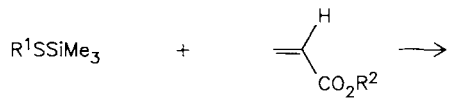
The molecular weight can be controlled by the amount of monomer added relative to the quantity of initiator used. Most of the reported molecular weights M_n lie between 1000 and 20000. There appear to be very few chain transfer or terminating events, which means that in a practical sense the polymers are living. Following the termination of a given polymerization, the same or a different methacrylic acid ester can be added, resulting in the continuation of polymerization.

Since the R^1 group in the initiator **1** can contain a protected functional group (e.g., $CH_2CH_2OSiMe_3$), one end of the polymer may bear a functional group (e.g., OH following hydrolytic deprotection) which can be used as an anchor point for the formation of graft polymers. Such functionalized polymers (chelic polymers) are useful for the production of dispersing agents and ABA block polymers.[7] Functionalization, coupling and dimerization at the chain end have also been reported.[3,7]

Since the details of the Dupont process have been delineated elsewhere,[7] no further information is given here, except to point out that *acrylic* acid esters were reported to cause problems.[7,8] Nucleophilic catalysts lead to broad molecular weight distributions. Lewis acid catalysts, especially ZnX_2, are better suited. They activate the monomer by coordinating at the carbonyl function. However, it was reported that the polymers are no longer living at room temperature, i.e., renewed addition of monomer following the termination of polymerization did *not* lead to a continuation of polymerization.[8]

It is generally accepted that the anionic polymerization of acrylates is more difficult than that of methacrylates.[4,7] Not only are the former monomers more reactive, but also the polymer chain contains C–H acidic positions which undergo undesirable deprotonations (metalations). In spite of this, we attempted the GTP of acrylic acid esters at room temperature using silylated thiols **7** as initiators. We were pleased to discover that ZnI_2 as catalyst (only 1% with respect to the *initiator*!) induces the quantitative polymerization of **8** in toluene with formation of *living* acrylates having excellent *D*-values (≈ 1.1).[9] Functionalized initiators (e.g. **7b**) behave similarly. This paves the way for preparing block, graft, chelic and telechelic polymers. In the polymerization of **8b** with **7b**/ZnI_2, further monomer was added at room temperature three hours after termination of polymerization; this led to a continuation of the polymerization with quantitative formation of a polymer having a molecular weight distribution which is only slightly broadened ($D = 1.25$). Following aqueous work-up, the isolated polymers are stable at higher temperatures, e.g., heating at 260 °C for three hours causes no loss of sulfur.[10]

The success of group transfer polymerization rests upon the migration of covalently bonded *O*-silyl groups along the polymer chain under mild conditions,[3,9] in contrast to the highly polar lithium enolates in classical anionic polymerization. The reactivity is expected to increase in the following sequence: Si-enolates < Li-enolates < K-enolates < NR_4-enolates. At first glance the ionic end of the scale, i.e., a metal-free system with ammonium as the counterion, might be expected to lead to disastrous results at room temperature. Nevertheless, we decided to venture into this area.



7a, $R^1 = CH_3$ **8a**, $R^2 = CH_3$
7b, $R^1 = CH_2CH_2OSiMe_3$ **8b**, $R^2 = n$Bu
7c, $R^1 = Ph$

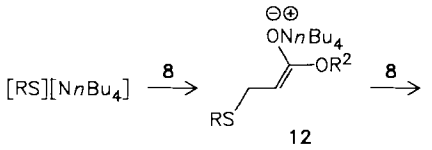
3. Metal-free Anionic Polymerization

We turned first to ammonium thiolates RSN*n*Bu$_4$ as initiators for the anionic polymerization of acrylic acid esters.[11] They are accessible by deprotonation of the corresponding thiols by HON*n*Bu$_4$ or by treating the sodium thiolates with ClN*n*Bu$_4$.

Upon adding methyl or *n*-butyl acrylates to the initiators at *room temperature* in the absence of catalysts, essentially quantitative formation of polyacrylates was observed! Equally surprising is the discovery that under proper conditions the molecular weight distribution is very narrow.[11] The best results are obtained in acetonitrile, nitrobenzene or mixtures of nitrobenzene and THF, whereas dimethyl sulfoxide (DMSO) should be avoided. Typically, the initiator **11a** induces the polymerization of *n*-butyl acrylate at room temperature in acetonitrile, *D* being 1.15 (M_n(calc.) = 1.37; M_n(obs.) = 1.28; $M_w = 1.47$).

Mechanistically, the ammonium thiolates undergo rapid Michael additions to form an ammonium enolate **12** which in turn sets the stage for further Michael additions. In the case of the functionalized initiator **11c** the polymer has a hydroxy group on one end following acidic work-up, the *D* value being 1.14. In spite of the above positive aspects, the method has several limitations. The initiators are generally not stable for long periods of time due to decomposition via dealkylation of the ammonium ion. Moreover,

when aiming at molecular weights of >2000, the M_n(obs.) values are much too low. This can be attributed to a side reaction involving thiolate elimination at one end of the polymer chain, a chain terminating process that is induced by the basic nature of the chain end.[11] The eliminated thiolate then starts a new chain. Since the *D* values are also poor in such cases, the process is limited to the synthesis of low molecular weight polymers. It is nevertheless important to note that sodium and lithium *n*-butylthiolates in acetonitrile are inefficient initiators, leading to incomplete polymerization and broad molecular weight distributions ($D > 3$).[11]

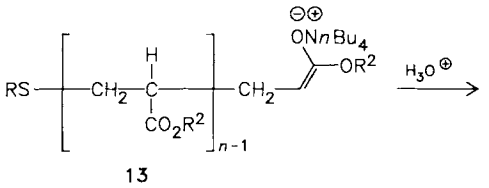


12

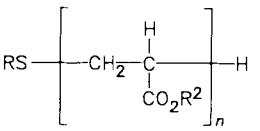
11a, R = *n*Bu

11b, R = Ph

11c, R = $CH_2CH_2OSiMe_3$



13



14

In order to eliminate the above drawbacks, we explored the possibility of employing metal-free carbon nucleophiles as initiators.[12] In particular, C-H-acidic compounds were deprotonated with $HONnBu_4$ or their sodium salts treated with $ClNnBu_4$ to form the resonance-stabilized compounds **15**–**17**. They are stable at 0°C for months and can be handled at room temperature without any decomposition.

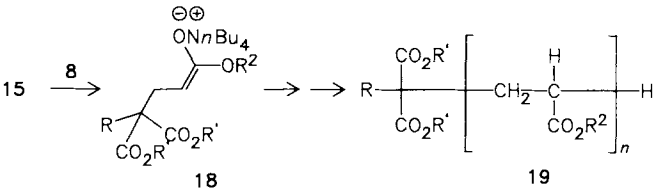
17

Although a number of ammonium carbanions have been reported, they were generally not fully characterized.[13] In the present case the compounds were studied by NMR and IR spectroscopy.

Upon adding *n*-butyl acrylate to solutions of **15** at room temperature, a spontaneous exothermic reaction was observed with formation of polyacrylate (>95% conversion to **19** after aqueous workup). Thus, the doubly stabilized initiators **15** add in a Michael fashion to form less stabilized carbanions **18** which then continue chain growth until no more monomer is added. It is possible to add a different *n*-alkyl acrylate immediately following the consumption of monomer and to continue the polymerization with formation of a polymer having two well defined blocks.



18 **19**

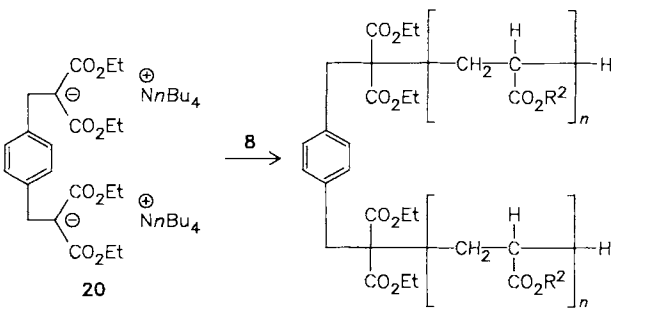
In contrast to the previous oligomerizations induced by thiolate anions, this new method allows the synthesis of polymers having molecular weights of >2000.[12] Moreover, the molecular weight distributions are surprisingly good (Table 1). For example, when aiming for a molecular weight of ca. 20000, M_n(calc.) and M_n(obs.) agree well, and the *D* value is 1.3 (entry 10 of Table 1). The other initiators also induce the polymerization of *n*-butyl acrylate, although the nitrostabilized initiator appears to be less efficient (entries 15 and 16 of Table 1).

Table 1. Polymerization of *n*-butyl acrylate **8b** at room temperature [a].

Entry	Initiator	Solvent	M_n(calc.) [kg mol^{-1}]	M_n(obs.) [kg mol^{-1}]	*D*
1	**15a**	THF	1.15	0.90	1.16
2	**15a**	THF	5.32	3.13	1.36
3	**15a**	THF	10.44	7.42	1.25
4	**15b**	THF	1.44	1.51	1.50
5	**15b**	Toluene	1.44	0.64	1.37
6	**15b**	THF	5.29	5.86	1.30
7	**15b**	Toluene	5.29	6.82	1.36
8	**15b**	Toluene	10.41	10.92	1.30
9	**15b**	THF	20.67	17.43	1.38
10	**15b**	Toluene	20.67	20.39	1.30
11	**16**	THF	1.36	0.61	1.14
12	**16**	Toluene	1.36	0.71	1.61
13	**16**	THF	5.21	2.59	1.43
14	**16**	Toluene	5.21	4.21	1.34
15	**17**	THF	1.37	0.85	2.71
16	**17**	Toluene	1.37	1.25	2.18

[a] During polymerization the temperature rises by 10–20°C.

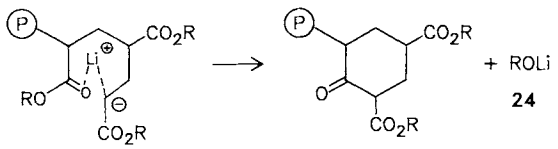
In a similar manner, dianions such as **20** are effective initiators in the polymerization of *n*-butyl acrylate (e.g., M_n(calc.) = 1717; M_n(obs.) = 1624; $D = 1.1$).[12]



20 **21**

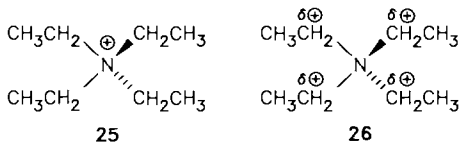
ADVANCED MATERIALS

It is difficult at present to explain why the ammonium carbanions are such excellent initiators at room temperature. One of the major chain-terminating processes of the classical anionic polymerization of acrylates and methacrylates is the "back-biting" reaction.[4] This intramolecular Claisen condensation requires a metal ion such as $Li^{\oplus}$ or $Na^{\oplus}$ for the activation of the ester group and the ready expulsion of alkoxide ions (cf. **22** → **23** + **24**). In the case of the present system, metal complexation is not possible. Even if the (reversible) addition step were to occur, it is likely that elimination of "naked" alkoxide is a kinetically and thermodynamically unfavorable process, certainly in comparison to chain propagation involving electrophilic monomers. Nevertheless, it remains to be tested how long the chain end survives following the complete consumption of monomer and prior to the addition of electrophiles (e.g., more monomer or $H_3O^{\oplus}$). It should be mentioned that the sodium salts of the above initiators are inefficient, leading to incomplete conversion and poor D values (>3).[12]



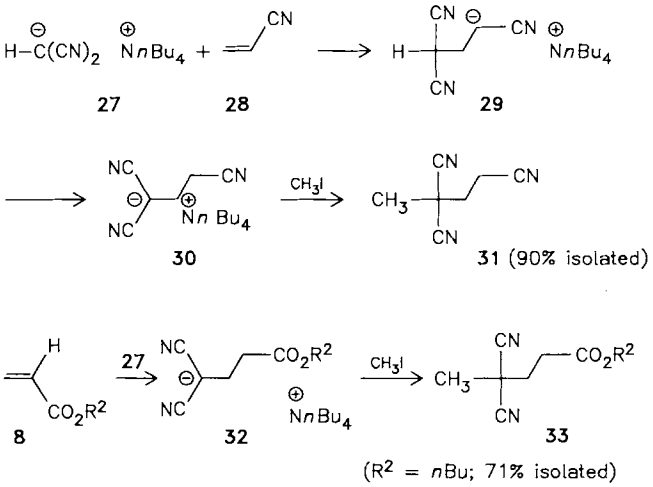
P = Polymer

Although detailed studies remain to be carried out, it is interesting to speculate about the mechanism. Strong electrostatic attractive forces between the anionic chain end and the ammonium counterions are likely to be involved.[11, 12] Molecular orbital calculations on tetraalkylammonium ions show that the positive charge is *not* localized on the nitrogen atom as indicated by the traditional representation **25**, but rather on the four α-carbon atoms, see **26**.[10] This means that a tetraalkylammonium ion has a tetrahedral distribution of charge.



The monomer may well approach one corner of the tetrahedron; this process might be looked on as a kind of solvation. As the Michael addition then proceeds, the ester function turns into the new enolate chain end. Concomitantly, the previous enolate becomes an ester function along the chain, perhaps solvating intramolecularly until the next monomer approaches. In line with these speculations is the observation that bulky ammonium ions such as tetraoctylammonium are not well suited for metal-free polymerizations.[10] The reactions are often sluggish, leading to polymers with broad molecular weight distributions. The long groups pointing from the tetrahedral positions probably prevent a tight and ordered transition state.

Experiments directed toward the synthesis of ammonium malonates having protected functional groups are in progress.[10] A different strategy for the preparation of chelic polymers pertains to the reaction of the carbanion **27** bearing a hydrogen atom at the reactive center. We discovered that in 1 : 1 reactions with various Michael acceptors smooth exothermic additions occur. Following the complete consumption of the reaction components at room temperature, the crude product was quenched with methyl iodide. The products turned out to be **31** and **33**, which means that proton transfer occurs (e.g. **29** → **30**) prior to alkylation.[10] Thus, the initiator **30** can be prepared without undesired polymerization of the very reactive acrylonitrile! This chemistry also suggests that an easily hydrolyzable ester (e.g., **8**, R^2 = *tert*-butyl) should react in the same manner, i.e., the *in situ* preparation of initiators of the type **32** (R^2 = *tert*-butyl) is probably an easy task. In experiments already performed, the nucleophilic *end* of the chain was *O*-silylated with Me_3SiCl.[10]



Finally, other α-activated olefins such as the extremely reactive acrylonitrile[10] as well as the less reactive methacrylates[12] can also be polymerized in a controlled manner. In the latter case the nitro-stabilized carbanion **17** is the best initiator, although an induction period of 30–60 s is generally observed.

4. Conclusions and Applications

Free radical initiation remains the method of choice for the production of high molecular weight homopolymeric acrylates and methacrylates. However, GTP with formation of living polymers results in a number of structural features generally not accessible by radical processes: narrow molecular weight distribution, controlled introduction of end groups, segmentation of chains in blocks, and accurate control of molecular weight in the range 1000 to

20000. GTP also produces polymers with linear backbones, in contrast to free radical polymerization in which branching may occur. One of the problems yet to be solved in GTP and metal-free polymerizations is the control of tacticity.[14]

As far as industrial applications are concerned, Dupont has invested great efforts towards developing such products as star polymers for use in toughening plastics and coatings, e.g., for the automobile industry. It remains to be seen whether the customer will pay a higher price for a more durable product. Other potential applications include thermoplastic elastomers, non-aqueous dispersions for the control of rheological properties,[7] and liquid crystalline polymers.[15] Chiral polymers made by GTP have also been reported.[16]

Although metal-free polymerization has only recently been developed, similar applications are in principle possible. The mechanism and theoretical basis also need to be explored. Finally, the question arises whether other types of anionic polymerizations (e.g., ring opening processes) can also be performed using metal-free initiators.

The author thanks Bayer AG for financial support. Discussions with D. Arlt, K. E. Piejko and B. Bömer are highly appreciated.

Conference Report

Photovoltaic Solar Energy in Europe

More than 750 materials scientists, physicists, engineers, marketing specialists, and government officials from 45 countries met from 9–13 May 1988 at the "8th European Photovoltaic Solar Energy Conference and Exhibition" in Florence, the largest European Conference ever held on this topic. Photovoltaic (PV) energy has now reached maturity. Crystalline and polycrystalline silicon modules have proven to be the most reliable decentralized source of energy. Their still rather high cost limits their applications at present to the electrification of isolated sites, which are however abundant. Performance and reliability of standalone PV systems in the 10 W to 60 kW range have been evaluated during the past ten years by the US Army, several American and European agencies, and by Third World organizations.

Whereas the reliability of crystalline and polycrystalline silicon modules complies with military standards, many peripherical components such as inverters and battery regulators still have reliability problems. For most household applications, low voltage direct current is therefore preferable to 220 V alternating current, in spite of the high price and poor choice of dc household appliances. The storage of electrical energy has turned out to be a crucial problem for photovoltaics. According to *E. Voss* (Varta, Kelkheim), the lead-acid battery is at present the only viable system for power applications. Possible alternative storage systems for the future are Zn–Br and Cr–Fe batteries, whereas Ni–Cd batteries will not be cost-competitive.

Progress in photovoltaics is intimately linked with the development of new materials and processing technologies. Amorphous hydrogenated silicon, discovered as an electronic material by *Spear* and *Lecomber* (University of Dundee) in 1975, is today a $ 200 million per year business in non-PV applications, and has become one of the leading thin film solar cell materials.

Progress that has recently been made in the production of silicon cells is mainly due to the minimization of optical and recombination losses. Crystalline cells with recombination-free interfaces have been developed by *M. A. Green* in Kensington, Australia (passivated emitter and laser-

grooved buried contact), and by *R. Swanson* of Stanford University (point contact cell). Light trapping is used now in all kinds of silicon solar cells, and has given a spectacular improvement in conversion efficiency. It enhances the optical path of poorly absorbed red or near-infrared light and allows one to make cells thinner. Thin amorphous silicon cells show less light-induced degradation than thicker ones.

The search for a low band-gap a-Si alloy for solar cells has not yet given conclusive results, as pointed out by *J. Bullot* (Orsay University), since the reproducibility and electronic quality of silicon-germanium alloys are not yet satisfactory. The recent improvement in conversion efficiency of a-Si p-i-n cells is mainly related to the p-doped window layer: microcrystalline a-$Si_{1-x}C_x$:H layers, doping with $B(CH_3)_3$ instead of B_2H_6, and superlattice p-layers. Efficiencies of 10% (active area) for $10 \times 10\ cm^2$ modules were announced by Sanyo (Osaka). *D. Carlson* (Solarex, Newtown, PA) reviewed in-line processing technology for large area a-Si modules. Initial efficiencies of 8% on 1000 cm^2 modules are currently achieved by several American and Japanese companies. Stability of a-Si cells has greatly improved. Light-induced degradation can be reduced to 15% in very thin (0.2 to 0.3 μm) cells.

Polycrystalline cells have seen spectacular progress, too, both in fundamental research (*L. L. Kazmerski*'s (SERI, Denver)talk on the analysis of hydrogen at grain boundaries by scanning tunneling microscopy was one of the highlights of this conference) and on the technological side. *A. Barnett* (University of Delaware) reported efficiencies of over 12.5% with small polycrystalline cells processed on low-cost ceramic substrates.

Non-silicon materials are outsiders in PV technology. In spite of the high price of indium, $CuInSe_2$ continues to attract much attention, especially due to progress in material processing (sputter and spray methods). Stacked a-Si/$CuInSe_2$ cells were described by ARCO. Economic criteria will determine the future of this technology.

It remains an open question whether crystalline, polycrystalline or amorphous silicon will be the leading material for the solar cell technology in the next century. Amorphous silicon seems to have the highest potential for cost reduction. However, this requires large scale plants (well above 1 MW/year), since the initial investment is very high.

The vigorous financial effort of the Commision of the European Comunity and national governments (especially in West Germany) to encourage photovoltaics research and development in Europe has so far been a success. 35 companies exhibited PV modules and systems and showed that photovoltaics is already an industrial reality.

Research News

Lord Kelvin Updated

William Thompson, better known to science as Lord *Kelvin*, demonstrated theoretically as long ago as 1853 that the rate of temperature change in a cyclically loaded body is directly related to the rate of change of the sum of the principal stresses, if conditions are adiabatic. If a specimen is stressed inhomogeneously, in cyclic fashion, then the distribution of stresses is expressed by a distribution of mean ΔT (relative to the undisturbed temperature of the sample). The ΔT oscillate with the same frequency as the applied cyclic stress. (An increasing tensile stress gives a temperature fall, an increasing stress, a temperature rise.)—Kelvin's principle can be thought of as the thermoelastic analogue of Faraday's principle of electromagnetic induction, established at roughly the same time.

Kelvin's principle has been exploited for some years now to map the distribution of stresses in an inhomogeneously stressed thin flat body—for instance, a sheet containing a hole or a notch—by measuring the time-averaged temperature change at each point by means of a scanning infrared emission camera: the camera is electronically controlled to read ΔT at each test point in synchrony with the frequency of the applied stress. The strategy has been used for non-destructive examination (NDE) of an object's resistance to fatigue damage. Here the cyclic stress is used to modify the state of the material rather than as a mere probe to examine stress distributions. Incipient fracture, or delamination of a fibre-reinforced composite, leads to enhanced local temperature changes, and such damage sites show up in *vibrothermography*—as the technique is sometimes called—long before they can be detected by any other NDE method.[1] The method has been found especially favourable for NDE of fibre-reinforced composites.[1]

However, vibrothermography can do more than provide NDE: given sufficiently sensitive equipment and appropriate theory, the distribution of stresses which would result from an applied steady load can be determined by a ΔT scan with a low-frequency cyclic load which itself is far too small to damage the specimen in any way. A new instrument based on a design by SIRA in England, named

SPATE (for *S*tress *P*attern *A*nalysis by measurement of *T*hermal *E*mission) can be used in this way. (Spatial resolution is 0.25 mm^2 and temperature resolution, 0.001 °C). The infrared signal at each point the specimen at the peak of the stress cycle is averaged over many cycles to achieve an accurate estimate of the stress distribution.

Recent work[2-4] at the Aeronautical Research Laboratory in Melbourne, Australia, has now advanced the technique to new and unexpected level of subtlety. *Machin* et al.[2] found experimentally that, contrary to Kelvin's theory, not only the cyclic stress amplitude but also the mean stress affect the output of the SPATE instrument. Sustained attempts to develop the theory to account for this finding led to an expression[3] in which ΔT is linearly related to the mean stress when measured at the primary frequency, but is modified by a second term with a coefficient proportional to the square of the stress range when measured at the second harmonic (twice the primary frequency). This new theoretical relationship was obtained by taking into account the variation of Young's modulus with temperature, something that *Kelvin* omitted to do. This new analysis offers the prospect of using vibrothermography to separate out oscillating stress amplitudes (which mimic the distribution of stress which would be created by an externally applied load) from a fixed, *residual* stress distribution which exists in the absence of any external load.

In another recent paper,[4] the Australian team has demonstrated that such separation is indeed feasible. For this purpose, the electronic processor which filters out non-primary frequencies has to be by-passed so that any component of thermal response at twice the primary frequency can be separated out. *Wong* and his coworkers[4] prepared an aluminum alloy plate which was plastically loaded to create a predetermined distribution of residual stresses across the plate width. These stresses were also measured with an array of strain gauges cemented to the plate before the plastic loading. The plate was then cyclically loaded, well inside the elastic range, with a non-zero mean load. Use of SPATE with the electronic bypass referred to then allowed the ΔT distribution at each of the two key frequencies to be determined, and from this the residual stress distribution could be calculated. (This was straightforward because the cyclic stress distribution was uniform across the plate). The Figure 1 taken from reference[4] compares the stress distribution obtained in this way, with error bars, with that directly determined by means of the array of strain gauges (solid line). The agreement is very satisfactory.

A few points are not quite clear in the published paper. The ordinate of the graph is simply labelled "residual stress": presumably the sum of the principal stresses is meant. Also, it is not clear whether the use of a non-zero mean load in the cyclic loading regime is essential in order to be able to determine the residual stresses, presumably a non-zero mean load helps in separating out the weak double-frequency term from the background noise.

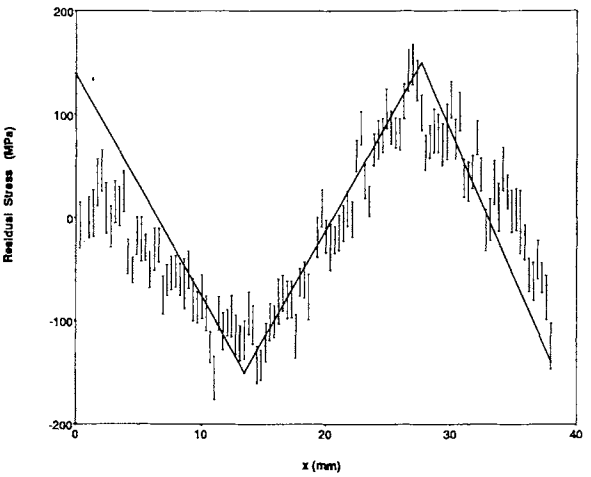

Fig. 1. Residual stress profile for a four-point straightened specimen.

The authors point out that their demonstration was conducted under artificially simple circumstances: the simple rectangular shape of the sample, without holes or other disturbances, meant that the cyclic stress was uniform throughout the specimen. (However, the technique, in this simplified form, could be applied to difficult cases such as that of a glass sheet; the only extant NDE method of estimating residual stresses involves X-ray diffraction and this cannot be used with a non-crystalline material.)—With more realistic specimens of more complex shape, the cyclic stress as well as the residual stress will vary from point to point. To separate out such variables, the sensitivity of SPATE will need to be greatly enhanced, and microstructural features such as grain boundaries and preferred crystallographic orientation of the grains, would also need to be taken into account in these interpretations. Meanwhile, Lord *Kelvin* is well on the way to becoming the most frequently cited nineteenth century physical scientist: his paper on the theory of the instability of liquid jets is already a firm current favourite, and now the even earlier paper on the thermoelastic effect may well join it in its lonely eminence.

Book Reviews

Materials Engineering for Nobody

The Technology and Applications of Engineering Materials. By *M. S. Ray*. Prentice Hall, Englewood Cliffs, N. J., USA 1987. xxv, 736 pp., paperback, $ 27.95.—ISBN 0-13-902081-0

Many years ago, a review of another book on materials opened with the words: "Of books on Shakespeare's plays, the Malaise of Modern Man, and materials science, there is no end. No blinding new insights are to be expected on any of these topics: selection, clarity and economy must be our touchstones." Since I wrote those despairing words in 1974, my shelf of such books has grown to bend increasingly under the burden of several dozens of such volumes (see the book under review, pp. 458–60, 'Bending of Beams'). Any new general text on the science and technology of materials has to be of exceptional quality to succeed in a crowded market place. *Martyn Ray*'s book, I regret to say, fails the tests of selection, clarity and economy: I cannot give it even a qualified welcome.

Texts for students of Materials Science and Engineering (MSE) set out with different objectives. At one extreme is the physics-centered, fundamental interpretative approach, setting out to explain properties in terms of atomic and crystal structure, quantum mechanics and statistical mechanics. The first such book was Cottrell's *Theoretical Structural Metallurgy* of 1948, followed some years later by Wert and Thomson's *Physics of Solids* (1964). Another, even earlier, and extremely influential physics-based book was Barrett's *Structure of Metals* (1943), which has lasted well in the form of successive editions. The same fundamental approach is possible in regard to the chemical approach to materials. The classic here is Darken and Gurry's *Physical Chemistry of Metals* of 1953. Midway between the physical and chemical approaches one finds Swalin's *Thermodynamics of Solids* (1962).

The fundamental approach to polymers was a little slower in coming and probably began with Treloar's 1958 book, *The Physics of Rubber Elasticity*. Since then, the polymer scientists have also been well served with fundamentally biased texts, with a strong undertow of statistical mechanics. From the 1970s on, basic texts began to use the term *materials science*. Notable examples include Ruoff's *An Introduction to Materials Science* of 1972 and Hornbogen's *Werkstoffe* of 1973.

At the other extreme there are texts aimed at the engineer who selects materials for incorporation in his designs, and also at the materials processing specialist who converts materials into semi-finished or finished products. These have been, if anything, even more numerous than the science-centered texts. Early ones had titles such as *Metallurgy for Engineers* (Rollason, 1939) and *Physical Metallurgy for Engineers* (Clarke and Varney, 1952). Later titles covered a broader range of materials; among the better are *Engineering Materials* by Jastrzebski (1959), *The Principles of Engineering Materials* by Barrett, Nix and Tetelman (1973), *Structure and Properties of Engineering Materials* by Harris and Bunsell (1977), as well as the comprehensive *Metals, Ceramics and Polymers* by Wyatt and Dew-Hughes (1974), which was the volume that drew forth the reviewer's words cited at the outset.

A good example of a book aimed specifically at processes is Alexander and Brewer's *Manufacturing Properties of Materials* (1963). More recently still have come some splendid texts aimed directly at developing for fledgling engineers a systematic approach for selecting materials during the design process: *Engineering Materials—An Introduction to their Properties and Applications*, by Ashby and Jones (1980) is a good example.

The titles cited here are only a small selection and include some of the best and most durable. Some of them, especially in the "engineering" group, are really broad treatments that succeed in marrying the S and E of MSE: the books by *Wyatt* and *Dew-Hughes* and by *Harris* and *Bunsell* are examples. The engineers who are to learn from these books are paid the compliment of being supposed intelligent and curious, of wanting to understand complex facts rather than to learn them by rote (and then promptly forget them). By contrast, *Ray*'s book (the volume under review) assumes that his readers do not want to understand—or, perhaps, are incapable of understanding? I am sorry to have to add that this attitude may well stem from a frequent and unmistakable lack of understanding by the author himself. A diet of bare uninterpreted fact, often so vague as to be unintelligible even as fact, has to substitute for insight.

A few quotations will give the flavor: "The molecular weight used to characterize a polymer may be based upon several criteria. The most popular are the viscosity average, number average and weight average molecular weights. For a molecular weight distribution these averages have different values, although they would be identical if the polymer possessed a unique molecular weight." That is all on this subject. Another quotation: "The creep process occurs because of two mechanisms; these are grain boundary sliding and dislocation movement by climbing past obstacles." That is all there is in the book on the role of dislocations in plastic deformation ... yet the cover is decorated by a large diagram of an edge dislocation! Another: "The TTT diagrams described so far are obtained by cooling a

steel isothermally at a series of temperatures." One of the illustrations in the chapter on joining consists of a variety of screw heads!

Several features of the book, especially the very extensive lists of standard specifications and numerous tables of numerical values of properties, betray a measure of confusion between the roles of a textbook and a handbook (such as the *Metals Reference Book*). 100 pages are devoted to elementary school mechanics, which have no place in a book of this kind, supposedly directed at professional engineers-to-be. According to the preface, the book is in fact directed not only at these but also at technicians taking pre-degree courses. But these, also, need and deserve understanding, not just a diet of undigested and sometimes erroneous fact.

Ray also has the peculiar habit of providing a list of keywords for each chapter, apparently in the hope that the reader can check for himself whether he has learned key concepts. In a chapter on engineering design, the list of keywords includes, inter alia, "perseverance, willpower, scientific knowledge, conceptual ability". The author has demonstrated the first two but not, alas, the last two.

Liquid Crystals

Thermotropic Liquid Crystals. Edited by *G. W. Gray*. Wiley, New York 1987. 178 pp., £ 38.00.—ISBN 0-471-91504-1

As long ago as 1962, *G. W. Gray* published the book "Molecular Structure and the Properties of Liquid Crystals", which was a classic for a long time. Display technology has stimulated the synthesis of thousands of new liquid crystal compounds; many of the technologically relevant ones come from *Gray*'s laboratory. Usually, a purely physical approach is chosen for the presentation of the field of thermotropic and lyotropic liquid crystals. This is convenient because it is necessary to describe precisely the properties of anisotropic fluid systems. Furthermore, a great variety of physical measurement techniques directly related to technological applications has to be mastered. Chemists, however, will be more familiar with the approach chosen in this book that has been edited by *G. W. Gray*; it contains six articles written by different authors.

The wealth of mesomorphic phases in organic compounds, and in particular the recently discovered phases, require a refinement of the classification scheme. This is outlined by *A. J. Leadbetter* (27 pages) with special regard to structural analysis by X-ray and neutron diffraction. The phases are characterized essentially by positional order, orientational order, and molecular orientation. This makes it possible to distinguish between different smectic phases and, more generally, between a liquid crystal and a true (though disordered) crystal; such a clear cut distinction has not always been made in the literature. Discotic phases are briefly mentioned. They are not formed exclusively by aromatic compounds, as is erroneously stated.

K. Toyne (36 pages) presents a detailed discussion of the influence of individual structural elements of the rigid backbone and the terminal or lateral substituents on transition temperatures, especially for the nematic to isotropic phase transition. The correlation of this temperature with the length/breadth ratio and the packing density is outlined. The influence of the chemical structure of a compound on properties relevant for technological applications is only briefly mentioned. However, *I. Sage* (35 pages) describes the known correlations with optical and dielectric anisotropy, elastic constants and viscosity. The structures and modes of operation of the most important types of displays employing nematic phases are also discussed.

The requirements for compounds and mixtures with smectic A and C phases are considered by *D. Coates* (21 pages). In this chapter the reader is familiarized with displays that make use of these smectic phases. *D. G. McDonnell* (25 pages) gives a survey on the current state of development of thermochromic cholesteric liquid crystals. He outlines clearly the influence of different parameters on the selective reflection of light. The description of the influence of chemical structure on the optical rotatory power and the sign of rotation of the helix characteristic for the cholesteric phase is particularly interesting to read. *H. Finkelmann* (26 pages) gives a good overview of the synthesis, the phase behavior (as influenced by the molecular structure), and the properties and applications of liquid crystalline linear and branched polymers. This contribution contains many details that are important for a deeper understanding.

All the articles are written with great care, and focus on the essentials of this rapidly progressing field. An extensive up to date reference list is also provided. Thermotropic liquid crystals are discussed with particular regard to their application potential in display technology. For this reason the book treats almost exclusively calamitic, as opposed to discotic or other recently discovered molecular assemblies of fluid systems. The figures, chemical formulas, tables and physical equations are well selected and useful. The book can be recommended as a reference work to chemists active in the field, as well as to physicists having a basic knowledge of chemistry. It will also be valuable for newcomers.

ADVANCED MATERIALS

Molecular Crystals and Organic Solids

Molecular Crystals. By *J. D. Wright.* Cambridge University Press, Cambridge 1987. VIII, 178 pp., bound, £ 32.50.—ISBN 0-542-26460

Twenty years ago the three volumes entitled "Physics and Chemistry of the Organic Solid State", edited by *Fox, Labes* and *Weissberger* and published between 1963 and 1967 provided an excellent introduction to the subject, which was then covered by some 30 authors in 26 chapters, encompassing more than 2300 pages. The series was as successful as such books can be, and many of the chapters are still well worth reading. Since then the subject has grown enormously; some of the then existing areas have been developed beyond anything that could have been foreseen: crystal growth, the effect of solvents and impurities on crystal morphology, organic solid-state reactions, to name only a few. At the same time important new areas have been added: force field calculations and lattice dynamics (made possible by computer developments), organic metals and superconductors, second-harmonic generators, the study of molecular motion in crystals by solid-state NMR as well as diffraction methods. Also, since the mid-60s the number of molecular crystal structures available, so to say, for detailed scrutiny has increased from around 2000 to more than 70000.

As Dr. *Wright* correctly points out in his preface, there is a serious gap in the teaching of this subject in that most of the current solid-state chemistry and physics textbooks scarcely mention molecular crystals. There are excellent advanced texts covering limited areas, but apart from their specialized coverage they tend to be difficult for newcomers.

In this book, Dr. *Wright* has made a brave attempt to cover the whole subject, single-handed, in less than 180 pages. There are short chapters on purification and crystal growth (10 pages), intermolecular forces (9 pages), crystal structures (12 pages), impurities and defects (24 pages), molecular motion in crystals (22 pages), optical properties of molecular crystals (20 pages), chemical reactions in molecular crystals (23 pages), and, finally, electrical properties (the pièce de résistance with 46 pages). The author whisks us briskly through all these topics, in one door, out of another, and it is all a little like being taken on a ten-minute tour of the Louvre. Thus the book does provide an overall impression of the richness and variety of the subject matter. There are many illuminating explanations and comments, as well as a few slips and other mishaps, but the pace is so breathtaking that they do not really matter. On almost every topic, the beginner is likely to be dazed as much as enlightened, and the research worker will find the treatment far too superficial for his needs.

As an example, take the chapter on crystal structures. Dr. *Wright* considers a few very simple structures out of the 70000 available and has some sensible things to say about them. But he gives the impression that a classification of molecular crystal structures into three groups (nonpolar molecules, molecules with polar substituents, and intermolecular donor-acceptor or charge-transfer complexes) provides genuine insight into the complexity of this enormously intricate subject. Such a classification could at best serve as a basis for defining three special types of interaction that could be invoked in the discussion of crystal structures, but in the vast majority of actual structures all three types of interaction come into play. We are still very far from an understanding of why particular molecules crystallize as they do. We may understand the general principles, but there are far too many details. It is true that when energy calculations based on fairly simple types of force field are made for an *observed crystal structure*, they usually produce an energy minimum at or close to the structure in question, but they give no hint of what other molecular arrangements may be possible. Nearly all the structures discussed here are built from planar aromatic molecules, a very small sample of the real, messy world. More stereodiagrams (I found only one) would have helped the reader, in this chapter and in others, to visualize the three-dimensional packing of the molecules.

In my opinion, Dr. *Wright* has undertaken a hopeless task in his effort to provide an elementary textbook on molecular crystals in such a short book. Perhaps it is the publishers who are to be blamed for imposing this limitation (as well as for the price, which will surely drive much of the prospective readership to the photocopier). Solid-state NMR in less than five pages! Lattice dynamics in three! It is difficult to see how a student can benefit from such superficial coverage. Many of the topics that are compressed here into a few pages would take an entire book to do them justice. His publishers should encourage him to expand one or two of his chapters into such a book. That would be a really worthwhile venture!

Organic Solid State Chemistry. Edited by *G. R. Desiraju.* Elsevier Science Publishers, Amsterdam 1987. xx, 550 pp., hard cover, Hfl 360.00.—ISBN 0-444-42844-5

This book is a collection of 14 review articles that describe developments in solid state chemistry during the last two decades. First a description of the contents: The book opens with five chapters on "Organic solid state reactions: topochemistry and mechanism". The reactions discussed are mainly photochemical intramolecular hydrogen abstractions *(Scheffer)* and [2+2] additions *(Theocharis* and *Jones,* and *Hasegawa),* there is a chapter on the prediction of reactivity using geometric criteria *(Kearsley)* and one on phonon spectroscopy *(Prasad).* The middle section consists of four chapters on the theme "Some stereochemical questions: pure and applied chemistry". *J. M. Thomas* and *Harris* discuss experimental and computational techniques for studying the structure and properties of molecules em-

bedded within solid hosts. This is followed by a long, informative chapter on clathrates *(Tsoucaris)* and one on the structural complexities of phenols and their expression in different types of solid state reactivity *(Perrin, Lamartine, Perrin,* and *Thozet).* A chapter by *Paul* and *Curtin* on gas–solid reactions and polar crystals concludes this section. The five chapters of the final section entitled "Intermolecular interactions: from crystallography to chemical physics" form what is perhaps the most interesting part of the book. *Rao* summarizes what is known about phase changes in molecular crystals, *Gavezzotti* and *Simonetta* discuss the nature and magnitude of molecular motions in solids, and *Ramdas* and *N. W. Thomas* take up again the problem of modeling the packing energy in terms of inter- and intramolecular interactions. *Bernstein* provides a wealth of examples of conformational polymorphism—structural relationships that a physicist would describe as phase transformations, a chemist as conformational isomerizations—and finally *Desiraju* takes up the question of why some planar chloro aromatic molecules crystallize with a 4 Å translation and others not.

In a way, this book is a tribute to the memory of *G. M. J. Schmidt* and *A. I. Kitaigorodskii*, who did so much to pioneer the systematic study of organic chemical crystallography and whose names are mentioned in nearly every chapter. For the non-specialist the book provides a useful survey of current research in a complex, rapidly developing field, and also the experienced researcher in solid-state organic chemistry will find many fascinating snippets of information even in his own speciality besides an introduction to less familiar areas.

Yet I do not think the editor has succeeded in the attempt to produce "a reference work for specialists and non-specialists alike". As in many other multi-authored books, there is a sad lack of coordination among the various chapters. There seems to have been little agreement about the level of knowledge to be taken for granted in the imaginary reader; in one chapter, for example, this shadowy person knows all about the Metropolis algorithm but needs to be reminded that inversion of the cyclohexane ring interchanges axial and equatorial substituents. A work of reference needs a better index than the one provided. The end result is not much more than a collection of disconnected essays. Even visually, the book makes a disjointed impression as it was obviously prepared from camera-ready copy with a noticeable lack of agreement even about such matters as the choice of fonts, styles, literature citations, etc.

There are advantages to a type-set book. If this one had been type-set it could have benefited from the services of a copy editor, who would have corrected most of the spelling mistakes and noticed, for example, that Figures 10 and 11 of Chapter 2 are not mentioned in the text, besides other minor blemishes, such as, in one place, 10^{16} s (for 10^{-16} s). Moreover, the authors themselves would have had a second chance to correct undetected errors and mishaps at the galley proof stage. All this costs time and money, it must be assumed. The advantages of making a book from camera-ready copy would then, one might suppose, be cheapness and speed of publication. But there is no evidence that this volume was produced with any remarkable alacrity, and the price of 360 Hfl is certainly not cheap but rather seems outrageously expensive for a book produced from camera-ready copy.

Zeolites

Synthesis of High-Silica Aluminosilicate Zeolites. By *P. A. Jacobs* and *J. A. Martens*. Elsevier, Amsterdam 1987. xvi, 390 pp., bound, Hfl 280.00.—ISBN 0-444-42814-3

For about 15 years high-silica zeolites have been attracting much interest. Meanwhile, they have become important especially as catalysts for petrochemical processes, although their application potential is not limited to this field. The variety of possible applications can be demonstrated with the best-known example of this class of compounds, the zeolite ZSM-5.

The intense research activity, especially on the synthesis of high-silica zeolites, is documented by a large number of publications, a very important fraction of which is patent literature. The great variety of zeolites makes it difficult, even for the expert, to keep up with the literature. Who, for instance, is familiar with the classification of the zeolite ZETA-1?

Therefore, it was time for a comprehensive account, such as the one *P. A. Jacobs* and *J. A. Martens* now present as volume 33 of the series "Studies in Surface Science and Catalysis". The authors restrict their topic to zeolites which can be synthesized directly as high-silica zeolites, and which have potential uses as shape-selective catalysts. They exclude zeolites that can be obtained by isomorphic replacement of aluminum lattice atoms by other elements. There may be some controversy about this restrictive interpretation of the term "high-silica zeolites", but not about the great usefulness of this monograph, in spite of the mentioned limitations.

The first part ("experimental", 40 pages) gives detailed and tested recipes for the preparation of 14 high-silica zeolites. The resulting materials are characterized by X-ray diffraction, electron microscopy, and IR spectroscopy. These instructions will be welcomed, and not only by newcomers.

The much larger second part of the book is devoted to zeolites having the structures MFI (ZSM-5), MEL (ZSM-11), TON, MTT, MTW, and FER (ferrierite). In addition

to the discussion of experimental conditions for their synthesis, information on structure and crystal morphology can be found in the individual chapters. As expected, the authors put the main emphasis on the various preparation methods of ZSM-5. For this zeolite they also briefly discuss molding methods, a topic highly relevant to applications. The book concludes with a short third part on zeolites with unknown structures.

The keyword "synthesis of zeolites" provokes a comparison with *R. M. Barrer*'s classic "Hydrothermal Chemistry of Zeolites" (Academic Press, London 1982). Such a comparison is, however, difficult because the two monographs follow completely different approaches: While *Barrer* focuses on the general principles of zeolite synthesis, *Jacob* and *Martens* present a collection of facts, especially on high-silica zeolites. The authors have critically reviewed the literature up to and including 1985. They have succeeded in giving a clear and understandable presentation of their topic, which is partly due to a large number of well presented diagrams and figures. In particular, the numerous X-ray diffraction data may often save the reader a lot of tedious literature searching. In summary, this book will be a valuable tool for the expert as well as for novices in the field of high-silica zeolites.

The Design of Molecular Hosts, Guests, and Their Complexes (Nobel Lecture)**

By Donald J. Cram

Origins

Few scientists acquainted with the chemistry of biological systems at the molecular level can avoid being inspired. Evolution has produced chemical compounds exquisitely organized to accomplish the most complicated and delicate of tasks. Many organic chemists viewing crystal structures of enzyme systems or nucleic acids and knowing the marvels of specificity of the immune systems must dream of designing and synthesizing simpler organic compounds that imitate working features of these naturally occurring compounds. We had that ambition in the late 1950's. At that time, we were investigating π-complexes of the larger [m.n]paracyclophanes with $(NC)_2C{=}C(CN)_2$, and envisioned structures in which the π-acid was sandwiched by two benzene rings. Although no intercalated structures were observed,[1,2] we recognized that investigations of *highly structured complexes* would be central to simulation of enzymes by relatively simple organic compounds.

In 1967, *Pedersen*'s first papers appeared[3,4] which reported that alkali metal ions bind crown ethers to form highly structured complexes. We immediately recognized this work as an entree into a general field. The 1969 papers on the design, synthesis, and binding properties of the cryptands by *J.-M. Lehn, J.-P. Sauvage,* and *B. Dietrich*[5,6] further demonstrated the attractions and opportunities of complexation chemistry. Although we tried to interest graduate students in synthesizing *chiral crown ethers* from 1968 on, the efforts were unsuccessful. In 1970 we insisted that several postdoctoral co-workers enter the field. During 1973, we published five Communications on the subject.[7–11] In 1974 with *Jane M. Cram*, we published a general article entitled "Host-Guest Chemistry", which defined our approach to this research.[12]

Aeschylus, the Athenian Poet-Dramatist, wrote 2500 years ago, "Pleasantest of all ties is the tie of host and guest."[13] Our research of the past 17 years has dealt with the pleasant tie between host and guest at the organic molecular level. The terms *host, guest, complex,* and their binding forces were defined in 1977 as follows:[14] "Complexes are composed of two or more molecules or ions held together in unique structural relationships by electrostatic forces other than those of full covalent bonds ... molecular complexes are usually held together by hydrogen bonding, by ion pairing, by π-acid to π-base interactions, by metal-to-ligand binding, by van der Waals attractive forces, by solvent reorganizing, and by partially made and broken covalent bonds (transition states) ... high structural organization is usually produced only through multiple binding sites ... a highly structured molecular complex is composed of at least one host and one guest component ... a host-guest relationship involves a complementary stereoelectronic arrangement of binding sites in host and guest ... the host component is defined as an organic molecule or ion whose *binding sites converge* in the complex ... the guest component is defined as any molecule or ion whose *binding sites diverge* in the complex ..." In these definitions, hosts are synthetic counterparts of the receptor sites of biological chemistry, and guests, the counterparts of substrates, inhibitors, or cofactors. These terms and concepts have gained broad international acceptance.[15] A new field requires new terms which, if properly defined, facilitate the reasoning by analogy on which research thrives.

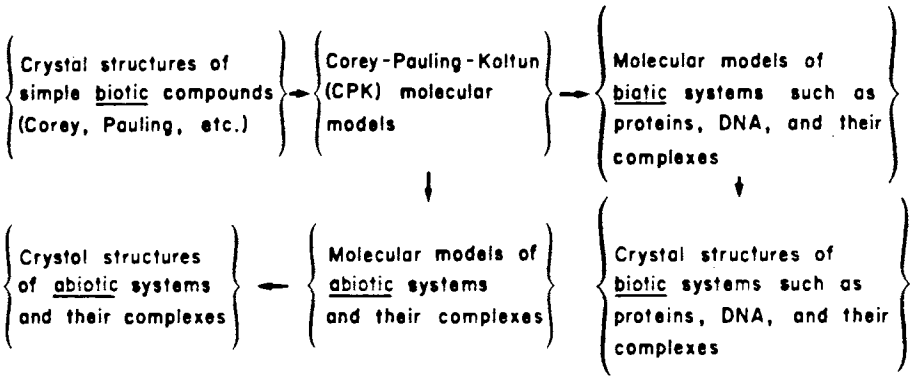
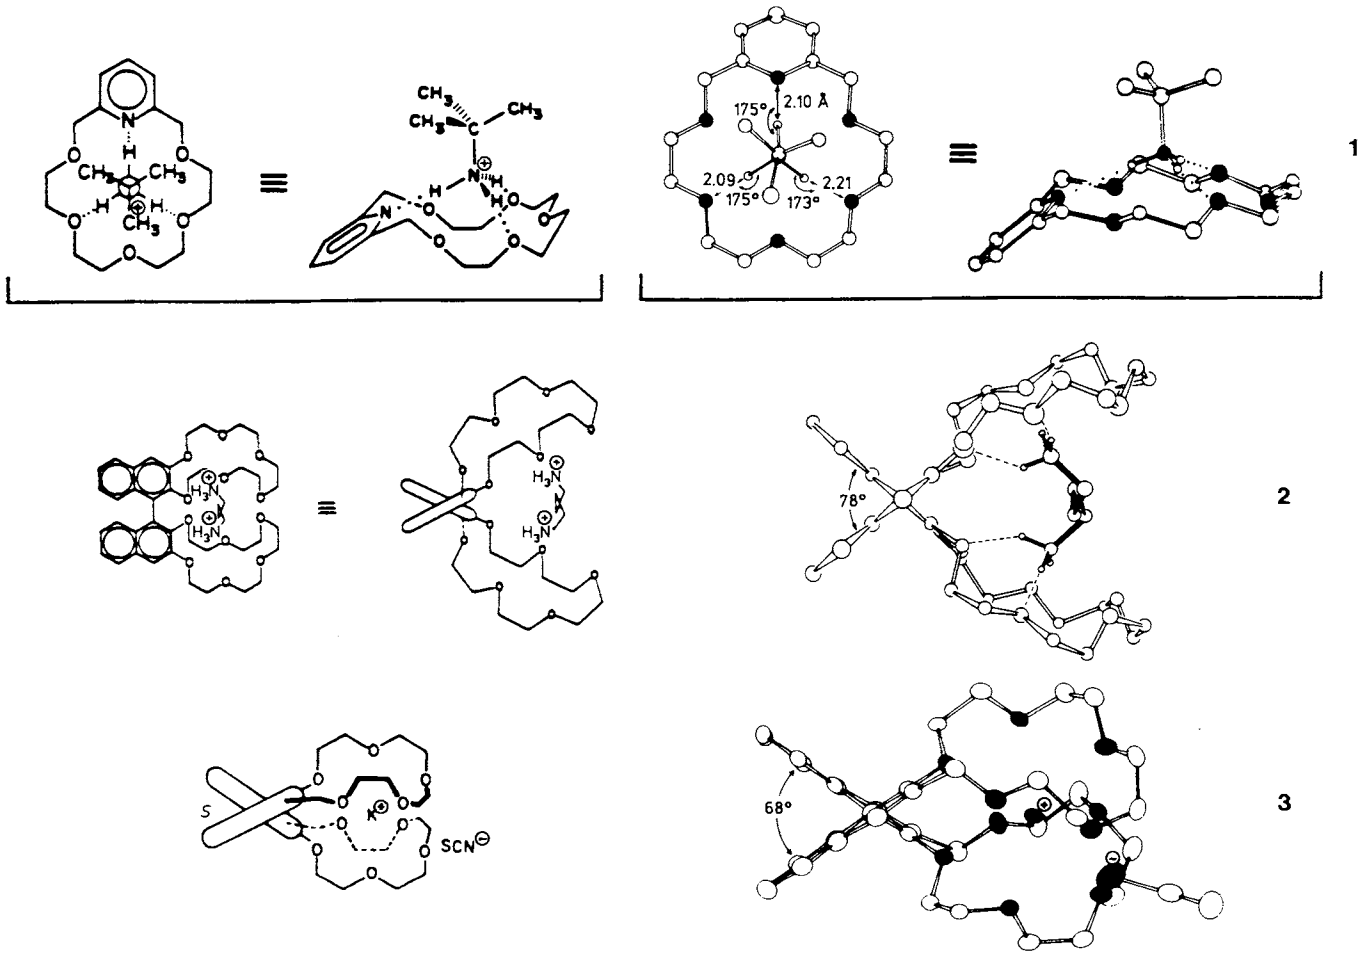
From the beginning, we used Corey-Pauling-Koltun (CPK) molecular models,[16] which served as a compass on an otherwise uncharted sea full of synthesizable target complexes. We have spent hundreds of hours building CPK models of potential complexes, and grading them for desirability as research targets. Hosts were then prepared by my co-workers to see if they possessed the anticipated guest-binding properties. Crystal structures of the hosts and their complexes were then determined to compare what was anticipated by model examination with what was experimentally observed. By the end of 1986, Drs. *K. N. Trueblood, C. B. Knobler, E. F. Maverick,* and *I. Goldberg,* working at UCLA, had determined the crystal structures of over 50 complexes, and those of another 25 hosts. These crystal structures turned our faith into confidence. Scheme 1 traces the steps involved in linking the structures of *biotic complexes* of evolutionary chemistry with our *abiotic complexes* designed with the aid of CPK molecular models.[17]

In molecular modeling, we made extensive use of the self-evident principle of complementarity: "to complex, hosts must have binding sites which cooperatively contact and attract binding sites of guests without generating strong nonbonded repulsions."[18] Complexes were visualized as having three types of common shapes: 1) perching complexes, resembling a bird perching on a limb, an egg



Scheme 1. Crystal structures of biotic compounds are correlated with those of abiotic compounds through CPK models.

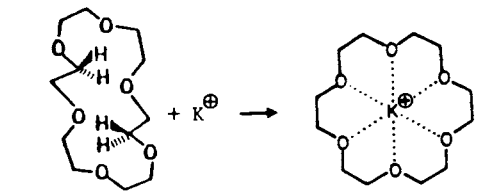


Scheme 2. Three types of complexes. **1** is a perching complex, **2** is a nesting complex, and **3** is a capsular complex. Left: CPK models; right: crystal structures.

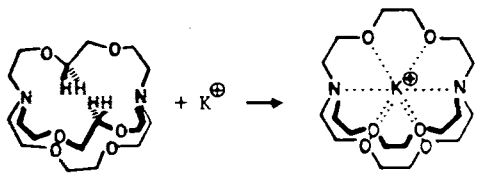
protruding from an egg cup, or a scoop of ice cream sitting on a cone; 2) nesting complexes, similar to an egg resting in a nest, a baby lying in its cradle, or a sword sheathed in its scabbard; 3) capsular complexes, not unlike a nut in its shell, a bean in its pod, or a larva in its cocoon. Scheme 2 provides a comparison of CPK models of the three types of complexes (**1**, **2**, and **3**) and their actual crystal structures.[19,20]

Principle of Preorganization

Crystal structures of *Pedersen*'s [18]crown-6[21] and *Lehn*'s [2.2.2]cryptand[22,23] show that in their uncomplexed states, they contain neither cavities nor convergently-



4 **5**



6 **7**

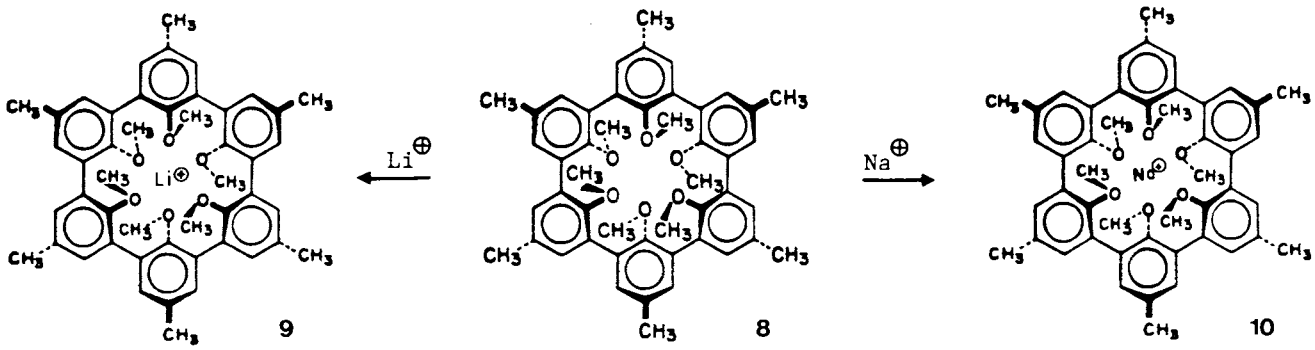
arranged binding sites. Comparisons of the crystal structure of host **4** with that of its $K^{\oplus}$ complex **5**, and of host **6** with that of its $K^{\oplus}$ complex **7** indicate that the complexing act must be accompanied by host reorganization and desolvation.

With the help of CPK molecular models, we designed ligand system **8**, whose oxygens have no choice but to be octahedrally arranged around an enforced spherical cavity complementary to $Li^{\oplus}$ (**9**) and $Na^{\oplus}$ ions (**10**). We have given the family name, *spherand*, to completely preorganized ligand systems, and the name, *spheraplex*, to their complexes, which like **7**, are capsular.[24] The syntheses of **8**–**10** and their structures **11**–**13** have been reported.[25] As expected, **11** contains a hole lined with 24 electrons, which are shielded from solvation by six aryl and six methyl groups. The snowflake-like structures **11**, **12**, and **13** are nearly identical. Thus **8** is the first ligand system to be designed and synthesized which was completely organized for complexation during synthesis, rather than during complexation.

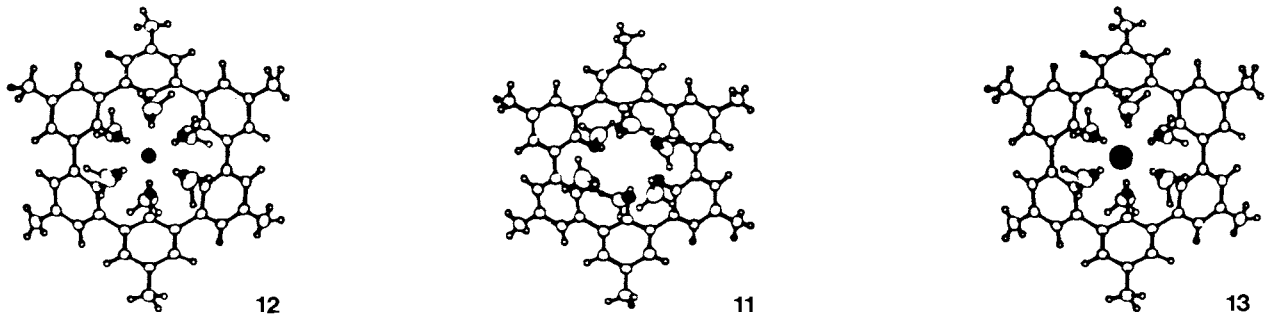
A method was developed for determining the binding free energies of lipophilic hosts **H** toward guest picrate salts of $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$, $Rb^{\oplus}$, $Cs^{\oplus}$, $NH_4^{\oplus}$, $CH_3NH_3^{\oplus}$, and *t*-$BuNH_3^{\oplus}$. The guest salts **G**Pic were distributed between $CDCl_3$ and D_2O at 25 °C in the presence and absence of host. From the results, K_a [mol^{-1}] and $-\Delta G^0$ values [kcal mol^{-1}] were calculated [Eq. (a)]. This method was rapid

$$\mathbf{H} + \mathbf{G}\,\mathrm{Pic} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{H}\cdot\mathbf{G}\cdot\mathrm{Pic} \qquad K_a = k_1/k_{-1};\ -\Delta G^0 = RT\ln K_a \quad \text{(a)}$$

and convenient for obtaining $-\Delta G^0$ values at 25 °C ranging from about 6 to 16 kcal mol^{-1} in $CDCl_3$ saturated with D_2O.[26] Higher values (up to 22 kcal mol^{-1}) were obtained by equilibration experiments between complexes of known and those of unknown $-\Delta G^0$ values.[18,27,28] Others were determined from measured k_{-1} and k_1 values, all in the same medium at 25 °C.[18] Spherand **8** binds LiPic with

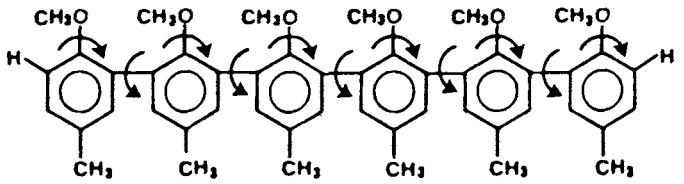


9 **8** **10**



12 **11** **13**

>23 kcal mol^{-1}, NaPic with 19.3 kcal mol^{-1}, and totally rejects the other standard ions, as well as a wide variety of other di- and trivalent ions.[18] The open-chain counterpart of **8**, podand **14**, binds LiPic and NaPic with $-\Delta G^0 < 6$ kcal mol^{-1}.[29] *Podand* is the family name given to acyclic hosts.[15]



14

Podand **14** differs constitutionally from spherand **8** only in the sense that **14** contains two hydrogen atoms in place of one Ar–Ar bond in **8**. The two hosts differ radically in their conformational structures and states of solvation. The spherand possesses a single conformation ideally arranged for binding $Li^{\oplus}$ and $Na^{\oplus}$. Its oxygens are deeply buried within a hydrocarbon shell. The orbitals of their unshared electron pairs are in a microenvironment whose dielectric properties are between those of a vacuum and of a hydrocarbon. No solvent can approach these six oxygens, which remain unsolvated. The free energy costs of organizing the spherand into a single conformation and of desolvating its six oxygens were paid for during its synthesis. Thus spherand **8** is preorganized for binding.[30] The podand can, in principle, exist in over 1000 conformations, only two of which can bind metal ions octahedrally. The free energy for organizing the podand into a binding conformation and desolvating its six oxygens must come out of its complexation free energy. Thus the podand is not preorganized for binding, but is randomized to maximize the entropy of mixing of its conformers, and to maximize the attractions between solvent and molecular parts.

The difference in $-\Delta G^0$ values for spherand **8** and podand **14** binding $Li^{\oplus}$ is >17 kcal mol^{-1}, corresponding to a difference in K_a of a factor of $>10^{12}$. The difference in $-\Delta G^0$ values for **8** and **14** binding $Na^{\oplus}$ is >13 kcal mol^{-1}, corresponding to a difference in K_a of a factor of

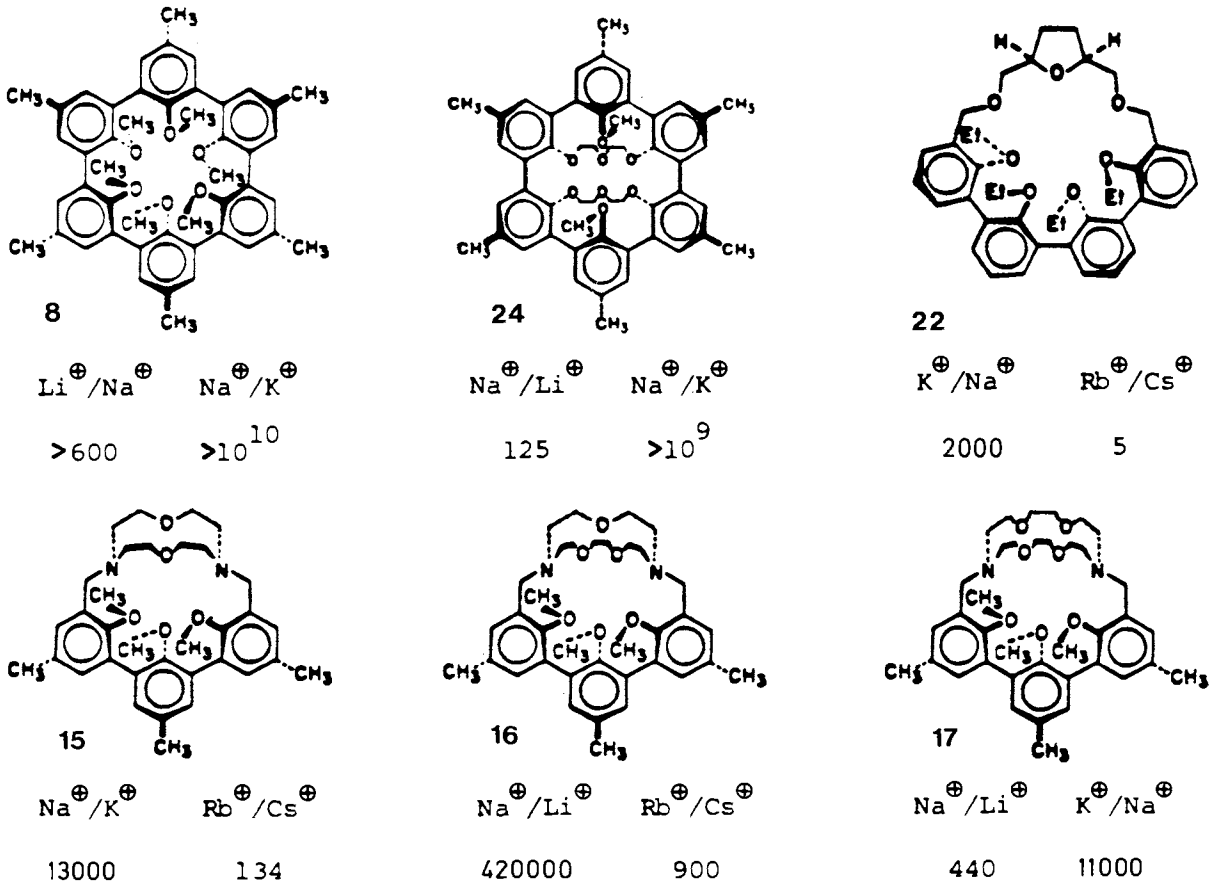
$> 10^{10}$. These differences are dramatically larger than any we have encountered that are associated with other effects on binding power toward alkali metal ion guests. We conclude that *preorganization is a central determinant of binding power*. We formalized this conclusion in terms of what we call the principle of preorganization, which states that "the more highly hosts and guests are organized for binding and low solvation prior to their complexation, the more stable will be their complexes." Both enthalpic and entropic components are involved in preorganization, since solvation contains both components.[29] Furthermore, binding conformations are sometimes enthalpically rich. For example, the benzene rings in spherand **8** and spheraplexes **9** and **10** are somewhat folded from their normal planar structures to accommodate the spacial requirements of the six methoxy groups.[30] The anisyl group is an intrinsically poor ligand.[31,32] That **8** is such a strong binder provides an extreme example of the power of preorganization.

Families of hosts generally fall into the order of their listing in Scheme 3 when arranged according to their $-\Delta G^0$ values with which they bind their most complementary guests: spherands > cryptaspherands > cryptands > hemispherands > corands > podands. Corand is the family name given to modified crown ethers.[33] Spheraplex **9** (= **8** · $Li^{\oplus}$) provides a $-\Delta G^0$ value of > 23 kcal mol^{-1}. Cryptaspheraplexes **15** · $Na^{\oplus}$, **16** · $Na^{\oplus}$, and **17** · $Cs^{\oplus}$[34] give values of 20.6, 21.0, and 21.7 kcal mol^{-1}, respectively.[27] Cryptaplexes **18** · $Li^{\oplus}$, **19** · $Na^{\oplus}$, and **6** · $K^{\oplus}$ give respective values of 16.6, 17.7, and 18.0 kcal mol^{-1}.[27] Hemispheraplexes **20** · $Na^{\oplus}$, **21** · $Na^{\oplus}$, and **22** · $K^{\oplus}$ are bound by 12.2, 13.5, and 11.6 kcal mol^{-1}.[35,36] Coraplex **23** · $K^{\oplus}$ has a $-\Delta G^0$ value of 11.4[26,37] and podaplexes **14** · $M^{\oplus}$ values of < 6 kcal mol^{-1}.[29] Although the numbers of binding sites and their characters certainly influence these values, the degree of preorganization appears to be dominant in providing this order.

Structural Recognition

Just as preorganization is the central determinant of binding power, complementarity is the central determinant of structural recognition. The binding energy at a single contact site is at most a few kilocalories per mole, much lower than that of a covalent bond. Contacts at several sites between hosts and guests are required for structuring of complexes. Such contacts depend on complementary placements of binding sites in the complexing partners.

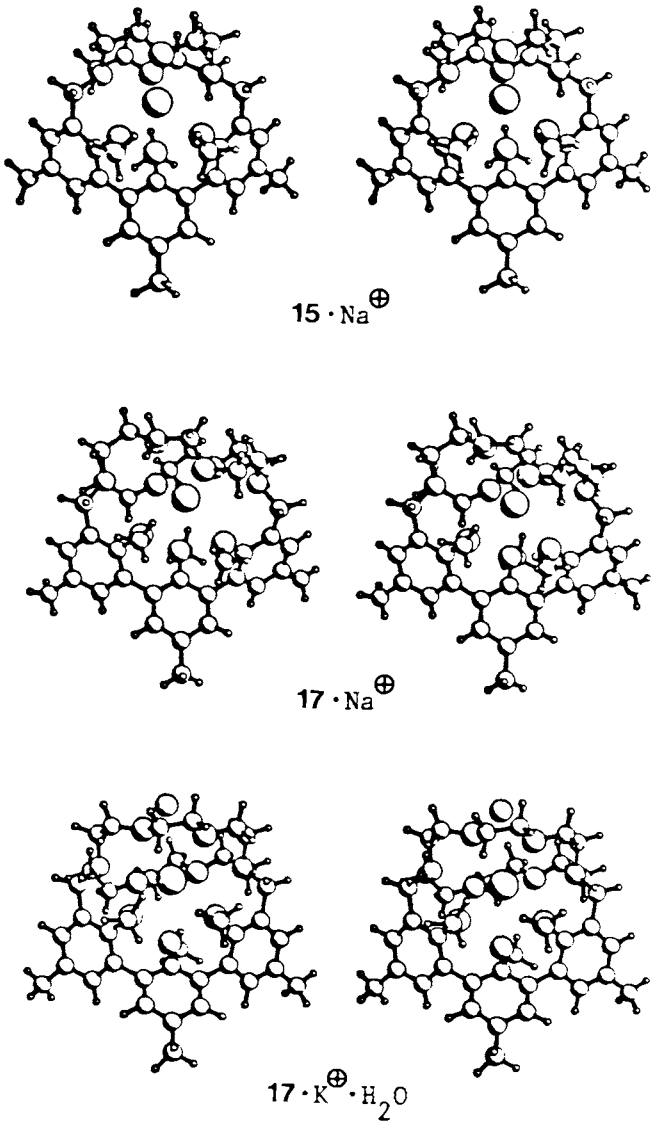
The most extensive correlations of structural recognition with host-guest structure involve the K_a values with which the spherands, cryptaspherands, cryptands, and hemispherands associate with the various alkali metal picrate salts at 25 °C in $CDCl_3$ saturated with D_2O. Scheme 4 lists the $K_a^A/K_a^{A'}$ ratios for various hosts binding two alkali metal ions A and A′ that are adjacent to each other in the periodic table.[33] Notice that factors as high as $> 10^{10}$ are observed for the spherands binding $Na^{\oplus}$ better than $K^{\oplus}$.



Scheme 4. Structural recognition measured by $K_a^A/K_a^{A'}$ values for alkali metal picrates at 25 °C in $CDCl_3$ saturated with D_2O.

Cryptaspherand **15** provides a factor of 13000. The highest factors for hosts binding $K^{\oplus}$ better than $Na^{\oplus}$ are observed for cryptaspherand **17** (11000) and hemispherand **22** (2000). The highest factors for a host binding $Li^{\oplus}$ over $Na^{\oplus}$ are found for cryptand **18** (4800). These particular selectivities are important because of the physiological importance of these ions. These hosts, or modifications of them, are being developed for commercial use in the medical diagnostics industry.

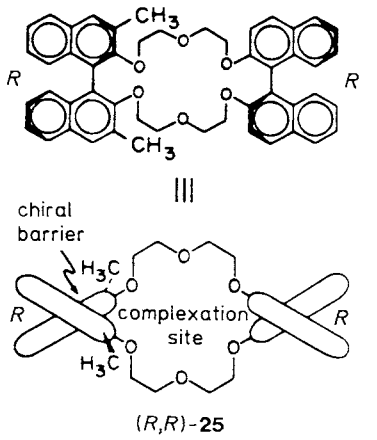
Scheme 5 provides stereoviews of crystal structures of capsular complexes **15** · $Na^{\oplus}$, **17** · $Na^{\oplus}$, and **17** · $K^{\oplus}$. Notice that in **15** · $Na^{\oplus}$ and **17** · $K^{\oplus}$ the metal ions contact all of the heteroatoms, whereas in **17** · $Na^{\oplus}$, the $Na^{\oplus}$ ion does not. Here is a visual example of complementarity vs. noncomplementarity. The $K_a^A/K_a^{A'}$ ratio for **17** · $K^{\oplus}$/**17** · $Na^{\ominus}$ = 11000.[34]



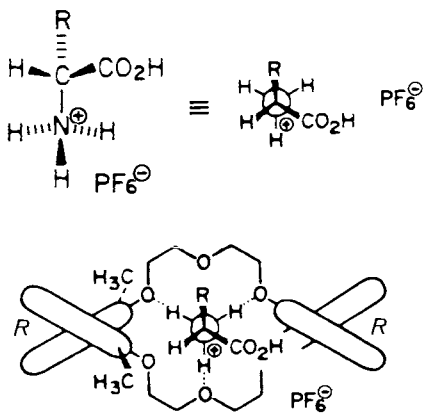
Scheme 5. Stereoviews of crystal structures of cryptaspheraplexes.

Arrangement of the classes of hosts in decreasing order of their ability to select between the alkali metal ion guests provides spherands > cryptaspherands ~ cryptands > hemispherands > corands > podands. This order is similar but less rigidly followed than that for host preorganization. In some cases, rather small changes in structure provide a substantial spread in $-\Delta G^0$ values for binding under our standard conditions.[33]

Chiral recognition in complexation is a fundamental aspect of structural recognition in complexation in the biotic world. We synthesized host **25** in an enantiomerically pure form to study its ability to distinguish between enantiomers in the complexation of amino acids and ester salts in solution. We were careful to design a system containing at least one C_2 axis of symmetry, a tactic that made the hosts *nonsided* with respect to perching guests. A solution of (*R,R*)-**25** in $CDCl_3$ at 0°C was used to extract D_2O solutions of racemic amino acid or ester salts. As predicted in advance by CPK molecular models, the D-enantiomers were extracted preferentially into the organic layer. Chiral recognition factors ranged from a high of 31 for $C_6H_5CH(CO_2CH_3)NH_3PF_6$ to a low of 2.3 with $CH_3CH(CO_2H)NH_3ClO_4$. These factors represent free energy differences between diastereomeric complexes of 1.9 kcal mol^{-1} and 0.42 kcal mol^{-1}, respectively. Other amino acid and ester salt guests ranged between these values. We interpreted these results in terms of the complementarity between host and guest of the (*R,R*)-D-configurations as visualized in the complex **26**, and the lack of complementarity in those of the (*R,R*)-L-configurations, which were designed not to form.[38,39]



(*R,R*)-**25**



26

An amino acid and ester resolving machine was designed, built, and tested, which is pictured in Figure 1. It made use of chiral recognition in transport of amino acid or ester salts through lipophilic liquid membranes. From the central reservoir of the W-tube containing an aqueous

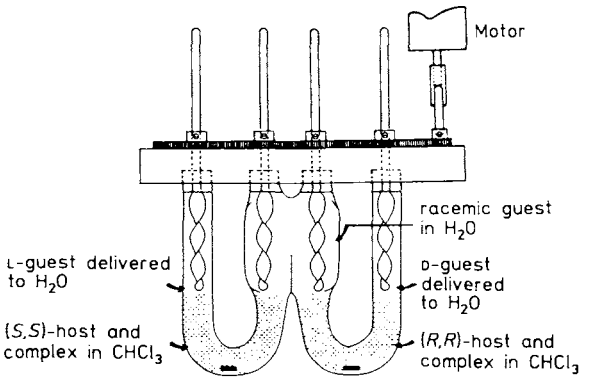


Fig. 1. Enantiomer resolving machine.

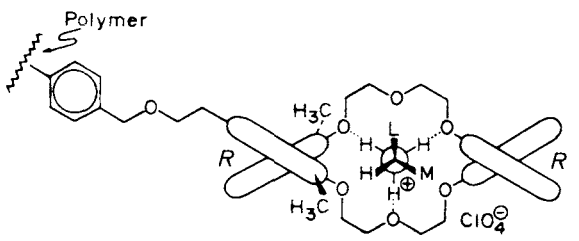
solution of racemic salt, the L-enantiomer was picked up by (*S,S*)-**25** in the-left hand chloroform reservoir and delivered to the left-hand aqueous layer, while the D-enantiomer was transported by (*R,R*)-**25** in the right-hand chloroform reservoir and delivered to the right-hand aqueous layer. The thermodynamic driving force for the machine's operation involved exchange of an energy-lowering entropy of dilution of each enantiomer for an energy-lowering entropy of mixing. To maintain the concentration gradients down which the enantiomers traveled in each arm of the W-tube, fresh racemic guest was continuously added to the central reservoir, and L- and D-$C_6H_5CH(CO_2CH_3)NH_3PF_6$ of 86–90% enantiomeric excess were continuously removed from the left- and right-hand aqueous reservoirs, respectively.[40]

In another experiment, we covalently attached the working part of (*R,R*)-**25** at a remote position of the molecule to a macroreticular resin (polystyrene-divinylbenzene) to give immobilized host of ~18000 mass units per average active site. This material (the host part of **27**) was used to give complete enantiomeric resolution of several amino acid salts. The behavior in the chromatographic resolution paralleled that observed in the extraction and transport experiments, and was useful both analytically and preparatively. Separation factors ranged from 26 to 1.4, the complexes of the (*R,R*)-D- or (*S,S*)-L-configurations always being the more stable. The structure envisioned for the more stable complex is formulated in **27**.[41]

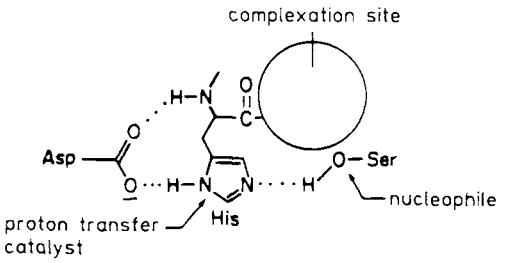


27

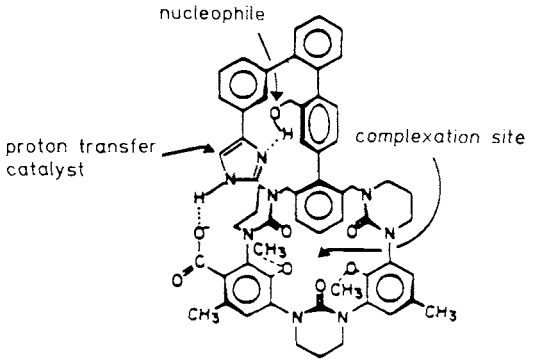
Partial Transacylase Mimics

The design and synthesis of enzyme-mimicking host compounds remains one of the most challenging and stimulating problems of organic chemistry. We chose to examine transacylase mimics first because the mechanism of action of these enzymes had been so thoroughly studied.

The active site of chymotrypsin combines a binding site, a nucleophilic hydroxyl, an imidazole, and a carboxyl group in an array preorganized largely by hydrogen bonds as indicated in **28**. With the help of molecular models, we designed **29** as an "ultimate target" host possessing roughly the same organization of groups as that of **28**.

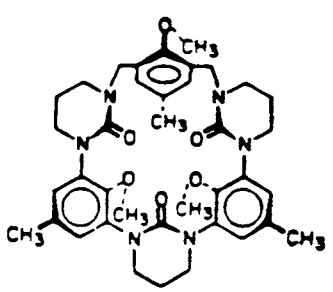


28

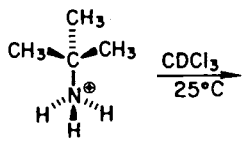


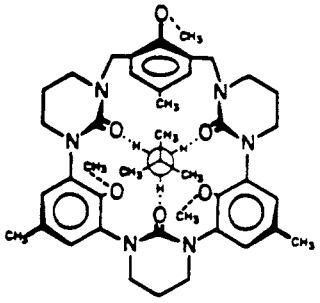
29

Compound **29** is much too complicated to synthesize without getting encouragement from simpler model compounds. An incremental approach to **29** was employed. We first prepared **30**, and found that it binds *t*-$BuNH_3Pic$ in $CDCl_3$ saturated with D_2O with $-\Delta G^0 = 13.2$ kcal mol^{-1}. The complex, **30** · $tBuNH_3^{\oplus}$, had the expected crystal structure.[42] Accordingly, **31** was prepared, and found to bind CH_3NH_3Pic and NaPic under our standard conditions with $-\Delta G^0 = 12.7$ and 13.6 kcal mol^{-1}, respectively.[43] Host **31** was acylated by **32** to give **33** and *p*-nitrophenol. The kinetics of formation of **33** were measured in $CHCl_3$, and found to be first order in added Et_3N/Et_3NHClO_4 buffer ratio. Thus the alkoxide ion is the nucleophile. The rate constant for acylation of **31** by **32** was calculated to be ~10^{11} higher valued than the rate constant for the noncomplexed model compound, 3-phenylbenzyl alcohol.[44] This high factor demonstrates that collecting and orienting reactants through highly structured complexation can result in an enormous rate acceleration. When $NaClO_4$ was added to the medium, the acylation rate of **31**

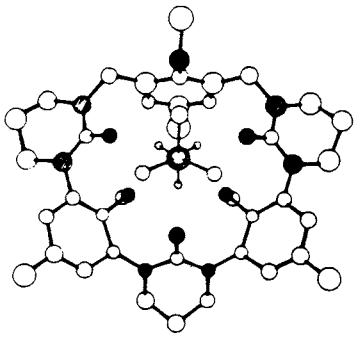


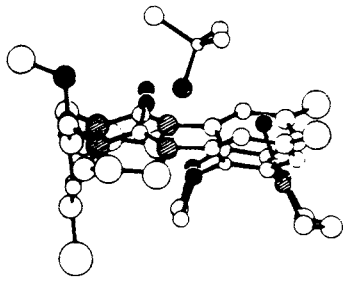
30





30 · $(CH_3)_3CNH_3^{\oplus}$

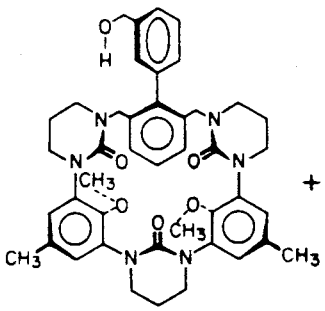




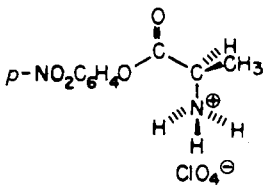
30 · $(CH_3)_3CNH_3^{\oplus}$

was depressed by several powers of ten. Thus the acylation of **31**, like that of the serine esterases, is subject to competitive inhibition.

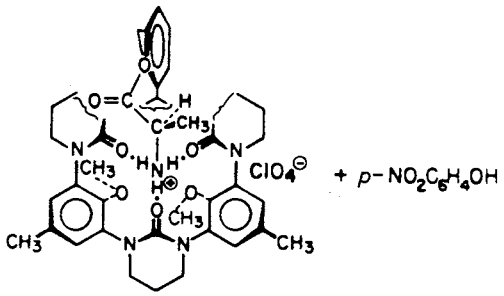
gave **36**. In $CHCl_3$ in the absence of any added base, the observed rate constant for acylation of **34** by **32** was higher by a factor of 10^5 than that for acylation of an equal



31



32



33

A thirty-step synthesis of **34** was then devised, and about 0.5 g of the compound prepared.[45] This compound combines the binding site, the nucleophilic hydroxy group, and the imidazole proton-transfer agent in the same molecule, lacking only the carboxylate group of final target compound **29**. Compound **34** complexed CH_3NH_3Pic and NaPic with respective $-\Delta G^0$ values of 11.4 and 13.6 kcal mol^{-1} in $CDCl_3$ saturated with D_2O at 25°C. In pyridine-chloroform, amino ester salt **32** instantaneously acylated the imidazole group of **34** to give **35**, which more slowly

molar mixture of noncomplexing model compounds **39** or **40** under the same conditions. The same ratio was obtained when **37** was substituted for **34**. Thus the imidazole groups of **34** and **37** are the sites of acylation. Introduction of $NaClO_4$ into the medium as a competitive inhibitor of complexation destroyed much of the rate acceleration. When **32** added to **38** was substituted for **34**, the resulting complex acylated imidazole **40** with a 10 rate-constant factor increase. Thus complexed **32** is a better acylating agent than **32** alone.

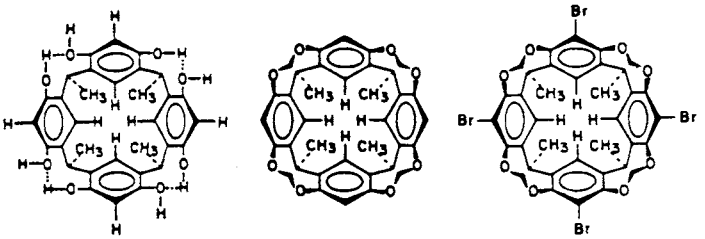
The disadvantages of comparing rate constants for reactions with different molecularities are avoided by referring to uncomplexed **34** or **37**, noncomplexing imidazole **40**, and uncomplexed acylating agent **32** as standard starting states, and the rate-limiting transition states for transacylation as standard final states. This treatment introduces K_a into the second order rate constant expression when complexation precedes acylation. The resulting second order rate constants for **32** acylating **34** or **37** are higher by factors of 10^{10} or 10^{11} than the second order rate constant for **32** acylating **40**. This work clearly demonstrates that complexation of the transition states for transacylation can greatly stabilize those transition states to produce large rate factor increases over comparable noncomplexed transition states.[46] Others have shown that the imidazole of chymotrypsin is acylated first by esters of nonspecific substrates.[47]

These investigations demonstrate that totally synthetic systems can be designed and prepared which mimic the following properties of enzymes: the ability to use complexation to vastly enhance reaction rates and the sensitivity to competitive inhibition. In a different, chiral system, we demonstrated that a synthetic host was capable of distinguishing between enantiomeric reactants.[48,49] We anticipate that as the field matures, many of the other remarkable properties of enzyme systems will be observed in designed, synthetic systems. Our results illustrate some of the strategies and methods that might be applied in this expanding field of research.

Cavitands—Synthetic Molecular Vessels

Although enforced cavities of molecular dimensions are frequently encountered in enzyme systems, RNA, or DNA, they are almost unknown among the seven million synthetic organic compounds. In biological chemistry such cavities play the important role of providing concave surfaces to which are attached convergent functional groups which bind substrates and catalyze their reactions. If synthetic biomimetic systems are to be designed and investigated, simple means must be found of synthesizing compounds containing enforced concave surfaces of dimensions large enough to embrace simple molecules or ions. We applied the name cavitand to this class of compound.[50]

Cavitands designed and studied include compounds **42**–**45**, many of which were prepared from **41**. The structure and conformational mobility of **41** had been established by *A. G. S. Högberg*.[51] The substance is prepared in good



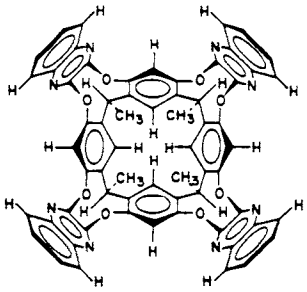
41 42 43

yield by treatment of resorcinol with acetaldehyde and acid. We rigidified **41** and its derivatives by closing four additional rings to produce **42**–**45**.[50,52]

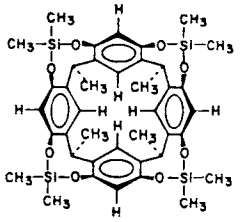
As anticipated by molecular model examinations, **42**–**45** crystallize only as solvates because these rigid molecules taken alone are incapable of filling their voids either intermolecularly or intramolecularly. They are shaped like bowls of differing depth supported on four methyl "feet." Compound **42** forms crystallates with SO_2, CH_3CN, and CH_2Cl_2, molecules to which it is complementary (molecu-

lar model examination). Cavitand **43**, whose cavity is deeper, crystallizes with a mole of $CHCl_3$. Crystal structures of **42** · CH_2Cl_2 and **43** · $CHCl_3$ show they are caviplexes, as predicted.[53] Cavitand **44** is vase-shaped. It crystallizes with one mole of $(CH_3)_2NCHO$, which is just small enough to fit into the interior of **44** in models. Although the amide cannot be removed at high temperature and low pressure, it is easily displaced with $CHCl_3$, one and one-half moles of which appear to take the place of the $(CH_3)_2NCHO$ in the crystallate.[50]

Treatment of octol **41** with R_2SiCl_2 gave a series of cavitands, of which **45** is typical. In molecular models, **45** has

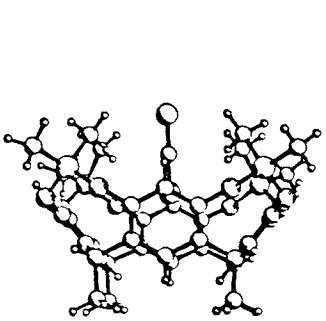


44

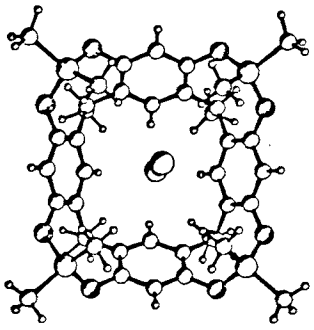


45

a well-shaped cavity, defined by the bottoms of four aryls and by four inward-turned methyl groups. In molecular models, this well is complementary to small, cylindrical molecules such as S=C=S, $CH_3C{\equiv}CH$, and O=O, but not to larger compounds such as $CDCl_3$ or C_6D_6. Cavitand **45** and its analogues when dissolved in $CDCl_3$ or C_6D_6 complex guests such as those mentioned above, whose external surfaces are complementary to the internal surface of the host cavity. Association constants were determined for **45** and its analogues binding S=C=S. Values of $-\Delta G^0$ as high as 2 kcal mol^{-1} have been observed. A crystal structure of **45** · CS_2 shows that CS_2 occupies the well in the expected manner. Compound **45** in $CDCl_3$ was also shown to bind dioxygen reversibly.[52] Dissolution of **45** in solvents such as $CDCl_3$ or C_6D_6 is the equivalent of dissolving "holes" in a medium into which appropriately shaped solutes fall. The discrimination shown by the holes for the guests exemplifies the principle of complementarity as applied to cavitand complexation.



45·CS_2 (side view)

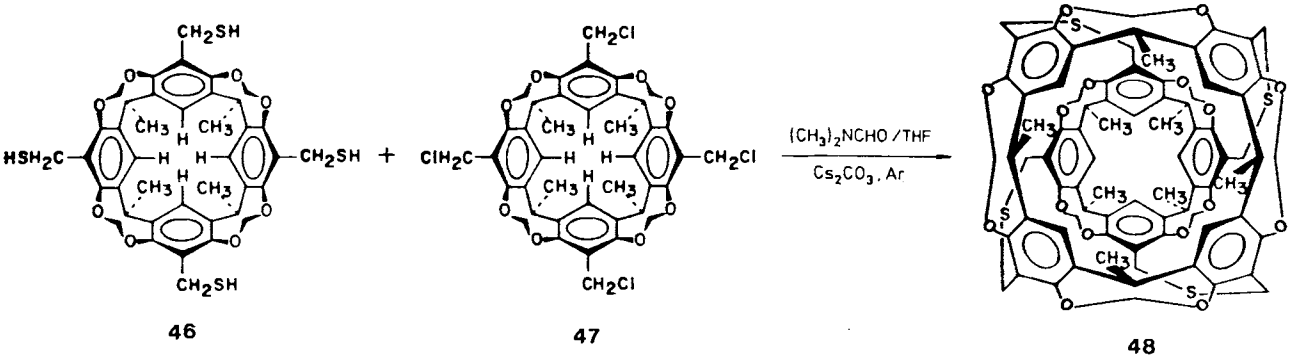


45·CS_2 (top view)

The next steps in research on these cavitands is to append to them water-solubilizing and catalytic groups. The former will provide them with hydrophobic driving forces to complex nonpolar guests, and the latter to catalyze reactions of such guests.

Carcerands—Synthetic Molecular Cells

Absent among the millions of organic compounds hitherto reported are closed-surface hosts with enforced interiors large enough to imprison behind covalent bars, guests the size of ordinary solvent molecules. After much thought and molecular model examination, we chose **48** as the target for synthesis of the first molecular cell. The term *carcerand* was applied to this class of compound. The synthesis involved treating Cs_2CO_3 with a solution in $(CH_3)_2NCHO$–$(CH_2)_4O$ of equal molar amounts of cavitands **46** and **47** under an atmosphere of argon. The first question to be answered was: what guest compounds would be trapped inside during the shell closure? This



46 **47** **48**

question is akin to asking whether two soup bowls closed rim-to-rim under the surface of a kettle of stew would net any stew. The answer was that **48** "contained" essentially every kind of component of the medium present during ring closure.[54]

The product (**48** and guests) was very insoluble in all media, and was purified by extracting it with the most powerful solvents of each type. The remaining material was subjected to elemental analysis for C, H, S, O, N, Cl, and Cs. Nitrogen analysis and an IR spectrum of the substance revealed that $(CH_3)_2NCHO$ had been entrapped. The presence of equivalent amounts of Cs and Cl demonstrated that one or the other ion or both had to be encapsulated in the host.

A fast atom bombardment mass spectrum of **48**·**G** showed the presence of the following host-guest combinations, the species trapped in the interior of **48** being enclosed by parentheses:

48 (no guest)	**48**·$(Cs^{\oplus})\cdot Cl^{\ominus}$
48·$[(CH_3)_2NCHO]$	**48**·$(Cs^{\oplus} + H_2O)\cdot Cl^{\ominus}$
48·$[THF + H_2O]$	**48**·$[(CH_3)_2NCHO + Cs^{\oplus}]\cdot Cl^{\ominus}$
48·$(Cs^{\ominus} + Ar)\cdot Cl^{\ominus}$	**48**·$(Cs^{\oplus} + H_2O + Cs^{\oplus})\cdot 2Cl^{\ominus}$
48·$(Cs^{\oplus} + Cl^{\ominus})$	**48**·$(Cs^{\ominus} + Cs^{\ominus} + Cl^{\ominus})\cdot Cl^{\ominus}$

No peaks were found at molecular masses above that of the last carcaplex listed. None were observed that could not be interpreted in terms of appropriate host-guest combinations. When highly dried **48** was boiled with D_2O, the **48**·$(Cs^{\oplus} + H_2O)$ peak was substantially replaced by a **48**·$(Cs^{\oplus} + D_2O)$ peak. Models suggest that **48** has two small portals lined with methyl groups through which molecules as small as H_2O can pass.

Molecular models of **48** show that its interior surface is complementary to the outer surface of *anti*-$ClCF_2CF_2Cl$. Shell closure of **46** and **47** in the presence of this Freon resulted in entrapment of a small amount of this gas in the interior of **48**.

The FAB-MS coupled with the elemental analyses indicated that about 5% of the mixture was noncomplexed **48**, about 60% encapsulated $Cs^{\oplus}$, about 45% encapsulated $(CH_3)_2NCHO$, 15% encapsulated $(CH_2)_4O$, but only 1–2% encapsulated $Cl^{\ominus}$. Thus $Cs^{\oplus}$ was mainly inside and $Cl^{\ominus}$ mainly outside the carcaplex. Models show that if the final covalent bond leading to **48**·**G** involves an intramolecular SN_2 linear transition state as in **48**, any $Cs^{\oplus}$ ion-paired to the $S^{\ominus}$ is trapped inside the cavity and the $Cl^{\ominus}$ must be external to the cavity.[54]

49

We anticipate that unusual physical and chemical properties will provide unusual uses for carcaplexes, particularly when their design renders them soluble and separable.

I warmly thank the following co-workers for carrying out the research described here: L. A. Singer, R. H. Bauer, M. G. Siegel, J. M. Timko, K. Madan, S. S. Moore, T. L. Tarnowski, G. M. Lein, J. L. Toner, J. M. Mayer, S. P. Ho, M. P. de Grandpre, S. P. Artz, G. D. Y. Sogah, S. C. Peacock, L. A. Domeier, H. E. Katz, I. B. Dicker, J. R. Moran, and K. D. Stewart as graduate students; E. P. Kyba, L. R. Sousa, K. Koga, R. C. Helgeson, G. W. Gokel, D. M. Walba, J. M. Cram, T. Kaneda, S. B. Brown, K. E. Koenig, P. Stückler, G. D. Y. Sogah, G. R. Weisman, Y. Chao, F. C. A. Gaeta, M. Newcomb, P. Y. S. Lam, S. Karbach, A. G. S. Högberg, Y. H. Kim, and M. Lauer as postdoctoral fellows. The crystal structure work of colleagues K. N. Trueblood, C. B. Knobler, E. F. Maverick, and I. Goldberg was indispensable.

I gratefully acknowledge the financial support of the following granting agencies: the Division of Basic Energy Sciences of the Department of Energy for the work on the metal ion binding; the National Science Foundation for the work on structural recognition; the National Institutes of Health for research on catalysis. I warmly thank all former and present co-workers, over 200 in number, and the many others whose results and discussions have stimulated and instructed me over the years. My long-time colleague, Roger C. Helgeson, has not only provided me with excellent ideas and results, but also with continuity. The artwork displayed here and in my slides and publications for the last twelve years was done by Mrs. June Hendrix, to whom I am much indebted.

The Discovery of Crown Ethers (Noble Lecture)**

By Charles J. Pedersen*

Introduction

In this lecture I would like to discuss the discovery of the crown ethers. I will divide my lecture into three parts.

First, because every discovery takes place in more than a scientific context, I would like to touch on my life and background. In the weeks since it was announced that I would share this year's Noble prize in chemistry, people have expressed as much interest in my early life as they have in my later work. So I think it appropriate to say a few words myself on the matter. It may also be that details of my past have more than casual bearing on my work.

Second, I would like to describe for you my research program and some of the specific events that led to the discovery of the first crown ether. Since I am the only one who knows at firsthand the excitement and pleasure of the discovery, I will devote a portion of my time to sharing this experience with you.

And third, I would like to discuss the properties and preparation of crown ethers. In doing so, I hope I will convey to you that I was always a "hands-on" chemist; I took satisfaction from what I did in the laboratory. Also, I was very much an industrial chemist and was always interested in the potential application of my work. In fact, when I submitted my first major paper on the discovery of the crown ethers, the editor of the Journal of the American Chemical Society, *Marshall Gates*, remarked that my descriptions were replete with industrial jargon. Fortunately he published the paper anyway.

Personal Background

My father, *Brede Pedersen*, was born in Norway in 1865 and trained as a marine engineer. Due to sibling disharmony, he left home for good as a young man and shipped out as an engineer on a steam freighter to the Far East. He eventually arrived in Korea and joined the fleet of the Korean customs, which was administered by the British. He rose in rank and later joined one of the largest Japanese steamship lines and became a chief engineer. Then a tragedy occurred that changed the course of his life. A childhood disease took the life of my elder brother while my father was away from home on a long journey. He abandoned the sea and became a mechanical engineer at the Unsan Mines in what is now the northwestern section of present-day North Korea.

My mother, *Takino Yasui*, was born in 1874 in Japan. She had accompanied her family to Korea when they decided to enter a large-scale trade in soybeans and silkworms. They established headquarters not far from the Unsan Mines, where she met my father.

The Unsan Mines were an American gold and lumber concession, 500 square miles in area. It had been granted by the Emperor of Korea to an American merchant named *James R. Morse* prior to 1870. I was conceived there in mid-winter just before the start of the Russo-Japanese war. Frequent incursions by Cossacks across the Yalu River into the region of the mines were considered to endanger my mother, so she and several American ladies were sent south by carriage to the railhead for safety. I was thus born on October 3, 1904, in the southern Port of Fusan, the largest in Korea. My arrival was doubly welcomed because mother was still grieving the loss of her firstborn. She devoted the next 10 years to overseeing my education and that of my sister, *Astrid*, five years my senior, in foreign language schools.

I spent my first and last winter at the mines when I was 4 years old. The region was known for severe weather due to the confluence of the Siberian steppes, Mongolian Gobi Desert and the mountains of Korea. Large Siberian tigers still roamed the countryside and were frightened away with bells on the pony harnesses. Wolves killed children during the cold winter nights, and foxes slept on rooftops against the chimneys to keep warm.

Because the Unsan Mines were an American enclave—the top management being all Americans—great emphasis was placed on making life as American as possible. The country club was the center of social activities and life was considerably more gentle than at the typical gold mine of the legendary American West. So my contacts with Americans began early, and I spoke English which was the common language at the mines.

I do not know if such an environment had a lifelong influence on me, but I can speculate that perhaps it did. Freedom of the Americans to administer their affairs in taking care of themselves in the wilds, where things could not be ordered for overnight delivery, no doubt taught a certain independent approach to problem solving. As for chemistry, I recall that the gold was recovered by the cyanide process, and the monthly cleanup day was marked by the pervasive odor of the process. The pouring of the molten gold was always a beautiful sight, and that might have started my interest in chemistry. Also, my sister claimed that I loved to play with a collection of colorful Siberian minerals.

Foreign language schools did not exist in Korea then, and so at the age of eight, I was sent to a convent school in Nagasaki. When I was ten years old, my mother took me to Yokohama where she remained with me for a year as I began my studies at St. Joseph College, a preparatory school run by a Roman Catholic religious order of priests and brothers called the Society of Mary. There I received a

general secondary education and took my first course in chemistry.

When the time came for me to start my higher education, there was no question of where it would be obtained. I had lived among Americans and had determined, with my father's encouragement, to study in America. I selected the University of Dayton in Ohio for two reasons: First, we had family friends in Ohio, and secondly, the same organization, the Society of Mary, ran both St. Joseph College and the University of Dayton.

My four years in Dayton and a year in graduate school at Massachusetts Institute of Technology were pleasant and taken up with activities that made me into an American. This perhaps also molded my scientific character and represented something of a personal metamorphosis. The sequence—Dayton first and then MIT—was also good, making a false start by a young man much less likely. The University of Dayton was a college of 400 men, most of them living in dormitories under strict monastic regimen. Training of the spirit was considered as important as training of the body and soul. I enjoyed all phases of the training. I became vice president of my graduating class, won letters in tennis and track and a gold medal for excellence that reflected my four years of performance there. Excellence in general was encouraged; I was even awarded a gold medal for conduct.

MIT was another matter. Boston, where I lived, is an old city of great charm and a center of the arts. I did not apply myself to my courses as I should, but my extracurricular activities contributed to the formation of my ultimate character. It was while studying at MIT that I first felt the exhilaration of utter freedom. MIT was considered deficient in the humanities, but with a little effort that deficiency could be remedied delightfully by visiting second-hand book stores. Why second-hand books appealed to me more than library books still remains a mystery—thought it possibly was the prospect of finding unexpected treasures. I celebrated my graduation from MIT as a chemist by taking a walking tour of the Presidential Range in New Hampshire.

In spite of the urging of *James F. Norris*—a very prominent professor and my research advisor—I did not remain at MIT to take a Ph.D. My bills were still being paid by my father, and I was anxious to begin supporting myself. In 1927, I obtained employment at Du Pont through the good offices of Professor *Norris*, and I was fortunate enough to be directed to research at Jackson Laboratory by *William S. Calcott*. My career of 42 years had begun.

The research environment at Du Pont during those years was not altogether typical of industrial laboratories of the time. The company had formed the nucleus of a basic research department that in a few years' time would have scientists such as *Wallace Carothers* and the young *Paul Flory* working on the polymer studies that led to nylon and other breakthroughs. And in general, Du Pont was a productive center of research where many interesting and important problems were being solved. For example, one day while visiting *Julian Hill* at the Du Pont Experimental Station in Wilmington, Delaware, I observed him pull the first oriented fiber of polyester. On another occasion, at Jackson Laboratory, across the Delaware River in New Jersey where I worked, I noticed commotion in the laboratory of *Roy Plunkett*, which was across the hall from my own. I investigated and witnessed the sawing open of a cylinder from which was obtained the first sample of Teflon® fluoropolymer. At Jackson Laboratory, during that time, other important advances were taking place in tetraethyllead and new petroleum chemicals, new elastomers, and a new series of fluorocarbons for refrigeration and aerosols. The atmosphere was vibrant and exciting, and success was expected. It was in this atmosphere I began my career.

As a new scientist I was initially set to work on a series of typical problems, the successful solution of which buoyed my research career.[1-5] After a while, I began to search for oil-soluble precipitants for copper, and I found the first good metal deactivator for petroleum products.[6-8] As a result of this work, I developed a great interest in the effects of various ligands on the catalytic properties of copper and the transition elements generally, and I worked in that field for several years. I noticed a very unusual synergistic affect wherein a metal deactivator greatly increased the efficacy of antioxidants.[9, 10]

So more and more, I became interested in the oxidative degradation of the substrates themselves, particularly petroleum products and rubber. As my interests moved in that direction, I left off working on metal deactivators and coordination chemistry. By the mid-1940s, I was in full career, having established myself in the field of oxidative degradation and stabilization.[11-13] I was independent in terms of the problems I might choose and had achieved the highest non-management title then available to a scientist at Du Pont. During the 1940s and 1950s, my interests became more varied. For example, I became interested in the photochemistry of new phthalocyanine adducts and of quinoneimine dioxides. I found some polymerization initiators, discovered that ferrocene was a good antiknock agent for gasoline, and made some novel polymers.[14-23]

Discovery of the Crown Ethers

But then there arose a challenging opportunity that led me back to ligand chemistry. In response to my desire to contribute to the elastomer field, my colleague *Herman Schroeder* suggested that there was an interesting problem in the coordination chemistry of vanadium. This sparked my curiosity, and I began work with the initial goal of understanding factors which govern the catalytic activity of vanadium in oxidation and polymerization. This was a relatively unexplored area, and previous work had been empirical. It was my work in this area that led to the discovery of crown ethers, which I will now describe.

As I have related, I studied for many years the autoxidation of petroleum products and rubber and its retardation by antioxidants. Autoxidation is greatly catalyzed by trace metals, such as copper and vanadium. Hence, I had developed the compounds referred to earlier, namely the "metal deactivators" which suppress the catalytic activity of the metal salts by converting them into inactive multidentate complexes. The first of these was *N,N'*-bis(*o*-hydroxybenzylidene)-1,2-propanediamine (Fig. 1), an excellent deactivator for copper which has been used industrially for many years.

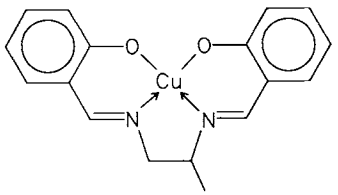

Fig. 1. Copper complex of *N,N'*-bis(*o*-hydroxybenzylidene)-1,2-propanediamine.

In 1960, when I returned to investigations in coordination chemistry, I decided to study the effects of bi- and multidentate phenolic ligands on the catalytic properties of the vanadyl group, VO.[24] The multidendate ligand I selected was bis[2-(*o*-hydroxyphenoxy)ethyl] ether **3**, whose synthesis is depicted in Figure 2. As I proceeded, I knew

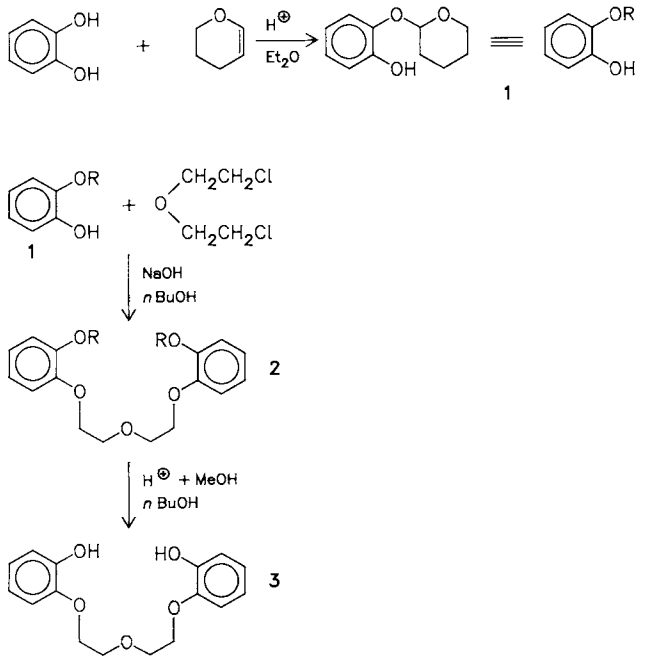

Fig. 2. Synthesis of **3** from catechol and dihydropyran. **1** is a partially protected catechol.

that the partially protected catechol **1** was contaminated with about 10 percent unchanged catechol. But I decided to use this mixture for the second step anyway since purification would be required at the end. The reactions were carried out as outlined and gave a product mixture in the form of an unattractive goo. Initial attempts at purification gave a small quantity (about 0.4 percent yield) of white crystals which drew attention by their silky, fibrous structure and apparent insolubility in hydroxylic solvents.

The appearance of the small quantity of the unknown should have put me in a quandary. It probably was not the target compound because that would be obtained in a higher yield. My objective was to prepare and test a particular compound for a particular purpose. Had I followed this line, I would have doomed the crown ethers to oblivion until such a time as another investigator would retrace my steps and make the better choice at the critical moment. Crown ethers, however, were in no danger, because of my natural curiosity. Without hesitation, I began to study the unknown substance.

It was fortunate that I used an ultraviolet spectrophotometer to follow the reactions of the phenols. These compounds and their ethers in neutral methanol solutions absorb in the region of 275 mμ. On treatment with alkali, the absorption curve is not significantly altered if all the hydroxy groups are covered, but it is shifted to longer wavelengths and higher absorption if one or more hydroxy groups are still free, as shown by the dashed curve in Figure 3.

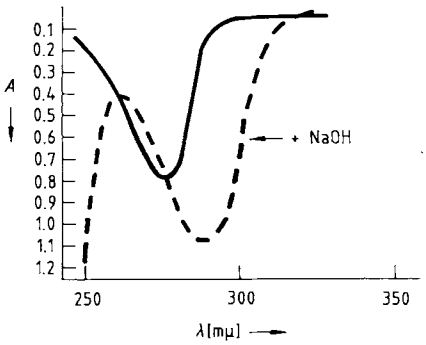

Fig. 3. Influence of NaOH on the UV spectrum of free or only partially protected catechol. *A* = absorption.

The unknown product was very sparingly soluble in methanol, and the neutral solution gave an absorption curve characteristic for a phenolic compound (Fig. 4, left). The solution was rendered alkaline with sodium hydroxide with the expectation that the curve would either be unaffected or shifted to longer wavelengths. The resulting spectrum, however, showed neither effect, but rather the one shown in Figure 4. At the same time, I noticed that the

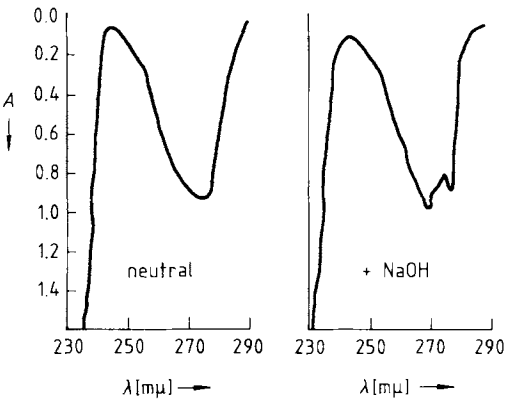

Fig. 4. Influence of NaOH on the UV spectrum of the unknown compound formed in the reaction shown in Fig. 2 in methanol.

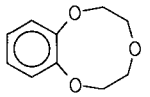
fibrous crystals were freely soluble in methanol in the presence of sodium hydroxide. This seemed strange since the compound did not contain a free phenolic group, a fact confirmed by its infrared and NMR spectra. I then found that the compound was soluble in methanol containing any soluble sodium salt. Thus, the increased solubility was not due to alkalinity but to sodium ions. But there was no

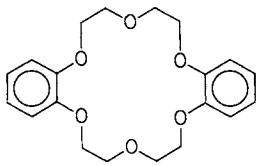
obvious explanation for the behavior of the compound because its elementarly analysis corresponded with that of 2,3-benzo-1,4,7-trioxacyclonon-2-ene **4** (Fig. 5), a plausible



4

Fig. 5. 2,3-Benzo-1,4,7-trioxacyclonon-2-ene **4**.

product from the reaction of catechol and bis(2-chloroethyl) ether in the presence of sodium hydroxide. However, the moment of revelation came when I learned that its molecular weight was exactly twice that of the above compound. The true structure was that of an 18-membered ring, dibenzo[18]crown-6 (**5**), the first and most versatile of the aromatic crown compounds (Fig. 6). The shape is that of a torus or a doughnut.



5

Fig. 6. Structural formula of the first crown ether 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene **5**.

It seemed clear to me now that the sodium ion had fallen into the hole in the center of the molecule and was held there by the electrostatic attraction between its positive charge and the negative dipolar charge on the six oxygen atoms symmetrically arranged around it in the polyether ring. Tests showed that other alkali metal ions and ammonium ion behaved like the sodium ion so that, at long last, a neutral compound had been synthesized which formed stable complexes with alkali metal ions. Up to that point, no one had ever found a synthetic compound that formed stable complexes with sodium and potassium.

My excitement, which had been rising during this investigation, now reached its peak and ideas swarmed in my brain. One of my first actions was motivated by esthetics more than science. I derived great esthetic pleasure from the three-dimensional structure as portrayed in the computer-simulated model in Figure 7. What a simple, elegant

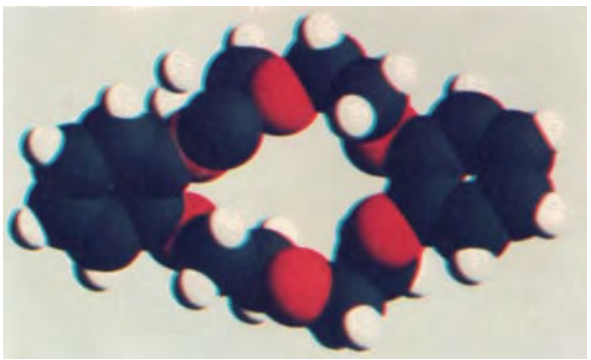


Fig. 7. Computer-simulated space-filling model of **5**.

and effective means for the trapping of hitherto recalcitrant alkali cations! I applied the epithet "crown" to the first member of this class of macrocyclic polyethers because its molecular model looked like one and, with it, cations could be crowned and uncrowned without physical damage to either, as shown for the potassium complex in Figure 8. As my studies progressed, I created the system of

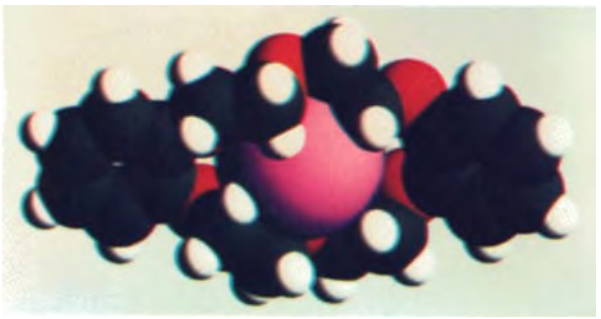

Fig. 8. Computer-simulated space-filling model of the potassium complex of **5**.

crown nomenclature chiefly because the official names of the crown ethers were so complex and hard for me to remember. It is a source of special satisfaction to me that this system of abbreviated names, devised solely for the ready identification of the macrocyclic polyethers, has been retained by the scientific establishment. In Figure 9 I have illustrated how the nomenclature system is made up of the side-ring substituents, the total number of oxygen atoms in the main ring and the size of the ring.

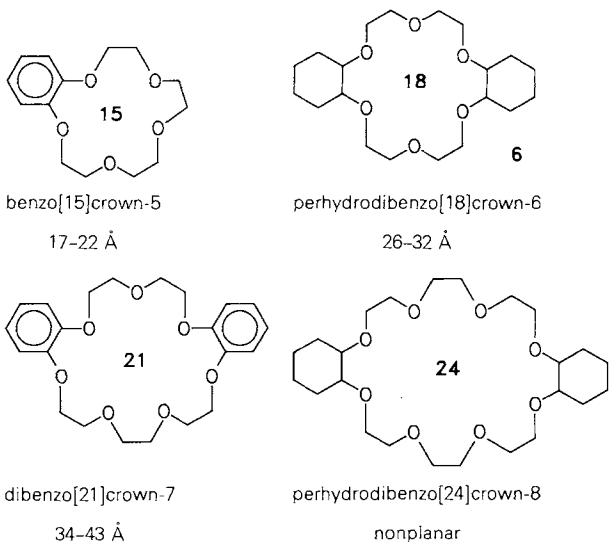

Fig. 9. Some macrocyclic polyethers. The numbers within the diagrams are the numbers of atoms in the polyether rings. The numbers under the names are the estimated diameters of the holes in Å. Cyclohexane rings of crown ethers are referred to here as perhydrobenzo rings; they are usually, but misunderstandingly, referred to as cyclohexyl rings.

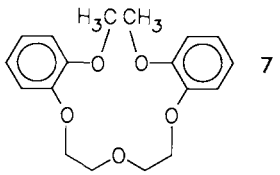
Another aspect of this discovery filled me with wonder. In ordinary organic reactions only rings of 5, 6, or 7 members form easily. Here a ring of 18 atoms had been formed in a single operation by the reaction of two molecules of catechol, which was present as a minor impurity, with two

molecules of bis(2-chloroethyl) ether. Further experiments revealed that **5** can be synthesized from these intermediates in a 45 percent yield without resorting to high dilution techniques. This was most unexpected and some good reason must exist for such an unusual result. I concluded that the ring-closing step, either by a second molecule of catechol or a second molecule of bis(2-chloroethyl) ether, was facilitated by the sodium ion which, by ion–dipole interaction, "wrapped" the molecular pieces around itself to form a three-quarter circle and disposed them for the final ring closure in much the same fashion as is involved in the synthesis of the porphyrins and phthalocyanines. Later experiments appear to support this hypothesis. The yields of **5** are higher when it is prepared with sodium or potassium hydroxide than when lithium or tetramethylammonium hydroxide is used. Lithium and the quaternary ammonium ions are not strongly complexed by the polyether. The best complexing agents are rings of 15 to 24 atoms including 5 to 8 oxygen atoms. They are formed in higher yields than smaller or larger rings, or rings of equal sizes with only four oxygen atoms. Finally, even open-chain polyethers such as **7** (Fig. 10) were found to form complexes with sodium and potassium ions.



7

Fig. 10. The open-chain polyether 3,4,12,13-dibenzo-2,5,8,11,14-pentaoxapentadeca-3,12-diene **7** complexing sodium and potassium ions.

Thus did I discover dibenzo[18]crown-6 **5**, the first crown ether and the first neutral synthetic compound capable of complexing the alkali metal cations.[25,26]

With the realization that I had something very unusual and with the utmost curiosity and anticipation, I devoted all my energies over the next several years to the study of this fascinating class of ligands and their interaction with inorganic cations. Every successful experiment produced a significantly novel result and led to new thoughts on what to synthesize and also as to the many potential uses of these extraordinary substances.

I was especially interested in the stability of the "complexes" and the reason for their behavior. For example, I found that for maximum stability of its salt complex, each cation has an optimum size of the ring of the polyether. A complex can form even if the fit is not the best by forming a sandwich complex consisting of two molecules of polyether per cation. The thermal stability of some salt complexes, for example that with KCNS, is attested to by their having melting points higher than those of the components.

Preparation and Properties of Macrocyclic Polyethers

Spurred by curiosity regarding the factors involved in the stability of the salt complexes (such as the relative sizes of the hole and the cation, and the number and symmetrical arrangement of the oxygen atoms in the polyether ring), I initiated an extensive program of syntheses. Ultimately, about 60 macrocyclic polyethers were prepared containing 12 to 60 atoms to a polyether ring including 4 to 10 oxygen atoms and some with nitrogen and sulfur atoms. Many of these compounds were found to be useless as complexing agents, but they served to define the effective ones which are compounds containing 5 to 10 oxygen atoms in the ring, each separated from the next by 2 carbon atoms. I also noted that even whole molecules such as the thioureas formed complexes with some crown compounds. I accomplished all this working alone with the help of my able technician, *Ted Malinowski.*

Some of the general properties of the aromatic macrocyclic polyethers are as follows: They are neutral, colorless compounds with sharp melting points, and are sparingly soluble in water and alcohols, moderately soluble in aromatic solvents, and very soluble in methylene chloride and chloroform. They undergo substitution reactions characteristic for aromatic ethers (halogenation, nitration, etc.), and form formaldehyde resins when treated with paraformaldehyde under acid conditions. They are decomposed by reactions which cause the scission of ethers.

The saturated macrocyclic polyethers are obtained most simply by catalytically hydrogenating the aromatic compounds using ruthenium catalyst. Bridge-bond isomers are obtained from compounds containing two or more aromatic side-ring substituents. For example, dibenzo-[18]crown-6 **5** gives a mixture of stereoisomers of perhydrodibenzo[18]crown-6 **6** (see Fig. 9). The saturated polyethers are colorless, viscous oils or solids with low melting points. They are thermally stable, but, like the aromatic compounds, must be protected from oxygen at high temperatures. They are, as a group, very much more soluble than the aromatic compounds in all solvents, and most of them are even soluble in petroleum ether.

The unique property of the macrocyclic polyethers as complexing agents is their preference for alkali metal ions, which do not form complexes with the numerous ligands used for the transition metal ions. The crown compounds form stable crystalline complexes and solutions of the complexes with some or all of the cations of alkali and alkaline earth metals plus ammonium ions and others. Some of them, for example **6**, form complexes with Co^{II}, and some other transition metal ions. The saturated compounds are better complexing agents than the corresponding aromatic compounds.

Three criteria have been used for the formation of complexes between macrocyclic polyethers and salts: (a) isolation of the complexes as crystals; (b) characteristic changes in the ultraviolet spectra of the aromatic compounds; and (c) changes in the solubilities of the polyethers and salts in different solvents.

As is evident from Table 1, these compounds have holes of different diameters in the center of the polyether rings. The uncomplexed cations also differ in size, given in Table 2 in Ångström units: sodium 1.94, potassium 2.66, ammonium 2.86, rubidium 2.94, and cesium 3.34. Depending, therefore, on the relative sizes of the hole and the cation, crystalline complexes with polyether/cation ratios of 1 : 1,

3 : 2, and 2 : 1 have been prepared as illustrated in Table 3. The aromatic macrocyclic polyethers tend to give high melting complexes which are not readily soluble in aprotic solvents, while the saturated compounds give lower melting complexes which are more soluble. Most of the pure complexes are decomposed by water, the rate and extent of decomposition depending on the proportion of water and the temperature.

It was postulated from the beginning that complexes of macrocyclic polyethers containing less than seven oxygen atoms consisted of a cation surrounded by the oxygen atoms arranged symmetrically in a single plane. The essential correctness of this view of the structure has been confirmed by Professor *M. R. Truter* and her collaborators who have been the first to determine the structures of a number of crystalline salt complexes of crown compounds by X-ray diffraction methods.[27]

All macrocyclic polyethers containing one or more benzo groups have a characteristic absorption maximum at 275 mμ in methanol, and the shapes of the curves are altered by the addition of complexable salts as shown in Figure 4. The spectral evidence is nearly always confirmed by the other two criteria.

Macrocyclic polyethers and complexable salts mutually increase their solubilities in solvents wherein the complexes are soluble. Sometimes these effects are spectacular; for instance the solubility of the potassium thiocyanate complex is about 0.1 mol L^{-1}, a 100-fold increase. Some of the saturated polyethers, e.g. **6**, have the useful property of solubilizing alkali metal salts, particularly those of potassium, in aprotic solvents. Crystals of potassium permanganate, potassium *tert*-butoxide, or potassium tetrachloropalladate ($PdCl_2 + 2KCl$) can be made to dissolve in liquid aromatic hydrocarbons merely by adding **6**. This is dramatic for the crown complex of potassium permanganate which colors toluene purple. Benzylpotassium is rendered soluble in *n*-heptane by the polyether, but the polyether ring is gradually decomposed by this organometallic compound. The solubilizing power of the saturated macrocyclic polyethers permits ionic reactions to occur in aprotic media. It is expected that this property will find practical use in catalysis, enhancement of chemical reactivity, separation and recovery of salts, electrochemistry, and in analytical chemistry.

The complexing efficiencies of saturated macrocyclic ethers can be ranked numerically by measuring the relative distribution of a colored alkali metal salt (such as picrate) between an immiscible organic solvent and water in the presence of the crown ether as depicted. If the polyether is ineffective, the organic phase will be colorless; if the polyether is very powerful, most of the color will be in the organic phase. The efficiencies of the polyether will lie between these two limits as shown in Table 4.[28–35]

Table 4. Extraction results [a].

Polyether	Picrate Extracted [%]			
	$Li^{\oplus}$	$Na^{\oplus}$	$K^{\oplus}$	$Cs^{\oplus}$

[a] Two-phase liquid extraction: dichloromethane and water.

Dr. *K. H. Frensdorff* has determined the stability constants for 1 : 1 complexes of many macrocyclic polyethers with alkali metal ions by potentiometry with cation-selective electrodes. Selectivity toward the different cations varies with polyether ring size, the optimum ring size being such that the cation just fits into the hole, that is, 15–18 for sodium ion, 18 for potassium ion, and 18–21 for cesium ion.[33]

That concludes my remarks on the discovery, properties and preparation of the crown ethers. It remains only for me to mention certain individuals who contributed to the success of my research and to add a few words concerning my interest and hope for the future of research in this area.

First, I want to remember on this occasion my wife *Susan* who died in 1983. It would have been wonderful to share with her all that has happened to me of late as we shared everything else during our marriage of 36 years.

Next, I would like to thank the Du Pont Company, They encouraged me to pursue my research on crown ethers, even when it was evident that, at least initially, my work might not have a significant practical impact. At another company, I might not have met with such encouragement and latitude.

Within the company I received support from certain individuals. I appreciate the advice and counsel of my close friend, Dr. *Herman Schroeder*, who was always interested in my research and whose companionship has meant so much to me during the many years we have known each other. I also thank my friend Dr. *Rudolph Pariser*, who has been tireless in his efforts to assure recognition for my accomplishments.

Finally, I want to thank the analytical groups of the company for making all their resources available to me; my technical colleagues for their scientific consultation; and our academic friends for their interest.

Of course, I must mention my respect and admiration for the two scientists with whom I share this year's prize. If I may use an analogy reflecting my youth at the Unsan gold mines, I see the discovery of the crown ethers as comparable to the finding of a new field with a lot of action in it. Professor *Cram* and Professor *Lehn* staked claims to particular veins of rich ore and went on to discover gold mines of their own.

I know that the crown ethers continue to create great interest among biologists for studying the mechanism of transport of ions across cell membranes.[36] But whether it be in biology or some other field, it is my fervent wish that before too long it matters not by whom the crown ethers were discovered but rather that something of great benefit to mankind will be developed about which it will be said that were it not for the crown compounds it could not be.

Somatic Generation of Immune Diversity (Nobel Lecture)**

By Susumu Tonegawa*

One day in the fall of 1970, I received an airmail letter from *Renato Dulbecco*, who was traveling in Europe. At that time I was a postdoctoral fellow in his laboratory at the Salk Institute. The letter, written on stationery of the Hotel Hassler in Rome said:

> Dear Susumu,
>
> I don't know what arrangements you have made for after your departure from La Jolla at the end of the year but I would like to mention to you another possibility. The Institute of Immunology in Basel, Switzerland, will start operating in a month. They already have an excellent collection of immunologists, but have not yet built an adequate background in molecular biology. I talked about you to Niels Jerne, the Director, and they are interested in having you there ... There are many immunologically interesting phenomena obtained with crude RNA preparations but they are unreliable because RNA is not characterized. In general, it seems the best system for understanding development at a molecular level and you may like to get into such a field. If you are interested, write to Niels K. Jerne, Basel Institute for Immunology, 487 Grenzacherstrasse ...

Thanks partly to the remarkably prophetic letter and partly to the U.S. immigration law that prevented me from remaining in the USA, in February 1971 I found myself in this cozy Swiss town almost completely surrounded by immunologists. For someone who had no formal training in immunology whatsoever and had never even visited Switzerland, it was a rather drastic change. Indeed, the first twelve months at the Basel Institute were not easy.

After I arrived in Basel I initially attempted to continue the project of my days in *Dulbecco*'s laboratory, namely, the transcriptional control of the simian virus 40 genes. However, I soon realized that this was not a subject that aroused great interest in an Institute almost entirely staffed by immunologists nor one that allowed me to take full advantage of my many talented colleagues. I therefore decided to learn immunology by talking to them, reading papers, and asking questions. An immunologist, *Ita Askonas*, and a geneticist, *Charlie Steinberg*, became my tutors and were most helpful to me in getting into a new field. It was during this process that I was introduced to the problem of the origin of antibody diversity.

The Problem

Immunologists agreed that an individual vertebrate synthesizes many millions of structurally different forms of antibody molecules even before it encounters an antigen. Moreover, *Gerald Edelman* and *Rodney Porter* had shown that a typical antibody molecule is composed of two identical light chains and two identical heavy chains.[1,2] It had also been found that each of these two types of chain exhibits great sequence variability in the amino terminal region between one antibody molecule and the next and no sequence variability in the carboxyl terminal regions.[3] These two regions were then referred to as the variable, or V, and the constant, or C, regions. However, immunologists and geneticists were divided for many years into two schools of thought with respect to the issue of whether the genetic diversity required for the synthesis of these proteins is generated during evolution and is carried in the germ line or during development, in which case it would be present in somatic but not germ-line cells. One school of thought held that the germ line must include a separate gene for every polypeptide that ultimately appears in an antibody molecule.[4] In this germ-line theory, antibody or immunoglobulin genes are expressed in exactly the same way as those for any other protein, and no special gene-processing mechanisms are needed. On the other hand, the model requires an enormous number of immunoglobulin genes inherited from the parents. While the four-chain structure of an immunoglobulin molecule allows diversity to be generated by chain pairing, the number of genes required for both light and heavy chains is still very large. One major difficulty for germ-line theories of antibody diversity was the observation that all antibody polypeptide chains of a given type share a common genetic marker (allotype) that segregates as a single Mendelian gene. If there were many thousands of light- and heavy-chain genes, how could the same genetic marker in all of these genes have been maintained?

The second theory supposed that there are only a limited number of antibody genes in the germ line, and that these genes somehow diversify as the antibody-forming B lymphocytes emerge from their stem cells. In other words, the diversification of antibody gene sequences takes place in specialized somatic, or body, cells rather than being carried from generation to generation by the germ cells.[5-7] One attraction of this latter theory is that it relieves the host of the need to commit a disproportionately large fraction of the inherited genes to code for antibodies, but the theory demands an unprecedented mechanism for diversifying the inherited genes somatically.

Arguments for and against these contrasting ideas were made both vocally and in written form for many years. However, all of these arguments were based on the inter-

pretation of amino acid sequences of immunoglobulin polypeptide chains or on the generally accepted principles of evolution and genetics. No direct evidence for either view had been obtained. This was because no technique was available that would allow an analysis of the fine structure of specific genes from higher organisms.

Gene Counting

In the early seventies the technology for purifying a specific eukaryotic mRNA was just becoming available. Furthermore, a method to determine the number of copies of a specific gene by kinetic analysis of nucleic acid hybridization had already been established.[8,9] These technical developments led some scientists, including myself, to think that one can experimentally determine the number of immunoglobulin genes contained in a germ-line genome and thereby decide which of the two major theories of antibody diversity is correct. The validity of this approach is based in part on the fact that the V region of a given chain type, while being different, exhibits a high degree of amino acid sequence homology. It was therefore thought that an mRNA coding for a specific immunoglobulin polypeptide chain would hybridize not only with its own gene but also with many other immunoglobulin genes, if they existed in a germ-line genome.

I thus obtained mouse myeloma cells and put my effort to purifying immunoglobulin mRNA and carrying out the hybridization studies. However, the initial studies focusing on the mouse κ-light-chain and heavy-chain genes gave ambiguous results. The difficulty was primarily due to uncertainty about the purity of the mRNA used as the hybridization probe as well as a lack of knowledge on the extent to which a probe will hybridize with the related but not identical genes and the precise effect of sequence differences on hybridization kinetics. Thus it turned out to be nearly impossible to make a convincing interpretation of the data obtained in these early studies in relation to the issue of the evolutionary versus somatic generation of antibody diversity.

One subsequent series of experiments that I carried out on genes coding for the mouse λ light chains, however, was very encouraging.[10] Using an mRNA preparation that was more than 95% pure, I could show that the mouse λ-light-chain gene is reiterated no more than the β-globin gene. The latter gene had been shown to be essentially unique. Fortunately, *Weigert*, *Cohn* et al. had identified at least eight different V_λ-region sequences among BALB/c-derived myelomas.[11] Since these V regions were highly homologous, differing by only one, two, or three amino acid residues, it was very likely that the corresponding genes would cross-hybridize extensively if they existed separately in the germ-line genome. Furthermore, statistical analysis of λ-light-chain-secreting myelomas strongly suggested that a BALB/c mouse has the capacity to synthesize many more than the eight different V_λ regions identified. Thus the number of the mouse λ genes determined experimentally (no more than a few) was far smaller than the number of different V_λ regions (at least eight, most probably many more) detected in proteins. On the basis of these results I was convinced that a somatic diversification occurs in this gene system.

Rearrangement

In the meantime I became aware that some immunologists had been speculating that immunoglobulin polypeptide chains may be encoded by two separate DNA segments, one each for the V and C regions. Drawing an analogy from the elegant Campbell model[12] on the integration and excision of a phage λ genome, *Dreyer* and *Bennett* had further suggested that one of many "V genes" may be excised from the original chromosomal position and joined with the single "C gene" in an immunoglobulin-producing B cell.[13] This model successfully explained the maintenance of the common genetic marker in all immunoglobulin polypeptide chains of a given type by postulating a single C gene for that chain type. Although a somatic recombination between the "V and C genes" is an inherent aspect of the model it is clearly a version of the germ-line theory of antibody diversity because the model assumed that the germ-line genome carries many "V genes", one for every V region that an organism can synthesize.

When the Dreyer and Bennett model was published in 1965, it was not accepted widely by biologists. This is understandable because the model was built on two hypotheses, both of which violated the then current dogmas of biology. These are the principles of one gene encoding one polypeptide chain and the constancy of the genome during ontogeny and cell differentiation. My personal reaction to the model when I learned of it in the early nineteen seventies was also that of skepticism. At the same time, however, I thought that the model might be testable if one were to use restriction enzymes. While in *Dulbecco*'s laboratory I had heard of *Daniel Nathan*'s breakthrough in the analysis of the SV40 genome by an application of the then newly discovered restriction enzymes.[14] As one who used to struggle to define the transcriptional units of this DNA virus, I was keenly aware of the power of these enzymes for the analysis of DNA structure. However, an extension of the restriction enzyme analysis from a viral genome of 5×10^3 base pairs to the 2×10^9 base-pair genome of a eukaryote as complex as a mouse required the use of an additional trick for the detection of a specific DNA fragment in a vast array of irrelevant fragments. An obvious solution seemed to lie in the combination of an electrophoretic separation of enzyme-digested DNA and the sensitive technique of nucleic acid hybridization. I discussed with *Charlie Steinberg* the need for developing a method that allows an in situ detection of a specific DNA sequence among the electrophoretically fractionated DNA fragments, but we really could not come up with a good idea worthy of exploring. As we all now know, a very simple and elegant method ideal for this purpose was later developed by *Edward Southern*.[15]

A few weeks passed before I accidentally saw in one of the Institute's cold rooms a huge plexiglass tray in which someone was fractionating serum proteins by starch gel electrophoresis. I thought one may be able to fractionate a sufficient amount of digested DNA in a gel of such dimen-

sions, so that the DNA eluted from gel slices could be used for liquid-phase hybridization. A quick calculation seemed to indicate that the experiment was feasible. *Nobumichi Hozumi*, a postdoctoral fellow in my laboratory, and I therefore decided to give it a try although we were keenly aware of the intense labor required by this type of experiment. As hybridization probes we used purified κ or λ light-chain mRNA (V+C probe) and its 3'-half fragment (C probe) that had been radioiodinated to a high specific activity. The rationale of the experiment was as follows: first, if an immunoglobulin polypeptide chain is encoded by two "genes" (V and C) in the germ-line genome, it is highly probable that treatment with a restriction enzyme will separate these DNA sequences into fragments of distinct size, thus allowing their electrophoretic separation. Second, if a somatic rearrangement joins the V and C "genes" it is also highly probable that the myeloma DNA digested with the same restriction enzyme will contain a DNA fragment carrying both V and C "genes".

The results obtained were clear-cut: To our pleasant surprise the patterns of hybridization of the embryo DNA (a substitute of germ-line DNA) and a κ-myeloma DNA were not only drastically different but also perfectly consistent with the occurrence of separate V and C "genes" and a joined V plus C gene, respectively.[16] We were of course aware of the alternative interpretations of the results, such as a fortuitous modification of the enzyme cleavage sites in one of the two types of DNA. However, we considered these alternative explanations of the results unlikely because they all required multiple fortuitous events. Our confidence was fortified soon afterwards as the development of Southern blot techniques allowed us to carry out more extensive analyses using a variety of restriction enzymes and myeloma cells.

Joining of Gene Segments

While the experiments with restriction enzymes were informative, details of the rearrangement were difficult to come by with this approach. Fortunately, recombinant DNA technology was just becoming available and was the ideal means for this purpose. Debates on the possible hazards of this type of research were flaring, initially in the United States and, shortly afterwards, in European countries. In order to make sure that our research would not become a target of controversy, *Charlie* and I got in touch with *Werner Arber* at the University of Basel who was coordinating recombinant DNA research activities in Switzerland. A small informal work group was set up by the local researchers interested in this technique. The consensus of the group, which was supported by most of the other Swiss researchers, was that we should all follow the practices and guidelines being adopted in the United States. We met about once a month and exchanged information regarding both ethical and practical aspects of the technology.

On the basis of the previous experiments attempting to count immunoglobulin genes, I thought that it would be wise to start with the mouse λ-light-chain system, the simplest of all chain types that had been studied. Our goal was to clone the V_λ and C_λ "genes" in the germ-line state from embryonic cells, as well as the rearranged V plus C "genes" from a λ myeloma, and to determine the relationship between these genomic DNA clones by electron microscopy and DNA sequencing. No precedent existed at that time for cloning "unique" eukaryotic genes. We therefore had to devise a few tricks as we attempted to clone the first immunoglobulin gene. For instance, our available probe at that time was again 95% pure mRNA rather than a cDNA clone. This situation made the screening of a large number of DNA clones difficult because of the high background. To avoid this problem, we pre-enriched the λ-gene-containing genomic DNA fragments as much as possible using preparative R-loop formation,[17,18] so that the DNA library constructed would have the clone of interest at a high frequency.

Starting with the embryonic DNA, we could isolate a clone that clearly hybridized specifically with the λ mRNA.[18] When an electron microscopist, *Christine Brack*, who had just joined us from the Biozentrum of the University of Basel, examined the mixture of this clone and λ mRNA that had been annealed under appropriate conditions, she found a beautiful R-loop from which about half of the mRNA strand protruded. This and additional analysis convinced us that we had cloned a V_λ "gene" to which no C "gene" was contiguously attached, thus confirming at the DNA clone level that the V and C "genes" are indeed separate in the germ-line genome. A subsequent DNA sequencing study carried out in collaboration with *Allan Maxam* and *Walter Gilbert* of Harvard University revealed that this DNA clone corresponded to the V "gene" for the λ_2 subtype.[19]

In the meantime *Minoru Hirama*, another postdoctoral fellow, succeeded in preparing λ and κ cDNA clones. Once these probes became available, isolation of the genomic clones became much easier. My assistant *Rita Schuller* and I isolated a number of genomic DNA clones from λ- and κ-chain-synthesizing myelomas as well as from embryos.[20,21] Analysis of these DNA clones by electron microscopy, by restriction enzyme mapping, and by DNA sequencing not only confirmed the somatic rearrangement of immunoglobulin genes but also revealed some striking features of their arrangement and rearrangement (Fig. 1). These can be summarized as follows:

1. Although the V and C "genes" are rearranged and are much closer to each other in myeloma cells than in embryo cells, they are not contiguous and are separated by a few kilobases of DNA sequence that does not participate in coding of the polypeptide chain. This untranslated DNA sequence present within the rearranged, complete immunoglobulin gene was unanticipated and was also among the first demonstrations of an intron in eukaryotic genes.[22]
2. The V "gene" found in the germ-line genome is about 13 codons short when it is compared to the length of the conventionally defined V region. The missing codons were found in a short stretch of DNA referred to as a *J* (or joining) gene segment that is located many kilobases away from the incomplete V "gene" (referred to as a *V* gene segment) and a few kilobases upstream of the C

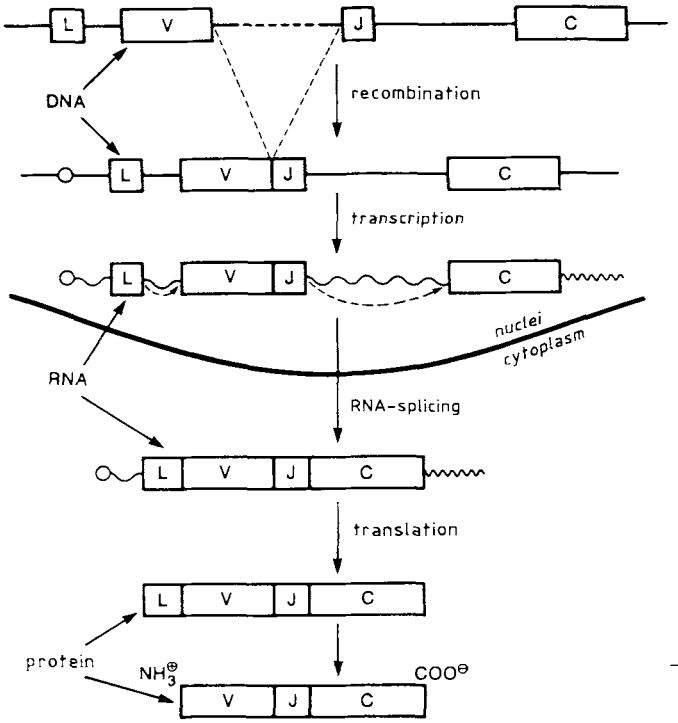

Fig. 1. The basic scheme for rearrangement and expression of an immunoglobulin light-chain gene. At top is an arrangement of the gene segments on a germ-line genome. Somatic rearrangement links the *V* and *J* gene segment and generates a complete light-chain gene shown just below the germ-line genome. The entire gene containing the leader exon (L), the V-region exon (V and J), the C-region exon (C), and the introns present between these exons are transcribed into a pre-mRNA in the nuclei of the B cell. The pre-mRNA is processed by RNA splicing as it is transported from the nuclei to the cytoplasm. The resulting mRNA devoid of introns is translated in the endoplasmic reticulum into a nascent polypeptide chain from which a mature λ light chain is generated after cleavage of the signal peptide.

"gene" (also referred to as a *C* gene segment). In myeloma cells the rearrangement event attaches the *J* gene segment to the *V* gene segment and thereby creates a complete V-region "gene".[20,23]

3. The signal peptide is encoded in yet another DNA segment referred to as the *L* (or leader) exon which is separated from the *V* gene segment by a short intron.[19,23]

Finding that the V_λ "gene" was split into two gene segments, V_λ and J_λ, in the germ-line genome was completely unexpected. But as soon as this discovery was made its implication for the somatic generation of antibody diversity was obvious. If the germ-line genome carries multiple copies of different *V* and *J* gene segments, the number of complete V "genes" that can be generated by random joinings between these two types of gene segments would be much greater than the total number of the inherited gene segments. Thus, contrary to the original concept of *Dreyer* and *Bennett*, DNA rearrangement can provide a major means for the somatic diversification of antibody molecules. The amino acid sequence data of the κ light chains and heavy chains were consistent with this concept.[24,25] Indeed, the nucleotide sequence analysis of the mouse κ-chain gene complex carried out both in my laboratory and in *Phillip Leder*'s laboratory at the United States National Institutes of Health confirmed that a germ-line genome contains multiple *V* and *J* gene segments and that these gene segments are joined in different combinations in each myeloma cell.[20,26] Four different J_κ gene segments were found several kilobases upstream of the C_κ gene segment. The exact number of V_κ gene segments is unknown even today, but it is estimated to be two to three hundred.[27]

Heavy-Chain Genes

Inasmuch as an immunoglobulin heavy chain is also composed of V and C regions, it was reasonable to expect that its gene also would undergo the type of DNA rearrangement described for the light-chain genes. This supposition was confirmed by *Leroy Hood* et al. at California Institute of Technology and by ourselves (Fig. 2).[28,29] As in κ genes, four *J* gene segments were found several kilobases upstream of the *C* gene segments coding for the C region of the μ-class heavy chain. Multiple *V* gene segments were also identified.

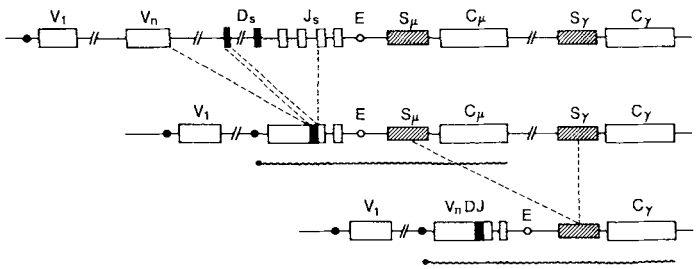

Fig. 2. Organization of the immunoglobulin heavy-chain gene family. At top, middle, and bottom are the organization in a germ-line genome, in a genome of B cells synthesizing a μ-class heavy chain, and in a genome of a plasma cell synthesizing a γ-class heavy chain, respectively. A mouse haploid genome carries several hundred different *V* gene segments, about a dozen *D* gene segments, four *J* gene segments, and one copy of a *C* gene segment for each of the eight different classes or subclasses of immunoglobulin heavy chains. In a virgin B cell one copy each of the *V*, *C*, and *J* gene segment pools have been linked up and the joined *VDJ* DNA sequence is transcribed into a pre-mRNA together with the C_μ gene segment. In different B cells of the same organism a different set of *V*, *D*, and *J* gene segments are usually hooked up and expressed. As the virgin B cell differentiates either to a plasma cell or to a memory B cell (see Fig. 5), the second type of somatic recombination, called "switch recombination", often occurs between a region (S_μ) located upstream of the C_μ gene segment and another region (S_γ) located upstream of the C_γ gene segment. As shown at the bottom, the switch recombination replaces the C_μ gene segment with the C_γ gene segment without changing the *VDJ* exon. Filled circles designate transcriptional promoters present upstream of every *V* gene segment. The open circle designates the transcriptional enhancer [102, 103] which, together with the promoter, activates the rearranged heavy-chain gene for a high-level expression.

While these features of the organization of heavy-chain genes are essentially the same as those of the light-chain genes, one observation made during these studies suggested that the somatic assembly of gene segments plays an even more prominent role in the diversification of heavy chains than of light chains. It was found that from one or two to a dozen amino acid codons that are present in the V–J junction region of the assembled gene are not found in either of the apparently corresponding germ-line *V* or *J* gene segments.[30,31] This suggested that a third type of short gene segment, referred to as *D* (or diversity), might participate in the somatic assembly of a heavy-chain gene. Indeed, *Hitoshi Sakano* and *Yoshi Kurosawa*, two postdoctoral fellows in my laboratory, soon discovered about a

dozen D gene segments,[32,33] which were subsequently mapped in a region upstream of the J cluster in the germline genome.[34,35] Thus the construction of a complete heavy-chain V "gene" requires two DNA-recombination events, one joining a V with a D gene segment and the other the same D with a J gene segment.

Recombination Rule

The joining of V-J or V-D-J gene segments involves a site-specific recombination. It might therefore be expected that these gene segments would carry sequences in the vicinity of the joining ends that are recognized by a putative site-specific recombinase. Furthermore, such recognition sequences are likely to be common for all gene segments of a given type (e.g., V_κ's), because they all seem to be capable of joining with the common set of gene segments of the appropriate type (e.g., J_κ's). There indeed are a heptamer and a nonamer that are conserved in the region immediately downstream of each V_κ gene segment (Fig. 3).[36,37]

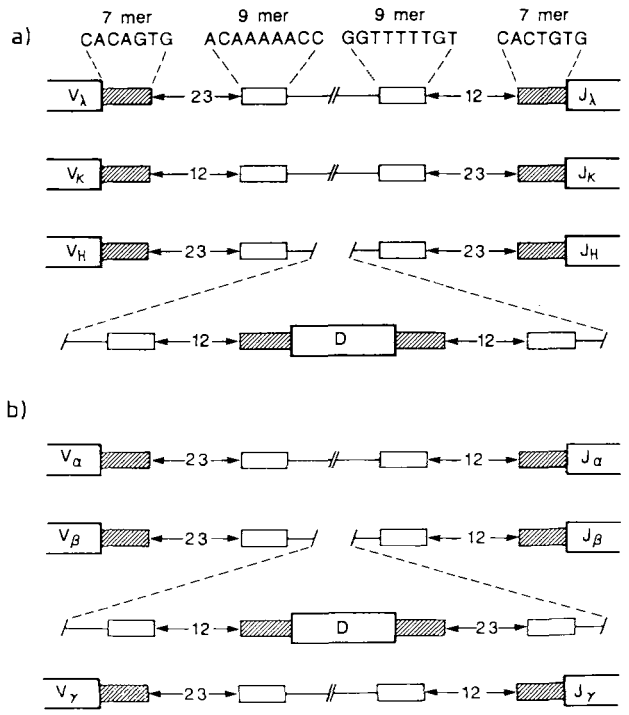

Fig. 3. Putative recognition sequences for the rearrangement of immunoglobulin and T-cell receptor genes. The conserved heptamer and nonamer sequences and the length of the spacer between these sequences are schematically illustrated for immunoglobulin (a) and for T-cell-receptor (b) gene families. The sequences shown on top are consensus sequences. Individual sequences may deviate from these consensus sequences by a few nucleotides.

Sequences complementary to the V_κ heptamer and nonamer were also found in the region immediately upstream of each of the four J_κ gene segments. The same sets of sequences were also found in the corresponding regions of the V_λ and J_λ gene segments.[36] When the heavy-chain V and J gene segments were analyzed subsequently, they too had the common conserved sequences.[30,31] Furthermore, D gene segments carry the heptamer and nonamer sequences both upstream and downstream.[32,33] Another interesting feature of these putative recognition sequences is the fact that the length of the spacer between the heptamer and nonamer is either 12 or 23 base pairs.[30,31] Furthermore, a gene segment carrying a recognition sequence with one type of spacer is able to join only with a gene segment with the spacer of the other type. This 12/23 base-pair spacer rule seems to be adhered to strictly. Little is currently known about the recombinase, but proteins with an affinity for the heptamer or nonamer have been identified in the extract of Abelson-virus-transformed pre-B-cell lines in which the rearrangement occurs in vitro at a relatively high frequency.[38,39]

Diversity Generated at the Joining Ends

When the deduced amino acid sequence of a germ-line J_κ gene segment was compared with the determined amino acid sequences of those κ chains that are encoded in part by that J_κ gene segment, it was noticed that the 5′ end of the J_κ gene segment is not prefixed but rather shifts upstream or downstream by several base pairs in different joining events.[36,37] This flexibility in the precise site of the joining was subsequently found to be a characteristic of the joining ends of other gene segments rather than of just J_κ gene segments.[31] It applies even when the same pair of gene segments were joined in different B-cell precursors, such that the completed V "genes" are likely to have slightly different codons in the junction regions.

The V-D and D-J junctions exhibit diversity of yet another type. We found that up to a dozen base pairs of essentially random sequence are inserted in these junctions apparently without a template during the breakage and reunion of the recombining gene segments.[32,33] While the precise mechanism is yet unknown, the terminal deoxynucleotide transferase that is found in early B-lymphatic nuclei or an enzyme with similar characteristics is thought to play a role in this phenomenon.[40]

The part of the V region affected by the above two diversification mechanisms is limited. But this does not mean that they do not play a significant role in the determination of antibody specificity. On the contrary, the junctions encode the most variable two of the six loops of polypeptides that make up the antigen binding region of the antibody molecule (Fig. 4). Furthermore, specific cases are known where the affinity of an antibody for a defined antigen is drastically altered by a slight change in one junctional sequence.[41] Thus the junctional variation also is a potent somatic generator of antibody diversity.

Somatic Mutation

When *F. Macfarlane Burnet* proposed the clonal selection theory, he recognized the need for some kind of random genetic process in order to generate antibodies able to bind specifically to the vast variety of antigens.[42] He considered somatic mutations as the most plausible mechanism. Subsequently, this idea was adopted and forcefully presented by many, including *Joshua Lederberg*, *Niels Kaj Jerne*, and *Melvin Cohn*.[5,6,7]

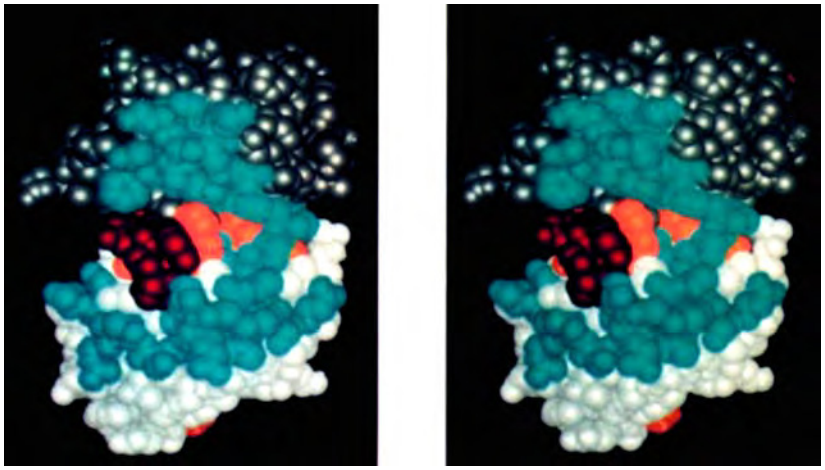

Fig. 4. Space-filling, stereo image of an antibody combining site. Atomic coordinates of mouse immunoglobulin MOPC 603 [104] were used to produce the picture. The heavy-chain variable domain is color-coded dark grey, the light-chain variable domain light grey. The hypervariable regions (except the VH third hypervariable region) are blue, the heavy-chain segment coded for by the D gene is red, and the heavy- and light-chain segments coded for by the J genes are yellow. The D segment corresponds virtually exactly to the third heavy-chain hypervariable region; hypervariable regions were defined as in *Novotney* et al. [105] except for the second heavy-chain hypervariable region, which is marked as defined by *Kabat* et al. [25]. The antigen of this particular immunoglobulin, phosphorylcholine, binds into the cavity in the middle of the picture in between the VH and VL domains, making contacts to amino acid residues belonging to the VH and J segments of the heavy chain and the VL segment of the light chain. The importance of the D segment is well illustrated in the two crystallographic structures of antibodies which bind the protein antigen lysozyme [106, 107]. There, the contact areas contributed by the D segment amount to 60% and 24%, respectively, of the total heavy-chain contact area. This image was computer-generated by *Jiri Novotny* using the program SPHERE of *Robert Bruccoleri*.

The amino acid sequence data accumulated by *Martin Weigert* in *Melvin Cohn*'s laboratory at the Salk Institute provided an excellent opportunity to examine directly the role of somatic mutations in antibody diversity.[7, 11] They had analyzed the λ_1 light chains derived from 18 myelomas. All the mice were of an inbred strain, BALB/c, and so should have been genetically identical. They found that twelve of the $V_{\lambda 1}$ regions were identical but that the other six differed both from the majority sequence and from one another by only one, two, or three amino acid residues. They proposed that BALB/c mice may carry only one germ-line $V_{\lambda 1}$ "gene" which codes for the majority sequence, and that all the other $V_{\lambda 1}$ regions observed are encoded by somatic mutants of this single $V_{\lambda 1}$ "gene" that arose in B-cell development. As I already mentioned in the section on gene counting, the hybridization kinetics suggested that the germ-line BALB/c genome carries no more than a few $V_{\lambda 1}$ "genes". This number was reduced to one when we reevaluated the copy number by the more reliable Southern blotting method.[20] The final proof of somatic mutation in $V_{\lambda 1}$ came when we cloned and sequenced the sole germ-line $V_{\lambda 1}$ gene segment and the rearranged λ_1 genes expressed in a myeloma.[23] As *Weigert* and *Cohn* guessed, the nucleotide sequence of the germ-line $V_{\lambda 1}$ gene segment corresponded to the major amino acid sequence, while the λ_1 gene expressed in the myeloma had been altered by single base changes.

Since this work, several subsets of κ light chains and heavy chains and their germ-line *V* gene segments have been analyzed by cloning and sequencing.[43–46] These results have all confirmed that somatic mutations further amplify the diversity encoded in the germ-line genome. Particularly revealing was the analysis carried out by *Patricia J. Gearhart, Leroy Hood* et al. for the V_H regions associated with the binding of phosphorylcholine (PC). They demonstrated that the single base changes can be extensive and yet are restricted to the joined VDJ sequences and the immediately adjacent regions.[47, 48]

Developmental Control of Rearrangement and Hypermutation

Why have two extraordinary somatic genetic mechanisms, recombination and hypermutation, evolved in the immune system in order to carry out what appears to be one task, namely, to diversify antibodies?

I believe that the answer may be the differential roles of these two genetic mechanisms. Thanks to the efforts of several independent groups of cellular and molecular immunologists, a general picture is emerging that describes the relationship between the stages of B-cell development and the occurrence of somatic recombination or mutation (Fig. 5).[49–55] Somatic recombinations contributing to diversity are initiated first for the heavy chain and then for the light chain during the differentiation of progenitor cells, and the completion of somatic recombination is accompanied by the appearance of virgin B cells.[56–58] These B cells form clones, each of which is composed of cells bearing homogeneous IgM molecules as surface receptors. Thus, somatic recombination is completed *prior to* any possible interaction of a B cell with antigens.

When an antigen enters the lymphatic system for the first time, it will be screened by these virgin B cells. The

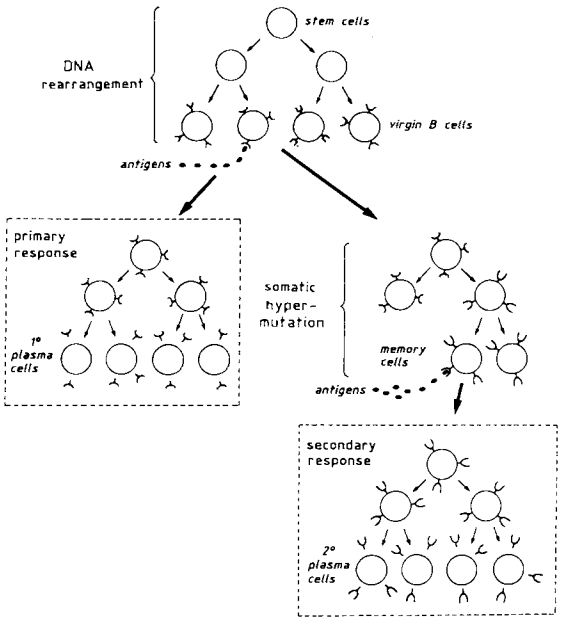

Fig. 5. Differentiation of B cells. Note that the receptors present on the memory cells and the antibody molecules secreted by the plasma cells of the secondary response have a tighter fit to the antigen than the receptors on the ancestral virgin B cells or the antibodies secreted by the plasma cells of the primary response. See text for the full explanation.

small fraction of these B cells that happen to have sufficient affinity for the antigenic determinants in question will respond and follow either of two pathways: they will produce the primary antibody response, or they will contribute to the generation of memory B cells. In the former pathway, the selected B cells will proliferate and differentiate into antibody-secreting plasma cells. During this process, the C region of the heavy chain can switch from μ to another class, but mutation is rare in either the heavy- or the light-chain V region. Consequently, the antibodies secreted by plasma cells in the primary response would largely have the same V regions as the immunoglobulin receptors on the virgin B cells from which they derive.

By contrast, immunoglobulin remains in the cell surface receptor form during the other pathway taken by the antigen-activated virgin B cells, namely, the generation of memory B cells. During this process the hypermutation apparatus appears to be most active and the rate of the mutation approaches 10^{-3} base substitution per cell per generation. Antigen selects, in a stepwise fashion, better and better fitting mutants so that the immunoglobulins on the surface of memory B cells achieve a substantially higher affinity than the immunoglobulins on the ancestral virgin B cells. Switch recombination also occurs frequently during this process. When the same antigen as the one that elicited the primary response reenters the body, the memory B cells are selectively propagated and differentiate into plasma cells. This is the so-called secondary antibody response, which, therefore, consists of high-affinity antibodies of "mature" isotype showing extensive somatic mutation in their V regions. Somatic mutations appear to cease after memory cells are generated, and little or no further mutation takes place during the secondary antibody response.

This scheme of B-cell differentiation can be rephrased as follows. An organism is prepared for infection by pathogens bearing virtually any antigens with a large variety of resting B cells. These B cells bear unique immunoglobulin receptors encoded by one copy each of complete light- and heavy-chain genes that have been constructed by a random or quasi-random assembly of the inherited gene segments. Since the assembly occurs independently of antigens and since the inherited gene segments are not usually selected during evolution for precise fit to particular antigens, the antibodies secreted by the plasma cells derived directly from the selected resting virgin B cells during a primary antibody response usually have a relatively low affinity. By contrast, the frequent single base changes that occur during the generation of memory B cells provide the organism with a great variety of finely altered immunoglobulin receptors from which only those with the best fit to the antigen in question will be selected. Since the plasma cells generated during the secondary antibody response are mostly direct descendants of these memory B cells having no further alterations in the antigen-combining sites, these antibodies usually exhibit a much higher affinity for antigen than do primary antibodies. This explains the long-known phenomenon of affinity maturation of antibodies during the course of repeated immunizations.[59]

Thus somatic creation of antibody genes can be viewed as a two-step process. In the first step, blocks of gene segments are employed to build, in an antigen-independent fashion, a set of genes coding for antibodies of great diversity but with low affinity. In the second step, once the antigen is defined, a small selected set of B cells bearing low-affinity antibodies as cell surface receptors undergo somatic mutations with the result that a fraction of them develop a higher affinity for that antigen and can be selected for further expansion. This process improves the ability of the immune system to detect a low concentration of antigens. One wonders what happens to those cells in which mutation did not improve affinity. A recent study suggests that at least some of these cells may be set aside for selection by different antigens.[54] Thus somatic mutation may also contribute to the repertoire of receptors specific for antigens not previously introduced into an immune system.

T-Cell Receptors

As the mystery of the genetic origins of antibody diversity was unraveled at least in its basic outlines, it seemed natural to extend our research to "the other half" of the lymphoid system, namely, T cells. Although we often discussed the idea of research on the nature of antigen recognition by T cells in the laboratory in the late seventies while I was still in Basel, the real work did not start until the early eighties in my new laboratory at MIT. Although T cells were known to recognize and distinguish antigens as precisely as B cells, nothing was known about the biochemical nature of the molecules responsible for this task, namely, T-cell receptors (TCR). This lack of information was in stark contrast to the wealth of information about antibodies. Much debate took place among cellular immunologists on the nature of these molecules. Some argued that T-cell receptors are just another class of immunoglobulins. Others thought T-cell receptors would have to be

quite different from immunoglobulins. Indeed, studies carried out in the late seventies had shown that the way in which a T cell recognizes an antigen is quite different from the way a B cell does: The T cell reacts to antigens on a cell surface, and the T-cell receptor simultaneously recognizes both an antigen and a determinant present on a glycoprotein encoded by a gene in the major histocompatibility complex (MHC).[60-62] This discovery raised another issue: Does a T cell recognize two determinants with one receptor or does it have two receptors, one for antigen and the other for an MHC product?

The receptor protein was first detected in 1983 in experiments carried out by three independent groups of scientists headed by *James P. Allison, Ellis L. Reinherz,* and *Phillipa Marrack* and *John Kappler.*[63-65] They prepared antibodies that bind to a protein on the T-cell surface: Since these proteins were similar but exhibited clonally distributed structural diversity, they were thought to be a good candidate for the receptor. Furthermore, the antibodies they prepared were T-cell clone-specific and they could show that these antibodies blocked activation of the T-cell clone in a clone-specific fashion. The receptor identified by these experiments was composed of two polypeptide subunits, designated α and β, which are held together by a disulfide bond. These studies were critical in the sense that the receptor was finally identified, its overall structure defined, and its predicted structural variability confirmed. However, the paucity of the protein on the T-cell surface and the absence of the secreted form of the receptor made it very difficult to obtain further information about the structure of this molecule, especially its amino acid sequence.

α and β Genes

In the meantime, molecular biologists were attempting to identify the genes coding for the T-cell receptor. This turned out to be a much more difficult endeavor than the cloning of immunoglobulin genes. Although T-cell lines and hybridomas expressing a homogeneous receptor were becoming available, these cells were more difficult to grow than myelomas and the amount of the receptor made was at least two orders of magnitude less than the amount of immunoglobulin produced by a myeloma cell. In 1984, *Mark Davis* et al. at Stanford University and *Tak Mak* et al. at the University of Toronto independently made a breakthrough.[66-68] Their experimental strategy depended on two assumptions: first, that mRNAs coding for the α and β polypeptide chains are present in a T-cell hybridoma or T-cell tumor but are absent in B-cell tumors; second, that the α- and β-chain genes are rearranged in T cells in a manner similar to that of the immunoglobulin genes in B cells. Thus, they made a library from the fraction of T-cell cDNA that did not hybridize with B-cell-derived mRNA and tested each T-cell-specific cDNA clone for rearrangement of the corresponding gene in T cells. As the source of T cells, *Davis'* group used a hybridoma obtained by fusing a mouse helper T cell recognizing antigen plus self class II MHC molecules with a T-cell tumor while *Mak*'s group used a human T-cell tumor. The two groups came up with one common class of cDNA clones that satisfied the above criteria. The nucleotide sequence showed that the corresponding polypeptide chain is significantly (30–35%) homologous to immunoglobulin chains. Furthermore, the cDNA clones contained sequences homologous to V and C regions in the correct orientation. Thus it seemed certain that the gene represented by this class of cDNA clones codes for one of the two subunits of the T-cell receptor. That this gene encodes the β-subunit was soon confirmed by determination of the partial amino acid sequence of the human β chain.[69]

In my laboratory at MIT *Haruo Saito* and I collaborated with *David Kranz* and *Herman Eisen* to isolate both α and β cDNA clones from another type of T cell, namely, a cytotoxic T-cell clone specific for class I MHC molecule. In 1984, using a modified subtractive cDNA library method, we identified two classes of cDNA clones that also satisfied the criteria for a T-cell receptor gene.[70] One class of these clones represented the β-subunit. Taken together with the earlier finding by *Davis'* group, this demonstrated that the two major classes of T cells, helper T cells and cytotoxic T cells, employ the same set of genes at least for the β subunit. The same conclusion was drawn subsequently for the α subunit. This point is significant because the two types of T cell are specific for two distinct subclasses of MHC gene products. Thus, the same T-cell receptor genes mediate recognition of both class I and class II MHC.

The polypeptide chains encoded by the other class of rearranging T-cell-specific cDNAs isolated by *Saito* and myself was also homologous to immunoglobulin chains by 30–35%. These cDNA clones were, however, clearly distinct from β cDNA clones because the polypeptide chains encoded by the two sets of cDNAs were homologous by only 30–35% not only in the V regions but also in the C regions. Since only two subunits, α and β, were known for the T-cell receptor, we initially proposed that this second class of cDNAs represented the α gene.[70] However, even before the work was published a question arose about the assignment of this gene as encoding the α chain. The putative α cDNAs do not carry codons for N-linked glycosylation sites, while unpublished studies from *Charlie Janeway*'s laboratory at Yale University and *Jim Allison*'s at Berkeley indicated that both α and β subunits of at least some T cells carry N-linked carbohydrates. While it was still possible that the apparent discrepancy in glycosylation could be explained by differences in the type of T cell or in the mouse strains used, continued screening of our subtracted cDNA library yielded within a few weeks a third class of clones whose genes also rearrange specifically in T cells.[71] This gene not only was as homologous to immunoglobulin genes as the first two classes of T-cell-specific genes, but also had two potential sites for N-linked glycosylation, and therefore was a better candidate for the α gene. This proposition was soon confirmed by comparing its nucleotide sequence with the partial amino acid sequence of the human α subunit.[72] Furthermore, the α gene was also cloned at about the same time from a helper hybridoma.[73]

Once cDNAs encoding the α and β chains were identified, it was straightforward to determine the organization of

the corresponding genes in genomic DNA. These studies demonstrated that both α and β genes are organized in the germ-line genome and rearranged in T cells in a way remarkably similar to that of the immunoglobulin genes.[74-77] Thus, the organism inherits the genetic information for these polypeptide chains as V_α and J_α gene segments or V_β, D_β, and J_β gene segments, and a random assembly of these gene segments occurs exclusively during T-cell development to generate a diversity comparable to that of immunoglobulins for receptors expressed on the surface of mature T cells. Even the presumed recognition sequences for the site-specific recombinase, the so-called heptamers and nonamers with a 12- or 23-base-pair spacer, seem to be common for both the immunoglobulin and T-cell receptor genes (see Fig. 3).

The complete primary structure of a T-cell receptor can be deduced from the nucleotide sequences of the α and β cDNA clones. Its comparison with the primary structure of an immunoglobulin molecule suggests that the external part of the receptor is composed of four compact, immunoglobulin-like globular domains associated in two noncovalently bound pairs V_α-V_β and C_α-C_β, and further stabilized by an interchain disulfide bond between the C domain and the transmembrane region. This extracellular part of the receptor is anchored on the membrane lipid bilayer through two transmembrane peptides, one each from the α and β chains (Fig. 6).[70]

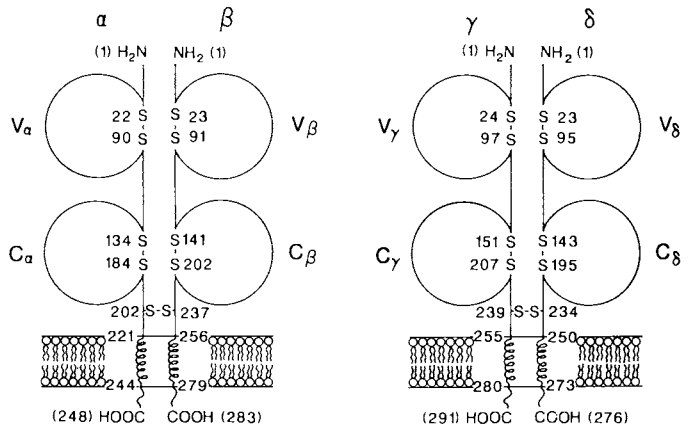

Fig. 6. Diagram showing the subunit structures of T-cell receptors αβ (left) and γδ (right) as deduced from the nucleotide sequences of cDNA clones. The αβ receptor is from an alloreactive cytotoxic mouse T-cell clone, 2C, and the γδ receptor from a mouse thymocyte hybridoma, KN6, prepared by *Osami Kanagawa* of Lilly Research Laboratories, La Jolla, California. Intra- and interchain disulfide bonds are indicated. The receptors are thought to be anchored on the membrane lipid bilayer by transmembrane peptides. The invariant CD3 complex associated with the heterodimers is not shown.

Determining the structure and organization of genes encoding the T-cell receptors settled the issue of their relationship with immunoglobulins and accounted for the genetic origins of their diversity. However, these studies did not illuminate the mechanism by which these receptors can accomplish the dual recognition of an antigen and an MHC determinant. This last issue is particularly tantalizing because recent studies using a technique for injecting T-cell receptor genes into cloned, functional T cells confirmed that the αβ heterodimer alone is sufficient to mediate this dual specificity.[78] In order to understand how the heterodimer simultaneously recognizes the two determinants, much more information is needed as to the structure of the receptor and of its compound ligand. It seems that the ultimate solution has to come from X-ray crystallographic analysis of the receptor protein.

A New T-Cell Receptor, γδ

Since it was established that the third T-cell-specific rearranging gene discovered was for the α subunit, the second one became an orphan. This gene is so closely related to the other two genes, however, that it seems certain that it must have some role in recognition by T cells. Nevertheless, previous immunochemical studies did not reveal any polypeptide chain that might be considered as a candidate for the protein product of this gene. The γ gene is also assembled somatically from *V*, *J*, and *C* gene segments and shares a number of characteristics with the α and β genes as well as with immunoglobulin genes.[79,80]

A number of possibilities were considered initially as firsthand roles for the putative γ chain. For instance, it was thought that the γ chain may be a subunit for a second T-cell receptor coexpressed with the αβ heterodimer. This hypothesis is in line with the two-receptor model of dual recognition of antigen and MHC by T cells. Another possibility proposed was that there may be a switch in the subunits of the T-cell receptor during T-cell development. A model was proposed in which a T-cell receptor composed initially of an γβ heterodimer switches to an αβ heterodimer as T cells differentiate in the thymus.[81,82] This model, which seemed to be supported by the time-course kinetics of appearance of α-, β-, and β-specific RNA in developing thymocytes, was an attempt to explain an apparent dilemma in the intrathymic selection of the T-cell repertoire (for instance, see Ref. [83]).

Subsequent studies carried out in my and several other laboratories, however, revealed a number of features of the γ gene and its expression which are not necessarily consistent with these hypotheses. First, the γ gene is not rearranged in some T-cell clones or hybridomas. Furthermore, even in many of those T cells in which this gene is rearranged, the joining of the *V* and *J* gene segments does not allow the *J*-region codons to be translated in phase with the *V*-region codons.[84-86] Thus, the γ gene product does not seem to be universally expressed in conventional, αβ-receptor-positive cytotoxic and helper T cells. Second, the γ polypeptide chain is expressed on the surface of a small (less than 0.5%) subset of peripheral T cells as a component of a heterodimer referred to as γδ.[87-89] The majority of these T cells exhibit none of the CD4 or CD8 glycoproteins of conventional αβ-receptor T cells on their surface, and therefore belong to a distinct cell population. Third, like the αβ heterodimer, the γδ heterodimer is associated relatively tightly with another glycoprotein, CD3.[87] The invariant CD3-protein complex contains a subunit that seems to play a critical role in the transmission of the signal received by the variable heterodimer into the cell.[90] Thus, the similarity between the γδ- and αβ-receptor heterodimer includes both their structure and transmembrane

signal transmission. Fourth, γδ-bearing cells are relatively abundant in the $CD4^-$, $CD8^-$ fraction of fetal and adult thymocytes.[91-94] For instance, thymocytes of 16-day-old fetal mice, which are mostly double-negative (i.e., $CD4^-$ and $CD8^-$) cells, are a relatively rich source of γδ-bearing cells. Since double-negative thymocyte populations contain precursors for mature, functional, αβ-bearing T cells,[95] a natural question that arises is whether γδ-bearing thymocytes are precursors for αβ-bearing T cells. Fifth, another major site of expression of the γδ receptor is epidermal tissues. It was recently found by two groups that this tissue contains Thy-1^+ (another cell surface marker shared by all types of T cells), $CD3^+$, $CD4^-$, and $CD8^-$ cells bearing γδ heterodimers.[96,97] Unlike conventional T cells, these cells look more like dendritic cells and are therefore referred to as dendritic epidermal cells (DEC). Finally, the δ gene also undergoes rearrangement. *D*, *J*, and *C* gene segments for δ polypeptide chains have recently been mapped within the α gene family between V_α and J_α gene segments.[98] The nested configuration of α and δ gene segments is intriguing and provokes curiosity about the possible relationship of gene organization to the regulation of the rearrangement and expression of the two types of genes. Another intriguing question is whether and to what extent the pool of V_α and V_δ gene segments overlap.

Despite the rapid progress made in the characterization of the γ and δ genes and their products, the most intriguing problem, namely, the physiological role of the γδ-receptor-bearing cells, is currently unknown. One can only speculate on this matter using the currently available information. As to the ligand of this new receptor, it is probably correct to emphasize the fact that the receptor shares with the immunoglobulin B-cell and the αβ T-cell receptors the same genetic basis for somatic diversification. It therefore is likely that the ligand in question will also exhibit structural diversity. In this respect it is interesting that recent studies by us and others suggest that at least part of the ligand is encoded in the MHC.[99,100] The effector function of the cells bearing γδ receptors has not yet been defined with certainty, but recent studies using human and mouse γδ-cell clones suggest that many of these cells have cytotoxic capacity.[89,100,101] The finding of a new type of T cell with an apparently distinct set of T-cell receptors in epidermal tissues stimulates one's imagination. It may be that occurrence of this type of T cell is not restricted to the outer epithelial tissues but extends to all epithelial layers including the lining of various internal organs (*C. Janeway*, personal communication). If so, these cells may have evolved to protect the part of the body that is most vulnerable to infection, namely, its external and internal epithelial surfaces that are in direct contact with the environment. However, the prominence of γδ cells in the thymus suggests an intrathymic role of these cells as well. An exciting possibility that has not been ruled out is a role for these cells in the intrathymic selection of appropriate αβ T cells.

Concluding Remarks

Use of restriction enzymes and recombinant DNA methods allowed resolution of a long-standing and central issue in immunology, the genetic origins of antibody diversity. It turned out that an organism does not inherit even a single complete gene for antibody polypeptide chains. Rather, the genetic information is transmitted in germ line as no more than several hundred gene segments. Through a series of specialized somatic recombinations occurring specifically during the differentiation of B lymphocytes, these gene segments are assembled into tens of thousands of complete genes. Somatic hypermutation occurring in these assembled genes further diversifies antibody polypeptide chains, so that B cells displaying immunoglobulin receptors having a better fit to a given antigen can be selected in a later phase of B-cell differentiation. Thus, in the immune system, organisms have exploited two major processes for modification of DNA, recombination and mutation, as a means to diversify somatically the limited amount of inherited genetic information in order to cope with the vastly diverse antigen universe.

Why has somatic diversification been necessary in the evolution of the immune system? Microorganisms and substances produced by them are the primary source of biologically relevant antigens against which vertebrates need to produce antibodies for survival. Since the generation time of microorganisms is several orders of magnitude shorter than that of vertebrates, the former can produce genetic variants much faster than the latter. Thus, if genetic alterations in the germ-line genome were to be the only source of antibody diversity, vertebrates would be unable to deal effectively with the rapidly changing world of antigens. Somatic diversification allows the individual organism to generate a virtually limitless number of lymphocyte variants. Like organisms in an ecosystem, these lymphocytes are subject to selection by antigens and the fittest will survive. Thus, as *Jerne* and *Burnet* were aware, the individual immune system can be conceived of as a kind of Darwinian microcosm.

The molecular biological approach played an even more fundamental role in the analysis of the T-cell receptor in that very little structural information existed prior to the cloning of the receptor genes. It was demonstrated that the polypeptide chains composing the receptor protein are encoded by genes that share a common ancestor with the immunoglobulin genes. Like immunoglobulins, T-cell receptors are diversified by somatic recombination, but unlike immunoglobulins, these receptor proteins have not been observed to undergo further diversification by somatic mutation. The reason for this difference is unknown, but it seems likely that the explanation will be as follows. First, unlike immunoglobulins, T-cell receptors function exclusively as cell surface receptors which are specialized for interacting with cell-bound antigens. Since both ligand and receptor are distributed in two-dimensional space when a T cell interacts with an antigen-presenting cell, and since T cells have mechanisms for transiently adhering to other cells, these receptor–ligand interactions occur under conditions of high local concentration. Thus, improvement of the affinity beyond the one accomplished by somatic rearrangement may not be necessary in T-cell recognition.

Second, the ligand consists in part of an essentially invariant component, self MHC. As the T-cell receptor is selected both during development and during immunization

for self-MHC recognition, the extreme variability available via somatic mutation may not only be unnecessary but even disadvantageous. Finally, and probably more important, T cells appear to be selected early in development for self tolerance, the inability to recognize self antigen. Somatic mutation during antigenic stimulation, as occurs in B lymphocytes, could lead to the development of autoreactivity. While autoreactive B cells depend upon the additional presence of autoreactive helper T cells to generate autoimmunity, this is not true of autoreactive T cells, which can directly produce disease. Thus, *Ehrlich*'s famous concept of "honor autotoxins", originally developed for antibodies, is probably critical only for T cells. It will be interesting to examine autoreactive T-cell receptors for any evidence of post-thymic somatic diversification.

Finally, it is interesting to notice that during the fifteen years in which I have studied the immune system, the role of molecular genetics in immunological research has altered radically. When I started investigating the problem of antibody diversity, there was abundant information about the structure and function of antibody molecules, while virtually nothing was known about their genes. By contrast, in the most recent study on T-cell recognition no gene product was known at all when the rearranging gene γ was discovered. From the structure of the gene and its rearranging behavior, it was deduced to be a receptor gene, and this discovery has led directly to new insights into T-cell development and T-cell biology. This short history of research in one area, lymphocyte receptors, is yet another witness to the power of DNA technology, and to the ability of this approach not only to explain known biological phenomena, but also to contribute to the discovery of new biological systems.

The work summarized in this article is the result of collaboration with many colleagues, students, and technical assistants. I wish to extend my sincere thanks to every one of them. I also extend my thanks to Hoffman La Roche which so generously supported my work in Basel. My special thanks are extended to Charles A. Janeway, Jr., Nancy Hopkins, and Yohtaroh Takagaki for many useful comments on the manuscript, to Jiri Novotny for preparing Figure 5, and to my secretary, Eleanor Lahey Basel, for her tireless devotion.

Protein Phosphorylation in Bacteria—Regulation of Gene Expression, Transport Functions, and Metabolic Processes

By Josef Deutscher* and Milton H. Saier, Jr.

The importance of protein phosphorylation to the regulation of physiological processes in eukaryotic cells has been known for almost half a century. In contrast, the first conclusive evidence for functionally relevant protein phosphorylation in bacteria was obtained less than a decade ago. To date, only five functionally well-characterized bacterial proteins have been shown to be regulated by reversible phosphorylation. (1) Phosphorylation of isocitrate dehydrogenase in *Escherichia coli* controls the relative flux of carbon through the Krebs cycle and the glyoxylate shunt. (2) In gram-positive bacteria, phosphorylation of HPr, a phosphoryl carrier protein of the phosphoenolpyruvate-dependent sugar phosphotransferase system, regulates carbohydrate uptake via this system. (3) Phosphorylation of glycerol kinase in *Streptococcus faecalis* probably serves to regulate the degradation of glycerol. (4) Phosphorylation of the nitrogen regulatory protein I (NR_I) in *E. coli* controls expression of genes encoding the enzymes which participate in nitrogen metabolism. (5) Phosphorylation of citrate lyase ligase in *Clostridium sphenoides* regulates the conversion of citrate lyase from the inactive sulfhydryl form to the active acetylated form. Recent investigations have shown that more than one hundred proteins in *E. coli* are phosphorylated. It can therefore be anticipated that protein phosphorylation will prove to be as important to the regulation of physiological processes in bacteria as it is in eukaryotes.

1. Introduction

The activities of numerous enzymes are controlled by protein-modifying reactions which occur post-translationally. Covalent, reversible derivatization of a protein requires both the enzyme-catalyzed transfer of the modifying group from a donor molecule to the protein as well as the enzymatic cleavage of this group from the protein (Fig. 1). These two opposing activities are frequently regulated by so-called second messengers (cAMP, cGMP, $Ca^{2\oplus}$) or by cellular metabolites. The coordination of these two activities determines the ratio of the free to the derivatized form of the protein. Since the modified and unmodified enzyme derivatives frequently (but not always) exhibit different K_m or V_{max} values, functional regulation of the enzyme results. When the enzyme is also subject to allosteric regulation, modification can alter its affinity for the effector. Another, recently described mechanism by which protein modification can control enzymatic reactions, the so-called zero-order ultrasensitivity, will be discussed in detail in Section 2.

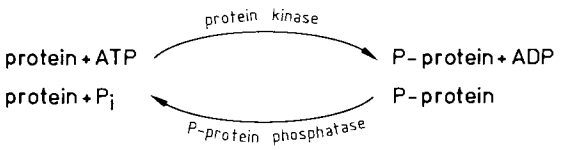

Fig. 1. Generalized reactions for reversible protein modification illustrated by protein phosphorylation.

Among the various reversible, post-translational protein modification reactions (Table 1), protein phosphorylation is by far the most prevalent. In 1943, *Cori* and *Green* observed that glycogen phosphorylase, which degrades glycogen with the formation of glucose-1-P, exists in two interconvertible forms which they designated "a" and "b".[1] Twelve years later phosphorylase a was shown to be a phosphorylated derivative of the enzyme while phosphorylase b was the free form.[2,3] Thus, glycogen phosphorylase was the first protein for which a phosphorylation/dephos-

Table 1. List of the most frequently occurring, reversible protein modification reactions, the respective donor molecules, and the amino acids in the protein that are modified.

Modification	Donors	Modified amino acids
phosphorylation	ATP, GTP, PEP	serine threonine tyrosine histidine
methylation	*S*-adenosylmethionine	aspartate glutamate lysine histidine glutamine
acetylation	acetyl-CoA	lysine cysteine
sulfation	3-phosphoadenosine 5-phosphosulfate	tyrosine
ADP-ribosylation	$NAD^{\oplus}$	arginine lysine glutamate
nucleotidylation (adenylylation, uridylylation)	ATP, UTP	tyrosine serine
tyrosylation	tyrosine	carboxyl terminus

phorylation cycle was demonstrated. Since the phosphorylated and unphosphorylated forms of the enzyme differed in their activities, and since they were differentially activated by adenosine monophosphate, the enzyme derivatization process was shown to be functionally significant.[4] Subsequently, it was found that phosphorylase kinase, the enzyme that catalyzes the phosphorylation of glycogen phosphorylase,[5] and glycogen synthetase, which synthesizes glycogen,[6] were also regulated by reversible phosphorylation. Although it was initially assumed that the phenomenon of reversible protein phosphorylation was limited to the proteins of glycogen metabolism, the activities of other enzymes, such as the mitochondrial pyruvate dehydrogenase complex,[7] were subsequently shown to be similarly regulated. Phosphorylase kinase is phosphorylated by a cAMP-dependent protein kinase which also phosphorylates numerous other protein substrates. This observation partly explains the many physiological effects exerted by cAMP.[8,9] Today, we know that protein phosphorylation in eukaryotes regulates such widely differing processes as protein, carbohydrate, lipid, and nucleic acid metabolism, DNA repair, gene expression, muscle contraction, receptor functions, and transmembrane transport. In all of these processes, phosphorylation of the relevant proteins occurs most frequently on serine residues and less frequently on threonine residues (Fig. 2).

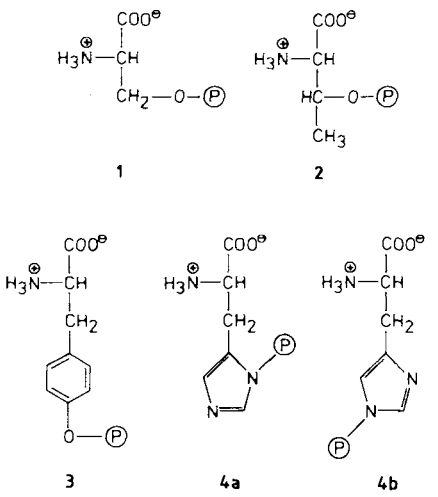

Fig. 2. Structural formulas of the most frequently found phosphorylated amino acids in phosphoproteins (serine **1**, threonine **2**, tyrosine **3**, and histidine **4a** and **4b**). More than one amino acid can be phosphorylated in a single protein.

At the end of the 1970s, it was discovered that $pp60^{v\text{-}src}$, the protein responsible for the transforming properties of Rous sarcoma virus, possessed protein kinase activity.[10] In contrast to the previously known protein kinases, $pp60^{v\text{-}src}$ phosphorylated tyrosine residues in proteins.[11] Viral oncogenes are probably derived from cellular protooncogenes, the products of which fulfill normal regulatory functions in the cell. They are believed to exhibit alterations which give rise to the transformed state after successful viral infection. Thus, identification of the physiologically relevant protein substrates of oncogene-encoded protein-tyrosine kinases should lead to an understanding of growth regulation and the mechanisms of cancerous transformation.[*]

In contrast to the situation in eukaryotes and their viruses, it was long doubted that protein phosphorylation represented a significant bacterial regulatory mechanism. In 1964, *Roseman* et al. discovered the bacterial phosphotransferase system (PTS), a transport system for sugars and sugar alcohols in *Escherichia coli*,[12] and they demonstrated that one of the proteins of this system was phosphorylated. Other enzymes of the PTS were subsequently shown to be phosphorylated. Each of these proteins was phosphorylated either on N-3 of a histidine residue or on N-1 (**4b** and **4a**, respectively, in Fig. 2). The phosphorylation of these proteins did not fulfill a regulatory role but instead served a catalytic function, since the proteins comprise a phosphoryl transfer chain in which the phosphoryl group is transferred from phosphoenolpyruvate (PEP) to the sugar via the various phosphoprotein intermediates (cf. Fig. 4). Although the PEP-dependent phosphorylation of the proteins of the PTS does not fall into the category of the reversible protein phosphorylations discussed here, which do serve regulatory functions, it is discussed in detail in Sections 3 and 4.

In 1969, *Kuo* and *Greengard* reported the presence of a cAMP-dependent *E. coli* protein kinase which phosphorylated histones from calf thymus,[13] but this report has never been confirmed. In fact, the existence of cAMP-regulated, bacterial protein kinases is still in question. A few years later, *Rahmsdorf* et al. observed protein phosphorylation in *E. coli* after infection with the bacteriophage T7.[14] It was soon realized that the protein kinase was encoded by one of the early phage genes.[15] This protein kinase was found to be synthesized shortly after successful infection and phosphorylates 40 to 50 different *E. coli* proteins. These proteins include ribosomal proteins and the β and β′ subunits of the *E. coli* RNA polymerase.[16] The phosphorylation of these proteins presumably halts synthesis of *E. coli* host proteins and promotes synthesis of bacteriophage T7 proteins.

The first unambiguous evidence for a functionally active, prokaryotically encoded protein kinase was obtained by *Wang* and *Koshland* using *Salmonella typhimurium*.[17] By pulse-labeling cells with [^{32}P]phosphate, they detected four phosphorylated proteins and subsequently provided evidence for four protein kinases with differing substrate specificities and sensitivities towards inhibitors.[18] The first bacterial protein to be identified as the target of a protein kinase was isocitrate dehydrogenase from *E. coli*.[19] The regulation of this protein is discussed together with the phosphorylation of isocitrate lyase in Section 2. In Section 3, we concern ourselves with the ATP-dependent phosphorylation of HPr of the bacterial phosphotransferase system in gram-positive bacteria, and then, in Section 4, we consider the unusual regulation of the dihydroxyacetone/glycerol kinase from *Streptococcus faecalis*. This latter process occurs by reversible, PTS-mediated phosphorylation. Thereafter, we discuss in Section 5 the phosphory-

[*] Protein phosphorylation in eukaryotes has been comprehensively reviewed in P. D. Boyer, E. G. Krebs (Eds.): *The Enzymes, Vol. 17* (1986) and *Vol. 18* (1987), Academic Press, New York.

lation of the nitrogen regulatory protein I (NR_I) by the nitrogen regulatory protein II (NR_{II}), a process that controls transcription of genes involved in nitrogen utilization in *E. coli*. In the final section, we mention several additional, less well characterized bacterial protein phosphorylation reactions and discuss future research directions.

2. Regulation of Isocitrate Dehydrogenase in *E. coli* by Reversible Phosphorylation

Isocitrate dehydrogenase (ICDH) is an enzyme of the tricarboxylic acid (TCA) cycle that converts isocitrate into α-ketoglutarate in a reaction involving the $NADP^{\oplus}$-dependent oxidation of the substrate followed by its decarboxylation. The degradative route via the TCA cycle serves to provide energy and biosynthetic precursors. Isocitrate can also be cleaved to glyoxylate and succinate by isocitrate lyase in the first step of the glyoxylate cycle. Glyoxylate is then condensed with acetyl-CoA to yield malate, and the glyoxylate bypass thus merges with the TCA cycle to yield two C_4 acids from one C_6 acid and acetyl CoA (Fig. 3).[20] The succinate and malate formed can be used for biosynthetic purposes.

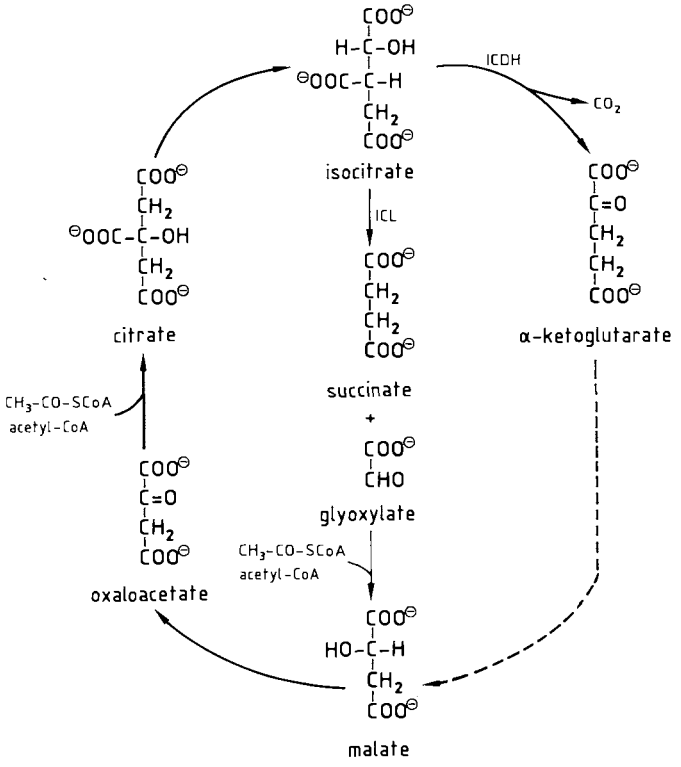

Fig. 3. Depiction of the degradative pathways for isocitrate by *E. coli* illustrating the glyoxylate bypass (involving isocitrate lyase, ICL) and the TCA cycle (involving isocitrate dehydrogenase, ICDH). The succinate formed from isocitrate via the glyoxylate cycle can be used for biosynthetic purposes.

The enzymes of the glyoxylate bypass are inducibly synthesized. They are produced in enhanced amounts when the cells are grown on acetate, ethanol, or a fatty acid as the sole source of carbon. Under these conditions, the glyoxylate cycle is required for the synthesis of cellular building blocks. Isocitrate must be metabolized, therefore, via both the TCA cycle (for the production of energy) and the glyoxylate cycle (for the formation of biosynthetic precursors) in order for cells to grow at the sole expense of a C_2 compound.

Garnak and *Reeves* first observed that reduction of the ICDH activity during growth of *E. coli* on acetate as the sole carbon source occurred concomitantly with phosphorylation of the enzyme.[19] The phosphorylated form of the enzyme could be purified after growth of the cells in a medium containing [^{32}P]phosphate. Partial acid hydrolysis of the purified, [^{32}P]phosphate-labeled protein and subsequent separation of the hydrolysis products established that phosphorylation of ICDH had occurred on a serine residue. Phosphorylation of ICDH led to almost complete loss of activity.[21,22]

Cleavage of the phosphorylated, radioactively labeled ICDH by trypsin[23] or chymotrypsin[24] gave rise to a single radioactively labeled peptide that was isolated and sequenced. The sequence around the phosphorylated serine residue at position 113 in ICDH is shown in Table 2. This

Table 2. Amino acid sequences of the phosphorylation sites in isocitrate dehydrogenase (ICDH) from *E. coli* as well as the HPr proteins from *S. aureus*, *S. faecalis*, and *B. subtilis*. The asterisks indicate the amino acid phosphorylated in each protein. ATP-dependent phosphorylation of HPr from *E. coli* could not be demonstrated.

ICDH	-Pro-Val-Gly-Gly-Gly-Ile-	-Arg-Ser*-Leu-Asn-Val-Ala-Leu-Arg-

sequence does not show homology with the phosphorylation sites of known eukaryotic phosphoproteins. It is of interest to note that the sequence around the phosphorylated serine residue (Arg-Ser-Leu-Asn) is also present in another $NADP^{\oplus}$-dependent enzyme, dihydrofolate reductase from chicken liver.[25] Since this sequence is near the $NADP^{\oplus}$ binding site in dihydrofolate reductase, it was suggested that phosphorylation of ICDH might lead to loss of coenzyme binding. In fact, as demonstrated by fluorescence titration experiments, NADPH does not bind to phosphorylated, inactive ICDH although it binds stoichiometrically to the nonphosphorylated enzyme.[26] The negative charge of the phosphate group is apparently responsible for this effect. When the serine residue at position 113 in ICDH is replaced by an aspartate residue, complete inactivation of the enzyme results.[114]

ICDH kinase, the enzyme that catalyzes the phosphorylation of ICDH, was first purified by *LaPorte* and *Koshland*.[27] This enzyme, with a molecular mass of 66000 daltons, possessed not only ICDH kinase activity but also P-ICDH phosphatase activity. Thus, two enzyme activities with opposing actions were found in a single polypeptide chain. A similar observation had been made previously for other regulatory enzymes including 6-phosphofructo-2-kinase/phosphatase and glutamine synthetase adenylyltransferase.[28]

Regulation of ICDH kinase/phosphatase is effected by a variety of intracellular metabolites. Isocitrate, ADP, pyruvate, phosphoenolpyruvate, 3-phosphoglycerate, and oxaloacetate all inhibit the kinase while stimulating the phosphatase. The latter activity is inhibited by NADPH.[29] Citrate, fructose 6-phosphate, and glyoxylate inhibit the kinase but have no effect on the phosphatase.[30] Under in vivo conditions, pyruvate stimulates ICDH both in wild-type strains and in strains unable to metabolize pyruvate.[30] The latter observation suggests a direct interaction between ICDH kinase/phosphatase and pyruvate. However, isocitrate appears to be the most important effector of this regulatory enzyme. During growth of *E. coli* on acetate, high concentrations of isocitrate (up to 0.6 mM) accumulate. Higher levels of isocitrate allow its metabolism via the glyoxylate bypass since isocitrate lyase possesses relatively low affinity for isocitrate ($K_m = 1$ mM). They also lead to dephosphorylation of P-ICDH and thus to increased ICDH activity.[31]

In connection with the regulation of ICDH by reversible phosphorylation, the phenomenon of "zero order" ultrasensitivity has been discussed.[32] Although it had been previously formulated mathematically, the first experimental evidence for this type of regulatory mechanism was obtained in experiments with ICDH kinase/phosphatase. This phenomenon is based on the fact that a relatively small increase in the activity of a converter enzyme (in this case, ICDH phosphatase or ICDH kinase) can lead to a substantial shift in the ratio of the modified to free form of the protein.[33]

The importance of ICDH phosphorylation to the regulation of carbon flux through the glyoxylate bypass is emphasized by the fact that the gene encoding the ICDH kinase/phosphatase, together with those encoding the enzymes specific to the glyoxylate bypass (isocitrate lyase and malate synthase), comprise the glyoxylate (*ace*) operon. Thus, synthesis of these three enzymes must be coordinately regulated.

Regulation of the two competing metabolic pathways is further complicated by the recent observation that isocitrate lyase (cf. Fig. 3) can also be phosphorylated in vitro.[34] The phosphorylation of this enzyme takes place at N-1 of a histidine residue (cf. **4a** in Fig. 2) and not on serine, threonine, or tyrosine.[115] Unlike ICDH, the phosphorylated form of the isocitrate lyase appears to be the more active form. While the significance of isocitrate lyase phosphorylation is not known, it is clear that regulation of branch-point enzymes is of prime importance to all living organisms. The ability to utilize a wide variety of substrates, one of the more conspicuous features of bacteria, requires the integration of all requisite metabolic processes into a coordinated whole. Section 3 further illustrates this fact employing a second highly complex regulatory system dependent on protein phosphorylation.

3. Regulation of Carbohydrate Uptake via the Phosphotransferase System in Gram-Positive Bacteria

Anaerobic and facultatively anaerobic bacteria possess a transport system for carbohydrates which was first described in 1964 by *Kundig, Ghosh,* and *Roseman* and designated the bacterial phosphotransferase system (PTS).[12] An essential feature of this transport system is that a sugar or sugar alcohol is phosphorylated during transport in a tightly coupled process.[35] The energy and phosphate donor for sugar transport and phosphorylation is phosphoenolpyruvate. The phosphate group is transferred to the incoming sugar via a chain of three or four phosphorylated proteins (Fig. 4). Sugars transported via the PTS include

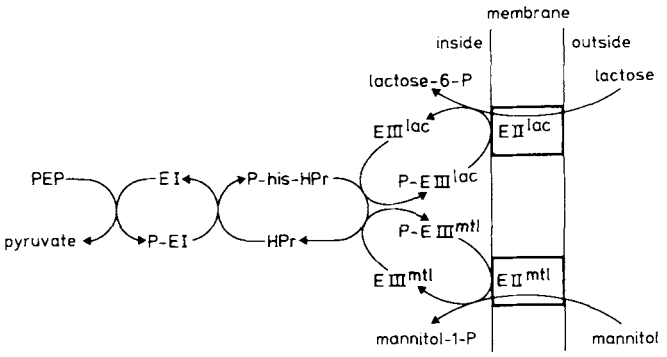

Fig. 4. Schematic representation of phosphoryl transfer via the phosphotransferase system in *S. aureus*. The phosphate group is transferred from phosphoenolpyruvate (PEP) to the sugar via the proteins enzyme I (EI), HPr, enzyme III (EIII), and enzyme II (EII). There is a specific enzyme II/enzyme III pair for each sugar. Lactose and mannitol are transported across the membrane in a process coupled to sugar phosphorylation.

glucose, fructose, mannose, mannitol, glucitol, lactose, and sucrose. Enzyme I and HPr are the general protein components of the PTS and are not sugar-specific. Enzymes II and the enzyme II/III pairs exhibit sugar-specificity as illustrated in Figure 4 for lactose and mannitol. Enzyme I, HPr, and enzymes III are water-soluble proteins while enzymes II are integral membrane proteins. The polypeptide chains of enzymes II pass through the lipid bilayer of the membrane several times.[36]

As mentioned in Section 1, the phosphoryl groups in all PTS proteins are bonded at N-1 (HPr, enzymes II) or N-3 (enzyme I; enzymes III) of histidine residues. In connection with the phenomenon of inducer expulsion, it was discovered that HPr is subject to ATP-dependent phosphorylation.[37] Inducer expulsion is a regulatory mechanism by which sugars taken up via the PTS and accumulated as phosphorylated derivatives are expelled from the cell as the free sugars upon addition of a metabolizable PTS sugar.[38,39] In vivo experiments revealed that the process was probably dependent on cytoplasmic ATP and a glycolytic intermediate. Possibly, the sugar phosphate phosphatase that cleaves the phosphoryl group from the intracellular sugar phosphates is activated by protein phosphorylation.[40]

Under the conditions of inducer expulsion in *Streptococcus pyogenes*, a protein of low molecular weight was found to be phosphorylated,[40] but it did not possess the expected sugar phosphate phosphatase activity. It was subsequently identified as HPr of the PTS.[37] Although the exact mechanism of inducer expulsion remains unclear, the ATP-dependent phosphorylation of HPr was found to be important to the regulation of the PTS in gram-positive

bacteria. In addition to HPr from *S. pyogenes*, HPr's from *Streptococcus faecalis, Streptococcus lactis, Streptococcus mutans, Streptococcus salivarius, Staphylococcus aureus, Staphylococcus carnosus, Bacillus subtilis, Bacillus stearothermophilus, Clostridium histolyticum, Lactobacillus casei,* and *Lactobacillus brevis* have all been found to undergo ATP-dependent phosphorylation. HPr from gram-negative bacteria such as *E. coli* was not phosphorylated.[41-44,62]

In contrast to the PEP-dependent, enzyme I-catalyzed phosphorylation of HPr, which occurs on a histidine residue, a serine residue was shown to be modified in the ATP-dependent phosphorylation reaction. The phosphorylated protein, P-Ser-HPr, was not able to transfer its phosphate group to a sugar.[37] Phosphorylated, radioactively labeled peptides were isolated from [^{32}P]Ser-HPr of *S. faecalis*[45] and *S. aureus*[*] and sequenced (Table 2). Because the amino acid sequences of the two proteins were known, the phosphorylated serine residue could be identified as serine-46. The regions around serine-46 in the three gram-positive HPr proteins of known amino acid sequences (those from *S. aureus, S. faecalis,* and *B. subtilis*[46,47]) showed striking sequence identity (Table 2). In contrast, HPr from *E. coli* showed much less homology around serine-46, possibly explaining why this protein was not phosphorylated by the HPr kinases from gram-positive bacteria.

ATP-dependent HPr kinases, which catalyze the formation of P-Ser-HPr, have been purified from *S. faecalis*,[41] *S. pyogenes*,[42] *L. brevis*,[**] and *B. subtilis*.[***] The activities of these enzymes are stimulated by metabolites such as gluconate-6-P, 2-P-glycerate, and fructose-1,6-diphosphate (FDP), and they are inhibited by phosphate. P-Ser-HPr phosphatase has been purified from *S. faecalis*.[48] The enzyme requires high phosphate concentrations (about 50 mM) for optimal activity.

The ATP-dependent phosphorylation of HPr at serine-46 inhibited the PEP-dependent enzyme I-catalyzed phosphorylation reaction by about three orders of magnitude,[49] and a reciprocal effect was also observed.[41,42] Thus, formation of doubly phosphorylated P_2(ser,his)HPr occurs very slowly.

The PEP-dependent phosphorylation of P-Ser-HPr was found to be accelerated by the presence of any one of the various enzymes III.[49] The physiological significance of this observation is still not clear. It is possible that some PTS sugars are transported preferentially over others and that the formation of P-Ser-HPr serves to regulate the PTS-mediated uptake of carbohydrates. Phosphorylation of *o*-nitrophenylgalactoside, a lactose analogue[48] and of mannitol[****] by the PTS proteins of *S. aureus* was found to occur 150-fold slower in the presence of P-Ser-HPr compared with HPr. Since growth of staphylococcal cells on lactose or mannitol as well as other PTS sugars led to elevated levels of intracellular P-Ser-HPr, this was additional evidence that the formation of P-Ser-HPr serves to regulate the PTS-mediated uptake of carbohydrates. In this context, investigations on the regulation of pyruvate kinase by intracellular metabolites in *S. lactis*[50] are of interest. This enzyme is regulated in practically the same way as the HPr kinases from *S. faecalis* and *S. pyogenes*; i.e., it is inhibited by phosphate (>3 mM) and stimulated by FDP (25 mM). Investigations on the changes in the concentrations of FDP, PEP, and phosphate that occur when resting cells of *S. lactis* are transferred to a medium containing glucose revealed that the FDP concentration increased (from 1 mM to about 25 mM) while the concentrations of phosphate and PEP decreased (from 50 mM to about 3 mM and from 5-10 mM to about 1 mM, respectively).[50,51] Similar effects would be expected for other carbohydrates degraded via the Embden-Meyerhof pathway and thus for virtually all PTS sugars.

The uptake of a PTS sugar into the cell and the associated changes in the concentrations of glycolytic intermediates probably lead to the formation of P-Ser-HPr by the mechanism proposed in Figure 5. A high concentration of

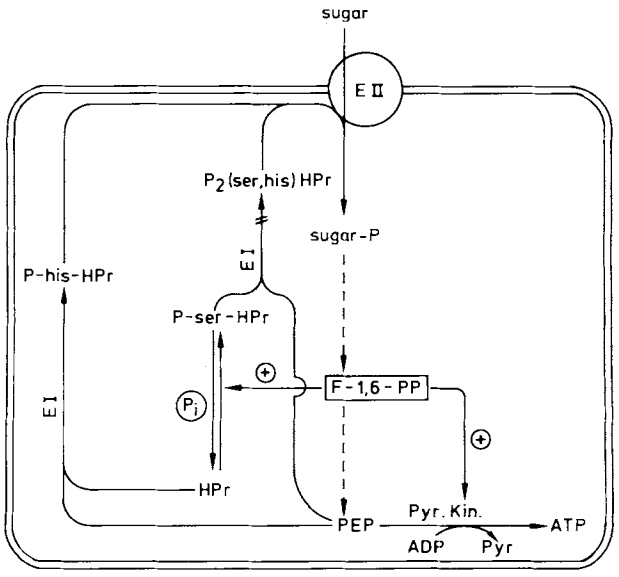

Fig. 5. Effect of HPr (Ser) phosphorylation on sugar uptake by the phosphotransferase system in gram-positive bacteria. Abbreviations are as follows: EI, enzyme I; EII, enzyme II; P-Ser-HPr, HPr phosphorylated at serine-46; P-His-HPr, HPr phosphorylated at histidine-15; P_2(ser,his)HPr, HPr phosphorylated at serine-46 and histidine-15; Pyr. Kin., pyruvate kinase; F-1,6-DP, fructose-1,6-diphosphate; Pyr, pyruvate; ⊕, stimulation.

cytoplasmic phosphate inhibits the HPr kinase and stimulates the P-Ser-HPr phosphatase so that free HPr predominates. When a PTS sugar is taken up, its degradation leads to a rapid increase in the FDP concentration and to a decrease in the phosphate concentration. FDP stimulates the HPr kinase, and the formation of P-Ser-HPr results in a depressed rate of uptake. Simultaneously, FDP stimulates pyruvate kinase, giving rise to an increased rate of ATP synthesis and depletion of the PEP concentration. The activities of HPr kinase, pyruvate kinase, and P-Ser-HPr are thereby adjusted so that the uptake of a carbohydrate via the PTS correlates with its consumption.

Recently, serine-46 in HPr from *B. subtilis* was replaced by alanine by site-specific mutagenesis. The mutant pro-

[*] W. Hengstenberg, unpublished results.

[***] J. Reizer, M. H. Saier, unpublished results.

[****] N. Meyer, J. Deutscher, unpublished results.

tein possessed about 50% of wild-type HPr activity.[47][*] Use of this HPr, which no longer can be phosphorylated by the HPr kinase, in appropriate gram-positive HPr mutant bacteria should permit estimation of the significance of P-Ser-HPr formation to the regulation of the PTS and to inducer expulsion.[47]

In *S. salivarius*, the ATP-dependent phosphorylation of HPr at N-3 of a histidine residue has been reported.[43] Nothing is yet known about the physiological significance of this reaction, and it has not been determined whether histidine-15 is the site of phosphorylation. Nor are the consequences of this ATP-dependent phosphorylation event with respect to PTS activity known.

4. Regulation of Glycerol Kinase from *Streptococcus faecalis* by P-His-HPr-Mediated Phosphorylation

Glycerol is believed to be taken up into bacteria by facilitated diffusion.[52] This process is catalyzed by the glycerol facilitator, which forms a pore specific for glycerol and dihydroxyacetone.[53] Glycerol is then converted by glycerol kinase into glycerol phosphate or by glycerol dehydrogenase and dihydroxyacetone kinase into dihydroxyacetone phosphate. These phosphorylated metabolites are trapped in the cell. In the gram-negative bacteria *E. coli* and *Salmonella typhimurium* the activity of glycerol kinase is regulated by allosteric interactions with fructose-1,6-diphosphate and enzyme III^{glc} of the PTS.[54,55] In the course of a search for a gram-positive enzyme III^{glc} it was found that a protein from *S. faecalis* with a relative molecular mass of 55000 daltons can be phosphorylated in the presence of PEP and the two energy-coupling proteins of the PTS, enzyme I and HPr[56] (Fig. 4). No enzyme III activity was found to be associated with this protein. Attempts to demonstrate a regulatory function for this protein similar to that of the enzyme III^{glc} in gram-negative bacteria led to its identification as glycerol kinase.[57] Dihydroxyacetone (DHA), however, proved to be a better substrate for this enzyme (lower K_m and higher V_{max} values), and thus it was designated DHA/glycerol kinase.

Depending on the oxygen supply, glycerol can either be phosphorylated to glycerol phosphate by *S. faecalis* (under aerobic conditions) or it can be oxidized to DHA and then phosphorylated (under anaerobic conditions).[58] Phosphorylation of both DHA and glycerol is presumably catalyzed by the DHA/glycerol kinase. The PEP-dependent phosphorylation of the DHA/glycerol kinase by P-His-HPr occurs at N-3 of a histidine residue and leads to a tenfold increase in activity.[57] Phosphorylation of the kinase by P-His-HPr takes place slowly in comparison to phosphorylation of an enzyme III, but the process is apparently reversible.

The uptake of a PTS sugar in *B. subtilis* has been shown to inhibit glycerol uptake.[59] Furthermore, it was observed that mutants without enzyme I activity took up glycerol very slowly. Based in part on earlier work,[60] a dependence of glycerol uptake on the PTS was proposed.

When the results described above for both *S. faecalis* and *B. subtilis* are considered, a potential regulatory mechanism can be proposed. When the PTS proteins are phosphorylated, DHA/glycerol kinase will also be phosphorylated, and it will show high activity. However, when a PTS sugar is added to the medium, the PTS proteins will become dephosphorylated,[61] and, consequently, DHA/glycerol kinase will also be dephosphorylated.[57] This model can explain both the decreased rate of glycerol uptake in the presence of a PTS sugar and the dependence of glycerol uptake on a functioning PTS.

Phosphorylation of the *S. faecalis* DHA/glycerol kinase is unusual in three respects. First, a phosphorylated protein (P-His-HPr), in which the phosphate group originates from PEP rather than from a nucleoside triphosphate, is the phosphate donor. Second, there is no P-protein phosphatase which cleaves the phosphate group from P-DHA/glycerol kinase. Third, the phosphate group is bonded to N-3 of a histidine residue in P-DHA/glycerol kinase. This last fact should render phosphoryl transfer between HPr and DHA/glycerol kinase fully reversible. In spite of these peculiarities, the phosphorylation of DHA/glycerol kinase by the PTS fulfills the criteria of a reversible protein modification which serves to regulate an enzyme activity. The relevance of this phosphorylation reaction to the regulation of glycerol uptake in intact cells has yet to be determined.

Also worthy of note is the recent demonstration that glycerol kinase of *Bacillus stearothermophilus* is phosphorylated by PEP, enzyme I, and HPr.[62] However, no results indicative of an increase of the enzyme activity or of reversibility are available. It is possible that the regulation of glycerol kinase in *B. subtilis* may utilize a mechanism involving allosteric interaction with enzyme III^{glc}, as has been demonstrated for *E. coli* and *S. typhimurium*.[62]

5. Transcriptional Regulation of *glnA* Gene Expression by Protein Phosphorylation in Enteric Bacteria

Enteric bacteria such as *E. coli*, *S. typhimurium*, and *Klebsiella aerogenes* can grow on a variety of inorganic nitrogen compounds such as N_2, NH_3, and $NO_3^{\ominus}$ as sole sources of nitrogen. They can also utilize organic nitrogen compounds such as histidine, proline, and arginine. As a result of work in several laboratories, a molecular mechanism accounting for the regulation of the various anabolic and catabolic reactions of nitrogen metabolism is emerging.[63] For the regulation of the activity of glutamine synthetase, allosteric interactions with several effectors have been demonstrated.[63-66] This enzyme is a dodecahedron, built of twelve identical subunits. It is subject to cumulative feedback inhibition by various end products of nitrogen metabolism such as histidine, tryptophan, alanine, glycine, AMP, CTP, carbamoyl phosphate, and glucosamine 6-phosphate. This mechanism in part enables bacteria to adjust the rate of nitrogen metabolism to their needs.

The activity of glutamine synthetase is also controlled by reversible, covalent protein modification. Adenylylation of glutamine synthetase at a tyrosine residue within each subunit results in reduced enzyme activity and altered allo-

[*] J. Reizer, unpublished results.

steric regulation. The enzyme that catalyzes the adenylylation of glutamine synthetase is itself subject to allosteric regulation by a tetrameric protein designated P_{II}.[67] P_{II}, in turn, is subject to uridylylation, a reaction analogous to adenylylation.[68] Both the adenylyl transferase and the uridylyl transferase are bifunctional enzymes which, like the ICDH kinase/phosphatase, catalyze both the modification and demodification reactions. Intracellular metabolites, such as α-ketoglutarate, glutamine, and glutamate, the concentrations of which reflect the availability of nitrogen in the medium, regulate the activities of these two enzymes by allosteric interactions.[66,69] Indicators of energy availability (ATP and inorganic phosphate) also regulate their activities, allowing the coordination of nitrogen metabolism with carbon utilization.

In addition to the regulation of glutamine synthetase by allosterism and protein modification, transcription of the *glnA* gene, which encodes the enzyme, is subject to regulation. The direct participation of glutamine synthetase was initially assumed,[70–72] but subsequent investigations demonstrated that the products of two regulatory genes (*ntrB* and *ntrC*), adjacent to the *glnA* gene, as well as the product of an additional regulatory gene (*ntrA* or *rpoN*) function in *glnA* regulation (Fig. 6).[73,74] The products of the *ntrA, B,* and *C* genes coordinately control expression of *ntrB* and *ntrC*[75] since the latter two genes together with the *glnA* gene comprise an operon.

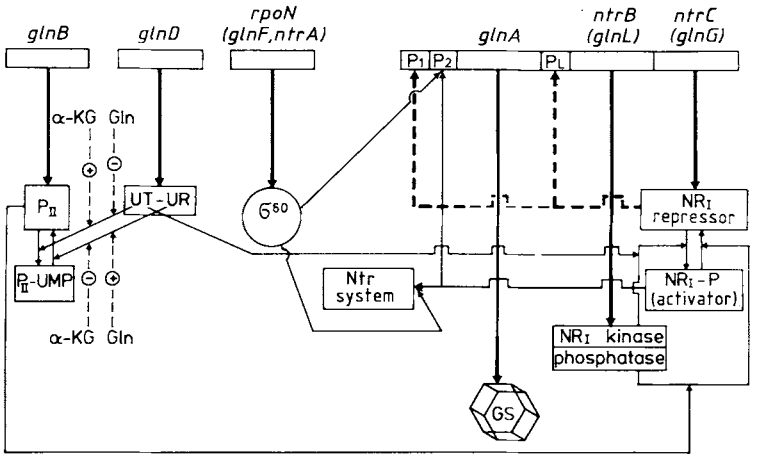

Fig. 6. Suggested mechanism for regulation of the expression of genes encoding enzymes participating in nitrogen metabolism in *E. coli* [63]. The thick unbroken arrows point to the respective gene products; the thin unbroken arrows signify protein-protein interactions; the thick broken arrows signify protein-DNA interactions, and the thin broken arrows signify interactions of metabolites with proteins (⊕, stimulatory; ⊖, inhibitory). Abbreviations are as follows: GS, glutamine synthetase; UT-UR, uridylyltransferase-uridylyl removing enzyme; P_{II}-UMP, uridylylated P_{II}; NR_I-P, phosphorylated NR_I; α-KG, α-ketoglutarate; Gln, glutamine; *rpoN*, additional regulatory gene; P_1, P_2, and P_L, promoters (binding sites for RNA polymerase on the DNA). For further explanation, see the text.

In the last few years, the products of the three regulatory *ntr* genes were identified and partially characterized. This accomplishment has resulted in a clearer understanding of the molecular processes involved in the transcriptional regulation of the *glnA* gene. The product of the *ntrA* gene is a sigma factor (σ^{60}) with a molecular mass of 60000 daltons. It binds to RNA polymerase to displace other sigma factors. RNA polymerase with bound σ^{60} preferentially transcribes operons whose protein products participate in nitrogen metabolism.[75]

The *ntrC* gene encodes a DNA-binding protein, designated NR_I,[76,77] which, in addition to the σ^{60}-loaded RNA polymerase, is necessary for the in vitro transcription of the *glnA* gene.[78] The product of the *ntrB* gene, designated NR_{II},[79] changes the activity of NR_I from a transcriptional repressor to a transcriptional activator by means of reversible protein modification. This modification reaction has been identified as the ATP-dependent phosphorylation of NR_I.[80] NR_{II} is a bifunctional enzyme that catalyzes both the phosphorylation and the dephosphorylation of NR_I and has, therefore, been termed NR_I kinase/phosphatase.

The previously mentioned proteins P_{II} and uridylyl transferase, which are encoded by the genes *glnB* and *glnD*, respectively, are also involved in transcriptional regulation of the glutamine synthetase gene. A series of protein-modification reactions, which lead to altered protein-protein and protein-DNA interactions, enable the bacterium to enhance rates of synthesis of the nitrogen biosynthetic enzymes under conditions of nitrogen insufficiency. This mechanism is illustrated schematically in Figure 6. The activity of the NR_I kinase/phosphatase is regulated by P_{II} and the enzyme that catalyzes the uridylylation and deuridylylation of P_{II}, the uridylyltransferase/uridylyl-removing enzyme (the UT/UR enzyme).

UT, which catalyzes synthesis of P_{II}-UMP, is stimulated by α-ketoglutarate and inhibited by glutamine whereas UR is stimulated by glutamine and inhibited by α-ketoglutarate.[66] A nitrogen insufficiency, which effects a high intracellular concentration of α-ketoglutarate and a low glutamine concentration, consequently leads to conversion of P_{II} to P_{II}-UMP, whereas a sufficient supply of nitrogen gives rise to unmodified P_{II}. Genetic data indicate that P_{II} not only controls the adenylylation of glutamine synthetase but also controls the activity of the NR_I kinase/phosphatase. P_{II}-UMP apparently exerts no influence on this enzyme. Thus, mutants that lack P_{II} (due to mutations in the *glnB* gene) exhibit an increased transcriptional rate of the *glnA-ntrB-ntrC* operon when the nitrogen supply is adequate.[81] Conversely, loss of UT-UR activity (by mutation of the *glnD* gene) causes a low rate of *glnA-ntrB-ntrC* operon transcription even under conditions of nitrogen deficiency.[82] The effects observed for both mutants require an active NR_I kinase/phosphatase since *ntrB* mutants are not responsive to mutations in the *glnB* and *glnD* genes.[83] This observation permits the conclusion that P_{II} and UT-UR exert their effects on gene expression by way of the NR_I kinase/phosphatase.

Some *ntrB* mutants specifically exhibited loss of NR_I phosphatase activity. These mutants always showed an increased rate of transcription of the *glnA* operon regardless of the growth conditions and the presence or absence of

P_{II}.[84] As shown in Figure 6, the effects on expression of the *glnA-ntrB-ntrC* operon caused by widely differing genetic and physiological manipulations can be explained by the assumption that P_{II}, but not P_{II}-UMP, interacts with the NR_I kinase/phosphatase to stimulate the NR_I phosphatase and inhibit the NR_I kinase. Conversely, according to this model, UT-UR inhibits the NR_I phosphatase while stimulating the NR_I kinase. Figure 6 also illustrates the fact that phosphorylation of NR_I leads to altered interactions with the DNA. In contrast to NR_I, which binds to promoter P_1, resulting in inhibition of transcription, P-NR_I binds to promoter P_2, thereby stimulating transcription of the *glnA* operon. Under certain conditions, expression of *ntrB* and *ntrC* are controlled similarly. Expression of these two genes, however, appears to also be controlled by binding of NR_I to the promoter P_L with inhibition of transcription.[85] Expression of amino acid permeases and enzymes involved in nitrogen metabolism is also apparently regulated by the *ntr* gene products.

The Ntr regulatory system represents the first example in which a transcriptional repressor is converted into a transcriptional activator by protein phosphorylation. The participation of protein phosphorylation in the regulation of transcription in eukaryotic cells has been discussed.[86-88] There is substantial genetic evidence that transcription of certain proteins of the bacterial phosphotransferase system is also controlled by protein phosphorylation.[89] It is interesting to note that NR_I exhibits sequence homology to a series of other transcriptional activators, such as the proteins of the genes *phoB* and *ompR* of *E. coli*.[116] By analogy with NR_I, it may be assumed that the proteins PhoB and OmpR are each subject to a reversible protein modification in which the proteins PhoR and EnvZ, respectively, serve as the modifying enzymes. PhoR and EnvZ show homology to NR_{II}, the NR_I kinase/phosphatase.

The protein pair PhoB/PhoR is important for the expression of certain enzymes during growth of the cells under phosphate-limiting conditions. The protein pair OmpR/EnvZ responds to changes in the extracellular osmolarity.[116] Homology of these proteins to the chemotaxis proteins of *E. coli*, Tar, Tsr, and Trg, which likewise respond to extracellular signals, has also been noted.[117] The latter three proteins are integral membrane proteins that function as chemoreceptors for aspartate (Tar), serine (Tsr), and ribose and galactose (Trg). They signal changes in the extracellular concentrations of their respective ligands to the interior of the cell. Reversible protein modification (methylation of glutamyl residues) by the *cheB* and *cheR* gene product plays a major role in this process. It is possible that signal transfer in all of these systems is based on a common principle in spite of the nature of the differing, reversible protein modifications.

6. Less Well Characterized Bacterial Phosphoproteins

The report by *Wang* and *Koshland* on protein phosphorylation in *S. typhimurium*[17] initiated an intensive search for protein phosphorylation in a variety of bacteria. In addition to the work cited in the previous sections, publications have appeared on protein phosphorylation in *Halobacterium halobium*,[90] *Myxococcus xanthus*,[91] *Rhodospirillum rubrum*,[118] *Sulfolobus acidocaldarius*,[92] *Clostridium sphenoides*,[93] *Synechococcus 6301*,[91] *Rhodocyclus gelatinosus*,[95] *Rhodomicrobium vannielii*,[96] *Bacillus subtilis*,[97] and *Mycoplasma gallisepticum*.[98] An apparently distinct protein derivatization reaction, involving ADP ribosylation[103] has been described for *Rhodospirillum rubrum*,[99,100] *Rhodobacter capsulatus*,[101] and *Chromatium vinosum*.[102] Some of the above-mentioned examples are discussed briefly below.

Halobacteria possess light-driven $H^{\oplus}$ and $Cl^{\ominus}$ pumps which lead to the formation of ion gradients that can be used for transport and other energy-dependent processes. When cells of *Halobacterium halobium* that have been labeled in the dark with [^{32}P]phosphate are exposed to light, the dephosphorylation of three phosphoproteins occurs. These proteins are rapidly rephosphorylated during a subsequent dark period.[90,104] Dephosphorylation was found to be dependent on retinal, the chromophore of bacteriorhodopsin and halorhodopsin. It was therefore assumed that these three phosphoproteins are involved in phototransduction.

Light-dependent phosphorylation of two proteins has also been observed in the cyanobacterium *Synechococcus 6301*.[94] One of these proteins is localized in the thylakoid membrane, which also contains photosystems I and II. The functions of these proteins have not been identified.

Myxococcus xanthus and *B. subtilis* are bacteria that are capable of forming spores. In both organisms, the formation of spores from vegetative cells is accompanied by a change in the protein phosphorylation pattern.[91,97] In *Myxococcus xanthus*, the phosphorylation states of two principal membrane proteins are changed after initiation of sporulation by the presence of glycerol.[91] These proteins are possibly of importance for the maintenance of cell shape. A role for a 55000-dalton phosphoprotein in the maintenance of cell shape in *Mycoplasma gallisepticum* has also been suggested.[98]

In *Rhodospirillum rubrum*,[99,100] *Rhodobacter capsulatus*,[101] and *Chromatium vinosum*,[102] nitrogenase, which reduces molecular nitrogen to ammonia, is regulated by a covalent modification reaction that was initially thought to involve phosphorylation. The enzyme consists of two dissimilar subunits, a molybdenum-containing subunit and an iron-containing protein. Interconvertible active and inactive forms of the iron-containing protein have been demonstrated.[99,101] The active form is present when the cells are exposed to conditions of ammonia insufficiency. In the active form, the iron-containing protein of *R. rubrum* is a dimeric protein with a subunit molecular mass of 30000 daltons. The inactive form, however, has two apparently dissimilar subunits with molecular masses of 30000 daltons and 31500 daltons, as determined on SDS-polyacrylamide gels.[99] Labeling experiments with [^{32}P]phosphate indicated that the heavier subunit (31500 daltons) of the inactive complex contained covalently bound phosphate. The derivatizing moiety could be cleaved from this subunit, which was then reconverted into the active form. A similar change in size, as determined by SDS-polyacrylam-

ide gel electrophoresis, was observed upon derivatization of the iron-containing protein of the nitrogenase complex from *Rhodobacter capsulatus* (from 33500 to 38000 daltons). Experiments with the *R. rubrum* enzyme established that the modifying group was adenosine diphosphoribose, and that the guanidinium moiety of an arginine residue was modified.[103] These experiments suggest that the activities of nitrogenase in these bacteria are regulated by reversible ADP ribosylation, rather than phosphorylation, that nitrogen insufficiency produces the active, free form of the iron-containing protein, and that nitrogen sufficiency gives rise to the inactive form. By analogy with other ADP ribosylation reactions, the donor molecule is probably NAD® (see Table 1).

In *Clostridium sphenoides*, the enzyme citrate lyase ligase is reversibly phosphorylated.[93] This enzyme catalyzes the conversion of the inactive, sulfhydryl form of citrate lyase to the active, acetylated form. The phosphorylated derivative of citrate lyase ligase is the active form. Dephosphorylation of the phosphoenzyme leads to inactivation. Glutamate stimulates the conversion of the inactive, unphosphorylated citrate lyase ligase to the active, phosphorylated form. Additionally, glutamate plus citrate are required for the acetylation of citrate lyase by the active, phosphorylated form of citrate lyase ligase.[105] A protein modification cascade evidently operates to regulate the degradation of citrate either to glutamate or to acetate and oxaloacetate.

Autophosphorylation of the *dnaK* gene product from *E. coli* has been observed.[106] This protein is assumed to participate in DNA replication of the bacteriophages λ and M13.[107, 108] Autophosphorylation is frequently a characteristic of protein kinases. Indeed, it was found that the *dnaK* gene product participates in the phosphorylation of glutaminyl tRNA synthetase and threonyl tRNA synthetase.[109] It is interesting to note that infection of *E. coli* cells with phage M13 results in altered phosphorylation of the protein encoded by the *dnaK* gene. Not only was the extent of phosphorylation of this protein considerably increased, but the position of phosphorylation shifted from serine to threonine.[110]

Protein-tyrosine phosphorylation has been found both in *E. coli* and *Rhodospirillum rubrum*.[111, 118] In *E. coli*, a protein associated with the ribosome was phosphorylated.[112] A two-dimensional gel analysis of *E. coli* phosphoproteins was attempted. Separation in the first dimension was performed on the basis of isoelectric point and in the second dimension on the basis of size. Under anaerobic conditions, 20 phosphorylated proteins were found,[113] but under aerobic growth conditions, 128 phosphorylated proteins were detected.[112] Exact knowledge of the isoelectric points and the relative molecular masses of these proteins should facilitate their identification. Recognition of the fact that numerous unidentified proteins in bacteria are reversibly phosphorylated leads to the suggestion that protein phosphorylation plays a central role in the regulation of widely differing cellular processes as has been shown previously for eukaryotic cells.

Say It in English, Please!*

By Robert Schoenfeld †

Robert Schoenfeld, managing editor of the *Australian Journal of Chemistry* until his retirement in 1985, was known to countless scientists as the author of *The Chemist's English*. He was widely admired for his outgoing manner, his enlivening humor, and his keen insight into the interplay of language and science, and he will be deeply missed. Shortly before his untimely death on November 24, 1987, he began writing a series of essays directed initially at German-speaking writers of English. As in *The Chemist's English*, he hoped through "Say It in English, Please!" to foster an awareness of good English, this time by pointing out the pitfalls and finer problems awaiting the non-native speaker. His intention was not to dictate usage but rather to entertain and to provoke discussion. By sharing his own joy in language, he wanted to make writing English more enjoyable for others. The nine completed essays are printed here as a fitting tribute to *Bob*, who might have begun the series as follows: "I submit these columns to the kind judgment of my readers."

David Loewus
Angewandte Chemie

1. A Singular Beginning

What's that? What you said just now sounded pretty strange. Of course I understood what you meant: you wanted some help with your written English. I'll be glad to do my best. But one of the words you just used was not quite right. You said: I want *advices*. You should have stuck to the singular: I want *advice*.

It is one of the mysterious features of idiomatic English that *advice*, in the sense of "helpful recommendation", is practically never found in the plural. The word apparently suggests "an ensemble of recommendations", something not countable, therefore not multipliable. In a German–English dictionary *advice* is likely to be given as synonym for both *Rat* and *Ratschlag*. But in spirit it is closer to *Rat*, which in idiomatic German also is seldom found in the plural form. No native German speaker (or am I mistaken?) is likely to say "Geben Sie mir einige Räte". He or she will say "einige Ratschläge". You had this last phrase in mind and let your dictionary betray you into misusing *advice* as its plural. Don't ever ask for "some advices" in an English-speaking country, or you'll be greeted by a condescending smile and a reply in very basic English.

But I have been talking about advice without explaining who I am and what right I have to offer you any. I am the author of a book on the English language that most critics found pretty entertaining. This book dealt mostly with the needs of native English writers, but it provoked surprising interest among those "non-natives" who often publish papers or reports in English. My publisher, VCH, thought that I should try to write some short articles specially for this second group.

Please don't expect miracles, and above all don't believe that you can learn a second language as you learn geometry, by filling your mind with rule after rule. First of all, English is so capricious that, no sooner do you think you have found a general rule, you can think of an exception to it.[**] And then, if you really want to master a language, you must reach a point where you can forget all the rules. In other words, I don't set out to teach, but to entertain. I hope to give you a feeling for the English language, and to communicate some of my love for it.

Just how hard it is to teach the finer points of a language, and to devise rules for them, can be seen from the example I have given. English usage treats *advice*, in most of its meanings, as a "noncount noun". It cannot be divided into units, hence cannot be multiplied, and therefore does not take the plural **advices* (the asterisk is the grammarian's way of telling the reader that what follows is wrong). The same is true of *information*, which the English mind treats as an indivisible continuum (just like the German *Wissen*), and *progress*. A German speaker, thinking of *Informationen*, is apt to write **informations* but an English editor, with a shudder, will cross the plural out.

Now you may well ask: What is the rule concerning noncount nouns?; How do I spot them?; How does English usage differ from German? Sorry, there I cannot help you at all. Noncount nouns are not specially marked in the dictionary. Many nouns (as in German) have a sense in which they are noncount, and another in which they take the plural:

The philosopher seeks after *truth*.
I told him some unpleasant *truths*.

This last pair of sentences is perfectly translatable into German, and so are many others. But in words like *advice* customs differ, and there are no rules to help the nonnative. He has to develop his own feeling for English, until

[*] Reprints of this article are available upon request. Please address all inquiries to Redaktion Angewandte Chemie, Postfach 1260/1280, D-6940 Weinheim (FRG).

[**] Modern linguists, who do not like to lose an argument, do not talk of "exceptions" but of "optional transformation rules".

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1988 0570-0833/88/0808-1050 $ 02.50/0 Angew. Chem. Int. Ed. Engl. 27 (1988) 1050–1057

he stops using his native language as a crutch. In fact, if you want to learn the finest details of a strange language, you have to proceed exactly as you did when you learned your native language as a child: pay attention to the data base of words and sentences around you, try analogous sentences, be prepared to make the occasional mistake, and figure out where you went wrong.

Let me, to help you get into the right mood, say something in praise of this great love of mine, English. Books on linguistics proclaim that all languages are equally efficient, and that only the known cultural and economic factors have made English into the international language of science. I beg to disagree. English is predestined for its dominant role by its peculiar virtues. It is the perfect language "in between". It is, for instance, easier to learn for a German speaker than is Chinese, and easier for a Chinese speaker than is German.

Let me explain. Linguists would classify German as very strongly "inflected"; that means, the word stems are modified so as to show how the words of the sentence are connected. When you write

Die bekannte Zeitschrift veröffentlichte einen interessanten Artikel

the ending of the verb indicates the third person singular, and the changes to the articles and adjectives show which noun they belong to, which is the subject and which the object.

Chinese is an "isolating" language. The words remain unmodified and sit loosely side by side. Anyone studying such a language does not have to conjugate verbs or decline nouns; all he or she has to do is to pay attention to the order of the words.

English is inflecting (inflect, inflects, inflected) but only weakly so—think of how the adjective sits unmodified beside the noun. Its basic rules of grammar will not seem unduly difficult to a Chinese speaker, and they will seem ridiculously simple to a German speaker. It is easy to get a start in English—the difficulties come afterwards.

2. Caesar's Revenge

I made the point that English was a "weakly inflecting" language and its grammar was about halfway between German and Chinese. Let me follow that thought a little further.

Latin is one of the most heavily inflected languages—I still remember with horror the many endings to nouns and verbs: *amo, amas, amat*, etc. But these endings had a practical use: they served as grammatical labels. This word, so the labels said, will be the verb of the sentence, this the subject, this the direct object, this the indirect object, and so on.

With words so carefully labeled, there is really no need to insist that they be kept in a rigid order. At some stage, every Latin student is asked to translate *Brutus killed Caesar* and he dutifully comes up with *Brutus Caesarem interfecit*. But the endings *-us* and *-em* so clearly indicate killer and victim that the meaning remains the same no matter how the words of the sentence are permuted. In fact, Latin poets shuffle their words about so radically to make them fit their hexameters that the poor student is left dizzy.

Now let us try less inflected languages. If you change the nouns about in *Brutus tötete Caesar* you have changed the meaning: the boot is now on the other foot, or rather the dagger is in the other man's hand. And now remember that English is an even more weakly inflecting language than German—that means, the order of words is even more rigid.

In fact, English is what linguists call an SVO language. In every normal sentence the expectation is that the subject S will precede the verb V and this will then be followed (if the sense permits) by the object O. Every 18-month-old child who lisps *Bobby want banana* or *Daddy drive car* has mastered the SVO principle.

German, being more inflected, is less rigid. It is true that the standard sentence is SVO but there are numerous inversions between S and V. Consider

Sobald ich rufe, *kommt er* gelaufen.
As soon as I call *he comes* running.

In fact, English puts up a furious resistance to this inversion. If it does occur, it inevitably involves an auxiliary verb. Here we go again:

Sprechen Sie Englisch?
Do you speak English?

In the last sentence, the "dummy" auxiliary verb *to do* has been created specially so that you/speak/English will appear in their customary SVO order.

So what is the non-native to do about English word order? If he is not confident, he should stick to SVO and avoid inversions like the plague. But, at the same time, he should develop an eye for exceptions. There *are* some exceptions. For example, they often occur if in a normal sentence the predicate or some part of it is moved to the front for emphasis:

Inversion occurs only in exceptional circumstances.	(normal)
Only in exceptional circumstances *does inversion* occur.	(emphasis)
Of particular importance *were the two peaks* in the high-frequency region.	(emphasis)

Note that the second sentence resorts to the dummy auxiliary *does* and the third has the normal auxiliary *were*. Only in such conditions *will the inversion* be acceptable.

There are some other exceptions, one of which was made famous by the early years of *Time* magazine: "Said President Coolidge ..."; "Spoke J. Edgar Hoover ..."

But these exceptions belong to literary style and not to the plain prose of the simple scientist. Let us draw the conclusion that English is a pretty rigid SVO language, almost as rigid as Chinese. Wenn Sie da etwas ändern wollen, *brauchen Sie (you need)* ein feines Ohr.

3. Where Is the Verb?

German and English, you might think, are closely related languages; their kinship expresses itself in such similarities as *house* and *Haus*. But the differences between the

languages are deep-seated and important. To startle you, I shall now argue that English grammar is nearer to Chinese than to German grammar!

That is so because both Chinese and English are dominated by the SVO word order (English admits some rare exceptions). German is not dominated so absolutely by the SVO pattern. Most of the *Hauptsätze*, it is true, appear in this form, but we have already noted how readily the inversion to VSO occurs. About an even more radical reshuffling of the order, more in a moment.

How did German and English, whose grammars were practically identical through most of the Middle Ages, drift so far apart? Professional philologists will give you a multitude of reasons, but I shall wildly oversimplify and point out the two main ones.

First, when modern high German *(Neuhochdeutsch)* replaced middle high German *(Mittelhochdeutsch)*, there occurred a change in word order. The main clause remained SVO (like Chinese) but the *Nebensatz* took the form SOV (like Japanese!).

Second, an even more fateful development took place in England. Towards the late Middle Ages, its language shed many of its inflected forms, and above all the ending of the infinitive: *werk-en/work-en* and *drink-en* became *work* and *drink*. That meant that noun and verb became formally indistinguishable, and one could be readily formed from the other. Note how easy it is to tell the verb from the noun in German, and how hard in English:

I *drink* (verb). I enjoy my *drink* (noun).
Ich *trinke* (verb). Ich genieße meinen *Trunk* (noun).

In German, you never have any doubt which is which. But as you "enter" an English sentence, you are forced to ask yourself instantly, Where is the verb?

These differences between English and German are so fundamental that I beg my readers to retain this mental image of the two languages:

German has a relatively elastic word order: the verb stands out sharply; the subordinate clauses are neatly distinguished from the main clause. This allows the construction of long sentences, and if the verb appears late at their end, this may be helpful to create emphasis.

English is firmly based on the SVO principle. The effective sentence is the one in which the reader understands immediately what the subject is and where the verb is.

I shall give an example, not infrequently found in the literature, in which a perfectly sound German sentence has been translated all-too-faithfully into English:

With light petroleum 8–10% of a green waxy material and with chloroform 25–27% of a tarry fraction of high molecular weight were obtained.

It is not that the English version is grammatically incorrect, it is just that it is clumsy. First of all, where is the subject S? A careful search reveals the unexpected: the first of two subjects is *8–10%*. And which and where is the verb? It is *were*, and it occurs right near the end of the sentence, miles away from the subject, when the reader has just about given up hope.

Of course, it is easy enough to remedy our limping text. Here are two suggestions:

Chromatography gave, with light petroleum, 8–10% ...
Elution with light petroleum gave 8–10% ...

Here our S is very prominent, V and O follow promptly, and our two versions have the additional advantage that V is in the more colorful active form.

Perhaps a comparison will make the meaning of this essay clear. German and English are two different card games. In German you are free to finesse about, play your weaker cards first and finally, with great effect, throw your trumps on the table. In English the best strategy is to lead with your strong cards.

I said "the *best* strategy". English is flexible enough to permit unorthodox strategies, and often the most brilliant stylists are the ones who defy the rules. If your English is advanced enough to let you read *William Faulkner* or *James Joyce*, you will find that these two obsessed sentence-spinners have turned the English language on its head. But you are not *Faulkner* or *Joyce*, your editors are not *Maxwell Perkins*[*] or *Sylvia Beach*,[**] and these articles are not a guaranteed cookbook for the English sentence. All I can do is to increase your appetite, and to a humble extent improve your taste. Don't give yourself any complexes about being a non-native. Cooking sentences is a delicate art, and "natives" have their troubles, too.

4. That Strange Particle, the Article

What a nice, helpful, user-friendly language English seems at first! Think only of the article. Just *the* one for all genders, and the choice of genders is usually dictated by logic, not custom! One should think no foreigner could have trouble with the English article—unless of course such a foreigner comes from a language like Russian or Japanese, where such particles of speech are unknown. But even with the simplest parts of a sentence there are tricky differences between languages, so let us have *a* look at *the* English article.

German or French speakers will have little trouble with the indefinite article. In their languages, this word (*ein/eine* or *un/une*) means "one". In English, the indefinite article started the same way. "One" became corrupted to *an* and the final *n* of that word then disappeared before consonants.

That gives us an approximate rule for the function of the indefinite article. It pulls a single item or individual, about which or whom nothing definite is known, out of a group. When we say "I saw *a* house", what we mean is that "I saw *one unspecified member of the class* house".

Such a complex explanation for such a simple word! Things now get worse, because we must remember that by saying *a* we have indicated (1) that nothing specific is known about the noun that follows and (2) that the noun belongs to a class that can be divided into units (in other words, it is countable).

[*] *Maxwell Perkins* (1884–1947), editor of many major American writers, including *F. Scott Fitzgerald* and *Ernest Hemingway*.

[**] *Sylvia Beach* (1887–1962), first publisher of *James Joyce*'s *Ulysses*.

Since the indefinite article means one, no such article can occur with plural nouns:

I saw *a* house.
I saw houses.
Among the pyrolysis products were *a* ketone and several olefins.

Notice that here German runs exactly parallel to English.

When do we exchange an indefinite article for the definite article, then? As soon as the noun is either specified beforehand (I saw *a* house; *The* house was large) or will be specified right away (*The* largest house in the street was painted in white). It goes without saying (but does anything ever go without saying in linguistics?) that the definite article can be used with plural nouns (He investigated *the* pyrolysis products).

Back to the indefinite article. Suppose our sentence contains a singular, unspecified noun [condition (1)] but this noun fails condition (2) by not being countable? In that case no article is used at all (modern grammarians say "the zero article is used"). Let us have some examples:

I saw *destruction* everywhere.
We used *chromatography* to separate the mixture.

In the second example, *chromatography* clearly has non-countable status. But this status can be subtly changed:

We separated the components by *a* chromatographic technique.

Thus, chromatography is perceived as an unstructured concept, whereas techniques are countable.

All the above are just rough rules, designed to give the non-native writer a start. In the great English grammars, the rules about articles go on for dozens of pages, and there is no unifying logic that holds them together. For instance, why do we say *a* in "Such *a* technique is helpful"? Surely the use of *such* specifies the noun *technique*? All I can say is that between *such* and a singular noun there occurs either *a(n)* or the zero article (I approve of *such* determination) but never *the*.

German speakers will be relieved to learn how little English differs from their native language. The main problems come with the use of the zero article. The German speaker is a bit hesitant about this, and prefers "*Die* Chemie ist eine noble Wissenschaft" and "*Das* Klettern macht mir Vergnügen". The English speaker just "zeroes" the two articles out (Chemistry is a noble science; I enjoy climbing).

The French language is at one with German and English about the indefinite article, but has a real horror of the zero article. A French speaker says "J'aime *les* chats", but an English speaker says "I love cats". And, alas, *le langage se moque de la logique* translates as *language laughs at logic*.

5. Lest We Forget

Recently, for the first time in my life, I had occasion to help translate a book from the German, and that caused me to wonder about what must have caused multitudes of translators to wonder before me: how hard it is to replace *a single word* in one language with a completely equivalent word in another. If the word is highly scientific or technical, there is generally no trouble: *acetone* is *Aceton* in German, not an electron more or less; and an equally efficient exchange is *Schraubenzieher* for *screwdriver*. But the nearer you get to everyday life, the harder it is to achieve such a perfect match. Words acquire multiple meanings, and each of these meanings resonates with characteristic cultural overtones. For instance, the meaning of English *security* may oscillate between German *Sicherheit* and *Sorgenfreiheit*, and *Sicherheit* may mean *security* in one sentence and *certainty* in another.

Eventually (note that this word means *später* or *schließlich* in German but never *eventuell*) we reach the domain of the so-called untranslatable words—words so characteristic of one language they simply cannot be expressed in another, except perhaps by paraphrasing. It is often said that German *Gemütlichkeit* is such a word, and psychologists generally do not attempt to translate *Schadenfreude* but write it in the original language (along with *Gestalt* and *Angst*). During my recent attempt at translation I had trouble with *Verlauf*; several English words suggested themselves but none was a perfect fit—in the end I had to reword the difficult phrases. And I do believe Italian has the delightful words *magari* and *pure* all to itself. *Cercate pure, cari lettori, magari troverete qualcosa*! ([Go ahead and] look, dear readers, [with some luck] you may find something!)

However, my article is not about these oddities of the vocabulary but about something far more surprising. One expects that nouns, verbs, or adverbs will not match perfectly in translation, but the other day it occurred to me, to my astonishment, that there is no perfect one-to-one correspondence even among conjunctions. These words, after all, are so simple, so impersonal, so devoid of double meanings, that one would assume they must match from language to language, and no vocabulary could exist without a one-word expression for *and, or, but, if,* and the like.

Of simple, one-word conjunctions the English language contains at most three dozen. One should think other languages would have a perfectly matching set of equivalents for these humble and elementary tools of language, but no. *But* no? The commonplace English conjunction *but* translates perfectly into French *mais*, but in German it sometimes means *aber*, sometimes *doch*, sometimes (especially when followed by *instead* or *rather*) *sondern*. In fact, the conjunction *sondern* is rather a specialty of the German language because at times it implies a sharp contrast between two alternatives:

Schweitzer verfolgte seine Konzert-Karriere nicht weiter, *sondern* vergrub sich in Afrika.

In such cases it takes the two words *but instead* to translate one simple conjunction.

I shall now talk about two conjunctions that are highly peculiar to English, and which non-natives are therefore afraid to use. One of these, *lest*, is a rather literary word and more at home in a novel than in a scientific paper. The other, *unless*, is in common and frequent use, and anyone who wants to be confident in the English language should get to the point where he or she employs the word spontaneously.

Unless is the synonym of the two words *if ... not*, and can take the place of *wenn ... nicht*. I shall give a few examples, to make readers familiar with its use:

> You cannot be certain of priority *unless* you check the literature.
> *Unless* conditions are rigorously followed the yields will be low.

And a very vivid poetic example, from *Yeats*:

> An aged man is but a paltry thing,
> a tattered coat upon a stick, *unless*
> soul clap its hands and sing, and louder sing
> for every tatter in its mortal dress.

Such splendid language should make you feel at home with this conjunction, *unless* of course you have no ear for verse. In that case you need not bother with the second conjunction, *lest*, which is a word so literary that it is always used with the subjunctive. In German it can be translated with *damit ... nicht*, but with *lest* there is always an implication that the motive of the action is fear. *Lest* I *be* accused of negligence I shall give you two examples, both from poetry. In the first, *Kipling*, at the height of British imperialism, has a sudden premonition of the crumbling of the Empire:

> Lord God of Hosts, be with us yet,
> *lest* we forget ... *Lest* we forget.

In the second, *Oscar Wilde* imagines a fellow prisoner in Reading Gaol, about to be hanged, under the supervision of warders:

> ... who watched him *lest* himself should rob their scaffold of its prey.

There, *unless* you have hearts of stone, you will not want to forget these two characteristic conjunctions, *lest* they give you bad dreams. There is a lesson in this. If you wish to become confident in scientific English, you will of course read the appropriate scientific books, and learn the required nouns and verbs from these. But *unless* you spare some time for poetry, your sentences will sound creaky, because you will not know how to link them together properly. So study your poets, *lest* you forget your conjunctions.

6. The Great Ugliness Contest

There are some German words, especially simple and honest ones like *gelassen* and *schlicht*, that I love and admire. Indeed, they make me feel envious, like the child who sees an attractive toy in a neighbor's household and complains, "Why can't *we* have that, Daddy?"

On the other hand, there are some German words that get enormously on my nerves, and among these *beziehungsweise* is in the front rank. Such a bumbling, pompous, bureaucratic-sounding word! And how can a modern language tolerate a conjunction five syllables long?

Many writers, in fact, seem to be aware that the word is too long for its grammatical function, and abbreviate it to *bzw.* (I must confess that, when I first saw these letters in a German manuscript, I guessed at Bayerische Zündkerzen-Werke!)

Be that as it may, German speakers, who, after all, are perfectly free to disregard my personal prejudices, have become fond of the word and it may appear not only in official documents, newspaper reports, and scientific texts, but also in serious novels. I found it in one recently, by a respectable Swiss writer. It described a celebration on board a ship whose passengers were of various nationalities, and read:

> Die Deutschen tranken Champagner, *beziehungsweise* Sekt.

Now of course I have no business teaching Swiss novelists their trade. But what does the 15-letter monster right after the comma contribute to the meaning of the sentence? Would not a simple *oder* have been sufficient?

All right, dear readers, I know that the correct use of *beziehungsweise* is a point of contention and apologize for inflicting my personal prejudices on you. You don't have to take the slightest notice of outsiders, and in your own writings you can spark off as many Bayerische Zündkerzen as you like. What concerns me, though, is what happens if you export your BZW into the English language.

It is at this moment that trouble strikes. The German speaker looks at his text and finds that the word *beziehungsweise*, abbreviated to *bzw.*, occurs frequently. He next looks at the English journals on his desk and finds that in these the word *respectively*, abbreviated to *resp.*, is of common occurrence. He then makes the fatal mistake of believing that the two words are equivalent in meaning.

Now it is true that there are occasions when the meanings of *bzw.* and *resp.* overlap, but this does not happen all that often. Let us examine what each word means. German usage may be typified by the following sentence:

> Die beiliegende Tabelle gibt eine Übersicht über die elektropositiven *bzw.* elektronegativen Eigenschaften der Reagentien.

What does the word *beziehungsweise* mean here? Surely only "or, according to circumstances". The word *or* offers a choice. *Beziehungsweise* adds to this the information that the choice obeys certain laws. Let us push semantic analysis one step deeper: in German usage *beziehungsweise* applies to a situation where a certain number of entities will vary in properties or behavior, but this variation is nonrandom. It is not necessary (but it is permissible), in German, to list these entities one by one.

In this lies the key difference to *respectively*. This word means exclusively "in the order named". In other words, it is obligatory to name the members of the set of entities one by one (E_1, E_2, etc.) and then match them, in the same order, to the properties P_1, P_2, etc. An example is provided by the following sentence:

> The percentages of iron, manganese, nickel, and zinc were, *respectively*, 30, 26, 24, and 20.

Here it would indeed be legitimate to translate *respectively* with *beziehungsweise* (if this was placed before the last number). The question is: Is *respectively* in this example really needed?

The two ugly sisters, *beziehungsweise* and *respectively*, so often confused by translators, have this in common: They sound clumsy, and nearly always they are useless. Let German writers ask themselves if, most of the time, they cannot replace *bzw.* by a simple *und* or *oder*. And let English writers ask themselves whether they really need *respectively*—after all, the orderly correspondence of E_1, E_2, etc. to P_1, P_2, etc. emerges generally quite obviously from the text.

I hasten to add that *beziehungsweise* cannot be translated by **relationwise*—thank goodness, nobody has added this ghastly word to the English language yet. Since we are engaged in an interlanguage ugliness contest, and I have mentioned *relation*, let me parade another unlovely word that turns up frequently in everyday and scientific writing, namely *relationship*. Not only is the word unaesthetic but most writers (and especially English-language journalists) misuse it most of the time. A *Beziehung* between two people or things is, in correct English, a *relation*. *Relationship* is, all too frequently, used interchangeably with *relation*, but it should not be; it really means "the nature of a relation". But why should I ask my readers to be careful with words that are daily misused in the Anglo-Saxon press? I shall already be happy if they do not create improper *Beziehungen* between *resp.* and *bzw.*!

7. A Meticulous Investigation into a "Non-Problem"

So you want to submit a paper in English. To a journal of the American Chemical Society? Of the Royal Society of Chemistry? Or an international multilingual journal?

You are probably worried about what "subspecies" of English to write, and how to spell it. No doubt you have been told that there are great differences between British and American usage. I note that in the literary pages of the best West German dailies it is always meticulously stated that the novel reviewed has been translated "aus dem Englischen" or "aus dem Amerikanischen".

There, I think, meticulous Germans are going too far. There is no such thing as a separate "amerikanische" language. Indeed, when it comes to Spoken Everyday English, there will be problems of communications for a resident of Newcastle-on-Tyne who has suddenly decided to settle in Peoria, Illinois. There are also certain differences (but definitely not leading to a communications gap) in The Journalist's English because of the highly personal style of certain popular American columnists.

In The Novelist's English, in our times, the differences have been reduced to the vanishing point (except, naturally, for the spoken word the novelist records). A German publishing house, satisfied with the rendering "aus dem Englischen" of a novel by *Anita Brookner*, may well ask the translator to try his or her hand next on a book by *Joyce Carol Oates*, "aus dem Amerikanischen". There are, of course, the oft-quoted differences in vocabulary, such as (American usage first) *faucet/tap, gas/petrol, trunk/boot,* and *store/shop*. As for differences in grammar, it is very hard to think of any, and in most cases usages overlap. American English has two past participles for the word *to get*: *got* to express a condition or state (you've got a problem there, pal) and *gotten* to express completed action (I've just gotten a new car). Americans also have a preference for the present subjunctive (I suggested that he *take* immediate action) where the British favor the auxiliary verb (... that he *should take* ...). I confess that my sympathies in the matter are with the Americans, for I should hate to see such an interesting verb form as the subjunctive driven out of the language altogether.

If differences in The Novelist's English are small, in The Chemist's English (that is, the English you write your papers in) they are practically nonexistent. These days, if you do not glance at the authors' names and addresses, you have little chance of knowing whether the work originated in the United States, Canada, Great Britain, or Australia (as every editor knows, if the English is particularly faultless, the authors are likely to be Dutch or Scandinavian!).

It was not always so, and when I wrote my first essays on language in 1972 I thought I could detect a slight preference by American authors for the first person plural over the passive voice. But these days we all publish so much, and travel so much, that the "accents" in our writing have disappeared. Moreover, we all dream of writing one day the definitive text on our special subject, and we do not wish to limit the sales of this masterpiece on either side of the Atlantic.

There remains only, really, the question of spelling, and even that is not truly a problem. In the case of ACS or RSC publications, there are efficient copy editors at work, and anyway corrections such as *favor/favour* will almost automatically trip out of the keyboard operator's fingers—as for international journals, they will generally remain neutral. The only thing you really need watch out for is consistency—don't start out the British way and then suddenly opt for the American. Bear in mind the distinctions *meter/metre*, *liter/litre*, and remember that in the United States you might find your lecture theat*re* in the conference cent*er*.

One point you might care to note is the doubling of the last consonant in a verb before *-ing* and *-ed*, if the preceding vowel is spelled with a single letter (so *to seem* is outside the rule). The general rule is: if the last syllable is stressed in pronunciation, double the consonant (*occurring, distilled, pipetting*), otherwise do not (*entering*).

Now the British have a habit of transgressing this rule for the *un*stressed form of final *-l* (*travelled, counselled, cancelled, modelled*); the majority of Americans stay true to the rule. The British also double unstressed *-p* in *worshipping* and many Americans join them in this in *handicapped*.

Note also that the doubling of *-c*, even in unstressed syllables, expresses itself as *-ck* (*panicked*). But, with verbs like *panic* and *worship*, we have already left the realm of the more unemotional Chemist's English. Why *plow/plough* over minuscule differences about how a word is *spelled/spelt*? How about going *picnicking*, everybody?

8. Say It Out Loud

I was recently privileged to help in the translation of a most instructive and entertaining German book. Its author is Professor *Volker Neuhoff* and its German title is *Der Kongress*, which we changed to *Scientists in Conference* because a literal translation might have misled American

readers into thinking of the legislative body in the Capitol. The author and his translator-consultant had a most enjoyably stimulating time and became firm friends. The book, for all its careful coverage of its subject matter, sparkles with human insight and humor and our task was to see that the English paragraphs gave off a similar sparkle. The translation grew almost by itself and wittily annotated drafts flew across the continents. My feeling is that, during a few months of translation, I gained more insight into the German language than I would have acquired during a full-time course in Germanistics at an Australian university. My friend felt similarly enriched.

Anyhow, the book is about scientific conferences; and all the preparatory work that precedes them bears fruit at the moment when a lecturer faces an audience, which is intent on *hearing* his or her words.

This prompts me to take the title of this series literally and to consider the case when you, a native German speaker, deliver a lecture in English to a British, American, or international audience. First of all, are you worried about an accent? Don't be. Audiences at scientific meetings are tolerant. In Australia, most visiting German-speaking scientists, seniors or young postdocs, have gained the admiration of their listeners for their fluency, and the teaching of English in modern *Gymnasien* or *Gesamtschulen* (called *high schools* in the Anglo-Saxon world) deserves the highest praise.

If you are in a higher age group, have not benefited from modern teaching methods, and have ingrained habits of speech, your best allies are the English-speaking research scholars in your department. Read your manuscript to them and ask them to point out recurrent errors, then record the talk again and ask them to be so kind as to check it once more.

If you do not have access to such help, and are worried about how a certain word should be pronounced, consult a good dictionary. Note that certain English words have stresses that are in totally illogical contradiction to etymology: PREFerable, COMParable, PREValent. (My own pet explanation for this phenomenon is that, in the Age of Humanism and in the High English Renaissance under *Elizabeth I*, educated men enriched the vocabulary by borrowing very large numbers of words from Latin and Greek, but were not sure of the pronunciation themselves. What we now stress as PARasite was pronounced as paRAsite by *Shakespeare*.)

The most painful proof of this total lack of logic is the difference between PERjure (swear a false oath) and abJURE (renounce a vice). Consider the difference in how the vowel is pronounced, and you will ask yourself why etymology was ever so trampled on.

If in doubt, stick to etymological logic; pronounce the syllables clearly and you will be understood. Certain stresses vary throughout the Anglo-Saxon world: LABoratory/laBORatory; REsearch/reSEARCH. Let me repeat that the main thing to do is to speak clearly and not to try to solve your problems by mumbling. Your audience will follow you.

Your audience will follow you, anyway, once you are well launched into your talk and showing your slides. There is no greater magic of communication than that between an audience and a lecturer animatedly discussing a slide. It is your opening remarks and historical review you have to worry about. Here take note of cultural gaps, especially at international congresses. Professor *Potapenko* may not be familiar with a quotation from the Bible, and Dr. *Hirakawa* may not know what the "labors of Hercules" were.

I speak as repentant sinner. I once arrived in Vancouver, Canada, at an IUPAC Congress with a prepared speech in which I referred to a certain type of organizational structure as a "hydra-headed monster". I saw a number of Chinese and Japanese faces stare at me in incomprehension, apologized to my colleagues from the Far East, and explained at the blackboard that "hydra" had nothing to do with hydrogen but was a creature from Greek fable, a snake with many heads.

There may be moments of confusion during discussion time after a lecture. Most Japanese laboratory chemists travel frequently and are therefore as good in their spoken as in their written English, but "computer chemists" travel less often (perhaps because there is less need) and there may be difficulties. Or an Indian delegate may address a question to you in excellent but to your ears monotonous English. A little blackboard work may be of help there.

In these and similar circumstances the best way is to turn to the Chair with a smile: "Mr. Chairman, we seem to have a little communications problem there." If your Chairman is good, he will help out ever so tactfully; and he is bound to be good if he has first read the proper chapter in *Volker Neuhoff*'s volume. Not for nothing does this bear the subtitle "The Congress Organizer's Handbook. The Congress Visitor's Companion".

9. No Flamin' Flashbacks!

Students at the University of Melbourne are often required to do a "prac". For this "practical exercise" they have to prepare a compound known from the literature of the thirties and forties and then to characterize it according to modern physical organic methods. And so, during "prac" time, there is often a knock at my door, and a student thrusts a photocopy of a paper at me with the words: "Bob, you know the language. Can you tell me what it means?"

I look and find that the author is someone I used to hero-worship in my youth: *Butenandt, Diels, Ruzicka* ... I say "sure", pick up the copy confidently enough and find myself confronted with a typical specimen of *Geheimratsdeutsch* such as this:

> Die gekühlte und filtrierte Lösung wurde, nach sorgfältigem Auswaschen, in einen Kolben transferiert.

I rattle the words off and I find my student is more perplexed than ever. "So what am I to do first, Bob? Cool? Filter? Wash?"

I laugh. "You know what your problem is, Jim? Your author published his paper before the last chapter of *The Chemist's English* appeared in print."

And indeed, in this last chapter of my book I got ambitious and proposed a "universal stylistic grammar". It took the following form: take the meaning of what you have

written and transcribe it into the script for a silent documentary film. The version in which the images follow in the most logical order, so that the script is shortest, is the best version:

> The solution was cooled. It was then filtered, and the solid material washed.

Now the *Geheimräte* had no way of reading my mind. Their great classical papers are full of "*zuerst* auf eine Aluminiumoxydsäule gegossenen Extrakten" and of such phrases as "*nach* Ausschüttelung" and "*vorher* aufgearbeitet". The *Geheimräte*, in their movie-making, were all too fond of the device known as flashback and used it with the enthusiasm of *Alain Resnais* in *Last Year in Marienbad*. I loved that film, but only because I yielded to its sweet confusion. But for your next chemistry paper, would you go to the scriptwriter *Robbe-Grillet* and ask him for help with its structure?

Now I don't want to be accused of disrespect towards the heroes of my youth. I proudly proclaimed my "documentary" device as a universal grammar. It works pretty well in English; sentence by sentence and paragraph by paragraph it points the way towards the logical order of presentation. But in "heavily inflected" languages it may work less well on the sentence level. The words hang more closely together, and *Die Lösung nach Neutralisierung* or *le précipité après calcination* may well constitute *one* image in the reader's mind.

But such constructions sound pretty awkward in English. This brings me to the following problem: You want to publish a paper in the English language. Do you write in German first, and then translate? Or straight in English?

Here my advice is very firm, and I am sure my readers have no need of it. If you want to be published in English, start writing your first version in that language. If you use your native language as a crutch, your prose will limp. Scholarly readers please correct me if I am wrong, but my guess is that, in the past, the great German-speaking Nobel Prize winners in chemistry were stronger in their French than in their English. Had this not been so, and had they read more *Hemingway* and less *Jules Romains*, then perhaps there might have been a slight movement away from *Geheimratsdeutsch*. Anyhow there is no excuse for you good fellows: you are not *Geheimräte*, and you have my last chapter. So fill that blank sheet with lovely, lively, loosely inflected English. But please (and here comes a vigorous Australian word), no flamin' flashbacks!

When submitting manuscripts, authors of articles intended for publication as "Communications" are requested to read the "Notice to Authors" reproduced in the January issue of the journal following the list of contents; upon request, a copy can be obtained from the editorial office.

Triple Proton Abstraction from a 1-Methylallyl Ligand on Thermolysis: Formation of a $Hf_3(C_4H_4)$ Cluster**

By *Bart Hessen, Anthony L. Spek,* and *Jan H. Teuben**

Transition-metal complexes with 1- or 2-methylallyl ligands can, upon thermolysis, yield butadiene[1] or trimethylenemethane[2] species, respectively. We used this method successfully for the preparation of the butadiene complexes **2** by thermolysis of the 1-methylallyl complexes **1**.[3] While exploring the reactivity and thermolysis of the complex **3**,[4] we observed a unique multiple proton abstraction from the 1-methylallyl ligand.

$$\underset{\mathbf{1}}{[Cp^*M(1\text{-}C_4H_7)_3]} \xrightarrow{\Delta} \underset{\mathbf{2}}{[Cp^*M(C_4H_6)(1\text{-}C_4H_7)]} + C_4H_8$$

$Cp^* = \eta^5\text{-}C_5Me_5$; M = Ti, Zr, Hf;
$1\text{-}C_4H_7$ = 1-methylallyl; C_4H_6 = butadiene

$$4\underset{\mathbf{3}}{[Cp^*Hf(1\text{-}C_4H_7)Cl_2]} \xrightarrow{\Delta} \underset{\mathbf{4}}{[Cp^*_3Hf_3Cl_5(C_4H_4)]} + [Cp^*HfCl_3] + 3\,C_4H_8$$

Thermolysis of **3** (toluene, 90 °C) produced a poorly soluble, orange, crystalline compound, which contains two nonequivalent Cp* groups (ratio 1:2) and four nonequivalent CH groups.[5] An X-ray structure determination[6] showed that the trinuclear species **4** (Fig. 1) had been formed.

Both C_4H_8 (mixture of 1-butene and *trans*-2-butene in a 2:3 ratio, GC) and $[Cp^*HfCl_3]$ (NMR) could be identified in the reaction mixture. Complex **4** contains a *cis*-1,3-butadiene-1,4-diyl unit that is symmetrically η^4-bound to both Hf2 and Hf3 and, at the same time, asymmetrically σ^2-bound to Hf1. Complexes of the unsubstituted 1,3-butadiene-1,4-diyl ligand are very rare. For the early transition metals only the thermally rather labile **5** has been reported.[7] In **4** the fragment is stabilized by being completely incorporated into the trinuclear cluster arrangement. For the late transition metals dinuclear complexes like **6**[8] and **7**[9] are known.

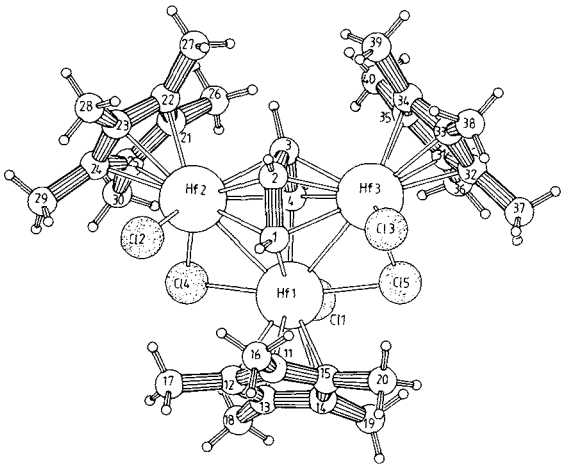

Fig. 1. Crystal structure of **4**. Selected bond lengths [Å] and angles [°]: Hf1-Cl 2.227(9), Hf1-C4 2.36(1), Hf2-C1 2.48(1), Hf2-C2 2.37(1), Hf2-C3 2.40(1), Hf2-C4 2.47(1), Hf3-C1 2.48(1), Hf3-C2 2.38(1), Hf3-C3 2.38(1), Hf3-C4 2.50(1), C1-C2 1.46(2), C2-C3 1.45(1), C3-C4 1.44(1), Hf1-Cl1 2.521(3); Hf1-Hf2-Hf3 81.53(3), C1-Hf1-C4 64.6(3), Hf1-C1-C2 129.2(7), C1-C2-C3 110.9(8), C2-C3-C4 109.5(9), C3-C4-Hf1 125.7(7).

$$\underset{\mathbf{5}}{[Cp_2Ti(C_4H_4)]}$$

$$\underset{\mathbf{6}}{[CpCo(\sigma^2,\eta^4\text{-}C_4H_4)CoCp]}$$[8]

$$\underset{\mathbf{7}}{[(CO)_3Fe(\sigma^2,\eta^4\text{-}C_4H_4)(\mu\text{-}CO)Fe(CO)_2]}$$

The coordination sphere of Hf1 in **4** can be viewed as a severely distorted octahedron with the Cp* group and C4 in the axial positions (C4-Hf1-Cp*(centroid) 170.5(2)°). As in structures of CpZr compounds with distorted octahedral geometry, like $[CpZrCl_3]_x$[10] and $[CpZrCl_3(dme)]$,[11] significant elongation of the axial bond is observed in **4** (Hf1-C4 2.36(1) Å). However, the equatorial bond (Hf1-C1 2.227(9) Å) is normal for a Hf–C σ bond.[12] The fully delocalized π-electron density in the C_4H_4 fragment contrasts with the localized structure in the monomeric 2,3,4,5-tetraphenylhafnacyclopenta-2,4-diene complex $[Cp_2Hf(\sigma^2\text{-}C_4Ph_4)]$.[13] The chlorine-bridged Hf–Hf distances (Hf1-Hf2 3.2261(9) Å, Hf1-Hf3 3.2061(9) Å) are comparable to the hydrido-bridged distances in $[Cp^*Hf(H)_2Cl_4]\cdot C_6H_6$ (average 3.233 Å[14]) and it is unlikely that there is any intermetal bonding interaction in **4**. The strongly asymmetrical chlorine bridges (e.g., Hf1-Cl4 2.610(3) Å, Hf2-Cl4 2.432(2) Å) indicate donation of electron density from Cl4 and Cl5 to the (formally neutral) $Cp^*Hf1(C_4H_4)Cl$ fragment. The overall structure of **4** is probably an average of four resonance structures (Scheme 1), through which the formal quadrivalence of Hf is conserved.

Formation of **2** (albeit in a low isolated yield, 23%) shows that multiple proton abstractions from methylallyl

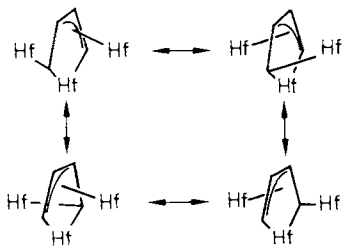

Scheme 1. Resonance structures for the $Hf_3(C_4H_4)$ unit in **4**.

ligands are possible and that Hf can form small organometallic clusters without metal–metal bonds supporting the framework.

Experimental Procedure

3: At 0°C, 19.2 mL of a 0.63 M [(1-C_4H_7)MgBr] solution in ether was added dropwise to a suspension of [Cp*$HfCl_3$] (1.679 g, 4.00 mmol) in ether. After stirring for 2 1/2 h the ether was pumped off and the residue extracted twice with 50 mL of pentane. Evaporation of the pentane yielded **3** as an orange oil [3]. This was dissolved in 25 mL of toluene together with [Cp*$HfCl_3$] (3.310 g, 7.89 mmol) and stirred for 15 h at room temperature. From the yellow solution **3** could be obtained by concentrating and cooling. Yield (after a cold washing with pentane) 3.740 g (8.51 mmol, 71%). Satisfactory elemental analysis.

3, 2-C_4H_7 instead of 1-C_4H_7: According to the same procedure but using instead [(2-C_4H_7)MgCl] in THF, [Cp*$Hf(2\text{-}C_4H_7)Cl_2$] can be prepared as well (74% yield). Satisfactory elemental analysis.

4: **3** (0.390 g, 0.887 mmol) was dissolved in 10 mL of toluene and heated to 90°C for 24 h. A deep red solution with orange crystals was formed. The toluene was pumped off and the residue washed with 5 mL of pentane (to remove red oil) and repeatedly with 10 mL of ether (to remove [Cp*$HfCl_3$]). Orange, crystalline **2** was isolated (0.060 g, 0.051 mmol, 23%). Satisfactory elemental analysis.

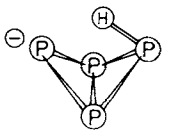
Alkali-Metal Hydrogen Tetraphosphides, M^IHP_4—the First Salts of Bicyclo[1.1.0]tetraphosphane**

By *Marianne Baudler,* Christoph Adamek, Sylvia Opiela, Herbert Budzikiewicz,* and *Dimitrios Ouzounis*

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

The simplest bicyclic phosphane, tetraphosphane(2), P_4H_2, was identified some time ago during mass spectroscopic investigation of phosphane mixtures.[1,2] The only derivatives of this phosphorus–hydrogen compound so far known are the three covalent compounds $P_4[N(SiMe_3)_2]_2$,[3] $P_4(2,4,6\text{-}tBu_3C_6H_2)_2$,[4] and $P_4(C_5Me_5)_2$[5] as well as the complex $[(\eta^5\text{-}C_5Me_5)_2ZrP_4]$.[6] We have now found the first salts containing the $HP_4^{\ominus}$ ion **1** and report herein on their formation and structural characterization.



1

One or two electrons should be transferred initially to a P_4 molecule upon reduction with white phosphorus. The resulting radical anion or dianion, respectively, reacts immediately with further P_4 molecules to give P-richer polyphosphide ions such as $P_7^{3\ominus}$, $P_{19}^{3\ominus}$, $P_{26}^{4\ominus}$, $P_{21}^{3\ominus}$, and $P_{16}^{2\ominus}$.[7] Under suitable conditions, however, it is possible to suppress these subsequent reactions and to isolate **1**.

The reaction of white phosphorus with naphthalenesodium/potassium solution in 1,2-dimethoxyethane (DME) has proven particularly advantageous for the preparation of alkali-metal hydrogen tetraphosphides. Fractional extraction of the resulting polyphosphide mixture with the same solvent and separation of the phosphorus-richer compounds by low-temperature crystallization affords a red-orange solution of (Na/K)HP_4, which contains, in addition, only a small amount of phosphorus and possibly some naphthalene.[8] This solution can be stored for approximately 24 h at −78°C without undergoing decomposition. Warming the solution to room temperature results in a transformation to P-richer phosphides, especially $M_2^IP_{16}$ and also some M^IP_5.[9] More stable (Na/K)HP_4 solutions, which can be kept for approximately 70 h at

[**] Contributions to the Chemistry of Phosphorus, Part 189. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 188: M. Baudler, D. Grenz, U. Arndt, H. Budzikiewicz, M. Fehér, *Chem. Ber.*, in press.

$-78\,^{\circ}C$ or for 1 h at room temperature, can be prepared by removing the DME at $0\,^{\circ}C$ under vacuum followed by dissolving the residue in cold dimethylformamide (DMF). Their composition was established by positive-ion FAB mass spectrometry.[10] Besides the ions characteristic of DMF (*m/z* 74, $[DMF+H]^{\oplus}$; 73, $DMF^{\oplus}$; and 58, $[DMF-CH_3]^{\ominus}$), as well as further ions (*m/z* 125, $[P_4+H]^{\oplus}$ and 129 $[C_{10}H_8+H]^{\oplus}$, see above), the most intense peaks correspond to $NaHP_4^{\oplus}$ (*m/z* 148) and $[NaHP_4+DMF+H]^{\oplus}$ (*m/z* 222), and a peak of lower intensity to $[NaHP_4+2\,DMF+H]^{\oplus}$ (*m/z* 295). $HP_4^{\ominus}$ cannot be detected in the negative-ion FAB spectrum. This finding indicates that, under these measuring conditions, $NaHP_4$ is present as a tight ion pair, since, otherwise, desorption of the free ions by the FAB beam should occur.

$LiHP_4$ is formed in the analogous reaction of white phosphorus with naphthalenelithium solution.[8] Furthermore, it is formed upon addition of phosphorus to lithium dihydrogen phosphide (ratio $P_4:LiPH_2\approx 3:2$) in THF followed by addition of DMF to the soluble reaction products.

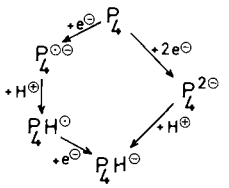
The alkali-metal hydrogen tetraphosphides are each characterized in the ^{31}P-NMR spectrum by a downfield signal group and two upfield signal groups (intensity ratio 1:1:2). A singlet is observed in the ^{7}Li-NMR spectrum of $LiHP_4$.[11] Proof of the constitution of **1** is provided by the complete analysis of the ^{31}P-NMR spectrum of the $(Na/K)HP_4$ solution (Table 1); the hydrogen atom on P_M

Table 1. ^{31}P- and ^{1}H-NMR data [a] of $(Na/K)HP_4$ (in 1,2-dimethoxyethane, $-20\,^{\circ}C$) [b].

	δ	J(PP)	J(PH)
^{31}P	+ 71.3 (P_A)	−194.4 (P_AP_N)	
	−329.5 (P_M)	−244.2 (P_MP_N)	
	−355.1 (P_N)	+ 12.5 (P_AP_M)	
^{1}H	− 4.54 (H_X)		+129.2 (P_MH_X)
			+ 3.2 (P_NH_X)
			+ 16.5 (P_AH_X)

[a] J [Hz]. [b] RMS value of the spectrum calculation, 0.6; 48 of 64 calculated transitions were assigned.

is also revealed directly in the ^{1}H-NMR spectrum.[11] As shown by the positions of the signals for P_M and P_N as well as by the ^{1}J(PP) coupling constants, **1** has a tetraphosphabicyclobutane framework. Whereas the bridgehead atoms P_N exhibit nearly the same chemical shift as in $P_4(C_5Me_5)_2$ ($\delta=-357$[5]), in the case of the bridging atoms P_A and P_M, only the average of the resonance positions largely agrees with the $\delta(^{31}P)$ values of the organosubstituted nuclei in $P_4(2,4,6\text{-}t\text{Bu}_3C_6H_2)_2$ ($\delta=-130$[4]) and $P_4(C_5Me_5)_2$ ($\delta=-134$[5]). Surprising is the downfield position of the signal for the charge-bearing atom P_A. Since electronegative substituents, especially oxygen, are not present, only electronic effects come into consideration (see below). The value of $J(P_MP_N)$ is characteristic of coupling between three-membered ring atoms having lone pairs in *cis* positions.[12] The hydrogen atom on P_M is therefore arranged in the *endo* position. Further support for this conclusion is provided by the strongly upfield position of the proton signal, which should be due to anisotropy effects. Evidence of a hydrogen exchange between P_M and P_A was not found by ^{31}P-NMR spectroscopy. Noteworthy is the dependence of the chemical shift of the phosphidic atom P_A on the solvent and counterion; by contrast, the positions of the other phosphorus signals are hardly affected.



1

Anion **1** is directly related to the unknown initial product formed in the reductive cleavage of P_4; owing to its hyperreactivity, this product is immediately protonated by the solvent. It remains an open question whether the radical anion or the dianion is initially formed. The remarkably downfield position of the ^{31}P-NMR signal for the phosphidic atom P_A of **1** is an indication of an unusual electronic structure as a consequence of change in hybridization (decrease in the s character of the electron pair[13]), partial delocalization of the anionic charge into the phosphorus framework,[14] and interaction between **1** and the counterion.[15]

[8] *(Na/K)HP₄ solution:* A naphthalenesodium/potassium solution (11 mL, 6.87 mmol (prepared by reaction of 4 g of naphthalene in 50 mL of DME with 1 mL of Na/K alloy (1:3) at $-78\,^{\circ}C$) was injected as quickly as possible under inert gas with stirring to freshly distilled, finely dispersed white phosphorus (1.01 g, 0.033 g-atom; prepared by dissolution in 250 mL of refluxing THF and subsequent removal of the solvent with stirring at $10\,^{\circ}C$) at $-78\,^{\circ}C$. After 30 min, the reaction mixture was warmed to $-55\,^{\circ}C$. As soon as the color of the reaction solution had turned from green to red, the mixture was cooled once again to $-78\,^{\circ}C$ and stirred for an additional 15 min. The reaction solution was then filtered in the cold and the residue was washed with 50 mL of DME ($-78\,^{\circ}C$), the wash solutions being discarded. Extraction with cold DME (ca. 150 mL) in portions was carried out until the filtrate was colorless. The combined extracts were concentrated under vacuum at $0\,^{\circ}C$ to 30 mL and allowed to stand at $-78\,^{\circ}C$ for 12 h to enable the remaining P-richer polyphosphides to separate. Filtration in the cold gave a largely pure solution of $(Na/K)HP_4$ in DME, which contained, in addition, only a small amount of phosphorus and possibly some naphthalene. Yield (by comparison of the intensities of the ^{31}P-NMR signals of **1** with the singlet of a $(Ph_3P)_2NCl$ solution of known concentration in [D₆]acetone): 4%, based on phosphorus. If the solution is not intended for immediate further use, DME can be completely removed at $0\,^{\circ}C$ without causing decomposition.—*LiHP₄ solution:* White phosphorus (0.94 g, 0.030 g-atom) was allowed to react at $-78\,^{\circ}C$ with naphthalenelithium solution (10 mL, 6.24 mmol; prepared by reaction of 0.3 g of thin Li sheet with a solution of 1.2 g of naphthalene in 15 mL of DME)

and the reaction solution was worked up quickly as described above. The solution of $LiHP_4$ in DME contains, in addition, only a small amount of phosphorus.

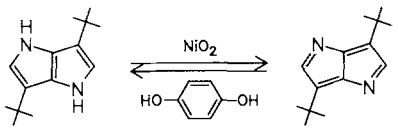
Synthesis and Physical Properties of 3,6-Di-*tert*-butyl-1,4-diazapentalene

By *Shoji Tanaka, Kyosuke Satake, Akira Kiyomine, Tsutomu Kumagai,* and *Toshio Mukai**

The aza analogues of pentalene possessing a planar 8π-electron system are theoretically of interest to predict the degree of antiaromaticity, which appreciably depends on the positions of the nitrogen atoms.[1] Although several aza- and diazapentalenes have been synthesized, all of them are resonance-stabilized by conjugative interactions with substituents.[2] Herein we describe the synthesis of 3,6-di-*tert*-butyl-1,4-diazapentalene **2** from the 1,4-dihydro derivative **1**,[3] and report its physical properties, which provide information concerning the antiaromatic nature of this 8π-electron system.



1 **2a**

The oxidation of **1** was carried out with an excess of nickel peroxide in benzene at 20°C, producing a dark red solution. The solvent was removed by the freeze-dry method. The resulting crude material was then purified by high-vacuum sublimation (20°C, 10^{-6} torr) to give red-brown, fine needles (m.p. 93°C) in 68% yield. Compound **2** could be recrystallized from hexane at −70°C, but was not so stable at room temperature in the presence of air. The spectral data are listed in Table 1. Compound **1** was regenerated in 56% yield when a benzene solution of **2** was treated with 1.2 equivalents of hydroquinone at room temperature.

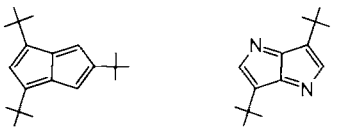
[+] Present address: Department of Industrial Chemistry, College of Engineering, Nihon University
Koriyama 963 (Japan)

Table 1. Spectroscopic data for **2**. A correct elemental analysis was obtained.

MS (25 eV): m/z 216 ($M^{\oplus}$, 7%); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3035, 2945, 2890, 2845, 1617, 1478, 1465, 1450, 1382, 1359, 1350, 1297, 1262, 1210, 1186, 1098, 1041, 975, 967, 924, 905, 808, 696, 628, 543, 470; ^{1}H-NMR (90 MHz, CCl_4, 35°C): $\delta = 7.17$ (s, 2H; H-2,5), 1.20 (s, 18H; 2*t*Bu); ^{13}C-NMR (50 MHz, CD_2Cl_2, 20°C): $\delta = 173.0$ (d; C-2,5), 163.2 (s; C-3a,6a), 145.7 (s; C-3,6), 32.4 (s; CMe_3), 28.5 (q; CH_3); UV (cyclohexane): $\lambda_{max}(\varepsilon) = 245$ (1510), 330 (8620) nm.

In contrast to pentalene **3**,[4] diazapentalene **2** could not be subjected to X-ray analysis, because a single crystal could not be obtained. However, the ^{1}H- and ^{13}C-NMR data indicate that, of the two bond-alternated structures **2a** and **2b**, the structure **2a** is more important. In the ^{13}C-



3 **2b**

NMR spectrum of diazapentalene, the signal of C-2(C-5) appears at $\delta = 173.0$, which is at appreciably higher frequency than that of C-3a(C-6a) at $\delta = 163.2$. The ^{13}C-NMR chemical shifts in azaheterocycles are reported to be correlated linearly with the total electron densities of the respective carbons by $\Delta\delta = 60$ ppm per electron.[5] Thus, the electron densities at C-2 and C-3a in structures **2a** and **2b** were calculated by the MNDO method, which gave values of 3.94 and 4.07, respectively, for **2a** and 4.00 and 4.01, respectively, for **2b**. Based on these values, the difference in chemical shift between these positions is predicted to be 7.8 ppm for **2a** and 0.6 ppm for **2b**. The observed difference, 9.8 ppm, is in good agreement with the calculated one for **2a**, but not for **2b**, supporting the existence of double-bond fixation as in the case of pentalene.[6] The MNDO calculation also indicates that the structure **2a** is 7.8 kcal mol^{-1} more stable than **2b**.

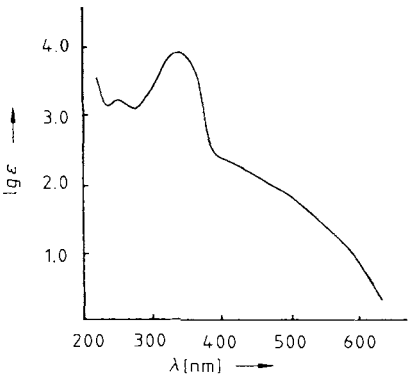


Fig. 1. Electronic spectrum of **2** in cyclohexane. ε in cm^2 mol^{-1}.

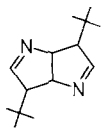
The UV/VIS spectrum of **2** (Fig. 1) is characteristic of the pentalene system. The long tail throughout the visible region indicates the existence of a low-energy excited state having potential energy curves appreciably different in shape from the ground state.[7] The low-energy excited state can contribute to inducing the π-orbital paramagnetism.[8] The degree of paramagnetic shielding in the diaza-

pentalene **2** is estimated by comparing the chemical shift of the ring proton with that of the CH=N protons of **4** ($\delta = 7.23$).[9] The extension of the conjugation by introduction of double bonds in **4** should induce a downfield shift



4

of the proton signal. Assuming that the chemical shift difference is the same as that ($\Delta\delta = 0.82$ ppm) for the olefinic protons on going from cyclopentene ($\delta = 5.60$) to cyclopentadiene ($\delta = 6.42$ ppm), the signal for the ring proton of **2** is expected to be located at $\delta = 8.05$ ppm. The difference between the expected and observed value ($\Delta\delta = 0.88$ ppm) can be attributed to the paramagnetic shielding effect in this diazapentalene. The degree of the shielding is comparable to that in 1,4-dihydropyrazines ($\Delta\delta \approx 0.75$ ppm), which is considered to be a typical antiaromatic molecule.[10]

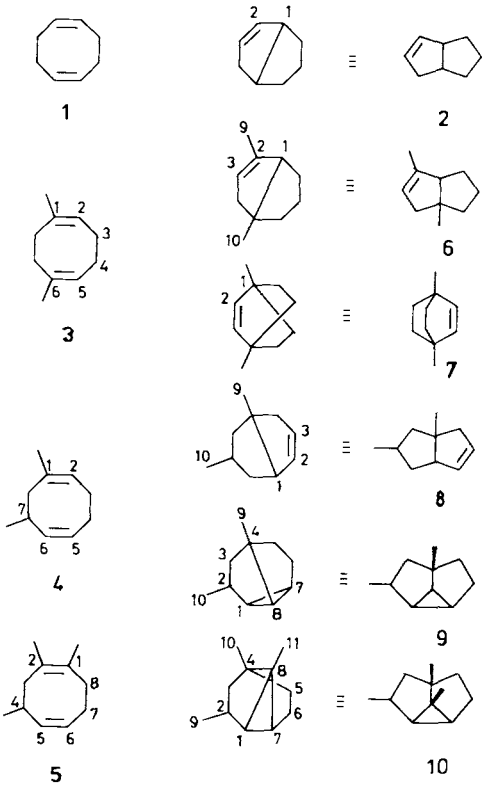
Catalytic Isomerization of Methylated 1,5-Cyclooctadienes**

By *Michael Mallien, Erhard T. K. Haupt,* and *Heindirk tom Dieck**

Dedicated to Professor Heinrich Nöth on the occasion of his 60th birthday

1,5-Cyclooctadiene **1**, which is readily accessible by catalytic cyclodimerization of butadiene on nickel complexes, undergoes facile rearrangement in the presence of catalysts to give bicyclo[3.3.0]oct-2-ene **2**. This reaction may be effected in a particularly selective fashion under mild conditions using a catalyst prepared from bis(2-ethylhexanoato)nickel and dichloroethylaluminum, as described by *Farona* et al.[1] The analogous reaction with substituted 1,5-cyclooctadienes can, depending on the pattern of substitution, lead to numerous isomers, analysis of which affords insight into the stereochemical course of the catalytic isomerization.

Isoprene reacts on diazadieneiron(0) catalysts at room temperature to give directly 1,6-dimethyl-1,5-cyclooctadiene **3**, and a 1:1 mixture of isoprene and *trans*-piperylene selectively affords 1,7-dimethyl-1,5-cyclooctadiene **4**.[2] Piperylene and 2,3-dimethylbutadiene also react to give codimers (89%); these consist mainly (70%) of 1,2,4-trimethyl-1,5-cyclooctadiene **5** (62% overall yield). All three cyclooctadienes react on the Farona catalyst to give unexpected products, which depend on the solvent and temperature. The topology and stereochemistry of the products could be elucidated by 2D INADEQUATE experiments[3] and other 2D NMR methods.



In benzene, **3** reacts at 81 °C to give 2,5-dimethylbicyclo[3.3.0]oct-2-ene **6** as the main product (93% after 4 h); this corresponds to the transformation **1** → **2**. At 69 °C in hexane, on the other hand, 1,4-dimethylbicyclo[2.2.2]oct-2-ene **7** is found (63% after 8 h). Its formation cannot be explained alone by C–C bond formation and hydride shift; C–C bond breaking is also required. Compound **6** does not isomerize to **7** in refluxing benzene.

Reaction of **4** for a longer time in benzene yields primarily 5,7-dimethylbicyclo[3.3.0]oct-2-ene **8**. The reaction appears to be analogous to that of **1** to **2** and of **3** to **6**. However, in contrast to **6**, the methyl group is not located in the unsaturated but rather in the saturated five-mem-

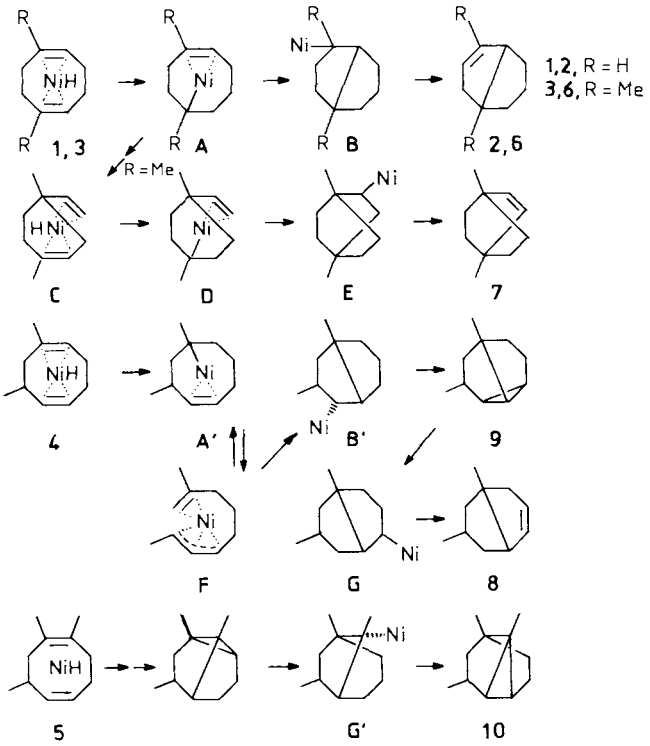
bered ring. Reaction of **4** in refluxing hexane, on the other hand, gives a fully saturated compound as the main product, which was identified as 2,4-dimethyltricyclo[5.1.0.0^{4,8}]octane **9**. The catalytic formation of such a highly strained cyclopropane system may at first seem surprising. Reaction times longer than 2 h, however, result in the slow isomerization of **9** to **8** (50% after 40 h) and the formation of six further, unidentified products having similar retention times upon gas-chromatographic separation. Reaction of **5** in refluxing hexane also results in rapid and exclusive formation of a tricyclic compound, 2,4,8-trimethyltricyclo[5.1.0.0^{4,8}]octane **10**, which, on first sight, resembles **9**. The positions of the methyl groups reveal once again that the route to **10** does not occur only via the formation of C–C bonds but also by bond breaking.

A nickel hydrido complex, which coordinates **1** and **3–5** is presumably the active species involved in the isomerization, since other nickel hydrido systems also allow the isomerization of **1** to **2**.[4] The first step, after coordination of the cyclooctadiene, is a hydrogen transfer from the nickel center to one of the sp^2 carbon atoms. A Ni–C σ bond to a tertiary C atom is thereby formed (**A**, **A'**), since the products **6–10** all have at least one angular methyl group. Because bonds to secondary C atoms should be more favorable, the activation barrier for a product with a Ni–C$_{sec}$ σ bond in the catalytic cycle must be higher and the yield of the corresponding catalysis product lower. Formation of a transannular C–C bond results in transformation of **A** to the bicyclo[3.3.0]octylnickel intermediate **B**, from which **2** or **6** are formed by β-elimination. In the corresponding intermediate involved in the isomerization of **4**, the nickel center would have a methyl group and a bridgehead H atom as neighbors. If the methyl group is *cis* to the nickel atom, then no β-elimination to this side is possible, so that a product containing a double bond to a bridgehead C atom should be formed. This does not occur, but instead **9** is obtained. Its formation can easily be explained by an intermediate containing a methyl group and a nickel center in *endo* positions, **B'**, since γ-elimination from such a species with formation of the cyclopropane ring of **9** should be sterically facile. However, an *endo* Ni atom can only be attained by opening of the eight-membered ring (e.g., **A'** → **F** → **B'**). The Ni–H elimination leading to **9** is apparently reversible, as shown by the isomerization of **9** to **8**. If "Ni–H" adds to **9** in such a way that **G** and not **B'** is formed, a normal β-elimination can readily occur leading to **8**. This mechanism would explain why—in contrast to **6**—compound **8** contains the double bond in the unsubstituted five-membered ring.

The formation of **7** formally requires, among other steps, the opening of the C3–C4 bond of **3** to give **C**. A second hydride transfer would give the new enyl complex **D**. A bicyclo[2.2.2]octylnickel complex can be formed in one step from this species. Ni–H elimination from this complex, in turn, gives **7**. Evidence for the intermediacy of **C** is provided by the appearance of traces of a product having the retention time of a 1,4-dimethyl-4-vinylcyclohexene. However, a catalytic rearrangement of 1,4-dimethyl-4-vinylcyclohexene itself to **7** cannot be detected.

Finally, the formation of the tricyclic compound **10** from **5** is a complete surprise. The INADEQUATE experiment, in connection with a ^{13}C APT spectrum (APT = attached proton test) unambiguously gives, without any presuppositions, the molecular topology. Two of the methyl groups are found at mutually linked quaternary C atoms; the molecule has a three-membered ring containing a quaternary and two tertiary C atoms; the third methyl group is found on a tertiary C atom, the configuration of which cannot be derived with certainty from the ^{1}H-NMR data, and is in proximity to the three-membered ring. Therefore, this tricyclic structure must have been formed by (formal!) breaking of the C1–C8 bond and formation of the bonds C2–C8 as well as C1–C5 and C1–C6 (numbering of **5**). The formation of **9** could also have occurred in a sequence of steps analogous to the path **5** → **10** instead of the "simple" way via **F**, **B'**.



The formation of **7** and **10** clearly shows that the primary coordination of the active nickel species is capable of activating different σ bonds of the eight-membered ring. The formation of methylene-2-vinylcyclopentane, often observed upon dimerization of butadiene to the usual cyclodimers, can also be explained by opening of the C3–C4 bond of **B** and Ni–H elimination. The extremely selective formation of the various types of products as a function of the pattern of substitution and the temperature, however, still remains to be explained.

Experimental Procedure

The ^{13}C-NMR assignment for **2** reported by *Benn* et al. [6a] and by *Whitesell* et al. [6b] could be confirmed.

6, **7**: Bis(2-ethylhexanoato)nickel (0.1 mmol) [1] as a 0.1 M solution in hexane was added to **3** (2.7 g, 20 mmol) in hexane (15 mL) and activated with 2 mL of a 1 M solution of $EtAlCl_2$ (2 mmol) in hexane. After refluxing for 9 h, the reaction was quenched by adding 5 mL of EtOH. **3** had reacted completely, resulting in the formation of **7** (63%), **6** (7%), and three further products in 7–8% yield. The same reaction in benzene yielded **6** (93%) along with three further products (together 7%).—^{13}C-NMR ($CDCl_3$): **6**: δ = 15.45 (C9), 25.90 (C7), 28.92 (C10), 30.80 (C8), 43.05 (C6), 48.25 (C4), 49.07 (C5), 61.14 (C1), 122.71 (C3), 141.80 (C2); the ^{13}C-NMR assignment in [6b], which corrected that in [6c], was confirmed by 2D INADEQUATE NMR experiments. **7**: δ = 25.37 (C9, C10), 33.95 (C1, C4), 35.04 (C5, C6, C7, C8), 138.21 (C2, C3). Hydrogenation afforded 1,4-dimethylbicyclo[2.2.2]octane, whose ^{13}C-NMR spectrum is in agreement with the data given in [5].

8, **9**: The precatalyst and activator were added to **4** (2.7 g, 20 mmol) in 15 mL of hexane as described above. After refluxing for 2 h, 60% of **4** had reacted to give virtually exclusively **9**. After 4–5 h, **4** had undergone complete reaction. Analysis of the products showed the presence of **9** (63%), **8** (10%), and unidentifiable products having similar retention times (16, 5, 5, 3, and 2%). After 40 h, the proportion of **8** had attained 50% and **9** was no

longer present. In addition, isomers were formed in yields of 16, 5, 5, and 4% along with further compounds (<3%). The course of reaction is similar, but faster, in refluxing benzene or heptane. — ^{13}C-NMR ($CDCl_3$): **8**: δ = 19.10 (C10), 29.51 (C9), 33.52 (C7), 41.14 (C8), 48.10 (C5), 49.80 (C4), 52.27 (C6), 58.31 (C1), 129.35 (C3), 134.13 (C2). **9**: δ = 22.19 (C10), 24.29 (C6), 25.27 (C9), 26.97 (C7), 31.35 (C2), 34.08 (C1), 35.70 (C8), 47.40 (C5), 50.99 (C4), 57.06 (C3).

10: **5** was prepared according to the procedure in [2] by reaction of 2,3-dimethylbutadiene and *trans*-piperylene (30 mmol each) with $(dad)_2Fe/AlEt_3$ (dad = 1,4-dicyclohexyl-1,4-diaza-1,3-butadiene; 1 mmol Fe/5 mmol Al) at room temperature for 60 h (after complete conversion: 63% **5**, 22% 1,2-dimethyl-4-propenylcyclohexenes (DMPC), 9% piperylene codimer, and 6% of an unidentified codimer). Reaction of the mixture of **5** and DMPC with the nickel catalyst in refluxing hexane for 2 h resulted in exclusive and complete conversion to **10** together with unreacted DMPC. After 3 additional hours of refluxing, another isomerization occurs which has not yet been identified. **10**: ^{13}C-NMR ($CDCl_3$): δ = 16.59 (C11), 22.50 (C9), 22.98 (C6), 23.24 (C10), 30.18 (C2), 33.76 (C7), 38.72 (C8), 40.79 (C1), 47.21 (C5), 51.66 (C4), 56.76 (C3).

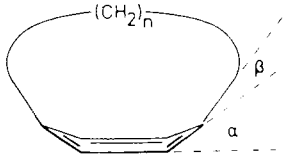
Strongly Bent Naphthalene Units in [2](2,6)Naphthalino[2]paracyclophane and [2](2,6)Naphthalino[2]paracyclophane-1,11-diene

By *Norman E. Blank, Matthias W. Haenel,* Carl Krüger, Yi-Hung Tsay,* and *Heike Wientges*

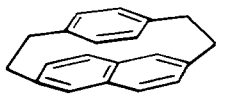
In the series of [n]paracyclophanes **1**, n = 4–8, the decreasing length of the aliphatic bridge increasingly forces the benzene ring to adopt a deformed boatlike structure. The effects of this deformation on the spectroscopic and chemical properties of the aromatic benzene ring can therefore be investigated.[1–7] In the stable derivatives of [6]paracyclophane **1**, n = 6, the benzene ring is bent by an



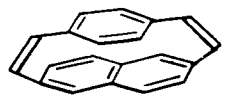
1

angle of $\alpha = 19.4$–$21.1°$, as determined by X-ray crystallography.[4] [5]Paracyclophanes exist only in solution at low temperatures,[5] and, according to calculations, are bent by an angle α of approximately 23°.[6] [4]Paracyclophanes are reactive intermediates which can only be detected by trapping reactions.[7] The deformation of *poly*cyclic arenes, on the other hand, has been little investigated.[8]

We have already described the synthesis of [2](2,6)naphthalino[2]paracyclophane **2** from the dithia[3.3]phanes **4** and **5**, which were ring-contracted by photolytic sulfur extrusion and pyrolytic sulfur dioxide extrusion, respectively.[9] Since, formally, **2** can be viewed as the product in



2



3

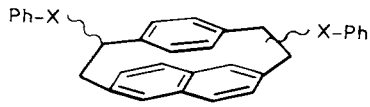
5, X = SO_2



6, X = S
7, X = SO

which the two ends of the longer 2,6-dimethylnaphthalene are linked with the ends of the shorter *p*-xylene, a "bow" (naphthalene) and a "bow string" (benzene) must be formed. Indeed, an X-ray structure analysis of **2** (Fig. 1) reveals an extremely bent naphthalene moiety bridged by a nearly planar benzene ring.[10, 11]

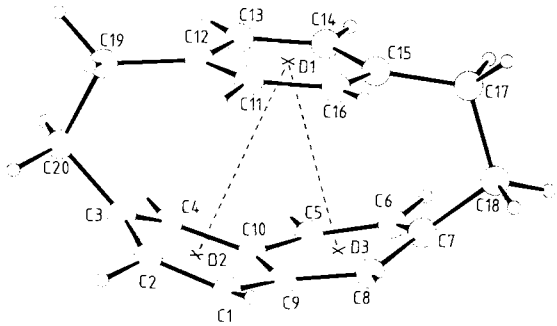


Fig. 1. Molecular structure of **2**.

To bend the "naphthalene bow" still further, we have synthesized the [2](2,6)naphthalino[2]paracyclophane-1,11-diene **3**. Two Stevens rearrangements, accomplished by reaction of **4** with dehydrobenzene (prepared from 1-(2'-carboxyphenyl)-3,3-dimethyltriazene in refluxing xylene[12]) led to the ring-contracted bis(phenylthio)[2.2]phane **6** (isomeric mixture,[13] m.p. 128–135°C, 15–20%), which was oxidized to the disulfoxide **7** (>95%) with *m*-chloroperbenzoic acid. Thermal elimination of phenylsulfenic acid by gas-phase pyrolysis of **7** at 320°C or by heating a solution of **7** in toluene to 160°C in a sealed tube gave **3** together with diphenyl disulfide **8**, which is apparently formed from phenylsulfenic acid.[14] Compound **8**, which could not be separated from **3** by chromatography, was reduced with excess *threo*-1,4-dimercapto-2,3-butanediol (racemate) **9**[15] in ethanol. Thiophenol **10**, thereby formed, was removed by extraction with aqueous sodium carbonate solution, and 4,5-dihydroxy-

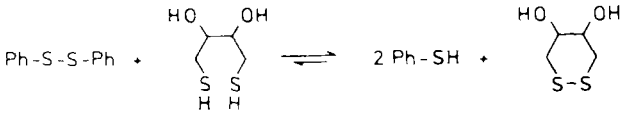
1,2-dithiane **11** was easily separated by chromatography on alumina with cyclohexane as eluent. Colorless crystals of **3** (m.p. 124°C, 15–20%) were thus obtained.[16]



8 9 10 11

The X-ray structure analysis (Fig. 2) shows that the naphthalene moiety in **3**[17] is somewhat more strongly deformed than that in **2**. This is particularly revealed by the dihedral angles C4-C10-C9/C8-C9-C10 (32.8° and 33.1°) in the two crystallographically independent molecules of **3**, compared with that in **2** (28.1°). Most of the other dihedral angles in the naphthalene moiety of **3** are also larger

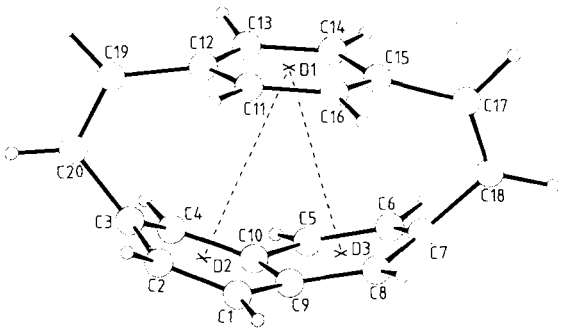


Fig. 2. Molecular structure of one of the two independent molecules of **3**.

(by an average value of 2°) than those in **2**. The large degree of bending is reflected well by the angle between the lines through C20-C3 and C7-C18, which is 94.5° in **2** and 85.0° and 84.5° in **3**. The benzene ring in both compounds is only slightly deformed toward a boatlike structure (dihedral angle between C11-C12-C13 and C11-C13-C14-C16 and between C11-C13-C14-C16 and C14-C15-C16 in **2**: 4.9/2.8°; in **3** (two molecules): 5.0/5.2° and 5.6/4.9°). By contrast, the angle formed at the benzene C atoms C12 and C15 (angle between the line through C19-C12 and the plane C11-C12-C13 and between the line through C17-C15 and the plane C14-C15-C16) is 5.4/5.8° and 5.7/5.7° in **3** (two molecules) and therefore considerably larger than the corresponding angle in **2** (1.4/2.5°). The distance between the center of the benzene ring plane C11-C13-C14-C16 and the center of the central naphthalene bond C9-C10 in **3** (3.423 and 3.432 Å) is slightly longer than that in **2** (3.379 Å). The center of the benzene ring (D1) in **2** is 3.33 Å from the centers D2, D3 of the bent naphthalene moieties; the lines through D2-D1 and D1-D3 form an angle of 41.8°. The corresponding average values in **3** are 3.36 Å and 41.3°.

In the UV absorption spectra of **2**[9] and **3**[16] the three characteristic naphthalene bands (α, p, and β) are shifted by about 20 nm to longer wavelengths compared with those of 2,6-dimethylnaphthalene, the bathochromic shift of the p and β bands of **3** being slightly (3–5 nm) larger than that of **2**. The pronounced vibrational fine structure of the naphthalene α band, which is largely retained for **2**, is completely lost for **3**. Since, additionally, the extinction coefficient of the α band is significantly smaller for **3**, this band is only observed as a shoulder of the p band. Investigations of the emission spectra and of the excited triplet state are now being carried out to differentiate between the effects of deformation, transannular π-electron interaction, and through-bond interaction via the bridges on the electronic properties.

As shown here, condensed polynuclear arenes can be deformed considerably. The structures of **2** and **3** also indicate that molecules such as C_{60}, "Buckminsterfullerene" or "Footballene",[18] should be stable, since, to form this three-dimensional sphere-shaped cluster containing 60 sp^2-hybridized carbon atoms, neighboring six-membered rings must be bent in a similar fashion to the deformations observed in the naphthalene moieties of **2** and **3**.
